The influence of MCT and lauric acid on intravascular lipoprotein metabolism. Despite the fact that both MCT and 12:0 raised blood cholesterol levels when substituted for PUFA, their influence on cholesterol metabolism was not identical. For example, the lauric acid diet enhanced some factors involved in RCT, but MCT sometimes had a different or less pronounced effect. In comparison to corresponding baseline values, the mean rates of cholesterol esterification (LCAT) and transfer (CETP) increased significantly on the lauric acid diet but not on the MCT diet, although there was less conformity in the response to MCT. The concentrations of both HDL_2-C and HDL_3-C increased when lauric acid replaced PUFA whereas the concentration of HDL_2-C declined and HDL_3-C increased in serum when subjects consumed MCT instead. This finding suggests the MCT diet reduced conversion of HDL_3-C to HDL_2-C, which involves TG-rich lipoproteins, LCAT, CETP, and lipoprotein lipase, or increased reconversion of HDL_2 to HDL_3, which involves removal of lipid components by the liver (35). Previous studies (12,36–38) indicated that MCT decrease HDL-C levels. One explanation is that MCT reduces chylomicron production, and chylomicron metabolites are used in part to produce the HDL fraction (39). In this study, total HDL-C concentrations were not changed by the MCT diet. Cater *et al*. (32) also found that MCT did not influence total HDL-C levels. Furthermore, serum TG level was increased on MCT in many studies (31,32,37) possibly because MCT may enhance hepatic *de novo* FA synthesis. In this study, serum TG levels were not changed by MCT feeding although LDL-TG levels were higher on the MCT diet than on the baseline ($P < 0.05$). In summary, in this study and in a companion study (34), SFA ranging in chain length from 8:0 to 18:0 had subtly different effects on intravascular lipoprotein remodeling. The physiological implications of these differences are unclear at this point.

The influence of MCT and lauric acid on LDL receptor activity. MCT, but not lauric acid, had an unusual effect on LDL receptor activity. In a previous study (18), we noted that changes in serum LDL cholesterol concentration and specific LDL degradation were moderately and negatively associated ($r = -0.4$ to -0.6) when diets high (>20 en%) in either saturated fat (butter) or polyunsaturated fat (corn oil) were compared, an effect that might be expected. Curiously, in this study, receptor-mediated degradation of LDL in MNC was positively associated ($r = 0.53$) with an increase in LDL-C concentration in serum on the MCT diet despite the fact that polyunsaturated fat, which is presumed to upregulate the LDL receptor, was lower on the MCT diet than on the baseline comparison diet. In agreement with our observation, Woollett *et al*. (40) noted in hamsters that addition of MCT and cholesterol to a chow diet increased receptor-mediated LDL transport and LDL-cholesterol production but did not alter plasma LDL-C concentrations.

When the intake of either cholesterol or SFA increases, a marked increase of LDL-C delivery into the plasma and a reduction of the receptor-dependent LDL uptake by the liver occur in hamsters (41). With both the decreased hepatic clearance and increased LDL production, the plasma LDL-C level elevates progressively until the velocity of the remaining receptor-dependent and -independent activities in the various tissues achieve a rate of LDL-C clearance equaling the rate of LDL-C introduction into the plasma (42). Another determinant of the plasma LDL-C is the rate of LDL-C entry into plasma. According to Woollett *et al*. (41), both MCT and longer-chain FA (mainly 12:0) had similar effects on the rate of delivery of LDL-C into the plasma pool. As reported in one baboon study (43), this increased LDL-C delivery rate might result from the increased production rate of cholesterol-rich particles. The increased rate of LDL-C delivery may be associated with an elevated rate of hepatic apoB synthesis, an elevated rate of conversion of VLDL to LDL, or an elevated transfer of cholesterol from other lipoproteins (44). In addition, although MCT and longer-chain SFA are delivered to the liver differently (45,46), both of them could expand the hepatic lipid pool either by *de novo* FA synthesis from acetyl CoA or *via* chylomicron remnants, which may increase the secretion of hepatic VLDL and then increase LDL-C production (47,48). Since in this study both plasma apoB level and CETP activity on the MCT diet did not change, a high rate of VLDL conversion to LDL may cause LDL-C level to increase. Meanwhile, as suggested by Cater *et al*. (32), the newly synthesized elongated FA from MCT in the liver could act like dietary longer-chain SFA. Therefore, a single parameter such as LDL receptor activity, may not predict the change in plasma LDL-C level. In agreement with the hamster study by Woollett *et al*. (41), the feeding of 12:0 suppressed LDL

receptor activity and increased LDL-C levels in the plasma in this study.

The composition of LDL as well as receptor activity influences LDL turnover (49). When we assayed LDL receptor activity in MNC, we used a constant donor pool as the source of LDL in order to eliminate the effect of dietary-induced changes in LDL composition. Thus, there is a possibility that MCT-induced changes in the composition of LDL of the subjects may influence the uptake of this particle by LDL receptors. There was an indication in this study that LDL particle size (diameter) increased although not significantly, and LDL number (protein content) declined when MCT or 12:0 replaced the baseline diet (Table 5). However, the two diets did not differ significantly in their effect on LDL composition.

Although receptor-mediated LDL degradation and serum LDL-C concentrations were positively associated with each other when the subjects consumed MCT, there was a significant negative correlation between LDL degradation activity and serum TG concentrations ($r = -0.54$, $P < 0.05$). Since VLDL remnants are normally cleared from the plasma by hepatic LDL receptors without conversion to LDL (50–52), LDL receptor activity is not only associated with LDL-C clearance. Possibly, the output by liver of TG-rich particles increased on MCT. Since serum TG concentrations did not increase significantly, the TG-rich lipoproteins may have been cleared from serum relatively rapidly at the expense of uptake of cholesterol-rich particles *via* a receptor-mediated mechanism. This may be one of the factors to promote upregulation of receptor-mediated activity.

In summary, the results of this study indicate that lipoproteins produced during MCT and lauric acid feeding are metabolized somewhat differently. An enhancement of LDL receptor activity in MNC, which presumably is coordinated with an enhancement in liver LDL receptors, did not guarantee a reduction in LDL-C concentration in serum. Not only receptor-mediated uptake of LDL but also rate of LDL-C production, RCT, rates of efflux and clearance of individual lipoproteins, and gene expression of various apo may be involved in mediating the lipoprotein response to the fats fed in this study. These variables need further investigation before MCT can be promoted for use in therapeutic diets and designer fats.

Hepatic Zonation of the Formation and Hydrolysis of Cholesteryl Esters in Periportal and Perivenous Parenchymal Cells

José Ramón Romero, Olatz Fresnedo, Efrén Isusi, Javier Barrionuevo, and Begoña Ochoa *
Department of Physiology, University of the Basque Country Medical School, E-48080-Bilbao, Spain

ABSTRACT: The periportal (PP) and perivenous (PV) zones of the liver acinus differ in enzyme complements and capacities for cholesterol and bile acid synthesis and other metabolic processes. The aim of this investigation was to determine the acinar distribution of the catalytic activity of the enzymes governing the formation and hydrolysis of cholesteryl esters using PP and PV hepatocytes from normal or cholestyramine-fed rats. The hepatocyte subpopulations were isolated by centrifugal elutriation, characterized according to the distribution pattern of a number of cell parameters and marker enzymes, and assayed for acyl-CoA:cholesterol acyltransferase (ACAT) and lysosomal, cytosolic and microsomal cholesteryl ester hydrolase (CEH). In normally fed rats, no zonation was found in the activity of lysosomal CEH and ACAT, and the activity of both cytosolic and microsomal CEH zonated toward the PV zone of the acinus. Concentrations of free and esterified cholesterol in homogenates, cytosol, and microsomes of PP and PV cells were, however, similar. Cholestyramine raised significantly the PV/PP ratio of ACAT because of an exclusive PP reduction of activity and abolished the heterogeneity in microsomal CEH because of a greater inhibitory PV response, whereas the PV dominance of cytosolic CEH and the homogeneous distribution of lysosomal CEH were unaffected. These results demonstrated homogeneity within the liver acinus for the enzymatic degradation of endocyted lipoprotein-derived cholesteryl esters, a structural zonation of the cytosolic CEH and a dynamic zonation of ACAT and the microsomal CEH, with a PV dominance of the enzymatic capacity for the degradation of stored cholesteryl esters in normal livers.

Paper no. L8068 in *Lipids 34*, 907–913 (September 1999).

That the microcirculation-related heterogeneity of parenchymal liver cells is an important factor in the regulation of many liver functions is firmly established (see 1). Cells in the periportal (PP) afferent zone are exposed to blood richer in oxygen, substrates, hormones, and mediators than cells in the perivenous (PV) efferent zone, and the two subpopulations have been shown to differ in their subcellular structures and enzyme complements and therefore to elicit different functional capacities (1). Different types of zonation may, however, exist. Zonation of nitrogen metabolism seems to be static and structural, whereas that of carbohydrate and lipid metabolism seems dynamic and functional.

The liver is the central organ in maintaining whole body cholesterol homeostasis. It is responsible for the uptake of cholesterol from the circulating lipoproteins and the subsequent excretion of cholesterol from the body into bile, and it is also a major site for the synthesis of free and esterified cholesterol and for their secretion into plasma in new lipoproteins. These multiple functions are mainly carried out by the parenchymal cells. A number of processes involved in cholesterol metabolism have been found to be heterogeneously distributed in the PP and PV liver parenchyma. Most of the available data result from studies on the enzymes 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase and cholesterol 7α-hydroxylase (C7αH), rate-limiting cholesterol and bile acid synthesis (2,3), and on bile formation itself. In intact livers of normally fed rats, HMG-CoA reductase was found to be located mainly in the PP zone (4,5), whereas under simultaneous administration of the HMG-CoA reductase inhibitor, mevinolin, and of the bile acid sequestrant, cholestyramine, HMG-CoA reductase was induced in all hepatocytes (5,6). The capacity for bile formation predominates in hepatocytes that are localized periportally (7), although C7αH activity has been reported to be approximately eightfold higher in PV as compared to PP hepatocytes, and mass production of bile acids by cultured hepatocytes showed a PV/PP ratio of 4.4 (8). These apparently contradictory observations can be explained by greater feedback inhibition of bile acid synthesis by bile acids returning to the liver in the enterohepatic circulation in the PP zone (9). Hence, cholestyramine, which releases this feedback inhibition (10), decreases the PV/PP ratio of C7αH activity (8). In view of the separated dominance of the enzymes governing cholesterol and bile acid synthesis, and to fulfill cellular and body cholesterol homeostasis, we hypothesize that the cholesterol-cholesteryl ester (CE) cycle would also exhibit heterogeneity within the liver acinus. To date, however, no information is available about such zonal regulation.

The metabolism of CE in the liver is primarily controlled

at four levels. Esterification of cholesterol with long-chain fatty acyl-CoA to form CE is accomplished by the action of acyl-CoA:cholesterol acyltransferase (ACAT), which is an integral membrane protein located in the endoplasmic reticulum and allosterically regulated by cholesterol (recently reviewed in 11). CE and triacylglycerols (TG) entering hepatocytes *via* receptor-mediated endocytosis of plasma lipoproteins are broken down by the lysosomal cholesteryl ester hydrolase (lCEH) or lysosomal acid lipase (12). The resulting cholesterol is released into the cytosol and plays a key role in cellular sterol homeostasis (13,14). The hydrolysis of CE from intracellular lipid is achieved by the two neutral cholesteryl ester hydrolase (CEH) isoforms located in cytosol (cCEH) and microsomes (mCEH) (15). Although the contribution of the latter to the mobilization of metabolically active free cholesterol is greater in the female than in the male rat liver, the cCEH is the dominant activity in both sexes (16,17). The aim of this work was to investigate the acinar distribution of the specific activity of the enzymes governing the formation and hydrolysis of CE using PP and PV liver parenchymal cells. The flexibility of zonation was evaluated under conditions that are known to perturb the cholesterol flux across the liver, namely, in hepatocytes isolated from rats with a portal bile acid load decreased by cholestyramine feeding, which upregulates C7αH and HMG-CoA reductase (10). Separation of liver parenchymal cells into subpopulations originating from the PP and PV regions has been used to study zonal differences in a wide variety of metabolic liver functions (i.e., see 1). The main limitation of this approach is that the conditions used *ex vivo* do not necessarily reflect the situation that occurs *in vivo*. Notwithstanding, this approach allows the quantitative assessment of functional parameters and rates of metabolic processes under defined conditions. Our findings demonstrate homogeneity within the liver acinus for the acid lysosomal hydrolysis of CE and complex zonation of the formation and neutral hydrolysis of CE, with an acinar location-dependent response of each individual enzyme activity to cholestyramine.

EXPERIMENTAL PROCEDURES

Animals and chemicals. Female Sprague-Dawley rats weighing 200 g were housed under constant day length (12 h, lights off 0300–1500) and temperature (25°C), and allowed access to food and tap water *ad libitum*. Rats were fed either a normal low-fat pellet diet or the same diet supplemented with 5% (w/w) cholestyramine (Laboratorios Rubió, Barcelona, Spain). After 7 d, the rats were used at the sixth hour of the dark period. Cholesteryl [1-^{14}C]oleate (59.5 mCi/mmol), [1-^{14}C]oleic acid (57 mCi/mmol), and [1-^{14}C]oleoyl CoA (56 mCi/mmol) were from Amersham International plc (Buckinghamshire, United Kingdom). Cholesteryl [^{3}H]oleate (47 Ci/mmol) was from DuPont New England Nuclear (Boston, MA). Collagenase was purchased from Boehringer Mannheim GmbH (Mannheim, Germany). All other chemicals were from Sigma Chemical Co. (St. Louis, MO).

Preparation and characterization of PP and PV hepatocytes. Liver parenchymal cells were isolated by the two-step collagenase perfusion technique of Seglen (18) and fractionated by centrifugal elutriation as described in detail previously (19). Briefly, cells were washed twice in Krebs-Henseleit buffer containing 20 mM glucose and 2.5 mM $CaCl_2$ and once in the so-called incubation medium consisting of Dulbecco's modified Eagle's medium supplemented with 20 mM glucose, 1% bovine serum albumin, 10 mM pyruvate, 10 mM HEPES, and 40 mM sodium bicarbonate. Hepatocytes were fractionated using a Beckman JE6-B elutriator rotor on a Beckman J2-21 centrifuge adapted for operation at low speed. Routinely, 120×10^6 cells suspended in 6 mL of the incubation medium were submitted to centrifugal elutriation. PP and PV cells were eluted from the rotor using Krebs-Henseleit buffer with 1 mM $CaCl_2$, 5 mM glucose, 10 mM pyruvate, 6.5 mM HEPES, and 0.05% gelatin (elutriation buffer) by changes in rotor speed and buffer flow rate. Four populations of cells were recovered at 950 rpm–18 mL/min, 950 rpm–21 mL/min (PP cells), 950 rpm–24 mL/min, and 880 rpm–24 mL/min (PV cells). Cells were counted and sized using a Coulter counter (Multisizer II) with a 70-µm diameter aperture. The final hepatocyte suspension contained cells from two animals with a viability, as determined by Trypan Blue exclusion, exceeding 85%. The enrichment of PP and PV parenchymal cells was monitored by the distribution pattern of a number of marker enzymes and cell parameters that have been shown to reflect the asymmetry. Alanine and tyrosine aminotransferase activities were measured with a commercial assay kit (Sigma Chemical Co.) and according to Granner and Tomkins (20), respectively. The size, cytoplasmic complexity, mitochondria content, and ploidy of the PP and PV cells were determined in a flow cytometer (EPICS, model 752; Coulter, Hialeh, FL) equipped with an argon laser, using conventional fluorescent dyes (21,22). The estimated PP/PV ratio of alanine aminotransferase activity (1.5) and tyrosine aminotransferase activity (1.2) was in good agreement with published values (22–24), as was the size (PP, 18.69 ± 0.13 µm; PV, 23.13 ± 0.15 µm; means ± SEM for 20 preparations), cytoplasmic complexity (PP/PV ratio of 0.6), mitochondria content (PP/PV ratio of 1.4), and ploidy (higher in PV than in PP) (21–24). According to a dual parameter statistical analysis performed by the EPICS flow cytometer that considers the data of cytoplasmic complexity and size, the purity of the preparations in PP and PV hepatocytes averaged 93 and 72%, respectively, and cross-contamination of the populations was not significant.

Determination of ACAT, and lysosomal, microsomal, and cytosolic cholesterol esterase activities. The cell pellets were homogenized and submitted to differential centrifugation as described earlier (25). The lysosome-enriched fraction was resuspended in 250 mM sucrose solution at a 1 mg/mL protein concentration, and the microsome fraction in 20 mM Tris-HCl buffer pH 7.4 containing 250 mM sucrose at a protein concentration of 5 mg/mL. ACAT activity was assayed in microsomes under saturation cholesterol conditions by

measuring the rate of transfer of labeling from [1-^{14}C]oleoyl-CoA to cholesterol as described previously (26). CEH activity was estimated in lysosomes, cytosol, and microsomes, in terms of the release of labeled oleic acid from a cholesteryl [1-^{14}C]oleate micellar substrate as described previously (26).

Other analytical methods and statistical analysis. Protein was determined by the dye-binding method of Bradford (27) using bovine serum albumin as standard. TG and free and esterified cholesterol in cell homogenates, cytosol, and microsomes were quantified by the method of Ruiz and Ochoa (28) using a Bio Image image analysis system equipped with a Kodak Videk Megaplus digital camera and Whole Band Sun View commercial software from Bio Image Corporation (Ann Arbor, MI). Data were analyzed by Student's *t*-test, with $P \leq 0.05$ taken as indicating a statistically significant difference.

RESULTS

The present study was aimed at investigating the functional heterogeneity of liver PP and PV parenchymal cells for the metabolism of CE. To this end, specific activities of the enzymes catalyzing the formation and hydrolysis of CE were measured in PP and PV hepatocytes isolated from rats fed a normal diet or the same diet supplemented with cholestyramine. Table 1 shows that, in normally fed rats, ACAT activity and lysosomal acid lipase activity in PP cells did not differ from those in PV cells, while both neutral cCEH and mCEH activities zonated toward the PV zone of the acinus. It seems that the ratio between the enzymatic capacities for the esterification of cholesterol and for the hydrolysis of CE from lipoproteins taken up by receptor-mediated endocytosis does not depend on the acinar location of the hepatocyte, while the ratio between the enzymatic capacities for cholesterol esterification and for the mobilization of stored CE by cCEH and mCEH is moderate, though significantly higher in PP than in PV hepatocytes. This relative PP dominance of the esterification side of the cholesterol–CE cycle was not, however, accompanied by a higher net content of CE. Table 2 shows that the levels of TG, and free and esterified cholesterol in cell homogenates, cytosolic fractions, and microsomal fractions did not differ substantially in PP and PV cells. Nevertheless, the ratios of free to esterified cholesterol and of TG to esterified cholesterol were about 35-40% higher in PP cell microsomes. This suggests a superior relative availability of the former lipids in PP hepatocytes and of CE in PV hepatocytes for those metabolic events involving the endoplasmic reticulum.

Adding cholestyramine to the diet is well known to drain cell cholesterol to bile acids. This upregulates cholesterogenesis and low density lipoprotein receptor-mediated lipoprotein uptake, this latter leading to a depressed portal load of plasma lipoproteins (10). As shown in Table 1, PP and PV hepatocytes responded to cholestyramine with specific changes of activity of the enzymes controlling the cholesterol-CE cycle. Esterification of cholesterol decreased selectively in hepatocytes from the PP zone, which elevated the PV/PP ratio of ACAT activity from 1 to near 1.5. The specific activity of the acid CEH dropped by about 50% in both types of hepatocyte subpopulations, hence the homogeneous distribution of the lCEH activity within the liver acinus was not altered significantly by cholestyramine. The PV dominance of the cCEH activity was also maintained, since no significant change in activity was found in the two cell subpopulations. And finally, the initial asymmetry of the mCEH was abolished because of an inhibition of activity which was more prominent in PV than in PP hepatocytes. In consequence, the ratio between the activities of ACAT and lCEH doubled in PV cells, and the ratio between ACAT activity and neutral CEH activity, considered as the addition of cCEH and mCEH, increased also exclusively in hepatocytes from the PV zone. Therefore, the two ratios zonated toward the PV zone of the acinus by cholestyramine. It is also of interest to note that both the formation and the hydrolysis of CE occur at lower rates in hepatocytes isolated from cholestyramine-fed rats.

The contribution of non-PP-non-PV hepatocytes to CE metabolism and confirmation of cholestyramine effects were assessed in aliquots of the whole hepatocyte suspensions used for Table 1 taken prior to elutriation. Cells were homogenized and subfractionated, and enzyme activities were determined in the corresponding subcellular fraction simultaneously with those performed in fractions from PP and PV hepatocytes.

TABLE 1
Specific Activities of the Enzymes Catalyzing the Formation and Hydrolysis of Cholesteryl Esters in Periportal (PP) and Perivenous (PV) Hepatocytes from Rats Fed a Normal or a Cholestyramine Diet[a]

	Normal diet			Cholestyramine diet		
Enzyme	PP cells	PV cells	PV/PP ratio	PP cells	PV cells	PV/PP ratio
ACAT (pmol/min/mg protein)	2315 ± 435 (8)	2409 ± 410 (8)	1.04	1667 ± 336 (6)[d]	2497 ± 303 (6)[a]	1.50
lCEH (pmol/min/mg protein)	3575 ± 505 (8)	3300 ± 304 (8)	0.92	1719 ± 179 (6)[d]	1591 ± 153 (6)[d]	0.93
cCEH (pmol/min/mg protein)	24.4 ± 3.3 (10)	32.4 ± 3.0 (10)[c]	1.33	23.9 ± 3.6 (6)	34.8 ± 4.4 (6)[b]	1.46
mCEH (pmol/min/mg protein)	67.9 ± 10.1 (10)	83.4 ± 12.3 (10)[c]	1.23	50.6 ± 4.9 (7)[d]	52.9 ± 5.1 (7)[d]	1.05
Ratio ACAT/lCEH	0.648 ± 0.093	0.730 ± 0.108	1.13	0.969 ± 0.152	1.563 ± 0.144[a,d]	1.61
Ratio ACAT/(cCEH + mCEH)	40.76 ± 5.11	20.80 ± 2.60[c]	0.51	22.37 ± 3.11[d]	28.34 ± 2.96	1.27

[a]The specific activity of ACAT and lysosomal, cytosolic, and microsomal CEH was determined in the corresponding subcellular fraction of PP and PV hepatocytes isolated from normal or cholestyramine-fed rats. All values are means ± SEM for the number of preparations indicated in parentheses. Significant differences from the PP zone in the same diet group are indicated by [a]$P \leq 0.05$, [b]$P \leq 0.01$, and [c]$P \leq 0.001$ (Student's paired *t*-test). Significant differences from the same parameter in normally fed rats are indicated by [d]$P \leq 0.05$ minimum (Student's unpaired *t*-test). ACAT, acyl-CoA:cholesterol acyltransferase; lCEH, lysosomal cholesteryl ester hydrolase; cCEH, cytosolic CEH; mCEH, microsomal CEH.

TABLE 2
Lipid Composition of the Cell Homogenate and the Cytosolic and Microsomal Subcellular Fractions of PP and PV Hepatocytes Isolated from Normal Fed Rats[a]

Cell fraction	Lipid (nmol lipid/mg cell protein)	PP cells	PV cells
Homogenate	Triacyglycerides	58.4 ± 12.8	56.8 ± 14.8
	Free cholesterol	23.3 ± 3.6	23.2 ± 0.6
	Cholesterol ester	5.69 ± 0.50	4.93 ± 0.57
	Ratio FC/CE	4.38 ± 1.13	4.94 ± 0.67
Cytosol	Triacylglycerides	15.7 ± 2.5	18.2 ± 6.6
	Free cholesterol	1.35 ± 0.17	1.19 ± 0.12
	Cholesterol ester	2.36 ± 0.49	2.06 ± 0.22
	Ratio FC/CE	0.63 ± 0.12	0.62 ± 0.15
Microsomes	Triacylglycerides	32.9 ± 6.1	28.0 ± 3.9
	Free cholesterol	19.4 ± 1.9	14.7 ± 2.3
	Cholesterol ester	3.45 ± 0.29	3.94 ± 0.55
	Ratio FC/CE	5.84 ± 0.98	4.18 ± 0.92[a]
	Ratio TG/CE	9.54 ± 1.21	7.10 ± 0.42[a]

[a]Levels of triacylglycerol (TG), free (FC) and esterified cholesterol (CE) were determined in the cell homogenate and the cytosolic and microsomal fractions of PP and PV hepatocytes isolated from normally fed rats. All values are means ± SEM for the number of preparations indicated in parentheses. Significant differences from the PP zone were analyzed by the Student's paired *t*-test and are indicated by $^{a}P \leq 0.05$ minimum. For other abbreviations see Table 1.

Comparison of data in Tables 1 and 3 concerning normally fed animals indicates that all enzyme activities were slightly higher in the total cell population than in PP or PV hepatocytes. This suggests that the formation and hydrolysis of CE might function actively in hepatocytes located in any acinar zone. Irrespective of the various models proposed to date to explain the microstructure of the liver acinus, PP hepatocytes seem to account for the bulk of the parenchymal cells within the acinus (i.e., see 1,31). In line with this, a good relationship was observed between the changes caused by cholestyramine on ACAT and lysosomal, cytosolic, and microsomal CEH in total hepatocytes and those caused in the PP hepatocyte subpopulation. Even the response of the PP cells, which are in a minority, may be masked by that of PP cells, as it is for the high capacity for cholesterol esterification through ACAT maintained by PV hepatocytes after cholestyramine feeding. In general, qualitative changes in total hepatocytes with cholestyramine were as expected, although the increase in cCEH activity, which was consistent for Ghosh *et al*. using whole livers harvested during the light period from male rats fed cholestyramine for 10 d (32), did not reach statistical significance in this study using hepatocytes isolated at midnight from female rats fed cholestyramine for 7 d. Diurnal rhythms were identified for the acid and neutral cholesterol esterases (25) and the above differences in cCEH activity are likely related, at least in part, with the time of the day at which the animals were used. As a matter of fact, a significant 30% increase in cCEH activity was observed in livers of cholestyramine fed rats over the control fed group when rats were used at the beginning of the light period (experiments not shown).

DISCUSSION

Our results demonstrate for the first time symmetry within the liver acinus of the lCEH activity, responsible for the degradation of endocyted lipoprotein-derived CE, a structural zonation of the cCEH, and a dynamic zonation of the microsomal enzymes mCEH and ACAT, with a PV dominance of the enzymatic capacity for the degradation of stored CE in normally fed rats and an exclusive PP reduction of the cholesterol esterifying ACAT activity after cholestyramine feeding. The difficulty of extrapolating these observations to the whole animal is evident: the experiments show a potential but do not reveal how it would be modified by whole body hormonal influences. We are also aware that the time lag between the handling of the intact liver and the performance of experimental determinations might produce changes in metabolic fluxes. This problem could be important in the case of ACAT activity, which is quite dependent on the conditions of hepatocyte isolation and incubation (11). Disturbance of hepatic zonation by cholestyramine offers an interesting model for the study of the significance of zonation in cholesterol metabolism. Our current view of the metabolism of CE in PP and PV hepatocytes is illustrated in Figure 1; this should not be interpreted to mean that PP and PV cells are located adjacent in a hepatic lobule. The scenario is based on results and ideas from this and other laboratories (4–9,19,24,29,30) and involves the following assumptions: (i) there is a gradient of bile acids and

TABLE 3
Specific Activities of the Enzymes Catalyzing the Formation and Hydrolysis of Cholesteryl Esters in Hepatocytes from Rats Fed a Normal or a Cholestyramine Diet[a]

Enzyme	Normal diet	Cholestyramine diet	Decrease (%)
ACAT (pmol/min/mg protein)	2752 ± 407 (8)	1496 ± 371 (6)[d]	45.6
lCEH (pmol/min/mg protein)	4074 ± 469 (8)	2463 ± 319 (6)[d]	39.5
cCEH (pmol/min/mg protein)	38.3 ± 5.1 (10)	41.1 ± 3.7 (6)	– 7.3
mCEH (pmol/min/mg protein)	91.9 ± 10.6 (10)	72.5 ± 6.9 (7)[d]	21.1
Ratio ACAT/lCEH	0.675 ± 0.077	0.607 ± 0.054	10.0
Ratio ACAT/(cCEH + mCEH)	21.14 ± 3.04	13.17 ± 2.11[d]	37.7

[a]One aliquot of each preparation of hepatocytes from normal or cholestyramine fed rats used in the experiments reported in Table 1 was homogenized before submission to centrifugal elutriation, and the specific activities of ACAT, lCEH, cCEH, and mCEH were determined in the corresponding subcellular fraction. All values are means ± SEM for the number of preparations indicated in parentheses. Significant differences from normal fed rats were analyzed by the Student's unpaired *t*-test and are indicated by $^{d}P \leq 0.05$, minimum. For abbreviations see Table 1.

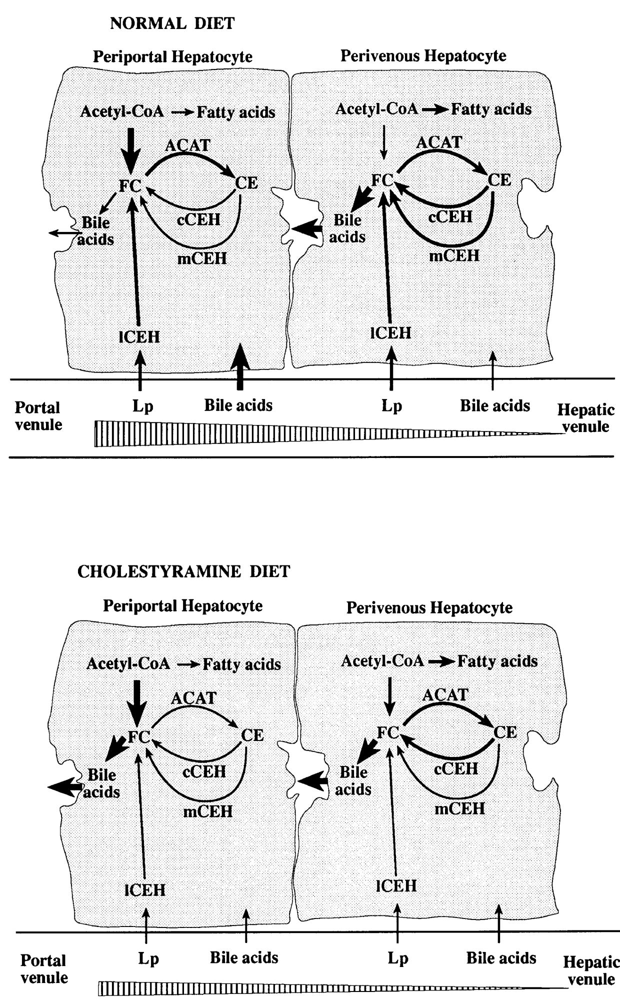

FIG. 1. Hypothetical scheme of cholesteryl ester metabolism in PP and PV hepatocytes from rats fed a normal or a cholestyramine diet. This model involves three key assumptions. (i) There is a gradient of bile acids and lipoproteins (Lp) from the portal to the hepatic venule that is attenuated by cholestyramine, with higher PP uptake of bile acids and symmetrical uptake of lipoproteins. The concentration gradients are represented by the elongated triangles shown at the bottom of each panel. (ii) There is no zonation of lCEH and ACAT activity, and PV dominance of cCEH and mCEH activity exists in normally fed rats. (iii) There is a predominance in the increase in bile acid synthesis and the decrease in ACAT activity in PP hepatocytes, and of the increase in cholesterol synthesis and the decrease in mCEH in PV cells in response to cholestyramine. The close proximity of the PP and PV cell types in the scheme does not indicate that these cells are located adjacent in a hepatic lobule. Abbreviations: FC, free cholesterol; ACAT, acyl-CoA:cholesterol acyltransferase; CE, cholesteryl ester; cCEH, cytosolic cholesteryl ester hydrolase; lCEH, lysosomal CEH; mCEH, microsomal CEH; PP, periportal; PV, perivenous.

lipoproteins from the portal to the hepatic venule that is attenuated by cholestyramine, with a higher PP uptake of bile acids and a homogeneous uptake of lipoproteins, (ii) there is no zonation of lCEH and ACAT activity, and PV dominance of both neutral cCEH and mCEH activities exists in livers of normally fed rats, and (iii) in response to cholestyramine feeding, the increase in bile acid synthesis and the decrease in ACAT activity dominate in PP hepatocytes, and the increase in cholesterol synthesis and the decrease in mCEH dominate in PV cells.

Comparable lCEH activity in PP and PV hepatocytes from normal or cholestyramine-fed rats was observed in this work. PP hepatocytes, *in vivo*, are likely to be exposed to higher concentrations of lipoproteins than PV cells, and such an acinar lipoprotein gradient might be expected to lead to zonal differences of the processes involved in lipoprotein uptake and processing. Unfortunately, this is as yet hardly explored. Results, though indeed not conclusive, suggest little zonation. For example, Fong *et al.* (29) found that low density lipoprotein receptors in the normally fed rat liver were present on the sinusoidal membranes without an obvious portal to central gradient. Vooschur *et al.* (24) reported that the lipoprotein-remnant receptor density and the binding of β-migrating very low density lipoproteins to cell membranes was similar in PP and PV hepatocytes, and recent research has revealed that, although PP hepatocytes have a greater capacity for the uptake of ^{125}I-chylomicron remnants than PV cells, both PP and PV cells bind and internalize similar amounts of remnants up to a certain remnant protein (19). Moreover, little zonation of the lysosomal degradation of proteins was reported (30). All these findings are in apparent harmony with the observed lack of zonation for the lysosomal acid lipase activity in normally fed rats and the identical decrease of lCEH activity in PP and PV cells promoted by cholestyramine. A minor activity in the putative regulatory enzyme of the hydrolysis of lipoprotein-derived CE and TG may underlie a minor uptake concomitant to the well-described lipoprotein-lowering effect of cholestyramine. It might thus be hypothesized that, although there is a concentration gradient in blood levels of lipoproteins between the PP and PV parenchyma, the uptake and internalization of lipoproteins and further degradation of components by the two subpopulations of hepatocytes are similar. This would guarantee effective nutrient extraction even when the circulating lipoprotein load is low. The question is open as to whether there are zonal differences for the selective uptake of lipoproteins where intracellular nonlysosomal lipolytic enzymes, such as the cCEH, may be involved.

ACAT plays a crucial role in the maintenance of cellular cholesterol homeostasis. The enzyme activity is highly activated by cholesterol substrate, which also acts as an allosteric activator of the enzyme (11). Here ACAT activity was determined in microsomes with saturated cholesterol as the substrate. ACAT showed a symmetrical distribution in control livers. However, zonation toward the PV region was induced by cholestyramine because of an exclusive depression of activity in cells from the PP zone. Hence, if the cellular demand of unesterified cholesterol increases, cholesterol esterification *via* ACAT might not occur at its maximal velocity in PP hepatocytes, although it might in PV hepatocytes. On the contrary, PP upstream hepatocytes adapt more actively than PV downstream cells to cholestyramine when C7αH is considered. The fact that opposite changes in ACAT and C7αH activity occur only in PP cells suggests that restriction of the esterification in favor of the 7α-hydroxylation of cholesterol

may not be a common hepatocyte response to cholestyramine but may be reserved to the PP hepatocytes. The balance between cholesterol esterification and hydrolysis of CE by cCEH and mCEH was also affected by cholestyramine only in PP cells, in which provision of metabolically active cholesterol dominates over cholesterol esterification as compared to normal PP cells. On the contrary, adaptation of cholesterogenesis and hydrolysis of CE by mCEH to cholestyramine seem to be more pronounced in hepatocytes from the PV area of the acinus. HMG-CoA reductase is widely accepted to be localized mainly in the PP zone of normal rat livers (4–6), though with a questionable degree of zonation, and it has been shown to be induced more efficiently in PV than in PP hepatocytes by increased cholesterol demand underlying dietary manipulations (5,6). Here we report that the activity of mCEH declined more markedly in PV than in PP hepatocytes, thus leading to the loss of the initial PV dominance of this activity. Taken together, the observed changes in the hepatic enzyme activities would stabilize free cholesterol in cholestyramine-fed rats by decreasing ACAT and mCEH, as well as by enhancing *de novo* cholesterol synthesis and the conversion of cholesterol to bile acids. This occurs with prominent contributions of PP cells to bile acid and CE formation and of PV cells to cholesterol synthesis and the microsomal hydrolysis of CE.

The metabolic scenario illustrated in Figure 1 restricts a direct linkage between all these pathways and points to a more complex integrated regulation than originally stated. Further, the purpose of this compartmentation is not entirely clear. With regard to this and the microsomal CEH isoform, whose function is not still ascribed, it is noteworthy that the observed qualitative changes indicate that mCEH does not seem to mediate the provision of a pool of cholesterol that is particularly committed to esterification or to hydroxylation. In contrast with the dynamic zonation displayed by the mCEH, the cCEH showed a structural type zonation. Not only the specific but also the total cCEH activity was always predominant in PV over PP hepatocytes, irrespective of the perturbation in the hepatic flux of cholesterol. Complex regulation of rat liver cCEH by hormones, signal transduction, and changes in cholesterol flux, which takes place by changes both in mRNA levels and postranscriptional mechanisms, has been reported recently (32). The identity of the factors involved in creating and maintaining the acinar heterogeneity of the hepatic cCEH activity deserves further investigation. At least part of the difference between the PP and PV zones involves long-term mechanisms that survive hepatocyte isolation. The physiological significance of an elevated neutral enzymatic capacity for the mobilization of CE in PV cells is unclear, since PV hepatocytes apparently constitute only a minor fraction of the parenchymal cells within the liver acinus (1,31). Nevertheless, PV hepatocytes are localized in the less aerobic, efferent side of the acinus, and an intriguing possibility is that the secretion of CE as components of plasma lipoproteins is zonated. The question of whether there is acinar heterogeneity of hepatocytes for very low density lipoprotein assembly and secretion is a matter of ongoing research.

The hepatic zonation of some pathways of lipid metabolism has been recently reviewed (31). These pathways appear to be less zonated than those of carbohydrate or amino acid metabolism, and the zonation of a certain step or pathway by biochemical studies appears to be less marked than by immunohistochemical approaches, in which information about the amount of total enzyme protein but not of enzyme activity is acquired. A general conclusion that may be inferred from our investigation is that the acinar distribution of the formation and the neutral hydrolysis of CE is complex and changes according to the requirements of the organ itself, whereas the acid lysosomal hydrolysis of CE shows a symmetrical distribution. Overall, this indicates that acinar heterogeneity may be an additional factor in the regulation of CE metabolism.

ACKNOWLEDGMENTS

This work was supported by grants PI96/83 and PI97/77 from the Basque Government. The authors are grateful to Montse Busto for skillful technical assistance and Euclides Sabino for scheme drawing. J.R.R. thanks the University of the Basque Country for a predoctoral fellowship.

Eicosapentaenoic Acid and Docosahexaenoic Acid Selectively Attenuate U46619-Induced Smooth Muscle Cell Proliferation

Rajbabu Pakala*, Rajashree Pakala, and Claude Benedict

ABSTRACT: It is well known that vascular smooth muscle cell (SMC) proliferation is a key step in atheromatous plaque formation. Thromboxane A_2 (TxA_2), released from aggregating platelets and an injured vessel wall, may play an important role in the development of atheromatous plaque. Many animal studies have suggested that n-3 polyunsaturated fatty acids eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) present in the fish oils have antiatherosclerotic effects. In the present study, we investigated the effect of EPA and DHA on TxA_2-induced SMC proliferation. To determine the functional selectivity of n-3 fatty acids, we also tested the effect of arachidonic acid (AA, 20:4n-6), γ-linolenic acid) (LNA, 18:3n-6), and oleic acid (OA, 18:1n-9) on TxA_2-induced SMC proliferation. Only EPA and DHA prevented the SMC proliferation induced by the TxA_2 mimetic U46619. When EPA and DHA were added together in the ratio in which they are present in menhaden oil, EPA and DHA acted synergistically to block the SMC proliferation induced by the TXA_2-mimetic. These findings suggest that the n-3 polyunsaturated fatty acids in fish oils may exert antiatherosclerotic effects by blocking the mitogen-stimulated proliferation of SMC.

Paper no. L8029 in *Lipids 34*, 915–920 (September 1999).

The amount and source of dietary lipids can affect a variety of disease processes in humans (1,2). In particular, dietary long-chain polyunsaturated fatty acids (PUFA) have been shown to modulate a number of cellular responses to environmental stimuli (3,4). Among PUFA, a clear distinction of properties has emerged between the n-3 and n-6 families with some notable exceptions (5). Epidemiological studies have suggested an inverse relationship between intake of n-3 PUFA and incidence of cardiovascular disease (6–8). Consumption of n-3 PUFA diminishes atherogenesis in some non-human primate models (9), as well as in other animal species (3,4). In addition to atherothrombotic disease, intimal hyperplasia in autologous vein grafts (10,11) has been inversely associated with dietary intake of n-3 PUFA. Efforts to understand the mechanism of action of n-3 PUFA have largely focused upon their effects on eicosanoid production. However, the hypothesis that n-3 PUFA act through alterations of eicosanoid metabolism cannot explain many aspects of their biological activity. These include decreased production of tissue factor (12), cytokines from monocyte-derived macrophages (13), platelet-derived growth factor-like mitogens from endothelial cells (14), and monocyte macrophages (15,16). Thus, there is a need to understand the noneicosanoid effect that may play a role in antiatherogenic effects of n-3 PUFA.

Production of thromboxane A_2 (TxA_2) at sites of vascular injury contributes to lesion formation characteristic of atherosclerosis and restenosis (17,18). Although well known as a potent vasoconstrictor and inducer of platelet aggregation (19,20), TxA_2 also has been shown to induce smooth muscle cell (SMC) migration and proliferation (21–29). In this study, we demonstrate that when the TxA_2 mimetic U46619 was added together with n-3 fatty acids eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA), U46619 failed to induce vascular SMC proliferation as measured by ^{3}[H]-thymidine incorporation. We also show that this inhibitory effect is specific for n-3 fatty acids because the n-6 fatty acids arachidonic (AA) and γ-linolenic acid (LNA) or the n-9 fatty acid oleic acid (OA) failed to inhibit TxA_2-induced ^{3}[H]-thymidine incorporation.

MATERIALS AND METHODS

Serotonin (as the creatine sulfate), EDTA, pargyline, AA (20:4n-6), LNA (18:4n-6), OA (18:1n-9), and Hank's balanced salts were obtained from Sigma Chemical Co. (St. Louis, MO). Dulbecco's modified Eagle's medium (DMEM) and fetal bovine serum (FBS) were obtained from Whittaker Bioproducts (Walkersville, MD), and ^{3}[H]-thymidine (20 Ci/mole) came from New England Nuclear Corp. (Boston, MA). Other reagents were purchased from local vendors. EPA and DHA were provided by the FOTM program, United States Department of Commerce, National Oceanic and Atmospheric Administration (Charleston, SC).

Isolation, culture, and characterization of canine aortic SMC. Primary aortic SMC were isolated using the explant method previously described (29). The intima was peeled off from the aorta and the media was carefully stripped away

from the adventia and placed in a petri dish containing warmed DMEM (37°C). The media layer was cut into approximately 1-mm squares, which were transferred to a 25-cm^2 tissue culture flask and barely covered with DMEM supplemented with 10% FBS. The blocks of tissue were cultured in a humidified atmosphere of 95% air and 5% CO_2 (vol/vol) at 37°C. After 1–2 wk, the tissue blocks were removed and the migrated SMC were cultured. Following isolation, the identity of the SMC was confirmed by morphological examination and by staining for β-actin.

Subcultures of SMC were done once they became confluent; media from the plates was aspirated and the cells were washed with 10 mL of phosphate-buffered saline (PBS). Then, 2–3 mL of trypsin EDTA solution (0.05% trypsin, 0.53 mM EDTA in Ca^{2+}-, Mg^{2+}-free Hank's balanced salts) was added to the cells and incubated at room temperature for 2–3 min. The action of trypsin on cells was blocked by the addition of 7–8 mL of DMEM containing 10% FBS. The cells were collected by centrifugation at 150 × *g* for 10 min. After removing the supernatant, the pelleted cells were dispersed in 10 mL of DMEM containing 10% FBS and fresh cultures were initiated from these cells.

^{3}[H]-thymidine incorporation. Aortic SMC from passages 2 and 3 were seeded into 35-mm diameter plates at a density of 65,000 to 75,000 cells/plate in DMEM containing 10% FBS and allowed to proliferate for approximately 72 h. After 72 h, the growth medium was replaced with 2 mL of DMEM containing 0.1% FBS and incubated for approximately 72 h to arrest cell growth and cause synchronization. After growth arrest, the medium was replaced with 2 mL of DMEM containing 1% FBS and 100 mM pargyline. Where indicated, U46619 (a TxA_2 mimetic) alone or the indicated fatty acid (EPA, DHA, AA, OA, LNA) alone or both together were added to this medium. After 20 h of incubation with U46619 and/or indicated fatty acid, 1 μCi of [^{3}H]-thymidine was added to each plate and then incubated for an additional 4 h. The medium was removed and the plates were washed three times with ice-cold PBS. Then, 6% trichloroacetic acid was added to the cells and the acid-insoluble material containing [^{3}H]-thymidine was collected on a glass fiber filter. The filters were washed with 100% ethanol, air dried, and [^{3}H]-thymidine was quantified using a liquid scintillation counter. In a selected number of dishes, the cells were counted (Coulter counter) on the day of seeding (before cells were attached) and before changing to 0.1% serum medium (on day 3) to ensure that they were growing, and finally on day 6 to determine that the cells were growth-arrested. To determine the cell number on days 3 and 6, dishes were first washed with PBS, followed by the addition of 0.2 mL of 2% (wt/vol) crude pancreatic trypsin in PBS, containing 0.152 M EDTA. The dishes were incubated for 2–3 min at room temperature before addition of 0.4 mL FBS. The contents of each dish were diluted to 10 mL with isoton II (Coulter Electronics, Luton Beds, England) and cell numbers determined. All experiments were performed in triplicate.

Statistical analyses. Data were analyzed by one-way analysis of variance. When a statistically significant difference was obtained, further analysis was conducted using Scheffe's Post-hoc tests. In each figure, mean ± SD are shown. For all comparisons, statistical significance was assumed as $P < 0.05$.

RESULTS

Effect of TxA_2 on ^{3}[H]-thymidine incorporation by SMC. The effect of increasing concentrations of U46619 on the [^{3}H]-thymidine incorporation by growth-arrested SMC is shown in Figure 1. When U46619, in 1% FBS-containing medium was added to growth-arrested SMC at concentrations higher than 0.33 μM, it significantly induced ^{3}[H]-thymidine incorporation. The maximal increase in ^{3}[H]-thymidine incorporation was observed at a concentration of 3.33 μM of U46619 where there was approximately a fivefold increase in [^{3}H]-thymidine incorporation, as compared to the untreated control. However, with further increases in concentrations of U46619, there was a gradual, but significant, decrease in the amount of ^{3}[H]-thymidine incorporated.

Effect of n-3, n-6, and n-9 fatty acids on ^{3}[H]-thymidine incorporation by SMC. The effect of increasing concentrations of n-3 fatty acids EPA and DHA, n-6 fatty acids AA and LNA, and n-9 fatty acid OA (in 1% FBS-containing medium) on ^{3}[H]-thymidine incorporation into growth-arrested SMC was examined. Incubation of growth-arrested SMC with LNA or OA at the concentrations tested showed no significant effect on ^{3}[H]-thymidine incorporation (Fig. 2). When growth-arrested SMC were incubated with AA up to an added concentration of 1.67 μM, AA did not have a significant effect on ^{3}[H]-thymidine incorporation. However, at higher concentrations, AA induced a significant increase in the extent of ^{3}[H]-thymidine in-

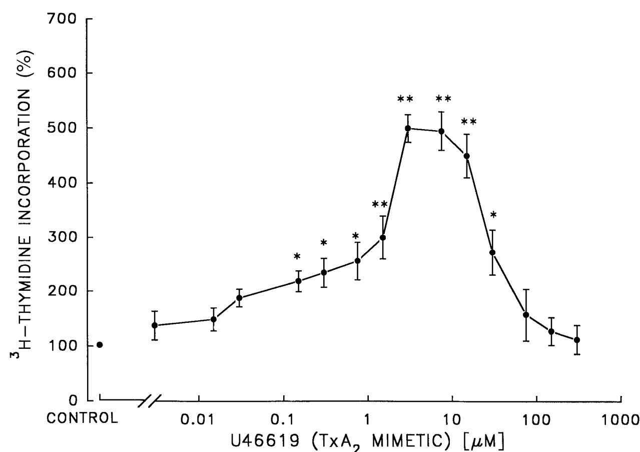

FIG. 1. Concentration-dependent stimulation of smooth muscle cells (SMC) by thromboxane A_2 (TxA_2). ^{3}[H]-thymidine incorporation into DNA was measured in growth-arrested SMC stimulated by various concentrations of U46619 in 1% fetal bovine serum (FBS), as described in the Materials and Methods section. One hundred percent equals the baseline value of ^{3}[H]-thymidine uptake (100% = 15856 ± 650 counts per minute (cpm)/10^6 cells). The experiments were performed with two different batches of cells and each batch was tested in triplicate. *$P < 0.05$, **$P < 0.01$ as compared to the control.

corporation, reaching a fourfold increase at 16.7 μM. (Fig. 2). When growth-arrested SMC were incubated with EPA or DHA, EPA up to 3.3 μM and DHA up to 7.5 μM did not have any significant effect on ^{3}[H]-thymidine incorporation. In contrast, with concentrations of EPA higher than 3.3 μM or DHA higher than 7.5 μM, there was a gradual decrease in the amount of ^{3}[H]-thymidine incorporated. At concentrations greater than 75 μM, both EPA and DHA completely inhibited ^{3}[H]-thymidine incorporation and the cells failed to respond when transferred to normal growth medium, indicating that these concentrations of EPA and DHA are cytotoxic to SMC (Fig. 2).

Effect of n-3, n-6, and n-9 fatty acids on TxA_2-induced ^{3}[H]-thymidine incorporation by SMC. To determine whether U46619-induced ^{3}[H]-thymidine incorporation into SMC can be inhibited by n-3 fatty acids, growth-arrested SMC were incubated with different concentrations of U46619 (0.05–5 μM), along with EPA or DHA in concentrations at which they did not have any significant growth inhibitory effect (0.165–0.83 μM). In addition, SMC also were incubated with the same concentrations of U46619 and varying concentrations of AA, LNA, or OA (0.165–0.83 μM). When SMC were incubated with 0.33 μM EPA or DHA, they partially blocked (≈ 25%) the U46619-induced ^{3}[H]-thymidine incorporation. However, when SMC were incubated with 0.83 μM EPA or DHA, even 5 μM of U46619 failed to stimulate any ^{3}[H]-thymidine incorporation (Fig. 3). In contrast, when SMC were incubated with AA, OA, or LNA, even at a concentrations as high as 0.83 μM, they did not inhibit U46619-induced ^{3}[H]-thymidine incorporation (Fig. 4).

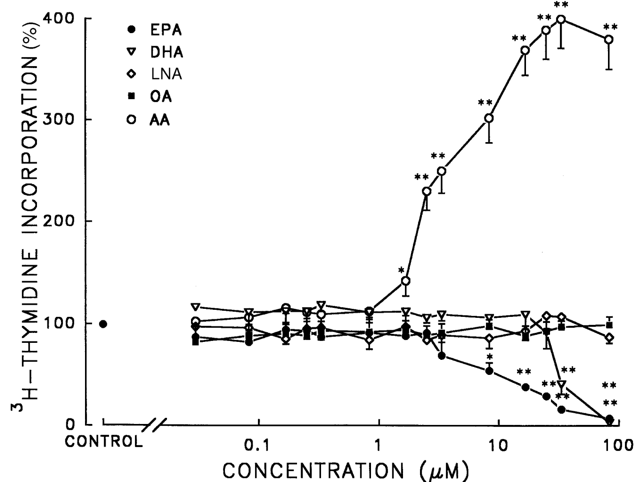

FIG. 2. Effect of eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), oleic acid (OA), γ-linolenic acid (LNA), and arachidonic acid (AA) on SMC growth. Various concentrations of EPA, DHA, LNA, OA, or AA in 1% FBS containing Dulbecco's modified Eagle's medium (DMEM) were added to growth-arrested SMC and the amount of ^{3}[H]-thymidine incorporated into the DNA was measured as described in the Materials and Methods section. One hundred percent equals the baseline value of ^{3}[H]-thymidine uptake (100% = 16,580 ± 760 cpm/10^6 cells). The experiments were performed with two different batches of cells and each batch was tested in triplicate. *$P < 0.05$, **$P < 0.01$ as compared to the control. See Figure 1 for other abbreviations.

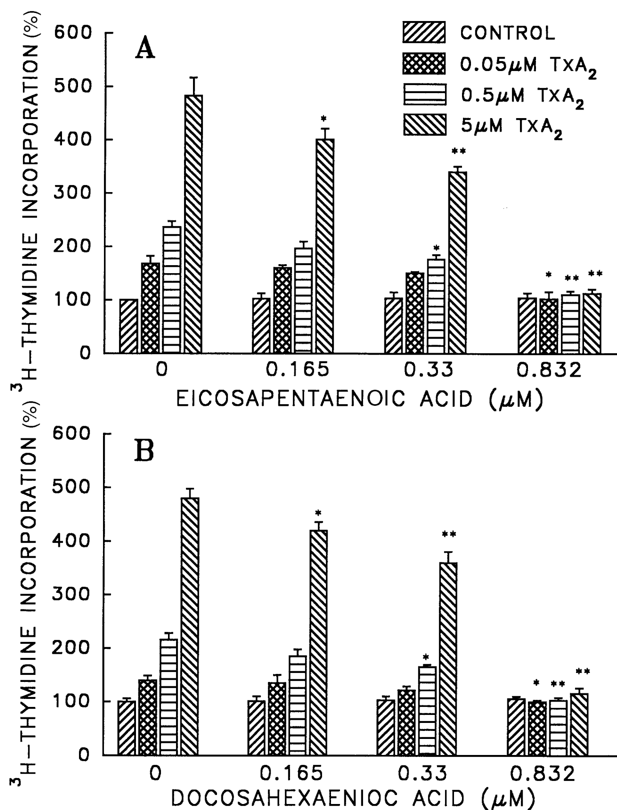

FIG. 3. Interaction between U46619 and (A) EPA or (B) DHA in modulating SMC growth. Growth-arrested canine aortic SMC were incubated with indicated concentrations of U46619 and EPA or DHA in 1% FBS containing DMEM, and the amount of ^{3}[H]-thymidine incorporated was determined as in the Materials and Methods section. One hundred percent equals the baseline value of ^{3}[H]-thymidine uptake [100% = (A) 16,120 ± 740 cpm/10^6 cells, (B) 100% = 16,470 ± 810 cpm/10^6 cells]. The experiments were performed with two different batches of cells and each batch was tested in triplicate. *$P < 0.05$, **$P < 0.01$ as compared to the corresponding control. See Figures 1 and 2 for abbreviations.

In menhaden oil, widely used in human and animal studies, EPA and DHA are present in approximately a 2:1 ratio. Therefore, we also tested the combined effects of EPA and DHA in this ratio on U46619-induced ^{3}[H]-thymidine incorporation. Growth-arrested SMC were incubated with 0.11 and 0.22 μM EPA or 0.055 and 0.11 μM DHA or 0.165 μM total n-3 fatty acids (0.11 μM EPA + 0.055 μM DHA) or 0.33 μM n-3 fatty acids (0.22 μM EPA + 0.11 μM DHA) as a mixture along with mitogenic concentrations of U46619. Although at a concentration of 0.165 μM or 0.33 μM EPA or DHA partially reversed (≈ 10 and 20%, respectively) the mitogenic effect of U46619 (Fig. 3), the same concentration of total n-3 fatty acids (0.11 μM EPA + 0.055 μM DHA and 0.22 μM EPA + 0.11 μM DHA) almost completely reversed (≈ 60 and 90%, respectively) U46619-induced ^{3}[H]-thymidine incorporation (Fig. 5). These results suggest that when present in a 2:1 ratio, EPA and DHA act synergistically in reversing U46619-induced mitogenic effects.

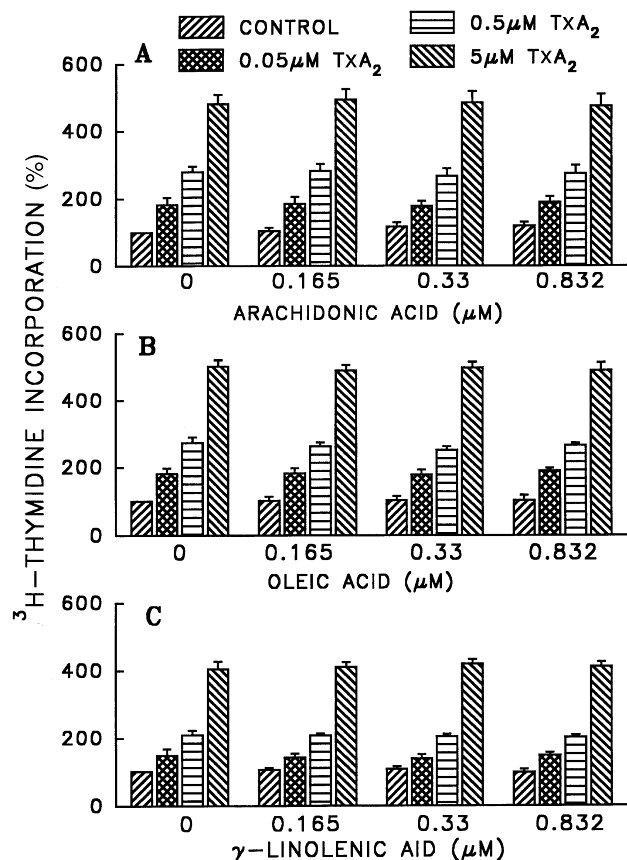

FIG. 4. Interaction between U46619 and (A) AA, (B) OA, or (C) LNA in modulating SMC growth. Growth-arrested SMC were incubated with indicated concentrations of U46619 and AA, OA, or LNA in 1% FBS containing DMEM, and the amount of ^{3}[H]-thymidine incorporated was determined as described in the Materials and Methods section. One hundred percent equals the baseline value of ^{3}[H]-thymidine uptake (100% = 16970 ± 820 cpm/10^6 cell for A; 100% = 16820 ± 640 cpm/10^6 cells for B; 100% = 17128 ± 860 cpm/10^6 cells for C). The experiments were performed with two different batches of cells and each batch was tested in triplicate. See Figures 1 and 2 for abbreviations.

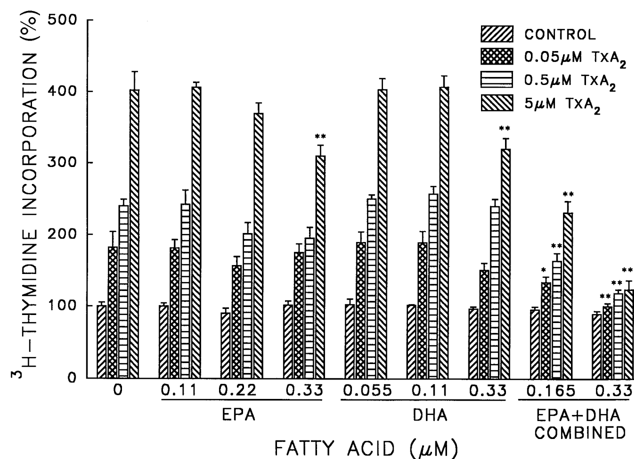

FIG. 5. Synergistic interaction between EPA and DHA in modulating U46619-induced SMC growth. Growth-arrested SMC were incubated with indicated concentrations of U46619, EPA, and DHA in 1% FBS containing DMEM and the amount of ^{3}[H]-thymidine incorporated was determined as described in the Materials and Methods section. One hundred percent equals the baseline value of ^{3}[H]-thymidine uptake (100% = 16820 ± 790 cpm/10^6 cells). The experiments were performed with two different batches of cells and each batch was tested in triplicate. *$P < 0.05$, **$P < 0.01$ as compared to the corresponding control. For abbreviations see Figures 1 and 2.

DISCUSSION

The present study demonstrates that the major n-3 PUFA present in fish oils, EPA and DHA, can attenuate the vascular SMC proliferation induced by the TxA_2 mimetic U46619. TxA_2 is A major metabolite of AA released during platelet aggregation (19,20). It also has been suggested that the vascular wall produces significant amounts of TxA_2, especially in some genetic models of hypertension (21,22). Although well known as a potent inducer of platelet aggregation and as a vasoconstrictor, TxA_2 also has been shown to induce SMC migration and hyperplasia of the cells (21,29) of the sort that is typically encountered in many occlusive vascular lesions. In studies involving cultured vascular SMC, several investigators have reported that TxA_2/prostaglandin endoperoxide (TxA_2/PGH_2) receptor agonists can induce hypertrophy or hyperplasia of the cells (24,29). Antagonism of TxA_2/PGH_2 receptors with specific receptor antagonists has been shown to reduce atheromatous plaque formation in coronary arteries of hypercholesterolemic rabbits (17), neointima formation in mechanically injured canine coronary arteries (18), and proliferation of vascular SMC in culture (28,29). Based on these studies, it seems possible that TxA_2 released from aggregating platelets and/or vascular walls may play a role in the development of atherosclerosis and/or restenosis following angioplasty.

In this study, EPA up to an added concentration of 3 μM and DHA up to an added concentration of 7.5 μM had no significant effect on ^{3}[H]-thymidine incorporation by SMC. At concentrations higher than these, both EPA and DHA were growth inhibitory. This inhibitory effect is not due to cytotoxicity because we could revive cell growth after transferring the cells to normal-growth medium (data not presented). However, at concentrations greater than 75 μM, both EPA and DHA were cytotoxic. Several investigators have reported that PUFA like EPA and DHA inhibit the proliferation of cells in culture mainly through the formation of free radicals (30–32) and this inhibition could be reversed by incubating the cells with antioxidants (32). This may explain the inhibitory and cytotoxic effects of EPA and DHA at higher concentrations. In this study, neither OA nor LNA had a significant effect on ^{3}[H]-thymidine incorporation by SMC. However, AA at concentrations greater than 3 μM significantly increased ^{3}[H]-thymidine incorporated into SMC. AA, as well as its metabolites, has been shown to modulate the proliferation of SMC (33). When added to cell cultures, AA itself has been shown to stimulate mitogen-activated protein kinases (34), which also results in increased ^{3}[H]-thymidine incorporation (35). When tested in concentrations at which they do not have any

significant effect by themselve, EPA and DHA prevented TxA_2-stimulated ^{3}[H]-thymidine incorporation, whereas similar concentrations of OA, LNA, and AA failed to prevent TxA_2 stimulation. When present together, EPA and DHA appear to exert an additive effect to prevent the TxA_2-induced stimulation of SMC.

Conflicting reports exist about the effect of TxA_2 mimetics on vascular SMC. Dorn *et al.* (27) reported that U46619 stimulates only protein synthesis, indicating that TxA_2 mimetics induce only vascular SMC hypertrophy, but not hyperplasia. In contrast, Sachinidis *et al.* (28) demonstrated that TxA_2 mimetics can stimulate DNA synthesis. However, both groups have shown that TxA_2 analogs stimulated phospholipase C, with subsequent formation of IP_3 (inositol triphosphate) and diacylglycerol and an increase in intracellular free calcium. A common response of many G protein-coupled vasoactive agents known to be mitogens is elevation of phosphoinositide turnover and elevation of intracellular free calcium. The calcium channel blocker verapamil has been shown to block U46619-induced ^{3}[H]-thymidine incorporation by rat aortic SMC (36) and I-BOP [1*S*-(1α,2β(5*Z*), 3α(1*E*,3*R**), 4α)]-7-[3-(3-hydroxy-4-(4′-iodophenoxy)-1-butenyl)-7-oxabicyclo-[2.2.1]heptan-2-y1]-5-heptenoic acid]-induced ^{3}[H]-thymidine incorporation by guinea pig coronary artery SMC (24). This indicates that influx of extracellular calcium is required for the mitogenic response of TxA_2 analogs U46619 and I-BOP. Little information is available about the influence of n-3 fatty acids on calcium transport systems. Hallaq *et al.* (37) have shown that enriching cardiac myocyte membranes with fish oil fatty acids reduced the ouabain-stimulated increase in intracellular calcium. Locher *et al.* (38,39) have shown that fish oils and EPA can attenuate the elevation of intracellular calcium in rat aortic SMC stimulated by angiotensin II, low density lipoprotein, and platelet-derived growth factor. In another report, Locher *et al.* (40) have also shown that fish oils and EPA can attenuate IP_3 formation in rat aortic SMC stimulated by low-density lipoprotein and angiotensin II. Similarly, Chetty *et al.* (41) have demonstrated that EPA interferes with the formation of inositol phosphates in U46619-stimulated rabbit platelets.

Since it has been shown that TxA_2 analogs can exert their mitogenic effects by increasing IP_3 formation and elevating intracellular calcium, a mechanism by which EPA and DHA may inhibit SMC proliferation could be by inhibiting the U46619-induced increase in IP_3 formation and preventing the increase in intracellular calcium. Another possible mechanism by which EPA and DHA might inhibit U46619-induced SMC proliferation may be by directly competing for the TxA_2 receptor. Swann *et al.* (42,43) have demonstrated that when platelets were incubated with either esterified or nonesterified EPA or DHA, there was a significant decrease in the specific binding of ^{3}[H]-U46619 to TxA_2/prostaglandin H_2 receptor. They have also shown that this effect was specific for EPA and was not shared by LNA.

In summary, we have demonstrated that EPA and DHA at very low concentrations selectively inhibit TxA_2-stimulated vascular SMC proliferation. Since it is well established that fish oils inhibit platelet aggregation resulting in a decreased production of TxA_2, fish oils may have several beneficial effects to inhibit platelet aggregation and decrease TxA_2 production, and also to directly inhibit the effect of TxA_2 on vascular SMC proliferation.

ABSTRACT: The present study was designed to investigate the effect of dietary n-6 and n-3 polyunsaturated fatty acids (PUFA) on anti-CD3 and anti-Fas antibody-induced apoptosis and its mediators in mouse spleen cells. Nutritionally adequate semipurified diets containing either 5% w/w corn oil (n-6 PUFA) or fish oil (n-3 PUFA) were fed to weanling female Balb/C mice, and 24 wk later mice were sacrificed. In n-3 PUFA-fed mice, serum and splenocyte lipid peroxides were increased by 20 and 28.3% respectively, compared to n-6 PUFA-fed mice. Further, serum vitamin E levels were decreased by 50% in the n-3 PUFA-fed group, whereas higher anti-Fas- and anti-CD3-induced apoptosis (65 and 66%) and necrosis (17 and 25%), compared to the n-6 PUFA-fed group, were found when measured with Annexin V and propidium iodide staining, respectively. In addition, decreased Bcl-2 and increased Fas-ligand (Fas-L) also were observed in the n-3 PUFA-fed group compared to the n-6 PUFA-fed group. No difference in the ratio of splenocyte subsets nor their Fas expression was observed between the n-3 PUFA-fed and n-6 PUFA-fed groups, whereas decreased proliferation of splenocytes was found in n-3 PUFA-fed mice compared to n-6 PUFA-fed mice. In conclusion, our results indicate that dietary n-3 PUFA induces higher apoptosis by increasing the generation of lipid peroxides and elevating Fas-L expression along with decreasing Bcl-2 expression. A reduced proliferative response of immune cells also was observed in n-3 PUFA-fed mice.

Paper no. L8261 in *Lipids 34,* 921–927 (September 1999).

In recent years, it has been increasingly apparent that long-chain polyunsaturated fatty acids (PUFA) are involved in maintaining a variety of physiological processes and therefore currently are viewed to play a key role in human nutrition, both in normal health and disease states (1,2). Further epidemiological evidence suggests that the low incidence of breast and colon cancer seen among traditional Mediterranean and Japanese populations may be related to diets with higher fish consumption, which can enrich tissue n-3 PUFA levels (3,4). Recently, several studies, including our own investigations, have shown that feeding a diet rich in fish oil (FO) inhibits autoimmune renal disease (5–9) and growth of human breast cancer cells in nude mice (10–12). Other studies have shown that n-3 PUFA decrease cell proliferation, induce apoptosis in *in vitro* systems (13,14), and are found more susceptible to lipid peroxidation (LPO) than n-6 PUFA (15–17). A positive correlation was established between the number of double bonds in fatty acids, their increased susceptibility to LPO, and their potential for inducing apoptosis (18). Metabolites of lipid peroxides have been implicated in many pathological conditions due to the increased oxidative stress they cause (19,20). Indeed oxidative stress is found to induce higher apoptosis in a variety of cultured cell lines and is thought to play a major role in the regulation of apoptosis (21).

Apoptosis is an essential process for normal development and for the maintenance of tissue homeostasis in multicellular organisms (22,23). In lymphocytes, apoptosis plays an important role in maintaining the T cell repertoire and deletion of autoreactive T and B lymphocytes, thus limiting autoimmune responses (24). Apoptosis can be triggered by various stimuli, such as glucocorticoids, oxidative stress, activation of Fas-ligand (Fas-L), and deprivation of cytokines and growth factors (25,26).

Apoptosis is also regulated by a number of gene products that could either promote cell death or extend cell survival (26,27). For instance, both Fas/apolipoprotein-1 (apo-1, CD95) and apolipoprotein-2L (TRAIL), members of a cell surface tumor necrosis factor-receptor family (28), mediate both T and B lymphocyte apoptosis (29). Fas-L, which is expressed predominantly in activated T cells (30,31), is a type 2 membrane protein belonging to the tumor necrosis factor receptor family. Whereas TRAIL-mediated pathways involve activation of the transcription factor, nuclear factor (NF)-κB (32), Fas-L mediates cell death by cross-linking Fas-receptor (33,34). Other gene products that modulate lymphocyte apoptosis are those of the Bcl-2 or Bcl-x1 family. Bcl-2, which is primarily located on the mitochondrial outer membrane, acts as an effective inhibitor of apoptosis in many target tissues (35).

Recently, we showed that dietary n-3 fatty acids are able to enhance the spontaneous as well as dexamethazone-induced apoptosis in murine splenocytes when compared to n-6 fatty acids (6,36). The present study was undertaken to determine the influence of dietary n-3 and n-6 fatty acids on mediators of apoptosis and the generation of lipid peroxides in immune cells obtained from a non-autoimmune-prone strain (Balb/C) of mice.

METHODS AND MATERIALS

Materials. Thiobarbituric acid, 1,1,3,3-tetraethoxy propane, butyl hydroxyanisole, brefeldin A, ionomycin, phytohemagglutinin, and lipopolysaccharide (LPS) were obtained from Sigma Chemical Co. (St. Louis, MO). Dichlorofluorescein diacetate (DCFH-DA), dexamethasone, Annexin V, propidium iodide (PI), and all fluorescein isothiocyanate (FITC)- and phycoerythrin (PE)-labeled antibodies and antibody isotype controls were purchased from Pharmingen (San Diego, CA). Concanavalin A (Con A) was obtained from Pharmacia. All other chemicals (analytical grade) were obtained from Sigma Chemical Co.

Animals. Two-month old Balb/C female mice, five per cage, were housed in a temperature-controlled room at 24°C and were maintained on a 12/12-h dark–light cycle. The mice were provided an AIN-76 formula (37) diet containing either 5% (w/w) corn oil (CO, n-6 PUFA) or 4% FO + 1% CO (n-3 PUFA) and water on an *ad libitum* basis. FO was obtained from the National Marine Fisheries Service (Charleston, SC). The composition of the diet was 20% casein, 50% dextrose, 15% starch, 5% cellulose, 5% oil, 3.5% AIN salt mixture, 1% AIN vitamin mixture, 0.3% DL-methionine, and 0.2% choline chloride. The oils had equal levels of antioxidants, i.e., 1.3 g (1300 IU) α-tocopherol per kg oil, 1.2 g (13.2 IU) γ-tocopherol/kg, and 1 g/kg *tert*-butylhydroxyquinone, as per the guidelines of the National Institutes of Health. Food intake and weight gain were monitored at regular intervals. Fresh, semipurified moist diet prepared weekly was provided to mice daily. Leftover food was discarded to prevent lipid rancidity.

After 24 wk of feeding, mice were fasted overnight and given a mild anesthesia. Peripheral blood was then collected by retro-orbital bleeding, and mice were killed by cervical dislocation. Spleens were aseptically removed and placed in RPM1 complete medium (5% heat-inactivated fetal calf serum, 2 mM l-glutamine, and 100 U/mL each of penicillin and streptomycin). Serum was separated by centrifuging blood at 1000 × *g* for 15 min and analyzed immediately. Serum lipid peroxides (malondialdehyde) were determined using the fluorescence method as previously described (36).

Vitamin E (Vit E, α-tocopherol) assay. Vit E was quantitated by high-performance liquid chromatography as described by Rushing *et al*. (38).

Splenocyte preparation. Single-cell suspensions were prepared by disrupting the spleen between frosted-glass slides in RPMI 1640 media with 2% heat-inactivated fetal calf serum. After a 5-min centrifugation at 100 × *g* to separate cells from debris, the cells were washed twice in RPMI medium (8). Spleen lymphocytes were purified by layering over lympholyte (Cedarlane Labs. Lit., Hornby, Ontario, Canada), centrifuging at 1000 rpm for 15 min at 22°C, then washing twice in the RPMI 1640 medium.. Cells were counted and viability was determined by trypan blue exclusion.

Measurement of intracellular peroxides by flow cytometry. DCFH-DA is a lipophilic fluorophore that is converted intracellularly when exposed to peroxides into a fluorescent molecule and retained by viable cells. It is a well-established indicator of cellular peroxides. Cellular peroxide levels were measured using the method of Hockenberry *et al.* (39). In brief, 1×10^6 lymphocytes were washed with 1× PBS (phosphate-buffered saline), suspended in 1 mL of PBS, then incubated for 30 min with 10 μM DCFH-DA at 37°C. After incubation cells were washed by centrifuging at 200 × *g*, resuspended in PBS, and kept on ice in the dark until analysis. Cellular fluorescence was analyzed by flow cytometry with a Becton Dickinson FACScan flow cytometer following excitation and emission at 488 and 530 nm, respectively. For visual comparison of lymphocyte population histograms, each analysis was recorded at a single amplification setting.

Quantification of apoptosis and necrosis by flow cytometry. Lymphocytes, 1×10^6, were incubated for 8 h in RPMI complete medium with or without 1 μg anti-Fas or anti-CD3 monoclonal antibody (mAb) in a final volume of 1 mL in a 5% CO_2 humidified incubator at 37°C. After incubation, cells were washed twice with binding buffer (10 mM HEPES/NaOH, pH 7.4, 140 mM NaCl, 2.5 mM $CaCl_2$), resuspended in 200 μL binding buffer in the presence of 0.2 μg FITC-Annexin V and 2 μg PI, then incubated in the dark for 10 min (40). Annexin V and PI staining were used as indications of apoptosis and necrosis, respectively, and were measured with a FACScan (Becton Dickinson) using Cell Quest software. The percentage of apoptotic (stained with Annexin V alone) and necrotic (stained with Annexin and PI) cells was calculated *via* measurements of forward and side light scatter, which are proportional to cell diameter and internal density, respectively.

Flow cytometric analysis of Fas, Fas-L, Bcl-2, and splenocyte subsets. Cells were washed with isotonic NaCl/phosphate buffer containing 0.5% bovine serum albumin and 0.2% NaN_3 (wash buffer). Cells (1×10^6) were incubated with 0.1 μg of Fc block (anti mouse CD16/CD32 antibody to block the Fc receptors) for 10 min at room temperature. After two washes, 1×10^5 cells in 200 μL wash buffer were incubated at 4°C in the dark for 30 min with 2 μL of one of the following monoclonal antibodies: anti-CD4-PE, CD8-PE, or CD19-PE and anti-Fas-FITC. Isotype control for anti-Fas-FITC was used in all experiments. Cellular fluorescence was analyzed by flow cytometry with a Becton Dickinson (Mountain View, CA) FACScan flow cytometer using the Cell Quest program.

Because Fas-L is expressed on activated T cells, splenocytes (1×10^6 cells) were activated in the presence of soluble anti-CD3 (2 μg/mL) for 24 h after washing, the cells were further stimulated with Brefeldin A, phytohemagglutinin, and

ionomycin (2 µg, 10 ng, and 1 µg/mL respectively) for 4 h. For Fas-L (activated cells) and Bcl-2 staining, cells were washed with wash buffer and fixed with 200 µL of 1% paraformaldehyde in wash buffer for 15 min with continuous shaking at room temperature. Lymphocytes were washed with wash buffer, then permeabilized by suspending in 200 µL of 0.33% saponin at 4°C for 45 min. Permeabilized cells were washed and stained with anti-Fas-L-PE and Bcl-2-FITC in 200 µL of wash buffer at 4°C for 45 min. Proper isotype controls for anti-Fas-L PE and anti-Bcl-2-FITC were used in all experiments.

Cell proliferation. Splenocytes were cultured at 5×10^5 cells/well in 0.2 mL of RPMI with 10% FCS at 37°C for 48 h with or without Con A, LPS, or soluble anti-CD3 at 0.5 µg/mL, 2 µg/mL, and 1 µg/mL, respectively, in 96-well microtiter plates (8). The cells were pulsed with 1 µCi[^{3}H] thymidine ([^{3}H]TdR; sp. act. 6.7 Ci/mmol; NEN, Boston, MA) for 16 h, harvested onto glass fiber filters, and counted with a liquid scintillation counter (Becton Dickinson). [^{3}H]TdR incorporation was determined after subtracting background incorporation. A control (medium alone) was also included.

Statistical analysis. The data are expressed as means ± SEM. Data were statistically analyzed using a Student's *t*-test and $P < 0.05$ was considered significant.

RESULTS

The amount of moist semipurified AIN diet provided and consumed by mice in both groups was found similar over the 24 wk of the experimental period (5 g d^{-1} $mouse^{-1}$). There were no significant differences in weight gain among the mice fed n-6 and n-3 dietary lipids (15.5 ± 2.0 g $mouse^{-1}$, mean ± SEM, n = 10 mice/treatment). The fatty acid composition of dietary lipids (Table 1) shows that the CO (5%) diet contained 59.7% 18:2n-6, whereas the FO diet contained 9%. The FO (5%) diet contained 15.5% of 20:5n-3 and 13.7% of 22:6n-3 fatty acids which are not present in the CO diet. The FO diet had a 57.6% higher unsaturation index than the CO diet.

TABLE 1
Fatty Acid Composition of Experimental Diets

Fatty acid	Corn oil (% of total fatty acids)	Fish oil (% of total fatty acids)
14:0	0.23	8.43
16:0	10.40	17.30
16:1	N	10.00
18:0	1.60	3.30
18:1	26.34	9.12
18:1	N	2.77
18:2	59.7	9.00
18:3	0.98	1.33
18:3	N	3.00
20:0	0.44	0.56
20:1	0.31	0.97
20:2	N	0.88
20:4	N	1.33
20:5	N	15.50
22:5	N	2.80
22:6	N	13.70
Unsaturation Index[a]	149	234.70

[a]Unsaturation Index is the sum of the products of fatty acid concentration times the number of double bonds for each fatty acid. Values are the mean of two determinations; N, not detected.

Serum lipid peroxides and Vit E levels. Serum lipid peroxides measured as thiobarbituric acid reactive substances (TBARS) were 20% higher in n-3 PUFA-fed mice compared to n-6 PUFA-fed mice. Also, serum Vit E levels were found decreased in n-3 PUFA fed mice by 50% compared to n-6 fed mice (Table 2).

Cellular peroxides. DCFH-DA oxidation reflects a prooxidative state due to intracellular peroxide content (41). The n-3 PUFA-fed mice splenocytes contained 28.3% more peroxides than n-6 PUFA fed mice, as measured by DCFH oxidation (CO 64.24 ± 1.63 vs. FO 77.62 ± 4.05).

Apoptosis in splenocytes. Apoptosis of splenocytes was analyzed by flow cytometric detection of Annexin V and PI staining. In living cells, phosphatidylserine is exclusively located in the membrane leaflets that face the cytosol. The surface expression of phosphatidylserine is a feature of apoptosis and occurs before the loss of membrane integrity (42). Early apoptotic cells bind Annexin V, a Ca^{2+}-dependent phospholipid-binding protein with high affinity for phosphatidylserine, but exclude PI and can therefore be specifically detected and quantified by FACScan (43). Cells from n-3 PUFA-fed mice, incubated in media alone, showed a 50% increase in apoptosis compared to those of n-6 PUFA-fed mice. Furthermore, cells incubated with anti-Fas and anti-CD3 monoclonal antibodies showed an increase of 65 and 66% apoptosis and 17 and 25% necrosis, respectively, in n-3 PUFA-fed mice compared to those of n-6 PUFA-fed mice (Fig. 1).

Expression of Fas, Fas-L, and Bcl-2 in splenocytes by flow cytometry. No significant changes were observed in the levels of subsets among the dietary groups (CD4: CO 20.63 ± 0.78 vs. FO 21.87 ± 0.81; CD8: CO 7.8 ± 0.44 vs. FO 8.01 ± 0.1; CD19: CO 56.21 ± 3.83 vs. FO 59.21 ± 3.83). Flow cytometric analysis demonstrated that the Fas antigen expression in splenocytes (32.8 ± 1.11 vs. 33.1 ± 1.47 in n-6 and n-3 PUFA-fed mice, respectively) was not altered by dietary lipids. Fas-L expression was increased by 30% in splenocytes from n-3 PUFA-fed mice cultured with anti-CD3 for 24 h, compared with splenocytes from CO (n-6 PUFA)-fed mice (Fig. 2A). Interestingly, intracellular Bcl-2 levels were decreased by 21% in n-3 PUFA-fed mice compared with n-6 PUFA-fed mice (Fig. 2B).

Proliferative response of splenocytes to mitogens. The proliferative response of spleen cells to an optimal concentration

TABLE 2
Effect of Dietary Lipids on Serum Lipid Peroxides and Vitamin E Levels

	Lipid peroxides (MDA nmol/mL serum)	Vitamin E (ng/mL serum)
Corn oil	5.69 ± 0.21	190.76 ± 55.44
Fish oil	6.84 ± 0.15[a]	95.21 ± 16.29[a]

[a]Significantly different at $P < 0.05$ (corn oil vs. fish oil); values are mean ± SEM of five individual values from five mice. MDA, malondialdehyde.

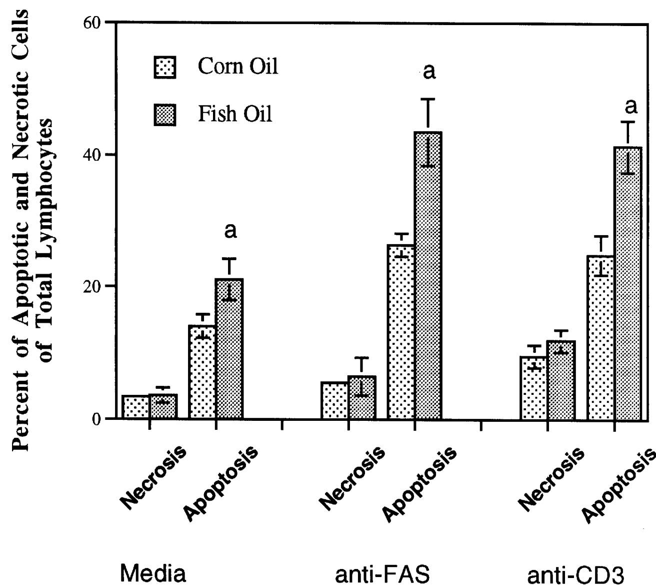

FIG. 1. Effect of dietary lipids on necrosis and apoptosis in splenocytes. Splenocytes were incubated for 8 h in medium alone or with anti-Fas or anti-CD3 and rate of apoptosis was measured as described in the Materials and Methods section. Values are mean ± SEM of five individual values of five mice. Bars marked "a" are statistically significant at $P < 0.05$.

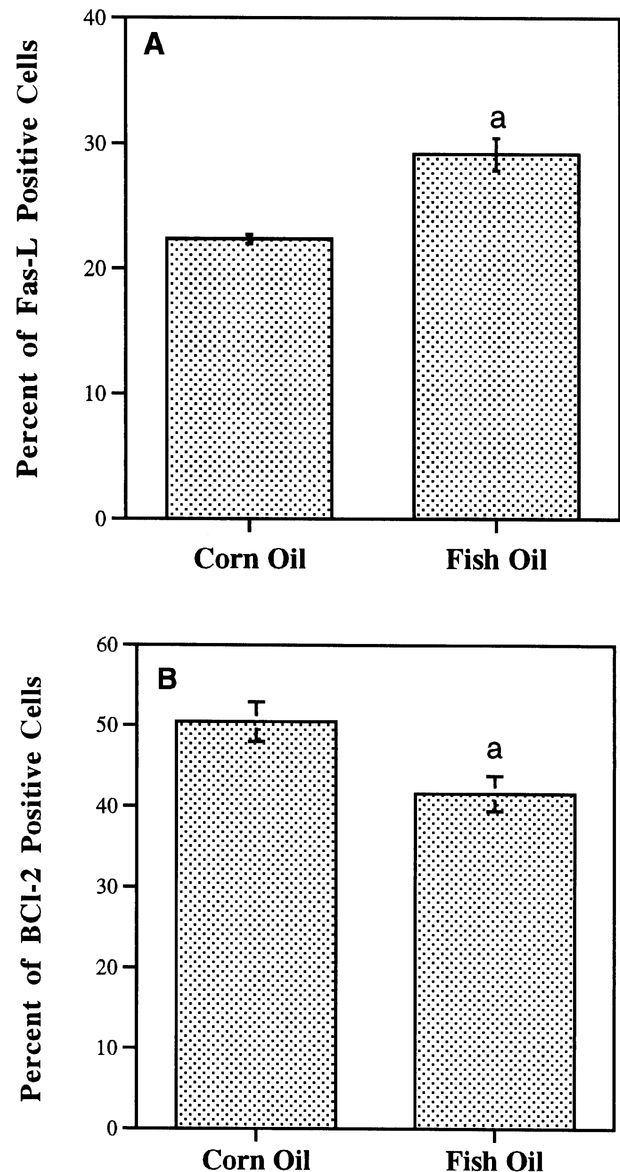

FIG. 2. Effect of dietary lipids on phenotype expression of (A) Fas-L and (B) Bcl-2 on total splenocytes. Values are mean ± SEM of five individual values of five mice; bars marked "a" are statistically significant at $P < 0.05$.

of three regularly used mitogens is summarized in Figure 3. The proliferation of unstimulated cells was decreased by 11% in n-3 PUFA-fed mice. The cell responses to Con A and anti-CD3 were significantly decreased by 16 and 23%, respectively, in n-3 PUFA-fed mice, whereas B cell response to LPS mitogen was found not altered compared to n-6 PUFA-fed mice.

DISCUSSION

Increased tissue DCFH fluorescence and plasma TBARS are the two key parameters related to the generation of reactive oxygen species. Our current findings revealed that both DCFH fluorescence in spleen cells and serum TBARS were increased in n-3 PUFA-fed mice when compared to mice fed n-6 PUFA diets. These findings are consistent with our previous results with rodents and studies in humans described by others (16,36,44,45). It is well established that the source and levels of dietary lipids influence tissue fatty acid composition and differences in immune response *in vivo* (8,36). Since the tissue fatty acid composition can be altered even by low levels of dietary lipids, the susceptibility to peroxidation and subsequent immune function appears to be closely linked to dietary lipid manipulations.

As expected, a low 5% n-3 PUFA diet significantly lowered the serum Vit E levels. In agreement with previous studies, a diet rich in n-3 PUFA increases the requirement for antioxidants such as Vit E (16,44,45). Feeding FO enriches n-3 PUFA in splenocyte membranes (8,36), lowers Vit E levels, and causes increased peroxides in both serum and spleen cells.

Our present results on apoptosis and necrosis also show that dietary FO (rich in n-3 PUFA) increases spontaneous and anti-Fas- and anti-CD3-induced cell death in long-lived nonautoimmune disease-prone mice as measured by PI and Annexin V staining. Previously, we also found that dietary n-3 PUFA increase spontaneous and dexamethazone-induced apoptosis in autoimmune-prone and -resistant strains of mice (36,46). Earlier, however, we did not measure the generation of intracellular free radicals by DCFH staining. Calviello *et al.* (47) also reported that dietary supplementation of eicosapentaenoic acid and docosahexaenoic acid increased apoptosis in Morris hepatocarcinoma 3924A tumors in rats. It has been observed that high levels of dietary FO suppress the growth of human carcinoma cell lines in athymic nude mice, presumably caused by increased accumulation of LPO prod-

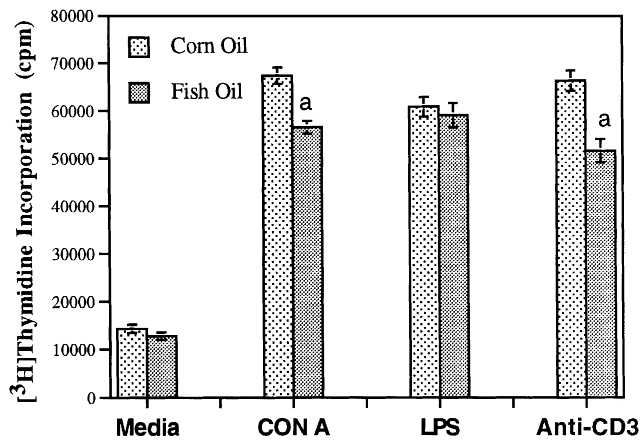

FIG. 3. Effect of dietary n-6 and n-3 polyunsaturated fatty acids on the proliferation of splenocytes. Values are mean ± SEM of five individual values of five mice; bars marked "a" are statistically significant at $P < 0.05$. ConA, concanavalin A; LPS, lipopolysaccharide.

ucts in tumor tissue (48,49), which may contribute to increased apoptosis.

Interestingly, the addition of antioxidant supplements to FO reduced the levels of tumor LPO products, which simultaneously caused an increase in tumor growth, suggesting that the tumor-suppressing activity of long-chain n-3 PUFA could be at least partly due to elevated LPO (48,50). It has been shown that with an increased number of fatty acid double bonds, increased apoptosis and necrosis, a feature of late apoptosis, were preceded by progressively increasing LPO (18). The extent of PUFA-induced LPO measured as malondialdehyde also correlated with the proportion of apoptotic cells (18). Taken together, these observations clearly indicate that highly unsaturated fatty acids are susceptible to LPO and that these lipid peroxides appear to induce apoptosis.

It is well known that the interaction of Fas-L with Fas results in intracellular signals that lead to apoptosis in lymphocytes (34,51). Activation-induced cell death is an important form of programmed cell death because it is crucial for elimination of preactivated cells and is also critical in the elimination of potentially harmful autoreactive lymphocytes (52,53). In the present study, we further showed that n-3 PUFA increase Fas-L expression in splenocytes. The Fas/Fas-L system plays a very important role in the modulation of B and T lymphocyte development and function (29). Defects in the Fas/Fas-L pathways have been shown to result in autoimmune disease (54). Further, defective antigen-mediated cell death can contribute to an increased number of activated auotoreactive cells (55). In earlier studies we showed that dietary n-3 PUFA decrease the severity of autoimmune lupus nephritis in B/W mice (8,9). Further, there is increasing evidence that alterations in cancer cell sensitivity to Fas-mediated apoptosis are a key factor in controlling tumor progression (56), and perturbations in the Fas/Fas-L cell death pathway appear to be important in determining the viability of transformed cells (57). It is well established that the functional activity of T lymphocytes is controlled by delayed sensitization of Fas/Fas-L-mediated apoptosis after activation (58). The results presented here suggest that n-3 PUFA enhance the sensitivity of splenocytes to Fas- and anti-CD3-mediated cell death leading to elimination of hyperactive lymphocytes.

Bcl-2 also plays an important role in the fate of cells committed to undergoing apoptosis (59). Bcl-2, considered a protooncogene and known to block apoptosis, is found to act as an antioxidant either by protecting cell constituents from oxidation or by decreasing the cellular generation of reactive oxygen species (39,60). Recently Hotchkiss *et al.* (61) have reported that overexpression of Bcl-2 in transgenic mice decreases apoptosis in thymic and splenic lymphocytes during sepsis. We therefore measured the basal expression of Bcl-2 in splenocytes. We observed a decreased Bcl-2 expression in n-3 PUFA-fed mice compared with n-6 PUFA-fed mice. Decreased Bcl-2 expression and higher levels of Fas-L in n-3 PUFA-fed murine splenocytes may play a role in the higher susceptibility to anti-Fas- and anti-CD3-induced apoptosis in these mice. Lymphocytes that express high levels of Fas/Fas-L and decreased levels of Bcl-2 would undergo cell death earlier (62). The anticarcinogenic and/or antitumor property of FO may be in part due to induction of elevated Fas-L, which may induce higher cell death and thereby decrease the proliferation of tumor cells.

It is well established that uncontrolled cell proliferation is closely associated with the carcinogenic process (63). Antiproliferative effects of n-3 PUFA have been shown in cancer cells *in vitro* as well as in normal cell lines (13,14). In our present study, we also found decreased proliferation of spleen cells from mice fed dietary n-3 PUFA in the presence (as well as absence) of mitogens. In agreement with our present results (18,47), it has been shown by others that n-3 (20:5 and 20:6) fatty acids are able to suppress tumor cell proliferation. In addition, the antitumor and anticancer properties of FO (n-3 PUFA), at least in part, may be due to increased apoptosis associated with increased expression of Fas-L, decreased expression of Bcl-2, and increased peroxide levels.

In conclusion, these results describe one of the possible mechanisms by which dietary n-3 PUFA enhance or increase both induced and spontaneous apoptosis compared to n-6 PUFA. n-3 PUFA increase the expression of the apoptotic inducer Fas-L and decrease the cell death inhibitor Bcl-2. The increased rate of apoptosis was also found to be closely associated with decreased *in vitro* splenocyte proliferation which is similar to previous observations in both mice and humans (64–66).

Acyltransferase Activities in the Yolk Sac Membrane of the Chick Embryo

Alison M.B. Murray*, Raphael Denis, and Brian K. Speake

Department of Biochemistry and Nutrition, Scottish Agricultural College, Ayr, KA6 5HW, United Kingdom

ABSTRACT: The activities of some enzymes of glycerolipid synthesis and fatty acid oxidation were measured in subcellular fractions of the yolk sac membrane (YSM), an extra-embryonic tissue that mediates the transfer of lipid from the yolk to the circulation of the chick embryo. The activities of monoacylglycerol acyltransferase and carnitine palmitoyl transferase-1 in the YSM (respectively, 284.8 ± 13.2 nmol/min/mg microsomal protein and 145.6 ± 9.1 nmol/min/mg mitochondrial protein; mean ± SE; $n = 4$) at day 12 of development appear to be the highest yet reported for any animal tissue. Also, the carnitine palmitoyl transferase-1 of the YSM was very insensitive to inhibition by malonyl CoA. The maximal activities of glycerol-3-phosphate acyltransferase and diacylglycerol acyltransferase in the YSM (respectively, 26.7 ± 2.2 and 36.1 ± 2.1 nmol/min/mg microsomal protein) were also high compared with the reported values for various animal tissues. The very high enzymic capacity for glycerolipid synthesis supports the hypothesis that the yolk-derived lipids are subjected to hydrolysis followed by reesterification during transit across the YSM. The monoacylglycerol pathway appears to be the main route for glycerolipid resynthesis in the YSM. The results also suggest that the YSM has the capacity to perform simultaneously β-oxidation at a high rate in order to provide energy for the lipid transfer process.

Paper no. L8246 in *Lipids 34,* 929–935 (September 1999).

The transfer of lipid from the yolk to the embryo and the utilization of the various lipid moieties by the developing tissues are the predominant metabolic features of avian embryonic development. This transfer is especially intense during the second half of the developmental period when essentially all the energy needs of the embryo are provided by the β-oxidation of yolk-derived fatty acids. The uptake of lipid from the yolk is performed by the yolk sac membrane (YSM), a highly vascularized extra-embryonic structure that grows outward from the body of the embryo during the early stages of development so as to completely surround the yolk by about the midpoint of the developmental period. Within the endodermal cells of the YSM, the yolk-derived lipids are assembled into particles of the very low density lipoprotein (VLDL) type, which are then secreted into the vascular system for delivery into the embryonic circulation (1–6).

The question arises regarding the degree to which the yolk-derived lipids are modified during their transit across the endodermal cell layer of the YSM. Because the yolk essentially consists of a tightly packed mass of VLDL particles originating from synthesis in the maternal liver (7–9), the most parsimonious explanation would be the transcytosis, without alteration, of these lipoproteins across the YSM. Such a simplistic scenario is, however, very unlikely for several reasons. Most crucially, the yolk-precursor VLDL secreted by the maternal liver is a highly-specialized lipoprotein, uniquely adapted to fulfill its singular function of delivering lipid to the oocyte maturing in the ovary (1,7–11). By contrast, the primary fate of the VLDL that emerges from the YSM is to serve as a substrate for lipoprotein lipase in the capillaries which permeate the adipose tissue and muscle of the embryo, thus delivering fatty acids to the developing tissues (12). Such distinct roles must require differences in lipoprotein structure, and it is pertinent that the maternally derived VLDL particles that form the yolk are unusually small and regular (30 nm diameter) (7–9) whereas those which are exocytosed from the basal face of the YSM endodermal cells are large and polydisperse (50–150 nm diameter) (1,3–5).

In light of these considerations, the alternative situation in which the triacylglycerol (TAG), phospholipid (PL) and cholesteryl ester (CE) of the yolk are subjected to extensive hydrolysis following uptake into the YSM, thus releasing a range of products such as free fatty acids, glycerol, partial glycerides and free cholesterol into the endodermal cytoplasm, would appear to be more likely. The transfer of these hydrolytic products to the endoplasmic reticulum of the endodermal cells, followed by reesterification to re-form TAG, PL and CE in concert with the synthesis of apoproteins (13), would enable the assembly of VLDL particles with a composition suited to their functions in the embryo.

A key prediction of this "lipid remodeling" hypothesis is that the YSM should express the enzymic capacity necessary for the reesterification process. Moreover, the activities of the acyltransferases involved in glycerolipid resynthesis in the

YSM would need to be commensurate with the sheer intensity of lipid transfer during the second half of the embryonic period (1). Previous work by Sansbury and coworkers (14) delineated the ontogeny of acyltransferase expression in the liver of the chick embryo. In the present study we focused on the levels of acyltransferase activity exhibited by the YSM. The activities of glycerol-3-phosphate acyltransferase (GPAT) (EC 2.3.1.15) which catalyzes the first committed step of the glycerol phosphate pathway (15,16), monoacylglycerol acyltransferase (MGAT) (EC 2.3.1.22) which acylates *sn*-2-monoacylglycerol to form *sn*-1,2-diacylglycerol and thus catalyzes the defining step of the monoacylglycerol pathway (15), and diacylglycerol acyltransferase (DGAT) (EC 2.3.1.20) which catalyzes the conversion of *sn*-1,2-diacylglycerol to TAG, a step common to both the above pathways (15), were determined in the YSM throughout the second half of development. The levels of carnitine palmitoyl transferase-1 (CPT-1) (EC 2.3.1.21) expressed in mitochondria from the YSM of the embryo were also determined as an indication of the capacity of this tissue for β-oxidation (17,18).

MATERIALS AND METHODS

Embryos. Fertile eggs of the Ross 1 broiler–breeder strain were obtained from a commercial supplier (Ross Poultry, Thornhill, Scotland). The eggs were incubated at 37.8°C and 60% relative humidity in a bench-top incubator (Brinsea Products, Banwell, United Kingdom) with automatic egg turning. At various stages throughout development, the required number of embryos were sacrificed, and the YSM and liver were collected. The YSM was washed thoroughly in 0.85% (wt/vol) NaCl at 4°C to remove any adherent yolk. Hatching occurred after 21 d of incubation, and the required number of chicks were maintained for 1 d with the provision of drinking water but with no food prior to sacrifice.

Preparation of subcellular fractions. Tissue samples were finely chopped with scissors and gently homogenized using a hand-held glass-Teflon homogenizer in 5 vol of 0.25 M sucrose containing 5 mM Tris-HCl buffer (pH 7.4) and 1 mM EGTA at 0°C. All subsequent centrifugations were performed at 4°C. The homogenate was centrifuged at 500 × *g* for 10 min, and the resultant supernatant was recentrifuged at 9,000 × *g* for 10 min to isolate mitochondria. The mitochondrial pellet was washed with homogenization medium and recentrifuged at 9,000 × *g* for 10 min. The washed mitochondria were then suspended in 5 mM Tris-HCl buffer (pH 7.4) containing 0.15 M KCl and 1 mM EGTA prior to enzyme assay. The 9,000 × *g* supernatant was then centrifuged at 100,000 × *g* for 60 min (Centrikon T-1170 Ultracentrifuge; Kontron Ltd., Watford, United Kingdom) to obtain the microsomal fraction. The microsomal pellet was resuspended in homogenization buffer and recentrifuged at 100,000 × *g* for 60 min. The washed microsomal pellet was then resuspended in the appropriate enzyme assay buffer.

The purity of the mitochondrial and microsomal fractions was assessed by marker enzyme assays. Lactate dehydrogenase, citrate synthase, and NADPH-cytochrome c reductase were determined by published methods (19–21). Both fractions were free of cytosolic contamination as indicated by the absence of lactate dehydrogenase in the final washed suspensions. The mitochondrial preparation contained no detectable NADPH-cytochrome c reductase and the microsomal preparation contained no detectable citrate synthase, indicating a lack of cross-contamination between these subcellular fractions.

Assay of MGAT. For each of the four enzymes investigated in this study, the reaction rate was linear with incubation time and with the concentration of microsomal or mitochondrial protein under the assay conditions described. Also, for each enzyme assay, the blank value obtained by stopping the reaction at time zero was subtracted from the measured incorporation. MGAT activity was determined by a previously reported method (22) with minor modification. The reaction mixture consisted of 24 mM Tris-HCl buffer (pH 7.5), 50 mM KCl, 8 mM $MgSO_4$, 0.75 mM dithiothreitol, 0.625 mg bovine serum albumin (fatty acid-free), 15 µg each of phosphatidylcholine and phosphatidylserine, 0.25 mM *sn*-2-monoolein and 25 µM palmitoyl CoA, [^{14}C] palmitoyl CoA (0.01 µCi), and 2 µg microsomal protein in a final volume of 0.5 mL. The *sn*-2-monoolein substrate, which was at least 99% pure as described by the suppliers (Sigma Chemical Co., Poole, Dorset, United Kingdom), was added as a dispersion in 0.1% (wt/vol) Tween 20; the final concentration of Tween 20 in the assay was 0.002% (wt/vol). The reaction was started by the addition of the microsomal protein, and the mixture was incubated at 37°C for 5 min. The reaction was terminated by the addition of 0.75 mL of 2-propanol/heptane/water (80:20:2, by vol). After 5 min, 0.5 mL heptane and 0.25 mL water were added, the samples were mixed and centrifuged at 600 × *g* for 5 min. The heptane layer was removed and washed twice with 1 mL of 0.5 M NaOH/ethanol/water (10:50:50, by vol). The radioactivity in a portion (0.25 mL) of the heptane layer was determined by scintillation counting. The reaction products in the heptane layer were identified as diacylglycerol (DAG) and TAG by thin-layer chromatography on silica gel G using a solvent system of heptane/isopropyl ether/acetic acid (60:40:4, by vol). The bands corresponding to DAG and TAG were scraped from the plates and the radioactivities were determined. The specific activity of MGAT was calculated from the radioactivity in DAG plus half that in TAG.

Assay of GPAT. GPAT activity was determined by a previously described method (30) with slight modification (23). The reaction mixture consisted of 50 mM Tris-HCl buffer (pH 7.5), 0.12 M KCl, 1 mg bovine serum albumin (fatty acid-free), 100 µM palmitoyl CoA, 3 mM *sn*-glycerol-3-phosphate, [^{14}C] glycerol-3-phosphate (0.2 µCi), and 50 µg of microsomal or mitochondrial protein in a final volume of 0.25 mL. The reaction was initiated by the addition of the microsomal or mitochondrial protein, and the mixture was incubated for 5 min (YSM) or 10 min (liver) at 30°C. The reaction was terminated by the addition of 2 mL water-saturated 1-butanol followed by 0.75 mL of butanol-saturated water.

After shaking, the samples were centrifuged at 600 × *g* for 10 min, and the butanol layer was removed and washed three times with butanol-saturated water. The radioactivity in 1 mL of the washed butanol layer was determined by scintillation counting. To correct for any cross-contamination between subcellular organelles, we performed the assays after pre-incubation of the subcellular fractions at 37°C for 15 min in the presence or absence of 4.5 mM *N*-ethylmaleimide (NEM). The enzyme in the mitochondrial fraction showed no detectable inhibition by NEM indicating the absence of any contamination with the microsomal form. Up to 5% of the GPAT activity present in the microsomal fraction was resistant to inhibition by NEM, suggesting some contamination of the fraction by the mitochondrial form of the enzyme; the NEM-resistant activity was subtracted from the total microsomal activity in order to provide a corrected value for the activity of microsomal GPAT.

Assay of DGAT. DGAT activity was assayed as previously described (22). The assay mixture consisted of 50 mM Tris-HCl buffer (pH 7.5), 10 mM $MgSO_4$, 0.25 mM dithiothreitol, 0.625 mg bovine serum albumin (fatty acid-free), 1.2 mM *sn*-1,2-DAG, 100 µM palmitoyl CoA, [^{14}C]palmitoyl CoA (0.025 µCi), and 10 µg microsomal protein in a final volume of 0.5 mL. The *sn*-1,2-DAG was added as a dispersion in 0.1% (wt/vol) Tween 20; the final concentration of Tween 20 in the assay was 0.004% (wt/vol). The reaction was initiated by the addition of the microsomal protein, and the mixture was incubated at 37°C for 10 min. Termination of the reaction and extraction of the products were performed as described for the MGAT assay. Radioactivity associated with the TAG fraction isolated by thin-layer chromatography was used to calculate the enzyme activity.

Assay of CPT-1. CPT-1 activity was measured in intact mitochondria as previously described (24). The assay mixture consisted of 5 mM Tris-HCl (pH 7.4), 0.15 M KCl, 5 mM $MgCl_2$, 1 mM EGTA, 1 mM dithiothreitol, 5 mM ATP, 10 mg bovine serum albumin (fatty acid-free), 2 µg antimycin A, 4 µg rotenone, 250 µM palmitoyl CoA, 0.5 mM carnitine, [^{3}H]carnitine (0.18 µCi), and 0.25 mg mitochondrial protein in a volume of 1 mL. The reaction was initiated by the addition of the mitochondrial protein, with the [^{3}H]carnitine added 2 min later. The assay was for 2 min at 37°C and was terminated by the addition of 0.3 mL of 6 M HCl. The [^{3}H]palmitoylcarnitine formed was quantified as described previously (25). Maximal CPT-1 activity was determined in the presence of 250 µM palmitoyl CoA whereas the sensitivity to inhibition by malonyl CoA was determined in the presence of 35 µM palmitoyl CoA. In the latter case, the enzyme activity in the presence of a range of malonyl CoA concentrations was determined and the sensitivity to this regulatory molecule was expressed as the ID_{50}; i.e., the concentration (µM) of malonyl CoA which inhibited CPT-1 activity by 50%. In all experiments, the formation of palmitoylcarnitine was suppressed by over 90% by the highest malonyl CoA concentration (100 µM). This suggests that a high degree of membrane integrity was maintained in the mitochondrial preparations and that only CPT-1 activity was measured without any significant contribution from CPT-II.

Protein determination. Mitochondrial and microsomal protein content was determined by the method of Lowry *et al.* (26) using bovine serum albumin as standard.

Materials. L-[Methyl-^{3}H]carnitine hydrochloride and [1-^{14}C]palmitoyl CoA were obtained from Amersham International (Aylesbury, Buckinghamshire, United Kingdom). [U-^{14}C]Glycerol-3-phosphate was obtained from ICN Biomedicals Ltd. (Thame, Oxfordshire, United Kingdom). Palmitoyl CoA was purchased from Pharmacia Biotech. (St. Albans, Hertfordshire, United Kingdom), and bovine serum albumin (fatty acid-free) was supplied by Advanced Protein Products (Brierley Hill, West Midlands, United Kingdom). All other biochemicals were obtained from Sigma Chemical Co. (Poole, Dorset, United Kingdom).

Expression of results. Data are expressed as the mean ± SE of measurements on three to five replicate samples at each stage. In the case of the YSM, each replicate sample represents the subcellular fraction derived from an individual YSM. Because of the small size of the livers at days 10, 12, and 14, each replicate subcellular fraction was derived from four pooled livers. At the later developmental stages, the replicate samples were derived from individual livers. Statistical comparisons were performed using Student's *t*-test.

RESULTS

MGAT activity in the YSM. The activity of MGAT in the microsomal fraction of the YSM was determined throughout the second half of the developmental period, from day 10 of embryonic life to 1 d after hatching (i.e., day 22). Very high levels of MGAT activity were maintained in the YSM between days 10 and 19 of embryo development, with a dramatic decrease ($P < 0.001$) in this activity then occurring betweeen days 19 and 20 (Fig. 1).

GPAT activity in the YSM. The developmental changes in GPAT activity in the microsomal and mitochondrial fractions

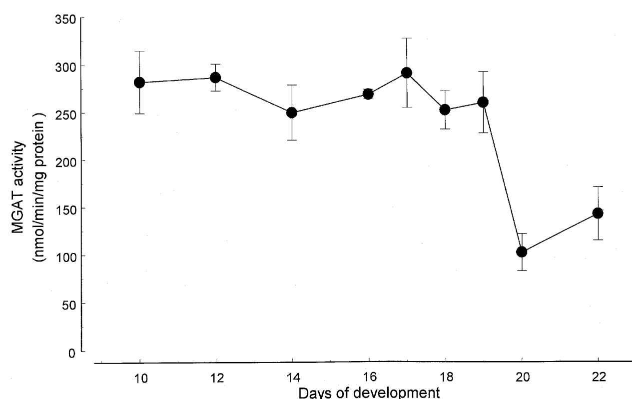

FIG. 1. Activity of monoacylglycerol acyltransferase (MGAT) in the microsomal fraction of the yolk sac membrane during development. Values are means obtained from four yolk sac membranes at each stage, and vertical bars represent SE.

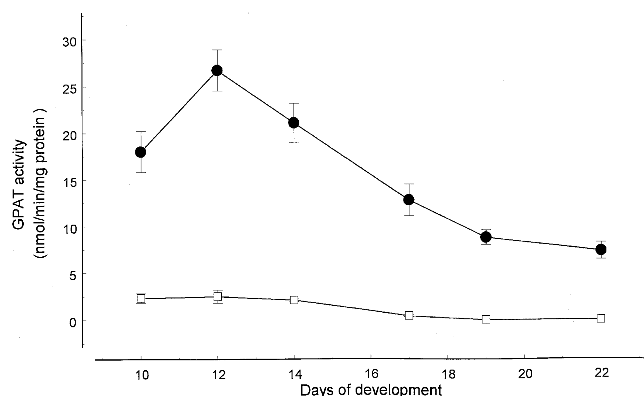

FIG. 2. Activity of glycerol-3-phosphate acyltransferase (GPAT) in the microsomal (●) and mitochondrial (□) fractions of the yolk sac membrane during development. Values are means obtained from four yolk sac membranes at each stage and vertical bars represent SE.

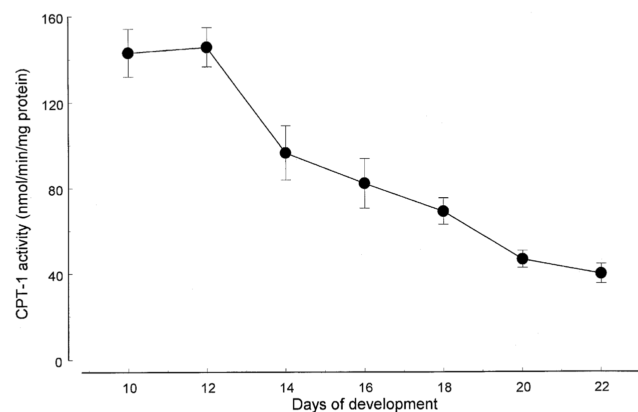

FIG. 4. Activity of carnitine palmitoyl transferase-1 (CPT-1) in the mitochondrial fraction of the yolk sac membrane during development. Values are means obtained from three to five yolk sac membranes at each stage and vertical bars represent SE.

of the YSM are shown in Figure 2. The activity of the microsomal enzyme increased between days 10 and 12 ($P < 0.05$) and decreased continuously thereafter so that the activity at day 22 was only 25% ($P < 0.001$) of the peak value at day 12. Only a small proportion of the total YSM GPAT activity was accounted for by the mitochondrial form of the enzyme at all stages. For example, at day 12 the microsomes contained 92% of the total activity with only 8% present in the mitochondria. By day 19, the mitochondrial enzyme was undetectable.

DGAT activity in the YSM. Substantial levels of DGAT activity were expressed in the microsomes of the YSM throughout the developmental period studied (Fig. 3). Although this activity appeared to reach a peak value around days 12 to 14 with a decrease thereafter, these changes were not statistically significant.

CPT-1 activity in the YSM. Very high activities of CPT-1 were expressed in the mitochondria of the YSM at days 10 and 12 (Fig. 4). After this stage the activity decreased continuously with the result that the level of this enzyme at day 22 was only 27% of the peak value at day 12 ($P < 0.001$). The sensitivity of CPT-1 from the YSM of the embryo to inhibition by malonyl CoA did not change to any major extent during the embryonic period. The ID_{50} (μM) values for this inhibitory effect were 18.5 ± 2.4, 20.0 ± 2.0, 16.0 ± 1.1, 21.0 ± 3.4, and 15.0 ± 2.2 at days 10, 12, 14, 16, and 18, respectively.

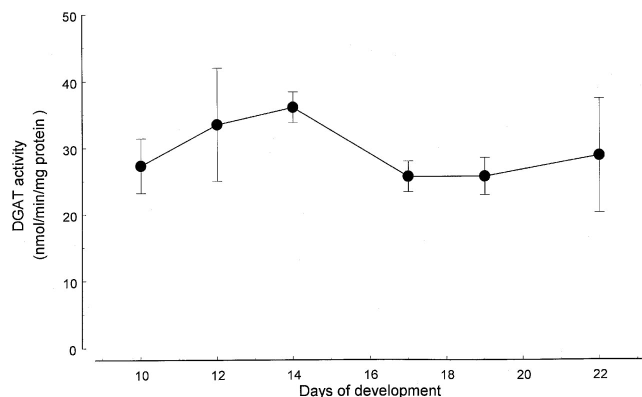

FIG. 3. Activity of diacylglycerol acyltransferase (DGAT) in the microsomal fraction of the yolk sac membrane during development. Values are means obtained from four yolk sac membranes at each stage and vertical bars represent SE.

Enzyme activities in the liver of the embryo. The activity of MGAT in the embryonic liver increased almost threefold ($P < 0.001$) between days 12 and 19 of development and then decreased by about 50% ($P < 0.001$) over the hatching period (Table 1). These hepatic activities were, however, far lower than the activities of MGAT determined in the YSM. At day 12, for example, the level of MGAT in the liver was only 9% of the activity expressed in the YSM ($P < 0.001$). The activity of GPAT in the liver microsomes showed little change from day 12 to day 22 of development, was far lower than the activity of MGAT in the liver, and was also far lower than the activity of GPAT in the YSM. About 16 to 25% of the total GPAT expressed in the liver was due to the mitochondrial form of the enzyme. The hepatic DGAT activity increased by 2.3-fold ($P < 0.05$) from day 12 to day 19, and this elevated activity was maintained over the hatching period. The activities of DGAT in the liver at days 19 and 22 were not significantly different from the concurrent activities of this enzyme in the YSM. The activity of CPT-1 in the liver mitochondria

TABLE 1
Acyltransferase Activities in the Liver of the Chick Embryo[a]

Enzyme	Day 12	Day 19	Day 22[b]
MGAT (*n* = 4)	24.9 ± 4.3	70.0 ± 2.7	38.0 ± 3.1
GPATmic (n = 6)	2.7 ± 0.1	2.5 ± 0.3	3.6 ± 0.3
GPATmit (n = 6)	0.5 ± 0.1	0.6 ± 0.1	1.2 ± 0.1
DGAT (n = 4)	9.8 ± 2.2	22.5 ± 4.1	26.4 ± 4.7
CPT-1 (n = 4)	80.3 ± 13.7	53.7 ± 6.2	52.0 ± 2.1

[a]nmol/min/mg microsomal (for MGAT, $GPAT_{mic}$, DGAT) or mitochondrial (for $GPAT_{mit}$, CPT-1) protein (mean ± SE).
[b]Represents 1 d after hatching. MGAT, monoacylglycerol acyltransferase; $GPAT_{mic}$ and $GPAT_{mit}$, glycerol-3-phosphate acyltransferase (microsomal and mitochondrial forms, respectively); DGAT, diacylglycerol acyltransferase; CPT-1, carnitine palmitoyl transferase-1.

was high at day 12, decreasing by about 33% at the later stages. The activity of CPT-1 in the liver at day 12 was, however, only about half the activity expressed in the YSM at this time ($P < 0.01$). As a measure of the sensitivity of hepatic CPT-1 to inhibition by malonyl CoA, the ID_{50} values were 11.0 ± 1.1 and 7.3 ± 0.8 μM at days 12 and 19, respectively.

DISCUSSION

A degree of caution is required in extrapolating the activities of the enzymes of glycerolipid synthesis as determined *in vitro* to the actual levels of expression of these activities *in vivo*, particularly since these assays involve membrane-bound enzymes and hydrophobic substrates/products. However, with this proviso, a major finding of the present study is that the YSM of the chick embryo displays an exceptionally high enzymic capacity for glycerolipid synthesis. This is particularly evident in the case of MGAT, which is expressed in the YSM at an unprecedented level compared with the reported activities for other avian or mammalian tissues at various developmental stages (22,27–29). Even the intestinal mucosa of adult mammals, regarded as the classic tissue for the operation of the monoacylglycerol pathway, exhibits much lower MGAT activities than those reported here for the YSM. For example, the activity (nmol/min/mg protein) of this enzyme in the intestinal mucosa of the neonatal (28) and adult (22) rat is approximately 100 compared with a peak of almost 300 in the YSM. Apart from its expression in the intestine, the tissue-specific distribution of MGAT in the adult mammal is very restricted (15). In particular, the adult liver is normally almost devoid of MGAT activity although this enzyme is transiently expressed in neonatal rat liver, attaining a level that is 30–40% of that achieved by the YSM (28). Thus the YSM of the avian embryo should be added to the select list of animal tissues possessing high MGAT activity.

The activity of GPAT in the YSM is also very high in comparison with the reported levels of this enzyme in tissues of the adult mammal. For instance, the activities of this enzyme (nmol/min/mg protein) in the liver and intestine of the adult rat are approximately 6.0 and 0.5, respectively (22), compared with 26.7 in the YSM at day 12. The activity of DGAT, the only enzyme concerned exclusively with TAG synthesis, was also relatively high in the YSM. For example, the DGAT activities (nmol/min/mg protein) in the liver and intestine of the adult rat are approximately 3.0 and 5.0, respectively (22), compared with a maximum of 36.1 in the YSM.

An additional point is that the activities of MGAT, GPAT, and DGAT are far higher in the YSM than in the developing liver, or indeed in any other tissue, of the chick embryo. These activities have previously been reported for the liver and certain other chick embryo tissues (14), and our present values obtained for the liver are consistent with this earlier study. The overall conclusion is that the YSM possesses an almost unprecedented enzymic potential for the synthesis of glycerolipids *via* the acylation of partial glycerides or glycerol-3-phosphate.

This conclusion clearly lends support to the hypothesis that, during their transit across the YSM, the lipids of the yolk are hydrolyzed to their constituent free fatty acids, glycerol, partial glycerides, free cholesterol, and the like, which are then reesterified to resynthesize TAG, PL, and CE in a process coupled to the assembly of VLDL particles. The fact that MGAT activity in the YSM was greater than that of GPAT by an order of magnitude may be taken to indicate that the monoacylglycerol pathway forms the predominant means of reesterification in this tissue, with the glycerol phosphate pathway performing a supporting role. Previous observations that the YSM also displays very high levels of acyl-CoA:cholesterol acyltransferase activity (ACAT) (30) as well as a high expression of the mRNA for apoprotein B (31) are also consistent with this view.

Complementary to these biochemical studies is the evidence from electron microscopy (1–5). In brief, this indicates that yolk droplets and granules are engulfed by the apical surface of the YSM endodermal cells and that this uptake is followed by the fusion of the phagocytotic vesicles within the cell to form large lipid-rich vacuoles. During the second half of the embryonic period, this uptake is so intense that these lipid-rich vacuoles occupy a large proportion of the cytoplasmic space and totally dominate the appearance of the cells. Meanwhile, the opposite side of the cell is observed to be extremely active in the exocytosis of lipoproteins into the vascular system of the YSM. Lipid-rich spherules corresponding to VLDL particles are packed into the cisternae of the endoplasmic reticulum and Golgi. Moreover, secretory vesicles containing VLDL particles can be observed in the process of fusion with the basal plasma menbrane, thus releasing these lipoproteins into the circulation.

The results described in the present study may help to define the biochemical processes that link the absorptive events at the apical surface with the subsequent secretory events at the basal surface of the endodermal cells. There is evidence that, as a result of fusion with lysosomes, the large lipid-rich vacuoles formed by the phagocytotic process are converted to so-called lipolysosomes in which the hydrolysis of the vacuolar contents proceeds at a high rate, catalyzed by lysosomal lipases and proteases (32). We propose that the products of this hydrolysis (free fatty acids, partial glycerides, glycerol, free cholesterol, lyso-PL, and the like) diffuse out of the large vacuoles and are transported to the endoplasmic reticulum where reesterification to synthesize TAG, PL, and CE is rapidly achieved by the very high activities of MGAT, GPAT, DGAT, acyl-CoA:acyltransferase, and presumably of the other enzymes required for complex lipid synthesis. The coordination of this reesterification process with the translation of the mRNA for apoprotein B (31) will promote the assembly of VLDL particles in the lumen of the endoplasmic reticulum (13). The exceptional activity of MGAT in the YSM implies that *sn*-2-monoacylglycerol is a major product of yolk lipid hydrolysis in the large vacuoles with the further inference that the lysosomal lipase which acts on the yolk-derived TAG preferentially hydrolyzes the ester bonds at the *sn*-1 and -3 positions.

The very high activity of CPT-1 in the mitochondria of the YSM, as reported in the present study, is indicative of an exceptionally high capacity for β-oxidation in this structure. The maximal CPT-1 activity measured in the YSM was about three times greater than the highest levels of this enzyme reported for the rat liver under any physiological state (17,18,24). Furthermore, the YSM enzyme was relatively insensitive to the physiological inhibitor, malonyl CoA. In fact, the CPT-1 activity of the adult rat liver is almost 10 times more sensitive to malonyl CoA inhibition compared with the YSM enzyme (17,18). These results suggest that a proportion of the yolk-derived lipid is oxidized in the mitochondria of the YSM in order to provide the energy for the translocation of the bulk of lipid across the endodermal layer. The present paper also reports for the first time the developmental expression of CPT-1 activity in the liver of the chick embryo; at day 12, this hepatic activity was only about half that concurrently expressed in the YSM but was nevertheless about 50% greater than the highest activities reported for the liver of the adult rat (17,18,24). CPT-1 in the mitochondria of the chick embryo liver was more sensitive than the YSM enzyme to inhibition by malonyl CoA, but was still relatively resistant to this inhibitor when compared with the enzyme from the liver of the adult rat (17,18). In the present study, we also determined the activity of CPT-1 in mitochondria isolated from the liver of the adult chicken (female, fed state). The activity of this enzyme in the adult was 20.8 ± 1.4 nmol/min/mg mitochondrial protein (n = 4 livers), far lower than the values obtained from the YSM and liver of the embryo at all stages.

The aim of the present work was to determine the activities of the acyltransferases in the YSM during the second half of the developmental period when the transfer of lipid from the yolk to the embryo is most intensive. The results indicate that the maximal or near-maximal activities of these enzymes have already been attained by day 10 of development, the earliest time-point studied. In future work, it would be of interest to measure these enzyme activities in the YSM during the first half of the developmental period in order to delineate the ontogeny of their expression and to determine the timing of their induction.

Lipid Composition of Hepatocyte Plasma Membranes from Geese Overfed with Corn

J.L. Cazeils, M. Bouillier-Oudot*, A. Auvergne, M. Candau, and R. Babile

École Nationale Superieure Agronomique de Toulouse, F 31326 Castanet-Tolosan, France

ABSTRACT: Twelve-week-old Landes male geese were overfed with corn for 21 d in order to induce liver steatosis (fatty liver). Lipid composition of hepatocyte plasma membranes from fatty livers was compared to that of lean livers obtained from geese fed a normal diet. The ratio cholesterol/phospholipids was higher in fatty hepatocyte plasma membranes (0.63 vs. 0.47), whereas the phospholipid/protein ratio was less than half. Overfeeding induced changes in fatty acid composition of hepatocyte plasma membranes, including a greater than twofold increase in the percentage of oleic acid (29.7 vs. 13.8%) and a somewhat lesser increase in lauric, palmitic, and palmitoleic acid contents of plasma membrane lipids of fatty livers. A concomitant reduction in the proportion of stearic acid (18.4 vs. 25.1%) was also observed. In fatty livers, the increased ratio of saturated to polyunsaturated fatty acids (PUFA) (1.5 vs. 1.0) was related to a significant decrease in PUFA content. Among all the PUFA, only the eicosatrienoic acid (20:3n-9) percentage was increased by liver steatosis. Overfeeding with corn appeared to induce competition between *de novo* synthesized and dietary fatty acids incorporated in hepatocyte plasma membranes. This resulted in an accumulation of *de novo* synthesized monounsaturated and derived fatty acids in plasma membranes from overfed birds. A defect in the incorporation of linoleic acid and linoleic- and linolenic-derived PUFA was observed despite the high proportion of these essential fatty acids in the diet. It was conclued that in overfed palmipeds, *de novo* hepatic lipogenesis prevails over dietary lipid intake to modulate lipid composition of the fatty liver plasma membrane.

Paper no. L7906 in *Lipids 34*, 937–942 (October 1999).

In mammals, liver steatosis generally originates from metabolic or infectious disease and is associated with an alteration of hepatic tissue structure. Fatty liver syndrome also has been described as a metabolic disease in laying chickens. When induced by overfeeding (1), this syndrome involves a twofold increase in liver weight, a liver fat content not exceeding 25%, hemorrhage, and hematoma.

In some palmiped breeds, overfeeding with a carbohydrate-rich diet also leads to the accumulation of triglycerides by hepatocytes. This susceptibility to nonhemorrhagic steatosis is used in the production of fatty liver ("foie gras"). Two or three weeks of overfeeding induces as much as a 10-fold increase in liver weight, and liver fat content can reach 60% wet weight. If overfeeding is not prolonged, tissue lesions generally do not occur (2,3), and despite overt histological fatty liver changes (2,3), metabolic activities are conserved (4). Moreover, interruption of overfeeding leads to a rapid decrease of liver weight, indicating the continuous exportation of liver fat. Histological and physiological parameters of the liver return to preoverfeeding values, showing the rapid reversibility of palmiped hepatic steatosis (5).

As in all bird species, the liver of palmipeds is the major site of *de novo* lipogenesis (6). According to Hermier *et al.*, a high lipid synthesis activity (4) and a triglyceride incorporation defect in circulating lipoproteins (7,8) could induce hepatic enlargement in overfed palmipeds. But liver enlargement also involves cellular hypertrophy and hyperplasia (9). On the other hand, geese that resist steatosis exhibit an enhanced exportation of polyunsaturated fatty acids (PUFA) in very low density lipoprotein-phospholipid (VLDL-PL) and high density lipoprotein-phospholipid (HDL-PL) which has been hypothesized to limit membrane growth and hepatocyte hypertrophy (10). The ability to use the PL for hepatocyte membrane synthesis, rather than for secretion as VLDL and HDL, could explain the differing susceptibility to steatosis among palmiped strains (11).

Thus, steatosis induced by overfeeding in palmipeds may be considered as a physiological process as opposed to hepatic steatoses usually considered as pathological in mammals or other avian species. The susceptibility of palmipeds to nonpathological liver steatosis seems to be related to a limited ability to export liver PL as lipoproteins while having continued hepatocyte membrane synthesis. This is thought to allow growth and preservation of functional and structural integrity of plasma membranes whereas triglycerides accumulate in the hepatocytes. But, to our knowledge, there are few data on the structure of hepatocyte plasma membranes of palmiped fatty liver (11), or its fatty acid composition.

The high *de novo* hepatic lipogenesis induced by carbohydrate overfeeding leads to an accumulation of the newly synthesized fatty acids in triglycerides of hepatocytes (8). Once incorporated into PL, these fatty acids can also influence the

plasma membrane lipid composition. On the other hand, corn is usually the only component of the diet when inducing steatosis of palmipeds. Corn lipids comprise greater than 50% linoleic acid. We can hypothesize that, as in mammals, a high intake of an essential fatty acid will change the lipid composition of hepatocyte plasma membranes.

The aim of this work was to investigate the influence of corn overfeeding on lipid and fatty acid composition of goose hepatocyte plasma membranes and to study the proportions of *de novo* synthesized and dietary lipids in altering the composition.

MATERIALS AND METHODS

Animals and samples. Liver samples were taken from a French Landes male goose flock, bred at the Station for Goose Breeding (Asseldor, Coulaures, France) under specified conditions (12).

Eight-week-old animals were fed a commercial diet (palmiped K34, provided by COFNA, 24 Sarlat, France) (control diet). A quantitative rationing resulted in a 2.6 MJ metabolizable energy and 35 g protein intake per day. Lipid content and fatty acid composition of the diets are shown in Table 1. The intakes of 18:2n-6 and 18:3n-3 were approximately 1.70 and 0.17 g/d, respectively. After 4 wks of control diet feeding, a part of the flock was commercially processed in a slaughterhouse. (Breeding and slaughtering methods are in accordance with French regulation for welfare and humane treatments of animals). Evisceration was performed just after plucking, and liver samples were collected by taking about 50 g from the middle of lobes of five 95-g average-weight lean livers (control).

For the next 21 d, the other geese of the flock were submitted to a soaked-corn overfeeding, corresponding to an average 13 MJ metabolizable energy, 80 g protein, 18.5 g 18:2n-6, and 0.37 g 18:3n-3 intake per day. Liver samples were harvested as described above from five 950-g average-weight fatty livers. All samples were frozen in liquid nitrogen and kept at –60°C until analysis.

Preparation of plasma membranes. Plasma membranes of goose livers were prepared by an adaptation of a procedure described by Evans (13). Briefly, membranes were isolated from filtered tissue homogenate with a loose-fitting Dounce homogenizer. The use of a minimum of strokes permitted large plasma-membrane fragments to be recovered into the pellet after a low-speed centrifugation. Steatosis-affected liver tissue has a high triglyceride content. Pelleting of the plasma membrane fraction separated it from most of the triglycerides, which were recovered in the supernatant. Nevertheless, the membranes isolated from fatty livers contained 35 and 1.6% of total lipids as triglycerides and cholesteryl esters, respectively (see footnotes A, B, Table 2). Subsequent lipid class separation removed neutral lipids before PL composition determination. Plasma membranes were isolated from nuclear and mitochondrial material through a 60,000 × *g* centrifugation for 3.30 h over a discontinuous density gradient (1.076, 1.125, 1.174, 1.222 g/mL). This density gradient was prepared according to Graham *et al.* (14) by diluting Iodixanol (available commercially as OptiPrep from Nycomed Pharma, Oslo, Norway) in a solution containing 8.0% (wt/vol) sucrose, 20 mM Tris-HCl, pH 7.8, and 1 mM $MgSO_4$. Plasma membranes were collected in a strip located in a median position. This fraction was then suspended in a physiological solution (NaCl 9‰) and centrifuged to eliminate most of the related nonmembrane proteins (15). To evaluate the recovery and contamination of the plasma membrane fraction, the activities of the following enzymes were used as the markers of various subcellular organelles: 5′-nucleotidase (EC 3.1.3.5) for plasma membrane (16), succinate dehydrogenase (EC 1.3.99.1) for internal mitochondria membrane (17), NADH dehydrogenase (EC 1.6.99.3) for endoplasmic reticulum membrane (18), and acid phosphatase (EC 3.1.3.2) for lysosomal membrane (19). In the purified fraction, the recovered activity of the 5′-nucleotidase enzyme was more than 20 and 50% (in control and fatty liver, respectively) of the total homogenate activity. The contamination in control and fatty liver preparations of NADH dehydrogenase and acid phosphatase activities was lower than 10 and 5%, respectively. Succinate dehydrogenase activity was never recovered in the purified fractions.

Membrane composition. Membrane protein content was determined by the method of Lowry *et al.* (20) with bovine serum albumin as standard. Total lipids were extracted from the isolated plasma membrane preparations following the procedure of Bligh and Dyer (21). PL were estimated by an organic phosphorus assay according to the method of Vaskovsky *et al.* (22). The removal of neutral lipids and the separation of PL classes was achieved by high-performance liquid chromatography (Hewlett-Packard) according to the Hax (23) procedure. We used a Lichrosorb SI-60 chromatography column (5 µm, 25 cm × 7.5 mm) and an *n*-hexane/2-propanol/water mixture as solvent gradient system. PL absorbance was measured at 206 nm using an ultraviolet detector. Purity of each PL class was confirmed by thin-layer chromatography (24). Fatty acid composition of total PL and major PL classes was determined after transmethylation (25). Fatty acid methyl esters were analyzed using a gas chromatograph (Hewlett-Packard 5890 series II) fitted with a 0.25-µm film thickness reticulated polyethyleneglycol phase 30 m × 0.25 mm i.d. capillary column (Innowax, Hewlett-Packard),

with nitrogen as carrier gas. The temperatures of the injector and the detector were 250 and 300°C, respectively, and the column temperature was set from 200 to 250°C with a 5°C/min rise. Total cholesterol in the membrane extract was quantified by a colorimetric enzymatic method using Sigma Diagnostics procedure n° 352. Removed neutral lipids were pooled and classes were separated by gas chromatography on an apolar capillary column (DB5, J&W Scientific Inc., Folsom, CA), after silylation (26). Neutral lipids, PL, and fatty acid standards were provided by Sigma Chemical (St. Louis, MO).

Statistics. Results were expressed as mean ± SEM, and their significance were analyzed using unpaired Student's *t*-test.

RESULTS

Corn overfeeding induced changes in lipid composition of goose hepatocyte plasma membranes (Table 2). Nevertheless, we considered the huge triglyceride content (35% of total lipids) of plasma membrane isolated from fatty liver as an artifact. Triglycerides accounted for 50% of fatty liver wet weight and could remain associated with plasma membrane fragments or be included into vesicles during homogenization, preventing a complete separation from plasma membranes.

Concerning the main lipids of plasma membranes, the ratio of total cholesterol to proteins was 30% lower in fatty liver than in controls whereas the PL/protein ratio exhibited a 54% decrease. This resulted in a significantly higher cholesterol/PL ratio in fatty liver than in controls. Cholesteryl esters, which were insignificant in control plasma membranes, seemed to increase in fatty liver but represented no more than 10% of total cholesterol.

As found in most animal cell membranes, phosphatidylcholine (PC) and phosphatidylethanolamine (PE) largely prevailed as they formed more than 80% of the total PL of hepatocyte plasma membrane in goose. Overfeeding did not generate any modification in the distribution of major PL classes. Only an increase in the sphingomyelin fraction content was significant.

Plasma membrane lipid fatty acid compositions of control and fatty liver are shown in Table 3. In control livers, saturated fatty acid (SFA) and PUFA contents were similar, both being around 40% of total fatty acids. The predominant SFA were stearic and palmitic acids, whereas the major PUFA were, in decreasing order, arachidonic, linoleic, and docosahexaenoic (22:6n-3) acids. Monounsaturated fatty acids were mainly represented by oleic acid (14%). The other fatty acids each represented less than 1% of total fatty acids.

Overfeeding largely modified the fatty acid profile of hepatocyte plasma membrane PL. Among SFA, the relative amounts of myristic and palmitic acids increased, whereas the

percentage of stearic acid was significantly reduced. Monounsaturated fatty acids were significantly increased, with the oleic acid content being over twofold higher in fatty than in control liver (30 vs. 14% of total fatty acids, respectively). In fatty livers, all the n-3 and n-6 PUFA proportions significantly decreased, and their total percentage was reduced from 41 to 24%. On the other hand, eicosatrienoic acid (20:3n-9) content increased about sixfold without exceeding 2%.

If the ratio of unsaturated fatty acids to SFA was slightly but significantly increased between control and fatty liver, the unsaturation index (UI), taking into consideration the number of double bonds, decreased while the SFA/PUFA ratio was markedly increased (50%).

Fatty acid compositions of both PL main species, PC and PE, were different in control and fatty liver plasma membrane (Table 4). The intensity of the modifications of fatty acid content induced by overfeeding appeared to be peculiar to each PL class. Nevertheless, fatty acid profiles for both PC and PE are modified in the same way. Thus, 18:1 and 20:3n-9 content of PC and PE was increased in fatty liver, whereas stearic acid and total n-6 and n-3 PUFA contents were greatly decreased. Only the palmitic acid proportion remained unchanged for PE and significantly increased for PC in fatty livers when compared to controls.

DISCUSSION

In palmipeds, the marked increase in liver weight after corn overfeeding corresponds to a greatly increased lipid synthesis and accumulation. In animals with fatty liver, total lipids represent over 50% of the hepatic mass. These lipids consist of more than 90% triglycerides (27). The syntheses induced by carbohydrate overfeeding also involve transport lipoproteins and structural components that are part of the cell hyperplasia and hypertrophy (9). This is highlighted by the increase in total proteins, PL and cholesterol in fatty liver (27). Nevertheless, in agreement with observations reported by Salichon *et al.* (10), our results showed that overfeeding sharply reduced the lipid content of hepatocyte plasma membranes with respect to the protein matrix. Although the proteins were not characterized, perhaps an increased level of membrane proteins is related to increases in metabolic activity of hepatocytes during overfeeding. The cholesterol/PL ratio was significantly higher in fatty liver membranes, showing that PL were relatively more reduced in plasma membranes than was total cholesterol. A decrease in liver PL retention could be also involved (28), originating in a relative deficiency in synthesis together with an enhanced secretion through VLDL and HDL (11).

By contrast, the relative proportions of the two main species of membrane PL, PC and PE, were unaffected by overfeeding. In corn-overfed ducks, Gabarrou *et al.* (29) observed a decrease in hepatic PC content, deemed to be the result of a dietary choline deficiency. Our results in geese, however, do not support a possible choline deficiency since the PC content was stable and the sphingomyelin content increased by overfeeding. Nevertheless, we had previously shown that, in the whole hepatic tissue, the content of these PL species evolved differently during the postprandial period, according to hepatic lipoprotein synthesis and flow (30). Their relative content therefore depended on the digestive status of the animals at the time of slaughter.

Palmiped overfeeding with a carbohydrate-rich diet results in high *de novo* liver lipogenesis. Palmitic and oleic acids are the main products of fatty acid synthesis, and they constituted over 80% of the hepatic triglyceride fatty acid content. Our present study showed that these two fatty acids were also the predominant species incorporated in membrane PL. Their proportion in membrane lipids increased from 30% in the control to 50% in fatty liver. Therefore, it can be concluded that increased lipogenesis induced by overfeeding in palmipeds leads to greatly increased amounts of palmitic and oleic acids and that these fatty

acids readily contribute to both PL and triglyceride synthesis. The increase in triglyceride and PL oleic acid content, together with a concomitant decrease in stearic acid content, could correspond to an increase in Δ9 desaturase enzyme activity.

In liver plasma membrane lipids of geese, the increase in palmitic and oleic acid contents is associated with a reduction in proportion of PUFA. Thus the proportion of linoleic acid was markedly reduced by steatosis. Arachidonic acid (20:4n-6), formed from linoleic acid (18:2n-6) through successive elongation and desaturation steps, also exhibited a slight but significant decrease. A similar phenomenon was observed for the main n-3 PUFA (22:6n-3) formed from elongation and desaturation of the essential fatty acid linolenic acid (18:3n-3). Only the eicosatrienoic acid (20:3n-9), produced by oleic acid elongation and desaturation, increased significantly in membrane lipids of fatty livers. These modifications occurred in both major classes of PL but to a greater extent in PC than in PE. The changes in fatty acid composition of liver plasma membrane lipids in overfed geese are comparable to those observed in hepatocyte membrane lipids of rats fed essential fatty acid-deficient diets, resulting in a decrease of n-6 and n-3 PUFA contents and increased oleic acid and n-9 PUFA (31,32).

In the present experiment, geese were overfed only with corn. The high level of carbohydrate content of corn intake was responsible for increased liver lipogenesis and probably Δ9 desaturase activity. Corn contains 4% lipids, with linoleic acid representing more than 50% of total fatty acids. Considering the very high linoleate intake during overfeeding, compared to the control period intake (18.5 vs. 1.7 g/d), the very low incorporation of linoleic acid and its elongation/desaturation products in hepatic plasma membrane lipids is even more surprising. In geese overfed with corn, Blum *et al.* (33) also reported a low linoleic acid content of hepatic lipids, but a 10-fold increased level in adipose tissue. In consequence it can be concluded that, during overfeeding, dietary and *de novo* synthesized fatty acids come into competition for their incorporation in hepatocyte membrane lipids. The high level of hepatic lipogenesis induced by overfeeding results in enrichment of hepatic membranes with oleic acid to the exclusion of dietary linoleic acid. In the same way, 22:6n-3, the main fatty acid derived from linolenic acid, was also decreased in fatty liver. However overfeeding increased the linolenate intake twofold (0.37 vs. 0.17 g/d). Hence, the same mechanism seems to limit the incorporation of both essential fatty acids. In response to overfeeding, the dramatic triglyceride accumulation in hepatocytes and the continuous secretion of lipoproteins by exocytosis could limit dietary lipid capture in hepatic pools. This limited capture could involve triglyceride-rich particles, as it was assumed in chickens with normal feeding conditions (34), as well as nonesterified fatty acids. Possibly in concert with these processes, a high *de novo* oleic acid synthesis in hepatocytes and a preferential incorporation of dietary fatty acids, especially PUFA, in VLDL and HDL, could explain the altered fatty acid profile of fatty liver plasma membranes and increased PUFA content of extrahepatic tissues (10,28).

This study shows that corn overfeeding in geese induces a modification of hepatic plasma membrane constituents, especially in cholesterol/PL, and PL/protein ratios and in fatty acid composition of PL. In general, PUFA content is significantly decreased with an increase in oleic acid content. However, changes in the fatty acid profile of hepatic plasma membranes are closely related to *de novo* lipogenesis induced by high carbohydrate intake. Consequently, the modulation of fatty liver plasma membrane composition by dietary lipid intake is masked if not strongly limited.

ACKNOWLEDGMENTS

We are grateful to the Regional Council of Midi-Pyrenees for supporting part of this work. We are indebted to Jean-Pierre Dubois, manager of the Station of Goose Breeding (ASSELDOR), and to his team for liver supply.

ABSTRACT: Saturated very long chain fatty acids (fatty acids with greater than 22 carbon atoms; VLCFA) accumulate in peroxisomal disorders, but there is little information on their turnover in patients. To determine the suitability of using stable isotope-labeled VLCFA in patients with these disorders, the metabolism of 22-methyl[23,23,23-$^2H_3$]tricosanoic (*iso*-lignoceric) acid was studied in rats *in vivo* and in human skin fibroblasts in culture. The deuterated *iso*-VLCFA was degraded to the corresponding 16- and 18-carbon *iso*-fatty acids by rats *in vivo* and by normal human skin fibroblasts in culture, but there was little or no degradation in peroxisome-deficient (Zellweger's syndrome) fibroblasts, indicating that its oxidation was peroxisomal. Neither the 14-, 20-, and 22-carbon *iso*-fatty acids nor the corresponding odd-chain metabolites could be detected. In the rat, the organ containing most of the *iso*-lignoceric acid, and its breakdown products, was the liver, whereas negligible amounts were detected in the brain, suggesting that little of the fatty acid crossed the blood-brain barrier. Our data indicate that VLCFA labeled with deuterium at the ω-position of the carbon chain are suitable derivatives for the *in vivo* investigation of patients with defects in peroxisomal β-oxidation because they are metabolized by the same pathways as the corresponding *n*-VLCFA. Moreover, as *iso*-VLCFA and their β-oxidation products are readily separated from the corresponding *n*-fatty acids by normal chromatographic procedures, the turnover of VLCFA can be more precisely measured.

Paper no. L8122 in *Lipids 34,* 943–949 (September 1999).

Saturated fatty acids with greater than 22 carbon atoms (very long chain fatty acids; VLCFA) are components of many human tissues, and, in particular, are enriched in the myelin fraction of brain (1). The VLCFA in human tissues are believed to arise from dietary sources and by *de novo* synthesis from shorter-chain fatty acids such as palmitic and stearic acids. Synthesis may take place in either microsomes or mitochondria, and there is evidence that the enzymes involved in the synthesis of VLCFA are different from those catalyzing the synthesis of fatty acids with up to 20 carbon atoms (2). Degradation of VLCFA takes place exclusively in peroxisomes in rat liver (3,4) and in human skin fibroblasts (5,6). In human skin fibroblasts, acetyl CoA released from VLCFA by peroxisomal β-oxidation is metabolized further *via* the citric acid cycle or is used for various biosynthetic reactions, including the biosynthesis of fatty acids (7). Acetyl CoA generated from peroxisomal β-oxidation in rat liver is also used for anabolic processes including incorporation into the 1-alkenyl group of ethanolamine plasmalogens (8). The role of peroxisomal β-oxidation is generally assumed to be that of chain-shortening fatty acids to products which can then be further oxidized in mitochondria (9–11).

As part of our ongoing interest in inherited disorders affecting peroxisomal β-oxidation, we synthesized a deuterated VLCFA that we hoped to use for turnover studies in patients with X-linked adrenoleukodystrophy (ALD), a rare neurodegenerative disorder caused by mutations in an ABC transporter protein (12,13), but characterized biochemically by an accumulation of saturated VLCFA (14–17), as well as in patients with peroxisomal biogenesis defects (e.g., Zellweger's syndrome; 15,16). Because ethical approval was contingent on establishing the suitability of using the deuterated VLCFA for human studies, we undertook a preliminary study of the metabolism of the fatty acid in rats *in vivo* and in human skin fibroblasts in culture. For these studies we used 22-methyl-[23,23,23-$^2H_3$]tricosanoic (*iso*-lignoceric, *iso*-24:0) acid rather than a deuterated lignoceric acid derivative as a substrate because *iso*-lignoceric acid and its metabolites are readily separated from the corresponding straight-chain fatty acids by gas chromatography and hence are more readily quantified. Our data indicate that trideuterated *iso*-lignoceric acid is oxidized in peroxisomes in human tissues and is suitable for the *in vivo* investigation of patients with defects in peroxisomal β-oxidation. There was no evidence that *iso*-lignoceric was degraded by α-oxidation in either the rat or human tissues examined.

EXPERIMENTAL PROCEDURES

Materials. Analytical grade solvents were purchased from May and Baker Pty. Ltd., Melbourne, Australia, or from Ajax Chemicals, Sydney, Australia. Basal Eagle's medium (BME) was purchased from Flow Laboratories, Irvine, Scotland, and fetal calf serum was obtained from Gibco New Zealand Ltd. [24,24,24-$^2H_3$]Tetracosanoic acid (lignoceric acid, 99% deuterium) was purchased from Larodan Fine Chemicals (Malmo, Sweden). Undecylenic acid, 11-bromoundecanoic acid, and lithium aluminum deuteride (98 atom deuterium %) were purchased from Sigma-Aldrich, Castle Hill, Australia. All other chemicals used for the synthesis of deuterated fatty acids were also obtained from Sigma-Aldrich.

Synthesis of trideuterated iso-*lignoceric acid.* 22-Methyl-[23,23,23-$^2H_3$]tricosanoic acid (trideuterated *iso*-lignoceric acid) was synthesized from 10-undecenoic acid *via* the reaction sequence outlined earlier (18). Briefly, 1-chloro-2-ketododec-10-ene was synthesized from 10-undecenoic acid and converted to 2-methyl 10-undecenoic acid *via* a base-mediated rearrangement as outlined by Johnson and Poulos (19). The acid was converted into its methyl ester, reduced to its alcohol with lithium aluminum deuteride, then converted to its mesylate. [1,1,1-$^2H_3$]-2-Methylundec-10-ene was prepared by reduction of the mesylate with lithium aluminum deuteride, hydroboration, and bromination to form [1,1,1,-$^2H_3$]-2-methyl 11-bromo-undecane. 11-Bromo-undecanoic acid methyl ester was coupled to TOSMIC (*p*-toluenesulfonylmethylisocyanide), and the product was reacted with [1,1,1,-$^2H_3$]-2-methyl 11-bromo-undecane (20). The methyl ester of 22-methyl [23,23,23-$^2H_3$]tricosanoic acid was isolated after hydrolysis of the TOSMIC ester and subsequent reduction, and converted to the free acid by alkaline hydrolysis. Combined gas chromatography–mass spectrometry of the trideuterated *iso*-lignoceric acid confirmed an abundance of >95% deuterium at the 23-position of the carbon chain, and the purity of the product was assessed as >97%.

Tissue culture. Skin fibroblast cultures were established from skin biopsies of patients with Zellweger's syndrome, and from individuals without any biochemical or clinical evidence of an abnormality in peroxisomal β-oxidation. The diagnosis of Zellweger's syndrome was based on the patient's case history, and on clinical and biochemical investigations (15,16). Human skin fibroblasts were grown in 75-cm^2 culture flasks in 10 mL BME containing 10% fetal calf serum until confluent. The medium was then removed and replaced with 10 mL BME containing 0.5% fetal calf serum. After incubation for 24 h the medium was replaced with BME containing 0.5% fetal calf serum and 136 nmol trideuterated *iso*-lignoceric acid, or 68 nmol trideuterated lignoceric acid plus 68 nmol trideuterated *iso*-lignoceric acid, dissolved in ethanol, and the cells were maintained in culture for a further 3 d. At the end of this period, the medium was removed and 5 mL of water was added; and the cells were scraped from the flask, sonicated, and stored at –20°C until ready for lipid and protein analysis. Protein assays were carried out as described by Bradford (21).

Animal feeding experiments. Four young Sprague-Dawley rats (purchased from the Institute of Medical and Veterinary Science Field Station, Adelaide, Australia) (weighing 133–151 g) were gavaged with an aqueous suspension of trideuterated *iso*-24:0 (20 µmol) and egg yolk lecithin (10 µmol) per 100 g body weight (Experiment A). Single animals were sacrificed by exposure to carbon dioxide gas after 1, 4, 7, and 10 d. Brain, liver, kidney, and heart were removed, weighed, and stored at –20°C until ready for analysis. Two adult animals weighing 465 and 495 g were fed a similar suspension of trideuterated *iso*-24:0 and egg yolk phosphatidylcholine (Experiment B) and were sacrificed using carbon dioxide gas after 1 and 2 d, respectively. Organs were removed, weighed, and stored at –20°C until ready for analysis.

To test for the degree of gut absorption of the trideuterated *iso*-24:0, four young rats (average weight 150 g) were placed in metabolism cages (Tecniplast, Sieper and Company, Strathfield, Australia) for 2 d. The feces which were produced over two successive 24-h periods were collected and stored until ready for analysis.

Lipid extraction and analysis. Cell suspensions were extracted according to the Bligh and Dyer method (22) after the addition of nonadecanoic acid (19:0, 80 nmol) as internal standard. Lipids were extracted from 0.5 g of tissue or pulverized feces (23) after the addition of appropriate amounts (150–750 nmol) of octacosanoic acid (28:0) as internal standard. The lipid extracts were transesterified with 1.5% (vol/vol) sulfuric acid in methanol for 4 h at 100°C, and the fatty acid methyl esters were purified by thin-layer chromatography (7). The saturated fatty acid methyl esters were isolated from the total fatty acid methyl esters by argentation chromatography (7) and dissolved in a small volume of hexane. Aliquots were injected into a Hewlett-Packard 5890 gas chromatograph equipped with a 25 m × 0.22 mm (internal diameter) (0.25 µm phase thickness) BP-1 capillary column, and the temperature was programmed from 160 to 320°C at 4°C/min. Quantitation of the *iso*-fatty acid methyl esters (16:0, 18:0, 24:0, 26:0) was performed by reference to the internal standard. The fatty acid methyl esters were then subjected to gas chromatography–mass spectrometry analysis using a JEOL DX-303 mass spectrometer and a Hewlett-Packard 5890 gas chromatograph equipped with an identical BP-1 capillary column. The ratio of the trideuterated fatty acid to total trideuterated and unlabeled fatty acid for each *iso*-fatty acid was obtained from the peak height ratio of the molecular ions of the trideuterated and unlabeled methyl esters. Quantitation of the deuterated fatty acids was then determined by multiplying the mass spectrometric ratio for each *iso*-fatty acid by its total weight obtained by gas chromatography.

RESULTS

The exact uptake of trideuterated *iso*-lignoceric acid by skin fibroblasts in culture could not be established because of the difficulties in assessing the proportion of the fatty acid that was completely oxidized to CO_2. However, the data obtained

using the peroxisome-deficient (Zellweger's syndrome) cell lines, where there was negligible oxidation of the fatty acid, indicated that, at least in these lines, <5% of the total trideuterated *iso*-lignoceric acid recovered from the cells and medium was taken up into the cells during the incubation period. It is likely that similar amounts were taken up by control cells in this period because the combined amounts of the substrate and its various products in control cells were not greatly different from the values obtained in the mutant cell lines (Table 1).

Trideuterated *iso*-24:0 was relatively slowly metabolized by normal cells, and there was considerable variability in the turnover of the fatty acid. This variability may reflect the combined effects of the poor uptake of *iso*-24:0 as well as cell line differences. Similar variability was reported earlier when using lignoceric acid as a substrate (24). The substrate and the main products, i.e., the corresponding 16- and 18-carbon *iso*-fatty acids, eluted faster from the gas chromatographic column than the corresponding straight-chain fatty acids and were well separated from them (Fig. 1, Table 1). Despite very careful analysis of the extracts, 22- and 20-carbon homologs were not detected. Moreover, α-oxidation products, for example, the corresponding *iso*-23:0, -21:0, -19:0, and -17:0 fatty acids, could also not be detected. Analysis of the extracts of peroxisome-deficient cells incubated with trideuterated *iso*-24:0 showed the expected marked reduction in the levels of the *iso*-16:0 and *iso*-18:0 products, indicating a block in peroxisomal β-oxidation (6), which is consistent with the nearly complete or total absence of peroxisomes in this syndrome (25). Instead, peroxisome-deficient cells contained significant amounts of trideuterated *iso*-26:0, the elongation product of *iso*-24:0 (Table 1 and Fig. 1). The difference between Zellweger's cells and control cells in the metabolism of *iso*-lignoceric acid is highlighted when the amount of elongation product (*iso*-26:0) is expressed as a ratio of the amount of oxidized products (*iso*-18:0 and *iso*-16:0), with the Zellweger's cells having a ratio >6.5 and control cells a ratio <0.14. It is likely that the variability in the levels of trideuterated *iso*-24:0 in peroxisome-deficient cell lines is associated with differences in uptake of the fatty acid, which may reflect differences in the genotype and/or growth characteristics of the individual cell lines.

To study the influence of the n-2 methyl group on the metabolism of 24:0, normal fibroblasts were incubated with a mixture of equal amounts of trideuterated *n*-24:0 and *iso*-24:0. Trideuterated *n*- and *iso*-derivatives of 16:0 and 18:0, products of the β-oxidation of *n*-24:0 and *iso*-24:0, respectively, were detected in the cell extracts. While the trideuterated *n*-24:0/*iso*-24:0 fatty acid ratios for two normal cell lines were around 1 (0.96 and 0.91), the corresponding trideuterated *n*-16:0/*iso*-16:0 (3.37 and 3.0) and *n*-18:0/*iso*-18:0 (3.37 and 2.65) fatty acid ratios, formed by β-oxidation of the deuterated VLCFA, were much greater, indicating that the *n*-24:0 was preferentially metabolized. Although we were unable to estimate the *n*-16:0/*iso*-16:0 and *n*-18:0/*iso*-18:0 fatty acid ratios in a Zellweger cell line because of the very low conversions, the ratio of trideuterated *n*-26:0/*iso*-26:0, the major product in these cells, was close to 1.

On average, 58% (range, 45 to 75%) of the trideuterated *iso*-24:0 administered to rats was recovered in the feces in a 2-d period, and greater than 90% of the recovered fatty acid was detected within the first 24 h. Analysis of fecal lipids confirmed that the fatty acid had not been metabolized during passage through the gut. Analysis of liver, brain, kidney, and heart taken from rats fed trideuterated *iso*-lignoceric acid confirmed the presence of small amounts of endogenous (i.e., nondeuterated) *iso*-lignoceric acid, with liver containing the most and brain the least. Other *iso*-fatty acids (also nondeuterated), notably *iso*-16:0 and -18:0, were also detected in all tissues examined. Once again, the brain contained the lowest amounts of these fatty acids and liver the most.

Trideuterated *iso*-lignoceric acid was detected in liver, kidney, and heart up to 10 d after a single dose of the fatty acid was fed (by gavage) to young rats (Table 2, Experiment A). However, the fatty acid was detected in the brain only in the early time period and only in trace amounts (<1% of the labeled fatty acid recovered from the tissues). The data indicate a drop in the levels of trideuterated *iso*-lignoceric acid, at least in the liver, over the 10-d period. One day after the gavage, and assuming an even distribution of the fatty acid, around 8% of trideuterated *iso*-24:0 was recovered in liver, kidney, and heart, with about a further 4% of the deuterium label recovered in *iso*-16:0 and *iso*-18:0. A similar result was obtained by feeding the fatty acid to adult animals (Table 2, Experiment B), although the amount of *iso*-24:0 recovered in the younger animals was greater. It is possible that this difference relates to the age of the animals. As around 58% of the labeled fatty acid passed through the gut without being absorbed, approximately one-third was not accounted for, but

[a]Human skin fibroblasts were incubated with trideuterated *iso*-24:0, and the fatty acid products were determined by gas chromatography–mass spectrometry as described in the text. The data shown here represent the mean of duplicate assays carried out on four separate control and Zellweger syndrome cell lines. The mean ± the standard deviation are also shown.

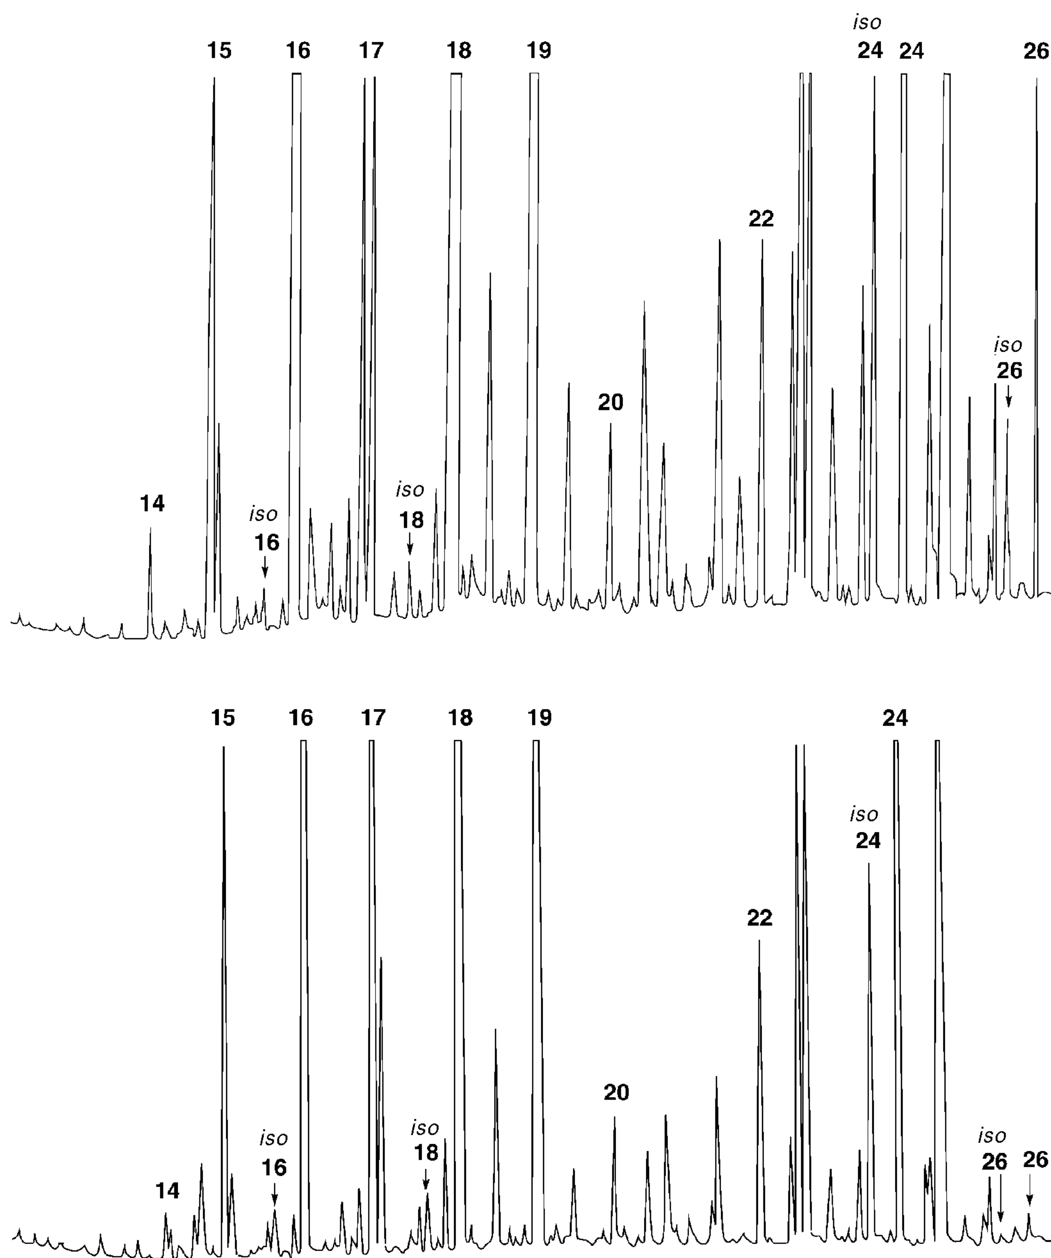

FIG. 1. Gas chromatography of *iso*-fatty acids in human skin fibroblasts was carried out as described in the text. The carbon chain length of the various fatty acids is shown. Top panel, Zellweger syndrome; bottom panel, control fibroblasts.

much of this may represent fatty acid taken up into other tissues and blood.

Metabolites of deuterated *iso*-24:0 were detected in all six animals investigated, indicating that the substrate was oxidized *in vivo*. In particular, oxidation products were detected in the liver and heart up to 10 d after feeding the deuterated fatty acid to the animals. These included 16- and 18-carbon fatty acids, presumably formed by β-oxidation of *iso*-24:0. As observed with skin fibroblasts, *iso*-22:0 and *iso*-20:0, presumed intermediates in *iso*-16:0 and *iso*-18:0 formation, were either not detected or observed only in small amounts (*iso*-22:0 was detected only at day 1 in Experiment A in much smaller amounts than the other metabolites, Table 2).

DISCUSSION

The oxidation of *iso*-lignoceric acid was greatly diminished in peroxisome-deficient human cells, indicating that, as with lignoceric acid, this *iso*-fatty acid is oxidized exclusively in peroxisomes. The metabolic products formed from *iso*-24:0 in the rat were similar to those produced in control human fibroblasts, implying that its oxidation was also peroxisomal in rat tissues. Our studies indicate that the fatty acid is readily

[a]Animals were fed trideuterated *iso*-lignoceric acid and sacrificed at the times shown. Analysis of *iso*-fatty acids was performed as outlined in the Experimental Procedures section. Animals used for Experiment A were younger than those used for Experiment B (see Experimental Procedures section). ND, <0.001 μmol/g.
[b]Traces of *iso*-22:0 (0.021 μmol/g) were also detected in liver on day 1.

taken up from the gut in rats with, of the tissues examined, most ending up in the liver. Whereas liver, kidney, and heart had easily demonstrable quantities of *iso*-24:0 (and its metabolites), the fatty acid was not detected in the brains of the animals, except in trace amounts, indicating that little crossed the blood-brain barrier over the experimental period. Although the effect of repeated doses over a longer period is not known, under our conditions, there is little evidence that exogenous VLCFA contribute to the pool of endogenous fatty acids in the brain. Earlier studies indicated that exogenous saturated VLCFA could cross into the brain, but these were based on experiments carried out on a single terminally ill patient with X-linked ALD (26). It is entirely possible therefore that this does not occur in normal individuals or in all patients. Support for this conclusion is provided by more recent studies showing that erucic acid (22:1), which has a carbon chain length approaching that of *iso*-lignoceric acid, does not enter the brain of ALD or adrenomyeloneuropathy patients even after long-term dietary supplementation (27,28).

A number of other tentative conclusions can be drawn from our studies. First, the almost complete absence of trideuterated *iso*-22 and *iso*-20 carbon intermediates in normal human cells, and in rat tissues, indicates that 18- and 16-carbon fatty acids are major products of peroxisomal β-oxidation of saturated VLCFA. If production of 20- and 22-carbon fatty acids *via* the peroxisomal β-oxidation pathway is limited, and given that VLCFA oxidation does not take place in mitochondria, synthesis of these fatty acids must occur *via* the elongation of shorter-chain precursors. Since the acetate released from the peroxisomal β-oxidation of VLCFA is used for chain elongation of fatty acids (7), the puzzling reduction in 22:0 in patients with abnormalities in peroxisomal biogenesis (15) could be explained by a reduced elongation of shorter-chain fatty acids to form 22:0. Second, as we were unable to detect odd-chain breakdown products of lignoceric acid, our data demonstrate that VLCFA are poor substrates for the α-oxidation system in cultured skin fibroblasts. Earlier studies by Tsuji *et al.* (29) had indicated that odd-chain fatty acids (17-, 19-, 21-, 23-, and 25-carbon saturated fatty acids) were formed from [^{3}H]24:0 and -26:0, and it was suggested that they were formed by α-oxidation. These earlier studies by Tsuji *et al.* (29) utilized 24:0 and 26:0 fatty acids, labeled with tritium in positions 15,16 and 17,18 of the carbon chain, respectively. One possible explanation for the differences between our data and theirs is that the tritium attached to the 15,16- and 17,18-carbons is more readily exchangeable than the deuterium bound to the ω-carbon atom. Another possibility is that tritium released by β-oxidation of the fatty acid was reutilized for the synthesis of odd carbon-number chain fatty acids. There is also the possibility that at least some of the odd carbon-number chain metabolites reported by Tsuji *et al.* (29) had been derived from the appreciable amounts of odd carbon-number chain VLCFA and other radiolabeled contaminants present in the substrates used (up to 7.5% of the total label). Although confirmation of the structure of the various metabolites formed in our investigations was based on rigorous gas chromatography–mass spectrometry procedures, in the earlier studies of Tsuji *et al.* (29) identification of odd carbon-number chain metabolites was based largely on gas chromatographic retention times, and there may have also been greater errors in structural assignment. Our observed lack of α-oxidation of *iso*-24:0 by human skin fibroblasts in culture is supported by other studies showing that formic acid, a major product of α-oxidation of fatty acids, is not formed from lignoceric acid (30; Poulos, A., and Sharp, P., unpublished data). Moreover, there is no indication that odd carbon-number chain fatty acids accumulate in patients with defects in peroxisomal β-oxidation (24). Finally, our data obtained using equimolar mixtures of lignoceric and *iso*-lignoceric acids indicate that the insertion of a methyl group, at a position in the carbon chain far removed from the carboxyl group, can have a marked effect on the oxidation of a fatty acid. It is not surprising that the β-oxidation activity

toward *iso*-24:0 is less than the activity toward lignoceric acid as a number of peroxisomal enzyme proteins are involved in this process, and the affinity of many of these enzymes for different substrates may vary. Similarly, fatty acid elongation is also a complex process requiring a number of enzyme proteins. Our earlier studies demonstrated elongation of a straight-chain fatty acid, but not a branched-chain fatty acid with a γ-methyl group (31), suggesting that there is some substrate specificity for the elongation system. However, our present data indicate that the elongation system does not distinguish between straight-chain VLCFA and VLCFA with a methyl branch at the ω-end of the molecule.

Our *in vivo* studies with rats, and the earlier studies of Kishimoto *et al.* (26) carried out on a single ALD patient, demonstrate that unesterified deuterated straight-chain VLCFA, and deuterated *iso*-VLCFA, are absorbed from the gut. However, for *in vivo* investigations, either with patients or animals, deuterated *iso*-VLCFA have an advantage as they separate from the corresponding straight-chain VLCFA on gas chromatography (Fig. 1). As straight-chain VLCFA are significant components of plasma and patient tissues, precise determination of the level of deuterium is difficult, particularly if the levels of the deuterated VLCFA are small in comparison with the corresponding endogenous VLCFA. In addition, the shorter-chain deuterated *iso*-fatty acids which are formed from deuterated *iso*-VLCFA by peroxisomal β-oxidation, such as for example the *iso*-18:0 and *iso*-16:0 formed from *iso*-24:0, are completely separated from the corresponding *n*-fatty acids (Fig. 1). As the latter are major fatty acid components of normal tissues and body fluids (see Fig. 1), the measurement of small levels of deuterium enrichment in these fatty acids is technically more difficult than the corresponding measurements in shorter chain *iso*-fatty acids derived from *iso*-VLCFA. We conclude therefore that *iso*-24:0 is a potentially useful substrate for studying turnover of VLCFA in human subjects whose peroxisomal β-oxidation pathway is compromised. In particular, following the turnover of deuterated *iso*-lignoceric in plasma would be a useful tool for monitoring the immediate effectiveness of various new drug therapies (e.g., phenylbutyrate (32) and lovastatin (33) treatments for ALD patients) in stimulating VLCFA oxidation *in vivo.*

ACKNOWLEDGMENTS

The authors are indebted to Kathy Nelson for culturing the fibroblasts used in this study. This work was supported by the National Health and Medical Research Council of Australia and the Women's and Children's Hospital Foundation.

ABSTRACT: Decreased triacylglycerol synthesis within hepatocytes due to decreased diacylglycerol acyltransferase (DGAT) activity has been suggested to be an important mechanism by which diets rich in fish oil lower plasma triacylglycerol levels. New findings suggest that eicosapentaenoic acid (EPA), and not docosahexaenoic acid (DHA), lowers plasma triacylglycerol by increased mitochondrial fatty acid oxidation and decreased availability of fatty acids for triacylglycerol synthesis. To contribute to the understanding of the triacylglycerol-lowering mechanism of fish oil, the different metabolic properties of EPA and DHA were studied in rat liver parenchymal cells and isolated rat liver organelles. EPA-CoA was a poorer substrate than DHA-CoA for DGAT in isolated rat liver microsomes, and in the presence of EPA, a markedly lower value for the triacyl[^{3}H]glycerol/diacyl[^{3}H]glycerol ratio was observed. The distribution of [1-^{14}C]palmitic acid was shifted from incorporation into secreted glycerolipids toward oxidation in the presence of EPA (but not DHA) in rat liver parenchymal cells. [1-^{14}C]EPA was oxidized to a much greater extent than [1-^{14}C]DHA in rat liver parenchymal cells, isolated peroxisomes, and especially in purified mitochondria. As the oxidation of EPA was more effective and sensitive to the CPT-I inhibitor, etomoxir, when measured in a combination of both mitochondria and peroxisomes, we hypothesized that both are involved in EPA oxidation, whereas DHA mainly is oxidized in peroxisomes. In rats, EPA treatment lowered plasma triacylglycerol and increased hepatic mitochondrial fatty acid oxidation and carnitine palmitoyltransferase (CPT)-I activity in both the presence and absence of malonyl-CoA. Whereas only EPA treatment increased the mRNA levels of CPT-I, DHA treatment increased the mRNA levels of peroxisomal fatty acyl-CoA oxidase and fatty acid binding protein more effectively than EPA treatment. In conclusion, EPA and DHA affect cellular organelles in relation to their substrate preference. The present study strongly supports the hypothesis that EPA, and not DHA, lowers plasma triacylglycerol by increased mitochondrial fatty acid oxidation.

The hypolipidemic effect of fish oils enriched in eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) has been extensively studied in both humans and different animal models (1,2). Reduced triacylglycerol synthesis due to reduced diacylglycerol acyltransferase (DGAT) activity, diminished production, and/or increased removal of lipoprotein particles has been proposed as contributing to the hypolipidemic effect (3–9). Moreover, results from both *in vivo* and *in vitro* experiments indicate that the instant hypotriacylglycerolidemic effect observed after fish oil or EPA administration could, at least in part, be attributed to sudden increased mitochondrial fatty acid oxidation (10–15). The availability of triacylglycerol is a major driving force in the secretion of very low density lipoproteins by the liver (16,17). Factors influencing the balance between triacylglycerol biosynthesis and/or fatty acid oxidation may therefore ultimately influence plasma lipoprotein levels and metabolism (18). The finding that triacylglycerol synthesis, and not cholesterol ester synthesis, correlated with apolipoprotein B-100 secretion in HepG2 cells further supports this hypothesis (19).

The two components of fish oil attracting most attention, namely EPA and DHA, are still often referred to as n-3 fatty acids without any further distinction. Nearly all studies that have been conducted have used a mixture of EPA and DHA. However, several studies have reported that EPA and DHA possess different metabolic properties in rats and humans (20–26).

We earlier demonstrated that EPA treatment, and not DHA, lowers plasma triacylglycerol levels in rats (14,15,24). This has also been demonstrated in humans (23,27). In contrast, Hirai *et al.* (28) showed a significant reduction of postprandial serum triacylglycerol in hyperlipidemic patients and Grimsgaard *et al.* (29) showed a significant drop in plasma triacylglycerol after both EPA and DHA treatment in healthy Norwegians. The cause of these differences is not clear. However, retroconversion of DHA to EPA has been reported to occur in cultured rat hepatocytes (30), rats (25), and man (31). This implies that it will be difficult to study the unique effects of DHA, as some of it will always be converted to EPA. Moreover, EPA is more rapidly released from different tissues than DHA (32). The mol% of DHA is more than 10-fold

Copyright © 1999 by AOCS Press

higher than EPA in rat liver (25). Standard chow for rats does not contain EPA or DHA (25), and the daily intake of these fatty acids is therefore easier to control in rats than humans. Also, in countries with low intake levels of n-3 fatty acids, the level of EPA in plasma phospholipids is often one-fifth of the normal concentration of EPA (22). Subsequently, basal levels of EPA and DHA and the dose and length of treatment may influence the results.

Short-time regulation of fatty acid oxidation after EPA and 3-thia fatty acid treatment is well documented (14,33,34). Therefore, to contribute to the understanding of the triacylglycerol-lowering mechanism of fish oil, the different metabolic and hypolipidemic properties of EPA and DHA were studied in rat liver parenchymal cells. By using [1-^{14}C]-labeled fatty acids dissolved in an accurately defined culture medium, the flux of fatty acids and more precise metabolic properties of the fatty acids can be observed. Moreover, as it has previously been demonstrated that EPA and its CoA ester are poor substrates for triacylglycerol synthesis and DGAT compared to oleic acid (4,5), decreased triacylglycerol synthesis within the hepatocytes has been suggested to be an important mechanism by which diets rich in fish oil lower plasma triacylglycerol. Therefore, the effect of both EPA-CoA and DHA-CoA on DGAT activity was studied.

MATERIALS AND METHODS

Chemicals and drugs. [α-^{32}P]dCTP, L-[methyl-^{14}C]carnitine hydrochloride, [1-^{14}C]palmitoyl-CoA, and L-3-phosphatidylcholine,1,2-di[1-^{14}C]oleoylglycerol (114 mCi/mmol) were purchased from the Radiochemical Centre (Amersham, England). [1-^{14}C]Palmitic acid (50 mCi/mmol), [1-^{14}C]oleic acid (50 mCi/mmol), [1-^{14}C]EPA (50 mCi/mmol), [1-^{14}C]DHA (50 mCi/mmol), [1-^{14}C]oleoyl-CoA (59 mCi/mmol), and [4,5-^{3}H]DHA were obtained from New England Nuclear (Boston, MA). [1.2.3-^{3}H]glycerol (5.0 mCi/mmol) was purchased from New England Nuclear (Buckinghamshire, United Kingdom). [5,6,8,9,11,12,14,15,17,18-^{3}H]EPA was from American Radiolabeled Chemicals Inc. (St. Louis, MO). Nylon membranes (NY ^{13}N) were obtained from Schleicher & Schuell (Dassel, Germany). The sulfur-substituted fatty acids were prepared at the Department of Chemistry, University of Bergen, as previously described (35). EPA and DHA as ethyl esters (97 and 91.2% pure, respectively) were obtained from Norsk Hydro AS Research Centre (Porsgrunn, Norway). EPA acyl-CoA and DHA acyl-CoA were synthesized as described by Kawaguchi *et al*. (36). Etomoxir was from Research Biochemicals International (Natick, MA) and dissolved in water before used. All other chemicals and solvents were of reagent grade from common commercial sources.

In vivo *experiments. (i) Treatment of animals.* Male Wistar rats from Möllegaard Breeding Laboratory (Ejby, Denmark), weighing about 250 g, were housed in pairs in metal-wire cages and maintained on a 12-h cycle of light and dark at 20 ± 3°C. The animals were acclimatized under these conditions for at least 1 wk before the experiments. The fatty acids were suspended in 0.5% sodium carboxymethyl cellulose (CMC) and administered by orogastric intubation once a day for 3–7 d, at a dose of 1500 mg/d/kg body weight. The control animals received CMC only. Control and fatty acid-treated animals had free access to water and standard rat pellet food during the experiment. Each test and control group consisted of four animals. After 12 h of fasting, the rats were anesthetized with 0.2 mL of Hypnorm-Dormicum (fluanisone-fentylmidazolam)/100 g body weight. Cardiac puncture was performed and blood was collected in vacutainers. The livers were removed, samples immediately freeze-clamped, weighed, and stored at −80°C. Other pieces of the liver were chilled on ice and weighed. The Norwegian State Board of Biological Experiments with Living Animals approved the use of the animals.

(ii) Preparation of subcellular fractions and protein measurements. The livers from individual rats were homogenized in ice-cold sucrose medium [0.25 M sucrose, 10 mM HEPES (pH 7.4), and 2 mM EDTA]. Subcellular fractions were prepared according to DeDuve *et al*. (37) using preparative differential centrifugation. Modifications, purity, and yield were as previously described (38). The mitochondrial preparations were further purified by Percoll-gradient centrifugation to minimize contamination (39). A Bio-Rad protein kit (Bio-Rad, Richmond, CA) was used for protein measurement. Bovine serum albumin (BSA) dissolved in distilled water was used as a standard.

(iii) Preparation of plasma and measurement of plasma triacylglycerol. Plasma was prepared from whole blood by centrifugation at 10 × *g* for 10 min. Analysis of triacylglycerol was carried out with a Biopak triacylglycerol enzymatic kit (Bristol, France).

(iv) Measurement of enzyme activities. Acid-soluble products were measured in the mitochondrial-enriched fractions using palmitoyl-CoA as substrate (24). Briefly, the assay mix (0.3 mL) contained 12 mM HEPES buffer (pH 7.3), 11 mM $MgCl_2$, 12 mM dithiothreitol, 5.6 mM ADP, 0.2 mM NAD^+, 0.6 mM EDTA, 125 mM KCl, and 1.0 mg mitochondrial protein. Palmitoyl-L-carnitine oxidation was measured with 80 μM [1-^{14}C]palmitoyl-L-carnitine, and the palmitoyl-CoA oxidation was measured with 80 μM [1-^{14}C]palmitoyl-CoA supplemented with 1 mM L-carnitine. When included, malonyl-CoA was added prior to the start of the reaction. After a 2-min incubation at 30°C, the reaction was terminated with 150 μL 1.5 M KOH. Then, 2.5 mg BSA and 500 μL 4 M $HClO_4$ were added. The test tubes were centrifuged at 1880 × *g* for 10 min and 500 μL of the supernatant was assayed for radioactivity. Acid-soluble products also were measured using fatty acids as substrates (26). The assay medium (0.25 mL) contained 13.3 mM HEPES, pH 7.3, 83.3 mM KCl, 16.7 mM $MgCl_2$, 13.3 mM dithiothreitol, 0.7 mM EDTA, 1.25 mM L-carnitine, 0.2 mM NAD^+, 2.0 mM ATP, 0.4 mM CoASH, 150 μM [1-^{14}C]fatty acid, and 0.25–0.5 mg protein. All samples were preincubated for 3 min at 30°C. After incubation for 4 min (mitochondrial fraction) or 10 min (peroxisomal frac-

tion), the reaction was terminated by addition of 150 µL 1.5 M KOH. Fatty acid-free BSA (25 µL; 100 mg/mL) was added to the suspension in order to bind nonoxidized substrates. $HClO_4$ (4M; 500 µL) was added to precipitate protein and nonoxidized substrates bound to BSA. The total solution was centrifuged at 2010 × *g* for 10 min. Aliquots of 500 µL were assayed for radioactivity.

Carnitine palmitoyltransferase (CPT)-I and -II activities were measured as described by Bremer with minor modification (40). The assay for CPT-I contained 20 mM HEPES, pH, 7.5, 70 mM KCl, 5 mM KCN, 100 µM palmitoyl-CoA, 10 mg BSA/mL, and 0.6 mg mitochondrial protein/mL. The reaction was started with 200 µM [methyl-^{14}C]-L-carnitine (200 cpm/nmol). When included, malonyl-CoA was added prior to the start of the reaction. Assay conditions for CPT-II were identical except that BSA was omitted and 0.01% Triton X-100 was included. Mitochondrial protein concentration was 0.1 mg/mL.

Acyl-CoA synthase activity was measured according to Bar-Tana *et al.* (41) with some modifications. The reaction mixture at a total volume of 250 µL contained 120 mM Tris-HCl buffer, pH 7.4, 0.05% Triton X-100, 2 mM EDTA, 5 mM $MgCl_2$, 2 mM ATP, 0.5 mM CoA, 8 mM dithiothreitol, and 10 to 20 µg protein. The reaction was started with 25 µL, 1.5 mM [1-^{14}C]fatty acid. Incubations were carried out for 3 min at 37°C and terminated with 3.25 mL methanol/chloroform/heptane (141:125:100, by vol). The contents were mixed for 5 min and centrifuged, and 0.5 mL of the water phase was assayed for radioactivity.

Fatty acyl-CoA oxidase activity was measured in the peroxisomal fraction by the coupled assay described by Small *et al.* (42). The production of H_2O_2 was measured by monitoring the increase in dichlorofluorescein absorbance in the presence of palmitoyl-CoA.

DGAT was performed as described by Coleman and Bell (43) and by Rustan *et al.* (5). The assay was performed at 23°C in a shaking water bath in a total volume of 0.5 mL of Tris-buffer (175 mM, pH 7.8) containing BSA (15 µM, fatty acid-free), $MgCl_2$ (8 mM), and oleoyl-CoA in the presence or absence of different acyl-CoA derivatives. After a 10-min preincubation, the reaction was started by adding rat liver microsomes (10–20 µg protein/mL) followed immediately by 1,2-di[1-^{14}C]oleoylglycerol (125 µM, dissolved in absolute ethanol, 10% vol/vol final concentration), and blended in a vortex mixer. The reaction was terminated after 10 min by the addition of 10 mL chloroform/methanol (2:1, vol/vol) and the lipids were extracted and separated by thin-layer chromatography as explained above. The triacylglycerol band was cut out, and the amount of ^{14}C was determined by scintillation counting. 1,2-di[1-^{14}C]oleoylglycerol was prepared from L-3-phosphatidylcholine,1,2-Di[1-^{14}C]oleoyl by treatment with purified phospholipase C as described elsewhere (44). More than 98% of the labeled phosphatidylcholine,1,2-dioleoyl, was converted to 1,2-dioleoylglycerol (0.92–1.1 µCi/mL) by this method. The dioleoylglycerol was extracted twice with diethyl ether, redissolved in absolute ethanol, and stored at ~20°C.

(vi) Purification of RNA and hybridization analysis. Total RNA was isolated using the guanidinium thiocyanate–phenol method (45) and the RNA concentrations were determined by measuring absorbance at 260 nm. Northern- and slot-blotting were performed as previously described (46). Three different RNA concentrations were applied. Hybridization reactions were performed as described by Sambrook *et al.* (47), and the membranes were stringently washed three times. Kodak XAR-5 X-ray films (Rochester, NY) were exposed to the membranes and autoradiograms were obtained as described elsewhere (46). The relative levels of mRNA expression were estimated as the amount of radioactive probe hybridized to each sample of RNA relative to the levels of 28S rRNA in each sample.

(vii) Preparation of hybridization probes. The appropriate DNA fragments were cut from plasmids by restriction enzymes. Purified fragments were then [^{32}P]-labeled using the oligolabeling technique (48), resulting in specific activities ranging from 0.8–5 × 10^9 cpm/mg. The probes were purified fragments of CPT-I, 2600 bp *Eco*RI fragment of pBK2-CPT-I (49); partial CPT-II, 1600 bp *Xho* I/*Xba*I fragment of pBKS-CPT-II.4 (50); fatty acid-binding protein (FABP), 334 bp *Pvu*II-*Eco*RI fragment in pJG418 (51); and fatty acyl-CoA oxidase (FAO), 1400 bp Pst fragment of pMJ125 (52). As the control, we used 28S rRNA; 1.4 kb *Bam* HI insert in pA (53).

In vitro *experiments. (i) Preparation of cultured hepatocytes.* Rat liver parenchymal cells were isolated as described by Berry and Friend (54) with modifications according to Seglen (55). The hepatocytes were plated at a density of 2.0 × 10^6/dish (1–1.5 mg cell protein) in 2 mL of Dulbecco's modified Eagle's medium (DMEM) containing 20 mM HEPES and 2% Ultroser G. When indicated, 500 µM L-carnitine or 50 µM L-aminocarnitine was added. Cultures were maintained in a humidified incubator at 37°C in an atmosphere containing 5% CO_2. After overnight incubation, the medium was replaced with DMEM (2 mL/dish) containing [1-^{14}C]-labeled fatty acids (0.25 µCi/mL) bound to BSA. Additions of other fatty acids or [1.2.3-^{3}H]glycerol (5 µCi/mL) to cell cultures are stated in the legends to figures and tables. The molar ratio between fatty acids and BSA was 2.5:1. The cells were further incubated for 4 h.

(ii) Termination of incubation and harvesting of cells. Incubations were terminated by cooling the culture dishes on ice. Incubation medium was collected, centrifuged at 600 × *g* for 5 min, and the cell-free supernatant was treated as described below. The cells were scraped off the dish by a rubber policeman into 2 mL of phosphate-buffered saline (NaCl/Pi), pH 7.4, containing 137 mM NaCl, 2.7 mM KCl, 8 mM Na_2HPO_4, and 1.5 mM KH_2PO_4. The culture dishes were washed once with 2 mL of NaCl/Pi. The cell suspensions were centrifuged and the cells were resuspended in 0.5 or 1.0 mL distilled water and frozen. A Bio-Rad protein kit (Bio-Rad, Richmond, CA) was used for protein measurement in the cell suspensions. BSA dissolved in distilled water was used as a standard.

(iii) Determination of acid-soluble products and CO_2. The cell-free supernatant (250 µM) was precipitated with 1.0 mL

of ice-cold 0.75 M $HClO_4$. To secure complete precipitation of free fatty acids and lipids, 0.45% BSA was added. The extract was centrifuged at 1800 × *g* for 10 min, and 0.5 mL of the supernatant was assayed for radioactivity by liquid scintillation counting. $^{14}CO_2$ was trapped from sealed culture flasks essentially as described by Christiansen and Davies (56).

(iv) Lipid extraction and quantitation. Cellular lipids were extracted from the cell suspensions and according to Folch *et al.* (57). The cell suspension was mixed with 20 vol of chloroform/methanol (2:1, vol/vol), 4 vol of 0.9% NaCl (pH 2) were added, and the mixture was allowed to separate into two phases. The organic phase was evaporated under N_2 and the extracted lipids were dissolved in *n*-hexane and separated by thin-layer chromatography on silica gel plates developed in hexane/diethyl ether/acetic acid (80:20:1, by vol). The bands were visualized by iodine vapor, cut into pieces, and assayed for radioactivity by scintillation counting. Four volumes of chloroform/methanol (2:1) and 2% serum as lipid carrier were added to 1 mL of the cell-free medium. The water phase of the medium was reextracted once with 4 vol of chloroform/methanol (2:1, vol/vol), and the combined organic phases were further treated as the cells.

Statistical analysis and presentation of data. The data are presented as mean ± SD from four animals or at least three independent cell experiments. The results were evaluated by a two-sample variance Student's *t*-test (two-tailed distribution) where relevant. The level of statistical significance was set at $P < 0.05$.

RESULTS

Metabolism of [1-^{14}C]EPA and [1-^{14}C]DHA in cultured hepatocytes. To investigate the mechanism by which fish oils exert their hypolipidemic effect, the metabolism and flux of [1-^{14}C]-labeled EPA, DHA, oleic acid, and palmitic acid were studied in cultured hepatocytes. [1-^{14}C]-Labeled EPA, DHA, oleic acid, and palmitic acid were taken up by the hepatocytes to the same extent. The total metabolism (sum of incorporation into glycerolipids, cellular free fatty acids, and oxidation) of these fatty acids was not significantly different at equal concentrations (data not shown). Figure 1 shows that EPA and DHA were incorporated into cell-associated and secreted glycerolipids at a rate similar to that of palmitic and oleic acids up to 100 μM. At higher concentrations, i.e., 500 μM, DHA was incorporated more efficiently than EPA ($P < 0.005$) into cell-associated glycerolipids (Fig. 1A). On the other hand, at this concentration, EPA was more enriched in secreted glycerolipids than DHA ($P < 0.005$) (Fig. 1B).

Figure 2 summarizes the incorporation of different fatty acids (100 μM) into triacylglycerol and phospholipids (both secreted and cell-associated). Palmitic and oleic acids were equally distributed between triacylglycerol and phospholipids (Fig. 2). EPA, however, was incorporated more efficiently than DHA into triacylglycerol ($P < 0.05$). In contrast, DHA was preferentially incorporated into cell-associated phospholipids (Fig. 2). However, the most striking difference between the metabolism of EPA and DHA was that less than 1% of DHA was oxidized, independent of the concentration used, while EPA was easily oxidized (Fig. 1C and Fig. 2).

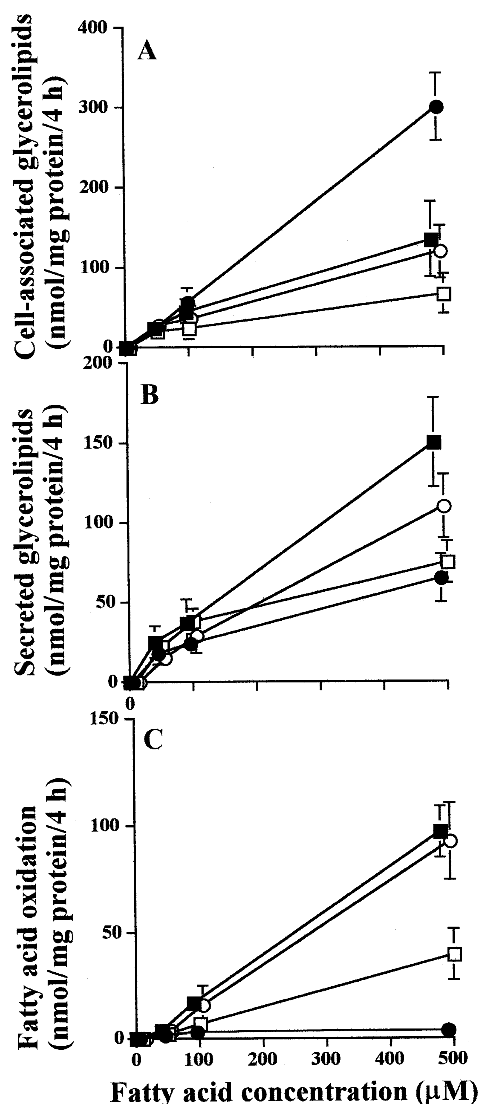

FIG. 1. Metabolism of 50, 100, and 500 μM [1-^{14}C]eicosapentaenoic acid (EPA) (■), [1-^{14}C]docosahexaenoic acid (DHA) (●), [1-^{14}C]oleic (□) and [1-^{14}C]palmitic acids (○) in hepatocytes plated overnight in Dulbecco's modified Eagle's medium (DMEM) and incubated for 4 h as described in the Materials and Methods section. The results were calculated as (A) the sum of [1-^{14}C]glycerolipids within the cells (synthesized), (B) the sum of [1-^{14}C]glycerolipids in the medium (secreted), and (C) the sum of acid-soluble ^{14}C in the medium. Experiments were run in triplicate, and the results are given as mean ± SD from four different rats.

EPA and DHA as substrates for mitochondrial and peroxisomal fatty acid oxidation. To further investigate the different oxidation of EPA and DHA, mitochondria and peroxisomes were isolated from rat liver. [1-^{14}C]EPA produced 10 times more acid-soluble products than [1-^{14}C]DHA in purified mitochondria (Table 1). The difference was, however, less pronounced when [^{3}H]-labeled fatty acids were used as substrates. As the labeled carbon atom is placed in the carboxyl

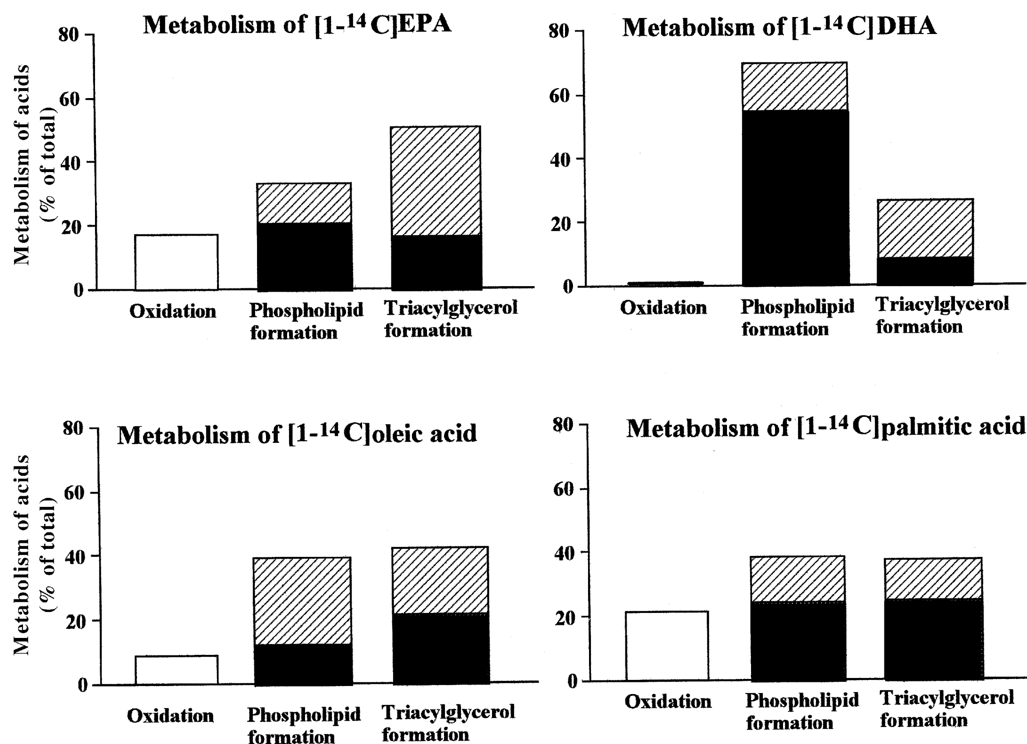

FIG. 2. Metabolism of 100 μM [1-^{14}C]EPA, [1-^{14}C]DHA, [1-^{14}C]oleic acid, and [1-^{14}C]palmitic acid in hepatocytes plated overnight in DMEM and incubated for 4 h as described in the Materials and Methods section. The results were calculated as acid-soluble ^{14}C in the medium (open bar) and [1-^{14}C]fatty acid-labeled cell-associated (closed bar) and secreted (ruled bar) glycerolipids (triacylglycerols and phospholipids). Experiments were run in triplicate, and the results are given as percentage of total metabolized fatty acids as mean from four different rats. The total metabolism (sum of incorporation into glycerolipids, cellular free fatty acids, and oxidation) of [1-^{14}C]EPA, [1-^{14}C]DHA, [1-^{14}C]oleic acid, and [1-^{14}C]palmitic acid was 99 ± 20, 82 ± 10, 72 ± 14, and 76 ± 18 nmol/mg protein/4 h, respectively. The levels of cellular [1-^{14}C]-labeled fatty acids and incorporation into mono- and diacylglycerol were less than 5%. See Figure 1 for abbreviations.

unit, oxidation of [1-^{14}C]fatty acids only takes the first round of oxidation into account. On the other hand, the [^{3}H]fatty acids are labeled beyond the third position. Thus, a second round of the fatty acid oxidation cycle, dependent on 2.4-dienoyl-CoA reductase and the enoyl-CoA isomerase, is necessary to detect activity.

TABLE 1
Oxidation of [1-^{14}C]EPA, [5,6,8,9,11,12,14,15,17,18-^{3}H]EPA, [1-^{14}C]DHA, and [4,5-^{3}H]DHA in Purified Mitochondria and Peroxisomes[a]

	[^{14}C]EPA	[^{3}H]EPA	[^{14}C]DHA	[^{3}H]DHA[b]
		(nmol/min/mg protein)		
Mitochondria	2.92	0.46	0.28	0.24
Peroxisomes	0.39	0.05	0.12	0.06
		Net dpm		
Net dpm summarized[c]	1388	261	176	137
Mitochondria and peroxisomes	2460	1134	223	209
+ 50 mM etomoxir	1585	857	202	248

[a]Mitochondria and peroxisomes were purified from rat liver; formation of acid-soluble products was measured in 0.24 mg pure mitochondria, 0.5 mg peroxisomes, and in a combination of both mitochondria and peroxisomes, as described in the Materials and Methods section.
[b]Values represent labeled acid-soluble products in 0.5 mL solution; the specific activity of [1-^{14}C]eicosapentaenoic acid (EPA), [5,6,8,9,11,12,14,15,17,18-^{3}H]EPA, [1-^{14}C]docosahexaenoic acid (DHA), and [4,5-^{3}H]DHA were 1648, 2083, 934, and 1987 disintegrations per minute (dpm)/nmol, respectively.
[c]Disintegrations per minutre summarized from two separate reactions using peroxisomes and mitochondria separately.

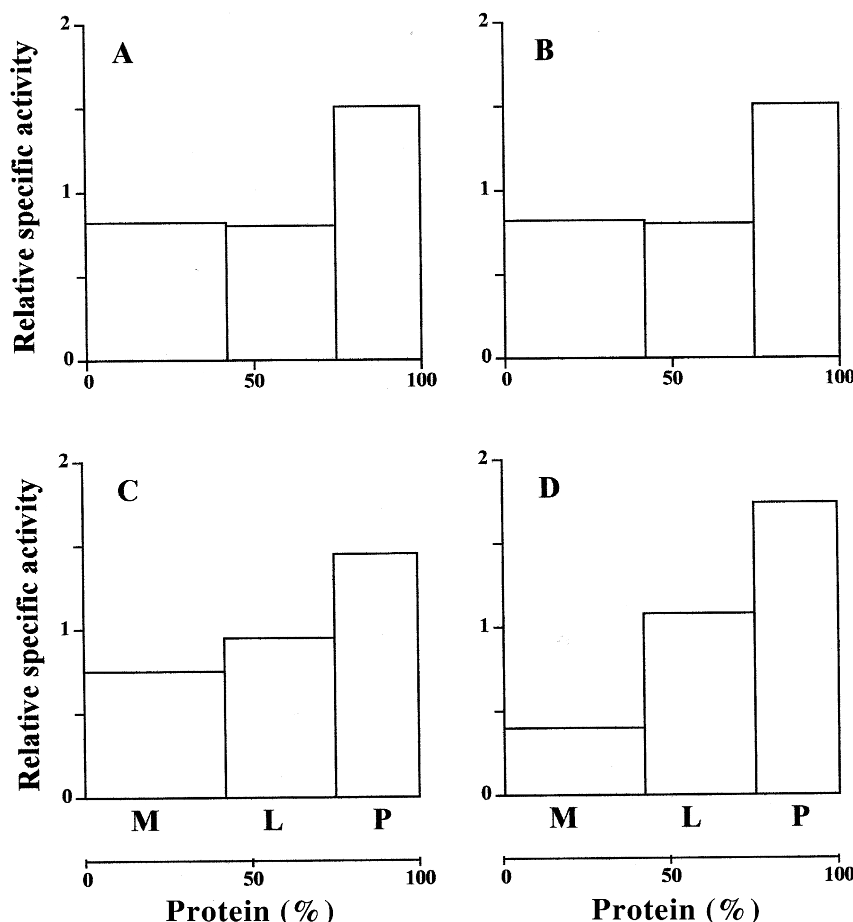

FIG. 3. Rats were fed palmitic acid at a dose of 1500 mg/d/kg body weight suspended in 0.5% carboxymethyl cellulose (CMC) for 7 d. The postnuclear homogenates from the livers of four individual rats were fractionated into mitochondrial (M), peroxisomal (L), and microsomal (P) fractions, and the acyl-CoA synthase activities were measured using (A) [1-^{14}C]palmitic acid, (B) [1-^{14}C]oleic acid, (C) [1-^{14}C]EPA, and (D) [1-^{14}C]DHA as substrates, as described in the Materials and Methods section. The abscissa represents the cumulative protein content for each fraction as a percentage of the total protein (M + L + P). The ordinate represents relative specific activity, i.e., the percentage of the total enzyme activity in the fraction over the percentage of total protein in the fraction. The respective specific activities, using [1-^{14}C]palmitic acid, [1-^{14}C]oleic acid, [1-^{14}C]EPA and [1-^{14}C]DHA as substrates, were 79 ± 9, 69 ± 6, 41 ± 5, and 9 ± 2 nmol/mg protein/min in the M fraction, 102 ± 20, 90 ± 15, 56 ± 24, and 19 ± 4 nmol/mg protein/min in the L fraction, and 153 ± 7, 142 ± 11, 101 ± 12, and 28 ± 2 nmol/mg protein/min in the P fraction. See Figure 1 for other abbreviations.

The formation of acid-soluble products from [1-^{14}C]EPA was also higher than from [1-^{14}C]DHA in peroxisomes, but the difference was much less pronounced. Oxidation of both [5,6,8,9,11,12,14,15,17,18-^{3}H]EPA and [4,5-^{3}H]DHA was almost negligible in the peroxisomes, suggesting that only one cycle of oxidation takes place in this organelle (Table 1). In a combination of mitochondria and peroxisomes, the formation of acid-soluble products from both [^{14}C]DHA and [^{3}H]DHA was comparable to the sum of acid-soluble products formed in the two organelles separately, and the reaction was not inhibited by the mitochondrial CPT-I inhibitor, etomoxir (Table 1). On the other hand, the formation of acid-soluble products from both [1-^{14}C]EPA and especially [5,6,8,9,11,12,14,15,17,18-^{3}H]EPA was much higher in a combination of mitochondria and peroxisomes, suggesting synergetic oxidation (Table 1).

Fatty acid activation. Activation to CoA esters is necessary prior to fatty acid oxidation. We earlier demonstrated that DHA is a much poorer substrate than EPA for the acyl-CoA synthetases (26). The present study shows the subcellular distribution of acyl-CoA synthetase using EPA, DHA, palmitic and oleic acids as substrates (Fig. 3). The activity was equally distributed between the mitochondrial and peroxisomal fractions when palmitic or oleic acid was used as substrate, but shifted toward the peroxisomes when EPA and especially DHA were used (Fig. 3). Neither EPA nor DHA treatment significantly changed the subcellular distribution of the acyl-CoA synthetases (not shown).

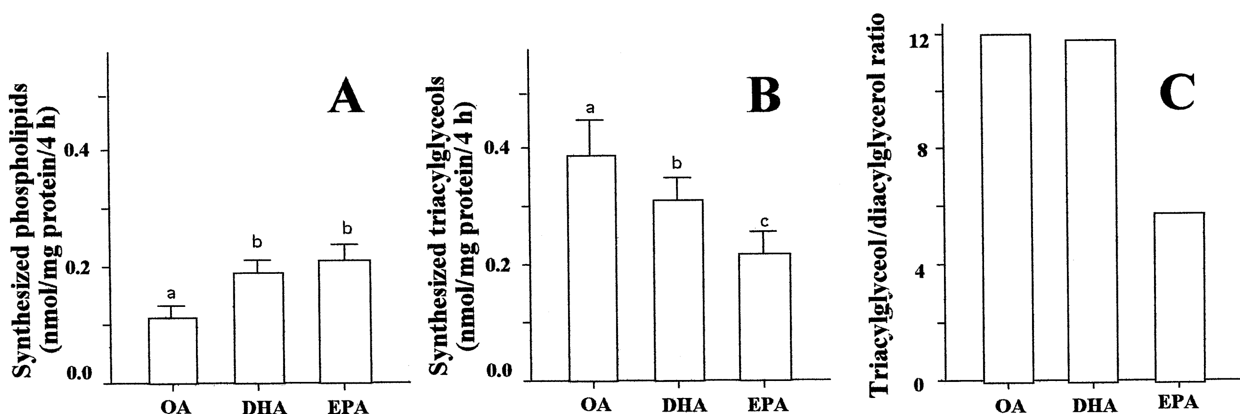

FIG. 4. Cells were plated overnight in DMEM supplemented with 0.5 mM L-carnitine and incubated for 4 h with 200 μM palmitic acid and 25 μM [^{3}H]glycerol in the presence of 200 μM EPA, DHA, or oleic acid (OA) as described in the Materials and Methods section. The results are presented as (A) formation of [^{3}H]phospholipids, (B) formation of triacyl[^{3}H]glycerol, and (C) as ratio of triacyl[^{3}H]glycerol/diacyl[^{3}H]glycerol. The experiments were run in triplicate, and the results are given as mean from three to five different rats. Columns with different superscript letters are significantly different at the $P = 0.05$ level. See Figure 1 for abbreviations.

Effects of oleic acid, EPA, and DHA on [^{3}H]glycerol incorporation into glycerolipids. The poor oxidation of labeled DHA confirmed that DHA was preferentially incorporated into glycerolipids as indicated in Figures 1 and 2. To further investigate the incorporation of EPA and DHA into glycerolipids, the metabolism of [^{3}H]glycerol was studied in rat hepatocytes. The formation of [^{3}H]phospholipids was not significantly different in the presence of EPA and DHA (Fig. 4A). However, compared to oleic acid, both EPA and DHA ($P < 0.05$) stimulated phospholipid formation (Fig. 4A). In contrast, the formation of triacyl[^{3}H]glycerols was reduced in the presence of both EPA and DHA, compared to oleic acid ($P < 0.05$) (Fig. 4B). The formation of triacyl[^{3}H]glycerols was, however, significantly lower in the presence of EPA compared to DHA ($P < 0.05$) (Fig. 4B). The finding that EPA reduced formation of triacyl[^{3}H]glycerols and stimulated formation of [^{3}H]phospholipids suggested specific inhibition of triacylglycerol synthesis. Moreover, compared to DHA and oleic acid addition, a markedly lower value for the triacyl[^{3}H]glycerol/diacyl[^{3}H]glycerol ratio was observed in the presence of EPA ($P < 0.05$), indicating that the last step in triacylglycerol synthesis was inhibited (Fig. 4C).

EPA-CoA and DHA-CoA as substrates for DGAT. The final step of the triacylglycerol synthetic pathway involves the conversion of diacylglycerol and acyl-CoA into triacylglycerol catalyzed by DGAT. In isolated rat liver microsomes, incorporation of oleoyl-CoA, palmitoyl-CoA, and DHA-CoA increased in a dose-dependent manner with 1,2-di[1-^{14}C]oleoylglycerol conversion into triacylglycerol, whereas EPA-CoA slightly increased triacylglycerol formation up to 10 μM and no further increase was seen (Fig. 5A). Triacylglycerol formation in the presence of EPA-CoA at 20 μM was less than 20%

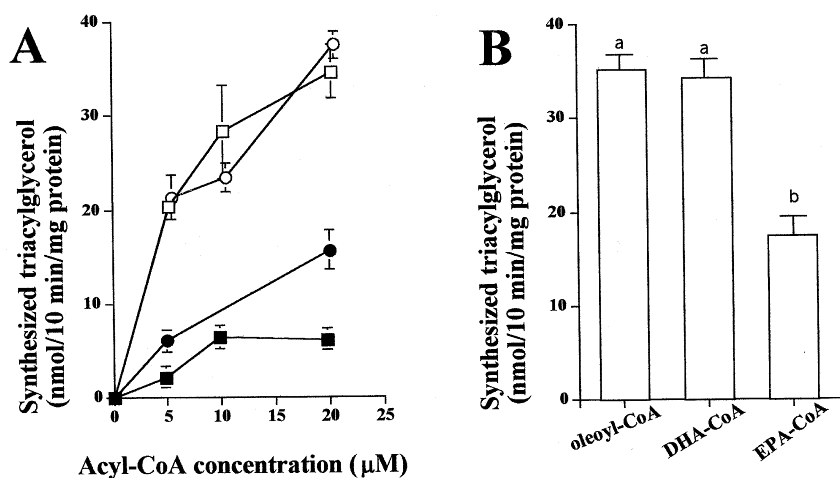

FIG. 5. Microsomes were isolated from four individual rat livers as described in the Materials and Methods section. The results are presented as formation of nmol [1-^{14}C]-labeled triacylglycerol formated per mg microsomal protein in 10 min from (A) 1,2-di[1-^{14}C]oleoylglycerol and different concentrations of EPA-CoA (■), DHA-CoA (●), oleoyl-CoA (□), and palmitoyl-CoA (○); and (B) 1,2-dioleoylglycerol and [1-^{14}C]oleoyl-CoA, in the presence of EPA-CoA, DHA-CoA or oleoyl-CoA. The values represent mean ± SD. Columns with different superscript letters are significantly different at the $P = 0.05$ level. See Figure 1 for abbreviations.

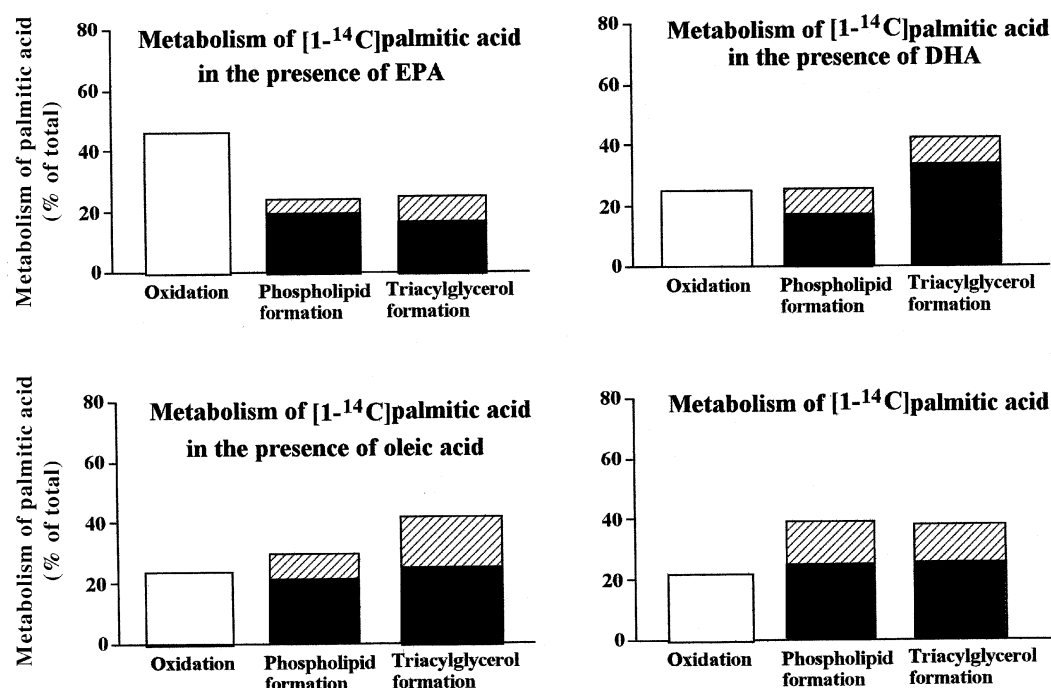

FIG. 6. Metabolism of 200 µM [1-^{14}C]palmitic acid in hepatocytes plated overnight in DMEM and incubated for 4 h in the absence and presence of 200 µM EPA, DHA, and oleic acid as described in the Materials and Methods section. The results were calculated as acid-soluble ^{14}C in the medium (open bar), [1-^{14}C]palmitic acid-labeled cell-associated (closed bar), and secreted (ruled bar) glycerolipids (triacylglycerols and phospholipids). Experiments were run in triplicate, and the results are given as the percentage of total metabolized fatty acids as mean from four different rats. The total metabolism (sum of incorporation into glycerolipids, cellular free fatty acids, and oxidation) of [1-^{14}C]palmitic acid in the absence of other fatty acids was 227 ± 25 nmol/mg protein/4 h. In the presence of EPA, DHA, and oleic acid, the total metabolism of [1-^{14}C]palmitic acid was 223 ± 27, 211 ± 26, and 172 ± 31, nmol/mg protein/4 h, respectively. The levels of cellular [1-^{14}C]palmitic acid and incorporation into mono- and diacylglycerol were less than 5%.

when compared to oleoyl-CoA ($P < 0.005$) and palmitoyl-CoA ($P < 0.005$), and 40% in comparison to DHA-CoA ($P < 0.05$) (Fig. 5A). Furthermore, [1-^{14}C]oleoyl-CoA was incorporated into triacylglycerol to a lesser extent when EPA-CoA, but not DHA-CoA, was added (Fig. 5B), suggesting that EPA, but not DHA, influenced triacylglycerol metabolism.

Effects of oleic acid, EPA, and DHA on [1-^{14}C]palmitic acid oxidation, glycerolipid synthesis, and secretion. To further investigate the different effects of EPA and DHA on triacylglycerol metabolism, the flux of [1-^{14}C]palmitic acid was studied in rat hepatocytes incubated 4 h in the presence of oleic acid, EPA, and DHA at 200 µM. Figure 6 shows that the proportion of [1-^{14}C]palmitic acid incorporated into triacylglycerols was reduced in the presence of EPA ($P < 0.05$, compared to DHA, oleic acid, and nonaddition). Moreover, in the presence of EPA, palmitic acid was oxidized to a greater extent than in presence of DHA, oleic acid, and nonaddition (Fig. 6). Table 2 illustrates the oxidation of [1-^{14}C]palmitic acid into acid-soluble products. CO_2 is lower in the presence of DHA than in the presence of EPA ($P < 0.005$), indicating that EPA, and not DHA, influences mitochondrial β-oxidation.

TABLE 2
Oxidation of [1-^{14}C]Palmitic Acid in the Presence of EPA and DHA[a]

	4-h incubation		9-h incubation	
Fatty acid	Acid-soluble products	CO_2	Acid-soluble products	CO_2
	(nmol/mg protein)			
EPA	62 ± 9	18 ± 3	79 ± 13	27 ± 5
DHA	38 ± 7	5± 2	51 ± 15	6 ± 1

[a]Cells were plated overnight in medium supplemented with L-carnitine (0.5 mM) and incubated for 4 or 9 h with labeled palmitic acid and 200 µM EPA or DHA at different concentrations, as described in the Materials and Methods section; values are presented as means ± SD from at least four independent experiments. See Table 1 for abbreviations.

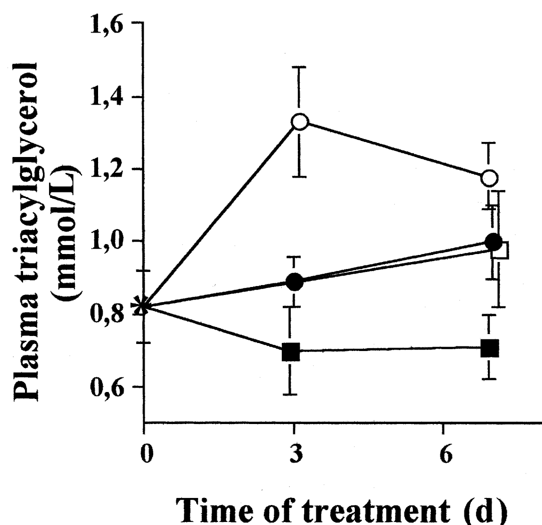

FIG. 7. Rats were fed EPA (■), DHA (●), oleic (□) and palmitic (○) acids at a dose of 1500 mg/d/kg body weight suspended in 0.5% CMC for 3 or 7 d. Control animals received CMC only (✱). The triacylglycerol was measured in plasma prepared from each rat. The values are presented as mean ± SD. See Figures 1 and 3 for other abbreviations.

Effect of EPA and DHA treatment on plasma triacylglycerol and fatty acid oxidation in rats. Confirming earlier studies, EPA treatment reduced plasma triacylglycerol levels in rats (Fig. 7). Moreover, compared to untreated rats, EPA treatment, in contrast to DHA treatment, significantly ($P < 0.05$) increased the oxidation of palmitoyl-CoA and the CPT-I activity in the presence and absence of malonyl-CoA in isolated mitochondria (Fig. 8). Also the CPT-I mRNA levels were significantly increased after EPA treatment (Table 3). It was interesting, however, that both EPA and DHA treatment increased the activities and mRNA levels of peroxisomal FAO and mitochondrial CPT-II, as well as FABP mRNA (Table 3).

DISCUSSION

The mechanism by which diets enriched in EPA and DHA reduce plasma triacylglycerol is still a matter of dispute, and the available literature is not consistent concerning the different effects. We earlier demonstrated that EPA reduces plasma triacylglycerol in rats (12,24). However, in most studies performed, a combination or a mixture containing both EPA and DHA is used. Different basal levels, retroconversion of DHA to EPA (25,30,31), and divergent release of EPA and DHA from different tissues (32) complicate the interpretation of animal and especially human studies. Even though retroconversion of DHA to EPA also has been demonstrated in cultured rat hepatocytes (30), most of these complicating factors are excluded when cultured hepatocytes are used.

In our system, the levels of total metabolism and flux of [1-^{14}C]-labeled EPA and DHA were similar at equal concentrations, but different metabolic pathways were preferred (Figs. 1 and 2). Reduced triacylglycerol synthesis has been suggested as a mechanism by which diets enriched in fish oil reduce plasma triacylglycerol, as EPA and EPA-CoA are poor substrates for DGAT (5,6). In the present study, we demonstrated, using labeled 1,2-di[1-^{14}C]oleoylglycerol or [1-^{14}C]-oleoyl-CoA as a precursor, that EPA-CoA reduced DGAT activity (Fig. 5). Moreover, as the formation of triacyl[^{3}H]glycerol (Fig. 4B) and the triacyl[^{3}H]glycerol/diacyl[^{3}H]glycerol ratio (Fig. 4C) from [^{3}H]glycerol were reduced in the presence of EPA compared to DHA, it is likely that EPA, and not DHA, influenced DGAT.

It has previously been shown that secretion of very low density lipoprotein particles is dependent on triacylglycerol synthesis and the availability of triacylglycerol within the hepatocytes (58,59). However, studies by Al-Shurbaji *et al.* (10) and Ikeda *et al.* (60) found that dietary treatment of rats with a mixture of n-3 fatty acids or EPA alone did not change hepatic DGAT activity. Willumsen *et al.* (12) have indicated that

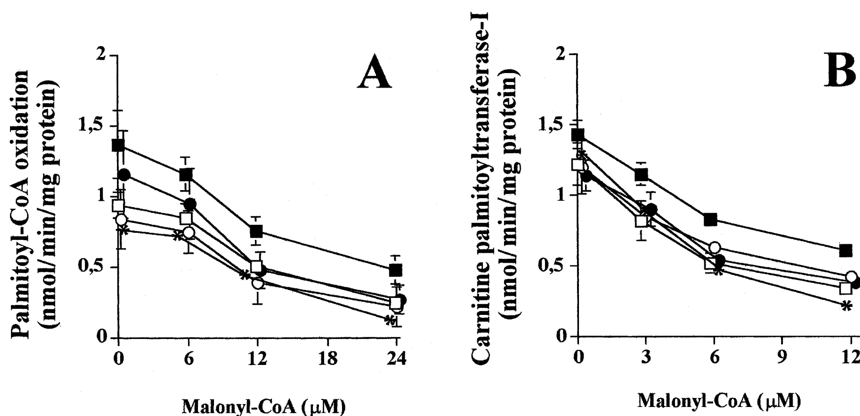

FIG. 8. Rats were fed EPA (■), DHA (●), oleic (□) and palmitic (○) acids, at a dose of 1500 mg/d/kg body weight, suspended in 0.5% CMC for 7 d. Control animals received CMC only (✱). (A) Palmitoyl-CoA oxidation and (B) carnitine palmitoyltransferase-I activity were measured in isolated mitochondria as described in the Materials and Methods section in four individual rat livers in the absence and presence of malonyl-CoA. The values are presented as mean ± SD. See Figures 1 and 3 for abbreviations.

TABLE 3
Effects of EPA, DHA, Oleic Acid, and Palmitic Acid on Hepatic Carnitine Palmitoyltransferase (CPT)-I and -II, Fatty Acid Binding Protein (FABP), and Fatty Acyl-CoA (FAO) Oxidase[a]

Treatment[b]	Control	Palmitic acid	Oleic acid	EPA	DHA
CPT-I mRNA (fold increase)	1.0 ± 0.1	1.1 ± 0.1	1.0 ± 0.1	1.5 ± 0.2[c]	1.2 ± 0.1
CPT-II mRNA (fold increase)	1.0 ± 0.1	1.0 ± 0.1	1.1 ± 0.1	1.3 ± 0.1[c]	1.7 ± 0.1[c]
CPT-II activity (nmol/mg protein)	26 ± 3	32 ± 3	33 ± 4	37 ± 4[c]	42 ± 5[c]
FABP mRNA (fold increase)	1.0 ± 0.1	0.7 ± 0.3	0.8 ± 0.1	1.3 ± 0.1[c]	1.6 ± 0.1[c]
FAO mRNA (fold increase)	1.0 ± 0.1	0.7 ± 0.2	1.0 ± 0.1	1.6 ± 0.3[c]	2.1 ± 0.5[c]
FAO activity (nmol/mg protein)	16 ± 5	20 ± 3	18 ± 3	29 ± 5[c]	33 ± 6[c]

[a]Animals were treated with different fatty acids at a dose of 1500 mg/d/kg body weight for 7 d; CPT-II and FAO activities were measured in mitochondrial and peroxisomal fractions prepared from individual rat livers as described in the Materials and Methods section.
[b]The mRNA were extracted from the livers of four different rats and hybridized with different cDNA as described in the Materials and Methods section; each value (mean ± SD) was normalized to the corresponding 28S rRNA levels, and the mean of the controls was set to 1.0. See Table 2 for abbreviations.
[c]Significantly different from controls ($P < 0.05$).

dietary EPA treatment stimulates DGAT activity, whereas Geelen *et al.* (61) demonstrated that hepatic DGAT activity in rats was significantly reduced when compared to rats fed corn oil. It is also noteworthy that treatment of rats with hypotriacylglycerolemic 3-thia fatty acids, which also leads to a reduced hepatic content of triacylglycerol (62), increased DGAT activity in the liver (63). On the other hand, 4-thia fatty acid treatment, which induced fatty liver and increased plasma triacylglycerol (62), strongly inhibited DGAT activity (63). Thus, changed DGAT activity does not appear to be coordinated with the triacylglycerol-lowering effect.

The oxidation of [1-^{14}C]palmitic acid into both CO_2 and acid-soluble products was significantly higher in the presence of EPA than DHA (Table 2). Moreover, the distribution of [1-^{14}C]palmitic acid shifted from incorporation into triacylglycerol to oxidation when EPA was added to cells (Fig. 6). Acute stimulation of fatty acid oxidation by EPA might thereby reduce fatty acid availability for synthesis and secretion of triacylglycerol.

The logical consequence of our *in vitro* findings would be that EPA, and not DHA, is the hypolipidemic component in fish oil. Indeed, in confirming earlier studies (12,24), there was a significant reduction in the plasma triacylglycerol levels after 7 d of treatment with pure EPA when compared to DHA in these rats (Fig. 7). Moreover, in agreement with a recent study by Ikeda *et al*. (60), EPA treatment increased the mitochondrial palmitoyl-CoA oxidation and CPT-I activity in the absence and presence of malonyl-CoA (Fig. 8).

The molecular mechanism involved in gene regulation by fatty acids remains unknown. It is, however, suggested that they act through the peroxisome proliferating activated receptor (PPAR). This is supported by the recent finding that PPARα is required for induction of FAO and cytochrome P450 4A2 but not for suppression of fatty acid synthase by polyunsaturated fatty acids (64). These findings suggest that PPARα activation upregulates both mitochondrial and peroxisomal fatty acid oxidation and provide evidence for two distinct pathways for polyunsaturated fatty acid control of hepatic lipid metabolism. A peroxisome proliferator responding element is located upstream the FABP gene (65), and it is likely that EPA and DHA treatment induces the FABP and FAO mRNA levels (Table 3) *via* PPARα activation. The increased mRNA levels of CPT-II (Table 3) after EPA, and especially DHA treatment, which is a stronger peroxisome proliferator than EPA (15), might occur by a similar mechanism. The recent finding that treatment with the classic peroxisome proliferator, Wy-14.643, increases CPT-II mRNA as well as FAO mRNA in wild type, but not PPARα-null mice (66), supports this hypothesis.

In contrast, EPA increased the mRNA levels of CPT-I (Table 3). Hepatic CPT-I, which is considered to be rate limiting for mitochondrial fatty acid oxidation, is to our knowledge not under the regulation of PPARα. In case of the CPT-I gene, the work by Chatelain *et al*. (67) suggested that peroxisome proliferators and long-chain fatty acids mediate their action on CPT-I through different mechanisms.

EPA was a far better substrate for fatty acid oxidation than DHA in rat parenchymal cells (Figs. 1C and 2), isolated mitochondria, and peroxisomes (Table 2). We have demonstrated that oxidation of EPA, and not DHA, is sensitive to CPT-II inhibition in rat parenchymal cells (46), suggesting peroxisomal, not mitochondrial, oxidation of DHA. The finding that oxidation of DHA in a combination of mitochondria and peroxisomes is not inhibited by the CPT-I inhibitor, etomoxir, further supports this hypothesis (Table 1), as the entry and oxidation of fatty acids in the peroxisomes are independent of carnitine (68). In addition, compared to EPA-CoA, DHA-CoA was more effectively synthesized in the microso-

mal and peroxisomal fractions than the mitochondrial fraction (Fig. 3). It is likely that peroxisomal oxidation of DHA, which is quantitatively less effective than mitochondrial oxidation, might divert intracellular DHA into the glycerolipids. Indeed, [1-^{14}C]DHA is preferentially incorporated into cell-associated phospholipids in rat parenchymal cells (Fig. 2).

In contrast, the formation of acid-soluble products from EPA was sensitive to CPT-I inhibition, suggesting mitochondrial oxidation (Table 1). However, the formation of acid-soluble products, especially from carbon atoms beyond the third position of EPA, was far more effective when peroxisomes were added (Table 1). Whereas the formation of acid-soluble products from DHA was comparable to the sum of acid-soluble products formed in the two organelles separately, EPA oxidation was much higher in a combination of mitochondria and peroxisomes, suggesting synergetic oxidation (Table 1). A possible explanation for those results would be that the peroxisomal chain-shortened EPA is delivered to mitochondria for further oxidation. The first round of β-oxidation might occur in both mitochondria and peroxisomes, in addition to plain mitochondrial oxidation.

Polyunsaturated fatty acids are more difficult to oxidize than their saturated counterparts due to their double bonds. Accumulation of DHA-CoA and EPA-CoA esters in the peroxisomes and mitochondria, respectively, might give a "fatty acid overload" signal, leading to increased fatty acid oxidation of palmitic acid. Thus, different metabolic properties of these polyunsaturated n-3 fatty acids also imply different effects, i.e., they affect organelle oxidation in relation to the substrate preference. This is consistent with the finding that EPA, but not DHA, treatment increased the mRNA levels of CPT-I (Table 3) and caused proliferation of mitochondria (15). On the other hand, DHA is a stronger peroxisome proliferator than EPA (15) and more effectively increases the mRNA levels of FAO (Table 3). However, stimulation of this quantitatively less effective peroxisomal fatty acid oxidation system might not be sufficient to influence the balance between fatty acid oxidation and triacylglycerol biosynthesis.

In conclusion, the different metabolic properties of EPA and DHA as shown in this study might be related to their different hypolipidemic properties. Our results suggest that EPA is the more metabolically active fatty acid, whereas DHA might have structural functions. The present study supports the hypothesis that EPA, and not DHA, lowers plasma triacylglycerol by increased mitochondrial β-oxidation. Evidently, EPA is the primary hypolipidemic component of fish oil.

ACKNOWLEDGMENTS

This work was supported by the Norwegian Cancer Society, Research Council of Norway, NOVO Nordisk Fonden, and Astri og Edvard Riisøens legat. The authors are obliged to Kari Helland Mortensen, Agnethe Stray-Pedersen, David Fraser, and Svein Kruger for excellent technical assistance. The assistance of Tore-Jacob Raa at Gade Institute is also appreciated. We are also grateful to Victoria Esser, J. Denis McGarry, and Takashi Hashimoto for generously providing the cDNA.

Effects of Conjugated Linoleic Acid Isomers on the Hepatic Microsomal Desaturation Activities *in Vitro*

L. Bretillon, J.M. Chardigny*, S. Grégoire, O. Berdeaux, and J.L. Sébédio
INRA, Unité de Nutrition Lipidique, Dijon, France

ABSTRACT: The influence of individual conjugated linoleic acid (CLA) isomers on the Δ6 desaturation of linoleic and α-linolenic acids and on the Δ9 desaturation of stearic acid was investigated *in vitro*, using rat liver microsomes. The Δ6 desaturation of 18:2n-6 was decreased from 23 to 38% when the ratio of 9*cis*,11*trans*-18:2 to 18:2n-6 increased from 0.5 to 2. The compound 10*trans*,12*cis*-18:2 exhibited a similar effect only at the highest concentration. The Δ6 desaturation of α-linolenic acid was slightly affected by the presence of CLA isomers. The sole isomer to induce an inhibitory effect on the Δ9 desaturation of stearic acid was 10*trans*,12*cis*-18:2.

Paper no. L8239 in *Lipids 34*, 965–969 (September 1999).

Conjugated linoleic acid (CLA) is a generic term that encompasses several isomers of linoleic acid with conjugated double bonds. CLA has been reported to have beneficial effects on different aspects of health, including cancer (1–3), body mass composition (4,5), and cardiovascular risk factors (6,7). However, most of the studies reported to date used mixtures of different CLA isomers, including 7,9-, 8,10-, 9,11-, 10,12-, and 11,13-18:2, with different combinations of *cis* and *trans* double bonds (8,9). On the other hand, the main dietary source of CLA is ruminant fat and dairy products (10), in which the main CLA isomer is 9*cis*,11*trans*-18:2. CLA has been found in different human tissues, including milk (11,12), bile (13,14), adipose tissue (15,16), and serum (17,18). It recently has been demonstrated in rats that only the 9*cis*,11*trans* and the 10*trans*,12*cis* isomers are desaturated and elongated into 18:3 and 20:3 conjugated fatty acids (19). The biosynthesis of conjugated 20:4 was low except when rats were fed a linoleic acid-poor diet (19).

Different mechanisms of action have been hypothesized, including alteration of eicosanoid synthesis even if CLA isomers and metabolites are poorly incorporated in tissue phospholipids (20). However, CLA intake modifies the fatty acid profile of tissues, particularly the long-chain polyunsaturated content. CLA decrease the expression of stearoyl-CoA desaturase mRNA in the liver of mice (21), and the authors of this research suggested the active form may be an isomer other than 9*cis*,11*trans*. However, the effects of CLA on the different desaturation steps involved in the biosynthesis of unsaturated fatty acids have not yet been investigated. In the present work, we studied the effects of different CLA isomers on the Δ6 desaturation of linoleic and α-linolenic acids, as well as on the Δ9 desaturation of stearic acid.

MATERIALS AND METHODS

Animals and diet. Male Wistar rats (IFFA CREDO, L'Arbresle, France) were fed a fat-free semisynthetic diet for 1 wk, as previously described (22).

Chemicals. [1-^{14}C]-18:0, [1-^{14}C]-18:2n-6, and [1-^{14}C]-18:3n-3 were purchased from NEN Life Science Products (Paris, France) and diluted to a specific activity of 370 M·mmol^{-1} using the corresponding unlabeled fatty acids from Sigma (L'Isle D'Abeau, France). The 9*cis*,11*trans*- and the 10*trans*,12*cis*-18:2 were obtained by total synthesis (23,24). All the fatty acids were dissolved in ethanol. Coenzymes were purchased from Sigma.

Preparation of microsomes. The animals were anesthetized with diethyl ether at 8:30 A.M. in order to avoid variation in enzyme activities due to circadian rhythm (25), exsanguinated, and the livers were quickly excised. Microsomes were prepared using a slight modification of the previously described method (26). Briefly, each liver (12.5 ± 0.33 g, mean ± SEM) was homogenized in sucrose and phosphate buffer (pH 7.4). The homogenate was first centrifuged at 400 × *g* for 5 min to pellet cellular debris. The supernatant was then centrifuged at 15,000 × *g* for 15 min to eliminate nuclei, mitochondria, lysosomes, and peroxysomes. Finally, the supernanant was ultracentrifuged at 105,000 × *g* for 60 min. The pellet was then resuspended into saccharose-phosphate buffer and cytosol. Microsomal proteins were quantified according to Lowry *et al.* (27).

Microsomal suspensions containing 5 mg of protein were immediately incubated with [1-^{14}C]-18:0 (40 nmoles) or [1-^{14}C]-18:2 or -18:3 (60 nmoles) in the presence of increasing concentrations of 9*cis*,11*trans*- or 10*trans*,12*cis*-18:2, in order to obtain inhibitor/substrate (I/S) ratios from 0 to 2. The incubations were carried out at 37°C for 15 min, as previously described (26), with the following modifications. Each incu-

bation medium contained 72 mM phosphate buffer, 4.8 mM $MgCl_2$, 0.5 mM CoA, 3.8 mM ATP, 1.2 mM NADPH, and 1.2 mM reduced glutathione, in a final volume of 2 mL.

Analysis of the conversion products. The reactions were stopped by addition of KOH in ethanol. The lipids were saponified by heating at 100°C for 1 h under nitrogen. Fatty acid methyl esters (FAME) were prepared according to Morrison and Smith (28). The FAME were then extracted with hexane and fractionated using reversed-phase high-performance liquid chromatography. The FAME were dissolved in 100 µL of acetone and analyzed using a Nucleosil C18 column packing (5 µm particle size, 250 × 4.6 mm i.d., Interchim, Montluçon, France) and a high-performance liquid chromatographic system (model 600, Waters, Saint Quentin en Yvelines, France). The mobile phase was acetonitrile at a flow rate of 0.5 mL·min^{-1}. The radioactivity was measured in the counting cell of a radiochromatographic Flo-One β detector (Series A-100, Radiomatic Instruments, Tampa, FL) after mixing the column effluent with a Uniscint BD scintillation cocktail (National Diagnostic, Atlanta, GA) in a ratio of 1:1.2 (effluent/scintillation cocktail).

Some samples were also analyzed by gas chromatography coupled with radioactive detection, as previously described (26). Briefly, microsomal methyl esters were analyzed on a Hewlett-Packard 5890 series II gas chromatograph (Palo Alto, CA), equipped with a splitless injector and a fused Stabilwax wide-bore silica column (60 m × 0.53 mm i.d.; film thickness; 0.50 µm; Restek, Evry, France). The outflow from the column was split between a flame-ionization detector (10%) and a copper oxide oven heated at 700°C in order to transform the labeled fatty acids into $^{14}CO_2$ (90%). The radioactivity was determined with a radiodetector (GC-RAM; Lablogic, Sheffield, United Kingdom) by counting $^{14}CO_2$ after mixing it with a 9:1 ratio of argon/methane. The data were computed using Laura software (Lablogic).

Statistical analysis. Results are expressed as means ± SD (n = 3). The comparisons between values were done by an analysis of variance and the Newman-Keuls' test using the NCSS software (Cork, Ireland).

RESULTS

To examine the effects of individual CLA isomers on the desaturation of C_{18} fatty acids, we incubated stearic, linoleic, and α-linolenic acids in the presence of increasing concentrations of CLA isomers and rat liver microsomes.

Analysis of the microsomal methyl esters by radio-gas chromatography was performed in order to ascertain the conversion of stearic acid into oleic acid and of linoleic and α-linolenic acids into their corresponding Δ6 desaturated metabolites. Indeed, stearidonic, γ-linolenic, and oleic acids were detected (Fig. 1).

The control microsomes exhibited a Δ9 desaturation activity toward stearic acid of 385 pmol·min^{-1}·mg protein^{-1} and a Δ6 desaturation activity toward linoleic and α-linolenic acids of 115 and 400 pmol·min^{-1}·mg^{-1} protein, respectively. These

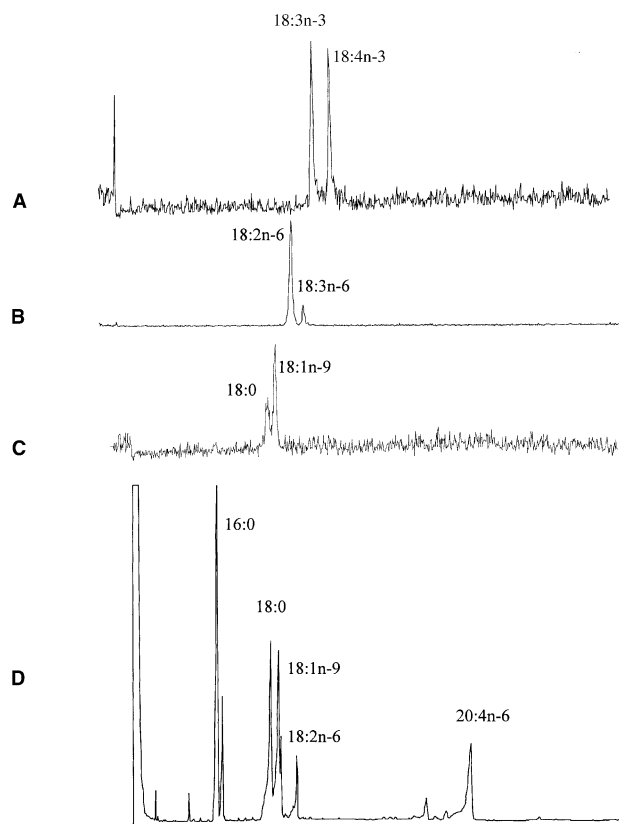

FIG. 1. Radiochromatograms and flame-ionization detector (FID) signal of methyl esters obtained from microsomes (5 mg of protein) incubated during 15 min at 37°C under control conditions [without conjugated linoleic acid (CLA) isomers] with 60 nmol of α-linolenic acid [1-^{14}C] (trace A), 60 nmol of linoleic acid [1-^{14}C] (trace B) or 40 nmol of stearic acid [1-^{14}C] (trace C). The D-trace corresponds to the FID signal (for radiochromatographic conditions, see the Material and Methods section).

values were comparable to those reported by several authors (29–32). Figure 2 presents the Δ9 desaturation of stearic acid in the absence (control) or presence of increasing concentrations of 9*cis*,11*trans*- or 10*trans*,12*cis*-18:2. Coincubation of 9*cis*,11*trans*-18:2 did not significantly modify the desaturation of stearic acid, whereas 10*trans*,12*cis*-18:2 significantly inhibited the conversion of stearic acid. This inhibition of conversion was 39% when the I/S ratio (CLA/radiolabeled substrate ratio) was 1 and reached 50% when the I/S ratio was 2; microsome concentration was constant.

The Δ6 desaturation of linoleic and α-linolenic acids is presented in Figures 3 and 4, respectively. The desaturation of linoleic acid was significantly decreased when 9*cis*,11*trans*-18:2 was present in the incubation medium. This inhibition ranges between 23 and 38% when the I/S ratio varies from 0.5 to 2. On the other hand, 10*trans*,12*cis*-18:2 inhibits the Δ6 desaturation of linoleic acid only at the highest I/S ratio. The desaturation of α-linolenic acid was only slightly affected by the presence of CLA isomers in the incubation medium.

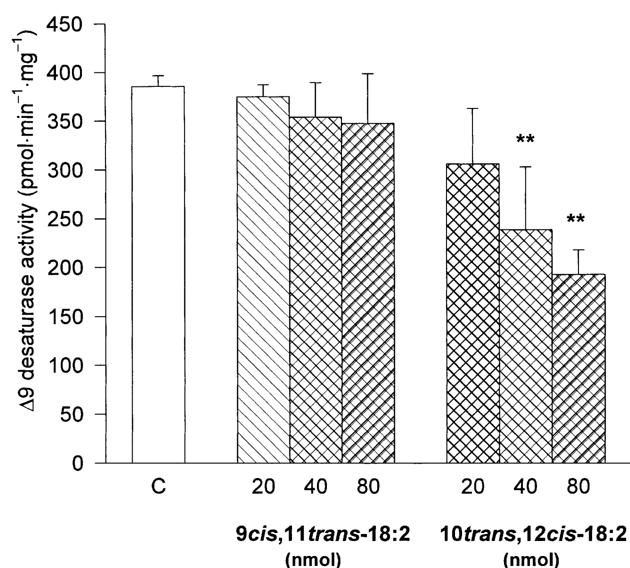

FIG. 2. Δ9 Desaturase activity of stearic acid (18:0, 40 nmol) by rat liver microsomes (5 mg protein) incubated under control conditions (without CLA) or in the presence of increasing concentrations of 9*cis*,11*trans*- or 10*trans*,12*cis*-18:2. For abbreviations see Figure 1. Vertical bars represent standard deviation ($n = 3$). **, significantly different from control (C) at $P < 0.01$.

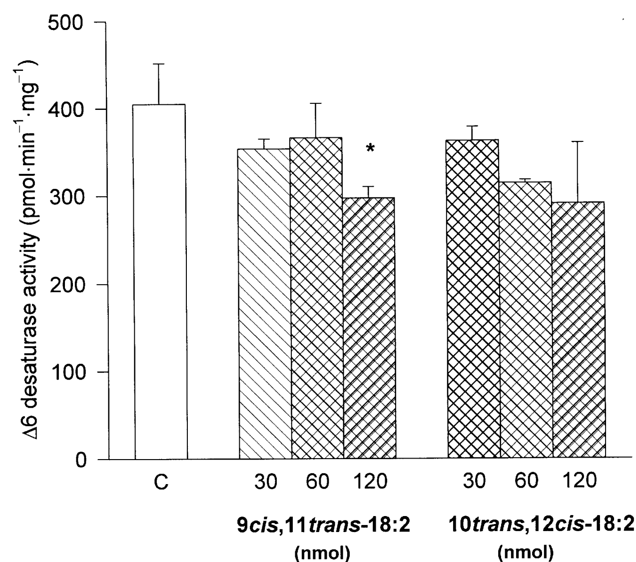

FIG. 4. Δ6 Desaturase activity of α-linolenic acid acid (18:3n-3, 60 nmol) by rat liver microsomes (5 mg protein) incubated under control conditions (without CLA) or in the presence of increasing concentrations of 9*cis*,11*trans*- or 10*trans*,12*cis*-18:2. For abbreviations see Figure 1. Vertical bars represent SD ($n = 3$). *, significantly different from control (C) at $P < 0.05$.

DISCUSSION

The interconversion of nonconjugated fatty acids may be implicated in different pathologies in which CLA has been reported to have beneficial effects. The present study reports selective effects of individual isomers of CLA on desaturation steps involved in the biosynthesis of unsaturated fatty acids. It has previously been suggested (33) that CLA isomers may alter the desaturation of saturated fatty acids, but no clear evidence for the role of each isomer has been reported. A recent study (21) indicated that CLA alter the expression of stearoyl-CoA desaturase mRNA in the liver from mice. The CLA isomer responsible for this effects has not been clearly identified.

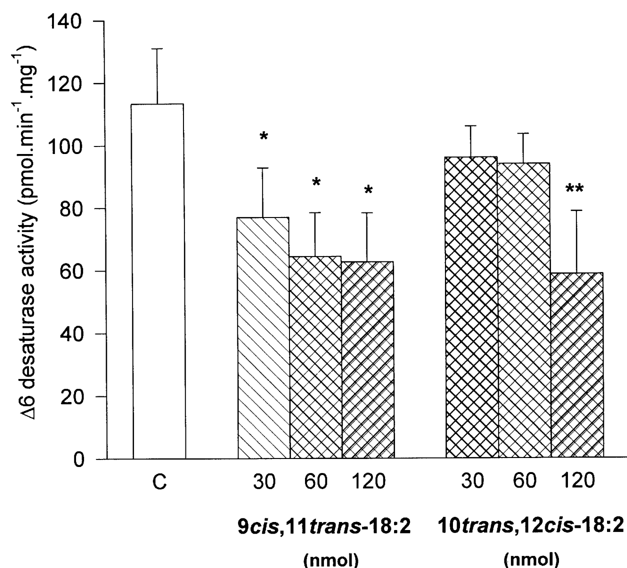

FIG. 3. Δ6 Desaturase activity of linoleic acid (18:2n-6, 60 nmol) by rat liver microsomes (5 mg protein) incubated under control conditions (without CLA) or in the presence of increasing concentrations of 9*cis*,11*trans*- or 10*trans*,12*cis*-18:2. For abbreviation see Figure 1. Vertical bar represents SD ($n = 3$). * and **, significantly different from control (C) at $P < 0.05$ and 0.01, respectively.

Data from Belury and Kempa-Stedzko (34) suggested that liver microsomes may desaturate linoleate as well as CLA. Our present work suggests that the 9*cis*,11*trans* isomer alters the Δ6 desaturation of linoleic acid, whereas the 10*trans*,12*cis* isomer is effective only when present at a high I/S ratio. Dietary CLA has been reported to modulate the fatty acid profile of different tissues (33,34). This might be explained by the alteration of desaturation activities by dietary CLA intake.

The Δ6 desaturation of linoleic acid is the well-known regulatory step in the biosynthesis of arachidonic acid, which is further released from phospholipids to be converted into bioactive lipids, i.e., eicosanoids. Eicosanoids are involved in cancer, immune function, and cardiovascular diseases, conditions in which CLA reportedly have beneficial effects. The present data show that the 9*cis*,11*trans* isomer is more active in this desaturation step than the 10*trans*,12*cis*-18:2. On the other hand, both CLA isomers studied here modify the Δ6 desaturation of α-linoleic acid only slightly, suggesting that they are not active on the n-3 polyunsaturated fatty acid (PUFA) biosynthesis cascade. The enrichment in long-chain n-3 PUFA by using pure dietary isomers (Sébédio, J.L., Juaneda, P., and Chardigny, J.M., unpublished data) and by using CLA

mixtures (34) might be due to an alteration of other enzymatic activities. Alternatively, such an inhibition of the n-6 PUFA biosynthesis, in conjunction with a preferential acylation of n-3 fatty acids over n-6, as previously shown (35), may be a valuable explanation of this result.

Previous reports indicated that dietary CLA may alter the Δ9 desaturase activity (21,33). However, no information on the specific effects of individual isomers was then available. Our present data clearly show that only the 10*trans*,12*cis* isomer is able to antagonize the desaturation of stearic acid into oleic acid, suggesting that it is the isomer responsible for the modification of saturated and monounsaturated levels in tissues from animals fed a CLA mixture. These data substantiate what was observed by Lee *et al.* (21), who suggested that the effect on the expression of stearoyl-CoA desaturase was not due to the 9*cis*,11*trans* isomer. It is suggested that the 9*cis*,11*trans*-18:2 mainly alters the Δ6 desaturation of linoleic acid whereas the 10*trans*,12*cis*-18:2 decreased the Δ9 desaturation of stearic acid, both of which are regulatory steps in the conversion of 18-carbon fatty acids.

The data reported here indicate that, *in vitro*, different CLA isomers alter the desaturation steps involved in the biosynthesis of unsaturated fatty acids differently. Further studies are needed to clarify the *in vivo* situation. In particular, it should be interesting to elucidate the influence of CLA on lipoprotein metabolism in light of the clear relationship, reported by Legrand *et al.* (36), between the inhibition of Δ9 desaturase activity and the decrease in the secretion of very low density lipoprotein-triacylglycerols in cultured chicken hepatocytes.

Δ^9 Desaturase Activity in Bovine Subcutaneous Adipose Tissue of Different Fatty Acid Composition

A. Yang[a], T.W. Larsen[a], S.B. Smith[b], and R.K. Tume[a,]*

[a]Food Science Australia, Brisbane Laboratory, Tingalpa D.C. Queensland 4173, Australia, and [b]Department of Animal Science, Texas A&M University, College Station, Texas 77843

ABSTRACT: Two experiments were conducted to investigate the relationship between Δ^9 desaturase (stearoyl-coenzyme A desaturase) activity and fatty acid composition in subcutaneous adipose tissue from cattle of different backgrounds. In Experiment 1, subcutaneous adipose tissue samples were taken from carcasses of pasture-fed cattle and feedlot cattle fed for 100, 200, or 300 d. Adipose tissue from pasture-fed cattle had significantly lower total saturated fatty acids and higher total unsaturated fatty acids than feedlot cattle. Desaturase activity correspondingly was 60–85% higher in pasture-fed cattle than in feedlot cattle. There was no difference in the fatty acid composition or desaturase activity among samples from the 100-, 200-, and 300-d feedlot cattle. In Experiment 2, adipose tissue samples were collected from carcasses of feedlot cattle fed for 180 d with either a standard feedlot ration (control group), or a ration containing rumen-protected cottonseed oil (CSO) for the last 70–80 d. Adipose tissue from the CSO-fed cattle was more saturated than that from the control group, having significantly more 18:0 and less 16:1 and 18:1. Correspondingly, adipose tissue from the CSO group had significantly lower desaturase activity. The elevated 18:2 in adipose tissue from the CSO group confirmed that unsaturated fatty acids (including cyclopropenoid fatty acids) were protected from biohydrogenation. Further studies are needed to determine whether the repression of desaturase activity results from direct inhibition by cyclopropenoic acids or by higher dietary contents of 18:2.

Paper no. L8086 in *Lipids 34*, 971–978 (September 1999).

Grain-feeding of beef cattle markedly improves meat marbling, fat color, and product uniformity. This is particularly important for the marketing of beef to certain countries such as Japan and Korea, where significant levels of marbling and white fat color are demanded. However, with certain dietary regimens, it has been observed that there is an increase in the degree of saturation of fatty acids in adipose tissues, resulting in hard fat (1). Often, this has been observed when whole cottonseed or cottonseed products are fed as a component of the feed. Feedlot cattle, particularly cattle on long-term grain feeding, generally produce large carcasses with excessive fat thickness and fat that often is very hard when chilled. This hard fat is a problem confronting the meat industry for a number of reasons. Japan is a valuable export market for beef, and this market highly regards fat that is soft, finely textured, and satin-like in appearance. Furthermore, in some countries, hard fat results in processing difficulties, safety issues, and inefficiencies, and attempts to overcome this hardness often result in a reduction in ultimate meat quality attributes. Finally, health authorities recommend reduced consumption of saturated fat, particularly that of animal origin.

The hardness of carcass fat at a given temperature is determined mainly by its overall fatty acid composition as the overall melting point of fat depends largely on the proportion of these individual fatty acids. There have been many studies of fatty acid composition of bovine adipose tissue (2–4), and generally, for a particular body location, composition has been shown to be fairly intransigent to change, as a result of rumen hydrogenation of dietary fatty acids. However, composition is affected to some degree by factors such as breed, sex, diet, weight, age, and environmental effects, such as climate and season (3–9). The observed difference in fat hardness between pasture-fed and feedlot beef also suggests a difference in their ability to synthesize monounsaturated fatty acids. Fatty acyl coenzyme A (CoA) desaturase (stearoyl-CoA desaturase) (EC 1.14.99.5) catalyzes the conversion of saturated fatty acids to Δ^9 monounsaturated fatty acids. Our previous results suggested that grain-feeding cattle leads to inhibition of desaturase activity (9). We therefore conducted two experiments to document the relationship between the fatty acyl CoA desaturase activity and fatty acid composition in adipose tissue from cattle of different backgrounds.

MATERIALS AND METHODS

Sample collection. Two experiments were conducted in this study. In Experiment 1, subcutaneous adipose tissue samples were taken from the loin region of carcasses from nine pasture-fed cattle and 30 feedlot cattle fed for either 100, 200, or 300 d at one feedlot (I). Feed consisted of mainly sorghum with 5% whole cottonseed together with roughage. Adipose tissue samples also were collected from the same anatomical location of carcasses from 10 feedlot cattle fed for 300 d at a

different feedlot (II). These cattle were fed a similar grain-based diet, but the ration contained a higher percentage of silage. All cattle were Angus-cross. In Experiment 2, subcutaneous fat samples were collected at two abattoirs from carcasses of feedlot cattle fed for 180 d. The animals were fed either a standard feedlot ration (control group), or a similar ration containing rumen-protected cottonseed oil (CSO) for the last 70 (Abattoir I) or 80 (Abattoir II) d of the feedlotting period before slaughter. The protected cottonseed lipid was included at 8.7% of dry matter. The grain used was dry-rolled sorghum with 6% whole cottonseed.

For both experiments, subcutaneous adipose tissue samples from the mid-loin region were collected on the slaughter floor, placed on dry ice within 30 min of stunning, and kept at −70°C until used for analyses.

Fatty acid composition. Adipose tissue (50–100 mg) was placed in 3 mL of 0.25 M sodium methoxide/diethyl ether (1:1, vol/vol) at 60°C for 2 min. After allowing to cool at room temperature, 5 mL 5% NaCl was added, and tubes were sealed and vortexed. Fatty acid methyl esters were extracted with 5 mL petroleum ether (b.p. 60–80°C). After the phases separated and the top phase became clear, a 1.5-mL gas chromatography sample bottle was filled with the top phase. The separation and distribution of fatty acid methyl esters were obtained using gas–liquid chromatography with a capillary column (CP-Sil-88, ChromPak, Middelburg, The Netherlands) as described previously (9). As *trans* 18:1 acids behave in a manner physiologically similar to saturated fatty acids and have a higher melting point than their *cis* equivalents, we included them in the calculation of total saturated fatty acids.

Desaturase activity. The method of Cameron *et al.* (10) was used with modifications. Frozen subcutaneous adipose tissue samples (~50 g) were diced and homogenized for 1 min in 2 vol of 0.02 M phosphate buffer (pH 7.4) containing 0.15 M KCl, 1 mM EDTA, and 1 mM dithiothreitol and filtered through cheesecloth into a flask. The homogenate was centrifuged at 1,500 × *g* for 10 min and filtered through glass wool. The fat-free supernate was centrifuged at 17,300 × *g* for 30 min, and the supernate was filtered through glass wool. The microsomal fraction was isolated by centrifugation of the resultant supernate at 104,000 × *g* for 60 min, and the microsomal pellet was resuspended in 1 mL cold buffer. Protein concentration was determined using the method of Bradford (11).

The reaction mixture for the measurement of desaturase assay (final volume 1.0 mL) contained 5 mM $MgCl_2$, 50 mM potassium phosphate, 5 mM ATP, 0.5 mM NADH, and 0.05 mM [1-^{14}C]palmitoyl-CoA (specific activity = 57.1 μCi/mmol) and was performed in duplicate. The reaction was initiated by the addition of 1 mg of the microsomal protein and was incubated at 37°C for 5 min before being stopped with 2 mL 10% KOH in methanol. Blanks were obtained by adding 2 mL 10% KOH in methanol to the reaction mixture prior to the addition of the microsomal protein. The tubes were then heated at 70°C for 30 min, and the solution was acidified with 6 mL 3 N HCl. Fatty acids were extracted three times with 6 mL petroleum ether, and the combined extract was washed with 6 mL acidic water (pH 3.0). The pooled upper layer was evaporated to dryness, and the fatty acids were methylated in 1 mL 5% H_2SO_4 in methanol at 60°C overnight. On the following day, 1 mL distilled water was added, and the methyl esters were extracted three times with 2 mL petroleum ether. The combined upper phase was then evaporated under nitrogen and redissolved in 100 μL petroleum ether. Aliquots of the methyl esters were separated on freshly activated thin-layer plates (silica G) impregnated with 3% $AgNO_3$, and the plates were developed in petroleum ether/diethyl ether (97:3, vol/vol) for about 30 min and sprayed with 0.02% dichlorofluorescein. Saturated and unsaturated species were identified under ultraviolet light, then cut and counted in 4 mL Opti-Fluor O (Packard, Downers Grove, IL) using a Packard Tri-Carb liquid scintillation counter (model 4530). The desaturase activity was calculated as the percentage of the counts for the unsaturated species over that for the unsaturated and saturated species and expressed as nmol palmitoleic acid formed per mg protein per min.

Source of chemicals and radioisotopes. All biochemicals were purchased from Sigma Chemical Co. (Sigma-Aldrich, Sydney, Australia). The radioisotope, [1-^{14}C]palmitoyl-CoA, was purchased from Dupont NEN (Boston, MA).

Statistical analysis. The results are expressed as mean ± SE and all data were analyzed as one-way analysis of variance (12).

RESULTS

Experiment 1—Pasture vs. grain feeding. Subcutaneous adipose tissue of pasture-fed cattle had significantly lower total saturated fatty acids and higher total unsaturated fatty acids compared with that from the 100-, 200-, or 300-d feedlot cattle, resulting in a higher unsaturated/saturated fatty acid ratio (Table 1). The adipose tissue from a 300-d fed group from another feedlot also contained significantly more saturated fatty acids than the pasture-fed group. Generally, the adipose tissue from pasture-fed cattle had lower percentages of 16:0 and 18:0 and higher percentages of 16:1, 18:1*c*9, and 18:3. These significant differences in fatty acid composition between pasture- and grain-fed cattle were supported by desaturase activities, which were 60–85% higher in pasture-fed cattle. There was no difference in either the fatty acid composition or desaturase activities among the 100-, 200-, and 300-d fed cattle from Feedlot I. Overall, adipose tissue from cattle of Feedlot II was similar to that from the groups fed in Feedlot I, except that it had a lower percentage of 18:0.

The fatty acid composition of the microsomal fraction of the adipose tissues is given in Table 2. For pasture-fed cattle, the total saturated fatty acids and unsaturation ratios for the membrane fraction were similar to those observed for whole adipose tissue (Table 1). However, the content of total monounsaturated fatty acids was lower, and there was a higher concentration of polyunsaturated fatty acids, especially 20:4. For the 300-d feedlot cattle, the total saturated fatty acids and monounsaturated fatty acids of the microsomal fraction were both significantly lower than those observed in whole subcu-

taneous adipose tissue. The polyunsaturated fatty acids constituted up to 16.5% of the membrane fatty acids. There was no difference in the saturated/unsaturated fatty acid ratios between adipose tissues from pasture-fed and 300-d feedlot cattle, although samples from the pasture-fed cattle had significantly higher percentages of monounsaturated fatty acids and lower polyunsaturated fatty acids.

Experiment 2—Effect of protected CSO. The adipose tissue from cattle fed the protected CSO formulation contained significantly more saturated fatty acids than adipose tissue from control cattle (Table 3). Correspondingly, the unsaturated/saturated fatty acid ratios also were lower for both groups fed the protected CSO (0.92 vs. 1.18 for Abattoir I and 0.81 vs. 1.10 for Abattoir II). Feeding the protected CSO supplement caused a large increase in 18:0 and 18:2, a decrease in 18:1*c*9, and small but significant decreases in most of the other monounsaturated fatty acids. Desaturase activity was reduced by over 50% in adipose tissue from cattle fed protected CSO (Table 3).

Feeding the protected CSO significantly reduced the microsomal concentrations of 16:1, 17:1, 18:1*c*9, and 18:1*c*11, and increased concentrations of 18:0 and 18:2 in adipose tissue from cattle slaughtered at Abattoir II (Table 4). However, only 18:2 was affected significantly in microsomes from adipose tissue of cattle slaughtered in Abattoir I.

The 18:2 content of the microsomes from Experiment 2 control cattle (17.3 and 18.7%; Table 4) was approximately twice as high as that from the pasture-fed cattle in Experiment 1 (9.5%; Table 2). The 18:2 content of the microsomes from Experiment 2 control cattle also was as high as or higher than that of the 300-d feedlot cattle of Experiment 1 (14.6 and 16.5%; Table 2).

Relationship between fatty acid composition and desaturase activity. Highly significant correlations (r^2) were observed between the desaturase activity and percentage contents of a number of fatty acids in adipose tissue (Fig. 1). Desaturase activity correlated positively with the major monounsaturated fatty acids (0.35 with 14:1, 0.55 with 16:1, 0.31 with 18:1*c*9, and 0.48 with total monounsaturated fatty acids), and negatively with the major saturated fatty acids (−0.49 with 16:0, −0.34 with 18:0, and −0.49 with the total saturated fatty acids). This resulted in a significantly positive correlation (0.49) of desaturase activity with the monounsaturated/saturated fatty acid ratio (Fig. 1G).

The relationship between desaturase activity and percentage of 18:2 was not significant in adipose tissue from cattle from Experiment 1. In contrast, there was a strong negative correlation ($r^2 = -0.51$) between desaturase activity and adipose tissue 18:2 in Experiment 2 (Fig. 1E).

DISCUSSION

We recently documented that subcutaneous adipose tissue from cattle fed whole cottonseed or protected CSO contained unusually high levels of saturated fatty acids (as much as 26% 18:0) and low concentrations of monounsaturated fatty acids

(9). This caused a migration of 18:0 from the *sn*-2 triacylglycerol position to the outer *sn*-1,3 triacylglycerol positions. More importantly, the reduction in monounsaturated fatty acids suggested that dietary whole cottonseed or protected CSO increased the saturated fatty acid concentration of adipose tissue by reducing Δ^9 desaturase activity. The effect of this was a significant increase in fat hardness, judged subjectively at 10°C, and an increase in the slip point of the isolated fat (9).

Whole cottonseed and some meals contain significant quantities of cyclopropenoid fatty acids, ranging from 0.6 to 2.1% of total fatty acids in oil (13). Although cyclopropenoid fatty acids are themselves unsaturated, they have been shown to increase the saturation of adipose tissue lipids 2.5-fold when fed to rats (14). This increase in saturation is caused by the inhibition of stearoyl-CoA desaturase activity in adipose tissue (15). The effect of cyclopropenoid fatty acids on desaturase activity in cattle apparently is not as great as in nonruminants, as these acids can be hydrogenated in the rumen and lose their inhibitory effect (16). Some cycloprenoid fatty acids escape hydrogenation, and this may be a contributing factor to the higher saturation of carcass fat when feeding whole cottonseed in commercial feedlots. Similarly, feeding rumen-protected cyclopropenoid acids to ruminants led to higher ratios of stearic/oleic acids in milk, suggesting that this resulted from an inhibition of mammary Δ^9 desaturase activity (17).

In the present study we were unable to detect the presence of sterculic or malvalic acids in adipose tissues, but that may be because of relatively low contents in the feeds. We have analyzed many samples of CSO and have found the contents of total cyclopropenoic acids to be about 0.6% of the total

[b] Number of cattle; fat tissue from each animal was analyzed in duplicate.

fatty acids present. In view of this, it may not be expected that we could detect these acids in adipose tissue. Where cyclopropenoic acids were detected in adipose tissues of rats, it was fed at subacute levels (14).

Feeding formaldehyde-protected fatty acid supplements such as CSO has been reported to improve growth performance and to alter the fat composition of cattle quite dramatically (18). CSO is highly unsaturated, having more than 50% 18:2 (19), and high percentages of 18:2 (up to 10%) were found in adipose tissue of cattle fed protected CSO (18). As significant amounts of dietary 18:2 were deposited in fat tissues, clearly some portion of these polyunsaturated fatty acids were protected from hydrogenation in the rumen. This was particularly obvious in samples from Abattoir II, where the cattle were on protected CSO ration for 10 d longer, resulting in more 18:2 being deposited in adipose tissue than in samples from Abattoir I. There was a highly significant negative correlation between the stearoyl-CoA desaturase activity and 18:2 in this experiment ($r^2 = -0.51$), which was not observed in Experiment 1.

There are a number of reports demonstrating that certain polyunsaturated fatty acids, including 18:2, repress stearoyl-CoA desaturase activity in adipocytes by depressing expression of stearoyl-CoA desaturase gene 1 (20,21). Waters and Ntambi (22) demonstrated that 18:2 inhibits stearoyl-CoA desaturase gene 1 transcription in hepatic tissue, possibly by elevating the prostaglandin $F_{2\alpha}$ concentration as reported in adipose tissue (23). Alternatively, enriching the microsomal membranes with 18:2 may cause a conformational change in stearoyl-CoA desaturase and a consequent loss in activity.

Gulati *et al.* (18) and Ashes *et al.* (24) recently have drawn attention to the observation that differences in fatty acid composition result from feeding protected canola and protected cottonseeds. When oilseeds such as sunflower seed meal were fed in protected form (18), the content of 18:2 in subcutaneous adipose tissue increased from 1.5% to 5.3%, but there was no significant effect on 18:0, which remained about 14%. When protected CSO was fed to cattle (18), there was a significant increase in the percentage of 18:0; the percentage of 18:2 increased much more than when unprotected plant oils were fed. Results of an early study in cattle (25), which also employed the feeding of protected 18:2 (in the absence of cyclopropenoic acids) demonstrated that, whereas feeding protected 18:2 substantially increased the concentration of 18:2 in adipose tissue, it did not alter the monounsaturated/saturated fatty acid ratio.

On the basis of the present work, we were unable to conclude that the reduction in desaturase activity was due entirely to cyclopropenoid fatty acids contained in whole cottonseed and in protected CSO. In fact, comparison of Experiments 1 and 2 suggests that 18:2 content, especially in the microsomal fraction, contributed to the reduction in Δ^9 desaturase activity. The highest desaturase activity and monounsaturated/saturated fatty acid ratio and lowest microsomal 18:2 concentration were observed in adipose tissue from the pasture-fed cattle of Experiment 1. Adipose tissue microsomes from the control cattle of Experiment 2 contained substantially more 18:2 than microsomes from either the pasture-fed or the feedlot cattle of Experiment 1, and desaturase activities

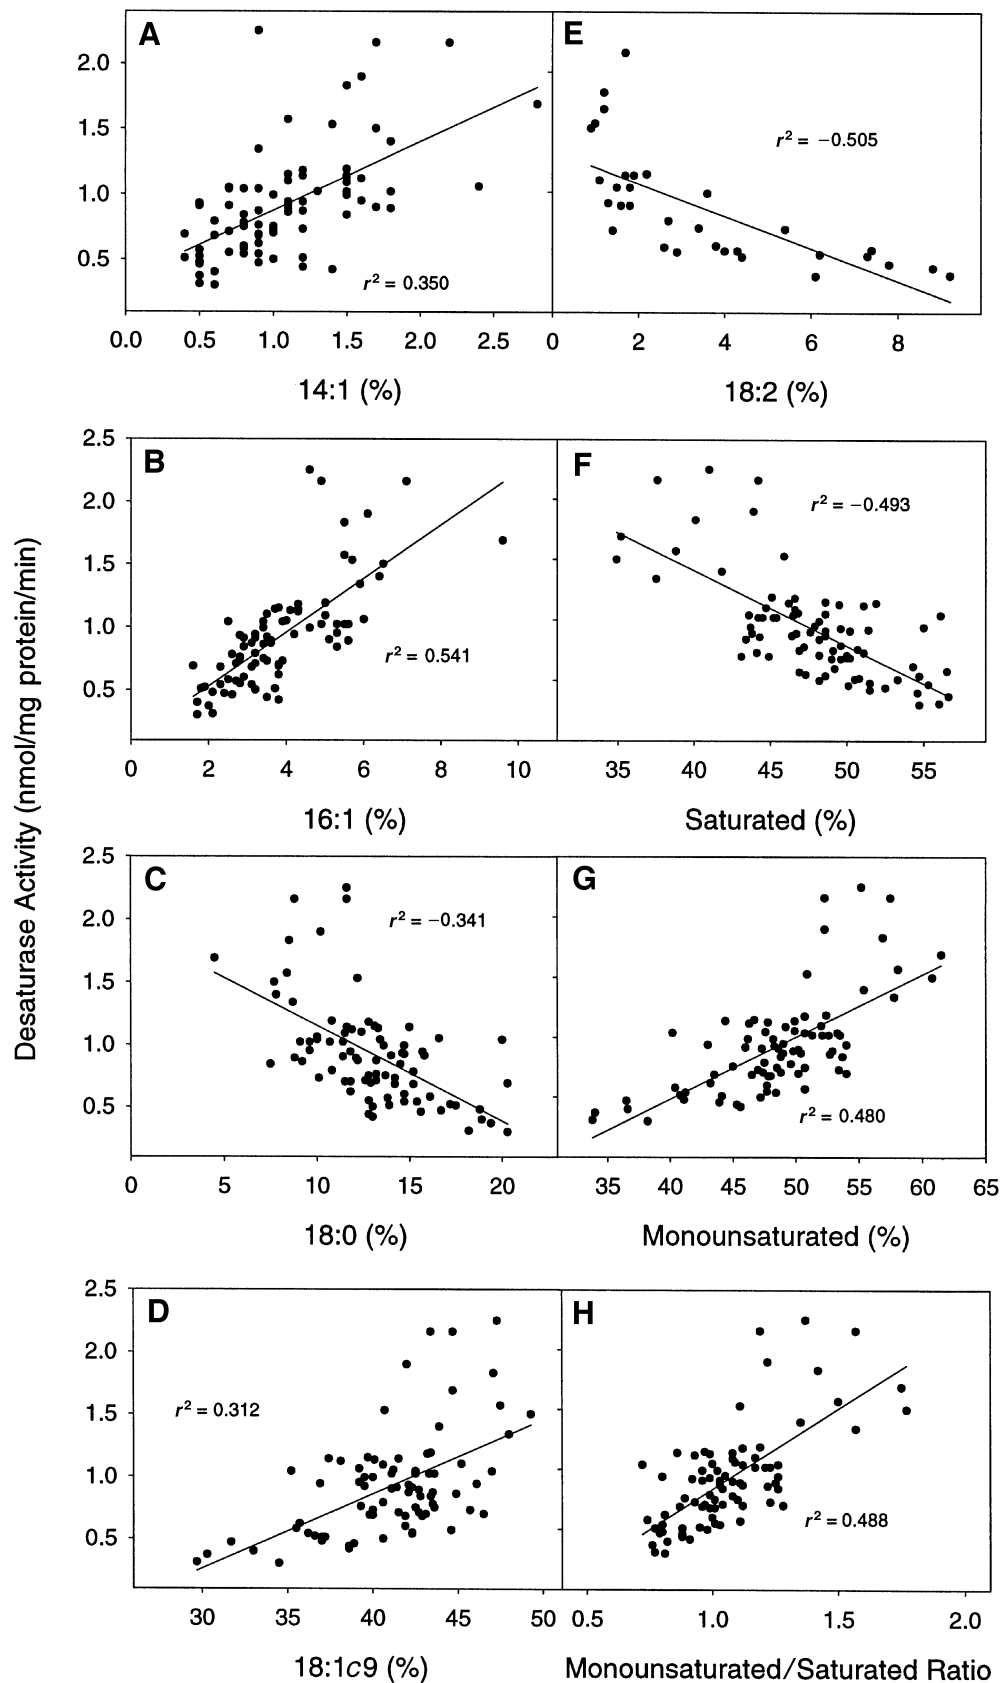

FIG. 1. Relationship between the desaturase activity and (A) 14:1, (B) 16:1, (C) 18:0, (D) 18:1*c*9, (E) 18:2, (F) total saturated fatty acids, (G) total monounsaturated fatty acids, and (H) the ratio between the monounsaturated and saturated fatty acids [n = 82 for all except (E) where n = 32].

and monounsaturated/saturated fatty acid ratios typically were lower in adipose tissue samples from Experiment 2.

If cyclopropenoids in whole cottonseed are reducing desaturase activity, then this phenomenon may be dependent upon the variety of whole cottonseed used for feeding. In experiments in the United States, feeding cattle up to 30% whole cottonseed for 54 d did not increase the concentration of 18:0, nor did it alter the monounsaturated/saturated fatty acid ratio (26). Furthermore, in other experiments in the United States, feeding 30% whole cottonseed for 180 d had no effect on stearoyl-CoA desaturase activity in subcutaneous adipose tissue, although it reduced the rate of lipogenesis from acetate by 30% compared to rates measured in adipose tissue from control cattle (27). The results of the present investigation indicate that feeding cattle for as little as 100 d was sufficient to elicit maximal inhibition of desaturase activity. Clearly there is a need to determine the content of cyclopropenoic fatty acids in the commercial cultivars of whole cottonseed used for feed. Also to be considered is that, in the United States, most of the metabolizable energy in finishing diets for cattle is derived either from corn or sorghum. In Australia, wheat, barley, and sorghum are fed in place of corn. Therefore, future studies will be designed to document the interaction between whole cottonseed and grain type on desaturase activity and fatty acid composition of bovine adipose tissue.

In summary, in this work we have demonstrated that feeding whole cottonseed or protected CSO to cattle increases the saturated fatty acid concentration of adipose tissue by reducing the activity of stearoyl-CoA desaturase. Whether this repression of activity resulted from direct inhibition by cyclopropenoic acids or by higher contents of 18:2 needs to be determined unequivocally. In addition, practices of feeding whole cottonseed or protected CSO need to be evaluated, and the consequent biochemical outcomes determined so as to avoid the problem of hard fat in beef carcasses.

ACKNOWLEDGMENTS

We thank Meat and Livestock Australia for their financial support and Maree Brewster for the fatty acid analysis.

METHOD

Lipase-Catalyzed Fractionation of Conjugated Linoleic Acid Isomers

ABSTRACT: The abilities of lipases produced by the fungus *Geotrichum candidum* to selectively fractionate mixtures of conjugated linoleic acid (CLA) isomers during esterification of mixed CLA free fatty acids and during hydrolysis of mixed CLA methyl esters were examined. The enzymes were highly selective for *cis*-9,*trans*-11-18:2. A commercial CLA methyl ester preparation, containing at least 12 species representing four positional CLA isomers, was incubated in aqueous solution with either a commercial *G. candidum* lipase preparation (Amano GC-4) or lipase produced from a cloned high-selectivity *G. candidum* lipase B gene. In both instances selective hydrolysis of the *cis-9,trans*-11-18:2 methyl ester occurred, with negligible hydrolysis of other CLA isomers. The content of *cis*-9,*trans*-11-18:2 in the resulting free fatty acid fraction was between 94 (lipase B reaction) and 77% (GC-4 reaction). The commercial CLA mixture contained only trace amounts of *trans*-9,*cis*-11-18:2, and there was no evidence that this isomer was hydrolyzed by the enzyme. Analogous results were obtained with these enzymes in the esterification in organic solvent of a commercial preparation of CLA free fatty acids containing at least 12 CLA isomers. In this case, *G. candidum* lipase B generated a methyl ester fraction that contained >98% *cis*-9,*trans*-11-18:2. *Geotrichum candidum* lipases B and GC-4 also demonstrated high selectivity in the esterification of CLA with ethanol, generating ethyl ester fractions containing 96 and 80%, respectively, of the *cis*-9,*trans*-11 isomer. In a second set of experiments, CLA synthesized from pure linoleic acid, composed essentially of two isomers, *cis*-9,*trans*-11 and *trans*-10,*cis*-12, was utilized. This was subjected to esterification with octanol in an aqueous reaction system using Amano GC-4 lipase as catalyst. The resulting ester fraction contained up to 97% of the *cis*-9,*trans*-11 isomer. After adjustment of the reaction conditions, a concentration of 85% *trans*-10,*cis*-12-18:2 could be obtained in the unreacted free fatty acid fraction. These lipase-catalyzed reactions provide a means for the preparative-scale production of high-purity *cis*-9,*trans*-11-18:2, and a corresponding CLA fraction depleted of this isomer.

Paper no. L8257 in *Lipids 34*, 979–987 (September 1999).

The identification of dietary components that have the potential to reduce the incidence of cancer is a topic of considerable interest to the research and medical communities and the general population. Pariza and colleagues identified a lipid fraction from beef fat that possessed anticarcinogenic properties and demonstrated that it was composed of conjugated double-bond isomers (designated CLA) of *cis*-9,*cis*-12-octadecadienoic (18:2) acid (linoleic acid) (1). It was shown that this fraction was similar to the CLA isomer mixture produced under some conditions by alkali isomerization of linoleic acid (2). Subsequent studies with animal models showed that consumption of CLA reduced body fat content and increased muscle mass (3–5), decreased atherosclerosis (6,7), and improved hyperinsulinemia in prediabetic rats (8), all of which further heightened interest in these compounds.

The richest natural dietary sources of CLA are the meat and milk of ruminants and products made from them. In these materials the predominant isomer is *cis*-9,*trans*-11-18:2, which constitutes over 75% of the total CLA (3,9). CLA can also be synthesized by alkali isomerization from linoleic acid (all-*cis*), resulting in either two (9,11- and 10,12-18:2) or four (8,10-, 9,11-, 10,12-, and 11,13-18:2) *cis/trans* positional isomers depending on the temperature of the reaction (10). In the predominantly two-isomer mixture, each isomer constituted about 40–42% of the product (11,12), while a commercially available four-isomer mixture contained the four positional *cis/trans* isomers at about 20% each, with smaller amounts of the corresponding *trans,trans* and *cis,cis* forms (12).

Not all isomers of CLA have comparable physiological effects, and much remains to be determined about the activities of the individual isomers. The *cis*-9,*trans*-11-18:2 isomer is believed to be the principal isomer responsible for the anticarcinogenic effects of CLA mixtures (13). A CLA isomer other than *cis*-9,*trans*-11-18:2 was shown recently to suppress liver stearyl-CoA desaturase mRNA expression (14), whereas the *trans*-10,*cis*-12 isomer has very recently been shown to regu-

late body composition in mice (15) and to influence serum lipid composition and body fat content in hamsters (16). It has not yet been established which CLA isomers are responsible for the antidiabetic and antiatherogenic effects reported for this family of molecules. Furthermore, the CLA isomers have been shown to be incorporated differently into tissue phospholipids of pigs fed a CLA mixture (17). The *cis*-11,*trans*-13-18:2 isomer was found preferentially incorporated into all heart lipids of the animals, particularly diphosphatidylglycerol (DPG). On the other hand, *cis*-9,*trans*-11-18:2 was preferentially incorporated into all liver lipids, with the exception of DPG, which incorporated a higher amount of the 11,13-18:2 isomer. DPG is a unique component of the inner mitochondrial membrane. These observations raise questions as to the effect of the 11,13 CLA isomer on the enzymes of oxidative phosphorylation. These studies indicate the need for evaluating each individual CLA isomer, which requires the preparation of larger amounts of enriched or purified CLA isomers.

To prepare sufficient amounts of some isomers for dietary supplementation, synthesis from methyl 12-hydroxyoctadec-*cis*-9-enoate (ricinoleate) was proposed (18). However, large-scale implementation of this method may be difficult. Thus, there is interest in the further development of methods for the fractionation of CLA mixtures.

Lipases (EC 3.1.1.3) are enzymes that hydrolyze or synthesize fatty acid esters and related compounds, the direction of the reaction being largely dependent on the water activity of the system. Depending on biological origin, lipases exhibit varying degrees of selectivity with regard to the alcohols or fatty acids upon which they will react. Such selectivities have been used for the selective enrichment of eicosapentaenoic (20:5) and docosahexaenoic (22:6) acids (19,20) and γ-linolenic acid (21). Enzyme-catalyzed fatty acid interchange reactions to alter the fatty acid content of glycerides have been conducted at the industrial scale for years (22), thus establishing the feasibility of large-scale enzymatic modification of fats and oils.

Lipases have recently been used to enrich triglycerides with CLA obtained by alkali isomerization of linoleic acid (23,24). Up to 70% of the CLA was incorporated into mono-, di-, and triacylglycerols (23). The isomeric content of the CLA used in those experiments was determined by a gas chromatographic method (2) incapable of resolving all CLA isomers (12,17). It is therefore not known if the synthetic mixture was a two- or a four-positional isomer mixture, and if the lipases used showed any selectivity toward any isomer. It would appear that the lipases investigated showed little selectivity, since the reported degree of CLA esterification exceeded the *cis*-9 content of either a typical two-isomer (41%) or four-isomer (29%) CLA mixture (12). If CLA-enriched lipid products are intended for experimental or general food use, it could be advantageous to enrich them with biologically efficacious CLA isomers.

Substrate-selective lipases are known, and among the premier examples of these are lipases produced by some fungi of the genus *Geotrichum*. Depending on the isolate and isozyme examined, these enzymes display various degrees of selectivity for fatty acids possessing a *cis*-9 double bond (25–29). We have examined the abilities of preparations of *G. candidum* lipase to distinguish between the various CLA isomers. Both the enzymatic esterification of mixtures of CLA as free fatty acids (FFA) with alcohols to form simple esters and the hydrolysis of mixed CLA esters were investigated in this study.

MATERIALS AND METHODS

Reagents and enzymes. The free fatty acid (#UC-59-A) and methyl ester (#UC-59-M) forms of mixed CLA isomers were obtained from Nu-Chek-Prep (Elysian, MN). Olive oil and polyvinylpyrrolidone were obtained from Sigma (St. Louis, MO). Linoleic acid (>95% purity) was obtained from Roche Products (Basel, Switzerland). *Geotrichum candidum* lipase preparation GC-4 was obtained from Amano Pharmaceutical (Nagoya, Japan). A lipase preparation obtained by expressing the highly *cis*-9 selective B lipase gene of *G. candidum* CMICC 335426 (29) in a *Pichia pastoris* expression system (30) was graciously provided by Drs. R. Schmid and U. Bornscheuer of the Institut für Technische Biochemie, University of Stuttgart (Stuttgart, Germany). Solvents and alcohols used in enzymatic reactions were dried over molecular sieves prior to use. All solvents were distilled-in-glass quality. A solution of (trimethylsilyl)diazomethane in hexane (2 M) was obtained from Aldrich Chemical Co. Inc. (Milwaukee, WI).

Laboratory preparation of CLA. The method was based on the procedure described by Ip *et al.* (31) as follows: 50 g of >95% pure linoleic acid was added to a solution of 15 g NaOH and 290 g ethylene glycol. The mixture was heated for 2 h under nitrogen at 180°C. The reaction mixture was cooled and after neutralization with HCl the fatty acids were extracted twice with hexane. The hexane was subsequently removed by rotary evaporation. The product contained 92% CLA of which 49.7% was the *cis*-9,*trans*-11 isomer and 50.3% was the *trans*-10,*cis*-12 isomer according to gas chromatography (GC) analysis. Traces of other CLA isomers were observed on gas chromatograms, but owing to their low concentrations were not considered for the purposes of this study.

Enzyme characterization and immobilization. Lipase activities were measured titrimetrically at 35°C using a continuous titrating pH meter and 10 mM NaOH to determine the rate of fatty acid release from emulsified olive oil in aqueous solution (32). Activities were determined at the pH values of maximal activity: pH 7.0 for *G. candidum* GC-4 (manufacturer's recommendation), and pH 8.5 for the lipase B preparation (30). One Olive Oil Unit of activity released 1 meq of FFA from emulsified olive oil per minute. The *G. candidum* B lipase preparation contained 1583 Olive Oil U/g, and the GC-4 preparation had an activity of 3556 Olive Oil U/g.

For use in organic solvents, *G. candidum* lipases (4000 U of lipase B or 9000 U of GC-4) were dissolved in 26 mL of 0.05 M Tris-HCl (pH 8.5 for lipase B, pH 7.2 for GC-4) and deposited by evaporation onto 10 g of Celite 545 (Fisher Scientific, Fair Lawn, NJ) (33).

Lipase-catalyzed hydrolysis of CLA methyl ester mixtures. Nonimmobilized *G. candidum* lipase B (4.5 U) or GC-4 (10.0 U) lipase was incubated under nitrogen with stirring at 35°C in 4 mL of emulsified substrate consisting of commercial CLA methyl ester (190 mM), $CaCl_2$ (15 mM) and polyvinylpyrrolidone (0.5%, wt/vol) in 0.1 M Tris-HCl, pH 8.5. At selected times, 0.5-mL aliquots were removed and extracted with 2.5 mL of hexane/isopropanol/acetic acid (57:38:5, by vol). To calculate degrees of hydrolysis, the amounts of FFA and fatty acid methyl ester (FAME) in the organic phase were determined by high-performance liquid chromatography (HPLC) using a modification of the method of El-Hamdy and Christie (34) that employed a Chrompack (Raritan, NJ) Spherisorb CN column (3 mm diameter × 10 cm, 5-mm particle size) connected to an evaporative light scattering detector (ELSD IIA; Alltech Associates, Inc., Deerfield, IL) and developed isocratically with hexane/methyl *tert*-butyl ether (98:2, vol/vol). Peak areas were quantitated by reference to standard curves for linoleic acid or methyl linoleate, as appropriate. To speciate the CLA isomers, the products of lipase action were isolated, the FFA fraction was methylated, and the isomers in each fraction were identified as described below in the section on separation and derivatization of products of lipolysis.

Lipase-catalyzed esterification of CLA FFA mixtures. Seventy milligrams (0.25 mmol) of commercial mixed CLA FFA, 0.25 mmol of methanol or ethanol, and 15 mg of immobilized *G. candidum* lipase were added to 1 mL organic solvent containing 0.02% water (vol/vol). The mixture was capped and incubated with mixing for 22.5 h at 30°C. The solvent was removed under N_2, the residue was resuspended in 4 mL hexane/isopropanol/acetic acid (57:38:5, by vol), and enzyme was removed by filtration through polytetrafluoroethylene filters. The FFA and FAME fractions were separated, the FFA fraction was methylated, and CLA isomer contents were determined as described in the next parargaph.

Separation and derivatization of the products of lipolysis. The lipase reaction product in the organic phase was concentrated with a stream of N_2 and separated into its FFA and FAME fractions by thin-layer chromatography (TLC) on Silica Gel G plates (20 × 20 cm, 250 µm thickness; Analtech, Newark, DE) developed with hexane/diethyl ether/acetic acid (80:20:1, by vol). The FFA and FAME bands were visualized under ultraviolet light after spraying the TLC plates with a solution of 2′,7′-dichlorofluorescein in methanol. The acid and ester bands were scraped off the plate and separately eluted with chloroform. The FFA samples were dried under a stream of N_2 and methylated in a screw-cap test tube with a Teflon liner by adding 2 mL of benzene/methanol (4:1, vol/vol) and 1 mL of (trimethylsilyl)diazomethane (35). The reaction was carried out at room temperature for 15 min, during which time the test tube was shaken occasionally. Unreacted (trimethylsilyl)diazomethane was destroyed by adding acetic acid until the yellow color disappeared. After addition of 1.6 mL of methanol and 0.1 mL of water, the FAME were extracted with 2 mL of hexane. The FAME fraction and the methylated FFA fraction were analyzed by silver-ion–HPLC (Ag^+–HPLC) as described below, and by GC as previously described (17).

Selective esterification of laboratory-prepared CLA with octanol using Amano GC-4 lipase preparation. Approximately 2.8 g of 1-octanol was mixed with 6 g of laboratory-prepared CLA isomers to give a mole ratio of 1:1. To this was added a solution of 60 mg of Amano GC-4 lipase powder in 18 mL of distilled water. No organic solvents were used. The reaction mixture was agitated magnetically at 25°C. Samples of the oil phase were periodically removed, and the course of the reaction monitored by titration of the FFA with dilute HCl. Octyl esters were separated from unreacted fatty acids by TLC as described above, and the CLA composition determined by GC as described below.

Analysis of laboratory-prepared CLA by GC. FFA were converted to methyl esters by reaction with methanolic HCl. Up to 100 mg of sample was transferred into a 15-mL screw-capped glass vial and dissolved in 4–5 mL of 5% (vol/vol) HCl in methanol and reacted on a hot block at 70°C for 2 min to minimize artifact formation. After cooling, 2 mL of isooctane and 5 mL of water were added. The upper isooctane layer was removed, dried over anhydrous sodium sulfate, and the concentration adjusted for GC analysis.

Octyl esters were transesterified to methyl esters by reaction with sodium methoxide/methanol. The sample (10–20 mg) was transferred to a 15-mL screw-capped glass vial. Two milliliters of 0.5 N sodium methoxide in methanol reagent was added and the solution reacted for 5 min at 70°C.

Methyl ester derivatives of octyl CLA were analyzed on a 50 m, 0.25 mm i.d., 0.2 µm film, Chrompack CP-Sil 88 capillary GC column using helium as the carrier gas. The column oven was held at 120°C for 1 min, then raised to 160°C at 20°C/min, 160–180°C at 0.5°C/min, and finally 180–230°C at 3°C/min. A Perkin Elmer (Norwalk, CT) 8420 GC system fitted with programmable temperature vaporizing (PTV) injection in split injection mode, an AS8300 autosampler, and a flame-ionization detector (FID) was used. The PTV injector was held at 50°C for 0.1 min during injection, then raised to 260°C for 3.5 min for transfer of the sample into the column oven zone. Injection volumes (0.5 µL) of 10–25 mg/mL solutions were used, with split ratios adjusted for optimal column loading. The FID detector temperature was set at 260°C. The total run time was 60 min.

Ag^+–HPLC. The identity and content of CLA isomers in the fatty acid ester and FFA (after conversion to FAME) fractions were determined by HPLC using three ChromSpher 5 Lipids (4.6 mm i.d. × 25 cm, 5-mm particle size) Ag^+–HPLC columns (Chrompack) in series (36). The columns were operated isocratically at a flow rate of 1.1 mL/min with a mobile phase of 0.1% (vol/vol) acetonitrile in hexane, freshly prepared daily. CLA esters were detected by monitoring absorbance at 233 nm, where conjugated dienes absorb strongly. The identities of the various CLA isomers were established by combined GC–electron impact mass spectrometry and GC–Fourier transform infrared spectrometry, and by comparison to CLA standards (12).

RESULTS AND DISCUSSION

Hydrolysis of CLA esters by G. candidum *lipase B*. The commercial methyl ester preparation of CLA was resolved into 12 CLA peaks using three Ag+–HPLC columns in series (Fig. 1A). These peaks consisted of four positional CLA isomers of each of the geometric *trans,trans*, *cis/trans,* and *cis,cis* isomers. The *cis/trans* geometric isomers of commercial CLA mixtures were previously identified, in the order of their elution under the HPLC conditions used, as *cis*-11,*trans*-13-18:2, *trans*-10,*cis*-12-18:2, *cis*-9,*trans*-11-18:2, and *trans*-8,*cis*-10-18:2 (12,36). In using three Ag+–HPLC columns in series as described here, it was not possible to cleanly resolve the opposite *cis/trans* isomers (e.g., *cis*-8,*trans*-10, *trans*-9,*cis*-11, etc.), given the vast excesses of their partner isomers. These opposite isomers have previously been shown to constitute but a very minor fraction of the commercial CLA employed here (12,36). On the basis of relative peak areas of the detector chromatogram, the *cis*-9,*trans*-11 CLA isomer constituted 34% of the total CLA content.

Representative Ag+–HPLC separations of the CLA methyl ester fraction remaining after 30 min and after 4 h of hydrolysis by *G. candidum* lipase B are shown in Figures 1B and 1C. A progressive reduction of the proportion of *cis*-9,*trans*-11-18:2 isomer to about 20% after 30 min, and 8% after 4 h, occurred (Table 1). The overall extent of hydrolysis after 4 h of reaction was 20%. There were no significant reductions in the normalized peak areas of any of the other components of the mixed CLA isomer ester mixture during incubation with lipase. The resultant FFA fractions contained 95% *cis*-9,*trans*-11-18:2 FFA after 30 min and 94% after 4 to 6 h (Table 1). The Ag+–HPLC separation of the FFA fraction produced during hydrolysis is shown in Figure 2A. Besides the major *cis*-9,*trans*-11-18:2 isomer, there were small amounts of *cis*-9,*cis*-11-18:2 and *trans*-10,*cis*-12-18:2, and trace amounts of *trans*-9,*trans*-11-18:2, *cis*-11,*trans*-13-18:2, and *trans*-8,*cis*-10:18:2 (Fig. 2A). By optimization of reaction conditions it may be possible to further reduce the levels of *cis*-9-CLA isomers in the ester mixture.

It was of interest to determine if *G. candidum* lipase B removed primarily the *cis*-9,*trans*-11-18:2 from the commercial

CLA FAME mixture in 4 h, leaving the ester of the opposite geometric isomer *(trans*-9,*cis*-11-18:2) unhydrolyzed, or if some *trans*-9,*cis*-11-18:2 ester was also hydrolyzed by the enzyme. GC is able to resolve the *cis/trans*-9,11 isomers of CLA. The results of GC analysis of the ester and FFA fractions obtained after CLA FAME hydrolysis by *G. candidum* lipase B are shown in Figure 3. The resolution, obtained using a 100 m CP-Sil 88 (Chrompack) fused-silica capillary column, was similar to that described previously (17). GC did not resolve the *cis/trans* CLA isomers *cis*-9,*trans*-11 and *trans*-8,*cis*-10. However, the *trans*-9,*cis*-11, *cis*-11,*trans*-13, and *trans*-10,*cis*-12 isomers were separated. All four positional *cis,cis* isomers were separated in the order 8,10-, 9,11-, 10,12-, and 11,13-18:2. The four positional *trans,trans* isomers were separated as two peaks: 11,13-18:2 followed by an unresolved mixture of 8,10-, 9,11-, and 10,12-18:2. By GC, only a trace peak was found corresponding to *trans*-9,*cis*-11-18:2 in the original CLA FAME mixture (Fig. 3A), and this peak remained in the ester fraction following incubation with lipase (Fig. 3B). None of this CLA isomer was detected in the FFA fraction generated during a 4 h incubation with *G. candidum* lipase B (Fig. 3C).

Further evidence for the lack of hydrolytic activity against the ester of *trans*-9,*cis*-11-18:2 was provided by Ag^+–HPLC. While a single ChromSpher 5 Lipids column did not resolve the geometric pair of 9,11 *cis/trans* CLA isomers (12), three Ag^+–HPLC columns in series just barely separated this pair (36), and six columns in series resulted in clear resolution (37). Analysis of the remaining FAME of the commercial CLA mixture after 4 h of incubation with *G. candidum* lipase B using six columns in series showed that the 9,11-18:2 peak was residual *cis*-9,*trans*-11-18:2 isomer (Fig. 4). There was no evidence of the opposite isomer. Therefore, by a combination of GC and Ag^+–HPLC it was possible to identify the CLA isomers by their relative elution order, and to characterize the specificity of the *G. candidum* lipase. The trace components were not confirmed by GC–mass spectrometry in this study.

Upon inspection of Figures 1 and 2 it is tempting to speculate that the *cis*-9,*cis*-11 isomer is also relatively enriched in the FFA fraction during hydrolysis by the *G. candidum* lipases. This would be expected on the basis of the known selectivity of the enzymes. However, owing to the very low levels of this isomer in the starting material and product, it is not possible to provide quantitative data.

The prominent enrichment of the *cis*-9,*trans*-11 isomer in the FFA fraction indicates that *G. candidum* lipase B exhibited high selectivity for *cis*-9 unsaturates in the hydrolysis of the methyl esters of mixed CLA isomers. The activity and degree of selectivity for *cis*-9,*trans*-11 CLA during hydrolysis were reproducible, as illustrated by the similar contents of this

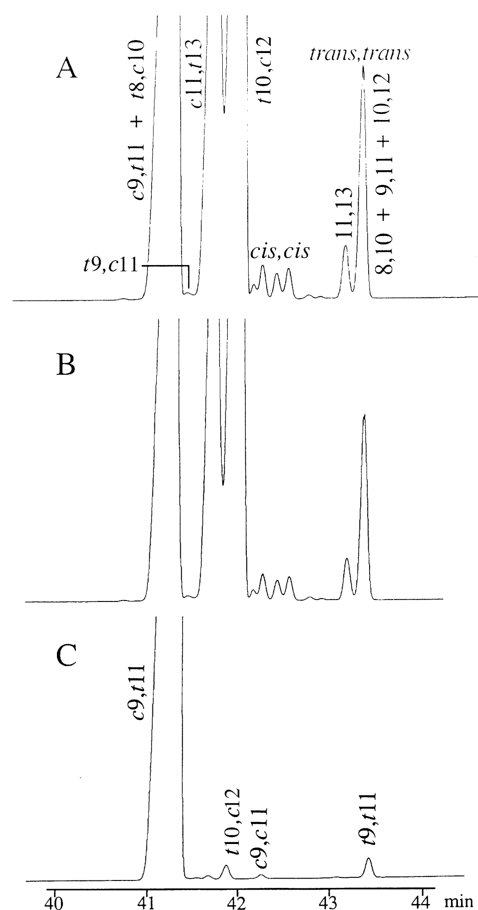

FIG. 3. Partial gas chromatograms of CLA methyl ester hydrolysis by *G. candidum* lipase B using a 100-m CP Sil 88 column. (A) Composition of the CLA methyl ester mixture before incubation with lipase. Composition of the remaining CLA methyl esters (B) and the FFA released by the lipase (C) after 4 h incubation. Peak identities are indicated. For abbreviations see Figures 1 and 2.

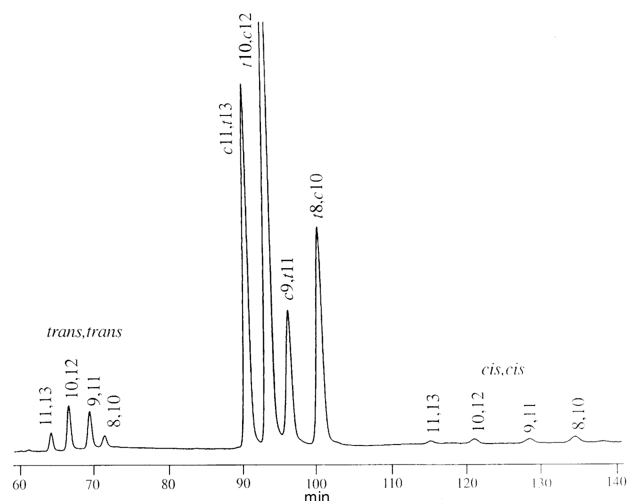

FIG. 4. Ag^+–HPLC separation, using six Ag^+–HPLC columns in series, of the fatty acid esters remaining after a 4 h incubation of a commercial mixture of CLA methyl esters with *G. candidum* lipase B. The *cis/trans* pairs of the 9,11- and 11,13-CLA isomers separate under these conditions (37). The 9,11-18:2 CLA isomer peak of this remaining ester fraction was *cis*-9,*trans*-11-18:2, with no detectable *trans*-9,*cis*-11-18:2. For abbreviations see Figures 1 and 2.

isomer in replicate reactions using the lipase B preparation (Table 1).

Hydrolysis of CLA esters by the Amano GC-4 preparation of G. candidum *lipase*. Similar, though less absolute, selectivity was exhibited by the Amano GC-4 preparation of *G. candidum* lipase in the hydrolysis of commercial mixed CLA methyl esters. The degree of overall hydrolysis during a 4-h incubation was 31%. The resulting FFA fraction contained 77% *cis*-9,*trans*-11 CLA (Table 1; Fig. 2B), significant amounts of the other three *cis/trans* positional isomers (8,10-18:2, 10,12-18:2, and 11,13-18:2), and trace amounts of several *trans,trans* and *cis,cis* CLA isomers (Fig. 2B).

Methylation of commercial CLA FFA isomers by G. candidum *lipase B*. The activity and selectivity of the *G. candidum* lipases when catalyzing the esterification of commercial mixed isomer mixtures of CLA FFA were also investigated. Preliminary experiments demonstrated that in the esterification of CLA with methanol, immobilized *G. candidum* lipase B was active in 3-heptanone but not in hexane or isooctane. Thus 3-heptanone was employed in esterification reactions with this enzyme when the alcohol was methanol. Water was added to the solvent to a concentration of 0.02% (vol/vol) since this increased activity by 10%. GC-4 lipase was not active in any of these solvents. However, when ethanol was the esterifying alcohol, both *G. candidum* lipase preparations were active in all three solvents at water levels of 0.02% (vol/vol). Activities in hexane and isooctane under these conditions were approximately twice that obtained with 3-heptanone.

Incubation of a commercial preparation of CLA FFA containing at least 12 different isomers (Fig. 5A) with methanol and *G. candidum* lipase B in 3-heptanone resulted in the selective esterification of the *cis*-9,*trans*-11 isomer. The proportion of this isomer in the FFA fraction was reduced from 34% to about 25% during a 22.5 h incubation (Table 2), with no apparent reductions in the amounts of other CLA isomers in the FFA fraction (Fig. 5B). Extents of esterification ranged from 8 to 13%. The fatty acid ester product of this reaction was highly enriched in *cis*-9,*trans*-11 CLA, which constituted more than 98% of this fraction (Fig. 5C). Only trace amounts of the other *cis/trans* isomers and of *trans*-9,*trans*-11-18:2 were observed (Fig. 5C). Thus, high specificity for the *cis*-9 isomer is displayed by *G. candidum* lipase B in the esterification of CLA FFA. However, as generally observed, enzyme activity in organic solvents (esterification) was considerably reduced compared to that seen in water (hydrolytic reactions).

Ethylation of CLA FFA isomers by G. candidum *lipase B.* Similarly high substrate selectivity was demonstrated during lipase B-catalyzed synthesis of the ethyl, rather than methyl, esters of CLA. In this case, the proportion of the *cis*-9,*trans*-11 CLA isomer in a mixture of FFA isomers of CLA was reduced from 34% (Fig. 6A) to as low as 16% (Fig. 6B, Table 2). Compared to isooctane, the enzyme exhibited higher activity, but no greater selectivity, in hexane (Table 2). The ethyl ester fraction produced was 96% *cis*-9,*trans*-11-CLA (Table 2). The *trans*-10,*cis*-12-18:2 isomer appeared to constitute the bulk of the contaminants (Fig. 6C).

Ethylation of CLA FFA by the Amano GC-4 preparation of G. candidum *lipase.* GC-4 lipase showed much less activity than did lipase B in the esterification of CLA isomers, esterifying 1.1% of the substrate during a 22.5 h incubation. The specificity of this enzyme for *cis*-9,*trans*-11 CLA was also lower than that of lipase B. The ethyl ester fraction generated by incubation of a commercial mixed CLA FFA preparation with GC-4 lipase consisted of 80% *cis*-9,*trans*-11-CLA (Fig. 6D, Table 2). The *cis*-11,*trans*-13-, *trans*-10,*cis*-12-, and *trans*-8,*cis*-10-18:2 isomers constituted the bulk of the remainder of the ethyl ester fraction, plus trace amounts of *trans,trans* and unidentified *cis/trans* isomers (Fig. 6D).

Selective esterification of laboratory-prepared CLA isomers using an aqueous solution of G. candidum *lipase.* The esterification of laboratory-prepared CLA with octanol was catalyzed using an aqueous solution of Amano GC-4 lipase as described in the Materials and Methods section. The course of the reaction was followed by measuring the decrease in FFA concentration. After 72 h of reaction, a conversion of 35% (i.e., a decrease in the FFA concentration of 35%) was attained. A sample of the oil was fractionated by TLC, and the fatty acid composition of the unreacted FFA and the octyl esters was determined by GC. The octyl ester fraction was composed of 97.6% of the *cis*-9,*trans*-11 isomer while the unreacted fatty acids were correspondingly depleted in this isomer, with a concentration of 70.7% of the *trans*-10,*cis*-12 isomer. Clearly the lipase had shown a strong preference for the *cis*-9,*trans*-11 isomer with a very low relative reaction rate toward the *trans*-10,*cis*-12 isomer.

In another experiment, the reaction was allowed to proceed for 96 h, resulting in a conversion of 53%. Analysis of the re-

[b]Results of representative independent experiments. For abbreviations see Table 1.

action products revealed that the octyl ester fraction contained 81% of the *cis*-9,*trans*-11 isomer, and the FFA fraction contained 85% of the *trans*-10,*cis*-12 isomer. At the higher degree of conversion, a lesser enrichment of the *cis*-9,*trans*-11 isomer was obtained owing to competition from the gradually increasing relative concentration of the unreacted *trans*-10,*cis*-12 isomer remaining in the FFA fraction. However, the higher conversion resulted in a high degree of enrichment of the *trans*-10,*cis*-12 isomer (85%). By careful control of the reaction conditions both the *cis*-9,*trans*-11 and the *trans*-10,*cis*-12 isomers can be enriched using this reaction system.

During the preparation of this manuscript, a brief report by Chen and Sih (38) demonstrated selectivities similar to those reported here for commercial enzyme preparations from *G. candidum* and *Aspergillus niger.* The substrate used was reported to be a two-isomer CLA mixture containing *cis*-9,*trans*-11-18:2 and *trans*-10,*cis*-12-18:2, not the more complex multiple-isomer mixture used in parts of the work reported here. Owing to differences in methods, the results of Chen and Sih (38) are not directly comparable to those reported here. However, it appears that the enzymes investi-

gated here display *cis*-9,*trans*-11-18:2 selectivities that are similar to or greater than those of the enzymes studied by Chen and Sih (38). Furthermore, a better resolution of the products of enzyme reaction, by the use of three to six Ag^+–HPLC columns as in the present study, is advisable in order to identify minor CLA isomers in the starting material and products.

CONCLUSION

In conclusion, two different preparations of *G. candidum* lipase were shown to be selective for *cis*-9,*trans*-11-18:2. The B lipase isoenzyme showed high selectivity for *cis*-9,*trans*-11-18:2 in both hydrolysis and esterification reactions. During aqueous hydrolysis, and also during esterification in a nonaqueous system, the GC-4 preparation displayed selectivity for *cis*-9,*trans*-11-CLA isomers, though it was less stringent, as well as less active, than the B lipase preparation. An aqueous esterification system using octanol with GC-4 resulted in higher selectivity, comparable to that displayed by lipase B.

Selective lipase-catalyzed fractionation has the potential of being scaled up to produce both *cis*-9,*trans*-11-18:2 and *trans*-10,*cis*-12-18:2 of considerable purity. Both may have use in determining the biochemical and physiological effects of these molecules, and as nutritional supplements. The enzyme-catalyzed esterification process would be more practical than the hydrolysis reaction, since the industrial preparation of CLA by alkali isomerization of linoleic acid produces FFA (10).

Enhancement of Both Reaction Yield and Rate of Synthesis of Structured Triacylglycerol Containing Eicosapentaenoic Acid Under Vacuum with Water Activity Control

Jeong Jun Han and Tsuneo Yamane*

Laboratory of Molecular Biotechnology, Department of Biological Mechanisms and Functions, Graduate School of Bio- and Agro-Sciences, Nagoya University, Nagoya 464-8601, Japan

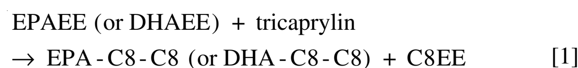
ABSTRACT: Production of structured triacylglycerols (sTAG) containing eicosapentaenoic acid (EPA) at the *sn*-1 (or 3) position using Lipozyme in a solvent-free system was studied. Optimal water activity (a_w) for the synthesis of the sTAG was investigated. Vacuum was applied to shift reaction equilibrium toward the synthesis reaction by removing by-products. During vacuum application, the water level of the reaction system was controlled at the optimal level by addition of a suitable amount of water at a predetermined interval. Intermittent periodic addition of a suitable amount of water into the reaction mixture made the reaction rate faster than that without adding water. A molar yield of 89.7% of the targeted sTAG was obtained after 16 h reaction with a_w control during the vacuum application as compared with the yield of 87.0% after 24 h of reaction without a_w control during the vacuum application.

Paper no. L8233 in *Lipids 34,* 989–995 (September 1999).

n-3 Polyunsaturated fatty acids (PUFA), such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), have several health benefits toward cardiovascular disease, immune disorders and inflammation, renal disorders, allergies, diabetes, and cancer (1). These fatty acids also may be essential for brain and retina development in humans. For PUFA-based therapy, structured triacylglycerols (sTAG) containing PUFA are effective (2). In particular, sTAG containing one molecule of PUFA and two medium-chain fatty acids (MCFA) are notable (3). Several studies have been carried out on the synthesis of sTAG containing PUFA at a specific site(s) on the glycerol backbone (3–5).

The absorption of PUFA into the body may be dependent upon the position of PUFA on the glycerol backbone, i.e., at the *sn*-1 (or 3) or the *sn*-2 position (6–8). TAG containing PUFA at the *sn*-2 position and MCFA at the *sn*-1 and 3 positions can be hydrolyzed into 2-monoacylglycerol containing PUFA and fatty acids by pancreatic lipase and efficiently absorbed into intestinal mucosa cells in normal adults (8). Therefore, for dietary supplementation for adult health, sTAG containing PUFA at the *sn*-2 position and MCFA at the *sn*-1 and 3 positions may be suitable. On the other hand, owing to the antiatherogenic, antineoplastic, and anti-inflammatory effects of n-3 PUFA, their intake is important from an early age for eicosanoid synthesis as well as for normal neonatal brain and nerve development and cell membrane structure (9). Although PUFA are essential to the neonate for both normal growth and metabolism, neonatal intestinal function is immature, resulting in reduced levels of pancreatic lipase and bile salts (10). In addition, pancreatic lipase does not hydrolyze ester bonds containing long-chain n-3 PUFA (10). Therefore, in the case of the newborn, PUFA absorption by pancreatic lipase is not feasible. However, for neonatal absorption of PUFA, there is an alternative mechanism. PUFA are released from gastric digestion, and gastric lipase exhibits stereospecificity for the position of TAG and hydrolyzes the *sn*-3 position twice as fast as the *sn*-1 position (6,10). Therefore, for PUFA therapy for the neonate, sTAG containing PUFA at the *sn*-1 (or 3) position and MCFA at the other sites might be suitable. TAG containing two or more PUFA resist hydrolysis by lipase owing to their bulky structure (11). Hence, TAG containing one molecule of PUFA at the *sn*-1 (or 3) position and two MCFA at the remaining positions of the glycerol backbone are the target product in this study.

We reported lipase-catalyzed incorporation of EPA or DHA onto tricaprylin by a transesterification between tricaprylin and EPA ethyl ester (EPAEE) or DHA ethyl ester (DHAEE) in a solvent-free system as follows (12,13):



$$\text{EPAEE (or DHAEE)} + \text{tricaprylin} \rightarrow \text{EPA-C8-C8 (or DHA-C8-C8)} + \text{C8EE} \quad [1]$$

where EPA-C8-C8 is 1-eicosapentaenoyl-2,3-dicaprylin and/or 1,2-dicapryl-3-eicosapentaenoin, DHA-C8-C8 is 1-docosahexaenoyl-2,3-dicaprylin and/or 1,2-dicapryl-3-docosahexaenoin, and C8EE is caprylic acid ethylester.

From previous results, we recognized that Lipozyme was very stereospecific for EPA or DHA incorporation into the *sn*-1 or 3 position. Therefore, Lipozyme may be useful for the

production of sTAG containing PUFA at the *sn*-1 or 3 position, which might be effective for newborns.

In this work, we report effective production of sTAG containing one EPA at the *sn*-1 or 3 position using Lipozyme in a solvent-free system as a model reaction for the synthesis of sTAG containing one PUFA. Vacuum application was performed to shift reaction equilibrium toward synthesis reaction by removing by-product, C8EE.

Enzyme activity in organic media critically depends on the water level in the reaction system (14–16). Therefore, maintaining the optimal water level in the reaction system is very important for maximal enzyme activity (17,18). However, use of a vacuum may also remove essential water of both reaction medium and enzyme. Hence, in this study, we attempted to control optimally the water level of the reaction system during the vacuum application for the production of our target sTAG.

MATERIALS AND METHODS

Materials. Tricaprylin (1,2,3-trioctanoylglycerol) was from Wako Pure Chemicals Co. (Osaka, Japan). Dicaprylin (1,3-dioctanoylglycerol) was purchased from Funakoshi Co. (Tokyo, Japan). Pure EPAEE (*cis*-5,8,11,14,17-eicosapentaenoic acid ethyl ester) was kindly donated by Nippon Suisan Co. (Tokyo, Japan). All chemicals used were reagent grade, and the solvents used were high-performance liquid chromatography grade and purchased from Wako Pure Chemicals.

Lipozyme (Novo Nordisk Bioindustry, Chiba, Japan) was used as a catalyst. The initial water content of the Lipozyme used in this work was 2.4 ± 0.3% as determined with a Karl Fischer moisture meter (MKS-I, Kyoto Electronics Co. Ltd., Kyoto, Japan).

Determination of water sorption isotherm of Lipozyme. Lipozyme samples were preequilibrated in desiccators containing saturated salt solutions for 7 d at 25°C. The salts used were (a_w shown in parentheses): LiCl (0.12), $MgCl_2$ (0.33), $Mg(NO_3)_2$ (0.55), LiAc (0.67), and KCl (0.86). The water contents of the preequilibrated Lipozyme samples were analyzed by the Karl Fischer moisture meter.

Determination of water sorption isotherm of Lipozyme for adsorption from substrate solution and reaction medium. Reportedly, deactivating Lipozyme by prolonged exposure to over 100°C does not significantly affect water retention characteristics of Lipozyme (19). Heat-deactivated Lipozyme is also needed to prevent enzymatic reaction during investigation of the sorption curve. Therefore, heat-deactivated anhydrous Lipozyme was used to investigate the water sorption curve of Lipozyme from the reaction medium. Lipozyme samples were heat-deactivated during 1 wk at 105°C. Substrate solution of tricaprylin and EPAEE (molar ratio = 3:1) was mixed and made anhydrous by adding molecular sieve. The resultant reaction mixture obtained from a transesterification reaction between tricaprylin and EPAEE (molar ratio = 3:1) after 9 h was centrifuged at 10,000 rpm for 5 min to remove the enzyme. Molecular sieves were added to remove water from the supernatant. Heat-deactivated anhydrous Lipozyme samples (50 mg) were put into each 1.5-mL microtube, and 580 mg of the anhydrous substrate solution or the 9-h reaction mixture was added into each microtube. An amount of water (2, 4, 6, 8, 10, or 12 µL) was added into each microtube, and the tubes were vigorously vortexed, maintained for 1 h at room temperature, and then centrifuged for 5 min at 10,000 rpm. Water contents of the supernatants were checked on the Karl Fischer titrator.

Determination of dewatering rate of substrate solution by vacuum. Water (580 µL) was added to the mixture of 17.4 g of substrate solution (molar ratio of tricaprylin and EPAEE = 3:1) and 1.5 g of heat-deactivated anhydrous Lipozyme. Vacuum (3 mm Hg) was applied to determine the dewatering rate at 40°C. Samples were withdrawn at predetermined time intervals, and the water contents of the samples were checked on the Karl Fischer titrator.

Transesterification reaction. In order to determine optimal a_w for the synthesis of the sTAG, 300 mg of Lipozyme and 6 mmol of tricaprylin were preequilibrated separately in desiccators containing saturated salt solutions for 7 d at 25°C. For the investigation of the effect of a_w on the synthesis of the sTAG, the a_w of enzyme and all the substrates should be adjusted to the same value. However, since the equilibration process takes time, the result may be complicated by oxidation of EPAEE. Water solubility in EPAEE is low enough to be ignored in comparison with that in tricaprylin and Lipozyme. Therefore, in the present investigation, only a_w of lipase and of tricaprylin were adjusted. The salts used were the same as described in the section of determination of sorption isotherm of Lipozyme. The preequilibrated tricaprylin at each a_w and EPAEE were mixed by a magnetic stirrer in a closed vial, and each vial was placed into a water bath at 40°C. The reaction was started by adding lipase preequilibrated at each a_w at 400 rpm.

Molar ratios of tricaprylin/EPAEE of 5:1, 6:2, 4:2, and 2:2 were investigated to study the effect of molar ratio on the incorporation of EPAEE with tricaprylin at 40°C. Unless otherwise stated, transesterification was performed at a molar ratio of 30 mmol tricaprylin to 10 mmol EPAEE at 40°C using 1.5 g of Lipozyme.

Intermittent addition of a suitable amount of water to the reaction mixture was intended to maintain the optimal a_w of the reaction system. From the polynomial data of the water sorption isotherms of reaction medium and Lipozyme was calculated the range of water content of reaction medium corresponding to the target range of a_w. From the polynomial data of the dewatering rate by vacuum from the mixture of substrate solution (molar ratio of tricaprylin and EPAEE = 3:1) and Lipozyme, the time interval of adding water and the necessary amount of water to be added were determined. The calculated amount of water was added into the reaction medium intermittently at the determined time interval (*ca.* 10 min). Yield was calculated according to the following equation:

$$\text{yield (\%)} = 100 \times \text{mole of EPA-C8-C8/mole of EPAEE used as a substrate} \quad [2]$$

Chromatographic analysis. For time-course analysis, aliquots were taken from the vial at predetermined intervals and diluted to 1% solutions in chloroform. Solid materials were removed by filtration through a polytetrafluoroethylene membrane filter. Eluates (1 μL) were analyzed by our previously reported method (12) using a gas chromatograph (Shimadzu GC14A, Shimadzu Co., Kyoto, Japan) equipped with an OCI-14 capillary on-column injector. The column used was Supelco SGE HT5 aluminum-clad fused-silica capillary column (6 m long, 0.53 mm i.d., 0.15 μm film thickness; Supelco Inc., Bellefonte, PA). *n*-Eicosane was used as an internal standard. The oven temperature was programmed with an initial temperature of 50°C, held for 0.5 min, then heated to 110°C at 30°C /min, then to 140°C at 10°C/min, then to 250°C at 20°C/min, then to 330°C at 10°C/min, and then to 360°C at 5°C/min. The detector was maintained at 393°C. On-column injection was used for sample transfer onto the analytical column. The on-column injector was programmed with an initial temperature of 55°C held for 0.01 min, and then heated to 370°C at 40°C/min and held for 18 min. Helium was used as carrier gas at 15 mL/min.

To check isomeric purity of the synthesized sTAG containing one EPA, a silver ion–high-performance liquid chromatography method developed in our laboratory was used (12,13). Each sample was made into 1% solution in *n*-hexane/isopropanol (350:100, vol/vol) solution; 5 μL of the sample was injected, and analyzed by silver ion–high-performance liquid chromatography. All analyses were performed on a Chrompack 5 Lipid column (250 × 4.6 mm; Chrompack, Middelburg, The Netherlands) with ultraviolet detection at 206 nm. JASCO (Japan Spectroscopic Co. Ltd., Tokyo, Japan) model 880-DU solvent delivery was used, together with JASCO model UVDEC 100 detector. The solvent gradient program was as follows. Two solvent reservoirs contained (A) hexane/isopropanol/acetonitrile (350:100:2.75, by vol) and (B) hexane/isopropanol/acetonitrile (350:100:10, by vol). The gradient program was started with 100% A over 3 min, then gradient of A to 100% B over 10 min, and held for 20 min. The flow rate was 0.7 mL/min.

RESULTS AND DISCUSSION

As we reported previously (12), during the reaction, the targeted TAG containing one EPA was formed as a main product, and a small amount of TAG containing two EPA was formed. One molecule of EPA was likely incorporated into tricaprylin relatively easily, but incorporation of the second EPA molecule was much slower. Our previous results showed that Lipozyme was very stereospecific to the *sn*-1 or *sn*-3 position for EPA incorporation into tricaprylin (12). Therefore, production of the sTAG containing one EPA molecule at the *sn*-1 or 3 position was performed using Lipozyme.

Effect of molar ratio of tricaprylin to EPAEE for the synthesis of sTAG containing one EPA. Time-course changes of the conversion based on EPAEE at various molar ratios of tricaprylin to EPAEE are shown in Figure 1. The conversion increased as the molar ratio of tricaprylin to EPAEE increased from 1:1 to 3:1, but it did not increase much at molar ratios higher than 3:1 of tricaprylin to EPAEE. Therefore, subsequent experiments were done at a molar ratio of 3:1 tricaprylin to EPAEE.

Effect of vacuum on the conversion of sTAG synthesis. The reaction equilibrium may be shifted toward the synthesis reaction by removal of by-products. In our study, high vacuum was applied for removing by-product, i.e., C8EE. The effect of vacuum on the conversion based on EPAEE is shown in Figure 2. When vacuum was applied from the initial stage of the reaction, the reaction rate was very slow, which may be due to the removal of water necessary for optimal enzyme activity (data not shown). When a reaction was run at normal pressure for 9 h and then vacuum was applied, C8EE was slowly removed and the yield was gradually increased to 87.0% after 24 h. In this condition EPAEE was not removed (data not shown).

Effect of a_w *on the synthesis of sTAG.* Enzyme reactions in organic media critically depend on the level of a_w in the reaction system (14–16). Therefore, maintaining optimal a_w of the reaction system is very important for maximal production of the targeted product. However, in this study, vacuum was used for removing C8EE, and it may also remove water from the reaction medium and the enzyme, resulting in a decrease in the water necessary for optimal enzyme activity. Although

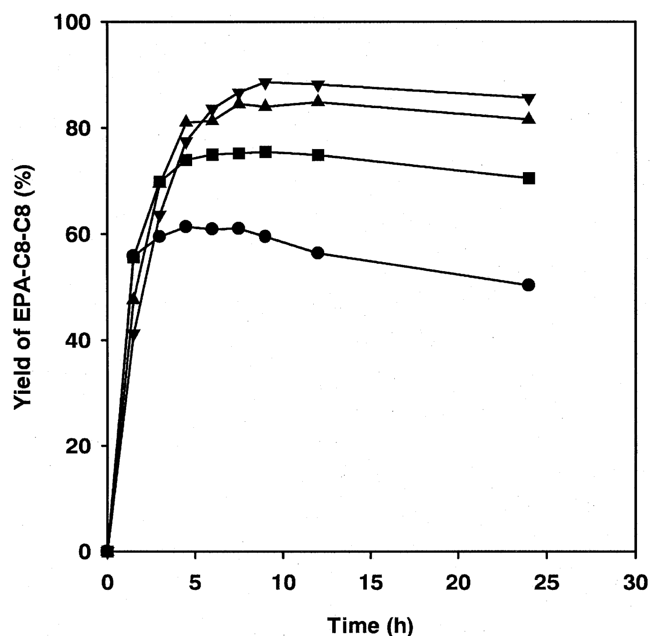

FIG. 1. Effect of molar ratio of substrates on molar yield of dicaprylleicosapentaenoin (EPA-C8-C8). Ratios of tricaprylin to eicosapentaenoic acid ethyl ester (EPAEE) are 2 mmol to 2 mmol (●), 4 to 2 (■), 6 to 2 (▲), and 5 to 1 (▼). The reaction was performed with 300 mg Lipozyme at 40°C and 400 rpm stirring speed.

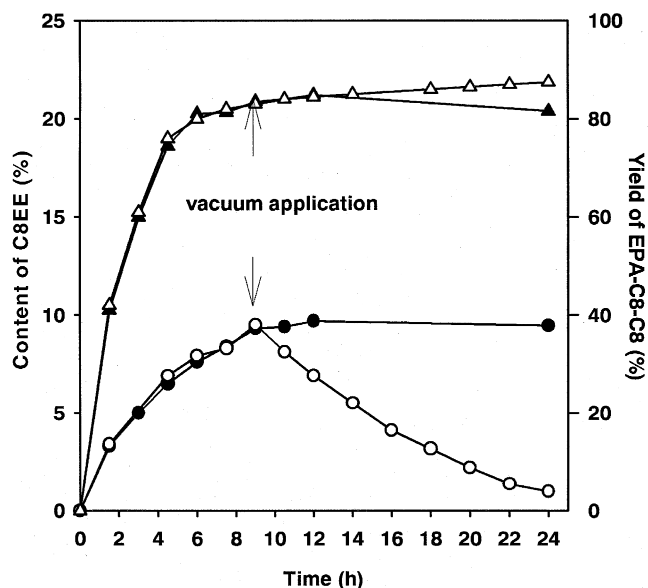

FIG. 2. Effect of vacuum on molar yield of EPA-C8-C8. The reaction was performed with 30 mmol tricaprylin, 10 mmol EPAEE, and 1.5 g Lipozyme at 40°C and 400 rpm stirring speed. The reaction was performed without vacuum at normal pressure in a closed vessel [▲, molar yield of EPA-C8-C8; ●, content of caprylic acid ethylester (C8EE)], followed by reaction under 3 mm Hg vacuum applied at 9 h thereafter (△, molar yield of EPA-C8-C8; ○, content of C8EE). For abbreviations see Figure 1.

it is often desirable to reduce the water content as much as possible so as to minimize unfavorable enzyme-catalyzed side reactions (i.e., hydrolysis), water also acts as a lubricant or plasticizer and allows enzymes to have more conformational mobility, required for optimal catalysis (20). Several reports have shown that water content has a profound influence on both yield and rate of reactions, and the suitable water content in the reaction medium is critical for optimal enzymatic activity (14–17).

The optimal water level must be determined empirically for each reaction. It would be desirable to be able to make some predictions. Unfortunately, this is hard to do in terms of the water content by weight or volume. Problems often arise in enzyme reactions in organic media because these reaction systems contain at least two distinct phases, and the water is distributed between them. Some of the water will be dissolved in the bulk organic liquid phase, and some will be in the more polar phase, sometimes as liquid water, sometimes bound to the solid-state enzyme (19). Water activity is preferable to moisture content for the characterization of all equilibria. The thermodynamic activity of water a_w is conventionally given relative to pure water at the same temperature and pressure, as follows:

$$a_w = P_{p,H_2O} / P_{p,H_2O,ref} \text{ (in equilibrium)} \quad [3]$$

where P_{p,H_20} is the vapor pressure of water in equilibrium with the system used and $P_{p,H_20,ref}$ is the vapor pressure at the same temperature above pure water. Like other activities, a_w is by definition equal in all phases at equilibrium. Hence, an organic reaction mixture may be characterized by a single a_w value, instead of water concentrations or contents in each phase (21–23).

Figure 3 shows the effect of initial a_w of substrate and lipase on the synthesis of the sTAG. Among the investigated a_w, synthetic rate of the targeted product was highest at 0.12, which means that optimal a_w of the reaction system for the product synthesis is near 0.12. Therefore, it was suggested that controlling a_w of the reaction system near 0.12 might maintain the highest reaction rate. Usually, however, water content of reaction medium can be checked easily during the reaction rather than a_w value. To this end, the relationship between the water content and a_w of the reaction medium is needed to know what level of water content of reaction medium corresponded to a certain value of a_w.

Sorption isotherm. The water sorption profile may be different as the result of a different partition of water in the medium if the polarity of the medium is different. That is, water content of a reaction medium at the same a_w may be different according to the polarity of the medium. In that case, estimating a_w by monitoring water content is very difficult. Isotherms for water sorption onto Lipozyme at two different conditions were investigated. In the first, water was adsorbed from a substrate mixture (molar ratio of tricaprylin to EPAEE = 3:1), whereas in the second case water was adsorbed from its 9-h reaction mixture. As shown in Figure 4A, the sorption isotherm curves had a similar profile, indicating that the polarity of medium was little changed. From the data fitting of

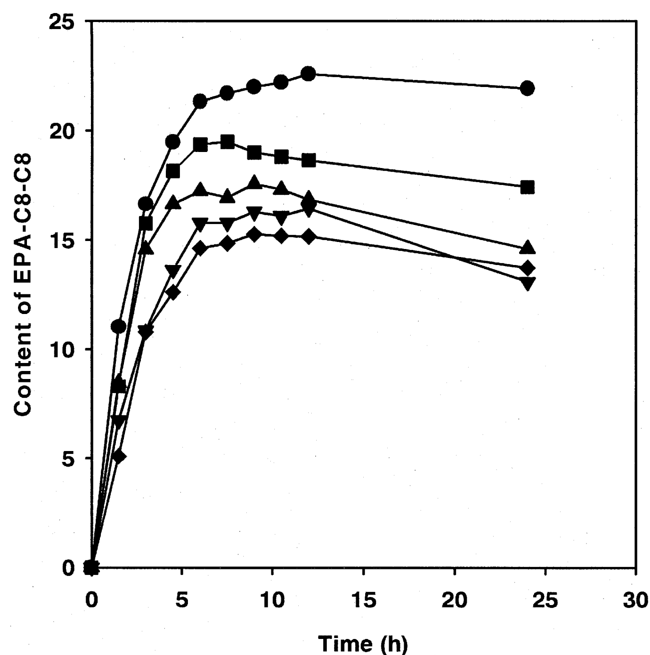

FIG. 3. Effect of initial water activity (a_w) on the synthesis of EPA-C8-C8. a_w = 0.12 (●); a_w = 0.33 (■); a_w = 0.55 (▲); a_w = 0.67 (▼); and a_w = 0.87 (◆). The reaction was performed with 6 mmol tricaprylin, 2 mmol EPAEE, and 300 mg Lipozyme at 40°C and 400 rpm stirring speed. For abbreviations see Figure 1.

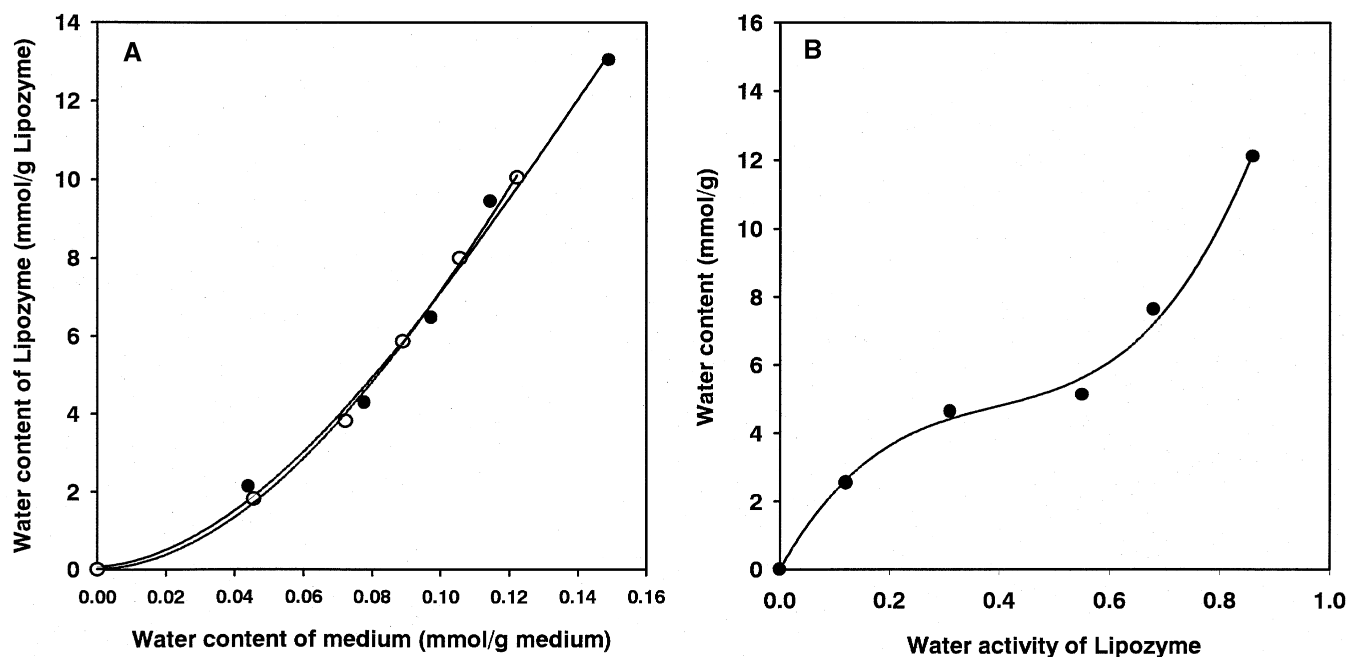

FIG. 4. Water sorption curves of substrate solution and its 9-h reaction mixture onto Lipozyme. (A) Water sorption curve of substrate solution (molar ratio of tricaprylin and EPAEE = 3:1) (○); water sorption curve of its 9-h reaction mixture (●). (B) Water sorption isotherm of Lipozyme. For abbreviation see Figure 1.

the isotherm of 9-h reaction mixture of water sorption onto Lipozyme, Equation 4 was obtained:

$$q_w = 5.30\, q_m + 851.40\, q_m^2 - 1990.25\, q_m^3 \quad [4]$$

where q_w is the water content of Lipozyme and q_m is the water content of the reaction mixture. From Figure 4A, one can know what level of water in reaction mixture corresponds to what level of water content of Lipozyme. The corresponding a_w of Lipozyme can be also estimated from the water sorption isotherm onto Lipozyme in Figure 4B, which shows the relationship between water content and a_w. From Figure 4B, the following polynomial equation was obtained:

$$q_w = 28.67\, a_w - 63.25\, a_w^2 + 53.97\, a_w^3 \quad [5]$$

where q_w is water content of Lipozyme and a_w is water activity of Lipozyme.

Since a_w is an equilibrium concept, it is equal in all phases at equilibrium. The a_w of Lipozyme may be also considered as the a_w of the reaction system under the assumption that the reaction system is in equilibrium state. The a_w of the reaction system could be inferred by monitoring water content of the reaction system during reaction.

Strategy for controlling a_w *of reaction medium during vacuum application.* As mentioned before, a lipase-catalyzed reaction is greatly influenced by a_w. In this study, vacuum application was intended to increase the reaction conversion by removing the by-product, i.e., C8EE. However, vacuum application also removes water from the reaction medium that is necessary for optimal enzyme activity. From the previous result of the effect of a_w on the sTAG synthesis, it was desirable to maintain the water level of the reaction system near 0.12 a_w during the reaction for the optimal production of the sTAG. In this study, intermittent addition of a suitable amount of water to the reaction mixture was intended to maintain the a_w of the reaction system near 0.12 during the vacuum application.

Our goal was to control a_w within the range of 0.07–0.17. From the polynomial data of sorption isotherms of Figure 4A and 4B, the range of water content of reaction medium corresponding to the target a_w range was calculated as 0.04–0.07 mmol/g reaction medium. To determine the time interval of adding water and the necessary amount of water to be added during the vacuum, the dewatering rate by vacuum from the mixture of substrate solution (molar ratio of tricaprylin and EPAEE = 3:1) and Lipozyme was investigated. The profile of dewatering rate was nonlinear as shown in Figure 5. The dewatering rate was high at higher water content, but it decreased as water content decreased. From the nonlinear regression of the data of dewatering profile, Equation 6 was obtained:

$$q_r = 0.0005 + 0.0026 \exp(-0.1883 t) \quad [6]$$

where q_r is water content of the reaction medium (mmol/g), and t is dewatering time (min).

From the nonlinear regression data of the dewatering rate by vacuum from the mixture of substrate solution (molar ratio of tricaprylin and EPAEE = 3:1) and Lipozyme, the time interval of adding water and the necessary amount of water to be added were determined. It took about 10 min for the water

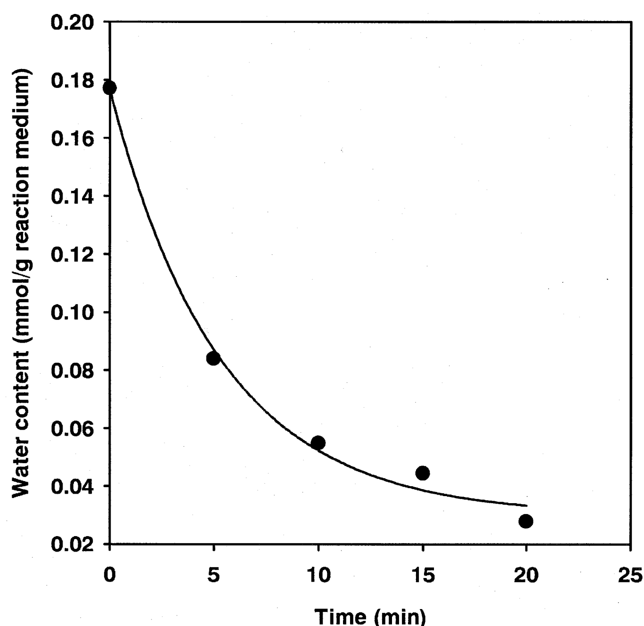

FIG. 5. Profile of dewatering rate by vacuum from the mixture of substrate solution and Lipozyme.

content of reaction medium to be decreased from 0.07 mmol/g reaction medium to 0.04 mmol/g reaction medium. The calculated amount of water (amount of water needed to replace the water evaporated from reaction medium and Lipozyme during vacuum application, *ca.* 2.46 μL/g reaction

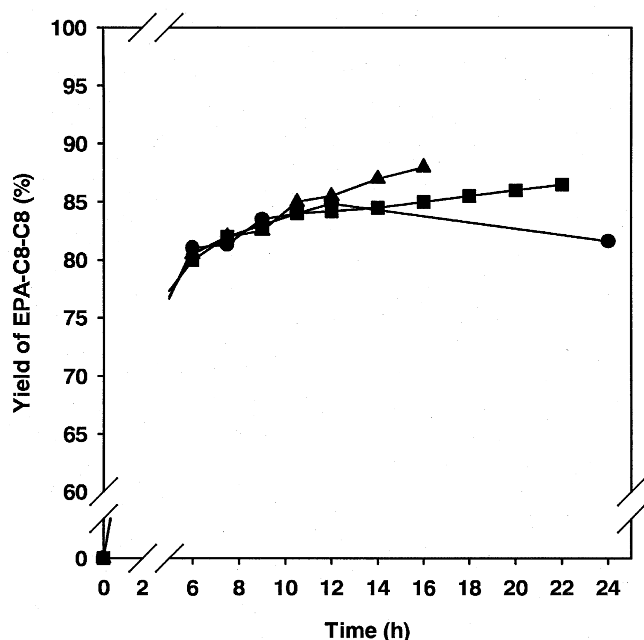

FIG. 6. Effect of a_w control during vacuum application on molar yield of EPA-C8-C8. Reaction performed without vacuum at normal pressure in a closed vessel (●); reaction under 3 mm Hg vacuum applied at 9 h thereafter without a_w control (■); reaction under 3 mm Hg vacuum applied at 9 h thereafter with a_w control at 0.07–0.17 (▲). The calculated amount of water was added about every 10 min. For the rest of the reaction conditions, see Figure 2. For abbreviations see Figure 1.

mixture) was added into the reaction medium intermittently at the determined time interval (*ca.* 10 min) during the vacuum application.

Figure 6 shows the time course of the sTAG synthesis reaction with or without maintaining a_w during the vacuum. When a suitable amount of water was added to the reaction medium at the predetermined time interval (*ca.* 10 min), the reaction rate was faster than that without adding water. A molar yield of 87.3% of EPA-C8-C8 from EPAEE was obtained after 16 h reaction with a_w control during the vacuum application as compared with 87.0% after 24 h reaction without a_w control. The converted EPAEE were incorporated as 91.5 mol% EPA-C8-C8, 3.1 mol% dieicosapentaenoyloctanoyl glycerol, and 5.4 mol% eicosapentaenoyloctanoyl glycerol, respectively.

Ltd., Nagoya, 155-0028, Japan, and [c]Faculty of Environmental and Symbiotic Sciences, Prefectural University of Kumamoto, Kumamoto 862-8502, Japan

ABSTRACT: The effects of dietary conjugated linoleic acid (CLA) and linoleic acid (LA) on ketone body production and lipid secretion were compared in isolated perfused rat liver. After feeding the 1% CLA diet for 2 wk, the concentration of post-perfused liver cholesterol was significantly reduced by CLA feeding, whereas that of triacylglycerol remained unchanged. Livers from CLA-fed rats produced significantly more ketone bodies; and the ratio of β-hydroxybutyrate to acetoacetate, an index of mitochondrial redox potential, tended to be consistently higher in the liver perfusate. Conversely, cumulative secretions of triacylglycerol and cholesterol were consistently lower in the livers of rats fed CLA, and the reduction in the latter was statistically significant. Thus dietary CLA appeared to exert its hypolipidemic effect at least in part through an enhanced β-oxidation of fatty acids at the expense of esterification of fatty acid in the liver.

Paper no. L8197 in *Lipids 34*, 997–1000 (September 1999).

Conjugated linoleic acid (CLA) is a mixture of geometrical and positional isomers of linoleic acid (*cis*,*cis*-9,12-octadecadienoic acid, LA). CLA occurs exclusively in ruminant meats and dairy products, although its concentration is as low as 5 mg/g fat (1). In addition to the diverse positive influence of CLA on carcinogenesis and atherogenesis (2–6), Park *et al.* found that dietary CLA reduces fat accumulation in adipose tissues (7). They suggested that this was due to increased oxidation of fatty acids as reflected by enhanced activity of carnitine palmitoyl transferase in fat pad and skeletal muscle. Belury *et al.* also reported that dietary CLA causes an increase in mRNA levels of acyl CoA oxidase, fatty acid-binding protein, and cytochrome P450, an indication of peroxisomal proliferation in the liver of mice fed CLA-containing diets for 6 wk (8). Thus, CLA may cause peroxisomes to proliferate, thus enhancing fatty acid oxidation in the liver. These observations suggest that beneficial effects of dietary CLA on lipid metabolism are attributable at least partly to enhanced fatty acid oxidation in the liver.

In the present study, we examined whether CLA added at a 1% level to the diet could influence lipid secretion and ketone body production by perfused rat liver.

MATERIALS AND METHODS

Male Sprague-Dawley rats (Kyudo Co., Kumamoto, Japan) weighing 140–150 g were housed individually at constant temperature (22–24°C) with lights turned on from 0700 to 1900. Rats were acclimated to the conditions for 5–9 d, and then divided into two groups with equal body weight. Each group was fed a CLA or LA diet formulated according to the AIN76^{TM} formula (9) (in wt%): 5, corn oil; 20, casein; 15, cornstarch; 5, cellulose; 3.5, mineral mixture (AIN76^{TM}), 1, vitamin mixture (AIN76^{TM}), 0.3, DL-methionine; 0.2, choline bitartrate; either 1 LA or CLA (supplied by Rinoru Oil Mills, Nagoya, Japan), and sucrose to 100. The fatty acid composition of dietary LA and CLA preparations is shown in Table 1. CLA prepared by alkaline isomerization of linoleic acid in safflower oil was provided by Rinoru Oil Mills. These diets were given *ad libitum* for 14 d. Food intake and body weight were recorded every other day.

On the day of the perfusion experiments, rats were given intraperitoneal injection of pentobarbital Na (5 mg/100 g body weight) around 0830. The liver was then isolated and perfused with 120 mL of recirculating Krebs-Henseleit perfusion medium (pH 7.4), which contained 25 mM glucose, 1.5% (wt/vol) bovine serum albumin (Fraction V, Boehringer Mannheim, Mannheim, Germany), and 25% (vol/vol) washed bovine erythrocytes, at the rate of 20 mL/min at 37°C, in the presence of exogenous oleic acid. Five milliliters of 20 mM potassium oleate (100 μmol) was added at the beginning of recirculation, and the same solution was continuously infused at the rate of 4.5 mL/h (90 μmol oleate/h). Every hour, 20 mL of the perfusate was removed for analyses of ketone bodies and lipids, and the same amount of the fresh perfusion medium was added to maintain 120 mL of recirculating volume. The perfusions were continued for 4 h, as described in detail previously (10–12).

TABLE 1
Fatty Acid Compositions of Linoleic Acid (LA) and Conjugated Linoleic Acid (CLA) Preparations

	LA	CLA
16:0	7.2	6.9
18:0	2.6	2.5
18:1	14.8	15.3
18:2	73.3	0.8
18:2 (CLA)	—	73.8[a]

[a]CLA was composed of 34.6, 35.9, 1.7, and 1.6% of 9*c*,11*t*/9*t*,11*c*-, 10*t*, 12*c*-, 9*c*,11*c*/10*c*,12*c*-, and 9*t*,11*t*/10*t*,12*t*-octadecadienoic acids, respectively.

TABLE 2
Effect of CLA Feeding on Body Weight, Liver Weight, and Postperfused Liver Lipids[a]

	Dietary group	
	LA	CLA
Body weight (g)	289 ± 2	296 ± 6
Liver weight (g)	15.9 ± 0.5	17.6 ± 0.8
Liver lipids (μmol/g liver)		
Total cholesterol	6.04 ± 0.38	4.25 ± 0.53[b]
Free cholesterol	3.13 ± 0.15	2.56 ± 0.12[b]
Triacylglycerol	22.7 ± 1.5	21.4 ± 2.6
Phospholipid	27.7 ± 2.2	28.8 ± 1.1

[a]Mean ± SE of 5 or 6 rats. Liver weight was measured at the end of perfusion.
[b]Significantly different from LA group at $P < 0.05$. Rats weighing 180–200 g were fed the diets supplemented with either 1% of LA or CLA preparation for 14 d. The livers were then isolated and perfused in the presence of an oleic acid substrate. For abbreviations see Table 1.

In another experiment, CLA and LA were added directly to the perfusion medium: 5 mL of 1% potassium salt solutions was added at the beginning of recirculation, and the same solution was continuously infused at the rate of 4.5 mL/h, to compare the direct effect of these fatty acids *per se* on ketone body production and lipid secretion in the perfused liver. Male Wistar rats (260–270 g) fed commercial rat chow served as liver donors in this experiment. All aspects of the experiment were approved by the Miyazaki University Animal Policy and Welfare Committee.

The methods employed for the lipid and ketone body analyses in perfusates and postperfused livers were described previously (10–13). Data were analyzed by Student's *t*-test (14) to evaluate significant differences of the means.

RESULTS

Dietary CLA did not influence food intake, growth, or relative liver weight of rats (Table 2). The concentration of postperfused liver triacylglycerol and phospholipid was not different between the groups, whereas that of total and free cholesterol was significantly lower in CLA-fed rats than in LA-fed rats. The amount of oleic acid taken up by the perfused livers was calculated to be constant at 1-h intervals, and the amounts for a total of 4 h were comparable; 427 ± 7 μmol/liver in the LA group, and 420 ± 8 μmol/liver in the CLA group. Therefore, the following observations on the diverse responses in ketone body production and lipid secretion by the livers were attributed in part to the influence of dietary fatty acids on intracellular fatty acid metabolism.

The livers of rats fed the CLA diet produced significantly more ketone bodies than those of rats fed the LA diet (Table 3). The ratio of β-hydroxybutyrate to acetoacetate tended to increase after feeding CLA. On the other hand, dietary CLA consistently lowered the secretion of triacylglycerol and cholesterol by the perfused liver, as compared to dietary LA, and the difference in cholesterol secretion after 2 h of perfusion was significant. Therefore, the relationship between ketogenesis and lipid secretion was inverse. Although this relationship was inconsistent with the observation with other chemi-

[a]Mean ± SE of 4 rats. For abbreviations see Table 1.

cals reported previously (10,15), the significant reduction in the secretion of cholesterol was characteristic for CLA.

The addition of CLA to the perfusion medium did not influence hepatic ketogenesis and lipid secretion when compared with the addition of LA (Table 4). These results indicate that the adaptive changes of fatty acid metabolism ocurred only when rats were fed CLA.

DISCUSSION

The present study demonstrated that dietary CLA enhanced hepatic fatty acid oxidation as reflected by a stimulated ketone body production, while CLA itself did not exert a direct influence on fatty acid oxidation. In accordance with the observation of Park *et al.* (7), that CLA increased mitochondrial activity of carnitine palmitoyl transferase of epididymal adipose tissues and muscles, we can suggest that CLA influences fatty acid metabolism not only of liver, but also of extrahepatic tissues.

On the other hand, feeding of CLA to mice resulted in proliferation of peroxisomes, another site in the liver of fatty acid oxidation (8). However, peroxisomal proliferators such as fibrate and drugs related to it commonly lead to an enlarged liver, accompanied by a marked increase in hepatic phospholipid and a decrease in the ratio of β-hydroxybutyrate to acetoacetate even when hepatic ketogenesis is stimulated (10,16). These changes were not confirmed in the present study as shown in Tables 2 and 3. Thus, stimulated hepatic ketogenesis with a concomitant elevation of the ratio of β-hydroxybutyrate to acetoacetate observed in the liver of rats fed CLA may be attributed to the mitochondrial process, but not to the response of peroxisomal oxidation, since the paralleled increase in these two parameters is mostly associated with an enhancement of fatty acid oxidation in mitochondrial compartments (10,12).

Stimulated ketogenesis was inversely related to the reduced secretion of triacylglycerol by the livers of rats fed CLA, a reciprocal response in these metabolic pathways. In this context, Yotsumoto *el al.* (17) recently reported that addition of 10*t*,12*c*-octadecadienoic acid, one of the major CLA constituents, to HepG2 cells resulted in an impairment of the synthesis and secretion of apolipoprotein B-containing lipoproteins. The inverse relationship between fatty acid oxidation and triacylglycerol secretion has been observed in livers of rats under various nutritional and physiological conditions (10–12,15). Therefore, dietary CLA seemed to be a potent stimulator for fatty acid oxidation in the liver.

CLA decreased secretion of cholesterol by the liver. Thus, the hypocholesterolemic effect of dietary CLA as observed in hamsters (6) may in part be attributed to this reduction. Lee *et al.* (5) reported that supplementation of 0.5 g/d CLA resulted in the reduction of serum low density lipoprotein cholesterol and triacylglycerol in rabbits fed the cholesterol-enriched diet. In these animal models, the extent of atherosclerosis of arterial walls was less marked (5,6).

In considering these reports as well as the present work, dietary CLA may exert the hypocholesterolemic effect at least in part through a decreased hepatic secretion of very low density lipoprotein-cholesterol. In addition, dietary CLA may reduce the biosynthesis of cholesterol in the liver, since CLA reduced liver cholesterol level.

Accumulation of CLA in rat liver lipids was also checked in the feeding experiment. The level of CLA was about 0.6% of the fatty acids in liver triacylglycerol of rats fed CLA. We detected no CLA peaks in phospholipids and cholesteryl ester fractions. The low incorporation of CLA into liver tissue may be attributed to either its oxidation during perfusion or the length of feeding period. However, it was observed that feeding CLA for as little as 2 wk induces fatty acid oxidation.

In conclusion, a decreased secretion of triacylglycerol-rich

lipoproteins by the liver from CLA-fed rats is a consequence of an increase in ketone body production. This specific fatty acid may also exert its hypocholesterolemic effect by decreasing hepatic cholesterol level. However, no such responses were observed when the liver from rats fed the diet free of CLA was perfused with CLA.

ARTICLE

On the Specificity of Allene Oxide Cyclase

Jörg Ziegler[a],*, Claus Wasternack[b], and Mats Hamberg[a]

[a]Department of Medical Biochemistry and Biophysics, Division of Physiological Chemistry II, Karolinska Institutet, S-171 77 Stockholm, Sweden, and [b]Abteilung Hormonforschung, Institut für Pflanzenbiochemie, Weinberg 3, D-06120 Halle, Germany

ABSTRACT: Jasmonic acid is a carbocyclic fatty acid that is biosynthesized from α-linolenic acid in several steps. The formation of the ring structure of jasmonic acid is catalyzed by the enzyme allene oxide cyclase (EC 5.3.99.6) and involves the cyclization of an unstable allene oxide into the cyclopentenone 12-oxo-10,15(*Z*)-phytodienoic acid. In this study, a number of allene oxides were generated, and their enzymatic and nonenzymatic cyclization into cyclopentenones was investigated. Nonenzymatic cyclization was observed with allene oxides having one pair of conjugated double bonds and an additional isolated double bond in the β,γ position relative to the epoxide group, i.e., the partial structure 4,5-epoxy-1,3,7-octatriene. Enzymatic cyclization took place provided that this structural element was inserted in the fatty acid chain with its epoxide group in the n-6,7 position and the isolated double bond in the n-3 position. A number of oxygenated fatty acids having structural features in common with the natural allene oxides were tested as inhibitors of allene oxide cyclase. Fatty acids having an allene oxide structure in the n-6,7 position but lacking the double bond in the n-3 position, as well as fatty acids having a saturated epoxide group in the n-6,7 position, served as competitive inhibitors of the enzyme. Data on the substrate specificity of allene oxide synthase (EC 4.2.1.92) from corn seeds indicated that fatty acid hydroperoxides with a double bond at n-3 and with the hydroperoxide function at n-6 exhibit the highest affinity but the slowest reaction velocity.

The cyclopentanones jasmonic acid (JA) and its methyl ester (MJ) are involved as signal molecules in plant defense reactions against herbivores and phytopathogens (1) as well as in mechanical responses such as tendril coiling (2). Additionally, they affect plant growth and developmental processes such as seed germination, leaf senescence, tuberization (3) and pollen development (4).

The biosynthesis of JA proceeds *via* an oxylipin pathway (5–7). Fatty acid hydroperoxides produced by lipoxygenase-catalyzed oxygenation of polyunsaturated fatty acids serve as important intermediates in this pathway. Hydroperoxide-metabolizing enzymes include lyases, which catalyze chain cleavage of hydroperoxides into short-chain aldehydes and ω-oxo-carboxylic acids (8,9), and divinyl ether synthases, which catalyze the dehydration of hydroperoxides into regio- and stereoisomeric divinyl ether derivatives (10–12). Fatty acid hydroperoxides can also be used as cosubstrates for plant peroxygenases in the epoxidation of unsaturated fatty acids (13,14). One specific hydroperoxide, i.e., α-linolenic acid 13(*S*)-hydroperoxide [13(*S*)-HPOT] serves as the precursor of the jasmonate family of compounds (15). The first step of the transformation of 13(*S*)-HPOT into jasmonates is catalyzed by allene oxide synthase (AOS) and results in the formation of an unstable allene oxide derivative, 12,13(*S*)-epoxy-9(*Z*),11,15(*Z*)-octadecatrienoic acid (16–18). This allene oxide is chemically degraded in aqueous media with a half life of 26 s at 0°C and pH 6.7 (16) mainly to α-ketol [12-oxo-13-hydroxy-9(*Z*),15(*Z*)octadecadienoic acid] and γ-ketol [12-oxo-9-hydroxy-10(*E*),15(*Z*)octadecadienoic acid]. Additionally, a fraction of the allene oxide (10–15%) undergoes cyclization to produce the cyclopentenone 12-oxo-10,15(*Z*)-phytodienoic acid (12-oxo-PDA) in racemic form (Scheme 1). In contrast to the chemical degradation, the allene oxide is converted by the next enzyme of jasmonate biosynthesis, allene oxide cyclase (AOC), to optically pure 9(*S*),13(*S*)-12-oxo-PDA (16,19,20). This compound is further

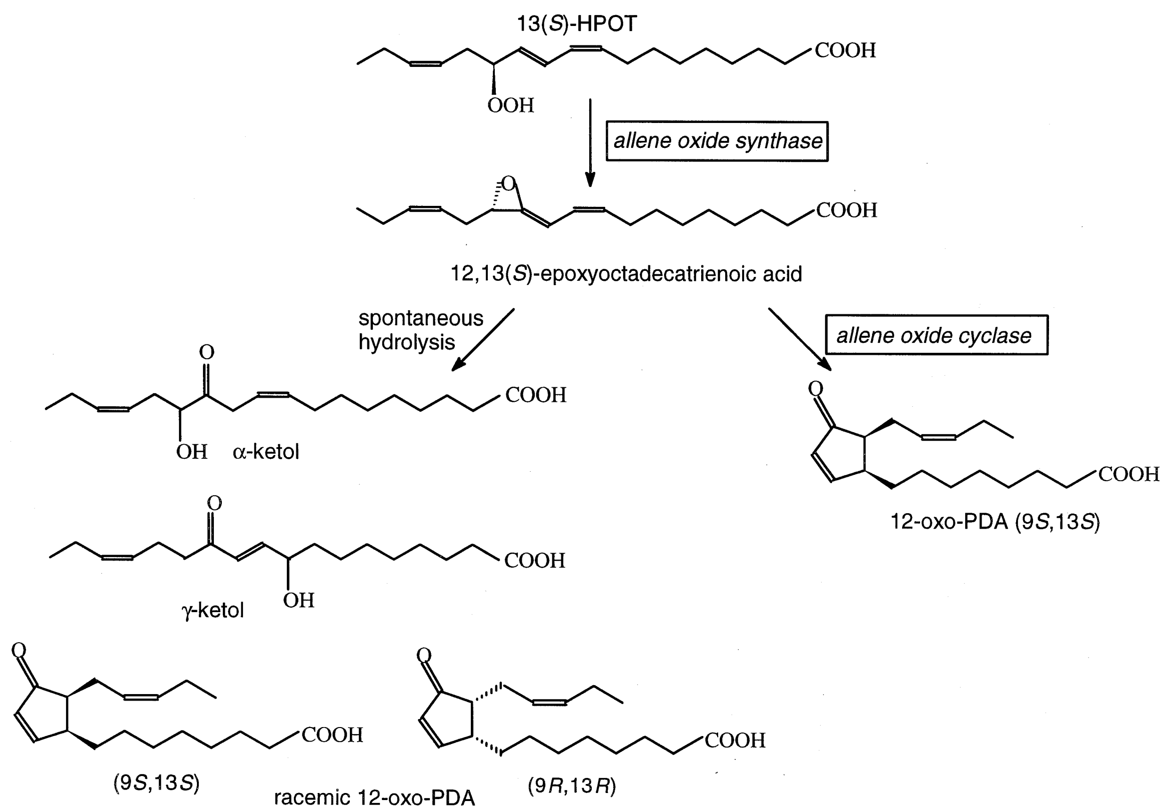

SCHEME 1

converted into JA by enzymatic reduction of the ring double bond followed by three steps of β-oxidation (15). Whereas lipoxygenase- and AOS-derived products can be diverged into pathways different from JA biosynthesis, the AOC-catalyzed reaction provides the first intermediate which, according to the current knowledge, ultimately leads to JA. It is therefore conceivable that this enzyme may represent an important regulatory point in the biosynthesis of this plant signal compound. AOC from corn kernels was characterized as a soluble enzyme having a molecular mass of about 45 kD (20). The enzyme was recently purified to homogeneity and characterized with respect to molecular properties, pH optimum, responsiveness to divalent ions, and feedback inhibition (21). The present work is concerned with the substrate specificity of AOC and with its inhibition by substrate analogs.

EXPERIMENTAL PROCEDURES

Fatty acids. For the preparation of 7(*Z*),10(*Z*),13(*Z*)-hexadecatrienoic acid, potato leaves were cut and homogenized in chloroform/methanol (2:1, vol/vol) containing 10 ppm of 2,6-di-*tert*-butyl-4-methylphenol. The oil was saponified, and the fatty acid fraction was esterified by treatment with diazomethane. Methyl 7(*Z*),10(*Z*),13(*Z*)-hexadecatrienoate was obtained following preparative reversed-phase high-performance liquid chromatography (RP-HPLC). Saponification followed by final purification by means of open-column SiO_2 chromatography afforded pure 7(*Z*),10(*Z*),13(*Z*)-hexadecatrienoic acid as a colorless oil. 9(*Z*),12(*E*)-Octadecadienoic acid was prepared by deoxygenation of methyl 12(*S*),13(*R*)-epoxy-9(*Z*)-octadecenoate (22). Briefly, a sample of the epoxyester was refluxed with glacial acetic acid for 3 h and the product saponified. Crystallization from ethyl acetate afforded pure *threo*-12,13-dihydroxy-9(*Z*)-octadecenoic acid having an m.p. of 50–52°C. A sample (500 mg) was methyl-esterified and refluxed with 1,1′-thiocarbonyldiimidazole (500 mg) in toluene (25 mL) for 3 h. The cyclic thionocarbonate derivative was purified by SiO_2 chromatography and subsequently refluxed with trimethylphosphite (20 mL) for 15 h under argon. The product (410 mg) was saponified and purified by SiO_2 chromatography to yield 9(*Z*),12(*E*)-octadecadienoic acid (220 mg; purity in excess of 97%). 9(*Z*),11(*E*)-Octadecadienoic acid and 10(*E*),12(*Z*)-octadecadienoic acid were purchased from Larodan AB (Malmö, Sweden). The remaining fatty acids were obtained from Nu-Chek-Prep (Elysian, MN).

Epoxy fatty acids. (±)-*cis*-9,10-Epoxy-12(*Z*)-octadecenoic acid and (±)-*cis*-12,13-epoxy-9(*Z*)-octadecenoic acid were prepared by monoepoxidation of methyl linoleate followed by separation by thin-layer chromatography (TLC), saponification, and crystallization (20). In a similar way, monoepoxidation of methyl 9(*Z*),12(*E*)-octadecadienoate and methyl 11(*Z*),14(*Z*)-eicosadienoate afforded (±)-*trans*-12,13-epoxy-9(*Z*)-octadecenoic acid and (±)-*cis*-14,15-epoxy-11(*Z*)-

eicosenoic acid, respectively. Methyl 12(*S*),13(*R*)-epoxy-9(*Z*)-octadecenoate was isolated from seeds of *Euphorbia lagascae* (23) by Soxhlet extraction, transmethylation, and purification by SiO_2 chromatography. The ester had $[\alpha]_D$ + 2.4° (c 5.5, hexane), thus confirming the 12(*S*),13(*R*) configuration of the epoxide group (24). Saponification under mild conditions followed by crystallization from hexane yielded 12(*S*),13(*R*)-epoxy-9(*Z*)-octadecenoic acid [(+)-vernolic acid] having a purity of 99%. Methyl 12(*R*),13(*S*)-epoxy-9(*Z*)-octadecenoate was isolated from seeds of *Malope trifida purpureae* (25) by Soxhlet extraction, transmethylation, and SiO_2 chromatography. The optical rotation measured on the ester corresponded to $[\alpha]_D$ −2.6° (c 4.7, hexane), thus demonstrating that the epoxide group had the *R*,*S* configuration (24). Saponification followed by crystallization from hexane yielded 12(*R*),13(*S*)-epoxy-9(*Z*)-octadecenoic acid [(−)-vernolic acid] having a purity of 99%.

Methyl 12-hydroxy-dinor-phytonoate (side chain trans *isomer*). The methyl ester of (±)-JA was hydrogenated and reduced with sodium borohydride as was earlier described for (+)-7-*iso*-JA (26). Part of the acetoxy acid obtained following saponification and acetylation (256 mg, 1 mmol) was subjected to anodic coupling with methyl hydrogen adipate (3 mmol) in methanol (15 mL) containing sodium methoxide (0.2 mmol). The reaction product was saponified, methyl-esterifed, and purified by open-column SiO_2 chromatography. Epimers A (R_f = 0.44) and B (R_f = 0.53) of methyl (±)-12-hydroxy-dinor-phytonoate (side chain *trans* isomer) were obtained in a 1:1 ratio by preparative TLC (solvent system: ethyl acetate/hexane, 25:75, vol/vol). On the basis of the data for the corresponding epimers of 18-carbon chain length (27), epimer A was identified as a racemic mixture of the two enantiomers methyl 12(*R*)-hydroxy-9(*S*),13(*R*)-dinor-phytonoate and methyl 12(*S*)-hydroxy-9(*R*),13(*S*)-dinor-phytonoate. In the same way, epimer B was due to a racemic mixture of methyl 12(*R*)-hydroxy-9(*R*),13(*S*)-dinor-phytonoate and methyl 12(*S*)-hydroxy-9(*S*),13(*R*)-dinor-phytonoate. The mass spectra of the two epimers were virtually identical and showed prominent ions at *m/z* 266 (M^+ – 18; loss of H_2O), 228, 209 [M^+ – (57 + 18); loss of $(CH_2)_3CH_3$ + H_2O], 195 [M^+ – (71 + 18); loss of $(CH_2)_4CH_3$ + H_2O], 164, and 137 [M^+ – (129 + 18); loss of $(CH_2)_5COOCH_3$ + H_2O]. Derivatization of epimer B with (−)-menthoxycarbonyl (MC) chloride followed by purification by TLC afforded two diastereomeric MC derivatives which were separable by gas–liquid chromatography (GLC) [diastereomer 1, MC derivative of methyl 12(*R*)-hydroxy-9(*R*),13(*S*)-dinor-phytonoate; retention time, 17.4 min; diastereomer 2, MC derivative of methyl 12(*S*)-hydroxy-9(*S*),13(*R*)-dinor-phytonoate; retention time, 18.0 min; methyl silicone capillary column; column temperature raised from 220 to 280°C at a rate of 5°C/min]. The mass spectra of MC-derivatives 1 and 2 were virtually identical and showed prominent ions at *m/z* 266 (M^+ – 200; loss of MC-OH), 235 [M^+ – (200 + 31); loss of MC-OH plus OCH_3], 138 ($C_{10}H_{18}$; menthyl – H), and 83.

Fatty acid hydroperoxides. The n-6 hydroperoxides were prepared by incubation of the corresponding fatty acids with soybean lipoxygenase (Sigma Chemical Co., St. Louis, MO) (28), whereas the n-10 hydroperoxides were obtained by incubation of the appropriate precursor acids with tomato fruit homogenates (29).

Enzyme preparations. The membrane fraction of corn seed homogenates sedimenting at 105,000 × *g* was used as source of AOS. As earlier shown, this preparation is devoid of AOC activity (20). The AOC preparation from corn consisted of the 50-fold enriched AOC activity after Octyl-Sepharose chromatography (21). The experiments with potato AOC were performed with a 20-fold-enriched AOC preparation from potato tubers. To obtain this, potato tubers were cut into small pieces and homogenized in 50 mM potassium phosphate buffer pH 6.7 containing 1 mM β-mercaptoethanol, 0.5 mM mercaptobenzothiazole (tissue to buffer ratio 1:2, wt/vol) with an Ultraturrax (Janke & Kunkel, Staufen, Germany). The homogenate was filtered through four layers of Miracloth (Calbiochem, La Jolla, CA) and centrifuged at 10,000 × g for 10 min. The supernatant was recentrifuged at 100,000 × *g* for 60 min, and the soluble fraction was subjected to acetone precipitation. The pellet containing the AOC activity obtained between 40 and 60% acetone saturation was dissolved in 0.75 M ammonium sulfate in 20 mM Tris-HCl pH 7.5 and loaded on an Octyl-Sepharose column (35 mL) equilibrated in 1 M ammonium sulfate 20 mM Tris-HCl pH 7.5. AOC activity was eluted with a linear-decreasing ammonium sulfate gradient over 350 mL at a flow rate of 2.5 mL/min.

Enzyme assays. AOS activity was measured in 50 mM potassium phosphate pH 6.7 in a total volume of 1 mL. The reaction was initiated by the addition of the fatty acid hydroperoxide, and the decrease in the absorbance at 235 nm was recorded. For the determination of the kinetic parameters of corn AOS, the initial reaction velocity was determined at 14 concentrations in the range of 5 to 90 μM for each substrate. The K_m and v_{max} values were calculated directly using the Michaelis-Menten equation and by plotting the data according to Eadie-Hofstee. Both methods gave similar results. AOC activity was determined by a method based on RP-radio-HPLC as described (21).

Analysis of cyclization products of allene oxides. Fatty acid hydroperoxides (150 μM) were stirred at 0°C for 10 min with 0.5 mL of a suspension of corn seed membranes [0.5 mg of protein; 28 nkat using 13(*S*)-HPOT as the substrate] in 0.1 M potassium phosphate buffer pH 6.7, and 2.5 mL of the AOC preparation in ammonium sulfate/20 mM Tris-Cl buffer pH 7.5 (total assay volume 5 mL). The activities of the corn and potato AOC added to these assays were equivalent to 178 nmol PDA and 156 nmol PDA, respectively, measured by the method based on RP-radio-HPLC. Control incubations, in which the AOC solution was replaced by potassium phosphate buffer, were run in parallel. The incubations were terminated by the addition of 10 mL of methanol, and the reaction products were extracted with diethyl ether, methylated, and subjected to TLC (solvent system: ethyl acetate/toluene

(15:85, vol/vol). Bands were visualized under ultraviolet (UV) light after spraying with 2′,6′-dichlorofluorescein, and the R_f value of the band due to cyclopentenone (the methyl ester of 12-oxo-PDA and its homologs and analogs) was recorded. A broad zone of silica gel containing bands due to the methyl esters of cyclopentenone, hydroxy acid, and α-ketol was scraped off and eluted with ethyl acetate. An aliquot of the material was trimethylsilylated and subjected to product analysis by GLC and gas–liquid chromatography–mass spectromety (GC–MS). The remaining part of the material was used for steric analysis of cyclopentenones (20,26). Briefly, cyclopentenones were treated with 0.1 M NaOH in 90% aqueous methanol in order to effect *cis* → *trans* isomerization of the side chain attached α to the ring carbonyl group. Following reesterification and purification by TLC (solvent system: ethyl acetate/hexane. 20:80, vol/vol), the material was treated with sodium borohydride and hydrogenated. The resulting epimers of methyl 12-hydroxyphytonoate and its homologs were separated by TLC (solvent system: ethyl acetate/hexane, 20:80, vol/vol) and separately derivatized with MC chloride. The MC derivatives were purified by TLC (solvent system: ethyl acetate/hexane, 7:93, vol/vol) and subsequently analyzed by GC–MS. Most analyses were performed in the selected-ion-monitoring (SIM) mode using the ion formed by elimination of MCOH ($M^+ - 200$). Authentic reference compounds having 16 or 18 carbon atoms chain length were synthesized (present work) or were available from earlier work (26), respectively.

Chromatographic and instrumental methods. Analytical RP-radio-HPLC was performed with a column of Nucleosil 100-5 C_{18} (250 × 4.6 mm) purchased from Macherey-Nagel (Düren, Germany). The solvent system used consisted of acetonitrile/water/acetic acid (55:45:0.02, by vol) and the flow rate was 1 mL/min. The absorbance (221 nm) and radioactivity of HPLC effluents were determined on-line using a Spectromonitor III UV detector (Laboratory Data Control, Riviera Beach, FL) and a liquid scintillation counter (IN/US Systems, Tampa, FL), respectively. GLC was performed with a Hewlett-Packard (Avondale, PA) model 5890 gas chromatograph equipped with a methyl silicone capillary column (length, 25 m; film thickness, 0.33 µM). Helium at a flow rate of 25 cm/s was used as the carrier gas. Retention times found on GLC were converted into C-values as described (30). GC–MS was carried out with a Hewlett-Packard model 5970B mass selective detector connected to a Hewlett-Packard model 5890 gas chromatograph. The scan mode was used for identification of reaction products, whereas the selected ion monitoring mode was used for accurate analysis of diastereomeric MC derivatives. Optical rotation was measured using a Schmitt & Haensch polarimeter (Berlin, Germany) model NH8. Hexane was used as solvent, and the path length was 1 dm.

RESULTS

Ten allene oxides were used to test the substrate specificity of AOC (Scheme 2). Based on the most commonly used linolenic acid derived substrate, 12,13(*S*)-EOT, we chose allene oxides derived from the n-3 or n-6 series of polyunsaturated fatty acids and differing with respect to the position of the epoxide group (n-6,7 or n-9,10), chain length (16 to 22 carbons) and number of double bonds at the carboxyl terminus.

Substrate specificity of AOS. The AOS-catalyzed generation of allene oxides from hydroperoxides is a prerequisite to perform the AOC assay. It was therefore necessary to check whether all the hydroperoxides were substrates for AOS. For this reason, we determined the K_m and v_{max} values for each hydroperoxide using the 100,000 × *g* membrane pellet from the corn seed homogenate as AOS preparation. As shown in Table 1, all hydroperoxides were converted by AOS, but with rather different kinetics. Roughly, one can sort the substrates into three different groups: group I with a high K_m (30–40 µM) and high v_{max} (above 100 nkat mg^{-1}), such as γ-9(*S*)-HPOT, 9(*S*)-HPOD and 13(*S*)-HPOD; group II with a rather high affinity (K_m value below 25 µM) and a lower reaction velocity [v_{max} between 15 and 60 nkat mg^{-1}), like 15(*S*)-HPET, 13(*S*)-HPOT, 11(*S*)-HPHT, 15(*S*)-HPETE]; and group III with the highest affinity (K_m below 15 µM) and a very low v_{max} of less than 15 nkat mg^{-1}, such as 17(*S*)-HPDP and 15(*S*)-HPEP. 9(*S*)-HPOT represents one exception in this ranking since it has a low affinity but a medium reaction velocity.

Nonenzymatic cyclization of allene oxides. Ten unstable allene oxides (Scheme 2) were generated by incubation of the appropriate hydroperoxide precursors with AOS and subsequently allowed to decompose in the absence of AOC. The material isolated by extraction with diethyl ether was methylesterified, purified by TLC, and analyzed by GC–MS following trimethylsilylation. All 10 allene oxides produced α-ketols which were readily identified by their C-values and mass spectra. Six allene oxides, i.e., those generated from 13(*S*)-HPOT, 11(*S*)-HPHT, 15(*S*)-HPET, 15(*S*)-HPEP, 17(*S*)-HPDP, and γ-9(*S*)-HPOT, produced cyclopentenones (Scheme 2, Table 2). The mass spectra of the six cyclopentenones all showed prominent ions due to M^+ and $M^+ - 31$ (loss of OCH_3). Cyclopentenones derived from the five first-men-

TABLE 1
Substrate Specificity of Allene Oxide Synthase[a,b]

Substrate[c]	K_m (µM)	v_{max} (nkat mg^{-1})
γ-9(*S*)-HPOT	37.1 ± 2.8	158.9 ± 17.4
9(*S*)-HPOD	32.0 ± 1.9	143.7 ± 6.7
13(*S*)-HPOD	37.4 ± 6.5	139.5 ± 32.8
9(*S*)-HPOT	38.9 ± 7.7	72.6 ± 6.7
15(*S*)-HPET	20.9 ± 6.2	51.6 ± 9.6
13(*S*)-HPOT	11.1 ± 1.5	33.9 ± 9.1
11(*S*)-HPHT	19.2 ± 5.3	24.7 ± 0.4

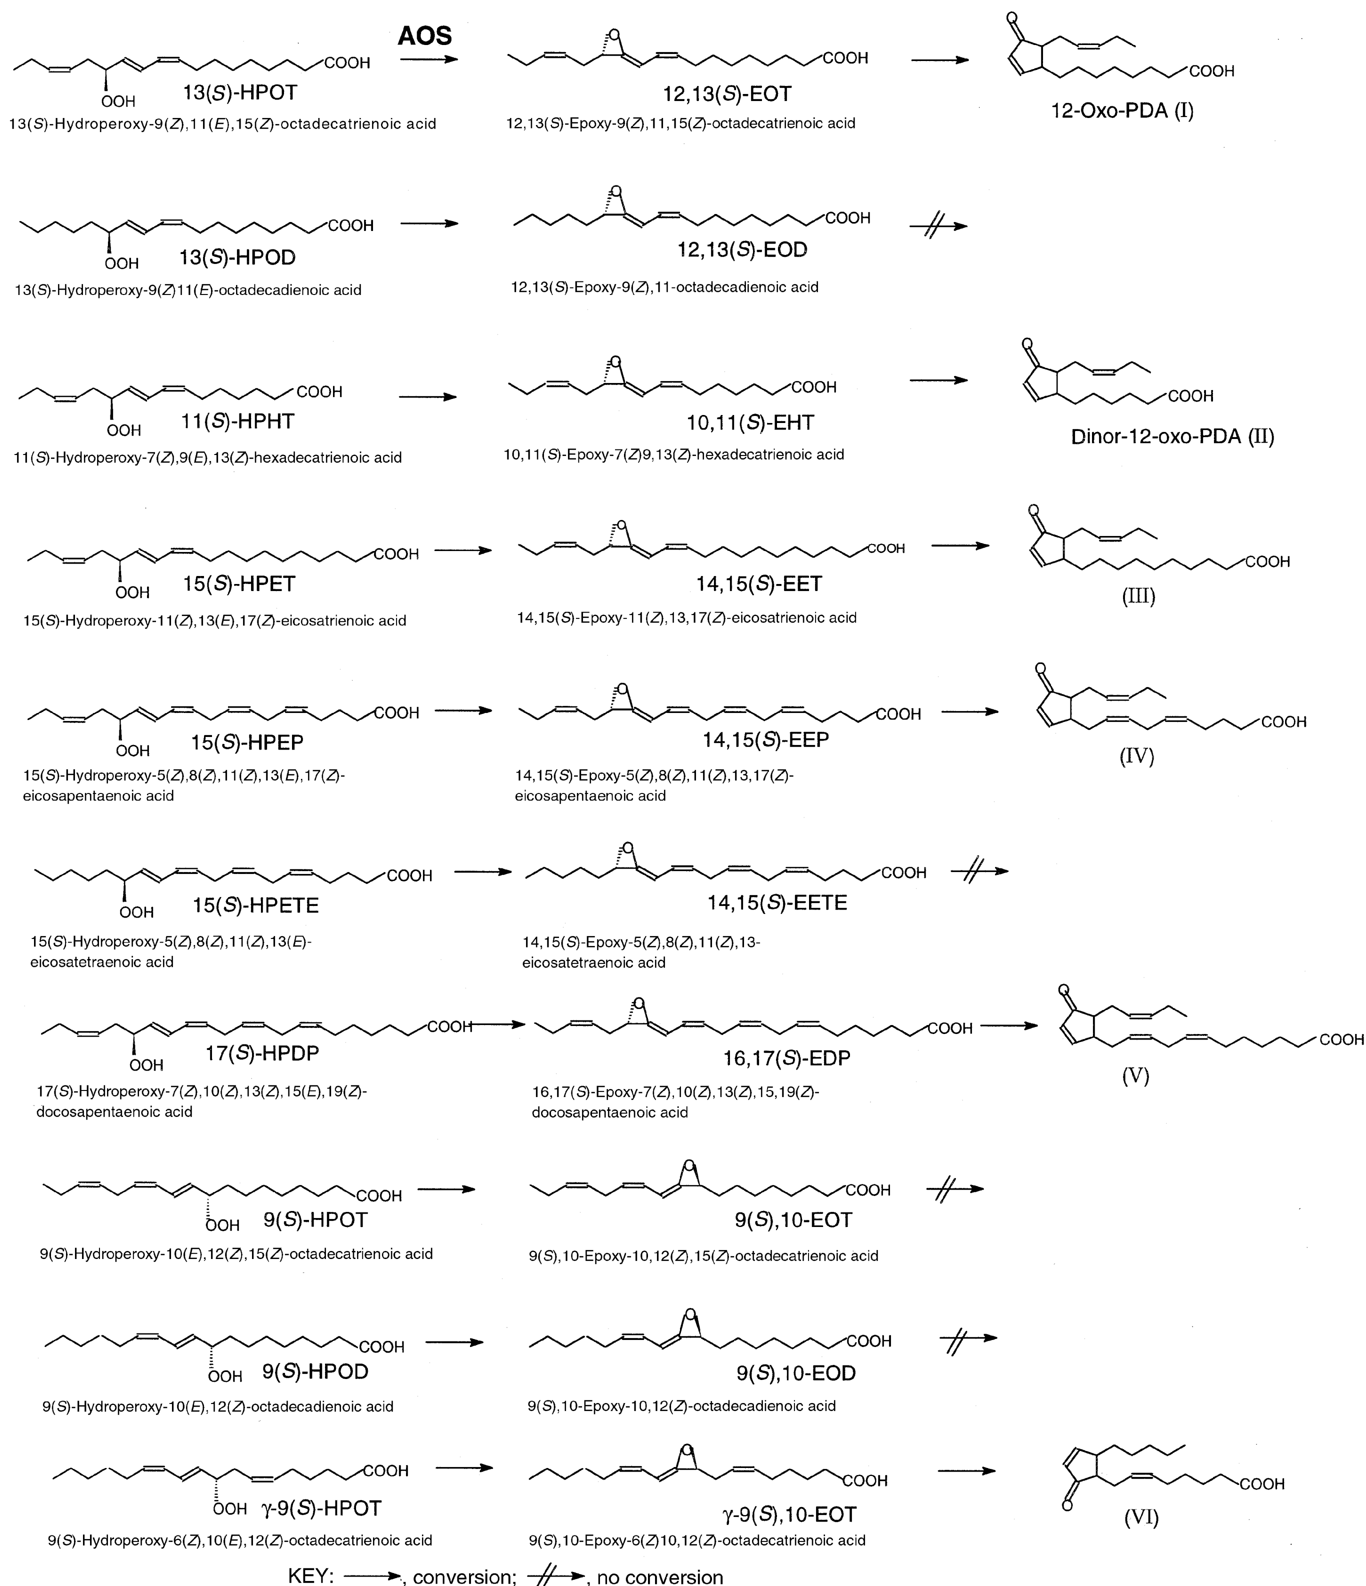
17(*S*)-HPDP	10.0 ± 2.0	12.4 ± 0.9
15(*S*)-HPEP	4.6 ± 1.3	7.4 ± 2.8

[a]Maximal initial velocity (v_{max}) and Michaelis constant (K_m) were determined as described in detail in the Materials and Methods section.
[b]Data represent the mean value ± SD of at least four replicates.
[c]Abbreviations and structures of substrates are given in Scheme 2.



SCHEME 2

tioned hydroperoxides showed an ion due to $M^+ - 68$ (loss of C_5H_8, i.e., the pentenyl side chain minus one hydrogen by cleavage β to the ring carbonyl). The three first-mentioned hydroperoxides afforded cyclopentenones that had a saturated carboxylic ester side chain. During electron impact, cleavage occurred α, β, or γ to the ring-carbon to which the carboxyl

chain was attached resulting in prominent ions at *m/z* 149, 163, and 177, respectively. Cyclopentenones produced from 15(*S*)-HPEP and 17(*S*)-HPDP possessed two double bonds in the carboxylic acid chain. In these cases, fragmentation took place mainly by α-cleavage at the carboxylic side chain-bearing carbon with elimination of the carboxylic side chain minus one hydrogen (*m/z* 150). Ions due to the charged carboxylic side chain (*m/z* 181 and 209, respectively) were also observed. The mass spectrum of the cyclopentenone formed from the allene oxide generated from γ9(*S*)-HPOT showed a diagnostic ion at *m/z* 152 (M^+ – 154) due to β-cleavage and loss of C_7H_{11}-$COOCH_3$, i.e., the carboxyl side chain minus one hydrogen. To determine the arrangement and stereochemistry of the side chains, a larger amount (1 mg) of the methyl ester of this cyclopentenone was prepared by scaling up the incubation protocol. The UV spectrum showed an absorption band with λ_{max} (EtOH) = 221 nm (ε 14,000). An aliquot of the material was reduced by treatment with sodium borohydride to afford two cyclopentanol epimers separable by TLC (solvent: ethyl acetate/hexane, 25:75, vol/vol), i.e., epimer A (minor; R_f = 0.42) and epimer B (major; R_f = 0.60) (Scheme 3). The mass spectra of the trimethylsilylated epimers showed prominent ions at *m/z* 382 (M^+), 367 (M^+ – 15; loss of CH_3), 311 (M^+ – 71; loss of C_5H_{11}), and 292 (M^+ – 90; loss of trimethylsilanol). The relative stereochemistry of the ring hydroxyl group and the carboxyl side chain of epimers A and B was determined by subjecting the acetylated epimers to oxidative ozonolysis. The product was saponified, acidified to pH 1, and extracted with 2 vol of diethyl ether. GC–MS analysis of the methyl-esterified oxidation product produced from epimer A demonstrated the presence of the methyl ester of a C_{12} cyclopentol fatty acid formed by cleavage of the side-chain double bond (Scheme 3). In the case of epimer B, the oxidation product was mainly due to the γ-lactone form of a C_{12} cyclopentanol fatty acid. These results demonstrated that the stereochemical relationship between the ring hydroxyl group and the carboxyl side chain was *trans* in epimer A and *cis* in epimer B (Scheme 3).

Aliquots of the six cyclopentenones obtained by nonenzymatic cyclization of allene oxides were subjected to steric analysis and found to be racemic or nearly so (Table 2). As seen in Table 2 and Scheme 2, cyclization of allene oxides lacking a double bond in the β,γ position relative to the epoxide group could not be detected. In the case of 12,13(*S*)-EOD, i.e., the allene oxide generated from 13(*S*)-HPOD, a specific search for its putative cyclization product (15,16-dihydro-12-oxo-PDA) was performed. In these experiments, 13(*S*)-HPOD (150 μM) was incubated with corn AOS in the presence or in the absence of AOC, and the product was treated with sodium hydroxide in order to isomerize any 15,16-dihydro-12-oxo-PDA into its side chain *trans* isomer, of which an authentic reference sample was available (27). By selected monitoring of the ion *m/z* 308 (M^+), the amount of the 15,16-dihydro-12-oxo-PDA derivative was found to correspond to a yield from the incubated 13(*S*)-HPOD of 0.2% or less. This yield is *ca.* 100 times lower than that of 12-oxo-PDA formed from 13(*S*)-HPOT in the absence of AOC. As expected, when bovine serum albumin (15 mg mL^{-1}) was added to such incubations, formation of the 15,16-dihydro-12-oxo-PDA isomer

[a]% *S/S* represents the amount of PDA in *S/S* form compared to the total amount of PDA.
[b]Structures of substrates and cyclopentenones are given in Scheme 2. N.D., not determined; AOC, allene oxide cyclase.

(side chain *trans* isomer; C-value, 19.71) was readily observed (27).

Enzymatic cyclization of allene oxides. Corn or potato AOC enhanced the formation of cyclopentenones from allene oxides generated from the three homologous trienoic acid hydroperoxides 11(*S*)-HPHT, 13(*S*)-HPOT, and 15(*S*)-HPET, as well as from the pentaenoic acid hydroperoxides 15(*S*)-HPEP and 17(*S*)-HPDP. Steric analysis demonstrated that these cyclopentenones were mainly due to the natural *S,S* isomers (Table 2, Scheme 2). The enantiomeric excess of cyclopentenones, which directly reflects the extent of enzyme catalysis in their formation, varied between 78 and 92%. As described above, the structural requirement for nonenzymatic cyclization of allene oxides to take place was found to be the presence of an isolated double bond located in the β,γ position with respect to the epoxide group. This structural element was present in all of the five allene oxides that served as substrates for AOC. Interestingly, the allene oxide γ-9(*S*),10-EOT, which also possessed such a double bond, but in which compound the epoxide group was located in the n-9,10 position rather than that at n-6,7, did not undergo enzymatic cyclization in the presence of corn or potato AOC (Table 2, Scheme 2).

Inhibition of AOC. As mentioned above, allene oxides lacking a double bond in the β,γ position relative to the epoxide group did not undergo chemical or enzymatic cyclization into cyclopentenones. It seemed conceivable that allene oxides belonging to this group might serve as competitive inhibitors of AOC. In order to test this possibility, allene oxides were generated by preincubation of the corresponding hydroperoxides (100 μM) with AOS in the presence of AOC. After 10 s, [1-^{14}C]13(*S*)-HPOT (40 μM) was added and the mixture was stirred for an additional 10 min. Analysis of the yield of ^{14}C-labeled 12-oxo-PDA relative to α-ketol by RP-radio-HPLC demonstrated a significant inhibition of AOC-catalyzed formation of 12-oxo-PDA in the presence of nonsubstrate allene oxides containing the epoxide group in the n-6,7 position [12,13(*S*)-EOD and 14,15(*S*)-EETE] (Fig. 1). Allene oxides having the epoxide group in the n-9,10 position [9(*S*),10-EOD, 9(*S*),10-EOT, γ-9(*S*),10-EOT] had no inhibitory effect. The inhibition by 12,13(*S*)-EOD and 14,15(*S*)-EETE was concentration-dependent and reversible with higher substrate concentrations (data not shown), indicating a competitive inhibition.

In another series of experiments, we explored the inhibition of AOC by chemically stable fatty acids incorporating one or more structural elements in common to the natural al-

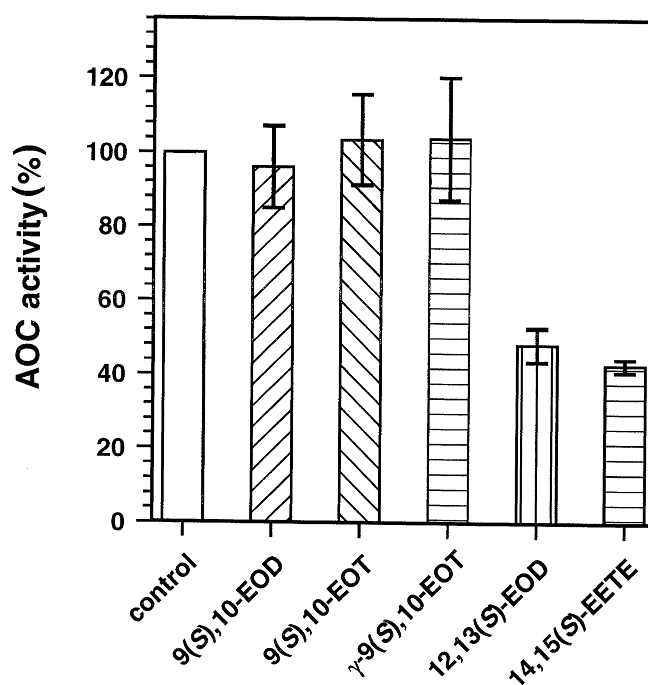

FIG. 1. Effect of nonsubstrate allene oxides on allene oxide cyclase (AOC) activity. The allene oxides were generated from their corresponding hydroperoxide precursors (100 μM). The substrate for AOC in all incubations consisted of 12,13(*S*)-EOT [12,13(*S*)-epoxy-9(*Z*),11,15(*Z*)-octadecatrienoic acid] generated from 13(*S*)-HPOT [13(*S*)-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid]. Error bars indicate SD (n = 3). Other abbreviations: 9(*S*),10-EOD, 9(*S*),10-epoxy-10,12(*Z*)-octadecadienoic acid; 9(*S*), 10-EOT, 9(*S*),10-epoxy-10,12(*Z*),15(*Z*)-octadecatrienoic acid; γ-9(*S*),10-EOT, 9(*S*),10-epoxy-6(*Z*),10,12(*Z*)-octadecatrienoic acid; 12,13(*S*)-EOD, 12,13(*S*)-epoxy-9(*Z*),11-octadecadienoic acid; 14,15(*S*)-EETE, 14,15(*S*)-epoxy-5(*Z*),11(*Z*),13-eicosatetraenoic acid.

lene oxide substrates (Scheme 4; abbreviations in parentheses in this scheme correspond to Fig. 2). As seen in Figure 2, AOC activity was strongly inhibited by a number of n-6,7 epoxy fatty acids, i.e., (±)-*cis*-12,13-epoxy-9(*Z*)-octadecenoic acid, (±)-*trans*-12,13-epoxy-9(*Z*)-octadecenoic acid, and (±)-*cis*-14,15-epoxy-11(*Z*)-eicosenoic acid. The two enantiomers of the first-mentioned epoxy acid were prepared and individually tested for inhibitory potency. The (−) form caused a significantly stronger inhibition compared to the (±)-epoxide, whereas the (+)-form was a weaker inhibitor than the (±)-epoxide (Figs. 2 and 3). Interestingly, the (−)-form [12(*R*),13(*S*)-epoxy-9(*Z*)-octadecenoic acid] has the same stereochemistry at C-13 as the natural substrate 12,13(*S*)-EOT. The strongest inhibition observed in this series of compounds was that of (±)-*trans*-12,13-epoxy-9(*Z*)-octadecenoic acid and (−)-*cis*-12,13-epoxy-9(*Z*)-octadecenoic acid (IC_{50}, 10–20 μM). The inhibitory effect of the n-6,7 epoxy acids was reversible with higher substrate concentration, indicating a competitive inhibition (data not shown). The methyl esters of the n-6,7 epoxy acids lacked the inhibitory effect. Furthermore, no inhibition was observed with an n-9,10-epoxy acid [(±)-*cis*-9,10-epoxy-12(*Z*)-octadecenoic acid].

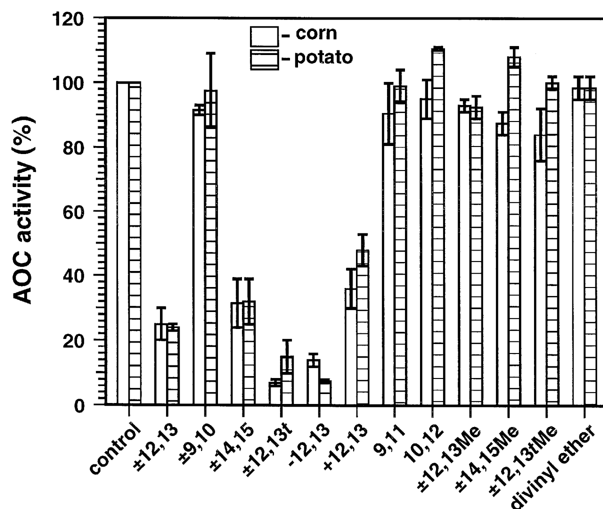

FIG. 2. Effect of substrate analogs on AOC activity at a final concentration of 100 μM each. Me = methyl ester of the respective compound. Error bars indicate SD (*n* = 3). For abbreviations see Figure 1 and Scheme 4.

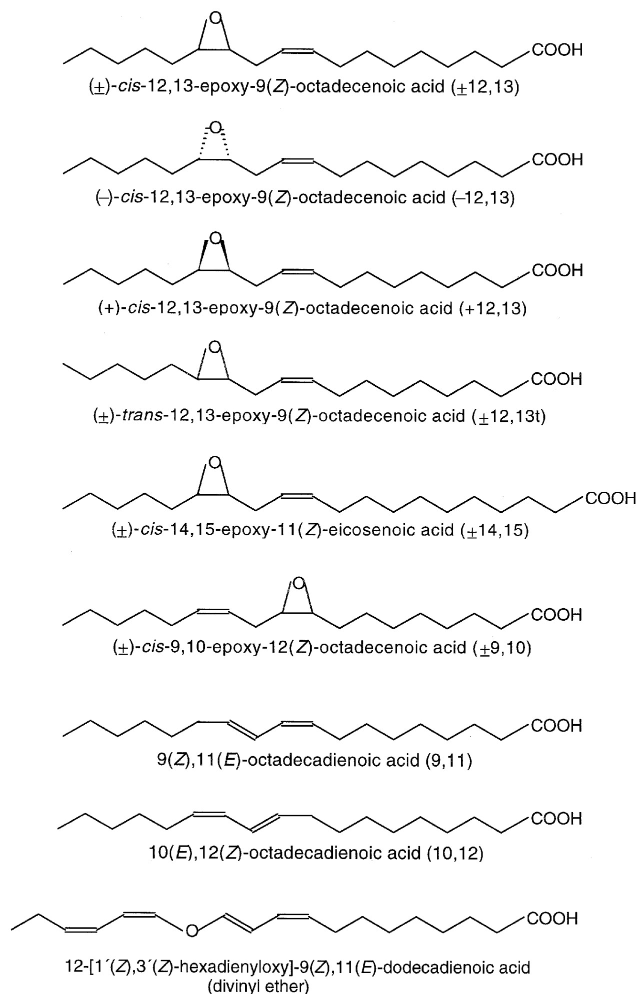

SCHEME 4

Besides the importance of the position and stereochemistry of the epoxide group, we also tested whether the arrangement of double bonds in a carbon chain solely might exert an influence on AOC activity. As shown in Figure 2, neither the 10,12 nor the 9,11 unsaturated fatty acids have any effect on the enzyme, although the position of double bonds in the latter compound is identical to the inhibitory allene oxide 12,13(*S*)-EOD.

To examine whether the oxygen in position 12,13 has to be present as an epoxide function, we included a divinyl ether fatty acid (12-[1′(*Z*),3′(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoic acid, see Ref. 12) in our study that bears the oxygen as an ether-bridge but also at position 12. This ether was not able to inhibit the AOC activity up to a concentration of 100 μM.

It may be concluded that the presence of an epoxide group (allene oxide or saturated epoxide) located in the n-6,7 position of the fatty acid chain is a critical structural feature of compounds serving as competitive inhibitors of AOC. Another important structural element is the carboxyl group, which apparently must exist in its nonesterified form.

DISCUSSION

The kinetic parameters of AOS from corn presented here for different substrates show that the enzyme tends to convert the n-10 hydroperoxides with a lower affinity, but with a higher reaction velocity than the n-6 hydroperoxides. Additional double bonds near the carboxyl terminus attribute to a further decrease in the K_m and v_{max} values, whereas the chain length does not show a pronounced effect. Furthermore, the presence of a double bond at position n-3 significantly increases the affinity and lowers the v_{max} of AOC. The substrate specificities shown here for the corn enzyme are similar to those of the recombinant AOS from barley leaves (Maucher, H.,

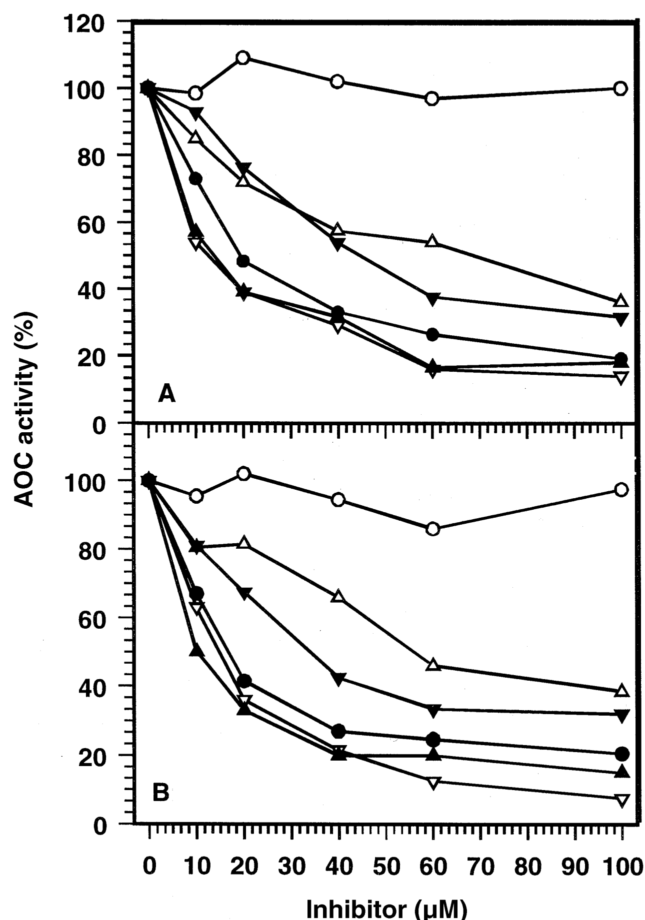

FIG 3. Dose-dependent effect of substrate analogs on AOC activity of (A) corn and (B) potato. (●), (±)-*cis*-12,13-epoxy-9(*Z*)-octadecenoic acid; (△), (+)-*cis*-12,13-epoxy-9(*Z*)-octadececenoic acid; (▽), (−)-*cis*-12,13-epoxy-9(*Z*)-octadecenoic acid; (▲), (±)-*trans*-12,13-epoxy-9(*Z*)-octadecenoic acid; (▼), (±)-*cis*-14,15-epoxy-11(*Z*)-eicosenoic acid; (○), (±)-*cis*-9,10-epoxy-12(*Z*)-octadecenoic acid. The mean values of three replicates are shown.

Hause, B., Feussner, I., Ziegler, J., and Wasternack, C., in preparation) and guayule (31), where a steady decrease in K_m and v_{max} in the order 13(*S*)-HPOD > 13(*S*)-HPOT > 15(*S*)-HPETE was also observed. The AOS from flax showed only minor differences in affinity toward 13(*S*)-HPOD, 9(*S*)-HPOD, and 9(*S*)-HPOT but, in contrast to AOS from corn and barley, converted the 13-hydroperoxide at a rate almost 40-fold higher than that of the 9-hydroperoxides (32).

Interestingly, the affinity of the corn AOS is generally higher toward substrates that give rise to allene oxides that can later be cyclized enzymatically. Regarding the "naturally" occurring substrates present in plants, it is worth mentioning that those hydroperoxides, which are precursors of physiologically active cyclopentenones, such as 12-oxo-PDA from 13(*S*)-HPOT and dinor-12-oxo-PDA from 11(*S*)-HPHT, possess a higher affinity to the AOS from corn and barley than 9(*S*)-HPOD, 9(*S*)-HPOT, or 13(*S*)-HPOD, whose allene oxides are not metabolized to physiologically active compounds known so far.

The occurrence and identification of cyclopentenones after incubation of isomeric fatty acid hydroperoxides with AOS either in the absence or presence of AOC was determined by GC–MS after TLC purification. The method chosen to distinguish between nonenzymatic and AOC-catalyzed cyclization of allene oxides was based on steric analysis of cyclopentenones. That the enantiomeric excess, i.e., the difference between percentage of 9(*S*),13(*S*)-cyclopentenone and of 9(*R*),13(*R*)-cyclopentenone, can be taken as a direct measure of the extent of enzymatic cyclization has been confirmed previously (20).

Nonenzymatic cyclization into cyclopentenones of the 12-oxo-PDA type was documented for six allene oxides, all of which had an isolated double bond in the β,γ position relative to the epoxide group (Table 2, Scheme 2). A zwitterionic species is formed as an intermediate in chemical cyclizations of allene oxides (33), and it has been suggested that a double bond in the β,γ position will stabilize such an intermediate by partial π-electron overlap and hence promote cyclization (34). The importance of this double bond for cyclization was pointed out in 1979, at a time when allene oxides and AOC were unknown in biochemistry (35).

The possibility of spontaneous, chemical cyclization of allene oxides raised the question whether 12-oxo-PDA in plant tissue is formed, partially or wholly, by a nonenzymatic reaction independent of AOC. Although JA isolated from plant tissues is optically pure and has a configuration corresponding to that of 12-oxo-PDA formed enzymatically *in vitro*, in theory this might be attributed to the stereospecificity of enzyme(s) catalyzing further conversion of 12-oxo-PDA to JA rather than to the stereospecificity of the cyclization step. Recent studies concerned with the absolute configuration and optical purity of 12-oxo-PDA in intact plant tissue are not in agreement with such a hypothesis and reaffirm the importance of AOC. Thus, 12-oxo-PDA extracted from plant leaves is the pure 9(*S*),13(*S*) stereoisomer (36). Furthermore, it was recently found that constitutive, as well as wound-induced levels of 12-oxo-PDA in tomato leaves, are exclusively due to the 9(*S*),13(*S*) enantiomer (Hamberg, M., in preparation).

For enzymatic cyclization to take place, it was found that the structural requirements for the chemical cyclization had to be fulfilled, with the added requirement that the allene oxide be located with its epoxide group in the n-6,7 position of the fatty acid chain (Table 2, Scheme 2). This is exemplified by γ-9(*S*),10-EOT, which only cyclizes chemically and is not a substrate for AOC from potato or corn. In flaxseed extracts, the conversion of γ-9(*S*)-HPOT into the respective cyclopentenone had been observed earlier (37), but at that time, the existence of allene oxides and the mechanisms of chemical and enzymatic cyclization were not known. Flaxseed does not contain AOC (38), and in retrospect it seems likely that the conversion of γ-9(*S*)-HPOT into a cyclopentenone observed in flaxseed extracts (37) was due to chemical cyclization of γ-9(*S*),10-EOT.

These two requirements will limit the AOC-catalyzed formation of cyclopentenones to allene oxides generated from

polyunsaturated fatty acids of the n-3 type. The biosynthesis of 15,16-dihydro-12-oxo-PDA from linoleic acid, an n-6 fatty acid, has been suggested (39); and minute amounts of 9,10-dihydro-JA have been isolated from plant tissue (40). In previous work (20,34,35), the formation of the putative 15,16-dihydro-12-oxo-PDA by enzymatic or nonenzymatic cyclization of the allene oxide derived from 13(*S*)-HPOD could not be detected. In the present study, the specific search for the putative 15,16-dihydro-12-oxo-PDA, made by mass spectrometry performed in the sensitive selected-ion-monitoring mode, showed that the extent of cyclization of the linoleic acid-derived allene oxide was 1% or less compared to that of the α-linolenic acid-derived allene oxide. Serum albumin of several mammalian species stabilizes allene oxides and also induces formation of a nearly racemic 15,16-dihydro-12-oxo-PDA derivative, which has, however, its two side chains arranged in the *trans* orientation instead of the *cis* for the natural 12-oxo-PDA (27). This also means that the mechanism of albumin-induced cyclization differs from that of chemical and AOC-catalyzed cyclization. Bovine serum albumin-induced cyclization of allene oxides was recently confirmed by co-incubation with 13(*S*)-HPOD with flaxseed AOS (41); however, the relevance of this finding for the biosynthesis of the putative 15,16-dihydro-12-oxo-PDA in plant tissues is unclear. It should be noted in this context that the albumin-promoted cyclization is not a general "protein effect" but requires that the allene oxide structure be bound to hydrophobic binding sites of the albumin molecule (27).

With respect to the substrate specificities of lipoxygenase and AOS, AOC seems to be the first (and probably only) enzyme of the jasmonate cascade that shows an absolute requirement for an n-3 fatty acid-derived substrate. In comparing the specificity of chemical and enzyme-catalyzed cyclization, it is likely that both types proceed by the same mechanism, which involves anchimeric assistance by π-electron overlap. This would identify a specific function for the n-3 double bond of α-linolenic acid, which can be described in purely chemical terms (4).

It was noteworthy that 10,11(*S*)-EHT could be cyclized in the presence of AOC from corn and potato into optically active dinor-12-oxo-PDA. This supports the suggestion that the biosynthesis of this cylopentenone, which was recently detected in *Arabidopsis thaliana* (42), occurs by the same steps as those in the formation of 12-oxo-PDA.

AOC was inhibited by allene oxides having the epoxide group in the n-6,7 position but lacking the n-3 double bond. Likewise, various stable n-6,7 epoxy fatty acids served as potent competitive inhibitors of AOC. The two enantiomers of one such epoxy acid were individually tested as inhibitors. The epoxy acid with the same absolute configuration at n-6 as the natural allene oxide substrates, i.e. "*S*," was a significantly better inhibitor compared with the racemic epoxide, whereas the n-6(*R*) epoxide was a weaker inhibitor than the racemic epoxide. Analogs with the epoxy group in n-9,10 or that carry the oxygen as an ether function, as well as nonoxidized unsaturated fatty acids, were ineffective.

One can assume therefore that recognition and binding of substrates proceed by the epoxide group in the n-6,7 position. In addition, the substrates seem to enter the active site of AOC *via* their ω-terminal end, since cyclization of allene oxides or inhibition by fatty acid derivatives is not affected by the number of carbons at their carboxyl terminus, whereas the position of the epoxide group in n-6,7 is critical. But the presence of a nonesterified carboxyl group also is required to ensure binding to AOC since methylation of substrate analogs abolished their inhibitory effect on the enzyme activity. Once recombinant AOC becomes available, it will be possible to broaden the current knowledge by mutational analysis of AOC to learn more about the biochemistry of this important step in the biosynthesis of jasmonic acid.

ABSTRACT: The effect of conjugated linoleic acid (CLA) on the relation between structure and function of membranes is described in this paper. Electron spin resonance (ESR) spin-label oximetry was used in the present study to evaluate if oxygen transport and oxygen depletion were affected by incorporation of CLA instead of linoleic acid into membrane phospholipids. Specifically, 1-stearoyl-2-(9*cis*,11*trans*-octadecadienoyl)-phosphorylcholine (SCLAPC) was incorporated into soy plant phosphatidylcholine (soy PC) or egg yolk PC (EYPC) bilayers. The use of spin labels attached to different carbons along the fatty acid chain makes it possible to carry out structural and oximetric determinations with the same test sample. For example, the incorporation of 5 mol% SCLAPC increased the oxygen diffusion-concentration product in soy PC or EYPC liposomes at 37°C, slightly decreased the ordering of the hydrocarbon chains at the C10 and C12 positions (in the region of the conjugated double bonds), and increased the rate of oxygen depletion from the aqueous medium. Similar results were not obtained by incorporating 5 mol% of 1-stearoyl-2-linoleoyl-PC (SLPC). In our model system, free-radical generation was initiated by extended incubation of the liposomes, by induction by 2,2′-azobis(2-amidinopropane)hydrochloride, or by ultraviolet irradiation of H_2O_2. The rate of consumption of molecular oxygen was studied by monitoring the oxygen concentration in the aqueous phases of the liposomes. The effect of 5 mol% SCLAPC in soy PC was significantly larger than 5 mol% SLPC in soy PC; the response patterns with soy PC and EYPC were similar. Furthermore, 5 mol% SCLAPC in 1-palmitoyl-2-linoleoyl-PC showed similar oxygen consumption to that observed with 5 mol% SCLAPC in EYPC. On the other hand, 5 mol% SCLAPC in synthetic PC membranes containing saturated or monounsaturated fatty acids showed low oxygen depletion rates. The perturbation of membrane structure and the increase of the relative oxygen diffusion-concentration products provided a potential mechanism by which CLA incorporated into membrane lipids could affect oxidative stress.

Paper no. L8220 in *Lipids 34,* 1017–1023 (October 1999).

Conjugated linoleic acid (CLA) has received unprecedented interest because of its reported anticarcinogenic (1,2), antiatherogenic (3,4), and fat repartitioning (5,6) effects. It also increases bone mass (7) and normalizes diabetic (8) effects in experimental animal models. At first, the anticarcinogenic response was attributed to the antioxidant activity of CLA (1,2). However, further investigation showed that CLA functions as a prooxidant (9,10), and its effectiveness is different depending on its chemical form, i.e., as free fatty acids, methyl esters, or as a constituent in triacylglycerols or phospholipids (9–11). In biological systems, CLA is incorporated into phospholipids (2,12,13), which are the major structural components of cell membranes. Visonneau *et al*. (14) reported that feeding 1% CLA in the diet inhibits local tumor growth of human breast adenocarcinoma cells inoculated subcutaneously into severe combined immunodeficient mice. Furthermore, CLA completely prevented the spread of breast cancer cells to lungs, peripheral blood, and bone marrow, whereas metastatic spread of transplantable mammary tumors was observed in control animals. This inhibition of metastasis suggests that CLA may provide protective biological effects.

Several matrices were previously used to evaluate the mechanism by which CLA functions in biological systems; however, each one of these experiments was conducted under nonphysiological conditions and/or had limitations. Ha *et al*. (1) used a phosphate buffer/ethanol mixture with free CLA. Ip *et al*. (2) used the thiobarbituric acid-reactive substances assay known to measure only selected oxidation products. Van den Berg *et al*. (9) prepared model phospholipid membranes consisting of 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-

phosphorylcholine (PLPC), but added CLA as the free fatty acid. Chen *et al*. (10) prepared mixtures of CLA (as free acid, methyl ester, or triacylglycerol) with canola oil in hexane and measured the decrease of oxygen in the headspace after heating the solutions at 90°C for 1–2 d. In the present study, we used 1-stearoyl-2-(9*cis*,11*trans*-octadecadienoyl)-phosphorylcholine (SCLAPC), prepared by custom synthesis, and compared it to other synthetic and natural phosphatidylcholines in membrane vesicles. The electron spin resonance (ESR) spin-label oximetry method was used to measure oxygen uptake and to study membrane structure and dynamic properties in the presence or absence of CLA containing phospholipids. There is much controversy on the anti- or prooxidation activity of CLA in membranes. In this work, we studied the effects of CLA on membrane structure and fluidity, on the collision rate between oxygen and lipids at different locations of the membrane, and on the oxygen depletion rates during lipid peroxidation in membranes.

Oxygen is essential to provide normal conditions for intact cell functions. Variation in oxygen availability often has a profound impact on physiological and homeostatic processes within living organisms. Because changes in oxygen concentration in living cells reflect the rate of oxygen consumption and degree of oxygen permeability of the plasma membrane, it is important to measure the effect of CLA on collision rate between oxygen and lipids in membranes to determine the structure–activity relationship of membranes. It is known that lipid peroxidation is a free radical-mediated chain reaction that consists of initiation, propagation, and termination (15–17). However, possible molecular mechanisms that specifically address the effect of CLA on oxidative stress in membranes are still under investigation (1,2,9–11).

Lipid peroxidation and biological defense mechanisms have been studied intensively (18–20). The highly sensitive, noninvasive ESR oximetry method enables one to study early stages of lipid peroxidation by measuring oxygen uptake (21–23). Ongoing conceptual and methodological advancements concerning measurements of oxygen concentration, diffusion, transport, and related issues, e.g., oxygen-mediated reactions, underscore the fundamental importance of this burgeoning field of studies pertaining to health and disease (24,25). ESR oximetry methods are based on bimolecular collisions of O_2 with spin labels, which effectively shorten the spin-lattice relaxation time and broaden the line width of the ESR signal. Possible methods for observing these collisions, classified as T_1- or T_2-sensitive, are outlined elsewhere (26,27). Among them, the T_2-sensitive method (or line width method) is the more widely used for ESR oximetry, for both *in vivo* and *in vitro* studies (28–32).

The ESR spin-labeling and ESR oximetry method have been successfully employed to investigate membrane structure and functions in the studies of fumonisin–membrane interactions (33–35). We found that there are apparent correlations between the perturbation effect of fumonisin (a mycotoxin) on membrane structure (on membrane surface) (33), enhancement on the relative oxygen diffusion-concentration production on membrane surface (34), increasing membrane leakage to small ions as well as hydrophilic solutes, and increasing lipid peroxidation rate in membranes under oxidative stress (35).

In this work, we have carried out systematic studies on the influence of 5 mol% SCLAPC on the structure and dynamic properties of phosphatidylcholine membranes. This percentage was selected based on the observed maximal effectiveness of 1% CLA in the diet in cancer prevention in animal models (2,14); this is equivalent to 5% CLA in the fat of the average human diet which consists of 20% fat. Multilamellar liposomes consisting of soy plant phosphatidylcholine (soy PC) or egg yolk PC (EYPC) were used, in addition to several synthetic phosphorylcholines: 14:0,14:0-PC (DMPC); 18:0,18:1n-9-PC (SOPC); 18:0,18:2n-6-PC (SLPC); and 16:0,18:2n-6-PC (PLPC). These phospholipids were chosen because they allowed us to compare a conjugated diene system to nonconjugated, monounsaturated, and saturated reference materials with different carbon chain lengths. Six different lipid spin labels were implemented to determine the effect of CLA on membrane structure and dynamics. These spin labels were used to study the influence of CLA on oxygen diffusion-concentration product in membranes by using a T_2-sensitive method. Free-radical generation was initiated either by incubation, induction by 2,2′-azobis(2-amidinopropane)-hydrochloride (AAPH), or ultraviolet (UV) irradiation of H_2O_2. Oxygen consumption during oxidative stress of membranes was studied by monitoring oxygen concentration in the aqueous phase.

MATERIALS AND METHODS

1-Stearoyl-2-octadec-9*cis,*11*trans*-dienoyl-*sn*-glycero-3-phosphorylcholine (18:0,CLA-PC; SCLAPC) and 1-stearoyl-2-octadec-9*cis,*12*cis*-dienoyl-*sn*-glycero-3-phosphorylcholine (18:0,18:2n-6-PC; SLPC) were custom synthesized by Matreya, Inc. (Pleasant Gap, PA). 1-Stearoyl-2-oleoyl-*sn*-glycero-3-phosphorylcholine (18:0,18:1n-9-PC; SOPC); 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphorylcholine (16:0,18:2n-6-PC; PLPC); 1-palmitoyl-2-stearoyl-(n-doxyl)-*sn*-glycero-3-phosphorylcholine (n-PCSL) where n is 5, 7, 10, 12, and 16; 2-dioleoyl-*sn*-glycero-3-phosphotempocholine (TEMPO-PC), EYPC, and soy plant PC (soy PC) were purchased from Avanti Polar Lipids Inc. (Alabaster, AL). The fatty acid compositions of EYPC and soy PC were: 16:0, 33.95%; 16:1, 1.00%; 18:0, 10.52%; 18:1, 31.06%; 18:2, 17.72%; 20:4, 3.10%; other, 1.74%; and 16:0, 17.58%; 18:0, 4.27%; 18:1, 11.05%; 18:2, 61.18%; 18:3, 5.11%; respectively. 3-Carbamoyl-2,2,5,5-tetramethyl-3-pyrroline-1-yloxyl (CTPO) and L-α-dimyristoylphosphorylcholine (DMPC) were obtained from Sigma Chemical Co. (St. Louis, MO). AAPH was acquired from Polysciences (Warrington, PA).

The membranes used in this work were a multilamellar dispersion of several phosphatidylcholines containing 0.5 mol% spin labels, n-PCSL or TEMPO-PC. The former was used as a depth probe, whereas the latter was used for

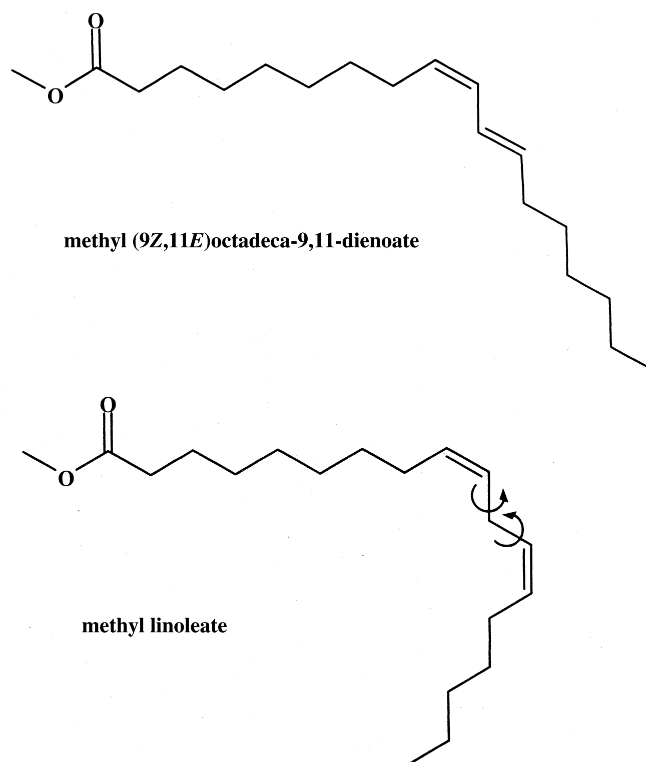
water–lipid interface measurements. Membranes were prepared according to methods of Kusumi *et al*. (36). For oxygen diffusion-concentration product studies, all test samples were run in capillaries made of the methylpentene polymer TPX (0.7 mm i.d). This plastic capillary is permeable to oxygen and nitrogen and is substantially impermeable to water (37). The TPX capillary was placed inside the ESR Dewar insert and equilibrated with a flow of various gases (nitrogen, oxygen, or air) which were also used for temperature control. Fifty-microliter glass capillaries were used for the ESR oximetry studies. CTPO is water soluble and was used at a concentration of 0.14 mM.

Conventional ESR spectra were obtained with a Varian E-109 X-band spectrometer and a variable temperature controller accessory. ESR signals were obtained with 1 mW incident microwave power and 100 kHz field modulation of 1 G (for order parameter), 0.1 G (for line broadening), or 0.05 G (for oxygen consumption) measurements. Spectra were recorded after 5 min sample preparation and temperature equilibration, stored, and manipulated in an IBM computer (program VIKING was obtained from The National Biomedical ESR Center, MCW, Milwaukee, WI). A total of 1024 data points were taken by using a scan width of 100 G (for order parameter) and 5 or 8 G (for line broadening and oxygen consumption). UV photolyses were performed *in situ* at 37°C in liposome suspensions, in 50-μL quartz capillaries placed in the ESR cavity, using a Schoeffel 1000 W xenon lamp coupled with a Schoeffel grating monochromator. The excitation light had a maximum centered at 270 nm. All experiments were performed in duplicate. The data were obtained with error of less than 10%.

RESULTS AND DISCUSSION:

Structural effects. The ESR spectra of n-PCSL (n = 5, 7, 10, 12, 16) incorporated in three membrane systems provided information about the degree of lipid organization. These systems were soy PC, 5 mol% SLPC, and 5 mol% SCLAPC in soy PC. At 37°C, spin labels underwent anisotropic rotational motion. The ESR spectra of 5, 7, 10, and 12-PCSL labeled membranes were characterized by calculating the values of the order parameter S (38,39). Our data show that there was no significant change in order parameters with incorporation of 5 mol% SLPC at all four C5, C7, C10, and C12 positions in the membranes. However, with 5 mol% of SCLAPC, some perturbation effects at C7, C10, and C12 positions in the membranes were observed as indicated by the decrease in the values of the order parameter. At those three positions, the values of S were 0.481 vs. 0.438; 0.291 vs. 0.227; and 0.212 vs. 0.171 in soy PC vs. 5 mol% SCLAPC in soy PC, respectively. The decrease in ordering in the region of the conjugated double bonds indicated that SCLAPC had a perturbation effect on the membrane that may be attributed to the configuration of the conjugated double bond system along the fatty acid chain of CLA. For comparison, the lowest energy configuration of 9*cis*,11*trans*-octadecadienoic (18:2) acid (CLA) and linoleic acid (9*cis*,12*cis*-18:2) are shown in Scheme 1. CLA shows a unique bend in the molecule (C9 to C12) which is not free to rotation, while the bend in linoleic acid (C9 to C13) can rotate about the methylene-interrupted carbon (C11). In the membrane center at C16, the spin labels underwent isotropic rotational motion, and the rotation correlation time τ (21) was used to describe this motion behavior. Our results indicated that there were no significant differences in rotation correlation times in all three different membrane systems investigated (data not shown).

Oxygen diffusion-concentration product. Because bimolecular collisions of molecular oxygen and nitroxide groups induce Heisenberg spin exchange, which yields ESR line broadening (40), the changes in the ESR line width, ΔH[x], are proportional to the oxygen diffusion-concentration product (41). This was used as an experimental parameter to assess the oxygen diffusion-concentration product (or bimolecular collision rate) of fluid phase membranes. The ESR line width changes, which were measured at six different depths in the three membrane systems discussed above, provided profiles (42) of oxygen diffusion-concentration product across membranes, as depicted in Figure 1. These depths (Fig. 1, *x* axis) were at the water-lipid interface (labeled T-PC), and at C5, C7, C10, C12, and C16 of the bilayer membrane. Changes were highest in the values of the line width (Fig. 1, *y* axis) near C7, C10, and C12 of the 5 mol% SCLAPC in soy PC bilayer (open circles) relative to the control (100% soy PC, solid circles). There were no significant changes with 5 mol% SLPC in soy PC (solid triangles) as indicated in Figure 1. The relative changes



SCHEME 1

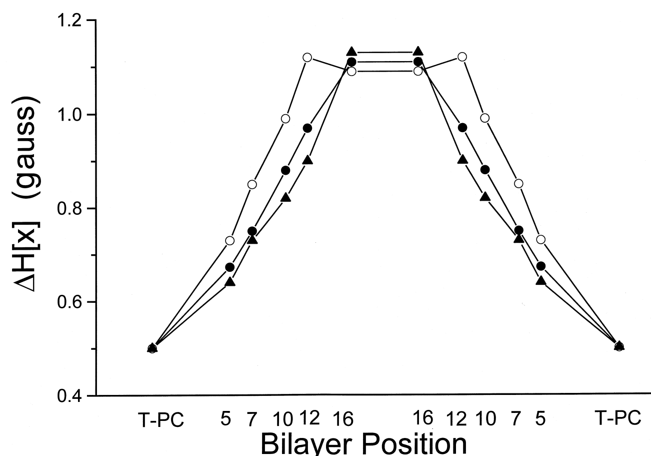


FIG. 1. Profiles of the oxygen electron spin resonance (ESR) line broadening (or relative oxygen permeability) across soy plant phosphatidylcholine (soy PC) membranes (●), with 5 mol% 1-stearoyl-2-(9*cis*,11*trans*-octadecadienoyl)-phosphorylcholine (SCLAPC) (○), and 5 mol% 1-stearoyl-2-linoleoyl-phosphorylcholine (SLPC) (▲) at 37°C. The abscissa indicates the approximate depth in the membrane bilayers at which each spin label is positioned (T-PC represents Tempocholine-PC at the water–lipid interface). $\Delta H[x] = H_{pp}(x, O_2) - H_{pp}(x, N_2)$, where $H_{pp}(x, O_2)$ and $H_{pp}(x, N_2)$ are the peak-to-peak ESR line widths of the first derivative spectrum, measured at the center line position for test samples saturated with oxygen and nitrogen, respectively.

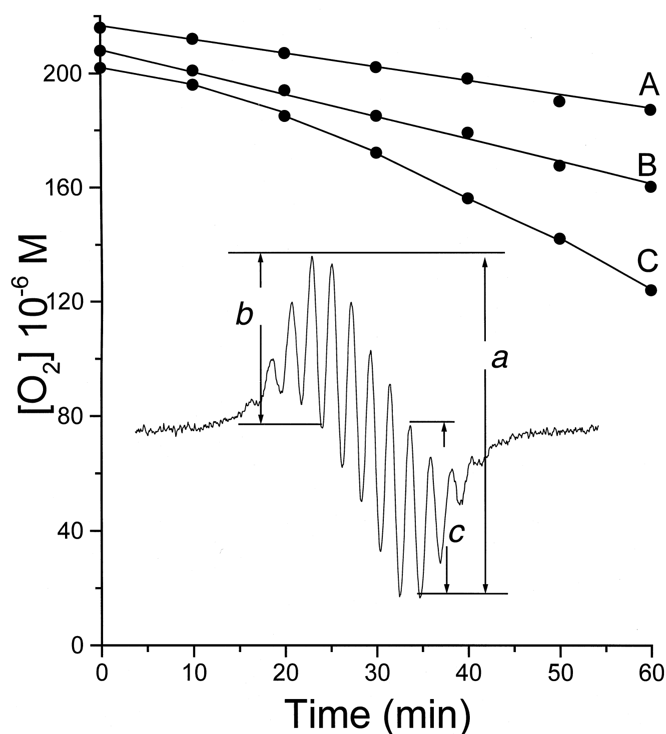

FIG. 2. Oxygen consumption measured in a closed chamber with samples of (A) 100% SLPC, (B) 100% SCLAPC, and (C) 100% soy plant PC (soy PC) membrane suspensions (30 mg/mL) at 37°C in Hepes buffer (pH 7.2) containing 3-carbamoyl-2,2,5,5-tetramethyl-3-pyrroline-1-yloxyl (CTPO) (0.14 mM). Aliquots were taken from (aerated) stock samples that had been incubated at 37°C for 45 min. The ESR spectra were taken 5 min after the temperature equilibration of sealed samples in the cavity. The inset illustrates the superhyperfine structure of the low-field line from ESR spectra of CTPO in nitrogen-saturated aqueous solution. The parameter *K*, which is used in calibration charts to determine the oxygen concentration, was calculated by using the equation $K = (b + c)/2a$, where *a, b,* and *c* are determined as shown in the figure. Spectra were recorded at 37°C, microwave power 1 mW, modulation amplitude 0.05 G, and scan range 5 G. For abbreivations see Figure 1.

in ΔH on the oxygen diffusion-concentration products indicate that SCLAPC enhanced the oxygen diffusion-concentration product in the region of the conjugated double bonds in the membranes.

Oxygen consumption. An oximetry method that requires ESR spin labels and a closed chamber (21,22) was used to measure the oxygen concentrations during lipid peroxidation. ESR spectra of nitroxide spin labels exhibit three lines because of the hyperfine interaction of the unpaired electron with the nitrogen nucleus. Each line is further split into another group of lines because of proton superhyperfine interaction. The resolution of the proton superhyperfine lines depends on the oxygen concentration due to the bimolecular collisions of the spin label with molecular oxygen, a paramagnetic molecule, broadening each line through Heisenberg exchange interactions. Resolution of the superhyperfine structure of the low-field line of the ESR spectrum of CTPO depended on the oxygen concentration of the test solution. Oxygen consumption was thus obtained from the calibration curves relating the *K* parameter (21,22; see Fig. 2) to oxygen concentration.

Loss of molecular oxygen in closed capillaries containing liposomes has been used as a diagnostic indicator of lipid peroxidation (21–23). The rate of oxygen consumption was monitored with the spin label CTPO. The insert in Figure 2 displays typical results when the spin-probe closed-chamber technique is used. The incubation of liposomes containing fatty acids with double bonds on the alkyl chain led to a depletion of oxygen from the medium; liposomes containing DMPC showed no depletion of oxygen (data not shown). The oxygen consumption rate in pure (100%) SLPC and SCLAPC was slower than for soy PC liposomes; EYPC gave similar results to soy PC.

Figure 3 shows the relative rates of oxygen consumption in different systems during extensive incubation. There was very slow depletion of oxygen in DMPC with 5 mol% SCLAPC. The oxygen consumption rates in soy PC with and without 5 mol% SLPC were similar. In marked contrast, enhanced rates of oxygen consumption occurred in soy PC with successively higher concentrations of SCLAPC (Fig. 3). The oxygen consumption of pure SLPC and SCLAPC were less than that of soy PC (data not shown). These results showed a unique effect attributed to a CLA-containing phospholipid as part of a liposome membrane. The effect of CLA-containing phospholipids on oxygen consumption increased with increasing concentration, up to 5 mol% (Fig. 3), a concentration shown previously to result in the greatest beneficial effects based on mammary cancer prevention in laboratory animals (2,14).

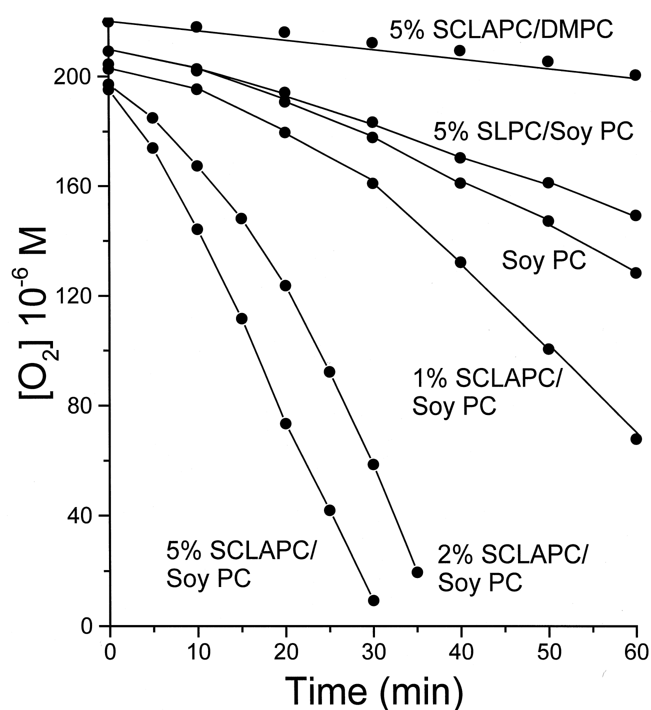

FIG. 3. Oxygen consumption measured in a closed chamber with test samples of 5 mol% SCLAPC in DMPC, 5 mol% SLPC in soy PC, 100% soy PC, and 1, 2, and 5 mol% SCLAPC in soy PC membrane suspensions (30 mg/mL) at 37°C in 25 mM Hepes buffer (pH 7.2) containing CTPO (0.14 mM). Aliquots were taken from (aerated) stock samples that had been incubated at 37°C for 45 min. The ESR spectra were taken 5 min after the temperature equilibration of sealed samples in the cavity. DMPC, L-α-dimyristoylphosphorylcholine; for other abbreviations see Figures 1 and 2.

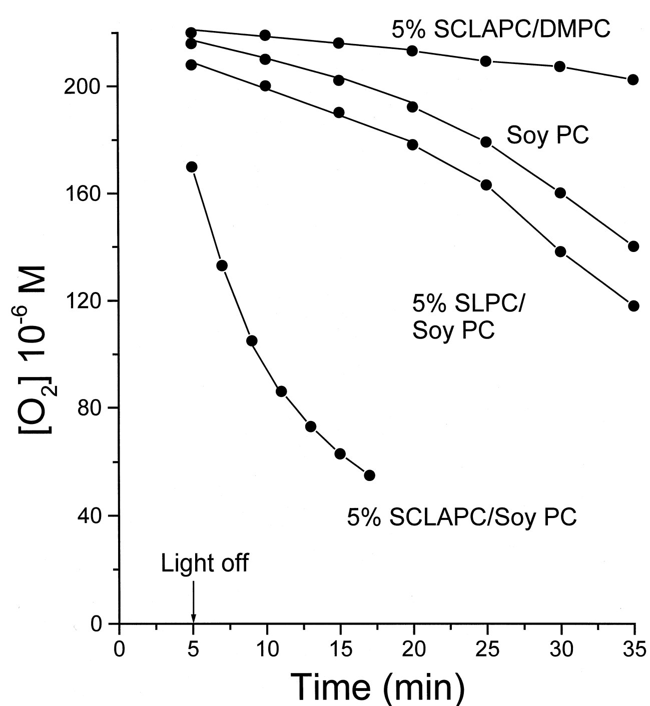

FIG. 4. Oxygen consumption measured in a closed chamber with samples of 5 mol% SCLAPC in DMPC, 5 mol% SLPC in soy PC, 100% soy PC, and 5 mol% SCLAPC in soy PC membrane suspensions (60 mg/mL) at 37°C in 50 mM Tris buffer (pH 7.4) containing CTPO (0.14 mM). Test samples were prepared at 37°C first, then aliquots were mixed with H_2O_2 (0.6%), transferred to the quartz capillary tube, and placed in the ESR cavity. Each test sample was ultraviolet-irradiated (270 nm, power 1 kW, from a distance of 70 cm) for 5 min, and spectra were recorded subsequently. For abbreviations see Figures 1–3.

The effects of 5 mol% SCLAPC or SLPC in soy PC (or EYPC) on oxygen consumption were also tested when membranes were exposed to free radical attack. Several representative experiments, in which hydroxyl radicals were generated by using UV illumination of H_2O_2, are depicted in Figure 4. Each test sample was exposed to UV irradiation for 5 min to initiate free-radical generation. Based on the *K* parameter obtained, test samples containing 5 mol% SCLAPC in soy PC exhibited markedly lower levels of residual oxygen in solution, or increased rates of oxygen consumption, than those consisting of 5 mol% SLPC in soy PC or 100% soy PC (Fig. 4). Our results indicated that the relative rates of oxygen consumption were enhanced by SCLAPC, both during and after UV irradiation. As a control, Figure 4 shows the slow oxygen consumption rate with 5 mol% SCLAPC in DMPC. The rate of oxygen consumption of 5 mol% SCLAPC in SOPC was similar to that in DMPC, whereas that of 5 mol% SCLAPC in PLPC was similar to that in EYPC (data not shown).

AAPH is known to strongly induce lipid peroxidations in cell and reconstituted membranes (43,44). Figure 5 shows the results of oxygen consumption of soy PC liposomes induced by AAPH in the presence of 5 mol% SCLAPC or SLPC. In this experiment, the lipid concentrations were reduced 10 times in order to discriminate between this and another potential pathway of oxygen consumption involving CLA oxidation products such as furans (45). Again, 5 mol% of SCLAPC in soy PC dramatically increased the oxygen consumption in comparison to 5 mol% SLPC in soy PC.

Results of the three different free radical generation experiments (Figs. 3–5) showed the same trends. The oxygen consumption rate in soy PC with incorporation of 5 mol% SCLAPC was always faster than that in soy PC alone or with incorporation of 5 mol% SLPC. In addition, the incorporation of 5 mol% SCLAPC into all the synthetic phosphorylcholine (DMPC, SOPC, and SLPC) resulted in low oxygen depletion rates, except into PLPC. Similar results were found with both EYPC and soy PC, but only the data for soy PC are presented. The apparent role of double-bond conjugation in SCLAPC and mixed chain length in the major PC on oxygen consumption in soy PC, EYPC, or synthetic PC membranes, is not fully understood.

The interaction between CLA and lipid bilayers is probably complex. SCLAPC may slightly disturb membrane structure and enhance oxygen diffusion-concentration product due to the rotational restriction dictated by the presence of a conjugated double bond system (Scheme 1). The increase in oxygen diffusion-concentration product induced by conjugation

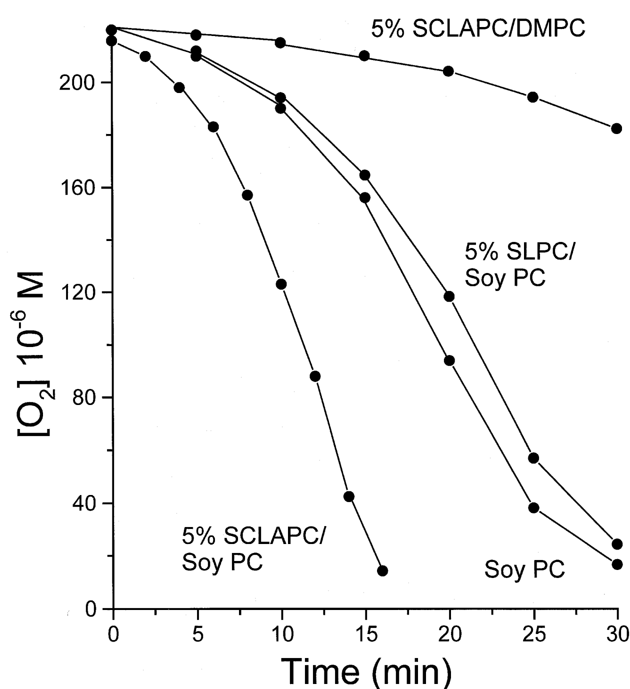

FIG. 5. Oxygen consumption measured in a closed chamber with samples of 5 mol% SCLAPC in DMPC, 5 mol% SLPC in soy PC, 100% soy PC and 5 mol% SCLAPC in soy PC membrane suspensions (3 mg/mL) at 37°C in 50 mM phosphate buffer (pH 7.4) containing CTPO (0.14 mM). Samples were prepared at 37°C first, then aliquots were mixed with 40 mM freshly made AAPH [2,2′-azobis(2-amidinopropane)hydrochloride], transferred to the capillary tube, and placed in the ESR cavity. Spectra were recorded after 5 min equilibration.

correlates with the decrease in the ordering of the membranes. As shown by Hubbell and McConnell (38), the disordering of lipid alkyl chains can be ascribed to an increase in the amplitude of motion of the long molecular axis and to an increase in the probability of gauche conformations, P_g, of carbon–carbon single bonds. The increase in P_g leads to an increase in the formation of alkyl chain "kinks," which provide a molecular mechanism for the associated increase in oxygen diffusion-concentration product. In addition to perturbation caused by double bonds, there is evidence that differences in chain length exacerbate membrane disturbance.

A correlation is apparent between the structural properties of membranes, the enhancement effect of SCLAPC on oxygen diffusion-concentration product, and the susceptibility to oxygen depletion. The results reported in this work indicate that CLA perturbs a complex interrelationship between membrane structure and the susceptibility to oxygen consumption. At physiological temperatures, the membrane, which is in the fluid phase, is altered and displays an increase in oxygen permeability. This leads to increased exposure of membrane components to oxygen and might make lipids more susceptible to attack by free radicals. The combined effects of perturbing membrane structure and increasing oxygen diffusion-concentration products by double bond conjugation imply that CLA molecules probably increase the bimolecular collision frequency of oxygen, and/or reactive oxygen species, with target molecules, thereby accelerating the oxygen consumption. Whether this increase in oxygen consumption is involved in, or contributes to, the observed beneficial physiological or anticancer effects of CLA requires further study.

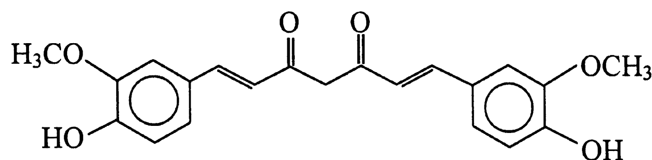
ABSTRACT: Curcumin (diferuloyl methane) has a wide range of physiological and pharmacological actions. Curcumin interaction with human serum albumin (HSA) has been followed by fluorescence quenching and circular dichroism (CD) measurements. Based on fluorescence measurements, the equilibrium constant for the interaction is $2.0 \pm 0.2 \times 10^5\ M^{-1}$. Binding of curcumin to HSA induces an extrinsic CD band in the visible region. From the induced CD band measurements, the equilibrium constant has a value of $2.1 \pm 0.3 \times 10^4\ M^{-1}$. Thus, HSA has two kinds of affinity sites for curcumin, one with high affinity and the other with lower affinity. Job's plot indicated a binding stoichiometry of 1:1 for the high-affinity site. The equilibrium constant was invariant with temperature in the range of 15 to 45°C, suggesting the role of hydrophobic interactions in the binding of curcumin to HSA. Curcumin does not change the conformation of the HSA molecule. These measurements have implications in the understanding of the curcumin transport under physiological conditions.

Paper no. L8214 in *Lipids 34,* 1025–1029 (October 1999).

Curcumin is the major coloring pigment present in the spice turmeric (1). Curcumin, a β-diketone, contains two ferulic acid molecules linked *via* a methylene bridge at the carbon atoms of the carboxyl groups (Scheme 1). This phenolic compound exhibits a wide range of physiological and pharmacological effects. Curcumin has antioxidant and antiinflammatory activities (2–4). Dietary curcumin reduces iron-induced hepatic toxicity in rats (5). Curcumin is a good scavenger of reactive oxygen species (6) and also protects hemoglobin from nitrate-induced oxidation (7). The anticarcinogenic properties of curcumin in animals have been demonstrated by its inhibitory role in both tumor initiation induced by benz[α]pyrene and 7,12-dimethyl benz[α]anthracene, and tumor promotion induced by phorbol esters (8,9). Recently, curcumin has been shown to be highly effective in inhibiting type I human immunodeficiency virus long terminal repeat directed gene expression and virus replication (10). It inhibits neutrophil activation, mixed lymphocyte reaction, and proliferation of smooth muscle cells, and it suppresses nitrogen-induced proliferation of blood mononuclear cells (11). Curcumin lowers the formation of inflammatory compounds such as prostaglandins and leukotrienes by inhibiting the arachidonic acid metabolism by lipoxygenase and cyclooxygenase enzyme systems in mouse epidermis (12).



SCHEME 1

Furthermore, curcumin can access both hydrophobic and hydrophilic environments of a microheterogeneous system; the corresponding radical is stable with respect to oxygen and can be repaired by the natural antioxidants vitamins C and E in hydrophilic and hydrophobic environments, respectively (13). Under certain conditions, curcumin accelerates oxygen radical formation by reducing ferric ion to give more active iron(II) (14). Curcumin was shown to lower carrageenan-induced edema in rats and to give relief from rheumatoid arthritis in patients (15,16). These studies indicate that curcumin probably reaches the target tissues to exhibit its diverse activities. However, its mode of transport *in vivo* is not clear.

Ravindranath and Chandrashekar (17) detected the presence of orally administrated curcumin in the portal blood, liver, and kidney of rats. Curcumin is a lipophilic molecule with phenolic groups and conjugated double bonds (1). Many lipophilic molecules, like long-chain fatty acids, are known to be carried by albumin in blood (18). However, it is not known whether albumin can function as a carrier molecule for curcumin. To assess this, the present investigation was undertaken to study the interaction of curcumin with human serum albumin (HSA). The interaction has been followed by fluorescence and induced circular dichroism (CD) measurements. These measurements indicate the existence of two kinds of binding sites for curcumin on the HSA molecule.

MATERIALS AND METHODS

HSA (fatty acid-free), *N*-acetyl tryptophan amide, and Trizma base were purchased from Sigma Chemical Co. (St. Louis, MO). Curcumin (>99% pure) was purchased from M/s

Flavours and Essence Pvt. Ltd. (Mysore, India). Concentration and purity of curcumin were determined by established spectral measurements and by high-performance liquid chromatography (19).

A stock solution of curcumin (1 mM) was prepared in ethyl alcohol and diluted to 10 μM with 0.05 M Tris-HCl buffer (pH 7.0). A working solution of HSA (1.13 μM) was prepared in Tris-HCl buffer (pH 7.0). Intrinsic fluorescence of HSA in the presence and absence of curcumin at different concentrations was followed after 280 nm excitation and at 330 nm emission wavelength in a Shimadzu RF5000 recording spectrofluorometer (Kyoto, Japan) attached with thermostat cuvette holder for constant temperature.

Quenching of relative fluorescence intensity of HSA by curcumin was analyzed in terms of the binding of curcumin to protein using an established method (20), with the assumption that the binding of each molecule of curcumin causes the same degree of fluorescence quenching. The percentage quenching of the fluorescence intensity of proteins by curcumin was corrected empirically for internal absorption and filtration by subtracting the percentage quenching by the same concentration of curcumin of the fluorescence of *N*-acetyltryptophan amide equivalent in absorption to protein at 285 nm. The equilibrium constant, *K,* is given by the following equation:

$$K = \frac{\beta}{(1-\beta)} \cdot \frac{1}{\mathrm{Cf}} \quad [1]$$

where $\beta = Q/Q_{max}$ (where Q_{max} = maximum quench), Cf = $C_T - n\beta T$, and C_T is the total concentration of curcumin added. The value of K is given by the slope of a plot of $\beta/(1-\beta)$ against Cf, the free ligand concentration. Q_{max} was determined by extrapolation of a double reciprocal plot of Q vs. C_T to intercept. The value of n for curcumin–HSA interaction was obtained by Job's method of continuous variation (21). The total concentration of curcumin and protein was held constant at 10 μM and relative proportions were varied.

CD studies. CD measurements were made with a JASCO J20-C automatic recording spectropolarimeter (Tokyo, Japan), calibrated with *d*(+)-10-camphor sulfonic acid. Quartz cells of 1-cm pathlength for the region 250–550 nm and 1 mm for the far-ultraviolet (UV) region were used. Slits were programmed to yield a 10-Å band width at each wavelength. Molar ellipticity values, $[\Theta]_M$, were calculated using a value of 368 for the molecular weight of curcumin.

RESULTS

Fluorescence spectroscopic studies. Fluorescence emission spectra of HSA after being excited at 280 nm were observed at 330 nm. Addition of increasing amounts of curcumin quenched the fluorescence of HSA without significantly affecting the fluorescence maxima (data not shown). The relative fluorescence emission intensities at 330 nm were plotted against curcumin concentration (Fig. 1). Fluorescence emission of HSA decreased by 25% at a curcumin concentration of 5.8 μM. From the corresponding double reciprocal plot of fluorescence quenching data, it is evident that curcumin quenches the fluorescence of HSA with a Q_{max} of 34 ± 2%. The stoichiometry of curcumin binding to HSA was established using Job's method of continuous variation (Fig. 2).

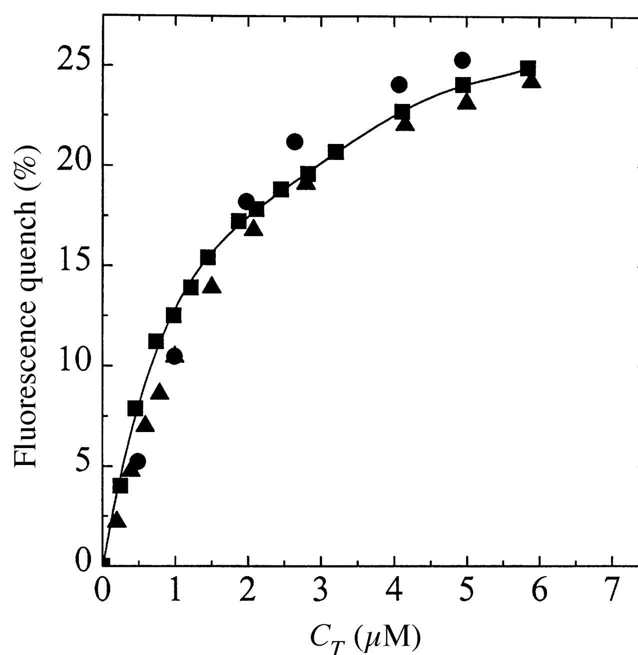

FIG. 1. Fluorescence quenching of human serum albumin (HSA) by curcumin at (■) 15°C , (●) 25°C, and (▲) 45°C. Concentration of HSA was 75 μg/m. Measurements were made in 0.05M Tris HCl, pH 7.0.

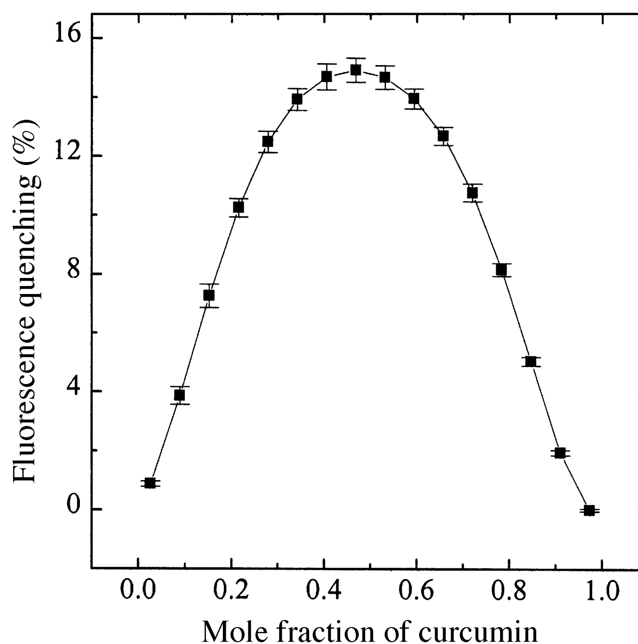

FIG. 2. Job's plot for the interaction of HSA with curcumin ([HSA] + [curcumin] = 10 μM). The error bars refer to the standard error of the mean of three sets of experiments. See Figure 1 for abbreviation.

The stoichiometry of the curcumin–HSA complex was found to be 1:1 ± 0.4. By using a value of $n = 1$ and the extent of maximal interaction obtained from the double reciprocal plot, the mass action plot (Fig. 3) was constructed. From the slope of the mass action plot, the equilibrium constant was found to be $2.0 \pm 0.3 \times 10^5\ M^{-1}$ at 25°C.

Effect of temperature on the curcumin–HSA interaction. The effect of temperature in the range 15 to 45°C on the interaction was followed by determining the equilibrium constant (K_{eq}), which was invariant over the temperature range studied. Thus, van't Hoff's $\Delta H° \approx 0$ kcal/mol and the binding reaction was entropy-driven; $\Delta S° = 25$ cal/mol/K at 27°C with activation free energy of $\Delta G° = -RT\ln K_{eq} = -7.5$ kcal/mol.

CD studies. HSA exhibited broad minima in the near-UV region of 260 to 300 nm. Addition of curcumin (80 µM) did not affect the ellipticity values in this region. Curcumin (80 µM) did not affect significantly the CD bands in the far-UV region (200–260 nm) either. The secondary structure content of HSA was not affected by the addition of curcumin. Curcumin does not exhibit any CD bands in the region of 300–600 nm. However, it becomes optically active upon binding to HSA and exhibits extrinsic CD bands in the region of 300–500 nm. It has a positive band at 400–500 nm and a small negative band at 320–410 nm (Fig. 4). The electronic transitions occurring at 464 nm were used for quantitative measurements. The induced CD amplitude at 464 nm was followed as a function of curcumin concentration. The CD amplitude increased with the concentration of curcumin for the fixed concentration of HSA (Fig. 5A). By assuming that the amplitude at 464 nm for any given molar ratio of curcumin to HSA is directly proportional to the fraction of curcumin that is complexed with HSA, the K_{eq} and Θ_{max} for the complete HSA–curcumin complex were calculated using the equation of Ikeda and Hamaguchi (22)

$$\ln\left[\frac{\Theta}{(\Theta_{max} - \Theta)}\right] = \ln K_{eq} + n \ln C_T \qquad [2]$$

The plot of $\ln[\Theta/\Theta_{max} - \Theta]$ vs. $\ln C_T$ was a straight line (Fig. 5B) with a slope of 1.0 ± 0.1, suggesting that one molecule of curcumin bound to one molecule of HSA. The K_{eq} for the interaction was $2.1 \pm 0.3 \times 10^4\ M^{-1}$. However, the K_{eq} value obtained by fluorescence titration is higher by one order magnitude ($K_{eq} = 2.0 \pm 0.2 \times 10^5\ M^{-1}$), suggesting that HSA has two kinds of affinity sites for curcumin, one with high affinity and the other with lower affinity.

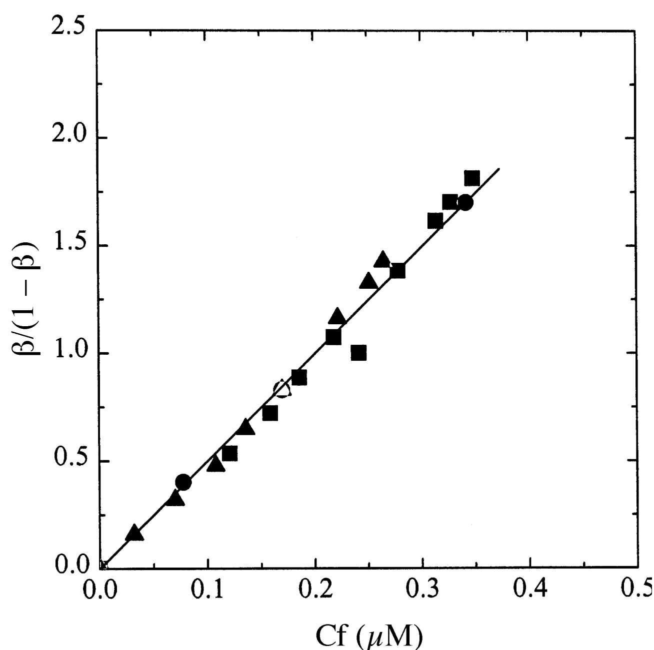

FIG. 3. Mass action plot β/(1 – β) against free curcumin concentration (Cf) at (■) 15°C, (●) 25°C, and (▲) 45°C. The slope of the straight line was used to obtain the equilibrium constant (K_{eq}).

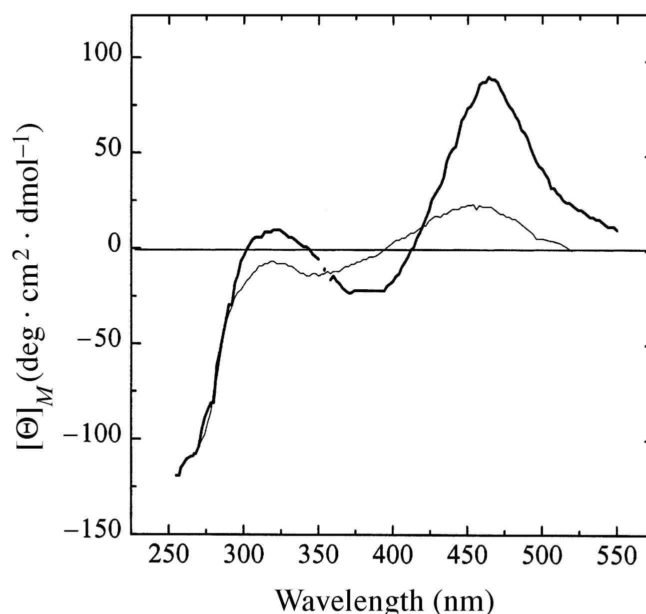

FIG. 4. Circular dichroism (CD) spectra of HSA–curcumin complex. The measurement was made in 1-cm cells with different concentrations of curcumin (solid line is 50 µM and thin line is 10 µM). The HSA concentration was 0.9 mg/mL. See Figure 1 for abbreviation.

DISCUSSION

These results indicate that curcumin binds to HSA with two binding sites characterized by K_{eq} of $2.0 \times 10^5\ M^{-1}$ and $2.1 \times 10^4\ M^{-1}$. The two binding constants obtained were not due to two different physical techniques used. They were due instead to two different types of sites: the high-affinity site (saturated at 7 µM) detected by fluorescence measurements and the low-affinity site (saturated in the concentration range of 0 to 100 µM) detected by CD. Technically, it is not possible to overlap the concentration range of curcumin with the two different techniques used. Curcumin has a phenolic structure with conjugated double bonds; proteins and phenols are thought to reversibly complex with each other *via* hydrogen bonding and hydrophobic interactions (23). The involvement of hydrophobic groups in the formation and stabilization of phenolic tan-

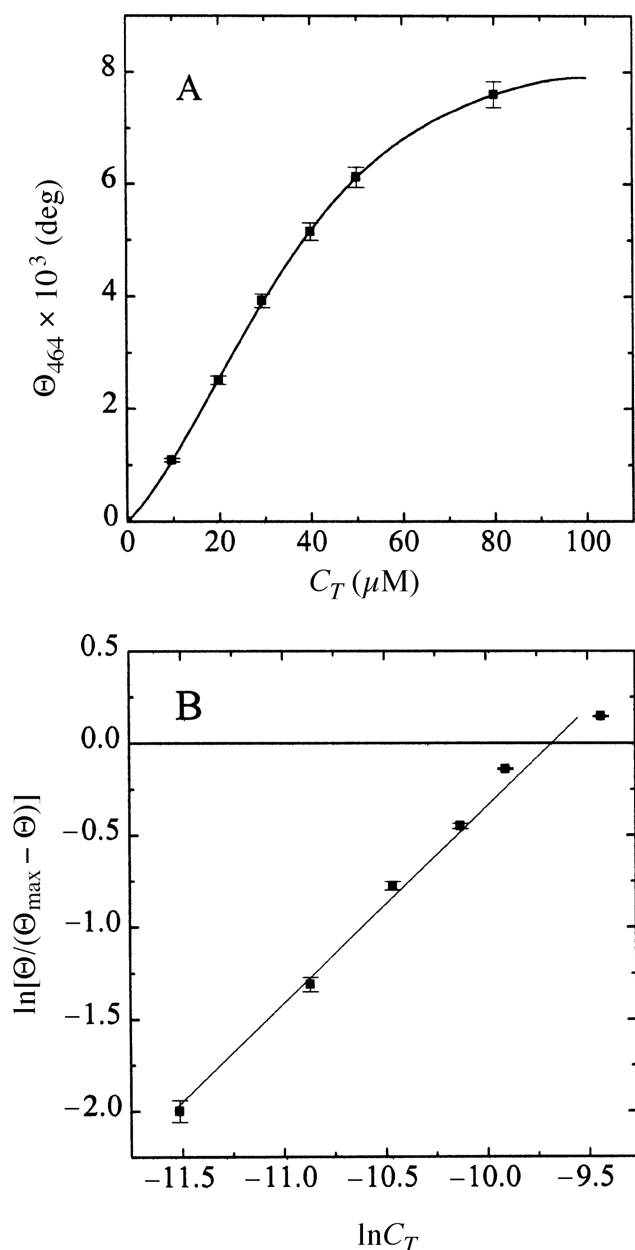

FIG. 5. (A) Variation of the ellipticity values at 464 nm as a function of curcumin concentration. (B) Plot of ln $[\Theta/\Theta_{max} - \Theta]$ vs. ln C_T for HSA–curcumin complex. The error bars indicate the variance of ellipticity values for two sets of experiments.

nins and protein complexes was established in several independent studies (24,25). Oh *et al.* (24) have drawn attention to the fact that hydrophobic interactions may dominate the ligand–protein interaction. The presence of hydrogen donors, in the form of phenolic hydrogen groups in the curcumin molecule and hydrogen acceptors of the peptide linkage of the protein, may lead to the formation of hydrogen bonds. However, our studies on the equilibrium constant as a function of temperature do not favor the concept of hydrogen bonding as a contributing factor for curcumin binding to HSA. The invariance of K_{eq} in the temperature ranges studied supports the role for hydrophobic interactions.

Earlier workers showned (26) that the capacity of ligands to bind to protein is determined by the chemical and physical nature of the phenolic nucleus itself. Both curcumin and protein contain hydrophobic regions. The aromatic nuclei of curcumin, which are essentially hydrophobic, have an affinity for the aliphatic and aromatic side chains of HSA. Binding stoichiometry of curcumin and HSA is indicative of mole-to-mole interaction. Since HSA is known to contain hydrophobic pockets, it is feasible that curcumin possibly binds to the hydrophobic pocket of albumin. The binding constant of curcumin with HSA is comparable with that of caffeic acid ($2.8 \times 10^4\ M^{-1}$), a simple dihydrophenolic compound, where it was shown that the hydroxyl groups play a major role in binding to HSA. Curcumin may also react with the amino acids of proteins through its reactive carbonyl and phenolic hydroxyl groups. Gossypol, a polyphenol present in cottonseed, binds to albumin with an association constant of $2.2 \times 10^6\ M^{-1}$ (27). HSA is the primary carrier of both exogenous and endogenous ligands. These ligands associate with HSA in the plasma by noncovalent linkages and some of them have very high association constants (28). Many of the ligands, like bilirubin, reversibly bind to albumin at neutral pH (29). Bilirubin binds to albumin with 1:1 stoichiometry. However, curcumin binds with 2:1 stoichiometry. Fatty acids in the serum are also carried by albumin. Albumin contains six binding sites for free fatty acids (18,30). Palmitic acid binds to albumin with an association constant of $5.2 \times 10^6\ M^{-1}$. An increase in acyl chain length and degree of acyl chain unsaturation for the same chain length increases the association constant, thus suggesting that fatty acid solubility in aqueous medium may play a significant role in the equilibrium between the fatty acid association with HSA and the aqueous phase. Curcumin with three unsaturated bonds between the two phenyl rings may have a role in the interaction of curcumin–HSA in the aqueous phase, as found in the association between fatty acid and HSA. The curcumin association constant one obtained for the high-affinity site is comparable to that of a free fatty acid binding association constant and gives an indication that curcumin may have binding sites similar to those of fatty acids on albumin. The CD measurements indicated that when curcumin was bound to the protein, it induced a CD band, which was used for quantitative measurement. Curcumin forms a 1:1 complex with HSA with an association constant of $2.0 \pm 0.2 \times 10^5\ M^{-1}$. Recently, we showed (31) that lipoxygenase-1 could be inhibited by phosphatidylcholine (PC)-micelle-bound curcumin. The binding of curcumin with PC micelles involved both hydrophilic and hydrophobic interactions. Similarly, several other studies have shown that curcumin could inhibit membrane-bound enzymes like phospholipase D, protein kinase C, and $pp60^{c\text{-}src}$ tyrosine kinase (32,33). The anticarcinogenic and antioxidant properties of curcumin are potentiated in the hydrophobic environment (13). In this context, the binding of curcumin to HSA was studied. Furthermore, the equilibrium constants obtained for the binding of curcumin with HSA are comparable to many of the K_{eq} reported for both exogenous and endogenous ligands with HSA (21). In conclusion, these measurements sug-

gest a role for hydrophobic interactions in the binding of curcumin to serum albumin. Curcumin may associate with serum albumin by hydrophobic interactions and may thereby be transported to appropriate target cells where it elicits its pharmacological effects.

ABSTRACT: The use of the organic cosolvents tetrahydrofuran and dimethylsulfoxide was found to be unsuitable for prostate tumor cell cultures because of solvent cytotoxicity and the poor solubility and instability of lycopene. For example, the half-life of lycopene in organic/aqueous solution was found to be less than 2 h. Therefore, a micellar preparation of lycopene was developed for the solubilization and stabilization of lycopene in cell culture media. Neither the micelles themselves nor lycopene solubilized in micelles at concentrations up to 10 μg/mL in the cell culture media produced cytotoxicity or inhibition of cell proliferation in either LNCaP human prostate cells or Hs888Lu human lung cells. Lycopene solubilized in micelles was stable for at least 96 h under standard cell culture conditions so that a constant lycopene supply could be provided to the cells. During the culture process, lycopene was taken up by LNCaP cells and reached a plateau at approximately 12 h. Micelles provide a convenient, inexpensive, and nontoxic vehicle for dissolving and stabilizing carotenes such as lycopene in tissue culture media and then delivering them to cells growing in culture.

Paper no. L8272 in *Lipids 34,* 1031–1036 (October 1999).

Carotenoids are highly conjugated, intensely colored isoprenoid plant pigments, which may be grouped into the set of hydrocarbons called carotenes or the oxygenated species known as xanthophylls (1). Unstable when exposed to light or oxygen, carotenoids are generally efficient quenchers of singlet oxygen (2). Approximately 50 carotenoids, such as β-carotene, serve as precursors of vitamin A in mammals (3). The carotene lycopene, the abundant red pigment in the tomato, is among the most efficient singlet oxygen quenchers of the carotenoids (4). Although isomeric with β-carotene ($C_{40}H_{56}$), lycopene has no provitamin A activity.

During digestion in humans, the hydrophobic carotenoids are solubilized by bile salts in the small intestine and then absorbed along with other lipids (5). After absorption, carotenoids are transported from the gut to the liver in the chylomicrons, where they are repackaged and transported through the bloodstream in low density lipoproteins (LDL) and high density lipoproteins (HDL) (6). Virtually insoluble in water, carotenoids require solubilization by bile salts, chylomicrons, or lipoproteins in order to be transported in the human body.

Pharmacological actions of carotenoids include enhancement of immune response and possible prevention of initiation, promotion, or progression of cancer (7). In particular, lycopene is under investigation as a possible anticancer or chemopreventive agent (8). In a prospective human study, Gann *et al.* (9) found that low levels of plasma lycopene, but not other abundant dietary carotenoids, were associated with increased incidence of certain cancers. In particular, the chemopreventive evidence for lycopene was strongest for cancer of the prostate, lung, and stomach (10). In this regard, we have been investigating the possible role of lycopene in the prevention of cancer and, in particular, the prevention of prostate cancer. As part of our studies, we needed to examine the uptake and possible effect of lycopene on human prostate cancer cells and other cells growing in tissue culture.

However, existing methods of solubilizing carotenoids were either inadequate or unsuitable for our studies. For example, the use of tetrahydrofuran (THF) as a cosolvent for carotenoid solubilization as reported by Cooney *et al.* (11) can be toxic to some cell lines, is limited to relatively low concentrations of the most hydrophobic carotenoids, such as lycopene, and does not contribute to the stability of lycopene in solution. Ukai *et al.* (12) reported that lycopene may be solubilized and partially stabilized by complexation with cyclodextrin for use as a food additive, but this approach has not been applied to cell culture. El-gorab and Underwood (13) and Martin *et al.* (14) reported the use of micelles to solubilize β-carotene. Because Martin *et al.* (15) found that their micellar preparation did not stabilize carotenoids, they advocated instead the use of human lipoproteins as a vehicle both to solubilize and to stabilize β-carotene. Given the ease of preparation and low cost and availability of reagents for micelles compared to human lipoproteins, we developed a micellar formulation that both stabilized and solubilized lycopene at physiologically relevant concentrations during cell culture.

EXPERIMENTAL PROCEDURES

All chemicals were reagent- or high-performance liquid chromatography (HPLC)-grade and were purchased from either Sigma Chemical Co. (St. Louis, MO) or Fisher Scientific (Fair Lawn, NJ). Purchased from Sigma Chemical Co., all-*trans* lycopene was 95% pure by ultraviolet/visible (UV/VIS) spectrophotometry at 502, 472, and 444 nm. HPLC analysis showed >95% purity (Fig. 1A). THF was high-purity, non-spectrophometric-grade containing butylated hydroxytoluene (BHT; 250 ppm), which was purchased from Burdick & Jackson (Muskegon, MI). Tests for peroxides (peroxide test, EM Science, Cherry Hill, NJ) showed that the THF used in this study contained no detectable peroxides (<1 ppm). Cell culture media were purchased from GibcoBRL (Grand Island, NY). LNCaP human prostate tumor cells and Hs888Lu human fibroblast-like lung cells were obtained from the American Type Culture Collection (Rockville, MD). LNCaP cells were maintained in Roswell Park Memorial Institute (RPMI) 1640 medium supplemented with 10% heat-inactivated fetal bovine serum, 2% L-glutamine, 1% antibiotic/antimycotic (prepared with 10,000 units/mL penicillin G sodium, 10,000 μg/mL streptomycin sulfate, and 25 μg/mL amphotericin B in 0.85% saline), 1.5 g/L sodium bicarbonate, 4.5 g/L glucose, 10 mM HEPES, and 1.0 mM sodium pyruvate at 37°C in a humidified atmosphere at 5% CO_2 in air. Hs888Lu cells were cultured in Dulbecco's modified Eagle's medium supplemented with 10% heat-inactivated fetal bovine serum, 2% L-glutamine, 1% antibiotic/antimycotic (prepared with 10,000 units/mL penicillin G sodium, 10,000 μg/mL streptomycin sulfate, and 25 μg/mL amphotericin B as Fungizone in 0.85% saline), 1% sodium pyruvate, 1% sodium bicarbonate, and 0.1 mM nonessential amino acids at 37°C in a humidified atmosphere at 5% CO_2 in air.

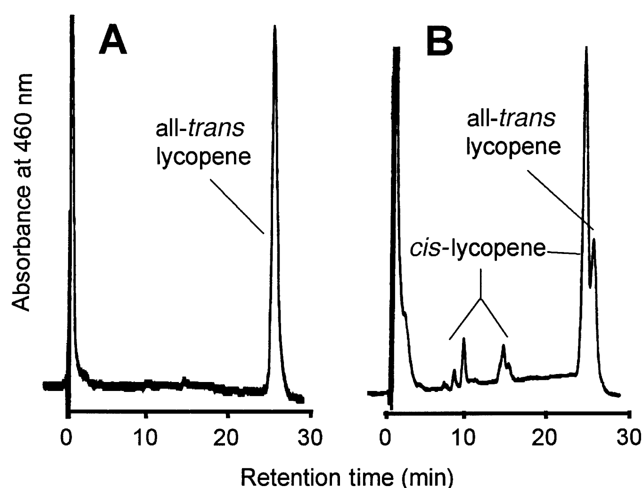

FIG. 1. Chromatograms obtained by high-performance liquid chromatography (HPLC) using a C_{30} carotenoid column showing (A) all-*trans* lycopene standard (5 μg/mL) dissolved in tetrahydrofuran (THF), and (B) lycopene after storage in THF in the dark and in an airtight polystyrene container for 24 h.

Several methods were evaluated for dissolving lycopene in cell culture media at physiological concentrations. Initially, lycopene was dissolved in THF and then diluted into cell culture media according to the method of Cooney *et al.* (11). A variation of this method was investigated in which dimethylsulfoxide was substituted for THF. Subsequently, an alternative approach was developed using a micellar formulation of lycopene as described below.

Preparation of micelles containing lycopene. In a glass container, 13 μL of L-α-phosphatidylcholine, 100 μL monoolein, 100 μL oleic acid, and 0, 5, 10, 20, 50, 100 or 200 μL of lycopene dissolved in THF (500 μg/mL) as the stock solution were combined, and the organic solvent was removed under a stream of nitrogen. Next, 10.76 mg of sodium taurocholate was added to 10 mL of complete cell culture and the mixture was sonicated in a water bath (Branson Ultrasonics Corp. model 2210 R-MTH; Danbury, CT) at room temperature for 15 min to form micelles containing lycopene. The final concentration of each component in the solution was as follows: 100 μM monoolein, 33.3 μM oleic acid, 2 mM sodium taurocholate, and 16.7 μM L-α-phosphatidylcholine. Lycopene concentrations in the cell medium ranged from 0 (for control incubations) to 10 μg/mL (18.63 μM). Each 10-mL batch of cell medium was sterilized by passage through a presterilized 0.22-μm filter.

Lycopene stability in THF or cell culture media. Lycopene dissolved in THF at 9.33 μM or cell culture medium (10 mL) containing 9.32 μM lycopene solubilized in micelles was incubated from 0–96 h using standard cell culture conditions in plastic (Falcon, polystyrene, nonpyrogenic tissue culture dish) or glass containers (Pyrex reusable petri dishes). In some stability experiments, samples were exposed to sunlight. Aliquots of 1 mL were removed at 0, 1, 2, 4, 8, 12, 24, and 48 h and then extracted immediately. First, 1 mL of 0.9% saline and 1 mL ethanol were added, and then the solution was vortexed for 30 s. Then, 3 mL of hexane was added followed by vortexing for another 30 s. The upper hexane layer was removed, and the aqueous solution was extracted twice more with 3-mL portions of hexane. Finally, the hexane fractions were combined in a glass test tube and evaporated to dryness in a vacuum centrifuge.

The amount of residual lycopene was measured using reversed-phase HPLC. All incubations and assays were carried out at least three times and the results were averaged. HPLC analyses were carried out using Waters (Milford, MA) model 501 pumps, 740 data module, and Lamda-Max model 481 UV/VIS absorbance detector. An isocratic solvent system, consisting of methyl-*tert*-butyl ether/methanol/acetic acid (50:49.5:0.5, by vol) at 1.0 mL/min on a YMC (Wilmington, NC) C_{30} 3 μm column (4.6 × 200 mm). The absorbance was measured at 460 nm.

Growth curves and protein assays for LNCaP and Hs888Lu cells. Sterilized medium containing micellar lycopene at 0.05, 0.5, 1.0, 5.0, or 10.0 μg/mL was prepared. LNCaP or Hs888Lu cells were seeded into 96-well plates at a density of 1×10^5 cells/mL (100 μL/well). After an overnight

preincubation, the standard culture medium was decanted, and the lycopene micelle medium solution was added to each well. The plates were incubated for 0–6 d. At each time point of 0, 1, 2, 3, 4, 5, and 6 d, cell viability was assayed as follows: (i) The medium was decanted, cold 20% trichloroacetic acid (100 μL/well) was added, and the cells were incubated at 4°C for 1 h. (ii) The cells were washed with water (1 mL/well) five times and air dried. (iii) The plates were stained using 4% sulforhodamine B (SRB) in 1% acetic acid, 100 μL/well for 30 min at room temperature. (iv) The SRB was decanted, the cells were washed with 1% acetic acid (1mL/time/well) four or five times and air dried again. (v) Then 200 μL 10 mM Tris base (pH 10) was added to dissolve the residue while shaking for 5 min on a gyrating shaker. (vi) The absorbance at 515 nm was measured to indicate protein contained in viable cells. Control incubations were carried out to which micelles containing no lycopene were added, or neither micelles nor lycopene was added.

Cellular uptake of lycopene. LNCaP and Hs888Lu cells were each plated at a density of 1×10^5 cells/mL in 25 cm^2 dishes (10 mL/dish). After preincubation overnight, the standard culture media were decanted and replaced with media containing micellar lycopene at 5 μg/mL. The plates were incubated for 0, 1, 2, 4, 8, 12, or 24 h, and at each time point, cells (alive or dead) were collected and centrifuged in a glass tube. To this tube were added 200 μL of water and 100 μL of internal standard (1 μg/mL retinyl acetate in absolute ethanol). Then 100 μL of absolute ethanol was added and vortexed for 30 s followed by 2 mL hexane (containing BHT, 100 mg/L) and vortexing another 1 min. The tube was centrifuged for 5 min, and the upper hexane layer was removed to another glass tube. The aqueous layer was extracted with another 2 mL hexane. The hexane fractions were combined in the glass tube and evaporated to dryness in a vacuum centrifuge. The residue was redissolved in 50 μL ethyl ether and 150 μL of the HPLC mobile phase to a total volume of 200 μL. Extracts were kept at 0°C until analysis the same day or kept at −30°C overnight.

HPLC was carried out on a Waters Novapak C_{18} column (3.9 × 150 mm, 5 μm particle size) at 1 mL/min with an isocratic elution system containing methanol/acetonitrile/THF (50:45:5, by vol). The HPLC analysis was completed in 15 min. The peaks were detected using a Waters programmable multiwavelength detector (model 490). Two channels were used simultaneously, one for retinyl acetate at 325 nm and the other for lycopene detection at 450 nm.

Measurement of cis/trans *lycopene in cells.* In order to determine the ratio of *cis/trans*-lycopene in cells and in the corresponding culture medium, extracts of LNCaP cell cultures, prepared as described above for the cellular uptake study, were analyzed using liquid chromatography–mass spectrometry (LC–MS). Based on our method for the analysis of β-carotene using LC–MS (16), a new method was developed for the measurement of *cis/trans* isomers of lycopene. Briefly, a Hewlett-Packard (Palo Alto, CA) G1946A LCMSD mass spectrometer equipped with atmospheric pressure chemical ionization (APCI) and an 1100 series HPLC system was used with a YMC C_{30} 3 μm carotenoid column (4.6 × 200 mm). An isocratic mobile phase consisting of 19% methyl-*tert*-butyl ether in methanol at 1.0 mL/min was used without solvent splitting during LC–MS. Under these conditions, the base peak of the positive ion APCI mass spectrum of lycopene was the protonated molecule at *m/z* 537. Therefore, selected ion monitoring of *m/z* 537 with a dwell time of 1 s was used to monitor the elution of lycopene isomers from the C_{30} column. No difference in mass spectrometric response has been observed between lycopene isomers. Other mass spectrometer parameters included a nitrogen nebulizer gas pressure of 60 psi, a nitrogen drying gas temperature of 300°C, a capillary voltage of 4000 V, a fragmenter voltage of 110 V, and a corona current of 4.0 μA.

RESULTS AND DISCUSSION

Because lycopene was found to be much less soluble in dimethylsulfoxide than in THF and the solubility limits of lycopene in dimethylsulfoxide and THF are approximately <0.01 and 4 mg/mL, respectively, only THF was investigated as a cosolvent for the delivery of lycopene to cell culture media. The stability of lycopene (5 μg/mL) in THF was investigated under a variety of conditions, and the results are summarized in Table 1. Lycopene rapidly degraded when exposed to air, was more stable in the dark than in the light (sunlight), and was more stable at 4°C than at room temperature. Unexpectedly, lycopene was much less stable in polystyrene than in glass containers. All-*trans* lycopene in THF solution rapidly isomerized to form at least six *cis* isomers as shown in Figure 1.

When lycopene was dissolved in THF, added to RPMI 1640 culture medium, and then incubated in glass under standard cell culture conditions at 37°C and 5% CO_2 in air, it degraded rapidly with a half-life of approximately 2 h (Fig. 2A). Even if the culture media were changed daily, this instability

raises questions regarding the feasibility of carrying out meaningful cell culture studies using lycopene, since most culture experiments require days to weeks to complete. Therefore, an alternative method was required to solubilize and at the same time stabilize lycopene in cell culture media.

As an alternative approach, lycopene was solubilized using micelles, which enabled lycopene concentrations of a maximum 10 μg/mL (18.6 μM) to be obtained in the cell culture media. This value exceeds the level of lycopene normally observed in human plasma, which is on the order of 0.5 μM (17). Even with dietary supplementation using tomato juice, plasma levels do not usually exceed 1.6 μM (18). Micelles containing lycopene were incubated in the cell culture medium under standard culture conditions for up to 96 h. The concentration of lycopene remaining at each time point was determined using HPLC, and the results show that lycopene is stable in micelles in cell culture media at 37°C and 5% CO_2 in air (see Fig. 2B). Once in micellar form, lycopene in plastic cell culture plates is stable. The next question to be addressed was whether micelles or lycopene produce cytotoxicity.

LNCaP human prostate tumor cells and Hs888Lu human lung cells were incubated for up to 6 d (144 h) with micelles prepared as described in the Experimental Procedures section (see Figs. 3A and 3B). Since the proliferation of Hs888Lu cells in the control incubations containing no micelles was identical to the growth of cells in media containing micelles, no toxicity was observed due to the micelles (Fig. 3B). However, a slight decrease in saturation density of LNCaP cells but not Hs888Lu cells was observed in micelle-treated cells after 4 d (Fig. 3A). In parallel experiments, cells were incubated in media containing five different concentrations of lycopene. Even at the maximal concentration of 10 μg/mL, no toxicity due to lycopene was observed (Fig. 3).

When the cell culture media were replaced daily with fresh media containing additional micelles, inhibition of cell growth was observed. Sodium taurocholate was determined to be the cause of the cytotoxicity, since higher concentrations of this surfactant in the micelles produced greater cytotoxicity. Therefore, the concentration of sodium taurocholate used throughout this investigation was empirically determined to be adequate for micelle formation and lycopene solubilization, and nontoxic when added to the cell culture just once. For comparison, the toxicity of THF was investigated in LNCaP cells. At the concentration of THF used by Cooney *et al.* (11) to solubilize carotenoids, proliferation of LNCaP cells was inhibited (data not shown). Therefore, the combination of poor solubility of lycopene in aqueous solutions of THF, the instability of lycopene in THF solutions, and the toxicity of THF to prostate cells growing in culture makes THF a poor choice for these studies. On the other hand, the solubility, sta-

Stability of lycopene (initial concentration, 263 μg/mL) in Roswell Park Memorial Institute 1640 medium at 37°C under standard cell culture conditions in polystyrene culture dishes measured using HPLC. (A) Lycopene was solubilized using THF, and (B) micelles were used to solubilize lycopene in the cell culture medium (*n* = 3). See Figure 1 for abbreviations.

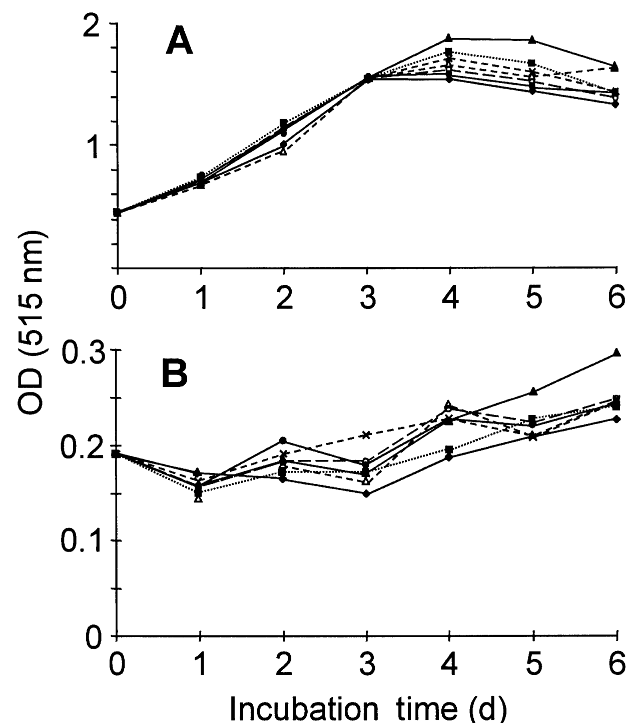

FIG. 3. The effect of media containing no micelles (▲), micelles alone (■), or micelles containing lycopene at final concentrations of (···) 0.05, (x) 0.1, (○) 0.5, (●) 1.0, (△) 5.0, and (◆) 10.0 μg/mL on the growth curves of (A) LNCaP human prostate tumor cells and (B) Hs888Lu human lung cells. Optical density was measured at 515 nm to determine cell protein, which represented cell numbers (*n* = 8).

bility, and minimal toxicity of micellar lycopene are all compatible with prostate cell culture studies.

The next question addressed was whether micellar lycopene could be taken up by prostate cells. LNCaP cells were cultured for up to 24 h in medium containing 5 µg/mL lycopene in micelles. Cells were harvested at different time intervals, rinsed with phosphate buffered saline, and the cellular lycopene was extracted and measured using HPLC. The concentrations of lycopene at each time point were normalized to cellular protein levels, and the results are summarized in Figure 4. Micellar lycopene was taken up by LNCaP cells, and a plateau was reached at approximately 12 h (Fig. 4A). These results show that micellar lycopene in the culture medium can be taken up by LNCaP cells.

The relative proportion of all-*trans* lycopene contained in LNCaP cells during uptake of micellar lycopene over 24 h was measured using LC–MS (16), and the results are shown in Figure 4. During the first 8 h, the concentration of cellular all-*trans* lycopene increased as micellar lycopene was incorporated into the cells (Fig. 4A). Simultaneously, the cellular concentration of *cis*-lycopene increased, too, which was probably the result of all-*trans* lycopene isomerizing as it was released from the stabilizing environment of the micelles during cellular uptake. In contrast, the concentration of extracellular (micellar) all-*trans* lycopene decreased only slightly during this time (Fig. 4B), and the concentration of extracellular *cis*-lycopene remained low. In addition to protecting lycopene from oxidation, the micellar preparation stabilized all-*trans* lycopene and prevented isomerization to its *cis* isomers (see Fig. 5A and 5B). Simultaneously, the proportion of *cis*-lycopene increased substantially within the LNCaP cells (Fig. 5C and 5D).

These results are consistent with those of Clinton *et al.* (19) who reported that the proportion of *cis*-lycopene in human prostate tissue is greater than that in human serum. Specifically, Clinton *et al.* found that lycopene in the prostate of men was 79–88% *cis*, but serum contained 58–73% *cis*-isomers. In our prostate cell culture study, LNCaP cells contained 20–50% *cis*-lycopene after incubation for 24 h. But in the corresponding cell culture medium, the amount of *cis* lycopene was always lower at 0–25%. The explanation for an excess of *cis*-lycopene within prostate cells remains unknown.

Because of the extreme hydrophobicity of carotenes such as lycopene, these compounds are insoluble in tissue culture media. Furthermore, lycopene is highly unstable and degrades rapidly when dissolved in organic solvents or aqueous sys-

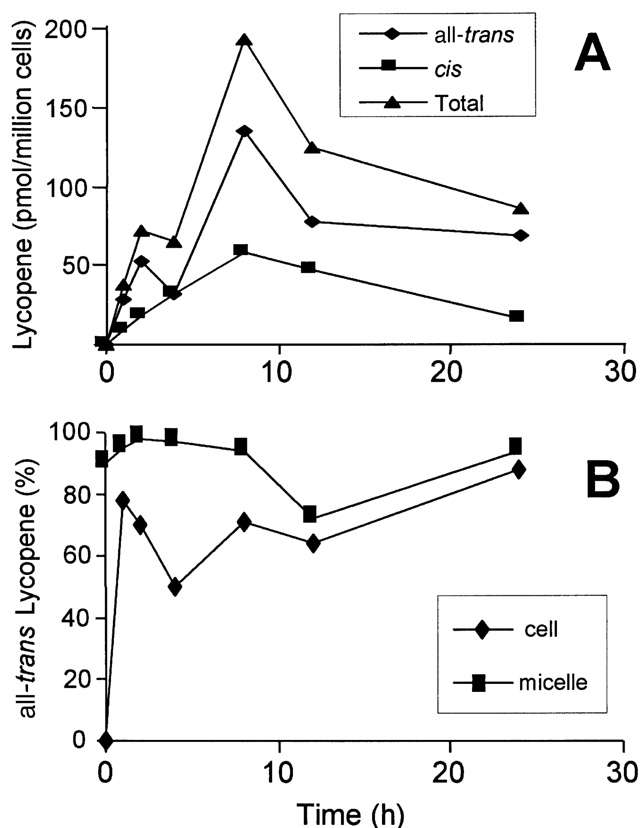

FIG. 4. (A) Cellular lycopene levels in LNCaP human prostate cells (pmol/million cells) measured at different time intervals after addition of 5 µg/mL (9.33 µM) lycopene in micelles. (B) Fraction of all-*trans* lycopene (as % of total lycopene) present in LNCaP cells and remaining in extracellular micelles at each time point measured using liquid chromotography–mass spectrometry (LC–MS) ($n = 2$).

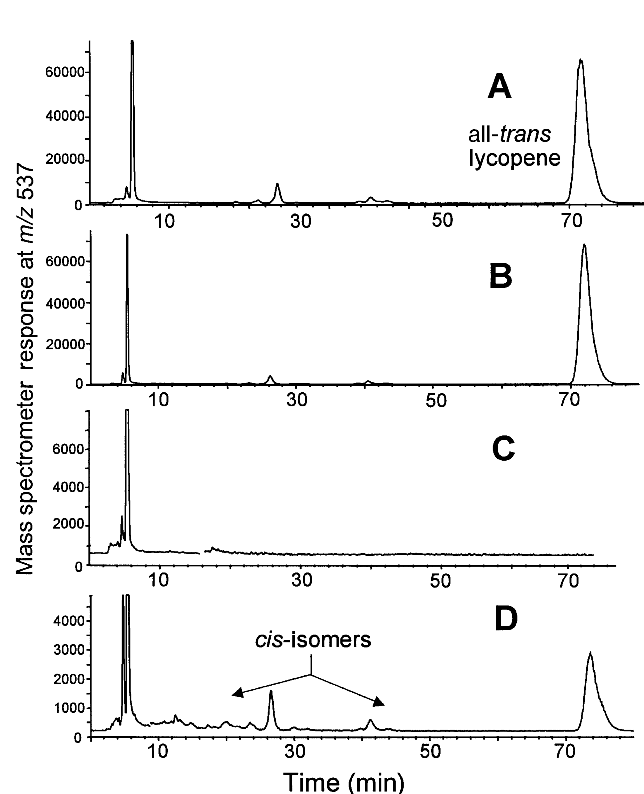

FIG. 5. LC–MS mass chromatograms showing the relative amounts of *cis*- and all-*trans* lycopene (A) in fresh cell culture medium containing micellar lycopene at 5 µg/mL ($t = 0$ h); (B) in the cell culture medium after incubation for 8 h; (C) in LNCaP cells at $t = 0$ h (no lycopene); and (D) in LNCaP cells after incubation with lycopene for 8 h. The proportion of *cis*-lycopene increased only within the cells during incubation. See Figure 4 for abbreviation.

tems containing organic cosolvents and exposed to light and/or air. Micelles provide a convenient, inexpensive, and nontoxic vehicle for dissolving carotenes, such as lycopene, in tissue culture media and then delivering these compounds to cells growing in culture at concentrations spanning the range of physiological levels and even beyond. Our studies show that lycopene contained in micelles may be taken up by cells growing in culture and that the cellular levels generally reflect the concentration of lycopene in the culture medium. Since the half-life of lycopene dissolved in aqueous/organic solutions is only 2 h, meaningful cell culture studies cannot be carried out using lycopene without some means of stabilization. Finally, micelles stabilize lycopene by preventing isomerization and degradation by air so that cell culture studies may be carried out with a constant supply of lycopene in the culture medium.

Regulation of Mevalonate Synthesis in Low Density Lipoprotein Receptor Knockout Mice Fed n-3 or n-6 Polyunsaturated Fatty Acids[1]

Ahmed El-Sohemy and Michael C. Archer*

Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, Canada, M5S 3E2

ABSTRACT: 3-Hydroxy-3-methylglutaryl (HMG)-CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis, catalyzes the formation of mevalonate which is also required for cell proliferation. Changes in HMG-CoA reductase may mediate the differential effects of n-3 and n-6 polyunsaturated fatty acids (PUFA) on experimental mammary tumorigenesis, but the mechanisms by which these fatty acids regulate HMG-CoA reductase are unclear. To determine whether the low density lipoprotein receptor (LDL-R) is required for this regulation, groups of female LDL-R knockout (–/–) and wild-type (+/+) mice were fed 7% fat diets rich in either n-3 (menhaden oil) or n-6 (safflower oil) PUFA for 1 wk. Dietary PUFA and deletion of the LDL-R had independent effects on HMG-CoA reductase and serum lipids, and a significant diet–gene interaction was observed. The effects of PUFA on HMG-CoA reductase in the mammary gland, but not the liver, were mediated by the LDL-R. We also observed that differences in HMG-CoA reductase and serum LDL-cholesterol, high density lipoprotein cholesterol, and triglycerides between –/– and +/+ mice were dependent on whether the mice were fed n-3 or n-6 PUFA. Differences between –/– and +/+ mice were much greater when animals were fed n-6 PUFA rather than n-3 PUFA. These results show that the LDL-R mediates the effects of PUFA on HMG-CoA reductase in the mammary gland but not the liver. Furthermore, the composition of dietary PUFA profoundly influences the effects of deleting the LDL-R on HMG-CoA reductase and serum lipids and suggests that diet may influence the phenotype of other knockout or transgenic animals.

Paper no. L8205 in *Lipids 34,* 1037–1043 (October 1999).

3-Hydroxy-3-methylglutaryl (HMG)-CoA reductase (EC 1.1.1.34) is the rate-limiting enzyme in cholesterol biosynthesis that catalyzes the formation of mevalonate (1). This enzyme is regulated through a multivalent feedback mechanism that is controlled, in part, by intracellular cholesterol levels (2). Cells meet their cholesterol requirements by *de novo* synthesis or uptake of cholesterol-rich lipoproteins through the low density lipoprotein-receptor (LDL-R) or a receptor-independent pathway (2,3). The liver is the major organ regulating serum cholesterol and is a major site of cholesterol biosynthesis (4). When uptake of lipoproteins is enhanced and intracellular cholesterol levels rise, HMG-CoA reductase is down-regulated to prevent excessive accumulation of cholesterol (2).

Mice with a targeted disruption of the *LDL-R* gene were developed as a model of familial hypercholesterolemia and have been used to study atherosclerosis and xanthomatosis (5,6). Deletion of the LDL-R results in a twofold increase in total serum cholesterol and a 14-fold increase in LDL-cholesterol in chow-fed mice (5,7). Steady-state cholesterol concentrations and rates of cholesterol synthesis in various organs, however, are not altered by LDL-R deletion (7).

We recently showed that mammary gland HMG-CoA reductase is lower in rats fed n-3 polyunsaturated fatty acids (PUFA) compared to those fed n-6 PUFA and postulated that this may be a mechanism by which n-3 PUFA inhibit, or n-6 PUFA promote, experimental mammary tumorigenesis. In addition to being a precursor of cholesterol, mevalonate is also required for cell proliferation and has previously been implicated in cancer development (9–12). Competitive inhibitors of HMG-CoA reductase inhibit the development of mammary tumors *in vivo* and the proliferation of human breast cancer cells *in vitro* (13–15). The mevalonate-derived metabolite required for cell-cycle progression has not yet been identified, but is known not to be cholesterol (9).

Spady and colleagues conducted a series of experiments to elucidate the mechanisms by which n-3 and n-6 PUFA regulate cholesterol metabolism (16–18). They observed that dietary n-3 PUFA enhance the internalization of LDL by the liver and various extrahepatic tissues in the rat (16–18), but not the hamster (18). In the rat, enhanced uptake of LDL by the liver appears to be mediated predominantly by the LDL-R and in extrahepatic tissues by a receptor-independent pathway (16). This mechanism may explain how n-3 PUFA lower serum cholesterol and decrease HMG-CoA reductase. The mammary gland, however, is capable of synthesizing choles-

terol for secretion during lactation and may be subject to unique regulatory mechanisms (19).

In the present study, we used wild-type C57Bl/6J mice and the same strain with a targeted disruption of the *LDL-R* gene to investigate whether the LDL-R mediates the effects of PUFA on HMG-CoA reductase and serum lipids. Our results showed that the LDL-R is required for PUFA to regulate HMG-CoA reductase in the mammary gland but not the liver. More importantly, we observed that the composition of PUFA in the diet influences the effects of deleting the LDL-R on serum lipids and HMG-CoA reductase in both the liver and mammary gland.

MATERIALS AND METHODS

Materials. All reagents for electrophoresis and immunodetection were purchased from Bio-Rad Laboratories (Richmond, CA). The anti-HMG-CoA reductase antibody was a generous gift from Dr. D.G. Hardie (University of Dundee, Scotland), and the anti-LDL-R antibody was a generous gift from Dr. A.D. Coooper (Stanford University, Palo Alto, CA). 3-Hydroxy-3-methyl[3-^{14}C]glutaryl-CoA and [5-^{3}H]mevalonolactone were from Du Pont-New England Nuclear (Mississauga, Ontario, Canada), and all other reagents and chemicals were obtained from Sigma (St. Louis, MO).

Animals and diets. Twenty virgin female C57Bl/6J mice that were homozygous for a deletion in the *LDL-R* gene (–/–) and 20 virgin wild-type mice (+/+) were purchased from Jacksons Lab (Bar Harbour, ME) at 7 wk of age. Animals were housed at 23°C and 50% humidity with a 12-h light/dark cycle and acclimatized on the AIN-93G standard reference diet (20) (Dyets, Bethlehem, PA) for 1 wk with free access to food and water. Knockout and wild-type mice (10 per group) were fed one of two diets in which the 7% soybean oil in the AIN-93G diet (devoid of cholesterol) was replaced with 1% soybean oil (to ensure adequate amounts of essential fatty acids) plus either 6% menhaden oil (rich in n-3 PUFA) or 6% safflower oil (rich in n-6 PUFA) for 1 wk. The cholesterol content of the n-3 diet was <0.03%. The fatty acid levels in the diets were determined using the method of Ulberth and Henninger (21). Mice were anesthetized with halothane, blood was collected by cardiac puncture, and the mice were killed during the fourth hour of the light cycle by cervical dislocation. The livers and mammary glands were dissected, immediately frozen in liquid nitrogen, and stored at −80°C until needed for further analysis.

Serum lipids. Blood samples were allowed to coagulate at ambient temperature then centrifuged at 2,500 × *g* for 10 min. Serum was assayed for total cholesterol using a kit obtained from Boehringer Mannheim (Laval, Québec, Canada), and triglycerides and high density lipoprotein (HDL) cholesterol using a kit from Sigma (St. Louis, MO). LDL cholesterol was then calculated as described by Sigma.

Tissue preparation. All tissue preparations were performed over ice or at 4°C. For the preparation of microsomes, tissues were homogenized in buffer A [20 mM Tris-HCl (pH 7.4), 0.25 M sucrose, 70 mM KCl, 5 mM EDTA, 5 mM EGTA, 1 mM dithiothreitol, 50 µM leupeptin] and centrifuged for 10 min at 500 × *g*. Supernatants were centrifuged for 15 min at 9,000 × *g* followed by a final spin for 1 h at 100,000 × *g*. Microsomes were assayed for HMG-CoA reductase activity or were solubilized in Laemmli buffer containing 8 M urea for immunoblotting. Plasma membrane fractions were isolated by homogenizing tissues in buffer B [250 mM Tris-maleate (pH 6.5), 150 mM NaCl, 2 mM $CaCl_2$, 1 mM phenylmethylsulfonyl fluoride, and 2 mM leupeptin]. Homogenates were centrifuged at 9,000 × *g* for 15 min, and the supernatants centrifuged at 40,000 × *g* for 40 min. Membrane pellets were resuspended in buffer B containing 30 mM 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS) and centrifuged at 40,000 × *g* for 40 min. Solubilized membranes were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) under nonreducing conditions. Protein was determined using a protein dye-binding assay (Bio-Rad) according to the manufacturer's protocol with bovine serum albumin as a standard.

Immunoblotting. The 130 kDa mouse LDL-R and 97 kDa HMG-CoA reductase proteins were detected using rabbit polyclonal antibodies as described previously (22,23). Equivalent amounts of protein were applied to SDS-polyacrylamide gels (6% for LDL-R or 7.5% for HMG-CoA reductase), separated by electrophoresis, and transferred to polyvinylidene difluoride membranes using a semidry transfer apparatus. Membranes were blocked overnight at 4°C with 5% nonfat dry milk in Tris-buffered saline (pH 7.4) containing 0.1% Tween-20, probed with anti-HMG-CoA reductase (1:3,000) or anti-LDL-R (1:5,000) for 2 h at room temperature, followed by a 1-h incubation with horseradish peroxidase-conjugated antirabbit antibody (1:5,000) (Santa Cruz Biotechnology, Santa Cruz, CA). Signals were detected using an enhanced chemiluminescence detection system (ECL; Amersham Corp., Arlington Heights, IL), and bands were compared with the migration of prestained molecular weight markers (Bio-Rad). Coomassie blue was used to stain total proteins to ensure equal loading.

HMG-CoA reductase enzyme activity. Total enzyme activity was determined as previously described (24) and expressed as picomoles of mevalonolactone formed per minute and per milligram of microsomal protein. All values are averages of duplicate measurements. Briefly, 50–100 µg of microsomal protein was preincubated at 37°C for 5 min in buffer C [100 mM phosphate (pH 7.4), 70 mM KCl, 10 mM dithiothreitol, 5 mM EDTA, 5 mM EGTA, and 50 µM leupeptin], followed by a further 5 min with an NADPH regenerating system (1 U glucose-6-phosphate dehydrogenase, 20 mM glucose-6-phosphate, 2 mM NADP). The assay was initiated by the addition of ^{14}C-HMG-CoA (20,000 dpm/nmol) at a final concentration of 80 µM and volume of 75 µL, and terminated after 30 min by the addition of 5 µL HCl containing ^{3}H-mevalonolactone as a recovery standard. After a 1-h incubation at 37°C to allow complete lactonization of the product, samples were centrifuged for 1 min at 3,000 × *g* to re-

move the denatured protein, 40 μL of supernatant was applied to a silica gel G plate (Analtech, Newark, DE), and mevalonolactone was separated by thin-layer chromatography using a toluene/acetone (1:1) solvent system. The region corresponding to mevalonolactone (R_f 0.7) was scraped into scintillation fluid and radioactivity measured using a β-counter with a dual-labeling program.

Statistical analyses. All values are shown as means ± SEM. Data were analyzed by one-way analysis of variance (ANOVA) followed by Student's *t*-test with Bonferroni *post hoc* for multiple comparisons. Two-way ANOVA was used to assess diet–gene interactions (GraphPad Prism™ San Diego, CA).

n-6	409.9 ± 44.6[c]	306.6 ± 28.0[c]	55.9 ± 4.7[b]	152.1 ± 19.5[c]
n-3	240.8 ± 51.7[d]	157.9 ± 37.0[d]	53.1 ± 9.6[b]	75.9 ± 11.9[a,b]

[a]Values not sharing the same superscript letters within each column differ significantly from each other ($P < 0.05$). LDL, low density lipoprotein cholesterol; HDL, high density lipoprotein cholesterol; (+/+), wild-type mice; (–/–), knockout mice.

RESULTS

Groups of +/+ and LDL-R –/– mice were fed cholesterol-free, 7% fat diets containing either menhaden oil (n-3 diet) or safflower oil (n-6 diet). Lipids were extracted from the diets, and their fatty acid content was analyzed (Table 1). As anticipated, the n-3/n-6 PUFA ratio was 100-fold greater in the n-3 diet than in the n-6 diet. Since chow diets have variable fatty acid and cholesterol contents and the effects of the AIN-93 reference diet on lipid metabolism and mammary carcinogenesis have not been established, we compared the effects of feeding n-3 or n-6 PUFA relative to each other.

The effects of n-3 and n-6 PUFA on cholesterol metabolism were first compared in +/+ mice. Compared to n-6 PUFA, serum triglycerides and total-, LDL- and HDL-cholesterol levels were significantly lower in mice fed n-3 PUFA (Table 2). A radiochemical assay was used to assess the effects on HMG-CoA reductase activity in the livers and mammary glands (Fig. 1). Compared to n-6 PUFA, n-3 PUFA reduced the specific activity of HMG-CoA reductase in the liver from 336 ± 80 to 109 ± 25 pmol/min/mg ($P < 0.005$) (Fig. 1A), and in the mammary glands from 36 ± 10 to 20 ± 9 pmol/min/mg ($P < 0.01$) (Fig. 1B). To determine whether the changes in enzyme activity were due to changes in the levels of HMG-CoA reductase protein, microsomes from livers and mammary glands were subjected to SDS-PAGE and probed using an anti-HMG-CoA reductase antibody. Figure 2 is a representative Western blot showing that the differences we

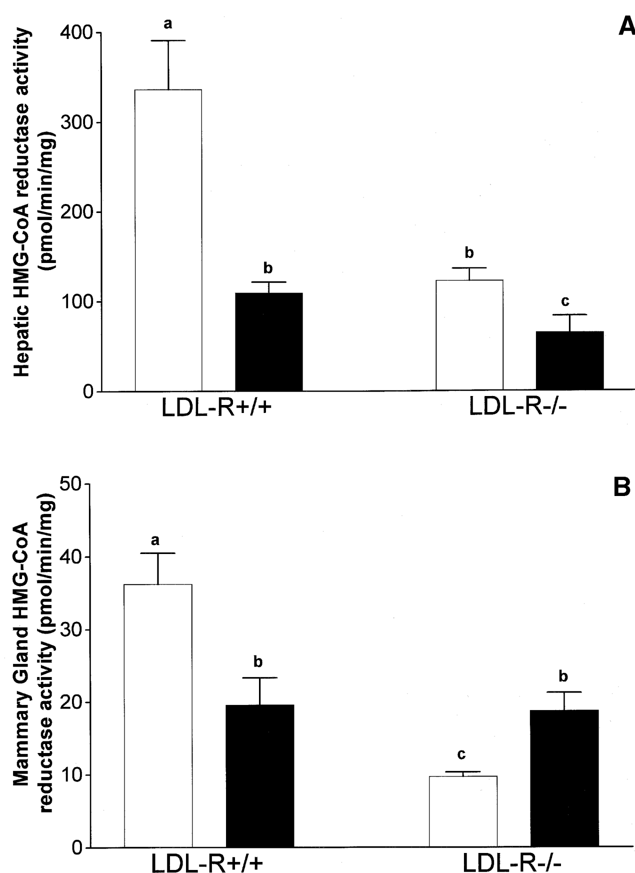

FIG. 1. Effects of n-3 (■) or n-6 (□) polyunsaturated fatty acids (PUFA) on 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase activity in low density lipoprotein receptor (LDL-R) knockout (–/–) and wild-type (+/+) mice. Liver (A) and mammary gland (B) HMG-CoA reductase enzyme activities were assayed from tissue microsomes prepared from LDL-R–/– and LDL-R+/+ mice fed either n-3 (menhaden oil) or n-6 (safflower oil) PUFA for 1 wk. Values are mean ± SEM ($n = 10$). Groups not sharing the same letter differ significantly ($P < 0.05$).

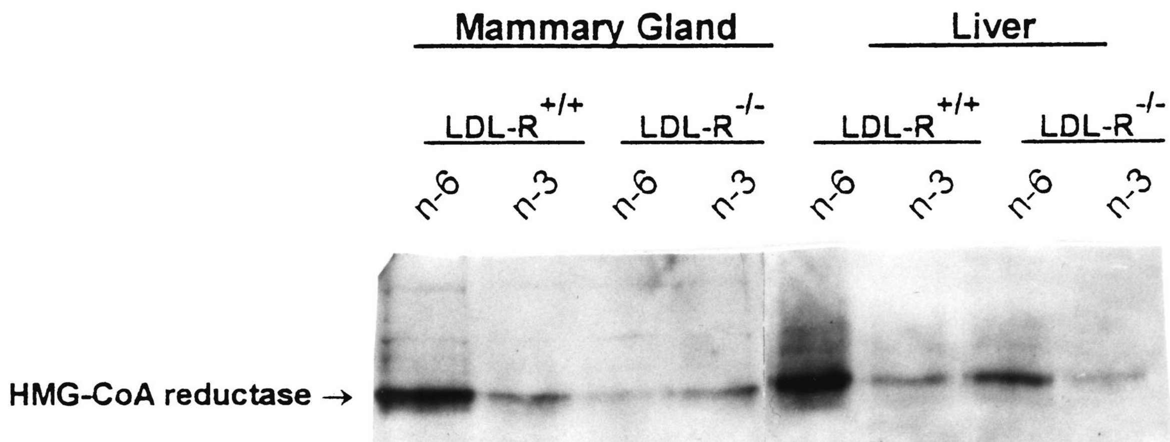

FIG. 2. Representative Western blot of HMG-CoA reductase. Microsomes from mammary glands and livers of LDL-R–/– and LDL-R+/+ mice fed either n-3 (menhaden oil) or n-6 (safflower oil) PUFA for 1 wk were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis and probed with a rabbit polyclonal anti-HMG-CoA reductase antibody. The blot shows a representative sample from each group. For abbreviations see Figure 1.

observed in enzyme activity are due, at least in part, to differences in the amount of HMG-CoA reductase protein. LDL-R protein levels were not different in the liver or mammary glands of +/+ mice fed either of the two diets (Fig. 3).

Next, we compared the effects of n-3 to n-6 PUFA in –/– mice to determine the role of the LDL-R in mediating the changes we observed in +/+ mice. In –/– mice fed n-3 PUFA, serum triglycerides and total- and LDL-cholesterol levels were also lower than in those fed n-6 PUFA (Table 2). HDL-cholesterol levels, however, did not differ between the two diets (Table 2). n-3 PUFA reduced hepatic HMG-CoA reductase activity from 123 ± 27 to 65 ± 38 pmol/min/mg ($P < 0.05$) (Fig. 1A), but unexpectedly increased activity in the mammary gland from 10 ± 2 to 19 ± 6 pmol/min/mg ($P < 0.05$) (Fig. 1B). These differences in enzyme activity corresponded with differences in the levels of HMG-CoA reductase protein (Fig. 2).

Comparisons between +/+ and –/– mice by two-way ANOVA revealed that the *LDL-R* gene had an effect, independent of PUFA, on HMG-CoA reductase and serum lipids, but a diet–gene interaction ($P < 0.05$) determined the magnitude of the differences. Serum LDL-cholesterol was 27-fold greater in –/– than in +/+ mice fed n-3 PUFA and only 10-fold greater in mice fed n-6 PUFA. HDL-cholesterol levels were lower and serum triglycerides were higher in –/– than in +/+ mice fed n-6 PUFA, but no differences were observed among those fed n-3 PUFA. Total serum cholesterol was approximately fourfold greater in –/– than in +/+ mice, regardless of the diet. Dietary PUFA also modulated the effects of LDL-R deletion on HMG-CoA reductase. Compared to +/+

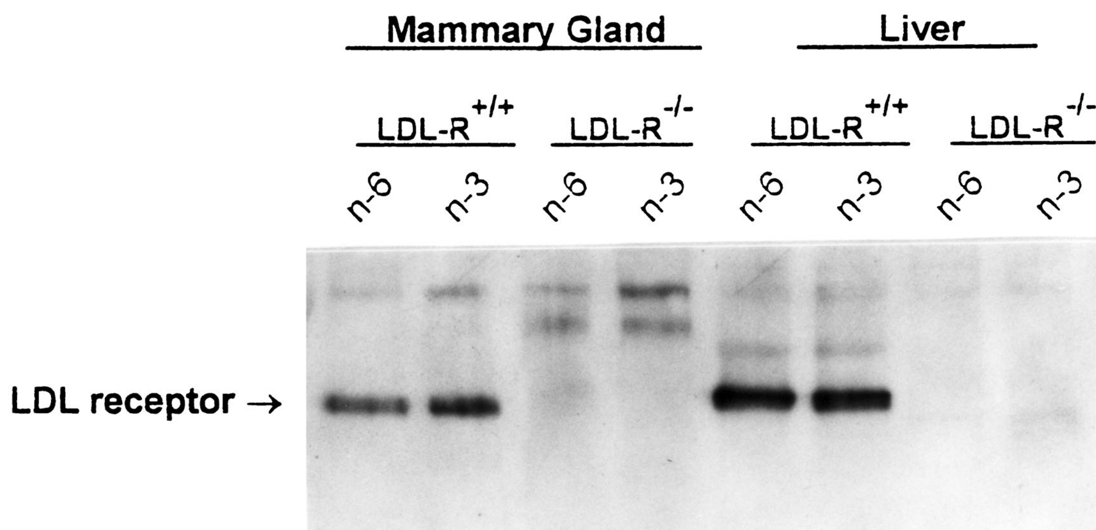

FIG. 3. Representative Western blot of LDL-R. Plasma membrane fractions were isolated from mammary glands and livers of LDL-R–/– and LDL-R+/+ mice fed either n-3 (menhaden oil) or n-6 (safflower oil) PUFA for 1 wk. Equal amounts of protein were resolved on 6% polyacrylamide gels and blotted proteins were probed using a rabbit polyclonal anti-LDL-R antibody. For abbreviations see Figure 1.

mice, hepatic HMG-CoA reductase was 2.7-fold lower in –/– mice when the groups were fed n-6 PUFA, but was only 1.7-fold lower when they were fed n-3 PUFA (Fig. 1A). Deletion of the LDL-R did not alter mammary gland HMG-CoA reductase in mice fed n-3 PUFA, but resulted in a significant decrease in enzyme activity (3.6-fold) and protein levels in those fed n-6 PUFA (Figs. 1B and 2). These analyses show that the composition of PUFA in the diet can profoundly influence the effects of deleting the LDL-R on serum lipids and HMG-CoA reductase.

DISCUSSION

We previously showed that n-3 and n-6 PUFA differentially regulate mammary gland HMG-CoA reductase and hypothesized that this may be a mechanism by which these fatty acids modulate experimental mammary tumorigenesis (8). To investigate the functional significance of the mevalonate pathway, we sought to identify an animal model in which the regulation of HMG-CoA reductase by PUFA may be perturbed. The present studies were designed to determine whether LDL-R –/– mice qualify as such a model. By comparing the effects of n-3 and n-6 PUFA in both +/+ and LDL-R –/– mice, we established that the LDL-R is indeed required for PUFA to regulate mammary gland HMG-CoA reductase. A two-way ANOVA also revealed that the LDL-R has an independent effect on HMG-CoA reductase as well as serum lipids. When we compared +/+ to –/– mice, it became clear that the differences in serum lipids and HMG-CoA reductase between these two groups were markedly dependent on the type of PUFA in the diet. These results provide an example of what has been described as diet–gene interactions (25,26).

LDL-R deficiency has previously been shown to have no effect on hepatic cholesterol synthesis in mice (7), but it leads to a 40% decrease in rabbits (27). Although this discrepancy may be due to genetic differences between these species, a role for the different diets consumed by these animals cannot be excluded. Chow diets used commonly in genetic studies vary considerably in their composition and may produce conflicting observations. Moreover, the effects of pharmacological or dietary factors in genetically altered animals may either be masked or augmented depending on the composition of the basal diet. This could ultimately lead to an incomplete understanding of the normal function of a gene.

Our previous studies (8) and those of others (16–18) on the regulation of HMG-CoA reductase or cholesterol biosynthesis by PUFA used rats. Since cholesterol metabolism is known to differ between species (4,28) and since the effects of PUFA in mice were not known, we needed to establish in the present experiment whether the mouse responds like the rat to the effects of PUFA on serum lipids and HMG-CoA reductase. Compared to mice fed n-6 PUFA, those fed n-3 PUFA had lower levels of serum triglycerides and total-, LDL-, and HDL-cholesterol and decreased HMG-CoA reductase in the liver and mammary glands. These results demonstrate that mice respond like rats to the effects of dietary PUFA. Although the fish oil we used contained low levels of cholesterol, the decrease in the HMG-CoA reductase is likely to be due to the long-chain n-3 PUFA; purified n-3 PUFA have effects on cholesterol metabolism similar to the fish oils from which they are derived (16,17).

To determine whether any of the effects we observed are mediated by the LDL-R, we also fed the experimental diets to mice lacking a functional LDL-R. Compared to n-6 PUFA, n-3 PUFA reduced total- and LDL-cholesterol levels while reducing hepatic HMG-CoA reductase. Although the rate of LDL uptake was not measured directly in these experiments, the effects observed are consistent with enhanced uptake of LDL by the liver in mice fed n-3 PUFA (28). It is also possible that n-3 PUFA decrease cholesterol secretion from the liver as has previously been shown in the rat (17). In the mammary glands of –/– mice, HMG-CoA reductase was greater in those fed n-3 compared with those fed n-6 PUFA. This unexpected difference may have been a response to the lower serum LDL-cholesterol levels in the n-3 PUFA group that were caused by enhanced receptor-independent uptake of LDL in the liver. Importantly, this observation demonstrates that the LDL-R is required for n-3 PUFA to decrease mammary gland HMG-CoA reductase but is not required for n-3 PUFA to decrease hepatic HMG-CoA reductase or serum lipoproteins.

The first report on LDL-R –/– mice showed a twofold increase in total cholesterol, a seven- to ninefold increase in intermediate density lipoproteins and LDL, and no significant changes in HDL or triglyceride levels compared to +/+ littermates (5). Osono *et al.* (7) were the first to examine the effects of LDL-R deletion on rates of cholesterol synthesis and cholesterol balance across the plasma space. They observed that deletion of the LDL-R results in a 14-fold increase in serum LDL and a significant increase in very low density lipoprotein and HDL (7). There were no changes in the rates of cholesterol synthesis in the liver or various extrahepatic tissues. The mice in those two studies (5,7), however, were fed chow diets that contain low levels of cholesterol and undefined fatty acids. In the present study, we observed that the type of PUFA in a semisynthetic diet profoundly influenced the effect on serum lipoproteins of deleting the LDL-R. For example, LDL-cholesterol was 27-fold greater in –/–than in +/+ mice when both groups were fed n-3 PUFA, but was only 10-fold greater when they were fed n-6 PUFA. Interestingly, HDL-cholesterol levels were slightly higher in –/– than in +/+ mice fed n-3 PUFA but were significantly lower when they were fed n-6 PUFA (Table 2).

The types of dietary PUFA were also important determinants of the effects of deleting the LDL-R on HMG-CoA reductase. In the liver, deletion of the LDL-R decreased HMG-CoA reductase to a greater extent in mice fed n-6 PUFA than in mice fed n-3 PUFA. These decreases in HMG-CoA reductase are likely due to receptor-independent uptake of LDL-cholesterol, which is stimulated by the extremely high circulating levels in –/– animals. A more striking effect was observed in the mammary gland where deletion of the LDL-R

had no effect on HMG-CoA reductase activity or protein levels when n-3 PUFA were fed but resulted in a marked (3.6-fold) decrease when n-6 PUFA were the major source of dietary fat. This decrease caused by LDL-R deletion in mice fed n-6 PUFA may, in part, be a consequence of the elevated serum cholesterol that enters the cells through a receptor-independent pathway, thereby down-regulating HMG-CoA reductase. However, the lack of an effect on HMG-CoA reductase by LDL-R deletion among mice fed n-3 PUFA suggests other mechanisms may also be involved. An alternative interpretation is that n-6 PUFA stimulate mammary gland HMG-CoA reductase through the LDL-R, whereas n-3 PUFA have no effect. This mechanism is unlikely since n-3 PUFA lower serum cholesterol and decrease cholesterol synthesis whereas n-6 PUFA do not have this effect compared to a diet rich in saturated fatty acids (16).

In addition to dietary differences, the background strain of LDL-R knockout mice used in previous studies also differs from the one used in the present study. Earlier studies used the B129 strain (5–7), which is a cross between the 129Sv and C57Bl/6J strains. The LDL-R-deficient mice we used in the present study are in a C57Bl/6J background and were developed by Jackson Labs by backcrossing the B129 with the C57Bl/6J strain. Mouse strains differ in their metabolism of cholesterol and expression levels of HMG-CoA reductase. Comparisons between some studies may therefore be further confounded by these genetic differences.

In summary, we have shown that the LDL-R mediates the effects of PUFA on HMG-CoA reductase in the mammary gland but is not required for the decrease in serum lipids or hepatic HMG-CoA reductase caused by n-3 PUFA. These results may lead to a better understanding of the mechanisms by which dietary PUFA modulate biochemical pathways that may be involved in mammary carcinogenesis. Furthermore, our observations show that the composition of dietary PUFA is a major determinant of the effects of LDL-R deletion on cholesterol metabolism and may alter the interpretation of studies using LDL-R knockout mice. This paradigm may also be applicable to other dietary factors and to other knockout or transgenic animals.

ABSTRACT: The majority of reduced calorie fats and fat substitutes available today, though similar in texture and flavor to natural fats, contain fatty acids that are not usually present in edible oils and fats and thus do not fully match the chemistry and functions of natural fats. For example, such products do not provide nutritionally important essential fatty acids (EFA). In this investigation, we prepared and evaluated a reduced calorie fat, prepared entirely from natural fats, taking advantage of the fact that long-chain saturated fatty acids (LCSFA), such as behenic acid (22:0), are poorly absorbed. Mustard oil (MO) and sunflower oil (SO) were used as substrates to yield a structured lipid (SL). The product, being derived from a natural vegetable oil, would thus provide EFA, as would a native fat, a feature not provided by the low-calorie fats available in the market. Erucic acid (22:1) was isolated from MO by a lipase (EC 3.1.1.3)-catalyzed reaction. It was then hydrogenated to behenic acid, the ethyl ester of which was subsequently enzymatically transesterified with SO to yield a plastic fat containing about 30–35% behenic acid. Absorption of this fat was studied in Wistar rats. In a preliminary single oral dose experiment, rats were fed equal amounts (2 mL) of SO and the SL. Plasma triacylglycerol (TAG) levels were estimated after 1, 2, and 3 h of feeding. The significantly lower concentration of plasma TAG in the 2-h sample, observed in the SL-fed group compared to the SO-fed group ($P < 0.001$), indicated poor absorption of the SL. In order to estimate the calorific value of the SL, we conducted a restricted diet growth experiment over 21 d on weanling Wistar male rats with SO as caloric control. Diets for the test groups were modified by adding 5, 10, and 15% SO for the control groups, and 5 and 10% SL for the experimental groups. Food consumption of the test groups was restricted to 50% of the feed containing 5% SO that had been consumed by the *ad libitum* group the previous day. Body weights were recorded during the experiment. Calorific value of the SL was estimated by comparing the 21st-d mean body weight gain of the control group with that of the experimental group. Estimated calorific value of the SL was 5.36 kcal/g. Most of the behenic acid fed was excreted, as indicated by the analysis of the fatty acids of plasma and fecal total lipid. A second growth experiment on *ad libitum* diet was conducted over 21 d on weanling Wistar male rats to compare the absorption behavior of the SL with that of natural oil. SO (10%) was added to the diet of the control group, and SL (10%) was added to the diet of the experimental group. Feed consumption, as well as body weights, was recorded during the experiment. The growth pattern of the experimental group was identical to that of the control group during the period of study. The mean feed intake (9.8 g/d/rat for the control group vs. 9.9 g/d/rat for the experimental group) indicated good palatability of the product. In conclusion, the enzymatically synthesized SL containing EFA and natural antioxidants has nutritional properties almost identical to those of natural fats, and can be used as a reduced calorie fat.

Paper no. L8210 in *Lipids 34,* 1045–1055 (October 1999).

The most energy-rich component of an animal's diet is fat, providing 9 kcal/g compared to the 4 kcal/g of carbohydrate and protein. Dietary fat also serves as a source of essential fatty acids (EFA) and is the carrier for fat-soluble vitamins and antioxidants (1,2). Moreover, the texture and flavor of fat are its two most pleasing organoleptic characteristics (3). However, high fat intake is linked to degenerative diseases such as heart disease, diabetes, high blood pressure, and cancer (4). With increasing consumer awareness of the risks associated with high fat intake, a market for reduced calorie fats and fat replacers has opened up. In addition to reduced calorie fats, fat replacers based on carbohydrates and proteins have entered the market. However, the latter two types are useful only in low-temperature applications, such as frozen desserts. They cannot be used where elevated temperatures are involved, as in cooking or deep frying (5). Only lipid-based fat substitutes can possibly mimic all the attributes of a natural fat.

Generally, structured lipids (SL) used in food products are triacylglycerols (TAG) composed of mixtures of long-chain with medium- or short-chain fatty acids that are randomly arranged on the glycerol molecule (6). They are beneficial to human nutrition, as they can be tailor-made to target specific diseases and metabolic conditions. Manipulations of their fatty acid compositions allow them to be used as reduced calorie fats. Reduced calorie SL are designed by taking advantage of either the limited absorption of long-chain satu-

rated fatty acids (LCSFA) or the lower caloric density of short-chain fatty acids (6,7). Caprenin, one of the first SL in the United States, was offered as a potential cocoa butter substitute. Developed as a reduced calorie fat with 5 kcal/g, Caprenin contains behenic acid, obtained from hydrogenated rapeseed oil, and two medium-chain fatty acids—caprylic and capric acids—from coconut and palm kernel oils (8–10). SALATRIM, another commercially availabile SL, contains long-chain (stearic acid) and short-chain (acetic, propionic, or butyric acids) aliphatic acids (11,12).

In this investigation, we wanted to synthesize a SL from natural vegetable oils for use as a reduced calorie fat. Such a product would contain EFA and natural antioxidants and would be close to native oils in its properties and metabolic functions. Behenic acid was incorporated into the *sn*-1 and *sn*-3 positions of sunflower oil (SO) TAG by a lipase-catalyzed transesterification reaction. A 1,3-specific lipase (Lipozyme from *Mucor miehei*) was used for this reaction. The product thus retained unaltered EFA in the *sn*-2 position, a desirable feature because fatty acids at the *sn*-2 position are better absorbed in the animal body than at *sn*-1 or *sn*-3 (13).

Literature suggests that LCSFA, like stearic acid and behenic acid, are poorly absorbed (14,15). This property of behenic acid was employed here for the synthesis of SL. Mustard oil (MO) was the source of behenic acid. Enzymatic hydrolysis of the oil under modified conditions (16) using *Candida cylindracea* lipase yielded 1,3-dierucin, which was hydrogenated to yield 1,3-dibehenin. Chemical transesterification of 1,3-dibehenin yielded ethyl behenate, which was used in the preparation of the SL.

The SL was studied for its absorption behavior and its calorific value. A preliminary single oral dose experiment was conducted on overnight-fast Wistar rats, with SO as control. This was followed by restricted diet growth studies and by growth studies on *ad libitum* diet, again using SO as control. The protocol of Finley *et al.* (17) was used for the estimation of calorific value of the SL. The basal diet for test groups in the restricted diet study was based on 50% of the diet consumed by a pilot *ad libitum* group the previous day. All absorption studies were conducted on inbred weanling Wistar rats.

EXPERIMENTAL PROCEDURES

Materials. Refined SO and MO of well-known brands were purchased from the local market. Lipases from *C. cylindracea* and from porcine pancreas (Type II) were obtained from Sigma Chemical Co. (St. Louis, MO), and Lipozyme IM20 from *Mucor miehei* in the immobilized form on a macroporous anion exchange resin was a generous gift of Novo Nordisk (Bangalore, India). All solvents needed for the preparation as well as analysis including the high-performance liquid chromatography (HPLC)-grade solvents, were purchased from Qualigen India Ltd. (Bombay, India). Chemicals needed for the estimation of plasma TAG, such as 2,4-pentanedione (acetyl acetone), potassium hydroxide, acetic acid, aluminum oxide (neutral), and sodium meta periodate, were obtained from Sisco Research Laboratory Pvt. Ltd. (Mumbai, India). Triolein, heptadecanoic acid, a standard mixture of fatty acid methyl esters (product no. O-7756), a standard mixture of TAG (product no. 178-12), and butylated hydroxytoluene (BHT) were purchased from Sigma Chemical Co. A standard mixture of fatty acid methyl esters (GLC-68) was purchased from Nu-Chek-Prep, Inc. (Elysian, MN). All ingredients needed for the preparation of AIN-93G diet, formulated for growth, were purchased from the local market. All feeding experiments were conducted on inbred Wistar/NIN male rats, bred at National Institute of Nutrition, Hyderabad, India.

Preparation of ethyl behenate. This was prepared from 1,3-dierucin isolated from MO by a lipase-catalyzed process developed in our laboratory (16). The crystallized 1,3-dierucin (203 g, melting point 45°C) was hydrogenated with 10% palladium on carbon (10 g) at 40 psi hydrogen pressure in chloroform (600 mL) for 4 h. The reaction mixture was filtered hot to separate the catalyst, and 1,3-dibehenin was crystallized from acetone (yield 180 g, melting point 87°C). The 1,3-dibehenin was transesterified with ethanol (200 mL) containing 2% H_2SO_4 to yield ethyl behenate, which was recrystallized from hexane (yield 140 g, melting point 52°C). The product had the composition: 16:0, 0.2%; 18:0, 0.6%; 20:0, 4.3%; 22:0, 91.9%; and 24:0, 3%.

Preparation of SL. SO (358 g) and ethyl behenate (165.5 g) were taken in a round-bottomed flask and stirred for 30 min at 60°C under vacuum. Lipozyme (2% w/w of total substrate) was added, and the reaction mixture was stirred at 60°C for 3 h. The product was filtered to remove the enzyme, and the enzyme was washed with hexane. The solvent was removed from the combined filtrate containing transesterified TAG and ethyl esters of fatty acids. The mixture was purified by silicic acid (60–120 mesh) column chromatography with a solvent system of 1% ethyl acetate in hexane to elute the ethyl esters of fatty acids followed by 5% ethyl acetate for the elution of the SL (yield 300 g).

Gas–liquid chromatography (GC). Analysis of the fatty acid methyl esters was carried out on a Hewlett-Packard (Palo Alto, CA) 5890 Series II gas chromatograph equipped with a flame-ionization detector. A fused-silica capillary column SP 2330 (30 m × 0.25 mm i.d. × 0.20 µm film thickness) was used with N_2 as carrier gas. The column was operated at 100°C for 5 min, raised to 160°C at a rate of 30°C/min, and held at this temperature for 1 min. Finally, the column temperature was raised again at a rate of 5°C/min to the final temperature of 235°C and held at this temperature until completion of the analysis. The injection port and detector temperatures were maintained at 235 and 260°C, respectively. Peak identification was accomplished by injecting a standard fatty acid methyl ester mixture. The relative percentage of individual fatty acids was identified and quantified using Chem Station software (Hewlett-Packard) based on the relative response of an internal standard of pure heptadecanoic acid of known concentration.

Analysis of TAG. (i) Measurement of slip melting points and solid fat content. The slip melting point of the SL was de-

termined by open capillary tube method (18). The solid fat content was measured by pulse nuclear magnetic resonance (NMR) (19) by using a Bruker MINISPEC NMS 120 Series NMR analyzer (Bruker Analytische Messtechnik Gmbh, Rheinstetten, Germany).

(ii) *Reversed-phase high-performance liquid chromatography (RP-HPLC)*. TAG molecular species of SO and the SL were analyzed by RP-HPLC on a Shimadzu LC system (model LC 10A) equipped with an evaporative light-scattering detector (Varex ELSD II A; Rockville, MD). The separations of the molecular species were effected on a 3.5 × 150 mm Nova-pak C18 (Waters) steel cartridge column. The ELSD was set at 105°C at a nebulizer gas (N_2) pressure of 30 psi, and the injection volume was 20 µL. The mobile phase consisted of 35% acetonitrile and 65% acetone for the initial 10 min at a flow rate of 1 mL/min. After 10 min, the composition of the mobile phase was changed over a period of 5 min to 25% acetonitrile and 75% acetone at a flow rate of 1 mL/min. The composition was further changed over a period of 10 min to 15% acetonitrile and 85% acetone at a flow rate of 1.2 mL/min. Finally, the mobile phase composition was brought back to 35% acetonitrile and 65% acetone over a period of 5 min at a flow rate of 1 mL/min. The total run time was 30 min. Peak identification was based on equivalent carbon number, and incorporated use of a standard TAG mixture whenever possible. Quantification of molecular species was made by a calibration method using the standard TAG mixture (20).

Porcine pancreatic lipase hydrolysis of the SL. A method modified from Luddy *et al*. (21) was followed. The SL (50 mg) was dissolved in diethyl ether (100 µL) in a stoppered vial. Tris buffer (1 M, pH 8.0, 1 mL), calcium chloride (2.2%; 0.25 mL), and bile salts (0.05%, 0.25 mL) were added to the SL solution. The entire solution was allowed to equilibrate at 40°C in a waterbath for 2–3 min with occasional vortexing. Porcine pancreatic lipase (50 mg) was added, and the reaction mixture was vortexed for 3–4 min. The reaction was quenched immediately by the addition of 1 mL of ethanol and 1 mL of 6 N HCl, and the reaction solution was extracted with 3 × 2 mL of diethyl ether. The ether layer was washed with water and dried over anhydrous sodium sulfate. Finally, the mixtures of products were separated by preparative thin-layer chromatography (prep-TLC) with hexane/ether/acetic acid (80:20:2; by vol) as solvent system. The monoacylglycerol (MAG) band was scraped off, converted to methyl ester, and analyzed by GC.

Diets and animal study designs. The experimental diets were prepared according to the recommendation of the American Institute of Nutrition (22). AIN-93G diet, formulated for growth, was taken as basal diet for the two growth experiments and contained (g/kg diet) corn starch 400, casein 200, α-corn starch 132, sucrose 100, cellulose 50, L-cystine 3, choline chloride 2.5, mineral mixture (AIN-93G-MX) 40, and vitamin mixture (AIN-93G-VX) 10. The dietary levels of calcium and magnesium per gram were 0.357 and 0.024 mg, respectively. Diets used in the growth studies were identical in all respects except for the sources of added fat and their percentages.

Three experiments were conducted for the absorption study of the SL. These were (i) single oral dose experiment, (ii) growth study on restricted diet, and (iii) growth study on *ad libitum* diet. In all these experiments SO was used as control. Results from the growth study on restricted diet were used to estimate the calorific value of SL. The protocol described below was reviewed and pre-approved by the Committee of Ethics on Animal Experiments of National Institute of Nutrition (Indian Council of Medical Research) and was carried out under the guidelines for animal studies of the Institute.

(i) Single oral dose experiment. An initial single oral dose experiment was conducted on male Wistar rats maintained at a temperature of 22 ± 2°C and a relative humidity of 55 ± 5%. Two sets of studies were conducted on rats having different body weights. The first group had a body weight of 120–130 g, and the second, 165–200 g. In each study, rats were divided into two groups of three rats, and all of them were fasted overnight. One group of rats was administered orally by gastric intubation 2 mL of SO (control group) and the other group was given 2 mL of the SL (experimental group). Blood (1.0 mL) samples were drawn from the orbital sinus of rats from both groups, before feeding (zero hour) and 1, 2, and 3 h after fat loading. The level of TAG in the plasma was estimated according to the method described by Foster and Dunn (23). During the period of experiment, no feed was provided to the test rats. After the 3-h blood withdrawal, all the rats were transferred to metabolic cages (Nalgene) and provided with standard animal feed containing 5% fat. Fecal samples were collected for the next 2 d.

(ii) Growth study on restricted diet. This experiment is meant for estimation of calorific value of the SL and is in line with the experiment of Finley *et al.* (17). In this experiment, 42 weanling Wistar/NIN male 21-d-old rats with initial body weights of 39–40 g were fed AIN-93G diet containing 5% SO for 1 wk prior to the start of the experiment. During this period, typical body weights attained were 65–70 g. Rats were then distributed randomly into six groups of seven rats each. Because animals bred within the facility were used and because the initial body weight range was narrow, the variability was minimal at the beginning of the experiment. Rats were housed separately in metal cages with numbered tags for identification. The room temperature was maintained at 22 ± 2°C with a 12-h light/dark cycle. Fresh, sterile deionized water was provided *ad libitum* by a glass bottle with stainless steel nozzle. Food was provided daily at the same time in a straight-walled glass container to minimize spillage. One group of rats was maintained on *ad libitum* diet containing 5% SO (pilot group). All other rats in the five test groups received 50% of the mean diet consumed by the pilot group the previous day. These diets were modified by adding 5, 10, and 15% of SO, respectively, for the three control groups and 5 and 10% of the SL, respectively, for the two experimental groups. Feed consumption was monitored daily. Rats on restricted diet consumed all feed with no spillage. Body weights were recorded on days 0, 3, 6, 9, 14, 17, and 21. After 21 d of the experiment, all rats were transferred to metabolic cages (Nalgene) and were fasted overnight. Blood sam-

ples and 24-h fecal samples of all the groups were collected for fatty acid composition analysis.

(iii) Growth study on ad libitum *diet*. In this experiment, 14 weanling Wistar/NIN male rats weighing 39–40 g were divided randomly into two groups. One group of rats was fed *ad libitum* AIN-93G diet supplemented with 10% of SO (control group), and the other group was fed *ad libitum* AIN-93G diet containing 10% of the SL (experimental group). Rats were housed separately in metal cages with number tags for identification. Fresh, sterile deionized water was provided *ad libitum* by a glass bottle with stainless steel nozzle. Diet consumption was monitored for all the rats on every day. Body weights were recorded on days 0, 3, 5, 7, 10, 13, 17, 19 and 21. The animals were maintained at 22 ± 2°C with 12-h light/dark cycle. After 21 d of the experiment, all rats were transferred to metabolic cages (Nalgene) and were fasted overnight. Blood samples and 24-h fecal samples of all the groups were collected for fatty acid composition analysis.

Extraction of plasma and fecal total lipid. Blood samples (1.5 mL) were centrifuged at 3000 rpm at 5°C for 15 min; the plasma layers were transferred to plastic tubes and stored under nitrogen at −78°C until the time of analysis. Plasma total lipid was extracted according to the method of Folch *et al.* (24). Plasma (100 µL) was mixed with 5 mL of chloroform/methanol (2:1, vol/vol) solution containing BHT (25 mg/L) and 1 mL of water. Before lipid extraction, 50 µL of heptadecanoic acid (1 mg/mL in chloroform) was added to the sample. Transmethylation of total lipid was carried out with 10 mL of 2% H_2SO_4 in methanol at 55°C for 5–6 h. After ether extraction, the methyl esters of fatty acids were purified by prep-TLC with a solvent system of hexane/ethyl acetate (95:5, vol/vol). The methyl ester band was scraped off and eluted with 3 × 5 mL of ether. The combined ether layer was evaporated to dryness by carefully flushing with N_2. Chloroform (1 mL) was added to the tube, washing the side of the test tube so that the entire extract was collected at the bottom of the tube, and 0.4 µL was injected into the gas chromatograph for fatty acid composition analysis. For extraction of total fecal lipid, the entire fecal sample collected over a period of 24 h (3.5–4 g) was crushed into a homogeneous mass and neutral lipids were extraccted with hexane for 16 h in a Soxhlet apparatus. The hexane was removed from the sample in a rotary evaporator, and 300 µL of heptadecanoic acid (1 g/100 mL in chloroform) was added. The neutral lipids were converted to methyl esters by refluxing with 50 mL of 2% H_2SO_4 in methanol for 4 h. After evaporating the methanol, the methyl esters were extracted with ether and washed with water until neutral. The ether layer was dried over anhydrous sodium sulfate and concentrated in a round-bottomed flask to a minimal volume. The methyl esters were finally purified by prep-TLC with a solvent system of hexane/ethyl acetate (95:5, vol/vol) as described above and analyzed by GC for fatty acid composition. For extraction of salts of fatty acids of fecal total lipid, the hexane-extracted fecal material was taken in a screw-cap test tube, soaked in 5 mL of 6 N HCl for 1 h, crushed with a spatula, and vortexed. The mixture was left at 50°C for 8 h with occasional vortexing. The mixture was cooled to room temperature, and 1 mL of heptadecanoic acid (1 g/100 mL in chloroform) was added to the tube followed by 6 mL of ether. The tube was vortexed for 3–4 min and then centrifuged, and the supernatant ether layer was placed in a second screw-cap test tube. This operation was repeated three times and the entire ether layer was washed free of mineral acid and dried over anhydrous sodium sulfate. The fatty acids were converted to methyl esters by treatment with diazomethane and purified by prep-TLC with a solvent system of hexane/ethyl acetate (95:5, vol/vol) as described before and analyzed by GC for fatty acid composition.

Statistical analysis. The data, presented as mean ± SE, were analyzed by a paired Student's *t*-test to evaluate the level of statistical significance. Differences were assessed by one-way analysis of variance. A *P*-value of less than 0.05 was considered significant.

RESULTS

By using the 1,3-specific lipase, Lipozyme, behenic acid was incorporated predominantly into *sn*-1 and/or *sn*-3 position of SO. Pancreatic lipase hydrolysis of the product showed the following composition for the MAG isolated from the hydrolysis products: 16:0, 4.4; 18:0, 6.3; 18:1, 20.6; 18:2, 63.2; 22:0, 3.7; and 24:0, 1.8%. The fatty acid compositions of SO and the SL are given in Table 1. An incorporation of 34.7% of behenic acid into SO gave a plastic fat having a slip melting point of 37°C. The solid fat content of the SL as determined by NMR showed that SL contained 11.5% of solid fat

at 15°C, 9.25% at 25°C, 3.64% at 35°C, and 0% at 40°C. RP-HPLC analysis of the molecular species of the SL was carried out and was compared with that of SO. As shown in Table 2, 66.3% of the total molecular species of the product contained at least one molecule of behenic acid.

Animal studies. The purpose of the initial single oral dose experiment was to elucidate the absorption characteristics of SL in Wistar rats, taking SO as control. The plasma TAG levels in two different groups of rats having different body weights 1, 2, and 3 h after fat or oil loading are indicated in Table 3. The concentration of TAG increased after 1 h of feeding, reached a peak value at 2 h, and thereafter decreased to initial levels in all the groups. TAG concentration always was higher in the control group than the experimental group. Plasma TAG concentration in the control group was significantly higher ($P < 0.001$) than the experimental group at the peak level, i.e., at 2 h in both studies. To check for the presence of 22:0 in the lipids, plasma and fecal total lipid fatty acids were analyzed. No behenic acid was measurable in the plasma lipids of either group. The absence of 22:0 in the plasma of the experimental group indicated that behenic acid did not enter the normal metabolic pathway and was excreted. This observation was confirmed by the analysis of fecal total lipid, where a large amount of 22:0 was observed. Excretion of 22:0 was greater in the form of salts than as neutral lipid. By calculation, the experimental group excreted 85% of the 22:0 fed within 48 h after fat loading.

All diets prepared for the two growth experiments conducted on weanling rats, with varying levels of SO for the control groups and of SL for the experimental groups, were analyzed for fatty acid composition. The results (Table 1) are means of two readings, before starting the experiment and after 21 d of the experiment.

Two basic assumptions are made in the assay of Finley *et al.* (17): (i) The weight gain of the rats is linearly related to kilocalories added to the diet, and, (ii) the weight gain is linear over 14 d of the experiment. The mean weight gains per gram of diet of all the test groups on restricted diet and also the pilot *ad libitum* group were recorded for each of the time intervals when body weights were recorded over the 21 d of the experiment and are given in Table 4, as are the slopes, intercepts and regression coefficients (r^2). Unlike the assay of Finley *et al.* (17), we prolonged our experiment for 21 d. When mean body weight gain was regressed against 21 d of assay for all the groups, regression coefficients were greater than 0.987. This fulfills the first assumption of this assay. Similarly, mean body weight gain of the control groups fed varying levels of SO was also regressed against kilocalories added to the diet on each day that body weights were recorded over 21 d of the experiment. Linearity was observed from ninth day of the study, satisfying the other assumption of this assay. When the 21st-d mean body weight gains of all the control groups were regressed against kilocalories added to the diet, a r^2 of 0.993, intercept of 21.13, and slope of 0.2111 were obtained. The slope and intercept calculated from the standard regression curve were used in the following formula to estimate the calorific value of the SL (17):

$$\text{kcal}_x = \frac{\text{BWG}_x - \text{INT}}{\text{SLP} \times K_x} \quad [1]$$

where kcal_x is the estimated kilocalories per gram of the unknown oil, i.e., the SL in this assay, BWG_x is the 21st-d mean body weight gain for rats fed diets containing 5% of the SL, INT is the intercept from the standard curve, SLP is the slope of the standard curve and K_x is the amount of SL added to the diet (g/100 g of diet). By substituting these values into Equation 1, the estimated calorific value of the SL was 5.36 kcal/g.

Six rats were chosen randomly from each group for the fatty acid composition analysis of plasma total lipid. The

mean individual fatty acid concentration (mg/100 mL plasma) and composition (in mol%) after 21 d of the 5 and 10% experiments are given in Table 5. No behenic acid was detected in the experimental groups (5 and 10% SL). The data indicate significantly higher amounts of 18:2 ($P < 0.001$) and 20:4 ($P < 0.05$) in the 5% SO group compared to the 5% SL group. No such differences were observed between 10% SO and 10% SL when individual fatty acid concentrations were compared statistically. This indicates that at 10% added fat level, the requirement of all major fatty acids was met in the experimental group.

Absence of 22:0 in the plasma of the experimental groups indicates that 22:0 did not enter the normal metabolic pathway and was excreted. This was confirmed by the analysis of fatty acid composition of fecal total lipid, collected under conditions of overnight fasting for a period of 24 h after 21 d of experiment. Three rats were chosen randomly from all the groups of the 5 and 10% experiments. Both neutral lipids and fatty acid salts were isolated and analyzed as detailed in the Experimental Procedures section. Mean fatty acid compositions (in mol%) of the excreted lipids are presented for comparison in Table 6. No excretion of behenic acid was found in the control groups, which is a clear evidence of excreted behenic acid being a direct consequence of dietary intake. Data indicate a significantly higher amount of excretion of total fecal lipid in the experimental group than the control group ($P < 0.001$).

[a]Data reported as mean ± SE: percentage calculated as (mol fatty acid/mol total fatty acid) × 100. n, number of rats.
[b]Values with different superscript roman letters are significantly different from the group fed SO-containing diet according to this designation: [b]$P < 0.02$, [c]$P < 0.001$, [d]$P < 0.01$, [e]$P < 0.05$. For abbreviations see Table 1.

In the second growth experiment on *ad libitum* diet, no difference in growth pattern was observed between the two groups over 21 d of the experiment (Table 7), indicating no abnormality in the absorption behavior of the SL. Similarly, no difference was observed between the two groups in their mean food intake. Mean food intake of the control group was 9.8 g/d/rat and that of the experimental group was 9.9 g/d/rat. This means that the flavor and palatability of the SL are very similar to natural oils, and the absorbable portion of SL meets the requirements of fat in the animal system and provides usable energy to sustain growth and development.

Blood samples from all rats of both groups were analyzed for the fatty acid composition of plasma total lipid. The mean individual fatty acid concentrations (mg/100 mL plasma) and compositions (in mol%) of plasma total lipid in the control and experimental group are given in Table 8. There was no difference in the individual fatty acid concentrations in the plasma lipids between the two groups. Three rats were chosen randomly from both the groups for fecal lipid fatty acid composition analysis (Table 9). The major fatty acids were 16:0 ($P < 0.01$), 18:0 ($P < 0.01$), 18:1 ($P < 0.001$), and 18:2 ($P < 0.01$) in the control group and 22:0 in the experimental group, both as neutral lipids and as salts. Consistent with earlier results, excretion of large amount of behenic acid was observed, mostly as salts. Compared to control, a significantly higher amount of total fecal lipid was excreted by rats in the experimental group. It was estimated that 78.8% of the fed behenic acid was recovered in the feces.

DISCUSSION

An SL was synthesized by incorporation of behenic acid into the TAG of SO to produce a plastic fat melting at ~37°C and containing EFA and natural antioxidants, as present in native oils. The presence of these latter components makes the SL clearly superior to other reduced-calorie fats currently available. The synthetic process is simple, and the 1,3-specific lipase, Lipozyme, used for transesterification reaction, incorporates behenic acid mainly at *sn*-1 and/or *sn*-3 position of the glycerol backbone, leaving the EFA at the *sn*-2 position mostly untouched. While carrying out enzymatic transesterification reactions, different reaction parameters like enzyme concentration, temperature, reaction time and substrate ratios were optimized to generate a product having a slip melting point of ~37°C. The solid fat index did not show a sharp decline, which may be due to the presence of different kinds of molecular species and lower amounts of saturated fatty acids in the SL. RP-HPLC analysis of the SL showed that the majority of molecular species produced by behenic acid incorporation contained one molecule of the acid. Species containing two behenic acid molecules constituted only 13.5% of the total. Overall, 66.3% of molecular species of the SL contained at least one behenic acid molecule (Table 2).

In the digestion of dietary TAG, major hydrolytic activity can be attributed to pancreatic lipase. Over 95% of dietary lipids are digested and absorbed in the upper intestine (25). Pancreatic lipase hydrolyzes TAG in association with co-li-

pase and bile salts to produce 2-MAG and free fatty acids (FFA). The physicochemical state of lipid in the intestinal lumen during the digestion of fat is that of a micellar phase, containing mainly the products of lipolysis solubilized in bile salt solutions, which are in continuous equilibrium with an emulsified oil phase (26). Because the digestion of fats takes place in a micellar phase, and because this condition is best achieved as FFA (i.e., the hydrolysis product of fats), fatty acid is the principal form in which fat is absorbed. Hence, the equilibrium between the oil and the aqueous phase, and in particular the rate and extent of formation by the FFA of mixed micelles in the system, is important in controlling the absorption of fatty acids. This means that when fatty acids are released into oil–bile salt dispersions, the rate at which the fatty acids establish equilibrium between the two phases is important for their absorption. This rate depends on chain length degree of unsaturation of fatty acids, i.e., the solubility of the fatty acid in aqueous solution. Poor diffusion of fatty acid from oil phase to the aqueous phase, because of very low solubility in water, may inhibit the enzyme action by block-

Amount of excreted lipid (mg/d)	2.9 ± 0.75	22.97 ± 4.36[c]	5.8 ± 2.1	134.7 ± 9.7[d]

[a]Data reported as mean ± SE: percentage calculated as (mol fatty acid/mol total fatty acid) × 100; n, number of rats.
[b]Values with different superscript roman letters are significantly different from the group fed 10% SO-containing diet according to this designation: [b]$P < 0.05$, [c]$P < 0.01$, [d]$P < 0.001$. For abbreviations see Table 1.

ing the interface. The solubility and the distribution coefficient of the fatty acid also depends on the pH of the medium and the concentration of divalent cations, like calcium and magnesium ions. The interaction of divalent cations and pH with the distribution coefficients of fatty acids has important physiological implications. In the presence of Ca^{2+} above a critical concentration of 1 meq/L and at pH 6.4 (which is the pH of the jejunal-ileal region of the intestine), the distribution in the micellar phase of very LCSFA having carbon numbers 18 and above becomes restricted. Under such circumstances, very LCSFA may react with divalent cations to form insoluble soap (27). Soap may constitute 5–50% of total fecal fat depending on the kind of fatty acid intake and the level of calcium and magnesium ions in the diet. Bliss *et al.* (28) found a linear relationship between the amount of fecal fat and the amount of calcium and magnesium that is excreted as insoluble soap. Mattson *et al*. (14) found poor absorption of stearic acid (18:0) from the *sn*-1,3 position of glycerol moiety. They also observed that the absorption of 18:0 depends on the kind of other fatty acid esterified along with it and the level of divalent cations in the diet. There is absolute absorption of 18:0 if it is esterified at the *sn*-2 position. In studying SALATRIM, Finley *et al*. (29) observed an identical absorption behavior of 18:0. The other very LCSFA whose non- or poorly absorptive nature was advantageously employed by researchers in designing a reduced calorie structured lipid is behenic acid. Yoshida *et al*. (30) in their absorption studies with saturated TAG having one LCSFA (18:0 or 22:0) and two medium-chain fatty acids (8:0 and 10:0) found higher absorption of 18:0 compared to 22:0 when it was esterified at the *sn*-1,3 position of glycerol moiety. But, unlike 18:0, they found poor absorption of 22:0 even when it was esterified at the *sn*-2 position. Behenic acid esterified at *sn*-2 position will be excreted in the feces as 2-MAG. In their work with Caprenin, a reduced calorie fat substitute, Peters *et al*. (10) found poor absorption of 22:0 in rats and hamsters. Caprenin provided usable energy to sustain growth, although the calorific availability of Caprenin was 5 kcal/g. Up to 75–82% of 22:0 remained unabsorbed, and 3–15% of that which was absorbed was recovered from total carcass fat at the end of the 28-d study. Fecal excretion of major portions of ingested 22:0 did not significantly affect calcium and iron balance in rats. Caprenin was nontoxic to rats when consumed for 28 consecutive days at level of up to 15% in the diet.

In the present work the absorption behavior of a structured TAG containing 22:0 in combination with SO fatty acids was studied. The enzymatically prepared SL had 34% of 22:0 esterified mainly at *sn*-1 and/or *sn*-3 position of SO. The presence of oleic and linoleic acids mostly at the *sn*-2 position of the SL makes it nutritionally improved compared to Caprenin and SALATRIM. In metabolic studies with Caprenin (9), corn oil was added as a source of EFA, whereas in our studies with the SL, no such supplementation was necessary as the product is already enriched with EFA.

The literature states that there will be an increase in the level of plasma TAG shortly after a fatty meal, reaching a peak in a period of time typical of the species and then decreasing to the pre- (or post-) absorptive level (31). An estimation of these elevated plasma TAG levels may help us understand not only the rate of metabolism but also the absorption of the particular fat product. Our initial single oral dose experiment was designed as a preliminary experiment to find the absorption pattern of SL in comparison with SO. This particular type of fat-loading experiment requires less time, fewer animals, and hence is less expensive. A series of experiments were conducted to find the time after dosing at which the peak value of plasma TAG is attained. This peak value was found to be 2 h after fat-loading. A significant reduction in the level of plasma TAG was obtained in the experimental group ($P < 0.001$) when peak values, obtained after 2 h, were compared with those from the control group. The near-total excretion of 22:0 observed in this short-term fat-loading experiment is an early indication of lower calorific availability from SL, which was confirmed in the growth studies.

The growth experiment on restricted diet was designed to estimate the calorific availability of the SL, taking SO as the caloric standard. The method is almost in line with the study of Finley *et al.* (17), which is a modified version of the method adopted by Rice *et al*. (32). The authors have tested the method by estimating the calorific availability of three fats (cocoa butter, tallow, and lard) and two simple esters (ethyl stearate and ethyl oleate). Good agreement was found between the calculated value and the reported value (17). The method provides good reproducibility within and between experiments. The modified method requires fewer animals, is simple to conduct, does not require highly specialized metabolic chambers or radiolabeled material, and provides an accurate estimate of calorific availability. The only difference was that we carried out our experiment over 21 d, instead of 14 d. The two basic assumptions of this method were found to apply even when the experiment was extended to over 21 d. A linear response was observed in all the groups when mean body weight gains were regressed against days of the study. Mean body weight gains of the control groups were also regressed against kilocalories added to the diet. An initial reduction in mean body weight gain of the 5% SO group, continuing to 6 d after initiation of the study, restricted our regression study. The reduction in mean body weight observed on the very first day on restricted diet became positive only after the sixth day of the experiment. A negative mean weight gain was also observed in the 10% SO group until the third day of the study. In the 15% SO group, no such negative mean weight gain was observed. When the ninth day mean weight gain of the control groups was regressed against kilocalories added to the diet, an r^2 of 0.780 was obtained. The slight deviation from linearity was due to poor weight gain in the 5% SO group. The r^2 value improved with time. The calorific value of the SL was estimated to be 5.36 kcal/g, which is 59.5% of the calories provided by natural oils.

The metabolic behavior of the SL can be determined from the fatty acid composition of the plasma as well as fecal lipid. For this purpose, the rats were fasted overnight, and the blood

and fecal samples were collected on the next day. No 22:0 was found in the plasma lipids of animals from the experimental groups. Significant differences were found in the level of 18:2 and 20:4 between the 5% SO group and the 5% SL group. When the oil content of the diet was increased from 5 to 10%, no such difference was observed. In the fecal lipid, a significantly higher amount of excretion of total fecal lipid was observed in animals of the experimental group ($P < 0.001$) than the control group, and 22:0 was the major fatty acid excreted in the experimental group. All these findings indicate that excretion of behenic acid is proportionally large. Behenic acid, in turn, may disturb the equilibrium between the oil and bile salt micelle, resulting in poor absorption of other fatty acids.

The growth experiment on *ad libitum* diet was designed to find how closely the SL resembles a natural oil in its metabolic behavior. An identical growth pattern of the control and experimental groups was observed (Table 7). The study was carried out for only 21 d, and a prolonged study would have probably shown differences in weight gain. In a similar study on SALATRIM (33), differences in weight gain were noticed only after 21 d. No difference was observed in mean food intake between the two groups, indicating that the taste and palatability of the SL were very similar to native fats. No difference was observed between the control and experimental groups in the levels of major fatty acids of the plasma total lipids. Fecal lipid analysis gave identical results to those observed in the previous growth experiment on restricted diet.

To conclude, an SL was synthesized from easily available renewable resources like MO and SO. The synthesized product delivered a reduced calorie value of 5.36 kcal/g, which is 59.5% of the calories provided by a natural oil. Because the substrate is a natural oil, the EFA and natural antioxidants present in the oil are carried over into the final product. The product thus is a definite improvement over the existing reduced calorie fats. The plastic nature of the fats widens the scope of utility of the product. The product may find applications in regular cooking and deep-frying as well as a bakery shortening or as a base for zero-*trans* margarine. The melting point of the product can be conveniently modified by altering the level of incorporation of behenic acid. Thus, we believe that the product has sufficient versatility to find varied applications.

ABSTRACT: This study evaluated the effects of dietary supplementation with γ-linolenic acid (GLA, 18:3n-6) and docosahexaenoic acid (DHA, 22:6n-3) on the fatty acid composition of the neonatal brain in gastrostomized rat pups reared artificially from days 5–18. These pups were fed rat milk substitutes containing fats that provided 10% linoleic acid and 1% α-linolenic acid (% fatty acids) and, using a 2 × 3 factorial design, one of two levels of DHA (0.5 and 2.5%), and one of three levels of GLA (0.5, 1.0, and 3.0%). A seventh artificially reared group served as a reference group and was fed 0.5% DHA and 0.5% arachidonic acid (AA, 20:4n-6); these levels are within the range of those found in rat milk. The eighth group, the suckled control group, was reared by nursing dams fed a standard American Institute of Nutrition 93M chow. The fatty acid composition of the phosphatidylethanolamine, phosphatidylcholine, and phosphatidylserine/phosphatidylinositol membrane fractions of the forebrain on day 18 reflected the dietary composition in that high levels of dietary DHA resulted in increases in DHA but decreases in 22:4n-6 and 22:5n-6 in brain. High levels of GLA increased 22:4n-6 but, in contrast to previous findings with high levels of AA, did not decrease levels of DHA. These results suggest that dietary GLA, during development, differs from high dietary levels of AA in that it does not lead to reductions in brain DHA.

Paper no. L8203 in *Lipids 34,* 1057–1063 (October 1999).

The period of brain development in mammals is a time of rapid accrual of lipids, including the long-chain polyunsaturated fatty acids (LCP) docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6) (1). Unlike cholesterol and the saturated fatty acids, which are preferentially formed *de novo* in the developing brain (2,3), DHA and AA must be obtained from dietary sources or derived from the 18-carbon precursor essential fatty acids, α-linolenic acid (LN, 18:3n-3) and linoleic acid (LA, 18:2n-6), respectively, through a series of metabolic steps involving the processes of chain elongation, desaturation, and β-oxidation (4). The extent to which these steps occur in the liver (5) and/or brain (6) is not known. In the adult, the LCP composition of the brain is relatively resistant to short-term alterations in dietary levels of n-3 and n-6 fatty acids (7). On the other hand, because of the rapid deposition of LCP into brain membranes during early development, alterations in dietary levels of n-3 and n-6 fatty acids have been shown to affect the composition of brain cell membranes (1).

Research into the relationship between the type and amount of n-6 and n-3 fatty acid in the diet, and subsequent LCP composition of the developing brain, has been hindered by our inability to directly manipulate the fatty acid composition of the nutrient supply during a large portion of the period of brain development. While manipulations of the fatty acid composition of the maternal diet have been informative (8), multigeneration feeding studies appear necessary to produce substantial alterations in brain fatty acid composition. A limitation of this maternal feeding model is the potential for effects on maternal milk composition secondary to changes in dietary n-6 or n-3 fatty acids. We have attempted to resolve at least part of this problem by using the artificial rearing (AR) model in infant rats. In this model, rat pups are removed from their mothers and fed, *via* gastrostomy tube, a rat milk substitute which closely resembles the composition of rat milk, and whereby the fatty acid composition can be altered experimentally. The brain of the rat is relatively immature at birth, and a greater proportion of its growth occurs during the first three postnatal weeks (9,10). This artificial feeding model thus allows us to manipulate precisely the dietary fatty acid composition throughout most of the brain growth spurt.

Rats reared by the AR method and fed formulae deficient in all n-3 fatty acids exhibited substantially lower levels of DHA in the brain (11). A subsequent study using this model established that LN-fed rats did not achieve brain DHA levels equivalent to the DHA-fed rats (12). We recently completed a 3 × 3 factorial study in which AR rats were fed diets containing fats with 1% (by weight) LN and 10% LA and either 0, 0.5, or 2.5% DHA and AA. In this study, we found significant correlations between the formula levels of these fatty acids and

levels in brain membrane phospholipids (13). Specifically, supplementation of DHA, without concurrent AA, increased DHA levels in the brain but also reduced AA levels, while supplementation of AA, without concurrent DHA, increased AA levels in the brain but decreased DHA levels. These effects generally were most noticeable after supplementation of relatively high (2.5%) levels. Whether such modifications in AA and DHA levels in the brain have functional consequences remains uncertain. Using the AR model with formula containing 1% LN, 10% LA, and similarly extreme levels of AA or DHA (2.5%), which allowed us to obtain a wide range of brain AA and DHA, we found no effects on spatial working memory in the Morris water maze (14). A previous study found that mice born to mothers who were fed high n-3 LCP diets with a low n-6/n-3 ratio throughout pregnancy and lactation performed more poorly in the Morris water maze, but that these differences could be accounted for by decreased swimming speed rather than by deficits in learning *per se* (15).

Dietary γ-linolenic acid (GLA, 18:3n-6), a metabolite of LA and precursor of AA, may offset the reduction in AA levels in the brain that results from diets containing high levels of DHA (16). In pregnant and lactating mice fed a fish-oil supplement, both AA and GLA offset the effects of long-chain n-3 fatty acids on brain AA composition (17). In the present study, infant rats were fed milk substitutes with fat containing 10% LA, 1% LN, and, using a 2 × 3 design, DHA (0.5 or 2.5%) and GLA (0.5, 1.0, or 3.0%). Our previous study had shown decreases in brain levels of AA as dietary DHA levels increased (13). In the present study, we were interested in the effects of dietary GLA in the presence of long-chain n-3 LCP, and thus all groups received at least some DHA in formula. Furthermore, these groups were compared to two different control groups. One group was artificially reared on a formula in which the essential fatty acid composition consisted of 10% LA, 1% LN, and 0.5% each of AA and DHA. The LCP composition was within the range noted for rodent breast milk (12,17,18). The other control group was nursed by dams. We hypothesized that levels of AA in the brain would be lower when dietary DHA levels were increased to 2.5% and that the addition of GLA to formula would prevent these reductions in brain AA levels resulting from high dietary DHA levels.

MATERIALS AND METHODS

Animals. Offspring of timed-pregnant, Long-Evans rats, acquired at 10–12 d gestation from a commercial supplier (Harlan Sprague Dawley, Indianapolis, IN), were used. Upon arrival in our lab, the pregnant rats were housed individually under a reversed dark/light cycle at 22 ± 1°C with free access to American Institute of Nutrition 93M laboratory chow (19) (Dyets Inc., Bethlehem, PA) and tap water. Litters were culled to 12 pups within 24 h of birth.

Diets. The procedure for making the rat milk substitutes used in this study has been described elsewhere (13), and the composition is shown in Table 1. The dietary oils were a mixture of medium-chain triglyceride oil (MCT oil), coconut, soy, high-oleic safflower, and borage oils (Ross Laboratories, Columbus, OH), to which DHA was added in the form of the single-cell microbial oil, DHASCO, a trademarked product of Martek Biosciences Corp. (Columbia, MD). All dietary oils were formulated to provide 10% LA and 1% LN. The compositions of these oils were determined by gas chromatographic analysis and are shown in Table 2. It should be noted that the protein and whey components of the diets were determined, again by gas chromatographic analysis, to contain 0.25 and 2.54% fat, by weight, respectively. The calculated amounts (in g/100 g formula) of the various essential fatty acids in the formula which were contributed by the combined protein powder were therefore very low. Specifically, the individual levels were as follows: LA, 0.423 g; GLA, 0.007 g; AA, 0.045 g; LN, 0.151 g; 20:5n-3, 0.027 g; 22:5n-3, 0.072 g; DHA, 0.0047 g. The fatty acid composition of the rat breast milk has been published previously (13).

Experimental design. This study used a 2 × 3 factorial design with two levels of DHA (0.5 or 2.5% of fatty acids) and three levels of GLA (0.5, 1, or 3% of fatty acids) (7–10 pups

[a]DHA, docosahexaenoic acid; GLA, γ-linoleic acid; ND, not detected; values are expressed as total fatty acids (g/100 g).

per group). A seventh group of eight pups was fed a diet in which the fat contained 0.5% each of both AA and DHA. This group constituted the reference control group. An eighth group of 10 pups was fostered to nursing dams and constituted a suckled control group.

AR procedure. The procedures used in this study were in compliance with the Animals for Research Act of Ontario (Revised Statutes of Ontario) and the Guide for the Care and Use of Experimental Animals from the Canadian Council on Animal Care, and were reviewed and approved by the Animal Care Committee at the University of Waterloo. On day 27 post-conception (approximately day 5 after birth), pups were separated from the nursing dam and reared artificially according to the procedure described in detail elsewhere (13). Briefly, gastrostomy tubes were implanted into anesthetized pups, who were then housed in an incubator and fed, *via* gastrostomy tube, their respective rat milk substitute for 10 min every h by an automated infusion pump system. The amount fed over each 24-h period was equivalent to 29% of their body weight, increasing to 36% of body weight by approximately 10 d of age. Pups were reweighed every day and their infusion volume was adjusted accordingly. The survival rate for gastrostomized Long-Evans rats in this study ranged from approximately 70 to 80%, with most mortality occurring during the first 48 h. There was no effect of dietary treatment on mortality in this study. Suckled control pups were raised and fed by nursing dams and, except for daily weighings, were not disturbed throughout the duration of the AR period. On day 40 postconception (day 18 after birth), the pups were killed under Halothane anesthesia, and their forebrains removed and stored at −80°C.

Biochemical analyses. Forebrain lipids were extracted by the method of Folch *et al.* (20) and separated into phosphatidylethanolamine (PE), phosphatidylcholine (PC), and phosphatidylserine/phosphatidylinositol (PI/PS) fractions by thin-layer chromatography using chloroform/methanol/water/triethylamine (4:5:1:4, by vol) as the developing solvent system. Fatty acid methyl esters were produced from these fractions by the method of Morrison and Smith (21) and analyzed by capillary gas chromatography (Hewlett-Packard 5890 II Plus; Hewlett-Packard, Palo Alto, CA) using a 30-m capillary column (i.d. = 0.32 mm, 0.25 µm film thickness; Omegawax, Supelco, Bellefonte, PA). Oven temperature was programmed to increase from 120 to 205°C at a rate of 4°C/min and to hold for 15 min. Heptadecanoic acid was used as an internal standard, and each fatty acid was identified by authentic standard mixtures (Nu-Chek-Prep, Elysian, MN).

Statistical analyses. Data were analyzed using SAS version 6.0.9 (SAS Institute, Cary, NC). The general linear models approach for analysis of variance was used to assess main and interactive effects of both DHA and GLA, and significant effects were further analyzed by planned comparisons (22). Effects of each dietary treatment were analyzed by comparing levels of one treatment collapsed across levels of the other treatment, and interactions were interpreted by comparing the simple main effects of one treatment among the levels of the other. The physiological and the suckled control groups were each compared with all other groups using Tukey's *t*-test to control for multiple comparisons. The significance level was set at 0.05.

RESULTS

The effects of GLA and DHA dietary supplementation were generally consistent across the PE, PC, and PS/PI phospholipid fractions (Tables 3, 4, and 5; Fig. 1). High dietary levels of GLA increased forebrain 22:4n-6, but had no significant effect on 20:4n-6, 22:5n-6, or 22:6n-3, nor on the n-6/n-3 ratio. High dietary levels of DHA had no significant effect on 20:4n-6, but resulted in lower levels of 22:4n-6 and 22:5n-6 and higher levels of 22:6n-3 and a lower n-6/n-3 ratio. High dietary levels (2.5%) of DHA also increased 18:2n-6 and

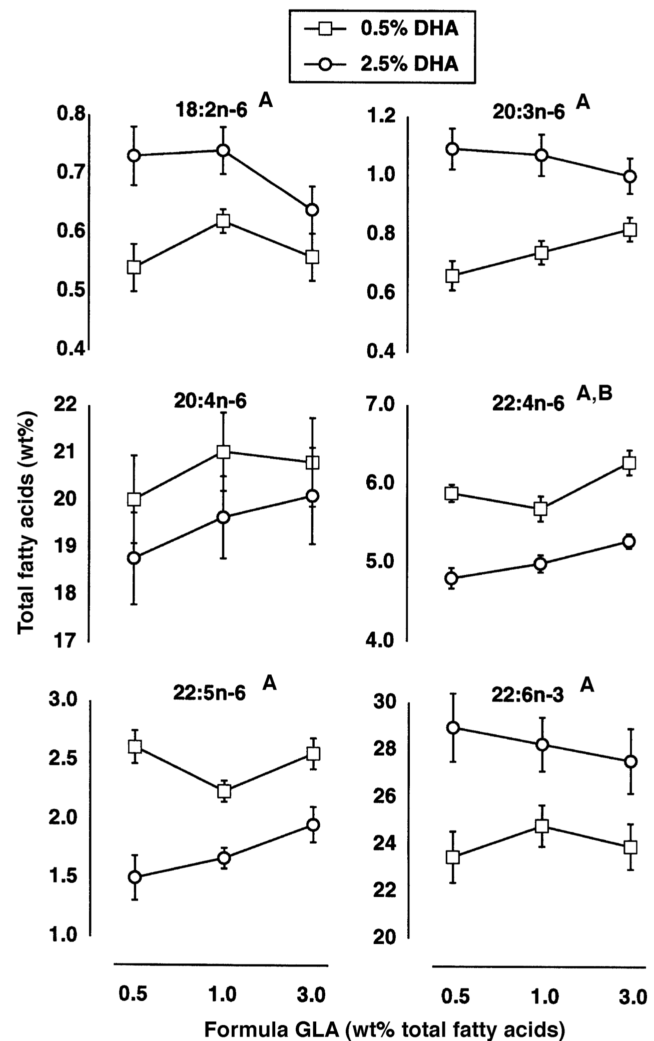

FIG. 1. Mean concentrations of selected forebrain polyunsaturated fatty acids in phosphatidylethanolamine membrane fraction from 18-d-old rats fed experimental formula from day 5. (A) Denotes main effect of docosahexaenoic acid (DHA), (B) denotes main effect of γ-linoleic acid (GLA).

20:3n-6, and individual group comparisons showed that these effects were present only when dietary GLA was low. There were no noteworthy effects of GLA or DHA supplementation on the saturated and monounsaturated fats. Similarly, the two control groups did not differ from each other in any meaningful way. In a comparison of the control groups with the experimental groups, groups fed high levels of DHA most often differed from both control groups, generally having higher levels of 18:2n-6 and 20:3n-6, and lower levels of 22:4n-6 and 22:5n-6, than the control groups. The levels of DHA in PC and PS/PI were generally similar for experimental and control groups while in the PE fraction, the group fed 2.5% DHA with 0.5% GLA had significantly higher levels of DHA than those of the suckled control group.

DISCUSSION

As with our previous study using this AR procedure (13), feed-

ing of formulae with different levels of DHA resulted in changes in the fatty acid composition of the rat brain at 18 d of age. In the present study, as expected, high dietary levels of DHA (2.5%) resulted in higher levels of 22:6n-3 and lower levels of 22:4n-6 and 22:5n-6 in the brain than did 0.5% DHA. In comparison, high dietary levels of GLA (3%) increased 22:4n-6 relative to medium and low levels, but had no significant effect on 22:6n-3. Neither DHA nor GLA at the levels used in this study had significant effects on levels of 20:4n-6. Nonetheless, the data did show trends in the directions expected, i.e., 20:4n-6 was decreased by DHA and increased by GLA, suggesting that the lack of statistical significance may be related to the large variability apparent in these data relative to the other fatty acids. High levels of DHA increased 20:3n-6 in the brain, but the effect was present only at the lower levels of GLA, and high levels of DHA also increased 18:2n-6.

It should be noted that the highest levels of DHA in the formulae in this study (2.5%) are beyond any reported physiological level for rat milk. For instance, the amount of DHA in milk of rats (11,18) and mice (17) fed diets containing LCP during pregnancy and lactation has been reported to range from 0.4–1.5% of total fatty acids. Therefore, findings based upon the use of high levels of DHA, while important for understanding the relationships among dietary LCP during brain development, should be interpreted with caution when studying variation in levels of LCP closer to the reported physiological range.

In order to compare these findings with our previous work (13), it is necessary first to consider the differences between the designs of the two studies. The 3 × 3 design of our previous study included groups that were not supplemented with either DHA or AA (0%), as well as those supplemented with low (0.4%) and high (2.4%) levels of DHA and AA. The inclusion of the unsupplemented groups in the first study allowed us to determine the amount of DHA and AA that was necessary to achieve a brain LCP composition similar to that of the suckled control group. The results indicated that this could be achieved by supplementation with low levels (0.5%) of both AA and DHA, and this group was thus considered the appropriate reference control group for the AR groups in the present study. In contrast to the first study, all AR groups (other than the reference control group) in the present study were fed diets that were supplemented with both DHA and GLA, at either low (0.5%) or high (2.5%) levels of DHA, and at either low (0.5%), medium (1%), or high (3%) levels of GLA. Generally the differences between the effects of AA in the first study and those of GLA in the second study were differences in magnitude. For example, in the first study, high levels (compared with low levels) of AA significantly increased both 20:4n-6 and 22:4n-6, and at the same time they significantly decreased DHA in the brain. In the present study, although high levels of GLA did signficantly increase 22:4n-6, the effects on 20:4n-6 were not significant, and there was not a significant overall decrease in 22:6n-3. Such differences in effectiveness between GLA and AA on tissue n-6 LCP levels might be expected, based upon their relative positions in the metabolic pathway. GLA is a precursor for 20:3n-6, which is then subsequently desaturated to form 20:4n-6 and then elongated to form 22:4n-6. When compared to the reference group (0.5% AA, 0.5% DHA), the groups fed formula containing 0.5% DHA and either 0.5 or 1% GLA had similar brain LCP compositions. What these results suggest therefore is that dietary GLA in the range of 0.5 to 3% total fatty acids prevents the reduction in levels of some 20- and 22-carbon n-6 fatty acids in the brain, which can occur in the presence of high dietary DHA levels. Furthermore, they suggest that even high levels of dietary GLA (3%) differ from high dietary levels of AA in that they do not lead to reductions in brain DHA.

In contrast to the effects on other n-6 LCP, high dietary levels of DHA led to increases in 20:3n-6 in the brain, which is consistent with previous findings in our lab (15,17,23,24) and with the findings of a study on the effects of DHA supplementation on lung LCP in piglets (25). Furthermore, a previous study in which AR rats were fed n-3 deficient diets found decreased levels of 20:3n-6 in the brain in n-3 deficient rats (11). This provides further support for the suggestion that high levels of dietary DHA may inhibit Δ5 and Δ6 desaturase activity and thereby decrease the formation of AA from 18:2n-6 (17). The finding that DHA also increased levels of 18:2n-6 would be consistent with this explanation. It is interesting to note that the addition of 3% GLA to formula acted to counter the effect of DHA.

While levels of most LCP were much lower in PC than in other phospholipid fractions, the effects of dietary DHA and GLA in the present study were generally consistent across all fractions. This is in contrast to the previous study, where effects in PC were less consistent with those in the PE fraction (13). Different effects on PC relative to PE and PI/PS, accompanied by low levels of long-chain LCP in PC relative to those in PE, also have been reported by others (26,27).

With the exception of 22:4n-6 in PS/PI, which was greater in the suckled control pups, there were no significant differences between the two control groups in this study. This is consistent with the findings of our previous study which found that pups fed a formula containing small amounts (0.5%) of both DHA and AA had a brain LCP composition similar to that of a suckled control group (13). As stated in the previous report, this is interesting in light of the fact that the milk of the dams did not contain detectable levels of DHA, although it did contain small amounts (0.7%) of 20:5n-3. This likely reflects the fact that the American Institute of Nutrition 93M chow fed to the dams comprised a mixture of corn and soybean oil and therefore contained LN and LA, but no LCP. While we did not assess the fatty acid composition of the rat milk in this study, it is likely to be similar to that found previously since the dams in the present study were fed the same diet, for the same period of time, as were those in the previous study.

In summary, formula-feeding of GLA offsets the effects of high levels of DHA in formula on n-6 LCP levels in the brain while leaving DHA levels unchanged. Additionally, these results confirm that the fatty acid composition of the develop-

ing brain can be affected by the type and amounts of n-3 and n-6 fatty acids provided in the diet.

ACKNOWLEDGMENTS

This research was supported by a collaborative research grant by Ross Laboratories and the Natural Sciences and Engineering Research Council of Canada (NSERC) to P.E. Wainwright. The authors thank Martek Biosciences for providing the microbial oils, and particularly Kim Boswell of Martek for help in preparing the dietary oil mixtures. Dawn McCutcheon, Nancy Gibson, Laura Foxcroft, and Amy Williamson provided invaluable help with the rearing of the animals.

ABSTRACT: There is little evidence as to the fatty acid composition of the cerebellum in infancy and it remains uncertain whether milk diet can influence its composition. We therefore examined cerebellar gray and white matter of infants less than 6 mon old who had died unexpectedly. The fatty acid content of 33 gray and 21 white matter specimens from infants born at term and 6 gray and 5 white matter specimens from preterm infants was assessed by gas chromatographic/mass spectrometric analysis. Infants were grouped according to whether they had received human or manufactured formula milk. Whereas cerebellar cortex docosahexaenoic acid (DHA, 22:6n-3) concentrations were significantly lower ($P < 0.01$) in the formula-fed than breast-fed infants, no differences existed between the term (n = 10) and preterm (n = 5) Scientific Milk Adaptation (SMA) formula-fed infants. Cerebellar white matter DHA concentrations were similarly lower ($P < 0.01$) in the SMA formula-fed infants (n = 8) than in an age-matched breast-fed group. Low concentrations of cerebellar white matter lignoceric (24:0) and nervonic acid (24:1n-9) in two 7-wk-old preterm infants appeared to correlate with postgestational rather than chronological age. Dietary long-chain polyunsaturated fatty acids, particularly DHA, are probably essential for normal development of the infant cerebellum.

Paper no. L8201 in *Lipids 34,* 1065–1071 (October 1999).

The cerebellum is composed of two hemispheres displaying numerous deep fissures with folia between and connected by the vermis in the midline. Like the cerebrum, it is also divided into lobes, the most primitive being the flocculonodular, followed by the anterior and posterior. The cerebellum acts to modulate and balance the sensory stimuli reaching the cerebral cortex with that of the generated neurological response, and its principal function is in the coordination of movement and balance. However, it may also undertake some of the higher sensory functions, which have been, until recently, considered the preserve of the cerebral cortex (1,2). In evolutionary terms, after the brain stem, the cerebellum was next to develop from the anterior dorsal part of the primitive midbrain. In humans it was believed that the increased cerebellar complexity, particularly the lateral expansion of the posterior lobe, accounted for our manual dexterity. However, positron emission tomography shows maximal activity in the cerebellar posterior lobe in response to cognitive and linguistic tasks simultaneously performed, with activity generally centered in the prefrontal cortex (3).

In comparison to the infant cerebrum, the cerebellum has a faster but shorter growth spurt, starting later but achieving adult proportions earlier (4). This growth necessitates incorporation of polyunsaturated fatty acids (PUFA) (5) and as it includes a period of rapid myelination, a supply of very long chain fatty acids (VLCFA) such as nervonic and lignoceric is essential. Our previous research identified dietary-related deficits in infant cerebral gray and white matter long-chain PUFA and VLCFA (6–8), and therefore one must consider that these may also affect cerebellar development during a critical time in infant nutrition (9). The cerebellums of animals fed a restricted diet have disproportionately fewer cells, especially granular neurons and glial cells, and the brain lipids, especially those characteristic of myelin, are permanently reduced (10). Martinez (11) found no difference in the concentration of cerebellar myelin-associated galactolipids when comparing a group of undernourished infants with those fed a normal diet.

This study reports cerebellar grey and white matter fatty acid compositions in early infancy with specific reference to diet. Cerebellar white matter glycosphingolipid (galactocerebroside and sulfatide) contents are also reported.

SUBJECTS AND METHODS

Tissue samples from both gray and white matter were obtained from precise loci in the folia of the anterior cerebellar lobe, distant from the nuclei. Specimens were obtained from 34 babies who had died in the first 6 mon of life from sudden infant death syndrome, after a pathologist's examination had excluded any other cause of death. Tissues were stored at −60°C pending analysis. Full medical and dietary histories were obtained soon after death and infants were grouped according to which milk diet they had received.

Formula and human milk compositions from a local population of mothers have been reported previously (6–8). In this

[b]Significant differences in fatty acid concentrations between the breast milk-fed group and the term and preterm formula-fed groups, calculated by Student's *t*-test (two-tailed), are shown. [a]$P < 0.01$; [b]$P < 0.001$.

study period (April 1986–June 1996), all formula milks were devoid of both long-chain PUFA and very long-chain monounsaturated fatty acids. Term-born infants were subsequently classified as either exclusively breast-fed ($n = 10$), Scientific Milk Adaptation formula (SMA)-fed ($n = 11$), or fed a regimen designated CGOST ($n = 7$), which included infants fed either Farley's Ostermilk (Heinz, United Kingdom) or Cow & Gate Premium (Cow & Gate, Trowbridge, United Kingdom). In addition, tissue from seven preterm infants was obtained, five of which were SMA-fed (delivered at 30, 32, 34, 35, and 36 wk gestation, respectively), one (34 wk gestation) CGOST fed (grey matter only), and the other (32 wk gestation) fed both human and SMA formula and designated mixed-fed (white matter only). α-Linolenic acid (18:3n-3) was present at 1.5% of the total fatty acids in SMA (linoleic/α-linolenic ratio *ca.* 10), whereas the CGOST formulas contained <0.4% as α-linolenic acid with a linoleic/α-linolenic ratio of about 40.

Age comparability between feeding groups was considered sufficient for the assessment of dietary-related differences in cerebellar grey matter fatty acid compositions. However because of the rapid postnatal changes in brain white matter fatty acid compositions (8,12) it was deemed essential to age-match (±1 wk) infants in the cerebellar white matter dietary groups. This proved possible with the breast-fed and SMA-fed groups but led to the exclusion of a 9-wk-old breast-fed and 17-wk-old SMA-fed infant. In addition, no cerebellar white matter was retained from a 7-wk-old breast-fed or 9- and 16-wk-old SMA-fed infants, although the last was substituted by a further specimen from an infant of the

[a]Significant differences in fatty acid concentrations between feeding groups were calculated by the Wilcoxon signed rank test for paired data ($n = 8$). [a]$P < 0.02$; [b]$P < 0.01$.
[b]Details regarding infants are given as means with standard deviations in parentheses.
[c]Fatty acid concentrations are expressed as weight percentage of total fatty acids and presented as medians and ranges.

same age. An insufficient degree of age-matching also excluded a cerebellar white matter CGOST group from the analysis. Details regarding infants and feeding group compositions are presented in Tables 1 and 2.

Tissues were extracted as previously described (5), and gray and white matter fatty acids were derivatized with boron trifluoride in methanol (BDH, Poole, United Kingdom) (14% wt/vol) and anhydrous methanolic 3 N HCl (Sigma-Aldrich, Poole, United Kingdom), respectively. The resulting fatty acid methyl esters were analyzed by gas chromatography/mass spectrometry (Hewlett-Packard 5972, Stockport, United Kingdom) using a 30-m Supelco Omegawax capillary column (Sigma-Aldrich). The column temperature was initially held at 150°C for 2 min, then programmed to 220°C at 5°C/min. Detector and injector temperatures were 280 and 250°C, respectively, and helium was used as carrier gas. Cerebellar grey and white matter fatty acid concentrations with respect to dietary group are shown in Tables 1 and 2.

To relate fatty acid compositions in the cerebellar white matter (particularly the VLCFA) with the lipid species present, we analyzed tissue extracts (nonderivatized) by high-performance thin-layer chromatography on silica gel plates (LHPK Silica Gel 60A, Whatman International Ltd., Maidstone, United Kingdom). One microliter (*ca.* 20 µg lipid) was spotted as a narrow band beside a mixed standard (10 µg) containing equal amounts of sulfatides, galactocerebrosides, and the major phospholipids all derived from bovine brain and obtained from Sigma-Aldrich. Plates were run at room temperature in 40 mL methyl acetate/propan-2-ol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:9, by vol) for 40 min. After drying, they were dipped in the developing reagent (3% copper acetate in 8% orthophosphoric acid) and charred at 160°C for 20 min. The resultant bands were analyzed by scanning densitometry (Shimadzu, Milton Keynes, United Kingdom) on reflectance mode at 340 nm wavelength. After correction for relative absorption, lipid classes were quantified after reference to the standard values.

Between-group differences in cerebellar cortex fatty acids were assessed by Student's *t*-test (two-tailed). After correction for multigroup analysis a significance level of $P < 0.01$ was adopted. Cerebellar white matter fatty acid data were assessed using the Wilcoxon signed rank test solely for the age-matched breast-fed and SMA-fed infants. The white matter results from the SMA-fed preterm infants are provided for information only, without statistical analysis. Distributions of age-related results, corrected for gestation, are provided for cerebellar cortex docosahexaenoic acid (DHA) (Fig. 1) and docosapentaenoic acid (DPA, 22:5n-6) (Fig. 2) and cerebellar white matter DHA (Fig. 3), nervonic acid (Fig. 4) and lipid subfractions (Fig. 5).

RESULTS

Cerebellar gray matter. None of the saturated or mono-unsaturated fatty acid concentrations differed between groups (Table 1). Cortical DHA concentrations in the human milk-fed group were generally above 8% of total fatty acids during the first 6 mon (Fig. 1) and were significantly greater than in the SMA-fed ($P < 0.001$), CGOST-fed ($P < 0.001$) and SMA-fed preterm infant ($P < 0.01$) groups where DHA levels declined

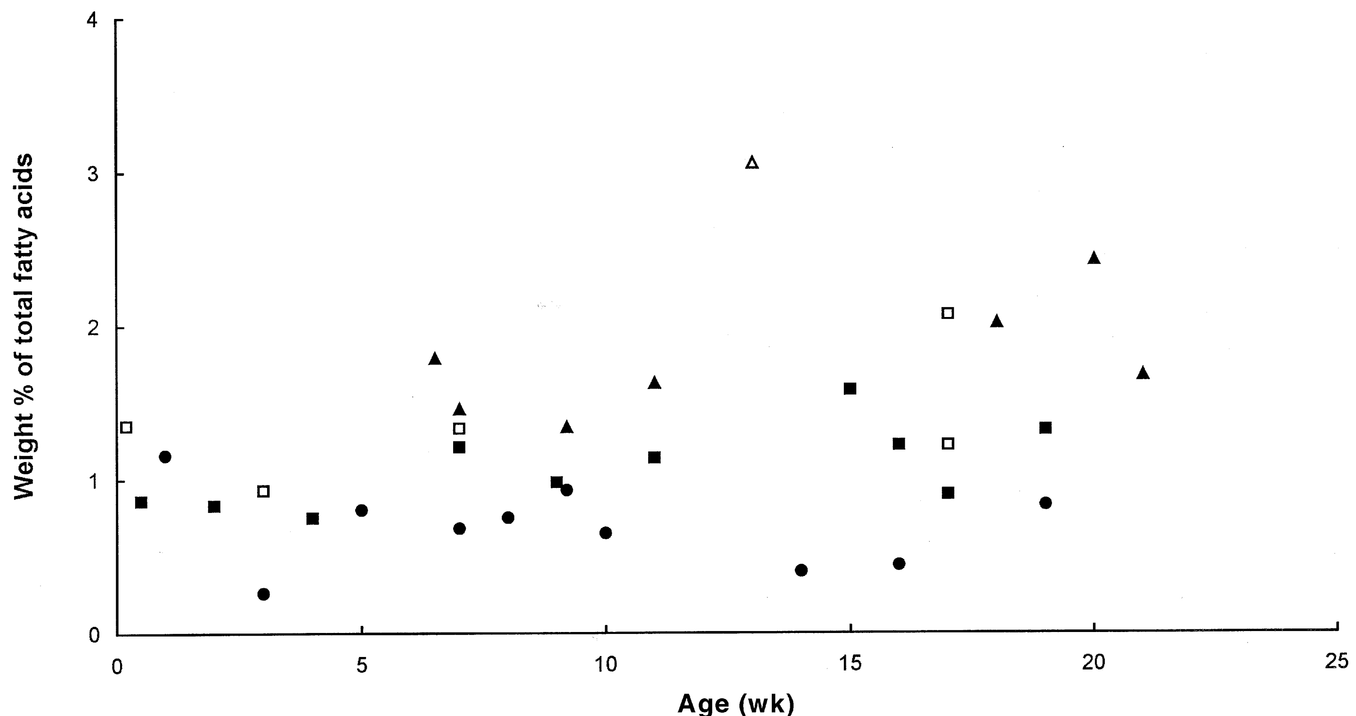

FIG. 1. Cerebellar cortex phospholipid docosapentaenoic acid (22:5n-6) in relation to infants' diet and age. (●, ■, ▲), term infants; (○, □, △), preterm infants. (●,○), breast-fed infants; (■,□), SMA-fed infants; (▲,△), CGOST-fed infants.

over the same period to about 4–5%. Partial substitution is suggested by a generalized increase in n-6 series PUFA, which, however, only reached statistical significance in DPA (Table 1). A similar pattern with greater DHA ($P < 0.01$) and lower DPA ($P < 0.001$) concentrations in the SMA-fed than CGOST-fed infants was observed. No significant differences in fatty acid compositions were found between the term and preterm SMA-fed groups. Overall, the highest DPA (3.06%) and lowest DHA (3.49%) concentrations were present in the 19-wk-old CGOST-fed preterm (34-wk gestation) infant (Figs. 1,2).

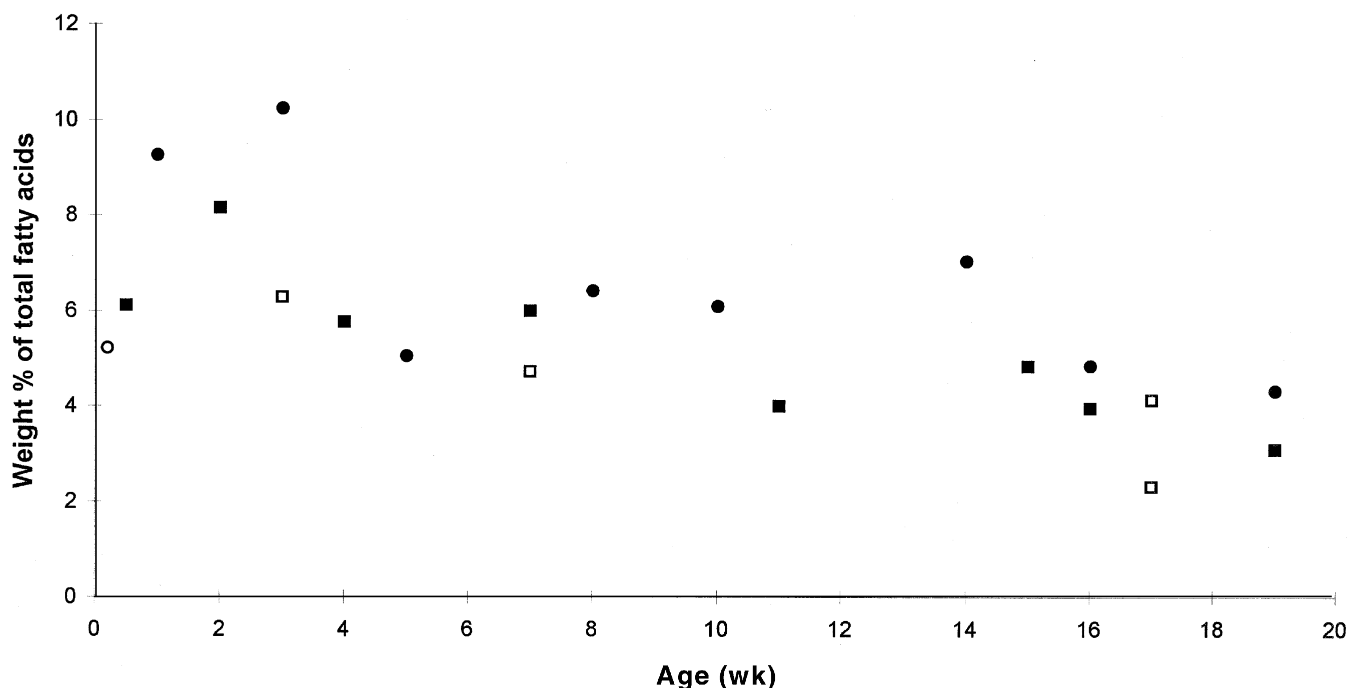

FIG. 3. Cerebellar white matter total lipid docosahexaenoic acid (22:6n-3) in relation to infants' diet and age. For symbols see Figure 1.

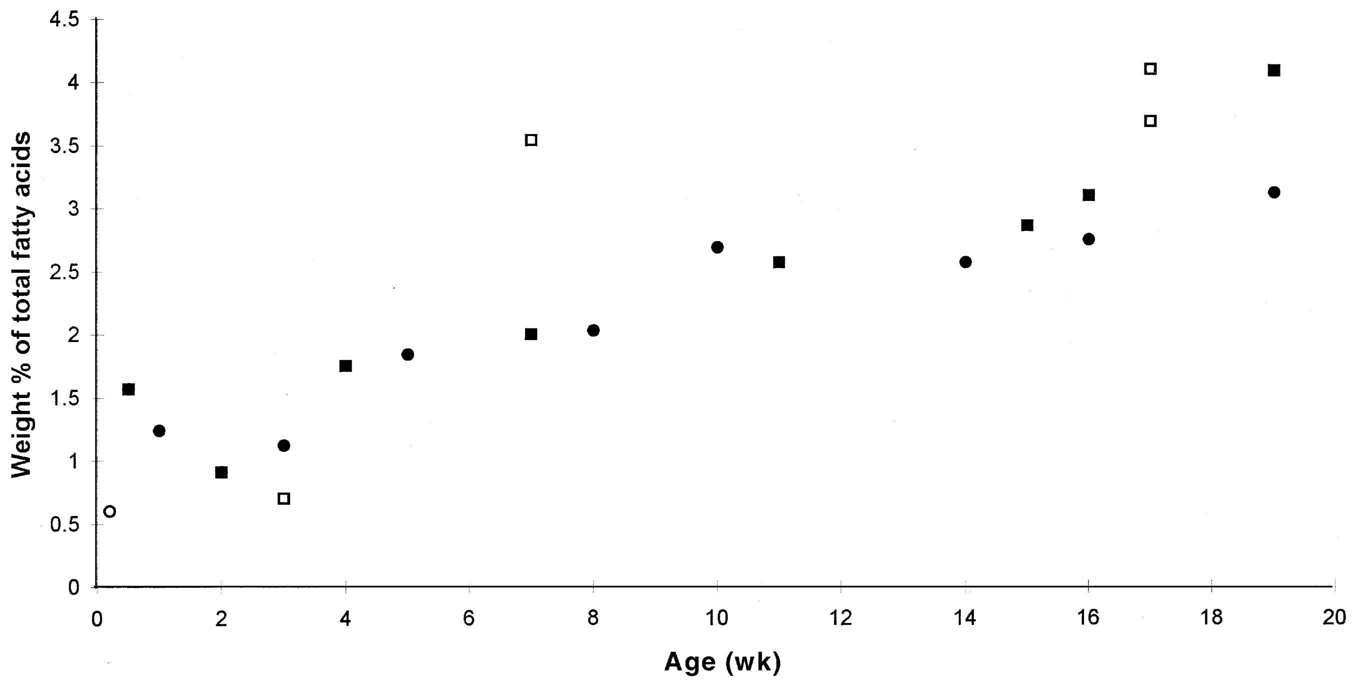

FIG. 4. Cerebellar white matter total lipid nervonic acid (24:1n-9) in relation to infants' diet and age. For symbols see Figure 1.

Cerebellar white matter. Again, no significant differences were found in mono-unsaturated fatty acids in respect of diet. Cerebellar white matter DHA incorporation was greater in the breast-fed group ($P < 0.01$) than the age-matched SMA group (Table 2) although a steady decline in concentrations with age to less than 5% of total fatty acids was a feature common to all feeding groups. In contrast to the cerebellar cortex, DPA was not prominent in cerebellar white matter, however, both docosatetraenoic (22:4n-6) ($P < 0.02$) and lignoceric acid concentrations ($P < 0.02$) were greater in the SMA- than the

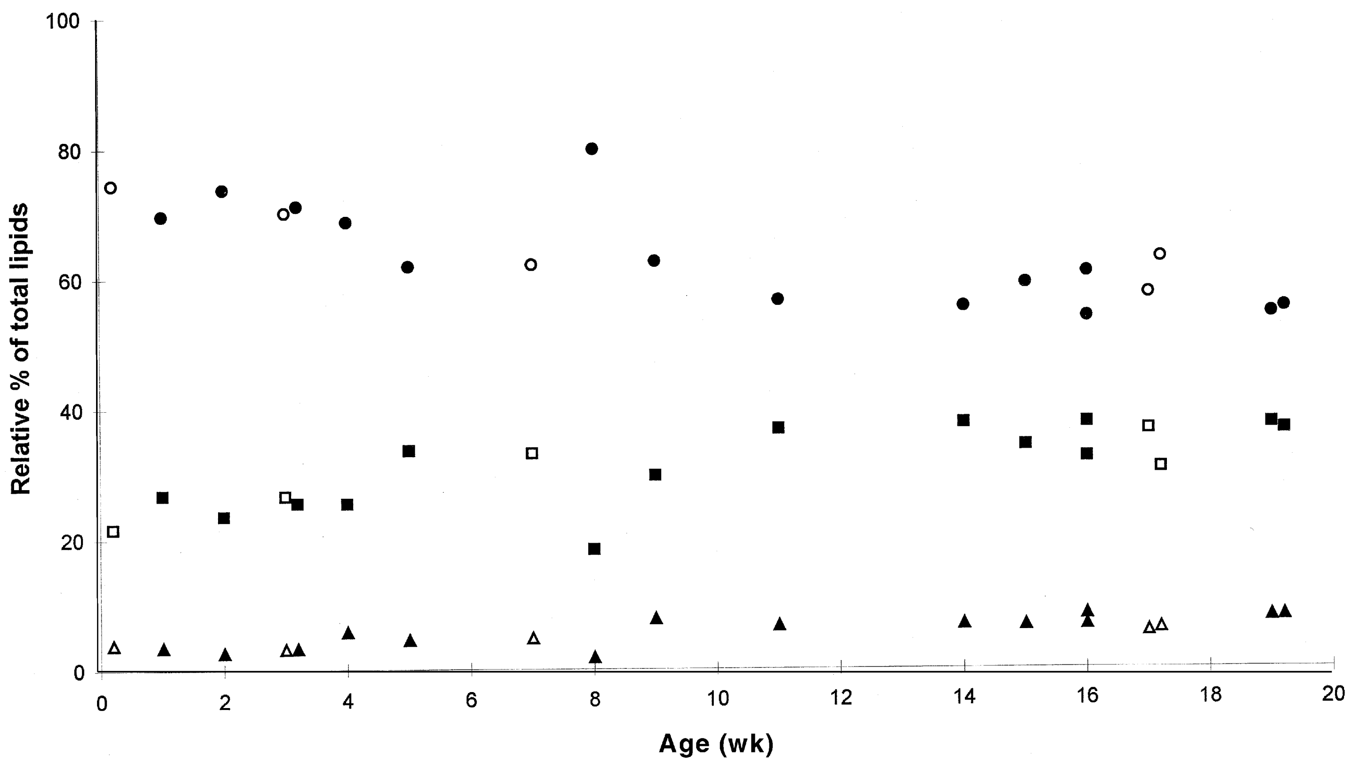

FIG. 5. Infant cerebellar white matter lipid compositions with respect to age. (●, ■, ▲), term infants; (○, □, △), preterm infants. (●,○), phospholipids; (■,□), galactocerebrosides; (▲,△), sulfatides.

breast-fed group (Table 2). In the SMA-fed preterm infant group DHA concentrations appeared consistent with those of the term-born SMA-fed infants (Fig. 3) although as previously stated no statistical between group analysis was possible. In the youngest, 7-wk-old SMA- and mixed-fed preterm infants, the lowest nervonic acid concentrations of 0.7 and 0.65%, respectively, were found (Fig. 4). Although not shown, a similar pattern was present in cerebellar white matter lignoceric acid. Subsequent high-performance thin-layer chromatographic analysis of lipid extracts failed to reveal a concomitant reduction in the VLCFA-rich galactocerebrosides and sulfatides in these premature infants (Fig. 5).

DISCUSSION

Researchers who have examined neonatal brains by magnetic resonance imaging have identified maturation of the cerebellum in advance of the cerebrum, with significant cerebellar myelination before birth (13). We found a very similar pattern of cerebellar cortex fatty acid concentrations in term-born infants to those previously observed in cerebral cortex (6), with a DHA "deficiency" associated with formula feeding and in conjunction with an increase in n-6 series PUFA, particularly DPA. In addition, limited dietary provision of α-linolenic acid (0.4% of total fatty acids) to the CGOST-fed infants was probably responsible for their low cortex DHA concentrations. Our findings, with respect to feeding groups, must be somewhat tempered by the relatively low mean birthweights in the cerebellar cortex SMA and CGOST groups at 3.0 kg, as compared with that of the breast-fed group at 3.35 kg.

It has been thought that preterm infants might be uniquely vulnerable to deficits in fatty acid accretion if they are born before the cerebellar growth spurt *in utero*. Although no exclusively human milk-fed preterm infants were included in this study, there were no differences in cerebellar cortex fatty acid concentrations between the term and preterm SMA fed groups in spite of mean gestational ages of 38.6 and 33.4 wk, respectively. It is known, however, that when precursor α-linolenic acid is provided, some DHA can be synthesized even in preterm infants (14). The supply of α-linolenic acid at 1.5% of total fatty acids in the SMA formula may have been adequate for that purpose.

The DHA concentration in cerebellar white matter was also significantly lower in the SMA-fed than the age-matched breast-fed group. This outcome, similar to that in the cerebellar cortex, may seem surprising as the cerebellum constitutes only 6–8% of total brain weight. Moreover, as cerebral and cerebellar DHA concentrations are equivalent at birth and decline in the white matter thereafter, cerebellar incorporation of DHA should amount to less than 1 g in the first year of life. If dietary DHA is not provided, endogenous synthesis of DHA may be sub-optimal or turnover of PUFA may be greater in the cerebellum than cerebrum. The relatively low cerebellar white matter lignoceric and nervonic acid concentrations in the 7-wk-old, preterm (32- and 36-wk gestation) infants (Fig. 4) seem to correlate more closely with postgestational than chronological age and may be as a result of them missing the late fetal accretion phase. It has been observed that "normal" concentrations of cerebellar glycosphingolipids (galactocerebrosides and sulfatides) are maintained even in undernourished infants (11); and the relative percentages of phospho- and sphingolipids, as measured by scanning densitometry after charring, do not appear to be compromised by preterm delivery or early milk feeding regimens devoid of both long-chain PUFA and VLCFA (Fig. 5). Whether the precise process of conversion of sphingosine to ceramide in the infant cerebellum, predominantly by incorporation of VLCFA, is disrupted cannot be assessed in this study.

Animal research has shown that nutritional deprivation in early postnatal life may affect motor coordination (15,16); however it is not known if the dietary-related structural differences in human cerebellar cortex and white matter DHA in this work could also affect functional neurodevelopment. Any alteration in cerebellar function might be expected to manifest in subtle modification in neurological activity associated specifically with fine motor coordination. Perhaps a parallel may be drawn between the increasing rates of formula feeding and the emergence of relatively benign, proprioception-related conditions, such as dyspraxia. An "epidemic" of uncoordinated, dyspraxic individuals has been identified in upward of 6% of school-age children (17), with a higher prevalence (14%) in children of low (<2.5 kg) birthweight (18). In conclusion, the authors assert that formula milk compositions should more closely resemble those of human milk, especially with respect to PUFA content.

Laboratory of Lipid Chemistry (Functional Biochemistry Section), National Research Institute of Fisheries Science, Ministry of Agriculture, Forestry and Fisheries, Yokohama-shi 236, Japan

ABSTRACT: The total lipid and fatty acid compositions of tissues and the stomach contents of three subtropical marine fish species, subfamily Caesioninae, *Caesio diagramma* and *C. tile,* and family Siganidae *Siganus canaliculatus,* were investigated to clarify the differences between these species. Triacylglycerols (TAG) were the dominant depot lipids of the three species, whereas wax esters were found as a minor component. In particular, muscle lipids were found to contain mainly glycerol derivatives such as TAG and phospholipids. The major fatty acids identified in the three species were 16:0, 18:0, 18:1n-9, and 22:6n-3 (docosahexaenoic acid, DHA). In addition, noticeable levels of 16:1n-7, 18:1n-7, 20:4n-6 (arachidonic acid, AA), and 20:5n-3 (eicosapentaenoic acid) were found. DHA was the most abundant polyunsaturated fatty acid (PUFA) in the muscle and viscera lipids of the three species. The high DHA levels in the lipids of all the organs were found to be higher than those of the lipid extracted from the stomach contents of the three fishes. In addition, the specimens of *S. canaliculatus* contained significantly higher levels of AA in its tissues than did the other two species. A high AA content is unusual since such high levels of n-6 PUFA are rarely found in higher marine organisms. These levels may be due to its characteristic feeding pattern, because *S. canaliculatus* prefer and mainly feed on seaweed, which often contains high amounts of n-6 PUFA, such as linoleic acid (18:2n-6) and AA.

Paper no. L8047 in *Lipids 34,* 1073–1082 (October 1999).

Reportedly marine pelagic fishes selectively store various fatty acids from their prey in the form of triacylglycerols (TAG) which are used as depot lipids. These lipids generally contain high levels of long-chain n-3 polyunsaturated fatty acids (PUFA), which predominate in phytoplankton lipids over α-linolenic acid (1–7). In particular, the tissue lipids of tuna species, which are highly migratory fishes, are markedly high in docosahexaenoic acid (DHA) (8–11). In the marine food chain, tuna species are at the highest trophic level, and their high DHA levels may be a result of their trophic position in the food chain and accumulation of planktonic DHA through feeding on small fishes. Marine fishes, with the exception of turbot, are generally unable to synthesize DHA (2,12–18).

On the other hand, it has been suggested that environmental conditions, such as temperature variations, have an influence on the n-3 PUFA content of lipids in small marine fish species (2,5,19–25). For example, the DHA content of lipids in tropical and subtropical marine fish species are reportedly lower than those of arctic and subarctic ones (26-29). Fishes living in warm-water seas do not appear to require as much DHA in their cell membranes as cold-water species (19–25). The lipid content of tropical fish species is generally influenced by high ambient temperature, and the membrane lipids of these fishes are easily fluidized even if the major fatty acids in their lipids are composed of saturated and monoenoic fatty acids. The n-3 PUFA ratios of the total fatty acids (TFA) in tropical and subtropical fish lipids are usually comparatively low, and this is a general tendency in the lipids of marine organisms living in warm seas. However, this trend in lipid utilization has been confirmed for only a few fish species (26–29).

In the present study, we assess the relationship between the lipids of the two subtropical Caesioninae species (*Caesio diagramma* and *C. tile*) and one Siganidae species (*Siganus canaliculatus*), and those of their prey, to determine the position of these fishes in the marine food chain. In this study, the lipid and TFA compositions of their tissues and stomach contents were analyzed. These species are abundant in the sea off the coast of the main island of Okinawa, Japan, and are an important marine resource that is consumed by the inhabitants of the southern islands of Japan.

MATERIALS AND METHODS

Materials. Details of the specimens of two subtropical fish species used, *C. diagramma* and *C. tile* are given in Table 1.

[a]Results are expressed as the mean ± standard error (n = 4–8) for each entry.

The *C. diagramma* specimens were caught in the East China Sea near Okinawa (four specimens: 26°15′ N, 127°30′ E, August 29, 1996; and seven specimens: 24°30′ N, 124°30′ E, May 6, 1997) in the subtropical Pacific Ocean. Specimens of *C. tile* were also caught in the same sea (24°30′ N, 124°30′ E) on September 9, 1996, and May 6, 1997. Specimens of *S. canaliculatus* were caught in the vicinity of Katsurenzaki Peninsula in Nakagusuku Bay (24°30′ N, 127°55′ E) in two different seasons: on November 22, 1992 (six specimens), and on August 18, 1997 (eight specimens). All samples were immediately frozen and kept at –40°C for 3 wk prior to analysis. All specimens were dissected and separated into respective tissues (muscle, liver, and other viscera) and stomach contents. Other viscera, containing abdominal lipids, and the stomach contents were separated from the stomach by scraping its inner wall.

Lipid extraction and the analysis of lipid classes. After the measurement of biological data, each tissue was minced and homogenized in a mixture of chloroform/methanol (2:1, vol/vol). A portion of the homogenized sample was extracted according to the procedure of Folch *et al.* (30). The crude total lipids (TL) were separated into classes on silicic acid columns, and the constituent lipids were quantified by gravimetric analysis of column chromatographic fractions. The first eluate (dichloromethane and *n*-hexane, 2:3, vol/vol) was used to collect the fraction containing wax esters and steryl esters. The second eluate (dichloromethane) from the column contained the TAG fraction. This was followed with dichloromethane/ether (9:1, vol/vol), eluting sterols; dichloromethane/methanol (9:1, vol/vol), eluting free fatty acids (FFA); dichloromethane/methanol (1:1, vol/vol), eluting phosphatidylethanolamine (PE), and dichloromethane/methanol (1:20, vol/vol), eluting phosphatidylcholine (PC). Individual lipids, separated from each lipid class, were identified by comparison with standard samples using thin-layer chromatography (TLC; thickness of 0.25 mm for analysis, Kieselgel 60, Merck and Co. Ltd., Darmstadt, Germany) and nuclear magnetic resonance (NMR). All sample lipids were dried under argon at room temperature and stored at –40°C.

Preparation of methyl esters and gas–liquid chromatographic analysis. Individual components of the TAG and phospholipid fractions were converted to fatty acid methyl esters by direct transesterification, refluxing each component with methanol containing 1% concentrated hydrochloric acid for 3 h (31). The methyl esters thus obtained were purified by column chromatography with silica gel by elution with dichloromethane.

The composition of the fatty acid methyl esters was determined by gas–liquid chromatography using a Shimadzu GC-8A gas chromatograph (Shimadzu Seisakusho Co. Ltd., Kyoto, Japan) equipped with two fused-silica capillary columns (TC-WAX, 30 m × 0.25 mm i.d.; 0.25 µm film, GL Science Co. Ltd., Tokyo, Japan; Omegawax-250, 30 m × 0.25 mm i.d.; 0.25 µm film, Supelco Japan Co. Ltd., Tokyo, Japan), and an HP 5890 series II gas chromatograph (Hewlett-Packard Co., Yokogawa Electric Corporation, Tokyo, Japan) equipped with an Omegawax-250 fused-silica capillary column. The injector port and column temperature were maintained at 250 and 200°C, respectively, and the split ratio was 1:100. Helium was used as the carrier gas at a constant inlet rate of 40 mL/min.

Quantitative area percentages of fatty acids from analyses performed on the capillary columns were provided by means of a Shimadzu Model C-R5A (Shimadzu Seisakusho Co. Ltd., Kyoto, Japan) electronic integrator.

Peak identification. Fatty acid methyl esters were identified using (i) marine lipid methyl esters as standards (Omegawax test mixture No. 4-8476, Supelco Japan Ltd.) and (ii) comparison of semilogarithmic plots of the relative retention time (RRT) against carbon chain lengths of known fatty acids from fish oil using the method of Ackman (32).

NMR spectrometry. Spectra were recorded on a GSX-270 NMR spectrometer (JEOL Co. Ltd., Tokyo, Japan) in the pulsed Fourier transform mode at 270 MHz in deuterochloroform solution using tetramethylsilane as an internal standard.

Statistical analyses. For all samples and treatments, more than three replications were made. The significant differences of the means were determined using Student's *t*-test at a significance level of $P < 0.05$.

RESULTS AND DISCUSSION

Lipid contents of the three subtropical species. The TL content of the three species, *C. diagramma*, *C. tile,* and *S. canaliculatus* are given in Table 2. The muscle lipids of these species contained low levels of lipid (Table 2) in comparison with those of other fish species (1–4). However, all the specimens examined accumulated most of their deposit lipids in the viscera, because the amount of visceral lipids were comparatively high (3.3–24.8%). These three species, in subtropical seawater, could hardly acquire these depot lipids directly from their prey, because the mean lipid levels of their stomach contents were 1.7% (1.7 ± 0.0%). This is low even when it is compared to that of their muscle. Very small amounts of partly digested zooplankton were found in the stomachs of the Caesioninae species, while only a moderate amount of partly digested seaweed was found in the stomachs of *S. canaliculatus*. The feeding behavior of *S. canaliculatus*, which is an herbivorous fish, differs greatly from those of the Caesioninae species, which are carnivorous fishes.

Lipid classes in the TL. The lipid classes in the tissues (muscle, liver, and other viscera) of *C. diagramma*, *C. tile*, and *S. canaliculatus* are shown in Table 2. In this study, the ratios of these components in the lipid classes in the respective individuals of the same species did not differ significantly ($P > 0.05$). The lipids of the tissues of these three species mainly contained glycerol derivatives similar to those of other epipelagic fish species. For example, the total amounts of TAG (a major neutral depot lipid) and phospholipids (major polar tissue lipids) in the muscle lipids were 67.8–83.5% of the TL. The high proportions of phospholipids (47.8–61.6%) in muscle lipids of the Caesioninae species differ from that of the Siganidae species. The mean numerical values of the phospholipids in the Caesioninae muscles were 47.8% for *C. diagramma* and 61.6% for *C. tile*, but that in *S. canaliculatus* was 7.8%. Therefore, only *S. canaliculatus*, among these three species, accumulated neutral deposit lipid in both muscle and viscera. The phospholipids in these fish species contained mainly PC and PE, which were identified by comparing them with authentic sample R_f values using TLC and NMR. FFA, which are presumably derived from the glycerides such as TAG and phospholipids through hydrolysis by enzymes during storage, were found in the lipids of all tissues—in particular, in the liver because these enzymes may be predominant and active there. Therefore, the total amount of glycerol derivatives such as TAG, FFA, and phospholipids may be more than 60% of the TL in all tissues of the three fish species. The lipids of these fishes contained only a small quantity of wax esters (0.6–5.4%).

Sterols (Table 2) were found at moderate levels (5.5–16.2%) in all samples. The purified sterols were immediately crystallized after isolation, and cholesterol was found to be predominant in the sterol fraction. It was identified with authentic cholesterol using TLC and NMR.

Fatty acid composition in the respective classes of each tissue. The fatty acid composition of the major components (TAG and phospholipids) separated from the lipids of the muscle, liver, and other viscera of the two Caesioninae species are shown in Tables 3 and 4. At least 50 compounds were detected and identified, of which more than 30 major compounds are shown. In TAG (the major neutral lipids), the fatty acid composition varied slightly between tissues, and the major components (>5%) of both species were 16:0 (23.7–30.4%), 18:0 (7.6–10.2%), 18:1n-9 (8.6–11.6%), and 22:6n-3 (DHA, 10.7–20.6%). Noticeable amounts (>2%) of other highly unsaturated fatty acids such as saturated fatty acid 14:0 (3.7–5.7%), monoenoic acids 16:1n-7 (2.3–4.2%),

[a]Results are expressed as weight percentage of total lipids.
[b]Data are mean ± standard error ($n = 6$).
[c]Results are expressed as weight percentage of wet tissues.
[d]Both WE and SE were contained as major components in fraction 1. WE, wax esters; TAG, triaclglycerols; FFA, free fatty acids; PE, phosphatidylethanolamine; PC, phosphatidylcholine.

[a]Results are expressed as weight percentage of the total fatty acids. Data are mean ± standard error (n = 6–8).
[b]The levels of PC in the other viscera of *C. diagramma* were very low, and its fatty acid composition could not be analyzed. For abbreviations see Table 2.

18:1n-7 (2.3–3.0%), and 20:5n-3, eicosapentaenoic acid (EPA) (2.8–4.3%) were detected.

In polar lipids, the major components in both the PE and PC of the Caesioninae species, were 16:0 (4.4–19.2% for PE and 15.9–19.3% for PC), 18:0 (10.3–20.2% for PE and 3.3–10.5% for PC), 18:1n-9 (2.8–8.8% for PE and 4.7–8.4% for PC), and DHA (20.8–41.2% for PE and 27.5–50.0% for PC). Noticeable amounts of other highly unsaturated fatty acids such as 20:4n-6 (arachidonic acid, AA; 2.8–6.8% for PE and 2.7–6.2% for PC), EPA (1.9–4.0% for PE and 3.5–7.1% for PC), and 22:4n-3 (3.1–5.6% for PE and 2.9–6.6% for PC) were detected. Among all these lipids, saturated fatty acids 16:0 and 18:0, monoenoic acids 16:1 and 18:1, and n-3 PUFA EPA and DHA were generally the dominant fatty acids.

In general, the n-3 PUFA levels in muscle lipids (32.1–63.7% for *C. diagramma* and 24.8–63.6% for *C. tile*) were higher than those in visceral lipids (16.8–40.9% for *C. diagramma* and 19.6–49.8% for *C. tile*). Furthermore, high levels of n-3 PUFA (51.2–55.3% in PE of muscles and 63.6–63.7% in PC of muscles) in the polar lipids were detected, compared with those in the neutral lipids (24.8–32.1% in TAG of muscles and 34.8–45.0% in FFA of muscles). Among the PUFA, DHA is predominant (Tables 3 and 4). Consequently, the n-3 PUFA levels in PE and PC of the muscles were the highest, and this confirms that n-3 PUFA is an

[a]Results are expressed as weight percentage of the total fatty acids. Data are mean ± standard error (n = 6–8). For abbreviations see Table 2.

important muscle membrane component. The fatty acid composition of all tissues of the two species were similar, having high DHA contents, especially with the DHA content of the PC of the muscle exceeding 50% (50.0% for *C. diagramma* and 50.1% for *C. tile*) of the TFA. Although various saturated, monoenoic, and polyunsaturated fatty acids were observed in the Caesioninae species (similar to those of other marine fish species), the high levels of n-3 PUFA in the fatty acid composition of tissue lipids of the Caesioninae were significantly different from those of the other tropical fish species ($P <$ 0.05) (26–29). Even the mean DHA content levels (15.5–20.6%) of the TAG reached more than 10% of the TFA, while those in the TL of tropical and subtropical fish are reported to be only several percentage. For example, the mean DHA content of TFA of 15 species of fishes caught in tropical waters is about 4% of TFA, and in some cases the DHA content is less than 2% of the TFA, whereas for those caught in temperate and subarctic zones the contents vary between 5 and 20% (2,26,27).

The fatty acid composition of the same major lipid classes of the *S. canaliculatus* are shown in Table 5. In neutral lipids, the major components in the TAG of *S. canaliculatus* were 14:0 (3.3–6.3%), 16:0 (30.1–33.6%), 18:0 (5.1–8.4%), 16:1n-7 (4.5–7.9%), 18:1n-9 (9.0–9.7%), and DHA (8.5–14.1%)—similar to those in the Caesioninae species. Noticeable amounts of other fatty acids, such as 18:1n-7

[a]Results are expressed as weight percentage of the total fatty acids. Data are mean ± standard error (*n* = 6–8).
[b]The levels of PC in the liver and other viscera of *S. canaliculatus* were very low, and its fatty acid composition could not be analyzed.

(2.6–3.4%), AA (2.7–6.3%), and 22:5n-3 (2.4–4.6%), were found in the TAG. In polar lipids, the major components, both in the PE and PC of this species, were 16:0 (14.8–23.3% for PE and 9.7% for PC), 18:0 (8.2–10.7% for PE and 16.9% for PC), 18:1n-9 (3.9–6.1% for PE and 4.2% for PC), AA (9.3–14.0% for PE and 10.3% for PC), and DHA (13.5–24.8% for PE and 32.5% for PC). Noticeable amounts of other fatty acids 16:1n-7 (2.5–4.8% for PE and 0.7% for PC) and 18:1n-7 (1.9–2.5% for PE and 1.6% for PC), 22:4n-3 (2.7–3.3% for PE and 4.6% for PC), and 22:5n-3 (2.4–5.4% for PE and 5.2% for PC) were found. In the lipids of *S. canaliculatus*, comparatively high levels of n-3 PUFA (40.8% for PE of muscle lipids and 48.1% for PC of muscle lipids) were also found in polar lipids of muscles, similar to those of the Caesioninae species.

In addition, high levels of n-6 PUFA were also present in the fatty acid composition of the *S. canaliculatus* lipid, and this high n-6 PUFA level differs from those of other marine fish species. In particular, the high levels of AA (9.3–14.0% in PE, and 10.3% in PC) in the fatty acid composition of the

[a]Results are expressed as weight percentage of the total fatty acids. Data are mean ± standard error (n = 6–8).
[b]The levels of PC in the stomach contents of *S. canaliculatus* were very low, and its fatty acid composition could not be analyzed. TL, total lipids; for other abbreviations see Table 2.

phospholipids in the tissues of *S. canaliculatus* were markedly different from those of the other fish species (Table 5), which contain very low levels of n-6 PUFA in their lipids (1–7).

Fatty acid composition of stomach contents. The fatty acid composition of the stomach contents of the three subtropical species is shown in Table 6. The lipid levels of stomach contents from the two Caesioninae species were very low, and their respective classes could not be analyzed. Only the fatty acid composition of total lipids could be analyzed. In the stomach contents of the two Caesioninae species examined, the fatty acid compositions of these species were very similar, and the major fatty acids were 16:0 (25.5–29.4%), 18:0 (10.3–12.7%), 18:1n-9 (9.5%) and DHA (9.9–12.4%). In most cases, 16:0 was the dominant fatty acid. The lipids in the stomach contents of both Caesioninae species contained comparatively low levels of n-3 PUFA (18.2–22.8%), similar to the levels of the TAG of the tissues of the species. This sug-

gests that the fatty acid composition of the deposit lipids was directly influenced by those of stomach content lipids.

On the other hand, the stomach content lipids of *S. canaliculatus* mainly contained 14:0 (3.7–6.1%), 16:0 (21.2–31.2%), 18:0 (5.5–13.2%), 16:1n-7 (4.1–6.2%), 18:1n-9 (6.2–9.9%), and DHA (5.5–11.2%); in addition, noticeable amounts of 18:1n-7 (2.6–3.5%), 18:2 n-6 (2.2–2.6%), AA (3.0–11.7%), 22:4n-3 (1.0–2.2%), and 22:5n-3 (1.5–3.7%) were measured. The n-3 PUFA level in its prey lipids was comparatively low, similar to those of the prey of Caesioninae. The comparatively low PUFA levels in the lipids of their prey were considered to be reasonable because these organisms, which live in warm seawater, do not require the high levels of n-3 PUFA for their cell membranes (19–25). In addition, in the stomach contents lipids of *S. canaliculatus*, noticeable levels of AA were found, similar to that in its tissue lipids.

Food chain of the subtropical fish species and accumulations of PUFA in their tissue lipids. It is generally known that n-3 PUFA are required by all marine fishes including subtropical fish species (12–18). In particular, DHA is an essential fatty acid and is important for growth and survival—for example, for the development of juvenile striped jack (*Pseudocaranx dentex*) and red sea bream (*Pagrus major*) (13,33). Watanabe *et al.* (33) and Kaneko *et al.* (36) reported that when fishes are starved they selectively use saturated and monoenoic fatty acids as an energy source and use very little n-3 PUFA, which are conservatively stored in the tissues of marine fish. Moreover, it has recently been found that marine fishes are largely unable to synthesize DHA because they may lack the necessary Δ4- and Δ5-desaturases, and therefore the DHA in the bodies of these fishes must originate from dietary lipid (12–18). The DHA content of total lipid of marine fish may gradually increase during predatory feeding, and high DHA contents in the lipid of highly migratory fish species, which are the final predators, have often been observed. This may have resulted from the continuous accumulation of DHA which originates from their prey in the marine food chain (8–11,35,36).

DHA may be also necessary for polar lipids in the three subtropical fishes that we examined, resembling the compositions found in other marine fishes. The fatty acid compositions of the Caesioninae and Siganidae tissue lipids were nearly constant within each species ($P > 0.05$). In particular, the polar lipids in their muscles contained very high levels of n-3 PUFA. These fatty acid compositions were different from those of their prey, which is consistent with the low levels of n-3 PUFA generally found in the lipids of other small fish species in the subtropical and tropical zones. This suggests that the three species might not simply incorporate these fatty acids from their prey in the same ratios, and the comparatively high DHA levels in their tissue lipids must be due to selective accumulation. This is because the high DHA levels were found only in their polar lipids while the visceral TAG were very similar to the total lipids of the stomach contents. Furthermore, the three fish species examined consumed very little food, and conditions were similar to fasting. They may also utilize mainly saturated and monoenoic acids for energy and store n-3 PUFA, similar to migratory fish species. Even in species living in the coral seas in the subtropical zone, DHA levels in their tissue lipids were higher than those of their prey. Although n-3 PUFA levels in the lipids of tropical and subtropical fish species are generally low, all marine fish species may have a tendency to accumulate n-3 PUFA, and this tendency may be a general characteristic not only of the highly migratory fishes but also of other small predacious and active marine fish species.

Accumulation of AA by characteristic feeding of S. canaliculatus. With respect to the accumulation of PUFA, freshwater fish generally consume terrestrial prey with lipids rich in n-6 PUFA and consequently have high levels of n-6 PUFA in their lipids (4,37,38). In contrast, marine fish species generally have only n-3 PUFA which originate from marine phytoplankton. Therefore, AA levels were generally undetectable or negligible in the TFA of lipid of marine fish species. However, there are several marine species whose lipids contain comparatively high levels of n-6 PUFA. For example, some kinds of seaweed contain n-6 PUFA and some marine animals, such as abalone, which may consume seaweeds, have very high levels of n-6 PUFA (39–43).

The mean levels of AA in tissue phospholipids of the muscle and viscera of *S. canaliculatus* consistently reached 10% or more of the TFA (Table 5). Therefore, this species may have a vegetarian feeding habit similar to that of abalone, and its lipids consequently differ from those of carnivorous marine fish species. The noticeable levels of AA (3.0–11.7%) in the stomach content lipids of *S. canaliculatus* would likely result in the high AA levels in its tissues. High levels of AA (more than 10% of the TFA) in the tissues of *S. canaliculatus* were accompanied by high levels of n-3 PUFA, while those in deposit lipids and stomach contents lipids were lower than in the polar tissue lipids. We suggest that *S. canaliculatus* prefer and consume seaweed with lipids containing noticeable levels of AA and may therefore accumulate AA in its tissue lipids throughout its life feeding on the marine food chain in the coral seas.

As for *S. canaliculatus*, this phenomenon of high tissue contents of both n-3 and n-6 PUFA were similar to the high n-3 PUFA levels in Caesioninae tissues. Therefore, the tropical species of marine fish may have a tendency to accumulate both n-3 and n-6 PUFA in their tissues if their diet contains substantial amounts of these fatty acids. Therefore, high levels of AA may be useful as a lipid biomarker of herbivorous fishes, which prefer seaweed (44), because most marine fish do not have very high levels of AA.

ACKNOWLEDGMENTS

We thank Yuko Uesugi for the valuable technical assistance. We also thank the Okinawa Prefectural Federation of Fisheries Cooperatives for donating the specimens which made this work possible.

Arachidonic, Eicosapentaenoic, and Biosynthetically Related Fatty Acids in the Seed Lipids from a Primitive Gymnosperm, *Agathis robusta*

Robert L. Wolff[a,*], William W. Christie[b], Frédérique Pédrono[a], and Anne M. Marpeau[c]

[a]ISTAB, Université Bordeaux 1, Talence, France, [b]Scottish Crop Research Institute, Dundee, Scotland, and [c]Institut du Pin, Université Bordeaux 1, Talence, France

ABSTRACT: The fatty acid composition of the seeds from *Agathis robusta*, an Australian gymnosperm (Araucariaceae), was determined by a combination of chromatographic and spectrometric techniques. These enabled the identification of small amounts of arachidonic (5,8,11,14-20:4) and eicosapentaenoic (5,8,11,14,17-20:5) acids for the first time in the seed oil of a higher plant. They were apparently derived from γ-linolenic (6,9,12-18:3) and stearidonic (6,9,12,15-18:4) acids, which were also present, *via* chain elongation and desaturation, together with other expected biosynthetic intermediates [bishomo-γ-linolenic (8,11,14-20:3) and bishomo-stearidonic (8,11,14,17-20:4) acids]. Also present were a number of C_{20} fatty acids, known to occur in most gymnosperm families, i.e., 5,11-20:2, 11,14-20:2 (bishomo-linoleic), 5,11,14-20:3 (sciadonic), 11,14,17-20:3 (bishomo-α-linolenic), and 5,11,14,17-20:4 (juniperonic) acids. In contrast to most other gymnosperm seed lipids analyzed so far, *A. robusta* seed lipids did not contain C_{18} Δ5-desaturated acids [i.e., 5,9-18:2 (taxoleic), 5,9,12-18:3 (pinolenic), or 5,9,12,15-18:4 (coniferonic)]. These structures support the simultaneous existence of Δ6- and Δ5-desaturase activities in *A. robusta* seeds. The Δ6-ethylenic bond is apparently introduced into C_{18} polyunsaturated acids, whereas the Δ5-ethylenic bond is introduced into C_{20} polyunsaturated acids. A general metabolic pathway for the biosynthesis of unsaturated fatty acids in gymnosperm seeds is proposed. When compared to Bryophytes, Pteridophytes (known to contain arachidonic and eicosapentaenoic acids), and species from other gymnosperm families (without such acids), *A. robusta* appears as an "intermediate," with the C_{18} Δ6-desaturase/$C_{18} \rightarrow C_{20}$ elongase/C_{20} Δ5-desaturase system in common with the former subphyla, and the unsaturated $C_{18} \rightarrow C_{20}$ elongase/C_{20} Δ5-desaturase system specific to gymnosperms. The following hypothetical evolutionary sequence for the C_{18} Δ6/Δ5-desaturase class in gymnosperm seeds is suggested: Δ6 (initial) → Δ6/Δ5 (intermediate) → Δ5 (final).

Abbreviations: DMOX, dimethyloxazoline, ECL, equivalent chain length; FAME, fatty acid methyl ester; GLC, gas–liquid chromatography; HPLC, high-performance liquid chromatography; MS, mass spectrometry; NMR, nuclear magnetic resonance; TAG, triacylglycerol; TLC, thin-layer chromatography; UPIFA, unsaturated polymethylene-interrupted fatty acid.

In the course of systematic studies on gymnosperm seed fatty acid compositions, *ca.* 170 species have been analyzed in our Institutes, which represent approximately one-fourth of all extant species from this plant group. The species analyzed belong to the families Taxaceae, Cephalotaxaceae, Podocarpaceae, Pinaceae, Taxodiaceae, Cupressaceae, Sciadopityaceae, Ginkgoaceae, Cycadaceae, and Ephedraceae (1–18). Although the peculiar Δ5-unsaturated polymethylene-interrupted fatty acids (Δ5-UPIFA) found in gymnosperms were structurally characterized almost 40 yr ago (19–22), and have been repeatedly reported to occur in a few species since then, their ubiquity in the seeds of practically all gymnosperm species was not recognized until recently (23,24). However, exceptions are known [Gnetaceae (25) and Welwitschiaceae (26)].

Δ5-UPIFA may belong to the n-9, n-7, n-6, or n-3 metabolic series, being derived from oleic, palmitoleic (*via cis*-vaccenic), linoleic, or α-linolenic acids. They have the structures of 5,9-18:2 (taxoleic), 5,11-18:2 (ephedrenic), 5,9,12-18:3 (pinolenic), 5,9,12,15-18:4 (coniferonic), 5,11-20:2, 5,11,14-20:3 (sciadonic), and 5,11,14,17-20:4 (juniperonic) acids (for the suggested trivial names, first occurrences are to be found in Refs. 4,18,27,28). Based on the preceding structures and on those of putative intermediary metabolites also characterized in gymnosperm seeds, a complete sequence of reactions for the biosynthesis of Δ5-UPIFA in gymnosperm seeds has been proposed. However, there are some uncertainties regarding the number and the specificity of the Δ5-desaturase(s) (1,2,18). Owing to the great antiquity, on a geological time scale, of most gymnosperm families, and to the ill-defined and tenuous inter-family evolutionary links, it was necessary to repeatedly confirm the occurrence of Δ5-UPIFA in these families, and this was done for most of them by mass spectrometry (MS) coupled to gas–liquid chromatography (GLC) (12,18,29) and by ^{13}C nuclear magnetic resonance (NMR) spectrometry (13,14,18,30,31).

In addition to their peculiar structures, Δ5-UPIFA also show a strong tendency to be almost exclusively esterified to the α positions of triacylglycerols (TAG), likely the *sn*-3 position, which leads to high proportions of TAG with only one Δ5-UPIFA per molecule (13,14,18,30–35). Besides these aspects relevant to chemistry and biochemistry, Δ5-UPIFA in combination with other common fatty acids have been used as interesting chemometric markers for the taxonomy of conifers (3–6).

Copyright © 1999 by AOCS Press

Also, there has been increasing interest in the biochemical, physiological, and nutritional properties of Δ5-UPIFA in rodents, particularly of pinolenic, sciadonic, and juniperonic acids (36–51). With regard to the latter two acids, their structures closely resemble those of arachidonic (5,8,11,14-20:4) and eicosapentaenoic (5,8,11,14,17-20:5) acids, with only the Δ8-ethylenic bond lacking.

Thus, we had many reasons to continue our systematic study of gymnosperm seed fatty acids. However, it should be emphasized that Δ5-UPIFA are not exclusively found in gymnosperms, though they are characteristic of plants of that subphylum, as they also occur in a few angiosperm species (52–54). We report here for the first time on the seed fatty acids prepared from a species of the Araucariaceae family (which was apparently not explored until this study), *Agathis robusta*. Araucariaceae encompass two principal genera, *Araucaria* and *Agathis*, totaling 32 to 40 species (and the newly discovered monotypic genus *Wollemia*) of tropical-subtropical Old World distribution (absent from Africa) (55,56). This family is considered especially ancient, and for some authors (57), "the most primitive of living conifers," with "the longest fossil history of any of the Coniferales, overlapping that of the Cordaitales," *ca.* 250–300 million years ago. *Agathis robusta* is a tall tree (50 m) native to the coastal zone of South Queensland in Australia, where it is known as "Southern Queensland Kauri." This nonthreatened species is sometimes planted elsewhere as an ornamental tree, e.g., in France, in the most temperate zone of the Côte d'Azur (Riviera) (58).

MATERIALS AND METHODS

Seeds, oil extraction, and fatty acid methyl ester (FAME) preparation. *Agathis robusta* seeds were purchased from Sandeman Seeds (Pulborough, England). The extraction of lipids from dehulled seeds and the preparation of FAME were performed as described in detail elsewhere for other gymnosperm seeds (2–4). For quantitative purposes, FAME preparations were made in duplicate and analyzed twice on a DB-Wax column and once on a CP-Sil 88 column.

Analytical GLC. FAME were analyzed with a Carlo Erba 4130 chromatograph (Carlo Erba, Milano, Italy) equipped with a DB-Wax column (30 m × 0.32 mm i.d., 0.5 µm film; J&W Scientific, Folsom, CA). The oven temperature was 190°C and the inlet pressure of the carrier gas (helium) was 140 kPa. Alternately, a CP-Sil 88 column (50 m × 0.25 mm i.d., 0.2 µm film; Chrom-pack) was operated with temperature programming in a Carlo Erba HRGC chromatograph from 150 to 185°C at 4°C/min with H_2 at 100 kPa. The injector (split mode) and the flame-ionization detector were maintained at 250°C for both columns. Quantitative data were calculated with a SP 4290 integrator (Spectra Physics, San Jose, CA).

Tentative identification of FAME peaks by their equivalent chain lengths (ECL). The seed lipids from selected conifer species (29) and from meadowfoam were used as a source of Δ5-olefinic acid methyl esters with known structures to identify fatty acids from *A. robusta* seed lipids by GLC, either by coinjection or by comparison of their ECL (DB-Wax column) or retention times (CP-Sil 88). Borage oil was the source of γ-linolenic acid. Liver lipids of adult rats fed a standard chow diet or a fat-free diet for 10 wk from the time they were weaned were used as a source of Mead's, bishomo-γ-linolenic, arachidonic, and eicosapentaenoic acids.

Preparation of picolinyl esters. Picolinyl esters were prepared from the free acids (2-mg scale) *via* imidazolide intermediates by the method of Balazy and Nies (59). Reagents were dried over anhydrous sodium sulfate or molecular sieve before use. Products were dissolved in isohexane containing butylated hydroxytoluene (50 ppm) for analysis by gas chromatography–MS.

Preparation of dimethyloxazoline (DMOX) derivatives. DMOX derivatives were prepared either by heating the oil directly with 2-amino-2-methyl-1-propanol according to Garrido and Medina (60) or *via* the free acids, acid chlorides, and cyclization with trifluoroacetic anhydride (61).

High-performance liquid chromatography (HPLC). In order to obtain better-quality mass spectra from minor components, the latter were concentrated in the form of either picolinyl esters or DMOX derivatives by reversed-phase HPLC (62). A Gynkotek model 480 HPLC pump was utilized with a column of Hichrom RPB™ (250 × 10 mm; Hichrom Ltd., Reading, United Kingdom) and acetonitrile as mobile phase, with the flow rate programmed from 1 to 3 mL/min over 60 min. The temperature of the column was maintained at 20 ± 0.1°C by means of a column oven/cooler (HPLC Technology model TC-955; Macclesfield, United Kingdom). The sample (1 mg) was injected in a solution (10 µL) of acetone/acetonitrile (1:9, vol/vol). An evaporative light-scattering detector (Varex model III, Alltech Ltd., Deerfield, IL) was used in test runs, but timed fractions were collected in micropreparative applications in the absence of a detector.

GLC–MS. The derivatives were subjected to GLC–MS with a Hewlett-Packard 5890 Series II plus gas chromatograph attached to an HP model 5989 MS engine (Hewlett-Packard Ltd., Stockport, United Kingdom). The latter was used in the electron impact mode at 70 eV with a source temperature of 250°C. The GLC was fitted with on-column injection. For picolinyl ester and DMOX derivatives, a capillary column of fused silica coated with Supelcowax 10™ (0.25 mm × 25 m, 0.25 µm film; Supelco UK, Poole, United Kingdom) was employed. After holding the temperature at 80°C for 3 min, the column was temperature-programmed at 20°C/min to 180°C, then at 2°C/min to 280°C, where it was held for 15 min. Helium was the carrier gas at a constant flow rate of 1 mL/min.

RESULTS AND DISCUSSION

Fatty acid characterization and composition. The first distinctive feature of *A. robusta* seed oil (46% on a weight basis of the dehulled seeds) is its solid consistency at ambient temperature. This is explained by the high proportion of saturated acids with long and very long hydrocarbon chains (16:0 to 24:0, mostly even-numbered: *ca.* 37% of total fatty acids) (Table 1). This is a

unique case among the 170 gymnosperm seed oils we have examined so far, which are liquid, though sometimes highly viscous. Among the unsaturated fatty acids commonly encountered in plant seed oils, the most abundant were C_{18} acids, i.e., oleic acid (and its isomer, *cis*-vaccenic acid, totaling 12.4%), linoleic acid (36.9%), and α-linolenic acid (11.0%). Surprisingly, no peaks corresponding to C_{18} Δ5-UPIFA, i.e., 5,9-18:2, 5,11-18:2, 5,9,12-18:3, and 5,9,12,15-18:4 acids, could be observed, even in trace amounts, in contrast to several other gymnosperm species, particularly from the Pinaceae family. On the other hand, two significant peaks (A and B in Table 1 and Fig. 1) not previouly observed in gymnosperm seed fatty acids were present in the C_{18} acid chromatographic zone. Neither of these two components coeluted with any of the former C_{18} Δ5-UPIFA when coinjected. Among "habitual" unsaturated C_{20} acids, eicosenoic acids included the main gondoic (11-20:1) acid, with possibly the 9-20:1 isomer visible as a small shoulder at the base of the 11-20:1 peak leading edge. Two C_{20} polyunsaturated acids frequently present in gymnosperm seeds, the 11,14-20:2 (bishomolinoleic) and 11,14,17-20:3 (bishomo-α-linolenic) acids, were also present in minor amounts. All C_{20} Δ5-UPIFA characterized in other gymnosperm species were present (or more rigorously speaking, peaks of the same ECL were observed) in *A. robusta* seed fatty acids; however, 5,11-20:2, 5,11,14-20:3, and 5,11,14,17-20:4 acids were present in abnormally low amounts. Four other peaks, C to F in Figure 1, were more or less intermingled with the preceding C_{20} Δ5-UPIFA and were tentatively attributed to C_{20} polyunsaturated acids owing to their elution in the C_{20} chromatographic zone, with some uncertainty for peak C, which partially overlapped a possible 21:0 acid.

The extra peaks (A to F) were not artifacts, as they remained unchanged when FAME were prepared with sodium methoxide at ambient temperature, or prepared with TAG purified by thin-layer chromatography (TLC). Moreover, the chromatographic profiles did not change whether FAME were purified by TLC or not (results not shown). This excluded any contamination by unsaponifiable components. Because cyclopropenic acids were shown to occur in some other Australian gymnosperm species (63), we performed the Halphen test, which produced negative results.

Fractionation of FAME by argentation TLC (Ag-TLC), followed by GLC analysis of individual fractions, allowed confirmation of the structures indicated above. In particular, the tentatively identified odd-numbered fatty acids, 17:0, 19:0, 21:0 and 23:0, were found in the saturated acid fraction. No *anteiso*-17:0 acid, such as was found in Pinaceae seed lipids (8), could be detected in that fraction. In addition to 9,12-18:2 acid, the dienoic acid fraction contained 5,11-20:2 and 11,14-20:2 acids, two other unknown minor eicosadienoic acids, and possibly a dienoic C_{16} acid. Components A to F had the following behavior: Peaks A and C coeluted with α-linolenic acid following Ag-TLC and had the same retention times as 6,9,12-18:3 (γ-linolenic; component A) and 8,11,14-20:3 (bishomo-γ-linolenic; component C) acids on two capillary columns, under isothermal or temperature-programming conditions. The 5,11,14-20:3 and 11,14,17-20:3 acids migrated along with the former trienoic acids. Peaks B, D, E, and F (not visible on the Ag-TLC plate, owing to their low concentration and the absence of a carrier component), not present in the 0, 1, 2, or 3Δ fractions, had probably migrated behind these fractions and were believed to contain at least four double bonds. This supposition was confirmed by comparison of the retention times of peaks D and F, which were identical to those of 5,8,11,14-20:4 and 5,8,11,14,14,17-20:5 acids, respectively, which were present in FAME prepared from rat liver lipids, here too on two columns with different polarities.

Calculation of the theoretical ECL for peaks B and E (no standards available), probably containing four ethylenic bonds, is based on the summation of ECL of related fatty acids with one less double bond, either on the methyl or on the carboxylic side, followed by subtraction of the ECL of the fatty acid having double bonds common to the fatty acids used in summation

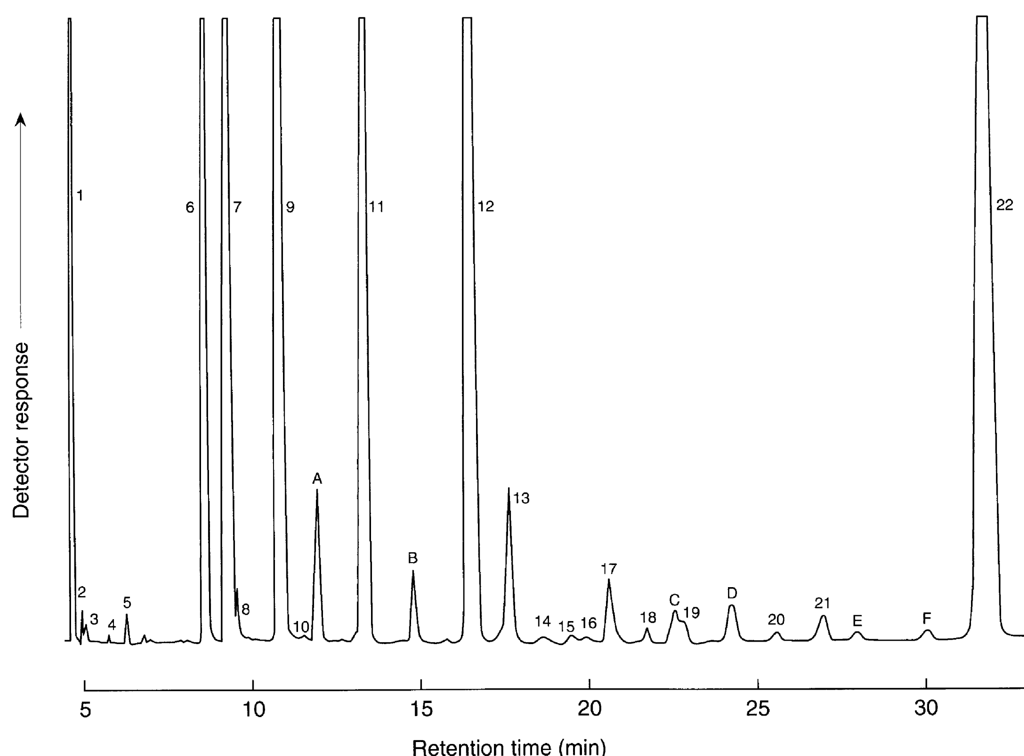

FIG. 1. Gas–liquid chromatogram of fatty acid methyl esters prepared from total lipids extracted from *Agathis robusta* seeds and analyzed on a polyethylene-glycol coated capillary column. Peak numbers and letters (corresponding to peaks not encountered in other gymnosperm species) are as in Table 1.

(64). The theoretical ECL of 6,9,12,15-18:4 acid, if corresponding to peak B, would be ECL (6,9,12-18:3) + ECL (9,12,15-18:3) – ECL (9,12-18:2) = 19.05 + 19.36 – 18.70 = 19.71 (experimental ECL, 19.72). Similarly, the theoretical ECL for peak E, possibly the 8,11,14,17-20:4 acid, would be ECL (8,11,14-20:3) + ECL (11,14,17-20:3) – ECL (11,14-20:2) = 20.98 + 21.36 – 20.69 = 21.65 (experimental ECL, 21.63). Calculations based on the same principle give theoretical ECL that are practically identical to experimental ECL when applied to sciadonic and juniperonic acids (Table 1). Consequently, theoretical ECL of peaks B and E support their tentative identification as 6,9,12,15-18:4 and 8,11,14,17-20:4 acids, respectively.

This accumulation of presumptions was quite indicative of the presence of arachidonic and eicosapentaenoic acids, as well as of their metabolic precursors, in the seed lipids of *A. robusta*, in addition to C_{20} Δ5-UPIFA. However, the two former polyunsaturated fatty acids had never previously been reported to occur in gymnosperm seeds, nor indeed in any other seed oil, and these tentative identifications obviously deserved further structural confirmations, i.e., by MS of appropriate derivatives.

With samples containing a complex mixture of fatty acids, experience has shown that it is often advisable to separate them into simpler fractions before proceeding to GLC–MS analysis, as picolinyl ester or DMOX derivatives of fatty acids may be less well resolved on GLC columns than methyl esters. Minor components that are incompletely resolved may give mixed mass spectra that are uninterpretable. Silver ion HPLC may be favored with such complicated samples as fatty acids from marine sources (65), but reversed-phase HPLC is easier to use with seed oils with a relatively limited range of chain lengths (62). The latter can be used with both picolinyl esters and DMOX derivatives *per se*, under identical conditions. It is our experience that both types of derivatives are of value for locating double bonds and other structural features, and they afford complementary structural information. In the discussion below for illustrative purposes, picolinyl ester derivatives form the basis of most descriptions, but in each instance, confirmation was obtained *via* the DMOX derivatives. A base-deactivated stationary phase was used for reversed-phase HPLC with a flow gradient of acetonitrile as mobile phase [this solvent is more easily removed from collected fractions than the water-containing mobile phases often recommended (66)]. With each derivative, five fractions were collected as illustrated for the picolinyl esters in Figure 2, and each fraction was subjected to GLC–MS.

Mass spectral data for key ions of both types of derivative of many of the fatty acids identified are listed in Table 2. In HPLC fraction 1, the main component was 6,9,12,15-18:4, as determined by the mass spectrum of each derivative. Fatty acids with Δ6 desaturation were not reported frequently in gymnosperms, except for an incorrectly identified γ-linolenic acid in *Pinus koraiensis* seed oil (67) [in fact, pinolenic acid (10)], and for the related 20:3n-6 acid [possibly confused with 7,11,14-20:3 (9) or 20:3n-3 acid] in conifer leaf lipids (68). Therefore the spectra are reproduced here. The spectrum of the picolinyl ester is pre-

[a]Data expressed as *m/z* value with percentage of base peak in brackets. DMOX, dimethyloxazoline.

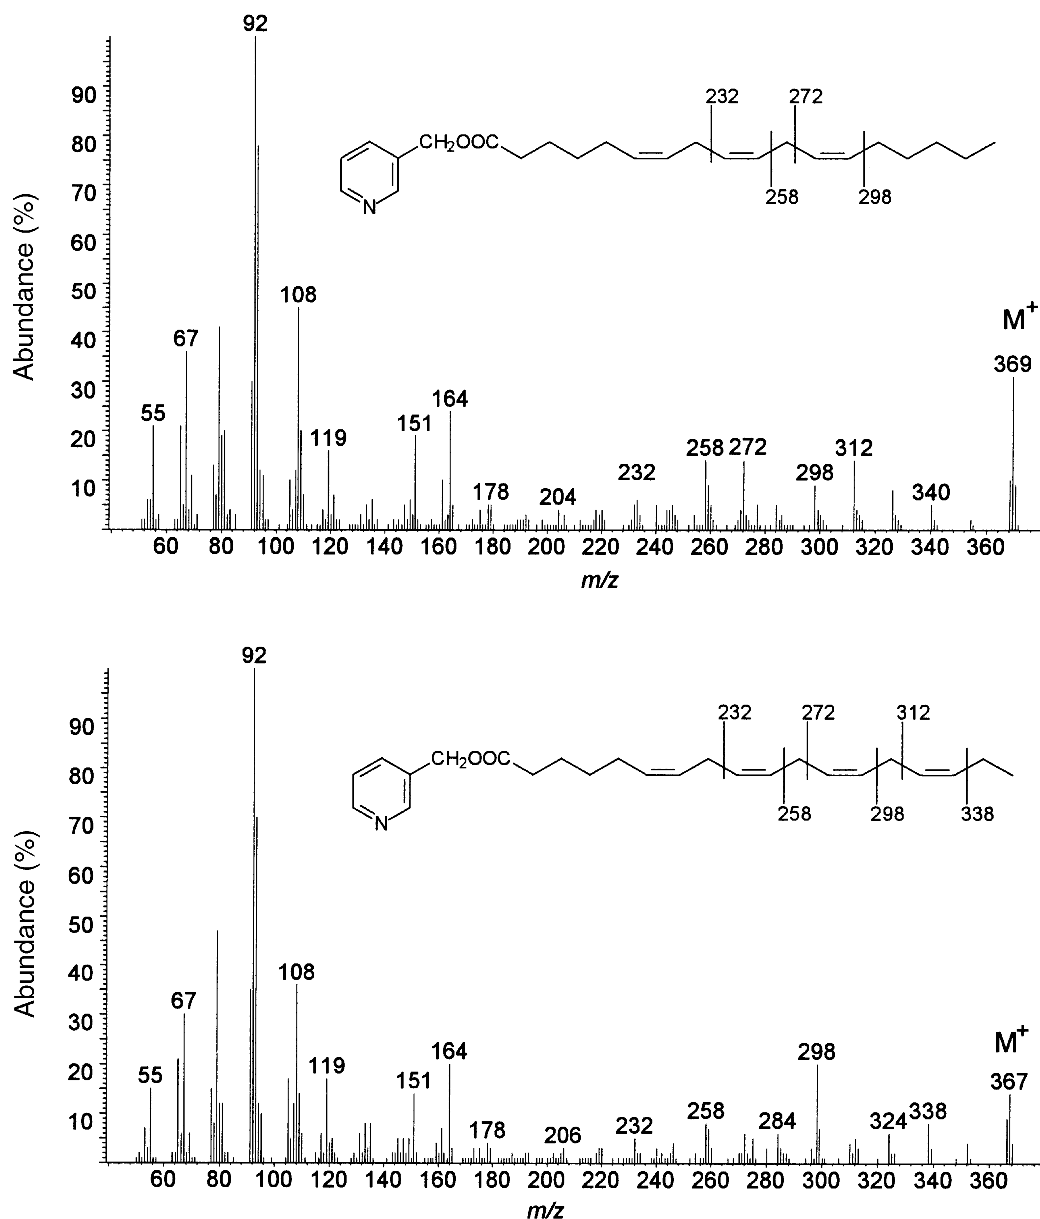

FIG. 3. Mass spectra of picolinyl esters of 6,9,12-octadecatrienoate (upper) and 6,9,12,15-octadecatetraenoate (lower).

sented in Figure 3. Key ions reflecting gaps of 26 amu for each double bond are at *m/z* = 232 and 258, 272 and 298, and 312 and 338 for double bonds in positions 9, 12, and 15, respectively. Diagnostic ions for the double bond in position 6 are less easily discerned, but experience has shown that other features would appear in the spectrum if the innermost double bond was in any other position. The spectrum is identical to that of the authentic fatty acid in borage oil (69). Similarly the spectrum of the DMOX derivative is identical to that of the authentic standard.

In addition, in HPLC fraction 1, 5,8,11,14,17-eicosapentaenoic acid was recognized for the first time in a seed oil. The GLC retention times and mass spectra of the picolinyl ester (70) and DMOX derivative (71) were identical to those of an authentic standard, and they are illustrated in Figure 4. The picolinyl ester had a molecular ion at *m/z* = 393, then a gap of 26 amu between *m/z* = 338 and 364 defined the double bond in position 17, while gaps of 26 amu between *m/z* = 298 and 324, 258 and 284, and 218 and 244 located the double bonds in positions 14, 11, and 8, respectively. The double bond in position 5 cannot be located unambiguously in this way, but the McLafferty ion at *m/z* = 151 is characteristically low in this instance (although this is not an absolute guide) (72). Again, other features would appear in the spectrum if the innermost double bond was in any other position. Interpretation of the spectrum of the DMOX derivative is somewhat different, but the result is equally clear.

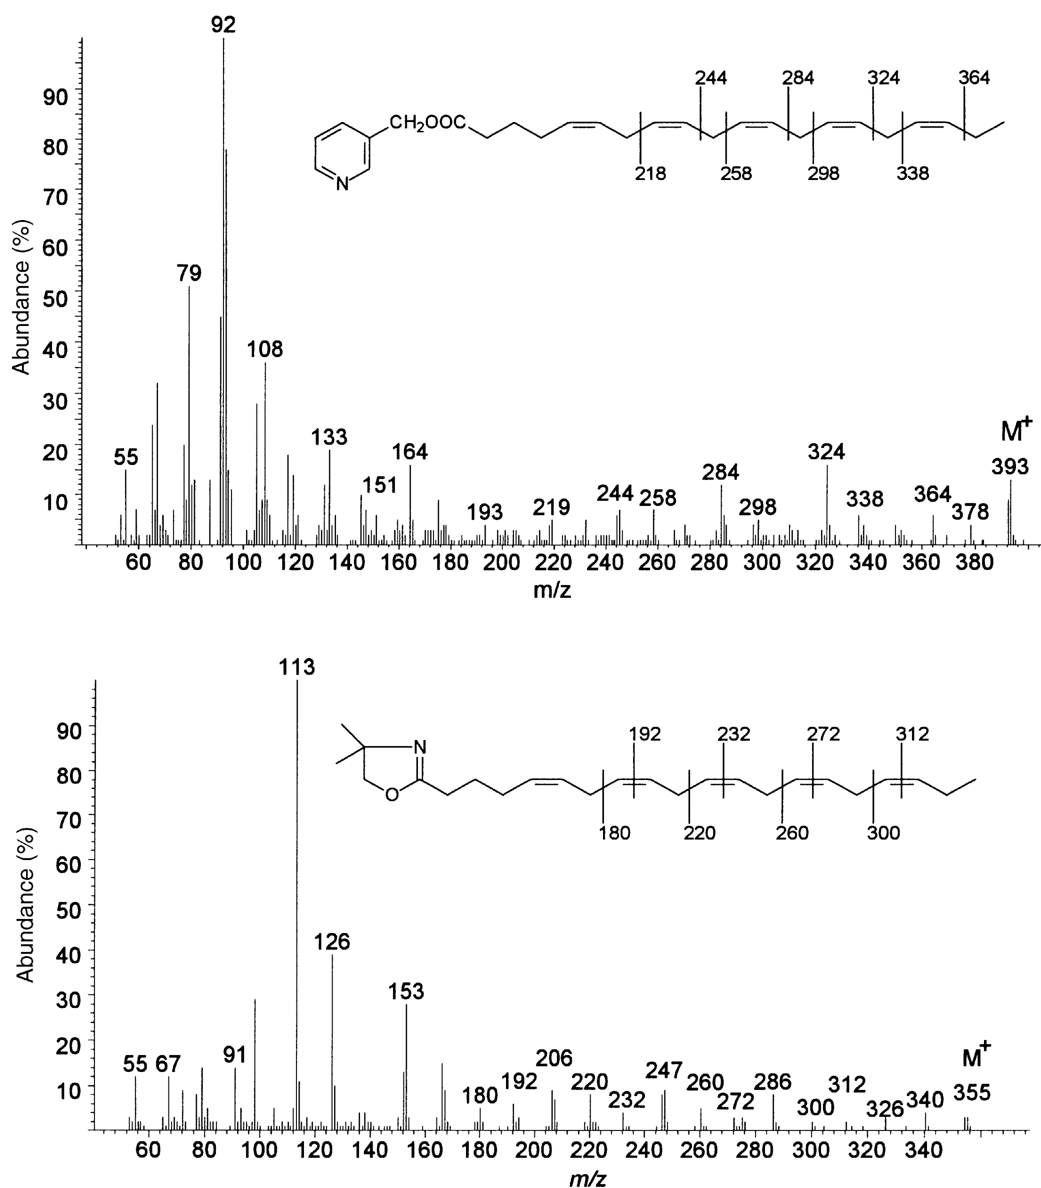

FIG. 4. Mass spectra of picolinyl ester (upper) and dimethyloxazoline (DMOX) derivative (lower) of 5,8,11,14,17-eicosapentaenoate.

Here, gaps of 12 amu, between ions at m/z = 180 and 192, 220 and 232, 260 and 272, and 300 and 312, locate the double bonds in positions 8, 11, 14, and 17, respectively. As with the picolinyl ester derivatives, the location of the innermost double bond is best confirmed by comparison with spectra of defined compounds.

A further minor component in this fraction was vernolic acid; the mass spectrum of its picolinyl ester derivative was identical to that of the true compound in the seed oil of *Vernonia galamensis*, and has been described elsewhere (59).

Fraction 2 from reversed-phase HPLC contained mainly α-linolenic acid, but rather unusually, γ-linolenic acid also was present, and its mass spectrum is illustrated in Figure 3. It is identical to that of the same compound in borage oil (59), and differs in significant details from the spectrum of picolinyl 5,9,12-octadecatrienoate (73), a fatty acid encountered more frequently in the seed oils of gymnosperms. However, a striking finding was that a small amount of arachidonic acid was also present in this fraction. As this is the first time this has been found in the seed oil of a higher plant, the spectrum of its picolinyl ester and DMOX derivative are recorded in Figure 5. In the lower molecular mass region, the spectra are analogous to those of eicosapentaenoate, but after the diagnostic ions for the double bond in position 14, there is a series of ions 14 amu apart for loss of successive methylene groups (and the terminal methyl group) only. A mass spectrum of picolinyl arachidonate has been published by Harvey (74), and of the DMOX derivative was reported by Zhang *et al.* (75). Two further tetraenoic

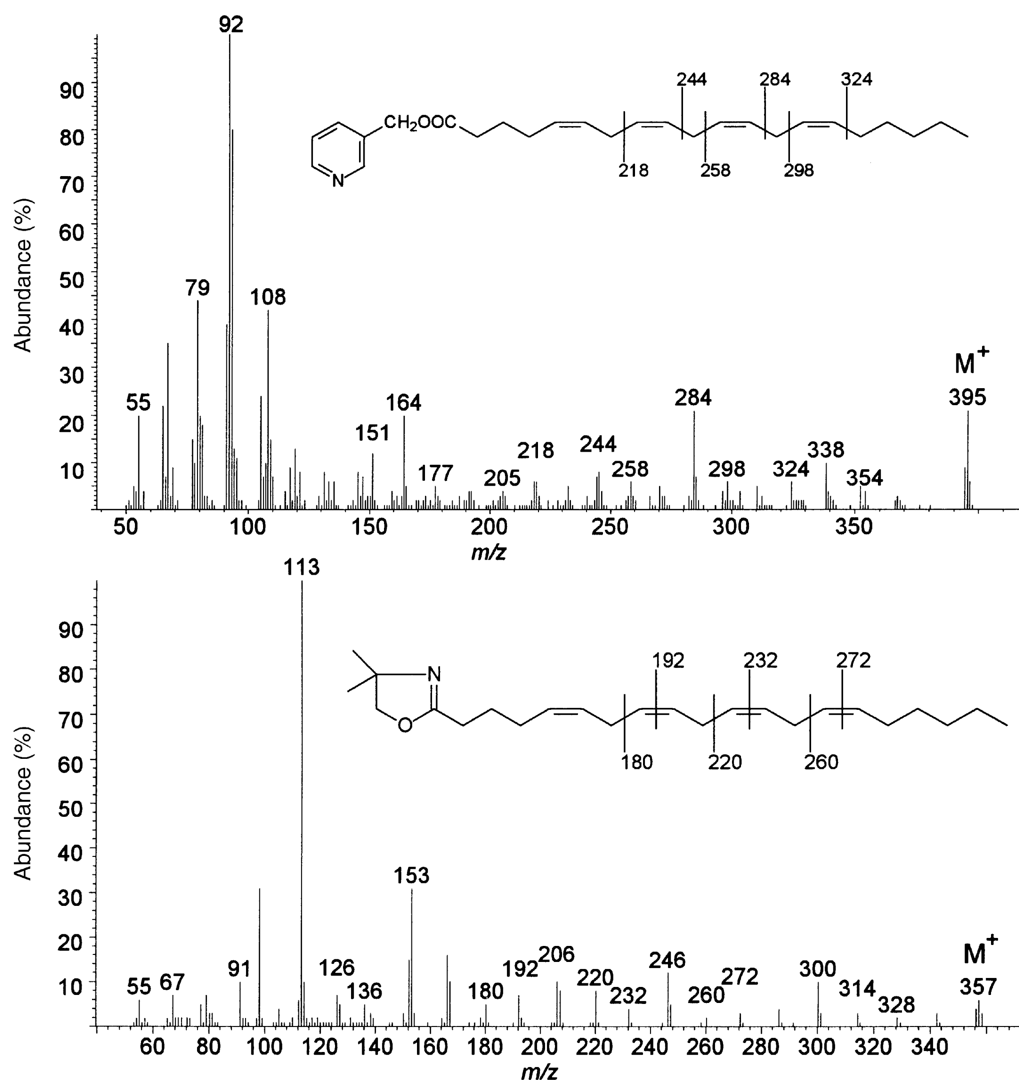

FIG. 5. Mass spectra of picolinyl ester (upper) and DMOX derivative (lower) of 5,8,11,14-eicosatetraenoate. See Figure 4 for abbreviation.

isomers were present, i.e., 5,11,14,17-20:4 and 8,11,14,17-20:4. The spectrum of the former as the picolinyl ester is illustrated in Figure 6. It can be seen that it differs appreciably from that of arachidonate and of eicosapentaenoate. In particular, gaps of 26 amu between *m/z* = 260 and 286, 300 and 326, and 340 and 366 define the double bonds in positions 11, 14, and 17, respectively; the fact that the ion at *m/z* = 151 is of low abundance and the presence of distinctive ions at *m/z* = 219 and 232 are characteristic of an isolated double bond in position 5 (76). Spectra for the DMOX derivatives of fatty acids with double bonds in position 5 have been described by Berdeaux and Wolff (29).

Linoleic acid was the main component of HPLC fraction 3, and it was accompanied by three eicosatrienoate isomers, i.e., 5,11,14-20:3, 8,11,14-20:3, and 11,14,17-20:3 acids. Mass spectra of picolinyl esters of the first and third of these are also illustrated in Figure 6, to illustrate the relationships of the spectra to those of the tetraenoate isomers. For example, that of 5,11,14-20:3 resembles the spectrum of 5,11,14,17-20:4 in the lower molecular mass region, and differs mainly in that the diagnostic ions for the double bond in position 17 are replaced by ions representing cleavage in successive methylene groups. The spectrum of picolinyl 8,11,14-20:3 has diagnostic ions at *m/z* = 262 and 288, 302 and 328, and 342 and 368 for double bonds in positions 11, 14, and 17, respectively (77).

The remaining reversed-phase HPLC fractions contained mainly saturated and monoenoic compounds with some C_{20} dienes, most of which were identified by GC–MS.

Biosynthetic pathways in gymnosperm seeds. To our knowledge, this is the first study describing the simultaneous presence of arachidonic *and* eicosapentaenoic *and all* their metabolic intermediates in a plant *seed*. With regard to the end products, arachidonic acid has not yet been reported to occur in gymnosperm seed lipids, though reports by Russian researchers (78) mention its presence in the cambium zone of *Larix sibirica*

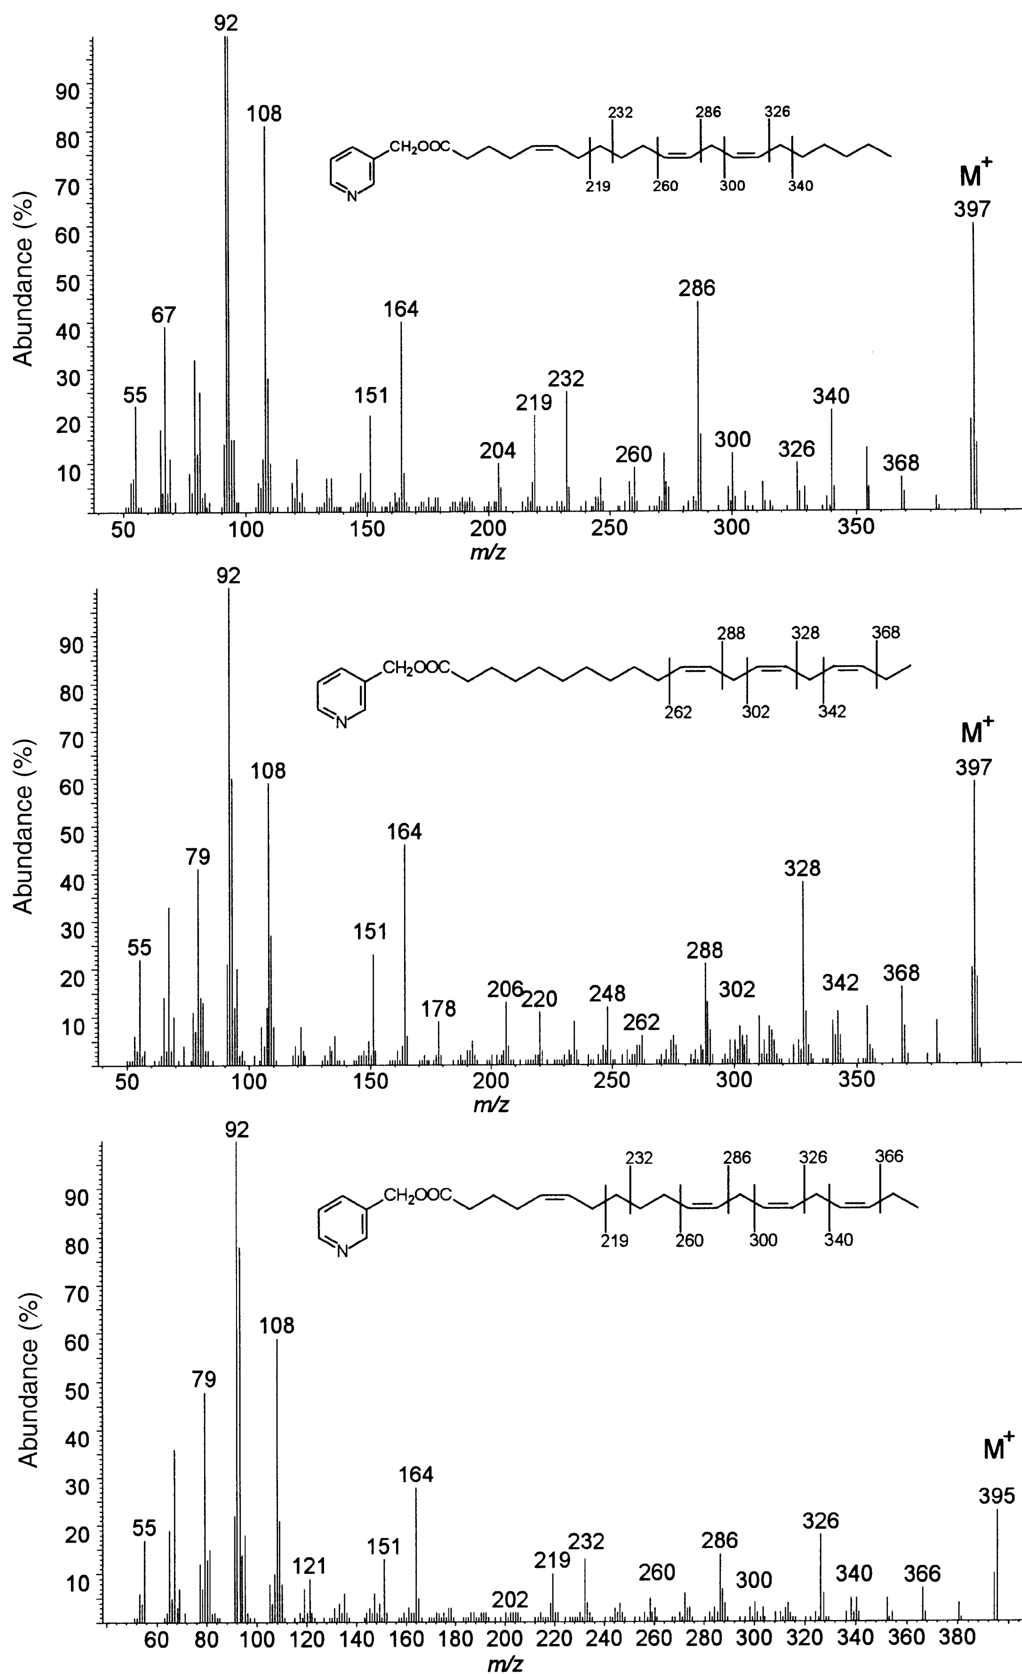

FIG. 6. Mass spectra of picolinyl esters of 5,11,14-eicosatrienoate (upper), 11,14,17-eicosatrienoate (middle), and 5,11,14,17-eicosatetraenoate (lower).

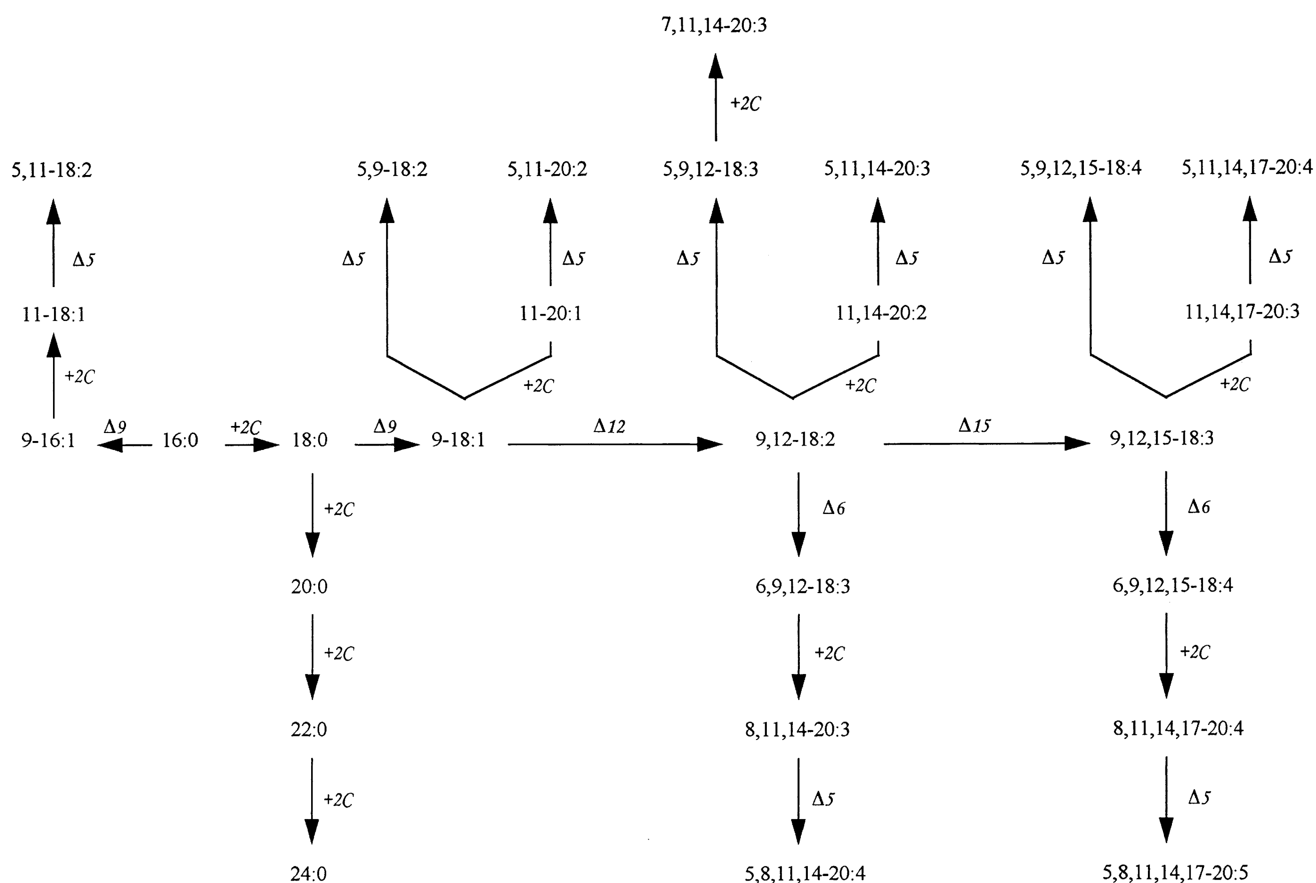
(Siberian larch), but not of intermediaries between linoleic acid and arachidonic acid. Similar observations were made by the same group on *Populus balsamifera* (balsamic poplar) buds (79). Though structural evidence was given, such as ^{1}H NMR data, iodine number and refractive index, that need relatively large amounts of material, details on the isolation procedure of arachidonic acid for these measurements were unfortunately lacking. It should be added, at least for *L. sibirica* wood, that other thorough and detailed GLC–MS studies of pine (*Pinus sylvestris*) and spruce (*Picea abies*) wood extracts did not mention arachidonic acid (80,81). Arachidonic acid also has been found in different parts of a few angiosperm species, e.g., garlic (*Allium sativum*) cloves (82) and *Aloe vera* above-ground parts (83). In the latter studies, arachidonic acid was identified by GLC only, and the presence of 41.7% γ-linolenic acid relative to total fatty acids was reported for *A. vera* (83). More convincing and intriguing is the characterization of arachidonic acid in virgin wheat-germ oil by GLC–MS of its methyl ester after fractionation by distillation (84). No intermediates were reported in that study. Eicosapentaenoic acid has been reported to occur in *A. sativum* cloves as well (82). To our knowledge, until now, these findings have not been not confirmed, though several reports (reviewed in Refs. 85 and 86) describe the prostaglandin-like effects of some plant extracts.

When considering angiosperm species that contain γ-linolenic acid or stearidonic acid in their seed lipids [e.g., borage (*Borago officinalis*), evening primrose (*Oenothera biennis*), or black currant and other *Ribes* spp.], the initial Δ6-unsaturated intermediates are present, but neither their higher homologs nor the potential end products, arachidonic and eicosapentaenoic acids, are found. Consequently, this is the first report on a Spermaphyte species whose seeds contain all the precursors and intermediaries needed for the simultaneous biosynthesis of arachidonic and eicosapentaenoic acids, and the latter acids themselves. With regard to this biosynthetic activity, *A. robusta* is close to more primitive plants, such as Bryophytes and Pteridophytes, with extant species (mosses, liverworts, ferns) still able to synthesize arachidonic and/or eicosapentaenoic acids in several parts of the plant (22,87–97). Horsetail (*Equisetum*), however, does not contain the latter polyunsaturated acids, though Δ5-UPIFA have been characterized in these plants (22).

In a previous paper (18), we suggested that gymnosperms might contain two Δ5-desaturases, one specific for C_{18}-unsaturated acids, and the other for C_{20}-unsaturated acids. It is necessary to define "unsaturated" because no 5-18:1 or 5-20:1 acids have been detected in gymnosperm seeds (our columns allow a clear-cut resolution of these monoenoic acids from their Δ9 isomers), indicating that 18:0 and 20:0 acids are not substrates of the Δ5-desaturases. An alternative designation of the C_{18}-specific and C_{20}-specific Δ5-desaturases could be "Δ9-specific" and "Δ11-specific," respectively, because the C_{18} and C_{20} substrates coincide with fatty acids containing a Δ9- and a Δ11-ethylenic bond, respectively. Owing to the existence in some species of a 5,11-18:2 acid [i.e., in *Ginkgo biloba* and *Ephedra* spp. (12,18)], which is both a C_{18} and a Δ11-unsaturated acid, a decision cannot be made regarding the true specificities, chain length, or position of the first double bond. From the absence of C_{18} Δ5-UPIFA in *A. robusta* seeds, it can be inferred that this species does not contain the C_{18}-specific Δ5-desaturase, or more rigorously, the corresponding activity. In lieu of this enzyme, a C_{18}-specific Δ6-desaturase would be present. However, *A. robusta* has the C_{20} Δ5-desaturase in common with other gymnosperm species, and also the unsaturated-$C_{18} \rightarrow C_{20}$ elongase. We have recapitulated in Scheme 1 the biosynthetic pathways that are likely to take place in gymnosperm seeds. All pathways seldom occur together in species of a given family, and the figure is only intended to show the variety of unsaturated fatty acids that is to be found in gymnosperm seeds. For gymnosperm leaves, C_{20} Δ5-UPIFA are present in all species analyzed so far (68). However, C_{18} Δ5-UPIFA would only occur in species from the Pinaceae family, which would indicate that the C_{18} Δ5-desaturase activity observed in the seeds is not forcefully expressed in the leaves. Thus, it cannot be inferred from the present study whether arachidonic and eicosapentaenoic acids are present or not in *A. robusta* leaves, as for example, in green parts of mosses and ferns. This deserves further investigation.

Considerations on the evolution of the Δ6- and Δ5-desaturases. The trivial term "higher plants," used to describe Bryophytes, Pteridophytes, and Spermaphytes (that include gymnosperms and angiosperms), is not generally accepted, and the name Cormophytes better applies to these vegetal phyla taken as a whole. "Higher plants" may also have a restricted definition, being limited to Spermaphytes (seed plants), and we will adopt the former definition. Among higher plants, the succession on a geological time scale of the three phyla is certain, though (extinct?) intermediates are difficult to identify. As regards the C_{18} Δ6- and C_{20} Δ5-desaturase activities, the former appears common to many microalgae, algae, fungi, Bryophytes, and Pteridophytes (at least to several species from these groups) and to some Araucariaceae, at least to the species studied here, *A. robusta*. On the other hand, the C_{18} Δ5-desaturase activity is characteristic of gymnosperms: Δ5-UPIFA with 18 carbon atoms have been found in the seeds of all Coniferophyte (Pinatae and Gingkoatae) families (in more or less high amounts, their absence being most probably linked to secondary events) and Cycadophytes, with the exception of Welwitschiaceae and Gnetataceae, the taxonomic positions for which are uncertain (they are regarded as members of either the gymnosperm or the chlamydosperm subphyla). *Agathis robusta*, undoubtedly a gymnosperm, would thus show an intermediate archaic state between Pteridophytes, or more likely some related extinct plants (e.g., the fossil Pteridospermaphytes, considered earlier as Pteridophytes and later as gymnosperms), and other gymnosperms, being characterized by C_{18} Δ6-desaturase activity. *Agathis robusta* would not be an isolated case among Araucariaceae, as γ-linolenic and arachidonic acids were also characterized in *Araucaria bidwillii* and *A. araucana* seeds, which additionally show typical C_{18} Δ5-UPIFA, and consequently "mixed" C_{18} Δ5/Δ6 activities (Wolff, R.L., Christie, W.W., Pédrono, F., and Marpeau, A.M., manuscript in preparation). Although complementary studies of other Araucariaceae species are obviously needed, the evolutionary sequence



SCHEME 1

Bryophytes, Pteridophytes → Araucariaceae → Coniferophytes can be suggested as a working hypothesis. Finally, Araucariaceae and all other Coniferophyte families share a common C_{20} Δ5-desaturase activity, demonstrated by the systematic presence of sciadonic acid in the seed lipids (they also are present in *Cycas* and *Ephedra* spp. among Cycadophytes). Because in Pinatae families other than the Araucariaceae the C_{18} Δ6-desaturase activity has evolved into a C_{18} Δ5-desaturase activity, though the C_{20} Δ5-desaturase activity in addition to the elongase activity were kept unchanged, arachidonic and eicosapentaenoic acids are no longer synthesized in these plants. Our study also shows that the C_{20} Δ5-desaturase does not need Δ8-desaturated substrates (i.e., 20:2n-6 and 20:3n-3 acids are substrates) to exert its activity in plants. The C_{20} Δ5-desaturase activity thus appears a rather constant feature throughout the entire plant kingdom, except in "modern" angiosperms, where this activity is apparently limited to a few species of the Ranunculaceae family (52,53).

A C_{18} Δ6-desaturase activity was probably the primeval status in higher plants as it occurs in Bryophytes and Pteridophytes, likely derived from some (micro) algae. This archaic enzymatic activity is still present in *A. robusta*. In *A. bidwillii*, the C_{18} Δ6-desaturase and Δ5-desaturase activities are simultaneously present. In other Coniferophytes, including *G. biloba* and some Cycadophytes, only the C_{18} Δ5-desaturase activity is present. The sequence Δ6 → Δ6/Δ5 → Δ5 C_{18} desaturation would parallel the phylogenetic series based on the evolution of the leaves in Araucariaceae from a dichotomous foliar nervation to a simple one (98,99). This hypothetical sequence would be: *Buriada heterophylla* (extinct) → *Agathis* → *Araucaria*, section *Columbea* → *Araucaria,* section *Eutacta*. In apparent disagreement with this point of view, fossil evidences indicate that *Araucaria* spp. (Jurassic) would have preceded *Agathis* spp. (Tertiary), though there is no certain way of distinguishing between *Agathis* spp. and *Araucaria* spp. permineralized wood (100–102). The fossilized wood of possible ancestors known as *Araucarioxylon* from the Lower Carboniferous is hardly distinguishable from that of extinct cordaites and glossopterids (100–102).

A recent study (103) has indicated that expression of a *Mortierella alpina* Δ5-desaturase cDNA in a *Saccharomyces cerevisiae* recombinant used either endogenous 9-18:1 or added 8,11,14-20:3 acids as substrates to give taxoleic and arachidonic acids, respectively. Expression of the *M. alpina* cDNA in transgenic canola seeds resulted in the production of taxoleic and pinolenic acids (103). Thus, in that experiment, the *M. alpina* Δ5-desaturase cDNA would allow expression of an enzymatic activity that may use both C_{20} and C_{18} unsaturated acids as sub-

strates, which would be at variance with our hypothesis of two distinct Δ5-desaturase activities in gymnosperm seeds. On the other hand, a mutant of *M. alpina* (1S-4 Mut 49) defective in the Δ6-desaturase activity is apparently able to accumulate sciadonic and juniperonic acids in TAG and phospholipids, but not taxoleic or pinolenic acids (103). The wild-type strain would not contain any Δ5-UPIFA, but rather large amounts of arachidonic acid, which needs a C_{18} Δ6-desaturase, an unsaturated $C_{18} \rightarrow C_{20}$ elongase system, and a C_{20} Δ5-desaturase. Finally, it has been demonstrated (105) that replacement of a few amino acids in a given desaturase is able to convert it into another enzyme with different specificities (chain length and position of desaturation). The picture that now emerges is that such mutational changes could have occurred at the very beginning of the history of gymnosperms, in conjunction with their emergence.

These experiments (103–105), as well as the present study, emphasize the molecular similitudes and possible evolutionary relationships between the Δ6- and Δ5-desaturases in primitive gymnosperms. *Agathis robusta*, and possibly other Araucariaceae species, may be a source for gene encoding for the complete enzymatic machinery that ensures the synthesis of arachidonic and eicosapentaenoic acids in seed lipids. On the other hand, γ-linolenic acid has, or is considered to have, great biomedical and economical promise, because it is a more immediate precursor of arachidonic acid than linoleic acid in humans, as it bypasses the crucial Δ6-desaturation step. The present findings indicate that it is conceivable, in principle, to directly produce arachidonic (instead of its precursor γ-linolenic acid only) and/or eicosapentaenoic acid in cultivatable seed plants in the future.

Lipids of the Pawpaw Fruit: *Asimina triloba*

Randall Wood[1],* and Scott Peterson

Department of Biochemistry and Biophysics, Texas A&M University, College Station, Texas 77843-2128

ABSTRACT: The fatty acid composition and structure of pawpaw fruit *(Asimina triloba)* triglycerides were examined and found to contain fatty acids ranging from C_6 to C_{20}. Octanoate represented 20% of the fatty acids while other medium-chain fatty acids were present in low amounts. Analysis of the intact triglycerides by high-temperature gas–liquid chromatography gave an unusual three-cycle carbon number distribution. Analysis of triglyceride fractions separated according to degree of unsaturation suggested that one octanoate was paired with diglyceride species containing long-chain fatty acids. Determination of the double-bond positions of monoene fatty acids revealed *cis* Δ9 and *cis* Δ11 hexadecenoate and *cis* Δ9, *cis* Δ11, and *cis* Δ13 octadecenoate isomers were present in significant quantities. Octanoate and positional monoene fatty acid isomers were found only in the fruit lipids and not in the seed lipids. Phenacyl esters of fatty acids were found to be useful derivatives for structure determination using multiple types of analyses.

Paper no. L8266 in *Lipids 34,* 1099–1106 (October 1999).

The pawpaw [*Asimina triloba* (L.) Dunal] is a large tree fruit that grows wild in a region from East Texas to the Eastern Seaboard and northward to the Great Lakes (1). The pawpaw is the only temperate member of the Annonaceae family that grows in North America (1,2). Eight other species of *Asimina* are native to the U.S. mainland, but they are of little commercial value at this time (3). The pawpaw fruit can grow as a singlet, but normally grows in bunches of three or more. The fruit is cylindrical in shape, typically 5 to 15 cm (2 to 6 in.) long, 3 to 8 cm (1 to 3 in.) wide, and can weigh up to 450 g (1 lb). During the growing season, the pawpaw has a whitish to light-green color that turns yellow to brownish at maturity. The ripe fruit is highly aromatic and the banana-like flesh surrounds two rows of large bean-shaped brown seeds.

Research, primarily at Kentucky State University and Purdue University, on pawpaw horticulture has led to a commercial interest in this fruit (1,3). Interest is also being generated in the popular press (4).

The present study examines the fatty acids and triglyceride structure of the pawpaw.

METHOD AND MATERIALS

Pawpaws. Immature pawpaws were collected in July and mature ones in September from a native stand near Palmer, Kentucky. Both the mature fruit flesh and the immature pawpaws were transported back to Texas in an ice chest. Seeds from immature pawpaws were removed and the lipids extracted without freezing. Flesh from mature pawpaws was stored at –20°C until extracted.

Lipid extraction and fractionation. Pawpaw fruit (flesh) and seeds (without seed coat) were homogenized with chloroform/methanol (2:1, vol/vol), filtered, washed twice with 2 vol of water, and the chloroform fraction was evaporated to dryness with a rotary evaporator at reduced pressure. The lipid samples were redissolved in chloroform, filtered through a fine porosity fritted-disc Buchner funnel, evaporated, held at high vacuum for 30 min, and weighed. Total lipids were separated into neutral lipid and polar lipid fractions by silicic acid chromatography (5) and weighed. The polar lipid fraction, predominantly phospholipids, was examined for fatty acid composition. The neutral lipid fraction was analyzed by thin-layer chromatography (TLC) on absorbent layers of Silica Gel G developed in hexane/diethyl ether/glacial acetic acid (80:20:1, by vol). A typical separation is shown in Figure 1A along with standards. Preparative TLC on 20 × 20 cm plates was used to isolate the triglyceride fraction for further analyses. Pawpaw fruit triglycerides were fractionated according to degree of unsaturation on 6% silver nitrate-impregnated Silica Gel G-60 chromatoplates developed in chloroform/methanol (99:1, vol/vol). Separated fractions were visualized by spraying with Rhodamine 6G and viewing under ultraviolet light (Fig. 1B). Triglycerides were released from the silver nitrate/Silica Gel G-60 absorbent with 1 mL of methanol and 1 mL of aqueous 20% sodium chloride after being scraped into a Teflon-lined screw-cap culture tube. Hexane was used to extract the triglycerides, which were filtered through a fine porosity fritted-disc Buchner funnel and stored at –20°C.

Derivative preparation and analyses. Methyl esters of the various lipids were prepared by the time-honored 2% sulfuric acid-catalyzed transesterification in methanol method (6). Butyl esters were prepared by the same transesterification method using *n*-butanol. Triglycerides were hydrolyzed with a mild saponification procedure (7) to yield free fatty acids after saponification. Phenacyl derivatives were prepared

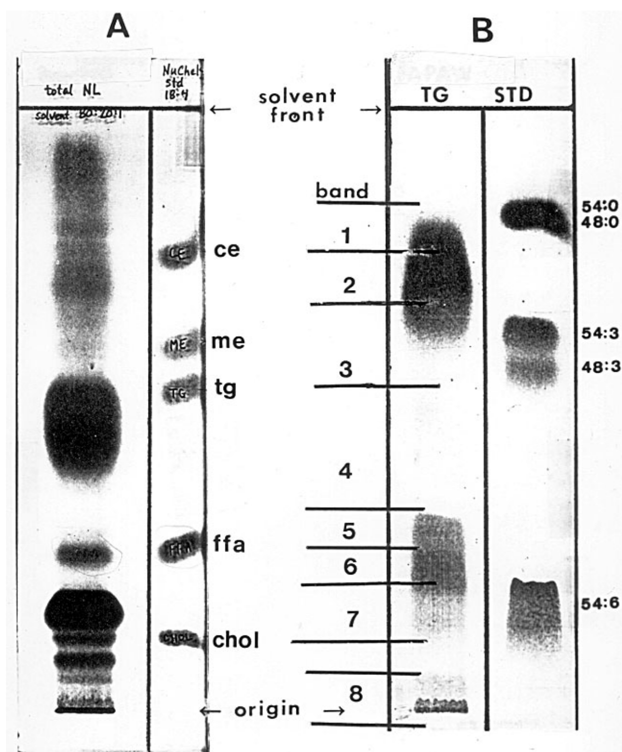

FIG. 1. (A) Thin-layer chromatoplates of total pawpaw fruit neutral lipids and (B) pawpaw fruit triglycerides separated on silver ion-impregnated adsorbent layers. Solvent systems were (A) hexane/diethyl ether/acetic acid (80:20:1, by vol) and (B) chloroform/methanol (99:1, vol/vol). Abbreviations: ce, cholesterol ester; me, methyl ester; tg, triglyceride; ffa, free fatty acid; and chol, cholesterol. Numbered bands (B) represent the area of fractions collected for additional analyses (see Tables 2 and 3).

using α-bromoacetophenone as described earlier (8). The ozonides used to determine the position of the double bonds in the monoenes were prepared as described previously (9). Hexadecenoate and octadecenoate phenacyl esters were isolated by high-performance liquid chromatography (HPLC) using a C_{18} reversed-phase column as previously described (8). Methyl esters and butyl esters were analyzed on a 30 m × 0.53 mm (i.d.) DB-225 (J&W Scientific, Folsom, CA) capillary column using a Varian 3700 gas chromatograph (Walnut Creek, CA). Column temperature was programmed from 140 to 225°C at 3°C/min and 60 to 225°C at 5°C/min for methyl and butyl esters, respectively. Intact triglycerides, phenacyl esters, and phenacyl ozonides were analyzed on a 15 m × 0.53 mm (i.d.) DB-PS1 (J&W Scientific) column. The phenacyl esters' column temperatures were programmed from 60 to 250°C at 8°C/min, while the injector temperature was programmed from 60 to 300°C at 150°C/min and held for 10 min. Column temperatures for triglyceride analyses were programmed from 100 to 225°C at 10°C/min and then to 350°C at 5°C/min. The injector temperature was programmed from 60 to 325°C at 150°C/min and held for 20 min. Phenacyl ozonide column temperatures, with and without triphenylphosphine, were programmed from 60 to 300°C at 8°C/min, and the injector temperature was programmed from 60 to 300°C at 150°C/min. Generally, the reproducibility for methyl ester analysis of fatty acids with C-12 or longer chain lengths and butyl esters of fatty acids of C-8 and longer was ±5% for major peaks (>10% total) and ±15% for minor peaks (<10% total). Quantities of positional isomers were determined from the gas–liquid chromatography (GLC) analysis of methyl esters. Reproducibility of results from the GLC analysis of intact triglycerides was equivalent to that of methyl ester analysis. The data were collected with an IBM model 9000 (Danbury, CT) laboratory computer. Peak identification was established by cochromatography with standard reference fatty acids. All the procedures used to extract, derivatize, and analyze the lipids have been described in detail (6).

RESULTS

The mature pawpaw fruit contained approximately 1% total lipid on a wet weight basis. The mature seed contained 9.0% total extractable lipid. The fruit lipids were composed of 51% neutral lipid and 49% polar lipid, whereas the mature seed consisted of 95% neutral lipid. The immature fruit and seed contained less than 25% of the lipids of mature fruit and seed lipids and had nearly equal levels of neutral and polar lipids.

Results from the analysis of the fatty acid methyl esters from the seeds and fruit neutral and polar lipids of mature and immature pawpaws by GLC are given in Table 1. The fatty acid composition of the mature and immature seeds was characterized by high levels of 18:2 and 18:1. Seed polar lipids contained more 16:0 than neutral lipids. Immature seeds contained more 16:0 and 18:3 than mature seeds. The 18:1 and 18:2 percentages that we observed in the seeds are almost the opposite of that reported by Hilditch (10); however, there are significant differences from the technology of 60 yr ago to that of today. The only other unusual feature of the seed fatty acid composition is the absence of the 14:0, hexadecenoate, and octadecenoate isomers found in the fruit (Table 1). The fatty acid compositions of the pawpaw fruit given in Table 1 are not accurate because, as we will show, a high percentage of octanoate methyl ester present was lost during solvent evaporation. The methyl ester percentages of the mature fruit triglycerides and polar lipids show the presence of 14:0 and elevated levels of octadecenoate isomers relative to the immature fruit lipids. Because of budgetary and time constraints, seed-, immature-, and polar-lipid analyses were not made beyond this point.

Analysis of fruit triglycerides. As shown in Figure 1A, the pawpaw fruit neutral lipids contained a variety of compounds of varying polarity. The large triglyceride band was isolated by preparative TLC for analysis by high-temperature GLC. The carbon-number distribution of the mature pawpaw fruit triglycerides is shown in Figure 2. The peak numbers represent the number of carbon atoms in the fatty acids of the glyceride; i.e., peak number 36 could be made up of 3 × 12:0 or any combination of fatty acids to yield 36. The chromatogram shows an atypical distribution. The low-molecular-weight

triglycerides indicated that shorter-chain fatty acids than indicated in Table 1 were present. The three-cycle appearance of the carbon number distribution indicated either a preferential pairing of fatty acids or an unusual fatty acid distribution pattern.

Figure 1B shows the separation of pawpaw fruit triglycerides and standard by Ag^+-TLC. Tristearin and tripalmitin were not separated, but triolein and tripalmitolein were resolved in the standard mixture. Trilinolein with six double bonds was retarded on the TLC plate near the origin. Because of the effect of fatty acid chain length as noted in triolein and tripalmitolein separations, the numbered bands in the pawpaw triglycerides lane may not correspond to the number of double bonds in the standards. The pawpaw triglyceride sample gave two major bands and origin material, but even band 4 shows that no material contained triglycerides.

The carbon-number ditribution of the total and the eight Ag^+-TLC bands (Fig. 1B) of pawpaw triglycerides is given in Table 2 along with a 1,2,3-random calculated distribution. The lower-numbered bands with less unsaturation had higher

agree completely with the percentages of the total, but the cyclic distribution was apparent.

Phenacyl and *n*-butyl ester derivatives were prepared to avoid the loss of low-molecular-weight fatty acids. Table 3 shows the fatty acid composition of coconut oil, pawpaw triglycerides, and pawpaw triglyceride fraction (Fig. 1B) derivatives. Coconut oil, which contains medium-chain fatty acids of known composition, was included for comparison. The unsaturated phenacyl esters of the fatty acids were not resolved on the DB-PS1 column, but even with this limitation the values were in good agreement with earlier values. Likewise, the butyl ester fatty acid composition of coconut oil was in good agreement with the earlier HPLC data (8). The composition of pawpaw triglyceride fatty acid phenacyl esters differed from the butyl ester profile in that the unsaturated octadecanoates eluting as a single peak represented a higher percentage of the total than the butyl ester values. Although these data do not appear to be quantitative, the utility of the phenacyl esters will become apparent later. The butyl ester derivatives of the pawpaw triglycerides show that octanoate represented more than 20% of the total fatty acids while hexanoate, decanoate, and dodecanoate values were low. The pattern of octanoate representing a significant percentage of the pawpaw triglycerides was prevalent in all fractions except number eight. The percentage of 18:3 increased as the degree of unsaturation in the triglyceride increased; i.e., band number eight contained nearly 50% 18:3.

Analysis of the hexadecenoates and octadecenoates. GLC analyses of the pawpaw fatty acid butyl esters or methyl esters on the DB-225 capillary column showed three peaks eluting near oleate. The identity of these fatty acids was established by two independent methods. Phenacyl esters of total pawpaw triglycerides as shown in Figure 3A were separated according to degree of unsaturation by Ag^+-TLC. The monoene phenacyl esters analyzed by GLC are shown in Figure 3B. This monoene fraction of phenacyl esters was used to isolate hexadecenoate and octadecenoate fractions by HPLC. The isolated 16:1 and 18:1 fractions of phenacyl esters as analyzed by GLC are shown in Figure 3C and 3D, respectively.

In Figure 4 the thermal degradation of phenacyl ozonides of pawpaw octadecenoates to yield phenacyl aldesters during GLC with (right) and without (left) triphenylphosphene is shown. The numbered peaks represent the position of the double bond with reference to the carbonyl carbon. The lettered peaks (A,B,C) are triphenylphosphine and degradation or rearrangement products. The hexadecenoate ozonide fractions gave rise to 9 and 11 phenacyl aldesters.

We found the phenacyl esters that we had previously used

FIG. 3. as a chromophore for the analysis of fatty acids by HPLC very useful in determining structure. The phenacyl esters are stable to analysis by GLC with good peak symmetry (Fig. 3). The phenacyl derivatives can be separated by Ag^+-TLC and then analyzed by GLC (Fig. 3B) or further fractionated by HPLC and then checked for purity by GLC (Fig. 3C and D). Ozonides can be prepared from the monoene phenacyl esters and their thermal degradation products analyzed by GLC (Figs. 4 and 5). The stability of the phenacyl esters of fatty acids allows one to alternate from one type of analysis to another; and the derivatives are stable at reduced temperatures for long storage periods.

Analyses of the pawpaw triglyceride monoene methyl esters by GLC on a DB-225 capillary column and of an authentic mixture of Δ9 octadecenoate, Δ11 octadecenoate, and Δ13 octadecenoate methyl esters are shown in Figure 5A and 5B, respectively. Cochromatography of the pawpaw monoene methyl esters and the standard methyl esters showed that the octadecenoates coeluted.

DISCUSSION

This appears to be the first study to examine the lipids of the mature pawpaw fruit. It is quite clear (Table 1) that seed lipid fatty acid composition shows little relation to the fruit lipids. Both mature and immature seed triglyceride and polar lipids exhibited a simple fatty acid composition without medium-chain fatty acids or monoene fatty acid isomers. Although the fatty acid composition of the fruit and seed can be different (11), the marked contrast between the pawpaw fruit and seed is striking. Comparison of the triglyceride and polar lipid fatty acid compositions of the mature and immature pawpaw indicates that the medium-chain and isomer monoene fatty acid biosyntheses occur in the latter stages of development or dur-

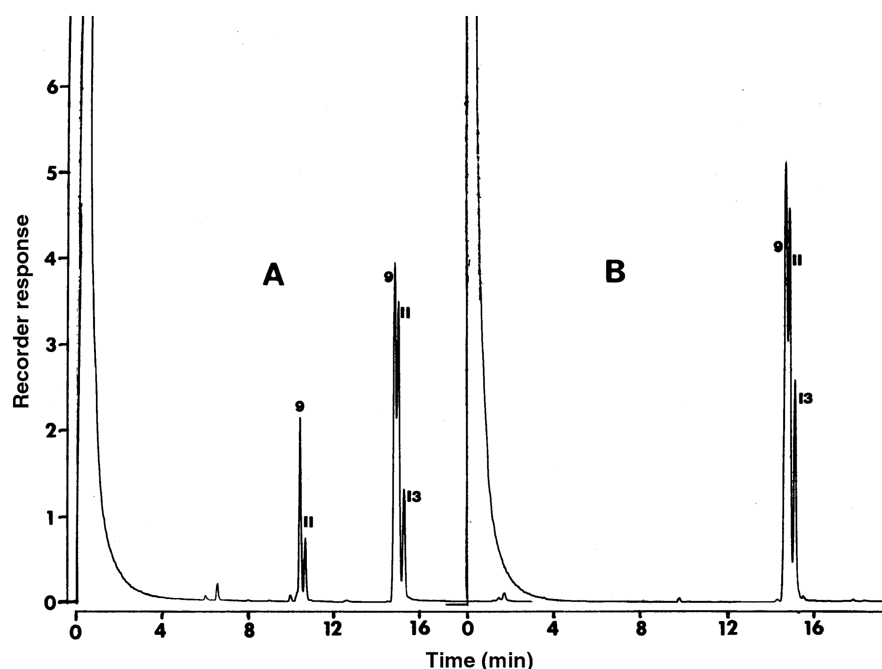

FIG. 5. These chromatograms show the separation of (A) pawpaw triglyceride monoene methyl esters and (B) authentic octadecenoate standards using a DB-225 capillary column. The first set of peaks in chromatograph A represent the hexadecenoates. Analytical conditions are described in the Methods and Materials section. Numbers beside the peaks represent the position of the double bonds relative to the carbonyl carbon.

ing ripening. Also, Table 1 indicates that 18:3, presumably linolenic acid, was more prominent in the immature seeds and fruit lipids. Elevated percentages of 18:3 in developing fibers of cotton were also observed (Wood, R., unpublished data). The involvement of 18:3 during the development of systems that have little or no 18:3 at maturity would seem to be an interesting area for investigation.

Analysis of the pawpaw fruit triglyceride intact and fatty acid derivatives by GLC on polar and nonpolar columns demonstrates that octanoate represents 20% of the total fatty acids. Methyl and ethyl octanoates, along with other volatiles, have been identified in the volatiles and head space volatiles of pawpaw fruit (12,13). Trace quantities of caprylic, capric, and lauric acids have been reported in the total lipids of the pawpaw fruit (14). The acids could have come from the volatile fraction (12,13). Our data appear to be the first to identify octanoate as a major component of the pawpaw fruit triglyceride. Presumably the triglyceride could be the source of the ethyl and methyl octanoates identified in the volatile fraction (12,13). This assumption is supported by TLC plate A in Figure 1, which shows a major band just above the standard cholesterol band, an area where diglycerides migrate. We did not examine this band to prove it was a diglyceride.

The carbon number distribution of the triglycerides fractionated according to degree of unsaturation (Table 2), and the fatty acid compositions of the fractions (Table 3) allow the triglyceride molecular species to be examined. Comparison of the calculated 1,2,3-random distribution with that of the determined total distribution shows a lack of agreement, but the reduced levels of carbon number 36 and 46 were apparent as observed in most fractions. The percentage of octanoate in all the fractions except band 8 (Table 3) indicates a selective pairing of octanoate with most diglyceride species. Examination of Figure 2 and Table 2, band 3, shows that carbon number 42 was one of the most abundant. Table 3 indicates that nearly one-third of the fatty acids was octanoate, or one for every triglyceride molecule. Figure 1B suggests that band 3 species probably contained two double bonds. Resolution 54:3 and 48:3 suggest that 42:2, of which one fatty acid is octanoate, would migrate in this region of the plate. The high percentage of 16:1 and 18:1 indicates the major triglyceride species in band 3 was 8:0-16:1-18:1. By using the same reasoning, carbon number 44 of band number 5 (Fig. 1B) contains 8:0-18:1-18:3 as the major species.

This study also appears to be the first to report the occurrence of significant quantities of three octadecenoate isomers in a single plant source. It can be assumed that there is one Δ9 desaturase and an active elongation system.

The occurrence of octanoate is not unique to the pawpaw fruit. Octanoate is found in edible oils (coconut and palm kernel oil), dairy products from milk goats, essential oils, and numerous other sources (11). Generally, the levels are relatively low and octanoate is flanked by shorter (6:0)- or longer (10:0)-chain fatty acids (or both), which are 25% or more of the concentration of octanoate. The high concentration of octanoate (20%) in the pawpaw fruit triglycerides, where the concentration of flanking fatty acids is about 3% of the total fatty acids, does appear to be unique. Clearly, there is an interesting metabolic process that leads to the accumulation of octanoate. It could be a unique fatty acid synthase or a unique

chain-shortening process. In the future, investigators may find the pawpaw a unique source of genes that can be used to improve the odor and flavor of other fruits and vegetables.

ACKNOWLEDGMENTS

I dedicate this manuscript to my dear departed mother, Tena Harris Wood (1918–1995), and my father, Ocie B. Wood, whose inspirations will last a lifetime. Thanks go to my sister, Linda Wood Sullivan, for collecting the pawpaws and to Shirley Edwards for manuscript preparations. Special thanks go to my loving wife, Arlene, for years of proofreading and being my best friend.

Stability of Cyclopropane and Conjugated Linoleic Acids During Fatty Acid Quantification in Lactic Acid Bacteria

Fabiola Dionisi, Pierre-Alain Golay, Marina Elli, and Laurent B. Fay*
Nestlé Research Centre, Nestec Ltd., Vers-chez-les-Blanc, 1000 Lausanne 26, Switzerland

ABSTRACT: Seven methods commonly used for fatty acid analysis of microrganisms and foods were compared to establish the best for the analysis of lyophilized lactic acid bacteria. One of these methods involves fat extraction followed by methylation of fatty acids, while the other methods use a direct methylation of the samples, under different operating conditions (e.g., reaction temperature and time, reagents, and pH). Fatty acid methyl esters were identified by gas chromatography–mass spectrometry and quantified by on-column capillary gas chromatography. Two reliable methods for the analysis of fatty acids in bacteria were selected and further improved. They guarantee high recovery of classes of fragile fatty acids, such as cyclopropane and conjugated acids, and a high degree of methylation for all types of fatty acid esters. These two direct methylation methods have already been successfully applied to the analysis of fatty acids in foods. They represent a rapid and highly reliable alternative to classical time- and solvent-consuming methods and they give the fatty acid profile and the amount of each fatty acid. Using these methods, conjugated linoleic acids were identified and quantified in lactic acid bacteria.

Paper no. L8208 in *Lipids 34*, 1107–1115 (October 1999).

Fatty acid (FA) composition in microorganisms is assessed for several purposes in the field of food science. For many years, FA analysis has been recognized as a useful and rapid tool for the characterization of microorganisms in foods (1,2) and as a complementary analysis to taxonomic classification (1–12). In addition, knowledge of the FA composition may help to evaluate the nutritional quality of alternative microbiological sources of fats (9,13–17).

Many articles describe the influence of growth conditions, such as temperature (18–23), pH (23,24), medium (13–17,23), and oxidative stress (21) on FA composition. However, the main aim of our studies is to understand the influence of FA composition on membrane structure and functionality (in terms of fluidity and permeability). Knowing the FA composition of cell membranes can also help in understanding the mechanism of antioxidant and antimicrobial molecules (25).

Depending on the objective, it is possible to analyze the FA composition of complete cells or the FA distribution of membrane phospholipids (PL) (14,21). Of course, in this latter case, previous purification of PL is necessary (14). Several methods for FA analysis are described in the literature. Scheme 1 summarizes the possibilities for the analysis of fatty acids in bacteria. It shows that bacteria may be directly saponified in an acid (18) or alkaline environment (5,11,16, 19,25–29), or directly transesterified to fatty acid methyl esters (FAME) (30). The lipids may also be extracted and then saponified and esterified to FAME (3,6,12,13,22,24).

The most commonly applied procedure is based on direct saponification of the sample using methanolic NaOH followed by HCl- or BF_3-catalyzed methylation. Another widely used method involves lipid extraction (principally carried out according to Folch *et al.*, 31) and successive saponification/methylation of the total lipids or of the separated fractions of PL and triglycerides (TG). Another technique, developed by Aluyi *et al.* (21, cited in 32), consists of a fat extraction according to Folch *et al.* (31) and direct analysis by fast atom bombardment/mass spectrometry (FAB/MS). This method has the advantages of being very rapid and of identifying both PL and TG in a single analysis.

Recently, direct methylation of a sample using sodium methoxide as catalyst was successfully performed (30). This procedure is less time- and solvent-consuming. Other similar procedures have already been applied to the quantification of FA in oils and foods (33–35).

A critical point of a method for FA analysis in bacteria is the high reactivity of certain categories of FA under acidic conditions. Cyclopropenic acids and conjugated linoleic acid (CLA), especially, are easily decomposed. For this reason, several authors (1,26,30,36) strongly recommended avoiding acidic conditions. On the other hand, Mayberry and Lane (37) have stressed that alkaline methylation may not be strong enough to cleave all types of FA. The same authors therefore proposed a sequential alkaline/acidic hydrolysis.

The aim of the present work was to find an optimal procedure for the quantification of FA in whole cells of freeze-dried bacteria. Methods were compared according to their reliability and rapidity. Special attention was paid to the recovery of cyclopropanic acids and CLA. The most promising methods were tested and compared: (i) fat extraction with chloroform/meth-anol (31) followed by methylation in alkaline environment; (ii) acid-catalyzed direct methylation (35); (iii) alkali-catalyzed direct methylation (30,33,34).

EXPERIMENTAL PROCEDURES

Reagents. Quantitative 37-component FAME standard and methanolic hydrochloric acid were purchased from Supelco (Division of Fluka Chemie AG, Buchs, Switzerland). Methyl esters of cyclopropane fatty acids (*cis*-9,10- and *cis*-11,12-methyleneoctadecanoate) were purchased from Larodan Fine Chemicals AB Chemie Brunschwig (Basel, Switzerland). Triundecanin, 1-tetradecene, methylpelargonate, dimethylformamide (DMF) and disodium hydrogen citrate sesquihydrate were purchased from Fluka Chemie AG. Methanol, methanolic sodium methoxide solution, and water were purchased form Merck (Geneva, Switzerland). Hexane was purchased from Mallinckrodt Baker P.H. Stehelin (Basel, Switzerland). *Tert*-butyl-methyl ether and heptane were purchased from Sigma (Division of Fluka Chemie AG, Buchs, Switzerland). Octadecadienoic conjugated FAME (CLA standard) were purchased from Nu-Chek-Prep. Inc. (Elysian, MN).

Solutions. The internal standard solution 1 contains triundecanin, 1-tetradecene, and methylpelargonate in *tert*-butyl-methyl ether (1 mg/mL for each standard). The internal standard solution 2 contains triundecanin, 1-tetradecene, and methylpelargonate in hexane (1 mg/mL of each). The methylation solution contains sodium methoxide in methanol (1 M). Disodium hydrogen citrate in water (0.57 M) is used as neutralization solution.

Samples. Lyophilized lactic acid bacteria (*Lactobacillus*), obtained by fermentation, were used throughout the study. After fermentation the culture was centrifuged at 4500 rpm for 20 min at 10°C. Cell pellets were washed twice with sterile saline solution and freeze-dried using a LSL-Secfroid Lyolab-G lyophilizer (Aclens, Switzerland) for 24 h, with a final temperature of 20°C and a condenser temperature of 80°C. The dried vials, containing about 1 g dry matter for 10 mL suspension, were capped under air and stored at 4°C prior to analysis.

Methods 1.1, 1.2, and 1.3. These methods are based on the procedure developed by Suter and Grob (33,34) with minor modifications. Three different pretreatments were carried out to maximize recovery.

(i) Method 1.1 [with dimethylformamide (DMF) pretreatment]. One hundred milligrams of bacterial sample was treated with 2 mL of DMF at 100°C for 30 min. The subsequent steps were carried out according to "method 1.3 (without pre-treatment)."

(ii) Method 1.2 (with water pretreatment). One hundred milligrams of bacterial sample was treated with 2 mL of distilled water at room temperature for 5 min. The subsequent steps were carried out according to "method 1.3 (without pretreatment)".

(iii) Method 1.3 (without pretreatment). After the addition of 500 μg of internal standard (solution 1 in *tert*-butyl-methyl ether), 100 mg of bacterial sample was transesterified with 2 mL of 1 M methanolic sodium methoxide for 2 min at room temperature. FAME were extracted using 1 mL heptane and 4 mL of neutralization solution. After centrifugation at 2000 rpm for 5 min, the upper organic layer was diluted 10 times with hexane before gas chromatographic analysis.

Method 2. This method is based on the procedure developed by Ulberth and Henninger (35) with minor modifications. One hundred milligrams of bacterial sample, after the addition of 500 μg of internal standard (solution 2 in hexane), was transesterified using 1 mL of methanolic hydrochloric acid (1.5 M) and 1 mL methanol, at 80°C for 10 min. Two milliliters of distilled water was then added and an aliquot of the upper organic phase was diluted 25 times with hexane and used for gas chromatographic analysis.

Methods 3.1 and 3.2. Method 3.1 is based on a procedure developed by Rozès *et al.* (30). One hundred milligrams of bacterial sample spiked with 500 μg of internal standard (solution 2 in hexane) was transesterified with 2 mL of sodium methoxide (1 M in methanol) for 1 min at room temperature. FAME were then extracted using 1 mL of hexane. After centrifugation at 2000 rpm for 5 min, the organic upper phase was diluted 10 times with hexane before gas chromatographic analysis. The same method was also modified (method 3.2) using a water pretreatment. One milliliter of water was previously added to the bacterial sample and, after 5 min, the procedure was completed as described above.

Method 4. This method was developed by Folch *et al.* (31). Six hundred milligrams of bacterial sample spiked with 500 μg of internal standard (solution 2 in hexane) was extracted twice using 25 mL of chloroform/methanol solution (3:2, vol/vol) for the first extraction, and 15 mL of chloroform/methanol/water solution (10:10:1, by vol) for the second extraction. The liquid phase was filtered and washed with 10 mL of distilled water, and the aqueous phase was again extracted with 5 mL of the chloroform/methanol/water solution. The two organic phases were collected and evaporated under vacuum at 40°C. Extracted fat was transesterified using the procedure described in "Method 1.3 (without pretreatment)."

Method 5. This method is based on the procedure described by Muuse *et al.* (38). It comprises methylation of the sample (100 mg, spiked with methyl tridecanoate as internal

standard) using 2 M methanolic potassium hydroxide (reaction time: 2 min at room tempearture). After centrifugation for 5 min at 2000 rpm, the supernatant is diluted with hexane before gas chromatographic analysis.

Gas chromatography. A Carlo Erba HRGC 5300 gas chromatograph (Brechbühler SA, Geneva, Switzerland) equipped with a flame-ionization detector was used. Hydrogen was used as carrier gas (purity >99.9997 %). A CP-Sil 88 capillary column (50 m length, 0.32 mm i.d.) coated with 100% cyanopropyl/polysiloxane (0.25 µm film thickness) was purchased from Chrompack (P.H. Stehelin). The column was operated at 60°C for 2 min, then the temperature was increased at 15°C/min to 135°C, held 1 min, then increased at 3°C/min until the final temperature of 215°C was reached. Five microliters of each sample solution was injected. Response factors for each FA relative to the internal standard (triundecanin) were calculated using a Supelco 37 standard solution. The performance of the methylation reaction was checked according to Suter and Grob (33,34) by using the ratios between triundecanin, 1-tetradecene, and methyl-pelargonate internal standards.

Mass spectrometry. The FAME were identified on a Finnigan MAT 8430 double focusing mass spectrometer (Finnigan MAT, Bremen, Germany) connected to a HP 5890 gas chromatograph (HP, Geneva, Switzerland) equipped with a CP-Sil 88 capillary column (Chrompack); 50 m × 0.32 mm i.d.; film thickness, 0.25 µm. Helium was used as the carrier gas at a pressure of 10 psi. The samples were injected using an on-column injector. Oven program was 60°C for 2 min, then 15°C/min up to 135°C, held for 1 min, then 3°C/min up to 220°C for 10 min. The transfer line was held at 220°C and the source at 180°C. Electron impact mass spectra were acquired at 70 eV from 20 to 500 Da. The location of double bonds in unsaturated FA was determined after 2-alkenyl-4,4-dimethyloxazoline derivatization (39) by gas chromatography–mass spectrometry (GC–MS) on a Finnigan MAT SSQ-7000 quadrupole mass spectrometer connected to an HP 5890 gas chromatograph. All the GC–MS parameters were identical to those described above.

RESULTS AND DISCUSSION

Method comparison. The FA composition of lyophilized lactic acid bacteria (*Lactobacillus*) was determined using seven different methods to check their performance and to select the best. Six direct methylation methods (1.1, 1.2, 1.3, 2, 3.1, and 3.2; see the Experimental Procedures section) were compared with a method (4; see the Experimental Procedures section) involving a preliminary fat extraction before methylation. The direct methods differ in the type of pretreatment performed and the methylation reactives used.

All the analyses were performed in duplicate and the results were expressed as the means of the two values obtained. All methylated FA were identified by comparing their retention times and mass spectra with the one obtained from commercial standard FAME. The location of double bonds in unsaturated FA was established after 2-alkenyl-4,4-dimethyloxazoline derivatization and GC–MS analysis. For example, all the 18:2 FAME showed, after electron impact at 70 eV, a molecular ion at *m/z* 294, fragments at *m/z* 279 ($[M - CH_3]^+$), 263 ($[M - OCH_3]^+$), and the ion series 123, 109, 95, 81, 67,

[a]Results expressed as g FA/100 g total FA and as g total FA/100 g bacteria. Methods are described in detail in the Experimental Procedures section.

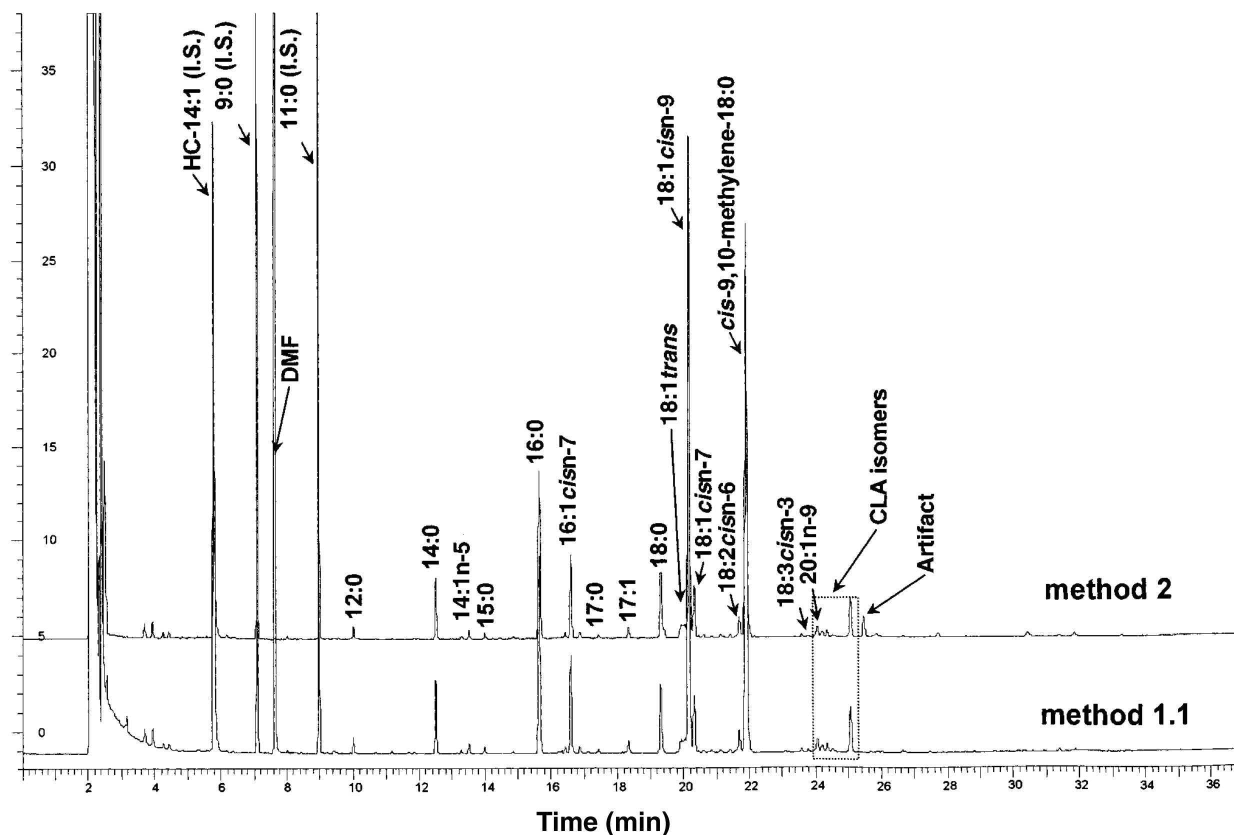

FIG. 1. Fatty acid (FA) profile of lyophilized bacteria obtained with methods 1.1 and 2 (see Experimental Procedures section). CLA, conjugated linoleic acid; DMF, dimethylformamide; I.S., internal standard; HC-14:1, 1-tetradecene.

55, and 41. After 2-alkenyl-4,4-dimethyloxazoline derivatization, the mass spectrum of a 18:2 Δ9,11 showed a molecular ion at *m/z* 333 and diagnostic fragments at *m/z* 234, 222, 208, and 196, whereas the spectrum of an 18:2 Δ10,12 isomer displayed a molecular ion at *m/z* 333 and diagnostic fragments at *m/z* 248, 236, 222, and 210 (39). Additional information about *cis/trans* isomerization was taken from Chardigny *et al.* (40), Shantha *et al.* (41), and Chin *et al.* (42). *cis*-9,10-Methyleneoctadecanoate methyl ester (dihydrosterculic acid methyl ester) was identified and is one of the major fatty acids found in the lactic acid bacteria analyzed.

In Table 1 the results are shown as FA composition (g FA/100 g total FA) and as total absolute quantity of FA recovered. The recovery of total FA varies widely between the different methods, being higher for methods 1.1 and 2 and lower for methods 1.2 and 3.1. Method 4 had a very low FA recovery.

Method 4 is widely used for the analysis of biological materials (3,6,12,13,22,24) and operates under mild conditions that avoid FA destruction (especially CLA and cyclopropane FA). Therefore, we have considered it as a reference for comparison of the other methods. From this comparison, we can immediately eliminate methods 1.2, 1.3, 3.1, and 3.2 which give a different FA composition and a decrease in fragile cyclopropane FA. Methods 1.1 and 2 gave the best results. Method 2 was also retained as a valuable procedure because of its high absolute total FA recovery. This method, in addition, involves acid methylation, which is effective on all the classes of lipids (43), is very rapid, and avoids pretreatment. On the other hand, alkaline-catalyzed methylation methods have been demonstrated in the literature not to be sufficiently effective on free FA or amide-linked FA (such as a part of hydroxylated FA) (37), while acting only on esterified FA (43).

Figure 1 shows the chromatograms obtained with methods 1.1 and 2. We retained methods 1.1 and 2 as valid alternatives to method 4 because of their high total FA recovery and accurate FA profile. In addition, these two methods are less solvent- and time-consuming than the other methods screened here.

Method repeatability. Repeatability was calculated for methods 1.1 and 2 by repeating the complete analysis four times. Repeatability of the two methods, as relative standard deviation (RSD%), was very similar and corresponded to 10% for values <1 g FA/100 g total FA; 5% for values between 1 and 5 g FA/100 g total FA; 2.5% for values >5 g FA/100 g total FA.

CLA analysis. Figure 2 shows the enlarged region of CLA isomers of the gas chromatogram (comparison of methods 1.1, 2, and 4). Because concerns were expressed in the literature (41,43) about the analysis of CLA FA in an acidic environment (as in method 2), several experiments were performed to check the stability of CLA during the analysis.

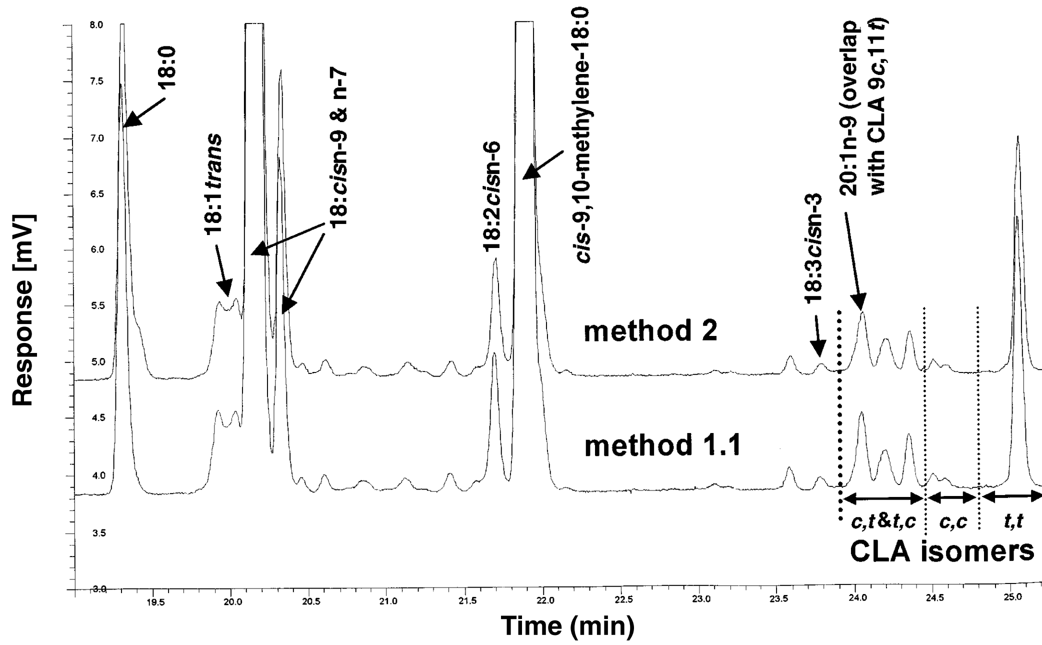

FIG. 2. Enlarged chromatogram of the region 18:0, 18:1, 18:2, and CLA isomers. See Figure 1 for abbreviation.

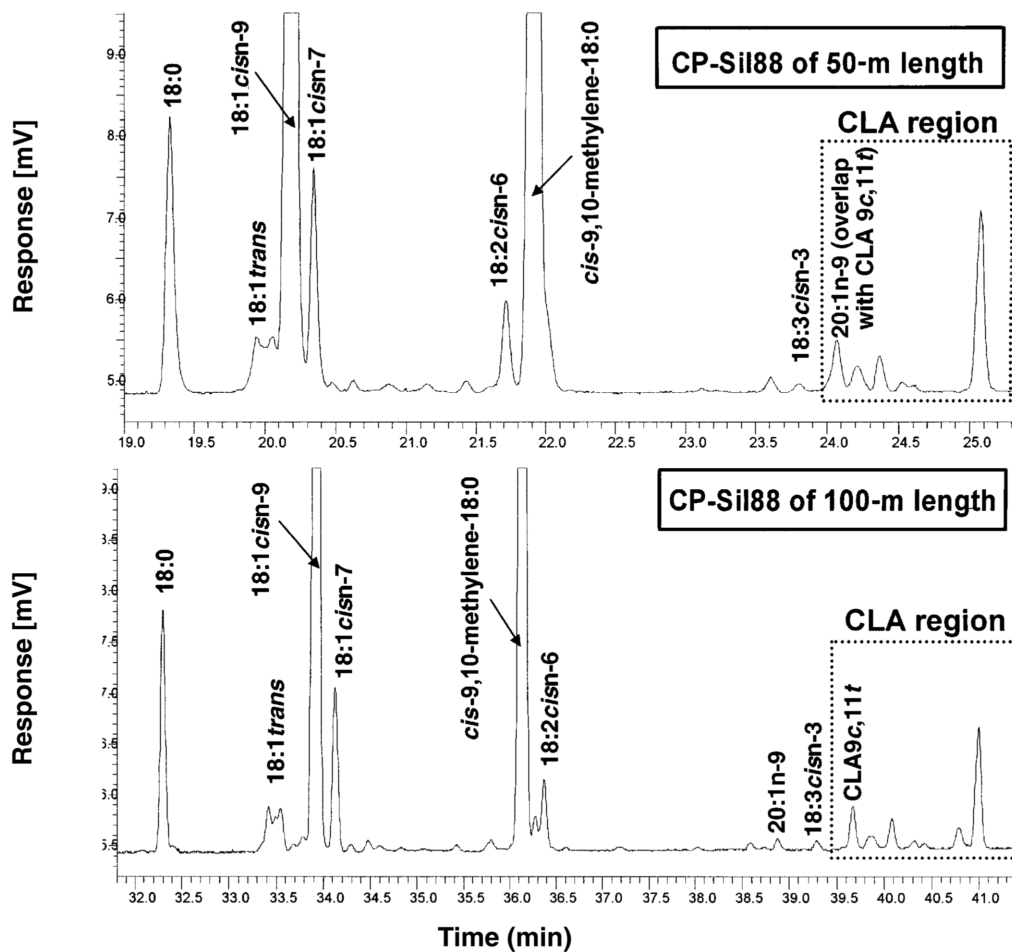

FIG. 3. Chromatogram of enlarged CLA region, obtained with 50- and 100-m CP-Sil 88 capillary columns. See Figure 1 for abbreviation.

TABLE 2
CLA Composition (as relative %) of a Butter Sample Analyzed by Methods 2 and 5[a]

	Method	
	2	5
Sum of *cis,trans* and *trans,cis* isomers	86	85
Sum of *cis,cis* isomers	3	5
Sum of *trans,trans* isomers	11	10
Total	100	100

[a]CLA, conjugated linoleic acid.

An experiment was carried out to check whether acidic pH and high temperatures during analysis lead to the formation of *trans,trans*-CLA isomers. A sample of butter (CLA < 1%) was analyzed using method 2 (acid-catalyzed methylation) and method 5 (alkaline cold methylation). For this experiment a 100-m CP-Sil 88 capillary column, with 0.25 mm i.d. and a film thickness of 0.2 μm, was used instead of the 50-m column used previously. With this column, better separation and quantification of the different CLA isomers were achieved due to separation of the 20:1n-9 and *c*9,11*t*-18:2 isomers. In Figure 3, the CLA profiles obtained with 50- and 100-m CP-Sil 88 columns are compared.

Table 2 summarizes the results obtained, expressed as normalized surfaces. They show that no transformation of *cis*-CLA forms into *trans*-CLA forms occurs. In order to assess the best analytical conditions (in terms of temperature, time, and acid concentration) for the analysis of lyophilized bacteria using method 2 (with methanolic HCl), a kinetic study was carried out. Four different temperatures (room temperature, 60, 80, and 100°C), four different reaction times (10, 30, 120 min, and 18 h), and three different acid concentrations (0.5,

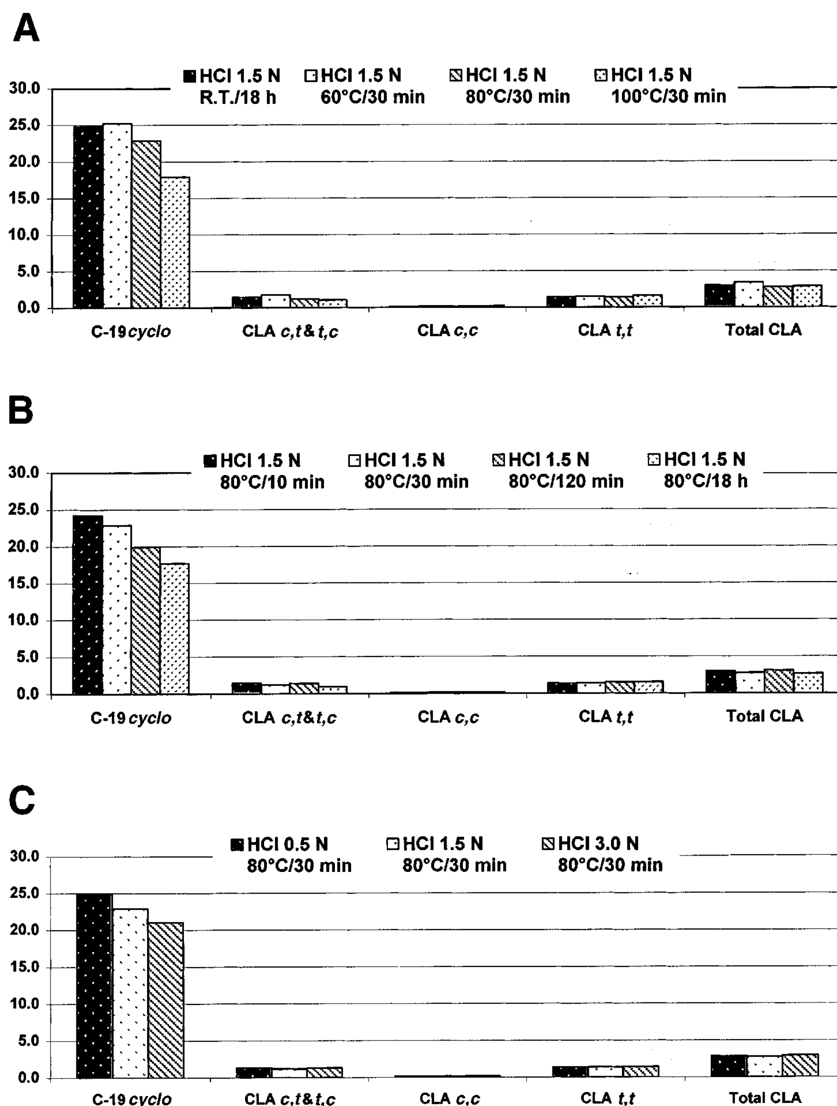

FIG. 4. Influence of temperature (A), time (B), and acid concentration (C) on the stability of cyclopropanic and CLA isomers in lyophilized lactic acid bacteria. Results expressed in g fatty acid/100 g total fatty acids. R.T., room temperature; for other abbreviation see Figure 1.

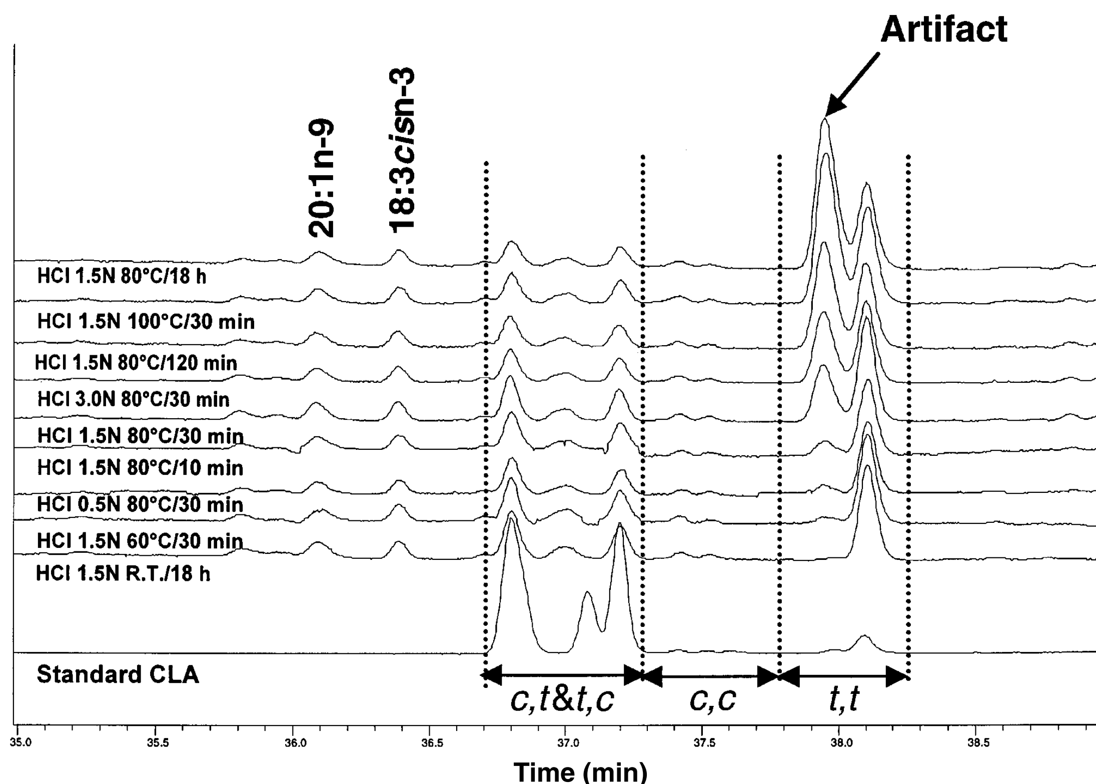

FIG. 5. Formation of degradation products during methylation of CLA isomers. The peak denoted "artifact" has been tentatively identified as 10-methyl-9-methoxy-octadecanoic acid methyl ester. See Figures 1 and 4 for abbreviations.

1.5, and 3.0 N) were compared. The results obtained for cyclopropane and CLA acids are shown in Figure 4, expressed as g FA/100 g of total FA. The results clearly demonstrate that a combination of a too-high acid concentration (higher than 1.5 N), at a too elevated temperature (higher than 60–80°C), and a too long reaction time (longer than 30 min) may degrade the FA. The formation of a degradation product is clearly visualized in Figure 5, where the chromatograms obtained under the different analytical conditions are compared. This artifact has been identified as 9-methoxy-10-methyl-octadecanoic acid methyl ester. Its mass spectrum showed a molecular ion at *m/z* 342 (<0.5%, confirmed after positive chemical ionization) and the diagnostic fragment ions at *m/z* 311 (2.9%), 279 (2.4%), 229 (3.4%), 201 (100%), 185 (12.4%), 169 (26.0%), 157 (71.9%), and 137 (36.9%). This compound is formed during derivatization by reaction between methanol and the cyclopropanic cycle of *cis*-9,10-methyleneoctadecanoic acid. In summary, the best combination of analytical parameters was (i) 80°C for 30 min with 0.5 N HCl; (ii) 60°C for 30 min with 1.5 N HCl; (iii) 80°C for 10 min with 1.5 N HCl; and (iv) room temperature for 18 h with 1.5 N HCl. These conditions lead to very similar profiles of CLA isomers with minimal formation of artifacts. Due to speed of analysis and minimization of artifact formation, the preferable conditions of analysis are 60°C for 30 min with 1.5 N HCl.

Evaluation of these results leads to the conclusion that method 2 (involving acid catalysis and heat treatment), when applied in the conditions specified, does not lead to substantial modification of CLA in lyophilized bacteria.

Analysis of lyophilized lactic acid bacteria. Method 2 was used to analyze five different types of lyophilized lactic acid bacteria to further confirm our findings. The results obtained are shown in Table 3 as duplicate values and means and confirm that method 2 is reliable and suitable for the analysis of FA composition in different types of lyophilized lactic acid bacteria.

A reliable and quantitative method for FA analysis in lyophilized lactic acid bacteria should respond to two principal criteria: first, to enable complete methylation and recovery of all types of FA esters (as well as amides and steryl esters) and, second, to avoid disruption of fragile FA (especially CLA and cyclopropane FA). Rapidity and facility of analysis are also prerequisites.

We have found two reliable methods (methods 1.1 and 2) for the quantification of FA in lyophilized lactic acid bacteria that guarantee high recovery of fragile classes of FA and a high degree of methylation for all the types of FA. These two direct methylation methods have already been successfully applied to the analysis of FA in foods. They represent rapid and reliable alternatives to classical time- and solvent-consuming methods. In addition, they not only give the FA composition but also allow the quantification of each FA. By

using these two preparative methods and GC–MS analysis, it was possible to identify and quantify CLA in lactic acid bacteria.

ACKNOWLEDGMENTS

The authors are grateful to Drs. Claudia Hischenhuber and Elisabeth Prior for critically reading the manuscript and to Dr. Tuong Huynh-Ba for helpful discussions about the artifact identification.

Synthesis of *trans*-4,5-Epoxy-(*E*)-2-decenal and Its Deuterated Analog Used for the Development of a Sensitive and Selective Quantification Method Based on Isotope Dilution Assay with Negative Chemical Ionization

Jianming Lin, Laurent B. Fay, Dieter H. Welti, and Imre Blank*

Nestec Ltd., Nestlé Research Center, CH-1000 Lausanne 26, Switzerland

ABSTRACT: The volatile compound *trans*-4,5-epoxy-(*E*)-2-decenal (**1**) was synthesized in two steps with good overall yields. The newly developed method is based on *trans*-epoxidation of (*E*)-2-octenal with alkaline hydrogen peroxide followed by a Wittig-type chain elongation with the ylide formylmethylene triphenylphosphorane. For the synthesis of [4,5-$^2H_2$]-*trans*-4,5-epoxy-(*E*)-2-decenal (***d*-1**), [2,3-$^2H_2$]-(*E*)-2-octenal was prepared by reduction of 2-octyn-1-ol with lithium aluminum deuteride and subsequent oxidation of [2,3-$^2H_2$]-(*E*)-2-octen-1-ol with manganese oxide. Compound ***d*-1** was used as internal standard for the quantification of **1** by isotope dilution assay. Among various mass spectrometry (MS) ionization techniques tested, negative chemical ionization with ammonia as reagent gas gave best results with respect to both sensitivity and selectivity. The detection limit was found to be at about 1 pg of the analyte introduced into the gas chromatography–MS system.

Paper no. L8265 in *Lipids 34*, 1117–1126 (October 1999).

trans-4,5-Epoxy-(*E*)-2-decenal (**1**) was first reported by Selke and coworkers (1) as a reaction product of autoxidized trilinolein. Model studies revealed 12,13-epoxy-9-hydroperoxy-10-octadecenoate, a degradation product of 13-hydroperoxy-9,11-octadecadienoic acid (13-HPOD), as a precursor of **1** (2). In addition, formation of **1** from 9-hydroperoxy-10,12-octadecadienoic acid (9-HPOD) and 2,4-decadienal as key intermediates has recently been reported in a systematic study (3). A reaction route was proposed for the formation of **1** from linoleic acid (4).

Compound **1** has been described in various food systems as a potent odorant eliciting metallic and green notes (5,6). It contributes to the development of off-flavors such as the green, hay-like flavor of soybean oil when stored in the dark (7) and "warmed-over" flavor of refrigerated cooked meat (8,9). Its sensorial relevance is due to low odor thresholds, i.e., 1.5 pg/L air (6), 15 ng/L water (10), and 1.3 [(μg/L oil (7)].

The role of **1** in biological systems has also been studied. Several α,β-unsaturated aldehydes formed upon lipid peroxidation have been shown to modify proteins, i.e., 4-hydroxy-2-alkenals (11) and 4,5-epoxy-2-alkenals (12). Compound **1** has been reported to be an intermediate in the formation of 4,5-dihydroxy-2-decenal (13), a cytotoxic aldehyde originating from the peroxidation of liver microsomal lipids (14). On the other hand, epoxyaldehydes such as *trans*-4,5-epoxy-(*E*)-2-heptenal and **1** may react with amino groups located in side chains of amino acids (15). Polymeric pyrrole derivatives identified in model systems containing such epoxyaldehydes and lysine are responsible for color formation and fluorescence (12,16). These reactions also generate 1-substituted pyrroles that have been proposed as indicators of oxidative stress in biological systems (12).

Compound **1** has recently been obtained by (salen)Mn(III)-catalyzed asymmetric epoxidation of (*E*,*Z*)-2,4-decenol with concomitant oxidation of the allylic alcohol to the aldehyde in 16% yield (17). However, most synthesis procedures reported so far are based on epoxidation of (*E*,*E*)-2,4-decadienal with 3-chloroperbenzoic acid (6,12). The deuterated analog (***d*-1**) was similarly prepared using labeled (*E*,*E*)-2,4-decadienal as starting material (4). Main limitations of the synthesis procedures are low yields, typically 5–10%, and time-consuming purification steps such as column chromatography (CC) and high-performance liquid chromatography.

In general, the amounts of **1** found in foods are low, i.e., up to ~11 μg/kg in refrigerated cooked meat (9,10), ~12 μg/kg in soybean oil stored in the dark (4), and 13–20 μg/kg in virgin olive oils (18). These values were obtained by the isotope dilution assay (IDA) quantification method (4,10), which is based on spiking the sample with known amounts of a labeled substance prior to sample preparation and analysis by gas chromatography–mass spectrometry (GC–MS) (19). In this way, losses can be accounted for because of the almost identical chemical and physical properties of the labeled internal standard and the analyte to be quantified. Unfortunately, quantification of **1** implies laborious cleanup steps such as distillation in high vacuum, CC and high-performance liquid chromatography

leading to extraction yields of about 1% (4). Thus, very sensitive detection methods are required for the quantification of **1**. Furthermore, neither **1** nor ***d*-1** is commercially available, but both are required for applying IDA. In this paper, we report a newly developed synthesis procedure of ***d*-1** and its unlabeled analog and an improved quantification method of **1** based on IDA using negative chemical ionization (NCI) as ionization technique.

EXPERIMENTAL PROCEDURES

Materials. Lithium aluminum deuteride ($LiAl^2H_4$, >99% deuterium), deuterium oxide (^2H_2O, heavy water, >99.8% ^2H), manganese oxide (MnO_2), formylmethylene triphenylphosphorane, anhydrous tetrahydrofuran (THF) (H_2O <0.005%, stored over molecular sieves), diethyl ether (Et_2O), methylenechloride (CH_2Cl_2), and Celite 545 were purchased from Fluka (Buchs, Switzerland). (*E*)-2-Octenal was obtained from Aldrich (Buchs, Switzerland) and 2-octyn-1-ol from Lancaster (Morecambe, England). Hydrogen peroxide (H_2O_2), salt (NaCl), sodium hydroxide (NaOH), sodium hydrogen carbonate ($NaHCO_3$), sodium sulfate (Na_2SO_4), hexane, heptane, methanol (MeOH), and silica gel 60 (70–230 mesh) were from Merck (Darmstadt, Germany). The egg phospholipids phosphatidylcholine (PC) and phosphatidyl-ethanolamine (PE) were obtained from Avanti Polar Lipids (Copenhagen, Denmark).

*Formation of **1** in heated phospholipids.* One gram of egg PC or egg PE was dispersed in a phosphate buffer (50 mL, 0.5 M, pH 5.6) by stirring magnetically. The dispersion was then heated for 30 min from room temperature to 145°C in a laboratory autoclave (Berghof, Eningen, Germany). After cooling, ***d*-1** (2.44 µg) was added to the reaction mixture that was then saturated with NaCl. The neutral compounds were continuously extracted from the aqueous phase for 15 h with Et_2O using a liquid-liquid extractor. The solvent extract was applied to high-vacuum transfer (20) in order to remove nonvolatile compounds. The condensate containing volatile compounds was concentrated to 1 mL before GC–MS analysis using a Vigreux column (50 × 1 cm).

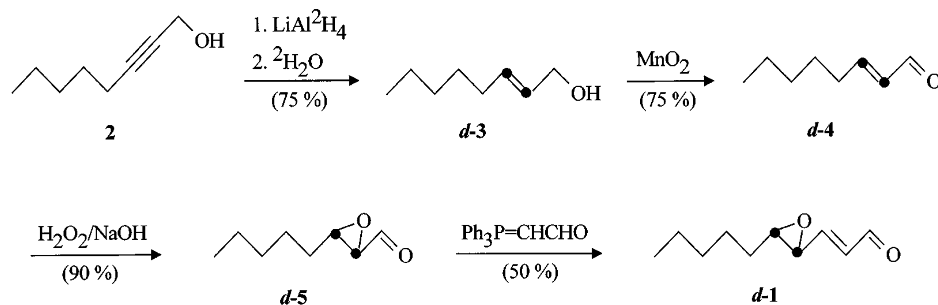
Capillary GC. This was performed on a Hewlett-Packard HP-5890 gas chromatograph (Geneva, Switzerland) equipped with a splitless injector and a flame-ionization detector. Fused-silica capillary columns were used, i.e., DB-5, DB-OV 1701, DB-FFAP, and DB-WAX (J&W Scientific, Folsom, CA; 30 m × 0.32 mm, film thickness 0.25 µm). Helium was used as carrier gas (100 kPa). The gas chromatograph was operated at an injector temperature of 250°C and a detector temperature of 250°C. The ovens were programmed as follows: 20°C, 70°C/min to 50°C, 4°C/min to 180°C, 10°C/min to 240°C (10 min) for DB-5; 20°C (2 min), 40°C/min to 50°C (2 min), 4°C/min to 150°C, 10°C/min to 240°C (15 min) for FFAP; and 20°C (1 min), 70°C/min to 60°C, 6°C/min to 180°C, 10°C/min to 240°C (15 min) for OV-1701 and DB-Wax. Linear retention indices (RI) were calculated (21).

GC–MS. Qualitative and quantitative GC–MS analysis was performed on a Finnigan SSQ 7000 mass spectrometer (Bremen, Germany) using the following conditions: electron ionization (EI) mass spectra were generated at 70 eV; positive chemical ionization (PCI) and negative chemical ionization (NCI) were carried out at 200 eV with ammonia or isobutane as reagent gas. Samples (2 µL) were introduced *via* a Hewlett-Packard HP-5890 gas chromatograph equipped with an HP-7673 autosampler using the following conditions: splitless injection at 250°C on fused-silica capillary column DB-OV 1701 described above. The carrier gas was helium (90 kPa). The temperature program was as follows: 60°C (2 min), 6°C/min to 180°C, 10°C/min to 240°C (10 min). Quantitative measurements were carried out in the selective ion monitoring (SIM) mode measuring characteristic ions of **1** and ***d*-1**. Calibration curves were obtained using mixtures of defined amounts of analyte (**1**) and labeled internal standard (***d*-1**) (4). Nine mixtures **1/*d*-1** were used, i.e., from 0.5 + 9.5, 1 + 9, 2 + 8, 3 + 7, and 5 + 5 to 7 + 3, 8 + 2, 9 + 1, and 9.5 + 0.5. The concentrations (µg/mL) of **1** and ***d*-1** used for preparing the mixtures were adapted to the varying sensitivity of the ionization modes used, i.e., 101.6/105.8 (PCI/isobutane), 10.2/10.6 (NCI/isobutane; PCI/ammonia), and 1.0/1.1 (NCI/ammonia). Samples for establishing the calibration curves and for quantification were injected twice.

Nuclear magnetic resonance (NMR) spectroscopy. The samples for NMR spectroscopy were prepared in WILMAD 528-PP 5-mm Pyrex NMR tubes, using as solvent about 0.7 mL of 99.8% C^2HCl_3 (Dr. Glaser AG, Basel, Switzerland) from a sealed vial. The NMR spectra were acquired on a Bruker AM-360 spectrometer (Karlsruhe, Germany), equipped with a quadrinuclear 5-mm probe head, at 360.13 MHz for ^1H and at 90.56 MHz for ^{13}C under standard conditions. The probe temperature was 21°C for the proton spectra and slightly higher for the carbon spectra, owing to heteronuclear composite pulse decoupling. All shifts are cited in ppm from the internal tetramethylsilane (TMS) standard. Where appropriate, proton nuclear Overhauser effect (NOE) difference spectra, distortionless enhancement by polarization transfer (DEPT) and/or fully proton-coupled spectra, and two-dimensional homonuclear and heteronuclear correlation spectra (COSY and HETCOR, respectively) were acquired as described earlier (22).

*Synthesis of [4,5-$^2H_2$]-*trans*-4,5-epoxy-(*E*)-2-decenal (**d-1**).* The synthesis procedure for ***d*-1** is shown in Scheme 1. Commercially available 2-octyn-1-ol (**2**) was used as starting material to prepare [2,3-$^2H_2$]-(*E*)-2-octen-1-ol (***d*-3**) by reduction with $LiAl^2H_4$ followed by deuterolysis (22). Oxidation of ***d*-3** with MnO_2 according to (23) resulted in [2,3-$^2H_2$]-(*E*)-2-octenal (***d*-4**). [2,3-$^2H_2$]-*trans*-2,3-Epoxyoctanal (***d*-5**) was obtained by reaction of ***d*-4** with alkaline H_2O_2 (24). Chain elongation was achieved by a Wittig reaction of ***d*-5** with the ylide formylmethylene triphenylphosphorane (25) resulting in ***d*-1** as the major product.

[2,3-$^2H_2$]-(E)*-2-Octen-1-ol* (**d-3**) (Scheme 1, step ***a***). In a three-necked reactor (200 mL) fitted with a reflux condenser and a thermometer, $LiAl^2H_4$ (4.2 g, 100 mmol) was suspended in anhydrous THF (50 mL). 2-Octyn-1-ol (10.0 g, 79 mmol) dissolved in anhydrous THF (50 mL) was slowly added to the



SCHEME 1

magnetically stirred solution. The mixture was refluxed for 1 h and then stored overnight at room temperature. GC analysis indicated complete reduction of **2** to ***d*-3**. On cooling in an ice bath, heavy water (25 mL) was added drop by drop, followed by aqueous H_2SO_4 (4 N, 80 mL) to dissolve any insoluble residual materials. The organic phase was separated and the aqueous solution was then extracted with Et_2O (3 × 50 mL). The combined organic phases were washed successively with saturated solutions of $NaHCO_3$ (2 × 10 mL) and NaCl (2 × 10 mL), then dried over anhydrous Na_2SO_4. After removing the solvent by evaporation, 7.7 g (59 mmol, 75% yield) of a colorless oil of ***d*-3** with a purity of >97% (GC) was obtained. GC: RI (DB-5) = 1169, RI (OV-1701) = 1188, RI (FFAP) = 1617, RI (DB-WAX) = 1615. MS (EI) *m/z* (rel%): 130 (1, $[M]^+$), 112 (6, $[M-H_2O]^+$), 97 (7), 96 (5), 85 (8), 84 (10), 83 (37), 82 (18), 71 (11), 70 (25), 69 (32), 68 (23), 59 (100), 58 (40), 57 (32), 56 (48), 55 (33), 45 (32), 44 (16). The molecular ion was confirmed by PCI, isobutane, *m/z* (rel%): 113 (100, $[M - H_2O + H]^+$).

*[2,3-$^2H_2$]-(E)-2-Octenal (**d-4**) (Scheme 1, step b).* MnO_2 (20 g) was suspended in a solution of ***d*-3** (2.0 g, 15.4 mmol) in hexane (50 mL). Oxidation of ***d*-3** to ***d*-4** was complete after stirring the mixture at room temperature for 18 h. The mixture was filtered through a short pad of Celite to remove the remaining solid, and the Celite was washed with Et_2O. The solvent was removed by evaporation, obtaining 1.5 g (11.7 mmol, 75% yield) of a pale yellow oil of ***d*-4** without further purification. GC: RI (DB-5) = 1059, RI (OV-1701) = 1171, RI (FFAP) = 1428, RI (DB-WAX) = 1424. MS (EI) *m/z* (rel%): 128 (1, $[M]^+$), 127 (2), 113 (5), 110 (5, $[M - H_2O]^+$), 100 (12), 99 (32, $[M - CHO]^+$], 97 (5), 96 (5), 95 (7), 94 (10), 86 (18), 85 (84), 84 (34), 83 (40), 82 (15), 81 (8), 73 (8), 72 (55), 71 (58), 70 (100), 69 (48), 68 (24), 67 (22), 59 (56), 58 (35), 57 (60), 56 (48), 55 (68), 53 (7), 44 (15), 43 (36), 42 (52), 41 (93), 40 (12), 39 (32). The molecular ion was confirmed by PCI, isobutane *m/z* (rel%): 129 (100, $[M + 1]^+$), 128 (10, $[M]^+$), 111 (10, $[M + H - H_2O]^+$). ^{1}H NMR δ (ppm, C^2HCl_3): 9.51 (1:1:1, pattern typical for coupling to ^{2}H, $^3J_{1\text{-H},2\text{-}^2H}$ = 1.0 Hz, 0.9 H, intensity slightly reduced because of the long spin-lattice relaxation time T_1, 1-H); 2.33 (*t*, slightly broad, $^3J_{4\text{-H},5\text{-H}}$ = 7.5 Hz, 2 H, 4-CH_2), 1.52 ("quintet," $^3J_{avg}$ = 7.3 Hz, ≥2 H, 5-CH_2), 1.40–1.25 (*m*, complex, ≥4 H, 6-CH_2 and 7-CH_2), 0.91 ("*t*," *J* ~ 6.9 Hz, ≥3 H, 8-CH_3). Residual signals 6.85 (*t* 1:1:1, $^3J_{3\text{-H},4\text{-H}}$ = 6.7 Hz, $^3J_{3\text{-H},2\text{-}^2H}$ = 2.3 Hz, 0.07 H, 3-H) and 6.12 (*m*, $^3J_{1\text{-H},2\text{-H}}$ = 8.0 Hz and further couplings, 0.02 H, 2-H) indicated mono- or undeuterated (*E*)-2-octenal as byproducts that accounted for about 9%. No evidence for the occurrence of (*Z*) isomer was seen in the NMR spectrum. NOE-difference experiments with unlabeled (*E*)-2-octenal proved the spatial vicinity of the 1-CHO and 3-CH protons, indicating the all-*trans* arrangement of the C=C and C=O double bonds. ^{13}C NMR (proton decoupled) δ (ppm, C^2HCl_3): 194.21 (*d*, 1-CHO), 158.67 (*s* 1:1:1, $^1J_{C^2H}$ = 23.2 Hz, 3-C^2H), 132.59 (*s* 1:1:1, $^1J_{C^2H}$ = 24.5 Hz, 2-C^2H), 32.55 (*t*, 4-CH_2), 31.30 (*t*, 6-CH_2), 27.49 (*t*, 5-CH_2), 22.41 (*t*, 7-CH_2), 13.95 (*q*, 8-CH_3). These chemical shifts corresponded well to the spectrum of the unlabeled compound (26). Small signals for the residual nondeuterated 2-C and 3-C in about 1:3 ratio were observed at 132.89 (*d*) and 159.04 ppm (*d*), respectively. The NMR assignments above were based on our data of undeuterated (*E*)-2-octenal (not cited here), the assignments of which were in turn derived from those of natural abundance and 2,3-deuterated (*E*)-2-nonenal (22).

*[2,3-$^2H_2$]-trans-2,3-Epoxyoctanal (**d-5**). (Scheme 1, step **c**).* A two-necked flask (100 mL) equipped with a thermometer was charged with a solution of ***d*-3** (2.6 g, 20 mmol) in MeOH (25 mL). After cooling the solution to 1–3°C in an ice bath, 6.6 g of a 30% aqueous H_2O_2 solution (6 mL, 60 mmol) was added. The mixture was stirred vigorously and kept well cooled in the ice bath. Then, 40 µL of a 15% aqueous NaOH solution (0.15 mmol) was added in one portion. After 1 h reaction at 3–5°C, brine (30 mL) was added and the resulting suspension was extracted with CH_2Cl_2 (3 × 50 mL). The extracts were dried over Na_2SO_4, and the solvent was removed by distillation through a Vigreux column, obtaining 2.9 g (20.1 mmol, 99% yield) of *trans*-2,3-epoxyoctanal (***d*-5**) with a purity of 90% (GC). The sample, containing the corresponding *cis* isomer as main byproduct, was used as such for the Wittig reaction. GC: RI (DB-5) = 1093, RI (OV-1701) = 1218, RI (FFAP) = 1542, RI (DB-WAX) = 1533. MS (EI) *m/z* (rel%): 144 (1, $[M]^+$), 97 (3), 85 (3), 73 (100, $[M - C_5H_{11}]^+$), 72 (8), 69 (9), 59 (10), 57 (10), 56 (15), 55 (15), 45 (5), 43 (32), 42 (10), 41 (40), 40 (15), 39 (10). The molecular ions were confirmed by PCI, ammonia, *m/z* (rel%): 162 (100, $[M + NH_4]^+$), 146 (8, $[M + NH_4 - O]^+$); PCI, isobutane *m/z* (rel%): 145 (10, $[M + H]^+$), 129 (100, $[M + H - O]^+$), 128 (15), 127 (5, $[M + H - H_2O]^+$).

*[4,5-$^2H_2$]-trans-4,5-Epoxy-(E)-2-decenal (**d-1**) (Scheme 1, step **d**).* A solution of ***d*-5** (1.9 g, 13.2 mmol) in heptane (50 mL) was added to a suspension of formylmethylene triphenylphos-

phorane (4.1 g, 13.3 mmol) in heptane (50 mL). The reaction mixture was refluxed for 30 min. After cooling, the precipitated phosphorine oxide was filtered off. The filtrate was evaporated to remove the solvent. Four isomers of epoxydecenal were formed, with one predominant product: the *trans*-(*E*) isomer accounted for 87% of the total peak area. Major by-products were the *cis*-(*E*) and *trans*-(*Z*) isomers with 7 and 5%, respectively. Isomers were separated by CC using a glass column (20 × 2 cm) packed with a slurry of silica gel in hexane. Elution was carried out with hexane/Et_2O (95 + 5, vol/vol), collecting fractions of 10 mL. The target compound ***d*-1** was found by GC analysis in the fractions eluted from 200 to 400 mL. About 0.9 g (5.3 mmol, 40% yield) of the target compound was obtained as a colorless oil smelling intensely metallic with a purity of 95% [GC, 5% *cis*-(*E*) isomer]. GC: RI (DB-5) = 1380, RI (OV-1701) = 1558, RI (FFAP) = 2011, RI (DB-WAX) = 1995. MS, ^{1}H NMR, and ^{13}C NMR data are shown in Figure 1 and Tables 1–3.

Synthesis of trans-*4,5-Epoxy-(*E*)-2-decenal (**1**).* The unlabeled compound was prepared by adapting the procedure illustrated in Scheme 1 using commercially available (*E*)-2-octenal (**4**) as starting material.

trans-*2,3-Epoxyoctanal (**5**).* This was obtained in analogy to ***d*-5** by epoxidation of **4** (5.0 g, 40 mmol) with alkaline H_2O_2. About 5.1 g of **5** was obtained (36 mmol, 91% yield) by distillation under vacuum (130°C, 2 mbar) with a purity of 94% (GC). GC: RI (DB-5) = 1092, RI (OV-1701) = 1218, RI (FFAP) = 1540, RI (DB-WAX) = 1531. MS (EI) *m/z* (rel%): 142 (1, $[M]^+$), 95 (5), 83 (5), 72 (5), 71 (100, $[M - C_5H_{11}]^+$), 69 (15), 57 (25), 55 (50), 43 (35), 41 (65), 39 (20). The molecular ions were confirmed by PCI, ammonia, *m/z* (rel%): 160 (100, $(M + NH_4]^+$), 144 (5, $(M + NH_4–O]^+$); PCI, isobutane *m/z* (rel%): 143 (10, $(M + H]^+$), 127 (100, $(M + H - O]^+$), 125 (5, $[M + H - H_2O]^+$).

trans-*4,5-Epoxy*-(E)-*2-decenal* (**1**). This was obtained in analogy to ***d*-1** with 7.1 g (23 mmol) formylmethylene triphenylphosphorane and 3.3 g (23 mmol) of compound **5**. The *trans*-(*E*) isomer accounted for 92%, the *cis*-(*E*) isomer for 7% of the total peak area. After purification by CC using the same conditions as described above, about 1.5 g (8.9 mmol, 39% yield) of **1** was obtained as a colorless oil with a purity of 95% [GC, 5% *cis*-(*E*) isomer]. GC: RI (DB-5) = 1378, RI (OV-1701) = 1557, RI (FFAP) = 2010, RI (DB-WAX) = 1993. MS, ^{1}H NMR and ^{13}C NMR data are shown in Figure 1 and Tables 1–3.

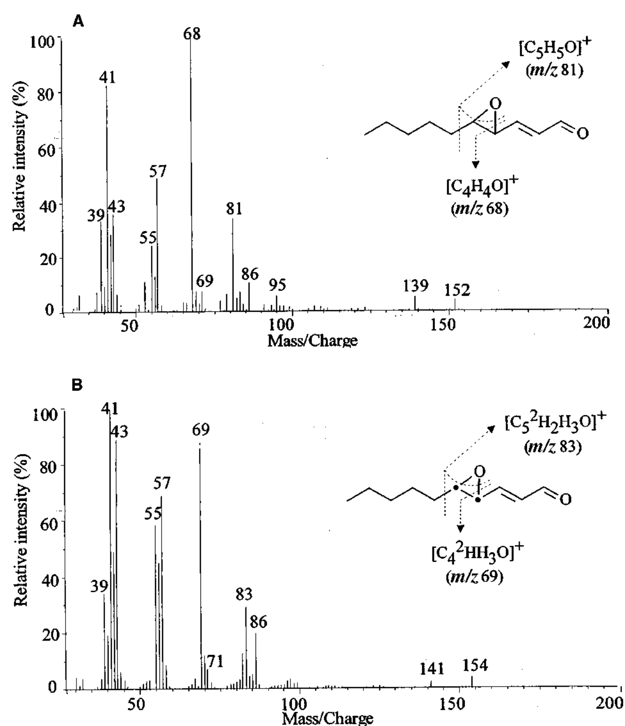


FIG. 1. Mass spectra of (A) *trans*-4,5-epoxy-(*E*)-2-decenal and (B) [4,5-$^2H_2$]-*trans*-4,5-epoxy-(*E*)-2-decenal obtained by electron impact ionization.

RESULTS AND DISCUSSION

*Preparation and characterization of [4,5-$^2H_2$]-*trans*-4,5-epoxy-(*E*)-2-decenal (**d-1**) and* trans-*4,5-epoxy-(*E*)-2-decenal (**1**). (i) Synthesis procedure.* The newly developed synthesis procedure for ***d*-1** is based on the preparation of deuterated (*E*)-2-octenal (***d*-4**) followed by *trans*-epoxidation to 2,3-epoxyoctanal (***d*-5**) and subsequent chain elongation by a Wittig-type reaction (Scheme 1). In general, the preparative procedures and purification techniques used were simple and the yields satisfactory. Deuteration of commercially available 2-octyn-1-ol (**2**) resulted in [2,3-$^2H_2$]-(*E*)-2-octen-1-ol (***d*-3**) in 75% yields. As recently shown, reduction of α-acetylenic alcohols with $LiAl^2H_4$ leads preferably to *trans*-configured olefinic alcohols (22). The high stereospecificity was explained by geometrical constraints of cyclic intermediate structures. Oxidation of the primary allylic alcohol ***d*-3** with MnO_2 led to the corresponding aldehyde (***d*-4**) in 75% yield. The reaction of ***d*-4** with alkaline H_2O_2 was nearly quantitative. The resulting labeled 2,3-epoxyoctanal (***d*-5**) was obtained as a mixture of *trans* and *cis* isomers in the ratio 9:1. Wittig reaction of ***d*-5** gave rise to a mixture of epoxydecenal isomers in about 50% yield. As major isomer, the target compound (***d*-1**) was separated from isomeric by-products by CC. Similarly, the unlabeled compound (**1**) was synthesized in a two-step procedure in good overall yields using (*E*)-2-octenal (**4**) as starting material.

(ii) Structure characterization by MS. MS–PCI data indicated the incorporation of two deuterium atoms in ***d*-1**, i.e., at *m/z* 171 ($[M + H]^+$), compared to *m/z* 169 for **1**, when using isobutane as reagent gas (Table 1). Similarly, MS–PCI (ammonia) resulted in *m/z* 188 for ***d*-1** compared to *m/z* 186 for **1**. These ions are represented by the species $[M + NH_4]^+$ with abundances of about 50–90%. Fragmentation of these ions resulted in two major products that correspond to $[M + NH_4 - O]^+$ (100%) and $[M + H - O]^+$ (~60%), suggesting that the molecular ions are unstable and readily lose oxygen. This phenomenon was also observed when using isobutane as reagent gas. Apart from the molecular ions at *m/z* 171 and 169, the major signals were at *m/z* 155 and 153, representing $[M + H - O]^+$ of the labeled and unlabeled compound, respectively.

Loss of oxygen also generated characteristic fragments in the

[a]Shifts in ppm from internal tetramethylsilane. Multiplicity abbreviations used to describe ^{1}H nuclear magnetic resonance (NMR) signals: *s* = singlet, *d* = doublet, *t* = triplet, *m* = complex multiplet. Quotation marks "…" mean approximate description of the multiplet.

MS–EI spectra, i.e., *m/z* 154 for ***d*-1** and *m/z* 152 for **1** (Fig. 1). In agreement with that, loss of oxygen has been reported for several 4,5-epoxy-2-alkenals of the chain length C_7–C_{11} (6). The fragment *m/z* 81 detected in the MS–EI spectra of this class of compounds, including **1**, is most likely a fragmentation product of $[M - O]^+$ with the composition C_5H_5O (12,27) that is formed by cleavage of the bonds at 5-C and 6-C. As ***d*-1** was labeled in the position 4-C and 5-C, the corresponding ion detected was *m/z* 83 with the composition $[C_5H_3{}^2H_2O]$. Therefore, the oxygen atom eliminated from the molecule is most likely originating from the oxirane ring.

However, the major ions did not reflect the shift of two units, i.e., *m/z* 69 and 68, which probably correspond to $[C_4{}^2HH_3O]^+$ and $[C_4H_4O]^+$, respectively. The data suggest that the said ions were generated by cleavage between 4-C and 5-C, which is in contrast to the fragmentation pattern proposed in the literature (6). Finally, the ions *m/z* 141 and 139 correspond to $[M - CHO]^+$. Loss of the aldehyde group has also been observed for 4,5-epoxy-2-heptenal (27) and 4,5-epoxy-2-nonenal (7).

(iii) Structure elucidation by NMR spectroscopy. NMR analysis was based on the non-deuterated compound **1**, for which a set of one- and two-dimensional spectra were acquired,

TABLE 3
^{13}C NMR Data of *trans*-4,5-Epoxy-(*E*)-2-decenal (1) and [4,5-$^2H_2$]-*trans*-4,5-Epoxy-(*E*)-2-decenal (*d*-1)[a]

Carbon	1	*d*-1
1-CHO	192.58, *d*	192.60, *d*

including proton NOE difference spectra, COSY, and HETCOR for direct carbon-proton couplings. The structure of **1** could be confirmed, as shown in Tables 2 and 3. The coupling constant $J_{2\text{-H},3\text{-H}}$ 15.7 Hz revealed the *trans* configuration of the carbon-carbon double bond. In analogy to literature values on α-epoxy alcohols (28), the coupling constant $J_{4\text{-H},5\text{-H}} = 2.1$ Hz suggested a *trans* form of the oxirane ring. NOE-difference experiments with 10-s pre-irradiation and 4.23-s acquisition periods yielded signal enhancements, i.e., irradiation of 4-H: 7% on 2-H, 3% on 3-H, and 1.8% on 6-CH_2; irradiation of 5-H: 4.7% on 3-H, 2.2% on 2-H, and 1.4% on both 5-CH_2 and 6-CH_2. The absence of an NOE between 4-H and 5-H confirmed the *trans* arrangement of the oxirane ring. These NOE-difference results also suggested a non-coplanar arrangement of the enal group with respect to the oxirane ring. For the enal group, an all-*trans* conformation could be assumed, based on the close similarity of the $^3J_{1\text{-CHO},2\text{-H}}$ coupling constant in **1** and in (*E*)-2-octenal.

The NMR spectra also indicated the presence of about 7% of an isomer. Among the clearly distinguished, isolated ^{1}H-NMR signals of this isomer (between 10 and 2 ppm), the shifts of the putative 4- and 5-protons deviated more from the shifts of the main compound than those of any other proton. The coupling patterns of those same protons were the only ones to change, whereas the couplings of the 1-CHO and 3-H signals were practically the same for both isomers. The isomer is therefore presumably *cis*-4,5-epoxy-(*E*)-2-decenal. The low-field deviations (*ca.* 0.3 ppm) of the 4-H and 5-H signals could also indicate *cis* substitution of the oxirane ring, according to the shift rules established by Pierre *et al.* (28) for α-epoxy alcohols. Complete data for this second isomer were not available because of signal overlap with the dominating compound (especially for the 2-H and the aliphatic signals in the proton spectrum).

Both the ^{1}H NMR data of **1** in Table 2 and the ^{13}C-NMR data in Table 3 were in good agreement with those recently reported by Zamora and Hidalgo (12). The data of **1** are only given in this paper for closer comparison with the deuterated analog ***d*-1** that is reported for the first time. Other ^{1}H-NMR results on **1** (6) are not directly comparable with ours because of a different solvent used ($C^2H_2Cl_2$). Earlier ^{1}H NMR data of *trans*-4,5-epoxy-(*E*)-2-heptenal in C^2HCl_3 (27) are well compatible with ours on **1** for the unsaturated and oxirane part of the molecule, considering the different experimental temperature (35°C) and eventual concentration effects.

The NMR spectra of ***d*-1** clearly demonstrated a nearly quantitative deuteration at 4-C and 5-C (e.g., absence of couplings $^3J_{3\text{-H},4\text{-H}}$ and $^3J_{5\text{-H},6\text{-H}}$ on the 3-H and 6-H proton signals, characteristic deuterium patterns in the ^{13}C NMR spectrum). The proton spectrum indicated about 98 and 93% deuterium substitution, respectively. No undeuterated **1** could be detected in the proton spectrum. As in **1**, about 7% of the putative, equally 4,5-deuterated *cis* isomer were found in ***d*-1**, i.e., [4,5-$^2H_2$]-*cis*-4,5-epoxy-(*E*)-2-decenal.

Quantification of trans*-4,5-epoxy-(*E*)-2-decenal by IDA. (i) Mass spectra obtained by various ionization techniques.* The characteristic ions $[M - O]^+$ at *m/z* 152 (**1**) and 154 (***d*-1**) were not sufficiently abundant for quantification by IDA (Fig. 1). The $[M - CHO]^+$ fragments at *m/z* 139 and 141, showing the mass difference of two units, were also too weak. On the other hand, the more abundant ions were less characteristic (e.g., *m/z* 81/83, 55/57, 41/43) or they did not reflect the shift of two mass units (*m/z* 68/69). As no characteristic ions with sufficient abundance could be found in the MS–EI spectra of **1** and ***d*-1**, further ionization modes were tested to evaluate their suitability for IDA.

GC–MS using chemical ionization is known as a soft ionization method generating abundant molecular ions that are most characteristic of the compound to be analyzed. PCI using ammonia as a reagent gas resulted in characteristic and abundant ions for **1** and ***d*-1** (Table 1), i.e., at *m/z* 186/188 (~60–90%), 170/172 (100%), and 153/155 (~60%), respectively. The PCI spectra with isobutane generated mainly the ions at *m/z* 153/155 (100%). The NCI spectra of **1** and ***d*-1** obtained with ammonia and isobutane revealed abundant ions at *m/z* 97/99 (100%) which represent the characteristic part of the molecules. They correspond to the species $[C_5H_5O_2]^-$ and $[C_5H_3{}^2H_2O_2]^-$, respectively. Fragments formed by loss of oxygen ($[M - O]^-$) were also found, particularly when ionized with isobutane, i.e., at *m/z* 152 and 154. All these ions were estimated as suitable for IDA, and those finally selected were *m/z* 170/172 (PCI/ammonia), 153/155 (PCI/isobutane), and 97/99 (NCI with either ammonia or isobutane).

(ii) Sensitivity. Decreasing amounts of mixtures containing the analyte (**1**) and internal standard (***d*-1**) were analyzed by PCI and NCI in the SIM detection mode using isobutane or ammonia as reagent gas (Fig. 2). In general, NCI was found to result in more abundant signals than PCI. The sensitivity could further be improved when replacing isobutane by ammonia as a reagent gas. Signal-to-noise ratios (S/N) revealed NCI/ammonia as the most suitable method for the quantitative analysis of **1** (Fig. 2). The detection limit was determined to be at about 1 pg injected into the ion source with an acceptable S/N ratio of 3 (Table 4). PCI/isobutane was about 200 times less sensitive (detection limit: ~200 pg) whereas PCI/ammonia and NCI/isobutane gave comparable results, i.e., a detection limit of about 10 and 20 pg, respectively.

(iii) Selectivity. In addition to the high sensitivity, the NCI technique was also found to significantly improve selectivity in the detection of **1** and ***d*-1** (Fig. 3). When analyzing an aroma extract obtained from heated egg PE, no interferences were detected with NCI using either isobutane or ammonia. On the contrary, PCI resulted in further peaks, thus complicating data interpretation and calculation of reliable values. Therefore, NCI can be suggested as an ideal ionization technique for the quantitative analysis of **1**, particularly when using ammonia as a reagent gas.

(iv) Calibration curves. The calibration curve was established using mixtures containing defined amounts of analyte (**1**) and labeled internal standard (***d*-1**) in different ratios by measuring the characteristic ions of **1** and ***d*-1** (4). The ions indicated in Table 4 were monitored in the SIM mode. Linear curves were obtained for all of the ionization modes tested. As an example, the calibration curve using NCI/ammonia is presented in Figure 4A. Similar curves were obtained for the other ionization modes

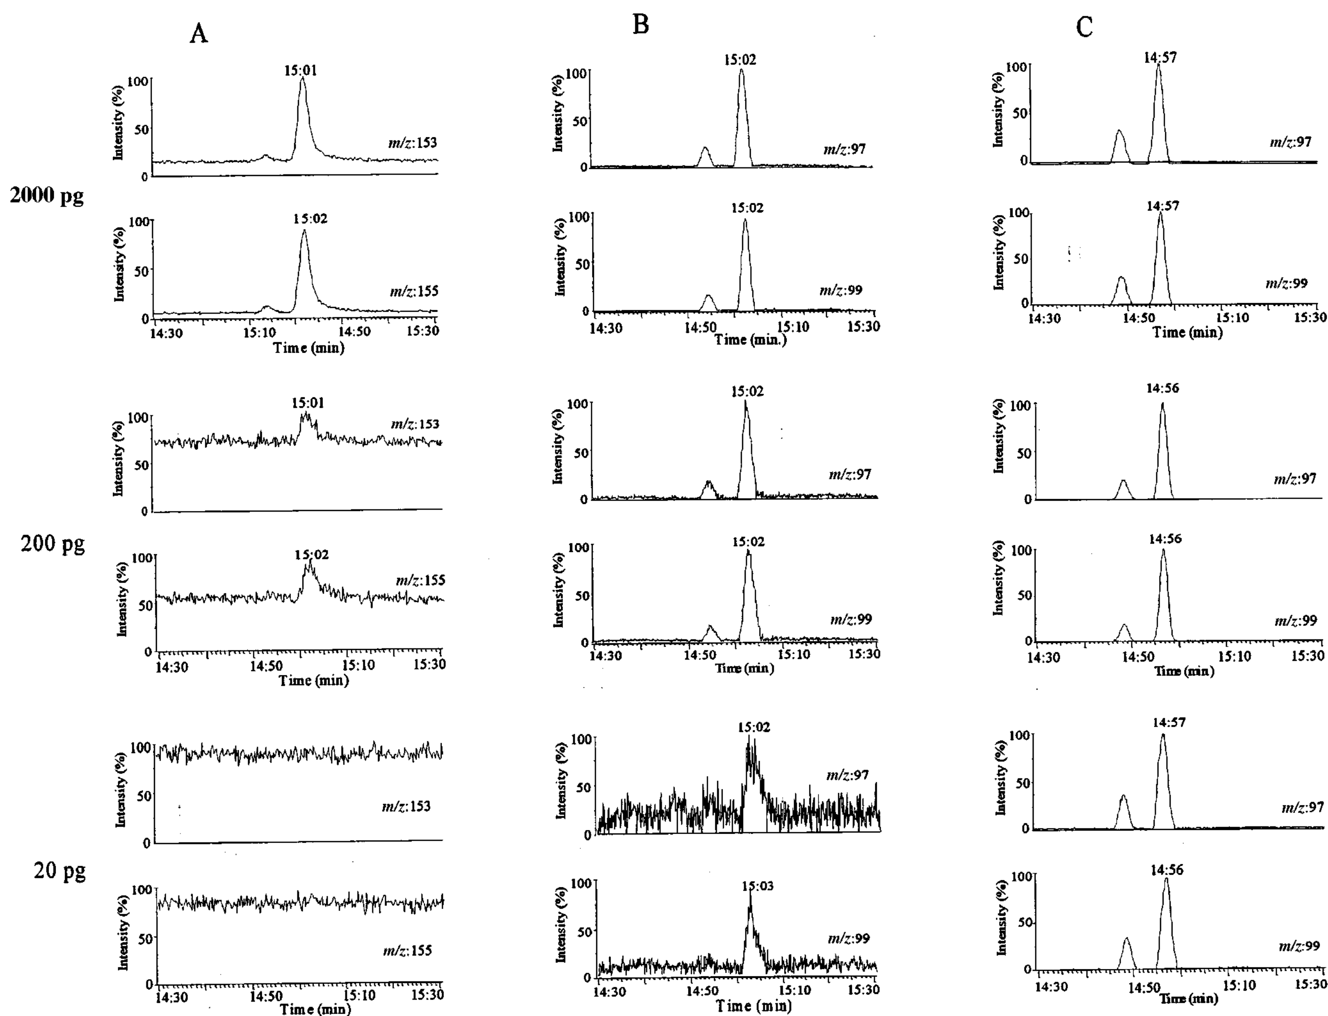

FIG. 2. Traces of decreasing amounts (2000, 200, and 20 pg) of *trans*-4,5-epoxy-(*E*)-2-decenal (**1**) and [4,5-$^2H_2$]-*trans*-4,5-epoxy-(*E*)-2-decenal (***d*-1**) using various ionization techniques in the selected ion monitoring (SIM) mode. (A) Positive chemical ionization (PCI), isobutane; (B) negative chemical ionization (NCI), isobutane; (C) NCI, ammonia. The major peak represents the *trans* isomer, the minor peak the *cis* isomer of **1** and ***d*-1**.

tested, i.e., $y = 0.8404x + 0.155$, $r^2 = 0.9952$ (PCI/isobutane), $y = 0.7181x + 0.1121$, $r^2 = 0.9966$ (PCI/ammonia), and $y = 0.6365x + 0.0732$, $r^2 = 0.9985$ (NCI/isobutane). It should be pointed out, however, that if the amount ratios were extended to values higher than 10, second-order curves were obtained because of the natural deuterium isotope peaks of **1**, which coincide with the acquired ions of ***d*-1** (29).

The accuracy of the measured values with the theoretical values was checked according to the procedure described by Staempfli and coworkers (30). On the basis of knowing the amount of **1** and ***d*-1** in the mixture, the theoretical enrichment of ***d*-1** was calculated for each calibration point and expressed in mol percent excess (MPE). The measured deuterium enrichment was plotted vs. theoretical deuterium enrichment, resulting in linear curves for the four ionization modes (see example with NCI/ammonia in Fig. 4B). The slopes of the calibration curves were close to 1.000 proving the accuracy of the measurement, i.e., 0.9558 (PCI/isobutane), 0.9723 (PCI/ammonia), and 0.9029 (NCI/isobutane). The observed differences might be due to chemical impurity of **1**, chemical and isotopic impurities of ***d*-1**, and slight variation in the fragmentation pattern of **1** and ***d*-1**.

Quantification of trans-*4,5-epoxy-(*E*)-2-decenal (1) in heated phospholipids.* The linear ranges shown in Table 4 of the calibration curves were used to quantify **1** in heated aqueous dispersions of egg PC. Comparison of the data obtained from the same sample by the four ionization modes revealed good agreement in the results (Table 4), i.e., 1.61–1.67 μg **1** per g PC with an average of 1.64 ± 0.02, which correspond to a variation coefficient of less than 2%. As IDA has already been shown to be an accurate method for the quantification of **1** (4,9,10), the use of NCI/ammonia represents a significant improvement in terms of higher sensitivity and selectivity, thus allowing reduction of sample preparation time by applying simple cleanup procedures.

Conclusions. The newly developed synthesis procedure allows the preparation of both [4,5-$^2H_2$]-*trans*-4,5-epoxy-(*E*)-2-

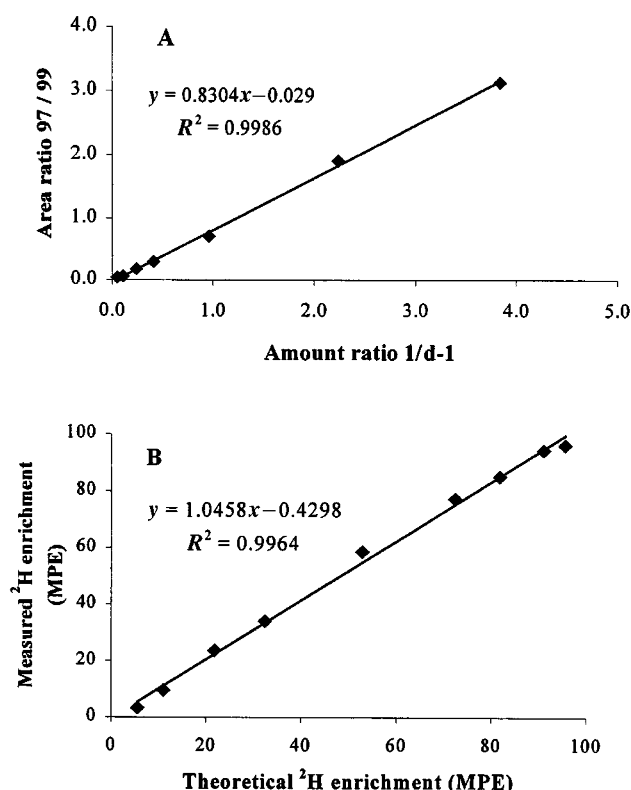

FIG. 4. (A) Calibration curve obtained for the quantification of *trans*-4,5-epoxy-(*E*)-2-decenal (**1**) using the ionization technique NCI/ammonia. The **1/*d*-1** ratios were 0.05, 0.11, 0.25, 0.43, 1.0, 2.33, 4.0, and 9.0. (B) Determination of the accuracy of the calibration curve obtained by using the ionization technique NCI/ammonia. The theoretical enrichments were calculated according to Wolfe (29) using known amounts of labeled and unlabeled *trans*-4,5-epoxy-(*E*)-2-decenal (**1**). MPE, mol percent excess; for other abbreviation see Figure 2.

using ammonia as a reagent gas. The low detection limit of 1–10 pg combined with increased selectivity by NCI are interesting features for obtaining reliable quantitative data of **1** and similar labile epoxyaldehydes at low concentration levels in complex mixtures allowing simplified clean-up procedures.

ACKNOWLEDGEMENT

We are grateful to Mrs Francia Arce Vera and Sylviane Metairon for expert technical assistance and Dr. Elizabeth Prior for critical proofreading of the manuscript.

ARTICLE

An Epoxy Alcohol Synthase Pathway in Higher Plants: Biosynthesis of Antifungal Trihydroxy Oxylipins in Leaves of Potato

Mats Hamberg*

Department of Medical Biochemistry and Biophysics, Division of Physiological Chemistry II, Karolinska Institutet, S-171 77 Stockholm, Sweden

ABSTRACT: [1-^{14}C]Linoleic acid was incubated with a whole homogenate preparation of potato leaves (*Solanum tuberosum* L., var. Bintje). The methyl-esterified product was subjected to straight-phase high-performance liquid chromatography and was found to contain four major radioactive oxidation products, i.e., the epoxy alcohols methyl 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoate (14% of the recovered radioactivity) and methyl 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoate (14%), and the trihydroxy derivatives methyl 9(*S*),10(*S*),11(*R*)-trihydroxy-12(*Z*)-octadecenoate (18%) and methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoate (30%). The structures and stereochemical configurations of these oxylipins were determined by chemical and spectral methods using the authentic compounds as references. Incubations performed in the presence of glutathione peroxidase revealed that lipoxygenase activity of potato leaves generated the 9- and 13-hydroperoxides of linoleic acid in a ratio of 95:5. Separate incubations of these hydroperoxides showed that linoleic acid 9(*S*)-hydroperoxide was metabolized into epoxy alcohols by particle-bound epoxy alcohol synthase activity, whereas the 13-hydroperoxide was metabolized into α- and γ-ketols by a particle-bound allene oxide synthase. It was concluded that the main pathway of linoleic acid metabolism in potato leaves involved 9-lipoxygenase-catalyzed oxygenation into linoleic acid 9(*S*)-hydroperoxide followed by rapid conversion of this hydroperoxide into epoxy alcohols and a slower, epoxide hydrolase-catalyzed conversion of the epoxy alcohols into trihydroxy-octadecenoates. Trihydroxy derivatives of linoleic and linolenic acids have previously been reported to be growth-inhibitory to plant-pathogenic fungi, and a role of the new pathway of linoleic acid oxidation in defense reactions against pathogens is conceivable.

Oxylipins constitute a family of oxygenated derivatives of fatty acids. Hydroperoxides, formed from fatty acids by action of lipoxygenases (1,2) or α-dioxygenase (3), serve as important primary products in oxylipin formation. Further conversion of the hydroperoxides into various compounds belonging to the plant oxylipin family is catalyzed by the enzymes allene oxide synthase, divinyl ether synthase, hydroperoxide lyase, peroxygense, vicinal diol synthase, and epoxy alcohol synthase (4–7). One specific lipoxygenase product, i.e., the 13(*S*)-hydroperoxide derivative of linolenic acid, is of special importance because of its precursor role in the biosynthesis of 12-oxo-10,15(*Z*)-phytodienoic acid and the plant hormone jasmonic acid (2,5,8).

Certain oxylipins are involved as mediators in plants' defensive reactions against pathogens and also exert a direct inhibitory effect on the growth of pathogenic fungi. Leaves are the most important site of attack by plant pathogens, and knowledge about the pathways of oxylipin biosynthesis and metabolism in leaf tissue is therefore a prerequisite for understanding the roles of oxylipins in plant–pathogen interactions. This paper is concerned with a new oxylipin pathway in green leaves consisting of sequential oxidation of linoleic and linolenic acids into fatty acid epoxy alcohols and trihydroxy fatty acids.

EXPERIMENTAL PROCEDURES

Plant materials. Potato (*Solanum tuberosum* L., var. Bintje) was grown in soil under a 16-h light/8-h dark photoperiod. Leaves of 2–5-wk-old plants were used.

Fatty acids. Linoleic, linolenic, and oleic acids were purchased from Nu-Chek-Prep (Elysian, MN). [1-^{14}C]Linoleic, [1-^{14}C]linolenic, and [9,10-$^{3}H_2$]oleic acids (Du Pont NEN, Boston, MA) were mixed with the corresponding unlabeled acids and purified by SiO_2 chromatography to afford specimens with specific radioactivities of 4.6, 6.7, and 184 kBq/μmol, respectively. [1-^{14}C]9(*S*)-Hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid [9(*S*)-HPOD] and [1-^{14}C]13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid [13(*S*)-HPOD] were prepared by incubation of linoleic acid with tomato lipoxygenase (9) and soybean lipoxygenase (10), respec-

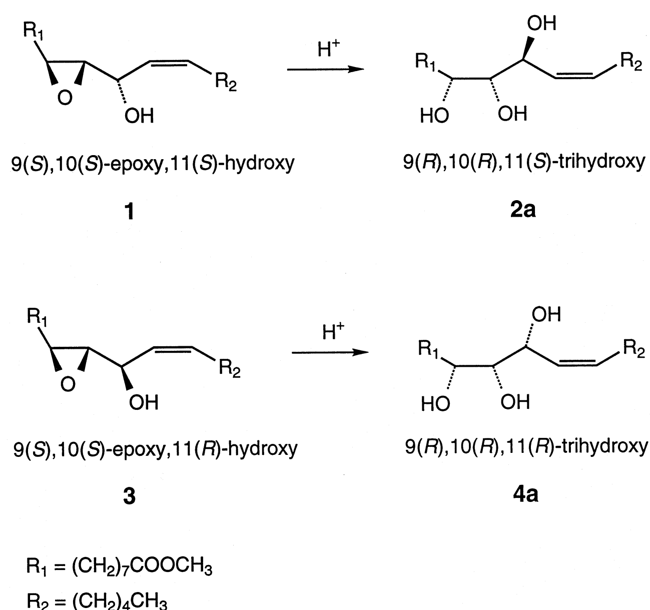
tively. The ketols methyl 13-hydroxy-12-oxo-9(*Z*)-octadecenoate and methyl 9-hydroxy-12-oxo-10(*E*)-octadecenoate were obtained by incubation of 13(*S*)-HPOD with allene oxide synthase from corn followed by isolation of the methyl esters by thin-layer chromatography (TLC) (11).

*Methyl 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoate (**13**) and methyl 10(*R*),11(*R*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoate*. The title compounds were prepared from the methyl ester of 9(*S*)-HPOD by vanadium-catalyzed epoxidation as described in detail elsewhere (12,13).

*Methyl 9(*S*),10(*S*)-epoxy-11(*S*)-hydroxy-12(*Z*)-octadecenoate (**1**) and methyl 9(*S*),10(*S*)-epoxy-11(*R*)-hydroxy-12(*Z*)-octadecenoate (**3**)*. 9(*S*)-HPOD (23 mg) in ethanol (0.5 mL) was treated with a solution of bovine hemoglobin (2.5 g) in 0.1 M potassium phosphate buffer pH 7.4 (50 mL) at 37°C for 10 min (*cf.* Ref. 14). The solution was acidifed to pH 3 and kept at this pH for 3 min in order to hydrolyze the allylic epoxy alcohol 9,10-epoxy-13-hydroxy-11-octadecenoic acid into trihydroxy acids and in this way facilitate isolation of the nonallylic epoxy alcohols. Material extracted with diethyl ether was methyl-esterified by treatment with diazomethane and subjected to TLC using solvent system B, described below in the paragraph on "Chromatographical methods." Bands appeared due to methyl 9-oxooctadecadienoate, methyl 9-hydroxyoctadecadienoate, and methyl trihydroxyoctadecenoates as well as **1** (nonallylic *erythro* epoxy alcohol; R_f 0.53; approx. 9% of the product) and **3** (nonallylic *threo* epoxy alcohol; R_f 0.48; approx. 14% of the product) (Scheme 1) (bold Arabic numbers represent methyl esters of epoxy alcohol and trihydroxy fatty acids. Enantiomers are designated by **a** or **b**). The two latter compounds were recovered from the silica gel and further purified by reversed-phase high-performance liquid chromatography (RP-HPLC) using a solvent system of acetonitrile/water (60:40, vol/vol) (Table 1). The mass spectra of the Me_3Si derivatives of **1** and **3** were very similar. Prominent ions in the mass spectrum of the derivative of **1** were observed at *m/z* 383 (2%; $M^+ - 15$; loss of $\cdot CH_3$), 277 [1; $M^+ - (90 + 31)$; loss of Me_3SiOH plus $\cdot OCH_3$], 241 [3; $M^+ - 157$; loss of $\cdot(CH_2)_7$-$COOCH_3$], 212 (10),



SCHEME 1

199 [91; Me_3SiO^+=CH–CH=CH–$(CH_2)_4$–CH_3], 155 [40; tentatively HO^+=CH–$(CH_2)_6$–CH=C=O formed by cleavage of the C-9/C-10 bond and loss of CH_3OH], 129 (38; Me_3SiO^+=CH–CH=CH_2), and 73 (100; Me_3Si^+). Fourier transform infrared (FTIR) spectrometry of **1** and **3** showed bands at 3460 cm^{-1} (alcohol), 1741 cm^{-1} (ester carbonyl), and 903 cm^{-1} (*trans* epoxide). It has been shown earlier for the two *trans*-12,13-epoxy-11-hydroxyoctadecenoates produced from 13(*S*)-HPOD upon treatment with hemoglobin that the less polar diastereomer has the *erythro* relative configuration at C-11/C-12, whereas the more polar one is *threo* (14,15). In order to confirm the relative configurations of C-10/C-11 of **1** and **3** obtained from 9(*S*)-HPOD, aliquots of the hydrogenated derivatives (**14** and **17**, respectively) were deoxygenated by treatment with triphenylphosphine selenide and trifluoroacetic acid (15). The (–)-menthoxycarbonyl (MC) derivatives of the resulting methyl 11-hydroxy-9(*E*)-octadec-

TABLE 1
Chromatographic Properties of Epoxy Alcohols

Compound[a]	GLC[b]	SP-HPLC[c]	RP-HPLC[d]
Methyl 9(*S*),10(*S*)-epoxy-11(*S*)-hydroxy-12(*Z*)-octadecenoate (**1**)	20.76	12.0	22.8
Methyl 9(*S*),10(*S*)-epoxy-11(*R*)-hydroxy-12(*Z*)-octadecenoate (**3**)	20.75	15.7	20.4
Methyl 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoate (**13**)	20.85	8.9	26.1
Methyl 10(*R*),11(*R*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoate	20.76	12.9	22.1
Methyl 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoate	21.28	34.7	18.0
Compound **I**	20.85	8.9	26.1
Compound **II**	21.28	34.7	18.0

[a]Bold numbers designate methyl esters of epoxy alcohol and trihydroxy fatty acids. Compound **I**, methyl 10(*S*),11(*S*)-epoxy-9(*S*)hydroxy-12(*Z*)-octadecenoate; compound **II**, methyl 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoate.
[b]The retention times found on gas–liquid chromatography (GLC; column temp., 230°C) are expressed as C-values (*cf.* Ref. 20).
[c]Retention volumes (mL) using a solvent system of 2-propanol/hexane (1:99, vol/vol) are given. SP-HPLC, straight-phase high-performance liquid chromatography.
[d]Retention volumes (mL) using a solvent system of acetonitrile/water (60:40, vol/vol) are given. RP-HPLC, reversed-phase HPLC.

enoates were subjected to oxidative ozonolysis, and the configurations of the resulting 2-hydroxynonanoates (MC derivatives) were established by gas–liquid chromatography (GLC) using the authentic derivatives as references (16). It was found that **1** produced 2(*S*)-hydroxynonanoate, thus proving that this epoxy alcohol had the *S* configuration at C-11. This result combined with the configuration of C-9 (*S*) and the geometry of the epoxide group (*trans*) showed that the relative configuration of C-10/C-11 of **1** was *erythro*. In the same way, **3** produced 2(*R*)-hydroxynonanoate, and thus had the *R* configuration at C-11 and the *threo* relative configuration at C-10/C-11 (Scheme 1).

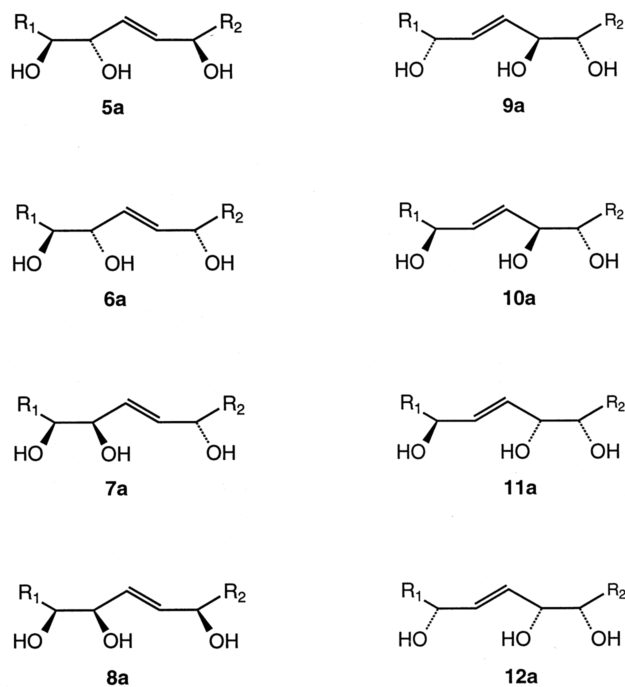
*Methyl 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoate*. Either of three enzymes could be used to prepare 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoic acid and its methyl ester from 9(*S*)-HPOD, i.e., epoxy alcohol synthase from the fungus *Saprolegnia parasitica* (13), peroxygenase from seeds of broad bean (17), or peroxygenase from oat seeds (18). The biosynthesized epoxy alcohol was isolated as its methyl ester by TLC (solvent system B, R_f 0.39) followed by straight-phase HPLC (SP-HPLC) [solvent system, 2-propanol/hexane (1:99, vol/vol); effluent volume, 34.7 mL].

*Methyl 9(*R*),10(*R*),11(*S*)-trihydroxy-12(*Z*)-octadecenoate (***2a***)*. *erythro*-Epoxy alcohol **1** (1 mg) was dissolved in 50% aqueous tetrahydrofuran (2 mL), and 70% perchloric acid (0.2 mL) was added. The solution was kept at 23°C for 1 h and subsequently extracted with diethyl ether. Analysis by TLC using solvent system A, described below in the paragraph on "Chromatographic methods." showed the presence of a major trihydroxyester (**2a**; R_f 0.72). The Me_3Si derivative of **2a** had a C-value of 22.30 and a mass spectrum which showed prominent ions at *m/z* 560 (0.5%; M^+), 361 (26; M^+ – 199), 313 [5; M^+ – (157 + 90); loss of $\cdot(CH_2)_7$-$COOCH_3$ plus Me_3SiOH], 301 (1; M^+ – 259); 271 (100; 361 – 90), 259 [12; Me_3SiO^+=CH–$(CH_2)_7$–$COOCH_3$], 199 [15; Me_3SiO^+=CH–CH=CH–$(CH_2)_4$–CH_3], 147 (15; Me_3Si–O^+=$SiMe_2$), and 73 (80; Me_3Si^+). In another experiment, **2a** was prepared by treatment of **1** with perchloric acid in tetrahydrofuran/$H_2{}^{18}O$. Mass spectrometric analysis of the Me_3Si derivative of **2a** obtained in this way demonstrated a shift of the ions *m/z* 259 and 361 to 261 and 363, respectively, whereas the ions *m/z* 199 and 301 remained unchanged. This result showed that formation of **2a** from **1** occurred by solvent attack and epoxide opening at C-9 (with inversion of the configuration of that carbon). Consequently, **2a** could be assigned the structure methyl 9(*R*),10(*R*),11(*S*)-trihydroxy-12(*Z*)-octadecenoate (Scheme 1).

*Methyl 9(*R*),10(*R*),11(*R*)-trihydroxy-12(*Z*)-octadecenoate (***4a***)*. *threo*-Epoxy alcohol **3** (1 mg) was hydrolyzed by treatment with perchloric acid, and the major trihydroxyester (**4a**; R_f 0.59) was isolated by TLC as described for **2a**. The C-value of the Me_3Si derivative was 22.47, and the mass spectrum was closely similar to that of the corresponding derivative of **2a**. Hydrolysis carried out with $H_2{}^{18}O$ resulted in incorporation of ^{18}O in the C-9 position, demonstrating that the configuration of this carbon was inverted in the formation of **4a** from **3** (Scheme 1).

*Methyl 9,10,13-trihydroxy-11(*E*)-octadecenoates and methyl 9,12,13-trihydroxy-10(*E*)-octadecenoates (***5a–12a***)*. Methyl 9,10,13- and 9,12,13-trihydroxyoctadecenoates with defined configurations at C-9 to C-13 (eight diastereomers; Scheme 2) were prepared by chemical hydrolysis of diastereomeric methyl 10,11-epoxy-9-hydroxyoctadecenoates and methyl 11,12-epoxy-13-hydroxyoctadecenoates as decribed in detail (12). Methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoate (**10a**) was also prepared by enzymatic hydrolysis of 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoic acid (18).

*Methyl 9(*S*),10(*S*),11(*R*)-trihydroxy-12(*Z*)-octadecenoate (***2b***) and methyl 9(*S*),10(*S*),11(*S*)-trihydroxy-12(*Z*)-octadecenoate (***4b***)*. Allylic *erythro* epoxy alcohol **13** (1 mg) was dissolved in 67% aqueous tetrahydrofuran (3 mL) and treated with 2 M hydrochloric acid (10 µL). After 3 min at 23°C, the solution was extracted with diethyl ether and subjected to TLC using solvent system A. In analogy with previous results obtained for epoxy alcohols generated from 13(*S*)-HPOD (19), this led to the appearance of two bands due to methyl 9,10,13-trihydroxy-11(*E*)-octadecenoates epimeric at C-13 [**7a** (R_f 0.38) and **8a** (R_f 0.47)] as well as two weaker bands due to methyl 9,10,11-trihydroxy-12(*Z*)-octadecenoates epimeric at C-11 [**2b** (R_f 0.72) and **4b** (R_f 0.59)] (Scheme 3). Hydrolysis of epoxy alcohol **13** carried out in tetrahydrofuran/$H_2{}^{18}O$ resulted in the formation of 9,10,11-trihydroxyoctadecenoates, which had incorporated ^{18}O at C-11 but not at C-9 or C-10. This was apparent from the mass spectra of the Me_3Si derivatives, in which the ion *m/z* 199 was shifted to



$R_1 = (CH_2)_7COOCH_3$
$R_2 = (CH_2)_4CH_3$

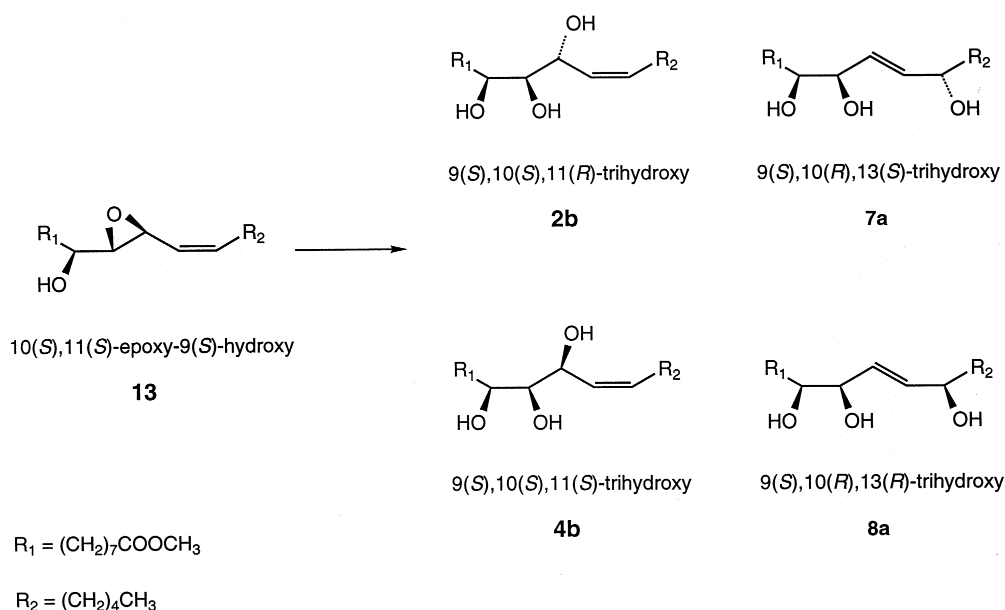
SCHEME 2

201, whereas the ions *m/z* 259 and 361 were not affected. Thus, in the formation of **2b** and **4b** from **13**, epoxide opening took place at C-11 (with or without inversion of absolute configuration), and the C–O bonds at C-9 and C-10 remained intact. Consequently, the two 9,10,11-trihydroxyoctadecenoates had the *S* configuration at C-9 and C-10, and were epimeric at C-11. Assignment of the absolute configuration at this carbon was made possible by chromatographic matching of **2b** and **4b** obtained from **13** with the 9(*R*),10(*R*),11(*S*)-trihydroxyoctadecenoate (**2a**) and the 9(*R*),10(*R*),11(*R*)-trihydroxyoctadecenoate (**4a**) prepared from **1** (Scheme 1). **2b** obtained from **13** was found to cochromatograph with **2a** on TLC (R_f 0.72) and GLC (C-value, 22.30); consequently **2b** could be identified as 9(*S*),10(*S*),11(*R*)-trihydroxy-12(*Z*)-octadecenoate. In the same way, **4b** formed from **13** had chromatographic properties identical to **4a** (R_f 0.59, C-22.47) and was therefore identical to 9(*S*),10(*S*),11(*S*)-trihydroxy-12(*Z*)-octadecenoate (Scheme 3).

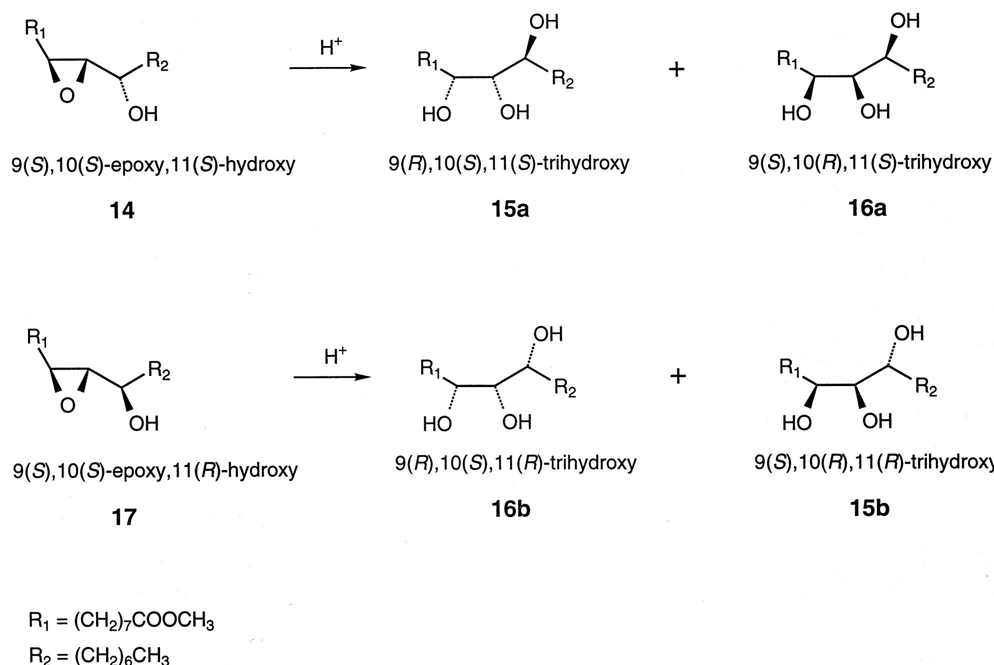
*Methyl 9(*R*),10(*S*),11(*S*)-trihydroxyoctadecanoate (***15a***) and methyl 9(*S*),10(*R*),11(*S*)-trihydroxyoctadecanoate (***16a***).* Epoxy alcohol **1** (2 mg) was hydrogenated and the resulting dihydro derivative (**14**) was dissolved in 50% aqueous tetrahydrofuran (2 mL) and treated with 70% perchloric acid (0.2 mL) at 23°C for 1 h. Analysis of the trimethylsilylated product by GLC showed the presence of two diastereomeric trihydroxyesters, i.e., **15a** (95%; C-22.77) and **16a** (5%; C-22.69) (Scheme 4). The mass spectra recorded on these compounds were closely similar and showed ions at *m/z* 531 (0.1%; $M^+ - 31$; loss of $\cdot OCH_3$), 434 [8; $M^+ - 128$; rearrangement with loss of OHC–$(CH_2)_6$–CH_3], 373 [7; $M^+ - (99+90)$; loss of $\cdot(CH_2)_6$-CH_3 plus Me_3SiOH], 303 (12; $M^+ - 259$), 259 [88; Me_3SiO^+=CH–$(CH_2)_7$–$COOCH_3$], 201 [63; Me_3SiO^+=CH–$(CH_2)_6$–CH_3], 155 [23; OHC–$(CH_2)_7$–C≡O^+], and 73 (100; Me_3Si^+). In a separate experiment, **14** was treated with perchloric acid in the presence of $H_2{}^{18}O$. Mass spectrometric analysis revealed that this led to the formation of trihydroxyesters **15a** and **16a,** which had incorporated one atom of ^{18}O at C-9 and C-10, respectively. Accordingly, **15a**, the major trihydroxyester, was formed from **14** by solvent attack at C-9 (with inversion of the configuration of that carbon) and had the structure methyl 9(*R*),10(*S*),11(*S*)-trihydroxyoctadecanoate. In the same way, the minor trihydroxyester (**16a**) was formed by epoxide opening at C-10 and was due to methyl 9(*S*),10(*R*),11(*S*)-trihydroxyoctadecanoate (Scheme 4).

*Methyl 9(*R*),10(*S*),11(*R*)-trihydroxyoctadecanoate (**16b**) and methyl 9(*S*),10(*R*),11(*R*)-trihydroxyoctadecanoate (**15b**).* Catalytic hydrogenation of epoxy alcohol **3** into the dihydro derivative **17** followed by perchloric acid-catalyzed hydrolysis afforded two diastereomeric 9,10,11-trihydroxyoctadecanoates, i.e., **16b** (90%; C-22.69) and **15b** (10%; C-22.77). Hydrolysis carried out in the presence of $H_2{}^{18}O$ afforded **16b** and **15b** which were labeled with ^{18}O at C-9 and C-10, respectively. Consequently, the configurations of these trihydroxyoctadecanoates were 9(*R*),10(*S*),11(*R*) (**16b**) and 9(*S*),10(*R*),11(*R*) (**15b**) (Scheme 4).

Enzyme preparations. Potato leaves were minced and homogenized at 0°C in 0.1 M potassium phosphate buffer pH 7.4 (1:10, wt/vol) with an Ultra-Turrax. The homogenate was filtered through gauze, and the filtrate (protein, 1.5 mg/mL) was directly used for the incubations. In some experiments, the filtrate was centrifuged at 1,100 × *g* for 15 min to afford a low-speed sediment and supernatant. Further centrifugation of the latter at 105,000 × *g* for 60 min provided a high-speed particulate fraction and a particle-free supernatant (protein, 0.9 mg/mL). The high-speed particulate fraction was resuspended in a volume of buffer equal to that of the high-speed supernatant (protein, 0.4 mg/mL). Reduced glutathione



SCHEME 3



SCHEME 4

(GSH) and glutathione peroxidase (GSH-px) were purchased from Sigma Chemical Co. (St. Louis, MO). $H_2{}^{18}O$ (95.0 atom% ^{18}O) was obtained from IsoTec (Miamisburg, OH).

Incubations and treatments. [1-^{14}C]Linoleic acid, [1-^{14}C]linolenic acid, [1-^{14}C]9(*S*)-HPOD, or [1-^{14}C]13(*S*)-HPOD (200 μM) was stirred with enzyme preparation (2–50 mL) at 23°C for 20 or 60 min. The mixtures were acidified to pH 5 and rapidly extracted with 2 vol of diethyl ether. Material obtained after evaporation of the solvent was methyl-esterified by treatment with diazomethane and analyzed by SP-HPLC. For assay of peroxygenase activity (18), a suspension of the 105,000 × *g* particulate fraction from homogenate of potato leaves was stirred at 23°C for 10 min with [9,10-$^3H_2$]oleic acid (200 μM) and hydrogen peroxide (5 mM). The methyl-esterified product was subjected to radio-TLC using solvent system C, described in the paragraph below on "Chromatographic methods." in order to separate radioactive methyl 9,10-epoxystearate from methyl oleate.

Chemical methods. Catalytic hydrogenation of hydroxyesters (3) and epoxy alcohols (15), oxidative ozonolysis (16), and vanadium-catalyzed epoxidation (19) were performed as indicated. Configurational determinations of monohydroxy acids (16), nonallylic fatty acid epoxy alcohols (15), and trihydroxyesters (12) were carried out as described in detail.

Chromatographical and instrumental methods. SP-HPLC was carried out with a column of Nucleosil 50 (200 × 4.6 mm) purchased from Macherey-Nagel (Düren, Germany) and a mixture of 2-propanol/hexane (1:99 or 5:95, vol/vol) was used as the solvent. RP-HPLC was performed with a column of Nucleosil 100-5 C_{18} using a solvent system of acetonitrile/water (60:40 or 40:60, vol/vol). The absorbance (210 nm) and radioactivity of HPLC effluents were determined online, using a Spectromonitor III ultraviolet (UV) detector (Laboratory Data Control, Riviera Beach, FL) and a liquid scintillation counter (IN/US Systems, Tampa, FL), respectively. TLC was carried out with precoated plates (Kieselgel 60, 0.25 mm) from E. Merck (Darmstadt, Germany) and solvent systems consisting of either ethyl acetate (system A), ethyl acetate/hexane (30:70, vol/vol; system B), or ethyl acetate/hexane (10:90, vol/vol; system C). Radioactivity on TLC plates was determined using a Berthold Dünnschichtscanner II (Wildbad, Germany) interfaced with a Macintosh IIsi computer. GLC was performed with a Hewlett-Packard (Avondale, PA) model 5890 gas chromatograph equipped with a methylsilicone capillary column (length, 25 m; film thickness, 0.33 mm). Helium at a flow rate of 25 cm/s was used as the carrier gas. Retention times found on GLC were converted into C-values as described (20). Gas chromatography–mass spectrometry (GC–MS) was carried out with a Hewlett-Packard model 5970B mass selective detector connected to a Hewlett-Packard model 5890 gas chromatograph. UV spectra were recorded with a Hitachi (Tokyo, Japan) model U-2000 UV/VIS spectrophotometer. FTIR spectrometry was carried out using a Perkin Elmer (Norwalk, CT) model 1650 FT-IR spectrophotometer. Radioactivity was determined with a Packard Tri-Carb model 4450 liquid scintillation counter (Packard Instruments, Downers Grove, IL).

RESULTS

Isolation of oxidation products of linoleic acid. [1-^{14}C]-Linoleic acid (200 μM) was stirred at 23°C for 20 min with a whole homogenate of leaves of potato and the methyl-esterified product was subjected to SP-radio-HPLC. As seen in Figure 1A, four peaks of radioactive compounds appeared (compounds **I–IV**), in addition to the peak for methyl linoleate due

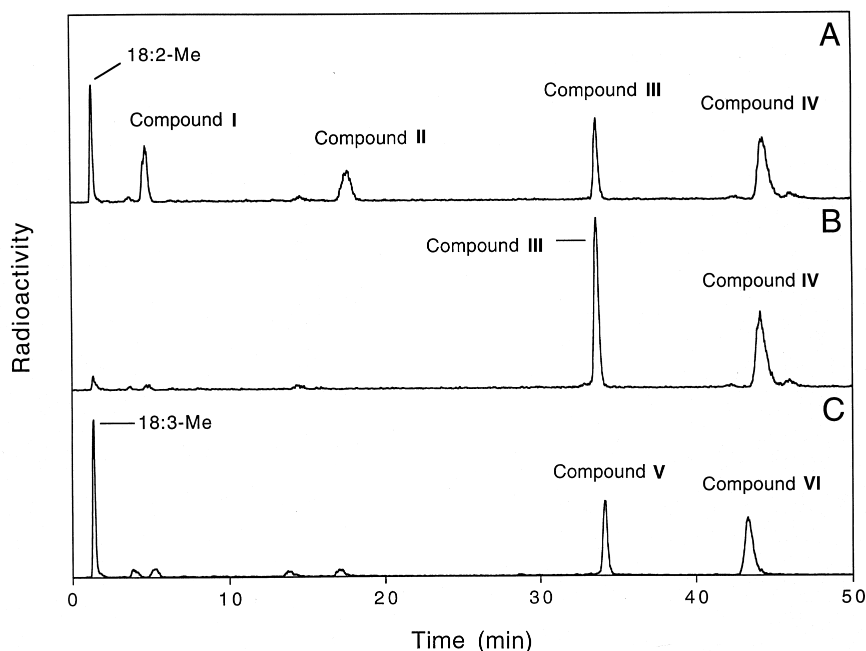


FIG. 1. Analysis by straight-phase radio high-performance liquid chromatography (SP-radio-HPLC) of methyl-esterified reaction products obtained following incubations of fatty acids with whole homogenate of potato leaves (10 mL; 15 mg of protein) at 23°C. (A) Incubation of 200 μM [1-^{14}C]linoleic acid for 20 min; (B) incubation of 200 μM [1-^{14}C]linoleic acid for 60 min; (C) incubation of 200 μM [1-^{14}C]linolenic acid for 20 min. The column was eluted with 2-propanol/hexane (1:99, vol/vol) (0–25 min) followed by 2-propanol/hexane (5:95, vol/vol) (25–50 min) at a flow rate of 2 mL/min. Compound **I**, methyl 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoate; compound **II**, methyl 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoate; compound **III**, methyl 9(*S*),10(*S*),11(*R*)-trihydroxy-12(*Z*)-octadecenoate; compound **IV**, methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoate; compound **V**, tentatively identified as methyl 9(*S*),10(*S*),11(*R*)-trihydroxy-12(*Z*),15(*Z*)-octadecadienoate; compound **VI**, tentatively identified as methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*),15(*Z*)-octadecadienoate.

to remaining unconverted substrate. Prolongation of incubation to 60 min led to the disappearance of compounds **I** and **II** and an increased yield of compounds **III** and **IV** (Fig. 1B). [1-^{14}C]Linolenic acid incubated with the enzyme preparation at 23°C for 20 min afforded two main products, i.e., compounds **V** and **VI**, which had polarities similar to those of compounds **III** and **IV**, respectively (Fig. 1C). The labeled oxidation products obtained by SP-HPLC were contaminated by chlorophyll and other pigments. To allow structural work, compounds **I** and **II** were further purified by RP-HPLC (Table 1) or by TLC using solvent system B. Purification of compounds **III** and **IV** was accomplished by RP-HPLC using acetonitrile/water (40:60, vol/vol) (effluent volumes of compounds **III** and **IV**, 34.5 and 22.2 mL, respectively) or by TLC (Table 2).

Structure of compound **I**. The UV spectrum of compound **I** was featureless, demonstrating the absence of conjugated diene or similar chromophores. The mass spectrum of the Me_3Si derivative showed prominent ions at *m/z* 398 (0.5%; M^+), 383 (7; $M^+ - 15$; loss of $\cdot CH_3$), 259 [100; $Me_3SiO^+=CH-(CH_2)_7-COOCH_3$], 225 (10), 155 [42; $OHC-(CH_2)_7-C\equiv O^+$], 143 (23), 130 (26), 109 (20), and 73 (72; Me_3Si^+), thus being in agreement with an epoxyhydroxyoctadecenoate having its hydroxyl group at C-9 and its epoxide group at C-10/C-11. Comparison of the mass spectrum and the chromatographic properties of compound **I** with those of reference epoxy alcohols oxygenated in the C-9, -10, and -11 positions showed a complete agreement between compound **I** and methyl 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoate **13** (Table 1). Catalytic hydrogenation of compound **I** was accompanied by hydrogenolysis of the allylic C–O bond at C-11 and resulted in the formation of methyl 9,10-dihydroxystearate. Analysis of the Me_3Si derivative of this product by GLC showed a C-value identical to that of the Me_3Si derivative of methyl *erythro*-9,10-dihydroxystearate (C-21.45) but different from that of the corresponding derivative of *threo*-9,10-dihydroxystearate (C-21.29). This finding thus provided independent proof for the *erythro* configuration of C-9/C-10 of compound **I**. Allylic epoxyhydroxyoctadecenoates undergo rapid hydrolysis into specific trihydroxyoctadecenoates at pH 3 and lower (12). As would be expected, compound **I** behaved identically to **13** in this respect and afforded 9,10,13-trihydroxyoctadecenoates **7a** and **8a** in a 1:1 ratio together with smaller amounts of 9,10,11-trihydroxyoctadecenoates **2b** and **4b** (Scheme 3). On the basis of these results, compound **I** was identified as methyl 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoate.

TABLE 2
Chromatographic Properties of Trihydroxyesters

Compound[a]	C-value[b]	R_f value[c]
Methyl 9(*R*),10(*R*),11(*S*)-trihydroxy-12(*Z*)-octadecenoate (**2a**)	22.30	0.72
Methyl 9(*S*),10(*S*),11(*R*)-trihydroxy-12(*Z*)-octadecenoate (**2b**)	22.30	0.72
Methyl 9(*R*),10(*R*),11(*R*)-trihydroxy-12(*Z*)-octadecenoate (**4a**)	22.47	0.59
Methyl 9(*S*),10(*S*),11(*S*)-trihydroxy-12(*Z*)-octadecenoate (**4b**)	22.47	0.59
Methyl 9(*S*),10(*R*),11-trihydroxy-12(*Z*)-octadecenoate[d]	22.33	0.66
Methyl 9(*S*),10(*R*),11-trihydroxy-12(*Z*)-octadecenoate[d]	22.50	0.69
Methyl 9(*S*),10(*R*),11(*R*)-trihydroxyoctadecanoate (**15b**)	22.77	—
Methyl 9(*S*),10(*R*),11(*S*)-trihydroxyoctadecanoate (**16a**)	22.69	—
Methyl 9(*S*),10(*S*),13(*R*)-trihydroxy-11(*E*)-octadecenoate (**5a**)	22.24	0.39
Methyl 9(*S*),10(*S*),13(*S*)-trihydroxy-11(*E*)-octadecenoate (**6a**)	22.31	0.50
Methyl 9(*S*),10(*R*),13(*S*)-trihydroxy-11(*E*)-octadecenoate (**7a**)	22.52	0.37
Methyl 9(*S*),10(*R*),13(*R*)-trihydroxy-11(*E*)-octadecenoate (**8a**)	22.53	0.47
Methyl 9(*R*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoate (**9a**)	22.32	0.39
Methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoate (**10a**)	22.40	0.50
Methyl 9(*S*),12(*R*),13(*S*)-trihydroxy-10(*E*)-octadecenoate (**11a**)	22.57	0.37
Methyl 9(*R*),12(*R*),13(*S*)-trihydroxy-10(*E*)-octadecenoate (**12a**)	22.60	0.47
Compound **III**	22.30	0.72
Compound **IV**	22.40	0.50
Compound **III**-H_2	22.77	—
Compound **V**-H_2	22.77	—

[a]Enantiomers are designated with letters **a** and **b** following the compound number. Compound **III**, methyl 9(*S*),10(*S*),11(*R*)-trihydroxy-12(*Z*)-octadecenoate; compound **IV**, methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoate; and compound **V**, tentatively identified as methyl 9(*S*),10(*S*),11(*R*)-trihydroxy-12(*Z*),15(*Z*)-octadecadienoate.
[b] Gas–liquid chromatography was carried out with a methylsilicone column operated at 230°C.
[c]The solvent system for thin-layer chromatography was ethyl acetate.
[d]Methyl 9(*S*),10(*R*),11-trihydroxy-12(*Z*)-octadecenoates epimeric at C-11 were prepared by hydrolysis of 10(*R*),11(*R*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoate. The configurations at C-11 of these compounds have not been established.

*Structure of compound **II***. No absorption bands in the range 210–300 nm were noticeable in the UV spectrum of compound **II**. The mass spectrum of the Me_3Si derivative showed ions at *m/z* 398 (2%; M^+), 383 (3; $M^+ - 15$; loss of $\cdot CH_3$), 259 [18; $Me_3SiO^+{=}CH{-}(CH_2)_7{-}COOCH_3$], 241 [87; $M^+ - 157$; loss of $\cdot(CH_2)_7{-}COOCH_3$], 225 (21), 99 [100; $^+O{\equiv}C{-}(CH_2)_4{-}CH_3$], and 73 (80; Me_3Si^+), thus indicating the presence of an epoxide group at C-12/C-13 and a hydroxyl group at C-9. The mass spectrum and the chromatographic data found for compound **II** (Table 1) were identical to those of a reference sample of the allylic epoxy alcohol methyl 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoate. Oxidative ozonolysis performed on the MC derivative of compound **II** followed by methyl-esterification afforded the MC derivative of dimethyl 2(*S*)-hydroxy-1,10-decanedioate, thus establishing the presence of a double bond in the Δ^{10} position and the *S* configuration of C-9. In agreement with the allylic epoxide structure of compound **II**, rapid hydrolysis took place at pH 3 with the formation of trihydroxyoctadecenoate **10a** as the major product (67%). In addition, smaller amounts of trihydroxyoctadecenoates **11a**, **7a**, and **6a** appeared. As shown in previous work (12,18), such a pattern of hydrolysis products is diagnostic for one specific epoxy alcohol, i.e., methyl 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoate.

Structure of compound **III**. The mass spectrum of the Me_3Si derivative of compound **III** (Fig. 2A) was in agreement with a 9,10,11-trihydroxy-12(*Z*)-octadecenoate. This structure possesses three chiral carbons, and eight stereoisomers (four separable diastereomers) are possible. For reference purposes, the *erythro*-9,10-*erythro*-10,11 diastereomer (enantiomers **2a** and **2b**), as well as the *erythro*-9,10-*threo*-10,11 diastereomer (enantiomers **4a** and **4b**), was prepared by acid-catalyzed hydrolysis of the appropriate epoxy alcohol precursors (Schemes 1 and 3). The *threo*-9,10-*erythro*-10,11 and *threo*-9,10-*threo*-10,11 diastereomers also were prepared (Table 2), although the absolute configurations of these compounds could not be established due to lack of the necessary *cis*-9,10-epoxy-11-hydroxy-12(*Z*)-octadecenoate precursor. By comparing the chromatographic data of compound **III** with those of the four chemically prepared diastereomers (Table 2), it was apparent that compound **III** had the *erythro*-9,10-*erythro*-10,11 configuration and was identical to **2a** or **2b**. As shown below, 9(*S*)-HPOD served as the precursor of compound **III**, and an incubation of [9-$^{18}O_2$]9(*S*)-HPOD led to the formation of compound **III** in which the ^{18}O-label at C-9 was retained. The fact that the carbon–oxygen bond at C-9 remained intact and that the stereochemistry of this carbon was thus preserved during the conversion of 9(*S*)-HPOD into compound **III** showed that compound **III** had the *S* configuration at C-9 and was identical to the enantiomer **2b**, i.e., methyl 9(*S*),10(*S*),11(*R*)-trihydroxy-12(*Z*)-octadecenoate. In a separate experiment, compound **III** was hydrogenated and the Me_3Si derivative was analyzed by GC–MS. As expected,

the mass spectrum and C-value (22.77) were identical to those of the Me_3Si derivative of **15b** prepared by perchloric acid-catalyzed hydrolysis of the dihydro epoxy alcohol **17** (Scheme 4).

Structure of compound **IV**. The mass spectrum of the Me_3Si derivative of compound **IV** (Fig. 2B) showed ions at *m/z* 545 (0.4%; $M^+ - 15$; loss of $\cdot CH_3$), 460 [15; $M^+ - 100$; rearrangement with loss of $OHC–(CH_2)_4–CH_3$], 439 [2; $M^+ - (31 + 90)$; loss of $\cdot OCH_3$ plus Me_3SiOH], 387 (4; $M^+ - 173$), 259 [16; $Me_3SiO^+=CH–(CH_2)_7–COOCH_3$], 230 [5; rearrangement with loss of $OHC–CH=CH–CH(OSiMe_3)–CH(OSiMe_3)–(CH_2)_4–CH_3$], 173 [100; $Me_3SiO^+=CH–(CH_2)_4–CH_3$], 147 (11; $Me_3Si–O^+=SiMe_2$), 103 (11; $Me_3SiO^+=CH_2$), and 73 (69; Me_3Si^+), thus indicating a 9,12,13-trihydroxyoctadecenoate (*cf.* Ref. 12). Comparison of the chromatographic properties of compound **IV** with those of the eight possible diastereomers of methyl 9,12,13-trihydroxy-10(*E*)-octadecenoate (**9a**–**12a** and **9b**–**12b**) established that compound **IV** was identical to **10a** or its enantiomer (Table 2). Oxidative ozonolysis performed on the tris-MC derivative of compound **IV** followed by methyl-esterification afforded the MC derivative of dimethyl 2(*S*)-hydroxy-1,10-decanedioate, thus locating the double bond to the Δ^{10} position and assigning the *S* configuration to C-9. The latter finding demonstrated that compound **IV** was identical to the enantiomer **10a**, i.e., methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoate.

Incubations in the presence of GSH-px. [1-^{14}C]Linoleic acid (200 μM) was stirred at 23°C for 20 min with a whole homogenate of potato leaves in the presence of GSH (2 mM) and GSH-px (0.5 U/mL). This led to a virtually complete block of the formation of compounds **I**–**IV** and also to approximately 50% inhibition of the rate of oxygenation of linoleic acid. The product was mainly due to two monohydroxy esters, i.e., the methyl ester of 9(*S*)-hydroxy-10(*E*),12(*Z*)-octadecadienoic acid [9(*S*)-HOD] (91%) and the methyl ester of 13(*S*)-hydroxy-9(*Z*),11(*E*)-octadecadienoic acid [13(*S*)-HOD] (9%). The structures and stereochemistry of these compounds were established by GC–MS and by steric analysis of chiral fragments formed upon oxidative ozonolysis. By performing a series of incubations with increasing activity of GSH-px (0–2 U/mL) and plotting the yields of 9- and 13-HOD vs. GSH-px activity, it was obvious that the 9-lipoxygenase activity was partially inhibited by GSH-px. Extrapolating the proportions of 9- and 13-HOD to zero activity of GSH-px gave a result of 95:5.

*Incubation of 9(*S*)-HPOD*. Incubation of [1-^{14}C]9(*S*)-HPOD (200 μM) with whole homogenate of potato leaves at 23°C for 20 min gave a product consisting of compounds **I**–**IV** in amounts closely similar to those observed after incubation of linoleic acid. When a suspension of the 105,000 × *g* sediment fraction in buffer was used as the enzyme source, formation of compounds **III** and **IV** was almost completely abolished and compounds **I** and **II** were obtained as the major products (Fig. 3A).

*Incubation of 13(*S*)-HPOD*. Incubation of [1-^{14}C]13(*S*)-HPOD (200 μM) with either whole homogenate of potato leaves or the 105,000 × *g* sediment fraction of leaf homogenate and analysis of the methyl-esterified product by SP-radio-HPLC showed the presence of one main radioactive product (6.2 mL effluent) (Fig. 3B). This material was identified as methyl 13-hydroxy-12-oxo-9(*Z*)-octadecenoate (α-

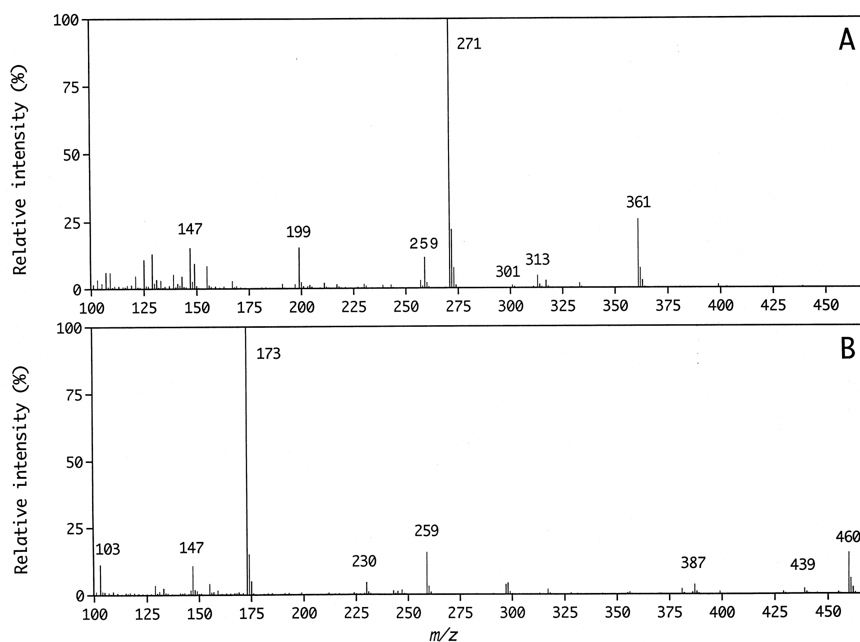

FIG. 2. Mass spectra of the Me_3Si derivatives of (A) compound **III** [methyl 9(*S*),10(*S*),11(*R*)-trihydroxy-12(*Z*)-octadecenoate] and (B) compound **IV** [methyl 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoate].

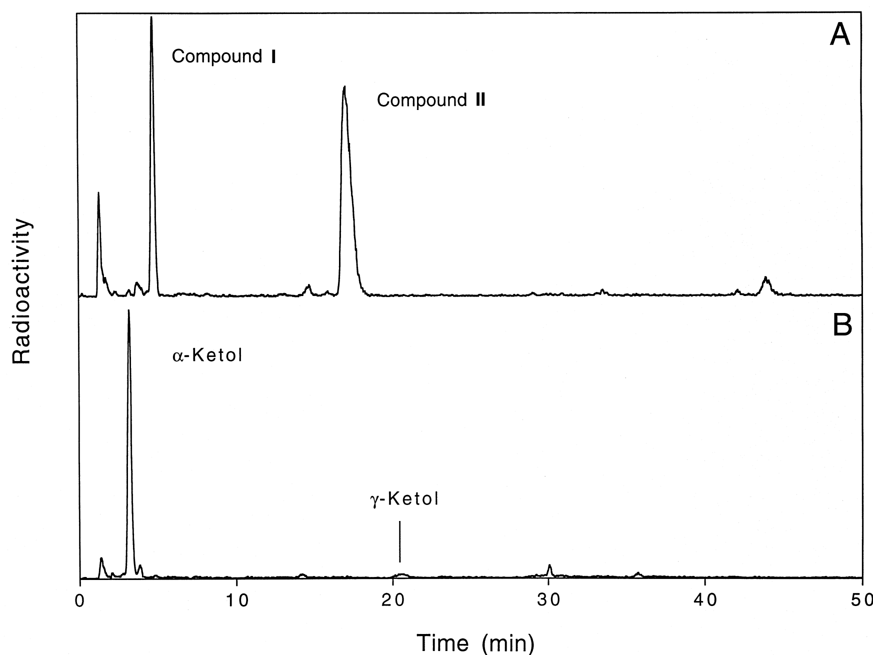

FIG. 3. SP-HPLC radiochromatograms of methyl-esterified products obtained following incubations of (A) 200 μM [1-^{14}C]9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid or (B) 200 μM [1-^{14}C]13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid with suspensions of the 105,000 × *g* particulate fraction of homogenate of potato leaves (5 mL; 2 mg of protein) at 23°C for 20 min. α-Ketol, methyl 13-hydroxy-12-oxo-9(*Z*)-octadecenoate; γ-ketol, methyl 9-hydroxy-12-oxo-10(*E*)-octadecenoate. For HPLC conditions and structures of compounds **I** and **II,** and abbreviation, see Figure 1.

ketol) by GC–MS using a sample of the authentic compound as the reference. A minor peak of radioactivity appeared at 40.9 mL effluent. This material was identified as methyl 9-hydroxy-12-oxo-10(*E*)-octadecenoate (γ-ketol) by comparison with an authentic sample. Formation of these ketols demonstrated the presence of allene oxide synthase activity in the 105,000 × *g* particle fraction of potato leaf homogenate (*cf.* Ref. 11). 13(*S*)-HPOD incubated in concentrations up to 1 mM was completely metabolized into ketols, whereas incubations of 9(*S*)-HPOD at concentrations >300 μM led to incomplete conversion into epoxy alcohols and accumulation of residual hydroperoxide. These results showed that 13(*S*)-HPOD, but not 9(*S*)-HPOD, served as a substrate for allene oxide synthase in potato leaves. No conversion of 13(*S*)-HPOD into epoxy alcohols was detectable in these experiments, however, it remains to be determined whether this was due to the specificity of the epoxy alcohol synthase or whether its activity on 13(*S*)-HPOD was masked by the strong allene oxide synthase activity.

Characterization of oxidation products of linolenic acid. Analysis the methyl-esterified product obtained after incubation of [1-^{14}C]linolenic acid (200 μM) with potato leaf homogenate showed two main products, i.e., compounds **V** and **VI** (Fig. 1C). The mass spectrum of the Me_3Si derivative of the first-mentioned compound (C-value, 22.30) showed ions at *m/z* 558 (0.4%; M^+), 361 (24; $M^+ - 197$), 271 (100; 361 – 90), 259 [17; Me_3SiO^+=CH–$(CH_2)_7$–$COOCH_3$], 197 [6; Me_3SiO^+=CH–(CH=CH–$CH_2)_2$–CH_3], and 73 (88; Me_3Si^+), thus suggesting a 9,10,11-trihydroxyoctadecadienoate. Catalytic hydrogenation afforded a stereoisomer of methyl 9,10,11-trihydroxyoctadecanoate which had the same C-value (22.77) and mass spectrum as methyl 9(*S*),10(*R*),11(*R*)-trihydroxyoctadecanoate (**15b**) prepared by hydrolysis of dihydro epoxy alcohol **17** or by hydrogenation of compound **III**. These data suggested that compound **V** was identical to the methyl ester of 9(*S*),10(*S*),11(*R*)-trihydroxy-12(*Z*),15(*Z*)-octadecadienoic acid.

The mass spectrum of the Me_3Si derivative of compound **VI** (C-value, 22.46) showed prominent ions at *m/z* 543 (0.5%; $M^+ - 15$; loss of $\cdot CH_3$), 460 [16; $M^+ - 98$; rearrangement with loss of OHC–CH_2–CH=CH–CH_2–CH_3], 387 (5; $M^+ - 171$), 259 [28; Me_3SiO^+=CH–$(CH_2)_7$–$COOCH_3$], 171 (100; Me_3SiO^+=CH–CH_2–CH=CH–CH_2–CH_3), and 73 (95; Me_3Si^+), suggesting the identity of compound **VI** with a di-unsaturated 9,12,13-trihydroxyoctadecanoate. That this compound was a more unsaturated analog of compound **IV** was indicated by the fact that catalytic hydrogenation of compound **VI** resulted in the formation of a trihydroxyoctadecanoate which had a C-value (22.74) and mass spectrum identical to those of methyl 9(*S*),12(*S*),13(*S*)-trihydroxyoctadecanoate prepared by hydrogenation of compound **IV**. These data suggested that compound **VI** was identical to the methyl ester of 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*),15(*Z*)-octadecadienoic acid; however, unambigous identification of com-

pounds **V** and **VI** produced from linolenic acid must await synthesis of the appropriate, stereochemically defined reference compounds.

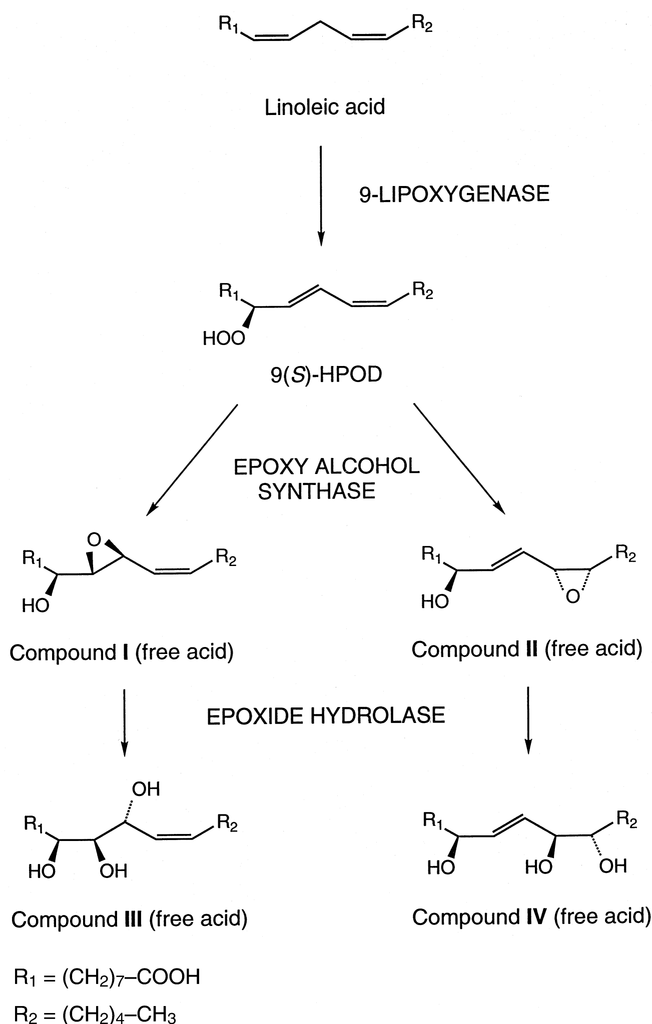
Assay of peroxygenase activity. Suspensions of the 105,000 × *g* particle fraction of potato leaf homogenate were incubated with [1-^{14}C]oleic acid and 5 mM hydrogen peroxide. Labeled 9,10-epoxystearate was undetectable by radio-TLC, indicating the absence of peroxygenase activity (<0.5 nmol/min · mg protein).

DISCUSSION

The present study is concerned with a new pathway of fatty acid metabolism in a higher plant, i.e. biosynthesis of epoxyhydroxy and trihydroxy fatty acids in leaves of potato. The first step of the transformation was catalyzed by a 9-lipoxygenase as indicated by the structures of the products formed, and by the fact that incubation of linoleic acid performed in the presence of GSH-px led to the formation of 9(*S*)-HOD by diversion of 9(*S*)-HPOD. That the major lipoxygenase activity in leaves of potato was of the 9 type was in agreement with the recent isolation from infected potato leaves of colneleic and colnelenic acids, compounds which are formed from the 9(*S*)-hydroperoxides of linoleic and linolenic acids, respectively (21). In contrast to these results, it has been reported that the two mainly expressed lipoxygenase genes in leaves of potato code for 13-lipoxygenases, and that wounding of potato leaves leads to induction of 13- and not 9-lipoxygenase (22). No data concerning lipoxygenase activity or lipoxygenase products in potato leaves were given in this study.

The second step of the transformation studied in the present work consisted of enzymatic isomerization of 9(*S*)-HPOD into two acid-labile fatty acid epoxy alcohols, i.e., the α,β-epoxy alcohol 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoic acid (free acid form of compound **I**) and the γ,δ-epoxy alcohol 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoic acid (free acid form of compound **II**) (Scheme 5). This step was conveniently studied using the 105,000 × *g* particle fraction of potato leaf homogenate, which lacked the enzyme activity catalyzing breakdown of the epoxy alcohols (Fig. 3). A related conversion of hydroperoxides has been observed in preparations of the primitive fungus *S. parasitica*, in which case linoleic acid 9- and 13-hydroperoxides, as well as arachidonic acid 15-hydroperoxide, were each converted into an α,β- and a γ,δ-epoxy alcohol by intramolecular epoxidation of the α,β- and γ,δ-double bonds, respectively (13,23). Interestingly, the γ,δ-epoxy alcohol formed in the potato leaf homogenate was identical to the γ,δ-epoxy alcohol formed from 9(*S*)-HPOD in the fungal preparation, whereas the α,β-epoxy alcohols biosynthesized in the two systems differed with respect to the stereochemistry of the epoxide group, i.e., 10(*S*),11(*S*) in the potato leaf epoxy alcohol and 10(*R*),11(*R*) in the *S. parasitica* epoxy alcohol. The enzyme peroxygenase also catalyzes formation of epoxy alcohols from fatty acid hydroperoxides (17), and this enzyme is responsible for the biosynthesis of 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoic acid in preparations of oat seeds (18,24). Peroxygenase activity was undetectable in the preparations of potato leaves used in the present study, and formation of epoxy alcohols is proposed to take place by action of a specific epoxy alcohol synthase activity (Scheme 5). It should be mentioned in this context that the epoxy alcohols *trans*-9,10-epoxy-*threo*-11-hydroxy-12(*Z*)-octadecenoic and *trans*-12,13-epoxy-*threo*-11-hydroxy-9(*Z*)-octadecenoic acids have previously been generated from 9- and 13-HPOD, respectively, in a 9-lipoxygenase-promoted process (25) or by "pseudo-enzymic" reactions taking place in preparations of potato tuber (26). These epoxy alcohols differ chemically from those biosynthesized in *S. parasitica* or potato leaves and are formed from hydroperoxides by a mechanism involving alkoxyl radical cyclization rather than by a double bond epoxidation mechanism (see Ref. 27 for a discussion of mechanisms of formation of fatty acid epoxy alcohols).

The third step of the transformation studied in the present work consisted of conversion of fatty acid epoxy alcohols into trihydroxyoctadecenoic acids. It seemed likely that the en-



SCHEME 5

zyme responsible for this step was an epoxide hydrolase similar to or identical to the epoxide hydrolase in oat seeds (18). This enzyme catalyzed regio- and stereospecific hydrolysis of 12(*R*),13(*S*)-epoxy-9(*S*)-hydroxy-10(*E*)-octadecenoic acid into 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoic acid and was characterized as a soluble 47 kD protein (18). The epoxide hydrolase activity of potato leaves was relatively weak, thus allowing epoxy alcohol intermediates to be isolated when the time of incubation was kept short (*cf.* Fig. 1A and 1B). From the stereochemistry of the epoxy alcohols and their trihydroxy acid products, it could be deduced that the epoxide hydrolase reaction consisted of stereospecific attack by water at the allylic epoxide carbons C-11 and C-12 of the α,β- and γ,δ-epoxy alcohols, respectively, followed by opening of the epoxide ring by an S_N2-type reaction.

The existence of two partially different pathways for biosynthesis of 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoic acid (free acid form of compound **IV**), i.e., one involving peroxygenase in oat seeds (18) and one involving epoxy alcohol synthase activity in potato leaves, is noteworthy and may suggest a specific function for this particular trihydroxy acid. Studies in the rice plant have shown that 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoic acid is produced in plants suffering from rice blast disease and that it exerts a growth-inhibitory effect against the rice blast fungus (28,29). Furthermore, a 9,12-13-trihydroxy-10(*E*)-octadecenoate (stereochemistry not determined) has been isolated as an antifungal principle from tubers of taro infected with the black root fungus (*Ceratocystis fimbriata*) (30). Further studies are needed to establish whether 9(*S*),12(*S*),13(*S*)-trihydroxy-10(*E*)-octadecenoic acid and the other oxylipins encountered in the present study play a role as endogenous defensive substances in potato.

Factors Enhancing Diacylglycerol Acyltransferase Activity in Microsomes from Cell-Suspension Cultures of Oilseed Rape

Susan D. Byers[a], André Laroche[b], Kevin C. Smith[a], and Randall J. Weselake[a,*]

[a]Department of Chemistry and Biochemistry, University of Lethbridge, Lethbridge, Alberta, T1K 3M4 Canada and [b]Lethbridge Research Centre, Agriculture and Agri-Food Canada, Lethbridge, Alberta, T1J 4B1 Canada

ABSTRACT: Several factors, including an unidentified endogenous component, were found to stimulate microsomal diacylglycerol acyltransferase (DGAT, EC 2.3.1.20) from a microspore-derived cell-suspension culture of oilseed rape (*Brassica napus* L. cv. Jet Neuf). At a concentration of 25 mM, $MgSO_4$ and $MgCl_2$ stimulated microsomal DGAT 25- and 10-fold, respectively. ATP and CoA at concentrations of 2 and 1 mM stimulated the enzyme 2.4- and 12-fold, respectively, although the effects were lessened in the presence of higher Mg^{2+} concentrations. Although microsomal DGAT activity was increased only slightly by the addition of exogenous *sn*-1,2-diacylglycerol to the reaction mixture, it was increased substantially by the addition of exogenous phosphatidate. *sn*-Glycerol-3-phosphate and other phospholipids tested did not have this stimulatory effect. DGAT activity did not decrease when microsomes were incubated with ATP in the presence of the cytosolic fraction. This fraction, however, contained a small organic compound(s) that stimulated microsomal DGAT activity.

Paper no. L8252 in *Lipids 34*, 1143–1149 (November 1999).

In developing oilseeds, triacylglycerol (TAG) is formed through a series of enzymatically catalyzed reactions known as the Kennedy pathway (1,2). Diacylglycerol acyltransferase (DGAT, EC 2.3.1.20) catalyzes the final step in this pathway *via* the acyl-CoA dependent acylation of *sn*-1,2-diacylglycerol (DAG) and has been implicated as a rate-limiting step in the formation of TAG in both plants (3–6) and animals (7). An examination of the factors that may affect the activity of this enzyme in plants may enable the development of strategies to increase seed oil content and/or alter the fatty acid composition of the oil.

DGAT activity is associated with the endoplasmic reticulum (2), and in mammalian systems, the activity of the enzyme may be altered through allosteric interactions and covalent modification (8,9). While the characteristics of microsomal DGAT have been studied extensively in mammalian systems, studies with the plant enzyme have been more limited. Factors affecting DGAT activity have been investigated in several systems. For example, phospholipids have been found to stimulate fungal DGAT, with phosphatidate (PA) having the greatest effect (10). Organic molecules known as chalcones (11) and amidepsines (12) also have been shown to inhibit mammalian DGAT activity. The chalcones were extracted from hops (*Humulus lupulus*) and inhibited DGAT activity in rat liver microsomes and inhibited TAG production in intact Raji cells (11). The amidepsines were isolated from the fungal culture, *Humicola* sp. FO-2942 (12).

Cultures derived from oil-forming plants have proven useful for studying the biochemistry of TAG accumulation (13,14). The synthesis of storage oils in seeds and fruits is a dynamic and stage-dependent process. The use of these cultures, however, permits the study of oil-forming species year-round without the need to obtain seeds (zygotic embryos) at specific stages of development. Recently, a microspore-derived (MD) cell-suspension culture of winter oilseed rape (*Brassica napus* L. cv. Jet Neuf) has been utilized in biochemical and molecular genetic studies of TAG accumulation (15–18). The cell-suspension culture was generated in 1983 (19) and initially was used for studies of freezing tolerance (20–22). The cell-suspension culture has been shown to accumulate about 3–6% TAG on a dry weight basis when maintained in growth medium containing 6% (wt/vol) sucrose (15,18). Increasing the sucrose concentration to 22%, however, has been shown to increase TAG content to about 9% (18). In contrast, mature seed and late-cotyledonary-stage MD embryos (35 d in culture) of oilseed rape have been shown to accumulate TAG in excess of 45% of the dry weight of the tissue (23). MD cell-suspension cultures, however, are easier to maintain than MD embryos and offer the advantage of allowing study of TAG biosynthesis in the absence of the cellular differentiation associated with zygotic and MD embryos.

The current study examined the effects of various compounds on microsomal DGAT activity in the MD cell-suspension culture in an effort to further characterize this enzyme. The effects of various salts, ATP, CoA, exogenous substrates, phospholipids, and *sn*-glycerol-3-phosphate (G-3-P) on DGAT activity were determined. During investigation of the possible alteration of microsomal DGAT activity by phosphorylation, the cytosolic fraction was found to stimulate TAG biosynthesis.

MATERIALS AND METHODS

Chemicals. [1-^{14}C]Oleic acid (51 Ci mol^{-1}) was obtained from Amersham Canada, Ltd. (Oakville, Ontario, Canada). Merck silica gel 60 H, used for preparing thin-layer chromatography (TLC) plates, was from VWR Canlab (Mississauga, Ontario, Canada). Ecolite^{TM} (+) biodegradable scintillant was from ICN Biomedicals, Inc. (Irvine, CA). Dye reagent concentrate for protein assays was from Bio-Rad (Richmond, CA). High-performance liquid chromatography-grade solvents were from BDH, Inc. (Toronto, Ontario, Canada). *sn*-1,2-Dioleoylglycerol was from Avanti Polar Lipids, Inc. (Alabaster, AL). Ultrafiltration membranes were from Amicon, Ltd. (Oakville, Ontario, Canada). Acyl-CoA synthetase from *Pseudomonas fragi* was from Boehringer Mannheim Canada (Laval, Québec, Canada). Acyl-CoA was synthesized from radiolabeled fatty acids (24). Disodium ATP (treated to remove divalent cations) and all other biochemicals used were of the highest purity available and were obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO).

Plant material. The MD cell-suspension culture of *B. napus* L. cv. Jet Neuf was provided by Dr. J. Singh of the Eastern Cereal and Oilseed Research Centre, Agriculture and Agri-Food Canada, Ottawa, and essentially maintained according to Orr *et al.* (20). The culture was grown on a rotary shaker (set at 150 rpm) at 25°C under constant light with an intensity of 36 μmol m^{-2} s^{-1}. One-third of the mass of cells grown in 125-mL Erlenmeyer flasks was routinely transferred to fresh medium at 2-wk intervals. The remainder of the cells, obtained after 2 wk of culture, were washed with water over a nylon sieve, blotted with filter paper to remove excess water, and the fresh weight was determined. Cells were either immediately used or frozen in liquid N_2 and stored at –80°C until use.

Preparation of microsomes. Cells were ground in four volumes of grinding buffer (0.5 M sucrose, 0.2 M Hepes-NaOH, pH 7.4) using a chilled mortar and pestle. Differential centrifugation of the homogenate was performed at 4°C. The homogenate was centrifuged at 10,000 × *g* for 20 min and the supernatant was filtered through glass wool. The 10,000 × *g* supernatant was then centrifuged at 100,000 × *g* for 1 h. The resulting microsomal pellet was washed with 10 mM Hepes-NaOH buffer (pH 7.4) and resedimented at 100,000 × *g* for 1 h. The washed pellet was resuspended in a volume equivalent to one-tenth of the original mass of cells using 10 mM Hepes-NaOH buffer (pH 7.4) (i.e., microsomes were resuspended in 100 μL of buffer if 1 g of cells was used). Both the first 100,000 × *g* supernatant (cytosolic fraction) and the resuspended microsomes were divided into small aliquots, flash-frozen with liquid N_2, and stored at –80°C.

Enzyme assays and protein determination. Microsomal DGAT was assayed essentially as described by Little *et al.* (16) except that ATP and CoA were not included in the standard reaction mixture. Microsomes used in the enzyme assays were thawed once. Different batches of microsomes were used, but each series of experiments (e.g., effect of salt concentration) was conducted with the same batch of microsomes. Each experiment was repeated three times in triplicate, resulting in a total of nine enzyme assays for each condition. The 60-μL reaction mixture contained 0.2 M Hepes-NaOH (pH 7.4), 330 μM *sn*-1,2-dioleoylglycerol, 15 μM [1-^{14}C]oleoyl-CoA (51 Ci mol^{-1}), 0.1% (wt/vol) Tween-20, 6 mg bovine serum albumin (BSA) mL^{-1} and 5–10 μL resuspended microsomes. Microsomal protein introduced into the reaction mixture ranged from 20 to 90 μg. Enzyme reactions were allowed to proceed at 30°C for 10 min. The enzyme reaction was initiated with microsomes and terminated by adding 10 μL of 5% (wt/vol) sodium dodecyl sulfate (SDS). A reaction mixture consisting of 120 μL (final reaction volume) was used to test the effect of various volumes of cytosolic fraction on DGAT activity in order to allow for a greater range of concentrations. Studies of other reaction components and additives were carried out under the standard conditions except that the concentration of the component of interest was varied. A 50-μL aliquot of each reaction mixture was spotted onto a silica gel 60 H preparative TLC plate and developed in hexane/diethyl ether (80:20, vol/vol) with a trioleoylglycerol standard. Sections of silica containing TAG from each lane were scraped into scintillation vials, combined with 5 mL Ecolite^{TM} (+), and assayed for radioactivity.

Thioesterase activity was assayed under the same reaction conditions described above for the DGAT assay except that the preparative TLC plates were developed in hexane/diethyl ether/acetic acid (70:30:1, by vol) with oleic acid as a standard.

Acyl-CoA synthetase from *P. fragi* was used to test cytosolic fractions for CoA content. The enzyme was assayed at 35°C for 3 h using a 90-μL reaction mixture containing 0.1 M Mops [3-(*N*-morpholino)propanesulfonic acid]-NaOH (pH 7.5), 10 mM dithiothreitol, 10 mM ATP, 0.05 μCi [1-^{14}C]oleic acid, 0.1% (wt/vol) Triton X-100, 2 μL of acyl-CoA synthetase (0.5 mg in 50 μL 0.1 M Mops-NaOH, pH 7.4), and varying concentrations of CoA or quantities of cytosolic fraction. Reactions were quenched with 10 μL 5 % (wt/vol) SDS, and 75 μL of each mixture was run on a silica gel H plate in *n*-butanol/water/acetic acid (5:3:2, by vol) as described by Taylor *et al.* (25) with oleoyl-CoA as a standard. Silica sections containing acyl-CoA were assayed for radioactivity as described for the DGAT assay.

The protein content of microsomes was determined using the Bio-Rad protein microassay based on the Bradford procedure (25), using BSA as a standard.

Ashing. Two milliliters of the 100,000 × *g* supernatant were ashed by placing the sample into a crucible in a steam bath and slowly adding 20 drops of concentrated aqueous HCl. When the sample approached dryness and was beginning to char, the crucible was placed in a cold muffle furnace and ignited by gradually heating to 600°C overnight. The sample was then cooled to room temperature and resuspended in 2 mL of 10 mM Hepes-NaOH buffer (pH 7.4).

Ultrafiltration. Ultrafiltration experiments were carried out on the 100,000 × *g* supernatant using Amicon ultrafiltration cells with YM 30, YM 10, and YM 1 membranes (nominal molecular mass cutoff of 30, 10, and 1 kDa, respectively).

RESULTS AND DISCUSSION

Effect of salts on DGAT activity. A systematic study of potential factors affecting the activity of DGAT was undertaken. In vari-

ous systems, divalent cations have been shown to alter acyltransferase activity either negatively or positively (26–28). Mg^{2+} is sometimes included in reaction mixtures for assaying acyltransferase activity (26–30). The effects of various salts on microsomal DGAT activity from the cell-suspension culture are shown in Figure 1. DGAT activity of the microsomes prepared from MD cell-suspension cultures was not affected by one cycle of freezing and thawing. Mg^{2+} salts had the greatest effect on DGAT activity with $MgSO_4$ and $MgCl_2$ at 25 mM concentrations stimulating microsomal DGAT by about 25- and 10-fold, respectively. Mg^{2+} also has been shown to activate DGAT from *Mortierella ramanniana* var. *angulispora* (10). High concentrations of Mg^{2+} previously have been shown to decrease the solubility of fatty acyl-CoA (31). Consequently, it may be favorable to use a moderate concentration of Mg^{2+} in order to balance high activity levels with substrate solubility. $CaCl_2$ and NaCl were found to have lesser effects on DGAT in this system (results not shown). Ichihara and Noda (32) reported that DGAT activity in microsomes from maturing safflower seeds is not stimulated by Ca^{2+}.

Effect of ATP and CoA on DGAT activity. ATP and CoA are sometimes added to reaction mixtures for assaying TAG biosynthetic enzymes (16,33). The concentration dependence of microsomal DGAT on ATP and CoA was systematically examined using various concentrations of each compound. Addition of 2 mM ATP increased DGAT activity up to 2.4-fold in the absence of added Mg^{2+} (Fig. 2A) and up to 1.5-fold in the presence of 3 mM Mg^{2+} (Fig. 2B). ATP did not have a significant effect, however, in the presence of 25 mM Mg^{2+} (Fig. 2C). Bacterial diacylglycerol kinase activity has been shown to be dependent on the concentration of a Mg-ATP complex as well as being activated by free Mg^{2+} (34).

CoA, at a concentration of 1 mM, stimulated DGAT up to 14- and 13-fold in the absence of added Mg^{2+} and in the presence of 3 mM Mg^{2+}, respectively (Figs. 3A and 3B). In the presence of 25 mM Mg^{2+}, however, 1 mM CoA only increased DGAT activity 1.5-fold (Fig. 3C).

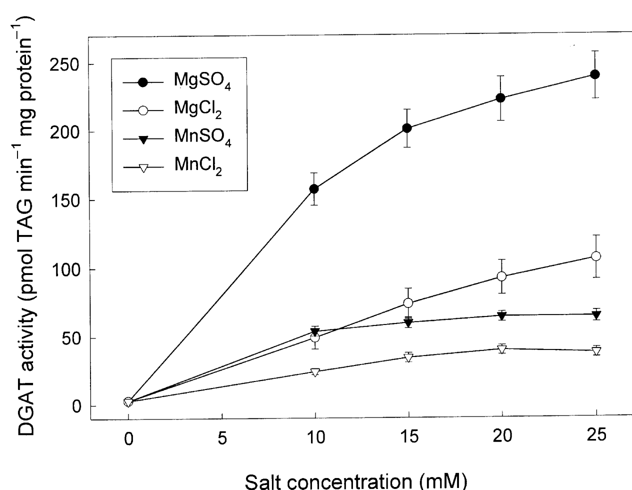

FIG. 1. Effect of various concentrations of $MgSO_4$, $MgCl_2$, $MnSO_4$, and $MnCl_2$ on microsomal diacylglycerol acyltransferase (DGAT) activity from microspore-derived (MD) cell-suspension cultures of *Brassica napus* L. cv. Jet Neuf. Data points represent the mean ± SE (*n* = 9).

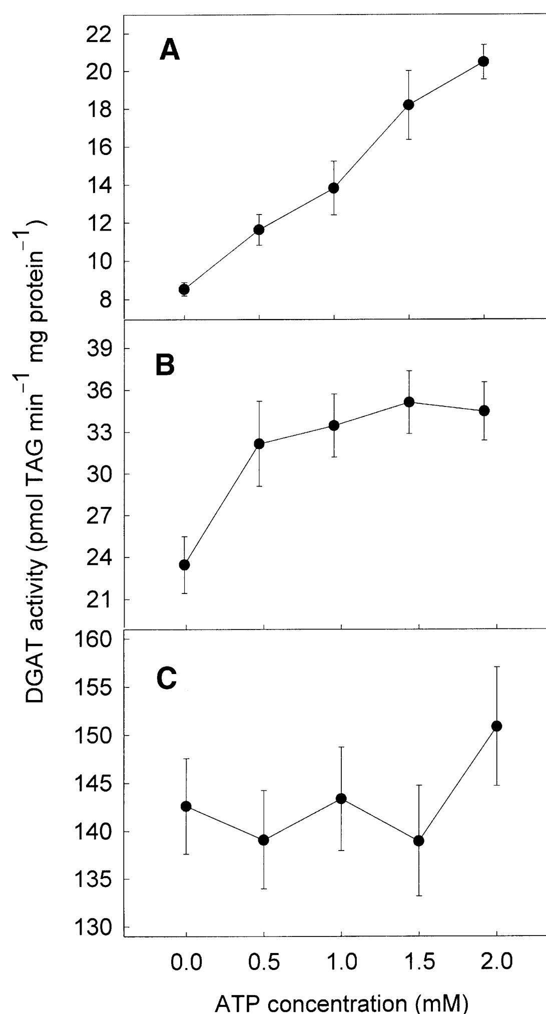

FIG. 2. Effect of ATP concentration on microsomal DGAT activity from MD cell-suspension cultures of *B. napus* L. cv Jet Neuf (A) without Mg^{2+}; (B) with 3 mM Mg^{2+}; (C) with 25 mM Mg^{2+}. Note the differences in the scales for DGAT activity among the three panels. Data points represent the mean ± SE (*n* = 9). See Figure 1 for abbreviations.

It was previously reported that thioesterase activity was high enough in MD embryos of *B. napus* L. to interfere with the determination of DGAT activity and that ATP and CoA were required to restore the acyl-CoA pool through the action of an endogenous acyl-CoA synthetase (23). Microsomes from the MD cell-suspension culture degraded between 1 and 6.5% of the radiolabeled acyl-CoA under the same conditions that the DGAT assay was conducted. This suggested that although ATP and CoA caused an increase in DGAT activity, it did not occur through restoration of the acyl-CoA pool. Instead, these compounds may be acting as allosteric modulators of DGAT in this system.

Effect of exogenous substrates on DGAT activity. The dependence of DGAT activity on oleoyl-CoA and *sn*-1,2-dioleoylglycerol concentration in the presence of 3 and 25 mM $MgCl_2$

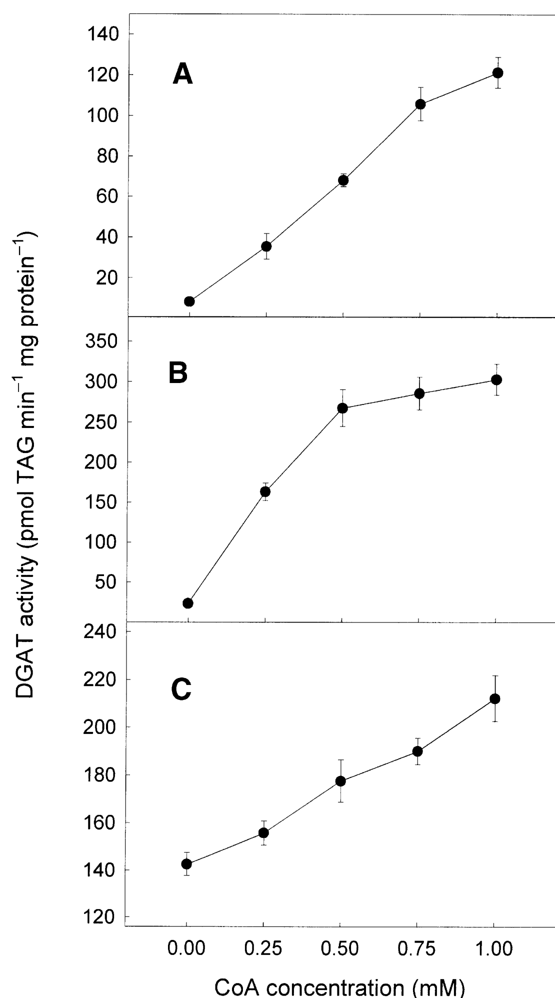

FIG. 3. Effect of CoA concentration on microsomal DGAT activity from MD cell-suspension cultures of *B. napus* L. cv. Jet Neuf. (A) Without Mg^{2+}; (B) 3 mM Mg^{2+}; (C) 25 mM Mg^{2+}. Note the differences in the scales for DGAT activity among the three panels. Values represent the mean ± SE (n = 9). See Figure 1 for abbreviations.

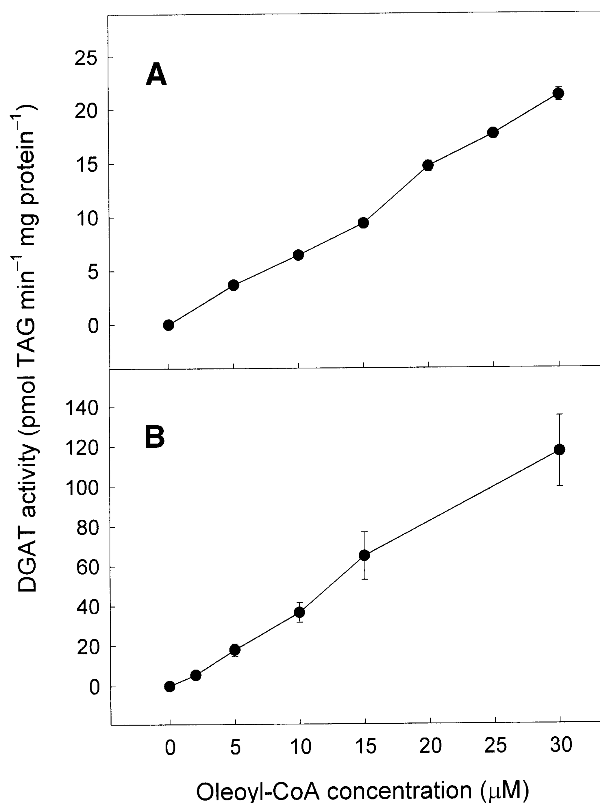

FIG. 4. Effect of oleoyl-CoA concentration on microsomal DGAT activity from MD cell-suspension cultures of *B. napus* L. cv. Jet Neuf. (A) 3 mM Mg^{2+}; (B) 25 mM Mg^{2+}. Note the differences in the scales for DGAT activity between the two panels. Data points represent the mean ± SE (n = 9). See Figure 1 for abbreviations.

was examined. The effect of oleoyl-CoA concentration seemed to be similar in the presence of both low (Fig. 4A) and high Mg^{2+} concentrations (Fig. 4B), even though the solubility of fatty acyl-CoA has been shown to be greatly reduced in the presence of high Mg^{2+} concentrations (31).

DGAT activity was not dependent on exogenous *sn*-1,2-dioleoylglycerol when assayed in the presence of 3 mM Mg^{2+} (Fig. 5A), but 100 μM (bulk concentration) *sn*-1,2-dioleoylglycerol caused a 1.3-fold increase in activity when 25 mM Mg^{2+} was present (Fig. 5B). This may have been a result of the increased activity at high Mg^{2+} concentration that led to rapid utilization of the endogenous substrate during the reaction. Little *et al.* (16) previously reported that DGAT activity in fractions solubilized from microsomes of cell-suspension cultures was not dependent on exogenous DAG. Cao and Huang (29) also reported that endogenous DAG was present in microsomes from maturing oil seeds of maize.

Effect of phospholipids and G-3-P on DGAT activity. Phospholipids have been shown to affect DGAT activity in mammalian (35) and fungal (36) systems, and may represent allosteric modulators of the enzyme. In the current study, the addition of 500 μM (bulk concentration) PA to the reaction mixture caused a twofold increase in DGAT activity (Fig. 6). Other phospholipids and G-3-P, tested at 500 μM, had no significant effect on DGAT activity (Fig. 6). Although PA is a precursor for DAG production, the addition of DAG to our system (in the presence of 3 mM Mg^{2+}) did not stimulate DGAT activity. This suggested that PA may be acting as an allosteric modulator. Alternatively, the PA may have been used by microsomal PA phosphatase to produce DAG that was presented to DGAT in a manner that enabled it to be used more efficiently than exogenous DAG. Stimulation by PA was concentration dependent with almost a 2.5-fold stimulation at 1 mM PA (Fig. 7). Although we found that G-3-P had no significant effect on DGAT activity in the cell-suspension system, Taylor *et al.* (33) have reported that G-3-P results in increased TAG production in MD embryo microsomes and suggested that the compound could be a positive effector of TAG biosynthetic enzymes. Kamisaka and Nakahara (36) examined the effects of various phospholipids on solublized DGAT from *M. ramanniana* and also found that

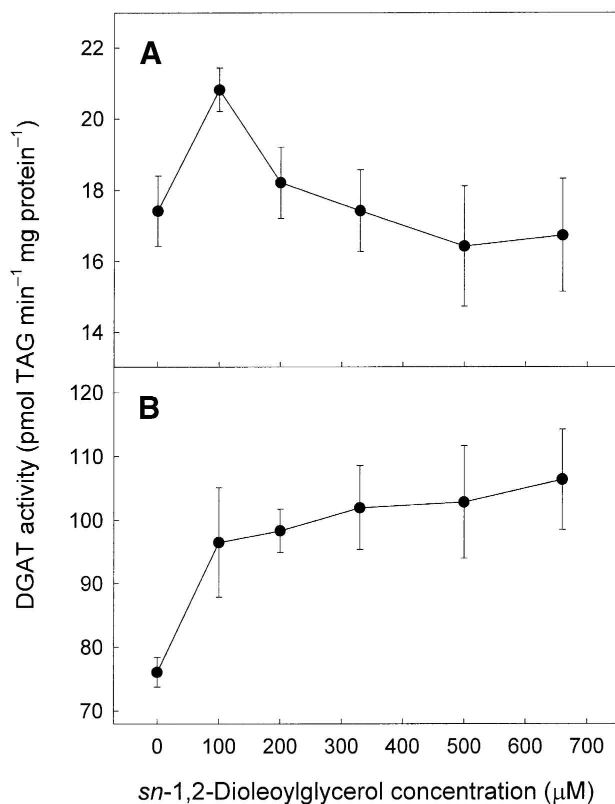

FIG. 5. Effect of bulk concentration of *sn*-1,2-dioleoylglycerol on microsomal DGAT activity in MD cell-suspension cultures of *B. napus* L. cv. Jet Neuf. (A) 3 mM Mg^{2+}; (B) 25 mM Mg^{2+}. Note the differences in the scales for DGAT activity between the two panels. Data points represent the mean ± SE (n = 9). See Figure 1 for abbreviations.

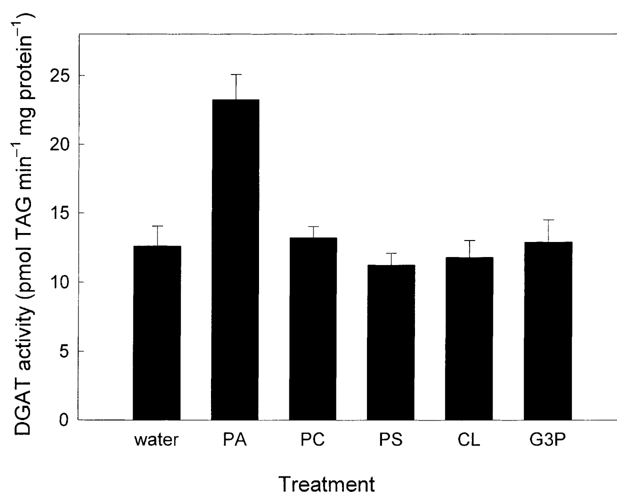

FIG. 6. Effect of 500-μM bulk concentrations of phosphatidate (PA), phosphatidylcholine (PC), phosphatidylserine (PS), cardiolipin (CL), and *sn*-glycerol-3-phosphate (G-3-P) on microsomal DGAT activity from MD cell-suspension cultures of *B. napus* L. cv. Jet Neuf. Stock mixtures (0.5 mL) of PA (from egg yolk lecithin), PC (from egg yolk lecithin), PS (from bovine brain), and CL (from bovine heart) were prepared using 10 mM Hepes-NaOH buffer, pH 7.4. The stock mixtures were sonicated in small glass vials on ice for 10 min using a Cole-Palmer Ultrasonic Cleaner, model 8845-44 (Cole-Palmer Instrument Co., Chicago, IL). The dispersed phospholipids were diluted into the reaction mixtures at the appropriate final bulk concentration immediately prior to assaying for enzyme activity. Bar heights represent the mean ± SE (n = 9). See Figure 1 for other abbreviations.

PA had the greatest effect and that G-3-P had little effect on the activity of the enzyme.

Stimulation of DGAT activity by a cytosolic factor(s). In mammalian systems, DGAT activity may be altered by a phosphorylation–dephosphorylation mechanism (37). The reversible inactivation by phosphorylation was detected by incubating rat liver microsomes with an aliquot of the cytosolic fraction, plus ATP and Mg^{2+}. The resulting inactivation was reversed upon incubation of the microsomes with the cytosolic fraction in the absence of ATP. The decrease in DGAT activity implicated the action of a soluble DGAT-kinase (9,38). In an attempt to determine if a similar mechanism was operative in the MD cell-suspension culture, an aliquot of the cytosolic fraction (100,000 × g supernatant) was added to the DGAT assay, either in the presence or absence of ATP. The cytosolic fraction stimulated DGAT activity when added back to the microsomal fraction in the presence of 3 mM Mg^{2+}, with 5 μL of the cytosolic fraction resulting in about twofold stimulation of DGAT activity (Table 1). In the presence of 25 mM Mg^{2+}, however, a much lower level of stimulation by the cytosolic fraction was observed (Table 1). Unlike results from mammalian studies, no inhibition was detected under any of the conditions tested. The stimulation by the cytosolic fraction was not dependent on exogenous ATP (Table 1) or affected by preincubation with microsomes (data not shown), but was dependent on the quantity of cytosolic fraction added. The degree of stimulation showed an essentially linear dependence on the quantity of cytosolic fraction added to the reaction mixture (Fig. 8). Thirty microliters of the cytosolic fraction resulted in a sixfold stimulation of DGAT activity.

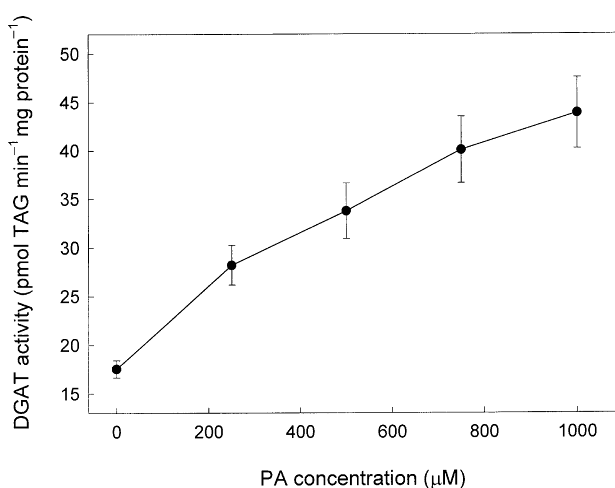

FIG. 7. Effect of bulk concentration of PA on microsomal DGAT activity in MD cell-suspension cultures of *B. napus* L. cv. Jet Neuf. A stock dispersion of PA was prepared as described in the legend to Figure 6. Data points represent the mean ± SE (n = 9). See Figures 1 and 6 for abbreviations.

TABLE 1
Effect of 5 μL Cytosolic Fraction on Microsomal DGAT Activity in MD Cell-Suspension Cultures of *Brassica napus* L. cv. Jet Neuf in the Presence of 3 or 25 mM Mg^{2+} and 0, 1, or 2 mM ATP

	Specific activity of DGAT[a] (pmol TAG min^{-1} mg $protein^{-1}$)	
	Control	Cytosolic fraction
3 mM Mg^{2+}		
0 mM ATP	18.52 ± 1.33	40.54 ± 3.40
1 mM ATP	50.12 ± 4.45	99.97 ± 8.41
2 mM ATP	52.25 ± 4.43	103.52 ± 7.42
25 mM Mg^{2+}		
0 mM ATP	98.38 ± 7.26	112.13 ± 6.64
1 mM ATP	190.11 ± 14.39	222.61 ± 16.12
2 mM ATP	189.38 ± 12.38	223.10 ± 14.01

[a]Values represent the mean ± SE (n = 9). DGAT, diacylglycerol acyltransferase; MD, microspore-derived; TAG, triacylglycerol.

Ashing of the cytosolic fraction resulted in a loss of the stimulatory effect, which indicated that the factor was organic. Furthermore, ultrafiltration indicated that the stimulatory factor(s) had a nominal molecular weight of less than 1,000 with 80% of the stimulatory activity recovered after passage through a YM1 membrane. There have not been any previous reports of a small organic stimulator of DGAT in plant systems, although xanthohumols (which are chalcones) isolated and characterized from hops of *H. lupulus* have been shown to inhibit DGAT activity in microsomes from rat liver cells (11).

CoA was the most potent of the exogenous organic stimulators of microsomal DGAT activity identified in this study (Fig. 3). In order to determine if CoA present in the cytosolic fraction might be responsible for the stimulation, the effects of CoA and the cytosolic fraction on *P. fragi* acyl-CoA synthetase were compared. Bacterial acyl-CoA synthetase activity was found to be highly dependent on exogenous CoA concentration (data not shown). Some enzyme activity (1.7 nmol h^{-1} mg $protein^{-1}$) was detectable without exogenous CoA, suggesting the enzyme preparation contained some CoA. Incorporation of 2 μM exogenous CoA into the reaction mixture increased the enzyme activity by fourfold. Addition of increasing volumes of the cytosolic fraction, in the absence of exogenous CoA, however, did not increase bacterial acyl-CoA synthetase activity. Therefore, under these experimental conditions, CoA was not detectable in the cytosolic fraction.

ATP was found to stimulate DGAT activity only up to 1.5-fold (Fig. 2B) under the conditions used to test the stimulation of DGAT by the cytosolic fraction. Thus, ATP alone could not be responsible for all of the stimulatory activity present in the cytosolic fraction.

Collectively, the results indicated that DGAT in microsomes of MD cell-suspension cultures of *B. napus* L. cv. Jet Neuf was affected by a number of molecules, including inorganic divalent ions, PA, CoA, ATP, and an unidentified organic factor(s). Endogenous DAG was the preferred substrate of the enzyme because microsomal DGAT activity was independent of exogenous DAG. Also, the stimulatory effect of PA may have involved the generation of DAG that was more readily utilized by DGAT than exogenous DAG. Thus, it is possible that substrate

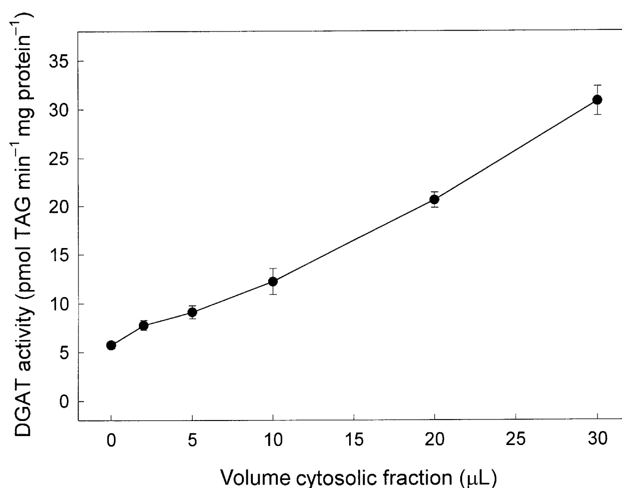

FIG. 8. Effect of the volume of cytosolic fraction on microsomal DGAT activity in MD cell-suspension cultures of *B. napus* L. cv. Jet Neuf. Enzyme assays were conducted using standard reaction conditions (the reaction mixture contained 3 mM Mg^{2+} in the absence of ATP and CoA). Data points represent the mean ± SE (n = 9). See Figure 1 for abbreviations.

channeling (39) is involved in TAG biosynthesis in the endoplasmic reticulum. Although addition of exogenous CoA and ATP resulted in enzyme stimulation, the cytosolic fraction, prepared from cell homogenate, may have been too dilute to reflect the endogenous effects of these compounds. Attempts to demonstrate a decrease in DGAT activity by phosphorylation revealed the presence of a cytosolic factor(s) that stimulated the enzyme. Future identification of the stimulator(s) may provide additional insight into the characteristics of plant DGAT.

ABSTRACT: The triterpene alcohol constituents of the nonsaponifiable lipids of two Theaceae seed oils, sasanqua and camellia oils, and two Gramineae seed oils, wheat germ and rice bran oils, were investigated. This led to the isolation and characterization of one acyclic and eight incompletely cyclized triterpene alcohols. They are camelliol A, camelliol B, camelliol C, achilleol A, helianol, isohelianol, sasanquol, graminol A [(13*R*,14*R*)-3,4-*seco*-25(10→9)*abeo*-8α,9β,10α-podioda-4,17,21-trien-3-ol], and (2*Z*,6*Z*,10*Z*,14*E*,18*E*)-farnesylfarnesol. Two other compounds isolated were characterized as (2*Z*,6*Z*,10*E*,14*E*)-geranylfarnesol, a sesterterpene alcohol, and phytol, a diterpene alcohol. Graminol A and (2*Z*,6*Z*,10*E*,14*E*)-geranylfarnesol are considered to be new natural products.

Paper no. L8279 in *Lipids 34,* 1151–1157 (November 1999).

In the course of our study on the triterpene alcohol constituents of higher plants, we have isolated seven incompletely cyclized triterpene alcohols from the nonsaponifiable lipids (NSL) of sasanqua oil and characterized them as camelliol A (**I**), camelliol B (**II**), camelliol C (**III**), and achilleol A (**IV**) (1); helianol (**V**) and isohelianol (**VI**) (2); and sasanquol (**VII**) (3) (see Scheme 1 for the structures), in addition to several tetracyclic and pentacyclic triterpene alcohols (4). In continuing our work on camellia oil, wheat germ oil, and rice bran oil, we have isolated four compounds, in addition to **I–VII**, from their NSL fractions and characterized them as graminol A [**VIII**: (13*R*,14*R*)-3,4-*seco*-25(10→9)*abeo*-8α,9β,10α-podioda-4,17,21-trien-3-ol], (2*Z*,6*Z*,10*Z*,14*E*,18*E*)-farnesylfarnesol (**IX**), (2*Z*,6*Z*,10*E*,14*E*)-geranylfarnesol (**X**), and phytol (**XI**; phyt-2-en-1-ol). This paper describes further characterization of the incompletely cyclized triterpene alcohols (**I–VIII**), and acyclic triterpene (**IX**), sesterterpene (**X**), and diterpene alcohols (**XI**) in the NSL fractions of the four seed oils investigated in our recent (1–3) and present studies.

MATERIALS AND METHODS

General. Crystallizations were performed from MeOH. Infrared (IR) spectra were recorded on a JASCO IR-300 IR spectrometer as liquid films. Optical rotations were measured on a JASCO DIP-370 polarimeter in $CHCl_3$ at 25°C. High-resolution electron impact mass spectra (HREIMS) were recorded on a Hitachi M-80B double-focusing gas chromatography–mass spectroscopy (GC–MS) instrument (70 eV) using a direct inlet system. Nuclear magnetic resonance (NMR) spectra were recorded with a JEOL LA-500 spectrometer at 500 MHz (^{1}H NMR) and 125 MHz (^{13}C NMR) in $CDCl_3$ with Me_4Si (^{1}H NMR) and $CDCl_3$ at δ 77.0 (^{13}C NMR) as internal standard. Chemical shifts were recorded in δ values. Reversed-phase high-performance liquid chromatography (HPLC) was carried out on an ODS column [Superiorex ODS S-5 µm column, 25 cm × 10 mm i.d. (Shiseido Co., Ltd., Tokyo, Japan), temperature 25°C] with MeOH as mobile phase (flow rate 4 mL/min) using an SSC Flow System 3100K (Senshu Scientific Co., Ltd., Tokyo, Japan) and an ERC-7520 refractive index detector (ERC Co., Ltd., Tokyo, Japan). Gas–liquid chromatography (GLC) was run on a Shimadzu GC-14B apparatus using a DB-17 fused-silica capillary column (30 m × 0.3 mm i.d., column temperature 275°C). For both HPLC and GLC, cholesterol (cholest-5-en-3β-ol) was the standard for the determination of the relative retention times (RRT) (i) of hydroxy terpenes; cholesterol acetate was the standard for the determination of RRT (ii) for the acetoxy terpenes. Acetylation (Ac_2O/pyridine) and hydrolysis of acetates (5% KOH in MeOH) were performed at room temperature overnight.

Materials. Sources of commercially prepared crude oils—sasanqua oil from the seeds of *Camellia sasanqua* Thunb. (4), camellia oil from the seeds of *C. japonica* L. (4), and wheat germ oil from the seeds of *Triticum aestivum* L. (5)—were described in our previous articles. Crude rice bran oil from the seeds of *Oryza sativa* L. was donated by Boso Oil and Fat

Co. (Tokyo, Japan). **I–IV** (1), **V** and **VI** (2) and **VII** (3) and their acetyl derivatives were used as the reference specimens.

Extraction and isolation. Alkaline hydrolysis (5% KOH in MeOH, reflux, 3 h) of oil materials followed by diisopropyl ether extraction yielded a neutral NSL fraction. The NSL were chromatographed on a silica gel (silica gel 60, 230–400 mesh; Merck KGaA, Darmstadt, Germany) column with hexane, hexane/EtOAc (9:1 → 4:1, vol/vol) as eluants. Hexane/EtOAc (9:1) eluted a fraction that, after rechromatography over silica gel, yielded a triterpene alcohol fraction (a fraction containing predominantly triterpene alcohols) which, upon acetylation, gave an acetylated fraction. Chromatography of this fraction over an ODS (Chromatorex ODS, 100 mesh; Fuji Silysia Chemical Ltd., Kasugai-shi, Aichi, Japan) column, eluted with MeOH, followed by HPLC afforded individual compounds as the acetyl derivatives. Alkaline hy-

TABLE 1
Chromatographic Data of the Compounds Described in This Paper, and Yields of Triterpene Alcohol Fractions and Isolated Compounds from the Oil Materials

		Chromatographic data				Yield from 1 kg of oil material			
		RRT(i)[a]	Free alcohol	RRT(ii)[b]	Acetate	Sasanqua	Camellia	Wheat germ	Rice bran

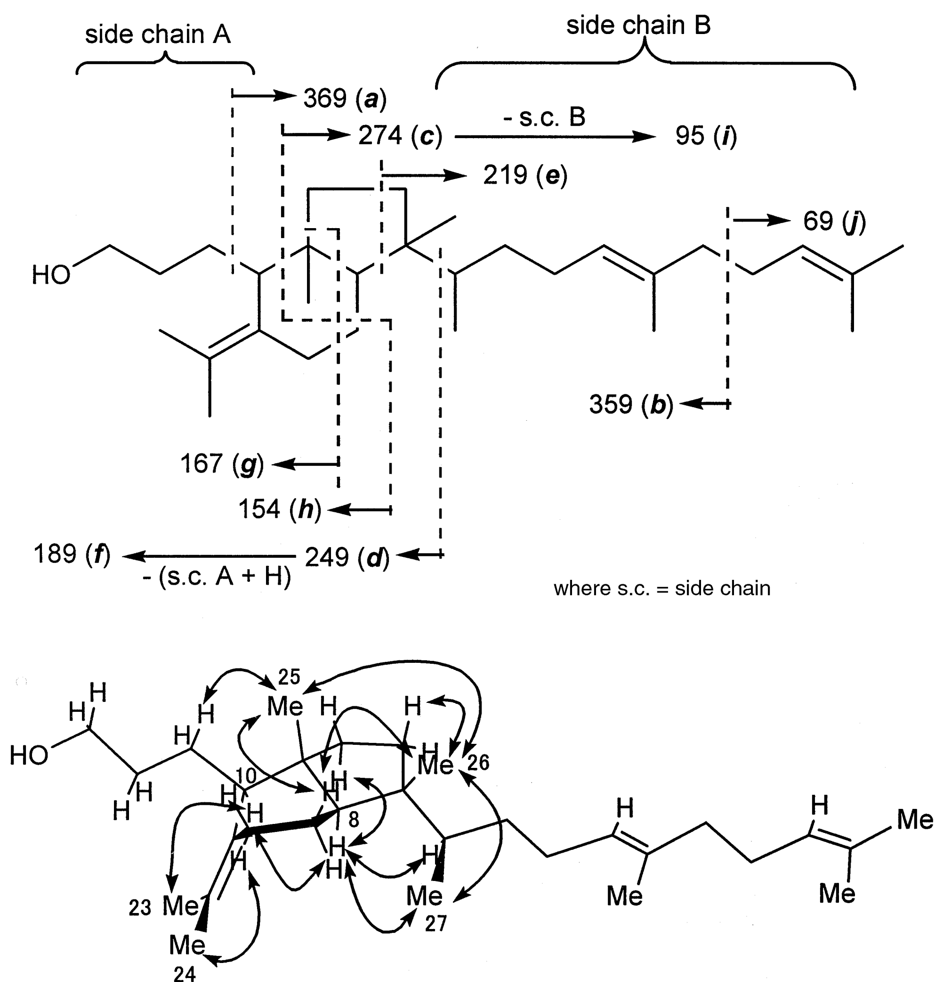
drolysis of the acetates yielded free alcohols. Yields of triterpene alcohol fractions and individual compounds from the oil materials are shown in Table 1 accompanied by their chromatographic data.

Conformational analysis for **VIII**. One thousand-step systematic Monte Carlo conformation searches were carried out for **VIII** with the extended molecular mechanics 3 (MM3*) force field as implemented in MacroModel Version 6.0 to predict the fully optimized lowest-energy structure (6).

RESULTS

As shown in Table 1, 11 acyclic and incompletely cyclized terpene alcohols, **I**–**XI**, were isolated in our recent and present studies, i.e., seven compounds, **I**–**VII**, from sasanqua oil (1–3); eight compounds, **I**–**VII** and **XI**, from camellia oil; five compounds, **IV**, **VIII**, **IX**, **X**, and **XI**, from wheat germ oil; and two compounds, **IV** and **VIII**, from rice bran oil. The seven compounds, **I**–**VII**, were identified as camelliol A (**I**), camelliol B (**II**), camelliol C (**III**), achilleol A (**IV**), helianol (**V**), isohelianol (**VI**), and sasanquol (**VII**) by chromatographic (HPLC and GLC) and spectral (MS and ^{1}H NMR) comparison with authentic compounds. Identification of two compounds, **IX** and **XI**, as (2*Z*,6*Z*,10*Z*,14*E*,18*E*)-farnesylfarnesol (7) and phytol (phyt-2-en-1-ol) (8), respectively, was performed by comparison of MS and NMR spectral data with the literature. Characterization of two other compounds, **VIII** and **X**, was performed as described below.

Characterization of compound **VIII**. Compound **VIII** was obtained as an amorphous gum after crystallization. It showed $[\alpha]_D$ −48.0° (*c* = 0.10) and IR absorptions at 3377 and 837 cm^{-1} HREIMS of **VIII** exhibited ions at *m/z* 428.4018 ($[M]^+$, relative intensity 32%; calc. $C_{30}H_{52}O$, 428.3978), 413 (38), 385 (9), 369 (35; fragment ***a*** in Scheme 2), 359 (2; ***b***), 287 (6), 274 (18; ***c***), 249 (100; ***d***), 231 (15), 219 (7; ***e***), 205 (13), 189 (24; ***f***), 167 (61; ***g***), 154 (17; ***h***), 149 (37), 135 (63), 109 (75), 95 (94; ***i***), and 69 (95; ***j***). The ^{1}H and ^{13}C NMR data for **VIII** are shown in Table 2. Compound **VIII** ($C_{30}H_{52}O$) has a primary hydroxyl group [ν_{max} 3377 cm^{-1}; δ_C 63.7 (CH_2); δ_H 3.61 (2H, *dd*, *J* = 5.8, 5.8 Hz)], two trisubstituted double bonds [ν_{max} 837 cm^{-1}; δ_C 124.4 (CH) and 125.0 (CH); δ_H 5.10 (*tt*, *J* = 1.2, 6.6 Hz) and 5.11 (*dt*, *J* = 1.2, 5.8 Hz)], a tetrasubstituted double bond (four quaternary sp^2 carbon signals with δ_C 124.2, 130.9, 131.3, and 134.8, two of which are associated with the trisubstituted double bonds), and two tertiary [δ_H 0.71 and 1.01 (each *s*)], one secondary [δ_H 0.85 (*d*, *J* = 6.7 Hz)], and five olefinic [δ_H 1.60 (6H), 1.62, 1.66, and 1.68 (each *s*)] methyl groups. These data, in combination with prominent MS fragment ions at *m/z* 369 [fragment ***a*** in Scheme 2; loss of side chain A (C_3H_5O)], 249 [***d***; loss of side chain B ($C_{13}H_{23}$)], and 189 (***e***; loss of both side chains A and B), suggested that **VIII** possesses a 3,4-*seco*-triterpen-3-ol structure (1–3) with a bicyclic skeleton, constituted with one five- and one six-membered ring (9), and two side chains A and B. The other fragment ions at *m/z* 274 (***c***), 219 (***e***), 167 (***g***), 154 (***h***), and 95 (***i***) suggested that the two tertiary methyls to be located at C-9 and C-13. Analysis of the ^{13}C distortionless enhancement by polarization transfer (DEPT), ^{1}H–^{1}H correlation spectroscopy (COSY), ^{1}H detected multiple quantum coherence (HMQC), and heteronuclear multiple-bond correlation (HMBC) spectra (Table 2) revealed the structure of **VIII** to be 3,4-*seco*-25(10→9)*abeo*-podioda-4,17,21-trien-3-ol. The stereochemistry of **VIII** was determined by phase-sensitive nuclear Overhauser effect (NOE) difference spectroscopy experiment. Compound **VIII** showed significant NOE correlations between [H-1—H-25—H-26—H-27] and [H-27—H-8α—H-10α—H-23] (Scheme 2). This allowed the assignment of H-25 and H-26 to be oriented at the β-face and



SCHEME 2

H-8 and H-10 at the α-face of the ring system, and it also allowed 14*R* stereochemistry. We conclude that structure **VIII** is (13*R*,14*R*)-3,4-seco-25(10→9)*abeo*-8α,9β,10α-podioda-4,17,21-trien-3-ol, which we named graminol A. The most stable conformation of **VIII** with minimum steric energy was simulated using MacroModel (6) and the corresponded drawings were shown in Scheme 2. The conformation of **VIII** was fairly consistent with the results from the NOE experiment carried out in solution. Graminol A acetate (**VIIIa**) was obtained as an amorphous gum, which showed $[\alpha]_D$ – 10.7° (*c* = 0.15) and IR absorptions at 1730, 1243, and 840 cm^{-1}. Its electron impact-MS exhibited ions at *m/z* 470.4101 ($[M]^+$, relative intensity 3%; calc. $C_{32}H_{54}O_2$, 470.4120), 455.3879 (4; $C_{31}H_{51}O_2$), 427.3542 (1; $C_{29}H_{47}O_2$), 401.3372 (1; $C_{27}H_{45}O_2$, corresponded to fragment ***b*** in Scheme 2), 369.3519 (3; $C_{27}H_{45}$, ***a***), 291.2296 (26; $C_{19}H_{31}O_2$, ***d***), 274.2640 (3; $C_{20}H_{34}$, ***c***), 231.2135 (4; $C_{17}H_{27}$), 219.2126 (1; $C_{16}H_{27}$, ***e***), 209.1551 (8; $C_{13}H_{21}O_2$, ***g***), 196.1461 (1; $C_{12}H_{20}O_2$, ***h***), 189.1632 (6; $C_{14}H_{21}$, ***f***), 177.1641 (3; $C_{13}H_{21}$), 175.1466 (4; $C_{13}H_{19}$), 163.1484 (5; $C_{12}H_{19}$), 95.0852 (54; C_7H_{11}, ***i***), and 69.0704 (100; C_5H_9, ***j***). The ^1H NMR spectrum of **VIIIa** showed signals of H-3 [4.03 (2H, *dd*, *J* = 6.7, 6.7 Hz)], H-17 [5.13 (*dt*, *J* = 1.2, 6.7 Hz)], H-21 [5.10 (*tt*, *J* = 1.5, 7.0)], H-23 [1.65 (*br s*)], H-24 [1.63 (*s*)], H-25 [1.00 (*s*)], H-26 [0.71 (*s*)], H-27 [0.85 (*d*, *J* = 7.0 Hz)], H-28 [16.0; 1.60 (br *s*)], H-29 [1.60 (br *s*)], H-30 [1.68 (*d*, *J* = 0.9 Hz)], and OCO*Me* [2.04 (*s*)].

Characterization of compound **X**. Compound **X** was a colorless viscous mass which showed $[\alpha]_D$ + 46.7° (*c* = 0.10) and IR absorptions at 3334, 2921, 2858, 1668, 1444, 1379, 999, and 835 cm^{-1}. The HREIMS exhibited ions at *m/z* 358.3246 ($[M]^+$, relative intensity 0.4%; calc. $C_{25}H_{42}O$, 358.3413), 340.3152 (1; $C_{25}H_{40}$), 325.2862 (0.1; $C_{24}H_{37}$), 289.2519 (0.2; $C_{20}H_{33}O$, $[M - C_5H_9]^+$), 273.2572 (0.4; $C_{20}H_{33}$), 271.2390 (1; $C_{20}H_{31}$), 257.2309 (0.2; $C_{19}H_{29}$), 229.1999 (0.5; $C_{17}H_{25}$), 221.1948 (0.5; $C_{15}H_{25}O$, $[M - C_{10}H_{17}]^+$), 215.1834 (0.4; $C_{16}H_{23}$), 205.1935 (1; $C_{15}H_{25}$), 203.1756 (2; $C_{15}H_{23}$), 189.1650 (2; $C_{14}H_{21}$), 177.1595 (1; $C_{13}H_{21}$), 137.1296 (6; $C_{10}H_{17}$), 135.1153 (5; $C_{10}H_{15}$, $[M - C_{15}H_{25} - H_2O]^+$), 85.0645 (2; C_5H_9O), 81.0689 (43; C_6H_9), and 69.0695 (100; C_5H_9). The ^1H NMR of **X** showed signals of H-1 [δ_H 4.09 (2H, *dd*, *J* = 1.0, 7.3 Hz)], H-2 [5.45 (*dq*, *J* = 1.2, 7.0 Hz)], H-6 [5.12 (*tt*, *J* = 1.5, 7.0 Hz)], H-10 [5.12 (*tt*, *J* = 1.5, 7.0 Hz)], H-14 [5.13 (*tt*, *J* = 1.5, 7.0 Hz)], H-18 [5.10 (*tt*, *J* = 1.5,

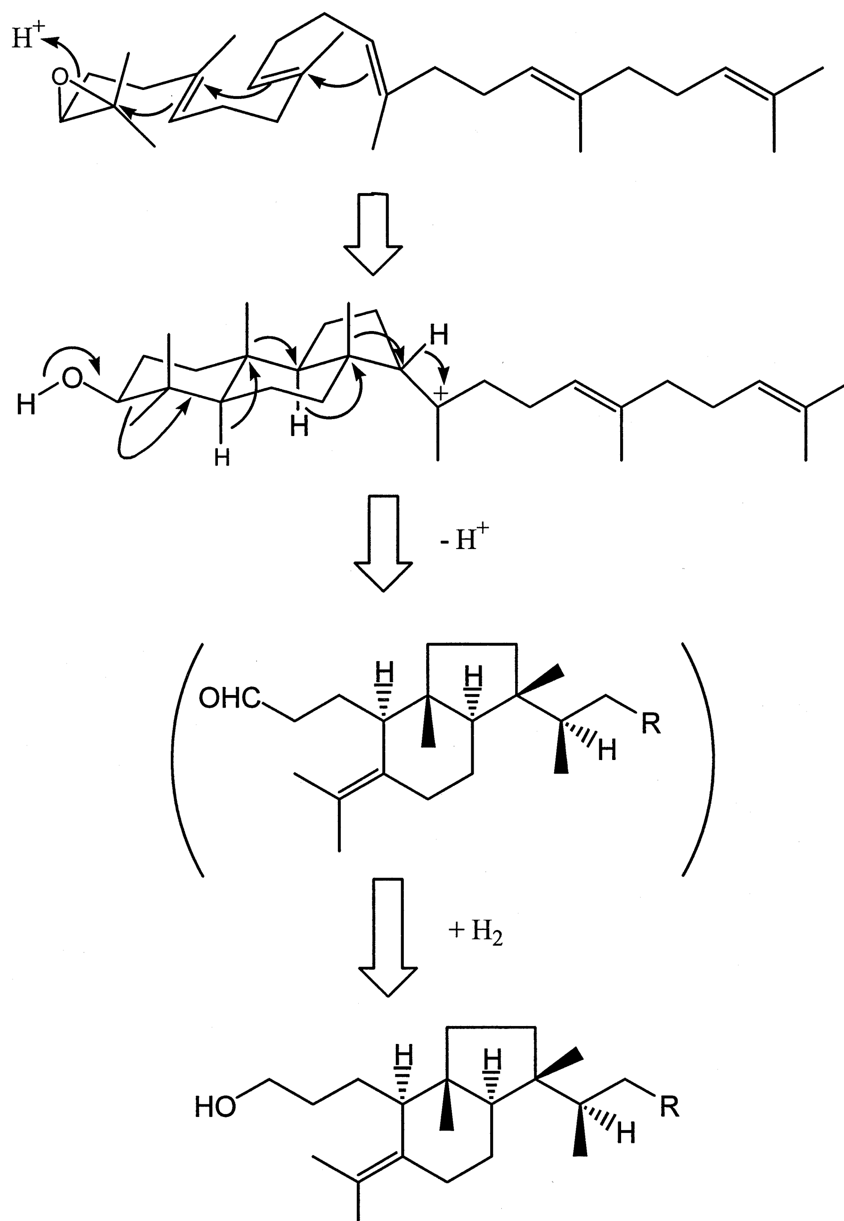
[a]Obtained by DEPT (distortionless enhancement by polarization transfer); ^{1}H-^{1}H COSY (correlation spectroscopy); HMQC (^{1}H detected multiple quantum coherence); and HMBC (heteronuclear multiple-bond correlation).
[b]For numbering see **VIII** in Scheme 1.
[c]Figures in parentheses in the ^{1}H chemical shift column denote *J* values (Hz).

7.0 Hz)], H-20 [1.75 (*d*, J = 0.9 Hz)], H-21 [1.70 (*d*, J = 1.2 Hz)], H-22 [1.60 (*s*)], H-23 [1.61 (*s*)], H-24 [1.60 (*s*)], and H-25 [1.68 (*d*, J = 0.9 Hz)]. Compound **X** ($C_{25}H_{42}O$) has a hydroxymethylene group [ν_{max} 3334 cm^{-1}; δ_H 4.09 (2H, *dd*, J = 1.0, 7.3 Hz)], five trisubstituted double bonds [ν_{max} 835 cm^{-1}; δ_H 5.10, 5.12 (2H) and 5.13 (each *tt*, J = 1.5, 7.0 Hz), and 5.45 (*tq*, J = 7.0, 1.2 Hz)], three *cis*-olefinic [δ_H 1.60 (6H, *s*) and 1.61 (*s*)], two *trans*-olefinic [δ_H 1.68 (*d*, J = 0.9 Hz) and 1.70 (*d*, J = 1.2 Hz)] methyl groups, and a *cis*-olefinic methyl group adjacent to a terminal hydroxymethylene group [δ_H 1.75 (*d*, J = 0.9 Hz)]. These data, in combination with a series of MS fragment ions at *m/z* 289, 273, 221, 205, 137, 85, and 69 due to allylic cleavages, suggested an acyclic pentaprenyl alcohol structure (7,10). Careful comparison of the ^{1}H NMR spectral data of **X** with those of **IX** (7) allowed us to assign the structure of **X** as (2*Z*,6*Z*,10*E*,14*E*)-geranylfarnesol. (2*Z*,6*Z*,10*E*,14*E*)-Geranylfarnesol acetate (**Xa**) was obtained as a colorless viscous mass. It showed $[\alpha]_D$ + 20.0° (*c* = 0.10) and IR absorptions at 2921, 2858, 1741, 1446, 1375, 1232, 1022, and 835 cm^{-1}. The HREIMS exhibited ions at *m/z* 400.3332 ($[M]^+$, relative intensity 1%; calc. $C_{27}H_{44}O_2$, 400.3332), 340 (2), 331 (0.5), 297 (0.5), 271 (2), 257 (0.5), 229 (1), 215 (1), 203 (3), 189 (3), 175 (1), 81 (45), and 69 (100). The ^{1}H NMR of **Xa** showed signals of H-1 [δ_H 4.55 (2H, *dd*, J = 1.5, 7.0 Hz)], H-2 [5.36 (*dq*, J = 1.5, 7.3 Hz)], H-6 [5.11 (*tt*, J = 1.5, 7.0 Hz)], H-10 [5.11 (*tt*, J = 1.5, 7.0 Hz)], H-14 [5.11 (*tt*, J = 1.5, 7.0 Hz)], H-18 [5.10 (*tt*, J = 1.5, 7.0 Hz)], H-20 [1.76 (*d*, J = 1.3 Hz)], H-21 [1.69 (*d*, J = 1.2 Hz)], H-22 [1.60 (*s*)], H-23 [1.61 (*s*)], H-24 [1.60 (*s*)], H-25 [1.68 (*d*, J = 1.2 Hz)], and OCO*Me* [2.04 (*s*)].

DISCUSSION

Among the 11 compounds **I**–**XI** detected in this study, two compounds, **VIII** and **X**, are new natural products to the best of our knowledge although the all-*trans* form of **X**, i.e., (2*E*,6*E*,10*E*,14*E*)-geranylfarnesol, has previously been isolated from the insect wax of *Ceroplastes albolineatus* (10). These acyclic and incompletely cyclized compounds occur only as minor components (less than 1%) of the triterpene alcohol fractions of the oil materials investigated, except for **VI** (*ca*. 1% of the triterpene alcohol fraction) in sasanqua oil, and



SCHEME 3

IV (*ca*. 2.7%), **X** (*ca*. 5.8%), and **XI** (*ca*. 4.5%) in wheat germ oil (Table 1). Major triterpene alcohol constituents of sasanqua and camellia oils (4) and wheat germ and rice bran oils (11) have previously been reported.

Only a few acyclic and incompletely cyclized triterpenoids possessing a monohydroxyl group at C-3 had been isolated from natural sources prior to our isolation of compounds **I–VII** from sasanqua oil (1–3) and **V** from several Compositae flowers (12). They are **IV** (13) and achilleol B (14) from *Achillea odorata* (Compositae), **IX** from *Phyllanthus niruri* (Euphorbiaceae) (7), and malabarica-14(18),17(20),24-trien-3β-ol from *Pyrethrum santalinoides* (Compositae) (15). Our present study suggests wider occurrence of these acyclic and incompletely cyclized triterpene alcohols in plants. On the other hand, various incompletely cyclized triterpene hydrocarbons, including podioda-7,17,21-triene and its Δ^8-isomer (8), and incompletely cyclized triterpenes with a hydroxyl group other than at C-3 have been isolated from fern plants (16, and references cited therein).

A possible biosynthetic pathway for the formation of **VIII** is shown in Scheme 3. Cyclization of squalene oxide would afford a tricyclic triterpene alcohol with a podiodane skeleton that, on stepwise hydride and methyl shifts, would yield an aldehyde. Reduction of the aldehyde would give compound **VIII**. This type of biosynthetic pathway for the formation of 3,4-*seco*-triterpene alcohol was proposed recently for iridals, the 3,4-*seco*-triterpenoids found in sword lilies (Iridaceae) (17). The other 3,4-*seco*-triterpene alcohols, **V–VII**, may

have this kind of biosynthetic pathway for their formation. Several other biosynthetic pathways for the ring A cleavage which lead to 3,4-*seco*-triterpene 3-oic acids have been proposed (18).

ACKNOWLEDGMENT

The authors are indebted to Boso Oil and Fat Co. for a supply of rice bran oil.

ABSTECT: The synthesis/hydrolysis of wax esters was studied in an aqueous solution using purified rat pancreatic lipase, porcine pancreatic carboxylester lipase, and *Pseudomonas fluorescens* lipase. The equilibrium between wax ester synthesis and hydrolysis favored ester formation at neutral pH. The synthesizing activities were measured using free fatty acid or triacylglycerol as the acyl donor and an equimolar amount of long-chain alcohol as the acyl acceptor. When oleic acid and hexadecanol emulsified with gum arabic were incubated with these lipases, wax ester was synthesized, in a dose- and time-dependent manner, and the apparent equilibrium ratio of palmityl oleate/free oleic acid was about 0.9/0.1. These lipases catalyzed the hydrolysis of palmityl oleate emulsified with gum arabic, and the apparent equilibrium ratio of palmityl oleate/free oleic acid was also about 0.9/0.1. The apparent equilibrium ratio of wax ester/free fatty acid catalyzed by lipase depended on incubation pH and fatty alcohol chain length. When equimolar amounts of trioleoylglycerol and fatty acyl alcohol were incubated with pancreatic lipase, carboxylester lipase, or *P. fluorescens* lipase, wax esters were synthesized dose-dependently. These results suggest that lipases can catalyze the synthesis of wax esters from free fatty acids or through degradation of triacylglycerol in an aqueous medium.

Paper no. L8076 in *Lipids 34,* 1159–1166 (November 1999).

Wax esters (long-chain fatty alcohols esterified to long-chain fatty acids) are widely distributed in living organisms. They are especially abundant in the cuticles of leaves and insects, in marine algae, and in certain bacteria. In mammals, wax esters are synthesized in most tissues, especially the liver (1). Sebaceous glands secrete a lipid mixture containing wax esters onto the skin surface (2). The microsomal membranes of meibomian glands catalyze wax ester synthesis (3,4). Rat brain and murine ascites cells also synthesize wax esters (5,6). Cofactors such as ATP, Mg^{2+}, and CoA reportedly stimulate wax ester formation (7,8). However, the wax ester-synthesizing enzymes have not been purified and characterized.

In specific organic solvents lipases have been reported to synthesize certain esters when alcohol (acyl acceptor) is present at high concentration. For example, pancreatic lipase catalyzes the acyl transfer reaction in a 99% organic medium (9), and microbial lipase synthesizes acylglycerols from fatty acids and glycerol in a glycerol medium (10). These lipases are used industrially for ester and peptide synthesis in organic media.

Riley *et al.* (11) found that pancreatic lipase catalyzes the synthesis of alcohol ester from fatty acid and ethanol in aqueous medium. Other lipases and carboxylesterase synthesize ethyl esters (12,13). However, high concentrations of ethanol (about 1 to 1.5 M) were used for the assay of ethyl ester synthesis; the ratio of ethanol (acyl acceptor)/free fatty acid (acyl donor) was over 2500.

In this study, we focused on the acyl transfer reaction catalyzed by lipases at the surface of the substrate emulsion, and demonstrated that these enzymes catalyze the formation of wax esters from free fatty acids or triacylglycerols and an equimolar amount of long-chain alcohol in an aqueous medium. Our results suggest that lipases generally catalyze wax ester formation on the surface of substrate emulsions at a low concentration of alcohol. Therefore, we postulate that wax esters can be formed in the various organs by various lipases, independently of the presence of ATP, Mg^{2+}, and CoA.

MATERIALS AND METHODS

Materials. The following enzyme substrates and reagents were used: [1-^{14}C]trioleoylglycerol (3.95 Gbq/mol) and [1-^{14}C]oleic acid (2.1 Gbq/mmol) were from Dupont NEN (Boston, MA). Trioleoylglycerol, bile salts, and colipase were from Sigma (St. Louis, MO). Oleic acid, dioleoylglycerol, monooleoylglycerol, palmityl oleate, lauryl oleate, and fatty alcohols were from Funakoshi (Tokyo, Japan). Bovine serum albumin (BSA) was from Wako Pure Chemical Industries (Osaka, Japan) and was extracted by the method of Chen to remove free fatty acid (14).

Enzyme sources. Rats (Crj: Wistar) were cared for under guidelines for animal experimentation of the Laboratory Animal Center at Ehime University School of Medicine. Pancreatic lipase from rat pancreas (3200 U/mg protein, at pH 6.8) (15) and carboxylester lipase from porcine pancreas (159 U/mg protein, at pH 6.8) (16) were purified as described previously. Crystalline lipase from *Pseudomonas fluorescens* was from Amano Pharmaceutical Co. (Nagoya, Japan), and was purified further as described previously (4200 U/mg protein, at pH 6.8) (17). A lingual lipase fraction was prepared from rat tongues. The entire lingual serous glandular region

was homogenized in cold 25 mM potassium phosphate buffer, pH 6.3, containing 0.9% NaCl. The homogenate was centrifuged at 100,000 × *g* for 60 min, and the supernatant, which was used as the enzyme solution, was stored at −80°C (0.28 U/mg protein, at pH 5.0) (18). Crude microbial lipases from *Mucor lipolyticus* (480 U/mg protein, at pH 8.4), *Candida cylindracea* (526 U/mg protein, at pH 6.8), and *Rhizopus* sp. (99 U/mg protein, at pH 6.8) were obtained from Amano Pharmaceutical Co. One U (unit) will produce 1.0 µmol of oleic acid from trioleoylglycerol emulsified with gum arabic per minute at 37°C.

Enzyme assays. All of the enzyme assays were done in aqueous medium. Wax ester synthesis from oleic acid was determined using [^{14}C]oleic acid. A suspension of 30 µmol [^{14}C]oleic acid (5,000,000 dpm) and 30 µmol fatty alcohol in 2 mL 5% (wt/vol) gum arabic solution was placed in an ice bath and sonicated for 5 min with a Tomy model UD-200 (Tomy, Tokyo, Japan) equipped with a microtip at setting 2–3. The assay mixture consisted of 0.2 mL of 200 mM potassium phosphate buffer (pH 6.8) containing 0.75 µmol [^{14}C]oleic acid (125,000 dpm), 0.75 µmol fatty alcohol, and 2.5 mg gum arabic. Colipase (0.75 µg/mL) and cholic acid (6.25 mM) for pancreatic lipase, and cholic acid (6.25 mM) for carboxylester lipase were added in the assay mixture. The incubation was carried out for 1 h at 37°C, and the reaction was stopped by adding 1.5 mL chloroform/methanol (1:2, vol/vol) containing standard lipids (10 nmol hexadecanol, palmityl oleate, and oleic acid). The mixture was shaken for 15 s, then 0.5 mL chloroform and 0.75 mL H_2O were added, and the mixture was shaken again for 5 s, followed by centrifugation at 1,000 × *g* for 10 min. The lower phase was dried with a stream of nitrogen, solubilized in 50 µL chloroform, and separated by thin-layer chromatography (Whatman silica gel K-5). The plates were developed with hexane/diethyl ether/acetic acid (85:15:1, by vol). The radiolabeled lipid spots (substrate-product distribution) were directly determined using Bio-Imaging Analyzer, BAS 1000 (Fuji Film, Tokyo, Japan). The radioactivity of lipids was also determined using a liquid scintillation counter. Lipids were located with iodine vapor, and spots of wax ester were cut out for radioactivity measurement.

Wax ester hydrolysis was determined using palmityl [^{14}C]oleate or lauryl [^{14}C]oleate as substrate. A suspension of 30 µmol [^{14}C]wax ester (5,000,000 dpm) in 2 mL 5% (wt/vol) gum arabic solution was sonicated for 5 min as described above. The assay mixture consisted of 0.2 mL of 200 mM potassium phosphate buffer (pH 6.8) containing 0.75 µmol [^{14}C]wax ester (125,000 dpm) and 2.5 mg gum arabic. Colipase (0.75 µg/mL) and cholic acid (6.25 mM) for pancreatic lipase, and cholic acid (6.25 mM) for carboxylester lipase were added in the assay mixture. The incubation was carried out for 1 h at 37°C. The lipids were extracted as described above and separated by thin-layer chromatography (Whatman silica gel K-5) with hexane/diethyl ether/acetic acid (85:15:1, by vol). The radiolabeled lipid spots were directly determined using the BAS 1000. The radioactivity of lipids was also determined using a liquid scintillation counter as described above.

Wax ester synthesis from trioleoylglycerol was determined using [^{14}C] trioleoylglycerol. A suspension of 30 µmol [^{14}C]trioleoylglycerol (5,000,000 dpm) and 30 µmol fatty alcohol in 2 mL 5% (wt/vol) gum arabic solution was sonicated for 5 min as described above. The assay mixture consisted of 0.2 mL of 200 mM potassium phosphate buffer (pH 6.8) containing 0.75 µmol [^{14}C]trioleoylglycerol (125,000 dpm), 0.75 µmol fatty alcohol, 2.5 mg gum arabic, and 5 mg BSA. Colipase (0.75 µg/mL) and cholic acid (6.25 mM) for pancreatic lipase, and cholic acid (6.25 mM) for carboxylester lipase were added in the assay mixture. The incubation was carried out for 1 h at 37°C. The lipids were extracted as described above and separated by thin-layer chromatography (Whatman silica gel K-5). The plates were developed with hexane/diethyl ether/acetic acid first at 60:40:2, by vol, and then at 95:5:1, by vol. The separated radioactive lipid spots were determined using the BAS 1000.

Preparation of [^{14}C] wax esters. Palmityl [^{14}C]oleate and lauryl [^{14}C]oleate were synthesized by pancreatic lipase-catalyzed esterification of [^{14}C]oleic acid and isolated by preparative thin-layer chromatography. A suspension of 10 µmol [^{14}C]oleic acid (640 kBq) and 20 µmol fatty alcohol in 1 mL 5% (wt/vol) gum arabic solution was sonicated for 5 min. The oleic acid emulsion was incubated with 500 µg of pancreatic lipase at pH 6.5. After incubation for 1 h at 37°C, lipids were extracted as described above and separated by thin-layer chromatography (Whatman silica gel K-5). The plates were developed with hexane/diethyl ether/acetic acid (85:15:1, by vol), and then the lipid spots were scraped off and extracted with chloroform/methanol (2:1, vol/vol).

RESULTS

Effect of enzyme concentration. When emulsified oleic acid and hexadecanol (molar ratio 1:1) were incubated with pancreatic lipase, wax ester (palmityl oleate) was synthesized in a dose- and time-dependent manner (Fig. 1). Similar results were obtained using carboxylester lipase and *P. fluorescens* lipase (data not shown). By using high concentrations of lipases, the ratios of palmityl oleate/free oleic acid reached constant values, and the apparent equilibrium ratios were 0.90:0.10 for pancreatic lipase and 0.94:0.06 for carboxylester lipase and *P. fluorescens* lipase (Fig. 2). Similar results were obtained using oleic acid and dodecanol emulsion as substrates (data not shown).

Wax ester-hydrolyzing activities of these lipases were determined using palmityl [^{14}C]oleate as a substrate. Pancreatic lipase was able to hydrolyze palmityl oleate in a concentration-dependent manner, and the ratio of palmityl oleate/free oleic acid also reached a constant value (0.89:0.11) (Fig. 3). This ratio was essentially the same as the ratio obtained for wax ester synthesis (0.90:0.10) and was not changed during long-term incubation (at 84.5 µg/mL lipase for 48 h incubation). Similar results were observed using lauryl [^{14}C]oleate as a substrate (data not shown). Carboxylester lipase and *P. fluorescens* lipase were also able to hydrolyze palmityl

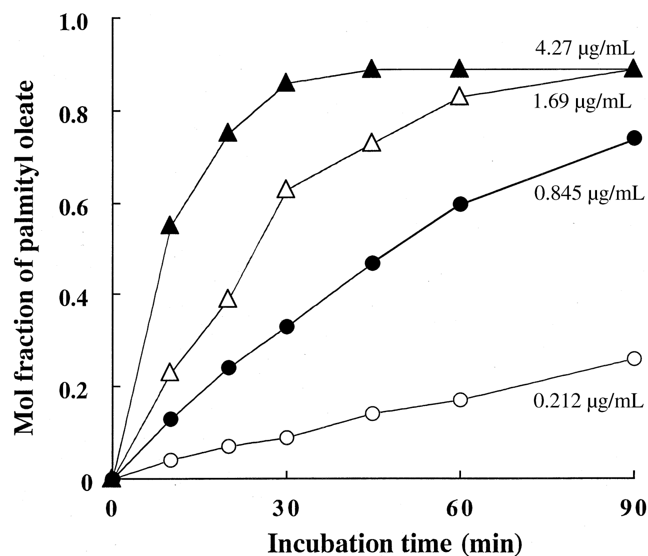

FIG. 1. Effect of incubation time on the synthesis of palmityl oleate by pancreatic lipase. The synthesis of palmityl oleate was determined using [^{14}C]oleic acid (3.75 mM) and hexadecanol (3.75 mM) as substrates. After incubation at 37°C, lipids were extracted and the molar fraction of palmityl oleate was determined.

oleate in a concentration-dependent fashion, and the apparent equilibrium ratios of palmityl oleate/free oleic acid were 0.93:0.07, essentially the same as the ratio (0.94:0.06) for the

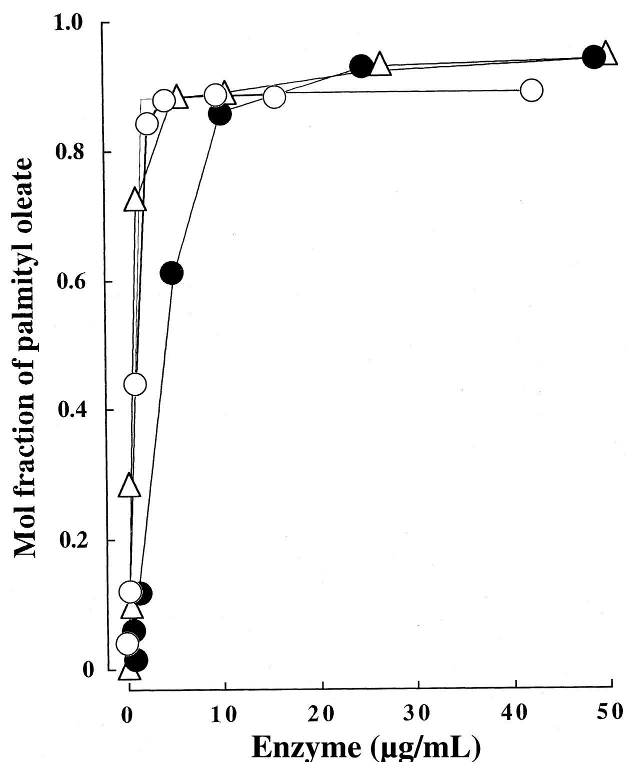

FIG. 2. Effect of lipase concentration on the synthesis of palmityl oleate. The synthesis was determined using [^{14}C]oleic acid (3.75 mM) and hexadecanol (3.75 mM) as substrates. After incubation at pH 6.8 and 37°C for 1 h, lipids were extracted and the molar fraction of palmityl oleate was determined. ○, Pancreatic lipase from rats; ●, carboxylester lipase from porcine pancreas; △, *Pseudomonas fluorescens* lipase.

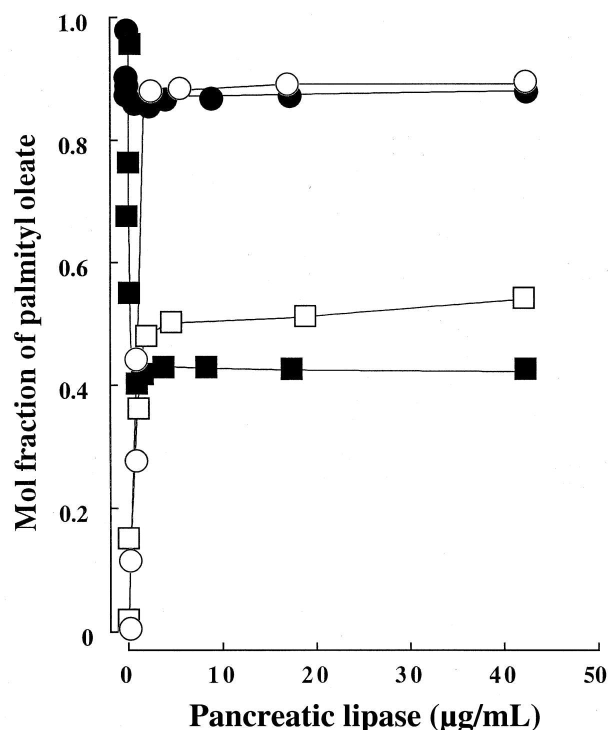

FIG. 3. Effect of pancreatic lipase concentration on the synthesis/hydrolysis of palmityl oleate with or without bovine serum albumin (BSA). Palmityl [^{14}C]oleate (3.75 mM) hydrolysis and palmityl oleate synthesis from [^{14}C]oleic acid (3.75 mM) and hexadecanol (3.75 mM) were determined with or without BSA (25 mg/mL). After incubation at 37°C for 1 h, lipids were extracted and the molar fraction of palmityl oleate was determined. ○, Synthesis without BSA; □, synthesis with BSA; ●, hydrolysis without BSA; ■, hydrolysis with BSA.

synthesis (data not shown). In these condition, these lipases completely degraded ethyl oleate: the apparent equilibrium ratios of ethyl oleate/free oleic acid were about 0.005:0.995 (data not shown). Upon addition of 2.5% BSA, the apparent equilibrium ratio changed, the ratio of palmityl oleate/free oleic acid being 0.47:0.53 for hydrolysis and 0.51:0.49 for synthesis (Fig. 3).

Effect of alcohol chain length and pH. Figure 4 shows the effect of saturated alcohol fatty acyl chain length on wax ester synthesis. The patterns of three enzymes were superimposable. The apparent equilibrium ratio of wax ester/free oleic acid was around 0.9:0.1 when fatty alcohols with acyl chains longer than decanol were used as substrates. The ratio decreased when fatty alcohols with acyl chains shorter than octanol were used, and no wax ester-synthesizing activity was detected when ethanol was used as a substrate. Figure 5 shows the pH activity curves for palmityl oleate synthesis by three lipases. The three pH activity curves were superimposable. Below pH 7.0, the apparent equilibrium ratios of palmityl oleate/free oleic acid were about 0.9:0.1. The ratio of palmityl oleate/free oleic acid decreased sharply at alkaline pH. Above pH 8.0, wax ester-synthesizing activity decreased and wax ester-hydrolyzing activity increased. When the activity of hydrolysis/synthesis was measured at pH 9.0 for 48 h using a high concentration of pancreatic lipase (84.5 μg/mL), the ratio

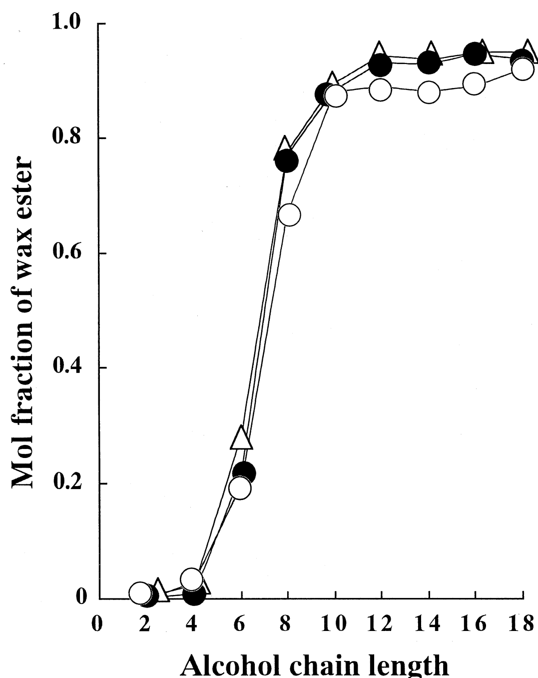

FIG. 4. Effect of fatty alcohol acyl chain length on synthesis of wax ester, as determined using [^{14}C]oleic acid (3.75 mM) and saturated alcohols of various chain lengths (3.75 mM) as substrates. After incubation at pH 6.8 and 37°C for 1 h, lipids were extracted and the molar fraction of wax ester was determined. ○, Pancreatic lipase (84.5 µg/mL); ●, carboxylester lipase (100 µg/mL); △, *Pseudomonas fluorescens* lipase (100 µg/mL).

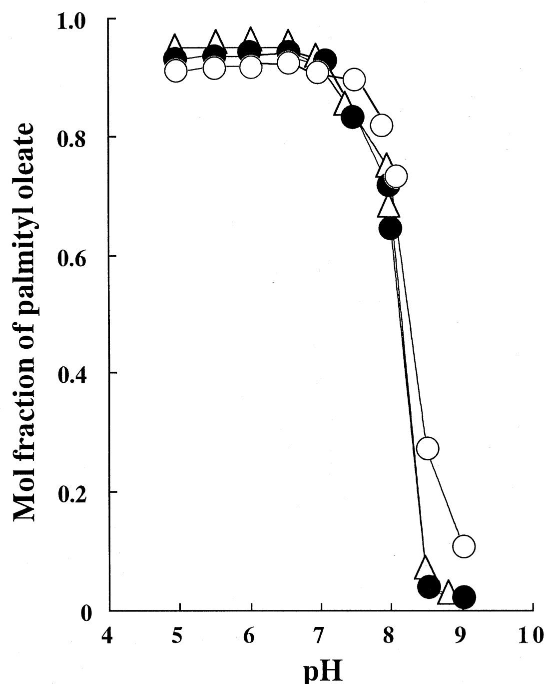

FIG. 5. Effect of pH on the synthesis of palmityl oleate, as determined using [^{14}C]oleic acid (3.75 mM) and hexadecanol (3.75 mM) as substrates. After incubation at 37°C for 1 h, lipids were extracted and the molar fraction of palmityl oleate was determined. Acetate buffer (pH 5.0 and 5.5), phosphate buffer (pH 6.0–8.0), and Tris buffer (pH 8.0–9.0) were used. The ionic strength of reaction mixture was 0.1. Symbols and lipase concentration are as in Figure 4.

of palmityl oleate/free oleic acid was 0.22:0.78 for synthesis and 0.46:0.54 for hydrolysis (data not shown).

Wax ester synthesis by other lipases. Other lipases obtained from rat tongues, *M. lipolyticus*, *C. cylindracea,* and *Rhizopus* species also synthesized wax ester dose-dependently from oleic acid and hexadecanol (data not shown). However, the enzyme concentrations at which equilibrium was reached were not the same: the apparent equilibrium ratio (0.89:0.11 for palmityl oleate/oleic acid) was reached by 0.6 U/mL of lingual lipase, 3 U/mL *C. cylindracea* lipase and 5 U/mL *Rhizopus* sp. lipase, but the equilibrium ratio was not reached by 5 U/mL of *M. lipolyticus* lipase (0.51:0.49 for palmityl oleate/oleic acid); the equilibrium ratio (0.92:0.08 for palmityl oleate/oleic acid) was reached by 20 U/mL of *M. lipolyticus* lipase. No wax ester-synthesizing activity from oleic acid and hexadecanol was detected when carboxylesterases from rat adipose and kidney were used as enzymes (data not shown).

Wax ester synthesis from triacylglycerol. Figure 6 shows the effect of lipase concentrations on palmityl oleate formation from trioleylglycerol with 2.5% BSA. When [^{14}C]trioleylglycerol/hexadecanol (molar ratio, 1:1) emulsion was incubated with pancreatic lipase, carboxylester lipase, or *P. fluorescens* lipase, the formation of oleic acid and palmityl oleate increased with increasing lipase concentration. At a high concentration of pancreatic lipase (84.5 µg/mL), the molar ratio of wax ester, oleic acid, and monooleoylglycerol was about 1:1.2:1. At a high concentration of *P. fluorescens* lipase (over 20 µg/mL), the molar ratio of wax ester to oleic acid was about 1:2. Rat lingual lipase and microbial lipases also synthesized wax ester from trioleoylglycerol (Table 1). The effect of saturated fatty alcohol acyl chain length on wax ester formation from trioleoylglycerol by pancreatic lipase, carboxylester lipase, and *P. fluorescens* lipase is shown in Figure 7. Trioleoylglycerol was almost completely degraded by high concentrations of lipases. The patterns of oleic acid formation were roughly the inverse of wax ester formation: free oleic acid formation decreased with an increase in the acyl chain length of fatty alcohol, whereas wax ester formation increased. Wax ester formation was not detected when fatty alcohols with acyl chains shorter than hexanol were used. Figure 8 shows the effect of pH on palmityl oleate synthesis from trioleoylglycerol by three lipases. Trioleylglycerol degradation and oleic acid formation increased with rising pH up to 9.0. However, palmityl oleate synthesis decreased sharply at alkaline pH. Similar results were observed using other lipases: palmityl oleate synthesis decreased at pH 9.0 compared to pH 6.8 (Table 1).

DISCUSSION

The typical substrates for lipase(s) are long-chain triacylglycerols, which are separated from the aqueous medium by the surface phase. Thus, lipase must be adsorbed to the lipid surface, and the quality of the surface is an important factor for lipase activity. At the lipid surface, the adsorbed lipase can

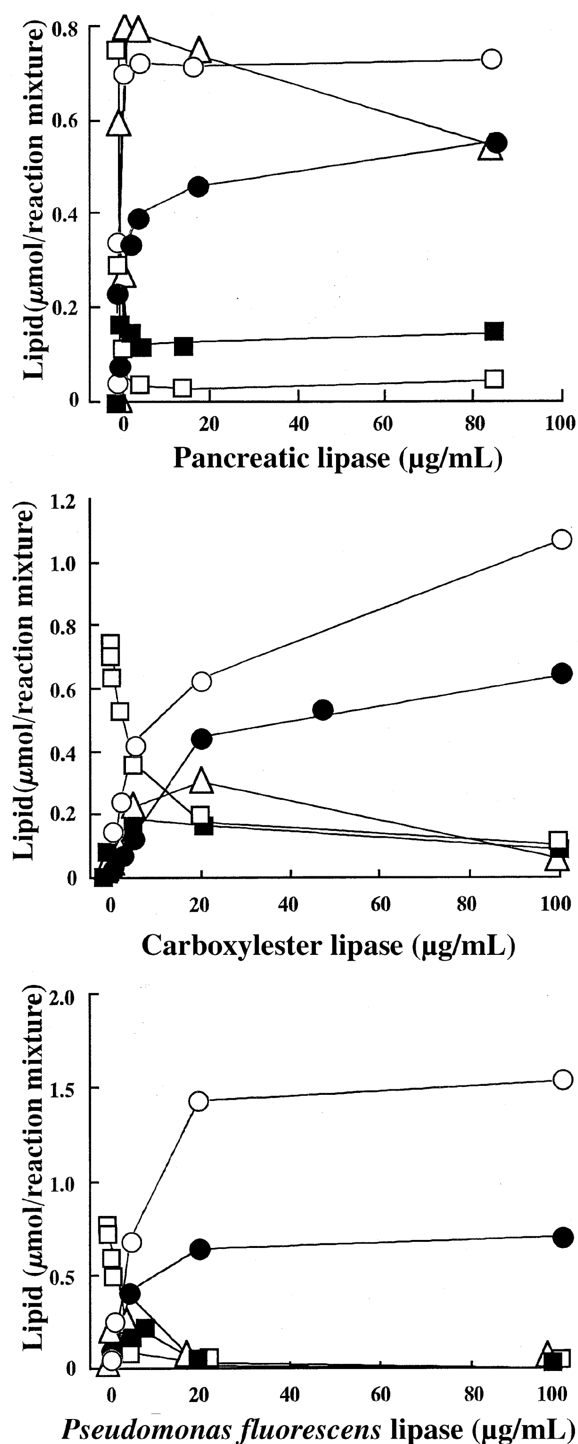

FIG. 6. Effect of lipase concentration on synthesis of palmityl oleate from trioleylglycerol, as determined using [^{14}C]trioleoylglycerol (3.75 mM) and hexadecanol (3.75 mM) as substrates with BSA (25 mg/mL). After incubation at pH 6.8 and 37°C for 1 h, lipids were extracted and their molar concentrations determined. ●, Palmityl oleate; □, trioleylglycerol; ○, oleic acid; ■, dioleoylglycerol; △, monooleoylglycerol. [a]Wax ester synthesis was determined using [^{14}C]trioleoylglycerol (3.75 mM) and hexadecanol (3.75 mM) as substrates with bovine serum albumin (25 mg/mL). After incubation at 37°C for 1 h, lipids were extracted and the molar concentrations of palmityl oleate (PO), trioleoylglycerol (TO), dioleoylglycerol (DO), monooleoylglycerol (MO), and oleic acid (OA) were determined. Lingual lipase concentration was 0.45 U/mL, and *M. lipolyticus, C. cylindracea,* and *Rhizopus* sp. lipase concentrations were 10 U/mL.

catalyze various reactions such as hydrolysis, esterification and transesterification. Therefore, substances that affect the surface would be expected to influence the lipase reaction rate. Fatty alcohols affect lipase activity in this way. Ferreira and Patton (19) suggested that the inhibition of lipase activity by fatty alcohols was due to inhibition of interfacial activation of the lipase by dilution of the high surface concentration of substrate. Mattson *et al.* (20) reported that the inhibitory effect of long-chain fatty alcohol is due to its adsorption on the substrate, thus blocking the interaction with enzyme. Both of these groups suggested that the slight inhibition of lipolysis was due to the esterification of fatty acid by fatty alcohols. However, they assayed lipase activities at alkaline pH (pH 8.0 and 9.0). If the lipase activities had been assayed at neutral pH, the contribution of esterification to the inhibition of lipolysis (fatty acid release) might have been greater, because the equilibrium favored ester formation at neutral pH.

Pancreatic lipase (21,22), carboxylester lipase (23,24), and *P. fluorescens* lipase (25) contain the common active site sequence (Gly-Xaa-Ser-Xaa-Gly) and Asp-His-Ser triad, which are characteristics of serine proteinase. Its catalytic mechanism resembles that of serine proteinases, proceeding *via* an acyl-enzyme intermediate. In this study, we demonstrated that lipases catalyze the synthesis of wax ester from fatty acid/triacylglycerol and long-chain fatty acyl alcohols by the mechanism shown in Scheme 1. Incubation of lipases with free fatty acid or triacylglycerol results in the formation of an acyl-enzyme intermediate, which is deacylated by nucleophilic attack of water or alcohol. When water is the fatty acid acceptor, hydrolysis occurs, but when alcohol is the acceptor, wax ester synthesis (alcoholysis) occurs. Long-chain fatty acyl alcohols such as hexadecanol are more efficient acyl acceptors than water. One explanation for this phenomenon is that alcohol is much more hydrophobic than water. Therefore, the long-chain alcohols may transfer to the lipid–water interface more easily than to water.

At neutral pH, only 10% of the wax esters were hydrolyzed by a high concentration of lipase during long-term incubation (48 h). Conversely, about 90% of oleic acid was esterified by lipase at high concentration. Therefore, the ap-

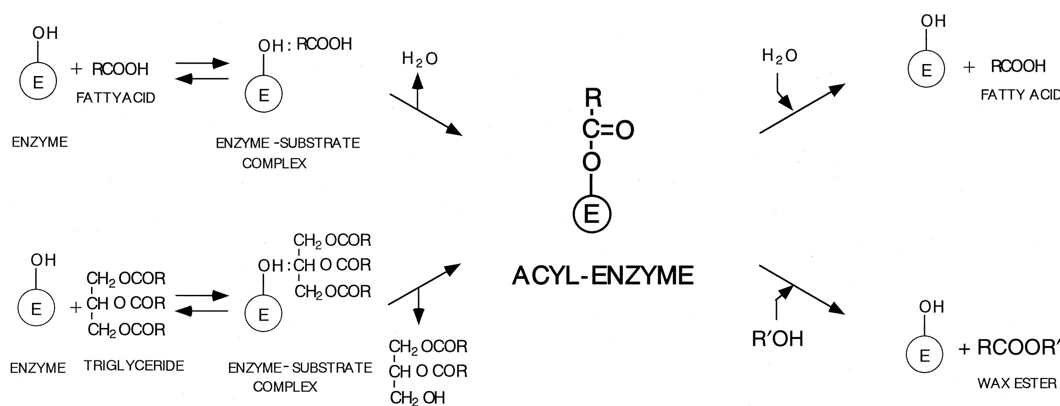
FIG. 7. FIG. 8. Effect of pH on palmityl oleate synthesis from trioleylglycerol. Wax ester synthesis was determined using [^{14}C]trioleoylglycerol (3.75 mM) and hexadecanol (3.75 mM) as substrates with BSA (25 mg/mL). After incubation at 37°C for 1 h, lipids were extracted and their molar concentrations determined. Acetate buffer (pH 5.0 and 5.5), phosphate buffer (pH 6.0–8.0) and Tris buffer (pH 8.0–9.0) were used. The ionic strength of reaction mixture was 0.1. Symbols are as in Figure 6. For abbreviation see Figure 3.



SCHEME 1

parent equilibrium ratio of ester/oleic acid reached 0.9:0.1 (Fig. 3). However, the equilibrium ratio was affected by addition of BSA: the equilibrium ratio was changed to around 0.5/0.5 in the presence of BSA (25 mg/mL) (Fig. 3). But when triacylglycerol was used as the acyl donor, the equilibrium ratio was not affected in the presence of BSA: the molar ratio of wax ester/oleic acid/monooleoylglycerol was about 1:1.2:1 at a high concentration of pancreatic lipase, and wax ester/oleic acid was 1:2 at a high concentration of *P. fluorescens* lipase (Fig. 6). With a fatty acid as substrate (upper portion, Scheme 1), the enzyme competes for acyl-enzyme intermediate formation with BSA, which traps free fatty acid. With triacylglycerol as a substrate (lower portion, Scheme 1), BSA cannot affect the process of acyl-enzyme intermediate formation and nucleophilic displacement.

Enzymatically catalyzed wax ester synthesis may proceed any of in three ways (26): (i) Free fatty acids are directly incorporated into wax esters. Wax ester is synthesized from palmitic acid and hexadecanol in the liver of both rat and dogfish, and this reaction is not influenced by ATP, CoA, or Mg^{2+} (27). (ii) Fatty acyl-CoA is used as the acyl donor for the esterification of alcohols. Wax ester synthesis in murine preputial gland tumor is catalyzed by an acyltransferase which uses fatty acyl-CoA as the acyl donor (6). Acyl-CoA:fatty alcohol acyltransferase in microsomal preparations from the meibomian gland catalyzes the synthesis of wax ester from acyl-CoA and long-chain fatty acyl alcohols (28). (iii) Acyl moieties are transferred from phospholipids to alcohols. Wax ester is synthesized by retinal pigment epithelial membranes *via* acyl transfer of a palmityl group from the *sn*-1 position of an endogenous lecithin to alcohols (29). The present findings suggest that lipases catalyze the synthesis of wax esters in two ways: direct esterification of free fatty acid and acyltransfer from triacylglycerol to alcohol.

In conclusion, various lipases can catalyze the synthesize wax ester from free fatty acid or triacylglycerol, independent of the presence of ATP, Mg^{2+}, and CoA. At neutral pH and by using long-chain fatty acyl alcohols, the equilibrium ratio of wax ester and free fatty acid favored ester formation: the ratio was about 0.9:0.1. Therefore, various lipases might catalyze the synthesis of wax esters in the various organs.

Metabolism of n-3 and n-6 Fatty Acids in Atlantic Salmon Liver: Stimulation by Essential Fatty Acid Deficiency

B. Ruyter* and M. S. Thomassen

AKVAFORSK, Institute of Aquaculture Research,1432 Ås, Norway

ABSTRACT: Oxidation, esterification, desaturation, and elongation of [1-^{14}C]18:2n-6 and [1-^{14}C]18:3n-3 were studied using hepatocytes from Atlantic salmon (*Salmo salar* L.) maintained on diets deficient in n-3 and n-6 polyunsaturated fatty acids (PUFA) or supplemented with n-3 PUFA. For both dietary groups, radioactivity from 18:3n-3 was incorporated into lipid fractions two to three times faster than from 18:2n-6, and essential fatty acids (EFA) deficiency doubled the incorporation. Oxidation to CO_2 was very low and was independent of substrate or diet, whereas oxidation to acid-soluble products was stimulated by EFA deficiency. Products from 18:2n-6 were mainly 18:3n-6, 20:3n-6, and 20:4n-6, with minor amounts of 20:2n-6 and 22:5n-6. Products from 18:3n-3 were mainly 18:4n-3, 20:5n-3, and 22:6n-3, with small amounts of 20:3n-3. The percentage of 22:6n-3 in the polar lipid fraction of EFA-deficient hepatocytes was fourfold higher than in n-3 PUFA-supplemented cells. This correlated well with our other results obtained after abdominal injection of [1-^{14}C]18:3n-3 and [1-^{14}C]18:2n-6. In hepatocytes incubated with [4,5-^{3}H]-22:6n-3, 20:5n-3 was the main product. This retroconversion was increased by EFA deficiency, as was peroxisomal β-oxidation activity. This study shows that 18:2n-6 and 18:3n-3 can be elongated and desaturated in Atlantic salmon liver, and that this conversion and the activity of retroconversion of very long chain PUFA is markedly enhanced by EFA deficiency.

Paper no. L8243 in *Lipids 34*, 1167–1176 (November 1999).

Dietary fatty acids of the n-3 and n-6 families provide the polyunsaturated fatty acids (PUFA) that fish, like all animal species so far studied, cannot synthesize *de novo*. In general, the polar lipids of fish are characterized by high contents of the n-3 fatty acids 20:5 and 22:6 and a lower content of the analogous n-6 fatty acid 20:4, with only a very small amount of 22:5 (1). The C_{20} and C_{22} fatty acids of the n-6 and n-3 families are vital structural components of biological membranes and also act as precursors for a variety of short-lived regulating molecules including the prostaglandins and leukotrienes (2). To carry out their biological functions, dietary n-3 and n-6 PUFA must be effectively metabolized in the animal. Their metabolism depends on the ability of the fish to desaturate and elongate the dietary fatty acids for esterification in neutral and polar lipids, the level of oxidation for energy production, and the possibility for peroxisomal retroconversion in order to produce shorter-chain fatty acids (3). In liver cells, these metabolic pathways compete for fatty acid substrates, and the particular pathway used may depend on the nutritional status of the animal and the dietary level of fatty acids, as well as hormonal and physiological factors.

The ability to desaturate and elongate C_{18} PUFA to longer-chain C_{20} and C_{22} PUFA varies between fish species. Rainbow trout (*Onchorhynchus mykiss*), for instance, readily convert 18:3n-3 to 20:5n-3 and 22:6n-3 (4,5), whereas red sea bream (*Pagrus major*) seem to lack the Δ5-desaturase necessary for this conversion (6). Atlantic salmon (*Salmo salar* L.) are able to convert C_{18} PUFA to C_{22} PUFA (7); however, the rates of synthesis of C_{20} and C_{22} PUFA from 18:3n-3 may be insufficient to meet the Atlantic salmon's requirement for these very long chain PUFA (8). It is believed that 18:1n-9, 18:2n-6, and 18:3n-3 all compete for the same Δ6-desaturase, which limits the rate of conversion of C_{18} PUFA to C_{20} and C_{22} PUFA. Although not investigated in any detail in fish (9), the affinity of C_{18} PUFA for Δ6-desaturase seem to vary in the order 18:3 > 18:2 > 18:1, as in mammals (10). Recently it has been discovered that this Δ6-desaturase is also involved in the formation of 22:6n-3 and 22:5n-6 (11). Evidence for this pathway operating also in fish has recently been presented (12). In addition, the Δ6-desaturase may be subjected to retroinhibition by C_{20} and C_{22} PUFA (13). Thus, a balanced proportion in the diet of the three C_{18} fatty acids is required for the synthesis of C_{20} and C_{22} PUFA of the n-6 and n-3 families.

Although Atlantic salmon is an important species in fish farming, little is known about the importance of n-3 and n-6 PUFA in its diet. The aim of the present study was to determine how a deficiency of dietary essential fatty acids (EFA) affects the metabolism of n-3 and n-6 PUFA in Atlantic salmon liver. Our focus was on esterification in neutral and polar lipid fractions and on the desaturation, elongation, and oxidation of n-3 and n-6 PUFA. The results obtained with isolated hepatocytes have further been compared with results from *in vivo* injection of radiolabeled fatty acids, in order to evaluate the significance of the *in vitro* model.

MATERIALS AND METHODS

Materials. The radiolabeled fatty acids [1-^{14}C]18:2n-6, [1-^{14}C] 18:3n-3, and [4,5-^{3}H]22:6n-3 were obtained from Amersham (Buckinghamshire, United Kingdom), and the nonlabeled fatty acids, palmitoyl-CoA, essentially fatty acid-free bovine serum albumin, HEPES, 2′,7′-dichlorofluorescein, and collagenase type 1, were obtained from Sigma Chemical Co. (St. Louis, MO). 2′7′-Dichlorofluorescein diacetate (LDCF) was obtained from Eastman Kodak (Rochester, NY). Acetic acid, chloroform, petroleum ether, diethyl ether, and methanol were all obtained from Merck (Darmstadt, Germany). Benzene was obtained from Rathburn Chemicals Ltd. (Wakerburn, Scotland). Methanolic HCl and 2,2-dimethoxypropane were purchased from Supelco Inc. (Bellfonte, PA), and partially hydrogenated coconut oil (PHCO) was a gift from Denofa (Fredrikstad, Norway). Fatty acid methyl esters were a gift from Hydro Martens (Bergen, Norway). Nycodenz was obtained from Nycomed (Oslo, Norway). Glass-baked silica gel K6 plates were obtained from Whatman International Ltd. (Maidstone, England). The gas chromatography (GC) capillary column was obtained from J&W Scientific (Folsom, CA), and the gas chromatograph from Dani Strumentazione Analitica (Monza, Italy). A radioactive flow detector A100 (Packard 1900TR Tri-Carb) was obtained from Radiomatic Instruments & Chemicals (Tampa, FL).

Experimental fish and diets. The experiment was performed at AKVAFORSK's research station at Sunndalsøra, Norway, with Atlantic salmon fry (*S. salar* L.) reared on a commercial diet to an average weight of 4 g. The fish were then divided into two dietary groups and maintained in 0.5-m^3 freshwater tanks for 18 mon at 10°C. Both groups were fed semisynthetic diets with PHCO added to give a fat content of 8 g per 100 g diet. One group was fed a diet which provided the experimental fish with the recommended dietary intake of n-3 PUFA (8), that is, a diet where 0.5 g of the PHCO was replaced by 0.5 g methyl esters of 20:5n-3 and 22:6n-3 (1:1). When measured by gas chromatography, 20:5n-3 and 22:6n-3 constituted 5.3% of the total fatty acids in the diet. The other group was fed a diet in which PHCO was the only lipid source, rendering it almost deficient in n-6 and n-3 PUFA (Table 1). Both groups were fed using automatic feeders that provided the complete estimated feed requirement based on the expected daily weight gain (14). The semisynthetic diet consisted of a casein–gelatin mixture supplemented with vitamins, minerals, and amino acids (8).

Intraperitoneal injection of radiolabeled fatty acids. Fish that had been starved for 48 h were injected intraperitoneally with 4 μCi radiolabeled 18:2n-6 or 18:3n-3 in an ethanol solution. Specific radioactivity was 0.02 μCi/g fish. The fish were killed 24 h after injection, whereupon liver, blood, and muscle were analyzed for radioactive fatty acids.

Preparation of salmon hepatocytes. Parenchymal cells were prepared using a two-step collagenase perfusion procedure as described by Seglen (15) and modified by Dannevig and Berg (16). The parenchymal cells were suspended in a buffer (300

[a]The quantity of each fatty acid is given in percentage of total fatty acids. Data are means ± SEM.
[b]Asterisk (*) denotes significant difference from n-3 supplemented diet, based on 95% confidence interval. ND = not detectable; *n* = 4; EFAD = essential fatty acid-deficient diet; DB index = number of double bonds per 100 moles fatty acid.

mOsm) containing 137 mM NaCl, 5.4 mM KCl, 0.34 mM Na_2HPO_4, 0.35 mM KH_2PO_4, 0.81 mM $MgSO_4$, 2 mM $CaCl_2$, 40 mM HEPES at pH 7.5, and 1% bovine serum albumin (BSA), and purified by conducting three 2-min 50 × *g* sedimentations. The hepatocytes were suspended and mixed with 24 mL Nycodenz (density 1.15 g/mL), overlaid with 5 mL buffer, and centrifuged for 15 min at 3,500 × *g*. Under these conditions, viable cells will float to the interface between Nycodenz and the buffer, whereas leaky and dead cells will settle. Cells from the interface were washed twice (2-min 50 × *g* sedimentations) and resuspended in buffer. Cell viability was assessed by Trypan blue (0.4%) staining. The protein content was determined according to Lowry *et al.* (17).

Incubations with radiolabeled fatty acids. Immediately after preparation, *ca.* 6×10^6 hepatocytes (20–25 mg of protein) were incubated in 25-mL Erlenmeyer flasks with 0.1 mM radiolabeled fatty acids and 10 mM lactate in a total volume of 2 mL. The specific radioactivity of the fatty acids was 7mCi/mmol in the incubation. The radiolabeled fatty acids were added to the medium in the form of their potassium salts bound to BSA. The incubation time with labeled fatty acids varied from 30 to 180 min at 15°C.

Lipid extraction and fatty acid analysis. Total lipids were extracted from homogenized tissues using a method described by Folch *et al.* (18). The solutions used for lipid extraction contained 2,6-di(*tert*-butyl)-*p*-cresol (50 mg/L) as an antioxidant, and the lipid extracts were stored under nitrogen in the dark at –50°C to prevent the oxidation of unsaturated fatty acids. The chloroform phase was dried under nitrogen and dissolved in hexane. Radioactivity in an aliquot of the total lipid was measured with a scintillation spectrometer.

Polar lipids were separated from neutral lipids by thin-layer chromatography (TLC) using a mixture of petroleum ether, diethyl ether, and acetic acid (113:20:2, by vol) as the mobile phase. The lipids were visualized by spraying the TLC plates with 0.2 % (w/v) 2′,7′- dichlorofluorescein in methanol and were identified by comparison with known standards under ultraviolet (UV) light. The spots corresponding to phospholipids (PL), triacylglycerols (TG), diacylglycerols (DG), and free fatty acids (FFA) were scraped into glass tubes and transmethylated overnight with 2,2-dimethoxypropane, methanolic HCl, and benzene at room temperature, as described by Mason and Waller (19). Radioactivity in each lipid fraction was determined with a scintillation spectrometer.

The radioactive fatty acid compositions of the PL and TG fractions were determined by reversed-phase high-pressure liquid chromatography as described by Narce *et al.* (20). The mobile phase was acetonitrile/H_2O (80:20, vol/vol). The flow rate was 1 mL/min, and the temperature 30°C. Radioactivity in the different fatty acids was measured in a radioactive flow detector A100 (Radiomatic Instruments & Chemicals, Tampa, FL). Absorbance of nonradioactive fatty acids was measured in a UV detector (SPD-6AV UV-visible spectrophotometric detector; Shimadzu, Kyoto, Japan). Peaks were identified by comparing the sample retention volumes with the retention volumes of known fatty acid standards.

The total fatty acid composition of hepatocytes was determined according to the method described by Røsjø *et al.* (21). The methyl esters were separated on a nonpolar fused-silica capillary column by gas chromatography, and the relative quantity of each fatty acid present was determined by measuring the area under the peak corresponding to a particular fatty acid.

Fatty acid oxidation. Radioactive acid-soluble products and radioactive CO_2 (as a measure of the rate of β-oxidation) were measured as described by Christiansen *et al.* (22).

Acyl-CoA (palmitoyl-CoA) oxidase was assayed by determination of H_2O_2 production coupled to the oxidation of LDCF, mainly as described by Small *et al.* (23). The oxidation of LDCF by H_2O_2 to 2′,7′-dichlorofluoroescein was followed spectrophotometrically at 502 nm. The reaction mixture contained 0.1 M Tris-HCl (pH 8.5), 0.05 mM LDCF, 50 µg horseradish peroxidase type II (EC 1.11.1.7), 0.015 mM FAD, 0.6 mg/mL BSA, and 0.02% Triton-X100, and the reaction was started with 60 µM palmitoyl-CoA. All concentrations are given as final values. The reaction mixture contained 10–40 µg of protein in a total volume of 1 mL at 20°C. The LDCF was prepared daily at 5.1 mM in 0.01 M NaOH and stored in a light-proof container under nitrogen.

RESULTS

Fish growth and performance. Atlantic salmon fed the diet supplemented with n-3 PUFA increased in weight from 4 g at the start of the 18-mon feeding period to 302 ± 19.4 g at the end, whereas salmon fed the n-3 and n-6 PUFA-deficient diet increased in weight to 207 ± 21.3 g. In contrast, salmon fed a regular commercial diet for 18 mon under similar growth conditions weighed approximately 350 g. At the end of the trial, *ca.* 30% of the fish fed the EFA-deficient diet had swollen, pale livers and showed fin erosion, whereas these symptoms were not observed in the n-3 supplemented fish. There were, however, no significant differences in numbers of viable hepatocytes prepared from fish in either dietary group, with the percentage of viable cells routinely exceeding 90%.

Fatty acid composition of dietary lipids and of total lipids in salmon hepatocytes. In the diet not supplemented with additional PUFA, n-3 and n-6 PUFA together constituted only 0.2% of the total fatty acids; thus the diet was practically deficient in EFA. In the n-3 supplemented diet, however, 20:5n-3 and 22:6n-3 together constituted 5.3% of the total fatty acids, whereas the n-6 fatty acids constituted only 0.2% (Table 1).

Percentages of 20:5n-3 and 22:6n-3 of the total lipid fraction of hepatocytes from salmon fed the EFA-deficient diet were about threefold lower compared with the corresponding values of hepatocytes from salmon fed the n-3 supplemented diet. Percentages of longer-chain n-6 fatty acids (20:4n-6 and 22:5n-6) and 20:3n-9 in hepatocytes from EFA-deficient fish were about five- and fourfold higher, respectively, compared with hepatocytes from n-3 supplemented fish.

Incorporation of [1-^{14}C] fatty acids into hepatocyte lipid classes and metabolism into oxidation products. Both the disappearance rate of fatty acid substrates and the incorporation

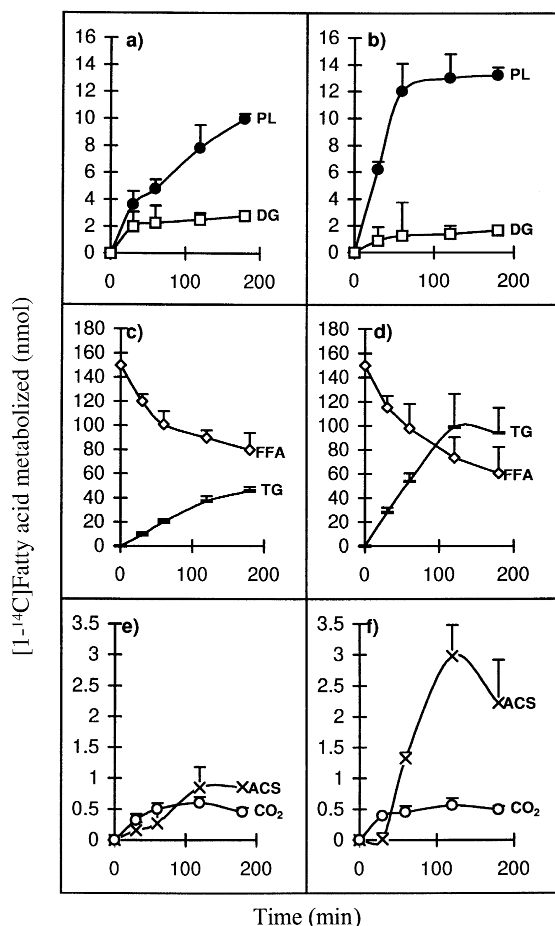

FIG. 1. Esterification in phospholipids (PL), triacylglycerols (TG), diacylglycerols (DG), and free fatty acids (FFA) and oxidation to acid-soluble products (ACS) and CO_2 from [1-^{14}C]18:3n-3 substrate in hepatocytes from fish fed an essential fatty acid (EFA)-deficient diet (b,d,f) and an n-3 supplemented diet (a,c,e). The incubation conditions are described in the Materials and Methods section. The results are expressed as nmol of ^{14}C-labeled fatty acid esterified or oxidized. Mean values and SEM of two parallel incubations of hepatocytes from three livers are given.

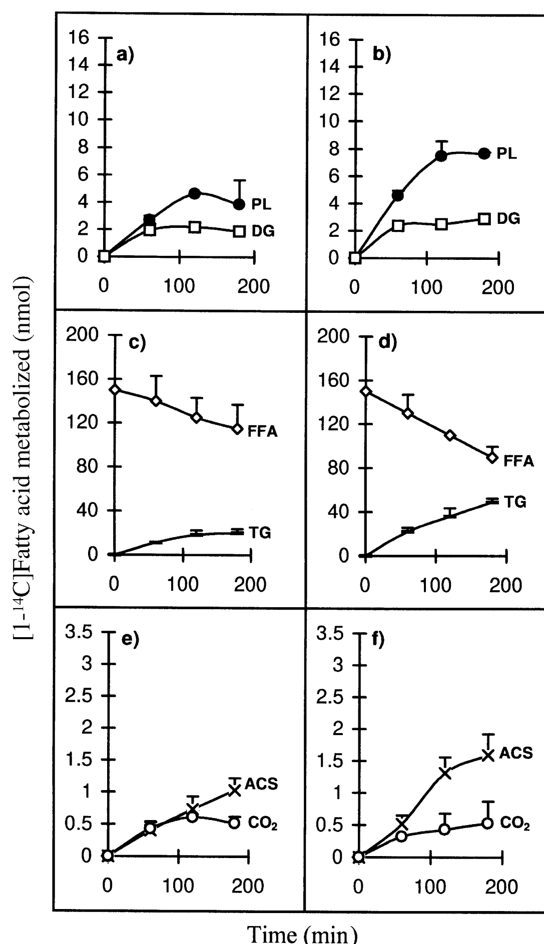

FIG. 2. Esterification in PL, TG, DG, and FFA and oxidation to ACS and CO_2 from [1-^{14}C]18:2n-6 substrate in hepatocytes from fish fed an EFA-deficient diet (b,d,f) and an n-3 supplemented diet (a,c,e). The incubation conditions are described in the Materials and Methods section. The results are expressed as nmol of ^{14}C-labeled fatty acid esterified or oxidized. Mean values and SEM of two parallel incubations of hepatocytes from three livers are given. For abbreviations see Figure 1.

of radioactivity into products proceeded fairly linearly for the first hour (Figs. 1,2). Later, reduced rates were observed, especially in the incorporation into CO_2 and PL, and most prominently in the hepatocytes from the EFA-deficient fish. When comparing the initial rates, a disappearance of free 18:3n-3 four to five times higher than of 18:2n-6 was observed in cells from n-3 supplemented fish. EFA deficiency increased these rates by a factor of 1.5–2, but the ratio was not significantly affected.

Most of the radioactivity from both substrates was recovered in the neutral lipids (60–80% during the first hour), less in PL (15–20%), with very little in oxidation products (2–5%). The initial rates of incorporation into TG and PL were found to be about twice as high for 18:3n-3 as for 18:2n-6, while no difference could be seen in the production of radiolabeled CO_2. For acid-soluble products there seemed to be a lag phase with 18:3n-3, making comparisons of the initial rates somewhat difficult. After 2 h, no difference was seen in acid-soluble products in hepatocytes from the n-3 supplemented fish, while in hepatocytes from the EFA-deficient fish about two times more acid-soluble products were observed with 18:3n-3. EFA deficiency also increased the rate of incorporation of radioactivity into TG and PL by a factor of two, while incorporation into DG was unaffected (18:2n-6) or slightly reduced (18:3n-3).

[1-^{14}C]PUFA in hepatocytes. [1-^{14}C]18:3n-3 was rapidly esterified into PL of EFA-deficient hepatocytes during the first 30 min of the incubation, but during prolonged incubation, the initial rapid increase in the 18:3n-3 content of the PL was followed by a gradual decrease. Concomitantly, the contents of 18:4n-3, 20:5n-3, 22:5n-3, and 22:6n-3 gradually increased (Fig. 3). The rate of incorporation of radiolabeled 18:3n-3 into PL and the desaturation and elongation rates of this substrate were higher in EFA-deficient hepatocytes than in cells from n-3 supplemented fish. In hepatocytes from both dietary groups, the main products formed during the 3-h incubation were

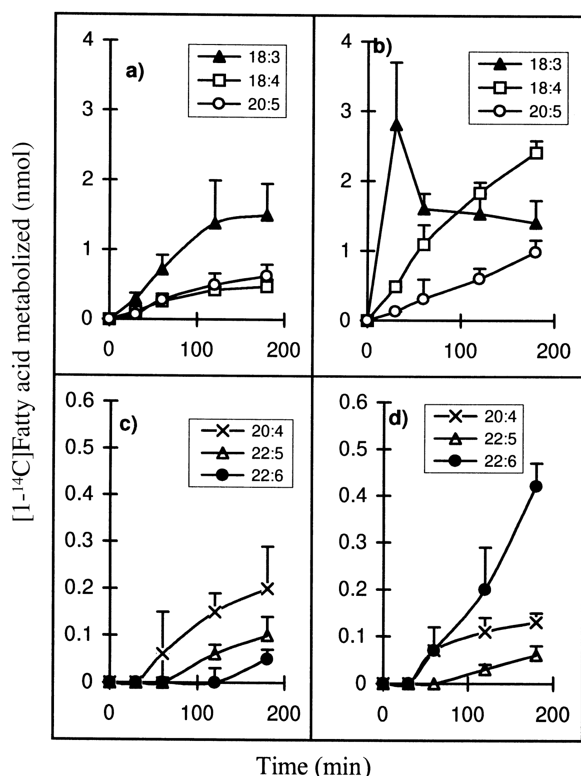

FIG. 3. Radiolabeled fatty acid metabolites found in PL of hepatocytes during a 3-h incubation with [1-^{14}C]18:3n-3 in hepatocytes from fish fed an EFA-deficient diet (b,d) and an n-3 supplemented diet (a,c). The incubation conditions are described in the Materials and Methods section. The results are expressed as nmol of esterified ^{14}C-labeled fatty acid. Mean values and SEM of two parallel incubations of hepatocytes from three livers are given. For abbreviations see Figure 1.

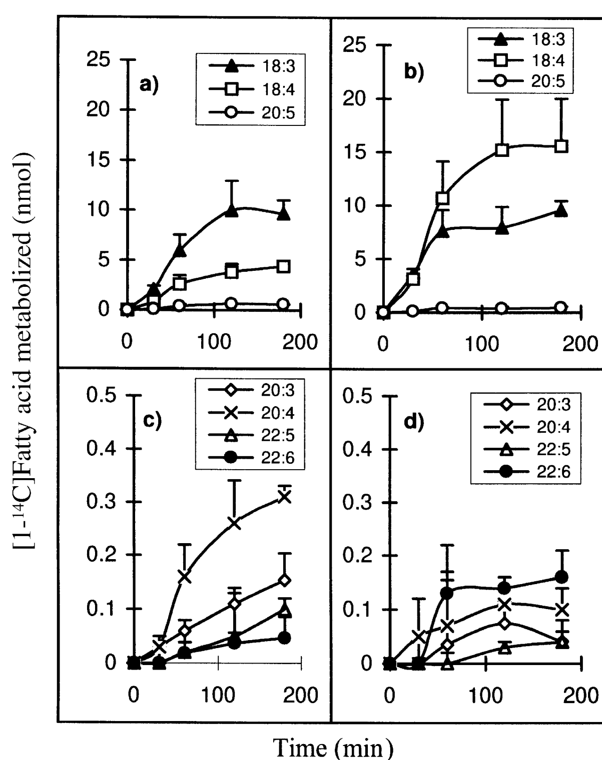

FIG. 4. Radiolabeled fatty acid metabolites found in TG of hepatocytes during a 3-h incubation with [1-^{14}C]18:3n-3 in hepatocytes from fish fed an EFA-deficient diet (b,d) and an n-3 supplemented diet (a,c). The incubation conditions are described in the Materials and Methods section. The results are expressed as nmol of esterified ^{14}C-labeled fatty acid. Mean values and SEM of two parallel incubations of hepatocytes from three livers are given. For abbreviations see Figure 1.

18:4n-3 and 20:5n-3 plus minor amounts of the n-3 20:4, 22:5, and 22:6 fatty acids. The C_{20} and C_{22} fatty acids resulting from the desaturation and elongation of 18:3n-3 were mainly incorporated into the polar lipid fraction, whereas the neutral lipids were the main recipients of the unmetabolized [1-^{14}C]18:3n-3 substrate and the desaturation product 18:4n-3 (Fig. 4). The "dead end" elongation product of 18:3n-3, i.e. 20:3n-3, also appeared mainly in the neutral lipid fraction. The amount of radioactivity recovered in 20:3n-3 and 20:4n-3 was greater in cells from the n-3 supplemented fish than in hepatocytes from EFA-deficient fish, whereas the incorporation into 22:6n-3 was substantially enhanced by EFA deficiency.

Figure 6 illustrates that for both dietary groups [1-^{14}C]18:2n-6 was incorporated into neutral lipids of hepatocytes primarily in unmetabolized form, and the incorporation rate was higher in EFA-deficient cells than in cells from n-3 supplemented fish. The main product formed from 18:2n-6 in the neutral lipid fraction was the desaturation product 18:3n-6, whereas in the polar lipids 18:2n-6 was primarily converted to longer-chain PUFA such as 20:3n-6, 20:4n-6 and 22:5n-6 (Fig. 5). The amounts of radiolabeled desaturation and elongation products formed from [1-^{14}C]18:2n-6 during the 3-h incubation were higher in EFA-deficient cells than in cells from n-3 supplemented fish.

Retroconversion of [4,5-^{3}H]22:6n-3 and peroxisomal β-oxidation of palmitoyl-CoA by hepatocytes. In addition to incubation studies with the 18-carbon fatty acids, hepatocytes from fish in both dietary groups were incubated with tritiated 22:6n-3 in order to investigate retroconversion ability and any possible influence of dietary n-3 fatty acids on this system. As shown in Table 2, most of the tritiated 22:6n-3 was esterified unchanged in polar and neutral lipids, but 4.1% had been chain- shortened to 20:5n-3 in hepatocytes from n-3 supplemented fish incubated for 3h, while in EFA-deficient cells, 10.7% of the substrate was retroconverted to 20:5n-3. The specific activity of acyl-CoA oxidase (ACO) was also measured. In hepatocytes from n-3 supplemented fish, this activity was found to be 30% less than in hepatocytes from fish fed the EFA-deficient diet, at 0.39 ± 0.03 mU/mg and 0.56 ± 0.06 mU/mg, respectively.

In vivo *metabolism of [1-^{14}C]PUFA.* Fish from both dietary groups were injected abdominally with either [1-^{14}C]18:2 n-6 or [1-^{14}C]18:3n-3. Twenty-four hours after injection, 20–30% of the injected radioactivity was recovered in the total lipid fraction of the carcass, *ca.* 0.5% in the total blood lipid fraction, and 3–8% in the total liver lipid fraction. There were no significant differences between the two dietary groups in the amount of radioactive fatty acids incorporated in carcass and

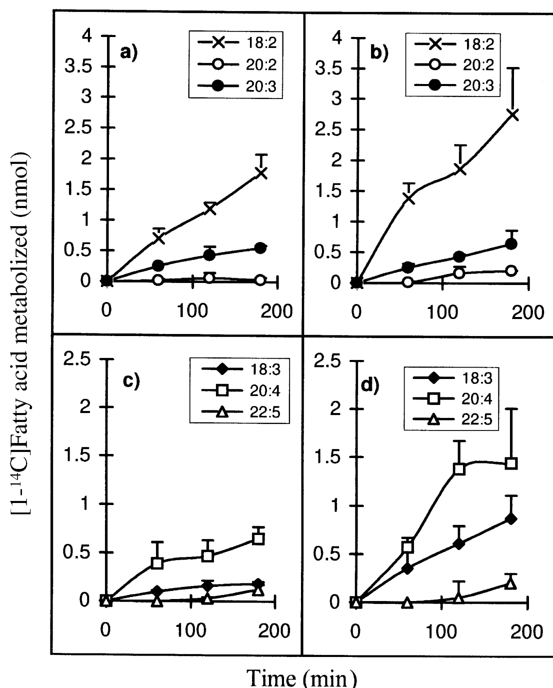

FIG. 5. Radiolabeled fatty acid metabolites found in PL of hepatocytes during a 3-h incubation with [1-^{14}C]18:2n-6 in hepatocytes from fish fed an EFA-deficient diet (b,d) and an n-3 supplemented diet (a,c). The incubation conditions are described in the Materials and Methods section. The results are expressed as nmol of esterified ^{14}C-labeled fatty acid. Mean values and SEM of two parallel incubations of hepatocytes from three livers are given. For abbreviations see Figure 1.

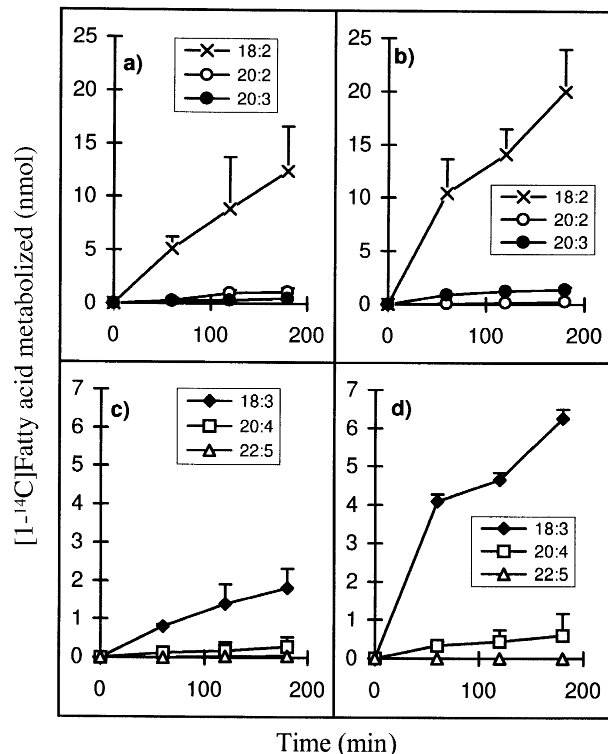

FIG. 6. Radiolabeled fatty acid metabolites found in TG of hepatocytes during a 3-h incubation with [1-^{14}C]18:2n-6 in hepatocytes from fish fed an EFA-deficient diet (b,d) and an n-3 supplemented diet (a,c). The incubation conditions are described in the Materials and Methods section. The results are expressed as nmol of esterified ^{14}C-labeled fatty acid. Mean values and SEM of two parallel incubations of hepatocytes from three livers are given. For abbreviations see Figure 1.

blood lipids. However, the amount of radioactivity recovered from the total liver lipids fraction was twice as high for fish fed the EFA-deficient diet as for fish fed the n-3 supplemented diet.

A comparison between the proportional distributions of radioactivity from [1-^{14}C]18:3n-3 in PUFA of hepatocytes (*in vitro*) and of liver (*in vivo*) is presented in Table 3. Of the total radioactivity esterified in the salmon liver *in vivo*, *ca.* 90% was recovered in the PL fraction and 10% in the TG fraction. By contrast, in isolated hepatocytes, the corresponding recoveries were near 80% in TG and 20% in PL. Each ^{14}C-labeled fatty acid metabolite formed was, however, distributed in a characteristic way between the PL and TG fractions. Both *in vivo* and *in vitro*, the C_{20} and C_{22} desaturation and elongation metabolites were primarily found in the polar lipids, whereas unaltered 18:3n-3 and its desaturation product 18:4n-3 were found mainly in the neutral lipids. The main products found in the polar lipids were the desaturation product 18:4n-3 and the desaturation and elongation products 20:5n-3, 22:5n-3, and 22:6n-3. Minor amounts of the "dead end" elongation product 20:3n-3 were also found. In the n-3 supplemented fish, the proportion of desaturated and chain-elongated fatty acids esterified in the PL fraction was higher in the liver *in vivo* (71%) than in isolated hepatocytes *in vitro* (49%). In cases of EFA deficiency, corresponding values were higher both *in vivo* (82%) and *in vitro* (74%). The percentage of radioactivity recovered in 22:6n-3 was fourfold higher in EFA-deficient hepatocytes than in cells from n-3 supplemented fish, whereas in EFA-deficient liver *in vivo,* the recovery was twice as high compared with n-3 supplemented fish. The only significant difference in the distribution of radioactivity from [1-^{14}C]18:3n-3 incorporated into the neutral lipid was an increased recovery in 18:4n-3 in EFA deficiency, both *in vivo* and *in vitro*.

Table 4 shows the proportional distributions of radioactivity from [1-^{14}C]18:2n-6 in PUFA in hepatocytes (*in vitro*) and liver (*in vivo*). More than 70% of the total radioactivity esterified in the salmon liver *in vivo* was recovered in the PL fraction, whereas less than 30% was recovered in the TG fraction. The opposite relationship was found in isolated hepatocytes, with 85% of the total esterified radioactivity recovered in TG and 15% recovered in PL. The percentage of desaturated and chain-elongated fatty acids was increased by ca. 10% by EFA deficiency both *in vivo* and *in vitro*. The main radiolabeled fatty acids esterified in the PL fraction from radiolabeled 18:2n-6, both *in vivo* and *in vitro*, were the desaturation and elongation products 20:3n-6 and 20:4n-6 and the desaturation product 18:3n-6. The longer-chain 22:4n-6 and 22:5n-6 were only found in the studies with isolated hepatocytes. In the TG fraction of n-3 supplemented fish *in vivo*, the substrate was almost exclusively esterified unchanged, whereas in EFA-deficient fish, the desaturation product 18:3n-6 was found. The content

of the elongation product 20:2n-6 in the neutral fraction of hepatocytes was higher in cells from n-3 supplemented fish than in EFA-deficient hepatocytes.

DISCUSSION

Fatty acid composition. The use of PHCO as the only lipid source in the experimental diet almost deprived the Atlantic salmon of a dietary supply of n-3 and n-6 PUFA. It was clear that the fatty acid composition of liver tissue was affected by the fatty acid composition of dietary lipids. In the total lipid fraction of hepatocytes from fish fed the EFA-deficient diet, the percentage of n-3 fatty acids, especially 22:6, was substantially lower, and the percentage of the long-chain n-6 fatty acids 20:4 and 22:5 was markedly higher as compared to the fatty acid composition of hepatocytes from fish fed the n-3 supplemented diet. Thus, in the hepatocyte lipid fraction of fish fed the EFA-deficient diet the ratio of n-3 to n-6 PUFA was tenfold lower, and the percentage of 20:3n-9 was fourfold higher than in hepatocytes from fish fed the n-3 supplemented diet. Under EFA-deficient conditions n-9 PUFA, and 20:3n-9 in particular, are synthesized instead of the normal products of Δ5-desaturation in tissue lipids (24–26). Consequently, 20:3n-9 is widely used as an indicator of EFA deficiency. For instance, if the ratio of 20:3n-9 to 22:6n-3 in rainbow trout liver exceeds 0.4, the fish is considered EFA-deficient (24). In the present study, the high ratio (3.5) of 20:3n-9 to 22:6n-3 in the total lipid fraction of hepatocytes from salmon fed the EFA-deficient diet, together with the appearance of swollen pale livers and fin erosion, indicates an EFA-deficient status. The latter two symptoms are known signs of EFA deficiency in fish (27,28). Even though no dietary n-6 fatty acids were available to fish from either of the two dietary groups, the percentage of the n-6 fatty acids 20:4 and 22:5 was higher in hepatocytes from fish fed the EFA-deficient diet as compared to hepatocytes from fish fed the n-3 supplemented diet. The higher percentage could have been due in part to mobilization of 18:2n-6 PUFA from lipid reserves in other parts of the body. Furthermore, because of the lack of dietary 18:3n-3, which is normally considered to be the preferred substrate for Δ6-desaturase, 18:2n-6 may readily be chain-elongated and desaturated to 20:4n-6 and 22:5n-6. These results are in agreement with what has previously been found in mammals, where the conversion of 20:4n-6 to 22:5n-6 has been demonstrated only in animals fed a diet deficient in EFA (29–31).

[b]Activity corresponds to nmol mg^{-1} of ^{14}C-fatty acid incorporated into lipid fractions of isolated hepatocytes during 3-h incubation, or nmol g^{-1} liver of ^{14}C-fatty acid incorporated during 24-h *in vivo*. The desaturation index (DI) is given as (18:4 + 20:4 + 20:5 + 22:5 + 22:6)/(18:3 + 20:4 + 20:5 + 22:5 + 22:6). nd= not detectable. EFAD = essential fatty acid deficient

Oxidation vs. incorporation into lipids. Nearly all of the metabolized radioactivity was esterified into neutral and polar lipids in cells from fish fed both the EFA-deficient and the n-3 supplemented diet, whereas only 2–4% of the radiolabeled substrate was oxidized to acid-soluble products and CO_2. These results are in agreement with findings in isolated rainbow trout hepatocytes incubated with radiolabeled 18:2n-6 or 18:3n-3 where only trace amounts of oxidation products were found, showing a substantially lower oxidation than observed in rat hepatocytes (32).

The initial disappearance rate of [1-^{14}C]18:3n-3 was found to be four to five times higher than for [1-^{14}C]18:2n-6, and the rate of esterification two to three times higher. This suggests that the acyl-CoA synthetase in these fish has a higher activity toward 18:3n-3 than toward 18:2n-6, which is, again, in agreement with what is found in mammals (33). In EFA deficiency these rates increased by a factor of two, indicating that the acyl-CoA synthetase activity may be increased by the lack of dietary PUFA. These results are also consistent with the observed increase in radioactivity recovered in the livers of EFA-deficient salmon.

In isolated hepatocytes, radioactivity from both [1-^{14}C]18:3n-3 and [1-^{14}C]18:2n-6 was preferentially esterified into the TG fraction, whereas in the liver lipids of Atlantic salmon *in vivo,* it was preferentially incorporated into the PL fraction irrespective of diet. This discrepancy between the *in vivo* and the *in vitro* results may be partly due to the time difference between the *in vivo* and the *in vitro* exposure to radiolabeled fatty acids. The liver lipids were extracted 24 h after intraperitoneal injection of radiolabeled fatty acids, whereas the hepatocyte lipids were extracted after only 3 h of exposure of the cells to radiolabeled fatty acids. One would expect the majority of the PUFA to be initially incorporated into TG and then to be transesterified and modified into PL. A difference in the concentration of fatty acid substrate available to the liver cells in the two experimental situations may also influence the distribution of radiolabeled fatty acids in PL and TG. Excess fatty acids in the *in vitro* system are probably preferentially stored as depot lipids in TG. These results agree with previous findings in rainbow trout. Almost 70% of the total radioactivity from [1-^{14}C]18:3n-3 was recovered in hepatocyte TG in the study of Buzzi *et al.* (5), whereas rainbow trout receiving radiolabeled 18:3n-3 in their feed, incorporated most of the radioactivity into the PL fraction (4).

Desaturation and elongation. In keeping with the studies of Tocher and Dick (36) and Bell *et al.* (7), our results show that Atlantic salmon hepatocytes possess the ability to desaturate and elongate C_{18} n-6 and n-3 fatty acids to the longer-chain PUFA. Radioactivity from [1-^{14}C]18:3n-3 was mainly found in the Δ6- and Δ5-desaturase products 18:4 and 20:5, and from [1-^{14}C]18:2 n-6 in 20:3 and 20:4. Very similar distributions were observed in liver lipids after *in vivo* injection, confirming the relevance of the *in vitro* hepatocyte system as a model for studies of fatty acid metabolism in fish. Both systems further revealed that the percentage of overall desaturated and chain-elongated radiolabeled fatty acids was increased by EFA deficiency, thus indicating that Δ6-desaturase activity was higher in EFA-deficient cells than in cells from fish fed n-3 supplemented diets. These results are consistent with previous findings in rainbow trout, where the rate of the first step in the conversion of 18:3n-3 to 22:6n-3 by Δ6-desaturation to form 18:4n-3 was increased by a deficiency of n-3 EFA (5). The same has been shown for mammals (34,35).

It has traditionally been accepted that 18:3n-3 is converted to 22:6n-3 *via* a pathway combining the sequential action of Δ6, Δ5-, and Δ4-desaturases with chain-elongation reactions. However, recent studies with rat hepatocytes have established that 22:5n-3 is elongated to 24:5n-3, further Δ6-desaturated to 24:6n-3, and then chain-shortened to 22:6n-3 by partial β-oxidation (peroxisomal retroconversion) (36,37). In both dietary groups of our trial, the products 22:5n-6 and 22:6n-3 were seen, but substantially more 22:6n-3 was produced, and especially in cells from EFA-deficient fish. Why this pathway seems to be several times more active with the n-3 fatty acids as compared

to n-6 fatty acids is not fully elucidated. Since the Δ6-desaturase most probably is involved in this pathway, the higher affinity for n-3 observed with the C-18 fatty acids may perhaps also apply to the C-24 intermediates. Possible differences in the affinity of peroxisomal chain-shortening system should, however, also be considered. Recently Buzzi *et al.* (12) have provided supporting evidence for a similar metabolism of n-3 fatty acid by the "Sprecher pathway" in rainbow trout hepatocytes. Thus, an increased production of 22:6n-3 from 18:3n-3 in our EFA-deficient hepatocytes may be due to increased Δ6-desaturation of both 18:3 to 18:4 and 24:4 to 24:5, but perhaps there is also an increased retroconversion rate of 24:6 to 22:6. In the present study, we found that the retroconversion of [4,5-^{3}H]22:6n-3 to [4,5-^{3}H]20:5n-3 was twice as high in hepatocytes from fish fed the EFA-deficient diet, compared with cells from fish fed the n-3 supplemented diet. The retroconversion is known to take place in peroxisomes (38), and the increased retroconversion in our trial was in keeping with the high activity of the peroxisomal enzyme ACO found in EFA-deficient hepatocytes.

In summary, we found that among the dietary fatty acids available to hepatocytes, the proportion of n-3 fatty acids metabolized was greater than that of n-6 fatty acids. The results demonstrate that the rates of conversion of 18:3n-3 and 18:2n-6 to 22:6n-3 and 22:5n-6 were enhanced by EFA deficiency as well as their incorporation into polar and neutral lipids and also the rate of retroconversion by peroxisomal β-oxidation.

Effects of Postnatal Ethanol Exposure on Brain Growth and Lipid Composition in n-3 Fatty Acid-Deficient and -Adequate Rats

G.R. Ward*, H.-C. Xing, and P.E. Wainwright

Department of Health Studies and Gerontology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1

ABSTRACT: The artificial rearing model was used to investigate the effects of short-term exposure to ethanol on growth and fatty acid composition of forebrain (FB) and cerebellum (CB) during the brain growth spurt in either n-3 fatty acid-adequate (AD) or n-3 deficient (DEF) rat pups. On postnatal day 5, offspring of female rats that had been fed AD or DEF diets from day 5 of life were assigned to three groups: members of two groups were gastrostomized and artificially fed formulas appropriate for their maternal history, and the third group (suckled control) was fostered to lactating dams of a similar dietary history. Half of the artificially reared pups in each dietary condition were fed ethanol in their formula (7% vol/vol) in one-quarter of their daily feedings, while the others received maltose-dextrin substituted isocalorically for ethanol. Blood alcohol concentrations did not differ betwen the dietary groups. FB weight on postnatal day 9 was lower in ethanol-exposed offspring in both dietary conditions. Brain fatty acid composition reflected dietary history in that, compared with AD pups, DEF pups had lower percentages of docosahexaenoic acid, higher percentages of 22:5n-6, and a higher n-6/n-3 fatty acid ratio. However, the effects of ethanol exposure were inconsistent, lowering the n-6/n-3 ratio in the phosphatidylethanolamine (PE) fraction in FB but not in CB, while increasing this ratio in the phosphatidylcholine (PC) fraction in FB of the DEF pups only. Thus, while ethanol had some effects on lipid composition, there was no difference between the dietary groups in their vulnerability to the effects of early short-term ethanol exposure on brain growth.

Paper no. L8236 in *Lipids 34*, 1177–1186 (November 1999).

Ethanol exerts powerful effects on brain development, as well as on subsequent physiological and behavioral regulation (1). In the search for mechanisms underlying these effects, diet and, in particular, the possible interaction of ethanol with dietary lipids have been implicated as contributing factors (2–5). Docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6), the predominant polyunsaturated fatty acids (PUFA) in the mammalian brain, are found primarily in the phospholipid fractions of neural membranes and accrue rapidly in the mammalian brain during development (6). These long-chain PUFA must be obtained either directly through dietary sources or derived from their precursor dietary fatty acids, linolenic acid (LNA, 18:3n-3) and linoleic acid (LA, 18:2n-6), through a series of desaturation and elongation reactions. It has been suggested that ethanol may alter membrane PUFA composition by altering the activity of Δ-6 and Δ-5 desaturases, two of the desaturation enzymes important in this pathway (7,8). Several studies report changes in brain fatty acid composition in adult rats and mice following several weeks of ethanol administration (9,10), although these findings have been inconsistent (11). In our laboratory, we have shown that feeding ethanol to mice during gestation lowered the n-3/n-6 ratio in pup brains, particularly by lowering the concentrations of DHA in brain phosphatidylcholine (PC) fraction (12). Similarly, a study in guinea pigs reported that administration of ethanol during pregnancy, while having complex effects on various phospholipid molecular species, was also associated with impaired accumulation of DHA in fetal brain phospholipids (13).

The essential role of AA in growth and development is well documented, and its functional role in the brain may be related to its contributions to regulatory function by serving as a precursor to the 2-series eicosanoids (14) as well as possibly to its action as a second messenger (15). The importance of DHA for retinal function is supported by studies in which laboratory animals, such as rats (16,17), guinea pigs (18), and monkeys (19), made deficient in n-3 fatty acids exhibit alterations in their electroretinograms. These alterations have been extended to functional visual outcomes in n-3 deficient monkeys (19) and in both preterm and term human infants fed formula without long-chain n-3 PUFA (20–23). There are also reports of deficits in performance on learning tasks in n-3 deficient animals (24–30). However, these findings are not consistent solely with deficits in learning, but could also be due to nonspecific effects on behavioral regulation (14,31–33). Nonetheless, they support the importance of understanding the effects of exposure to agents such as ethanol during the developmental period on brain long-chain PUFA, since it is possible that some of the neurobehavioral effects of ethanol may be mediated through such changes.

Because ethanol, administered during pregnancy can alter maternal lipid metabolism, subsequent changes in offspring lipid composition may not be due to the direct effects of ethanol, but rather may reflect changes in maternal supply of fatty acids. The artificial rearing model in rats allows the direct administration of both dietary fatty acids and ethanol to the developing pup and thereby avoids the potential confounding effects of maternal changes due to the effects of ethanol, particularly at high doses. By feeding ethanol during the early postnatal period, which encompasses the time of rapid brain growth in the rat (34), this model has been useful in describing ethanol-induced developmental abnormalities (35,36). The effects of ethanol during this period are robust, and exposure for periods even as short as 1–2 d has been found to produce deficits in brain growth (37) and in later behavior (38,39). We therefore used this approach in the present study to examine the effects of ethanol on brain development and lipid composition in rats. If the harmful effects of ethanol on brain development are associated in part with reductions in PUFA concentrations in the brain, ethanol exposure during postnatal days 5–9, which is known to produce deficits in brain growth, should also produce alterations in brain PUFA composition.

In addition to the ethanol treatment, this study incorporated a dietary manipulation by including rats that were already deficient in n-3 fatty acids. It has been shown previously that the feeding of n-3 deficient formula in the artificial rearing model is capable of producing substantial increases in the n-6/n-3 ratio of the rat brain (40). When mated, female rats that have been raised in this way and maintained on deficient diets give rise to offspring that are also n-3 deficient (27). Because previous work suggested that rats and mice made n-3 deficient are more susceptible to the effects of pentobarbital (41) and to the effects of toxic doses of triethyltin (24), we were interested in whether the effects of ethanol during the early postnatal period on brain growth and fatty acid composition would be more pronounced in n-3 deficient, compared with n-3 adequate, rat pups.

EXPERIMENTAL PROCEDURES

Animals and diets. The maternal generation in this study consisted of female offspring of Sprague-Dawley rats from a colony maintained at the University of Waterloo. These animals were fed, beginning on postnatal day 5, one of two diets differing only in their fatty acid composition. One group received a diet containing both LA and LNA in what was considered to be adequate levels (n-3 adequate or AD group), while the other was fed a diet containing adequate amounts of LA but only negligible amounts of LNA (n-3 deficient or DEF group). Until day 19, these pups were fed their appropriate diets in the form of a synthetic rat milk substitute *via* a gastrostomy tube, as described below. They were then weaned onto either AD- or DEF-modified AIN-93M chow diets (Dyets, Inc., Bethlehem, PA). Beginning at approximately 28 wk of age, these females were bred with ACI male rats purchased from Harlan Teklad (Madison, WI), and the pups used in this study were offspring of that mating.

[b]Arginine (512 g/kg), glycine (310 g/kg), taurine (156 g/kg), picolinic acid (22 g/kg).
[c]The fat mixture was prepared from the following oils (all quantities shown in g/kg of diet). For the n-3 adequate group, medium-chain triglyceride (MCT) oil (Ross Laboratories, Columbus, OH) (49.28 g/kg), safflower oil (President's Choice, Sunfresh, Ltd., Toronto, Canada) (6.16 g/kg), olive oil (Bertoli Canada, Inc., Laval, Canada) (61.6 g/kg), and linseed oil (NATUR, Bioforce Canada, Inc., St. Laurent, Canada) (6.16 g/kg). For the n-3 deficient group, MCT oil (45.58 g/kg), safflower oil (43.12 g/kg), and olive oil (34.50 g/kg).
[d]*p*-Aminobenzoic acid (11.01 g/kg), ascorbic acid (97.5%) (101.66 g/kg), biotin (0.044 g/kg), vitamin B_{12} (0.1%) (2.97 g/kg), calcium pantothenate (6.6 g/kg), choline dihydrogen citrate (349.69 g/kg), folic acid (0.20 g/kg), inositol (11.01 g/kg), menadione (4.96 g/kg), niacin (9.91 g/kg), pyridoxine HCl (2.20 g/kg), riboflavin (2.20 g/kg), thiamine HCl (2.20 g/kg), vitamin A palmitate (500,000 U/g) (3.96 g/kg) vitamin D (500,000 U/g) (0.44 g/kg), vitamin E acetate (500 U/g) (24.23 g/kg), corn starch (466.69 g/kg).
[e]Riboflavin (16.7 g/kg), niacin (26 g/kg), pyridoxal (13.9 g/kg), inositol (929.4 g/kg).
[f]Calcium phosphate (720 g/kg), calcium chloride (205 g/kg), calcium hydroxide (75 g/kg).
[g]KH_2PO_4 (812 g/kg), $MgSO_4$ (152 g/kg), $FeSO_4$ (4 g/kg), KI (0.29 g/kg), NaF (0.246 g/kg), $Al_2(SO_4)_3$ (0.156 g/kg), $MnSO_4$ (0.042 g/kg).

The rat milk substitute in these experiments consisted of a powdered protein base that was fortified with protein, carbohydrates, fat, vitamins and minerals so that it approximated the composition of rat milk (Table 1). Although the percentage fat content was the same for all pups, the fat composition differed among experimental groups in terms of the makeup of the essential fatty acids (Table 2). Specifically, whereas the AD diet contained both LA and LNA in a ratio of 3.18, the DEF diet contained approximately three times as much LA and very small amounts of n-3 fatty acids. The increase in LA in the DEF group was primarily at the expense of LNA, saturated fatty acids, and the monounsaturate 18:1n-9, which was reduced by 35% in the DEF group compared to the AD group. The protein powders also contained small amounts of fat, and the total amount of n-3 fatty acids contributed to the diet by the protein was calculated to be 0.028 g/kg of diet or 0.00023% of total di-

etary fatty acids. The n-3 PUFA in the greatest concentration in the protein powder was 22:5n-3 (0.00765 g/kg of diet), which constituted less than 0.0001% of all fatty acids in the diet

Experimental design. This study consisted of a 2 × 2 factorial design with two levels of n-3 PUFA status (either AD or DEF) and two levels of ethanol [either 7% (vol/vol) (ETOH) or 0% (MD)]. In the MD groups, an isocaloric amount of maltosedextrin (MD) was substituted for ethanol. Also, for each level of PUFA status, there was a third group of pups [suckled control (SC)] that was fostered to a dam from that level, and these two groups acted as reference groups to evaluate the effects of the artificial rearing and formula feeding. Furthermore, they acted as a measure of the effects of the dams' PUFA status, as mediated through the milk, on fatty acid composition in the pups.

Procedure. This study was conducted in compliance with the Animals for Research Act of Ontario (Revised Statutes of Ontario) and the Guide for the Care and Use of Experimental Animals from the Canadian Council on Animal Care, and all procedures were reviewed and approved by the Animal Care Committee at the University of Waterloo. For both the maternal and F1 generations, rat pups were anesthetized with methoxyfluorane (Metofane) and gastrostomized as described previously (42). Briefly, a length of polyethylene tubing (PE 10 Intramedic Tubing; Clay Adams, Parsippany, NJ) was inserted into the mouth, down the esophagus, and out through the lateral wall of the stomach. The tube was fitted with small plastic flanges to hold it in place, and was attached, *via* a larger tube, to a Harvard infusion pump. The pump was calibrated to deliver a volume of food equal to 33% of the pup's body weight each day, in 12 equally spaced feedings of 20 min each. The pups were housed in plastic cups floating in a tank of water maintained at 36 ± 1°C. Each morning, the pups were reweighed and the pumps recalibrated accordingly, and the pups were bathed and their anogenital region stimulated gently with a soft, wet tissue to facilitate urination and defecation.

For the F1 offspring, ethanol was administered by adding a 95% ethanol solution to the formula to make a 7% (vol/vol) ethanol solution. For the artificially reared control pups, the ethanol was replaced by an isocaloric solution of MD. In both cases, the experimental treatments were administered for four consecutive feedings each day. Other pups from each litter were fostered to lactating dams that were fed diets identical to their own mothers', and these pups were weighed daily but otherwise left undisturbed. The litter size of these SC litters was maintained at 10–12 pups.

Ninety minutes after the onset of the final ethanol feeding on day 9, all pups were anesthetized with an overdose of halothane and at least 0.1 mL of blood was removed by cardiac puncture for determination of blood alcohol concentration (BAC). The pups, still under anesthesia, were then killed by decapitation and their brains removed and stored at −80°C.

BAC. Blood was centrifuged immediately after collection and the plasma stored at −80°C until analysis. EtOH concentrations were subsequently determined by the ultraviolet NAD/NADH method (Sigma Technical Bulletin 332-UV; St. Louis, MO). All standards and reagents were obtained from Sigma, and all assays were run in duplicate. All samples obtained from ethanol-fed pups, as well as some from control pups, were compared to a standard curve.

Biochemical analysis. Lipids were extracted from the forebrain (FB) and cerebellum (CB) by the method of Folch *et al.* (43) and were separated into phospholipid fractions by thin-layer chromatography on silica gel plates using a chloroform/methanol/acetic acid/water (100:75:7:4, by vol) solvent system. Fatty acid methyl esters were produced from the phosphatidylethanolamine (PE) and PC fractions with 6% methanolic sulfuric acid and analyzed by capillary gas chromatography (Shimadzu GC-17A gas chromatograph; Shimadzu Corp., Kyoto, Japan). The instrument was equipped with a flame-ionization detector and a 15 m × 0.32 mm × 0.25 μm fused-silica capillary column (Supelcowax 10; Supelco Park, Bellefonte,

TABLE 2
Selected Fatty Acid Composition of Experimental Diets[a,b]

[b]E, main effect of ethanol, $P < 0.05$; FF[A], significant difference (Tukey's, $P < 0.05$) between suckled control pups and formula-fed pups of adequate maternal feeding; FF[D], significant difference (Tukey's, $P < 0.05$) between suckled control pups and formula-fed pups of n-3 deficient maternal feeding.

PA). The column temperature was held at 150°C for 2 min, then increased to 210°C at 3°C/min and held for another 10 min. The carrier gas (helium) flow rate was 2 mL/min, with a split ratio of 50, and the injector and detector temperatures were maintained at 250°C. Fatty acids were identified by comparison with retention times of authentic standards (Nu-Chek-Prep, Elysian, MN).

Statistical analysis. Data were analyzed using the general linear models approach for analysis of variance (ANOVA) (SAS v. 6.0.9; SAS Institute, Cary, NC) to assess main and interactive effects of both ethanol and diet. Any significant interaction effects were further interpreted by comparing the individual groups using *post-hoc* Tukey's *t*-test. Similarly, Tukey's tests were used to assess the effect of diet between the two SC groups as well as to compare these SC groups with their respective formula-fed (MD) control groups.

RESULTS

Morphological variables. Pup body and brain weights are shown in Table 3. There were no significant differences in body, FB, or CB weight at the end of the treatment period that were due to the concentrations of n-3 fatty acids in the diet. Ethanol reduced FB weight but, despite a similar trend in the CB weight data, this was not significant, nor was there an effect on body weight. Furthermore, artificial rearing reduced both FB and CB weight in the AD groups, relative to the weights in the SC groups, and lowered FB weight in the DEF group.

BAC. Mean BAC of the ethanol-exposed pups were 287 ± 15.6 mg/DL and 251 ± 11.6 mg/DL for the AD and DEF groups, respectively, and this difference was not significant.

Brain fatty acid composition. Brain fatty acid compositions resulting from the experimental treatments are shown in Tables 4–7. For clarity, only the effects on n-3 and n-6 essential fatty acids are described.

(i) Effects of n-3 deficiency. SC pups. The effects of long-term feeding of n-3 deficient diets in the maternal generation can be seen by comparing the two groups of SC pups on day 9. There were consistent effects of diet in that the percentages of DHA in both PE and PC for both FB (Tables 4 and 6) and CB (Tables 5 and 7) were significantly lower in the DEF SC pups relative to the AD SC pups. Concentrations of 22:5n-3 in both PE and PC in FB and in PC in CB were also significantly lower. There were reciprocal effects on the long-chain n-6 PUFA 22:5n-6, in that percentages in FB and CB PE were higher in the SC DEF pups. Thus, in FB PE and CB PC, the ratio of all n-6/n-3 fatty acids was significantly higher in the DEF SC pups.

Artificially reared pups. The effects of formula feeding of the AD and DEF diets, beginning on postnatal day 5, in pups of AD and DEF dams are addressed by the main effects of diet in the 2 × 2 ANOVA in the artificially reared groups. In PE and PC fractions of both FB and CB, there were main effects for diet in that n-3 deficiency led to a higher n-6/n-3 ratio, consistently lowered DHA percentages, and increased the percentage of 22:5n-6. In FB PE, n-3 deficiency lowered the percentage of 22:5n-3 and increased the percentage of the individual n-6 PUFA AA, and 22:4n-6. In FB PC and in the CB, there were no significant effects of diet on any other long-chain PUFA.

(iii) Effects of ethanol. The effects of ethanol administration from postnatal days 5 to 9 were assessed through the main effects of ethanol in the 2 × 2 ANOVA in the artificially reared groups. Relative to those of n-3 deficiency, the main effects of ethanol were inconsistent. In the PE fraction of the FB, ethanol treatment interacted with diet in that ethanol led to increased percentages of DHA in pups fed the AD diet, but did not affect percentages in the pups fed the DEF diets. Although ethanol also led to higher percentages of the individual n-6 PUFA 22:4n-6 and 22:5n-6, these increases were less than that seen in DHA, so that the overall ratio of n-6/n-3 fatty acids was significantly lowered by the ethanol treatment. In the PC fraction of the FB, ethanol decreased percentages of AA. There were interactive effects of diet and ethanol on the 22-carbon PUFA DHA, 22:4n-6, and 22:5n-6, as well as on the n-6/n-3 ratio. In all cases, ethanol decreased PUFA concentrations only in the DEF group; there was no difference between EtOH and MD groups in the

[b]D, main effect of diet, $P < 0.05$; E, main effect of ethanol, $P < 0.05$; INT, interaction effect, $P < 0.05$. Means of artificially reared groups with different superscripts are significantly different (Tukey's *t*-test, $P < 0.05$); MF, significant difference (Tukey's, $P < 0.05$) between suckled control kpups of adequate and deficient maternal feeding; FF^{A}, significant difference (Tukey's, $P < 0.05$) between suckled control pups and formula-fed pups of adequate maternal polyunsaturated fatty acid (PUFA) status; FF^{D}, significant difference (Tukey's, $P < 0.05$) between suckled control pups and formula-fed pups of n-3 deficient maternal PUFA status.

adequate condition. In the case of the n-6/n-3 ratio, ethanol increased the ratio but, again, affected only the DEF group.

In the PE fraction of the CB, ethanol led to decreases in AA and increases in 22:5n-3. In the PC fraction, ethanol interacted with diet to decrease percentages of 22:5n-3, but only in the AD pups.

(iv) Effects of formula feeding. There were also some effects of formula feeding of the rat milk substitute on fatty acid composition, as shown by differences between the SC pups and the artificially reared control MD pups. Relative to those in the AD SC pups, percentages of DHA in FB PE and of AA in CB PE were significantly lower in the AD MD pups. The ratio of all n-6/n-3 fatty acids in FB PE were increased by formula-feeding in the DEF pups.

DISCUSSION

In this study, the use of the artificial rearing paradigm allowed us to produce a generation of dams that were deficient in n-3 fatty acids relative to the control dams. When mated, their offspring, in turn, were also deficient, with FB n-6/n-3 ratios about four times as great as those of the AD offspring and CB ratios between two and four times as great. The most noticeable difference was in the percentages of DHA, which were substantially lower in DEF pups. There were reciprocal increases in the long-chain n-6 fatty acids, particularly 22:5n-6. The effects of ethanol exposure were less consistent than those of diet. Generally, ethanol affected percentages of some long-chain PUFA in both PE and PC fractions in the developing FB, but less so in

the CB. The direction of the effects was complex, increasing the percentage of AA in CB PE but decreasing it in FB PC, and increasing 22:5n-6 in FB PE but not in any other fraction. Effects of ethanol on DHA in the FB interacted with those of diet, with ethanol increasing DHA percentages in PE, but in the AD group only, while decreasing DHA in PC, but this time only in the DEF group.

A recent study (44) reported that ethanol consumption may increase the rate of biosynthesis of long-chain PUFA, presumably in response to the ethanol-induced peroxidation of, and subsequent lowering of, tissue PUFA concentrations. It is interesting to note that, in the present study, ethanol's effects on PUFA concentrations in PE were usually in the direction of an increase in PUFA (i.e., 22:4n-6 and 22:5n-6 in FB, AA in CB). When the effects of ethanol interacted with those of dietary fatty acid composition, as was the case for DHA in FB PE, ethanol increased DHA in the AD group but had no effect in the DEF group. If ethanol were stimulating the synthesis of long-chain PUFA in this study, one would expect the concentrations of certain PUFA to increase only if there were adequate amounts of the precursor fatty acids. Although there would be adequate levels of n-6 precursors in both the AD and DEF groups in this study, the amounts of n-3 precursors would be expected to be very low in the DEF group, and any stimulatory effect of ethanol on the n-3 series would be expected to be minimal. Therefore, if ethanol can increase biosynthesis of long-chain PUFA to compensate for increased peroxidation of PUFA in the tissues, this mechanism would only be effective in cases where there were adequate amounts of the precursor fatty acids.

Within each of the dietary conditions, there were some dif-

[b]For abbreviations see Table 4.

ferences between the concentrations of long-chain PUFA in the SC offspring, which were fed breast milk, and the artificially reared control pups, which received the synthetic formula. These differences may be due to the fatty acid composition of the formula. For example, in the AD condition, breast-fed AD pups exhibited higher percentages both of DHA in FB PE and of AA in CB PE than did the formula-fed pups, suggesting that the AD formula, while adequate in total amounts of both n-6 and n-3 fatty acids, was less than optimal during this stage of development because it did not contain long-chain PUFA. Furthermore, the fact that formula-feeding increased the ratio of fatty acids in DEF pups could be due to the fact that the n-6/n-3 ratio of 116.8 in the deficient formula was at extremely high levels.

There were no differences in body, FB, and CB growth between the suckled DEF and AD pups, supporting previous findings that n-3, unlike n-6, fatty acids are not necessary for normal growth. Furthermore, despite the trend in the data towards lower CB weights in the ethanol-treated animals, effects on CB were not significant, nor was there an effect on body weight. The lack of effect of ethanol on body growth is consistent with other studies on artificially reared rat pups (45,46), and supports the specific nature of ethanol's neuroteratogenic effects when maternal nutrition is not a mediating variable. On the other hand, the lack of effect on CB weight is surprising, particularly since other work has reported that the CB is particularly sensitive to the harmful effects of ethanol during this early postnatal period (47). It should be noted that, in the present study, both FB and CB weights were lower on day 9 in the MD than in the SC pups. This finding is specific to this particular study: in previous studies in our lab (42), and in work published by other labs (47), the CB weight of artificially reared pups raised on a formula did not differ significantly from that of SC pups. However, the pups in the other studies were born to dam-reared rats, not to rats which had themselves been artificially reared. While the suckled pups of the artificially reared dams in this study appeared to have FB and CB weights similar to those reported in the literature, they may have been more susceptible to the

stresses associated with artificial rearing. The suggestion that artificial rearing, while not having detrimental effects on reproduction *per se*, may have long-term effects on the vulnerability of subsequent generations warrants further study.

The fact that the BAC did not differ between the DEF and AD groups is not consistent with our previous findings in which the BAC of pregnant mice fed an n-3 deficient diet were significantly higher than those of dams fed a diet with relatively high levels of n-3 PUFA (12). However, it should be kept in mind that the present study was conducted directly in infant rats, in which enzyme function may still be developing. Thus, direct comparison of BAC in the two studies may not be appropriate.

The fact that the effects of ethanol did not occur exclusively or predominantly in the DEF group suggests that n-3 deficiency did not render the developing rat brain more susceptible to the effects of ethanol in this model. When the ethanol treatment interacted with diet, it was often in a direction opposite to that predicted. For example, the effects on DHA in FB PE and on 22:5n-6 in CB PC were seen only in the AD groups. One explanation for the effect on DHA could be a "floor" effect, in which the concentrations of n-3 PUFA in the DEF brains were already so low that ethanol effects were masked. However, it should be noted that the effects on 22:5n-6 were seen only in the AD group even though total amounts of this PUFA were much higher in the DEF group, suggesting that, if a floor effect was present, it was specific to n-3 PUFA.

The changes seen in lipid composition caused by ethanol in this study are smaller than those produced by dietary manipulation, which is consistent with our previous work using ethanol administration in a maternal feeding model in mice (5,12). In other work, we have evaluated the behavioral effects of such dietary treatments and found that the effects, when present, are quite small (27,48,49). Therefore, it seems unlikely that changes in brain membrane lipid composition can be contributing to the

functional concequences that have been associated previously in rats with exposure to ethanol during this period of rapid brain development.

In summary, the findings of this study support previous work in showing that exposure of artificially reared rat pups to high levels of ethanol on postnatal days 5–9 reduces FB weight, but are not consistent with the hypothesis of increased susceptibility to the effects of ethanol in the n-3 deficient pups. This short-term exposure of pups directly to ethanol during the brain growth spurt did lead to some alterations in brain membrane fatty acid composition. However, these effects, compared with those of diet, were small and somewhat inconsistent and are not supportive of a role for alterations in brain membrane lipid composition in the neurobehavioral effects of this regimen of ethanol exposure.

Column and High-Performance Size Exclusion Chromatography Applications to the *in vivo* Digestibility Study of a Thermoxidized and Polymerized Olive Oil

Francisco J. Sánchez-Muniz[a,]*, Sara Bastida[a], and M. José González-Muñoz[b]

[a]Departamento de Nutrición y Bromatología I (Nutrición), Sección Lípidos, Facultad de Farmacia, Universidad Complutense de Madrid. E-28040-Madrid, Spain, [b]Departamento de Nutrición y Bromatología, Facultad de Farmacia, Universidad de Alcalá de Henares, E-28871-Madrid, Spain

ABSTRACT: This study aimed (i) to design an *in vivo* model to study fat digestibility, and (ii) to apply this design to test the *in vivo* digestibility of a highly thermoxidized olive oil. True digestibility of unheated olive oil was tested 2, 4, 6, and 7 h after administering 1 g of olive oil/100 g body weight to young adult Wistar rats by means of esophageal probes. Remaining gastrointestinal lumen fat showed an inversely linear relationship ($r = -0.9932$; $P < 0.001$) with the length of the experiment. A 4-h test was considered adequate because after this period, half of the oil administer still remains in the lumen, making it possible to accurately measure the different nondigested, nonabsorbed thermoxidized compounds. In a second experiment, fresh olive oil (3.6 mg polar content/100 mg oil) was heated at 180°C for 50 h in the presence of air; the polar content in this oil rose to 46.0 mg/100 mg oil. After 4 h, the true digestibility coefficient of 50-h heated olive oil did not significantly change, although it tended to decrease (24%) with respect to the unheated oil. Silica gel column chromatography and high-performance size exclusion chromatography were used to quantify nonthermoxidized and thermoxidized products present in the oils and in the gastrointestinal lumen after these test periods. True digestibility of the different thermoxidized compounds from the heated oil was 30–40%, whereas that of thermoxidized compounds from the fresh oil was much higher (~80%). Nonoxidized triacylglycerol hydrolysis was negatively affected by the presence of large amounts of thermoxidized compounds. The present proposed model seems to be a useful tool for the study of thermoxidized oils. Data also show that thermoxidized compounds from abused olive oil are poorly but actively hydrolyzed and absorbed *in vivo*.

Paper no. L8022 in *Lipids 34*, 1187–1192 (November 1999).

The current diet of the population of Westernized countries contains substantial quantities of fat that has been subjected to different processing and heat treatments. Heating these fats in the presence of air produces oxidative and thermal degradation in the unsaturated acyl groups of triacylglycerols. These changes modify the nutritional properties of culinary fat and lead to the formation of many different oxidized and polymerized compounds with a higher polarity than that of the original triacylglycerols (1–4). Moreover, oils heated at frying temperature have been used as models for studying the thermoxidation produced in the frying process.

Stapräns *et al.* (5,6) have suggested that oxidized lipids in the diet are absorbed by the small intestine. Sánchez-Muniz *et al.* (7) found that hepatic thiobarbituric acid-reactive substances increased after feeding rats a diet containing thermoxidized sunflower oil used 75 times in frying potatoes.

Digestibility is generally believed to decrease when heated fats are consumed (8), although some authors do not report important changes (for reviews, see 9,10). Triacylglycerols containing at least one oxygenated function are absorbed quite well (11–13). Moreover, it appears that triacylglycerol monohydroperoxides are hydrolyzed by pancreatic lipase to almost the same degree as the original triacylglycerols (11,12). However, data concerning triacylglycerol oligomer digestibility are confusing (14,15).

Studies on altered fat digestibility often use radiolabeled markers, which do not always have the same composition as the altered compounds present in heated or used frying fats. Moreover, these markers are potentially harmful and rather expensive. In the present work, two different but complementary studies were designed. In the first one, the elapsed time required to test for *in vivo* oil hydrolysis was assessed. In the second study, a combination of *in vivo* short-term fat digestibility, column chromatography, and high-performance size-exclusion chromatography (HPSEC) techniques was employed to study the digestibility of 50-h heated olive oil, and of the different altered compounds formed during heating. The possible inhibitory role of some altered compounds, such as oligomers, on fat digestibility of nonthermoxidized triacylglycerols was also tested.

MATERIAL AND METHODS

Materials. Commercial olive oil (Koipe, Andujar, Jaén, Spain) was purchased in a local store and maintained at 15°C in darkness.

Experiment 1 Methods. (i) Animals and maintenance. The protocol used for this experiment was authorized by an Internal

Commission of the Pharmacy Faculty (Facultad de Farmacia) of the Universidad Complutense of Madrid (Spain). Male Wistar rats [Instituto de Nutrición y Bromatología (CSIC), Facultad de Farmacia, Universidad Complutense de Madrid], weighing approximately 200 g each, were used. Groups of animals were housed together in plastic cages under controlled temperature conditions (22.3 ± 1.81°C) and a 12-h light/dark cycle; they were fed standard commercial rat pellets (Panlab S.L., Barcelona, Spain). Food and drinking water were supplied *ad libitum.* The rats were starved the night before the experiment took place, but had free access to water until used. They were given a single dose (1 g/100 g body weight) of raw olive oil by means of an esophageal probe. Control rats were administered isotonic saline solution at the rate of 1 mL/100 g body weight. Experiments were started between 0800 and 0900 to avoid variations due to circadian cycles. After 2, 4, 6, and 7 h exposure to the fat, the rats were anesthetized with an intraperitoneal injection of sodium pentobarbital (60 mg/kg body wt) and euthanized by blood extraction from the descending aorta using a syringe. Afterward, 50 mL of isotonic saline solution was slowly passed from the distal esophagus to the distal ileum in order to obtain the luminal fat.

To determine the fat recovery of the technique, 2 g of fat was added into the lumen of whole intestine fresh biopsies and gently distributed through it. Afterward, 50 mL of saline solution was slowly passed from the proximal duodenum to the distal ileum in order to obtain fat. The percentage recovery obtained ranged between 93 and 101%.

(ii) Fat extraction procedure. Luminal fat was separated from the saline solution using a chloroform/methanol mix according to the method of Bligh and Dyer (16), and then purified using the Folch *et al.* method (17).

(iii) Fat digestibility test. Luminal fat was corrected by taking into account the endogenous fat obtained from control rats and compared to the amount of fat administered.

Experiment 2 methods. (i). Heating procedure. Olive oil (200 mL) olive oil was heated for 50 h at 180°C on a thermostatied plate with free access to atmospheric air.

(ii) Analytical determinations. The polar fraction of the unheated and heated olive oil was evaluated using the column chromatographic method of Waltking and Wessels (18), modifying the proportion of petroleum ether/diethyl ether used to fill the column and to elute the nonpolar fraction. A sample of ≈1 g of olive oil was dissolved in 20 mL petroleum ether/diethyl ether 87:13 (vol/vol) when fresh olive oil was analyzed, and 90:10 (vol/vol) when heated oil was tested (19). The sample was then transferred to a silica gel chromatographic column. A final elution of the column with chloroform/methanol 1:1 (vol/vol) was performed to improve recovery of the sample (20). Two samples each of the unheated and 50-h heated olive oil were analyzed. The separation of nonpolar fractions was checked by thin-layer chromatography on 0.5-mm thick 60 F250 silica gel plates (20 × 20 cm glass). Polar and nonpolar fractions were diluted 50 times (wt/vol) in hexane/diethyl ether 80:20 (vol/vol). Samples were applied as 10 µL spots using a 705 Hamilton microsyringe. Plates were developed with hexane/ethyl ether/acetic acid 80:20:1 (by vol) in a lined tank for *ca.* 25 min (*ca.* 17 cm) and then removed for the solvent to evaporate. Spots were visualized by exposure to iodine vapors.

(iii) HPSEC. Hydrolytic and/or thermoxidative alterations which occurred in the olive oil during heating were analyzed by HPSEC, following the method of Dobarganes *et al.* (2). Isolated polar fractions were studied using a Waters 501 chromatograph (Milford, MA) with a 20-µL sample loop. A Waters 410 refractive index detector and two 300 × 7.5 mm i.d. (5 µm particle size), 0.01 µm and 0.05 µm Hewlett-Packard PLgel (polystyrene-divinylbenzene) columns, connected in series, were operated at 40°C. High-performance liquid chromatography grade tetrahydrofuran served as the mobile phase at a flow of 1 mL/min. The sample concentration was 10–15 mg/mL in tetrahydrofuran. All eluents and samples were precleaned by passage through a 2-µm filter. The quantity of each polar compound was calculated as previously indicated (20).

(iv) Animals and maintenance. The protocol used for this experiment was similar to the one explained in the first experiment, and it also was authorized by an Internal Commission of the Pharmacy Faculty (Facultad de Farmacia) of the Universidad Complutense of Madrid (Spain). Male Wistar rats were studied after 4 h administration of a single dose (1 g/100 g body weight) of raw olive oil or the same amount of heated olive oil by means of an esophageal probe. Control rats were administered isotonic saline solution at the rate of 1 mL/100 g body weight. Experiments were started between 0800 and 0900. After a 4-h exposure to the fat, the rats were anesthetized with an intraperitoneal injection of sodium pentobarbital (60 mg/kg body wt) and euthanized by blood extraction from the descending aorta using a syringe. Afterward, 50 mL of isotonic saline solution was slowly passed from the distal esophagus to the distal ileum in order to obtain the luminal fat.

(v) Fat extraction procedure. After the wash-out with saline solution, luminal fat was separated using a chloroform/methanol mix according to (16) and then purified (17).

(vi) *Fat digestibility test.* The content and composition of luminal fat were corrected by taking into account the endogenous fat obtained from control rats. Purified samples of the luminal fat were transferred to a silica gel chromatographic column, polar and nonpolar fractions were separated, and purity was checked as indicated previously. Highly polar lipids, such as phospholipids, are retained by the silica gel stationary phase and therefore do not elute together with acylglycerols and free fatty acids. Moreover, lecithin (the most abundant bile phospholipid) is poorly soluble in tetrahydrofuran. Therefore, although lecithin has a molecular weight between oxidized triacylglycerols and diacylglycerols and thus might present an HPSEC retention time similar to these compounds, it does not appear in the HPSEC analysis because of these methodological reasons. Polar fractions were studied by means of HPSEC, as mentioned above. The amount of thermoxidized compounds (triacylglycerol polymers and dimers, and oxidized triacylglycerols) and hydrolytic compounds (diacylglycerols, monoacylglycerols, and free fatty acids) was corrected taking into account the amount present in control rats and comparing that with the

amount of polar compounds present in the oil administered to the rats. As cholesterol and bile acids are present in the intestinal tract and have apparent molecular weights, and thus HPSEC retention times, that are similar to those of free fatty acids, the influence of these compounds in HPSEC determinations was tested. High amounts of cholic acid resulted in only minor chromatographic peaks, for which reason the influence of bile acids can be considered inconsequential. However, the addition of cholesterol to the samples increased the peak area related to free fatty acids. Cholesterol content in the luminal fat samples was calculated using Boehringer Mannheim's enzymatic colorimetric method (Mannheim, Germany), and the HPSEC free fatty acid data were corrected.

(vii) Statistical analysis. Data from heated and nonheated olive oil were compared by unpaired Student's t -test.

RESULTS

First experiment. Figure 1 shows the relationship between the recovery ratio of fat administered (%) and the time-length of the experiment (h). According to these results this relationship presents a very significant linear equation ($r = -0.9932$; $P < 0.001$) that is described by:

$$y = 98.380 + 13.200\, x \qquad [1]$$

where y is the percentage of remaining fat and x the time (h) of the experiment.

According to this graphic representation, after 4 h, about 50% of the amount of administered fat is still present in the gastrointestinal lumen, thus 1 g fat is still available to be studied by gas chromatography and HPSEC.

Second experiment. Heating olive oil at 180°C for 50 h produced a notable increase in the content of polar and thermoxidized compounds (polymers and dimers of triacylglycerols and oxidized triacylglycerols) whereas the amount (g/100 mg oil) of hydrolytic compounds (diacylglycerols and free fatty acids) was significantly decreased (Table 1). Luminal fat from animals administered the heated olive oil contained higher amounts of thermoxidized compounds and lower quantities of hydrolytic compounds (Table 1).

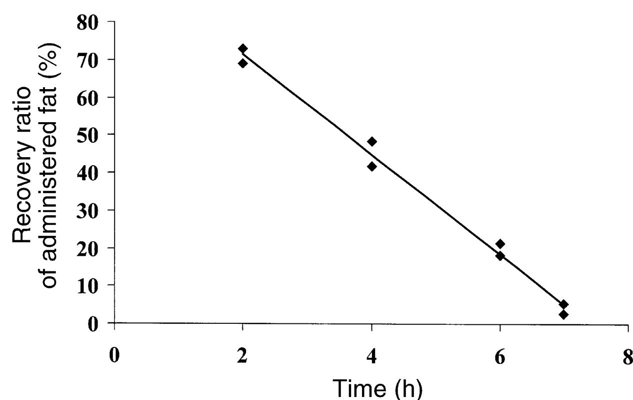

FIG. 1. Relationship between length of the experimental period (h) and luminal fat (recovery ratio of administered fat, %).

Table 2 indicates that in the case of the heated olive oil the percentage of luminal fat after the 4-h experiment tended to increase with respect to the fresh oil. Nonoxidized triacylglycerols, diacylglycerols, and free fatty acids were the major compounds present in the luminal fat after unheated olive oil was administered. However, in the heated oil, nonoxidized triacylglycerols, oxidized triacylglycerols, and polymers and dimers of triacylglycerols were the major compounds present. Thus, luminal fat displayed significantly higher amounts and percentages of triacylglycerol polymers and dimers and oxidized triacylglycerols (all $P < 0.0001$) and total triacylglycerols ($P < 0.05$). Nonoxidized triacylglycerols tended to increase. However, hydrolytic compounds (diacylglycerols, monoacylglycerols and free fatty acids) were significantly reduced in the luminal fat after the 4-h treatment (Tables 1 and 2).

Table 3 indicates the true digestibility coefficient of the whole unheated or heated oils and of thermoxidized compounds. Digestibility of dimers ($P < 0.001$), nonoxidized triacylglycerols ($P < 0.05$), and total triacylglycerols ($P < 0.001$) was significantly reduced with respect to the unused oil. The true digestibility coefficient was calculated using the ratio between injected fat minus remainder lumen fat and the injected fat after endogenous correction.

DISCUSSION

Heating olive oil at frying temperature during 50 h produces detectable changes in the oil composition, leading to the formation of new compounds. In fact the polar fraction of the olive oil increased about 13 times after the heating treatment. This increase is agreement with previous data published in frying oil (21–25) and heated oils (19,26).

According to Yoshida and Alexander (26), two typical groups of products—volatile breakdown derivatives and nonvolatile oxidation products—are produced by oil heating. The latter products include monomeric, dimeric, and polymeric compounds.

According to previous studies (1,20–22,27), HPSEC data show that after repeated frying uses, the amount of thermoxidized compounds clearly increases. In the present study, triacylglycerol polymers that were not detected in the unheated oil rose to be the third major product in the heated oil. Dimers and oxidized triacylglycerols increased in percentage of polar fraction (mg/100 mg polar fraction) and in absolute amount (mg/100 mg oil). This increase, together with the tendency of the number of products of hydrolytic alteration to decrease, confirms that thermoxidative reactions are more prevalent than hydrolytic ones when heating oil.

After the administration of unheated olive oil, the amount of polar components in the luminal fat increased *ca.* 19-fold. The percentage of monoacylglycerols and free fatty acids in the polar fraction increased noticeably, suggesting that after 4 h, active hydrolysis by the pancreatic lipase had taken place. However, data on monoacylglycerol and free fatty acid contents are

the result of a balance between hydrolysis of altered and nonaltered tri- and diacylglycerols by pancreatic lipase, and intestinal absorption. Polar content of the luminal fat from the heated oil was similar to that obtained from the unheated oil. However, a high proportion of oxidized triacylglycerols triacylglycerol polymers and dimers were still present in this polar fraction. The percentage of diacylglycerols and free fatty acids decreased. Thus, the nonpolar fraction/polar fraction ratio also tended to increase in the luminal fat of rats administered the heated oil.

Reduced digestibility and absorption is observed in all cases in which heated fats have been studied (9,10). In this study, the true digestibility coefficient of the heated olive oil (dimers and total triacylglycerols) decreased with respect to the unheated one, results that concur with previous data of other authors (28,29).

Some decades ago, Crampton *et al.* (30) reported that the principal reason for the lower nutritive value of diets that included linseed oil heated to 275°C was the presence of one or more dimer fatty-acid radicals in this polymerized fat. Deuel (31) considered that the extent to which frying fats were polymerized was one of the principal factors behind their diminished digestibility.

Potteau *et al.* (32,33) likewise reported that as polymerization of oil increased, its digestive utilization declined, as evidenced by elimination of part of the polymers were eliminated in the feces. Márquez-Ruiz *et al.* (34), studying the susceptibility to enzymatic hydrolysis of oxidized and polymeric triacylglycerols formed during frying, found a high hydrolysis rate of oxidized triacylglycerol monomers in contrast to the significant discrimination of pancreatic lipase against triacylglycerol dimers, and particularly triacylglycerol polymers.

According to the unheated olive oil data, true digestibility of triacylglycerol dimers was high (~80%). However, in the altered oil, the true digestibility ratio of dimers decreased noticeably (~30%). Henderson *et al.* (35) reported that in the case of oils containing low amounts (less than 4%) of triacylglycerol polymers, both triacylglycerols and polymers of triacylglycerols were almost completely hydrolyzed by pancreatic lipase after 1 h *in vitro*; but when highly oxidized oils, containing 20 or 30% of triacylglycerol polymers, were used some triacylglycerols re-

mained intact. Yoshida and Alexander (26) found that dimeric compounds from thermally oxidized oils are absorbed by the rats. However, the cross-linking in the dimers is *via* a C–C bond (36), which is hydrolyzed with more difficulty by rat pancreatic lipase. With monomers, it is possible to hydrolyze readily two out of three of the ester bonds, whereas with the dimers which are larger, because of a number of different chemical entities and C–C linkages, internal ester groups would not be available for hydrolysis. Besides, much of the dimeric structure is more complex than just indicated (37), and intramolecular C–C linkages could form an addition to the intermolecular ones as a result of heating. This would inhibit hydrolysis even more, leading to the lower percentage values with longer heating periods. Yoshida and Alexander (26) found no appreciable enzymatic hydrolysis of polymeric compounds obtained from the oxidized oils. These compounds are rather complicated and more polar, capable of inactivating the enzyme. In the current study a higher proportion of oligomers (polymers and dimers) from the heated oil remain in the rat lumen suggesting hydrolytic inhibition by pancreatic lipase in relation to the unheated oil.

The present results suggest that, in our experimental conditions, hydrolysis of nonoxidized triacylglycerols by pancreatic lipase is inhibited or at least retarded by the presence of altered compounds. These data are in accordance with those of Márquez-Ruiz *et al.* (37) who found that hydrolysis of intact triacylglycerols can be affected by the presence of dimers and polymers in abused frying oils.

After a 4-h test the amount of oxidized triacylglycerols in the luminal fat from the unheated and the heated olive oils did not change significantly with respect to the heated oil. These data are not easy to explain, but suggest a kinetic balance between oxidized triacylglycerol formation from oligomers and hydrolysis to diacylglycerols, monoacylglycerols, and free fatty acids. Matsuchita (11) and Miyashita *et al.* (12) suggested that oxidized triacylglycerols are well absorbed and appear to be adequately hydrolyzed by pancreatic lipase because of the higher polarity and similar molecular weights of oxidized triacylglycerols compared to nonaltered triacylglycerols. As already indicated, luminal fat in the animals administered the heated oil tended to contain a lower percentage and amount of monoacylglycerols and free fatty acids (Table 2). This could be attributed to lower pancreatic lipase activity. However, the possibility of increased absorption of these compounds, because of their major polarity, should be not discarded, although the actual amount of luminal fat increased.

In conclusion, the present experimental design combining column chromatography, HPSEC, and 4-h *in vivo* digestibility seems to be a useful tool for the study of the enzymatic hydrolysis behavior of heated oils. After a 4-h experiment, true digestibility coefficients for triacylglycerol dimers and triacylglycerol monomers were significantly lower than those of the unheated oil. True digestibility of dimers was quite high but decreased as the alteration of the oil increased. Nonoxidized triacylglycerol hydrolysis was negatively affected by the presence of large amounts of thermoxidized compounds.

ACKNOWLEDGMENT

Thanks are due to Cécile Tulasne, visiting student from the Erasmus Project, and to Dr. Antonio Romero for their assistance

Thioglycolate-Elicited Rat Macrophages Exhibit Alterations in Incorporation and Oxidation of Fatty Acids

C.M. Peres, J. Procopio, M. Costa, and R. Curi*

Department of Physiology and Biophysics, Institute of Biomedical Sciences, University of São Paulo (ICB-USP), São Paulo, Brazil

ABSTRACT: Incorporation and oxidation of fatty acids (FA) were investigated in resident and thioglycolate-elicited (TG-elicited) rat macrophages (Mϕ). Both cell types presented a time-dependent incorporation of [^{14}C]-labeled palmitic acid (PA), oleic acid (OA), linoleic acid (LA), and arachidonic acid (AA) up to 6 h. The total amount of [^{14}C]-FA incorporated by resident Mϕ after 6 h was: AA > PA = LA > OA. TG-elicited cells presented a 50% reduction in the incorporation of LA, PA, and AA, whereas that of OA remained unchanged as compared to resident Mϕ. The FA were oxidized by resident Mϕ as follows: LA > OA > PA > AA. TG elicitation promoted a reduction of 42% in LA oxidation and a marked increase in AA oxidation (280%). The increased oxidation of AA in TG-elicited cells may account for the lower production of prostaglandins in Mϕ under these conditions. The full significance of these findings for Mϕ function, however, remains to be examined.

Paper no. L8084 in *Lipids 34*, 1193–1197 (November 1999).

Unstimulated macrophages (Mϕ) are cells that have not encountered foreign materials and have low functional activities, e.g., low rates of secretion of neutral proteinases and/or low production of reactive metabolites of oxygen (1,2). Mϕ obtained from animals that have been submitted to nonmicrobial inflammatory stimuli (which do not stimulate lymphocytes to secrete cytokines), such as exposure to thioglycolate (TG), display increased phagocytic function and plasma membrane turnover, and enhanced activities of lysosomal enzymes (2). Previous studies on phagocytosis, respiratory burst, and fuel metabolism of elicited Mϕ indicated that these effects of TG are caused by changes in glucose, glutamine, and fatty acid (FA) metabolism (2,3). In fact, TG elicitation induces increases in hexokinase and citrate synthase activities, glucose consumption, and $^{14}CO_2$ production from [U-^{14}C]glucose and keeps unchanged the rate of production of lactate compared with resident Mϕ, indicating that elicited Mϕ have an increase in glycolysis and Krebs cycle activities (4).

FA play a key role in modulating cellular metabolism. FA can regulate glucose and glutamine metabolism in both resident and TG-elicited Mϕ (3). Indeed, FA-rich diets (with 20% by weight of hydrogenated coconut oil or unsaturated olive, safflower, or menhaden oil) can lead to changes in phagocytosis, enzyme activities (hexokinase, citrate synthase, glucose-6-phosphate dehydrogenase, and glutaminase), and production of cytokines (interleukin-1 and -6, tumor necrosis factor-α), eicosanoids (prostaglandins PGE_2 and 6-keto-$PGF_{1\alpha}$), and reactive oxygen species (superoxide, hydrogen peroxide, and nitric oxide) in resident and TG-elicited Mϕ (3,5).

FA can also be transferred from Mϕ to lymphocytes in coculture. First, [^{14}C]FA-labeled or triacylglycerol-loaded (TAG) Mϕ can export labeled lipid substances (6,7), [mainly FA themselves and phospholipids (PL) (6), to the supernatant and this process is decreased in TG-elicited Mϕ (6). After the co-culture of lymphocytes with Mϕ pretreated with labeled FA, radioactivity is found in the lipid fractions of the co-cultivated lymphocytes. TG elicitation induces a reduction of the transfer of FA from Mϕ to lymphocytes in culture (6).

In this study, the effect of TG elicitation on incorporation and oxidation of FA by rat peritoneal Mϕ was studied. To investigate the effect of chain length and degree of unsaturation of the FA, the following FA were considered: [U-^{14}C]palmitic (PA, 16:0), [1-^{14}C]oleic (OA, 18:1n-9), [1-^{14}C]linoleic (LA, 18:2n-6), and [1-^{14}C]arachidonic (AA, 20:4n-6) acids. Previous studies examined the incorporation and export of AA by Mϕ (8–10), but a comparative study with other FA has not been carried out yet.

MATERIALS AND METHODS

Animals. The experimental procedure used in this study was approved by the Ethical Committee of the Institute of Biomedical Sciences, University of São Paulo. Male Wistar rats (3–4 mon old, weighing 250 ± 25 g) obtained from the Department of Physiology and Biophysics (University of São Paulo, Brazil), were used. The animals were kept in cages of five rats each and housed under a light–dark cycle of 12/12 h (lights on at 0600) at 23 ± 2°C. The rats were fed *ad libitum* a diet containing 52% carbohydrate, 21% protein, and 4% lipid (NUVILAB CR1, Nuvital Nutrientes LTDA, Curitiba, PR, Brazil) and had free access to tap water.

Chemicals. Lipid solvents were obtained from Merck

(Darmstadt, Germany). Penicillin (2.5 U/mL) and streptomycin (2.5 µg/mL) were purchased from Sigma (Sigma Chemical Co., St. Louis, MO). Eagle's minimum essential medium (MEM), pH 7.4, supplemented with 10% (by volume) heat-inactivated (56°C for 30 min) fetal calf serum (FCS) was obtained from Adolfo Lutz Institute (São Paulo, São Paulo, Brazil.

[U-^{14}C]PA (specific activity: 824 mCi/mmol), [1-^{14}C]OA (specific activity: 60 mCi/mmol), [1-^{14}C]LA (specific activity: 58.0 mCi/mmol), and [1-^{14}C]AA (specific activity: 55.0 mCi/mmol) were purchased from Amersham (Little Chalfont, Buckinghamshire, United Kingdom).

Preparation of Mϕ. For Mϕ isolation, eight rats per experiment were exsanguinated by decapitation and 20 mL of phosphate-buffered saline (PBS) was injected i.p. Resident Mϕ were collected from the peritoneal cavity using a Pasteur pipette. TG-elicited Mϕ were collected in a similar manner 4 d after an i.p. injection of 3 mL of a 40 g/L sterile Brewer's thioglycolate broth (Merck). Mϕ were centrifuged at 200 × *g* for 10 min. The supernatant fraction was then discarded, and the pellet was resuspended in 30 mL of a hemolysis solution (Tris-base, 0.017 M; and NH_4Cl, 0.0114 M, pH 7.4), with penicillin (2.5 U/mL) and streptomycin (2.5 µg/mL). The tube was then centrifuged after being kept in ice for 5 min. The supernatant was discarded and the pellet was resuspended in 30 mL of a PBS solution. This procedure was carried out three times with PBS. The Mϕ preparation was resuspended in MEM supplemented with FCS. Cells were diluted with culture medium to achieve a final suspension of 0.82×10^6 cells/0.5 mL/well. Mϕ were pre-incubated for 2 h at 37°C in an artificially humidified atmosphere of 5% CO_2 in air, under sterile conditions, in a Microprocessor CO_2 Incubator (LAB-LINE Instruments Inc., Melrose Park, IL). This process is essential to promote the adherence of Mϕ to the plate. After this time, the Mϕ supernatant fraction that was free of adhered cells was discarded. Less than 6% of resident or TG-elicited cells were discarded in the supernatant.

Time-course incorporation of [^{14}C]-labeled FA by Mϕ in culture. Adhered Mϕ were cultivated between 15 min and 6 h in 0.5 mL of MEM containing one of the [^{14}C]-labeled FA. The amount of radioactivity added to the cells was 0.013 µCi/well (0.5 mL) for OA, LA, and AA (due to the similarity in the specific activity), and 0.145 µCi/well for PA, which had the highest specific activity. At the end of each incubation period, the supernatant fluid was discarded and the wells were washed three times with PBS to remove any remaining labeled FA. All cells were scraped from the adhering surface, washed with PBS (3 times, 1 mL each), and transferred to microcentrifuge tubes. The tubes were centrifuged at 15,000 × *g* for 1 min (model Spin-I; INCIBRAS, São Paulo, Brazil). Mϕ were resuspended with 50 µL of ethanol, and then the total radioactivity incorporated was determined in Ecolume scintillation cocktail (ICN Biochemicals, Inc., Costa Mesa, CA) using a Beckman-LS 6000 IC liquid scintillation counter (Beckman Instruments, Fullerton, CA).

Oxidation of FA by Mϕ. Resident and TG-elicited Mϕ were incubated in siliconized Erlenmeyer flasks modified in the following manner: to the inside of a conventional flask was used a glass cylinder that effectively divided the flask into two compartments. To the main portion of the flask (Compartment 1) was added sample, which was incubated at 37°C with 0.82×10^6 Mϕ in a final solution of 2 mL MEM and 1.5% albumin–FA complex (0.1 µCi/mL of labeled FA and 0.9 mM of unlabeled FA). After 6 h the cells were disrupted using 400 µL of 25% perchloric acid solution. The labeled CO_2 was the collected over a period of 1 h in a solution of 1:1 (vol/vol) phenylethylamine/methanol contained in the inner glass cylinder (Compartment 2), and radioactivity was determined in a Beckman counter. A similar procedure has previously been used in our laboratory (11).

Statistical analysis. The results were assessed by using analysis of variance (ANOVA) at a significance level of $P < 0.05$.

RESULTS

Incorporation of PA, OA, LA, and AA by resident and TG-elicited macrophages. The incorporation of [^{14}C]-labeled PA, OA, LA, and AA during 6 h by resident Mϕ presented a time-dependent increase, which was modulated by TG elicitation (Fig. 1). For all FA, the incorporation was linear over a 6 h period. TG elicitation induced a decrease of the incorporation rate, keeping the linearity. The equations of the regression lines and Pearson's coefficients (r^2) are presented in the legend of Figure 1. AA showed the highest incorporation, even under TG elicitation. OA was the least incorporated, and PA and LA showed similar incorporation rates during the time-course, even under TG elicitation. The total radioactivity found in resident Mϕ after 6 h of culture was as follows: AA > PA = LA > OA (AA, 1,173 ± 136; PA, 492 ± 8; LA, 490 ± 7; and OA, 128 ± 13 nmol/10^{10} plated cells, as mean ± SEM, $n = 4$). TG elicitation induced a decrease of 50% in the rate of incorporation of PA, LA, and AA. OA was the only FA to remain unchanged after elicitation.

Oxidation of PA, OA, LA, and AA by resident and TG-elicited Mϕ. These experiments were carried out to evaluate the differences in FA oxidation by Mϕ and the modulation of this process by TG elicitation. The values of FA oxidation are presented in Table 1. During 6 h, resident and TG-elicited Mϕ were incubated in the presence of [^{14}C]-labeled FA, and $^{14}CO_2$ production was measured. For resident Mϕ, the oxidation was as follows: LA > OA > PA > AA (5,795 ± 267, 1,949 ± 263, 892 ± 113, and 442 ± 41 nmol/10^{10} Mϕ/6 h, respectively as mean ± SEM). LA had a reduction of 41.6% and AA an increase of 280% in the rate of oxidation after TG elicitation.

DISCUSSION

Monocyte (blood cells that are the original resident Mϕ) diameters range between 12 and 20 µm (12). Assuming a discoidal cell shape with average diameter of 15 µm and 5 µm height that exchanges FA through the upper and lateral sides but not through the bottom, we obtain an average cell volume of 8.8×10^{-10} cm^3 and average cell membrane exchange area of 4.12×10^{-6} cm^2. Applying data on FA permeability, derived from

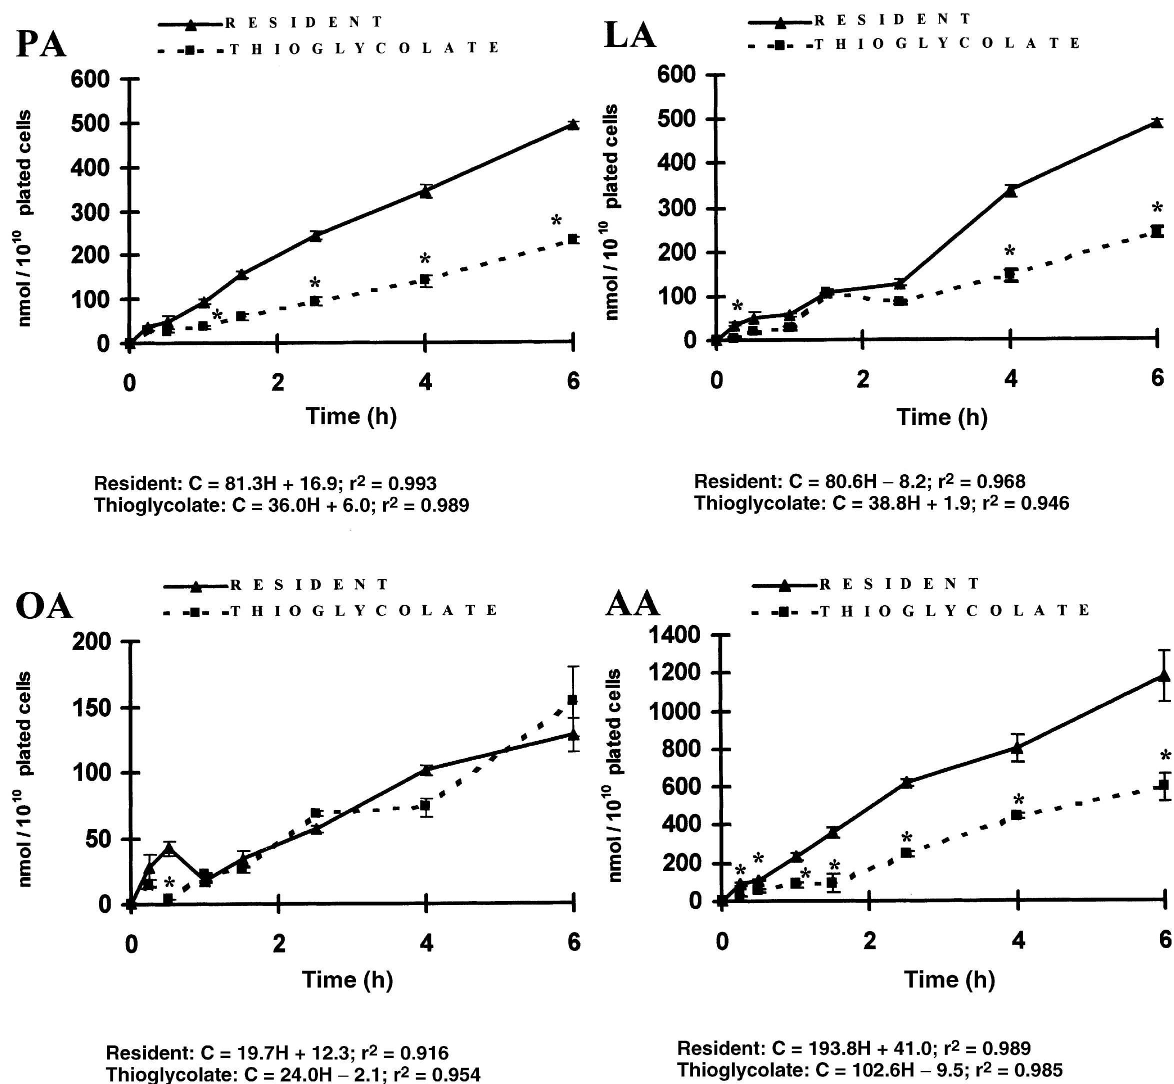

FIG. 1. Time-course incorporation of [U-^{14}C]palmitic acid (PA), [1-^{14}C]oleic acid (OA), [1-^{14}C]linoleic acid (LA), and [1-^{14}C]arachidonic acid (AA) by resident (▲) and thioglycolate-elicited (■) macrophages in culture during 6 h. The results are expressed as nmol/10^{10} plated cells as mean ± SEM of four experiments. Cells were cultivated with labeled fatty acids and after each time, collected and washed with phosphate-buffered saline. Radioactivity was determined as described in Materials and Methods section. Abbreviations C, radioactivity concentration of labeled fatty acids; r^2, Pearsons's coefficient; H, time (h). *, significantly different ($P < 0.05$) owing to thioglycolate elicitation.

vesicular systems (13) (P = 10^{-5} cm/s), to the geometrical parameters of Mϕ cells in our culture conditions, we obtained an "estimated half-life" ($t_{1/2}$) for FA entry of 15 s using Equation 1,

$$t_{1/2} = 0.693 \times \frac{\text{cell volume}}{\text{cell membrane permeability to FA} \times \text{cell membrane area}} \quad [1]$$

where cell volume is the estimated average cell volume, cell membrane permeability is the unmodified bilayer permeability for FA as derived from FA movement across unilamellar vesicles (13), and cell membrane areas is the estimated cell membrane area available for FA exchange (discounting cell bottom). This means that, in the time scale of our [^{14}C]FA uptake protocols (measured in hours), Mϕ can exchange FA many times between the cytosol and the supernatant. The existence of three FA pools can then be postulated with respect to the exchange time of FA: a very fast pool represented by the cell membrane compartment ($t_{1/2}$ = nano- to microseconds), a fast pool represented by the cytosol fluid compartment ($t_{1/2}$ = seconds), and a slow pool that constitutes FA incorporation into cell architecture during several hours. The resolution of our experimental protocol does not allow for obtaining information regarding the very fast and fast pools, as evidenced in Equation 1. Table 2 indicates that the amount of FA-derived radioactivity incorporated into the cell after 6 h is much (one order of magnitude) larger than the amount estimated from the uptake of FA into the free cytosolic compartment. This fact indicates that the radioactivity measured in the cell compartment after 6 h is essentially due to FA molecules that were incorporated and processed by the cell.

As seen in Table 2 and Figure 1, TG elicitation decreased

the incorporation of all tested FA into Mϕ except for OA. Since the rate of crossing the cell membrane is not a limiting factor for FA entry in a time scale of hours (as evidenced by the small estimated $t_{1/2}$), thioglycolate might affect the process of incorporation of FA into cell elements such as PL, acylglycerols (AG), cholesterol (CHOL), cholesterol ester (CEST) and TAG rather than their uptake from the medium to the cytosol. As shown previously (6), the incorporation of AA and LA into total lipid fraction of TG-elicited Mϕ is increased by 28 and 67%, respectively, as compared with resident cells. On the other hand, PA and OA incorporation into the total lipid fraction was not different between the two cell types. In both cell types the four FA were incorporated mainly into PL (≥ 62.8%), and most of that was in phosphatidylcholine (PC) (≥ 51.5%). In fact, the distribution of [^{14}C] from the FA into lipid fractions (PL, TAG, CHOL, CEST and AG) was not markedly changed by TG elicitation. The same occurred with respect to the distribution of radioactivity into the PL classes tested: PC, phosphatidylethanolamine, phosphatidic acid, phosphatidylserine, and phosphatidylinositol.

FA oxidation was also measured to explore further the effect of thioglycolate. LA was less incorporated and less oxidized after elicitation. Concerning OA, TG elicitation did not induce significant changes in incorporation and oxidation. However, the decreased incorporation of AA (Fig. 1) occurred concomitantly with a marked increase (280%) in oxidation of this FA. These findings may be implicated in the lower production of PG by TG-elicited as compared to resident cells (1,14,15). In fact, mouse TG-elicited Mϕ produce and secrete lower amounts of PGE_2 than resident Mϕ, even when exposed to zymosan (8).

The reduction in the incorporation of PA by Mϕ due to TG elicitation was not caused by increased oxidation. The reduced incorporation of PA may be a consequence of a higher export of this FA to the medium. In fact, 24-h-cultured Mϕ incorporate [3-^{14}C]pyruvate and [1-^{14}C]acetate into lipid fractions, and these lipid molecules (mostly in the form of PL and FA) are actively exported to the supernatant (16). The same exporting process is observed when resident or TG-elicited Mϕ are labeled with [^{14}C]FA, and the radioactivity exported to supernatant can be transferred to co-cultivated lymphocytes (6). Therefore, the export of lipids to the medium may also play an important role for the findings described, since the radioactivity found in co-cultivated lymphocytes was also changed when these latter cells were obtained from TG-injected rats (6).

It remains controversial how FA can cross PL membranes inward and become an intracellular component. There is evidence that nonionized FA can cross the membrane quickly by the flip-flop mechanism in vesicles (13,17), adipocytes (18), and pancreatic β-cells (19). Some authors have described that fatty acid-binding proteins (FABP) can be isolated from membranes (mFABP) and may improve transmembrane FA transport (20,21). On the other hand, the presence of FABP in the cytoplasm could play a role in intracellular FA transport, but it could also facilitate the inward flux (22,23) and metabolism of FA (24) including oxidation (25). Therefore, further studies should be performed to investigate the effect of TG elicitation on the content of FABP in these cells.

The findings presented herein and those previously published (6) led us to conclude that: (i) AA is the main FA incorporated by Mϕ, (ii) PL is the main lipid fraction of FA incorporation (PC is the major class), (iii) TG elicitation reduces PA, LA, and AA incorporation but does not change OA incorporation; (iv) TG elicitation reduces LA oxidation and raises the oxidation of AA. The significance of these findings for the function of Mϕ during inflammatory and immune responses remains to be elucidated.

Fatty Acid Δ^9-Desaturation in the *Triatoma infestans* Fat Body: Response to Food and Trehalose Administrations

María S. González* and Rodolfo R. Brenner

Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), UNLP-CONICET,
Facultad de Ciencias Médicas, (1900) La Plata, Argentina

ABSTRACT: The effects of food intake and carbohydrate administration on fatty acid Δ^9-desaturation were investigated in isolated microsomes from *Triatoma infestans* fat body. Fifth instar nymphs, which were solely blood-fed just after the molt and then fasted, were used as controls and for determination of optimal assay conditions. Both [1-^{14}C]palmitic and [1-^{14}C]stearic acids in a medium containing ATP, CoA, $MgCl_2$, NADH, NaF, and O_2 were tested. For the control group, optimal conditions were a pH of 6.8–7.2, an incubation temperature of 29°C, and an incubation time of 10 min. Δ^9-Desaturation depended on the presence of reduced pyridine dinucleotides; NADH and NADPH were equally efficient. Stearic acid showed a higher apparent V_{max} than palmitic acid, but the apparent K_m were very similar. When fifth instar nymphs were blood-fed weekly, a marked increase of Δ^9-desaturation was observed for both acids. Higher desaturation activity was also induced by injection of the carbohydrate trehalose into the hemolymph of fasted nymphs. These results indicate that insect Δ^9-desaturation, like the mammalian counterpart, is sensitive to dietary changes and carbohydrate administration.

Paper no. L8216 in *Lipids 34,* 1199–1205 (November 1999).

The major fatty acid components of insect tissues are usually, as in most other forms of life, the common C_{16} and C_{18} saturated and monounsaturated acids. Insect tissues convert acetate, glucose, and some amino acids to fatty acids, with palmitic acid as the major product. In several studies on whole insects, C_{16} and C_{18} saturated fatty acids were directly desaturated to their monoenoic derivatives (1–4). The oxidative introduction of the *cis*-double bond at the Δ^9 position in the fatty acyl-CoA substrates is catalyzed by stearoyl-CoA desaturase, probably the best-studied fatty acyl desaturase in mammalian and avian systems (5–8). The preferred substrates, palmitoyl- and stearoyl-CoA, are converted into palmitoleoyl- and oleoyl-CoA, respectively (6,7).

Most of the work on Δ^9-desaturation in insects has focused on the characterization of this process. In this regard, Tietz and Stern (9) showed that the fat body of *Locusta migratoria* is able to convert stearic into oleic acid. The desaturase activity resides within the microsomal fraction and has an absolute requirement for oxygen, in common with desaturases from higher animals. More recently, acyl-CoA Δ^9 desaturase activity in *Musca domestica* has been subjected to a detailed study on its properties and variations with insect age, sex, and development (10). The most dramatic difference occurred when the reproductive process was initiated in the female, at which time the activity decreased significantly.

The control mechanism that governs the conversion of saturated to monounsaturated fatty acids is important because the balance of the acids is one of the factors influencing the physical properties of cell membrane phospholipids (11). Thus, many investigators have attempted to elucidate the metabolic regulation of stearoyl-CoA desaturase; these studies, mainly in rats and mice, reveal that this enzyme is modulated by nutritional state (12–18). For example, enzyme activity is increased by a high carbohydrate diet (16) and decreased by extreme starvation (13,14) or administration of dietary polyunsaturated fatty acids (12,18).

To gain information about the regulation of fatty acid Δ^9-desaturation in an insect, we have studied the influence of different diets in *Triatoma infestans*, hematophagous hemipteran (i.e., true bug), the vector of the trypanosomiasis known as Chagas disease. *Triatoma infestans* nymphs ecdyse five times to develop into adults. In each stage, the insects need at least one blood meal for their normal development, metamorphosis, and reproduction. For this reason, to study the properties of Δ^9-desaturation, we used fat body microsomes obtained from fifth instar nymphs that were solely blood-fed 4 d after the molt and then fasted for 21 d (i.e., fasted control nymphs). We also evaluated this reaction when the nymphs were fed weekly and when trehalose was administered after a fast period. Trehalose was chosen for this study because it is the principal sugar in insect hemolymph. We found a strong dependence of fatty acid Δ^9-desaturation on the dietary conditions of the animal.

MATERIALS AND METHODS

Chemicals. [1-^{14}C]Palmitic acid (54 mCi/mmol, 98% radiochemically pure) and [1-^{14}C]stearic acid (57 mCi/mmol, 99% radiochemically pure) were purchased from Amersham Life Science (Amersham, England). Unlabeled fatty acids were

provided by Nu-Chek-Prep (Elysian, MN). The cofactors used for enzymatic reactions and the trehalose for insect administration were obtained from Sigma Chemical Co. (St. Louis, MO). All chemicals were of analytical grade.

Insects. Nymphs of *T. infestans* were reared on hen blood and kept in our laboratory at 28°C under 70–80% humidity. Four days after the molt to fifth instar, the insects were fed and separated into two groups: one was fasted for 21 d and the other was fed weekly during the same period of time. Experiments were performed with 25-d-old nymphs from both groups.

Fat body microsomes. Insects were anesthetized on ice and fat bodies were removed, immediately rinsed with buffer (ice cold 0.25 M sucrose, 0.15 M KCl, 62 mM potassium phosphate buffer at pH 7.4, 5 mM $MgCl_2$, and 1.4 mM *N*-acetyl-L-cysteine), and then homogenized in this buffer at a rate of 4 mL/g tissue. The homogenization was performed at 4°C in a ground-glass tube by 10 up-and-down hand-driven strokes of a Teflon pestle. The homogenate was centrifuged sequentially at 4°C at 400 × *g* for 5 min, 10,000 × *g* for 20 min, and 110,000 × *g* for 60 min to obtain the microsomal pellet (19). The microsomes obtained were suspended in fresh homogenization buffer and stored at −80°C. Microsomal protein was estimated by the method of Lowry *et al.* (20) utilizing bovine serum albumin as standard.

Fatty acid desaturation assay. Unless otherwise indicated, microsomes were incubated with either 40 μM [1-^{14}C]palmitic or 60 μM [1-^{14}C]stearic acid in a final volume of 400 μL at 30°C . The reaction mixture consisted of 0.25 M sucrose, 0.15 M KCl, 40 mM potassium phosphate buffer at pH 7.4, 1.41 mM *N*-acetyl-L-cysteine, 40 mM NaF, 0.45 mM NADH, 1.3 mM ATP, 60 μM CoA (sodium salt), and 5 mM $MgCl_2$.The reaction was initiated by addition of 0.4 mg microsomal protein, and the mixture was incubated in open tubes in a thermoregulated shaking water-bath. Blank incubations without microsomes were done concurrently to assess the percentage of labeled palmitoleic or oleic acids already present in the original substrates.

Separation and identification of desaturation products. The desaturation reaction was stopped and CoA thioesters were hydrolyzed by addition of 1 mL 10% KOH in ethanol, followed by saponification at 80°C for 60 min under nitrogen. The unsaponifiable fraction was extracted twice with petroleum hydrocarbon (b.p. 30–40°C) and discarded. After acidification with HCl, the fatty acids were extracted three times with petroleum hydrocarbon. The solvent was evaporated under nitrogen, and the free fatty acids were dissolved in methanol/water/acetic acid (85:15:0.2, by vol).

Free fatty acids were then fractionated by reversed-phase high-performance liquid chromatography and identified on the basis of their retention times relative to appropriate standards (21). Separations were performed on an Econosil C_{18}, 10 μm particle size, reversed-phase column (250 × 4.6 mm) (Alltech Associates, Inc., Deerfield, IL) coupled to a guard column (10 × 4 mm) filled with pellicular C_{18} (Alltech); methanol/water/acetic acid (90:10:0.2, by vol) at a flow rate of 1 mL/min was the mobile phase. The column eluate was monitored by an ultraviolet spectrometer at 205 nm. Radioactivity was detected by a Radiomatic Instruments (Tampa, FL) Flo-one/Beta flow-through liquid scintillation counter fitted with a 0.5-mL cell. Ultima Flo-M scintillation cocktail (Packard Instruments, Downers Grove, IL) was used at a rate of 3 mL/min.

Hemolymph collection and carbohydrate estimation. For hemolymph collection, the insect legs were amputated and the insect was placed in a centrifuge tube with the head toward the pointed end and centrifuged at 120 × *g* for 1 min at 4°C. The resulting material was centrifuged at 12,000 × *g* for 2 min at 4°C to remove hemocytes. An aliquot of the hemocyte-free hemolymph was used for the enzymatic-colorimetric determination of glucose using a commercial kit (GOD-PAP; Wiener, Argentina). For the measurement of trehalose, an aliquot of hemocyte-free hemolymph was deproteinized with 5% trichloroacetic acid (22). After removal of denatured protein, the total hemolymph carbohydrates were determined using the anthrone reagent (23) with glucose as standard; from this value, the glucose concentration was subtracted and the data were converted to mg trehalose/mL hemolymph.

Trehalose administration. For trehalose treatment, 23- or 24-d-old nymphs fed once, 4 d after the molt to fifth instar, were injected through the abdominal intersegmental membrane with 100 μg trehalose dissolved in 0.15 M NaCl. The amount of trehalose administered was chosen in order to double its concentration in the hemolymph. At determined post-administration times, the insects were anesthetized on ice, and hemolymph and fat body samples were collected as described above. Control insects were injected with 0.15 M NaCl solution.

Changes in Δ^9-desaturation activity. To examine the effect of food intake patterns on Δ^9-desaturation, fifth instar nymphs were fed on day 4 after the molt and separated into two groups: one kept without food until they were sacrificed (fasted control nymphs) and the other fed weekly (continually fed nymphs). A third group was administered on day 23–24 after the molt with trehalose solution (trehalose nymphs). Δ^9-Desaturation was measured in fat body microsomes obtained from the three nymph groups using the optimal assay conditions established for the fasted group.

Statistical analysis. Data are presented as means ± SD. The significance of the effects of food and trehalose treatment was analyzed by analysis of variance using Instat v. 2.0 (Graph Pad Software, San Diego, CA). Where significant differences between the control fasted group and treatment occurred, a *post-hoc* Tukey's honest significant difference test was performed to identify the differing means.

RESULTS

Δ^9-Desaturation properties. For fat body microsomes obtained from fasted control nymphs and incubated with 0 to 100 μM [1-^{14}C]palmitic or [1-^{14}C]stearic acids, Figure 1 shows the Lineweaver-Burk double-reciprocal plot of the ini-

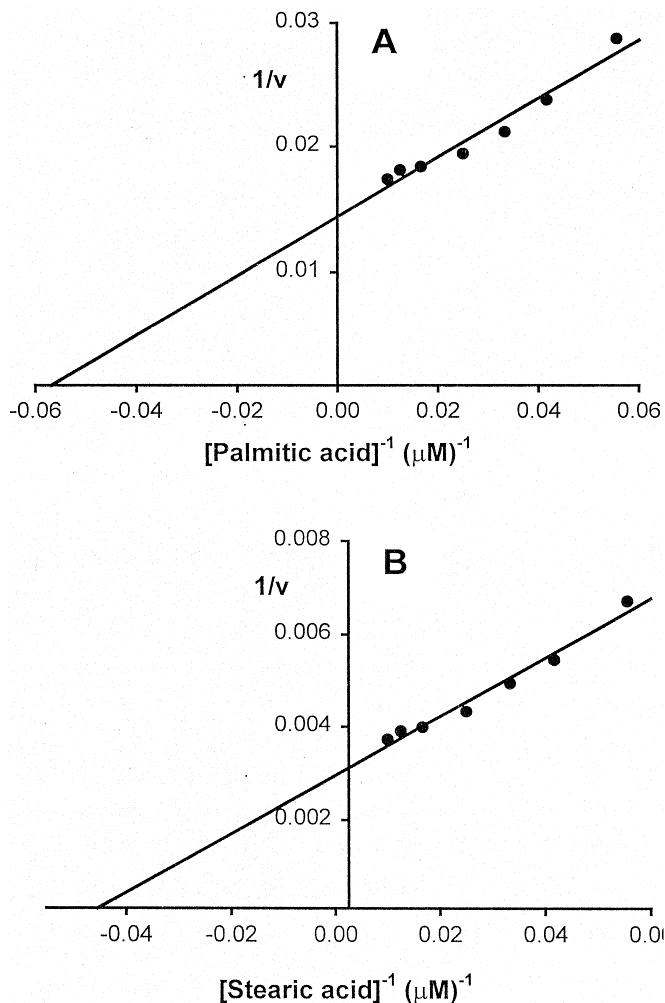

FIG. 1. Double-reciprocal plots of the rate of synthesis of palmitoleic acid and oleic acid as a function of varying concentrations of palmitic and stearic acids, respectively, using fat body microsomes from *Triatoma infestans.* Microsomal protein (400 μg) was incubated with increasing concentrations of either [1-^{14}C]palmitic acid (A) or [1-^{14}C]stearic acid (B). The assay mixture contained 60 μM CoA, 1.3 mM ATP, 0.45 mM NADH, 5 mM $MgCl_2$ in 40 mM potassium phosphate buffer, 0.25 M sucrose, 0.15 M KCl, 1.41 mM *N*-acetyl-L-cysteine, 40 mM NaF, final pH 7.0; final volume of 400 μL. Reactions were performed at 30°C for 10 min. Results are means of duplicate samples from three separate experiments, and the values are expressed as pmol palmitoleic acid formed/min·mg protein (A) or pmol oleic acid formed/min·mg protein.

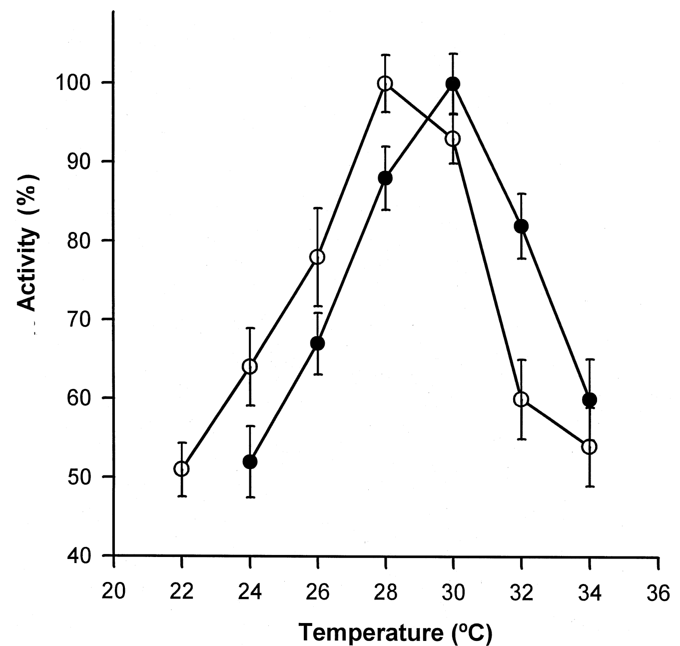

FIG. 2. Effect on fat body microsomal Δ^9-desaturation of incubation temperature. The assay medium contained either 40 μM palmitic acid (●) or 60 μM stearic acid (○) and 1 mg/mL microsomal protein. Reaction mixture and cofactors were as described in Figure 1. Incubation time: 10 min. Results are expressed as percentage of the maximal activities obtained: 65 pmol palmitoleic acid/min·mg protein or 275 pmol oleic acid/min·mg protein. Data represent the mean of triplicate determinations.

tial velocity vs. the substrate concentration. The apparent V_{max} for stearic acid (337 pmoles oleic acid/min·mg protein) was higher than that for palmitic acid (69 pmoles palmitoleic acid/min·mg protein). The effect of pH on the Δ^9-desaturation using either 40 μM palmitic acid or 60 μM stearic acid was investigated every two pH units in the pH range 5.8–8.0 using 40 mM potassium phosphate buffer in the reaction mixture. The optimal pH was about 6.8–7.2 (data not shown) for both acids. In incubation temperature–activity experiments, desaturation activities for palmitic and stearic acids had maxima between 28 and 30°C (Fig. 2). Time-course studies showed a linear increase in the formation of palmitoleic or oleic acids from palmitic and stearic acids, respectively, for the first 10 min of the reaction. Longer incubation times did not increase the amount of products formed (Fig. 3). Both NADH and NADPH were effective electron donors when they were supplied at concentrations of 0.45 mM. The omission of NADH (or NADPH), CoA, and ATP in the reaction mixture resulted in a lack of Δ^9-desaturation.

Trehalose administration. In fifth instar nymphs fed on day 4 after the molt and then fasted for 21 d, the concentrations of trehalose and glucose were 1.74 ± 0.25 and 0.18 ± 0.31 mg/mL hemolymph, respectively. When the fasted insects were injected with trehalose on day 25, trehalose levels increased to 3.57 ± 0.29 mg/mL 5 min after administration. This value was maintained for a further 2 h and then fell rather slowly to reach values (after 12 h) not significantly different from those in the fasted control group. Injection of the 0.15 M NaCl solution used as the vehicle for sugar administration did not significantly affect trehalose levels (1.65 ± 0.15 mg/mL hemolymph). The hemolymph concentration of trehalose in weekly-fed insects on day 25 after the molt was 4.38 ± 0.75 mg/mL.

Changes in Δ^9-desaturation activity. A highly significant ($P < 0.001$) increase in Δ^9-desaturation was observed in the continually fed nymphs when compared with the fasted control group when palmitic (Fig. 4A) or stearic acid (Fig. 4B) was substrate. For the first 12 h, the injection of trehalose had

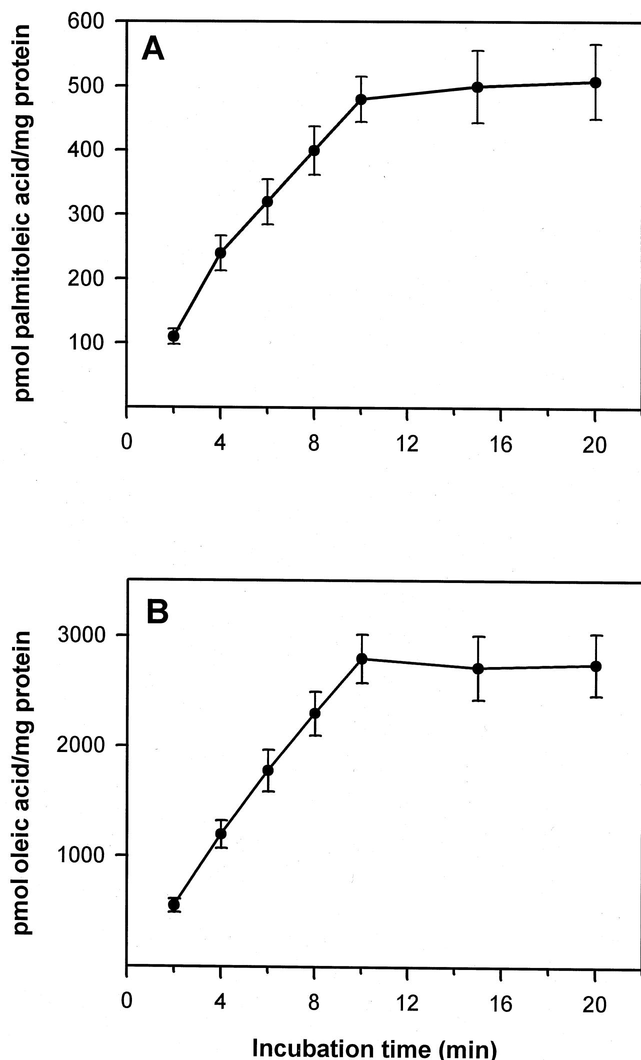

FIG. 3. Time course of fat body microsomal Δ^9-desaturation. The assay medium contained either 40 μM palmitic acid (A) or 60 μM stearic acid (B) and 1 mg/mL microsomal protein. The reactions were carried out at 29°C. Reaction mixture and cofactors were as described in Figure 1. Data represent the mean ± SD of triplicate determinations.

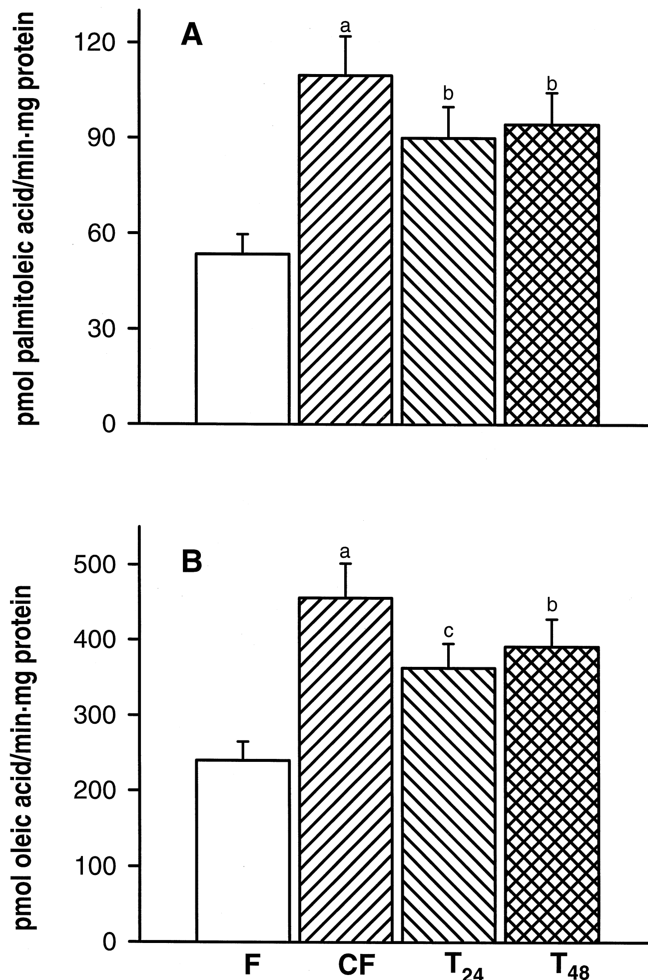

FIG. 4. Response of fatty acid Δ^9-desaturation to insect food intake and trehalose administration: (A) [1-^{14}C]palmitic acid; (B) [1-^{14}C]stearic acid. Reactions were performed under optimal assay conditions as described in the text. F: nymphs that received only one blood meal just after the molt (fasted control group); CF: nymphs continually fed; T_{24}: nymphs injected with trehalose and sacrificed 24 h later; T_{48}: nymphs injected with trehalose and sacrificed 48 h later. The significance of differences between fasted control group and treatments was analyzed by analysis of variance. Columns with different letters are significantly different from fasted control group; $^aP < 0.001$, $^bP < 0.005$, $^cP < 0.02$ as determined by Tukey's range test. Each column with a bar represents the mean ± SD of four samples.

no effect on Δ^9-desaturation (data not shown), but at 24 h very significant ($P < 0.005$) and significant ($P < 0.02$) increases were observed when palmitic (Fig. 4A) and stearic acids (Fig. 4B) were used. Interestingly, this 24-h requirement was at a time when hemolymph trehalose concentrations returned to normal values (see preceding paragraph). Forty-eight hours after trehalose administration, Δ^9-desaturation was similar to that found at 24 h. A fivefold higher trehalose dose slightly modified the Δ^9-desaturation obtained with 100 μg/insect, whereas a tenfold higher dose killed the insects. Insects injected with 0.15 M NaCl solution (used for trehalose administration) did not show any difference in Δ^9-desaturation when compared to the fasted ones. Taken together, the data from the three nymph groups suggest that feeding behavior and carbohydrate administration exert an inductive effect on Δ^9-desaturation of fatty acids.

DISCUSSION

In most organisms, palmitic and stearic acids are synthesized *de novo* from acetate and then converted to the required monounsaturated fatty acids by desaturation. A previous study demonstrated that *T. infestans* is also capable of synthesizing C_{16} and C_{18} saturated and monounsaturated fatty acids *de novo* (3). In addition, when the microsomal fraction from fat body was incubated in an appropriate medium to estimate Δ^9-, Δ^6-, and Δ^5-desaturations, only the first was detectable (19). These observations indicate that *T. infestans* is unable to synthesize linoleic acid (18:2n-6) and convert it to arachidonic (20:4n-6) acid and, therefore, depends upon the host blood

meal for their provision. Therefore, for the control of the saturated-unsaturated fatty acid ratio, the main endogenous regulatory system remaining in *T. infestans* is the biosynthesis of monounsaturated acids by Δ^9-desaturation. This fatty acid ratio plays an important role as a factor determining cellular membrane fluidity and membrane enzymatic activities.

In the present study, we optimized the conditions for Δ^9-desaturation measurement using microsomes from nymphs solely fed just after the molt. The desaturase system in *T. infestans* is quite similar to that found in higher vertebrates (5–8). Under our assay conditions, the Δ^9-desaturase accepted both 16- and 18-carbon saturated fatty acids as substrates. In the housefly, *M. domestica*, the substrate specificity for the Δ^9-desaturase microsomal fraction was 18:0-CoA > 16:0-CoA ≥ 14:0-CoA; and this fraction contained four to five times the desaturase activity found in the mitochondrial fraction (10). *Triatoma infestans* Δ^9-desaturation displayed maximal activity near neutrality (pH range 6.8–7.2), as was observed for *M. domestica* (10). The current study also shows that ATP, CoA, and NADPH or NADH are essential for desaturation of the free acids. Moreover, the replacement of NADPH by NADH resulted in a similar rate of desaturation for the saturated substrates. The Δ^9-desaturase from the locust, *L. migratoria* (9), was active with either NADH or NADPH; NADH is the most efficient source of reducing power for the majority of animal desaturases (24). Interestingly, the desaturase in *M. domestica* (10) prefers NADPH as the electron donor.

Earlier studies, primarily in mice and rats, revealed that Δ^9-desaturase activity was strongly sensitive to changes in diet (12–18) and was decreased by diabetes (25). The most obvious response to dietary changes occurred during the extreme situation of starvation (13,14), when Δ^9-desaturase activity fell to abnormally low levels. Hepatic Δ^9-desaturation in rats increases when a natural diet containing unsaturated triacylglycerides is replaced by a regimen of fasting followed by refeeding a fat-free, high-carbohydrate diet (16,26). The close correlation between diet and Δ^9-desaturation is reflected in the work of Actis Dato *et al.* (27), who showed the existence of a circadian rhythm in its activity and found the maximal activity around midnight, a time coinciding with the maximal food intake of a mouse feeding *ad libitum*. Similarly, the present study demonstrates that Δ^9-desaturation in *T. infestans* fat body is influenced by changes in the insect nutritional state; Δ^9-desaturation increased when the usual single blood meal just after the molt was replaced by a regimen of weekly food intake. The results also demonstrate that when insect fasting is prolonged for 21 d and then is followed by trehalose administration, the injected carbohydrate has disappeared from the hemolymph 12 h later (presumably as a result of rapid body tissues uptake) and the Δ^9-desaturation increase occurs 24 h after administration.

Trehalose was chosen for this study since in most insect species it is the predominant circulating saccharide and plays a central role in carbohydrate metabolism (28,29). Its hemolymph concentration ranges from about 4 to 20 mg/mL, whereas the glucose concentration is generally 10-fold lower. Furthermore, when ^{14}C-glucose is injected into insects, it is rapidly converted into blood trehalose, with the fat body as the principal site of synthesis (30). The lowest levels of hemolymph trehalose occur in coleopteran and hemipteran nymphs (31). The trehalose level in the *T. infestans* fasted nymphs (1.74 mg/mL hemolymph) is similar to that of nymphs of *Oncopeltus fasciatus* (2.5 mg/mL), another hemipteran (31). Hemolymph trehalose levels fall during flight or starvation. The glycogen energy reserve is mobilized from the fat body not as glucose but as trehalose (28–30).

Our study is the first to demonstrate that fatty acid Δ^9-desaturation in insects responds to dietary changes and to carbohydrate administration in a manner typical of higher animals. Early works showed that the activation of rat Δ^9-desaturation produced by carbohydrate feeding was suppressed when protein synthesis was interrupted by injection of actinomycin D (26). The increase in hepatic stearoyl-CoA desaturase activity in response to high carbohydrate diets is paralleled by an increase in stearoyl-CoA desaturase mRNA in total liver mRNA (16,32). This induction is due to an enhancement in the transcription of the stearoyl-CoA desaturase gene (33). The carbohydrate-mediated induction of stearoyl-CoA gene transcription in the fasted mouse can be explained by the stimulation of endogenous insulin release from the pancreas into the bloodstream. As already mentioned, diabetes decreases Δ^9-desaturation in rats and insulin administration restores enzyme levels to normal values (25,34). Furthermore, the insulin-mediated induction of stearoyl-CoA desaturase mRNA is inhibited by cycloheximide administration, indicating that protein synthesis is necessary for this induction (35).

Based on the foregoing reports, we hypothesize that the inductive effect of food and trehalose on *T. infestans* Δ^9-desaturation may result from the secretion of an insulin-like peptide that would be inhibited in the fasted insects. The secretion of this peptide would evoke an increase in Δ^9-desaturase mRNA. We have attempted to evaluate its presence in *T. infestans* hemolymph by an indirect ELISA (enzyme-linked immunosorbent assay) based on the technique of Engwall and Perlmann (36), but with a first antibody of commercial anti-insulin bovine serum. With this technique, we were unable to detect any insulin immunoreactivity in hemolymph samples, at least none greater than 20 pg/μL, the lowest limit of the method using bovine insulin. In spite of our results, the peptide was found in the hemolymph of the tobacco hornworm, *Manduca sexta*, and it modulates trehalose levels when injected into larvae (37). The authors reported that the total amount of immunoreactive insulin was less than that typically found in vertebrate serum. The affinity of mammalian antibodies for the insect peptide is probably less than that for the vertebrate hormone.

The similarity between arthropod and mammalian Δ^9-desaturases is striking in another manner. Recently, Wicker-Thomas *et al.* (38) and Luo *et al.* (39) reported the cloning and partial characterization of *Drosophila melanogaster* (fruit

fly) and *Amblyomma americanum* (tick) Δ^9-desaturase genes, respectively. Interestingly, the deduced amino acid sequence of the arthropod Δ^9-desaturase genes have strong homology with the Δ^9-desaturase gene from the rat (40).

Lipid Composition of Eggs of an Oviparous Lizard (*Bassiana duperreyi*)

Brian K. Speake[a,]*, Michael B. Thompson[b], and Ruth J. McCartney[a]

[a]Department of Biochemistry and Nutrition, Scottish Agricultural College, Ayr, KA6 5HW, United Kingdom, and [b]School of Biological Sciences and Wildlife Research Institute, University of Sydney, New South Wales 2006, Australia

ABSTRACT: Lipid analysis was performed on freshly ovulated eggs (n = 5) of the oviparous lizard *Bassiana duperreyi*. The fresh weight of the whole egg contents was 132.0 ± 4.3 mg (mean ± SE) of which lipid constituted 21.9 ± 1.1% (w/w). Triacylglycerol formed an exceptionally high proportion (85.4 ± 0.5%, w/w) of the total lipid, whereas phospholipid, free cholesterol, cholesteryl ester, and free fatty acid, respectively, contributed 11.2 ± 0.3, 1.4 ± 0.1, 1.3 ± 0.1, and 0.6 ± 0.1% of the total lipid mass. Linoleic and α-linolenic acids were the major polyunsaturates of the triacylglycerol fraction, respectively, forming 16.3 ± 0.1 and 8.3 ± 0.1% (w/w) of the fatty acids. Linoleic acid was the major fatty acid (29.0 ± 0.1%) of the total phospholipid, which also contained substantial amounts of arachidonic (6.4 ± 0.1%) and eicosapentaenoic (3.0 ± 0.1%) acids, but a relatively low proportion (1.6 ± 0.1%) of docosahexaenoic acid. Phosphatidylcholine formed the major phospholipid class (73.8 ± 2.3% w/w of total phospholipid) and was enriched in linoleic acid, whereas phosphatidylethanolamine, which formed 20.4 ± 1.9% (w/w) of total phospholipid, contained higher proportions of arachidonic and docosahexaenoic acids.

Paper no. L8264 in *Lipids 34*, 1207–1210 (November 1999).

Lipids are major nutritive components of the amniotic eggs of birds and reptiles, acting as a source of energy and providing substrates for cell membrane biosynthesis during the development of the embryo (1,2). A considerable amount of information is available on the lipid composition of avian eggs, albeit heavily biased by the plethora of detail obtained from eggs of the domestic chicken (3–6). Knowledge of the lipids of reptilian eggs is, by comparison, relatively limited (2). Although the composition and utilization of yolk lipids have been studied in some detail in crocodilians (2,7–13) and, to a lesser extent, in turtles (14,15), such information with regard to squamates (lizards and snakes) is currently limited to a single report (16). Moreover, as this sole example was concerned with eggs of the viviparous lizard, *Sceleropus jarrovi* (16), there is at present a total lack of information on the lipid composition of eggs from oviparous squamates.

In the present study, we describe the lipid and fatty acid profiles of eggs of the Australian scincid lizard *Bassiana duperreyi*, providing the first report of such data for an oviparous squamate.

MATERIALS AND METHODS

Sample collection and lipid analysis. The research was conducted under the University of Sydney Animal Care and Ethics protocol number L04/1-93/3/646. Freshly ovulated and incompletely shelled eggs (n = 5) were dissected from the oviduct of a female *Bassiana duperreyi* (snout–vent length 66 mm) captured on Flinders Island off the north coast of Tasmania (40°17′ S, 147°46′ E) in late October, 1997. Eggs were weighed and then frozen prior to analysis. Whole eggs were homogenized in a suitable excess of chloroform/methanol (2:1, vol/vol) with subsequent washing of the organic phase with KCl (0.88%, wt/vol) (17). The amount of total lipid in the samples was determined gravimetrically: half of the total chloroform extract was placed in a preweighed flask, the solvent was totally removed by evaporation, and the lipid mass was determined using an electronic balance accurate to 0.1 mg. The triacylglycerol (TAG), phospholipid (PL), free cholesterol (FC), cholesteryl ester (CE), and free fatty acid (FFA) components were isolated by thin-layer chromatography on silica gel G using a solvent system of hexane/diethyl ether/formic acid (80:20:1, by vol). Visualization of the bands and elution of the lipid classes from the silica were performed as previously described (12). The amount of FC recovered from the silica was determined using an enzymatic-colorimetric assay kit (Boehringer Mannheim, Lewes, United Kingdom). The isolated PL fraction was further subfractionated by thin-layer chromatography on silica gel D using a solvent system of chloroform/methanol/acetic acid/water (25:15:4:2, by vol). The major PL classes, phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), and sphingomyelin (Sph), were visualized and eluted from the silica (12).

Gas–liquid chromatography. The isolated acyl-containing lipid and PL classes were transmethylated to form fatty acid methyl esters as described previously (12). Analysis of the fatty acid methyl esters was performed by gas–liquid chromatography using a capillary column (Carbowax, 30 m × 0.25 mm, film thickness 0.25 µm; Alltech, Carnforth, United Kingdom) in a CP9001 Instrument (Chrompack, Middleburg, The Nether-

lands) connected to an EZ Chrom Data System (Scientific Software Inc., San Ramon, CA). The column was maintained at 185°C for 2 min following injection of the sample, then increased at 5°C/min for 9 min and maintained at 230°C for a further 24 min. The EZ Chrom Data System enabled the expression of the fatty acid compositions in terms of wt%. Peaks were identified by comparison with the retention times of standard fatty acid methyl ester mixtures (Sigma, Poole, United Kingdom) and were quantified by comparison with a 15:0 standard. The amounts of each lipid and PL class present in the extracts were calculated from the amount and composition of the fatty acyl groups derived from each class, together with the acyl group contribution to the molecular weights of these compounds.

RESULTS AND DISCUSSION

The wet mass of the whole eggs was 132.0 ± 4.3 mg of which 21.9 ± 1.1 % (w/w) was lipid (mean ± SE, $n = 5$). The proportions of the major lipid classes in the eggs of *B. duperreyi* (Table 1) differed markedly from those reported for the yolks of birds, crocodilians, and turtles. TAG formed approximately 85% (w/w) of the total lipid of the eggs of *B. duperreyi* compared with only 69% in yolk lipids of the alligator (2,9) and 68–73% in those of turtles (14,15). The proportion of TAG in the yolk lipid of birds such as the chicken, which is precocial (hatchlings active, capable of independent feeding and thermoregulation), is typically 67–70% (2,5), whereas TAG make a lesser contribution (about 58%) to the yolk lipid of birds such as the pigeon (18), which produces altricial hatchlings (inactive, dependent on parents for food and warmth). On the other hand, only about 11% of the total lipid of the *B. duperreyi* eggs consisted of PL compared with about 20% in the yolks of crocodilians and precocial birds (2,5) and 30% or more in the yolks of altricial birds (18). The proportion of FC was also relatively low in the lizard eggs, forming only 1.4% of total lipid compared with about 5% in the yolks of birds and about 7% in the alligator (2,5). CE, at around 1% of total lipid, was present in the lizard eggs in similar proportions to those found in the yolks of crocodilians and precocial birds (2,5).

Therefore, a major finding of the present work is that the contribution of TAG to the total lipid content of the yolk is greater in eggs of the oviparous lizard *B. duperreyi* than in eggs of birds, crocodilians, and turtles. Since TAG contain three fatty acyl groups, compared with two in PL and one in CE, the lipid of the lizard egg represents a more concentrated source of metabolizable energy than the yolk lipids of the other amniote groups. It should, however, be pointed out this energy difference is relatively modest: 1 mg of yolk lipid contains about 0.88 and 0.94 mg of fatty acid in eggs of the chicken and of *B. duperreyi,* respectively, an increase of only 7%. In birds, the higher proportion of TAG in the yolk lipids of precocial species compared with those of altricial species represents a greater reserve of metabolizable energy to help sustain the embryo through a longer incubation period resulting in a more advanced stage of development by the time of hatching (19,20). The relevance of the high proportion of TAG in the lizard egg in terms of the energetic requirements of the embryo (21,22) is not clear.

The proportions of the lipid classes in eggs of *B. duperreyi* are very similar to those reported for the viviparous lizard *S. jarrovi* (16) where TAG formed 87% and PL 9% of total egg lipid. It should, however, be noted that gestation in *S. jarrovi* utilizes a simple placental structure (Type I chorioallantoic placenta) involving respiratory exchange and the transport of water and inorganic ions but lacking the ability to deliver organic nutrients to the embryo (23). The absence of placentotrophy with regard to lipids in *S. jarrovi* implies that all the lipid components required for embryonic development must be derived from the egg, as is the case for the oviparous *B. duperreyi*. Comparative data on the lipid class profiles of the eggs of highly placentotrophic viviparous lizards are currently unavailable.

The major saturated fatty acid present in the lipid classes of the *B. duperreyi* eggs was palmitic acid (16:0) (Table 1). The monounsaturated fatty acid, oleic acid (18:1n-9) was the major acyl component of the TAG, CE, and FFA fractions. With regard to the polyunsaturates, linoleic acid (18:2n-6) was present

[a]wt% of fatty acids (means ± SE, $n = 5$). PL, phospholipid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; Sph, sphingomyelin. For other abbreviations see Table 1.

at high concentrations in all the lipid classes and was the major component of the PL fraction. Significant proportions of α-linolenic acid (18:3n-3) were also present in all the lipid classes. The profile of the $C_{20–22}$ polyunsaturates in the egg lipids of *B. duperreyi* differed from the pattern normally found in the yolks of crocodilians and domestic poultry. The proportion of arachidonic acid (20:4n-6) in the PL fraction was similar to the values reported for eggs of the domestic chicken but only about half that of alligator eggs (2,5). A notable feature was the very low proportion of docosahexaenoic acid (22:6n-3) in the PL of the lizard eggs, only 1.6% compared with about 5% in the chicken and 10% in the alligator (2,5). Since adequate levels of 22:6n-3 are essential for the differentiation of the neural tissues (24), the embryos of *B. duperreyi* must have some means of optimizing the provision of this fatty acid during development. It may be significant that, in contrast to the chicken and the alligator, the PL of the lizard eggs contained a relatively high proportion of eicosapentaenoic acid (20:5n-3) plus a lesser amount of docosapentaenoic acid (22:5n-3), both of which are potential precursors of docosahexaenoic acid and may therefore possibly be converted to 22:6n-3 by desaturation/elongation reactions in the yolk sac membrane or the embryonic tissues.

The small Australian scincid lizards are generally insectivorous (25,26). The polyunsaturate profile of the egg lipids of *B. duperreyi* may reflect the fatty acid composition of the insects eaten by the female lizard during the period of oocyte maturation. Although we were unable to collect samples of the relevant insects for analysis, the fatty acid profile of the lizard eggs was similar in some respects to the reported compositions of certain terrestrial invertebrates. The lipids of slugs and snails, for example, are rich in 20:4n-6 and 20:5n-3 but are deficient in 22:6n-3 (27).

PC was the major class of PL in the lizard eggs although a considerable proportion of PE and much lower proportions of PS and Sph were also present (Table 2). PC was characterized by high proportions of 16:0 and 18:2n-6 with relatively low proportions of the $C_{20–22}$ polyunsaturates. PE was rich in 18:1n-9 and and contained higher proportions of the $C_{20–22}$ polyunsaturates than did PC. The major saturated fatty acid of PS was stearic acid (18:0), and a high proportion of 20:4n-6 was also present. Sph contained primarily the saturated fatty acids 16:0, 18:0, and 20:0.

In summary, the egg lipids of *B. duperreyi* exhibit several distinct features, differing from those of birds and crocodilians both in the proportions of the lipid classes and in their fatty acid profiles. Since this species is oviparous, these lipids must provide the embryo with all the essential fatty acids required for membrane biogenesis, eicosanoid synthesis, and specific tissue differentiation as well as the requisite amount of fatty acids for energy production. It should be emphasized that the present study was based on a limited number of eggs collected from a single site in a single year. The possibility of geographical and annual variations in the fatty acid composition of yolk lipid as a result of dietary and climatic differences cannot be excluded.

ABSTRACT: The mode of action of the lithium ion (Li^+) in the treatment of manic depression or bipolar illness is still under investigation, although this inorganic drug has been in clinical use for 50 yr. Several research reports have provided evidence for Li^+/Mg^{2+} competition in biomolecules. We carried out this study to characterize the interactions of Li^+ and Mg^{2+} with red blood cell (RBC) membrane components to see whether Li^+/Mg^{2+} competition occurs. ^{31}P nuclear magnetic resonance chemical shift measurements of the phospholipids extracted from the RBC membranes indicated that the anionic phospholipids, phosphatidylserine and phosphatidylinositol, bind Li^+ and Mg^{2+} most strongly. From ^6Li relaxation measurements, the Li^+ binding constant to the phospholipid extract was found to be $45 \pm 5\ M^{-1}$. Thus, these studies showed that the phospholipids play a major role in metal ion binding. ^7Li spin-lattice relaxation measurements conducted on unsealed and cytoskeleton-depleted RBC membrane in the presence of magnesium indicated that the removal of the cytoskeleton increases lithium binding to the more exposed anionic phospholipids ($357 \pm 24\ M^{-1}$) when compared to lithium binding in the unsealed RBC membrane ($221 \pm 21\ M^{-1}$). Therefore, it can be seen that the cytoskeleton does not play a major role in Li^+ binding or in Li^+/Mg^{2+} competition.

Paper no. L8058 in *Lipids 34,* 1211–1221 (November 1999).

To test the Li^+/Mg^{2+} competition hypothesis for the pharmacological action of lithium, investigators have used small biomolecules or biomembranes as model systems (1–3). In the human body, blood transports Li^+ to the central nervous system; therefore, it is important to understand the interaction of Li^+ with the red blood cells (RBC) and their components. Rong *et al*. (3), using ^7Li nuclear magnetic resonance (NMR) relaxation measurements (T_1 and T_2), observed that the interactions of Li^+ with the RBC components ATP, 2,3-bisphosphoglycerate, spectrin, and Hb in different oxygenation forms were very weak. The RBC membrane did provide, however, most of the high-affinity Li^+ binding sites. The erythrocyte membrane displays very high mechanical stability and resilience, which comes from a partnership between the plasma membrane and an underlying meshwork called the membrane cytoskeleton. The major constituent of the membrane cytoskeleton that provides the infrastructure is spectrin, which binds indirectly to the RBC membrane *via* interactions with protein 4.1 and ankyrin (2).

In previous NMR studies based on Li^+ binding to agar gels (2) or on Na^+ binding to human RBC membranes measured by double-quantum experiments (4), investigators speculated that the cytoskeletal proteins provide binding sites for alkali metal ions in human RBC membranes. An NMR study with purified spectrin, however, did not show evidence of Li^+ binding to the major component of the cytoskeleton (3). In this study, we tested the contribution of the spectrin–actin network toward Li^+/Mg^{2+} competition by conducting ^7Li NMR relaxation measurements with unsealed and cytoskeleton-depleted RBC membrane suspensions.

The major class of lipids present in the RBC membrane is that of phospholipids. The most common in the RBC membrane are phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI), and sphingomyelin (SM). It is interesting to note that both of the anionic phospholipids, PI and PS, are found only in the inner leaflet of the RBC membrane (5,6). The intrinsic binding constants for interactions between some alkali and alkaline earth metal ions and PS have been reported (7). Evidence for Li^+ interactions with PS-containing liposomes was previously obtained from ^7Li and ^2H NMR relaxation data (8–10). Measurements conducted on inside-out and right-side-out vesicle suspensions clearly indicated that the inner leaflet of the RBC membrane provided the major Li^+ binding site (3). Significant differences between T_1 and T_2 values were also observed for suspensions of phospholipids extracted from the RBC membrane, suggesting that phospholipids, and not the proteins in or anchored to the membrane, provided the major Li^+ binding sites (3). Therefore, it is believed that the anionic

phospholipids PS and PI, present in the inner leaflet of the RBC membrane, contribute to Li^+ binding.

Merchant and Glonek (11) used ^{31}P NMR spectroscopy to determine the relative interaction potentials of each of the phospholipids for various cations, which was determined by ^{31}P NMR chemical shift (δ) changes, signal broadening, signal quenching, or a combination of these. One of the useful features of NMR spectroscopy is that complex mixtures can be analyzed directly (11). Thus, for example, in examination of the spectrum of rat heart membrane phospholipids, all of the common phospholipids can be analyzed qualitatively and quantitatively in a single sample after extraction, without the need for a separation. Mota de Freitas *et al.* (12) reported an increase in the ^{31}P NMR chemical shift anisotropy parameter for increasing concentrations of either Li^+ or Mg^{2+} in the presence of human RBC membrane. These results suggested metal ion binding to the phosphate head groups in the membrane; this study (12), however, did not identify which phospholipids were predominantly involved in the Li^+/Mg^{2+} competition mechanism. This is because the ^{31}P NMR spectrum of the human RBC membranes is not resolved into resonances corresponding to specific phospholipids without extraction of phospholipids with a suitable organic solvent mixture. We have utilized the method of Merchant and Glonek (11) to test Li^+/Mg^{2+} competition for human RBC membrane phospholipids, and also to identify the phospholipids in the RBC membrane that interact most strongly with Li^+ and Mg^{2+} ions.

Investigating Li^+ binding to RBC anionic phospholipids is important because these interactions may affect the extent of lipid–protein interactions in the RBC membrane. The Na^+-Na^+ exchange protein, which mediates RBC Na^+-Li^+ countertransport (13), is a membrane protein. It is therefore possible that variable Li^+ binding to different phospholipids may lead to different interactions between anionic phospholipids and the membrane-bound Na^+-Na^+ exchange protein. These differences in phospholipid–protein interactions may be responsible for the variations in RBC Na^+-Li^+ countertransport rates reported for bipolar (14,15) and hypertensive (16–18) patients relative to normal individuals.

MATERIALS AND METHODS

Materials. Human RBC were obtained from a blood bank (Life Source, Glenview, IL) and were used prior to the expiration date. Inorganic salts and $CDCl_3$ were purchased from Aldrich Chemical Co. (Milwaukee, WI). Pure phospholipids were obtained from Sigma Chemical Co. (St. Louis, MO) or Avanti Polar Lipids (Alabaster, AL). D_2O was purchased from Cambridge Isotopes (Cambridge, MA). The dye reagent used for protein determination was from Bio-Rad Laboratories (Hercules, CA), and items used for sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) using the Phast system were purchased from Pharmacia Biotech (Uppsala, Sweden). ^6LiCl (95.7% isotope-enriched) was obtained from Oak Ridge National Laboratory (Oak Ridge, TN). All remaining chemicals were purchased from Sigma.

Preparation of unsealed RBC membranes. RBC were washed once in an isotonic choline wash solution and then lysed by 5 mM HEPES buffer, pH 8, as described previously (12,19,20). The membranes were stored at −20°C for no more than a week before they were used.

Preparation of cytoskeleton-depleted RBC membranes. Cytoskeleton-depleted unsealed RBC membranes were obtained by a procedure outlined by Fairbanks *et al.* (19), with a low ionic strength buffer. The supernatant was removed after centrifugation and checked for the presence of spectrin and actin, the major cytoskeletal proteins, by SDS-PAGE for confirmation of the removal of the cytoskeleton (4). We washed the pellet three to four times with 5 mM HEPES buffer, pH 8, to obtain cytoskeleton-depleted RBC membranes.

Extraction of phospholipids from human RBC membranes. RBC membranes (1–1.5 mL, membrane protein concentration 5.2 ± 0.4 mg/mL) were extracted using a procedure reported by Meneses and Glonek (21). The dried lipid film was suspended in a solvent mixture of chloroform/methanol/aqueous 0.2 M EDTA reagent at a ratio of 125:8:3 for ^{31}P NMR experiments. For Li^+ relaxation measurements, the extracted dried phospholipid film was dissolved in a chloroform/methanol solvent mixture at a ratio of 5:2. The aqueous EDTA phase removed the paramagnetic impurities which would otherwise have caused the ^{31}P NMR resonances to broaden; this would have interfered with the resolution of the various classes of phospholipids (22).

The ^{31}P NMR chemical shift values of the individual phospholipids are dependent on the amounts of water and methanol in the chloroform layer of the sample. Overlapping ^{31}P NMR resonances in a specific solvent system can be resolved by variation of the solvent composition (22). For all ^{31}P NMR experiments, the solvent composition was kept constant in order to prevent changes in the chemical shifts of the phospholipids associated with solvent effects (23,24). For all experiments described herein, concentrated stock solution (1M) of the metal ions was used, and the amount of water added to the sample was less than 1%. However, it should be noted that in these types of experiments, solvent effects upon the chemical shift cannot be prevented, especially for PS, which is more sensitive to solvent effects (23–25). The NMR sample tube was sealed to prevent changes in the solvent composition due to evaporation of such low-boiling solvents as methanol and chloroform. Instead of carrying out the NMR experiments at 37°C, we performed all measurements with phospholipids at 27°C to minimize the evaporation of the low-boiling solvents. However, prior to metal ion addition, as much of the aqueous EDTA phase was removed as possible to prevent EDTA chelation of the added metal ions. Before metal ion titration, ^{31}P NMR spectra were recorded before and after the removal of the aqueous EDTA layer, and we found no significant changes in δ values after the removal of the aqueous phase.

Phospholipid–metal ion titration. Prior to metal ion addition, we recorded a ^{31}P NMR spectrum of the sample by ad-

justing the spinning turbine so that only the organic phase of the sample was exposed to the receiver coil of the NMR spectrometer. The EDTA phase was then removed, and appropriate amounts of 1 M $MgCl_2$ or 1 M LiCl solution were added directly to the organic phase (11). The sample was mixed thoroughly, and the spectrum was recorded with the organic phase in the NMR window. Addition of 3 mM $MgCl_2$ or 20 mM LiCl to the phospholipid suspension caused precipitation. Metal ion titration was stopped when precipitation occurred or when one of the signals quenched.

Calculation of Li^+ and Mg^{2+} binding constants from ^7Li or ^6Li NMR T_1 measurements. The calculation of the apparent binding constants, K_{app}, of Li^+ to RBC membrane and phospholipid extracts from ^{7}Li or ^{6}Li T_1 measurements assumed a two-state (*f,* free; and *b,* bound metal ions) model undergoing fast exchange and a total Li^+ concentration, $[Li^+]_t$, that is large with respect to the binding site concentration, [B] (26,27):

$$\Delta R^{-1} = (R_{obs} - R_f)^{-1} = K_{app}^{-1}\{[B](R_b - R_f)\}^{-1} + [Li^+]_t\{[B](R_b - R_f)\}^{-1} \quad [1]$$

where R_{obs}, R_f, and R_b are the reciprocals of T_{1obs}, T_{1f}, and T_{1b}, respectively. K_{Mg} and K_{Li}, the binding constants of Mg^{2+} and Li^+ to biological membranes and phospholipids, were calculated from K_{app} values, which were in turn determined from ^{7}Li or ^{6}Li T_1 values measured in the presence of increasing Mg^{2+} concentrations:

$$1/K_{app} = 1/K_{Li}\,(1 + K_{Mg}\,[Mg^{2+}]) \quad [2]$$

These equations assume 1:1 stoichiometry for Li^+ and Mg^{2+} binding to sites in biomembranes and phospholipids.

Calculation of Mg^{2+} and Li^+ binding constants from ^{31}P NMR spectroscopy. The Mg^{2+}-binding constants, K_{Mg}, to individual phospholipids were calculated from the chemical shift changes, $\Delta\delta$, observed in Mg^{2+}-containing suspensions (no Li^+) of phospholipids extracted from human RBC membranes according to the following equation:

$$1/\Delta\delta = 1/(\delta_{obs} - \delta_{free}) = 1/\{K_{Mg}[Mg^{2+}](\delta_{bound} - \delta_{free})\} + 1/(\delta_{bound} - \delta_{free}) \quad [3]$$

where δ_{obs}, δ_{free}, and δ_{bound} are, respectively, the chemical shifts of the observed, Mg^{2+}-free, and Mg^{2+}-saturated ^{31}P NMR resonances of the individual phospholipids. From a linear plot of $1/\Delta\delta$ vs. $[Mg^{2+}]$, K_{Mg} can be determined by taking the ratio of the slope to the *y*-intercept. The Li^+ binding constants, K_{Li}, to individual phospholipids were calculated from the δ values observed in Li^+-containing suspensions (no Mg^{2+}) of phospholipid extract from an equation similar to Equation 3.

Limitations of the calculations of binding constants. The binding constants calculated from ^{31}P NMR data are approximate and can only be used to establish the observed trends of the affinities of the various phospholipids for Li^+ and Mg^{2+}. This is because the phospholipid extract sample used for metal ion titration contained two phases, the organic as well as the aqueous EDTA layer. Although, prior to metal ion addition, attempts were made to remove the EDTA layer, complete removal could not be achieved. Hence the amount of metal ion in the organic phase was different from the amount added, because some amount of metal ions was chelated by the EDTA or was more soluble in the aqueous phase.

Several methods were used in an attempt to obtain the amount of metal ions in the organic phase. Atomic absorption (AA) spectroscopy was used for quantifying the Mg^{2+} concentration in the organic layer by taking an aliquot from the organic layer of the NMR sample. Because the solvent system contained chloroform, the flame was not very stable and the readings obtained were not reliable. Attempts also were made to evaporate the solvent and dissolve the residue in water. The presence of the phospholipids resulted in a suspension instead of a solution. AA results, however, indicated that only about 50–60% of the Mg^{2+} added was going into the organic layer. By AA with a flame source, we were not able to detect Li^+ because aliquots from the NMR samples were too dilute to provide a sufficient sample.

Determination of protein and phospholipid concentrations. The protein concentration was determined by the Bio-Rad Bradford method, with bovine serum albumin used as a standard for generating the calibration curve (28). Because the samples contained membrane-bound protein, a modified procedure with detergent was used (29). The phospholipid concentration was determined from a revised procedure reported by Avanti Lipids (30).

NMR spectrometers. ^{31}P, ^{7}Li, and ^{6}Li NMR experiments were conducted with Varian VXR-300 or VXR-400 NMR spectrometers (Palo Alto, CA) equipped with multinuclear probes. A 5- or a 10-mm broad-band probe was used, depending on the availability of the sample. All samples were run by spinning of the sample at 16–18 Hz. A variable-temperature unit was used for maintaining the probe temperature at 27°C. T_1 relaxation measurements were conducted with the inversion recovery pulse sequence, using at least seven τ values for each T_1 value. Under our conditions, the relaxation measurements were accompanied by a uncertainty factor of less than 10%, and the reported values represent the range or the standard deviation obtained by averaging the values from two or three separately prepared samples. The changes in chemical shift of the ^{31}P NMR phospholipid resonances are reliable to 0.01 ppm because of instrument inaccuracy, whereas a change of greater than 10% in T_1 values is due to experimental error. Therefore, changes in δ values of 0.01 ppm or greater, and T_1 value changes of 10% or greater, are significant. Binding constants were calculated from T_1 values from at least five data points by use of James-Noggle plots (31).

RESULTS

This investigation was conducted by means of ^{31}P NMR chemical shift measurements and ^{31}P, ^{7}Li, and ^{6}Li NMR relaxation measurements. We used the ^{31}P NMR chemical shift variation upon metal ion addition to identify the phospholipids that interact most strongly with the metal ion added. ^{7}Li

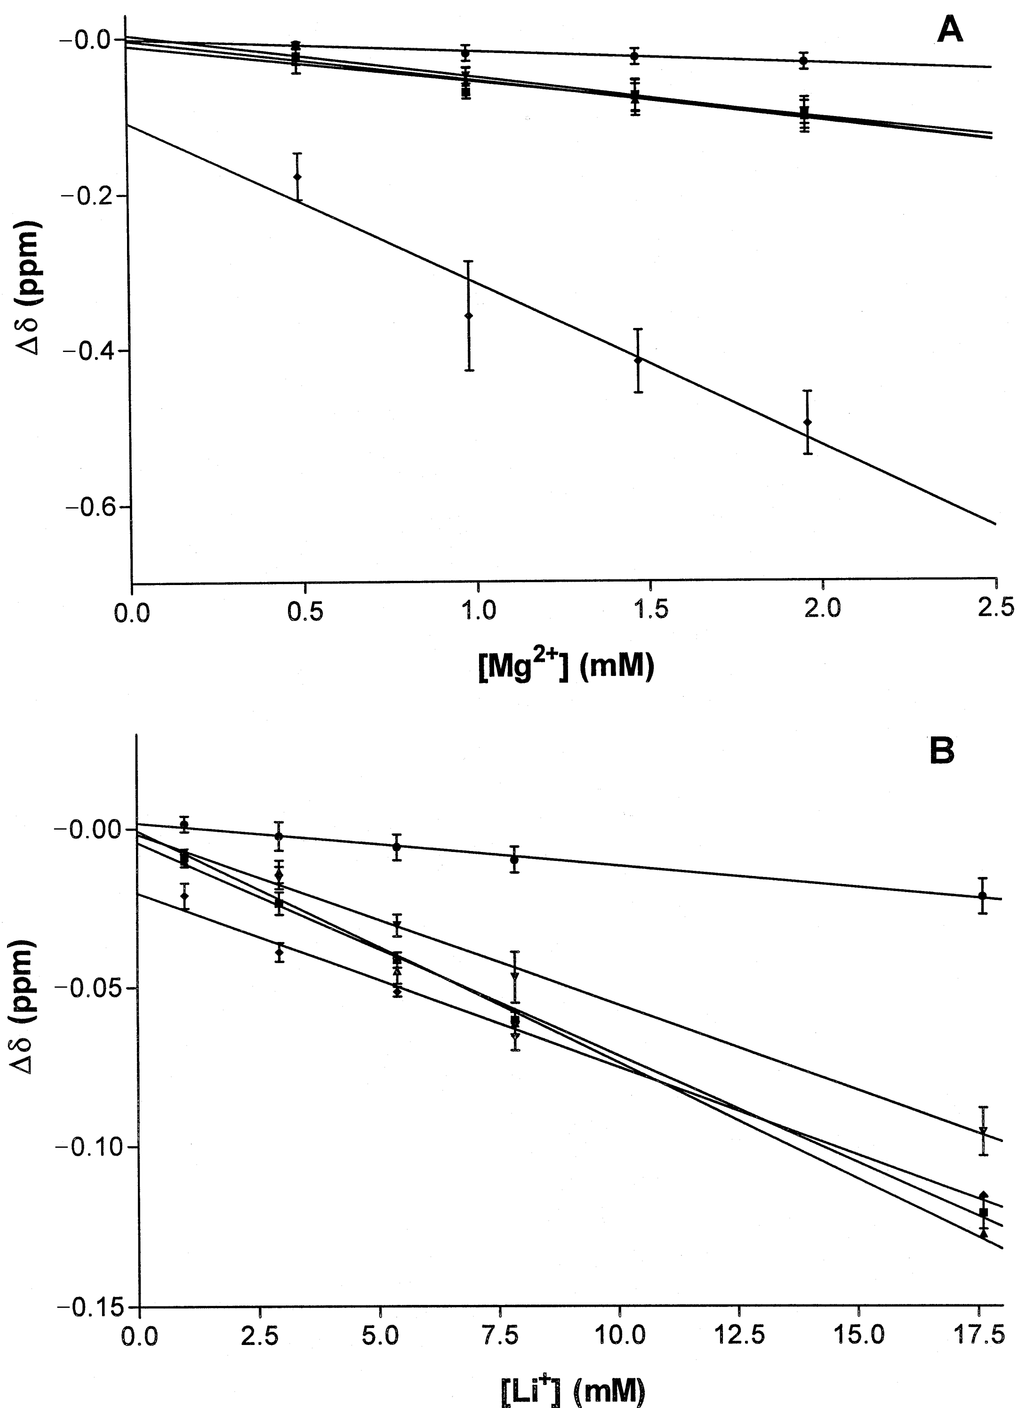

FIG. 1. Plot of the changes in ^{31}P nuclear magnetic resonance (NMR) chemical shifts of human red blood cell (RBC) membrane phospholipids upon addition of varying amounts of chloride salts of (A) Mg^{2+} and (B) Li^+. The phospholipids correspond to the following symbols: (●) phosphatidylcholine (PC); (▲) phosphatidylethanolamine (PE); (■) plasmalogen PE (PEPLAS); (◆) phosphatidylserine (PS); (▼) sphingomyelin (SM). The bars represent the range values obtained from two separate measurements.

and ^{6}Li T_1 measurements were used for computing the Li^+ association constant to the phospholipid extract as well as RBC membrane suspensions. We also used both approaches to investigate whether Li^+/Mg^{2+} competition was present for the phosphate head groups of the phospholipids.

^{31}P NMR δ measurements of phospholipid extracts. The phospholipids extracted from the human RBC membranes were titrated with varying amounts of $MgCl_2$. The variations of the δ values with Mg^{2+} addition are presented in Figure 1A. Upon Mg^{2+} addition, the ^{31}P NMR resonances of all of the

[a]All samples were run at 27°C in a 10-mm nuclear magnetic resonance (NMR) probe with the sample spinning at 16–18 Hz. The chemical shifts (δ) were referenced to 85% phosphoric acid. At the beginning of each titration, the δ value of the phosphatidylcholine (PC) resonance was referenced to –0.84 ppm. Reported δ are average values obtained from two separate trials. The $[Mg^{2+}]$ concentrations are the amount added to the suspension and not the amount in the organic phase.

[c]The phospholipid extract was spiked with PI so that the NMR sample contained 0.25 mg of PI/mL of the sample.

phospholipids shifted upfield, but the extent was different for the various phospholipids. The change in ^{31}P NMR chemical shift was largest for the anionic phospholipid PS when 1.96 mM Mg^{2+} was added (Fig. 1A); for the same Mg^{2+} concentrations, the PE, plasmalogen PE (PEPLAS), and SM resonances shifted upfield roughly 4.5 times less than that for PS. The PC resonance did not show any appreciable change in δ upon metal ion addition.

The effect of Mg^{2+} addition on PI could not be investigated in this manner because the percentage of PI in the RBC membranes is less than 2%, and its resonance was not observed clearly, even with overnight accumulations of the ^{31}P NMR spectrum (17,32). Moreover, because the interaction of PI with the metal ion caused broadening of the PI signal (11), PI with only a 2% abundance would make it difficult to observe the signal after metal ion addition. Hence, to the human RBC membrane phospholipid extract a known amount of PI was added, and Mg^{2+} titration was carried out. The amount of PI added to the extract was adjusted so that the mixture contained equal amounts of PI and PS. The addition of up to 1.96 mM Mg^{2+} caused the ^{31}P NMR resonances of PI and PS to move upfield by 0.56 and 0.43 ppm, respectively (Table 1). The K_{Mg} value calculated from Equation 3 for PS present in the phospholipid extract sample was 383 ± 18 M^{-1}. A pure PS sample under identical experimental conditions was found to bind Mg^{2+} with a binding constant of 385 M^{-1}. However, other phospholipids, such as PC, PE and SM, were found to bind to Mg^{2+} weakly (K_{Mg} in the range of 225–270 M^{-1}). The binding constants reported are subject to some error because they were calculated for the amount of Mg^{2+} added to the solvent mixture and not the amount present in the organic phase. The K_{Mg} to PI was calculated to be $(2.0 \pm 0.2) \times 10^3$ M^{-1}. The K_{Mg} value for PI is significantly larger than the value obtained for the other anionic phospholipid, PS. Thus, it was found that the anionic phospholipid, PI, interacted most strongly with Mg^{2+}; PS was found to bind Mg^{2+} with intermediate affinity, whereas SM, PE, and PC interacted weakly.

Figure 1B shows the changes in the ^{31}P NMR δ values as a function of added LiCl. Addition of up to 17.6 mM LiCl caused the δ values of PS, SM, PE, and PEPLAS to move upfield by approximately 0.1 ppm, whereas the δ value of the PC resonance did not change appreciably with Li^+ titration. When compared with the Mg^{2+} titration, larger amounts of Li^+ were needed for an effect on the ^{31}P NMR spectrum of human RBC membrane phospholipids. In order to characterize the interaction between PI and Li^+, we spiked the phospholipid extract from human RBC membranes with the same amount of pure PI as described above for the Mg^{2+} titration, and this sample was titrated with LiCl. Addition of up to 14.0 mM LiCl caused the PI resonance to move downfield (Table 2), whereas the SM resonance shifted upfield; the change in the δ value for all other resonances, including PS, was very small. The K_{Li} to PS was calculated to be 121 ± 17 M^{-1}, whereas for the other neutral phospholipids, the K_{Li} values were in the range of 55–65 M^{-1}. K_{Li} to PI and SM were calculated to be 102 ± 4 M^{-1} and 63 ± 1 M^{-1}, respectively.

^{31}P NMR δ changes of the phospholipid extracts containing both Li^+ and Mg^{2+} are shown in Figure 2. The addition of 0.50 mM $MgCl_2$ caused the ^{31}P NMR resonances to move upfield, whereas the ^7Li titration of this phospholipid sample caused the resonances to move downfield. This effect is clearly seen for the anionic phospholipid, PS, where addition of 0.50 mM $MgCl_2$ caused the resonance to move by 0.20 ppm upfield, as well as to broaden the PS signal. However, addition of 7.8 mM LiCl caused the PS resonance to move downfield by 0.03 ppm. A plot of the δ changes for the mixed ion titration is shown in Figure 3, with the PS signal displaying the greatest difference of the various phospholipids.

^{31}P NMR T_1 measurements of phospholipid extracts. We carried out ^{31}P NMR T_1 measurements of phospholipid extracts with and without metal ions in an effort to quantify metal ion binding to the phosphate head groups of the phospholipids. However, the T_1 variations within each class of phospholipids were too small (0.1 s) upon addition of either 0.50 mM $MgCl_2$ or 7.0 mM LiCl to be measured accurately (data not shown). The addition of metal ions did not cause any

significant changes in the ^{31}P NMR T_1 values either, and hence this technique could not be used for quantitative measurements.

^{7}Li and ^{6}Li NMR T$_1$ *measurements of phospholipid extracts*. The phospholipid extract in a chloroform/methanol solvent system was titrated with increasing amounts of LiCl;

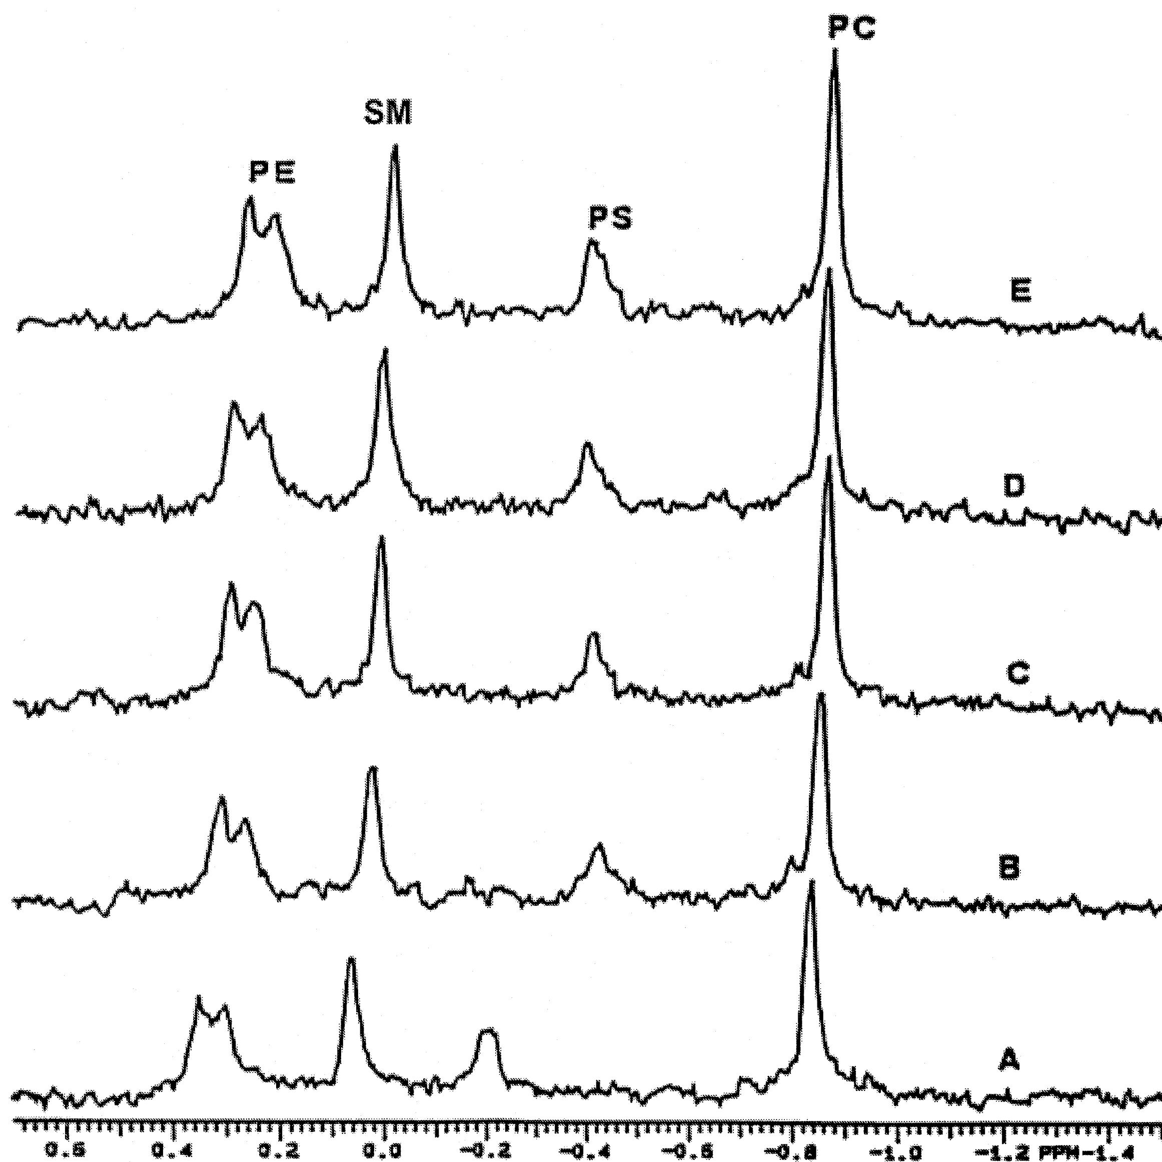

FIG. 2. ^{31}P NMR spectra of human RBC membrane phospholipids with (A) no metal ions added; (B) 0.50 mM Mg^{2+}; (C) 0.50 mM Mg^{2+} and 2.0 mM Li^{+}; (D) 0.50 mM Mg^{2+} and 3.9 mM Li^{+}; and (E) 0.50 mM Mg^{2+} and 7.8 mM Li^{+}. The peak assignments are indicated in spectrum E. See Figure 1 for abbreviations.

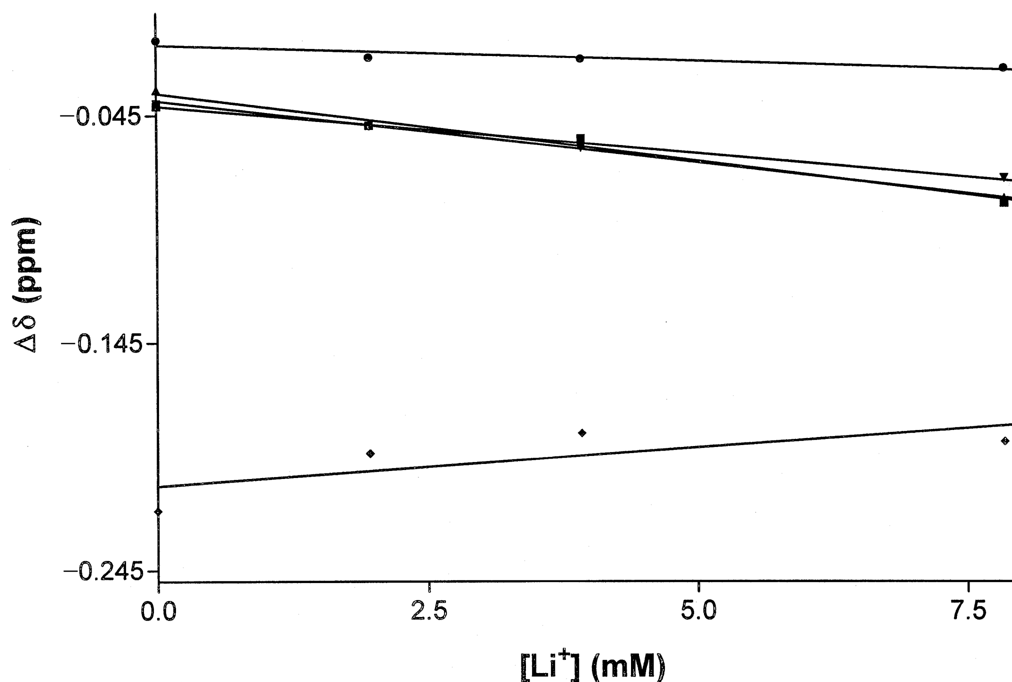

FIG. 3. Plot of the changes in ^{31}P NMR δ of human RBC membrane phospholipids containing 0.50 mM Mg^{2+} and varying amounts of LiCl. The phospholipids correspond to the following symbols: (●) PC; (▲) PE; (■) PEPLAS; (◆) PS; (▼) SM. For the regression line of PS, $r^2 = 0.74$, whereas for the other phospholipids, the r^2 for each regression line was greater than 0.94. See Figure 1 for abbreviations.

as the $^7Li^+$ concentration increased from 3.0 to 20 mM, the ^7Li T_1 values increased from 0.75 ± 0.16 s to 1.81 ± 0.13 s. However, for each Li^+ increment of 3.0 mM, the T_1 changes were very small (0.2 s) and only slightly sensitive to variations in Li^+ concentration. This method was therefore deemed unreliable for quantitative analysis. To see whether this effect was a mere ionic strength effect, we titrated the phospholipid extract containing 6.0 mM LiCl with $(Me)_4NCl$. Addition of up to 20 mM $(Me)_4NCl$ caused the ^7Li T_1 values to increase by only 0.2 s; therefore, the changes noticed in the ^7Li T_1 values are due to binding of the Li^+ to the phospholipids and are not due to ionic strength effects.

The ^6Li nucleus exhibits much larger relaxation time values than the ^7Li nucleus (27). Hence, we used ^6Li T_1 measurements to quantify Li^+ binding to the phospholipids. The ^6Li T_1 values increased from 7.63 ± 0.76 s to 13.13 ± 1.30 s upon addition of 5.0 to 30 mM ^6LiCl. The K_{Li} to the phospholipid extract was calculated to be 45 ± 5 M^{-1} ($n = 2$, $r^2 > 0.90$) using Equation 1. The phospholipid extract was titrated with ^6LiCl in the presence and absence of 0.1 mM Mg^{2+}. Addition of $^6Li^+$ caused an increase in the ^6Li T_1 values for both samples (Fig. 4), indicating Li^+ binding. However, at a given $^6Li^+$ concentration, the T_1 values were much higher for the sample containing 0.1 mM $MgCl_2$.

^7Li and ^6Li NMR T_1 measurements of RBC membranes. ^7Li T_1 measurements were conducted with samples of unsealed and cytoskeleton-depleted RBC membranes. As the LiCl concentration increased from 2.0 mM to 12.0 mM, the cytoskeleton-depleted membrane sample consistently gave higher T_1 values when compared to the unsealed-membrane sample. From Equation 1, the K_{app} for the cytoskeleton-depleted RBC membrane sample was 304 ± 30 M^{-1}, and for the unsealed RBC membrane sample, K_{app} was 202 ± 20 M^{-1}.

^7Li T_1 measurements were also conducted on the unsealed and cytoskeleton-depleted RBC membranes containing 4.0 mM LiCl and titrated with increasing amounts of $MgCl_2$. These results showed that, as the Mg^{2+} concentration increased from 0.0 to 0.6 mM, the ^7Li T_1 values for the unsealed membranes increased from 8.41 ± 0.04 to 13.16 ± 1.17 s, whereas for the cytoskeleton-depleted membranes the ^7Li T_1 values increased from 8.94 ± 0.06 to 14.15 ± 0.63 s.

In order to determine the actual Li^+ and Mg^{2+} binding constants (Eq. 2) for the unsealed and cytoskeleton-depleted RBC, we titrated the respective samples with increasing amounts of LiCl in the presence of either 0.05, 0.10, 0.15, or 0.20 mM $MgCl_2$. As Table 3 shows, the K_{app} for the unsealed RBC membrane was consistently lower when compared to values obtained for the cytoskeleton-depleted RBC membrane. The actual K_{Li} for the unsealed RBC was 221 ± 21 M^{-1} ($n = 3$), and for the cytoskeleton-depleted, the actual K_{Li} was 357 ± 24 M^{-1} ($n = 3$), whereas the K_{Mg} for the unsealed and cytoskeleton-depleted RBC membranes were 4397 ± 252 M^{-1} ($n = 3$) and 6996 ± 870 M^{-1} ($n = 3$), respectively.

^6Li T_1 measurements were also conducted on the two membrane samples. As the ^6Li concentration increased from 10 to 40 mM, the T_1 values were again larger for the cytoskeleton-depleted RBC membrane samples in comparison to the un-

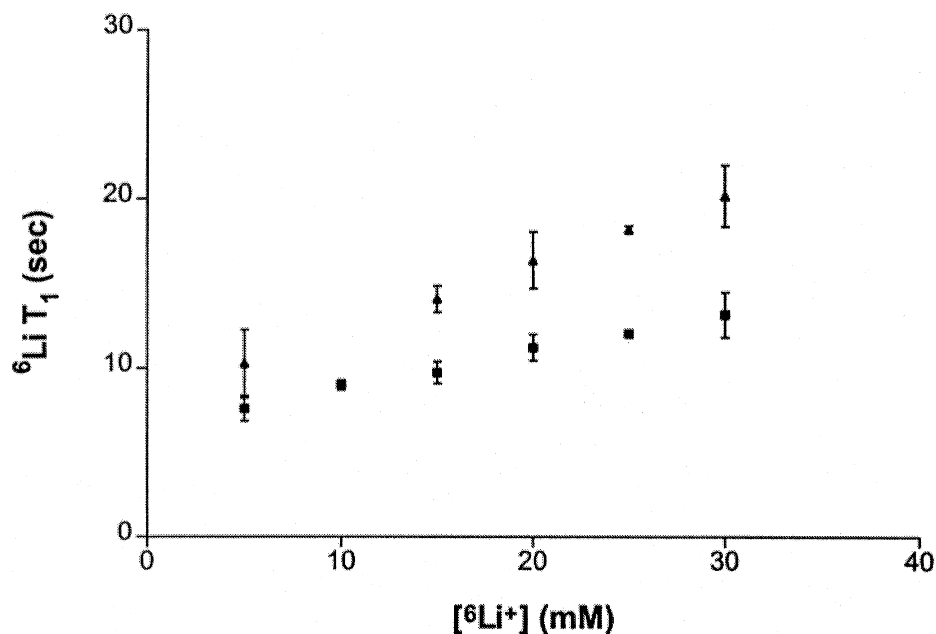

FIG. 4. Variations in ^{6}Li spin-lattice relaxation time values of the phospholipids extracted from human RBC membranes in the (■) absence and (▲) presence of 0.1 mM Mg^{2+}. The extracted dried phospholipids were suspended in a chloroform/methanol solvent mixture at a ratio of 5:2. The reported values are average values obtained from two separate measurements. See Figure 1 for abbreviation.

sealed RBC membrane samples. Using Equation 1, the calculated K_{app} value for the cytoskeleton-depleted RBC membrane samples was larger (259 ± 90 M^{-1}), when compared to the unsealed RBC membrane samples (115 ± 33 M^{-1}).

DISCUSSION

Li^+ and Mg^{2+} have similar ionic radii, and a "diagonal relationship" exists between these elements in the periodic table. As a result, the chemistry of Li^+ often resembles that of Mg^+. Hence, competition between these two ions could occur for biological ligands. Previous reports from our research group have shown evidence for competition between Li^+ and Mg^{2+} ions for Mg^{2+}-binding sites in biomolecules (12,33–36). Because Mg^{2+} is a cofactor for several enzymes, displacement of Mg^{2+} by Li^+ from biomolecules can affect several biological processes, and a combination of several effects, including metal ion binding to phospholipids, may be involved in the mode of action of Li^+ in the treatment of manic depression. Therefore, this study was devoted to probing Li^+/Mg^{2+} competition for RBC phospholipids and the RBC membrane by use of multinuclear NMR techniques.

In our NMR experiments, there are two layers: one organic and one aqueous. The organic layer contains essentially phospholipids, whereas the metal ions will reside in the aqueous layer. Because of the amphiphilic nature of phospholipid molecules, the tails will be fully embedded in the organic layer and the charged head groups will reside at the interface of the two layers. Therefore, the experimental design of our NMR experiments represents a good model system for understanding metal ion interactions to phospholipid head groups in biological membranes.

For human RBC membrane phospholipids, addition of up to 2.0 mM Mg^{2+} caused the ^{31}P NMR resonance shifts of PS to change by 0.5 ppm; this was the largest change that was observed (Fig. 1A). PS therefore interacted most strongly with Mg^{2+}, with marked broadening of the PS signal upon Mg^{2+} addition followed by quenching of the signal due to excessive broadening. Qualitatively, the signal that disappears first from the phospholipid spectral profile is considered to be interacting most strongly with the added cation. This obser-

TABLE 3
K_{app}, K_{Li}, and K_{Mg} for Unsealed and Cytoskeleton-Depleted RBC Membrane in Varying Concentrations of $MgCl_2$[a]

$[MgCl_2]$/(mM)	Unsealed RBC membrane K_{app} (M^{-1})	Cytoskeleton-depleted RBC membrane K_{app} (M^{-1})
0.0	202 ± 20	304 ± 30
0.05	190 ± 6	278 ± 21
0.10	167 ± 7	246 ± 11
0.15	134 ± 3	177 ± 15
0.20	113 ± 9	141 ± 17
K_{Li} (M^{-1})	221 ± 21	357 ± 24
K_{Mg} (M^{-1})	4397 ± 252	6996 ± 870

[a]These experiments were conducted in a 10-mm NMR probe. The values reported are the average values ± SD obtained from three separate trials. The r^2 values for all trials were greater than 0.90. The protein concentrations of the unsealed and the cytoskeleton-depleted RBC membranes were 6.9 ± 0.8 and 6.7 ± 0.9 mg/mL, respectively. The total phospholipid content was comparable for all samples. K_{app}, apparent binding constant; K_{Li}, lithium binding constant; K_{Mg}, magnesium binding constant.

vation was consistent with the K_{Mg} for PS, which was determined from a phospholipid extract. The relative order of K_{Mg} in the phospholipid extract samples calculated from the ^{31}P NMR δ values was PI ≫ PS > PE ≈ PEPLAS ≈ SM > PC.

Li^{+} titration of human RBC membrane phospholipids caused the ^{31}P NMR chemical shift of all phospholipids to move upfield by approximately 0.1 ppm, except for PC, when 17.6 mM LiCl was added (Fig. 1B). The changes in ^{31}P NMR δ values induced by an increase in Li^{+} concentration are very small when compared to the changes observed for Mg^{2+}. The relative order of Li^{+} binding constants in the phospholipid extract samples calculated from the ^{31}P NMR δ values was PS > PI > SM ≈ PE ≈ PEPLAS > PC. ^{7}Li NMR T_1 titrations also revealed that PS binds Li^{+} most strongly; SM and PI were found to have intermediate interaction. From the ^{31}P NMR δ data, it is interesting to note that in a phospholipid mixture, Mg^{2+} showed a preference for PI, whereas Li^{+} binds PS more strongly than PI.

The reversal of ordering of Li^{+} and Mg^{2+} binding to PS and PI is most likely related to a combination of two factors: differing coordination numbers and charge of the two metal ions. Because Li^{+} has a predominant coordination number of four, it binds to PI *via* one negatively charged oxygen of the phosphate group, whereas with PS, Li^{+} can bind in a bidentate manner to two charged oxygens of the phosphate head group and the carboxylate group of serine. Although the amino group of serine carries a +1 charge at the pH used in our studies, its repulsion by the low charge of Li^{+} is not very important. The PS-Mg^{2+} affinity constant is larger than that for the PS-Li^{+} affinity constant due to the higher charge of Mg^{2+}, thus making stronger interactions with the phosphate and carboxylic groups of PS (albeit also increasing the repulsion for its NH_4^{+} group).

Because Mg^{2+} has a coordination number of six (in contrast to four for Li^{+}), Mg^{2+} can bind simultaneously to phosphate and several hydroxyl groups of inositol. Formation of Mg^{2+} complexes of PI involving hydroxyl groups is more favored than in Li^{+} complexes of PI. The larger coordination number of Mg^{2+} allows binding of three hydroxyl groups of the inositol moiety pointing toward the same side of the ring, filling three vertices of its coordination polyhedron, whereas this ligand arrangement is not possible for Li^{+}. This type of proposed Mg^{2+} coordination to inositol has been observed before with Ca^{2+} chelates of inositol triphosphate (36,37). The fact that the ^{31}P shifts induced on PS and PI by Mg^{2+} binding are all upfield, whereas the ^{31}P shift induced on PI by Li^{+} binding is downfield, reflects the presence of chelate structures in the first two cases and their absence in the latter. Chelate formation drastically alters the torsion angles of the P–O bonds in the phosphodiester moieties of the phospholipids, which are one of the three factors that modify the chemical shielding of the ^{31}P nucleus (38).

It should be noted that Merchant and Glonek (11) saw a similar metal-binding trend in extracts containing various phospholipids present in the rat heart. In that study, it was determined that phosphatidic acid preferentially bound Ca^{2+}, whereas cardiolipin bound Mg^{2+} more strongly. Again, the reasoning behind this seems to be the difference in the coordination numbers of Mg^{2+} (six) and Ca^{2+} (greater than six).

To see whether there is competition between Li^{+} and Mg^{2+} for the phospholipid extract, we titrated the phospholipid extract sample with 0.50 mM Mg^{2+}. Addition of Mg^{2+} caused all of the resonances, except that of PC, to move upfield, with the maximum effect being the PS resonance with a 0.20-ppm shift (Figs. 2 and 3). When titrated with increasing amounts of LiCl, the resonance for the anionic phospholipid, PS, shifted downfield, whereas the resonances shifted slightly upfield. Therefore, a decrease in the δ change was observed. This effect is clearly seen in Figure 3; the slope of the δ difference for PS is positive, whereas for the other phospholipids present in the extract, the slope is negative. The signal of PS also sharpened; this, we believe, is due to Li^{+} displacing Mg^{2+} from the phosphate head group of PS.

^{6}Li NMR T_1 measurements were conducted with the phospholipid extracts both in the presence and absence of $MgCl_2$ (Fig. 4). The T_1 values were sensitive to LiCl addition to both samples. This is consistent with ^{31}P NMR results indicating that the phospholipids interact with Li^{+}. Moreover, the samples with Mg^{2+} gave higher T_1 values than did the samples without Mg^{2+} at the same Li^{+} concentration. This increase in T_1 values in the presence of Mg^{2+} is due to an increase in the free Li^{+} concentration, and this, we believe, is due to Mg^{2+} and Li^{+} occupying the same binding site. Mg^{2+} is presumably displacing Li^{+} from the phosphate head group of the phospholipids. Both the ^{31}P NMR δ measurements and the ^{6}Li T_1 measurements provide evidence for Li^{+}/Mg^{2+} competition.

The K_{Li} to the phospholipid extract without Mg^{2+} was calculated to be 45 ± 5 M^{-1} ($n = 2$, $r^2 > 0.90$) from the James-Noggle plot. This value is lower than the binding constant determined for the unsealed RBC membranes, which is close to 200 M^{-1} (3). These differences in Li^{+} binding constants may be attributed to the different media used—organic solvent mixture vs. water—in the two samples.

Although the phospholipids provide major binding sites for the metal ions, the removal of the lipids from the membrane skeleton could have decreased their affinity for the metal ions. This prompted us to characterize the role played by the cytoskeleton in metal ion binding and competition. To identify whether the cytoskeleton anchored on the inner leaflet of the lipid bilayer plays any significant role in metal ion binding and competition, we conducted ^{7}Li and ^{6}Li NMR studies with unsealed and cytoskeleton-depleted membranes. ^{7}Li NMR T_1 measurements were conducted for unsealed and cytoskeleton-depleted human RBC membranes titrated with increasing amounts of LiCl. It was previously determined from ^{7}Li NMR relaxation measurements that unsealed RBC membrane samples showed a biexponential relaxation of the ^{7}Li nucleus when the Li^{+} concentration was 20 mM (3). However, when the Li^{+} concentration exceeded 150 mM, Rong *et al.* (3) did not see evidence for the same biexponential decay. Removal of the cytoskeleton did not affect the sensitivity of the ^{7}Li T_1 values to the changes in LiCl concentra-

tion; this indicated that the removal of the cytoskeleton did not prevent Li^+ binding to the membranes. The Li^+ affinity binding constant to the cytoskeleton-depleted membrane was found to be 357 ± 24 M^{-1}, which is approximately twofold higher than the value determined for the unsealed membranes (221 ± 21 M^{-1}). It should also be noted that a similar trend was seen for ^6Li T_1 experiments; the binding constant was again larger for the cytoskeleton-depleted RBC membrane samples (259 ± 90 M^{-1}) compared to the unsealed RBC membrane samples (115 ± 33 M^{-1}). This increase in Li^+ affinity for the cytoskeleton-depleted membranes could be due to exposure of the anionic phospholipids. The inner leaflet of the RBC membrane contains a greater percentage of the negatively charged phospholipids (PI and PS) as compared to the outer leaflet, and removal of the spectrin–actin network could allow for easy interaction between Li^+ and the anionic phospholipids in the lipid bilayer. The competition between Li^+ and Mg^{2+} was found to be present even after the removal of the cytoskeleton. Hence, it was clear that the cytoskeleton had no major role in Li^+ binding or in Li^+/Mg^{2+} competition.

In summary, this study indicated that there is competition between Li^+ and Mg^{2+} for human RBC membranes and phospholipids. This study also showed that PS and PI bind Li^+ and Mg^{2+} most strongly, whereas the neutral phospholipid PC does not contribute significantly toward metal ion binding. These observations provide a possible explanation for the elevated K_{Li} obtained for the RBC membranes from manic-depressive patients undergoing Li^+ therapy, because their cell membranes contain a greater percentage of the anionic phospholipids (32).

Fullerene Lipids: Synthesis of C_{60} Fullerene Derivatives Bearing a Long-Chain Saturated or Unsaturated Triester System

Marcel S.F. Lie Ken Jie* and Sunny Wai-Hung Cheung

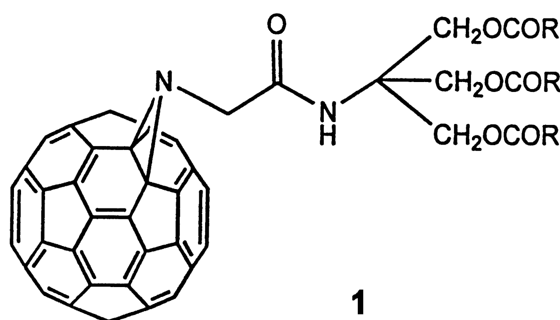
Department of Chemistry, The University of Hong Kong, Hong Kong, People's Republic of China

ABSTRACT: Tris(hydroxymethyl)aminomethane was successfully esterified with saturated and unsaturated long-chain fatty acids. The resulting amino-triester intermediates were successively reacted with chloroacetyl chloride, sodium azide, and C_{60} fullerene. Spectral evidence showed that the aziridine ring is joined to the junction of [6,6]-fused rings of the fullerene. The structures of the various C_{60} fullerene derivatives bearing a long-chain saturated or unsaturated triester system were characterized by spectroscopic and spectrometric methods.

Paper no. L8286 in *Lipids 34,* 1223–1230 (November 1999).

Studies of the reactivity and chemical derivatization of fullerenes have drawn keen and continuous attention after a method for bulk production of C_{60} fullerene was reported (1). A large range of functionalized fullerenes have been prepared for material and pharmaceutical applications (2–8). For instance, methanofullerene derivatives bearing the salts of carboxylic acids possess inhibitory activity against human immunodeficiency virus (HIV) protease (9,10). The biological activity of water-soluble fullerenes has also been explored, with results showing structural dependence of DNA cleavage, cytotoxicity, and enzyme inhibitory activities including HIV-protease inhibition (11). However, only two reports on C_{60} fullerene with lipophilic groups (containing long-chain ester functions) have been published (12,13). We have recently reported the synthesis of a series of 14 dialkyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate derivatives containing saturated and unsaturated alkyl groups (12). Murakami *et al.* (13) have described the synthesis of a C_{60} fullerene derivative containing three saturated fatty ester system attached *via* an aziridine bridge **1** (Scheme 1).

Compound **1** appears to be a very interesting fullerene lipid, as it can form self-organized multibilayer films despite the presence of a large spherical cage structure in the molecule. The degree of phase transitions between the crystalline phase and liquid crystalline phase of lipid bilayer membranes is very much dependent on the structure of the acyl chains. In view of this important factor, we propose to study the physical properties of a wider range of similar fullerene lipids by synthesizing analogs of compound **1** containing saturated acyl moieties of different chain lengths and analogs containing mono- and polyunsaturated acyl groups.



SCHEME 1

In this paper we describe the synthesis of seven fullerene lipids with structures similar to that of compound **1**, but containing either saturated (C_{12}, C_{14}, C_{16}, C_{18}, **1a–1d**, respectively) or unsaturated (oleic, linoleic, and stearolic acids, **1e–1g**, respectively) fatty acid moieties in the triester system (Schemes 2 and 3, respectively). The results of the study of the nuclear magnetic resonance (NMR) spectroscopic and other physical properties of these novel C_{60} fullerene derivatives are described.

MATERIALS AND METHODS

Melting points were determined by using a hot-stage apparatus and are uncorrected. Infrared (IR) spectra were recorded on a Bio-Rad FTS-165 FT IR spectrometer. Samples were made into KBr discs for solids or were run as neat films for liquids on KBr discs. Ultraviolet (UV) spectra of solutions in dichloromethane were recorded on a Hewlett-Packard Diode Array Spectrophotometer, model 8452A (Hewlett-Packard, Palo Alto, CA). NMR spectra were recorded on a Bruker Avance DPX_{300} (300 MHz) Fourier-transformed NMR spec-

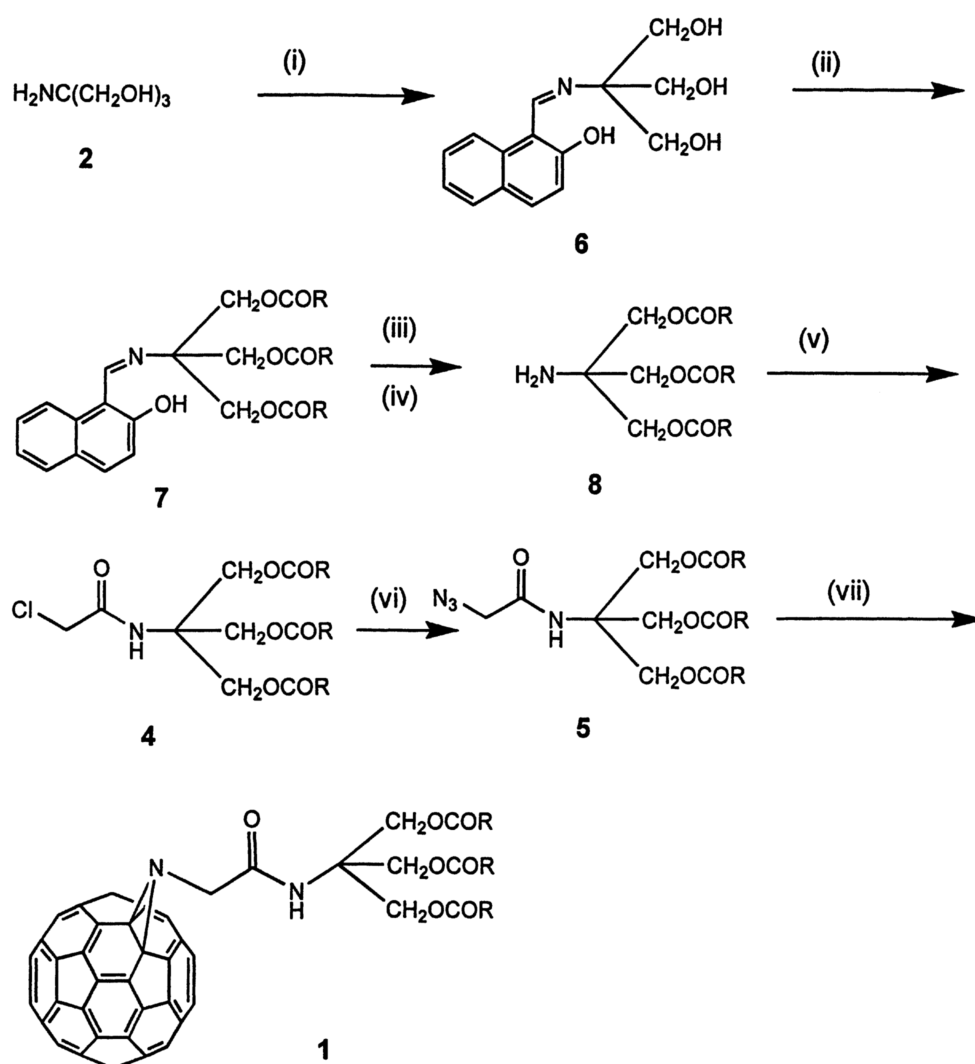
SCHEME 2

trometer (Bruker, Fallanden, Switzerland) from solutions in deuteriochloroform ($CDCl_3$) with tetramethylsilane (TMS) as the internal reference standard. Chemicals shifts are given in δ-values in ppm downfield from TMS (δ_{TMS} = 0 ppm). Mass spectral analyses were carried out on Finnigan MAT-LCQ [atmospheric pressure chemical ionization (APCI)] (Finnigan Corp., San Jose, CA).

Oleic and linoleic acids were purchased from Aldrich Chemical Co. (Milwaukee, WI). Octadec-9-ynoic acid (stearolic acid) was prepared by bromination–dehydrobromination reaction of the corresponding oleic acid as described elsewhere (14). C_{60} fullerene was purchased from Lancaster Synthesis Ltd. (Eastgate, Lancashire, United Kingdom) or from Materials and Electrochemical Research Corp. (Tucson, AZ). Tris(hydroxymethyl)aminomethane was purchased from Sigma Chemical Co. (St. Louis, MO).

*General procedure for the preparation of C_{60} fullerene lipids containing saturated fatty acid moieties in the triester system (**1a–1d**) as exemplified by the synthesis of compound **1a** (Scheme 2).* A mixture of tris(hydroxymethyl)aminomethane **2** (1.6 g, 13.2 mmol), dodecanoic acid (9.5 g, 47 mmol), *p*-toluenesulfonic acid (4.7 g), and toluene (150 mL) was refluxed (fitted with a Dean-Stark trap) for 20 h. The reaction mixture was cooled, and the precipitate was isolated by filtration. The precipitate was recrystallized from a solution of acetonitrile and diethyl ether (4:1, vol/vol) to give the tridodecyl ester derivative **3** (9.2 g, 81.3%). The latter compound (2.44 g, 2.9 mmol) was mixed with triethylamine (363 mg, 3.6 mmol) in tetrahydrofuran (THF, 20 mL) at room temperature, followed by the addition of chloroacetyl chloride (542 mg, 4.8 mmol). The whole mixture was then stirred for 14 h. The solution was filtered, and the filtrate was evaporated under reduced pressure. The residue was recrystallized from methanol to give the chloroacetyl derivative **4** (1.2 g, 55%). Compound **4** (1.0 g, 1.48 mmol) was stirred with sodium azide (210 mg, 3.2 mmol) in dimethylsulfoxide (15 mL) at 70°C for 5 h. Water (50 mL)



1 e R = $(CH_2)_7CH{=}CH(CH_2)_7CH_3$ (*cis*)

1 f R = $(CH_2)_7CH{=}CHCH_2CH{=}CH(CH_2)_4CH_3$ (*cis*, *cis*)

1 g R = $(CH_2)_7C{\equiv}C(CH_2)_7CH_3$

Reagents and conditions: (i) 2-hydroxy-1-naphthaldehyde, methanol, reflux, 12 h; (ii) RCOOH, dichloromethane, dicyclohexylcarbodiimide, 4-dimethylaminopyridine, 24°C, 48 h; (iii) bromoacetic acid, tetrahydrofuran, 2°C, 2 h; (iv) *n*-butylamine, tetrahydrofuran, 2 min; (v) chloroacetyl chloride, triethylamine, tetrahydrofuran, 24°C, 12 h; (vi) sodium azide, dimethylsulfoxide, 70°C, 5 h; (vii) C_{60} fullerene, chlorobenzene, reflux, 12 h.

SCHEME 3

was added, and the reaction mixture was extracted with diethyl ether (4 × 50 mL). The ethereal extract was successively washed with water, brine, water (30 mL), dried over Na_2SO_4, and filtered. The filtrate was evaporated to give the corresponding azido derivative **5** (0.99 g, 89%). Compound **5** (315 mg, 0.42 mmol) in chlorobenzene (30 mL) was added dropwise to a refluxing solution of C_{60} fullerene (200 mg, 0.28 mmol) in chlorobenzene (150 mL) under an atmosphere of argon and was refluxed for a further 12 h. The reaction mixture was cooled, and the chlorobenzene was evaporated under re-

duced pressure to give a brown viscous residue. The residue was separated on a silica (30 g) column using toluene/*n*-hexane (1:1, vol/vol, 600 mL) to elute the unreacted C_{60} fullerene. The product was isolated by careful gradient elution using mixtures of diethyl ether/*n*-hexane (starting with 2:98, vol/vol, gradually increasing the amount of diethyl ether in the eluent until the final proportion reached 50:50, vol/vol; total volume of eluent used was 650 mL). Fractions of 10 mL each were collected during the chromatographic run, and the purity of the product was closely monitored by silica thin-layer chromatography. The requisite fullerene lipid **1a** (78.1 mg, 25% based on the amount of C_{60} fullerene consumed) was obtained as a brown solid.

*General procedure for the preparation of C_{60} fullerene derivatives containing unsaturated fatty acid moieties in the triester system (**1e–1g**) as exemplified by the synthesis of compound **1e** (Scheme 3).* A mixture of tris(hydroxymethyl)aminomethane **2** (3.0 g, 25 mmol), 2-hydroxy-1-naphthaldehyde (5.9 g, 25 mmol), and methanol (40 mL) was refluxed for 12 h. The solvent was evaporated under reduced pressure. The brown solid residue was washed with diethyl ether (2 × 20 mL) to give crude *N*-(2-hydroxynaphthyl)tris(hydroxymethyl)iminomethane **6** (5.3 g, 19.3 mmol, 77%) as a brownish yellow powder. The latter compound was mixed with oleic acid (5.0 g, 17.7 mmol), dicyclohexylcarbodiimide (5.0g, 24 mmol), 4-dimethylaminopyridine (90 mg, 0.7 mmol), and pyridine (20 mL), and the mixture was stirred vigorously at room temperature for 2 d. The reaction mixture was filtered. Water (30 mL) was added to the filtrate. The mixture was extracted with dichloromethane (2 × 30 mL). The organic extract was successively washed with dilute HCl (2 M, 30 mL) and water (20 mL), and dried over anhydrous Na_2SO_4. The solvent was evaporated under reduced pressure. The residue was separated on a silica (200 g) column by gradient elution using mixtures of diethyl ether/*n*-hexane to yield the triester **7** (1.42 g, 36%) as a fluorescent yellow oil.

A solution of the triester **7** (1.0 g, 0.94 mmol) in THF (20 mL) was cooled to 0°C in an ice bath. A precooled solution of bromoacetic acid (3.0 g) in THF (10 mL) was added dropwise to the triester solution, and the temperature of the reaction mixture was maintained at 0–2°C for 2 h. During this period the fluorescent yellow solution turned to a pale nonfluorescing yellow color. An additional amount of THF (20 mL) was added, and the reaction temperature was allowed to reach 20°C. *n*-Butylamine (2 mL) was then added when the reaction turned fluorescent yellow in color. Water (30 mL) was

added, and the reaction mixture was extracted with *n*-hexane (3×50 mL). The organic extract was washed with water (3×30 mL) and dried over anhydrous Na_2SO_4. The filtrate was evaporated under reduced pressure, and the residue was separated by flash silica (100 g) column chromatography (gradient elution with a mixture of diethyl ether/*n*-hexane) to give the amino-triester **8** (0.43 g, 50%) as a pale yellow oil.

Compound **8** (0.43 g, 0.47 mmol) and triethylamine (77 mg, 0.76 mmol) were dissolved in THF (20 mL). Chloroacetyl chloride (142 mg, 1.26 mmol) was slowly added. The reaction mixture was stirred for 12 h at room temperature and filtered. The filtrate was evaporated under reduced pressure, and the residue was separated by silica (70 g) column chromatography (gradient elution with a mixture of diethyl ether/*n*-hexane) to give the chloro-amido derivative **4** (0.39 g, 84%) as a viscous oil.

The chloro-amido derivative **4** (0.36 g, 0.36 mmol) was heated at 55°C with sodium azide (0.47 g, 0.73 mmol) in dimethyl sulfoxide (20 mL) for 12 h. A reddish orange oil was found to float on top of the reaction mixture. Aqueous sodium chloride solution (10%, 50 mL) was added, and the reaction mixture was extracted with diethyl ether (3×30 mL). The organic extract was washed with aqueous sodium chloride solution (10%, 2×20 mL) and dried over anhydrous sodium sulfate. The filtrate was evaporated under reduced pressure to give the corresponding azido derivative **5** (0.36 g, 98%) as a reddish orange oil.

A solution of the azido derivative **5** (0.36 g, 0.36 mmol) in chlorobenzene (50 mL) was added through a condenser to a refluxing solution of C_{60} fullerene (0.25 g, 0.35 mmol) in chlorobenzene (250 mL) under an argon atmosphere. The reaction mixture was refluxed for a further 12 h. The color of the reaction mixture turned from purple to dark brown. The solvent was evaporated under reduced pressure. The resulting viscous brown residue was dissolved in diethyl ether (100 mL) and filtered. The filtrate was evaporated, and the residue was separated by silica (30 g) chromatography using mixture of toluene/*n*-hexane, 1:1 vol/vol (100 mL), followed by gradient elution with mixtures of diethyl ether/*n*-hexane (starting with 2:98, vol/vol, gradually increasing the amount of diethyl ether in the eluent until the final proportion reached 50:50, vol/vol: total volume of eluent used was 650 mL). Fractions of 10 mL each were collected during the chromatographic run, and the purity of the product was closely monitored by silica thin-layer chromatography. The requisite fullerene lipid **1e** (72 mg, 24% based on the amount of C_{60} fullerene consumed) was obtained as a brown liquid.

DISCUSSION

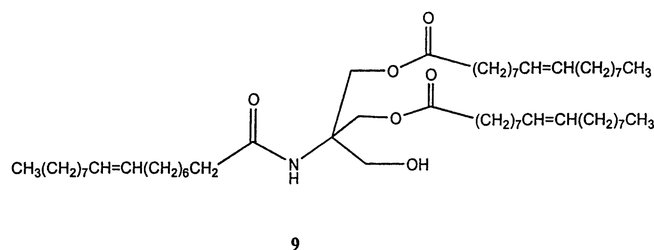
The formation of aziridinofullerene by reacting C_{60} fullerene with an azide is one of the promising protocols of fullerene functionalization (15). Murakami *et al.* (13) have reported a C_{60} fullerene lipid molecule **1** containing an interesting triester system, which was attached to C_{60} fullerene *via* an

aziridino bridge. These workers have produced only one C_{60} fullerene lipid where the triester system was made up of saturated C_{16} (palmitic) acyl chains. They have studied the phase transition properties of this molecule. Details of the synthesis methods used were not included in the publication. As fullerene chemistry is still in its infancy, we propose to study the synthesis of a series of homologs (containing C_{12} , C_{14}, C_{16}, C_{18} fatty acid acyl chains) of the C_{60} fullerene lipid **1** and to produce three similar C_{60} fullerene lipids but containing unsaturated fatty acid moieties in the triester (oleic, linoleic, and stearolic) system.

We found that preparation of the four C_{60} fullerene lipids (compounds **1a–d,** containing C_{12}, C_{14}, C_{16}, C_{18} fatty acid acyl chains) could be readily achieved once the precise methodology was established (Scheme 2). The esterification of tris(hydroxymethyl)-aminomethane **2** with saturated fatty acids in the presence of *p*-toluenesulfonic acid proceeded smoothly in high yields. The sulfonate salt of the amino-triester **3** reacted with chloroacetyl chloride to give the chloroamido derivative **4.** The latter, on treatment with sodium azide, furnished the key azido intermediate **5**. Reaction of C_{60} fullerene with the azido intermediate **5** furnished the requisite products **1a, 1b, 1c** and **1d** in 28, 46, 45, and 27%, respectively (based on the amount of C_{60} fullerene reacted). The most difficult part was encountered during silica column chromatographic separation of the fullerenoid products at the final stage. It was necessary to use a very careful gradient elution system (with small and increasing amounts of diethyl ether in *n*-hexane as the eluting solvent). The entire process was closely monitored by thin-layer chromatography.

When unsaturated fatty acids (oleic, linoleic, and octadec-9-ynoic acid) were reacted with tris(hydroxymethyl)aminomethane **2** in the presence of *p*-toluenesulfonic acid, a complex mixture of products was obtained in each case. *p*-Toluenesulfonic acid was also found to attack the double or acetylenic bond in the fatty acid. The reaction products could not be separated or purified by silica column chromatography for detailed analysis. The mixture of products showed that both the unsaturated centers of the fatty acids and the amino group of the reactant **2** were attacked by *p*-toluenesulfonic acid. Attempts to conduct the esterification process in the presence of dicyclohexylcarbodiimide (DCC) and 4-dimethylaminopyridine (DMAP) as described by Hassner and Alexanian (16) or by using a lipase (Novozyme 435, C*andida antarctica)* as the catalyst for the esterification were likewise unsuccessful.

It was therefore decided to block the amino function by reaction of this group with 2-hydro-1-naphthaldehyde (17). The blocked amino intermediate **6** was readily esterified with oleic acid in the presence of dicyclohexylcarbodiimide and 4-dimethylaminopyridine in pyridine to yield the corresponding ester **7** in good yields. Problems arose when attempts were made to deblock the protected amino group of compound **7** by the standard method (18) (*viz*., with 2 M HCl, CF_3COOH at room temperature). The ester groups were completely or partially hydrolyzed to yield fatty acids. We then decided to perform the deprotection procedure with bromoacetic acid, instead of HCl/CF_3COOH. However, when this reaction was carried out at room temperature, an undesired product **9** was isolated in >50% yield (Scheme 4). The structure of compound **9** was elucidated by a combination of spectroscopic analyses. Absorption bands in the IR spectrum showed the presence of a hydroxy group (3687 cm^{-1}), amide N-H (3602 cm^{-1}) group, and C=O stretching vibrations for the ester (1736 cm^{-1}) and amide (1665 cm^{-1}). The shifts of the N-H proton of the amide and O-H (D_2O-exchangeable) appeared at δ_H 5.99 (*s*) and 4.75 (*br.*, *s*), respectively. The presence of a hydroxy group was confirmed by the signal at δ_H 3.76 (*s*, CH_2OH, 2H). The shifts of the protons of the methylene group located between the quaternary carbon atom and the two oleyl acyl chains appeared as two distinct doublets at 4.43 (*d*, J = 11.5, CH_2OCOR, 2H) and 4.16 (*d*, J = 11.5, CH_2OCOR, 2H).



SCHEME 4

There were also two signals (2:1 intensity) for the 2-*H* shifts of the oleyl chains, which could be assigned to the ester acyl chains 2.34 (*t*, J = 7.5, CH_2COO, 4H) and to those of the amide acyl chain 2.19 (*t*, J = 7.5, CH_2CONH-, 2H). The shifts of the olefinic protons of the oleyl chains appeared at 5.20–5.40 (*m*, CH=CH, 6H). The following carbon shifts provided further proof of the structure of compound **9**: ^{13}C NMR ($CDCl_3$, δ_C) 174.60 (C=O, amide), 173.75 (C=O, ester), 130.06, 129.68 (CH=CH), 63.81 (-CH$_2$OCO-), 63.00 (-CH$_2$OH), 60.42 [NC(CH_2OCOR)$_2$$CH_2OH$], 37.29 ($CH_2$CONH), 34.12 ($CH_2$COOR), 31.92 (C-16 of acyl), 29.78, 29.75, 29.72, 29.55, 29.34, 29.29, 29.20, 29.13 (CH_2), 27.24, 27.18 (allylic carbon), 25.68 (CH$_2$CH$_2$CONH), 24.89 (CH$_2$CH$_2$COOR), 22.70 (C-17), 14.14 (C-18).

We rationalized that during this deprotection process, one of the three acyl groups in compound **7** migrated to the amino group to form an amido function (compound **9**). No anticipated free amino-triester **8** was isolated. Some of the starting material (compound **7)** was recovered.

After many trials to find a suitable deprotection procedure for compound **7**, we ultimately discovered a successful method for this purpose. Deprotection (to the extent of 50%) was made possible when the reaction was carried out with bromoacetic acid at 2°C for 2 h. Excess *n*-butylamine was immediately added to neutralize the reaction in order to prevent acyl migration. Despite the low temperature conditions, followed by neutralization of the reaction medium (with *n*-butylamine), the undesired product **9** was still obtained at about 20%. However, this undesired side product was readily sepa-

rated by silica column chromatography from the requisite amino-triester **8**. The isolated amino-triester **8** was then reacted with chloroacetyl chloride without delay. The reactions with sodium azide and subsequently with C_{60} fullerene were successfully accomplished.

By esterifying the protected amino intermediate **6** with oleic acid, linoleic acid, or octadec-9-ynoic acid, compounds **1e**, **1f**, and **1g** were obtained in 24, 37, and 23% yield (based on the amount of C_{60} fullerene reacted), respectively, at the last step of the reaction sequence. The four saturated C_{60} fullerene lipids (**1a–1d**) are brown solids with melting points in the range of 51–54°C. The three unsaturated C_{60} fullerene derivatives (**1e–1g**) are very viscous brown oils. Both sets of fullerene lipids are readily soluble in diethyl ether, dichloromethane or chloroform.

The proton NMR spectra of all C_{60} fullerene lipids **1** showed the characteristic shift of the N-H proton at δ_H 7.88. The signal for the shift of the methylene protons located between the aziridine ring and the amido function appeared at δ_H 4.35 as a singlet. The shifts of the methylene protons of the initial triol (δ_H 4.61, *s*) were readily differentiated from the 2-*H* (δ_H 2.34, *t*, J = 7.6 Hz) methylene of the long-chain acyl chain. The olefinic protons of the triesters containing oleic acid or linoleic acid appeared in the δ_H 5.3–5.0 region of the spectrum.

The ^{13}C NMR spectra showed 9–12 signals (δ_C 140–146) for the sp^2 carbon nuclei of the fullerene cage. The appearance of a signal (2C equivalent) at δ_C 83.4 is characteristic of the shifts of sp^3 carbon nuclei of the fullerene cage at which the aziridine ring is attached. This specific signal also indicates that the aziridine ring is joined to the junction of [6,6]-fused rings of the fullerene (13).

The shift of the carbonyl carbon for the ester and the amide were δ_C 173 and 168 respectively. The methylene carbon of the initial triol appeared at δ_C 54.1, whereas the quaternary carbon nucleus was shifted to δ_C 58.3. The signals corresponding to saturated and unsaturated (olefinic and acetylenic) fatty acyl chains were readily assigned by referring to results described for the carbon NMR properties of long-chain saturated and unsaturated fatty acids or esters (19). IR spectra of both saturated and unsaturated products showed vibrations for the N-H stretching (3370–3472 cm^{-1}), C=O stretching (1744–1748 cm^{-1}), and $(CH_2)_n$ rocking (about 720 cm^{-1}) (20). The characteristic C_{60} fullerene stretching vibrations appeared in 526–527 cm^{-1}.

The mass spectrometric analysis of the fullerene lipids (**1a–1g**) gave the corresponding M + 1 peak by atmospheric pressure chemical ionization (APCI) technique with the base peak appearing at 720. When these compounds were analyzed by either electron ionization or by fast atom bombardment technique, only the base peak was found at m/z = 720.

We conclude from this study that the synthesis of fullerenoid lipids containing saturated or unsaturated fatty acid moieties in the ester system can be achieved. From the NMR spectroscopic study it is evident that the aziridine ring is joined to the junction of [6,6]-fused rings of the fullerene.

Separation and Determination of Glycolipids from Edible Plant Sources by High-Performance Liquid Chromatography and Evaporative Light-Scattering Detection

Tatsuya Sugawara and Teruo Miyazawa*

Biodynamic Chemistry Lab, Graduate School of Life Science and Agriculture, Tohoku University, Sendai 981-8555, Japan

ABSTRACT: Glycolipids from edible plant sources were accurately quantified by silica-based, normal-phase high-performance liquid chromatography using an evaporative light-scattering detector. Five major glycolipid classes (acylated steryl glucoside, steryl glucoside, ceramide monohexoside, monogalactosyldiacylglycerol, and digalactosyldiacylglycerol) were separated and determined with a binary gradient system consisting of chloroform and methanol/water (95:5, vol/vol) without any interference from other lipid classes and pigments. The described method was applied to 48 edible plants available in Japan including cereals, legumes, vegetables, and fruits. Examined plant species contained glycolipids in wide concentration ranges, such as 5–645 mg/100 g tissue.

Paper no. L8289 in *Lipids 34,* 1231–1237 (November 1999).

Glycolipids in higher plants mainly consist of steryl glucosides (SG), sphingoglycolipids, and glyceroglycolipids. These glycolipids are widely distributed in edible plants such as cereals, legumes, vegetables, and fruits (1,2). In previous studies (3–10), plant glycolipids have been quantified gravimetrically or colorimetrically after separating and isolating them with column chromatography or with thin-layer chromatography (TLC); however, these techniques are time-consuming and labor intensive.

High-performance liquid chromatography (HPLC) is one of the most popular tools for the analysis of lipid classes. Since gradient solvent systems have been employed for the separation of glycolipids, quantitative analysis with HPLC has been recognized to be difficult even with post-column detection by ultraviolet (UV), refractive index (RI), and fluorescence detectors. Recently, an evaporative light-scattering detector (ELSD) for HPLC, which is insensitive to the mobile-phase solvents and thus allows direct quantification, has been applied to lipid class analyses (11–20). Christie (11,12) and Lutzke and Braughler (13) have quantified lipid classes in rat liver, heart, plasma, and brain by HPLC–ELSD with a ternary gradient elution system. The HPLC–ELSD analyses of phospholipids in cooked beef (14), soybean lecithin (15), rat liver and heart (16), and human brain (17) have also been carried out.

For the HPLC–ELSD analysis of plant glycolipids, a complex ternary solvent gradient system (19) and several pretreatments for sample lipid fractionation before HPLC (20) have been needed. HPLC–ELSD has never been applied to the analysis of ceramide monohexoside (CMH) which is commonly distributed in plants (21–24).

The aim of this study was to develop the optimal HPLC–ELSD conditions for the separation and quantification of glycolipids in edible plants by using a simpler binary gradient system without any pretreatment of the Folch's lipid extract.

MATERIALS AND METHODS

Materials. Monogalactosyldiacylglycerol (MGDG) and digalactosyldiacylglycerol (DGDG) from wheat flour, and phosphatidylglycerol (PG) sodium salt from egg lecithin were purchased from Sigma Chemical Co. (St. Louis, MO). SG and acylated steryl glucoside (ASG) from soybeans were purchased from Funakoshi Co. (Tokyo, Japan). Phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI) from porcine liver, phosphatidic acid (PA) from egg PC, and phosphatidylserine (PS) from bovine brain were purchased from Funakoshi Co.

To isolate wheat flour CMH and remove glycerolipids, the total lipids extracted with chloroform/methanol (2:1, vol/vol) were saponified with 0.4 M KOH in methanol at 38°C for 2 h (23). The alkali-stable lipid fraction was recovered and applied to silica TLC (silica gel 60 F_{254}, 20 × 20 cm; Merck, Darmstadt, Germany) developed in chloroform/methanol/water (65:16:2, by vol) for the purification of CMH. Under UV light irradiation, the visualized lipid band corresponding to CMH was collected and extracted with chloroform/methanol (2:1, vol/vol). The wheat flour CMH isolated was analyzed by electrospray ionization mass spectrometry (ESI–MS) using a Mariner ESI/time of flight (ESI/TOF) mass

spectrometer (PE Biosystems, Milford, MA). In the mass spectrum of CMH, $[M + H]^+$ ions demonstrating molecular weight were found at *m/z* 716 and 772 corresponding to the principal species having ceramide moieties, in which 8-sphingenine was combined with hydroxy fatty acids of C_{16} or C_{20} (24). Thus, the wheat flour CMH served as a standard in HPLC.

All other reagents and chemicals used were extra-pure grade. All edible plants or products were purchased from a local supermarket in Sendai, Japan.

Lipid extraction. Five grams of the edible part of fresh plant samples was cut into pieces and heated for 1 min in a microwave oven (model RE-26-H5P, 500 W; Sharp Co., Osaka, Japan) to inactivate hydrolytic enzymes. Then the sample plants were further homogenized in a Waring blender with 20 mL of chloroform/methanol (2:1, vol/vol), and the total lipids (the Folch's lipid extract) were prepared as followed by the method of Folch *et al.* (25). The total lipids were redissolved in an aliquot of chloroform and were subjected to HPLC–ELSD for the analysis of glycolipids. The glycolipid concentrations were expressed as the mean of a paired analysis of the same sample.

HPLC–ELSD conditions. The HPLC system consisted of a sample injector (100 µL, Rheodyne model 7125; Rohnert Park, CA), two JASCO 980-PU HPLC pumps (Japan Spectroscopic Co., Tokyo, Japan), and a JASCO 860-CO column oven (40°C). The ELSD detector at post-column was an SEDEX model 55 (Sedere, Virty sur Seine, France), kept at an evaporation temperature of 60°C and at 2.0 bar pressure (2.7 L/min) for nebulization gas (nitrogen). The photomultiplier sensitivity was adjusted to gain six. The peak area was calculated with a Chromatocorder 21 (System Instruments, Tokyo, Japan). The HPLC column was a LiChrospher Si 60 (5 µm, 125 × 4 mm i.d., Merck).

The mobile phase consisted of chloroform and methanol/water (95:5, vol/vol) (Table 1), and the flow rate was 1.0 mL/min. It was necessary to reequilibrate the column with the starting solvent mixture for 10 min prior to a subsequent injection.

Liquid chromatography–mass spectrometry (LC–MS) analysis. LC–MS analysis was performed using a Mariner ESI/TOF mass spectrometer with a NANOSPACE HPLC apparatus (Shiseido, Tokyo, Japan) using the same conditions as described above, except that the methanol/water included 5 mM ammonium acetate as the mobile phase. The ESI mode (positive) was used for detection.

30	99	1

[a]Solvents: (A) chloroform; (B) methanol/water (95:5, vol/vol).

RESULTS

HPLC–ELSD of glycolipids. The glycolipids (ASG, MGDG, SG, CMH, and DGDG) were completely separated from each other with the new HPLC–ELSD conditions (Fig. 1). The elution order was ASG, MGDG, SG, CMH, and DGDG. The detection limits at a signal-to-noise ratio of 3 were 0.2 µg for SG, MGDG, and DGDG, and 0.5 µg for ASG and CMH.

The calibration curves were run with concentrations from 5 to 40 µg of glycolipids. The calibration curves were expressed as the equation $y = ax^b$, and the regression correlation coefficients were above 0.998 (Fig. 2). Detection sensitivity was highest for SG, with peak areas about three times greater than those of ASG and CMH. For three determinations at different concentrations of glycolipids, the standard deviation values were within 4% of the mean.

HPLC–ELSD of tomato and pumpkin extract. Figure 3 shows HPLC–ELSD chromatograms of Folch's extract of tomato. At least 10 peaks were detected for the tomato extract (Fig. 3A). ASG, MGDG, SG, CMH, and DGDG were eluted between 5 and 13 min following injection. The neutral lipids and pigments were eluted within the first 3 min. Phospholipids such as PE, PA, PI, and PC were eluted at retention times between 15 and 25 min. PI was coeluted with PA. The peak components detected by HPLC–ELSD of tomato extract were fur-

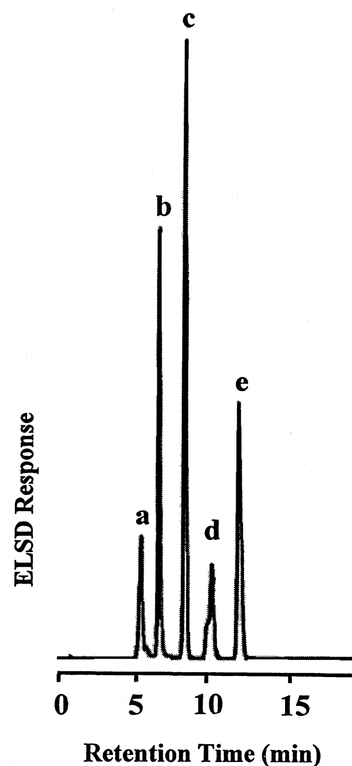

FIG. 1. High-performance liquid chromatograph–evaporative light-scattering detector (HPLC–ELSD) chromatogram of standard glycolipids. A mixture of 20 µg each of standard glycolipids was injected. Peaks: (a) acylated steryl glucoside (ASG); (b) monogalactosyldiacylglycerol (MGDG); (c) steryl glucoside (SG); (d) ceramide monohexoside (CMH); and (e) digalactosyldiacylglycerol (DGDG).

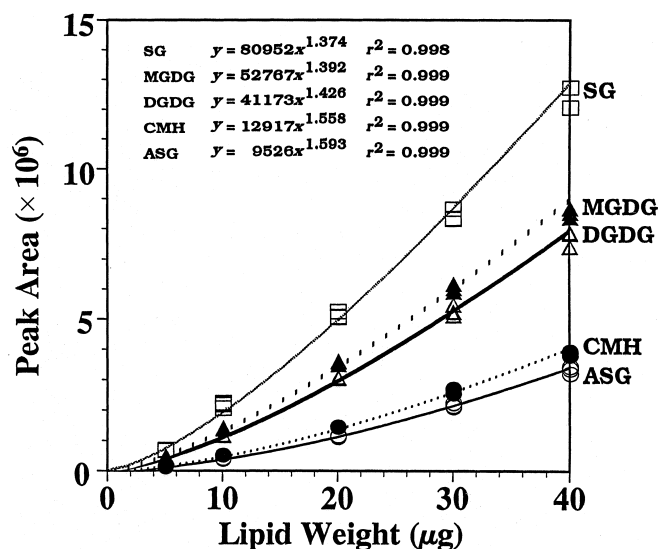

FIG. 2. Calibration curves of major plant glycolipids in HPLC–ELSD. Three determinations for each sample were given at different concentrations. ○, ASG; ●, CMH; ▲, MGDG; △, DGDG; and □, SG. See Figure 1 for abbreviations.

ther identified by LC–MS. In the mass spectra, the SG and ASG showed mainly molecular ions $[M + NH_4]^+$ at *m/z* 594 and 832 identical to the β-sitosteryl glucoside and the palmitate of β-sitosteryl glucoside, respectively (Fig. 4). The molecular ion peaks corresponding to the different constituent sterols (campesterol and stigmasterol) were also found. The MGDG and DGDG gave $[M + NH_4]^+$ at *m/z* 792 and 954, respectively, corresponding to the predominant species including 18:3 (α-linolenic acid)/18:3. In the mass spectrum of CMH, $[M + H]^+$ ion was found at *m/z* 714 originating from the species having 4,8-sphingadienine and C_{16} hydroxy fatty acid

(26). After mild alkaline treatment of plant lipid extract, only two peaks ascribed to SG and CMH were recovered (Fig. 3B).

For the pumpkin extract (Fig. 5), more than 10 peaks were detected and identified by co-chromatography with standard lipids. A peak component at retention time of 16.1 min was tentatively identified as trigalactosyldiacylglycerol (TGDG) because its molar ratio in fatty acid/sugar was 2.00:2.84. An LC–MS assay was further conducted to confirm the structure of TGDG. The mass spectrum of TGDG peak component showed $[M + NH_4]^+$ peak at *m/z* 1120 corresponding to the predominant molecular ion including 18:2/18:2 acyl residues (Fig. 6). The TGDG was also found in Folch's extract prepared from potato (data not shown).

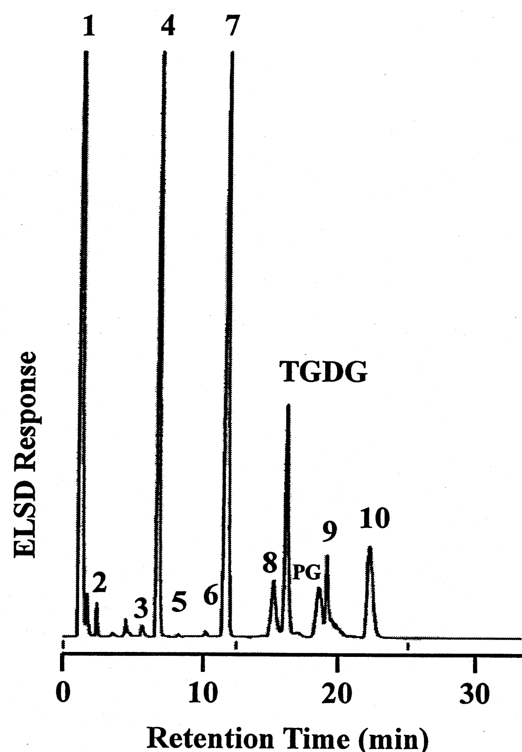

FIG. 5. HPLC–ELSD chromatogram of pumpkin extract. The Folch's extract (230 μg of lipid extract) from fresh pumpkin was injected into the HPLC–ELSD. Peak numbering and abbreviations are the same as given in Figure 3. TGDG, trigalactosyldiacylglycerol; PG, phosphatidylglycerol.

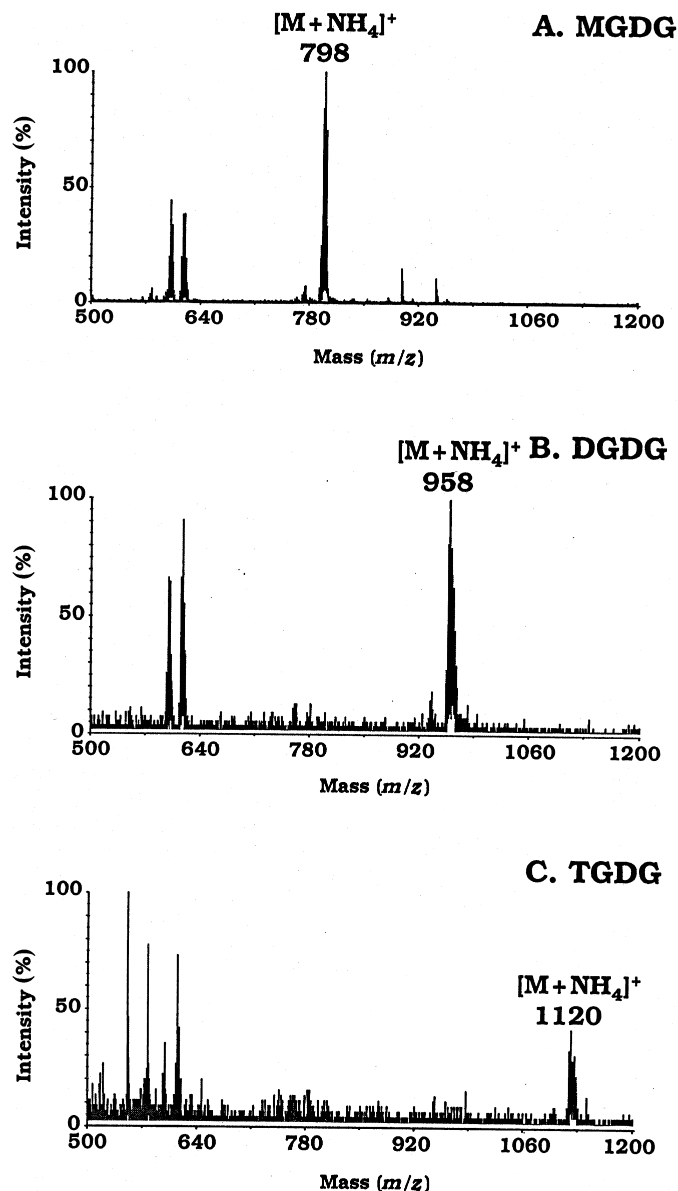

FIG. 6. ESI–MS spectra of glyceroglycolipids of pumpkin extract. See Figures 1, 4, and 5 for abbreviations.

Glycolipid composition of edible plants. Table 2 summarizes the glycolipid composition as tentatively determined by HPLC–ELSD method. The glycolipid profile was profoundly different among the plants examined, i.e., from 5.3 mg/100 g for Japanese radish to 644.9 mg/100 g for perilla leaf. Total glycolipid content was high in cereals (barley, corn, wheat flour), legumes (azuki bean, black soybean, pea), and leafy vegetables (leek, parsley, perilla, spinach). Barley, corn, and wheat flour were rich in DGDG; leek, parsley, perilla, spinach, and pumpkin were rich in MGDG and DGDG; azuki bean, black soybean, and perilla also contained remarkably high concentrations of ASG. Many fruits showed lower glycolipid concentrations, but were relatively high in ASG. The CMH also was uniformly distributed in those plants.

DISCUSSION

This study demonstrated the new HPLC–ELSD procedures for the separation and quantitative analyses of plant glycolipids using a binary solvent system. Since the plant glycolipids could be detected and quantified in a single HPLC run without any interference from other nonglycolipids, the procedure has advantages because it does not require subfractionation of glycolipids from Folch's lipid extract by TLC or solid-phase extraction before HPLC analysis. The present study revealed that the standard curves are quite different for ASG, MGDG, SG, CMH, and DGDG and are not linear relationships. Such variation as observed for the ELSD response may be partly ascribed to a dissimilarity in lipid specific particle sizes causing different light scattering (27).

Previous studies have reported that the ELSD response of neutral lipids (18), phospholipids (18,20,28), and glycolipids (20) is not proportional to their concentrations. Therefore, a separate calibration curve for each glycolipid was needed for accurate quantitative analysis with ELSD. Although dependent on lipid content, approximately 0.3 g of plant fresh weight was sufficient to determine glycolipid concentration by the present HPLC–ELSD conditions.

One strength of the present chloroform/methanol/water HPLC method is that it achieves better separation of the glycolipids than previously reported for hexane/2-propanol/

[a]Values are the mean of a paired analysis of the same tissue sample. ND, not detected.
[b]S:C:G = (ASG + SG)/CMH/(MGDG + DGDG) (%). ASG, acylated steryl glucoside; SG, steryl glucoside; CMH, ceramide monohexoside; MGDG, monogalactosyldiacylglycerol; DGDG, digalactosyldiacylglycerol.
[c]Fresh weight basis (barley, rice, wheat flour, azuki bean, black bean, pea, soybean were obtained by dry matter). HPLC–ELSD, high-performance liquid chromatography–evaporative light-scattering detection.

water methods (19,20). The mobile phase based on chloroform/methanol/water is popular for glycolipid separation in open-column silica gel chromatography (29). The ELSD detection made the gradient elution possible even with chloroform as mobile phase, which has low UV transparency, because chloroform emerging from HPLC column is immediately evaporated under a stream of nebulization gas.

Under the present chromatographic conditions, the retention times of human Gaucher's spleen glucocerebroside (9.4 and 11.2 min) and of bovine brain galactocerebroside (9.0 and 9.9 min) were clearly different from those of wheat flour CMH (10.1 and 10.4 min). The sphingoid bases (4-sphingenine, *d*18:1 and sphinganine, *d*18:0) of sphingolipids in mammals differ from those of plant CMH including 8-sphingenine (*d*18:1), 4,8-sphingadienine (*d*18:2) and 4-hydroxy-8-sphingenine (*t*18:1) (22). With mild alkaline treatment of plant lipid extracts, only two peaks ascribed to SG and CMH remained (Fig. 3B), since only O-acyl linkage is hydrolyzed, but N-acyl linkage is not (30). Thus, saponification was helpful to identify SG and CMH.

Morrison *et al*. (7) have reported that glycolipids in a high-grade spring wheat flour consist of 72 mg ASG, 94 mg MGDG, and 230 mg DGDG per 100 g dry weight. From our present data, wheat flour glycolipid concentrations were 30 mg ASG, 47 mg MGDG, and 158 mg DGDG per 100 g dry weight. Since the concentration of glycolipids in plants can vary tremendously depending on the cultivar, growth condition, stage of development, and harvested days, the data as given in Table 2 do not imply universal glycolipid contents. Furthermore, the natural diversity between members of the same species needs recognition. Thus, the data given in Table 2 represent typical glycolipid contents of commercial plant foodstuffs available in Japan from summer to winter. However, the present data compare well with those of previous studies (3–10) in light of probable differences in cultivar, locality, and harvest time of plants. The HPLC–ELSD condition as described here seems useful for the quantitation of plant glycolipids.

As shown in Table 3, glycolipids were not degraded and no artifacts were yielded as compared with the conventional hot 2-propanol during the present inactive procedure by microwave oven (31). The data given in Table 3 differ from those of Table 2 because of variations in locality, growth conditions, and harvest time.

TABLE 3
A Comparison of Recovery of Spinach Glycolipids When Hydrolytic Enzymes Are Inactivated by Conventional Hot 2-Propanol and Microwave Oven[a]

	Hot 2-propanol	Microwave oven
	(mg/100 g fresh spinach)	
ASG	19.5 ± 1.0	20.5 ± 1.6
SG	5.2 ± 0.6	4.8 ± 0.2
CMH	10.1 ± 1.2	10.6 ± 0.3
MGDG	112.4 ± 1.4	113.5 ± 0.6
DGDG	73.7 ± 2.1	78.3 ± 2.9

[a]Values are the mean ± SD of three experiments of the same sample. Spinach was harvested at Hokkaido in September 1999. Microwave oven from Sharp Co. (Osaka, Japan). See Table 2 for abbreviations

Dark green plants with abundant chloroplasts, such as leek, parsley, perilla and spinach leaves, had more glyceroglycolipids than light green plants (Table 2). It has been reported that in photosynthetic tissues, the amount of MGDG commonly exceeds DGDG, while in nonphotosynthetic tissues, DGDG is predominant (1,2). The occurrence of TGDG has been reported previously (1,32–34). In the present study, TGDG was detected in the pumpkin lipid extract by HPLC–ELSD and identified by LC–MS (Figs. 5 and 6). TGDG was also found in Folch's extract prepared from potato.

Although a limited number of samples were collected from local markets, the glycolipid composition of different species is given in Table 2. The biological significance of the ratio of sterol lipids/sphingoglycolipids/glyceroglycolipids is extremely interesting and merits further attention because of their nutritional function in humans.

Edible plant glycolipids have been expected to play a role in human nutrition as a nutrient, but little is known about them in intestinal digestion and absorption in mammals (35–37). Since linolenic acid (18:3n-3) accounts for more than 90% of the total fatty acids of MGDG in most plant leaves (2), plant glycolipids would be expected to be an important source for such n-3 essential fatty acid. To clarify the nutritional roles of plant glycolipids, estimating the daily intake in human body may be necessary. Based on the present data as given in Table 2 and the average daily food consumption per person (38), the average daily intake of glycolipids is estimated to be 140 mg ASG, 65 mg SG, 50 mg CMH, 90 mg MGDG, and 220 mg DGDG in a human.

In conclusion, the new HPLC–ELSD condition as described here is convenient and reliable for separation and determination of the plant glycolipids.

REVIEW

Lipids in Human Milk

Robert G. Jensen*

Department of Nutritional Sciences, University of Connecticut, Storrs, Connecticut 06269-4017

ABSTRACT: I have reviewed recent (March 1995–December 1997) papers on human milk lipids including many on fatty acid (FA) composition. The effects of maternal diets on the profiles are apparent. However, more data on the composition of milk lipids are needed. It is noteworthy that so few papers on milk FA composition have reported analyses using high-resolution gas–liquid chromatography columns. Two of these were on milk from women in North America. The diets in North America are varied and the number of analyses few. We do not have a reliable data base showing the ranges of biologically important acids. Except for the gangliosides, few new data on the other lipids appeared during this period.

Paper no. L8263 in *Lipids 34,* 1243–1271 (December 1999).

In this paper, I review and evaluate papers on human milk lipids that were published from March 1995 through December 1997. Some relevant earlier papers are included. It is the latest in a series of my reviews on the subject, which began in 1978. The last was published in 1996 (1).

THE NATURE OF MILK

Milk is a very complex fluid, containing carbohydrates and salts in true solution, caseins in colloidal dispersion, cells and cellular debris, and lipids mostly in emulsified globules.

The lipids are triacylglycerols (TG, 98%), phospholipids (PL, 0.8%), cholesterol (C, 0.5%), and many others. The lipids (3–5%) occur as globules emulsified in the aqueous phase (87%) of milk. Nonpolar lipids, e.g., TG, cholesteryl esters, and retinyl esters, are found in the core of the globules (1,2). The globules are covered with bipolar materials—PL proteins, mucopolysaccharides, C, enzymes—organized into a loose layer called the milk lipid globule membrane (MLGM) (2). The MLGM acts as an emulsion stabilizer and represents the membrane of the secretory mammary gland cell. The globules range in size from 1 to 10 μM, with most of the globules less than 1 μM, but those around 4 μM accounting for the most weight. The globules present a large surface area (500 cm^2/mL) to lipolytic enzymes and other adhesive components.

Effects of milk lipids. Based on my earlier reviews, I have listed in Table 1 effects of milk lipids, both beneficial and detrimental. Further discussion will be found throughout the review. The unperturbed system delivers energy, nutrients, protective components, and metabolic messages to the infant. The emulsion is thermodynamically unstable, maintaining its original compartmentation for the few minutes of nursing. Thereafter, some constituents may change compartments, but the original value of milk for the infants apparently remains. However, off-flavors may develop to the extent that the infant will not consume stored milk.

Fatty acids (FA) in milk lipids (90% of TG as esters) are the only components that can be altered to any extent by maternal dietary manipulation. This observation suggests that the FA composition of milk may not be usable as a standard for the preparation of formulas because the range in contents is broad. However, profiles of milk FA related to the optimal growth and development of the infant could be used. As of December 1997, more analyses of milk FA by the best methods available were needed.

SAMPLING FOR AND DETERMINATION OF LIPIDS

Sampling. It is difficult to sample milk and obtain an aliquot that contains the true amount of lipid. The heterogeneously sized globules, which have a density of 0.9, rise at different rates and must be shaken at ≥38°C, to achieve a random distribution. The globules must be liquid. The globules also clump and these must be dispersed. In addition to the problems caused by the physical nature of the globules, the lactation process causes more difficulties, e.g., the lipid content rises as a nursing proceeds. Detailed sampling protocols are available and must be followed to obtain a representative sample (3–5). However, not discussed in References 3–5 are the cyclic changes in lipid content that occur in milks from malnourished women on low-fat, high-carbohydrate diets, relative to ingestion of meals. The lipid content changes diurnally, reaching maxima about 8 h after a meal. Several samples that bracket meal time should be taken and averaged to ascertain the true lipid content.

TABLE 1
The Effects of Lipids in Human Milk[a]

1.	Source of 50–60% of the calories, about 70 kcal/dL, in human milk. Not usually responsive to diet.
2.	Fatty acids combined into triacylglycerols to maintain a bulk melting point below 38°C.
3.	Provide about 15 mg of cholesterol/dL. May predispose the infant to efficiently metabolize dietary cholesterol as an adult. Precursor of steroid hormones and other derivatives in humans. Not affected by changes in maternal diet.
4.	Contain the essential polyunsaturated fatty acids 18:2n-6 and 18:3n-3 and their products, 20:4n-6, 20:5n-3, and 22:6n-3. Required in maternal diet.
5.	The 20:4n-6, 20:5n-3, and 22:6n-3 in proper balance may be required for maturation and optimal function of the visual process and brain and nervous system.
6.	Contain 8:0–14:0, which if absorbed in the stomach, are transported to the liver and oxidized in decreasing amounts as the molecular weight increases. Quantities in milk dependent on amount of carbohydrate in diet.
7.	If present, the conjugated fatty acid, *c*9, *t*11-18:2, or rumenic acid, may exert anticarcinogenic, antiatherosclerotic, and other beneficial effects. Responds to ruminant products, particularly dairy products.
8.	*Trans* unsaturates believed by some to adversely affect infants growth. Some positional isomers of *c*-18:1 may ameliorate atherosclerosis.
9.	When produced by lipolysis in the stomach and small intestine, 12:0 and 18:2 and their monoacylglycerols have potent cidal effects against some microorganisms. Soluble and dispersible salts of fatty acids may act against microorganisms.
10.	Milk gangliosides inactivate cholera and other enterotoxins.
11.	Contain eicosanoids and their precursors, which act as first and second messengers. Precursors respond to diet.
12.	Lipolysis of triacylglycerols by gastric lipase, regioselective for *sn*-3/*sn*-1,3/1; produces *sn*-1,2-diacylglycerols, which can be second messengers in stomach and small intestine.
13.	Milk lipid globule membrane binds, protects, and releases bioactive compounds as needed. Graded doses of lipid provided. Membrane stabilizes globules in an oil/water emulsion.
14.	Increases in lipid content and numbers of globules during a nursing may help develop appetite and its control in the infant by approaching satiety and by the tactile effect of the globules.
15.	Lipid content increases as lactation progresses to help provide for growth and development of infant.
16.	Carrier of fat-soluble vitamins.
17.	Can transport undesirable compounds such as dioxins.
18.	When milk is stored in the frozen state, it can be the source of soapy flavor due to free 12:0 and to oxidized flavors (cardboardy) due to polyunsaturated fatty acids.
19.	Carotenoids, tocopherols, and conjugated 18:2 may be antioxidants.

[a]Derived from References 1–9. Specific references are given in the text.

To obtain the measured intake of milk and its contents by the infant, the amount of milk consumed must be determined. The phrase "measured intake" was used by Quinsey *et al*. (6) and aptly defines our goal: What does the infant receive in milk? The methods as described by Neville (7) are: (i) weighing of infant or mother before and after nursing, (ii) dilution of stable isotopes, and (iii) topographical computer imaging of the breast. Weighing is the least expensive and most readily applicable method. In brief, to determine the measured intake of milk lipids by a nursing infant, the investigator must (i) obtain a representative sample of milk, (ii) record descriptive data about the mother, the infant, and the event, and (iii) acquire the amount of milk consumed by the baby. With regard to point (i), it should be remembered that unless external manipulation is applied, there is no time during nursing or storage thereafter that the lipid globules in milk will be randomly dispersed to provide a sample containing the true amount of lipid.

Factors affecting total lipid content. These are listed in Table 2 with an indication of the nature of the change where known. Investigators must design their research and identify their subjects to control the relevant factors. Events that alter volume, i.e., time postpartum, mastitis, etc., must be considered.

The lipid content of milks from mildly malnourished women who were consuming a low-fat, high-carbohydrate diet oscillated diurnally. The maxima were reached in many but not all women about 8 h after a meal (8). The apparent causes of the decrease in lipid content were a rise in the synthesis rate of 8:0–14:0 and a drop in dietary 18:1 (see Fatty Acid section, which follows)

Determination. The methods most widely used are the Creamatocrit and solvent extraction followed by gravimetry (1,5,9). In the Creamatocrit procedure, a capillary tube containing milk is centrifuged and the length of the fat column is measured and calculated as a percentage of the total length of the milk column (10). This figure is converted to percentage fat using standard curves obtained by one of the other methods of determining fat, usually solvent extraction. The method is useful for fieldwork or where large numbers of samples must be analyzed. The Folch extraction, originally done with 2:1 chloroform/methanol, is and has been employed (11). Since chloroform is toxic and possibly carcinogenic, we and others substituted dichloromethane. A useful dry column extraction with these solvents is available (12). Jensen *et al*. (5,13) discussed the basics of and problems associated with solvent extraction of milk lipids.

TABLE 2
Factors Associated with Changes in the Total Lipid Content of Human Milk[a]

Factor	Effect
Duration of a nursing or feed	Increases
Age postpartum, stage of lactation	Increases
Diurnal rhythm	Variable; related to time of samples and maternal meals
Between breasts	Occurs
Gestational age at birth; preterm vs. term	Occurs
Diet regionality	May occur
Nutritional status	Malnourished women, decrease
High carbohydrate, low fat diet	May decrease
Infections, metabolic disorders	Usually decreases
Medication	
Mothers menstrual cycle or pregnancy	
Parity	Decreases
Season	Related to diet and regionality
Age	
Individuality	Adiposity increases
Miscellaneous	

[a]Adapted from Jensen (1).

Other procedures for quantitation are enzymatic, turbidimetry, colorimetry, gas–liquid chromatography (GLC), and infrared spectrophotometry (1,3,9).

Data on changes in the total lipid, protein, carbohydrate, and energy contents in 2,554 Danish milk samples from 224 donors to a milk bank, not previously shown in my reviews, are presented in Table 3 (14). The contents were measured by infrared spectrophotometry. Few papers are available with results based upon such a large number of samples. The authors observed that the lipid content (i) decreased during the first 4 mon, followed by an almost linear increase; (ii) increased slightly with increasing body mass index of the mother; (iii) was related in a U-shaped fashion to the infant's birth weight; <3.1 kg, 3.72%; 3.5, 3.21 after 4 mo., and ≥4.0, 4.04; and (iv) was higher in mothers who delivered large amounts of milk. We have accepted as fact the belief that volume and lipid content are inversely related. Volume and lipid content may respond to the infant's requirements.

LIPIDS IN MILK

Data on the general classes of lipids in humans are shown in Table 4. These data have been corrected for the products of lipolysis, that is, diacylglycerols (DG), monoacylglycerols (MG), and free fatty acids (FFA). Traces of these compounds will be found unless new milk is extracted immediately. The amounts will increase as storage lengthens at all temperatures except −70°C. The lipases in milk are inactive at this temperature.

TRIACYLGLYCEROLS

About 98% of the total lipid in milk is TG, and 90% of this is FA. Thus, esterified FA are 88% of the total lipid. Because of this and because it is much easier to analyze milk lipids for FA than for TG with more data on FA, we tend to ignore TG. This is a mistake because milk FA are secreted, consumed, and hydrolyzed as TG in globules.

The organization of FA into TG creates another factor to consider in the metabolism of TG—their structure. Structure can be defined as the identity of the FA in each of the *sn*-1, -2, and -3 positions of TG and the arrangement of these into individual TG. The positional identities are determined by stereospecific analyses and the individual TG by a variety of procedures (17). Structure of TG is important because it controls both the liquidity of the lipid globules and the identity of the products formed by the sequential lipolysis of the TG in the stomach and small intestine (18). The resultant FFA and MG are absorbed.

Milk lipids must be liquid so as to form microdroplets in the secreting cells; subsequently these fuse into droplets, which are then secreted as globules (19). The globules remain liquid as they encounter the lipases in the infant's stomach and small intestine. The large total surface of the globules

TABLE 3
Percentile Distribution of Protein, Fat, Carbohydrate, and Energy Contents of Milk from Danish Mothers[a]

	Percentiles								
	Avg.	2.5	10	25	50	75	90	97.5	Number of samples
Protein (g/L)	9.0	6.3	6.9	7.6	8.6	9.7	11.4	14.3	2553
Fat (g/L)	39.0	18.4	23.8	29.4	36.1	43.4	54.6	89.0	2554

[b]Mean ± SEM, wt%.
[c]Total cholesterol content ranges from 10 to 20 mg/dL after 21 d postpartum in most milks.
[d]From Bitman *et al.* (16). ND, none detected.

provides a supersubstrate for the lipases. Holman *et al*. (20) developed a measure of liquidity or fluidity of membranes. They calculated the mean melting point (MMP) of the FA in plasma phospholipid (PL). We calculated MMP for some milk fats, finding a range of 27 to 32°C. A temperature of 27°C has been reported for milk lipids (21). Obviously, it would be much easier to determine melting point (MP) of extracted lipid in a capillary tube. This might show a relation between MP and changes in the FA composition. The MP is the average of all TG MP in the mixture. Changes in the FA composition of TG have a profound effect on MP, e.g., 16:0-16:0-16:0 has a MP of 66°C; 16:0-18:1-18:0, 38°C; and 18:1-18:1-16:0, 24°C (17).

Structure. Human milk generally contains seven major FA in amounts >1%. If these are randomly distributed among the three hydroxyls of glycerol, 343 (or 7 to the third power) TG would result (17). If a new FA is introduced to the maternal diet, then there would be more types of TG, i.e., 8^3 or 512. If the amount of an acid already present is increased, the quantities of the TG containing the acid are increased. Although the distribution of FA in milk TG is not random, the potential number of TG is probably in the thousands because about 200 FA have been detected. The total theoretically possible is 200^3, or 8,000,000! The TG structure is organ-specific because of the greater than random amounts of 16:0, 60–70 mol%, in the *sn*-2 position. The random quantity would be 33.3 mol%. Very little has been reported on TG structure since my last review (1).

The identities of the FA in *sn*-1, -2, and -3 positions have been determined by stereospecific analyses. Some data from French milks are given in Martin *et al.* (22). The structure of TG in colostrum was very similar to that of mature milk. Other data are presented in References 23–29. The distributions are unique with much of the 16:0 at *sn*-2 and other acids located unequally. The location of 16:0 at the *sn*-2 position improves the absorption of fat and calcium in the small intes-

TABLE 5
Amounts Exeeding 1% of Triglyceride (TG) in Pooled Human Milk with Proven Fatty Acid Profiles[a]

% of total (mol/100 mol TG)	Type of TG	% of total Type of TG (mol/100 mol TG)	Type of TG
11.8	16:0-18:1-18:1	2.1	16:0-18:1*t*-18:1
10.0	16:0-18:1-18:2	2.1	18:1-18:1-18:1
4.4	16:0-16:0-18:1	1.9	18:1-18:2-18:2
3.3	18:1-18:1-18:2	1.9	16:0-16:1-18:1
3.3	14:0-16:0-18:1	1.7	16:0-18:0-18:2
3.2	16:0-18:2-18:2	1.5	14:0-16:0-18:2
3.1	12:0-16:0-18:1	1.4	12:0-18:1-18:1
3.1	16:0-18:0-18:1	1.3	12:0-16:0-18:2

2.4	16:0-16:0-18:2	1.1	12:0-14:0-18:1
2.3	14:0-18:1-18:2	1.0	18:0-18:1-18:2

[a]Adapted from Winter *et al.* (28). Amounts are rounded to one decimal point. The most abundant TG of 170 are reported. Samples were obtained from Dutch mothers on a typical Western diet. The fatty acid sequences listed may not correspond with the actual structures.

tine. Carnielli *et al*. (24) fed formulas containing 13, 39, and 66% 16:0 esterified at the 2-position to infants. Absorption of fat was 90.4, 93.0, and 97.6% in the 13, 39, and 66% formulas. Calcium excretion was lowest in the 66% preparation.

Winter *et al*. (28) utilized high-performance liquid chromatography (HPLC) separation of milk TG with a silver ion column and light-scattering detector. Further fractionation and analyses resulted in a determination of 170 TG. Those present in quantities of 1% or more are given in Table 5. The amounts were nonrandom. According to Winter *et al*., the relatively nonpolar 16:0 and 18:0 appeared to be balanced by association with 18:1 and 18:2 or 8:0–12:0, thus maintaining the liquidity of the globule TG. The 8:0–12:0 FA were present in 19.0 mol% of the TG. Of these, 7.2 mol% were likely to be associated in enantiomeric structures, with an 8:0–12:0 at *sn*-3, 16:0 or 14:0 at *sn*-2, and 18:1 or 18:2 at *sn*-1.

To evaluate milk TG as a substrate for the lipase system described below, we need not determine individual TG. Identification of the acids in the *sn*-1, -2, and -3 positions will show the FA available to the lipases with different selectivities. Liquidity can be easily assessed by determining the MP of the extracted lipid in a capillary tube. Whether MP is related to TG structure in milk remains to be seen. A positive relationship has been observed in other fats (17).

Digestion of TG. Digestion of milk TG occurs in two phases, gastric and intestinal (17,18,30,31). Gastric lipase initiates lipolysis in the stomach, hydrolyzing 40–60% of dietary TG. The enzyme is regioselective for primary esters stereoselective for *sn* 3/1; 4/1, and it preferentially hydrolyzes shorter acids from a TG such as 18:1-18:1-10:0. A relatively large amount of *sn*-1,2 DG and shorter FA are produced. The DG could act as second messengers, and the acids are absorbed through the stomach wall in decreasing amounts as the molecular weight increases. They are then transferred *via* the portal vein to the liver. Gastric lipolysis is needed to initiate intestinal lipolysis because the globules resist pancreatic and bile salt-stimulated lipases (BSSL). Armand *et al*. (32) fed milk and formula to premature infants. They found that different FA profiles of globule sizes did not affect the level of gastric lipase. The TG within the milk lipid globules appeared to be more accessible than those in formula. Lauric acid (12:0) and 18:1 and their MG are potent microbicides at the high concentrations attained during digestion, helping control the growth of some microorganisms in the stomach and small intestine (33).

In the intestinal phase, the globules partially hydrolyzed by gastric lipase are further digested by the pancreatic-colipase system and by milk BSSL (18,31). Pancreatic lipase is highly regiospecific for *sn*-1+3 esters of TG. BSSL hydrolyzes esters from all positions, i.e., it has no regiospecificity. The lipase is elaborated in the mammary gland of humans, a few other primates, and some carnivores. The enzyme contributes to absorption of milk FA in the infant when pancreatic lipase and bile salt concentrations are suboptimal (32). With a nonregiospecific lipase present, there is a possibility that all of the milk acylglycerol FA are hydrolyzed. However, Innis *et al*. (34) recently found that the *sn*-2 16:0 was preserved in plasma TG of breast-fed infants (23.3% of the acids), but not in babies fed formula (7.4%). These results are convincing evidence that some 16:0 is absorbed as the 2-MG. The three lipases hydrolyze long-chain polyunsaturated fatty acids (LCPUFA) from the TG (35).

PL AND COMPLEX LIPIDS

The average amount of total PL is 0.6% of mature milk lipid, with a range of 0.39 to 0.97% (1). This is about 25 mg/dL of mature milk containing 4% fat [see also Glew *et al*. (36)]. The sources of variation are the decrease in PL content as lactation progresses (37) and the methods used. A method for the analysis of organic PL in milk lipids that does not require acid digestion is available (38). References 38–41 include data on types and amounts of milk PL. The PL originate on the secreting cell and envelop the globule as it is extruded. Most of the PL are located in the milk lipid globule membrane. In Reference 42, analyses of 2,000 Japanese milk samples showed seasonal changes in milk PL. Postpartum decreases in milk PL are given in Reference 43.

Classes. Recent data on kinds and quantities of PL are shown in Table 6. The separations carried out by Harzer *et al*. (39), Bitman *et al*. (37), and Glew *et al*. (36) were done with thin-layer chromatography (TLC) and those of Hundreiser

TABLE 6
Phospholipids (% of total, means ± SD) in Human Milk

	Glew *et al.*[a]		Holmes-McNary *et al.*[b]
Phospholipid	MM (mol%)	SM (mol%)	(mol%)
Phosphatidyl choline	27.7 ± 0.9	22.1 ± 1.1	82 ± 6
Phosphatidyl ethanolamine	15.2 ± 1.9	12.8 ± 1.3	
Phosphatidylserine + -inositol	5.9 ± 1.0	5.6 ± 2.5

and Clark (40), van Beusekom *et al*. (41), and Holmes-McNary *et al.* (44) with HPLC. The breast-fed infant derives most of its choline, a conditional required nutrient, from the compounds containing choline (44), as listed in Table 6. Glyceryl ethers have also been identified in human milk (45,46).

Complex lipids other than PL. Milk contains sphingomyelins, acidic glycosphingolipids or gangliosides, and neutral glycosylceramides (1,13). The amounts of those components are: sphingomyelins, 100–200 µM (47–49); neutral glycosylceramides, 1–20 mg/L (49–52); and gangliosides, 1–20 mg/L (51–53). Sphingomyelin is usually classified and reported as a PL, but it is also a sphingolipid. It is the phosphorylcholine ester of an *N*-acyl-sphingosine or ceramide. Neutral glycolipids are composed of a ceramide bound to one or more glycosyl units. Monoglycosylceramides are termed cerebrosides. Sulfatides are galactosyl-3-sulfate esters of cerebrosides and are acidic. Information about these lipids in human milk is available in References 1, 13, and 53–57. Gangliosides are glycosphingolipids that contain sialic acid (*N*-actylneuraminic acid, NANA) as part of the carbohydrate group and are acidic. The nomenclature of Svennerholm (58) will be used in the remainder of this section for the gangliosides. Briefly, G is ganglioside; M, D, and T are mono-, di-, and trisialo groups, respectively, and the number is arbitrarily assigned on the basis of chromatographic migration. These compounds are amphiphilic (bipolar), have several important biological effects, and are concentrated in the milk lipid globule membrane.

The FA attached to sphingosine in milk by a peptide linkage are 18:1 (61.8%) with most of the remainder being 20:0, 22:0, 24:0, and 24:1 (13). The monohexosyl ceramides contained long-chain hydroxylated and nonhydroxylated FA, mostly 24:0.

Takamizawa *et al*. (52) noted that GD3 was high early in lactation, decreasing as lactation progressed and GM3 increased. The ganglioside GM1 binds the enterotoxins of *Vibrio cholerae, Escherichia coli,* and *Campylobacter jejuni* (51,57). Keenan and Patton (59) postulated that gangliosides promote fusion of microdroplets of lipid into globules in the mammary gland secreting cell. Newburg *et al.* (56) found that the globo- series of glycolipids bound shigatoxin and the shiga-like toxin receptor, Gb3. Sulfatide and sulfated lactosyl ceramides have been identified in milk (54). The same compounds may be relevant to the protection of the breast-fed infant from several pathogens including HIV.

New information on gangliosides was reported by Rueda *et al*. (53,60,61). In addition to GM3 and GD3, they found six others, possibly GD1a, GD1b, GT1b, and GQ1b. Two were tentatively identified as polysialogangliosides. They observed that GD3 was relatively the most abundant ganglioside during the first 3 wk of lactation (53) and was higher in preterm than in term colostrum (60). Conversely, GM3 was present in greater amounts 1 mon postpartum and in term as compared to preterm colostrum. They noted that GD3 is usually found in developing tissues. Rueda *et al.* (61) found no significant changes in content and distribution of gangliosides in human milk from Spanish and Panamanian mothers. Profound differences would not be expected since gangliosides are part of the MLGM and originate from the secreting cell. The ganglioside content, expressed as µg lipid-bound sialic acid (LBSA) per g of lipid, decreased as lactation progressed. The decrease was significant in Panamanian milks but not in samples from Spain. These data were obtained by TLC separation, utilization of the bands, and densitometry and are given as µg of LBSA.

Readers who are interested in the relation between the complex lipids and brain development should read the book by Jumpsen and Clandinin (62). It contains useful and enlightening information.

Sterols. Very few papers on milk sterols have appeared during the review period. Earlier research established that the sterol content in mature human milk ranges from 10 to 20 mg/dL with C as the major component (1,13). Glew *et al*. (36) found 25 mg/dL with TLC and GLC. Huisman *et al*. (63) detected 12 to 16.6 mg/dL using GLC and did not report any other sterols. They also present data on mono- and disaccharides and sugar alcohols. Japanese data on C contents relative to time postpartum appeared in References 42 and 43. Most of the C is located in the MLGM, and the amount is not affected by diet or by maternal plasma levels, but is correlated with fat content (1,2). About 15% occurs as the ester. C has been determined by colorimetry (*o*-phthalaldehyde), enzymatic treatment, GLC, and HPLC. We use and recommend the *o*-phthalaldehyde method of Bachman and Wilcox (64) for routine measurement of C. GLC must be employed for analysis of sterols. Kallio *et al*. (65) analyzed milk for C, its precursors, and other sterols by GLC–mass spectrometry (MS) (Table 7). They concluded that in the mammary gland, C is synthesized from lanosterol *via* preservation of the side-chain double bond. However, the amount of C synthesized in the gland is unknown. Note that C accounted for 88.2% and desmosterol 8.4% of the total sterols at 2 mon. In contrast to earlier reports, the amounts of phytosterols were negligible. Small amounts of other sterols have been reported (65–69).

C content increases along with fat content during a nursing (1,13). Diurnal rhythms have been detected, but this may

TABLE 7
Amounts (µg/dL) of Cholesterol and Its Precursors and Triacylglycerol in Human Milk at 2, 6, and 9 mon of Lactation[a]

	Months of lactation		
	2 (*n* = 88)	6 (*n* = 28)	9 (*n* = 6)
Squalene	386	493	452
Lanosterol	94	98	115

Methostenol	48	72	88
Lathosterol	43	89	112
Desmosterol	1,509	1,351	1,140
Cholesterol	15,800	18,000	18,900
Triacylglycerol (g/dL)	2.96	3.89	4.25

[a]Adapted from Kallio *et al.* (65).

be dependent on the interval of sampling (70). The infants in this study consumed 94 mg C/d. Wong *et al*. (71) reported an intake of 116 mg/d. A range of consumption can be calculated as 75 to 150 mg/d based on milk contents of 10 to 20 mg/dL and a daily consumption of 750 mL. The C content of milk decreases [incorrectly stated as increases in (1)] as lactation advances: for example, (i) days postpartum; (ii) mg C/dL of milk; and (iii) lipid content (%); 0 to 4, 36.0, 1.0; 5 to 9, 19.7, 2.7; and 10 to 30, 19.0, 4.3 (72; see also 42,43). Boersma *et al*. (72) suggested that this continual decline in mg C/dL while fat levels were also increasing, was associated with the increase in globule diameter and thinner membranes that occur as lactation lengthens. No data have been published yet on globule numbers and diameters and C content. With a given amount of fat, the total globule area decreases as the average globule diameter increases.

Reiser *et al*. (73) suggested that the "high" levels of C in human milk could contribute to homeostasis of the sterol in the adult who was breast-fed as an infant. Although the C content of milk is not high (15 mg/dL), the consumption by the infant as compared to the adult is elevated. A 4-kg infant can have a daily intake of 25 mg/kg body weight (100 mg C/4 kg). A 70-kg adult should consume no more than 300 mg of C daily or 4.3 mg/kg body weight. The infant's intake is 5.8 times that of the adult.

In this summary, the effects of milk and formulas fed to infants on C metabolism were compared. Exceptions are noted. Concentrations of mRNA for low density lipoprotein (LDL) receptors were increased in baboons (74). The fractional synthesis rate of C was decreased (71), while concentrations of LDL and total serum C increased (73–76). C excretion was increased and endogenous synthesis decreased (76). Weaning from milk increased the concentrations of serum lipoprotein (a), which is associated with higher risk of coronary artery disease (77). Cruz *et al*. (78) noted that isoflavones (phytoestrogens) in soy-based formulas were absorbed, excreted, and negatively associated with the synthesis of C, but not serum C. The soy isoflavones daidzein and genistein were quantified in human milk (79). The contents were raised when roasted soybeans were fed to the donors.

FA AND RELATED COMPOUNDS

I have discussed how to analyze FA with GLC in previous reviews (1,9,13,80) and will not repeat all of it here. I will present the contents of relevant papers and summarize my suggestions for analysis of milk FA. The important message is that there are few papers containing data on milk FA in which GLC analyses were done with high-resolution columns. Nevertheless, some reliable data have been published. A method for determination of total TG content of milk by GLC of FA has been described (81). An added internal standard is the basis for the calculation of the weight in each GLC peak. Kohn *et al*. (82) examined several methods for the transesterification of milk TG, PL, and CE to fatty acid methyl esters (FAME). They used extracted milk fat that contained 10% FFA, prepared FAME, and analyzed these by GLC. They recommended the boron trifluoride method for milk and the sodium methoxide method for formulas, but not milk. Their milk sample contained FFA, which cannot be methylated by sodium methoxide. Instead, calcium salts (i.e., soaps) formed, which cannot be methylated. This is well known and has been mentioned (80). Acid and base catalysts are required (discussed below). Unless stored, human milk samples contain very low concentrations of FFA. Kohn *et al*. (82) did not test the use of 10% sulfuric acid (83) or the direct, no extraction method of Lepage and Roy (84). These, the boron trifluoride (85), and the HCl-catalyzed (86) methylations have all been employed for analysis of human milk. Assessing the conversion of TG to FAME would have been much easier with TLC. The disappearance of TG and appearance of FAME can be easily monitored. We have done this with all the methods above and observed complete conversion to FAME.

Kramer *et al*. (87) found that sodium methoxide-catalyzed methylation was the best compromise for bovine milk FA followed by hydrochloric acid or boron trifluoride. This procedure caused less isomerization of conjugated dienes, but sphingomyelin was ignored. However, there is very little sphingomyelin in milk PL. The failure of sodium methoxide to methylate FFA can be eliminated as described above, and the recommended methods can be used to methylate the FA in human milk lipids.

Analysis of milk FA by HPLC was done by Takayama (88). The method, as reported, was not superior to GLC analysis. For example, 14:0 and 22:6n-3 coeluted.

FA compositions are usually reported as relative weight percentages based on the peak areas from the GLC chart. Although rarely given, weights of FA/dL or gravimetric reports are necessary so that the actual FA intake by the infant can be calculated and the real effects of intervention seen. The amounts of FA can be ascertained gravimetrically or by use of an internal standard (81).

Another method for presentation of total fat and FA contents on food labels is being required in the United States by the U.S. Food and Drug Administration and the Department of Agriculture (89). Fat must be expressed as the sum of TG equivalents. For example, if the weight of 16:0 taken from the GLC chart is 1 g, then it is reported as 1.04946 g of tripalmitin. The conversion factor of 1.04946 is derived as follows:

$$\frac{\text{mol wt of tripalmitin}}{3\ (\text{mol wt of 16:0}} = \frac{807}{3(256)} = 1.04946 \qquad [1]$$

This calculation is to be done for each acid, or the factors published in Reference 89 can be used for total fat. The factors range from 1.074 for 10:0 to 1.037 for 22:0. Most are close to 1.05, which can be used. If FAME (16:0 ME, 3 × 270 = 810) are inserted into the calculation, a factor for conversion of ME to TG of 0.99+ results. Although not stated in Reference 89, this means that the weights of FAME and triglyceride fatty acid are equal and that the FAME units summed equal the

sample weight with allowance for dilutions. Conversely, the sample weight multiplied by the relative percentage of a FAME equals the weight of the FAME. The glyceride fragments of CH_3O- and CH_2O- and the methyl portion CH_3O esterified to FA have almost the same molecular weights, 30 and 31. The point is that the weights of FA calculated from the areas on a GLC chart in relation to an internal standard will not equal the weight of the extracted lipid because the glyceride fragment is not included. The difference can be corrected by using the conversion factors, usually 1.05 (Eq. 1). Milk FA enter the infant as TG, but we ignore the glycerol. It can be oxidized, enter a biosynthetic sequence, or be absorbed as a 2-MG. It is not lost and should be reported as a portion of the TG.

My instructions for determination of milk FA are these: (i) Obtain a representative sample of milk with documentation (3–5). (ii) Extract the sample using an approved method and weigh the total lipid (3). If not used immediately, store in hexane at −70°C. (iii) Convert the TG to FAME using sodium methoxide (85) for fresh samples and for samples with minimal lipolysis or else use a procedure that employs base and acid catalysts when lipolysis is suspected in samples stored at −20°C for two or more weeks (90). Add an internal standard for calculation of sample total lipid weight (81,89). (iv) Analyze the FAME by GLC using a wall-coated open tubular column with a polar coating of SP-2340, SP-2560 (Supelco, Bellefonte, PA), or equivalent, at least 30-m long, preferably 100 m. The column must be capable of resolving polyunsaturated fatty acids (PUFA) and *cis* and *trans* isomers of 18:1. (v) Identify every FA to the extent possible. Report the amounts of unknown FA. (vi) Report the total lipid content, the relative weight percentage of every FA that has an integration value, the weight (mg or g) of each FA/dL milk, and the TGFA in weight/dL. Do not eliminate FA because they are less than some arbitrary value. Use both acid- and base-catalyzed transesterification for frozen samples kept longer than 3 wk (90).

Factors affecting composition. Many of the factors affecting lipid content, listed in Table 2, do not alter the FA profile of milk, although the absolute quantities can be changed. Exceptions are time postpartum, gestational age, parity, diseases, individuality, and diet (1,8,80). Diet has the greatest effect. The effects of geographic region and season are undoubtedly due to diet. I will present information from recent papers and some earlier publications that were not quoted in my recent reviews. First, I shall include information about the regulation of TG synthesis in the mammary gland from a review by Neville and Picciano (91).

Neville and Picciano (91) discuss evidence that FFA inhibit acetyl CoA carboxylase in a feedback regulatory loop. This hypothesis explains why synthesis of 8:0–14:0 in the mammary gland is decreased on high-fat and fasting diets. Lipoprotein lipase produces FFA on the endothelial surface of the mammary gland cells on the high-fat diet. Adipose tissue lipase releases FFA in the fasting regimen. These enter the circulation and are transported to the gland and other tissues.

Conversely, it is well known that a high-carbohydrate, low-fat diet stimulates synthesis of 8:0–14:0 in the mammary gland. The total 8:0–14:0 rises from about 10 to 20% or greater. The quantities of FFA, from the diet or from adipose tissue, needed to inhibit acetyl Co-A carboxylase are not available. Glucose is the precursor of the mammary gland 8:0-14:0 FA.

The data from papers that I should have included in my last review are presented in Tables 8–13. These papers contain (i) data from regions where information is deficient, i.e., Japan, Hungary (Tables 8–10); (ii) data on changes in FA composition as lactation progresses (Tables 8–10); and (iii) a comparison of omnivorous and macrobiotic diet (Table 11). These studies give us information on the effects of regionally unique diets and adherence to them, which would be impossible to obtain in controlled experiments where costs and numbers of experiments would be prohibitive. Ethical considerations would prevent the initiation of research that could, even remotely, be harmful. An excellent example is the data in Table 11. The consumers of macrobiotic diets avoid foods of animal origin, except fish. Their fat consumption is 20% of energy intake (94). Interestingly, the increase in 8:0–14:0 usually observed when the donor is on a high-carbohydrate diet did not occur. The study was confounded since dietary cross-over between both groups occurred. The macrobiotic milk contained less vitamin B_{12} than the regular milks. Tables 12 and 13 contain data on milks from women in Nigeria, Japan, and Israel.

Most of the findings of Chen *et al.* (97) in Tables 14–16 were reviewed before (1). They are included here because they contain almost the only information on FA in milks from North American women in which a GLC column of high resolution was used. Researchers in Europe are using these columns (98). Chen *et al.* (97) found a relatively high *trans* FA content of 7.19 ± 3.03% (range 0.10 to 17.15%) not reported in earlier papers. The distribution of 18:1 positional isomers (Table 16) was similar to that in partially hydrogenated soybean and canola oils. I will discuss *trans* FA at length shortly. Chen *et al.* found one previously unidentified FA; 20:2Δ8*c*,14*c*.

Chardigny *et al.* (98) reported, along with Chen *et al.* (97), the most comprehensive analyses of milk FA to date (December 1997) in Tables 17–19. They employed techniques not utilized in most other analyses. They noted cyclic monomers for the first time and identified six (Table 19). These monomers made up 0.04% of total FA. The compounds are produced by thermal degradation of 18:3n-3 during vegetable oil deodorization–heat treatments. That these compounds have been detected in human milk is not surprising. Any compound that is fat soluble, is in the maternal diet, and passes through the metabolic gates should appear in milk lipids. Chardigny *et al.* (98) identified the same positional isomers of 18:1*t*, 6-16, as Chen *et al.* (97), but the total amount was only 1.91%. Most of these were the 11-isomer, vaccenic acid, derived from dairy products. In the milk sample analyzed by Chardigny *et al.*, 50% of the total 18:3n-3 were *trans* isomers. Four times a week, the women ate French fries cooked in rapeseed oil, which contains relatively large amounts of *trans* FA.

Data on Nigerian milks can be seen in Table 20. Information on milk from malnourished women was derived from analyses by a packed GLC column, but the quantities were given as μmol/mL. While this mode is scientifically accept-

[a]Adapted from Chen *et al.* (97). One hundred-meter capillary column, SP-2560 coating. Samples taken 3 to 4 wk postpartum. n = 198, lipid content, 3.16 ± 0.94%. Prior separation with $AgNO_3$–TLC. Other FA detected include FA < 10:0, minor Br FA, 18:2 conjugated FA, and unknowns. For abbreviations see Tables 6 and 14.

able, the nutritionist and others must calculate the actual weights of each quantity per deciliter and know the volume of milk consumed so as to determine the absolute amounts of FA in the milk the baby received. The TG in Table 20 were lipolyzed about 7% then separated by TLC. The FA composition of postlipolysis TG is about the same as the original because the bile salt-stimulated lipase of human milk is not regioselective (30,31) except that *sn*-2 16:0 is not hydrolyzed. This FA profile may be atypical. The enzyme loses its bile salt dependency and remains active at −20°C, and the TG content is reduced. The Nigerian milks were high in 12:0 and 14:0, the typical response to a high-carbohydrate diet deficient in

14:0	4.77–8.86	6.90	0.45				

[a]Adapted from Chardigny *et al.* (98). Fifty- and 30-m capillary GLC columns with polar coatings, HPLC, and $AgNO_3$–TLC employed. Samples taken from 0–90 d postpartum, $n = 10$. See Tables 6, 8, and 14 for abbreviations.

18:3n-3, the precursor of 22:5-6. Palm oil was the major dietary fat. This oil contains about 40% each of 16:0 and 18:1 and virtually no 12:0, 14:0, or 18:3n-3 (99).

FA profiles of milks from Sudanese and Chinese mothers are listed in Tables 21–23. I have presented the grouped results of Laryea *et al*. from Sudan (101). They analyzed their data for the possible effects of maternal age, time postpartum, and parity. The quantities of 22:6n-3 in Sudanese milk (Table 23) were low, 0.07 ± 0.03 wt%. Laryea *et al*. (Table 22) detected 0.61 wt% total *trans* FA, mostly the 18:1 isomer. The major dietary fat was unhydrogenated cottonseed oil. The data in Tables 21–23 prove that regional diets are diversified and the FA profiles of milk from those regions typify the diets, i.e., high carbohydrate–low fat, and the sources of particular fatty acids (102). The 22:6n-3 contents of the milk from women in the marine region of China were 2.78% (Table 23), which is extraordinarily high. These women had access to seafood. The regional diets are given in Table 24.

More FA profiles are presented in Tables 25 and 26, i.e., Spanish (103); Dutch, days postpartum (63), and Dutch,

Methyl 9-(propylcyclohexyl) nonanoate *cis*	16

[a]Adapted from Chardigny *et al.* (98) based on gas chromatographic analysis of methyl esters. Amount 0.04% of total FA. Listed in order of elution on GLC chart.
[b]Proportions calculated by author based on peak height, are approximate. For abbreviations see Tables 6 and 8.

preterm (104). I have pooled the Spanish data. De la Presa-Owens *et al.* (103) showed profiles from two regions, Navarre and Catalonia. The compositions are similar to those in milk from other studies of European women herein and in Reference 1. The purpose of the research by Huisman *et al.* (63) was to compare the composition of Dutch milks to 10 types of formulas. Beijers and Schaafsma (104) analyzed milk for FA in response to the recognized importance of 20:4n-6 and 22:6n-3 in the nutrition of preterm infants. They observed (data not shown in Table 26) that the 22:6n-3 and 20:4n-6 contents of very preterm milks (<31 wk) decreased as lactation progressed. In preterm milks (31 to 36 wk), 22:6n-3 did not change and 20:4n-6 decreased. They suggested that 0.34%, the mean amount of 22:6n-3 from their study, be regarded as the norm. The expected increases in quantities of 8:0, 10:0, 12:0, and 14:0, the only FA synthesized by the mammary gland as lactation progresses, were observed. Useful information on 24-h volumes of milk produced by these mothers is shown in this paper (104) and in Table 27.

[a]Adapted from Glew *et al.* (36). Packed column. ND, not detected; NR, not reported. Ibadan and Udo are villages.
[b]MM moderately malnourished, body mass index (BMI), 20.2; SM, severely malnourished; BMI, 16.4.
[c]Adapted from Koletzko *et al.* (100), capillary GLC column. Included for comparison. For abbreviations see Tables 8, 14, and 17.

The changes in FA profiles of term and preterm milks were investigated by Genzel-Boroviczeny *et al.* (105), who employed a high-resolution GLC column (Table 28). Their purpose, similar to that of Beijers and Schaafsma (104), was to determine the contents of LCPUFA in preterm milk as a guide for the design of infant formulas. Significant increases were seen in 10:0, 12:0, 18:2n-6, and 18:3n-3 from day 5 to day 10. Total n-6 LCPUFA, 22:6n-3, and total n-3 LCPUFA decreased significantly from day 5 to day 10. Amounts of 18:2n-

6, 18:3n-3, and LCPUFA did not differ in term and preterm milks at any time. There was significantly more 10:0, 12:0, and 14:0 in preterm as compared to term milk on days 5, 10, and 20. The authors concluded that milk from mothers of preterm infants is not better suited to provide their infants with all the required LCPUFA than other sources during the first few weeks postpartum. The slightly greater contents of 10:0–14:0 might enhance fat and calcium absorption in the preterm infant. These differences in FA profiles are probably due to immaturity of the mammary gland and not to a process resulting from evolution to provide necessary nutrients for the preterm infant. A premature birth is an abnormal event.

Desci *et al*. (106) analyzed milks obtained from Hungarian mothers at 3 to 9 d postpartum. The results (not presented) are similar to those in Table 28.

The effects of time postpartum on the PUFA contents in milks from French mothers (107) and from Australian women (108) are presented in Table 29 (see also Reference 109). Information on the effects of n-3 PUFA-enriched eggs (110) or 22:6n-3 (111) in the maternal diet on milk FA profiles is

[a]Adapted from Chulei *et al.* (102).
[b]Except for cholesterol, values are means ± SD.
[c]Milk products expressed as whole fat fluid. Within a row of data, values with different superscript roman letters are significantly different, $P < 0.05$.

shown in Table 30. The subjects on eggs consumed two per day. Each enriched egg contained 690 mg of n-3 FA and 165 mg of n-3 LCPUFA. The amounts of plasma C and TG were not changed by ingestion of the eggs. The n-3 enriched eggs could be used as an alternative source of 18:3n-3 in the maternal diet. In the study by Makrides *et al*. (111), six capsules containing 500 mg of a special oil with 200 mg of 22:6n-3 (42.9%) were taken per day by the subjects. The effects on milk FA are also presented in Table 30. These authors employed appropriate capillary columns, but did not report *trans* FA. The FA contents were typical of milks from mothers on Western diets, although Makrides *et al*. observed that the 22:6n-3 contents, 0.21%, were lower than the 0.32% they gave in a 1981 paper (109). Although this could be related to differences in columns [packed (109) vs. capillary], Makrides *et al*. (111) suggested that changes in the maternal diets were responsible. They noted, "It does demonstrate the sensitivity of breast milk FA to dietary change and highlights the need

for studies on appropriate diets for lactating women." Milk levels of 22:6n-3 were increased from 0.2 to 1.7% by supplementation. Maternal plasma and erythrocyte contents also went up. Maternal vitamin A and E levels, indicators of antioxidants status, were not affected.

Other pertinent references are discussed briefly below for purposes of completeness. Similar information on most of these points is available in papers discussed previously.

Al-Othman *et al*. (112) analyzed the milks from Saudi mothers. They utilized a packed GLC column and did not detect 20:4n-6, 20:5n-3, and 22:6n-3. The FA profiles were not unique. The FA compositions reported by Luukkainen *et al*. (113) on milks donated by Finnish subjects resemble those from other women consuming Western diets. They also presented data on regional formulas. Jorgensen *et al*. (114) compared the FA profiles of Danish formulas to human milk. Again the data were typical of milks from mothers ingesting Western foods. Jorgensen *et al*. did find 2.5% *trans* FA. The *trans* FA included 18:1, *tt* 18:2, *ct* 18:2, and *tc* 18:2. Although not stated, most of the *trans* FA was probably 18:1 (97,98). The conjugated isomer, *c*9,*t*11-18:2, may have been present. Once again, very few investigators have sought, identified, and reported *trans* FA. Some researchers have employed GLC columns which resolve these FA, but did not identify them. Sera *et al.* (115) analyzed the FA in milks from Italian women obtained twice a day from postpartum days 1 through 28. There were no differences between the A.M. and P.M. samples. The amounts of LCPUFA declined as lactation progressed.

Villalpando *et al*. (116) presented evidence which possibly explains the abnormally low lipid contents and variations in FA profiles often seen in milks from malnourished women. They noted that in milks from individuals, diurnal changes occurred in relative wt% and real amounts of total lipids and some FA. Unsaturated FA, 16:1, 18:1, and 18:2, identified as of dietary origin, increased after each meal. These peaks were associated with troughs in the wt% of 8:0–14:0; these acids

TABLE 27

[e]$P < 0.05$ vs. term milk.

were identified as being synthesized solely in the mammary gland. Peaks and troughs in total lipid content occurred at the same time as in the unsaturated FA. Gravimetric data not provided in Reference 116 were sent to me by Dr. Villalpando. It appears that when the relative or real weights of unsaturated FA decreased postprandially, these amounts of 8:0–14:0 increased to compensate. However, the total lipid contents dropped at these times. These changes were seen in 8 of 10

TABLE 29
Influence of Time Postpartum on FA (wt% ± SD) in Milks from French[a] and Australian[b] Women

[b]Adapted from Makrides *et al.* (108). Fifty-meter capillary column coated with BPX-70. Values with common superscript roman letters are significantly different, $P < 0.01$. Australian donors. Each analysis represents a pooled breast milk sample collected over seven consecutive days in the 6th, 16th, and 30th week of lactation, term infants.

subjects. The curves were flat in the other two, i.e., very little postprandial response. When the FA were grouped according to time and types (8:0–14:0, 16:0, 18:0, and 16:1, 18:1, 18:2), the peaks and troughs were not seen. This is the first time that these variations in milks from marginally malnourished women have been reported. Investigators face a difficult problem in obtaining a representative milk sample from these women. It could be done as in Reference 116, the portions pooled, and the FA in all of these analyzed to find the best match in profiles.

The effects of Western and non-Western maternal diets on the FA profiles of milk (published March 1995 to December 1997) are summarized in Table 31. The means are averages of the sums. Similar earlier data (1) are included for comparison. The major differences between Western and non-Western milks are less 18:2n-6 and LCPUFA in the Western milks and less *trans* FA in the non-Western milks. The availability of seafood (Table 23) greatly increased the contents of LCPUFA, and the lack of partially hydrogenated fats and oils was responsible for these differences in non-Western milks. High carbohydrate–low fat diets increased 10:0, 12:0, and 14:0, as can be seen in the older non-Western data and in the results from Nigeria (Table 20). The pooling I have done for Table 31 eliminates the effects of regional diets. These should be evaluated on an individual basis. Notably missing from Tables 8–31 are any data on milks from U.S. mothers.

COMMENTS ON MONOUNSATURATED FA

The major monounsaturated FA; *c*9-18:1 (oleic acid), in addition to the usual roles of FA (source of energy and structural components), reduces the melting point of TG, thus providing the liquidity required for the formation, transport, and metabolism of milk fat globules. Other *cis* isomers are present (Table 16). Desaturation of 18:0 to 18:1 occurs in the mammary gland of cows and rats (117). This step helps maintain the liquidity of milk fat. The reaction has not been detected in the human mammary gland.

All *trans* FA found in milk originate from the maternal diet. Some of the *trans* monomers, which present different profiles when derived from partially hydrogenated oils or from bovine milk fat, may cause problems. These will be discussed later.

Amounts of unsaturated FA in milk. The mean contents and ranges of unsaturated FA can be seen in Table 31. The changes observed are due to variations in maternal diet. This is indicated by the differences in 18:1*t* and 18:2 between

[a]From Tables 14–19, 25, 26, 28–30 for Western diets; Tables 12, 13, 20–23 for non-Western diets. Term mature milks used. Means are the averages of all amounts for each acid.
[b]From Tables 35–37 in Reference 1 for comparison. For abbreviation see Table 14.

Western and non-Western women. Western women ingest more partially hydrogenated oils, hence more *trans* FA, than non-Western women.

Monounsaturated FA: trans *isomers*. The major problems here may be the *trans* isomers. Their effects on infant and fetal development were reviewed by Carlson *et al*. (118). They will not have been resolved and identified unless long (100 m) capillary columns with polar coatings (CP-88 or SP-2560) are used (119).

We know the following about the sources and transport of *trans* FA and early development. (i) They are produced in foods by biohydrogenation in the rumen and appear in ruminant milks and their products and by processing of oils, partial hydrogenation, and heating. The procedures produced different FA profiles (97). (ii) They originate from the diet. Geometric isomerization (elaidinization) is not an inherent mechanism in humans. (iii) They are transferred to the fetus *via* cord blood and to the infant through milk. The amounts are related to the quantities consumed in the maternal diet.

Craig-Schmidt *et al*. (120) derived the following equation relating the amounts of *trans* FA 18:1 in milk to the quantities in the maternal diet:

$$y = 1.49 + 0.42\,x \qquad [2]$$

where y = % *trans* 18:1 in milk fat and x = % *trans* 18:1 in dietary fat. With this formula, Chen *et al*. (97) found that 90% of the Canadian women whose milks they analyzed were consuming moderate (14.2%) to large (26% of total fat) amounts of *trans* FA. The total per capita *trans* FA content of the U.S. diet has been estimated as 8.0 g/d with 6.4–6.7 g from partially hydrogenated vegetable oils (118). Reference 118 has a table presenting the *trans* FA contents of many foods. Data can also be obtained from http://www.nal.usda.gov/fnic/foodcomp.htlm.

Trans FA in milk may have deleterious effects. To evaluate the possibility, we must know how much and what kinds of *trans* FA are in human milk. Data on the former are given in Tables 32 and 33 (121). The differences in quantities are

due to maternal diet. Consumption of oils containing *trans* FA has been increasing. The older analyses (Table 32), done with packed GLC columns, did not resolve the *trans* FA as well as the capillary columns (Table 33). We do not know the amount of *trans* FA in the diet that could initiate difficulties. A list of the effects associated with intakes of *trans* FA is provided in Table 34. While the findings are persuasive, the Expert Panel on *trans* fatty acids and fetal and infant development (138) stated that an influence on the normal metabolism of other acids by the amounts of trans FA consumed by the infant in milk during early growth has not been definitively established. Feeding studies that would provide answers are difficult because ethics committees would never authorize a trial that might have even a remote possibility of causing problems with infant or mother. During the interval, what should we recommend to mothers who are nursing their infants about *trans* FA in the diet? At this time we do not have data upon which advice can be given, except for the information below.

Ascherio and Willett (139) reemphasized their belief that consumption of *trans* fatty acids should be decreased. Conversely, Shapiro (140) doubts that the epidemiological data used in Reference 139 are sufficient to support a decrease in consumption. Nevertheless, a degree of risk may possibly be present and could be avoided. Reduction of intake might reduce risk of coronary heart disease in women (139) and possibly their infants.

COMMENTS ON PUFA

Linoleic (18:2n-6) and linolenic (18:3n-3) acids. Linoleic acid (144) and 18:3n-3 or α-linolenic acid (145) are essential, that is, they are required because they cannot be produced in the human. Innis (146) reviewed the roles of these acids in growth and development. Linoleic acid is the precursor of 20:4n-6 and 18:3n-3 of 20:5n-3 and 22:6n-3. These acids are formed from their precursors by elongation–desaturation and, for 22:6n-3, an oxidation reaction converting 24:6n-3 to 22:6n-3 and by recycling (147,148).

The quantities of 18:2n-6, 18:3n-3 and the LCPUFA derivatives in milk can be found in Table 31. The amounts in milk respond to their quantities in the maternal diet. This was shown by Insull *et al*. (149), who increased the contents of 18:2 in milk to 43% by feeding large amounts of corn oil to their subject.

From 1978, when our first review appeared (150), the av-

TABLE 34
Effects of *trans* FA[a]

1. Reduction in fat content of mice (134) and dairy cattle (135,136) but possibly not in lactating women (97).
2. Linear correlation between amounts of 18:1*t* in human diet and milk; $y = 1.49 + 0.42x$ where y = 18:1*t* in diet of previous day; % of total acids and x = % in milk (120).
3. Hypercholesterolemic in adults (137–139). Not considered high risk according to References 138 and 140.
4. Negative correlation between milk contents of 18:1*t* and of 18:2 and 18:3 (97).
5. None on amounts of prostaglandins in milk (120).
6. Impairment of biosynthesis of LCPUFA in premature infants (141) and children (142) and of growth in premature infants (143). However a causal relationship between *trans* FA intake and changes in early development not established (118).
7. *Trans* fatty acids found in plasma triglycerides, sterol esters, and phospholipids of premature infants (143). *Trans* negatively correlated with birth weight and with the biochemical reactions 18:3n-3 to 22:6n-3 and 18:2n-6 to 20:4n-6. Both LCPUFA required for maturation of brain and nervous system of infants (see Ref. 6).
8. Effects in 7 seen in children, 1–15 yr where applicable (143).
9. Vaccenic acid, *t*11-18:1, from ruminant fats may have less or no effect on coronary heart disease in women (140). Inferred from Retrospective Dietary Study.
10. *Trans* FA in plasma of premature infants may be inversely associated with LCPUFA in membrane lipids (118).

[a]Adapted from Reference 121. For abbreviations see Tables 10 and 14.

TABLE 35
Effects of Conjugated Linolenic Acids (CLA) Containing *c*9,*t*11-18:2[a]

1. Anticarcinogenic for carcinogen-induced tumors and neoplasias in stomachs and colons of mice and rats (186,187), mammary tumors of rats (188), and cultured human mammary cells (189).
2. Overcame catabolic responses to endotoxin injection (190).
3. Improved weight gain and feed efficiency in rats (191).
4. Enhanced select immune functions in several animals (192).
5. Antiatherosclerotic in rabbits (193). Reduced total LDL cholesterol and triglycerides. Reduced total cholesterol and early atherosclerosis in hypercholesterolemic hamsters (194).
6. Is a potent antioxidant (195) although this has been questioned (196).
7. Modulated bone metabolism (197).
8. Altered lipid composition in mouse liver (198). Reduced body weight; increased feed efficiency.
9. Decreased body fat and increased lean body mass in mice (199).

erage content of 18:2n-6 in milk has increased from about 8 to 14–16%. Has this caused an imbalance with the other unsaturated FA? The report by Sheaff *et al*. (151) indicated that high levels of 18:2n-6 did not inhibit the conversion of 18:3n-3 to 22:6n-3 in rats. Nevertheless, Lands has expressed concern about the imbalance (152). He hypothesized that an overproduction of n-6 prostaglandins produced from high levels of 20:4n-6 arising from large amounts of 18:2n-6 results in chronic inflammatory disorders. It may be that maternal diets are being consumed that will result in abnormally high levels of 18:2n-6 compared to 18:3n-3 in milk. A desirable ratio of 5:1 to 15:1 has been established (153). However, the ratio in many milks is greater than 15:1 (Table 31).

Sauerwald *et al*. (154) checked the effects of varying amounts of 18:3n-3, 0.4, 1.0, or 3.2%, with a fixed quantity, 16%, of 18:2n-6. They found greater fractional incorporation rates of 18:3n-3 into the plasma PL pool at 3.2% than at 1.0 or 0.4% levels. Yet, the fractional rates of conversion of 18:2n-6 to 20:4n-6 and incorporation of 20:4 into the plasma PL pool were lower at 3.2% 18:3n-3. According to the authors (154), their data cannot be used to estimate the amounts of LCPUFA synthesized daily. Obviously, without these amounts the adequacy of endogenous availability cannot be determined. The high intakes of 18:2n-6 did not inhibit the conversion of 18:3n-3 to 22:6n-3 (154). Furthermore, the premature infant with a very low birth weight is capable of synthesizing 20:4n-6 from 18:2n-6 and 22:5n-3 from 18:3n-3 (155). In term infants, 23% of plasma 20:4n-6 originates from 18:2n-6 (156). Microsomes from infant livers are capable of desaturating 18:2n-6 and 18:3n-3 (157).

A question remains: Is endogenous synthesis sufficient for the infant's requirements in growth and maturation of the brain, nervous system, and visual process? We do not know the answer, but it may be that LCPUFA are conditionally essential for preterm infants, and term babies may require them in their diets, but usually do not (158).

The functions of LCPUFA in human milk. The functions of LCPUFA have been reviewed by Gibson and Makrides (158) and I will use their paper as a guide for this presentation. Others who have recently reviewed all or parts of the literature are Innis (146), Nettleton (159), and Carlson and Werkman (160). Most of the recent papers describe studies on the effects of supplementation with FA on the development of preterm infants, e.g., Uauy and de Andraca (161). Many papers on the subject have appeared and the ones discussed below are useful for historical purposes. Beginning in 1973 and continuing, Crawford *et al*. (162) noted that the brain and nervous systems of infants, as well as human milk, contained LCPUFA. Crawford *et al*. (163) stated that the contents in brain and nerve tissues "probably indicated a remarkable thirst for long chain n-6 and n-3 fatty acids for fetal development." In 1993, Crawford *et al*. (164) emphasized the necessity for including 20:4n-6 and 22:6n-3 in formulas for preterm infants. Later, Crawford *et al*. (165) reviewed the requirements of preterm infants. They concluded that the amounts of these acids in formulas for preterm infants should be increased.

It has been known for years that human milk contains LCPUFA that were not being added to formulas. Nonetheless, the significance was not apparent until the results of feeding trials using diets containing formula-type fats done in 1984 and 1986 by Neuringer *et al*. (166,167) with rhesus monkeys showed the effects of a deficiency in 18:3n-3. The monkeys' tissues were low in 22:6n-3 and their vision was impaired. These findings led to investigations on the effects of 20:4n-6 and 22:6n-3 (168–170). However, some of the results with formulas for preterm infants were contradictory. The acids were known to be components of cellular membrane PL, but their importance was clarified when it was discovered that 18:2n-6 and 18:2n-3 were the precursors *via* 20:4n-6 and 22:6n-3 of eicosanoids. These bioactive compounds mediate many metabolic reactions and are regarded as hormones.

Is 22:6n-3 essential for infants? The amounts in milk range from 0 to 2.78 wt% with means of 0.45 for Western women and 0.88 for non-Western women (Table 31). Amounts of 0.2 to 0.3% are generally accepted as representative. The quantities in milk respond to the amounts of DHA in foods, primarily fish, in the maternal diet. It is almost always present in milk. An apparent absence may be due to analytical problems, such as failure to inject enough sample into the gas–liquid chromatograph. However, presence is not an indicator of essentiality. Gibson and Makrides (158) observed that the data are equivocal for specific health benefits of DHA supplementation to healthy term infants. Innis *et al*. (168) found in a study of term infants fed formula (no LCPUFA) as compared to those receiving human milk that the plasma and red blood

cell PL, docosahexaenoic acid (DHA), arachidonic acid, C, and apolipoprotein B were lower. There were no differences in visual acuity or growth between the groups. There was no evidence on the basis of these parameters suggesting the formula contained inadequate n-6 and n-3 fatty acids. The infants fed formula were assumed to be able to convert 18:2n-6 and 18:2n-3 to sufficient 20:4n-6 and 22:6n-3 for normal growth and visual acuity. This is because after about 2 wk postpartum, they may be able to synthesize the amounts required. Therefore, 22:6n-3 is not essential, because while needed, the infant can probably synthesize the amount required if precursor is available. In contrast, 18:2n-6 and 18:3n-3 are essential, because they are not synthesized.

Preterm infants do not have normal access to a uterine supply of LCPUFA; they also have very little adipose tissue and decreased reserves of essential FA. Therefore, the preterm infant may require more dietary DHA than the term infant. There is evidence that for infants born at less than 32 wk gestation, dietary DHA provides a measurable benefit on visual outcomes. However, DHA is still not essential as defined classically.

Gibson and Makrides (158) commented on the essentiality of 20:4n-6. There is no evidence of a dietary need of 20:4n-6 for healthy term infants. There have not been any reports of reduced growth related to a low 20:4n-6 status induced by n-3 LCPUFA. This has been observed in some preterm infants but not others (170). Carnielli *et al*. (155) showed that the very low birth weight infant can synthesize 20:4n-6 and 22:6n-3 from 18:2n-6 and 18:3n-3. Their data reveal that these infants have adequate levels of Δ-6 desaturation. Demmelmair *et al*. (156) found that 18:2n-6 conversion in term infants produced 23% of the 20:4n-6 in the infant's plasma. It appears that 20:4n-6 is not an essential FA in the diets of term or preterm infants.

Johnson *et al*. (171) identified free 9- and 13-hydroxyoctadecadienoic acids (9- and 13-HODE and their *R* and *S* isomers) in mammary gland tissue from mice. These oxygenated products of 18:2 are produced by free-radical (autooxidation) and/or enzymatic mechanisms. The amounts were increased by feeding a diet high in 18:2. Consumption of increased amounts of dietary fats high in 18:2, e.g., corn oil, increases the development of mammary tumors. Johnson *et al*. (171) proposed that 9- and 13-HODE may contribute to mammary tumorigenisis. They found that most of the hydroxy acids were produced by enzymatic processes and small quantities by autooxidation. To summarize, a diet high in 18:2 increases enzymatic production in the mammary gland of oxidation products that have been proposed to be associated with tumorigenesis. These products should appear in milk but the usual GLC analysis will not detect them. They would not appear on the chart because the highly polar hydroxy groups retard elution and are not methylated by esterification methods. Johnson *et al*. (171) converted the hydroxy groups in the methylated acids to trimethylsilyl ethers for GLC analysis. The authors also noted that there was no autooxidation when the mammary tissues were stored at –80°C for up to 1 mon.

Two excellent reviews on LCPUFA have recently been published by Hamosh and Salem (172) and Bendich and Brock (173). The latter authors describe the rationale for inclusion of LCPUFA in infant formulas as well as an increase in vitamin E levels.

Conjugated linoleic acid (CLA). CLA is the collective name of the positional and geometric isomers of octadecadienoic acid with conjugated double bonds. Such bonds are found at positions 9 and 11 or 10 and 12. The geometric configurations of each double bond can be *cis* or *trans*. The CLA are produced by biohydrogenation of PUFA in the rumens of dairy and beef cattle, sheep, etc. Meats, milk, and milk products from these animals contain CLA. Smaller amounts are found in processed oils, presumably as the result of heating and oxidation. The properties of CLA have been reviewed (121,174–181). The CLA have been reported to have a variety of beneficial effects including anticarcinogenicity. Because the properties of the acid have stimulated research and publications, Kramer *et al*. (182) have recommended that the trivial name rumenic acid be applied to *c*9,*t*11-18:2 to identify the source. Rumenic acid is the major and occasionally the only one of these acids in ruminant-derived foods; and it is believed, but not proven, to be the bioreactive fatty acid of CLA. CLA were known to exist, primarily in dairy products, for many years. Riel (183) analyzed bovine milk fat spectrophotometrically for CLA, finding a seasonal range of 0.24 to 2.81% with the highest values occurring when the cows were on pasture during the summer. Parodi (184) identified the major acid as *c*9,*t*11-18:2. The acid is not a normal constituent in the feed of dairy cattle. CLA are produced by ruminal biohydrogenation. The acid was identified earlier by Kepler *et al*. (185) as an intermediate when 18:2 was incubated with the rumen microorganism, *Butyrivibrio fibrisolvens,* an obligate anaerobe. Other isomers are also produced in the rumen, primarily *t*10,*t*-12-18:2.

The CLA are resolvable by GLC with an SP-2560 fused-silica capillary column, 100 m × 0.25 mm i.d. with a 0.2-mm film thickness (85) as previously mentioned. However, acid catalysts, HCl, BF_3, acetyl chloride, or H_2SO_4, employed for preparation of FAME, reduce the quantities of *c*9,*t*11-18:2 in bovine milk (85). The isomer is converted to *t*9,*t*11-18:2 and allylic methoxy artifacts (85). Base catalysts, for our purposes, sodium methoxide, do not affect rumenic acid and therefore must be used.

Attention has centered on CLA because they inhibited mouse epidermal tumors induced by 7,12-dimethylbenz(α)-anthracene (186). Several additional beneficial attributes have since been reported. These and other points are listed in Table 35. Since any FA in the maternal diet, even in trace amounts, will appear in human milk, the acid has been detected therein. These results are shown in Table 36. All of the investigators used polar capillary GLC columns and standards to separate and identify the acid. We confirmed identity with mass spectrometry (204). I noted in several papers that the acid was separated and identified in some as 18:2 *ct*, but not as rumenic acid. Fogerty *et al*. (202) observed that milk from members of

a Hare Krishna group had two times more rumenic acid than subjects on normal diets. This group consumed large quantities of butter and ghee (heated, clarified butter oil), which, based on a high fat content (at least 80%) contain large amounts of the acid. Huang *et al*. (205) fed 112 g (4 oz) of Cheddar cheese per day to male subjects. Plasma contents of rumenic acid were increased 19–27% without affecting C contents. While 4 oz is more cheese than one would usually consume during a meal or snack, these results indicate the content of rumenic acid in serum (and likewise in milk) can be increased by manipulation of the (maternal) diet. Park *et al*. (206) showed an increase in milk contents of rumenic acid when large amounts of foods containing CLA were ingested.

One of the most attractive properties of CLA listed in Table 35 is anticarcinogenicity. Parodi (179) discussed this property in a paper with the provocative title, "Milk fat conjugated linoleic acid: Can it help prevent breast cancer?" He noted that physiological concentrations of CLA suppressed cultured cell growth in human malignant melanoma, colorectal, breast, lung, prostate, and ovarian cell culture lines. Growth in all lines of leukemia, mesothelioma, glioblastoma, and hepatoma was also inhibited. Linoleic acid, the precursor of CLA, did not inhibit growth and was often stimulatory to these cell lines. CLA is an excellent inhibitor of mammary tumors in rats. Supplementations of the diet by 1% by weight or less are protective. When feeding occurs during the period of mammary gland development to adult stage morphology only, protection for life results. The type of dietary fat does not affect protection.

The CLA content of ruminant meat and milk can be increased by manipulation of the cow's dietary regimen. Consumption of these foods by humans increases the CLA content of breast milk and blood plasma. By extrapolation from rat studies, more CLA in the diet might protect against breast cancer. Ip *et al*. (188) calculated that 0.1% dietary CLA, the preventive amount for rats, would be equivalent to a daily intake of 3 g for humans. The estimated consumption in the United States is 1 g/d. However, these amounts are based on the mixture of isomers in the CLA used. The mixture contained about 42% rumenic acid, and this was the only isomer incorporated into membrane PL. McGuire *et al*. (178) gave an average consumption in the United States as 50 to 180 mg/d for adults and 224 mg/d for lactating women. We must have more reliable data on how much of the acid is required and how much of the isomer-rich foods should be consumed to attain this level. McGuire *et al*. (178) noted that consumption of only two glasses (16 oz, or 469 mL) of milk/d (55 mg/d of rumenic acid) by Finnish women decreased the risk of breast cancer. An increase of 55 mg/d would require modest increases in beef and dairy product consumption. Even so, the intake of fat, saturated FA, and C would also be increased slightly. Since this is counter to current dietary recommendations, only women with a family history of breast cancer and none of heart disease should consider a high rumenic acid diet after consulting their physicians. The acid is fat-soluble and increases with the fat content. Remember that CLA are antiatherogenic in test animals and some cultured cancer cells and that few physicians and nutritionists are knowledgeable about rumenic acid.

Ip (207), who with his colleagues has evaluated the dietary aspects of CLA, states that CLA are unique. They are the only mixture of FA, with rumenic acid (presumably anticarcinogenic), that significantly inhibits tumors. Paradoxically, the public relations effect of a nutrient can be gauged by how rapidly it is adopted by groups who hope for beneficial results beyond those described above. There are anecdotal reports that body builders, attracted by the apparent ability of CLA to shift nutrients from adipose to muscle tissue, are consuming CLA. Unfortunately, the amounts of rumenic acid in these preparations are not subjected to quality control. One commercial sample contained these *cis,trans* isomers: 8,10 (84%), 9,11 (30 %), 10,12 (31 %), and 11,13 (24 %) (208). This reference described a discriminating analysis of CLA isomers. Much more information is needed, but it is tempting to believe that women who do not have a family history of heart disease should increase their ingestion of foods containing rumenic acid while nursing their babies and protect themselves from breast cancer. Milk and its products contain many other desirable nutrients, e.g., calcium, high-quality proteins, B vitamins, etc. Preparations containing mostly rumenic acid are only now becoming available for feeding studies. Some of the many questions that have arisen should be answered.

FA IN HUMAN MILK

In Table 37 I have listed the FA known to be present in human milk. The number has increased from 199 in my last review (1) to 214. The new acids represent nine positional isomers of oleic acid, *c*9-18:1, and six cyclic pentyl and hexyls at C-9 and C-10 terminated by butyl and propyl chains to total 18 carbons. Many more are certainly present, awaiting the attention of the FA taxonomists. These minor acids should not be ignored. Rumenic acid is found in small amounts, but it has major physiological effects.

ACKNOWLEDGMENTS

I thank Ross Products Division, Abbott Laboratories; Wyeth-Ayerst International Inc., and Mead Johnson Research Center for funds to pay for typing and purchase reprinting. I also thank Nancy Auestad of Ross Products for sending me Reviews of Long Chain Polyunsaturated Supplementation of Preterm and Term Infant Formulas, inhouse publications of Ross Products.

ARTICLE

Cerebrospinal Fluid Lipoproteins Are More Vulnerable to Oxidation in Alzheimer's Disease and Are Neurotoxic When Oxidized *ex Vivo*

ABSTRACT: Brain regional oxidative damage is thought to be a central mechanism in the pathogenesis of Alzheimer's disease (AD). Recent studies of cerebrospinal fluid (CSF) have suggested that increased lipid peroxidation of CSF and CSF lipoproteins also may occur in AD patients. In the present study, we determined the susceptibility of human CSF to *ex vivo* lipid peroxidation and tested the hypothesis that oxidized CSF lipoproteins may be neurotoxic. Whole CSF or a CSF lipoprotein fraction (d < 1.210 g/mL) was oxidized with 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH), a hydrophilic free-radical generator. Kinetics of CSF lipid peroxidation were followed by a standard fluorescence product accumulation assay. Oxidation of AD CSF yielded significantly shorter fluorescent lag times than controls, indicating reduced antioxidant capacity. Electrophoretic mobilities of CSF apolipoproteins were specifically reduced upon oxidation of CSF with AAPH, suggesting that lipoproteins are primary targets of CSF lipid peroxidation. Cultured neuronal cells were exposed to physiological concentrations of isolated CSF lipoproteins oxidized with increasing concentrations of AAPH; the resulting neurotoxicity showed a significant linear AAPH concentration-response relationship. These results suggest that oxidized CSF lipoproteins may contribute to the pathogenesis of neurodegeneration in AD.

Paper no. L8326 in *Lipids 34,* 1273–1280 (December 1999).

Alzheimer's disease (AD) is a devastating and common neurodegenerative disease that currently afflicts about 4 million Americans, a number predicted to approach 12 million by the year 2020 (1). AD is a clinical-pathological entity that probably derives from different causes. Autosomal dominant AD is relatively rare, accounting for less than 5% of all patients with AD. The majority of autosomal dominant AD is caused by mutations in one of three different genes: amyloid precursor protein, presenilin 1, or presenilin 2 (2). In contrast, sporadic AD is by far the most common form of the disease, but its causes have not been clearly defined. Several risk factors for sporadic AD have been identified, including advancing age, previous head trauma, and inheritance of the ε4 allele of the apolipoprotein E gene (*APOE*) (3). Despite differences in etiology, clinical and pathological data indicate that both autosomal dominant and sporadic forms of AD share common pathogenic steps (4). One pathogenic step proposed to be important in the progression of AD is regionally increased brain oxidative damage (5).

Oxidative damage results when oxidative stress exceeds the antioxidant capacity of tissue. Although several different classes of molecules may be affected, lipid peroxidation is thought to be a prominent and especially deleterious form of oxidative damage in brain due to this organ's relative enrichment in polyunsaturated fatty acids (6). Regionally increased brain lipid peroxidation has been demonstrated consistently in postmortem studies of AD patients compared with age-matched controls (5). Recent work also has shown increased central nervous system (CNS) lipid peroxidation in the early stages of AD in living patients compared to controls (7). Moreover, several experimental studies have demonstrated that products of lipid peroxidation may cause neurodegeneration that mimics some of the features of AD (8). The causes of increased brain oxidative damage in AD are not fully resolved but may involve both increased oxidative stress from several potential sources and reduced antioxidant defenses.

Human cerebrospinal fluid (CSF) contains lipoproteins that are distinct from their counterparts in blood (9). CSF lipoproteins are small high density lipoprotein-like particles that are enriched with either apolipoprotein E (apoE) or apoAI (10–13). CNS apoE is derived primarily from astrocytes, whereas apoAI is derived from hepatocytes and enterocytes; there is no apoB in the CNS (10,12–17). Therefore, apoE is thought to be the major protein for receptor-mediated lipoprotein trafficking in the CNS (9). Recently, we showed that CSF lipoproteins from AD patients contain reduced concentrations of polyunsaturated fatty acids compared to age-matched controls (16); however, the importance of these changes in the

pathogenesis of AD is not known. One explanation for this finding is that lipoproteins in AD brain extracellular fluid are more vulnerable to oxidation than controls. Here we have tested this hypothesis by quantifying the susceptibility of CSF from AD patients and controls to lipid peroxidation. In addition, we have tested directly the hypothesis that oxidized CSF lipoproteins may contribute to neurodegeneration.

EXPERIMENTAL PROCEDURES

Collection of CSF. CSF from seven patients with AD and five control subjects was obtained from autopsies performed at Vanderbilt University Medical Center or the University of Kentucky Medical Center between 1996 and 1998. All AD patients carried a clinical diagnosis of probable AD during life and were verified as definite AD postmortem using standard criteria (18). Control subjects were age-matched individuals without clinical evidence of dementia or other neurological disease and who underwent annual neuropsychological testing with all test scores in normal ranges. All control subjects also underwent postmortem examination and were demonstrated to have age-related changes only. The histopathologic staging protocol of Braak and Braak was applied to all individuals (19). CSF was removed postmortem from the lateral ventricles, sedimented at 1,000 × *g* for 10 min, and frozen at –80°C until analyzed. Freezing at –80°C with a single thaw does not significantly alter CSF lipoprotein lipid or protein content (16,17). *APOE* genotype was determined postmortem in all cases (20).

Oxidation of CSF. Oxidation of CSF was initiated by the addition of 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH; Wako Chemicals USA, Richmond,VA) dissolved in phosphate-buffered saline (PBS) at pH 7.4 at 37°C under air.

Fluorescence of oxidized CSF. Oxidation of CSF was measured by spectrofluorometry (excitation 360 nm, emission 430 nm) as described for low density lipoprotein (LDL) oxidation (21,22). Relative fluorescence units (RFU) were measured continuously for 24 h with readings taken every 15 min. Lag time, maximal change in fluorescence (ΔRFU), and propagation rate were calculated for each sample from a plot of RFU vs. time (h).

Electrophoresis and immunoblotting. Following a 24-h incubation with AAPH, aliquots of native or oxidized CSF were boiled for 5 min in 2× Laemmli sample buffer (1:1 vol/vol dilution), and samples were electrophoresed on a 10% polyacrylamide gel (60 min at 150 V). CSF proteins were visualized by Coomassie staining or by immunoblotting with rabbit antihuman apoE antibody (Dako Corp., Carpinteria, CA) or rabbit antihuman apoAI (Calbiochem, La Jolla, CA) according to previously published methods (17). Electrophoretic mobility was determined by measuring the distance traveled by the monomeric protein from the origin.

Cell culture. Mouse Neuro2A cells were obtained from the American Tissue Culture Collection (Rockville, MD) and grown according to established methods (23). Cells were incubated in medium (DMEM/F12 with N2 supplement; Gibco, Grand Island, NY) in a humidified incubator at 37°C with an atmosphere of 5% CO_2/95% air. Neuro2A cells were plated onto 10-mm slides in cell culture medium at a cell density of 5×10^4 cells per slide for both fluorescent labeling and cytotoxicity experiments.

CSF lipoprotein isolation. CSF lipoproteins were prepared by ultracentrifugation and isolation of the $d < 1.210$ g/mL fraction exactly as previously described (16). The CSF lipoprotein fraction was then dialyzed against PBS at 4°C, and protein concentration determined using the bicinchoninic acid (BCA) method (Pierce, Rockford, IL).

Fluorescent labeling. CSF lipoproteins were diluted to 50 µg protein/mL and then labeled with 1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate (DiI) based on published methods used for plasma lipoproteins (24). Briefly, DiI (3 mg/mL in dimethylsulfoxide) was incubated with CSF lipoproteins for 18 h at 37°C and then filter-sterilized with a 0.22-micron filter to prepare the solution for cell culture and to remove unbound DiI. The labeled lipoproteins were then diluted 1:1 (vol/vol) with culture medium (final CSF lipoprotein concentration of 25 µg protein/mL) and incubated with cells for 1 h. The DiI-containing medium was removed, the cells washed, and then fixed in 4% paraformaldehyde/PBS for 30 min. DiI incorporation into cells was visualized with a Zeiss Axiovert 135 fluorescence microscope equipped with rhodamine filters (23).

Cytotoxicity assay. CSF lipoproteins were diluted to a protein concentration of 50 µg/mL in PBS. Diluted lipoprotein samples or PBS alone was oxidized with AAPH exactly as described above for whole CSF. Following oxidation, all samples were dialyzed against PBS at 4°C. CSF lipoprotein-containing samples were diluted into cell culture medium to give a final concentration of 25 µg protein/mL; samples without CSF were similarly diluted with cell culture medium. Cells were incubated with the oxidized samples for 24 h immediately after dilution into cell culture medium. Cell viability was determined using the Live/Dead Kit (Molecular Probes, Eugene, OR). Cytotoxicity was quantified by counting over 500 cells per culture (23).

Fatty acid quantification. Fatty acid composition of CSF lipoproteins was determined exactly as previously described (16). Briefly, after dialysis of the $d < 1.210$ g/mL fraction and determination of protein concentration by the BCA method, total fatty acids were quantified by gas chromatography following transmethylation using BF_3/methanol (25). Fatty acids were identified by comparison with known standards.

Statistics. Statistical analyses were performed using Prism 2.0 (GraphPad Software Inc., San Diego, CA) software.

RESULTS

Descriptive data as well as *APOE* genotype for the 12 individuals whose CSF was analyzed in this study are presented in Table 1. There was no significant difference between AD patients and controls when compared for age, gender, or postmortem interval. AD patients did have significantly lower

brain weights than controls ($P < 0.05$), a well-described consequence of cerebral atrophy in AD.

AAPH is a hydrophilic compound that generates a constant radical flux under the conditions used in these experiments, and that property has been used extensively in the study of lipoprotein oxidation (21). Oxidation of CSF was monitored using a fluorescence-based assay that has been widely employed to study plasma lipoprotein oxidation in both isolated lipoproteins and in whole plasma (21,22,26). This method detects fluorophores formed by reactions of lipid peroxidation products with amino groups on proteins and is characterized by three phases: a lag phase when there is no change in RFU, a propagation phase with steep change in RFU vs. time, and a plateau phase with no further increase in RFU (21,22). The concentration–response relationships for CSF oxidation by AAPH are presented in Figure 1. Oxidation of CSF from the 7 AD patients with 1, 5, and 10 mM AAPH significantly increased the RFU of CSF. Incubation of CSF with increasing concentrations of AAPH shortened lag times, an indicator of antioxidant capacity (ANOVA: $P < 0.001$, Fig. 1A). Lag times significantly decreased from 1 to 5 mM AAPH (paired analysis with Bonferroni correction, $P < 0.01$), but not from 5 to 10 mM AAPH. Lag times could not be determined for CSF samples not exposed to AAPH because there was no significant change in RFU over time in these samples. Propagation rate is an index of oxidizable fatty acid content and depends on the lipid composition of lipoproteins. The propagation rate of fluorescence did not change significantly with increasing AAPH concentration from 1 to 10 mM (Fig. 1B). Maximum change in RFU (ΔRFU) is the difference between RFU at the plateau and lag phases. All oxidized samples reached plateau by 18 h. ΔRFU significantly increased from 1 to 10 mM AAPH (ANOVA: $P < 0.05$); paired analyses with the Bonferroni correction showed a significant difference for 1 and 5 mM AAPH but not for 5 and 10 mM AAPH (Fig. 1C).

Comparison of the concentration-response relationships between controls and AD patients revealed significant differences in lag times, but not ΔRFU or propagation rate. Oxidation of AD CSF yielded significantly shorter lag times compared to CSF from controls at both 5 and 10 mM AAPH ($P < 0.05$, Fig. 2A). Lag times among CSF samples from AD patients and controls were inversely correlated with Braak stage (Spearman's ranked correlation: $P < 0.01$, data not shown). Lag times did not correlate with gender, age, or the number of ε4 alleles of *APOE* (APOE4). Although ΔRFU at both 5 and 10 mM AAPH tended to be greater in AD patients than in controls, these were not statistically significant differences (Fig. 2B). There was no significant difference in the propagation rates between AD and control CSF (data not shown).

In addition to generating fluorophores, extensive modification of protein with lipid peroxidation products can increase apparent molecular mass and in some cases lead to protein cross-linking (27). Such changes in the electrophoretic mobilities of apoAI and apoE were observed after oxidation of CSF with 5 and 10 mM AAPH (Fig. 3A and 3B). The apparent molecular masses of apoAI and apoE monomers increased with increasing oxidation by AAPH. Nonreducible abnormally high molecular weight species that were immunoreactive for apoAI and apoE also were observed with 5 and 10 mM AAPH (data not shown). The electrophoretic migrations of apoAI and apoE were significantly altered from the control at 5 and 10 mM AAPH (ANOVA: $P < 0.001$, Fig. 3C). In contrast to these two major CSF apolipoproteins, there was no change in the migrations of the two major CSF proteins not contained in lipoproteins, albumin and immunoglobulin, after oxidation with AAPH. Changes in electrophoretic mobilities of apoAI and apoE did not differ significantly between AD and control CSF, nor was there any relationship to the number of APOE4 alleles. These data suggest that CSF lipoproteins were a target for lipid peroxidation when CSF was incubated with the hydrophilic radical generator, AAPH.

The previous experiments were performed on whole CSF rather than isolated CSF lipoproteins because of the likely interactions between lipid- and water-soluble antioxidants in CSF. The next goal was to determine whether oxidized CSF lipoproteins carry some pathological significance. To accomplish this, CSF lipoproteins ($d < 1.210$ g/mL fraction) were isolated and oxidized with AAPH exactly as described for whole CSF. The alterations in electrophoretic mobilities of apoAI and apoE following incubation with AAPH under these conditions were identical to those described for whole CSF (data not shown). CSF lipoproteins were incubated with Neuro2A cells to assess neurotoxicity. Neuro2A cells were selected because this neuronal cell line has been used extensively to study the neurotrophic effects of human apoE-containing lipid particles, and Neuro2A cells have been shown to bind and internalize artificial lipid particles bearing human apoE isoforms (28).

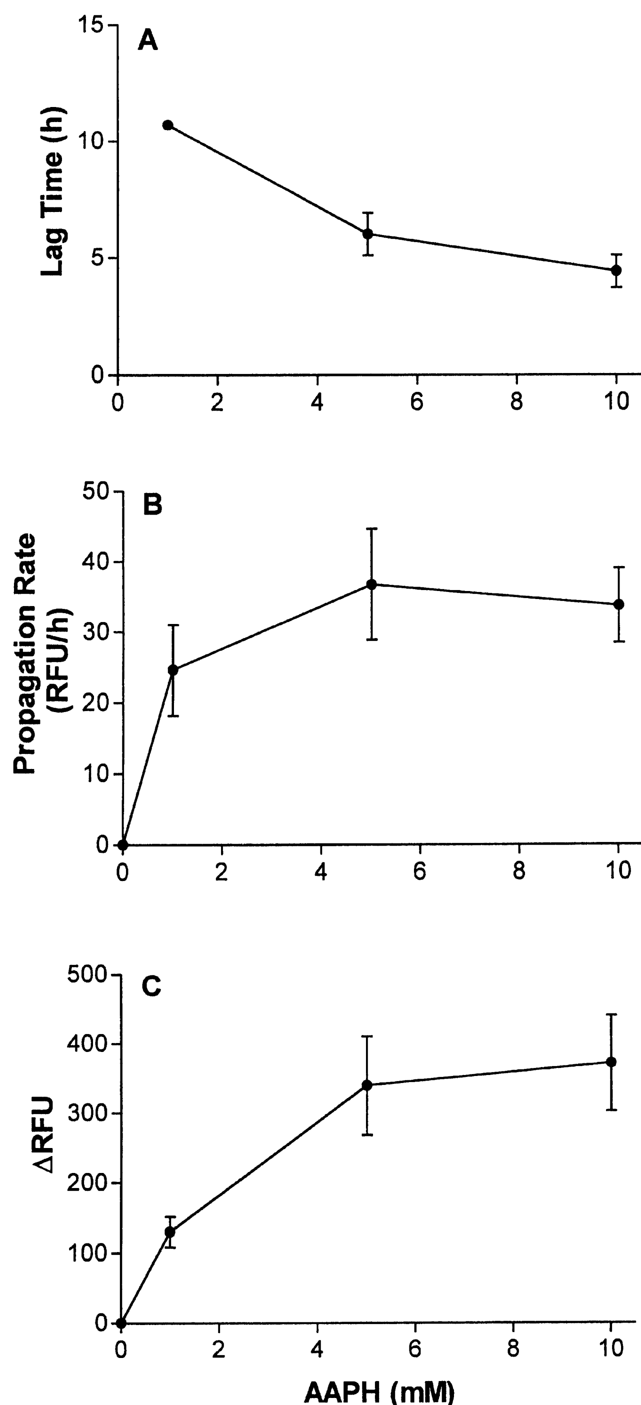

FIG. 1. Cerebrospinal fluid (CSF) oxidation by 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH). Alzheimer's disease (AD) CSF samples (n = 7) were incubated with 0, 1, 5, or 10 mM AAPH at 37°C for 24 h. Fluorescence (excitation at 360 nm, emission at 430 nm) was measured every 15 min. Plots of relative fluorescence units (RFU) vs. time were used to compute (A) lag time (h), (B) propagation rate (RFU/h), and (C) ΔRFU for each CSF sample. Values are presented as mean ± SEM of triplicate determinations. Analyses of variance were significantly different for lag time ($P < 0.001$) and ΔRFU ($P < 0.05$) over the concentration range 1 to 10 mM AAPH. Propagation rate did not change significantly over these concentrations of AAPH. There were no differences between 5 and 10 mM AAPH for any of the three variables.

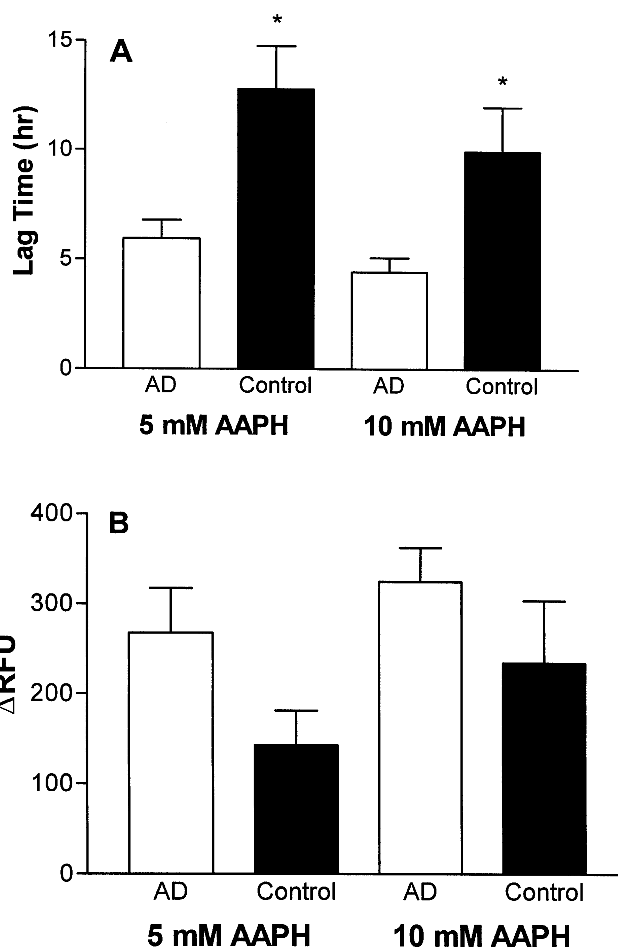

FIG. 2. Comparison of CSF oxidation between AD patients and controls. CSF from AD patients (n = 7) and controls (n = 5) was incubated with 5 or 10 mM AAPH at 37°C for 24 h. Fluorescence (excitation at 360 nm, emission at 430 nm) was measured every 15 min. Plots of RFU vs. time were used to compute (A) lag time (h) and (B) ΔRFU for each sample. Values are presented as mean ± SEM. Lag times for AD patients were significantly shorter than controls at both 5 and 10 mM AAPH (*, $P < 0.05$). Neither lag time nor ΔRFU was significantly different between 5 and 10 mM AAPH in AD patients or controls. For abbreviations see Figure 1.

Uptake of human CSF lipoproteins by mouse Neuro2A cells was confirmed by labeling CSF lipoproteins with DiI and visualizing incorporation into cells by fluorescence microscopy. Incubation of cells with DiI-labeled CSF lipoproteins led to rapid incorporation of fluorescent label into cells (Fig. 4). The vesicular pattern of fluorescence observed in Neuro2A cells following incubation with DiI-labeled CSF lipoproteins is characteristic of lipoprotein uptake into the endosomal-lysosomal system. A similar pattern of DiI uptake was observed with CSF lipoproteins oxidized with 10 mM AAPH. No DiI incorporation into cells was observed with lipoprotein-free medium (data not shown).

Nonoxidized and oxidized CSF lipoproteins were incubated with Neuro2A cells at physiologic concentrations and cell death was quantified. Sufficient CSF lipoproteins were

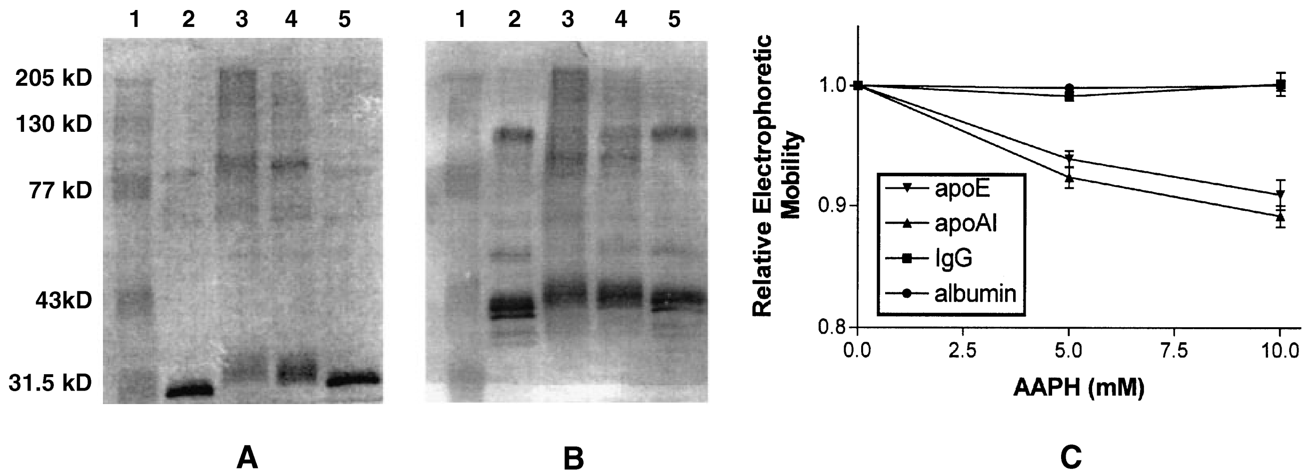

FIG. 3. Effects of AAPH on electrophoretic mobilities of CSF proteins. CSF from all 12 individuals were incubated with increasing concentrations of AAPH at 37°C for 24 h and then aliquots were taken, diluted 1:1 (vol/vol) in 2× Laemmli sample buffer, and boiled for 5 min. Proteins were separated by 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis and either stained with Coomassie Blue or transferred to nitrocellulose and probed with anti-apoprotein (apo)AI or anti-apoE antibodies. (A) Anti-apoAI immunoblot and (B) anti-apoE immunoblot demonstrating the apparent increase in molecular mass of apoAI and apoE and the appearance of abnormally high molecular weight immunoreactive species. Lane 1 is molecular weight markers; lane 2 is CSF; lanes 3 to 5 are the same individual's CSF oxidized with 10, 5, or 1 mM AAPH, respectively. (C) Electrophoretic mobilities were determined by measuring the distance that the monomeric proteins migrated from the gel origin. Results from AAPH-exposed CSF are expressed relative to unexposed CSF. Electrophoretic mobilities were determined for apoE, apoAI, albumin, and immunoglobulin (IgG). Values are presented as mean ± SEM of triplicate determinations of all CSF samples. Eletrophoretic mobilities of apoE and apoAI, but not albumin and IgG, changed significantly over this concentration range (analysis of variance: $P < 0.001$). There was no difference between AD patients ($n = 7$) and controls ($n = 5$). For other abbreviations see Figure 1.

available to perform these experiments with samples from four individuals, two AD patients and two controls. Incubation of Neuro2A cells with nonoxidized CSF lipoproteins from control or AD patients did not produce significant neurotoxicity. Oxidized preparations using PBS rather than CSF lipoproteins were not neurotoxic. Incubation of Neuro2A cells with increasingly oxidized CSF lipoproteins resulted in a highly significant linear relationship between the extent of lipoprotein oxidation and neurotoxicity ($P < 0.001$, Fig. 5). There was no apparent difference in CSF lipoprotein-mediated neurotoxicity between AD patients and controls; however, the number of individuals is too small to allow a valid comparison between groups.

A final series of experiments was performed to determine whether the extent of CSF lipoprotein oxidation by AAPH correlated with degree of neurotoxicity. The concentration–response relationship for AAPH-mediated consumption of fatty acids in CSF lipoproteins was determined in two individuals from whom there was the largest volume of CSF (Fig. 6). Absolute concentrations of CSF lipoprotein fatty acids were similar to those previously reported (16). There was a significant concentration–response relationship between AAPH and reduction in total fatty acids, arachidonic acid, and docosahexaenoic acid ($P < 0.001$ for each measure). As expected, docosahexaenoic acid was most vulnerable, arachidonic acid was intermediate, and total fatty acids were least vulnerable to oxidation by AAPH (29).

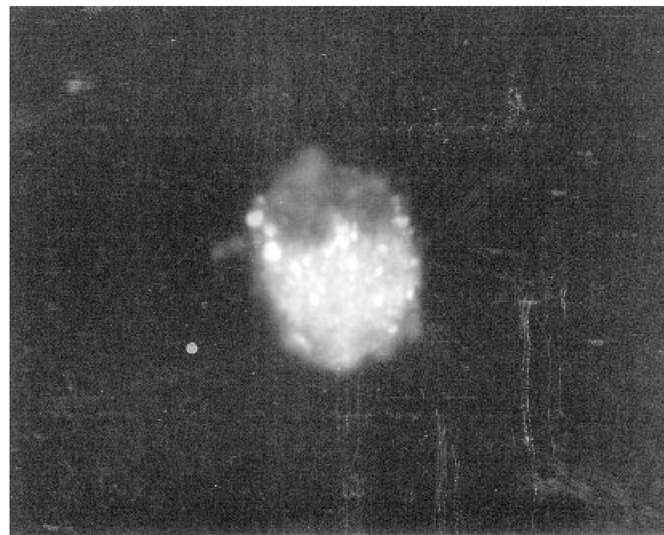

FIG. 4. Incorporation of fluorescent-labeled CSF lipoproteins into Neuro2A cells. CSF lipoproteins ($d < 1.210$ g/mL fraction) were labeled with 1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate, filter sterilized, diluted in growth medium (1:1 vol/vol), and then incubated with Neuro2A cells for 1 h at 37°C. Cells were then washed, fixed, and examined by fluorescence microscopy using rhodamine filters (× 1000). For abbreviation see Figure 1.

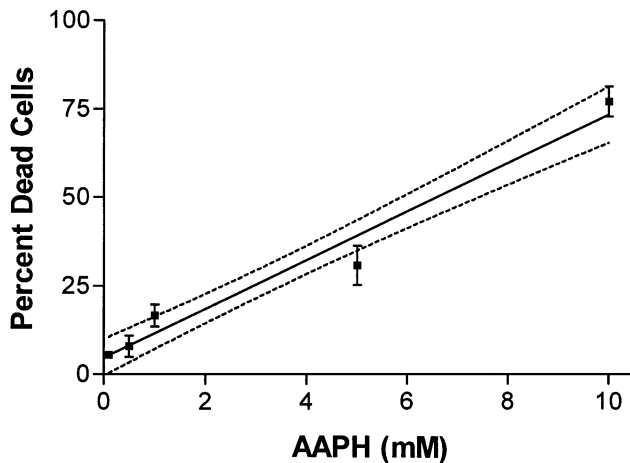

FIG. 5. Cytotoxicity of oxidized lipoproteins in Neuro2A cells. CSF lipoproteins (d < 1.210 g/mL fraction) were prepared from four different individuals (two control subjects and two AD patients). CSF lipoproteins or phosphate-buffered saline (PBS) alone was oxidized by incubation with increasing concentrations of AAPH for 18 h at 37°C and then dialyzed against PBS. CSF lipoprotein-containing samples were diluted with culture medium to give a final concentration of 25 μg protein/mL; samples without CSF lipoproteins were similarly diluted. All samples were incubated with Neuro2A cells for 24 h. Cytotoxicity was determined using the Live/Dead Kit (Molecular Probes, Eugene, OR) and counting over 500 cells per culture. Duplicate experiments were performed with each sample, and the average value for each of the four patients was then used to compute the mean and SEM. Oxidized PBS without CSF lipoproteins was nontoxic. Drawn are the best fit regression line (P < 0.001) and the 95% confidence intervals for CSF lipoprotein-containing samples. For abbreviations see Figure 1.

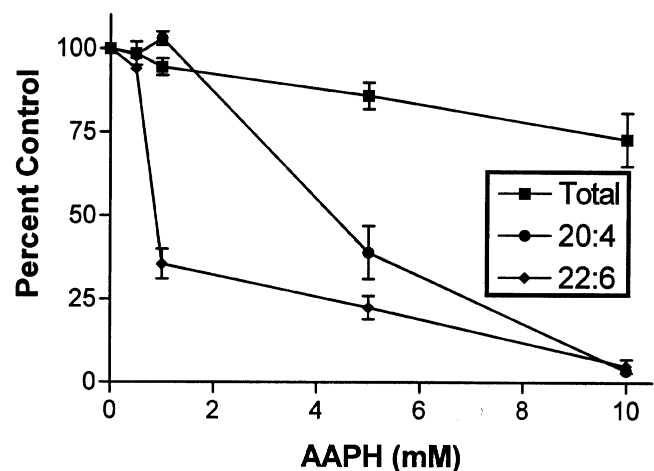

FIG. 6. Changes in CSF lipoprotein fatty acids following oxidation with AAPH. CSF lipoproteins (d < 1.210 g/mL fraction) were prepared from two different individuals (one control subject and one AD patient) and then incubated with 0, 0.5, 1, 5, or 10 mM AAPH for 18 h at 37°C. The concentrations of fatty acids (μg/mg protein) were determined twice for each sample using gas chromatography. Data are presented as a percentage of nonoxidized fatty acid levels. For abbreviations see Figure 1.

DISCUSSION

Regionally increased brain lipid peroxidation has been a consistent finding in postmortem studies of the AD brain (5), and increased CNS lipid peroxidation recently has been demonstrated in probable AD patients early in the course of dementia (7). In combination with these clinical studies, several experimental investigations have shown that lipid peroxidation products may cause neurodegeneration that mimics some of the features of AD (8). Here we have shown that CSF from AD patients was more vulnerable to lipid peroxidation than CSF from age-matched controls, that CSF lipoproteins were a target of oxidative damage to CSF, and that oxidized CSF lipoproteins were neurotoxic. These results suggest that oxidized CSF lipoproteins could play a role in the pathogenesis of neurodegeneration.

Several sources of increased free radical production have been proposed in AD. Recent attention has focused on extracellular sources of free radicals such as aggregated Aß peptides and products released by activated glia and inflammatory cells (8,30). These data would predict that brain extracellular fluid, and not just intracellular contents, could be exposed to oxidative stress in AD. We selected AAPH *ex vivo* oxidation of CSF to model the excess free radical generation in brain extracellular fluid that may occur in AD because CSF derives in large part from brain extracellular fluid and there is extensive literature on AAPH-mediated plasma lipoprotein oxidation (21,31). Earlier studies have shown that AAPH is a hydrophilic radical generator that, under the conditions used here, generates a constant low radical flux in the aqueous phase (32). Thus, AAPH-mediated oxidation of CSF *ex vivo* is a reasonable model of excess free radical generation in brain extracellular fluid *in vivo*.

Our results showed significantly shortened lag times for CSF oxidation by AAPH in AD patients compared with controls, indicating reduced antioxidant capacity in CSF from AD patients. Although this is the first demonstration of reduced antioxidant capacity in CSF, others have shown that brain tissue from AD patients may have reduced antioxidant capacity compared to controls (33–35). Moreover, recent clinical trials have shown a therapeutic benefit from α-tocopherol supplementation in AD patients (36). In combination, these data suggest that AD brain oxidative damage results in part from reduced antioxidant defenses. A potential application of our finding of reduced lag times in AD CSF resides with the ability to obtain CSF during life, thus raising the possibility of measuring CNS antioxidant status and assessing the efficacy of antioxidant therapeutics in living AD patients.

Braak staging is a histopathological grading system for AD; increasing Braak stage from I to VI indicates increasing severity of AD pathological changes (19). Shorter lag times for CSF oxidation, indicating reduced antioxidant capacity, were significantly associated with more severe AD pathological changes. It is noteworthy that lag times did not correlate with the number of APOE4 alleles. *In vitro* evidence has suggested that apoE may act as an antioxidant and that apoE4 is the least effective of the human apoE isoforms in this role (37). Investigation of apoE isoforms was not a goal of this study, and our results are limited by a relatively low number patients with different *APOE* genotypes and only one homozygous APOE4 individual. Despite these limitations, our data do not support a major

difference in the antioxidant function of native apoE3 vs. apoE4 in CSF under these experimental conditions.

The fluorescent products generated during lipoprotein oxidation are formed primarily by complex protein adducts from lipid peroxidation products (38). Some of these lipid peroxidation products covalently cross-link apolipoproteins (21,27). For example, oxidation of plasma LDL or exposure of LDL to lipid peroxidation products results in changes in electrophoretic mobility of apoB and covalent cross-linking of apoB (22,39). There is no apoB in human CSF (10,12,13,17). Rather, apoE and apoAI are the two major apolipoproteins in CSF. Protein adduct formation was confirmed on CSF apolipoproteins by the progressive increase in molecular masses of apoE and apoAI with increasing concentrations of AAPH. The very high molecular weight species containing epitopes for apoE and apoAI likely represent proteins that have been covalently cross-linked. Our results also showed that CSF proteins not contained within lipoproteins were not significantly modified by incubation with the hydrophilic agent, AAPH. These data suggested that lipoproteins were a major target for lipid oxidation in CSF. This is not surprising given that most of the lipid in CSF is contained within lipoprotein particles. However, these data are important because they underscore the potential for CSF lipoproteins to harbor a disproportionate load of lipid peroxidation products following oxidation of CSF.

Oxidized plasma lipoproteins, especially LDL, are thought to contribute importantly to the pathogenesis of another age-related disease, atherosclerosis. Our results with oxidized CSF and CSF lipoproteins parallel several findings with oxidized plasma and LDL. First, the vulnerability to oxidation of plasma and LDL is greater in patients with coronary artery disease, atherosclerosis, and hyperlipidemia compared to controls (40–45). Here we showed that CSF from AD patients is more susceptible to lipid peroxidation than controls. Second, oxidation of plasma or LDL results in modifications of apoB (21,22). Our study demonstrated that CSF apolipoproteins are relatively selectively modified under oxidizing conditions. Finally, oxidized plasma lipoproteins are cytotoxic to a variety of cell types (21), including neurons (46–49). We showed for the first time that oxidized CSF lipoproteins at physiologic concentrations are cytotoxic to neurons.

Despite these similarities, plasma lipoproteins and CSF lipoproteins have several important differences in their concentrations, lipid content, and apolipoprotein composition (10–13,16,17). It is important to note that, despite using physiologic concentrations of CSF lipoproteins, the extent of CSF lipoprotein oxidation necessary to induce significant neurodegeneration in our assay (i.e., 5 or 10 mM AAPH) produced changes in CSF lipoproteins that exceed those observed in AD patients (16,17). A similar situation exists for LDL oxidation and atherosclerosis; numerous experiments have shown that *ex vivo* oxidized LDL may contribute to atherogenesis, but appropriately modified LDL has been difficult to demonstrate in plasma (21). One explanation for this apparent discrepancy is that oxidized LDL is generated locally in atherosclerotic plaques and does not reach significant concentrations in the general circulation. This argument also may apply to oxidized lipoproteins in brain extracellular fluid vs. CSF and potentially explains why we did not observe neurotoxicity with nonoxidized CSF lipoproteins from AD patients. Moreover, we measured relatively acute neurotoxicity, in contrast to a disease that typically spans a decade. Protracted exposure to less extensively oxidized CSF lipoproteins possibly could contribute to neurodegeneration *in vivo*.

ABSTRACT: This study examines the relationship between high density lipoprotein-3 (HDL-3) glycation and cholesteryl ester transfer mediated by cholesteryl ester transfer protein (CETP). HDL-3 were glycated with various glucose concentrations (0–200 mM) for 3 d at 37°C with sodium cyanoborohydride as reducing agent and antioxidants. About 47% of the lysine residues were glycated in the presence of 200 mM glucose, resulting in an increase in the cholesterol ester (CE) transfer of about 30%. Apparent kinetic parameters [expressed as maximal transfer (appT_{max}) and CE concentration at half of T_{max} (appK_H)] of CETP activity with glycated HDL-3 showed conflicting and paradoxical data: an increase in CETP activity associated with a decrease of CETP affinity. These alterations were not due to a change in HDL-3 lipid and protein composition nor to a peroxidative process but were associated with an increase in HDL-3 electronegativity and a decrease of HDL-3 fluidity. This study suggests that glycation modifies the apolipoprotein's conformation and solvation which are major determinants of interfacial properties of HDL-3. These modifications in turn affect CETP reactivity.

Paper no. L8082 in *Lipids 34,* 1281–1286 (December 1999).

The glycation of proteins in the pathogenesis of diabetes has been extensively investigated (1–4). As regards high density lipoproteins (HDL), recognized as protective against the atherosclerotic process (5), previous studies have shown that HDL glycated *in vitro* are functionally abnormal. They impair HDL-receptor-mediated cholesterol efflux (6), inhibit the high-affinity binding to cultured cells (7), and alter lecithin-cholesterol acyl transferase (LCAT) reactivity (8,9).

Cholesteryl ester (CE) transfer, a central step in reverse cholesterol transport, is mediated by the cholesteryl ester transfer protein (CETP), which is responsible for all of the neutral lipid transfer activity between lipoproteins (10–12). Furthermore, CETP is one of the major factors that remodels the concentration of HDL in circulation by mediating the heteroexchange of CE from HDL for triacylglycerols (TG) from very low density lipoproteins, which results in an enrichment of apoprotein (apo) B-containing lipoproteins with CE and HDL with TG. Bagdade *et al.* (13,14) have reported that the cholesteryl ester transfer is increased in both insulin-dependent diabetes mellitus and noninsulin-dependent diabetes mellitus (NIDDM). They have suggested that the compositional modifications of lipoproteins may enhance their interaction with CETP. In contrast, Ahnadi *et al.* (15) observed low *in vitro* rates of CE transfer using HDL from NIDDM patients and concluded that HDL from these patients have a decreased ability to transfer CE. As proposed by Van Tol (16), the reason for this low transfer could be that an accelerated *in vivo* transfer makes these HDL an inferior CE donor *in vitro*. Recently, Passarelli *et al.* (17) observed greater transfer rates with glycation of the donor and acceptor lipoproteins simultanously and suggested that glycation of HDL alone plays the major role in enhancing the transfer rate. Given the extreme complexity involved in CETP-mediated lipid exchanges, we chose to investigate the effects of *in vitro* glycation of HDL-3 alone (the more homogeneous of the HDL subfractions) on CE transfer. We demonstrate that *in vitro* glycation of HDL-3 affects the apparent kinetic parameters (appT_{max} and appK_H) of CETP in a paradoxical way.

MATERIALS AND METHODS

Isolation of HDL-3 particles. Fresh citrated plasma from nondiabetic donors was provided by the Centre de Transfusion Sanguine (Hôpital Larrey, Angers, France). HDL-3 were isolated as the plasma fraction of density 1.125–1.21 g/mL by sequential ultracentrifugation at 130,000 × g for 40 h. The HDL-3 fraction was subsequently washed with one 40-h spin at its upper density. The isolated lipoproteins were dialyzed 48 h against 10 mM Tris-HCl buffer (pH 7.4) containing 150 mM NaCl, 0.01% NaN_3 (wt/vol), and 0.01% EDTA (wt/vol).

CETP preparation. CETP was purified from normolipidemic human plasma as described by Lagrost *et al.* (18). Briefly, the plasma protein fraction precipitated with ammonium sulfate between 35 and 65% of saturation was then subjected to ultracentrifugation at a density of 1.21 g/mL. The re-

sulting d >1.21g/mL fraction was then subjected successively to hydrophobic interaction chromatography on a phenyl-Sepharose column (CL-4B; Pharmacia Biotech, Uppsala, Sweden), to cation exchange chromatography on a carboxymethyl-cellulose column (CM52; Whatman, Maidstone, England), to affinity chromatography on an heparin hyper-D column (Biosepra), and to anion exchange chromatography on a DEAE-Trisacryl column (Biosepra, Villeneuve La Garenne, France). All chromatographic separations were carried out on a fast protein liquid chromatography system (Pharmacia Biotech) at 4°C. A linear gradient ranging from 0 to 0.5 M NaCl was used to elute the CETP from the DEAE-Trisacryl column. The active fractions, which were eluted with a Tris 20 mM–NaCl 150 mM (pH 7.4) buffer were pooled, aliquotted and stored at −80°C. The CETP preparation was deprived of apo A1 and of both LCAT and phospholipid transfer protein. Its activity was increased by about 2,000×.

Preparation of radiolabeled lipoproteins. HDL-3 labeled with ^{3}H-CE were prepared by combination of the LCAT and CETP reactions (9). ^{3}H cholesterol (50 µCi) dissolved in 100 µL absolute ethanol was added to 10 mL of a d > 1.125 g/mL fraction of human plasma and incubated at 37°C for 18 h. The density fraction 1.125–1.21 g/mL was isolated. Trace amounts of this fraction were incubated with a large excess of native HDL-3 and partially purified CETP at 37°C for 18 h. At the end of the incubation, CE-labeled HDL-3 was reisolated without CETP by ultracentrifugation at 1.21 g/mL; 94% of the radioactivity was in the form of CE, and the chemical composition of the labeled HDL-3 was very similar to that of native HDL-3. The specific radioactivity was about 3,500 dpm/nmol CE.

HDL-3 glycation. HDL-3 was glycated *in vitro* as previously described by Duell *et al.* (7). Briefly, ^{3}H-CE-HDL-3 were incubated 3 d at a concentration of 1 mg protein/mL in 0.9% NaCl/1 mM EDTA containing 0–200 mM glucose, sodium cyanoborohydride (12 mg/mL), and the antioxidants butylated hydroxytoluene (25 mM) and diethylenetriaminepentaacetic acid (50 mM). Control and glycated HDL-3 were dialyzed four times against 0.9% NaCl/1 mM EDTA before use. The amount of glycation was quantified with the trinitrobenzenesulfonic acid (TNBS) assay which specifically reacts with free amino groups of amino acid residues (19). Briefly, 50 µg glycated HDL-3 (1 mg/mL) was added to 1 mL 4% $NaHCO_3$, pH 8.4, mixed with 50 µL 0.1% TNBS, and incubated for 1 h at 37°C. The absorbance at 340 nm is a linear function of the concentration of trinitrophenyl derivatives. Hence, the relative reduction in absorbance for glycated HDL-3 (gHDL-3) compared with control HDL-3 is a direct indication of the relative loss of free lysine and $-NH_2$ terminal amino groups. The percentage of derivatized residues was calculated as follows:

$$\% = \frac{\text{absorbance of control HDL} - \text{absorbance of glycated HDL}}{\text{absorbance of control HDL}} \times 100 \quad [1]$$

CETP activity. CETP activity was assayed in duplicate using different CETP and HDL-3 preparations. Transfer rates were measured in conditions where transfer was linear with time of incubation; that is, less than 30% of HDL-3 radiolabeled CE (^{3}HCE) transferred. Transfer of ^{3}HCE was measured by incubating gHDL-3 (0.2 mM CE) with LDL (1 mM CE) and CETP. All incubations were carried out for 3 h at 37°C in Tris buffer pH 7.4, in a final volume of 250 µL. Then HDL and LDL were immediately separated by a single-spin centrifugation at d = 1.07 g/mL. Radioactivity in donor and acceptor lipoproteins was determined by liquid scintillation counting, and the percentage of cholesteryl ester radioactivity transferred was calculated. Incubations lacking CETP were used as control and were subtracted from that measured for the test. To investigate the effects of HDL-3 glycation on the CETP activity, the kinetic parameters that represented the maximal velocity of transfer T_{max} and the concentration required for half-maximal velocity K_H of the CE transfer were analyzed. gHDL-3 with an extent of glycation of about 21 and 47% and in a concentration range from 12.5 to 500 mM CE were incubated with LDL (1 mM CE) and CETP. As described by Sparks and Pritchard (20), we have determined values analogous to V_{max} and K_m as T_{max} and K_H.

Fluorescence polarization studies. Fluidity of lipoproteins was studied by determining the fluorescence anisotropy (r) of the probe 1,6-diphenyl-1,3,5-hexatriene (DPH). Lipoproteins were labeled with DPH following the procedure described by Dachet and coworkers (21). Briefly, a fresh dispersion of DPH was incubated in 1.5 mL of a buffer containing 10 mM Tris, 150 mM NaCl, 0.01% NaN_3 (wt/vol), and 0.01% EDTA (wt/vol), pH 7.4 with 50 µL of lipoprotein, for 20 min at 24°C with gentle agitation. The probe concentration was chosen so that the final probe/phospholipids ratio was always less than 1:1000, and incubation time was controlled in order to limit the probe diffusion into the lipoprotein core. Immediately after labeling, fluorescence measurements were carried out on a PerkinElmer MPF 66 spectrofluorimeter (Norwalk, CT) equipped with a fluorescence polarization accessory and a controlled temperature cell holder. The excitation and emission wavelengths were 360 and 430 nm, respectively. The fluorescence anisotropy was obtained from the fluorescence intensities parallel ($I_{\parallel}$) and perpendicular ($I_{\perp}$) to the polarization direction of excitation light using the equation of Schachter and Shinitsky (22):

$$r = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}} \quad [2]$$

Characterization of gHDL-3. Oxidation of control and gHDL-3 was measured as the amount of thiobarbituric acid-reactive species (TBARS) (23). Total and free cholesterol, phospholipids, and triacylglycerols were determined with enzymatic test kits from (total and free cholesterol: Boehringer-Mannheim; triglycerides: Ultimate, Roche; phospholipids: PAP150, Biomerieux). Protein concentrations were determined as described by Lowry *et al.* (24) using serum albumin as standard. In order to qualitatively check modifications elicited by glucose, electrophoretic mobility of gHDL-3 was analyzed on agarose gel stained with Oil red (Ciba Corning, Cergy Pontoise, France) and on 2–3% polyacrylamide gels stained with

Sudan black and Coomassie blue (Sebia, Issy les Joulineaux, France). The *z* potential was analyzed in distilled water with a DELSA 440 apparatus (Coultronics, Margency, France). Particles size was evaluated by nondenaturing gradient gel electrophoresis on 1.5–25% spiragel (Spiral, Couternom, France).

Statistical analysis. Means ± SD are given. Paired *t* tests (two-tailed) were used to determine the significance of differences. *P* values <0.05 were considered significant.

RESULTS

HDL-3 glycation. The extent of HDL-3 glycation assessed by the TNBS assay was positively related to the glucose concentration. about 21 ± 4.7% ($n = 4$) and 47 ± 8.9% ($n = 8$) of free lysine residues in HDL-3 were glycated after 3 d in the presence of 50 and 200 mM glucose, respectively, with sodium cyanoborohydride and antioxidants (Fig. 1). This result is in agreement with the results of Duell *et al.* (7) and Passarelli *et al.* (17), who reported that about 40 and 70% of free lysine residues in HDL-3 were glycated after incubation for 4 d with 150 and 200 mM glucose, respectively.

CETP activity. In experiments with 0.2 mM ^{3}HCE of control and gHDL-3 incubated with LDL (1 mM CE) and CETP, the CETP-mediated lipid transfer and the extent of HDL-3 glycation appeared to be positively related to the glucose concentration. Figure 1 shows that CETP activity increases whatever the level of HDL-3 glycation and that a low level of glycation (derived residues <10%) leads to a significant increase of CETP activity (13.7%). For high levels of HDL-3 glycation [derived residues 21 and 47%, a value near that obtained by Passarelli *et al.* (17) on diabetic HDL-3] the percentage of increase of CE transfer (compared with control HDL-3) was about 23 and 30%, respectively.

The curves presented in Figure 2 were the most representative of four saturation curves. The kinetic analysis of CETP activity with high levels of glycated HDL-3 shows that the CETP-mediated CE transfer in the presence of control or modified HDL-3 tends toward a saturable process. The apparent T_{max} and K_H calculated from experimental data using linear regression (1/*T* vs. 1/s) are significantly increased in gHDL-3 compared to control HDL-3 (Table 1). The T_{max}/K_H ratio which represents the CETP protein efficacy is identical for the control and gHDL-3.

Fluorescence polarization studies. The mean steady-state fluorescence anisotropy values at 24°C of DPH in control and

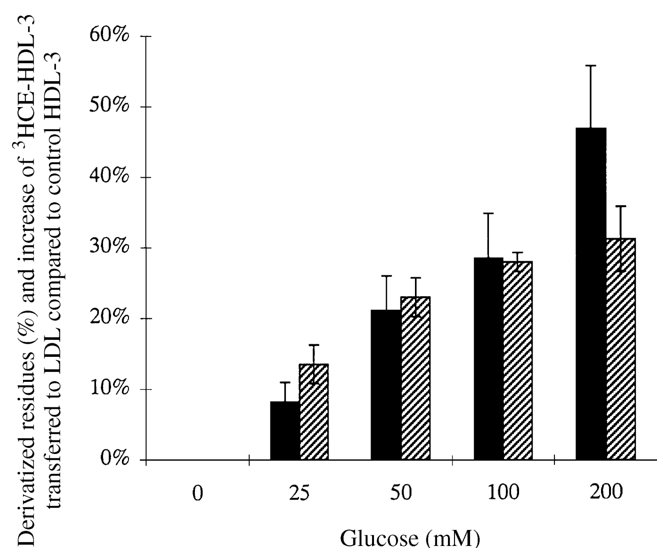

FIG. 1. Influence of glucose concentration on high density lipoprotein-3 (HDL-3) glycation level and on tritiated cholesterol ester (^{3}HCE)-HDL-3 transfer. Incubations were carried out with 0.2 mM CE-HDL-3 and 1 mM CE-low density lipoprotein (LDL) and cholesterol ester transfer protein (CETP) at 37°C for 3 h; solid block, % derivatized residues; diagonally lined block, % increase of ^{3}HCE-HDL-3 transferred by CETP to LDL as compared to control HDL-3. Data are means of four determinations (±SD) for 0, 25, and 100 mM glucose and eight determinations (±SD) for 50 and 200 mM glucose.

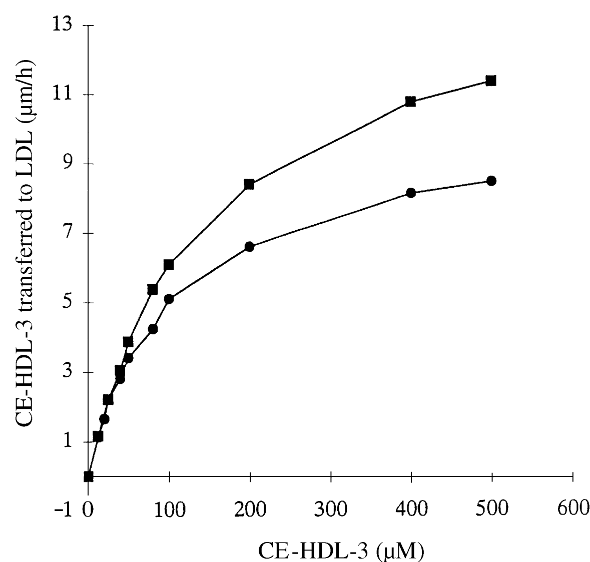

FIG. 2. Kinetic analysis of cholesteryl ester transfer by CETP from (●) control HDL-3 or (■) *in vitro* gHDL-3 (47%) to LDL during 1 h incubation, in a range of 12.5 to 500 µM CE-HDL-3. Concentration of acceptor lipoprotein (LDL) was 1 mM CE. The curve is the most representative of four different experiments made in duplicate. See Figure 1 for abbreviations.

TABLE 1
Kinetic Parameters of the CE Transfer from HDL-3 to LDL Mediated by CETP[a]

	appK_H (µM CE-HDL-3)	appT_{max} (µM CE-HDL-3/transferred/H)
Control-HDL-3	100 ± 17.2	10.1 ± 1.5
gHDL-3 (21%)	111 ± 18	11.6 ± 0.9
gHDL-3 (47%)	138.7 ± 40	14.5 ± 2.2
	($P < 0.05$)	($P < 0.01$)

[a]appK_H and appT_{max} values are means ± SD from four different gHDL-3 (47%) and two different gHDL-3 (21%). They were determined from 1/*T* vs. 1/*S* curves. Linear regression factors ranged from 0.98 to 0.99. CE, cholesterol ester; HDL-3, high density lipoprotein-3; LDL, low density lipoprotein; CETP, cholesterol ester transfer protein; gHDL-3, glycated HDL-3.

in vitro gHDL-3 (47%) were determined with the following results [glucose concentration (mM); fluorescence anisotropy (mean ± SD, $n = 4$; $*P < 0.05$ vs. control)]: 0, 0.181 ± 0.007; 25, 0.184 ± 0.007*; 50, 0.185 ± 0.004*; 100, 0.186 ± 0.004*; 200, 0.191 ± 0.005*. At all four glucose concentrations, values were significantly greater than those of the HDL-3 control (0.181 ± 0.007). As with the extent of glycation, most of the increase in fluorescence anisotropy was observed for the HDL-3 incubated with 200 mM glucose.

HDL-3 charge and composition. As shown in Table 2, the lipid and protein compositions of *in vitro* control and gHDL-3 (47%) are very similar to native HDL-3. However the determination of the ζ potential showed an increase of the electronegativity of gHDL-3 of about 49 ± 19%. Analysis of native and glucose-treated HDL-3 by electrophoresis showed that gHDL-3 moved faster on agarose gel and slower on acrylamide gel in proportion to glucose incorporation. Moreover, glycation had little influence on the staggering of the migration pattern (data not shown). These results did not agree with the observation of Fournier *et al.* (9) and Passarelli *et al.* (17) who found no change in the electrophoretic mobility of their *in vitro* glycated HDL.

On a polyacrylamide gradient gel (1.5 to 25%) a slight increase in size was observed according to the level of glycation: 6 to 11.5 nm for native HDL-3; 8 to 12.5 nm for control HDL-3; 8.15 to 13.2 nm for gHDL-3 (21%), and 9.3 to 16.3 nm for gHDL-3 (47%). The pattern of control HDL-3 is comparable to native HDL-3 one, and about 60% of gHDL-3 (47%) had a size less than 12 nm (data not shown).

DISCUSSION

The plasma activity level of CETP is a controversal subject in the development of atherosclerosis in diabetes. Recently, Passarelli *et al.* (17) observed greater transfer values between lipoproteins of diabetic subjects compared to those of control subjects and also observed that a high glycation level of HDL increases CETP activity. They also suggested that *in vitro* glycation of HDL-3 alone plays the major role in enhancing the transfer rate. This work showed that CETP activity increases with HDL-3 glycation level in a proportional way even at a low glucose concentration (25 mM), which could represent a plasma glucose concentration in a diabetic subject. In order to explain this result, we analyzed the kinetics parameters of CETP activity and some physicochemical properties of glycated HDL-3.

TABLE 2
Composition of Control and *in vitro* gHDL-3 (47%)[a]

	Control HDL-3 ($n = 4$)	gHDL-3 (47%) ($n = 8$)
Proteins	56 ± 3	58 ± 2
Phospholipids	25.4 ± 3.1	24.3 ± 2.1
Free cholesterol	1.9 ± 0.2	1.9 ± 0.3
Esterified cholesterol	14 ± 1.2	13.5 ± 1.7
Triglycerides	2.6 ± 1.1	2.1 ± 1.
ζ potential (mv)	–16.8 ± 5.5	–24.4 ± 4.9[b]
Size (nm)	8–12.5	9.3–16
Electrophoretic mobility (cm)	15.6 ± 0.6	17.2 ± 0.3

[a]The values are expressed as the percentage of each component (mean ±SD). [b]The values are expressed as the mean obtained with two different preparations of HDL-3. For abbreviations see Table 1.

The use of two levels of glycation (~21 and 47%) led to a significant increase of both appT_{max} (11.6 and 14.5 μM CE transferred/H) and appK_H (111 and 138.7 μM CE) as compared to control HDL-3 (appT_{max} = 10.1 μM CE transferred/H, appK_H = 100 μM CE), reflecting a reduced affinity of CETP for the glycated HDL-3 substrate and associated with a higher velocity of CE transfer. Similar paradoxical alterations of the LCAT activity were observed by Fournier *et al.* (9) for moderate *in vitro* glycated HDL-3 (derived residues <30%).

Our data, like those of Passarelli *et al.* (17), did not appear to be due to changes in HDL-3 chemical composition. No apparent alteration occurred in glycated HDL-3 in terms of lipid and protein composition or TBARS assay results. Glycation induced a slight increase in size, which could contribute to modifying interfacial properties of gHDL-3 without generating two distinct populations of small and large particles. However, the results obtained by electrophoresis (agarose and polyacrylamide gels) and measurements of potential showed an important increase in electronegativity of the modified HDL-3 due to decreased ionization of lysine residues. Masson and coworkers (25) reported that an optimal charge value is required for the maximal CETP transfer activity. Nishida *et al.* (26) proposed that the increased CETP activity observed with an increased lipoprotein negative charge was due to an increased affinity of CETP for lipoprotein and that above the optimal lipoprotein electronegativity, the decline in the transfer activity was caused by an excessive CETP–lipoprotein interaction. But in our glycation conditions, an increase in the extent of *in vitro* glycation corresponds to an increase in modified HDL-3 electronegativity and to a decrease in CETP affinity. This indicates that the CETP transfer activity is governed not only by electrostatic affinity but also by some other factor(s) such as the apo A-I conformation stability. In this way, Sparks and coworkers (27), who characterized structural spherical and discoidal recombinant HDL (rHDL), have demonstrated a strong relationship between the stability of apo A-I α helices and the surface charge characteristics of the apo A-I particles. It is known that glycation of apo A-I induces a decrease in its content of α helices (28) and a decrease in the stability of lipid–apolipoprotein complexes that affect the structural cohesion of HDL particles (29,30). We suggest that glycation, by increasing the soluble part of apoproteins as well as the surface electronegativity, alters the stability of apo A-I α helices and induces interfacial molecular reorganization of HDL-3. Such general events interfering with proteins functions are well described by Nylander (31).

Previous studies showed that addition of cholesterol to a discoidal rHDL directly affects both the conformation and charge of apo A-I by causing a significant reduction in the amount of α-helical structure in apo A-I and by modifying the physical properties of the rHDL particles (32). Increased cholesterol content has also been reported to affect LCAT activity by causing an increase of both appK_H and appV_{max} (33). Rajaram *et al.* (34) reported that the enhancement of CETP activity due to the

presence of unesterified cholesterol did not correlate with any increased binding of CETP to the emulsion surface. These elements led us to conclude that *in vitro* glycation affects CETP activity through a change in protein conformation, which causes a change of protein solvation in the lipoprotein envelope and an impaired association of lipids and apolipoproteins at the surface of the glycated HDL-3. This conclusion could be compatible with the work of Meng *et al.* (35) who propose a competition between apo A-1 and cholesterol for hydrophobic solvation by phospholipids and the possible existence of different pools of cholesterol within the lipoprotein whose distribution may vary in relation to apo A-1 domains. These events could induce a new repartition of lipids in HDL-3 and increase the solubilization of CE in the envelope, contributing to the reduced fluidity of glycated HDL-3 since cholesterol analogs like cholesterol-hemisuccinate are known as rigidifying agents (36). This agrees with the studies of Mac Ritchies (37), who has shown that interfacial pressure and electrical potential influence reaction rate by altering the distribution of species between bulk and interface. The mechanism responsible for the reduced fluidity of the glycated HDL-3 is not elucidated. It is not related to alterations in the cholesterol to phospholipids molar ratio but could be related to the extent of glycation as reported by Winocour and coworkers for platelet membranes from diabetic subjects (38). We think that this observed decrease of fluidity is a consequence of the decrease of the apo A-I helicity and the consecutive reorganization of the lipid–protein interactions. This supports earlier studies which showed that phospholipid order and apo A-I conformational stability are inversely related and together modulate the structural integrity of the discoidal rHDL (39–42).

The *in vitro* glycation of HDL-3, by increasing the hydrophobic part and the negative charge of the apolipoproteins, changes the apolipoproteins' conformation. This affects the lipidic solvation of the apoproteins and could increase the CE solubilization in the phospholipid envelope and create a better access of CE to CETP. Moreover, the curvature radius and the interfacial pressure are affected. These changes probably influence the CETP HDL-3 surface affinity. This is in good agreement with our recent work (43) in which we showed that CETP can penetrate a mixed lipid monolayer with a maximal penetration for unesterified cholesterol/phospholipid (UC/PL) ratio of 0.2, a value close to the ratio in native HDL-3, suggesting the presence of an optimal UC/PL ratio for a maximal CETP affinity. Glycation by inducing changes in packing density and in envelope composition modifies CETP activity.

Effect of Eicosapentaenoic Acid on the Proliferation and Incidence of Apoptosis in the Colorectal Cell Line HT29

Rosemary G. Clarke, Elizabeth K. Lund*, Peter Latham, Andrew C. Pinder, and Ian T. Johnson

Institute of Food Research, Norwich Research Park, Colney, Norwich, NR4 7UA United Kingdom

ABSTRACT: Fish oil has been shown to reduce the induction of colorectal cancer in animal models by a mechanism which may involve suppression of mitosis, increased apoptosis, or both. We used the human colonic adenocarcinoma cell line HT29 to explore the effects of the long-chain n-3 polyunsaturated fatty acid eicosapentaenoic acid (EPA) on cell proliferation and death *in vitro*. Cells were cultured in media containing EPA at 5, 10, and 15 μg/mL. Cell number and thymidine incorporation were used to quantify proliferation, and cell cycle effects were studied using flow cytometry. Gel electrophoresis, annexin-V binding, and morphological criteria were used to characterize apoptosis. Adherent cells and freely floating detached cells were treated as two distinct populations. In the presence of EPA at 10 and 15 μg/mL there was a marked reduction in the growth rate of adherent HT29 colonies, owing to an increased detachment of adherent cells. After treatment with 10 or 15 μg/mL EPA the proportion of adherent cells in S-phase increased, indicating either a block in late S-phase or early G2. Floating cells showed evidence of extensive DNA cleavage, but the proportion of floating cells with sub G0 DNA content declined on treatment with 10 or 15 μg/mL EPA even though the number of floating cells increased. We conclude that EPA does not inhibit mitosis of adherent cells, but increases the rate at which they become detached from the substrate, probably at an early stage in the initiation of apoptosis. This mechanism may be analogous to "anoikis," or induction of apoptosis in response to loss of cell contact, and may contribute to the anticarcinogenic effects of fish oil *in vivo*.

Paper no. L8189 in *Lipids 34,* 1287–1295 (December 1999).

Cancer of the colon is one of the major causes of mortality in the Western world (1). The most common route of disease progression is through development of adenomatous polyps, a small proportion of which develop into full-blown adenocarcinomas (2).The colonic crypts of healthy individuals have well-defined regions of cell proliferation, migration, and cell death (3). Increased rates of cell proliferation, associated with an enlargement of the proliferative compartment, have been observed in patients with adenomatous polyps (4), as well as other diseases known to predispose to colon cancer (5,6). The progression of colon cancer is thought to depend on the acquisition of mutations in genes controlling cell division and differentiation (7). A reduced rate of cell proliferation and an extension of the cell cycle time may therefore reduce the risk of mutation by allowing the repair of damaged DNA during S phase.

Epidemiological evidence suggests that diets rich in n-3 series polyunsaturated fatty acids (PUFA) found in marine fish oil are associated with a reduced risk of cancers (8,9) including colorectal carcinoma (10). Furthermore, dietary supplementation with n-3 PUFA has been found to reduce cell proliferation in the colonic crypts of patients who have previously undergone surgery for the removal of adenomas (11–13). In animal models, dietary supplementation with fish oil inhibits chemically induced colon carcinogenesis in rats (14,15) and mice (16), increases apoptosis in rats (17), and reduces colonic crypt cell proliferation in normal rats (17,18).

The effects of n-3 PUFA derived from marine oils on cell growth have previously been investigated using a variety of cultured tumor cell lines, including those derived from mammary (19,20) prostate (21), pancreatic (22,23), cervical (24), and colonic tissue (25). On the basis of this work two major theories have been proposed to account for the inhibition of tumor growth by n-3 PUFA. The first is that increased availability of n-3 PUFA modifies the lipoxygenase and cyclooxygenase pathways for eicosanoid synthesis so as to reduce the rate of cell proliferation (19,26). The second is that incorporation of n-3 PUFA into the membranes of cells increases their susceptibility to oxidative damage (27–29), and hence to programmed cell death (apoptosis). Since the rate of tumor growth is a function of the relative rates of mitosis and apoptosis (30), both theories provide plausible explanations for the inhibition of tumor growth by n-3 PUFA *in vivo*.

Apoptotic cell death in healthy colon tissue is well documented and is thought to be the means by which cell numbers are controlled within the crypt, and by which mature cells are lost from the epithelium into the colonic lumen (31). It has also been shown that reductions in the susceptibility to apoptosis play a role in the progression of colon cancer (32). In this study we explored the effects of the n-3 PUFA eicosapentaenoic acid (EPA) on the relative rates of proliferation and death of colon cancer cells, using the colonic adenocarcinoma cell line HT29. In preliminary studies using clonal survival assays we established that EPA was significantly more effective than either oleic or linoleic acid in reducing HT29 cell survival. The doses of EPA used in this study, 0–15 μg/mL,

are equivalent to the 10–20 μg/mL found in the plasma of unsupplemented individuals and are well below the 120 μg/mL found in subjects consuming approximately 1.5 g of EPA per day (33). A particular aim was to examine systematically both adherent cells and those that had become detached and were freely floating in the media, treating them as two distinct populations of cells. Proliferation was quantified using both cell numbers and incorporation of tritiated thymidine into the DNA. Apoptosis was examined using acridine orange staining (34), gel electrophoresis (35), and flow cytometric analysis of annexin V binding to cell membranes with externalized phosphatidylserine, characteristic of early apoptotic cells (36). The effects on adherent cell number following blocking of the protease, caspase, known to be involved in apoptosis were also tested.

MATERIALS AND METHODS

Cell culture. The colon adenocarcinoma cell line, HT29, was obtained from the European Collection of Cell Cultures (Salisbury, United Kingdom). On receipt, the cells had already gone through 140 passages and were used in this study after a further 5 to 10 passages. HT29 cells were grown in Eagle's minimal essential medium (MEM) containing Earle's salts (Sigma Chemical Company, Poole, United Kingdom) supplemented with 5% fetal calf serum, 2 mM glutamine, 50 units/mL penicillin, and 50 μg/mL streptomycin (all obtained from Imperial Laboratories, Andover, United Kingdom). Cells were grown at 37°C, 5% vol/vol CO_2 in a humidified atmosphere and harvested using phosphate-buffered saline (PBS) containing 0.05% wt/vol trypsin and 0.02% wt/vol EDTA (Imperial Laboratories). Cells were then washed in medium to inactivate the trypsin before reseeding or analysis.

Treatment of cells with EPA. Cis-5,8,11,14,17-EPA (Sigma Chemical Company) was dissolved in ethanol to give a 25 mg/mL stock solution and stored under nitrogen in an amber vial at −20°C. This stock solution was further diluted in complete medium to supplement HT29 cells at levels of 5, 10 and 15 μg/mL, while maintaining ethanol concentrations at less than 0.1% vol/vol. Control cultures initially contained either the appropriate amount of ethanol or ethanol-free medium, but as no significant effect of this concentration of ethanol was detected subsequent control samples were grown in ethanol-free medium. The media were refreshed every 24 h. Floaters were obtained by gently tapping of the plates, removal of the supernatant, and one wash of the plate with PBS. Adherent cells were obtained by trypsinization, as described above.

Determination of cell growth rate. Cells were obtained from late log phase cultures, seeded in complete media onto 35-mm diameter plates (Imperial Laboratories) at a density of 5×10^4 cells per plate (5.2×10^3/cm^2) and allowed to settle for 24 h before treatment with the appropriate level of EPA. Floating and adherent cells were harvested and counted from three plates per treatment at 24-h intervals. A second set of identical plates was used to determine the incorporation of tritiated thymidine (see below).

Incorporation of ^{3}H-thymidine. The method used was a modification of that described by Mengeaud *et al.* (25). Sterile PBS (10 μL) containing ^{3}H-thymidine (37 kBq; Amersham, Little Chalfont, United Kingdom) was added to the medium in each 35-mm diameter plate and samples of medium (2 × 10 μL) were obtained immediately to determine the activity of the media. Plates were incubated at 37°C for 4 h to allow incorporation, washed twice in cold PBS, treated with 5% trichloroacetic acid for 10 min at 4°C, washed a further three times in absolute ethanol, and the cell layer was dissolved in 1 mL of 0.1 M NaOH. Samples of media (2 × 10 μL) and dissolved cells (2 × 400 μL) were each added to 10 mL of Quicksave A scintillant (Zinsser Analytic, Maidenhead, United Kingdom) and counted using an automatic scintillation counter (Packard, Reading, United Kingdom).

Light microscopy. The medium was removed from each 35-mm diameter dish of treated and untreated HT29 cells, and a coverslip placed over the cells. The samples were observed using a differential interference contrast light microscope and photographed using FP4 film (Ilford Ltd., London, United Kingdom) and a Photoautomat MPS 45 camera (Leitz Instruments Ltd., Luton, United Kingdom).

Acridine orange staining of apoptotic nuclei. HT29 cells were grown in 8 × 2 cm flaskettes (Nunc, Life Technologies, Paisley, United Kingdom) consisting of a microscope slide base, to which cells adhere, covered by a detachable plastic cover. Floating cells were obtained from triplicate 88-mm diameter tissue culture dishes, pooled, and resuspended in 200 μL PBS. Both adherent and floating cells were stained with 5 μg/mL acridine orange for 10 min and washed once with PBS. Adherent cells were mounted in DPX mounting fluid (BDH, Merk, Lutterworth, United Kingdom) and floating cells were observed while in solution. A cover slip was placed on the sample which was then viewed using a Nikon Optiphot fluorescence microscope (Nikon, Kingston-Upon-Thames, United Kingdom).

Gel electrophoresis of apoptotic DNA fragments. For gel electrophoresis and flow cytometry, HT29 cells were obtained from late log phase cultures and seeded in complete medium onto 88-mm diameter plates at a density of 8.5×10^5 cells per plate (1.4×10^4/cm^2). Cells were allowed to adhere to the plate and grow for a total of 48 h before treatment with EPA or control medium. Unless otherwise stated, floaters from three identical plates were pooled in order to obtain sufficient cells for analysis and adherent cells were obtained from a single plate. Both floating and adherent cell samples were taken and washed twice in PBS. After counting, samples containing 1×10^6 cells were transfered to Eppendorf tubes and resuspended in 10 mM EDTA, 50 mM Tris-HCl (pH 8.0) containing 0.5% wt/vol *N*-lauryl sarcosine and 0.5 mg/mL proteinase K (all obtained from Sigma). Samples were mixed gently and incubated at 50°C for 1 h. To each sample, 10 μL of 0.5 mg/mL ribonuclease A (Sigma) was added and samples were further incubated for 1 h. Samples were heated to 70°C, and 10 μL of the following buffer was added: 10 mM EDTA, 50 mM Tris-HCL (pH 8.0), containing 1% wt/vol low melting point agarose, 0.25% wt/vol bromophenol blue, and

40% wt/vol sucrose (all from Sigma). Samples were mixed and loaded into dry wells of a 2% agarose gel using siliconized pipette tips. The gel was run at 40 V using TBE running buffer (130 mM Tris, 75 mM boric acid, 2 mM EDTA) until the dye front had migrated approximately 3 cm. The gel was stained with 1 µg/mL ethidium bromide in H_2O for 30 min, after which the gel was observed under ultraviolet illumination and photographs were taken.

Flow cytometric cell cycle analysis. A modification of the whole cell method described by Nicoletti *et al.* (37) was used. Cells, grown as for gel electrophoresis, were washed twice in PBS containing 1 mM EDTA, and the concentration was adjusted to approximately 5×10^5 cells/mL. Samples were resuspended in 80% vol/vol ice-cold ethanol and fixed on ice for 30 min. After washing twice in PBS, cells were resuspended in 1 mL of staining solution, consisting of PBS containing 30 µg/mL ribonuclease A, 0.1% vol/vol Triton X-100, and 50 µg/mL propidium iodide (all Sigma). Cells were stained for 30 min at room temperature and analyzed using a flow cytometer designed and built in-house, which has been described elsewhere (38). Data were analyzed on logarithmic scales for forward angle and right angle light scatter, and on a linear scale for red fluorescence. Noncellular material was excluded from the analysis by gating on the forward angle and right angle light-scattering characteristics of either adherent or floating cells. Red fluorescence intensity was used for the determination of position within the cell cycle, using Phoenix Multicycle for Windows cell cycle analysis software (Coulter Electronics Ltd., Luton, United Kingdom). Data are plotted as cell number against DNA content as detected by level of red fluorescence. Cells with a DNA content ranging from 2n to 4n were designated as being in G0/G1, S, or G2/M phases of the cell cycle, as defined by the level of red fluorescence per cell, using the above software. Cell cycle distributions were compared using analysis of variance, and where the *F*-statistic was significant, Student's *t*-test was used to determine direction.

Flow cytometric analysis of annexin V binding to apoptotic cells. Externalization of phosphatidylserine and membrane integrity were quantified, by a modification of the method of van Engeland *et al.* (36), using the ApoDetect Annexin V-FITC kit (Zymed Laboratories Inc., San Francisco, CA). Adherent cells grown in 35-mm diameter plates were labeled prior to harvesting. After removal of media plates were washed in PBS, before addition of binding buffer (1 mL) and 50 µL Annexin V-FITC (10 µg/mL) and 50 µL (20 µg/mL) propidium iodide. After 10 min at room temperature, plates were washed twice in binding buffer and cells then harvested by scraping and then resuspended in binding buffer (5×10^5/mL) before analysis by flow cytometry. Cells were identified on the basis of their forward and right angle light-scattering characteristics. Red and green fluorescence were analyzed on a logarithmic scale. Live cells were defined as those showing no fluorescence and apoptotic cells those showing only green fluorescence. Cells exhibiting both green and red fluorescence were designated late apoptotic/necrotic and red cells were regarded as damaged (39).

Caspase inhibition. The effect of inhibiting caspase activity on cell number was undertaken using a 96-well plate assay. Cells were plated out at 1.5×10^4 per well and allowed to adhere for 24 h. Cells were then exposed to EPA (15 µg/mL) or the caspase inhibitor Z-DEVD-FMK [Calbiochem-Novabiochem (UK) Ltd., Nottingham, United Kingdom] at a final concentration of 75 µM, or EPA (15 µg/mL) plus Z-DEVD-FMK, for 48h. Cell number was compared by incubation for 3 h at the end of each experiment with 50 µM Neutral Red supravital dye (Sigma) in complete Dulbecco's modified Eagle's medium. Following fixation in 40% (vol/vol) formaldehyde (BDH)/10% (wt/vol) calcium chloride hexahydrate (Fisher Chemicals, United Kingdom) for 30 s, plates were washed three times in PBS, air dried and the neutral red was solubilized from cultured cells by addition of 200 µL per well ethanol (50%)/acetic acid (1%). Absorbancies were measured at 550 nm, in 16 wells for each treatment, using a Dynatech MR5000 plate reader (Dynex Technologies, Chantilly, Virginia). Results were calculated as a percentage of the absorbance for control cells.

RESULTS

Effect of EPA on the growth of HT29. Over a period of 8 d treatment with 5 µg/mL EPA caused a slight reduction in the rate of accumulation of adherent cells compared to controls between day 0 and day 1, after which the treated cells and controls grew at similar rates. Treatment at a level of 10 µg/mL EPA caused a similar reduction in adherent cell count, which became more marked in comparison to the controls after 4 d. Treatment with 15 µg/mL EPA caused adherent cell numbers to remain static throughout the experiment (Fig. 1A). In the same experiment the number of floating cells was similar in the control samples and those samples treated with EPA at a level of 5 µg/mL. However, in samples treated with 10 and 15 µg/mL EPA, there were significantly more floaters than in the controls, with the number of floating cells increasing with increased EPA supplementation (Fig. 1B). To represent the effect of EPA more clearly, floating cell numbers were expressed as a percentage of the total number of floating plus adherent cells (Fig. 1C). At the higher levels of EPA (10 and 15 µg/mL) there was a significantly greater proportion of floating cells, indicating that the rate at which cells were shed from the plate into the media had increased under these conditions.

Effect of EPA on the proliferation of HT29. Having established that EPA causes a reduction in the number of cells adhering to the plate, incorporation of ^{3}H-thymidine was expressed per adherent cell rather than per plate, in order to compensate for the reduction in cell number. Supplementation of the media with 0, 5, 10, or 15 µg/mL EPA did not significantly reduce the proliferation of HT29 cells (Fig. 2A). Indeed supplementation at the higher dose of EPA was associated with increased thymidine incorporation at each time point up to and including day 6 (Fig. 2B).

Microscopical analysis of cell morphology. Cells treated with 5 µg/mL EPA were similar in appearance to control

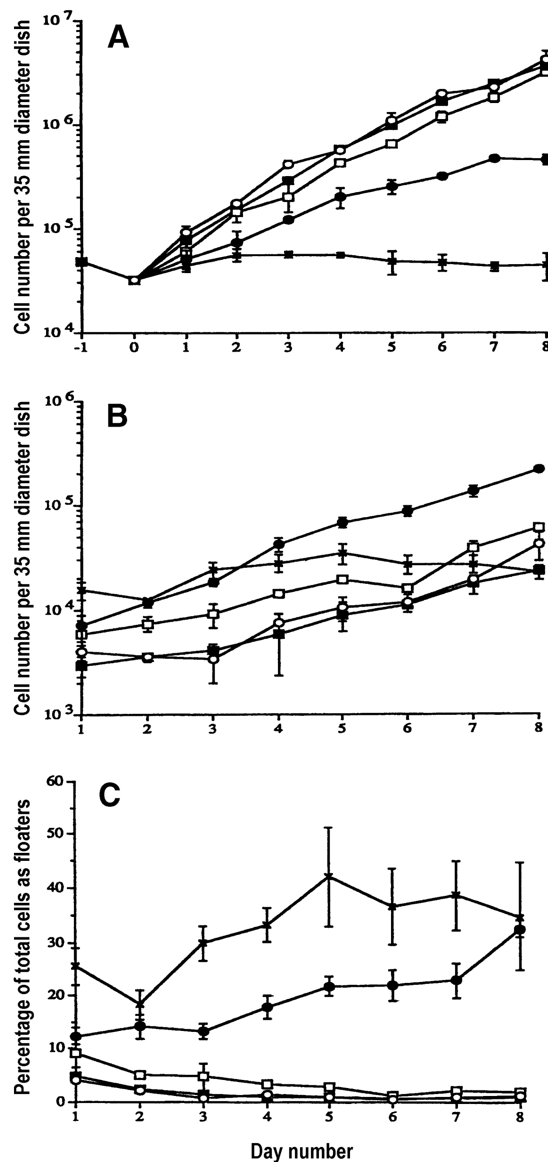

FIG. 1. The effect of supplementation with eicosapentaenoic acid (EPA) at various levels on the growth of HT29 colon adenocarcinoma cells. Complete media was supplemented with either 0 µg/mL (■), 0 µg/mL + ethanol (○), 5 µg/mL (□), 10 µg/mL (●) or 15 µg/mL (×). Growth of the cells was monitored over an 8-d period. Day −1 represents the cell seeding density, and day 0 shows the number of adherent cells after a 24-h cell adhesion period. Part A depicts the number of adherent cells, part B the number of floating cells and part C the percentage of total cells which were detached. Error bars represent the standard deviations of triplicate samples.

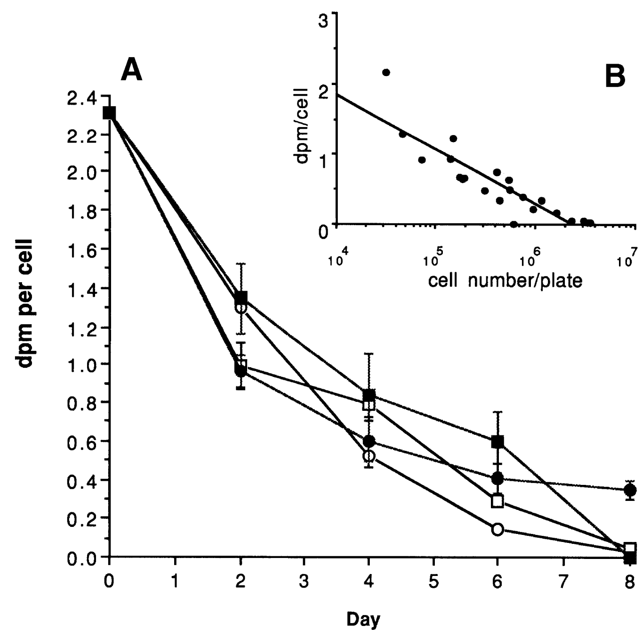

FIG. 2. The effect of supplementation with EPA on the proliferation of HT29 colon adenocarcinoma cells. Complete media was supplemented with either 0 (○), 5 (□), 10 (●), or 15 µg/mL (×). Cell proliferation was determined by measuring the incorporation of ^{3}H-thymidine into adherent cells over an 8-d period, as detailed in the Materials and Methods section. Error bars represent the standard deviation within the dpm values at each time point. Part B shows that proliferation is dependent on cell density, $R^2 = 0.787$. For abbreviation see Figure 1.

cells. At 10 µg/mL EPA, the cells became more granular in appearance, due the presence of large numbers of lipid droplets in their cytoplasm and colony morphology was less well defined. At 15 µg/mL EPA, there were discernible gaps between neighboring cells, and the remaining adherent cells had become more rounded.

No differences in acridine orange staining intensity between control adherent cells and those treated with EPA (15 µg/mL) were observed, and less than 1% of cells exhibited condensed chromatin characteristic of apoptosis. Many control detached cells contained condensed chromatin typical of cells entering mitosis, and some showed typical apoptotic features. In contrast, EPA-treated detached cells were generally smaller and less regularly shaped. Many showed typical apoptotic characteristics, and only a few the seemingly premitotic chromatin condensation of the control cells.

Gel electrophoresis. Samples were subjected to gel electrophoresis after 4 d growth. The results of gel electrophoresis carried out on floating and adherent cells treated with 10 and 15 µg/mL EPA are compared to controls in Figure 3. In adherent cells, treated or untreated, there was no DNA laddering, and intact genomic DNA was situated near the well at the top of the lanes. DNA laddering was, however, clearly evident in floating cells, irrespective of treatment.

Cell cycle analysis. Figure 4 shows the cell cycle distribution of adherent cells obtained from control samples, and those supplemented with 10 and 15 µg/mL EPA, over a period of 4 d. On day 2, cells treated with 10 and 15 µg/mL EPA had significantly more S phase cells than those in controls ($P < 0.05$ and $P < 0.01$, respectively), but no significant differences were seen between the two levels of EPA treatment. After 4 d, both treatments again led to significantly more cells in the S phase of the cell cycle when compared to control cells ($P < 0.01$ and $P < 0.01$, respectively), and differences were also seen in the numbers of cells in G2/M. There was no significant difference between control cells and those treated with 10 µg/mL EPA.

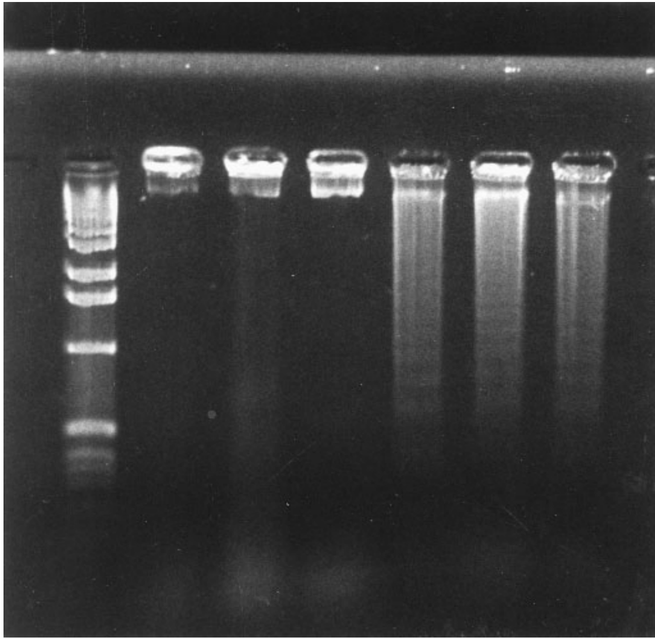

FIG. 3. DNA fragmentation in HT29 colon adenocarcinoma cells by agarose gel electrophoresis after growth in the presence of EPA. HT29 cells were grown in the presence of a range of concentrations of EPA for 4 d, the media being refreshed every 24 h. After this period, adherent and floating cells were harvested and analyzed for DNA fragmentation as detailed in the Materials and Methods section. Lane 1 represents a 1 Kb DNA ladder. Lanes 2, 3, and 4 represent adherent cells after treatment with 0, 10, and 15 μg/mL EPA, respectively. Lanes 5, 6, and 7 represent floating cells after treatment with 0, 10, and 15 μg/mL EPA, respectively. For abbreviation see Figure 1.

However, cells treated with 15 μg/mL EPA had significantly fewer cells in G2/M than both control cells ($P < 0.05$) and those treated with 10 μg/mL EPA ($P < 0.01$).

Cell cycle analysis on the floating cells was not possible because loss of fragmented DNA from apoptotic and necrotic cells means their position in the cell cycle is ambiguous. For example, detached cells with a DNA content equal to that of adherent S phase cells could not be distinguished from G2/M cells with reduced DNA content. Similarly, cells with a DNA content equal to that of adherent G0/G1 cells could be G0/G1 cells, or S, G2, or M cells that had lost varying amounts of DNA. The DNA profiles of floating cells treated for 4 d with control medium show that these cells contain considerably more DNA in the sub G0 peak, and few cells are present in the G1 and G2 peaks, compared to those exposed to medium containing 15 μg/mL EPA (Fig. 5), although both cell populations have been left for the same 24 h period.

Detection of early apoptotic cells by annexin-V labeling. The effects of EPA supplementation on the incidence of apoptosis (fluorescent green cells) in adherent HD29 cells, determined by the extent of binding of annexin V, were as follows: 0 μg/mL EPA, 1.8 ± 0.8; 15 μg/mL EPA, 1.6 ± 0.4; and 400 μM indomethacin (positive control), 27.4 ± 4.5. There were no significant differences between the numbers of apoptotic adherent cells, i.e. those stained green but not red, under control conditions compared to those treated with 15 μg/mL EPA. Treatment with 400 μM indomethacin, which is a well-documented inducer of apoptosis in HT29 cells (40,41), resulted in high numbers of apoptotic adherent cells.

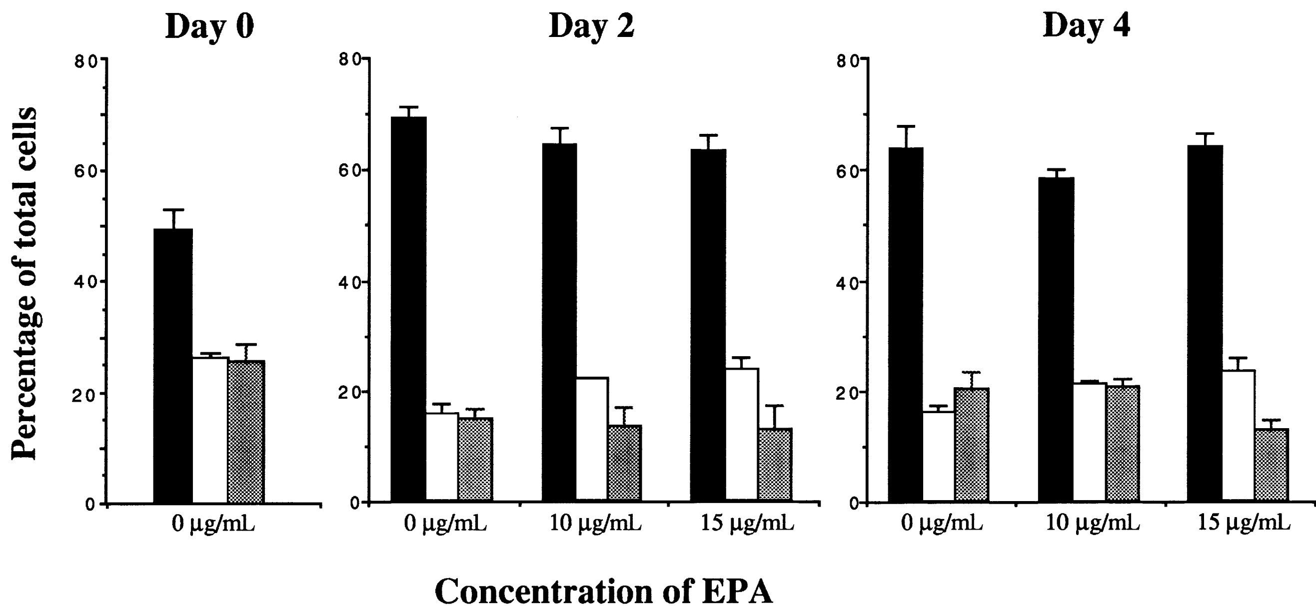

FIG. 4. The effect of supplementation with EPA at various concentrations on the cell cycle distribution of adherent HT29 colon adenocarcinoma cells over 4 d. HT29 cells were grown in complete media supplemented with either 0, 10, or 15 μg/mL EPA. After 2 and 4 d treatment, adherent cells were harvested and their position within the cell cycle determined by staining cellular DNA with ethidium bromide and quantifying red fluorescence by flow cytometry (see Materials and Methods section). ■ represents cells in G0/G1, □ cells in S, and ▩ cells in G2/M of the cell cycle. Error bars represent the standard deviations of triplicate samples. For abbreviation see Figure 1.

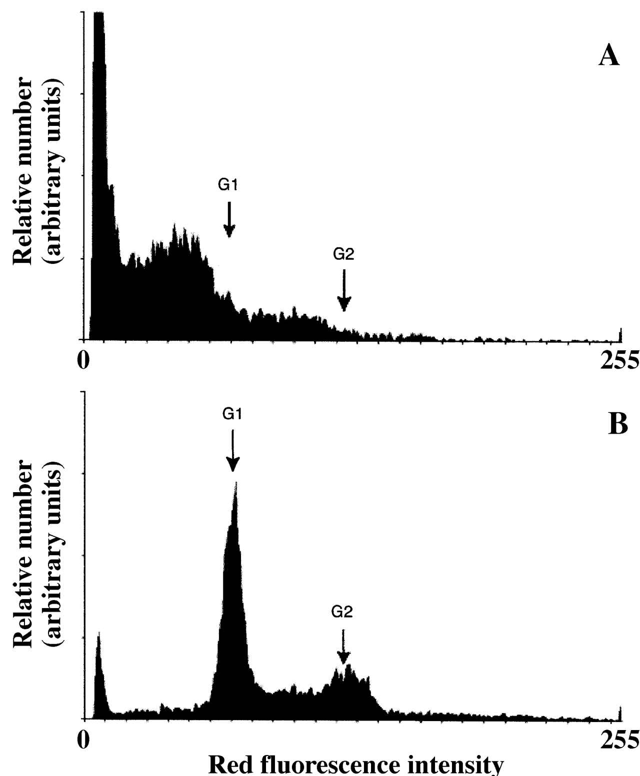

FIG. 5. The effect of EPA supplementation on the DNA content of nonadherent HT29 colon adenocarcinoma cells. HT29 cells were grown for 4 d in either complete media (A) or media supplemented with 15 μg/mL EPA (B), the media being refreshed every 24 h. Nonadherent cells were harvested and their DNA content determined by staining cellular DNA with ethidium bromide and quantifying red fluorescence by flow cytometry (see Materials and Methods section). In both panels, the position of cells with a DNA content corresponding to G1 and G2 are indicated. The data represent only those cells collected during the previous 24 h. For abbreviation see Figure 1.

Reduction in cell loss by caspase inhibition. The exposure of cells grown in 96-well plates to 15 μg/mL EPA reduced cell number to 52.7 ± 4.4% (mean ± SD) of control values. The addition of the caspase inhibitor Z-DEVD-FMK (75 μM) alone had no effect on cell number (104.1 ± 8.8%) but in combination with EPA cell number returned to 85.5 ± 3.4% of that of control cells.

DISCUSSION

When investigating the effects of exogenous compounds on the cytokinetics of adherent cell lines a reduction in the adherent cell number is commonly assumed to indicate a reduction in the rate of mitosis (19,40,41). However, it is theoretically possible for the rate of proliferation to remain constant, while a reduction in the number of adherent cells occurs owing to an increase in the rate at which the cells are shed from the plate into the surrounding medium. Previous studies on the effect of PUFA (20,22,25) and other compounds have not addressed this issue. The present study concentrates on the effects of EPA, as preliminary studies from our group established that EPA (10 μg/mL) reduced clonal survival of HT29 cells by more than 99% whereas cell survival was virtually 100% in the presence of either linoleic or oleic acid at the same concentration (42). In the present study we have shown that as the numbers of adherent cells were reduced on treatment with higher levels of EPA, the numbers of floating cells increased in comparison to controls. This suggests that treatment with EPA increased the rate at which adherent cells were shed into the medium without reducing the rate of mitosis.

In order to examine more closely the proliferation rate of adherent cells we determined ^{3}H-thymidine incorporation in treated and untreated cultures. Supplementation with EPA at 5, 10, and 15 μg/mL did not reduce the proliferation of HT29 cells compared to controls. In fact there was an apparent increase in proliferation at the higher dose of EPA, which was probably due to the lower cell density in these samples. This reinforces the view that the reduced adherent cell numbers seen on supplementation with the higher levels of EPA were due to an increase in the rate at which cells were shed from the substrate, rather than reduced cell division. This cell loss could have been due to increased cell death, either by apoptosis or necrosis, or to changes in the adherence properties of the cells, leading to detachment from the substrate.

Compounds that modulate cell growth commonly exert their effect at a particular stage of the cell cycle. This has been shown to be true of EPA acting on the promyelocytic leukemic cell line HL-60 (43) and on the pancreatic cancer cell line MIA PaCa-2 (44), where arrest occurs in G1/S and S/G2, respectively. Our results showed that after treatment with 10 and 15 μg/mL EPA there was an accumulation of HT29 cells in the S phase of the cell cycle, which could indicate blockade of the cell cycle in either late S phase or early G2. It is more common for chemotherapeutic agents to cause cell cycle arrest in G1, where damage to DNA can be repaired before it is replicated during the S phase. This G1 arrest is usually controlled *via* a p53 dependent pathway (45), but it is probably of little relevance to the present study because we have no evidence that DNA damage is induced by EPA, and in any case HT29 lacks wild type p53. It may be that EPA-mediated arrest occurs in late S or early G2/M *via* another control pathway (46). Unlike a cell cycle arrest in G1, the arrest of cells in S/G2 will not cause a reduction in the level of ^{3}H-thymidine incorporation into individual cells. If the cells are lost from the substrate at, or shortly after, the point of arrest there will be no apparent reduction in the amount of ^{3}H-thymidine incorporated per remaining adherent cell, as was observed in this study.

A well-documented characteristic of apoptosis is the internucleosomal cleavage of DNA into fragments 180 bp long, and multiples thereof. When subjected to agarose gel electrophoresis, such apoptotic DNA forms a discreet ladder (35). Our results confirm previous reports (47,48) that adherent cells, treated or untreated, show no DNA laddering, whereas floating cells do, regardless of treatment. Previous authors have tended to assume that floating cells are uniformly apoptotic and that the degree of apoptosis can be deduced directly

from the rate at which cells detach from their substrate and become floaters (49). However, this assumption may be flawed because gel electrophoresis only confirms that some of the floating cells contain fragmented DNA; there is no indication of the proportion of the floating cell population undergoing apoptosis. In addition, detection of apoptosis by DNA laddering in floating cells does not demonstrate whether the cells are detaching because they are apoptotic or are becoming apoptotic because they have detached.

The loss of fragmented DNA, producing cells with a DNA content of <2n (i.e., sub-G0), is now an accepted feature of apoptotic cells. When studying substrate-growing cell lines, we observed two distinct populations; those which were intact and adhering to the substrate, and those which had become, or were about to become, detached. Some previous studies, using flow cytometry, have examined only the adherent cells (49,50), others have examined the total cell population (41,43,51), but few have examined the characteristics of adherent cells and floating cells separately (52,53). In using morphological criteria, apoptotic adherent cells were rarely observed. Given such small numbers, the process of removing background debris and aggregates from the calculation for cell cycle analysis of adherent cells effectively excluded cells with a sub-G0 DNA content. It was not possible therefore to give a value for sub-G0 cells in the adherent cell populations using this flow cytometric technique. The absence of any characteristic features of apoptosis in adherent cells suggests that detachment of floaters, if associated with apoptosis, occurs at an early stage of the process.

While not directly affecting the rate of DNA synthesis of HT29 cells, measured using incorporation of ^{3}H thymidine, EPA did influence cell cycle distribution and increased the rate at which adherent cells became detached from the substrate. Although this detachment may be associated with the process of apoptosis, the flow cytometric data suggests that it occurred before any change in membrane asymmetry or the cleavage of DNA. The binding of annexin V to externalized phosphatidylserine is considered to be an earlier event in the apoptotic process than the fragmentation of DNA. However, treatment with EPA at 15 μg/mL did not lead to any increase in annexin V binding in adherent cells, reinforcing the view that treatment with EPA did not cause loss of cells from the substrate *via* the classical apoptotic process. Significant numbers of floating cells collected under control conditions contained sub-G0 quantities of DNA, implying that these cells are apoptotic, while the population of floating cells, collected over the final 24 h period of EPA treatment (4 d), contained virtually no sub-G0 cells. This suggests that the nonadherent cells found in response to EPA exposure may be detaching by a different mechanisms or at different stages in the cell cycle. For example, cell detachment following blocking in late S phase will mean that cells detach with 4n DNA content which is then lost from the cell to give sub-G2 DNA content, but by the time DNA levels are at a sub-G0 level the cell membrane is no longer intact and thus these cells will be excluded from the measurements. In contrast, the nonadherent cells found in control conditions may become detached at G1 and thus loss of DNA during the process of apoptosis will lead to a detectable sub-G0 peak. The difference in results cannot be explained by a delayed effect of EPA as these cells have been continuously exposed to EPA for the previous 72 h.

We propose that EPA supplementation leads to changes in the adherence properties of cells, causing them to be shed from the substrate prior to identifiable apoptosis, a process which may be analogous to "anoikis" (induction of apoptosis as a result of loss of cell contact) typical of exfoliating epithelial cells (54,55). In this context it is interesting to note that dietary supplementation with fish oil has recently been reported to increase differentiation in the colonic epithelium of rats (56) and to cause reduced expression of cell adhesion molecules in human monocytes (57). In normal mucosa colonocytes cease to divide in the upper third of the crypt and rapidly undergo differentiation. In tumor-bearing colorectal mucosa, and apparently even in healthy subjects at risk of neoplasia, there is increased mitosis in the colorectal mucosa (58). If some general spatio-temporal delay in differentiation occurs within the crypt before or during the onset of neoplasia, increasing differentiation induced by fish oil may contribute to its anticarcinogenic effects in animal models.

The question remains as to whether the loss of cell adhesion induced by EPA should be regarded as an early stage in apoptosis or as part of a distinct differentiation pathway ending in cell death, which occurs as a secondary consequence of detachment. The addition of the caspase inhibitor Z-DEVD-FMK to the medium suppressed the reduction in adherent cell number seen in response to EPA. This inhibitor blocks caspase 3 (CPP32) (59), which is a key enzyme activated during the early stages of apoptosis, and responsible for the cleavage of several substrates including poly(ADP-ribose) polymerase, β-catenin, and focal adhesion kinase (FAK) (60,61,63). The latter is intimately involved in cell signaling events necessary for the maintenance of cell adhesion. Van de Water *et al.* (63) have recently reported that caspase-mediated FAK cleavage is a critical step preceding detachment of renal epithelial cells undergoing anoikis. Thus caspase-mediated loss of cell adhesion may be an early stage in the programmed cell death of adherent cells, which, although showing no classical features of apoptosis, are already committed to self-destruction. The issue of whether EPA-mediated cell detachment is part of a single unified pathway of apoptosis in these cells, or alternatively, a separate form of programmed cell death, which should be termed "anoikis," is outside the scope of the present study, but it certainly deserves further attention.

To what extent are the present findings of relevance to the effect of fish oil on the intact intestinal mucosa *in vivo*? As mentioned earlier, substances or conditions which favor differentiation and apoptosis, or suppress mitosis, of tumor cells *in vitro* may be anticarcinogenic *in vivo*. On this principle, the short-chain fatty acid butyrate, which promotes differentiation of many tumor cell lines including HT29, has been proposed as a possible anticarcinogen which can be derived from the human diet (64). If the increased exfoliation of HT29 cells from

adherent cultures in response to EPA described in this study is an outcome of increased terminal differentiation, the same mechanisms might also favor differentiation and suppression of mitosis within the intact crypt, and hence contribute to the anticarcinogenic effects of fish oil observed in animal models. It may therefore be important to search for evidence for effects of n-3 PUFA on markers of cell differentiation in the intestine and other rapidly proliferating tissues *in vivo*.

ABSTRACT: We investigated the relative effects of n-3 eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) on the plasma membrane fluidity of endothelial cells (EC) cultured from the thoracic aorta by determining fluorescence polarization of 1,6-diphenyl-1,3,5-hexatriene (DPH) and its cationic derivative trimethylamino-DPH (TMA-DPH). Fluidity assessed by TMA-DPH demonstrated no significant differences in plasma membranes of vehicle (dimethyl sulfoxide; DMSO)-, EPA-, and DHA-treated EC. Plasma membrane fluidity assessed by DPH polarization, however, was significantly higher in the order of DHA > EPA > DMSO. Total cholesterol content decreased significantly by 28.4 and 15.9% in the plasma membranes of DHA- and EPA-treated cells, respectively. Total phospholipid content remained unaltered in the plasma membranes of the three groups of cells; however, the molar ratio of total cholesterol to phospholipid decreased significantly only in the membranes of DHA-treated EC. The unsaturation index in the plasma membranes of EPA- and DHA-treated cells increased by 35.7 and 64.3%, respectively, compared with that in the plasma membranes of control cells. The activities of catalase and glutathione peroxidase in the whole-cell homogenates, and levels of lipid peroxides in either the whole-cell homogenates or in plasma membrane fractions were not altered in EPA- or DHA-treated EC. These results indicate that the influence of DHA is greater than that of EPA in increasing plasma membrane fluidity of vascular EC. We speculate that the greater effect of DHA compared to EPA is due to its greater ability to decrease membrane cholesterol content or the cholesterol/phospholipid molar ratio, or both, and also to its greater ability in elevating the unsaturation index in the plasma membranes of EC.

Paper no. L8187 in *Lipids 34,* 1297–1304 (December 1999).

Although regular consumption of fish oil is associated with a reduced risk of coronary heart disease (1,2), the association is probably of a multifactorial nature, and many of the underlying mechanisms at the molecular level for polyunsaturated fatty acids (PUFA) are not clearly understood (3). Fatty acids cause endothelium-dependent vasodilation, probably by changing the fluidity of endothelial membranes (4). Several other lines of evidence indicate that membrane fluidity may modulate endothelial cell (EC) membrane-dependent functions such as receptor–ligand interaction (5), membrane transport (6) and membrane-bound adenylate cyclase activity (7). Therefore, it is likely that some significant physiological responses would depend on the alterations of physical properties occurring at the cellular bilayer membrane level. Repression of blood pressure by eicosapentaenoic acid (EPA, 20:4n-3) (8,9) and docosahexaenoic acid (DHA, 22:6n-3) (10), and alterations of β-adrenergic responsiveness by DHA (11) have also been tentatively attributed to their influences on membrane fluidity.

Studies with purified components of fish oil, EPA and DHA have shown differences in their effects on plasma lipid profiles. EPA has hypotriglyceridemic and hypocholesterolemic properties (12), and DHA has no effect on plasma triglycerides (13). These two fatty acids have also been described as differing in activity at the cellular level. Bates *et al.* (14) reported that treatment of neutrophils with DHA, but not EPA, increases neutrophil-mediated endothelial detachment. Likewise, DHA has been shown to be less effective than EPA in inhibiting vascular smooth muscle proliferation (15), a phenomenon thought to be involved in the genesis of atherosclerosis. Khalfoun *et al.* (16) suggested that DHA is a more potent inhibitor of lymphocyte adhesion to EC than is EPA. In addition, in human skin fibroblasts, DHA but not EPA has been shown to increase membrane fluidity and membrane-associated enzyme activities, including 5′-nucleotidase and adenylate cyclase (17). Previously we showed that a decrease in the membrane DHA/AA (arachidonic acid, 20:4n-3) molar ratio with age is correlated with the deterioration of platelet membrane fluidity, but EPA/AA does not have a significant relation with membrane fluidity (18). Whether similar differential effects of EPA and DHA can be exerted in endothelial cell membrane fluidity has, however, remains obscure. DHA contains one more double bond per molecule than does EPA. Thus, it is likely that DHA's high content in the membrane bilayer has a specific role in membrane dynamics. Of vital im-

portance to the maintenance of EC integrity is the preservation of membrane function and structural properties, such as plasma membrane (PM) fluidity.

Optimal membrane function requires a fluid state of the membrane (19), and this fluidity is largely dependent on lipid composition, such as the extent of membrane unsaturation, cholesterol levels and the cholesterol/phospholipid ratio (20). Nonetheless, it should be kept in mind that a high level of PUFA would readily increase PM susceptibility to peroxidative attacks (21). Peroxidation of membrane PUFA results in the formation of lipid peroxides including malondialdehyde and aldehyde breakdown products (22). Lipid peroxidation, which is increasingly attributed to a decrease in membrane fluidity that accompanies aging (18,23), was demonstrated in *in vitro* oxidation (24) and also has been shown to modulate the activity of membrane-bound enzymes (25). The lipid peroxidation-related exacerbation of membrane functions, however, depends on the imbalance between scavenging and production of free radicals. Thus, we were aware of the potential for oxidative antioxidation of the EC during incubation with EPA and DHA. With respect to the effects of EPA and DHA on plasma membrane profiles of cholesterol, phospholipid, fatty acid unsaturation, and lipid peroxide, we investigated the relative influence of these PUFA on the plasma membrane fluidity of EC isolated from rat thoracic aortas.

MATERIALS AND METHODS

Cell culture of EC from rat thoracic aortas. All animal experiments were performed in accordance with the Guidelines for Animal Experimentation of Shimane Medical University, compiled from the Guidelines for Animal Experimentation of the Japanese Association for Laboratory Animal Science. Thoracic aortas of young (5-wk-old) female Wistar rats were prepared, and the primary cultures of EC were established as described (26). After growing to confluency, the cells were harvested with 0.05% trypsin and 0.01% EDTA and passaged. The EC were characterized by immunoperoxidase staining using Factor VIII-related antigen (Biomeda Histo Scan Kit, Cosmo Bio Co., Ltd., Tokyo, Japan) and by their uptake of acetylated low density lipoprotein labeled with the fluorescent probe 1,1′-dioctadecyl-1-3,3,3′,3′-tetramethyl-indocarbocyanine perchlorate (Biomedical Technologies, Inc., Stoughton, MA). The EC at the second passage were used in this study.

Fatty acid enrichment of EC. Cells were grown in medium to confluence in 95-mm collagen plates (Celltight C-1, Sumitomo Bakelite Co. Osaka, Japan). Highly purified ethyl ester of all-*cis*-5,8,11,14,17-EPA (Mochida Pharmaceutical Co., Ltd., Tokyo, Japan) and all-*cis*-4,7,10,13,16,19-DHA (Sagami Chemical Research Center, Sagamihara, Japan) were dissolved in dimethyl sulfoxide (DMSO), each at a final concentration of 5 µg fatty acid/mL culture medium; the controls, designated as "DMSO," were cultured to the same concentration as that of the vehicle. DMSO was used at a concentration of 0.02%. The medium was further renewed twice at 24-h intervals. After treatment of the cells with PUFA or vehicle for 72 h, the culture medium was removed and the cell layers were washed with Dulbecco's PBS(+) (phosphate-buffered saline). The trypsinized cells, after several washes in excess 25 mM Tris-HCl buffer (pH 7.4) containing 137 mM NaCl, 5.4 mM KCl, and 11 mM glucose, were used to prepare plasma membranes.

Preparation of PM. PM were isolated as previously described (27) with a slight modification. Twenty collagen culture plates (95-mm diameter) were pooled to obtain sufficient PM. After trypsinizing and centrifuging, 1 mL of chilled 0.1 M sucrose in 10 mM Tris (pH 7.4 at 4°C) was added to the cell pellets. The cells were lysed by five freeze-thaw cycles, then by a bath sonicator at ice-cold temperatures; the lysates were subjected to a microtip Branson sonifier (Cell disruptor 200; Branson Sonic Power Co., Danbury, CT) for 30 to 60 s. After centrifugation at 1,000 × *g* for 10 min at 4°C, the supernatant was transferred to Eppendorf centrifuge tubes. The remaining pellet was rehomogenized in 400 µL of the above Tris-sucrose buffer, and the supernatant was obtained as above. The rehomogenizing step was repeated one further time, then all the supernatants were combined and centrifuged at 9,000 × *g* for 10 min. The supernatant was further centrifuged at 40,000 × *g* for 30 min and then discarded, and the remaining membrane-rich pellet was vigorously suspended in the Tris-sucrose buffer in a mixer. The protein was determined by the method of Lowry *et al*. (28). Purity of the PM fraction was confirmed by measuring the activity of 5′-nucleotidase, with a Sigma Chemical Co. diagnostic kit (St. Louis, MO). The PM fraction was enriched ~sixfold over the initial crude homogenate.

*Measurement of membrane fluidity***.** Fluorescence probes, 1,6-diphenyl-1,3,5-hexatriene (DPH; Sigma Chemical Co.) and 1-(4-trimethylammonium-phenyl)-6-phenyl-1,3,5,-hexatriene (TMA-DPH; Sigma Chemical Co.) were used as an index of rotational mobility in PM. DPH and TMA-DPH labeling of PM and the measurements of steady-state fluorescence polarization were carried out by the methods of Shinitzky and Barenholz (29) and Kuhry *et al*. (30), respectively. A quantity of 100 µL PM suspension containing 100 µg protein was added to 1.4 mL of Tris-HCl buffer (25 mM Tris-HCl buffer, containing 137 mM NaCl, 5.4 mM KCl, and 11 mM glucose, pH 7.4) with a final probe concentration at 1 µM. This dispersion was incubated at 37°C for 60 min for DPH and 30 min for TMA-DPH. Fluorescence intensity was measured with a Hitachi 850 spectrofluorometer (Hitachi Ltd., Tokyo, Japan) equipped with rotating polarizer filters and a thermostatic cell holder set at 37°C. The effect of light scattering on intensity values was minimized with a 390-nm cutoff filter and by subtracting the values of unlabeled preparations. Excitation wavelengths of 360 and 365 nm, and emission wavelengths of 430 and 435 nm were used for DPH and TMA-DPH, respectively. The slit width was 8 nm for excitation and 14 nm for emission for each of the probes. Fluorescence polarization was calculated as $P = (I_{VV} - I_{VH})/(I_{VV} + 2\,I_{VH})$ (29,30). I_{VV} and I_{VH} are the intensities measured parallel and perpendicular to the vertical axis of the excitation beam. Plasma membrane fluidity was expressed as 1/polarization (1/*P*).

Fluorescence lifetime measurement of DPH. Fluorescence lifetime of embedded DPH was measured from the normalized total fluorescence intensity decay with a single photon-counting fluorometer (Horiba Naes-1100 time-resolved spectrofluorometer, Horiba Ltd., Kyoto, Japan) equipped with a computer program that enables it to analyze decay curves of one to three components. The samples were excited with a free-running spark gap-type nanosecond flash lamp. The light of the hydrogen lamp was first passed through a glass filter 1 plate-mesh with a 360 nm band pass for excitation (Horiba). The emitted fluorescence was filtered through a combination of two glass prisms, L-380 and UV 390 (Horiba).

Lipid peroxide product (LPO) analysis. LPO were assessed by the thiobarbituric acid-reactive substances (TBARS) assay of Ohkawa *et al*. (31). Briefly, 200 µL of 8.1% sodium dodecyl sulfate, 3.0 mL of 0.4% thiobarbituric acid in 20% acetic acid (pH 3.5), and 700 µL of double-distilled water (DDW) were added to 100 µL of PM suspension or whole cell homogenate containing 100 µg protein; the mixture was then incubated at 95°C for 1 h. After cooling in tap water, 1.0 mL of DDW and 4.0 mL *n*-butanol/pyridine (15:1, vol/vol) were added, and the mixture was shaken vigorously for 20 min. After centrifugation at 3,000 rpm for 10 min, the fluorescence intensity of the upper organic layer was determined with a Hitachi 850 spectrofluorometer. The excitation and emission wavelengths were 515 and 553 nm, respectively. Malondialdehyde levels were calculated relative to a standard preparation of 1,1,3,3-tetraethoxypropane.

Enzyme activity. Cell homogenates were used to measure activities of catalase (CAT; EC 1.11.1.6) and glutathione peroxidase (GPx; EC 1.11.1.0). The activity of CAT was measured by exploiting its peroxidation function at 20°C according to the procedures of Johansson and Borg (32) and Wheeler *et al*. (33), as previously described (34) with one modification of total assay volume of 1.0 mL. CAT activity was determined by linear least-squares regression of the absorbance of formaldehyde standards. GPx was assayed as described previously (34) with one modification of total assay volume of 1.0 ml. Units of enzyme activity were calculated as µmol of NADPH oxidized per min using a millimolar extinction coefficient of 6.22 mM^{-1} for NADPH.

Fatty acid analysis. Fatty acid profiles of EC plasma membranes were determined by the one-step analysis procedure of Lepage and Roy (35) as described previously (9,10), using capillary gas chromatography of the corresponding methyl esters prepared by transesterification with acetyl chloride.

Total cholesterol and phospholipid analysis. To determine the PM contents of cholesterol and phospholipid, endothelial PM total lipids were extracted with chloroform/methanol (2:1, vol/vol) by the method of Folch *et al*. (36). The extract was passed through glass Pasteur pipettes filled with glass wool and divided into two aliquots, one for total cholesterol estimation and the other for total membrane phospholipid estimation. The extract was dried extensively with a stream of N_2 gas. Total cholesterol and phospholipid were analyzed with commercially available analytical kits (Cholesterol E-test and Phospholipid B-test, Wako Pure Chemical Industries Ltd., Osaka, Japan, respectively).

Statistical analysis. Results are expressed as means ± SE. Data were subjected to analysis of variance followed by Fisher's partial least-squares differences test for *post hoc* comparison and regression analysis with the computer program Stat View® 4.01; MindVision Software (Abacus Concepts, Inc., Berkeley, CA). A level of $P < 0.05$ was considered statistically significant.

RESULTS

Cellular cholesterol-phospholipid composition. Figure 1A shows that PM cholesterol content of DHA-treated and EPA-treated EC decreased by 28.4 and 15.9%, respectively, compared with that in the PM of DMSO-treated control cells.

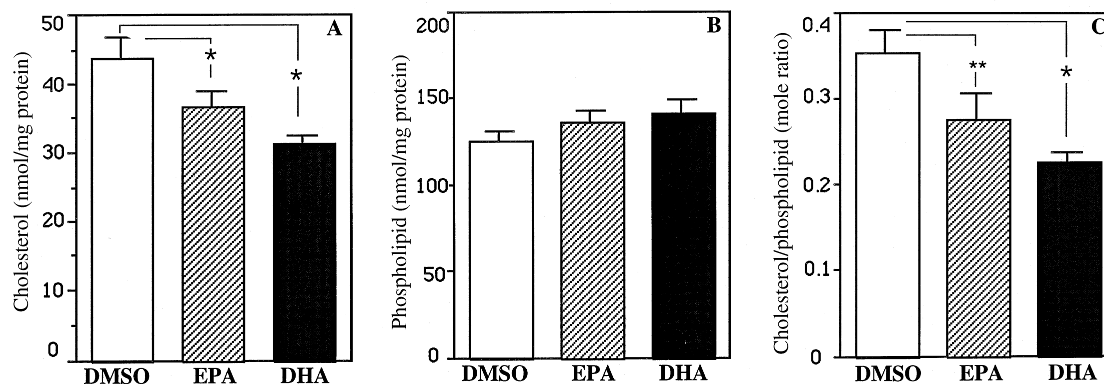

FIG. 1. Effect of eicosapentaenoic acid (EPA) and docosahexaenoic (DHA) on (A) cholesterol, (B) phospholipid, and (C) cholesterol/phospholipid molar ratios of endothelial cell (EC) plasma membranes (PM). Cells were grown in 10% fetal bovine serum to confluence in 95-mm plastic dishes (Falcon, Oxnard, CA). Highly purified ethyl esters of EPA and DHA were dissolved in dimethyl sulfoxide (DMSO) as a vehicle. All media containing supplemental DMSO, EPA, and DHA were sterilized by passage through a low-binding 22-µm Millipore filter (Milford, MA). After treatment with polyunsaturated fatty acid or vehicle alone for 72 h, the endothelial cells were used for plasma membrane isolation and total cholesterol and phospholipid estimation. Results are mean ± SE (bars) values from four independent experiments, each with at least duplicate determinations. *$P < 0.05$. **$P < 0.05 \sim 0.10$.

[a]Values are means ±SE (nmole/mg protein) of 9 or 10 independent experiments. EC, endothelial cell; PA, palmitic acid (16:0); SA, stearic acid (18:0); OA, oleic acid (18:1); LA, linoleic acid (18:2); LLN, linolenic acid (18:3); AA, arachidonic acid (20:4); EPA, eicosapentaenoic acid (20:5); DPA, docosapentaenoic acid (22:5); DHA, docosahexaenoic acid (22:6); USI, unsaturation index. USI was calculated as [∑ (mole% of each polyunsaturated fatty acid × number of double bonds)/100)]. Values in the same column for a given fatty acid sharing the same lowercase roman superscripts are not significantly different at $P < 0.05$.

Total phospholipid content was found to be unaltered in the PM of EPA- and DHA-enriched cells (Fig. 1B). The PM cholesterol/phospholipid molar ratio decreased by 36.3% in the DHA-treated EC and by 21.5% in the EPA-treated EC compared with that in control cells. However, it reached significance only in the PM of DHA-enriched endothelial cells (Fig. 1C).

Effect of EPA and DHA on PM fatty acid composition. As shown in Table 1, a highly significant increase in both EPA and DHA content occurred in the PM of both EPA- and DHA-enriched EC compared with the DMSO-treated cells. The PM of EPA-enriched EC showed a 246% increase in EPA and those of DHA-enriched cells showed a 155% increase in DHA content compared with the increase in the PM of control cells. Both docosapentaenoic acid (DPA) and DHA increased ($P < 0.05$) in the PM of EPA-enriched cells; both EPA and DPA increased ($P < 0.05$) in the PM of DHA-enriched cells compared with the PM of control EC. AA decreased ($P < 0.05$) in the PM of both the EPA- and the DHA-enriched EC. Oleic acid (OA, 18:1) increased only in the EPA-treated PM. Linoleic acid (LA, 18:2) and linolenic acid (LLN, 18:3) increased in both the EPA- and DHA-treated PM. Palmitic and stearic acids decreased in the PM on EPA or DHA treatment. Stearic acid decreased by ~43% in the DHA-treated PM and by 18% in the PM of EPA-treated EC. Compared with the PM of DMSO-treated cells, both EPA- and DHA-enriched EC showed a significant increase in the total unsaturation index (USI), a measure of the extent of double bonds; however, the latter showed a 29% higher increase in membrane unsaturation compared with that in the PM of EPA-enriched EC.

Effect of EPA and DHA on lipid peroxide levels and antioxidative enzymes. Lipid peroxide (TBARS) values of EC PM did not change significantly on either EPA or DHA treatment as compared with those in the PM of DMSO-treated control cells (Table 2). Whole cell lipid peroxide values and catalase or glutathione peroxidase activities also did not change to a significant extent in either of the treated cells.

*Effect of EPA and DHA on EC PM fluidit*y. The term fluidity is inversely related to fluorescence polarization; thus, the higher the polarization, the lower the fluidity, and vice versa. DPH-determined membrane fluidity increased significantly in the PM of both EPA- and DHA-enriched EC compared with that in the PM of control EC; however, DHA showed a higher increase in PM fluidity relative to that of EPA compared with the fluidity of control cell PM (Fig. 2A). The PM fluidity (determined by the measurement of TMA-DPH polarization) of both EPA- and DHA-enriched cells did not change compared with that of the PM of DMSO-treated control EC (Fig. 2B).

Effect of EPA and DHA on the rotational relaxation time of DPH embedded in PM. The purpose of the measurement of the DPH fluorescence lifetime was to evaluate the

TABLE 2
Effect of EPA and DHA on Catalase and Glutathione Peroxidase Activities in Whole Cell Homogenates and on Lipid Peroxides Either in the Whole Cell Homogenates or Plasma Membrane Fractions of Rat Aortic EC[a]

	Catalase (mU[b])	Glutathione peroxidase (mU[c])	Lipid peroxide (nmol/mg protein)

DMSO	25.30 ± 2.70	30.65 ± 1.50	8.25 ± 1.45	16.40 ± 1.60
EPA	24.70 ± 1.60	33.00 ± 2.00	8.90 ± 0.85	20.00 ± 2.20
DHA	29.50 ± 1.75	36.70 ± 5.40	11.75 ± 2.05	21.00 ± 1.65

[a]Results are mean ± SE of four independent experiments each with at least duplicate determinations.
[b]One unit is defined as μmol of methanol converted to formaldehyde equivalent to μmol H_2O_2 oxidized/min.
[c]One unit is defined as μmol of NADPH oxidized/min. For abbreviations see Table 1.

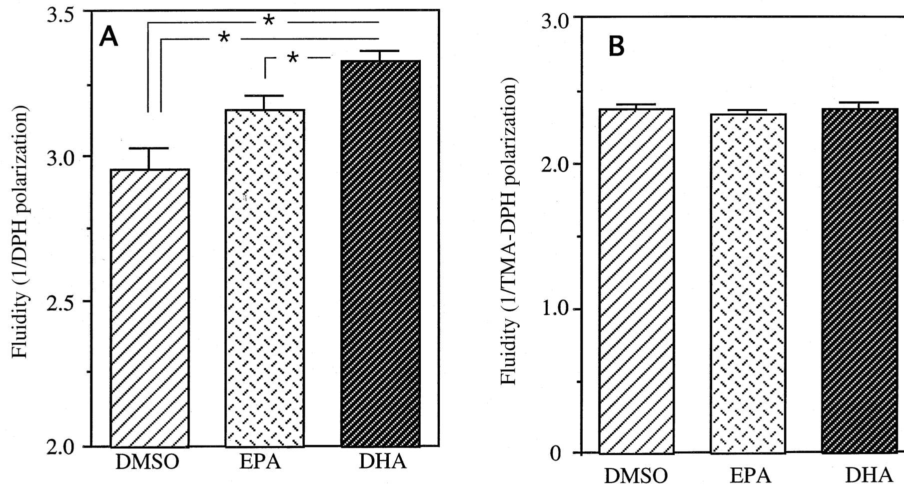

FIG. 2. Effect of EPA and DHA on the whole EC PM fluidity determined by (A) nonpolar 1,6-diphenyl-1,3,5-hexatriene (DPH) probe and (B) polar derivative of DPH, trimethylamino-1,6-diphenyl-1,3,5-hexatriene (TMA)-DPH. PM (100 μg) were incubated with either DPH or TMA-DPH, and membrane fluidity was expressed as 1/polarization. The PM of DHA-treated EC had the highest fluidity compared with the PM of EPA-treated EC or control EC. TMA-DPH-determined membrane fluidity was found not to change either upon EPA or DHA treatment as compared with that in the PM of control EC. Results are mean ± SE (bars) values from six independent experiments each with at least quadruplicate determinations. *$P < 0.05$. For abbreviations see Figure 1.

rotational relaxation time (ρ) using the Perrin equation: $r_o/r_s = 1 + (3\tau)/\rho$, as previously described, where r_o is the limiting anisotropy of DPH [i.e., the ansiotropy in the absence of rotational motion is 0.362 (29)]; r_s is the steady-state anisotropy calculated from the measured polarization (P) as $r_s = (2P)/(3 - P)$ (26); τ is the excited-state lifetime of DPH; and ρ is the time taken by the DPH probe molecule within the membrane to rotate through an angle θ such that $\cos\theta = e^{-1}$, which reflects the rotational motion of the fluorescent probe incorporated into the lipid bilayer membranes (37,38). Unlike other fluidity parameters such as microviscosity, ρ has distinct advantages because it quantifies both the rate and range of rotational motion of the probe and does not depend on calibration curves derived from reference solvents. The fluorescence decay data for lifetime measurements are best fitted by two-component analysis, as indicated by least χ^2 (chi square) values. Thus, average fluorescence lifetime (39) was used in the calculation of ρ. The rotational relaxation time (ρ) of the embedded DPH probe changed significantly on either EPA or DHA treatment. The ρ of DPH was 63.0 ± 1.3 ns in the PM of DMSO-treated controls; 57.6 ± 1.70 ns in those of EPA-enriched EC; and 48.6 ± 0.95 in those of DHA-enriched EC.

Correlation of EC PM fluidity with its fatty acid and cholesterol-phospholipid composition. As shown in Table 3, a highly significant positive correlation of PM fluidity was observed only with DHA, whereas its correlation with EPA, although not significant, was positive. Likewise, DHA/AA correlated significantly with membrane fluidity while EPA/AA did not. All other PUFA, except AA, correlated positively; however, their correlation coefficients were insignificant. AA was negatively correlated with PM fluidity. Stearic acid also was negatively correlated with PM fluidity, while the correlation with palmitic acid was not significant. Finally, PM fluidity was directly correlated with the USI. Cholesterol and cholesterol/phospholipid molar ratios were negatively correlated with membrane fluidity, and phospholipid had no correlation with PM fluidity.

DISCUSSION

The present study was designed to evaluate the differential effects of EPA and DHA on the membrane fluidity in PM of EC. The causal affectors of these differential effects were described in terms of their influence on PM total cholesterol, phospholipid, fatty acid unsaturation, and lipid peroxide profiles. Our results have confirmed that the effect of DHA ex-

ceeds that of EPA in human skin fibroblasts (17), demonstrating that despite being members of the same n-3 family, EPA and DHA have different effects on membrane structures in EC. Our results are qualitatively consistent with those found with cardiomyocytes in which the incubation of EC with EPA displays a high content of EPA and DPA (20:5n-3) (11). Also, incubation of EC with DHA induces a significant retroconversion to DPA and EPA. Fatty acid composition of both EPA- and DHA-enriched EC revealed a significant decrease in the content of AA with concomitant increases in both the EPA/AA and DHA/AA molar ratios. The decrease in AA content is in agreement with other studies (40) and also consistent with our previous studies where significant increases of both the EPA/AA and DHA/AA ratios were found in rat caudal artery after chronic administration of EPA and DHA (10). The PM of DHA-enriched EC showed a larger increase in membrane fluidity and a shorter rotational relaxation time of DPH than did those of EPA-enriched cells. This assumption is in accordance with the work of Stubbs *et al*. (41), which showed a definite increase in the rate of motions (hence shorter rotational relaxation times) with the number of double bonds. This indicates that the lipid constituents of the PM of DHA-enriched EC in the present study probably experienced a greater motional freedom than those in the PM of either EPA- or DMSO-treated cells. Our speculation is also consistent with some previous investigations (42) demonstrating that rotational relaxation time increases with membrane rigidification.

Other indicators of membrane fluidity that were also altered to a greater extent in the PM of DHA-enriched EC compared to EPA-enriched EC included stearic acid, the USI, cholesterol content, and the cholesterol/phospholipid molar ratio. Membrane fluidity of EC exposed to stearic acid decreased as compared with that of the EC exposed to OA, LA, or LLN (43). Although the mechanism of the stearic acid-induced decrease in membrane fluidity is not direct (44), the increased membrane content of saturated fatty acid is associated with decreased membrane fluidity (45). Thus, our detection of a greater decrease ($P < 0.05$) in stearic acid suggests a partial contribution to a greater fluidity in the PM of DHA-enriched EC compared with PM of EPA-enriched EC. The negative correlation of AA with PM fluidity implies membrane rigidity. This observation is consistent with our previous study with platelet membrane (18). AA is presumed to produce endoperoxides not only through cyclooxygenase pathways but also by autoperoxidation (46). These endoperoxides may decrease membrane fluidity by peroxidizing membrane lipids. The reason for the absence of any direct correlation of plasma membrane fluidity with its EPA content is not clearly understood, yet it can be explained as follows: in the absence of EPA and DHA being added to the culture, these two PUFA represent 0.95 and 2.7% of the total fatty acid determined, respectively. Upon EPA enrichment these percentages rose to 2.7 and 2.9%; and with the addition of DHA these values were 2.3 and 7.1%, respectively. Thus, the maximal accumulation of EPA was found to be the basal level of DHA. Our speculation that EPA might exert its fluidizing effects indirectly through its retroconversion product, DHA, is lent further credence from the increasing support to the conception that DHA is primarily a structural fatty acid (47,48). From the physicochemical point of view, it could also be surmised that the lower capability of EPA than that of DHA in increasing membrane fluidity is related to the qualitative differences between these two fatty acids. For example, the differences in the *in situ* three-dimensional structure in the bilayer leaflet (cross-sectional area per fatty chain and motional freedom along the long axis of the acyl chain between EPA and DHA) might be involved in their differential effect on membrane fluidity. Also, in accordance with our previous studies with platelets, the correlation of endothelial PM EPA/AA with membrane fluidity was not significant, whereas the correlation with DHA/AA was highly significant (18). Moreover, the results of an increased USI in the PM of DHA-enriched cells over that of the PM of EPA-enriched cells led to the premise that the higher USI most likely accounted for the higher increase in membrane fluidity upon DHA enrichment.

We observed a greater decrease in total cholesterol content in the PM of DHA-enriched cells than in the PM of the EPA-enriched EC. The reason(s) for this greater decrease are not clearly understood; however, a higher increase (64 vs. 36% as compared to that of the control cells) in unsaturation in the DHA-enriched EC might be involved in such a greater decrease in the cholesterol level. It has been assumed that the higher the extent of unsaturation, the greater the inhibition of the rate-limiting enzyme of cholesterol biosynthesis, hydroxymethylglutaryl (HMG)-CoA reductase (49), and hence, the lower the cholesterol synthesis. Thus it is conceivable that the longer PUFA, DHA, may thus have a somewhat stronger hypocholesterolemic effect than that of EPA. Recently, a decrease in endogenous cholesterol biosynthesis by sivastatin—a HMG-CoA reductase inhibitor—has also been ascribed to the enhancement of membrane fluidity (50). That cholesterol has significant effects on membrane structure (51) and fluidity (52) has been provided by investigations carried out under various methodologies, including fluorescence polarization (53). Thus the higher increase in membrane fluidity upon DHA enrichment over that of EPA is, in part, due to the greater decrease in membrane cholesterol content along with a significant decrease in the molar ratio of cholesterol/phospholipid (20) only in the plasma membranes of DHA-enriched cells. This observation is consistent with other membrane systems including platelets (54,55) and synaptosomal membranes (56).

PUFA increase membrane fluidity; conversely, they increase susceptibility to oxidation and, as a result, may increase lipid peroxide concentrations in the cellular systems (21). In this context, PM fluidity should decrease because lipid peroxidation rigidifies the membrane by extensive cross-linking of the membrane constituents (57). Under the present experimental condition, although both antioxidative defenses (CAT and GPx activity) and oxidative potential (LPO level) increased quantitatively, the values did not reach significance on either

EPA or DHA treatment. Thus these data indicate that the dose (5 μg/mL medium) used did not elicit oxidative insults and failed to deteriorate, rather ameliorated, membrane fluidity. Regarding antioxidative-oxidative potential, however, our results contrast with those of Vankatraman *et al.* (58) and L'Abbé *et al*. (59), where feeding of fish oil increased both CAT and GPx activity along with lipid peroxide concentration. The reason for this discrepancy is not clear; however, differences in *in vivo* and *in vitro* conditions may be responsible, and this deserves further clarification.

Our results with the TMA-DPH fluoroprobe appear to conflict with those of Brown and Subbaiah (17), who found an increase in membrane fluidity in DHA-enriched fibroblasts but no effect of EPA on membrane fluidity. These discrepancies may relate to the differences in cell types, in the extent of membrane perturbations conferred by EPA or DHA, or both, and in techniques employed to determine membrane fluidity. Our experiments with EC suggest, however, that both EPA and DHA probably failed to generate perturbations at the water-lipid interfacial region (as probed by TMA-DPH) of the EC bilayer membrane. Conceivably therefore these two fatty acids failed to alter the bulk fluidity of the fatty acyl chains at or in the polar vicinity of the phospholipid head groups.

In conclusion, EPA and DHA have differential effects on EC PM fluidity. Three major factors that play significant roles in the determination of the higher fluidity of DHA over that of EPA in the PM of EC are lower contents of stearic acid and cholesterol, lower cholesterol/phospholipid molar ratios, and a higher fatty acid USI. Thus, we predict that the fluidity-dependent functions of EC would be influenced to a greater extent by DHA than that by EPA.

Effect of Peanut Oil and Randomized Peanut Oil on Cholesterol and Oleic Acid Absorption, Transport, and Distribution in the Lymph of the Rat

Subramaniam Satchithanandam[a,*], Thomas J. Flynn[b], Richard J. Calvert[c], and David Kritchevsky[d]

Divisions of [a]Science and Applied Technology and [b]Toxicological Research, and [c]Clinical Research and Review Staff, U.S. Food and Drug Administration, Laurel, Maryland 20708, and [d]The Wistar Institute, Philadelphia, Pennsylvania 19104

ABSTRACT: Peanut oil was shown to be atherogenic in cholesterol-fed rats, rabbits, and monkeys. However, after randomization, a process in which the fatty acids in peanut oil are randomly rearranged, its atherogenicity was significantly reduced in cholesterol-fed rabbits and monkeys. The mechanism for this effect remains unknown. This study was designed to investigate whether the absorption, transport and distribution of dietary cholesterol and oleic acid in the lymph were altered in the presence of peanut oil or randomized peanut oil. Previous investigators collected lymph through the mesenteric duct for 6 h and analyzed lymph for cholesterol. In the present study, lymph fluids were collected at timed intervals for up to 8 h and then at 24 h *via* the thoracic duct. Cholesterol and oleic acid (fatty acid) were estimated not only in the whole lymph but also in lymph lipoprotein fractions and in major lipid fractions. A 24-h lymph collection will enhance accuracy as short-term fluctuations in lipid absorption will not affect the results. Thoracic duct lymph collection is quantitative compared to mesenteric duct lymph collection, which provides only a fraction of the total lymph. Rats were given a lipid emulsion containing either peanut oil or randomized peanut oil. The emulsion also contained cholesterol, oleic acid, and sodium taurocholate in saline and was given through a duodenal catheter. Results show that absorption, transport, and distribution of cholesterol and oleic acid in the lymph fluids were similar in both dietary groups. These results suggest that the atherogenicity of peanut oil may be due to other events taking place subsequent to the release of cholesterol-containing chylomicrons and very low density lipoprotein by the small intestinal epithelial cells into the blood or may be due to the triglyceride structure itself.

Paper no. L8269 in *Lipids 34,* 1305–1311 (December 1999).

Peanut oil is atherogenic in rats (1), rabbits (2,3), and monkeys (4,5). However, when peanut oil is randomized, it is less atherogenic than native peanut oil in monkeys (5) and rabbits (6). The mechanism for this effect is not known. Randomization of peanut oil is carried out by pancreatic lipase (7). Several attempts were made to determine if any of the chemical changes during randomization were responsible for the decrease in atherogenic response. The rate of lipolysis was not different between peanut oil and randomized peanut oil using either pancreatic lipase or milk protein lipase (8), suggesting that lipolysis was not related to atherogenicity. Analysis of the triglyceride structure of native and randomized peanut oils showed that the native oil had more triglycerides with linoleic acid (18:2n-6) in the *sn*-2 position and saturated fatty acids in the *sn*-1 and *sn*-3 positions than the randomized peanut oil (9). In lymph-fistulated rats (10), the amounts of triglyceride, cholesterol, and phospholipid in the lymph were similar, as was the absorption of dietary cholesterol in both peanut oil and randomized peanut oil groups. From these results, it was concluded that differences in atherogenicity between peanut oil and randomized peanut oil are not due to differences in the amount of cholesterol transported into the lymph, but resulted from events subsequent to the release of cholesterol-containing chylomicrons and very low density lipoproteins (VLDL) by the small intestinal epithelial cells. In healthy individuals, substituting randomized butter for natural butter reduced serum cholesterol and triglycerides (11). Infants fed randomized lard had a 50% lower efficiency of absorption of stearic acid compared to consumption of regular lard (12). The rearrangements might have influenced the absorption of cholesterol and subsequently its entry into chylomicrons and lipoprotein fractions. The effect of peanut oil and randomized peanut oil on the main route of cholesterol transport, particularly *via* chlylomicrons, VLDL, low density lipoproteins (LDL), and high density lipoproteins (HDL) and its distribution in the major lipid classes, e.g., phospholipids (PL), mono- (MG), di- (DG), and triglycerides (TG), free fatty acids (FFA), and cholesterol ester (CE) has not been examined. In the present study, lymphatic transport and distribution of cholesterol and fatty acids in the chylomicron and lipoprotein fractions and their distribution in major lipid classes are compared in rats given peanut oil or randomized peanut oil.

MATERIALS AND METHODS

Animals and diets. Male Wistar rats (Harlan Sprague Dawley, Indianapolis, IN), weighing 200–250 g, were divided ran-

domly into two groups (10 rats/group) of comparable weights and maintained at 23°C in an animal room with a 12-h light/dark cycle. They were individually housed in suspended stainless-steel mesh cages. Rats were fed a commercial diet (Purina Rodent Chow 5002; Purina Mills Inc., St. Louis, MO) and distilled water *ad libitum* for 1 wk prior to surgical procedures and treatment with lipid emulsions. This study was conducted in accordance with the *Guide for the Care Use of Laboratory Animals,* Institute of Animal Resources, National Research Council.

Thoracic duct cannulation and lymph collection. After 1 wk on a standard diet, the animals were anesthetized with pentobarbital (50 µg/kg of body weight), and the thoracic duct was cannulated with PE-50 tubing (Clay Adams, Parsippany, NJ) according to the method of Bollman *et al.* (13). A second indwelling infusion catheter, PE-60 (Clay Adams), was placed in the duodenum at the pylorus for constant infusion of glucose–normal saline at 3 mL/h (glucose, 50 g/L; NaCl, 9 g/L) and for the administration of the test lipid emulsions. The test lipid emulsion was prepared and administered as described by Vahouny *et al.* (14) as follows: 0.5 mL stock I (150 mg cholesterol and 870 mg oleic acid in 3 mL of ethyl ether), 0.5 mL stock II (150 mg albumin and 834 mg sodium taurocholate in 3 mL saline), and 1.0 mL saline were mixed in a grinding vessel (Thomas Scientific, Swedesboro, NJ) and homogenized and the ether was evaporated under nitrogen. This process was repeated until no smell of ether was detected in the emulsion. The albumin was included in the preparation of the emulsion to provide a more physiological mixture and to aid in complete dispersion of the water-insoluble ingredients (15). Bovine serum albumin fraction V (fatty acid-poor), oleic acid (>99% pure), sodium taurocholate, and cholesterol were obtained from Sigma Chemical Co. (St. Louis, MO). Peanut oil (Planters, East Hanover, NJ) was purchased locally, and randomized peanut oil was obtained from Standard Brands, Inc. (Wilton, CT). The composition of the test lipid emulsions was as follows: albumin, 25; sodium taurocholate, 139; cholesterol, 25; oleic acid, 145; peanut oil or randomized peanut oil, 170 mg/1.5 mL lipid emulsion. The fatty acid composition of the two oils is given in Table 1. Animals were placed in restraining cages and allowed free access to glucose–normal saline. Lymph was collected from each rat from the time they were cannulated until they were administered the lipid meal. Amounts of cholesterol and oleic acid were estimated in the lymph. The average value for cholesterol was 7.4 ± 3.0 mg/dL and for oleic acid was 19.1 ± 4.2 mg/dL. These amounts were deducted from the values of cholesterol and oleic acid after the lipid emulsion was administered. After a constant infusion of glucose–normal saline overnight, 1.5 mL of the lipid emulsion was administered through the duodenal catheter, and then the constant infusion of glucose–normal saline was reestablished. Lymph samples were collected every 2 h for the first 8 h following the lipid administration, and then again at 24 h.

Separation of chylomicron and lipoproteins. Aliquots of 2- and 8–24-h lymph samples were pooled for each animal to obtain a 24-h collection. Portions of the 24-h lymph specimens were ultracentrifuged on density gradient by the method of Havel *et al.* (16) to separate chylomicrons ($d < 1.006$ kg/L; 3×10^6 g average minimum); VLDL ($d < 1.006$ kg/L; 1×10^8 g average minimum); LDL ($d < 1.063$ kg/L; 1.3×10^8 g average minimum); and HDL ($d < 1.063$ to 1.21 kg/L; 1.7×10^8 g average minimum). Appropriate fractions of chylomicron and lipoproteins were collected, and aliquots of 50 to 100 µL of each lipoprotein fraction were taken for fatty acid and cholesterol analysis by the method of Liebich *et al.* (17) as described below.

TABLE 1
Fatty Acid Composition of Oils (mg/100 mg total fatty acids)[a]

Fatty acid	Peanut oil	Randomized peanut oil
14:0	0.03	0.04
16:0	10.06	11.42
16:1	0.8	0.07
18:0	2.47	3.08
18:1	48.70	49.39
18:2	31.02	25.55
18:3	0.14	0.09
20:0	1.32	1.52
20:1	1.53	1.39
20:2	0.13	0.09
20:4	3.38	3.46
22:0	0.12	0.17
22:3	0.15	0.08
22:6	0.08	0.51
24:0	0.22	0.26

[a]Fatty acid analysis was performed as described in the Materials and Methods section.

Separation of lipids on thin-layer chromatography (TLC). Aliquots of 1.0 mL of 24-h lymph were extracted using chloroform/methanol (2:1, vol/vol) according to the method of Folch *et al.* (18). The chloroform/methanol extracts were evaporated under nitrogen and lipids were solubilized in hexane and separated into major lipid classes (19) by silica gel TLC (Analab, Norwalk, CT) using hexane/diethyl ether/acetic acid (80:16:2, by vol) as solvent. The separated lipid fractions were stained with iodine, which was placed in the bottom of the TLC tank. Areas on each plate co-migrating with authentic PL, MG/DG, TG, FFA, CE, and free cholesterol standards were individually scraped from the TLC plates and transferred to tubes.

Fatty acid analysis. Aliquots of chylomicron and lipoprotein fractions obtained by ultracentrifugation and fractions containing PL, MG/DG, FFA, TG, and CE separated and isolated on TLC plates were analyzed for fatty acids and cholesterol by the method of Liebich *et al.* (17). The fractions were extracted with chloroform/methanol (2:1) (18). The lipid-soluble fractions were then converted to fatty acid methyl esters (FAME) by the method of Liebich *et al.* (17) as described below. Lymph samples were heated at 100°C for 1 h with methanol, toluene, and acetyl chloride. The mixtures were partitioned with 6% potassium carbonate, and the upper toluene layer was decanted, heated with trifluoroacetic anhydride, dried, and dissolved in isooctane. Derivatized FAME

and cholesterol (as trifluoroacetate) were quantitated on a gas chromatograph (Hewlett-Packard, Palo Alto, CA) fitted with a capillary column optimized to separate FAME and cholesterol. Methyl tricosanoate (23:0) was used as an internal standard. The column was 30 m long (i.d. 0.25 mm) and coated with DB-23, cyanopropyl/methylpolysiloxane (J&W Scientific, Folsom, CA). Peanut oil and randomized peanut oil were analyzed by gas chromatography for fatty acid composition as described above.

Statistical analysis. Means and standard errors were calculated, and significant differences between groups were assessed by a Kruskal-Wallis test followed by Dunnett's procedure for pair-wise comparisons (20). Results were considered statistically significant at $P < 0.05$.

RESULTS

Lymph flow rate. The average lymph flow rate in the peanut oil group was 5.2 ± 1.6 mL/h and was 7.1 ± 2.0 mL/h in the randomized peanut oil group. There were no significant differences between the two groups.

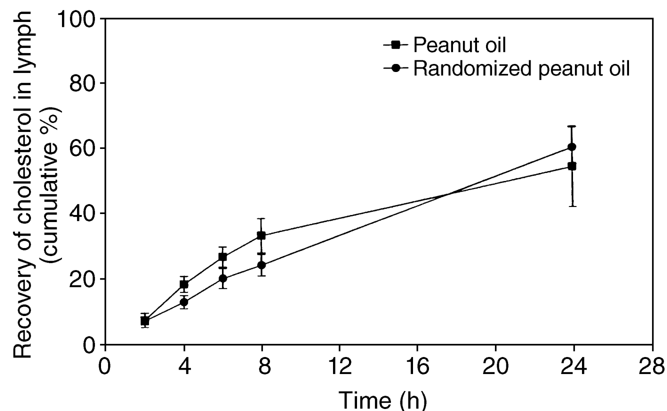

FIG. 1. Percentage recovery of cholesterol in lymph of rats that received either peanut oil or randomized peanut oil. Values are mean ± SEM; n = 10 rats/group.

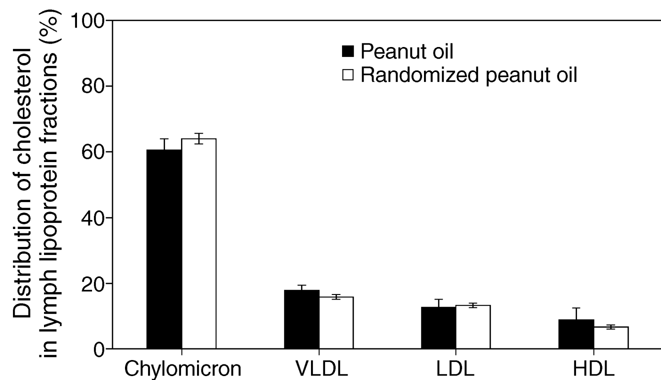

FIG. 2. Percentage distribution of cholesterol in lymph lipoprotein fractions (VLDL, very low density lipoprotein; LDL, low density lipoprotein; HDL, high density lipoprotein) of rats that received either peanut oil or randomized peanut oil. Values are mean ± SEM; n = 10 rats/group.

Cholesterol absorption and recovery. The cumulative percentage absorption of total cholesterol into the thoracic duct of rats that received either peanut oil or randomized peanut oil is shown in Figure 1. Cumulative percentage of absorption of cholesterol during 24 h continued to increase in both groups. During this period 55–60% of the infused cholesterol was re-

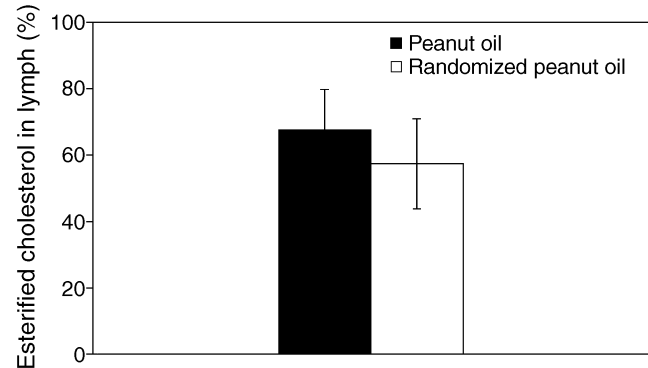

FIG. 3. Percentage of esterified cholesterol in the lymph of rats that received either peanut oil or randomized peanut oil. Values are mean ± SEM; n = 10 rats/group.

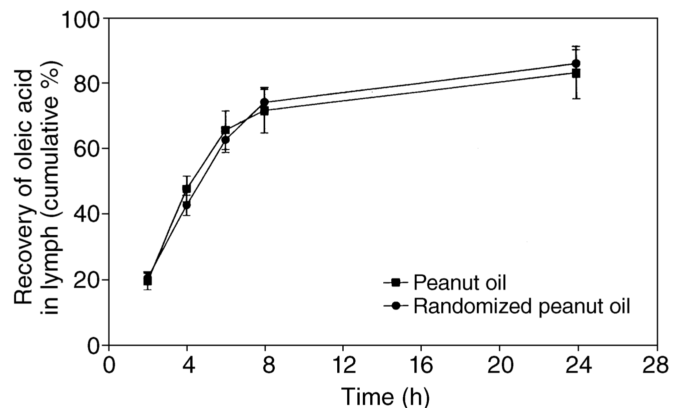

FIG. 4. Percentage recovery of oleic acid in the lymph of rats that received either peanut oil or randomized peanut oil. Values are mean ± SEM; n = 10 rats/group.

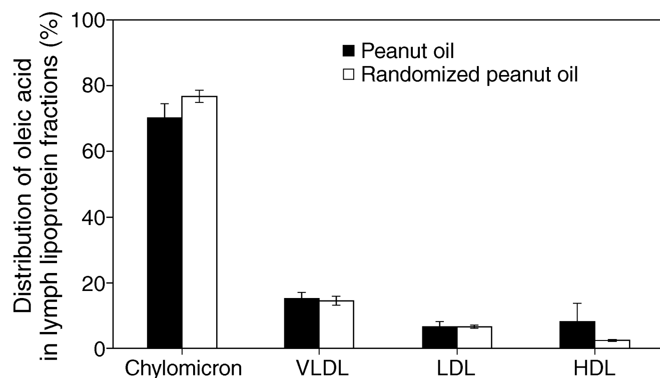

FIG. 5. Percentage distribution of oleic acid in lymph lipoprotein fractions of rats that received either peanut oil or randomized peanut oil. Values are mean ± SEM; n = 10 rats/group. See Figure 2 for abbreviations.

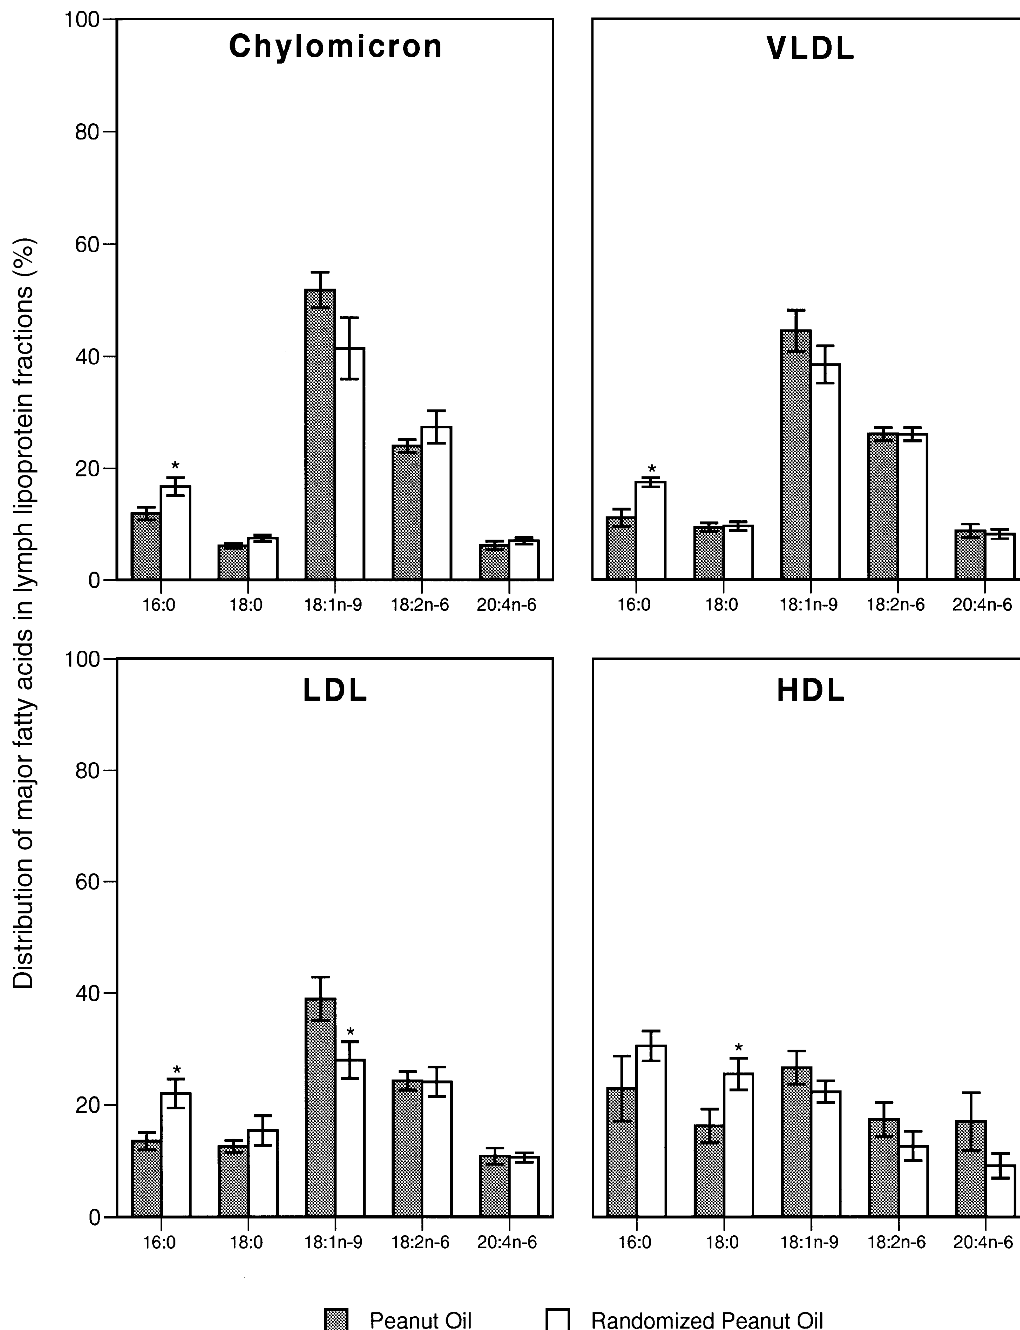

FIG. 6. Percentage distribution of major fatty acids in lipoprotein fractions of rats that received either peanut oil or randomized peanut oil. Mean ± SEM; $n = 10$ rats/group. *Significantly different from peanut oil group, $P < 0.05$. See Figure 2 for abbreviations.

covered in the lymph of both groups. There were no significant differences either in cumulative absorption of cholesterol or total recovery of cholesterol between the two groups.

The percentage distribution of total cholesterol in lymph lipoprotein fractions is shown in Figure 2. About 60–63% of the absorbed cholesterol was associated with the chylomicron fraction ($d < 1.006$ kg/L); the remaining 37–40% was distributed in the VLDL, LDL, and HDL fractions—about 15–17% in the VLDL, 12–13% in the LDL, and 6–8% in the HDL fractions. There were no significant differences between the two groups.

The percentage of esterified cholesterol in the lymph of rats that received either peanut oil or randomized peanut oil is shown in Figure 3; 67.4 ± 12.3% of cholesterol was esterified in the group that received peanut oil, whereas 57.2 ± 13.5% of cholesterol was esterified in the group that received randomized peanut oil. However, there were no significant differences between the groups.

Oleic acid absorption and recovery. The cumulative percentage absorption of oleic acid (18:1n-9) in the lymph of rats that received either peanut oil or randomized peanut oil is shown in Figure 4. Cumulative absorption of 18:1n-9 increased rapidly until 8 h. From 8–24 h, absorption slowed. In both groups, about 82–85% of the infused 18:1n-9 was recovered in the lymph over a 24-h period. There were no significant differences between the two groups.

Distribution of fatty acids in lipoprotein fractions. The percentage recovery of 18:1n-9 in lymph lipoprotein fractions is shown in Figure 5. In both groups, about 69–76% of the absorbed 18:1n-9 was recovered in the chylomicron fraction. The remaining 24–31% was distributed as follows: 14–15% in VLDL, 6% in LDL, and 7% in the HDL fractions. There were no significant differences between the two groups.

The percentage distribution of major fatty acids in lymph lipoprotein fractions is shown in Figure 6. The major fatty acids isolated from both groups were palmitic (16:0), stearic (18:0), oleic (18:1n-9), linoleic (18:2n-6), and arachidonic (20:4n-6) acids. The percentage of 16:0 in the chylomicron, VLDL, and LDL fractions was significantly higher in rats fed randomized peanut oil compared to the peanut oil-fed group. The LDL fraction also showed significant reduction in the percentage of 18:1n-9 in the randomized peanut oil group compared to the peanut oil-fed group. In the HDL fraction, only 18:0 is significantly higher in the randomized peanut oil group compared to the peanut oil group.

The percentage of total fatty acids estimated in each lipid fraction is shown in Figure 7. About 62–71% of the total fatty acids was recovered in the TG fraction, 13–19% in the PL fraction, 7–9% in the FFA fraction, 3–4% in the MG/DG fractions, and 2–3% in the cholesterol and CE fractions between the two groups. There were no significant differences in the percentage of total fatty acids distributed in the lipid fractions. The percentage of major fatty acids distributed in lipid fractions is shown in Figure 8. Major fatty acids isolated from both groups were 16:0, 18:0, 18:n-9, 18:2n-6, and 20:4n-6. There were no significant differences in the distribution of major fatty acids between the groups.

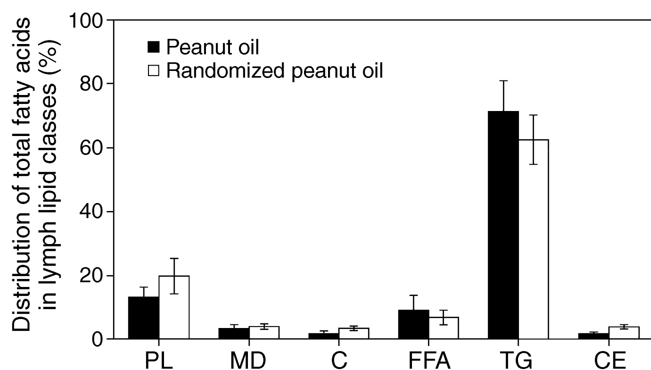

FIG. 7. Percentage distribution of total fatty acids in each lipid fractions (PL, phospholipid; MD, mono- and diglycerides; C, cholesterol; FFA, free fatty acid; TG, triglyceride; CE, cholesterol ester) of rats that received either peanut oil or randomized peanut oil. Values are mean ± SEM; *n* = 10 rats/group.

DISCUSSION

The present studies were conducted to evaluate whether peanut oil and randomized peanut oil affect absorption, transport, or distribution of cholesterol and 18:1n-9 in the lymph of rats. The lipid emulsion that was used contained cholesterol, oleic acid, sodium taurocholate (bile acid), and albumin, all of which form micelles in the lumen of the small intestine. Earlier studies by Vahouny *et al.* (15) found this composition of emulsion to be the ideal mixture that produced maximal sterol absorption. The sterols in the emulsion are taken up by the enterocytes, undergo obligatory esterification, and are incorporated into the nonpolar core of chylomicrons, which then enter the lymph (15). Our results show that in the presence of either oil, cholesterol and 18:1n-9 were absorbed equally into the lymph. There were no significant differences in the distribution of cholesterol and 18:1n-9 in various fractions of lymph lipoprotein. Figure 3 indicates that cholesterol was esterified equally in both groups. However, there were some statistically significant differences in the fatty acid composition of some of the lipoprotein fractions. With randomized peanut oil infusion, palmitic acid in the chylomicron, VLDL, and LDL fractions was significantly increased, while 18:0 was significantly increased in the HDL fraction and 18:1n-9 was significantly decreased in the LDL fraction compared to peanut oil. We do not know how important these statistically significant increases may be in relation to atherogenicity. The observed significant increase in palmitic acid observed in Figure 6 was due to the rearrangement of palmitic acid in the randomized peanut oil. In native peanut oil, palmitic acid was present in a high amount and equally distributed between *sn*-1 and *sn*-3 positions, while a low amount was present in *sn*-2 position of the triacylglycerol molecule (10). Once the native peanut oil was randomized, palmitic acid in the *sn*-2 position of the triacylglycerol molecule increased and resulted in high amounts of palmitic acid as observed in lipoprotein fractions. As shown in Figures 7 and 8 there were no significant differences in either the total fatty acid distribution or amount of major individual fatty acid distribution in the lipid fractions (PL, MG/DG, FFA, TG, or CE) of rats administered peanut oil or randomized peanut oil.

The results of this study show that there were no significant differences between peanut oil and randomized peanut oil on cholesterol and 18:1n-9 absorption, distribution, and transport in the lymph. Tso *et al.* (10) also reported that TG, cholesterol, and PL outputs were similar in both dietary groups. The recovery of cholesterol from the intestinal lumen and mucosa showed that absorption and transport also were similar in both groups. In their study, analysis of the fatty acid of both lymph and intestinal mucosal lipids failed to reveal any differences between the two groups. Based on this study and others (8–10), it can be concluded that the atherogenicity of peanut oil may be due to events taking place subsequent to the entry into the plasma of the cholesterol-containing chylomicrons or VLDL. Recently, lectins present in peanut oil have been implicated in the atherogenic effect. Kritchevsky *et al.* (21,22) showed that the randomization process could destroy lectins

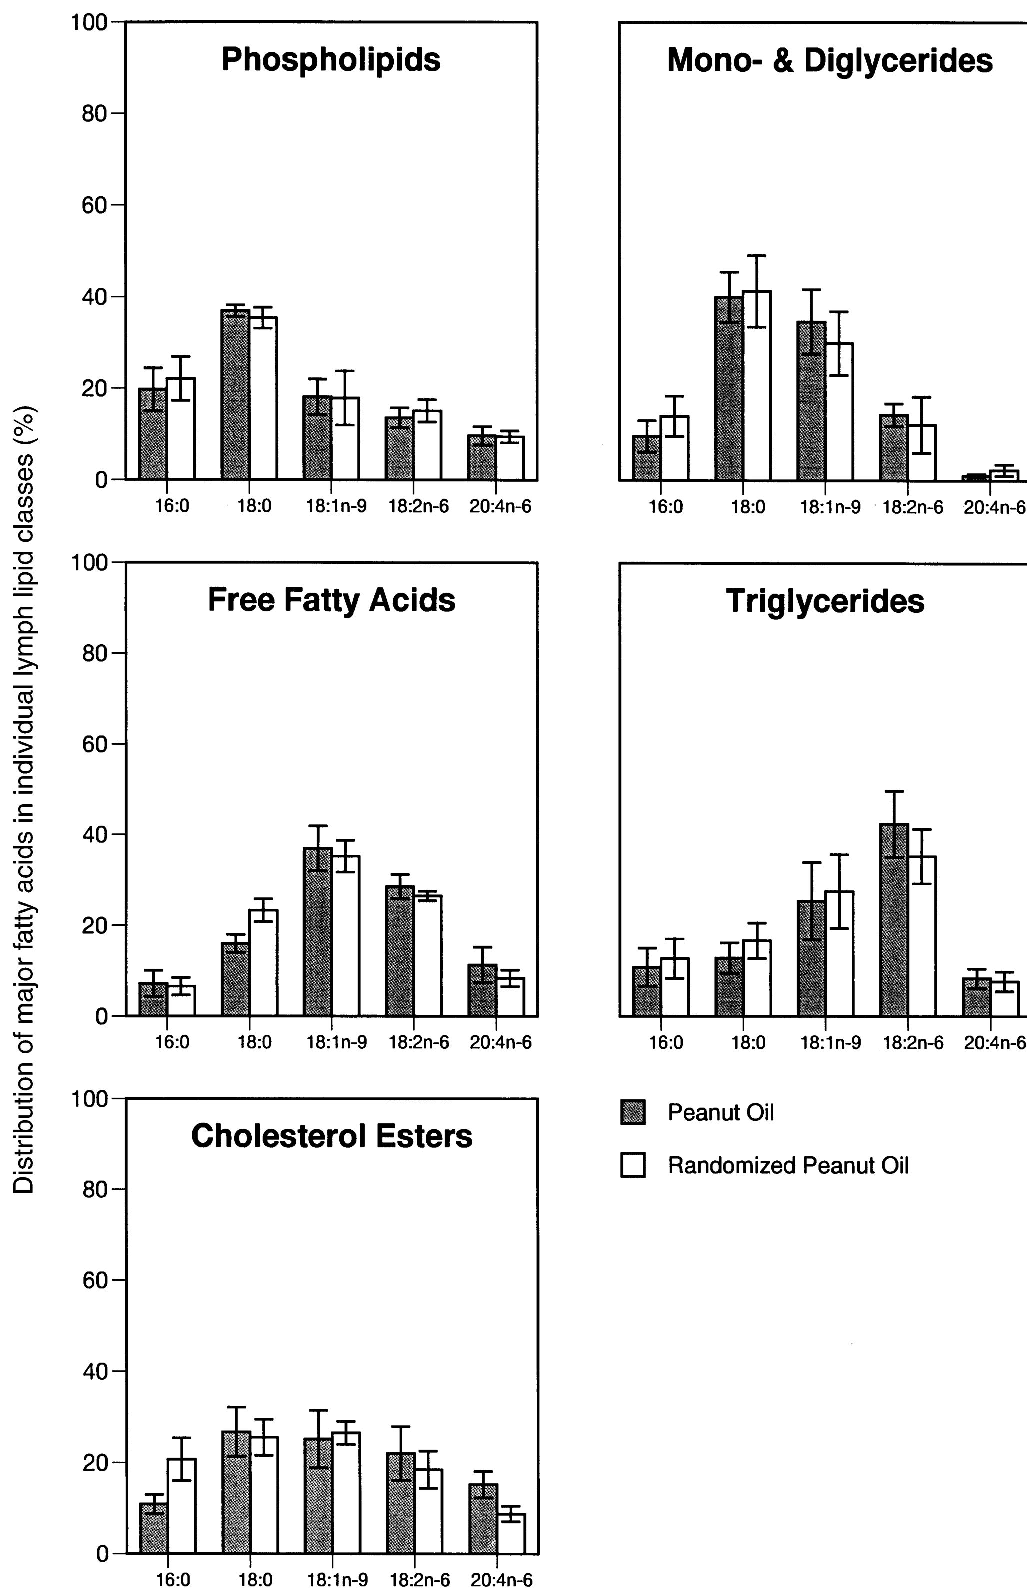

FIG. 8. Percentage distribution of major fatty acids in each lipid fractions of rats that received either peanut oil or randomized peanut oil. Values are mean ± SEM; n = 10 rats/group. See Figure 7 for abbreviations.

and thus prevent atherogenicity. In their study, they reported that randomized peanut oil had 36% less lectin than peanut oil, suggesting that reducing the lectin content of peanut oil reduces its atherogenicity (22). It is also possible that randomized peanut lectins inhibit recruitment of macrophages, which are the major cell type occurring in aortic fatty streaks (23).

Dietary Phospholipid Alters Biliary Lipid Composition in Formula-Fed Piglets

Angela M. Devlin and Sheila M. Innis*

Department of Paediatrics, Faculty of Medicine, University of British Columbia, Vancouver, British Columbia, Canada

ABSTRACT: Plasma cholesterol, arachidonic acid (AA, 20:4n-6), and docosahexaenoic acid (DHA, 22:6n-3) are higher in breast-fed infants than in infants fed formula without cholesterol, AA, or DHA. This study investigated differences in plasma, hepatic, and bile lipids and phospholipid fatty acids, and expression of hepatic proteins involved in sterol metabolism that result from feeding formula with cholesterol with egg phospholipid to provide AA and DHA. For this study, three groups of piglets were evaluated: piglets fed formula with 0.65 mmol/L cholesterol, the same formula with 0.8% AA and 0.2% DHA from egg phospholipid, and piglets fed sow milk. Piglets fed the formula with phospholipid AA and DHA had higher plasma high density lipoprotein, but not apoprotein (apo) B cholesterol or triglyceride; higher bile acid and phospholipid concentrations in bile; and higher liver and bile phospholipid AA and DHA than piglets fed formula without AA and DHA ($P <$ 0.05). Hydroxy methylglutaryl (HMG)-CoA reductase and 7-α-hydroxylase, the rate-limiting enzymes of cholesterol and bile acid synthesis, respectively, and low density lipoprotein receptor mRNA levels were not different between piglets fed formula without and with phospholipid AA and DHA, but HMG-CoA reductase and 7α-hydroxylase mRNA were higher, and plasma apo B containing lipoprotein cholesterol was lower in all piglets fed formula than in piglets fed milk. These studies show that supplementing formula with AA and DHA from egg phospholipid alters bile metabolism by increasing the bile AA and DHA, and bile acid and phospholipid.

Paper no. L8199 in *Lipids 34,* 1313–1318 (December 1999).

Human milk provides small amounts of arachidonic acid (20:4n-6, AA) and docosahexaenoic acid (22:6n-3, DHA) (1,2), and as a result blood lipid concentrations of AA and DHA are higher in infants fed human milk than in infants fed formula without AA and DHA (3–6). Plasma concentrations of cholesterol, particularly low density lipoprotein (LDL) cholesterol, are also higher in infants fed milk than infants fed formula (7), but whether this is due to the presence of cholesterol in milk but not formula is not clear. Much of the current interest with respect to AA and DHA in infant lipid nutrition has focused on the important role of AA and DHA in growth, and brain and visual function (3–6,8–10). The n-6 and n-3 polyunsaturated fatty acids, however, are involved in numerous important metabolic processes, including eicosanoid synthesis, gene expression, and hormonal signaling and are known to influence triglyceride and lipoprotein metabolism (11,12). AA and DHA can be synthesized in the liver from the precursors, linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3), respectively (13), or provided in the diet as preformed dietary AA and DHA. In the liver, AA and DHA can be incorporated into membrane phospholipids (PL), or secreted in lipoprotein or bile PL. Several studies have shown that dietary long-chain polyunsaturated fatty acids influence bile acid metabolism and bile flow (14–19). Diet-related differences in bile acid and hepatic lipid metabolism between breast-fed and formula-fed baboons (20,21) and piglets (22,23) have been reported. Longer-term studies have also shown altered cholesterol and bile acid metabolism in older baboons who had been fed formula when compared with baboons that had been breast-fed as infants (24–26). Whether the long-chain fatty acids present in milk but absent from formula influence hepatic bile lipid metabolism is not known.

The objective of this study was to investigate the effect of supplementing infant formula with egg PL containing AA and DHA (i) on hepatic and bile lipids, (ii) on hepatic levels of mRNA for cholesterol 7-α-hydroxylase (C7H; EC 1.14.13.15) and HMG-CoA reductase (EC 1.1.1.34), the rate-limiting enzymes in bile acid and cholesterol synthesis, respectively, and (iii) on hepatic LDL receptor mRNA in formula-fed piglets. Egg PL has been used to provide AA and DHA to infants in studies considering the role of neonatal dietary AA and DHA on infant visual development (3,4).

MATERIALS AND METHODS

Animals and diets. Male Yorkshire piglets with birth weight >1 kg were obtained within 24 h of birth, from Peter Hill Holdings (Langley, British Columbia, Canada) and randomly assigned to be fed formula without (n = 9) or with egg PL to provide AA and DHA (n = 6), until 15 d of age. A group of

piglets ($n = 7$) left on the farm and fed by their natural mothers (milk) was also studied for reference. Piglets from the same litter were not assigned to the same diet group. The housing and procedures for feeding piglets have been described (27).

The formula fatty acids contained about 25% 16:0, 7% 14:0, 20% 18:2n-6, and 1.8–2.1% 18:3n-3 compared with 30% 16:0, 4% 14:0, 11% 18:2n-6, and 1.1% 18:3n-3 in the sow milk (Table 1). The levels of 18:2n-6 and 18:3n-3 in the formulas were similar to those in currently available term infant formula: human milk typically has about 12–16% 18:2n-6 and 1% 18:3n-3 (1,2). The formula with egg PL had 0.8% AA and 0.25% DHA, and the sow milk had 0.7% AA and 0.1% DHA.

At 15 d of age, between 0900 and 1030, the piglets were anesthetized and blood samples were drawn by cardiac puncture (27). Plasma was prepared by centrifugation, and with the exception of aliquot samples for high density lipoprotein (HDL) cholesterol, the samples were frozen at −80°C. After laparotomy, the liver was removed, bile was drawn from the gallbladder, the liver was weighed, and a portion was immediately frozen in liquid nitrogen and stored at −80°C until preparation of RNA. The remaining organ was homogenized and stored at −80°C for later lipid analysis. All procedures involving the piglets were approved by the Animal Care Committee of the University of British Columbia and conformed to the guidelines of the Canadian Council on Animal Care.

Lipid analysis. The plasma and liver total cholesterol and triglyceride concentrations were determined using enzymatic reagents (Diagnostic Chemical Ltd., Charlottetown, Prince Edward Island, Canada; Boehringer Mannheim Diagnostics, Montréal, Québec, Canada) (27). Plasma HDL cholesterol was determined following precipitation of apoprotein (apo) B-containing lipoproteins with heparin-manganese chloride (28). The amount of cholesterol associated with apo B-containing lipoproteins (chylomicron + VLDL + LDL) was calculated as the difference between the total and HDL cholesterol. Plasma, liver, and bile lipid were extracted, the lipid fractions separated by thin-layer chromatography, and the PL, triglyceride, and cholesterol ester fatty acids analyzed by gas–liquid chromatography (29). The bile lipid extracts were

exposed to fluorescent light overnight to permit photodegradation of biliary pigments, prior to quantifying total cholesterol, total bile acids (30), and PL (31). Total protein was determined according to the method of Lowry *et al.* (32) using bovine serum albumin (BSA) as a standard.

mRNA assays. The reverse transcription polymerase chain reaction (RT-PCR) method, as well as the primer sequences used in the RT-PCR reactions, used to assess the levels of LDL receptor, HMG-CoA reductase, and C7H mRNA have recently been described (22). This procedure involved reverse-transcribing a known quantity of total RNA to generate a pool of cDNA representing the RNA in the original sample. PCR was used to amplify the cDNA corresponding to the mRNA of interest. The expression of β-actin was also determined for each sample and used as an internal control for the efficiency of each RT-PCR reaction.

Total RNA was isolated from liver tissue using TRIzol® (Gibco BRL, Burlington, Ontario, Canada) following the protocol described by the manufacturer. The RNA preparations were treated with 10U of RQ1 RNase-free DNase (Promega, Madison WI) to ensure no genomic DNA contamination, and 2.5 µg of total RNA was used for first strand cDNA synthesis as previously described (22). The resulting cDNA pool for each RNA sample was divided into aliquots (3 µL) with one aliquot used in each PCR reaction. Separate PCR reactions were run for LDL receptor, HMG-CoA reductase, C7H and β-actin (22). The number of cycles used for the PCR reactions for LDL receptor, HMG-CoA reductase, C7H and β-actin were gene specific and were determined to be in the exponential phase of the amplification process. The number of cycles for each gene was: LDL receptor 35 cycles, HMG-CoA reductase 35 cycles, C7H 35 cycles, β-actin 25 cycles. The PCR reactions (10 µL each) were resolved on a 1.5% agarose-1XTBE gel and stained with ethidium bromide. A photograph was taken with Kodak TRI-X pan film. The negatives were scanned with a video densitometer (model 620; Bio-Rad, Mississauga, Ontario, Canada) to determine the relative intensity of the bands, and this was expressed per microgram RNA used in the original RT reaction. The intra- and interassay variability between RT-PCR reactions was less than 10%.

Statistical analysis. Analysis to determine the effect of feeding formula in comparison with milk feeding, and of supplementing formula with PL AA and DHA was done with one-way analysis of variance (ANOVA). Fisher's least significant difference was used to determine specific group differences for ANOVA results with $P < 0.05$. All calculations were performed using the Statistical Package for the Social Sciences (SPSS) for windows, renewable version (release 6.1).

RESULTS

There were no differences in body weight or liver weight among the piglets fed the formula without ($n = 9$) or with PL ($n = 6$), or those fed sow milk ($n = 7$) (body weight, 5.15 ± 0.13, 4.83 ± 0.15, 4.78 ± 0.40 kg; liver weight, 28.3 ± 1.24, 26.6 ± 0.50, 24.7 ± 0.90 g, respectively). The piglets fed for-

[a]Data are expressed as means ± SEM; formula, $n = 9$; formula + PL, $n = 6$; milk, $n = 7$. Values with a different roman superscript a–c are significantly different, $P < 0.05$. HDL, high-density lipoprotein; apo B, apoprotein B; for other abbreviation see Table 1.

mula all had significantly ($P < 0.001$) lower plasma total and apo B containing lipoprotein (VLDL + LDL) cholesterol concentrations than piglets fed milk (Table 2). Piglets fed the standard formula had a significantly lower plasma concentration of HDL cholesterol than the piglets fed milk. Although the plasma HDL cholesterol concentration was significantly higher in piglets fed the formula with PL than in piglets fed the standard formula, it was still significantly lower than in the milk-fed group. Piglets fed the formula with PL also had significantly higher plasma triglyceride concentrations than piglets fed milk.

There were no significant differences in the liver cholesterol, triglyceride, or PL concentrations among the piglets fed formula and those fed sow milk, with the exception that piglets fed the formula with PL had a significantly higher liver PL concentration than piglets fed milk (Table 2).

Piglets fed the formula with PL had significantly higher liver PL AA and DHA than piglets fed the standard formula or sow milk (Table 3). Supplementation with egg PL also resulted in significantly higher AA, but not DHA in the liver triglyceride when compared with piglets fed the standard formula or sow milk. Consistent with the lower 16:0 and higher 18:2n-6 in the formula than milk (Table 1), the liver PL, triglyceride, and cholesterol ester 16:0 was lower and the triglyceride and cholesterol ester 18:2n-6 was higher in the formula than milk-fed piglets.

Piglets fed the standard formula had significantly lower bile acid and PL in bile than piglets fed milk (Table 4). Including egg PL in the formula significantly increased concentrations of PL and bile acid in bile of the formula-fed piglets to concentrations not different from those of piglets fed milk. Piglets fed the formula with PL also had significantly higher bile PL AA and DHA than piglets fed milk or the standard formula.

The piglets fed formula had significantly higher levels of HMG-CoA reductase and C7H mRNA than piglets fed milk (Fig. 1). However, whereas the group comparisons found HMG-CoA mRNA was significantly lower in both the piglets fed the standard and those fed the PL supplemented formula, the differences in C7H mRNA from the sow milk group were not significant ($P = 0.07$). The levels of LDL receptor mRNA was not different between the milk-fed piglets and piglets fed the formulas.

DISCUSSION

Formula feeding results in lower plasma cholesterol, particularly in apo B-containing lipoproteins, and lower AA and DHA concentrations than breast feeding (3–10), and also produces short- and long-term changes in hepatic and plasma lipid metabolism in animals (20–25). Some evidence also suggests early nutrition may influence chronic diseases, including coronary heart disease, in adult humans (33). Previous studies have shown piglets fed formulas resembling infant formulas have lower plasma cholesterol, and higher hepatic C7H and HMG-CoA reductase mRNA and enzyme

[a]Values shown are means ± SEM; formula, $n = 9$; formula + PL, $n = 6$; milk, $n = 7$. Values in a row with a different roman superscript a–c are significantly different, $P < 0.05$.

activity than piglets fed milk (22,23,34). Similarly, stable isotope measures of cholesterol synthesis have indicated that cholesterol synthesis is increased in infants fed formula (35). PL supplementation increased liver and bile PL AA and DHA, and increased the bile PL and bile acid concentrations of the formula-fed piglets such that the bile PL and bile acid concentrations were not different from those of piglets fed milk. Whether the increase in bile PL and bile acid was due to the AA and DHA or the PL is not clear from our studies.

Most studies have concluded that the secretion of PL in bile lipid is not increased by PL feeding (36,37), although short-term feeding with soybean-derived phosphatidylcholine high in 18:2n-6 increased bile cholesterol and PL output in rats (38). Dietary and biliary PL is hydrolyzed to lysophospholipid in the intestine prior to absorption, and subsequently reesterified for secretion to plasma in lipoproteins. This suggests the increased bile lipids secondary to PL feeding may be secondary to increased cholesterol or bile acid reabsorption, or hepatic lipoprotein PL or cholesterol uptake.

Inclusion of egg PL in the formula increased plasma HDL cholesterol concentrations in the formula-fed piglets. The concentration of plasma HDL cholesterol can be influenced by the rate of apo A-1 production (39). Further, recent studies reported that phosphatidylcholine increased apo A-1 secretion by newborn pig intestinal epithelial cells, possibly by a mechanism involving mobilization of a preformed pool of apo A-1 (40). However, it is not known if the plasma PL pool or turnover, or transfer of HDL cholesterol to the liver, which is thought to be important in the movement of cholesterol to liver for excretion (41), was increased by PL supplemention. The liver PL concentration of the formula-fed piglets, however, was not increased by PL supplementation, and no association was found between the liver and bile PL among piglets fed the milk and formula diets. Hepatic PL synthesis and secretion, on the other hand, have been shown to be in-

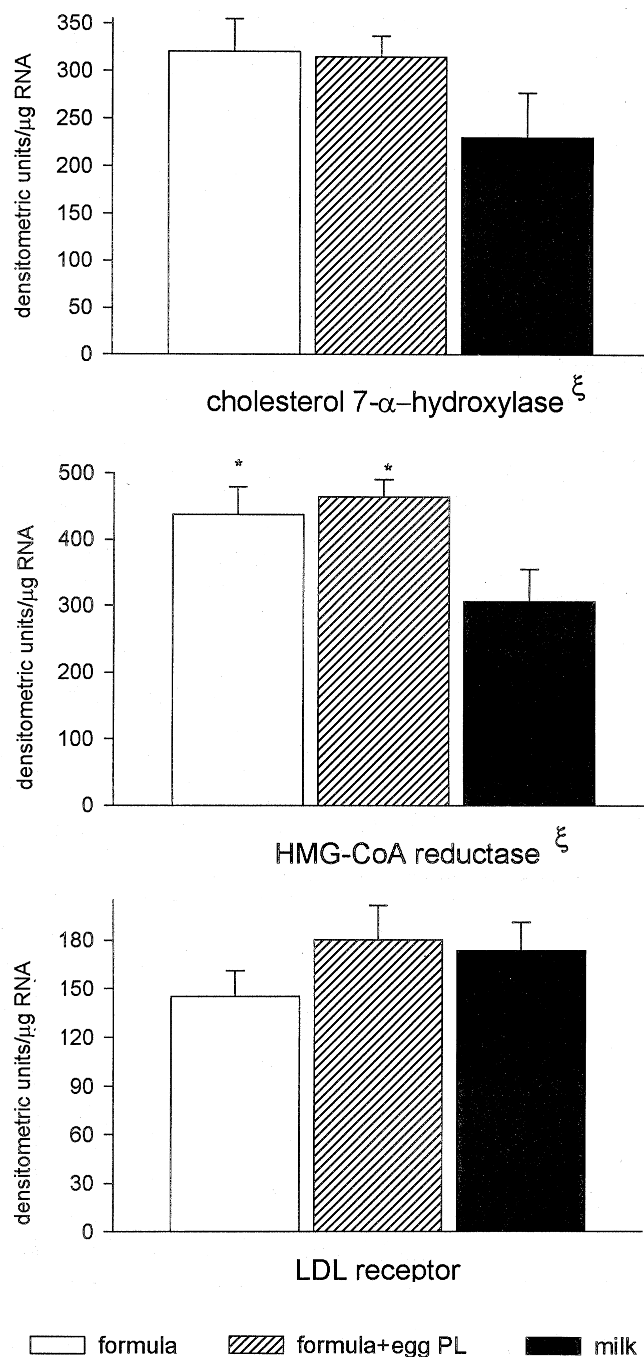

FIG. 1. Hepatic cholesterol 7-α-hydroxylase, low density lipoprotein (LDL) receptor, and 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase mRNA levels in piglets fed formula without and with phospholipid (PL) or milk. Values shown as mean ± SEM; formula, $n = 9$; formula + PL, $n = 6$; milk, $n = 7$. ξ, Significant effect of feeding formula compared with milk; value for group fed formula significantly different from value for group fed milk ($P < 0.05$).

creased by bile salt administration (42), and the fatty acid composition of dietary lipid is known to influence intestinal membrane lipids and transport functions (43). Whether the quantity of PL or AA and DHA in the intestine influences bile acid reabsorption does not appear to be known.

Several studies have provided evidence that the fatty acid composition of dietary lipid influences the fatty acid composition of bile phospholipid, as well as biliary lipid and bile acid secretion (15–19,44). Thus, it is possible that the increase in bile PL and bile acid in piglets fed formula with egg PL was secondary to the increase in hepatic AA and DHA. However, the liver and bile AA and DHA in piglets fed formula with PL was higher than in piglets fed milk, whereas the bile acid and PL were not different. It seems unlikely therefore that the effects of the formula PL supplementation on the piglet bile components are explained by the n-6 and n-3 fatty acid components.

It is well appreciated that infants (as well as piglets) fed milk have higher plasma LDL cholesterol concentrations than infants fed formulas (3,22,23,34,35). The plasma LDL cholesterol concentration is determined by the rate of VLDL production and metabolism to LDL, and the rate of LDL receptor-dependent and -independent clearance (39). Dietary lipids are able to influence both LDL production and hepatic LDL receptor activity. However, substantial information is available to show that LDL receptor activity is regulated by the cholesterol content of the tissue (39). The liver cholesterol concentrations were not different among piglets fed formula and milk, consistent with the absence of a difference in LDL receptor mRNA. However, it is possible that the lower 18:2n-6 + 18:3n-3 and higher 16:0 content of milk, or some other component of milk not present in formula might have altered LDL receptor activity, without accompanying changes in LDL receptor mRNA. Future work might also consider whether VLDL synthesis and secretion are increased in neonates fed milk rather than formula.

Piglets fed formula have lower hepatic mRNA for the major rate-limiting enzymes in cholesterol and bile acid synthesis, HMG-CoA reductase and C7H, and lower plasma cholesterol than piglets fed milk (Table 2; Refs. 22,23,34). Supplementation with PL increased bile PL and bile concentrations in formula-fed piglets, but had no effect on HMG-CoA reductase or C7H mRNA or on plasma cholesterol. Studies in baboons have shown lower bile acid synthetic rates and higher hepatic LDL receptor mRNA, bile acid cholesterol saturation, cholesterol production rates, and neutral steroid excretion in juvenile and adult animals that had been breast-fed rather than fed formula (24–26.) The formula cholesterol and polyunsaturated/saturated fat ratio had no measurable effect on these long-term changes in cholesterol and bile acid metabolism in baboons (24–26). The possibility that early nutrition may affect chronic diseases, such as coronary heart disease in humans, has also been raised (33). Our results, which show that early milk feeding compared with formula feeding alters mRNA for regulatory enzymes of hepatic cholesterol metabolism, suggests diet-induced changes in expression of these proteins during early neonatal development may be an important site of lasting nutrient-gene interactions. Further studies are needed to determine the possible significance of early diet-induced changes in hepatic cholesterol and bile lipid metabolism for intestinal absorptive functions and the potential longer-term implications for cholesterol metabolism.

ABSTRACT: Rats were fed a fat-free diet for 2 wk. After this period, while maintaining the animals on the same diet, the rats were given intragastrically 180 mg per day of a mixture of conjugated linoleic acids (CLA) as triacylglycerols. Gas chromatography–mass spectrometry (GC–MS) analyses of this mixture, as well as hydrazine reduction and GC–MS and GC–Fourier transform infrared analyses of the resulting monoenes, revealed the presence of two major isomers, the 9*c*,11*t*- and the 10*t*,12*c*-18:2 accompanied by smaller amounts of the 8*t*,10*c* and the 11*c*,13*t*-18:2 isomers. Minor quantities of *cis,cis* and *trans,trans* conjugated isomers also were detected. The total fatty acid methyl esters from the liver lipids were fractionated by reversed-phase high-performance liquid chromatography, and the fraction containing the 20:4 isomers was further fractionated by silver nitrate thin-layer chromatography. A band containing two 20:4 conjugated isomers was submitted to hydrazine reduction and the resulting monoenes analyzed by GC–MS as dimethyl-oxazoline derivatives. The two conjugated isomers were tentatively identified as 5*c*,8*c*,11*c*,13*t*-20:4 and 5*c*,8*c*,12*t*,14*c*-20:4. These could be formed by desaturation and elongation of the 9*c*,11*t*- and 10*t*,12*c*-18:2 present in the commercial CLA mixture.

Paper no. L7989 in *Lipids 34*, 1319–1325 (December 1999).

A series of studies have shown that conjugated isomers of linoleic acid (CLA) have anticarcinogenic (1–6) and antiatherogenic (7,8) properties. CLA are present in foodstuffs such as milk and dairy products (9–14), meat from ruminants (15), and to a lesser extent, in partially hydrogenated oils (16) and frying oils as a result of heat treatment (17). In dairy products, the major isomer is 9*c*,11*t*-18:2 (13,14,18), whereas commercial samples of CLA mainly contain a mixture of *cis*/*trans* isomers of 8,10-, 9,11-, 10,12, and 11,13-18:2 (19).

The antioxidant activity of CLA has been suggested to explain in part the anticarcinogenic properties of these molecules (1,3). However, van den Berg *et al.* (20) recently showed that in model membranes, CLA did not exhibit any antioxidant properties. Furthermore, supplementation of CLA in MCF-7 breast cancer cells did not reduce lipid peroxide formation (21). Another possibility that has been suggested is that CLA may compete with linoleic acid for biosynthesis of arachidonic acid and eicosanoids (22). For example, CLA were shown to be absorbed and incorporated into the phospholipid fraction of different tissues (3,23–25) and to reduce the concentration of prostaglandin E_2 in serum and spleen. Like other *trans* 18:2 isomers of linoleic acid (26–28), CLA can be metabolized and converted to conjugated isomers of eicosatrienoic and eicosatetraenoic acids (24,29,30).

Recently, the feeding of rats with a commercial CLA mixture, as described elsewhere (19), permitted the identification by gas–liquid chromatography coupled with mass spectrometry (GC–MS) of three unusual conjugated C_{20} fatty acids—8,12,14-20:3, 5,8,12,14-20:4, and 5,8,11,13-20:4—in their liver lipids (30). These fatty acids are likely to arise from desaturation and elongation of the 9,11- and 10,12-18:2 isomers. Unfortunately, it is impossible to conclude at the moment which of the geometrical isomers (*cis*,*trans*, *trans*,*cis* or *trans*,*trans*) present in the commercial CLA samples are the precursors of the 20:3 and 20:4 conjugated acids. The purpose of this study was therefore to fully identify the starting CLA mixture as well as the conjugated isomers of arachidonic acid in liver lipids of rats fed the commercial CLA mixture.

EXPERIMENTAL PROCEDURES

Chemicals and isolation of the 20:4 metabolites in the biological samples. All solvents were supplied by SDS (Peypin, France), and distilled before use. Most chemical reagents were supplied by Sigma (L'Isle d'Abeau, France). Silica gel plates (20 × 20 cm, 2.5 mm thickness) were from SDS. The animal experiment, the liver lipid extraction, the fatty acid methyl ester (FAME) preparation, and the isolation of the 20:4 metabolites have been described recently (30).

Hydrazine reduction of 18:2 and 20:4 conjugated isomers. The CLA mixture (42 mg; Sigma) was dissolved in 30 mL of 96% ethanol in a round-bottom flask fitted with a condenser and

a magnetic stirrer (31) and immersed in a water bath at 40°C. A 95% hydrazine solution (1 mL) was added, and oxygen was passed over the stirred solution for 3 h. After addition of water, the fatty acids were extracted with diethyl ether and then converted to methyl esters with BF_3-MeOH at 95°C for 5 min (32).

Hydrazine reduction of the isolated 20:4 fraction was carried out on 12 mg of sample for 1 h at 40°C.

GLC. All analytical GLC analyses were carried out using a Hewlett-Packard (Palo Alto, CA) 5890 series II chromatograph fitted with a split/splitless injector and a flame-ionization detector. The column used was a CP-Sil 88 (100 m × 0.25 mm i.d., 0.2 μm film thickness; Chrompack, Middelburg, The Netherlands). It was programmed from 60 to 180°C at 20°C · min^{-1} and held at this temperature until completion of the analysis. The isolated 20:1 isomers and the resulting silver nitrate thin-layer chromatography ($AgNO_3$-TLC) fractions were analyzed on a DB-Wax column (J&W, Courtaboeuf, France; 30 m length, 0.25 mm i.d., and 0.2 μm film thickness), which was programmed from 60 to 180°C at 20°C · min^{-1}.

GC–MS. FAME were converted to dimethyl-oxazoline derivatives (DMOX) according to Fay and Richli (33) prior to GC–MS analysis. GC–MS analyses were carried out using a BPX column, as described previously, and a Hewlett-Packard 5970 mass spectrometer. The temperature was programmed from 60 to 170°C at a rate of 20°C · min^{-1} (30).

GLC–Fourier transform infrared spectroscopy (GC–FTIR). Samples (methyl esters) were analyzed by gas chromatography (HP 5890 gas chromatograph; a BPX70 column, 30 m × 0.25 mm i.d., film thickness 0.25 μm, SGE, Melbourne, Australia). The instrument was fitted with a splitless injector maintained at 250°C and coupled with a Fourier transform infrared spectrometer (FTS 60A, Bio-Rad, Cambridge, MA). The two instruments were connected by a Digilab Tracer® direct-deposition interface. The oven temperature was programmed from 60 to 200°C (20°C/min).

RESULTS AND DISCUSSION

Fatty acid composition of the CLA fraction. Based on equivalent chain length, the elution sequence of the geometric *cis/trans*, *cis/cis,* and *trans/trans* CLA isomers was determined by Scholfield and Dutton (34) and Scholfield (35) and verified by Ha *et al.* (11) and Sébédio *et al.* (17).

GC–MS of the DMOX derivatives, as described previously for identification of CLA isomers in cheese and in animal tissues (18,30,36,37) and in commercial mixture (38), permitted us to show that the two major mono-*trans* isomers of the CLA mixture were 9,11- and the 10,12-18:2 and two minor mono-*trans* isomers were 8,10- and 11,13-18:2. The first-eluting peak contained mainly the 9,11 isomer (37.4% of the total CLA) accompanied by smaller quantities of the 8,10 isomer (7.6% of the total) (Fig. 1A), the second peak was composed of the 11,13 isomer (13.6% of the total), and the third peak was the Δ10,12 isomers (33.5% of the total). All these compounds were the mono-*trans* isomers. The di-*trans* isomers, namely, the 8,10/9,11/10,12 (4.3% of the total) and 11,13 (0.8% of the total),

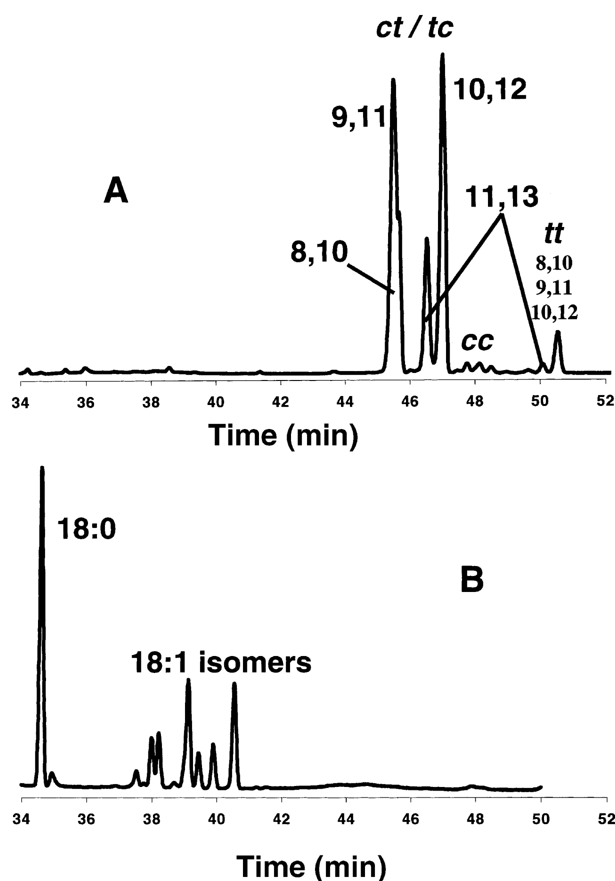

FIG. 1. Gas–liquid chromatographic analysis of (A) commercial conjugated linoleic acid (CLA) and (B) the commercial CLA mixture after hydrazine reduction. *c, cis; t, trans.*

were the two last eluting peaks. The minor peaks eluting between the di-*trans* and the mono-*trans* isomers contained the all-*cis* 8,10/9,11/10,12, and 11,13 isomers, representing 0.2, 0.9, 1.1, and 0.6% of the total, respectively, as previously described (38).

As GC–MS of the DMOX derivatives gave information only on the position of the double bonds and not on the geometry, the CLA mixture (Fig. 1A) was then submitted to hydrazine reduction. This method consists of partial reduction of the dienoic acid to give a mixture of saturates, monoenes, and unreacted dienes. Hydrazine reduction takes place without modification of either the position or the geometry of the ethylenic bonds, so the position(s) and geometry of the ethylenic bonds in the resulting monoenes represent those of the parent molecule (31). The resulting mixture (Fig. 1B) was submitted to high-performance liquid chromatography (HPLC) on a C18 reversed-phase column and the isolated monoene fraction submitted to $AgNO_3$–TLC. Three bands were obtained (Fig. 2). Each band was submitted to GC–FTIR, and aliquots of each fraction were also submitted to GC–MS after transformation into DMOX derivatives. Examination of GC–FTIR spectra revealed that all the 18:1 isomers present in the band of R_f 0.67 showed the characteristic absorption bands around 720 cm^{-1} and at 3,001 cm^{-1} of a

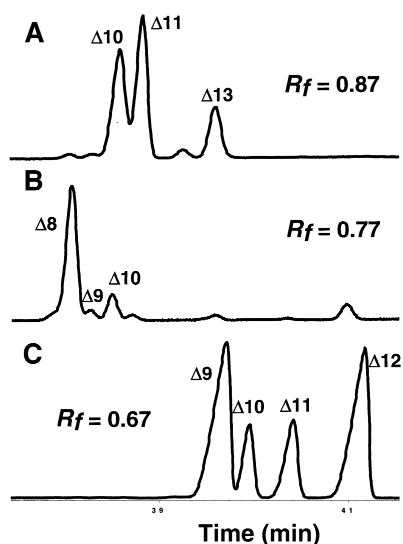

FIG. 2. Gas–liquid chromatographic analyses of the *cis* and *trans* 18:1 isomers isolated by a combination of high-performance liquid chromatography (HPLC) and silver nitrate thin-layer chromatography ($AgNO_3$-TLC) from commercial CLA which was submitted to a hydrazine reduction. For other abbreviation see Figure 1.

cis ethylenic bond, whereas the major isomers present in bands of R_f = 0.77 and 0.87 (Fig. 2) showed an absorption band at 968 cm^{-1} (Fig. 3), characteristic of a *trans* ethylenic bond (39).

The major MS fragments of the monoenes are reported in Table 1. As an example, for the Δ9 isomer in the R_f = 0.67 band, a mass interval of 12 units instead of the usual 14 units for a saturated chain occurred between *m/z* 196 (C8) and 208 (C9), indicating a double bond in the Δ9 position in the parent molecule. Examination of the other spectra of the R_f = 0.67 band permitted us to show that 18:1Δ9 and 18:1Δ12 were the major *cis* monoethylenic isomers. These were also accompanied by smaller amounts of the Δ10 and Δ11 *cis* isomers.

The two major *trans* isomers (band of R_f = 0.87) are the 18:1Δ10 and the 18:1Δ11. These are accompanied by a smaller amount of the Δ13 *trans* isomer. The major *trans* isomer contained in the band R_f = 0.77 is the 18:1Δ8. These data therefore indicate that the 9*c*,11*t*- and the 10*t*,12*c*-18:2 are the major CLA. These are also accompanied by smaller amounts of 8*t*,10*c*- and 11*c*,13*t*-18:2 isomers. The 8*t*,10*c*-18:2 is tailing the 9*c*,11*t* peak while the 11*c*,13*t* isomer is eluted ahead of the 10*t*,12*c*-18:2 isomer, as indicated by GC–MS of the DMOX derivatives (30,38). Examination of the other minor 18:1 isomers did not permit identification of the minor CLA peaks.

Identification of the 20:4 conjugated isomers. The combination of methods used to isolate and identify the 20:4 conjugated isomers is diagrammed in Scheme 1. Total liver lipids contained only 0.2% of conjugated 20:4 isomers (Table 2), identified previously (30) as 5,8,12,14- and 5,8,11,13-20:4. It was necessary to carry out one HPLC and two successive $AgNO_3$–TLC fractionations in order to isolate a fraction that was sufficiently enriched in these fatty acids. Along with the usual fatty acids, the total liver lipid FAME also contained the CLA given in the diet (0.6%) and one 20:3 conjugated isomer (0.1%), 8,12,14-20:3 (30). Arachidonic acid (20:4n-6) was also accompanied by small quantities of two mono-*trans* isomers, 5*c*,8*c*,11*c*,14*t*-20:4 and 5*c*,8*c*,11*t*,14*c*-20:4. These are known metabolites of 9*c*,12*t*-

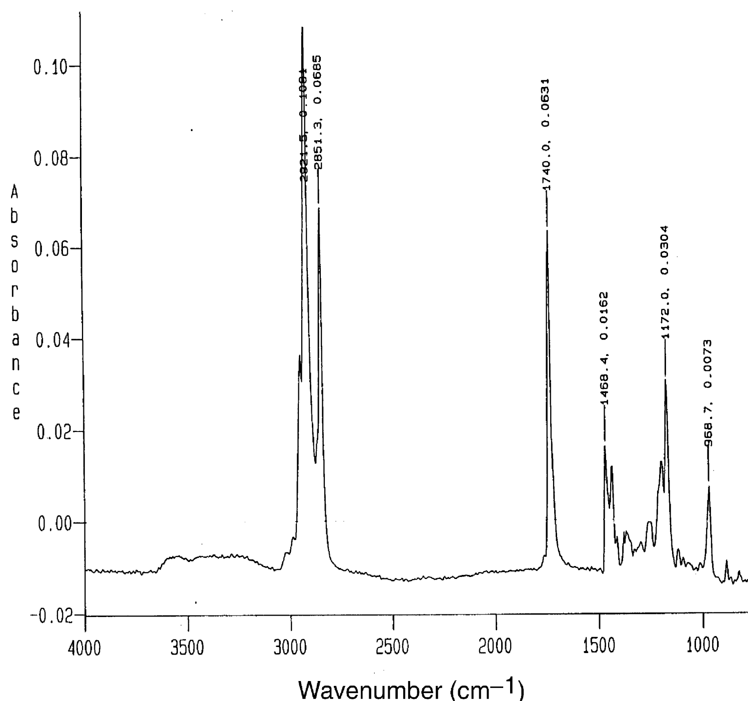

FIG. 3. Infrared spectrum of 18:1 Δ8 *trans* (R_f 0.77, Fig. 2) obtained after a combination of HPLC and $AgNO_3$-TLC from commercial CLA which was submitted to a hydrazine reduction. See Figures 1 and 2 for abbreviations.

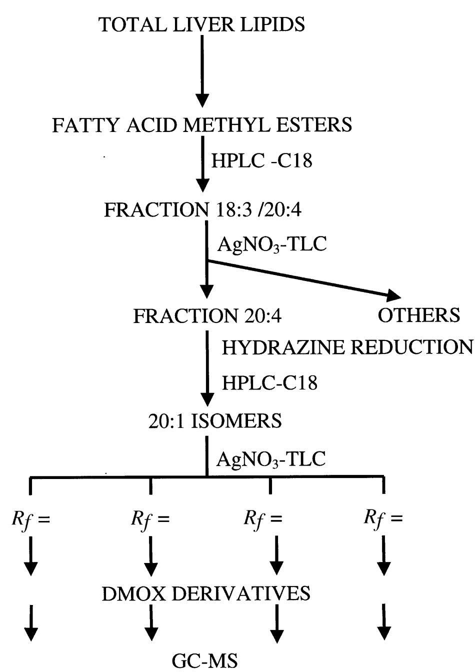
[a]DMOX, 4,4-dimethyloxazoline; CLA, conjugated linoleic acid; $AgNO_3$-TLC, silver nitrate thin-layer chromatography.

and 9*t*,12*c*-18:2 (27,28) which were present as minor components in the diet given to the rats (Juanéda, P., personal communication).

HPLC fractionation allowed isolation of a fraction enriched in 20:4 fatty acid isomers, the conjugated 20:4 isomers representing 3% of the total FAME. Two successive $AgNO_3$-TLC fractionations separated the conjugated 20:4 isomer from arachidonic acid. However, as the conjugated isomer migrated above 20:4n-6, this fraction also contained a large quantity of the 18:3 isomers (62%) (Fig. 4A).



SCHEME 1

Next, the isolated $AgNO_3$-TLC fraction was submitted to hydrazine reduction, yielding a complex mixture of 18:0, 18:1, 18:2, and unreacted 18:3 isomers accompanied by 20:0, 20:1, 20:2, 20:3, and unreacted conjugated 20:4 (Fig. 4B). The 20:1 monoenes, which represented 50% of the total C_{20} fatty acids, were isolated by HPLC and further submitted to $AgNO_3$-TLC. Four bands were obtained. The band of R_f 0.37 comprised two isomers, which were resolved as DMOX derivatives (Fig. 5); the bands at R_f 0.43 and R_f 0.50 constituted one major isomer each, while the band of R_f 0.60 revealed the presence of two 20:1 isomers.

The major MS fragments of the 20:1 monoenoic isomers are reported in Table 3. Sometimes the utilization of DMOX derivatives permits one to separate isomers that cannot always be resolved as methyl esters. This is the case for the two monoenes present in the band of $R_f = 0.37$. As previously reported, a gap of 12 mass units between ions containing n−1 and n carbon atoms indicates a double bond between carbons n and $n + 1$.

TABLE 2
Fatty Acid Composition (wt%) of the Total Liver Lipids or the HPLC and the $AgNO_3$-TLC Fractions[a]

	Total liver lipids	HPLC fraction	$AgNO_3$-TLC fraction
Σ Saturates	43.3		
Σ Monoenes	36.8		
Σ 18:2	4.6		
Σ CLA	0.6		
Σ 18:3	0.3	5.4	62.1

[a]HPLC, high-performance liquid chromatography; for other abbreviations see Table 1.

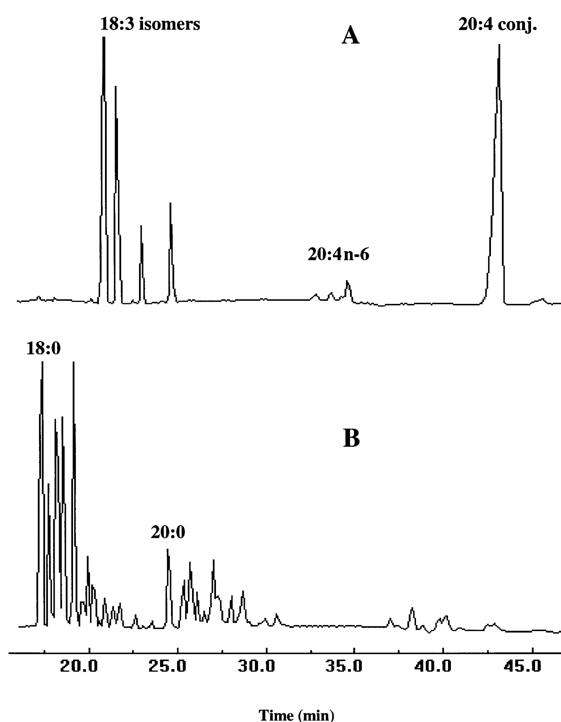

FIG. 4. Gas–liquid chromatographic analyses of the 18:3/20:4 fraction isolated by a combination of HPLC and $AgNO_3$-TLC from liver lipids before hydrazine reduction (A) and after hydrazine reduction (B). For abbreviations see Figure 2.

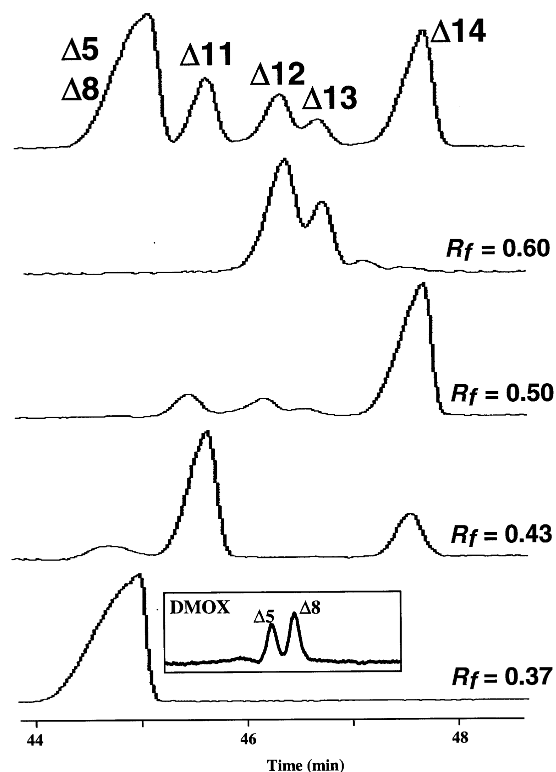

FIG. 5. Gas–liquid chromatographic analyses of the *cis* and *trans* 20:1 isomers isolated by a combination of HPLC and $AgNO_3$-TLC from the 18:3/20:4 fraction that was submitted to a hydrazine reduction (Fig. 4B). The band at $R_f = 0.37$ compressed two isomers, which were resolved as dimethyl-oxazoline (DMOX) derivatives.

Close examination of the spectra (Table 3) indicated that the band of $R_f = 0.37$ contained the Δ5 and Δ8 isomers; the band of $R_f = 0.43$, the Δ11 isomer and some of the Δ14 isomer present in band of $R_f = 0.50$; while the band with the highest R_f value contained the Δ12 and Δ13 isomers.

Unfortunately, considering that most of the monoenoic fraction available was used to prepare the DMOX derivatives for the GC–MS studies, FTIR spectra with bad signal-to-noise ratios were obtained. However, the position of the different monoenoic isomers on the $AgNO_3$-TLC plate is informative enough to enable the identification of both 20:4 conjugated isomers. First, the position of the band of $R_f = 0.60$ compared to a standard of elaidic acid indicates that both ethylenic bonds in Δ12 and in Δ13 are *trans*. Studies by Morris *et al.* (40) have shown that except for ethylenic bonds which are close to the carboxyl group (Δ2 position), *trans* isomers migrate ahead of all the *cis* isomers. Furthermore, for both the *cis* and the *trans* isomers (except for ethylenic bonds close to the carboxyl end),

Characteristic Ions in Mass Spectra of DMOX Derivatives of the Monoenes Obtained After Hydrazine Reduction of the 20:4 Conjugated Isomers[a]

$AgNO_3$-TLC band (R_f)	Component	M^+ *m/z* (intensity %)	Fragments *m/z* (intensity %)
0.37	Δ5	363 (3)	113 (100); 126 (12); 153 (9); 166 (4); 180 (9)
	Δ8	363 (14)	113 (76); 126 (100); 168 (26); 182 (6); 194 (3); 208 (8); 222 (31); 236 (12)
0.43	Δ11	363 (15)	113 (100); 126 (59); 210 (10); 224 (4); 236 (3); 250 (4); 264 (42); 278 (48)
0.50	Δ14	363 (18)	113 (100); 126 (54); 252 (12); 266 (3); 278 (5); 292 (8); 306 (45); 320 (47)
0.60	Δ12	363 (21)	113 (100); 126 (60); 224 (30); 238 (3); 250 (4); 264 (8); 278 (32); 292 (51)
	Δ13	363 (12)	113 (100); 126 (61); 238 (6); 252 (4); 264 (3); 278 (10); 292 (33); 306 (30)

[a]For abbreviations see Table 1.

the R_f increases with increasing Δ number (40). This is observed for bands of $R_f = 0.37$ (Δ5, Δ8), $R_f = 0.43$ (Δ11), and $R_f = 0.50$ (Δ14). The band of $R_f = 0.60$, which includes the Δ12 and the Δ13 isomers, can therefore only be of *trans* geometry.

We have previously demonstrated that the 20:4 isomers are 5,8,11,13-20:4 and 5,8,12,14-20:4. Results of the hydrazine reduction show that these compounds are the 5*c*,8*c*,11*c*,13*t*- and 5*c*,8*c*,12*t*,14*c*-20:4 isomers. These fatty acids may be formed by desaturation and elongation of 9*c*,11*t*- and the 10*t*,12*c*-18:2, the major isomers present in the CLA mixture. The identification of the 8*t*,10*c* isomer using hydrazine reduction confirmed the GC elution order proposed by Kramer *et al.* (37). Similar conversions for the cis/trans isomers of linoleic and linolenic acids have already been proposed (26–28,41). Further *in vivo* experiments will now be carried out to study if CLA modifies the bioavailability of arachidonic acid and therefore may affect eicosanoid synthesis.

ACKNOWLEDGMENTS

This paper is published as part as a concerted action (FAIR-3671) funded by the European Union. The authors are grateful to Etienne Semon for GC–FTIR analyses.

ABSTRACT: The effects of atorvastatin and simvastatin on hydroxy methylglutaryl (HMG)-CoA reductase activity and mRNA abundance were studied in guinea pigs randomized to three groups: untreated animals and those treated with 20 mg/kg of atorvastatin or simvastatin. Guinea pigs were fasted for 0, 6, 12, or 18 h in an attempt to remove the drug from their systems. Reductase activity and mRNA levels were analyzed after each time point. Reductase inhibitor treatment resulted in 50–62% lower cholesterol concentrations compared to untreated guinea pigs ($P < 0.0001$), while plasma triacylglycerol (TAG) concentrations did not differ among groups. Plasma cholesterol and TAG were 50–70% lower after 18 h fasting in the three groups ($P < 0.001$). In the nonfasting state, simvastatin and atorvastatin treatment did not affect HMG-CoA reductase activity compared with untreated animals. However, after 6 h of fasting, simvastatin-treated guinea pigs had higher HMG-CoA reductase activity than untreated animals ($P < 0.01$), suggesting that the drug had been removed from the enzyme. In contrast, atorvastatin-treated guinea pigs maintained low enzyme activity even after 18 h of fasting. Further, HMG-CoA reductase mRNA abundance was increased by sevenfold after atorvastatin treatment and by twofold after simvastatin treatment ($P<0.01$). These results suggest that simvastatin and atorvastatin have different half-lives, which may affect HMG-CoA reductase mRNA levels. The increase in reductase activity by simvastatin during fasting could be related to an effect of this statin in stabilizing the enzyme. In contrast, atorvastatin, possibly due to its longer half-life, prolonged inhibition of HMG-CoA reductase activity and resulted in a greater increase in mRNA synthesis.

Paper no. L8313 in *Lipids 34,* 1327–1332 (December 1999).

Hypercholesterolemia and hypertriglyceridemia are considered independent risk factors for the development of atherosclerosis and coronary heart disease (1). Because of the prevalence of hyperlipidemia in Western societies, different approaches are being used to reduce plasma low density lipoprotein (LDL) cholesterol and triacylglycerol (TAG) concentrations. Hydroxy methylglutaryl (HMG)-CoA reductase inhibitors are pharmacological agents often used in the treatment of hypercholesterolemia. Although they are quite effective in reducing plasma cholesterol levels, their effects on plasma TAG are less conclusive (2).

Atorvastatin, the newest of the statin class, is quite effective in decreasing both plasma LDL cholesterol and TAG, as well as increasing high density lipoprotein cholesterol in humans (3–5). Studies of the mechanism of action of atorvastatin in different animal models have demonstrated that atorvastatin reduces LDL cholesterol by two different means: decreased secretion of very low density lipoprotein particles from the liver (6–8) and increased LDL uptake (9,10). In addition, atorvastatin efficacy has been related to the prolonged inhibition of endogenous cholesterol synthesis as documented in cells, rats, and humans (11,12).

Studies in rats, mice, and cultured cells have demonstrated that statin treatment results in an up-regulation of HMG-CoA reductase activity and mRNA levels (11,13,14) as a compensatory mechanism to maintain cholesterol homeostasis. However, studies conducted on guinea pigs by our laboratory have indicated that atorvastatin and simvastatin treatment resulted in no effect or in lower HMG-CoA reductase activity compared to animals without treatment (8,9). These results suggest that in guinea pigs, atorvastatin and simvastatin may still be bound to the enzyme after isolation of hepatic microsomes, thus inhibiting activity. The present studies were conducted to further explore the effects of statins on HMG-CoA reductase activity and to determine whether HMG-CoA reductase gene expression was affected by statin treatment in guinea pigs. The guinea pig was used as an animal model because of its similarities in cholesterol metabolism to humans. In addition, guinea pigs have been proven to respond to drug treatment by decreasing the levels of LDL cholesterol as humans do. According to existing knowledge about statins and HMG-CoA reductase activity, we hypothesized that after removal of the drug, the activity of the enzyme would be increased and that the regulation of the enzyme by drug treatment would be in part at the level of gene expression.

MATERIALS AND METHODS

Materials. Glucose-6-phosphate, glucose-6 phosphate dehydrogenase, and NADP were obtained from Sigma Chemical

Co. (St. Louis, MO). DL-Hydroxy-[3-^{14}C]methyl glutaryl CoA (1.81 GBq/mmol), DL-[5-^{3}H]mevalonic acid (370 Gbq/mmol), [^{32}P]-dCTP (18.5 GBq/mmol), and aquasol were obtained from Amersham (Clearbrook, IL). Simvastatin and atorvastatin were provided by Parke-Davis Research, Warner-Lambert Division (Ann Arbor, MI).

Diets. Isocaloric diets were prepared and pelleted by Research Diets Inc. (New Brunswick, NJ). Diets were designed to meet the nutritional requirements of the guinea pigs. The concentration of HMG-CoA reductase inhibitors in the diet was 0.1% or 20 mg/kg per day. The amount of cholesterol in the diet was adjusted to 0.04%, which is equivalent to 112 mg/1,000 kcal or less than 300 mg/day for a human diet (15). The fat mix was olive oil/palm kernel oil/safflower oil (1:2:1.8), which is rich in lauric and myristic acids, known to cause endogenous hypercholesterolemia in guinea pigs (8). Detailed composition of the diet has been published elsewhere (8).

Animals. Male Hartley guinea pigs weighing 350–400 g were purchased from Harlan Sprague Dawley Inc. (Indianapolis, IN). Sixty-three guinea pigs were randomly assigned to one of the three different diets—control, 20 mg/kg simvastatin or atorvastatin for 21 d. Guinea pigs were kept in a light-cycle room (light from 0700 to 1900) and had free access to water and foods/statin. At the end of the feeding period animals were subdivided into four different groups with nine guinea pigs in the nonfasting group and four for each fasting period, which was either 6, 12, or 18 h. All animal experiments were conducted in accordance with U.S. Public Health Service/U.S. Department of Agriculture guidelines. Experimental protocols were approved by the University of Connecticut Institutional Animal Care and Use Committee.

After the different fasting periods, guinea pigs were anesthetized under halothane vapors and blood was obtained by heart puncture. Plasma samples were collected and a preservation cocktail was added (aprotonin 0.5 mL/100 mL, phenylmethyl sulfony fluoride 0.1 mL/100 mL, and sodium azide 0.1 mL/100 mL). Plasma was analyzed for cholesterol (16) and TAG (17) using enzymatic methods. Livers were excised from guinea pigs after exsanguination and were used for microsome isolation and for RNA extraction.

Hepatic microsome isolation. Microsomes were isolated as previously described (8,9). Briefly, livers were pressed through a tissue grinder, placed in cold buffer (50 mmol/L KH_2PO_4, 0.1 mol/L sucrose, 50 mmol/L KCl, and 50 mmol/L NaCl, 30 mmol/L EDTA, and 2 mmol/L dithiothreitol, pH 7.2), and homogenized with a Potter-Elvejhem homogenizer for measurement of total activity. In addition, microsomes were isolated in the presence of 50 mmol/L NaF to inhibit endogenous phosphatases to determine HMG-CoA reductase expressed activity (18). The microsomal fraction was obtained after two centrifugations at $10,000 \times g$ for 15 min (JA-20 rotor in a J2-21 centrifuge; Beckman Instruments, Fullerton, CA), and 1-h centrifugation at $100,000 \times g$ at 4°C. Samples were further homogenized and centrifuged for an additional hour at $100,000 \times g$ at 4°C. Microsomal pellets were resuspended in cold buffer, homogenized, and stored at −70°C for enzyme analysis. The protein content in the microsomes was determined according to Markwell *et al.* (19).

3-Hydroxy-3-methylglutaryl-CoA reductase (HMG-CoA reductase) assay. The activity of HMG-CoA reductase (EC 1.1.1.34) was measured in hepatic microsomes according to Shapiro *et al.* (20). Microsomal protein (200 µg, approximately 10 µL) was incubated at 37°C with 50 µL of a solution containing 7.5 nmol (0.33 Gbq/nmol) [3-^{14}C]HMG-CoA, 4.5 mmol glucose-6-phosphate, 3.6 mmol EDTA, 0.45 mmol NADP, and 0.3 IU glucose-6-phosphate dehydrogenase. [^{3}H]Mevalonic acid (0.024 Gbq) was added as a recovery standard.

The reaction was stopped after 15 min with 10 M HCl (0.025 mL per tube). An excess of mevalonic acid was added, and samples were incubated for another 30 min at 37°C to allow for the conversion of mevalonic acid to mevalonalactone. After incubation, microsomes were pelleted by centrifugation for 1 min at $1,000 \times g$. An aliquot of the supernatant (0.1 mL) was applied to silica gel thin-layer chromatography plates and developed with acetone/benzene (1:1 vol/vol), and the area containing the mevalonate (R_f = 0.6–0.9) was scraped and mixed with 5 mL aquasol. Radioactivity was measured using a liquid scintillation counter. HMG-CoA activity is expressed as pmol of [^{14}C]mevalonate produced per min per mg microsomal protein. Recoveries of [^{3}H]mevalonate were 60–70%.

RNA extraction. Total RNA was extracted using a modification of the method described by Chomczynski and Sacchi (21). Briefly, 0.5 g of liver tissue was homogenized in 5 mL of guanidinium thiocyanate buffer [4 M guanidinium thiocyanate, 25 mM Na citrate (pH = 7.0), 0.5% *N*-lauroylsarcosine]. Homogenates were extracted with acid phenol and chloroform followed by a centrifugation to separate the phases. The aqueous phase containing the RNA was removed and precipitated with 5 mL of ethanol at −20°C overnight. Samples were then centrifuged at $3,500 \times g$ for 20 min and pellets were resuspended in 1 mL diethylpyrocarbonate (DEPC) water and then extracted with an equal volume of chloroform/isoamyl alcohol (49:1 vol/vol). After centrifugation, the aqueous phase was transferred to a microfuge tube and reprecipitated with 1 mL of ethanol for 2 h at −20°C. RNA was dissolved in DEPC water and concentration was determined by absorbance at 260 nm. The ratios of absorbance at 260 and 280 nm were in the range of 2.0–2.2.

Northern analysis. Total RNA was size-separated by electrophoresis in a 1% agarose gel with formaldehyde as reported by Yeh *et al.* (22). RNA was then transferred overnight to a nitrocellulose membrane (0.45 mm; MSI NitroPure, Westborough, MA) by the Northern procedure, using 20× standard saline citrate (SSC) buffer (1 × SSC = 150 mM NaCl, 15 mM Na citrate). After transfer was completed, RNA was fixed to the membrane by exposure to ultraviolet light for 30 s and baking for 2 h at 80°C.

The plasmid containing the cDNA insert for human HMG-CoA reductase was obtained from American Type Culture Collection (Rockville, MD). This plasmid contains regions homologous to the hamster HMG-CoA reductase gene (23) and thus appeared likely to hybridize with guinea pig mRNA.

Isolated insert was labeled with [^{32}P]-dCTP using the random primer method (Life Technologies, Rockville, MD). Unincorporated radioactivity was removed using Sephadex spin columns (TE MIDI select-D, G-50, 5 prime-3 prime, Boulder, CO).

Membranes were prehybridized for 2 h at 42°C in a solution containing 10% dextran sulfate, 50% formamide, 1 M NaCl, 1% sodium dodecyl sulfate (SDS), and 200 mg/mL of denatured salmon testis DNA. Labeled probe was added (2×10^6 PM/mL) and hybridization was continued at 42°C for 20 h. Membranes were washed twice in 50 mL of 0.25 M NaH_2PO_4, 2% SDS, and 1mM EDTA for 20 min at 42°C. An additional wash was performed with 50 mL of 0.05 M NaH_2PO_4, 1% SDS, and 1mM EDTA for 20 min at 55°C. Membranes were exposed to X-ray film for an average of 5 d. Autoradiographic signals were quantified with a GS-670 densitometer using Molecular Analyst Software (Bio-Rad, Hercules, CA). HMG-CoA reductase mRNA levels were corrected for 18S mRNA measured in the same blot.

Statistical analysis. Data were analyzed by two-way analysis of variance to test differences due to fasting, drug effects, and interactions. P values less than 0.05 were considered statistically significant. Fisher's least significant difference protected was used for *post-hoc* analysis. Data are presented as means ± standard deviation.

RESULTS

Atorvastatin vs. *simvastatin effects on plasma lipids.* Atorvastatin and simvastatin treatment resulted in significant reductions in plasma total cholesterol at the different fasting times (Table 1). In the nonfasting state, guinea pigs treated with statins had 51–53% lower plasma cholesterol concentrations compared to animals with no treatment ($P < 0.0001$). Fasting had different effects depending on the drug treatment. For untreated animals, plasma cholesterol was 31–35% lower after 18 h of fasting compared to the earlier times ($P < 0.001$). Guinea pigs treated with atorvastatin had significantly lower plasma cholesterol concentrations after 12 and 18 h of fasting compared to nonfasting guinea pigs and 6-h-fasted animals ($P < 0.001$) (Table 1). However, cholesterol levels for simvastatin-treated animals remained the same during the different fasting times (Table 1).

Similar to our previous report (9), no changes due to drug treatment were found for plasma TAG. However, fasting decreased plasma TAG such that after 18 h, levels were reduced by 68, 55, and 43% in control, atorvastatin-, and simvastatin-treated guinea pigs, respectively (data not shown).

Atorvastatin vs. simvastatin effects on HMG-CoA reductase activity. Total HMG-CoA reductase activity was altered after treatment with statins and by the different fasting times (Table 2). In addition, there was an interactive effect between drug treatment and fasting ($P < 0.05$). In the nonfasted state (0 h), atorvastatin caused a significant decrease in HMG-CoA reductase activity, while simvastatin treatment had no effect, similar to our reports for atorvastatin in the guinea pig. It is known that fasting decreases dramatically the activity of HMG-CoA reductase (24), which explains the 88% reduction in activity after 6 h of fasting in the control group. Fasting decreased HMG-CoA reductase activity in atorvastatin-treated animals to a similar extent as in nontreated guinea pigs. However, in simvastatin-treated guinea pigs, fasting did not decrease reductase activity to the same extent ($P < 0.05$) (Table 2).

In addition to total activity, expressed HMG-CoA reductase activity was determined in microsomes isolated in the presence of NaF. Expressed activity was not affected by statin treatment but was reduced after 6, 12, and 18 h of fasting (Table 3). HMG-CoA reductase expressed activity was reduced by 20, 36, and 36% after 6, 12, and 18 h of fasting, respectively (Table 3). The ratio of expressed to total activity was higher after statin treatment and this was due mostly to a net decrease in total enzyme activity. Fasting resulted in decreased expressed activity and increased ratios. This suggests that during fasting most of the enzyme present is in the expressed form.

Atorvastatin vs. simvastatin effects on HMG-CoA reductase mRNA. The human cDNA probe used for measuring hepatic mRNA abundance for HMG-CoA reductase recognized two mRNA species 4.5 and 3.2 kb in size (Fig. 1). As indicated in Table 4, atorvastatin treatment resulted in a sevenfold increase in HMG-CoA reductase mRNA in the nonfasted animals, compared to the controls ($P < 0.001$). In contrast, simvastatin treatment produced only a twofold increase in the levels of mRNA compared to untreated guinea pigs. Fasting resulted in a significant decrease in mRNA levels in atorvastatin- and simvastatin-treated guinea pigs ($P < 0.01$), while fasting did not affect mRNA levels in untreated animals (Table 4).

DISCUSSION

HMG-CoA reductase activity is the main target for statin treatment. Since this enzyme is rate limiting and regulatory for cholesterol synthesis, the effect of atorvastatin and simvastatin on the activity of HMG-CoA reductase is of major importance. It has been reported in rat and cultured cell studies that HMG-CoA reductase activity is increased after treatment with statins (25,26). Cholesterol is a major regulator for HMG-CoA reductase synthesis (negative feedback regulation), and inhibition of reductase activity will reduce the amount of cholesterol being synthesized. Decreased intracellular cholesterol will lead to the production of more HMG-CoA reductase enzyme as a compensatory mechanism. Whether this increased enzyme amount will result in increased measurement of enzyme activity will depend on whether the statin is still bound to the enzyme during the assay procedure.

In the present study, both statins reduced or did not change reductase activity in nonfasted guinea pigs, suggesting that they are still bound to the enzyme at the time of assay. To further explore this hypothesis, studies were conducted with guinea pigs subjected to different fasting times in order to remove the drugs from the system.

Simvastatin treatment resulted in higher enzyme activity after 6, 12, and 18 h of fasting compared to nontreated guinea pigs. These data suggest that this statin was removed from the enzyme after 6 h of drug withdrawal. The results observed for simvastatin treatment agree with those reported by Del Puppo *et al.* (25), where, after removal of the drug, an up-regulation of reductase activity was observed. This may be the reason for the increased reductase activity observed after fasting in simvastatin-treated guinea pigs compared to untreated animals in the present study. The amount of HMG-CoA reductase mRNA was determined in liver of simvastatin-treated guinea pigs. In agreement with other studies (11,27), a twofold increase in mRNA levels was observed in HepG2 cells and rats with simvastatin treatment. The lower increase in reductase mRNA abundance with simvastatin compared to atorvastatin treatment in guinea pigs suggests that the observed increase in activity after fasting is probably due to activation of the already existing protein. Although the levels of immunoreactive protein were not determined in the pres-

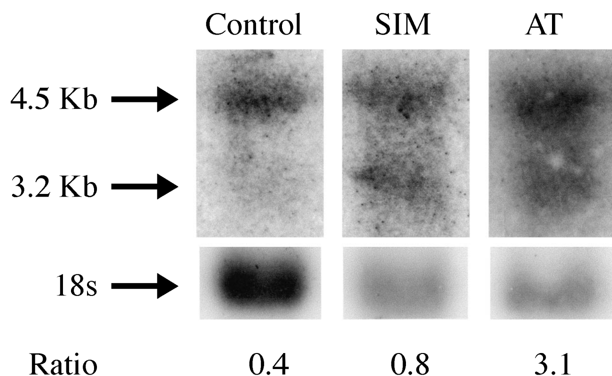

FIG. 1. Effect of atorvastatin and simvastatin on hydroxy methylglutaryl (HMG)-CoA reductase mRNA. AT, atorvastatin; SIM, simvastatin. Northern blot performed with human cDNA for HMG-CoA reductase. The sizes for HMG-CoA reductase and 18s mRNA are indicated. HMG-CoA reductase/18s mRNA ratio was used as a correction for amount of sample loaded. Figure shows a representative sample for each treatment.

ent study, it is possible that simvastatin conferred some protein stabilization as has been observed by Ness *et al.* (28).

In contrast to simvastatin, atorvastatin treatment continued to suppress HMG-CoA reductase activity even after 18 h of fasting, suggesting that either the drug is still tightly bound to the enzyme, or atorvastatin does not induce HMG-CoA reductase activity as do other reductase inhibitors. Ness *et al.* (26) have indicated in a recent study that atorvastatin binds very tightly to the enzyme active site and several washes of the microsomes were needed to remove some of the drug. Our data suggest that under our experimental conditions, 18 h of fasting were not sufficient to remove the drug from the enzyme.

It has been demonstrated in humans that atorvastatin has a half-life of 14 h compared to simvastatin's half-life of 1.9 h (2). In addition, atorvastatin metabolism results in the presence of two active metabolites, which are as potent as the parent drug (29). These properties may result in the lack of recovery of HMG-CoA reductase activity observed after fasting in atorvastatin treated guinea pigs. It has been observed that atorvastatin inhibits cholesterol synthesis longer than simvastatin in hypercholesterolemic patients (12) supporting the hypothesis that atorvastatin remains bound to the enzyme for longer periods of time.

HMG-CoA reductase mRNA abundance was sevenfold higher after atorvastatin treatment in nonfasted guinea pigs. An increase in reductase mRNA has also been observed in rats treated with atorvastatin (26). These results suggest that atorvastatin may be inducing the production of more protein at the transcriptional level through the compensatory mechanism known for statins. However, no increase in reductase activity was observed because atorvastatin was still bound to the enzyme.

Long-term fasting decreases the amount of HMG-CoA reductase mRNA as well as the amount of immunoreactive protein in rats (28). Ness *et al.* (26) also reported that rats fasted for 24 h had lower levels of HMG-CoA reductase mRNA. A fasting effect was observed for reductase mRNA in this experiment for guinea pigs treated with atorvastatin and simvastatin. However, fasting did not affect mRNA levels in untreated guinea pigs. At this point, the precise explanation for this discrepancy is not known, but it appears that in untreated guinea pigs, 18 h of fasting was not enough to cause a decrease in mRNA levels and the regulation of the enzyme activity may have taken place only at the level of phosphorylation. This may be similar to observations in the rat where with short fasting periods enzyme activity was dictated only by the degree of phosphorylation (30).

From these results, we may conclude that atorvastatin and simvastatin, despite similar cholesterol-lowering properties, have somewhat distinct effects on the regulation of HMG-CoA reductase activity and mRNA abundance. Either statins confer protein stabilization or they may interfere with translational efficiency of the reductase mRNA, as observed for dietary cholesterol in rats (31). Simvastatin effects on enzyme activity appear to be of shorter duration than atorvastatin and thus there is less up-regulation of mRNA levels compared to untreated guinea pigs. However, the observed increases in reductase activity after fasting in simvastatin-treated guinea pigs could be related to preservation of HMG-CoA reductase protein. In contrast, atorvastatin inhibits reductase activity for longer periods of time, which may be a plausible explanation for its higher efficacy observed in humans and for the greater up-regulation (sevenfold compared to twofold) of mRNA levels.

ABSTRACT: Docosahexaenoic acid (DHA) circulates in mammals in lipoproteins and bound to serum albumin as a nonesterified fatty acid as well as esterified in lysophosphatidylcholine (lysoPC). 1-Lyso,2-DHA-glycerophosphocholine (GPC) is an unstable isomer because of a primary alcohol at the *sn*-1 position. To keep DHA at the *sn*-2 position of lysoPC, its usual position for the corresponding lysoPC to be acylated into PC in tissues, we synthesized 1-acetyl,2-DHA-GPC and confirmed its structure by use of nuclear magnetic resonance (NMR) spectroscopy in comparison with its positional isomer, 1-DHA,2-acetyl-GPC. 1-Lyso,2-DHA-GPC was prepared from 1-stearoyl,2-DHA-GPC by enzymatic hydrolysis and purified by high-performance liquid chromatography. The isomerization of 1-lyso,2-DHA-GPC into 1-DHA,2-lyso-GPC was obtained by keeping the former overnight at room temperature under nitrogen. Both lysoPC isomers were acetylated by acetic anhydride into 1-acetyl,2-DHA-GPC and 1-DHA,2-acetyl-GPC, respectively, and the resulting phospholipids were fully characterized by NMR. In particular, the 1,2 substitution pattern of the acetyl and DHA chains could be easily detected by 2D heteronuclear multibond correlation. We conclude that 1-acetyl,2-DHA-GPC might be considered as a stable form of 1-lyso,2-DHA-GPC for its delivery to tissues, if the latter exhibits acetyl hydrolase activity.

Paper no. L8327 in *Lipids 34,* 1333–1337 (December 1999).

Since the pioneering epidemiological studies of Bang *et al.* (1), there has been a considerable interest in the potential health benefits of marine polyunsaturated fatty acids, namely eicosapentaenoic and docosahexaenoic (DHA) acids. In addition to the beneficial effects of those fatty acids in the circulatory cardiovascular system (2), DHA is of particular interest for the cerebrovascular system, especially the retina, in which it represents almost the only polyunsaturated fatty acid (3,4), and in brain grey matter, where it may be more prominent than arachidonic acid, depending on the area (5). Indeed, DHA is assumed to be required for proper visual functions and brain development (6,7). *In vivo*, DHA circulates in the bloodstream under various chemical forms attached to either albumin or lipoproteins (8). Previous studies in which ^{13}C-labeled DHA esterified in triglycerides or phosphatidylcholine (PC) was ingested as a single dose by human volunteers showed that nonesterified DHA and DHA esterified in lysophosphatidylcholine (lysoPC-DHA) are two chemical forms bound to albumin that could specifically bring DHA to platelets and erythrocytes, respectively (9,10). There is evidence that the incorporation of DHA into erythrocytes may serve as an indicator of DHA incorporation into the brain (11), and we consider this observation to be in agreement with the preferential brain uptake of DHA in the rat when DHA is injected as lysoPC-DHA compared to nonesterified DHA, both chemical forms being bound to albumin (12). Evidence for the preferential uptake of DHA has recently been provided using a reconstituted *in vitro* blood brain barrier with co-cultures of capillary endothelial cells and astrocytes (13). However, the metabolic fate of DHA in the brain is to accumulate at the *sn*-2 position of phospholipids. Although previous experiments have been done with 1-lyso,2-docosahexaenoyl-glycerophosphocholine (1-lyso,2-DHA-GPC), it is expected that part (if not the bulk) of this chemical form would have been isomerized into 1-DHA,2-lyso-GPC because of the primary alcohol reactivity at the *sn*-1 position.

The objective of the present study was to prevent such an isomerization by esterification of the *sn*-1 position with an acetyl group, keeping the molecule at a polarity closer to that of lysoPC-DHA. A stable molecule of this kind might be useful as a vehicle for delivering DHA through lysoPC-DHA, provided that the target tissues exhibit acetyl hydrolase activity.

EXPERIMENTAL PROCEDURES

Preparation of lysoPC-DHA. 1-Lyso,2-DHA-GPC was prepared by enzymatic hydrolysis from 1-stearoyl,2-DHA-GPC, which was provided by Avanti Polar Lipids (Alabaster, AL). The enzyme used was a lipase (EC 3.1.1.3) from *Rhizopus arrhizus* which exhibits phospholipase A_1 activity (14). The enzyme was furnished by Sigma (L'Isle d'Abeau, France). Two milligrams of substrate (PC) was dissolved in 1 mL of diethylether and sonicated for 4 min in a sonication bath with 1 mL of phosphoboric buffer (pH 6) containing 200,000 U of

enzyme. This mixture was further incubated with vigorous shaking for 1 h at room temperature under nitrogen. The reaction was stopped in ice and total lipids were extracted according to Bligh and Dyer (15) at pH 3 and 4°C to minimize lysoPC isomerization.

The lysoPC formed was separated from the remaining PC substrate and the fatty acid was released by the lipase treatment using thin-layer chromatography (TLC) on silica gel 60G (Merck, Darmstadt, Germany) with the eluent mixture chloroform/methanol/water (65:25:4, by vol) at 4°C (16). The R_f of the compounds were 0.2, 0.47, and 0.91, respectively. The purity of 1-lyso,2-DHA-GPC obtained was checked by high-performance liquid chromatography (HPLC) as shown in Figure 1. The isomerization of 1-lyso,2-DHA-GPC into 1-DHA,2-lyso-GPC was induced by keeping the former overnight at room temperature under nitrogen. Under these conditions, further isomerization of 1-DHA,2-lyso-GPC into 1-DHA,3-lyso-GPC is very unlikely because of the lower reactivity of the *sn*-2 secondary alcohol. The positional isomers were analyzed by HPLC with a 5-µm Superspher C_{18} column (4.6 × 250 mm, i.d.; Hewlett-Packard, Les Ulis, France) isocratically eluted with meth-anol/water/acetonitrile (90:25:2.5, by vol) containing 0.35% choline chloride at a flow rate of 1.2 mL/min. Each lysoPC was detected at 210 nm. Figure 1 gives an example of chromatograms. If 1-DHA,3-lyso-GPC was formed subsequent to isomerization of 1-lyso,2-DHA-GPC, it would presumably have migrated in peak 1 of Figure 1B together with 1-lyso,2-DHA-GPC, the sum representing at most 12% of the two isomers. In addition, the nuclear magnetic resonance (NMR) spectrum of the acetylated derivative (2) appeared at least 95% pure, and no signal could be detected for a putative 1-acetyl,3-DHA-GPC.

Each lysoPC isomer was quantified on the basis of its DHA content by gas–liquid chromatography (9). LysoPC was treated with 5% H_2SO_4 in methanol for 90 min at 100°C in the presence of an appropriate amount of 1-heptadecanoyl,2-lyso-GPC as an internal standard. The mixture of DHA and heptadecanoic acid methylesters were separated and measured as previously described by gas chromatography, using an SP2380 capillary column (30 m × 0.32 mm; Supelco, Bellefonte, PA) (9).

Acetylation of lysoPC isomers. Both lysoPC isomers (1-lyso,2-DHA-GPC and 1-DHA,2-lyso-GPC) stored in chloroform were dried under reduced pressure at low temperature in the dark. Each lysoPC isomer was dissolved in 0.55 mL of a 0.135 M chloroformic solution of 4-pyrrolidinopyridine and 0.8 mL of a 0.138 M chloroformic solution of acetic anhydride and was continuously agitated for 16 h at 4°C to ensure complete reaction. Added to this were 1.7 mL of chloroform and 1.5 mL of water. After stirring, the mixture was centrifuged for 10 min at 800 × *g*. The chloroformic phase was separated and evaporated under reduced pressure. The 1-acetyl,2-DHA-GPC and 1-DHA,2-acetyl-GPC were separated from the remaining 1-lyso,2-DHA-GPC and 1-DHA,2-lyso-GPC, respectively, by TLC on silica gel 60G with the chloroform/methanol/water (65:25:4, by vol) mixture. The expected 1-acetyl,2-DHA-GPC and 1-DHA,2-acetyl-GPC at

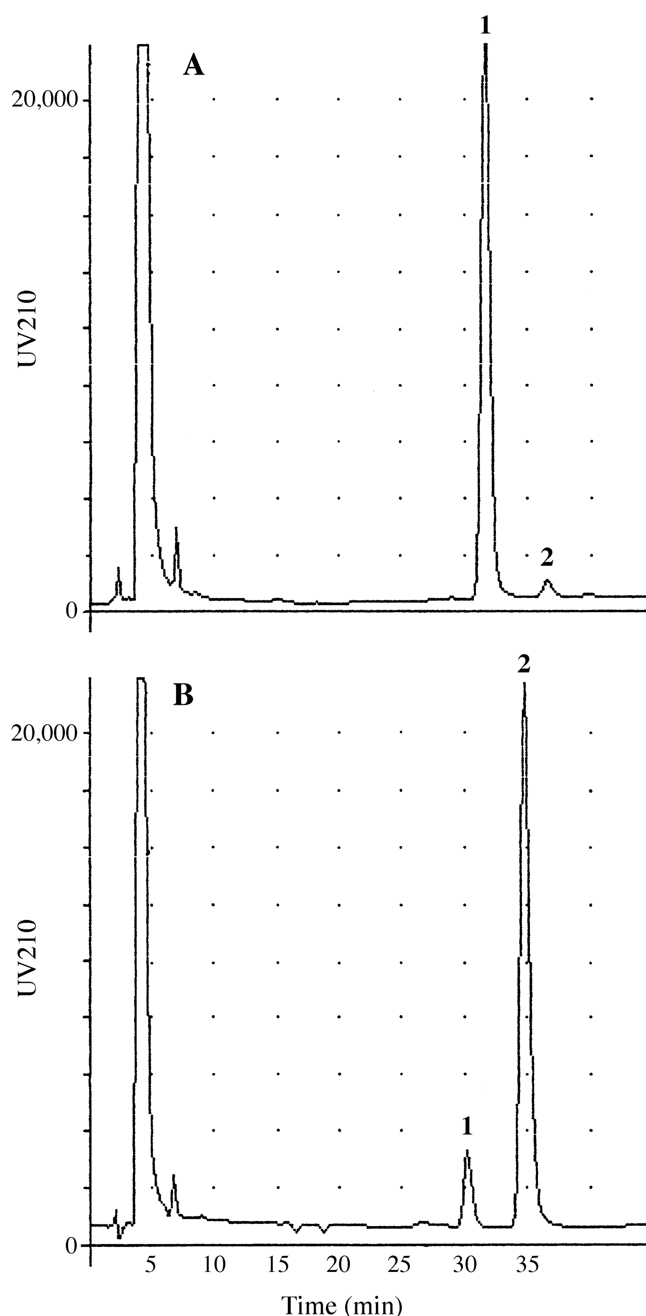

FIG. 1. Separation of 1-lyso,2-docosahexaenoyl-glycerophosphocholine (1-lyso,2-DHA-GPC) (peak 1) from 1-DHA,2-lyso-GPC (peak 2) by reversed-phase high-performance liquid chromatography. (A) Lysophosphatidylcholine (lysoPC) isomers obtained by enzymatic cleavage of 1-stearoyl,2-DHA-GPC were injected onto a 5-µm Superspher column (250 × 4.6 mm), and eluted at 1.2 mL/min by methanol/water/acetonitrile (90:25:2.5, by vol) containing 0.35% choline chloride. They were detected by ultraviolet light at 210 nm. (B) LysoPC isomers obtained by enzymatic cleavage were maintained overnight at room temperature. They were separated as indicated in A.

R_f 0.18 were scraped off the plate by extraction with chloroform/methanol/water (10:20:3, by vol) and the extract was dried under nitrogen before being dissolved in 0.4 mL of $CDCl_3$ for further NMR analysis.

NMR analysis. Nuclear magnetic spectra were recorded in $CDCl_3$ with a Bruker (Wissembourg, France) DRX-500 (500/125 MHz) spectrometer. Chemical shifts are given in ppm and are referenced to $CDCl_3$ resonances (7.26 and 77.0 ppm). Splitting pattern abbreviations are *s*, singlet; *d*, doublet; *t*, triplet; and *m*, multiplet. Resonance attributions were made according to the following experiments: Standard ^{1}H NMR, 2D H,H-correlation spectrocopy (COSY), 2D heteronuclear single quantum coherence (HSQC), and 2D gradient-selected heteronuclear multibond correlation (HMBC) with a mixing period of 60 ms.

SCHEME 1

RESULTS AND DISCUSSION

LysoPC isomers. The hydrolysis of 1-stearoyl,2-DHA-GPC by the *Rhizopus arrhizus* lipase led to 1-lyso,2-DHA-GPC with a yield recovery of about 93%, as based on ultraviolet quantitation. The lysoPC produced was extracted in acidic conditions to minimize its isomerization into 1-DHA,2-lyso-GPC. A typical HPLC profile of the lipase hydrolysis product is given in Figure 1. From this HPLC profile, it can be calculated that the isomerization was limited to around 4%. To prevent the 1-lyso,2-DHA-GPC isomer from its isomerization into 1-DHA,2-lyso-GPC, it was kept at pH 4 at 4°C. Leaving the 1-lyso,2-DHA-GPC isomer at room temperture overnight under neutral conditions was enough to provoke more than 85% isomerization into the 1-DHA,2-lyso-GPC isomer (Fig. 1). Both isomers have been taken into consideration in the present study as we found them bearing polyunsaturated fatty acids bound to human albumin, both forms being found in similar proportions (17). These lysoPC appear to be the main lysophospholipids released from the liver (18) and are considered to be the main form to provide polyunsaturated fatty acids in the brain (12,16). An important issue in this context is the biological relevance of 1-lyso,2-DHA-GPC, expected to result from liver phospholipase A_1 activity, compared to that of 1-DHA,2-lyso-GPC, which is unlikely to be acylated to yield PC, as that PC would contain DHA at the *sn*-1 position. In contrast, we may reasonably expect that 1-lyso,2-DHA-GPC could be easily acylated into physiological PC. In order to keep DHA stable at the *sn*-2 position, we aimed to chemically prepare 1-acetyl,2-DHA-GPC. This form could be then the precursor of 1-lyso,2-DHA-GPC, provided that it was first cleaved by an acetyl hydrolase.

NMR characterization of acetyl-DHA-GPC. 1-Acetyl,2-DHA-GPC **(1)** and its positional isomer, 1-DHA,2-acetyl-GPC **(2)** were obtained by acetylation of the corresponding DHA-lysoPC with acetic anhydride, and their structures (Scheme 1) were characterized by NMR spectroscopy, as described in the Experimental Procedures section.

As expected, the ^{1}H NMR spectra of compounds **1** and **2** were very similar and no distinction between them could be made on this basis. The 2D HMBC experiment, which is related to $^2J_{CH}$ and $^3J_{CH}$ connectivities (carbon–hydrogen connectivity through two or three bonds), appeared very useful to connect directly the carbon-1 of the glycerol backbone with the acetyl group in compound **1** or the DHA chain in compound **2**, thus revealing the 1,2 substitution pattern. In the 2D HMBC experiment with compound **1** (Fig. 2), cross peaks were observed between the carbon resonance at δ 171.13 (^{1}CH$_2$–O–<u>C</u>O–CH$_3$) and proton resonances at δ 2.06 (^{1}CH$_2$–O–CO–C<u>H</u>$_3$) and δ 4.17 (^{1}C<u>H</u>$_2$–O–CO–CH$_3$); a weak cross peak also was observed between the carbon resonance at

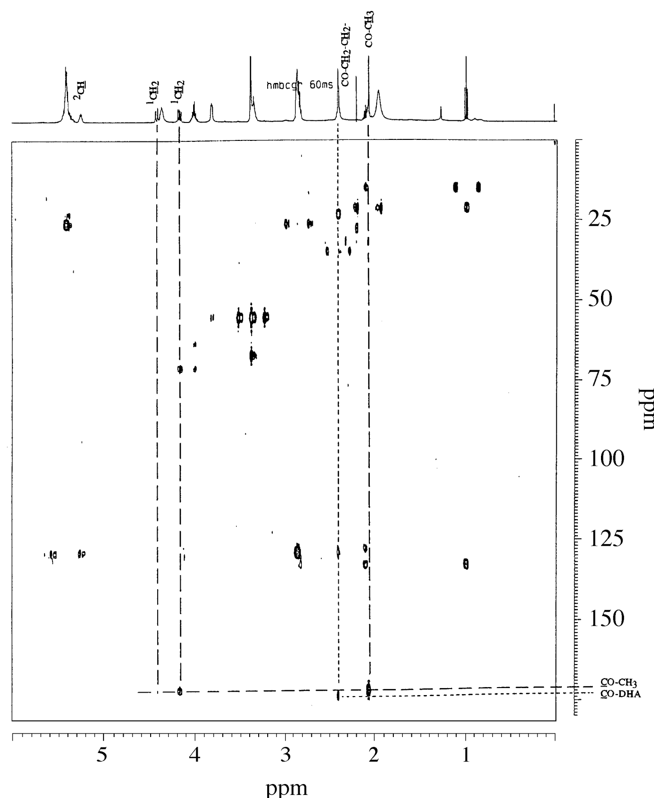

FIG. 2. 2D gradient-selected heteronuclear multibond correlation nuclear magnetic resonance spectrum of 1-acetyl,2-DHA-GPC (**1**). The presence of cross peaks on the $COCH_3$ line (horizontal) demonstrates the attachment of the acetyl group to C-1 of the glycerol backbone. The spectrum was obtained without filtering out the $^1J_{CH}$ coupling interaction since the expected information occurs in the carbonyl region where such a coupling is absent. Acquisition parameters: NS, 32; TD2, 2048; SW2, 6.008 ppm; relaxation delay, 1.5 s; mixing time, 60 ms; TDI, 128; SW1, 179.998 ppm. Processing parameters: F2 SI, 1024; F1 SI, 512. The time domain data were multiplied by a sine-bell function prior to Fourier transformation.

δ 171.13 and the other $^{1}CH_2$ proton resonance at δ 4.41 ($^{1}C\underline{H}_2$–O–CO–CH_3). Thus, the connection between the $^{1}CH_2$ and O–CO–CH_3 parts of the molecule was unambiguously established. A similar result was obtained with compound **2** since cross peaks were observed between the carbon resonance at δ 173.43 ($^{1}CH_2$–O–$\underline{C}$O–CH_2–CH_2) and proton resonances at δ 2.42–2.37 ($^{1}CH_2$–O–CO–$C\underline{H}_2$–$C\underline{H}_2$) and δ 4.18 ($^{1}C\underline{H}_2$–O–CO–CH_2–CH_2), establishing the connection between the $^{1}CH_2$ and O–DHA parts of the molecule (in this case, no cross peak was observed between the carbon resonance at δ 173.43 and the other $^{1}CH_2$ proton at 4.40). With chains bonded to carbon-2, DHA in **1** (Fig. 2), or acetyl in **2**, a cross peak was observed between the carbonyl carbon and the methylene or methyl protons of the chains, but we were unable to connect the chains with carbon-2 since the expected cross peaks between the carbonyl carbons and $^{2}C\underline{H}$ proton resonances at ~5.25 could not be observed. This missing observation is presumably related to the splitting of the $^{2}C\underline{H}$ proton resonances and to the small amount of product in the NMR sample. The following proton and carbon resonances were attributed to each compound from the different NMR experiments: 1-acetyl,2-DHA-GPC (**1**): ^{1}H NMR: δ 5.44–5.34 (*m*, 12H, $C\underline{H}$=$C\underline{H}$); 5.26–5.23 (*m*, 1H, $^{2}C\underline{H}$); 4.41 (*dd*, 1H, *J* = 12.0 and 3.2 Hz, $^{1}C\underline{H}_2$); 4.40–4.30 (*m*, 2H, O–$C\underline{H}_2$–CH_2–N); 4.17 (*dd*, 1H, *J* = 12.0 and 7.0 Hz, $^{1}C\underline{H}_2$); 4.04–3.96 (*m*, 2H, $^{3}C\underline{H}_2$); 3.84–3.79 (*m*, 2H, O–CH_2–$C\underline{H}_2$–N); 3.38 [*s*, 9H, $N(C\underline{H}_3)_3$]; 2.89–2.81 (*m*, 10H, =CH–$C\underline{H}_2$–CH=); 2.43–2.38 (*m*, 4H, O–CO–$C\underline{H}_2$–$C\underline{H}_2$–CH=); 2.12–2.03 (*m*, 2H, =CH–$C\underline{H}_2$–CH_3); 2.06 (*s*, 3H, CO–$C\underline{H}_3$); 1.00 (*t*, 3H, *J* = 7.5 Hz, =CH–CH_2–$C\underline{H}_3$). ^{13}C NMR: δ 172.81 (^{2}CH–O–$\underline{C}$O–CH_2–CH_2); 171.13 ($^{1}CH_2$–O–$\underline{C}$O–CH_3); 133.0–127.4 ($\underline{C}$H=$\underline{C}$H); 71.00 ($^{2}\underline{C}$H); 66.84 (O–CH_2–$\underline{C}H_2$–N); 63.55 ($^{3}\underline{C}H_2$); 63.37 ($^{1}\underline{C}H_2$); 59.40 (O–$\underline{C}H_2$–CH_2–N); 54.75 [$N(\underline{C}H_3)_3$]; 26.3–25.6 (=CH–$\underline{C}H_2$–CH=); 34.36 ($^{1}CH_2$–O–CO–$\underline{C}H_2$–CH_2); 22.86 (^{2}CH–O–CO–CH_2–$\underline{C}H_2$); 21.11 ($^{1}CH_2$–O–CO–$\underline{C}H_3$); 20.97 (=CH–$\underline{C}H_2$–CH_3); 14.47 (=CH–CH_2–$\underline{C}H_3$).

1-DHA,2-acetyl-GPC (**2**): ^{1}H NMR: δ 5.44–5.32 (*m*, 12H, $C\underline{H}$=$C\underline{H}$); 5.25–5.20 (*m*, 1H, $^{2}C\underline{H}$); 4.40 (*dd*, 1H, *J* = 12.0 and 3.2 Hz, $^{1}C\underline{H}_2$); 4.40–4.25 (*m*, 2H, O–$C\underline{H}_2$–CH_2–N); 4.18 (*dd*, 1H, *J* = 12.0 and 7.0 Hz, $^{1}C\underline{H}_2$); 4.04–3.98 (*m*, 2H, $^{3}C\underline{H}_2$); 3.80–3.74 (*m*, 2H, O–CH_2–$C\underline{H}_2$–N); 3.35 [*s*, 9H, $N(C\underline{H}_3)_3$]; 2.89–2.81 (*m*, 10H, =CH–$C\underline{H}_2$–CH=); 2.42–2.37 (*m*, 4H, O–CO–$C\underline{H}_2$–$C\underline{H}_2$–CH=); 2.13–2.02 (*m*, 2H, =CH–$C\underline{H}_2$–CH_3); 2.09 (*s*, 3H, CO–$C\underline{H}_3$); 1.00 (*t*, 3H, *J* = 7.5, =CH–CH_2–$C\underline{H}_3$). ^{13}C NMR: δ 173.43 ($^{1}CH_2$–O–$\underline{C}$O–CH_2–CH_2); 170.78 (^{2}CH–O–$\underline{C}$O–CH_3); 133.0–127.4 ($\underline{C}$H=$\underline{C}$H); 70.89 ($^{2}\underline{C}$H); 66.78 (O–CH_2–$\underline{C}H_2$–N); 63.79 ($^{3}\underline{C}H_2$); 63.25 ($^{1}\underline{C}H_2$); 59.45 (O–$\underline{C}H_2$–CH_2–N); 54.75 [$N(\underline{C}H_3)_3$]; 26.3–25.6 (=CH–$\underline{C}H_2$–CH=); 34.30 ($^{1}CH_2$–O–CO–$\underline{C}H_2$); 22.81 ($^{1}CH_2$–O–CO–CH_2–$\underline{C}H_2$); 21.34 (O–CO–$\underline{C}H_3$); 21.07 (=CH–$\underline{C}H_2$–CH_3); 14.48 (=CH–CH_2–$\underline{C}H_3$).

The carbonyl carbon chemical shifts deserve some comments. The carbonyl resonance of the C-1 DHA chain in **2** (173.43) appears at a higher chemical shift than its C-2 DHA chain counterpart in **1** (172.81), the same relationship being observed with the acetyl group (171.13 in **1** > 170.78 in **2**). This cross comparison may be related to the observed carbonyl chemical shifts in saturated or unsaturated α and β chains of triglycerides, the carbonyl of the α chain having the higher chemical shift (19–21).

ABSTRACT: Magic-angle spinning (MAS) ^{13}C nuclear magnetic resonance (NMR) spectroscopy is a convenient method for nondestructive, quantitative characterization of seed oil composition. We describe results for intact hybrid and transformed canola seeds. The MAS ^{13}C NMR technique complements and agrees with gas chromatography results. The spectral resolution approaches that of neat, liquid oils. MAS ^{13}C NMR data allow quantitative analysis of major oil components, including saturates and oleic, linoleic, and linolenic acyl chains. ^{13}C NMR directly and quantitatively elucidates, triglyceride regiochemistry and acyl chain *cis-trans* isomers that cannot be quickly detected by other methods. MAS ^{13}C NMR can serve as the primary method for development of near-infrared seed oil calibrations. These NMR methods are nondestructive and attractive for plant-breeding programs or other studies (e.g., functional genomics) where loss of seed viability is inconvenient.

Paper no. L8308 in *Lipids 34*, 1339–1346 (December 1999).

The analysis of plant seed oils is critical to assess the value of individual seeds as well as entire crops. Numerous methods are used to determine seed oil composition (1,2). Methods based on gas chromatography (GC), GC–mass spectrometry (GC–MS), and high-performance liquid chromatography–MS (HPLC–MS) are destructive and require chemical manipulation. GC analysis—the most common method—is inexpensive, precise, and efficient. By contrast, optical spectroscopy (near-infrared, NIR) and nuclear magnetic resonance (NMR) methods are nondestructive and attractive for plant-breeding programs or other studies where loss of seed viability is inconvenient. For example, an understanding of gene function relevant to oil composition could be gained from mutant plant screening. Single oilseeds would be screened to identify unique triglyceride (TAG) compositions. Linking the change back to the mutation could then lead to an understanding of gene function.

Whole seed NIR analysis is attractive from a cost per seed perspective. In addition, the information content of NIR is high. Total oil content and oil iodine number are measured with NIR. TAG compositions for multiple seed samples of *Brassica carinata* (mustard) are reported (3). However, NIR analysis is a secondary method and requires careful and comprehensive calibrations. In addition, seed variables, such as hull thickness, can complicate NIR data interpretation.

Low-resolution (wide-line) ^{1}H NMR spectroscopy is well known in seed oil analytical chemistry. Wide-line NMR measures total oil and moisture content for groups of seeds, but cannot determine oil composition. Low-resolution NMR is inexpensive; instrument calibration is straightforward and measurements are automated. High-resolution seed NMR studies to observe individual peaks from structurally distinct nuclei are less well known. The first high-resolution ^{13}C measurements on intact seeds appeared in 1974 (4). Reports on the application of ^{13}C NMR with a variety of intact seeds followed (5–12). Magic-angle spinning (MAS) methods give the highest spectral resolution (13–18). To date, published MAS seed spectra were acquired at moderate magnetic field strengths (^{1}H frequency ≤400 MHz) with sample probes designed to characterize amorphous solids. These probes are constructed with materials important for solid-state spectroscopy and do not emphasize high resolution. Solid-state probes are not readily adapted to provide high sample throughput. We report here results of initial seed oil studies using high-field NMR and a ^{13}C MAS probe designed specifically to obtain high-resolution spectra (19). Our experiments show high-resolution NMR quickly and accurately determines oil composition in whole seeds. This method can be automated to provide detailed seed oil compositions without the need for chemical extractions.

MATERIALS AND METHODS

Seeds. Canola seeds are from the Calgene hybrid and transgenic library. After NMR analysis, a sample of canola seeds germinated normally.

Sample preparation. Canola seeds were placed directly into wide-mouth MAS NMR sample tubes.

NMR spectroscopy. High-resolution spectra are measured at 11.7 tesla. (^{1}H = 500 MHz, ^{13}C = 125 MHz) using Varian NMR Instruments (Palo Alto, CA) Inova™ NMR spectrometers equipped with carbon-observe MAS Nanoprobes™. The ^{13}C spectra were acquired without a field-frequency lock at ambient

temperature (~21–22°C) in 10 min to 14 h using the following conditions: spectral width = 29.996 kHz, acquisition time = 2.185 s, $\pi/2$ pulse (3.8 µs) with no relaxation delay, $^{1}H\ \gamma B_2 = 2.5$ kHz with Waltz decoupling. The following conditions were typical of data processing: digital resolution = 0.11 Hz, 0.3 to 1.5 Hz line broadening, and time-reversed linear prediction of the first three data points. Chemical shifts are referenced by adding neat tetramethylsilane (TMS) to canola seeds and using the resulting referencing parameters for subsequent spectra. The ^{13}C resolution is 2–3 Hz for the most narrow seed resonances. Spectral resolution is independent of MAS spinning speeds (2.0–3.5 kHz) and data are typically obtained with 2.2 kHz spinning speeds. Spinning sidebands are <1% of the main resonance. TAG ^{13}C assignments are made from comparison with literature assignments or with shifts computed from a ^{13}C NMR database (20).

Preparation of fatty acid methyl esters and GC analysis. Twenty seeds from each Calgene canola line were crushed in a glass vial (12 × 32 mm) and extracted with toluene (500 µL) at room temperature for 3 h. An aliquot (100 µL) of the extracted seed oil TAG was subjected to methanolysis with 0.5 M sodium methoxide/methanol (500 µL) at 60°C for 20 min in another vial (capped). A saturated solution of NaCl (500 µL) and heptane (100 µL) was added to each sample and then centrifuged at 2,000 × *g* for 5 min. An aliquot (100 µL) of the upper phase containing methyl esters was recovered and subjected to compositional analysis using a GC–flame-ionization detector (FID) (model 6890; Hewlett-Packard, Wilminton, DE). The chromatographic conditions were 25 m × 0.25 mm fused-silica column (Omegawax 250; Supelco, Bellefonte, PA); 250°C injection and 270°C detection port temperatures; He was the carrier gas; H_2 at 40 mL/min; air at 450 mL/min; N_2 makeup at 35 mL/min; column temperature programmed from 172 to 242°C at 40°C/min; holding at 172°C for 1.7 min; column pressure programmed from 25 to 75 psi at 40 psi/min; holding at 25 psi for 1.7 min; 1.0 µL injected at a split ratio of 100. Peak retention time assignments were determined using authentic reference compounds (Sigma Chemical Co., St. Louis, MO) and the weight percent results were calculated from peak areas adjusted by theoretical FID response factors.

RESULTS AND DISCUSSION

High-resolution ^{13}C NMR of seeds. Figure 1 compares a ^{13}C spectrum acquired by placing about 80 canola seeds in a standard 5-mm NMR tube (Fig. 1A) with a spectrum of a single canola seed spinning at the magic angle (Fig. 1B). The resolution improvement is dramatic. The high-resolution MAS spectrum only contains carbon peaks from molecules with rapid molecular motions, i.e., molecules in liquid seed oil storage droplets. Long-chain saturated TAG are solids at room temperature, but they readily dissolve in seed oil droplets containing common amounts of unsaturated TAG. TAG and phospholipids immobilized in cell membranes do not appear in high-resolution MAS spectra. These components, and others with highly restricted global motion (proteins and carbohydrates), are seen in cross-polarization (CP) MAS ^{13}C NMR spectra of similar seeds (21). Figure 1C depicts a 10-min spectrum obtained from a single low-erucic (LEAR) canola seed. The 40-µL probe sample volume is larger than this seed, but the sensitivity is adequate to observe carbons from all oil components. This spectrum indicates that the MAS ^{13}C method can analyze hundreds of seed samples per week. The best compromise between sig-

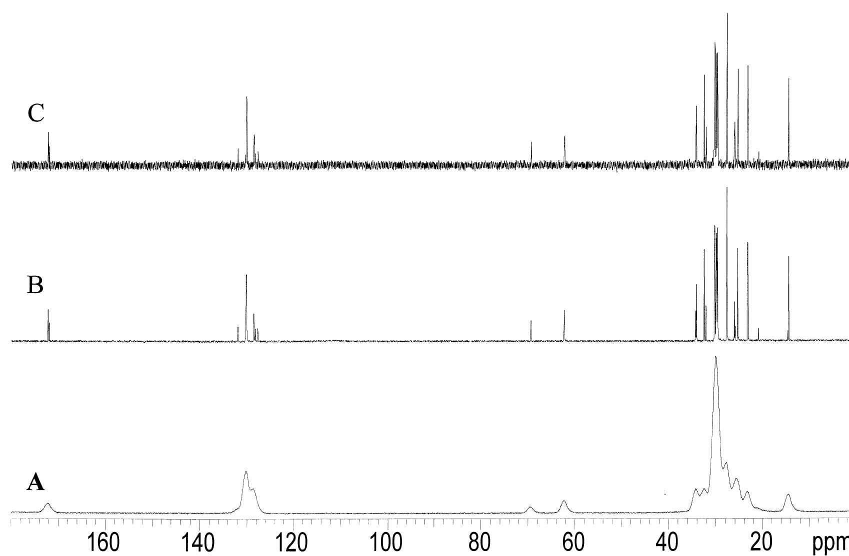

FIG. 1. The 125 MHz ^{13}C spectra of (A) about 80 canola seeds in a 5-mm nuclear magnetic resonance tube and (B) single (7.8 mg) canola seed collected with magic-angle spinning. Both spectra were signal-averaged for 4 h and processed with 1 Hz line broadening. (C) A 10-min (276 scans) single-seed spectrum represents the minimum signal-to-noise ratio suitable for seed screening.

nal-to-noise-ratio and time is achieved after 1 hr of signal averaging.

A set of canola seed and neat canola oil spectra obtained with the MAS probe (data not shown) demonstrates the importance of factors responsible for ^{13}C spectral resolution in seeds. The observed line widths in neat canola oil are about 0.5 Hz sharper than intact seed line widths. When the neat oil is diluted in $CDCl_3$ to ~20% (vol/vol), the line widths sharpen; at ~21–22°C, viscosity broadening in neat oil adds about 0.6 Hz to the sharpest lines. Heating seeds from 22 to 40°C decreases the line width by only 0.3 Hz. Taken together, these results verify earlier conclusions that the primary benefit of MAS is that it averages microscopic magnetic susceptibility gradients inherent in seed tissue (15,16).

Canola seed oil assignments. For initial analysis and carbon assignments, we discuss in detail the 4-h spectrum of a single LEAR canola seed. The terminal methyl, or ω_1, carbon region is well-separated from the other aliphatic resonances. This region (Table 1), along with the ω_2 methylene peaks (Fig. 2), is used to quickly determine the presence of n-3 and n-6 acyl chains. Methyls on saturated chains resonate just downfield of those on n-9 chains and are not resolved. Figure 2 shows how well MAS resolves the other aliphatic carbons at 125 MHz. The bulk methylene resonances (~29.9–30.8 ppm) are highly overlapped and will not be discussed further.

Methylenes near structural moieties relevant to oil composition (e.g., ω_1 methyls, olefin carbons, and ester groups) are readily assigned. Methylenes allylic to *cis* olefin carbons are found at ~26–26.5 ppm and at ~27.6–28 ppm (Figs. 2 and 3). This region is useful to identify mono-, di-, and trienes. The spectral region shown in Figure 3 contains all the peaks required for quantitative TAG analysis (*vide infra*). Identification of *cis* and *trans* isomers is problematic with GC methods. A 38-laboratory study concluded *trans* acyl chain analyses of unhydrogenated seed oils can give variable results (22). This study and another (23) found that canola oil contains 1 to 4% *trans* acyl chains. Allylic methylenes in *trans* olefins appear about 5 ppm downfield of their *cis* counterparts (24). Based on this *cis-trans* shift, we assign the small peak at ~32.5 ppm (Fig. 2) found in all spectra to *trans* acyl chain allylic carbons.

The olefin region (Fig. 4) is rich in important information about seed oil composition. The presence of 18:3n-3 acyl chains is determined by inspection. The 18:1n-9 C-10 and 18:2n-6 C-13 peaks overlap in the downfield (130.0–130.4 ppm) region. In the upfield region (128.4–128.8 ppm), the 18:3n-3 C-12 and C-13 peaks overlap. The other olefin methine carbons are well resolved. The 18:1n-9 C-9, 18:2n-6 C-9, C-10, and C-12 carbons, and the 18:3n-3 C-9 and C-10 carbons all separate into *sn*-1,3 and *sn*-2 regioisomer pairs (Fig. 5). The ability to identify all the olefin carbons for a given acyl chain reduces ambiguity due to resonance overlap.

The *sn*-1,3 and *sn*-2 glycerol backbone (~61, ~64 ppm, respectively) and ester carbonyl carbons (~172 ppm) have different chemical shifts, but do not contain information relevant to oil composition in these seeds.

Oil composition in transgenic canola seeds. Figure 6 compares the olefin region for LEAR, high erucic (HEAR) seeds, and seeds transformed to synthesize monoene acyl chains. The intense peak in the HEAR seed spectrum at ~130.2 ppm is from 22:1n-13 acyl chains. Seeds transformed to express 24:1n-15 acyl chains have a comparable resonance. The 24:1n-15 transformed seeds and the HEAR seeds have similar 18:1n-9, 18:2n-6, and 18:3n-3 compositions. Comparison with the LEAR spectrum shows the total amount of 18:3n-3 and 18:2n-6 chains is reduced in seeds with long acyl chains. A more subtle difference in the oil composition is apparent from comparison of allylic peak intensities (data not shown). Both hybrid and transformed seeds have a higher 18:3n-3 to 18:2n-6 molar ratio. Figure 6 indicates seeds transformed to express 18:1n-9 acyl chains do so at the expense of 18:3n-3 synthesis.

TABLE 1
^{13}C NMR Canola Seed Oil Peak Assignments

Carbon(s)	Acyl chain	Chemical shift (ppm)

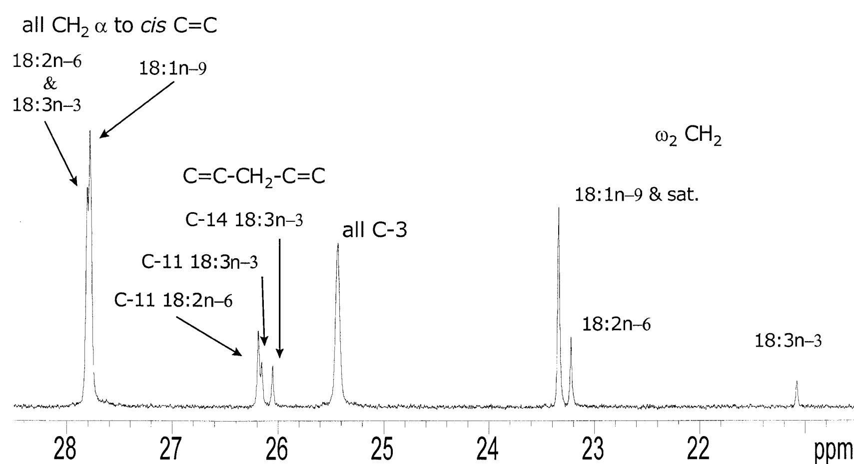

FIG. 3. Expansion of the spectrum in Figure 2 depicting the *cis*-allylic and ω_2 carbons.

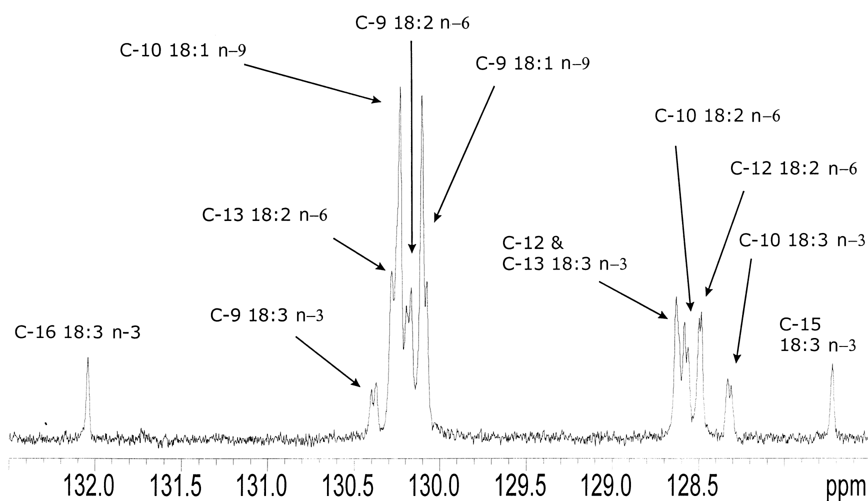

FIG. 4. The olefin-methine carbon assignments for four LEAR canola seeds. This is a 1-h spectrum with 0.3 Hz line broadening. See Figure 2 for abbreviation.

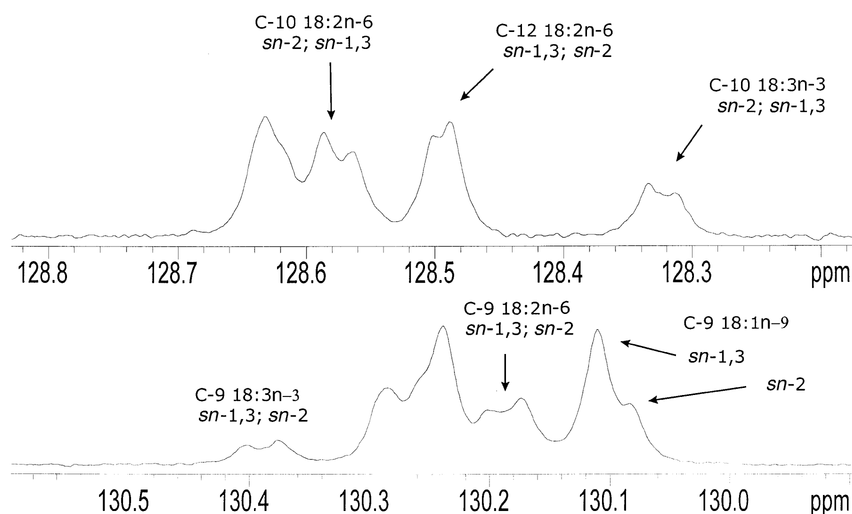

FIG. 5. Olefin-carbon regioisomer assignments for a LEAR canola seed. The *sn*-1,3 and *sn*-2 label order indicates downfield and upfield peak assignments. Unlabeled peaks do not have regioisomer shifts or resonance overlap obscures these shifts. See Figure 2 for abbreviation.

Figure 7 demonstrates how information in the olefin spectral region is used to assess oil composition in a set of closely related seed lines. Here, spectra for transgenic seeds high in 8:0/10:0, 12:0, 14:0, 16:0, and 18:0 acyl chains are shown. Based on the resonance assignments from Figure 5, it is possible to compare the 18:1n-9, 18:2n-6, and 18:3n-3 chain composition among these high-saturate seeds. Detail about saturated chain composition is difficult to extract from these spectra due to resonance overlap from similar methylene carbons in 8:0, 10:0, 12:0, 14:0, 16:0, and 18:0 chains. However, it is possible to compute the sum of all saturated chain concentrations (see below). These experiments demonstrate the potential of ^{13}C NMR in comparing TAG biosynthesis in transformed seed lines.

Canola seed oil quantitative analysis. In principle, the ^{13}C-peak area is directly proportional to the molar concentration of the corresponding carbon(s). In practice, ^{13}C peak areas also depend on relaxation parameters [e.g., nuclear Overhauser effect (NOE), and spin-lattice relaxation rates]. Use of suitable acquisition parameters provides quantitative results, but quantitative experiments require about a 10-fold increase in data collection time. As a result, ^{13}C NMR is often viewed as a qualitative method, well-suited for structure elucidation but inefficient for quantitative applications.

It is possible to correct ^{13}C peak areas to account for relaxation effects (24,25). Then, quantitative results are available with efficient data-collection times. For TAG mixtures in seed

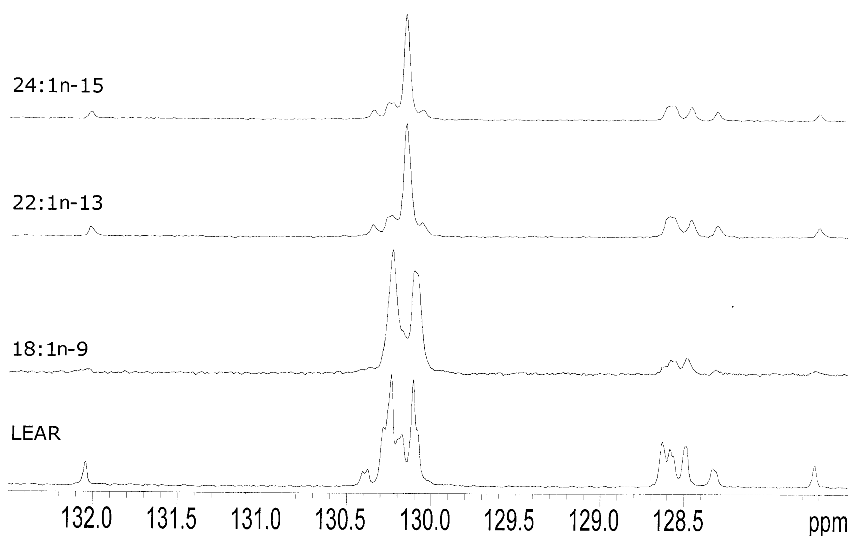

FIG. 6. The olefin region comparison of LEAR and high-erucic (HEAR, 22:1n-13) seeds and seeds transformed to synthesize monoene acyl chains. Assignments are given in Figure 4. For abbreviation see Figure 2.

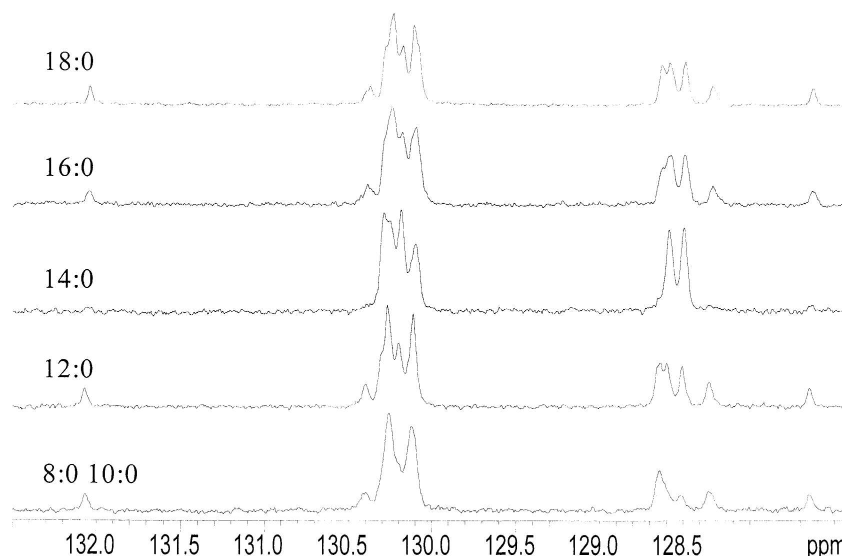

FIG. 7. The olefin region for seeds transformed to enhance saturated acyl chain composition. Assignments are shown in Figure 4.

oil storage droplets, NMR relaxation differences for similar carbons in similar molecules are comparable. If we collect a seed spectrum under both survey and quantitative conditions, we can establish a correction factor for each resonance to apply in survey spectra of similar seeds. Peak area correction factors for seeds for each carbon resonance in LEAR canola seeds are included in Table 2 (see below). The quantitative precision for ^{13}C NMR ranges from 1 to 15% and depends directly on the signal-to-noise ratio. Published studies comparing GC and ^{13}C NMR quantitative analysis indicate agreement between the two methods is 5 to 15% (9,11,16,24).

For intact seed oil composition quantitation, we focus on classes of CH_2 carbons found from 20–29 ppm (see Fig. 3 for assignments). With those assignments, we can describe how the acyl chain types contribute to each resolved peak (Table 3).

Algebraic combination of these relationships gives solutions for saturate (sat), 18:1n-9, 18:2n-6, and 18:3n-3 chain concentrations:

$$\text{sat} = P_{C\text{-}3} - \frac{P_{\omega 2}}{2} - \frac{P_{\alpha}}{2} \quad [1]$$

$$18{:}1\text{n-}9 = \frac{P_{\alpha}}{2} + \frac{3P_{\omega 2}}{2} \quad [2]$$

$$18{:}2\text{n-}6 = P_{v} - 2P_{\omega 2} \quad [3]$$

$$18{:}3\text{n-}3 = P_{18:3} \quad [4]$$

TABLE 2
Comparison of ^{13}C NMR and GC–FID Canola Seed Oil Compositions[a]

	Acyl chain ^{13}C NMR (mol%)[b] and GC–FID (wt%)			
Seed line[b]	18:3n-3	18:3n-6	18:1n-9[c]	Saturates

[b]Intact seeds were used. Acyl chain mole percentages from peak area ratios were calibrated with no nuclear Overhauser enhancement. Delay = 7.1 or 12.1 s.
[c]Includes all *cis* monoenes (16:1, 20:1, 22:1, 24.1).

TABLE 3
Acyl Chain Type Contribution to Resolved Peaks

Peak area	ppm	Assignment (acyl chain molar amounts)[a]
$P_{18:3}$	21.1	ω_2 (18:3n-3)
P_{n-2}	23.3	ω_2 [(sat) + (18:1n-9) + (18:2n-6)]
P_{C-3}	25.6	C-3 [(sat) + (18:1n-9) + (18:2n-6) + (18:3n-3)]
P_v	26.2–0.5	vinyl allylic [(18:2n-6) + 2(18:3n-3)]
P_α	28.0	allylic [2(18:1n-9) + 2(18:2n-6) + (18:3n-3)]

[a]sat, saturated.

where each peak area (P_n) is multiplied by its empirical correction factor to correlate quantitative and survey peak areas.

A quantitative summary of canola seed TAG chain compositions from MAS ^{13}C NMR and GC–FID is found in Table 2. Several factors complicate direct comparison of the ^{13}C and GC data. The GC and NMR data are from the same seed lines, but were not done using the same individual seeds. The NMR results are in mole percentages and the GC data are in weight percentages. The most common seed oil TAG (C-18 acyl chains) have similar molecular weights. In this case, mole percentage–weight percentage differences may be neglected. For seed oils with shorter and longer acyl chains, the mole percentage–weight percentage differences become significant. Inspection of the olefin region (Figs. 4 and 6) establishes the importance of long-chain monoenes. The sample handling procedures used in the NMR and chromatography methods could account for some of the differences in Table 2. ^{13}C NMR directly observes liquid TAG in seed oil storage vacuoles. Chromatographic analysis is from whole seed extracts and involves chemical derivatization. Despite these complications, the results affirm that MAS ^{13}C oil characterization is both a qualitative and quantitative method.

ACKNOWLEDGMENTS

The authors thank the Varian NMR Instruments Palo Alto Applications Laboratory for their kind hospitality during our initial experiments. We thank Dr. Paul Keifer for his technical assistance and advice regarding use of the Nano-probe™. We are grateful to Sanjay Panda for his assistance and for growing canola seeds after the NMR measurements.

A Rapid and Quantitative Method for Total Fatty Acid Analysis of Fungi and Other Biological Samples

M. Sönnichsen and B.W. Müller*

Department of Pharmaceutics and Biopharmaceutics, Christian-Albrecht-University, D-24118 Kiel, Germany

ABSTRACT: A quantitative method for the one-step esterification and determination of absolute amounts of polyunsaturated fatty acids in biotechnologically produced fungal mycelia is proposed. A system of two internal standards was used to quantify the total fatty acid content of the samples by gas chromatography. The degree of methylation of the analyzed fatty acids was calculated using the internal standards, and subsequently this quotient was used to validate the derivatization and extraction reactions. By utilizing this degree of methylation, the corrected amounts of the various fatty acids in the sample can be calculated.

Paper no. L8282 in *Lipids 34,* 1347–1349 (December 1999).

For the biotechnological production of polyunsaturated fatty acids (PUFA) by fungi, a fast and reliable method for determining the fatty acids in the mycelia is necessary for the optimization of the production process. That the handling procedures of such a method are simple is just as important as the calculation of absolute amounts of fatty acids in the sample in stating specific productivities and optimizing the production process.

Fatty acids are usually determined by gas chromatography (GC) using the corresponding methyl esters, prepared either by base- or acid-catalyzed esterification, depending on the composition of the samples (1–12). All these methods imply a time- and solvent-consuming extraction step prior to methylation. For small samples, a two-step analysis with extraction of the fatty acids followed by esterification is inaccurate because of loss of material during both steps. Consequently, a one-step reaction that forms a product that can be injected directly into the gas chromatograph is required. Recently, some one-step fatty acid analysis methods have been published (4–7). The reliability of the data resulting from these methods bears comparison with the standard two-step extraction and methylation procedures. The one-step methods have in common either that they do not state the total amount of fatty acids contained in the sample (4,6) or that a significant difference occurs between the total amounts indicated by the one- and two-step methods (5). Furthermore, the absence of a means to validate the chemical reactions involved in these procedures characterizes all these methods.

The use of an internal standard, which is added to the sample, quantifies the amounts of different fatty acids in the sample relating to the total amount of fatty acids that are determined (4,5). However, the results of the fatty acid quantification vary with the method used (7). Moreover, the determination of the exact amount of fatty acids is difficult owing to the loss of material during the chemical reactions or incomplete derivatization.

The objective of this study was to develop a fast and easy analytical method for the determination of fatty acids in small amounts of fungal mycelia. This procedure should be applicable as a standard method for a high number of samples and should determine lipids in both the polar and neutral fractions of the mycelium. In the present work, the use of a second internal standard is proposed as a means to calculate the degree of methylation of fatty acids in a fungal sample and, subsequently, the total fatty acid content of the sample. Concurrently the absolute amount of each single fatty acid contained in the sample can be estimated. Furthermore, the methylation method used can be verified with the suggested degree of methylation.

MATERIALS AND METHODS

All used solvents were of analytical grade and purchased from Merck (Darmstadt, Germany). Methanolic HCl (3 M) was supplied by Supelco (Bellefonte, PA).

External standards. A PUFA methylesters (PUFAME) kit (Supelco) containing 14 PUFAME (C_{14}–C_{24}) supplemented with four saturated FAME (14:0–20:0) and methyl γ-linolenate (18:3n-6) (ICN Pharmaceuticals, Costa Mesa, CA) was used as external standard. For calibration, a mixture containing 100 µg of each fatty acid in 1 mL hexane was used. The flame-ionization detector (FID) responses were processed by HP 3365 series II ChemStation (Hewlett-Packard, Palo Alto, CA) chromatography software. The concentration of each fatty acid in the sample was calculated in relation to the response factor of the internal FAME standard.

Internal standards. Methyl margarate (17:0; 100 mg) dissolved in 1 mL hexane was used as internal FAME standard (IS 1), and 50 mg pentadecanoic acid (15:0) in 1 mL di-

ethylether as internal fatty acid standard (IS 2), respectively, both purchased from Merck. One microliter of each standard solution was added to the sample.

Sample preparation. The filamentous fungus *Mucor circinelloides* CBS 108.16 (Centraal Bureau voor Schimmelcultures, Delft, The Netherlands) was cultivated in 500-mL Erlenmeyer flasks with 200 mL of glucose-containing growth medium for 3 to 7 d. The mycelium was filtered (Schleicher & Schüll filter paper, Dassel, Germany), washed twice with distilled water, and then immediately freeze-dried.

Direct esterification. At least three derivatization experiments per sample culture were made, each of which was analyzed in duplicate by means of GC. Of each sample culture approximately 5, 10, and 20 mg of lipid-containing, freeze-dried mycelium was precisely weighed and placed in a Pyrex® tube with a polytetrafluoroethylene screw-cap. Internal fatty acid standard IS 2 (50 µg) was added to the sample. Then 1 mL methanolic HCl (3 M) and 1 mL methanol were added to the sample in order to esterify the fatty acids. Finally, 0.5 mL hexane was added to aid the extraction of FAME from the mycelial tissue. After thorough mixing, the tubes were heated at 100°C for 1 h and shaken several times. The samples were cooled to ambient temperature and diluted with 2 mL hexane to achieve a suitable concentration for analyzing by GC. Internal FAME standard IS 1 (100 µg) was added to the sample. Afterward, 2 mL H_2O was added and carefully mixed to dissolve chloride ions (vigorous shaking of the sample causes gel formation and therefore loss of the sample). After phase separation, the upper organic layer was drawn off and an aliquot of 1 µL of this sample was analyzed by GC.

GC. A HP 5890 series II gas chromatograph equipped with FID (Hewlett-Packard) and WCOT fused-silica CP-WAX 52 CB capillary column, 25 m, 0.32 mm i.d., 0.2 µm film thickness (Chrompack, Middelburg, The Netherlands) was used. N_2 was the carrier gas, at a column head pressure of 35 kPa. Detector and injector temperatures were both 220°C. A temperature gradient was run from 160 to 190°C at 1°C/min. A sample amount of 1 µL was injected manually with split injection.

Degree of methylation. The degree of methylation (D_M) was calculated by analyzing the amount of methyl pentadecanoate ($C15_{FAME}$) of each sample and dividing it by the known amount of pentadecanoic acid ($C15_{FA}$), which was added to the sample.

$$D_M = \frac{[C15_{FAME}]}{[C15_{FA}]} \quad [1]$$

The D_M value was used as a validation factor to calculate the amounts of the various fatty acids contained in the sample cultures analyzed. The mean values of the amounts of each corrected fatty acid were summed to calculate the total amount of fatty acids in a sample culture.

RESULTS AND DISCUSSION

Because the determination of total amounts of a product is very important in fermentation technology, a system of two internal standards was developed to quantify the total content of saturated and unsaturated C_{14}–C_{18} fatty acids in fungal samples. Methyl margarate was used as internal standard (IS 1) to identify the detected peaks and simultaneously to calculate the individual response factors of the single fatty acids. As a second internal standard (IS 2), pentadecanoic acid was added to the sample before starting the derivatization. This fatty acid is esterified with the sample and is used for validation purposes assuming that the internal fatty acid standard (IS 2) is esterified in the same way as all other fatty acids in the sample. In contrast to enzymatic reactions, for example, there is only minimal dependency of the reaction kinetics on the chain length of the fatty acids examined. The reactivity of the derivatizing agents depends on the reactivity of the fatty acid carboxyl group, particularly on the p*K* value, which varies slightly within chain lengths from 14 to 18 carbon atoms (13).

A mixture of methanolic HCl/hexane (4:1, vol/vol) is used to combine the esterification step with the extraction step. After the GC analysis, the degree of methylation can be calculated by dividing the amount of analyzed methyl pentadecanoate by the amount of pentadecanoic acid initially added to the sample (Eq. 1). Thus this quotient can be used as a validation factor for both reaction steps of the combined method. In the case of incomplete methylation, the factor corrects the amount of analyzed fatty acids. As the more lipophilic FAME are mainly extracted by hexane, an insufficient extraction of the methyl esters can similarly be corrected by this factor to calculate the real amounts of the various fatty acids in the sample.

More than 60 different samples of freeze-dried mycelia of *M. circinelloides* were analyzed several times by GC with the proposed method. All FAME in the samples were completely separated by GC.

The proposed method was validated by analyzing (i) different sample quantities (5–25 mg), (ii) samples with different total amounts of fatty acids [3–11% (w/w)], and (iii) samples with different fatty acids compositions. As a selection of analyzed mycelia in Table 1 shows, the D_M correlated with none of these three factors.

TABLE 1
Total Amounts of Determined[a] and Corrected Fatty Acids and Degrees of Methylation (D_M) in Mycelia of Different Selected Cultures of *Mucor circinelloides* CBS 108.16

Sample culture	Total fatty acids (mg/$g_{dry\ mass}$)		
	Determined[b]	Corrected[b]	Mean D_M[b]
A	21.95 ± 1.30	31.03 ± 1.49	0.709 ± 0.050
B	41.65 ± 4.82	60.16 ± 4.18	0.691 ± 0.048
C	50.88 ± 1.79	59.41 ± 3.40	0.831 ± 0.047
D	52.02 ± 5.48	71.97 ± 1.73	0.722 ± 0.063
E	63.64 ± 5.80	84.77 ± 5.81	0.758 ± 0.114
F	77.91 ± 4.60	112.17 ± 8.85	0.701 ± 0.089

[a]Data achieved with proposed one-step esterification and extraction method.
[b]Values are means ± standard deviations of six experiments.

It can be deduced from the foregoing results that a combined esterification and extraction method without validation is not suitable for the fatty acid analysis of small amounts of fungal mycelia, as the degree of methylation of the fatty acids in the sample is not constant. Therefore, one cannot assume that all fatty acids will be esterified or extracted completely. However, no obvious explanation for the different degrees of methylation could be drawn as all experiments were carried out under identical conditions.

For the reasons discussed, a validation of a one-step esterification and extraction method, as proposed in this work, is imperative for the standard analysis of fungal fatty acids in order to achieve reliable results.

Essentiality of Fatty Acids

Arthur A. Spector*

Department of Biochemistry, College of Medicine, University of Iowa, Iowa City, Iowa 52242

ABSTRACT: All fatty acids have important functions, but the term "essential" is applied only to those polyunsaturated fatty acids (PUFA) that are necessary for good health and cannot be completely synthesized in the body. The need for arachidonic acid, which is utilized for eicosanoid synthesis and is a constituent of membrane phospholipids involved in signal transduction, is the main reason why the n-6 class of PUFA are essential. Physiological data indicate that n-3 PUFA also are essential. Although eicosapentaenoic acid also is a substrate for eicosanoid synthesis, docosahexaenoic acid (DHA) is more likely to be the essential n-3 constituent because it is necessary for optimal visual acuity and neural development. DHA is present in large amounts in the ethanolamine and serine phospholipids, suggesting that its function involves membrane structure. Because the metabolism of n-6 PUFA is geared primarily to produce arachidonic acid, only small amounts of 22-carbon n-6 PUFA are ordinarily formed. Thus, the essentiality of n-3 PUFA may be due to their ability to supply enough 22-carbon PUFA for optimal membrane function rather than to a unique biochemical property of DHA.

Fatty acids carry out many functions that are necessary for normal physiological function and good health. Saturated fatty acids are involved in energy production, energy storage, lipid transport, the synthesis of phospholipids and sphingolipids needed for membrane synthesis, and the covalent modification of many regulatory proteins. Monounsaturated fatty acids also are involved in many of these processes and play a key role in maintaining optimal fluidity of the membrane lipid bilayer. Although these are clearly vital physiological processes, the term "essential" is not applied to the saturated or monounsaturated fatty acids. The designation is reserved for those polyunsaturated fatty acids (PUFA) that are required for good health and, in addition, cannot be completely synthesized in the body. As it is presently used, essentiality implies that the fatty acid not only performs a vital function, but it also is a required dietary nutrient.

Essential fatty acids. PUFA have important effects on the structure and physical properties of localized membrane domains and, in addition, are involved in eicosanoid production, signal transduction, and the activation of nuclear transcription factors. Two classes of PUFA, designated as n-6 and n-3, normally are present in the tissues and body fluids. Neither of these classes can be completely synthesized by mammalian cells and, therefore, they must be obtained from the diet. The usual Western diet contains 10- to 20-times more n-6 than n-3 PUFA, and the plasma and most other tissues also contain 10- to 20-times more n-6 fatty acid. The exceptions are the brain and retina which are rich in n-3 PUFA.

A very serious systemic illness called essential fatty acid deficiency occurs if the body becomes deficient in n-6 PUFA. A similar debilitating disease does not occur if there is a deficiency in n-3 PUFA. However, accumulating evidence indicates that n-3 PUFA are required for optimal health, especially for normal neural development and visual function (1,2), and there is an increasing consensus that they, too, are essential fatty acids.

Mechanism of action of the essential fatty acids. Table 1 lists the biochemical actions of the key members of the n-6 and n-3 classes of essential fatty acids. The need for arachidonic acid (20:4n-6) almost certainly is the primary reason why n-6 PUFA are essential. Arachidonic acid is the main substrate for synthesis of the eicosanoid mediators produced by the cyclooxygenase, lipoxygenase, and cytochrome P450 pathways (3), and it is highly enriched in the inositol phospholipids that are involved in signal transduction (4). Linoleic acid (18:2n-6) also probably is essential because it is utilized for the synthesis of the complex lipids that form the permeability barrier of the epidermis (5).

The biochemical reason that the n-3 PUFA are essential is not presently known. In fact, it is not certain whether eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), or both carry out the essential biochemical functions. Like arachidonic acid, EPA (20:5n-3) is a substrate for eicosanoid synthesis (6), and EPA competes with arachidonic acid for the same metabolic pathways (7,8). However, no requirement for the eicosanoids produced from EPA has so far been demonstrated, and very little EPA is present in the tissues of individuals who consume the usual Western diet. Therefore, competition with arachidonic acid seems improbable unless an individual is consuming supplemental amounts of EPA. Under ordinary conditions, DHA (22:6n-3) is the most abundant n-3 PUFA contained in the tissues, especially in the brain and retina. For this reason, it seems more likely that DHA rather than EPA is the essential n-3 component.

TABLE 1
Biochemical Functions of the n-6 and n-3 Fatty Acids

Class	Fatty acid	Function
n-6	Arachidonic	Eicosanoid synthesis Component of the inositol phospholipids
n-6	Linoleic	Synthesis of lipids that form the epidermal permeability barrier
n-3	Eicosapentaenoic	Eicosanoid synthesis Structural analog and competitor of arachidonic acid
n-3	Docosahexaenoic	Structure of membrane lipid domains Modulation of integral membrane proteins Metabolism of phosphatidylethanolamine, ethanolamine plasmalogens, and phosphatidylserine Formation of free radicals Regulation of gene expression

DHA function. Considerable effort is being expended to determine the biochemical functions of DHA, and some recent progress has been made. DHA is contained primarily in three phospholipids, phosphatidylethanolamine, ethanolamine plasmalogens, and phosphatidylserine (9,10). This suggests that it may affect the trafficking or metabolism of these phospholipids, or it may produce structural changes in regions of the membrane lipid bilayer that are enriched in these phospholipids (11). Numerous effects produced by DHA are consistent with a membrane lipid effect. For example, DHA modulates the carrier-mediated transport of choline, glycine and taurine (12–14), the function of delayed rectifier potassium channels (15), and the response of rhodopsin contained in phospholipid vesicles (16). Specific interactions of phospholipid fatty acyl chains with membrane proteins could account for each of these effects. Other actions of DHA include the formation of free radicals in response to oxidative stress (17), transcriptional activation of genes (18), and the prevention of apoptosis (19). One or more of these effects probably constitutes an essential biochemical or developmental function and, hence, the molecular reason why DHA is essential.

Elongation and desaturation of n-3 and n-6 fatty acids. The same elongation and desaturation pathway involving 24-carbon intermediates and peroxisomal retroconversion is utilized by n-3 and n-6 PUFA (20). Studies of this process in cultured brain cells indicate that this pathway operates primarily in astrocytes and that the astrocyte pathway handles n-3 and n-6 PUFA differently (21). These differences are illustrated in Figure 1. DHA is the main product formed when the astrocytes are incubated with [1-^{14}C]linolenic acid, whereas arachidonic acid is the main product when they are incubated with an equivalent amount of [1-^{14}C]linoleic acid (21). DHA and arachidonic acid also are the main products released into the extracellular fluid during these incubations. About 20-times more DHA than n-6 docosapentaenoic acid (n-6 DPA), the corresponding 22-carbon fatty acid of the n-6 series, is formed by the astrocytes under these conditions. Furthermore, 10-times more radiolabeled DHA than n-6 DPA accumulates in the astrocytes, and 45-times more DHA is released into the medium.

Additional studies indicate that neurons cultured under similar conditions do not produce either DHA or DPA from n-3 or n-6 PUFA precursors, respectively (21). Therefore, the neurons apparently are dependent on an external source for these fatty acids, and it seems likely that they are supplied at least in part by release from the astrocytes (22). As described above (21), the astrocytes produce and release much more DHA than w-6 DPA. Taken together, these metabolic results probably explain why the brain accumulates DHA rather than n-6 DPA even though n-6 PUFA are usually much more abundant.

Basis for n-3 fatty acid essentiality. It is generally assumed that the n-3 class of PUFA is essential because the function of one of its components, probably DHA, is necessary and cannot be fully replaced by any other fatty acid. Because n-6 DPA has the same structure as DHA except for the Δ19 double bond, the unique action of DHA must somehow involve the methyl-end of its hydrocarbon chain.

While this remains the most likely biochemical explanation for the essentiality of the n-3 fatty acids, an alternative possibility should be considered in view of the astrocyte results

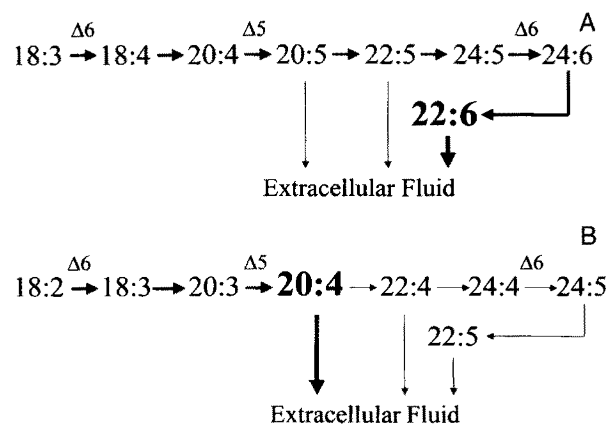

FIG. 1. Operation of the polyunsaturated fatty acid metabolic pathway in murine brain astrocyte cultures. A) illustrates the function of this pathway with n-3 fatty acids, B) with n-6 fatty acids. The fatty acids and arrows shown in bold type signify the main products that are formed and released to the extracellular fluid. Thus, docosahexaenoic acid (22:6) is the most abundant n-3 fatty acid product formed and released, whereas arachidonic acid (20:4) is the main n-6 product.

(21,22). It is possible that the fundamental need of the central nervous system is for a 22-carbon, highly unsaturated fatty acid containing a Δ4 double bond. Even though n-6 PUFA precursors are more abundant, enough n-6 DPA cannot be formed in the brain to fulfill this requirement because the astrocyte metabolic pathway utilizes n-6 PUFA primarily to produce arachidonic acid. By contrast, the pathway synthesizes mainly 22-carbon fatty acids from n-3 precursors, and DHA is the main product. Thus, n-3 PUFA may be essential because they are the only class that can generate a sufficient amount of a 22-carbon, unsaturated fatty acid containing a Δ4 double bond to satisfy the needs of the central nervous system.

The argument against this metabolic hypothesis is that although n-6 DPA replaces DHA when there is an n-3 PUFA deficiency, it does not completely overcome the functional deficit. However, recent findings in the rat pineal gland indicate that even though n-6 DPA increases during n-3 PUFA deficiency, it does not fully replace DHA (23). Although the decrease in total n-3 PUFA was almost entirely replaced by n-6 PUFA, arachidonic acid and docosatetraenoic acid (22:4n-6) accounted for about 50% of the replacement. There was a 12-fold increase in n-6 DPA, but the total pineal lipids contained only about half as much n-6 DPA as compared with the amount of DHA normally present. The reduction in n-6 DPA relative to the normal amount of DHA was especially evident in molecular species of phosphatidylethanolamine and ethanolamine plasmalogen that contain stearic acid.

Based on these observations, it appears that the functional abnormalities in n-3 PUFA deficiency may be due to an inability to fully replace the loss of DHA with n-6 DPA. If so, the quantitative differences in the products formed by the elongation and desaturation pathway with n-3 and n-6 fatty acids may be the underlying biochemical reason why n-3 PUFA are essential.

Sphingolipid Metabolism in the Regulation of Bioactive Molecules

Chiara Luberto and Yusuf A. Hannun*

Department of Biochemistry, Medical University of South Carolina, Charleston, South Carolina 29425

A living organism is an extraordinary complex system in which harmony and thus communication between parts is one of the most important goals to pursue. Communication within an organism occurs at different levels: intercellularly and intracellularly. In both cases one of the main targets involved in this process is the cellular membrane. From or through this compartment of one given cell, a wide variety of signals can be sent either to interact with other cellular units or to specifically direct the behavior of the same given cell. Important players in this communication system are not only the proteins present in the membrane but interestingly also the lipid counterpart. In this way the concept of lipids as bioactive molecules and not only as structural components of the membranes has evolved. At first, this concept was mainly applied to the glycerolipid class, such that the signal transduction pathways regulated by enzymes of glycerolipid metabolism are now well defined (1). More recently another class of lipids has been proposed to play a key role in the cellular communication system: the sphingolipids.

SPHINGOLIPIDS: STRUCTURE AND METABOLISM

Sphingosine and ceramide are the two structurally simplest molecules belonging to the sphingolipid family, from which all other complex sphingolipids derive (2). Sphingosine represents the sphingoid backbone, and ceramide carries the fatty acyl group in amide linkage to the sphingoid moiety. The wide variety of the naturally occurring sphingolipid species is due to the different chain length of either the sphingoid unit or the fatty acyl moiety, and to the nature of the functional group at the 1-position. For instance, sphingomyelin (SM) carries a phosphorylcholine moiety, the cerebroside subclass carries sugar residues (such as glucose and galactose), and the gangliosides contain acidic sialic acid residues in addition to the sugar units (3).

Abbreviations: A-SMase, a lysosomal acid SMase; DAG, diacylglycerol; GSH, glutathione; ICE, interleukin-converting enzyme; N-SMase, neutral magnesium-dependent; PC, phosphatidylcholine; PKC, protein kinase C; PLC, phospholipase C; Rb, retinoblastoma gene product; SM, sphingomyelin; SMase, sphingomyelinase; TNFα, tumor necrosis factor α.

Sphingolipid metabolism includes a series of biosynthetic and catabolic reactions in which ceramide plays a very central role (Scheme 1). The *de novo* synthesis starts with the condensation of palmitoyl-CoA with serine (forming 3-ketosphinganine) through the rate limiting action of serine palmitoyl transferase (3). Reducing and acylating reactions, through a NADPH-dependent reductase and ceramide synthase, then follow yielding ceramide formation probably by the final action of a dehydrogenase (4). At this point there are multiple fates of the newly synthesized ceramide. Ceramide can be converted into SM through the transfer of the choline phosphate group from phosphatidylcholine (PC) through the action of PC:ceramide phosphocholine transferase (SM synthase) (5,6). On the other hand, ceramide can be utilized as a precursor for cerebrosides and gangliosides through the sequential addition of carbohydrate units (from sugar nucleotide donors) and/or sialic acid residues (from CMP-*N*-acetylneuraminic acid donors) (7). Moreover, ceramide can be phosphorylated at the 1-position through the action of a distinct ceramide kinase yielding ceramide-1-P (8).

In sphingolipid catabolism clearly ceramide plays once again a crucial role. In fact, ceramide is the breakdown product of complex sphingolipids which are sequentially hydrolyzed in their head groups. Likewise, ceramide is the product of SM catabolism through the action of different sphingomyelinases (SMase), which hydrolyze the phosphocholine head group releasing choline phosphate (9). Ceramide, in turn, is the target of ceramidases which cleave off the fatty acyl chain, yielding sphingosine and its phosphorylated metabolite sphingosine-1-P (10).

SPHINGOLIPIDS AS SECOND MESSENGERS

As evidenced from the previous description, the web of sphingolipid metabolism is complex and leads to a large variety of molecules. In spite of this, it is only recently recognized that many of these metabolites have a role as bioactive molecules. The demonstration of inhibition of protein kinase C (PKC) activity by sphingosine was the first step in this direction (11). The discovery of SM hydrolysis and ceramide formation in response to certain stimuli represented a further move into the understanding of sphingolipid biology (12). Nowadays, significant effort is directed at the elucidation of the role of ceramide.
