[a]Marine Greens Laboratory Co., Ltd.,Iyo-city, Ehime 799-3125, Japan, and [b]The Central Research Laboratory and [c]Department of Medical Biochemistry, School of Medicine, Ehime University, Ehime 791-0295, Japan

ABSTRACT: The possible presence of an inhibitor of pancreatic lipase (triacylglycerol acylhydrolase, EC 3.1.1.3) was screened in 54 marine algae. An active inhibitor, caulerpenyne, was purified from an extract of *Caulerpa taxifolia,* using ethyl acetate extraction, followed by successive chromatographies on ODS and silica gel columns. The purified inhibitor was identified by thin-layer chromatography, infrared and nuclear magnetic resonance spectroscopy. Caulerpenyne competitively inhibited lipase activities using emulsified triolein and dispersed 4-methylumbelliferyl oleate (4-MU oleate) as substrates. The concentrations producing 50% inhibition against triolein and 4-MU oleate hydrolysis were 2 mM and 13 μM, respectively. *In vivo,* oral administration of corn oil with or without caulerpenyne to rats demonstrated a reduced and delayed peak plasma triacylglycerol concentration with caulerpenyne.

Paper no. L8092 in *Lipids 34,* 441–445 (May 1999).

Pancreatic lipase is a key enzyme of dietary triacylglycerol absorption, hydrolyzing triacylglycerols to 2-monoacylglycerols and fatty acids. Typical substrates for these enzymes are long-chain triacylglycerols which are separated from the aqueous medium by the surface phase. Thus, lipase must be adsorbed on the lipid surface, and the nature of the surface of the substrate is an important factor for lipase activity. Therefore, amphoteric substances would be expected to influence the lipase reaction rate. There have been many reports of lipase inhibitors derived from natural materials, for example, proteins (1,2), phytic acid (3), and tannin (4). Most of these inhibitors are amphoteric substances. It is well known that bile salts and synthetic detergents (5) behave as inhibitors of lipolysis. Hydrophobic proteins, such as bovine serum albumin and β-lactoglobulin (6), inhibit lipase activity toward triacylglycerol substrates by competing for the substrate surface.

Only a few substances directly interact with lipases themselves, one example being lipstatin (7), from *Streptomyces toxytricini,* which strongly inhibits lipases. In this study, we report the isolation from marine algae of caulerpenyne, an inhibitor which interacts directly with pancreatic lipase.

Abbreviations : 4-MU oleate, 4-methylumbelliferyl oleate.

MATERIALS AND METHODS

Materials. The enzyme substrates and reagents used were obtained as follows. Triolein, cholesterol oleate, taurocholic acid, pancreatic lipase (Type VI-S, from porcine pancreas), and 4-methylumbelliferyl oleate (4-MU oleate) were purchased from Sigma Co. (St. Louis, MO). Silica gel (Kiesel gel 60, Merck) was purchased from Kanto Chemicals (Tokyo, Japan). Dimethyl sulfoxide and octadecyl silica gel columns (Cosmosil 75C18-PREP) were purchased from Nacalai Tesque, Inc. (Kyoto, Japan). A normal-phase high-performance liquid chromatographic column (YMC-pack SIL-06) was obtained from YMC Co. (Kyoto, Japan).

Measurement of lipase activity and inhibitory activity. Lipase activity was determined by measuring the rate of release of oleic acid from triolein (8). A suspension of 90 μmol triolein, 45 mg gum arabic, and 9.45 μmol taurocholic acid in 9 mL 0.1 M *N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid (pH 7.0, containing 0.1 M NaCl) was sonicated for 5 min. The assay system comprised the following components in a total volume of 0.2 mL: 0.05 mL enzyme solution, 0.05 mL inhibitor solution, 1 μmol triolein, 0.106 μmol taurocholic acid, 0.5 mg gum arabic, 20 μmol *N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid, and 20 μmol NaCl. Incubation was carried out at pH 7.0 and 37°C for 30 min, and the amount of oleic acid produced was determined by the method of Zapf *et al*. (9) with a slight modification (10). The incubation mixtures were added to 3 mL of a 1:1 (vol/vol) mixture of chloroform/heptane containing 2% (vol/vol) methanol and extracted by shaking the tubes horizontally for 10 min in a shaker. The mixture was centrifuged (2000 × *g*, 10 min), the upper aqueous phase was removed, and 1 mL of copper reagent (10) was added to the lower organic phase. The tubes were then shaken for 10 min, the mixture was centrifuged (2000 × *g*, 10 min), and 1 mL of the upper organic phase, which contained the copper salts of the extracted oleic acid, was treated with 1 mL 0.1% (wt/vol) bathocuproine containing 0.05% (wt/vol) 3-*tert*-butyl-4-hydroxyanisole and the absorbance determined at 480 nm.

Lipase activity was also measured using 4-MU oleate as a substrate (11). The reaction mixture was prepared with 0.1 mL 0.1 mM 4-MU oleate and 0.05 mL inhibitor solution. The reaction was started by adding 0.05 mL lipase, all in a final volume of 0.2 mL. After incubation at 37°C for 15 min, 0.5

mL of 0.1 M HCl and 1 mL of 0.1 M sodium citrate were added. The amount of 4-methylumbelliferone released by the lipase was measured fluorometrically at an excitation wavelength of 320 nm and an emission wavelength of 450 nm.

The concentration of the tested compounds giving 50% inhibition of the enzyme activity was estimated from the least-squares regression line of the plots of the logarithm of the concentration vs. the inhibitory activity.

Extraction from marine algae. Fresh marine algae were collected around Shikoku Island, Japan, in 1993–1994, freeze-dried, powdered, and kept at −20°C. Ten grams of the marine algal powder was extracted with 100 mL methanol (or ethyl acetate) with shaking at room temperature for 24 h. After filtration, the extract was evaporated *in vacuo*, dissolved in 2 mL dimethyl sulfoxide, and used to measure the lipase inhibitory activity.

Purification of inhibitor. Caulerpa taxifolia, obtained from a tropical fish store, was cultured in a tank. The cultured alga was freeze-dried and ground to give 100 g of powder and then extracted with 1000 mL of ethyl acetate. After filtration, the extract was evaporated *in vacuo*. The evaporated sample was dissolved in a small amount of acetonitrile, passed through an octadecyl silica gel column (Cosmosil 75C18-PREP, 40 g) to remove pigments such as chlorophyll, and eluted with acetonitrile. The eluate was concentrated *in vacuo*, applied to a silica gel column (Kiesel gel 60, 200 g), and eluted with a stepwise solvent system of *n*-hexane/ethyl acetate. The eluate from hexane/ethyl acetate (4:1, vol/vol) that exhibited lipase inhibitory activity was applied to a normal-phase high-performance liquid chromatographic column (YMC-pack SIL-06) and eluted with hexane/ethyl acetate (2:1, vol/vol). The fractions containing lipase inhibitory activity were pooled and concentrated to dryness *in vacuo*.

Oral administration of caulerpenyne. A suspension of 6 mL corn oil, 80 mg cholic acid, and 2 mg cholesteryl oleate in 6 mL water was sonicated for 5 min. Male Wistar King rats, weighing 150–190 g, were starved overnight, then divided into two groups, and 1 mL corn oil suspension was administered to each rat *via* a stomach tube (8). One group received this suspension containing 1 mL caulerpenyne (15 mg) solution and the control group received the suspension containing 1 mL water. After caulerpenyne administration, blood samples were collected from the tail vein or artery into heparinized microcapillary tubes, at regular intervals, and centrifuged immediately at 10,000 rpm for 5 min. Plasma triacylglycerol concentrations were determined using the Triglyceride E-Test (Wako Pure Chemical Industries, Osaka, Japan).

Statistics. The data were analyzed for statistical significance using Student's *t*-test.

RESULTS

Screening of lipase inhibitors. Marine algae (54 species of natural materials) were extracted using methanol or ethyl acetate, and the inhibitory activities of these extracts were screened against triolein-hydrolyzing activity of porcine pancreatic lipase. The results from 27 species are shown in Table 1. Inhibitory activity was not observed in the extracts from *Gracilaria bursa-pastoris*, *G. chorda*, *G. textorii*, *Gymnogongrus flabelliformis*, *Eckloniopsis radicosa*, *Chaetomorpha crassa*, and algae of the genus *Laurencia* (data not shown). Higher activity was found in methanol extracts from *C. taxifolia* and *Asparagopsis tociformis.*

Purification of inhibitor. Since both the methanol and ethyl acetate extracts from *C. taxifolia* had relatively high lipase inhibitory activity, isolation of the lipase inhibitor from its ethyl acetate extract was attempted. Although the methanol extract had a higher lipase inhibitory activity than that of the ethyl acetate extract, it also contained a high amount of polyphenols or their oxidized compounds such as tannins. Since tannin-like compounds bind strongly to enzyme proteins and may inhibit their enzyme activity (12), we isolated the lipase inhibitor from the ethyl acetate extract. Purification was achieved by sequential chromatography on octadecyl silica gel, silica gel and normal-phase high-performance liquid chromatographic columns. The purified inhibitor (0.2 g, slightly yellowish oil) was obtained from 100 g of dried *C. taxifolia*. The purified inhibitor was identified as caulerpenyne by comparing its thin-

layer chromatographic, infrared and nuclear magnetic resonance spectroscopic, and electron impact-mass spectrometric data with those reported previously (13) (Scheme 1). ^{1}H and ^{13}C nuclear magnetic resonance spectra were measured using EX-270 (270 MHz) (JEOL Ltd., Tokyo, Japan), and electron impact-mass spectrometric data were obtained using JMS-SX102A (JEOL Ltd.).

Inhibitory action of caulerpenyne. The hydrolytic activity of porcine pancreatic lipase toward triolein emulsified with gum arabic and 4-MU oleate was determined in the presence of increasing concentrations of caulerpenyne (Figs. 1 and 2). In a concentration dependent manner caulerpenyne inhibited the triolein- and 4-MU oleate-hydrolyzing activities of pancreatic lipase, showing 50% inhibition at 2 mM and 13μM, respectively. Caulerpenyne also inhibited the tributyrin-hydrolyzing activity in a concentration-dependent manner (data not shown). The inhibitory action of caulerpenyne was examined using different concentrations of pancreatic lipase and substrates. In using triolein as a substrate, the inhibitory activity of caulerpenyne was not affected by an increase in the triolein concentration (Fig. 3A), but it decreased with increasing enzyme concentration (Fig. 3B). Similar results were observed using 4-MU oleate as a substrate; the inhibition was not affected by an increase of 4-MU oleate, but it decreased with an increase in enzyme concentration (data not shown). To clarify the enzyme-inhibiting mechanism, the kinetics of the inhibitory effect of caulerpenyne on lipase activity were studied. The mode of inhibition was analyzed by changing the concentration of substrate in the presence of two concentrations of caulerpenyne. A double-reciprocal plot of the reaction rate vs. triolein concentration was linear in the presence and absence of caulerpenyne, suggesting that the observed inhibition of lipase activity by caulerpenyne was due to competitive inhibition of the enzyme (data not shown). A similar result was obtained using 4-MU oleate as a substrate (data not shown).

Oral administration of caulerpenyne. Figure 4 shows the time course of the plasma triacylglycerol concentration when corn oil suspension with or without caulerpenyne was administered orally to rats. Two, 3 and 6 h after caulerpenyne administration, the plasma triacylglycerol concentration decreased significantly in comparison with the controls. The peak plasma triacylglycerol concentration was reduced and delayed by caulerpenyne administration.

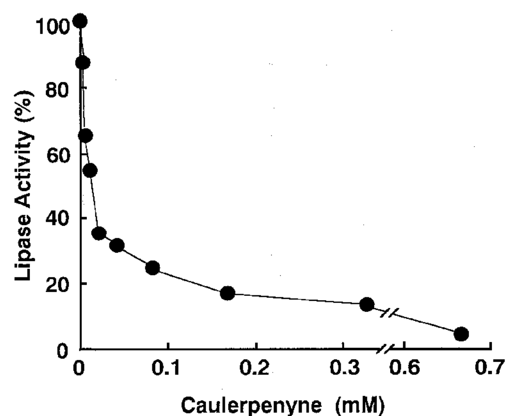

FIG. 2. Effect of increasing concentrations of caulerpenyne on the rate of hydrolysis of 4-methylumbelliferyl (4-MU) oleate by pancreatic lipase (18.75 μg/mL). The specific activity of 4-MU oleate-hydrolyzing activity was 17.8 μmol 4-methylumbelliferone released/mg protein of pancreatic lipase/min.

DISCUSSION

Caulerpenyne competitively inhibited the lipase activity. The inhibitory activity of caulerpenyne was dependent on the li-

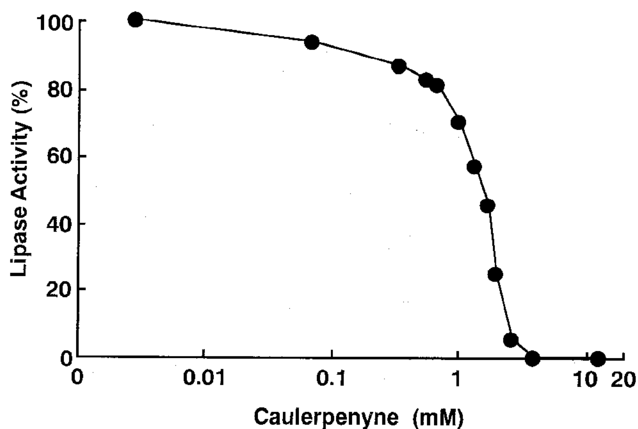

FIG. 1. Effect of increasing concentrations of caulerpenyne on the activity in hydrolysis of triolein emulsified with gum arabic by pancreatic lipase (1.0 μg/mL).

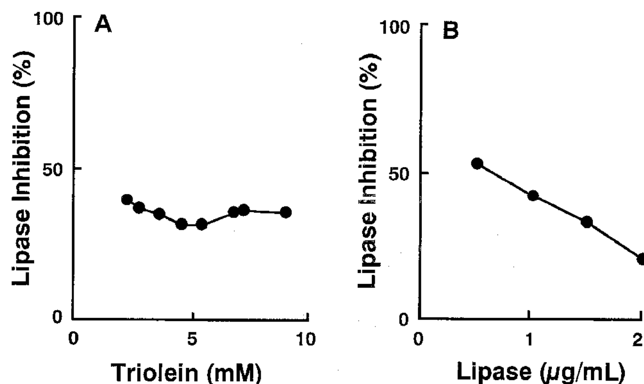

FIG. 3. Effect of substrate and enzyme concentrations on the inhibition by caulerpenyne. Lipase activity was determined using triolein as substrate with 330 μM caulerpenyne. (A) Effect of substrate concentrations (lipase, 1.0 μg/mL); (B) effect of enzyme concentrations (triolein, 5 mM).

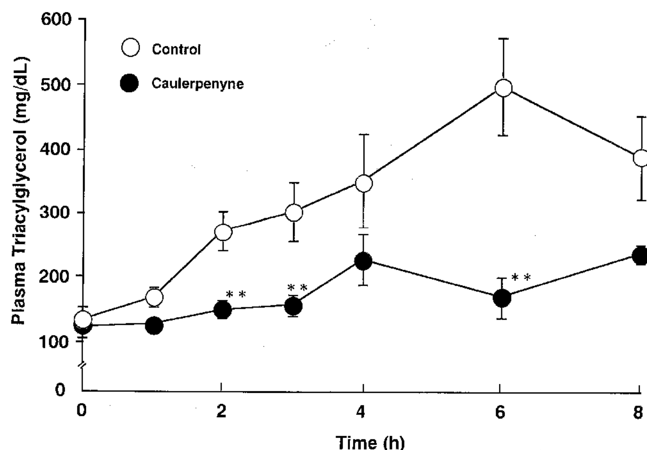

FIG. 4. Effect of caulerpenyne on rat plasma triacylglycerol levels after oral administration of lipid emulsion (○) or lipid emulsion containing caulerpenyne (●). The results are expressed as means ± SE of 10 experiments. $^{**}P < 0.01$ (compared with the corresponding control, Newman-Keuls' range test).

pase concentration but independent of substrate concentration (Fig. 3). Caulerpenyne also inhibited lipase activity for monomeric substrate such as 4-MU oleate or tributyrin, as well as when using emulsified triolein. These results suggest that caulerpenyne interacts directly with the lipase protein, rather than interacting with the substrate.

Caulerpenyne was the major metabolite in *C. taxifolia*, which is widely distributed in the tropics and is presently invading part of the Mediterranean (14). Fischel *et al.* (15) reported that caulerpenyne inhibited cell growth. However, as a result of evaluations conducted using human hematopoietic progenitors, melanocytes, and keratinocytes in culture, the toxicological risk of caulerpenyne to humans has been reported as low (16). In the Philippines, *C. taxifolia* is actually available as a food for medicinal purposes. It acts as an antifungal agent and reportedly decreases blood pressure (17). These results suggest that caulerpenyne (or *C. taxifolia*) may have potential as an agent that inhibits lipid absorption.

For lipase catalysis, the surface characteristics of substrate lipid micelles are the most important factors. Lipases are sometimes activated or denaturated by adsorption (or penetration) on to the substrate surface (18). Most lipase inhibitors reported thus far are adsorbed onto (or penetrate) the lipid surface, thus blocking the surface and affecting lipase activity. Several proteins, including mellitin, β-lactoglobulin A, serum albumin, ovalbumin and myoglobin, inhibit pancreatic lipase activity, and their inhibitory effects might be the result of lipase desorption from the substrate due to a change in interfacial quality (19,20). Hydrocarbons, fatty alcohols, and fatty acids also adsorb on the substrate interface and inhibit lipase activity (21–23). In this study, we purified caulerpenyne, a substance which may interact directly with lipase. A few substances acting as direct inhibitors of lipase have been reported. Lipstatin, isolated from *S. toxytricini,* is a stable covalent inhibitor of lipase (7). It interacts with lipase, probably with 1:1 stoichiometry, and inactivates the enzyme through the formation of a stable covalent intermediate. Fat absorption from the intestine of rats is also inhibited by lipstatin: the absorption of emulsified triolein was significantly decreased by 10^{-4} M lipstatin using the constant infusion method (24). We showed that caulerpenyne, administered orally in a single dose, reduced the concentration of plasma triacylglycerol in an *in vivo* experiment using rats (Fig. 4).

Marine algae (or seaweeds) have long been a food source for maritime people, as sea vegetables. In Japan, they have been eaten as a healthy food since antiquity. They contain proteins, fats, carbohydrates, cellulose, ash, minerals, and nucleic acids and are especially rich in iodine and certain vitamins. In this study, we demonstrated that many marine algae inhibited the activity of pancreatic lipase (Table 1), the extracts from Phaeophyta, Chlorophyta, and Rhodophyta having particularly high inhibitory activities. Phaeophyta generally contain large amounts of polyphenols such as tannin, which has lipase-inhibiting activity. It has been reported that most compounds with a porphyrin structure inhibit lipase activity (11). The weak inhibitory activities recognized in many algae might be caused by chlorophyll in the algal extracts. Therefore, algae are one of the most useful sources of lipase inhibitors.

ACKNOWLEDGMENTS

The authors express their thanks to Takaaki Suzuki of the Industrial Research Center of Ehime Prefecture for obtaining the mass spectra, and Maki Watanabe for laboratory assistance.

3-Thia Fatty Acid Treatment, in Contrast to Eicosapentaenoic Acid and Starvation, Induces Gene Expression of Carnitine Palmitoyltransferase-II in Rat Liver

Lise Madsen* and Rolf K. Berge

Department of Clinical Biochemistry, Haukeland Hospital, University of Bergen, N-5021 Bergen, Norway

ABSTRACT: The aim of the present study was to investigate the hepatic regulation and β-oxidation of long-chain fatty acids in peroxisomes and mitochondria, after 3-thia- tetradecylthioacetic acid (C_{14}-S-acetic acid) treatment. When palmitoyl-CoA and palmitoyl-L-carnitine were used as substrates, hepatic formation of acid-soluble products was significantly increased in C_{14}-S-acetic acid treated rats. Administration of C_{14}-S-acetic acid resulted in increased enzyme activity and mRNA levels of hepatic mitochondrial carnitine palmitoyltransferase (CPT)-II. CPT-II activity correlated with both palmitoyl-CoA and palmitoyl-L-carnitine oxidation in rats treated with different chain-length 3-thia fatty acids. CPT-I activity and mRNA levels were, however, marginally affected. The hepatic CPT-II activity was mainly localized in the mitochondrial fraction, whereas the CPT-I activity was enriched in the mitochondrial, peroxisomal, and microsomal fractions. In C_{14}-S-acetic acid-treated rats, the specific activity of peroxisomal and microsomal CPT-I increased, whereas the mitochondrial activity tended to decrease. C_{14}-S-Acetyl-CoA inhibited CPT-I activity *in vitro*. The sensitivity of CPT-I to malonyl-CoA was unchanged, and the hepatic malonyl-CoA concentration increased after C_{14}-S-acetic acid treatment. The mRNA levels of acetyl-CoA carboxylase increased. In hepatocytes cultured from palmitic acid- and C_{14}-S-acetic acid-treated rats, the CPT-I inhibitor etomoxir inhibited the formation of acid-soluble products 91 and 21%, respectively. In contrast to 3-thia fatty acid treatment, eicosapentaenoic acid treatment and starvation increased the mitochondrial CPT-I activity and reduced its malonyl-CoA sensitivity. Palmitoyl-L-carnitine oxidation and CPT-II activity were, however, unchanged after either EPA treatment or starvation. The results from this study open the possibility that the rate control of mitochondrial β-oxidation under mitochondrion and peroxisome proliferation is distributed between an enzyme or enzymes of the pathway beyond the CPT-I site after 3-thia fatty acid treatment. It is suggested that fatty acids are partly oxidized in the peroxisomes before entering the mitochondria as acylcarnitines for further oxidation.

Abbreviations: C_{14}-S-Acetic acid, tetradecylthioacetic acid; BSA, bovine serum albumin; CMC, carboxymethyl cellulose; CPT, carnitine palmitoyltransferase; EPA, eicosapentaenoic acid; PPAR, peroxisome proliferator activated receptor, Enzymes: carnitine palmitoyltransferase (EC 2.3.1.21); acetyl-CoA carboxylase (EC 6.4.1.2).

Not only are the 3-thia fatty acids peroxisome proliferators, they also increase the hepatic mitochondrial mass (1). The results from many years of studies strongly suggest that increased mitochondrial fatty acid oxidation is important for the hypotriglyceridemic effect of 3-thia fatty acids, such as tetradecylthioacetic acid (C_{14}-S-acetic acid) (1–4), and fibrates (5). Eicosapentaenoic acid (EPA), the hypotriglyceridemic component of fish oil (6–8), probably mediates its triglyceride-lowering effect by the same mechanism, as EPA also is reported to be a mitochondrion proliferator (5). Because of the potential use of EPA and 3-thia fatty acids as treatment for hypolipidemia in humans, this similarity is of especial interest.

Transport of long-chain fatty acyl groups into the mitochondrial matrix to undergo β-oxidation is controlled by the carnitine palmitoyltransferase (CPT) enzyme system. It is generally accepted that this process is regulated by carnitine palmitoyltransferase (CPT)-I, through different mechanisms: changes in activity and the transcription rate, changes in the concentration of its physiological inhibitor malonyl-CoA, and changes in its sensitivity to malonyl-CoA [reviewed by McGarry and Brown (9)]. CPT-II, on the other hand, is usually not considered rate-controlling for fatty acid oxidation, and less is known about the regulation of this activity. The effects of 3-thia fatty acids on the CPT system were investigated in order to study by which mechanisms the fatty acid oxidation rate in liver is increased.

The molecular mechanism involved in gene regulation by fatty acids is not fully elucidated. However, dietary polyunsaturated fatty acids directly modulate gene transcription as a primary event, rather than exert their influence by modifying membrane lipid fatty acid composition, which is a later event (10). Whether fatty acids and peroxisome proliferators act through the same or distinct mechanisms remains unclear. Chatelain *et al.* (11) suggested that the mechanism of action of long-chain polyunsaturated fatty acids differs from that of the classical peroxisome proliferators, such as clofibrate, which presumably works *via* the peroxisome-proliferator activated receptor (PPAR) α. Besides being fatty acids, the 3-thia fatty acids are both mitochondrion- and peroxisome-proliferators (1). The 3-thia fatty acids are activated to their respective CoA esters, accumulate in the phospholipid fraction

of the liver (12,13) and are metabolized as normal long-chain fatty acids, except that they are not β-oxidized (1), and, like a variety of other lipid-like compounds, they transcriptionally activate PPAR α (14–16).

The mechanism by which 3-thia fatty acids increase hepatic fatty acid oxidation is not known. In this study we report that in contrast to EPA treatment and starvation, 3-thia fatty acids marginally affect mitochondrial CPT-I activity and mRNA levels, but increase CPT-II activity and mRNA levels.

EXPERIMENTAL PROCEDURES

Chemicals and drugs. [^{32}Pα]dCTP, L-[methyl-^{14}C]carnitine hydrochloride, [1-^{14}C]palmitoyl-L-carnitine, and [1-^{14}C] palmitoyl-CoA were purchased from the Radiochemical Centre (Amersham, England). [1-^{14}C]Palmitic acid (50 mCi/mmol) was obtained from New England Nuclear (Boston, MA). Nylon membranes and slot-blot equipment were obtained from Schleicher & Schuell (Kassel, Germany). The sulfur-substituted fatty acids were prepared at Department of Chemistry, University of Bergen (Bergen, Norway), as earlier described (17). EPA as ethyl ester (94% pure) was obtained from Norsk Hydro AS, Research Centre (Porsgrunn, Norway). The CoA ester of C_{14}-S-acetic acid was synthesized as described by Kawaguchi *et al.* (18). Etomoxir was from Research Biochemicals International (Natick, MA). All other chemicals and solvents were of reagent grade from common commercial sources.

Treatment of animals. Male Wistar rats from Møllegard Breeding Laboratory (Ejby, Denmark), weighing about 250 g each, were housed in metal wire cages in pairs and maintained at a 12 h cycle of light and dark at 20 ± 3°C. The animals were acclimatized under these conditions for at least 1 wk before the experiments. The fatty acids were suspended in 0.5% sodium carboxymethyl cellulose (CMC) and administered by orogastric intubation once a day for 1 wk at different doses. The control animals received CMC only. One group was starved for 3 d with free access to water. Control and fatty acid-treated animals had free access to water and standard rat pellet food during the experiment. Each test and control group consisted of four animals. After 12 h fasting, the rats were anesthetized with 0.2 mL Hypnorm-Dormicum® (fluanisone-fentylmidazolam)/100 g body weight. Cardiac puncture was performed and blood was collected in vacutainers. The livers and hearts were removed, samples immediately freeze-clamped, weighed, and stored at −80°C. Other pieces were chilled on ice and weighed. The use of the animals was approved by the Norwegian State Board of Biological Experiments with Living Animals.

Preparation of subcellular fractions and protein measurements. The livers from individual rats were homogenized in ice-cold sucrose medium [0.25 M sucrose, 10 mM HEPES (pH 7.4), and 2 mM EDTA]. The hearts were homogenized in 0.25 M sucrose, 5 mM HEPES (pH 7.4), and 0.5 mM EGTA. Subcellular fractions were prepared according to DeDuve *et al.* (19) using preparative differential centrifugation. Modifications, purity, and yield were described earlier (20). Bio-Rad protein kit (Bio-Rad, Richmond, CA) was used for protein measurement. Bovine serum albumin (BSA) dissolved in distilled water was used as a standard.

Measurement of enzyme activities. Acid-soluble products were measured in the mitochondrial-enriched fractions, using palmitoyl-CoA and palmitoyl-L-carnitine as substrates (21). CPT-I activity was measured essentially as described by Bremer (22) in all subcellular fractions. The assay for CPT-I contained 20 mM HEPES, pH 7.5, 70 mM KCl, 5 mM KCN, 100 μM palmitoyl-CoA, and 10 mg BSA/mL, plus 0.6 mg tissue protein/mL. The reaction was started with 200 μM [methyl-^{14}C]-L-carnitine. When included, malonyl-CoA was added prior to start of the reaction. Assay conditions for CPT-II were identical except that BSA was omitted and 0.01% Triton-X included. Tissue protein concentration was 0.1 mg/mL.

Measurement of malonyl-CoA and CoASH. Malonyl-CoA and CoASH were measured by reversed-phase high-performance liquid chromatography according to Demoz and Netteland (23), with the following modifications of tissue preparation: (i) 100 mg liver was homogenized in 900 μL ice-cold 2.33 M $HClO_4$ and 2 mM DL-dithiothreitol. (ii) Aliquots of the homogenate were centrifuged at 10,000 × *g* for 2 min. (iii) 180 μL ice-cold 3 M K_2CO_3 with 0.5 M triethanolamine was added to 500 μL of the supernatant. (iv) After 10 min on ice, the solution was centrifuged at 10,000 × *g* for 2 min. (v) 20 μL of the homogenate was injected onto the high-performance liquid chromatography column. Owing to rapid degradation of malonyl-CoA, separate animals were used for this purpose, where parts of the liver were immediately freeze-clamped.

Preparation of cell suspensions. Cells were isolated from rats treated with C_{14}-S-acetic acid or palmitic acid at a dose of 300 mg/d/kg body weight for 12 wk, by *in vitro* perfusion of the liver using a two-step procedure as earlier described (24). After collagenase perfusion small tears were made in the capsule and the cells were released by gentle shaking in a 145-mM NaCl solution containing 5 mM KCl, 0.4 mM KH_2PO_4, 0.3 mM Na_2HPO_4, 0.8 mM $MgSO_4$, 1 mM $CaCl_2$, 20 mM HEPES, and 1% BSA. The cell suspension was subsequently preincubated at 37°C for 25–30 min in a shaking waterbath. The parenchymal cells were separated from the nonparenchymal cells by centrifugation (700 rpm/1 min). The precipitate containing the heavier parenchymal cells was discarded and the supernatant was recentrifuged at 1500 rpm for 5 min to remove the nonparenchymal cells from the solution. These cells were washed in 40–50 mL of incubation solution, recentrifuged, and assessed for viability.

The cells were subsequently resuspended in a preincubation medium (Dulbecco's modified Eagle's medium) containing 20 mM HEPES and 0.5 mM L-carnitine, at a concentration of 1×10^6 cells/mL medium. The cells were preincubated at 37°C for 30 min, with or without 50 μM etomoxir. The reaction was started with [1-^{14}C]palmitic acid bound to BSA at a ratio 2.5:1. The reaction tubes were immediately sealed. After 1 h the tubes were put on ice, and 250 μL 0.75 M $HClO_4$ was added. $^{14}CO_2$ was trapped from sealed culture flasks es-

sentially as described by Christiansen and Davies (25). Free fatty acids and lipids were then precipitated with addition of 1.0 mL ice-cold 0.75 M $HClO_4$ and 0.45% BSA. The extract was centrifuged at 1800 × *g* for 10 min, and 0.5 mL of the supernatant was assayed for radioactivity by liquid scintillation counting.

Purification of RNA and hybridization analysis. Total RNA was isolated using the guanidinium thiocyanate–phenol method (26), and the RNA concentrations were determined by measuring the absorbance at 260 nm. Northern- and slot-blotting were performed as earlier described (24). Three different RNA concentrations were applied. Hybridization reactions were performed as described by Sambrook *et. al.* (27), and the membranes stringently washed three times; Kodak XAR-5 X-ray films were exposed to the membranes, and autoradiograms were obtained as described earlier (24). The relative levels of mRNA expression were estimated as the amount of radioactive probe hybridized to each sample of RNA relative to the levels of 28S rRNA in each sample.

Preparation of hybridization probes. The appropriate DNA fragments were cut from plastids by restriction enzymes. Purified fragments were then ^{32}P-labeled using the oligolabeling technique (28), resulting in specific activities ranging from 0.8–5 × 10^9 cpm/mg. The probes were purified fragments of: CPT-I, 2600 bp *Eco*RI fragment of pBK2-CPT-I ; partial CPT-II, 1600 bp *Xho* I/ *Xba*I fragment of PbKs-CPT-II.4; and partial acetyl-CoA carboxylase cDNA, 485 bp *Eco*RI fragment of pUC 19.

Statistical analysis and presentation of data. The data are presented as mean ± standard deviation (SD) from 4 animals and were evaluated by a two-sample variance Student's *t*-test (two-tailed distribution) where relevant. The level of statistical significance was set at $P < 0.05$.

RESULTS

EPA feeding and especially starvation increased the oxidation palmitoyl-CoA both in the presence and absence of malonyl-CoA in isolated liver mitochondria, compared to palmitic acid treatment (Fig. 1A). In the absence of malonyl-CoA, the mitochondrial palmitoyl-CoA oxidation was increased 1.5- and 3.1-fold after EPA feeding and starvation, respectively. Moreover, EPA feeding and especially starvation lowered the sensitivity of palmitoyl-CoA oxidation to malonyl-CoA (Fig. 1A), i.e., in the presence of 12 μM malonyl-CoA the palmitoyl-CoA oxidation was inhibited 45 and 22% in EPA-fed and -starved rats, respectively, compared to 55% in palmitic acid-treated rats.

It is generally assumed that the rate-limiting enzyme of palmitoyl-CoA oxidation is mitochondrial CPT-I. Figure 1B shows that EPA feeding and starvation increased the mitochondrial CPT-I activity in both the absence and presence of malonyl-CoA, compared to palmitic acid treatment. Addition of 12 μM malonyl-CoA inhibited mitochondrial CPT-I activity by 35 and 47% in EPA-fed and -starved animals, respectively, compared to 59% in palmitic acid-treated rats (Fig. 1B). The mRNA levels of CPT-I reflected the activities measured in absence of malonyl-CoA after EPA feeding and starvation (Table 1).

In sharp contrast, after C_{14}-S-acetic acid treatment, the

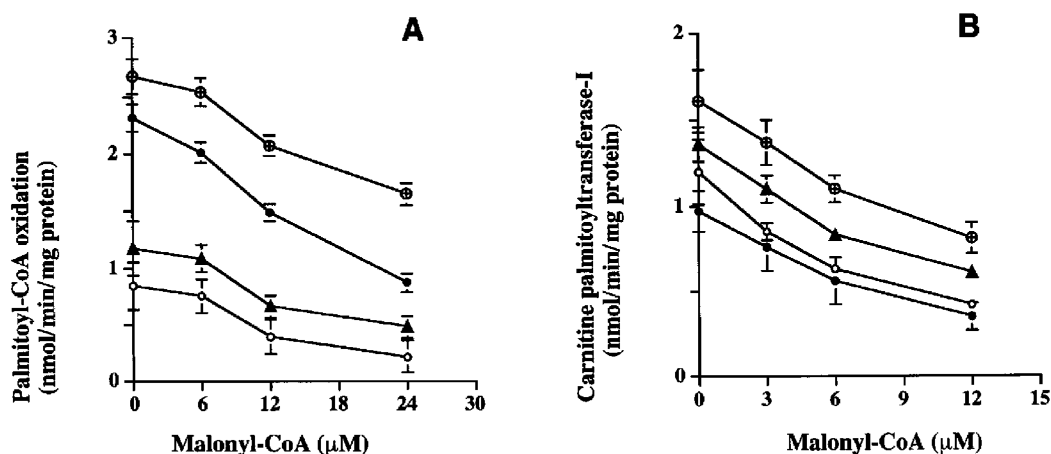

FIG. 1. Effect of tetradecylthioacetic acid (C_{14}-S-acetic acid) treatment (—●—), eicosapentaenoic acid (EPA) feeding (—▲—), and starvation (—⊕—) on mitochondrial palmitoyl-CoA oxidation (A) and mitochondrial carnitinepalmitoyltransferase (CPT)-I activity (B) in the presence and absence of malonyl-CoA. Rats were fed EPA at a dose of 1000 mg/d/kg body weight or C_{14}-S-acetic acid suspended in 0.5% carboxymethylcellulose (CMC) at a dose of 300 mg/d/kg body weight or for 7 d. Control animals received palmitic acid (—○—) suspended in 0.5% CMC at a dose of 300 mg/d/kg body weight or for 7 d. One group of rats was starved for 3 d. Palmitoyl-CoA oxidation and CPT-I activity were measured in isolated mitochondria as described in the Experimental Procedures section in four individual rat livers in the absence and in the presence of malonyl-CoA. The values are presented as mean ± SD.

TABLE 1
Effect of Starvation, EPA, Palmitic and Thia Fatty Acid Treatment on the mRNA Levels of CPT-I and CPT-II[a]

Treatment	Dose (mg/d/kg BW)	mRNA (fold increase) CPT-I	CPT-II
Control		1.00 ± 0.08	1.00 ± 0.04
Palmitic acid	150	1.05 ± 0.11	0.97 ± 0.07
	300	1.21 ± 0.15	1.06 ± 0.09
C_{14}-S-Acetic acid	150	1.17 ± 0.23	2.23 ± 0.31*
	300	1.32 ± 0.25*	3.79 ± 0.63*
EPA	1500	1.49 ± 0.18*	1.26 ± 0.32
Starvation		2.13 ± 0.21*	0.95 ± 0.09

[a]Rats were fed fatty acids at different doses for 7 d or starved for 3 d. The mRNA levels of CPT-I and CPT-II were measured as described in the Experimental Procedures section in four individual rats in each experimental group. The relative mRNA levels were normalized to the corresponding 28S rRNA levels. Control values were set to 1.0 and experimental values are given as fold increase ± SD. Values are means ± SD (n = 4). *Significantly different from control, P < 0.05. Abbreviations: BW, body weight; EPA, eicosapentaenoic acid; CPT, carnitine palmitoyltransferase; C_{14}-S-acetic acid, tetradecylthioacetic acid.

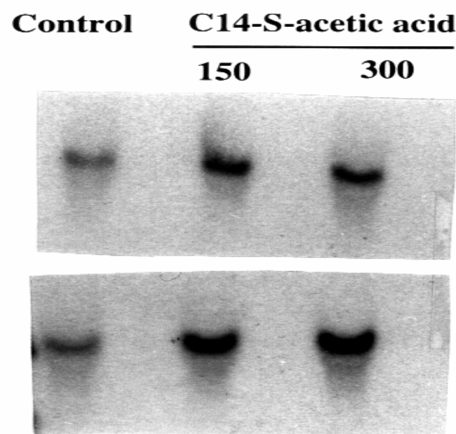

FIG. 2. Effects of C_{14}-S-acetic acid on CPT-I and CPT-II mRNA levels in liver. Rats were fed C_{14}-S-acetic acid suspended 0.5% in CMC at a dose of 150 or 300 mg/d/kg body weight for 7 d. Control animals received CMC only. Total mRNA were purified from each individual liver. Northern blotting and hybridization to immobilized RNA were performed as described in the Experimental Procedures section. Figure shows representative mRNA levels of CPT-I and CPT-II. For abbreviations see Figure 1.

palmitoyl-CoA oxidation increased 2.6-fold (Fig. 1A), whereas the specific mitochondrial CPT-I activity tended to decrease (Fig. 1B) in the absence of malonyl-CoA compared to palmitic acid treatment. Addition of 12 μM malonyl-CoA inhibited the CPT-I activity 55%, suggesting the sensitivity of CPT-I to malonyl-CoA was unchanged after C_{14}-S-acetic acid treatment (Fig. 1B). C_{14}-S-Acetic acid treatment increased the mRNA levels of CPT-I compared to control, but not compared to palmitic acid treatment (Fig. 2 and Table 1).

In contrast to EPA feeding and starvation, C_{14}-S-acetic acid treatment increased the oxidation of palmitoyl-L-carnitine 1.7-fold in isolated mitochondria (Fig. 3A), suggesting that C_{14}-S-acetic acid mediates its action on step(s) subsequent to CPT-I. Indeed, a 2.8-fold increased mitochondrial CPT-II activity was observed after C_{14}-S-acetic acid treatment (Fig. 3B). Moreover, the mRNA levels of CPT-II increased after different doses of C_{14}-S-acetic acid (Table 1), whereas both the mRNA levels and activities of CPT-II were unchanged after either EPA feeding or starvation (Fig. 3B, Table 1).

Figure 4A shows CPT-II activity in the liver of rats treated with different chain-length monocarboxylic 3-thia fatty acids, which are reported to increase β-oxidation in different ways (24). Significantly increased β-oxidation (24) and CPT-II activity (Fig. 4A) were observed in rats treated with C_{11}-S- to

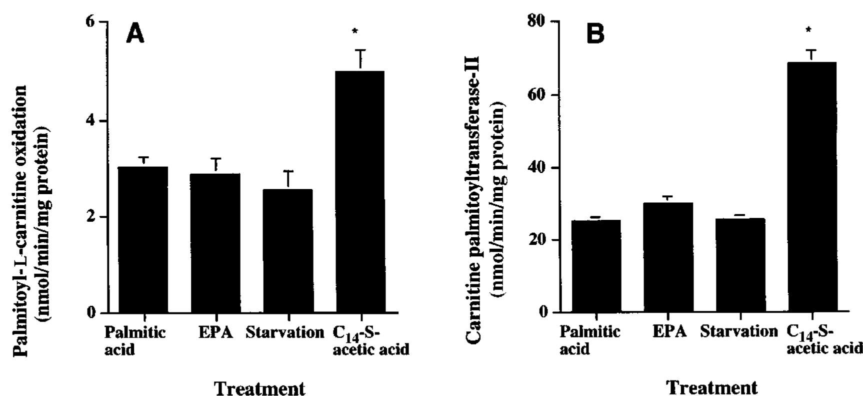

FIG. 3. Effect of C_{14}-S-acetic acid treatment, EPA feeding, and fasting on mitochondrial palmitoyl-L-carnitine oxidation (A) and mitochondrial CPT-II activity (B). Rats were fed EPA at a dose of 1000 mg/d/kg body weight or C_{14}-S-acetic acid suspended in 0.5% CMC at a dose of 300 mg/d/kg body weight for 7 d. Control animals received palmitic acid suspended in 0.5% CMC at a dose of 300 mg/d/kg body weight for 7 d. One group of rats was starved for 3 d. Palmitoyl-L-carnitine oxidation and CPT- II activity were measured in isolated mitochondria as described in the Experimental Procedures section in four individual rat livers in the absence, and in the presence of malonyl-CoA. The values are presented as mean ± SD. * P < 0.05. For abbreviations see Figure 1.

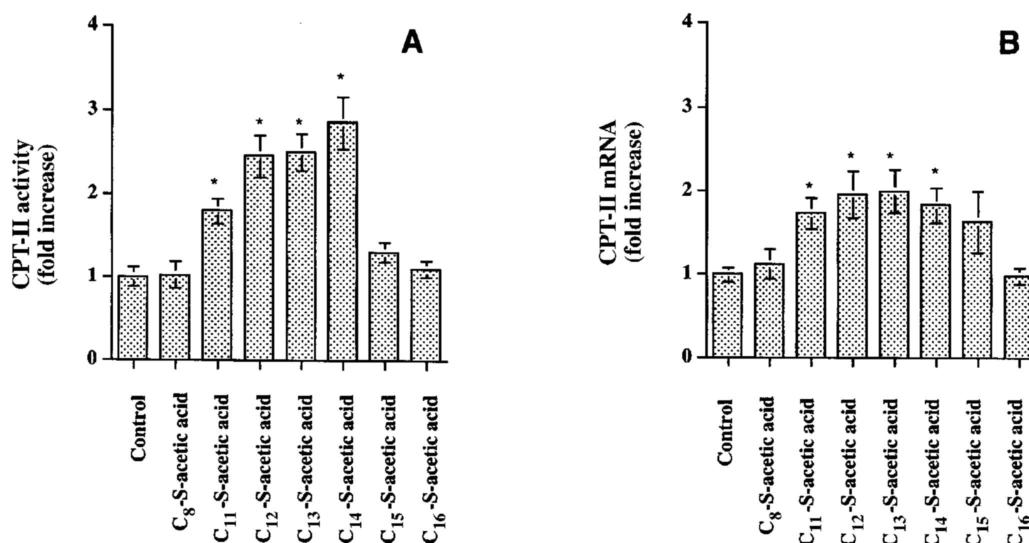

FIG. 4. Effects of different chain-length 3-thia fatty acids on CPT-II activity and mRNA levels in liver. Rats were fed palmitic or 3-thia fatty acids with different chain lengths at a dose of 150 mg/d/kg body weight for 7 d. CPT-II activities were measured in postnuclear homogenates, and the mRNA levels were measured as described in the Experimental Procedures section in four individual rats in each experimental group. The relative mRNA levels were normalized to the corresponding 28S rRNA levels. Control values were set to 1.0 and experimental values are given as fold increase ± SD. The activities in palmitic acid-treated animals were 5.18 ± 1.03 nmol/min/mg protein in liver postnuclear homogenate. *Indicates statistical difference between thia fatty acid- and palmitic acid-treated rat, fed a dose of 150 mg/d/kg body weight, $P < 0.05$

C_{14}-S-acetic acid. Concomitant increases in CPT-II mRNA levels were observed (Fig. 4B). There was a positive correlation between CPT-II activity and oxidation rate of both palmitoyl-CoA and palmitoyl-L-carnitine (Fig. 5), suggesting a regulatory function of CPT-II rather than CPT-I in oxidation of palmitic acid after 3-thia fatty acid treatment.

The rate of hepatic mitochondrial fatty acid oxidation might also be regulated through changes of the malonyl-CoA

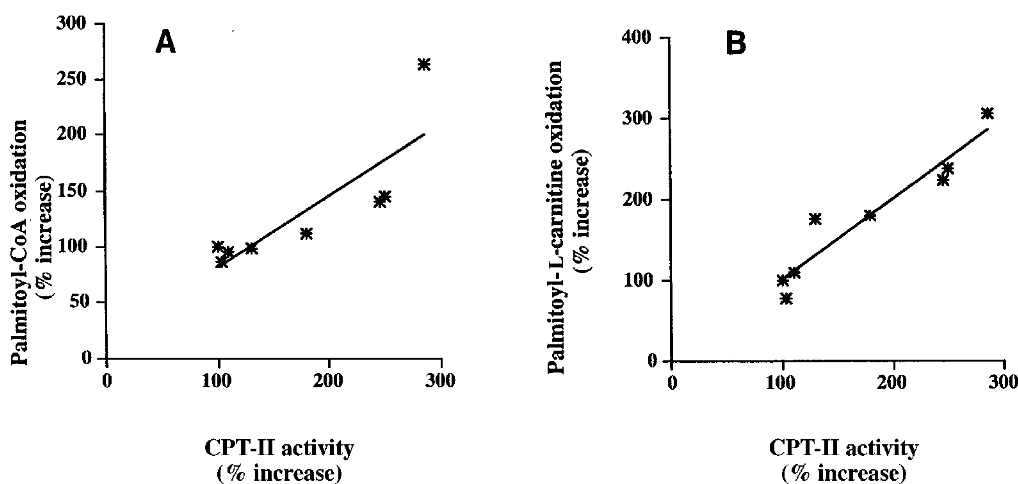

FIG. 5. Correlation between mitochondrial β-oxidation and CPT-II activity in 3-thia fatty acid-treated rats. Rats were fed palmitic or 3-thia fatty acids with different chain length at a dose of 150 mg/d/kg body weight for 7 d. CPT-II activity was measured in postnuclear liver homogenate as described in the Experimental Procedures section and presented in Figure 4. The mitochondrial β-oxidation was measured in liver homogenate as described in the Experimental Procedures section (24). The blots represent the mean of four animals in each group. The CPT-II activity was correlated to mitochondrial β-oxidation using palmitoyl-CoA (A) ($y = 0.641\ x + 17.624$, $r^2 = 0.703$) and palmitoyl-L-carnitine (B) ($y = 0.985x + 2.837$, $r^2 = 0.913$) as substrates, respectively. For abbreviations see Figure 1.

TABLE 2
Effect of Fatty Acid Treatment on the Hepatic Activities and mRNA Levels of Acetyl-CoA Carboxylase Activities and the Levels of Malonyl-CoA and CoASH[a]

Treatment	Acetyl-CoA carboxylase mRNA (fold increase)	Malonyl-CoA (nmol/mg liver)	CoASH (nmol/mg liver)
CMC	1.0 ± 0.1	8 ± 2	98 ± 9
Palmitic acid	1.0 ± 0.2	N.D.	N.D.
C_{14}-S-acetic acid	1.7 ± 0.2*	27 ± 5*	403 ± 41*

[a]Rats were fed palmitic or C_{14}-S-acetic acid at a dose of 300 mg/d/kg body weight suspended in 0.5% CMC for 7 d. Control animals received CMC only. The mRNA levels and activities of fatty acyl-CoA carboxylase were measured as described in the Experimental Procedures section. The relative mRNA levels were normalized to the corresponding 28S rRNA levels. Control values were set to 1.0 and experimental values are given as fold increase ± SD. The malonyl-CoA and CoASH levels were measured in separate animals as described in the Experimental Procedures section. Values are means ± SD (n = 4).
*Significant different from control $P < 0.05$. Abbreviations: ND, not determined; CMC, carboxymethylcellulose; for other abbreviation see Table 1.

in the liver. After treatment with C_{14}-S-acetic acid, the hepatic malonyl-CoA levels increased more than threefold (Table 2). Also the CoASH levels and the mRNA levels of the malonyl-CoA-producing enzyme, acetyl-CoA carboxylase, were increased (4.1- and 1.7-fold, respectively), suggesting that the production of malonyl-CoA is stimulated (Table 2). We earlier demonstrated that C_{14}-S-acetic acid is converted to its CoA ester in rat liver and C_{14}-S-acetic acid accumulates especially in the phospholipid fraction after treatment (12,13), suggesting that C_{14}-S-acetyl-CoA is formed *in vivo* (29). The C_{14}-S-acetyl-CoA is a poor substrate for mitochondrial CPT-I (30) and, when it was present in the assay mixture, the CoA ester of C_{14}-S-acetic acid consequently inhibited the conversion of palmitoyl-CoA to palmitoyl-L-carnitine (Fig. 6A). Figure 6A shows that the inhibition of CPT-I activity by C_{14}-S-acetyl-CoA was more pronounced in mitochondria isolated from C_{14}-S-acetic acid-treated rats than animals treated with palmitic acid. On the other hand, the CPT-II activity was not affected by the CoA ester of C_{14}-S-acetic acid (Fig. 6B).

Peroxisomal β-oxidation is independent of carnitine (31). However, an isoform of CPT-I is present in the peroxisomes (32), and acyl-carnitines are formed in this organelle (33). Significantly increased CPT-I activities measured in the peroxisomal- and microsomal-fractions after C_{14}-S-acetic acid treatment (Table 3) resulted in a shift of the subcellular distribution of CPT-I toward these organelles (Fig. 7). CPT-II activity was increased in all subcellular fractions (Table 3). However, more than 90% of the total CPT-II activity was localized in the mitochondria, and C_{14}-S-acetic acid treatment did not change the subcellular distribution (Fig. 8).

The formation of acid-soluble products + CO_2 expresses total fatty acid oxidation. As it appears that C_{14}-S-acetic acid increases the fatty acid oxidation independent of CPT-I, we measured the oxidation of [1-^{14}C]palmitic acid in cell suspensions prepared from rats treated with palmitic- or C_{14}-S-acetic acid. The formation of [1-^{14}C]-labeled acid-soluble products from [1-^{14}C]palmitic acid was 30-fold higher in cells cultured from C_{14}-S-acetic than from palmitic acid-treated rats (Table 4). Whereas addition of the CPT-I inhibitor etomoxir inhibited the formation of [1-^{14}C]-labeled acid-soluble products 91% in cells from control rats, the inhibition was only 21% in the cells from C_{14}-S-acetic acid-treated rats (Table 4). Addi-

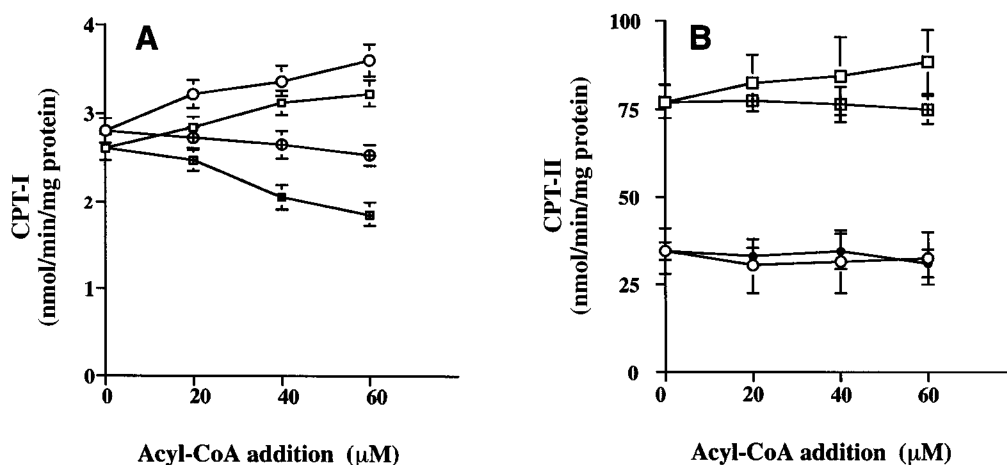

FIG. 6. Effect of C_{14}-S-acetyl-CoA on the mitochondrial CPT-I (A) and CPT-II (B) activity. Rats were fed C_{14}-S-acetic acid at a dose of 300 mg/d/kg body weight suspended in 0.5% CMC for 7 d. Control animals received CMC only. The CPT activities were measured in isolated mitochondria from four different control rat livers as described in the Experimental Procedures section using 100 μM palmitoyl-CoA as a substrate. The CPT-I activity in control rats was measured with additional 20, 40, and 60 μM palmitoyl-CoA (—○—) and C_{14}-S-acetyl-CoA (—⊕—) in the assay mix. The CPT-I activity in C_{14}-S-acetic acid-treated rats was also measured with additional palmitoyl-CoA (—□—) and C_{14}-S-acetyl-CoA (—⊞—) in the assay mix. The values are presented as mean ± SD. For abbreviations see Figure 1.

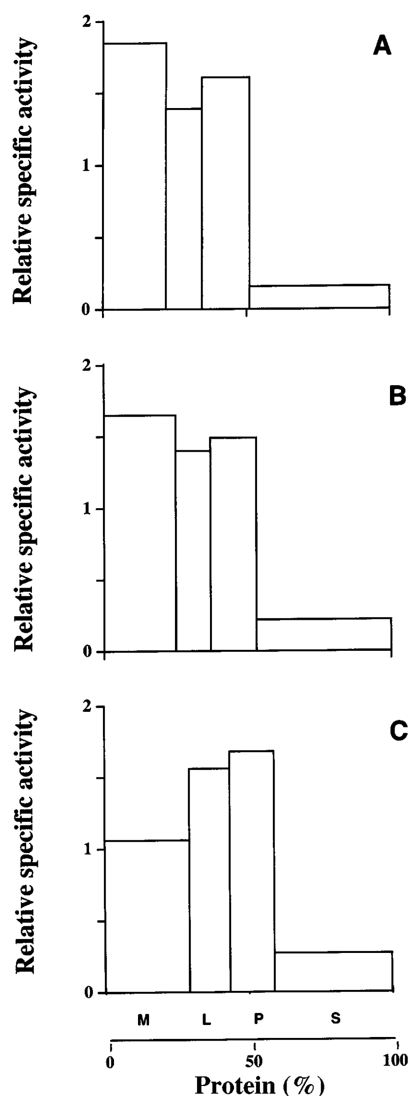

FIG. 7. The effects of C_{14}-S-acetic acid and palmitic acid on the subcellular distribution of CPT-I. Rats were fed palmitic (B) or C_{14}-S-acetic (C) acid at a dose of 300 mg/d/kg body weight suspended in 0.5% CMC for 7 d. Control animals received CMC only (A). The postnuclear homogenates from the livers were fractionated into mitochondrial (M), peroxisomal (L), microsomal (P), and cytosolic (S) fractions, and the CPT-I activity was measured as described in the Experimental Procedures section. The abscissa represents the cumulative protein content for each fraction as a percentage of the total postnuclear protein. The ordinate represents relative specific activity, i.e., the percentage of the total enzyme activity in the fraction over the percentage of total protein in the fraction. For abbreviations see Figure 1.

tionally, as the $^{14}CO_2$ formation was not statistically different, it is presumably that the first cycle of β-oxidation mainly occurred in the peroxisomes in C_{14}-S-acetic acid-treated rats (Table 4). Acyl-carnitines formed in the peroxisomes might be delivered to the mitochondria for further oxidation. (Scheme 1, where FAO is fatty acyl-CoA oxidase and CTL is carnitine translocase).

DISCUSSION

The present paper presents evidence that the effect of 3-thia fatty acids on CPT-I and CPT-II is different from those of EPA and starvation. Mitochondrial CPT-I are considered to be rate-controlling for mitochondrial β-oxidation through different mechanisms, such as changes in activity and the transcription rate, changes in the concentration of its physiological inhibitor malonyl-CoA, and changes in its sensitivity to malonyl-CoA (9). However, in contrast to starved and EPA-fed rats, there was unexpectedly no correlation between mitochondrial β-oxidation and mitochondrial CPT-I activity in C_{14}-S-acetic acid-treated rats (Fig. 1). Nor did C_{14}-S-acetic acid treatment increase the mRNA levels of CPT-I, compared to palmitic acid treatment (Table 1). In addition, the hepatic levels of malonyl-CoA increased and the sensitivity of malonyl-CoA to CPT-I activity appeared unchanged after C_{14}-S-acetic acid treatment (Fig. 1).

The increased hepatic malonyl-CoA levels after C_{14}-S-acetic acid treatment (Table 2) might inhibit CPT-I activity. Inhibition of CPT-I by increased hepatic levels of CoASH (Table 2) and C_{14}-S-acetyl-CoA (Fig. 6A) might also occur. By which mechanism the hepatic malonyl-CoA increases needs further investigation. However, increased mRNA levels of acetyl-CoA carboxylase and hepatic levels of CoASH (Table 2) suggest increased formation rather than reduced degradation by malonyl-CoA hydrolase.

In contrast to starvation and EPA feeding, C_{14}-S-acetic acid treatment also stimulated mitochondrial formation of acid-soluble products when palmitoyl-L-carnitine was used as substrate (Fig. 3), suggesting that enzyme(s) subsequent to CPT-I are involved in the regulation of fatty acid oxidation. CPT-II is not usually regarded as a regulatory enzyme for fatty acid oxidation, but our results are consistent with earlier findings of McGarry and co-workers (34,35), who showed a direct proportionality between ketogenesis from oleate and L-octanoylcarnitine in perfused livers from rats treated in different ways. Indeed, C_{14}-S-acetic acid treatment increased both CPT-II activity and gene-expression (Figs. 2 and 3 and Table 1). Increased CPT-II activities and mRNA levels were also observed in the liver of rats treated with different chain-length monocarboxylic 3-thia fatty acids (Fig. 4), which correlated to oxidation of both palmitoyl-CoA and palmitoyl-L-carnitine (Fig. 5).

It was recently reported that fibrate action on CPT-II gene-expression was PPARα-dependent (36). The 3-thia fatty acids might increase the CPT-II mRNA levels by PPARα-activation, as the trancriptional activity of C_{14}-S-acetic acid correlates with its ability to bind PPARα (15). The CPT-I mRNA levels were, on the other hand, marginally although significantly increased after C_{14}-S-acetic acid treatment compared to controls (Table 1 and Fig. 2). The increased mRNA levels were, however, not statistically significant when palmitic acid treatment was used as control (Table 1). Conversely, starvation

TABLE 3
Effect of Palmitic- and C_{14}-S-Acetic Acid Treatment on CPT-I and CPT-II Activities in Different Subcellular Fractions[a]

Treatment	E	M	L	P	S
CPT-I activity					
CMC	246 ± 23	102 ± 5	46 ± 5	64 ± 13	28 ± 4
Palmitic acid	248 ± 35	108 ± 12	45 ± 6	73 ± 24	21 ± 2
C_{14}-S-Acetic acid	296 ± 25*	109 ± 9	70 ± 7*	87 ± 22*	37 ± 8*
CPT-II activity					
CMC	1121 ± 190	981 ± 270	23 ± 13	28 ± 13	91 ± 27
Palmitic acid	1061 ± 226	878 ± 59	36 ± 17	30 ± 14	116 ± 31
C_{14}-S-Acetic acid	5211 ± 616*	4550 ± 529*	162 ± 11*	127 ± 62*	371 ± 75*

[a]Rats were fed palmitic- or C_{14}-S-acetic acid at a dose of 300 mg/d/kg body weight suspended in 0.5% CMC for 7 d. Control animals received CMC only. The postnuclear homogenates (E) from the livers were fractionated into mitochondrial (M), peroxisomal (L), microsomal (P), and cytosolic (S) fractions, and the CPT-I and CPT-II activities (recorded as nmol/min/g liver) were measured as described in the Experimental Procedures section. Values are means ± SD ($n = 4$).
*Significantly different from control $P < 0.05$. For other abbreviations see Tables 1 and 2.

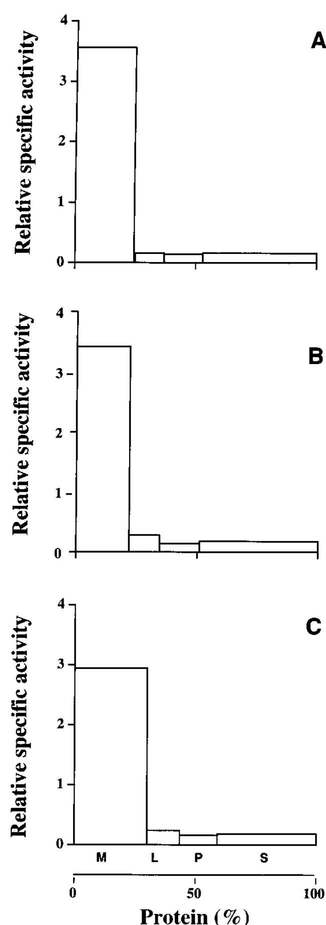

FIG. 8. The effects of C_{14}-S-acetic acid and palmitic acid on the subcellular distribution of CPT-II. Rats were fed palmitic (B) or C_{14}-S-acetic acid (C) at a dose of 300 mg/d/kg body weight suspended in 0.5% CMC for 7 d. Control animals received CMC only (A). The postnuclear homogenates from the livers were fractionated into mitochondrial (M), peroxisomal (L), microsomal (P), and cytosolic (S) fractions, and the CPT-II activity was measured as described in the Experimental Procedures section. The abscissa represents the cumulative protein content for each fraction as a percentage of the total postnuclear protein. The ordinate represents relative specific activity, i.e., the percentage of the total enzyme activity in the fraction over the percentage of total protein in the fraction. For abbreviations see Figure 1.

and EPA feeding significantly increased the mRNA levels of CPT-I, but not CPT-II (Table 1). It thus appears that C_{14}-S-acetic acid influences the CPT system by a different mechanism from that of EPA feeding and starvation.

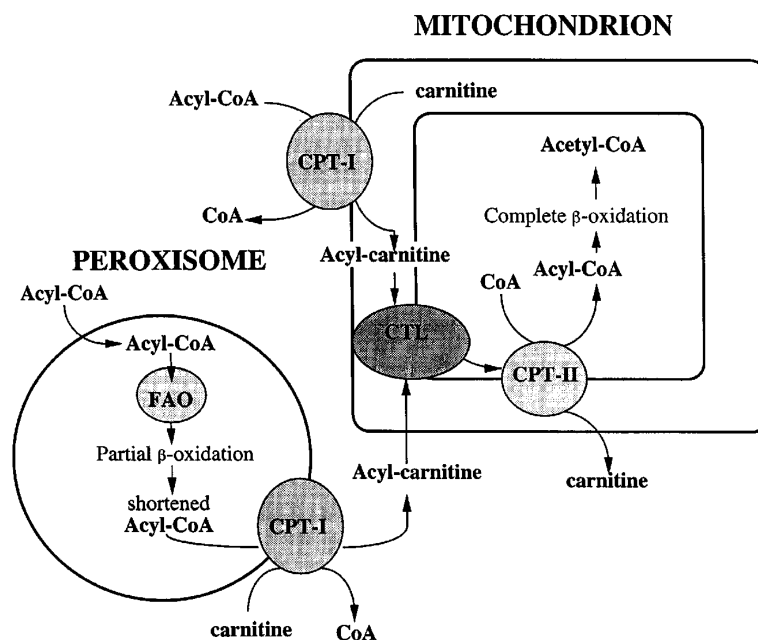
It is difficult to explain how the oxidation of palmitic acid can increase without any concomitant increased CPT-I activity, as it is believed that palmitate enters the mitochondia *via* this enzyme. However, the formation of [^{14}C]acid-soluble products, but not $^{14}CO_2$, from [1-^{14}C]palmitic acid, was increased in cell suspensions prepared from C_{14}-S-acetic acid-compared to palmitic acid-treated rats (Table 4). This suggest that the first cycle of β-oxidation in the liver of C_{14}-S-acetic acid treated rats primarily occurs in the peroxisome. The activity and gene-expression of the rate-limiting enzyme of peroxisomal β-oxidation, fatty acyl-CoA oxidase, are indeed upregulated by C_{14}-S-acetic acid treatment (24). Moreover, the formation of [^{14}C]acid-soluble products from [1-^{14}C]palmitic acid was marginally affected by the CPT-I inhibitor etomoxir in cell suspensions prepared from C_{14}-S-acetic acid-, as compared to palmitic acid-treated rats (Table 4).

Although hepatic CPT-I activity is shifted toward peroxisomes (and microsomes) (Fig. 7), the role of peroxisomal CPT-I is not elucidated. As acyl-CoA is transported into peroxisomes and can undergo peroxisomal oxidation independent of carnitine (31), presumably peroxisomal CPT-I are not involved in the transport of fatty acids into the peroxisomes.

TABLE 4
Oxidation of [1-^{14}C]Palmitic Acid in Hepatocytes Cultured from Palmitic Acid- and C_{14}-S-Acetic Acid-treated Rats[a]

		Acid-soluble products	
Fatty acid	CO_2	– Etomoxir	+ Etomoxir
Palmitic acid	1.8 ± 0.6	90 ± 11	8 ± 3
C_{14}-S-Acetic acid	2.2 ± 0.7	316 ± 48	249 ± 39

[a]Hepatocytes from rats treated with palmitic acid and C_{14}-S acetic acid-treated rats were cultured. Cells (2 × 10^6) were preincubated for 30 min in the presence of L-carnitine (0.5 mM) with and without the addition of 50 μM Etomoxir. The suspension was then incubated for 1 h, with labeled 200 μM palmitic acid as described in the Experimental Procedures section. The values represent nmol/h and are presented as means ± SD from at least three independent experiments. For abbreviations see Table 1.



SCHEME 1

Acyl-carnitines are also formed in the peroxisomes (33). Thus, it is possible that palmitate is partially oxidized in the peroxisomes and enters the mitochondria *via* peroxisomal CPT-I and mitochondrial CPT-II (Fig. 9), like phytanic and pristanic acids (37). Oxidation of palmitic acid by such a mechanism would be dependent on peroxisomal CPT-I and mitochondrial CPT-II, which indeed are upregulated after C_{14}-S-acetic acid (Figs. 2, 4, and 7 and Table 3).

In conclusion, the present study demonstrates that the effects of 3-thia fatty acids on CPT-I and CPT-II are different from those of EPA and starvation. Our results suggest that the crucial role of mitochondrial CPT-I in the control of entry- and β-oxidation of fatty acids in the hepatic mitochondria after EPA feeding and starvation does not seem evident after treatment with mitochondrion and peroxisome-proliferating 3-thia fatty acids. More work needs to be done to fully understand the mechanism by which CPT-II is being regulated.

ACKNOWLEDGMENTS

This work was supported by the Norwegian Cancer Society, the Research Council of Norway, and Astri og Edvard Riisøens legat. The authors are obliged to Kari Helland Mortensen, Bjørn Netteland, and Svein Kruger for excellent technical assistance. The help of Tore-Jacob Raa and his staff at Gade Institute is also appreciated. We are also grateful to Dr. V. Esser and Dr. J. D. McGarry for generously providing the CPT-I and CPT-II cDNA, Dr. T. Hashimoto for the fatty acyl-CoA oxidase, and Dr. K.-H. Kim for acetyl-CoA carboxylase cDNA. L.M. is a research fellow supported by the Norwegian Cancer Society.

ABSTRACT: The purpose of the present investigation was to determine whether the beneficial effects of polyunsaturated fatty acids (PUFA) may influence ischemia–reperfusion-induced alterations of myocardial α- and β-adrenoceptor (α-AR, β-AR) responsiveness. This study was carried out using monolayer cultures of neonatal rat ventricular myocytes in a substrate-free, hypoxia-reoxygenation model of ischemia. The cardiomyocytes (CM) were incubated during 4 days in media enriched either with n-6 PUFA (arachidonic acid, AA) or with n-3 PUFA (eicosapentaenoic acid, EPA, and docosahexaenoic acid, DHA). The n-6/n-3 ratio in n-3 CM was close to 1.2, compared to 20.1 in n-6 CM. The contractile parameters of n-6 CM and n-3 CM were similar in basal conditions as well as during hypoxia and reoxygenation. In basal conditions, the phospholipid (PL) enrichment with long chain n-3 PUFA resulted in an increased chronotropic response to isoproterenol (ISO) and to phenylephrine (PHE). After posthypoxic reoxygenation, the chronotropic response to β-AR activation in n-6 CM was significantly enhanced as compared with the control response in normoxia. In opposition, the ISO-induced rise in frequency in n-3 CM in control normoxia and after reoxygenation was similar. In these n-3 CM, the changes in contractile parameters, which accompanied the chronotropic response, were also similar in reoxygenation and in normoxic periods, although the rise in shortening velocity was slightly increased after reoxygenation. In response to PHE addition, only the chronotropic effect of n-6 CM appeared significantly enhanced after hypoxic treatment. These results suggested that increasing n-3 PUFA in PL reduced the increase in α- and β-AR functional responses observed after hypoxia-reoxygenation. This effect may partly account for the assumed cardiac protective effect of n-3 PUFA, through the attenuation of the functional response to catecholamines in the ischemic myocardium.

Abbreviations: AA, arachidonic acid; ANOVA, analysis of variance; AR, adrenoceptor; CD20, duration at 20% contraction amplitude from peak contraction; CD80, the duration at 80% contraction amplitude from peak contraction; CM, cardiomyocytes; +Cmax, time for 20–80% shortening; −Cmax, time for 20–80% relaxation; CR, contraction rate; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; ISO, isoproterenol; PHE, phenylephrine; PL, phospholipids; PUFA, polyunsaturated fatty acids.

The effects of dietary polyunsaturated fatty acids (PUFA) on serum lipids and membrane phospholipid (PL) fatty acid composition and their pathophysiological and biochemical consequences have been extensively studied in the cardiovascular system. Nevertheless, the mechanisms underlying the beneficial effects of PUFA, of either the n-6 or the n-3 series, are still unclear. In particular, previous results (1) challenged the view of the main influence of n-3 PUFA on vascular parameters and suggested that their protective effects may be mediated through other mechanisms, such as direct action on the myocardium.

The lipid composition of cardiac membranes can be modified by the diet according to the fatty acid unsaturation degree, with a specificity for the PL classes (2,3). Such changes were reported to influence the contraction rate and the systolic ejection volume of the rat heart and improve the metabolic recovery and oxygen consumption after ischemia and reperfusion (4,5). In addition, dietary PUFA appeared to influence the cardiac noradrenaline sensitivity through alteration of the receptor binding characteristics and the signalling pathway (6–8), although differences in methodological approaches led to discordant data (9,10). Less attention has been devoted to the specific effect of PUFA on sarcolemmal protein function in pathological conditions. It was shown that dietary fish oil may prevent the development of arrhythmias in the isolated working heart in response to ischemia (11,12). Also, we had shown from earlier studies that the enrichment of PL in C_{18} PUFA was able to modulate the cardiac myocyte resistance to substrate-free hypoxia and its recovery after reoxygenation (13). However, apart from the suggestion that the *in vitro* induction of tachyarrhythmias by isoproterenol (ISO) did not appeared to be influenced by PUFA (14), there are no available experimental data on the cross-influence of ischemia and PL fatty acids on the adrenergic function.

Therefore, the purpose of the present work was to assess the respective influence of the composition in long chain PUFA of PL on the adrenergic functional responsiveness of the postischemic myocardial cell. Monolayer cultures of ventricular myocytes from the neonatal rat were incubated in media enriched either with arachidonic acid (AA) or with a

mixture of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). The effects of these changes in PL composition of the cardiomyocytes (CM) were evaluated on their basal contractile properties and on their responses to α- and β-adrenergic stimulation in physiological conditions and in a substrate-free, hypoxia-reoxygenation cellular model of myocardial ischemia.

MATERIALS AND METHODS

Cell culture. Primary cultures of rat ventricular myocytes were prepared with the ventricles of neonatal Wistar rat hearts as previously described (15). The proportion of myocytes in the cell suspension was increased by a two-step selective adhesion procedure. The final suspension was plated in 6-cm diameter culture dishes (Falcon Primaria 3802, Becton Dickinson, Oxnard, CA) at a density of 2×10^6 cells per dish. The cells were grown at 37°C in a standard culture medium (Ham's F10 basal medium, Seromed, Berlin, Germany) containing 10% fetal calf serum (Seromed, Berlin, Germany), 10% human serum and antibiotics (200 international units (IU)/mL penicillin and 150 IU/mL streptomycin, Seromed) in a humidified atmosphere with 5% CO_2. After 24 hours, the cells were incubated for 4 additional days in the same medium supplemented with serum albumin-bound fatty acids: either AA (20:4n-6) or EPA (20:5n-3) plus DHA (22:6n-3), leading to two CM populations (n-6 CM and n-3 CM, respectively). Reference cells (Ham C CM) were obtained by 5-d incubation in the standard culture medium. Using this method, the cell attachment was achieved within hours after seeding and then the cell growth gave rise to a continuous layer of confluent cells beating synchronously. The myocyte-rich cultures were composed of at least 95% cardiomyocytes, as assessed with microscopic observation and immunofluorescence staining with an antibody against rat cardiac myosin.

Fatty acid analysis. Fatty acids were analyzed according to previously detailed procedures (13). The media were freeze-dried and the fatty acids were transmethylated without previous extraction. In the cell, the lipids were extracted and the phospholipids were separated from nonphosphorous lipids using silica gel cartridges (Setpack, Waters, Bedford, Massachusetts). Then, the lipids were transmethylated using BF_3-methanol and the fatty acid methyl esters were analyzed by gas chromatography on a Carbowax 20M capillary column. The composition of the media in PUFA of relevance is presented in Table 1, with content in the other fatty acids—i.e., 16:0, 18:0, 18:1, and 18:2n-6—being similar in the standard and in the PUFA-enriched experimental media.

Experimental set-up. The experiments were done in static bath conditions in the glucose-free, Puck's F balanced salt solution under a paraffin oil layer. Cultured neonatal CM display spontaneous and regular beatings in basal salt media, showing that the presence of serum factors or hormonal supplement, such as catecholamines, are not required for the initiation and/or the maintenance of automaticity and contractile function, even during long term experiments. Furthermore, it has been previously determined that cultured rat cardiomyocytes are able to display stable normal function for hours in the presence as well as in the absence of glucose in the bath (16). The culture dish was placed in a heated water-circulation, gas-controlled chamber (17), fitted on the moving stage of an inverted phase contrast microscope. The temperature was maintained at 37°C throughout the experiments. In normoxic conditions, the dish was continuously flushed with air (600 mL/min) and the average values of pH, p_{O_2} and p_{CO_2} were 7.4 ± 0.3, 118.2 ± 3.5 mm Hg and 10.8 ± 1.9 mm Hg, respectively. Hypoxia was obtained by a flow of 100% N_2 (600 mL/min) during 2.5 h. In these conditions, p_{O_2} was reduced to 20 ± 4.3 mm Hg, whereas pH remained constant at 7.31 ± 0.2 (mean ± standard error of the mean; n = 17). Thereafter, the initial normoxic p_{O_2} value was restored by flushing air during 1 h at the same rate.

TABLE 1
Long Chain (C_{20}) Polyunsaturated Fatty Acid (PUFA) Composition of the Standard Culture Medium (Ham C Med) and the n-3 and n-6 PUFA-Enriched Media (n-3 Med and n-6 Med, respectively)[a]

Fatty acids	Ham C Med	n-6 Med	n-3 Med
20:4n-6	6.7	12.5	6.1
20:5n-3	0.6	0.6	4.6
22:6n-3	2.0	1.7	6.5

[a]n-6 Med was supplemented in arachidonic acid (20:4n-6) and n-3 Med in both eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3). Values expressed as percentage of total fatty acids ($n = 3 \times 3$ three sets of each medium); minor fatty acids were omitted.

Recording of cell contractions. The contractile function of the cultured CM was assessed by video, single-edge detection (10), which is adapted to newborn heart cells in culture, i.e., to cells fully attached and spread out onto the bottom of the dish, as in the case of the present study (18). This technique relies on the measurement of light density changes on the screen of a video monitor using a high-precision, narrow-angle light-sensitive silicon photodiode (SD-1420 Honeywell, Minneapolis), selected for its good linearity and its maximal sensitivity (gray-green) adapted to the video image. The phototransducer was fixed in the middle of a black rubber disc, in order to attenuate external light sources. The edge of a cell was positioned on the video field covered by the photodiode by moving the stage of the microscope. The edge of the cell moves during contractions, which caused light intensity changes, which were converted into an electrical signal by the transducer. This contraction signal was displayed by a storage oscilloscope (Gould DSO 1604, Ilford, Essex, UK) and transcribed onto paper chart using an ink-jet recorder (Siemens-Elema EM 81, Solna, Sweden). The analyses of acquired data and calculations were performed on a personal computer using an ASYST-based processing program (Keithley Instrument, Taunton). This procedure gives access to the time and rate parameters of the rhythmic cell contractions, allowing the quantification of the chronotropic effects. Moreover, although direct measurement of the developed force was not feasible, inotropic status can be evaluated from the calculation of the

myocyte shortening velocity ($+C_{max}$, time for 20% to 80% contraction) and relaxation velocity ($-C_{max}$, time for 20% to 80% relengthening) (18, 19). In some hypoxia-reoxygenation protocols on reference cells, action potential recording was carried out, together with contraction monitoring, using conventional glass microelectrode as previously described (16).

Pharmacology. Stock solutions of ISO and phenylephrine (PHE) (Sigma Chemical CO, St. Louis, MO) were prepared in Puck's F salt solution and kept at 0–4°C in the dark until use. The cells were treated by addition of 10 µL of these solutions (ISO or PHE) with a Hamilton syringe (Bonaduz, Switzerland) using a micromanipulator (Leitz, Wetzlar, Germany). The final concentrations of ISO and PHE in the culture dishes were 10^{-7} M and 10^{-6} M, respectively. Single drug addition in each dish was done to avoid fast desensitization of adrenoceptors (AR). These concentrations and conditions have been selected according previous studies (10,20), taking into account functional and biochemical responses. The duration of exposure to adrenoceptor agonists was too short to induce myocyte hypertrophy (21), which could have interfered with the functional responses. In addition, we have controlled that the culture medium contain no measurable traces of catecholamines, which could have influenced the adrenoceptor properties prior to experiments (22).

Statistics. The experimental data were collected in the physiological conditions for each dish as the mean of 5 measurements made in 5 defined areas before addition of the drug, and 5 other measurements made 10 min after addition of the drug. Basal contractility data were subjected to a two-way analysis of variance (ANOVA) with a fixed factor (culture medium) and a random factor (dish). The analysis of the effects of ISO and PHE in n-3 and n-6 cells was made by a three-way ANOVA on data expressed as percentage of change induced by the drugs. In the investigations involving hypoxia and reoxygenation, 6 dishes were used in each group. The measurements were made at 30 min intervals during 2.5 h (H1 to H5) hypoxia and 1 h reoxygenation (R1 and R2). The results obtained for the contractile parameters were analyzed by a two-way ANOVA (medium, treatment). In the studies of the stimulation by ISO and PHE after hypoxia-reoxygenation, the data were expressed as percentage change from nonstimulated cells, and were analyzed by a three-way ANOVA. The differences were considered significant when $P < 0.05$. Reference data were obtained from cells maintained for 5 days in the standard culture medium and submitted to the same protocols. However, the statistical analysis was done on the PUFA-enriched cells only, because the large difference in total fatty acid supply between the experimental medium and control medium might have introduced cell differences which would not be interpretable in terms of qualitative phospholipid PUFA differences.

TABLE 2
PUFA Composition of the Phospholipids (PL) of Rat Cardiomyocytes Incubated 4 d in the n-3 and n-6 PUFA-Enriched Media (n-3 CM and n-6 CM, respectively), in Comparison of the Composition of the Phospholipids of CM Incubated in the Standard Ham C Medium (Ham C CM)[a]

[a]Data are expressed as percentage of total fatty acids ($n = 9$ in each group of CM: three dishes per culture preparation and 3 culture preparations). SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; NS, not significant. Statistical analysis compared n-3 CM vs. n-6 CM, $^{a}P < 0.05$, $^{b}P < 0.01$, and $^{c}P < 0.001$.

RESULTS

PL PUFA. The fatty acid composition of cell PL is presented in Table 2. The content in saturated fatty acids, monounsaturated fatty acids, and PUFA were similar in the three groups of CM, and represented 35, 20, and 45 % of the total fatty acids, respectively. In contrast, altering the long chain PUFA content of the culture medium resulted in significant qualitative modifications of the PUFA fraction of PL, since the PL n-6/n-3 ratio was 20.1 in n-6 CM and 1.2 in n-3 CM, in comparison to 8.2 in the reference CM. The PUFA composition of PL of the n-3 cells was characterized by a high content in EPA (5.5%), docosapentaenoic acid (22:5n-3) (4.3%), and DHA (8.3%). The n-6 cells were enriched in AA (28.1% vs. 12.5% for n-3 cells) and docosatetraenoic acid, (22:4n-6) (8.2%).

Contractile properties. Myocardial cells exhibited sustained, regular rhythmic contractions, in synchrony in the confluent monolayer (see Fig. 3A, CTRL). This spontaneous activity was determined by one or a very few myocardial cells regaining automaticity after isolation (23). These pacemaker cells exhibited characteristic diastolic depolarization and the voltage dependence of the rate of activity (24). The propagation of this spontaneous activity throughout the cell monolayer was achieved *via* permeable, low-resistance gap junctions, as in the native, *in vivo* myocardial tissue. The bulk of the monolayer was thus composed of driven cells, characterized by the absence of the pacemaker diastolic depolarization.

The contractile parameters of the reference CM and of the PUFA-enriched cells are presented in Table 3. The contraction rate was in the range of 181.7 to 313.6 cycles/min, with a mean of 230.1 cycles/min. The mean values of duration of the contraction peak (CD20, duration at 20% contraction amplitude from peak contraction) and of the overall contraction duration (CD80, the duration at 80% contraction amplitude from

P	NS	NS	NS	NS	NS

[a]Data are the means ± standard error of mean (SEM) (n = 13). CR, contraction rate; CD20, the duration at 20% contraction amplitude from peak contraction; CD80, duration at 80% contraction amplitude from peak contraction; $+C_{max}$, time for 20 to 80% shortening; $-C_{max}$, time for 20 to 80% relaxation; for other abbreviations see Table 2. As stated in the Materials and Methods section, the ANOVA comparison was between n-6 and n-3 CM.

peak contraction) were 77.7 and 188.4 ms, respectively. The time for 20 to 80% contraction ($+C_{max}$) varied from 38 to 66 ms. The time for 20 to 80% relaxation ($-C_{max}$) ranged between 46 and 78 ms.

The functional characteristics of the n-3 and n-6 CM appeared close to those expressed by the CM grown in the standard culture medium and defined as the cardiac muscle cells of reference. Therefore, important changes in the n-6/n-3 ratio did not significantly impede the development of normal contractile function of isolated CM. In basal conditions, moreover, the fatty acid composition did not influence the contractile properties of cardiomyocytes, as the apparent increase in contraction rate in n-6 CM was not significant. The modification of the n-6/n-3 PUFA ratio had no incidence on the contraction peak duration (CD20) or on the overall contraction duration (CD80) (76.8 and 185 ms, respectively). Similarly, the modifications in PL PUFA did not influence the shortening time ($+C_{max}$) or the relaxation time ($-C_{max}$) (49.5 and 61.6 ms, respectively).

Effect of ISO. In response to the addition of ISO (10^{-7}M), an increase in beating rate appeared within 2 min in the reference CM as well as in the PUFA-enriched cells (Fig. 1, inset). The effects of ISO on the measured values of contraction parameters measured from reference CM are presented in Table 4. In n-3 CM and n-6 CM, the β-agonist caused an increase in spontaneous beating rate and, as in the case of the basal contractile function, the ISO-induced functional responses in these two experimental cell groups were comparable to that observed in the reference CM (Fig. 1). Therefore, the PUFA enrichment did not affect the development of normal myocardial β-adrenergic responsiveness. The positive chronotropic effect was accompanied by a shortening of the contraction duration parameters (CD20 and CD80) (Table 4). Additionally, a decrease in the shortening velocity ($+C_{max}$) and in the relaxation velocity ($-C_{max}$) was observed, indicating a direct ISO-induced inotropic response (*cf.* Materials and Methods section).

The comparison of the chronotropic responses in the n-6 and n-3 CM (Fig. 1) showed that the ISO-induced increase in beating rate was significantly greater in n-3 CM than in the n-6 CM, since the addition of the drug increased the beating rate by 25% in the n-3 CM and by only 15% in the n-6 CM. The modifications of the other contraction parameters caused by ISO were not significantly influenced by the n-6/n-3 ratio of cell PL, although the ISO-induced decrease in the contraction duration indexes and in shortening and relengthening times seemed greater in n-3 CM (Fig.1).

Effect of PHE. The effects of PHE addition (10^{-6} M) on the myocardial cell contractions are shown in Figure 2. As in the case of the exposure to ISO, whatever the incubating medium, the addition of the α-agonist induced a gradual increase in the spontaneous beating rate. The peak response appeared within 2 min and was followed by a slight decline to a steady level, during which measurements were made (Fig. 2, inset). The corresponding changes in contraction parameters of reference CM are presented in Table 5. The functional response to PHE of n-3 CM and n-6 CM to PHE (Fig. 2) was close to that of Ham C CM, and therefore, the expression of a normal α-adrenergic response was not substantially influenced by the changes in n-6/n-3 ratio. This positive

chronotropic response was accompanied by a decrease in the contraction duration parameters (CD20 and CD80). The addition of PHE decreased the shortening time ($+C_{max}$) significantly but similarly in the two experimental groups of CM.

The diagrammatic comparison of the chronotropic responses to PHE between the two experimental groups of CM (Fig. 2) shows that these responses differed with respect to the PUFA composition of the PL, since the increase in rate was significantly greater in n-3 CM than in n-6 CM (+28% and +13%, respectively). In contrast, there was no significant difference between n-6 CM and n-3 CM in the contraction duration parameters (CD20 and CD80) and in the relaxation time ($-C_{max}$), in spite of an apparent larger decrease in n-3 CM.

Substrate-free hypoxia and reoxygenation. Figure 3A depicts the typical alterations and recovery of the spontaneous electrical and contractile activity of reference Ham C CM during control normoxia and during 150 min substrate-free hypoxia followed by reoxygenation. As detailed previously, hypoxia caused a progressive decrease in action potential plateau and duration, accompanied by rhythm disturbances (Fig. 3A, H1, H2). Thereafter, a drastic fall in rate, action potential amplitude and contraction were observed (Fig. 3A, H3, H4). Hypoxia led finally to the complete arrest of the electrical activity (Fig. 3A, H5). After reoxygenation (Fig. 3A, R2), the spon-

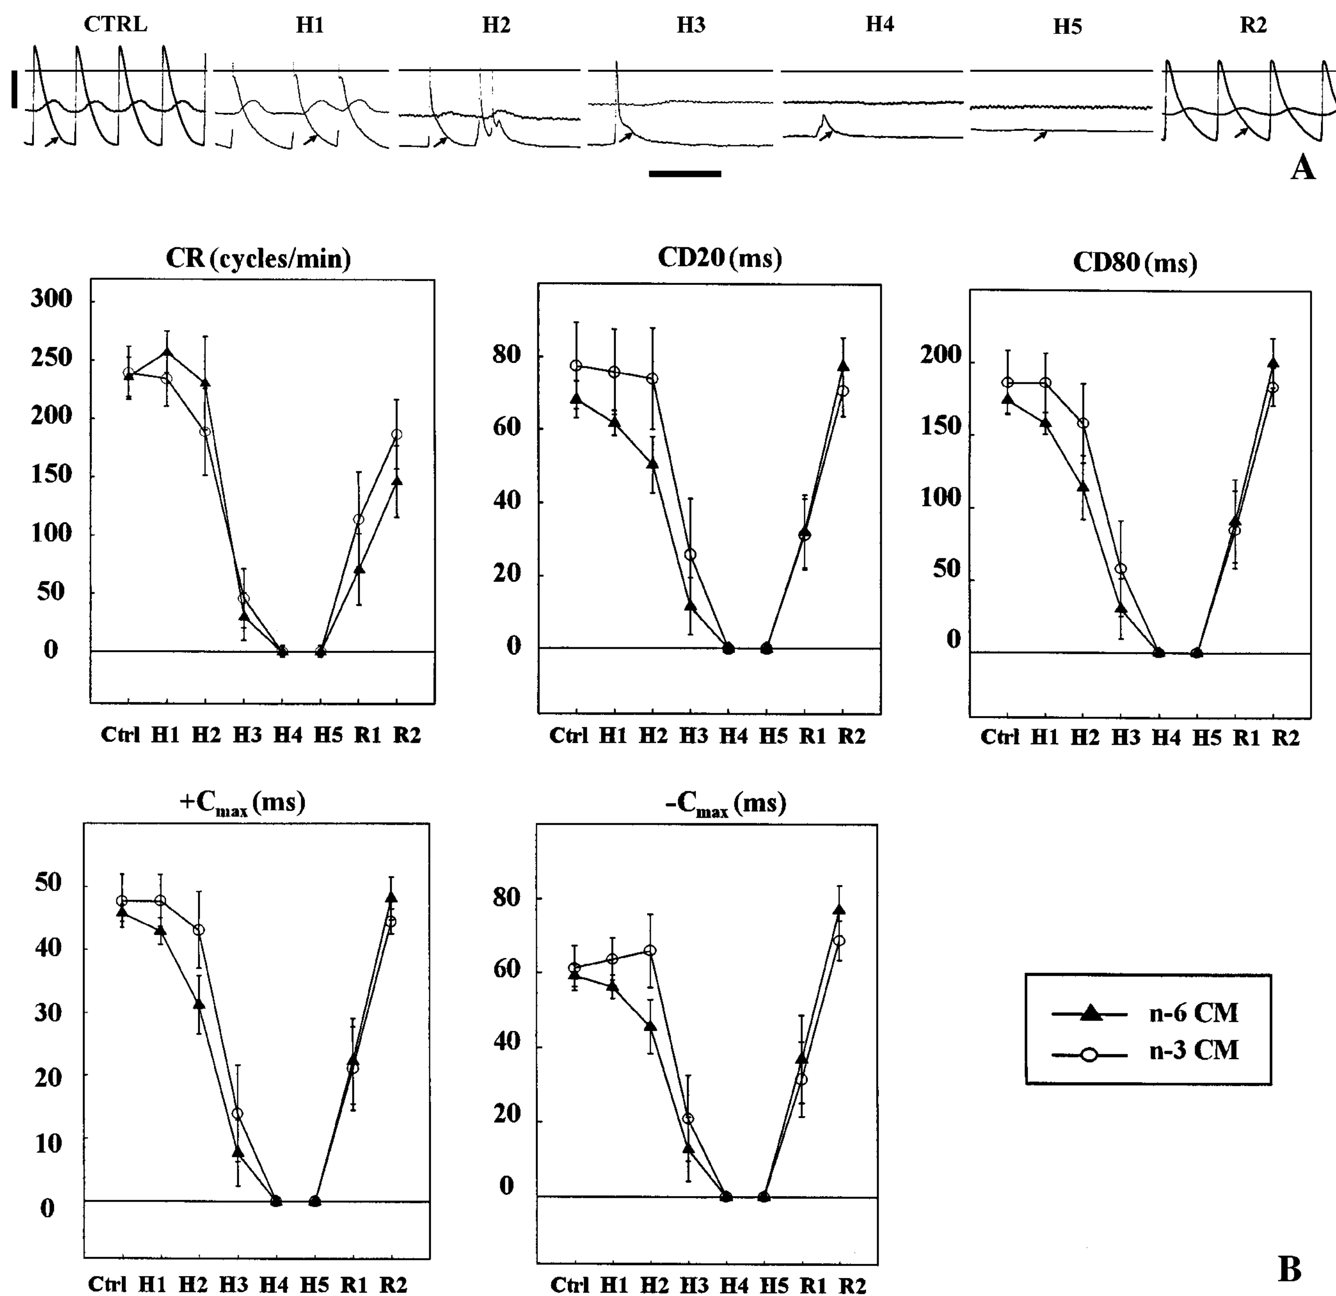

FIG. 3. (A) Typical changes in action potentials (arrows) and contractions (middle traces) simultaneously recorded from cultured rat ventricular myocytes before (CTRL, control) and during hypoxia (H1, H2, H3, H4, and H5; 0.5 h, 1 h, 1.5 h, 2 h, and 2.5 h N_2-induced, substrate-free hypoxia, respectively) followed by 1.0 h reoxygenation (R1 and R2; 0.5 h and 1 h air readmission). All records were obtained from the same cell culture dish. In each panel, the horizontal trace represents the zero potential level. Vertical bar: 40 mV; horizontal bar: 400 ms. Scale for contraction is arbitrary. Note the early rhythm irregularity (H1) followed by triggered afterpotentials (H2). (B) Time evolution of changes in the different contractile parameters before (Ctrl, control) and during hypoxia (H1, H2, H3, H4, and H5; 0.5 h, 1 h, 1.5 h, 2 h, and 2.5 h N_2-induced, substrate-free hypoxia, respectively) followed by 1.0 h reoxygenation (R1 and R2: 0.5 h and 1 h air readmission, respectively). n-3 CM, n-6 CM, cardiomyocytes incubated 4 days in n-3 and n-6 media, respectively. The data represent the mean ± SEM for 6 experiments per cell group. For abbreviations see Figure 1.

taneous electromechanical activity resumed, so that the action potential and contractions reverted close to their prehypoxic configurations. Dysrhythmias were never observed during reoxygenation nor under basal, normoxic conditions.

The time-evolution of the various contractile parameters of the n-3 and n-6 CM during substrate-free hypoxia is presented in Figure 3B. The rhythmic contractions were depressed after 1 h and ceased after 2 h hypoxia to a similar extent in the two PUFA groups of CM. The substrate-free hypoxia also altered the contraction duration and the shortening and relaxation times, which decreased significantly after 1 h hypoxia (H2). At the end of the 2.5 h period of hypoxia, the

CM were reoxygenated by resupplying the chamber with air for 1 h. During this reoxygenation period, the cardiomyocytes recovered spontaneous and regular automaticity and beatings. This recovery of contractile properties during reoxygenation was not influenced by the n-6/n-3 PUFA ratio of the CM. The changes in contractile parameters provoked by hypoxia-reoxygenation in n-3 and n-6 CM was also similar to those observed in the myocytes maintained in standard culture medium (Ham C CM) (16).

Posthypoxic adrenergic responses. Posthypoxic AR responsiveness was assessed through the addition of the receptor agonists 1 h after the reoxygenation following the hypoxic treatment. In these conditions, the response to the addition of ISO was a gradual increase of the contraction rate within 2 min. The corresponding changes in contractile parameters in the two experimental groups of CM are presented in Figure 4. In the n-6 CM, the ISO-induced rise in spontaneous frequency was significantly enhanced in comparison to the control response in normoxia (63.6% vs. 16.6%; Fig. 4A). In the n-3 CM conversely, the chronotropic effect measured after hypoxia-reoxygenation did not significantly differ from that obtained in normoxia. The ISO-induced changes in the other contractile parameters during normoxia and after hypoxia-reoxygenation were similar, although the rise in shortening velocity ($+C_{max}$) in n-3 CM was increased after reoxygenation (Fig. 4B).

The stimulation of the CM by PHE after hypoxia-reoxygenation induced a typical α-adrenergic positive chronotropic response followed by a partial progressive decline to a steady level. In comparison to normoxia, the chronotropic effect in n-6 CM was significantly increased after hypoxia-reoxygenation (55% vs. 17.4% in normoxia; Fig. 5). Conversely, the increases in contraction rate induced by PHE in n-3 CM were similar in normoxia and after hypoxia-reoxygenation. The PHE-induced modifications in the other contractile time parameters were not affected by hypoxia-reoxygenation treatment in n-3 CM and in n-6 CM (data not shown).

DISCUSSION

The objective of this work was to assess the cellular consequences of different fatty acid diets on the AR function in the normal and postischemic myocardium by the use of monolayer cell cultures from neonatal rat ventricles. In this cellular model, CM displayed regular and sustained spontaneous rhythm, without arrhythmias, in the basal conditions. Moreover, these cultivated CM retained differentiated electrical properties in monolayer cultures, including tetrodotoxin-sensitive rapidly rising action potentials (24), which are comparable with those of the tissue of origin (25).

Two groups of samples were prepared by incubating the cells in two different PUFA-enriched media. The PL of CM displayed similar global contents in saturated fatty acids, monounsaturated fatty acids, and PUFA. Conversely, their composition in individual PUFA was influenced by the fatty acids supplied by the media, leading to n-6 cells displaying an enhanced incorporation of AA in PL, and n-3 cells characterized by their high amount of docosapentaenoic acid and DHA. The n-6/n-3 PUFA ratio was hence close to 1 in n-3 cells and reached 20 in n-6 cells. These observations were in agreement with our preliminary results (26) and are comparable with those reported in the hearts of rats fed 8 weeks of fish oil or sunflower oil-enriched diets (4).

We found that the basal automaticity and contractile parameters of CM were not influenced by these large changes in

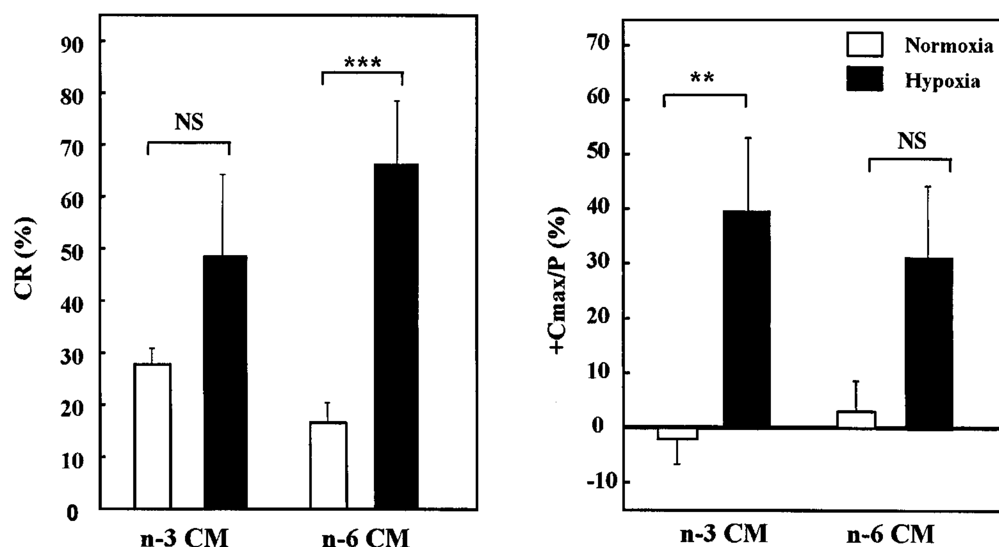

FIG. 4. Functional responses to isoproterenol addition (10^{-7} M) during normoxia (white bars) and during posthypoxic reoxygenation (black bars). n-3 CM, n-6 CM, cardiomyocytes incubated 4 days in n-3 and n-6 media, respectively; CR: contraction rate; $+C_{max}/P$: normalized shortening velocity, where P = 1/CR. the n-6/n-3 PUFA ratio. These results are consistent with our previous study using C_{18} PUFA precursors (10,13) and with other reports (27). Similarly, *in vivo* studies have shown that modifications of cardiac PUFA profile do not alter myocardial performances (28–30), although in these conventional experimental models the difference between the n-6 and n-3 PUFA series has not been clearly explored.

The α- and β-AR functions were assessed by addition of PHE and ISO, respectively, on the basis of the subsequent changes in automaticity and cell contractility. It must be emphasized that there was no interference with possible AR-dependent hypertrophy (21), because of the short duration of exposure.The modifications of the PL n-6/n-3 PUFA ratio had no effect on the inotropic response to α- and β-adrenergic stimulation, because ISO and PHE induced a similar reduction of the shortening and relaxation velocities ($+C_{max}$ and $-C_{max}$, respectively). In contrast, the positive chronotropic response induced by both agonists were more pronounced in n-3 CM, indicating that the rise in the contraction rate after α- and β-stimulation was influenced by the modifications of the membrane PUFA composition. These results confirmed and extended our previous study indicating that CM enriched with C_{18} n-3 PUFA precursors exhibit an enhanced β-adrenergic positive chronotropy (10).

As previously detailed, substrate-free hypoxia induced a gradual decline in rhythmic contractions of CM followed by the cessation of beatings (16). These changes in automaticity and contractility have been correlated (31) to electrophysiological (Fig. 3A) and biochemical alterations. In the present work, the hypoxia-induced alterations in contractile characteristics were not influenced by the n-6/n-3 PUFA ratio. Consistently, Karmazyn *et al.* (32) showed in isolated CM that neither the developed force nor the resting tension following hypoxia were affected by the PL fatty acid content. The recovery of the mechanical properties during reoxygenation was also similar in the two groups of CM. However, the influence of PUFA seems to depend on the function studied, since we previously showed that the posthypoxic electrophysiological recovery was faster in n-3 CM (33). In addition, dietary fish oils were also assumed to be beneficial against ischemic myocardial dysfunction (5) and on mitochondrial oxidative capacity (4) in conventional intact heart models of cardiac
ischemia.

Despite the absence of influence of the n-6/n-3 ratio of PUFA on the CM contraction and automaticity throughout the course of hypoxia-reoxygenation, the chronotropic response caused by ISO and PHE in reoxygenation following hypoxia was significantly enhanced in n-6 CM as compared with the control response in normoxia. In contrast, the n-3 CM exhibited statistically identical ISO- and PHE-induced increases in rate in normoxia and in reoxygenation. In parallel to the functional investigation described herein, a companion study has been carried out to evaluate the influence of the PUFA composition on adrenergic messenger production by the posthypoxic cardiac muscle cells (34). This study showed that hypoxia affects the β-adrenergic messenger production and that a n-3 PUFA profile accentuates this change, because the decrease in the cAMP (cyclic adenosine 3′,5′-monophosphate) production in posthypoxic reoxygenation was more pronounced in DHA-enriched cells than in AA-enriched cells. This may account at least partly for the relatively attenuated β-adrenergic response in the posthypoxic n-3 CM. Conversely, the changes in phospholipid PUFA composition had no effect on the α-agonist-induced inositide phosphate production in the posthypoxic CM, suggesting that the decrease in α-adrenergic functional response in n-3 CM noted in the present study could not be linked to an alteration of the corresponding messenger production.

To our knowledge, the cross-influence of dietary PUFA and ischemia-reperfusion on the myocardial AR function have not been studied hitherto. However, Anderson *et al.* (35) suggested an enhanced role for the α_1-adrenergic system in initiating reperfusion-induced pathological events. It was also suggested that the rat heart contractile failure after ischemia was caused by an impaired second messenger system downstream from cyclic adenosine 3′,5′-monophosphate formation (36). In contrast, Strasser *et al.* (37) proposed that a sensitization of the β-adrenergic system may contribute to the increased sensitivity of the infarcted heart to catecholamines. This upregulation would be accompanied by an increased β-adrenergic receptor (β-AR) kinase activity (38), which involves a translocation of the enzyme to the membrane. Since the translocation of the G protein-coupled receptor kinases

(including β-AR kinase) seems to be modulated by membrane lipids (39), it could be hypothesized that the current enhancement of the posthypoxic response to α-stimulation in n-6 CM may involve an interplay between the G protein-coupled receptor kinase activity and membrane PL.

Nevertheless, although the data obtained suggested a modulation by PUFA of the posthypoxic responsiveness of the myocardial adrenoceptors, their direct extrapolation to the *in vivo* situation must be done cautiously. The isolated cardiac muscle cell, which is considered as a valuable model of the *in situ* cardiomyocyte, cannot be representative of the much more complex situation *in vivo* that involves interference with the complex, extrinsic autonomic mechanisms regulating the cardiovascular functions.

Within these limitations, it can be concluded that the PUFA-induced modulation of the α- and β-adrenergic responsiveness could be considered as functional correlates of the assumed dependence of the membrane functional proteins on membrane dynamic properties (40). Other mechanisms could be involved, however, such as alterations in the intracellular steps of the transduction pathways, as suggested earlier (36–38). Moreover, this study demonstrates that PL enrichment with n-3 PUFA is able to attenuate the increase in α- and β-AR functional responses after posthypoxic reoxygenation. This effect may contribute to the beneficial effect of the n-3 PUFA, which may involve a depressed response to endogenously released catecholamines in the ischemic myocardium.

ABSTRACT: The fatty acid composition of plasma cholesteryl esters, plasma phospholipids, red blood cell (RBC) membrane phosphatidylcholine (corresponding to the outer membrane leaflet), and phosphatidylethanolamine (corresponding to the inner membrane leaflet) was investigated in weanling guinea pigs fed with diets of cacao (saturated fatty acids), sunflower oil [n-6 polyunsaturated fatty acids (PUFA)] or fish oil (n-3 PUFA) for 20 wk. RBC deformation was measured by means of a cell-transit analyzer (filtration) and a cone-plate rheoscope. The contents of saturated fatty acids in plasma phospholipids and RBC membrane leaflets were similar in all three groups. Diets with sunflower oil resulted in a high content of linoleic acid in plasma cholesteryl esters and in the outer leaflet of RBC membranes. Fatty acids of fish oil were mainly incorporated in plasma phospholipids and in the inner leaflet of RBC membranes. The arachidonic acid content was high in all groups in the plasma phospholipids and in the inner leaflet. The n-6 and n-3 PUFA were mainly incorporated in the inner leaflet. In all groups the polyunsaturated/saturated fatty acid ratio and the total PUFA content were similar in the inner RBC membrane. The RBC filtration times and the RBC deformation indices were not affected by the dietary treatment.

Paper no. L8018 in *Lipids 34*, 467–473 (May 1999).

Polyunsaturated fatty acids (PUFA) such as arachidonic acid (AA), docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), which are present in cell membrane phospholipids, are important for many biochemical and physiological functions (1,2). Synthesis of AA and DHA occurs *in vivo* by desaturation and elongation of linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3), respectively (3). A number of animal studies have demonstrated a close association between perinatal supply of essential fatty acids and long-chain PUFA contents of neural lipids (4,5). Human milk fatty acids usually contain sufficient amounts of essential fatty acids and other PUFA (6), whereas formula-fed infants have lower levels of PUFA (3,7). Addition of long-chain fatty acids to formula increases their concentration in the plasma and RBC membranes of preterm and full-term infants (3,8). Since phospholipids and cholesteryl esters of the plasma and phosphatidylcholine (PC) and phosphatidylethanolamine (PE) of the erythrocyte membranes correlate with the lipid composition of other cell membranes, the effect of dietary fatty acid supplementation may be studied by lipid analyses of plasma and RBC membranes (8,9).

Lipids compose about 45% by weight of the RBC membrane, and phospholipids make up about 60% of the RBC lipids (10). The phospholipids are distributed over the outer and inner leaflet of the lipid bilayer in an asymmetric fashion: The outer monolayer contains all the glycolipids and about 75% of PC, whereas 80% of PE are found in the inner monolayer (10,11). Thus, the PC fraction of the lipid analysis represents the outer part and the PE fraction the inner part of the RBC membrane (12).

Diets with saturated fatty acids or n-3 or n-6 PUFA result in incorporation of the different fatty acids into RBC membranes and may influence RBC deformability. Several studies reported improved RBC deformability (13–15) or recovery of disturbed RBC deformability to normal levels (16,17) after supplemetation of diets with n-3 PUFA. In contrast, other studies showed no effect of n-3 PUFA on RBC deformability (18–21). These contradictary results may be due to different amounts of fish oil having been consumed and to different methods of RBC deformability measurements, i.e., filtration (13–18) or constant shear methods such as the rheoscope (19).

Effects of saturated fatty acid or n-3 and n-6 PUFA diets on RBC deformability have not been studied.

The aim of this study was to investigate the incorporation of saturated fatty acids (cacao), n-6 PUFA (sunflower oil) or n-3 PUFA (fish oil) in plasma and RBC membrane lipids.

Furthermore, we studied the effect of the different diets on RBC deformability measured by means of a cone-plate rheoscope and by means of a cell-transit analyzer (filtration technique). The guinea pig was chosen because its fatty acid metabolism, especially the Δ5-desaturase enzyme activity, is similar to that of humans (2,22).

MATERIALS AND METHODS

Animals and diets. Twenty-four male weanling Duncan Hartley guinea pigs (Thomae Company, Biberach, Germany) were randomized into three feeding groups having similar body mass (250 ± 20 g). They were caged individually and provided with tap water *ad libitum*. They were fed for 2 wk on a ground standard laboratory diet (Unilever Co., Vlaardingen, The Netherlands) before shifting to fat diets containing 20.7% casein, 52.9% starch, 9.2% cellulose, 6.7% mineral mix, 0.5% vitamin mix, and 10% fat (weight %). The fat moieties (Table 1) were made by 8.7% cacao and 1.3% sunflower oil (saturated fatty acid group), 10% sunflower oil (n-6 group), 4.3% fish oil and 5.7% sunflower oil (n-3 group). Sunflower oil (5.7%) was added to fish oil to avoid linoleic acid deficiency. The diets were prepared in pellet form every 14 d (Unilever Co.), supplemented with vitamin E (200 mg/kg) and stored in polyethylene bags at −20°C. Menhaden was the source of fish oil. After 20 wk of dietary treatment (daily intake around 30–50 g) the weight gain was similar in the three groups, and the guinea pigs were sacrificed by cervical dislocation and blood was taken by cardiac puncture using EDTA as anticoagulant.

Blood samples. Blood was collected *via* cardiac puncture into EDTA. RBC, plasma, and buffy coat were separated by centrifugation. The plasma was taken for lipid analyses. The RBC were washed twice in an isotonic phosphate-buffered saline (PBS; 0.005 mol/L KH_2PO_4 and Na_2HPO_4, 0.153 mol/L NaCl, pH 7.4, 300 mosm/kg). RBC-PBS solution (20 μL) was used for RBC deformation studies.

Lipid analysis. Plasma and RBC were separated after centrifugation and the RBC pellet was washed three times with cold saline. The plasma lipid fractions (plasma phospholipids PL; and plasma cholesteryl esters, CE) were separated and analyzed according to a modification of the Folch *et al.* method (23), as described elsewhere (24). RBC lipids (PC and PE) were extracted and processed according to the Laryea *et al.* (25) method. This method avoided formation of alkenylether in the lipid fraction. Separation of the various lipid fractions was achieved by one-dimensional thin-layer chromatography on silica gel plate using chloroform/methanol/water (65:25:1, by vol) for separation of the plasma lipids. For RBC lipid separation chloroform/methanol/acetic acid/water (15:15:5:1, by vol) was used. The fatty acid composition of all lipid fractions was determined by using a Fisons VEGA 6000, series 2GC (Fisons Instruments, Mainz, Germany) capillary gas chromatograph equipped with a CP Sil 88 capillary column (Chrompack, Middleburg, The Netherlands; length 50 m, diameter 0.32 mm) and a flame-ionization detector. Helium was used as carrier gas. Identification of substances and regular calculations of appropriate response factors for each fatty acid were achieved by comparison with commercially available external standards GLC-68a (Nu-Chek-Prep. Inc., Elysian, MN). Data are presented as molar percentages of all fatty acids determined in each lipid fraction.

Red blood cell deformation. (i) Rheoscope studies. For the rheoscope deformability measurements 5 μL of the RBC suspension was diluted 1:50 in PBS containing 20 g/dL of dextran T-2000 (Sigma, Munich, Germany). The osmolality of this dextran solution was 300 ± 10 mosm/kg and the viscosity was 21 mPa·s. The deformability of single RBC was observed and measured by a counterrotating cone-plate rheoscope (26) (Effenberger, Munich, Germany), as described elsewhere (27). Four shear stresses of 1, 2, 4, and 6 Pa were applied, and the elongation of RBC was recorded on video. Length (L) and width (W) of 40 RBC were measured in each sample using a computerized micrometer system (MOP-Videoplan, Kontron Electronics, Eching-Munich, Germany). The RBC deformation index DI is defined as $DI = (L - W)/(L + W)$. DI increases with increasing cell elongation.

(ii) Red blood cell filtration. RBC filtration was determined by means of the cell-transit analyzer (CTA; ABX International, Levallois, France) (28). The CTA system employs a polycarbonate filter placed vertically between two reservoirs and an AC conductimeter. The oligofilter has 30 cylindrical pores with 5 μm diameter and 14 μm length. Pore transit times were measured at a pressure gradient of 4 cm H_2O. Transit times of at least 1000 RBC during 25.4 ms or 100 ms were measured for each sample. The pore transit times are inversely related to cellular deformability, but also dependent on RBC size. Results are given as mean passage time of the 1000 cells during the measuring time interval.

Miscellaneous methods. RBC count, white blood cell

TABLE 1
Fatty Acid Composition of the Diets (mol %)[a]

Fatty acids	Cacao	Sunflower oil	Fish oil
16:0	24.1	8.8	15.2
18:0	31.9	6.34	5.8
Saturated FA	58.2	16.9	26.7
16:1n-7	0.33	0.22	5.2
18:1n-9	30.6	23.2	19.1
20:1n-9)	0.1	0.18	0.65
Monounsaturated FA	31.0	23.6	25.3
18:2n-6	10.8	59.3	39.9

20:4n-6	0.01	0.04	0.23
n-6 PUFA	10.9	59.9	40.3
18:3n-3	0.00	0.02	0.07
20:5n-3	0.00	0.07	5.01
22:6n-3	0.03	0.03	3.03
n-3 PUFA	0.03	0.15	9.57
Total PUFA	11.8	59.5	48.3
P/S ratio	0.2	3.5	2.7

[a]Values are means of three determinations, corresponding to four weekly preparations of the diets. Abbreviations: FA, fatty acids; PUFA, polyunsaturated FA; P/S, PUFA/saturated FA ratio; N.D., not detected.

count, hemoglobin concentration, and the RBC indices mean cellular volume and mean corpuscular hemoglobin concentration (MCHC) were determined using a cell counter (Contraves, Zürich, Switzerland). The hematocrit was measured by means of a microcentrifuge.

Statistical analyses. Statistical evaluation of differences between the groups was performend by nonparametric test procedures (Kruskal-Wallis test). Comparison of the means was made using analysis of variance.

RESULTS

The three diets–cacao, sunflower oil, and fish oil–contained different percentages of saturated fatty acids, with the highest content in the cacao diet (Table 1). Nevertheless, the three groups showed similar amounts of total saturated fatty acids in PL and in RBC membrane PC and PE fractions (Tables 2–4).

Monounsaturated fatty acids, especially 18:1n-9 fatty acid, were highest in the cacao diet and in the plasma lipids of the cacao-fed animals when compared to the other groups. PUFA was lowest in cacao diet (12%), higher in fish oil (48%), and highest in sunflower oil (59%). These differences were roughly reflected by the PUFA content of the PL and CE. The polyunsaturated/saturated fatty acid ratio (P/S-ratio) of the diets was extremely low in cacao (0.2), higher in fish oil (2.7), and highest in sunflower oil (3.5). However, there were much smaller differences of P/S-ratio in PL and CE among the three groups (Table 2). The DHA and EPA were much higher in fish oil than in the other two diets (Table 1). This corresponded to the PL more than to the CE of fish oil-fed animals (Table 2).

Tables 3 and 4 show the fatty acid composition of the PC and the PE fraction in the RBC membrane of the three groups. In spite of the marked differences in the saturated fatty acid content of the three diets, both the total amount and the composition of the saturated fatty acids in the RBC membranes of the three groups of animals were quite similar. In all three animal groups the percentages of saturated fatty acids averaged about 50% in PC and 36–39% in PE.

The monounsaturated fatty acids in the RBC membranes corresponded to the contents of the different diets (i.e., in the RBC-PC fraction, 22, 10, or 13% and in the RBC-PE fraction, 9.7, 5.6, or 5.8% in the animals fed cacao, sunflower, or fish oil).

The different amounts of total PUFA in the three diets (Table 1) were in part reflected in the PUFA content of PC (Table 3), whereas total PUFA in PE was similar in the three diet groups (Table 4). The n-3 PUFA (EPA and DHA) showed high concentrations in both RBC leaflets of fish oil-fed animals, whereas RBC in the other groups contained very little EPA and DHA. However, the concentration of EPA was five times and that of DHA was four times higher in the PE fraction than in the PC fraction of fish oil-fed animals.

[a]$P < 0.05$ compared with each group made up of eight guinea pigs. Values are mean ± SE. AA, arachidonic acid. For other abbreviations see Table 1.

There were no influences of the different diets on RBC filtration time measured by CTA. The mean transit times during 25.4 ms and 101.6 ms measuring time were 1.43 ± 0.09 and 1.33 ± 0.08 ms in the cacao group, 1.48 ± 0.14 and 1.33 ± 0.16 ms in the sunflower group, and 1.43 ± 0.05 and 1.30 ± 0.07 ms in the fish oil group.

The RBC deformation measured by means of the cone-plate rheoscope was similar in the three diet groups at shear stresses of 1 to 6 Pa (Fig. 1). When going from a shear stress of 1 to 6 Pa, RBC deformation increased by 18% in the cacao group, by 19% in the sunflower oil group, and by 16% in the fish oil group.

The RBC indices mean cellular volume, mean corpuscular hemoglobin concentration, mean cellular hemoglobin, and RBC count were not significantly different among the three groups.

DISCUSSION

This study demonstrates that feeding of weanling guinea pigs for 20 wk with different diets enriched either with saturated and monounsaturated fatty acids (cacao), with n-6 PUFA (sunflower oil), or with n-3 PUFA (fish oil) influences incorporation of the fatty acids in plasma lipids and RBC membranes. Schick *et al.* (29) showed that feeding guinea pigs with marine oil-enriched diets resulted in a maximal change in lipid composition of platelets within 10 d. After 5 wk no further changes in lipid composition occurred. We studied RBC after dietary supplementation for 20 wk to achieve an equilibrium between plasma and RBC membrane. PL mainly consist of saturated and monounsaturated fatty acids, whereas CE have a higher content of PUFA.

PE, largely located in the inner leaflet of the membrane, is thought to be renewed by acylation of lysophospholipid, which is apparently a slow process (30). PC, located mainly in the outer leaflet, is renewed by exchange of PC between plasma lipoproteins and erythrocyte membrane (30). Of these fractions, PC in the outer leaflet is believed to be associated with the flexibility of the membrane. Persson *et al.* (12) studied membrane composition and RBC deformability in diabetic patients before and after 4 mon of treatment with insulin. They found no correlation between RBC deformability and saturated fatty acids or PUFA in the inner PE fraction. However, RBC filterability improved with increasing palmitic fatty acid (16:0) content and decreased with increasing stearic acid (18:0) content in the outer membrane PC fraction.

Studies of membrane lipid fluidity measured by fluorescence or electron spin resonance techniques have shown that

saturated fatty acid components of the lipid bilayer decrease the fluidity of the RBC membrane (31,32), whereas PUFA increase fluidity (33,34). Furthermore, the cholesterol content in membranes, which was not measured in our study, may influence membrane lipid fluidity. However, the parameter lipid fluidity characterizes molecular motion, not the mechanical behavior of the entire membrane, as exemplified by deformation (35). We showed that incorporation of saturated fatty acids (lipid A from bacteria) in RBC membranes of humans resulted in decreased RBC deformation (36,37), whereas feeding rats with DHA-rich diet improved RBC deformation without influencing the cholesterol/phospholipid ratio (19).

In the present study, the different diets had no effect on RBC deformability. The fatty acid composition of the PE fraction (i.e., inner leaflet) was markedly influenced by the monounsaturated fatty acids and PUFA. However, the total PUFA and P/S ratio in PE showed only small differences among the three groups (Table 4). Although the n-3/n-6 ratio increased from the sunflower group to the cacao and to the fish oil group, the total PUFA was not influenced. Previously, we adjusted the total amount of n-3 and n-6 PUFA in the different diets for rats to differentiate the effect of the single PUFA (19) and found a correlation between improved RBC deformation and DHA content in the RBC membrane. After

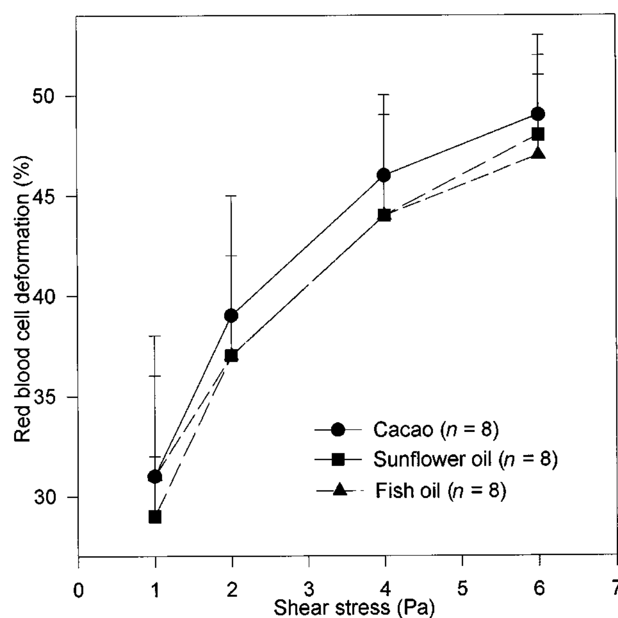

FIG. 1. Red blood cell deformation at shear stresses from 1 to 6 Pa measured in 22-wk-old guinea pigs fed with different diets. Mean ± 1 SD; each group comprised eight animals. The values were not significantly different among the three groups.

dietary supplementation with n-3 and n-6 PUFA, we expected changes in RBC deformation as shown in several studies (13,14,30), but this was not our finding. Thus, similar RBC deformability in the three groups suggests that the total amount of PUFA in the inner RBC leaflet rather than the percentage of individual fatty acids as DHA, EPA, or AA may determine RBC deformability.

The fatty acid composition of the outer PC fraction represents the fatty acid composition in the plasma. The phospholipid renewal occurs by a direct exchange of the phospholipids between the membrane and plasma (38). Our data clearly demonstrate that the saturated fatty acid composition of the PL and the PC fraction was identical in the three groups, although the cacao diet was much richer in saturated fatty acids than the other diets. This suggests either that the saturated fatty acid may be cleared from the plasma before incorporation into the PC fraction or that high saturated acid content in diets decreases their intestinal absorption, as shown in rats (39). The total PUFA and the P/S ratio were not different in the three groups between PL and PC fraction. However, the total PUFA and P/S ratio were significantly lower in the cacao group according to the lower PUFA content in the cacao diet.

The RBC deformability was not affected by the three diets. We suppose that the constant saturated fatty acid content in the two leaflets and the total PUFA content in the inner leaflet may be responsible for the unchanged RBC deformability.

We conclude that the three diets—cacao, sunflower oil, and fish oil—result in similar amounts of total PUFA in the inner RBC leaflet and similar amounts of saturated fatty acids in the outer leaflet. This results in similar RBC deformability.

ACKNOWLEDGMENTS

This study was supported by a grant from Deutsche Forschungsgemeinschaft (Pa 319/2-1) and (Li291/4). The generous support of the Unilever Company, Vlaardingen, The Netherlands, which delivered the fodder is greatly appreciated.

ABSTRACT: The aim of this study was to compare two different strategies to elevate brain, retina, liver, and heart docosahexaenoic acid (DHA) levels in guinea pigs. First, we used an increasing dose of α-linolenic acid (ALA) relative to a constant linoleic acid (LA) intake, and second, we used two levels of dietary DHA provided in conjunction with dietary arachidonic acid (AA). The percentage DHA and AA of total phospholipids in retina, liver, and heart, and in the brain phosphatidylethanolamine and phosphatidylcholine was studied in female pigmented guinea pigs (3 wk old) fed one of five semisynthetic diets containing 10% (w/w) lipid for 12 wk. The LA content in the diets was constant (17% of total fatty acids), with the ALA content varying from 0.05% (diet SFO), to 1% (diet Mix), and to 7% (diet CNO). Two other diets (LCP1 and LCP3) had a constant LA/ALA ratio (17.5:1) but varied in the levels of dietary AA and DHA supplementation. Diet LCP1 was structured to closely replicate the principal long chain polyunsaturated fatty acids (PUFA) found in human breast milk and contained 0.9% AA and 0.6% DHA (% of total fatty acids) whereas diet LCP3 contained 2.7% AA and 1.8% DHA. At the end of the study, animals were sacrificed and tissues taken for fatty acid analyses. We found no significant effects of diets on the growth of guinea pigs. Diets containing ALA had profoundly different effects on tissue fatty acid compositions compared with diets which contained the long chain PUFA (DHA and AA). In the retina and brain phospholipids, high-ALA diets or dietary DHA supplementation produced moderate relative increases in DHA levels. There was no change in retinal or brain AA proportions following dietary AA supplementation, even at the highest level. This was in contrast to liver and heart where tissue DHA proportions were low and AA predominated. In these latter tissues, dietary ALA had little effect on tissue DHA proportions although the proportion of AA was slightly depressed at the highest dietary ALA intake, but dietary DHA and AA supplements led to large increases (up to 10-fold) in the proportions of these PUFA. Tissue uptake of dietary AA and DHA appeared maximal for the LCP1 diet (replicate of breast milk) in the heart. There were no significant changes in the plasma levels of 11-dehydrothromboxane B_2 (a thromboxane A_2 metabolite) for any diet. The data confirm that dietary ALA is less effective than dietary DHA supplementation (on a gram/gram basis) in increasing tissue DHA levels and that tissues vary greatly in their response to exogenous AA and DHA, with the levels of these long chain metabolites being most resistant to change in the retina and brain compared with liver and heart. Dietary DHA markedly increased tissue DHA proportions in both liver and heart, whereas the major effect of dietary AA was in the liver. Future studies of the effects of dietary DHA and AA supplementation should examine a variety of tissues rather than focusing only on neural tissue.

Paper no. L8085 in *Lipids 34*, 475–482 (May 1999).

Human breast milk contains arachidonic acid (AA) and docosahexaenoic acid (DHA). Until recently, most infant formulas have lacked these fatty acids (1,2). Interest in the appropriate or "ideal" composition of infant formula is growing since it has been shown that formula-fed infants have reduced visual acuity (3,4) and altered cognitive development (5). These data might be explained by reports that brain DHA levels in infants fed formula are significantly lower than those receiving breast milk (6,7). In animals fed diets deficient in α-linolenic acid (ALA), large reductions in brain and retinal DHA proportions are associated with impairments in the visual function in primates (8), rats (9), and guinea pigs (10). These observations beg the question of how can we improve and maintain optimal tissue levels of AA and DHA.

It is possible to increase tissue DHA in one of two ways: by increasing either dietary ALA or dietary DHA. Human studies have indicated that increasing the ALA in an infant formula can result in significantly increased DHA levels in erythrocytes; however, the DHA levels are still below those found in breast-fed infants (2,11). One outcome from such a strategy is that high intakes of ALA can lead to reductions in plasma AA levels, which is considered an undesirable outcome (2,11).

The other way to increase tissue DHA levels is to supplement the diet with DHA. In particular, if DHA and AA are both included in the diet then the undesirable reduction of tissue AA levels can be avoided. This approach has been used for both term and preterm infants and has been shown to produce blood DHA and AA levels similar to that found with breast-fed infants (12,13). Whether the increased blood DHA and AA levels are reflected in tissues such as retina and brain is not known. For example, it has been reported that rats fed

dietary AA supplements show significant increases in the plasma level of AA but not in the brain (14). Clearly, such issues can only be addressed easily with animal studies.

In this paper we report the effect of two strategies aimed at increasing brain and retinal DHA levels in guinea pigs. First, we used an increasing dose of ALA relative to a constant linoleic acid (LA) intake, and second, we used two levels of dietary DHA supplements provided in conjunction with dietary AA. The hypotheses being tested were that addition of dietary AA and DHA will increase tissue DHA values beyond those obtained by diets high in ALA, and that the combined addition of dietary DHA plus AA will not decrease tissue AA levels. The novelty of this study is that it focuses on the response of a variety of tissues to fatty acid supplementation and shows that the tissue response to AA and DHA supplementation is not the same.

TABLE 1
Fatty Acid Composition of the Diets[a]

Fatty acid	Diet group SFO	CNO	Mix	LCP1	LCP3
8:0	6.1	1.9	1.6	1.4	1.1
10:0	5.0	1.6	1.4	1.2	1.0
12:0	36.4	11.5	9.8	8.5	6.9
14:0	14.0	4.6	4.2	3.9	3.7
16:0	8.9	6.1	20.7	20.4	19.9
16:1	0.1	0.2	0.1	0.2	0.2
18:0	8.9	4.6	5.7	5.6	5.5

18:2/18:3	323:1	2.3:1	17.5:1	17.7:1	17.4:1

[a]Results expressed as % of total fatty acids. SFO, safflower oil; CNO, canola oil; Mix, mixed vegetable oil; LCP1, mixed vegetable oil plus 0.9% arachidonic acid (AA) and 0.6% docosahexaenoic acid (DHA); LCP3, mixed vegetable oil plus 2.7% AA and 1.8% DHA.

MATERIALS AND METHODS

Animals and diets. Seventy pigmented female guinea pigs (English Shorthair) were randomly divided into five groups of 14 animals at 3 wk of age. The guinea pigs were fed one of five different semisynthetic diets *ad libitum* for 12 wk and were supplemented with fresh carrots and drinking water containing ascorbic acid (400 mg/L). The macronutrient composition of the diets (g/kg of diet) was: casein 300, sucrose 100, glucose 70, starch 200, solkafloc (cellulose) 100, kaolin 30, L-arginine 3, DL-methionine 2, mineral mix 68, and vitamin mix 27, as described by Weisinger *et al.* (10). The diets contained 10% (w/w) lipid, supplied by mixed vegetable oils, and each diet was designed to provide 17% LA (as % of total fatty acids).

In all diets, the lipids were based on mixed vegetable oils. In diet SFO, the main lipid was provided from safflower oil and the LA/ALA ratio was 323:1 (ALA 0.05% total fatty acids). In diet CNO, the main lipid was provided from canola oil with an LA/ALA ratio of 2.3:1 (ALA 7% total fatty acids). Diet Mix was based on mixed vegetable oils, with an LA/ALA ratio of 17.5:1 (ALA 1% total fatty acids). Diets LCP1 and LCP3 were similar to diet Mix, but they were designed to contain supplementary levels of AA (1%) and DHA (0.7%) (mimicking the levels in human breast milk) or 3% AA plus 2.1% DHA, respectively. AA was obtained from ARASCO oil (Martek Bioscience, Columbia, MD), processed from a common soil fungus widely distributed in nature, and DHA was obtained from DHASCO oil (Martek Bioscience), processed from a microalga.

Fatty acid assays of the five diets showed that the LA levels achieved the desired range of between 16.1 and 17.2% (% total fatty acids; Table 1). Assays of diet LCP1 gave AA and DHA values of 0.87 and 0.59%, respectively, whereas diet LCP3 gave 2.74 and 1.80% of AA and DHA, respectively.

At the end of the 12 wk of feeding, animals were sacrificed by CO_2 asphyxiation. The brain, retina, heart, and liver were removed for processing. The brain, heart, and liver were washed in saline, blotted dry, and stored at −70°C for fatty acid analysis. Each retina was removed and washed in ice-cold phosphate buffered saline and stored in 10 mL of chloroform/methanol (2:1,vol/vol) containing butylated hydroxytoluene (10 mg/L) as an antioxidant. Blood was drawn by cardiac puncture and 5 mL was transferred to a lithium heparin vacutainer tube. This was centrifuged for 10 min (1000 rpm, at 18°C), and the platelet-rich plasma was then stored at −70°C. The concentration of plasma 11-dehydrothromboxane B_2 was measured by competitive enzyme immunoassay (Caymen Chemical Company, Ann Arbor, MI) and the resulting plates were read at 410 nm.

Lipid analyses. Following lipid extraction from retina, heart, and liver by chloroform/methanol (2:1), the total phospholipids were separated from the neutral lipids by thin-layer chromatography (TLC) (15). There was insufficient retinal tissue to allow separation of the individual phospholipids, but brain lipids were separated by TLC (16) and the phosphatidylethanolamine (PE) and phosphatidylcholine (PC) fractions were scraped into tubes and the methyl esters of the phospholipid fatty acids were formed by saponification using KOH followed by transesterification in BF_3 in methanol (15). The fatty acid methyl esters were separated by capillary gas– liquid chromatography using a 50 m × 0.32 mm (i.d.) fused-silica bonded phase column (BPX70; SGE, Melbourne, Australia). The column oven was programmed to rise after 3 min at 125°C to 220°C at 8°C/min with a helium flow rate of 43 cm/s as the carrier gas. Fatty acids were identified by comparison with standard mixtures of fatty acid methyl esters, and the results were calculated using response factors derived from chromatographing standards of known composition (Nu-Chek-Prep, Elysian, MN).

Statistical analyses. Significant differences between dietary groups were tested using a one-way analysis of variance for each type of fatty acid. *Post hoc* comparisons were made using the Tukey test with a significance level of 0.05.

RESULTS

There was no significant difference in the body weights of animals at the start or finish of the experiment. The mean increase in body weight across all groups was 359 ± 46 g. The

proportion of total polyunsaturated fatty acids (PUFA) in the retinal lipids ranged between 41–45% regardless of diet. However, the fatty acid profiles varied as a function of diet group. The main retinal phospholipid fatty acids were 16:0, 18:0, 18:1n-9, AA, 22:5n-6, and DHA (Table 2). There were significant increases in the proportions of 22:5n-3, DHA, and 24:6n-3 and significant decreases of LA, AA, 22:4n-6, 24:4n-6, 24:5n-6, and 22:5n-6 as the ALA content of the diet increased (Table 2: diet SFO vs. diet CNO). The additions of AA and DHA supplements (diets LCP1 and LCP3) were associated with significant decreases in 22:4n-6, 22:5n-6, and 24:4n-6 and significant increases in 22:5n-3 and DHA (Table 2). Diet LCP3 resulted in significantly more DHA and less 22:5n-6 than did diet LCP1 or diet Mix (Table 2). Supplementing diets with DHA and AA resulted in significant increases in the proportions of the 24-carbon n-3 PUFA and significant decreases in the 24-carbon n-6 PUFA.

Table 3 shows that the main fatty acids of the brain PE fraction were 18:0, 18:1n-9, AA, 22:4n-6, 22:5n-6, and DHA. There was no difference in fatty acid composition between diets SFO or Mix. Diet CNO contained a significantly higher proportion of DHA and lower proportion of 22:5n-6 than found with diets SFO or Mix. Addition of dietary AA and DHA (diets LCP1 and LCP3) was associated with a significant decline in the 22:5n-6 proportion (from 9.2% in diet Mix to 4.0% in diet LCP3) and an increase in DHA (from 8.3% in diet Mix to 15.0% in diet LCP3). The highest DHA and AA diet (Diet LCP3) led to further significant changes in the proportions of 22:5n-6 and DHA compared with diet LCP1. There were no significant differences in the proportion of AA or 22:4n-6 in any of the dietary groups.

The major fatty acids of the brain PC were 16:0, 18:0, and 18:1 which accounted for 76–79% of the total (data not shown). In contrast to the brain PE fraction, brain PC fractions showed minor changes in PUFA as a result of dietary manipulations. Supplementation of the diet with AA and DHA did not significantly change the proportion of AA and DHA in this fraction.

Table 4 shows the effect of diet on the fatty acid composi-

tion of the liver total phospholipids, with the main fatty acids in this tissue being 16:0, 18:0, 18:1n-9, LA, and AA. The diets significantly affected all of these fatty acids. Increasing the ALA content significantly decreased the LA and AA proportions and significantly increased the proportions of ALA, 22:5n-3, and DHA; however, these changes in the long chain n-3 PUFA were minor. The most significant changes occurred with DHA and AA supplementation, particularly in the proportion of LA, AA, and DHA. Supplementing the diet with 0.6% DHA led to more than a 10-fold increase in the proportion of DHA in the liver, whereas supplementing at 1.8% DHA increased tissue proportions even further (from 6.1% on diet LCP1 to 14.6% on diet LCP3). Supplementing the diet with 0.9% AA produced a doubling in liver AA proportion, and a further significant increase was evident with 2.7% AA supplementation. There were marked decreases in liver phospholipid LA proportions in the diets which contained AA and DHA.

The main fatty acids in heart phospholipids were the same as those in the liver (Table 5), however, there was more than twice as much AA in heart compared with liver and a reduced proportion of LA. The most significant changes due to diet occurred with DHA and AA supplementation, particularly in the LA, AA, and DHA proportions. Supplementing the diet with 0.6% DHA led to more than a 10-fold increase in tissue DHA proportion, but supplementing at 1.8% DHA did not increase tissue proportion any further. Supplementing the diet with 0.9% AA produced a small increase in tissue AA, and the 2.7% AA supplementation produced little extra increase in tissue AA proportion. The increased DHA and AA proportions found with diets LCP1 and LCP3 were accompanied by substantial decreases in the proportions of LA.

The effects that diets have on the tissue levels of the principal metabolites of the n-3 (DHA) or n-6 (AA) families are shown in Figure 1, which indicates how the proportions of DHA and AA vary between the tissues. Retina and brain have moderate levels of DHA and AA whereas liver and heart have low levels of DHA and moderate to high levels of AA. Increasing the dietary ALA intake resulted in increasing DHA levels in the retina and brain with little effect being evident for the liver and heart. This DHA increase was associated with decreasing AA levels in liver and heart but stable AA levels in retina and brain. The change in retina and brain DHA was particularly evident with diet CNO. Supplementation with DHA (diets LCP1 and LCP3) resulted in further increases of tissue DHA in all cases although the heart showed a plateau in this effect beyond diet LCP1. Supplementation of AA (diets LCP1 and LCP3) appeared to have no effect on retina and brain levels of AA but showed a substantial increase for liver and heart, with heart levels stabilizing beyond diet LCP1.

In order to consider the more subtle aspects of these

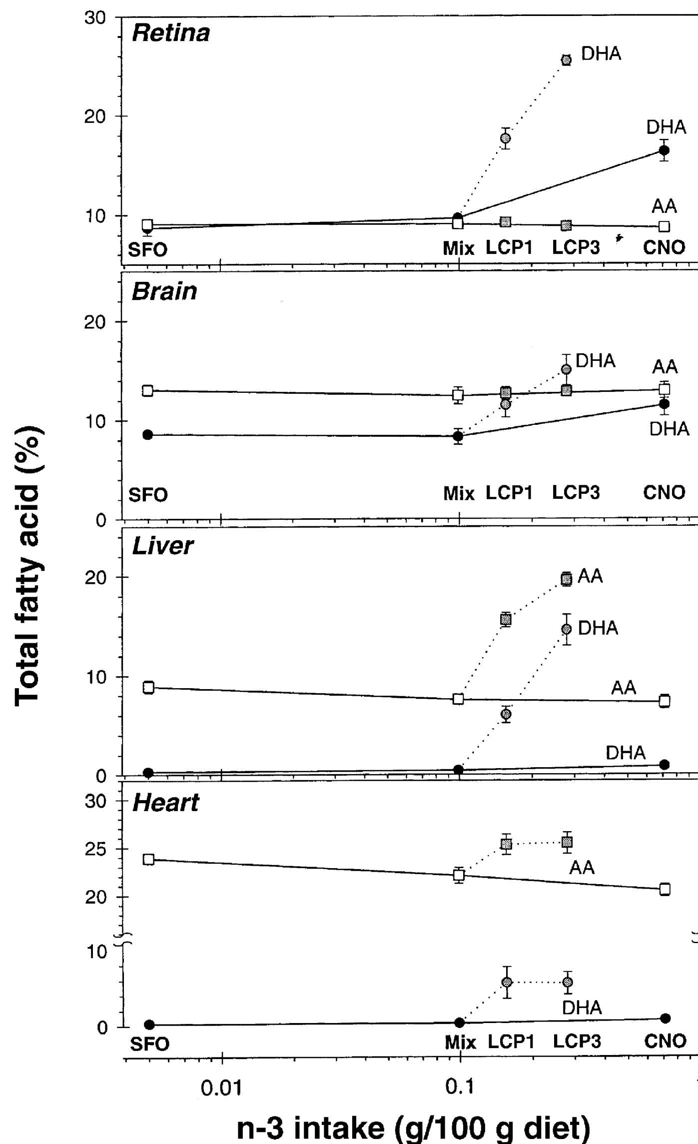

FIG. 1. The effects of diets containing α-linolenic acid (ALA) or docosahexaenoic acid (DHA) plus arachidonic acid (AA) on DHA and AA proportions in the phospholipids of guinea pig tissues. The dietary level of n-3 fatty acids is shown on the *x* axis in g/100 g diet, whereas the AA and DHA values are shown as percentage of total fatty acids in the tissue lipid fraction examined. DHA values are shown with circles (○) and AA as squares (□), and the effect of ALA on DHA levels is shown as a solid line whereas the effects of AA or of DHA are shown as a dashed line. Subsets of DMA or AA from diets with ALA are solid symbols; subsets from diets with ALA + DHA are gray symbols. The letters SFO (safflower oil), Mix (mixed vegetable oil), LCP1 (mixed vegetable oil plus 0.9% AA and 0.6% DHA), LCP3 (mixed vegetable oil plus 2.7% AA and 1.8% DHA) and CNO (canola oil) represent the five diets used in this study.

changes, Figure 2 shows them normalized to the baseline values found for diet SFO: values >1 indicate an increase in tissue levels compared with those found for diet SFO. Figure 2A shows the relative changes found for tissue AA levels and Figure 2B gives these for DHA. In essence, Figure 2 confirms the trends shown in Figure 1. It is evident that adding n-3 PUFA to diets results in improved DHA tissue proportions in all tissues (Fig. 2B) although the retina and brain showed the smallest relative change. Adding dietary DHA supplements also gave the smallest benefits for the central nervous system (CNS) as their starting DHA levels were moderate. On the other hand, dietary DHA supplementation showed an enormous increase in DHA levels for heart and liver (>10-fold) where the initial proportions were low. AA proportions were robust to changes regardless of diet (Fig. 2). However, subtle trends were evident in this data, with the heart and liver showing decreased tissue levels of AA as the n-3 intake increased, which was not seen in the CNS. Supplementation with dietary AA had no effect on the retina and brain, gave minor improvements in the AA levels of the heart, and a large (>2 fold) increase in liver AA content.

Determination of the plasma concentrations of 11-dehy-

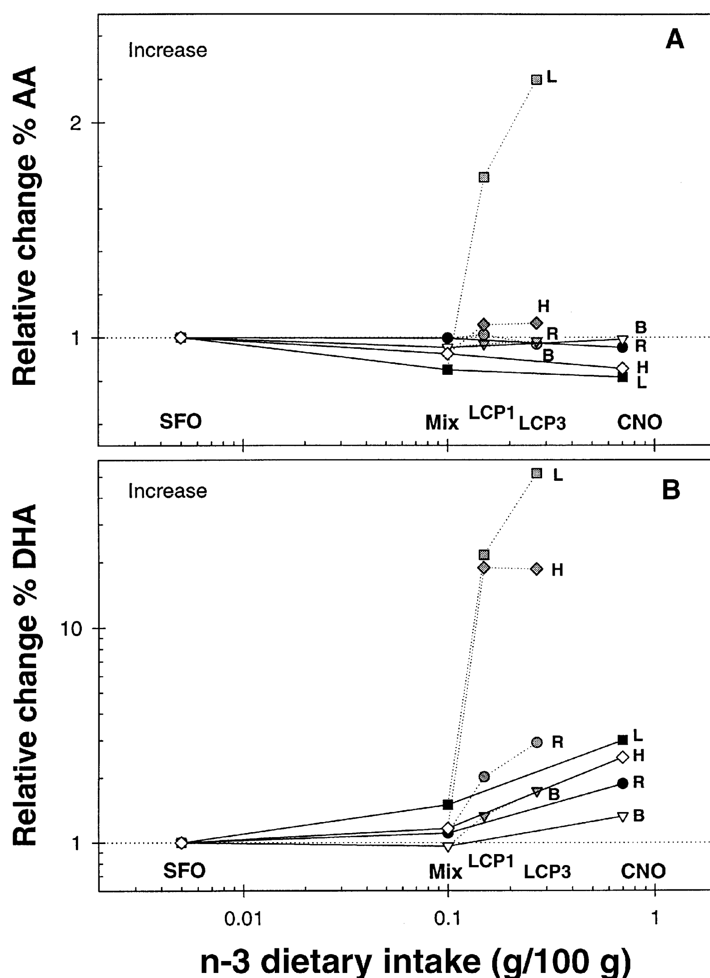

FIG. 2. The relative effects of diets containing ALA or DHA plus AA on tissue DHA and AA levels in the guinea pig, normalized to baseline values found in diet SFO (n-3 deficient diet). The dietary level of n-3 fatty acids is shown on the x axis in g /100 g diet, whereas the AA and DHA values are shown as relative change in DHA or AA in the tissue lipid fraction examined. Values greater than 1 indicate an increase in tissue levels compared with diet SFO. (A) Effects on AA levels in tissue; (B) effects on DHA tissue levels. The effect of ALA on tissue DHA and AA levels is shown with a solid line, whereas the effects of dietary AA and DHA are shown with a dashed line. The tissues are represented by different symbols and a letter, B = brain phosphatidylethanolamine, R = retina phospholipids, L = liver phospholipids, and H = heart phospholipids. See Figure 1 for diets and other abbreviations.

drothromboxane B_2, a metabolite of thromboxane A_2, revealed no significant difference between the five dietary groups. The concentrations were 61 ± 39 (n = 12) for diet SFO, 43 ± 28 (n = 12) for diet Mix, 47 ± 25 (n = 13) for diet CNO, 39 ± 22 (n = 12) for diet LCP 1, and 47 ± 30 (n = 12) pg/mL of plasma for diet LCP3.

DISCUSSION

Lipid nutrition during pregnancy and early postnatal life is important because rapid brain growth and phospholipid accumulation occur during this period. Animal studies have shown that extreme modifications of intake of LA and ALA can lead to alterations in the PUFA composition and function of the developing brain and retina (8–10,17). The present study compared dietary ALA with a combined supplement of DHA plus AA as strategies for elevating brain and retinal DHA levels. At the highest level of ALA (7% dietary fatty acids) increases in DHA were found in all tissues with no decrease in the proportion of AA in neural tissues, but there were significant declines in AA levels in heart and liver. The DHA increase in brain and retina on the high-ALA diet was quite marked (as a percentage of the total fatty acids), however, in the heart and liver the increase was small since the proportion of DHA in the phospholipid fraction of these tissues was less than 1% even at the highest ALA intake.

The other strategy to raise tissue DHA levels, which involved using dietary DHA plus AA, showed a completely different result. First, there were significant increases in neural DHA levels without alteration to the neural AA level. In the liver and heart tissues, however, there were two- to ten fold increases in both DHA and AA. These results clearly show

the diverse responses by different tissues and highlight the importance of examining more than just neural tissues in experiments that undertake dietary manipulation. That is, dietary DHA and AA supplements have the potential to influence the phospholipid fatty acid composition of all tissues in the body and also to influence physiological function in a number of these tissues through changes in eicosanoid production (18), membrane protein function (19), or ion flux through membranes (20). Diets containing ALA have markedly different effects on tissue fatty acid compositions compared with diets which contain the long chain PUFA (DHA and AA) in this species.

In the retinal lipids, there was very little alteration in the proportion of retinal AA in this experiment. However, the proportions of 22:5n-6 varied considerably and were inversely related to the proportion of DHA. This suggests that DHA might be an inhibitor of 22:5n-6 synthesis or, alternatively, a better substrate for reacylation of the phospholipids. Craig-Schmidt *et al.* (21) also reported that diets with DHA alone or with DHA plus AA did not lead to differences in the AA levels in the retinal PC or PE fractions in the piglet. Studies in the rat show that low dietary LA/ALA ratios (<1:1) can lead to significant decreases in retinal AA in animals fed diets with low LA intakes and high ALA levels (22). Other studies in piglets, rats, and monkeys have reported that increasing either ALA or DHA can increase the retinal DHA level (21,23–25), but none of these studies examined the relative effects of ALA vs. DHA. In this study we found that the diet containing 7.1% ALA gave the same retinal and brain PE DHA values as a diet which contained 0.6% DHA and 1% ALA, indicating the potent effect of dietary DHA as a source of neural DHA. Thus, as has been shown many times, dietary DHA is a more effective precursor of tissue DHA than equivalent amounts of ALA, perhaps because only a small fraction of ingested dietary ALA is converted to DHA (26).

The changes in the brain PE fraction were similar to those described for the retina, however, there was little effect of dietary n-3 PUFA on the brain PC fatty acid composition. This contrasts with data from piglet retinal PE and PC where changes were observed in both fractions following feeding with DHA (21).

The liver and heart data in the guinea pig are dissimilar to those reported for these tissues in the rat and the piglet. In rats and piglets, diets containing relatively high levels of ALA are associated with DHA values in liver and heart phospholipids of the order of 7–8% of fatty acids compared with values of less than 1% for the guinea pigs (27–29). These large differences in heart n-3 fatty acid levels in apparently normal animals suggest that the guinea pig might be an interesting animal model with which to study the role of these fatty acids in this tissue. The liver AA levels in the guinea pig were also substantially lower than in the rat or piglet (24, 29). This has been reported previously by Horrobin *et al.* (30) and is perhaps due to a reduced activity of the Δ-5 desaturase enzymes in the guinea pig, as reported by Willis (31).

This study has focused on tissue PUFA changes rather than functional changes such as retinal electrophysiology, behavior, or changes in enzyme activity. In addition to changes in function, there has been much concern about the effect of altering tissue PUFA levels because of the possible effects on eicosanoid synthesis, particularly thromboxane. Craig-Schmidt and Huang (18) have reported that there was reduced lung biosynthesis of prostacyclin in piglets fed DHA alone compared with diets containing AA alone or AA plus DHA; in contrast, thromboxane synthesis was reduced by DHA either alone or in combination with AA relative to the AA-fed group. In this study, we could not find any effect of diet on the plasma level of 11-dehydrothromboxane B_2 which is a marker of the systemic production of thromboxane A_2. Takasaki *et al.* (32) have reported that the plasma level of 11-dehydrothromboxane B_2 is a useful marker of *in vivo* thromboxane formation in rabbits.

In terms of animal models, it needs to be recognized that some mammals provide better models of the nutritional requirements in human retinal development than others. Mammalian species vary in their retinal development, where growth can be classified as prenatal, perinatal, or postnatal with respect to the major retinal growth spurt. Precocial mammals such as humans, primates and guinea pigs have both pre- and postnatal retinal growth spurts (33,34). In contrast, altricial species such as rats and dogs have the greater part of retinal development occurring after birth (33). As a consequence of these differences in retinogenesis, the development of retinal function has been reported as more similar in man and guinea pigs than it is in rats (34–36). Therefore, the effects that neonatal dietary manipulations have on function may be expected to vary between species. Moreover, the rate of conversion of 18-carbon PUFA to long chain metabolites is slower in guinea pigs than rats, and may be more closely related to the rate of conversion seen for humans (31,36). For these reasons, we believe that the guinea pig is a useful animal model for examining the effect that dietary manipulation of n-3 fatty acids can have on tissue DHA levels and physiological function.

In conclusion, this study in guinea pigs has highlighted the difference between the use of diets containing LA and ALA with those containing LA, ALA, AA, and DHA on tissue fatty acid composition. The effects observed in neural tissue are not the same as those in other tissues like liver and heart, and the potential that differences in long chain PUFA levels may have distinguishable effects on physiological function (eicosanoid production, enzyme activity, ion flux, etc.) should be explored in future studies.

ACKNOWLEDGMENTS

This research was supported by Wyeth Nutritionals International USA. Lorna Beulke, They Ng and Bang Bui are thanked for their assistance in obtaining tissue samples and Dr Neil Mann for his guidance with the thromboxane assays.

Dietary Supplementation with Arachidonic and Docosahexaenoic Acids Has No Effect on Pulmonary Surfactant in Artificially Reared Infant Rats

ABSTRACT: Despite the potential use of long-chain polyunsaturated fatty acid (LCPUFA) supplementation to promote growth and neural development of the infant, little is known about potential harmful effects of the supplementation. The present study determined whether supplementation with arachidonic acid (AA) and/or docosahexaenoic acid (DHA) in rat milk formula (RMF) affects saturation of pulmonary surfactant phospholipids (PL). Beginning at 7 d of age, infant rats were artificially fed for 10 d with RMF supplemented with AA at 0, 0.5, and 1.0% of total fatty acid, or supplemented with DHA at 0, 0.5, and 1.0%, or cosupplemented with AA and DHA at levels of 0:0, 0.5:0.3, and 1.0:0.6% of the fat blend. Lung tissue PL contained 43 weight percent palmitate (16:0) of total fatty acids in infant rats fed the unsupplemented RMF. The supplementation with AA at both 0.5 and 1.0% decreased the weight percentage of 16:0 and stearate (18:0), indicating a decrease in saturation of PL. The observed decreases were accompanied by increases in AA and linoleic acid (18:2n-6). Surfactant phosphatidylcholine (PC) consisted of 71 weight percent 16:0 in the unsupplemented group, and this highly saturated PC was not altered by the cosupplementation with AA and DHA although there was a slight increase in DHA. Similarly, the cosupplementation did not change fatty acid composition of surfactant PL when compared with the unsupplemented group. The cosupplementation slightly decreased the weight percentage of 16:0 with a proportional increase in 18:0 leading to an unchanged weight percentage of total saturated fatty acids. These results suggest that, unlike lung tissue PL, the composition of saturated fatty acids in surfactant PL, particularly PC, is resistant to change by dietary AA and DHA supplementation. This, together with the unchanged concentration of total fatty acids in surfactant PC, indicates that LCPUFA cosupplementation causes no effect on pulmonary surfactant.

Paper no. L7980 in *Lipids 34,* 483–488 (May 1999).

Pulmonary surfactant is composed of lipoprotein complexes rich in phospholipids (PL), especially phosphatidylcholine (PC) (1). Among lipids, disaturated phosphatidylcholine (DSPC) accounts for approximately two-thirds of the total PC and is the major metabolically active component of lung surfactant (2). Surfactant lipids stabilize pulmonary alveoli and prevent alveolar collapse by reducing surface tension at the air-liquid interface (3). An insufficient amount of surfactant causes respiratory distress syndrome in both newborns and adults (4,5).

Surfactant content in alveoli is regulated by its synthesis and secretion by alveolar type II cells (6,7). The synthesis of PL, on the other hand, is dependent on the availability of fatty acids (8,9). Although fatty acid synthesized *de novo* contributes about 40% of DSPC production (8), dietary fatty acids presented to tissue *via* the circulation play an important role in modulating the quantity and composition of surfactant lipids (10). Similar to tissues such as liver, heart, kidney and brain, lung tissue fatty acid content is responsive to dietary lipids (11–16). Thus, it is not surprising that supplementation with long-chain polyunsaturated fatty acids (LCPUFA) of the n-6 and n-3 families—including arachidonic acid (AA, 20:4n-6), eicosapentaenoic acid (EPA, 20:5n-3), and docosahexaenoic acid (DHA, 22:6n-3)—increased the corresponding fatty acids and increased the level of total unsaturated fatty acids of lung tissue PL (11–14). Despite the extensive studies with lung tissue little is known about the impact of dietary LCPUFA on surfactant PL.

DHA and AA are integral components of retina and neural tissue and are considered to be essential for growth and development in humans and animals (17,18). Accordingly, supplementation of LCPUFA has been studied to determine if dietary DHA and AA benefit neurodevelopment of human infants (19–24). In these studies, such supplementation increased LCPUFA concentrations in plasma and erythrocytes of human infants (19–24). Animal studies, on the other hand, showed that aside from an increase in LCPUFA in blood, the supplementation enhanced accretion of the fatty acids in the brain and liver leading to increased unsaturation of PL (16,25,26). Since increased unsaturation of surfactant PC could potentially perturb the respiratory function of pul-

monary surfactant (1), the present experiments were undertaken to determine whether LCPUFA supplementation in milk formula alters fatty acid composition and the degree of saturation of surfactant PL. To this end infant rats were artificially fed milk formula *via* an intragastric tube as described previously (16). The results showed that, unlike lung tissue PL, the fatty acid composition of surfactant PC and other PL is resistant to change by dietary AA and DHA.

MATERIALS AND METHODS

Animals. Pregnant Sprague-Dawley rats obtained from Harlan Sprague-Dawley (Indianapolis, IN) were housed in individual plastic containers. Water and food (Purina Rat Chow, Ralston Purina, St. Louis, MO) were available to the dams at all times. For each experiment, newborns from four pregnant rats were delivered naturally, culled to 10 pups per dam within 24 h postpartum, and were nourished by their dams until the beginning of artificial rearing (AR). At 7 d of age, one or two weight-matched rat pups from each litter were assigned to one of three AR groups. Thus, each group consisted of rat pups derived from four dams. In the first series of experiments, three groups of infant rats were fed rat milk formulas (RMF) which contained 0, 0.5, and 1.0% AA as a percentage of the total fatty acids. The second experiment featured three RMF that contained 0, 0.5, and 1.0% DHA. In the third series of experiments infant rats were fed RMF cosupplemented with AA and DHA at concentrations of 0:0, 0.5:0.3, or 1.0:0.6% for AA and DHA, respectively.

AR system. Artificially reared infant rats were used throughout the study. The detailed account of AR has been previously described (16). Briefly, at the age of 7 d infant rats were permanently implanted with intragastric cannulae, connected to a semiautomatic feeding pump, and fed intragastrically for 15 min each hour. The intragastric cannulation on day 7 after birth was essential to ensure the survival of the pups during the course of AR. The pups were weighed daily between 0930 and 1100 in the animal care room. All animal care and surgical procedures were in accordance with protocols established by the Institutional Animal Care and Use Committee of The Pennsylvania State University.

The RMF were adopted from that of Auestad *et al.* (27). As described in the previous study (16), all formulas contained 11.8% fat (w/w) consisting of fat from milk formula base (3.4%), medium-chain triglycerides (2.8%), and corn oil plus microbial oil (6.4%). A fungal source of AA (i.e., Microbial oil A) and an algal source of DHA (i.e., Microbial oil B) were employed (Martek Bioscience, Columbia, MD). Microbial oil A consisted of 23.4% 18:1n-9, 17.7% AA, 16.3% 16:0, 15.1% 18:0, 11.5% 18:2n-6, but no DHA and EPA. Microbial oil B contained 41.9% DHA, 19.1% 16:0, 15.5% 14:0, 13.8% 18:1n-9, but no AA and EPA. All RMF contained micro- and macronutrients comparable to those found in rat milk (27). Upon the completion of the preparation, RMF were degassed with nitrogen and allocated into 100-mL plastic bottles for storage at −20°C. The formulas were rehomogenized daily immediately prior to feeding.

Tissue preparation and lipid analysis. The AR system provides a useful model to investigate the effects of nutrients on postnatal development of the rat. In a series of studies we evaluated the effects of exogenous LCPUFA on brain lipid metabolism (16). In addition, lung tissues were obtained from the same study to assess whether highly unsaturated fatty acids provided in the diet alter the degree of saturation of lung tissue and surfactant PL. Artificial feeding was terminated at the age of 17 d (i.e., 10 d after AR began) when the rat is known to have reached the peak of brain myelination (28). On the day of termination the brain, liver, and lung were excised from the rat pups under anesthetic state after intraperitoneal injection of pentobarbital (5 mg/100 g body weight). Immediately after the removal, tissues were rinsed in 0.9% saline, blot-dried, frozen in liquid nitrogen, and then stored at −80°C until subsequent analyses. The brain and liver were analyzed for fatty acids as reported elsewhere (16). In the present study, lipids were extracted from lung tissues with chloroform/methanol (2:1, vol/vol) by the procedure modified from that of Folch *et al.* (29). In a series of experiments, surfactant isolated from lung tissue was used for lipid extraction. Lung tissues were homogenized using a Ten-Broek homogenizer, and surfactant was isolated by the method of Frosolono *et al.* (30) as modified by Sanders and Longmore (31). The extracted lipids were separated into lipid classes by thin-layer chromatography using Silica Gel H plates and a solvent system consisting of hexane/ethyl ether/glacial acetic acid (80:20:1; by vol) (32). After the plates had dried, they were exposed to iodine vapor to identify total PL with standards. For analysis of PL species, the lipid extracts were separated into PC and phosphatidylethanolamine (PE) as described elsewhere (16). The isolated PL and PL species were scraped into ampules and immediately transmethylated with 12% boron trifluoride in methanol (wt/vol). Heptadecanoate (100 µg) was added to the transmethylation ampule as an internal standard. The sealed ampules were heated at 100°C in a heating block for 30 min. The methylated fatty acids were analyzed by using a gas chromatograph (Model 5890 Series II; Hewlett-Packard, Palo Alto, CA) equipped with a fused-silica capillary column (SP-2330, 30 m × 0.25 mm, 20 µm film; Supelco, Inc., Bellefonte, PA). The gas chromatographic analyses were performed under the following conditions: column temperature, 150°C; injector temperature, 220°C; detector temperature, 250°C; flow rate of the carrier gas (helium), 21.4 mL/min; and a split ratio of 76:1. Appropriate methyl ester standards (Supelco, Inc., Bellefonte, PA) were used to identify fatty acids. Fatty acid composition was expressed as weight percentage (wt%) of total fatty acids or µg fatty acid/g tissue.

Data and statistical analysis. All statistical analyses were performed on an IBM PS/2 computer using Minitab 10.1 (Minitab, Inc., State College, PA). Data were expressed as mean ± SD, and significance was assigned at $P < 0.05$. Difference in values among experimental groups was analyzed by one-way analysis of variance, and Tukey's pairwise com-

parisons were used to identify where the difference existed (33).

RESULTS

Rat milk formulas were analyzed for fatty acids. As expected, the formulas supplemented with AA, or DHA, or AA plus DHA were enriched with the respective fatty acids (Table 1). The actual wt% of AA (i.e., 0.4 and 1.1%) and of DHA (i.e., 0.5 and 0.9%) were close to the targeted 0.5 and 1.0%, respectively (Table 1). Similarly, the AA to DHA ratios of 0.5:0.3 and 0.9:0.5 in AA- and DHA-supplemented formula were the same as or close to the expected target ratio of 0.5:0.3 and 1.0:0.6. There was no significant difference in other fatty acids except a decrease in 18:2n-6 in AA-supplemented formula, and a slight reduction in 18:1n-9 in 1.0% DHA-supplemented formula. The supplementation did not affect the sum of saturated fatty acids and of polyunsaturated fatty acids.

At 7 d of age infant rats were weight-matched and randomly assigned to three groups for AR. After 10 d of feeding of RMF supplemented with or without AA plus DHA, the body weights ranging from 32.6 to 34.6 g, and lung weights ranging from 0.37 to 0.38 g were comparable among the three groups (Table 2). These values resulted in unaltered lung to body weight ratios. Comparable body weights were also noted in the experiments in which infant rats were fed diets supplemented with or without AA, or DHA alone (data not shown).

Total PL of lung tissue contained 43% palmitate (16:0) as a portion of the total fatty acids in infant rats fed the unsupplemented formula (Table 3). The supplementation with AA at 0.5 and 1.0% equally lowered the weight percentage of 16:0 and stearate (18:0) by 12–16% and 14–16%, respectively. Conversely, the AA supplementation resulted in higher weight percentages of AA and linoleate (18:2n-6) by 38–72% and 25–33%, respectively. These changes led to decreased total saturated fatty acids and increased total polyunsaturated fatty acids. The supplementation with DHA, on the other hand, did not alter fatty acids composition of total PL except that the weight percentage of DHA was higher in the supplemented groups than in the unsupplemented group (Table 3). Despite the small net change in weight percentage of DHA, total saturated and polyunsaturated fatty acids remained unchanged.

Table 4 shows the fatty acid composition of total PL and PL species isolated from pulmonary surfactant. The weight percentage of 16:0 was the highest in PC (71%), and the lowest in total PL (49%) in rat pups fed the unsupplemented RMF (Table 4). Conversely, the highest weight percentage of 18:0 was found in PE (24%) and the lowest in PC (5.5%). The cosupplementation with AA and DHA at either the 0.5:0.3 or the 1.0:0.6 ratio did not alter fatty acid composition of total PL. Similarly the cosupplementation did not change the composition of PC despite a slight increase of AA in the group supplemented with a high ratio of AA to DHA. The weight percentage of 16:0 in PE was lower in the cosupplemented groups by 11–12% than that of the unsupplemented counterparts. Also, the weight percentage of 20:2n-6 in PE was lower in the cosupplemented group than in the unsupplemented group. The observed reduction in 16:0 and 20:2n-6 was accompanied by an increase in 18:0. The sum of all saturated fatty acids was unchanged by dietary AA and DHA supplementation. The determination of the fatty acid concentration in surfactant isolated from 1 g of lung tissue disclosed that total fatty acids in PC were comparable in all three groups of infant rats (i.e., 400 ± 66 vs. 403 ± 12 vs. 415 ± 32 µg/g tissues). Similarly, fatty acid concentrations in PE and total PL remained unchanged by the AA and DHA cosupplementation.

DISCUSSION

Dietary fat is the most important determinant of tissue lipid both quantitatively and qualitatively. For example, a number of studies have shown that lipid composition of brain tissue

[a]Values expressed as weight percentage of total fatty acids are means ± SD for four samples. Fatty acids included only major saturated and unsaturated (n-9, n-6, and n-3) species, and hence did not add up to 100%. Values for each supplement with different superscript roman letter in the same row are significantly different at $P < 0.05$. AA, arachidonic acid; DHA, docosahexaenoic acid; SFA, saturated fatty acids; PUFA, polyunsaturated fatty acids.

TABLE 2
Body and Lung Weights of Infant Rats Fed Milk Formulas Containing Arachidonate and Docosahexaenoate[a]

	AA/DHA (%/%)		
	0:0	0.5:0.3	1.0:0.6
Body wt (g)	32.8 ± 1.9	34.6 ± 0.1	32.6 ± 1.1
Lung wt (g)	0.37 ± 0.05	0.38 ± .01	0.38 ± 0.02
Lung/body (%)	1.20 ± 0.11	1.10 ± 0.01	1.15 ± 0.07

[a]Values are means ± SD for four rats. Lung/body (%) = lung (g)/body weight (g) × 100. For abbreviations see Table 1.

(15,34,35), cells (36), and subcellular organelles (25,36) of infant rats reflected that of maternal diets. Specifically, the tissue and cellular levels of n-6 and n-3 LCPUFA were effectively enriched by the corresponding fatty acids presented in maternal diets (15,25,26,34–36). These fatty acids supplemented in rat milk formulas also were rapidly incorporated into various tissues (e.g., liver and brain) in artificially reared infant rats (16,25). The present study further determined the role of dietary fat in lung tissue and surfactant during postnatal development in AR model. Aside from many advantages of AR described elsewhere (16), the model permits evaluation of the direct impact of dietary nutrient on neonates without interference of maternal involvement.

Consistent with earlier studies by other investigators (11–14), the results of the present study showed that dietary AA increased the accretion of AA with a proportional decrease in saturated fatty acids, i.e., 16:0 and 18:0 in PL isolated from lung tissue. These changes led to a reduction in PL saturation as indicated by the decreased weight percentage of total saturated fatty acids and increased weight percentage of total polyunsaturated fatty acids. However, the supplementation of DHA had no such effect on saturation of lung tissue PL despite a slight increase in DHA accretion. Although the effect of cosupplementation with AA and DHA on lung tissue PL was not determined, the fatty acid composition and the level of saturation of surfactant PL was not altered by simultaneous supplementation with the two LCPUFA. An analysis of individual PL species of surfactant revealed that the cosupplementation with AA and DHA did not reduce the degree of saturation of PE or PC, which is the major component of surfactant lipids. This finding was consistent with our previous study which showed that fish oil rich in DHA and EPA did not decrease the proportion of saturated fatty acids

[a]Values expressed as weight percentage of fatty acids are means ± SD for four samples. Fatty acids included only major saturated and unsaturated (n-9, n-6, and n-3) species, and hence did not add up to 100%. Values for each phospholipid with different superscript roman letters in the same row are significantly different at $P < 0.05$. For abbreviations see Table 1.

in PL of alveolar type II cells (37). Clearly, unlike lung tissue PL, surfactant PL, especially PC, is resistant to modification by dietary AA and DHA. The reason for the differential effects on lung tissue and surfactant is not completely understood but may be attributed to the complex cellular organization of the lung, which is known to consist of more than 40 cell types (38). Surfactant is synthesized by alveolar type II cells which constitute only 14% of the total cell mass in the lung (38). It is reasonable to speculate that the lack of modification of surfactant PC by dietary LCPUFA may stem in part from preferential incorporation of saturated fatty acids into PC by alveolar type II cells. In support of such speculation, we showed that PL of alveolar type II cells were able to maintain the level of saturated fatty acids without increasing the sum of n-3 and n-6 LCPUFA by fish oil supplementation (37). Alternatively, the maintenance of PC saturation under the present experimental conditions may be achieved by the deacylation-reacylation mechanism by remodeling of *de novo* synthesized unsaturated PC (1).

The function of alveoli depends not only on the composition of surfactant PL but also on the amount of surfactant secreted onto alveolar space (39). It is therefore important to determine whether dietary AA and DHA influence the amount of surfactant present in the lung. Although no attempt was made in the present study to quantify surfactant, the constant concentration of total fatty acids measured in surfactant PC among three groups of infant rats strongly suggests that dietary LCPUFA did not reduce the quantity of lung surfactant. However, it is not known whether the findings of lung surfactant reflect that of alveolar surfactant. In an earlier study we demonstrated that fish oil fed to adult rats had no effect on mass of DSPC and unsaturated PC in alveolar surfactant isolated from lung lavage (37). This, together with the fact that tissue surfactant isolated in the present study represents extracellular and intracellular materials (31), led us to speculate that saturation of surfactant PC on the alveolar space remains unchanged by AA and DHA supplementation.

In summary, the neutral effect of the LCPUFA supplementation on lung surfactant observed in the present study lend support for n-6 and n-3 fatty acid supplementation to promote growth and development of infants (17,18).

Lipophilic Aldehydes and Related Carbonyl Compounds in Rat and Human Urine

Song-Suk Kim, Daniel D. Gallaher, and A. Saari Csallany*

Department of Food Science and Nutrition, University of Minnesota, St. Paul, Minnesota 55108

ABSTRACT: Rat and human urine samples were analyzed for lipophilic aldehydes and other carbonyl products of lipid peroxidation. The following compounds were identified as their 2,4-dinitrophenyl hydrazones by cochromatography with pure standards using three solvent systems: butanal, butan-2-one, pentan-2-one, hex-2-enal, hexanal, hepta-2,4-dienal, hept-2-enal, octanal, non-2-enal, deca-2,4-dienal, 4-hydroxyhex-2-enal, and 4-hydroxynon-2-enal. In general, fasted rats excreted less of these compounds than fed rats, indicating they were partially of dietary origin or that the endogenous compounds were excreted in a form not susceptible to hydrazone formation. The compounds excreted in human urine were similar to those excreted in rat urine but were present in lower concentrations. Identification of the conjugated forms of the lipophilic aldehydes and related carbonyl compounds excreted in urine may be a source of information about their reactions *in vivo*.

Paper no. L7533 in *Lipids 34,* 489–496 (May 1999).

The decomposition of lipid hydroperoxides in biological systems is accompanied by the formation of a variety of aldehydes and other carbonyl compounds. The main mechanism for their formation is the so-called β-cleavage reaction of lipid alkoxyl radicals (1). Recent evidence indicates that some saturated and unsaturated aldehydes, including malondialdehyde (MDA), hydroxyaldehydes and other short chain carbonyl compounds, contribute to peroxidative cell damage by reacting with sensitive biomolecules (2). Low molecular weight aldehydes such as 4-hydroxyalkenals and MDA are sufficiently long-lived to damage target molecules distant from the site of their formation (3,4). These aldehydes are capable of impairing protein function, inhibiting protein synthesis, causing cell lysis, and affecting cellular reproductive integrity (5–7). Recently, a lysine-4-hydroxynonenal adduct has been identified in an *in vitro* study on the modification of glucose-6-phosphate dehydrogenase by 4-hydroxynon-*trans*-2-enal (HNE) (8). Thus 4-hydroxyalkenals and other reactive carbonyl compounds formed by lipid peroxidation may be seen as secondary toxic messengers emanating from the initial free-radical event (9,10).

Studies on the formation of aldehydes other than MDA have concentrated on their *in vitro* production in whole cells (11,12), subcellular fractions (13,14), plasma and tissues (15) in response to prooxidant stimuli. A great variety of carbonyl compounds, including alkanals, alk-2-enals, 4-hydroxyalk-2-enals, alk-2,4-dienals, and alk-2-ones from ADP-Fe^{2+}-stimulated peroxidation of rat liver microsomes, has been characterized by Esterbauer and colleagues (16).

Few studies have been carried out on the *in vivo* formation of aldehydes other than MDA. The formation of HNE in rat liver was shown to be increased following administration of the prooxidants carbon tetrachloride, bromobenzene, or bromotrichloromethane (17,18), and in the renal cortex by administration of celiptium (19). Yoshino *et al*. (20) found that the concentrations of 4-HNE and hexanal in plasma and of HNE, hexanal, and pentanal in the liver of rats were significantly increased by vitamin E deficiency. Similarly, Dratz *et al*. (21) found elevated amounts of 4-hydroxyalkenals in the retinas of vitamin E-deficient rats and dogs. Goldring *et al*. (22) found 4-HNE in normal human plasma and Strohmaier *et al.* (23) in the plasma of humans with lung injury. Recently several endogenous saturated and unsaturated aldehydes such as 2-butenal, 2,4-pentadienal, hexanal, heptanal, octanal, 2-octenal, 2-nonenal, and decanal were found in significantly elevated levels in diabetic rat and human sera (24). Some of these compounds have been shown to be potent inhibitors of glycolytic enzymes such as phosphofructokinase and glyceraldehyde-3-phosphate dehydrogenase. Thiobarbituric acid-reactive substances in human urine include lipophilic alkadienals and/or alkanals as well as MDA (25). Based on the above observations, we see that a variety of aldehydes of medium chain length are produced as degradation products of lipid peroxidation *in vivo*. These aldehydes range from 4 to 10 carbons, may be saturated or unsaturated, and may be hydroxylated. The cell pathology of these lipophilic compounds is largely unknown. Identification of the free and conjugated forms of these aldehydes and carbonyl compounds excreted in the urine may, as in the case of MDA ([26]), provide information on the nature of their reactions *in vivo*.

In our previous studies, analysis of rat urine by high-performance liquid chromatography (HPLC) revealed the presence of several carbonyl compounds besides free and conjugated MDA and showed that the excretion of some of these compounds was increased in vitamin E deficiency (27). The objective of this study was to identify the lipophilic aldehydes and related carbonyl compounds excreted into urine of normal rats and human subjects.

MATERIALS AND METHODS

Chemicals. 2,4-Dinitrophenylhydrazine (DNPH) and hexanal were obtained from Sigma Chemical Company (St. Louis, MO); pentan-2-one (97%), hept-2-enal (97%), hepta-2,4-dienal (90%), decanal, and deca-2,4-dienal from Aldrich Chemical Co. (Milwaukee, WI); and hydrochloric acid and HPLC-grade acetone, methanol, dichloromethane, hexane, and water from EM Science (Gibbstown, NJ). DNPH derivatives of butanal, butanone, hexanal, octanal, non-2-enal, 4-hydroxyhex-2-enal, and 4-hydroxynon-2-enal were a gift from Dr. Hermann Esterbauer, University of Graz (Graz, Austria). Pentan-2-one, hept-2-enal, hepta-2,4-dienal, and deca-2,4-dienal DNPH derivatives were synthesized from pure standards and purified by repeated recrystallization from methanol. Silica gel thin-layer chromatography (TLC) plates (Silica gel 60, aluminum backed, 20 × 20 cm, 0.2-mm thickness) were purchased from Alltech Associates Inc. (Deerfield, IL).

Instrumentation. The HPLC system consisted of an Altex Model 110A solvent metering pump, an Altex Model 110A sample injector (Beckman Instruments, Berkeley, CA), a Spectra-Physics Model SP8400 ultraviolet/visible detector, and a Spectra-Physics Model SP4100 computing integrator (Spectra-Physics, Arlington, IL). The HPLC separations were performed on an Ultrasphere ODS C_{18} reversed-phase column (25 cm × 4.6 mm i.d., 5 µm particle size) (Altex, Berkeley, CA) with a 2 cm × 2 mm i.d. guard column (Chrom Tech, Apple Valley, MN). Disposable syringes were equipped with a 0.2 µm PUDF filter (Chrom Tech).

Animals, diets, and urine collections. Seven male Wistar rats (Harlan, Indianapolis, IN) weighing 165–190 g were fed standard AIN-76 semipurified diet (28). After 7 wk, urine was collected for 24 h without fasting. Nine Sprague-Dawley female weanling rats (Harlan, Indianapolis, IN) were fed a normal purified diet for 19 wk (29). They were then housed individually in stainless steel metabolic cages and fasted for 48 h with access to water *ad libitum*. Urine was collected during the second 24 h of fasting and stored at −70°C until analysis. Urine samples from nonfasting humans were collected from five healthy female subjects aged 20 to 40 yr.

Measurement of urinary lipophilic aldehydes and carbonyl compounds: Preparation of DNPH reagent. The reagent was prepared daily by a modification of the method of Esterbauer *et al*. (16). DNPH reagent (12.5 mg), recrystallized three times, was mixed with 25 mL of 1 N hydrochloric acid and the suspension was kept at 50°C for about 1 h. After cooling it was extracted four times with 20 mL of hexane to remove impurities. The purified DNPH reagent was used immediately.

Synthesis of 2,4-dinitrophenylhydrazones (DNP-hydrazones). Pentan-2-one, hexanal, hept-2-enal, hepta-2,4-dienal, decanal, and deca-2,4-dienal were synthesized by a method modified from Cheronis and Entrikin (30). DNPH (80 mg), 8 mL warm methanol, 0.2 mL 6 N hydrochloric acid, and 100 µL of an aldehyde standard were mixed and heated in a water bath at 60°C for 10 min. After cooling overnight at 4°C, 10 drops of water was added to induce crystallization. The fine crystals were filtered using a Büchner funnel and recrystallized from 20 mL of methanol.

Ultrafiltration of urine. Four milliliter aliquots of urine samples were filtered using an Amicon cell equipped with a YC05 Diaflo Ultrafilter (Amicon Corp., Beverly, MA) to remove compounds with a molecular mass larger than 500 daltons. The Amicon cell was pressurized to 50 psi with N_2 gas.

Isolation of DNP-hydrazones of urinary aldehydes and related compounds. The isolation and identification of the DNP-hydrazones was accomplished using a modification of the method of Esterbauer *et al*. (16). Three milliters of ultrafiltered urine samples was reacted with an equal volume of DNPH reagent. The reaction mixtures were mixed and incubated in the dark at room temperature overnight. The reagent blank and the acetone-DNPH standard were prepared as described above but instead of urine 3 mL DNPH reagent or 3 mL acetone/water (1:99 vol/vol) were used, respectively.

The urinary DNPH derivatives, the reagent blank, and the acetone-DNPH standard were each extracted three times with 3 mL of dichloromethane, and the organic phase was separated by centrifugation at 1360 × *g* for 10 min. The pooled extracts were evaporated to 500 µL under N_2 gas and applied to TLC plates.

The total dichloromethane extract (500 µL) was applied to a silica gel TLC plate, which was developed with dichloromethane for a preliminary separation. The nonpolar and polar carbonyl compounds were separated and located by comparison to the R_f values of acetone-DNPH (0.55) and purified DNPH reagent (0.23). The nonpolar carbonyl compounds (NONPOL) such as alkanals, alkenals, ketones and dienals were located between R_f 0.55 and the solvent front. Osazones were separated from NONPOL and polar carbonyl compounds (POL) on TLC between acetone-DNPH (R_f 0.55) and DPNH reagent (R_f 0.23) reference bands. POL, containing hydroxyl groups, were located between the origin and R_f 0.23. The nonpolar and polar regions were individually cut from the plates and eluted three times with 5 mL of methanol. The pooled methanol extracts of NONPOL and POL samples were centrifuged at 1360 × *g* for 20 min. The clear supernatant fractions were concentrated to about 300 µL under N_2 gas and made up to exactly 600 µL with methanol/water (50:50 vol/vol). Aliquots of the NONPOL and POL DNPH derivatives were then analyzed separately by HPLC using two different solvent systems.

Identification of DNPH derivatives. Aliquots (100 µL) of NONPOL-DNPH derivatives were injected onto an HPLC re-

versed-phase C_{18} column, equipped with a guard column, using isocratic elution for 10 min with methanol/water (75:25 vol/vol), followed by a linear gradient of methanol/water (75:25 vol/vol) to methanol for 30 min at a flow rate of 0.8 mL/min. Operating conditions for the HPLC separation of POL-DNPH derivatives were identical with those for NONPOL-DNPH derivatives except that methanol/water (50:50 vol/vol) was used as the starting eluent and the flow rate was 1.0 mL/min. Absorbance was monitored at 378 nm. Hexanal, hept-2-enal, and decanal DNP-hydrazones were used as standards to measure the reproducibility of the HPLC system before the application of samples.

Identification of individual urinary NONPOL and POL compounds was accomplished by cochromatography in HPLC solvent systems of different polarities. The retention times of the DNPH derivatives of the carbonyl standards were established in three different solvent systems according to their polarity (Table 1). The DNPH derivatives of the urinary compounds were tentatively identified by comparing their retention times with those of standards. Further evidence of identity was obtained by cochromatography using three solvent systems. The quantity of standard added was selected so as not to increase the peak area of the DNPH derivatives more than two times. Hexanal DNP-hydrazone standard was used to estimate the recovery of the urinary NONPOL and POL. To 3 mL of urine 7.6 µg of pure hexanal-DNPH standard was added and the percentage recovery was calculated from the resulting increase in peak area.

[a]The three solvent systems used for cochromatography of the nonpolar and polar carbonyl compounds are indicated by an asterisk.

Statistical analysis. Student's unpaired, two-sided *t*-test was used to test the significance of differences between the values obtained in nonfasted female and fasted male animals. The data were normally distributed and showed equality of variances and therefore were expressed as the mean ± SEM. The level of statistical significance employed was $P < 0.05$.

RESULTS AND DISCUSSION

Typical HPLC chromatograms obtained for the DNPH derivatives of the nonpolar and polar compounds in rat urine are presented in Figures 1 and 2, respectively. The NONPOL and POL DNPH derivatives were well separated on the C_{18} reversed-phase column. The results of cochromatography of standard hexanal-DNPH and HNE-DNPH with their urinary counterparts are illustrated in Figures 3 and 4. The retention times of the standards (Figs. 3A and 4C) corresponded exactly with those of the DNPH derivatives of urinary origin (Figs. 3C and 4B). Mixing the derivatives of the urinary compounds with the standards resulted in coelution (Figs. 3B and 4A). Similar results were obtained using three solvent systems of different polarity (Table 1). In each case, the peak area for the mixture of compounds approximated the sum of the peak areas for the standards and the urinary metabolites (Table 2). By using these criteria the following urinary NONPOL were tentatively identified: butanal, butan-2-one, pen-

[1]Calculation: $a/(b + c)$, where a = area from the cochromatography of urinary compound plus standard; b = area of urinary compound; c = area of standard. Values represent mean of duplicate samples.

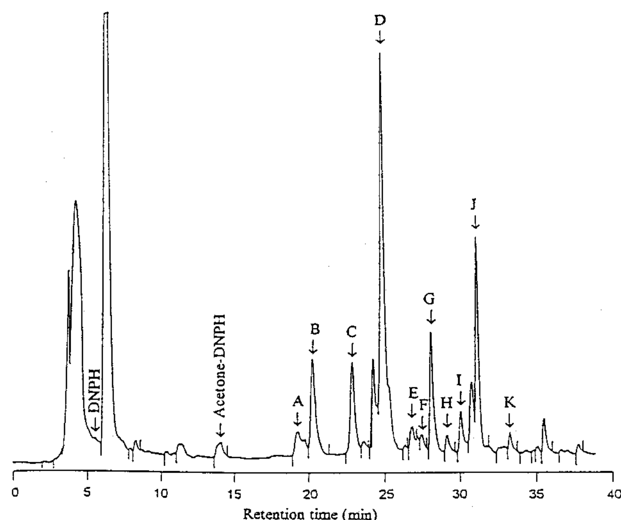

FIG. 1. High-performance liquid chromatography (HPLC) separation of 2,4-dinitrophenylhydrazine (DNPH) derivatives of urinary nonpolar aldehydes and carbonyl compounds from fasted male rats. A, butanal; B, butan-2-one; D, pentan-2-one; F, hex-2-enal; G, hexanal; H, hepta-2,4-dienal; I, hept-2-enal; K, octanal; C, E and J, unidentified. Absorbance was monitored at 378 nm.

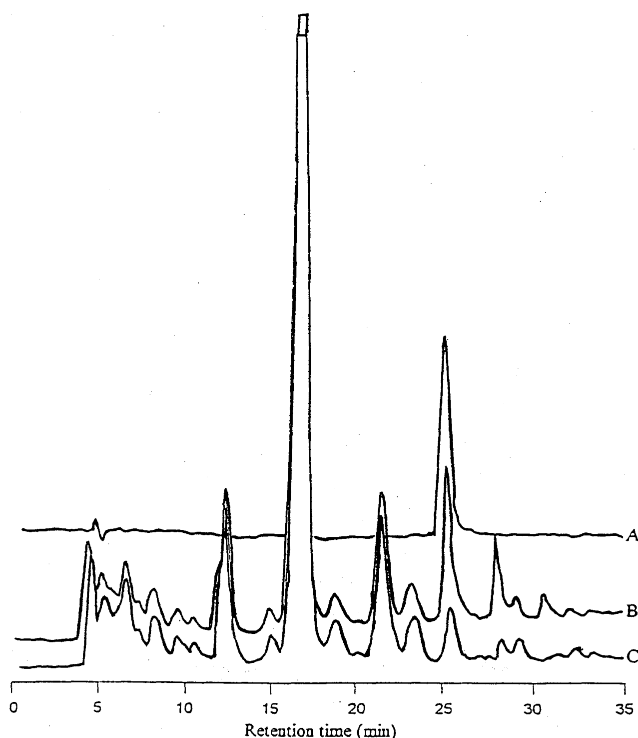

FIG. 3. Cochromatography of DNPH derivatives of urinary hexanal with hexanal standard. A, hexanal standard; B, cochromatogram of urinary nonpolar carbonyl compounds with hexanal standard; C, urinary nonpolar carbonyl compounds. Absorbance was monitored at 378 nm. For abbreviation see Figure 1.

tan-2-one, hexanal, hex-2-enal, hept-2-enal, hepta-2,4-dienal, octanal, non-2-enal, and deca-2,4-dienal. The hydroxyaldehydes 4-hydroxyhex-*trans*-2-enal and HNE also were tentatively identified. Some nonpolar and polar compounds were not identified because of a lack of appropriate standards.

In general, nonfasted male animals excreted higher levels of NONPOL and POL than fasted females (Figs. 5 and 6). Although these two groups were of opposite sexes, several studies suggest sex is unlikely to have influenced the excretion of NONPOL and POL. Rats chronically fed ethanol had greatly elevated hepatic MDA concentrations; however, these concentrations were not influenced by sex (31). Similarly, in a

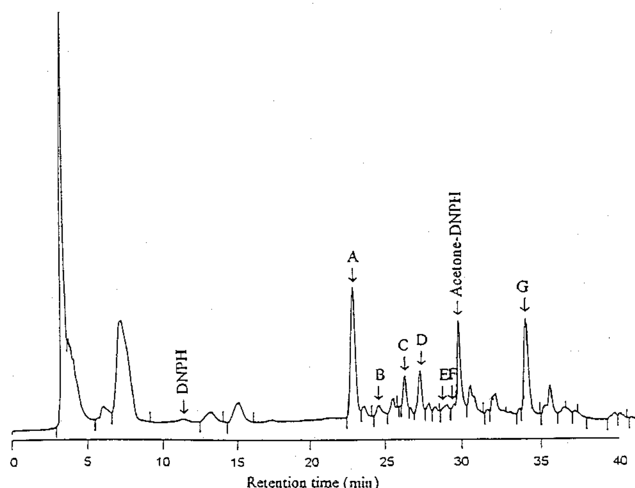

FIG. 2. HPLC separation of DNPH derivatives of urinary polar aldehydes and carbonyl compounds from fasted male rats. E, 4-hydroxyhex-2-enal; A, B, C, D, F and G, unidentified. Absorbance was monitored at 378 nm. For abbreviations see Figure 1.

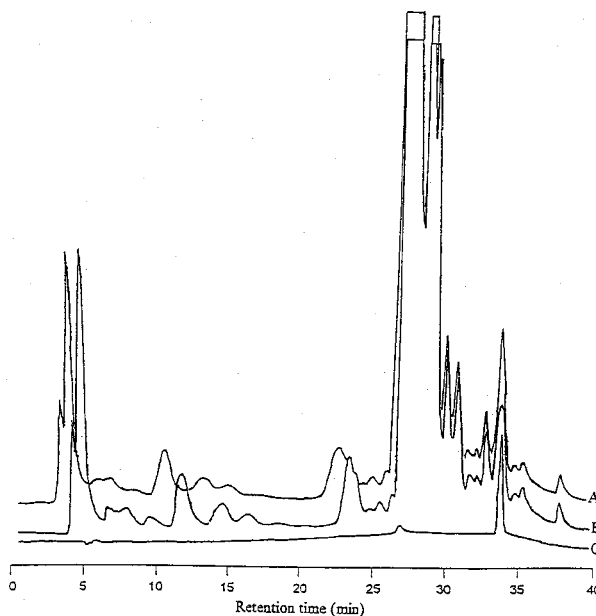

FIG. 4. Cochromatography of DNPH derivatives of nonfasted female rat urinary 4-hydroxynon-2-enal with 4-hydroxynon-2-enal standard. A, cochromatogram of urinary polar compounds with 4-hydroxynon-2-enal standard; B, urinary polar carbonyl compounds; C, 4-hydroxynon-2-enal standard. Absorbance was monitored at 378 nm. For abbreviation see Figure 1.

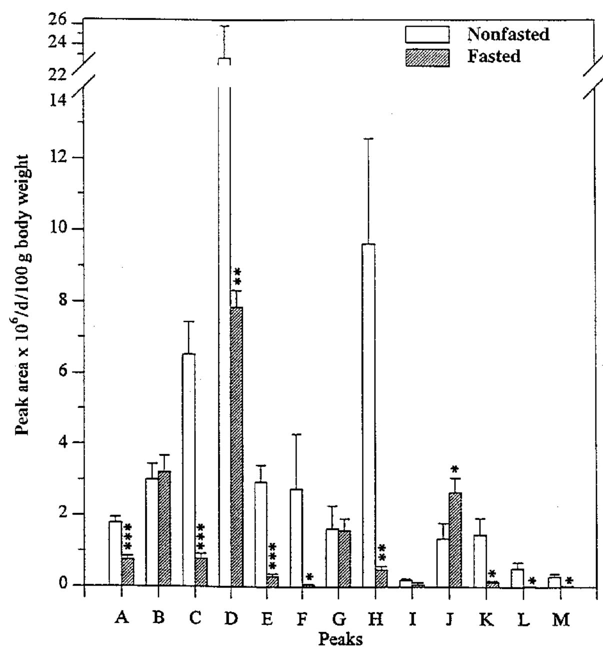

FIG. 5. Urinary excretion of nonpolar carbonyl compounds in nonfasted female and fasted male rats measured as DNPH derivatives. A, butanal; B, butan-2-one; F, hex-2-enal; G, hexanal; H, hepta-2,4-dienal; I, hept-2-enal; K, octanal; L, non-2-enal; M, deca-2,4-dienal; C, E and J, unidentified. Values represent mean ± SEM for $n = 7$ and $n = 9$, respectively, in nonfasted and fasted animals. Statistical significance of difference is determined by Student's *t*-test; $^*P < 0.05$, $^{**}P < 0.005$, and $^{***}P < 0.0001$. For abbreviation see Figure 1.

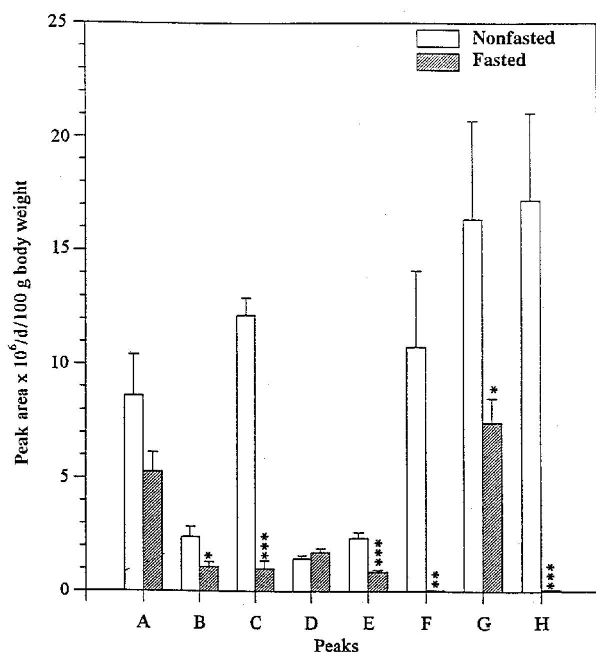

FIG. 6. Urinary excretion of polar carbonyl compounds in nonfasted female and fasted male rats measured as DNPH derivatives. E, 4-hydroxyhex-2-enal; H, 4-hydroxynon-2-enal; A, B, C, D, F, and G, unidentified. Values represent mean ± SEM of 7 and 9 animals in Experiments I and II, respectively. Statistical significance of difference is determined by Student's *t*-test; $^*P < 0.05$, $^{**}P < 0.01$, and $^{***}P < 0.001$. For abbreviation see Figure 1.

study of thiobarbituric acid reactivity in human urine, no differences due to sex were noted (32). Significant differences in NONPOL excretion were found for A, butanal; D, pentan-2-one; F, hex-2-enal; H, hept-2-enal; K, octanal; L, non-2-enal; M, deca-2,4-dienal and the unidentified compounds C, E, and J. No significant differences were found for B, butan-2-one; G, hexanal; and I, hept-2-enal (Fig. 5). The unidentified compound J was the only NONPOL compound that was significantly higher in the urine of fasted animals. Significant differences in the excretion of the following POL were found between nonfasted male and fasted female animals: E, 4-hydroxyhex-*trans*-2-enal; H, HNE and the unidentified compounds B, C, F, and G. Unidentified compound A tended to be lower in fasted animals but the difference was not significant (Fig. 6). The source of the increased urinary POL and NONPOL in the fed animals is possibly dietary fat. It has been shown in rats that secondary lipid oxidation products of linoleic acid are largely excreted in the urine (33).

The virtual disappearance of HNE in the urine of the fasted animals is noteworthy, as it is unlikely that none is formed *in vivo*. This observation suggests that HNE is excreted in a form that is not susceptible to hydrazone formation. This possibility is supported by the findings of Alary *et al.* (34), who showed that HNE is conjugated with glutathione in the rat and excreted as mercapturic acid conjugates. It is also possible that HNE is bound firmly to proteins and not released into the urine. The preponderance of stable Michael-type addition products to proteins over the easily hydrolyzable Schiff base adducts of α-β unsaturated aldehydes such as HNE was demonstrated by Bruenner *et al.* (35). Uchida and Stadtman (36) reported a similar type of stable addition of HNE to histidine. Szweda *et al.* (37) described the formation of a stable secondary lysine-HNE adduct between the ε-amino group of a lysine residue, in glucose 6-phosphate, and the double bond of HNE.

When the urinary NONPOL and POL were summed, highly significant differences were found between the results for nonfasted male and fasted female animals (Fig. 7). This difference indicates that some of the POL and NONPOL found in the urine may have originated in the diet. In both experiments, significantly greater amounts of POL than NONPOL were excreted in the urine ($P < 0.05$ for both nonfasted and fasted animals).

The chromatographic patterns for NONPOL and POL in human urine were similar to those for rat urine (Figs. 8 and 9) except for a relatively higher level of the peak coeluting with the hexanal-DPNH standard and a lower level of the one corresponding to pentan-2-one. These differences may be due to the differences in the aldehydes and carbonyls coming from dietary fats. The distribution of lipophilic compounds found for rat and human urine is similar to that reported by Esterbauer *et al.* (16) for microsomes peroxidized by treatment with ADP-Fe^{2+} (Table 3). Similar lipophilic POL and NONPOL have been detected *in vitro* by other investigators (11,13). The formation of HNE and 4-hydroxy-*trans*-2-hexenal in peroxidizing tissues has been documented by several investigators (38,39). 4-Hydroxyoctenal, 4-hydroxydece-

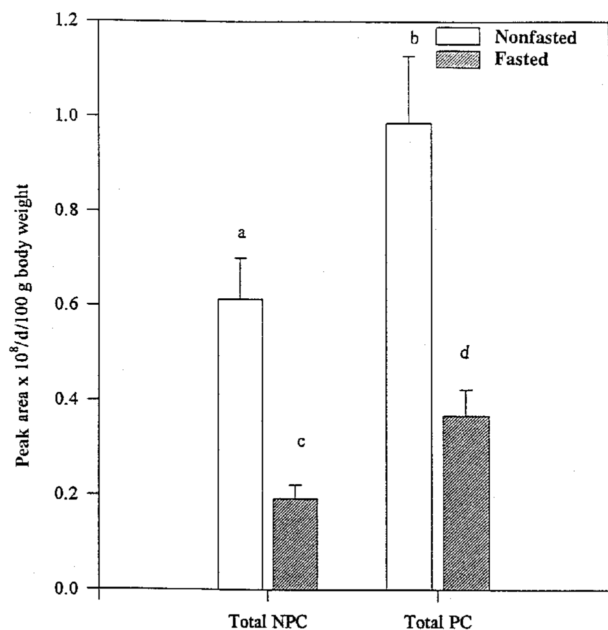

FIG. 7. Urinary excretion of total, HPLC separated, nonpolar (NPC) and total polar (PC) carbonyl compounds in nonfasted female and fasted male rats measured as DNPH derivatives. Values represent mean ± SEM of $n = 7$ and $n = 9$, respectively, in nonfasted and fasted animals. Statistical significance of difference is determined by Student's *t*-test; a vs. b, $P < 0.05$; c vs. d, $P < 0.05$; a vs. c, $P < 0.001$; b vs. d, $P < 0.001$. For other abbreviations see Figure 1.

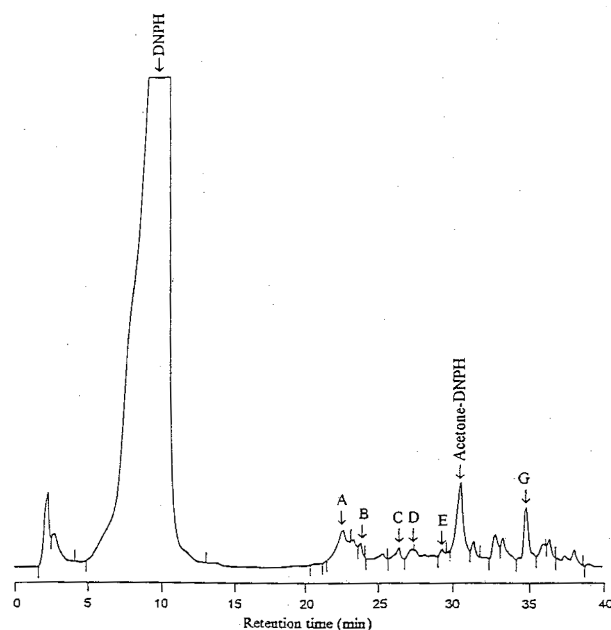

FIG. 9. HPLC separation of DNPH derivatives of urinary polar aldehydes and carbonyl compounds from a representative nonfasted human subject. E, 4-hydroxyhex-2-enal; A, B, C, D, and G, unidentified. Absorbance was monitored at 378 nm. For abbreviations see Figure 1.

nal, and 4-hydroxyundecenal have been detected in peroxidizing liver microsomes (40) and 5-hydroxypentanal in plasma and liver of normal rats (41). In addition to hydroxyaldehydes, hexanal is formed in foods and animal tissues as a product of the peroxidation of n-6 polyunsaturated fatty acids (12,15) along with various alkanals, alkenals, and alkadienals as products of n-6 and n-3 PUFA oxidation (42,43). Recently the α-hydroxyaldehydes 2-hydroxyheptenal and 2-hydroxyhexanal were identified in bovine lipids (44). Kaneko *et al.* (45) found that the lethal effect of hydroxyaldehydes is enhanced with increases in chain length and unsaturation.

The present findings indicate that there is a general similarity between the lipophilic products of lipid peroxidation formed *in vivo* and those formed *in vitro*. Identification of the conjugates of the lipophilic carbonyl compounds excreted in urine may provide valuable information on the nature of their reactions *in vivo*, as has been the case with MDA (26).

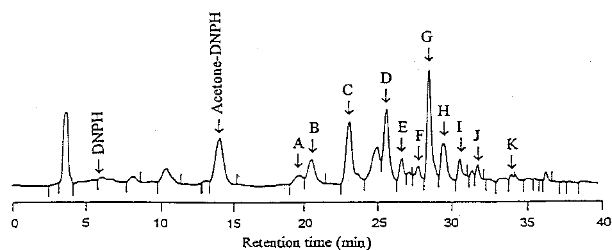

FIG. 8. HPLC separation of DNPH derivatives of urinary nonpolar aldehydes and carbonyl compounds from a representative nonfasted human subject: A, butanal; B, butan-2-one; D, pentan-2-one; F, hex-2-enal; G, hexanal; H, hepta-2,4-dienal; I, hept-2-enal; K, octanal; C, E, and J, unidentified. Absorbance was monitored at 378 nm. For abbreviations see Figure 1.

Fenofibrate Protects Lipoproteins from Lipid Peroxidation: Synergistic Interaction with α-Tocopherol

Evelyne Chaput, Dominique Maubrou-Sanchez, François D. Bellamy, and Alan D. Edgar*

Laboratoires Fournier, Department of Atherosclerosis, 21121 Daix, France

ABSTRACT: One of the earliest steps of atherosclerotic plaque formation is an increase of circulating apolipoprotein B-containing lipoproteins which, after infiltrating the subendothelial space, undergo oxidative modification. Fenofibrate is an effective cholesterol- and triglyceride-lowering agent which has been shown to be beneficial in the treatment of atherosclerosis. Vitamin E, or α-tocopherol, is a powerful antioxidant which has been shown in a variety of studies to prevent lipoprotein peroxidation. The purpose of the present study was to investigate the effect of fenofibrate treatment, either alone or in combination with α-tocopherol, in reducing the susceptibility of lipoproteins to oxidative modification. Rats fed a normal diet were treated for up to 27 d with fenofibrate, either alone or in combination with equimolar doses of α-tocopherol. Combined VLDL (very low density lipoproteins) and LDL (low density lipoproteins) isolated after fenofibrate treatment were more resistant to copper-mediated oxidation, as assessed by conjugated diene formation. Lag time was prolonged up to 3.2-fold, while the maximal rate of diene production was significantly decreased by up to 2.2-fold. Treatment of rats with α-tocopherol alone at the selected dose had no significant effect on lag time, while the propagation rate was slightly decreased. Coadministration of fenofibrate with α-tocopherol prolonged the lag phase to a greater extent than fenofibrate alone, showing a synergistic interaction between the two compounds. Finally, the combination of fenofibrate and α-tocopherol was significantly more effective in modifying lipoprotein oxidation parameters than what was observed with α-tocopherol and bezafibrate or gemfibrozil. Thus, in addition to its well-established effects on lipoprotein concentrations and atherogenic parameters, fenofibrate reduces the susceptibility of VLDL and LDL to oxidative modification and exerts its action synergistically with α-tocopherol.

Paper no. L8075 in *Lipids 34,* 497–502 (May 1999).

Atherosclerosis is a multifactorial disease, the incidence of which is still increasing in Western society, along with being a marker disease of emerging affluence for developing countries (1). In accordance with metabolic diseases of aging, characterized by slow progression and irreversible oxidative alteration of biological parameters, the role of low density lipoprotein (LDL) modification in atherogenesis has been evoked (2). While the antioxidant defense mechanisms present in serum are sufficient under most conditions to prevent modification of circulating lipoproteins, LDL having diffused to the subendothelium may no longer be resistant to oxidation. Furthermore, alterations in LDL metabolism may alter its half-life and resident time in the arterial lumen (2,3).

Fenofibrate is a member of the fibrate class of lipid-lowering drugs (4) and its mechanism of action derives from activation of the peroxisome proliferator-activated receptor α (PPARα) (5). PPARα, as well as its congener PPARγ, are members of the steroid hormone nuclear receptor super family and have the potential to interact with several proteins, including RXRα, NF-κB and HSP72, leading to the modification of the expression of a wide variety of genes of intermediate metabolism (5–7). PPARα differs from PPARγ by its pattern of tissue expression as well as the nature of its endogenous ligands (5,8,9).

Hepatic and vascular expression of PPARα has the potential to favorably alter several aspects of atherogenesis (5,10). In the liver, activated PPARα modifies a panel of genes linking fatty acid, cholesterol, and glucose metabolism (5). In macrophages and smooth muscle cells, PPARα activators, including fenofibrate, have been shown to have an antiinflammatory effect and promote apoptosis (10–12). The role of PPARγ in atherogenesis is still uncertain as both pro- and antiatherogenic functions have been suggested (7,13).

In addition to lowering apolipoprotein β-containing lipoproteins in man, fenofibrate has been shown to alter the quantity of small, dense LDL (14). This latter subfraction of LDL is particularly susceptible to oxidative modification and is present in increased concentration in Type II diabetics (15). While essentially all lipid and protein components of LDL are subject to peroxidative modification, it is currently unknown which molecular components of LDL confer antioxidant protection or susceptibility (16). The effects of fenofibrate on liver apolipoprotein as well as macrophage and smooth muscle cell antiinflammatory gene expression have been well characterized, as have the effects on the quantity of small, dense LDL. Little is known concerning the ability of fenofibrate to qualitatively modify the intrinsic antioxidant potential of lipoproteins. In an initial study to explore the utility of associating a lipid-lowering drug with a known antioxidant, we attempted to determine the potential of fenofibrate

to retard the extent and rate of lipoprotein modification when administered alone or with vitamin E. We next determined whether effects were strictly fibrate class effects or dependent upon the individual fibrate, by comparing fenofibrate with bezafibrate and gemfibrozil.

EXPERIMENTAL PROCEDURES

Animals and treatments. Male Sprague-Dawley rats weighing approximately 230–250 g were obtained from Iffa-Credo (L'Arbresle, France). Animals were fed a standard pelleted chow (Ets Piètrement, Provins, France) with tap water *ad libitum*, and were housed under light and dark cycles of 12 h each.

Rats were treated for 3, 8, 15, or 27 d with equimolar doses of fenofibrate (43 mg/kg/d, Laboratoires Fournier, Daix, France), *d,l*-α-tocopherol acetate (55 mg/kg/d; Sigma Chemical Co., St. Louis, MO), or both. Drugs were administered once daily by oral gavage in soybean oil. Control rats received drug vehicle alone (2 mL/kg/d).

In a second experiment, groups of rats were given *d,l*-α-tocopherol acetate (55 mg/kg/d) either alone or in combination with equimolar doses of fenofibrate (43 mg/kg/d), bezafibrate (42 mg/kg/d, Sigma Chemical Co.) or gemfibrozil (29 mg/kg/d, Sigma Chemical Co.) in soybean oil for 15 d by gastric intubation. Control animals received vehicle alone (2 mL/kg/d).

At the end of the experiments, rats were fasted for 5 h and then anesthetized with sodium pentobarbital. Blood was collected from the abdominal aorta on EDTA (1 mg/mL). Plasmas were separated by low-speed centrifugation and pooled by two in order to carry out all the measurements foreseen.

Lipoprotein isolation. Combined very low density lipoproteins (VLDL) and LDL were isolated from plasma by density gradient ultracentrifugation. Briefly, 4 mL plasma was adjusted to density 1.050 g/mL with solid KBr and overlaid with 4 mL of a solution containing NaCl (9 mg/mL), EDTA (1 mg/mL) and KBr at a density of 1.050 g/mL. Samples were centrifuged [22 h, 15°C, 134,000 × *g* ($r_{av.}$ 5.91 cm)] in a Beckman 50Ti fixed-angle rotor in a Beckman L8-M ultracentrifuge (Beckman Instruments Inc., Palo Alto, CA). The top layer of each tube was harvested by aspiration using a Pasteur pipette and kept at 4°C in the dark in a nitrogen atmosphere until use.

Lipoprotein oxidation. The isolated VLDL + LDL fraction was dialyzed at 4°C in the dark against three changes of Dulbecco's phosphate-buffered saline solution without Ca^{2+} and Mg^{2+}. EDTA was present during the two first changes at a concentration of 10 μM. Lipoproteins from the various treatments were diluted in phosphate-buffered saline to a common protein concentration of 20 μg/mL, and oxidation was initiated by the addition of 5 μM $CuSO_4$. Conjugated diene formation was monitored by recording the absorbance at 234 nm at 37°C at 10-min intervals over 10 h with a Shimadzu UV-160A spectrophotometer (Shimadzu Corporation, Kyoto, Japan). Lag time and maximal rate of conjugated diene production were calculated as previously described by Esterbauer *et al.* (17). The length of the lag phase was defined as the intercept with the time scale axis of the absorbance curve during the propagation phase, while the maximal rate of conjugated diene formation was calculated from the slope of the absorbance curve during the propagation phase. Lag phase was expressed in minutes, and propagation rate as nanomoles of conjugated dienes formed per minute per milligram protein, using a molar extinction coefficient for conjugated dienes of $2.95 \times 10^4\ M^{-1}\ cm^{-1}$ (18).

Biochemical analysis. Total cholesterol, triglyceride, and phospholipid levels in plasma and isolated lipoproteins were determined using assay kits from Biomérieux (Marcy-l'Etoile, France). Proteins were measured by the method of Lowry, as modified by Markwell *et al.* (19).

Statistical analysis. Results were expressed as mean ± standard deviation. Statistical differences between treatment groups were established by variance analysis followed by Student's *t*-test, using Statistical Analysis System software (SAS Institute Inc., Cary, NC). Differences were considered significant if $P \leq 0.05$.

RESULTS

Effect of fenofibrate and α-tocopherol on plasma lipid levels in rats. Fenofibrate and α-tocopherol acetate were administered either individually or in combination to rats for 3, 8, 15, or 27 d. There was no evidence of altered growth rate in rats as measured by body weight after 27 d of treatment compared to controls (data not shown). As expected, plasma total cholesterol levels were significantly reduced after fenofibrate administration. Modifications varied from −31 to −40%, and as is routinely seen in rats (20), reductions were in high density lipoprotein levels and not apolipoprotein B-containing lipoproteins (results not shown), and were already maximal after 3 d of treatment (Table 1). Phospholipid levels were initially decreased by the drugs at 3 and 8 d of treatment, but returned to control values by 15 d of drug administration. Triglyceride concentrations were not significantly affected by treatment. Administration of α-tocopherol alone had no effect on plasma lipid parameters while coadministration of α-tocopherol and fenofibrate gave similar modifications of plasma parameters as observed with fenofibrate alone.

A β-lipoprotein fraction, containing VLDL and LDL (VLDL + LDL) was isolated. Mean levels of total cholesterol and triglyceride in this fraction were not modified by fenofibrate, when administered either alone or in combination with α-tocopherol (data not shown). No modification of the above parameters could be observed after administration of α-tocopherol alone.

Effect of fenofibrate and α-tocopherol on VLDL + LDL oxidation in vitro. The kinetics of oxidation of the VLDL + LDL fraction were studied by monitoring the formation of fatty acid conjugated dienes at 234 nm. VLDL + LDL lipoproteins from the fenofibrate group exhibited an increased lag time and a much slower rate of oxidation, compared with controls (Fig. 1). The lag phase was 2.7-fold

TABLE 1
Influence of Fenofibrate, α-Tocopherol, and Their Combination on Plasma Lipid Levels[a]

Treatment	Days	Total cholesterol	Phospholipids	Triglycerides
Control	3	0.81 ± 0.07	1.33 ± 0.07	0.65 ± 0.24

α-Tocopherol		0.65 ± 0.10	1.30 ± 0.15	0.86 ± 0.20
Fenofibrate		0.41 ± 0.05[b]	1.23 ± 0.05	0.69 ± 0.12
Fenofibrate + α-tocopherol		0.39 ± 0.05[b]	1.23 ± 0.10	0.71 ± 0.20
Control	27	0.70 ± 0.10	1.46 ± 0.12	1.16 ± 0.12
α-Tocopherol		0.65 ± 0.07	1.35 ± 0.12	0.94 ± 0.27
Fenofibrate		0.43 ± 0.05[b]	1.29 ± 0.10	1.24 ± 0.56
Fenofibrate + α-tocopherol		0.41 ± 0.12[b]	1.30 ± 0.17	0.99 ± 0.27

[a]Rats were given co-micronized fenofibrate (43 mg/kg/d), α-tocopherol acetate (55 mg/kg/d) or their combination for 3, 8, 15, or 27 d. Control animals received soybean oil alone. At the end of treatment, blood was collected and six pools of two plasmas were obtained for each group. Results are expressed as g/L and are mean ± standard deviation of six values.

[b]Significantly different from control group with $P \leq 0.05$.

longer after fenofibrate administration for 8 d, and results obtained after 8, 15, and 27 d of treatment were comparable. The propagation rate was significantly decreased as early as 3 d of treatment. Decreases were between 36 and 55% compared to controls while no clear time-effect was noted. No statistically significant increase in (VLDL + LDL) lag time was noted with administration of α-tocopherol alone, though the propagation rate was slightly decreased (from −12 to −20%). Coadministration of fenofibrate and α-tocopherol prolonged the lag time to a greater extent than with fenofibrate alone, whatever the duration of treatment and in spite of a lack of effect of α-tocopherol alone. Statistical analysis demonstrated a significant interaction between the two drugs, meaning that the efficacy of one drug differed depending on the presence of the other.

Effect of the combined administration of α-tocopherol with fenofibrate, bezafibrate, or gemfibrozil on VLDL + LDL oxidation. Combined treatments with α-tocopherol and either fenofibrate, bezafibrate, or gemfibrozil were compared in a second experiment. All compounds were administered at equimolar doses for 15 d. Coadministration of α-tocopherol with fenofibrate or bezafibrate similarly decreased plasma total cholesterol levels by 44 and 38%, respectively, while gemfibrozil was less effective, with a 13% reduction (data not shown). α-Tocopherol alone was again ineffective, consistent with the results from the first experiment. Lag time as well as propagation rate was significantly modified by all three combinations, compared to controls (Fig. 2), but the association between fenofibrate and α-tocopherol was more effective than the association with the other two fibrates. Coadministration of fenofibrate along with α-tocopherol induced a 4.2-fold increase in lag phase duration and a 2.6-fold decrease in propagation rate, while these parameters were modified 3.3, and 1.9-fold, respectively, after bezafibrate + α-tocopherol treatment. Gemfibrozil + α-tocopherol were the least effective, and results did not differ significantly from those obtained after administration of α-tocopherol alone.

DISCUSSION

Intraluminal oxidative modification of β-lipoproteins increases their uptake by monocyte-macrophages, thus initiating a cascade of events leading to fatty streak formation and atherogenesis (2). In circulating blood, lipoproteins are resistant to peroxidation. The passage of lipoproteins into the subendothelium may prolong their half-lifes while exposing lipoproteins to an environment depleted of antioxidant defense mechanisms. While pharmacological modification of this cascade could target (i) reduction in β-lipoproteins (LDL and/or VLDL), (ii) increased lipoprotein antioxidant reserves, (iii) decreased percentage of polyunsaturated fatty acids (PUFA), or, eventually (iv) decreased lipoprotein penetration into the subendothelium, the factors controlling *in vivo* lipoprotein modification are still incompletely understood (3).

Fenofibrate belongs to the fibrate class of lipid-lowering drugs whose mechanism of action is largely dependent upon the nuclear receptor PPARα (5). PPARα mediates a plethora of key genes overlapping fatty acid, glucose, and cholesterol

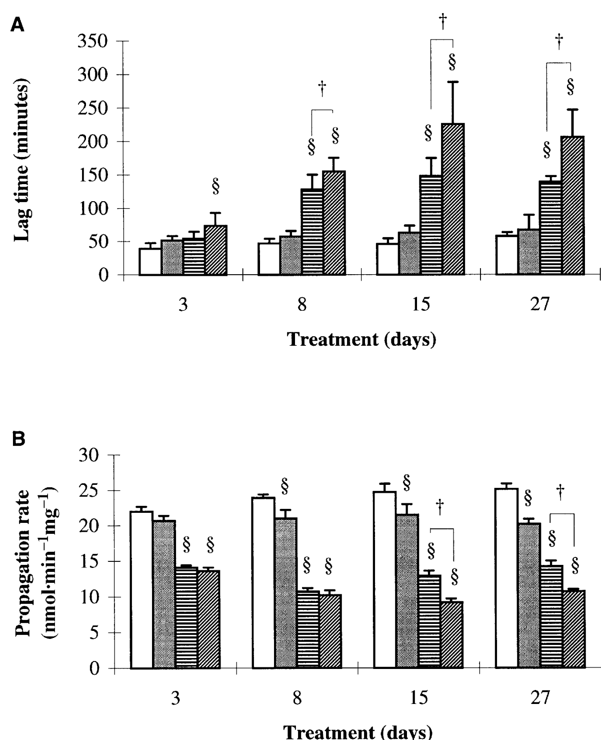

FIG. 1. Bar graphs showing the effect of drug administration on combined very low density lipoprotein (VLDL) and low density lipoprotein (LDL) susceptibility to *in vitro* oxidation. (VLDL + LDL)-containing samples were isolated from rats treated with vehicle (open bars), α-tocopherol (shaded bars), fenofibrate (horizontally striped bars) or fenofibrate + α-tocopherol (diagonally striped bars) for 3, 8, 15, or 27 d, and incubated in phosphate-buffered saline with 5 μM $CuSO_4$ at 37°C. metabolism. As PPARα activation has the potential to directly and indirectly modify a wide range of metabolic processes, we attempted to determine possible effects of fenofibrate on the various steps of lipoprotein peroxidation. In this initial study, we investigated the utility of combining an antioxidant, vitamin E, with a lipid-lowering drug to prevent lipoprotein peroxidation. We used low, nonsaturating doses of each drug so as to detect possible synergistic effects. We employed the measurement of lipoprotein peroxidation lag time and propagation rate as a surrogate estimate of the antioxidant potential of lipoproteins in the intraluminal space. While the quantification of endogenous antioxidants could give an additional indication of the factors responsible for the observed changes, quantitative modifications in antioxidants alone do not always translate into parallel changes in peroxidative susceptibility of lipoproteins (21,22).

Apolipoprotein B-containing lipoproteins from fenofibrate-treated rats were more resistant to oxidative modification than lipoproteins from control animals. When added *in vitro* to lipoproteins, fenofibrate as well as fenofibric acid, the active metabolite of fenofibrate (23), did not prevent VLDL + LDL oxidation, even at high concentrations (data not shown). Fenofibrate treatment did not alter the total cholesterol, phospholipid, or triglyceride content of the combined fraction of VLDL and LDL. In the experimental conditions described, increases in lag time after α-tocopherol administration to rats did not reach statistical significance. In contrast, the propagation rate of lipid peroxidation was slight but significantly decreased. This latter effect of α-tocopherol was not unexpected, as decreased propagation rate upon vitamin E feeding had already been reported in a number of studies (24–26).

Esterbauer *et al.* (27) observed that the lipid peroxidation process does not enter the propagation phase unless LDL are nearly completely depleted of all their antioxidants, including α-tocopherol. Enrichment of LDL with α-tocopherol, either *in vitro* or through dietary vitamin E supplementation, was shown to delay the onset of lipid peroxidation (26–29). In subjects consuming a normal diet and hence low amounts of α-tocopherol, there is no correlation between resistance of LDL to lipid peroxidation and α-tocopherol content (27,30–32). Thus, a number of factors may alter LDL peroxidation including the ratio of PUFA/α-tocopherol (23), cholesterol content, and other endogenous antioxidants including ubiquinol-10, through

α-tocopherol sparing and/or recycling (34–38). Studies by Tribble *et al.* (39,40) showed that small, dense LDL, which are readily oxidized, exhibit a higher rate of α-tocopherol consumption as compared with large, buoyant LDL, suggesting a lower efficiency of the antioxidant within these particles. An increasingly labile α-tocopherol has been hypothesized to relate to a lower ubiquinol-10 content of the particles, together with an increased PUFA/α-tocopherol ratio, as depletion rates are lower after dietary monounsaturated fatty acid intake. Similarly, experiments in which both dense and buoyant LDL were enriched with vitamin E after dietary supplementation demonstrated a lower efficacy of vitamin E in the dense LDL subfraction (41). Changes in the content of other antioxidants such as ubiquinol-10 cannot be ruled out, while the role of the latter is still a matter of debate due to its low concentration within lipoproteins (18,42). Thus, the quantity of α-tocopherol *per se* may not be a sufficiently accurate parameter to predict either *ex vivo* or *in situ* protection against LDL peroxidation.

The current data demonstrate that fenofibrate affords protection against lipid peroxidation synergistically with α-tocopherol. Simultaneous administration of fenofibrate and α-tocopherol to rats was much more effective in extending the oxidation resistance of lipoproteins than expected from the data obtained for each compound taken separately. The idea of an interaction between these two substances has been suggested by Steinerova *et al.* (43). The explanation for this prolongation of the lag phase could be related to an effect of fenofibrate on the relative amounts of PUFA and monounsaturated fatty acids (44). The synergistic effect observed with fenofibrate plus vitamin E could then be due to a favorable ratio of vitamin E/PUFA whereby the antioxidant defense is bolstered concomitant to a reduction in the free radical-propagating PUFA. In addition to the ability of fenofibrate to modify fatty acid composition, activation of PPARα has recently been shown to be associated with decreased tissue oxidative stress (45) which may be indirectly related to lipoprotein peroxidative stress. The effect of fenofibrate alone and the synergistic effect observed with the addition of vitamin E were more pronounced after 8 d of treatment. The gradual effects could be due to the time necessary for the remodeling of the composition of serum lipoproteins and would reflect the half-lives of the various molecular components.

The combination of fenofibrate and α-tocopherol was significantly more effective than that with bezafibrate, despite comparable hypocholesterolemic activities, suggesting differences between the two fibrates possibly impinging upon other parameters. There are known qualitative as well as quantitative differences between the various members of the fibrate class (4). While fenofibrate and bezafibrate lower fibrinogen in man, gemfibrozil has no effect. Furthermore, fenofibrate alone decreases serum uric acid levels. Although both bezafibrate and fenofibrate lowered serum cholesterol to a comparable degree, the dose employed may have been saturating for both compounds with respect to changes in serum cholesterol, yet less so for bezafibrate with respect to another unknown gene target directly relevant to lipoprotein peroxidation. For example, fenofibrate has a dose-dependent differential effect on apolipoprotein AI and apolipoprotein AII gene expression, although both genes are modified *via* PPARα activation (46).

In conclusion, combined VLDL + LDL from rats treated with fenofibrate were resistant to copper-mediated oxidation. A synergistic effect on the reduction of lipoprotein peroxidation was observed when fenofibrate and vitamin E were coadministered relative to the effect observed with each compound given separately.

Microemulsion of Seal Oil Markedly Enhances the Transfer of a Hydrophobic Radiopharmaceutical into Acetylated Low Density Lipoprotein

Wu Xiao[a], Lili Wang[a], Philip J. Davis[b], and Hu Liu[a,b,]*

[a]School of Pharmacy and [b]Department of Biochemistry, Memorial University of Newfoundland, St. John's, Newfoundland, Canada

ABSTRACT: Four different microemulsions differing in their core lipid component (triolein, canola oil, squalene, or seal oil) and containing 1,3-dihydroxypropan-2-one 1,3-diiopanoate (DPIP), a potential radioimaging probe, were prepared by means of ultrasonication. The DPIP microemulsions were incubated with acetylated human low density lipoprotein (AcLDL) and the amount of DPIP transferred into AcLDL was examined. The amount of DPIP in the microemulsions expressed as DPIP/oil (w/w) was dependent on the core lipid component of the microemulsion in the order of seal oil (0.19 ± 0.04, mean ± standard deviation) > squalene (0.15 ± 0.02) > canola oil (0.12 ± 0.02) > triolein (0.07 ± 0.004). With the exception of canola oil, all microemulsions were effective in enhancing the transfer of DPIP into AcLDL in comparison with commonly used methods, i.e., direct diffusion and detergent solubilization. DPIP in seal oil resulted in the highest amount of DPIP transferred into AcLDL [309.16 ± 34.82 vs. 203.19 ± 64.51 using squalene and 151.31 ± 28.54 using triolein (DPIP molecules per AcLDL particle)]. For the first time, oil from harp seals, was studied as a major core lipid component of formulating pharmaceutical microemulsions. DPIP in seal oil resulted in the highest transfer of DPIP into AcLDL which is likely due to the highest DPIP concentration found in this microemulsion as well as the high fluidity of seal oil.

Paper no. L8055 in *Lipids 34,* 503–509 (May 1999).

Although the etiology of atherosclerosis is not fully understood, the involvement of monocyte-macrophages in the arterial intima and their subsequent accumulation of modified low density lipoprotein (LDL) has been well elucidated (1). Macrophages express a scavenger receptor for modified LDL such as oxidized LDL and acetylated LDL (AcLDL) (2). This receptor is involved in the formation of macrophage-derived foam cells in human atherosclerotic lesions (3). We therefore proposed to use AcLDL as a carrier to deliver radioimaging probes, such as radiolabeled cholesterol iopanoate (CI), to atherosclerotic lesions for the purpose of early diagnosis, and results have been promising (4). Our group is now investigating a polyiodinated diglyceride analog, 1,3-dihydroxypropan-2-one 1,3-diiopanoate (DPIP, Scheme 1), as another potential radioimaging agent. In order to achieve sufficient accumulation of radioactive DPIP for detection at the sites of atherosclerotic lesions, it is desirable to load a large amount of DPIP into AcLDL. Methods including direct diffusion and detergent solubilization have been reported for loading drug molecules into LDL or AcLDL particles (5–7). In this paper, we report on the transfer of DPIP into AcLDL *via* the preparation of DPIP microemulsions using triolein, canola oil, squalene, and seal oil as the core lipid component. The amount of DPIP transferred from the microemulsions to AcLDL was determined and compared. For the first time, seal oil was used to formulate microemulsions. The harp seal, a marine mammal, lives in an environment that can be extremely cold (−40 to −70°C). In such cold conditions, its circulatory system can still function well and its hydrophobic lipids such as triglycerides, cholesterol and cholesteryl esters remain uncrystallized in the liquid state. Although little research has been done to explain such fascinating phenomena, the unique long chain polyunsaturated fatty acids may contribute to greater fluidity of hydrophobic compounds in harp seal at the extremely low temperatures. In addition seal oil has strong antioxidant property which is useful in formulating stable microemulsions.

MATERIALS AND METHODS

Materials. Thin-layer chromatography was carried out on Fisher Scientific silica gel 60, F-254 polyethylene-backed plate and visualized by ultraviolet light. High-performance liquid chromatography analyses were performed using a Beckman system with a Phenomenex Bondclone 10C18, 150 × 3.0 mm column. Radioactivity was measured using a CKB-Wallac 1277 Gammamaster automatic gamma counter. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) was performed on a Bio-Rad Mini-Protein® II Electrophoresis Cell. A Philips EM 300 was used for electron microscopy (EM) and particles were negatively stained with 1% uranyl acetate. Image analysis was done by Bioquant™ System IV.

Carrier-free aqueous solutions of $Na^{125}I$ were purchased from DuPont NEN Research Products (Boston, MA). Pivalic acid was obtained from Aldrich Chemical Co. Canada. Sephadex® G-25 was purchased from Pharmacia Biotech AB (Uppsala, Sweden). Poly-Prep® chromatography columns were obtained from Bio-Rad Laboratories (Hercules, CA). SDS-PAGE molecular weight standards and Bio-Rad protein assay kits were purchased from Bio-Rad Laboratories (Richmond, CA). L-α-Phosphatidylcholine dipalmitoyl, DL-α-phosphatidylethanolamine dipalmitoyl, and squalene were purchased from Sigma-Aldrich Canada, Oakville, Ontario, Canada. Canola oil was purchased from a local supermarket. Seal oil from harp seal, *Phoca groenlandica*, was obtained from Terra Nova Fishery Ltd., St. John's, Newfoundland, Canada.

Methods. (i) Preparation of DPIP and 125I-DPIP. DPIP was synthesized as reported (8) and radiolabeled with ^{125}I *via* an isotope exchange reaction in a pivalic acid melt (9). The chemical and radiochemical purities of ^{125}I-DPIP were determined by high-performance liquid chromatography and thin-layer chromatography as described before (9).

(ii) Preparation of DPIP microemulsions. DPIP microemulsions were prepared using triolein, canola oil, squalene, and seal oil, respectively, as the core lipid component. L-α-Phosphatidylcholine dipalmitoyl (12 mg), DL-α-phosphatidylethanolamine dipalmitoyl (8 mg), triolein, canola oil, squalene, or seal oil (20 mg), DPIP (10 mg) and ^{125}I-DPIP (0.05 mg) were dissolved in chloroform, dried with a gentle stream of nitrogen, and suspended in 10 mL of saline at 25°C. ^{125}I-DPIP was used as a radioactive tracer for analysis. The suspension was sonicated for 2 h with a Virosonic Cell Disrupter Model 16-850 at 40–50 watts while being cooled in a −10°C salt–ice water bath under a nitrogen stream. The mixture was then centrifuged at 40,000 rpm for 20 h at 4°C using a Beckman SW41 rotor and a Beckman L5-65 ultracentrifuge. The microemulsion that floated to the top of the centrifuge tubes was collected and subjected to EM and image analysis. The amount of DPIP in the individual microemulsions was determined using a CKB-Wallac 1277 Gammamaster automatic gamma counter.

(iii) Preparation of AcLDL. Fresh human plasma was obtained from the Canadian Red Cross Society, St. John's, Newfoundland, Canada. LDL was isolated as previously described (10) by sequential ultracentrifugation of fresh human plasma at 40,000 rpm for 24–40 h at 8°C using a Beckman L8-M ultracentrifuge and a 60Ti rotor. LDL was dialyzed at 4°C overnight against a buffer containing 0.3 mM EDTA, 150 mM NaCl, and 50 mM Tris (pH 7.4). Protein concentrations were determined by the method of Bradford (11). Acetylation of LDL was performed as described by Basu *et al.* (12). The AcLDL was dialyzed and protein concentrations were determined as above.

(iv) Incorporation of DPIP into AcLDL. The ^{125}I-DPIP microemulsions were incubated with AcLDL at 37°C for 24 h at a molar ratio of DPIP to AcLDL of 1000:1. AcLDL loaded with ^{125}I-DPIP (^{125}I-DPIP/AcLDL) was then separated from microemulsions by ultracentrifugation as described (10). The DPIP content in ^{125}I-DPIP/AcLDL was determined by γ-counting.

DPIP was also incorporated into AcLDL using direct diffusion (13) and detergent solubilization (14) with minor modifications. In brief, for the method of direct diffusion, DPIP was dissolved in chloroform in a glass vial and dried under a stream of nitrogen to form a thin film on the wall of the vial. AcLDL was added to the vial and incubated at 37°C for 24 h. For the method of detergent solubilization, DPIP was dissolved in saline in the presence of Tween 20 (<3%) and incubated with AcLDL at 37°C for 24 h. The molar ratio of DPIP to AcLDL used remained the same as above.

(v) Characterization of ^{125}I-DPIP/AcLDL. ^{125}I-DPIP/AcLDL (500 µL), about 1 mg/mL, was loaded onto 1 g of Sephadex® G-25 in a Poly-Prep® chromatography column and eluted with phosphate-buffered saline (pH 7.4). Fractions of 0.5 mL were collected, and radioactivity and protein content of each fraction were measured and plotted.

In order to assess the integrity of the apolipoprotein B-100 of ^{125}I-DPIP/AcLDL, samples were analyzed by SDS-PAGE and EM as described (15).

RESULTS AND DISCUSSION

Our previous studies suggested that AcLDL could be used as a carrier to deliver radiolabeled CI, a cholesterol ester analog, to atherosclerotic lesions in rabbits (4). Compared to CI, DPIP is considered to be a better probe for the detection of atherosclerotic lesions. Through radio-iodination, the six iodine atoms on each DPIP molecule (Scheme 1) provide even higher specific radioactivity than CI. This is desirable for the accumulation of the high radioactivity required for diagnostic purposes. In this report, the loading of DPIP into AcLDL was studied.

Owing to their simplicity, the direct diffusion and detergent solubilization methods have been widely used for loading lipophilic drugs into LDL or AcLDL (16). Microemulsions have also been employed to transfer various drugs into LDL or AcLDL (5–7,17), and triolein has been one of the most commonly used core lipid components. In this study,

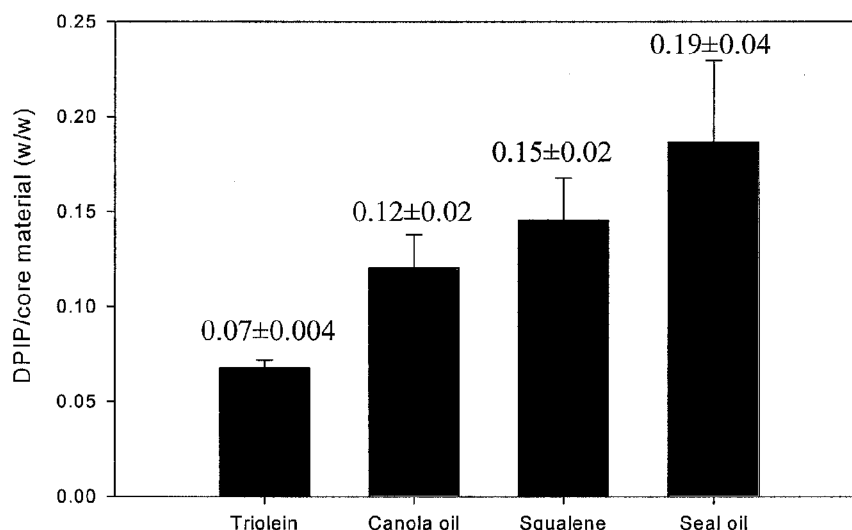

FIG. 1. Comparison of 1,3-dihydroxypropan-2-one 1,3-diiopanoate (DPIP) concentrations in microemulsions using triolein, canola oil, squalene, and seal oil as the core lipid component. The results are expressed as the ratio (mean ± standard deviation) of DPIP to the oil used (w/w).

squalene and seal oil were used as the core lipid components of microemulsions for the first time. Squalene, a highly unsaturated hydrocarbon ($C_{30}H_{50}$), is capable of resupplying the cells with oxygen (18), and is an intermediate product in the synthesis of cholesterol. In recent years, seal oil has been of interest for its potential use in the maintenance of human health (19–22). The n-3 polyunsaturated long chain fatty acids found in seal oil are beneficial in lowering blood pressure (23), reducing triacylglycerols (24), and modulating cell function and cell reactivity to external stimuli (25). In addition, seal oil is very resistant to oxidation, which is desirable for preparing stable microemulsions.

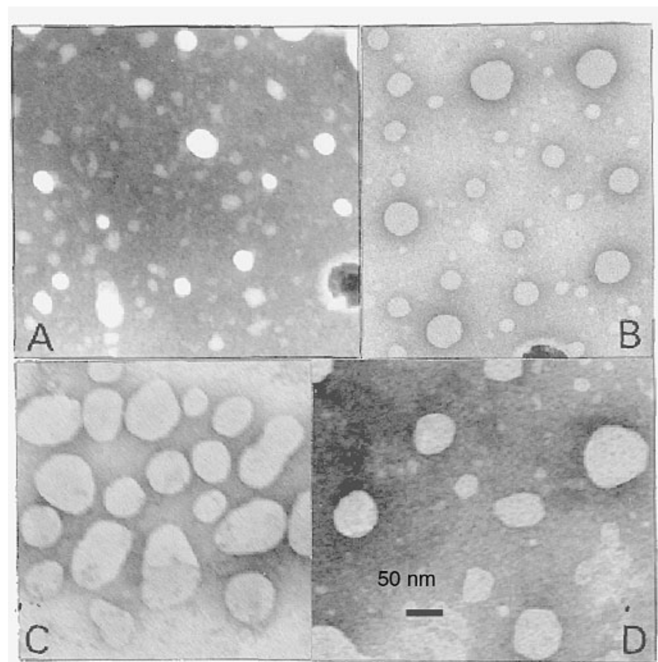

FIG. 2. Electron micrographs of DPIP microemulsions using triolein (A), canola oil (B), squalene (C) and seal oil (D) as the core lipid component. For abbreviation see Figure 1.

Microemulsions were prepared by hydrating a dried film of the lipid mixtures with saline at room temperature, followed by ultrasonication, during which the aqueous dispersions were cooled in a salt–ice bath at −10°C to prevent overheating due to the sonication. Preparation of the microemulsions at a temperature below the gel-liquid crystalline phase transition temperature of the phospholipids would possibly result in limited hydration of the phospholipids. However, electron micrographs show structures that are typical of those observed by Redgrave and Maranhao (26) in preparations of microemulsions formed by sonication at temperatures above the phospholipid transition temperatures. Furthermore, those authors reported microemulsions that were 50–200 nm in diameter. This compares well with our preparations, which had diameters of 30–90 nm. The slightly larger diameters seen by Redgrave and Maranhao could be due to the use of a phosphatidylcholine species containing unsaturated fatty acids that increases the molecular area of the phospholipid compared with the fully saturated phosphatidylcholines in our preparations.

The concentrations of DPIP in microemulsions with triolein, canola oil, squalene, and seal oil as the core lipid component were compared. The amount of DPIP eventually loaded into the microemulsions, expressed as DPIP/oil (w/w), was in the order of seal oil (0.19 ± 0.04, mean ± standard deviation) > squalene (0.15 ± 0.02) > canola oil (0.12 ± 0.02) > triolein (0.07 ± 0.004) as shown in Figure 1. EM (Fig. 2) and image analysis (Fig. 3) results showed that the particle size of the microemulsions is in the same order of seal oil [longest diameter (LD) = 67.8 ± 25.37 nm] > squalene (LD = 58.2 ± 22.01 nm) > canola oil (LD = 52.9 ± 16.05 nm) > triolein (LD = 40.6 ± 13.5 nm).

Upon incubation of the DPIP microemulsions with

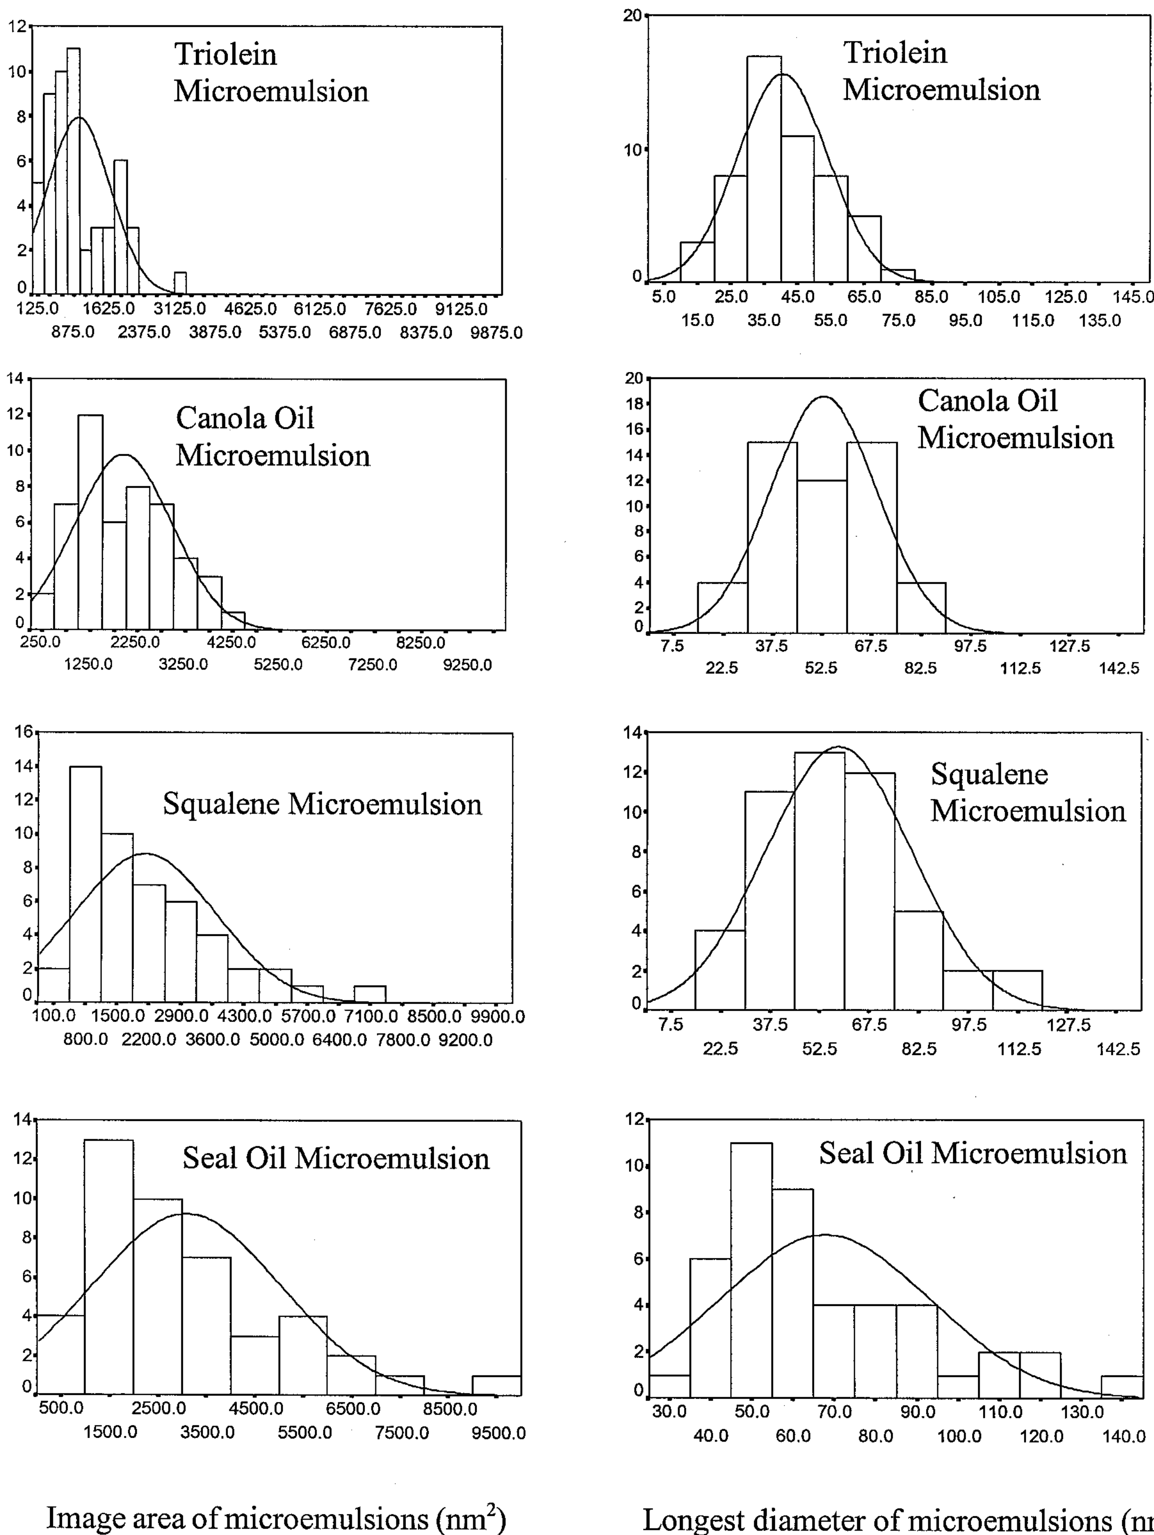

FIG. 3. Image analysis of DPIP microemulsions using triolein, canola oil, squalene, and seal oil as the core lipid component. The left four panels are the distributions of image areas of four microemulsions (nm^2) and the right four panels are the distributions of longest diameters of the four microemulsions (nm). The *y* axes of Figure 3 represent the frequency of the number of tested samples located in the correspondent scale. The curve was fitted by Gaussian normal distribution. For abbreviation see Figure 1.

AcLDL, DPIP was successfully transferred into AcLDL with the exception of the canola oil microemulsion, in which AcLDL was found to be aggregated. DPIP/AcLDL preparations were subjected to gel filtration. The chromatograms of radioactivity and protein contents were plotted. As shown in Figure 4, radioactivity (due to ^{125}I-DPIP) and protein content

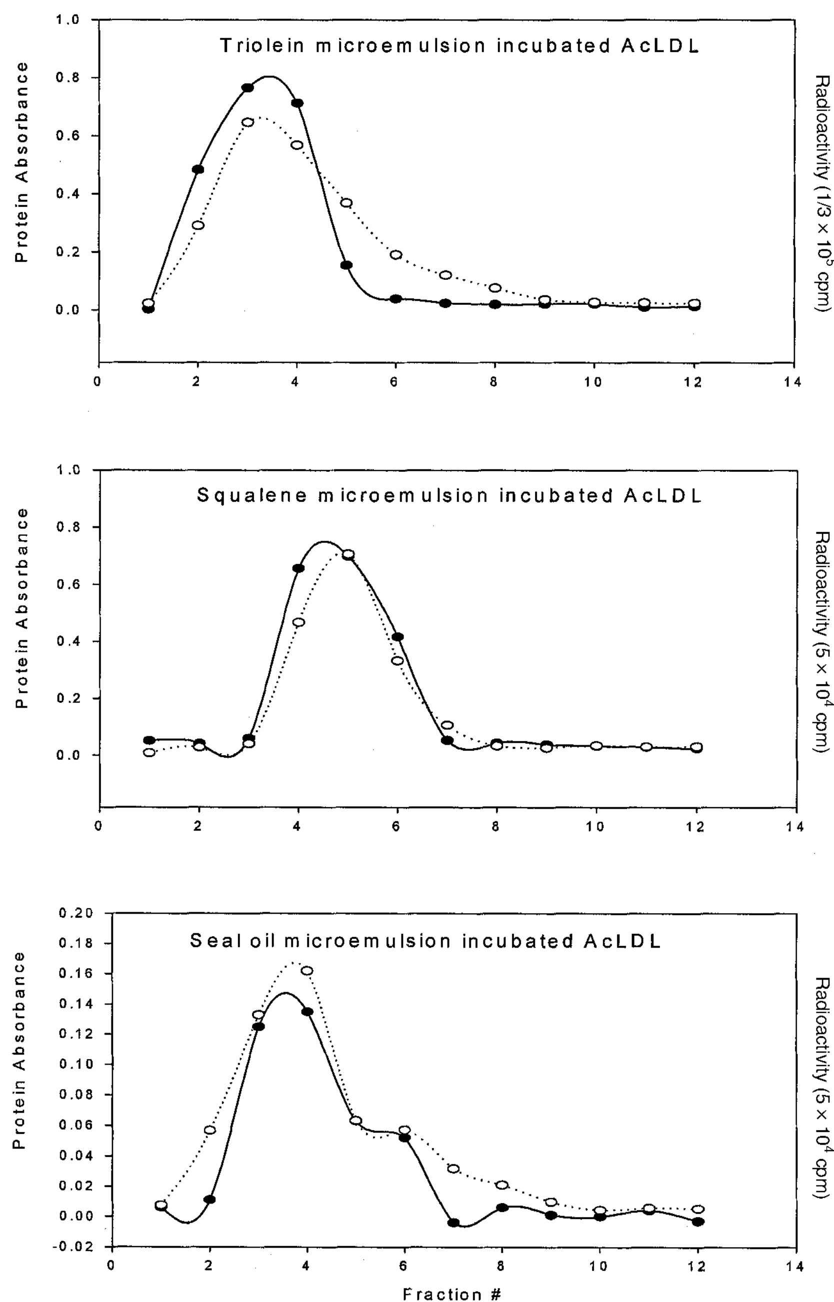

FIG. 4. Confirmation of ^{125}I-DPIP incorporation into acetylated low density lipoprotein (AcLDL) particles by using three different lipid microemulsions. ^{125}I-DPIP/AcLDL conjugates were analyzed by gel filtration chromatography through Sephadex G-25 with phosphate-buffered saline. The radioactivity and protein content of each fraction were determined as described in the Materials and Methods section. For other abbreviations see Figure 1.

were superimposed, suggesting that DPIP was transferred to AcLDL (or DPIP/AcLDL formed). SDS-PAGE results of DPIP/AcLDL indicated that the integrity of apolipoprotein B-100 was intact in comparison with native LDL and AcLDL (data not shown). The poor results obtained with canola oil are possibly due to the presence of preservatives or other additives in the commercial canola oil.

The transfer efficiency of DPIP from the different microemulsions to AcLDL was also compared with direct diffusion and detergent solubilization. As shown in Figure 5, the amount of DPIP transferred into AcLDL through the different DPIP microemulsions was higher than that through direct diffusion (27.70 ± 1.99 DPIP molecules/per AcLDL) and solubilization (66.97 ± 14.81 DPIP molecules/per AcLDL). Among the microemulsions studied, the seal oil microemulsions resulted in the highest amount of DPIP transferred into AcLDL (309.16 ± 34.82 vs. 151.31 ± 28.54 using triolein and 203.19 ± 64.51 using squalene expressed as DPIP mole-

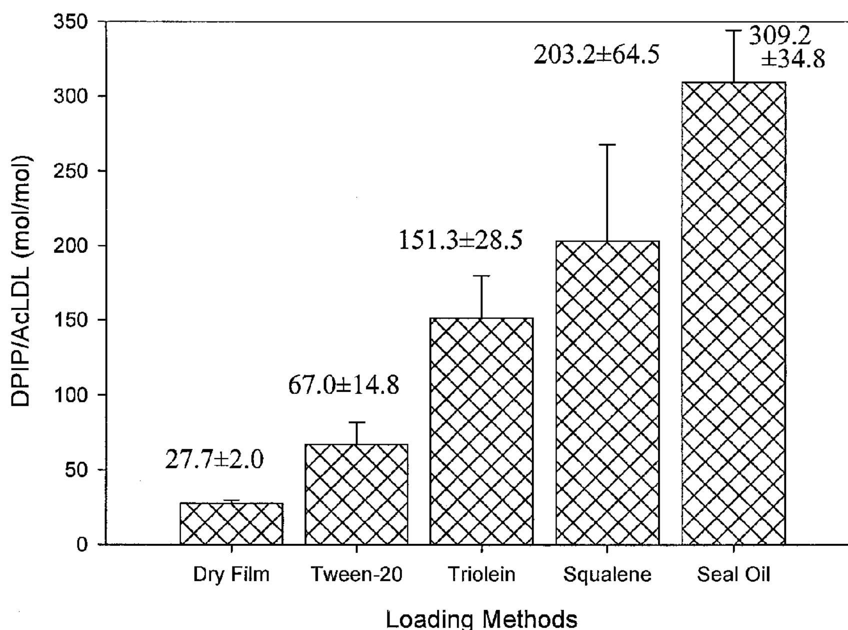

FIG. 5. Comparison of the DPIP loading efficiency into AcLDL using different methods. Results are expressed as DPIP/AcLDL. For abbreviations see Figures 1 and 4.

cules/per AcLDL). The similar trend found in Figures 1 and 5 suggests that the concentration of DPIP found in the microemulsion is the decisive factor for the transfer of the drug into AcLDL.

Possible explanation for these observations may lie in the differences in the physical behavior of the different core lipids. Seal oil contains high levels of highly unsaturated triglycerides. These may allow for solvation of more hydrophobic DPIP than triolein and may also, because of increased fluidity, allow for more rapid transfer of DPIP to the lipoprotein particles.

In summary, we prepared different DPIP microemulsions, using seal oil and squalene for the first time. All DPIP microemulsions resulted in a higher DPIP incorporation into AcLDL than the commonly used methods. More interestingly, DPIP microemulsions using seal oil and squalene loaded more DPIP into AcLDL than that using triolein, which is likely the result of the higher DPIP concentrations found in these microemulsions. Therefore, seal oil and squalene may be appropriate substitutes for triolein in manufacturing microemulsions. Obviously, significant studies, such as safety and stability of those marine mammal oils, are required.

ABSTRACT: The determination of cellular content of octadecylphosphocholine (D-19391) and hexadecylphosphocholine (HePC, D-18506), two anticancer agents of the alkylphosphocholine group, using capillary gas chromatography is described. The compounds' cytotoxicity was first determined by the MTT [3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyltetrazolium] assay, being indicative for the concentration used in the uptake and retention measurements. D-19391 was added to the SK-BR-3 breast cancer cell line and HePC to the Molt-4 leukemia cell line in concentrations of, respectively, 18.6 and 15.0 μM, during a 36-h incubation period at 37°C, 5% CO_2. HePC uptake in the leukemia cells was followed by a 24-h reversibility test in drug-free medium. Subsequently, sample clean-up was performed on a weak cation-exchange column. For the quantitative analysis, HePC was used as internal standard for the D-19391 measurements and vice versa. Derivatization of the samples with trimethylsilylbromide was followed by capillary gas chromatographic analysis. From these data we conclude that our uptake results are quite similar with those of a previous study of HePC cellular uptake in the more resistant Caco-2T colon cancer cell line. Without having investigated the mechanism that underlies the cellular uptake results obtained, our study points to no direct correlation between the compounds' cellular uptake and their cytotoxic effects.

Paper no. L7999 in *Lipids 34*, 511–516 (May 1999).

Hexadecylphosphocholine (HePC, D-18506) and octadecylphosphocholine (D-19391) are representatives of the alkylphosphocholine (APC) class, a new group of antitumor agents with, as far as we know, no mutagenic, carcinogenic or immunosuppressive properties like common chemotherapeutics (1). Clinical studies of HePC proved its efficacy for the treatment of skin metastases in patients with breast cancer (2). Other APC and alkyllysophospholipids (ALP) are entering clinical trials. Although promising results were obtained in laboratories and in clinical studies, the mechanism of their antineoplastic and selective action remains unknown (3–5). Based on their lipid-soluble structure, it is generally accepted that the main target of APC/ALP appears to be the plasma membrane: they incorporate into cellular membranes, influencing membrane fluidity (6), inhibiting normal phospholipid metabolism (7) and affecting several membrane proteins including protein kinase C (8) and phospholipase C (9). Moreover, these agents are selectively cytotoxic and anti-invasive (10), they affect the cell cycle progression in tumor cells (11), and they promote apoptosis (12). These findings indicate that a combination of all these molecular events may contribute to the explanation of the antineoplastic activity of these agents on tumor cells. In our laboratory a capillary gas chromatography (cGC) method was established (13) and further optimized (14) to determine APC and ALP in cell cultures and cell culture media. Based on this cGC procedure, the HePC uptake and retention in the human colon cancer cell line Caco-2T (15) and in the human breast cancer cell line SK-BR-3 (14) have already been investigated. Our aim was to analyze the uptake of D-19391 as a HePC structural analog in the same SK-BR-3 cells and to extend this study to the HePC determination in the suspension leukemia cell line Molt-4. Since similar uptake results were obtained for both compounds on the breast cancer cell line, and since these cellular measurements are quite time-consuming, HePC was chosen as representative compound of the APC class to measure the cellular uptake and retention in the Molt-4 suspension cells. By determining the uptake and retention of these compounds in an adherent and a suspension cell line, insight will be gained in the relation between the compound's cytotoxicity and the cellular uptake and retention in these two different types of cell lines. Since the cellular uptake is the initial step finally leading to the compound's antitumor action, this study can contribute to the elucidation of the mechanism of these antineoplastic agents.

MATERIALS AND METHODS

Reagents. HePC (D-18506) and D-19391 (clinical grade) were kindly provided by Dr. Th. Klenner from Asta Medica (Frankfurt am Main, Germany). Trimethylsilylbromide and

the MTT reagent [3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyltetrazolium] were obtained from Acros Chimica (Kortrijk, Belgium). Bond Elut columns containing a weak cation-exchange sorbent of the carboxylic acid (CBA) type were provided by Varian Belgium N.V./S.A. (Brussels, Belgium). Trypan Blue solution (0.4%) was supplied by Sigma Biosciences (Antwerp, Belgium). *n*-Hexane for spectroscopy was obtained by Merck-Belgolabo (Brussels, Belgium). Other products and solvents were of analytical grade and used without further purification.

Cell culture. The SK-BR-3 human breast cancer cell line was maintained in minimum essential medium supplemented with 11% heat-inactivated fetal bovine serum, 65 IU/ml penicillin/streptomycin solution, and 2 mM L-glutamine. The Molt-4 T-lymphoma cells were cultured in RPMI 1640 supplemented with 10% heat-inactivated fetal bovine serum and 2 mM L-glutamine. Both cell lines were maintained in plastic culture flasks in a humidified incubator at 37°C, 5% CO_2. For subculturing or experiments, the adherent cells were detached from the culture flask by the use of trypsin/EDTA solution, after washing the cells with Hanks' Balanced Salt Solution. Suspension cultures were centrifuged and resuspended in fresh medium. Cell number and cell viability were determined using a cell counting chamber by trypan blue exclusion. All reagents and materials for cell culture were provided by Life Technologies (Paisley, United Kingdom).

Solid-phase extraction. Sample clean-up was performed according to the solid-phase extraction procedure described by Coene *et al.* (13), with minimal alterations (14). Bond Elut columns of the CBA type, containing 500 mg sorbent, were initially conditioned with 2 mL of 100% methanol, 2 mL of distilled water, and 2 mL of 0.1 M phosphate buffer (pH 5.2). Each standard together with the internal standard was buffered with 5 mL 0.1 M phosphate buffer to obtain optimal retention of the APC on the CBA column. For quantitation of the D-19391 uptake measurements in the SK-BR-3 cell line, a standard curve was obtained with standard concentrations ranging from 2.3 to 11.5 µM and 12.3 µM HePC as internal standard. In the same way, standards with a concentration of 1.2 to 12.3 µM HePC, combined with 9.2 µM D-19391 as internal standard, allowed us to determine HePC uptake and retention in the Molt-4 suspension cell line. The buffered standard solution was applied to the column and subsequently washed with 2 mL 0.01 M HCl/0.01 M KCl in water (pH 2.0) and 2 mL 30% methanol in water. These washings were discarded. Finally the APC were eluted with 2 mL 100% methanol and transferred into a 250-mL round-bottomed flask. After evaporation of the solution under a gentle stream of nitrogen, the residue was dissolved in 2 mL dry acetonitrile followed by 5 min sonication making the sample ready for derivatization. Therefore, the flasks were equipped with a condenser and a $CaCl_2$ drying tube after adding 100 µL trimethylsilylbromide. The samples were derivatized at 98°C for 1 h in the absence of light. After derivatization, the samples were transferred into tubes and evaporated under nitrogen. The residue was dissolved in 1 mL *n*-hexane and sonicated for 10 min. To remove impurities, another sample clean-up step was performed by filtration of the obtained solution, followed by evaporation under nitrogen. By dissolving the residue in 100 µL *n*-hexane and sonicating for 10 min, the sample was made ready for cGC injection.

Instrumentation. After derivatization with trimethylsilylbromide, the samples were injected into a Hewlett-Packard (HP) series II gas chromatograph, connected with an HP A/D converter interface to an HP Chemstation. The column was a cross-linked methyl silicone gum Ultra (25 m × 0.32 mm i.d.; film thickness 0.17 µm). Cold on-column injections of 1 µL were done manually in the oven-track mode. The oven temperature was held at 50°C for 1 min following injection, and programmed at 20°C/min to 200°C and then at 10°C/min to 300°C. As carrier gas helium was used (3.0 mL/min), and nitrogen and air were used as make-up gas for flame-ionization detection at 250°C (13). For the performance of the MTT assay, a V_{max} microtiter plate reader (Bio-Tek Instruments, Winooski, VT) and a CO_2 incubator (Precision Scientific, Chicago, IL) at 37°C, 5% CO_2 were used.

MTT cell viability assay. The D-19391 cytotoxic effect on the adherent SK-BR-3 cell line was evaluated by the MTT assay according to Romijn *et al.* (16) and is based on the enzymatic reduction of the tetrazolium salt into formazan crystals. Since dead cells are unable to reduce the tetrazolium salt, this assay allows the discrimination between metabolically active cells and dead cells. By measuring the optical density (OD) of the formazan crystals produced, this colorimetric assay is very useful for quantitating the cytotoxicity induced by a compound. Therefore, 100 µL of a cell suspension with a cell density of approximately 62×10^3 cells/mL was transferred into the wells of rows 3 to 11 of the microplate, sealed with Micropore tape (3M, St. Paul, MN) and incubated for 4 h at 37°C, 5% CO_2. Subsequently, 200 µL SK-BR-3 medium without compound was transferred to the wells in row 2 (blank), 100 µL medium to the wells in row 3 (control), and 100 µL of increasing concentrations of D-19391 prepared in cell medium to the wells in rows 4 to 11. The plate was sealed with Micropore tape and now incubated for 4 d in a humidified incubator at 37°C, 5% CO_2. After this incubation period, 100 µL medium of every well was replaced by 100 µL of a 1 mg/mL MTT solution in phosphate-buffered saline (pH 7.4), followed by a 4-h incubation in the absence of light at 37°C, 5% CO_2. During this reaction the mitochondrial enzymes in viable cells reduce the tetrazolium salt into formazan crystals. After having removed most of the medium in each well, 200 µL dimethylsulfoxide was added following a 1-h incubation at 37°C. After solubilization of the formazan crystals in dimethylsulfoxide and homogenization of each well, the amount of formazan produced is quantified by measuring the OD of the wells with a V_{max} microtiter plate reader at 540 nm.

To examine Molt-4 cell viability after incubating the cells with increasing HePC standard concentrations, the MTT test was performed as just described, with some adjustment. The cell density of the cell suspension used was generally 4.4×10^5 cells/mL. After 4 d of incubation of the Molt-4 cells with

increasing concentrations of HePC, 20 µL of a 5 mg/mL MTT solution prepared in phosphate-buffered saline (pH 7.4) was added to each well. The plate was sealed with Micropore tape and incubated under the same conditions as already described. Formazan crystals were dissolved in 100 µL acidified isopropyl alcohol (0.04 N HCl in isopropyl alcohol). After homogenization the concentration of the colored crystals in each well, proportional to the number of viable cells, was measured at 490 nm.

Each cell viability assay was performed in duplicate. For both cell lines, the OD of rows 3 to 11 were diminished by the mean OD value of row 2 (blank) and these were expressed as percentages of the mean control OD value, in reporting cell survival as function of increasing drug concentrations.

Uptake and retention. After subculturing the SK-BR-3 cells at different cell densities in 25-cm^2 culture flasks and 1-d growth, the medium was removed and 4.0 mL of the prepared D-19391 solution was added to the cell culture followed by a 36-h incubation at 37°C, 5% CO_2. Therefore, the compound was dissolved in SK-BR-3 medium at a concentration of 18.6 µM (approximately 75% of the compound's ID_{50} value derived from the MTT results, where ID_{50} represents 50% inhibitory concentration). At the end of this incubation period, the medium was removed and retained for analysis. The SK-BR-3 cells were trypsinized during 6 min at 37°C after washing the cell culture with 5 mL 0.1 M phosphate buffer pH 7.4. The cells were then collected in a volumetric flask and brought to a constant volume of 3.0 mL with cell medium. The cell density of this cell suspension was determined using a cell counting chamber by trypan blue exclusion. Because of the similar results obtained for the D-19391 and HePC uptake in the SK-BR-3 cells, the study of the D-19391 cellular retention in this adherent breast cancer cell line was not further investigated. For the uptake and retention measurements of HePC in the Molt-4 cell line, a full-grown cell culture was centrifuged at 360 × *g* for 8 min at 25°C. The supernatant was removed and the cell pellet resuspended in fresh Molt-4 medium, followed by cell density determination. The cell density could eventually be corrected at this point. Of the cell suspension obtained, 1.0 mL was transferred to a 25-cm^2 cell culture flask containing 5.0 mL HePC solution prepared in cell medium at a concentration of 17.9 µM, whereby a compound concentration of 15.0 µM was reached. HePC uptake was determined after 36 h of incubation. The cell suspension culture was first centrifuged at 1250 × *g* for 6 min at 25°C. The medium was then removed and retained for analysis. The cell pellet was resuspended in 3.0 mL fresh Molt-4 medium, and the cell density of this cell suspension was determined, followed by cGC analysis of HePC cellular uptake. For the retention measurements, the cell pellet was resuspended in 6.0 mL fresh sterile Molt-4 medium and transferred to a cell culture flask, followed by another 24-h incubation at 37°C, 5% CO_2. At the end of this incubation, the cell suspension was centrifuged at 1250 × *g* for 6 min at 25°C and further handled as described for the uptake measurements of HePC in the Molt-4 cell line.

For the analysis of the obtained cell suspensions and cell culture media, 1.0 mL of the samples was buffered with 5 mL 0.1 M phosphate buffer (pH 5.2) and sonicated for 6 min to obtain cell membrane disruption. Sample clean-up was performed by solid-phase extraction, followed by derivatization and 1 µL sample injection in the cGC as described in the instrumentation paragraph above. The use of an internal standard made quantitative determination of the compound in cells and cell culture media possible. Data collection was performed with the HP Chemstation, whereby the ratios of the areas of the examined compound vs. the internal standard were calculated to obtain the quantitative amount of compound.

As control, culture flasks without cells (blank) were subjected to the same conditions as described for the cell cultures and subjected to the same analysis as well as data collection.

RESULTS

Cytotoxic effect of D-19391 on the SK-BR-3 and of HePC on the Molt-4 cell line. The effect of D-19391 cytotoxicity on the SK-BR-3 cell viability was examined by the MTT assay, performed in duplicate as described in the Materials and Methods section. The SK-BR-3 cell line was incubated with increasing concentrations of compound ranging from 5 to 100 µg/mL (11.5–230.0 µM) for 4 d in the microtiter plate. At the end of this time a dose-dependent decrease in cell survival was observed for the SK-BR-3 cell line as shown in Figure 1. The mean concentration of D-19391 that is responsible for a 50% decrease in cell viability (ID_{50} value) was 10.8 ± 0.1 µg/mL. This indicates the high sensitivity of the adherent breast cancer cell line for D-19391 cytotoxicity.

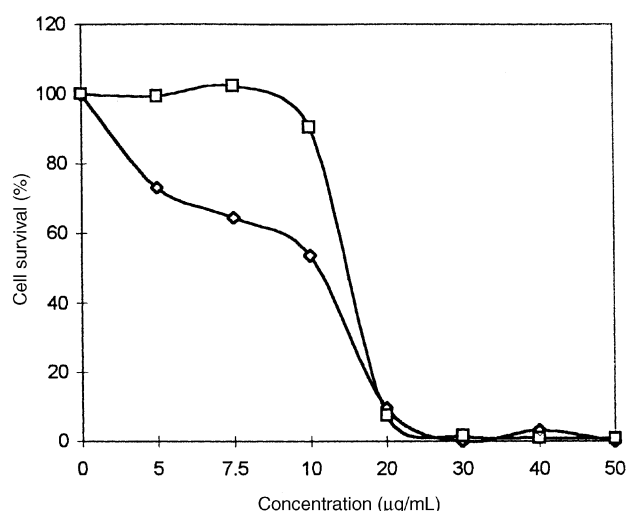

FIG. 1. Cell viability (MTT) test of D-19391 on the SK-BR-3 (◇) and of HePC on the Molt-4 (□) cell line. The test conditions of the MTT assay are given in the Materials and Methods section. The results of one representative assay, with concentrations ranging from 0 to 50 µg/mL alkyllysophospholipid, are shown. Abbreviations: MTT, 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-tetrazolium; D-19391, octadecylphosphocholine; HePC, hexadecylphosphocholine.

TABLE 1
Uptake Measurements of D-19391 in SK-BR-3 Cell Cultures and Cell Culture Media[a]

Sample (n = 3)	Cell density (10^3 cells/mL)	D-19391 in the cells (%)	D-19391 in media (%)	D-19391 recovered (%)
1	6.25	10.1 ± 0.5	76.1 ± 8.3	86.2 ± 8.3
2	6.94	11.5 ± 0.2	81.5 ± 2.8	93.0 ± 2.8
3	10.76	30.1 ± 0.04	82.5 ± 5.2	112.6 ± 5.2
4	13.89	19.5 ± 2.4	90.1 ± 3.3	109.6 ± 4.1
5	14.24	18.4 ± 0.3	89.9 ± 11.4	108.4 ± 11.4
6	15.63	17.9 ± 8.1	73.9 ± 5.7	91.8 ± 9.9
7	21.53	19.0 ± 2.5	81.1 ± 10.8	100.1 ± 11.1
8	29.86	17.1 ± 2.8	67.5 ± 1.8	84.6 ± 3.3

[a]The D-19391 amount obtained in the cell cultures and cell culture media is calculated in relation to the recovered drug amount in the blanks. Data represent the mean ± SD. Abbreviation: D-19391, octadecylphosphocholine.

The MTT cell viability assay on the Molt-4 cell line was performed with a HePC concentration range of 5 to 60 µg/mL (12.3–147.2 µM). A dose-dependent decrease in cell survival was observed, resulting in a mean ID_{50} value of 13.2 ± 2.5 µg/mL (Fig. 1). Uptake and retention measurements were performed with compound concentrations below the obtained ID_{50} values.

Uptake of D-19391 in the SK-BR-3 cell line. These antitumor ether lipids possess a high affinity for serum albumin, present in the cell culture medium. Knowing that the cell plasma membrane is the main localization and action site of these agents, one can expect a possible back-extraction of the compound from the plasma membrane into the cell culture medium by serum albumin (17), accompanied by a lowered compound cytotoxicity (18). Therefore, a time-dependent uptake study has been performed for HePC on the SK-BR-3 cell line (14). Based on this previous experiment, a maximal drug uptake in the cells was reached after 36 h of incubation. After incubating the SK-BR-3 cells with D-19391 in a concentration of 18.6 µM, the cells and cell culture media were collected and analyzed as described in the Materials and Methods section. Table 1 shows the results obtained for the D-19391 cellular uptake and the remaining concentration in the cell medium at different cell densities. For the quantitative determination of D-19391 in cells and cell culture media, a standard curve ranging from 2.3 to 11.5 µM with 12.3 µM HePC as internal standard was used. A correlation coefficient of 0.991 was obtained. The average recovered D-19391 percentage in the cells and cell culture media shown in Table 1 is 98.3 ± 11.0% (n = 8) taking into account the values obtained for the recovery in blank experiments. D-19391 cellular uptake was performed at lower cell densities, ranging from 6 to 30 × 10^3 cells/mL of this adherent growing breast cancer cell line, to avoid cell release from a full-grown culture flask during the investigation. The results of a 36-h D-19391 uptake into the SK-BR-3 cells point to a mean cellular uptake of 18.0 ± 6.0% at the tested cell densities.

Uptake and retention of HePC in the Molt-4 cell line. Molt-4 cells were incubated with 15.0 µM HePC during 36 h, eventually followed by a 24-h recovery in drug-free medium. Subsequently the cells and cell culture media were collected and analyzed as described in the Materials and Methods section. In Table 2 the results of the HePC cellular uptake are shown. A standard curve in a concentration range from 1.2 to 12.3 µM HePC in Molt-4 medium with 9.2 µM D-19391 as internal standard was used to determine the compound's cel-

TABLE 2
Uptake Measurements of HePC in Molt-4 Cell Cultures and Cell Culture Media[a]

Sample (n = 3)	Cell density (10^5 cells/mL)	HePC in the cells (%)	HePC in media (%)	HePC recovered (%)
1	1.01	23.0 ± 0.9	67.0 ± 18.2	90.0 ± 18.2
2	2.68	20.2 ± 3.3	69.2 ± 20.0	89.4 ± 20.3

lular uptake and retention. A correlation coefficient of 0.998 was obtained. The amount of HePC that was recovered from cell cultures and cell culture media after 36-h incubation was 100.6 ± 15.4% (n = 12) taking into account the values obtained for the recovery in blank experiments. The HePC cellular uptake and retention were performed at different cell densities. The uptake of HePC at varying Molt-4 cell densities amounts to an average of 20.6 ± 4.6% (n = 12). The retention of HePC in Molt-4 cells, after an incubation of 24 h in drug-free medium amounts to 12.8 ± 3.3% (n = 11).

DISCUSSION

By the use of the described cGC method, it was possible after sample clean-up by solid-phase extraction and derivatization to determine the amount of D-19391 and HePC in two cancer cell lines. The cell survival assay proves that the breast cancer cell line SK-BR-3 has a comparable sensitivity to HePC [ID_{50} value of 8.9 ± 2.1 µg/mL (14)] and to D-19391 (ID_{50} value of 10.8 ± 0.1 µg/mL). This is not so uncommon since HePC and D-19391 are structural analogs, differing in alkyl chain length by only two carbon atoms. Also the leukemia cell line Molt-4 is rather sensitive for the HePC action, unlike the human colon cancer cell line Caco-2T [(ID_{50} values of 13.2 ± 2.5 µg/mL and 70.0 ± 3.2 µg/mL, respectively (15)].

Previous experiments performed in our laboratory show that an average of 20% HePC is taken up by the Caco-2T cells after a HePC treatment of 48 h in a concentration of 98.1 µM. After a 48-h recovery period in drug-free medium, 7% is still present in the cells (15). To compensate for the difference in cell counts of each cell culture, the amount of HePC taken up by the cells was expressed per milligram protein. We preferred to determine the cell density to compensate for these cell culture variations. In this way a maximal D-19391 uptake of approximately 18.0 ± 6.0% was reached after a 36-h incubation period in the adherent growing SK-BR-3 cell line. Since the measurements of uptake performed with HePC (14) and D-19391, as structural analogs, in the SK-BR-3 cell line give comparable results we may expect similar retention measurements as well for both agents. HePC still remains present in the breast cancer cells from 6.8 to 9.5% after incubation for 24 h in drug-free medium (14). The uptake of HePC in Molt-4 cells growing in suspension is 20.6 ± 4.6% (n = 12) and the retention after incubation for 24 h in drug-free medium is 12.8 ± 3.3% (n = 11).

Compound cellular uptake is the initial step in a series of events finally leading to cell death. The main target site of these antitumor lipids appears to be the plasma membrane, where they accumulate principally in the phospholipid bilayer. Owing to the lipophilicity of ET-18-OMe (1-octadecyl-2-methyl-*rac*-glycero-3-phosphocholine), a representative of this antitumor class, and its main localization in the cell plasma membrane, Kelley *et al.* (19) propose passive diffusion as the possible uptake mechanism of this ether lipid. Knowing that temperature can influence the cell membrane fluidity, one can adjust this parameter to obtain optimal compound uptake. Bazill and Dexter (20), on the other hand, suggest that endocytotic uptake of antitumor ether lipids is the beginning step in their antitumor activity. Agents interfering with endocytosis inhibit uptake of ether lipids and analogs into cells. The effects of endocytotic as well as metabolic inhibitors, and the use of inhibitors of ATP generation, could give more insight in the mechanism responsible for the results obtained in this study.

We cannot completely compare our results with those obtained for the Caco-2T cell line because of the difference in incubation conditions and the differences in expression of the results. Still, even in a resistant cell line like Caco-2T there is a high HePC uptake that is not very different from the uptake percentage of the compound in the sensitive SK-BR-3 cell line. The difference in cell line sensitivity does not really point to cellular uptake differences. Fleer *et al.* (17) came to the conclusion that both sensitive and resistant cell lines take up HePC in similar amounts, taking the cellular lipid content into account. Other parameters besides uptake must explain the differences in the sensitivity of the cell lines. We are now in the process of investigating apoptosis of these different cell lines under the influence of APC and ALP in order to get more insight in the selective mechanism of action of these antitumor agents.

ABSTRACT: The tapetum cells in the developing anthers of *Brassica napus* contained abundant elaioplasts, which had few thylakoid membranes but were packed with globuli of neutral esters. Of the neutral esters, the major ester group possessed mainly 24-methylenecholesterol, 31-norcycloartenol, 24-dehydropollinastanol, and pollinastanol esterified to 18:3 and other unsaturated and saturated fatty-acyl moieties. The minor ester group had a dominant component tentatively identified as 12-dehydrolupeol esterified to mostly 18:0, 16:0, and 20:0 fatty-acyl moieties. The elaioplasts also contained a high proportion (16% w/w of total lipids) of monogalactosyldiacylglycerols (MGDG). This is the first report of plastids having steryl esters as the predominant lipids. We propose that the globuli contain steryl esters and are stabilized by surface MGDG and structural proteins. The tapetosomes, the other abundant lipid-containing organelles in the tapetum, possessed triacylglycerols (TAG) as the predominant lipids. At a late stage of anther development, the minor group of neutral esters and MGDG of the elaioplasts, as well as the TAG of the tapetosomes, were degraded. Steryl esters similar to those of the elaioplasts were recovered from the pollen surface and were the major lipids of the pollen coat. The pollen coat steryl esters and proteins could be extracted with moderately polar or nonpolar solvents. These proteins, which were mostly fragments of oleosins derived from the tapetosomes, had a high proportion of lysine (13 mol %). The possible functions of the steryl esters and the proteins on the pollen surface are discussed.

Paper no. L8118 in *Lipids 34*, 517–523 (May 1999).

Pollen is produced in the locules (pollen sacs) in the anthers of flowers (1,2). The maturing pollen grains interact with the tapetum, which consists of one layer of metabolically active cells enclosing the locule. The tapetum serves several important roles (2). Throughout the maturation process, the tapetum regulates the flow of nutrients and secretes enzymes to the locule for pollen maturation. At a late stage of anther development, the tapetum cells lyse and discharge molecules onto the surface of the pollen, forming the pollen coat. The pollen coat consists of lipids, proteins, and small molecules such as sugars. The pollen coat may play diverse physiological roles, such as protecting the pollen from solar radiation, giving the pollen color, preventing water loss from the pollen, attracting insect pollinators, acting as an adhesive to affix the pollen together and to the insect pollinators and the stigma surface, aiding hydration and thus the initial germination of the pollen, and exerting self-compatibility and incompatibility (2).

The constituents of the pollen coat of most species are largely unknown, but those of the pollen coat of *Brassica* species have been studied (3–6). In *Brassica*, the pollen coat can be extracted from the pollen with an organic solvent such as cyclohexane or diethyl ether without apparent damage to the pollen protoplast. The coat consists of neutral esters as the major lipid constituents, and its predominant proteins are specifically fragmented oleosins. The oleosins belong to the family of proteins described earlier as abundant structural proteins on the storage oil bodies in seeds (7). The neutral esters and oleosin fragments that constitute the pollen coat are produced in the tapetum cells. At a late stage of anther development immediately before lysis of the tapetum, the tapetum cells contain two dominant organelles. Both organelles are spherical and about 3 µm in diameter (8,9). One of the organelles is a novel lipid particle termed tapetosome, which does not have an enclosing membrane and contains patches of triacylglycerols (TAG) situated among densely packed vesicles (6). The other organelle is the elaioplast, which is packed with globuli of neutral esters. Whereas the predominant proteins of the tapetosomes are oleosins, those of the elaioplasts include lipid-associated structural proteins (10), presumably located on the surface of the globuli. Just before or shortly after lysis of the tapetum cells, some of the constituents of the two organelles are degraded, whereas the other constituents remain unchanged or are modified, and are released onto the surface of the maturing pollen (4–6). These latter constituents include fragmented oleosins of the tapetosomes and the neutral esters of the elaioplasts.

We here report that the abundant neutral lipids in the elaioplasts are steryl esters. This is the first report of plastids contain-

ing steryl esters as the predominant lipids. Also, we demonstrate the selective recovery of the lipids and proteins of the tapetum elaioplasts and tapetosomes on the pollen surface.

EXPERIMENTAL PROCEDURES

Plant materials. Brassica napus L. var. Westar seeds were obtained from Calgene Inc. (Davis, CA) and used to produce flowering plants in a greenhouse maintained at 26.5/18.5°C, 14/10 h day/night cycle. The florets were divided into five developmental stages according to the following criteria (10): at stage 1, the florets were 2 mm long or less, and more than half of the microspores (i.e., the maturing pollen) were in a tetrad condition; at stage 2, the florets were 2–3 mm long, and all the microspores were solitary; at stage 3, the florets were 3–4 mm long, and the tapetum cells were unlysed and filled with organelles; at stage 4, the florets were 4–5 mm long, and the tapetum cells had just lysed; and at stage 5, the florets were 5–6 mm long, and the microspores were almost mature as pollen. Mature pollen was collected from flowers that had opened on the same day.

Isolation of tapetosomes and elaioplasts from the florets. All the solutions described in this paragraph contained 0.05 M HEPES-NaOH, pH 7.5. The florets of stage-3 anthers were finely minced with a razor blade in a petri dish containing a grinding medium of 0.8 M sucrose (125 florets of 3.1 g per 8 mL) (6). Light microscopy revealed that chopping broke most of the sporophytic floral tissues, especially the tapetum, but left the gametophytic microspores intact. These microspores were stained positively with the vital dye fluorescein diacetate (observed by light microscopy). The homogenate was filtered through a layer of Nitex cloth (20 × 20 µm pore size), which removed the microspores. The filtrate (4 mL) was placed in a 17-mL centrifuge tube (6). For the preparation of a mixture of the two organelles (tapetosomes and elaioplasts) in a one-step density gradient, a solution of 0.4 M sucrose solution was layered on top of the filtrate. For the separation of the two organelles in a three-step density gradient, successive layers of 4 mL each of 0.4, 0.2, and 0 M sucrose solutions were placed on top of the filtrate. The tube was centrifuged at 9,000 rpm in a Beckman SW 28.1 rotor for 2 h. In the one-step density gradient, the low-density organelle fraction floating on top was collected with a pipet. In the three-step density gradient, the two visible organelle fractions banding at the interfaces between 0.4 and 0.2 M (tapetosomes), and 0.2 and 0 M (elaioplasts) sucrose solutions were collected from the bottom of the centrifuge tube after a hole was punctured through the tube with a needle.

Preparation of surface fractions from the mature pollen. The procedure followed that described earlier (6). Mature pollen was mixed with 2 vol of diethyl ether (or other solvents, to be described in the Results and Discussion section) for 1 min by repeated inversion in a capped test tube. The pollen was separated from the solvent by centrifugation for 10 min at 800 × *g*. The supernatant was retained and evaporated under vacuum.

Analyses of the proteins in the pollen surface fraction. The amino acid composition was analyzed by the Protein Structure Facility at the University of Iowa, Iowa City, IA. The polypeptide composition was analyzed by 12.5% (wt/vol) sodium dodecyl sulfate-polyacrylamide gel electrophoresis for 2.5 h at 100 V (6). After electrophoresis, the gel was stained with Coomassie blue and then destained.

Extraction of lipids from the various samples. Lipids in the various samples were extracted with chloroform/methanol (2:1, vol/vol) using the procedure of Folch *et al.* (11).

Separation of neutral lipids in pollen coat extracted with different solvents. Lipids in chloroform/methanol (2:1, vol/vol) were applied to thin-layer chromatography plates (silica gel 60A, Whatman Inc., Clifton, NJ). The plates were developed in hexane/diethyl ether/acetic acid (80:20:2, by vol), and then charred with sulfuric acid.

Quantitative analyses of the neutral and polar lipids. Nonpolar lipids were quantitatively analyzed using a high-performance liquid chromatography (HPLC) system that consisted of a Hewlett-Packard (Avondale, PA) Model 1050 Quaternary Solvent HPLC and autosampler, and an Alltech-Varex (Deerfield, IL) Mark III Evaporative Light-Scattering Detector. The column was a LiChrosorb Diol column (Chrompack, 3 × 100 mm), and the flow rate was 0.5 mL/min. The solvents were A, hexane/acetic acid, 1000:0.3, vol/vol; and B, hexane/isopropanol, 100:1, vol/vol. (Both were mixed fresh daily to eliminate variability caused by evaporation and/or absorption of moisture). The linear gradient timetable was as follows: at 0 min, 100:0; at 8 min, 100:0; at 10 min, 75:25; at 40 min, 75:25; at 41 min, 100/0 (%A/%B, respectively), with a total run time of 60 min. Polar lipids (glycolipids and phospholipids) were quantitatively analyzed using an HPLC-evaporative light-scattering detection system as previously described (12).

Analysis of alcohols from E1 and fatty acids from E1 and E2. Lipids in HPLC fractions E1 (defined as lipids with a retention time of 2.3 min) and E2 (retention time of 3.4 min) were saponified with 1 N KOH in 80% ethanol (reflux 1 h at 90°C). After cooling, the alcohols were extracted with hexane, the ethanolic phase was acidified with 6 N HCl, and free fatty acids were recovered by a second hexane extraction. The free fatty acids were then derivatized to methyl esters (FAME) with 14% boron trifluoride in methanol (20 min at 70°C sealed under N_2) for gas–liquid chromatography (GLC) analysis. Prior to GLC and gas chromatography–mass spectrometry (GC–MS) analyses, alcohol and FAME fractions were partially purified by hexane/diethyl ether step gradient elution from Pasteur pipet silicic acid columns (13). Free sterols derived from the steryl esters in HPLC fraction E1 were quantified by capillary GLC–flame-ionization detection on a 30 m × 0.25 mm i.d., 0.25-µm SPB-1 film column (Supelco, Bellefonte, PA) as described previously (14). Sterols were identified on the basis of their retention times relative to authentic standards and by GC–MS followed by comparison of their electron impact (EI) mass spectra with those from standards, from the literature, and/or from the NIST (National Institute of Standards and Technology, e-

mail: http://webbook.nist.gov) spectral library. FAME derived from fraction E1 and E2 lipids were quantified by capillary GLC–flame-ionization detaction, with separation on a 15 m × 0.25 mm i.d., 0.20-µm SP-2330 film column (Supelco) as previously described (15). Identification was based on FAME retention times relative to authentic standards, with confirmation by electron impact (EI) GC–MS. Electron ionization spectra (70 eV, source temperature 180°C) of free sterols and FAME were collected from *m/z* 40 to 500 using a Hewlett-Packard 6890 series gas chromatograph and mass-selective detector fitted with a 30 m × 0.25 mm i.d., 0.25-µm SPB-1 film capillary column. For sterols, the column oven was programmed to increase from 200 to 240°C at 10°C per min, followed by an increase from 240 to 260°C at 1°C per min, with a final 12 min at 260°C. For FAME, the column oven program included an initial rise from 100 to 150°C at 10°C per min, followed by a further increase from 150 to 200°C at 2°C per min and a final 10 min at 200°C.

Analysis of E2 and alcohols from E2. The lipids were analyzed by HPLC–MS–atmospheric pressure chemical ionization (APCI). The HPLC system for separation of nonpolar lipids described in an earlier section was connected to a Hewlett-Packard Model 5989A mass spectrometer, with an APCI interface operated in the positive ion mode. The ion source was at 100°C, and the instrument scanned from 50–1000 *m/z* at 2.0 s/scan.

RESULTS AND DISCUSSION

Lipid composition of the florets and the subcellular fractions. Lipids extracted from the whole florets (omitting the maturing pollen) and the various organelle fractions were analyzed *via* one HPLC system for the nonpolar lipids and another HPLC system for the polar lipids (Table 1). The abundant lipids in all the samples were neutral lipids and glycolipids. Those in the whole florets included a major (E1, about 80%) and a minor (E2, about 20%) group of fatty-acyl esters, TAG, and monogalactosyldiacylglycerol (MGDG). E1 and E2 ester fractions were separated in the nonpolar HPLC system, with retention times of 2.3 and 3.4 min, respectively. Whereas the E1 esters co-chromatographed with steryl-fatty acyl ester standards, no known standards co-chromatographed with the E2 ester. The abundant lipids and the minor lipids of the whole florets were also present in roughly the same proportion in the two-organelle fraction, which was a mixture of approximately equal amounts of the elaioplasts and the tapetosomes of the tapetum. The similarity is expected because the tapetum cells contained the two organelles as the predominant constituents and were the most metabolically active cells in the anthers (other than the maturing pollen).

The isolated elaioplast fraction contained E1, E2, and MGDG as the major neutral lipids, whereas the isolated tapetosome fraction contained mostly TAG. Using the neutral esters and TAG as markers of the two organelles (6), we estimate that the elaioplast fraction contained little contaminating tapetosomes, whereas the tapetosome fraction had some (about 15% w/w) contaminating elaioplasts. This pattern of cross contamination is expected because the elaioplasts moved to a lower density region than the tapetosomes during flotation gradient centrifugation, resulting in a relatively pure elaioplast fraction and a less pure tapetosome fraction containing some tailing elaioplasts. The elaioplast fraction possessed a high amount of MGDG (about 16% w/w of total lipids). Since the elaioplasts have minimal envelope and thy-

Lyso-PC	9	5	27	4	4

[a]The two-organelle fraction was a mixture of approximately equal amounts of the elaioplasts and tapetosomes.
[b]Lipids that were not accounted for in each sample were very nonpolar lipids (e.g., squalene, β-carotene, or other hydrocarbons) that eluted as a single peak in the void volume (1.5 min) by nonpolar high-performance liquid chromatography (HPLC).
[c]For unknown reasons, some preparations of the whole floret, the two-organelle, and the elaioplast fractions contained higher amounts of E2 relative to E1 (about 50–80% rather than the indicated 30–32%)).
[d]The peak fraction of monogalactosyldiacylglycerols (MGDG) resolved by HPLC might contain some steryl glycoside and glucocerebroside. TAG, triacylglycerols; FFA, free fatty acids; ST, sterols, DGDG, digalactosyldiacylglycerols; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PA, phosphatidic acid; PC, phosphatidylcholine. For explanation of EI and E2 see the Experimental Procedures section.

lakoid membranes and are packed with small (about 0.2 µm in diameter) globuli (6), which presumably are made up of the neutral esters, it is likely that the MGDG is present on the surface of the globuli. The tapetosomes contained abundant internal vesicles of presumably membranous nature (6), and their predominant phospholipids were phosphatidylcholine and phosphatidylethanolamine. The lipids on the pollen surface contained mostly E1 and had little E2 and TAG.

All the fractions (Table 1) contained very nonpolar lipids, which were eluted with the void volume (1.5 min.) in the nonpolar HPLC system. These represented a complex mixture of various lipids, such as squalene, ß-carotene, or other hydrocarbons. No attempts were made to further separate and characterize them.

Characterization of the major neutral esters in the elaioplasts. The major group of neutral esters, E1, and the minor group of neutral esters, E2, were characterized further after saponification. The acyl moieties in E1 and E2 were very different (Table 2). In E1, 50% of the acyl moieties were 18:3, 18:2, and 18:1, and the remaining 50% were the saturated acids 16:0, 14:0, 18:0, and 20:0. In E2, only 6% of the acyl moieties were unsaturated, and the saturated moieties included mostly 18:0, and 16:0.

TABLE 2
Fatty-Acyl Composition of the Elaioplast E1 and E2 Neutral Esters

Acyl moiety	E1	E2
	% (wt/wt) of the fatty-acyl methyl esters	
14:0	11.6	6.7
16:0	17.8	37.8
18:0	10.7	35.9
18:1	3.9	2.3
18:2	11.8	2.6
18:3	34.9	1.7
20:0	8.7	10.0
22:0	0.6	1.3
24:0	0	0.9
26:0	0.9	0.8

The saponified E1 contained a mixture of at least 16 sterols, 14 of which (accounting for about 98% of the total) were identified and quantified by GLC and GC–MS (Table 3). Of these sterols, the common desmethyl sterols typically found in plant cell membranes (i.e., sitosterol, campesterol, stigmasterol, and cholesterol) constituted less than 16%. These desmethyl sterols are likely to represent the constitutive components of the limited envelope and internal membranes (6). The four most abundant components included 24-methylenecholesterol and three unusual 9ß,19-cyclopropane sterols (pollinastanol, 24-dehydropollinastanol, and 31-norcycloartenol) derived from a branch pathway of cycloartenol metabolism. They are likely the major constituents of the globuli in the elaioplasts (6,9). These steryl esters are known to be present in pollen from various species (16).

We have so far been unable to identify definitely the predominant alcohol moiety of E2. For both the intact E2 esters and the major alcohol moiety recovered after saponification, the soft-ionization achieved with APCI–MS in the positive mode yielded an intense peak at *m/z* 407. In assuming that this high-mass fragment represented the molecular ion of the E2 alcohol minus water plus a proton ($M^+ - 18 + 1$), which is often observed in mass spectra of sterols and triterpenols, the alcohol should have a molecular weight of 424. Although the EI GC–MS spectrum of the underivatized E2 alcohol showed only a small number of minor peaks above *m/z* 200, the highest mass ion was *m/z* 424, thus supporting the molecular weight proposed on the basis of the APCI–MS data. The pattern of ions ≤ *m/z* 203 obtained with EI GC–MS was similar to that reported for lupeol, a triterpenol with a molecular

[a]Gas chromatography retention time relative to cholesterol.
[b]Sterol nomenclature: cholesterol, cholest-5-en-3ß-ol; lathosterol, cholest-7-en-3α-ol; pollinastanol, 14α-methyl-9ß,19-cyclo-5α-cholestan-3ß-ol; 24-methylenecholesterol, ergosta-5,24(28)-dien-3ß-ol; 24-dehydropollinastanol, 14α-methyl-9ß,19-cyclo-5α-cholest-24-en-3ß-ol; campesterol, 24[*R*]-ergost-5-en-3ß-ol; 31-norcycloartanol, 4α,14α-dimethyl-9ß,19-cyclo-5α-cholestan-3ß-ol; stigmasterol, stigmasta-5,22-dien-3ß-ol; 24-methylene-pollinastanol, 4α-methyl-9ß,19-cyclo-5α-ergost-24(28)-en-3ß-ol; 31-norcycloartenol, 4α,14α-dimethyl-9ß,19cyclo-5α-cholest-24-en-3α-ol; ß-sitosterol, stigmast-5α-en-3ß-ol; isofucosterol, stigmasta-5,24(28)-dien-3ß-ol; cycloeucalenol, 4α,14α-dimethyl-9ß,19-cyclo-5α-ergost-24(28)-en-3ß-ol; cycloartenol, 4,4,14α-trimethyl-9α,19-cyclo-5α-cholest-24-en-3ß-ol.

weight of 426 (the base ion, however was *m/z* 81 rather than 43 as in lupeol). These limited data are consistent with the E2 alcohol being the triterpenol 12-dehydrolupeol, which has been reported to occur as an acetate ester in *Hemidesmus indicus* (17). Further analysis of this alcohol is required for unequivocal identification.

Green or nongreen plastids containing steryl esters as the predominant lipids have not been previously reported. The best-studied nongreen plastids containing high amounts of specific lipids are the chromoplasts, which possess abundant pigments (18). These pigments, mainly carotenoids, are present in globuli in the stroma or fibril structures associated with the thylakoids. The globuli in chromoplasts of some species also contain a high percentage of TAG. The globuli or the fibrils are covered with special structural proteins that are highly conserved in amino acid sequences among species (19). In comparison with these chromoplasts and other plastids, the *Brassica* tapetum elaioplasts are unique. They contain minimal internal membranes and stroma and are packed with lipid globuli. These globuli contain steryl esters and are presumably covered with MGDG (Table 1) and structural proteins similar to those in chromoplasts (10). Elaioplasts of *in situ* morphology similar to that of *Brassica* elaioplasts have been observed in the tapetum of diverse species (2), indicating that they may also have similar lipid and protein compositions.

Developmental changes of the major neutral lipids in the florets. Changes during floret maturation in the contents of the major neutral lipids in the sporophytic anthers, and ultimately on the pollen surface, were determined (Fig. 1). Elaioplast E1 (steryl esters) accumulated during maturation from stage 1 to stage 5. Electron microscopic observations (8,9) showed that at stage 5, the tapetum cells started to lyse, and the elaioplasts or the released globuli were transferred to the surface of the maturing pollen. Steryl esters similar to those of the elaioplasts were recovered quantitatively from the pollen surface (Fig. 1). The current biochemical analysis and the earlier electron microscopic observations strongly suggest that the steryl esters were transferred from the tapetum elaioplasts to the pollen surface. In contrast with the elaioplast E1 steryl esters, the elaioplast E2 (Fig. 1) and MGDG (Table 1), as well as the tapetosome TAG (Fig. 1), increased to a maximum at developmental stage 3 and then declined to minimal amounts on the pollen surface (Fig. 1). Thus, the pollen surface contained only E1 as the predominant lipid component (Fig. 1 and Table 1). The relatively high percentage of lysophosphatidylethanolamine in the pollen coat (Table 1) is indicative of the presence of phospholipase A2 in the anthers during development.

The physiological significance of the accumulation of E2 in the elaioplasts and TAG in the tapetosomes during the mid-maturation stage of the anthers and of their subsequent degradation rather than transfer to the pollen surface is unknown.

Extraction of lipids and proteins from the surface of the pollen. It was reported that the lipids and proteins on the surface of the pollen could be extracted with cyclohexane or diethyl ether without apparent damage to the pollen protoplasts (3,4,6).

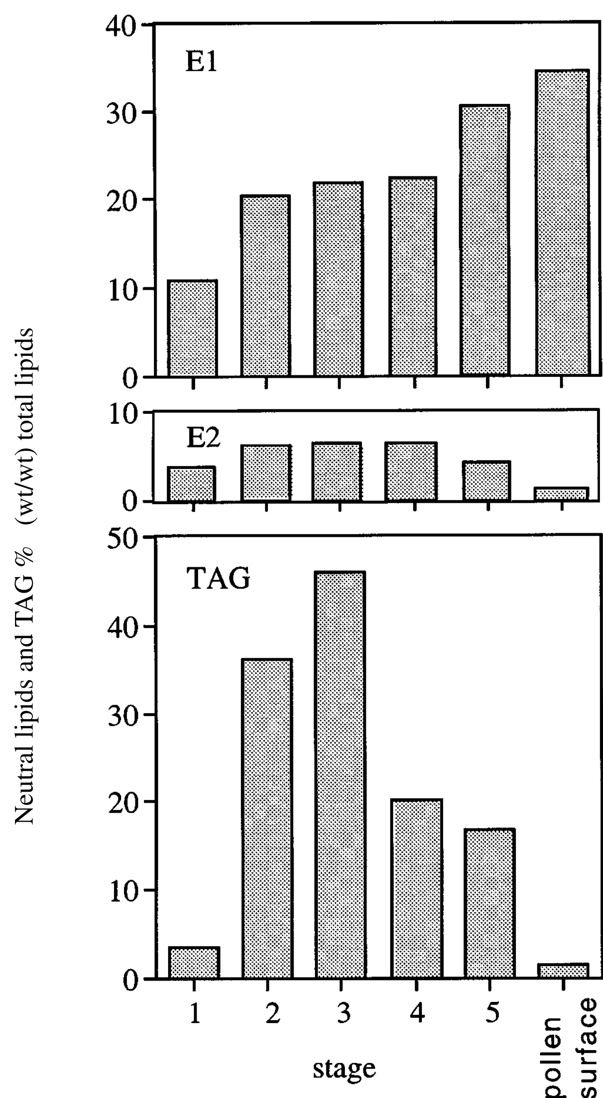

FIG. 1. Proportions of major neutral lipids in *Brassica napus* sporophytic florets at five stages of development and in the pollen coat. Data on the neutral esters E1 and E2 and triacylglycerols (TAG) are expressed as % wt/wt of total lipids. The amounts of total lipids in the florets at stages 1 to 5 and on the pollen surface were 1.01, 2.40, 2.20, 2.22, 2.28, and 2.29 mg per 15 florets, respectively.

In the present study, we found that all the neutral lipids and proteins of the pollen coat could be simultaneously extracted with nonpolar and moderately polar solvents (Fig. 2). They were extracted incompletely with methanol, and not at all with water. The pollen surface lipids shared some similarities with the total pollen lipids (Fig. 2). The total pollen lipids contained the pollen surface E1 and other neutral esters of the pollen interior (6), which comigrated with E1. They also contained TAG, which should be those in the storage lipid bodies in the cytoplasm. The pollen surface proteins were resolved into a pattern by sodium dodecyl sulfate-polyacrylamide gel electrophoresis, which differed from that of the total pollen proteins (Fig. 2).

Most of the polypeptides in the pollen coat had sizes in the ranges of 30–37 kDa and <14 kDa (Fig. 2). They largely repre-

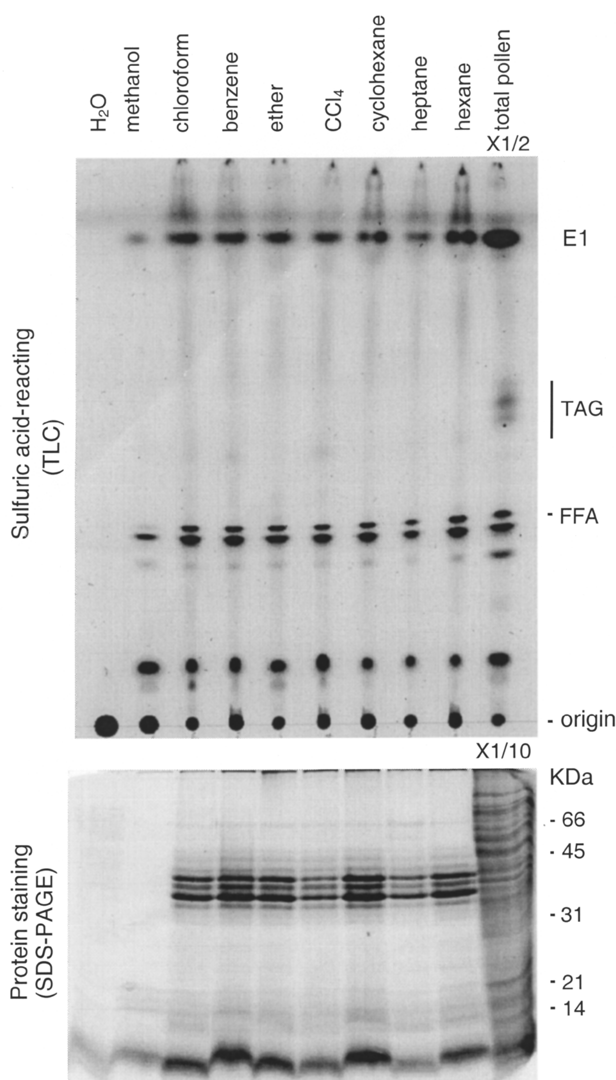

FIG. 2. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of proteins and thin-layer chromatography (TLC) of neutral lipids of pollen coat extracted from the pollen of *Brassica napus* by different solvents. Loading of extracts obtained with various solvents was arranged in the order of decreasing solvent polarity from left to right. Total pollen extract was prepared by grinding pollen in diethyl ether in glass beads with a mortar and pestle. A pollen-coat sample equivalent to an extract from 2 mg (TLC) or 3 mg (SDS-PAGE) of pollen, or total pollen extract from 1/2 of 2 mg (TLC) or 1/10 of 3 mg (SDS-PAGE) of pollen was loaded to each lane. Positions of markers for protein molecular weights and standard lipids are shown on the right. For other abbreviations see Figure 1.

sented specifically fragmented oleosins of the tapetosomes (4, 10). The amino acid sequences of these fragments, as predicted from their gene nucleotide sequences, indicate that they are very hydrophilic. Yet, these very hydrophilic polypeptides and the very hydrophobic steryl esters were extractable by moderately and strongly nonpolar solvents. These findings suggest that on the pollen surface, the neutral lipids of the elaioplasts and the polypeptides of the tapetosomes are mixed and emulsified with amphiphilic molecules, such as phospholipids and galactolipids (Table 1).

TABLE 4
Amino Acid Compositions of the *Brassica* Pollen Coat Proteins and the Two Major Oleosin Fragments Known to Be in the Pollen Coat[a]

	Pollen coat	Fragment from 45-kDa oleosin	Fragment from 48-kDa oleosin

Tyr	1.5	0.38	0.32

[a]The amino acid compositions of the oleosin fragments were deduced from their known amino acid sequences (4,10).

An analysis of the amino acid composition of the total proteins on the pollen surface revealed a very high proportion (13 mol%) of lysine (Table 4). This is a reflection of the high lysine content in the short repeated sequences of the two predominant oleosin fragments on the pollen surface (4,20).

The high-lysine proteins and the plentiful steryl esters are both essential nutrients of the pollinating bees and other insects. Whether these components make a substantial impact in increasing the population of the pollinating insects is unknown. Some minor constituents of the pollen coat are originated from the pollen gametophyte and involved in self-incompatibility (3). The steryl esters on the pollen surface could play one or more of the roles of the pollen coat described in the Introduction. In addition, they could act as feeding stimulants of insects (21) or hormonal stimulants of pollen germination and tube growth (22).

COMMUNICATION

Occurrence of γ-Linolenic Acid in Compositae: A Study of *Youngia tenuicaulis* Seed Oil

Nanzad Tsevegsüren[a], Kurt Aitzetmüller[b,*], and Klaus Vosmann[b]

[a]Chemistry Institute, Mongolian Academy of Sciences, Ulaanbaatar 51, Mongolia, and [b]Institute for Chemistry and Physics of Lipids, BAGKF, D-48147 Münster, Germany

ABSTRACT: Seeds of *Youngia tenuicaulis* and other species from the plant family Compositae (Asteraceae) were studied for their oil content and fatty acid composition. The seed oil of *Y. tenuicaulis* growing in Mongolia was found to contain 5.6% γ-linolenic acid (18:3Δ6*cis*,9*cis*,12*cis*) in addition to common fatty acids. The oil was analyzed using chromatographic [capillary gas–liquid chromatography (GLC), thin-layer chromatography] and spectroscopic (infrared, gas chromatography–mass spectrometry) techniques. Seed oil fatty acids of *Saussurea amara* (containing γ-linolenic acid) and of *Arctium minus* (containing 18:3Δ3*trans*,9*cis*,12*cis*), as well as Δ5*cis*- and Δ5*trans*-18:3 were used as GLC reference substances. The evolution in this plant family of a large number of different 18:3 acids as well as the corresponding evolution of unusual desaturases should be investigated. On the other hand, the Δ6*cis*-desaturase required for the biosynthesis of γ-linolenic acid may have evolved independently several times in unrelated families of the plant kingdom.

Paper no. L8090 in *Lipids 34,* 525–529 (May 1999).

Three species of *Youngia* (*Y. tenuicaulis*, *Y. tenuifolia,* and *Y. stenoma*) are known to occur in Mongolia (1). *Youngia* is a genus of the plant family Compositae (Asteraceae). A large number of species of Compositae have been studied, and their seed oils were found to contain a whole range of unusual fatty acids, e.g., *cis*- or *trans*-unsaturated fatty acids with double bonds in positions 3 or 5 (2–4), or conjugated (5), acetylenic (6,7), epoxidized (8–10), or hydroxylated fatty acids (11). A number of these unusual fatty acids are now of interest because they are natural phytochemicals (12–15). The plant family Compositae also contains species that produce edible oils, such as sunflower and safflower. However, the pharmaceutically interesting γ-linolenic acid has never been found in seed oils of Compositae until we recently discovered it in *Saussurea* (16).

γ-Linolenic acid (γ-Ln, 18:3Δ6*c*,9*c*,12*c* or 18:3n-6) is an important essential fatty acid, both as a nutrient and as a therapeutic agent (17). The occurrence of γ-Ln as a seed oil component was reported by previous workers in the plant families Boraginaceae, Onagraceae, Liliaceae, Aceraceae, Moraceae, Scrophulariaceae and Saxifragaceae (18), and by us in Ranunculaceae (19), Primulaceae (20) and in *Saussurea,* a genus of plant family Compositae (16). Seed oils of *Oenothera biennis, Borago officinalis,* and *Ribes nigrum* are currently the most common commercial sources of γ-Ln. However, further screening for the occurrence and distribution of γ-Ln in the plant kingdom is justifiable. This may have practical consequences with respect to genetic engineering or plant breeding for renewable lipid resources. It may also be of academic interest with regard to natural product chemistry, plant chemotaxonomy, and the phylogenetic evolution of fatty acid structures in seed oils. Δ6-Desaturases that take part in the biosynthesis of γ-Ln should also be of interest in future attempts at enzyme design. These enzymes must have evolved several times, independently, during the course of evolution of otherwise unrelated plant families, and so they may contain different primary structures or amino acid sequences.

Capillary gas–liquid chromatography (GLC) on columns of different selectivity is a powerful analytical tool to detect and identify γ-Ln and other unusual positional or geometrical isomers of fatty acids that occur as seed oil components (21–24). However, some care is needed in investigations of Compositae seed oils, because other 18:3 fatty acid isomers may be present. For example, γ-Ln and Δ3*trans*-18:3 peaks may overlap on certain polar GLC columns.

In continuation of our screening project for exploring the oilseed potential of wild species of Compositae, we have analyzed seed oils from many other less well-studied species. These include a large number of species growing in Central Asia, including *Saussurea* spp. (16), *Y. tenuicaulis,* and various *Artemisia* spp. (Tsevegsüren, N., and Aitzetmüller, K., unpublished data). There is no information in the available literature on seed oils from genus *Youngia*. The present communication is one of a series resulting from a project intending to supplement the literature with respect to species not previously studied, as well as to discover new natural seed oil sources for unusual fatty acids in the plant kingdom. γ-Ln was found as a component fatty acid (5.6%) in seed oil from *Y. tenuicaulis*, the second known source of γ-Ln in the Compositae [*Saussurea* (16) was first]. *Youngia tenuicaulis* oil was characterized by capillary GLC separation of fatty acid

methyl esters and mass fragmentation of the dimethyloxazoline (DMOX) derivative of γ-Ln. Results on *Youngia*, *Saussurea,* and *Arctium* are compared with other seed oils of the Compositae.

EXPERIMENTAL PROCEDURES

Seed materials. Seeds of *Y. tenuicaulis* were collected in September 1994 in Bayan zag, Bulgan sum region, Umnegobi aimak, Mongolia. Sources of seeds for the other species used were as described (16,19–23,25).

Oil extraction and preparation of fatty acid derivatives. Ground seeds were extracted with *n*-hexane in a Soxhlet extractor. Fatty acid methyl esters (FAME) of the seed oils were prepared by transesterification with 2.0 M sodium methoxide in methanol as described previously (25). The DMOX derivatives of fatty acids were prepared as described by Zhang *et al*. (26).

Thin-layer chromatography (TLC). To obtain additional information on unusual components in oils, we carried out analytical TLC of oils and FAME on 0.25-mm layer TLC plates of Silica gel G (Merck, Darmstadt, Germany) using a solvent system of *n*-hexane/diethyl ether (70:30 and 80:20 vol/vol, respectively). Spots were visualized by spraying with phosphomolybdic acid (5% in ethanol) and heating at 100°C.

Capillary gas–liquid chromatography (GLC). GLC of FAME was performed on either a Hewlett-Packard HP 5890 or a Perkin-Elmer F22 gas chromatograph equipped with a flame-ionization detector and a fused-silica WCOT capillary column (length 50 m, internal diameter 0.25 or 0.22 mm) packed with one or a number of stationary phases of different polarity (Silar 5 CP, CP Sil 88 and BPX 70).

(i) GLC conditions, Silar 5 CP. The temperature was held at 165°C for 1 min, then programmed from 165 to 205°C at 1°C/min, then held at 205°C for *ca*. 60 min before cooling to 165°C. The injector and detector temperatures were 230 and 260°C, respectively.

(ii) BPX 70. The temperature was programmed from 100 to 240°C at 2°C/min and maintained at 240°C for 32 min. The injector temperature was 260°C and the detector temperature was 240°C.

(iii) CP Sil 88. The temperature was programmed from 100 to 220°C at 1.5°C/min and maintained at 220°C for 20 min. The injector temperature was 270°C and the detector temperature was 240°C.

Nitrogen (Silar 5 CP and BPX 70) and hydrogen (CP Sil 88) were used as carrier gases. Flow rates were 1.13 mL N_2/min for the Silar 5 CP, 0.69 mL N_2/min for the BPX 70, and 1.0 mL H_2/min for the CP Sil 88 columns.

Chromatographic data were evaluated with an integrator (Chromato-Integrator D2000, HP 3396 Series II Integrator, or Shimadzu Chromatopac C-R3A). Identification of FAME was confirmed by chromatographic comparison with authentic standards, including seed oils of known composition, and by co-chromatography and calculation of equivalent chain lengths (ECL) (21).

GC–mass spectrometry. GC–mass spectrometric analysis was carried out using the electron impact ionization mode (70 eV) on a Hewlett-Packard instrument Model 5890 Series II/5989A, equipped with a 0.23 μm Permabond OV-1 fused-silica capillary column (Macherey-Nagel, Düren, Germany; 25 m × 0.32 mm i.d.). The column temperature was initially held at 150°C for 5 min, then programmed 150 to 270°C at 4°C/min. The final temperature was held for 5 min. Other operating conditions were split/splitless injector temperature of 300°C, interface temperature of 280°C, and ion source temperature 200°C. The carrier gas was helium at a flow rate of 1.5 mL/min.

Infrared (IR) absorption spectra. IR spectra were determined from oil films deposited on sodium chloride cell windows using a Perkin-Elmer 781 Infrared Spectrophotometer (Beaconsfield, England) with a focusing attachment to check the presence of any unusual (*trans* unsaturated or oxygenated) fatty acid.

RESULTS AND DISCUSSION

The extraction of seeds of *Y. tenuicaulis* yielded 16.2% seed oil. The fatty acid compositions of this oil and some others used for comparison are given in Table 1. Since IR spectra of the *Youngia* oil showed no bands in the 960 cm^{-1} region, *trans*-fatty acids are absent and any unsaturation in the oil has the *cis* configuration only. Analytical TLC and IR spectra of the seed oil and TLC of the mixed FAME confirmed the ab-

sence of any oxygenated fatty acids. The typical GLC pattern or fingerprint (23) of mixed FAME of *Y. tenuicaulis* seed oil on a Silar 5 CP column is illustrated in Figure 1A. One interesting aspect of the fatty acid analysis was the appearance of an unusual component with ECL 19.09 (5.6% abundance) on the Silar 5 CP column in addition to linoleic (65.1%) and oleic (16.4%) acids as the predominant fatty acids. The ECL suggests that this peak is an isomeric 18:3 acid. Further tentative identification of γ-Ln was carried out by capillary GLC analyses of the methyl esters on capillary columns of BPX 70 and CP Sil 88, which resulted in good separation of the FAME, with ECL values for γ-Ln of 19.66 and 19.95, respectively. These ECL values correspond well to those found with authentic γ-Ln methyl ester (test substance) and to those found with several well-known seed oils containing γ-Ln.

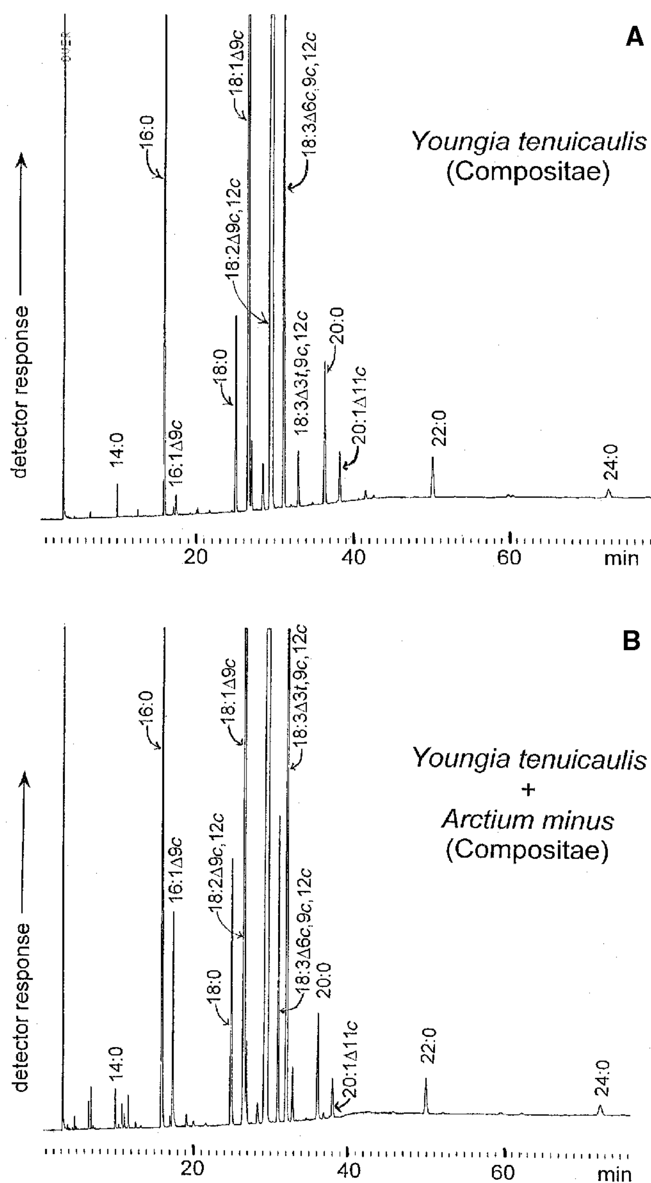

FIG. 1. Gas–liquid chromatograms of the fatty acid methyl esters (FAME) (A) of *Youngia tenuicaulis* (Compositae) seed oil separated on a Silar 5 CP column, and (B) from *Y. tenuicaulis* seed oil mixed with FAME from *Arctium minus* seed oil separated on a Silar 5 CP column. FAME peaks are labeled as usual; 18:3Δ3*t*,9*c*,12*c* is caleic acid and 18:3Δ6*c*,9*c*,12*c* is γ-linolenic acid.

γ-Ln (18:3Δ6*c*,9*c*,12*c*) had never been observed in seed oils of members of the Compositae until it was recently found in several *Saussurea* spp. (16) during the present series of investigations. Another 18:3 isomer (18:3Δ3*t*,9*c*,12*c*, caleic acid) was previously reported to occur more frequently in the Compositae and it is present, for example, in *Arctium minus* seed oil (2). Therefore, seed oils from *Saussurea amara* and *A. minus*, both belonging to the plant family Compositae, were used as reference substances to compare the gas chromatograms and ECL values under our three different gas chromatographic conditions. The absence of 18:3Δ5*c*,9*c*,12*c* and of 18:3Δ5*t*,9*c*,12*c* was also established as described before (21).

We know that caleic acid (18:3Δ3*t*,9*c*,12*c*) is difficult to separate from γ-Ln (18:3Δ6*c*,9*c*,12*c*) on the BPX 70 column under the given conditions. Baseline separation, however, is obtained on Silar 5 CP columns. Co-injection of mixed FAME from *Y. tenuicaulis* seed oil with those from *A. minus* seed oil gave a split peak, with the unknown from *Y. tenuicaulis* eluting just before the peak of 18:3Δ3*t*,9*c*,12*c* from *A. minus* (Fig. 1B). This indicated that the unknown in *Y. tenuicaulis* was not caleic acid. The presence of 18:3Δ6*c*,9*c*,12*c* was established in a similar manner by comparison with *S. amara* which contains this fatty acid in its seed oil. Co-chromatography of *Y. tenuicaulis* seed oil FAME with those from *S. amara* on a Silar 5 CP column resulted in a single peak for the unknown from *Y. tenuicaulis* which coeluted with 18:3Δ6*c*,9*c*,12*c* from *S. amara.* This comparison supported the presence of γ-Ln (18:3Δ6*c*,9*c*,12*c*) in *Y. tenuicaulis.*

The separation of Δ6*cis*-, Δ5*cis*-, and Δ5*trans*-18:3 isomers had been studied in detail before (21), using *Aquilegia* oil as a source of Δ5*trans*-18:3 and *Xeranthemum* as a representative of the Compositae that contains the Δ5*cis* isomer, i.e., pinolenic acid or 18:3Δ5*cis*,9*cis*,12*cis*. Our GLC data in the present case, however, clearly established the absence of both these fatty acids in *Youngia*. No Δ3*trans*- *or* Δ5*trans*-fatty acid or any other peak representing a *trans* fatty acid was found in *Y. tenuicaulis*, thus confirming the earlier IR evidence for the absence of a *trans* peak.

Further evidence for the double bond positions in the unusual 18:3 fatty acid of *Y. tenuicaulis* seed oil is given by the GC–mass spectrometric fragmentation pattern of the DMOX derivatives. The molecular ion at *m/z* 331 indicates the presence of three double bonds. Their position was easily recognized by applying the empirical rule for double bond location (26). The peak indicating the first double bond in mass spectra of polyunsaturated fatty acid DMOX derivatives with a Δ6 double bond (*m/z* 166) was accompanied by a strong odd-mass ion at *m/z* 167, in good agreement with literature data (26–28). The mass intervals of 12 *m/z*, instead of 14 *m/z*, occurred between *m/z* 194 (C_8) and *m/z* 206 (C_9) as well as between *m/z* 234 (C_{11}) and *m/z* 246 (C_{12}). This pattern indicates the presence of a Δ9 and a Δ12 double bond.

In conclusion, this study demonstrates for the first time that a seed oil of the genus *Youngia* contains γ-Ln. γ-Ln was unambiguously identified as a component fatty acid in *Y. tenuicaulis* seed oil which, therefore, besides *Saussurea,* seems to be only the second hitherto known γ-Ln-bearing genus of Compositae. γ-Ln, which is a very common seed oil constituent in the Boraginaceae (25), occurs only sparsely and sporadically in other plant families. The list of the natural sources for this pharmaceutically interesting fatty acid is now extended by another genus of the plant family Compositae, which is presently the only plant family where four different nonconjugated isomers of 18:3 are known to occur: 18:3Δ9*cis*,12*cis*,15*cis* (linolenic acid), 18:3Δ5*cis*,9*cis*,12*cis* (pinolenic acid), 18:3Δ3*trans*,9*cis*,12*cis* (caleic acid), and 18:3Δ6*cis*,9*cis*,12*cis* (γ-linolenic acid). Besides these, conjugated 18:3 acids have also been described in members of the Compositae, for example in *Calendula* and *Osteospermum*. Thus the Compositae are apparently capable of producing a whole range of different 18:3 fatty acids in phylogenetically closely related species or genera. Given the fact that these plant species or genera have evolved from one common ancestor by way of mutations, the biosynthetic pathways and the nature and structure of the enzymes involved in the production of so many different 18:3 fatty acids, including the conjugated ones, should be investigated and may prove useful in any future attempts at desaturase enzyme design. Similar cases had been discussed recently in the Ranunculaceae, where the evolution of desaturases producing Δ5*trans*-, Δ5*cis*- and Δ6*cis*-fatty acids, and changes of substrate preference, appeared to be linked to the phylogenetic evolution of the individual plant genera (29,30).

ACKNOWLEDGMENTS

N.T. is indebted to the Alexander von Humboldt Foundation, Bonn, for a 2-yr fellowship. The authors wish to thank Mrs. Gisela Werner for the assistance in GLC on the Silar 5 CP column, Dr. Ludger Brühl for GLC analysis on the CP Sil 88 column, Mrs. Barbara Sandner for the preparation of a GC–mass spectroscopic derivative, and Mrs. Stephanie Enste for her assistance in the preparation of the electronic manuscript (all from the Institute for Chemistry and Physics of Lipids, BAGKF, Münster, Germany). Thanks are also due to Dr. Sharav Darimaa, a botanist, of State Pedagogical University, Ulaanbaatar, Mongolia, for the identification of the *Y. tenuicaulis* plants and seeds.

ARTICLE

Metabolism of Individual Fatty Acids During Infusion of a Triacylglycerol Emulsion

Barbara A. Fielding*, Jaswinder S. Samra[1], Cate L. Ravell, and Keith N. Frayn

Oxford Lipid Metabolism Group, Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford OX2 6HE, United Kingdom

ABSTRACT: The triacylglycerol emulsion Intralipid was infused into six normal subjects to investigate the metabolism of individual fatty acids in subcutaneous adipose tissue and forearm muscle, by measurement of arteriovenous differences. The composition of plasma nonesterified fatty acids changed steadily after passage through adipose tissue and became similar to that of the emulsion, reflecting hydrolysis of the Intralipid-triacylglycerol by lipoprotein lipase, since endogenous lipolysis (hormone-sensitive lipase activity plus lipoprotein lipase hydrolysis of very low density lipoprotein triacylglycerol) was decreased. There was no significant net release of total or individual fatty acids from forearm muscle although there was a tendency for the composition of the fatty acids in forearm venous plasma to change during passage through the tissue to reflect the composition of the emulsion. This may reflect hydrolysis of emulsion particles by lipoprotein lipase situated in capillaries which drain into the forearm vein. The behavior of stearic acid in the plasma nonesterified fatty acid pool was consistently aberrant, with arterialized concentrations considerably higher than predicted from adipose tissue release, both before and during Intralipid infusion. We conclude that there are no significant differences in the metabolism of specific fatty acids, with the exception of stearic acid.

Paper no. L8035 in *Lipids 34,* 535–541 (June 1999).

The enzyme lipoprotein lipase (LPL) is attached to the capillary endothelium in a number of extrahepatic tissues and acts on circulating triacylglycerol (TAG) to release fatty acids. These fatty acids may be taken up into the tissue for oxidation or, once reincorporated into TAG by esterification pathways within the cell, they can be stored. Alternatively, they may be released into the plasma as nonesterified fatty acids (NEFA). Both pathways occur in adipose tissue (1), but whether LPL-derived fatty acids may be released as plasma NEFA in other tissues is not known.

The exact mechanism of fatty acid transport into and out of the adipocyte has not been elucidated, although there is evidence to suggest that in mammalian cells, membrane uptake of long-chain fatty acids is mediated by both passive and facilitated processes (2). There is some indirect evidence that the partitioning of LPL-derived fatty acids between tissue uptake and release into the plasma is fatty-acid specific. For instance, after a high-fat meal the composition of plasma NEFA changes to partially reflect the fatty acid composition of the meal (3,4). Unsaturated fatty acids tend to be underrepresented in the change in the plasma NEFA pool (3). Similarly, when a synthetic TAG emulsion is infused, the composition of plasma NEFA changes to reflect that of the emulsion, but again unsaturated fatty acids are underrepresented (5). One possible explanation is preferential tissue uptake of unsaturated fatty acids at the site of LPL action. There is now considerable evidence in both small animals (6,7) and humans (8) for preferential release of certain fatty acids from adipose tissue during fat mobilization. For a given chain length, unsaturated fatty acids are more highly mobilized than saturated, and for a given degree of unsaturation, shorter-chain fatty acids are more highly mobilized than longer-chain. This suggests that the physicochemical properties of fatty acids are important determinants of their transport across the adipocyte cell membrane. Since the composition of adipose tissue TAG broadly reflects that of the diet (9,10) and therefore does not become depleted of specific fatty acids, there must be corresponding replenishment of unsaturated and shorter-chain fatty acids. Perhaps at times of fat deposition there is preferential uptake of the fatty acids that are more readily mobilized. Preferential uptake of certain fatty acids has not been demonstrated directly.

To test this idea directly, we investigated the handling of individual fatty acids in subcutaneous adipose tissue by measurement of their arteriovenous differences during a time of expected fat storage. This technique involves sampling from a cannula inserted into a vein draining the subcutaneous abdominal adipose tissue. At the same time, samples are taken from a cannula inserted in a retrograde fashion into a vein draining a warmed hand, providing arterialized blood (11). Arteriovenous differences across the forearm (mainly skeletal muscle) were measured at the same time to elucidate the fate of LPL-derived fatty acids in skeletal muscle. Since there are problems in interpreting data in the nonsteady state following a fat-rich meal, we infused a synthetic TAG emulsion.

Concentrations of other metabolites including plasma

TAG and NEFA in this study have been reported previously (12,13). The findings of that study, in brief, were that plasma TAG and NEFA concentrations increased markedly in response to the lipid infusion. As discussed in Reference 13, the rise in arterialized plasma NEFA was not associated with increased release of fatty acids from subcutaneous adipose tissue as we previously found after the ingestion of a mixed meal. Increased net release of NEFA from adipose tissue during the postprandial period partly represents increased release of fatty acids into the adipose venous plasma by the LPL-mediated hydrolysis of dietary TAG, circulating in the plasma in chylomicron particles (14).

Another unexpected finding was that the calculated adipose tissue hormone-sensitive lipase (HSL) activity was decreased during and after the infusion (13), despite the absence of an increase in plasma insulin concentrations. This finding aids the interpretation of data in the present study by minimizing the dilution of fatty acids leaving adipose tissue with those from intracellular lipolysis. We therefore now report our measurements of specific fatty acids in plasma lipid fractions in order to try to further our understanding of the handling of individual fatty acids in peripheral tissues.

METHODS

Subjects and protocol. The studies were approved by the Central Oxford Research Ethics Committee, and all subjects gave informed consent. Six normal, healthy male subjects aged 21–37 yr, with body mass index 23.0–25.9 $kg \cdot m^{-2}$, ate a low-fat evening meal and were studied the next morning after an overnight fast.

Blood samples from arterialized, forearm venous and adipose venous sites were obtained as previously described in detail (13). Briefly, a cannula was inserted retrogradely into a hand vein and the hand was warmed in a box at 60–70°C in order to obtain arterialized blood samples. Another cannula was inserted retrogradely into an antecubital vein draining deep forearm tissues on the contralateral arm. A 10-cm, 22-gauge catheter was then introduced over a guide wire into one of the superficial veins on the anterior abdominal wall and threaded toward the groin, so that its tip lay just superior to the inguinal ligament. Samples from this cannula represent the venous effluent from the subcutaneous abdominal adipose tissue, uncontaminated by muscle drainage and with only a minor contribution from skin. Blood samples were taken immediately before the start of an intravenous infusion of Intralipid 10% (wt/vol) (Pharmacia Ltd., Milton Keynes, United Kingdom) at a rate of 1.85 $mL \cdot kg^{-1} \cdot h^{-1}$, and at 60, 120, and 240 min during the infusion.

Analytical methods. Blood samples were taken into heparinized syringes and the plasma was separated rapidly at 4°C. A portion (1 mL) was used for preparation of a chylomicron-rich fraction as described previously (2) ("chylomicrons" in this case representing the infused TAG emulsion). Portions of plasma (0.75 mL) and of the "chylomicron" fraction were extracted with chloroform/methanol in tubes containing heptadecanoic acid as an internal standard. The lipid classes were separated by thin-layer chromatography, and specific fatty acids estimated by gas chromatography after methylation, as described previously (8). Samples of Intralipid were analyzed in the same way.

Changes in concentrations with time, and arteriovenous differences across the tissues, were assessed by repeated-measures analysis of variance using time and site (arterialized, forearm venous, and adipose venous) as within-subjects factors. Calculations were done with SPSS for Windows Release 7.1 (SPSS Inc., Chicago, IL). Results are shown as mean value ± SEM.

The proportion of the adipose tissue NEFA veno-arterial difference (AT v-a) that could be attributed to the hydrolysis of endogenous TAG (the total of LPL and HSL-mediated hydrolysis) was calculated from the concentration of palmitoleic acid (16:1) in the adipose venous and arterial plasma. The concentration of palmitoleic acid in Intralipid is less than 0.1%, so it can only arise in the plasma from endogenous sources.

$$\text{endogenous hydrolysis at time } t = \frac{\%\ (\text{mol/mol})\text{ of 16:1 in AT v-a at time } t}{\%\ (\text{mol/mol})\text{ of 16:1 in AT v-a at time 0}} \times 100 \quad [1]$$

At time 0, endogenous hydrolysis is 100%. It is assumed that the proportion of 16:1 to other endogenous fatty acids remained constant during the period of the infusion.

RESULTS

The concentration of TAG in the plasma increased rapidly after the onset of the infusion (Fig. 1) and the concentration of chylomicron-TAG represented over 50% of the total plasma TAG after 120 min. However, despite a high infusion rate, with plasma TAG concentrations increasing threefold within the first 60 min, there was efficient removal of TAG in

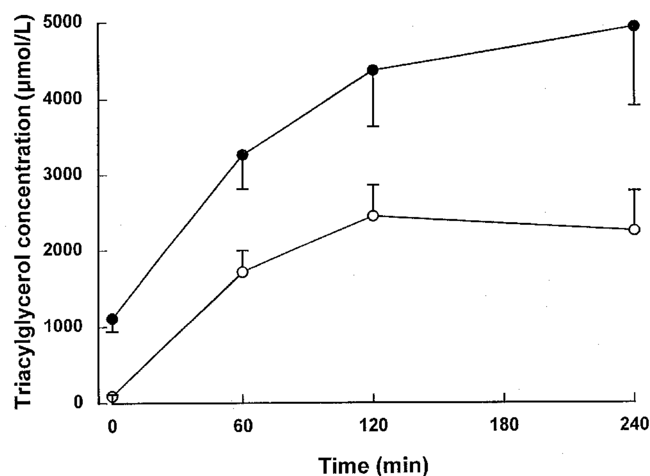

FIG. 1. Plasma triacylglycerol (TAG) (●) and chylomicron-TAG (○) concentrations in arterialized plasma before and during intravenous infusion of Intralipid, as described in the Methods section. The results are plotted as the mean ± SEM for 6 subjects. Error bars have been represented on one side of the mean only for clarity.

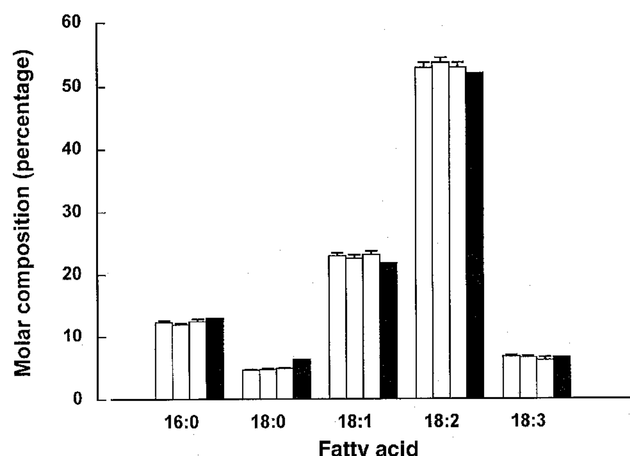

FIG. 2. Fatty acid composition of TAG in the chylomicron fraction taken from arterialized plasma. For each fatty acid the following values are shown (left to right): 60, 120, and 240 min after beginning intravenous infusion of Intralipid. The black bar to the right of each group represents the measured composition of Intralipid. Values are molar percentage composition, shown as mean value ± SEM for 6 subjects. For abbreviation see Figure 1.

the chylomicron-rich fraction, with no further increase in the concentration of chylomicron-TAG after 120 min. The composition of TAG in Intralipid (black bars, Fig. 2), estimated by gas chromatography, was as expected from the manufacturer's literature with a preponderance of 18:2n-6 (linoleic acid). The fatty acid composition of the chylomicron fraction TAG closely resembled Intralipid-TAG throughout (Fig. 2). The concentration and composition were similar in blood samples from all three sites (data not shown).

The concentration of individual fatty acids in the adipose venous plasma (hatched bars) was significantly higher than in arterialized or forearm venous sites ($P < 0.01$ for site effect, for all fatty acids shown on Fig. 3) as found for total plasma NEFA concentrations (13). However, the extent of release of stearic acid into the adipose venous plasma was considerably less than the other fatty acids shown. The relative concentrations of specific plasma NEFA initially (time 0) resembled that usually found after overnight fast (8), with a preponderance of 16:0 (palmitic acid) and 18:1n-9 (oleic acid), a lesser amount of 18:2n-6 (linoleic acid) and very little 18:3n-3 (α-linolenic acid). This changed with time during Intralipid infusion, so that the composition resembled increasingly that of the infused lipid. For example, after 240 min of Intralipid emulsion, 18:2 was the most predominant NEFA in the adipose venous plasma (Fig. 3). There were significant increases ($P < 0.001$) in the proportions of 18:2 and 18:3 and decreases ($P < 0.001$) in the proportions of palmitoleic acid (16:1n-7), 18:1, and 16:0. The composition of the veno-arterial differences for NEFA across adipose tissue initially (time 0) resembled that of plasma NEFA, and again changed with time increasingly to resemble the infused lipid (Fig. 4A). It was noticeable, however, that for stearic acid alone there was no systematic change with time in either its proportion in the veno-arterial difference (Fig. 4A) or its proportion in arterialized plasma NEFA (Fig.4B, black bars). There was no significant release of total NEFA (the sum of individual fatty acids represented in Fig. 3) from forearm muscle into the forearm vein. This was also true for individual fatty acids although there was a tendency for the composition of the fatty acids in forearm venous plasma to change during passage through the tissue to reflect the composition of the emulsion (Fig. 4B). For example, the proportion of 18:2 in the forearm venous plasma was consistently higher than that of the arterialized plasma at each time point, reflecting the high proportion of

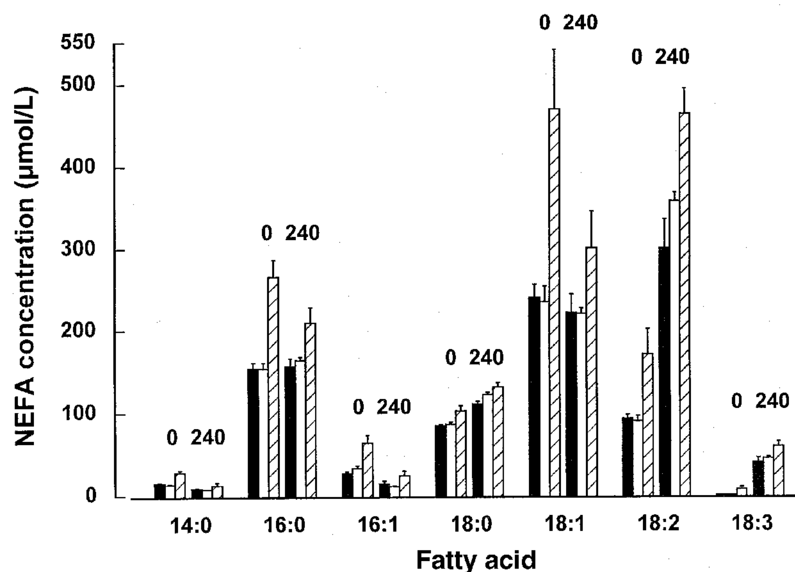

FIG. 3. Concentrations of specific fatty acids in the plasma nonesterified fatty acid (NEFA) fraction. Bars represent mean ± SEM for 6 subjects. For each fatty acid, the following values are shown: arterialized (solid bar), forearm venous (open bar) and adipose venous (hatched bar) plasma NEFA concentrations at time 0 and 240 min.

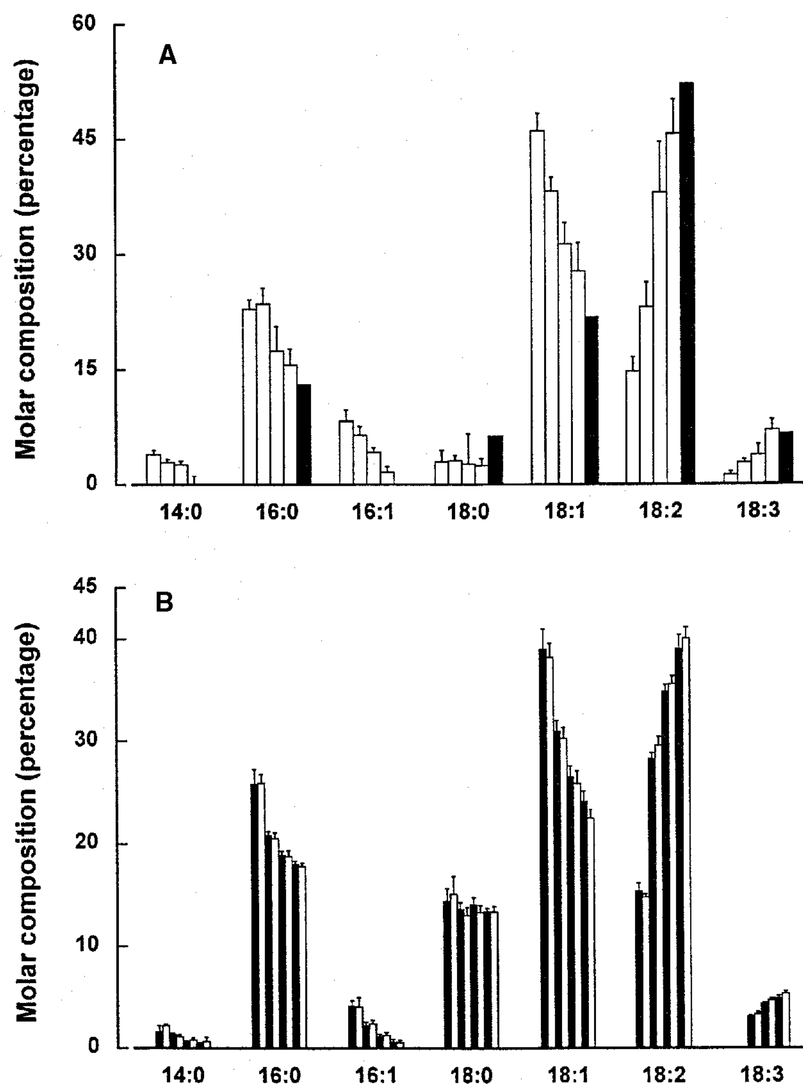

FIG. 4. Fatty acid composition (molar percentages) of the plasma NEFA fraction. Bars represent mean ± SEM for 6 subjects. (A) Composition of the veno-arterial difference for NEFA across adipose tissue (i.e., the composition of the net NEFA release from adipose tissue). For each fatty acid the following values are shown: time 0; 60, 120, and 240 min. The black bar without SEM to the right of each group represents the measured composition of Intralipid triacylglycerol, as in Figure 2. (B) Plasma NEFA composition. For each fatty acid the following values are shown: arterialized (solid bar), forearm venous (open bar) at time 0, 60, 120, and 240 min, respectively. 18:3 was not detected in arterialized and forearm venous samples at time 0. For abbreviation see Figure 3.

18:2 in the lipid emulsion. This may reflect uptake of plasma NEFA by muscle, matched by hydrolysis of emulsion particles by LPL situated in capillaries that drain into the forearm vein.

There is a strong positive relationship between the proportion of each fatty acid in the arterialized plasma NEFA fraction and the composition of the adipose tissue veno-arterial NEFA difference (Fig. 5). That is, the fatty acid composition of the arterialized plasma at any one time can be predicted by the change in fatty acid composition as plasma crosses the adipose tissue depot. The position of individual fatty acids on this relationship changed with time during Intralipid infusion. The proportion of each fatty acid increased or decreased as the composition of the arterialized plasma became similar to the composition of the Intralipid. For example 18:2 (Fig. 5, diamonds) increased from an arterialized value of 15.3 mol% before infusion to a value of 38.9 mol% at the end of infusion, approaching its representation in Intralipid TAG of 52.2 mol%. Despite these changes in arterialized plasma and veno-arterial compositions for individual fatty acids, the relationship over all fatty acids (slope of the line in Fig. 5) did not change. However, it was again noticeable that stearic acid was an outlier in the relationship shown in Figure 5 (black star), and its position remained virtually unchanged during Intralipid infusion (open star). Its concentration in arterial NEFA compared with other fatty acids was therefore higher

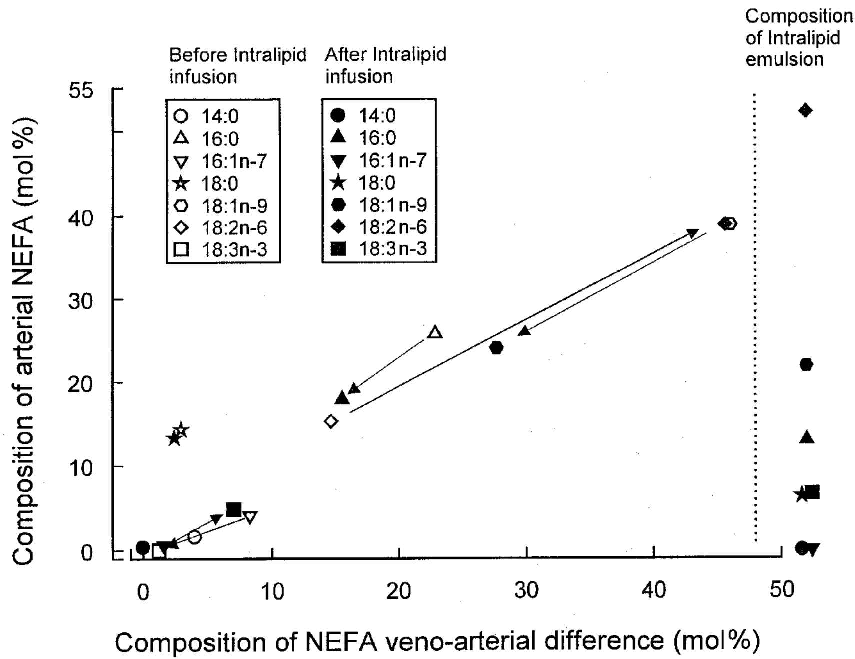

FIG. 5. Relationship between the composition of arterialized plasma NEFA and the composition of NEFA released from adipose tissue before and at the end of Intralipid infusion (comparison of values for 0 and 240 min on Fig. 3). Results are the mean of 6 subjects. Open symbols: 0 min (before Intralipid infusion); solid symbols, 240 min (end of Intralipid infusion). Each symbol represents a different fatty acid (see legend on figure). Arrows illustrate the change in proportions of different fatty acids during the infusion. The column to the right of the dashed line shows the measured composition of Intralipid TAG (mol%). For abbreviations see Figures 1 and 3.

than would be predicted from its composition in Intralipid, despite a relatively low veno-arterial difference.

The difference in concentration of palmitoleic acid (16:1) in the adipose venous and arterial plasma can be assumed to reflect endogenous lipid hydrolysis (LPL-derived fatty acids plus HSL-derived fatty acids) since its concentration in Intralipid was found to be less than 0.1%. We have previously shown that in the fasting state, NEFA leaving the adipose tissue (i.e., the veno-arterial difference) originates mainly from HSL-mediated hydrolysis of adipose tissue stores of TAG (75%) and only 25% from LPL hydrolysis (16). In the fasting state, the source of TAG for both enzymes is endogenous. From Figure 6 in the present study, one can see that the proportion of fatty acids originating from endogenous lipolysis fell steadily during the infusion and, by 240 min, over 80% of the release of NEFA from subcutaneous adipose tissue could be accounted for by exogenous lipid hydrolysis. Since the adipose tissue NEFA veno-arterial difference decreased during Intralipid infusion (13), the decrease in proportion of endogenous fatty acids leaving adipose tissue is likely to be mainly due to suppression of HSL action.

DISCUSSION

The composition of the chylomicron fraction during Intralipid infusion matched closely the measured composition of Intralipid, as expected. However, a surprising finding was that there was no significant change in the concentration of chylomicron-TAG during passage through adipose tissue. This

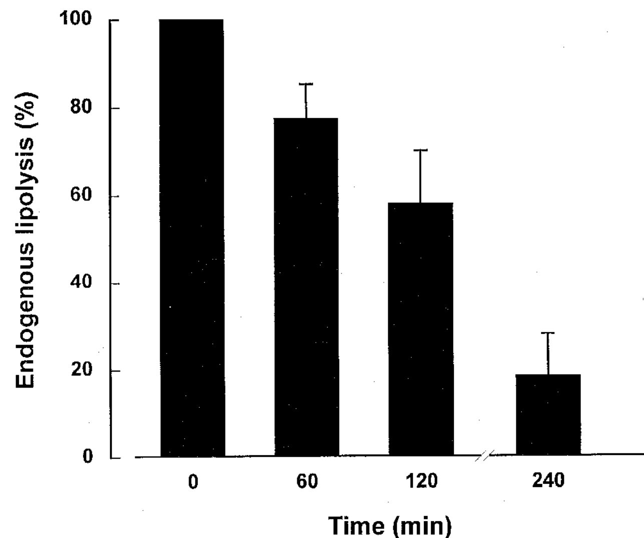

FIG. 6. Calculation of the proportion of plasma NEFA released from adipose tissue (the veno-arterial difference) that is derived from endogenous lipolysis, based on the measurement of 16:1 in the plasma NEFA fraction. Endogenous lipolysis is the net hydrolysis of TAG stored in adipose tissue plus the hydrolysis of very low density lipoprotein-TAG. The calculation and assumptions made are explained in more detail in the Methods section. The results are plotted as the mean ± SEM for 6 subjects. For abbreviations see Figures 1 and 3.

was in accordance with the total plasma TAG measurements in this study, as previously reported (13). Although not measured, the concentrations of very low density lipoprotein (VLDL)-TAG are likely to have increased during the Intralipid infusion owing to increased competition for LPL (17). As discussed in our previous paper, emulsion uptake by extrahepatic tissues may contribute to the clearance of lipid emulsions containing medium- and long-chain TAG (15). In the circumstances of this study, the detection of small changes in the concentration of chylomicron-TAG across the adipose tissue would be difficult to make because of the high concentration of chylomicron-TAG. By ignoring the action of HSL and assuming that reesterification of fatty acids within the adipocytes is virtually zero, one can calculate that the proportion of chylomicron-TAG that would be hydrolyzed to account for the difference in adipose venous and arterial plasma NEFA is 8.4, 5.5, and 3.9% for the time points 60, 120, and 240 min, respectively. However, since HSL was not completely suppressed at those time points, these will be overestimates. Therefore, it is not incompatible that changes in the composition of adipose venous NEFA (reflecting the action of LPL) were detected, and yet LPL-mediated hydrolysis of chylomicron-TAG was not measurable. The composition of the plasma NEFA pool changed steadily during Intralipid infusion, toward that of the Intralipid, as expected from previous work (5). We have shown previously that the composition of arterial NEFA reflects that of NEFA released from adipose tissue (8). This was borne out in the present studies both in the fasting state and as the composition changed during Intralipid infusion, even though arterialized NEFA concentrations did not show the close relationship with the rate of release from subcutaneous adipose tissue that we have shown before (13). NEFA released from adipose tissue arise either from intracellular lipolysis of TAG stores, under the control of HSL, or from the hydrolysis of VLDL- and chylomicron-TAG. In the present study, there was a significant decrease in the calculated action of HSL, derived either from measurements of the transcapillary flux of glycerol (13) or independently from the use of palmitoleic acid as a marker of endogenous lipid. This occurred despite no increase in plasma insulin concentrations (13). This is consistent with the plasma NEFA composition, which rapidly changed to reflect the fatty acid composition of emulsion particles, rather than VLDL- or adipose tissue-TAG. It is also consistent with the finding that the plasma NEFA composition did not appear to have reached equilibrium after 4 h of Intralipid infusion.

The relationship between arterialized NEFA composition and release from adipose tissue appeared consistent for all fatty acids other than stearic. This is somewhat different from the results of Siderova *et al*. (5), who found α-linolenic acid to be almost absent from plasma NEFA during Intralipid infusion. This difference may be explained by the fact that their study used an indirect method for the study of intravascular metabolism of fatty acids. In contrast, the technique of arterio-venous difference is much more direct. The discrepant result for stearic acid is reminiscent of our previous observation that this fatty acid is overrepresented in arterialized plasma compared with its release from adipose tissue (8). This observation could be explained by a rate of clearance of stearic acid which is less than that for other fatty acids. There is evidence of this in the case of splanchnic removal (18). In addition, the proportion of stearic acid among plasma NEFA failed to change during Intralipid infusion, which may result from a low rate of release from adipose tissue, compared with its composition in the emulsion.

In summary, infusion of Intralipid raised chylomicron-TAG and NEFA concentrations as expected. However, clearance of Intralipid-TAG across both subcutaneous adipose tissue and skeletal muscle was considerably less than would have been expected if its metabolism truly reflected chylomicron-TAG metabolism. Intralipid infusion resulted in a decrease of intracellular, HSL-catalyzed lipolysis by mechanisms which are not clear, with the result that the release of fatty acids from adipose tissue changed steadily to reflect hydrolysis of the Intralipid-TAG, presumably brought about by LPL. Our measurements of specific fatty acids again highlight the aberrant behavior of stearic acid among plasma NEFA.

High-Fat Dairy Product Consumption Increases Δ9*c*,11*t*-18:2 (rumenic acid) and Total Lipid Concentrations of Human Milk[1]

ABSTRACT: Conjugated octadecadienoic acids (18:2, conjugated linoleic acids) have been shown to be anticarcinogenic and may influence growth and nutrient partitioning. The Δ9*c*,11*t*-18:2 isomer (rumenic acid, RA) is most common in both food sources and human tissues. To determine if maternal diet can influence milk RA concentration, breastfeeding women ($n = 16$) were enrolled in a 3-wk crossover study. Women initially consumed minimal amounts of food containing RA during week 1, then were assigned randomly to consume diets rich in high-fat dairy foods (and thus RA) during week 2 or 3. Milk was collected by complete breast expression twice during each experimental week. Current and chronic RA intakes were estimated by 3-d dietary records and food frequency questionnaires, respectively. Estimated chronic RA intakes ranged from 49 to 659 mg/d. Dietary RA intake was greater during the high compared to the low dairy period (291 ± 75 vs. 15 ± 24 mg/d, respectively; $P < 0.0001$). Milk contained more RA during the high than the low dairy period (13.5 ± 0.1 vs. 8.2 ± 0.4 μmol/g lipid, respectively; $P < 0.0001$). Milk lipid concentration was influenced by diet, such that lipid concentration was greater during the high than the low dairy period (46.6 ± 5.0 vs. 38.3 ± 1.6 mg/g milk, respectively; $P < 0.05$). Additionally, multiple regression analyses suggested that body mass index was the primary predictor of milk RA and lipid concentrations. In summary, these data indicate that both lipid and RA concentrations of human milk can be influenced by diet.

Paper no. L8007 in *Lipids 34,* 543–549 (June 1999).

Conjugated dienoic derivatives of linoleic acid (conjugated linoleic acids; CLA) are a mixture of geometric and positional isomers of linoleic acid (Δ9*c*,12*c*-18:2) that have been identified primarily in ruminant meats and dairy products (1–3). Because of the high CLA content in beef and milk fat, it is estimated that CLA consumption in the United States may be several hundred mg/person/d if meat and dairy products are a significant part of the diet (4). The most prominent isoform of CLA in foods and human tissues is Δ9*c*,11*t*-18:2, which has been recently given the trivial name of rumenic acid (RA; 6).

Industrially produced mixtures of CLA have been shown to inhibit the initiation of mouse skin carcinogenesis by 7,12-dimethylbenz[a]anthracene (6) and mouse forestomach tumorigenesis induced by benzo[a]pyrene (7). Ip *et al.* (8,9) also reported that increased dietary intake of these CLA reduced significantly the number and incidence of mammary tumors in rats. Whereas these studies elucidated the role of CLA in modulating the initiation stage of cancer, the work of Belury *et al.* (10) reported CLA inhibition of mouse skin tumor promotion by the phorbol ester tetradecanoyl-phorbol-13-acetate in a dose-responsive manner. Additionally, Shultz and colleagues (11–13) reported that CLA was cytostatic and cytotoxic to human malignant melanoma, colorectal and MCF-7 breast cancer cells *in vitro*. Other types of dietary lipid such as n-3 fatty acids, when fed to animal models, have also exhibited anticarcinogenic properties (14). Although the amount of fish oil needed to elicit this response usually exceeds 10% in the diet, the effective dose of CLA to produce significant cancer protective effects might be as low as 0.1% (15). Therefore, increasing the dietary intake of CLA may be a possible, nonpharmacologic approach to cancer prevention.

Additionally, consumption of CLA during lactation has been shown to increase the concentration of CLA in milk of rats, as well as the growth and feed efficiency of the suckling pups (16). However, no studies have been conducted to determine the influence of maternal dietary CLA intake on human milk CLA concentration and health of the breastfed human infant. Recently, we reported that human milk but not infant formula contains substantial amounts of the naturally occurring active isomeric form of CLA (i.e., RA) (17); the range of RA concentrations in human milk was 8 to 19.4 μmol/g lipid. Fogerty *et al.* (1) reported values for human milk CLA concentration of 11.1 to 30.3 μmol/g lipid among mothers eating conventional diets, and values of 34.6 to 44.6 μmol/g lipid among Hare Krishna mothers. These data suggest that diet may influence human milk CLA concentration, because members of the Hare Krishna faith consume large amounts of

butter or ghee, as well as cheese. However, dietary intake was not reported, nor was the CLA isoform distribution.

Because of the potential influence of CLA exposure in decreasing risk of cancer in breast tissue and the possible growth-modifying effects of CLA in the neonate, we were interested in determining factors influencing the concentration and variation of CLA, especially RA, in human milk. Therefore, the purpose of this study was to determine whether high-fat dairy product consumption might affect RA concentration in human milk. We tested the following main hypotheses: (i) Short-term consumption of high-fat dairy foods by lactating women increases the concentration of RA in human milk. (ii) Chronic total RA consumption (as contributed mostly from beef and dairy products) by lactating women is correlated positively with the concentration of RA in human milk.

SUBJECTS, MATERIALS AND METHODS

Subjects. Healthy breastfeeding women ($n = 16$) between 1 and 26 mon postpartum (mean ± SEM: 9.1 ± 2.0 mon) were recruited from the Moscow, Idaho–Pullman, Washington, area. The general purpose and hypotheses of the study were explained to each subject, and written informed consent was obtained. Average age of subjects was 32 ± 2 yr (range: 21 to 38 yr). All procedures were approved by the University of Idaho Human Assurances Committee and the Washington State University Institutional Review Board.

Study design and milk collection. This study was conducted as a crossover experiment lasting 3 wk and beginning on a Sunday. Upon enrollment, women were blocked by number of months postpartum (<12 vs. ≥12 mon) and randomized to be in either Group A (high-fat dairy period during week 2; $n = 8$) or Group B (high-fat dairy period during week 3; $n = 8$). Women were asked to eat diets low in RA throughout the experiment except during their assigned week of eating diets high in dairy foods. In an attempt to standardize initial milk RA concentration, subjects were asked to consume foods containing minimal amounts of RA during week 1 (depletion period). All women were provided with a supply of food items containing an abundance of RA (i.e., cheese, yogurt, whole milk, and ice cream) during the high-fat dairy period. Because of a concern that energy intake would be decreased during the baseline and low dairy periods, subjects were advised to consume sufficient nondairy, high-energy foods during these periods.

Milk was collected by complete breast expression using an electric breast pump (Model SMR-B-R; Ameda-Egnell, Inc., Cary, IL) on days 3 and 7 of each period between 1500 and 2200 h. Subjects were asked either (i) to pump all milk from both breasts or (ii) to pump all milk from one breast while nursing on the other breast until milk flow ceased. Milk was frozen immediately in the homes of the subjects and then transported to the laboratory and stored at −80°C until later analyses.

Dietary assessments. Subjects were requested to keep complete records of their dietary intakes during the last 3 d of each period for estimation of current dietary RA intake. Chronic intake of RA was estimated by a semiquantitative food frequency questionnaire developed by the investigators which estimated mean daily dietary RA consumption. This food frequency questionnaire was designed to obtain information concerning the chronic intake of several ($n = 24$) commonly consumed food items, mostly of beef and dairy origin.

Data from the 3-d dietary records and food frequency questionnaire were analyzed using a nutrient database (18) modified by us to contain previously published values for the RA contents of foods (1–3,19–22). Results obtained from the 3-d dietary records were averaged for each period, and this value is referred to herein as "current" RA intake. Each dietary record was also analyzed for intakes of energy, protein, carbohydrate, fiber, lipid, 18:2 (linoleic acid), 18:3 (linolenic acid), 18:1 (oleic acid), and saturated, monounsaturated and polyunsaturated fatty acids as well as cholesterol. Results obtained from the food frequency questionnaire are referred to herein as "chronic" RA intake and are thought to reflect typical intakes during the previous year.

Anthropometric assessments. Self-reported height and weight of all subjects were obtained at the beginning of the study. For 11 subjects, body weight was measured weekly using an electronic scale (Model 770; Seca Alpha, Germany). Body mass index (BMI) was calculated as measured weight (kg) divided by height squared (m^2) for each subject. For the five subjects for whom weights were only self-reported, BMI was calculated from these self-reported values.

Lipid extraction and analysis of fatty acids. Lipid was extracted from milk in duplicate using standard procedures (23). Hydrolysis of lipid and methylation procedures were performed as described previously (2,24). Briefly, the lipid extract (45 mg) was hydrolyzed with 1 mL 1 N NaOH in methanol, and the free fatty acids were methylated with 1 mL 14% boron trifluoride in methanol at room temperature for 30 min. Hexane (2 mL) and water (1 mL) were added; samples were vortexed thoroughly. Following phase separation, the organic layer was dried with sodium sulfate and quantified by gas chromatography (GC). A lipid extract from a human milk pool was analyzed to determine interassay variability.

Fatty acid methyl esters were analyzed on a Hewlett-Packard gas chromatograph (model 5890; Hewlett-Packard, Avondale, PA) with an on-column injector port and flame-ionization detector. A Supelcowax 10 capillary column (60 m × 0.75 mm i.d.; phase thickness, 1.0 µm; Supelco Inc., Bellefonte, PA) was used for separation of the CLA fatty acid isomers. Conditions of GC analysis were set according to the method of Werner *et al.* (24). CLA peaks (including that of RA) were identified by comparison with the retention time of a CLA standard mixture obtained from Dr. Michael W. Pariza (Food Research Institute, University of Wisconsin, Madison, WI). Fatty acid concentrations were quantified based on a linoleic acid methyl ester standard curve. The coefficient of variation of duplicate extracts was <6.5%, while interassay variabilities of RA and linoleic acid were 6.7 and 7.2%, respectively ($n = 9$).

Statistical analysis. Data were analyzed using the General Linear Models procedure of the Statistical Analysis System

(25). The effects of low and high dairy consumption on milk lipid, RA, and fatty acid concentrations were analyzed using an analysis of variance model for a three-period, crossover design with two treatments. The model parameters included two groups (8 subjects nested within each group), three measurement periods, two dietary treatments (high and low dairy products consumption), and carry-over of treatment into the subsequent measurement period (26). Paired *t*-tests were performed to compare the milk lipid and fatty acid concentrations between sampling days within a dietary period. In all instances these were found to be statistically nonsignificant ($P > 0.05$). Subsequently, the two measurements for milk lipid, RA, and fatty acid concentrations within a dietary period were averaged, and the analysis of variance model was used to assess differences in milk lipid, RA, and fatty acid concentrations for the group, period, treatment, and carry-over means. Differences between means were considered statistically significant at the $P < 0.05$ level.

The relationships among intakes of several nutrients (as assessed by 3-d dietary records) and day 7 milk lipid and RA concentrations were tested by partial Pearson correlation analyses. Multiple regression analyses were conducted to investigate the possible relationships among milk RA and lipid concentrations, BMI, and chronic and current intake of RA. Independent effects were considered statistically significant at the $P < 0.05$ level, and interactions were considered significant at the $P < 0.10$ level.

RESULTS

Maternal anthropometrics. Self-reported height and weight of subjects at enrollment were 1.63 ± 0.01 m and 63.7 ± 3.1 kg (mean ± SEM), respectively. For the 11 subjects for whom weights were measured weekly, there was no difference between weight after the high- and low-fat dairy periods (65.3 ± 4.1 and 64.7 ± 4.1 kg, respectively). BMI was 23.9 ± 1.0, 22.0 ± 1.3, and 22.1 ± 1.3 during the baseline, high and low dairy periods, respectively.

Dietary intake. Dietary intake data are presented in Table 1. Consumption of energy, protein, lipid, RA, oleic, saturated, and monounsaturated fatty acids and cholesterol was greater during the high than the low dairy period. However, dietary intakes of carbohydrate, fiber, linoleic, linolenic, and polyunsaturated fatty acids did not differ. Chronic intake of RA as estimated from the food frequency questionnaire ranged from 49 to 659 mg/d (mean ± SEM: 227 ± 180 mg/d).

Milk fatty acid and lipid concentrations. Concentrations of RA, myristic (14:0), palmitic (16:0), stearic (18:0), and oleic acids increased ($P < 0.05$), while linoleic acid concentration tended to decrease ($P < 0.06$) during the high dairy period as compared to the low dairy period (Table 2). In addition, linolenic acid expressed as μmol/g lipid was lower, whereas palmitoleic acid (16:1), expressed as μmol/g milk, was higher during the high than the low dairy period. Milk RA concentrations of all subjects increased during the high dairy period (Fig. 1). Overall, increased high-fat dairy product consumption resulted in a significant ($P < 0.0001$) increase in RA concentration of milk [8.2 ± 0.4 (0.3 ± 0.1) vs. 13.5 ± 1.1 (0.6 ± 0.1) μmol/g lipid (μmol/g milk) during low and high dairy periods, respectively].

TABLE 1
Mean Daily Nutrient Intakes During Depletion, High and Low Dairy Periods as Estimated from 3-d Dietary Records[a]

	Dietary periods		
Variables	Depletion	High dairy	Low dairy
Energy (kJ)	10,200 ± 628	12,500 ± 1,560[b]	9,180 ± 599
Protein (g)	84 ± 6	137 ± 21[b]	82 ± 7
Carbohydrate (g)	370 ± 29	378 ± 59	327 ± 19

18:3	17.2 ± 1.5	10.7 ± 3.6[c]	17.6 ± 1.2
	(1.4 ± 0.3)	(1.6 ± 0.5)	(1.5 ± 0.1)

[a]Mean ± SEM; *n* = 16.
[b]These fatty acids accounted for approximately 92, 89, and 91% of the total fatty acid composition identified in milk samples during the baseline, high and low dairy periods, respectively.
[c]Values differ ($P < 0.05$) between the high and low dairy periods. For abbreviation see Table 1.

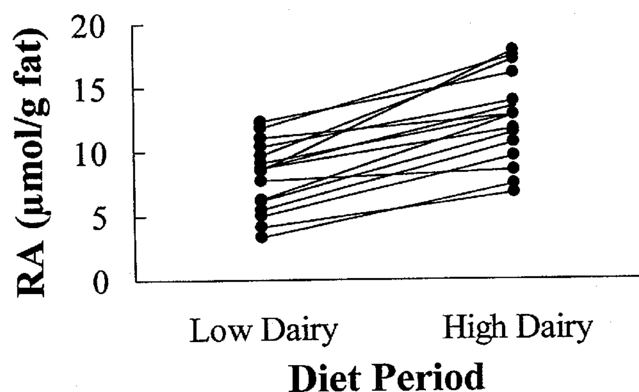

FIG. 1. Concentration of rumenic acid (RA; 9*c*,11*t*-18:2) in milk from individual subjects during the low and high dairy periods. Mean RA concentration was lower during the low than the high dairy periods (8.2 ± 0.4 vs. 13.5 ± 1.1 μmol/g lipid, respectively; $P < 0.0001$).

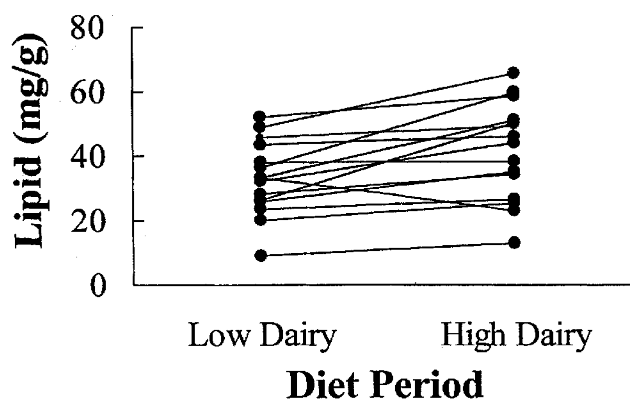

FIG. 2. Lipid concentrations in milk from individual subjects during the low and high dairy periods. Mean lipid concentration was lower during the low than the high dairy periods (38.3 ± 1.6 vs. 45.6 ± 5.0 mg/g milk, respectively; $P < 0.05$). It should be noted that data from one subject (26 mon postpartum; 108.2 and 114.7 mg lipid/g milk during the low and high dairy periods, respectively) were omitted from the figure, because they were substantially greater than all others, and thus were not suitable for this illustration.

Milk lipid concentrations for each subject are illustrated in Figure 2. Consumption of high-fat dairy products resulted in an overall increase in milk lipid, as compared to that found in the low dairy period (45.6 ± 5.0 vs. 38.3 ± 1.6 mg/g milk, respectively; $P < 0.05$).

Factors related to milk composition. After controlling for dietary intakes of energy, protein, lipid, linoleic acid, saturated fatty acids, and cholesterol, analyses using partial Pearson correlation coefficients suggested that current dietary intakes of RA ($r = 0.32$), oleic ($r = -0.41$), and monounsaturated fatty acids ($r = 0.38$) were correlated with milk RA concentration (μmol/g lipid). However, when milk RA was expressed as μmol/g milk, there were no statistical relationships between these dietary components and milk RA. Further, there were no significant relationships between milk lipid concentrations and any of the dietary nutrients investigated.

Although milk RA and lipid concentrations of most subjects increased during the high dairy period, there was considerable between-subject variation in all periods. Thus, multiple regression analyses were conducted to explore the possible relationships among milk lipid and RA concentrations, BMI, and chronic and current RA intakes; the interaction between BMI and chronic RA intake was also included in the model, because the effect of chronic RA intake on milk RA concentration may be influenced by BMI of subjects (Table 3). BMI was related positively to milk lipid concentra-

TABLE 3
Results (β ± SEM) of Multiple Regression Analyses Investigating the Relationships Among BMI, Chronic and Current RA Intakes, and Milk Lipid and RA Concentrations During Depletion, High and Low Dairy Periods[a]

Dietary period	Independent variables	Dependent variables: Lipid (mg/g milk)	CLA (μmol/g lipid)
Depletion	Constant	−87.2 ± 42.1	−9.31 ± 5.38
	BMI	5.68 ± 1.78[b]	0.60 ± 0.23[b]
	Chronic RA intake	0.23 ± 0.15	0.04 ± 0.02
	Current RA intake	−0.23 ± 0.14	0.02 ± 0.02
	BMI × chronic RA intake	−0.01 ± 0.006	−0.001 ± 0.0007
High dairy	Constant	−86.1 ± 53.9	−7.88 ± 5.56
	BMI	5.55 ± 2.30[b]	0.69 ± 0.24[b]
	Chronic RA intake	0.27 ± 0.18	0.07 ± 0.02[b]
	Current RA intake	−0.004 ± 0.04	0.003 ± 0.004
	BMI × chronic RA intake	−0.01 ± 0.007	−0.002 ± 0.00072[b]
Low dairy	Constant	−91.4 ± 48.4	−6.16 ± 6.26
	BMI	5.31 ± 2.02[b]	0.51 ± 0.26
	Chronic RA intake	0.21 ± 0.17	0.03 ± 0.02
	Current RA intake	0.08 ± 0.25	0.02 ± 0.03
	BMI × chronic RA intake	−0.008 ± 0.007	−0.001 ± 0.0009

[a]$n = 16$; BMI, body mass index (kg/m^2); CLA, conjugated linoleic acid; for other abbreviation see Table 1.
[b]Significant relationship ($P \leq 0.05$ for individual effects and $P < 0.10$ for interactions).

tion during all periods and to RA concentration during the depletion and high dairy periods. After controlling for BMI, chronic RA intake was correlated positively with milk RA concentration during the high dairy period. Interestingly, after controlling for BMI and chronic RA intake, current RA intake was not a significant predictor of milk lipid or RA concentration in any period.

The interaction between BMI and chronic RA intake was related to milk RA concentration during the high dairy period, such that the positive effect of chronic RA intake on milk RA concentration was greater in subjects with lower BMI. In addition, we observed similar relationships for milk RA concentration when expressed as μmol/g milk (data not shown).

DISCUSSION

Results from this study indicate that the RA concentration in human milk increases when the consumption of high-fat dairy products increases. Previously, we reported that human milk contains predominantly the RA isomer of CLA (17), and we suspected that variation among milk samples was primarily due to maternal intake of RA. The presence of RA in human milk has been confirmed by Jensen and colleagues (27) using GC/mass spectrometry. Data from the only other study reporting CLA concentration in human milk also suggested that diet may also influence the CLA concentration of human milk, such that women of the Hare Krishna faith produced milk with higher CLA concentration than did women consuming conventional diets (1). It is noteworthy that the CLA concentration of milk produced by Hare Krishna women was much higher and of greater range than concentrations reported in this study, and that this difference may be due to their greater use of butter or ghee in food preparation (28).

Data from the present study also suggest that dietary RA, especially chronic intake, is related positively to milk RA concentration. Although the dietary intakes of energy, protein, lipid, and cholesterol increased during the high dairy period, the aforementioned dietary nutrients were not correlated with milk RA concentration. The dietary intakes of oleic and monounsaturated fatty acids were correlated with milk RA concentration, although their correlation coefficients were not as strong as that of current dietary RA with milk RA concentration. However, when both current and chronic intake of RA were included in the multiple regression analyses, only chronic RA intake remained significant, suggesting that current intake of RA is not as strong of a predictor of milk RA concentration, at least not in the time frame used for this study. This may mean that small changes in milk RA concentration can be made in a short period of high-fat dairy product consumption. However, to observe large changes in milk RA concentration a high RA diet must be consumed chronically.

In addition, multiple regression analyses showed that BMI was a primary factor in predicting milk RA concentration. Analyses also suggest that BMI modifies the effect of chronic RA on milk RA concentrations, such that chronic RA intake was a more powerful predictor of milk RA concentration in women with lesser body fat content. These observations suggest that the leaner subjects experience substantial mobilization of adipose stores even when consumption of high-fat dairy foods is encouraged. The interactions between current RA intake and BMI, and between energy intake and BMI on milk RA concentration were not significant.

To our surprise, these data also show that milk lipid concentration increased during the high dairy period. One explanation may be that RA enhanced *de novo* lipid production in the mammary gland or lipid partitioning to the mammary gland. However, results of the partial Pearson correlation and multiple regression analyses showed that neither chronic nor current dietary RA intakes were related to milk lipid concentration. Additionally, the intakes of energy, protein, lipid, and carbohydrate were not correlated with milk lipid concentration. Other investigators have shown previously that milk fat concentration in humans is not influenced by energy intake (29–31). Thus, our findings raise an important question as to what dietary factor(s) resulted in milk lipid depression observed during the low dairy period.

Ruel *et al*. (31) reported that variability in milk lipid concentration could be explained partly by body fatness. Multiple regression analyses of our data also suggested that BMI was a significant factor in predicting milk lipid concentration. Further, Lovelady *et al*. (32) found a significant association between maternal percent body fat and milk lipid. These investigators suggested that an interaction between body fatness and dietary lipid existed for milk lipid concentration. Secondary analysis of our data, however, shows no interaction between dietary lipid intake and BMI on milk lipid concentration.

Recent reports indicate that lactating cows (33–36) and mice (37) are susceptible to milk lipid depression when they are fed partially hydrogenated vegetable oils containing *trans* fatty acids. Koletzko (38) found that *trans* fatty acid concentrations in plasma of premature infants were inversely related to long-chain polyunsaturated fatty acid biosynthesis pathways. Therefore, it is possible that substitution of foods containing industrially produced *trans* fatty acids for dairy lipid (e.g., substitution of margarine for butter) during the low dairy period may have decreased milk lipid content by inhibition of lipid partitioning to or *de novo* fatty acid synthesis in the mammary gland. Unfortunately, we have no information on the *trans* fatty acid intakes of our study participants.

Noteworthy are two limitations in this study. First, the food frequency questionnaire used to estimate chronic RA intake is semiquantitative in nature and is not expected to provide an accurate estimate of chronic RA intake (39). Nonetheless, it is clear that, although information collected using this instrument may not be quantitatively accurate, it does provide useful qualitative information concerning relative chronic RA intakes. Second, the relative homogeneity of subjects in regard to body weight and adiposity resulted in limitations of power when conducting multiple regression analyses using these variables. It is suggested that further studies designed

to investigate the influence of body fatness on milk fat and fatty acid concentrations take this factor into account.

The significance of milk RA concentration to maternal and infant health is not known. However, the potential for RA to prevent cancerous growth in mammary tissue of breast-feeding women is of public health importance. During both pregnancy and lactation, the mammary gland may be sensitive to the effects of dietary lipid, such as carcinogenic (e.g., n-6 polyunsaturated) and anticarcinogenic (e.g., RA) fatty acids. In fact, Hilakivi-Clarke *et al*. (40) recently reported that a diet high in n-6 polyunsaturated fatty acids, mainly linoleic acid, consumed by rats during pregnancy increases their susceptibility to mammary tumorigenesis. Epidemiologic data suggest independent protective effects of lactation (41–43) and bovine milk consumption (44) on breast cancer incidence in humans; to our knowledge, the importance of the interaction between lactation and dairy consumption has not been tested. Thus, we suggest further research be done to test the hypothesis that a portion of the inhibitory nature of lactation on the incidence of breast cancer might be due to the increased exposure of mammary tissue to dietary anticarcinogens (such as RA) due to lactation. Further, we hypothesize that an increase in RA intake during lactation might be related to an increased magnitude of this exposure, thus resulting in decreased risk of breast cancer.

CLA consumption may also have health benefits to the infant, since RA has been shown to enhance growth of the suckling rat pup (16) and to increase lean body mass in mice (45). However, the relevance of these findings in animal models to the human infant is unknown.

In conclusion, our data show that increased maternal intake of high-fat dairy foods can increase the concentrations of both lipid and RA in human milk. Further, chronic RA intake is correlated positively with milk RA concentration. Thus, these data support our initial hypotheses. Further research is necessary to determine the public health significance of these findings.

ACKNOWLEDGMENTS

The authors would like to very sincerely thank the women and infants who participated in this study and Ameda-Egnell for use of their breast pumps. This work was supported in part by the University of Idaho (MKM, MAM; University of Idaho Agricultural Experiment Station manuscript #98A04), the Washington State University Agricultural Experiment Station (TDS), and the Washington State Dairy Products Commission (TDS)

ABSTRACT: Cystic fibrosis (CF) is associated with chronic lung infection, inflammation, and elevated indices of oxidative stress. Recently, isoprostanes were shown to be a reliable *in vivo* marker of oxidant injury with 8-*iso*-$PGF_{2\alpha}$, shown to cause airflow obstruction and plasma exudation in guinea pig lung. The present study was designed to examine the relationship between 8-iso-$PGF_{2\alpha}$ levels, plasma antioxidants, and clinical status in CF. We hypothesized that plasma 8-iso-$PGF_{2\alpha}$ levels would be higher in subjects with CF compared to healthy controls. Plasma 8-iso-$PGF_{2\alpha}$ levels were prospectively measured in 22 subjects with CF and nine healthy controls using an 8-isoprostane enzyme immunoassay kit along with plasma vitamins A, E, and β-carotene. Plasma 8-*iso*-$PGF_{2\alpha}$ levels were shown to be significantly elevated in the CF subjects compared to controls (319.6 ± 52.6 vs. 145.0 ± 21.0 pg/mL, $P = 0.005$). Plasma levels of antioxidants were significantly lower for the CF subjects compared to the controls (vitamin A, $P < 0.003$; vitamin E, $P < 0.001$; and β-carotene, $P < 0.01$). This study confirms significantly elevated lipid peroxidation in CF using 8-*iso*-$PGF_{2\alpha}$ levels.

Paper no. L7982 in *Lipids 34*, 551–556 (June 1999).

Cystic fibrosis (CF) is associated with chronic lung infection and inflammation leading to progressive lung destruction. While mediators are important to resolution of inflammation, they do have some negative effects, which include free radical generation and release of hydrogen peroxide and proteinases by activated immunocytes, which contribute to cellular damage and reduced lung function (1–3). Peroxidation of lipids is the main feature of oxidant injury (4), and many authors reported increased lipid peroxidation in CF (2,5–9). In a comprehensive review, van der Vliet *et al.* (10) reported potential contributors to oxidative stress in CF, such as factors which increase oxidative reactions and metabolic rate, chronic infection and inflammation with increased immune responses, cytokine-mediated reactions, malabsorption of antioxidants, and disordered iron metabolism. Much of the morbidity and most of the mortality in CF are due to progressive lung disease (11), so strategies that have the potential to impact on the rate of progression seem worthy of further investigation. Antioxidant supplementation may attenuate lipid peroxidation (5), and Winklhofer-Roob *et al.* (1) showed that supplementation with β-carotene (a potent lipid-soluble antioxidant) can attenuate both lung inflammation and lipid peroxidation. Reduced levels of plasma antioxidants in CF were also associated with increased lipid peroxidation compared to controls.

Many authors (10,12–14) questioned the reliability of some commonly used methods of assessing lipid peroxidation. In a review of methodology used to study free radical reactions in humans, Halliwell and Grootveld (13) point out that lack of adequate methodology hindered examination of the contribution of free radical production to tissue injury vs. production secondary to the injury. The assessment of breath pentane (14) and thiobarbituric acid-reactive substances were reported to be unreliable measures of lipid peroxidation in human body fluids (12). While these methods appear to be accurate for measurement of lipid peroxidation *in vitro*, they have limitations when used to measure oxidative stress *in vivo*.

Morrow *et al.* (4) reported (4) the discovery of a unique series of prostaglandin-like compounds, termed isoprostanes, produced in humans *in vivo*, with 8-*iso*-$PGF_{2\alpha}$ being the most abundant. Isoprostanes are produced by free-radical catalyzed peroxidation of arachidonic acid, independently of the cyclooxygenase enzyme (4). They are a reliable measure of *in vivo* oxidant injury while being produced in quantities an order of magnitude higher than cyclooxygenase-derived prostaglandins (4). In a recent review of the isoprostanes, Morrow and Roberts (4) reported that 8-*iso*-$PGF_{2\alpha}$ is an extremely potent renal vasoconstrictor. In the pulmonary bed in rats and rabbits, it acts primarily as an antagonist of platelet thromboxane receptors but interacts with a receptor on vascular smooth muscle that is distinct from the thromboxane receptor (4). Recently, 8-*iso*-$PGF_{2\alpha}$ was shown to cause airflow obstruction and plasma exudation in guinea pig lung *in vivo* (15). However, the role of the isoprostanes in the progression of lung disease in CF was not investigated.

The objectives of this study were to measure 8-*iso*-$PGF_{2\alpha}$ levels, plasma levels of β-carotene, retinol and α-tocopherol

and red blood cell (RBC) membrane fatty acids in patients with CF, to compare these levels to those in normal controls and to examine the relationship of these variables with measures of clinical status in the CF patients. The hypothesis to be tested was that 8-*iso*-$PGF_{2\alpha}$ levels were elevated in CF.

METHODS

This study was a cross-sectional measurement of plasma 8-*iso*-$PGF_{2\alpha}$ levels, plasma antioxidant (retinol, α-tocopherol, and β-carotene), RBC membrane fatty acids, clinical status in 22 patients with CF, mean age 17.4 yr (range 5.8 to 37.8 yr) attending the John Hunter Children's Hospital Cystic Fibrosis clinic and 9 healthy controls, mean age 29.8 yr (range 22.8 to 46.1 yr). Ethics approval was obtained from the Hunter Area Health Service and the University of Newcastle Ethics Committees. Written consent was obtained from the subjects, parent, or both. Subjects were enrolled continuously through the CF outpatient clinic, and a 2-mL blood sample was obtained for isoprostane and fatty acid analysis. An exclusion criterion was aged less than 4 yr. Healthy controls were recruited from advertisements placed on hospital and university notice boards. For control subjects, exclusion criteria were relevant gastrointestinal, medical, or surgical history. Clinical status was measured by the Shwachman score as part of routine clinical care (16) which evaluates subjects in the four categories of nutritional status, physical findings, X-ray findings, and general activity. Ten of the CF subjects were receiving antibiotics for acute pulmonary exacerbation with 10 not experiencing acute exacerbation. The methods of Cameron (17) were used for all the anthropometric measures. Heights were measured with a Holtain, Crymych, Dyfed, stadiometer. Weights were recorded to the nearest 0.001 g on GEC/Avery digital scales, model number 824/890. FEV1, the forced expiratory volume in 1 s (18), was expressed as the percentage predicted based on weight and height.

Blood collection. Whole blood was collected into EDTA-coated tubes containing 2 mg of reduced glutathione acting as an antioxidant (Sigma Chemical Company, St. Louis, MO). The samples were centrifuged at 3000 rpm for 10 min at 4°C to separate the RBC from the plasma. Aliquots 1-mL of each of the lower cell layer and the upper plasma fraction were removed and stored separately at −80°C until commencement of analysis with 200 μg butylated hydroxytoluene (Sigma Chemical Company) added to the plasma fraction and vortexed prior to storage.

Total (free and esterified) isoprostane analysis. To 1 mL of sample, tritiated thromboxane B_2 (Amersham, Buckinghamshire, United Kingdom) of a known amount of counts per minute (cpm) was added to enable later determination of recovery. Thromboxane behaves similarly to isoprostane during subsequent purification, allowing recovery to be determined. An equal volume of 15% wt/vol KOH was added, and the sample was incubated at 40°C for 60 min to cleave esterified isoprostane. The sample was purified by passing through a Sep-Pak C-18 reverse-phase cartridge (Waters, Milford MA), and the solvent was evaporated with N_2 to permit reconstitution in assay kit buffer. Using a liquid scintillation counter, 500 μL of the purified sample was counted with 15 mL of aqueous biodegradable counting scintillant (Amersham, Arlington Heights, IL). A quantity of the remaining portion was analyzed with an 8-isoprostane enzyme immunoassay kit (Cayman Chemical, Ann Arbor, MI). Absorbance values were measured using a plate reader (Molecular Devices, V_{max}, Kinetic microplate reader; Beckman) set to record at a wavelength of 405 nm, and the raw data corrected for recovery. The immunoassay was validated to obtain a high correlation (0.99) between added known amounts of 8-*iso*-$PGF_{2\alpha}$ and the concentration measured by the immunoassay kit.

Sep-Pak extraction procedure. The Sep-Pak C-18 reverse-phase cartridges (Waters) were rinsed with 5 mL of methanol followed by 5 mL of ultrapure water. The samples were passed through the cartridges then rinsed with 5 mL of ultrapure water and allowed to dry. They were then rinsed with 5 mL of hexane. The 8-*iso*-$PGF_{2\alpha}$ was eluted with 5 mL ethyl acetate (containing 1% methanol).

Preparation of erythrocyte membranes. RBC previously stored at −80°C were thawed to room temperature. The erythrocytes were lysed and their membranes solubilized and purified using a method described by Tomoda *et al.* (19), and modified by Brown *et al.* (20). Cells were washed with 12 mL of hypotonic Tris buffer (10 mM Tris hydroxymethylamino methane/5 mM ascorbate buffer, pH 7.4) and vortexed. After standing on ice for 5 min, 12 mL of 0.25 M glucose solution was added. The sample was vortexed, allowed to stand on ice for a further 5 min, then centrifuged at 10,000 rpm for 10 min, 4°C. This procedure was repeated twice more (resuspending the pellet by vortexing), using the same quantities of Tris and glucose solutions as described above, but centrifuged at 12,000 rpm for 10 min, 4°C, and then 15,000 rpm for 20 min, 4°C, respectively. The pellet was then resuspended in approximately 1 mL of the remaining final supernatant and stored at −20°C prior to analysis for fatty acid composition.

Total (free and esterified) fatty acid analysis. Total fatty acids were determined using the method established by Lepage and Roy (1986) (21). Two mL of a methanol/toluene (4:1, vol/vol) mixture containing 13:0 (0.02 mg/mL) and 21:0 (0.02 mg/mL) as internal standards (Nu-Chek-Prep, Elysian MN) was added to the RBC membrane preparation. Methylation of fatty acids was carried out by addition of 200 μL of acetyl chloride while vortexing, then subsequent heating for 60 min at 100°C. After cooling, the reaction was then stopped by the addition of 5 mL 6% K_2CO_3. The sample was centrifuged at 3000 rpm for 10 min at 5°C, to facilitate separation of layers. An aliquot of the upper toluene layer was used for gas chromatographic analysis of the fatty acid methyl esters, using a 30 m × 0.25 mm (DB-225) fused carbon-silica column, coated with cyanopropylphenyl (J&W Scientific, Folsom, CA) and a method modified from Garg and Blake (22). Both injector and detector port temperatures were set at 250°C. The oven temperature was 170°C for 2 min, increased 10°C/min to 190°C

and held for 1 min, then increased 3°C/min up to 220°C and maintained for 15 min to give a total run time of 30 min. The chromatograph was equipped with a flame-ionization detector. Sample fatty acid methyl ester peaks were identified by comparing their retention times with those of a standard mixture.

Vitamin intake. Subjects' self-reported current intake of vitamin and mineral supplements and the quantities of vitamins A, E, β-carotene, C, zinc, and selenium were determined from these.

Data analysis. Statistical analysis was performed using Minitab 10Xtra for Windows. The mean ± standard errors are reported. Statistical comparisons were performed using *t*-tests for normally distributed data with a significance level of $P < 0.05$. Correlation studies were undertaken to assess how closely the variables studied were related within both subject groups (CF and controls), and regression analysis was used to explore how much of the variation in isoprostane levels could be explained by the other variables.

RESULTS

Twenty-two subjects with CF and nine controls were studied. Clinical data are provided in Table 1. Clinical characteristics of the subjects with CF and the controls are summarized in Table 1. There was a significant difference in age between the subject groups, and mean height z-score was significantly lower in CF. Although mean weight for height was lower in the CF group, this did not reach significance. All plasma antioxidant levels were significantly lower in the CF subjects despite 13 subjects taking vitamin supplements routinely. These self-reported vitamin intakes are reported in Table 2. Nine subjects with CF were not taking multivitamin supplements. One subject with CF was taking a 50 mg/d selenium supplement (with a corresponding total 8-*iso*-$PGF_{2\alpha}$ level = 133.3 pg/mL), and one person was taking 3 mg/d β-carotene (with a total 8-*iso*-$PGF_{2\alpha}$ level = 155.0 pg/mL).

Isoprostane results. Figure 1 compares the 8-*iso*-$PGF_{2\alpha}$ values in CF subjects and controls. Significantly higher levels of 8-*iso*-$PGF_{2\alpha}$ were found in the CF group compared to the controls (319.6 ± 52.6 pg/mL vs. 145.0 ± 21.0 pg/mL, $P = 0.005$). While there was a trend toward increased 8-*iso*-$PGF_{2\alpha}$ levels in the CF subjects, less than 14 yr compared to controls (Table 1), $P = 0.059$ the 8-*iso*-$PGF_{2\alpha}$ levels were greater for the CF subjects greater than 14 yr compared, $P = 0.038$. While higher levels of 8-*iso*-$PGF_{2\alpha}$ were found in the group experiencing an acute exacerbation of pulmonary disease at the time of blood collection for the study, the difference was not statistically significant [nonacute ($n = 10$) 275 ± 184 pg/mL vs. acute ($n = 12$) 374 ± 308 pg/mL, $P > 0.05$]. For CF subjects taking any type of vitamin supplement, there was no difference between mean total 8-*iso*-$PGF_{2\alpha}$ level when compared to those not taking supplements (334 ± 73 pg/mL, $n = 13$ vs. 299 ± 78 pg/mL, $n = 9$, $P = 0.75$). When the 8-*iso*-$PGF_{2\alpha}$ levels for the 12 subjects with CF ≥ 14 yr of age were compared with the controls, the difference still remained significant [$P = 0.038$, 95% confidence interval (13,373 pg/mL)]. Mean 8-*iso*-$PGF_{2\alpha}$ levels (± standard error) for subjects with CF < 14 yr ($n = 10$) were 297.9 ± 68.4 pg/mL, for those ≥ 14 yr ($n = 12$), 337.9 ± 80.1 pg/mL and for controls 145 ± 21.0 pg/mL.

Within each subject group, there were no significant correlations between 8-*iso*-$PGF_{2\alpha}$ and age (Fig. 1), growth parameters, or plasma levels of vitamins A and E. For the CF group alone, there were no significant correlations between 8-*iso*-$PGF_{2\alpha}$ and FEV_1 (Fig. 2) function or erythrocyte membrane fatty acids. There was, however, a significant correlation be-

TABLE 2
Self-Reported Vitamin Intake from Supplements for Subjects with CF Who Regularly Consume Them[a]

Supplement	*n*	Median (interquartile range)
Retinol (i.u.)	13	1250 (650, 7000)
α-Tocopherol (i.u.)	13	70 (5, 126)
Ascorbic acid (mg)	13	86 (0, 86.3)
β-Carotene (mg)	1	3 mg
Zinc (mg)	13	1.7 (0, 1.7)
Selenium (mg)	1	50 mg

[a]Data are median and interquartile range to highlight the intersubject variability of the CF subjects. See Table 1 for abbreviation.

TABLE 1
Clinical Characteristics of Subjects with CF <14 yr, ≥14 yr, and Healthy Controls Highlighting Shorter Stature and Lower Plasma Antioxidant Concentrations[a]

Clinical variable	CF < 14 yr (*n* = 10)	CF ≥ 14 yr (*n* = 12)	Control (*n* = 9)
Age (yr)	11.2 ± 0.8*	22.5 ± 1.8	29.8 ± 2.7
z-score for height	–0.67 ± 0.43*	–1.0 ± 0.24*	0.12 ± 0.29
%Weight for height	105.5 ± 5.1	105.6 ± 4.4	114.1 ± 6.8

8-*iso*-$PGF_{2\alpha}$ (pg/mL)	297.6 ± 68.4	337.9 ± 80.1	145.0 ± 21.0
Retinol (μmol/L)	1.28 ± 0.15**	1.2 ± 0.19**	2.18 ± 0.19
α-Tocopherol (μmol/L)	14.1 ± 1.9**	11.0 ± 1.6**	27.1 ± 2.55
β-Carotene (μmol/L)	0.09 ± 0.03**	0.04 ± 0.01**	0.48 ± 0.11

[a]Data are mean ± standard error. *Difference from controls = $P < 0.05$. **Difference from controls = $P < 0.01$. CF, cystic fibrosis; FEV, forced expiratory volume in 1 s as a percentage of the predicted; n/a, not applicable; $PGF_{2\alpha}$, prostaglandin $F_{2\alpha}$.

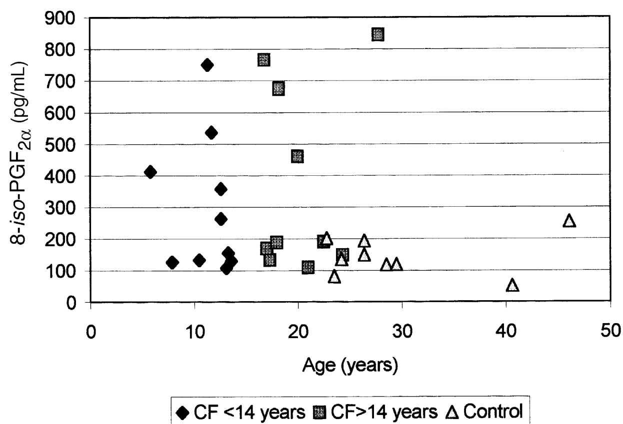

FIG. 1. Plot of 8-*iso*-prostaglandin $F_{2\alpha}$ (8-*iso*-$PGF_{2\alpha}$) concentrations in subjects with cystic fibrosis (CF) <14 yr ($n = 10$), ≥ 14 yr ($n = 12$), and controls ($n = 9$).

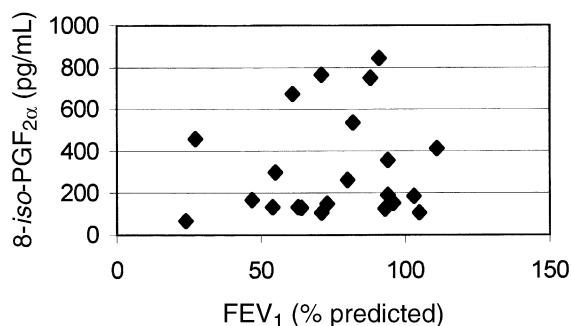

FIG. 2. Plot of 8-*iso*-$PGF_{2\alpha}$ concentrations vs. pulmonary function [forced expiratory volume in 1 s as a percentage of the predicted (FEV_1), % predicted].

tween β-carotene and FEV_1% predicted, r = 0.58, P = 0.009 (Spearman's rank correlation), which remained significant when the one outlier with a high plasma β-carotene was removed, r = 0.57, P = 0.013.

Fatty acid results. Table 3 summarizes the erythrocyte membrane fatty acid results for CF and controls. Subjects with CF had significantly more 18:1 with less 24:0 than normal controls. Females with CF had significantly less 22:5 compared to the males (2.74 ± 0.08% vs. 3.13 ± 0.11%, P = 0.011) with no other significant differences in fatty acid content. Subjects taking vitamin supplements had significantly less 22:5 compared to those not taking supplements (3.2 ± 0.11% vs. 2.78 ± 0.09%, P = 0.0078).

DISCUSSION

We demonstrated that the level of 8-*iso*-$PGF_{2\alpha}$, a reliable marker of *in vivo* oxidative stress in CF, is higher in relatively healthy, young people with CF. This is despite mean plasma levels of vitamins A and E within the laboratory normal range and a clinic policy of multivitamin supplementation, with vitamins A and E supplements for patients known to have low-plasma vitamin A and/or E. This finding is consistent with other reports (2,5–9) and confirms that lipid peroxidation is increased in CF using a reliable *in vivo* marker of oxidative stress. The 8-*iso*-$PGF_{2\alpha}$ levels for the 12 subjects with CF ≥ 14 yr of age were elevated when compared with the controls (P = 0.038).

No correlation exists between 8-*iso*-$PGF_{2\alpha}$ levels and the degree of pulmonary dysfunction. However, the group with acute exacerbation of pulmonary disease did show higher levels of 8-*iso*-$PGF_{2\alpha}$ compared to those who were clinically stable, although this difference was not statistically significant, $P > 0.05$. The numbers in each CF group (10 nonacute, 12 acute) were small, and baseline data were not available for the acute CF group. Therefore the potential bias toward increased 8-*iso*-$PGF_{2\alpha}$ levels could not be assessed and the results should be interpreted with caution. Further studies are currently underway to examine 8-*iso*-$PGF_{2\alpha}$ levels during pulmonary exacerbation as the results will be important in determining whether a rationale for reducing 8-*iso*-$PGF_{2\alpha}$ levels is important in CF lung disease.

Subjects with CF were relatively healthy, as indicated by their high percentage predicted FEV_1, high percentage weights for height, and, as we have previously shown, high energy intakes (23). There was, however, a degree of height stunting, as suggested by the lower mean z-score for height. There was no significant linear relationship between 8-*iso*-$PGF_{2\alpha}$ levels and clinical status or plasma antioxidants (A, E, and β-carotene) although antioxidant levels were all significantly lower in the CF subjects, despite supplementation with vitamins A and E in 13 of the 22 subjects. Plasma β-carotene for the CF group was lower than the lower limit of the laboratory normal range, with eight patients having no β-carotene detectable in their plasma (Table 2). There was also a significant correlation with pulmonary function although this should be interpreted with caution due to the large number of patients whose plasma β-carotene was less than this lower limit of detection. Low β-carotene in CF was also found by other groups (1,2,5,24) and was recently the subject of intervention trials (1,5,25). Supplementation with β-carotene reduced lipid peroxidation (5) and also lung inflammation (1). Winklhofer-

Roob *et al.* (25) found that the β-carotene dose required to normalize β-carotene status was 0.5 mg/kg/d. While plasma β-carotene correlated significantly with pulmonary function in the present study, the total antioxidant intake may be more important in limiting lipid peroxidation. Because antioxidants inhibit 8-*iso*-$PGF_{2\alpha}$ production by scavenging free radicals, any potential association with clinical status may have been confounded by other factors we did not measure such as plasma vitamin C, iron, copper, and selenium. Relative efficacies of antioxidant vitamins to reduce lipid peroxidation are not known and deserve further investigation. Lepage *et al.* (5) found that lipid peroxidation in CF is inversely related to plasma β-carotene, and our findings of low plasma β-carotene and increased oxidative stress are consistent with this.

In order to adequately assess the effects of antioxidant supplementation on lipid peroxidation, it is important to choose a reliable *in vivo* marker. The limitations of previous measures of oxidative stress in CF (12) and current knowledge of the isoprostanes (4) suggest that measurement of 8-*iso*-PGF_2 levels could be a useful outcome measure in clinical trials of antioxidant treatment. While problems with the use of the enzyme-linked immunosorbent assay (ELISA) kit to measure 8-*iso*-$PGF_{2\alpha}$ are acknowledged, we subsequently completed an age- and gender-matched comparison of 8-*iso*-$PGF_{2\alpha}$ levels in CF patients and healthy controls. In this follow-up intervention study, we confirmed significantly higher 8-*iso*-$PGF_{2\alpha}$ levels in the CF patients ($P << 0.01$) with the levels the same order of magnitude as the results in the present study (Wood, L., Collins, C.E., and Garg, M.L., unpublished observations).

As Morrow *et al.* repeatedly acknowledged, the gas chromatography, mass spectrometric method of assay is a procedure that, while highly accurate, is expensive and labor-intensive, with the technology not available to all laboratories. While the ELISA kit was used in a number of recent studies (28–31), further development of specific immunoassays should expand research in this area.

Erythrocyte membrane fatty acids were measured to determine if 8-*iso*-$PGF_{2\alpha}$ production was circuitous to reduced levels of arachidonic acid and if this contributed to essential fatty acid deficiency, commonly found in CF (32). However, these subjects did not exhibit reduced levels of arachidonic acid or essential fatty acid deficiency compared to the controls, which is likely to be due to the relative good health and high energy intakes of the CF subjects, a finding which was suggested previously by dietary intervention studies (33,34). Fatty acid composition, particularly essential fatty acids, depends in part on the availability of fatty acids (32). While normal erythrocyte fatty acids were reported previously for patients who were pancreatic-sufficient (35), all of these subjects were pancreatic-insufficient.

Increased lipid peroxidation in CF could plausibly exacerbate essential fatty acid deficiency in CF by increasing peroxidation of arachidonic acid and upregulating conversion of 18:2 to 20:4. Lower linoleic acid levels (18:2) are associated with higher $PGF_{2\alpha}$ levels in CF (32), and reduced levels of 18:2 in association with increased 16:1 or monoenes in RBC membranes were previously described in CF (32,36). Differences in eicosanoid levels between subjects with CF and controls were found (32), and it was hypothesized that eicosanoid production contributes to the progression of disease (37). A higher percentage of 22:5 was found in males with CF compared to the females which potentially impacts on differences in eicosanoid production. The gender differences in erythrocyte fatty acids in the CF subjects suggest that future studies, particularly in subjects with worsening clinical status, should examine gender differences in both erythrocyte fatty acid composition and eicosanoid production in light of gender differences in survival.

In conclusion, this study found significantly increased lipid peroxidation in CF using 8-*iso*-$PGF_{2\alpha}$ levels as a marker of *in vivo* oxidative stress. It appears that current level and/or type of antioxidant supplements in CF may not be sufficient to reduce lipid peroxidation to comparable levels in healthy controls. The optimal antioxidant supplementation regime for people with CF, whether achieved through megadosing a single antioxidant or through a combination of supplements, is yet to be determined.

Cholesterol-Derived Hydroperoxides in Alcoholic Liver Disease

Migiwa Asano, Junko Adachi*, and Yasuhiro Ueno

Department of Legal Medicine, Kobe University School of Medicine, Kobe, Japan

ABSTRACT: Human liver samples from 33 patients were collected at autopsy (controls, $n = 9$; fatty liver, $n = 12$; liver cirrhosis, $n = 12$), and samples homogenized. Lipids extracted with chloroform and methanol were injected into the octyl column of a high-performance liquid chromatograph with post-column chemiluminescence. Liquid chromatography–mass spectrometry was developed to identify 7-hydroperoxycholest-5-en-3β-ol (7-OOH). We found that two cholesterol-derived hydroperoxides, 7α-hydroperoxycholest-5-en-3β-ol (7α-OOH) and 7β-hydroperoxycholest-5-en-3β-ol (7β-OOH), are present in significantly elevated amounts (12.4 and 25.0 nmol/g tissue, respectively) in lipid extracts from alcoholic fatty liver, but not in extracts from alcoholic cirrhotic liver. 7α-OOH and 7β-OOH are early intermediates produced during free radical-mediated cholesterol oxidation and can serve as molecular indicators of chain peroxidative damage in cell membranes. This is the first demonstration of 7α-OOH and 7β-OOH accumulations in human liver, and it is presumed to reflect greater oxidative stress pathology in alcoholic fatty liver.

Paper no. L8105 in *Lipids 34,* 557–561 (June 1999).

Results of animal studies show that lipid peroxidation modulates liver injury induced by alcohol (1,2). Thus far, lipid peroxidation was monitored in various ways; e.g., by the thiobarbituric acid assay as malondialdehyde equivalents in plasma and erythrocytes of rats chronically treated with ethanol (3) and in the liver (4), by conjugated diene formation (5), and by the 4-hydroxynonenal concentration in microsomes of rats fed ethanol intragastrically (4,6). These methods lack specificity, in that lipid peroxide itself was not measured. The recent development of high-performance liquid chromatography with chemiluminescence (HPLC-CL) detection made direct measurement of lipid peroxides with high sensitivity and specificity possible.

Previously, we identified cholesta-3, 5-dien-7-one, a metabolite of 7α-hydroperoxycholest-5-en-3β-ol (7α-OOH) and 7β-hydroperoxycholest-5-en-3β-ol (7β-OOH), in erythrocyte membranes of alcoholic patients using gas chromatography–mass spectrometry (7).

The purpose of this investigation was to clarify the relationship between lipid peroxidation and alcoholic liver disease. We used liquid chromatography–mass spectrometry (LC–MS) with an atmospheric-pressure chemical ionization interface to identify cholesterol-derived hydroperoxide in human liver sample, and quantified cholesterol hydroperoxides in alcoholic fatty liver (FL), liver cirrhosis (LC), and control liver using HPLC-CL.

MATERIALS AND METHODS

Materials. Cholesterol was obtained from Sigma (St. Louis, MO). 3,5-Di-*tert*-butyl-4-hydroxytoluene, luminol (3-aminophthaloylhydrazine), and cytochrome c (from horse heart, type VI) were purchased from Wako Pure Chemical Co. (Osaka, Japan). 5α-Hydroperoxycholest-6-en-3β-ol (5α-OOH), 7α-OOH, and 7β-OOH were synthesized as described previously (8,9). β-Sitosterol 5α-hydroperoxide as internal standard was prepared by irradiating a solution of β-sitosterol and hematoporphyrin.

Liver samples. Human liver samples were obtained at autopsy. Historical information on alcohol intake and previous illness was reviewed in medicolegal autopsy files. Twenty-four male, heavy drinkers who had drunk ethanol equivalent to more than 160 g per day for almost uninterrupted periods of longer than 10 yr were included in this study. The control liver group ($n = 9$) consisted of nonalcoholics, who had been teetotalers or, in some cases, drank less than 20 g of ethanol per day. Those who had viral hepatitis, neoplasms, or metabolic disorders were excluded from the study.

The liver samples were cut immediately into small sections and immersed in a 10% volume of formol saline for fixation, after which hematoxiline- and eosin-stained sections were prepared for microscopic examination. The remaining tissue was used for the chemical examination. The diagnosis of alcoholic liver disease was established by microscopic examination. In the FL group ($n = 12$), the histological criterion was fat infiltration with fat vacuoles in more than 30% of the hepatocytes. In the LC group ($n = 12$), the criterion was micronodular- to macronodular-type cirrhosis with necrosis, fi-

brosis, and varying severity of fatty change. The control subjects had histologically normal livers.

Extraction. In the analysis of lipid oxidation products, total lipid was extracted as follows: 5 mL of ice-cold chloroform/methanol (2:1, vol/vol) containing 0.005% butylated hydroxytoluene as the antioxidant and 1,000 pmol β-sitosterol 5α-hydroperoxide as the internal standard was added to *ca.* 0.2 g of liver, and the mixture homogenized under the ice-cold condition. The homogenate was combined with 5 mL of chloroform/methanol (2:1, vol/vol) and 1 mL of distilled water, and the whole was mixed vigorously for 1 min in a vortex mixer. The mixture then was centrifuged at 800 × *g* for 20 min, after which the chloroform layer was collected and concentrated in a rotary evaporator then dried under a nitrogen stream, leaving the residue total lipid.

The cholesterol-rich fraction was subsequently isolated from the total lipid by solid-phase extraction: A silica column (Sep-Pak®; Waters Co., Milford, MA) of 3-mL capacity packed with aminopropyl-derivatized silica ($-NH_2$) and conditioned by washing it with 5 mL of acetone and 10 mL of *n*-hexane was used. The total lipids dissolved in a small amount of chloroform were applied to the column, which then was flushed with a mixture of 2 mL chloroform and 1 mL isopropanol, giving an eluate which mainly consisted of cholesterol. This was concentrated in a rotary evaporator and dried under a nitrogen stream. The cholesterol-rich fraction obtained was dissolved in 1 mL methanol, and a 10 µL portion injected to the HPLC column and LC–MS column.

LC–MS. A Hitachi L-7000 series LC system fitted with Spherisorb ODS-2-5 (250 × 4.6 mm i.d.) and a model M-1200AP LC–MS system which incorporated an atmospheric chemical ionization system (Hitachi, Tokyo, Japan) were used to identify 7-hydroperoxycholest-5-en-3β-ol (7-OOH). The mobile phase, methanol containing 10 mM ammonium acetate, was delivered at the flow rate of 0.7 mL/min. Application parameters for the mass spectrometer were positive-ion measurement mode, a nebulizer temperature of 170°C, a desolvator temperature of 400°C, and a needle-electrode voltage of 3000 V.

HPLC–CL. Cholesterol hydroperoxides were determined by HPLC–CL comprised of two LC-10AD vp pumps (Shimadzu, Kyoto, Japan), a CLD-10A chemiluminescence detector (Shimadzu), and a Chromatopac C-R4A integrator (Shimadzu). A TSK gel Octyl-80Ts column (Tosoh, Tokyo, Japan) was used (150 × 4.6 mm i.d.). As the mobile phase methanol/water/acetonitrile (89:9:2, by vol) was delivered by one pump at the flow rate of 0.7 mL/min, the chemiluminescent reagent was delivered by the other pump at the flow rate of 0.5 mL/min. The reagent, prepared by the method of Miyazawa *et al.* (10), consisted of cytochrome c and luminol (10 and 2 µg/mL, respectively) in alkaline borate buffer (pH 10). After the column eluant passed through an ultraviolet detector set at 210 nm to determine cholesterol appearing at retention time of 12.8 min, it was mixed with the luminescent reagent in the post-column mixing joint of the chemiluminescence detector. Standard curves were prepared from the analyses of 1, 2, 4, 10, and 20 ng of 5α-OOH and 7β-OOH and from 0.5, 1, 2, 5, and 10 ng of 7α-OOH using 2.5 ng of the internal standard. Regression lines of the ratios of hydroperoxides to the internal standard vs. the standard concentrations (pmol) were linear ($r > 0.998$). The recoveries of 7α-OOH and the internal standard varied from 55 to 65%. The coefficient of variation within-day was 4.5 (%) and between-day 7.8 (%).

Statistical analysis. Comparisons of the experimental data for all the groups were made using a one-way analysis of variance or the Kruskal-Wallis test followed by Scheffe's test. The difference in the mean values of the two cholesterol hydroperoxides (7α-OOH and 7β-OOH) in each group was assessed by the Student's *t*-test. $P < 0.05$ was deemed significant.

RESULTS

Demographic data on the subjects studied are presented in Table 1. There were no differences among the three groups with regard to age, body weight, height, or postmortem period.

Analyses of lipid extracts from human liver in alcoholic FL and the control by LC–MS gave four peaks in the total ion chromatograms. Amounts of oxysterols in FL were greater than control. The peak in alcoholic FL, appearing at a retention time of 7.0 min, was subjected to MS. The mass spectra of standard 7-OOH, cholest-5-ene-3β 7-diol (7-OH), and the peak from FL are shown in Figure 1. Standard 7-OOH had an ion $[M + H - H_2O]^+$ at *m/z* 401 and fragment ions at *m/z* 385 and 367, whereas standard 7-OH had an ion $[M + H - H_2O]^+$ at *m/z* 385 and a fragment ion $[M + H - 2H_2O]^+$ at *m/z* 367 but not at *m/z* 401. The retention times of standard 7-OOH, and 7-OH, and the peak were all about 7.0 min, almost identical. Accordingly, the peak from FL which had a larger ion at *m/z* 385 than at *m/z* 401 was assumed to be a mixture of 7-OOH and 7-OH.

Cholesterol hydroperoxide measurements were made by HPLC–CL. Figure 2 shows the chromatograms of a mixture of standard 7β-OOH, 7α-OOH, 5α-OOH, and the internal standard, when a TSKgel Octyl-80Ts column with methanol/water/acetonitrile as the mobile phase was used. The retention times of standard 7β-OOH, 7α-OOH, 5α-OOH, and the internal standard, respectively, on the chromatograms were 6.8, 7.3, 7.8, and 9.5 min, and they were separable. Figure 2

TABLE 1
Demographic Data for the Samples Studied[a]

	Control	FL	LC
n	9	12	12
Age (yr)	54.0 ± 12.6	61.3 ± 15.0	55.6 ± 7.9
Body weight (kg)	67.7 ± 11.3	60.8 ± 15.5	57.9 ± 10.3
Height (cm)	165.6 ± 5.5	164.9 ± 6.4	162.1 ± 5.6
Postmortem time (h)	13.4 ± 4.7	12.4 ± 4.5	14.6 ± 5.1

[a]Values are means ± SD. FL, fatty liver; LC, liver cirrhosis.

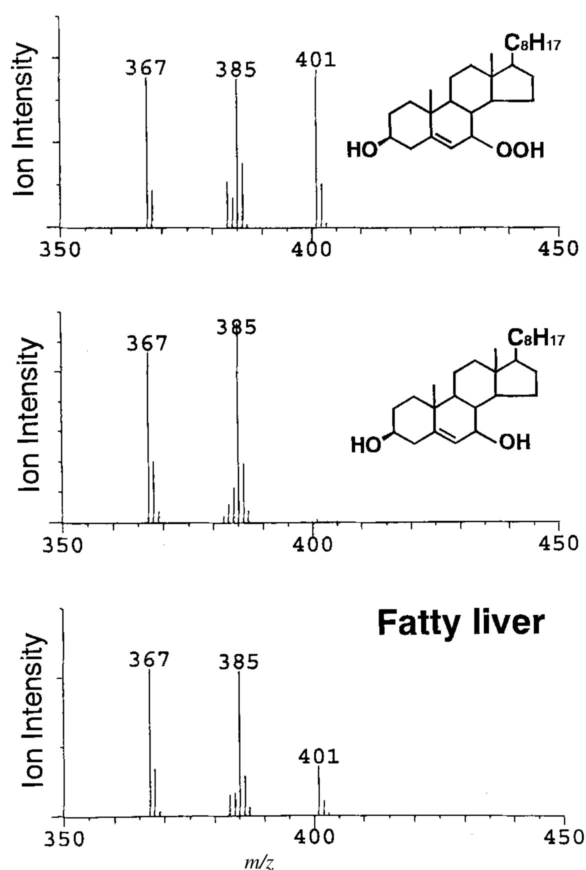

FIG. 1. Mass spectra of standard 7-OOH, 7-OH, and the peak from alcoholic fatty liver sample obtained by liquid chromatography–mass spectrometry with an atmospheric-pressure chemical ionization interface. 7-OOH, 7-hydroperoxycholest-5-en-3β-ol; 7-OH, cholest-5-ene-3β, 7-diol.

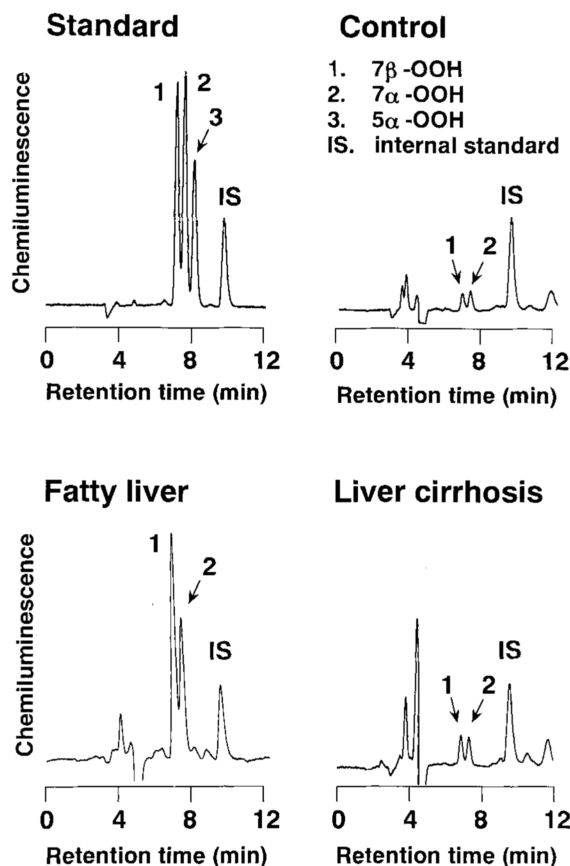

FIG. 2. High-performance liquid chromatograms for standard hydroperoxycholesterols, and the control, fatty, and cirrhotic liver samples. 5α-OOH, 5α-hydroperoxycholest-6-en-3β-ol; 7α-OOH, 7α-hydroperoxycholest-5-en-3β-ol; 7β-OOH, 7β-hydroperoxycholest-5-en-3β-ol.

also shows HPLC–CL chromatograms for liver samples of the control, FL, and LC groups. Peaks 1 and 2 of the liver samples, at the respective retention times of 6.8 and 7.3 min, corresponded with those of the respective standards 7β-OOH and 7α-OOH. Not only lipid extracts from FL but also those from LC and the control liver had 7β-OOH and 7α-OOH, but no 5α-OOH was detected in these samples.

The concentrations of 7α-OOH and 7β-OOH in human liver samples are shown in Table 2. In FL both 7-OOH (7α-OOH = 12.4 nmol/g, 7β-OOH = 25.0 nmol/g) were significantly higher than in the control and LC, whereas both 7-OOH in LC (7α-OOH = 2.3 nmol/g, 7β-OOH = 3.2 nmol/g) were as low as in the control. The reason why the standard deviations in Table 2 were high was that we used human liver samples. The postmortem period varied from 4 to 24 h although there was no significant difference among the three groups. The concentration of cholesterol in human liver samples as determined by HPLC at 210 nm also is shown in Table 2. The percentages of 7α-OOH and 7β-OOH compared to cholesterol in liver samples are also shown in Table 2. The

TABLE 2
7-Hydroperoxycholest-5-en-3β-ol Concentrations[a]

	n	7α-OOH (nmol/g)	7β-OOH (nmol/g)	Cholesterol (μmol/g)	7α-OOH/cholesterol (%)	7β-OOH/cholesterol (%)
Control	9	1.2 ± 1.7	2.0 ± 3.3	3.8 ± 1.3	0.027 ± 0.029	0.045 ± 0.054
FL	12	12.4 ± 7.1[b]	25.0 ± 14.0[b,c]	4.1 ± 1.6	0.33 ± 0.20[b]	0.71 ± 0.43[b,d]
LC	12	2.3 ± 3.5	3.2 ± 5.8	3.9 ± 1.5	0.079 ± 0.13	0.11 ± 0.22

[a]Values are means ± SD. FL, fatty liver; LC, liver cirrhosis; 7α-OOH, 7α-hydroperoxycholest-5-en-3β-ol; 7β-OOH, 7β-hydroperoxycholest-5-en-3β-ol.
[b]7α-OOH, 7β-OOH, 7α-OOH/cholesterol and 7β-OOH/cholesterol in FL are significantly higher than in the control and LC groups ($P < 0.05$).
[c]7β-OOH is significantly higher than 7α-OOH in FL ($P < 0.05$).
[d]7β-OOH/cholesterol is significantly higher than 7α-OOH/cholesterol in FL ($P < 0.05$).

data expressed by percentage in liver samples were similar to those by concentration. Moreover, 7β-OOH in FL was significantly higher than 7α-OOH. The ratio of 7β-OOH to 7α-OOH was 2.09 ± 0.38 in FL. There were no significant differences between 7α-OOH and 7β-OOH in the LC and control groups.

DISCUSSION

Many researchers reported that lipid peroxides contributed to the pathogenesis of alcoholic liver disease. To assess the effect of lipid peroxidation on alcoholic liver disease, we tried to analyze directly cholesterol-derived hydroperoxide. Phospholipid and cholesterol esters consist of many kinds of fatty acids. When active oxygen species and free radicals attack them, several fatty acid-derived hydroperoxides of them should be present. We must have many standard compounds of fatty acid hydroperoxides, phospholipid hydroperoxides or cholesterol ester hydroperoxides when we analyze such lipid peroxidation products. The reason why we chose cholesterol-derived hydroperoxide as the indicator of lipid peroxidation was that we could synthesize standard compounds of cholesterol hydroperoxides.

Ozawa *et al*. (11) reduced 7-OOH to 7-OH by $NaBH_4$ and then, using gas chromatography–mass spectrometry, identified the 7-OOH in rat skin as the *O*-trimethylsilyl esters of 7-OH. We are the first to succeed in identifying 7-OOH directly in human FL samples using LC–MS. We could distinguish 7-OOH with its base peak at *m/z* 401 from 7-OH without a peak at *m/z* 401, by using LC–MS with methanol containing ammonium acetate as the mobile phase.

Previously, we examined the extraction procedure and some antioxidants to avoid artifact formation of cholesterol hydroperoxides from cholesterol itself. We proceeded to analyze 7α-OOH and 7β-OOH in erythrocyte membranes of seven healthy volunteers. The respective mean concentrations of 7α-OOH and 7β-OOH were 2.5 ± 1.6 and 5.4 ± 3.5 pmol/mL blood (12). Thus, we confirmed that in the previous measurement, artifact formation was minimal. As we developed the method to determine 7-OOH-preventing artifact formation, artifact formation was not included in the present study even if the concentration of the 7-OOH in FL was high enough.

Ours are the first measurements of 7α-OOH and 7β-OOH in human liver samples. We found that the amounts of 7α-OOH and 7β-OOH in FL, respectively, were 12.4 ± 7.1 and 25.0 ± 14.0 nmol/g tissue (mean ± standard deviation). The 7-OOH concentrations in rat skin reported by Ozawa *et al.* (11) were higher than in the liver of the present study, partly because lipid peroxides accumulate readily in rat skin. The concentration of 7β-OOH in human FL was significantly higher than that of 7α-OOH and was similar to the findings for rat skin (11). The reason for the higher level of 7β-OOH may be that 7α-OOH is easily epimerized to 7β-OOH. In contrast, both the 7-OOH in LC were as low as in the control. As the cholesterol per liver tissue in LC might decrease due to fibrosis, we calculated the percentage of 7-OOH to cholesterol. As shown in Table 2, significantly elevated percentage was observed in FL, but not in LC.

It is a well-known fact that cytochrome P4502E1 (CYP2E1) contributes to generation of free radicals. Chronic ethanol administration resulted in CYP2E1 induction (13,14). Albano *et al.* (15) showed the evidence of links between the induction of CYP2E1 by ethanol and the formation of hydroxyethyl radicals and suggested the stimulation of lipid peroxidation. Several investigators reported an association between the induction of CYP2E1 by ethanol and an increase in lipid peroxidation. (16,17). Moreover, animal studies by Takahashi *et al*. (18) and Koivisto *et al*. (19) provided evidence that ethanol-induced CYP2E1 was associated with the pathogenesis of alcoholic liver disease. Kato *et al*. (20) showed that pretreatment with xanthine oxidase inhibitor decreased xanthine metabolism and reduced ethanol-induced lipid peroxidation. They suggested that xanthine oxidase has a role in ethanol-induced lipid peroxidation in rats. We recognized the possibility of enhanced generation of lipid peroxides owing to increased production of active oxygen species (superoxide and hydroxyl radicals) in alcoholic FL.

In view of a decrease in antioxidants, the acute administration of ethanol resulted in a substantial decrease in the reduced glutathione concentration in the human liver, indicative that the ability to eliminate oxygen radicals was diminished (21). This difficulty in eliminating oxygen radicals may permit enhanced lipid peroxidation which, in turn, may cause the accumulation of cholesterol hydroperoxides. Glutathione peroxidase could play a major role in protecting mammals from the toxicity of ingested lipid peroxides. Plasma glutathione peroxidase as well as classical cellular glutathione peroxidase is present in liver (22). Plasma glutathione peroxidase can reduce phospholipid hydroperoxides but cannot reduce cholesterol hydroperoxides (23). In addition, plasma glutathione peroxidase has a low level of reducing activity toward cholesterol 7α-OOH (24). In contrast, it was unknown if cellular glutathione peroxidase can reduce cholesterol hydroperoxide. The present result showing the accumulation of 7-OOH in FL suggests that cellular glutathione peroxidase does not have enough reducing activity against oxidative stress. We therefore assume that long-term ethanol ingestion leads to excessive oxidative stress and to the accumulation of cholesterol hydroperoxides in alcoholic FL.

Finally, mention must be made of the 7-OOH concentration in alcoholic LC being as low as that in the controls. Tsukamoto *et al.* (4) succeeded in producing an animal model of LC and reported that malondialdehyde and 4-hydroxynonenal, indicators of lipid peroxidation, increased in their model. Our findings, which show that 7-OOH values in human LC are not significantly higher than control values, contradict the findings of previous investigators. Although as yet we have no satisfactory data to explain this contradiction, differences of the substance used to measure the index of lipid peroxidation may partly account for the conflicting results. Generation of free radicals by enzymatic reaction might occur

in alcoholic FL, whereas it could scarcely occur in LC due to decrease of normal liver cells.

In conclusion, the markedly high accumulation of 7-OOH in FL and the low level in LC suggest elevated lipid peroxidation in the early stage of alcoholic liver disorder.

ABSTRACT: Two of the main classes of oxyphytosterols (7-keto and epoxides) were synthesized from sitosterol and campesterol and given to mesenteric duct-cannulated adult male rats. Lymph was collected during 24 h and was analyzed for oxysterols. The results showed that the lymphatic recovery of the phytosterol oxides was low: 4.7% of the given dose for epoxy derivatives and 1.5% for 7-keto compounds. The campesterol oxides presented a better absorption than the sitosterol oxides. During the process of absorption, the epoxyphytostanols were also partly transformed in campestanetriol and stigmastanetriol.

Paper no. L8104 in *Lipids 34,* 563–570 (June 1999).

Cholesterol oxides are compounds containing additional oxygenated functional groups such as ketone, epoxide, hydroperoxide, or hydroxyl on the cholesterol molecule (1). These oxycholesterols (often called oxysterols) are described to elicit potent biological effects including cytotoxicity, atherogenicity, mutagenicity, and carcinogenicity. They are also involved in the biosynthesis of bile acids, steroid hormones, and cholesterol (2–5). Some of these compounds are formed *in vivo* (6,7), but they can also originate from foods (8–13). Several studies on laboratory animals showed that these dietary oxycholesterols can be absorbed by the intestine (14–18). Direct evidences of the absorption of such compounds in man were also brought out by Emanuel *et al.* (19) using an egg powder meal and by Linseisen and Wolfram (20) on men fed with meals containing salami and Parmesan cheese.

In foods, several sterols other than cholesterol occurred. In particular, the plant sterols (phytosterols) are often found in similar amounts as cholesterol in our diet (21) and may be ingested in large quantities by vegetarians (22). Their chemical structure is very close to that of cholesterol: campesterol contains only an additional methyl group at C24; sitosterol is characterized by an ethyl group at C24; stigmasterol has an ethyl group at C24 and an ethylenic bond at C22. These phytosterols can be oxidized in the same way as cholesterol (23–25). The occurrence of oxyphytosterols in foods was much less studied than that of oxycholesterols. Some studies pointed out little amounts of these compounds in french fries and chips (26–28), in wheat flour (29), and in coffee (30). Data on biological effects of these compounds are very scarce: abortifacient effects were described in mice (31); more recently Meyer and Spiteller (32) described an increase in oxyphytosterols during aging of cell cultures of *Chenopodium rubrum*, as well as cytotoxicity of these compounds on mealworms *Tenebrio molitor* (33).

However, there was a lack of data about the intestinal absorption of these oxyphytosterols, and we cannot presume their possible biological effects in humans. It is well-known that the nonoxidized phytosterols are less absorbed by the human intestine than cholesterol: 5% for sitosterol and 10–16% for campesterol as compared to about 30–43% for cholesterol (34–37). It is sometimes assumed that the reduced absorption of phytosterols could lead to a low absorption of the oxyphytosterols. The present study was undertaken to investigate the intestinal absorption of such compounds.

A blend containing mainly sitosterol oxides and a small amount of campesterol oxides was chosen, in order to better look like the processed foods (27,28). Epoxides and 7-keto derivatives were used, because they are usually present among the sterol oxides (27,28).

EXPERIMENTAL PROCEDURES

Reagents. The compounds used for chemical syntheses (*t*-butyl hydroperoxide, chromium hexacarbonyl, *m*-chloroperoxybenzoic acid) as well as pyridine, cholestanetriol, and 5α-cholestane were purchased from Sigma-Aldrich (L'Isle d'Abeau Chesnes, France). Pyridine was dehydrated and maintained on 4Å molecular sieves. The phytosterol blend, containing 76.2% sitosterol, 8.6% campesterol, 1.4% stigmasterol, and 13.8% Δ5-avenasterol, was provided by Merck (Darmstadt, Germany). Triolein and acetic anhydride were

purchased from Prolabo (Fontenay sous bois, France). The silylation reagent bis-trimethylsilyl-trifluoroacetamide with 1% trimethylchlorosilane was obtained from Pierce (Rockford, IL). The other solvents were obtained from SDS (Peypin, France) and were distilled before use. All chemicals and reagents were of the highest grade available.

Chemical syntheses. The method used by Chicoye *et al.* (38) to prepare 7-ketocholesterol was adapted to 7-ketositosterol and 7-ketocampesterol. Briefly, the phytosterol blend was acetylated using acetic anhydride. After purification, the phytosterol acetates were oxidized by *t*-butylhydroperoxide in acetonitrile, in the presence of chromium hexacarbonyl. The oxidized compounds were purified by silica column chromatography, using hexane/ethyl acetate (8:2, vol/vol) as eluent. The acetyl radical was then removed using a sodium hydrogen carbonate solution. After purification on a silica column, using hexane/ethyl acetate (1:1, vol/vol), a blend containing 90.3% of 7-ketositosterol and 9.7% of 7-ketocampesterol was obtained. The structure of these compounds was checked by gas chromatography–mass spectrometry (GC–MS) after formation of trimethylsilyl (TMS) derivatives as described later.

The phytosterol epoxides were synthesized as described by Nourooz-Zadeh and Appelqvist (29). The obtained mixture contained 2.1% of 5β,6β-epoxycampestanol, 8.2% of 5α,6α-epoxycampestanol, 13.6% of 5β,6β-epoxysitostanol, and 76.1% of 5α,6α-epoxysitostanol. Their chemical structures were also checked by GC–MS of their TMS derivatives.

The oxidized derivatives of Δ5-avenasterol and stigmasterol were discarded during the purification steps of the synthesis processes, and only sitosterol- and campesterol-oxides were retained for experiment.

Animals and diets. Specific pathogen-free Wistar male rats, weighing about 250 g, were obtained from Iffa-Credo (L'Arbresle, France). They were separated into three groups of seven animals. Under ether anesthesia, the main mesenteric lymphatic duct was cannulated using a heparinized polyethylene catheter (i.d. 0.3 mm, o.d. 0.7 mm, Guerbet Medical, Louvres, France). Postoperatively, the rats were placed in restraining cages in an air-conditioned room (25°C). They did not receive solid food but had free access to a water solution containing sodium chloride (7 g/L) and potassium chloride (2 g/L). The morning after surgery and immediately before lipid administration, basal lymph of fasting rats was collected for 1 h in tubes placed inside a polystyrene insulating box containing ice. They received then intragastrically 1 mL of triolein heated at 37°C containing the experimental lipids (Table 1). Triolein was chosen as carrier oil to avoid feeding other sterols. The rats of the control group received 5 mg of the nonaltered phytosterols. Group K rats were given 5 mg of the synthesized 7-ketophytosterols and group E rats 5 mg of the synthesized epoxyphytostanols fraction. The lymph was then collected during the first 6 h and for the next 18 h from the conscious animals. The two samples were pooled, and the entirety of lymph (about 15–20 mL) was used for oxyphytosterols analysis.

Oxyphytosterols and phytosterols analysis. Lipids of the lymph were obtained by extraction with chloroform/methanol (2:1, vol/vol) (39). They were saponified at room temperature during 18 h (40). Unsaponifiable matter was extracted by diethyl ether, redissolved in hexane, and purified by solid-phase extraction on silica cartridges (LC-Si, 3 mL, 500 mg; Supelco, L'Isle d'Abeau, France) according to Morgan and Armstrong (41). As recommended by Lai *et al.* (42), a vacuum manifold (Supelco) was used to ensure a regular solvent flow rate of 0.6 mL/min through the cartridge. A known amount of 5α-cholestane was added as internal standard to the acetone fraction containing the oxyphytosterols. The blend was evaporated to dryness under nitrogen in a conic glass vial. The compounds were redissolved in 100 µL of anhydrous pyridine, and 100 µL of bis-trimethylsilyl-trifluoroacetamide containing 1% of trimethylchlorosilane was added. After vortex mixing, the TMS ether derivatives were obtained by heating 15 min at 60°C. The reagents were evaporated under nitrogen and the residue dissolved in hexane for gas chromatographic analysis as described later.

TABLE 1
Composition of the Sterols Given to Rats by Gastric Intubation (in mg/rat)

	Control group: phytosterols	Group K: 7-ketosterols	Group E: epoxystanols
Campesterol	0.43		
Stigmasterol	0.07		
Sitosterol	3.81		
Δ5-Avenasterol	0.69		
7-Ketocampesterol		0.48	
7-Ketositosterol		4.52	
β-Epoxycampestanol			0.11
α-Epoxycampestanol			0.41
β-Epoxysitostanol			0.68
α-Epoxysitostanol			3.81
Total sterols	5	5	5

The eventual loss of oxysterols during analysis was checked by adding 50 µg of each oxyphytosterol blend to aliquots of control lymphs. The obtained recovery was between 85 and 105%.

The purification of the phytosterols in the lymph samples of the control group was effected using the method of Pie *et al.* (11) originally described for cholesterol. The TMS derivatives were obtained as described above and analyzed by GC.

GC and GC coupled with MS. The TMS ether derivatives were analyzed on a 5890 Series 2 Hewlett-Packard (Palo Alto, CA) gas chromatograph with a flame-ionization detector. A 20 m × 0.32 mm i.d. DB-5 (0.25 µm film thickness) capillary column (J&W Scientific, Folsom, CA) with helium as carrier gas was used. The injection was made in splitless mode. After 1 min at 50°C, the oven temperature was raised at 20°C/min until 270°C, and then reached 290°C at 1°C/min. The completion of analysis was effected at 290°C. The injector and detector temperatures were, respectively, 290 and 320°C. Quantitative analyses were performed using a Chromjet SP 4490 integrator and Winner software (Thermo Separation Products, Les Ulis, France).

The structure of the compounds was checked by GC cou-

pled with MS using a Hewlett-Packard 5890 gas chromatograph equipped with a 5970 mass selective detector. A 30 m × 0.25 mm i.d. HP-5 column (Hewlett-Packard) was used. The chromatographic conditions were the same as for flame-ionization detection GC. The mass spectrometer was operated at an ionization energy of 70 eV. Mass spectra were recorded between 100 and 700 a.m.u.

RESULTS AND DISCUSSION

The mass spectrometric fragmentation of the synthesized oxyphytosterols as TMS derivatives is summarized in Table 2. The *m/z* values were similar to those of the corresponding cholesterol derivatives (43–45), with increments of 14 or 28 for the fragments including the lateral chain. The spectra of the synthesized 7-ketophytosterols were very close to those recently published (27), with some minor differences: in particular in our conditions, the major fragment was not 174, but the molecular ions 500 and 486 for 7-ketositosterol and 7-ketocampesterol, respectively. Moreover, the (M^+ − TMS − CH_3) fragments 395 and 381 were bigger than the (M^+ − TMS) ions (410 and 396). Some little differences with the results of Dutta and Appelqvist (27) could also be noted for α-epoxysitostanol, β-epoxysitostanol, and α-epoxycampestanol concerning base ions or relative intensities. In a recent review including data on MS of cholesterol oxides, Addis *et al.* (45) found that there was little agreement in terms of relative intensities of characteristic ions in the mass spectra literature concerning the epoxycholestanol epimers. The same is probably true for the epoxyphytostanols. Concerning the β-epoxycampestanol, the difference with the spectrum published by Dutta and Appelqvist is rather important: the ion 470 is the base ion in their study and is only 4.5% of the base ion in our study. The different instrumental conditions may explain these little discrepancies.

The recovery of phytosterols in the lymph of the control animals was reported in Table 3. We observed that the intestinal absorption of these compounds was low (about 1.6%), but with important differences between phytosterols: the amount of campesterol in the lymph is about six times higher than that of sitosterol. These results agree with the data of the literature (46,47). It was assumed (36,37) that increasing the length of the side chain of cholesterol decreases the absorbability of the sterol. However, the absorption results obtained in this study are lower than some published data. For example, Vahouny *et al*. (48) obtained 3 to 4% absorption for sitosterol and stigmasterol. However, they used a higher dose of phytosterols (50 vs. 5 mg in this study), and they added a high level of sodium taurocholate in their lipid sample to improve the absorption. The absorption of stigmasterol seemed very low. However, the ingested level was low, and it was difficult to quantify accurately its recovery in the lymph. Concerning the Δ5-avenasterol, we do not know any data on its intestinal absorption. This study indicated that the absorption of this compound is low.

To evaluate the quantity of phytosterols eventually transformed into oxyphytosterols during the analytical process, the oxyphytosterols were checked in the lymph of control animals, which were given 5 mg of the nonoxidized phytosterol blend. It is well-known indeed that the sterols are rather fragile and that artifactual formation of oxysterols could occur during analysis (1,9,49–51). In our experimental conditions, only trace components were observed by GC. The MS of these compounds revealed some characteristic ions of oxyphytosterols. However, the total amount of these compounds was less than 0.5 µg, corresponding to 10^{-4} of the given phytosterols.

The results concerning the lymph of the K group are summarized in Table 4. The 7-ketophytosterols were recovered in the lymph of the rats, but in very low quantities, similar to those of nonoxidized phytosterols. In our experimental conditions, the mean absorption value was only 1.5% of the in-

Mean percentage of absorption (%)	2.5	1.4	1.5
Minimal absorption (%)	1.3	0.8	0.9
Maximal absorption (%)	4.5	2.2	2.5

[a]Results expressed as mean ± standard deviation.

gested oxyphytosterols. A large variability between rats was observed: the standard deviation was rather important and the ratio between maximal and minimal values of absorption was about 3. This variability was in the range of that observed by other authors investigating lipid absorption in similar experimental conditions (16,52,53). The 7-ketocampesterol appeared to be more absorbed than 7-ketositosterol (2.5% vs. 1.4%). As for nonoxidized phytosterols, the length of the side chain seemed to have an effect on the absorption of the 7-ketophytosterols.

In the E group rats, the four epoxyphytostanols intubated to the animals were recovered in different proportions in the lymph, but an additional peak appeared on all the chromatograms (Fig. 1). The mass spectrum of this compound (Fig. 2) showed some characteristic ions at *m/z* 431, 129, 484, 349, 574, 395, 469, 545, and 559. This fragmentation is very close to that obtained by Dutta and Appelqvist (27) for dihydroxysitosterol (stigmastanetriol) as TMS derivative. The only standard available for this kind of compounds is the cholestane-3β,5α,6β-triol. Using our conditions of derivatization, the cholestane-3β,5α,6β-triol was found to form the bis-TMS with the hydroxyl groups at the 3- and 6-positions being derivatized, as described by Park and Addis (54). If we compare the mass spectra of cholestane-3β,5α,6β-triol and that of our unidentified peak as TMS derivatives, we observed many similar ions with an increment of 28, corresponding to an ethyl group (Fig. 2). The major ions corresponding to the fragmentation of cholestane-3β,5α,6β-triol as TMS are fragments including the lateral chain (55). Then it appears that the unknown compound has an additional ethyl group on its lateral chain and is supposed to be a triol issued from the epoxysitostanols. To confirm this assumption, we prepared stigmastanetriol and campestanetriol from the blend containing the epoxysitostanols and the epoxycampestanols, using periodic acid (56). Thus we verified that the stigmastanetriol and the unknown compound had the same retention time by GC and the same mass spectrum, after transformation in TMS derivatives. The unknown compound is then a stigmastanetriol, probably the stigmastane-3β,5α,6β-triol.

We can wonder why no campestanetriol peak was detected on the chromatogram (Fig. 1). So, we made a research of the ions 417, 470, and 560, considered as characteristic of the TMS derivative of campestanetriol (27) and detected them as very minor components in the beginning of the peak of 5α,6α-epoxysitostanol. Unfortunately, our chromatographic

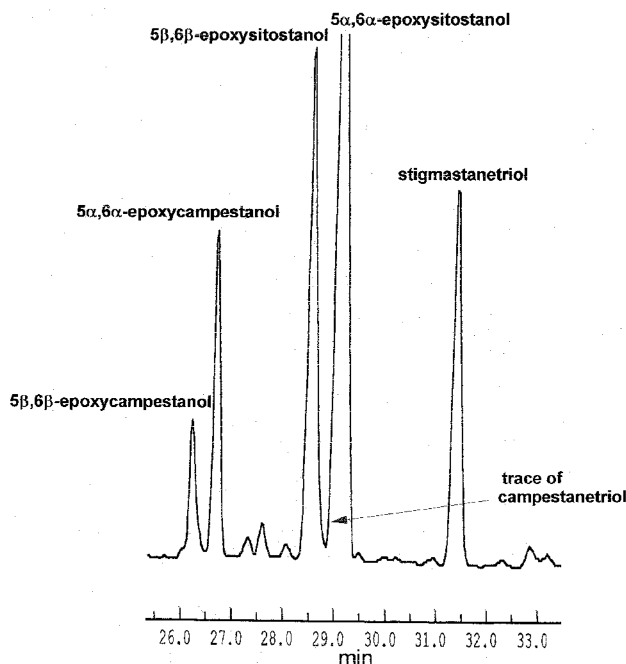

FIG. 1. Part of a gas–liquid chromatogram of oxyphytosterols as trimethylsilyl (TMS) ethers, originating from a sample of lymph of a rat of group E (given the epoxyphytosterols blend). Gas chromatographic conditions are described in the Experimental Procedures section.

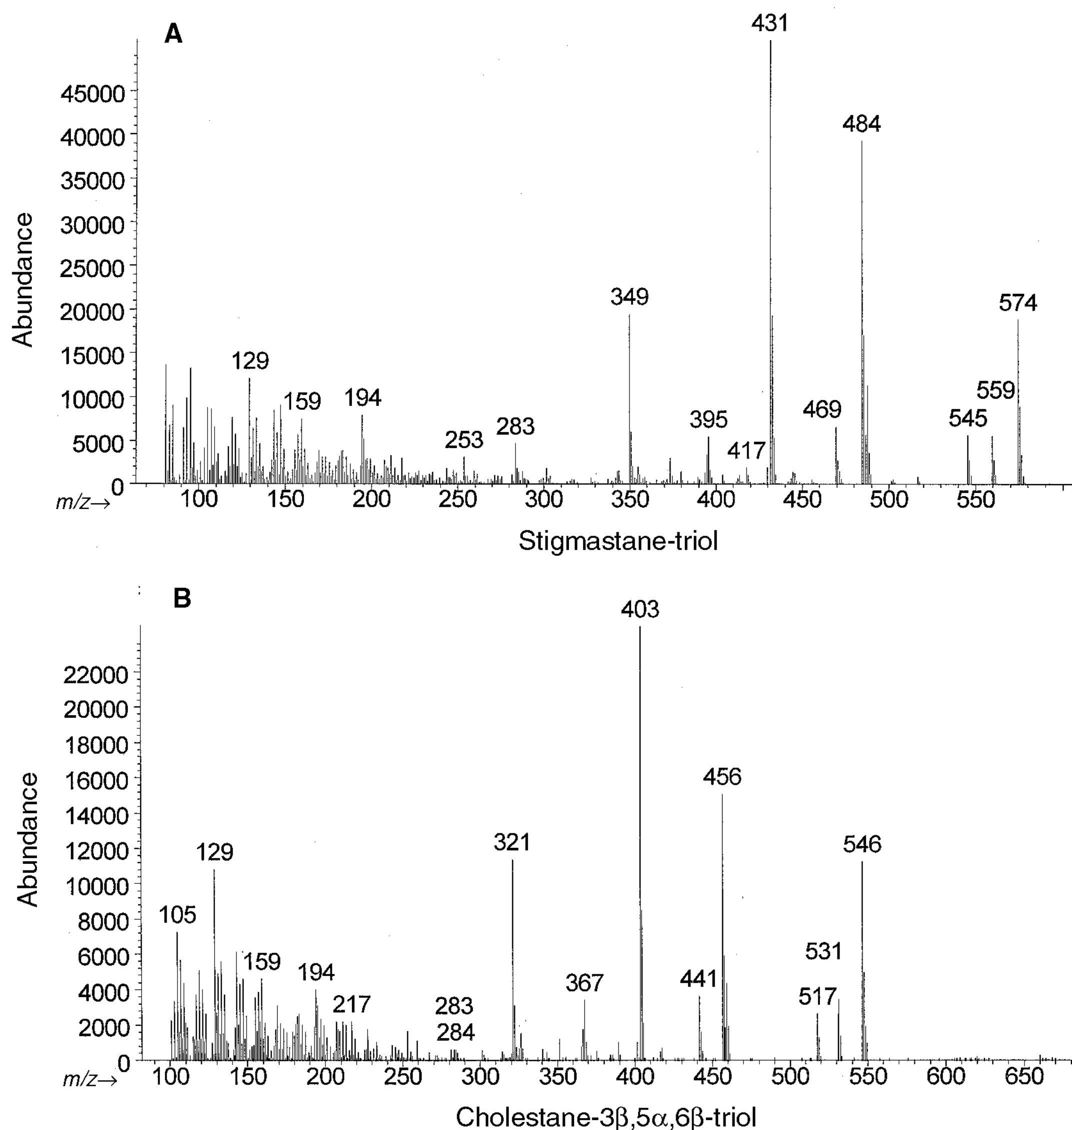

FIG. 2. Mass spectra of (A) an unknown compound (presumed to be stigmastane-3β,5α,6β-triol) and (B) cholestane-3β,5α,6β-triol as TMS ethers. Mass spectrometric conditions in the Experimental Procedures section. See Figure 1 for abbreviation.

conditions failed to separate 5α,6α-epoxysitostanol from campestanetriol.

Only few reports were concerned with the metabolism of oxyphytosterols. In some of them, there were data evidencing the possibility of conversion of epoxyphytostanols as well as epoxycholestanols (57). It is then interesting to look at all the data concerning the transformation of epoxystanols in triols. About 30 yr ago, the transformation of cholesterol epoxides in cholestanetriol in the gastrointestinal tract of the rat was already described (58). Maerker *et al.* (59) studied this event, using simulated gastric juice and demonstrated that both epoxides produced α- and β-chlorohydrins which were then partly hydrolyzed in triols. In less acidic conditions, such as those prevailing in the small intestine, the residual chlorohydrins could revert to epoxycholestanols (59). Another possibility is that the epoxides could be modified by the intestinal flora: an epoxide hydrase activity was indeed described in human intestinal microflora (60). But, we can also hypothesize that the epoxides were hydrolyzed inside the intestinal cells: a microsomal hydrolase able to convert epoxysitostanols and epoxycholestanols in triols was indeed described in rat liver (57). However, there were also descriptions of artifact formation of cholestanetriol during analysis, by simple hydration (61), or due to exposure to light (62). We determined if the triols could be formed during lymph analysis, using blank samples containing similar epoxide quantities as our lymph samples, but deprived of triols. The results of this test showed that a very little transformation of epoxides in triol cannot be excluded, but that the compounds originating from this reaction did not exceed 1% of the initially added epoxides.

The lymph recovery of oxyphytostanols from rats given

TABLE 5
Oxyphytosterols in Lymph of Rats Given the Epoxyphytosterols

	β-Epoxy-campestanol	α-Epoxy-campestanol	β-Epoxy-sitostanol	α-Epoxy-sitostanol[a]	Stigmastane-triol	Total oxyphytosterols
Ingested amount (μg)	105	410	680	3805		5000
Amount found in lymph[b] (μg)	8.3 ± 3.5	21.0 ± 9.0	39.3 ± 17.1	102.2 ± 51.7	62.9 ± 23.5	233.8 ± 92.5
Mean percentage of absorption (%)	7.9	5.1	5.8	2.7		4.7
Mean percentage of absorption for all epoxycampestanols (epoxysitostanols)	5.7		4.6			
Minimal absorption (%)	2.8		2.3			2.5
Maximal absorption (%)	8.5		6.9			7.0

[a]The α-epoxy-sitostanol peak also contains a little amount of campestanetriol.
[b]Results expressed as mean ± standard deviation.

the epoxyphytostanols is reported in Table 5. It appeared that these compounds were better absorbed than the 7-ketophytosterols (4.7 vs. 1.5%). The β-epoxy compounds were recovered in larger proportions in lymph than the α-epoxyphytostanols. This could be due either to a better absorption, or to a lower metabolic transformation into triol, as compared with the conversion process noted in rat liver microsomes (57). The epoxycampestanols were slightly better absorbed than the epoxysitostanols (5.7 vs. 4.6%). However, the peak of α-epoxysitostanol contains an unknown quantity of campestanetriol. On the assumption that the epoxycampestanols were transformed into triol in the same proportion as the epoxysitostanols, their absorption would reach 6.9 and 4.4%, respectively. The campesterol oxides, as well as the campesterol, seemed to be always better absorbed than sitosterol oxides and sitosterol.

The results of this study provide evidence that some phytosterol oxides, eventually present in food, can pass the intestinal barrier. Nevertheless, their lymphatic recovery is rather low and depends on the kind of administered oxysterols. The epoxides are recovered in larger quantities in lymph than the 7-keto compounds. The campesterol derivatives are better absorbed than those of sitosterol. Phytostanol epoxides are partly transformed in corresponding triols which appeared in lymph lipids. Further studies are necessary to elucidate if this conversion occurs in stomach, or if intestinal cells' hydrolases are able to modify the epoxides. Despite their low absorption, it would also be of great interest to study the metabolic fate and the physiological effects of these compounds.

The Incorporation of Fatty Acids of Different Chain Length into Liver and Biliary Lipids in the Perfused Rat Liver

Moshe Rubin[a,*], **Ronit Pakula**[b], **Tuvia Gilat**[b], **and Alisa Tietz**[c]

[a]Department of Surgery "B", Beilinson Medical Center and Felsenstein Medical Research Center, Petah-Tikva 49100, [b]Sackler Faculty of Medicine, Minerva Center for Cholesterol Gallstones and Lipid Metabolism in the Liver, Tel Aviv University, and Department of Gastroenterology, Tel Aviv Medical Center, Tel Aviv 64239, and [c]Department of Neurobiochemistry, Tel Aviv University, Tel Aviv, Israel

ABSTRACT: In an attempt to correlate the incorporation of fatty acids (FA) of different chain length into liver and biliary lipids, isolated rat livers were perfused for 2 h with Krebs-Ringer bicarbonate containing 1% albumin and 10 μmol of [1-^{14}C]-labeled FA: C_2, C_8, C_{10}, C_{12}, C_{16}, and $C_{18:1}$. One to 1.36 μmol of medium-chain fatty acids (MCFA, C_8, C_{10}, and C_{12}) and 6.6 μmol of long-chain FA (LCFA) were incorporated into liver lipids, 40% of the latter into phosphatidylcholine (PC). ^{14}C-acetate (13 nmol) was incorporated into biliary cholesterol; ^{14}C-MCFA contributed only 3.2–5 nmol; LCFA did not lead to newly synthesized cholesterol. Newly synthesized liver PC (2.75 to 3.25%) and newly synthesized liver cholesterol (6.5 to 10%) were secreted into bile. The specific radioactivity of biliary PC after infusion of all-saturated FA was 3.8–6.8 times higher than that of liver PC; for $C_{18:1}$ it was only 1.7-fold. The specific radioactivity of biliary cholesterol, as compared to liver cholesterol, was 12 times higher for C_2 and five times higher for MCFA. This indicates that a considerable proportion of the newly synthesized lipids was secreted into bile prior to significant mixing with preexisting liver PC and cholesterol pools. Liver PC contained 8% of unchanged ^{14}C-C_{12}; while ^{14}C-C_{10} was not detected. Biliary PC, in contrast, contained 18% of unchanged ^{14}C-C_{12} and 3% ^{14}C-C_{10}. These results suggest that after prolonged infusion of medium-chain triacylglycerols/long-chain triacylglycerols to patients, biliary PC may become enriched with MCFA. In addition, the oxidation of these FA may provide C-2 units which increase cholesterol synthesis.

Paper no. L7865 in *Lipids 34,* 571–578 (June 1999).

The correlation between cholesterol solubility and the concentration of biliary bile salts, phospholipids (PL), and cholesterol were formulated by Admirand and Small (1). Subsequent research on factors affecting cholesterol gallstone formation concentrated mainly on the role of cholesterol and bile salts (1,2). The importance of PL in cholesterol solubilization was appreciated only more recently (3–5).

Biliary PL are generally composed of 95% phosphatidylcholine (PC) and 4% phosphatidylethanolamine (PE) (6). Biliary PC is a complex mixture of different molecular species. In all animal and human studies, PC was found to contain saturated fatty acids (FA) (mainly 16:0 and 18:0) in the *sn*-1 position and unsaturated FA (mainly 18:2, 18:1, and 20:4) in the *sn*-2 position. In man, 1-palmitoyl-2-linoleyl-glyceryl-phosphoryl choline amounted to over 40% of the PC (7,8). Addition of different PC to human bile samples *in vitro* (5,9) caused a marked prolongation of the nucleation time. Since *in vitro* addition of bile acids did not affect the cholesterol nucleation time, it was suggested that increasing PL concentrations in bile might be more effective for prevention of cholesterol crystallization (9).

Experiments performed in animals and humans attempted to induce changes in the composition or concentration of PL in native bile by dietary manipulations. Nervi *et al.* (10) correlated the high incidence of gallstones among young Chilean men with a selective decrease in biliary PL, possibly due to a large intake of legumes. A similar abnormality was induced in rats by a high legume diet (11). Dietary supplementation of fish oil in contrast to more saturated triacylglycerols (TAG) markedly increased the percentage of 20:5 and 22:6 in biliary PC, reducing the lithogenicity and incidence of cholesterol precipitates in rats (12), African green monkeys (13), and hamsters (14–16). Likewise, addition of fish oil to the diet of gallstone patients induced an increase in 20:5 and 22:6 in biliary PC with a concomitant reduction in 18:2 concentration (17). Robins and Patton (8) pointed out that in order to understand the changes occurring in biliary PC, analysis of the molecular species is required. When rats were fed pure TAG-containing FA which were more hydrophilic than the FA normally present in bile PC, bile became highly enriched in new molecular species containing the particular FA fed. In contrast when the fat contained less hydrophilic FA, the composition of biliary PC did not change. To further characterize these changes, rat livers were perfused with FA of different chain lengths and degree of unsaturation (18). Results indicated that whereas 18:1, 20:4, and 20:5 were enriched in the *sn*-2 position of biliary PC, 16:1, 17:1, and 18:2 were found

in both positions. The above findings clearly indicate that the FA composition of biliary PC can be selectively changed. Only relatively few experiments were carried out attempting to change the head-group composition. Addition of ethanolamine and linoleic acid to the diet of rats and hamsters caused a slight increase in biliary PE; cholesterol concentration and the cholesterol saturation index were significantly lower (19). In humans addition of PE (rich in 18:2) to the diet was found to increase the percentage of 18:2 in biliary PC without changing PE concentration (20).

Total parenteral nutrition may result in the development of gallstones (21,22). In our clinical studies (23) we observed marked differences in the concentration of lipids in blood and bile following short-term infusion (24 h) of TAG containing a mixture of long-chain triacylglycerols (LCT) and medium-chain triacylglycerols (MCT). To try to understand the effect of MCT, we carried out a systematic *in vitro* study (24) on the metabolism of FA of various chain lengths by HepG-2 cells. It was found that C_8 was incorporated only after β oxidation. C_{10}, C_{12}, and C_{16} were largely incorporated unchanged into cellular TAG and PL. In the HepG-2 model, the secretion of biliary lipids could not be studied. In contrast, in the perfused rat liver model, both lipid synthesis and secretion into bile could be studied simultaneously. In the present manuscript, we report the effect of FA of different chain lengths on liver and biliary lipid composition.

MATERIALS AND METHODS

Materials. [1-^{14}C]Sodium acetate (52.1 mCi/mmol), [1-^{14}C]-lauric acid (52.8 mCi/mmol) and [1-^{14}C]palmitic acid (57.0 mCi/mmol) were obtained from Amersham (United Kingdom); [1-^{14}C]sodium octanoate (55.0 mCi/mmol) and [1-^{14}C]oleic acid (50.0 mCi/mmol) from NEN (Boston, MA); and [1-^{14}C]sodium decanoate (10.6 mCi/mmol) from Sigma (St. Louis, MO). All ^{14}C-labeled FA were diluted with nonlabeled FA to yield a final specific radioactivity of 2 mCi/mmol; ^{14}C-acetate was diluted to a specific radioactivity of 4 mCi/mmol. All FA were obtained from Sigma. Thin-layer Silica gel 60 plates (0.25 mm) were obtained from Merck (Darmstadt, Germany), KC 18 Silica gel plates (0.2 mm) from Whatman (Maidstone, England). All solvents were of analytical grade (Merck). Albumin, bovine-fat poor, was obtained from Sigma. Scintillation fluid-Ultima-Gold was obtained from Packard (Meriden, CT).

Isolated perfused rat liver studies. Male Wistar rats weighing 300–360 g were used. They were fed Purina Rodent Chow *ad libitum* and maintained under a constant light cycle of 12 h. The surgical procedures were performed as described by Corasanti *et al.* (25). Rats were anesthetized with pentobarbitone (50 mg/kg body wt i.p.) (Ceva, Paris, France). The bile duct was cannulated with PE-10 tubing (Clay Adams, Parsippany, NJ). The portal vein was cannulated with a 16-gauge Teflon intravenous catheter (BOC Ohmeda AB, Helsingborg, Sweden). The liver was then perfused at a constant flow of 20 mL/min with oxygenated Krebs-Ringer bicarbonate (KRB) buffer containing (in mM) 120 NaCl, 4.7 KCl, 1.2 KH_2PO_4, 1.2 $MgSO_4$, 1.8 $CaCl_2$, and 25 $NaHCO_3$. Added to the KRB buffer were 5.5 mM glucose and 200 U heparin/100 mL.

After cannulation of the inferior vena cava, the livers were removed from the rat, transferred into a heated perfusion chamber, and perfused in a recirculating closed system (volume: 200 mL) at a constant flow rate of 40 mL/min with KRB buffer containing 5.5 mM glucose and 1% bovine serum albumin. The KRB buffer was gased continuously with a humidified mixture of 95% O_2–5% CO_2 and maintained at 37 ± 0.5°C. After 10 min of equilibration, a bolus of the following lipids was added: 10 μmol of [1-^{14}C]-labeled FA: C_2, C_8, C_{10}, C_{12}, C_{16}, and $C_{18:1}$. Taurocholic acid (30 μM) was infused continuously to stimulate bile secretion. The livers were perfused for 2 h. At the end of the experiment, the livers were perfused for 15 min with fresh KRB. Perfusion pressure was monitored continuously. Bile and perfusate samples were collected every 15 min. Bile was collected into pretared tubes which were changed every 15 min. The tubes were then weighed, and bile flow was calculated as μg bile/min/g liver. At the end of the experiments, bile samples were pooled. Livers, bile, and perfusate samples were frozen at −70°C for lipid analysis. Each perfusion experiment was done twice, and livers and biles were analyzed separately. Approximately 2 mL of bile was collected. The mean weight of the livers was 10.4 ± 1.0 g. Two 1-g samples of each liver were used for lipid extraction and analysis. The results presented in the tables are the mean of these four determinations. A sample of the perfusate was removed at the end of the experiment, and the distribution of the radioactivity among the different lipid classes was determined.

The viability of the perfused liver was assessed throughout the perfusion by monitoring perfusion pressure (7–12 cm H_2O), determining baseline bile flow, and measuring the release of lactate dehydrogenase as well as observing the general appearance of the liver.

Liver and bile lipid extraction and analysis. Liver samples of 1 g were homogenized with 5 mL of saline using an Ultra-Turax (Janke and Kunkel Ika-Werk, Staufen, Germany). The homogenates were then extracted with chloroform/methanol according to Bligh and Dyer (26). Pooled bile (1 mL) from each experiment and 5 mL of the perfusate collected at the end of the experiment were similarly extracted (26).

The amount of the radioactivity in the extracts was determined using a Kontron-Betamatic counter (Switzerland). Aliquots of the lipid extracts were used for the separation of neutral lipids and PL by thin-layer chromatography (TLC) as previously described (24). Neutral lipids were separated on Silica gel G plates employing hexane/diethylether/methanol/acetic acid (90:20:3:2, by vol) as solvent. PL were separated using chloroform/methanol/acetic acid/water (100:20:12:5, by vol) as solvent. For determination of radioactivity, lipid spots were scraped into scintillation vials and suspended in 3.5 mL scintillation fluid. The overlapping spot of diglycerides and cholesterol on the TLC plates was collected and

saponified with 0.5 M methanolic KOH for 30 min at 50°C. Samples were than acidified and extracted with hexane. Aliquots were placed on TLC plates as described above.

To determine the chain length of the FA which were incorporated into PL and TAG, the corresponding spots were collected and saponified with 0.5 M methanolic KOH. FA were recovered and separated according to their chain length by reversed-phase TLC on KC18 plates utilizing acetonitrile/methanol/water (6:3:1, by vol) as solvent (24,27). Under our experimental conditions, 18:0 and 18:1 co-migrated with 16:0. Spots were scraped directly into scintillation vials, and the radioactivity was determined immediately after addition of scintillation fluid.

To determine the FA composition of PL and TAG, the FA recovered after alkaline hydrolysis were methylated with diazomethane (28). The methyl esters were separated by gas–liquid chromatography (GLC) on a 30 m PAG (poly alkylene glycol) column (0.25 μm film thickness; Supelco, Bellefonte, PA) at a temperature range of 185–220°C, employing a Hewlett-Packard 5790A gas chromatograph equipped with a flame-ionization detector. The relative composition of FA mixtures was calculated employing a Hewlett-Packard 3396 integrator. For quantitative analysis, heptadecanoic acid was added as an internal standard, assuming that the response of the detector for all methyl fatty esters was identical. Saturated and unsaturated methyl FA were separated on $AgNO_3$-impregnated plates (29), employing hexane/diethyl ether (80:20, vol/vol) as solvent.

Free cholesterol was determined directly from the chloroform/methanol extracts by an enzymatic colorimetric method using a cholesterol oxidase kit from Boehringer Mannheim GmbH (Ingelheim, Germany).

RESULTS

Incorporation of ^{14}C-labeled FA into liver lipids. Addition of 10 μmol of [1-^{14}C]-labeled FA (C_2, C_8, C_{10}, C_{12}, C_{16}, and $C_{18:1}$) to the perfusion buffer resulted in the incorporation of 0.66 to 6.61 μmol (6.6 to 66.1% of the radioactivity added to the perfusate) of ^{14}C-FA into liver lipids (Table 1). More long-chain FA (LCFA) (C_{16} and $C_{18:1}$) were incorporated than medium-chain FA (MCFA) (C_8, C_{10}, and C_{12}). Only acetate was extensively incorporated into cholesterol (25% of the amount incorporated into liver lipids). The other FA were incorporated mainly into PC (*ca.* 40%) and to a lesser extent into TAG and PE. Diacylglycerols, FA, cholesterol ester, and phosphatidylserine contained only relatively small amounts of radioactivity (not shown). LCFA did not lead to newly synthesized cholesterol.

Incorporation of ^{14}C-labeled FA into biliary lipids. Bile was collected throughout the perfusion period. Figure 1 shows that bile secretion became stable after 30 min at an average rate of 1.8 μg/min/g liver and remained constant for the rest of the perfusion period. As can be seen in Figure 2 secretion of ^{14}C-labeled metabolites into bile was dependent on the ^{14}C-FA added. In most cases, maximal values were obtained 40 to 50 min after addition of the ^{14}C-substrate. ^{14}C-Metabolites include ^{14}C-lipids and ^{14}C-water-soluble compounds. For C_2, C_8, C_{10}, and C_{12} the ^{14}C-water-soluble compounds amounted to 65–75% of the total radioactivity secreted into bile. In the presence of C_{16} and $C_{18:1}$, only 15% of the radioactivity was water-soluble. ^{14}C-Free fatty acid (FFA) were not secreted into bile. ^{14}C was not detected in bile acids (30). Attempts to identify the water-soluble compounds indicated that these were not volatile and could not be extracted into ether (after acidification). ^{14}C-Acetoacetate was not detected after incubation with β-hydroxybutyrate dehydrogenase (31).

Table 2 shows the incorporation of ^{14}C-FA into biliary lipids. When ^{14}C-acetate was perfused, 17 nmol were recorded in biliary lipids—75.5% of which were incorporated into cholesterol. In the presence of MCFA, 19 to 22 nmol were incorporated into biliary lipids—71–78% into PC; in the presence of C_{16} and $C_{18:1}$, 90 and 70 nmol were incorporated into biliary lipids; over 95% of the radioactivity was detected

TABLE 1
Incorporation of Different ^{14}C-FA into Liver Lipids[a]

FA	^{14}C-FA-incorporated (μmol)	Radioactivity incorporated (%)			
		TAG	Cholesterol	PC	PE

C_{16}	6.61 ± 1.88	22.77 ± 1.87	Trace	46.51 ± 1.15	13.91 ± 1.65
$C_{18:1}$	6.61 ± 1.78	35.01 ± 4.58	Trace	33.38 ± 5.03	12.60 ± 0.59

[a]Lipids were extracted from liver samples and separated by thin-layer chromatography (TLC) as described in the Materials and Methods section. Hexane/diethylether/methanol/acetic acid (90:20:3:2, by vol) was used for the separation of neutral lipids, chloroform/methanol/acetic acid/water (100:20:12:4, by vol) for the separation of phospholipids (PL). Lipid spots were scraped directly into scintillation vials and radioactivity determined after addition of scintillation fluid. The incorporation of ^{14}C-fatty acid (FA) is expressed as μmol per total liver, assuming incorporation of intact FA. Diacylglycerols, FA, cholesterol esters, and phosphatidylserine contained 1–3% each. The results given are the mean (±SD) of data obtained from two different experiments. Liver weight was in the range of 9 to 11 g. TAG, triacylglycerols; PC, phosphatidylcholine; PE, phosphatidylethanolamine.

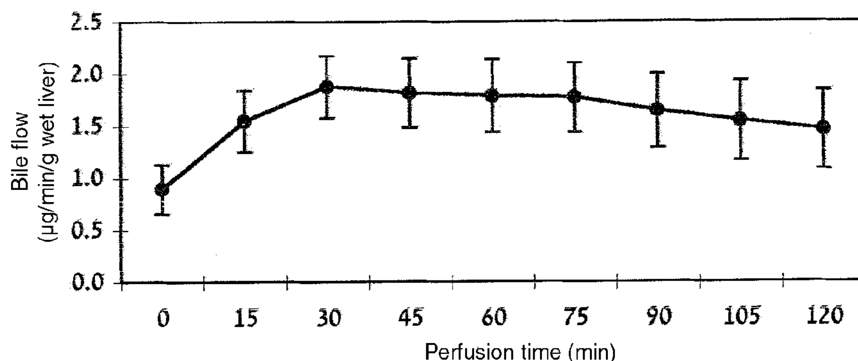

FIG. 1. Bile flow rate. Bile was collected into pretared tubes each 15 min. The bile flow was calculated as µg bile/min per gram wet liver. The results presented are the mean values ± SD of all bile samples collected during the study period (n = 12).

in PC. Biliary PE contained *ca.* 2–3%, and phosphatidylserine contained less than 1% (not shown).

Comparison of FA composition of liver and biliary PL. Table 3 compares the quantities and FA composition of liver and biliary PC and PE. Since the amounts of these PL and their FA composition were not affected by the addition of the different ^{14}C-FA to the perfusate, the mean results for all experiments are presented in the table. As can be seen from Table 3, biliary PL contained mainly PC (93%) and PE (6%); phosphatidylserine amounted to less than 1% (not shown).

Comparison of the incorporation of ^{14}C-FA into liver and biliary PC and cholesterol. Table 4 compares the specific radioactivity of liver and biliary PC and cholesterol. The specific radioactivity of biliary PC after administration of all saturated FA was 3.8 to 6.8 times higher than that of liver PC; for $C_{18:1}$ it was only 1.7-fold, suggesting a higher dilution of 18:1 by liver PC. The specific radioactivity of biliary cholesterol (as compared to liver cholesterol) was 12 times higher for C_2 and five times higher for MCFA. LCFA did not lead to ^{14}C-cholesterol synthesis.

From the data presented in Tables 1 and 2, it can be calculated that 200 nmol of acetate and 400–550 nmol of MCFA were incorporated into liver PC; 4.1 nmol acetate and 13–17 nmol of MCFA were incorporated into biliary PC. The incorporation of the LCFA into liver and biliary PC was considerably higher, 3312 and 85 nmol (into liver and bile, respectively) for ^{14}C-C_{16} and 2235 and 68 nmol (into liver and bile, respectively) for $C_{18:1}$. Although the incorporation of LCFA (16:0 and 18:1) was considerably higher, nevertheless in all experiments ^{14}C-labeled biliary PC amounted to 2.75 to 3.25% of the ^{14}C-labeled liver PC. Secretion of PL, TAG, and cholesterol into the perfusate reached 0.5–1% of that present in the liver. The distribution of radioactivity between the different lipids in the perfusate was generally similar to that de-

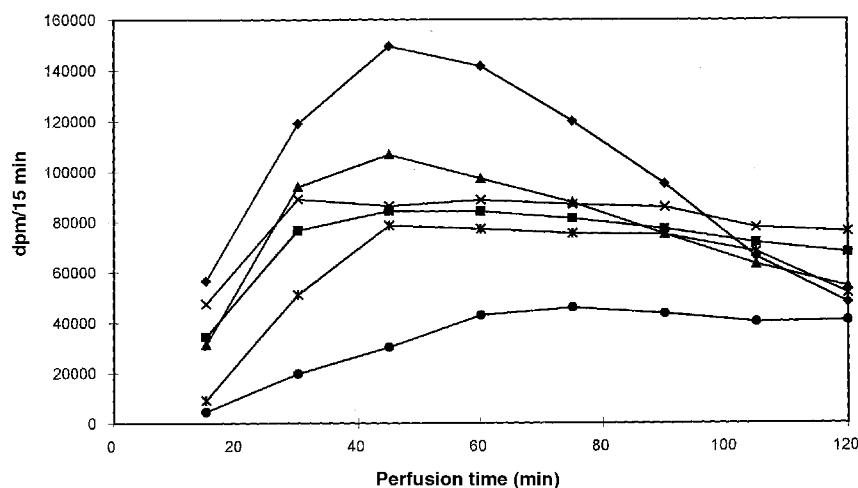

FIG. 2. Secretion of ^{14}C-labeled metabolites into bile. The secretion of ^{14}C-labeled metabolites into bile was measured for each fatty acid (FA): C_2 ◆, C_8 ■, C_{10} ▲, C_{12} X, C_{16} ✳, and $C_{18:1}$ ●. Bile samples were collected as described in the legend to Figure 1. A sample of 10 µL of bile from each time point was counted to determine ^{14}C-content.

TABLE 2
Incorporation of Different ^{14}C-FA into Biliary Lipids[a]

	^{14}C-FA in bile (nmol)	^{14}C incorporated (%)	
		Cholesterol	PC
C_2	17.02 ± 3.13	75.47 ± 6.8	23.85 ± 6.77
C_8	18.62 ± 10.24	17.54 ± 6.81	79.89 ± 6.99
C_{10}	19.00 ± 7.24	26.22 ± 12.04	71.34 ± 12.00
C_{12}	21.99 ± 1.25	21.22 ± 3.61	75.96 ± 3.99
C_{16}	89.18 ± 38.43	Trace	95.03 ± 0.91
$C_{18:1}$	70.65 ± 14.07	Trace	95.79 ± 0.39

[a]Lipids were extracted from 1 mL bile samples and separated by TLC as described in the legend to Table 1. The incorporation of ^{14}C-FA is expressed as nmol per total bile sample, assuming that the ^{14}C-FA reached the bile *via* the liver without processing. The results are the mean (±SD) of the two different bile samples analyzed. See Table 1 for abbreviations.

tected in the liver. Only when ^{14}C-acetate was added, the percentage of PL in the perfusate was higher and that of cholesterol was lower than in the liver.

Occurrence of C_{10} and C_{12} in liver and biliary lipids. ^{14}C-TAG and PL synthesized by the liver during perfusion with ^{14}C-C_2, -C_8 and -C_{16} were isolated and the ^{14}C-FA recovered after saponification were separated by TLC. Only ^{14}C-LCFA (^{14}C-C_{16} and -C_{18}) were identified. However, after perfusion with ^{14}C-C_{10}, saponification of ^{14}C-TAG yielded *ca.* 10% ^{14}C-C_{10} (Fig. 3) and 90% of ^{14}C-C_{16} and C_{18}; ^{14}C-C_{10} was not detected in liver PL. After perfusion with ^{14}C-C_{12} saponification of liver TAG yield *ca.* 35% ^{14}C-C_{12} and 65% ^{14}C-C_{16} and -C_{18}. Liver PC contained *ca.* 8% of ^{14}C-C_{12}. Biliary PC contained 3% ^{14}C-C_{10} and 18% ^{14}C-C_{12}.

For further identification of the newly incorporated FA, methyl-FA were separated on $AgNO_3$-impregnated plates. Less than 1% of the radioactivity was associated with monounsaturated FA (not shown), indicating that desaturation did not occur under our experimental conditions. After ^{14}C-$C_{18:1}$ perfusion, 98% of the radioactivity of the FA isolated from liver and biliary lipids was present in oleic acid.

DISCUSSION

In the present paper the metabolism of ^{14}C-labeled FA of different chain lengths by the isolated perfused rat liver was studied. This experimental approach permitted the simultaneous measurement of FA incorporation into liver and biliary lipids. We previously reported (23) that short-term infusion of MCT/LCT to patients resulted in significant changes in bile composition, whereas LCT alone did not elicit any changes. The aim of this and our previous studies (24) was to examine *in vitro* the mechanism underlying these *in vivo* effects. LCT (500 μL) which contained 113 μmol of soya-TAG and 0.53 μmol of (^{3}H-oleate)-labeled trioleylglycerol were added to the perfusate. After 2 h, 50% of the remaining TAG (12 μmol) were detected as free FA, indicating extensive lipolysis of the added LCT. Although the liver was perfused for 30 min with LCT-free buffer, most of the radioactivity isolated from the liver (61.4 μmol) was detected in TAG (39.8%), FFA (22.9%), and diacylglycerols (18.5%) and only 10.6% was incorporated into PL. The occurrence of large amounts of FFA in the perfusate and the liver suggests the role of FFA uptake under our experimental conditions. Since radioactively labeled MCT was not available to us, ^{14}C-labeled MCFA (C_8, C_{10}, and C_{12}) and LCFA (C_{16} and $C_{18:1}$) were added instead. ^{14}C Acetate was used in these experiments to represent acetyl CoA, the β-oxidation product of the added FA.

The major finding of the present investigation is that C_2, C_8, C_{10}, and C_{12} were largely used for the synthesis of saturated LCFA, which were subsequently incorporated into liver PL and TAG, whereas C_{16} and $C_{18:1}$ were used directly for PC and TAG synthesis. For C_8, C_{10}, and C_{12} to yield LCFA, they have to be either oxidized to C_2 units prior to being used for *de novo* FA synthesis or elongated after internalization. The occurrence of water-soluble metabolites in the bile after administration of ^{14}C-C_2 and ^{14}C-MCFA suggests that acetyl CoA was formed by β-oxidation of MCFA (32) and was further metabolized. We did not succeed in identifying the water-

TABLE 3
Lipid Content and PL-FA Composition of Liver and Bile[a]

	Content[b]	16:0	18:0	18:1	18:2	20:4	22:6
		FA composition (%)					
Liver PC	21.1 ± 4.2	19.3 ± 0.9	20.5 ± 1.0	8.5 ± 0.5	17.4 ± 1.0	20.5 ± 2.1	6.37 ± 0.6
PE	10.8 ± 2.4	15.3 ± 1.5	18.5 ± 1.8	8.2 ± 0.4	17.0 ± 4.0	22.5 ± 1.9	10.9 ± 0.9

Cholesterol	0.26 ± 0.07						

[a]To determine the cholesterol and PL content and FA composition, lipids were extracted from liver and bile samples and separated by TLC as described in the Materials and Methods section and legend to Table 1. PL spots were collected and saponified with 0.5 M methanolic KOH. FA were recovered after acidification, methylated with diazomethane (Ref. 28) and separated by gas–liquid chromatography as described in the Materials and Methods section. Minor FA components such as 16:1, 18:3, 20:1, and 20:5 are not included in the table. The PL content and FA composition of liver and biliary lipids were similar for all samples analyzed. The results are the mean (±SD) of 12 independent experiments.
[b]Lipid contents of liver and bile are presented as μmol/g and μmol/mL, respectively. See Table 1 for abbreviations.

TABLE 4
Specific Radioactivity of Liver and Biliary PC and Cholesterol[a]

	PC		Cholesterol	
	Liver (dpm/μmol)	Bile (dpm/μmol)	Liver (dpm/μmol)	Bile (dpm/μmol)

C_8	7582	48395	2057	10870
C_{10}	7291	27815	4230	23040
C_{12}	6070	25844	1780	8414
C_{16}	54521	248931	—	—
$C_{18:1}$	23503	39032	—	—

[a]Liver and biliary PC and cholesterol were isolated and their concentration and radioactivity determined as described in Tables 1, 2, and 3. See Table 1 for abbreviations.

soluble compounds. The most likely metabolites, 3-hydroxybutyrate and acetoacetate, were not detected.

During the perfusion period, irrespective of the FA administered, 2.75 to 3.25% of the ^{14}C-labeled PC were secreted into bile. The specific radioactivity of biliary PC was higher than that of liver PC, indicating the secretion of the ^{14}C-labeled PC into bile prior to mixing with the liver pools of PC. Whereas after perfusion with MCFA, newly synthesized biliary PC amounted to 0.57–0.70% of total biliary PC, with LCFA newly synthesized PC reached 2.8 to 3.5%. Biliary secretion of PC by the perfused liver was previously studied by Robins *et al.* (18,33). In these experiments ^{14}C-choline was continuously added. Although PC secretion was four times higher than in our experiments, secretion of newly synthesized PC amounted to 3.4% of total biliary PC.

In contrast to the results obtained with HepG-2 cells (24) in which ^{14}C-C_{12} was incorporated into cellular lipids to the same extent as ^{14}C-C_{16}, in the perfused rat liver its incorporation was like that of C_8 and C_{10}. Furthermore, whereas in HepG-2 cells, C_{12} was largely incorporated unchanged (80–90% of all ^{14}C-FA in TAG; 50–60% in PL), in the perfused rat liver ^{14}C-C_{12} amounted to 30–40% of all ^{14}C-FA in TAG and 10% in PL. Unchanged ^{14}C-C_{10} was not detected in liver PL. Biliary PC contained 3% of unchanged ^{14}C-C_{10} and 18% unchanged ^{14}C-C_{12}. Thus the percentage of C_{10} and C_{12} in biliary PC was significantly higher than in liver PC.

Using GLC, we could not detect C_{10} and C_{12} in biliary PC. The calculated amount of C_{12} present in PC (500 ng) was only 0.04% of total biliary PC-FA and thus below our detection limit.

Robins *et al.* (18) previously showed that there were significantly greater amounts of the administered 16:1, 17:1, and 18:2 in the PC of bile than the liver leading to the secretion of 16:1-16:1, 17:1-17:1, and 18:2-18:2 species, indicating preferential secretion of newly synthesized PC. The occurrence of ^{14}C-C_{12} in biliary PC in our experiments is compatible with these observations.

^{14}C-Acetate, in contrast to MCFA, was preferentially incorporated into liver and biliary cholesterol (Table 2). However, since during β-oxidation of MCFA dilution of ^{14}C-acetyl CoA occurs, the actual incorporation is probably higher. During the 2-h infusion, 6.5 to 10% of the newly synthesized cholesterol was secreted into the bile. The specific radioactivity of biliary cholesterol, like that of PC, was higher than that of liver cholesterol, indicating secretion of newly synthesized

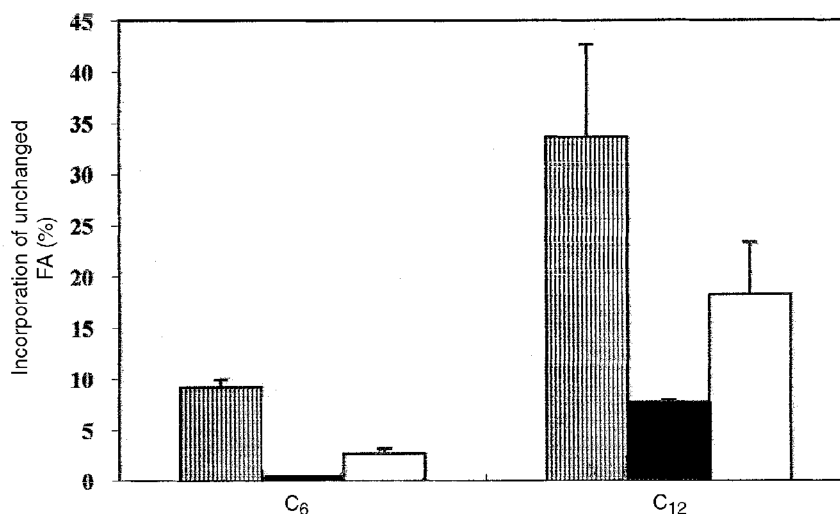

FIG. 3. Recovery of ^{14}C-C_{10} and ^{14}C-C_{12} in liver and biliary lipids. To determine the occurrence of ^{14}C-C_{10} and ^{14}C-C_{12}, lipids were extracted from liver and bile samples and separated by thin-layer chromatography as described in the Materials and Methods section. Liver triacylglycerols (TAG) ▥, liver phosphatidylcholine (PC) ■, and biliary PC □ were scraped off the plate and subjected to alkaline hydrolysis. FA were recovered after acidification and separated by reversed-phase thin-layer chromatography as described in the Materials and Methods section. FA spots were scraped into scintillation vials and the radioactivity determined. Each point is the mean of two to four different analyses ± SD. See Figure 2 for abbreviation.

cholesterol prior to its mixing with liver pools. The preferential secretion of newly synthesized cholesterol was reported previously (34,35). The percentage of newly synthesized cholesterol of the total biliary cholesterol reached 12.8% when acetate was administered and 3.2 to 5% in the presence of MCFA. Our present data on the secretion of ^{14}C-PC and ^{14}C-cholesterol and those previously reported by Robins *et al.* (18,33,35) indicate that most of the biliary PC and cholesterol were recruited from preexisting liver-lipid pools.

The effect of MCFA on the composition of biliary PC was not described previously. Feeding coconut oil (rich in 12:0 and 14:0) to hamsters (15,16) resulted in a reduction of biliary PL secretion and an increase in the lithogenic index. Occurrence of 12:0 and 14:0 in biliary PC was not recorded. Furthermore, the contribution of MCFA to biliary cholesterol and PC in the perfused rat liver as shown in the present communication may explain the mechanisms responsible for the different effects of MCFA and LCFA on bile composition as observed in our clinical studies as well others. Further studies are being conducted to clarify this issue.

ABSTRACT: Reportedly, randomly rearranging the position of fatty acids (FA) in butterfat triacylglycerol (TAG) by interesterification, thereby lowering the proportion of saturated FA in the *sn*-2 position, reduces its hypercholesterolemic and hypertriglyceridemic properties when fed to humans. The aim of this work was to determine if these reductions in plasma cholesterol and TAG could be explained by an improved rate of clearance from the plasma of chylomicrons composed of randomized butterfat, using a rat model. Acute chylomicron clearance studies demonstrated no differences in fractional clearance rates of cholesteryl esters and TAG from the plasma of rats infused with chylomicrons produced from gastric feeding of either native (NBF) or randomized (RBF) butterfat. Although there was a 14% decrease in the level of saturated FA occupying the *sn*-2 position of TAG in RBF compared with NBF, this difference became negligible (~5%), following digestion of the fat and subsequent repackaging of TAG into chylomicrons. These observations suggest that the previously observed reduction in hypercholesterolemic properties of randomized butterfat in rat is unlikely to be explained by improved clearance of chylomicron TAG.

Paper no. L8100 in *Lipids 34*, 579–582 (June 1999).

The consumption of butterfat in the human diet was consistently demonstrated to cause the elevation of plasma total cholesterol levels, in particular low density (LDL)-cholesterol (1–3), and was also shown to lead to the development of atherosclerotic lesions of the aorta when fed to rats as part of a diet containing cholesterol and cholic acid (4). Mechanisms proposed to explain how fats rich in saturated fatty acid (FA), such as butterfat, result in these consequences include possibility that saturated FA modify the composition of LDL, resulting in the decreased binding, internalization, and degradation of LDL by tissues (5). Saturated FA can directly act to suppress receptor-mediated endocytosis of LDL by causing alterations in the free cholesterol pool in the liver which is thought to regulate LDL-receptor transcription within the cell as reviewed by Dietschy (6).

The physiological effects of dietary fat are influenced not only by the relative proportion of saturated and unsaturated FA in triacylglycerol (TAG) but also by their arrangement among the three available esterification sites present on the backbone of TAG molecules. In particular, Christophe *et al.* (7,8) described reduced hypercholesterolemic and hypertriglyceridemic properties of butterfat when fed to people in a randomized form when compared with native butterfat. These findings, along with evidence that randomized butterfat (RBF) was hydrolyzed *in vitro* by pancreatic lipase at a much faster rate than butterfat in the native form (9), demonstrated the possible importance of positional distribution of FA in lipid metabolism. Redgrave *et al.* (10) and Mortimer *et al.* (11) also demonstrated that the saturated FA in the *sn*-2 position of TAG directly affected the rate at which chylomicron remnant particles were cleared from the bloodstream by the liver.

In the present study, randomization of butterfat resulted in a ~14% decrease in the amount of saturated FA occupying the *sn*-2 position of TAG. This study set out to determine if this decrease affected the measured rate of clearance of chylomicron-borne TAG and cholesterol ester (CE) from the bloodstream of rats injected with chylomicrons produced during absorption of RBF vs. NBF, thereby providing a possible mechanism to explain the reduced lipidemic effects seen in the studies of Christophe *et al.* (7,8).

METHODS

Interesterification (randomization) of butterfat. Anhydrous butterfat was randomized using sodium metal as a catalyst as previously described (12). After the reaction, the butterfat was washed in water and then dried under vacuum at 110–120°C to clarify its appearance and finally bleached with 2% bleaching earth (bleaching earth and filter aid; Meadowlea Foods, Sunshine VIC, Australia) for 30 min at 110–120°C. The bleaching earth was then filtered off at 60–70°C in a Buchner funnel using a filter aid to give a clear oil. Native butterfat was bleached to obtain a clear fat similar to the randomized form before being used.

TAG and FA analysis of dietary fats. Dietary fats were examined for total FA composition and positional distribution

of FA in the backbone of TAG using pancreatic lipase digestion. About 20 mg of TAG was isolated by thin-layer chromatography (13), followed by reaction of ~5 mg of TAG with pancreatic lipase as described by Luddy *et al*. (14). The fatty acid methyl esters (FAME) of TAG were formed by saponification in KOH for 10 min followed by methylation with BF_3 in methanol for 10 min (13). FAME were analyzed by capillary gas–liquid chromatography (DANI 6500HR; DANI S.P.A., Monza, Italy), equipped with a flame-ionization detector, using a 60 m × 0.32 mm i.d. crossbonded 90% bis-cyanopropyl: 10% phenyl cyanopropyl capillary column (RTX 2330; Restec Corporation, Bellefonte, PA), programmed from 95°C for 3 min to 190°C at 10°C/min with helium as carrier gas at a flow rate of 5 mL/min. FAME were identified by comparison with standard mixtures of FAME, and the results were calculated using response factors derived from chromatographing standards of known composition. Indication of successful randomization of butterfat was obtained by examination of TAG species separated by high-performance liquid chromatography using a Supelco LC-18 column, dimensions 150 mm × 4.6 mm i.d. (Supelco Inc., Bellefonte, PA) and with detection by evaporative light-scattering (ACS Model 750/14; ACS Ltd.; Macclesfield, Cheshire, United Kingdom).

Animals and diets. Male Sprague-Dawley rats weighing 230–280 g, which had been allowed free access to water and commercial rodent diet, were used in the production of chylomicrons. Male rats of the same strain weighing 200–230 g fed commercial rodent diet were used in the reinjection studies.

Collection of lymph and isolation of chylomicrons. Chow-fed rats were infused gastrically with 300 mg of NBF or RBF or corn oil (control) along with 50 μCi [1α,2α(*n*)-^{3}H] cholesterol and 15 μCi [1-^{14}C]palmitic acid. Intestinal lymph was collected for 6 h *via* a vinyl tube (0.8 mm o.d. × 0.5 mm i.d.; Dural Plastics and Engineering, Auburn, NSW, Australia) surgically implanted in the cisterna chyli, and chylomicrons were isolated using the centrifugal method described by Redgrave *et al.* (10).

Characterization of chylomicrons. Relative proportions of TAG, cholesterol, phospholipid, and protein in chylomicron particles were measured enzymatically on an autoanalyzer (Hitachi autoanalyser 704; Tokyo, Japan), using commercially available kits (Boehringer Mannheim, Mannheim, Germany). Chylomicron TAG FA and *sn*-2 FA composition were determined as for dietary fat TAG (13). Electron microscopy of chylomicron particles was performed using a Jeol 2000 FX transmission electron microscope (Tokyo, Japan) following negative-staining of particles with 2% phosphotungstic acid in 0.15 M NaCl, pH 4.8. Briefly, 10 μL of diluted sample (<100 mg/mL of protein) was dropped onto a 150-mesh copper grid for 30 s. The pointed end of a very coarse blotting paper was used to touch the edge of the grid to draw off the excess fluid, leaving a layer of particles in the grid. Phosphotungstic acid (10 μL) was then dropped on the grid and left for 60 s before being drawn off using the blotting paper method. Particles were then viewed under electron microscopy after air drying for several minutes. Particle size was determined from the average diameter of 100 chylomicrons measured from high-quality photographs.

Acute chylomicron reinjection studies. Labeled chylomicrons were injected into the venous cannula of conscious rats. Blood samples of 0.35 mL were then taken from the arterial cannula (with physiological saline injected to replace the blood volume) at 3, 5, 8, 12, 20, 25, and 30 min. At 30 min, the rat was anesthetized by injecting 35 mg/kg of Nembutal *via* the venous cannula, the liver and spleen were excised, and the radioactive lipids were extracted from minced whole spleen and from minced 1-g pieces of liver. Lipids were extracted into 30 mL of chloroform/methanol 2:1. Aliquots were taken, the solvent was evaporated, and radioactivity was measured in Readyvalue liquid scintillation cocktail (Beckman Instruments Inc., Fullerton, CA) by liquid scintillation spectrometry (1215 RACKBETA Liquid scintillation counter; LKB-Wallac, Turku, Finland) as described by Redgrave *et al* (10). Radioactivity in plasma was measured in 150-μL aliquots without extraction. Plasma clearance kinetics were computed from exponential curves fitted by least squares procedures to samples taken during the first 12 min after injection. The fractional clearance rate then represents the slope of the exponential fit of the data (10).

RESULTS AND DISCUSSION

The total FA and *sn*-2 FA compositions of NBF and RBF and the total FA and *sn*-2 FA composition of chylomicron TAG are shown in Table 1. Total FA composition of the dietary fats was similar for both NBF and RBF forms of butterfat. Analysis of *sn*-2 position FA composition of NBF revealed that ~65% of FA was saturated. Randomization decreased the total level of saturates in the *sn*-2 position to 51%. This net decrease resulted from a 44% reduction in 14:0 and 29% decrease in 16:0. The amount of 18:0 present in the *sn*-2 position increased by 83% but only contributed 11% of *sn*-2 position FA in the randomized form (Fig. 1). The conditions of the interesterification reaction produced 100% randomization of FA for butterfat as judged by comparison of *sn*-2 position FA composition with total FA composition of the native fat, since the *sn*-2 position FA composition mirrored that of the total FA composition.

There were no significant differences in lipid composition between NBF and RBF chylomicrons, with TAG constituting ~89%, phospholipid ~9%, cholesterol ~1%, and protein ~1% of total weight (data not shown). Chylomicrons were viewed by transmission electron microscopy, and the mean diameters and appearance were similar for each dietary fat (data not shown). Total FA composition was similar for both NBF and RBF chylomicrons and reflected the total composition of the infused fats. The amounts of 18:2n-6 in the chylomicron TAG were increased, indicating supply of endogenous 18:2n-6 to intestinal TAG synthesis while the longer chain 20:4n-6 and 22:6n-3 polyunsaturated fatty acids, which were not present in the initial fats, also appeared in chylomicron TAG in small amounts. The *sn*-2 FA composition varied between dietary

TAG and chylomicron TAG for both NBF and RBF with 18:1 and 18:2 present in increased proportions in the *sn*-2 position of chylomicron TAG compared with the dietary fat for both NBF and RBF. The chylomicrons from the RBF had decreased proportions of 14:0 and increased 18:0 and 18:1 in the 2-position compared with NBF chylomicrons which reflected the 2-position composition of the fed fats (Fig. 1). However, there was no significant difference in 16:0 levels in the *sn*-2 position in the chylomicrons which was unlike the fed fats where the RBF had a 29% lower 16:0 level than NBF. In fact, the proportion of 16:0 in the *sn*-2 position of the NBF chylomicrons was lower than in the fed fat (33% compared with 37%) while the proportion of 16:0 in the *sn*-2 position of RBF chylomicrons was higher than that in the RBF (30 vs. 26%). This suggests rearrangement of 16:0 in the 2-position of the RBF occurred during the formation of the chylomicrons (Fig. 1), unlike what was reported in humans (15). An earlier study found 75% conservation of the fatty acids located in the *sn*-2 position during absorption in the rat (16). Pufal *et al.* (17) reported that rats fed palmitate in the *sn*-2 position vs. the *sn*-1(3) position led to chylomicron TAG with very similar *sn*-2 position compositions compared with the test fats; however they did find that the difference in palmitate was less in the chylomicrons than in the test fats.

Conscious chow-fed rats were injected *via* the left jugular vein with a bolus dose of either NBF, RBF, or corn oil chylomicrons. Fractional clearance rates for injected chylomicrons were calculated from exponential curves fitted by least squares procedures to plasma samples taken during the first 12 min after injection and are shown in Table 2. The results show that there were no significant differences in rate of clearance of either chylomicron TAG or CE between NBF, RBF, or corn oil chylomicrons

While the recovery of radioisotopes in liver and spleen was based on one time point only, there were differences between the two test fats. There was a significantly increased labeling of NBF TAG in the liver and spleen compared with the corn oil control group ($P < 0.05$), while there was a significantly reduced labeling of CE in the RBF group in both

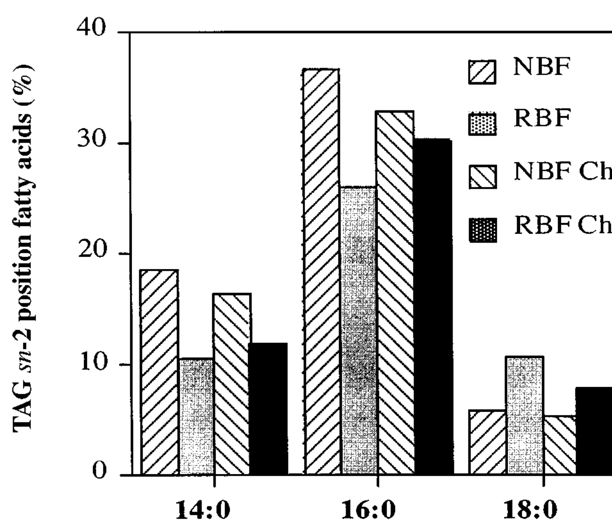

FIG. 1. Proportion of triacylglycerols (TAG) *sn*-2 14:0, 16:0, and 18:0 in fed diets and chylomicrons. Abbreviations: NBF, native butterfat diet; RBF, randomized butterfat diet; NBF Ch, native butterfat chylomicrons; RBF Ch, randomized butterfat chylomicrons.

Native butterfat	0.200 ± 0.009	0.097 ± 0.016	19.5 ± 0.6[a]	67.7 ± 1.8[a]	0.8 ± 0.1[a]	1.9 ± 0.1[a]
Randomized butterfat	0.190 ± 0.007	0.090 ± 0.008	17.5 ± 0.8[a,b]	59.5 ± 2.5[b]	0.6 ± 0.1[a,b]	1.3 ± 0.1[b]
Corn oil	0.224 ± 0.021	0.100 ± 0.013	16.5 ± 0.1[b]	74.8 ± 2.4[a]	0.5 ± 0.0[b]	1.6 ± 0.1[a,b]

[a]Different roman superscripts in the same column are significantly different, $P < 0.05$, one-way analysis of variance, Duncan's new mutiple range test. CE, cholesterol esters. See Table 1 for other abbreviations.

tissues compared with the NBF group ($P < 0.05$). The physiological significance of these observations is not clear at the present since these data were collected in a very short-term study; however, it is possible that the reduced labeling of CE in the RBF group might signify a reduced activity of LDL receptors (6). While these data suggest the need for a long-term study using these test fats, Pufal *et al.* (17) reported that hamsters fed fat blends with palmitate in the *sn*-2 position vs. the *sn*-1(3) position for 28 d showed no significant difference in plasma lipoprotein levels.

In conclusion, this study did not demonstrate a significant difference in the fractional turnover rate of chylomicron lipids between animals fed NBF vs. RBF. Possibly the difference in the proportion of saturated fatty acids in the 2-position of TAG between the chylomicrons resulting from the two test fats was so small that it was not possible to detect the differences in chylomicron metabolism reported by Redgrave *et al.* (10) and Mortimer *et al.* (11) who used model TAG.

Cholesterol Synthesis and Degradation in Normal Rats Fed a Cholesterol-Free Diet with Excess Cystine

Yoritaka Aoyama[a,*], Nobuyuki Amano[b], and Akira Yoshida[b]

[a]Division of Applied Bioscience, Graduate School of Agriculture, Hokkaido University, Sapporo 060-8589, Japan, and [b]Department of Applied Biological Chemistry, School of Agricultural Sciences, Nagoya University, Nagoya 464-8601, Japan

ABSTRACT: Feeding a diet with excess cystine to rats resulted in hypercholesterolemia. To understand the mechanism of the hypercholesterolemia, cholesterol synthesis and degradation, bile acid content of bile, and fecal steroids were determined. The *in vivo* incorporation of tritiated water into hepatic cholesterol, and activity of hepatic 3-hydroxy-3-methylglutaryl-CoA reductase in rats fed a high-cystine diet were significantly higher than those in rats fed a control diet. The activity of hepatic cholesterol 7α-hydroxylase was similar between two groups. Little effect of cystine supplementation was found on fecal sterol excretion although there were some changes in biliary excretion of cholic acid derivatives. These results indicate that hypercholesterolemia caused by feeding of a high-cystine diet may be due to the stimulation of hepatic cholesterol synthesis.

Paper no. L7969 in *Lipids 34,* 583–589 (June 1999).

The addition of high levels of single amino acids to the diet can cause growth retardation (1,2). Excess dietary cystine can cause hypercholesterolemia in rats after feeding for 2 mon (3–6). We also reported that the elevation in serum cholesterol by this diet was observed within 7 d (7–10), and this was prevented by the addition of dietary fiber (8). These findings were different from the results obtained when cholesterol was added to a 25% casein diet. In the latter study, blood cholesterol concentrations were increased by the addition of methionine, and this increase was partially reversed by the addition of cystine (11,12).

The hypercholesterolemia induced by excess dietary cystine was not due to increases in exogenous cholesterol because this diet was free of cholesterol. The mechanism for the elevation in blood cholesterol was investigated. Rukaj and Serougne (4) demonstrated that, except for absorption and external secretion, all other aspects of cholesterol turnover were increased when dietary cystine was increased. Serougne *et al.* (5) reported that the *in vivo* incorporation of [^{14}C]acetate into rat liver cholesterol was significantly higher in a cystine-supplemented group compared to controls. These results suggested that cholesterol synthesis was stimulated by excess dietary cystine.

The determination of cholesterol synthesis using ^{14}C-substrates may underestimate or overestimate the true rate of cholesterol synthesis (13–15). Therefore, in the present study, we used [^{3}H]water in order to examine *in vivo* the rate of cholesterogenesis in rats fed the high-cystine diet. It is well-known that 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase [EC 1.1.34] is the rate-limiting enzyme of cholesterol synthesis (16–18). The total activity of completely dephosphorylated HMG-CoA reductase was significantly higher in the livers of rats fed a cystine-excess diet than in those of rats fed a control diet (19). While cholesterol degradation in the liver was not studied when rats were fed the cystine-excess diet, cholesterol 7α-hydroxylase [EC 1.14.13.17] is the initial step in the conversion of cholesterol to bile acids and is rate-limiting for bile acid synthesis (20). Therefore, we assessed the *in vivo* synthetic rate of hepatic cholesterol using [^{3}H]water, hepatic activities of HMG-CoA reductase (dephosphorylated and native) and cholesterol 7α-hydroxylase, bile acid composition in bile, and fecal steroids to investigate their possible involvement in the elevation of blood cholesterol in rats fed a cystine-excess diet.

MATERIALS AND METHODS

Diets. Compositions of the basal and the cystine-excess diet are shown in Table 1. In the high-cystine diet, 3.5% by weight of L-cystine (Katayama Chemical Industries Co., Ltd., Osaka, Japan) was added to a basal diet at the expense of corn starch.

Animals. Male Wistar rats (Japan SLC, Inc., Hamamatsu, Shizuoka, Japan) were used. All rats were housed individually in stainless-steel wire-bottomed cages in an air-conditioned room kept at *ca.* 23°C, with a 12-h cycle of light (0800–2000 h) and dark (2000–0800 h). Animals were cared for under Guidelines for Animal Experimentation of the Committee of Experimental Animal Care, Nagoya University.

The rats (5 wk old) were fed a basal diet (Table 1) for 3 to 5 d, allowing them to adapt the shifted feeding pattern described below, and then were offered *ad libitum* either a basal or a high-cystine diet (Table 1). Pair-fed rats were offered the

same amount of a basal diet as consumed by rats fed the high-cystine diet for 7 d. Rats were allowed free access to water throughout the experimental periods.

Liver and serum components (Expt. 1). Rats were fed a basal *(ad libitum),* a basal diet pair-fed with the high-cystine group, and a high-cystine *(ad libitum)* diet for 7 d. Rats were sacrificed between 2300 and 2330 h by decapitation.

After sacrifice, blood was collected and allowed to clot at room temperature; serum was obtained by centrifugation. The livers were immediately excised and weighed. Serum and samples of liver were stored at −30°C until analysis. Serum cholesterol (21), phospholipids (22), and triacylglycerol (23) were measured by enzymatic methods. Liver lipids were extracted and purified according to the procedure of Folch *et al.* (24). Liver total lipid content was gravimetrically estimated after removing chloroform and methanol. Cholesterol (21) and triacylglycerol (23) in the liver were measured enzymatically. Liver phospholipids were calculated by the differences between liver total lipids minus the sum of cholesterol plus triacylglycerol.

In vivo *incorporation of [^{3}H]water into cholesterol (Expt. 2)*. Rats were fed a basal *(ad libitum),* a pair-fed basal, or a high-cystine *(ad libitum)* diet for 7 d. The rats were injected intraperitoneally between 2300 and 2330 h (25) with 250 µL of [^{3}H]water (1 mCi, 37 MBq) (Amersham Japan Ltd., Tokyo, Japan). At 60 min after injection, the rats were sacrificed by cardiac puncture. The liver and small intestine (0.5 cm below pylorus and 0.5 cm above cecum) were quickly removed. Intestinal contents were removed by rinsing with ice-cold saline. Both liver and small intestine were frozen in liquid nitrogen and stored at −20°C. Portions of the stored liver, small intestine, and serum were saponified in 15% ethanolic potassium hydroxide at 75°C for 60 min. The hydrolysate was then extracted four times with petroleum ether hydrocarbon (b.p., 30–60°C). An aliquot of the petroleum hydrocarbon fraction was counted for radioactivity in the unsaponifiable fraction. Sterols in another portion of the petroleum hydrocarbon fraction were purified as digitonin-precipitable sterols (DPS) by the method of Kelley and Tsai (26). The rate of synthesis was estimated by the formula of Turley *et al.* (27) using the serum ^{3}H-content. The rate of synthesis was expressed as nmoles or µmoles of [^{3}H]water incorporated into DPS or fatty acids per g of tissue per h or per whole organ per 100 g body weight per h.

HMG-CoA reductase activity (Expt. 1). Rats were fed a basal, a pair-fed basal, or a high-cystine diet for 7 d. The rats were sacrificed between 2300 and 2330 h by decapitation (25).

(i) Preparation of liver microsomes. An aliquot of liver (1.5 g) was weighed and homogenized with 4 vol of cold buffer containing 0.3 M sucrose, 10 mM 2-mercaptoethanol, 10 mM sodium EDTA (pH 7.4), and 50 mM sodium fluoride (28) using Potter-Elvehjem type Teflon homogenizer. The resulting homogenate was centrifuged at 12,000 × *g* at 4°C for 15 min, and the postmitochondrial supernatant was then centrifuged at 105,000 × *g* at 4°C for 60 min to sediment microsomes. The pellets were immediately stored at −80°C for 10 d without loss of enzyme activity and resuspended in 1 mL of incubation medium. Microsomal protein was assayed according to Lowry *et al*. (29) using bovine serum albumin as the standard.

(ii) Assay of microsomal HMG-CoA reductase activity. The activity of HMG-CoA reductase was assayed according to Brown *et al.* (28). To assay the total (dephosphorylated + phosphorylated) activity of HMG-CoA reductase, the microsomes were preincubated at 37°C for 60 min. The preincubation mixture contained the following concentrations of components in a volume of 45 µL: 20 mM imidazole chloride (pH 7.4), 5 mM dithiothreitol, 1.0–1.5 mg of microsomal protein, and 10 units of alkaline phosphatase *(Escherichia coli)* to dephosphorylate all of the HMG-CoA reductase to its active form. To assay the activity of (native) HMG-CoA reductase dephosphorylated *in vivo,* alkaline phosphatase was not added.

To the preincubation mixture, 45 µL of solution containing 0.2 M potassium phosphate (pH 7.4), 20 mM NADPH, 20 mM sodium EDTA, and 10 mM dithiothreitol was added. The HMG-CoA reductase assay was then initiated with the addition of DL-[3-^{14}C]HMG-CoA (2,500 dpm/nmol) (52 mCi/mmol, 1.92 GBq/mmol)(Amersham Japan, Ltd.) to a final concentration of 470 µM (final assay vol, 100 µL). After incubation at 37°C for 30 min, 50 µL of 6 N HCl and 10 µL of [^{3}H]mevalonate as carrier were added. The mixture was left overnight at room temperature in order to lactonize the formed [^{14}C]mevalonate and the added [^{3}H]mevalonate. After centrifugation of the lactonized mixture at 10,000 × *g* for 15 min, the supernatant was spotted on a thin-layer chromatographic plate and developed with acetone/benzene (1:1). The silica gel containing the [^{14}C]- and [^{3}H]mevalonolactone was scraped and counted. The recovery was corrected for by recovered [^{3}H]mevalonolactone. HMG-CoA reductase activity was expressed as the nmoles of [^{14}C]mevalonate formed per mg of microsomal protein per min, nmoles per g of liver per min, and nmoles per liver per 100 g body wt per min.

Cholesterol 7α-hydroxylase (Expt. 3). Rats were fed a basal *ad libitum* diet, a pair-fed basal diet, or a high-cystine *(ad libitum)* diet for 7 d. Rats were sacrificed between 2300 and 2330 h by decapitation (25).

(i) Preparation of liver microsomes. Aliquots of liver (1.0 g) were weighed and then homogenized with a Potter-Elvehjem-type homogenizer with a Teflon pestle in 4 vol of ice-cold 0.154 M potassium chloride isotonic solution. The homogenate was centrifuged at 12,000 × *g* at 4°C for 15 min, and the supernatant was then centrifuged at 105,000 × *g* at 4°C for 60 min. The pellets were finally resuspended in 0.1 M potassium phosphate buffer (pH 7.4) (30,31). Microsomal protein was assayed by the method of Lowry *et al*. (29) using bovine serum albumin as the standard.

(ii) Assay of microsomal cholesterol 7α-hydroxylase. The final incubation mixture (1 mL) contained 100 mM potassium phosphate buffer (pH 7.4), 20 mM cysteamine, 4 mM magnesium chloride, 5 mM NADPH, and 1.0–1.5 mg of microsomal protein. The substrate of [7(*n*)-^{3}H]cholesterol (5 µCi, 185 KBq) (7.45 Ci/mmol, 276 GBq/mmol) (Amersham Japan Ltd.) and 300 µM cholesterol were introduced into the incubation medium in trace amounts of saturating concentrations solubilized with help of a detergent, Tween-80. The incubations were run in a shaking bath at 37°C for 30 min. The enzymatic reaction was stopped by adding 3 vol of 20% trichloroacetic acid solution. The tubes were centrifuged at 3,000 × *g* for 5 min, and aliquots of the supernatants were transferred to tubes containing chloroform and mixed to remove nonmetabolized [7(*n*)-^{3}H]cholesterol. The procedures to remove nonmetabolized substrate were performed twice. The water layer finally obtained was counted for radioactivity.

The composition of bile acids in the bile (Expt. 4). Bile samples were collected for 60 min in the morning from rats treated by nembutal after feeding either a basal *(ad libitum)* or a high-cystine *(ad libitum)* diet for 7 d.

Each bile acid was analyzed by high-performance liquid chromatography (HPLC; TRIROTAR; Jasco, Tokyo, Japan), with an immobilized 3α-hydroxysteroid dehydrogenase column (Enzymepak-HSD) (32). Bile acids (33), cholesterol (21), and phospholipids (22) in bile were estimated by enzymatic methods.

Bile acids, coprostanol, and cholesterol in feces (Expt. 5). After feeding a basal *(ad libitum),* a pair-fed basal, or a high-cystine *(ad libitum)* diet for 7 d, bile was collected for 60 min in the morning from rats treated with nembutal. Feces were collected during the final 3 d of the study. Frozen fecal samples were lyophilized and weighed.

Aliquots of blended and powdered feces were used for the extraction of bile acids (34) and neutral steroids (35). Total bile acids were enzymatically estimated using 3α-hydroxysteroid dehydrogenase (33). For the determination of neutral steroids, the unsaponifiable fraction was transformed to trimethylsilyl derivatives by using the silylating mixture containing *N,N*-dimethylformamide, hexamethyldisilazane, and trimethylchlorosilane in proportions 40:40:1. The reaction for forming the trimethylsilyl derivatives was held at room temperature for 30 min. The derivatives were analyzed by gas–liquid chromatography on a 1.5% OV-17 column coated on silicon, 60–80 mesh (Shimadzu Corporation, Kyoto, Japan), which was slightly modified by the method of Miettinen *et al.* (35) using 5α-cholestane as an internal standard.

Statistical analysis. Data were analyzed by Student's *t*-test (36).

RESULTS

Changes in lipid composition in liver and serum of rats fed either a basal, a pair-fed basal, or a high-cystine diet (Expt. 1). Food intake, body weight gain, liver weight, and lipid composition of the liver and serum of rats fed for 7 d are summarized in Table 2. Food intake and body weight gain were suppressed by the high-cystine diet. Liver weight in rats fed the high-cystine diet was significantly higher than that of rats fed the basal diet *(ad libitum)*. The contents of liver total lipids and triacylglycerol in rats fed a basal diet *(ad libitum)* were higher than those of rats fed a high-cystine diet. The contents of liver cholesterol and phospholipids were similar for rats fed a basal *(ad libitum)* or a high-cystine diet. When liver lipid composition of rats fed a pair-fed basal and a high-cystine diet were compared, the liver total lipids and triacylglycerol contents were decreased in rats fed a high-cystine diet.

Serum cholesterol and triacylglycerol of rats fed a high-cystine diet increased compared with those fed a basal *(ad libitum)* or a pair-fed basal diet. The concentration of serum phospholipids in rats fed a basal diet *(ad libitum)* was significantly different from those on a pair-fed basal and high-cystine diets, the latter two of which values were similar.

Food intake and body weight gain of rats fed a high-cystine diet were lower than those of rats fed the basal diet *(ad libitum)*. Pair-fed rats were fed the same amount of food as that eaten by rats fed the cystine-excess diet, and the change in body weight of pair-fed rats was similar to those of rats fed the high-cystine diet.

In vivo *incorporation of [^{3}H]water into sterols (Expt. 2).* The effects of dietary excess cystine on the *in vivo* incorpora-

tion of [^{3}H]water into DPS and fatty acids in the liver and intestine are summarized in Table 3. The *in vivo* incorporation of tritium from [^{3}H]water into liver DPS in rats fed a cystine-excess diet was significantly greater than that of rats fed either basal diet (*ad libitum* or pair-fed). The incorporation of tritium into DPS of small intestine in rats fed a high-cystine diet was not affected as compared with those in rats fed the basal diet *(ad libitum)*. When expressed as gram tissue per hour, the incorporation of tritium into DPS in small intestine of rats fed a cystine-excess diet was increased as compared with that of a pair-fed basal group. The tritium incorporation into DPS in the liver and small intestine by pair-feeding of the basal diet was reduced when compared with those of the basal diet. Whereas the incorporation into liver fatty acids in rats fed the high-cystine diet did not alter as compared with that of a basal diet *(ad libitum),* excess dietary cystine decreased the tritium incorporation into fatty acids of the small intestine as compared with those of the basal diet *(ad libitum)*.

Liver HMG-CoA reductase activity (Expt. 1). The activities of hepatic HMG-CoA reductase in rats fed a basal, a pair-fed basal, or a high-cystine diet are summarized in Table 4. Dephosphorylated and native liver HMG-CoA reductase activities in rats fed the cystine-excess diet were both higher than those in rats fed either amount of the basal diet (*ad libitum* or pair-fed). Dephosphorylated and native HMG-CoA reductase activities in the liver were decreased by pair-feeding as compared with the basal diet *(ad libitum)*.

Liver cholesterol 7α-hydroxylase (Expt. 3). Hepatic cholesterol 7α-hydroxylase activities of rats fed the high-cystine diet *(ad libitum)* were essentially similar to those of animals fed the basal diet *(ad libitum)*. The activities of this enzyme in livers of rats fed a basal *(ad libitum)* or a high-cystine diet were significantly ($P < 0.05$) higher than those of rats fed a pair-fed basal diet only when expressed as nmoles per liver per 100 grams body weight per hour (Table 5).

Composition of bile acids in bile (Expt. 4). Of bile acids analyzed, tauroursodeoxycholic acid, glycochenodeoxycholic acid, and taurochenodeoxycholic acid were increased by 59, 102, and 58%, respectively, when fed a high-cystine diet. Ursodeoxycholic acid was markedly decreased. Bile acid derivatives of cholic acid other than those described above were not affected by the diet. Total bile acid content was similar between two groups (Table 6).

Bile acids, cholesterol, and phospholipids in bile (Expt. 5). Bile flow rate and the content of bile acids and cholesterol in bile were similar between animals fed a basal *(ad libitum)* and a high-cystine diet, but the content of phospholipids in bile was increased by feeding the high-cystine diet. The content of phospholipids in bile of rats fed a high-cystine diet was higher than that of a pair-fed basal diet, but the contents of bile acids and cholesterol were similar between animals fed a pair-fed basal or a high-cystine diet (Table 7).

Bile acids, coprostanol, and cholesterol in feces (Expt. 5). Weight of feces from rats fed a high-cystine diet was decreased as compared with that of those eating a basal diet *(ad libitum)*. Fecal weight was lower still for rats fed a pair-fed basal diet. Excess dietary cystine did not alter the content of bile acids, coprostanol, or cholesterol in feces. Total amounts of bile acids and neutral steroids in the feces were similar

among the three dietary groups. Pair-fed rats excreted a lower amount of bile acids as compared with rats fed a basal diet *(ad libitum)* (Table 8).

DISCUSSION

Feeding of a high-cystine diet caused growth retardation, hepatomegaly, and hypercholesterolemia, consistent with previous reports (3–10). The large amount of cystine added to the diet may exert pharmacological and/or toxic effects, and may not occur in humans under normal conditions.

Dietschy and McGarry (13) and Stange and Dietschy (15) demonstrated that substrate labeling with ^{14}C such as acetate or octanoate can be used for the estimation of sterol synthesis (DPS). Using [^{14}C]substrate, the ability of the substrate to penetrate cell membrane and intracellular dilution may also have profound effects (14), suggesting that such methods using [^{14}C]substrates may underestimate or overestimate the true rate of cholesterol synthesis. Therefore, the use of [^{3}H]water seems to be a satisfactory way to assay the rates of cholesterogenesis. The results concerning hepatic cholesterol synthesis *in vivo* using either [^{3}H]water (Table 3) or [^{14}C]substrates (5) were essentially the same. Our overall results for hepatic cholesterogenesis *in vivo* (Table 3) and those of Serougne *et al*. (5) may parallel the activities of hepatic HMG-CoA reductase (both dephosphorylated and native, Table 4) and (native) (19). Indeed, the activities of hepatic HMG-CoA reductase were higher in rats fed the high-cystine diet than those eating the basal diet (Table 4).

Food intake of rats fed the cystine-excess diet was lower than that of rats fed the basal diet (Table 2). To exclude a confounding influence of reduced food intake by excess cystine on our results, the HMG-CoA reductase activity was also examined in a pair-fed basal group receiving the same reduced ration. Food intake of pair-fed rats was restricted to *ca.* 50% of that eaten by rats consuming the basal diet *ad libitum* (Table 2). Hepatic HMG-CoA reductase activities of rats fed the pair-fed basal diet were decreased as compared with those in rats fed the basal diet *(ad libitum)* (Table 4), suggesting that lower food intake in rats fed the high-cystine diet had the significant effect on the activities of this enzyme. Thus, the increased activity of this enzyme in livers of rats fed the high-cystine diet was not due to reduced food intake.

It is well-known that HMG-CoA reductase activity is modulated by both short- and long-term mechanisms (37–40). Short-term changes in enzyme activity depend on the modulation of this enzyme by phosphorylation and dephosphorylation (37,38), while long-term changes in activity of this enzyme may depend on the changes in the rate of protein synthesis and/or degradation. The total activity (native dephosphorylated + phosphorylated form) of HMG-CoA reductase is considered to reflect the total protein level of HMG-CoA reductase itself in the liver (40). In the present study, total HMG-CoA reductase activity in rats fed the high-cystine diet was significantly higher than that in rats fed the basal diet, suggesting that the content of HMG-CoA reductase protein may be higher in rats fed the high-cystine diet as compared

TABLE 7
Composition of Bile Acids, Cholesterol, and Phospholipids in Bile

[a]Data represent means ± SEM for seven rats. Experiment 5. [a]Significantly different from a basal group *(ad libitum)* ($P < 0.05$). [b]Significantly different from a basal group (pair-fed) ($P < 0.05$).

with rats fed the basal diet (Table 4). Furthermore, the percentage of dephosphorylated form to total activity was constant (*ca.* 20%) whether excess cystine was fed or not (Table 4). HMG-CoA reductase has a short half-life of about 2 h (41), so its level can easily be changed by dietary conditions (40) or during its circadian rhythm (42). Although the cholesterol level was high in serum from rats fed the high-cystine diet, circulating cholesterol may not exert regulatory effects on hepatic HMG-CoA reductase under these circumstances.

The activities of hepatic cholesterol 7α-hydroxylase, the regulatory enzyme for the bile acid synthesis, were unchanged between a basal *(ad libitum)* and a high-cystine *(ad libitum)* diet (Table 5). Thus, from both the enhanced activities of hepatic HMG-CoA reductase and the lack of change in hepatic cholesterol 7α-hydroxylase activities, a possible mechanism by which excess dietary cystine produces an increase in circulating cholesterol may be the stimulation of cholesterol synthesis. Excess dietary cystine caused the stimulation of cholesterogenesis in the liver, but did not stimulate cholesterol synthesis in the small intestine (Table 3). Thus, cholesterol synthesized in the small intestine of rats fed a high-cystine diet may not contribute to an increase in circulating cholesterol.

As shown in Table 8, excess dietary cystine had no effects on bile acids, coprostanol, and cholesterol in feces. These results are supported by the facts that cholesterol 7α-hydroxylase activities in the liver were similar between rats fed the basal *(ad libitum)* and the high-cystine *(ad libitum)* diet (Table 5), and that the content of total bile acids in bile was not affected, although proportions of some bile acids were changed by excess dietary cystine (Table 6).

Although the amount of total bile acids in bile was not affected by excess dietary cystine (Table 6), ursodeoxycholic acid was markedly reduced. Ursodeoxycholic acid is one of the tertiary bile acids. Chenodeoxycholic acid is altered by enzymes of intestinal bacteria to form ursodeoxycholic acid (43). Thus, possibly excess dietary cystine altered the intestinal bacteria as compared with the basal diet, resulting in the decreased formation of ursodeoxycholic acid. The increased content in tauroursodeoxycholic acid, glycochenodeoxycholic acid, and taurochenodeoxycholic acid in the bile of rats fed the cystine-excess diet might be due to their increased synthesis from precursors or the decreased degradation of these bile acids.

The reason why serum triacylglycerol concentration was increased by feeding a cystine-excess diet (Table 2) remains obscure. It may be due to either the increased transport of triacylglycerol-rich particles from liver into the circulation or the decreased removal into extrahepatic tissues. Further work will be needed to elucidate the efforts of high dietary cystine on triacylglycerol metabolism.

Regulation of HepG2 Cell Apolipoprotein B Metabolism by the Citrus Flavanones Hesperetin and Naringenin

Nica M. Borradaile, Kenneth K. Carroll, and Elzbieta M. Kurowska*

Department of Biochemistry, The University of Western Ontario, London, Ontario, N6A 5C1 Canada

ABSTRACT: Our previous studies showed that replacing the drinking water of rabbits fed a casein-containing diet with either orange juice or grapefruit juice reduced serum low density lipoprotein cholesterol and hepatic cholesteryl ester concentrations. To determine whether the changes observed in rabbits were due to flavonoids present in the juices acting directly on the liver, the effects of hesperetin and naringenin on net apolipoprotein B (apoB) secretion by HepG2 cells were investigated. These flavanones dose-dependently reduced net apoB secretion by up to 81% after a 24 h incubation, while doses of 60 µg/mL reduced net apoB secretion by 50% after 4 h. Coincubation with the proteasome inhibitor, MG-132, did not alter the ability of the flavonoids to reduce net apoB secretion over 4 h, suggesting that the flavonoid-induced changes in apoB metabolism were not due to a direct increase in proteasomal activity. However, the flavonoids were unable to reduce net apoB secretion after 4 h in the presence of oleate, suggesting that these compounds may interfere with the availability of neutral lipids for lipoprotein assembly. Furthermore, our ^{14}C-acetate-labeling studies showed a 50% reduction in cholesteryl ester synthesis in the presence of either flavonoid, which could account for the reduction in net apoB secretion caused by incubation with these compounds. These *in vitro* studies suggest that hesperetin and naringenin may, in part, reduce net apoB secretion by HepG2 cells by inhibiting cholesteryl ester synthesis and that these compounds are good candidates for further *in vivo* studies to determine whether they are responsible for the cholesterol-lowering properties of dietary citrus juices.

Paper no. L8101 in *Lipids 34,* 591–598 (June 1999).

The concentration of low density lipoprotein (LDL) in the bloodstream is controlled partly by expression of LDL receptors in the liver (1). However, it has been known for some time that, in many patients, overproduction of LDL and very low density lipoprotein (VLDL) may cause the hyperlipidemias responsible for increased risk of coronary heart disease (2). Consequently, a surge of recent research focused on investigation of the regulatory mechanisms involved in the secretion of apolipoprotein B (apoB)-containing lipoproteins by the liver.

The assembly and secretion of apoB-containing lipoproteins from hepatocytes make up a complex and highly regulated process. As originally proposed by Alexander *et al.* (3), lipoprotein assembly is generally divided into two stages. During the first step, apoB is translated on the cytoplasmic surface of the rough endoplasmic reticulum (ER) and is either fully or partially translocated through the endoplasmic reticulum membrane. During this time, the nascent polypeptide is susceptible to rapid degradation by either the cytosolic proteasome or by ER lumenal proteases (reviewed in Ref. 4). Subsequently, newly formed apoB either is degraded or enters a secretion pathway, depending on the availability of cellular lipids (5). The addition of a small amount of lipid to apoB, catalyzed by microsomal triglyceride transfer protein (MTP) (reviewed in Ref. 6), leads to the formation of small, dense primordial lipoprotein particles and signifies the completion of the first step.

The addition of bulk quantities of triglycerides, cholesterol esters, and phospholipids to apoB is considered the second step of lipoprotein formation (3,7). Numerous studies showed that triglyceride availability is the major factor controlling posttranslational regulation of apoB secretion from hepatocytes (8–13). However, several reports also suggested a critical role for cholesteryl esters (14–17). Phospholipid synthesis is also required for normal apoB secretion (18,19), and perturbations of the normal phospholipid composition of the ER membrane reduce apoB secretion (20,21).

HepG2 human hepatoma cells, a commonly used model of human hepatocytes, have a defect in the second step of lipoprotein assembly which prevents the addition of substantial quantities of triglyceride to the primordial particle (10). As a consequence, these cells secrete small triglyceride- and apoB-containing particles with a density similar to that of LDL (22,23). However, as explained by Graham *et al.* (24), changes in triglyceride secretion in response to endogenous compounds suggest that these cells are an appropriate model for measuring qualitative changes in lipoprotein secretion. We therefore used the HepG2 cell line to investigate the ability of the citrus flavanones, hesperetin (from oranges) and naringenin (from grapefruit), to alter hepatic lipoprotein metabolism.

Naringenin

SCHEME 1

Our recent studies demonstrated that dietary orange juice and grapefruit juice reduced serum LDL and hepatic cholesteryl ester concentrations in a rabbit model of endogenous hypercholesterolemia (25). We hypothesized that these effects could be due to the flavanone glycosides, hesperidin and naringin, which are present in significant quantities in orange juice and grapefruit juice, respectively. It has been postulated that these compounds are deglycosylated by bacteria in the gastrointestinal tract to hesperetin and naringenin (Scheme 1) prior to absorption (26,27). Thus, these aglycone flavonoids could act directly in the liver. In support of this hypothesis, previous studies showed that dietary hesperidin reduces serum cholesterol (28–30) and triglycerides (28), as well as hepatic free and esterified cholesterol concentrations (30) in rats. In the present studies, we investigated the ability of hesperetin and naringenin to reduce net apoB secretion by HepG2 cells. Further experiments were conducted to determine whether the observed effects were likely to be the result of increased proteasomal degradation or altered lipid availability during the first step of lipoprotein assembly.

MATERIALS AND METHODS

Cell culture. Minimum essential medium (MEM), fetal bovine serum (FBS), disposable Nunclon culture flasks, Falcon culture plates, and other tissue culture supplies were obtained from Life Technologies Inc. (Burlington, Ontario, Canada). Fatty acid-free bovine serum albumin (BSA) fraction V was obtained from Sigma (St. Louis, MO). HepG2 cells (American Type Culture Collection, Rockville, MD) were grown and maintained in MEM containing 10% FBS and 100 IU penicillin/streptomycin/amphotericin at 37°C in a humidified atmosphere of 95% air and 5% CO_2. Flasks were subcultured at a 1:4 ratio every 7 d, using 0.25% trypsin in Ca^{2+}- and Mg^{2+}-free phosphate-buffered saline for 10 min at 37°C. For experiments, cells were seeded in 6- or 24-well plates (6×10^5 cells/plate) and used at confluence (usually about 7 d after plating). Cell medium was changed every 2 to 3 d. Before each experiment, cells were preincubated for 24 h with MEM containing 1% BSA instead of FBS.

Hesperetin and naringenin obtained from Sigma were solubilized in dimethyl sulfoxide (DMSO) so that the final concentration of solvent in the media was not greater than 0.1% by vol.

ApoB determination. For the dose-response, time-course, reversibility, proteasome inhibitor, and oleic acid studies described below, apoB concentrations in the cell culture media following experimental incubations were determined by a competitive enzyme-linked immunosorbent assay (ELISA) developed by Young *et al.* (31) and modified by Ortho Diagnostics (La Jolla, CA). The coefficient of variance for this assay was *ca.* 3%. Human LDL for preparing standard curves and for coating microtiter plates was isolated from fresh human EDTA-plasma, by sequential density gradient ultracentrifugation (32). Soluble cellular protein was extracted with 0.1 N sodium hydroxide, measured using the Coomassie Plus Protein Assay (Pierce, Rockford, IL), and apoB content was calculated per mg of total cellular protein before conversion to percentage of control.

Dose-response and time-course studies. In order to determine whether hesperetin and naringenin could dose-dependently reduce net apoB secretion, HepG2 cells were grown to confluence in 24-well plates and incubated for 24 h in the absence or presence of 7.5–60 μg/mL of either hesperetin or naringenin. These flavonoid concentrations were determined to be noncytotoxic by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) viability assay (33). The time course of the flavonoid effects on net apoB secretion was determined by incubation of confluent HepG2 cells in the absence or presence of effective apoB-reducing concentrations (60 μg/mL) of either hesperetin or naringenin for 2–48 h. At the end of each incubation, culture media were collected and assayed for apoB content as described above.

Radiolabeling of intracellular and secreted proteins. To determine whether the flavonoids affect cellular protein synthesis and secretion, confluent HepG2 cells were washed with Hank's balanced salt solution and then incubated with or without 60 μg/L hesperetin or naringenin in the presence of 4,5-^{3}H-leucine (5 dpm/pmol) (ICN Pharmaceuticals, Irvine, CA) for 0–240 min. The media and cells were collected at the indicated time points, and aliquots were applied to 20-mm cellulose acetate filters. Proteins were precipitated with 10% trichloroacetic acid (TCA) for 30 min and then washed in 5% TCA as described by Everson *et al.* (34). Filters were dried,

and the precipitate was solubilized in 0.1 N NaOH and Scintigest (Fisher Scientific, Fairlawn, NJ). Incorporation of radioactivity into intracellular and secreted proteins was expressed as dpm ^{3}H-leucine incorporated/mg cell protein.

Reversibility studies. To investigate the ability of HepG2 cells to recover from flavonoid-induced reduction of net apoB secretion, cells were incubated for 24 h in the absence or presence of 60 µg/mL of either hesperetin or naringenin. Flavonoid-containing media were then removed and replaced with flavonoid-free medium for further 10 and 24 h incubations (postincubations). Aliquots of media collected after the initial 24 h incubation, as well as those collected after the postincubations, were assayed for apoB content as described above.

Proteasome inhibitor and oleic acid studies. To determine whether the flavonoids reduce net apoB secretion by increasing proteasomal degradation of the nascent protein, a highly selective inhibitor of the 26S proteasome, MG-132 (carbobenzoxy-L-leucyl-L-leucyl-L-leucinal; Calbiochem-Novabiochem, LaJolla, CA), was used to prevent apoB degradation prior to secretion. MG-132 was solubilized in DMSO and diluted in MEM containing 1% BSA to a concentration of 10 µM, a concentration previously shown to inhibit the 26S proteasome in HepG2 cells effectively (35). As with the flavonoids, the final concentration of DMSO in the media was less than 0.1% by vol. Confluent cells were then preincubated for 1 h in the absence or presence of 10 µM MG-132, followed by a 4 h incubation with 60 µg/mL of either hesperetin or naringenin, in the absence or presence of 10 µM MG-132.

A similar protocol was used to determine the effect of increased lipid synthesis on flavonoid-induced reduction of net apoB secretion. Experimental medium was enriched with oleate by dissolving 0.8 mM sodium oleate (Sigma) in MEM containing 1% of fatty acid free BSA (Sigma), according to the method described by Dixon *et al.* (36). HepG2 cells were then preincubated for 1 h in the absence or presence of oleate-enriched medium, followed by a 4 h incubation in the absence or presence of 60 µg/mL of either hesperetin or naringenin, with or without 0.8 mM sodium oleate.

For both of these experiments, apoB content in the media was subsequently determined by ELISA, as described above.

Intracellular cholesterol and triglyceride metabolism. To determine whether exposure to flavonoids altered the metabolism of cholesterol and/or triglycerides, HepG2 cells grown to confluence in 6-well plates were incubated for 24 h in MEM plus 1% BSA or 5% lipoprotein-deficient serum with 60 µg/mL of either hesperetin or naringenin. During the final 5 h of incubation, 1-^{14}C-acetate (0.5 µCi/mL medium) (Amersham, Oakville, Ontario, Canada) was added to each well. Cells were washed three times with ice-cold phosphate-buffered saline, and radiolabeled lipids were subsequently extracted, using heptane/isopropyl alcohol (3:2, vol/vol). A small amount of ^{3}H-cholesterol (Amersham) was added to each extract as an internal standard. Free cholesterol, cholesterol esters, and triglycerides were then separated by thin-layer chromatography, using a hexane/ethyl ether/acetic acid (75:25:1, by vol) solvent system (37). Portions of silica-containing lipid fractions were then placed into scintillation vials. Radioactivity was measured with a Rackbeta 1214 scintillation counter and calculated as dpm/mg cellular protein before conversion to percentage of control.

Statistical analysis. All results were evaluated by one-way analysis of variance. Differences between groups were determined using Bonferroni and Tukey *t*-tests, where appropriate (SigmaStat; Jandel Corporation, San Rafael, CA). Significant differences were reported at $P < 0.05$.

RESULTS

Incubation of HepG2 cells with increasing, nontoxic concentrations (as determined by an MTT cell viability assay, data not shown) of either hesperetin or naringenin caused a dose-dependent reduction of net apoB secretion relative to cellular protein content (Fig. 1). The highest nontoxic dose of either hesperetin or naringenin (60 µg/mL) significantly lowered medium apoB by 76 and 81%, respectively, and naringenin, at a dose of 30 µg/mL, significantly reduced apoB content by 29%. The effect induced by incubation with 60 µg/mL of either flavonoid was rapid in onset. Net apoB secretion was reduced to *ca.* 50% of control values after a 4 h exposure to either hesperetin or naringenin (Fig. 2). As was expected, the reduction in net secretion became more pronounced with longer incubation times. DMSO at a concentration of 0.1% by vol, the highest concentration present in the media, had no effect on net apoB secretion.

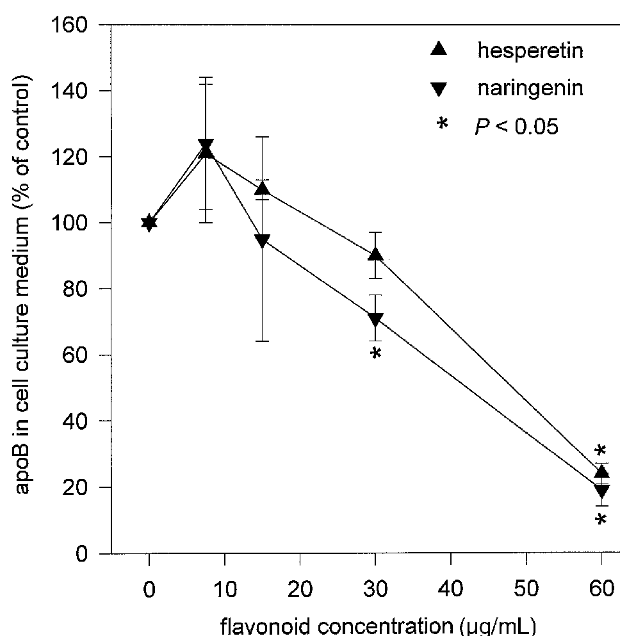

FIG. 1. Dose-response of flavonoid effects on apolipoprotein B (apoB) accumulation in the media of HepG2 cell cultures. Confluent HepG2 cells were incubated for 24 h in the presence of 0–60 µg/mL of either hesperetin or naringenin. ApoB in the cell culture media was quantified by enzyme-linked immunosorbent assay (ELISA) and expressed per mg cell protein before conversion to percentage of control. Values are means ± SEM, $n = 3$.

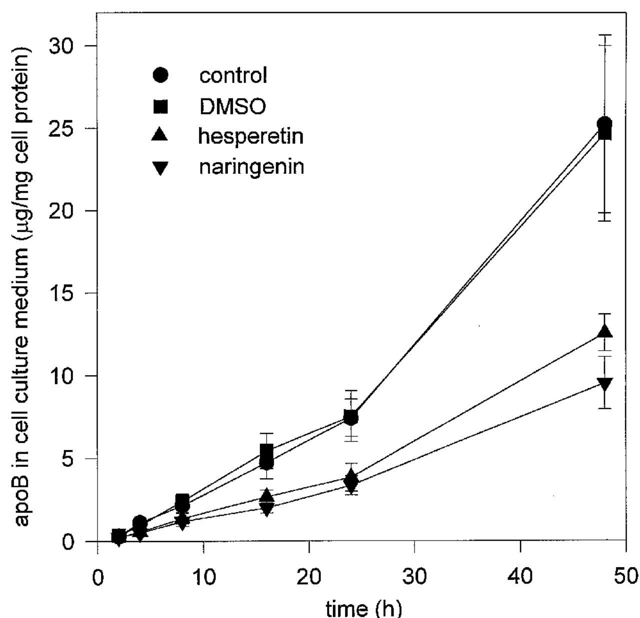

FIG. 2. Time-course of flavonoid effects on accumulation of apoB in the media of HepG2 cell cultures. Confluent HepG2 cells were incubated for 2–48 h in the absence or presence of 60 µg/mL of either hesperetin or naringenin. ApoB in the cell culture media was quantified by ELISA and expressed per mg cell protein. Values are means ± SEM, n = 4. All values for flavonoid treatments from 4–48 h were significantly lower than control values ($P < 0.05$). DMSO, dimethylsulfoxide; see Figure 1 for other abbreviations.

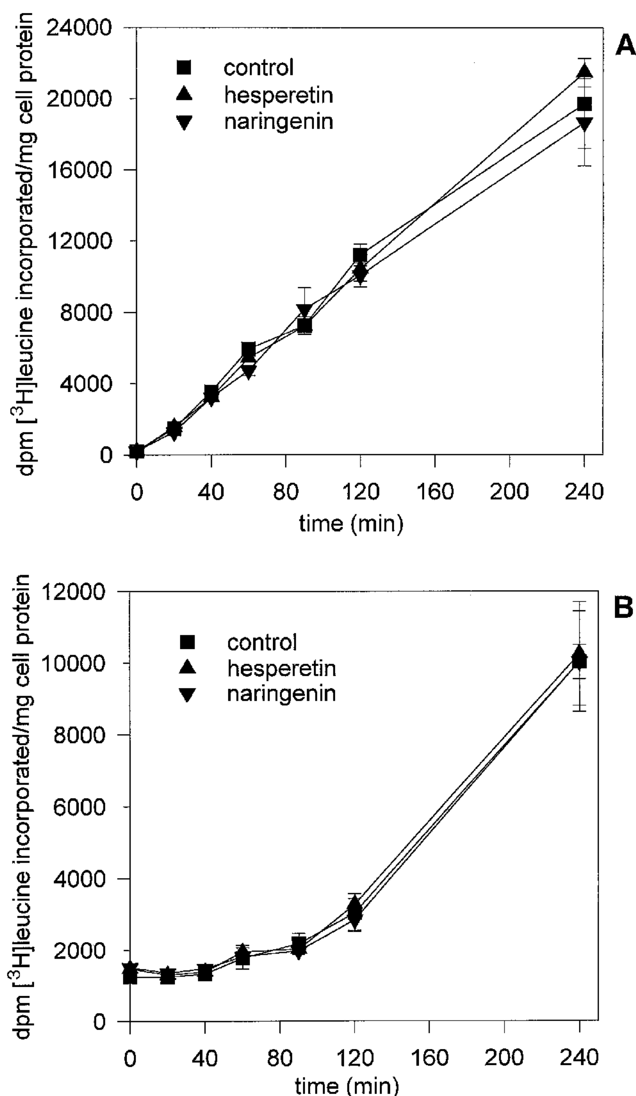

FIG. 3. Effects of hesperetin or naringenin on incorporation of ^{3}H-leucine into (A) nonsecreted and (B) secreted proteins. HepG2 cells were incubated for 0–240 min in serum-free medium with 1% bovine serum albumin in the absence or presence of 60 µg/mL of either hesperetin or naringenin. Radiolabeled intracellular and media proteins were precipitated with trichloroacetic acid and counted. Results of a representative experiment are expressed as mean dpm of ^{3}H-leucine incorporated per mg of cell protein ± SEM.

Exposure of HepG2 cells to either flavonoid at concentrations that substantially reduced net apoB secretion (60 µg/mL) did not affect incorporation of ^{3}H-leucine into cellular (Fig. 3A) and secreted (Fig. 3B) TCA-precipitable proteins over a 4 h period.

HepG2 cells were able to partially recover from the reduction in net apoB secretion induced by 24 h incubation with 60 µg/mL of either hesperetin or naringenin. After both 10 and 24 h postincubations in flavonoid-free medium, net apoB secretion returned to within 60–70% of control values (Fig. 4).

Incubation of HepG2 cells with the proteasome inhibitor, MG-132, had no effect on the reduction of net apoB secretion induced by incubation with 60 µg/mL of either hesperetin or naringenin (Fig. 5). Incubation with MG-132 for 4 h in the absence of either flavonoid nearly doubled net apoB secretion. However, after 4 h exposure to either flavonoid, net apoB secretion was reduced by *ca.* 50%, as compared to the untreated control, regardless of the presence of inhibitor.

Incubation with oleate-enriched medium, on the other hand, prevented the reduction of net apoB secretion induced by a 4 h incubation with 60 µg/mL of either hesperetin or naringenin (Fig. 6). Regardless of the presence of either flavonoid, oleate increased net apoB secretion by *ca.* 50%, as compared to the untreated control.

Incubation of HepG2 cells with 60 µg/mL of either hesperetin or naringenin decreased the incorporation of ^{14}C-acetate per mg protein into cholesteryl esters by *ca.* 50% (Table 1). Label incorporation into free cholesterol was slightly reduced in the presence of the flavonoids; however, this change was not statistically significant. Label incorporation into triglycerides was unaffected. DMSO at a concentration of 0.1% by vol had no effect on radiolabel incorporation and recovery for each sample was between 70 and 100%.

DISCUSSION

The results of these studies showed that both hesperetin and naringenin significantly reduced net apo B secretion by HepG2 cells in a dose-dependent manner (Fig. 1), without affecting the incorporation of ^{3}H-leucine into TCA-precipitable

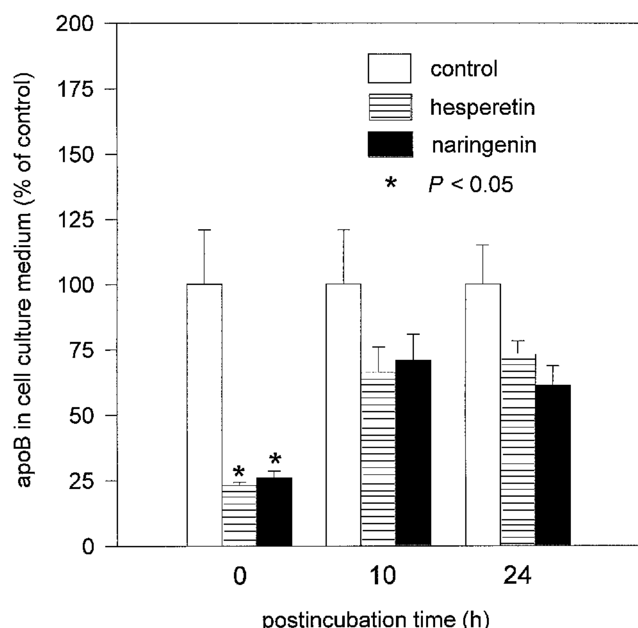

FIG. 4. Reversibility of flavonoid effects on net apoB secretion. Confluent HepG2 cells were incubated for 24 h in the absence or presence of 60 µg/mL of flavonoid. Medium was removed and assayed for apoB content (ELISA). The cells were then incubated for a further 10 or 24 h in flavonoid-free conditions; medium apoB content was again quantified and calculated per mg cell protein before conversion to percentage of control. Values are means ± SEM, $n = 3$. See Figure 1 for abbreviations.

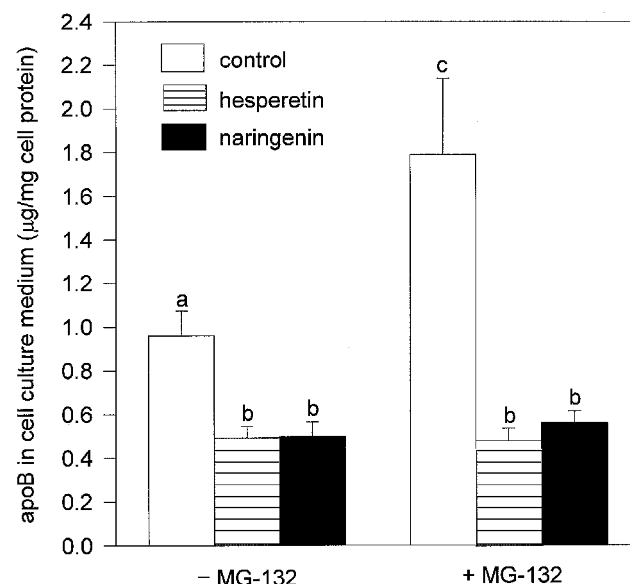

FIG. 5. Effects of citrus flavonoids on net apoB secretion in the presence of MG-132. Confluent HepG2 cells were preincubated for 1 h in the absence or presence of 10 µM MG-132, and incubated for a further 4 h in the absence or presence of flavonoid, with or without MG-132. Medium apoB was then quantified (ELISA) and expressed per mg cell protein. Values are means ± SEM, $n = 5$. a, b and c are significantly different from each other at $P < 0.05$. MG-132, carbobenzoxy-L-leucyl-L-leucyl-L-leucinal; see Figure 1 for other abbreviations.

cellular and secreted proteins (Fig. 3). This suggests that the flavonoids selectively inhibit net apoB secretion.

The flavonoid effect is relatively rapid in onset (Fig. 2). However, the 50% reduction in net apoB secretion after 4 h exposure to either hesperetin or naringenin does not exclude the possibility that these compounds could directly suppress the transcription and/or translation of apoB. Nevertheless, this mechanism of action is unlikely since most reports indicate that rapid changes in apoB secretion in both cultured hepatocyte and animal models are controlled posttranslationally (38–42).

As shown in Figure 4, the majority of the flavonoid effect on net apoB secretion is reversible after 10 and 24 h postincubations with flavonoid-free media. The inability of the cells to recover completely from exposure to the flavonoids could be due to cytotoxicity caused by either the parent compounds or their metabolites. However, MTT cell viability assays indicated no significant toxicity after 24 h incubations with 60 µg/mL of either flavonoid. A more likely explanation for the incomplete reversal may be that the flavonoids and/or their metabolites induce multiple biochemical changes which affect

TABLE 1
Percentage of Incorporation of ^{14}C-Acetate into Cellular Lipids of HepG2 Cells in the Presence of Citrus Flavonoids[a]

Treatment	Free cholesterol	Cholesteryl esters	Triglycerides
Control	100 ± 6	100 ± 6[a]	100 ± 6
Hesperetin	62 ± 14	48 ± 4[b]	118 ± 19
Naringenin	78 ± 7	53 ± 10[b]	109 ± 22

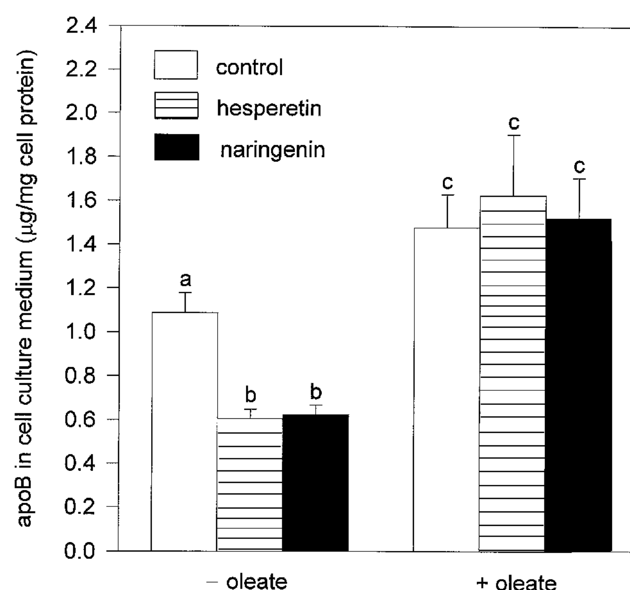

FIG. 6. Effects of citrus flavonoids on net apoB secretion in the presence of exogenous oleate. Confluent HepG2 cells were preincubated for 1 h in the absence or presence of 0.8 mM sodium oleate and incubated for a further 4 h in the absence or presence of flavonoid, with or without oleate-enriched media. Medium apoB was then quantified (ELISA) and expressed per mg cell protein. Values are means ± SEM, $n = 4$. a, b and c are significantly different from each other at $P < 0.05$. See Figure 1 for abbreviations.

lipoprotein secretion, some of which are irreversible. Further studies are needed to determine the nature of these changes.

Many studies showed that altered rates of degradation of newly synthesized apoB can produce rapid changes in net apoB secretion by hepatocytes (reviewed in Ref. 4). Wu *et al.* (43) proposed a two-site model for the degradation of apoB in HepG2 cells. According to this model, newly synthesized apoB associated with the ER membrane is degraded by cytosolic proteasomes (26S multicatalytic protease complex) at the first site, while fully translocated apoB is degraded by a second proteolytic pathway in the lumen of the ER. This second site may be responsible for the degradation of primordial apoB-containing particles which are inadequately lipidated during the second step of lipoprotein assembly. In order to determine whether a direct increase in proteasomal degradation could be responsible for the observed reduction in net apoB secretion in the presence of the flavonoids, we used a highly selective proteasome inhibitor, MG-132, to protect apoB from degradation at the first site. Our results showed increased net apoB secretion in the presence of MG-132 alone (Fig. 5). This is in agreement with data obtained by Sakata *et al*. (5) which showed increased net apo B secretion in the presence of *N*-acetyl-leucyl-leucyl-norleucinal which, however, is a less selective inhibitor of the 26S proteasome than MG-132 and has protease inhibitory activity which may account for part of the observed increase in net apoB secretion. More recent studies in HepG2 cells, using *N*-carbobenzoxy-leucyl-leucyl-norvalinal and lactacystin, showed that selective inhibition of the proteasome results in intracellular accumulation of ubiquitinated apoB, the substrate for proteasomal degradation (44), and that this accumulated apoB can be assembled into lipoproteins and secreted if sufficient lipid is available (35). Our results suggest that inhibition of the proteasome with MG-132 may allow the accumulation of secretion-competent apoB within HepG2 cells. In the case of the flavonoids, our results showed that inhibition of the proteasome by incubation with MG-132 had no effect on the ability of either hesperetin or naringenin to reduce net apoB secretion (Fig. 5). This suggests the flavonoids do not act by directly increasing the activity of the proteasome in degrading apoB during the earliest stages of lipoprotein assembly.

Since subsequent events in the process of lipoprotein assembly involve the addition of lipids to newly translated apoB, we studied the effect of exogenous oleate on the ability of hesperetin and naringenin to reduce net apoB secretion. Oleate added to the media of HepG2 cells rapidly increases net apoB secretion (8,9,11,13,36,39). This is thought to be due to increased triglyceride synthesis (9,11,13,39), but may also involve changes in cholesteryl ester synthesis (14,15). Our results showed that, in cells pre- and co-incubated with medium containing sodium oleate, the flavonoids were unable to reduce net apoB secretion (Fig. 6). This experiment suggests that the flavonoids did not limit lipid availability by directly inhibiting MTP, since recent studies showed that addition of exogenous oleic acid cannot overcome the reduced apoB secretion observed in MTP-inhibited cells (45). However, it should be noted that our experiments involved incubation with oleic acid prior to the addition of flavonoids. Therefore, further experiments are required to more directly assess flavonoid effects on MTP activity. The flavonoids could also act by inhibiting the synthesis of one or more cellular lipids. In support of this hypothesis, our experiments using ^{14}C-acetate to label cellular lipids showed a 50% decrease in cholesteryl ester synthesis in the presence of either hesperetin or naringenin (Table 1), which could account for the decrease in net apoB secretion caused by these compounds. These results are supported by recent studies by our collaborators which showed that naringenin substantially reduced apoB secretion and cholesterol esterification in HepG2 cells, as well as *in vitro* acyl-CoA acyltransferase (ACAT) activity (46). The slight reduction in label incorporation into free cholesterol in the presence of the flavonoids (Table 1), although not statistically significant, may also contribute to the observed reduction in apoB secretion. However, studies on the effects of specific ACAT inhibitors on apoB secretion also showed reduced incorporation of ^{14}C-acetate into cholesterol by HepG2 cells (16,17). Although phospholipid synthesis was not measured in the present studies, Wilcox *et al*. (46, abstract) showed no change in the synthesis of phospholipids in the presence of 200 μM naringenin after a 24 h incubation.

In summary, the studies presented in this report demonstrate that the citrus flavanones, hesperetin and naringenin, rapidly and selectively reduce net apoB secretion by HepG2 cells. This partially reversible effect may be, in part, the result of reduced cholesteryl ester synthesis, which suggests that these compounds may inhibit ACAT. However, since there have been reports of increased (13), decreased (14), and unchanged (8,11,12) secretion of apoB in response to direct ACAT inhibition, it is likely that hesperetin and naringenin have additional actions in HepG2 cells which contribute to and, perhaps, drive the effect on apoB secretion. Whether ACAT inhibition is a property of a number of classes of flavonoids remains to be determined. However, Yotsumoto *et al.* (47) reported that a Japanese–Chinese traditional herbal mixture containing the flavone, baicalein, significantly reduced the incorporation of ^{14}C-oleate into the cellular cholesteryl ester fraction of HepG2 cells over 6 and 24 h incubations. Furthermore, this report showed that baicalein, which is structurally similar to the flavonones, hesperetin and naringenin, dose-dependently reduced ACAT activity *in vitro*.

Since recent studies showed that hesperetin and naringenin are absorbed after consumption of orange juice and grapefruit juice, respectively (27), the ability of these compounds to reduce apoB secretion and cholesteryl ester synthesis could be responsible for the reductions in serum LDL and hepatic cholesteryl esters observed in endogenously hypercholesterolemic rabbits given either citrus juice (25). However, further studies are required to determine (i) whether hesperetin and naringenin, when given in isolation, can lower LDL cholesterol *in vivo* and (ii) whether dietary intake of citrus juices

leads to significant concentrations of these flavonoids in hepatic-portal blood and liver tissue.

ABSTRACT: Supplementation with low doses of eicosapentaenoic (EPA) or docosahexaenoic (DHA) acid was used here to investigate changes in epithelial proliferation, differentiation, and apoptosis in normal rat colonic mucosa. ACI/T rats received by oral administration low doses of purified EPA or DHA ethyl esters (1g/kg body weight) and colonic mucosa was analyzed for cell proliferation, differentiation, and apoptosis. n-3 Polyunsaturated fatty acid incorporation into membrane phospholipids was investigated as reflections of fatty acid metabolism. Both EPA and DHA suppressed colonocyte proliferation and increased the numbers of differentiating and apoptotic cells without modification of the crypt morphology and the number of cells per crypt columns. A significant incorporation of the supplemented fatty acids into total phospholipids was observed. This enrichment was accompanied by a decreased content in arachidonic acid. The observation that EPA and DHA do not alter crypt morphology although they modify cell turnover in normal colonic mucosa suggests a possible use of these fatty acids as dietary chemopreventive agents.

Paper no. L8088 in *Lipids 34*, 599–604 (June 1999).

n-3 Polyunsaturated fatty acids (PUFA) were shown to inhibit tumor development in frequent experimental studies (1–3). We reported that dietary supplementation with n-3 PUFA normalized altered proliferative patterns in the colonic mucosa of human subjects at high risk for colon cancer (4,5). This was confirmed recently by Huang *et al.* (6), who found a decreased cell proliferation in the colonic mucosa of patients with colon carcinoma after treatment with n-3 PUFA. Moreover, we reported the inhibitory effects of oral administration of eicosapentaenoic acid (EPA, 20:5n-3) or docosahexaenoic acid (DHA, 22:6n-3), the main components of n-3 PUFA family, on the growth of a highly malignant hepatocarcinoma transplanted into rats (7). Both fatty acids exerted an antitumoral effect, with different mechanisms. EPA inhibited cell proliferation and DHA-induced apoptosis.

The findings overall suggest that n-3 PUFA supplement can be considered a candidate dietary agent for reduction of cancer risk. To determine whether the inhibition of growth by n-3 PUFA is specific for tumor cells or is a general effect in normal tissues with high degree of cell turnover, the present study investigated effects of dietary supplementation with EPA or DHA on cell proliferation, cell differentiation, and apoptosis in the normal colonic mucosa of rats. In this study n-3 PUFA were given separately as highly purified EPA or DHA to establish the specific effects of each fatty acid, and at doses comparable to the minimum used in our previous human studies (4,5).

The results showed both fatty acids have antiproliferative and proapoptotic effects on normal colonic mucosa, influencing cell differentiation without modification of the physiological homeostasis of the colonic crypts. EPA and DHA were found to be incorporated differentially in the main classes of phospholipids (PL).

MATERIALS AND METHODS

Animals and treatments. Sixty male inbred ACI/T rats (200 g) were housed in groups of two or three in wire cages. They had free access to a standard laboratory diet (Altromin-Rieper, Rieper Company, Bz, Italy) and water. The animals were divided randomly into three groups of 20. One group received in the morning, by oral administration, a single dose of 1 g/kg body weight/d of oleic acid-ethyl ester (OA, control); a second group received EPA-ethyl ester and a third DHA-ethyl ester. Preliminary experiments comparing OA-treated animals with untreated animals showed that OA treatment did not modify fatty acid composition of cells in the colonic mucosa (Table 1). No significant differences in body weight between control and treated animals were observed

[a]Values are means ± SEM of seven separate determinations. Means in a row with a different superscript are significantly different at $P < 0.05$ (one-way analysis of variance followed by Fisher's test).Values without superscripts are not significantly different. *Isomers of n-9 and n-7 series are calculated together. OA, oleic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid; PUFA, polyunsaturated fatty acid.

during the study. All fatty acid ethyl esters (provided by Hoffmann-La Roche Ltd., Basel, Switzerland) contained 3 mg of α-tocopherol per g. Purity of 92% was verified by gas–liquid chromatography.

After 10-d treatment, the animals were sacrificed and colonic specimens were removed immediately, fixed in Metha-Carnoy, and then embedded in paraffin for histochemical processing (see below). The remaining tissue was excised, flushed with Ca-Mg free Hanks' solution pH 7.4, and freed of fecal material. Colonic mucosal cells were isolated as described by Bjerknes and Cheung (8).

The animal use protocol was approved by the Ministry of Health, Veterinary Service, Rome, Italy.

Analysis of fatty acids. Lipids were extracted from suspensions of colonic mucosal cells as described by Bligh and Dyer (9). Total PL were separated from neutral lipids by thin-layer chromatography with toluene/diethyl ether/ethanol (35:3.5:1, by vol) as a solvent system (7). All major PL [phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylinositol (PI)] were separated in chloroform/methanol/acetic acid/water (50:37.5:3.5:2, by vol) (10). After transmethylation, fatty acid methyl esters were analyzed by gas–liquid chromatography as previously described (7).

Cell proliferation, differentiation, and apoptosis. One hour prior to sacrifice, 10 animals from each group received an intraperitoneal injection of 50 mg/kg bromodeoxyuridine (BrdU, Sigma Chemical Co., St. Louis, MO). BrdU incorporated into S-phase DNA was determined immunoistochemically on deparaffinized colon sections by the method of avidine-biotine peroxidase complex using the mouse anti-BrdU monoclonal antibody (4IU; Lawrence Livermore National Laboratory, Livermore, CA) (7). The colon sections from the rats not injected with BrdU were processed for differentiation and apoptosis assay. Differentiation of epithelial colonocytes was assessed histochemically by measuring the binding of *Dolichos biflorus* agglutinin (DBA) to α-*N*-acetyl-galactosamine residues (11,12). The percentage of apoptotic cells in the crypts was determined by *in situ* nick-end labeling (TUNEL) (13). For determination of BrdU-, DBA- and TUNEL-labeling index (LI%), 20 well-oriented crypt sections displaying a U-shaped configuration per colon section were evaluated.

Statistical analysis. Data are shown as means ± SEM. One-way analysis of variance was used to determine significant differences among groups. When appropriate, a Fisher's test was used (Minitab software; Minitab Inc., State College, PA)

to determine the significance of differences between pairs of means. Statistical significance was accepted at $P < 0.05$.

RESULTS

Treatment for 10 d with low doses of EPA or DHA did not change the morphology and the average number of cells per crypt section (Fig. 1). The numbers were 91.7 ± 5.5 and 93.4 ± 8.4, respectively, as compared to 92.4 ± 6.8 for the OA group. The number of cells in S-phase, measured by the BrdU labeling index (LI%), was significantly decreased in EPA and DHA groups relative to the control group (Fig. 2A). Conversely, the percentage of differentiated cells, labeled by lectin histochemistry using *D. biflorus* (DBA LI%), increased significantly in colon mucosa from both EPA- and DHA-treated rats (Fig. 2B). Similarly, the number of apoptotic cells, measured by *in situ* nick-end labeling technique (TUNEL LI%) was significantly increased by both EPA and DHA treatment (Fig. 2C).

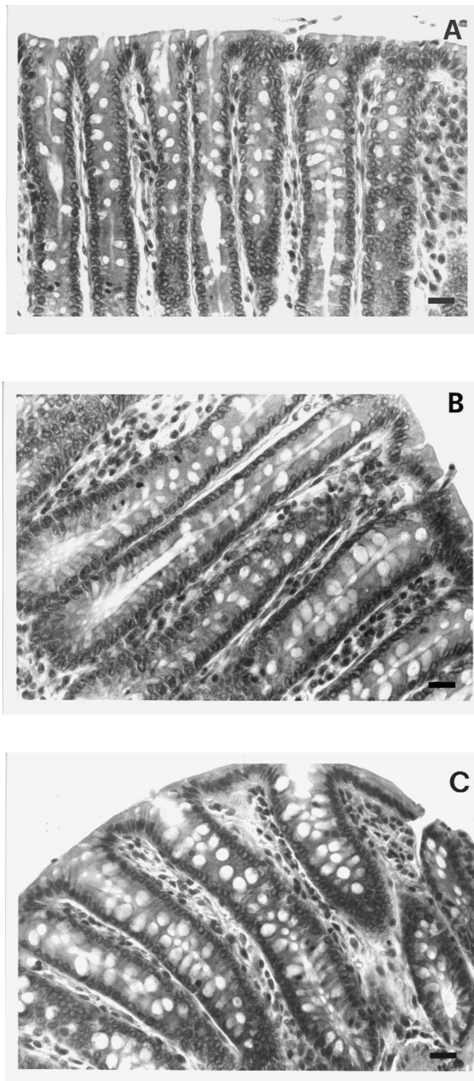

FIG. 1. Crypt morphology of colonic mucosa from rats treated with oleic acid (OA) (A), eicosapentaenoic acid (EPA) (B), and docosahexaenoic acid (DHA) (C). Specimens were stained with hematoxylin-eosin. Note the unchanged morphology and size of crypts after EPA and DHA treatments. Space bars, 20 µM.

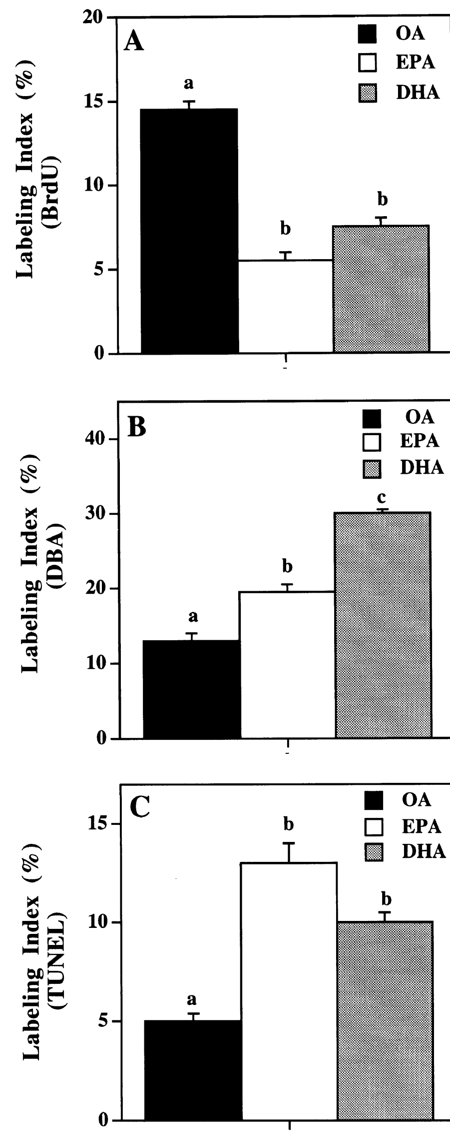

FIG. 2. Effect of EPA and DHA supplementation on cell proliferation, apoptosis, and differentiation in colonic crypts of rats. (A) Proliferation was evaluated as labeling index (%) in bromodeoxyuridine (BrdU)-immunostained specimens. (B) Differentiation was histochemically measured by binding of the lectin *Dolichos biflorus* agglutinin (DBA) to the colonocytes. (C) Apoptotic cells were evaluated with terminal deoxynucleotidyl transferase-mediated dutP-biotin nick end-labeling (TUNEL) method. Values are means ± SE of 10 determinations. Bars with different letters are significantly different ($P < 0.05$, one-way analysis of variance followed by Fisher's test). For other abbreviations see Figure 1.

Fatty acid composition of total PL obtained after dietary treatments is shown in Table 1. The content of saturated fatty acids was unaffected by supplementation with EPA or DHA. EPA treatment significantly reduced the level of both palmitoleic and oleic acids, as compared to the OA group. The content of total and individual PUFA was significantly affected by the treatment with the two n-3 fatty acids with respect to

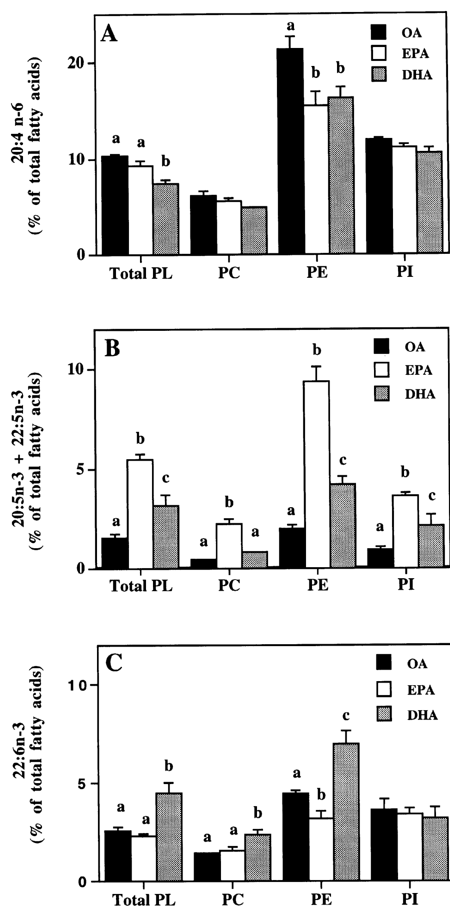

FIG. 3. Content of the principal polyunsaturated fatty acids in total phospholipids (PL) and in the different PL classes. PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol. Values are means ± SE of six determinations. Bars in each group with different letters are significantly different ($P < 0.05$, one-way analysis of variance followed by Fisher's test). Bars in a group without superscripts are not significantly different from each other. For other abbreviations see Figure 1.

the OA group. EPA treatment significantly increased EPA (20:5n-3) and its metabolite docosapentaenoic acid (DPA, 22:5n-3) without modifying the level of DHA (22:6n-3). Conversely, DHA supplementation increased the amount of DHA itself (22:6n-3) and of EPA (20:5n-3), but not of DPA (22:5n-3). Linoleic acid was unchanged in both groups of animals, and arachidonic acid (20:4n-6) was significantly decreased only in the DHA group. All the observed modifications led to a large decrease in n-6/n-3 PUFA ratio in total PL of both EPA- and DHA-treated groups.

Modifications in the content of principal PUFA in the single PL classes (PC, PE, and PI) with respect to total PL after EPA and DHA treatment are illustrated in Figure 3. Arachidonic acid was very stable in PC and PI after both treatments. EPA and DPA were sensitive to treatments with both EPA and DHA in all PL classes, whereas DHA was not modified in PI even after DHA treatment.

DISCUSSION

The data show that dietary administration with either EPA or DHA does not modify the physiological homeostasis of normal rat colonic mucosa. Indeed, they do not alter crypt morphology and the number of cells per crypt section, although they inhibit cell proliferation and enhance cell differentiation and apoptosis. Inhibition of cell proliferation by n-3 PUFA was recently reported *in vitro* (14,15) and *in vivo* (4,16,17) in both normal and tumor cells. In particular, treatment with fish oils decreased cell proliferation in colonic mucosa of humans and rats (18,19). Fish oil induction of apoptosis was recently reported in rat colonic mucosa and in cell lines (11,15). Lai *et al.* (20) observed an enhancement of apoptosis by n-3 PUFA in pancreatic cancer cells *in vitro*, and Fernandes *et al.* (21) in lymphocytes of lupus-prone mice. Recently Chang *et al.* (22) reported that colon tumorigenesis was inhibited in rats treated with fish oil. This inhibition was related to an increase of cell differentiation and apoptosis rather than a decrease of cell proliferation. In our previous study we found that both EPA and DHA administered separately, in the same dose used in this study, decreased the growth of a highly malignant hepatocarcinoma after transplantation into rats by altering cell proliferation and apoptosis (7). In particular EPA significantly inhibited cell proliferation while DHA increased apoptosis. In the present study, in a normal tissue at high degree of cell turnover such as colonic mucosa, both fatty acids inhibited cell proliferation, induced apoptosis, and in addition increased the number of differentiating cells. Notably, however, in spite of these modifications, the tissue morphology or the number of cells per crypt section was unchanged. A possible explanation for this is that the primary effect of the two fatty acids in normal tissues is the expansion of the differentiated cellular pool and that the alterations on cell proliferation and apoptosis are a homeostatic response to this effect. This hypothesis is further supported by the observations of several authors who found an induction of differentiation in cultured cells treated with n-3 PUFA (23,24).

The results on fatty acid composition of total PL show an enrichment with the supplemented fatty acids and with 22:5n-3 that occurred only with EPA supplementation. Concerning the PL classes, PE was more sensitive than PC and PI to incorporate the supplemented n-3 fatty acids. We observed also a depressed content of 20:4n-6 that occurred primarily with DHA supplementation both in total PL and in PE. These modifications are similar to those observed by us and others in normal and tumor tissue and cells (7,25,26).

It is well known that arachidonic acid metabolites have a key role in signal transduction pathways involved in the control of cell growth. Therefore, it is possible that the effects of both n-3 PUFA on cell proliferation and apoptosis observed in our study are due to a decrease in arachidonic acid content in colonic PL. Recently the decrease of arachidonic acid in membrane PL induced by dietary n-3 PUFA was shown to inhibit the expression of cyclooxygenase-2, a key enzyme in

the conversion of arachidonic acid to prostaglandins (27). This enzyme appears to have a regulatory role in the colonic mucosa cell growth. Its selective inhibition decreases the growth of human colon cancer cells (28), and its increased expression is observed in human colorectal adenocarcinoma (29). Moreover, overexpression of cyclooxygenase-2 in rat intestinal epithelial cells cultured *in vitro* inhibits apoptosis (30). In our study, however, we observed that arachidonic acid was modified in total PL and in PE, but not in PC and PI, which represent the two major substrates for phospholipase activity. This suggests that in our conditions alteration of arachidonic acid metabolism may not be the only mechanism involved in PUFA effects. However, to better clarify this point, it would be of interest to explore the effects of alteration of colonic mucosa PL arachidonic acid levels by other dietary manipulation such as feeding ethyl arachidonate or providing a diet with almost equal proportions of linoleic and linolenic acids.

Consideration of the overall results of the study leads to the conclusion that dietary supplementation with EPA and DHA modifies the rate of cell proliferation, cell differentiation, and cell death in the colonic mucosa. The observation that EPA and DHA modify cell turnover without altering crypt morphology in normal colonic mucosa suggests a possible use of these fatty acids as dietary chemopreventive agents.

ACKNOWLEDGMENTS

The authors thank Hoffmann-La Roche Ltd., Basel, Switzerland, for the generous provision of purified n-3 PUFA ethyl esters. We are grateful to Dr. J.D. Wood for helpful suggestions. This study was supported by grants from CNR (PF ACRO n.96.00506.PF39.) and MURST 60%.

Enhancement of Sterol Synthesis by the Monoterpene Perillyl Alcohol Is Unaffected by Competitive 3-Hydroxy-3-methylglutaryl-CoA Reductase Inhibition

Sonia R. Cerda, John Wilkinson IV, Steven K. Branch, and Selwyn A. Broitman*

Boston University School of Medicine, Department of Microbiology and The Mallory Institute of Pathology, Boston City Hospital, Boston, Masschusetts 02118

ABSTRACT: Monoterpenes such as limonene and perillyl alcohol (PA) are currently under investigation for their chemotherapeutic properties which have been tied to their ability to affect protein isoprenylation. Because PA affects the synthesis of isoprenoids, such as ubiquinone, and cholesterol is the end product of the synthetic pathway from which this isoprenoid pathway branches, we investigated the effects of this compound upon cholesterol metabolism in the colonic adenocarcinoma cell line SW480. PA (1 mM) inhibited incorporation of ^{14}C-mevalonate into 21–26 kDa proteins by 25% in SW480 cells. Cholesterol (CH) biosynthesis was assessed by measuring the incorporation of ^{14}C-acetate and ^{14}C-mevalonate into 27-carbon-sterols. Cells treated with PA (1 mM) exhibited a fourfold increase in the incorporation of ^{14}C-acetate but not ^{14}C-mevalonate into cholesterol. Mevinolin (lovastatin), an inhibitor of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase, at 2 μM concentration, inhibited CH synthesis from ^{14}C-acetate by 80%. Surprisingly, concurrent addition of mevinolin and PA did not significantly alter the stimulatory effects of PA. As observed differences in ^{14}C-acetate and ^{14}C-mevalonate precursor labeling could indicate PA affects early pathway events, the effects of this monoterpene on HMG-CoA reductase activity were evaluated. Unexpectedly, 1 mM PA did not stimulate activity of this enzyme. Consistent with its action as a reversibly bound inhibitor, in washed microsomes, 2 μM mevinolin pretreatment increased reductase protein expression causing a 12.7 (±2.4)-fold compensatory HMG-CoA reductase activity increase; concurrent treatment with 1 mM PA attenuated this to a 5.3 (±0.03)-fold increase. Gas chromatographic analysis confirmed CH was the major lipid present in the measured thin-layer chromatography spot. Since ^{14}C-acetate incorporation into free fatty acid and phospholipid pools was not significantly affected by PA treatment, nonspecific changes in whole acetate pool sizes were not indicated. Because increases in endogenous CH synthesis should result in compensatory changes in exogenous sterol utilization, the effects of PA upon low density lipoprotein (LDL) receptor activity were evaluated. Consistent with the observed increases in CH synthesis, 1 mM PA decreased ^{125}I-LDL internalization to 50% of the fetal bovine serum control; concurrent addition of 2 μM mevinolin attenuated this effect to a reduction of 80% of the control value. Data suggest that in certain colonic tumor cells PA strongly affects cholesterol metabolism *via* a mechanism of action that is insensitive to the HMG-CoA reductase inhibitor mevinolin.

Paper no. L7929 in *Lipids 34,* 605–615 (June 1999).

The primary rate-limiting step in cholesterol biosynthesis is catalyzed by 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase (EC 1.1.1.34) which directly yields mevalonate, an important precursor to cellular sterol and nonsterol isoprenoids such as dolichol, ubiquinone, and isopentenyl tRNA (1). Labeled mevalonate also incorporates as farnesyl or geranylgeranyl isoprenoid moieties into a number of isoprenylated proteins in mammalian cells, thereby imparting the hydrophobicity needed for membrane anchorage (2) and function or cellular localization (3). Examples include heterotrimeric G proteins, nuclear lamins, p21ras, and low molecular mass GTP-binding proteins (4).

Dysregulation of mevalonate metabolism in neoplasia is complex (5–8) and was reviewed (9). Studies by Maltese *et al*. (10) demonstrated reduction of neuroblastoma tumor growth in nude mice with the HMG-CoA reductase inhibitor mevinolin (MVN) (lovastatin). Other studies reporting a variety of effects induced by HMG-CoA reductase inhibitors followed (11–16), demonstrating the effectiveness of these compounds as inhibitors of human tumor growth.

Limonene is the predominant monoterpene in orange peel oil and was demonstrated to possess chemopreventive and chemotherapeutic activity against solid tumors (17,18). These actions result from the induction of hepatic phase I and phase II detoxifying enzymes during initiation and the suppression of growth in chemically initiated and transplantable tumors (17,18). In addition, d-limonene and PA (a hydroxyl derivative of limonene) were shown to cause apoptosis, induce differentiation and mammary carcinoma regression, and inhibit the posttranslational isoprenylation of cell growth-regulatory proteins, such as Ras (17–23).

Perillyl alcohol (PA) was reported to inhibit ubiquinone

and cholesterol (CH) synthesis using a ^{14}C-mevalonate precursor (24). While mevalonate labeling does specifically target the isoprenoid pathway, its use cannot detect changes in early pathway enzyme activity including HMG-CoA reductase (1). For this reason the effects of this monoterpene on CH production were determined in SW480 colonic adenocarcinoma cells using a ^{14}C-labeled acetate precursor. This cell line was shown to contain a K-ras mutation and is highly sensitive to the action of the HMG-CoA reductase inhibitor MVN (12,25). While the mechanism(s) are unknown, PA was observed to enhance CH biosynthesis from a ^{14}C-labeled acetate precursor. Increased CH content, measured by an enzymatically based colorimetric assay system, was also observed in PA-treated cultures as compared to control groups. Intracellular CH homeostasis in humans is maintained by a balance among uptake of exogenous CH primarily *via* the low density lipoprotein receptor (LDL-R), endogenous synthesis (primarily regulated at the HMG-CoA reductase catalyzed step), and storage as cholesteryl-esters *via* the acyl-cholesteryl-acyl-transferase enzyme (26). While overall CH synthesis in human colonic adenocarcinomas is relatively insensitive to exogenous sterol presence, LDL-R expression, while low (12), remains sterol-regulated (27). Analysis of LDL-R activity indicated PA caused a decreased expression consistent with the observed increase in CH synthesis.

MATERIALS AND METHODS

Tissue culture. Cultures of the human colonic cancer cell line SW480, obtained from American Type Culture Collection (Rockville, MD), were grown and harvested as described (27). In brief, stock cultures were grown in monolayer in plastic 75 cm^2 flasks and incubated at 37°C in a 5% CO^2/95% air atmosphere. Culture medium comprised Eagle's minimal essential medium (MEM) containing antibiotics (penicillin, 200 units/mL; streptomycin, 0.2 mg/mL), glutamine (0.2 mg/mL), and nonessential amino acids and nonessential vitamins both at 10 mL of 100× solution (Gibco, Grand Island, NY), per 500 mL MEM and supplemented with 10% fetal bovine serum (FBS) (Sigma, St. Louis, MO). Cells were plated at a density of 10^6 cells per flask, and cultures divided weekly (1:19 or 1:20) using 0.05% trypsin/0.02% disodium EDTA. After removal of media, cells were rinsed with isotonic phosphate buffered saline (PBS) (pH 7.4), and 4 mL of trypsin was added. Flasks were incubated at 37°C until cells began to detach, after which 4–6 mL of fresh medium was added. Cell cultures were assayed for the presence of mycoplasma using the gen-Prove Mycoplasma T.C.11 Rapid Detection System (San Diego, CA).

Preparation of lipoprotein deficient serum (LPDS). Lipoproteins were removed from FBS by density gradient centrifugation (28) and prepared as described (12,27). FBS was adjusted to a density of 1.21 g/mL with solid potassium bromide (64.4 g KBr per 200 mL FBS) and centrifuged for 48 h at 5°C at 244,000 × g_{max} (45,000 rpm in a 50.2 ti rotor in a Beckman L8-70 ultracentrifuge). The top lipoprotein fraction (d < 1.21 g/mL) was removed, and the bottom lipoprotein-deficient fraction dialyzed extensively against 0.01% EDTA/double-distilled water (pH 8) and then PBS. The LPDS was sterilized by passage through a 0.22 μ filter.

Preparation of MVN. MVN (lovastatin) was kindly provided by A. Alberts of Merck Sharp & Dohme (Rahway, NJ) in the lactone form. This reagent was prepared as described and used at a concentration of 2 μM in MEM (12,27). Saponification was carried out by adding 0.1 mL absolute ethanol and 0.1 mL of 0.1 N NaOH to 4 mg of MVN and by heating at 50°C for 2 h. MVN was neutralized with 5% HCl to pH 7.3. Stock solutions (4 mg/mL) were prepared by bringing the volume to 1 mL with dimethyl sulfoxide and stored at −20°C. At the concentrations used, dimethyl sulfoxide was found to have no effect on cell growth.

Preparation of PA. PA stocks (Fluka, Ronkonkoma, NY) were made up in FBS before addition to the media. To control for osmotic stress, equivalent amounts of ethanol (dissolved in FBS) were added to control groups. PA was used in this study at a dose of 1 mM for a 24-h period. This dose was shown to inhibit growth of SW480 cells without causing toxicity (29).

Protein determinations. Proteins were determined by the bicinchoninic acid reagent method (Pierce Chemical Company, Rockford, IL). A standard curve was prepared using a stock bovine serum albumin standard in sample diluent. Samples and standard were mixed with the protein reagent and absorbance read at 562 nm by spectrophotometry.

CH synthesis. Assays were conducted using ^{14}C-acetate as described (27) or ^{14}C-mevalonate precursors, by the method of Brown *et al*. (28). Briefly, cells were seeded in 6-well (35 mm^2) dishes at 20,000 cells/well in triplicate per group studied per experiment, in MEM-supplemented media with 10% FBS. Cells were grown to subconfluency (≈50% of the plate was covered), rinsed with Dulbecco's PBS, and switched to a LPDS-based medium (1 mL/well). After 24 to 48 h, the media were replaced with media containing 5 μCi/mL of 2-^{14}C-acetate (51 mCi/mmole New England Nuclear, Boston, MA) or 7.5 μCi/mL of RS-[2-^{14}C]-mevalonate (54.1 mCi/mmol) (New England Nuclear) and the following supplements: (i) 10% LPDS, (ii) FBS, the basal medium for all subsequent treatments (each of which contains 10% FBS), (iii) MVN 2 μM, (iv) PA at 1 mM, and (v) MVN plus PA. After a 24-h incubation, the medium was removed and saved; monolayers were harvested in 1 mL 0.1 N NaOH and pooled with their respective saved media (whole culture assessment) to be saponified following the methodology of Brown *et al.* (28). Briefly, these mixtures were treated with 0.5 mL 50% KOH, 3 mL ethanol, and (1,2) ^3H-CH (10^5 cpm, 50 Ci/mmole) as internal standard. After saponification at 80°C for 2 h, unsaponifiable lipids were extracted three times with petroleum ether followed by two washes with NaOH. Samples were dried with nitrogen gas, resuspended in chloroform, spotted on silica gel "G" thin-layer chromatography (TLC) plates (Analtech Inc., Newark, DE) and separated using chloroform (EM Science Inc., Gibbstown, NJ) as a running solvent to iso-

late the ^{14}C-CH with appropriate CH markers. Lipid spots were scraped and collected in liquid scintillation vials (VWR Scientific, Philadelphia, PA) containing 7 mL of econofluor scintillation fluid (New England Nuclear). Radioactivity was counted in an LKB Model 1209 Rackbeta Liquid Scintillation Counter using a program simultaneously counting the two isotopes [^{3}H] and [^{14}C]. The samples were subsequently corrected for quenching. Results were expressed as nanomoles of acetate incorporated into CH per mg cellular protein per 24-h period, taking into account the efficiency of the machine for each isotope and the specific activity of the label. Losses during the extractions were accounted for using the internal standard ^{3}H-CH. These values were then normalized to the LPDS control within each experiment. Results of various treatments were expressed as percentage of LPDS control, which was given a value of 100.

Enzymatic colorimetric CH measurement. To determine actual levels of CH in samples, a colorimetric assay system purchased from Sigma was adapted to use with tissue culture-derived samples. This assay was based on three enzymatic reactions: (i) CH esters were converted to CH by the action of CH esterase; (ii) CH was converted to a CH oxide by CH oxidase, a reaction which generates peroxide; and (iii) the peroxide was then coupled to the chromagen 4-aminoantipyrine and *p*-hydroxybenzenesulfonate by a peroxidase causing a color change measurable at 490 nm. Cells were seeded, grown, treated, and harvested as described above for the CH synthesis assay, except that no radioactive precursor was used, and cells and media were assessed separately. Samples were saponified and extracted, as described above. One-half of the extract was brought up in (200 µL) absolute ethanol, and 25–50 µL of this was used to determine actual CH levels in the colorimetric assay. A standard curve was generated from CH (Sigma) dissolved in absolute ethanol. Samples and standards were placed in a 96-well plate, and the ethanol solvent was evaporated overnight at room temperature. To each well, 100 µL of assay buffer containing the enzymes (actual contents are unknown) was added. Reactions occurred for 30 min, and wells were read in an ELISA plate reader at 490 nm. Absorbance values of the standards were plotted to generate a standard curve, which was used to obtain corresponding CH concentrations for the absorbance values of the samples. Data were normalized to protein as determined by the BCA assay.

Derivatization procedure: Esters of benzoic acid. Cells were cultured and treated as above for the CH biosynthesis experiments. After saponification and separation by TLC, lipids were visualized using the fluorescent dye 1,6-diphenyl-2,3,5,-hexatriene (Sigma) by ultraviolet light. The CH spots were then scraped, and lipids were extracted by the addition of 1 mL of chloroform. Samples were vortexed and centrifuged at 2,000 rpm to remove the silica. To dried chloroform extracts was added 300 µL of a solution of 4-dimethylaminopyridine (Sigma) dissolved in pyridine (1 g/300 mL) (30). Benzoyl chloride (50 mL; Sigma) was then added, and the samples were capped, vortexed vigorously, and allowed to stand overnight at room temperature. Next, 300 µL of 0.12 N HCl (American Bioanalytical, Natick, MA) was added, the samples vortexed again, and then chloroform (300 µL) for extracting the newly-formed sterol esters was added. To facilitate separation of the organic and aqueous layers, the samples were centrifuged in a Beckman (Fullerton, CA) tabletop GPR centrifuge equipped with a swinging-bucket rotor at 800–1000 rpm for 5 min. The top aqueous layer was then removed by aspiration, and the organic layer was reduced to a thick, oily liquid under a gentle stream of nitrogen gas while the samples were secured in a low-temperature water bath. Reconstitution of the sterol esters for gas chromatography was with 50 mL of chloroform.

Lipid analysis by gas chromatography. The gas chromatograph (GC-14A; Shimadzu Corporation, Kyoto, Japan) was fitted with an SE-30 capillary column (length, 30 m; internal diameter, 0.25 mm; Alltech, Deerfield, IL). Helium was the carrier gas at a volumetric flow rate of 1.0 mL/min, and a split ratio of 1:20 was utilized. Oven, injector port, and detector temperatures were maintained isothermally at 300°C. Retention times for the various sterol esters on the SE-30 column were determined from freshly derivatized standards prepared from relatively pure chemicals (Sigma). The retention times of the derivatized compounds were as follows: CH, 21.2 min; 7-dehydrocholesterol, 22.2 min; desmosterol, 22.5 min; and lathosterol, 23.7 min. Peak areas and retention times were determined using a CR501 Chromatopac integrator (Shimadzu Corporation, Kyoto, Japan) electronically linked to the gas chromatograph.

^{125}I-LDL binding to colonic adenocarcinoma cell lines. The ^{125}I-LDL binding assays were conducted using the following methodology adapted from Goldstein *et al.* (31). Cells were seeded in 6 wells of 6-well (35 mm^{2}) dishes (Costar, Cambridge, MA) at 2.5×10^{5} cells/well in MEM supplemented with 10% FBS. A duplicate plate for each experiment received only MEM 10% FBS, as a control for nonspecific binding to plastic. After 48 h of growth, cells were washed with PBS and changed to media supplemented 10% LPDS, which we prepared in-house from FBS (Sigma) for 24 h to generate maximal responses in terms of receptor activity. After 24 h, the cells received the following treatments in FBS-based MEM for a duration of 24 h: FBS alone, MVN 2 µM, PA 1 mM, and MVN + PA. Following treatments, the cells were incubated in 1 mL LPDS/MEM with 5–10 µg/mL ^{125}I-LDL (Biomedical Technologies Inc., Stoughton, MA) for 5 h. Typically, four wells of a 6-well dish were used to measure hot or total binding per experiment. To control for nonspecific binding, two wells received 25–40-fold increase of cold LDL (125–200 µg/mL) above the level of the hot LDL in the media. One empty, cell-free, 6-well plate was treated with media, washed, and incubated just as the other groups, and used as a blank.

Surface binding. After incubation for 5 h, cells were shown to reach a steady state in which binding, internalization, and degradation of the lipoprotein are equilibrated. The cells were then placed on an ice bed and rinsed: five times with 2 mL ice-cold Tris-buffered saline with albumin buffer [50 mM Tris/150

mM NaCl/(2 mg/mL albumin) @ pH 7.4], one time with ice-cold Tris-buffered saline, and finally incubated with 1.5 mL of Dextran sulfate release buffer [50 mM NaCl/10 mM HEPES/(4 mg/mL dextran sulfate) @ pH 7.4] for 1 h in a 4°C cold room. Polyanionic macromolecules such as dextran sulfate or heparin sulfate cause LDL to be released from its receptor; thus the activity of the released tracer is a measurement of the surface binding capacity for the cells. Following this incubation, 750 µL aliquots were taken for gamma counting.

Internalization. To measure internalization, the cells were returned to the ice bed and washed two times with 2 mL Tris-buffered saline. Then, the monolayers were removed to a benchtop and dissolved in 1.5 mL hot 60°C NaOH (0.1 N), and aliquots were taken for gamma counting (750 µL) and protein (20 µL) measurement.

Incorporation of ^{14}C-mevalonate into isoprenylated proteins in PA treated cells. Isoprenylation of proteins was assessed following the methodology of Repko and Maltese (32) with some modifications as described below. Briefly, cells were seeded at a density of 5×10^5/35 mm^2 dish (Costar). When cells reached 50% confluence, they were divided into two groups. One group was labeled with 2 µCi of ^{14}C-mevalonate at 54.1 mCi/mmol (New England Nuclear), and subjected to the following treatments for 24 h in MEM + 10% FBS: (i) FBS, (ii) PA 1 mM, (iii) MVN 2 µM, and (iv) PA + MVN. Another set of cells was subjected to each of the above for 24 h and then labeled with 15 µCi of ^{14}C-mevalonate for three additional hours in the presence of cycloheximide at 20 µg/mL. Cells were harvested after trypsin treatment, centrifuged at 3,000 × *g*, and washed twice with PBS. Pellets were then suspended in 150 µL of electrophoresis sample buffer containing 2 M urea, 2% SDS, 5% 2-mercaptoethanol, 10% glycerol, 0.05% bromphenol blue, and 0.0625 M Tris-HCl pH 6.8. Equal amounts of protein were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis as described by Laemmli (33) using 12% separating and 4% stacking polyacrylamide gels. Instruments were from Hoeffer Scientific Instruments (San Francisco, CA) and reagents from Biorad Life Science (Hercules, CA). Gels were then stained with Coomassie blue, permeated with fluorographic enhancer (En^{3}Hance, New England Nuclear), and dried with a Biorad Gel Dryer for 2.5 h at 70°C. They were then left to cool for an additional 30 min, followed by exposure to preflashed X-OMAT AR film (Eastman-Kodak Co., Rochester, NY) at –70°C for 14 d. Film was then developed using an X-ray film processor (Fuji, Photofilm USA Inc.), and fluorograms were scanned with a phosphorimager:SI (Molecular Dynamics, Sunnyvale, CA).

Basic lipogenesis assay. Cells were cultured and treated and labeled with 2.5–5 µCi/mL [1-^{14}C]acetate (51 mCi/mmole, New England Nuclear), as described for CH synthesis experiments. After labeling was complete (24 h), cells were harvested as described for whole culture assessment of CH synthesis, but saponified overnight at 70°C. After extraction of CH under alkaline conditions with petroleum ether as described above, the samples were acidified with 500 µL of concentrated HCl, vortexed and incubated for 30 min at 70°C to maximize protonization of COOH groups. The samples were extracted twice with 4 mL of petroleum ether and the ether evaporated. Samples were then brought up in 200 µL ether, and 100 µL of this was spotted on silica "G" TLC plates. These were run in hexane/diethyl ether/HOAc (70:30:1), allowed to dry, and incubated in an iodine chamber to visualize the lipids. Standards were: for phospholipids, phosphatidylcholine (R_f 0), and for free fatty acids, oleic acid (R_f 0.39). Spots corresponding to the standards were marked, iodine was allowed to dissociate, and spots were scraped and counted in econofluor. Results are reported as nanomoles of acetate incorporated into lipid type per mg cell protein.

HMG-CoA reductase activity assay in washed microsomal preparations. Cells were grown to subconfluence in 150 mm dishes, and treated for 24 h with MEM/10% FBS (control and basal media for all subsequent groups), 2 µM MVN, 1 mM PA, or a combination of the two treatments. Cells were rinsed once with PBS, scraped into 4°C PBS, and pelleted at 250 × *g*. The enzymatic preparation essentially follows the methodology of Ness *et al.* (34). In this process competitive inhibitors, such as MVN, are removed from the HMG-CoA reductase enzyme preparation. Pellets were homogenized in ice-cold solution 1 (0.25 M sucrose with 5 mM EGTA, 1 mM dithiothreitol, and 40 mM leupeptin, pH 7.1), in a Dounce homogenizer. The homogenate, after removing unlysed cells by centrifugation at 12,000 × *g* (supernatants were reserved), was centrifuged at 100,000 × *g*. The pellet was resuspended in solution 1 and centrifuged again at 100,000 × *g* to generate a washed microsomal preparation. The pellet was resuspended in solution 2 (solution 1 with 33% glycerol). Aliquots for Lowry protein determination were taken, and 10 to 100 µg of protein was used in the standard assay described below.

Specific activity measurements were made as described by Shapiro *et al.* (35) and represent the cell's total amount of reductase enzyme (36). Reductase activity was measured by incubating 10–100 µg of protein in 50 µL of a 100 mM phosphate buffer, pH 7.1, with 200 mM NaCl, 1mM EDTA, 3 mM NADPH, 30 mM glucose 6-phosphate, one unit of glucose 6-phosphate dehydrogenase, and 50 mM [3-^{14}C]HMG-CoA (3.3 mCi/mmole) at 37°C for 60–120 min. The reaction was stopped by the addition of 10 mL of 6 N HCl. [^{3}H]-mevalonic acid (0.015 µCi) was then added and the mixture was incubated for 20 min to allow for lactonization of mevalonic acid. Isolation of the product was achieved by TLC on silica gel "G" in benzene/acetone (1:1, vol/vol). The silica containing mevalonolactone was visualized against normal light, and scraped off into a counting vial, and radioactivity determined in a beta scintillation counter. Corrections for losses were accounted for by the tritium-mevalonate internal standard. Results are expressed as pmoles of mevalonate formed per milligram of protein per minute.

RESULTS AND DISCUSSION

Limonene and PA, are terpene inhibitors of protein isoprenylation, which are synthesized in plants from geranyl pyrophos-

phate, a component of the mevalonate pathway (23). These compounds were demonstrated to inhibit growth and proliferation of tumors (13,17–23). Monoterpenes were demonstrated to suppress hepatic HMG-CoA reductase activity (37) and to inhibit cellular protein isoprenylation, specifically for the small molecular weight 21–28 kDa proteins (19,22,23). These findings are consistent with the observation that PA can inhibit the enzymatic action of protein/farnesylpyrophosphate transferase (38). As nonsterol isoprenoid intermediates are responsible for a posttranscriptional control of HMG-CoA reductase activity (26) at both translational and degradational levels (39), the impact of monoterpene treatment on CH metabolism was investigated in the colonic adenocarcinoma cell line SW480.

PA was found to increase the incorporation of ^{14}C-acetate into CH fourfold as compared to the FBS or LPDS controls (Fig. 1). While MVN treatment significantly ($P < 0.001$) inhibited acetate incorporation into CH 80% relative to the controls, the combination of PA and MVN treatment resulted in an increased incorporation which was similar to that with PA treatment alone. Thus, the presence of a strong HMG-CoA reductase competitive inhibitor did not block PA's action. Control studies showed the same effects at 1.5 and 3 h of treatment, even when the specific activity was diluted to one-third of the original values used in this study (data not shown).

To investigate whether the observed changes in ^{14}C-acetate label incorporation into CH as a result of PA treatment were resulting in actual changes in steady-state levels of CH, an enzymatically based colorimetric assay system was employed to measure CH content in treated cultures. Unlike the radioactive precursor assays, cell monolayers and culture media were separately assessed. Results are depicted in Figure 2. As compared with either the FBS-treated control or the MVN-treated group, increases in the cellular fraction were only significant in the combination group, while both PA and combination treatments caused a significant accumulation of CH in the media fraction of the culture ($P < 0.01$ by analysis of variance; Bonferoni test for multiple comparisons). While these results are consistent with the findings of increased CH production seen using an acetate precursor, unfortunately, we cannot say with certainty that residual PA in the media or the cells did not have an effect on the enzymes or reactions used to drive the colorimetric reaction. Results from the MVN group indicated that 24-h treatment did not result in an overall net change in total CH in either cell or media fractions of

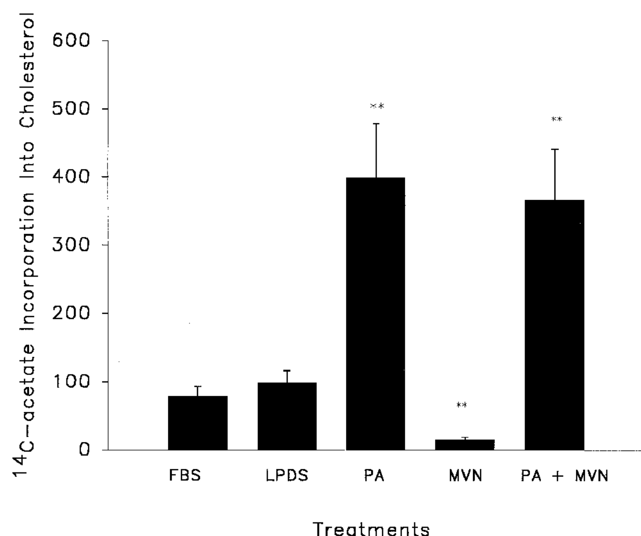

FIG. 1. Effects of mevinolin (MVN) and perillyl alcohol (PA) treatments upon the incorporation of ^{14}C-acetate into cholesterol. Cells were grown in minimum essential medium (MEM) + 10% fetal bovine serum (FBS) to 80% confluency and incubated with ^{14}C-acetate. Nonsaponifiable lipids were extracted and subjected to thin-layer chromatography as indicated in the Materials and Methods section. Endogenous cholesterol synthesis, as estimated by nanomoles of acetate-incorporated per mg cellular protein, was determined per sample. Values were normalized to the lipoprotein-deficient serum (LPDS) control within each experiment. Results of challenge for cells treated in FBS, LPDS, FBS plus PA 1 mM, FBS plus MVN (2 μM), and FBS plus MVN + PA, are expressed as percentage of LPDS control and depicted as bar graphs, where the filled area represents the mean of three different experiments carried out in triplicate. Error bars represent the standard deviation of the mean. Significance of findings was evaluated by general linear model analysis of variance comparing treatments with the LPDS control. **Significantly different from FBS and LPDS groups ($P < 0.001$).

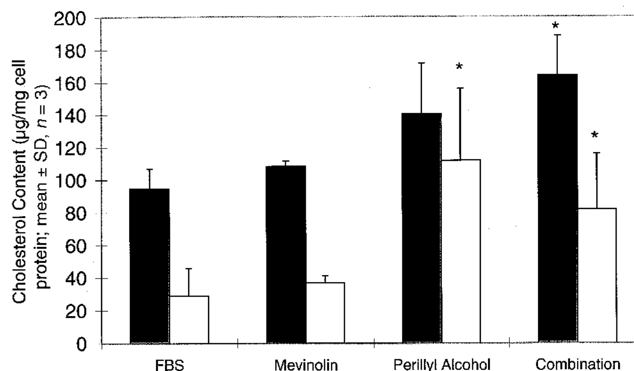

FIG. 2. Effects of MVN and the monoterpene PA upon total cholesterol levels in SW480 cells. Cells were seeded, grown, treated, and harvested as in the cholesterol synthesis assay described in the Methods section, except that no radioactive precursor was used, and cells and media were assessed separately. Treatments depicted under the bars were FBS/MEM (basal medium for all subsequent groups), 2 μM MVN, 1 mM PA, and a combination of the two treatments. Media (open bars) and cellular (solid bars) samples were saponified and extracted, as described in the Materials and Methods section. One-half of the extract was brought up in (200 μL) absolute ethanol, and 25–50 μL of this was used to determine actual cholesterol levels in the colorimetric assay. This assay is based on three enzymatic reactions: (i) cholesterol esters are converted to cholesterol by the action of cholesterol esterase; (ii) cholesterol is converted to a cholesterol oxide by cholesterol oxidase, a reaction which generates peroxide; and (iii) the peroxide is then coupled to the chromagen 4-aminoantipyrine and *p*-hydroxybenzenesulfonate by a peroxidase causing a color change measurable at 490 nm. A standard curve was generated from standards dissolved in absolute ethanol. Reactions occurred in a 96-well plate, and samples were read in an ELISA plate reader at 490 nM. Differences between groups (* = $P < 0.01$ vs. control and MVN groups) were determined by analysis of variance as described in the Materials and Methods section. See Figure 1 for abbreviations.

the culture. Thus the cells were either able to overcome the CH biosynthetic block imposed by MVN at a 2 μM concentration to generate their required sterols, or they decreased sterol usage to preserve sterol stores. This was consistent with the continued growth of the cells, albeit at a 50% reduced rate (12), and the dramatic compensatory increase in reductase activity generated by the cells to overcome the MVN imposed blockage of the pathway (26). Indeed, the disparity between results with MVN-treated cells between the ^{14}C-acetate incorporation assay (strong inhibition of synthesis) and the colorimetric assay (no change in content) illustrates pointedly the disadvantage of using either method alone. Presumably part of the reason total CH levels do not drop in 24-h treatment with MVN is a decrease in sterol utilization, particularly to meet cellular growth needs. This level of MVN treatment permits enough CH to be made to support a reduced growth rate (12). Thus the colorimetric results, which indicated no change in CH, taken alone, would imply there were no differences in CH metabolism as a result of MVN treatment. However, the results of ^{14}C-acetate incorporation assays in MVN-treated cells indicate that CH biosynthesis was greatly reduced by the drug. Yet total CH levels remain the same. When both sets of results are evaluated together, it is suggested that MVN treatment, which was ultimately compensated for by the cells, results in a dramatic upregulation of at least the early steps of the pathway.

Gas chromatography was employed to evaluate the content of the TLC spot where C_{27}-sterols from cells in the various treatment groups migrate (Fig. 3). Chloroform-extracted sterols from the TLC scrapings were derivatized to benzoyl esters and run using a SE-30 column. The major peak constituting >90% of the injected lipid corresponded to cholesteryl-ester. Depicted is a representative chromatograph of sterols from the TLC spot derived from PA-treated cells. Minor peaks included desmosterol and lathosterol, and these were never greater than 6 and 1.9%, respectively, of the CH peak area.

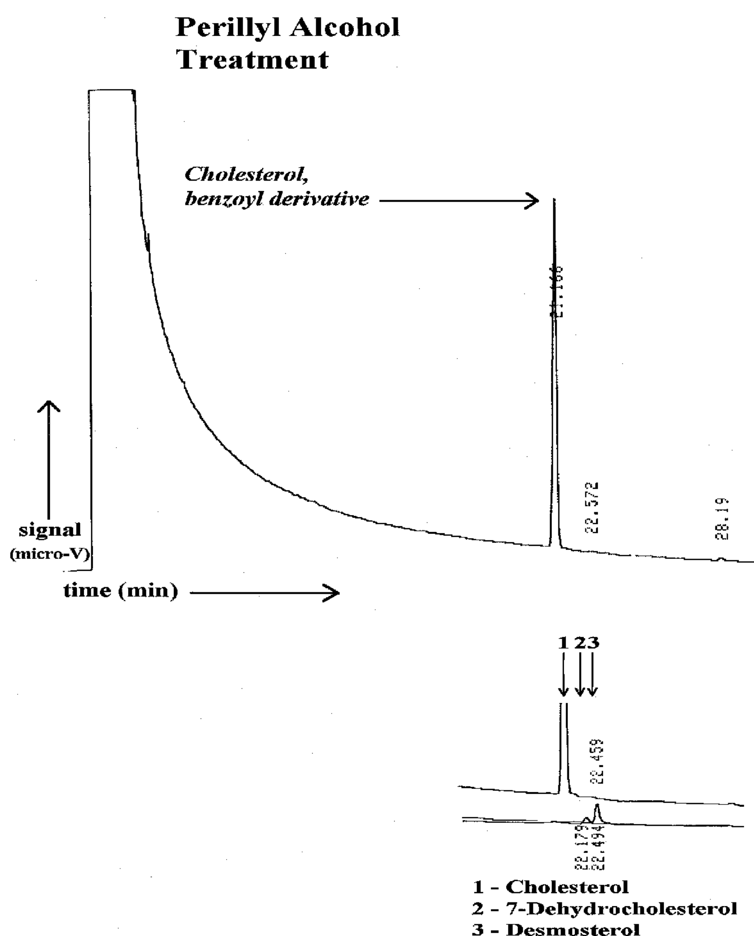

FIG. 3. Gas chromatography of PA treated cells. SW480 cells were treated with an FBS control or with 1 mM PA. Lipids were extracted, saponified, and unsaponifiable lipids were separated by thin-layer chromatography along with appropriate standards. Lipids were visualized, scraped, and derivatized for analysis by gas chromatography as described in the Materials and Methods section. The retention times of various sterol-ester derivatized standard compounds (depicted in the inset below the chromatograph) were as follows: cholesterol, 21.2 min; 7-dehydrocholesterol, 22.2 min; desmosterol, 22.5 min; and (not depicted) lathosterol, 23.7 min. Chromatograph of sterol spot from PA-treated cells is depicted; this was virtually identical to that from FBS-treated cells (not shown). See Figure 1 for abbreviations.

To determine if the PA-mediated enhancement of sterol synthesis could affect expression of sterol-controlled proteins, the activity of LDL receptors was assessed in treated cells by measuring ^{125}I-LDL binding and internalization. LDL-R activity is reported as ng ^{125}I-LDL bound per mg cell protein, and one representative assay is depicted in Table 1. The major count found in this assay represents the LDL that is internalized by the cells which has not yet been degraded. In normal cells this will typically be 80–90% of the total cell-associated radioactivity. Because the same cell line under the same treatment, when measured on different days, can vary by as much as tenfold (31), we concentrated on the relative differences observed between treatment groups within distinct assays. All findings were statistically significant by $P <$ 0.001 unless otherwise indicated. Under conditions where synthesis of C_{27}-sterols was enhanced fourfold, LDL receptor activity was markedly reduced (See Table 1), a finding consistent with the sterol-repressible nature of the gene for this protein. As the enhancement of CH synthesis by PA is unaffected by MVN, the ability of this inhibitor to ameliorate the effects of PA pretreatment upon LDL-R activity was evaluated. MVN, which usually causes an increase in LDL-R activity, had only a slight effect upon LDL-R expression in PA-treated cells, bringing it from 50 to 80% of the control value. Treatment with LPDS-supplemented media, which enhanced LDL-R activity threefold relative to the FBS controls, provided a basis to determine if removal of exogenous sterols would alter the ability of PA to affect LDL-R expression. The LDL-R activity of cells cultured in PA/LPDS was reduced to 47% of the LPDS-treated cells, indicating the ability of PA to cause sterol-mediated suppression in even sterol-poor environments.

At this point the data suggested that PA treatment caused an increase in CH derived from acetate. The inability of MVN to block this increase indicated PA could be acting at a later step than HMG-CoA reductase, the primary control point of the pathway (26). To test this hypothesis, the direct product of this enzyme, mevalonate, was added in radiolabeled form to determine if increases in incorporation of ^{14}C-acetate into CH, as compared to untreated cells, was due to enzymes subsequent to mevalonate production in the CH biosynthetic pathway. However, this was not found to be the case; when ^{14}C-mevalonate was added as a label (Fig. 4), sterol synthesis from this metabolite was inhibited by 65% under PA treatment, as compared to the FBS control. A combination of MVN with PA similarly resulted in a decreased synthesis relative to the controls to an extent that was even greater than PA treatment alone.

We hypothesized that an increase in endogenous mevalonate synthesis may reflect as decreases in ^{14}C-mevalonate incorporation into CH or isoprenylated proteins. An analogy for this mechanism of action can be found in the effects of MVN on protein isoprenylatation where the drug, which acts by depleting endogenous mevalonate, results in increased incorporation of ^{14}C-mevalonate into isoprenylated proteins (19). To test this hypothesis, the effects of these inhibitors alone and in combination upon protein isoprenylation in the

TABLE 1
Representative Experiment Measuring Surface-Bound and Internalized LDL in SW480 Cells

	LDL (ng/mg cell protein)			
	Surface-bound[a]		Internalized	
Treatments[b]	Mean[c]	SD	Mean	SD
FBS	1.99	0.30	14.9	1.5
PA/FBS	0.98	0.31	8.5	0.7
PA + mevinolin/FBS	1.07	0.14	11.9	1.4
LPDS	4.42	0.27	46.9	2.1
PA/LPDS	2.14	0.73	23.8	1.7

[a]Cells were evaluated as described in the Materials and Methods section for their ability to bind (surface activity) and internalize ^{125}I-human low density lipoprotein (LDL). PA, perillyl alcohol.
[b]SW480 cells were treated for 24 h with the basal media supplemented with fetal bovine serum (FBS) and various agents as depicted, unless lipoprotein-deficient serum (LPDS) was used as basal media and indicated in the group designation.
[c]Activity is reported as ng of radiolabeled LDL per mg cellular protein (quadruplicate samples). All groups were statistically different from the respective basal media controls by analysis of variance ($P < 0.001$; Bonferoni test for multiple comparisons).

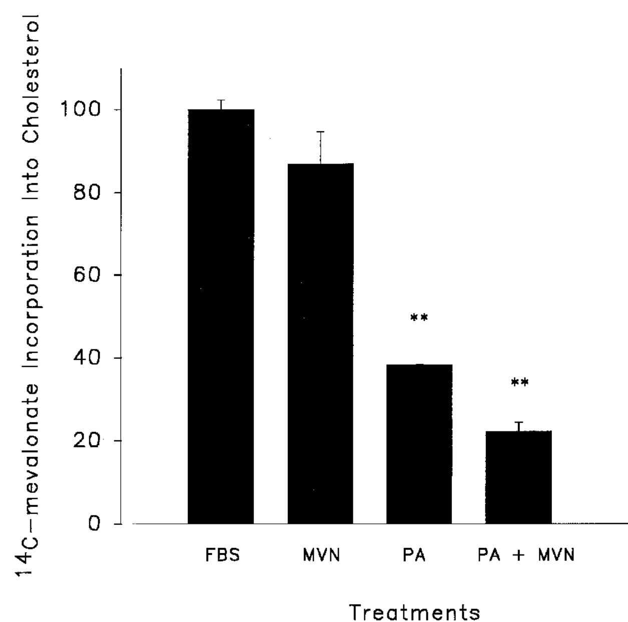

FIG. 4. Effects of MVN and PA treatments upon the incorporation of ^{14}C-mevalonate into cholesterol. Cells were grown in MEM + 10% FBS to 80% confluency and incubated with ^{14}C-mevalonate. Nonsaponifiable lipids were extracted and subjected to thin-layer chromatography as indicated in the Materials and Methods section. Endogenous cholesterol synthesis, as estimated by nanomoles of mevalonate incorporated per mg cellular protein, was determined per sample. Values were normalized to the FBS control within each experiment. Treatments in MEM + 10% FBS comprised: (i) FBS alone, (ii) MVN (2 μM), (iii) PA 1 mM, and (iv) MVN + PA. Results are expressed as percentage of FBS control and depicted as bar graphs, where the filled area represents the mean of two different experiments carried out in triplicate. Error bars represent the standard deviation of the mean. Significance of findings was evaluated by general linear model analysis of variance comparing treatments with the FBS control. **Significantly different from LPDS control ($P < 0.001$). See Figure 1 for abbreviations.

adenocarcinoma cell line SW480 were evaluated. Protein isoprenylation was assessed by measuring the incorporation of ^{14}C-mevalonate into proteins as described in the Materials and Methods section. Figure 5 shows an autoradiogram of ^{14}C-mevalonate-labeled proteins under the following treatments: FBS, 1 mM PA, 2 µM MVN, and PA + MVN. Densitometric analysis of ^{14}C-mevalonate incorporation into the 21–28 kDa proteins showed a 25% decrease in label incorporation in 1 mM PA-treated cells as compared to the FBS control (lane 3 vs. lane 1). In contrast, 2 µM MVN treatment resulted in a 2.2-fold increase in labeling (lane 2 vs. lane 1). Treatment with MVN left a pool of unisoprenylated proteins which resulted in incorporated label when chased with 15 µCi/mL of ^{14}C-mevalonate in the presence of cycloheximide at 20 µg/mL, as compared to untreated cells (lane 6 vs. lane

TREATMENT	LANES							
	1	2	3	4	5	6	7	8
MVN 2 µM	-	+	-	+	-	+	-	+
PA 1 mM	-	-	+	+	-	-	+	+
CHX 20 µg/	-	-	-	-	+	+	+	+

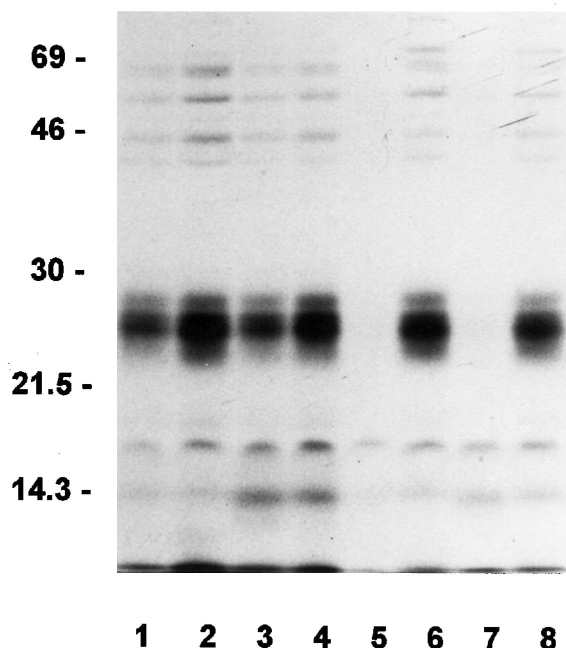

FIG. 5. Inhibition of protein isoprenylation in SW480 under MVN and PA treatments. SW480 cells were seeded at a density of 5×10^5/35 mm^2 dish and cultured for 2 d in MEM + 10% FBS. Cells were then subjected to the following treatments and divided into two groups. Group A [to which no cycloheximide (CHX) was added] was labeled with 2 µCi of ^{14}C-mevalonate with (i) FBS, (ii) MVN (2 µM), (iii) PA (1 mM), and (iv) PA + MVN. In Group B, cells were treated as above with no label for 24 h after which they were labeled with 15 µCi of ^{14}C-mevalonate in the presence of CHX at 20 µg/mL. Cells were harvested after trypsin treatment, centrifuged, and washed twice with phosphate buffered saline, and suspended in electrophoresis buffer in the presence of 2 M urea. Equal aliquots of protein from whole cell extracts were then analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis in 12% polyacrylamide gels, stained, and enhanced. Incorporation of label into 21–28 kDa proteins was analyzed by densitometry. Results are depicted in lanes (1,5) FBS; (2,6) MVN; (3,7) PA; (4,8) PA + MVN. See Figure 1 for other abbreviations.

5, respectively). PA at 1 mM did not result in incorporation of label in the presence of cycloheximide (see lane 7). Concurrent addition of PA and MVN to cells with cycloheximide further decreased the label by ≈20% as compared to its respective MVN treated group (Fig. 2, lane 8 vs. lane 6), suggesting that PA inhibited protein isoprenylation at a step in the pathway subsequent to mevalonate synthesis. In fact, PA was suggested to be an inhibitor of the enzymatic action of protein/farnesylpyrophosphate transferase (38). Finally, as studies indicated that PA treatment can cause decreased protein expression for such isoprenylated proteins as Ras, the authors note that small decreases in ^{14}C-mevalonate incorporation into proteins may be reflective of a more generalized effect on protein synthesis (20,29).

Together, these results suggest that terpenes affect CH synthesis at an early step in the pathway *via* a mechanism of action that is not affected by HMG-CoA reductase competitive inhibition. This effect was also observed in the murine colonic carcinoma cell line CT-26 (13). This decrease in labeled mevalonate incorporation into CH is consistent with (i) a dilution by endogenous mevalonate diverted from isoprenoid synthesis or (ii) an actual endogenous enhancement of mevalonate production caused by this terpene. Because increased incorporation of ^{14}C-acetate into CH is not a direct measurement of CH synthesis, as differences in intracellular acetate uptake, acetate pools, or activation of acetate to acetyl-CoA can occur, rates of sterol synthesis based on this assay could be regarded as estimates only. However, preliminary studies showed that the action of PA upon sterol synthesis was not blocked by MVN when ^{14}C-octanoate was utilized as a source of cytosolic acetyl CoA derived from the rapid intramitochondrial oxidation of this medium-chain fatty acid (data not shown). Nevertheless, we used ^{14}C-acetate and not ^{14}C-octanoate for our experiments, because intestinal cells preferentially use this substrate as a source of acetyl CoA to synthesize CH (40). While the possibility that this alcohol may affect membrane permeability cannot be dismissed, PA-treated cells were viable at 1 mM concentration for at least 4 d (data not shown), and all treatments received equal amounts of ethanol to control for osmotic differences between groups.

Despite the procedures employed to determine the putative identity of the radioactive material generated by PA-treated cells from a ^{14}C acetate precursor, some doubts remained as to whether this apparent enhancement of CH synthesis could be the result of a change in acetate pool sizes. If a treatment causes the general cellular levels of acetate in a cell to decrease, this would cause a nonspecific increase in the specific activity of ^{14}C-acetate label within the cells, subsequently resulting in apparent increases in all compounds that draw substrate from the affected acetate pool. As this type of artifact is nonspecific, a good means of detecting it is to assess the incorporation of acetate label into other compounds, to determine if there is a broadly based enhancement of apparent synthesis. Toward this end, SW480 cells were treated with MVN and PA, labeled with ^{14}C-acetate, and harvested for determination of CH synthesis according to the

standard methodology. Samples were then acidified with HCl to protonate-charged lipids, and reextracted. The free fatty acids and phospholipids in the resultant extracts were isolated and identified by TLC, and counted to determine the extent of ^{14}C-acetate incorporation. Results depicted in Figure 6 indicated that these three lipid classes, CH, free fatty acids and phospholipids, incorporated ^{14}C-acetate in a manner consistent with specific effects of the treatments. Nonspecific changes in whole acetate pool sizes were not indicated.

Although terpenes were reported to suppress hepatic HMG-CoA reductase activity (37) and decrease CH synthesis from ^{14}C-mevalonate in MVN-pretreated NIH 3T3 cells (19), this may not be the case for all tumor cells. The fact that PA treatment caused increased incorporation of ^{14}C-acetate into CH and decreased incorporation of ^{14}C-mevalonate implies that PA may be affecting as early a step as mevalonate synthesis, most probably increasing the activity of HMG-CoA reductase. Such stimulation could yield a buildup in intracellular CH. It is known that nonsterol derivatives of mevalonate affect HMG-CoA reductase activity post-transcriptionally (26).

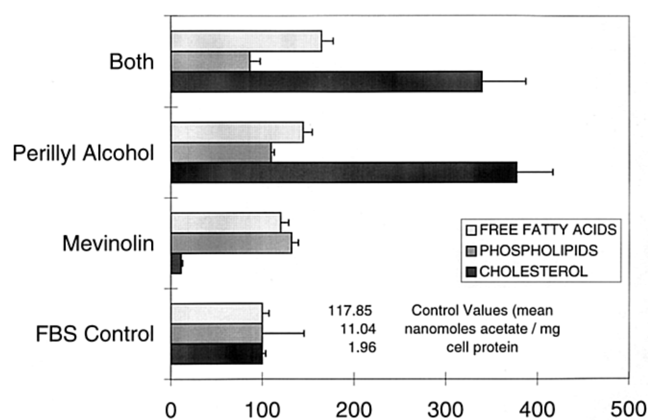

FIG. 6. Effects of MVN and the monoterpene PA upon total lipogenesis in SW480 cells. Cells were cultured and treated and labeled with 2.5–5 µCi/mL of [1-^{14}C]-acetate (51 mCi/mmole; New England Nuclear, Boston, MA), as described in the Materials and Methods section for cholesterol synthesis experiments. Cells were treated with FBS/MEM (basal medium for all subsequent groups), 2 µM MVN, 1 mM PA, and a combination of the two treatments. After labeling was complete (24 h), cells were harvested as described in the Materials and Methods section for whole culture assessment of cholesterol synthesis, with overnight saponification @ 70°C. After extraction of cholesterol under alkaline conditions with petroleum ether, the samples were acidified with 500 µL of concentrated HCl, vortexed, and incubated for 30 min at 70°C to maximize protonization of COOH groups. The samples were extracted twice with 4 mL of petroleum ether, and the ether evaporated. Samples were then brought up in 200 µL ether, and 100 µL of this was spotted on silica G thin-layer chromatography plates. These were run in hexane/diethyl ether/HOAc (70:30:1), allowed to dry, and incubated in an iodine chamber to visualize lipids. Standards were: for phospholipids, phosphatidylcholine (R_f 0), and for free fatty acids, oleic acid (R_f 0.39). Spots corresponding to the standards were marked, iodine was allowed to dissociate, and spots were scraped and counted in scintilant. Results are reported as nanomoles of acetate incorporated into lipid-type per mg cell protein, normalized to the FBS control group values within each group which were: free fatty acids, phospholipids, cholesterol. See Figure 1 for abbreviations.

Studies indicate that the mevalonate-derived mediator required for the accelerated degradation of HMG-CoA reductase enzyme is derived from farnesyl diphosphate and/or squalene (41). Maximal degradation requires synergistic action of both sterols and this mediator in the endoplasmic reticulum. A digitonin-permeabilized cell system was then utilized to identify farnesol as the nonsterol derivative that can specifically initiate and promote this degradation (42). Because PA is derived from the farnesol precursor geraniol, and was recently shown to inhibit farnesyl pyrophosphate transferase (38), we hypothesized that this terpene may act in a fashion similar to that of farnesyl pyrophosphate, by sending regulatory signals to HMG-CoA reductase, thereby inhibiting its degradation. Alternatively, PA treatment could stimulate an HMG-CoA reductase isoform that expresses different enzymatic responses to certain mevalonate-derived nonsterol isoprenoids. This enzyme could originate either from different genes, as occurs in yeast (43), or from different HMG-CoA reductase transcripts, whose translation could be regulated by a mevalonate-derived substance (26), as occurs in eukaryotic cells. Thus, a second transcript of HMG-CoA reductase could be predominant in neoplastic cells, as a result of increased demands of mevalonate-derived products in cancer cells.

For these reasons, and to investigate whether the ability of MVN to inhibit HMG-CoA reductase in the presence of PA is abrogated, the impact of PA upon HMG-CoA reductase was examined in washed microsomal preparations from pretreated SW480 cells. In this assay system, inhibitors such as MVN, which bind HMG-CoA reductase protein reversibly, are washed free of the reductase in the microsomal preparation. For this reason, groups treated with strong HMG-CoA reductase inhibitors, which cause strong compensatory increases in HMG-CoA reductase protein synthesis to overcome the effects of the inhibitor, increased activity relative to untreated control groups. Results depicted in Figure 7 indicate that MVN pretreatment caused a 12.7 (±2.4)-fold compensatory increase in microsomal HMG-CoA reductase activity, consistent with this concept. Unexpectedly, PA did not stimulate activity of this enzyme. Cells treated with both PA and MVN showed a 5.3 (±0.03)-fold compensatory increase in activity relative to the control group, but this increase was only 42% of that seen with MVN alone. It is suggested that this attenuation occurs because of the nature of the compensatory increase in reductase activity seen as the result of MVN treatment. This compensation results from the increased cellular need for all products of mevalonate metabolism—of which sterols are the bulk product. If the sterol availability in PA-treated cells is sufficient to downregulate sterol-controlled genes, then the ability of MVN to cause an upregulation in HMG-CoA reductase protein expression (measured as an increase in activity) would be attenuated. This is precisely what the "internalized" ^{125}I-LDL receptor activity data suggest (Table 1), where the PA-treated group demonstrates a rough decrease in receptor activity to 50% of the FBS control, while, in the presence of both MVN and PA, there is only a decrease to 80% of the FBS control. This is

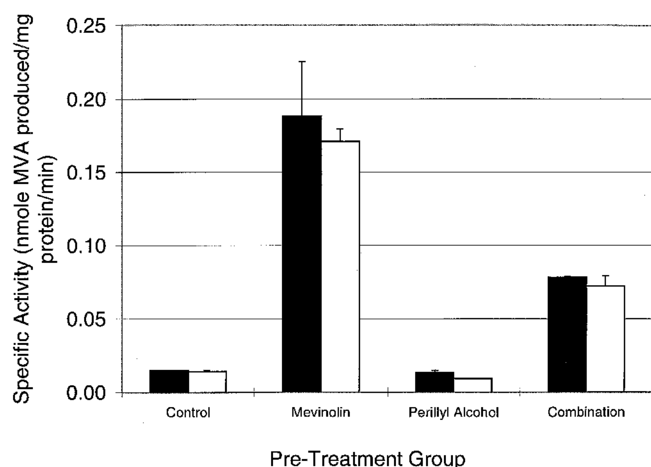

FIG. 7. Effects of pretreatment of SW480 cells with MVN and the monoterpene PA on 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase activity in washed microsomal preparations. Cells were grown to 70–80% confluence in 150 mm dishes. Cells were treated for 24 h with FBS/MEM (basal medium for all subsequent groups), 2 μM MVN, 1 mM PA, and a combination of the two treatments. Cells were harvested for preparation of microsomes, and samples were evaluated in the HMG-CoA reductase activity assay as described in the Materials and Methods section. Results are reported by listed treatment group as mean (± SD) specific activity (nmoles mevalonate formed/mg protein/min) after 60 min (solid bars) and 120 min (open bars) of incubation with substrate. MVA, mevalonic acid.For other abbreviations see Figure 1.

consistent with the increases in CH seen by CH synthesis from ^{14}C-acetate and in the colorimetric assay. Finally, when 12 nM MVN was tested in extracts from control and PA-treated cells, HMG-CoA reductase activity was similarly inhibited, indicating that the reductase protein did not aquire, as the result of cellular PA exposure, a resistance to effects of MVN (data not shown).

It is concluded that while the mechanisms for its action are unknown, PA increases sterol biosynthesis. Primarily, this occurs *via* a step sensitive to discrimination with ^{14}C-acetate precursor labeling but not with ^{14}C-mevalonate precursor labeling. Within the known paradigm for CH biosynthesis regulation, this step may involve: (i) Increased enzyme activity at an early step in the pathway above mevalonate production, such as HMG-CoA synthase or other earlier enzymes, causing an enhancement of endogenous mevalonate synthesis that leads to an overall increase in sterol production as measured by a labeled acetate precursor, or (ii) nonspecific effects on acetate pools. However, the latter possibility seems unlikely because synthesis of other lipids from ^{14}C-acetate was not affected by PA treatment, and this terpene caused an increase in ^{14}C-acetate incorporation into sterols when a mitochondrial source of ^{14}C-acetate was used, such as ^{14}C-octanoate (data not shown). In addition, increased culture CH content upon PA treatment was also verified using an enzymatic colorimetric assay to measure CH, and the decreases in LDL receptor activity caused by PA treatment were consistent with sterol repression. It is attractive therefore to suggest that PA, due to its structural analogy to isoprenes of the CH biosynthetic pathway such as geraniol (23), may somehow enter the CH biosynthetic pathway, possibly by a salvage pathway similar to that described by Crick *et al.* (44). To explain labeling increases which result from ^{14}C-acetate vs. ^{14}C-mevalonate precursors, we suggest that the PA-derived isoprenoids incorporate an acetate-radiolabeled carbon as part of the process (i) of either entering the pathway or (ii) at a latter step as sterol products, in either case by unknown mechanisms which do not involve mevalonate. An enhancement of the CH biosynthetic pathway by PA which cannot be detected through mevalonate labeling would be consistent with earlier observations in which PA was found to cause decreased incorporation of ^{14}C-mevalonate into isoprenylated proteins (19), ubiquinone, and CH (24). However, the interpretation of these prior studies using a labeled mevalonate precursor (that PA treatment was inhibitory of the studied processes) may be in question. Understanding this mechanism may enable eventual therapeutic exploitation of altered pathways for CH metabolism in certain tumors.

ACKNOWLEDGMENTS

Studies discussed were supported in part by a research grant (R01 CA57684) and by training grants (5T 32 CA 09423 and 1 F31CA639226-01) from the National Cancer Institute of the National Institutes of Health, and by a research grant (93-B34) from the American Institute for Cancer Research. Portions of this work were presented at the annual meetings of the American Association for Cancer Research.

Biosynthesis of *R*-(+)-Octane-1,3-diol. Crucial Role of β-Oxidation in the Enantioselective Generation of 1,3-Diols in Stored Apples

Till Beuerle and Wilfried Schwab*

Lehrstuhl für Lebensmittelchemie, Universität Würzburg, D-97074 Würzburg, Germany

ABSTRACT: The biosynthesis of *R*-octane-1,3-diol and *R*-5(*Z*)-octene-1,3-diol, two natural antimicrobial agents in apples and pears, was investigated in stored apples after application of [9,10,12,13-^{3}H]linoleic acid, [9,10,12,13,15,16-^{3}H]linolenic acid, [1-^{14}C]linoleic acid, [U-^{14}C]oleic acid, lipoxygenase-derived metabolites of [9,10,12,13-^{3}H]linoleic acid, $^{13}C_{18}$-labeled linoleic acid hydroperoxides, and ^{2}H-labeled octanol derivatives. Analysis of the products and quantification of incorporation and labeling pattern were achieved by high-performance liquid chromatography-radiodetection, capillary gas chromatography (GC)-isotope ratio mass spectrometry, and GC-mass spectrometry analysis. Almost all the applied precursors were partly transformed into *R*-octane-1,3-diol. Linoleic acid derivatives, still containing the 12,13 *cis* double bond, and octanol derivatives oxy-functionalized at carbon 3 were the most efficient precursors of the 1,3-diol. The data imply that *R*-octane-1,3-diol is generated in stored apples in the course of the β-oxidation from *R*-3-hydroxy-octanoyl-SCoA originating from 2-*cis*-octenoyl-SCoA by enoyl-CoA hydratase. In an analogous fashion, *R*-5(*Z*)-octene-1,3-diol is formed from the unsaturated intermediate.

Paper no. L8185 in *Lipids 34,* 617–625 (June 1999).

Several apple cultivars such as Peau de Chien, Douce Moen, and Rheinischer Bohnapfel accumulate high concentrations of the antimicrobial β-glycols *R*-octane-1,3-diol and its unsaturated analog *R*-5(*Z*)-octene-1,3-diol, as well as their glucosylated forms during storage (1–3). The diols are effective in controlling microorganisms associated with infections in humans and animals (4). Studies indicated that inhibition of amino acid transport is the primary antimicrobial effect of the β-glycols (5). The diols are harmless to humans at concentrations exhibiting antimicrobial effects. In humans, *R*-octane-1,3-diol is completely resorbed and metabolized as previously observed for butane-1,3-diol (6). Due to their chemical structures, both diols are considered to be intermediates of fatty acid metabolism, and their biosynthesis may be explained by at least three possible pathways: (i) generation *via* fatty acid synthesis (*de novo*) (1), (ii) a catabolic route of formation (β-oxidation) (7), or (iii) a lipoxygenase-like reaction (7). Recently, we investigated the biogenesis of *R*-octane-1,3-diol and its glucosylated form by administering [1-^{14}C]hexanoic acid, [1-^{14}C]octanoic acid, and [U-^{14}C]linoleic acid into intact ripe apple fruits (8). The study presented evidence that both *R*-octane-1,3-diol and its glucoside are derived primarily from linoleic acid. In the present work, we demonstrate the crucial role of β-oxidation in the enantioselective generation of 1,3-diols in stored apples.

MATERIALS AND METHODS

Materials. Linoleic acid and soybean lipoxygenase were purchased from Sigma (St. Louis, MO); linoleic acid-$^{13}C_{18}$ from Isotec (Emmerich, Germany); [1-^{14}C]linoleic acid (58 mCi/mmol) from DuPont (Boston, MA); [U-^{14}C]oleic acid (768 mCi/mmol) from DuPont; [9,10,12,13-^{3}H]linoleic acid (60 Ci/mmol) from Biotrend (Cologne, Germany); [9,10,12,13,15,16]linolenic acid (120 Ci/mmol) from Biotrend; silica gel thin-layer chromatography (TLC) plates (0.25 mm, 60 F254) from Merck (Darmstadt, Germany). Solvents or reagents were of analytical or high-performance liquid chromatography (HPLC) grade. Fresh, ripe apple fruits (cv. Douce Moen) were kindly provided by Pernod Ricard (Créteil, France).

Synthesis of $^{13}C_{18}$-labeled linoleic acid hydroperoxides. A solution consisting of 50 mg $^{13}C_{18}$-linoleic acid, 18 mg methylene blue, and 20 mL methanol was irradiated with a mercury lamp at −10°C for 24 h with 300 W. A similiar reaction was conducted with 1 g of unlabeled linoleic acid. The solvent was removed *in vacuo,* and the residue was dissolved in diethyl ether. The precipitate consisting of methylene blue was filtered off. TLC analysis showed a yield of 75% hydroperoxides, which were separated from linoleic acid by flash chromatography on silica gel with hexane/diethyl ether/acetic acid (85:15:1). The individual compounds 9-hydroperoxy-10(*E*), 12(*Z*)-octadecadienoic acid (9-HPOD), 10-hydroperoxy-8(*E*),

12(*Z*)-octadecadienoic acid (10-HPOD), 12-hydroperoxy-9(*Z*), 13(*E*)-octadecadienoic acid (12-HPOD), 13-hydroperoxy-9(*Z*), 12(*E*)-octadecadienoic acid (13-HPOD), and 13-hydroperoxy-9(*E*), 12(*E*)-octadecadienoic acid [13(*E,E*)-HPOD] were isolated by analytical normal-phase HPLC analysis according to Reference 9.

Synthesis of $^2H_2$-labeled octanol derivatives. 2,3-$^2H_2$-octenal: Lindlar catalyst (Pd/$CaCO_3$) (300 mg) was added to a solution of 1,1-diethoxy-2-octyne (12.5 mmol, 2.48 g) and pentane (75 mL). The flask was evacuated and closed with a balloon filled with H_2 or $^2H_2$. The suspension was stirred overnight. The catalyst was removed by filtration. (2,3-$^2H_2$)-1,1-Diethoxy-2-octene: yield: 86% by gas chromatography (GC) analysis. Retention index (R_i) 1448, $R_{i(\text{deuterated})}$ 1446. ^1H nuclear magnetic resonance (NMR) ($CDCl_3$, 250 MHz) δ 5.63 (1H, *m*, C-3*H*), 5.46 (1H, *m*, C-2*H*), 5.29 (1H, *dd*, *J* = 7.5 Hz, 1.0 Hz, C-1*H*), 3.57 (4H, *m*, OCH_2), 2.11 (2H, *m*, C-4H_2), (6H, *m*, C-5H_2, C-6H_2, C-7H_2), 0.89 (9H, *m*, C-8H_3, OCH_2CH_3); ^{13}C NMR ($CDCl_3$, 63 MHz) δ 135.3 (C-3), 127.6 (C-2), 98.1 (C-1), 60.9 (OCH_2CH_3), 32.3 (C-6), 29.5 (C-5), 28.9 (C-4), 23.1 (C-7), 15.7 (OCH_2CH_3), 14.5 (C-8); electron impact mass spectrometry (EIMS) *m/z* (%) 85 (100), 155 (95), 57 (80), 129 (64), 103 (63), 62 (62), 109 (62), 83 (61), 75 (58), 55 (55), 73 (54), 47 (49), 69 (47), 101 (38), 111 (25), 156 (20), 171 (5), 199 (4) $[M-H]^+$, 200 (1) $[M]^+$; deuterated: 59 (100), 87 (97), 157 (95), 58 (78), 103 (76), 75 (76), 131 (72), 86 (70), 111 (68), 57 (63), 85 (55), 47 (58), 72 (50), 69 (49), 56 (45), 113 (27), 158 (25), 130 (17), 156 (13), 173 (5), 201 (4) $[M-H]^+$, 202 (1) $[M]^+$. 4-Toluenesulfonic acid (100 mg) and (2,3-$^2H_2$)-1,1-diethoxy-2-octene (10 mmol, 2.0 g) were dissolved in acetone (40 mL), and the mixture was stirred overnight (10). The solvent was removed *in vacuo,* and the product was purified by flash chromatography on silica gel with pentane/diethyl ether (8:2). Yield: 71% by GC analysis. R_i 1426, $R_{i(\text{deuterated})}$ 1423, retention factor (R_F) 0.39 (pentane/diethyl ether 8:2). ^1H NMR ($CDCl_3$, 250 MHz) δ 9.50 (1H, *d*, *J* = 8 Hz, C-1*H*), 6.85 (1H, *m*, C-3*H*), 6.11 (1H, *m*, C-2*H*), 2.33 (2H, *m*, C-4H_2), 1.25–1.4 (6H, *m*, C-5H_2, C-6H_2, C-7H_2), 0.89 (3H, *t*, *J* = 7 Hz, C-8H_3); ^{13}C NMR ($CDCl_3$, 63 MHz) δ 194.5 (C-1), 159.5 (C-3), 133.4 (C-2), 33.1 (C-6), 31.7 (C-5), 27.9 (C-4), 22.8 (C-7), 14.3 (C-8) ; EIMS *m/z* (%) 70 (100), 83 (76), 55 (68), 57 (50), 67 (45), 84 (26), 97 (24), 82 (24), 93 (19), 79 (15), 111 (6), 108 (5), 125 (2) $[M-H]^+$; deuterated: 41 (100), 57 (85), 55 (75), 59 (68), 85 (60), 72 (57), 70 (57), 71 (53), 83 (30), 69 (27), 99 (18), 95 (9), 113 (5), 110 (4), 127 (1) $[M-H]^+$.

2,3-$^2H_2$-Octenol. Sodium borohydride (1.6 mmol, 60.5 mg) was carefully added to a solution containing (2,3-$^2H_2$)-2-octenal (4 mmol, 504 mg) and methanol (10 mL). The mixture was stirred overnight. After addition of 2 N HCl (5 mL), the solution was extracted (3×) with diethyl ether (20 mL). The combined organic layer was dried (Na_2SO_4) and was concentrated *in vacuo*. Purification by flash chromatography on silica gel with pentane/diethyl ether (2:1) afforded pure product. Yield: 83% by GC analysis. R_i 1615, $R_{i(\text{deuterated})}$ 1612, R_F 0.33 (pentane/diethyl ether, 2:1). ^1H NMR ($CDCl_3$, 250 MHz) δ 5.64 (2H, *m*, C-2*H*, C-3*H*), 4.08 (2H, *d*, *J* = 5.5 Hz, C-1H_2), 2.02 (2H, *m*, C-4H_2), 1.2–1.4 (6H, *m*, C-5H_2, C-6H_2, C-7H_2), 0.88 (3H, *t*, *J* = 7 Hz, C-8H_3); ^{13}C NMR ($CDCl_3$, 63 MHz) δ 133.5 (C-2), 128.8 (C-2), 63.8 (C-1), 32.1 (C-6), 31.4 (C-5), 28.8 (C-4), 22.5 (C-7), 14.0 (C-8); EIMS *m/z* (%) 57 (100), 55 (60), 81 (59), 68 (50), 67 (45), 71 (24), 95 (20), 85 (15), 110 (8) $[M-H_2O]^+$, 99 (6), 128 (2) $[M]^+$; deuterated: 59 (100), 56 (67), 69 (64), 83 (53), 57 (50), 68 (47), 82 (31), 84 (23), 97 (14), 112 (7) $[M-H_2O]^+$, 130 (4) $[M]^+$.

5,6-$^2H_2$-Ethyl-3-oxooctanoate. Ethyl-3-oxo-5(*Z*)-octenoate (6.1 mmol, 1.12 g), synthesized according to Reference 2, was dissolved in degassed benzene (25 mL), and tris (triphenylphosphine)-chlororhodium (I) (0.07 mmol, 70 mg) was added (11). The flask was evacuated and closed with a balloon filled with H_2 or $^2H_2$. The suspension was stirred for several days until complete conversion was detected by TLC and GC. Yield: 98% by GC analysis. R_i 1859, $R_{i(\text{deuterated})}$ 1851, R_F 0.5 (pentane/diethyl ether, 9:1). ^1H NMR ($CDCl_3$, 250 MHz) δ 4.18 (2H, *q*, *J* = 7 Hz, OCH_2CH_3), 3.42 (2H, *s*, C-2H_2), 2.51 (2H, *t*, *J* = 7 Hz, C-4H_2), 1.28 (3H, *t*, *J* = 7 Hz, OCH_2CH_3), 1.1–1.65 (8H, *m*, C-5H_2, C-6H_2, C-7H_2), 0.87 (3H, *t*, *J* = 7 Hz, C-8H_3); ^{13}C NMR ($CDCl_3$, 63 MHz) δ 202.0 (C-3), 167.2 (C-1), 61.2 (OCH_2CH_3), 49.2 (C-2), 42.8 (C-4), 30.6 (C-6), 22.7 (C-5), 22.2 (C-7), 13.8 (C-8), 13.9 (C-9); EIMS *m/z* (%) 43 (100), 99 (55), 84 (42), 71 (42), 88 (39), 130 (33), 69 (20), 55 (15), 115 (13), 97 (12), 87 (10), 56 (10), 102 (9), 143 (8), 144 (3), 168 (2), 186 (1) $[M]^+$; deuterated: 43 (100), 44 (90), 101 (75), 45 (65), 73 (33), 88 (31), 84 (30), 130 (24), 131 (20), 85 (17), 56 (15), 115 (15), 69 (14), 102 (12), 98 (12), 144 (9), 145 (3), 170 (2), 188 (1) $[M]^+$.

5,6-$^2H_2$-Ethyl-3-hydroxyoctanoate. Sodium borohydride (1.9 mmol, 73 mg) was carefully added to a solution of (5,6-$^2H_2$)-ethyl-3-oxooctanoate (1.6 mmol, 298 mg) and ethanol (10 mL). The mixture was stirred overnight. After addition of 2N HCl (5 mL), the solution was extracted (3×) with diethyl ether (20 mL). The combined organic layer was dried (Na_2SO_4) and was concentrated *in vacuo*. Purification by flash chromatography on silica gel with pentane/diethyl ether (1:1) afforded pure product. Yield: 43% by GC analysis. R_i 1887, $R_{i(\text{deuterated})}$ 1883, R_F 0.33 (pentane/diethyl ether, 1:1). ^1H NMR ($CDCl_3$, 250 MHz) δ 4.18 (2H, *q*, *J* = 7 Hz, OCH_2CH_3), 3.97 (1H, *m*, C-3*H*), 2.42 (2H, *m*, C-2H_2), 1.28 (3H, *t*, *J* = 7 Hz, OCH_2CH_3), 1.2–1.6 (8H, *m*, C-4H_2, C-5H_2, C-6H_2, C7H_2); ^{13}C NMR ($CDCl_3$, 63 MHz) δ 173.6 (C-1), 68.3 (C-3), 60.3 (OCH_2CH_3), 41.5 (C-2), 36.8 (C-4), 31.9 (C-6), 25.4 (C-5), 22.8 (C-7), 14.2 (OCH_2CH_3), 13.9 (C-8). Synthesis of ^{3}H-labeled linoleic acid transformation products. An ethanolic solution (10 µL) of [9,10,12,13-^{3}H]linoleic acid (14.5 µCi) was injected into an apple, and the apple was worked up after 1 d of incubation as described in the *General work-up procedure* below. The diethyl ether extract was separated by reversed-phase HPLC analysis, and the four major radioactive peaks were collected. The individual fractions were diluted with the same amount of water and were subjected to RP18 solid-phase extraction (500 mg cartridge). The column was rinsed with water (3 mL), dried with nitrogen, and the compounds were eluted with 3 mL of diethyl ether. Fraction 1 consisted of a mixture of 13-keto-9(*Z*), 11(*E*)-octadecadienoic acid (13-KODE) and 9-keto-10(*E*), 12(*Z*)-octadecadienoic acid (9-KODE); fraction 2 contained a mixture of 13(*R*)-hydroxy-9(*Z*), 11(*E*)-octadecadienoic acid (13-HODE) and 9(*S*)-hydroxy-10(*E*), 12(*Z*)-octadecadienoic acid (9-HODE); fraction 3 was tentatively identified as a mixture of 11-hydroxy-12,13-epoxy-9-octadecenoic acid and 11-hydroxy-9,10-epoxy-12-octadecenoic acid; and fraction 4 was a mixture of the positional isomers of 9,10,13- and 9,12,13-trihydroxyoctadecenoic acid.

Application of substrates. Ethanolic solutions (up to 100 µL) of [1-^{14}C]linoleic acid (2.0 µCi), [1-^{14}C]oleic acid (2.0 µCi), [9,10,12,13-^{3}H]linoleic acid (15.7 µCi), [9,10,12,13,15,16-^{3}H]linolenic acid (23.0 µCi), $^{13}C_{18}$-linoleic acid (20 µg), unlabeled linoleic acid (20 µg), ^{3}H-labeled linoleic acid transformation products (0.25–0.47 µCi), $^{13}C_{18}$-9-HPOD (20 µg), $^{13}C_{18}$-10-HPOD (20 µg), $^{13}C_{18}$-12-HPOD (20 µg), $^{13}C_{18}$-13-HPOD (20 µg), $^{13}C_{18}$-13(*E,E*)-HPOD (20 µg), 2,3-$^2H_2$-2-octenol (5 mg), 2,3-$^2H_2$-2-octenal (5 mg), 5,6-$^2H_2$-ethyl-3-oxooctanoate (5 mg), 5,6-$^2H_2$-ethyl-3-hydroxyoctanoate (5 mg), 1,1-$^2H_2$-3-oxooctanol (5 mg), and 4,5-$^2H_2$-3-hydroxyoctanal (5 mg) were injected subepidermally with a syringe into ripe apples (*ca*. 40 g). Apples were kept up to 4 mon at 4°C connected to a hood.

General work-up procedure. Apples were cut into small pieces and homogenized with 100 mL of water. After centrifugation (4000 × *g*, 15 min), the solid residue was washed with 100 mL of water (3×). The supernatants were combined and passed through a conditioned polystyrene resin (XAD) column. After being rinsed with 500 mL of water, the column was eluted with 500 mL of diethyl ether and 750 mL of methanol. The extracts were concentrated and were analyzed by HPLC with ultraviolet (UV) and radiodetection, UV and evaporative light-scattering detection (ELSD), as well as GC–MS analysis and GC-isotope ratio mass spectrometry (IRMS). Solid residues were dried at 80°C for 24 h. Aliquots of liquid samples were added to 10 mL of scintillation cocktail (Emulsifier-Safe). Solid samples were combusted in a biological oxidizer. The formed $^{14}CO_2$ was absorbed in 12 mL of the scintillation cocktail, Oxysolve 400 (Zinsser, Frankfurt, Germany). Recoveries of ^{14}C as $^{14}CO_2$ from test combustions fortified with ^{14}C standards, immediately before combustion, were greater than 90%. All measurements were carried out by means of liquid scintillation counting using corrections for chemiluminescence.

GC–MS analysis. Analysis of the synthesized substrates and quantification of the labeling pattern of formed *R*-octane-1,3-diol was performed with a Fisons MD 800 Quadrupol mass spectrometer coupled to a Fisons GC 8000 with split injector (1:20) equipped with Fisons MassLab software (version 1.3). A J&W DB Wax 20 M fused-silica capillary column [30 m × 0.25 mm i.d.; thickness of the film (df) = 0.25 µm], which was programmed from 50°C for 3 min, then to 240°C at 4°C/min, was used with helium gas at a flow rate of 3 mL/min. The EIMS-operating parameters were: ionization voltage, 70 eV (electron impact ionization); ion source and interface temperature, 230 and 240°C, respectively. Chemical ionization (CI)–MS was performed with methane as reagent gas at 5 psi head pressure, source temperature 150°C and 70 eV.

On-line GC/combustion/IRMS (*GC–IRMS*). GC–IRMS analyses were performed on a Hewlett-Packard 5890 gas chromatograph connected to a Finnigan MAT delta S isotope mass spectrometer *via* a combustion interface. Isotope ratios were expressed as δ-values [‰] vs. the PDB standard ([^{13}C]/[^{12}C] isotope ratio = 0.0112372 for CO_2, yielded by the reaction of fossil $CaCO_3$ (Pee Dee Belemnite). The GC was equipped with a polyethylene glycol fused-silica capillary column (DB-Wax 20M 25 m × 0.32 mm i.d.; df 0.3 µm). Helium was used as carrier gas (14 psi head pressure). Samples were injected in the cool on-column mode. The following temperature program was applied: starting isothermal at 50°C for 3 min, then programmed to 240°C at 4°C/min, and finally held for 20 min.

HPLC analysis. Reversed-phase HPLC was carried out on an Eurospher 100 C-18 column (250 × 4 mm, 5 µm; Knauer, Berlin, Germany), using a flow rate of 1 mL/min, employing a Knauer HPLC pump MaxiStar coupled on-line to a Knauer multiwavelength UV/VIS detector (205, 234, or 254 nm) and an ELSD (SEDERE) at 40°C and 2.4 bar compressed air. Data acquisition was achieved using Eurochrom 2000 software (Knauer). Radio-HPLC was conducted using a Waters HPLC system equipped with a variable wavelength detector and a Canberra Packard A100 radioactivity detector with a 300 µL YSi scintillation tube. The following gradient was applied: solvent A (0.05% formic acid), solvent B (CH_3CN): 0–30 min, 5–80% B, 30–40 min, 80–100% B, 40–45 min, 100% B.

Normal-phase HPLC analysis was performed on an Eurospher Si 100 column (250 × 4.6 mm, 5 µm; Knauer), using a mixture of isohexane/2-propanol/acetic acid (98:2:0.5, by vol) at a flow rate of 1 mL/min.

NMR. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker WM 250 spectrometer with $CDCl_3$ ^{1}H (δ $CDCl_3$ 7.27 ppm) ^{13}C (δ $CDCl_3$ 77.0 ppm) (Merck, Darmstadt, Germany) as solvent. NMR data of the nonlabeled compounds were determined.

RESULTS

Application of [1-^{14}C]linoleic acid and [9,10,12,13-^{3}H]-linoleic acid. [1-^{14}C]Linoleic acid and [9,10,12,13-^{3}H]-

TABLE 1
Time Course and Distribution of Recovered Radioactivity (expressed as percentage of applied ^{14}C) in Different Fractions After the Application of [1-^{14}C]Linoleic Acid to Apple Fruits[a]

	Incubation time (d)					
	0.5	1	2	4	9	64

[a]XAD, polystyrene resin.

linoleic acid were injected subepidermally into ripe apples, and the fruits were stored for up to 4 mon at 4°C. Apples were taken after defined periods and were subjected to solid-phase extraction. Tables 1 and 2 show the ^{14}C and ^{3}H recovery data, respectively, for the different fractions as a percentage of the applied radioactivity. After 0.5 d, *ca*. 31% of the applied ^{14}C is lost as $^{14}CO_2$, indicating a rapid degradation of linoleic acid by β-oxidation (Table 1). The further release of $^{14}CO_2$ is probably caused by the degradation of transformation products formed from linoleic acid, e.g., 13(*R*)-hydroxy- and 13-keto-9(*Z*), 11(*E*)-octadecadienoic acid (13-HODE and 13-KODE), 9(*S*)-hydroxy- and 9-keto 10(*E*), 12(*Z*)-octadecadienoic acid (9-HODE and 9-KODE), and the stereoisomers of the 9,10,13- and 9,12,13-trihydroxyoctadecenoic acids were identified as major products in the diethyl ether extract after 0.5 d (data not shown). Already after 12 h, linoleic acid was completely degraded. The values for ^{14}C quantified in the methanol extract and the nonextractable residues remained stable at *ca*. 2 and 17% of the applied radioactivity, respectively (Table 1). The XAD flowthrough containing highly polar compounds, which do not adsorb to XAD, showed high amounts of radioactivity at days 2 and 4. ^{14}C-Acetate formed by β-oxidation accounts probably for the majority of this radioactivity. This result is consistent with the data obtained after the application of [9,10,12,13-^{3}H]linoleic acid (Table 2), as 40.3, 45.0, and 45.2% of applied ^{3}H were recovered in the XAD flowthrough at days 2, 4, and 9, respectively. The radioactivity in the diethyl ether extract gradually decreased during the incubation period of 129 d. In contrast, the content of ^{3}H gradually increased in the methanol extracts. In the diethyl ether extract obtained after 0.5 and 1 d 13- and 9-HODE (12:1), 13- and 9-KODE (4:1), and the stereoisomers of the 9,10,13- and 9,12,13-trihydroxyoctadecenoic acids were identified as the major degradation products of [1-^{14}C]- and [9,10,12,13-^{3}H]linoleic acid. However, *R*-octane-1,3-diol was the major compound detected by HPLC analysis in the diethyl ether extract obtained after 9, 16, 32, 64, and 129 d of incubation with [9,10,12,13-^{3}H]linoleic acid. Furthermore, 3-hydroxyoctyl β-D-glucoside accounted for more than 30% of the radioacivity in the methanol extract after 9, 16, 32, 64, and 129 d. Although 26.9% of the applied ^{3}H is recovered in the nonextractable residues after 12 h, this value constantly decreased to 14.4% after 129 d (Table 2). We assume that linoleic acid degradation products with chain lengths shorter than 18 carbon atoms are still attached to the insoluble β-oxidation complex, and therefore they contribute significantly to the radioactivity found after 0.5 d in the nonextractable residues (Tables 1 and 2). After 4 d, the majority of the ^{3}H linoleic acid pulse was degraded, and the rate of decrease slowed for ^{3}H recovered in the nonextractable residues.

Application of [U-^{14}C]oleic acid and [9,10,12,13,15,16-^{3}H]linolenic acid. Radio-labeled *R*-octane-1,3-diol was also detected after the application of [U-^{14}C]oleic acid to apples and 64 d of storage. The distribution of ^{14}C in the different fractions is shown in Table 3. The total incorporation into octane-1,3-diol, 3-hydroxyoctyl β-D-glucopyranoside and diol released by glycosidase from the nonextractable residue was *ca*. 9%. The respective values obtained for [1-^{14}C]hexanoic acid, [1-^{14}C]octanoic acid, and [U-^{14}C]linoleic acid were 5.2, 4.0, and 20.6% of applied radioactivity, respectively (8). Radio-labeled *R*-5(*Z*)-octene-1,3-diol was formed after the application of [9,10,12,13,15,16-^{3}H]linolenic acid. The recovery of radioactivity in the different fractions after solid-phase extraction is displayed in Table 3. *R*-5(*Z*)-Octene-1,3-diol, *R*-5(*Z*)-3-hydroxyoctenyl β-D-glucopyranoside, and *R*-octene-1,3-diol released by glycosidase from the nonextractable residue accounted for *ca*. 11% of the applied radioactivity. A comparable value was obtained for the incorporation of [9,10,12,13-^{3}H]linoleic into tritium-labeled octane-1,3-diol derivatives. The incorporation for [9,10,12,13-^{3}H]linoleic acid into *R*-octane-1,3-diol was smaller than the

incorporation of [U-^{14}C]linoleic acid into the diol. This implies that during the transformation a higher percentage of ^{3}H is lost compared to ^{14}C.

Application of ^{3}H-labeled linoleic acid transformation products. Tritium-labeled 13- and 9-HODE, 13- and 9-KODE and a mixture of the stereoisomers of the 9,10,13- and 9,12,13-trihydroxyoctadecenoic acids were produced by application of [9,10,12,13-^{3}H]linoleic acid to apples and were separated by semi-preparative HPLC analysis. Three fractions containing a mixture of ^{3}H-13- and 9-HODE (12:1), a mixture of ^{3}H-13- and 9-KODE (4:1), and a mixture of ^{3}H-labeled trihydroxyoctadecenoic acids, respectively, were injected into apples, and radioactively labeled *R*-octane-1,3-diol was determined after 9 d of incubation. Incorporation of HODE, KODE, and trihydroxy acids amounted to 3.6, 3.1, and 3.1% of the applied radioactivity, respectively.

Application of $^{13}C_{18}$ hydroperoxides. Uniformly labeled ^{13}C hydroperoxides 9-HPOD, 10-HPOD, 12-HPOD, 13-HPOD, and 13(*E,E*)-HPOD were synthesized according to Reference 9, and the individual compounds were separated by normal-phase HPLC analysis. After application of $^{13}C_{18}$-linoleic acid and $^{13}C_{18}$-HPOD to apples, δ ^{13}C values of formed *R*-octane-1,3-diol were determined by GC–IRMS (Table 4). Comparison of δ ^{13}C values ($^{13}C/^{12}C$ isotope ratios compared to the international standard) of the diol obtained from untreated apples (control) with those obtained after the administration of hydroperoxides and linoleic acid demonstrated the incorporation of ^{13}C isotopes into the target molecule. The most efficient precursor was linoleic acid followed by 10-HPOD and 9-HPOD. A common feature of these compounds was the *cis* double bond at carbon 13. Dilution of the isotopically labeled diol by the natural pool of octane-1,3-diol was similar in the individual experiments, as the apples contained similar amounts of the diol (Table 4). The lowest concentration of the diol was quantified in the experiment with 12-HPOD. Therefore, the actual δ ^{13}C value for octane-1,3-

[a]HPOD, hydroperoxyoctadecadienoic acid.

diol might be even lower when corrected by the amount of the natural pool.

Application of $^{2}H_2$*-labeled octanol derivatives*. Deuterated octanol derivatives were prepared by chemical synthesis, and 5 mg of each compound was administered to apples. After 9 d, apples were worked up by solid-phase extraction, and the labeling pattern of formed *R*-octane-1,3-diol was determined by GC–CI–MS. We used CI–MS in order to gain sensitivity, as the intensities for *m/z* 128 $[M - H_2O]^+$ and *m/z* 110 $[M - 2H_2O]^+$ in the EI mass spectrum of *R*-octane-1,3-diol were less than 1% and a molecular ion $[M]^+$ was not detected. The CI–MS fragment ion *m/z* 129 $[M - 2H_2O + H]^+$ exhibited an intensity of 25% and was used for the determination of the labeling pattern of the formed diol. A ratio (heavier isotopomer is expressed as the percentage of the lighter isotopomer) of 0.6% was obtained for *R*-octane-1,3-diol formed after the application of unlabeled linoleic acid. This value did not significantly increase after the administration of 2,3-$^{2}H_2$-octenol (0.8%) and 2,3-$^{2}H_2$-octenal (0.8%). Analysis showed that these substances were completely degraded and predominantly reduced to 2,3-$^{2}H_2$-octanol. Labeling patterns of 1.8 and 2.8% were obtained after the administration of 5,6-$^{2}H_2$-ethyl-3-oxooctanoate and 5,6-$^{2}H_2$-ethyl-3-hydroxyoctanoate, respectively. Complete degradation of the esters was observed. Although appreciable amounts of 1,1-$^{2}H_2$-3-oxooctanol and 4,5-$^{2}H_2$-3-hydroxyoctanal were detected after the incubation period, they showed the highest isotope content with 4.0 and 5.6%, respectively.

DISCUSSION

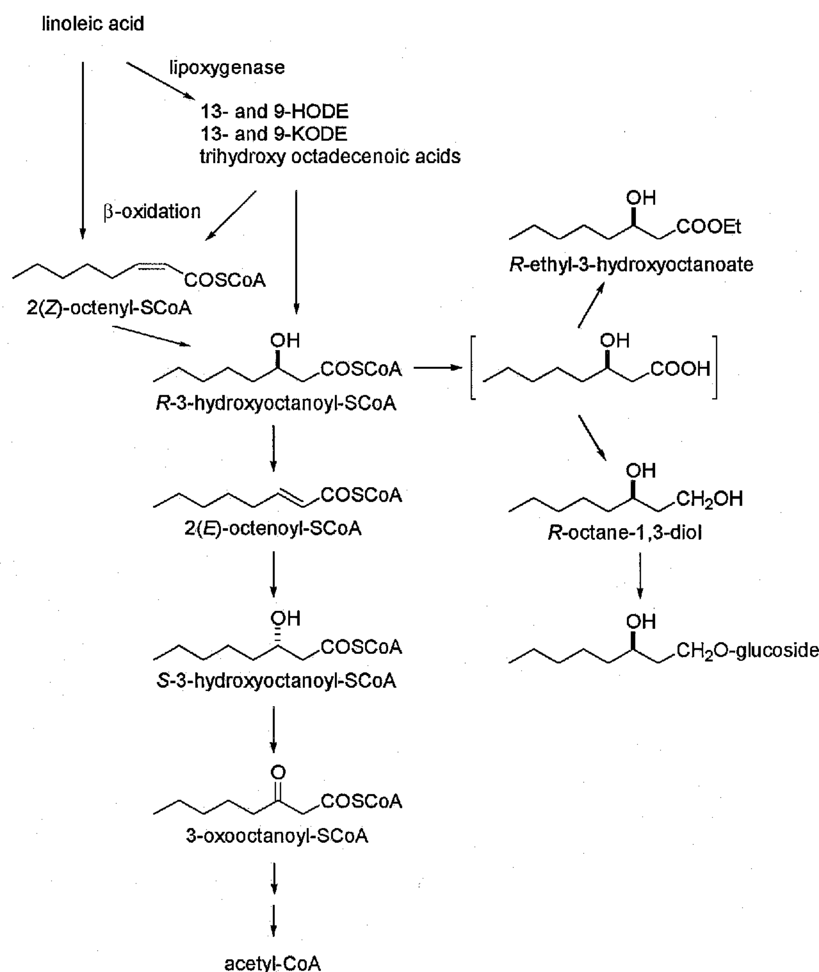
After harvesting, ripening of fruit is characterized by changes in color, texture, and aroma development that are related to physiological and metabolic processes. Apples are climacteric fruits, and carbon dioxide production as well as oxygen uptake increases by 50 to 100% during ripening, apparently without any change in respiratory quotient (16). Ethylene production increases about 1000-fold and at the same time as the respiratory rise (17). Softening, color change, formation of cuticular waxes, and synthesis of aroma compounds all seem to be associated with the climacteric.

Several apple cultivars such as Douce Moen, Peau de Chien and Rheinischer Bohnapfel accumulate high amounts of the enantiomerically pure *R*-octane-1,3-diol during this period. Early studies demonstrated that the diol is formed by degradation of linoleic acid either by β-oxidation or by a lipoxygenase-like reaction followed by the action of a lyase (8).

The time-course experiment with [1-^{14}C]- and [9,10,12,13-^{3}H]linoleic acid demonstrated rapid degradation of the unsaturated fatty acid. 13- and 9-HODE, 13- and 9-KODE, and the stereoisomers of trihydroxyoctadecenoic acid were identified as the major products after 12 h. They are probably artifacts formed by apple lipoxygenase during the injection of the substrate. However, radioactively labeled C_{10} compounds were not observed. In addition, a high portion of the fatty acid entered the β-oxidation pathway, as *ca*. 31% of the applied radioactivity was released as CO_2, and only even-carbon-numbered metabolites were formed. Degradation of HODE, KODE, and trihydroxy acids accounted for the additional release of $^{14}CO_2$ in the course of the experiment. Highest concentration of radioactively labeled *R*-octane-1,3-diol in the diethyl ether extract was obtained at days 4–9. After that period, the amount of the ^{3}H-labeled diol in the diethyl ether extract decreased, but in parallel the content of 3-hydroxyoctyl β-D-glucopyranoside in the methanol increased. However, diol derivatives accumulated constantly throughout the course of the study.

On the basis of the presented results we assume that *R*-octane-1,3-diol is formed by β-oxidation from linoleic acid in stored apples as shown in Scheme 1. Within the higher plant cell, fatty acid degradation is located in a distinct subcellular compartment, the peroxisome (18). Following activation by acyl-CoA synthase, the fatty acid is degraded by repetitive passages through the β-oxidation reaction sequence. As the *cis* double bonds form a barrier to degradation by continuous passages through the β-oxidation reaction sequence, additional enzymes (Δ^2, Δ^3-enoyl-CoA isomerase, 2,4-dienoyl-CoA reductase, D-3-hydroxyacyl-CoA dehydratase) are involved in the degradation of the activated unsaturated fatty acids (18). Common, straight-chain fatty acids are activated to their corresponding acyl-CoA by acyl-CoA synthase. The acyl-CoA synthase shows low activity toward short- and medium-chain acids, and it activates preferentially the C_{18} unsaturated fatty acids. However, low or no activity of acyl-CoA synthases toward oleic acid was reported. A single protein catalyzes the hydration of 2-*trans*-enoyl-CoA to 3-hydroxyacyl-CoA and the subsequent oxidation. In the course of peroxisomal β-oxidation the L(*S*)-isomer of 3-hydroxyacyl-CoA is a product of the enoyl-CoA hydratase activity as well as a substrate of the 3-hydroxyacyl-CoA dehydrogenase. However, D(*R*)-3-hydroxyacyl-CoA is formed by the 2-enoyl-CoA hydratase activity of the multifunctional protein when 2-*cis*-enoyl-CoA is the substrate instead of 2-*trans*-enoyl-CoA (18). Circumvention of the 12-*cis* double bond of linoleic acid can be achieved by involvement of D(*R*)-3-hydroxyacyl-CoA dehydratase at the C_8-intermediate level. By using purified enzymes in a reconstituted β-oxidation system, conversion of 4-*cis*-decenoyl-CoA (intermediate in linoleate degradation) to 2-*cis*-octenoyl-CoA was demonstrated (19), indicating that the plant multifunctional protein is able to perform this reaction. Hydration of 2-*cis*-octenyl-CoA yields D(*R*)-3-hydroxyoctanoyl-CoA. An epimerase converting D(*R*)-3-hydroxyacyl-CoA into L(*S*)-3-hydroxyacyl-CoA was thought to be involved in the β-oxidation pathway at this point. It was recently demonstrated that the epimerase activity results from two reactions: dehydration to 2-*trans*-enoyl-CoA and subsequent hydration to L(*S*)-3-hydroxyacyl-CoA.

We propose that during storage of the apples D(*R*)-3-hydroxyoctyl-CoA is formed from 2-*cis*-octenyl-CoA, and it accumulates due to an increased turnover of lipids and a limited capacity of the following enzyme(s) to convert the *R*-3-hydroxyoctyl-CoA to the *S*-enantiomer. Therefore, 3-hydroxy-



SCHEME 1

octanoic acid is released and subsequently reduced to *R*-octane-1,3-diol or transformed to *R*-ethyl-3-hydroxyoctanoate (2,7) in order to avoid feedback inhibition of the accumulated intermediate. In parallel, *R*-5(*Z*)-octene-1,3-diol is formed from the respective unsaturated intermediate *R*-3-hydroxy-5(*Z*)-octenyl-CoA.

Phospholipids and fatty acyl groups typical of cell membranes remain constant or increase slightly during apple ripening. However, [^{14}C]acetate incorporation by apple cortex into various phospholipids increases approximately tenfold from pre- to post-climacteric; this indicates that turnover of lipid increases during storage of apples, even though composition does not change (20,21). Apple alcohol dehydrogenase activity was demonstrated in apple tissues and whole apples (22,23). Apple tissue metabolizes fatty acyl precursors by β-oxidation to shorter-chain compounds and by reduction to alcohols (20). The activity decreases with carbon number of the substrate (24). Dehydrogenase activity is also responsible for the complete reduction of 2,3-$^2H_2$-octenol and 2,3-$^2H_2$-octenal to 2,3-$^2H_2$-octanol. Therefore, incorporation into *R*-octane-1,3-diol was negligible for these compounds. Our experiments demonstrated that the incorporation of labeled fatty acids into *R*-octane-1,3-diol increases from hexanoic acid, octanoic acid, oleic acid to linoleic acid, whereas linolenic acid was transformed to *R*-5(*Z*)-octene-1,3-diol. The 12-*cis* double bond was an important feature of fatty acid derivatives exhibiting a high incorporation (Table 4). The results showed that the diols are formed by β-oxidation of linoleic acid, and the point of regulation may be located at the C_8-intermediate level where the β-oxidation barrier caused by the 12-*cis* double bond of linoleate has to be surmounted. Comparison of the incorporation of [U-^{14}C]linoleic acid (20.6%) with [U-^{14}C]oleic acid (8.8%) demonstrated that the introduction of the *cis* double bond led to a significant increase of incorporation into *R*-octane-1,3-diol derivatives.

We expected a high labeling pattern of *R*-octane-1,3-diol after the application of 5,6-$^2H_2$-ethyl-3-hydroxyoctanoate and 5,6-$^2H_2$-ethyl-3-oxooctanoate. However, the values were smaller than those for 1,1,-$^2H_2$-3-oxooctanol and 4,5-$^2H_2$-3-hydroxyoctanal. The latter ones are probably reduced by a nonspecific reductase to *R*-octane-1,3-diol. In our opinion, the ketone and the aldehyde are not the natural precursors, as they are still detectable in the extracts. On the other hand, $^2H_2$-labeled ethyl-3-hydroxyoctanoate and ethyl-3-oxooctanoate are either degraded by β-oxidation in peroxisomes or used by the fatty acid *de novo* synthesis in the cytosol or plastids. The 3-

oxo-ester, a good substrate for both transformations, is converted to *R*-octane-1,3-diol only after its incorporation into linoleic acid and subsequent degradation. The low transformation of the 3-hydroxyester to the diol can be rationalized by the fact that the *R*-enantiomer is removed from the cytosol by *de novo* synthesis. Therefore, only small amounts of *R*-ethyl-3-hydroxyoctanoate enter the peroxisomes and act as precursor for the diol. The *S*-enantiomer, which is not used by *de novo* synthesis in the cytosol, is degraded in the peroxisomes without formation of *R*-octane-1,3-diol.

Summarizing, the biosynthesis of the C8-diols resembles the biogenesis of jasmonic acid, alkanolides, and the synthesis of mono-, di-, and triunsaturated esters identified in the aromas of quince and Bartlett pear (25). They can all be accounted for by β-oxidation of polyunsaturated linoleic and linolenic fatty acids as well as their oxygenated derivatives. The fatty acids are transformed to intermediates which cannot further be degraded by the multienzyme complex, and thus they are released and metabolized.

ACKNOWLEDGMENTS

We thank Dr. Pascal Brunerie for providing the apples and Thorsten König, Katja Hör, and Christiane Ruff for the GC–IRMS analyses. We extend appreciation to Prof. Gerhard Bringmann (Institute of Organic Chemistry) for the use of the radiochemical laboratory, and the assistance of Rene Roscher is gratefully acknowledged. The authors wish to thank the Deutsche Forschungsgemeinschaft (SCHW 634/1-2) and Fonds der Chemischen Industrie for funding.

Excess Vitamin E Decreases Canthaxanthin Absorption in the Rat

Susan H. Hageman, Li She, Harold C. Furr, and Richard M. Clark*

Department of Nutritional Sciences, University of Connecticut, Storrs, Connecticut 06269-4017

ABSTRACT: The recent attention given to the possible role of α-tocopherol (α-Toc) and carotenoids in the prevention and treatment of a variety of illnesses resulted in segments of the population increasing their consumption of these nutrient/antioxidants. Once consumed, α-Toc and carotenoids are thought to follow the same absorptive pathway and may influence each other's absorption, particularly when taken in large doses. The purpose of this study was to determine if α-Toc and the carotenoid, canthaxanthin (CTX), interact during absorption. Rats were intraduodenally infused with corn oil emulsions containing combinations of α-Toc (0 or 300 μmol/L) and CTX (5, 10, 15, 20 μmol/L) in a 2 × 4 factorial arrangement. Absorption was determined by measuring recovery of CTX and α-Toc in the mesenteric lymph. The amount of CTX in the lymph increased significantly with the amount infused into the duodenum. The overall efficiency of CTX absorption from emulsions without α-Toc averaged 12% with individual animals having a range of 8 to 18%. Efficiency of absorption was not related to concentration of CTX infused. When α-Toc (300 μmol/L) was added to the oil emulsion, the absorption of CTX was decreased by at least 50%. Recovery of α-Toc in the lymph averaged *ca.* 10% and was not affected by CTX. These results suggest that concurrent consumption of a large dose of α-Toc may influence carotenoid bioavailability.

Paper no. L8182 in *Lipids 34,* 627–631 (June 1999).

A vast amount of epidemiological data supports a positive relationship between the consumption of foods high in carotenoids and vitamin E and a decrease in chronic illnesses such as cardiovascular disease, certain cancers, cataract formation, and macular degeneration (1–3). As a result many individuals increased consumption of vitamin E and carotenoids by altering their diet or consuming dietary supplements (4). However, consumption of large amounts of these nutrient/antioxidants may be of concern as studies suggest that carotenoids interact with vitamin E during absorption (see recent reviews 5–7). The purpose of the current study was to investigate the interaction between vitamin E and carotenoids during absorption by using the mesenteric lymph duct cannulated rat intraduodenally infused with lipid emulsions. This animal model was previously used in our laboratory to study the absorption of canthaxanthin (CTX) and lycopene (8).

In designing the current study, two factors were of primary consideration. One factor was the type of carotenoid used. Carotenoids are often classified as either nonpolar carotenes (hydrocarbon carotenoids containing no oxygen) or as polar oxycarotenoids (xanthophylls containing at least one alcohol or carbonyl group). The physical properties of the two groups of carotenoids differ, affecting how they are handled during the lumenal phase of absorption. Within the intestinal lumen the nonpolar carotenes, such as β-carotene, are thought to locate in the hydrophobic core of lipid emulsions and bile salt micelles, while the more polar xanthophlls are thought to locate at the surface (9). Vitamin E is also thought to locate on the surface of lipid emulsions and micelles (10). Because vitamin E and polar xanthophylls are both surface components, the potential for their interaction within the intestinal lumen is greater than interaction between vitamin E and a nonpolar carotene. To maximize the potential for interaction between vitamin E and carotenoids, a xanthophyll was used in the current study. The xanthophyll selected was CTX. While CTX (4,4′-diketo-β-carotene) is not a major dietary carotenoid, it is widely used as a model carotenoid because it is relatively stable, has physical properties similar to other xanthophylls, and is commercially available (5–7).

The second factor considered when designing this study was the relative amounts of α-tocopherol (α-Toc) and CTX. Recently, concurrent consumption of equal molar concentrations of α-Toc and β-carotene was reported to enhance absorption of β-carotene in the ferret (11). This was somewhat unexpected as previous work with rats fed an excess of β-carotene observed a decrease in plasma and tissue levels of β-carotene in response to vitamin E supplementation (12,13). Interestingly, as indicated in literature from more than 50 yr ago, small doses of vitamin E enhanced utilization of β-carotene in the rat while large doses inhibited utilization (14,15). These observations suggest that the nature of vitamin E interaction with carotenoids may depend on their relative concentrations. We, therefore, decided to study the effect of an excess of α-Toc on CTX absorption.

MATERIALS AND METHODS

Animals and surgical procedures. The animal protocol used in this study was approved by The University of Connecticut Institutional Animal Care and Use Committee. Male Holtzman albino rats obtained from Harlan Sprague-Dawley (Indianapolis, IN) weighing 300–350 g at the time of surgery were used. Prior to surgery, animals were housed individually in stainless-steel cages in the Department of Nutritional Sciences Animal Facility. The animals were fed a standard laboratory diet—Purina Rodent Chow 5001 (Purina Mills, St. Louis, MO) and water *ad libitum*.

Surgery was performed under methoxyflurane-pentobarbital as previously described (16). A right subcostal incision was made, and the major mesenteric lymph duct was located. A beveled heparin-filled vinyl tube (medical grade, 0.50 mm i.d., 0.80 mm o.d.; Dural Plastics and Engineering, Dural, Australia) was threaded into the lymph duct and secured using methylcyanoacrylate adhesive. All visible accessory lymph ducts were blocked. A feeding tube was placed in the duodenum by passing micro-renathane tubing (MRE 040; Braintree Scientific, Braintree, MA) in a caudal direction through a gastric puncture. The abdominal wall was closed by suturing the muscle layer and skin.

Immediately following surgery, the rats were placed in a warm, dark environment and allowed to recover for *ca.* 36 h. The rats had access to water and received a glucose/electrolyte solution (Pedialyte; Ross Laboratories, Columbus, OH) at 2.0 mL/h during the recovery period *via* the duodenal feeding tube.

Following their recovery, three rats per treatment were infused (2.0 mL/h) for 12 h through the feeding tube. After infusing the emulsion for 6 h, lymph was collected for analysis during the final 6 h of infusion. After collection, the lymph was stored at −70°C until analyzed.

Preparation of carotenoid and tocopherol stock solutions. A stock solution of CTX (Sigma Chemical, St. Louis, MO) was prepared with dichloromethane. A stock solution of α-Toc (all-*rac*-α-tocopherol, 95%; Sigma Chemical) was prepared in methanol. The concentration of each stock solution was determined by absorption spectrometry. The concentration of CTX was estimated using the molar extinction coefficient E at 466 nm ($E^{1\%}_{1\,cm}$ = 2200) and α-Toc was estimated at 292 nm ($E^{1\%}_{1\,cm}$ = 75.8).

Treatment emulsions. Eight treatment emulsions containing combinations of α-Toc and CTX were used in this study. The final emulsion consisted of a phosphate-buffered saline solution (6.8 mmol/L Na_2HPO_4, 16.5 mmol/L NaH_2PO_4, 115 mmol/L NaCl, and 5 mmol/L KCl), 10 mmol/L sodium taurocholate (Sigma Chemical) and 3% (wt/vol) tocopherol-stripped corn oil (ICN, Costa Mesa, CA) with two levels of α-Toc (0, 300 μmol/L) and four levels of CTX (5, 10, 15, 20 μmol/L) in a 2 × 4 factorial arrangement.

To prepare emulsions, corn oil was placed in a round-bottomed flask, and appropriate amounts of CTX and α-Toc were added to the oil and mixed. Solvent was removed with a stream of nitrogen. Sodium taurocholate and buffer were added to the flask. The contents of the flask then were emulsified using a probe sonicator producing *ca.* 40 watts output for 15 s, repeated four or five times until no lipid droplets were observed (Branson Sonifier, Model 185; Baranson Sonic Power, Danbury, CT). An aliquot of the emulsion was extracted three times with hexane and the final concentration of CTX and α-Toc determined by high-pressure liquid chromatography (HPLC) as described below for lymph analysis.

Analysis of carotenoid and vitamin E in lymph. To correct for loss of CTX during preparation for HPLC analysis, ethyl β-apo-8′-carotenate (Fluka, Ronkonkoma, NY) was used as an internal standard. To correct for recovery of α-Toc, α-Toc acetate (Sigma Chemical) was added to the lymph as an internal standard. Extraction of total lipid from the lymph was by the method of Folch *et al*. (17).

Canthaxanthin and α-Toc were analyzed by HPLC using a Waters C18 Resolve column (15 cm × 3.9 mm; Millipore, Milford, MA) protected with an Upchurch C18 guard column (Upchurch Scientific, Oak Harbor, WA) and an isocratic mobile phase consisting of acetonitrile/dichloromethane/methanol/*n*-butanol /ammonium acetate (90:15:10:0.1:0.1, by vol) (18). CTX and ethyl β-apo-8′-carotenate were identified and quantified at a wavelength of 450 nm. α-Toc and its internal standard, α-Toc acetate, were identified and quantified at a wavelength of 290 nm.

Statistical analysis. Values presented are means ± standard deviation. This study was a completely randomized design with treatments in a 2 × 4 factorial arrangement (19). The statistical analysis was a two-way analysis of variance with three animals per treatment. Because the amounts of CTX infused were equally spaced, the linear, quadratic, and cubic relationship between amount CTX infused and the amount absorbed was tested. Simple correlation analysis and linear regression also were used to determine the statistical relationship between the amount of CTX infused and the amount recovered in the lymph. Values were considered statistically significant if P values were less than or equal to 0.05.

RESULTS

The lymph flow for rats in the study ranged from 2.0 to 3.3 mL/h with an average of 2.4 mL/h. Lymph flow was not influenced by treatment. Rats with a lymph flow of less than 2.0 mL/h or rats with less than 90% recovery of total lipid in the lymph were excluded from the study.

The results of the study are presented in Table 1. The concentration of CTX infused into the duodenum significantly ($P < 0.01$) affected CTX absorption. As shown in Figure 1, there was a significant ($P < 0.05$) linear relationship between CTX infused and the amount absorbed. The quadratic and cubic relationships were not significant. The amount of CTX infused and lymphatic output of CTX were highly correlated, for the treatments without α-Toc ($r = 0.99$; $P < 0.01$) and for the treatments with α-Toc ($r = 0.98$; $P < 0.01$). There was a significant negative effect of α-Toc on CTX absorption. For each

TABLE 1
Recovery of Canthaxanthin and α-Tocopherol in the Mesenteric Lymph of Rats[a]

	Treatments			
CTX (μmol/L)	α-Toc (0 μmol/L)	α-Toc (300 μmol/L)	α-Toc (0 μmol/L)	α-Toc (300 μmol/L)
	Lymphatic CTX (nmol/h)		Lymphatic α-TOC (nmol/h)	
5	1.22 ± 0.15	0.79 ± 0.44	N.D.	55.48 ± 26.44
10	2.74 ± 0.95	1.39 ± 0.54	N.D.	65.54 ± 40.05
15	3.53 ± 0.33	1.71 ± 0.62	N.D.	62.33 ± 32.54
20	4.92 ± 0.85	2.48 ± 0.98	N.D.	58.42 ± 37.43

[a]Values are means of lymph collected from three rats ± SD. Abbreviations: CTX, canthaxanthin; α-Toc, α-tocopherol; N.D., not detected (<10 (mol/L).

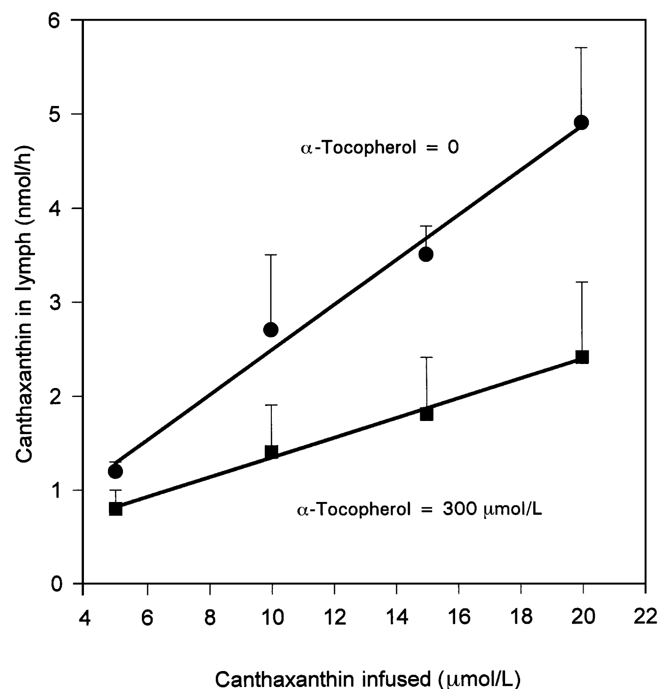

FIG. 1. Canthaxanthin absorption into the mesenteric lymph of rats intraduodenally infused with emulsions containing canthaxanthin and either no α-tocopherol or 300 μmol/L α-tocopherol. Values are means from three rats per treatment ± SD.

10 nmoles of CTX infused in treatments without α-Toc, 1.21 nmoles were recovered in the lymph (*ca.* 12% absorption). When CTX was infused with α-Toc, for each 10 nmoles of CTX infused only 0.53 nmoles was recovered in the lymph (*ca.* 5% absorption).

The interaction term in the analysis of variance for CTX and α-Toc was not significant at the .05 level. This is interpreted to mean that α-Toc decreased CTX absorption approximately the same for all treatment levels of CTX. This may be due to the large amount of α-Toc used in the study relative to CTX. The molar ratio of α-Toc/CTX at the lower treatment level of CTX was 60:1 and at the higher level of CTX the ratio was 15:1.

As shown in Table 1, the amount of α-Toc recovered in the lymph was not significantly affected at the .05 level by the amount of CTX infused. The average α-Toc recovered in the lymph from the treatments containing α-Toc was 60.4 nmoles/h (*ca.* 10% absorption). Comparing the standard deviations in Table 1, the variation associated with recovery of α-Toc in the lymph was greater than for CTX.

DISCUSSION

Reports of carotenoid and α-Toc interactions are often based on observations from animals fed very high levels of carotenoid, making the relevance of these observations to normal nutrition uncertain. The amounts of CTX and α-Toc infused per unit of body weight in the current study were comparable to those administered in human studies. Supplementation of β-carotene in human studies ranges from 20 to 300 mg/d (20). For an adult weighing 70 kg, the daily dose of β-carotene would be 0.29 to 4.3 mg/kg body weight. The CTX infused in the current study ranged from *ca.* 0.1 to 0.9 mg/kg body weight. The suggested therapeutic range for α-Toc starts at several hundred mg/d, with doses of up to *ca.* 10 mg/kg per day not expected to cause side effects (21). The amount of α-Toc provided to the rats in the current study was *ca.* 10 mg/kg body weight. This dose would be considered pharmacological.

The efficiencies of absorption of CTX and α-Toc in the current study were within the range of values reported in the literature. In a previous study we observed the efficiency of CTX absorption to range from 10–20% with an average of *ca.* 16% (8). The overall 12% efficiency of absorption of CTX in the current study is slightly less than we observed in our previous study. Actual measurements of carotenoid absorption are sparse. In studies using hospitalized patients with cannulated thoracic ducts, Goodman *et al.* (22) reported that 10% of an oral dose of radioactive β-carotene was absorbed into the lymph, while Blomstrand and Werner (23) presented data from a similar study reporting 23% absorption. Using a stable isotope of β-carotene, Novotny *et al.* (24) suggested that 22% of an oral dose of β-carotene in olive oil was absorbed in humans.

As presented in Table 1, the recovery of α-Toc in the mesenteric lymph averaged between 8 and 15% and was not influenced by CTX. These values are on the lower end of a range of values from animal studies. In a recent study of marginal zinc deficiency, Kim *et al.* (25) reported the efficiency of α-Toc absorption by control rats to be 13–17%. In a study comparing absorption of tocotrienols and α-Toc, the recovery of α-Toc in the thoracic lymph of rats was 10.5–24.5% (26). In an earlier study with rats, Bjorneboe *et al.* (27) reported 15% recovery of radioactive α-Toc in lymph, although this value may be low due to poor overall fat absorption in this study. A factor that may have influenced α-Toc absorption in the current study is the relatively large amount infused. Traber *et al.* (28) observed 65% recovery in the lymph when small amounts of α-Toc were infused into the duodenum and 18% when much greater amounts were infused.

Another difference between the current study and previous studies that may have decreased absorption of both CTX and α-Toc was the use of corn oil emulsions. Polyunsaturated fatty acids, such as those in corn oil, are reported to decrease the absorption of fat-soluble vitamins A, E, and K in rats (29). A similar study with rats by Gallo-Torres and colleagues (30) also reported a decrease in absorption of vitamin E with polyunsaturated fatty acids. They observed *ca.* 7% absorption of α-Toc when rats consumed α-Toc in emulsions with linoleic acid and 25% absorption of α-Toc when emulsions contained triolein. The mechanism by which polyunsaturated fatty acids decrease absorption of fat-soluble vitamins is unknown and deserves further study.

There are several animal studies reporting that carotenoids and vitamin E affect each other's bioavailability. Blakely *et al.* (31) fed rats β-carotene or CTX (at 0.048 or 0.2% of the diet) and observed a decrease in plasma α-Toc in response to feeding CTX, but not β-carotene. In a similar study Bendich and Shapiro (32) fed growing rats either CTX or β-carotene (2 g/kg body weight) and observed a reduction in plasma α-Toc in response to both carotenoids. Mayne and Parker (33) fed chicks CTX (0.5 g/kg body wt) for 6 wk and reported a decrease in plasma α-Toc. A similar study with chicks fed either astaxanthin or β-carotene resulted in a decrease in plasma α-Toc (34). Ferrets fed CTX (50 mg/kg body wt/d) for 2 yr also had a decreased plasma α-Toc (35). In these animal studies, it should be noted that high levels of carotenoids were fed to attain the effects on vitamin E.

As shown in Figure 1, addition of α-Toc (300 μmol/L) to the emulsion significantly ($P < 0.01$) decreased CTX absorption by *ca.* 50%. The effect of α-Toc on CTX absorption was similar at all treatment levels of CTX. While the mechanism by which α-Toc decreases the absorption of CTX is unclear, one possibility is that α-Toc and CTX compete for incorporation into bile salt micelles.

Normal absorption of carotenoids and α-Toc includes the transfer from lipid emulsion particles in the lumen of the small intestine into bile salt micelles. The incorporation of carotenoids into micelles is limited and was suggested as a controlling step in carotenoid absorption (36). As previously mentioned, CTX and α-Toc are thought to preferentially incorporate onto the surface of bile salt micelles while the less polar carotenes incorporate into the core of the micelle (9,10). If α-Toc and CTX compete for incorporation into the surface of the micelle, the presence of large amounts of α-Toc compared to CTX may decrease the incorporation of CTX into micelles and therefore depress absorption.

Recently, concurrent consumption of equal molar concentrations of α-Toc and β-carotene was reported to enhance absorption of β-carotene (11). This appears to be contrary to the observations in the current study. There are at least two major differences between the current study and the ferret study. One major difference is the relative amounts of carotenoid and α-Toc given to the animals in the two studies. The interaction observed when equal molar concentrations of α-Toc and carotenoid are given may be different from that observed when the amount of α-Toc consumed is 15 to 60 times greater than the amount of carotenoid consumed.

The second major difference between studies was the type of carotenoid used. In our study, α-Toc and CTX most likely compete for incorporation into the bile salt micelle surface. The β-carotene used in the ferret study would solubilize into the center of the micelle. Rather than compete for incorporation into micelles, α-Toc may actually enhance β-carotene inclusion into the micelle. This suggestion is based on observations made by El-Gorab and Underwood (37), who studied the solubility of retinol (polar) and β-carotene (nonpolar) into solutions containing bile salt micelles. Retinol was incorporated into the micelle surface, expanding the micelle and enhancing β-carotene solubilization into the micelle core. Possibly, α-Toc or CTX, being more polar than β-carotene, may function similarly to retinol and enhance solubilization of β-carotene into micelles.

In conclusion, concurrent consumption of a large amount of α-Toc with CTX was observed to decrease the absorption of CTX by roughly 50%. Additional research is needed to determine if the observed negative effect of α-Toc on CTX absorption varies with their relative concentrations. The observation that CTX did not influence α-Toc absorption should be viewed with caution as the study was not specifically designed to measure this. The large amount of α-Toc relative to CTX used in the current study and the large variation in measurement of lymphatic α-Toc made it difficult to detect any influence of CTX on α-Toc absorption.

The Metabolism and Distribution of Sesame Lignans (sesamin and episesamin) in Rats

Rumi Umeda-Sawada*, **Megumi Ogawa, and Osamu Igarashi**
Institute of Environmental Science for Human Life, Ochanomizu University, Tokyo 112-8610, Japan

ABSTRACT: In this study, we examined the distribution and metabolism of refined sesame oil lignans (sesamin and episesamin) in rat. For 8 wk rats were fed the diet including 0.5% (w/w) sesame lignans (sesamin and episesamin) with 5% (w/w) corn oil or eicosapentaenoic acid (EPA)-rich oil. The concentrations of sesamin and episesamin in rat liver after their administration for 8 wk were very low; both of them were less than 0.5 μg/g liver. These were observed in both oil groups although the fatty acid compositions of dietary oils were completely different. No significant difference existed in lymphatic absorption between sesamin and episesamin. To investigate the distribution of sesamin and episesamin in rats, the concentrations of sesamin and episesamin were determined in tissues and serum within 24 h after administration to rats. Sesamin and episesamin may be, at first, incorporated into the liver and then transported to the other tissues (lung, heart, kidney, and brain). They are lost from the body within 24 h after administration. There was no significant difference in lymphatic absorption between sesamin and episesamin, but the amount of sesamin was significantly lower than that of episesamin in all tissues and serum. These results suggest that sesamin is absorbed in lymph the same as episesamin, but that sesamin is subsequently metabolized faster by the liver.

Paper no. L8194 in *Lipids 34*, 633–637 (June 1999).

The sesame lignans (sesamin and episesamin) are compounds commonly found in refined sesame seed oil. Actually, episesamin is rarely found in unrefined sesame seed oil but is generated in equivalent amounts from sesamin by isomerization during the acid–clay bleaching of the oil (1). Sesame lignans (sesamin and episesamin) are known to have multiple physiological functions including antioxidant activity (2,3), anticarcinogenenicity (3), antihypertensive effects (4,5) in rats, and alleviation of hepatic injury caused by alcohol or carbon tetrachloride (6) in mice. In addition, sesame lignans also affect lipid metabolism by inhibiting cholesterol absorption from the small intestine, reducing 3-hydroxy-3-methylglutaryl CoA reductase activity in liver microsomes (7,8), and affecting the incorporation of linoleic acid into lipid subfractions (9) in rats. They also increase the content of dihomo-γ-linolenic acid by inhibition of Δ5 desaturase activity in the *Mortierella alpina* fungus and rat liver microsomes (10–13) and inhibit marked changes of the n-6/n-3 fatty acid ratio during dietary manipulation by reducing hepatic polyunsaturated fatty acid content in rat (14,15). Sesame lignans were also reported to have hypocholesterolemic effects in humans (16).

Almost all of the studies on the physiological effects of sesame lignans were performed using a mixture of sesamin and episesamin. The inhibitory effects of episesamin on the Δ5 desaturase in rat liver microsomes are almost the same as those of sesamin (17). However, the effect of sesamin and episesamin has been independently investigated only on Δ5 desaturase in rat microsomes. Since almost all of the sesame lignan studies have used a mixture of sesamin and episesamin, neither the functions of seamin and episesamin nor their distribution and metabolism *in vivo* have been studied independently.

The aim of this study was to investigate the distribution and metabolism of sesamin and episesamin and to compare them in rats. In this study, the following three experiments were done: (i) the investigation of the accumulation of sesamin and episesamin in rat liver after a long-term administion (8 wk), (ii) the comparison of lymphatic absorption of sesamin and episesamin, and (iii) the investigation of the distribution of sesamin and episesamin in rat tissues within 24 h after administration by measuring sesamin and episeamin *in vivo*.

MATERIALS AND METHODS

Materials. Sesame lignans (a mixture of sesamin and episesamin, 47:53,w/w) prepared from refined sesame seed oil and purified by the method of Fukuda *et al.* (1) and arachidonic acid (AA) ethyl esters (purity >99%) were kindly donated by Suntory Ltd. (Osaka, Japan). Eicosapentaenoic acid (EPA) ethyl esters (purity >97%) were kindly donated by Sagami Chemical Research Center (Kanagawa, Japan). Rapeseed oil was provided by Ajinomoto Co., Inc. (Tokyo, Japan), and corn oil was provided by Eisai Co. (Tokyo, Japan).

Experimental procedure. All experiments were approved by the Animal Experimentation Ethics Committee of Ochanomizu University (Tokyo, Japan).

Experiment 1. Administration of sesame lignans (sesamin

and episesamin) for 8 wk in rats. Three-week-old male Wistar rats were purchased from Nippon Clea Co. (Tokyo, Japan). The rats were initially fed on a commercial diet (CE-2; Nippon Clea Co.) for 1 wk. The animals, weighing an average of 98 g, were then divided into two groups of six animals each. They were housed individually in an air-conditioned room at 23 ± 1°C with a 12-h light–dark cycle and were given experimental diets (15 g/d, 1–7 d; 20 g/d, 8–17 d; 25 g/d, 18–28 d) and water *ad libitum* for 8 wk. The basal diet, prepared according to the standards given by the American Institute of Nutrition (AIN) (18), was provided by Eisai Co., and contained the following percentage of ingredients according to weight: casein, 20; glucose, 25; sucrose, 25; cornstarch, 15; filter paper, 5; AIN mineral mixture, 3.5; AIN vitamin mixture, 1; choline bitartrate, 0.2; and DL-methionine, 0.3. The test diets were prepared by mixing 0.5% (w/w) sesame lignans (a mixture of sesamin and episesamin, 47:53, w/w) and 5% (w/w) experimental oil mixtures with the basal diet. The oil mixtures used were: (i) the corn oil group, (ii) the EPA-rich oil group (EPA); EPA ethyl esters/rapeseed oil = 2:3. The fatty acid compositions of the corn oil and of the EPA mixture, similar to that in our previous study (13), are shown in Table 1. After having been fed the test diets for 8 wk, all rats were fasted overnight before they were sacrified and their livers were collected.

Experiment 2. Lymphatic absorption of sesame lignans (sesamin and episesamin). Seven-week-old male Wistar rats, weighing an average of 194 g, were purchased from Nippon Clea Co. and were maintained on a commercial diet (CE-2; Nippon Clea Co.) for 1 wk. Under Nembutal anesthesia, rats were subjected to cannulation of the left thoracic lymphatic channel, and an indwelling catheter was placed in the stomach by the method of Ikeda *et al.* (19,20). Normal osmotic solution containing 139 mM glucose and 85 mM NaCl was infused continuously until the end of lymph collection at a rate of 3 mL/h through the gastric tube. After surgery, animals were placed in restraining cages under lights to recover and allowed free access to drinking water containing 139 mM glucose and 85 mM NaCl. The next morning, after collection of lymph for 2 h (blank lymph), each animal was administered 3 mL of a test emulsion through the gastric tube, and the lymph was collected for 24 h. Lipid emulsions for intragastric administration contained 200 mg of sodium taurocholate, 50 mg bovine serum albumin (fatty acid-free, Sigma Chemical Co., St. Louis, MO), 100 mg EPA ethyl esters, 100 mg AA ethyl esters, and 50 mg of sesame lignans (sesamin and episesamin) per 3 mL of distilled water. In this experiment, EPA and AA ethyl esters were used because sesame lignans affected EPA and AA metabolism in rats in our previous studies (13–15). The mixture was emulsified by sonication just prior to use, and the lymph was collected periodically for 24 h.

TABLE 1
Major Fatty Acid Composition of Dietary Oils[a]

	16:0	18:0	18:1 (n-9)	18:2 (n-6)	18:3 (n-3)	20:5 (n-3)
Corn oil	11.2	2.3	31.0	55.6		
EPA	3.0	1.3	36.0	14.8	6.6	38.4

[a]Values are expressed as percentage of weight. EPA; eicosapentaenoic acid, acid-rich oil diet (EPA ethyl esters/rapeseed oil = 2:3).

Experiment 3. Incorporation of sesame lignans (sesamin and episesamin) into rat tissues. Seven-week-old male Wistar rats, weighing an average of 193 g, were purchased from Nippon Clea Co. and were maintained on a commercial diet (CE-2; Nippon Clea Co.) for 1 wk. They were then fasted overnight and given 1 g of an oil mixture, that is, EPA ethyl esters/rapeseed oil = 2:3, containing 100 mg sesame lignans (sesamin and episesamin). This amount corresponded to a day's dietary fat intake and sesame lignan intake in the previous experiment (13). The fatty acid composition of the oil mixture was the same as that of EPA group in Experiment 1 (Table 1). The liver, lung, heart, kidney, brain and serum were collected at 1, 3, 6, 9, and 24 h after the administration.

Determination of sesamin and episesamin in the tissues, lymph, and serum. The liver, lung, heart, kidney, and brain samples were homogenized in 3 vol of distilled water. Sesamin and episesamin were extracted from the homogenate solution, serum, and lymph by the Bligh-Dyer method (21). Sesamin and episesamin were analyzed using high-performance liquid chromatography (Waters LC Module I as an instrument and Waters 805 data station as a detector; Japan Millipore Ltd., Tokyo, Japan) on Unisil Pack 5C18-150A (4.6 × 150 mm) column. The mobile phase was methanol/water (70:30, vol/vol) at a flow rate of 1 mL/min. The ultraviolet detection wavelength for sesamin and episesamin was 290 nm.

Statistical analysis. All values are expressed as means ± SD. Significance of the difference in mean values was evaluated by Students' *t*-test.

RESULTS

Table 2 shows the concentrations of sesamin and episesamin in rat liver after administration of sesame lignans for 8 wk. Only small amounts of sesamin and episesamin were found in both groups; their concentrations were less than 0.5 µg/g liver.

Figure 1 shows the cumulative concentrations of sesamin and episesamin in lymph. There was no significant difference in lymphatic absorption between sesamin and episesamin, and their ratio of lymphatic absorption was almost the same.

To investigate the distribution of sesamin and episesamin

Corn oil	0.28 ± 0.11	0.49 ± 0.07***
EPA	<0.16	0.43 ± 0.07

[a]Results are means ± SD (n = 6). Value sharing asterisk is significantly different from sesamin of the same dietary oil group. ***$P < 0.001$.
[b]The detection limit of sesamin concentration is 0.09 µg/g liver, and two samples in the EPA group had undetectable amounts. See Table 1 for abbreviation.

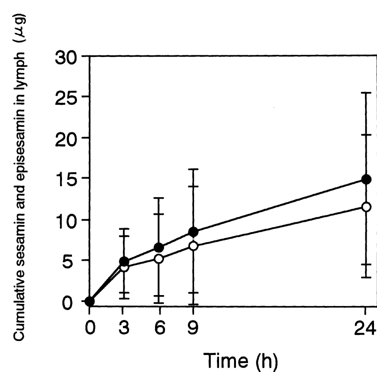

FIG. 1. Lymphatic absorption of sesamin (●) and episesamin (○). Lignans were extracted from the lymph collected at 3-h intervals during the first 9 h, and once at 24 h after their administration and analyzed by high-performance liquid chromatography (HPLC). The absorbed amounts are shown as cumulative values.

in rats, we administered sesamin and episesamin to rats and determined their concentrations in tissues within 24 h after administration. Time-dependent changes of orally administered sesamin and episesamin in the tissues and serum are shown in Figure 2. In the liver (Fig. 2A), the concentrations of sesamin and episesamin had reached a maximum at 3 h after administration, and were rarely found after 24 h. However, hepatic episesamin concentration was significantly greater than sesamin, despite the fact that equivalent amounts were administered. In the serum (Fig. 2B), episesamin concentration was also significantly greater than that of sesamin. The highest sesamin and episesamin concentrations were found between 3 and 6 h after administration. In the lung, heart, and kidney (Fig. 2C, D, E), episesamin concentration was significantly greater than sesamin, similar to liver and serum. The highest sesamin and episesamin concentrations were found at 6 h after administration. In the brain (Fig. 2F),

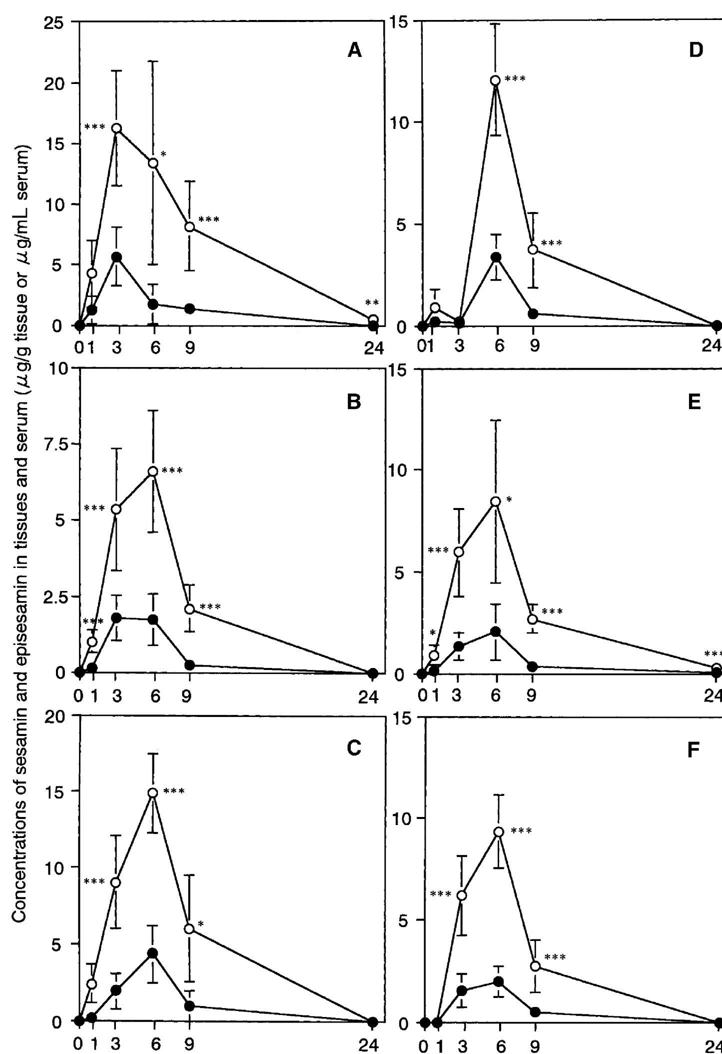

FIG. 2. Time-dependent changes of sesamin (●) and episesamin (○) concentrations in rat tissues and serum after oral administration. Lignans were extracted from the tissues and serum collected at 0,1,3,6,9, and 24 h after their administration and analyzed by HPLC. Differences at each time point are significant at ***$P < 0.001$, **$P < 0.01$, *$P < 0.05$. A, liver; B, serum; C, lung; D, heart; E, kidney; F, brain. See Figure 1 for abbreviation.

sesamin and episesamin were first detected at 3 h after administration—comparatively later than the other tissues. As in other tissues, episesamin concentration was significantly greater than sesamin. The highest sesamin and episesamin concentrations were found at 6 h after administration. Sesamin and episesamin were rarely found after 24 h in any tissues or serum.

DISCUSSION

In this study, we measured the concentrations of sesamin and episesamin in rats to investigate: (i) the accumulation of sesamin and episesamin in rat liver after long-term administering (8 wk), (ii) the lymphatic absorption of sesamin and episesamin, and (iii) the distribution of sesamin and episesamin in rat tissues and serum within 24 h after administration.

The concentrations of sesamin and episesamin in rat liver after their administration for 8 wk were very low; both of them were less than 0.5 μg/g fresh weight (Table 2). These were observed in both oil groups, despite the fact that the fatty acid compositions of dietary oils corn oil and EPA-rich oil were completely different. These results suggest that sesamin and episesamin are not accumulated in rat liver regardless of dietary oil variety even if administrated for 8 wk.

The lymphatic absorption of sesamin and episesamin was also investigated. Hirose *et al.* (8) reported that sesamin was absorbed and found in the rat lymph, and the proportion of sesamin recovered during 24 h was 0.15 ± 0.01%. In this study, the recovery of sesamin and episesamin was 0.06 ± 0.04% and 0.06 ± 0.03%, respectively. The proportion of lymphatic absorption of sesamin was lower than in the report of Hirose *et al.* (8), but we found that there was no significant difference in lymphatic absorption between sesamin and episesamin (Fig. 1).

It was observed that sesamin and episesamin were incorporated into rat tissues and serum after administration (Fig. 2). The highest sesamin and episesamin concentrations were found at 3 h after administration in the liver, between 3 and 6 h after in the serum, and after 6 h in the other tissues (lung, heart, kidney, and brain). These results suggest that sesamin and episesamin may be, at first, incorporated into the liver and then transported to the other tissues. Sesamin and episesamin are lost from the body within 24 h after their administration; that is the reason why they do not accumulate in rat tissues, even if administered for 8 wk. Hirose *et al.* (8) also reported that fecal excretion of sesamin was 15–35%.

There was no significant difference in lymphatic absorption between sesamin and episesamin (Fig. 1), but the amount of sesamin was significantly lower than that of episesamin in all tissues and serum (Fig. 2). These results suggest that sesamin is absorbed in lymph the same as episesamin but that sesamin is subsequently metabolized more rapidly by the liver. The results of our present study also suggest that sesamin may be metabolized in the liver, and it is possible that the metabolites may have physiological effects. Further investigation is needed about metabolism of sesamin and its metabolites in the liver.

This study has yielded three important findings: (i) sesamin and episesamin may at first be incorporated into the liver, after which they are transported to peripheral tissues through the bloodstream; (ii) sesamin and episesamin are lost from the body within 24 h and are not accumulated, and (iii) there was no significant difference in lymphatic absorption between sesamin and episesamin, but the concentration of sesamin was significantly lower than episesamin in rat tissues and serum. In this study, we revealed a part of the metabolism and distribution of sesamin and episesamin in rat.

ACKNOWLEDGMENTS

We greatly thank Suntory Ltd. and Dr. K. Akimoto, Institute for Fundamental Research, Suntory Ltd., Osaka, Japan, for the donation of sesame lignans and AA ethyl esters. We also express our thanks to Dr. K. Yazawa and Dr. K. Watanabe of Sagami Chemical Research Center for the donation of EPA ethyl esters.

Seasonal Variation in the Fatty Acid Composition and Quality of Sardine Oil from *Sardinops sagax caeruleus* of the Gulf of California

N. Gámez-Meza[a,]*, I. Higuera-Ciapara[b], A.M. Calderon de la Barca[b], L. Vázquez-Moreno[b], J. Noriega-Rodríguez[a], and O. Angulo-Guerrero[c]

[a]Departamento de Investigaciones Científicas y Tecnológicas de la Universidad de Sonora, Hermosillo, Sonora, Mexico, [b]Centro de Investigaciones en Alimentos y Desarrollo, A.C., Hermosillo, Sonora, Mexico, and [c]Unidad de Investigación y Desarrollo en Alimentos, Instituto Tecnológico de Veracruz, Vera Cruz, Mexico

ABSTRACT: One of the few sources of long-chain n-3 polyunsaturated fatty acids is fish oil, but considerable variation may exist according to species and season. In this study, the fatty acid profiles of sardine oils from *Sardinops sagax caeruleus* of the Gulf of California, Mexico, were evaluated in three seasonal catch periods. Oil quality was also evaluated by peroxide and free acid values. The most abundant fatty acids found in the oils were palmitic acid (19.3%), oleic acid (14.3%), eicosapentaenoic acid (EPA, 20.4%), and docosahexaenoic acid (DHA, 12.2%). There was no significant difference in the composition and quality among the six reduction plants where the samples were obtained. However, a significant difference in the proportion of EPA and DHA in one of the catch seasons analyzed was observed.

Paper no. L8186 in *Lipids 34,* 639–642 (June 1999).

Hydrogenated fish oil was widely consumed in the United States during the period 1921–1951, but this ceased when the California sardine fishery failed in the late 1940s (1,2). In the Gulf of California, sardine capture began in 1967. The greatest annual landing was 322,000 tons during 1988–1989, made up of 91% *Sardinops sagax caeruleus* (3), the most important species supporting the commercial fish industry in northwest Mexico (Fig. 1). Most landings are used by the fish meal industry in providing protein for animal feeds. By-product sardine oil from these factories could be an inexpensive source of long-chain n-3 polyunsaturated fatty acids (PUFA) for human consumption.

The potential health role of marine oil n-3 fatty acids, principally eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), was demonstrated in the prevention and treatment of cardiovascular diseases (4,5). In spite of this knowledge, diets in Western countries do not fulfill the daily requirements of n-3 PUFA, and people need to eat more fish, take dietary supplements, or consume fortified processed foodstuffs to obtain the beneficial effects (6,7). Although the best source of long-chain n-3 PUFA is fish and fish products (7,8), the fat content and the fatty acid profiles are variable among fish species because of differences in season and type of feed (9,10).

The seasonal variation in the fatty acid compositions of the sardine oil (*Sardinops* sp.) from the Gulf of California is unknown. For this reason, our objective was to study the fatty acid composition and quality of the sardine oil (*S. sagax caeruleus)* as related to the season of catch in the Gulf of California.

EXPERIMENTAL PROCEDURES

Sample handling. Fresh crude oil from whole sardine (*S. sagax caeruleus*) was collected from six different fish meal factories, from the two main ports in the Gulf of California, three in Guaymas, Sonora, and three in Yavaros, Sonora, Mexico (Fig. 1). The fish meal factories were chosen according to their processing capacity. The catch sample date was selected in accordance with the seasons of February, April, and June. All sardine oils were received in sealed 4-L glass

containers (dark color). The samples were kept on ice for transportation to the laboratory (≅5 h). Immediately upon arrival, the oil was stored at −40°C, and before use it was held at room temperature and allowed to reach 22ºC.

Methods. The fatty acid compositions of the sardine oils were determined after methyl esterification according to methods of the American Oil Chemists' Society (11), by procedure Ce 2-66, followed by gas–liquid chromatography on a Varian 6000 chromatograph (Varian de Mexico, Mexico City, Mexico), equipped with a 2-m long column, packed with 3% SP-2310/2% SP-2300 on Chromosorb WAW (Supelco Inc., Bellefonte, PA) (12). The oven program was 190°C (2 min), 190–220°C (2°C/min). The injector and flame-ionization detector were held at 250°C. The carrier gas was nitrogen at a flow of 20 mL/min. Retention times and peak areas were processed by a Varian CDS-401 computing integrator (Varian de Mexico). Identification and quantification were done by comparison with the retention times and peak areas of methyl ester standards of each fatty acid (Supelco Inc.). Menhaden oil fatty acid methyl esters (Sigma Chemical Co., St. Louis, MO) were also utilized as secondary standard. Three different commercial samples of fish oil capsules (A, B, and C) from the United States, labeled as high in n-3 fatty acids, were also analyzed for comparison.

Chemical analyses of the fresh crude oils were carried out according to official AOCS procedures (11). Saponification value was obtained by procedure Cd 3-25; conjugated dienes (Ti 1a-64) were measured using a spectrometer PE UV-vis Lambda 2S (Perkin-Elmer de Mexico, Mexico City, Mexico); refractive index (Cc 7-25) was measured using an Abbé refractometer (Bausch & Lomb, Rochester, NY). Peroxide value (PV) and free fatty acid (FFA) as percentage oleic acid were determined by titration (methods Cd 8-53 and Ca 5a-40, respectively). Reagents, including boron trifluoride (16% in methanol), and all solvents were of analytical grade and were purchased from Merck (Darmstadt, Germany).

Oil quality. A quality index (70–100 points) was applied to the fish oil samples according to the following scale: 90–100, good; 80–89, regular; 70–79, bad.

An oil with 10 meq/kg PV and 5% of FFA (as oleic acid) was indexed at 100 points according to suggested criteria (13–15). Five points were subtracted for each PV unit over 10 meq/kg as well as 5 points for each unit of FFA over 5%.

Statistical analysis. All values represent the mean of three analytical replications. Data obtained were subjected to one-way analysis of variance and Tukey's test analysis. Significance was declared at $P < 0.05$. Statgraphic computer software was used for statistical analysis (Statistical Graphics Corp., Rockville, MD).

RESULTS AND DISCUSSION

Fatty acid composition. There were no significant differences ($P < 0.05$) in the fatty acid composition between samples from Guaymas and Yavaros, probably because the vessels from each port fished in the same area of the Gulf of California. The most abundant fatty acids found in all the samples of sardine oil were palmitic acid (19.3%), oleic acid (14.3%), EPA (20.4%), and DHA (12.2%). The mean content of all saturated fatty acids was 31.9%, and PUFA totaled 37.6% (Table 1). Docosenoic acid (22:1) was very low in all samples and did not prejudice the measurement of EPA. The

PUFA/SFA	1.21	1.14	1.31	1.91	1.81

[a]Values are means of at least duplicates ± standard deviations. These values do not total 100% because minor fatty acids are not reported. Asterisk = encapsulated commercial oil labeled as "high n-3." Values in the rows with different superscripts (a–m) are significantly different ($P < 0.05$). PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids.

DHA and EPA accounted for 86.5% of total PUFA. The oil fatty acid profile is characteristic of filter-feeding fish such as menhaden and sardine (8,15).

The total n-3 content in the oil sardine samples was similar to that of one encapsulated fish oil labeled as "high n-3" (A) and significantly higher than another (C); this suggests that sardine oil could be an equally good source of n-3 PUFA for encapsulation (Table 2).

Effect of the catch season on EPA and DHA content. The EPA content in oil collected in February was significantly higher ($P < 0.05$) than that obtained at the other two sampling times, presenting a mean value of 23.9% (Table 1). In contrast, the DHA content of 9.6% was inversely decreased in the samples obtained in February. A similar observation was made for these species but in other areas of catch and in different months (16). This increase in EPA concentration could result from the sardine diet, because EPA is a principal fatty acid of phytoplankton subject to seasonal blooms. These changes may also be attributed to the spawning cycle (17), and the highest gonadosomatic index in the sardine *S. sagax*

caeruleus from the Gulf of California was observed during February (17,18).

Oil quality. Table 3 shows the chemical and physical characterization of the oils examined. The low PV and FFA guarantee the good quality of the fresh crude oils collected over 5 mon, the quality index ranging from 96 to 100. Oil samples from the different fish meal plants did not show severe oxidation (PV below 10 meq/kg), presumably because the samples analyzed were freshly produced oils. This ensures that the proportions of DHA and EPA are not affected, according to Fritsche and Johnston (19), who examined the effects of oxidation on the EPA and DHA content.

The fatty acid composition of the sardine from the Gulf of California represents a good source of long-chain n-3 PUFA year-round and could be useful as a nutritional supplement. The fatty acid content is similar to that found in several commercial encapsulated fish oils.

The sardine oil could be used after refining for either encapsulation or inclusion in processed foodstuffs for human consumption. Recently the use of similar fish oil such as menhaden oil was approved for human consumption, with specific limitations by the regulatory agencies of different countries (20).

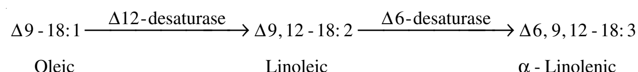
ABSTRACT: Two cDNA clones with homology to known desaturase genes were isolated from the fungus *Mortierella alpina*. The open reading frame in one clone encoded 399 amino acids and exhibited Δ12-desaturase activity when expressed in *Saccharomyces cerevisiae* in the presence of endogenous fatty acid substrate oleic acid. The insert in another clone contained an open reading frame encoding 457 amino acids and exhibited Δ6-desaturase activity in *S. cerevisiae* in the presence of exogenous fatty acid substrate linoleic acid. Expression of the Δ12-desaturase gene under appropriate media and temperature conditions led to the production of linoleic acid at levels up to 25% of the total fatty acids in yeast. When linoleic acid was provided as an exogenous substrate to the yeast cultures expressing the Δ6-desaturase activity, the level of γ-linolenic acid reached 10% of the total yeast fatty acids. Co-expression of both the Δ6- and Δ12-desaturase cDNA resulted in the endogenous production of γ-linolenic acid. The yields of γ-linolenic acid reached as high as 8% of total fatty acids in yeast.

Paper no. L8157 in *Lipids 34,* 649–659 (July 1999).

The primary products of fatty acid biosynthesis in most organisms are 16- and 18-carbon compounds. The relative ratio of chain lengths and degree of unsaturation of these fatty acids vary widely among species. Mammals, for example, produce primarily saturated and monounsaturated fatty acids, while most higher plants produce fatty acids with one, two, or three double bonds. Indeed, polyunsaturated fatty acids, such as linoleic acid (Δ9,12-18:2) and α-linolenic acid (Δ9,12,15-18:3), are regarded as essential fatty acids in the diet because mammals lack the ability to synthesize them. However, when ingested, mammals have the ability to metabolize linoleic and α-linolenic acids to form the n-6 and n-3 families of long-chain polyunsaturated fatty acids (LC-PUFA), respectively. These LC-PUFA are important cellular components conferring fluidity to membranes and functioning as precursors of biologically active eicosanoids such as prostaglandins, prostacyclins, and leukotrienes which regulate normal physiological functions (1).

In mammals, the formation of LC-PUFA is rate-limited by the step of Δ6-desaturation, which converts linoleic acid to γ-linolenic acid (GLA, Δ6,9,12-18:3) and α-linolenic acid to stearidonic acid (Δ6,9,12,15-18:4). Many physiological and pathological conditions have been shown to depress this metabolic step, and consequently, the production of LC-PUFA (2). However, bypassing the Δ6-desaturation *via* dietary supplementation with GLA can effectively alleviate many pathological diseases associated with low levels of PUFA (1). This beneficial effect prompted GLA-rich oil to become a much-demanded commodity. GLA is currently used in the treatment of eczema and mastalgia (1). At the present time, the predominant sources of GLA are oils from plants such as borage, evening primrose and black currant, and from microorganisms, such as *Mortierella* spp., *Mucor* spp. and cyanobacteria (3). However, these GLA sources are not ideal for dietary supplementation due to high fluctuations in availability, production/purification costs, unpleasant tastes and odors, and safety concerns. Thus, interest in developing more reliable and economical alternative sources of GLA and other LC-PUFA is growing.

The primary product of fatty acid biosynthesis in most plants and yeast is the monounsaturated, 18-carbon oleic acid. Two desaturation steps, at the Δ12 and Δ6 positions, necessary for the production of GLA from oleic acid, are shown below.



The cDNA clones encoding Δ12-desaturases were isolated from several species of cyanobacteria (4,5) and plants including *Arabidopsis* (6), soybean (7), and parsley (8). Δ6-Desaturase-encoding cDNA were isolated from cyanobacteria (9), borage (10), and nematode (11). These enzymes, as well as numerous examples of Δ15/n-3 desaturases (12,13), are all believed to be integral membrane proteins utilizing an acyl-

lipid substrate, and with the exception of the cyanobacterial enzymes, requiring cytochrome *b5* for the electron transport. The deduced amino acid sequences of these desaturases show a good deal of similarity, most notably in the region of three histidine-rich motifs that are believed to be involved in iron binding (14).

In this study, we utilized the filamentous fungus, *Mortierella alpina*, as the source for desaturase genes. This approach was based on the fact that this fungus is rich in linoleic acid and its LC-PUFA n-6 metabolites, GLA, and arachidonic acid (Δ5,8,11,14-20:4). Using a strategy based on degenerate oligonucleotide primers designed to amplify sequences present at the second and third His boxes of known acyl lipid desaturases (14), we previously isolated a cDNA clone encoding the *M. alpina* Δ5-desaturase (15). A similar strategy utilizing different degenerate primers was also successful in amplifying the same Δ5-desaturase (16). Such polymerase chain reaction (PCR) approaches are limited, however, by the degree of homology of the target cDNA to the particular primers and conditions utilized. In order to achieve a more thorough examination of the fatty acid desaturases present in the fungus, an alternate approach of sequencing random cDNA clones was also employed. Since it was known that the previously characterized membrane-bound Δ12- and Δ15-desaturases, as well as the available cyanobacterial Δ6-desaturase sequences, showed significant amino acid sequence conservation, particularly in the histidine-rich regions, it was postulated that potential *Mortierella* desaturase cDNA could be recognized based on their deduced amino acid sequences. Indeed, this was the strategy that led to the identification of a borage Δ6-desaturase (11) and a castor oleate 12-hydroxylase (17). Because the first histidine-rich motif (His-box) region can occur from 80 to 160 amino acids (240–480 bp) from the N-terminus, and the third region can be roughly 250–300 amino acids (750–900 bp) into the desaturase sequence (14), 300–400 bp of DNA sequence information obtained from the 5′-end of full-length clones might not contain the regions of highest homology among desaturases. Since at the time this work was initiated, no desaturase sequence was identified from *M. alpina* and it was not known how much homology they might display to known sequences, we chose to obtain information from the internal sequences of cDNA clones instead of the 5′-end of full-length clones.

Expression of the *Mortierella* desaturase candidates was carried out in baker's yeast, *Saccharomyces cerevisiae*. This eukaryotic organism was previously shown to be a suitable host containing the necessary cofactors for functional expression of acyl-lipid desaturases. *Saccharomyces cerevisiae* contains a Δ9-desaturase capable of producing monounsaturated palmitoleic and oleic fatty acids, but does not carry out further desaturations. Expression of an *Arabidopsis FAD2* cDNA in *S. cerevisiae* resulted in the production of linoleic and Δ9,12-hexadecadienoic acids from the endogenous oleic acid and palmitoleic acid substrates, respectively (18,19). By culturing *S. cerevisiae* in the presence of exogenous fatty acid substrates, functional expression of a nematode Δ6-desaturase (11) and a fungal Δ5-desaturase (15,16) were demonstrated. In this study, we report the isolation of Δ12- and Δ6-desaturases from *M. alpina*. Simultaneous expression of these two genes in *S. cerevisiae* drives production of GLA at levels of up to 8% of the total fatty acids without the requirement for exogenous fatty acid substrates.

MATERIALS AND METHODS

cDNA library construction. Synthesis of *M. alpina* cDNA was described previously (15). Briefly, double-stranded cDNA were sized fractionated by column chromatography. The two fractions containing the largest cDNA were pooled and packaged to produce a "full-length" library (M7+8) containing *ca.* 6×10^6 clones with an average insert size of 1.77 kb. An additional library, (M11), to be used for random sequencing was constructed by packaging a fraction containing smaller cDNA, which would most likely contain less than full-length clones as well as full-length copies of shorter messages. The average insert size of this library was 1.1 kb; the titer was 240 pfu/µL. Library screening and plaque purification were carried out with the M7+8 library using standard protocols as described previously (20).

Random DNA sequencing. The cDNA-containing plasmids were excised from the λ-ZipLox clones following manufacturer's recommendations (Life Technologies, Gaithersburg, MD). Bacterial cells were plated on ECLB plates containing 50 µg/mL penicillin. DNA sequence was obtained from the 5′-end of the cDNA insert and compared to the National Center for Biotechnology Information nonredundant database using a BLAST server.

Plasmid construction. For expression in yeast, the *M. alpina* cDNA clones for Δ6- and Δ12-desaturase genes were first modified to create *Eco*RI and *Xho*I restriction sites adjacent to the start and stop codons, respectively. Each gene was amplified from the respective cDNA clone using PCR with a pair of primers which have homology to the 5′-end and 3′-end of the gene (restriction sites underlined):

RO-192 (5′-TAGGCTGAATTC**ATG**GCTGCTGCTCCCAGTGTGAGGACG-3′)

and

RO-193 (5′-AACTGCCTCGAG**TTA**CTGCGCCTTACCCATCTTGGAGGC-3′)

are forward and reverse primers with homology to the sequences around the initiation and termination codons of Δ6-desaturase (Ma524), respectively (shown in bold).

RO-194 (5′-TACCTCGAATTC**ATG**GCACCTCCCAACACTATCGATGCC-3″

and

RO-195 (5′-AACCGTCTCGAG**TTA**CTTCTTGAAAAAGACCACGTCTCC-3′)

are forward and reverse primers homologous to the 5′- and 3′-ends of the Δ12-desaturase (Ma648), respectively.

The *Eco*RI/*Xho*I putative desaturase gene fragments were cloned into the vector pYES2 (Invitrogen, San Diego, CA) for inducible expression under the control of GAL1 promoter

in yeast. This vector contains a selectable marker gene which confers uracil prototrophy in the host. The plasmids containing the putative Δ6-desaturase (Ma524) and Δ12-desaturase (Ma648) genes were designated as pCGR-5 and pCGR-7, respectively. To construct pCGR11 and pCGR12, the Δ6- and Δ12-desaturase coding regions were isolated from pCGR5 and pCGR7, respectively, as *Eco*R1-*Xho*I fragments and cloned into the pYX242 vector (Novagen, Madison, WI) digested with *Eco*R1-*Xho*I. The pYX242 vector contains a marker gene for selection of leucine prototrophy in the host and has the promoter of TPI (yeast triose phosphate isomerase gene), which allows constitutive expression. Co-expression of recombinant Δ6- and Δ12-desaturases can be achieved by simultaneous introduction of pCGR5 with pCGR12 or pCGR7 with pCGR11 in the appropriate host requiring both uracil and leucine for growth.

Yeast transformation and expression. Different combinations of pCGR5, pCGR7, pCGR11, and pCGR12 were introduced into a host strain of *S. cerevisiae*, SC334, which contains a mutation (*reg1-501*) that alleviates catabolite repression of GAL1 promoter (21). Transformation was done using the PEG/LiAc protocol as described previously (22). Transformants were selected by plating on synthetic medium plates with appropriate selection (21). Cells containing pCGR5 and pCGR7 were selected on media lacking uracil, whereas the pCGR11 and pCGR 12 constructs were selected on media lacking leucine.

Results from our preliminary studies showed that expression of genes (Δ6- and Δ12-desaturases) was enhanced when cultures were grown in synthetic medium at 15°C. In the present study, colonies of transformants were first grown overnight at 30°C in synthetic media. Overnight cultures (2–4 mL) were then used to inoculate 100 mL of minimal media for studying the activities of recombinant desaturases. Galactose was added at a final concentration of 2% to the medium for induction of GAL1 promoter in the strains containing pCGR5 and pCGR7. When the enzyme substrate was provided as the exogenous fatty acid, the fatty acid was supplemented at a concentration of 25 μM. The culture was grown for 48 h at 15°C, and subsequently harvested by centrifugation. Cell pellets were washed once with sterile *dd* H_2O to remove the media. The host strain transformed with vector alone was used as a negative control in all experiments.

Fatty acid analysis. The extraction of the yeast lipids followed the procedures described previously (15). Briefly, washed yeast pellets were extracted with 15 mL of methanol and 30 mL of chloroform containing 100 µg of tridecanoin. After extraction, the yeast lipids were first saponified, and the liberated fatty acids were methylated. The distribution of fatty acid methyl esters was then analyzed by gas chromatography (GC) using a Hewlett-Packard 5890 II Plus gas chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a flame-ionization detector and a fused-silica capillary column (Supelcomega; 50 m × 0.25 mm, i.d., Supelco, Bellefonte, PA). In the present study, the quantity of the product formed and the rate of conversion of substrate to product (conversion rate = product/(substrate + product)) were calculated to reflect the expression/activity of a given desaturase in this yeast cell assay system.

The identification of a given novel fatty acid was verified by gas chromatography–mass spectrometry (GC–MS) using a Hewlett-Packard mass selective detector (model 5920) operating at an ionization voltage of 70 eV with a scan range of 20–500 Da. The mass spectra of new peaks were compared with those of authentic standards (Nu-Chek-Prep, Elysian, MN) and those in the database NBS75K.L (National Bureau of Standards).

RESULTS

Isolation of a Δ6-desaturase-like cDNA clone from M. alpina. DNA sequence was obtained from the 5′-end of cDNA in randomly picked clones from the *M. alpina* M11 library. Sequence of one such clone, Ma524, exhibited limited homology to a known *Synechocystis* Δ6-desaturase (9) when compared to the databanks. Overall, the level of homology was low (BLAST score 114; P 4.7×10^{-7}). The partial cDNA was used as a probe to isolate a full-length clone, designated pCGN5532, from the M7+8 library. The cDNA insert in pCGN5532 (GenBank accession AF110510) was 1617 bp and contained an open reading frame encoding 457 amino acids flanked by 70 and 75 bp of 5′- and 3′-untranslated regions, respectively. The deduced amino acid sequence is aligned to that of borage Δ6-desaturase (10) in Figure 1. The three "His-boxes," known to be conserved among membrane-bound desaturases (6,14), were found to be present at amino-acid positions 172–176, 209–213, and 395–399 in this sequence. Similar to other membrane-bound Δ6- and Δ5-desaturases, the final "HXXHH" histidine box motif was found to be QXXHH (11,15,16). The predicted amino-acid sequence from this clone is similar to the Δ6-desaturases from the *Synechocystis* spp. and *Spirulina* spp. (9), the borage Δ6-desaturase (10), the nematode *Caenorhabditis elegans* (11), and a cytochrome *b5*/desaturase fusion protein from sunflower (23). As reported for other Δ5/Δ6 desaturases, the amino terminus of the protein encoded by pCGN5532 was also homologous to cytochrome *b5* proteins.

Isolation of a Δ12-desaturase-like cDNA clone from M. alpina. DNA sequence obtained from the 5′-end of another random clone, Ma648, showed homology to the soybean n-6 desaturase (7). The homology of the partial *M. alpina* sequence was again relatively weak (BLAST score 110, P 2.0×10^{-6}). Analysis of the open reading frames beginning at the 5′-end of Ma648 indicated that the first possible methionine was in frame +1 which was the frame that showed desaturase homology. Alignment of this open reading frame to 5′-sequence of other Δ12-desaturases indicated that the *M. alpina* Ma648 clone was full-length. This cDNA was designated pCGN5533, and no other corresponding clones were obtained by library screening. The 1488 bp cDNA insert in pCGN5533 (GenBank accession AF110509) contains 78 bp of 5′- and 113 bp of 3′-noncoding sequences flanking an open

FIG. 1. Comparison of the deduced amino-acid sequences of *Mortierella alpina* and a prototype Δ6-desaturase from borage. Conserved amino acids are shaded light; identical residues are shaded dark. Ma Δ6, *M. alpina* Δ6-desaturase, pCGN5532; Bo 6, Δ6-desaturase from *Borago officinalis* (10). The three regions containing histidine residues (His-boxes) conserved among acyl-lipid desaturases and hydroxylases are overlined.

reading frame encoding 399 amino acids. Figure 2 shows the alignment of the deduced amino acid sequence of pCGN5533 to the *FAD2* (microsomal Δ12 desaturase) from *Arabidopsis* (6). The three His-boxes are again present at positions 111–115, 147–151, and 338–342. Unlike Ma524, no homology to cytochrome *b5* sequence is present on the N-terminus of this clone.

Functional expression of M. alpina *desaturase clone pCGN5533 (Ma648) in yeast*. In order to assess the functional specificity of the various *M. alpina* desaturase clones, the coding regions were expressed in *S. cerevisiae* using the inducible GAL1 promoter found in the commercial vector pYES2. As described previously (15), recombinant yeast cells were grown in the presence of various fatty acids in order to provide substrates for desaturases involved in LC-PUFA production. The deduced coding region of pCGN5533 (Ma648) was inserted into the yeast expression vector pYES2 to create pCGR7. Fatty acid profiles of lipid fractions from yeast grown in the absence of exogenous fatty acid substrate show that two novel fatty acids were produced in SC334(pCGR7) (Fig. 3A). The first fatty acid showed a mass peak $m/z = 266$ (the expected molecular ion of 16:2), a retention time of 13.48 min, and a fragmentation pattern identical to those of Δ9,12-16:2 (Fig. 3B). The second novel fatty acid exhibited a retention time (17.28 min) in GC (Fig. 3A), mass peak ($m/z =$ 294) and fragmentation pattern in GC–MS (data not shown) identical to those of the authentic linoleic acid (Δ9,12-18:2). These findings indicate that the endogenous oleic acid (Δ9-18:1) was converted to linoleic acid (Δ9,12-18:2) by a Δ12-desaturase activity expressed from the plasmid pCGR7. The rate of conversion was found to be 71.4% (Table 1).

Functional expression of M. alpina *desaturase clone pCGN5532 (Ma524) in yeast*. The recombinant yeast SC334(pCGR5), containing the Ma524 cDNA, was grown in the presence of exogenous linoleic acid (Δ9,12-18:2) which is the substrate for Δ6-desaturation. Analyses of the fatty acid profile in the yeast lipid fraction indicate that the exogenous linoleic acid was incorporated into lipids of both nontransformed and transformed yeast (Fig. 4). However, GC analysis revealed the presence of a novel fatty acid in the SC334(pCGR5) yeast that was not present in yeast transformed with vector alone. This novel fatty acid had a retention time of 17.96 min in GC (Fig. 4). Mass peak $m/z = 292$ and fragmentation pattern of this fatty acid in GC–MS were identical to those of the authentic GLA (Δ6,9,12-18:3) standard; however, the fragmentation pattern was different from that of the α-linolenic acid (Δ9,12,15-18:3) standard (data not shown). Thus, the Ma524 cDNA expressed from pCGR5 encodes a Δ6-desaturase. The expressed enzyme converted 29.4% of the incorporated linoleic acid to GLA (Table 1).

Since there were no traces of α-linolenic acid (Δ9,12,15-18:3) produced from the exogenous linoleic acid (Δ9,12-18:2) in the recombinant yeast strains, it is suggested that the enzyme produced by pCGR5 does not possess Δ15-desaturase activity. In addition, when exogenous α-linolenic acid was included in the growth medium, 3.9% of the incorporated α-linolenic acid (Δ9,12,15-18:3) was converted to stearidonic acid (Δ6,9,12,15-18:4). The identity of stearidonic acid was verified by both GC and GC–MS (data not shown). This finding further confirms the enzyme to be a Δ6-desaturase.

TABLE 1
Production of Linoleic Acid and GLA in Yeast Lipid Fraction

SC334 containing	Total fatty acids[a] (μg)	Oleic (wt%)	Linoleic (wt%)	GLA[c] (wt%)
pYES2	440.1	23.2	—	—
pCGR5[b]	497.1	10.2	25.1	10.3
pCGR7	460.9	10.0	24.8	—
pCGR11/pCGR7	340.8	10.2	10.1	7.9
pCGR5/pCGR12	367.9	6.7	7.0	6.6

[a]The volume of culture used for lipid extraction was 100 mL.
[b]Exogenous linoleic acid (25 μM) was added.
[c]No α-linolenic acid was detected. GLA, γ-linolenic acid.

In the absence of exogenous linoleic acid, the lipid fraction of the yeast strain expressing the Δ6-desaturase cDNA produced two novel fatty acids (Fig. 5A). The first novel fatty acid showed a mass peak $m/z = 266$, which is the expected molecular ion of 16:2. Although the GC–MS fragmentation patterns of this novel fatty acid and the authentic Δ9,12-16:2 were similar, they were different in intensity (Figs. 3B and 5B), and retention time (12.89 vs. 13.48 min) in GC (Figs. 3A and 5A). Since this novel fatty acid was produced in the presence of the Δ6-desaturase, it was most probably the Δ6,9-16:2. The second novel fatty acid produced in SC334(pCGR5) had an identical retention time (16.95 min) in GC (Fig. 5A), mass peak $m/z = 294$, and fragmentation pattern in GC–MS to that of the Δ6,9-18:2 standard (data not shown).

Production of GLA. As shown above, the recombinant Δ12- and Δ6-desaturases were effective in converting their substrates (endogenous oleic acid and exogenous linoleic acid) to their respective products, linoleic acid (Fig. 3) in SC334(pCGR7) and GLA (Fig. 4) in SC334(pCGR5). We were interested in determining the feasibility of producing GLA in a recombinant yeast strain in the absence of exogenously added fatty acid substrates. The biosynthesis of GLA from the endogenous oleic acid in *S. cerevisiae* would require the simultaneous expression of Δ12- and Δ6-desaturases. In order to allow co-expression of the Δ6- and Δ12-desaturase cDNA, they were cloned under the control of the constitutive TPI promoter into the leucine-selectable vector pYX242 to create pCGR11 and pCGR12. Both combinations of promoters GAL1 and TPI were assayed for production of GLA. The co-expression of pCGR11 (containing Δ6-desaturase gene under the control of TPI) and pCGR7 (containing Δ12-desaturase gene under the control of GAL1) resulted in *ca.* 7.9% of GLA in total fatty acids of SC334(pCGR7, pCGR11) (Table 1). The rates of conversion from oleic acid to linoleic acid and from linoleic acid to GLA were *ca.* 50 and 44%, respectively. In SC334 (pCGR12, pCGR5) containing the Δ6-desaturase gene behind GAL1 and the Δ12-desaturase gene behind TP1, a level of 6.6% of GLA was found in the total fatty acids (Table 1). In these recombinant yeast strains, the

FIG. 2. Comparison of the deduced amino-acid sequences of *M. alpina* and a prototype Δ12-desaturase from *Arabidopsis*. Conserved amino acids are shaded light; identical residues are shaded dark. Ma Δ12, *M. alpina* Δ12-desaturase, pCGN5533; Athfad2, Δ12-desaturase from *A. thaliana* (6). The three regions containing histidine residues (His-boxes) conserved among acyl-lipid desaturases and hydroxylases are overlined. See Figure 1 for abbreviation.

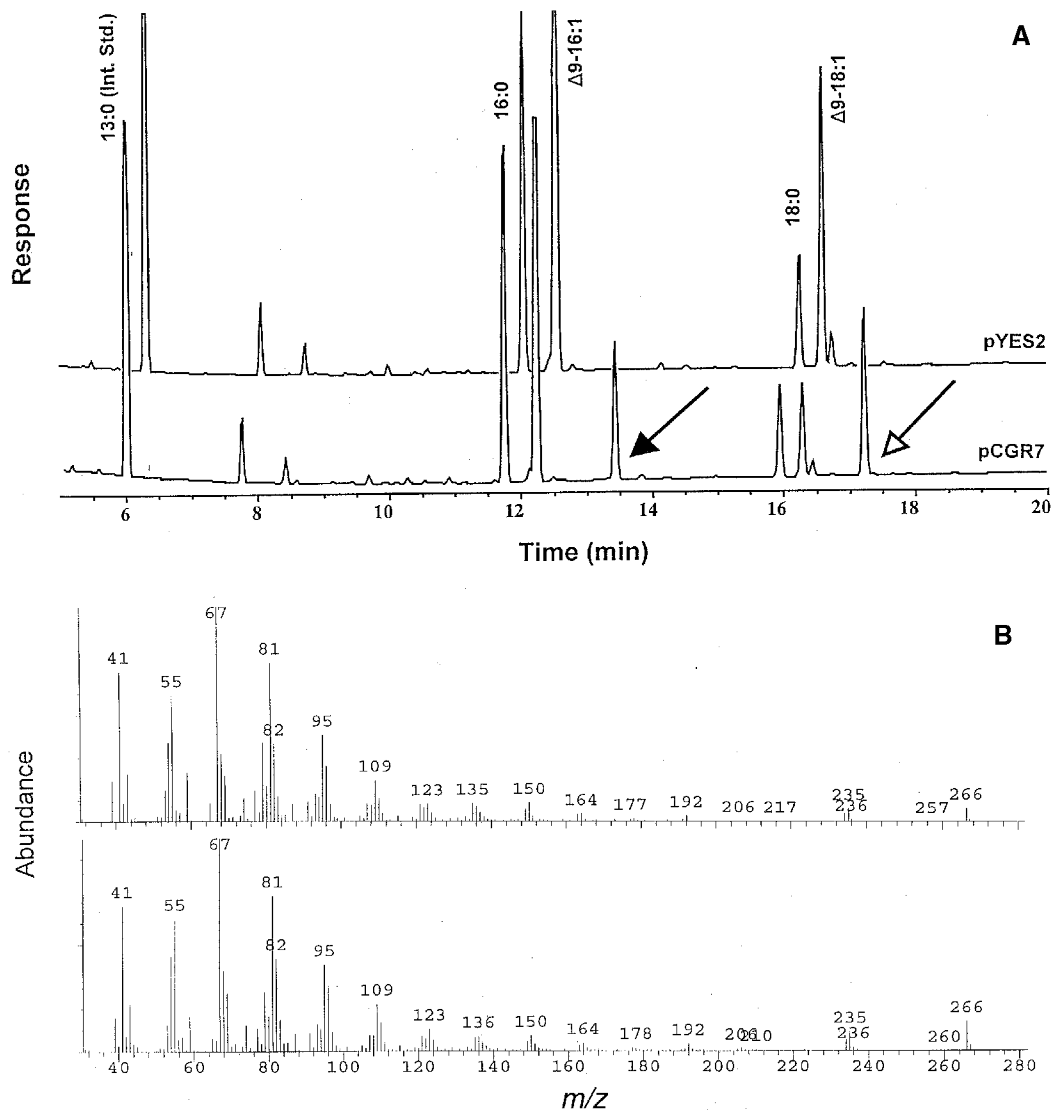

FIG. 3. (A) Gas chromatographic analysis of fatty acid methyl esters (FAME) from the lipid fraction in yeast containing pYES2 or pCGR7. Solid and open arrows indicate the fatty acids Δ9,12-16:2 and Δ9,12-18:2, respectively, present in SC334(pCGR7) cultures. (B) Gas chromatography–mass spectrometry (GC–MS) analysis of the novel peak (identified by the solid arrow in Fig. 3A) in yeast carrying pCGR7. The fragmentation pattern of the first novel peak (top) was compared with that of the authentic Δ9,12-16:2 standard (bottom). pYES2 contained only vector whereas pCGR7 contained the coding region of the *M. alpina* Δ12-desaturase cDNA clone, pCGN5533. All yeast strains were grown in the minimal medium. See Figure 1 for other abbreviations.

conversion rate for both oleic acid to linoleic acid and linoleic acid to GLA was about 50%. Among them, SC334(pCGR11, pCGR7) produced a higher level of GLA, and the GLA accumulated predominantly in the phospholipid fraction (data not shown). Hence, co-expression of *M. alpina* Δ6- and Δ12-desaturase genes under the control of independent promoters in yeast resulted in *de novo* synthesis of GLA.

Comparison of desaturase amino acid sequences. The availability of three desaturase sequences from *M. alpina* was used to examine the interspecies and interclass relationships of these sequences. The amino-acid sequences between the first and third His-boxes of representative desaturases were used to construct a similarity dendrogram (Fig. 6). Two major classes of desaturases can be discerned in this dendrogram. One class contains the Δ12/n-6 and Δ15/n-3 desaturases, while all known examples of Δ5- or Δ6-desaturases fall into a separate class. Although only the central amino-acid core sequence was used in the alignments, all the desaturase sequences with an N-terminal cytochrome *b5*-like sequence cluster into the latter sequence group. The presence of the cytochrome *b5* extension appears to be related to the functionality of the desaturase and not the source of the gene; of the three desaturases from *M. alpina*, only the Δ5- and Δ6-desaturases have the fused cytochrome sequence. In addition, all of the members of this class contain the H-Q substitution in the third His box.

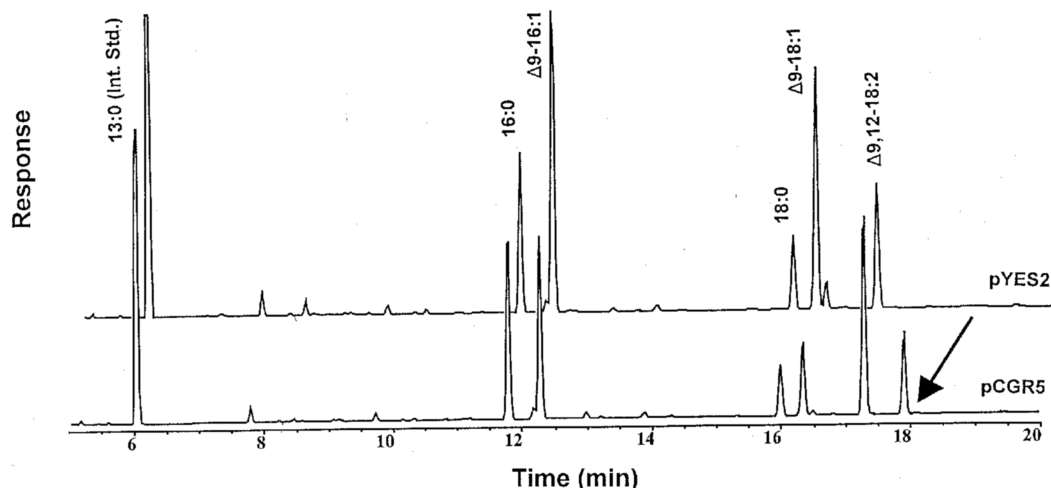

FIG. 4. Gas chromatographic analysis of FAME from the lipid fraction in yeast containing pYES2 or pCGR5. The arrow indicates a novel fatty acid (Δ6,9,12-18:3) present in SC334(pCGR5) cultures. pYES2 contained only vector, whereas pCGR5 contained the coding region of the *M. alpina* Δ6-desaturase cDNA clone, pCGN5532. All yeast strains were grown in minimal medium supplemented with the exogenous linoleic acid (Δ9,12-18:2). See Figures 1 and 3 for abbreviations.

DISCUSSION

We utilized a random sequencing approach to identify cDNA clones encoding fatty acid desaturases from the fungus, *M. alpina*. Partial sequence obtained from the 5′-end of randomly-selected clones was compared to the databanks, and homologies to known acyl-lipid desaturases were noted. This report describes the isolation of two different desaturase-like cDNA clones encoding Δ6- and Δ12-desaturases. These clones were identified in a first-phase sequencing of ~1200 cDNA. In addition to the two clones described in this work, the first phase of sequencing also revealed clones corresponding to the Δ5-desaturase originally obtained by heterologous PCR (15,16) and clones homologous to the yeast stearoyl-CoA desaturase (24) (data not shown). A more thorough sequencing effort of 5400 additional cDNA resulted in the identification of 13 sequences with homology to stearoyl-CoA desaturases, 8 Δ6-desaturases, 9 Δ5-desaturases, and 5 Δ12-desaturases. It should be noted that several of the random clones encoding Δ5- and Δ6-desaturases actually showed cytochrome *b5* matches in the BLAST results, due to the highly homologous cytochrome domain at the N-terminus of these desaturases. Had this domain not been previously identified, several of these cDNA might not have been recognized as desaturases in such a mass sequencing effort. This is an important point to keep in mind when interpreting BLAST results of all sequences; the presence of one highly conserved domain may lead to mis-annotation of the sequence.

The comparison of the desaturase amino-acid sequences shown in Figure 6 indicates that the *M. alpina* Δ5-desaturase is more closely related to the cyanobacterial Δ6-desaturases than to the plant and animal Δ6-desaturase sequences. The ultimate significance of this is hard to evaluate, due to the lack of other Δ5-desaturases for comparison. It should, however, be noted that the *C. elegans* ORF on cosmid T13F2 (GenBank accession number Z81122) that was proposed to be a possible Δ5-desaturase (16) shows more similarity to the *M. alpina* Δ6-desaturase sequence than to the *M. alpina* Δ5-desaturase sequence (data not shown).

In the present study, we showed that the recombinant enzyme expressed by a *M. alpina* desaturase-like gene (Ma648) in pCGR7 converted Δ9-16:1 to Δ9,12-16:2 and oleic acid (Δ9-18:1) to linoleic acid (Δ9,12-18:2) (Fig. 3A). These findings clearly demonstrated that this gene encodes the Δ12-desaturase. We also showed that the recombinant enzyme expressed by another *M. alpina* gene (Ma524) in pCGR5 converted n-6 fatty acid linoleic acid (Δ9,12-18:2) to GLA (Δ6,9,12-18:3) (Fig. 4). When an n-3 fatty acid, α-linolenic acid (Δ9,12,15-18:3), was used as the substrate, the SC334(pCGR5) produced the expected product, stearidonic acid (Δ6,9,12,15-18:4) (data not shown). In the absence of linoleic acid as substrate, this recombinant enzyme could convert the endogenous Δ9-16:1 to Δ6,9-16:2, and oleic acid (Δ9-18:1) to Δ6,9-18:2 (Fig. 5A). These findings demonstrate that this gene encodes the Δ6-desaturase.

In order to evaluate the feasibility of producing GLA—a high-value PUFA in this microorganism, we co-expressed the genes encoding Δ6- and Δ12-desaturases in yeast. When both genes were presented in a single construct in yeast, and expressed from a single promoter, GAL1, none of these transformed yeast strains produced a significant amount of GLA (data not shown). Therefore, it seemed likely that two independent promoters would be needed for the concurrent expression of these two desaturases. Indeed, when these desaturases were co-expressed *in trans* from two independent promoters, GAL1 and TPI, the production of GLA reached as high as 8% of the total lipids in yeast grown without exogenous substrates (Table 1). By the action of two separate pro-

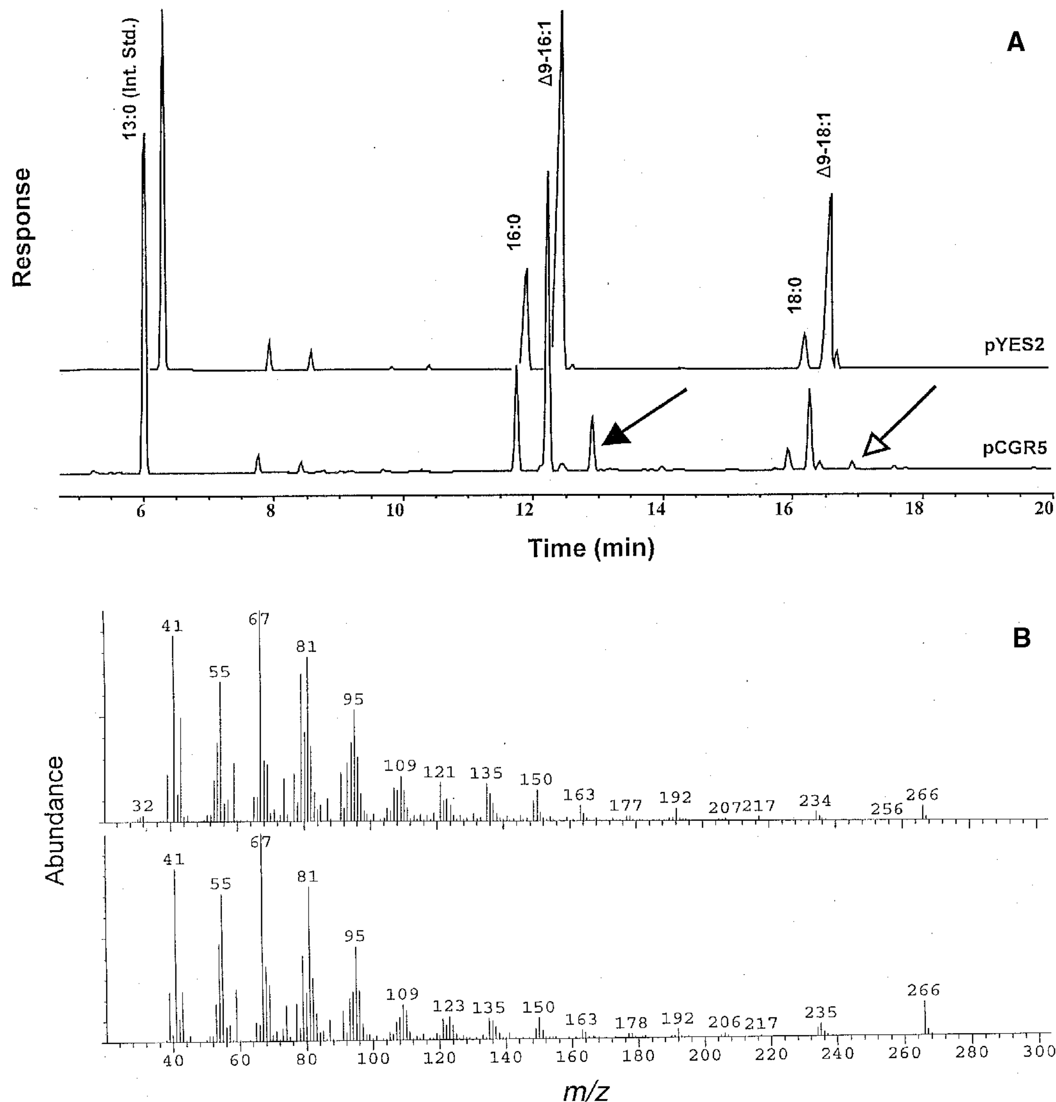

FIG. 5. (A) Gas chromatographic analysis of FAME from the lipid fraction in yeast containing pYES2 or pCGR5 grown without exogenous substrate. Solid and open arrows indicate novel fatty acids Δ6,9-16:2 and Δ6,9-18:2, respectively. (B) GC–MS analysis of the novel peak (identified by the solid arrow in panel A) in yeast carrying pCGR5. The fragmentation pattern of the first novel peak was compared with that of the authentic Δ6,9-16:2 standard pYES2 contained only vector, whereas pCGR5 contained *M. alpina* cDNA clone encoded with Δ6-desaturase. See Figures 1 and 3 for abbreviations.

moters, these enzymes were able to effectively convert (*ca.* 50%) their respective substrates to products.

In summary, we isolated two cDNA from *M. alpina* encoding the Δ6- and Δ12-desaturase genes using a random sequencing-based strategy. The identities of the two cDNA confirmed by functional expression and analysis in a widely used microorganism, baker's yeast. By introducing the two required desaturases (Δ6- and Δ12-) under the control of independent promoters in yeast, we developed a novel approach to synthesize GLA.

ACKNOWLEDGMENTS

The nucleotide sequences reported in this paper were submitted to the GenBank/EBI Data Bank with accession numbers AF110509 and AF110510.

Intermediates and Products Formed During Fatty Acid α-Oxidation in Cucumber *(Cucumis sativus)*

Grethe I. Andersen Borge*, Gjermund Vogt, and Astrid Nilsson

MATFORSK, Norwegian Food Research Institute, N-1430 Ås, Norway

ABSTRACT: Fatty acid α-oxidation is an essential metabolic pathway both in plants and in mammals which is still not completely understood. We previously described and purified an α-oxidation enzyme in cucumber which has been used in the present investigation of the α-oxidation reaction mechanism. Free fatty acids, and not the CoA thioesters, were found to undergo α-oxidation in cucumber. 2-Hydroxy- and 2-oxopalmitic acids were identified as palmitic acid α-oxidation intermediates by high-performance liquid chromatography and gas chromatography–mass spectrometry analysis in cucumber subcellular 150,000 × g_{max} pellets obtained by differential centrifugation. Incubation of purified α-oxidation enzyme with [1-^{14}C]palmitic acid resulted in the formation of both the above-described intermediates and the C_{n-1} product, pentadecanal, and $^{14}CO_2$. Besides $^{14}CO_2$, ^{14}C-formate was identified as an α-oxidation product from [1-^{14}C]palmitic acid in cucumber subcellular fractions. Fe^{2+} stimulated the $^{14}CO_2$ and ^{14}C-formate production, and the addition of ascorbate and 2-oxoglutarate together with Fe^{2+} resulted in optimal α-oxidation activities, suggesting a dioxygenase reaction mechanism, as previously shown in mammals. NADPH and, to a lesser extent, NADH stimulated the total ^{14}C-formate plus $^{14}CO_2$ production but had only slight or no effects on $^{14}CO_2$ production. H_2O_2 showed concentration-dependent inhibitory effects, while FAD had neither effect on $^{14}CO_2$ nor $^{14}CO_2$ plus ^{14}C-formate production. The results in the present study demonstrate that an α-oxidation enzyme in cucumber is capable of oxidizing palmitic acid *via* 2-hydroxy- and 2-oxopalmitic acid to produce pentadecanal and CO_2. In contrast to the subcellular 150,000 × g_{max} fraction, the purified α-oxidation enzyme could neither produce formate nor convert ^{14}C-formate into $^{14}CO_2$, indicating two possible α-oxidation routes in cucumber.

Paper no. L8110 in *Lipids 34,* 661–673 (July 1999).

When intact plant tissues are subjected to stress factors such as physical wounding or infection, their membrane lipids are susceptible to enzymatic degradation (1–4). In plants, the free fatty acids formed by lipolytic enzyme action have several pathways for partial or complete oxidation of the hydrocarbon chain. Saturated long-chain fatty acids (C_{12}–C_{18}) and unsaturated C_{18} fatty acids can readily undergo α-oxidation to yield a hydrocarbon with one less carbon atom and CO_2 (4,5), catalyzed by an α-oxidizing enzyme previously purified from cucumber (6).

The metabolic role of fatty acid α-oxidation in plants is still uncertain, although the α-oxidation pathway was implicated in initial wounding and cell damage respiration. Long-chain fatty aldehydes produced in the α-oxidative pathway seem connected to characteristic flavors which have different functions in plants (for review see Refs. 4,7). The α-oxidation reaction has been known since 1952 (8), and the reaction mechanism and subcellular localization of the enzyme(s) in plants, and later, also in mammals, algae, bacteria, and yeast have been regularly discussed since. The earliest proposed mechanism of fatty acid α-oxidation in higher plants, based on a series of studies on fat metabolism in peanut seeds (9) and pea leaves (10–12), involves the proposed intermediates 2-hydroxy and 2-oxo fatty acids and the products CO_2 and a C_{n-1} fatty aldehyde. Later, a reaction sequence involving the 2-hydroperoxyl-C_n fatty acid as a transitory intermediate was proposed (13). The aldehyde is finally oxidized to the C_{n-1} fatty acid by an NAD-dependent aldehyde dehydrogenase .

Fatty acid α-oxidation was studied in cucumbers (*Cucumis sativus*) because of the very active α-oxidation system in this tissue (5,6,14). Pentadecanal was identified as an α-oxidation product from palmitic acid (hexadecanoic acid) in cucumber homogenates (14) and subcellular fractions (6). In edible seaweeds, cultivated on the Japanese coast, long-chain fatty aldehydes were identified as characteristic flavor compounds, originating from fatty acid α-oxidation (15,16). Matsunaga *et al.* (17) reported bacterial α-hydroxylation activity with the formation of 2-hydroxymyristic acid from myristic acid in the presence of H_2O_2. Recently, the bacterial fatty acid α-hydroxylase was cloned and identified as a member of the cytochrome P450 superfamily (18).

In mammals, α-oxidation is essential for the metabolism of 3-methyl-substituted fatty acids such as the naturally occurring phytanic acid (3,7,11,15-tetramethylhexadecanoic acid) which cannot initially undergo β-oxidation (for review see Ref. 19). Recently, it was demonstrated that 3-methyl-substituted fatty acid α-oxidation consists of an activation step leading to the fatty acyl-CoA ester (20), followed by a 2-

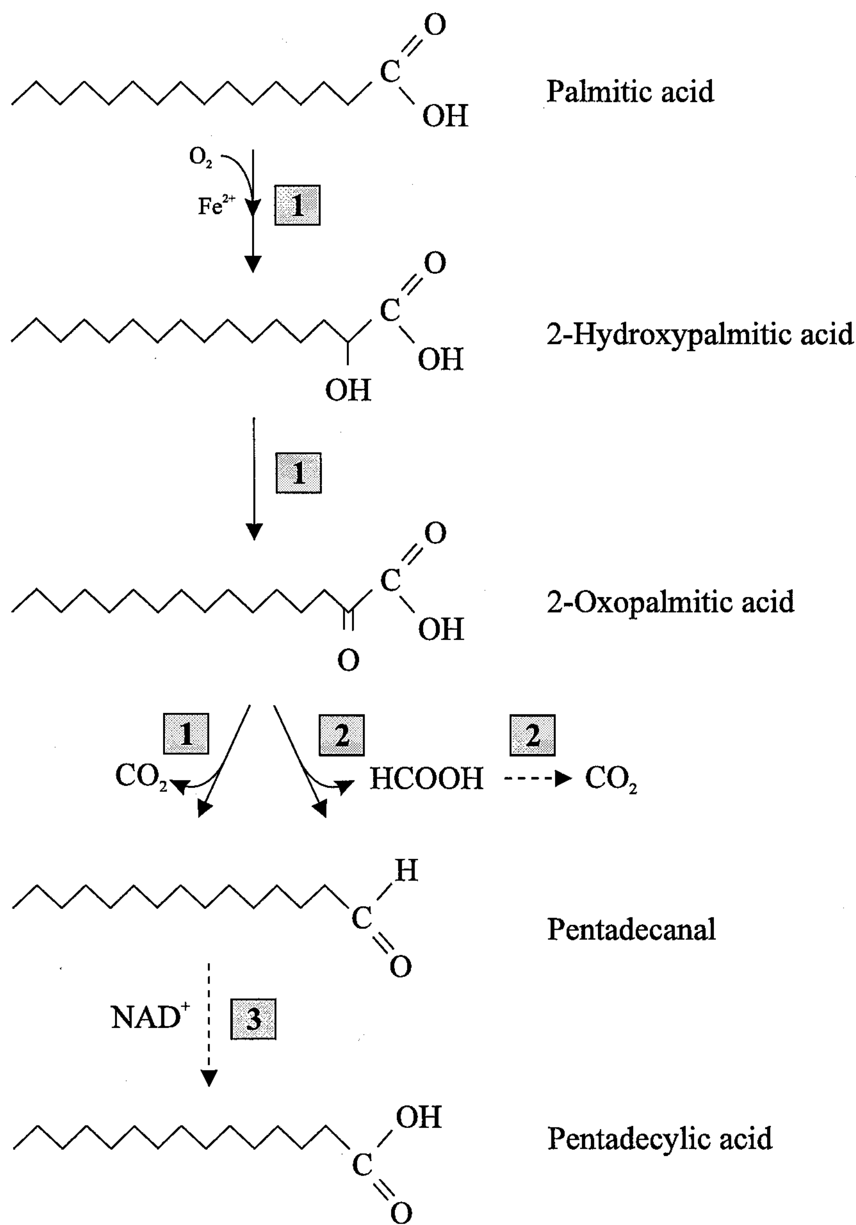

SCHEME 1

hydroxylation, yielding a 2-hydroxy-3-methylacyl-CoA intermediate in rat (21,22) and human (23,24) liver peroxisomes. The gene encoding phytanoyl-CoA hydroxylase was cloned and identified in humans (25,26). Formic acid was demonstrated to be the nonlipid α-oxidation product in human fibroblasts (27) and in rat liver (28). Recently, formyl-CoA, rather than formate, was shown to be the end product of α-oxidation of 3-methyl palmitic acid in rat liver peroxisomes (29). The fatty end product generated in mammalian α-oxidation was very recently shown to be an aldehyde (30,31) as in plants (4).

The aim of the present study was to further investigate the formation of α-oxidation intermediates and products in cucumber subcellular fractions and in purified α-oxidation enzyme fraction. The results presented show that palmitic acid, and not palmitoyl-CoA, is the preferred α-oxidation substrate, which can be converted to pentadecanal with 2-hydroxy and 2-oxopalmitic acid as intermediates by the purified α-oxidation enzyme. The only nonlipid long-chain fatty acid α-oxidation end product identified in plants is the C_1- unit in the form of CO_2. In the present study we investigated whether ^{14}C-formate was produced from [1-^{14}C]palmitic acid during fatty acid α-oxidation. Based on the results obtained, a fatty acid α-oxidation pathway in cucumber was proposed (Scheme 1, where the numbered boxes indicate the proposed enzymes involved: 1 is α-oxidation enzyme; 2 is unknown; 3 is aldehyde dehydrogenase). Several cofactors were examined in earlier plant studies; however, none has been reported to give markedly positive effects on fatty acid α-oxidation activity measured as $^{14}CO_2$ production (3,5,9,10,14). Finally,

the effects of possible required cofactors on α-oxidation activity were examined in cucumber.

MATERIALS AND METHODS

Materials. Cucumber fruits (*C. sativus*) were purchased from the local markets. [1-^{14}C]Palmitic acid (55.0 mCi/mmol), [1-^{14}C]palmitoyl-CoA (47.8 mCi/mmol), and sodium [^{14}C]-formate (56.0 mCi/mmol) were provided by Amersham Pharmacia Biotech (Buckinghamshire, United Kingdom). Pentadecanal was synthesized by oxidation of 1-pentadecanol using pyridinium chlorochromate as described (32). Tridecanal was provided by Chem Service Inc. (West Chester, PA). Unlabeled palmitic acid, palmitoyl-CoA, 2-hydroxypalmitic acid, sodium formate, and Triton X-100 were obtained from Sigma Chemical Co. (St. Louis, MO). Mercuric acetate and ethyl acetate were from Fluka Chemie AG (Buchs, Switzerland), methanolic-HCl (3 M) was from Supelco, Inc. (Bellefonte, PA), and BCA Protein Assay Reagent was from Pierce (Rockford, IL).

Preparation of subcellular fractions and purification of α-oxidation enzyme. Fresh cucumbers were washed, peeled, cut, and homogenized in 50 mM HEPES, 0.25 M sucrose, and 1 mM EDTA, pH 7.4 at 4°C, before filtration and differential centrifugation as described previously (6) (see Fig. 1). All organellar fractions were assayed for $^{14}CO_2$ liberation and ^{14}C-formate formation, and the pellet obtained after centrifuging a 37,500 × g_{max} supernatant at 150,000 × g_{max} for 70 min re-

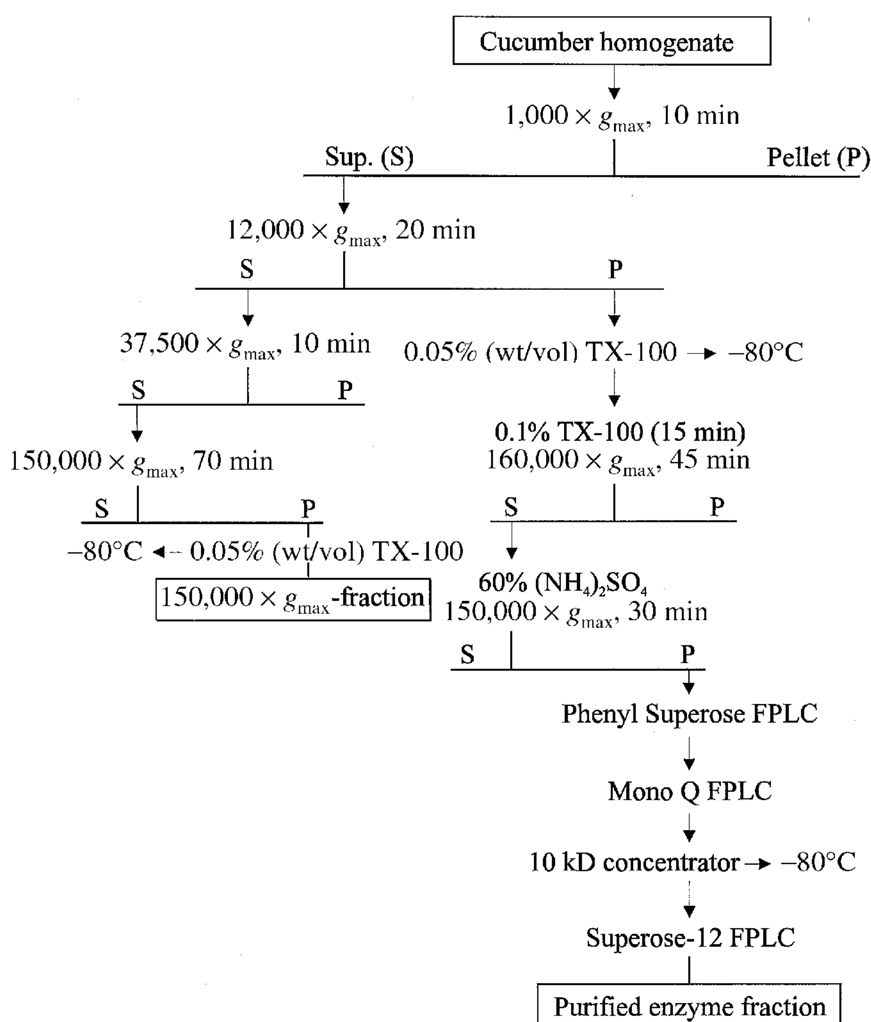

FIG. 1. Purification scheme for α-oxidation enzyme activity from cucumber. Cucumbers were peeled, coarsely cut, and homogenized in 50 mM HEPES, 0.25 M sucrose, 1 mM EDTA, pH 7.4 with a vertical cutter. After filtration the cucumber homogenate was subcellular fractionated by differential centrifugation as described before (6) and shown in this scheme. The 150,000 × g_{max} fraction was used as the crude α-oxidation enzyme source in our studies. The purification of the α-oxidation activity started with the 12,000 × g_{max} pellet and resulted in a near homogeneity purified α-oxidation enzyme with the molecular mass 240,000 (6). The α-oxidation activity in Superose-12 purified enzyme fraction, measured as $^{14}CO_2$ production, was 550 nmol × min^{-1} × (mg protein)$^{-1}$.

vealed the highest rates of $^{14}CO_2$ and ^{14}C-formate plus $^{14}CO_2$ formation per mg protein. The 150,000 × g_{max} pellets were resuspended in homogenization buffer with 0.05% (wt/vol) Triton X-100, and the 150,000 × g_{max} fraction was stored in small aliquots at −80°C and used in the further incubations.

The 12,000 × g_{max} pellets were subjected to further purification (6), and the purification steps are shown in Figure 1. The fractions with α-oxidation activity collected from fast protein liquid chromatography on Mono Q column (Amersham Pharmacia Biotech, Uppsala, Sweden) were subjected to concentration in 10 kDa Centriplus concentrators (Amicon, Bedford, MA). This enzyme material was stored in aliquots at −80°C over a period of several weeks without losing enzyme activity. When used for incubations, the enzyme samples were thawed and gel-filtered on a Superose-12 column (Amersham Pharmacia Biotech, Uppsala). The α-oxidation activity in the Superose-12 fractions was measured and the peak fractions were combined. The purity of the α-oxidation enzyme fraction was checked using native 4–15% gradient polyacrylamide gel electrophoresis. This enzyme fraction is described as "purified enzyme fraction" in the following.

Protein concentrations were determined with bicinchoninic acid (33) using bovine serum albumin as the standard protein.

Substrate preparation, incubation, and measurement of α-oxidation C_1-products. Fatty acid substrate solution was made of 10.0 mg unlabeled palmitic acid and [1-^{14}C]palmitic acid dissolved together in 0.2 mL toluene. Substrate buffer [50 mM HEPES, pH 7.4, containing 0.1% (wt/vol) Triton X-100 and 1 mM EDTA] was added dropwise to the toluene solution under mixing and taken up to the stock concentrations 0.1–2.0 mM (0.08 μCi). Unlabeled 2-hydroxypalmitic acid substrate solution was prepared as the palmitic acid substrate solution. [1-^{14}C]Palmitoyl-CoA was dissolved in 50 mM HEPES, pH 7.4 to the stock concentration 0.1 mM. The purity of the substrates was confirmed by high-performance liquid chromatography (HPLC) and gas chromatography–mass spectrometry (GC–MS) before incubation.

Incubations and measurement of liberated $^{14}CO_2$ from [1-^{14}C]fatty acids were performed essentially as described previously (6) using a variation of the method described by Galliard and Matthew (14). Samples were incubated in 25-mL conical flasks sealed with rubber caps (Kontes Glass Co., Vineland, NJ). The incubation mixture (final volume 1.0 or 2.0 mL) contained 50 mM HEPES buffer (pH 7.4), 1 mM EDTA, 150,000 × g_{max} fraction (0.09–0.2 mg protein) or purified enzyme fraction (2.5 μg protein), and the reaction was started by the addition of 0.05 mM [1-^{14}C]palmitic acid (0.04 μCi) in substrate buffer. The control samples consisted of all assay components together with protein boiled for 5 min. The reaction was performed at 25°C with shaking for 20 min (or other indicated periods of time), after which termination was achieved by adding 0.2 mL 1.0 M HCl, except when otherwise mentioned. $^{14}CO_2$ was trapped in hanging wells (Kontes) with 0.2 mL β-phenylethylamine in methanol (1:1, vol/vol). The radioactivity was measured by liquid scintillation counting (Beckman LS6000IC, Beckman Coulter, Inc., Fullerton, CA) after adding 5 mL Insta Gel II (Packard Instruments, Groningen, The Netherlands).

^{14}C-Formic acid was measured as described by Yang (34) with minor modifications of the method described by others (27,28). The incubations were performed as described above, and the reactions were terminated after 10 min (or as otherwise described) with 0.2 mL 1 M potassium phosphate, pH 2. Mercuric acetate (0.25 g in 1 mL H_2O) was added using a syringe through the rubber caps. After 40 min at 85°C, liberated $^{14}CO_2$ was trapped and measured as described above. The recovery was based on $^{14}CO_2$ production from ^{14}C-formate (0.05 mM).

HPLC analysis of palmitic acid α-oxidation intermediates. After termination of the enzyme reaction, the flasks with the incubated 150,000 × g_{max} fraction or purified enzyme fraction were kept on ice until, as soon as possible, they were transferred to an extraction tube and extracted twice with 3 vol of ethyl acetate. The organic phase was washed with 1 mL water, and the ethyl acetate was evaporated to dryness under N_2 after which 0.1 mL methanol was added. The samples were analyzed by reversed-phase HPLC essentially as described by Huang *et al.* (35) on a Spectra-Physics HPLC equipped with Spectra System P4000 Quat Gradient pump and a Nova-Pak C_{18} column (150 × 3.9 mm) (Waters, Milford, MA). The [1-^{14}C]metabolites were separated with a gradient of methanol and water, both with 0.1% (vol/vol) acetic acid, starting with 70% methanol, isocratic for 15 min, and then increasing to 100% methanol in 20 min, at a flow rate of 0.8 mL/min. Column effluents were monitored on-line using a radioactivity detector (Packard Radiomatic Flo-One/β, series A-100; Packard Instrument, Palo Alto, CA), with liquid scintillant (Pico Aqua from Packard Instrument) mixed with the eluate in a ratio of 3:1 (vol/vol). When fractions were collected for further analysis by GC–MS, aliquots of each column fraction were counted for radioactivity, and the radioactive fractions in each peak were combined. Unlabeled fatty acids and fatty acid derivatives were monitored with a DDL21 light-scattering detector (Eurosep Instruments, Cergy-Pontoise Cedex, France).

HPLC analysis of water-soluble products. The α-oxidation incubations were performed with a total volume of 1.0 mL, and the reactions were terminated with 0.2 mL of 6% (wt/vol) perchloric acid. The samples were then transferred to Eppendorf tubes and centrifuged at 13,000 × g for 10 min at 4°C. The pellet was resuspended in 0.1 mL 6% perchloric acid and centrifuged again. The total supernatant was frozen at −20°C and thawed just prior to the injection of 0.25 mL on an Aminex HPX-87H column (300 × 7.8 mm, 9 μm) (Bio-Rad Laboratories, Richmond, CA). The column was eluted with 6.0 mM sulfuric acid at a flow rate of 0.4 mL/min, isocratic for 40 min, and with 40% acetonitrile in 6.0 mM sulfuric acid for an additional 30 min. The eluate was monitored on-line at 210 nm using a Spectra Focus scanning detector (Spectra-Physics Inc., San Jose, CA), and 0.8 mL fractions were collected and counted for radioactivity. ^{14}C-Labeled formate was used as a standard and for determination of method recovery. Other organic acid standards were unlabeled.

GC–MS of α-oxidation intermediates and products. Incubations of the 150,000 × g_{max} fraction or purified enzyme fraction with the fatty acid substrate solution were performed as described above. The collected and combined radioactive fractions from reversed-phase HPLC were dried under N_2. The fatty acid moieties were derivatized using 3 M methanolic-HCl and extracted into 50 µL hexane. The identification of the α-oxidation intermediates was performed by a Hewlett-Packard 5890 series II gas chromatograph equipped with a split/splitless injector and an electron impact mass selective detector HP 5970 MSD (Hewlett-Packard Co.). The injection port and GC–MS interface were kept at 250°C. After splitless injection of 2 µL sample, the methyl esters were separated on a DB-23 MS column (30 m, 0.25 mm i.d., 0.25 µm film thickness) (J&W Scientific, Folsom, CA) with helium as carrier gas. The column oven temperature program was 100°C (4 min); 20°C/min; 160°C (2 min); 3°C/min; 220°C; 15°C/min; 240°C (10 min).

For analysis of fatty aldehydes in incubations of purified enzyme fraction (40 µg protein) with unlabeled palmitic acid (1.0 mM), tridecanal was added as internal standard (50 nmol) after termination of the reactions. The acidified samples were extracted twice with 3 vol of ethyl acetate. The ethyl acetate phase was washed with water and evaporated to dryness under N_2. The residue was dissolved in 50 µL hexane; 2 µL of the sample were subjected to GC–MS analysis, and the components were separated on a DB-23 MS column with the temperature program 60°C (1 min); 10°C/min, 220°C (2 min); 15°C/min, 240°C (20 min).

Aqueous fractions (50 µL) eluted from the Aminex HPLC column were applied into a glass tube packed with silanized glass wool. Volatiles from the glass wool were desorbed in a Perkin-Elmer Automatic Thermal Desorber ATD 400 (Perkin-Elmer Co., Norwalk, CT) and concentrated on a Tenax GR-packed coldtrap before injection on the gas chromatograph. The injected volatile compounds were separated on a DB-5 MS column (30 m, 0.25 mm i.d., 1 µm film thickness) (J&W Scientific) in an HP5890 series II GC. The volatiles were detected with an HP 5970 mass-selective detector in the scanning mode from molecular mass 29 to 350. Analyses of the mass spectra were based on the reference spectra of authentic standards.

Statistical analysis. The enzyme activities are expressed as mean values ± SEM of the indicated number of experiments. The significance of the differences within the cofactor experiments was tested by analysis of variance (ANOVA function in Minitab, Release 11.12, 32 bit, Minitab Inc., State College, PA) and two sample *t*-tests (Minitab).

RESULTS

Incubation of free fatty acid and acyl-CoA. To investigate whether an acyl-CoA thioester could act as a substrate for the cucumber α-oxidation system, we incubated cucumber homogenate, 150,000 × g_{max} fraction, or purified enzyme fraction with [1-^{14}C]palmitoyl-CoA. Incubation of the crude fraction for 60 min or more revealed very small amounts of $^{14}CO_2$, most likely because the palmitoyl-CoA solution contained small quantities of free palmitic acid due to thioester hydrolysis. No ^{14}C-formate production was detected in the [1-^{14}C]-palmitoyl-CoA incubations. Purified enzyme fraction incubated with [1-^{14}C]palmitoyl-CoA did not result in any production of $^{14}CO_2$ or ^{14}C-formate. HPLC and GC analysis of the ethyl acetate phase revealed no production of any ^{14}C-labeled intermediates, or pentadecanal as product with [1-^{14}C]palmitoyl-CoA as substrate (data not shown). These results establish the fact that the free fatty acids, and not CoA thioesters, are substrates for α-oxidation enzymes in cucumber.

Studies of palmitic acid α-oxidation intermediates. In our earlier studies (6), purified α-oxidation enzyme fraction from cucumber formed $^{14}CO_2$ from [1-^{14}C]palmitic acid without added cofactors. This finding introduced the possibility of an α-oxidative multifunctional enzyme with a possible hydroxylation and decarboxylation activity rather than two or more single enzymes catalyzing the α-oxidation reaction steps.

In order to identify putative palmitic acid α-oxidation intermediates, the subcellular 150,000 × g_{max} fraction was incubated with [1-^{14}C]palmitic acid, extracted, and analyzed by reversed-phase HPLC and GC–MS. The HPLC profile of the ethyl acetate extracts showed three radioactive peaks, void peak I, peaks II and III, in addition to the peak S corresponding to the unreacted palmitic acid (Fig. 2A). When heat-inactivated enzyme fraction was incubated, only the substrate peak S appeared. The small radioactive peak I in the void volume was further studied under HPLC conditions described for water-soluble products described in the Materials and Methods section. In a typical experiment, where 150,000 × g_{max} fraction (0.1 mg protein) was incubated with 0.05 mM [1-^{14}C]palmitic acid for 20 min, the percentage distribution of radioactivity was *ca*. 1–2% in void peak I, 10% in peak II, 30% in peak III, and the rest in the unreacted substrate peak S (Fig. 2A). The unknown peak III co-eluted with an unlabeled authentic 2-hydroxy palmitic acid standard on HPLC, measured with a light-scattering detector (data not shown). To verify the identity of this ^{14}C-labeled intermediate, the HPLC peak III fractions were collected, and the material was methylated before being subjected to combined GC–MS. One major peak at 24.5 min, whose elution time and mass spectra corresponded to the methyl ester of the authentic 2-hydroxy palmitic acid standard, was observed in the GC chromatogram (GC profile not shown). Figure 2B shows the electron impact mass spectrum of peak III, which corresponded to that of 2-hydroxy palmitic acid. The most characteristic ion at *m/z* 227 is caused by fragmentation alpha to the 2-hydroxyl group, and the elimination of methanol gives the ion at *m/z* 195. The expected molecular ion is present at *m/z* 286 and a typical McLafferty rearrangement at *m/z* 90. The second unknown ^{14}C-labeled peak in the HPLC profile, (peak II in Fig. 2A), was collected, methylated, and analyzed by GC–MS. This compound was identified as 2-oxopalmitic acid methyl ester using Wiley mass spectral data base (John Wiley & Sons Inc., licensed to Hewlett-Packard, Rev. 00.00.1989). The mass spectrum is shown in Figure 2C, and the fragmen-

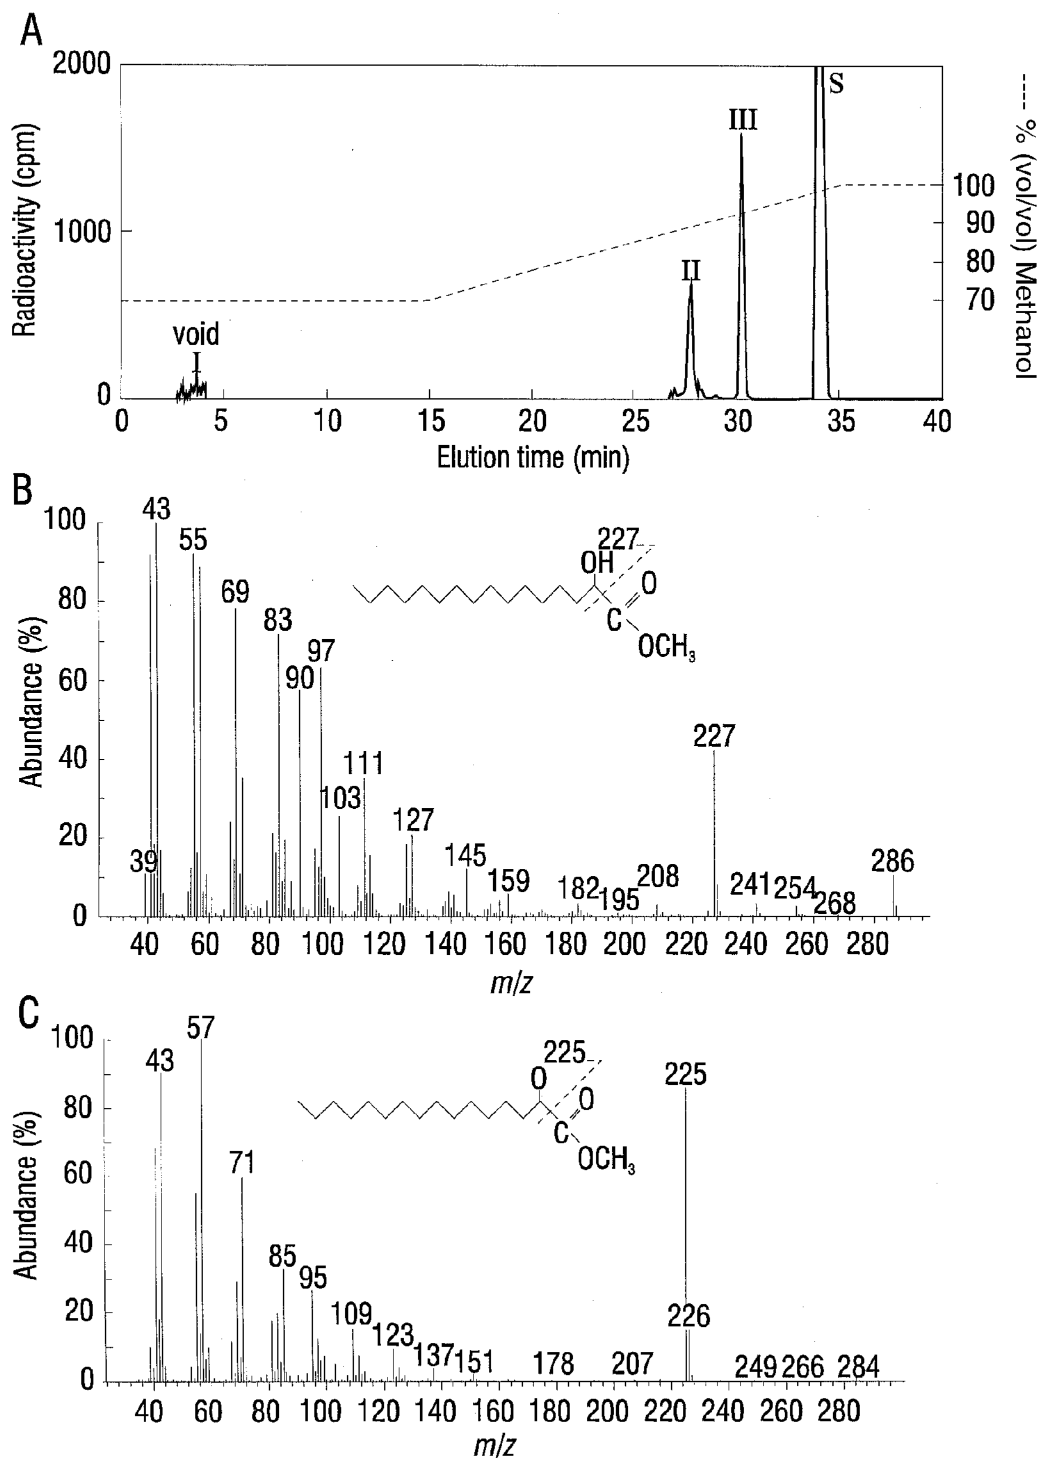

FIG. 2. Reversed-phase high-performance liquid chromatography (HPLC) analysis of palmitic acid α-oxidation products and identification of reaction intermediates by gas chromatography–mass spectrometry (GC–MS). Subcellular 150,000 × g_{max} pellets (0.2 mg protein), resuspended in 50 mM HEPES, pH 7.4, 0.05% Triton X-100 and 1 mM EDTA, were incubated with 0.05 mM [1-^{14}C]palmitic acid in 25-mL flasks sealed with rubber caps at 25°C. Incubations (total volume 2.0 mL) were terminated after 20 min by the addition of 0.2 mL 1 M HCl, and the reaction media were extracted with ethyl acetate. After evaporating the solvent, the organic residues were dissolved in 0.1 mL methanol and analyzed by reversed-phase HPLC on a C_{18}-column eluted with methanol and water both with 0.1% (vol/vol) acetic acid at 0.8 mL/min. The palmitic acid and the metabolites were separated with a gradient starting with 70% (vol/vol) methanol increasing to 100% in 20 min as shown in A (dashed line). The radioactivity in the column eluate was monitored on-line (solid line). For identification of peaks II and III, fractions from HPLC were collected, and the methylated moieties were analyzed by GC–MS. The mass spectrum of the methylated compound in peak III was identified as 2-hydroxypalmitic acid (B) and peak II was identified as 2-oxopalmitic acid (C), with molecular peaks at *m/z* 286 and 284, respectively.

tation patterns include the intense *m/z* 225 ion formed by a characteristic α-cleavage to the 2-oxo group and the molecular ion present at *m/z* 284.

When purified enzyme fraction was incubated with [1-^{14}C]palmitic acid, the HPLC elution patterns showed the same two ^{14}C-labeled peaks described above for the subcellular 150,000 × g_{max} fraction, identified as the 2-hydroxy and 2-oxopalmitic acids (data not shown).

Palmitic acid α-oxidation products in the purified enzyme fraction. In this work the formation of pentadecanal, which is the [1-^{14}C]palmitic acid α-oxidation product beside $^{14}CO_2$, was investigated. Since purified enzyme was shown to convert [1-^{14}C]palmitic acid into $^{14}CO_2$, a fatty product with one carbon less than the substrate was expected to be found. Figure 3A shows the GC profile of the aldehyde standards, and Figure 3B shows that the α-oxidation products in the purified enzyme fraction co-eluted with the synthesized pentadecanal standard. The peak with retention time 14.1 min is consistent with pentadecanal, and the mass spectrum of this peak confirmed this identity. A linear increase of pentadecanal, as quantified relative to the internal standard tridecanal (ret. time 12.0 min), was observed during the first 30 min of reaction (data not shown). The estimated specific activity of pentadecanal formed was 340 ± 26 nmol × min^{-1} × (mg protein)$^{-1}$ (±SEM), calculated by dividing the peak area and ion abundances of four different ions of pentadecanal by the same peak area and ion abundances of the internal standard tridecanal.

Incubations of crude enzyme fraction or purified enzyme fraction with unlabeled 2-hydroxypalmitic acid, one of the proposed intermediates, resulted in formation of pentadecanal. Figure 4 shows a time-dependent increase of the C_{15}-aldehyde from 2-hydroxypalmitic acid in purified enzyme fraction. The estimated amount of pentadecanal formed was *ca*. 20-fold less with 2-hydroxypalmitic acid than with palmitic acid as the α-oxidation substrate. When pentadecanal was added to the incubations, a concentration-dependent inhibitory effect on the α-oxidation activity was observed (data not shown).

Identification of formate as an α-oxidation product in the crude 150,000 × g_{max} fraction. Since the existence of formate as an α-oxidation end product besides CO_2 was described in mammals (24,25), but not in plants, we analyzed the incubation mixtures for water-soluble ^{14}C-labeled products by ion-exchange HPLC, to investigate whether or not formate was produced in the 150,000 × g_{max} fraction. The HPLC chromatograms of the samples incubated for 5, 10, and 20 min showed two major ^{14}C-labeled peaks eluted with 6 mM sulfuric acid (Fig. 5A–C). The first peak appeared after 22 min (elution volume 8.8 mL) and the second peak after 27 min (10.8 mL), and both peaks showed a time-dependent increase. The first peak co-eluted with an authentic formate standard (Fig. 5D), and GC analysis confirmed this identification. The second radioactive peak corresponded to propionic acid from the HPLC analysis of an authentic standard (Fig. 5D); however, GC–MS identification was not successful.

When cucumber 150,000 × g_{max} fraction was incubated with [1-^{14}C]palmitic acid, a significant amount of formate was produced, measured as $^{14}CO_2$ after oxidizing the ^{14}C-formate with mercuric acetate. In Figure 6, the time-dependent formate and CO_2 production in 150,000 × g_{max} subcellular fraction shows that the CO_2 formation exceeded the formate production already after 10 min reaction time, and after 20 min twice as much CO_2 as formate was measured. Under standard incubation conditions, $^{14}CO_2$ seemed to be the major α-oxidation product in cucumber subcellular 150,000 × g_{max} (Fig. 6).

Surprisingly, no ^{14}C-formate production could be detected in the incubations of purified α-oxidation enzyme. Furthermore, incubation of purified enzyme fraction with ^{14}C-formate (0.05 mM) for 10 or 20 min did not result in significant $^{14}CO_2$ production. In contrast, a small but significant amount of $^{14}CO_2$ was formed from ^{14}C-formate in subcellular 150,000 × g_{max} fraction (5.3 ± 0.15 nmol × min^{-1} × (mg protein)$^{-1}$, n = 3). The addition of a cytosolic fraction (150,000 × g_{max} supernatant) did not increase the rate of $^{14}CO_2$ production from ^{14}C-formate significantly (data not shown). However, no $^{14}CO_2$ formation from ^{14}C-formate was observed in boiled 150,000 × g_{max} fraction.

Oxygenase cofactor requirements. Oxygen requirements were investigated in the cucumber 150,000 × g_{max} fraction. Oxygen depletion by nitrogen flushing of the solutions prior to the incubations inhibited $^{14}CO_2$ formation by 84 ± 12% (n = 6), and air supply to the incubation mixture restored the α-oxidation activity.

The mammalian α-oxidation involves a dioxygenase type of enzyme using 2-oxoglutarate as cosubstrate and Fe^{2+} and ascorbate as cofactors (21–23). Whether similar positive effects by these dioxygenase cofactors on α-oxidation activity could be obtained in plant material was investigated. Table 1 shows the effect of Fe^{2+}, 2-oxoglutarate, and ascorbate on the production of $^{14}CO_2$ and ^{14}C-formate plus $^{14}CO_2$ in cucumber 150,000 × g_{max} fraction with [1-^{14}C]palmitic acid as substrate. Fe^{2+} (0.5 mM) showed a significant stimulating effect on the formation of $^{14}CO_2$ and ^{14}C-formate plus $^{14}CO_2$. However, the increase in the rate of ^{14}C-formate plus $^{14}CO_2$ formation was not higher than the increase of $^{14}CO_2$, i.e., Fe^{2+} had no effect on the formate production. The effects of adding 2-oxoglutarate (0.75 mM) and/or ascorbate (1.0 mM) to the incubation media were less clear to interpret according to the analysis of variance. The rate of $^{14}CO_2$ production was further increased from 26.80 ± 2.90 nmol × mg protein^{-1} × min^{-1} with Fe^{2+} present alone to 34.46 ± 2.83 nmol × mg protein^{-1} × min^{-1} with ascorbate and 2-oxoglutarate in addition to Fe^{2+} (P = 0.035). The effect on the total rate of production of $^{14}CO_2$ plus ^{14}C-formate was even higher, increasing from 46.99 ± 0.38 to 62.56 ± 0.24 nmol × min^{-1} × (mg protein)$^{-1}$ with Fe^{2+} and Fe^{2+}, ascorbate, and 2-oxoglutarate present, respectively (P < 0.001).

Monooxygenases require a second oxidizable substrate, e.g., NADPH or NADH. Table 2 shows that the total α-oxidation rate, ^{14}C-formate plus $^{14}CO_2$ production, was stimu-

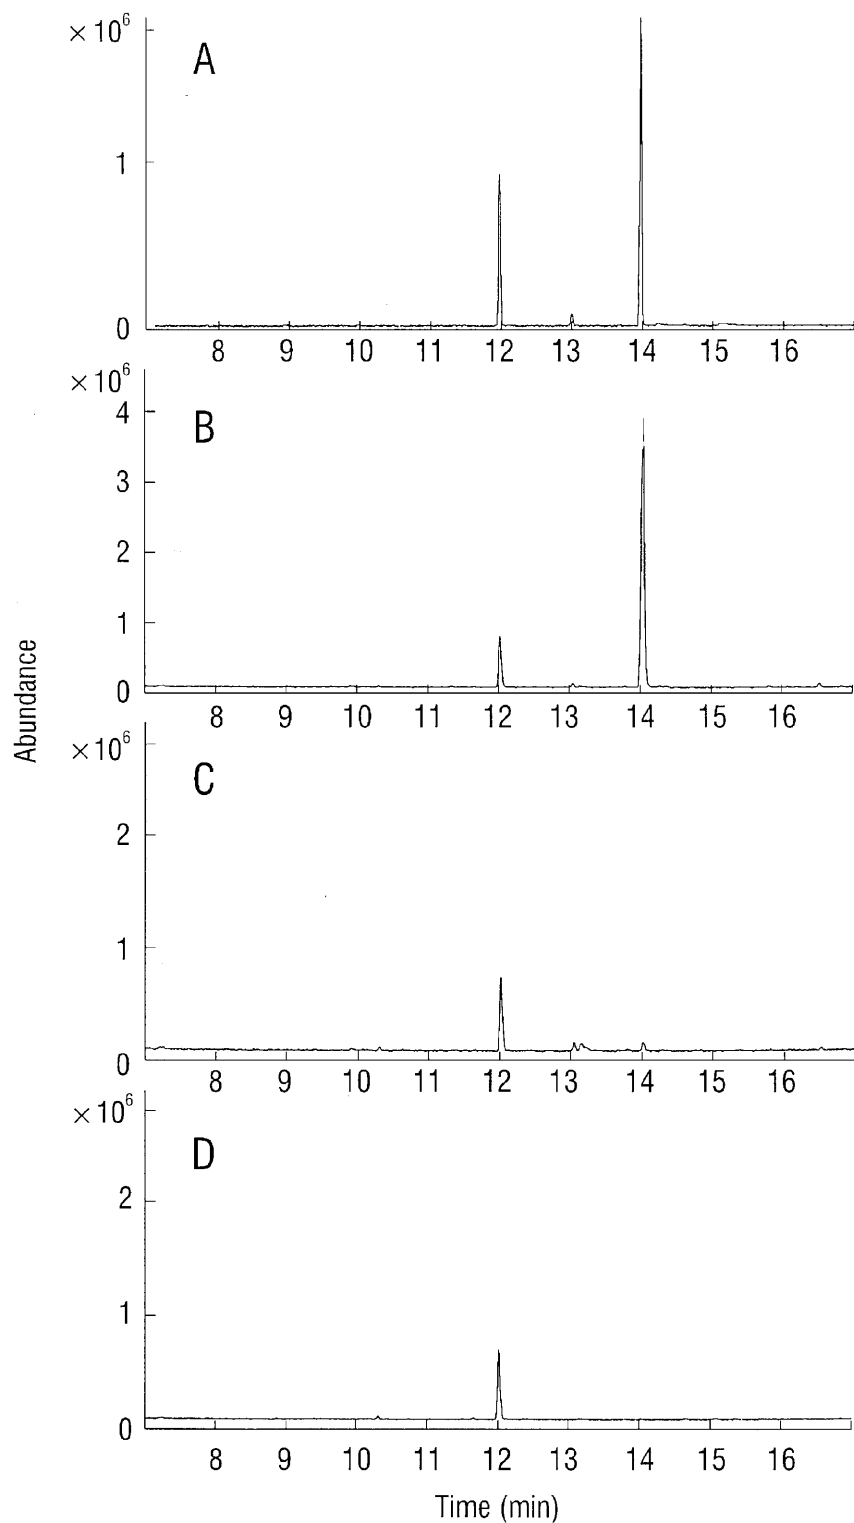

FIG. 3. Formation of pentadecanal from palmitic acid in purified α-oxidation enzyme fraction analyzed by GC. Incubations were performed with purified enzyme fraction (40 μg protein) and 1.0 mM palmitic acid, and the reactions were terminated after 20 min with acetic acid. The reaction mixtures received 50 nmol tridecanal as internal standard and were extracted with ethyl acetate. (A) The total ion chromatogram of a standard solution containing tridecanal (retention time 12.0 min) and pentadecanal (retention time 14.1 min). (B) The extracts from incubation medium with active enzyme, (C) boiled enzyme, and (D) without enzyme were analyzed by GC–MS for aldehydes with the temperature program described in the Materials and Methods section. See Figure 2 for abbreviations.

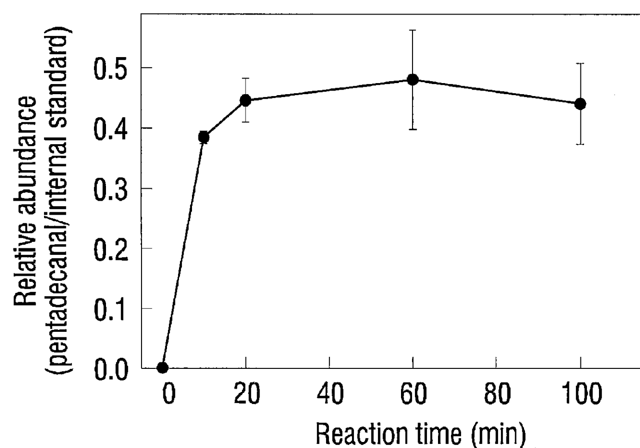

FIG. 4. Production of pentadecanal from 2-hydroxypalmitic acid in purified enzyme fraction. Purified enzyme fraction (40 μg protein) was incubated with 1.0 mM 2-hydroxypalmitic acid for 0, 10, 20, 60, and 100 min at 25°C. The reaction mixtures received 50 nmol tridecanal as internal standard and were extracted with ethyl acetate. The samples were analyzed by GC–MS and the amount of pentadecanal was calculated relative to the internal standard tridecanal. The results presented are mean ± SEM of two experiments. See Figure 2 for abbreviations.

lated with 0.5 mM NADPH or 0.5 mM NADH, 1.5- and 1.3-fold, respectively, compared to the controls. In contrast, NADPH and NADH had marginal or no effect on the $^{14}CO_2$ production. The analysis of variance showed significant effects of both NADPH and NADH, depending on the presence of Fe^{2+}, and both reductants decreased the positive effect obtained by Fe^{2+} alone ($P < 0.001$).

Involvement of H_2O_2 in fatty acid α-oxidation was discussed in several earlier studies (5,9,17,35,36). Consistent with the previous observations in cucumber (5), H_2O_2 was shown to be a potent inhibitor of the palmitic acid α-oxidation activity (Table 3). Micromolar concentrations decreased the rate of $^{14}CO_2$ and ^{14}C-formate plus $^{14}CO_2$ production by 23 and 32%, respectively, relative to the incubations without cofactors. Neither low (20 μM) nor high (0.5 mM) concentrations of FAD increased the $^{14}CO_2$ or the ^{14}C-formate plus $^{14}CO_2$ production. The stimulatory effect of Fe^{2+} (0.5 mM) was maintained in the presence of FAD, and no additional increase in the α-oxidation activity was observed (Table 3).

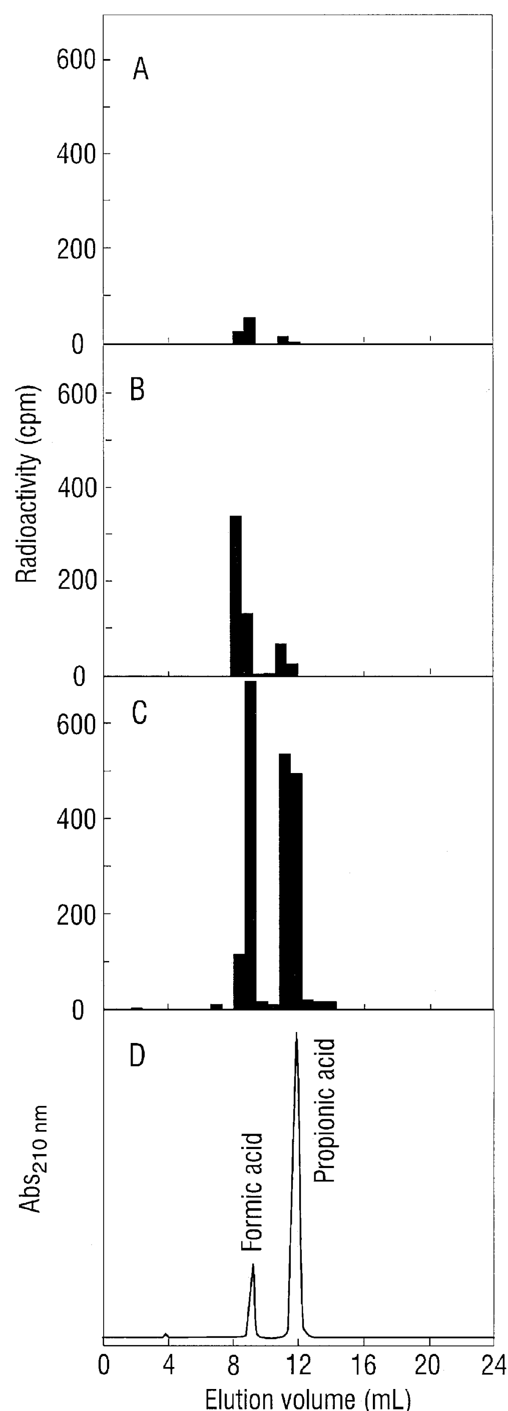

FIG. 5. Ion-exclusion HPLC analysis of the incubation mixture after α-oxidation of [1-^{14}C]palmitic acid. Cucumber 150,000 × g_{max} subcellular fraction (0.1 mg protein) was incubated with 0.05 mM [1-^{14}C]palmitic acid, and the reactions were terminated after 5, 10, or 20 min with $HClO_4$. The samples were centrifuged, and an aliquot of the supernatant was injected on a cation-exchange column eluted with 6 mM H_2SO_4 at a flow rate of 0.4 mL/min. HPLC effluents were monitored using an ultraviolet detector on-line, and fractions were collected for radioactivity counting. The radioactive peaks absorbed light at 210 nm and co-eluted with the unlabeled standards shown in the bottom panel. (A) 5 min; (B) 10 min; (C) 20 min reaction time; (D) standard mixture of unlabeled formate and propionic acid. The results are representative for three separate experiments. See Figure 2 for abbreviation.

DISCUSSION

The main purpose of this study was to identify the α-oxidation reaction intermediates in cucumber and to study the products formed by the α-oxidation enzyme purified from cucumber as previously described (6). The use of purified enzyme allowed us to study the α-oxidation reaction pathway in a more direct manner.

Different reaction mechanisms and intermediates were proposed in earlier studies of fatty acid α-oxidation in crude fractions from higher plants (9,13,14). In agreement with previous α-oxidation studies in higher plants (5,9,10,14), we found no evidence for any requirement for activated fatty

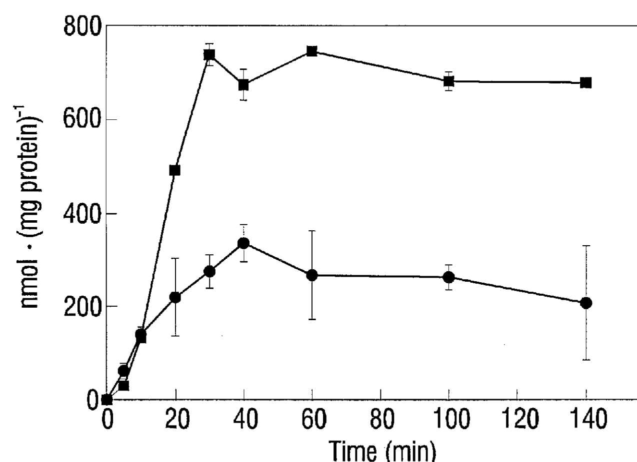

FIG. 6. Time course of ^{14}C-labeled formate and CO_2 formation in 150,000 × g_{max} subcellular fraction from cucumber. Cucumber 150,000 × g_{max} subcellular fraction (0.1 mg protein) was incubated with 0.05 mM [1-^{14}C]palmitic acid, and the production of $^{14}CO_2$ (■) and ^{14}C-formate (●) was measured. ^{14}C-Formate was determined as the total $^{14}CO_2$ released after mercuric acetate treatment of the incubation mixture minus release of $^{14}CO_2$ in the parallel sample. Each value represents the means ± SEM (n = 3).

acids in α-oxidation, either in cucumber crude fractions or in purified enzyme fraction. [1-^{14}C]Palmitoyl-CoA could not be oxidized to $^{14}CO_2$ in a crude fraction containing the entire α-oxidation system, and this result rules out the presence of a cucumber α-oxidation system dependent on CoA derivatives. In contrast, recent studies of mammalian α-oxidation showed the necessity of an activating step leading to the fatty acyl-CoA esters, before α-oxidation of methyl-substituted fatty acids occurs optimally (20).

In the present study, purified enzyme α-oxidized palmitic acid to yield the end products CO_2 and pentadecanal, which suggests that α-oxidation of fatty acids in cucumber involves an enzyme complex with more than one catalytic activity, most likely with at least an α-hydroxylase and a decarboxylase activity. 2-Hydroxy and 2-oxopalmitic acids were identified as palmitic acid α-oxidation intermediates in 150,000 × g_{max} subcellular cucumber fraction and were also shown to be formed by purified enzyme fraction as well. The intermediate and final product formation by the purified α-oxidation enzyme confirmed our proposals of a multifunctional nature of the α-oxidation enzyme in cucumber. Galliard and Matthew (14) earlier described an α-oxidation enzyme system in cucumber acetone powder which converted [U-^{14}C]palmitic acid to $^{14}CO_2$ and a mixture of products which involved aldehydes, alcohols, and small amounts of 2-hydroxypalmitic acid. An even earlier study proposed a 2-hydroxy fatty acid intermediate which first has to be oxidized to the 2-oxo fatty acid before decarboxylation (37). Our findings support an α-oxidation pathway such as 16:0 → 16OH → 16=O → 15al (Scheme 1). Incubation of cucumber subcellular 150,000 × g_{max} fraction or purified enzyme fraction with the proposed reaction intermediate, 2-hydroxypalmitic acid, resulted in a time-dependent production of pentadecanal, however, in lower amounts than with palmitic acid as substrate.

A more unstable 2-hydroperoxy α-oxidation intermediate was suggested in plant leaves (13) and mammalian brain microsomes (38). According to this proposal, the 2-hydroperoxyl-C_n intermediate is preferentially decarboxylated to the C_{n-1} fatty aldehyde, but to some degree reduced to 2-hydroxy C_n fatty acids. Recent substrate selectivity studies of the α-oxidation enzyme system in pea leaves show that pure (*R*)-2-hydroxy acids were enantiomerically formed (39). Consistent with the last proposed pathway, studies of long-chain aldehyde formation in green seaweeds showed the formation of 2-hydroperoxy-, 2-hydroxy-, and 2-oxopalmitic acid from palmitic acid, separated with reversed-phase HPLC, and that (*R*)-2-hydroperoxy acid was formed in high enantiomeric purity (40). We were not able to detect any 2-hydroperoxy fatty acid in the ethyl acetate extracts of the incubation mixtures with our HPLC separation system. Nor could the GC–MS analysis of the incubations with or without fatty acid derivatization give any evidence for a 2-hydroperoxypalmitate formation in cucumber enzyme fractions. In mammalian tissues, the existence of a 2-hydroxy α-oxidation intermediate was shown in early studies by Tsai *et al.* (41), and the formation of 2-hydroxy acyl-CoA was observed in broken cell systems, peroxisomes, and homogenates from rat liver (21,22). However, others were unable to confirm these findings in rat liver (42) or in intact liver cells (22). The most probable explanation for the difficulty in extracting the enzyme intermediate(s) is that channeling and/or tight binding of the intermediate(s) on the multimeric enzyme keeps the amount of intermediates at a low level.

The enzymatic formation of pentadecanal and $^{14}CO_2$ from [1-^{14}C]palmitic acid by our purified α-oxidation enzyme is in accordance with earlier studies. C_{n-1} long-chain aldehydes are well-established α-oxidation products of C_n long-chain fatty acids in higher plants (9,14), as well in algae (15). Very recently, the fatty end product was also identified as the C_{n-1} aldehyde in rat liver peroxisomes (31) and in human liver homogenate (30).

In the present study, formate was identified as a product of palmitic acid α-oxidation besides the previously described products, C_{n-1} long-chain aldehyde and CO_2, in cucumber $150{,}000 \times g_{max}$ subcellular fraction. The rather unusual decarboxylation product formate was not reported as an end product of the α-oxidation pathway in plants. However, our results are in agreement with recent mammalian studies, where α-oxidation of 3-methyl-substituted fatty acids was shown to result in the formation of formate as the end product besides CO_2 in human fibroblasts (27), in isolated rat hepatocytes (22,28), and *in vivo* in humans (43). Our experiments revealed a surprisingly low enzymatic activity for the conversion of formate into CO_2 in cucumber subcellular fractions. The overall high CO_2 production is not consistent with the low reaction rate of the formate step, indicating the existence of one pathway with direct liberation of CO_2 and another which could involve the enzymatic formation of formate. Furthermore, formate was not produced at all by purified α-oxidation enzyme fraction incubated with palmitic acid, which further supports our suggestion of two different α-oxidation pathways, at least in cucumber. These experiments clearly indicated that another enzyme other than the purified α-oxidation enzyme was responsible for the formate formation and the further conversion of formate into CO_2. The level of formate was reduced very slowly over time (Fig. 6), indicating no further metabolic conversion in the subcellular fractions studied. The putative formation of propionate as an α-oxidation product from saturated straight-chain fatty acids is not easily explained. Propionate is one of the mammalian oxidation products of branched-chain fatty acids which can undergo β-oxidation (27,44,45). The enzymatic production of the ^{14}C-labeled compound in our experiments was not due to peroxisomal or mitochondrial β-oxidation, as this would not be functional in our incubation systems. This was, however, an interesting observation which needs to be studied further before final conclusions can be drawn.

The fatty acid α-oxidation activity in plants, especially in cucumber, was found to be high without any added exogenous cofactors, compared to mammalian organellar fractions, e.g., rat liver peroxisomes, fortified with cofactors (21). The molecular oxygen requirement in our experiments suggests the involvement of an enzyme of the oxygenase family. In mammalian studies, the dioxygenase cofactors 2-oxoglutarate, Fe^{2+}, and ascorbate were reported to be required for optimal α-oxidation enzyme activity (21–23). In our experiments, Fe^{2+} stimulated the α-oxidation rate about twofold for both the $^{14}CO_2$ and the ^{14}C-formate plus $^{14}CO_2$ formation. Further addition of 2-oxoglutarate and ascorbate to the incubations with Fe^{2+} provided optimal rates of α-oxidation in cucumber $150{,}000 \times g_{max}$ fraction, indicating a dioxygenase reaction. This is in full agreement with the findings recently reported in mammalia (22). However, exogenous supply of these dioxygenase cofactors was not essential for the α-oxidation activity in cucumber. Most likely, minor quantities of cofactors are present in the cucumber subcellular fraction. Earlier studies of α-oxidation in cucumber suggested a metal-requiring enzyme, although 0.1 mM Fe^{2+} and Fe^{3+} inhibited $^{14}CO_2$ production, while Mg^{2+} stimulated the activity (14).

Monooxygenase cofactors were investigated in several tissues with different effects on the α-oxidation rate (5,13,14, 17,21,46,47). The stimulation of the α-oxidation activity with NADPH (0.5 mM) was consistent with earlier observations in plants (5,13) and in mammalian studies (46,47), where at least one of the α-oxidation steps is suggested to be mediated by a cytochrome P-450 monooxygenase (48). NADPH stimulated the rate of formate production better than it did CO_2 production. On the other hand, Fe^{2+} favored CO_2 formation, at the sacrifice of formate production. In summary, some discrepancies in the effects of the cofactors tested in this work on the $^{14}CO_2$ vs. the total ^{14}C-formate plus $^{14}CO_2$ production, respectively, were observed. These results indicate different routes for formate and CO_2 formation in palmitic acid α-oxidation in cucumber.

The inhibitory effect of H_2O_2 addition to our enzyme incubations can be explained by different inactivation

processes. The ability of H_2O_2 to convert Fe(II)-enzymes into the Fe^{3+} form and a reactive and denaturing hydroxyl radical was reported for dioxygenases (49). The involvement of a flavoprotein was proposed in the α-oxidation pathway involving a hydroperoxide intermediate in peanut cotyledons (13). In agreement with earlier studies in cucumber (5), no effect on CO_2 formation, nor on the formate production, was observed with FAD.

In summary, our results from the incubations of subcellular fractions and purified enzyme fraction suggest a multifunctional nature of the cucumber α-oxidation enzyme, which converts palmitic acid into CO_2 in a reaction involving two possible intermediates, a 2-hydroxy- and a 2-oxopalmitic acid, and which rate is stimulated by Fe^{2+} and Fe^{2+} in combination with ascorbate and 2-oxoglutarate. We demonstrate here, for the first time, that not only CO_2, but also HCOOH (formate), is an α-oxidation product in plant tissue. The possibility of more than one α-oxidation pathway in plants must be considered and investigated further.

Department of Food Science and Technology, Tokyo University of Fisheries, Tokyo 108-8477, Japan

ABSTRACT: The proportion of geometrical hydroperoxide isomers generated by aerobic oxidation of methyl linoleate (18:2 Me) in either aqueous emulsion consisting of Tris-HCl buffer (pH 7.4) or in a homogeneous dichloromethane solution was determined to understand the mechanism of lipid oxidation in different reaction systems. Four geometrical isomers were generated after oxidation of 18:2 Me in dichloromethane: methyl 13-hydroperoxy-*cis*-9,*trans*-11-octadecadienoate, methyl 13-hydroperoxy-*trans*-9,*trans*-11-octadecadienoate, methyl 9-hydroperoxy-*trans*-10,*cis*-12-octadecadienoate, and methyl 9-hydroperoxy-*trans*-10,*trans*-12-octadecadienoate in the ratios of 1:4:1:4, respectively. The ratios between each isomer did not change until the peroxide value (PV) increased to 58 meq/kg. Oxidation of 18:2 Me in aqueous emulsion yielded the same geometrical isomers of hydroperoxide. However, the ratios were different: 3:2:3:2 until the PV increased to 110 meq/kg. Predominant (60%) formation of *trans,trans* hydroperoxide isomers was obtained in the oxidation of a mixture of 18:2 Me and methyl laurate (12:0 Me). These results are interpreted to reflect the importance of the concentration of hydrogen atom-donating equivalents to the kinetic preference for different products. The high effective concentration of hydrogen donors in the oxidation of 18:2 Me in emulsions favored the formation of the less stable *cis,trans* isomers. The lower concentration of hydrogen donor in the dichloromethane solution effectively slowed hydrogen donation and led to the strong preference for the more stable *trans,trans* isomers. This interpretation was further tested by preparing emulsions of 18:2 Me and 12:0 Me to dilute concentration of hydrogen-donating species using the nonhydrogen-donating 12:0 Me. Consistent with the proposed hypothesis, the proportion of *trans,trans* isomers increased as a result of 12:0 Me addition.

Paper no. L8188 in *Lipids 34,* 675–679 (July 1999).

Lipid oxidation affects many properties of food, including texture, nutritive value, color, aroma, and functionality (1–4). Oxidation of cellular lipids also causes functional abnormalities and pathological changes in biological systems (5). Numerous promoting and inhibitory factors affect, to some extent, the oxidation of lipids in food systems. It has been generally accepted that the oxidizability of unsaturated fatty acids in homogeneous solution depends on the number of bis-allelic carbons available for hydrogen abstraction (6–9). The chemical environment in which oxidation occurs, however, can have an effect on the overall progress of oxidation.

This is perhaps most vividly seen by the observation that stability against oxidation of unsaturated fatty acids in aqueous micelles increases with increasing the number of bis-allelic carbons (10,11). Studies on aerobic oxidation kinetics explained the mechanism of the higher stability of polyunsaturated fatty acid in aqueous emulsion to be due to the polarity of the peroxyl radicals derived from polyunsaturated fatty acids (12,13). It is known that the ratio between *cis,trans* and *trans,trans* hydroperoxide products is affected by the concentration of hydrogen donor substrate and other conditions including temperature and stage of oxidation. For the oxidation of the mixture of linoleic acid and 1,4-cyclohexadiene (CHD), which is an excellent hydrogen-donating medium, almost 25 times higher *cis,trans* hydroperoxide isomer was generated in the system with 97% CHD. However, the ratio of the *cis,trans* isomer to *trans,trans* isomer decreased to 0.27 when cumene, a relatively poor hydrogen donor, was added to linoleic acid (14). In the present study, the effect of the colloidal reaction system in which lipid oxidation occurs on the distribution of unsaturated fatty acid hydroperoxide geometrical isomers was investigated by determining the geometrical isomers of methyl linoleate (18:2 Me) hydroperoxides.

MATERIALS AND METHODS

Lipids. 18:2 Me (over 99% purity) was purchased from Nu-Chek-Prep (Elysian, MN). The purchased 18:2 Me was dissolved in *n*-hexane and further purified by elution from a Sep-Pak silica cartridge (Waters Associates, Milford, MA) with 4.5% diethyl ether in *n*-hexane (15). Methyl laurate (12:0 Me, over 99.5% purity; Tokyo Chemical Ind., Tokyo, Japan) was reduced by sodium borohydride (Aldrich, Milwaukee, WI), followed by hydrogenation and further purification with a Sep-Pak silica cartridge.

Aerobic oxidation of lipids. For aerobic oxidation of 18:2 Me in a homogeneous solution, oxidation of 250 mg of the purified 18:2 Me was carried out in the presence of the free radical initiator 1 mM 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN; Wako Pure Chemicals, Osaka, Japan) in 10 mL of dichloromethane at 30°C in the dark. For aerobic oxidation of 18:2 Me in an aqueous emulsion, 625 mg of 18:2 Me was emulsified in 25 mL of Tris-HCl buffer (pH 7.4) by 0.3% Tween 20 under continuous and gentle stirring with a magnetic stirrer at 30°C in the dark. As a radical initiator, each of 1 mM AMVN or 1 mM 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH; Wako Pure Chemicals) was added to the aqueous emulsion (16,17). Aerobic oxidation of a mixture of 18:2 Me and 12:0 Me (1:28 in molar ratio) was initiated in the presence of 1 mM AMVN in bulk system at 30°C in the dark.

Determination of isomeric hydroperoxides of 18:2 Me. Geometrical isomers of the hydroperoxides generated by aerobic oxidation of 18:2 Me were analyzed by high-performance liquid chromatography (HPLC) equipped with a post-column diphenyl-1-pyrenylphosphine (DPPP) fluorescence detection system (18,19). In this system, the confounding effects of nonperoxy conjugated dienes such as hydroxy compounds were avoided by comparing fluorescence detection to ultraviolet (UV) detection at 235 nm. Briefly, geometrical isomers of hydroperoxides were separated along a Supelcosil LC-Si silica column (2.1 mm i.d. × 250 mm, 5 µm; Supelco, Bellefonte, PA) using a mixture of 500 mL of *n*-hexane and 34 mL of diethyl ether as a mobile phase at a flow rate of 0.6 mL/min. The eluting and separated hydroperoxides were mixed with DPPP solution (3 mg in a mixture of 200 mL 1-butanol and 200 mL methanol) pumped at a flow rate of 0.3 mL/min to form DPPP oxide in the postcolumn reaction coil. The fluorescence intensity of the DPPP oxide was monitored at the emission wavelength at 380 nm with the excitation wavelength of 352 nm.

The positional distribution of the hydroperoxy groups on 18:2 Me was determined by gas chromatography–mass spectrometry (GC–MS). Briefly, the corresponding trimethylsilyl ether (TMS) derivatives of the hydroxy methyl octadecanoates that were obtained by reduction followed by hydrogenation and subsequent TMS derivatization were separated and analyzed by GC–MS as described (18,19).

UV spectra of hydroperoxide isomers were determined with a photodiode array detector model 1050 (Hewlett-Packard, Boise, ID) positioned in the elution stream between the HPLC column and the reaction coil of the HPLC system.

Determination of peroxide value (PV). The PV of the oxidized 18:2 Me was determined photometrically by the ferric thiocyanate method (20). The PV of oxidized lipids in the aqueous emulsion was determined after extraction by *n*-hexane.

RESULTS

Changes in PV. In the aerobic oxidation of 18:2 Me in homogeneous dichloromethane solution, the PV increased almost rectilinearly to 70 meq/kg after 4 h of oxidation period when the hydroperoxide equivalent to 1.9% of the original 18:2 Me was generated (Fig. 1). In the aerobic oxidation of the lipid in aqueous solution, the trace of the PV did not show a significant induction period in either the AAPH- or AMVN-initiated aerobic oxidation (Fig. 1). When the reaction was terminated after 7 h, hydroperoxides equivalent to 5.5% of the original 18:2 Me had been formed.

Composition of geometrical hydroperoxide isomers of 18:2 Me. The various isomers formed from oxidized 18:2 Me were separated by HPLC and the hydroperoxide-containing isomers detected by postcolumn detection resolved into four distinct peaks (Fig. 2). No significant peaks other than hydroperoxy products of 18:2 Me were detected by either UV or fluorescent detection when the detection time was extended to more than 20 min. The positional distribution of hydroperoxy groups on these oxidation products of 18:2 Me was determined by GC/MS of the corresponding hydrogenated and reduced TMS-ether derivatives. The TMS-ether derivatives obtained from the peak component #1 and/or #2 on the HPLC chromatograms (Fig. 2, A and B) yielded two prominent fragment ions of *m/z* 173 and *m/z* 315. The TMS-ether derivatives obtained from peak component #3 and/or #4 yielded two prominent fragment ions of *m/z* 229 and *m/z* 259. These characteristic fragment ions were yielded by cleavage of C-C bond and to the carbon on which the TMS-ether group attached (21,22).

The geometrical configuration of the hydroperoxide isomers was determined by the UV spectra (data not shown). The bathochromic shift of the UV spectrum (from λ_{max} = 231 nm of peaks #1 and #3 to λ_{max} = 235 nm of peaks #2 and #4 in the present HPLC mobile phase) reflected the *trans,trans* and *cis,trans* isomers of conjugated fatty acid hydroperoxides (23,24).

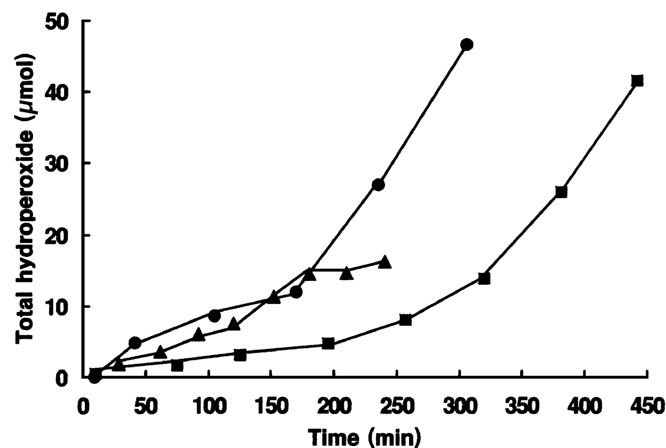

FIG. 1. Hydroperoxides formed with time during the oxidation of methyl linoleate in different physical states. Methyl linoleate in a Tween 20-stabilized emulsion (250 mg/10 mL) was initiated by the water-soluble free radical initiator, 2,2′-azobis(2-amidinopropane) dihydrochloride, AAPH (■) or by the oil-soluble free radical initiator, 2,2′-azobis(2,4-dimethylvaleronitrile, AMVN (●). Methyl linoleate in dichloromethane solution (625 mg/25 mL) was initiated by the oil-soluble free-radical initiator, AMVN (▲).

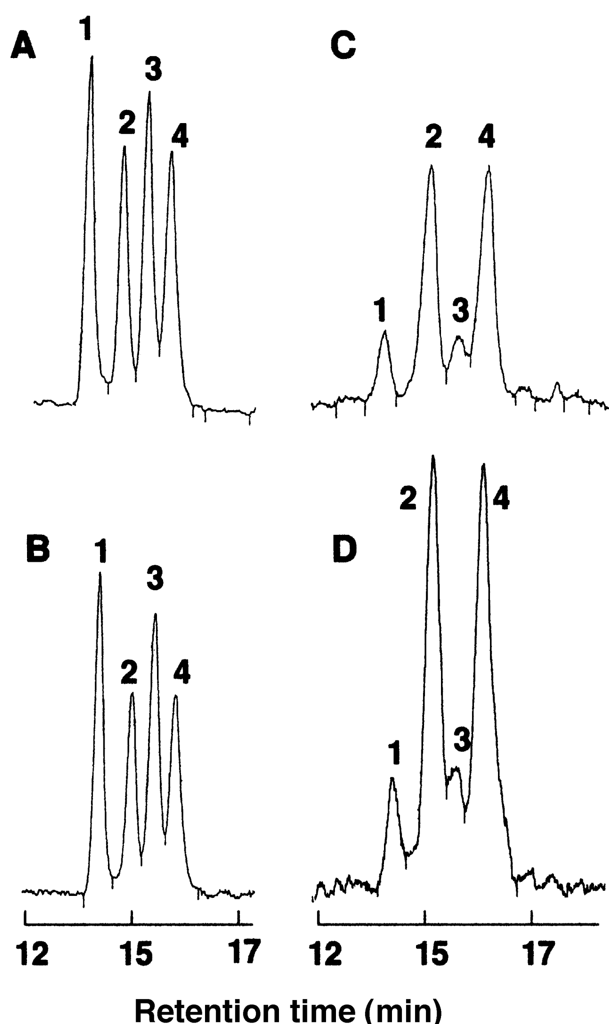

FIG. 2. Typical chromatograms of the positional and geometrical isomers of hydroperoxides generated by the oxidation of methyl linoleate. (A) Methyl linoleate in a Tween 20-stabilized aqueous emulsion initiated by the hydrophilic initiator AAPH; (B) methyl linoleate in a Tween 20-stabilized aqueous emulsion initiated by the hydrophobic initiator AMVN; (C) methyl linoleate in a dichloromethane solution initiated by AMVN; (D) methyl linoleate and methyl laurate (1:28 , w/w) initiated by AMVN. Peaks 1, 2, 3, and 4 were identified as methyl 13-hydroperoxy-*cis*-9,*trans*-11-octadecadienoate, 13-hydroperoxy-*trans*-9,*trans*-11-octadecadienoate, methyl 9-hydroperoxy-*trans*-10,*cis*-12-octadecadienoate, and methyl 9-hydroperoxy-*trans*-10,*trans*-12-octadecadienoate, respectively. See Figure 1 for abbreviations.

These spectral data supported the assignments that the hydroperoxide isomers were methyl 13-hydroperoxy-*cis*-9,*trans*-11-octadecadienoate (13-*cis,trans*), methyl 13-hydroperoxy-*trans*-9,*trans*-11-octadecadienoate (13-*trans,trans*), methyl 9-hydroperoxy-*trans*-10,*cis*-12-octadecadienoate (9-*trans,cis*) and methyl 9-hydroperoxy-*trans*-10,*trans*-12-octadecadienoate (9-*trans,trans*), similar to those generated in the homogeneous solution. The ratio of these isomers was 3:2:3:2, respectively, in the aqueous emulsion as calculated from peak areas (Fig. 2, A and B) and did not change during 4 h of oxidation period as shown in Figure 3. When the oxidation in the aqueous emulsion was extended until the PV reached its maximal value (280 meq/kg, 9.2% of 18:2 Me was oxidized) after which PV decreased, the ratios of the four hydroperoxide isomers remained unchanged. In the aqueous emulsion, the yield of the *cis,trans*-hydroperoxide isomers was similar to that of *trans,trans*-hydroperoxide isomers.

Hydroperoxides generated from the oxidation of 18:2 Me in homogeneous solution included the same four positional and geometrical isomers, 13-*cis,trans*-, 13-*trans,trans*-, 9-*trans,cis*- and 9-*trans,trans*-isomers, as shown in Figure 2C. The ratio of these hydroperoxide isomers was determined from the peak areas to be 1:4:1:4, respectively. In homogeneous solution, the yield of the *trans,trans*-hydroperoxide isomers was greater than that of *cis,trans*- and *trans,cis*-hydroperoxide isomers. As shown in Figure 3, the composition of the positional isomers of the hydroperoxides did not change during 7 h of oxidation period. Similar distribution of the hydroperoxide isomers was obtained in the aerobic oxidation of 18:2 Me mixed with 12:0 Me as shown in Figure 2D. In this reaction system, the formation of *trans,trans* hydroperoxide isomers was predominant compared to *cis,trans*- and *trans,cis*-hydroperoxide isomers.

DISCUSSION

In the oxidation conditions used in these studies using azoradical initiators, the formation rate of hydroperoxides was higher than their decomposition rate. As a result, the monohydroperoxide products of 18:2 Me were the predominant oxidation products found in the present study. The hydroperoxide isomers obtained under these experimental conditions in aqueous emulsions were the same as those found in previous results (15,18–20,25–27) obtained from the autoxidation of 18:2 Me in bulk phase. When linoleic acid or its various esters oxidize, one of the bis-allelic hydrogens attached to the 11-carbon position is abstracted to yield a 1,4-pentadiene radical structure, followed by reaction with oxygen at the end-carbon positions to form a mixture of the terminal hydroperoxide isomers, including 9-hydroperoxy and 13-hydroperoxy 18:2 Me (14). The distribution of the four geometrical isomers, 9-*trans,cis*- and *trans,trans*-hydroperoxides and 13-*cis,trans*- and *trans,trans*-hydroperoxides, depends on the overall ability of coexisting molecules to donate hydrogen atoms to the peroxy radical. Free-radical oxidation of linoleic acid in bulk yields 9-hydroperoxy and 13-hydroperoxy products in a similar molar ratio (15,25,26). However, proportions of the geometrical isomers of hydroperoxides obtained in homogeneous solution and in the mixture with 12:0 Me were significantly different from the previous results obtained in the oxidation of 18:2 Me in bulk phase. It is well accepted that the *trans,trans*-isomers of peroxy radicals are formed by further oxidation of the initially formed *cis,trans* peroxy radicals (28). Therefore, the distribution of geometrical isomers, *cis,trans* and *trans,trans* hydroperoxides, depends on the ability of coexisting substrate to donate hydrogen to the peroxy radicals (14).

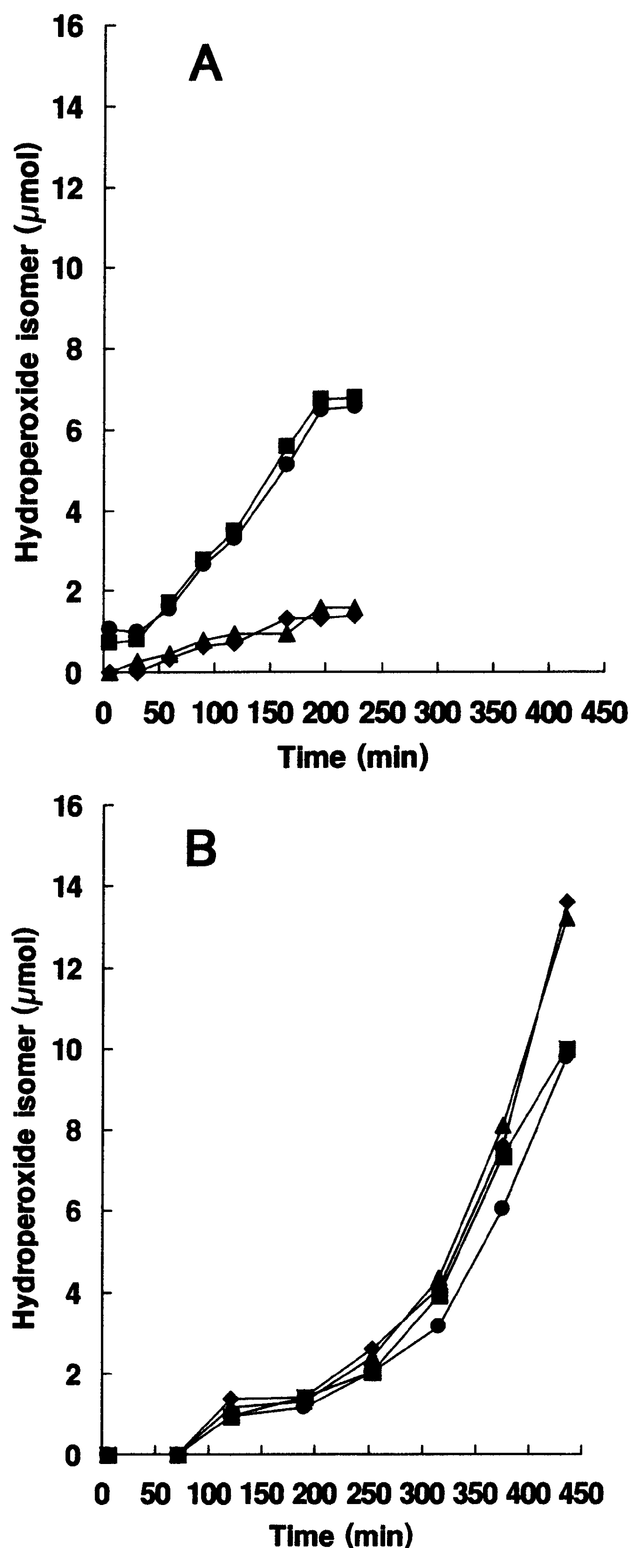

FIG. 3. Changes with time in the quantities of hydroperoxide isomers generated by aerobic oxidation of 250 mg of methyl linoleate in dichloromethane (A) and in aqueous emulsion (B). ■, Methyl 13-hydroperoxy-*trans*-9,*trans*-11-octadecadienoate; ●, methyl 9-hydroperoxy-*trans*-10,*trans*-12-octadecadienoate; ▲, methyl 13-hydroperoxy-*cis*-9,*trans*-11-octadecadienoate; ◆, methyl 9-hydroperoxy-*trans*-10,*cis*-12-octadecadienoate.

The formation of hydroperoxide comes about upon hydrogen atom donation to peroxy radicals. It is also known that only *cis,trans*-hydroperoxide isomers are produced in the presence of sufficiently high concentration of hydrogen atom donors. It is well accepted that the antioxidative activity of α-tocopherol is due to quenching the hydroperoxy radicals as an efficient hydrogen donor (29,30). Peers *et al.* (31) showed that α-tocopherol was effective in altering the distribution of *cis,trans*- and *trans,trans*-hydroperoxide isomers. The formation of *trans,trans*-hydroperoxide isomers was almost completely suppressed at a concentration of 0.1 M α-tocopherol in the autoxidation of methyl linolenate. When a large amount of dipalmitoyl phosphatidylcholine was incorporated into liposomes of soybean phosphatidylcholine and autoxidized, the yield of *trans,trans*-hydroperoxides was much greater than that of *cis,trans*-isomers (32). The dilution of soybean phosphatidylcholine rich in linoleic esters by dipalmitoyl phosphatidylcholine suppressed the hydrogen abstraction by peroxyradical yielded mostly the *cis,trans*-isomers as elaborated by Porter *et al.* (28), because dipalmitoyl phosphatidylcholine is a poor hydrogen atom donor relative to the polyunsaturated fatty acids linoleate and linolenate in soybean phosphatidylcholine.

The results from the present study showed that the *trans,trans*-isomers of 18:2 Me hydroperoxide were formed to a greater extent in the dichloromethane solution compared to oxidation in the aqueous emulsion. In the dichloromethane solution of 18:2 Me, the effective concentration of 18:2 Me as a hydrogen atom donor was expected to be lower compared to that of the aqueous emulsion. Thus, the distribution of the two kinds of geometrical isomers of hydroperoxide depends on the effective concentration of the hydrogen atom donors in the reaction system. It is therefore logical to expect that the formation of the *cis,trans*-products of oxidized 18:2 Me would be preferred in aqueous emulsions in which the 18:2 Me molecules exist as 100% of the oil phase. Contrary to this, the ratio of *trans,trans*-hydroperoxide isomers is larger than that of *cis,trans*-hydroperoxides in the diluted solution of linoleic acid, because the concentration of hydrogen atom donor is effectively lower. The predominant distribution of *trans,trans*-isomers in the oxidation mixture of 18:2 Me mixed with 12:0 Me strongly supports this assumption. Thus, we conclude that the actual concentrations of hydrogen atom donors in the lipid particles of the emulsion are in sufficient concentration to donate hydrogen atoms to the *cis,trans*-hydroperoxide isomers of oxidized 18:2 Me. Contrary to this, the concentration of hydrogen atom donor in the dichloromethane solution was too low to provide sufficient hydrogen atom to the *cis,trans*-peroxyradical of oxidizing methyl linoleate. This lack of hydrogen donor resulted in a net higher concentration of the *trans,trans*-hydroperoxide isomers. The present observation in which the predominant formation of hydroperoxide with *trans,trans* configuration can be explicitly controlled provides a powerful methodology to obtain all *trans* fatty acid hydroperoxides.

19-Azasqualene-2,3-epoxide and Its *N*-Oxide: Metabolic Fate and Inhibitory Effect on Sterol Biosynthesis in *Saccharomyces cerevisiae*

Paola Milla, Franca Viola, Maurizio Ceruti, Flavio Rocco, Luigi Cattel, and Gianni Balliano*

Dipartimento di Scienza e Tecnologia del Farmaco, 10125, Torino, Italy

ABSTRACT: 19-Azasqualene-2,3-epoxide was more inhibitory than the corresponding *N*-oxide against 2,3-oxidosqualene cyclase (OSC) solubilized from *Saccharomyces cerevisiae* (IC_{50} 7 ± 2 and 25 ± 5 μM, respectively). Both compounds showed a reversible, noncompetitive-type inhibition on solubilized OSC. Different inhibitory properties between the compounds were especially evident when measuring [^{14}C]acetate incorporation into nonsaponifiable lipids extracted from treated cells. In cells treated with 19-azasqualene-2,3-epoxide at 30 μM, the radioactivity associated with the oxidosqualene fraction, which was negligible in the controls, rose to over 40% of the nonsaponifiable lipids, whereas it remained at a slightly appreciable level in cells treated with the *N*-oxide derivative under the same conditions. 19-Azasqualene-2,3-epoxide was also more effective than the *N*-oxide as a cell growth inhibitor (minimal concentration of compound needed to inhibit yeast growth: 45 and >100 μM, respectively). The two inhibitors underwent different metabolic fates in the yeast: while 19-azasqualene-2,3-epoxide did not undergo any transformation, its *N*-oxide was actively reduced to the corresponding amine in whole and in "ultrasonically stimulated" cells. The *N*-oxide reductases responsible for this transformation appear to be largely confined within the microsomal fractions and require NADPH for their activity. A possible relationship between the inhibitory properties of the two compounds and their metabolic fates is discussed.

Paper no. L8184 in *Lipids 34,* 681–688 (July 1999).

2,3-Oxidosqualene-lanosterol cyclase (OSC; EC 5.4.99.7) is a membrane-bound enzyme that plays a key role in the biosynthesis of sterols in animals and fungi because it catalyzes the conversion of an acyclic compound, (3*S*)-2,3-Oxidosqualene (OS), into lanosterol, the first cyclic precursor of C_{27}-sterols. The reaction, catalyzed by OSC and other OS cyclizing enzymes, is a multistep process, which starts with an initial protonation of the oxirane ring of the substrate and involves a series of transient carbocationic high-energy intermediates, to give a C-20 carbonium ion: this intermediate undergoes a series of 1,2 hydride and methyl shifts to form the cyclized product, after the loss of a proton (Scheme 1) (1–3).

Understanding this complex enzyme-mediated reaction at the molecular level requires knowledge of the active site structure and the precise hydrophobic interactions that control the conformation of the substrate during the cyclization process. In the last 10 yr, different and often partially overlapping strategies were employed to elucidate these points: (i) purification and characterization of OSC from different sources (4–6), (ii) determination of amino acid sequence from cloned and sequenced genes (7–10), and (iii) study of the effect of several types of rationally designed inhibitors (11–16).

In the field of OSC inhibitors, one of the most profitable designing strategies was to mimic the high-energy intermediates (formed during the cyclization process) by replacing their positively charged carbonium ion with a nitrogen atom, protonated at physiological pH (17). Several laboratories synthesized cyclic isoprenoid derivatives bearing a nitrogen atom corresponding to the C-10 or C-8 carbocationic intermediates formed during the cyclization process (1). Among these, mono- and bicyclic derivatives proved to be potent inhibitors of OSC, whereas the tricyclic derivatives showed only modest inhibition of OSC *in vitro* (17). Our strategy was to design acyclic aza-squalenoid derivatives possessing a nitrogen atom corresponding to the postulated C-2, C-8, and C-20 carbonium ions arising from the cyclization of OS: these derivatives act as potent inhibitors of OSC from mammals, fungi, and higher plants (17–20).

In this study we describe the biological effect of 19-azasqualene-2,3-epoxide (**1,** Scheme 2) and its *N*-oxide (**2,** Scheme 2) on OSC from *Saccharomyces cerevisiae*. The activity of these inhibitors was evaluated *in vitro* on solubilized OSC, and *in vivo* on proliferating cells, to estimate the effect on growth and ergosterol biosynthesis. The metabolic fate of these compounds was also carefully studied in different subcellular preparations, in order to find a possible correlation between biological activity and metabolic involvement.

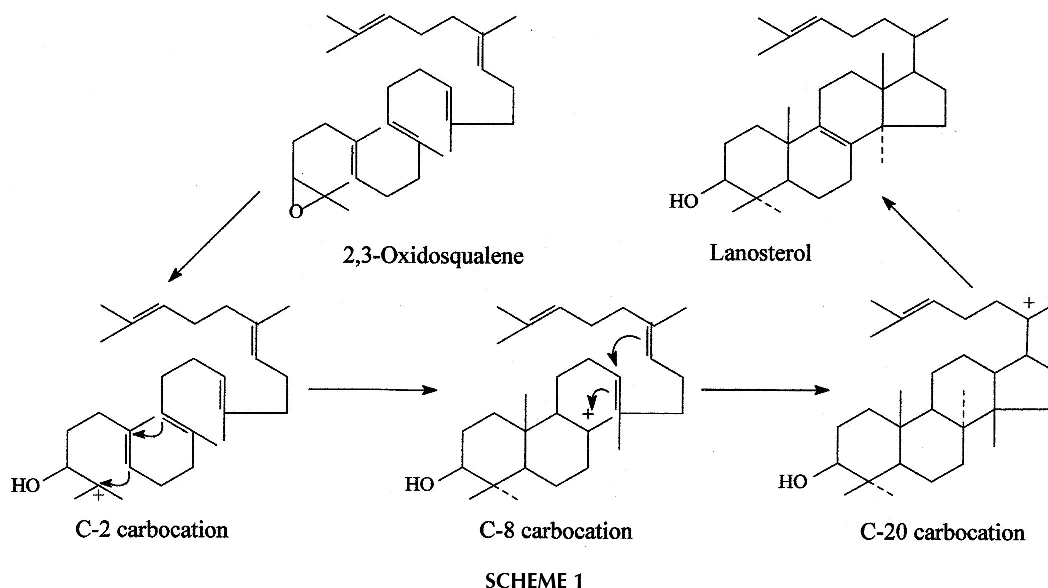


SCHEME 1

MATERIALS AND METHODS

Yeast strain, growth conditions, and microsome preparation. *Saccharomyces cerevisiae* ATCC 12341 was cultured as reported by Balliano *et al.* (18). For the preparation of microsomes, an earlier method was slightly modified (18). The yeast homogenate, obtained by sonication of washed cells in 2.5 vol of 0.1 M KH_2PO_4/NaOH buffer, pH 7.1 (Buffer A), was clarified by low-speed centrifugation (10,000 × *g* for 30 min) and then centrifuged at 150,000 × *g* for 60 min. The resulting supernatant (soluble or nonsedimentable fraction) was stored at −80°C. The pellet was resuspended in Buffer A and recentrifuged at 150,000 × *g* to give the washed microsomal fraction. The microsomal fraction was rapidly frozen in liquid N_2 and stored at −80°C. Protein was determined by the method of Bradford (21) using Bio-Rad Protein Assay with γ-globulin as standard. Microsomes, stored at −80°C, retained OSC activity for several months. In a typical preparation, 50 g cells (wet weight) gave 0.3 g microsomal protein.

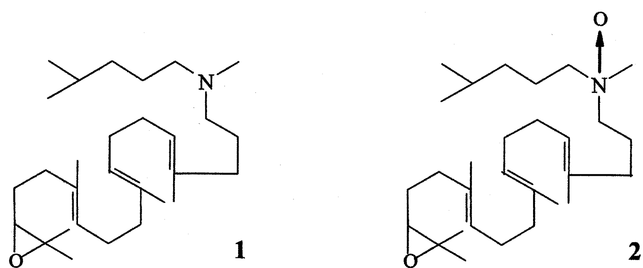
Preparation of ultrasonically stimulated cells. Ultrasonically stimulated cells were prepared as reported by Bujons *et al.* (22). Briefly: cells harvested at the late logarithmic phase were suspended in 3 vol of Buffer A and irradiated ultrasonically at 0°C for 1 h at intensities of 44 W/cm by using a Vibra Cell Ultrasonic Processor (Sonics & Materials, Danbury, CT) with a titanium immersion tip. The resulting dispersion was diluted at 4×10^6 cells/mL with Buffer A.

Removal of peripheral proteins and solubilization of OSC. Washed microsomes were sedimented at 150,000 × *g* and resuspended (12 mg/mL protein concentration) in 0.5 M KH_2PO_4/NaOH buffer, pH 6.2. The suspension was gently stirred for 30 min at 4°C and then centrifuged at 150,000 × *g* for 60 min. The supernatant (containing the peripheral proteins) was discarded, and the pellet was resuspended in 10 mg Polidocanol/mL at a protein concentration of 12 mg/mL. The solution was gently stirred for 60 min at 4°C and then centrifuged at 150,000 × *g* for 60 min, giving a supernatant containing the enzymatic activity (0.6 to 0.7 mg/mL protein concentration). The protein concentration of the solubilized sample was determined with Lowry's method, modified by Peterson (23). The solubilized OSC was stored at −80°C.

Isolation of mitochondria from yeast cells. Mitochondrial fraction was prepared as reported by Rickwood *et al.* (24). *Saccharomyces cerevisiae* was homogenized as described for microsome preparation. The cell lysate was centrifuged at 2,500 × *g* for 10 min at 5°C, to pellet unbroken cells, cell wall debris, and nuclei. The supernatant was centrifuged at 15,000 × *g* for 10 min at 5°C to pellet the mitochondria. Pellet was gently resuspended in 0.8 M sucrose, 1 mM EDTA, 10 mM Tris-HCl, pH 7.4, and 0.1% bovine serum albumin and loaded onto a continuous 1–2 M sucrose gradient containing 1 mM EDTA, 10 mM Tris-HCl, pH 7.4 and 0.1% bovine serum albumin.

The gradient was centrifuged in a swing-out rotor at 80,000 × *g* for 90 min at 5°C: the "mitochondrial fraction" was found as a brown band at a density of about 1.18 g/mL and collected using a Pasteur pipette.

Effects of inhibitors on yeast growth. The growth of *S. cerevisiae* with different concentrations of inhibitors as such was followed turbidimetrically, measuring the absorbance (*A*) of the culture at 640 nm (18). The evaluation was limited to



SCHEME 2

the logarithmic phase of the growth. A calibration curve of A_{640} vs. concentration of colonies forming cells was made in order to determine the yeast cell concentration during the logarithmic phase.

Acetate incorporation into nonsaponifiable lipids. Sterol biosynthesis in whole yeast cells was measured by incorporation of [2-^{14}C]acetate into nonsaponifiable lipids as described elsewhere (18). Briefly: washed cells (10–20 × 10^6 cells), resuspended in 5 mL of 25 mM KH_2PO_4/NaOH buffer (pH 6.5) containing 1% glucose, 0.1 mg/mL Tween 80 and inhibitors at different concentrations, were fed with 2 µCi [2-^{14}C]acetate (50 mCi/mM) and shaken for 2 h at 30°C. Nonsaponifiable lipids were extracted and separated on silica gel plates (Merck, Darmstadt, Germany) developed in *n*-hexane/ethyl acetate (85:15, vol/vol) with authentic references of ergosterol, lanosterol, dioxidosqualene, OS and squalene. The ^{14}C radioactivities of the chromatographed bands were evaluated by a System 2000 Imaging Scanner (Packard, Palo Alto, CA).

Assay of OSC activity and kinetic determinations. Enzyme activity of OSC was determined as elsewhere described (18). Briefly: the reaction mixture, containing (*R,S*)[3-^{3}H]-2,3-oxidosqualene (100,000 dpm, 25 µM), Tween 80 (0.2 mg/mL) and solubilized enzyme (0.3 mg protein/mL) in Buffer A, was incubated for 30 min at 35°C in a shaking water bath. The nonsaponifiable extract was separated by thin-layer chromatography (TLC), and bands co-migrating with 2,3-oxidosqualene and lanosterol were scraped off and monitored by liquid scintillation counting. The amount of product formed was calculated with respect to total recovered radioactivity.

IC_{50} values (the concentration of inhibitor that reduced the enzymatic conversion of 2,3-oxidosqualene to lanosterol by 50%) were determined at 25 µM substrate and different concentrations of inhibitors.

The kinetics of inhibition was analyzed by the Lineweaver-Burk graphical method (25).

Time-dependent inactivation and irreversible inhibition of OSC. Time-dependent inactivation was evaluated as described by Lindsey and Harwood (26). Solubilized OSC (0.3 mg protein/mL) was incubated for the set times at 35°C in Buffer A containing (*R,S*)[3-^{3}H]-2,3-OS (100,000 dpm, 200 µM), Tween 80 (0.2 mg/mL), and 0, 5, 20, and 100 µM inhibitor. Following incubation, OSC activity was calculated as described above and expressed as percentage of control (no inhibitor).

Irreversible inhibition was tested by determining the residual activity of preincubated enzyme after complete removal of inhibitors. Solubilized enzyme was preincubated for 20 min at 35°C with 200 µM of **1** or **2**. After preincubation, the enzyme solution (1 mL) was passed through a small column (1 mL) of DEAE Biogel A (Bio-Rad) equilibrated with 0.005 M KH_2PO_4/NaOH buffer pH 7.0, containing 2 mg Polidocanol/mL. After washing with the same buffer, the enzyme was eluted with 0.2 M KH_2PO_4/NaOH buffer buffer pH 7.0, containing 2 mg Polidocanol/mL, and the OSC activity was tested as described above. The activity of enzyme preincubated with inhibitors was compared with the activity of a control, preincubated without inhibitor and passed through the column.

*Metabolic fates of compounds **1** and **2***. The metabolism of azasqualene derivatives **1** and **2** was studied by incubating different preparations (2 mL each in Buffer A and 0.1 mg/mL Tween 80) with radioactive inhibitors (100 µM, 2 µCi) for 30 min at 35°C with or without a NADPH-generating system (0.15 mM $NADP^+$, 0.25 mM glucose 6-phosphate, and 0.5 unit glucose 6-phosphate dehydrogenase/mL). Nonsaponifiable lipid extracts were then chromatographed on silica gel plates (Merck) developed in two different TLC systems: (i) methanol and (ii) dichloromethane/methanol/NH_3 (97:1:2, by vol), with authentic samples of compounds **1** and **2**. Chromatographic bands were visualized with I_2. Transformation of compounds **1** and **2** was evaluated by scanning chromatographic plates with a System 2000 Imaging Scanner (Packard). To identify the main metabolite of **2**, 200 mL of cells were incubated with 100 µM unlabeled inhibitor **2** under the above conditions. The metabolite, recovered from TLC plates, was analyzed by ^{1}H nuclear magnetic resonance (NMR) and mass spectroscopy.

Chemistry. Synthesis of compounds **1**, **2,** and *R,S*-[3-^{3}H]-2,3-OS was described elsewhere (27,28). Polidocanol (polyoxyethylene 9 lauryl ether) and Tween 80 were from Sigma (Milan, Italy), [2-^{14}C]acetate was from Amersham International (United Kingdom), DEAE Biogel A and Bio-Rad Protein Assay were from Bio-Rad (Milan, Italy), and $NADP^+$, glucose 6-phosphate and glucose 6-phosphate, dehydrogenase were from Merck.

Tritium-labeled 19-azasqualene-2,3-epoxide **1** and its *N*-oxide **2** were synthesized as follows: pure C_{22} squalene aldehyde bromohydrin, synthesized as described recently (14), was added to a vial containing NaB^3H_4 (total activity 100 mCi, 200 × 10^9 dpm, specific activity 8.0 Ci/mmol). Purification on TLC afforded [1-^{3}H]C_{22} alcohol bromohydrin which was added to a suspension of pyridinium chlorochromate in dichloromethane. After workup and purification by column chromatography, pure [1-^{3}H]C_{22} aldehyde bromohydrin was obtained. Reductive amination of [1-^{3}H]aldehyde with *N*-methyl-4-methylpentylamine (27) and $NaBH_3CN$ directly afforded [18-^{3}H]-19-azasqualene-2,3-epoxide **1**. The large molar excess of *N*-methyl-4-methylpentylamine, with respect to the tritium-labeled aldehyde bromohydrin, afforded the contemporary reductive amination and closure of the bromohydrin to epoxide. Reaction with 30% hydrogen peroxide in methanol afforded [18-^{3}H]-19-azasqualene-2,3-epoxide *N*-oxide **2**. Inhibitors **1** and **2** (1 Ci/mmol) were obtained with high radiochemical yield and high purity. For determination of specific and total radioactivity, three samples of each pure product, diluted in benzene, were counted for radioactivity by liquid scintillation. Isotope counting was carried out as described elsewhere (28) and the mean value was used.

The ^{1}H NMR spectra were recorded on either a JEOL EX 400 (Tokyo, Japan) or a Bruker AC 200 instrument (Milton, Ontario, Canada) in $CDCl_3$ solution at room temperature, with tetramethylsilane as internal standard. Mass spectra were

recorded on a Finnigan MAT TSQ 700 spectrometer (Milan, Italy); infrared spectra were recorded on a Perkin-Elmer 781 spectrophotomer (Milan, Italy).

RESULTS

*Effects of compounds **1** and **2** on yeast growth.* MIC (= minimal concentration of compound that inhibits yeast growth) for 19-azasqualene-2,3-epoxide **1** was 45 ± 5 μM; the *N*-oxide **2** was ineffective on yeast growth even at the highest concentrations tested (100 μM), as judged by turbidimetric method.

Effects on yeast sterol biosynthesis. The influence of compounds **1** and **2** on sterol biosynthesis was evaluated by incorporation of [^{14}C]acetate into nonsaponifiable lipids, extracted from yeast cells cultured in the absence (control) or in the presence of different concentrations of inhibitors (Fig. 1). Compound **1** caused a dose-dependent accumulation of radioactivity in OS, accompained by a sharp drop in the radioactivity incorporated into the 4,4-desmethyl sterol fraction (ergosterol fraction). In cells treated with 30 μM compound **1**, the radioactivity associated with the OS fraction, which was negligible in the controls, increased to account for 40% of the nonsaponifiable lipids, and the ergosterol fraction, which accounted for 60% of the radioactivity in the control cultures, fell to 10% in treated cells. No increase in the radioactivity associated with the squalene fraction was noted after treatment of cells with **1** at concentrations up to 30 μM, suggesting that OS cyclase was the primary target of the inhibitory action. At higher concentrations (100 μM), compound **1** also inhibited squalene epoxidase, as suggested by the accumulation of radioactivity in the squalene fraction (Fig. 1).

The *N*-oxide derivative **2** was less efficient than **1** in inhibiting sterol biosynthesis. Its action seemed to be less specific, as shown by the complex distribution of radioactivity among the components of the nonsaponifiable extract (Fig. 1).

Both compounds seem to affect the uptake of the labeled acetate by the cells: radioactivity incorporated into nonsaponifiable fraction increased from 2% of the administered acetate in control culture to 5% in cells treated with either inhibitor.

Inhibition of solubilized OSC. The direct effect of compounds **1** and **2** on yeast oxidosqualene cyclase was evaluated by incubating solubilized enzyme with radioactive OS, in the presence of different amounts of inhibitors (no metabolization of either compound was observed in this enzymatic system). The results confirmed the differences in the inhibitory activities of the two compounds, compound **1** (IC_{50} 7 ± 2 μM) being more active than compound **2** (IC_{50} 25 ± 5 μM).

The kinetics of the inhibition of solubilized OSC by compounds **1** and **2** were apparently noncompetitive, as shown by the Lineweaver-Burk plot (K_i 14 and 20 μM, respectively).

The ability of compound **1** to inactivate yeast OSC in a time-dependent manner was evaluated as described by Lindsey and Harwood (26), using the solubilized enzyme. As shown in Figure 2, inhibition of OSC activity by **1** seems not to be strictly dependent on the duration of incubation.

To evaluate the ability of compounds **1** and **2** to inactivate yeast OSC irreversibly, solubilized enzyme was preincubated with **1** or **2** as described in the Materials and Methods section. After removal of the inhibitor by chromatographic passage through DEAE column, the recovery of enzyme activity was above 85% of control for both inhibitors.

*Metabolism of compounds **1** and **2** in cell cultures.* Two possible metabolic fates of compounds **1** and **2**, namely, interconversion (29) and cyclization (30), were monitored by feeding either whole or ultrasonically stimulated cells with radiolabeled inhibitors. While compound **1** was always recovered unchanged, compound **2** was found to be extensively transformed into a metabolite cochromatographing with **1**. The metabolite cochromatographing with **1**, isolated from cells incubated with cold compound **2**, had the same biological activity (IC_{50} and MIC) as an authentic sample of **1**. Of this metabolite 1.5 mg was analyzed by ^{1}H NMR and electron impact mass spectrometry and gave the following data: ^{1}H NMR ($CDCl_3$) δ 0.89 [*d*, 6 H, $(CH_3)_2CH$], 1.18 [*m*, 2 H, $(CH_3)_2CHCH_2$], 1.27 and 1.31 (two peaks, 6 H epoxidic CH_3), 1.43–1.64 [*m*, 16 H allylic CH_3, $(CH_3)_2CHCH_2CH_2CH_2NCH_2CH_2$ and epoxide-CH_2], 1.96–2.12 (*m*, 12 H, allylic CH_2), 2.22 (*s*, 3 H, CH_3N), 2.30 (*t*, 4 H, CH_2NCH_2), 2.71 (*t*, 1 H, epoxidic CH), 5.12–5.18 (*m*, 3 H vinylic CH); electron impact mass spectrum *m/z* 431 (8), 360 (35), 278 (25), 210 (42), 128 (100). Spectroscopic data were identical to those of an authentic sample of **1** (27). Tracer experiments and spectroscopical results suggest that an *N*-oxide reductase activity is responsible for the transformation of **2** into **1**.

Attempts at identifying minor transformation products of compound **2**, appearing as more polar bands on TLC plates, were unsuccessful. However, it was ruled out that they were cyclization products arising from catalytic involvement of OSC, as they were also formed in the presence of a powerful inhibitor of yeast oxidosqualene cyclase, the 2-aza-2,3-dihydrosqualene 100 μM (31).

Subcellular localization of N*-oxide reductase activity.* The results of the search for the subcellular localization of *N*-oxide reductase activity are summarized in Table 1. The ultrasonically stimulated cells retained almost the same activity as the intact cells. Among the fractions recovered by cellular fractionation, microsomes supplemented with NADPH generating system proved to be able to reduce actively 19-azasqualene-2,3-epoxide *N*-oxide **2** into the corresponding amine **1**. A weaker *N*-oxide reductase activity was detectable in mitochondrial fraction.

DISCUSSION

19-Azasqualene-2,3-epoxide was designed by our group as 19-aza analog of the C-20 carbocationic intermediate formed during the enzymatic cyclization of OS. Such inhibitor was previously tested on purified pig liver OSC and on microsomes from rat and pig liver, *S. cerevisiae* and *Candida albicans* (27), as well as in hepatoma cells (20), proving to be a

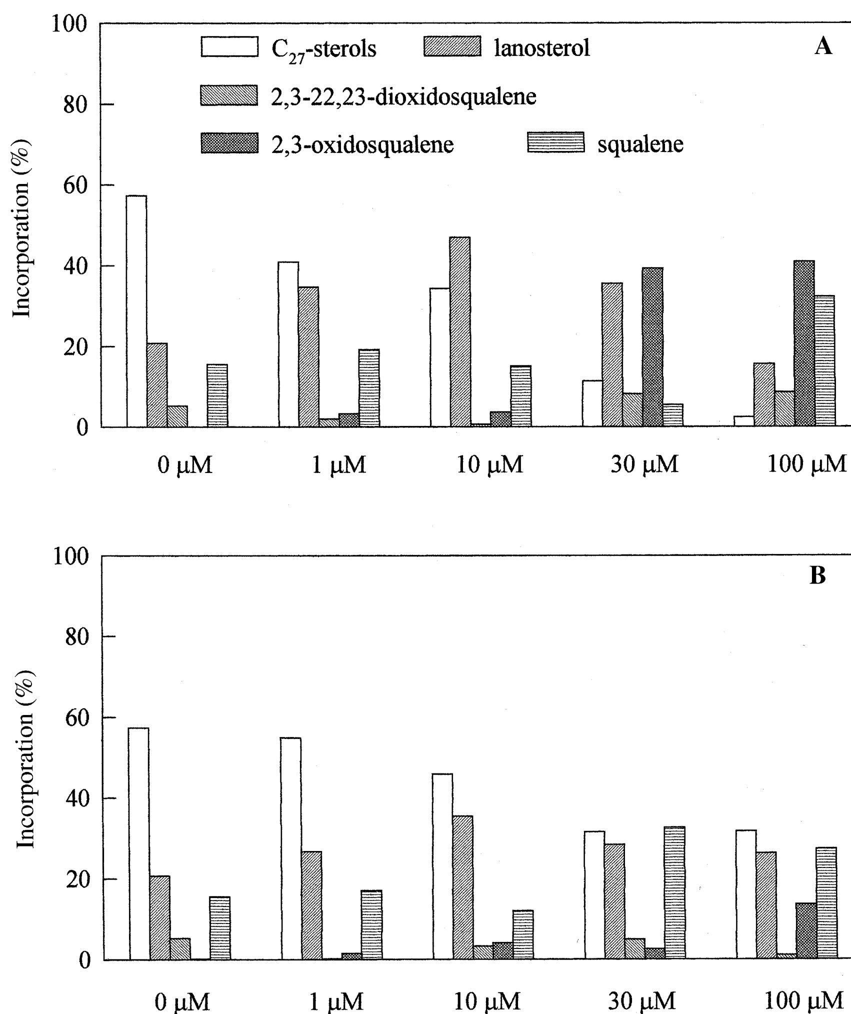


FIG. 1. Effect of (A) 19-azasqualene-2,3-epoxide (**1**) and its (B) *N*-oxide (**2**) on the incorporation of [^{14}C]acetate into the nonsaponifiable lipid fraction of *Saccharomyces cerevisiae*. Cells were incubated as described in the Materials and Methods section. Nonsaponifiable lipids were extracted and analyzed by thin-layer chromatography (TLC) on silica gel plates developed in *n*-hexane/ethyl acetate (85:15, vol/vol) with authentic references of ergosterol, lanosterol, dioxidosqualene, oxidosqualene, and squalene. Average incorporation of radioactivity into total nonsaponifiable extract ranged from 2% of initial acetate in control culture to 5% in cells treated with 100 μM inhibitors (see text). Results are means of two separate experiments, each with duplicate incubation. Maximal deviations from the mean were less than 10%.

good inhibitor of OSC. In the present study we focused our attention exclusively on *S. cerevisiae*, examining the inhibitory properties of the azasqualene derivative **1** either on OSC solubilized from microsomes (an enzyme preparation more homogeneous than microsomal pellet previously tested) or in whole cells.

Assays on solubilized enzyme confirmed the effectiveness of 19-azasqualene-2,3-epoxide as inhibitor of yeast OSC and revealed that its kinetic behavior was of reversible noncompetitive type. Tracer experiments with cell cultures fed with labeled acetate accounted for a highly specific action of the inhibitor. In fact, the most remarkable effect of treating cells with increasing concentration of inhibitor was the accumulation of radioactivity into OS, the substrate of OSC. The effect, already appreciable at 1–10 μM inhibitor, burst at 30 μM, a concentration approaching that causing the inhibition of cell growth.

The activity of 19-azasqualene-2,3-epoxide **1** was compared with that of the corresponding *N*-oxide **2**, a molecule designed on the basis of the hypothesis that squalenoid molecules bearing amine *N*-oxide group could mimic the positively charged intermediates involved in the enzymatic cyclization of OS (31). *N*-Oxide derivative **2** proved to be less-effective than the corresponding amine **1** as inhibitor of solubilized OSC. The difference, however, did not appear dramatic especially if evaluated through kinetic analysis in carefully controlled steady-state conditions (K_i of **1** and **2**, 14 and 20 μM, respectively).

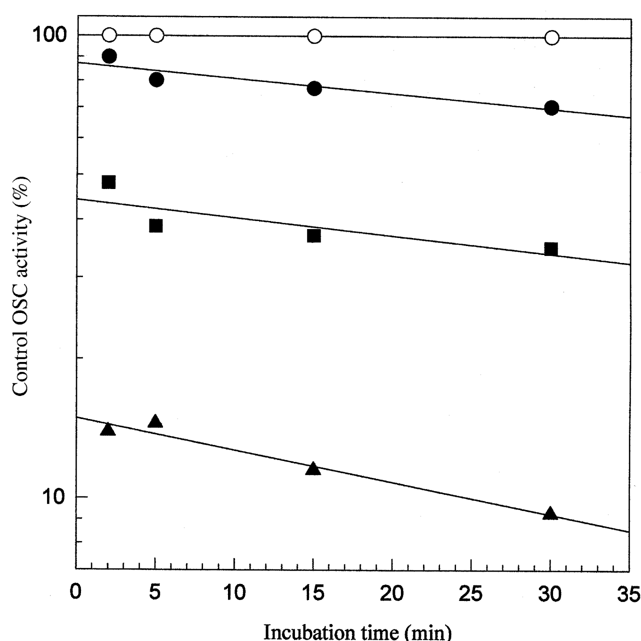

FIG. 2. Time-dependent inhibition of 2,3-oxidosqualene-lanosterol cyclase (OSC) by compound **1**. Solubilized OSC (0.3 mg/mL) was incubated for the given time at 35°C in the presence of the inhibitor 0 μM (○), 5 μM (●), 20 μM (■), and 100 μM (▲). Residual activity (% of the control incubated without the inhibitor for the same duration) was determined as described in the Material and Methods section. Points are means of two separate experiments, each with duplicate incubation. Maximal deviation from the mean was less than 10%.

The most impressive difference between **1** and **2** arose from experiments with whole cells. *N*-Oxide derivative **2** was found to be a poorer and less specific inhibitor of sterol biosynthesis as well as almost ineffective as inhibitor of cell growth at up to 100 μM concentration.

A comparison between the properties of two inhibitors of OSC of *S. cerevisiae* led us to investigate the reasons of the differences observed.

Our interest in this subject began more than 10 yr ago, from the observation that, among the azasqualene derivatives, the *N*-oxides were always less effective inhibitors of yeast OSC than the corresponding amines (18). This difference was especially evident in cell cultures treated with inhibitors: *N*-oxide derivatives inhibited cell growth as well as produced an accumulation of OS in the lipid fraction at much higher concentrations of inhibitor than the amine derivatives (18,29,32).

In a preceding paper (29) we observed that, when cells were treated with 2-aza-2,3-dihydrosqualene or 22,23-epoxy-2-aza-2,3-dihydrosqualene, inhibitors were recovered unchanged, whereas under the same conditions, *N*-oxide derivatives were actively transformed into compounds cochromatographing with the corresponding amines, i.e., into products of a putative *N*-oxide reductase activity. Experimental proof supporting the transformation did not, however, go beyond the TLC level. In the present investigation, the transformation of 19-azasqualene-2,3-epoxide *N*-oxide into the

TABLE 1
Subcellular Localization of *N*-Oxide Reductase Activity[a]

Assayed preparations	Starting compound	Products obtainted
Whole cells (4 × 10^6 cells/mL)	19-Azasqualene epoxide *N*-oxide	100% 19-azasqualene epoxide
	19-Azasqualene epoxide	100% 19-azasqualene epoxide
Ultrasonically stimulated (44 W) cells (4 × 10^6 cells/mL)	19-Azasqualene epoxide *N*-oxide	100% 19-azasqualene epoxide
	19-Azasqualene epoxide	100% 19-azasqualene epoxide
Mitochondria (12 mg/mL protein)	19-Azasqualene epoxide *N*-oxide	100% 19-azasqualene epoxide *N*-oxide
	19-Azasqualene epoxide	100% 19-azasqualene epoxide
Microsomes (4 mg/mL protein)	19-Azasqualene epoxide *N*-oxide	90% 19-azasq. epox. *N*-oxide, 10% 19-azasq. epox.
	19-Azasqualene epoxide	100% 19-azasqualene epoxide
Soluble fraction (10 mg/mL protein)	19-Azasqualene epoxide *N*-oxide	95% 19-azasq. epox. *N*-oxide, 5% 19-azasq. epox.
	19-Azasqualene epoxide	100% 19-azasqualene epoxide
Mitochondria (12 mg/mL protein) + NADPH-generating system	19-aAzasqualene epoxide *N*-oxide	85% 19-azasq. epox. *N*-oxide, 15% 19-azasq. epox.
	19-Azasqualene epoxide	100% 19-azasqualene epoxide

	19-Azasqualene epoxide	100% 19-azasqualene epoxide
Soluble fraction (10 mg/mL protein) + NADPH-generating system	19-Azasqualene epoxide *N*-oxide	90% 19-azasq. epox. *N*-oxide, 10% 19-azasq. epox.
	19-Azasqualene epoxide	100% 19-azasqualene epoxide

[a]The different preparations (2 mL each in Buffer A and 0.1 mg/mL Tween 80) were incubated, in the absence or in the presence of a NADPH generating system, for 30 min at 35°C, with [18-^{3}H]-19-azasqualene-2,3-epoxide (100 μM, 2 μCi) or [18-^{3}H]-19-azasqualene-2,3-epoxide *N*-oxide (100 μM, 2 μCi). The cells were then collected by centrifugation, and nonsaponifiable lipids were analyzed by thin-layer chromatography (CH_3OH) with authentic references of the two compounds. Radioactivity on the plates was evaluated with a radiochromatogram scanner. Boiled extracts were used as controls.

amine was unambigously demonstrated by mass spectrometry and NMR analysis of the recovered metabolite, as well as by its biological activity. Although on one hand these results confirmed the occurrence in yeast of a *N*-oxide reductase activity similar to that described in mammals (33), on the other hand they complicated the question of the different effects of two types of inhibitor: why should cells treated with the less active compound respond differently from cells treated with the more active compound, if the former is rapidly transformed into the latter within the cell? Why should the behavior of an active compound produced within the cell be different from that of the same molecule taken up from the outside? A careful examination of the subcellular localization of *N*-oxide reductase and OSC activity could provide the answers. Reducing enzymes appeared to be confined mainly within the microsomal compartment, whereas OSC is shared between the microsomes and the nonsedimentable fractions of the cell, the latter retaining the bulk of the activity (34). One could postulate that the inhibitor 19-azasqualene-2,3-epoxide, after entering the cell, is immediately ready to hit the target enzyme wherever it is located, while the *N*-oxide derivative is readily captured by the endoplasmic reticulum, where it is actively reduced to the corresponding more active amine. If this is the case, the only target enzyme left to the inhibitor formed *in situ* is microsomal OSC activity, which is only a small part of the total activity of the cell.

We very recently observed that the localization of OSC in yeast cells seems even more complex than previously thought. Part of the activity, which had simply been defined as a "nonsedimentable form" of the enzyme in a previous investigation (34), was found to be associated with lipid particles (Balliano, G., unpublished results), a subcellular compartment involved in lipid metabolism and trafficking (35), containing other enzymes of sterol biosynthesis, such as Δ^{24}-methyltransferase and squalene epoxidase (36–38). Leber *et al.* (35), who studied lipid particles in yeast in considerable depth, observed that their structural characteristics resemble those of mammalian serum lipoproteins, with protein exposed at the surface of the particle. If this is true of OSC, any inhibitor able to enter the cell can easily reach its target enzyme, provided the molecule is not captured by some different compartment of the cell, rapidly and specifically.

To summarize, the lower effectiveness of 19-azasqualene-2,3-epoxide *N*-oxide as inhibitor of yeast OSC in cell cultures may be ascribed to the combined effect of the following factors: (i) intrinsic properties of the molecule, (ii) rapid removal of the inhibitor from soluble compartment of the cell by the action of microsomal *N*-oxide reductases, and (iii) trapping of the reduction product within microsomal membranes.

In conclusion, the differences observed between the new inhibitors, 19-azasqualene-2,3-epoxide **1** and the *N*-oxide **2**, of yeast OSC make it clear that designing new inhibitors and evaluating their effects in whole cells require knowledge not only of the structural properties of the molecules but also of the subcellular distribution of both the target enzymes and any enzymes possibly involved in their metabolic transformation.

ABSTRACT: In the present study, we examined the effects of cell-permeable C_2-ceramide on contraction of aortic smooth muscle and intracellular free Ca^{2+} ($[Ca^{2+}]_i$). C_2-ceramide (10^{-7} to 10^{-4} M) alone did not elicit any significant changes in either basal tension or resting levels of $[Ca^{2+}]_i$ in rat aortic smooth muscle. However, C_2-ceramide (10^{-7} to 10^{-4} M) attenuated phenylephrine-induced contractions in isolated rat aortic rings in a concentration-related manner, and inhibited elevations in $[Ca^{2+}]_i$ in cultured rat aortic smooth muscle cells induced by phenylephrine. C_2-ceramide-induced relaxation was found to be only slightly endothelium-dependent. However, nitric oxide inhibitors (L-NNA, L-NMMA), an inhibitor of prostanoid synthesis (indomethacin), an inhibitor of opiate actions, and several inhibitors of the pharmacologic actions of various vasoactive amines all failed to interfere with the vasorelaxant responses of C_2-ceramide. Three different inhibitors of protein kinase C, when used in a wide concentration range, also failed to interfere with the ceramide-induced relaxations. Our results suggest that the sphingomyelin-signaling pathway may play an important regulatory role in arterial wall tone.

Paper no. L8039 in *Lipids 34,* 689–695 (July 1999).

Sphingolipids are invariably present in the outer leaflet of the plasma membrane, and well over 300 types of sphingolipids were identified in eukaryotic cells (1). Sphingolipid metabolites participate in key events of signal transduction and cell regulation. The sphingomyelin pathway is a new signal transduction system. Numerous extracellular agonists, including 1,25-dihydroxyvitamin D_3, tumor necrosis factor alpha, endotoxin, interferon, interleukin I, Fax ligands, dexamethasone, retinoic acid, progesterone, ionizing irradiation, chemotherapeutic agents, heat, and nerve growth factor (2,3) cause the activation of neutral sphingomyelinase, which hydrolyzes plasma membrane sphingomyelin to produce ceramide (4–6). Ceramide, released as a consequence of sphingomyelinase, is now thought to play roles in fundamental processes such as cell proliferation, membrane-receptor functions, oncogenesis, and immune inflammatory responses (1–6).

Recently, ceramide was implicated in atherogenesis (7,8). The diverse effects of ceramide suggest that it may serve as a pleotrophic modulator of many types of cell functions. However, little is known about the role for this lipid molecule in vascular smooth muscle tone. Since intracellular free Ca^{2+} concentration ($[Ca^{2+}]_i$) plays a key role in regulating vascular tone, and α_1-adrenergic responses are potently elicited by the agonist phenylephrine (9), on vascular muscle, the present studies were designed to investigate the effects of ceramide on phenylephrine-induced contraction of isolated rat aorta and Ca^{2+} mobilization in cultured rat aortic smooth muscle cells.

MATERIALS AND METHODS

Animals, vessels, cell preparations, and solutions. The experiments were performed on thoracic aortae obtained from adult Wistar male rats (weighing 200–250 g). The animals were killed by stunning and subsequent decapitation. Aortae were isolated according to previously established methods (10,11). The vessels for the ring segments were carefully excised and cleaned, and the tissues cut into *ca.* 3 to 4 mm lengths. For intact tissue preparations, extreme care was taken to avoid damage of endothelial cells. For denuded arteries, the intima of the vessels were gently rubbed with a wire to rub off endothelial cells (11), and the tissues were placed in normal Krebs-Ringer bicarbonate solution (NKRB) at room temperature. The composition of the NKRB was (in mM): NaCl 118, KCl 4.7, $KHPO_4$ 1.2, $MgSO_4$ 1.2, $CaCl_2$ 2.5, glucose 10, and $NaHCO_3$ 25.

The procedure employed to isolate and culture single aortic vascular smooth muscle cells, and the use of digital imaging microscopy with the fluorescent indicator, fura-2, were reported (12,13). Briefly, aortic vascular smooth muscle cells were cultured in Dulbecco's modified Eagle's medium mixed 1:1 with Ham's (vol/vol) nutrient mixture F-12, penicillin 100 U/mL, streptomycin 100 μg/mL, 0.1% lipid mixture and supplemented with 20% fetal bovine serum at 37°C in a humidi-

fied atmosphere composed of 95% air, 5% CO_2. Morphological examination of confluent cultures revealed vascular smooth muscle cells exhibiting a crisscross pattern, hills-and-valleys, and nodular structures when examined by phase-contrast microscopy. Immunohistochemical staining with a monoclonal antibody, recognizing exclusively α-smooth muscle actin, indicated that over 97% of the cultures were pure vascular smooth muscle cells (13). Cells were maintained in the culture medium through passage 3 and harvested with 1% trypsin-EDTA and then seeded onto 12-mm circular coverslips at an almost confluent density.

Assessment of vascular reactivity, denudation of endothelium, and drugs used. The ring segments of rat thoracic aortae were arranged, isometrically, under resting tensions of 1.5–3.0 g, respectively. All tissues were equilibrated, initially, for 2 h in chambers containing 20 mL of NKRB at 37°C, gassed continuously with a 95% O_2–5% CO_2 mixture, and connected to force displacement transducers using Grass Model 7 polygraphs (Grass Model FT 03, Grass Instrument Company, Quincy, MA) before data collection. The loading tensions were adjusted periodically and maintained throughout the equilibration period. The incubation media were routinely changed every 10–15 min as a precaution against interfering metabolites (14), and only then were changes in isometric tensions of the vascular smooth muscle preparations recorded. The stable level of tension developed in response to the addition of 60 mM KCl was always measured prior to collection of the data; this was utilized as a reference contractile maximal response. To examine the functional viability of an intact endothelium, a concentration-response curve to phenylephrine (10^{-8}–10^{-5} M) was determined for each ring in order to determine the concentration (EC_{50}) producing a half-maximal contractile response to phenylephrine. After the effects of the concentration-response curves were washed out, vascular rings were precontracted with EC_{50} doses of phenylephrine (10^{-6} M), and the presence and absence of endothelium were confirmed by testing for relaxation to acetylcholine (10^{-7}–10^{-4} M), which generally resulted in 90% relaxation in aorta with intact endothelium.

Experimental procedures for aortic rings. Before phenylephrine EC_{50} doses were added, the ring aortic segments were exposed to NKRB containing various concentrations of C_2-ceramide (10^{-7}–10^{-4} M), for each dose, for at least 15 min to determine whether or not the sphingolipid derivative had any effects on base-line tension and/or development of spontaneous mechanical activity. A C_2-ceramide inactive analog (i.e., C_2-dihydroceramide) was used as above, as a negative control. C_2-ceramide and C_2-dihydroceramide were dissolved in dimethyl sulfoxide, and aliquots were added to an aqueous medium with sonication to a stock concentration of 1 mM. The stock solution was diluted in the NKRB solution and aliquots added to the chamber and allowed to rapidly mix at concentrations over the range of 10^{-7}–10^{-4} M. In other experiments, phenylephrine EC_{50} doses were added, and when the contraction reached a plateau phase the C_2-ceramide was added cumulatively to the bath, as well as C_2-dihydroceramide. The results of these experiments are expressed in percentage relaxation of the stable contraction induced by phenylephrine (10^{-6} M) (reference contraction). For studies on the role of endothelium in C_2-ceramide-induced relaxation, the rings were exposed to various, specific pharmacologic antagonists for 20 min prior to stimulation with ceramide. To determine whether the induced relaxations were affected by endogenous release of prostanoids and nitric oxide (NO), from the blood vessels, various inhibitors of NO formation were added, e.g., N^G-nitro-L-arginine (L-NNA), and L-N^G-monomethyl-arginine (L-NMMA), as well as indomethacin (5×10^{-5} M). These specific pharmacologic antagonists were added to the baths for at least 20–30 min periods prior to ceramide. Other pharmacologic amine antagonists, such as atropine (10^{-6} to 10^{-5} M), diphenhydramine (10^{-5} M), cimetidine (10^{-5} M), propranolol (10^{-5} M), and methysergide (10^{-6} to 10^{-5} M) were also used (added 20 min prior to ceramide) to determine whether the ceramide responses were due to release of different types of vasoactive amines. To determine whether protein kinase C (PKC) activation plays any role in ceramide-induced relaxation, three different inhibitors of PKC (i.e., staurosporine, H7, and bisindolylmaleimide I) were tested over a wide concentration range; these drugs were also added 15–20 min prior to phenylephrine and before ceramide addition.

$[Ca^{2+}]_i$ studies in single cultured vascular smooth muscle cells. $[Ca^{2+}]_i$ in single vascular smooth muscle cells was measured according to previously established methods (12,13). Cultured cells were preloaded with 2 μM fura-2 acetoxymethyl ester in the culture medium without fetal bovine serum for 45–60 min in a humidified 37°C air incubator. To improve the loading efficiency, 0.12% pluronic F-127 was used in the loading medium. Following dye-loading, the coverslips, containing fura-2-loaded cells, were washed three times with HEPES buffer solution and placed in a tissue chamber on a temperature-controlled stage of a Nikon fluorescence microscope and subsequently superfused with HEPES buffer solution (pH 7.4, 37°C). The HEPES buffer solution contained (in mM): NaCl 118, KCl 4.8, $CaCl_2$ 2.5 , KH_2PO_4 1.2, $MgSO_4$ 1.2, HEPES 5, and glucose 10. The pH was brought to 7.4 with NaOH. Measurement of $[Ca^{2+}]_i$ was performed using a PTI model 4000 Deltascan, LPS-220 Image Analyzer, Video Scope (Photon Technology International, Inc., South Brunswick, NJ), and the $[Ca^{2+}]_i$ was measured 20 min after C_2-ceramide or C_2-dihydroceramide adminstration without superfusion. The cultured cells, preloaded with fura-2 acetoxymethyl ester, were excited, alternately, at 340 and 380 nm. The emission intensity was recorded at 510 nm using a silicon intensified target camera.

Fluorescence ratios (R) were obtained by dividing the 340-nm images by the 380-nm images. Then $[Ca^{2+}]_i$ of single vascular smooth muscle cells was calculated by using the equation:

$$[Ca^{2+}]_i = K_d \times B \times \left[(R - R_{\min})/(R_{\max} - R)\right] \quad [1]$$

A K_d (dissociation constant) of 224 nM was used for the fura-2/Ca^{2+} complex. B is the ratio of fluorescence intensity of

fura-2 to Ca-bound fura-2, with excitation at 380 nm. Calibration parameters were determined using small volumes of buffered calibrating solutions (pH 7.2, 37ºC) containing 3 μM fura-2 pentapotassium salt and various $[Ca^{2+}]$ (12,13,15). The intensity of the recorded images at 340 and 380 nm was corrected by subtracting them from background fluorescence recorded at the corresponding wavelengths. The resulting images were then used to calculate $[Ca^{2+}]_i$ in vascular smooth muscle cells. Calibration showed that our 340:380 ratio fell on the linear portion of the calibration curve. Particular care was taken to minimize photobleaching of the dye. Experiments were carried out in total darkness, and exposure to excitation light was less than 2 s in all experiments.

Chemicals and reagents. C_2-ceramide and naloxone HCl were obtained from Sigma Chemical Co. (St. Louis, MO). Indomethacin was purchased from Merck (Rahway, NJ); C_2-dihydroceramide, acetylcholine, L-NNA, L-NMMA) propranolol HCl, and diphenhydramine HCl were obtained from Calbiochem Co. (La Jolla, CA). Phenylephrine HCl and atropine sulfate were obtained from Mann Research Lab. Inc. (New York, NY). Fura-2 acetoxymethyl ester was purchased from Molecular Probes Inc. (Eugene, OR). Cimetidine HCl was obtained from Smith-Kline Beecham (Philadelphia, PA). Staurosporine, H7, and bisindolylmaleimide I were all obtained from Sigma Chemical Co. All other chemicals and reagents were obtained from Fisher Scientific (Fairlawn, NJ); these were commercial products of the highest grade available.

Statistical analyses. Where appropriate, results are expressed as means ± SEM. Differences between means were analyzed using nonpaired *t*-tests or analysis of variance followed by a Newman-Keule test. Statistical significance was assumed when $P < 0.05$.

RESULTS

Effects of C_2-ceramide on rat thoracic aorta vasomotor tone. C_2-ceramide (10^{-7}–10^{-4} M), added to organ chambers containing resting rat thoracic aortic rings, did not elicit any significant changes in basal tension (data not shown, $n = 8$). However, treatment of phenylephrine-contracted rat aortic rings with and without endothelium, with C_2-ceramide (10^{-7}–10^{-4} M), resulted in concentration-dependent relaxation, respectively, during stable contraction evoked by 10^{-6} M phenylephrine (Fig. 1C, D; Fig. 2). The relaxation responses in endothelium intact rings were of a somewhat greater magnitude ($P < 0.001$) compared to endothelium-denuded rings, indicating that the responses were only partially dependent on intact endothelial cell function. At lower concentrations (i.e., 10^{-7}–10^{-6} M), C_2-ceramide also elicited a 25% reduction (relaxation), which could be deemed physiologic, of phenylephrine-induced contractions (Fig. 2). In con-

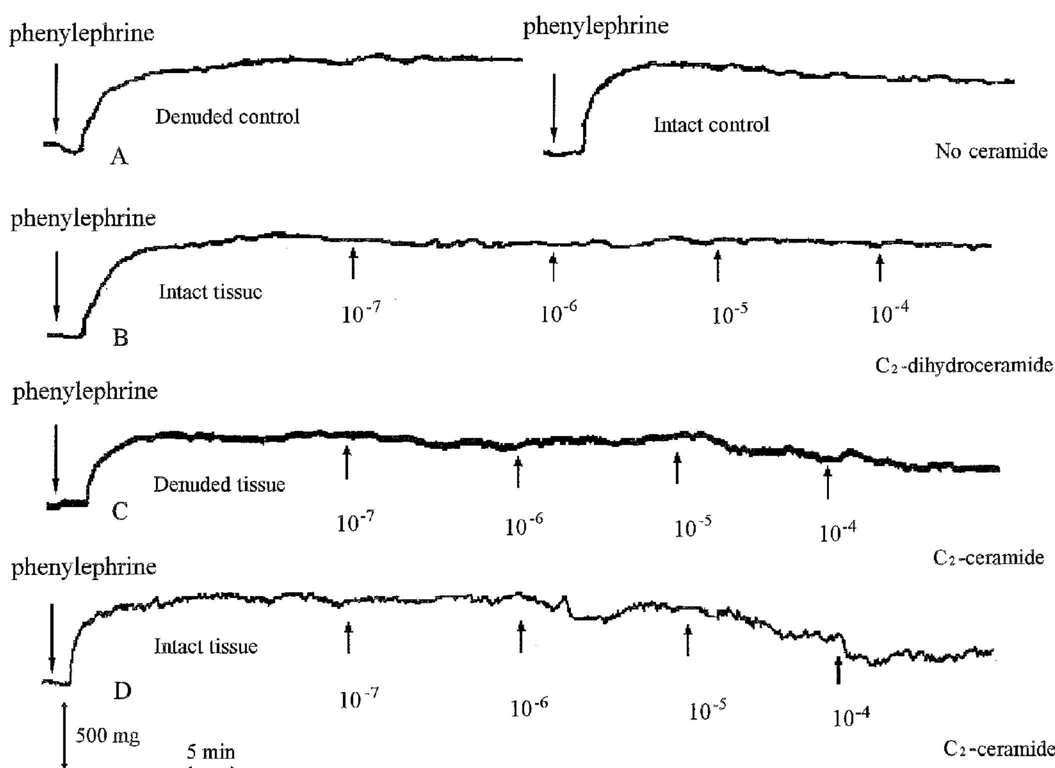

FIG. 1. Typical recording of C_2-ceramide-induced relaxations of phenylephrine-contracted aortic rings in intact and denuded tissue and inactive C_2-dihydroceramide controls. Vertical bar = tension; horizontal bar = time. C_2-dihydroceramide, unlike active C_2-ceramide, failed to elicit any relaxation. (A) Timed controls with phenylephrine added but no ceramide; (B) addition of C_2-dihydroceramide after phenylephrine; (C) C_2-ceramide added to denuded tissue; (D) C_2-ceramide added to intact tissue.

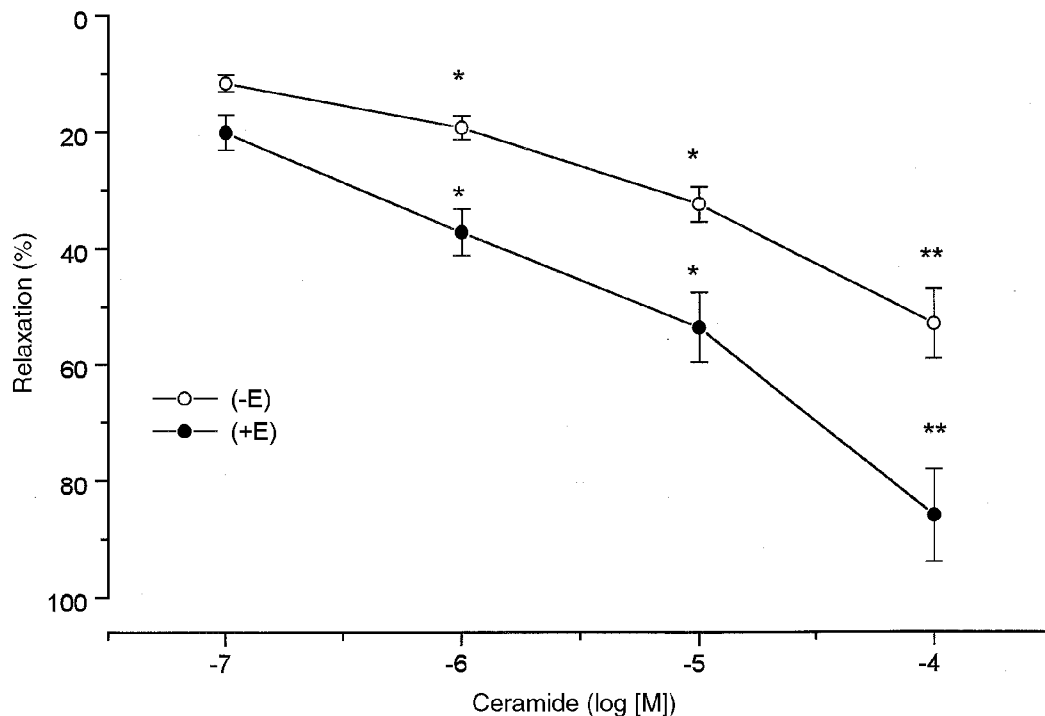

FIG. 2. Effects of ceramide on phenylephrine (10^{-6} M)-induced contractions in rat aortic segments in the absence or presence of endothelium. Values are expressed as means ± SE. All concentrations of ceramide at 10^{-6} to 10^{-4} M are significantly different between rings with and without endothelium (*$P < 0.05$, **$P < 0.01$), $n = 8$ each.

trast, C_2-dihydroceramide, an inactive analog of ceramide, had no relaxant effects (Fig. 1B).

Effects of NO inhibitors, indomethacin, and pharmacologic antagonists on C_2-ceramide-induced vasorelaxation. As normal endothelial cells can release several vasoactive substances, such as NO and prostacyclin, and endogenous amines can also be released from the arterial wall, we determined whether C_2-ceramide-induced relaxations were due to release of any these substances. In the presence of two different inhibitors of NO [i.e., L-NNA (5×10^{-5} M), L-NMMA (5×10^{-5} M)] or the cyclooxygenase inhibitor, indomethacin (5×10^{-5} M), the vasorelaxations in response to C_2-ceramide were not attenuated significantly ($n = 6$ each, $P > 0.05$, data not shown). These results suggest that the partial endothelium-dependent relaxations to C_2-ceramide probably do not depend on either an L-NNA-sensitive or L-NMMA-sensitive NO release from endothelium, or cyclooxgenase-sensitive prostacyclin generation. Thus, there may exist another possible vasodilator(s) which are synthesized and released from endothelium in response to C_2-ceramide. Because endothelial cells may also release a variety of vasorelaxation factors other than NO (e.g., endothelium-dependent hyperpolarizing factors, epoxyeicosatrienoic acids, etc.) (16), potential vasorelaxant effects of active ceramide metabolites must be postulated until either ruled in or out. That the response to C_2-ceramide was only slightly attenuated, but not abolished, after de-endothelialization implies that C_2-ceramide exerts most of its relaxant effects by direct actions on smooth muscle cells that are not dependent on endothelium-derived relaxing factor(s). Although not shown, a wide variety of amine pharmacologic antagonists (i.e., atropine, diphenhydramine, cimetidine, propranolol, methysergide) and an opiate antagonist (naloxone) all failed to attentuate or interfere with the ceramide-induced relaxations ($n = 6$–8 each, $P > 0.05$) (data not shown).

Effects of protein kinase C (PKC) inhibitors, staurosporine, H7, and bisindolylmaleimide I, on C_2-ceramide-induced vasorelaxation. The purpose of these experiments was to determine whether the C_2-ceramide-induced relaxation is dependent on activation of PKC. Various PKC inhibitors were added 15 min before and 15 min after treatment of phenylephrine-contracted intact and denuded aortic rings, using staurosporine (5×10^{-8}–5×10^{-6} M), H7 (5×10^{-8}–5×10^{-6} M) or bisindolylmaleimide I (5×10^{-7}–5×10^{-6} M), respectively. We found that all of these agents, which collectively act on all active sites of PKC, did not significantly attenuate or interfere with the C_2-ceramide-induced relaxations ($n = 6$ each, $P > 0.05$, data not shown). These results suggest that activation of a PKC pathway cannot explain ceramide's relaxant action on phenylephrine-induced vasoconstriction.

Effects of C_2-ceramide on phenylephrine-induced changes in $[Ca^{2+}]_i$ in cultured rat aortic smooth muscle cells. Since Ca^{2+} plays a critical role in the regulation of smooth muscle tone, we examined the effect of ceramide on phenylephrine-induced changes in $[Ca^{2+}]_i$ .Table 1 shows that addition of 10^{-6} M phenylephrine to cultured rat aortic smooth muscle cells caused a significant rise in $[Ca^{2+}]_i$ from a mean resting level of 84.8 ± 6.0 nM (35–40 cells) to 116.7 ± 4.8 nM

TABLE 1
Ceramide Attenuates Rises in $[Ca^{2+}]_i$ Concentration Induced by Phenylephrine in Single Rat Aortic Smooth Muscle Cells

Treated with	$[Ca^{2+}]_i$ (nM)
Control	84.8 ± 6.0
Ceramide alone (10^{-5} M)	89.9 ± 6.3[a]
Phenylephrine alone (10^{-6} M)	116.7 ± 4.8*,[b]
Phenylephrine + ceramide	77.2 ± 5.3**,[a]

[a]The $[Ca^{2+}]_i$ was measured 20 min after ceramide was added to the chamber. [b]Phenylephrine-induced $[Ca^{2+}]_i$ value, alone, was measured 5 min after its addition to the organ bath. Values are means ± SEM of at least 15–20 cells. Significantly different from control (*P < 0.01). Significantly different from phenylephrine alone (**P < 0.01).

(15–20 cells) ($P < 0.01$). Exposure of cultured rat aortic smooth muscle cells to 10^{-5} M C_2-ceramide, alone did not significantly change the resting levels of $[Ca^{2+}]_i$. However, after addition of C_2-ceramide, phenylephrine-induced elevations of $[Ca^{2+}]_i$ were inhibited (from 116.7 ± 4.8 nM to 77.2 ± 5.3 nM, n = 20, $P < 0.01$). Although not shown, lower concentrations of C_2-ceramide (e.g., 10^{-7}, 10^{-6} M) exerted weaker inhibitory actions on phenylephrine-induced rises in $[Ca^{2+}]_i$. Figure 3A shows that addition of 10^{-6} M phenylephrine to cultured rat aortic smooth muscle cells caused a biphasic rise in $[Ca^{2+}]_i$. The first phasic component reached a peak fairly quickly and then fell rapidly to a lower steady-state level which is the second component; this is clearly above the basal steady-state level. Chelation of extracellular Ca^{2+} in the complete absence of $[Ca^{2+}]_o$, with EGTA (2 mM) added, almost abolished the phenylephrine-induced secondary phase rise of $[Ca^{2+}]_i$ (Fig. 3B), indicating attenuation of influx of extracellular Ca^{2+}. Treatment with C_2-ceramide (10^{-5} M), before or after phenylephrine was added, resulted in an inhibition of the secondary phase rise of $[Ca^{2+}]_i$ in a manner clearly distinguishable from that of control cells cultured for the same period of time (Fig. 3C, D). The time course of this reduction in $[Ca^{2+}]_i$ was similar to the time required for ceramide-induced relaxation. Although not shown, the inactive analog, C_2-dihydroceramide, did not significantly inhibit phenylephrine-induced elevation in $[Ca^{2+}]_i$.

DISCUSSION

To our knowledge, the present results represent the first demonstration that C_2-ceramide can attenuate phenylephrine-induced contractions in isolated rat aortic rings, as well as inhibit elevations of $[Ca^{2+}]_i$ produced by a contractile agent in cultured, single primary rat aortic smooth muscle cells. This action may be of real physiologic importance, as the biologically active concentrations of ceramide shown herein (e.g., 10^{-7} to 10^{-6} M) are in the range thought to be generated *in vivo*. The concentration of C_2-ceramide used here for $[Ca^{2+}]_i$ measurement in cultured rat aortic smooth muscle cells (10^{-7} to10^{-5} M) is consistent with those used in earlier studies on HL-60 cell differentiation (1–10 μM) (17), phospholipase D inhibition in fibroblasts (10–50 μM) (18), and rat pinealocytes (10–100 μM) (21). However, the mechanism(s) for the inhibitory action of C_2-ceramide on phenylephrine's action are not as yet fully understood.

The rise in cytosolic Ca^{2+} induced by α_1-adrenergic stimulation of vascular smooth muscle is due initially to the release of Ca^{2+} from internal stores, resulting in transient elevation of $[Ca^{2+}]_i$ (primary Ca^{2+} spike). The internal release of Ca^{2+} is responsible for the initial phasic component of contraction, which is succeeded by a slower tonic component dependent on influx of extracellular Ca^{2+} and involving increased Ca^{2+} permeability of the plasma membrane (9). As shown in Figure 3B, chelation of extracellular Ca^{2+} with

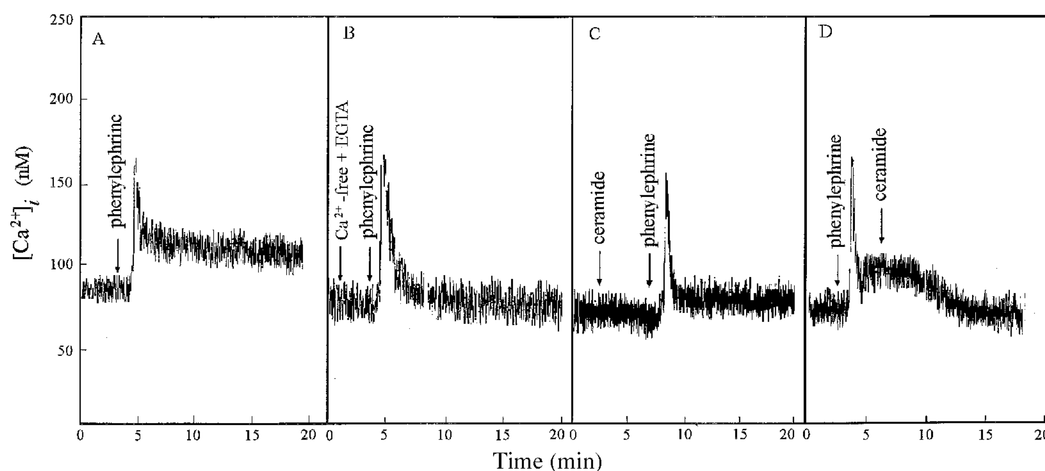

FIG. 3. Effects of C_2-ceramide (10^{-5} M) on phenylephrine-induced rises in $[Ca^{2+}]_i$ in single aortic smooth muscle cells. Effects of phenylephrine alone on $[Ca^{2+}]_i$ in single aortic smooth muscle cells (A). Phenylephrine-induced rises in $[Ca^{2+}]_i$ in the absence of extracellular Ca^{2+} with 2 mM EGTA added (B). Effects of C_2-ceramide addition before (C) and after (D) phenylephrine (10^{-6} M) on rises in $[Ca^{2+}]_i$ in single aortic smooth muscle cells. Traces shown are representative examples of typical responses of single cells from at least 10 similar separate experiments in various assay conditions. Phenylephrine—(10^{-6} M); ceramide—(10^{-5} M).

EGTA (in the absence of $[Ca^{2+}]_o$) markedly reduced the phenylephrine-stimulated secondary phase rise of $[Ca^{2+}]_i$, indicating diminution of influx of extracellular Ca^{2+}. Treatment with C_2-ceramide (10^{-5} M), before or after phenylephrine was added, did not affect the initial increase in $[Ca^{2+}]_i$ or the peak value (Fig. 3A, C, D), but did cause a rapid decline in the secondary phase rise of $[Ca^{2+}]_i$ in a manner distinguishable from that of control cells cultured for the same period of time (Fig. 3C, D). The phenylephrine-induced $[Ca^{2+}]_i$ increase under such conditions is due to its release from internal stores by myo-inositol-1,4,5-trisphosphase (9). This agrees with the result that Ag^+-induced formation of myoinositol-1,4,5-trisphosphase is not affected by C_2-ceramide (19). The $[Ca^{2+}]_i$ profiles obtained herein in the presence of C_2-ceramide were nearly the same as those observed in the Ca^{2+}-depleted cells in the presence of EGTA (Fig. 3B). Thus, these results lead us to consider that C_2-ceramide blocked phenylephrine-stimulated Ca^{2+} influx from the extracellular source.

Wong *et al*. (20) reported that C_2-ceramide can inhibit human peripheral blood polymorphonuclear leukocyte Ca^{2+} influx induced by *n*-formyl-methionyl-leucyl-phenylalanine and suggested that ceramide-activated protein phosphatase (CAPP), activated by ceramide, may dephosphorylate a calcium influx factor and thereby inactivate it. Very recently, ceramide was shown to inhibit L-type Ca^{2+} channels in rat pinealocytes (21) and L-type Ca^{2+} channel current in rat ventricular myocytes (22). Our findings, in the present study, are thus in line with these suggestions. Whatever its precise molecular mechanism of action, C_2-ceramide inhibition of Ca^{2+} influx promotes a decrease of $[Ca^{2+}]_i$ and may result in dephosphorylation of myosin, resulting in relaxation.

In recent *in vitro* investigations, CAPP, a serine/threonine protein phosphatase, was shown to be activated directly and specifically by ceramide (2,3). CAPP is related to and regarded as a subtype of the protein phosphatase 2A (PP2A) family (2,3). Dobrowsky *et al*. (23) reported that C_2-ceramide can activate heterotrimeric PP2A. Moreover, PP2A was shown to catalyze the dephosphorylation of calponin and caldesmon (24,25). Calponin and caldesmon, in smooth muscle cells, inhibit smooth muscle contraction by decreasing the actin-activated Mg-ATPase activity of myosin; and the phosphorylation of calponin and caldesmon by PKC or Ca^{2+}/calmodulin-dependent kinase II results in loss of their ability to inhibit the actomyosin Mg-ATPase (26,27). Therefore, an increased activity of smooth muscle PP2A induced by ceramide might result in relaxation *via* a dephosphorylation of calponin and caldesmon.

In conclusion, our experiments demonstrate that ceramide, a putative sphingolipid second messenger, can inhibit phenylephrine-induced contractions and phenylephrine-induced elevations in $[Ca^{2+}]_i$ in rat aortic smooth muscle. Although the mechanisms underlying the precise relaxant actions of ceramide remain to be established, a reduction in intracellular Ca^{2+} is clearly a key factor in causing relaxation. Our results suggest that a sphingomyelin-signaling pathway may play an important regulatory role in arterial wall tone.

Specific Modifications of Phosphatidylinositol and Nonesterified Fatty Acid Fractions in Cultured Porcine Cardiomyocytes Supplemented with n-3 Polyunsaturated Fatty Acids

Sudheera S.D. Nair[a], James Leitch[b], and Manohar L. Garg[a,]*

[a]Discipline of Nutrition and Dietetics, University of Newcastle, Callaghan, New South Wales 2308, and [b]Department of Cardiology, John Hunter Hospital, Newcastle, New South Wales 2305, Australia

ABSTRACT: Mechanisms for the antiarrhythmic effect of n-3 polyunsaturated fatty acids (PUFA) are currently being investigated using isolated cardiac myocytes. It is still not known whether the incorporation of n-3 PUFA into membrane phospholipids is a prerequisite for its protective action or if n-3 PUFA exert antiarrhythmic effects in their nonesterified form as demonstrated by recent studies. Adult porcine cardiomyocytes were grown in media supplemented with arachidonic acid (AA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA). After 24 h, analysis of total lipids showed that the myocytes were enriched with the respective fatty acids compared to control cells. Large proportions of all three fatty acids supplemented (69% AA, 72% DHA, and 66% EPA) remained unesterified. Fatty acid analyses of total phospholipids (PL) revealed that the incorporation of EPA and DHA, though small, was significantly different ($P < 0.05$) from that of the control cells. The PL fraction was further separated into phosphatidylinositol (PI), phosphatidylethanolamine, phosphatidylcholine, and phosphatidylserine to study the pattern of incorporation of the fatty acids in these fractions. It became apparent that EPA and DHA were selectively incorporated into the PI fraction. This study demonstrates that in adult porcine cardiomyocytes, the n-3 PUFA supplementation selectively modulates two important lipid fractions, nonesterified fatty acid and PI, which were implicated in the mechanisms of prevention of cardiac arrhythmias.

Paper no. 7993 in *Lipids 34,* 697–704 (July 1999).

The role of dietary n-3 polyunsaturated fatty acids (PUFA) in the prevention of cardiac arrhythmia in animal models and in cardiomyocytes is now well established. The mechanisms by which these dietary n-3 PUFA may confer their protective effects were reviewed (1–3). The n-3 PUFA in fish oil can cause a reduction in the rate of sudden cardiac death by decreasing lethal ventricular arrhythmias in patients with coronary heart disease (4). Early pioneering studies by McLennan (5) and Charnock *et al.* (6) reported that n-3 PUFA exhibit their beneficial effects *via* incorporation into sarcolemmal phospholipids (PL), thereby changing membrane properties and altering eicosanoid metabolism. In a study by Hallaq *et al.* (7), the protective effect of n-3 PUFA was demonstrated by its prevention of ouabain-induced rise of free cytosolic calcium to toxic levels within myocytes. Studies conducted by Leaf *et al.* (8,9) demonstrated the antiarrhythmic effects of the free (nonesterified) form of the n-3 PUFA on isolated rat neonatal ventricular cardiomyocytes. A recent study by Billman *et al.* (10) performed on conscious, exercising mongrel dogs involved intravenous infusion of fish oil fatty acids as an emulsion prior to ischemic challenge. They report statistically significant prevention of ischemia-induced ventricular arrhythmias in dogs by acute infusions of n-3 PUFA.

Cardiac membrane PL play a central role in electrical signal generation and conduction. Many of the biological effects of n-3 and n-6 fatty acids were attributed to the result of the alteration of membrane PL by their inclusion in the diet. Altering membrane PL has a direct consequence for the maintenance of cardiac rhythm through several pathways (11). Less attention, however, was given to the effect of n-3 PUFA supplementation on the cellular nonesterified fatty acid (NEFA) compartment. Recently, it was established that NEFA interacts with a variety of intracellular factors (12,13), and its role in cell signaling without metabolic transformation is particularly relevant to our investigation of its role in the antiarrhythmic mechanism of fish oils. Most studies used isolated neonatal ventricular cardiomyocytes from rats to investigate the effect of n-3 PUFA supplementation; very few studies were using adult cardiomyocytes. The purpose of this experiment was therefore to study the effect of n-3 PUFA supplementation in isolated adult porcine cardiomyocyte and the extent of incorporation into myocyte membrane PL and NEFA. These stud-

ies demonstrate for the first time that in adult cardiomyocytes a major proportion of n-3 PUFA remains in the NEFA fraction, and a significant amount is selectively incorporated into the phosphatidylinositol (PI) fraction.

MATERIALS AND METHODS

Cell culture. Freshly harvested adult pig hearts were obtained from a local abbatoir (F.C. Nicholls, New South Wales, Australia). Cardiomyocytes were isolated from ventricles of adult pigs using the method of Spinale *et al*. (14) with some modifications. After the ventricles were excised from the heart, they were washed free of blood using a modified Krebbs solution (composition in mmol/L: NaCl 145, KCl 5, NaH_2PO_4 1.2, HEPES 20, glucose 10, taurine 30, succinate 5, L-glutamine 25, adenosine 1, and creatine 5). The tissue was then dissociated in two successive enzyme treatments. The first incubation was carried out at 37°C with gentle shaking in a water bath using collagenase (0.11 mg/mL; Sigma, St. Louis, MO). After 35 min, the supernatant was discarded and the tissue was minced very finely. This was followed by the second incubation in a solution containing collagenase (0.11 mg/mL), DNase (type II, 50 Kunitz/mL; Sigma), 300 mM $CaCl_2$, and 2% bovine serum albumin for 15 min in similar conditions as the first incubation. The tissue and solution were filtered, centrifuged, and the pellet resuspended in Dulbecco's Modified Eagle Medium (DMEM; CSL, New South Wales, Australia) supplemented with 10% (vol/vol) fetal calf serum and 2.0 mM Ca^{2+}.

Cell viability. The number of viable cells was counted at 100× magnification by trypan blue exclusion in a hemocytometer. Only cells that were rod-shaped and excluding trypan blue were defined as viable. Proportion of viable cells was between 88 and 90% in each cell culture. The cells were plated at a live cell density of 1.5×10^6 cells/mL and cultured in a tissue culture incubator at 37°C (5% CO_2, 95% humidity) for 48–72 h until the cells had all adhered.

Fatty acid incubations. After 5–6 d in culture, the plates containing cells were divided into four groups. The cells in each group were incubated for 24 h in a medium (DMEM containing 10% fetal calf serum) supplemented with either 400 µM arachidonic acid (AA), 400 µM eicosapentaenoic acid (EPA), or 400 µM docosahexaenoic acid (DHA). The fourth group of cells was incubated in unsupplemented DMEM and treated as the control group. The fatty acids used for the incubations were obtained from Sigma and were >99% pure. They were dissolved in a small volume of ethanol before addition into medium. The final concentration of ethanol in the medium was 0.04%. Before commencement of this study, numerous experiments were conducted to determine the concentration of fatty acids required for incubation as well as the length of incubation time needed to ensure maximal incorporation in the adult myocytes. Fatty acid concentrations of 50, 100, and 250 µM in the incubation medium were not enough to enrich the myocytes even after 48 h. Increasing the concentration of the fatty acids to 400 µM ensured a significant incorporation (compared to controls) in only 24 h. Before the start of fatty acid analyses, the incubation medium was carefully and completely removed by at least three successive washes to ensure that the fatty acids were not carried over during lipid extraction. Albumin was not included in the wash media because in preliminary experiments addition of albumin caused considerable loss of cells from the plates. Since it was very essential to maintain cell numbers for lipid extraction, addition of albumin was discontinued.

Fatty acid analyses. Fatty acid composition of total lipids of cells after 24-h incubation was determined by direct transesterification using the method of Lepage and Roy (15). Fatty acid composition of cellular PL and nonesterified fatty acid (NEFA) was determined after extraction of lipid from the cells (16) and separation by thin-layer chromatography (TLC). Briefly, lipid was extracted with chloroform/methanol (2:1, vol/vol) containing butylated hydroxytoluene (0.005% wt/vol) to prevent oxidation. The samples were dried under nitrogen, reconstituted in a small volume of chloroform, and separated on TLC plates (Silica gel 'G'; Alltech, New South Wales, Australia), using a solvent system comprising hexane/diethylether/acetic acid (85:15:1, by vol) (17). Heptadecanoic acid (200 µg) was added as a reference standard. After spraying the plates with 2,7-dichlorofluoresceine (0.1% wt/vol in methanol; Ajax Chemicals, New South Wales, Australia) for identification, the PL and NEFA bands were scraped from the plates and redissolved in hexane. The fractions were methylated using BF_3/methanol (14% wt/vol; Sigma) for at least 45 min to 1 h at 100°C (18) to ensure complete transesterification (19) and analyzed by gas chromatography.

Fatty acid composition of the PL fraction of myocytes was determined by separation on TLC plates (Silica gel 'H'; Alltech), using a solvent system comprising chloroform/methanol/2-propanol/triethylamine/0.25 KCl (15:4.5:12.5:9:3, by vol). The PL fractions were identified using authentic individual standards as reference and R_f values as per Touchstone *et al.* (20). The R_f values from our experiments were 0.647, 0.47, 0.382, 0.232, and 0.176 for PI, phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylcholine (PC), and sphingomyelin, respectively. The separated PL were methylated as above and analyzed by gas chromatography. A fused carbon-silica column (30 m × 0.25 mm; J&W Scientific, Folsom, CA) was used to analyze the derivatized fatty acids in a Hewlett-Packard 6890 gas chromatograph (Palo Alto, CA) (21). The injector and detector port temperatures were set at 250°C. The oven temperature was initially held at 170°C for 2 min, then increased by 10°C/min to 190°C, held for 1 min, and then increased by 3°C/min up to 220°C and maintained for 15 min. The total run time was 30 min. A split ratio of 10:1 and an injection volume of 5 µL were used. Sample fatty acid peaks were identified by comparing their retention times with those of authentic standards (Nu-Chek-Prep, Elysian, MN) and area percentage resolved.

Statistical analyses. All data are shown as means ± SEM. The results of fatty acid supplementation were analyzed using analysis of variance using Statview 4.5 and Fisher's Exact Test.

RESULTS

Total fatty acid content. Analysis of total fatty acid content of myocytes after 24 h in media supplemented with 400 μM fatty acid confirmed that incorporation had taken place (Table 1). To distinguish cells grown in control media from cells grown in media supplemented with the three different fatty acids, they have been referred to as control cells (c-cells), EPA-supplemented cells (EPA-cells), DHA-supplemented cells (DHA-cells), and AA-supplemented cells (AA-cells). The results indicate that there was a significant increase in the fatty acid content of supplemented cells compared to controls. AA increased from 11.83 ± 0.05 to 26.37 ± 1.05% in AA-cells, EPA increased from 0.36 ± 0.3 to 18.68 ± 0.55% in EPA-cells, and DHA increased from 1.37 ± 0.03 to 19.88 ± 0.23%.

Myocyte NEFA content. There was a very large increase in the amounts of all three supplemented fatty acids, AA, EPA and DHA, in the NEFA fraction of all the three fatty acid-supplemented groups compared to c-cells ($P < 0.001$). The highest incorporation was in DHA-cells (72.8 ± 0.1% DHA) followed by AA in AA-cells (69.5 ± 5.0%) and then EPA in EPA-cells (66.3 ± 0.2%). The increase in these fatty acids in all groups was accompanied by the decrease in palmitic and stearic acids (saturated fatty acids), oleic acid (monounsaturated fatty acid), and linoleic acid compared to c-cells ($P <$ 0.0001) (Table 2).

Myocyte PL composition. The incorporation of the supplemented fatty acids was modest in the cellular PL compared to the NEFA fraction. In the cellular PL, EPA in EPA-cells was significantly different from that in c-cells ($P < 0.05$). The same difference was observed for DHA in DHA-cells, but interestingly this trend was not seen in the AA-cells. Unlike the NEFA, there was no significant difference in palmitic, stearic, oleic, and linoleic acids among groups (Table 3).

Myocyte triacylglycerol composition. The incorporation of supplemented fatty acids in the triacylglycerol fraction was very small compared to the other fractions, and only AA in AA-cells was significantly different ($P < 0.05$) from control (Table 4).

Fatty acid composition of PL fractions. Total PL were fractionated into PI, PE, PC, and PS, the results of which are shown in Table 5 and Figure 1. Incorporation of EPA and DHA in EPA-cells and DHA-cells, respectively, was highest in the PI fraction (36.9 ± 1.1% EPA and 52.5 ± 1.7% DHA) followed by the PE fraction compared to the c-cells ($P <$ 0.05).The increase of EPA and DHA in the PI fraction was associated with a decrease in the linoleic acid and AA content. In the PC and PS fractions, there was little or no change in the incorporation of EPA and DHA. AA levels in AA-cells were significantly different from c-cells only in the PC fraction ($P < 0.05$) but not in the PI, PE, and PS fractions (Table 5).

DISCUSSION

In order to elucidate the mechanism(s) by which dietary n-3 PUFA exhibit antiarrhythmic properties, we examined the modification of cardiomyocytes isolated from adult pigs by incubating them in the presence of long-chain n-6 and n-3 PUFA. Most studies investigating the role of n-3 PUFA in the prevention of cardiac arrhythmia used neonatal ventricular myocytes isolated from rats. Studies of fatty acid incorporation in porcine cardiac myocytes are not common. A review of literature indicates that our study is the first of its kind using adult porcine myocytes. Therefore, comparison with other similar studies is difficult. Pigs have a cardiac physiology and fatty acid metabolism similar to humans (22). Neonatal cardiac myocytes have a variety of structural and functional differences from adult myocytes (23). Unlike myocytes from neonatal hearts, myocytes from adult heart do not undergo cell division but remain differentiated in culture (24). Earlier studies (25–30) measured fatty acid composition of

total lipid and PL fractions after growing cardiomyocytes in media enriched with individual fatty acids and in combinations of n-3 and n-6 PUFA. While some looked at the effect of n-3 and n-6 fatty acid supplementation of cardiomyocytes to investigate the essential fatty acid metabolism (27,28), others studied their effect on electrophysiology and contraction (30,31) and on hypoxia and hypoxia-induced phospholipase A_2 activity (25,26). These studies all used neonatal rat ventricular myocytes grown in media supplemented with fatty acid concentrations ranging from10 to 100 μM and incubated for periods of 24 h up to 4 d. Of these studies, two examined the total fatty acid content of modified myocytes (27,28), four examined only the PL fatty acid composition of modified myocytes (25,26,29,30) and only one analyzed the fatty acid content of total lipids and PL fatty acid composition of myocytes after supplementation (32).

None of these previous studies measured the NEFA content and composition in the myocytes. The results presented here documented for the first time the incorporation of n-3 PUFA in the NEFA fraction in an adult myocyte model. We found that the n-3 PUFA were selectively incorporated into the NEFA and PI fraction after growing myocytes for 24 h in media supplemented with these fatty acids. Using growing pigs, we recently demonstrated that cell lipid fractions (NEFA, PL, and triglycerides) are uniformly enriched with n-3 PUFA following feeding of n-3 PUFA-enriched diets (Nair, S., Leitch, J., and Garg, M., unpublished observations). Whether specific modifications of NEFA and PI fractions occur in myocytes isolated from adult animals fed a diet supplemented with n-3 PUFA remains to be determined. If the same is true for adult human myocytes following dietary n-3 PUFA supplementation, then the accumulation of n-3 PUFA

in the NEFA fraction would be available to interact with ion channels for the prevention of cardiac arrhythmias.

Early evidence for the role of NFA in ischemia was mostly obtained from studies using myocardial tissue (33–35). The "free fatty acid" hypothesis, as it was called, was considered controversial because of the conflicting values obtained by the different groups. Recent studies (9,10,36–38) using neonatal isolated cardiomyocytes renewed the interest in NEFA by demonstrating that n-3 PUFA in their nonesterified forms are able to exert antiarrhythmic action by their effect on Na^+ and Ca^{2+} channels. They also found that AA by itself was antiarrhythmic, but because of its rapid metabolism to arrhythmogenic eicosanoids, it exhibits proarrhythmic activity. In a recent study by Billman *et al.* (10), after infusion of a fatty acid emulsion containing n-3 PUFA to exercising dogs, the NEFA content of plasma increased considerably, supporting the hypothesis that the action of nonesterified PUFA is sufficient to prevent arrhythmia.

The incorporation of n-3 PUFA into the different PL (particularly PI) fractions was studied with a view to understanding their role in the inositol lipid cycle. The inositol lipid cycle is an important aspect of membrane lipid metabolism which generates the second messengers inositol phosphate (IP_3) and diacylglycerol that are involved in intracellular cell signaling and consequently causing Ca^{2+} oscillations within the cells. Modulation of the PI substrate for phospholipase C is a prerequisite for alterations in the release of IP_3.

Studies on the effect of n-3 PUFA supplementation on IP_3 generation in cardiomyocytes are limited. Initial evidence for the role of dietary PUFA in regulation of Ca^{2+} release from endoplasmic reticulum was provided by Kinsella *et al.* (2). Their study revealed that there was an increase in Ca^{2+} uptake by endoplasmic reticulum that could be associated with the prevention of arrhythmias in rats raised on fish oil-enriched diet. A study by Medini *et al.* (39) showed that the administration of diets enriched with oleic, linoleic, or with n-3 PUFA, EPA, and DHA in rabbits resulted in modified production of IP_3 in platelets when stimulated. They found that stimulation of IP_3 generation was lower in the n-3 PUFA-fed animals compared

[a]Data are expressed as means ± SEM. Values with different superscripts across individual rows indicate statistically significant difference. *n* = 3 in each group. Only major fatty acids are listed. See Table 1 for abbreviations.

to other groups. Similar inhibitory effect of fish oil administration on IP_3 was also reported in guinea pig epidermis (40) and in stimulated platelets after *in vitro* incubation of EPA (41). In a study by Woodcock *et al*. (42) involving left atrial myocytes isolated from rats fed n-3 PUFA- and n-6 PUFA-enriched oils for 8 wk, the total release of IP_n was reduced both with and without stimulation by norepinephrine. All these studies indicate a role for n-3 PUFA in cell signaling.

Our results indicate that in adult porcine cardiomyocytes enriched with n-3 and n-6 PUFA, the pattern of incorporation of fatty acids is very different from that observed in neonatal rat cardiomyocytes. We recently completed an *in vivo* study where cardiac myocytes were isolated from pig hearts after a 6-wk dietary supplementation with fish oil (Nair, S., Leitch, J., and Garg, M., unpublished observations). The data are surprisingly similar to that of the *in vitro* data where the incorporation of the fatty acid AA is greater in the PI fraction than in the PC and the incorporation of fatty acids EPA and DHA is greater in the PE and PI compared to the PC. The difference in pattern of incorporation in the different PL fractions may be attributed to the age and the animal species used. A study that might illustrate the difference in incorporation is that by Lamers *et al*. (43). They studied the PL modification in neonatal cardiac myocytes grown in media supplemented with different fatty acids like 18:2n-6 and EPA. In the PI fraction of cell supplemented with EPA (214 μM), they found that EPA incorporation was highest (20.6 mol%) compared to the other fractions PC, PE, and PS. They also found that cardiomyocyte PC more readily incorporated 18:2n-6 than 20:5n-3 which might explain the pattern of incorporation seen in our study. Another study that illustrates the preferential uptake of DHA by cardiac myocyte is that by Bordoni *et al*. (44), where growing neonatal rat cardiac myocytes in a DHA-rich medium (60 μM) increased the content of DHA from 0.67 ± 0.36 to 3.13 ± 0.69 nmol/mg protein in the PI fraction. This was accompanied by a decrease in the content of AA from 13.4 ± 3.59 to 7.73 ± 0.70 nmol/mg protein, but there was no mention of the other PL fractions. Meij *et al*. (45) also found in their study that the PI was not enriched in 20:4n-6 (no values were provided), and they speculate that this could be due to the preferential degradation of this fatty acid in the PI fraction by kinases.

In our study, the increased incorporation of the fatty acids in the NEFA fraction and the selective incorporation of the n-3 PUFA into the PI fraction indicate that the n-3 and n-6 PUFA could be adopting different routes after entry into cell membrane. The results could also indicate a possible route through which these fatty acids could modulate the inositol lipid cycle. This study links two of the mechanisms proposed to explain the antiarrhythmic effect of n-3 PUFA from fish oil: (i) the direct effect of NEFA on the myocardium and (ii) effect on inositol lipid cycle and cell signaling *via* the modification of membrane PL. Studies on the effect of n-3 PUFA on IP_3 release and calcium oscillations are currently being conducted in our lab. In true sense, in the study of the antiarrhythmic mechanisms of n-3 PUFA, supplementations are warranted for adult human beings only, therefore research efforts should be focused on examination of the n-3 PUFA effects in cells/tissues from adult animals or adult human subjects.

ABSTRACT: Polyunsaturated fatty acids (PUFA) are important constituents of membrane phospholipids, whose levels are decreased in some tumor cells. This deficiency may cause alterations in signal transduction and an interruption of normal cellular events. The enrichment of tumor cells with PUFA may stimulate or inhibit tumor growth, probably depending on the type of PUFA and the cellular concentration of aldehydes derived from restored lipid peroxidation. We examined the effect of several doses of prooxidant on the growth of hepatoma cells with different aldehyde dehydrogenase activities, enriched with arachidonic acid. Two doses of prooxidant were sufficient to reduce growth of hepatoma cells with low aldehyde dehydrogenase activity, whereas three doses were necessary for those with high enzyme activity. In both cases, lipid peroxidation products blocked the cells in the S phase.

Paper no. L8190 in *Lipids 34*, 705–711 (July 1999).

Polyunsaturated fatty acids (PUFA) are important constituents of membrane phospholipids. After conversion to prostaglandins (PG), leukotrienes, or oxygen-derived free radicals, they mediate a variety of pathological processes (1). The PUFA content is drastically decreased in hepatoma cells in comparison with normal hepatocytes (2), in glioma cells in comparison with oligodendroglia cells (3,4) and in melanoma cells (5). This deficiency may cause alterations in signal transduction and an interruption of normal cellular events (3).

During differentiation, the fatty acid pattern shifts toward that of normal cells (6). This may be spontaneously occurring, or induced by several substances in glioma and neuroblastoma cells. Thus, there is great interest in the fields of chemoprevention and chemotherapy exploring in the effect of PUFA on tumors.

It appears certain that n-3 PUFA inhibit the induction and growth of tumors, such as carcinoma of the breast, colon, and pancreas (7–10). This inhibitory effect may be related to the accumulation of lipid peroxidation products in the tumor tissues (8) or to a decrease of oncogene expression (11), production of PGE_2, tumor necrosis factor, and interleukin-1 (11,12).

The effect of n-6 PUFA appears more contradictory. Studies have shown that arachidonic acid (ARA) is an effective stimulator of tumor growth *in vitro* and *in vivo* (13–15), by promoting cell proliferation or by suppressing apoptosis (16); it is also required for the invasive activity of tumor cells (17). The stimulatory effect of ARA is mediated by its metabolites, i.e., $PGF_{2\alpha}$ and 5-hydroperoxy-eicosatetraenoic acids (17). However, other studies have shown that exogenously supplied n-6 PUFA kill malignant cells selectively (18,19). For example, 7,12-dimethylbenz[a]anthracene-initiated mouse skin failed to result in a tumor if treated with ARA (20). HepG2 cells also undergo cytotoxicity and apoptosis when treated with ARA (21). The cytotoxic and apoptogenic effects are probably due to the involvement of lipid peroxidation (22,23).

Changes in PUFA content in membrane phospholipids have been shown to contribute to the resistance of tumors to chemotherapy (24). Many anticancer therapies, including irradiation, chemotherapy, hyperthermia and photodynamic therapy, kill tumor cells by processes involving free-radical generation leading to lipid peroxidation. Malignant cell resistance to such therapy may be due, in part, to the altered PUFA composition. It has been demonstrated that increasing the PUFA content in tumor cells increases the effect of some types of therapy (25–28).

In view of the importance of PUFA in controlling cell proliferation, we decided to concentrate on the fact that ARA levels are lower in hepatoma cells than in normal hepatocytes. Parallel to the decrease of PUFA, hepatoma cells show a decrease of lipid peroxidation, and in consequence, also of its products, especially the 4-hydroxyalkenals, which are probably involved in growth regulation. 4-Hydroxynonenal (HNE) added to leukemia HL-60 cells reduced cell growth and induced cell differentiation in granulocytes (29); when added to hepatoma cells it reduced their capability to form colonies (2). In previous research, we showed that enriching hepatoma cells with ARA to the normal value induced susceptibility to lipid peroxidation and increased adenylate cyclase activity (30,31). Subsequent exposure to prooxidants caused an in-

crease in lipid peroxidation products and, in parallel, a reduction in cell proliferation and death.

In view of the contradictory results obtained in regard to the effects of n-6 PUFA, we decided to continue our research into the cytotoxic effects of ARA, mediated by lipid peroxidation. The different behavior of n-6 PUFA might be related to the type of stimulatory agent used to induce PUFA metabolism, or to the different concentrations of lipid peroxidation products inside the cells (30). In this study, we considered the second hypothesis, and we carefully examined the effects of different concentrations of lipid peroxidation products on cell proliferation. At the same time, we aimed to identify the cell-cycle phase at which tumor cells are blocked.

MATERIALS AND METHODS

Culture conditions. Hepatoma cell lines (7777 and JM2) were routinely grown as monolayers under an atmosphere of 5% CO_2 and 95% air in 25 cm^2 tissue culture flasks. The 7777 hepatoma cell line was seeded (time 0) at 20,000 cells/cm^2, and JM2 hepatoma cell line at 15,000 cells/cm^2. Both cell lines were maintained for 24 h in medium A (DMEM/F12 plus 2 mM glutamine and 1% antibiotic/antimycotic solution) supplemented with 10% newborn calf serum. After 24 h, medium A was removed and replaced with medium B [medium A plus 0.4% albumin, 1% ITS (insulin, transferrin, sodium selenite), 1% nonessential amino acid solution, 1% vitamin solution]. The cells were divided into two groups: controls and ARA-treated. ARA, dissolved in newborn calf serum (0.2% final concentration in the flasks) with mechanical stirring, was added to the latter group of cells, so as to have a concentration of 250 or 400 nmoles/10^6 cells in each flask. ARA from porcine liver, approximately 98% pure, was purchased from Sigma Chemical Company. α-Tocopherol was not present in the ARA preparation as determined by high-performance liquid chromatography. To avoid the autooxidation of ARA during storage, fresh solution was prepared for each experiment. Twenty-four hours later (time 48 h), ARA-supplemented medium B was removed and replaced with ARA-free medium B. Over the next 48 h, the two groups (control and ARA) were divided into five subgroups each, as in Figure 1, and received 0, 1, 2, 3, or 4 doses of prooxidant (500 μM ascorbate and 100 μM iron sulfate) at 12-h intervals. Cells from each of the 10 subgroups were harvested with 0.5 mL of trypsin (0.25%) at the times noted in Figure 1. When malondialdehyde (MDA) determination was carried out, the cells were collected with trichloroacetic acid at the times shown in Figure 1.

Lipid peroxidation. Lipid peroxidation was measured as the production of MDA as described by Canuto *et al.* (30). Briefly, cold 50% TCA (0.1 mL/mL of culture medium) was added to the flasks maintained in ice. After 15 min, cells were harvested and centrifuged at 2500 × g for 15 min. Supernatants were used for MDA determination by spectrophotometric thiobarbituric acid assay.

Viability test. Cell viability was determined as lactate dehydrogenase (LDH) release. LDH was evaluated in the culture medium as described by Kornberg (32). Results are expressed as nmoles of NADH consumed per mL of medium.

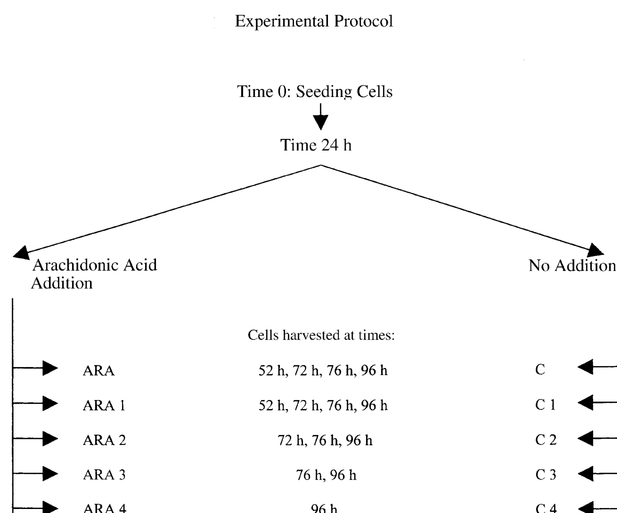

FIG. 1. Times of arachidonic acid (ARA) and ascorbate/iron sulfate addition and times of cell harvest for determination of the various parameters. ARA 1 and C 1, cells exposed to 1 dose of ascorbate/iron sulfate (asc/Fe^{2+}) at time 48 h; ARA 2 and C 2, cells exposed to 2 doses of asc/Fe^{2+} at times 48–60 h; ARA 3 and C 3, cells exposed to 3 doses of asc/Fe^{2+} at times 48–60–72 h; ARA 4 and C 4, cells exposed to 4 doses of asc/Fe^{2+} at times 48–60–84 h.

DNA content. Flow cytometric analysis of DNA was done with a FACScan (Becton Dickinson Immunocytometry Systems USA, San Jose, CA) on cells stained with propidium iodide (18 μg/mL final concentration), as indicated by Dolbeare *et al.* (33).

Fatty acid content. The percentage content of fatty acids in phospholipids extracted from cells was measured as described in Canuto *et al.* (30).

Enzyme activity determination. Aldehyde dehydrogenase (ALDH) activity was determined as described in Canuto *et al.* (2). Benzaldehyde (2.5 mM), HNE (0.1 mM), or propionaldehyde (1 mM) was used as substrate.

Statistical analysis. All data are expressed as means ± standard deviation. The significance of differences between group means was assessed by variance analysis, followed by the Newman-Keuls test.

RESULTS

We used two hepatoma cell lines, 7777 and JM2, both of which have a low content of ARA in the membrane phospholipids and low susceptibility to lipid peroxidation. However, the two cell lines differ in terms of ALDH content, which was the reason we chose them: this enzyme is involved in the metabolism of lipid peroxidation products and gives the hepatoma cells a different susceptibility to these products (2,30). Table 1 shows that JM2 hepatoma cells have an higher content of ALDH than 7777 hepatoma cells. The enzyme activity was measured in the cytosol using benzaldehyde, HNE, or propionaldehyde as substrate.

TABLE 1
Aldehyde Dehydrogenase Activity in Cytosol Isolated From Hepatocytes and Hepatoma Cell Lines[a]

Cells	BA	4-HNE	PA
Hepatocytes	2.27 ± 0.51[a]	1.64 ± 0.32[a]	2.33 ± 0.17[a]
7777 hepatoma	1.23 ± 0.19[b]	3.32 ± 0.51[b]	4.35 ± 0.46[b]
JM2 hepatoma	597.63 ± 93.21[c]	12.25 ± 4.71[c]	41.73 ± 6.89[c]

[a]Data are expressed as nmoles of NAD(P)H produced/min/mg of protein and represent mean ± SD of three experiments. For each substrate, means with different letters are statistically different ($P < 0.001$) from one another as determined by variance analysis followed by the Newman-Keuls test. BA, 2.5 mM benzaldehyde; 4-HNE, 0.1 mM 4-hydroxynonenal; PA, 1 mM propionaldehyde.

TABLE 2
Percentage of Arachidonic Acid (ARA) in Phospholipids Extracted from Hepatocytes and Hepatoma Cell Lines[a]

	ARA (nmoles/10^6 cells)		
	Unenriched cells	250	400
Hepatocytes	23.49 ± 1.91[a]

[a]Data are expressed as percentage of total fatty acids and are means ± SD of 5 experiments. Means with different letters are statistically different ($P < 0.001$) from one another as determined by variance analysis followed by the Newman Keuls test

Externally added ARA was incorporated into the phospholipids of hepatoma cells. Both the doses used increased the percentage content in both cell lines to the same extent. The higher dose completely restored the ARA level of normal hepatocytes (Table 2). However, the lower concentration was used in the following experiments, to avoid cytotoxicity.

7777 hepatoma cells. Figure 2 shows lipid peroxidation in 7777 hepatoma cells treated with ARA and different doses of ascorbate/iron sulfate. The production of MDA was proportional to the number of ascorbate/iron sulfate doses, and decreased over time after interruption of prooxidant administration. In this and the following figures, only control cells and cells treated with ARA and ascorbate/iron sulfate (ARA 1, ARA 2, ARA 3, and ARA 4) are reported, since cells treated with ARA alone and cells treated with ascorbate/iron sulfate alone (control cells 1–4) behaved in a similar way to control cells. Cell numbers (Fig. 3) indicated a reduction in growth correlated to the quantity of MDA produced, but no increase in growth even when only one dose of prooxidant was used. Growth of cells exposed to only one dose of ascorbate/iron sulfate was slower than that of controls, although they did continue to grow. When cells were exposed to two doses, growth was reduced and had stopped almost entirely by the end of the experimental time, although cells remained alive. On the other hand, three and four doses of ascorbate/iron sulfate caused cell death, evidenced by cells detached from the monolayer and the presence of LDH in the culture medium. Very few cells were still alive in the monolayer. About 20,000/cm^2 remained after three doses, 15,000/cm^2 after four doses. Table 3 shows the trend of LDH, which was present in the medium in large quantities only after three and four doses of prooxidant. The content of LDH in the culture medium was expressed as percentage of LDH present in the control cells. The cells enriched with ARA did not undergo modifications of LDH activity.

To investigate the cell-cycle phases and to determine at which phase lipid peroxidation products may affect cell proliferation, we used flow cytometry to analyze DNA content in treated cells. Figure 4 shows that the percentage of S phase cells increased with the number of doses of ascorbate/iron sulfate until dose three. After that, a below-normal percentage of the cells still alive was in the S phase, while more were in the G_0/G_1 phase than the untreated cells. In cells treated with one or two doses of prooxidant (ARA 1 and ARA 2) there was an increase in the percentage of cells in the S phase, which was larger with two doses than with one dose. The DNA distribution subsequently returned to a pattern similar to that of control cells. Moreover, cells treated with one dose continued to grow, although more slowly than controls, whereas growth of cells treated with two doses of prooxidant ceased almost entirely (Fig. 2).

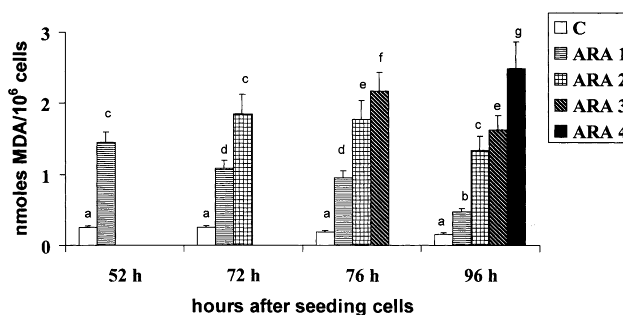

FIG. 2. Lipid peroxidation in 7777 hepatoma cells after enrichment with ARA. Lipid peroxidation was determined as malondialdehyde (MDA) production per 10^6 cells. ARA 1, 2, 3, 4 cells were harvested for MDA determination at the times indicated in the figure. Means with different letters are statistically different ($P < 0.05$) from one another as determined by variance analysis followed by the Newman-Keuls test. For abbreviations see Figure 1.

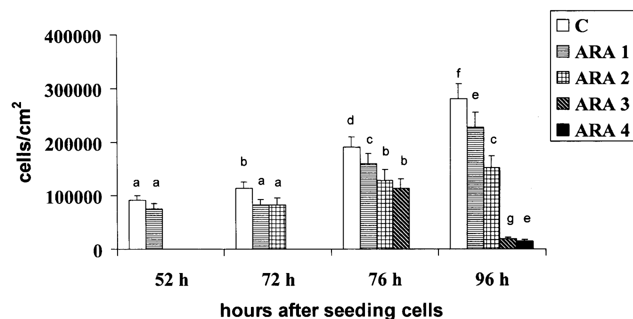

FIG. 3. Number of 7777 hepatoma cells after enrichment with ARA. ARA 1, 2, 3, 4 cells were harvested for counting at the times indicated in the figure. Means with different letters are statistically different ($P < 0.05$) from one another as determined by variance analysis followed by the Newman-Keuls test. For abbreviations see Figure 1.

Cells treated with the third dose of prooxidant maintained increase in the S-phase cells seen with two doses for 4 h after dose three; by the end of the experiment (24 h after dose 3), they were almost all in the G_0/G_1 phase, as were cells after four doses. With four doses, however, the number of cells in the G_0/G_1 was higher than after three doses. Thus, for 7777 cells, three doses of prooxidant are enough to cause inhibition of cell proliferation and death.

JM2 hepatoma cells. JM2 hepatoma cells enriched with ARA and exposed to ascorbate/iron sulfate showed an increase in lipid peroxidation over the controls, similar to that found with 7777 cells, but to a lesser extent (Fig. 5). Production of MDA decreased over time in cells exposed only to one or two doses of prooxidant. The effect of lipid peroxidation products on growth began to be evident after the third dose of prooxidant, and was more marked after the fourth dose (Fig. 6). It is of note that JM2 cells showed a reduction of growth after the third and fourth doses of prooxidant in comparison with the control cells, and that no cells died. Determination of both cell number and MDA production showed that these cells were more resistant than 7777 cells to lipid peroxidation products, and like 7777, they showed no increase in growth. The difference between the two cell lines is probably due to the different content of aldehyde deydrogenase, as reported elsewhere (34).

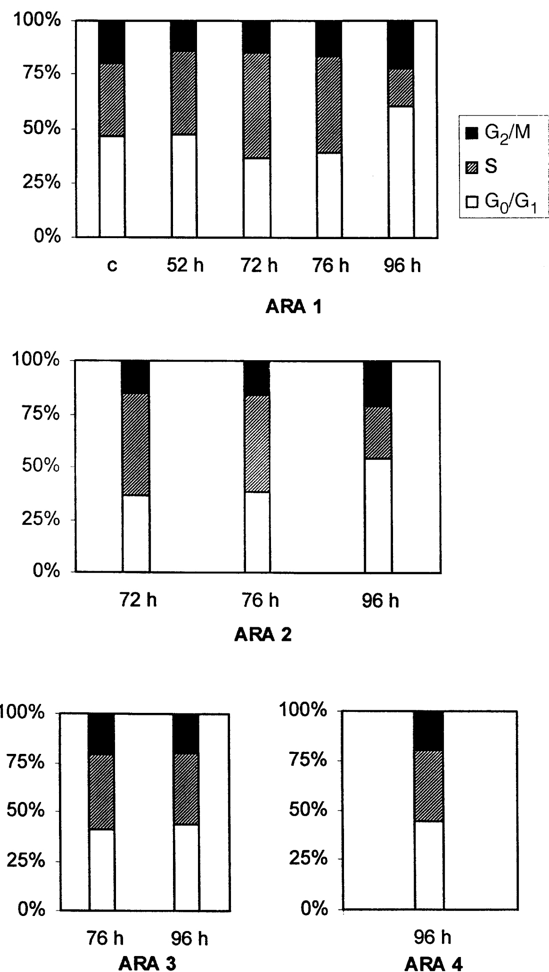

FIG. 4. Cell-cycle analysis in 7777 hepatoma cells. ARA 1, 2, 3, 4 cells were harvested for DNA analysis by cytofluorimetry at the following times: 52 h; 72 h; 76 h; 96 h, after seeding cells, as explained in the figure. Control data (c) are means of values obtained at each of the four harvesting times, since there was no significant variation. For abbreviations see Figure 1.

Analysis of DNA distribution showed that JM2 cells were blocked in the S phase by lipid peroxidation products, as were the 7777 cells, but only after three doses of prooxidant. DNA

TABLE 3
Lactate Dehydrogenase (LDH) Release from 7777 Hepatoma Cells After Enrichment with ARA[a]

	Hours after seeding cells			
Cells	52	72	76	96
C	0.85 ± 0.06^a	1.70 ± 0.15^a	1.20 ± 0.24^a	2.80 ± 0.35^b
ARA 1	1.30 ± 0.11^a	9.08 ± 1.34^b	5.58 ± 0.89^b	4.36 ± 0.71^b
ARA 2		8.09 ± 0.92^b	6.53 ± 0.78^b	6.81 ± 1.21^b
ARA 3			8.51 ± 1.10^b	92.23 ± 5.19^c
ARA 4				94.33 ± 6.67^c

[a]LDH was determined in the culture medium and expressed as percentage of total activity present in the control cells, where LDH activity was 204.73 ± 36.95 nmoles of NADH consumed per minute per 10^6 cells. C, cells not enriched with ARA and not exposed to ascorbate/iron sulfate; ARA 1, 2, 3, 4, cells enriched with ARA and exposed to 1, 2, 3 or 4 doses of 500 μM ascorbate and 100 μM iron sulfate, as in Figure 1. Culture media were removed for LDH determination at the times indicated in the table. Means with different letters are statistically different ($P < 0.001$) from one another as determined by variance analysis followed by the Newman-Keuls test. For abbreviation see Table 2.

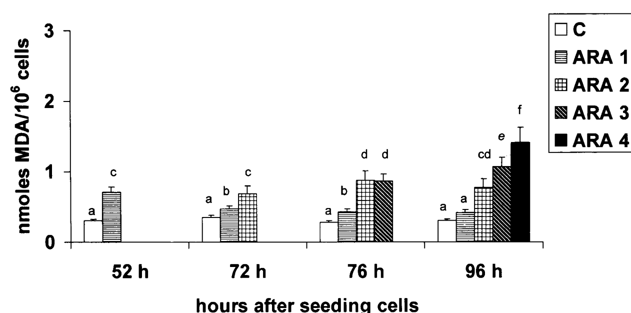

FIG. 5. Lipid peroxidation in JM2 hepatoma cells after enrichment with ARA. Lipid peroxidation was determined as MDA production per 10^6 cells. ARA 1, 2, 3, 4 cells were harvested for MDA determination at the times indicated in the figure. Means with different letters are statistically different ($P < 0.05$) from one another as determined by variance analysis followed by the Newman-Keuls test. For abbreviations see Figures 1 and 2.

distribution in JM2 cells treated with one or two doses of prooxidant was similar to that of control cells (Fig. 7). With four doses, the number of JM2 cells in the S phase tended to decrease, while cell numbers in the G_0/G_1 phase increased. This occurred to a lesser extent than with the 7777 cells. With JM2 cells the number of cells in the S phase was always higher than that of control cells. After four doses the JM2 cells were still able to proliferate; inhibition of cell growth was about 30% of the control growth.

DISCUSSION

ARA is an important substrate for lipid peroxidation, a process that may be considered not only a mechanism of cell damage, but also a mechanism of cell cycle regulation through its aldehyde products (35–37).

The decrease in ARA content in hepatoma cells may be seen as an advantage for cell proliferation. Thus, increasing its percentage content may affect hepatoma cell growth in a

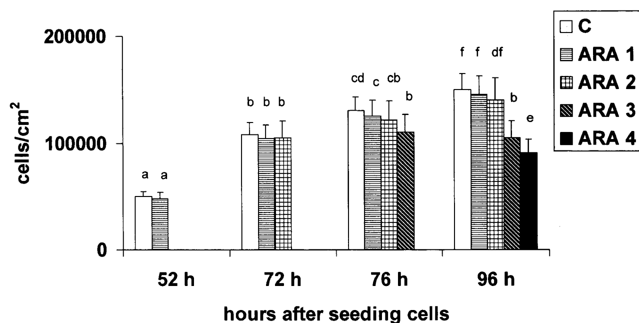

FIG. 6. Number of JM2 hepatoma cells after enrichment with ARA. ARA 1, 2, 3, 4 cells were harvested for counting at the times indicated in the figure. Means with different letters are statistically different ($P < 0.05$) from one another as determined by variance analysis followed by the Newman-Keuls test. For abbreviations see Figure 1.

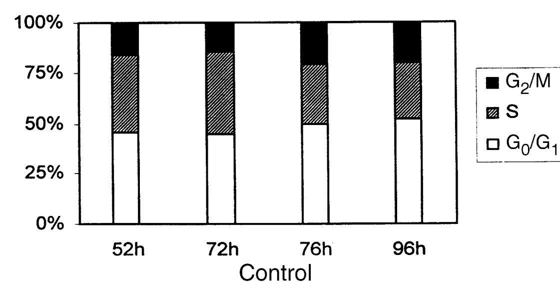

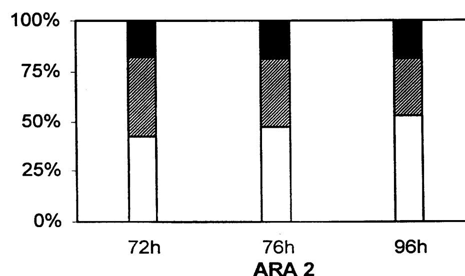

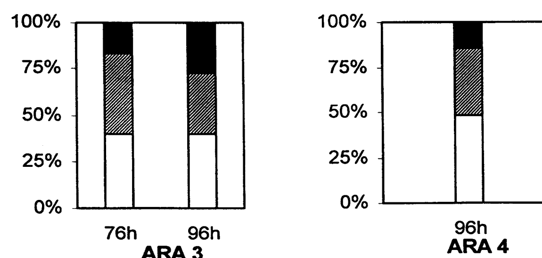

FIG. 7. Cell-cycle analysis in JM2 hepatoma cells. ARA 2, 3, 4 cells were harvested for DNA analysis by cytofluorimetry at the following times: 52 h; 72 h; 76 h; 96 h, after seeding cells, as explained in the figure. Data of cells enriched with ARA and exposed to one dose of prooxidant (ARA 1) were not reported, since the values were similar to those of control cells. For abbreviations see Figure 1.

dose-dependent manner. We used a concentration (250 nmoles/10^6) that does not affect cell growth. With this concentration, the percentage content of ARA inside hepatoma cell phospholipids did not quite reach that of hepatocytes, but this concentration was used to avoid the cytotoxic effect of ARA. At 24 h after addition of ARA, the number of cells was similar to that of control cells both for 7777 and for JM2 cells. Higher concentrations inhibit cell growth, as shown in our previous work (38,39) and by other researchers who have demonstrated that ARA inhibits cell growth (20,21,23). On the other hand, other groups have found that ARA induces cell growth and stimulates metastasis through PG or 5-hydroperoxy-eicosatetraenoic acid production (17). The different effects are probably due to the different concentrations of ARA used.

In the study reported here, 250 nmoles/10^6 cells ARA alone does not inhibit cell growth, but it can, after the addition of prooxidant, induce lipid peroxidation. If enrichment with ARA is followed by exposure to the prooxidant system, there is an increase in lipid peroxidation, and as a conse-

quence, an increase in aldehyde products, which inhibit cell proliferation or induce cell death, depending on the quantities existing within the cells.

This effect may be seen clearly by comparing 7777 and JM2 cells. In 7777 cells, two doses of prooxidant are enough to reduce cell proliferation and maintain the cells in a stable and alive state. The addition of the third and fourth doses of prooxidant causes cell death, drastically reducing the number of cells still alive.

The behavior of JM2 cells is different, these cells have a high specific activity of ALDH, which is an aldehyde-metabolizing enzyme. The effect on JM2 cell growth begins to be evident only after several doses of prooxidant (three or four), at which time ALDH activity is inhibited (36).

Since aldehyde products of lipid peroxidation reduce cell proliferation, we investigated the effect on the cell cycle, evaluating DNA content by flow cytometry. Very little is known about the effects of lipid peroxidation products on the cell cycle. Hammer *et al.* (40) have shown that lipid peroxidation inhibits the incorporation of ^{3}H-thymidine into DNA in hepatoma cells; Barrera *et al.* (41) have reported that administration of HNE to HL-60 cells inhibits proliferation, blocking them in the G_0/G_1 phase. In the work reported here, with both cell lines used, aldehydes produced by lipid peroxidation appear to block the cells in the S phase: the percentage of cells in the S phase increases with the number of doses of prooxidant used. In the case of 7777 cells, cells in the S phase are then detached from the monolayer when subsequent doses of prooxidant are added, and the cells remaining in the monolayer are mostly in the G_0/G_1 phase. This is evident 24 h after the third dose of prooxidant, and still more so after the fourth dose. In the case of JM2 cells, which are more resistant to the antiproliferative effect of aldehydes, the increase of cells in the S phase is less marked; the number of cells in the S phase is, however, above the control value at all times. The marked increase in cells in the G_0/G_1 phase found with the 7777 cells is not present with the JM2 cells: the cells' ability to proliferate is reduced, but they are all alive.

How the aldehydes block the cells in the S phase is unknown at present; we can hypothesize that they interfere with cyclins or cyclin-dependent kinases. Pizzimenti *et al.* (37) found that HNE, an active product of lipid peroxidation, inhibits cyclin D1, D2, and A in HL-60 cells; HNE, externally added, blocks the cells in the G_0/G_1 phase, interfering with these cyclins. It thus appears likely that production of aldehydes inside the cells, which blocks them in the S phase, inhibits cyclins involved in this specific phase.

The decrease in PUFA content in hepatoma cells is important for growth and viability. The reduction in PUFA decreases susceptibily to lipid peroxidation and consequently decreases cytotoxic and cytostatic aldehydes. This is one of the mechanisms able to induce tumor resistance. Enrichment with ARA followed by administration of prooxidant restores lipid peroxidation, which causes a decrease of growth, blocking the cells in the S phase, or killing them, depending on the aldehyde content. Aldehyde content is also correlated with the capability of cells to metabolize aldehydes, as is shown by the different behavior of the two types of hepatoma cells with different contents of ALDH (JM2 cells are less susceptible to lipid peroxidation than 7777 cells). However, lipid peroxidation aldehydes affect cell growth of both cell lines, blocking them in the S phase.

ACKNOWLEDGMENTS

This study was supported by grants from the Italian Ministry for University and Scientific and Technological Research (60% and Cofinanziamento 1997), and from the Italian Association for Cancer Research. R.A. Salvo was the recipient of a fellowship from the Cavalieri Ottolenghi Foundation, Turin, Italy.

Laboratory of Nutrition Chemistry, Division of Bioresource and Bioenvironmental Sciences, Graduate School, Kyushu University, Fukuoka 812-8581, Japan

ABSTRACT: Soy protein preparations were reported to have hypocholesterolemic actions in experimental animals and humans, while the active components and the mechanism by which this occurs are not clarified yet. The objective of this study is to address these issues by using exogenously hypercholesterolemic rats which are susceptible to dietary cholesterol. Two groups of five rats (male, 12-wk-old) were fed on AIN 93G-based diet with soy protein isolate (SPI) or ethanol-extracted SPI (EE-SPI) for 2 wk. EE-SPI was prepared by ethanol extraction to remove isoflavones and other components. Concentrations of serum and liver total cholesterol were lower in rats fed SPI than in those fed EE-SPI. The abundances of mRNA for 7α-hydroxylase and low density lipoprotein receptor in the liver were lower in EE-SPI group than those in SPI group. These results suggest that the ethanol extract from SPI has a factor(s) to alleviate hypercholesterolemia by increasing the removal of cholesterol from serum through the receptor pathway and then from liver through enhancement of bile acid synthesis.

Paper no. L8200 in *Lipids 34,* 713–716 (July 1999).

Soy protein preparations were reported to have a factor(s) to lower serum cholesterol in experimental animals (1) and humans (2). Active principles, however, have not been clarified yet. Recently, soy ethanolic extract containing isoflavones, saponins, phytic acid, and phospholipids was reported to have both hypocholesterolemic and antiatherogenic actions in rhesus monkeys (3). In contrast, Tovar-Palacio *et al.* (4) reported that, in gerbils, consumption of an isoflavone-containing extract does not contribute to the hypocholesterolemic effect of soy protein preparations. In our previous work, neither soy protein isolate (SPI) or the ethanol-extracted SPI (EE-SPI) showed hypocholesterolemic action in comparison with casein in apo E-deficient mice (5). Since the cholesterol metabolism in apolipoprotein E (apo E)-deficient mice is quite different from wild-type animal or humans (6), it seems that this is not an appropriate model for studying dietary SPI or its ethanol extract's effect on cholesterol metabolism. Kirk *et al.* (7) also reported that dietary soy protein did not reduce plasma cholesterol in low density lipoprotein (LDL) receptor-deficient mice.

Exogenously hypercholesterolemic (ExHC) rats, initially isolated from the Sprague-Dawley (SD) strain by Imai and Matsumura (8), show a ready hypercholesterolemia upon cholesterol feeding in the absence of hypothyroidism and bile salt in diet (9–12). It is considered that polygenes would be involved in stable hypercholesterolemia in this strain (8), but detailed mechanisms have not been clarified yet. So in this study, by using ExHC rats, the effects of ethanol extraction of SPI on the concentration of cholesterol in the serum and liver and the liver mRNA abundances for LDL receptor and cholesterol 7α-hydroxylase (7α-hydroxylase) were evaluated in comparison with intact SPI.

MATERIALS AND METHODS

Reagents. Human actin cDNA was purchased from Wako Pure Chemicals Co. (Osaka, Japan). Nylon membrane was purchased from Bio-Rad Japan (Tokyo, Japan). A multiprime DNA labeling system was purchased from Amersham Japan (Tokyo, Japan). [α-^{32}P] Deoxycytidine triphosphate (1.48 MBq/mmol) was from ICN Co. (Costa Mesa, CA). 18S ribosomal RNA was obtained from American Type Culture Collection (Rockville, MD). The sources of cDNA for apo A-IV, apo B and apo E, LDL receptor, and 7α-hydroxylase have been described (11).

Animals and diets. Two male (*Rattu rattus*, F55-1.2) and six female (F55-1.2.3.4.5.6.) ExHC rats were kindly donated by Takeda Chemical Industries, Ltd. (Osaka, Japan) in 1987; then they were bred and maintained in the Laboratory of Animal Experiments in Kyushu University, Faculty of Medicine (Fukuoka, Japan). They had free access to a commercial non-purified chow diet (NMF; Oriental Yeast Co., Tokyo, Japan) and nonionized water and were maintained in a temperature-controlled room at 22–25°C with a 12-h light cycle (0800 to 2000) until initiation of the experimental diets. In this experiment, ExHC rats (male, 12-wk-old, weighed 330–342 g) were

allowed free access to two experimental diets for 2 wk. Because ExHC rats, in comparison with SD rats, develop hypercholesterolemia as early as 3 d after a high-cholesterol diet, and gradually increased in concentration until 2 wk, they were fed the diets for 2 wk (9,10).

The composition of the experimental diets was based on AIN 93G formulation (13). As a source of dietary protein, SPI (in wt%: protein 90.5; fat 0.3; ash 4.3; water 4.9; Fujipro-R, Fuji Oil Co., Osaka) and EE-SPI (in wt%: protein 90.8; fat 0.7; ash 4.0; water 4.5) were used. The preparation of EE-SPI was described previously (5). The protein content in both experimental diets was adjusted to be the same at the expense of corn starch. To both experimental diets, 0.5% cholesterol was supplemented to induce hypercholesterolemia. As a source of dietary fat, olive oil was used instead of soybean oil, because previous experiments showed that olive oil induced higher serum total cholesterol levels in this animal model, compared with soybean oil (Sato, M., Yoshida, S., Nagao, K., and Imaizumi, K., unpublished observations). From 100 g SPI, 143 mg isoflavones were removed, composed (in wt%) of 15.2% genistein, 52.1% genistin, 8.1% daidzein, and 24.5% daidzin. Isoflavones were determined by high-performance liquid chromatography as described (5).

Diets were removed at 0800 and rats were killed by decapitation at 1200–1300. Serum was prepared by centrifugation at 1,000 × *g* for 15 min. The liver was immediately excised and frozen at −80°C until use for the determination of liver lipids and mRNA abundance. This experiment was carried out under the guidelines for Animal Experiments in the Faculty of Agriculture and the Graduate Course, Kyushu University, Fukuoka, Japan, and the Law (No. 105) and Nortification (No. 6) of the Government (20).

Determination of serum and hepatic lipid levels. Serum and liver lipids were analyzed as described previously (5). Briefly, serum cholesterol, triacylglycerols, phospholipids, and high density lipoprotein (HDL) cholesterol were determined by using commercially available kits from Wako Pure Chemicals. Liver lipids were initially extracted by Folch *et al.* method (14) and chemically determined.

Determination of hepatic LDL receptor, 7α-hydroxylase, and apo A-IV, B and E mRNA abundance. Total cellular RNA was isolated using the guanidinium thiocyanate/cesium chloride ultracentrifugal method according to Chirgwin *et al*. (15). Northern blotting was carried out as described in Nagao *et al.* (11). The hybridization was performed in hybridization solution containing cDNA labeled with [α-^{32}P]dCTP by multiprime DNA labeling system, according to Amersham's instruction. After quantification of the hybridization signals using a bio-imaging analyzer (BAS-1000; Fuji Photo Film Co., Tokyo, Japan), autoradiography was performed on X-ray film. Results were expressed as a relative value after normalization to 18S ribosomal RNA.

Statistical analyses. Data were expressed as means with pooled SEM for five rats in each group and analyzed by Student's *t*-test. Differences were considered significant at $P < 0.05$.

RESULTS

Food intake and growth parameters. There were no differences in body weight gain (24.0 and 24.4 g for SPI and EE-SPI group, respectively, pooled SEM = 2.9 g), liver weight (12.1 and 13.0 g for SPI and EE-SPI group, respectively, pooled SEM = 0.4 g), and food intake (18.8 and 20.7 g/d for SPI and EE-SPI group, respectively, pooled SEM = 0.6 g) between two groups.

Serum and liver lipid concentrations. Rats fed on the EE-SPI-containing diet had an elevated serum total cholesterol concentration, compared with those fed an intact SPI-containing diet (Table 1). There were no significant differences in the concentration of serum triacylglycerols, phospholipids, and HDL cholesterol between EE-SPI and SPI group. There was the same trend in liver lipid concentrations as those in the serum. Liver total cholesterol concentration in EE-SPI group was significantly higher than that of the SPI group, and the elevation was attributed to esterified cholesterol. There were no significant differences in liver free cholesterol, triacylglycerols, and phospholipids concentrations between the two groups.

Hepatic LDL receptor, 7α-hydroxylase and apo A-IV, B and E mRNA abundance. Northern blotting patterns of mRNA for LDL receptor, 7α-hydroxylase, apo A-IV, apo B, apo E, and 18S ribosome are shown in Figure 1. The abundance of 18S ribosome mRNA was similar between SPI and EE-SPI group. The relative abundance of the mRNA against the 18S ribosome mRNA is shown in Table 2. The level of 7α-hydroxylase mRNA was significantly lower in rats fed an EE-SPI-containing diet than those fed a SPI-containing diet. Similarly, the EE-SPI group had a lowered LDL receptor mRNA level, compared with the SPI group. There were no differences in apo A-IV, apo B, and apo E mRNA levels between the two groups.

DISCUSSION

In this study, ExHC rats fed the EE-SPI-containing diet had about twofold the elevated serum total cholesterol concentration in comparison with those fed intact SPI. The results are in agreement with those reported by Kirk *et al*. (7). They had a similar outcome in C57BL/6 mice fed soy protein with and without isoflavones. In the present study, there were no differences in serum HDL cholesterol concentrations between the two groups, thereby indicating increased cholesterol mass in the very low density lipoproteins (VLDL) and LDL fractions in EE-SPI group. It is therefore likely that the EE-SPI group had a higher concentration of the serum apo B than did the SPI group.

LeBoeuf *et al*. (16) suggested that in the liver of rodent and perhaps avian species, apo A-IV is needed for storage of triacylglycerol and/or packaging into VLDL, but that increased expression of apo A-IV does not lead to enhanced secretion of VLDL. In the present experiment, it is likely that removal of isoflavones from SPI exerted no significant influence on the expressions of apo A-IV, apo B, and apo E.

The EE-SPI group had a lower abundance of hepatic 7α-hydroxylase mRNA, suggesting that SPI loses most of its effectiveness in enhanceing bile acid synthesis by withdrawal of the ethanol extract. This is consistent with reports by several groups (17,18) that intact SPI preparations increase bile acid excretion, compared with casein. Although bile acid synthesis was not measured in the present experiment, it was reported that the abundance of 7α-hydroxylase mRNA correlates to the activity of 7α-hydroxylase, which is a rate-limiting enzyme of bile acid synthesis (19). Most likely the increased concentration of esterified cholesterol in the liver in EE-SPI-fed rats, in comparison with SPI-fed rats, was attributed to decreased synthesis of bile acids.

In addition, EE-SPI group also had a reduced hepatic LDL receptor mRNA level, compared with that of intact SPI group, which suggests that SPI ethanolic extract has the effect of increasing the transcription of the LDL receptor gene, probably by blocking the down-regulation of the LDL receptor by increasing cholesterol excretion as bile acid. Alternatively, it remains a possibility that the ethanol extracts directly influenced the LDL receptor gene expression.

In our preliminary experiment, the serum cholesterol concentration in ExHC rats fed a casein-containing diet supplemented with isoflavones which were derived from soybean germ hypocotyl was significantly lower than that from groups fed the diet without isoflavones, but still significantly higher than that from groups fed SPI-containing diets (Sato, M., Tsuda, Y., Takashima, S., and Imaizumi, K., unpublished observation). The major isoflavones of soybean germ hypocotyl are daidzein and its glycoside (88.9 wt%), while those of SPI are rich in genistein and the glycoside (67.3 wt%). Therefore, a type of isoflavone may differently influence the serum cho-

[b]Significantly different from SPI group by Student's *t*-test at $P < 0.05$.

lesterol concentration. Likely our ethanol extraction procedure inactivated other components of SPI which might be responsible for lowering serum cholesterol concentration.

In summary, the present results demonstrate that ethanol extract from SPI contains a factor(s) to lower serum total cholesterol concentration or non-HDL cholesterol and suggest that this may be mediated by increasing the transport of serum cholesterol into the liver through LDL receptor-mediated pathway and the subsequent excretion as bile acids. Hence, ExHC rats are an appropriate animal model to identify the active component(s) in SPI responsible for the hypocholesterolemic effect and the mechanism involved.

The Effects of a Dietary Oxidized Oil on Lipid Metabolism in Rats

Klaus Eder*

Institut für Tieremährung und Vorratshaltung, Martin-Luther-Universität Halle, D-06108 Halle (Saale), Germany

ABSTRACT: This study was carried out to investigate the effects of a dietary oxidized oil on lipid metabolism in rats, particularly the desaturation of fatty acids. Two groups of rats were fed initially for a period of 35 d diets containing 10% of either fresh oil or thermally treated oil (150°C, 6 d). The dietary fats used were markedly different for lipid peroxidation products (peroxide value: 94.5 vs. 3.1 meq O_2/kg; thiobarbituric acid-reactive substances: 230 vs. 7 μmol/kg) but were equalized for their fatty acid composition by using different mixtures of lard and safflower oil and for tocopherol concentrations by individual supplementation with DL-α-tocopherol acetate. In the second period which lasted 16 d, the same diets were supplemented with 10% linseed oil to study the effect of the oxidized oil on the desaturation of α-linolenic acid. During the whole period, all the rats were fed identical quantities of diet by a restrictive feeding system in order to avoid a reduced food intake in the rats fed the oxidized oil. Body weight gains and food conversion rates were only slightly lower in the rats fed the oxidized oil compared to the rats fed the fresh oil. Hence, the effects of lipid peroxidation products could be studied without a distortion by a marked reduced food intake and growth. To assess the rate of fatty acid desaturation, the fatty acid composition of liver and heart total lipids and phospholipids was determined and ratios between product and precursor of individual desaturation reactions were calculated. Rats fed the oxidized oil had reduced ratios of 20:4n-6/18:2n-6, 20:5n-3/18:3n-3, 20:4n-6/20:3n-6, and 22:6n-3/22:5n-3 in liver phospholipids and reduced ratios of 20:4n-6/18:2n-6, 22:5n-3/18:3n-3, and 22:6n-3/18:3n-3 in heart phospholipids. Those results suggest a reduced rate of desaturation of linoleic acid and α-linolenic acid by microsomal Δ4-, Δ5-, and Δ6-desaturases. Furthermore, liver total lipids of rats fed the oxidized oil exhibited a reduced ratio between total monounsaturated fatty acids and total saturated fatty acids, suggesting a reduced Δ9-desaturation. Besides those effects, the study observed a slightly increased liver weight, markedly reduced tocopherol concentrations in liver and plasma, reduced lipid concentrations in plasma, and an increased ratio between phospholipids and cholesterol in the liver. Thus, the study demonstrates that feeding an oxidized oil causes several alterations of lipid and fatty acid metabolism which might be of great physiologic relevance.

Paper no. L8153 in *Lipids 34*, 717–725 (July 1999).

Polyunsaturated fatty acids (PUFA) are labile compounds which, under the promoting effect of oxygen, high temperature or metallic catalysts, undergo peroxidative damage. In the course of this reaction, various products such as peroxides, aldehydes, acids or polymerization products are formed. To study metabolic effects of these compounds, experiments with animals were carried out which in most cases used highly oxidized vegetable oils or fish oil (1–7) as well as isolated lipid peroxidation products (8). Those experiments exhibited some effects of oxidized oils on lipid metabolism, with alterations of tissue fatty acid compositions being observed (1–7). Increased levels of arachidonic acid in tissue lipids suggested an elevated desaturation of linoleic acid in animals fed oxidized oils (1,4,5,7). However, experiments using highly oxidized oils must be regarded critically from some points of view. First, feeding diets with highly oxidized oils usually reduces the animals' food intake (1,2,6,9,10). Additionally, the digestibility of fatty acids from highly oxidized oils is affected as a consequence of fatty acid polymerization (2,7,10). Therefore, animals fed such oils usually exhibit a markedly lower growth rate than control animals fed equivalent fresh oils (1–3,5–7,9,10). Oxidized oils also contain significantly less PUFA and tocopherols than the equivalent fresh oils (1–7). Therefore, the effects observed after feeding oxidized oils are not caused solely by lipid peroxidation products but by a complex mixture of a different nutritional status and different growth rates between animals fed fresh oils and animals fed oxidized oils.

The present study was performed to investigate the effects of a dietary oxidized oil under a controlled feeding system. Thereby, differences in feed intake were avoided by a paired feeding system; dietary fats used were equalized for their fatty acid composition by using mixtures of safflower oil and lard in various ratios, and tocopherol concentrations of the oils were equalized by individual supplementation of both fats with DL-α-tocopherol acetate.

The main objective of this study was to study the effect of an oxidized oil on the desaturation of essential fatty acids which play an important role for the synthesis of eicosanoids.

Studies in the literature considered concentrations of arachidonic acid in animal tissues as a parameter of linoleic acid desaturation (1,4,5,7). However, this desaturation assessment method has a disadvantage in that levels of arachidonic acid are relatively high even at the beginning of the experiment. Therefore, it is to be expected that there is only a small change in arachidonic acid levels in tissue lipids in response to an altered desaturation rate. Besides the conversion of linoleic acid into arachidonic acid, the present study also considered the conversion of α-linolenic acid into highly unsaturated n-3 PUFA, particularly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) as an additional measure of essential fatty acid desaturation. This was done by including linseed oil as a source of α-linolenic (18:3n-3) acid in the diets. However, before linseed oil was used, an initial period was preceded in order to begin the metabolic effects of an oxidized oil. In that period, rats were fed either fresh or oxidized oils with similar fatty acid compositions which were poor in α-linoleic acid. This concept was based on the idea that an early marked incorporation of n-3 desaturation products into tissue lipids at a phase when the metabolic effects of the oxidized oil were not yet occurring could confound the investigation of the oxidized oil on desaturation of α-linolenic acid. In the second phase, after metabolic effects of the oxidized oils might have been induced, diets were supplemented with linseed oil which is rich in α-linolenic acid. At the end of this period, levels of highly unsaturated fatty acids deriving from desaturation of both linoleic acid and α-linolenic acid were determined in tissue lipids in order to assess desaturation of essential fatty acids.

Our recent studies using moderately oxidized oils revealed that lipid peroxidation products reduce lipid concentrations in plasma as well as the osmotic fragility of red blood cells (11–13). This study also aimed to investigate whether these surprising metabolic alterations can be reproduced in animals fed a stronger oxidized oil.

MATERIALS AND METHODS

Animals and diets. An experiment was carried out using 20 male Sprague-Dawley rats with an average initial body weight of 107 ± 5 g (±SD) which were divided into two groups of 10 rats each. In the first period, which lasted 35 d, the rats were administered diets with fresh or oxidized oil. The oxidized oil was prepared by the following procedure: 5 kg of a mixture of lard and safflower oil (2:1, w/w) was put into a glass beaker with a capacity of 10 L; the fat mixture was heated at a temperature of 150°C using a temperature-controlled hotplate. The temperature of the oil was checked several times per day using a glass thermometer. During the entire heating period, air was continuously bubbled through the fat mixture *via* a glass pipette. To control for the degree of oxidation, aliquots of the heated oil were taken at several time points and peroxide values (POV), and concentrations of thiobarbituric acid-reactive substances (TBARS) were determined. After 6 d of continuous heating, the peroxidation procedure was terminated. This treatment caused a marked loss of PUFA, a complete loss of tocopherols, and a marked elevation of the POV (Table 1). It was planned to equalize fatty acid composition and tocopherol concentrations of both fats. Therefore, the control diet included a fat mixture composed of lard and safflower oil in a ratio of 94.5:5.5 (w/w). This fat mixture had a similar fatty acid composition as the oxidized oil; the POV of this fat mixture was 2 meq O_2/kg. Both fat mixtures were adjusted to a vitamin E activity of 170 mg α-tocopherol equivalents per kg. In the second phase of the experiment which lasted 16 d, those diets were supplemented with 10% linseed oil. The composition of the experimental diets is shown in Table 2; analyzed concentrations of fatty acids and tocopherols are shown in Table 3. In both periods, a restrictive feeding system was used in which all the rats were administered identical quantities of diet. In order to achieve complete consumption of the diet, the quantity administered was 10 to 20% lower than expected for *ad libitum* consumption of the control diet according to a previous study using similar diets (14). The quantity of diet administered was gradually increased with increasing body weight of the rats from 11

to 22 g per day in period 1. Because of the higher fat concentration of the diet used, the quantity of diet administered in period 2 was between 16 and 18 g per day. Animals were kept individually in Macrolon cages in a room with a temperature of 23°C and a relative humidity between 50 and 60%. Water was provided *ad libitum* by nipple bottles.

Analyses. After the feeding period of 51 d was completed, all the rats were killed by decapitation after light anesthesia with diethyl ether. Blood was collected in heparinized polyethylene tubes; liver and heart were excised and stored at a temperature of −20°C until analysis. Lipids from liver and heart were extracted using a mixture of hexane and isopropanol (3:2, vol/vol) (15). Phospholipids of the extracts were isolated by high-performance liquid chromatography using a Merck-Hitachi (Darmstadt, Germany) system consisting of a gradient pump (L-6200), an ultraviolet detector (L-4250), a 25 × 0.4 cm (internal diameter) Si-60 (5 µm) cartridge (LiChroCART, Merck), and a fraction collector (L-5200). The gradient system was based on acetonitrile and methanol as mobile phases (16). Total lipids of liver and heart as well as isolated phospholipid fractions were methylated with boron fluoride/methanol reagent (17). Fatty acid methyl esters were separated by gas–liquid chromatography using a Varian system (model 3400; Darmstadt, Germany) equipped with a very polar capillary column (SP-2340, 60 m × 0.25 mm i.d., Supelco, Bellefonte, PA) and a flame-ionization detector. Helium was used as carrier gas. Fatty acid methyl esters were identified by comparing their retention times with those of individual purified standards and quantified using heptadecanoic acid methyl ester as an internal standard (18).

Concentrations of tocopherols in liver, plasma, oils, and diets were determined by high-performance liquid chromatography (19). Samples were mixed with 1 mL 1% pyrogallol solution (in ethanol, absolute) and 150 µL saturated sodium hydroxide solution. This mixture was heated for 30 min at 70°C. Then tocopherols were extracted three times with *n*-hexane. Individual tocopherols were separated using a mixture of *n*-hexane and 1,4-dioxane (94:6, vol/vol) as mobile phase and a LiChrosorb Si 60 column (5 µm particle size, 250 mm length, 4 mm internal diameter; Merck) and detected by fluorescence (excitation wavelength: 295 nm, emission wavelength: 320 nm).

For determination of liver and heart total cholesterol, triglycerides and phospholipids, aliquots of the extracts were dissolved in Triton X-100 (20). Total cholesterol and triglycerides were determined using enzymatic reagent kits obtained from Merck. The concentration of total phospholipids in heart and liver was calculated from the amount of its esterified fatty acids (26). The concentrations of total cholesterol, triglycerides, and phospholipids in plasma were measured enzymatically using an autoanalyzer (model EPOS; Eppendorf, Hamburg, Germany) and commercial available kit reagents (Merck; and bioMerieux, Marcy-l'Etoile, France).

The osmotic fragility of erythrocytes was determined according to the method of O'Dell *et al.* (21). Aliquots (40 µL) of fresh blood were added to 2-mL portions of hypotonic sodium chloride solutions. The suspensions were incubated for 15 min at ambient temperaure and were then centrifuged at 1,100 × *g* for 5 min. The absorbance of the supernatants at 540 nm was determined as a measure of hemoglobin release from erythrocytes during incubation and was used for calculation of percentages of erythrocytes hemolyzed during incubation.

Statistics. For statistical evaluation, means of the two dietary treatments were compared by Student's *t*-test.

RESULTS

Data on feed intake, growth, and food conversion are shown in Table 4. Feed intake because of the restrictive feeding sys-

[a]Results are means ± SD with n = 10 for both groups. Means with different superscript letters (b, c) differ significantly by Student´s t-test ($P < 0.05$).

tem used was nearly identical in both groups. The small difference observed in the first period was caused by one animal in the control group which did not completely consume the diet administered. Body weight gain and feed conversion rate were only slightly different between the two groups. The rats fed the oxidized oil exhibited 6% lower body weight gain and feed conversion over the whole feeding period. This effect was mainly due to differences in the first period; in the second period, the growth rate was nearly identical between both groups.

Tocopherol concentrations in liver and plasma measured to assess the vitamin E status of the rats are shown in Table 5. Although the diets were equalized for their tocopherol concentrations, rats fed the oxidized oil exhibited markedly lower concentrations of tocopherols in liver and plasma than rats fed the fresh oil. In liver, feeding the oxidized oil reduced the concentration of total tocopherols by *ca.* 80%, and in plasma by *ca.* 60%. The concentration of γ-tocopherol was more strikingly reduced by the oxidized oil than was the concentration of α-tocopherol.

To assess the effects of a dietary oxidized oil on fatty acid desaturation, the fatty acid composition of liver and heart total lipids and phospholipids was determined. In liver total lipids, the main effect of the dietary oxidized oil was an increased level of saturated fatty acids (SFA) at the expense of monounsaturated fatty acids (MUFA) (Table 6). Thus, the ratio between SFA and MUFA was significantly reduced. Levels of PUFA in liver total lipids were not significantly influenced by feeding the oxidized oil. Levels of long-chain n-3 PUFA, which were determined to assess the desaturation of α-linolenic acid, were relatively low and were not different between both groups of rats. Hepatic phospholipids contained relatively low levels of MUFA; the levels of both SFA and MUFA were not considerably influenced by the oxidized oil. Thus, the ratio between SFA and MUFA was not altered in hepatic phospholipids. However, hepatic phospholipids exhibited altered levels of some individual PUFA. Rats fed the oxidized oil had higher levels of linoleic acid, α-linolenic acid, dihomo-γ-linolenic acid, and docosapentaenoic acid than rats fed the fresh oil. In contrast, levels of arachidonic acid and DHA were lower in the rats fed oxidized oil than in the rats fed the fresh oil. Thus, the ratios between precursors and products of fatty acid desaturation reactions were altered by the dietary oxidized oil (Table 7).

The fatty acid composition of heart total lipids and phospholipids is shown in Table 8. In total lipids, levels of SFA and MUFA were not different between both groups. Levels of total PUFA were also not different between both groups. However, the levels of some of the individual PUFA were changed by the dietary oxidized oil. The level of α-linolenic acid was increased in the rats fed the oxidized oil, and levels of EPA and DHA were reduced. Heart phospholipids of rats fed the oxidized oil had increased levels of SFA and MUFA at the expense of PUFA. Within the group of PUFA, levels of precursors of desaturation such as linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3) were slightly elevated in rats fed oxidized oil, and those of products such as docosapentaenoic acid and DHA were slightly reduced. Thus, the ratios between products and precursor of Δ4-, Δ5-, and Δ6-desaturase in heart phospholipids were reduced by the dietary oxidized oil (Table 7).

Feeding the oxidized oil tended to reduce lipid concentrations in plasma and liver (Table 9). In plasma, concentrations of triglycerides were significantly ($P < 0.05$) reduced and those of cholesterol and phospholipids were slightly ($P < 0.10$) reduced by feeding the oxidized oil. In the liver, concentrations of cholesterol ($P < 0.05$) and triglycerides ($P < 0.1$) were

also reduced. However, rats fed the oxidized oil had a higher liver weight than rats fed the control oil; thus, amounts of triglycerides and cholesterol in the total liver were not different between both groups. In contrast, the total amount of phospholipids was 30% higher in rats fed oxidized oil than in rats fed the fresh control oil; the ratio between phospholipids and cholesterol in the liver was increased from 3.75 to 5.61 by the dietary oxidized oil. Heart weight was not significantly increased by feeding the oxidized oil, and concentrations of triglycerides and cholesterol in heart were also similar in rats of both groups. The concentration of phospholipids in the heart was slightly, though significantly, higher in the rats fed the oxidized oil; however, the total amount of phospholipids in the heart was not different between both groups.

The osmotic fragility of erythrocytes is shown in Table 10. In general, erythrocytes of rats fed the oxidized oil exhibited lower percentages of hemolysis during incubation in hypotonic solutions than erythrocytes of rats fed the fresh oil. Because of the relatively large standard deviations, significant differences were observed only at the incubation in the 0.34% sodium chloride solution.

DISCUSSION

The present study was performed to investigate the effects of a dietary oxidized oil on parameters of lipid metabolism in rats. The oxidized oil was prepared by heating a mixture of lard and safflower oil at a temperature of 150°C for 6 d. This treatment caused a large reduction of the PUFA concentration of the oil by free radical-mediated reactions. It is expected that under high temperature, the primary lipoxy radical is not stable, and thus predominately secondary products such as polymer compounds and carbonyls might have been formed during this treatment (22). This might be an explanation for the relatively low POV of the oxidized oil used in this study. Relative proportions of primary to secondary lipid peroxidation products are particularly significant for the discussion of the effects of an oxidized oil on animal metabolism. Primary

[b]— indicates that the amount of fatty acid was lower than 0.1 mole/100 moles of fatty acids). For abbreviations see Table 6.

products of lipid oxidation such as peroxides and hydroperoxides are highly toxic when administered parenterally, whereas they are less toxic when orally administered, probably due to low absorbability (23,24). In contrast, secondary products, in particular aldehyde compounds, were shown to be highly toxic because of a relatively high digestibility (25). The heat treatment for preparing the oxidized oil increased POV and TBARS concentration to a similar extent, by a factor of *ca.* 30 compared with the fresh oil. Although TBARS concentration is not a very specific indicator of secondary lipid peroxidation products (26), it suggests that the rats fed the oxidized oil had a high ingestion of both primary and secondary lipid peroxidation products.

Although this experiment was carried out over nearly the whole growth period of the rats, there were no considerable differences in the growth of the groups of rats. This suggests that, although the dietary vitamin E supply was relatively low, the oxidized oil used in this study did not produce toxic effects in the animals. It is known that a high vitamin E supply reduces the toxicity of lipid peroxidation products (6). Tissue and plasma tocopherol concentrations were markedly reduced by feeding the oxidized oil, although control and oxidized oils

were equalized for their vitamin E activities. This result agrees with other studies demonstrating adverse effects of dietary lipid peroxidation products on the vitamin E status of animals, which might be the consequence of an enhanced turnover or catabolism of tocopherols (4,7,9,27). Chemical processes that consume tocopherols include the oxidation of tocopherols by lipid peroxyl radicals. The observation that γ-tocopherol concentrations were depressed more by dietary lipid peroxidation products than were α-tocopherol concentrations suggests that γ-tocopherol is the main initial target for lipid peroxyl radical reaction. Besides an enhanced consumption of tocopherols by radical-induced oxidation, a reduced absorption of tocopherols also could contribute to the reduced tissue tocopherol concentrations in rats fed the oxidized oils (27).

The desaturation of fatty acids is an important physiological reaction because highly unsaturated fatty acids derived from linoleic acid and α-linolenic acid function as critical constituents of cellular membranes, influencing their properties or acting as precursors of eicosanoids. This study aimed to assess fatty acid desaturation in rats fed oxidized oils by determining the fatty acid composition of liver and heart total lipids and phospholipids. It is well known that SFA and unsaturated fatty acids containing one to three double bonds in most part and highly unsaturated fatty acids in minor part are catabolized by mitochondrial β-oxidation (28). In spite of this, the ratio between precursor and product of desaturation in tissue lipids commonly was used as an indicator of fatty acid desaturation (29,30). Since highly unsaturated fatty acids are mainly incorporated into tissue phospholipids and MUFA are mainly incorporated into triglycerides, it seems plausible to assess the rate of desaturation of essential fatty acids from the fatty acid composition of isolated phospholipid fractions and that of desaturation of SFA from the fatty acid composition of neutral or total lipids (30). Considering liver total lipids and phospholipids and heart phospholipids, our study suggests an impaired desaturation of SFA by Δ9-desaturase and an impaired desaturation of linoleic and α-linolenic acid by Δ6-, Δ5-, and Δ4-desaturases (Table 7). Reduced levels of fatty acids derived from desaturation in general also could be the result of an enhanced degradation of those fatty acids by mitochondrial β-oxidation or of an increased loss of highly unsaturated fatty acids by autoxidation. If the rate of mitochondrial β-oxidation, however, would be increased by feeding oxidized lipids, it would be expected that levels of saturated, mono-, di-, and triunsaturated fatty acids would be mainly reduced because they are the main substrate of β-oxidation (28). If losses of PUFA by autoxidation would play an important role, it would be expected that the reduction of individual PUFA would increase with increasing number of double bonds. Such an effect, however, was not observed. For instance, in liver phospholipids, levels of arachidonic acid and DHA were reduced, that of EPA remained unchanged, and that of docosapentaenoic acid was even increased. Hence, changes of individual PUFA levels might be the result of an impaired desaturation rate rather than the result of an increased rate of β-oxidation or increased losses by autoxidation. The results of this study are in contrast with other studies suggesting an enhanced desaturation of linoleic acid in animals fed oxidized oils by observing increased levels of arachidonic acid in tissue phospholipids (1,4,7). The different results could be due to different nutritional conditions of the animals. It is well-established that Δ6- and Δ5-desaturase activities are highly dependent on several nutritional and hormonal factors, particularly on the ingestion of linoleic acid. The studies reporting increased tissue levels of arachidonic acid used oxidized oil preparations with markedly lower levels of PUFA compared with control oils. Thus, it cannot be ruled out that the increased rate of fatty acid desaturation in those studies was caused by a lower intake of linoleic acid rather than by dietary oxidation products. Interestingly, feeding cholesterol oxidation products in rats caused an enhanced Δ6-desaturation if casein was used as the source of protein, whereas the activity of Δ6-desaturase activity remained unchanged by dietary cholesterol oxidation products if soybean meal was used as source of protein (31). These results suggest that the effect of oxidized lipids on the lipid metabolism, i.e., fatty acid desaturation, might be modified by several nutritive factors.

It is known that the activities of fatty acid desaturases are directly controlled by the fluidity of microsomal membranes (32). Thus, effects of dietary oxidized oils on desaturase activities might be mediated by an altered structure of microsomal membranes. A recent study in rats fed an oxidized linoleic acid preparation reported an increased ratio between phospholipids and cholesterol and an increased fluidity of hepatic microsomal membrane (1). Reduced activities of desaturating enzymes leading to lower levels of highly unsaturated fatty acids, as observed in this study, could be a compensatory means to maintain the membrane fluidity at a constant level. Interestingly, in contrast to liver microsomal membranes, erythrocyte membranes exhibited a reduced fluidity in rats fed oxidized lipids (3). It was suggested that incorporation of lipid peroxidation products apart from alterations of membrane lipid composition could account for the altered membrane fluidity observed in animals fed oxidized oils (3). A recent study investigating the effects of cyclic fatty acid monomers reported a decreased lipid packing order of membrane bilayers of cultured aortic endothelial cells associated with a reduced activity of Ca^{2+} ATPase (33). These studies demonstrate that dietary treatment of animals with oxidized

oils as well as incubation of isolated cells with lipid peroxidation products has profound effects on membrane structure and function.

This study shows that dietary oxidized oils reduce triglyceride concentrations in plasma and liver. Recent studies demonstrated that the activities of glucose-6-phosphate dehydrogenase (8) and other enzymes involved in the synthesis of fatty acids in the liver (13) are reduced by dietary lipid peroxidation products. Thus, reduced concentrations of triglycerides in plasma and liver might be caused by a reduced rate of lipogenesis. On the other hand, this study as well as others (6,7,11,34) reported increased liver weights in animals fed oxidized oils. It has been shown that the enlargement of liver is largely due to a proliferation of endoplasmic reticulum, which is indicated by the induction of microsomal detoxifying enzymes (8,10). This also might explain the significant increase in phospholipid content in the liver and the increased ratio between phospholipids and cholesterol. It is well known that cell organelle membrane generally has a lower cholesterol/phospholipid ratio than the plasma membrane (35).

The concentration of cholesterol in plasma plays a particular role in the risk of coronary heart disease in humans. In this study, plasma cholesterol was slightly reduced by feeding an oxidized oil. This result agrees with that of another study (10); however, there are also studies reporting increased plasma cholesterol concentration in animals fed oxidized oils (1,2). A reduced concentration of cholesterol in plasma observed in this study could be due to enhanced fecal excretion of cholesterol which was found in rats fed an oxidized oil (1).

This study observed that the osmotic fragility of erythrocytes is reduced rather than increased by feeding an oxidized oil. A similar effect was recently observed in rats fed a moderately oxidized fat (12). This effect might be due to an altered structure of the erythrocyte membrane. A study of Hayam *et al.* (3) which demonstrated a reduced fluidity of erythrocyte membranes in rats fed oxidized oils suggested the incorporation of lipid peroxidation products into erythrocyte membranes. Lipid peroxidation products, in particular malondialdehyde, can react with free amino groups of proteins and lipids to form cross-linked products between various membrane components (36), thereby leading to increased membrane rigidity.

In conclusion, this study shows that feeding an oxidized oil causes several alterations of the lipid metabolism which might be of physiologic relevance. However, further studies are required to understand the mechanisms underlying those alterations.

Absorption in Rats of Rapeseed, Soybean, and Sunflower Oils Before and Following Moderate Heating

Trine Porsgaard[a], Hong Zhang[b], Robert G. Nielsen[c], and Carl-Erik Høy[a,*]

Departments of [a]Biochemistry and Nutrition and [b]Biotechnology, The Technical University of Denmark, 2800 Lyngby, Denmark, and [c]Biotechnological Institute, 6000 Kolding, Denmark

ABSTRACT: Rapeseed, soybean, and sunflower oil were heated for 15 min in a 5-mm oil layer in a pan at 180°C. The fatty acid composition was almost unaffected by heating, while the polymer content rose slightly and the tocopherol content decreased, except in soybean oil. The absorption of oils before and after heating was investigated in lymph-cannulated rats. Oils were administered as emulsions through a gastrostomy tube and lymph was collected during the next 24 h. The highest accumulated lymphatic transport of total fatty acids was observed after administration of rapeseed oil, and the lowest after heated sunflower oil. The accumulated transport was similar for all unheated oils. The transport of fatty acids was significantly lower in rats receiving heated oil compared to those receiving the corresponding unheated oil. Small increases in polymers may have contributed to the decreased lymphatic transport of oil following heating, although this probably does not fully explain the effect. The absorption of sunflower oil was more affected by heating than the absorption of soybean or rapeseed oil. Furthermore, the largest decrease in total activity of tocopherols following heating was observed in sunflower oil. Overall, these results demonstrate that the absorption of vegetable oils is affected by moderate heating.

Paper no. L8040 in *Lipids 34,* 727–732 (July 1999).

According to the current dietary recommendations from the American Heart Association (1), a low intake of saturated fat and a high intake of unsaturated fat balanced between monounsaturated and polyunsaturated fatty acids, combined with a low intake of total fat, are advised as ways of reducing the risk for lifestyle-related diseases, such as coronary heart disease. From this point of view, rapeseed oil (RO) is a nutritionally healthy oil with a high content of the monounsaturated fatty acid, oleic acid, and also high contents of the essential polyunsaturated fatty acids linoleic and α-linolenic acid. With its high content of oleic acid, RO resembles olive oil, but it has a much higher content of polyunsaturated fatty acids, although not as high as oils such as soybean oil (SOO), corn oil, and sunflower oil (SUO).

The frying of fats, and especially highly unsaturated fats, results in thermoxidative and hydrolytic alterations. The deterioration of the lipid is correlated with the content of unsaturated fatty acids (2–5). Furthermore, the rate of oxidation depends on factors such as temperature, frying time, and antioxidant content (2,3,6–8). Heating causes several chemical alterations, e.g., elevations in the level of free fatty acids, changes in peroxide value, decreases in the degree of unsaturation and antioxidant content, and the formation of polymers resulting in a decreased nutritive value in the oils (4,9–12). The chemical changes are accompanied by changes in smell, taste, and color (3,6,13,14).

The potential toxicity of heated fats has been investigated in animal models. Most studies suggest that, in moderately heated oils, the suspected toxic components are not present in significant quantities, and combined with an otherwise adequate diet, these oils will have only limited or no detrimental effects when fed to animals (15–19).

Feeding experiments with rats have shown either no effect (20) or decreased absorbability of heated fats (16,17,21–23). In the present study, the aim was to investigate the stability of three vegetable oils during heating, with the use of a moderate heating procedure, thereby imitating pan-frying procedures in the kitchen (6,13). This was followed by a comparison of the lymphatic absorption of oils before and following heating in lymph-cannulated rats. The oils were a new Danish variety of low α-linolenic RO, SOO, and SUO, oils normally used in human nutrition. The physiological studies in rats were supplemented with extensive chemical and sensory analyses (to be reported elsewhere).

EXPERIMENTAL PROCEDURES

Animals. The following experiment was approved by the Danish Committee for Animal Experiments. Male Wistar rats (Møllegård Breeding Centre, Ll., Skensved, Denmark) weighing 250–290 g were anesthetized intramuscularly with a combination of zolazepam, xylazin, and butorphanol (Zoletil-mixture; 0.18 mL/350 g; The Royal Veterinary and Agricultural University, Denmark) and subjected to cannulation of the main mesenteric lymph duct with a clear vinyl tube (o.d. 0.8 mm, i.d. 0.5 mm; Critchley Electrical Products Pty. Ltd., New South Wales, Australia). A feeding silicone tube

Copyright © 1999 by AOCS Press

(o.d. 3.0 mm, i.d. 1.0 mm; Polystan, Værløse, Denmark) was inserted into the fundus region of the stomach and fixed with a purse-string suture. Following surgery, the rats were placed in individual restraining cages (24) with tap water freely available and a steady infusion of physiological saline (0.9% NaCl) at 2 mL/h through the feeding tube. Four to six hours after the operation, they received 0.2 mL of analgesic (Butorphanol; diluted 1:10 with sterile water, Fort Dodge). The rats were fasted until the following day.

Administration of oil and collection of lymph. The postoperative day, the experiment was started by collecting a baseline fraction of lymph from −1 to 0 h. At time "zero," a sonicated emulsion of 0.3 mL dietary fat and 0.3 mL of a solution containing 20 mM taurocholate (Sigma Chemical Company, St. Louis, MO) and 10 mg/mL choline (Sigma Chemical Company) in distilled water was injected through the feeding tube, followed by 0.6 mL saline. The infusion of saline was continued at 2 mL/h. Lymph was collected in tubes at 1-h intervals for the following 8 h, and a combined fraction was obtained from 8 to 23 h followed by a 1-h fraction from 23 to 24 h after the administration of fat. The tubes contained 100 µL of a 10% (wt/vol) Na_2-EDTA-solution (E. Merck, Darmstadt, Germany). They were frozen immediately after collection and kept at −20°C until analysis.

Oils and lipid analysis. The following oils were used for the experiment: a low α-linolenic RO (seed selected by DLF-Trifolium, St. Heddinge, Denmark; oil refined at the Department of Biotechnology, DTU, Lyngby), an SO, and an SUO (Aarhus Olie A/S, Aarhus, Denmark). The oils were heated in a stainless steel pan at 180°C in a 5-mm layer for 15 min. The unheated oils and corresponding heated oils were administered to 6 rats each as described above. The fatty acid composition of oils was determined by gas–liquid chromatography after methylation with KOH in methanol (25). Lipid was extracted from the lymph samples as described by Folch *et al.* (26) and methylated with KOH. The resulting fatty acid methyl esters were analyzed using a Hewlett-Packard 5880A chromatograph (Ingelsheim, Germany) with a SP2380 capillary column (30 m, i.d. 0.32 mm; Supelco, Bellefonte, PA), flame-ionization detection, and helium as the carrier gas. Initial oven temperature was 120°C, which was increased by 4°C/min until 160°C. This was maintained for 2 min, then increased by 8°C/min until 200°C, which was maintained for 10 min. The temperature was then raised to 225°C and maintained for 5 min. Peak areas were calculated using a Hewlett-Packard computing integrator and used to calculate the mol% of fatty acids in the oils and the lymphatic transport of fatty acids using internal standards (13:0 and 17:0 added as methyl esters before esterification), and based on response factors for actual standards (Nu-Chek-Prep, Elysian, MN).

Tocopherols. Tocopherols (α, γ, and δ) were determined by high-performance liquid chromatography (HPLC) using a Silica Chromsep 25231 column. The HPLC system consisted of the following equipment purchased from Waters Corporation, Milford, MA: a programmable 490 UV detector measuring at 292 nm (λ_{max} of α-tocopherol), an automated 717 sample injector, and a model 510 pump. HPLC-grade hexane with 0.03% ethanol was used as mobile phase at a flow rate of 1.0 mL/min. The sample preparations were performed in the dark. Two drops of oil (approximately 25–30 mg) were weighed precisely, diluted in 400 µL mobile phase, and mixed. Before injection of 10 µL into the HPLC, the sample was filtered (Chromafil filter, Type AO-45/3, Macherey-Nagel, Düren, Germany), mounted on 1-mL syringes, and transferred to colored vials. Quantification was based on peak area measurements using external standardization.

Polymers. Polymers were determined by high-performance size exclusion chromatography using the methods of Burkow and Henderson (27), Dobarganes and Márquez-Ruiz (28), and modified by Bo M. Jørgensen and R.G. Nielsen (unpublished). HPLC-grade tetrahydrofuran was used as dilution and elution solvent. The high-performance size exclusion chromatographic column (600 × 7.5 mm) was packed with 3-µm particle size PLgel of the mixed-E type (Polymer Labs, Aarhus, Denmark). A guard column (6 cm) packed with the same gel was mounted upstream the main column. An evaporative light-scattering detector (Cunow DDL 21) was used and operated with the following parameters: photomultiplier voltage at 400 V, temperature at 70°C, and filtered air flow rate at 4.0 L/min. The oil was diluted in tetrahydrofuran to a concentration of 50 mg/L in order to obtain detectable polymer peaks. This solution was further diluted 100 times to obtain the main peak of triacylglycerols. The injection volume was 20 µL, and the elution rate was 0.5 mL/min. All samples were analyzed consecutively at 15-min intervals. Polymer peak areas were calculated by commercial PC-software. Quantification was based on these areas and the dilution factor.

Statistical analyses. Results were expressed as mean ± SEM. Differences in lymphatic transport between the groups receiving different fats were tested using one-way analysis of variance after calculating the area under the curve using the trapezoidal rule (29) from 0 to 8 h, or by comparing selected time points. Student-Newman-Keuls method was used to determine the exact nature of the differences. All procedures were carried out using the Jandel SigmaStat statistical package (Jandel Corporation, Erkrath, Germany). The level of statistical significance was $P < 0.05$.

RESULTS

Changes in oils following heating. The main fatty acid in RO was oleic acid (18:1n-9, 58.4 mol%), while in SOO and SUO, linoleic acid (18:2n-6) was the dominating fatty acid, constituting 50.6 and 60.6 mol%, respectively (Table 1). No changes were observed in the fatty acid composition of the oils following heating, except for minor decreases in 18:2n-6 in SOO and SUO and concomitant increases in 16:0 and 18:1n-9. *Trans*-fatty acids were not detected following heating. The content of polymers in the oils was low (Table 2), especially in RO, with values below or close to 1 wt%. The differences between unheated and heated oils were small, al-

though the values in heated oils were higher than the values in the corresponding unheated oils. The content of total tocopherols was highest in soybean oil (1105 µg/g oil) and lowest in rapeseed oil (701 µg/g oil), and it decreased in all three oils during heating, although it was insignificant in SOO. The most biologically active tocopherol is α-tocopherol. The activities of different tocopherols are expressed as α-tocopherol equivalents (α-TE), 1 mg of *RRR*-α-tocopherol being assigned 1 α-TE and the activity of γ- and δ-tocopherol to 0.1 and 0.03 α-TE, respectively (30). Calculating the total α-TE in heated and unheated oils gave the highest value for SUO and the lowest for SOO. The largest decrease in α-TE caused by heating was observed in SUO (9% lower after heating) followed by RO (6%), while SOO was unaffected.

Lymphatic transport. The lymphatic transport of total fatty acids showed marked differences between the unheated and corresponding heated oils (Fig. 1), with significantly higher

transport of the unheated oils ($P < 0.05$). The transport of heated SUO was significantly lower than all other oils ($P < 0.05$). No difference was observed in the lymphatic transport of the three unheated oils. Maximum transport was obtained 2 h after administration of the unheated oils, reaching values between 27.9 and 33.5 mg/h, and 3 h after heated SOO and RO (23.4 and 28.0 mg/h), while the transport of heated SUO (16.7 mg/h) did not peak until 5 h after administration. Figure 2 shows the accumulated transport of total fatty acids following administration of oils. The transport at 8 h was significantly higher for all unheated oils compared to all heated oils ($P < 0.05$). At 24 h the transport of all unheated oils was significantly higher than the transport of heated SUO ($P < 0.01$), and the transport of RO was higher than the transport of

[a]The areas under the curve are calculated as the mean of results from six rats each.

heated RO ($P < 0.01$). The highest accumulated transport was observed after RO administration (316 mg) and the lowest after administration of heated SUO (200 mg). Each rat received 0.3 mL of oil, corresponding to 270 mg fat, and this led to a recovery after RO at 117%, and at 74% after heated SUO.

The transport of 18:2n-6 and 18:3n-3 is shown in Figures 3 and 4, respectively. The transport of 18:2n-6 after administration of unheated oils was significantly higher than the transport of the corresponding heated oils ($P < 0.05$). Administration of SOO and SUO led to transport of 18:2n-6 significantly higher than after all other oils. The transport of 18:2n-6 after heated RO was significantly lower than after all other oils. Administration of SOO resulted in transport of 18:3n-3 significantly higher than after all other oils. RO led to higher transport of 18:3n-3 compared to heated RO. Similar differences between heated and unheated oils were observed for the saturated fatty acids (not shown).

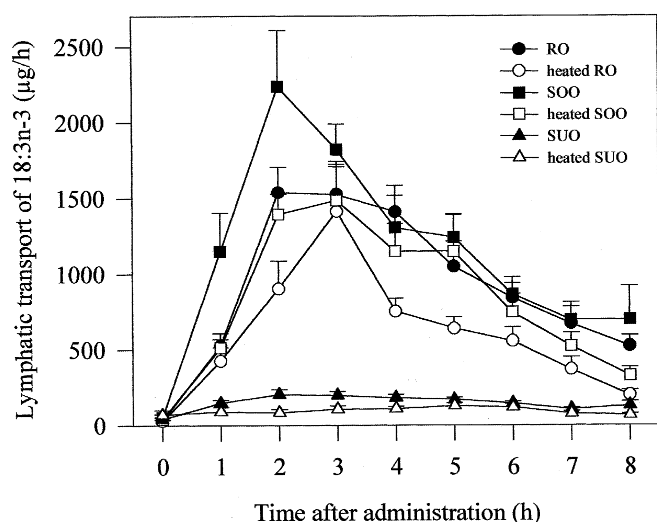

FIG. 4. Lymphatic transport (μg/h) of α-linolenic acid (18:3n-3) in rats after administration of dietary oils before and following heating. Values are means ± SEM (n = 6). See Figure 1 for abbreviations.

The ratio between the mean area under the curve from 0 to 8 h for lymphatic transport of unheated oil and the mean area under the curve for the corresponding heated oil was calculated for individual and total fatty acids (Table 3). The highest ratio was found for SUO (around 2.0) and the lowest ratio for SOO (around 1.3), with RO (around 1.8) in between. These ratios illustrate that the lymphatic transport of unheated SOO was only slightly higher than the transport of heated SOO, while the transport of unheated SUO was nearly twice as high as the transport of heated SUO. Thus the effect of heating on the lymphatic transport was most pronounced with SUO.

DISCUSSION

In this study, three vegetable oils, RO, SOO, and SUO, were heated in a pan for 15 min at 180°C. Heating resulted in insignificant changes in fatty acid composition, but a slightly increased content of polymers and decreased tocopherol contents. The unheated and corresponding heated oils were administered to lymph-cannulated rats, and the lymphatic absorption of fat was followed for 24 h. The lymphatic transport was significantly lower after feeding the heated oils compared to the unheated oils. This was observed for both total and individual fatty acids (Figs. 1–4), indicating that heating oils even for a short period of time at a moderate temperature, as with those conditions applied in the normal use of the oils, leads to changes affecting the absorptive process.

Several groups have investigated the effects of including heated fats in the diets fed to rats for different periods of time. Nolen *et al.* (17) and López-Varela *et al.* (20) observed decreased rate of body weight gain in groups of rats fed heated oils compared to those fed unheated oils. This is in contrast to the findings by Izaki *et al.* (15), Kok *et al.* (16), and Hageman *et al.* (18), in which no effect on body weight gain was observed. Nothing in the experimental conditions can explain the differences in these results. Although the weight gain was

unaffected in the study by Kok *et al.* (16), the food intake was increased, indicating a decreased feed efficiency of heated oils. In various studies, long-term feeding of heated oils led to increases in organ weights, especially in the liver (15,16,19), while shorter periods of feeding (4 wk) showed no changes in liver weights (18,20). Independent of the duration of the feeding period and the nature of the administered oils, changes in the activities of several liver enzymes, although sometimes inconsistent, have been observed after feeding heated oils. Izaki *et al.* (15) observed increases, while Kok *et al.* (16) found decreases in the activity of gluthatione peroxidase. Decreases in the activity of carnitine palmitoyl transferase-I, isocitrate dehydrogenase, and glucose-6-phosphate dehydrogenase and increases in NADPH-cytochrome P_{450} reductase were found by Lamboni and Perkins (31). From these studies, it appears that the heating of fat can lead to the development of possibly toxic substances affecting metabolism in the liver. But, as observed by Nolen *et al.* (17), in a 2-yr feeding study in rats with heated oils, the level of these substances and the degree of their toxicity are generally low, and if the diet is otherwise balanced and adequate, they have no practical dietary significance.

In several studies, the absorption of heated fats was lower than the absorption of unheated fats (16,17,21,22). Fat absorption was determined either by calculation of fat excreted in feces compared to that ingested or through lymph collection studies. The main factor responsible for this reduced fat absorption is the content of unabsorbable polymeric material formed during heating, as observed by many investigators (5,9,11,21,32). According to some investigators, both reduced hydrolysis by pancreatic lipase of the complex molecules formed during heating and poor absorption of the released complex fatty acids contribute to the reduced absorbability (22,32). Others have found that the *in vitro* hydrolysis by pancreas lipase is only influenced to a minor degree by the heating of oils, resulting in complete hydrolysis of oils with low polymer contents (5,33). In our experiment we observed a remarkable reduction in the lymphatic transport of fat following heating. This was observed even though the increases in polymer content were relatively low. These observations indicate that either this small increase in the content of polymers could be responsible for the reduced transport or the answer has to be searched for in other, yet unidentified components.

The absorption of the three vegetable oils was not affected to a similar degree by heating. The highest reduction in transport was observed after feeding heated SUO. This is illustrated by a ratio of around 2.0 for the transport of unheated oil compared to heated oil (Table 3), indicating that the transport is twice as fast after administration of unheated oil. The lowest ratio (1.3) was found after administration of SOO. Furthermore, the largest reduction in total tocopherol activity following heating was observed in SUO (Table 2). The activity of tocopherols in SOO was not affected by heating. Even though SUO had the highest total activity of tocopherols, it had the most pronounced decrease in activity following heating, resulting in diminished antioxidative protection. This might also influence the lymphatic transport. Yoshida and Alexander (32) compared the *in vitro* hydrolysis by pancreatic lipase of monomers and dimers originating from the heating of corn oil, SO, and SUO, but they did not observe any differences in hydrolytic activity in the three oils. Maybe answers to the observed differences in lymphatic transport of the heated oils have to be searched for in the differences in the absorption process, rather than in the digestion by pancreatic lipase. Cepinskas *et al.* (34) showed that luminal hydroperoxides, which may be present following intake of heated fats, could be injurious to the intestinal epithelium and thereby affect absorption, but this needs further investigation.

Fatty Acid Composition of Brain Glycerophospholipids in Peroxisomal Disorders

Manuela Martinez* **and Isabel Mougan**

Center for Research in Biochemistry and Molecular Biology, Maternity-Children's Hospital Vall d'Hebron, Barcelona, Spain

ABSTRACT: This paper shows for the first time the differential fatty acid composition of ethanolamine plasmalogens (EP) and phosphatidylethanolamine (PE) in the brains of 12 patients with disorders of peroxisomal biogenesis and compares the results to normal values for the age. Other important glycerophospholipids (GPL), such as phosphatidylserine (PS) and phosphatidylcholine (PC), are also included in this study. GPL were separated by two-dimensional thin-layer chromatography, and their fatty acid composition was determined by capillary column gas–liquid chromatography. Total brain GPL were slightly decreased in peroxisomal disorders (27.98 ± 2.95 µmol/g in the patients against 34.5 ± 6.21 µmol/g in age-matched controls, $P = 0.005$), and the distribution of the different GPL classes was much altered. In confirmation of known data, EP were very much decreased (2.18 ± 1.3 µmol/g in the patients against 6.9 ± 2.3 µmol/g in controls) at the expense of PE, which was increased (8.58 ± 2.17 µmol/g in the patients against 5.97 ± 0.58 µmol/g in controls, $P < 0.005$). PS and PC were both significantly decreased ($P = 0.0001$ and $P = 0.037$, respectively). The polyunsaturated fatty acid (PUFA) composition of all the GPL fractions was markedly abnormal. In absolute terms, docosahexaenoic acid (22:6n-3) was drastically decreased in all GPL classes (always at the $P < 0.0001$ level) while arachidonic acid (20:4n-6) was increased in PE and PS ($P < 0.001$ in both cases). In the alkenyl acyl form, EP, 22:6n-3, and 20:4n-6 were both very significantly decreased ($P < 0.0001$), although the former was always the most affected. The myelin PUFA adrenic acid (22:4n-6) was decreased in EP ($P < 0.0001$) and slightly increased in PS ($P < 0.05$). The changes found confirm that 22:6n-3 deficiency is a predominant defect in the brain in peroxisomal disorders.

Paper no. L8108 in *Lipids 34*, 733–740 (1999).

Zellweger's (cerebro-hepato-renal) syndrome (1) is a lethal genetic disease characterized by the absence of normally formed peroxisomes in the liver and proximal tubules of the kidneys (2). The deficiencies in enzymes known to be located in peroxisomes cause multiple biochemical abnormalities, mostly affecting lipid metabolism. Characteristically, there is an increase in very long chain fatty acids (fatty acids with more than 22 carbon atoms) (3), owing to a deficient peroxisomal β-oxidation (4), and a decrease in plasmalogen levels (5), owing to defects in the enzymes alkyldihydroxyacetone phosphate synthase and dihydroxyacetone phosphate acyltransferase (6). Defective α-oxidation of phytanic acid leads to accumulation of this ramified fatty acid in plasma (7). Bile acid synthesis is affected, with accumulation of abnormal metabolites (8). Most organs are involved, but the clinical picture is dominated by profound neurodevelopmental, sensorial, and hepatic damage. The disorder is rapidly progressive, and death occurs in the first few months of life. Postmortem examination reveals neuronal differentiation and migration defects, as well as white matter abnormalities with reduction in myelin volume, dysmyelination, or demyelination (9).

There are milder variants of Zellweger's syndrome (ZS), like neonatal adrenoleukodystrophy (10) and infantile Refsum's disease (11). Genetically, however, no clear distinction can be made between these variants (12), the whole group representing a disease continuum with different degrees of clinical severity. In all these disorders, peroxisomal biogenesis is defective and the enzymatic deficit generalized. Clinically, these diseases are constantly characterized by psychomotor retardation, progressive sensorineural deterioration with blindness and deafness, failure to thrive, and hepatomegaly.

The underlying mechanism leading to such a severe clinical picture is unknown. Much of the neurological damage is attributed to abnormal accumulation of very long chain fatty acids in brain lipid structures (9). The decrease in plasmalogen levels could also be a deleterious factor. Recently, a dramatic decrease of docosahexaenoic acid (DHA, 22:6n-3) in the brain, retina, liver, kidneys, and blood of peroxisomal-disorder patients was found (13–15). Interestingly, the DHA levels seemed to be specifically decreased in the brains of peroxisomal-disorder patients, while the other main polyunsaturated fatty acid (PUFA), arachidonic acid (20:4n-6), was generally spared, or even increased. The existence of such a specific deficiency in a PUFA known to be especially localized in brain synapse phospholipids and the photoreceptor cells of the retina (16,17) may be pathogenic and deserves fur-

ther attention. Thus, after studying the total fatty acid composition of the brain in peroxisomal patients, we wanted to assess the PUFA patterns of the isolated glycerophospholipids (GPL). Since brain plasmalogen levels are much decreased in peroxisomal disorders and these lipids are important in myelin, we separated the alkenyl acyl from the diacyl form of ethanolamine GPL, paying special attention to the PUFA composition of ethanolamine plasmalogens (EP). This study shows for the first time the PUFA changes of EP in the brain of peroxisomal-disorder patients compared with those in diacyl phosphatidylethanolamine (PE) and other important GPL.

EXPERIMENTAL PROCEDURES

Brain tissue. Postmortem brain tissue from 12 patients with disorders of peroxisomal biogenesis and 20 controls was collected. The ages of the controls ranged from 26 prenatal wk to 8 postnatal yr, and their developmental phospholipid fatty acid profiles have been reported elsewhere (18). Although for this study the results of the patients were compared to the whole age span, for statistical analysis only the eight age-matched controls (from 1 mon to 2 yr of age) were used. All the controls died from acute diseases unrelated to the central nervous system. Roughly half of the cases were males and half females, and no sex differences were found in their fatty acid profiles. Of the peroxisomal brains, one belonged to the first Zellweger patient studied by the authors (13) and the other 11 were kindly provided by Dr. Moser's laboratory. All the patients were diagnosed with classic ZS or severe Zellweger variants, and their ages ranged from 1 to 31 mon. Seven of the patients died before 6 mon of age, four before 1 yr and one before 2 yr. All autopsies were performed after obtaining the signed informed consent from the parents. Human tissue was always obtained and used with permission from the corresponding hospital ethical committee. The bodies were transferred to the mortuary immediately after death and kept at 4°C until autopsy, which was performed within the first 48 h of death. Brain tissue was stored frozen at –80°C in a double bag of aluminum foil and polyethylene until analyzed. Although the time of storage of the brain samples varied widely, repeated analyses proved that the lipid and fatty acid composition was remarkably stable for years, including the levels of the most unsaturated fatty acids.

Biochemical methods. The lipids of 50–100 mg of wet brain tissue were extracted with 20 vol of chloroform/methanol/water (50:50:10, by vol). After centrifugation, the pellet was reextracted twice with 10 vol of chloroform/methanol/water (50:50:15, by vol). The combined lipid extracts were concentrated under a stream of N_2 and made up with chloroform/methanol (2:1) to a convenient small volume (generally 1 mL) for direct application to the thin-layer chromatography (TLC) plate. All solvents were of the highest commercial quality (Merck, Darmstadt, Germany), and contained 50 mg/L of butylhydroxytoluene (Fluka, Buchs, Switzerland) as an antioxidant. Individual lipids were separated by two-dimensional TLC according to Horrocks and Sun (19). Briefly, an aliquot of the total lipid extract corresponding to about 10 mg of wet brain tissue was spotted on the lower left corner of a TLC silica gel 60 F_{254}, 20 × 20 cm, plate (Merck). After one development in the first dimension with chloroform/meth-anol/ammonia (65:25:4, by vol), the plate was dried with a stream of N_2 and exposed to fumes of 12 N HCl for 5 min. This split plasmalogens into aldehydes and lysophospholipids. A second development in the other dimension, with chloroform/methanol/acetone/acetic acid/water (75:15:30:15: 7.5), separated ethanolamine GPL into acid-stable diacyl PE, aldehydes, and the lyso PE derived from the split EP.

The plate was dried once more with an N_2 stream, and the phospholipid spots were visualized by developing the plate with bromothymol blue. The fatty acid methyl esters (FAME) were obtained by direct transmethylation of the phospholipid spots with HCl/methanol, basically by the method of Lepage and Roy (20) with some modifications (21). After scraping and transferring the spots into methanolysis tubes (Corning, NY), 50 µL of methanol/benzene 4:1 (vol/vol) containing 25 µg of 13:0 and 25 µg of 23:0 was added. The volume was made up to 2 mL with the same solvent, and the tubes were vigorously vortexed (Rotamixer, Hook & Tucker, Ltd., England). While still vortexing, 0.2 mL of acetyl chloride was slowly added. This procedure avoided spillage of the hot mixture and contamination of the sample by any external stirrer. The tubes were tightly stoppered and transferred to a heating block (Thermolyne 4600 Dri-Bath, Dubuque, IA) at 100°C for 1 h. Losses by evaporation were checked by weighing before and after the reaction. After centrifugation at 3,000 rpm for 10 min, the upper phase was concentrated under a stream of N_2 and an aliquot (1–3 µL) was injected into a Hewlett-Packard 5890 gas chromatograph (Hewlett-Packard GmbH, Waldbronn, Germany), equipped with a 25 m, 0.25 mm i.d., BPX-70 column (SGE, Australia). The carrier gas was helium, at a constant flow of 1.1 mL/min. Samples were analyzed at a split ratio of about 25:1, and the column was programmed from 140 to 210°C at 3°C/min. Injector and detector temperatures were 250°C. Detector response linearity was checked in each chromatogram by comparing the areas of the two internal standards (13:0 and 23:0). Only when the two internal standard areas were the same (within a range better than ± 10%) were the results considered acceptable. Otherwise, the analyses were repeated until obtaining totally linear responses.

Peaks were measured with a Merck-Hitachi D-2500 computer-integrator (Merck) and identified by comparison of their retention times with those of pure standards and of mixtures with known fatty acid composition. When necessary, peak identification was confirmed by mass spectrometry of picolinyl esters (22) using a Hewlett-Packard 5970B mass selective detector. Spectra were obtained at an ionization potential of 70 eV. FAME areas were measured and computed with a D-2500 computer-integrator. Total amounts of phospholipids were obtained on the basis of the known FAME molarities, as detailed elsewhere (23). Statistical analysis consisted of unpaired t-tests of the patients' data (n = 12) against those of

age-matched controls (n = 8), using the statistics package StatView IV (Abacus Concepts, Inc., Berkeley, CA) and a Macintosh IIfx computer (Apple Computer Inc., Cupertino, CA).

RESULTS

Figure 1 compares the GPL composition of the brain in peroxisomal patients with that in age-matched controls. The distribution of the different GPL is markedly altered in the patients. Notably, the peroxisomal brain has much less plasmalogens and more diacyl PE than the normal brain at the same developmental stage, agreeing with data from other authors (5). To a lesser extent, the amount and proportion of PS are also decreased in the brains of peroxisomal patients. The proportion of phosphatidylcholine (PC) does not change much in the peroxisomal brain although its amount is less than normal.

Figures 2–5 show the absolute values of the main long-chain PUFA, 22:6n-3, 20:4n-6, and 22:4n-6, in the different brain GPL classes, in neurologically normal children compared to the peroxisomal patients studied. As Figure 2 shows, all three PUFA are decreased in EP in the brains of peroxisomal patients when compared with normal controls of the same age, although DHA is clearly the most affected PUFA. In PE, on the other hand, Figure 3 shows that the drastic decrease in the DHA levels is accompanied by a significant increase in 20:4n-6. So the increase in arachidonic acid partly accounts for the marked increase in PE found in the peroxisomal brain (Fig. 1). A more general decrease of all fatty acids in EP was to be expected since plasmalogen levels are known to be very low in the peroxisomal brain (5), as confirmed in Figure 1. However, as in the other GPL, DHA was clearly the most affected PUFA in EP, a fact that can more clearly be detected when looking at the percentage fatty acid patterns (Table 1).

Figure 4 shows that DHA is the specifically deficient PUFA also in PS. As in PE, arachidonic acid is significantly increased in PS in the peroxisomal brain. A slight but significant increase in adrenic acid was also observed in PS. Although the changes are less marked in PC, Figure 5 shows that, again, DHA is the most affected PUFA in this GPL. The other two fatty acids do not show significant changes, although there is a tendency toward higher 20:4n-6 levels in the peroxisomal-disorder brain.

To obtain a more complete view of all the fatty acid changes in the brain of peroxisomal patients, Tables 1 and 2 show the fatty acid patterns of the four brain GPL in the patients studied and controls of the same age. Tables 1 and 2 show that in percentage terms, as well as in absolute values, 22:6n-3 is consistently decreased in all four phospholipid classes, whereas 20:4n-6 is augmented in PE and PS and 22:5n-6 is decreased in all GPL. This is the rule in classic ZS and its most severe variants, like all the cases included in the present study. It must be pointed out, however, that in some patients that survive longer, 22:5n-6 may behave differently.

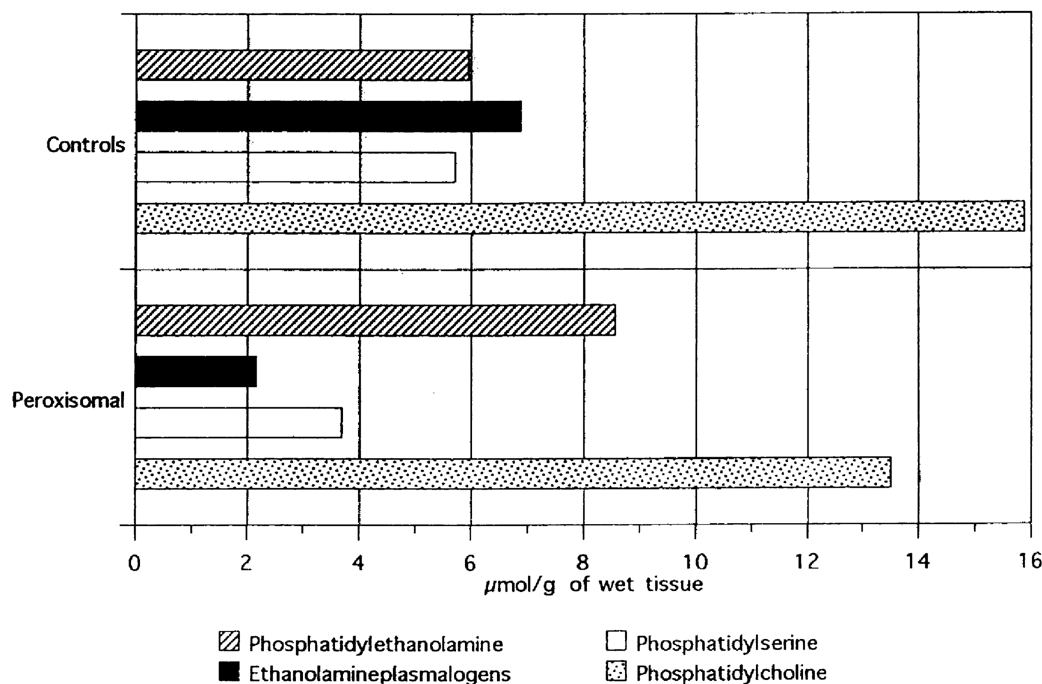

FIG. 1. Distribution of the main glycerophospholipids in the peroxisomal brain (n = 12) compared to that in the normal developing brain (n = 8). Both groups were matched for age (from 1 mon to roughly 2 yr). Although SD are not given here for clarity of the Figure, t-tests showed very significant statistical differences between patients and controls. While ethanolamine plasmalogen (EP) was much decreased in the Zellweger brain ($P < 0.0001$), phosphatidylethanolamine (PE) was increased ($P < 0.005$). Phosphatidylserine (PS) ($P = 0.0001$) and phosphatidylcholine (PC) ($P < 0.05$) were both decreased in the peroxisomal brain.

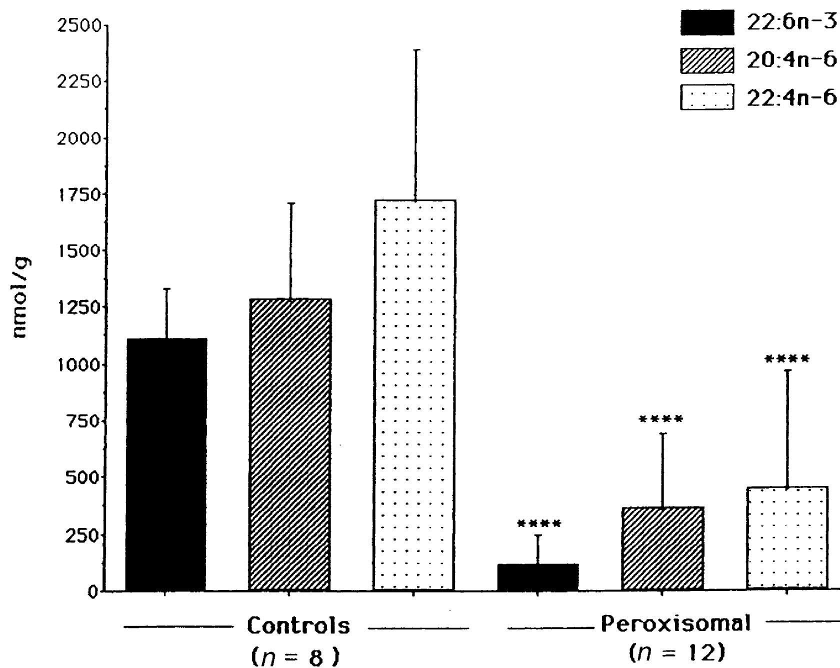

FIG. 2. Main polyunsaturated fatty acids (PUFA) of EP in the brains of peroxisomal disorder-patients compared to normal brains of the same age. All three PUFA are very significantly decreased in brain EP in peroxisomal patients, although 22:6n-3 is the most affected. Values are nmol/g of wet tissue; bars represent the means ±1 SD; ****, $P < 0.0001$. See Figure 1 for other abbreviation.

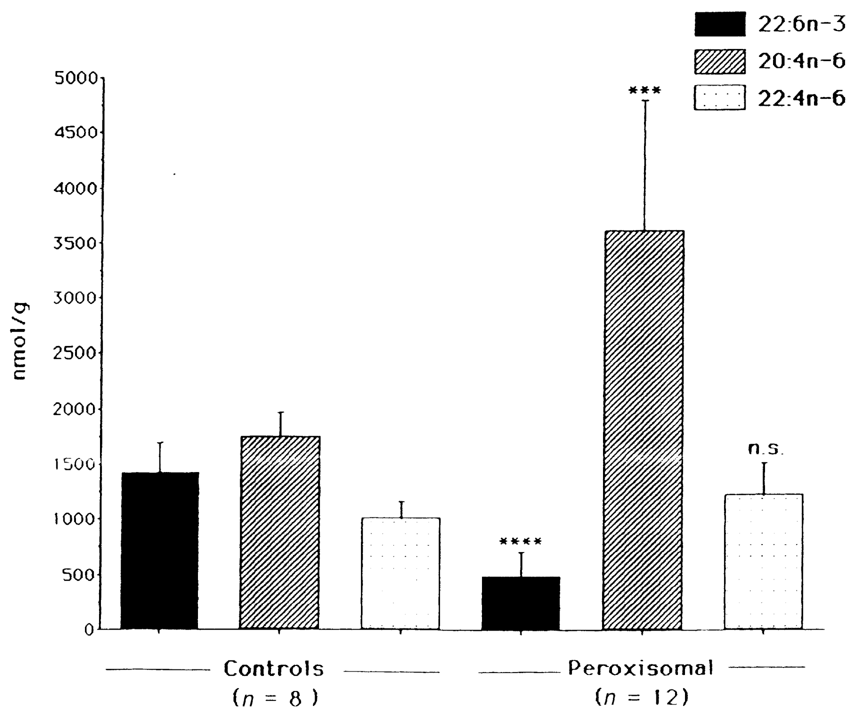

FIG. 3. Main PUFA of PE in the brains of peroxisomal disorder-patients compared to normal brains of the same age. Like in EP, 22:6n-3 is very significantly decreased in PE in the peroxisomal-disorder brain. In contrast to EP, however, 20:4n-6 is increased in PE in peroxisomal patients. Values are nmol/g of wet tissue; bars represent the means ±1 SD; ***, $P < 0.001$; ****, $P < 0.0001$, n.s., not significant. See Figures 1 and 2 for other abbreviations.

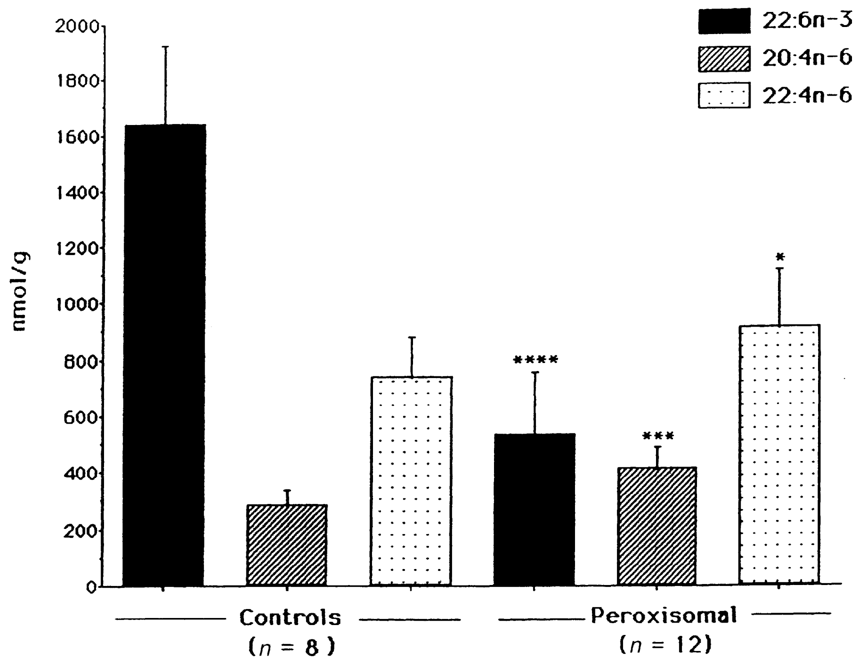

FIG. 4. Main PUFA of PS in the brains of peroxisomal disorder patients compared to normal brains of the same age. Again, 22:6n-3 is very significantly decreased in brain PS in peroxisomal disorders, while 20:4n-6 and 22:4n-6 are both significantly increased. Values are nmol/g of wet tissue; bars represent the means ±1 SD; *, $P < 0.05$; ***, $P < 0.001$; ****, $P < 0.0001$. See Figures 1 and 2 for abbreviations.

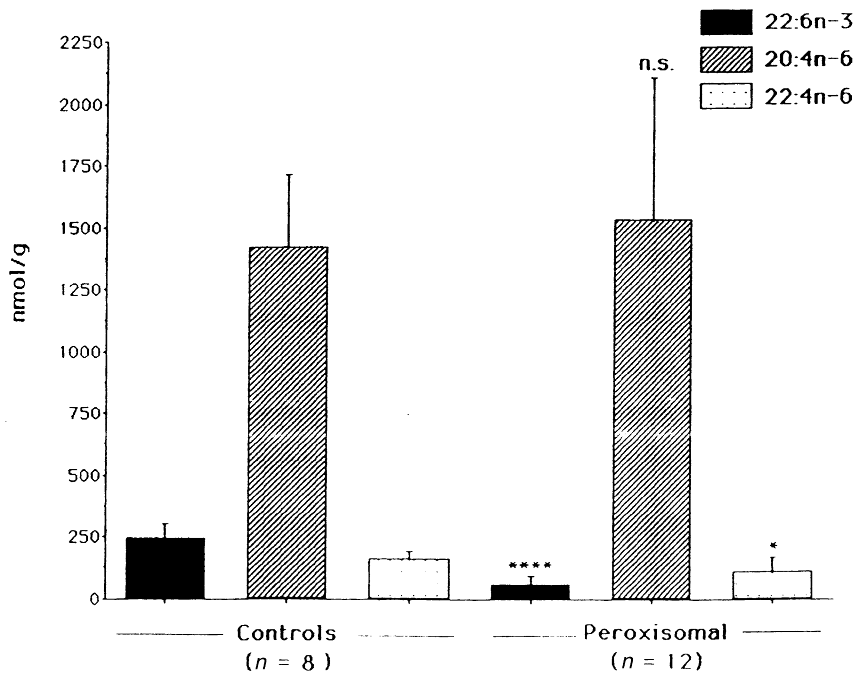

FIG. 5. Main PUFA of PC in the brains of peroxisomal disorder-patients compared to normal brains of the same age. In brain PC, 22:6n-3 is the only PUFA significantly decreased in peroxisomal patients. Values are nmol/g of wet tissue; bars represent the means ±1 SD; *, $P < 0.05$; ****, $P < 0.0001$; n.s., nonsignificant or $P > 0.05$. See Figures 1–3 for abbreviations.

22:6n-3	2.83 ± 1.37****	11.82 ± 1.62	5.12 ± 2.96****	17.03 ± 4.47

[a]Values are molar percentages (means ± 1 SD). An unpaired t-test was performed for all fatty acids, between peroxisomal patients and controls. Statistical significance worse than $P < 0.05$ is not given. * = $P < 0.05$; ** = $P < 0.01$; *** = $P < 0.001$; **** = $P < 0.0001$.

In some cases diagnosed with neonatal adrenoleukodystrophy, 22:5n-6 was found to be normal or even much increased (15), while 22:6n-3 is always decreased, in classic ZS as well as in the other phenotypes. Table 1 shows that, when only considering the percentage values, the changes of both 20:4n-6 and 22:4n-6 in EP are not significant, in contrast to the absolute values of these two PUFA. This stresses the importance of studying the data in the two forms, percentages as well as absolute amounts.

Apart from the long-chain PUFA, Table 1 shows some

Statistical significance worse than $P < 0.05$ is not given. * = $P < 0.05$; ** = $P < 0.01$; *** = $P < 0.001$; **** = $P < 0.0001$. See Table 1 for abbreviation.

marked changes in other brain fatty acids, especially in EP in the peroxisomal-disorder patients. The proportion of 18:1n-9 is very much decreased in the Zellweger EP, its ratio to 18:0 being the opposite of normal. In general, in the brain of patients with disorders of peroxisomal biogenesis, EP are richer in saturated fatty acids (14:0, 16:0, 18:0) and markedly poorer in monounsaturated and PUFA than in the normal brain. This makes EP the only GPL in which 22:6n-3, 20:4n-6, and 22:4n-6 are all significantly decreased in absolute terms in the peroxisomal brain. In PS, on the other hand, the proportion of 20:4n-6, 22:4n-6, and 20:3n-6 is much higher in the Zellweger brain than in the normal brain. As in EP, the proportion of 18:1n-9 is lower than normal in PS. With the exception of PE, 18:1n-9 is lower than normal in all GPL. Such a decrease in a fatty acid particularly enriched in myelin correlates with the hypomyelination found in patients with peroxisomal biogenesis disorders.

A smaller but very significant change found in all GPL classes was the increase in linoleic acid (18:2n-6), a finding that could already be detected when studying the total fatty acid composition of the Zellweger brain (13). Other n-6 intermediates, such as 20:2n-6 and 20:3n-6, were also increased in brain GPL in the Zellweger patients. In contrast, 20:2n-9 (like the parent fatty acid 18:1n-9) was lower than normal in the brain of peroxisomal-disorder patients, although this change only reached statistical significance in PC.

DISCUSSION

This study complements previous findings and confirms that 22:6n-3 is dramatically decreased in all GPL fractions in the brain of patients with disorders of peroxisomal biogenesis. The differential fatty acid composition of the diacyl and alkenyl forms of brain ethanolamine GPL is described for the first time in peroxisomal biogenesis disorders. Clear differences are found in the main PUFA changes in these two phospholipid classes. While in the peroxisomal brain PE, the decrease in 22:6n-3 is accompanied by an increase in 20:4n-6, both PUFA are decreased in brain EP in the peroxisomal patients. However, in all four GPL, the decrease in 22:6n-3 is the most marked. In the normal brain, the PUFA composition is quite constant and 22:6n-3, in particular, is maintained within narrow limits (24,25). An important role of 22:6n-3 in signal transduction was lately demonstrated at the synapse (26). Thus, the disruption in phospholipid structure and function caused by such a specific 22:6n-3 deficiency could be deleterious in the Zellweger brain.

During normal brain development, EP are progressively enriched in adrenic and oleic acids (18), two fatty acids characteristic of myelin. In the ZS brain, however, EP are deficient in both 22:4n-6 and 18:1n-9. So, apart from their very low levels of 22:6n-3, brain plasmalogens in patients with ZS and its variants are also poor in other important unsaturated fatty acids. Thus, in the Zellweger brain, plasmalogens are not only quantitatively insufficient but probably also qualitatively inefficient, owing to their altered PUFA composition.

The possible relationship between 22:6n-3 and plasmalogens in the ZS is unknown. However, when correcting 22:6n-3 deficiency in patients with peroxisomal biogenesis disorders, significant increases in erythrocyte plasmalogens were consistently found (27). Treatment with DHA also produced an improvement in myelination in DHA-deficient peroxisomal patients (28), suggesting some possible relationship between 22:6n-3, on the one hand, and myelin and/or plasmalogens, on the other. Although EP have a high proportion of 22:6n-3 in the normal brain and a very low one in the Zellweger brain, the present study indicates that the 22:6n-3 deficiency present in ZS does not affect plasmalogens more than other GPL classes. On the contrary, EP are the only GPL in which the main long-chain PUFA (22:6n-3, 20:4n-6, and 22:4n-6) are quite proportionally reduced, a finding that can only be fully appreciated when considering the absolute values of these PUFA. Thus, whatever the effect that the 22:6n-3 deficiency may have on plasmalogen synthesis and myelinogenesis, it seems not to be simply compositional. Rather than acting as a mere substrate for plasmalogen synthesis, DHA might have some more basic role in myelinogenesis.

Another GPL rich in 22:6n-3 and related to myelination is PS. The changes in PS in the brain of patients with peroxisomal biogenesis disorders are most significant, and they are not limited to a reduction of all PUFA, as happens in EP. Indeed, although 22:6n-3 is very much decreased in PS, the other PUFA 20:4n-6, 20:3n-6, and 22:4n-6 are all increased. Such a disproportion between n-3 and n-6 PUFA in PS might have an unfavorable effect on myelination. In this context, it should be remembered that PS specifically activates galactosylceramidase (29), an enzyme related to cerebroside metabolism whose activity reaches maximal levels during myelinogenesis in the rat (30). Thus, it is tempting to hypothesize that normalizing the DHA levels in peroxisomal patients could partly correct PS composition and thus have a favorable effect on myelin turnover. In any case, the deficiency of DHA is so constant and involves so many structures, that it may play some role in the pathogenesis of peroxisomal disorders.

ACKNOWLEDGMENTS

We want to thank Drs. Hugo W. Moser and Ann Moser for kindly providing the peroxisomal brains used in the present study. Without their invaluable help and advice, this work would not have been possible.

Application of High-Resolution, Two-Dimensional ^{1}H and ^{13}C Nuclear Magnetic Resonance Techniques to the Characterization of Lipid Oxidation Products in Autoxidized Linoleoyl/Linolenoylglycerols

Christopher J.L. Silwood and Martin Grootveld*

Bone and Joint Research Unit, St. Bartholomews and the Royal London Hospitals School of Medicine and Dentistry, London E1 2AD, United Kingdom

ABSTRACT: Subjection of polyunsaturated fatty acid (PUFA)-rich culinary oils to standard frying episodes generates a range of lipid oxidation products (LOP), including saturated and α,β-unsaturated aldehydes which arise from the thermally induced fragmentation of conjugated hydroperoxydiene precursors. Since such LOP are damaging to human health, we have employed high-resolution, two-dimensional ^{1}H-^{1}H relayed coherence transfer, ^{1}H-^{1}H total correlation, ^{1}H-^{13}C heteronuclear multiple quantum correlation, and ^{1}H-^{1}H J-resolved nuclear magnetic resonance (NMR) spectroscopic techniques to further elucidate the molecular structures of these components present in (i) a model linoleoylglycerol compound (1,3-dilinolein) allowed to autoxidize at ambient temperature and (ii) PUFA-rich culinary oils subjected to repeated frying episodes. The above techniques readily facilitate the resolution of selected vinylic and aldehydic resonances of LOP which appear as complex overlapping patterns in conventional one-dimensional spectra, particularly when employed in combination with solvent-induced spectral shift modifications. Hence, much useful multicomponent information regarding the identity and/or classification of glycerol-bound conjugated hydroperoxydiene and hydroxydiene adducts, and saturated and α,β-unsaturated aldehydes, present in autoxidized PUFA matrices is provided by these NMR methods. Such molecular information is of much value to researchers investigating the deleterious health effects of LOP available in the diet.

Paper no. L7951 in *Lipids 34,* 741–756 (July 1999).

The autoxidation of polyunsaturated fatty acids (PUFA) is an autocatalytic, self-perpetuating chain reaction system that has been implicated in the pathogenesis of many human diseases, e.g., atherosclerosis and inflammatory joint diseases (1–3). PUFA are particularly susceptible to oxidative damage by virtue of the facile abstraction of one of their bis-allylic methylene group hydrogen atoms on exposure to light or radical species of sufficient reactivity, a process facilitated by the low bond dissociation energy of the methylene group C–H bonds. Subsequently, one major reaction pathway for the resulting resonance-stabilized carbon-centered pentadienyl lipid radical generated in this manner involves its interaction with molecular oxygen to produce a peroxyl radical which in turn can abstract a hydrogen atom from an adjacent PUFA to form a conjugated hydroperoxydiene (CHPD) and a further pentadienyl lipid radical species. In the absence of sufficient quantities of chain-terminating, lipid-soluble antioxidants such as vitamin E (α-tocopherol), the process is repeated many times. CHPD are subsequently degraded to a wide variety of secondary autoxidation products which include saturated and unsaturated aldehydes, di- and epoxyaldehydes, lactones, furans, ketones, oxo and hydroxy acids, and saturated and unsaturated hydrocarbons.

Thermal stressing of culinary oils according to standard frying/cooking practices (domestic or otherwise) gives rise to and/or perpetuates the radical-dependent autoxidation of PUFA therein. Indeed, a wide range of aldehydes arises from the thermally induced decomposition of CHPD *via* several processes, including the β-scission of pre-formed alkoxyl radicals. Such aldehydic fragments (*n*-alkanals, *trans*-2-alkenals, *trans,trans*- and *cis,trans*-alka-2,4-dienals, 4-hydroxy-*trans*-2-alkenals, and malondialdehyde) have the capacity to exert a variety of toxicological effects in view of their extremely high reactivity with critical biomolecules [DNA base adducts, proteins such as the apolipoprotein B moiety of low density lipoprotein, peptides, free amino acids, endogenous thiols such as glutathione, etc. (4)]. Interaction of these aldehydes with DNA can give rise to genotoxic events and possibly cancer.

Our laboratory recently reported the detection and quantification of PUFA-derived autoxidation products (notably aldehydes and their conjugated hydroperoxy/hydroxydiene precursors) in culinary oils and fats by high-field proton (^{1}H) nuclear magnetic resonance (NMR) spectroscopy (5,6). Results obtained demonstrated that the thermally induced oxida-

tive stressing of PUFA-rich culinary oils produces much higher levels of cytoxic aldehydes than in corresponding samples of predominantly saturated fats (lard, drippings, etc.). The concentrations of aldehydes generated in culinary oils are critically dependent on PUFA content, the nature and capacity of the heating vessel employed, and the duration/conditions of heating and subsequent storage. More recently, we demonstrated that typical *trans*-2-alkenal compounds generated from the thermally induced autoxidation of PUFA are readily absorbed from the gut into the systemic circulation, metabolized (primarily *via* the addition of glutathione across their electrophilic carbon-carbon double bonds), and excreted in the urine as C-3 mercapturate conjugates in rats (7). Hence, such aldehydes have the ability to covalently modify lysine residues of the apolipoprotein B moiety of low density lipoprotein, rendering it susceptible to uptake by macrophages, a critical step in the production of foam cells *in vivo* (2). The hypothesis that dietary-derived lipid oxidation products (LOP) contribute significantly to the pathogenesis of atherosclerosis is further supported by reports that such agents can accelerate all three stages of the disease process, i.e., endothelial injury, accumulation of plaque, and thrombosis (8). Moreover, animal feeding studies showed that diets containing thermally-stressed [and therefore LOP-rich (5,6)] PUFA-laden culinary oils have a greater atherogenicity than those containing corresponding unheated oils (9). Indeed, Straprans *et al.* (10) recently examined the ability of oxidized dietary lipids to accelerate the development of atherosclerosis in New Zealand White rabbits and found that feeding with an oxidized lipid-rich diet gave rise to a 100% increase in fatty streak lesions in the aorta.

In view of the above observations, the detection and quantification of specific products arising from the autoxidation of culinary oil PUFA during standard frying practices are of paramount importance, and the multicomponent analytical ability of high-resolution ^{1}H NMR spectroscopy offers major advantages over alternative laboratory methods since it permits the rapid, simultaneous study of many primary and secondary LOP present in such samples (5,6). Indeed, the development of high-field NMR spectrometers with increased resolution, dynamic range, and sensitivity has given rise to rapid advances in the analysis of complex, multicomponent samples such as foodstuffs, human biofluids, and pharmaceutical formulations (11–14). The principles of this spectroscopic technique involve the absorption of energy from the radio frequency region of the electromagnetic spectrum to detect changes in the alignment of nuclear magnets during their exposure to a powerful external magnetic field. The absorption frequencies of such nuclei [for example, those of ubiquitous hydrogen nuclei (^{1}H)] present in the ^{1}H NMR spectrum of a particular chemical compound are critically dependent on their magnetic (and therefore, chemical) environment, and the appearance (multiplicity) of a resonance (signal) is influenced by neighboring ^{1}H nuclei in a well-characterized manner. Moreover, the intensity of each signal is directly proportional to the product of the number of magnetically equivalent nuclei in the structural/functional group responsible for it and the concentration of the molecule containing that group. Hence, much valuable molecular information regarding the nature and levels of a wide variety of compounds present in biological or biologically derived matrices can be obtained from high-field, high-resolution NMR investigations.

Although numerous prominent ^{1}H NMR signals ascribable to aldehydes and their CHPD precursors are observed in the less-crowded, higher-frequency regions of one-dimensional spectra acquired on such materials, there is a high degree of overlap between selected vinylic (isomeric CHPD and conjugated hydroxydienes, and α,β-unsaturated aldehydes) and aldehydic group proton resonances, even at operating frequencies as high as 600 MHz. However, the recent availability of spectrometers of operating frequencies ≥600 MHz has led to a synchronous increase in the development and application of both homonuclear and heteronuclear two-dimensional NMR methods in order to resolve the many overlapping multiplet resonances (many with higher-order coupling patterns) now detectable in very high field ^{1}H NMR spectra acquired on complex multicomponent samples. Indeed, the battery of such two-dimensional techniques employable facilitates the establishment of the molecular structures of specified organic compounds (15–19). Proton-proton and proton-carbon scalar couplings readily determine groups of resonances arising from individual components, and the unambiguous structural information derived therefrom is, in general, not obtainable from alternative analytical techniques.

Therefore, in this investigation we employed ^{1}H-^{1}H relayed coherence transfer (RCT), ^{1}H-^{1}H total correlation (TOCSY), ^{1}H-^{13}C heteronuclear multiple quantum coherence (HMQC), and ^{1}H-^{1}H *J*-resolved NMR spectroscopic techniques for the purpose of clarifying our spectral assignments and hence provide further useful information regarding the molecular structures of LOP present in thermally/oxidatively stressed culinary oils and model PUFA.

MATERIALS AND METHODS

Culinary oil and model linoleoylglycerol samples. Control (unheated) and repeatedly utilized culinary frying oil samples were kindly supplied by a fast-food retail establishment. Electronic integration of the bis-allylic-CH_2, ω-CH_3, and highly unsaturated fatty acid acyl chain terminal-CH_3 group ^{1}H resonances (δ = 2.76, 0.90, and 0.95 ppm, respectively) present in single-pulse 400 MHz proton NMR spectra of the control (unheated) sample acquired immediately after collection revealed that the material had a polyunsaturate content of 42 molar %, of which *ca.* one-quarter consisted of highly unsaturated fatty acids, i.e., those with ≥3 unconjugated double bonds (predominantly linolenoylglycerol adducts).

The above repeatedly used culinary oil samples were placed in glass vessels and stored in the dark at ambient temperature (22°C) for a period of 30 d prior to NMR analysis.

Sealed vials containing authentic samples of the model linoleoylglycerol species 1,3-dilinolein (Sigma-Aldrich

Chemical Co., Gillingham, Dorset, United Kingdom) were opened, and the compound therein allowed to autoxidize in the presence of atmospheric O_2 at an ambient temperature for a period of 2.0 h prior to subjecting it to NMR experiments.

Portions (300 g) of chipped potatoes and bacon were fried in 60- and 20-mL vol, respectively, of a commercially available sample of sunflower seed oil [PUFA content 62% (w/w)] in a 15-cm diameter shallow frying pan at 180°C for a period of 30 min in the presence of atmospheric O_2. A 60-mL volume of this culinary oil subjected to an identical thermal stressing episode in the absence of added food material, together with an unheated sample of this frying medium, served as controls. Subsequently, samples (1.00 mL) of oil were removed for ^{1}H NMR analysis.

Reagents. Tetramethylsilane (TMS) and the model autoxidized PUFA-derived aldehydes pentanal, hexanal, heptanal, octanal, *trans*-2-pentenal, *trans*-2-heptenal, *trans,trans*-nona-2-4-dienal, and *trans,trans*-deca-2,4-dienal were purchased from Sigma-Aldrich Chemical Co. Deuterated NMR solvents (C^2HCl_3 and ^2H_2O) were purchased from Goss Scientific Ltd. (Great Baddow, Essex, United Kingdom).

NMR measurements. NMR measurements on the above samples were conducted on Bruker AMX-600 (University of London Intercollegiate Research Services, Queen Mary and Westfield College Facility, University of London, United Kingdom) or Bruker AMX-400 (ULIRS; King's College Facility, University of London, United Kingdom) spectrometers, the former operating at frequencies of 600.13 (^{1}H) and 150.93 (^{13}C) MHz, the latter at 400.13 (^{1}H) MHz. ^{1}H-^{1}H *J*-resolved, ^{1}H-^{1}H TOCSY and ^{1}H-^{13}C transfer (HMQC) experiments were performed on the 600 MHz facility, while ^{1}H-^{1}H RCT experiments were performed on the 400 MHz spectrometer. The probe temperature was 298 K. Typically, 0.30-mL aliquots of culinary oil or 1,3-dilinolein samples were diluted to a volume of 0.90 mL with deuterated chloroform (C^2HCl_3) [or deuterated methanol (C^2H_3OH), where appropriate], which provided a field frequency lock, the solutions were thoroughly rotamixed and then were transferred to either 5- (one-dimensional ^{1}H, ^{13}C, ^{1}H-^{1}H RCT, ^{1}H-^{1}H TOCSY and ^{1}H-^{1}H *J*-resolved experiments) or 8-mm (^{1}H-^{13}C HMQC experiments) diameter NMR tubes.

Chemical shifts were referenced to internal TMS ($\delta = 0.00$ ppm) and/or the residual chloroform proton signal ($\delta = 7.262$ ppm), [and for samples in C^2H_3OH solution, the residual methanol methyl group signal ($\delta = 3.210$ ppm)]. For ^{13}C spectra recorded in C^2HCl_3 solution, chemical shifts were referenced to internal TMS ($\delta = 0.00$ ppm) and/or the chloroform carbon signal ($\delta = 77.00$ ppm). Resonances present in single-pulse ^{1}H NMR spectra of culinary oil and model PUFA compound samples were routinely assigned by a consideration of chemical shift values, coupling patterns, and coupling constants, where appropriate. The molecular nature of particular classes of aldehydes detectable was confirmed by performing standard additions of authentic, commercially available compounds [*n*-alkanals, *trans*-2-alkenals, and *trans,trans*-alka-2,4-dienals, the latter also containing trace (although ^{1}H NMR-detectable) levels of corresponding *cis,trans*-isomer impurities].

^{1}H-^{1}H RCT experiments employed the standard sequence 90°-t_1-90°-τ-180°-τ-90°-ACQ (20,21), 90° on the AMX-400 spectrometer being equivalent to 9.5 µs. Acquisition parameters were: 256 t_1 increments, each of magnitude 1,024 data points; spectral width 4,902 Hz in each dimension; 64 transients in each case; 4 dummy scans; relaxation delay (RD) 2.0 s; acquisition time 0.21 s. Unshifted sine-bell window functions were applied in each dimension, with zero-filling twice in f_1, prior to transformation of the matrix of size 1,024 × 1,024 data points. The delay period τ (0.05 s) was optimized for the appropriate vicinal coupling constants and rotameric equilibria existing in the expected constituent glyceride moieties.

^{1}H-^{1}H TOCSY spectra were recorded using the pulse sequence RD-(90°-t_1-spin lock)-ACQ (22), 90° on the AMX-600 spectrometer for that experiment being equivalent to 8.4 µs. The spin lock employed the MLEV-17 sequence (23), with a typical mixing time of 70 ms. For experiments where a restriction of carbon chain correlations was required, this mixing time was only 20 ms. Acquisition parameters were: 256 t_1 increments, each of magnitude 2,048 data points; spectral width 12,019 Hz in each dimension; 64 transients in each case; 4 dummy scans; RD 3 s; acquisition time 0.17 s. Sine-bell squared window functions shifted by π/2 (i.e., a cosine squared function) were applied in each dimension, with zero-filling twice in f_1, prior to transformation of the matrix of size 2,048 × 1,024 data points. The standard phase-sensitive (time-proportional phase incrementation) method (24) for optimal detection along the second dimension was utilized in such experiments.

^{1}H-^{1}H *J*-resolved experiments employed the standard sequence 90°-t_1/2-180°-t_1/2-ACQ (16), 90° on the AMX-600 spectrometer for that experiment being equivalent to 7.9 µs. Acquisition parameters were: 128 t_1 increments, each of magnitude 2,048 data points; spectral width 8,621 Hz in f_2 and 100 Hz in f_1; 64 transients in each case; 4 dummy scans; RD 2.0 s; acquisition time 0.24 s. Unshifted sine-bell window functions were applied in each dimension before transformation of the matrix of eventual size 2,048 × 256 data points.

The time-proportional phase incrementation phase-sensitive method was also utilized in the ^{1}H-^{13}C HMQC (25) experiments for optimal detection of ^{13}C frequencies in the second dimension, ^{1}H detection being achieved through the employment of a dedicated 8-mm inverse geometry probe in order to maximize sample information. Acquisition parameters were: 200 t_1 increments each of magnitude 2,048 data points; spectral width 13,228 Hz in f_2 and 63,381 Hz in f_1; 960 transients in each case; 4 dummy scans; RD 1.0 s. A delay equivalent to 3.7 ms (1/2 $^1J_{CH}$) was utilized for optimal refocusing of heteronuclear information, and composite pulse broadband ^{13}C decoupling (GARP) (26) was employed during the ^{1}H acquisition period. A sine-bell-squared function, shifted by π/2 (i.e., a cosine squared function) was applied in each dimension, with forward complex linear prediction from

200 to 400 data points and subsequent zero-filling to 1,024 data points in f_1, prior to transformation of the matrix of size 2,048 × 1,024 data points.

Confirmation of NMR assignments using computational methods. ^{1}H NMR assignments and appropriate chemical shift values and coupling constants of resonances of LOP possessing complex spin systems were confirmed with the HNMR prediction software (version 3.0) from the Advanced Chemistry Development (ACD Inc., Toronto, Canada) software suite. This software was employed to generate a theoretical spectrum which did not incorporate an allowance for solvent-mediated shielding effects, and the ^{1}H chemical shift and ^{1}H-^{1}H spin-spin coupling constant values generated therefrom were then adjusted to reflect those obtained from the experimental spectrum *via* a first-order analysis. The theoretical spectrum was then recalculated, a correct first-order analysis giving rise to an exact match between the experimentally and theoretically derived spectra. Calculations also made an allowance for the concentration of each LOP within sample mixtures. The ^{13}C facility of the ACD suite of programs (ACD Inc.), CNMR, was employed for predicting spectra of LOP expected to be contributing to ^{13}C spectra of autoxidized culinary oils and model PUFA compounds exhibiting a high degree of resonance overlap. For example, the ^{1}H simulations were based around an internal database containing data for >81,000 experimental ^{1}H spectra, the associated algorithms employing intramolecular interaction parameters for >300 structural fragments, the associated subalgorithms estimating initial values for unique structural fragments. Fragment lists are handled with a modified HOSE (Hierarchical Organization of Shells Expert)-code which allowed for explicit substituent charge and stereo bond conventions, optimizing to the maximal number of spheres. The subsequent quantum mechanical shielding calculations allowed for the number of these codes found in the internal database search, as well as the number of those sought. Calculational errors were determined as the standard deviations of the experimental values found within the database. Typically, predicted ^{1}H chemical shifts were accurate to within 0.05 ppm, and predicted coupling constants were accurate to within 0.2 Hz. Predicted ^{13}C chemical shifts were accurate to within 3 ppm.

RESULTS

Figure 1A shows the 0.5–6.8 ppm region of a 400 MHz ^{1}H-^{1}H RCT spectrum of a sample of the model linoleoylglycerol compound 1,3-dilinolein which was allowed to autoxidize in the presence of atmospheric oxygen as described in the Materials and Methods section, and subsequently dissolved in C^2HCl_3 solution. CHPD vinylic proton multiplets are present in the 5.4–6.6 ppm chemical shift range, whereas the 9- and/or 13-position proton bonded to the hydroperoxy group-bearing carbon has a chemical shift value of 4.38 and 4.30 ppm for the *cis,trans*- and *trans,trans*-isomers, respectively. Cross-peaks refer to protons **a–j** in Figure 2, the chemical shift values of which are listed in Table 1. Figure 1B shows the 0.40–6.60 ppm region of a 600 MHz ^{1}H-^{1}H TOCSY spectrum of the same sample, this time dissolved in C^2H_3OH solution. The selection of a comparatively short mixing time in this experiment yields a two-dimensional spectrum that is equivalent to that generated with the RCT method. Solvent-induced spectral shifts of the appropriate protons encountered in the spectrum served as a convenient means of improving the resolution of overlapping signals observed in spectra acquired in C^2HCl_3 solution. These shift changes are indicated in parentheses within the table. Such two-dimensional spectra afford the complete, unambiguous (and to our knowledge, the first) indexing of all vinylic, allylic, and neighboring aliphatic protons of both *cis,trans*- and *trans,trans*-isomers of 9- and 13-hydroperoxy-octadecadienoylglycerol species. Utilization of the RCT and short mixing time TOCSY methods in this case is particularly suited to the ^{1}H NMR study of these primary LOP derived from the peroxidation of PUFA, furnishing spin system information that is largely restricted to protons separated by five bonds, and thus generating less-crowded spectra. A predicted spectrum (ACD Inc.), based on spectral parameters derived from the *cis,trans*- and *trans,trans*-hydroperoxydiene assignments in the chloroform solution (corroborated with the further resolution of overlapped signal information in the methanol solution), was in excellent agreement with typical experimentally acquired spectra (Fig. 3).

A number of broad hydroperoxide-OO<u>H</u> group resonances were detectable in the 8.1–8.9 ppm chemical shift range of spectra acquired on autoxidized 1,3-dilinolein (data not shown). As expected, these signals were completely removed from spectra following treatment of samples with ^2H_2O (0.030 mL was added to C^2HCl_3 solutions, the mixture rotamixed, equilibrated at ambient temperature for 30 min, centrifuged, and the predominant, lower C^2HCl_3 phase removed for further ^{1}H NMR analysis).

A consideration of spectral parameters for the CHPD components derived from autoxidation of the above model dilinoleoylglycerol compound facilitated assignment of such LOP resonances present in two-dimensional ^{1}H-^{1}H NMR spectra acquired on thermally stressed culinary oil samples. Figure 4A exhibits the 5.0–10.0 ppm region of the 600 MHz ^{1}H-^{1}H TOCSY spectrum of a typical sample of repeatedly utilized frying oil obtained from a fast-food restaurant. The cross-peak signals indicated confirm the presence of the CHPD LOP components in this sample together with signals concordant with the spin systems expected for *trans*-2-alkenals and 13-hydroxy-*cis*-9,*trans*-11 and 9-hydroxy-*trans*-10,*cis*-12 hydroxydiene derivatives, their ^{1}H chemical shift values being consistent with previously published data (27). The confirmation of the presence of such aldehydes is of particular clinical importance since they, rather than the conjugated hydroperoxydienes, are absorbed from the gut into the systemic circulation (*in vivo*) (7), where they have the capacity to exert a range of deleterious health effects. Other correlations involving the aldehydic proton region highlighted the presence of two further alkenal species represented by spin systems with chemical shift values of 9.57, 6.83 and 6.35 ppm, and 9.55,

FIG. 1. (A) 0.50–6.80 ppm region of a 400 MHz ^{1}H-^{1}H relayed coherence transfer (RCT) spectrum of an autoxidized sample of 1,3-dilinolein in C^2HCl_3 solution, and (B) 0.40–6.60 ppm region of a 600 MHz ^{1}H-^{1}H total correlation (TOCSY) spectrum of the same sample in C^2H_3OH solution, the latter acquired with a short mixing time (20 ms). Typical spectra are shown. *Cis,trans-* and *trans,trans*-conjugated hydroperoxydiene [or more specifically 9-hydroperoxy-*trans*-10,*cis*-12- (and, in an analogous manner 13-hydroperoxy-*cis*-9,*trans*-11-) and 9-hydroperoxy-*trans*-10,*trans*-12- (and, in an analogous manner 13-hydroperoxy-*trans*-9,*trans*-11-) octadecadienoylglycerol isomers] cross-peak assignments are indicated as connectivities involving protons **a–j** in the accompanying molecular structures.

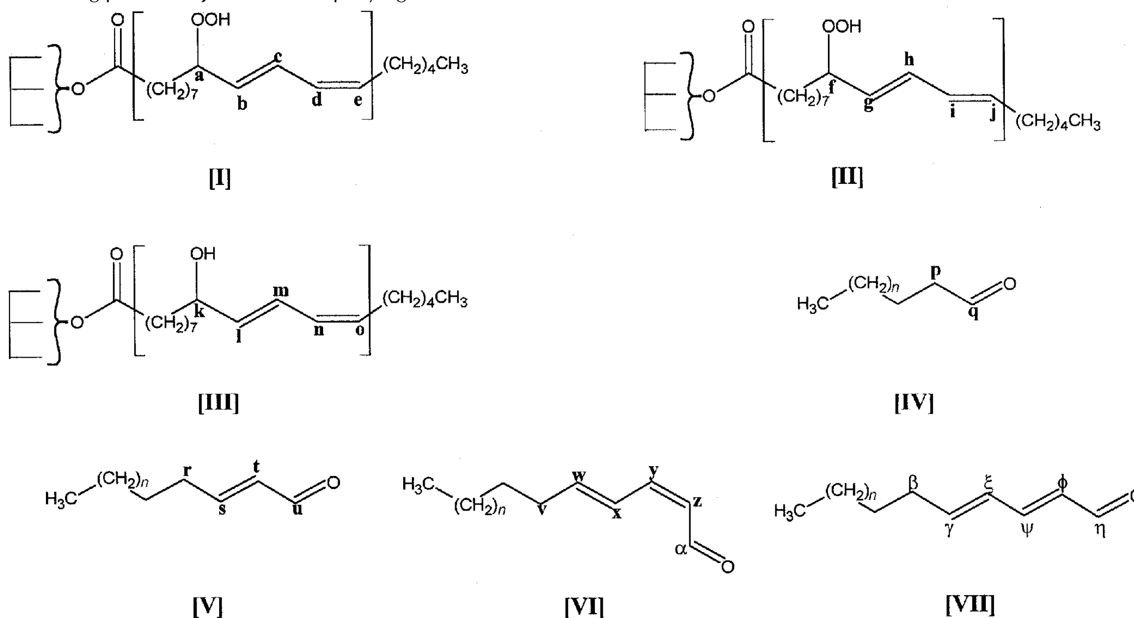

FIG. 2. Structural units of lipid oxidation products (LOP) detectable in peroxidized polyunsaturated fatty acids (PUFA) by high-resolution nuclear magnetic resonance (NMR) spectroscopy. The lower case letter labels correspond to ^{1}H (and/or) ^{13}C nuclei distinguishable by the two-dimensional techniques employed in this investigation. Key: **[I]**, 9-hydroperoxy-*trans*-10,*cis*-12-octadecadienoylglycerol adduct; **[II]**, 9-hydroperoxy-*trans*-10,*trans*-12-octadecadienoylglycerol adduct; **[III]**, 9-hydroxy-*trans*-10,*cis*-12-octadecadienoylglycerol adduct; **[IV]**, *n*-alkanals; **[V]**, *trans*-2-alkenals; **[VI]**, *cis,trans*-alka-2,4-dienals; **[VII]**, *trans,trans*-alka-2,4-dienals.

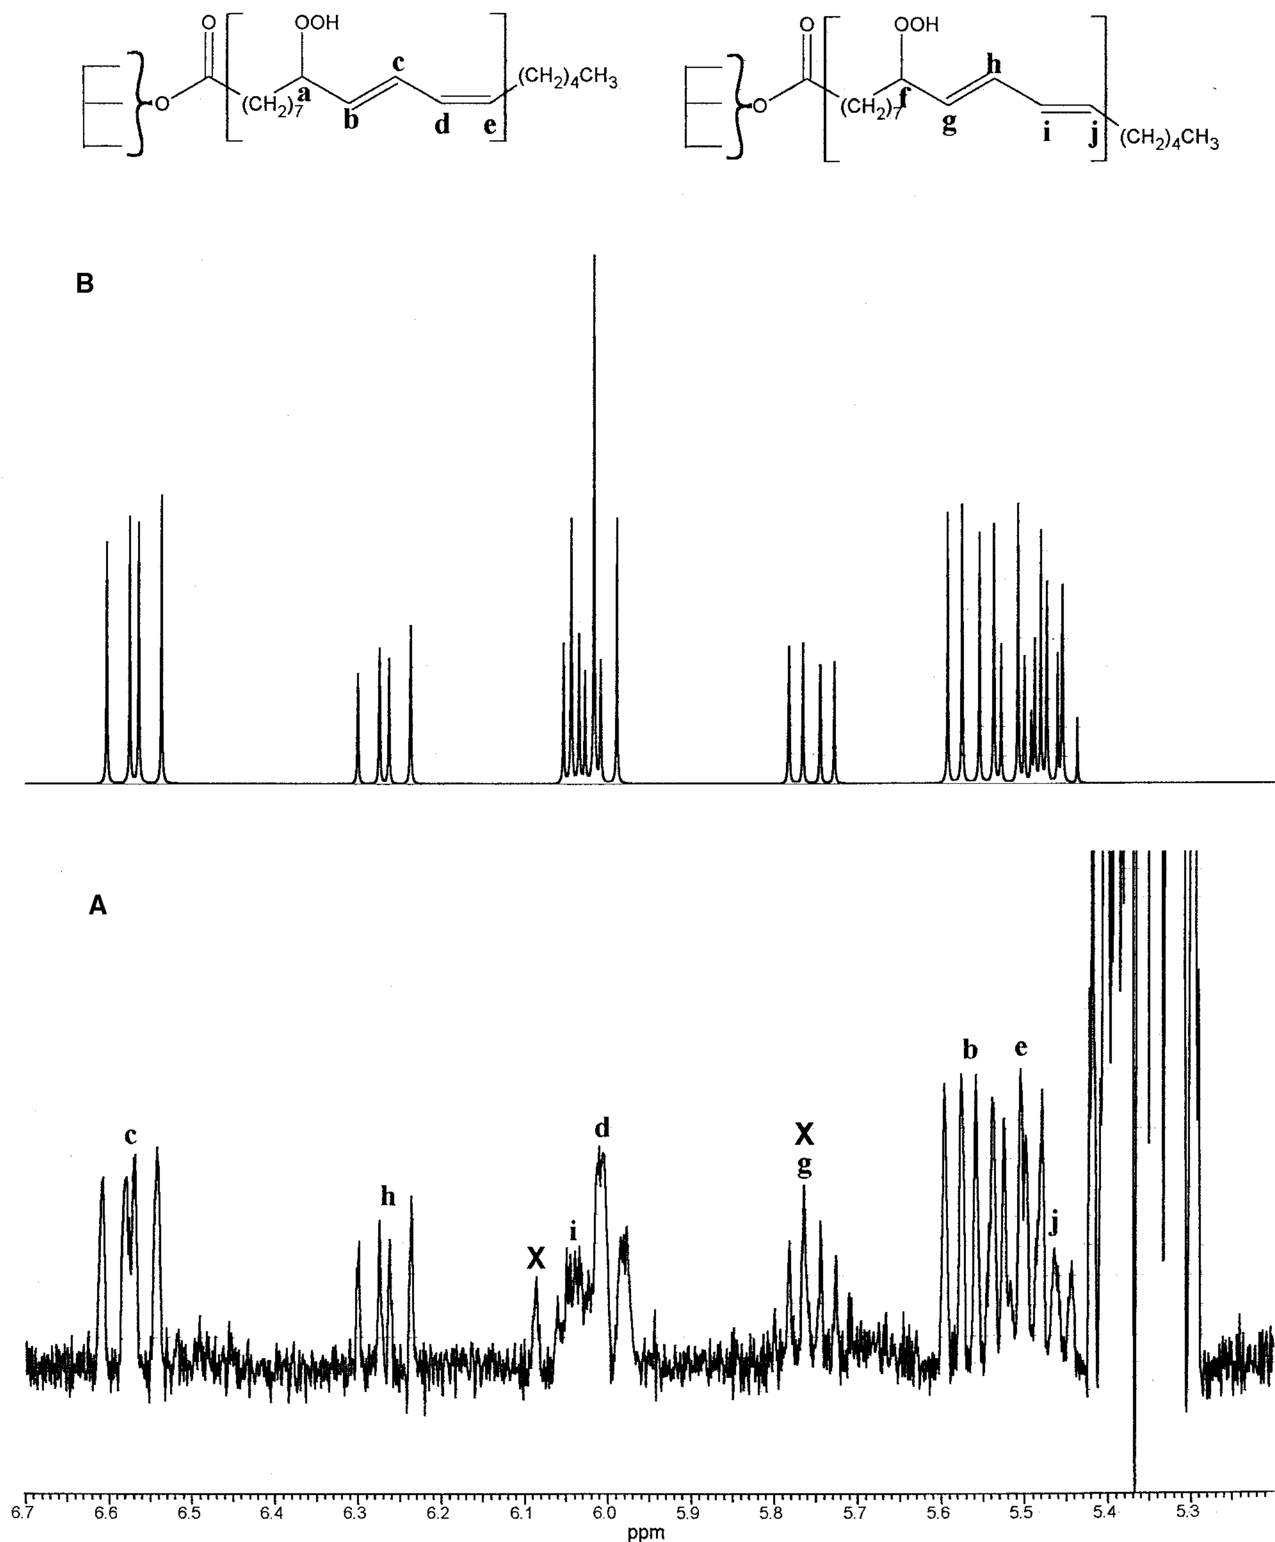

FIG. 3. Expanded 5.20–6.70 ppm regions of (A) an experimental 400 MHz one-dimensional ^{1}H NMR spectrum of an autoxidized sample of 1,3-dilinolein (in $C^{2}HCl_3$ solution), and (B) a corresponding computer-simulated spectrum generated using the software suite described in the Materials and Methods section, a system which employed spectral parameters obtained from all LOP assignments. A typical spectrum/simulation is shown. Abbreviations: ^{1}H nucleus labels of isomeric conjugated hydroperoxydienes (CHPD) correspond to those given in the molecular structures depicted above the spectra. Signals labeled as "X" indicate spectral artifacts. See Figure 2 for other abbreviations.

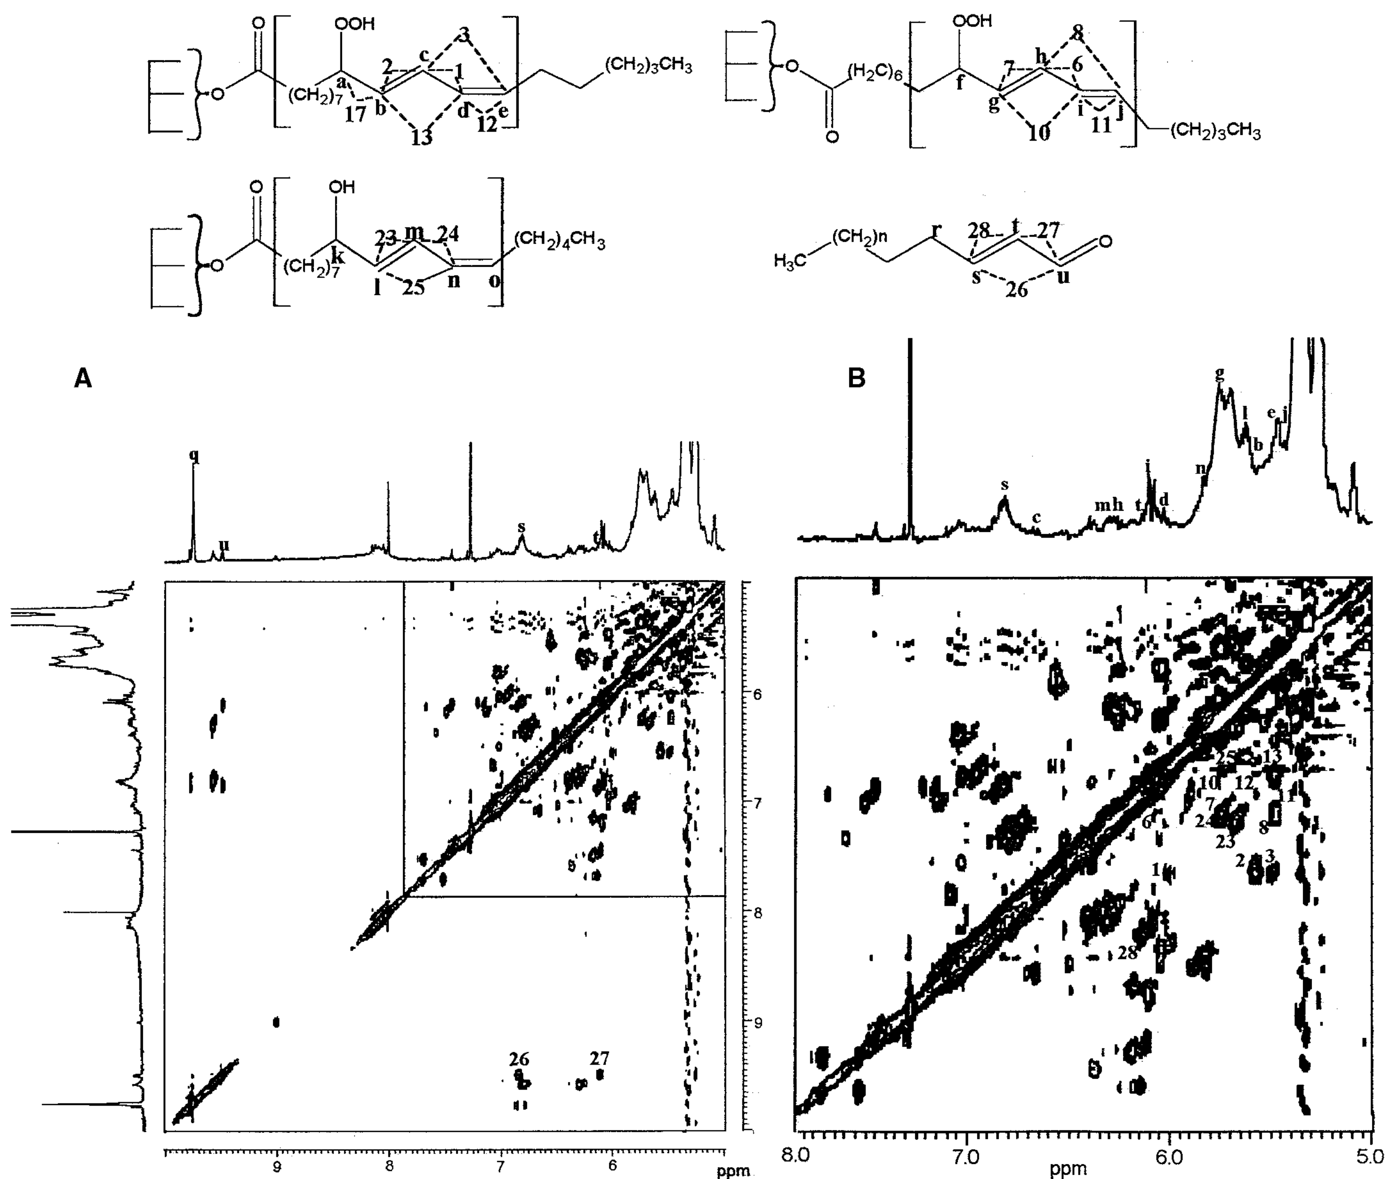

FIG. 4. (A) 5.0–10.0 ppm region of a 600 MHz ^{1}H-^{1}H TOCSY spectrum of a sample of repeatedly used culinary frying oil obtained from a fast-food retail outlet in C^2HCl_3 solution, acquired with a short mixing time (20 ms). The expanded 5.0–7.9 ppm region of this spectrum is shown in (B). A typical spectrum is shown. Abbreviations: ^{1}H nucleus labels of isomeric CHPD, 9-hydroxy-*trans*-10, *cis*-12-octadecadienoylglycerol adducts, and saturated and α,β-unsaturated aldehydes correspond to labeled protons in the accompanying molecular structures. See Figures 1 and 3 for abbreviations.

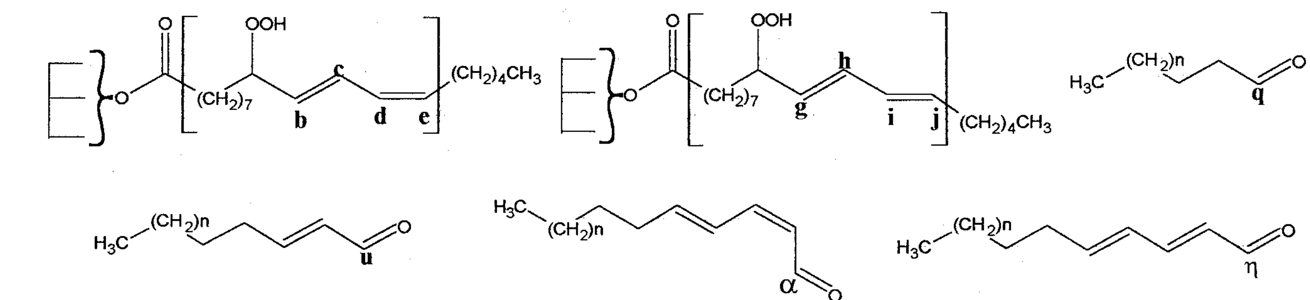
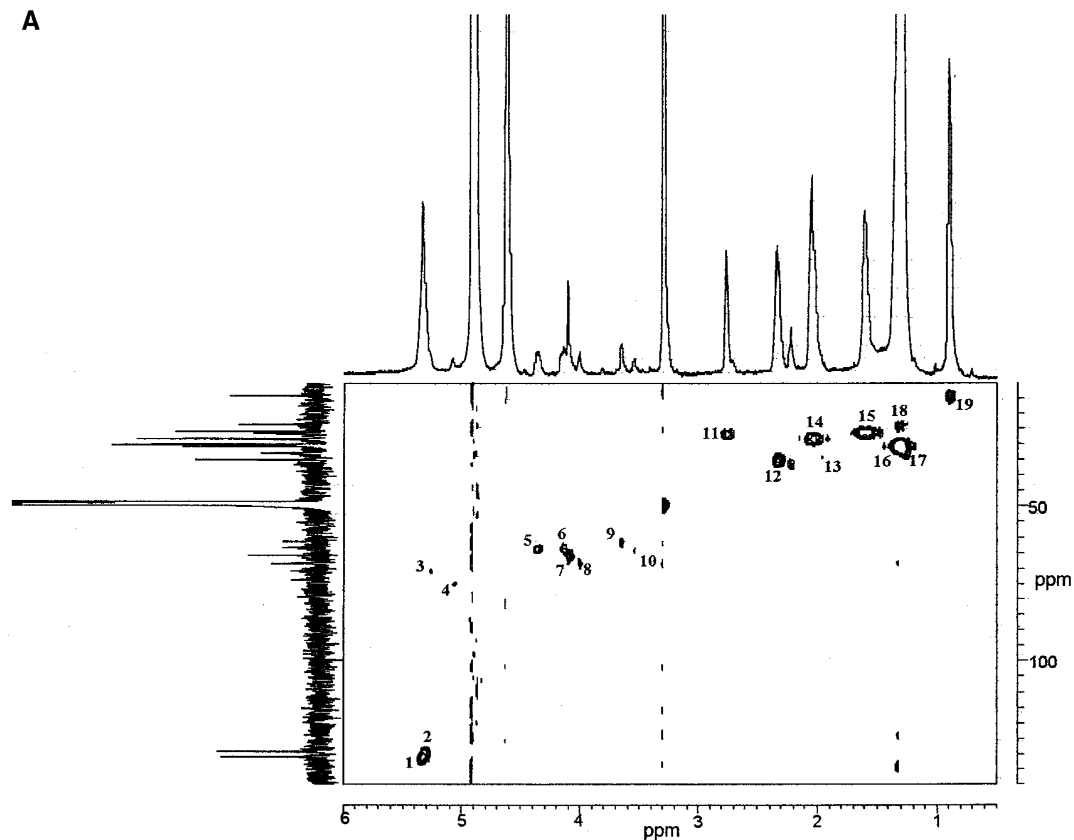
6.80 and 6.25 ppm. Moreover, the expanded 5.0–8.0 ppm region of this spectrum (Fig. 4B) revealed a complex range of additional overlapping signals, none of which corresponded to those expected for other known LOP such as *trans*-4,5-epoxyhept-*trans*-2-enal (28), various epoxides, hydroxyepoxides, 5- and 6-membered hydroperoxyepidioxides of linolenoylglycerol species [e.g., 5.40, 5.62, 6.00, and 6.64 ppm for the conjugated diene vinylic protons and characteristic 4.45 and 4.75 ppm multiplets for the methine group protons of the epidioxide ring of *cis,trans*-9- and 16-hydroperoxy epidioxides (29)], and conjugated oxodienes (30–32). This observation indicates that such LOP (important precursors of volatile components which reflect the oxidative degradation of linolenoylglycerols) are readily fragmented to peroxidation end products when exposed to a source of oxidative stress (i.e., prolonged thermal stressing episodes). Further experiments to establish the identities of these resonances are currently in progress.

Figure 5 exhibits complete and expanded regions of the ^{1}H-^{13}C HMQC spectrum of a further repeatedly utilized culinary oil sample (also obtained from a fast-food retail outlet), acquired in C^2HCl_3 solution, the full spectrum in (Fig. 5A) highlighting signals expected for glycerol backbones and their esterified fatty acid units. Consideration of the nature of the vinylic carbon ^{13}C signals and the average chain length as deduced from the single-pulse ^{1}H spectrum confirmed that



A



B

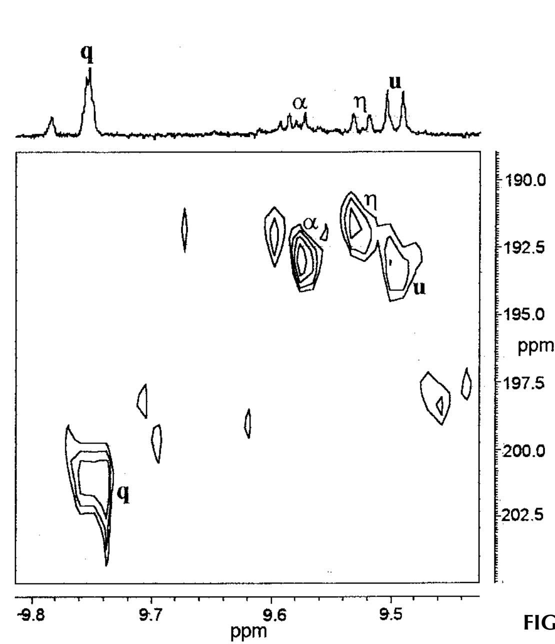

FIG. 5

glycerol-bound linoleate was the major PUFA constituent present in this material. Resolution of all glyceride acyl signal correlations provides information concerning the nature and distribution of glyceride esterification. The ^{1}H-^{13}C chemical shift correlations observed for 1-, 1,2-, 1,3- and 1,2,3-substituted glycerol backbone units were verified utilizing either previously reported data (33,34), or from predicitive software (ACD Inc.). Knowledge of the distribution of these species is of much importance since the nature of glyceride substitution was shown to significantly influence the rate of PUFA autoxidation. Indeed, dilenilenoyl-linoleoylglycerols are slightly less resistant to oxidation when linolenate is in the 1,2-rather than the 1,3-triacylglycerol positions, and dilinoleoyl-linolenoylglycerols are less resistant to oxidation when linoleate is in the 1,3- rather than the 1,2-triacylglycerol positions (35).

Glycerol, an end-product arising from the hydrolysis of triacylglycerols (a process occurring during standard frying practices), was undetectable in the HMQC spectra acquired. This observation is presumably a consequence of its volatilization during thermal stressing episodes since its boiling point (182°C) (36) is very similar to the temperature recommended for this process (180°C).

Comparisons of the one-dimensional ^{1}H NMR spectra of repeatedly-utilized frying oils with that of a corresponding control (unheated) material provided evidence consistent with the thermally-induced autoxidation of glycerol-bound PUFA therein. Indeed, the ratios of the intensities of the *bis*-allylic-$C\underline{H}_2$ group and the total unsaturated fatty acid vinylic- $-C\underline{H}=C\underline{H}-$ proton resonances (δ = 2.76 and 5.38 ppm, respectively) to that of the acyl chain terminal-$C\underline{H}_3$ group protons (*t*, δ = 0.90 ppm) were markedly lower in repeatedly-employed samples. Moreover, the low-field-shifted highly unsaturated fatty acid acyl chain terminal-$C\underline{H}_3$ group triplet resonance located at 0.95 ppm was found to almost completely disappear from spectra following subjection of the culinary oil to repeated frying episodes (together with perpetuation of the autoxidation process *via* storage in the manner described in the Materials and Methods section), an observation concordant with the fact that linolelenoylglycerols autoxidize at a faster rate than linoleoylglycerols (35).

Figure 5B in particular demonstrates the ability of the HMQC method to resolve overlapping signals, the use of the 8-mm ^{13}C probe in this case undoubtedly facilitating the detection and identification of many low-level LOP components. Corroboration of previous ^{1}H assignments (5) with the appropriate ^{13}C NMR data is also important for the purpose

[a]Where appropriate, corresponding ^{1}H assignments in C^2H_3OH solution are indicated in parentheses. The LOP nucleus (nuclei) positional labels correspond to those indicated in Figure 2. ^{13}C assignments for 13- and/or 9-hydroxy-substituted octadecadienoylglycerol adducts (the *cis*-9,*trans*-11 and *trans*-10,*cis*-12 isomers, respectively) are absent since the very low levels of this LOP present in autoxidized model polyunsaturated fatty acids (PUFA)/thermally stressed PUFA-containing culinary oil samples preclude their detection (i.e., their ^{13}C features are unreceptive to NMR analysis under such conditions). Vinylic and bulk chain $-CH_2-$ group ^{13}C resonance assignments for each class of aldehyde were unobtainable in view of a high degree of overlap with those of their primary LOP precursors and PUFA substrates, together with further glycerol-bound fatty acids.

FIG. 5. (See previous page) (A) Complete 600 MHz ^{1}H-^{13}C heteronuclear multiple quantum coherence transfer (HMQC) spectrum of a sample of repeatedly-used culinary frying oil obtained from a fast-food restaurant outlet. In (B), the spectral display was pre-set to emphasize ^{1}H-^{13}C correlations of lower intensity (i.e., those of LOP). (C) Expanded aldehydic group region of the above ^{1}H-^{13}C HMQC spectrum showing clear correlations between the ^{1}H and ^{13}C nuclei of the –CHO groups of saturated and α,β-unsaturated aldehydes. A typical spectrum is shown. Abbreviations for (A) (C_A, C_B, and C_C refer to substituted/unsubstituted glycerol carbon centers as indicated, and the indices 1,2 or 1,2,3 indicate substitution mode, i.e., 1,2 represents a diacylglycerol with fatty acids esterified at the 1- and 2-glycerol backbone positions, and 1,2,3 represents a triacylglycerol): 1, olefinic –CH = CH–; 2, as 1; 3, C_B 1,2,3; 4, C_B 1,2; 5, C_A/C_C 1,2,3; 6, as 5; 7, C_A 1,2; 8, C_A/C_C 1,3; 9, C_C 1,2; 10, C_A/C_C 1/3 (i.e., 1 or 3 positions unsubstituted); 11, bis-allylic-$C\underline{H}_2$ groups of PUFA; 12, fatty acid C-2; 13, fatty acid C-16; 14, allylic-$C\underline{H}_2$ (i.e., $-CH = CH-C\underline{H}_2$) group of unsaturated fatty acids ; 15, fatty acid C-3; 16, fatty acid bulk chain C-4 to C-15 $-(C\underline{H}_2)_n-$ groups ; 17, as 16; 18, fatty acid C-17; 19, fatty acid terminal $-CH_3$. ^{1}H-^{13}C correlated signal labels in (B) and (C) correspond to those indicated on the molecular structures displayed above the spectra. See Figure 2 for abbreviations.

of confirming the identity of particular LOP known to exert adverse toxicological (e.g., proatherogenic and proinflammatory) properties (1–3,37). The ^{13}C assignments and related HMQC correlated signals were confirmed with the aid of known chemical shifts for the appropriate model compounds (33,34) and predicted spectra (ACD Inc.). The conjugated hydroperoxydiene unsaturated carbon ^{13}C signals appear in the virtually exclusive 130–140 ppm region, their chemical shift values being in good agreement with those obtained in previous investigations (38). Correlated signals found in the region around 200 ppm serve to offer a useful confirmation of our earlier ^{1}H NMR assignments of different classes of aldehyde, i.e., *n*-alkanals, *trans*-2-alkenals, *cis,trans*- and *trans,trans*-alka-2,4-dienals (5) [the identity of each of these linked signals was verified by a combination of simulated (ACD Inc.) and reference (36) data]. None of the ^{1}H-^{13}C HMQC spectra acquired demonstrated the presence of the epoxide, hydroxyepoxide, hydroperoxyepidioxide, and oxodiene species described above, although there remains some unavoidable coincidence of ^{13}C resonances of similar frequencies.

^{1}H-^{1}H *J*-resolved NMR spectroscopy is a further important technique which can be employed for the purpose of precisely determining the chemical shift values of overlapping ^{1}H resonances (ideally in the absence of second-order coupling effects) through utilization of the "skyline" f_2 projection, and Figure 6 shows the expanded 5.0–10.0 ppm region of the 600 MHz ^{1}H-^{1}H *J*-resolved spectrum (f_2 "skyline" projection and corresponding contour plot of the two-dimensional matrix) of an additional repeatedly used culinary frying oil sample (the contour plot depicts the separation of signal splittings into the second dimension). The corresponding one-dimensional spectrum, also exhibited in Figure 6, illustrates the generation of "homonuclear proton-decoupled" signals in the f_2 "skyline" projection. With the exception of resonances ascribable to *cis,trans*-alka-2,4-dienals, all LOP signals were readily visible. After making appropriate allowances for the differing concentrations of each LOP, the computer-predicted spectrum of this particular mixture (Fig. 6A) has a high level of agreement with the experimentally obtained one-dimensional spectrum, demonstrating the applicability of the spectral simulation program employed as an aid to the analysis of complex, multicomponent LOP matrices.

The NMR techniques outlined above are, of course, also readily applicable to the analysis of LOP present in culinary oils employed in further food preparation methods, e.g., domestic frying episodes. Figure 7A and B display the 9.00–10.00 ppm aldehydic group proton regions of one-dimensional ^{1}H NMR spectra acquired on a sample of sunflower seed oil [polyunsaturate and monounsaturate contents 63 and 12% (w/w), respectively] both prior and subsequent, respectively, to heating at a temperature of 180°C for a period of 30 min. Corresponding spectra acquired on samples of this culinary oil utilized for the purpose of frying potato chips and bacon (30 min at 180°C) are illustrated in Figure 7C and D, respectively. Clearly, resonances ascribable to the aldehydic group protons of *trans*-2-alkenals, *trans,trans*- and *cis,trans*-alka-2,4-dienals, and *n*-alkanals are clearly visible in these spectra, demonstrating the ready generation of these cytotoxic LOP from the autoxidative deterioration of PUFA during standard frying practices. The ^{1}H-^{1}H TOCSY spectrum of the oil sample employed for frying potato chips is exhibited in Figure 7E. This two-dimensional spectrum displays clear connectivities between (i) ^{1}H resonances of the conjugated diene systems of CHPDs, (ii) the aldehydic, olefinic, and local bulk alkyl chain (–CH_2–) group resonances of α,β-unsaturated aldehydes, and (iii) the aldehydic and adjacent bulk *n*-alkyl chain (–CH_2–) group signals.

DISCUSSION

Employment of a combination of two-dimensional NMR spectroscopic methods for the analysis of products arising from the oxidative degradation of glycerol-bound PUFA in culinary oils (thermally stressed or otherwise) provides much valuable molecular information which is an essential requirement for future evaluations of the toxicological hazards putatively associated with the dietary consumption of LOP. Moreover, the identification of specific LOP also highlights particular reaction pathways which can be related to the degree of PUFA unsaturation, together with the nature of glyceride substitution.

The RCT and TOCSY spectroscopic techniques permit the transfer of magnetization from an ^{1}H nucleus [or magnetically equivalent group (2 or 3) of such nuclei] bonded to one specific carbon atom (C_1), (the former through a relayed spin), to one or more magnetically distinct nuclei located two or more carbon positions further along a molecular chain (C_3, C_4, C_5 position, etc.), i.e., the latter nucleus/nuclei is/are not directly coupled to the C_1-bearing ^{1}H nucleus. Hence, the technique is extremely useful for the identification of LOP, particularly isomeric CHPD which have complex overlapping vinylic resonance patterns in their one-dimensional ^{1}H NMR spectra.

Direct observation of ^{13}C nuclei is poorly sensitive in view of its low natural abundance (1.11%), especially for relatively low concentrations of components such as LOP present in

FIG. 6. (See previous page) (A) Computer-simulated one-dimensional spectrum generated by the software suite described in the Materials and Methods section, utilizing spectral parameters derived from the assignment of all the detected lipid oxidation products and making allowance for their relative concentrations within the mixture. (B) One-dimensional ^{1}H NMR spectrum of a repeatedly utilized culinary frying oil sample collected from a fast-food restaurant, and (C) corresponding "skyline" f_2 projection and two-dimensional matrix contour plot of a 600 MHz ^{1}H-^{1}H *J*-resolved spectrum. Typical spectra are shown. Abbreviations: ^{1}H nucleus labels of isomeric CHPD, conjugated hydroxydienes, and saturated and α,β-unsaturated aldehydes correspond to labeled protons in the accompanying molecular structures. The label –OO<u>H</u> represents hydroperoxide-OO<u>H</u> group proton resonances. See Figures 2 and 3 for abbreviatons.

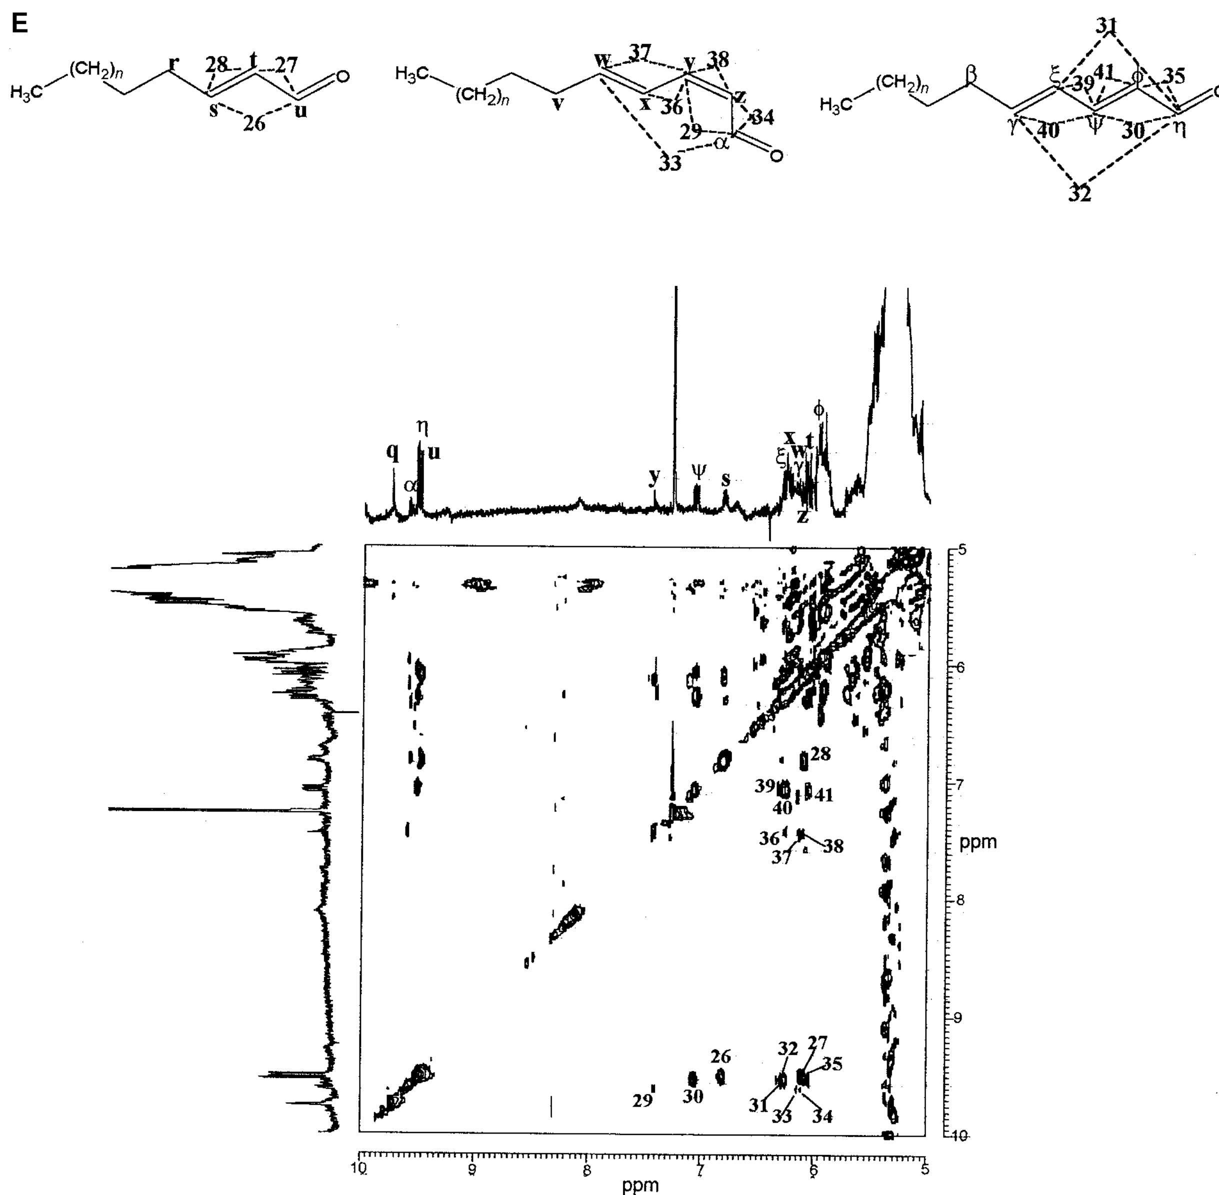

FIG. 7. (continued)

peroxidized triacylglycerol mixtures (the one-dimensional ^{13}C spectrum depicted as the f_1 projection of the HMQC profile displayed in Figure 5A required *ca.* 5,000 scans). However, the recent development of inverse-geometry probes and relevant accompanying pulse sequences has largely overcome this problem since HMQC spectroscopy and related techniques offer a substantial gain in sensitivity over conventional, one-dimensional spectroscopy. Hence, the HMQC technique is a particularly attractive one which readily facilitates investigations of the structure and dynamics of LOP.

Furthermore, application of the ^{1}H-^{1}H *J*-resolved spectroscopic method also serves to clarify the molecular nature of LOP present in autoxidized PUFA mixtures. Indeed, the technique is especially advantageous for the purpose of making resonance assignments in crowded spectral regions and enables the accurate determination of chemical shift and coupling constant values.

A high percentage of humans are frequently and continually exposed to LOP in the diet (arising, for example, from the shallow- or deep-frying of PUFA-rich culinary oils), and the possibility that regular consumption of such agents may be deleterious to human health has recently attracted much

interest. The short-term feeding of heated and/or oxidized oils and fats to experimental animals can give rise to loss of appetite, diarrhea, cardiomyopathy, hepatomegaly, hemolytic anemia, growth retardation, and an apparent accumulation of peroxides in adipose tissue (highly oxidized cod liver oil) (39). Moreover, cellular damage in various organs, elevated liver and kidney weights, and a modified fatty acid composition of tissue lipids in rats were shown to result from the short-term feeding of oils and fats subjected to the heat and oxidation associated with normal usage (40,41), and one long-term study revealed that the consumption of mildly oxidized culinary oils by rats throughout their lifespans produced an increased frequency of cardiac fibrotic and hepatic bile-duct lesions (42). Further toxicological investigations concerning thermally stressed oils and fats focused on their mutagenic properties (43,44). However, the precise molecular nature of mutagens formed during frying processes and their metabolic fate in humans were not considered by these researchers.

Although there is much epidemiological and experimental evidence available regarding the influence of the dietary consumption of saturated or PUFA to the development and/or progression of human diseases, the precise autoxidation status of the culinary oils and fats ingested (i.e., the structure and concentrations of CHPD, conjugated hydroxydienes, aldehydes, etc., therein) has not hitherto been sufficiently considered, and the two-dimensional NMR techniques employed here serve to provide a multicomponent profile of PUFA-derived autoxidation products, information not readily attainable from alternative analytical methods which generally require much prior information regarding the molecular nature of such LOP.

CHPD are acutely toxic to rodents when administered systemically, but such effects are much less severe when given orally. Indeed, a single intravenous (i.v.) dose of methyl linoleate hydroperoxide administered to rats gave rise to a high mortality within 24 h (animals dying from severe lung damage), whereas an oral dose of *ca.* 200 mg/kg was without effect (45). Holman and Greenberg (46) demonstrated that although the intravenous LD_{50} value for ethyl linoleate hydroperoxide in mice was 12 mg/kg, similar dose levels administered orally were nonlethal, an observation supported by the subsequent investigations of Olcott and Dolev (47). Furthermore, Bergen and Draper (48) obtained indirect evidence indicating that the lack of effect of orally administered CHPD is explicable by their failure to be absorbed across the gastric or intestinal epithelium.

Notwithstanding, CHPD have the capacity to exert damage to the gastrointestinal epithelium, and Jayaraj *et al.* (49) showed that oral administration of the aldehydic lipid oxidation end product 4-hydroxy-*trans*-2-nonenal to rats at a dose level of only 2.6×10^{-7} mol·dm^{-3}, a concentration similar to that found in healthy human blood plasma, induced peptic ulcers.

As noted in the introduction, aldehydic LOP have been implicated in the induction, development, and progression of atherosclerosis (2) (and therefore its associated pathological sequelae such as ischemic heart disease and peripheral vascular disease), and additional investigations established that these cytotoxic agents exert genotoxicological (50) and proinflammatory (51) actions.

The above two-dimensional NMR techniques are also applicable to the analysis of appropriate lipidic extracts of biofluids and tissues obtained from patients with clinical conditions in which the *in vivo* oxidation of PUFA (and/or the dietary ingestion of chemically reactive aldehydes) has been implicated (1–3,7–10), and experiments to investigate this are currently in progress.

ACKNOWLEDGMENTS

We thank the University of London Intercollegiate Research Services for the provision of NMR facilities; Vladimir Shilay, Dmitry Mitushev (ACD, Moscow, Russian Federation) for helpful discussions regarding the calculation of ^{1}H NMR spectra, Andrew Claxson for excellent technical assistance, and Colette Troy for typing the manuscript. We are very grateful to the Commission of the European Communities (Agriculture and Agro-industry, including Fisheries: DG-XII) for financial support.

ABSTRACT: The presence of 11-*cis* monoenoic fatty acids was detected in olive oil samples by means of ^{13}C nuclear magnetic resonance spectroscopy, and the positional isomery on the glycerol backbone was derived. The 11-*cis* vaccenic and eicosenoic fatty acid resonances were recognized and the amounts of the fatty acids quantified. For comparison purposes, a quantitative analysis was also made by gas chromatography.

Paper no. L8106 in *Lipids 34,* 757–759 (July 1999).

Numerous investigation methods, based mainly on chromatographic and spectroscopic techniques, were developed to characterize the molecular composition of the vegetable oils. Among these, the high-resolution ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectroscopies are giving detailed insight on both quantitative and qualitative aspects of the oil composition (1–4); particularly the simultaneous presence of mono-, di- and triacylglycerols, together with the fatty acid position on the glycerol backbone, was easily determined (5–6).

Among the minor components of the fatty acids, the *cis*-vaccenic (11*c*-18:1) acid and eicosenoic (11*c*-20:1) acid were identified in plant sources and in some vegetable oils (4,7–11), while recently their occurrence in extra-virgin olive oils was also detected by gas chromatography (GC) (2,12).

Here we report the results of a preliminary ^{13}C NMR investigation on a number of olive oil samples from different Mediterranean regions which show that *cis*-11 vaccenic and eicosenoic fatty acids can be identified *via* their carbonyl and olefinic resonances.

EXPERIMENTAL PROCEDURES

Solutions in $CDCl_3$ (50% vol/vol) of the olive oil samples were prepared and then filtered. The ^{13}C NMR spectra were run on a Varian VXR-300 spectrometer (Palo Alto, CA), operating at the frequency of 75.4 MHz, equipped with a 10-mm broad-band probe using the NOE (nuclear Overhauser effect)-suppressed, inverse-gated proton decoupled technique. The free induction decay of each oil sample was acquired at 30°C with a 4.8-s acquisition time, using a sweep width of 13 KHz. Typically, 2,000 scans were collected using a 90° excitation pulse and a 35-s delay.

Fatty acid methyl esters (FAME) were prepared as described by Morrison and Smith (13) and, dissolved in *n*-hexane, were analyzed by GC with a Hewlett-Packard HP-6890 gas chromatograph equipped with a flame-ionization detector. A capillary column of cyanopropyl-methylxyloxane HP-23 FAME (30 m × 0.32 mm × 0.25 μm) was used. Nitrogen was used as carrier at a flow rate of 2 mL/min. The oven temperature was set at 175°C, injector temperature 250°C, detector temperature at 300°C.

The tri-11 eicosenoin, the deuterated chloroform, and the standard compounds used to identify the FAME were purchased from Sigma Chemical Co. (St. Louis, MO). All the other reagents and chemicals were purchased from Carlo Erba (Milano, Italy).

RESULTS AND DISCUSSION

One peculiar aspect of the ^{13}C NMR spectra of olive oils is the occurrence of some resonances in the carbonyl and olefinic regions not yet exhaustively identified (Figs. 1A, 2A). In the region of the *sn*-1,3 carbonyl resonances of the fatty acids (Fig. 1A), among the already known absorption signals, a small peak appears at 172.82 ppm (peak 2) which has not been identified as yet. Also unidentified are the two peaks at 129.59 (peak 6) and 129.68 ppm (peak 5) in the olefinic region (Fig. 2A).

The general rules that apply to the resonances of triacylglycerols in vegetable oils and animal fats and the assignments reported in the literature (1,3,4,9,14,15) on similar systems suggest that these peaks belong to monoenoic *cis*-11 fatty acids, mainly in *sn*-1,3 position. This hypothesis was verified by the addition of a small amount of eicosenoic tri-

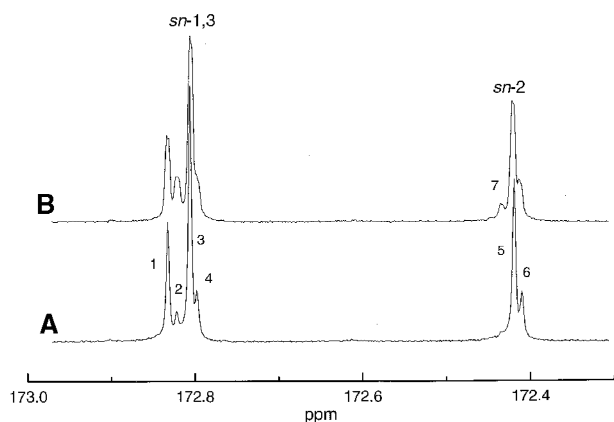

FIG. 1. (A) 75.4 MHz ^{13}C nuclear magnetic resonance (NMR) spectrum of the carbonyl region of triacylglycerols in extra-virgin olive oil in $CDCl_3$ at 30°C. Peak 1 belongs to saturates acyl group; peaks 3 and 5 belong to oleic (18:1,[*cis*]-9) and palmitoleic (16:1,[*cis*]-9); peaks 4 and 6 belong to linoleic (18:2,[*cis,cis*]-9,12) and linolenic (18:3,[*cis,cis,cis*]-9,12,15) acyl group; peak 2 belongs to *cis*-11 monoenoic group. (B) Same as Figure 1A after the addition of trieicosenoin. Peak 7 belongs to eicosenoin acyl group.

acylglycerol to one of the olive oil samples. In Figures 1B and 2B we show the resulting carbonyl and olefinic regions. The comparison of the two sets of spectra in the carbonyl region clearly shows that the enhancement of peak 2 is accompanied by the appearance of a small peak at 172.43 ppm (peak 7) in *sn*-2 position. Notably, although obscured by the noise, a corresponding peak seems to occur also in the neat sample. A similar comparison in the olefinic region shows the enhancement of the peaks 4, 5, and 6 and the simultaneous arising of peak 9 at 129.57 ppm. Again we note that probably a peak corresponding to the latter occurs also in the neat sample.

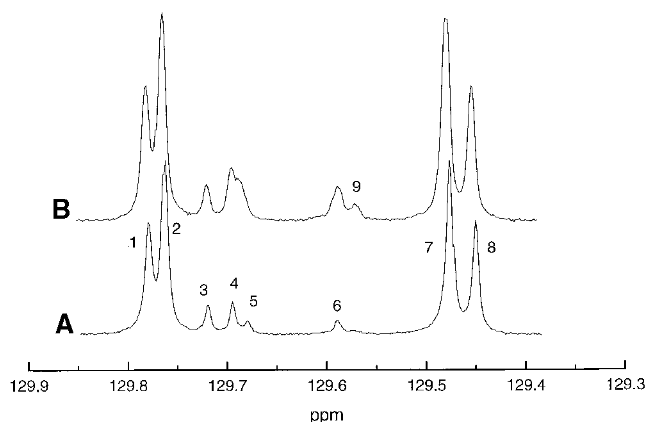

FIG. 2. (A) 75.4 MHz ^{13}C NMR spectrum of a portion of the olefinic region of triacylglycerols in extra-virgin olive oil in $CDCl_3$ at 30°C. Peaks 1 and 2 belong to C10 of oleic acyl group in *sn*-2 and *sn*-1,3 positions, respectively; peaks 3 and 4 belong to C9 of linoleic in *sn*-1,3 and *sn*-2 positions, respectively; peaks 7 and 8 belong to C9 of oleic in *sn*-1,3 and *sn*-2 positions respectively; peaks 5 and 6 belong to C12 and C11 of *cis*-11 monoenoic, respectively. (B) Same as Figure 2A after the addition of trieicosenoin. Peak 9 belongs to C11 of eicosenoin in *sn*-2 position. See Figure 1 for abbreviation.

TABLE 1
Fatty Acid Composition (% of the total fatty acids) of the *cis*-11 Monoenes in Olive Oils[a]

	Gas chromatography			Nuclear magnetic resonance
Source	*cis*-vaccenic ± SE	Eicosenoic ± SE	Total ± SE	Total ± SE
Puglia (Italy)	0.80 ± 0.01	0.43 ± 0.01	1.23 ± 0.01	1.66 ± 0.09
Spoleto (Italy)	1.61 ± 0.01	0.54 ± 0.01	2.15 ± 0.02	2.20 ± 0.06
Greece	1.42 ± 0.01	0.45 ± 0.01	1.87 ± 0.01	2.30 ± 0.11
Egypt	2.75	0.45	3.20	3.09

[a]The means and the standard errors were estimated from sets of at least six samples each. No statistics for the Egyptian olive oil could be obtained due to unavailability of a sufficient number of samples.

From the integrated peak areas of the olive oil samples, the amount of the eicosenoic fatty acid was found to be 1–3% of the total content of fatty acids, while the literature data quote this quantity as less than 0.6% (2,11,12).

Since the eicosenoic and *cis*-vaccenic fatty acids have quite close olefinic and carbonyl chemical shifts (1,4,9), a substantial signal overlapping should occur, and therefore these signals might comprise the *cis*-vaccenic fatty acid also. In fact the GC analysis revealed the presence of these two *cis*-11 fatty acids in amounts that add up to a value close to that found by NMR spectroscopy (see Table 1).

The extensive literature dealing with the comparison between NMR and GC sensitivity and errors indicates that the latter method is by all means the technique of choice in quantitating the composition of the vegetable oils. These remarks are also substantiated by the values of the relative standard errors reported in Table 1. However, it must be pointed out that the NMR analysis, although inherently much less sensitive and thus much more time-consuming, does not require the extensive chemical manipulations as in the GC methodology so that the overall experiment times of the two techniques are very similar. Furthermore, the NMR technique, as opposed to the GC analysis, allows within a single experiment the determination of combined *cis*-11 fatty acids composition and the positional distribution of these fatty acids on the glycerol backbone (although in each of the olive oil samples examined, *cis*-11 fatty acids are only detectable in the *sn*-1,3 position). However, it must be remarked that while the GC method gives separate measures of the two *cis*-11 fatty acids, the NMR technique only measures the sum of the two.

REVIEW

Olestra Formulation and the Gastrointestinal Tract

Ronald J. Jandacek*, Jeffrey J. Kester, A.J. Papa, Thomas J. Wehmeier, and Peter Y.T. Lin

Procter & Gamble Miami Valley Laboratories and Winton Hill Technical Center, Cincinnati, Ohio 45253-8707

ABSTRACT: Olestra is a mixture of compounds comprising sucrose esterified with 6–8 long-chain fatty acids. It is not hydrolyzed by pancreatic lipase and as a result is not absorbed from the small intestine. Olestra in general has physical properties similar to those of a triacylglycerol with the same fatty acid composition. Foods made with olestra are virtually identical in taste and texture to those made with typical triacylglycerols. Olestra consumption does not generate hydrolytic products in the small intestine and, therefore, does not generate some of the signals that alter motility in the gastrointestinal tract. A reduction in gastroesophageal reflux with olestra, in contrast to triacylglycerols, is consistent with a lack of effect on stomach emptying. Unlike triacylglycerols that are absorbed in the proximal small intestine, olestra is distributed throughout the small intestine during transit and passes into the colon. In the colon, olestra's effects depend on its physical properties. Liquid nondigestible lipids result in separation of oil from the fecal matrix. Olestra formulations made with specific fatty acid compositions, particularly those containing a solid sucrose polyester component including behenic acid, possess appropriate rheology to hinder separation of oil from the rest of the fecal matrix, thereby reducing gastrointestinal symptoms.

Paper no. L8115 in *Lipids 34,* 771–783 (August 1999).

Recent studies have shown that olestra consumed in a free-choice manner in prepared snacks does not alter the frequency of reports of common gastrointestinal symptoms (1,2). At this time, however, products that contain the zero-calorie fat substitute olestra are required to have a label that states, "Olestra may cause abdominal cramping and loose stools." This label reflects symptoms that were elicited during the history of olestra development in which fluid prototypes of the nonabsorbable fat substitute were studied, and in studies in which subjects consumed olestra as part of a fixed diet for many consecutive meals. A recent clinical study has demonstrated that consumption of olestra does not cause diarrhea but can result in a predictable, gradual, dose-responsive stool softening effect similar to that of dietary fiber (3). In the discussion that follows, we examine how the chemical structure of olestra influences its properties and effects during transit from the mouth to the colon.

Although olestra is a sucrose polyester (sucrose esterified with six or more fatty acids), the product that is sold commercially is a mixture of sucrose polyesters of specific fatty acids that was developed both to optimize the texture sensed in the mouth and minimize separation of oil in the gastrointestinal tract from other components in the large bowel. We discuss below how the rheology and optimized fatty acid composition relate to these benefits; this progress has resulted from an understanding of the relationship between the physical properties and chemical composition of sucrose polyesters.

WHAT IS OLESTRA AND WHAT CAN WE PREDICT ABOUT ITS EFFECTS?

Olean® is the Procter & Gamble Company brand name for a fat substitute made from sucrose and vegetable oil fatty acids. Its common and usual name is "olestra" and in its development stage it was referred to as "sucrose polyester" to denote its chemical composition, that is, sucrose multiply-esterified with long-chain fatty acids. In January 1996, olestra was approved by the U.S. Food and Drug Administration for use in the commercial preparation of savory snack foods, such as potato chips and crackers (4).

Olestra is a subset of many possible sucrose polyester molecules and is defined by specific chemical measures, such as fatty acid composition and ester distribution. In addition, olestra is a semisolid at room and body temperature and is characterized by a specific rheological measure of stiffness to be discussed in detail later. Its semisolid consistency distinguishes olestra from early sucrose polyester compositions that were liquid at body temperature. In this review, these early compositions are referred to as "liquid sucrose polyester." A listing of olestra's chemical and rheological properties as specified in the Food and Drug Administration approval can be found in the olestra food additive regulation as summarized in Table 1 (4).

Olestra that is ingested as a replacement for typical dietary fat does not provide the body with utilizable energy by virtue of its unique resistance to intestinal lipases (5). Because it is not hydrolyzed into absorbable products, such as the fatty acids and monoacylglycerols resulting from normal fat digestion, olestra is not absorbed into the lymphatic or blood circulations (6,7). Olestra therefore passes into the large intestine chemically unchanged.

TABLE 1
Specifications for Olestra[a]

Property	Specification
Definition	Mixture of octa-, hepta-, and hexaesters of sucrose with fatty acids derived from edible fats and oils
Degree of esterification	Total content of octa-, hepta-, and hexaesters is not less than 97%. The content of octaester is not less than 70%, hexaester not more than 1%, and pentaester not more than 0.5%
Fatty acid composition	The unsaturated fatty acid content is not less than 25% and not more than 83%. The content of C_{12} and C_{14} acids is each not more than 1%, and the content of fatty acids with 20 or more carbon atoms is not more than 20%. C_{16} and C_{18} fatty acids make up the remainder, not less than 78%
Free fatty acids	Less than 0.5%
Stiffness	Not less than 50 kPa/s

[a]From Reference 4.

Humans, like most higher mammals, have an extremely efficient fat digestion process. Estimates of the excess capacity of pancreatic lipase range from 10 to 20 times that needed to digest and absorb a typical 100-g daily fat intake. Support for this excess capacity is given by a study in which 13 subjects were administered exaggerated levels of fat (200–639 g/d) for 4–45 d (8). Although fat absorption varied among individuals, it was nearly normal for most with a range of 82–98% of that ingested. One subject absorbed 98% of the ingested amount of 639 g/d, equivalent to a daily intake of seven sticks of butter.

The typical disposition of dietary fat is hydrolysis and absorption in the jejunum; however, it has been shown that uptake into the ileal enterocytes will take place if fat should arrive there (9). Fecal fat content typically accounts for less than 5% of ingested triacylglycerols (8), and this value also reflects the efficient process by which the body utilizes dietary fat. It should be noted that some of the fecal fat is undoubtedly of endogenous origin, resulting from sources such as sloughed intestinal cells or biliary lipid.

Based on these observations, a typical Western diet will deliver approximately 5 g of triacylglycerol to the colon on a daily basis. Dietary olestra, being neither hydrolyzed nor absorbed, is all transported into the colon and subsequently excreted unchanged in the feces (10). Any ingested olestra will therefore add to the normal flow of hydrophobic material in the colon.

The biochemical inertness of olestra suggests that it might behave in a manner that differs from that of the normal load of fat in the colon. This review discusses the current understanding of events that occur in the gastrointestinal tract after the ingestion of olestra. For a reference point it also covers the gastrointestinal transit of typical triacylglycerols, including their effects in the colon. We will discuss both olestra and triacylglycerols during transit from mouth to excretion. The topics covered in this discussion include oral sensory perception, stomach emptying, gastroesophageal reflux, gallbladder contraction, emulsification in the small intestine, movement through the colon, combination with fecal matter, effects on colonic microflora, and fecal excretion. The effects of olestra on fecal rheology and mass are discussed in relation to other dietary constituents.

PHYSICAL PROPERTIES OF OLESTRA

Although olestra is biochemically inert, its physical properties contribute to its gastrointestinal effects. As discussed below, the physical form of olestra, including its phase behavior and rheology, has been shown to influence the form of the contents of the colon and feces.

Early studies with rats included both liquid and semisolid sucrose polyester compositions (11). It was observed that feeding elevated levels of the liquid sucrose polyester, typically made from safflower oil fatty acids (90% linoleic and oleic acids), resulted in poorly formed fecal pellets with separation of an oil phase from the rest of the fecal matter. This oil frequently accumulated on the tails and fur of the animals during the studies. It was found that this separation of the sucrose polyester oil phase occurred above a threshold of 300 mg of dietary liquid sucrose polyester per day in rats that weighed 250–300 g (11).

It was also found that separation of an oil phase from the other fecal matter did not occur when rats were fed semisolid sucrose polyester synthesized from partially hydrogenated cottonseed and soybean oils at dietary levels of 8% by weight (Jandacek, R.J., unpublished observation). A typical fatty acid composition of sucrose polyester made from a blend of the methyl esters derived from these partially hydrogenated oils constituted 18% palmitic acid, 38% stearic acid, 11% linoleic acid, and 31% oleic acid. This composition melted in a range from body temperature to 42°C.

Although the olestra made from the hydrogenated oils appeared to be solid, its consistency was similar to that of lard or solid shortenings, and it contained both liquid and solid components. Dilatometry, which was used to determine solid and liquid fat content by measurement of differences in the change of volume with temperature (12), showed olestra made from a blend of partially and completely hydrogenated soybean oil to consist of 84% liquid and 16% solid sucrose polyester components at body temperature (37.0°C) (10).

Different gastrointestinal effects associated with consumption of liquid and semisolid sucrose polyester formulations have also been observed in humans. Consumption of 25 g/d of liquid sucrose polyester was found to cause separation of a fecal oil phase (13). A semisolid composition, on the other hand, did not result in oil separation even when fed at 50 g/d (10). The experience with liquid and semisolid sucrose polyester compositions indicated that the melting point or melting

range of a nondigestible hydrophobic compound is a determinant of its separation from feces. A nondigestible lipid with a high melting point (above body temperature) is less likely to flow and separate from other fecal matter during gastrointestinal transit in the large intestine.

In light of this relationship between physical properties of nondigestible lipids and the gastrointestinal effects elicited, higher-melting compositions would seem more appropriate for use in foods. However, the successful substitution of a nondigestible lipid for triacylglycerol in the diet will result only if the substitution yields highly palatable food products. High-melting sucrose polyester compositions containing a high level of solids at mouth temperature can be perceived as waxy or excessively greasy in the mouth and may impart the sensation of a residue of fat on the palate and/or lips. The development of a fat substitute is therefore subject to the dual constraints of providing both satisfactory taste and texture and of minimizing the potential discomfort of fecal oil separation in the gastrointestinal tract. Low-melting nondigestible lipids, such as liquid sucrose polyesters (see Table 2 for representative fatty acid compositions), provide very desirable taste performance but run the risk of oil separation from the fecal matrix above threshold dietary levels, which vary from individual to individual. Higher-melting compositions can reduce or eliminate the problems in the gastrointestinal tract, but their perceived waxiness may limit sensory acceptance.

As with dietary triacylglycerols, the physical properties of olestra are related to the properties of the constituent fatty acids. Fatty acids with high melting points yield high-melting triacylglycerols and sucrose polyesters. The use of a solid or semisolid sucrose polyester composition as a substitute for a high-melting dietary triacylglycerol may appear to be relatively straightforward; however, similar substitition for liquid dietary oils is a challenge because of the need to balance sensory performance with the potential gastrointestinal effects discussed above. Much of the effort in developing and optimizing olestra has focused on finding the appropriate compositions that provide both good taste performance and appropriate consistency in the gastrointestinal tract. The progress that has been made in developing olestra compositions with continually improved taste performance, while delivering acceptable performance in the gastrointestinal tract, is illustrated in the following discussion comparing three different types of olestra.

One class of olestra compositions described in the patent literature is synthesized from a blend of methyl esters derived from partially and fully hydrogenated vegetable oil fatty acids (14,15). The iodine value of this type of olestra typically ranges between about 20 and 55, depending upon the degree of hardening of the partially hydrogenated source oil and the molar ratio of the two methyl ester feed stocks. A representative fatty acid composition is shown in Table 2. This type of olestra has a semisolid consistency, and the solids level at body temperature (37.0°C) may range between about 5–20%, again depending upon the specific fatty acid composition and molar ratio of the source oils used. While effective for the control of fecal oil separation, these olestra formulations may provide less than optimal taste performance when used in certain food products as a full replacement for liquid triacylglycerol. The reason for this is evident upon examination of a representative solid fat content profile, shown as olestra composition A in Figure 1. Olestra composition A has a relatively steep solid fat content profile over the temperature range of room to body temperature (21.1–37.0°C). Consequently, there is a relatively high solids level at and below mouth temperature (33.3°C), which may result in a greasy or waxy tex-

TABLE 2
Fatty Acid Composition of Selected Sucrose Polyesters[a,b]

Form of sucrose polyester	Fatty acid composition (wt%)								
	14:0	16:0	18:0	18:1	18:2	18:3	20:0	22:0	24:0

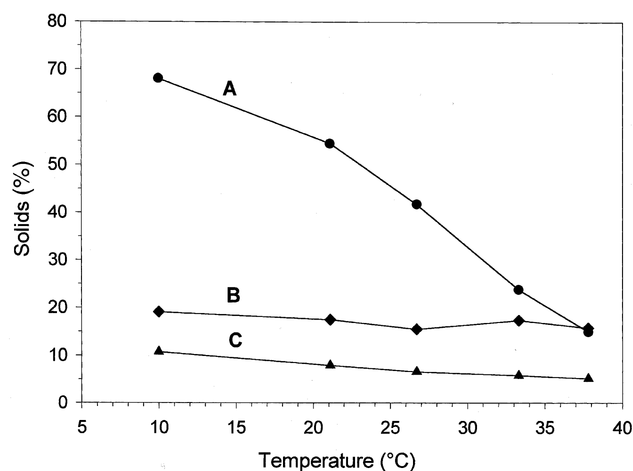

FIG. 1. Solid fat content profiles of three olestra formulations (Kester, J.J., and Wehmeier, T.J., unpublished data). (A) Olestra formulation synthesized from a blend of methyl esters of partially and fully hydrogenated soybean oil fatty acids; (B) olestra formulation comprising 82% liquid sucrose polyester (synthesized from partially hydrogenated soybean oil) and 18% solid sucrose polyester synthesized from fully hydrogenated soybean oil fatty acids; (C) olestra formulation comprising 92.5% liquid sucrose polyester (synthesized from partially hydrogenated soybean oil) and 7.5% solid sucrose polyester synthesized from C_{20}–C_{24} chain-length saturated and C_{18} chain-length unsaturated fatty acids. The solid fat contents were measured by pulsed nuclear magnetic resonance spectroscopy (22).

tural perception when composition A is used to completely replace liquid triacylglycerol. The U.S. patent issued to Bernhardt and Taylor (15), in fact, requires that a triacylglycerol be blended with this type of olestra in order to act as a solvent for the olestra solids, thereby helping to minimize the greasy or waxy mouth feel. A relatively steep solids profile is characteristic of olestra formulations synthesized from a blend of methyl esters derived from partially and fully hydrogenated vegetable oils. This profile is due to the extremely heterogeneous mixture of sucrose polyester molecules in the resulting olestra composition.

A second type of olestra is based on the physical blend of a liquid sucrose polyester and a high-melting, solid sucrose polyester derived from fully hydrogenated vegetable oil (see Table 2 for a representative fatty acid composition) (16). When solid sucrose polyester comprising primarily long-chain, saturated fatty acids is dissolved in liquid sucrose polyester by heating, spherulitic crystals are typically generated when the solution is allowed to cool (17). Sucrose polyester solids with a spherulitic crystal morphology have a relatively low surface area-to-mass ratio and hence are not particularly effective gelling agents for a liquid sucrose polyester oil phase. Nevertheless, if the level of the solid component is high enough, fecal oil separation can be controlled. Using an *in-vitro* fecal model to be discussed later, we have observed that ~18–20% solid sucrose polyester synthesized from fully hydrogenated soybean oil, when blended with liquid sucrose polyester and crystallized from a complete melt, will yield the appropriate rheology in the final olestra blend to control oil separation (Kester, J.J., unpublished observation). Measurement of the solid fat content profile for this olestra formulation (Fig. 1, composition B) reveals a relatively flat profile across the temperature range of room to body temperature (21.1–37.0°C). Compared to the previously discussed olestra formulation synthesized from a mixture of partially and fully hydrogenated fatty acid methyl esters (composition A in Fig. 1), olestra composition B would predictably display somewhat better taste performance when used as a full replacement for a liquid triacylglycerol (i.e., less greasy/waxy perception), owing to a lower solids level at and below mouth temperature (see Fig. 1).

The third olestra formulation to be discussed is also a physical blend of liquid sucrose polyester and a particular solid sucrose polyester component with unique crystallization behavior. The solid sucrose polyester was originally discovered by J.C. Letton and coworkers (18,19), who synthesized sucrose polyesters from fatty acids of disparate melting points. These solid sucrose polyesters are based on high-melting, long-chain saturated fatty acids (e.g., arachidic, 20:0, behenic, 22:0, and/or lignoceric, 24:0, acids) (18,19), combined at specific molar ratios with low-melting, fluid fatty acid chains. Typical molar ratios of the long-chain saturated fatty acids to the low-melting acyl chains are ~3:5–7:1 (19). The low-melting fatty acids may be short-chain, saturated (e.g., octanoic acid, 8:0, or lauric acid, 12:0) or long-chain, unsaturated fatty acids (e.g., oleic acid, 18:1, or linoleic acid, 18:2). A representative fatty acid composition for this type of solid sucrose polyester is shown in Table 2, in which the low-melting acyl chains are C_{18} chain-length, unsaturated fatty acids. When a solid sucrose polyester comprising fatty acids of disparate melting points is dissolved in liquid oil by heating and then the resulting solution allowed to cool and crystallize from a complete melt, thin platelet-shaped crystals are formed with a high surface area-to-mass ratio (17). The presence of the low-melting, fluid acyl chain in the solid sucrose polyester molecule is believed to be important for promoting formation of the platelet crystal morphology, presumbably by interfering with unrestrained three-dimensional crystal growth and thus promoting crystal growth, principally in two dimensions.

The platelet crystals of solid sucrose polyester constituting C_{20}–C_{24} chain-length saturated fatty acids and low-melting fatty acyl chains are highly effective gelling agents for liquid oils when cooled and crystallized from a complete melt (17,19). The efficient gelling performance is believed to arise from the high solid–liquid interfacial area. Depending upon the specific fatty acid composition of the solid, *in vitro* modeling studies and human clinical investigations have shown that ~5–10% of this solid type blended with liquid sucrose polyester will produce a semisolid gel with a stiffness sufficient to control fecal oil separation and passive oil loss.

Shortening and margarine prototypes can be made with mixtures of solid sucrose polyesters containing behenic acid and low-melting acyl chains, with either liquid sucrose polyester or triacylglycerol (18,19). The resulting products are extremely stable against phase separation. Therefore, these sucrose polyester solids are satisfactory replacements for β′ tri-

acylglycerol solids typically used in these food applications, such as those derived from fully hydrogenated palm or cottonseed oils.

Most importantly, however, olestra formulations containing sucrose polyester solids derived from fatty acids with disparate melting points display an optimized balance between taste performance and gastrointestinal effects. This balance is primarily a consequence of the relatively low level of solids required to provide a consistency sufficient to control fecal oil separation (i.e., these solids are efficient gelling agents). The low usage level of this solid sucrose polyester, combined with a flat solid fat content profile between room and body temperature (see Fig. 1, olestra composition C), results in a low solids level at mouth temperature that helps minimize greasy and/or waxy textural perception in finished food products. As a result, these olestra formulations provide optimal taste performance when used as fat substitutes in food products containing liquid triacylglycerols, such as in savory snack foods (20).

An important aspect of the work conducted to optimize the balance between olestra's taste properties and gastrointestinal effects involved developing an understanding of the relationship between the rheology of sucrose polyester compositions and fecal oil separation in the large bowel. This understanding was necessary in order to tailor semisolid olestra formulations to meet the required consistency for control of fecal oil separation, without incorporating excessive solids that negatively impact taste and texture. Rheological and fecal oil separation modeling studies of various sucrose polyester compositions were carried out and some of that work is summarized below.

Experience from animal studies previously discussed (11) led to the working hypothesis that separation of an unabsorbed lipid from the fecal matrix in the large intestine is a prerequisite to the occurrence of passive or uncontrolled oil loss through the anal sphincter. Furthermore, it is logical to assume that the greater the amount of fecal oil separation for any given unabsorbed lipid, the higher the risk that oil loss will occur. The same animal studies also provided evidence that oil separation from the fecal matrix and subsequent oil loss can be controlled by formulating olestra to have a semisolid consistency at body temperature (11). A semisolid consistency presumably allows an unabsorbed lipid to resist the thermodynamic tendency for oil separation from the hydrophilic fecal matrix, thereby remaining well dispersed within the stool. The objective of the following work was to define a rheological measurement of semisolid olestra that is predictive of the degree of fecal oil separation and hence the risk of oil loss. Definition and validation of an appropriate rheological measurement allowed subsequent human clinical testing to be conducted in order to set a minimal olestra rheological or stiffness specification that ensures the control of oil loss.

Definition of the olestra rheological measurement first required development of an *in vitro* fecal model that could be used as a quantitative tool to assess fecal oil separation of various olestra compositions. Use of an *in vitro* model allowed for more efficient screening of multiple olestra formulations than could have been accomplished through human clinical testing. A detailed description of the *in vitro* fecal model and methodology used in this work is provided in Elsen *et al.* (17). The objective of the fecal model was to simulate the peristaltic movement and dehydration of the contents in the large bowel, followed by measurement of the amount of free oil separation from the simulated fecal matrix that is elicited by any given nondigestible lipid. An aqueous dispersion of 9.4% simulated fecal solids (Feclone FPS-2 solids; Silicone Studios, Valley Forge, PA) was prepared by blending with hot (~100°C) distilled, deionized water. The dispersion was equilibrated at 37.8°C, after which 276.7 g of the dispersion was blended with a 26-g load of the sucrose polyester composition. Each lipid sample had been crystallized by cooling from a complete melt (~121°C) to approximately room temperature over ~3 min following the standard cooling profile described in Elsen *et al.* (17). The aqueous dispersion of simulated fecal solids (blended with the sucrose polyester composition of interest) was then added to dialysis tubing that allowed the passage of water vapor. After sealing both ends, the dialysis tubing and its contents were maintained at 37.8°C and subjected to a mild rolling mechanical action intended to simulate perstaltic movement in the colon (see Reference 17 for a further description of the apparatus used to induce the mechanical action). Over the course of approximately 20 h, water evaporation through the dialysis tubing led to partial dehydration of the simulated fecal matrix until the moisture content was reduced to ~75%, which is within the typical moisture content range for human feces (23). Dehydration of the simulated fecal matrix resulted in a change in consistency from a watery fluid to a stiffened consistency approximating that of a soft stool. Following completion of the dehydration step, the dialysis tubing was opened and the contents quantitatively transferred to a centrifuge bottle, after which the material was subjected to a mild centrifugation at 37.8°C (30 min at 115 × g) and the quantity of free oil that separated from the simulated fecal matrix was measured. This *in vitro* fecal model was validated by correlating oil separation for specific olestra formulations to reports of *in vivo* fecal oil separation from human subjects (as measured by oil droplets in the toilet after defecation) participating in clinical trials (Kester, J.J., unpublished data).

A variety of sucrose polyester formulations was assessed for level of oil separation in the *in vitro* fecal model, including the three olestra types previously discussed (see Fig.1). The sucrose polyester formulations included multiple solid crystal morphologies (e.g., spherulite, platelet) with expected variability in their efficiency of oil binding and gelation of the liquid sucrose polyester phase. Oil separation data were then statistically correlated to various rheological measurements made on the same sucrose polyester formulations crystallized from a melted state under an identical cooling regimen. The rheological measure that best correlated with oil separation data from the *in vitro* fecal model was the thixotropic area obtained from a shear rate vs. stress flow

curve (see Figs. 2 and 3). The flow curve was generated at 37.8°C using a controlled rate rheometer equipped with a cone and plate configuration. Shear rate was first increased from 0 to 800 s^{-1} over 7.5 min and then decreased back to 0 s^{-1} over 7.5 min, while shear stress was monitored. Thixotropic area, measured in units of kPa/s, is the area of hysteresis bounded by the ascending and descending portions of the flow curve (Fig. 3). The term thixotropy refers to the decrease of apparent viscosity of a material with time under shear and the subsequent partial or full recovery of apparent viscosity when the shear is discontinued (24). Colloidal dispersions, such as a dispersion of solid lipid crystals in a liquid oil phase, often display thixotropic behavior. This behavior arises from particle associations that exist in the absence of flow and, in the case of a gel, these associations give rise to a particulate network (24,25). Under increasing shear, these particle associations are broken and, consequently, the descending portion of the flow curve for a thixotropic material is displaced below the ascending portion of the curve (Fig. 3). The magnitude of thixotropic area enclosed by the ascending and descending portions of the flow curve can be expressed in terms of the energy per unit volume of sample being sheared, which indicates that thixotropic area is related to the energy required to break down the particulate network structure of the material being sheared (25,26). Therefore, thixotropic area may be interpreted as a relative measure of the solid-like structural strength or stiffness of a material that exists prior to shearing. This interpretation is valid as long as the flow curve is generated under a standardized testing protocol (e.g., sample handling, temperature, shear rate ramp, etc.) (26). A comparison of thixotropic areas measured for semisolid olestra and liquid sucrose polyester is shown in Figure 3.

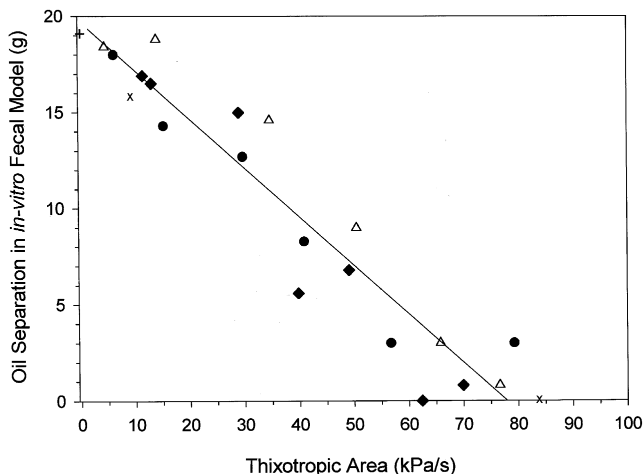

FIG. 2. Relationship of thixotropic area measured at 37.8°C of various sucrose polyester formulations to oil separation in the *in vitro* fecal model (Kester, J.J., and Wehmeier, T.J., unpublished data). Each data point is the average of duplicate measurements. The sucrose polyester formulations were as follows: Liquid sucrose polyester synthesized from partially hydrogenated cottonseed oil (+); semisolid sucrose polyester synthesized from a blend of methyl esters of partially and fully hydrogenated soybean oil fatty acids (×); physical blends of liquid sucrose polyester with 5, 10, 15, and 20% solid sucrose polyester synthesized from fully hydrogenated vegetable oil (●); physical blends of liquid sucrose polyester with 2, 4, 6, and 8% solid sucrose polyester synthesized from C_{20}–C_{24} chain-length saturated and C_{18} chain-length unsaturated fatty acids (◆); physical blends of liquid sucrose polyester with 2, 4, 8, 10, 12, and 14% solid sucrose polyester synthesized from C_{20}–C_{24} chain-length saturated fatty acids and lauric acid, 12:0 (△).

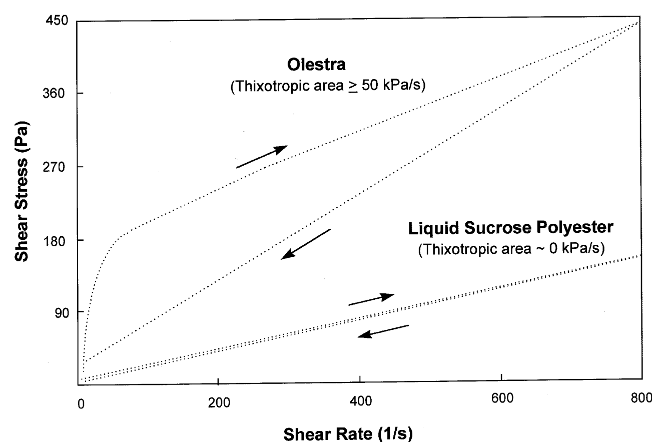

FIG. 3. Representative flow curves at 37.8°C for liquid sucrose polyester and semisolid olestra, both of which were derived from partially hydrogenated cottonseed oil. The flow curves were generated on a controlled rate rheometer with cone and plate configuration (model #RH115, Contraves AG, Zurich, Switzerland). The shear rate was increased from 0 s^{-1} to 800 s^{-1} in 7.5 min and then decreased back to 0 s^{-1} in 7.5 min. The lipid samples were cooled from a complete melt (~121°C) to approximately room temperature over a time period of ~3 min according to the cooling profile in Elsen *et al.* (17). Thixotropic area is the area of hysteresis between the ascending and descending portions of the flow curve.

Nondigestible lipids that display little or no thixotropic area have minimal solid-like structure or stiffness and therefore have a high propensity to separate from the fecal matrix in the large bowel. Consequently, if consumed at relatively high levels, these materials have a high risk of separation from the fecal matrix in the colon and subsequent leakage through the anal sphincter. Liquid sucrose polyester exhibits an extreme example of this phenomenon. Liquid sucrose polyester displays Newtonian flow behavior; consequently the ascending and descending portions of the flow curve are superimposed, yielding a thixotropic area that is essentially zero (Fig. 3). When liquid sucrose polyester was tested in the *in vitro* fecal model, over 70% of the lipid load separated from the simulated fecal matrix; i.e., ~19 g of the 26-g load (Fig. 2) (17).

Olestra formulations that are semisolid at body temperature display a measurable thixotropic area. As thixotropic area of the sucrose polyester formulations evaluated in this study increased, the amount of oil separation measured in the fecal model decreased in a linear manner (Fig. 2). Complete control of oil separation in the *in vitro* fecal model was achieved at a thixotropic area of ~80 kPa/s.

The relationship of the thixotropic area of various olestra formulations to the occurrence of oil droplets in the toilet (an indication of fecal oil separation) and underwear oil staining in humans was supported in a subsequent clinical investiga-

tion to be discussed in detail later. This investigation provided the basis for setting the current olestra rheological specification (termed "stiffness" in the olestra food additive regulation) that ensures control of oil leakage; i.e., thixotropic area greater than or equal to 50 kPa/s (see Table 1). Further details regarding the method for measuring thixotropic area of olestra can be found in Elsen *et al*. (17) and in the olestra food additive regulation (4).

OLESTRA INGESTION AND GASTROINTESTINAL TRANSIT

Mouth. The physical properties of olestra are important determinants of its effects in the mouth. Although lingual lipases are present in the mouth during mastication of a fat-containing food (27), the short residence time and low enzyme activity result in negligible hydrolysis of triacylglycerol in the oral cavity. In addition, since there is no evidence of olestra's absorption in the gastrointestinal tract (28,29), we may also conclude that olestra is not hydrolyzed by lingual lipase since absorbable products would be produced by hydrolysis.

The flavor of olestra is very similar to that of the triacylglycerols containing the same fatty acids from which it was derived. However, depending on the specific food application and the melting behavior of the triacylglycerol being replaced, there is potential for olestra to display differences in textural perception in the mouth. The perception of fat in the mouth depends on its melting point, viscosity, and interfacial tension with the aqueous phase. The oil/water interfacial tension of olestra that comprises predominantly octaesters is similar to that of analogous triacylglycerols (30), as might be predicted since the ratio of lipophilic to hydrophilic portions of the olestra and triacylglyerol molecules are similar. Sucrose polyester compositions can be made with a variety of melting points and apparent viscosities, depending on the fatty acids used in its production (30). However, as previously discussed, olestra for use in foods is formulated to possess a semisolid consistency at body temperature in order to control fecal oil separation. Therefore, when olestra is used as a replacement for liquid triacylglycerols (e.g., in the preparation of fried savory snacks), this physical property constraint necessitates careful control by the food manufacturer of the total olestra level and location in the finished food in order to yield optimal taste properties.

Stomach. There are measurable differences between the effects of olestra and triacylglycerols in the stomach. Although this differentiation may result from both local effects and different feedback signals from the small intestine, the effects manifest in the stomach will be discussed first.

(i) Gastric emptying. A fundamental question about olestra's effects on gastric motility was addressed in an early study by Cortot and coworkers (31). The rate of emptying of food components was measured in five healthy subjects by the use of a multilumen duodeno-jejunal tube and a double lumen gastric sump tube, along with nonabsorbable markers. ^{14}C-Labeled sucrose octaoleate and ^{3}H-labeled glyceryltriether were used as lipid markers, and polyethylene glycol 4000 and phenolsulfonphthalein as markers of the aqueous phase. Phenolsulfonphthalein and glyceryltriether were continuously infused into the duodeno-jejunal tube, and the other markers were fed with the test meal of steak, bread, orange sherbet, 20 g of sucrose octaoleate, and 210 mL of water containing 15 g of polyethylene glycol 4000. The intestinal contents were aspirated at sites 20 and 30 cm below the duodenal infusion site, with an occluding balloon placed at a point just past the most distal sampling site. The intestinal samples were continuously aspirated and the stomach samples were aspirated every 10 min.

This study showed the rates of stomach emptying of sucrose octaoleate and of polyethylene glycol 4000 to be similar. Virtually all of the sucrose octaoleate had left the stomach within 2 h after the test meal was consumed. The authors noted that this time was markedly shorter than that which they had observed for butter's exit from the stomach. They concluded that the difference was not due to a more rapid exit of the entire meal from the stomach as determined by food particles in the aspirate. The data were consistent with the slow rate of gastric emptying of dietary fat resulting from its ultimate hydrolysis and more rapid emptying of a nonhydrolyzable fat. Presumably feedback signals elicited by the hydrolytic products in the small intestine influenced the rate of emptying. The authors noted that gastric emptying has been observed to be faster in patients with impaired lipolysis. The physical properties of the fat, including viscosity and density, did not determine the rate of stomach emptying since the physical properties of sucrose octaoleate were similar to those of typical triacylglycerol fats that were observed to leave the stomach slowly.

In a study of the effect of olestra on the intestinal transit of food, Aggarwal and coworkers (32) followed regional movement of radiolabeled solid polystyrene pellets, which showed the transit of solid residue. They compared the effects of four different meals that contained 45 g of lipid, of which olestra accounted for 0, 7.5, 15, or 30 g. In addition, they included a low-fat (15 g) meal with no olestra. There were no differences between subjects consuming the different meals in the length of time to first entry of solid into the small intestine (lag phase) or in the rate of the solids leaving the stomach after the lag phase (postlag slope). This study, in which the transit of meal solids was followed, showed therefore that stomach emptying was not influenced by levels of olestra in the meals between 0 and 30 g. These results do not contradict those of Cortot *et al*. (31), since the latter workers followed the movement of a liquid oil form of sucrose polyester (sucrose octaoleate) from the intubated stomach, rather than solid pellets followed noninvasively.

(ii) Esophageal reflux and gastric acid. The results of a study of the effect of olestra on postprandial esophageal acid exposure are consistent with a difference in the behavior of olestra and triacylglycerols in the stomach (33). In this study, 19 subjects received in random order potato chips prepared either with olestra or vegetable oil (cottonseed oil) on two

consecutive days. An esophageal pH probe measured intraesophageal pH for 30 min prior to the meal and for 3 h after the consumption of the chips. Subjects were upright during the measurements. The postprandial gastroesophageal reflux, which was defined as a decrease in pH below 4.0, was measured in terms of cumulative minutes of duration. The number of times the pH decreased below 4.0 was also determined. The chips prepared in vegetable oil resulted in a significantly greater duration of esophageal acid exposure, 27 min, compared with 2 min after the olestra chips ($P < 0.05$). Similarly, the number of episodes over the 3-h study period was significantly greater with the triacylglycerol chips (25 vs. 9; $P < 0.05$) . The investigators suggested that the results are consistent with a lower production of serum cholecystokinin (CCK) after the olestra meal, since CCK is one signal involved in decreasing lower esophageal sphincter pressure.

A study by Maas *et al*. (34) examined the effect of sucrose polyester (presumably similar to marketed olestra; rheological and melting parameters not specified) on the secretion of gastric acid and the release of CCK. As discussed above, although the release of CCK is an event mediated by intestinal receptors, it affects gastric emptying. These investigators found that sucrose polyester differed from typical triacylglycerols in that it did not stimulate CCK release. This observation is consistent with the finding of Cortot *et al.* (31) that triacylglycerols left the stomach more slowly than sucrose octaoleate, presumably because the hydrolysis products of the triacylglycerol slowed stomach emptying by CCK-based feedback.

Maas and coworkers (34) also found that sucrose polyester did not reduce gastric acid secretion in the manner of triacylglycerols, and it is possible that the absence of feedback by free fatty acids also was involved in this effect. These authors' concerns about the risk of increased acid production with ingestion of a nonhydrolyzable lipid, thereby leading to more gastroesophageal reflux, were not borne out by the results in the prior paper by Just *et al*. (33). These results actually showed a decrease in esophageal acid reflux after ingestion of olestra.

The activity of gastric lipase on fat in the stomach can catalyze formation of some diacylglycerols and free fatty acids. This predigestion step is of more importance in neonates with pancreatic insufficiency than in normal adults (35). Since there is no evidence of olestra's absorption (28,29), we may conclude that hydrolysis of olestra is not catalyzed by gastric lipase.

Small intestine. (i) Pancreatic lipase. The most important distinctions between olestra and triacylglycerol are evident in the small intestine. Whereas, after emulsification, triacylglycerols are rapidly hydrolyzed by pancreatic lipase-colipase, olestra is biochemically inert in the presence of this enzyme complex. The presence of olestra in the proximal small intestine would not be predicted to cause any untoward effects since this region regularly accommodates unhydrolyzed fat.

The jejunal contents during the digestion of a fatty meal include droplets of unhydrolyzed triacylglycerol (36) that may differ from olestra in rate of emulsification. Oil/aqueous interfacial tension measurements of pure olestra and triacylglycerol are similar (30), but the influence of different concentrations of fatty acids associated with the oil droplets emptying from the stomach into the small intestine could result in different rates of emulsification. The emulsification of triacylglycerols may occur more rapidly in the small intestine relative to olestra since fatty acids produced by gastric lipase would be expected to associate with the triacylglycerol oil droplets that exit the stomach into the duodenum. Although intestinal fatty acids conceivably could diffuse to the olestra–water interface, the fatty acid (or soap) concentration at the triacylglycerol-aqueous interface will presumably be higher because of the local production of free fatty acids and monoacylglycerol by lipase at the triacylglycerol oil droplet surface. In addition, the semisolid consistency of olestra may tend to limit emulsification in the small intestine, since oils are more efficiently emulsified than solid or semisolid fats.

Bile salts readily emulsify sucrose polyesters as shown by *in vitro* preparations that require ultracentrifugation to separate sucrose polyester and bile salt micellar phases (37). Therefore, the complete absence of hydrolysis of olestra by pancreatic lipase cannot be attributed to reduced emulsification in the small intestine.

The ingestion of typical quantities of dietary fat allows the near completion of hydrolysis and absorption of fat in the jejunum, so that only small amounts reach the ileal region (9). The presence of fat in the distal small intestine is not an abnormal situation, however, and fat absorption takes place in this region if fat is delivered there (9). There do not seem to be untoward effects associated with the presence of unhydrolyzed fat in this part of the gastrointestinal tract.

In spite of the inability of pancreatic enzymes to split olestra into hydrolytic products, the pancreas does not "overproduce" to compensate for incomplete digestion as it does in response to a high level of absorbable fat in the diet (38). A study by Hager and Schneeman (39) compared pancreatic enzyme secretion in rats fed olestra with those fed triacylglycerol and found no differences. Therefore, olestra does not induce signals to the pancreas to increase lipase production in response to the presence of nondigestible lipid in the small intestine.

(ii) Bile acids. An effect of olestra that could hypothetically introduce a gastrointestinal change would be if it interfered with bile acid absorption. Reduced reabsorption of bile acids would introduce a higher than normal level of bile acids into the colon with accompanying irritant effects (40). A study in humans showed that bile acid excretion was not increased with moderate to high levels (8 to 50 g/d) of dietary olestra (41). In another trial with humans consuming 50 g/d of olestra, a modest increase in bile acid excretion was observed (from 225 ± 121 to 376 ± 222 mg/d; $P < 0.05$) (42). Studies with experimental animals showed no increase in the excretion of either total bile acid or ^{14}C-labeled chenodeoxycholic acid (a relatively lipophilic, dihydroxy bile acid) when olestra was included in the diet (43). These observations are

consistent with the relatively hydrophilic nature of the bile salts. Even one of the more lipophilic bile salts, chenodeoxycholic acid, has little affinity for olestra relative to an intestinal micellar phase.

(iii) Nutrient absorption. It is possible that olestra could interfere with the absorption of nutrients in the small intestine and subsequently carry them into the large intestine. Nutritional studies in pigs with olestra have shown that it does not alter the absorption of macronutrients (44). The study of excreted fat from humans fed sucrose polyester also showed no effect on the excretion of lipids from dietary triacylglycerol (10). In the latter study there was no difference in plasma triacylglycerol between the basal period and the end of the 20-d period in which 50 g/d of olestra was consumed. There was, however, a reduction in plasma low density lipoprotein cholesterol in the normocholesterolemic subjects. The absence of an effect of olestra on fat absorption was confirmed by Daher *et al*. (45) in a study of the absorption of ^{14}C-triolein, in which absorption was reduced by only 1.2% by 32 g/d of olestra. From these data, and from the biochemical inertness of olestra, we may conclude that the ingestion of olestra does not introduce macronutrients into the large intestine. Dietary olestra therefore does not add substances to the colon contents that cause irritation or reactions that produce irritant chemicals as in the fermentation of fiber.

Studies of the effects of olestra on lipophilic micronutrients have repeatedly shown that olestra can reduce the absorption of these materials. The probability of interference increases with the lipophilicity of the nutrient and the mass of ingested olestra (43,46). The absorption of cholesterol, the fat-soluble vitamins, and carotenoids is lowered by the presence of olestra, but that of water-soluble vitamins is not affected. Because the amount of these lipophilic micronutrients is small (approximately 500 mg/d for cholesterol; several milligrams or micrograms/d for the vitamins), and because their retention in the olestra phase reduces their aqueous chemical activity, they do not alter normal patterns of fecal consistency or gastrointestinal motility.

Large Intestine. (i) Comparison of malabsorbed triacylglycerol with olestra. Normal digestion and absorption removes virtually all dietary triacylglycerol from the gastrointestinal tract by the completion of transit through the small intestine. As discussed earlier, dietary loads of 600 g/d, approximately six times normal levels, can be digested and absorbed (8), giving evidence of a large excess capacity of the fat digestion/absorption enzymes and structures in the small intestine. This complete absorption results in the colon typically containing 3–5 g of unabsorbed fat each day. The abnormally high excretion of triacylglycerol or products of its hydrolysis is clinically considered to reflect fat malabsorption and is referred to as steatorrhea. As discussed below, the reactions of this fat in the colon are of clinical importance.

Fat malabsorption can result from a number of causes. Inadequate emulsification accompanying bile obstruction hinders the hydrolysis of fat in the intestine. Incomplete hydrolysis also occurs because of pancreatic insufficiency in diseases such as cystic fibrosis or sprue. Unabsorbed, unhydrolyzed triacylglycerols pass from the ileum to the colon in these cases. Fat absorption does not take place in the large intestine, and most of the fat that exits from malabsorbers is in the form of fatty acid soaps (47). The hydrolysis of fat in the colon is known to result from the lipases associated with colonic bacteria.

The symptoms of steatorrhea presumably reflect the effects of hydrolyzed fat in the large intestine, since most excreted fat is in the form of fatty acids and soaps, and since fatty acids are known to induce fluid secretion and epithelial cell damage in the colon (48). These symptoms would not be expected from an inert, nonhydrolyzed lipid, such as olestra. Olestra is completely insoluble in aqueous systems and, therefore, its chemical activity is quite low. In contrast, the products of triacylglycerols hydrolyzed by bacterial lipases, particularly soaps, have significant aqueous phase activity and cause irritant and osmotic effects in the colon.

Further support for the inertness of olestra in the colon is the study by Aggarwal *et al.* (32), in which colonic transit was studied with ^{111}In pellets. In six subjects who received up to 30 g of olestra in a meal, there was no alteration of colonic transit by the substitution of olestra for triacylglycerols. The absence of an effect of olestra on aqueous fluid secretion was shown in a study of 93 subjects who ate 24 g/d of olestra for 36 d (49). Dietary olestra decreased fecal water concentration, and this effect was attributed to its dilution of the fecal mass rather than an alteration of fluid secretion.

(ii) The effect of olestra on the fecal matrix. Much understanding of the effects of a chemically inert lipid in the colon was achieved in the studies of olestra in animals and in clinical trials. The phenomena that occur during transit in the colon may be divided into those that are dependent on the rheology of the olestra phase (e.g., liquid or semisolid), and those that are dependent on the mass of ingested olestra. A study that addresses these two types of effects is discussed below.

Olestra rheology. The relationship between rheology of sucrose polyester formulations and fecal oil separation in an *in vitro* model has been discussed. The *in vitro* modeling work was subsequently followed by a human clinical investigation to evaluate the effect of varying rheology of sucrose polyester formulations on the characteristics of the stool (4). Following is a summary of the study design and results.

The primary objective of the study was to determine how variation in stiffness (i.e., thixotropic area) of sucrose polyester formulations affects subjects' assessment of oil loss and other gastrointestinal effects when consuming a high daily intake of olestra in savory snacks. These results were then used to set the rheological specification for olestra to ensure control of oil leakage. The study was conducted in multiple cities and was a parallel, double-blind, and placebo-controlled design. The subjects were 1,228 healthy males and females 18–44 yr in age. For five consecutive days, subjects consumed 4 ounces of potato chips that had been fried in either triacylglycerol (cottonseed oil placebo) or one of several different sucrose polyester formulations (derived from cottonseed oil)

as part of their normal diet. The potato chips provided 34 g/d of the placebo or test lipid. The sucrose polyester formulations were of varying stiffness, ranging from 18 to 103 kPa/s thixotropic area (see previous discussion for details regarding measurement of stiffness). After the 5-d consumption period, subjects completed a questionnaire regarding any underwear staining experiences resulting from oil loss (yellow-orange oil stains), the observation of oil droplets in the toilet following defecation, and other gastrointestinal effects.

Oil loss caused by the consumption of the various sucrose polyester formulations was measured by the subjects' reports of underwear oil staining. There was a marked decrease in the percentage of subjects who experienced staining for the sucrose polyester formulations of stiffness ≥50 kPa/s, relative to the lower stiffness formulations (Table 3). The percentage of subjects who reported oil staining when consuming sucrose polyester formulations with stiffness ≥50 kPa/s was not significantly different from the triacylglycerol placebo group (2.7 vs. 1.2%, respectively; $P < 0.05$). These data provided the basis for setting the current rheological specification in the olestra food additive regulation; i.e., olestra is defined as having a stiffness at 37.8°C not less than 50 kPa/s (see Table 1).

The incidence of oil droplets in the toilet after defecation was also affected by stiffness of the sucrose polyester formulations. The most fluid formulation (stiffness = 18 kPa/s thixotropic area) yielded the highest incidence of oil droplets in the toilet, 32.0% of the subjects. Formulations of stiffness ≥50 kPa/s yielded significantly fewer reports of oil droplets in the toilet (15.8% of subjects; $P < 0.05$). However, this incidence was significantly higher than the placebo group (4.7%; $P < 0.05$).

The percentage of subjects reporting other gastrointestinal effects for the placebo and olestra (stiffness ≥ 50 kPa/s) treatment groups are presented in Table 4. There was no significant difference between the placebo and olestra groups in reports of diarrhea-like stools or bloating ($P < 0.05$). Reports of certain other gastrointestinal effects were, however, significantly higher for the olestra group relative to the placebo (e.g., soft and loose stools, flatulence, urgency, abdominal pain or cramps).

Consideration of the mass of olestra. While the incidence of oil droplets in the toilet and certain other gastrointestinal effects in this study (Table 4) were higher for the olestra treatment group relative to the placebo, it is important to keep in mind that the primary objective of this study was to define the olestra rheological specification that ensures control of oil leakage. Therefore, daily olestra consumption was mandatory and purposely set at a high intake in order to stress the technology; 34 g/d is equivalent to ~3–4 times the 90th percentile chronic daily intake of lipid from snack foods for the age group tested (50). When considering the high daily consumption level, the increase in percentage of subjects who reported various gastrointestinal effects on the olestra treatment group is rather modest; i.e., 6–10 percentage points higher vs. the placebo group (Table 4). As mentioned at the beginning of this review, when olestra savory snacks are consumed *ad libitum*, the frequency of reports of these same gastrointestinal effects is no different from placebo (1,2).

TABLE 3
Incidence of Oil Loss, as Measured by Percentage of Subjects Who Reported Yellow-Orange Oil Staining of Underwear, When Consuming Placebo (cottonseed oil) and Sucrose Polyester Formulations of Varying Stiffness (thixotropic area)[a]

Treatment group	# Subjects	Incidence of oil loss[b] (% subjects who reported oil staining)
Placebo (triacylglycerol)	172	1.2[a]
Sucrose polyester formulations		
Stiffness < 50 kPa/s	347	6.9[a,b]
Stiffness ≥ 50 kPa/s	709	2.7[b]

[a]Subjects consumed 4 ounces of potato chips per day, providing 34 g/d of lipid, for five consecutive days (4).
[b]Values with the same superscript roman letter are significantly different ($P < 0.05$).

TABLE 4
Incidence of Selected Gastrointestinal (GI) Effects Reported by Subjects Consuming Placebo (cottonseed oil) and Olestra (stiffness ≥ 50 kPa/s)[a]

GI effect	Subjects reporting GI effect in response to direct questions[b] (%) Placebo group (n = 172)	Olestra group (n = 709)	
Diarrhea-like stools	16	20	
Soft stools	51	60	s
Loose stools	28	35	s
Bloating	29	32	
Flatulence	63	70	s
Urgency	30	40	s
Abdominal pain or cramps	22	28	s

[a]Subjects consumed 4 ounces of potato chips per day, providing 34 g/d of lipid, for five consecutive days (4).
[b]s = values in that row are significantly different ($P < 0.05$).

(iii) Olestra in patients with inflammatory bowel disease. Patients with ulcerative colitis and Crohn's disease were studied to determine whether olestra would have any deleterious effects in subjects with inflammatory bowel disease (51). Eighty-nine patients with known inflammatory bowel disease of at least 2 yr of mild-to-moderate ulcerative colitis (53 subjects) or Crohn's disease (46 subjects) entered a double-blind, placebo-controlled, parallel trial at 13 sites. All subjects were in remission at time of entry. The olestra group ate potato chips and cookies that contained olestra with a daily dose of 20 g/d while the placebo group ate the same foods prepared with normal fats. The duration of the diet-phase of the study was 4 wk, and a 4-wk follow-up period of observation concluded the study. There was no significant difference between the two groups in the worsening of symptoms during either part of the 8 wk of study (3 ulcerative colitis and 3 Crohn's patients in the olestra group; 1 ulcerative colitis and 3 Crohn's patients in the placebo group; $P > 0.15$). In addition, specific tests including bowel permeability (by measurement of urinary excretion of polyethylene glycol), and assessment of condition of the ulcerative colitis patients by flexible sigmoidoscopy, did not show any significant differences between the

two groups. The investigators concluded that olestra did not affect the activity of the ulcerative colitis or Crohn's disease in the patients.

A study in an animal model of inflammatory bowel disease showed that mucosal damage did not result in absorption of olestra (52). Guinea pigs with gastrointestinal tract lesions from consumption of poligeenan did not absorb ^{14}C-labeled olestra as shown by analyses of tissue lipids and sucrose in urine.

(iv) Olestra and microflora in the colon. The interaction of olestra with microbes in the colon has been studied. Early studies showed no evidence that olestra was metabolized by microflora in the human colon (10), since quantitative recovery of excreted sucrose polyester was consistent with the absence of degradation. This observation was important since the entry of triacylglycerols into the colon results in the symptoms of steatorrhea including severe diarrhea due to hydrolysis of triacylglycerols by bacterial lipases to fatty acids and soaps. *In vitro* studies confirmed microflora from human feces did not metabolize olestra (53). Fecal samples from subjects who had consumed olestra for 3–4 wk were used to inoculate anaerobic media containing ^{14}C-labeled olestra, and there was no evidence of change to the olestra molecule or production of metabolites from it.

It was shown that olestra in the diet reduced the chemical modification of sterols in the colon, and this observation was attributed to isolation of the sterols from microflora by sequestration in the olestra phase rather than an alteration in the microflora (54). Siigur *et al.* (55) confirmed this result. In addition to measuring the conversion of cholesterol to coprostanol, Siigur *et al*. found that olestra did not consistently change three other markers of intestinal microecology. Fecal tryptic activity degradation, mucin degradation, and β-aspartyl glycine (a product of microorganisms in the colon) were altered by dietary olestra. In that study, dietary olestra did reduce the conversion of bilirubin to urobilin. This effect was attributed to partitioning of bilirubin, a lipophilic substance, into the olestra phase with a reduction in its availability for bacterial modification.

There is other evidence that microecology of the large intestine is normal when olestra is part of the diet. A study of olestra's effect on breath hydrogen and methane production and fecal microbe counts confirmed this conclusion (56). Among 94 subjects who received olestra for 36 d, there were no significant effects on the numbers or distribution of colonic bacteria. Breath hydrogen and methane were unaltered by dietary olestra. A trend was seen for lower hydrogen in the breath of subjects who ate both olestra and a high level of fiber, but the authors concluded that olestra does not interfere with normal intestinal fermentation of dietary fiber and does not alter gut microflora population.

(v) Intestinal morphology and histology. Studies of chronic ingestion of olestra, including lifetime studies of rodents, showed that olestra does not cause changes in the histology or morphology of any intestinal tissues (57). These observations are consistent with a lack of cell injury from olestra itself as well as the absence of any reactive chemical species produced from olestra during gastrointestinal transit. Neither pancreatic nor bacterial enzymes alter olestra into products with activities that are known to alter mucosal structure or function.

CONCLUDING COMMENTS

Olestra is currently approved for use only in the preparation of snack foods, as described in the olestra food additive regulation (4). Given the understanding of the ingestion patterns of snack food items, it has been possible to estimate the expected use of olestra (50). The estimates of mean chronic intake of olestra in the United States ranged from 1.8 (females above 64 yr) to 4.7 g/d (males of ages 13–17 and 18–44). The 90th percentile range of intake was 4.1 (females above 64) to 11.0 g/d (males 18–44). Estimated mean acute intakes ranged from 5.5 (females above 64) to 16.5 g/d (males 13–17). The 90th percentile acute intakes ranged from 10.2 (females above 64) to 24.0 g/d (females 13–17). All of these estimates are based on the assumption that 100% of the lipid in the snacks will be olestra. Initial postmarketing surveillance data show consumption to be less than these estimates. Based on interviews with 1525 adults who consumed olestra snacks, the median consumption was 8.1 g of olestra per month, with 90th percentile consumption of 64.4 g per month (58).

Studies which have shown that gastrointestinal effects do not differ between olestra-based snacks and regular triacylglycerol-based chips included realistic consumption levels that reflect these snack intake patterns. In one study, the olestra-chip group ate approximately 18 g/d of olestra (2 ounces of chips) and reported no more gastrointestinal symptoms than the regular triacylglycerol chip group (2). Another study rechallenged subjects who had called a toll-free number with reports of gastrointestinal problems after the use of purchased snacks that contained olestra (1). In this double-blind, placebo-controlled test, there were no differences in gastrointestinal symptoms between subjects who received olestra-based chips and those who received regular, digestible fat-based chips. In this study, subjects ate 2 ounces of chips, which contained approximately 18 g of olestra. These studies were carried out with snacks fried in a formulation of olestra (Olean®) that resulted from a basic understanding of the phase behavior and rheology of olestra. Through optimization of the solid sucrose polyester fatty acid composition, Olean® was produced to address the gastrointestinal issues associated with a nonabsorbable fat substitute while delivering the desired taste and texture benefits of fat in the mouth. Olean® is a direct consequence of a fundamental understanding of the properties and chemistry of edible lipids and lipid substitutes.

Effect of Dietary Docosahexaenoic Acid on Desaturation and Uptake *in vivo* of Isotope-Labeled Oleic, Linoleic, and Linolenic Acids by Male Subjects

E.A. Emken[a,*], R.O. Adlof[b], S.M. Duval[b], and G.J. Nelson[c]

[a]Midwest Research Consultants, Princeville, Illinois 61559, [b]USDA, ARS, NCAUR, Food Quality and Safety Research, Peoria, Illinois 61604, and [c]USDA, ARS, Western Human Nutritional Research Center, University of California, Davis, California 95616

ABSTRACT: The effect of dietary docosahexaenoic acid (22:6n-3, DHA) on the metabolism of oleic, linoleic, and linolenic acids was investigated in male subjects (n = 6) confined to a metabolic unit and fed diets containing 6.5 or <0.1 g/d of DHA for 90 d. At the end of the diet period, the subjects were fed a mixture of deuterated triglycerides containing 18:1n-9[d6], 18:2n-6[d2], and 18:3n-3[d4]. Blood samples were drawn at 0, 2, 4, 6, 8, 12, 24, 48, and 72 h. Methyl esters of plasma total lipids, triglycerides, phospholipids, and cholesterol esters were analyzed by gas chromatography–mass spectrometry. Chylomicron triglyceride results show that the deuterated fatty acids were equally well absorbed and diet did not influence absorption. Compared to the low-DHA diet (LO-DHA), clearance of the labeled fatty acids from chylomicron triglycerides was modestly higher for subjects fed the high DHA diet (HI-DHA). DHA supplementation significantly reduced the concentrations of most n-6[d2] and n-3[d4] long-chain fatty acid (LCFA) metabolites in plasma lipids. Accumulation of 20:5n-3[d4] and 22:6n-3[d4] was depressed by 76 and 88%, respectively. Accumulations of 20:3n-6[d2] and 20:4n-6[d2] were both decreased by 72%. No effect of diet was observed on acyltransferase selectivity or on uptake and clearance of 18:1n-9[d6], 18:2n-6[d2], and 18:3n-3[d4]. The results indicate that accumulation of n-3 LCFA metabolites synthesized from 18:3n-3 in typical U.S. diets would be reduced from about 120 to 30 mg/d by supplementation with 6.5 g/d of DHA. Accumulation of n-6 LCFA metabolites synthesized from18:2n-6 in U.S. diets is estimated to be reduced from about 800 to 180 mg/d. This decrease is two to three times the amount of n-6 LCFA in a typical U.S. diet. These results support the hypothesis that health benefits associated with DHA supplementation are the combined result of reduced accretion of n-6 LCFA metabolites and an increase in n-3 LCFA levels in tissue lipids.

Paper no. L8245 in *Lipids 34,* 785–791 (August 1999)

Various animal, human, and epidemiology studies have suggested that dietary docosahexaenoic acid (22:6n-3, DHA) has a beneficial effect on a variety of chronic diseases. These and other studies related to the physiological and health effects of n-3 fatty acids were recently reviewed (1,2).

Results from the clinical part of this dietary DHA study showed that supplementation of normal diets with 6.5 g/d of DHA increased the DHA content of platelet lipids by threefold and the eicosapentaenoic acid (EPA, 20:5n-3) content by more than sevenfold. The DHA and EPA content of plasma total lipid increased by 4.4- and 8.9-fold, respectively. Triglyceride concentrations were decreased by 16.7% and apolipoprotein E levels increased by 71% (3,4). Dietary DHA supplementation did not produce measurable changes in blood coagulation, *in vivo* bleeding times, platelet function, or thrombotic tendencies. Inhibition of immune response was not observed, but white blood cell count was significantly reduced due to a decrease in granulocytes (5). Synthesis of thromboxane was reduced by 35% ($P = 0.013$), and prostacyclin was not significantly reduced. (6).

Several studies investigated the inhibition by dietary n-6 fatty acids on conversion of 18:3n-3 to n-3 long-chain fatty acid (LCFA) metabolites (1,2). Conversion of 18:3n-3 to n-3 LCFA metabolites is reduced by 18:2n-6, and the DHA content of tissue lipids is not greatly increased by diets containing large amounts of 18:3n-3 (2). EPA and linoleic acid are reported to inhibit delta-6 and delta-5 desaturase activities in human CaCo-2 enterocyte cell lines (7). Recently we showed that dietary arachidonic acid significantly inhibited the accumulation of n-6 LCFA metabolites synthesized from isotope-labeled 18:2n-6 (8) and, paradoxically, stimulated the conversion of isotope-labeled 20:3n-6 to 20:4n-6 (9). Incorporation and acyltransferase selectivity of deuterated 20:4n-6 were not altered in subjects fed arachidonic acid-supplemented diets but turnover was reduced (10). In general, desaturase activity is inhibited by most dietary n-6 and n-3 fatty acids, but acyltransferase selectivity is generally not influenced.

The results from studies with a variety of fatty acid structures suggest that the physiological effects of dietary DHA may be related to its effect on desaturation and incorporation of 18:1n-9, 18:2n-6, and 18:3n-3. Thus, the objective of this

stable isotope study was to determine if DHA supplementation inhibits desaturation and elongation of 18:2n-6 and 18:3n-3 and to investigate the effect of DHA on absorption, uptake, and turnover of 18:1n-9, 18:2n-6, and 18:3n-3 in human subjects.

EXPERIMENTAL PROCEDURES

Study design. Six Caucasian male subjects between the ages of 28 and 39 yr were housed in a metabolic ward. Physical examinations and clinical blood profile data indicated that the subjects were in good health. Medical histories indicated no evidence of congenital ailments. The subjects' height/weight ratios, blood pressures, fasting serum cholesterol, and triglyceride concentrations were within normal ranges. Physical characteristics and plasma lipid profiles for the subjects are summarized in Table 1. Plasma lipid data were obtained at the end of the 90-d diet period. Institutional ethical approval for the study protocol was obtained from the Agricultural Research Service's Human Studies Institutional Review Committee and the University of California at Davis, Human Subjects Committee. Informed consent was obtained from each subject before initiation of the study.

Diets. The subjects were provided a high DHA (HI-DHA) diet that contained 6.5 g/d of 22:6n-3 or a low DHA (LO-DHA) diet that contained <0.1 g/d of 22:6n-3. DHASCO™ oil (15 g/d) was added as the source of 22:6n-3 in the HI-DHA diet. The DHASCO™ oil was provided by Martek Bioscience Corp. (Columbia, MD), and is the Trademark name for a microalgal single-cell oil that contains a high level of DHA. An equal amount of safflower oil (15 g/d) was added to the LO-DHA diet. The subjects were fed these diets for 90 d prior to the deuterium isotope experiment. The fatty acid compositions of the diets were similar except for 22:6n-3. The fatty acid and macronutrient compositions of the diets are summarized in Table 2. The fatty acid composition of the DHASCO™ oil (wt%) was 3.5% 12:0; 13.1% 14:0; 11.4% 16:0; 1.4% 16:1; 1.2% 18:0; 30.0% 9*c*-18:1; 1.1% 18:2n-6; <0.01% 18:3n-3; 0.4% 22:0; 38.0% 22:6n-3. All meals were prepared from weighed food portions and their consumption was monitored. Duplicate meals were collected and analyzed for fatty acid composition. Values for total fat, protein, and carbohydrate were obtained by analysis of diet composites and were similar to calculated values based on food composition data in USDA Handbook 8 (11). No significant changes in the subjects' weights were observed during the controlled diet period, indicating a stable energy balance. Detailed information on the study design and diet compositions was described previously (3).

Deuterated fatty acids. Deuterium-labeled methyl *cis*-9-octadecenoate-14,14,15,15,17,18-d6 (18:1n-9[d6]) and methyl *cis*-9,*cis*-12-octadecadienoate-12,13-d2 (18:2n-6[d2]) were synthesized, purified, and converted to their triglycerides by previously described methods (12,13). Methyl *cis*-9,*cis*-12,*cis*-15-octadecatrienoate-12,13,15,16-d4 (18:3n-3[d4]) was prepared by a Lindlar-catalyzed deuteration of the diacetylene precursor (9c,12a,15a-18:3). The preparation of 9c,12a,15a-18:3 was achieved by modification of a previously described procedure (14). The isotopic purity of the deuterated fatty acids was: 88.6% for 18:1n-9[d6], 78.6% for 18:2n-6[d2], and 83.6% for 18:3n-3[d4]. Chemical purity was 99% for 18:1n-9[d6], 88% for 18:2n-6[d2], and 95% for 18:3n-3[d4]. The impurities in these samples were *trans* fatty acid isomers. The 18:2n-6[d2] sample also contained small amounts of nonlabeled 16:0, 18:0, and 18:1n-9.

Stable isotope study design. A mixture of deuterated triglycerides containing 52.6 g of deuterated 18:1n-9[d6], 18:2n-6[d2], and 18:3n-3[d4] was emulsified with 763.5 g of no-fat yogurt. After a 12-h overnight fast, each subject was fed an equal portion of the total mixture between 7:00 and 7:50 A.M. The amount of deuterated triglycerides fed to each subject was 3.1 g 18:1n-9[d6], 2.4 g 18:2n-6[d2], and 2.3 g 18:3n-3[d4] after adjusting the weights for chemical and isotopic purity. Subjects were provided a no-fat breakfast at 8:00 A.M. to avoid dilution of the labeled fatty acid with exogenous fatty acids. A low-fat (*ca.*15% fat calories) lunch containing no added safflower or DHASCO™ oil was provided at 12:00, and the usual diets were fed at 5:00 P.M. and on subsequent days.

Sample collection. Blood samples (6 to 10 mL each) were collected by venipuncture at 0, 4, 6, 8, 12, 24, 48, and 72 h and used to isolate plasma lipid classes. Additional blood samples (*ca.*12 mL) were collected at 2, 4, 6, 8, and 12 h and used to isolate chylomicron total lipid. Chylomicron fractions were isolated by standard preparative ultracentrifuge meth-

ods (15). Several representative chylomicron samples were analyzed by electrophoresis to confirm the purity of the chylomicron fractions (16).

Analysis of plasma lipid fatty acids. Plasma lipids were extracted with 2:1 chloroform/methanol (17). Preparative thin-layer chromatography (TLC) was used to isolate triglyceride, cholesterol ester, and phospholipid fractions from plasma total lipid (18). Known weights of triheptadecanoin, cholesterol heptadecanoate, and diheptadecanyl-*sn*-phosphatidylcholine (Applied Science, State College, PA) were added as internal standards to the total lipid extract. Methyl esters of the isolated lipid classes were prepared by heating the samples with a 5% HCl–methanol solution (19).

The percentages of labeled and unlabeled fatty acids in the plasma lipid classes were obtained by gas chromatography–mass spectroscopy (GC–MS) analysis of their methyl esters. Data for the added 17:0 internal standards were used to determine the concentrations (μg/mL) of each deuterated and nondeuterated fatty acid. A Hewlett-Packard model 5988A quadrupole mass spectrometer (Palo Alto, CA) operated in a positive chemical ionization mode with isobutane as the ionization reagent was used to analyze the methyl ester samples. The GC–MS methodology utilized selected ion monitoring of the appropriate ion masses for the fatty acid in each GC peak. The areas for each of the ion masses monitored were obtained by integration of the peaks. The GC–mass spectrometer was equipped with a Supelcowax 10 fused-silica column (30 m × 0.25 mm; Supelco Inc., Bellefonte, PA). The column was temperature programmed from 165 to 265°C at 5°C/min with a 20-min final hold. The specific operating conditions and computer-assisted storage and processing of the MS data were described previously (20,21). Response factors were determined by analysis of standard mixtures containing weighed amounts of pure fatty methyl esters purchased from Nu-Chek-Prep Inc. (Elysian, MN) and Applied Science. The accuracy of the GC–MS data was determined by adding known weights of 18:1n-9[d6], 18:2n-6[d2], and 18:3n-3[d4] to samples of plasma triglyceride, phospholipid, and cholesterol ester from subjects that were not fed the deuterated fatty acid mixture. The weight for each of the deuterated fatty esters added was equal to about 0.3% of the total unlabeled fatty acids in the samples. Standard deviations were based on three replicate analyses. The standard deviations for the 18:1n-9[d6], 18:2n-6[d2], and 18:3n-3[d4] in the triglyceride, phospholipid, cholesterol ester spiked samples ranged from ± 0.002 to 0.004%.

The accuracy of the unlabeled methyl ester data obtained by GC–MS was checked by analysis of a subset of samples using a Varian model 3400 gas chromatograph (Varian, Walnut Creek, CA), equipped with a 100 m × 0.25 mm SP2560 fused-silica capillary column (Supelco) and a flame-ionization detector. Operating conditions were: split ratio, 1:100; linear velocity of helium, 21 cm/s; detector and injection temperature, 235°C. The identification and accuracy of the GC peaks areas were confirmed by comparison to data for authentic standards and mixtures of known composition.

Statistical analysis and calculations. Data were analyzed with the SAS-PC statistical software package from Statistical Analysis System Institute (Cary, NC). A two-tailed, unpaired *t*-test was used to test for significant differences between data from subjects fed the LO-DHA and HI-DHA diets (22). The concentration data (μg/mL) for the deuterated fatty acids and their metabolites were normalized to compensate for differences in subject plasma lipid concentrations. Normalization was achieved by dividing the μg of deuterated fatty acid/mL plasma data by the total plasma lipid methyl ester concentrations (mg/mL). The μg of deuterated fatty acid per mg of total plasma lipid data were then divided by the weight of deuterated fatty acids in the fed mixtures to normalize the data to a per gram of deuterated fatty acid fed basis. Time-course curves were produced by plotting the normalized μg deuterated fatty acid/mg of total lipid data for the eight samples collected over the 72-h study period. The n-6 and n-3 total area data shown in the bar graphs are weighted averages for the samples collected and were obtained by calculating the total area under the time-course curve, as described previously (8,9,23). The values obtained represent the weighted averages of the eight plasma lipid samples collected over the 72-h period.

RESULTS

Absorption. Time-course curves for the μg of deuterium-labeled fatty acids per mg of total chylomicron lipid are shown in Figure 1. The results show that the labeled fats were equally well absorbed. The shapes of all of the curves for the

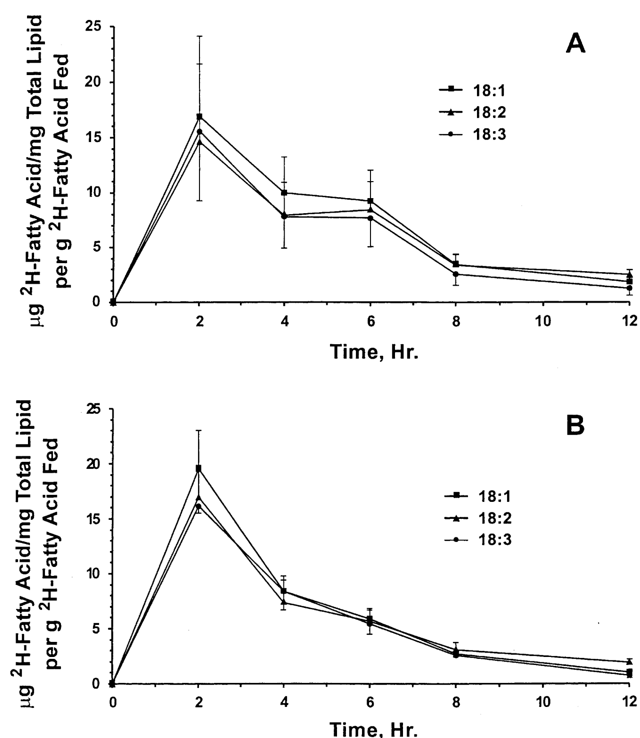

FIG. 1. Time-course plots for uptake and clearance of deuterium-labeled oleic, linoleic, and linolenic acids in chylomicron total lipids of subjects fed the low docosahexaenoic acid (LO-DHA) (A) and high docosahexaenoic acid (HI-DHA) (B) diets. Each data point is the average for data from three subjects. Error bars equal standard deviation. Error bars are not shown when less than the size of the symbol.

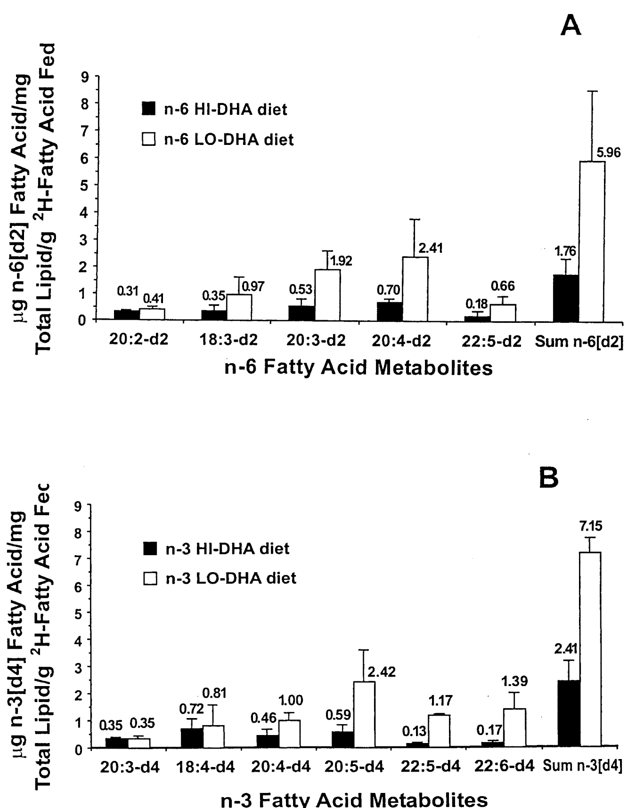

FIG. 2. Weights for n-6[d2] (A) and n-3[d4] (B) long-chain fatty acid metabolites in plasma total lipid from male subjects fed diets containing <0.1 g/d (LO-DHA) and 6.5 g/d (HI-DHA) of 22:6n-3. The value for each bar is the average of the area-under-curve data from three subjects. Error bars equal standard deviation. See Figure 1 for abbreviations.

LO-DHA and HI-DHA subject groups are similar except the amount of each labeled fatty acid was consistently about 30% lower ($P < 0.01$) in the 6-h samples from the HI-DHA group. These results suggest that dietary DHA supplementation produced a transient increase in chylomicron triglyceride clearance. The results are consistent with the decrease in triglyceride levels observed for the HI-DHA diet group in the clinical part of this study (4).

Conversion to LCFA metabolites. The incorporation of n-6 [d2] and n-3[d4] long-chain fatty acid products into plasma total lipid are compared in Figure 2 for subjects fed the LO-DHA and HI-DHA diets. Total weight data for the n-6[d2] and n-3[d4] LCFA metabolites were calculated from the areas under the time-course curves. Each bar represents the average for three subjects. The total amount of deuterated n-6 LCFA in the entire plasma pool was 9.3 ± 0.58 mg for the HI-DHA diet group and 40.25 ± 2.6 mg per g of 18:2n-6[d2] fed for the LO-DHA diet group. The total amount of deuterated n-3 LCFA was 12.7 ± 0.77 mg for the HI-DHA diet group and 48.25 ± 0.55 mg per g of 18:3n-3[d4] fed for the LO-DHA diet group.

The plasma total lipid data show that supplementation with dietary DHA significantly reduced the total amounts of n-6 [d2] and n-3[d4] LCFA metabolites synthesized by desaturation–elongation of 18:2n-6[d2] and 18:3n-3[d4]. Weights for the n-6[d2] LCFA metabolites were reduced by 64 to 73% with an overall decrease of 70% ($P < 0.05$), and weights for the n-3[d4] LCFA metabolites were reduced by 54 to 89% with an overall decrease of 66% ($P < 0.001$). The amount of elongated-only metabolites, 20:2n-6[d2] and 20:3n-3[d4], was not significantly different.

Uptake and turnover. Plasma triglyceride, total phospholipid, and cholesterol ester data for incorporation and disappearance of 18:1n-9[d6], 18:2n-6[d2], and 18:3n-3[d4] are compared in Figures 3, 4, and 5. Each time-course curve represents the average for three subjects from the LO-DHA and HI-DHA diet groups. The LO-DHA and HI-DHA diet time-course curves for each plasma lipid class are similar. Weights for the deuterated fatty acids were consistently lower in the plasma triglyceride 6-h samples for the subjects fed the HI-DHA diet ($P < 0.04$), but data for other time points were not significantly different. The average weight for 18:2n-6[d2] in the plasma total phospholipid and cholesterol ester samples from both diet groups was four to five times higher than for 18:1n-9[d6] and 18:3n-3[d4]. These results show that supplementation with dietary DHA does not affect uptake and turnover of dietary 18:1n-9, 18:2n-6, and 18:3n-3 in plasma triglyceride, total phospholipid, or cholesterol ester.

The total plasma lipid data for isotope-labeled oleic,

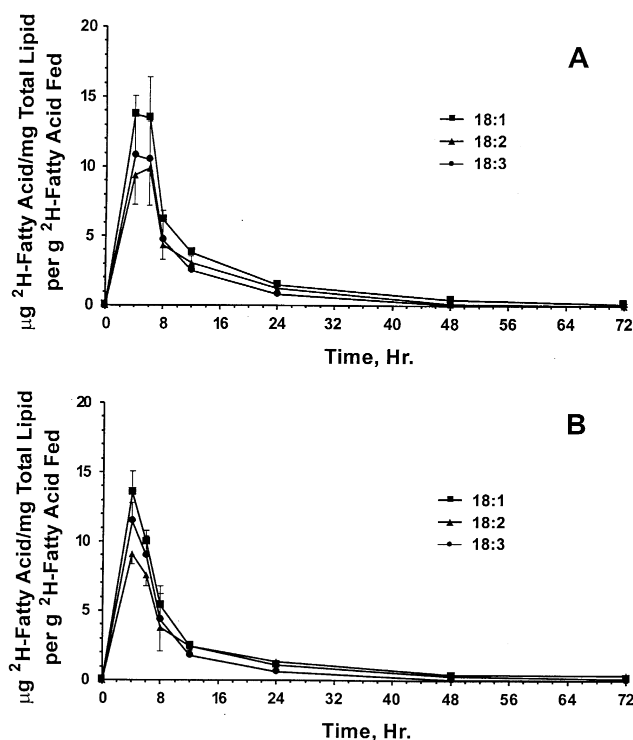

FIG. 3. Time-course plots for uptake and clearance of deuterium-labeled oleic, linoleic, and linolenic acids in plasma triglycerides of subjects fed the LO-DHA (A) and HI-DHA (B) diets. Each data point is the average for data from three subjects. Error bars equal standard deviation. Error bars are not shown when less than the size of the symbol. See Figure 1 for abbreviations.

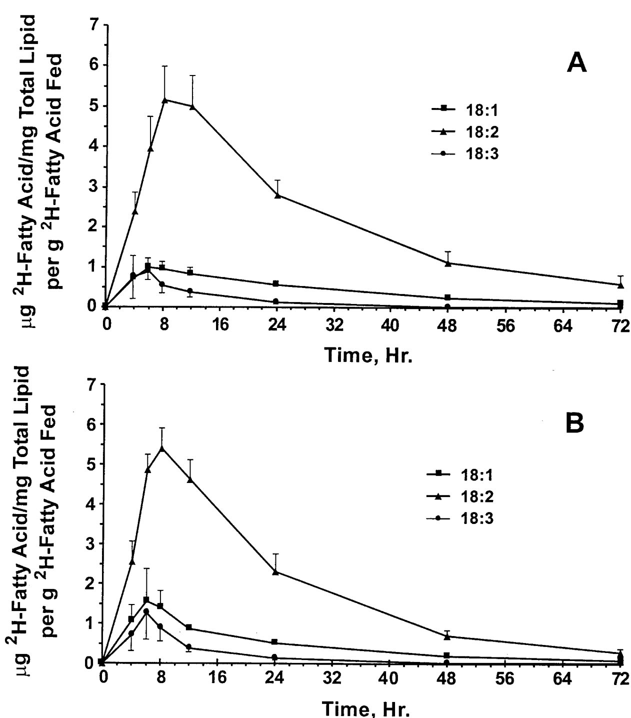

FIG. 4. Time-course plots for uptake and clearance of deuterium-labeled oleic, linoleic, and linolenic acids in plasma total phospholipid of subjects fed the LO-DHA (A) and HI-DHA (B) diets. Each data point is the average for data from three subjects. Error bars equal standard deviation. Error bars are not shown when less than the size of the symbol. See Figure 1 for abbreviations.

linoleic, and linolenic acids are plotted as a percentage of the total deuterated fatty acids in Figure 6. The percentage data are calculated from under-the-curve total weight data. The percentage of 18:2n-6[d2] was three to four times higher than for 18:1n-9[d6], and the percentage of 18:1n-9[d6] was 3 to 3.5 times higher than for 18:3n-3[d4]. Inspection of Figures 3, 4, and 5 indicates that plasma phospholipid and cholesterol ester lipid classes are responsible for most of the difference. These results illustrate the previously reported high selectivity for incorporation of 18:2n-6 and the strong discrimination against 18:3n-3 relative to 18:1n-9 (23). The combined results displayed in Figures 3 to 6 show that dietary DHA does not influence acyltransferase selectivity for the C18 unsaturated fatty acids.

DISCUSSION

In clinical studies long-chain n-3 fatty acids are observed to decrease fasting chylomicron and plasma triglyceride levels and to improve postprandial clearance (4,24,25). It was suggested that both effects reduce coronary heart disease risk (26–28). The enhanced clearance of the deuterium-labeled fatty acids in the 6-h chylomicron total lipid and plasma triglyceride samples from the HI-DHA diet group are consistent with results from clinical studies. These results provide additional evidence that supplementation with DHA containing no EPA may enhance postprandial triglyceride clearance.

Most clinical results, including this study, show that DHA supplementation does not affect serum cholesterol levels (4,24). These clinical results suggest that dietary DHA does not alter the mechanisms responsible for regulation of cholesterol synthesis and removal. This metabolic study shows that DHA supplementation did not alter phospholipid and lecithin/cholesterol acyltransferase selectivity or the relative proportions of deuterated 18:1n-9, 18:2n-6, and 18:3n-3 incorporated into plasma phospholipid and cholesterol ester. The absence of an effect of DHA supplementation on 18:1n-9, 18:2n-6, and 18:3n-6 metabolism is consistent with the lack of an effect of DHA on serum cholesterol levels. The plasma cholesterol ester results also suggest that dietary DHA may not alter liver cholesterol/cholesterol ester ratios and cholesterol oleate/cholesterol linoleate ratios that influence low density lipoprotein receptor activity. The metabolic results from this study suggest that the reason DHA does not influence serum cholesterol is that DHA does not affect dietary C18 unsaturated fatty acid metabolism and the cholesterol regulation mechanisms that are influenced by C18 unsaturated fatty acids.

DHA supplementation resulted in a substantial decrease in accumulation of most n-6[d2] and n-3[d4] LCFA metabolites. The results show that dietary 18:2n-6 and DHA do not

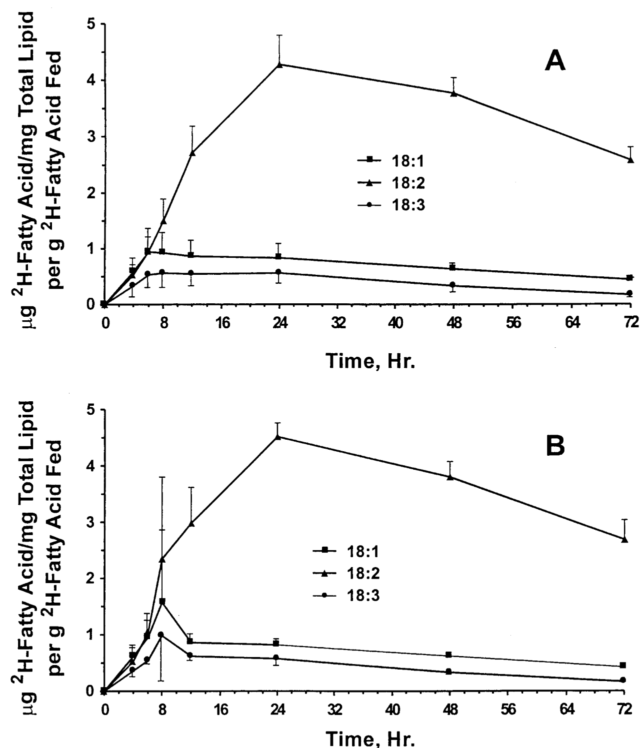

FIG. 5. Time-course plots for uptake and clearance of deuterium-labeled 18:1n-9, 18:2n-6, and 18:3n-3 in plasma cholesterol ester of subjects fed the LO-DHA (A) and HI-DHA (B) diets. Each data point is the average for data from three subjects. Error bars equal standard deviation. Error bars are not shown when less than the size of the symbol. See Figure 1 for abbreviations.

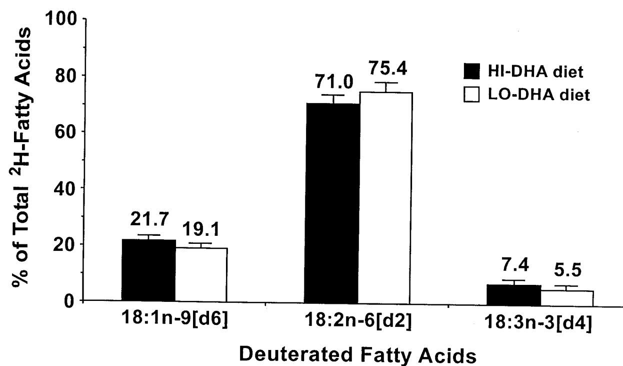

FIG. 6. Percentage of deuterated oleic, linoleic, and linolenic acids in human plasma total lipid. Each bar is the average for data from three subjects. Error bars equal standard deviation. See Figure 1 for abbreviations.

equally inhibit accretion of n-6 and n-3 LCFA metabolites. Dietary intake of 18:2n-6 was 7 g/d higher, and DHA intake was 6.5 g/d lower for the LO-DHA diet group compared with the HI-DHA group. The total plasma lipid data shown in Figure 2 for the HI-DHA and LO-DHA groups would have been similar if dietary 18:2n-6 and DHA equally inhibited accumulation of deuterated n-6 and n-3 LCFA metabolites.

Summary and implications. DHA supplementation slightly enhanced triglyceride clearance and reduced the concentrations of most desaturated-elongated n-6[d2] and n-3[d4] LCFA metabolites by more than 50%. Dietary 18:2n-6 and DHA did not equally inhibit accumulation of LCFA metabolites. DHA supplementation did not influence C18 unsaturated fatty acid absorption, incorporation or turnover in human plasma lipids. There was no effect on elongation or the relative selectivity of the acyltransferases for oleic, linoleic, and linolenic acids.

Feedback inhibition by 6.5 g/d of dietary DHA is estimated to reduce accumulation of n-3 LCFA metabolites synthesized from the 2.5 g of 18:3n-3 (29,30) in typical U.S. diets from 121 to 32 mg/d or by *ca.* 66%. Accumulation of n-6 LCFA metabolites synthesized from the 20 g of 18:2n-6 present in U.S. diets (29,30) is estimated to be reduced from 805 to 186 mg/d, or by *ca.* 70%. For the HI-DHA diet, inhibition by DHA supplementation on n-3 LCFA synthesis is relatively unimportant because it represents only about 1.5% of the *ca.* 6.5 g/d n-3 LCFA in the HI-DHA diet. Inhibition of n-6 LCFA metabolite accumulation is important. For the HI-DHA diet group, available n-6 LCFA metabolites were reduced from about 900 mg/d (100 mg from diet and 800 mg from 18:2n-6 conversion) to about 380 mg/d. This large difference suggests that an important effect of dietary DHA is the reduction of n-6 LCFA synthesized from 18:2n-6. The results of this study provide additional evidence to support the hypothesis that reduction of n-6 LCFA metabolite accretion and the increase in n-3 LCFA levels in tissue lipids both contribute to the health benefits attributed to fish oil and DHA supplementation.

ABSTRACT: Docosahexaenoic acid (DHA; 22:6n-3) is found in extremely high levels in human ejaculate with the majority occurring in the spermatozoa. However, the relative concentration of DHA and other fatty acids, in blood serum, seminal plasma, and spermatozoa of asthenozoospermic vs. normozoospermic individuals is not known. We analyzed the phospholipid fatty acid composition of blood serum, seminal plasma, and spermatozoa of normozoospermic men and asthenozoospermic men in order to determine if DHA levels, as well as the levels of other fatty acids, differed. The serum phospholipid DHA levels were similar in the two groups, suggesting similar intakes of dietary DHA. On the other hand, seminal plasma levels of DHA (3.0 vs. 3.7%) and total polyunsaturated fatty acids (PUFA) (11.8 vs. 13.5%) were significantly lower in asthenozoospermic vs. normozoospermic men, respectively, while 18:1 (19.0 vs. 16.8%) and monounsaturated fatty acids (MUFA) (24.2 vs. 21.7%) were significantly higher in the asthenozoospermic vs. the normozoospermic men. Spermatozoa from asthenozoospermic men had higher levels of 18:1, 20:0, 22:0, 22:1, and 24:0 than sperm from normozoospermic men, and lower levels of 18:0 and DHA (8.2 vs. 13.8%). Furthermore, total MUFA (19.3 vs. 16.5%) was higher and total PUFA (19.0 vs. 24.0%), n-3 fatty acids (9.3 vs. 14.6%), and the ratio of n-3 to n-6 fatty acids (1.0 vs. 1.6) were lower in the asthenozoospermic men. Therefore, in asthenozoospermic individuals, lower levels of DHA in the seminal plasma, but not in the blood serum, mimic the decreased concentrations of DHA in the spermatozoa. This suggests that the lower concentrations of spermatozoon DHA in these individuals are due not to dietary differences but to some type of metabolic difference in the asthenozoospermic men.

Paper no. L8237 in *Lipids 34*, 793–799 (August 1999).

In recent years, the prognosis for infertile couples has improved dramatically. Male-factor infertility, however, plays a role in the inability of approximately 45% of childless couples to achieve pregnancy, and still remains difficult to treat (1,2). Poor sperm-forward motility (asthenozoospermia) is considered to contribute to the infertility of a significant number of males, and many cases of decreased sperm motility are not completely understood (3).

Docosahexaenoic acid (DHA; 22:6n-3) is found in extremely high levels in human ejaculate (4,5), and the concentration of DHA in both ejaculate and spermatozoa has been suggested to be positively associated with sperm motility in various species including chickens (6) and humans (4,5,7,8). Phospholipids (PL) in normal human spermatozoa are approximately 14.3% DHA (7,9). In rhesus monkeys, the majority of DHA appears to be in phosphatidylethanolamine and phosphatidylcholine fractions (10). Interestingly, DHA levels have been shown to be lower in complete ejaculates from asthenozoospermic individuals vs. normozoospermic individuals (4,5), as well as in certain sperm fractions from asthenozoospermic vs. normozoospermic individuals (7). DHA may contribute to the membrane fluidity necessary for the motility of sperm tails (11), and as such it makes up almost 20% of PL fatty acids in the tails of monkey sperm and approximately 14% of PL fatty acids in the tails of human sperm (7). In humans (7), the majority of PL DHA appears to be in the head (33.7 vs. 14.0% in the tail), whereas in monkeys (11), the majority of DHA appears to be in the tail (20.0 vs. 4.5% in heads). The role of DHA in the motility of the spermatozoa is not completely clear although it has been suggested that DHA is involved in the regulation of free fatty acid utilization by sperm (12,13). DHA can also be slowly metabolized to 19,20-dihydroxy-4,7,10,13,16-docosapentaenoic acid by monkey seminal vesicles (14).

Measures of eicosapentaenoic acid (EPA) and DHA in serum and plasma PL have been considered useful biological indicators for EPA/DHA intake and nutritional status (15–17). It is not clear whether DHA status in other biological fluids (i.e., seminal plasma, sperm) also reflects dietary intake or whether the levels of DHA in the sperm or seminal plasma reflect the DHA status of blood serum.

The purpose of the present study was to determine whether DHA status of blood-serum PL, seminal-plasma PL, and sperm PL differs between normozoospermic men and astheno-

zoospermic men, and if so, to determine whether DHA levels in the sperm or seminal plasma reflect serum DHA levels. The fatty acid analysis of total sperm from the ejaculate of asthenozoospermic vs. normozoospermic individuals has never been investigated, nor has the comparison been made in terms of the fatty acid analysis of seminal plasma in these two groups. The inclusion of blood serum was of interest in order to rule out possible dietary differences influencing the sperm/seminal plasma fatty acid status.

MATERIALS AND METHODS

Subjects and experimental design. The subjects were 73 healthy males (43 control and 30 asthenozoospermic individuals) who were patients of the Reproductive Endocrinology and Infertility Program at the London Health Sciences Centre seeking diagnostic semen analysis. Approval for this study was granted by the Human Ethics Committee of the London Health Sciences Centre and the University of Western Ontario, and written informed consent was obtained from each subject. Subjects were determined to be either normozoospermic (control) or asthenozoospermic after analysis of sperm motility. The sperm motility criteria applied in our study to the normozoospermic and asthenozoospermic individuals were ≥60% and ≤50%, respectively, based on the recommendation of Mortimer (18).

Semen analysis. Semen samples were produced on-site by masturbation into a sterile container and allowed to liquefy for 30 min before analysis. Conventional manual assessments were performed by an experienced technician, in accordance with the recommendations of the World Health Organization (19), for ejaculate volume and sperm motility, as well as sperm concentration using hemacytometer count. Following the assessment, 0.5 or 1.0 mL aliquots (volume depending on the availability of the individual) of each sample were placed into an Eppendorf tube (1.5 mL capacity) and centrifuged at high speed (15,000 rpm) for 15 min to pellet the sperm. The supernatant seminal plasma was then carefully removed and transferred to a separate container. Both sperm and seminal plasma fractions were stored at −70°C until needed for fatty acid analysis of total PL.

Blood collection. Blood was collected from each subject (asthenozoospermics and normozoospermics) by antecubital venipuncture into siliconized tubes and centrifuged at 1200 × *g* for 10 min to obtain serum. Serum was stored at −70°C until analysis of serum total PL fatty acid composition.

Fatty acid analysis of PL of serum, seminal plasma, and sperm. The fatty acid composition of total PL from serum and seminal plasma was determined following lipid extraction as described by Folch *et al.* (20). Sperm total PL fatty acid composition was determined following lipid extraction as described by Bligh and Dyer (21). Thin-layer chromatography, transmethylation, and gas–liquid chromatography were used in procedures similar to those previously described (22–24). Gas–liquid chromatography of the fatty acid methyl esters was performed using a Varian 3800 gas chromatograph (Palo Alto, CA) with a 30-m DB-23 capillary column (0.32 mm internal diameter). The sperm PL fatty acid composition is presented for only 30 normozoospermic subjects (as opposed to 43 subjects for seminal plasma and serum PL analyses) due to insufficient sample volumes from 13 of the individuals.

Statistical analysis. All data are reported as SEM. Data analyzed by unpaired *t*-test (Tables 1–4) were normally distributed before analysis using SAS (SAS Institute, Cary, NC). Data that could not be normally distributed were analyzed using nonparametric analysis (Wilcoxon). Data in Figures 1–3 were analyzed by regression analysis using SAS (SAS Institute). Significance is reported if $P \leq 0.05$.

RESULTS AND DISCUSSION

Table 1 shows the subject and sperm characteristics for both groups. There were no significant differences in height, weight, body mass index, or age between the two groups (asthenozoospermic vs. normozoospermic; $P > 0.05$). Sperm forward motility (% of total) was significantly lower in the asthenozoospermic group [31.5 (2.3)%, where value in parentheses is the SEM; range 1–50%] vs. the normozoospermic group [73.3 (1.2)%; range 60–95%] ($P < 0.0001$). Spermatozoa concentration was also significantly lower in the asthenozoospermic [42.4 (7.0) M/mL] vs. normozoospermic group [119.5 (13.5) M/mL]. The normal range of sperm concentration is 20–250 M/mL (18), and thus the mean sperm concentration for the asthenozoospermic group was within the normal range. Thirty-three percent of the asthenozoospermic individuals were also oligospermic (sperm concentration < 20 M/mL); however, this did not confound the results obtained in this study since the outcome parameters were expressed on a percentage basis.

The fatty acid composition of the serum total PL of asthenozoospermic and normozoospermic individuals is given in Table 2 (SEM wt%). The levels of the various fatty acids of serum PL were similar between the two groups. Interestingly, however, the amount of 18:1 and total monounsaturated fatty acids (MUFA) were increased in the asthenozoospermic group. The levels of total saturated fatty acids, MUFA, and polyunsaturated fatty acids (PUFA), as well as total PL, n-3, and n-6 levels and the ratio of n-3 to n-6 fatty acids also were similar between the two groups.

Table 3 shows the levels of fatty acids in the total PL of

TABLE 1
Subject and Sperm Characteristics of Asthenozoospermic and Normozoospermic Men[a]

Characteristics	Normozoospermic	Asthenozoospermic
Height (m)	1.8 (0.0)	1.8 (0.0)
Weight (kg)	83.0 (2.4)	85.5 (2.6)
BMI (kg/m^2)	25.6 (0.7)	26.4 (0.5)
Age (yr)	34.8 (1.0)	36.2 (0.7)
Sperm motility (%)	73.3 (1.2)	31.5 (2.3)*
Sperm concentration (M/mL)	119.5 (13.5)	42.4 (7.0)*

[a]Values in parentheses are SEM where $n = 43$ (normozoospermic men) and 30 (asthenozoospermic men), *$P < 0.05$. BMI, body mass index.

n-3/n-6	0.13 (0.00)	0.13 (0.01)
Total PL (mg/dL)	204.8 (4.9)	213.5 (10.0)

[a]Values in parentheses are SEM where $n = 43$ (normozoospermic) and 30 (asthenozoospermic) individuals. Values with an asterisk are significantly different as measured by *t*-test ($P < 0.05$); DHA, docosahexaenoic acid; SFA, saturated fatty acid; MUFA, monounsaturated fatty acid; PUFA, polyunsaturated fatty acid; PL, phospholipid.

human seminal plasma. Seminal plasma total PL fatty acid differed between the two groups. The level of 18:1 was higher (by 13%) in the seminal plasma from asthenozoospermic men. Concentrations of 22:0 and DHA were lower in the seminal plasma from the asthenozoospermic men (7.2 vs. 8.2% and 3.0 vs. 3.7%, respectively; asthenozoospermic vs. control). Total MUFA were significantly higher [24.2 (0.4) vs. 21.7 (0.3) wt%] and total PUFA were significantly lower [11.8 (0.4) vs. 13.5 (0.8) wt%] in total seminal plasma PL from the asthenozoospermic vs. the control men. Interestingly, total PL (mg/dL) was also significantly lower in the seminal plasma from the asthenozoospermic men [31.5 (2.0) vs. 57.3 (5.1) mg/dL]. There were no differences in the total n-3 fatty acid levels or the total n-6 fatty acid levels or in the ratio of n-3 to n-6 fatty acids.

The fatty acid composition of total sperm PL (asthenozoospermic and normozoospermic) is given in Table 4. Levels of 18:1 (13.6 vs. 11.6 wt%), 20:0 (4.2 vs. 2.6 wt%), 22:0 (5.2 vs. 3.2 wt%), 22:1 (0.60 vs. 0.39 wt%), and 24:0 (4.4 vs. 2.6 wt%) were significantly higher in the sperm PL of asthenozoospermic vs. control men. On the other hand, levels of DHA (8.2 vs. 13.8 wt%) were significantly lower in the sperm PL of asthenozoospermic individuals. As observed with seminal plasma PL, the total MUFA levels were higher [19.3 (0.5) vs. 16.5 (0.5) wt%] and total PUFA significantly lower [19.1 (1.0) vs. 24.0 (1.2) wt%] in the sperm PL of asthenozoospermic vs. the normozoospermic men. Total n-3 fatty acid levels and the ratio of n-3 to n-6 fatty acids were also significantly lower in sperm PL from the asthenozoospermic subjects [9.3 (0.8) vs. 14.6 (0.9) wt% and 1.0 (0.1) vs. 1.6

[a]Values in parentheses are as SEM where $n = 30$ (normozoospermic) and 30 (asthenozoospermic) individuals. Values marked with an asterisk are significantly different as measured by *t*-test ($P < 0.05$). For abbreviations see Table 2.

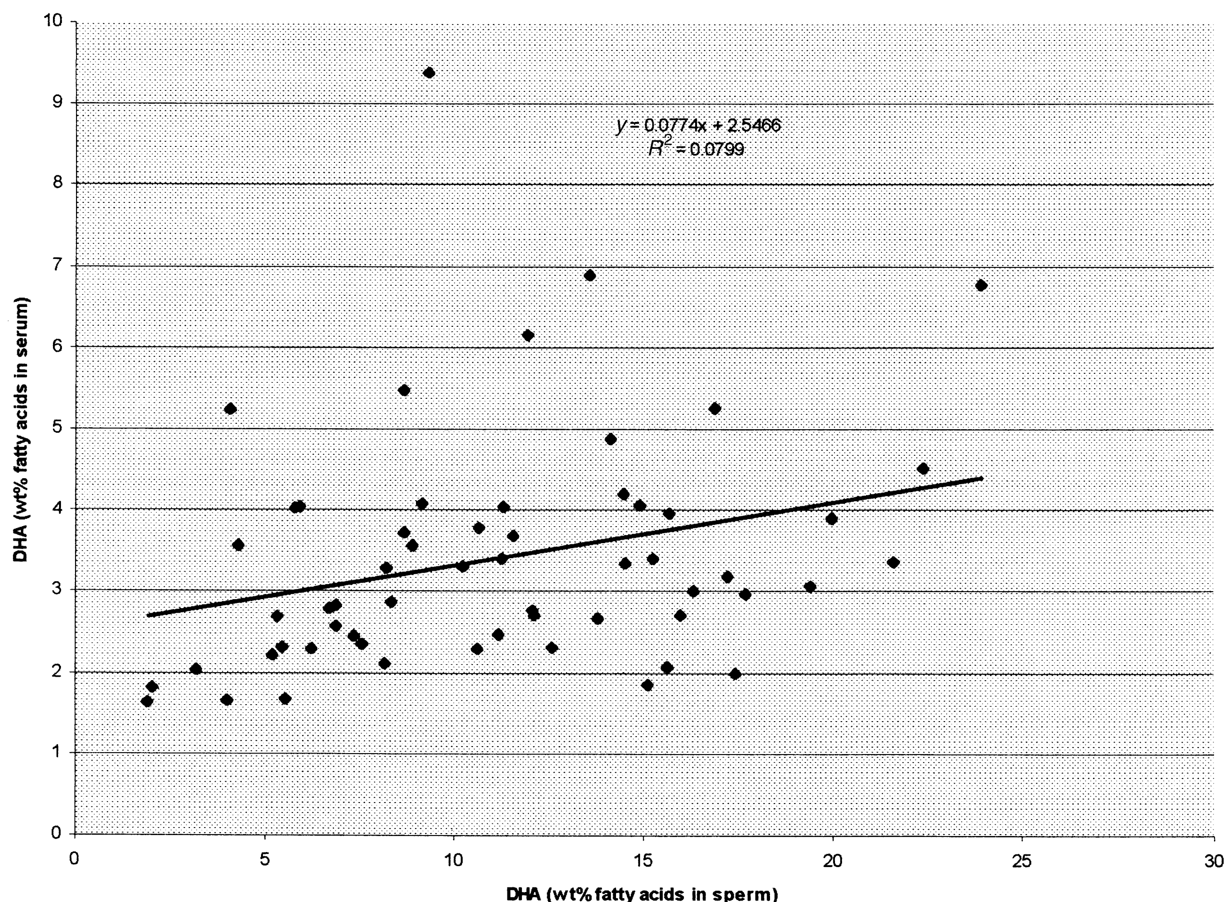

FIG. 1. Relationship of docosahexaenoic acid (DHA) concentration in serum to DHA concentration in sperm. Regression analysis is for a total of 58 men (both asthenozoospermic and normozoospermic). Statistical analysis was done using SAS (SAS Institute, Cary, NC). $P = 0.03$.

(0.1), respectively]. As would be expected due to the differences in total sperm count, the levels of total PL were also significantly lower in the sperm from the asthenozoospermic individuals [21.8 (1.6) vs. 38.1 (3.0) mg/dL].

Figure 1 shows the relationship between serum PL DHA concentration and sperm PL DHA concentration (% fatty acids). Serum PL DHA concentration was found to correlate with sperm PL DHA concentration ($r^2 = 0.08$, $P < 0.05$).

Figure 2 shows the relationship between sperm PL DHA concentration and sperm motility (%). Sperm motility was found to be highly correlated with PL DHA concentration ($r^2 = 0.26$, $P < 0.001$).

Figure 3 shows the relationship between sperm PL DHA concentration and sperm concentration (M/mL). Sperm concentration was found to be highly correlated with PL DHA concentration ($r^2 = 0.42$, $P < 0.0001$).

This is the first study to examine the differences and similarities in PL compositions of serum, seminal plasma, and total sperm of normozoospermic vs. asthenozoospermic individuals. In order to determine if dietary intakes of n-3 fatty acids were similar between the two groups of men, comparisons were made in the PL DHA status of serum. Dietary n-3 fatty acids consist mainly of α-linolenic acid (18:3n-3), EPA (20:5n-3), and DHA. Serum n-3 fatty acid status (including DHA status) represents n-3 dietary intake (15–17). Although metabolism of α-linolenic acid to EPA and DHA occurs in humans, it is limited (25). The similarities in fatty acid profile between the two subject groups as presented herein suggest that intakes of long-chain n-3 fatty acids (EPA and DHA) were similar between the normozoospermic and asthenozoospermic men. The serum PL levels of EPA (0.8%) and DHA (2.5%), as observed in this study, can be compared with previous results in our laboratory that suggest that omnivorous subjects with average North American n-3 intakes have PL EPA levels of 0.7% and PL DHA levels of 2.2% (23). A DHA level of greater than 6% can be observed in subjects consuming large amounts of this fatty acid (22–24). Although there is no published information suggesting that infertile men have different levels of n-3 fatty acids in blood serum, Lenzi *et al.* (26) have suggested that infertile men have a lower arachidonic acid/linoleic acid ratio (used as an indicator of PUFA metabolism) in red blood cell membranes.

The similarities in serum fatty acid status between the asthenozoospermic and normozoospermic men are of interest due to the differences both in the compositions of seminal plasma PL and sperm PL. Very little has been done on the

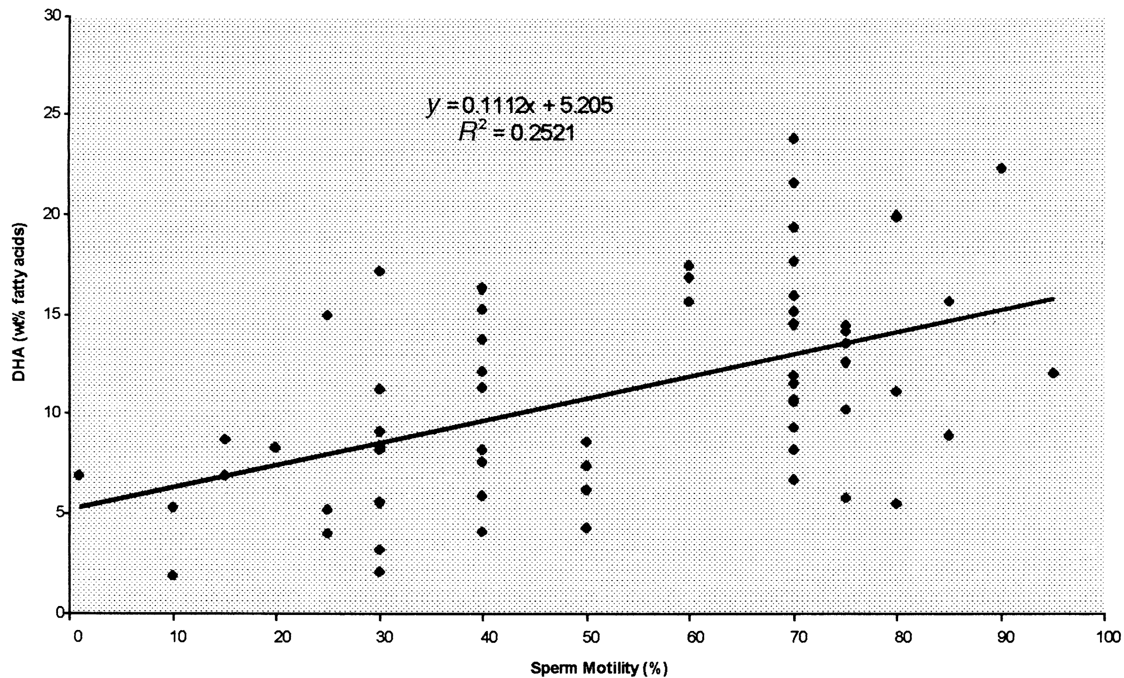

FIG. 2. Relationship of DHA concentration in sperm to sperm motility. Regression analysis is for a total of 60 men (both asthenozoospermic and normozoospermic). Statistical analysis was done using SAS (SAS Institute, Cary, NC). $P = 0.0001$. See Figure 1 for abbreviation.

lipid composition of the seminal plasma (27). Vignon *et al.* (27) determined the breakdown of the major lipid groups and published the nonesterified fatty acid composition of seminal plasma. They found minor levels of DHA (1.5%) in the seminal plasma nonesterified fatty acid. There was no indication of PL DHA levels in the seminal plasma. In addition, there was no mention of possible differences between the seminal plasma composition of asthenozoospermic vs. normozoosper-

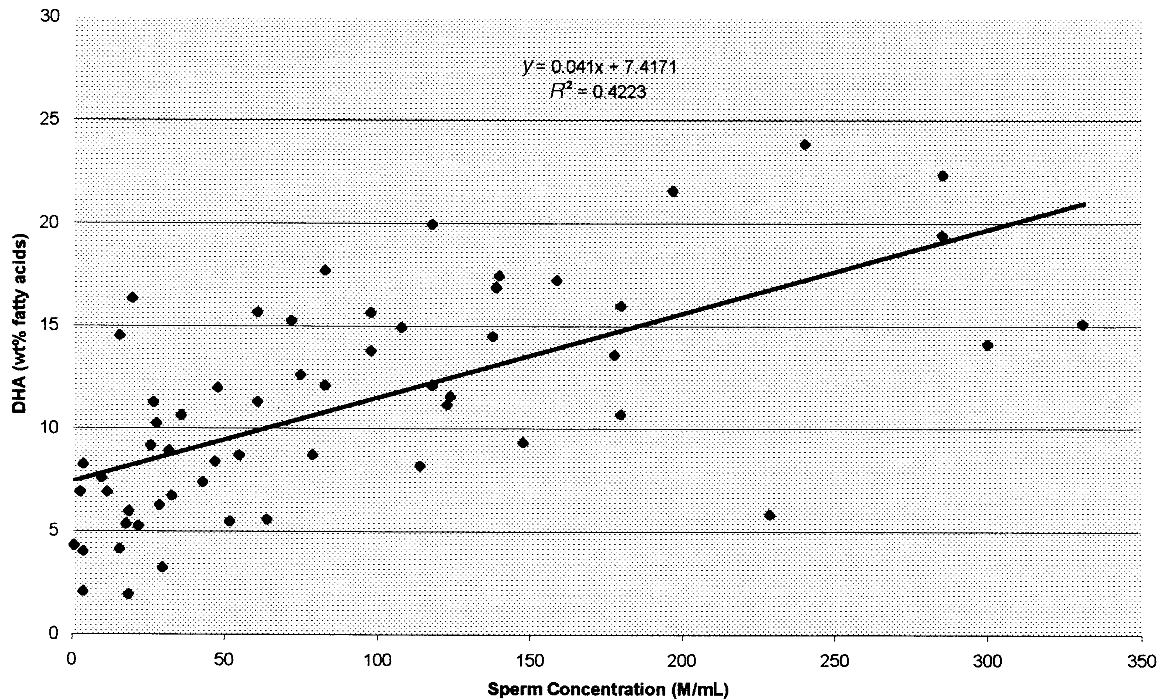

FIG. 3. Relationship of DHA concentration in sperm to sperm concentration. Regression analysis is for a total of 58 men (both asthenozoospermic and normozoospermic). Statistical analysis was done using SAS (SAS Institute, Cary, NC). $P = 0.0001$. For abbreviation see Figure 1.

mic men. In our study, we observed that seminal plasma from asthenozoospermic males was higher in total MUFA (mainly 18:1) and lower in total PUFA (mainly DHA) than seminal plasma from normozoospermic males. Interestingly, although DHA has been shown to retroconvert to EPA in humans, as evidenced by an increase in serum EPA with DHA supplementation (22–24), seminal plasma is essentially devoid of EPA and has extremely low levels of docosapentaenoic acid (22:5n-3). It is not clear why seminal plasma PL is lower in EPA and docosapentaenoic acid, and higher in DHA, than blood serum PL. Furthermore, it is not clear what effect, if any, an altered fatty acid composition of seminal plasma PL, in the asthenozoospermic men, would have on sperm motility. Decreased levels of DHA may be indicative of an altered seminal plasma oxidant status (28–31), but may not have an actual effect on progressive sperm motility.

The extremely high levels of DHA in spermatozoa, as suggested in the literature, are supported by our results, since the DHA levels in both groups were highest in sperm (13.8%) and lowest in blood serum (2.5%). The higher levels of MUFA (18:1, 22:1) and lower levels of PUFA, including DHA, in the sperm of the asthenozoospermic vs. normozoospermic individuals support the hypothesis of an increased breakdown and/or decreased accumulation of DHA in the sperm PL of asthenozoospermic males. We also observed higher levels of certain saturated fatty acids, including 20:0, 22:0, and 24:0, in the sperm PL of the asthenozoospermic group. As with seminal plasma PL, sperm PL is essentially devoid of EPA and has very low levels of docosapentaenoic acid. The fatty acid composition of sperm PL, as reported here, can be compared with those of past studies. Two studies comparing the PL fatty composition of total ejaculate suggest decreased levels of DHA in asthenozoospermic vs. normozoospermic men (4,5). In a third study (7), sperm PL fatty acid of asthenozoospermic individuals differed from that of normozoospermic individuals. In this case, sperm were separated on a Percoll (Pharmacia Biotech AB, Uppsala, Sweden) gradient (in order to separate the more active sperm from the least active sperm in a given individual) and recovered from the 90% Percoll and 47% Percoll fractions. In the 90% Percoll fraction, levels of 18:0, 18:2n-6, and total saturated fatty acids were higher in the asthenozoospermic group, and levels of DHA and total PUFA were lower. Interestingly, in the sperm recovered from the 47% Percoll gradient, DHA was similar between the normo- and asthenozoospermic individuals. Finally, in a study (8) involving sperm from patients with retinitis pigmentosa, (a hereditary disease causing blindness, which is accompanied by extremely low serum DHA levels), higher levels of 20:0, 22:0, 16:1, and 18:1 and lower levels of total PUFA, 20:3n-6, 20:4n-6, and 22:6n-3 were observed, in combination with reduced sperm motility. The exact mechanism by which this may occur is not completely clear although a lower antioxidant status and/or higher oxidant status may be at least partially responsible (9,28–31). It would also be of interest to determine possible differences in DHA concentration of the tails of sperm from asthenozoospermic vs. normozoospermic men.

This study suggests that the fatty acid composition of blood serum is similar between asthenozoospermic and normozoospermic men. However, the concentration of various fatty acids, including DHA, differs between the two groups in seminal plasma and sperm. The effect on sperm function of sperm/seminal plasma fatty acid composition, which is lower in polyunsaturates/DHA and higher in MUFA, is not clear, although previous publications in the literature suggest that DHA may play a role in sperm motility (4,5,7,8). Our results, showing a good correlation between sperm motility, as well as sperm concentration, and sperm PL-DHA concentration are in agreement with results of Nissen and Kreysel (4), in which they demonstrated an excellent correlation between sperm motility and concentration with PL DHA in total ejaculate. With respect to their findings, our group has recently undertaken a study in order to determine the effect of DHA supplementation on both sperm and seminal plasma DHA status, as well as sperm motility. Previous reports suggest that the synthesis of DHA is reduced in infertile men and that increased intake of preformed DHA (in the presence of EPA) is associated with poorer sperm parameters (32). Our results suggest a slight correlation between serum PL DHA and sperm PL DHA. Thus, we will examine next whether increasing dietary DHA, in the absence of EPA, will increase sperm DHA status as well as sperm motility in asthenozoospermic men.

ACKNOWLEDGMENTS

We would like to thank Martek Biosciences Corporation for funding this investigation. In addition, special thanks go to Dr. Bruce Holub for his input in all aspects of this investigation and to Dr. Diana Philbrick for reading the manuscript.

Department of Biochemistry and Molecular Biology, School of Pharmacy, University of Granada, Granada, Spain

ABSTRACT: Dietary fat intake influences plasma glucose concentration through modifying glucose uptake and utilization by adipose and skeletal muscle tissues. In this paper, we studied the effects of a low-fat diet on diaphragm GLUT4 expression and fatty acid composition in control and streptozotocin-induced diabetic rats. Control as well as diabetic rats were divided into three different dietary groups each. Either 5% olive oil, 5% sunflower oil, or 5% fish oil was the only fat supplied by the diet. Feeding these low-fat diets for 5 wk induced major changes in fatty acid composition, both in control and in diabetic rats. Arachidonic acid was higher in diabetic olive and sunflower oil-fed rats with respect to fish oil-fed, opposite to docosahexaenoic acid which was higher in diabetic fish oil-fed rats with respect to the other two groups. Animals receiving a fish oil diet had the lowest plasma glucose concentration. GLUT4 expression in diaphragm, as indicated by GLUT4 protein and mRNA, is modulated both by diabetes and by diet fatty acid composition. Diabetes induced a decrease in expression in all dietary groups. Plasma glucose levels correlated well with the increased amount of GLUT4 protein and mRNA found in fish oil-fed groups. Results are discussed in terms of the influence that arachidonic and n-3 polyunsaturated fatty acids may exert on the transcriptional and translational control of the GLUT4 gene.

Paper no. L8093 in *Lipids 34,* 801–807 (August 1999).

Skeletal muscle is the major site of insulin-mediated glucose utilization *in vivo* (1–3). In muscle, glucose is taken up through facilitated diffusion by two transporters, GLUT1 and, mainly, GLUT4 (2–4). Most of the GLUT4 protein is found in an intracellular organelle in the basal state from where it can be rapidly translocated to the plasma membrane (2–5). This translocation is typically elicited by insulin (2,3) or exercise (5,6) whereas GLUT1 transporter is generally considered to be insulin independent (2).

Both insulin- and noninsulin-dependent diabetes mellitus decrease muscle glucose utilization due to a defective expression and/or regulation of GLUT4 translocation (1–3). In fact, it has been reported that GLUT4 protein and mRNA levels are decreased in skeletal muscle of several rodent models of both genetically and experimentally induced diabetes (1,2).

Fatty acid composition of membranes is also a factor that may influence the action of insulin within skeletal muscle. It has been shown that incorporation of unsaturated fatty acids into muscle membrane phospholipids is associated with improved insulin action. Correspondingly, a higher proportion of saturated fats is linked to an impairment of insulin action (7–10).

Low-fat diet feeding is associated with changes in fatty acid cell membrane composition in normal rats (10,11) but the information is more limited in the diabetic state (12). Moreover, whether a low-fat diet also affects gene expression of GLUT4 glucose transporter in skeletal muscle of nondiabetic animals and of an animal model of diabetes is not known. In the present work, we studied the relationship between dietary fat and fatty acid composition of diaphragm membranes in nondiabetic and streptozotocin-induced diabetic rats and the ways in which differences in polyunsaturated fatty acid percentages in muscle membranes can influence gene expression of GLUT4 transporter in skeletal muscle.

MATERIALS AND METHODS

Animals and treatments. Female Wistar rats (Granada University breeding colony) (150–160 g) were housed at 22°C in a light-controlled (12-h cycle) animal facility. They were randomly divided into three groups of animals; each one had free access to water and food. They were fed for 1 wk with the same purified diet supplemented differentially with 50 g/kg of olive oil, sunflower oil, and fish oil, respectively. The composition of the diet per kg was 650 g corn starch, 50 g cellulose, 200 g vitamin-free casein, 35 g mineral mix, 10 g vitamin mix, 3 g DL-methionine, and 2 g choline bitartrate. The energy content of the three diets was 1.03 kJ/g distributed as (% energy) 68.0 carbohydrate, 21.5 protein, and 10.5 lipids. The fatty acid composition of the three diets is shown in Table 1. All three diets had equal levels of antioxidants per kg of oil: 1.3 g (1300 IU) α-tocopherol, 1.2 g (13.2 IU) γ-to-

copherol, and 1 g *tert*-butylhydroquinone to prevent peroxidation during 1 wk storage at 4°C. The final concentration of vitamin E (DL-α-tocopheryl acetate, γ-tocopherol, and α-tocopherol was 215 IU/kg of diet.

Within each group, experimental diabetes was induced in half of the rats by a single streptozotocin (STZ) injection (60 mg/kg i.p. in 50 mM sodium citrate buffer, pH 4.5) whereas control animals received citrate buffer alone. Only fed animals with blood glucose levels greater than 20 mM were considered diabetic.

Diabetic rats and the corresponding controls were maintained for five additional weeks on the corresponding dietary regime. At the end of the treatments, following one night of food deprivation, rats were killed by decapitation between 0900 and 0930. After blood collection, diaphragm was removed, rapidly frozen in liquid nitrogen and kept at −70°C until analysis. Animals were studied in compliance with our institution's guidelines for animal research. Ethical approval of the protocol was obtained in conformity with regulations for the care and use of laboratory animals.

Fatty acid composition of diaphragms. Muscle tissue was homogenized 1:10 (wt/vol) in 10 mM NaH_2PO_4 buffer, pH 7.4, and diaphragm lipids were extracted by a direct transesterification method according to Lepage and Roy (13). Basically, 100 µL of diaphragm homogenate were precisely pipetted into glass tubes and 3 mL of methanol/benzene (4:1) were added to the biological samples. While stirring, 200 µL of acetyl chloride was slowly added to each tube, over a period of 1 min. Tubes were tightly capped and subjected to methanolysis at 100°C for 1 h. After cooling the tubes, 5 mL of 6% K_2CO_3 solution was added to stop the reaction and neutralize the mixture. The tubes were then shaken and centrifuged, and an aliquot of the benzene upper phase was injected into a gas chromatograph (Hewlett-Packard, model 5880) as described (11) and expressed as the percent distribution of fatty acid methyl esters.

Preparation of total membrane fractions from diaphragm. Total membrane fractions from diaphragm muscle were prepared according to Kahn *et al.* (14). Briefly, 200 mg of tissue was minced in liquid nitrogen and homogenized by 10 strokes in a motor-driven Potter-Elvehjem homogenizer equipped with a Teflon pestle in a buffer containing 20 mM $NaHCO_3$, 0.25 M sucrose, 5 mM Na_3N, 1 mM leupeptin, 1 mM apoprotinin A, 1 mM pepstatin, pH 7.0 at 4°C. This homogenate was centrifuged at 1200 × *g* for 10 min and the pellet was resuspended, homogenized and recentrifuged to remove debris. The combined supernatants were centrifuged at 9000 × *g* for 10 min at 4°C to sediment mitochondria and nuclei. The resulting supernatant was then centrifuged at 200,000 × *g* for 60 min at 4°C to obtain the total membrane fraction. The membrane pellets were resuspended in the homogenization buffer, and total membrane protein content was assayed using the Bradford method (15).

GLUT4 and GLUT1 protein analyses. Muscle membrane fractions (10 µg protein for GLUT4 and 30 µg protein for GLUT1 from a pool of six different membrane fraction samples per condition) were subjected to electrophoresis in 12% SDS-polyacrylamide gels, and the resolved proteins were transferred to nitrocellulose filter membranes (Millipore, Bedford, MA). Samples were also analyzed individually by blotting 10 µg (GLUT4) or 20 µg protein (GLUT1) of each membrane fraction sample onto nitrocellulose membranes using a slot blot apparatus (Bio-Rad, Hercules, CA). The blots were incubated with a 1:500 dilution of a polyclonal anti-GLUT4 antibody or a 1:1500 dilution of a polyclonal anti-GLUT1 antibody (East Acres Biologicals, Southbridge, MA). The antigen-antibody complexes were detected with horseradish peroxidase-conjugated antibodies and an enhanced chemiluminescence detection system (Boehringer Mannheim, Mannheim, Germany). The Western blot autoradiograms revealed uniques bands of 45 kDa, compatible with the molecular weight of the transporters. Quantification was performed by densitometry after scanning of the autoradiographs using the NIH Image Software (16).

RNA isolation and analysis. Total RNA was extracted from diaphragm of control and diabetic rats fed different diets using a guanidinium thiocyanate method (17). All samples had a 260:280 absorbance ratio above 1.7. No differences in the yield per gram of tissue in control and diabetic rats were found. For Northern blot analysis, RNA pooled samples from six different animals per condition (20 µg) were denatured, electrophoresed in 1.0% agarose/formaldehyde gel and alkaline-transferred using a 5× sodium chloride/sodium citrate buffer (5× SSC; a 20× SSC stock solution is 3M NaCl/0.3 M Na citrate, pH7)/10 mM NaOH solution on BrightStar-Plus positively charged nylon membranes (Ambion Inc., Austin, TX) according to the manufacturer's instructions. After the transfer, the RNA in filters was visualized with ethidium bromide and photographed by ultraviolet transillumination to ensure the integrity of RNA, to check the loading of equivalent amounts of total RNA, and to confirm proper transfer. For slot blot analysis, 10 µg of the individual RNA samples were spotted onto BrightStar-Plus membranes by using a slot blot

apparatus. Blots were initially prehybridized in 10 mL preheated 50% formamide, 5× Denhardt's solution (1× Denhart's solution is 0.02% polyvinylpyrolidone, 0.02% Ficoll, 0.02% bovine serum albumin), 0.5% SDS, 5× SSC, and 100 mg/L of denatured salmon sperm DNA solution for 3 h at 42°C and then were hybridized with the random primer-labeled cDNA probes (5×10^4 Bq/mL) for 18 h at 42°C in the same solution with an added 10% dextran sulfate. Finally, the blots were washed in 0.1× SSC and 0.1% SDS at 65°C. Blots were exposed to Kodak Biomax film at −70°C using intensifying screens (Cronex Lightening Plus, Du Pont, Wilmington, DE). The relative amounts of mRNA in each sample were quantitated by densitometric analysis using NIH Image Software (16), and the data were normalized to that of β-actin mRNA.

cDNA probes. GLUT4 glucose transporter mRNA was quantitated by using a 2400 bp *Eco*RI fragment inserted in the pSM-1-1-1 plasmid (18) as probe, and β-actin mRNA was assayed by using a 1900 bp *Hind*III fragment of the gene (19) inserted in a pGEM 7Z plasmid. Glycogen synthase mRNA was measured by using two *Hind*III fragments coding for the human muscle glycogen synthase inserted in the pHMGS plasmid (20). A mouse glyceraldehyde-3-phosphate dehydrogenase probe was obtained from Ambion Inc. cDNA probes were labeled with α-[^{32}P]-deoxycytidine triphosphate (Amersham, Buckinghamshire, United Kingdom) by random oligonucleotide-priming (21).

Statistical methods. Significant differences among the groups of results were considered when $P \leq 0.05$ using two-way analysis of variance and *posthoc* Tukey tests. Statistical analyses were performed using the BMDP Computer Software program (Berkeley, CA) (22).

RESULTS

The three diets differ in the origin of lipid supplementation, olive oil, sunflower oil and fish oil, enriched, respectively, in monounsaturated, n-6 polyunsaturated and n-3 long-chain polyunsaturated fatty acids (Table 1). The amount of fat supplied in the diets was always 5% oil, so they were basically low-fat diets, fat contribution to energy being only 10.5% of the total intake.

After induction of diabetes by a single-dose STZ injection, animals were fed the supplemented diets for 5 wk. Plasma glucose levels significantly increased in diabetic compared to control animals ($P < 0.001$) (Table 2). Control fish oil-fed rats had significantly lower glycemia than those fed olive or sunflower oil ($P < 0.05$). No differences in body weight among groups were observed as an effect of diet. In diabetic rats body weight was moderately decreased ($P < 0.05$).

Table 3 shows the percentages of major fatty acids in diaphragms of control and diabetic animals fed diets varying in fat type. Dietary fatty acids clearly affected the relative abundance of the different fatty acids. Thus, the highest levels of oleic, linoleic, or n-3 polyunsaturated fatty acids were found in diaphragms of rats fed olive oil, sunflower oil, or fish oil diets, respectively. Arachidonic acid was similar in control and diabetic animals fed either olive or sunflower oil diets. Diabetes produced a significant increase ($P < 0.001$) in arachidonic acid when the diet was supplemented with either olive oil or sunflower oil. Arachidonic acid levels in control and diabetic fish oil-fed rats were similar and they were lower than in the other two diabetic groups ($P < 0.001$). Eicosapentaenoic acid was only detected in fish oil-fed animals. Docosahexaenoic acid increased by diabetes ($P < 0.001$) in the fish oil group compared to controls.

Total diaphragm membrane fractions were purified from control and diabetic rats after 5 wk of dietary treatment, and there were no differences in the yield of membrane protein obtained per gram of tissue. The content of GLUT4 protein was assayed by Western blot and by slot blot. The Western blot of six pooled membrane samples per condition showed a single band of 45 kDa (Fig. 1). Quantification of the signal detected for individual samples by densitometric scans gave the results shown in Table 4. Diabetes caused a decrease in protein content 40% higher than in any of the other groups ($P < 0.001$). The amount of GLUT4 protein was similar in the groups receiving olive or sunflower oil diets while muscle membranes isolated from animals having fish oil diets had significant higher concentration ($P \leq 0.05$) of the glucose transporter in both control and diabetic rats. The amount of GLUT1 protein was assayed by Western and slot blot. No differences in GLUT1 content were found between control and diabetic animals fed the different diets (data not shown).

We next determined the levels of diaphragm glucose transporter GLUT4 mRNA by Northern and slot blot. The Northern blot of six pooled RNA samples per treatment (Fig. 2) shows a single band of 2.8 kb corresponding to that described for the glucose transporter (18). The relative intensity (in arbitrary units) of the signal detected for six individual samples measured by slot blot are presented in Table 4. There is an agreement between data obtained by quantitation of the

[a]Results are expressed as means ± SEM (n = 6–8) of the percentages of total fatty acids methyl esters. Statistically significant differences ($P \le 0.05$) are as in Table 2.

Northern and slot blots. In both cases, data have been normalized to the values obtained for the expression of the β-actin gene. GLUT4 mRNA expression was significantly depressed ($P < 0.001$) in diabetes, as expected. Control animals fed the fish oil diet presented the higher content of GLUT4 mRNA ($P < 0.001$) when compared to olive or sunflower oil groups. No differences were found in GLUT4 mRNA levels among diabetic animals receiving the different diets.

As a control, the expression levels of two genes known to be down-regulated in diabetes (5,23,24), glyceraldehyde-3-phosphate dehydrogenase, implicated in glucose utilization, and glycogen synthase, implicated in glucose storage in the muscle, have been studied. Quantitation of the mRNA content for these proteins, after β-actin normalization, was carried out by Northern blot, detecting two single bands of 1.4 and 3.5 kb corresponding to the glyceraldehyde-3-phosphate dehydrogenase and muscle glycogen synthase, respectively. We measured a decrease in the mRNA levels of both genes (60% decrease in the glyceraldehyde-3-phosphate dehydrogenase mRNA levels and 39% decrease in the glycogen synthase mRNA levels) due to STZ-induced diabetes without significant differences among the dietary groups, confirming the purity of our RNA preparations (data not shown).

DISCUSSION

Glucose transporter GLUT4 is believed to be responsible for the insulin-mediated glucose uptake in muscle, and therefore, the reduction of its concentration in plasma membranes will account for development of insulin resistance. As dietary manipulations may improve the response to insulin, we have administered three experimental diets to assess the importance of different dietary fatty acids on GLUT4 expression. These diets have been fed to control and STZ-diabetic rats in order to study their effect in basal expression (control rats) or low-level expression (diabetic rats) of the GLUT4 glucose transporter (1–3,25).

The amount of fat supplied in the diets was always 5%, so they were basically low-fat diets. Low-fat diets prevent insulin resistance, whereas high-fat diets impair insulin-dependent glucose transport by reducing translocation of the transporter to the plasma membrane (26). Furthermore, low-fat diets allow rapid modifications in fatty acid content of membrane phospholipids (10,27).

Induction of diabetes by a single-dose STZ injection was effective, and after 5 wk plasma glucose was significantly increased in all diabetic animals compared to the controls.

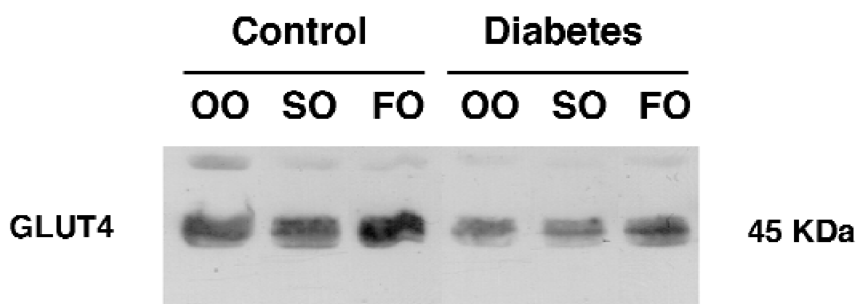

FIG. 1. Western blot analysis of GLUT4 protein levels in diaphragm of control and streptozotocin-diabetic rats fed 5% olive oil, sunflower oil, or fish oil diets for 5 wk. Aliquots of six different membrane fractions per condition were pooled and applied (10 μg) to a 12% SDS-polyacrylamide gel. Gels were blotted, and GLUT4 protein was detected using a polyclonal antibody. Bands were detected using chemiluminescence as indicated in the Materials and Methods section. OO, Olive oil-fed rats; SO, sunflower oil-fed rats; FO, fish oil-fed rats.

TABLE 4
Diaphragm GLUT4 mRNA and GLUT4 Protein Levels of Control and Streptozotocin-Diabetic Rats Fed Olive Oil, Sunflower Oil, or Fish Oil for 5 wk[a,b,c]

	Olive oil-fed		Sunflower oil-fed		Fish oil-fed	
Parameter	Control	Diabetic	Control	Diabetic	Control	Diabetic
GLUT4 mRNA	1517 ± 42	793 ± 48[c]	1224 ± 32	795 ± 68[c]	1890 ± 32[a,b]	782 ± 63[c]
GLUT4 protein	2611 ± 38	1474 ± 95[c]	2570 ± 61	1522 ± 83[c]	3515 ± 146[a,b]	2048 ± 76[a,b,c]

[a]Results are expressed as relative amounts of GLUT4 protein or mRNA. Quantification was performed by densitometry after scanning the autoradiographs corresponding to the slot blot determinations as described in the Material and Methods section.
[b]Values are means ± SEM, $n = 6–8$. Statistically significant differences ($P \leq 0.05$) are as in Table 2.
[c]Aliquots of individual mRNA (20 μg) and membrane fraction (10 μg) samples were analyzed by slot blot as described in the Material and Methods section.

Control fish oil-fed animals presented significantly lower glycemia than fed those olive or sunflower oil as an indication that glucose uptake by peripheral tissues may be favored by n-3 long-chain polyunsaturated fatty acids.

Low levels of fat intake, as those in our experimental protocol, induce changes in fatty acid composition of diaphragm membranes, and the type of oil supplement in the diet greatly influences the relative abundance of different fatty acids. However, a great deal of phospholipid remodeling occurs prior to deposition in muscle plasma membranes. As an example, oleic acid content in olive oil-supplemented diet is more than 70% while in the corresponding muscle membranes it only reaches 38%. Arachidonic acid is similar in membranes of animals fed either olive or sunflower oil supplements despite the big difference in the concentration of linoleic acid between these diets. Animals fed fish oil had the lowest levels of arachidonic acid, probably owing to a diminished Δ^5-desaturase activity as evidenced by the differences in 20:4n-6/20:3n-6 index. Significant changes in fatty acids in diabetes affect arachidonic acid, which is increased when the diet is supplemented with either olive or sunflower oil, while a rise in docosahexaenoic acid (22:6n-3) has been detected in diabetic fish oil-fed rats. Similar results have been shown in liver microsomal phospholipids (28).

Fatty acid composition within membranes may modulate the action of membrane proteins involved in glucose transport by several mechanisms. Borkman *et al.* (7) showed that long-chain polyunsaturated fatty acid content in muscle-membrane phospholipids may influence the action of insulin through the effects of their physical properties on proteins such as insulin receptors and glucose transporters. It has previously been shown that diets high in polyunsaturated fatty acids facilitate glucose transport into cells and that insulin action is partly affected by changes in the physicochemical micro environments of membrane lipid domains associated with glucose transporters. These changes can include an increased membrane fluidity of muscle tissue, which consequently increases or facilitates the penetration of glucose transporters into the membrane. Fatty acids have been demonstrated as physiological regulators of the glucose transport system (29). Oleic and arachidonic acids particularly seem to destabilize the mRNA for GLUT4. Arachidonic acid suppresses the transcription rate of GLUT4 gene in adipocytes (29,30). Our results clearly agree with this mechanism, as olive and sunflower oils in the diet occasion the highest concentration of arachidonic acid in muscle membranes and minimal levels of GLUT4 mRNA and protein.

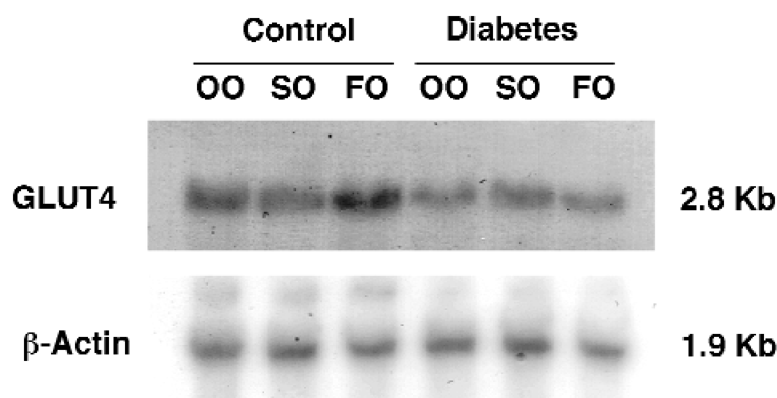

FIG. 2. Northern blot analysis of GLUT4 mRNA levels in diaphragm of control and streptozotocin-diabetic rats fed 5% olive oil, sunflower oil, or fish oil diets for 5 wk. Aliquots of six different RNA samples per condition were pooled and 20 μg (GLUT4 mRNA) or 10 μg (β-actin mRNA) were electrophoresed on 1% agarose/formaldehyde gel. Samples were transferred to positively charged nylon membranes and probed as described under the Material and Methods section either with a GLUT4 or a β-actin probe. For abbreviations see Figure 1.

mRNA and protein GLUT4 levels may be modulated both by the quality of fat in the diet and by diabetes when animals are subjected to a low-fat intake. In our experimental groups, dietary supplementation with fish oil enhances the amount of GLUT4 mRNA and protein in controls. Diabetes causes a decrease in GLUT4 mRNA levels in all groups that is not modulated by dietary fat. Thus, GLUT4 mRNA levels are similar, independent of the type of fat intake, although GLUT4 protein is increased by fish oil feeding both in control and diabetic rats. Fish oil-fed rats have the highest levels of eicosapentenoic acid (20:5n-3) and other n-3 polyunsaturated fatty acids. Fish oil, apart from its lowest content in n-6 fatty acids, could well provide high levels of substrates for prostaglandins and leukotrienes, particularly prostaglandin E_3, which would also contribute to increase the number of copies of GLUT4 transporter in muscle after fish oil feeding (8). Similar results have been shown by Ezaki *et al.* (31) in adipocytes from rats fed a high-fish oil diet or a high-safflower oil diet.

The increase found in GLUT4 protein levels after fish oil feeding, which does not correlate with GLUT4 mRNA levels in diabetes, has to be explained in terms of the stability of the protein. Olson and Pessin (32) reported that GLUT4 is apparently a very stable protein, whereas the GLUT4 message has a relatively rapid turnover rate. Thus, the depletion of GLUT4 mRNA occurs before any decrease in GLUT4 protein levels. Furthermore, there appears to be a compensatory mechanism that reduces the rate of GLUT4 protein degradation, for example in STZ-diabetic rats, which spares GLUT4 at a time when there is a pretranslational synthetic defect.

In summary, data presented in this paper indicate that fish oil supplementation to the diet seems to correlate well with a diminution of glycemia through changes in fatty acid composition of muscle membranes that directly or indirectly may influence GLUT4 protein levels through a transcriptional or translational mechanism control. Thus, the fatty acid composition of the diet may be an important regulator of the glucose transporter, GLUT4, in rat muscle.

ABSTRACT: We previously demonstrated increased apolipoprotein B (apoB) mRNA editing, elevated levels of mRNA for the catalytic component of the apoB mRNA editing complex, apobec-1, and increased secretion of the product of the edited mRNA, apoB48, in very low density lipoproteins (VLDL) in primary cultures of Sprague-Dawley rat hepatocytes following insulin treatment. In order to determine the effect of *in vivo* hyperinsulinemia on these processes, we determined apoB mRNA editing, apobec-1 expression, hepatic expression of mRNA for apoB and other VLDL apoproteins, and the quantity and composition of plasma VLDL in the hyperinsulinemic fatty Zucker rat. Total apoB mRNA content of the livers of the fatty rats and lean littermates did not differ; however, edited apoB message coding for hepatic apo B48, and abundance of mRNA for the catalytic subunit of the apoB mRNA editing complex, apobec-1, was increased by 1.7- and 3.3-fold, respectively, in fatty rats. ApoCIII mRNA abundance was increased in livers of fatty rats as well, but the abundance of hepatic apoE mRNA in the fatty animal was not different from that of the lean rat. Hepatic apoAI mRNA abundance was also increased in the fatty rats. Associated with increased apoB mRNA editing, was the 1.7-fold increase in the fraction of apoB in plasma as apoB48 in fatty rats. VLDL-triglyceride and -apoB in plasma were 15- and 3-fold higher, respectively, in fatty Zucker rats compared to lean littermates, indicating both enrichment of VLDL with triglycerides and increased accumulation of VLDL particles. Increased hepatic expression of mRNA for apoCIII and apoAI was associated with increased content of apoC (and relative depletion of apoE) in VLDL of fatty rats, and plasma apoAI was increased in fatty Zucker rats, primarily in the HDL fraction. The current study provides further evidence that chronic exposure to high levels of insulin influences both the quantity of and lipid/apoprotein composition of VLDL in plasma. The increased apoC and decreased apoE (as well as increased triglyceride) content of VLDL in the fatty Zucker rat observed in the current study may affect VLDL clearance and therefore may be a factor in the observed accumulation of VLDL in the plasma of the fatty hyperinsulinemic Zucker rats.

Paper no. L8044 in *Lipids 34*, 809–816 (August 1999).

Apolipoprotein B (apoB) is an essential component of chylomicrons, very low density lipoprotein (VLDL), intermediate density lipoprotein (IDL), and low density lipoprotein (LDL) (1,2). It is expressed in a full-length form, apoB100, and in a truncated form, apoB48, which is the amino terminal 48% of apoB100. A single gene generates both apoB100 and apoB48 through apoB mRNA editing, in which the CAA codon for glutamine 2153 in apoB is changed to UAA, an in-frame translation stop signal (3). Although human liver secretes only full-length apoB100, the livers of other species including rat, mouse, horse, and dog produce both apoB100 and apoB48 (4). The ratio of hepatic apoB48 to apoB100 produced in the rat is regulated nutritionally (5) and by several hormones, including insulin (6,7), estradiol (8), and thyroid hormone (9).

We previously demonstrated that insulin treatment in primary cultures of hepatocytes from Sprague-Dawley rats increases editing of apoB mRNA and increases hepatic expression of mRNA for apobec1, the catalytic subunit of the editing complex (6,7). Increased editing of apoB mRNA was associated with an increase in the secretion of apoB48 in VLDL (6). These findings support the hypothesis that insulin regulates both the quantity and composition of VLDL secreted by the liver. It is important to determine whether these effects of insulin are also observed *in vivo* and to determine the effect of hyperinsulinemia on hepatic apolipoprotein gene expression. The fatty Zucker rat (fa/fa), a strain with inherited obesity and hyperinsulinemia, provides a useful model to examine the effects of hyperinsulinemia (10). Our prior *in vitro* experiments predicted that livers of fatty Zucker rats would demonstrate increased expression of mRNA for apobec-1 and increased apoB mRNA editing, and that this would be reflected by increased apoB48 content in plasma lipoproteins in comparison with lean littermates (Fa/–). A recent preliminary communication by Phung *et al.* indicates that this indeed occurs (11). The present study confirms and extends these findings by demonstrating that hyperinsulin-

emia in the fatty Zucker rat not only results in increased apoB mRNA editing but is also accompanied by increased quantity and altered apolipoprotein composition of plasma VLDL, and that the expression of other apolipoprotein genes (apoCIII and apoAI) is also altered in the fatty Zucker rat.

MATERIALS AND METHODS

All chemicals and reagents used in these studies were analytical or molecular biology grade. Sources of special reagents are described below.

Animals and sample collection. Male Zucker rats were obtained from Harlan Industries (Indianapolis, IN) and fed standard Purina rodent chow diet *ad libitum*. Fatty Zucker rats (fa/fa) were received at an average weight of 390 g, and their lean littermates (Fa/–) were received at 260 g (about 10 wk of age). After 3 wk, obese animals had gained an average of 128 ± 11 g, and lean rats 63 ± 4 g. Livers were surgically removed from three fatty and three lean Zucker rats. Livers were quickly frozen in liquid nitrogen and stored at −70°C until processed. Blood was removed from the abdominal aorta and placed in tubes containing EDTA. Plasma samples were obtained after brief centrifugation to sediment the erythrocytes and analyzed immediately as described below. Lipids were extracted from aliquots of frozen liver and were analyzed as described below.

Preparation of RNA and cDNA. Total RNA was isolated from Zucker lean and fatty rat liver samples using RNA Stat-60 (Tel-Test, Inc., Friendswood, TX) according to the manufacturer's instructions and quantitated by absorbance at 260 nm. Following digestion with RNase-free DNase I (Ambion, Austin, TX) and heat denaturation of the enzyme, 5.0 µg of RNA from each liver sample was used to prepare cDNA with a cDNA Cycle Kit (Invitrogen, San Diego, CA), employing avian myeloblastosis reverse transcriptase. A 304 bp fragment of the rat apoB cDNA containing the edited site was amplified by reverse transcriptase-polymerase chain reaction (RT-PCR) using the cDNA samples generated from the Zucker rat liver RNA as templates as described (6).

Primer extension analysis. Editing of apoB mRNA was quantitated by primer extension analysis using a 27-base oligonucleotide primer complementary to the region starting eight bases downstream from the edited site in rat apoB mRNA, as described by Wu *et al.* (12). The primer (10 pmol) was 5′ end-labeled using a kit from Promega (Madison, WI), employing 150 µCi of (gamma-^{32}P)ATP (6000 Ci/mmol; DuPont NEN, Boston, MA). About 25 ng of the product from each PCR was assayed by denaturing the DNA at 95°C for 5 min, then annealing with a fivefold molar excess of labeled primer in 34 mM Tris-HCl (pH 8.3), 50 mM NaCl, and 5 mM dithiothreitol at 58°C for 30 min. The extension was carried out at 42°C for 30 min after the addition of dATP, dTTP, and dCTP to 0.5 mM and 2′,3′-dideoxy-GTP to 3 mM, plus 5 units of avian myeloblastosis virus reverse transcriptase (Invitrogen) according to Driscoll *et al.* (13). The reaction products were resolved on a 12% polyacrylamide sequencing gel and analyzed by autoradiography with Kodak X-Omat AR film (Kodak, Rochester, NY). The bands corresponding to edited or nonedited apoB mRNA were cut out of the gel and quantitated by liquid scintillation spectrometry.

DNA probes. A rat apoB cDNA probe (+126 to +643) was generated by PCR from rat liver cDNA using the following oligonucleotide primers: 5′-AGCAGTTATCTTCCCAAAGAAACG and 5′-CATGAAGATGTAGTGGAGAAACAAG. PCR reagents came from a GeneAmp kit (Perkin Elmer, Norwalk, CT), and the starting parameters used were those recommended by the manufacturer. After an initial denaturation for 3 min at 94°C, 35 cycles of amplification were carried out, with each cycle consisting of 30 s at 94°C, 1 min at 55°C, and 1 min at 72°C. A rat apobec-1 cDNA probe (+86 to +479) was also generated by PCR, following the above protocol, from rat liver cDNA using the primers 5′-GAGAAGAATTGAGCCCCACGAG and 5′-CTCCGTCATGATCTGGATAGTA. After PCR, all probes were purified through silica-binding using a Gene-Clean kit (Bio-101; Vista, CA). Probes were prepared for apoAI, apoCIII, and apoE using primers based on published sequences of rat liver cDNA for the corresponding proteins. Primers for apoAI were 5′-AAAGCTGCAGTGTTGGCTGTGGCC (upstream) and 5′ GTTCAGCTTCTTTTTGGCCTCATC (downstream), corresponding to sequences at the translation start and stop sites (14). Primers for apoCIII were 5′-CGGCTCAAGAGTTGGTGTTGTTAG (upstream) and 5′-CAGCCCCGAATGCTGCTCATCGTG (downstream). Primers for apoE were 5′-AAGGCTCTGTGGGCCCTGCTGTTG (upstream) and 5′-TTGATTTCTCCAGGGCACTGTGGT (downstream) (15).

Slot blot analysis of apoB mRNA. Five µg of total RNA from each sample was transferred to nylon membranes (Schleicher & Schuell, Keane, NH) in triplicate using a Schleicher & Schuell slot blot apparatus and ultraviolet cross-linked. Blots were prehybridized for 6 h at 42°C in 50% formamide, 5× SSPE (1× = 0.18 M sodium chloride, 0.01 M sodium phosphate, 1 mM EDTA, pH 7.4), 5× Denhardt's solution (5 Prime-3 Prime, Boulder, CO) (16), 7.5% dextran sulfate, 1.5% sodium dodecyl sulfate (SDS), and 100 µg/mL of sheared salmon sperm DNA (5 Prime-3 Prime). ApoB mRNA on the blots was detected by hybridization overnight with the apoB cDNA probe which was ^{32}P-labeled using the random primer method (17). The unbound probe was removed by washing membranes twice with 2× SSC, 0.1% SDS (1× = 0.015 M sodium chloride, 0.0015 M sodium citrate, pH 7.0) for 30 min at room temperature, and twice with 0.1× SSC, 0.1% SDS (1× = 0.015 M sodium chloride, 0.0015 M sodium citrate, pH 7.0) for 30 min at 65°C. Membranes were exposed to X-Omat AR film (Kodak) at −70°C for 1–2 d. The resulting films were digitized using an Alpha Innotech image analysis workstation (Alpha Innotech Corp., San Leandro, CA), and relative apoB mRNA was determined from the images using NIH Image (version 1.61) for Macintosh (National Institutes of Health USA shareware). Blots were corrected for mRNA loading by reprobing for poly A RNA using a biotinylated oligo (dT) probe from R&D Systems (Abingdon, United Kingdom) as described by Johnson *et al.* (18).

Northern blot analysis of apobec-1, apoCIII, apoE, and apoA1 mRNA. About 25 µg of total RNA, adjusted to contain the same amount of poly(A) RNA based on slot blot analysis, was loaded per lane onto a 1% agarose gel containing 2.2 M formaldehyde (16), electrophoresed, and transferred to a nylon membrane by capillary blotting with a Turbo Blotter (Schleicher & Schuell) using 20× SSC, according to manufacturer's instructions. RNA on the blot was UV cross-linked, and the blot was probed with the apobec-1 cDNA probe ^{32}P-labeled by the random primer method (17) using the same conditions employed for slot blot analysis.

These blots were subsequently reprobed for apoC III, apoE, and apoA1 using the probes described above.

Analyses of plasma, plasma lipoproteins, and liver tissue. Plasma lipoproteins were isolated by sequential ultracentrifugation at d = 1.006 (VLDL), d = 1.006–1.063 (IDL/LDL), and d = 1.063–1.21 high-density lipoprotein (HDL) after an initial centrifugation at 12,000 g (30 min) of plasma layered under a "mock plasma" (d = 1.006) to remove the "chylomicron" fraction. The "chylomicron" fraction was not further analyzed. The lipoprotein fraction isolated in the d 1.006–1.063 range contain some unmetabolized IDL from the liver and chylomicron remnants from the intestine, and is therefore referred to as IDL/LDL. Chemical analyses of all major classes of lipids (triglyceride, phospholipid, cholesterol, free fatty acid, and cholesteryl ester) from extracts of whole plasma, liver, and plasma lipoproteins were carried out after separation by thin-layer chromatography on silica gel G (19). Protein analyses on the isolated lipoproteins were carried out by the Lowry method as modified by Markwell *et al.* (20). Apolipoproteins of the various lipoprotein fractions of plasma were separated on Laemmli gradient gels (4 to 22% polyacrylamide) and stained with Coomassie Brilliant Blue R-250 (21). The mass of each apoprotein was estimated from densitometric scanning of the stained gels to determine the relative percentages in each lipoprotein. Separation of apoC species was not sufficient using this methodology to allow separate quantitation of apoCIII and apoCII. Therefore, total apoC content of lipoproteins is presented. Plasma apoB was also determined by radioimmunoassay as described previously (19). Plasma insulin levels were determined using a Micromedic Insulin RIA kit obtained from ICN (Costa Mesa, CA). DNA levels in liver samples were determined with a Hoefer DyNA Quant 200 (Pharmacia Biotech, Piscataway, NJ).

Statistics. All data are expressed as the mean ± SE (from values derived from three rats in each of the fatty and lean groups). Statistical comparisons were made with Student's t test (unpaired). Significance of difference was set at $P < 0.05$.

RESULTS

Characteristics of this group of fatty rats and their lean littermates are shown in Table 1. Fatty rats had plasma levels of insulin five times greater than those of the lean controls (273 vs. 58 µIU/dL). Although of similar age, the fatty rats were 1.6 times larger and their livers were twice as heavy as the lean controls. While there was a moderate increase in the total DNA content (54%) in livers from obese rats, total RNA and total protein contents were increased to a much greater extent (103 and 267%, respectively). Although total RNA content in the livers of fatty rats was increased, there was a reduction (28%) in mRNA as a fraction of total RNA (data not shown), indicating disproportionate increases in the ribosomal and/or transfer RNA content of the fatty livers.

TABLE 1
Characteristics of Lean and Fatty Zucker Rats[a]

	Lean (n = 3)	Fatty (n = 3)
Animal weight (g)	328.7 ± 7.5	515.7 ± 2.9*
Liver weight (g)	10.7 ± 0.7	22.0 ± 1.2*
Plasma insulin (µIU/mL)	58 ± 2	273 ± 62*
Protein (mg/g liver)	160.8 ± 5.7	210.0 ± 10*
Protein (g/liver)	1.72 ± 0.17	4.60 ± 0.12*
DNA (mg/g liver)	2.91 ± 0.03	2.19 ± 0.12*
DNA (g/liver)	31.1 ± 2.2	48.0 ± 1.7*
RNA (mg/g liver)	7.27 ± 0.70	7.14 ± 0.40
RNA (g/liver)	76.9 ± 6.5	156.4 ± 8.5*

[a]Results are means ± SE of 3 animals.
*$P < 0.05$ compared to lean rats.

Although total DNA per liver was greater in fatty Zucker rats, the content of DNA per gram of liver was significantly reduced. These relationships are consistent with a combination of hypertrophy and hyperplasia in the fatty rat livers. Because of significant differences in RNA and mRNA content in livers of fatty vs. lean Zucker rats, specific mRNA determinations are corrected for differences in total mRNA between livers of lean vs. fatty rats, and the abundance of the mRNA of interest in fatty livers is expressed relative to corresponding mRNA in lean controls. This provides an accurate representation of the abundance of specific mRNA species; however, relative to mRNA, since there is a twofold increase in total RNA per liver (28% less for mRNA) in the fatty Zucker rat (Table 1), this actually underestimates the amount of mRNA available for translation per liver by a factor of 1.7.

The fraction of hepatic apoB mRNA in the edited form was determined by primer extension assay (Fig. 1). Quantitative analysis of the bands revealed significantly higher levels of edited apoB mRNA in livers of fatty vs. lean Zucker rats [82.0

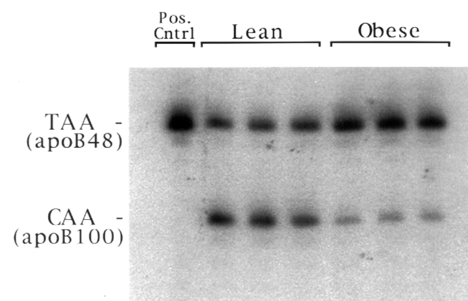

FIG. 1. The extent to which hepatic apolipoprotein B (apoB) mRNA had undergone editing was determined by primer extension as described in the Materials and Methods section. TAA and CAA refer to the sequence at codon 2153 of the apoB mRNA. CAA is the original, unedited sequence, while UAA is the edited sequence (TAA after polymerase chain reaction amplification).

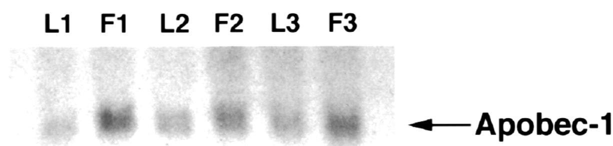

FIG. 2. Northern blot analysis of total RNA samples from lean (L) and fatty (F) Zucker rat livers, adjusted to contain equal amounts of poly (A) RNA, were analyzed for apobec-1 mRNA abundance as described in the Materials and Methods section.

± 0.4% (n = 3) vs. 47.6 ± 4.7% (n = 3)]. A direct correlation of the extent of hepatic apoB mRNA editing and of abundance of mRNA for the catalytic subunit of the editing complex, apobec-1, has been reported during induced hyperinsulinemia (high carbohydrate feeding) (22) and with insulin and estrogen treatment in rat hepatocytes (6,7). We therefore determined the abundance of apobec-1 mRNA in livers of lean and fatty Zucker rats by Northern blot analysis (Fig. 2). Apobec-1 mRNA was 3.3-fold more abundant in livers from obese rats than lean rats (16.4 ± 3.1 vs. 5.0 ± 3.4 arbitrary density units) when expressed relative to total mRNA (determined separately by slot blot analysis as described in the Materials and Methods section).

In addition to increased apoB mRNA editing, insulin may also regulate VLDL by altering overall expression of apoB and other VLDL apolipoproteins. We determined the abundance of mRNA for apoB, apoCIII, apoE, and apoA1 in the livers of fatty and lean Zucker rats by slot blot and Northern analysis. Apolipoprotein mRNA abundance was corrected for mRNA content measured with an oligo(dT) probe. Slot blot analysis of apoB mRNA revealed an average density of 0.85 ± 0.12 for fatty rats, and 1.00 ± 0.14 for lean rats (P < 0.10) (data not shown). The abundance of both apoCIII and apoAI mRNA, corrected for poly(A) mRNA content of fat vs. lean livers, was significantly greater in livers of fatty Zucker rats (1.77 ± 0.16 fold higher and 2.70 ± 0.31 fold higher than lean livers for apoCIII and apoAI, respectively, P < 0.05, n = 3) (Fig. 3), whereas that of mRNA for apoE was not significantly different (1.0 ± 0.13 vs. 0.87 ± 0.04 for lean and fatty livers, respectively).

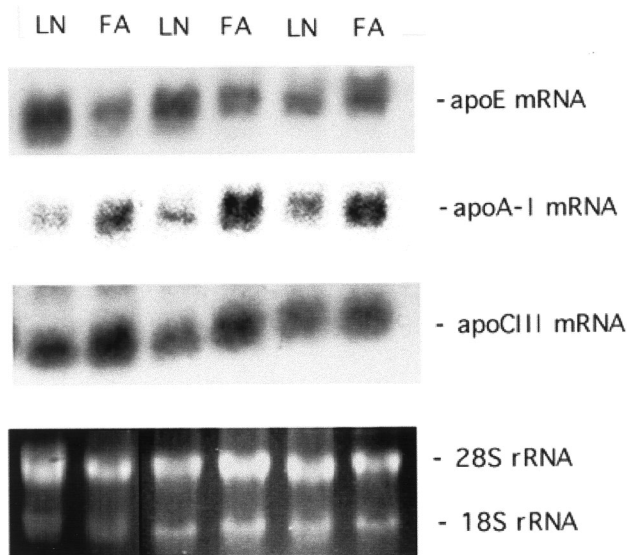

FIG. 3. After probing for apobec-1 mRNA, the blots were reprobed for apoCIII, apoE and apoAI mRNA. (LN) refers to individual liver samples lean and (FA) to liver samples from fatty rats.

To determine the effect of increased hepatic apoB mRNA editing and increased apoCIII and apoA1 gene expression on plasma lipoproteins in the fatty Zucker rat, we assessed plasma lipid and apolipoprotein levels in VLDL, LDL/IDL, and HDL fractions in lean vs. fatty Zucker rats. There was a marked increase in the amount of VLDL protein and lipid in plasma of fatty Zucker rats. In addition, there was a marked and disproportionate (32-fold) enrichment of VLDL of fatty Zucker rats with triglyceride (Table 2). Calculated molar ratios of surface/core lipids, i.e., cholesterol and phospholipid/triglyceride and cholesterol ester, for the VLDL of the lean and fatty rats were 0.79 ± 0.07 and 0.19 ± 0.02, respectively, indicating significantly larger particle size for circulating VLDL in the fatty rats. Similarly, VLDL of fatty Zucker rats also demonstrated a markedly higher ratio of triglyceride to apoB (17.25 ± 3.00 μmol/nmol vs. 1.70 ± 0.41 μmol/nmol for fatty and lean Zucker rats, respectively). Although the amount of IDL/LDL-protein, -phospholipid, and -cholesterol was not different in the plasma of the two groups, there was a significant triglyceride enrichment of this fraction in the plasma of the fatty animals as well (Table 2). In the fatty rats there was also a 1.6-fold elevation in the amount of plasma HDL protein accompanied by an increase in the lipid content (Table 2).

We determined plasma fatty acid and hepatic lipid content in lean vs. fatty Zucker rats. Total plasma-free fatty acid levels were not significantly higher in fatty Zucker rats than in lean rats (64.9 ± 6.1 vs. 51.7 ± 3.9 μmol/dL plasma, respectively). Livers of fatty Zucker rats had significantly higher levels of hepatic triglyceride compared to lean littermates [9.9 ± 0.7 and 4.3 ± 0.4 μmol/g liver, respectively (P < 0.05)]. The hepatic con-

TABLE 2
Plasma Lipoprotein-Lipid and -Protein Levels of Lean and Fatty Zucker Rats[a]

Protein (mg/dL)	17.0 ± 4.7*	9.2 ± 0.3	83.6 ± 3.6*

[a]Results are means ± SE of 3 animals.
[b]Lipoproteins were isolated at d < 1.006 (very low density lipoprotein, VLDL), d =1.006–1.063 (intermediate density lipoprotein, IDL/low density lipoprotein, LDL), and d = 1.063–1.21 (high density lipoprotein, HDL). *P < 0.05.

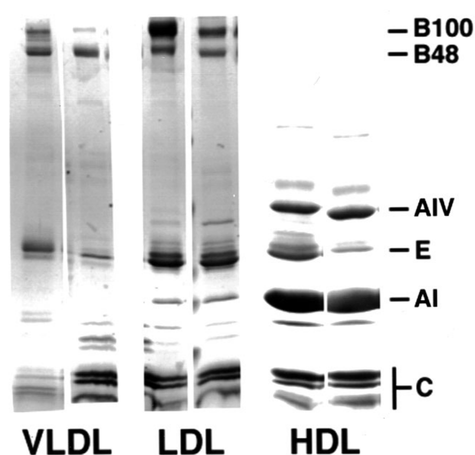

FIG. 4. A representative apoprotein pattern is presented for the very low density lipoprotein (VLDL), intermediate density lipoprotein/low density lipoprotein (IDL/LDL) and high density lipoprotein (HDL) isolated from the plasma of a lean and fatty Zucker rat. Within each lipoprotein fraction the left lane is from the lean Zucker rat and the right lane is from the fatty Zucker rat. An equal amount of protein was loaded in each lane, therefore this figure depicts the relative distribution of apoproteins in lipoprotein fractions. The increased relative content of apoB48, apoC, and decreased (relative to apoB) apoE is apparent in VLDL and LDL/IDL (apoB48 only). Quantitative data derived from densitometric scanning and calculated using total protein determination (Table 2) are presented in Figures 5A and 5B.

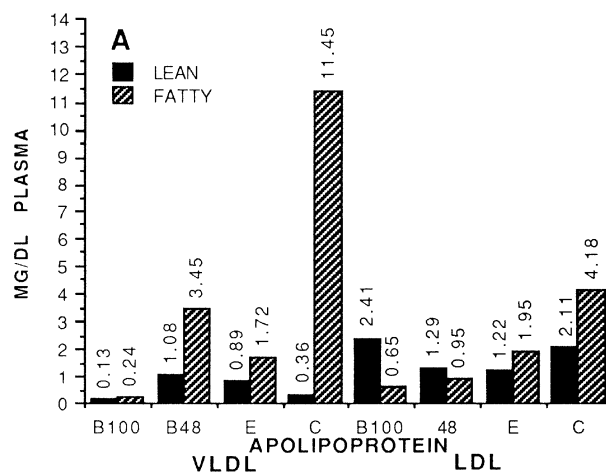

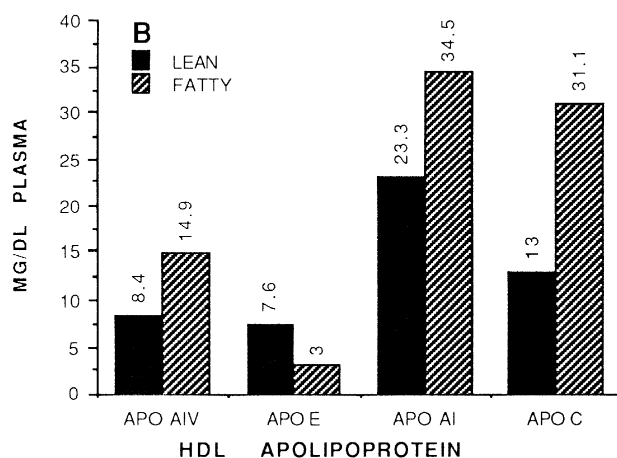

FIG. 5. (A) Apoproteins of VLDL and IDL/LDL, (B) apoproteins of HDL. Coomassie blue-stained polyacrylamide gels were digitized using Alpha Innotech image analysis workstation software (Alpha Innotech Corp., San Leandro, CA) and optical density of the protein bands quantitated using NIH Image (version 1.61) software for Macintosh (National Institutes of Health USA Shareware). Areas within a sample lane were totaled and the percentage of each individual apoprotein calculated. Corrections for potential differences in chromogenicity of each individual band were not made. The mass of each apoprotein was then calculated based on the measured mass of protein in the lipoprotein and the percentage of each apoprotein in each lipoprotein. Data are the mean of values derived from three experiments. See Figure 4 for abbreviations.

centrations of phospholipid and cholesterol in the fatty rat were significantly decreased (23 and 31% lower, respectively) but a 14% decrease in cholesteryl ester content was not statistically significant (data not shown).

Plasma lipoprotein–apoprotein patterns were examined by gradient sodium dodecyl sulfate polyacrylamide gel electrophoresis (Fig. 4). The mean calculated levels ($n = 3$ experiments) for apoprotein species in VLDL and IDL/LDL were derived from the densitometric scan of the stained gel. The amount of the lipoprotein-protein of each lipoprotein isolated from the plasma of each rat are presented in Figure 5A, while the data for the HDL fractions are given in Figure 5B. Although VLDL from fatty Zucker rats had higher contents of both apoB100 (twofold) and apoB48 (threefold), apoB48 content was disproportionately increased (Figs. 5A, Table 3), which is consistent with an increase in apoB mRNA editing in the liver of these animals. The isolated IDL/LDL fraction of the plasma of the fatty animals also had a much higher proportion of apoB48-containing particles than the lean rats (Fig. 5A, Table 3). The apoC content of both the IDL/LDL and HDL fractions were also increased both absolutely and relative to apoB (LDL/IDL) and apoE (Figs. 5A, and 5B). A higher plasma concentration of apoAI and apoAIV was also observed in the fatty Zucker rats, the majority of which was associated with HDL (Fig. 5B). The amount of apoAI associated with the VLDL and LDL was also increased, but this amount was small compared to that in the HDL.

The overall molar ratio of apoB48 to total apoB in the total lipoproteins of the plasma was 0.58 ± 0.06 and 0.85 ± 0.05 for the lean and fatty rats, respectively, which correlates with the proportion of edited apoB mRNA observed in the two groups. Altered levels of apoB48, apoC, and apoE in VLDL may reflect the presence of an increased number of particles, but also may reflect enrichment or relative depletion of apoproteins in individual VLDL particles. Therefore we calculated the relative content of apoC, apoE, and apoB48 relative to apoB100 or total apoB, using apoB as an index of VLDL particle number (each VLDL particle has one apoB molecule) to calculate molar ratios (Table 3). Molar ratios of apoB48 to apoB100 were increased in the VLDL and IDL/LDL of fatty vs. lean Zucker rats (Table 3). Although the total content of apoE in VLDL (and IDL/LDL) was higher in fatty rats (Fig. 5A), the molar ratio of apoE to apoB in the VLDL of fatty Zucker rats was reduced, in-

TABLE 3
Molar Ratios of ApoB48, ApoB100, ApoC, and ApoE in Selected Plasma Lipoproteins of Fatty vs. Lean Zucker Rats[a]

Apolipoprotein ratio (lipoprotein)	Fatty (n = 3)	Lean (n = 3)
ApoB48/apoB100		
VLDL	28.75 ± 5.75	16.60 ± 2.50
IDL/LDL	1.47 ± 0.27	0.54 ± 0.10
ApoE/apoB (VLDL)	3.60 ± 0.33	5.80 ± 1.93
ApoC/apoB (VLDL)	100.66 ± 43.4	9.83 ± 6.30

[a]Data are the relative content of apoproteins in VLDL (and IDL/LDL) expressed as molar ratios to apoB as an assessment of the difference in per particle content of apoE, apoC, and apoB48 between lean and fatty Zucker rats. See Table 2 for abbreviations.

dicating a relative reduction in the content of apoE per particle (Table 3). On the other hand the VLDL particles of the fatty rats were markedly enriched in apoC, both in absolute terms and on a per particle basis, compared to lean rats (Fig. 5A, Table 3).

Figure 6 depicts the total level of each apoprotein in plasma (the sum of the calculated values for VLDL, IDL/LDL, and HDL). The increase in apoB associated with VLDL in fatty Zucker rats was accompanied by an equivalent reduction in apoB in IDL/LDL, so that total plasma apoB (Fig. 6) was not different (4.9 ± 1.5 vs. 5.3 ± 1.1 mg/dL plasma for lean and fatty rats, respectively). The altered distribution of apoB in plasma of fatty Zucker rats (increased apoB48) might result in the underestimation of the number of apoB molecules using protein staining methodology (sodium dodecyl sulfate polyacrylamide gel electrophoresis) since the protein content of apoB48 is half that of apoB100. The similarity of the total apoB plasma levels, however, was confirmed using a method that assesses particle number (radioimmunoassay) rather than protein reaction (Coomassie blue). Total plasma apoB by radioimmunoassay was 4.3 ± 0.6 mg/dL in plasma of lean Zucker rats, compared to 3.0 ± 0.4 mg/dL in fatty Zucker rats (n = 3, P > 0.05).

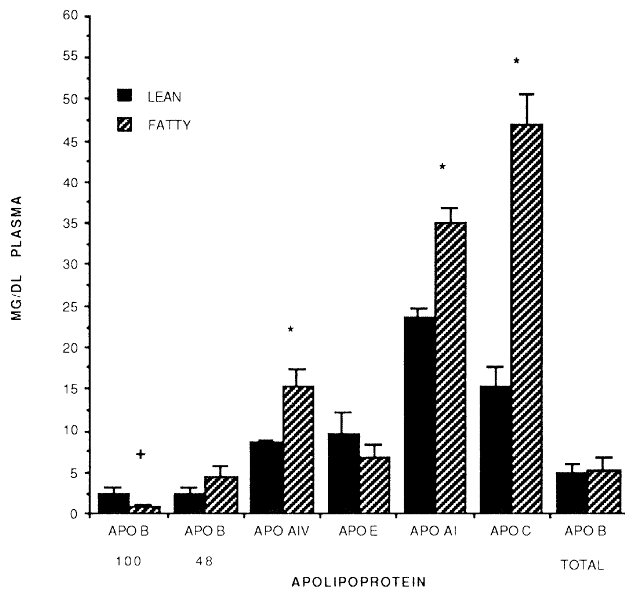

FIG. 6. Data represent the sum of the individual apoproteins in VLDL, IDL/LDL, and HDL. Also represented is the total apoB level in the plasma derived from the sums of apoB 48 and apoB 100 in the three lipoprotein fractions. The majority of the apoAI, apoAIV, and apoC was present in HDL (99, 98, and 84% for the lean rats and 99, 97, and 66% for that of the fatty rats, respectively). See Figure 5 for abbreviations. *(P < 0.05) and + (P < 0.10) compared to the lean controls; n = 3.

DISCUSSION

Our current findings on increased apobec-1 mRNA expression and increased apoB mRNA editing along with the resultant enrichment of plasma lipoproteins with apoB48 in the hyperinsulinemic fatty Zucker rat are consistent with our own previous studies of *in vitro* insulin treatment in primary cultures of Sprague-Dawley hepatocytes (6,7) and with those of Phung *et al.* (11). We also report here associated alterations in quantity and composition of plasma VLDL in fatty Zucker rats, specifically increased number of plasma VLDL particles (apoB) as well as enrichment of the VLDL with apoC and relative reduction in VLDL apoE content. In addition, we report that in the fatty Zucker rat, hyperinsulinemia is accompanied by increased hepatic expression of apoCIII and apoAI , but not total apoB or apoE mRNA. These alterations have significant implications for the pathogenesis of hyperlipidemia in the fatty Zucker rat and indicate that prolonged hyperinsulinemia, as found in the fatty Zucker rat, results in altered lipid and apoprotein composition of the VLDL, and in altered hepatic mRNA expression of key apoproteins involved in VLDL synthesis and clearance.

The increased content of apoB48 relative to apoB100 in plasma VLDL and IDL/LDL observed in the Zucker fatty rat in this study and in other reports (11,23) suggests that increased editing of the apoB message results in increased secretion of apoB48 relative to apoB100. Our previous *in vitro* studies and the current study indicate that this is a specific effect of insulin which is mediated, at least in part, by increased expression of apobec-1 (6,7). Other *in vivo* studies also support the hypothesis that insulin regulates apoB mRNA editing in the hyperinsulinemic fatty Zucker rat (11). During fasting, apoB mRNA editing is decreased concomitant with decreased levels of insulin (24). Conversely, the apoB48/apo-100 ratio is elevated in plasma (25) and the hepatic perfusate VLDL (26) of fed vs. fasted rats. Similarly, in the Goto-Kakizaki rat, a slightly obese, hyperinsulinemic, hyperglycemic model of noninsulin-dependent diabetes, editing of apoB mRNA has been shown to be increased (27) as well as the plasma levels of apoB48, but not apoB100.

The current study also demonstrates that hypertriglyceridemia in the fatty Zucker rat is the result both of marked enrichment of plasma VLDL with triglyceride and increased accumulation of VLDL particles (as indicated by increased plasma VLDL apoB content). Enrichment of VLDL with triglyceride in the fatty Zucker rat results from increased hepatic triglyceride synthesis and secretion (23,28,29). The reason for the presence of an increased number of VLDL particles in the plasma of fatty Zucker rats is less certain. Although

we have previously demonstrated that secretion of apoB by hepatocytes of the Sprague-Dawley rat is increased by insulin (6), studies of apoB secretion by perfused livers and hepatocytes of fatty Zucker rats by other workers have, with the exception of one report (23), failed to demonstrate increased secretion of apoB (29–32). Our findings that accumulation of apoB in plasma VLDL was accompanied by a concomitant reduction of apoB in IDL/LDL fractions also suggests that decreased clearance of VLDL may be, in part, responsible for net accumulation of VLDL in plasma of fatty Zucker rats.

Clearance of chylomicron remnant particles has been reported to be reduced in the fatty Zucker rat (33). Although, to our knowledge, VLDL clearance has not been specifically studied in the fatty Zucker rat, chylomicron remnants and VLDL share a common removal mechanism (34). Although the mechanisms which alter clearance of triglyceride-rich lipoproteins in the fatty Zucker rat have not been elucidated, our observation of increased apoC and reduced apoE content in VLDL of fatty Zucker rats, and of increased hepatic apoCIII expression, may provide insight into this process. ApoE (and apoCII) promote clearance of triglyceride-rich lipoproteins by the liver; whereas apoCIII reduces VLDL clearance by inhibiting lipoprotein lipase activity (35–39). Therefore, the VLDL composition which we have observed in the fatty Zucker rats, specifically enrichment with apoC and relative depletion of apoE, might be expected to result in delayed clearance of chylomicron remnants (and VLDL), as observed in the studies of Redgrave (33). Although the methodology used in the present study did not allow us to assess the distribution of apoC subspecies (apoCI, CII, CIII), Witztum and Schonfeld (29) observed previously that both apoCII and apoCIII are increased in VLDL of fatty Zucker rats. The interaction of apoCII and apoCIII on VLDL clearance when both are elevated deserves further study. Furthermore, our novel observation that steady-state levels of apoCIII mRNA are increased in livers of fatty Zucker rats indicates a possible role of altered apoCIII expression in the pathogenesis of hyperlipidemia in the fatty Zucker. This latter finding is unexpected in that the apoCIII gene is transcriptionally downregulated following insulin treatment of diabetic mice and in HepG2 cells transfected with an apoCIII luciferase reporter construct (39). The presence of increased apoCIII mRNA levels in the face of markedly increased plasma insulin in the fatty Zucker rat has important implications and is currently the subject of further study.

We found that increased apoA1 expression in livers of hyperinsulinemic fatty Zucker rats was accompanied by increased plasma apoA1, predominantly in HDL. Murao *et al.* (40) have, in fact, shown that insulin will induce apoAI mRNA in human hepatoma cells (Hep G2). Increased levels of HDL and apoAI have also been reported in the fatty Zucker rat by Witztum and Schonfeld (29).

The DNA, RNA, and protein data summarized in Table 1 reveal some interesting characteristics of the fatty Zucker liver. Although livers from the fatty rats were twice as large as those of lean rats the DNA, RNA, and protein contents increased to widely differing extents. The DNA content of the livers of the fatty rats was 1.5-fold greater, while those of RNA and protein were elevated 2- and 2.7-fold, respectively, indicating that there are both more and larger cells in the fatty livers. Metabolic and/or hormonal changes, including insulin, specific to the fatty Zucker rat may alter liver cell ploidy in these animals (41,42). It is also noteworthy that the content of poly(A) RNA, a measure of mRNA, per μg of total liver RNA was decreased by 28% in the fatty rats. This indicates that ribosomal and/or transfer RNA is increased to a greater extent in the livers of the fatty rats. These differences should be taken into consideration in interpreting both mRNA levels and lipoprotein production rates, and may explain why increased VLDL apoB secretion has been observed in perfused livers of fatty Zucker rats (23), but not in cultured hepatocytes where output is expressed as a function of cell number or mass (30–32).

In summary, we have demonstrated that hyperinsulinemia in the fatty Zucker rat is accompanied by increased apoB mRNA editing, increased expression of mRNA for the catalytic subunit of the editing complex, apobec-l, and increased hepatic mRNA expression of apoCIII and apoAI. These changes are accompanied by increased content of apoB48 relative to apoB 100 in plasma triglyceride-rich lipoproteins, and net accumulation of VLDL lipid and apoB in the plasma of fatty Zucker rats compard to lean littermates. In addition, the observed changes in VLDL lipid and apoprotein composition specifically, enrichment in triglyceride and apoC and relative reduction in apoE content, may alter VLDL clearance in and thereby contribute to hypertriglyceridemia in the fatty Zucker rat.

Effects of Cholestyramine on Hepatic Cholesterol 7α-Hydroxylase and Serum 7α-Hydroxycholesterol in the Hamster

Syoji Kuroki*, Tokio Naito, Kazuo Chijiiwa, and Masao Tanaka

Department of Surgery I, Kyushu University Faculty of Medicine, Fukuoka, 812-8582, Japan

ABSTRACT: Cholestyramine increases activities of hepatic cholesterol 7α-hydroxylase and serum levels of 7α-hydroxycholesterol. To examine if serum 7α-hydroxycholesterol levels parallel with enzyme activity, 0, 0.5, 1, 2, 4, and 10% of cholestyramine was administered to female golden Syrian hamsters for 28 d in the dose-dependent study, and 2% cholestyramine for 0, 1, 3, 7, 14, 21, and 28 d in the time-dependent study. In the dose-dependent study, hepatic and serum cholesterol levels were significantly decreased dose-dependently when more than 0.5% of cholestyramine was fed for 28 d. Cholestyramine increased the cholesterol 7α-hydroxylase activity in a dose-dependent manner, while the serum 7α-hydroxycholesterol level was essentially unchanged. No correlation was found between the serum level and the hepatic enzyme activity. In the time-dependent study, hepatic and serum cholesterol levels markedly decreased when 2% cholestyramine was fed for longer than 3 d. The serum triglyceride level increased significantly for the first 7 d and then decreased. Cholesterol 7α-hydroxylase activity increased significantly as early as day 1, reached maximum activity level on day 7, and then kept the significantly high values until day 28. The serum 7α-hydroxycholesterol level significantly increased for the first 7 d and decreased to the pretreatment level thereafter. 7α-Hydroxycholesterol levels significantly correlated with serum cholesterol and triglyceride levels. We conclude that the serum 7α-hydroxycholesterol level does not always reflect the activity of hepatic cholesterol 7α-hydroxylase, when cholesterol metabolism is severely disturbed by cholestyramine.

Paper no. L8016 in *Lipids 34*, 817–823 (August 1999).

The initial and rate-limiting step in bile acid biosynthesis is 7α-hydroxylation of cholesterol to form 7α-hydroxycholesterol by hepatic microsomal cholesterol 7α-hydroxylase (cholesterol 7α-monooxygenase, EC 1.14.13.17) (1). The activity of the enzyme is regulated by bile acids and cholesterol levels (1–3). Interruption of the enterohepatic circulation of bile acids by biliary diversion (4) and cholestyramine feeding (5) increases the cholesterol 7α-hydroxylase activity as well as the enzyme mass and mRNA expression. Cholesterol feeding (6,7) and depletion of dietary cholesterol by furnishing a lymph fistula (8) also stimulate the enzyme activity.

Enzyme activity was determined by isotope-incorporation technique, which measures the conversion of labeled cholesterol to 7α-hydroxycholesterol (9). Recently, more sensitive, accurate, and reproducible methods have been developed, measuring the actual mass of 7α-hydroxycholesterol by gas chromatography–mass spectrometry (GC–MS) (10) and by high-performance liquid chromatography (11). However, all these methods have a crucial limitation in human studies, because of the requirement of liver biopsy specimens.

We have recently shown a positive correlation between the serum level of 7α-hydroxycholesterol and the hepatic cholesterol 7α-hydroxylase activity in humans (12–14) and in experimental animals (15–17). From these results, we proposed that the serum level of total 7α-hydroxycholesterol may be a good indicator in assessing the enzyme activity and the amount of bile acid synthesized in the liver.

Cholestyramine is a sequestrant of bile acids and accelerates hepatic bile acid synthesis. The activities of cholesterol 7α-hydroxylase and the serum levels of 7α-hydroxycholesterol have been reported to increase with the administration of cholestyramine in rats (15) and humans (18). However, it has not been known if serum 7α-hydroxycholesterol levels reflect hepatic enzyme activity when variable doses of cholestyramine are fed for variable periods. In the present study, we examined dose- and time-dependent effects of cholestyramine on hepatic enzyme activity and serum 7α-hydroxycholesterol levels in hamsters.

MATERIALS AND METHODS

Materials. Cholestyramine (Questran, Bristol-Myers Co., Evansville, IN) was purchased from a commercial source. This preparation contains 4 g of cholestyramine in 9 g of Questran. Cholesterol, EDTA, and dithiothreitol (DTT) were obtained from Sigma Chemical Co. (St. Louis, MO). 7α-Hydroxycholesterol and 5α-cholestane-3β,7β-diol were synthesized as described previously (10). Bond-Elut silica cartridge columns were purchased from Analytichem International (Harbor City, CA). TMSI-H (hexamethyldisilazane/trimethylchlorosilane/pyridine, 2:1:10, by vol) was purchased from Gasukuro Kogyo (Tokyo, Japan). NADPH was obtained

from Kojin (Tokyo, Japan). All solvents used in the present study were of analytical grade or distilled prior to use.

Equipment. A Shimadzu GC15A GC, equipped with a flame-ionization detector, a van den Berg's solventless injector, and a data-processing system (Chromatopack C-R3A; Shimadzu, Kyoto, Japan), and a Shimadzu Auto GC–MS 9020DF GC–MS system with a data-processing system (SCAP 1123) were employed. A fused-silica capillary column (15 m × 0.2 mm) coated with a 0.25-μm layer of cross-linked methylsilicon (Hicap CBP1; Shimadzu, Kyoto, Japan) was used. Conditions for GC were as follows: column oven temperature, 280°C; injection port temperature, 290°C; detector temperature, 290°C; flow rate of helium carrier gas, 2.7 mL/min. Conditions for determination of 7α-hydroxycholesterol by GC–MS were the same as described previously (10).

Animal experiment. Female golden Syrian hamsters (Kyudo, Fukuoka, Japan), weighing 90–110 g, were used. The animals were kept in groups of 2–3 animals per cage and had free access to water and standard powder rodent chow (Oriental Yeast Co. Ltd., Tokyo, Japan) under a controlled 12-h light–dark cycle (light period from 8:00 A.M. to 8:00 P.M.) for at least a 1-wk acclimation period. In the dose-dependent study, varying concentrations of cholestyramine (0, 0.5, 1, 2, 4, and 10% in chow) were fed for 28 d to four animals in each group. In the time-dependent study, 2% cholestyramine was fed for various periods (0, 1, 3, 7, 14, 21, and 28 d, 5 to 6 animals in each group). After an overnight fast, the animals were sacrificed under ether anesthesia between 10:00 and 12:00 A.M. Blood was obtained by cardiac puncture and serum was separated and stored at −20°C until analyzed. The liver was excised, rinsed with an ice-cold homogenizing solution, and weighed. This protocol was reviewed and preapproved by the Committee of the Ethics on Animal Experiments in the Faculty of Medicine, Kyushu University, and was carried out under the control of the Guidelines for Animal Experiments of the Institute.

Determination of hepatic microsomal cholesterol 7α-*hydroxylase activity*. Cholesterol 7α-hydroxylase activity was determined by the method previously described (10). Liver homogenate was prepared in 50 mM Tris-HCl buffer (pH 7.4) containing 0.3 M sucrose, 10 mM DTT, and 10 mM EDTA. The homogenate was centrifuged at 20,000 × *g* for 15 min. The microsomal fraction was obtained by centrifugation of the supernatant fluid at 100,000 × *g* for 1 h. The microsomal pellet was suspended in the homogenizing medium without DTT and recentrifuged at 100,000 × *g* for 1 h. The resulting microsomal pellet was resuspended in 0.1 M potassium phosphate buffer (pH 7.4) containing 1 mM EDTA. An aliquot of microsomal suspension was used for protein determination using the method of Lowry *et al.* (19). The standard assay system consisted of 0.5 mL of the microsomal preparation corresponding to 0.5–1.0 mg of microsomal protein and 0.1M potassium phosphate buffer (pH 7.4) containing 1 mM EDTA and 1 mM NADPH in a total volume of 1.0 mL. The enzyme reaction was conducted for 15 min at 37°C. The reaction was terminated by addition of chloroform/methanol (2:1, vol/vol). 5α-Cholestane-3β,7β-diol was added as an internal standard. After extraction with chloroform/methanol (2:1, vol/vol), the organic phase was evaporated to dryness under a stream of nitrogen. Following purification with Bond-Elut silica cartridge column and TMS derivatization (10), the actual mass of 7α-hydroxycholesterol was analyzed by GC–MS. In the selected ion monitoring mode, the ion at *m/z* 456 (M − 90) was scanned for the trimethylsilyl ether derivative of 7α-hydroxycholesterol, and *m/z* 458 (M − 90) for that of the internal standard.

Assay of serum 7α-hydroxycholesterol. The serum concentration of 7α-hydroxycholesterol was determined as described previously (13). In brief, 200 pmol of 5α-cholestane-3β,7β-diol dissolved in 50 μL of ethanol was added to 0.5 mL of serum as the internal standard. After the addition of 0.7 mL of 0.9% NaCl solution and 1.8 mL of ethanol, sterols were extracted with *n*-hexane. The collected *n*-hexane layer was evaporated to dryness under a stream of nitrogen. Sample was then hydrolyzed in 2.0 mL of 2.5% KOH in 90% ethanol at 55°C for 45 min. After the addition of 1 mL of distilled water, the sterols were extracted with *n*-hexane and the solvent was evaporated under nitrogen. Following purification and derivatization, the serum total 7α-hydroxycholesterol level was quantitated as described above.

Determination of hepatic cholesterol and serum lipids. Approximately 100 mg of the liver was hydrolyzed with 10% KOH in 95% ethanol, containing 20.2 mg of 5α-cholestane as an internal standard, at 70°C for 2 h. Lipids were extracted and the cholesterol content was determined by GC (20). Serum cholesterol and triglyceride concentrations were determined by an automatic multichannel analyzer (Hitachi 736-40 Automatic Analyzer, Hitachi Co., Tokyo, Japan).

Statistical analysis. Values were expressed as means ± SEM. The statistical difference was evaluated using the Mann–Whitney U test. Probability values less than 0.05 were considered statistically significant. Correlations between the parameters were examined by Spearman's rank correlation test.

RESULTS

Dose-dependent study. The animals ingested approximately 10 g of chow per day, and there were no significant differences in food intake among the groups. Body weight and liver weight are summarized in Table 1. The growth of the animals was suppressed significantly in animals fed 10% cholestyramine. In 4 and 10% cholestyramine groups, one out of 4 and 2 out of 4 animals died during the experiment, respectively. The liver weight decreased significantly in animals fed more than 1% cholestyramine for 28 d. In the 10% cholestyramine group, the liver weight was approximately 50% of the controls. Serum triglyceride, serum cholesterol, and liver cholesterol concentrations are depicted in Figure 1. Serum total cholesterol concentration decreased significantly and was dose-dependent. The serum cholesterol level of animals in the 10% cholestyramine group was only 32% of the control value (186.0 ± 12.6 mg/dL in the control group). Serum triglyceride level became less than that of the control animals (322.3 ± 57.8 mg/dL). In cholestyramine-fed animals, however, a sta-

TABLE 1
Effects of Cholestyramine on the Body and Liver Weight of the Hamster, Dose-Dependent Study[a]

Dose (%)	Body weight (g)	Liver weight (g)
0	145.8 ± 3.2 (4)	6.4 ± 0.4 (4)
0.5	151.3 ± 2.7 (4)	6.3 ± 0.2 (4)
1	144.3 ± 5.3 (4)	5.2 ± 0.3 (4)
2	143.4 ± 2.6 (4)	4.4 ± 0.2[b] (4)
4	139.7 ± 7.2 (3)	4.3 ± 0.4[b] (3)
10	103.2 ± 8.3[b] (2)	3.0 ± 0.2[b] (2)

[a]A variable dose of cholestyramine (0, 0.5, 1, 2, 4, and 10% in chow) was fed for 4 wk to 4 hamsters in each group. Values are expressed as mean ± SEM; and figure in parentheses indicates number of animals.
[b]$P < 0.01$, significantly different from the value of the control group (0% cholestyramine).

tistically significant decrease was observed only in the 10% cholestyramine group. The total cholesterol concentration in the liver was significantly lower in groups fed more than 0.5% cholestyramine for 28 d; the level was nearly one-tenth that of the controls.

The cholesterol 7α-hydroxylase activities and the serum 7α-hydroxycholesterol levels after the feeding of different doses of cholestyramine for 28 d are shown in Figure 2. Cholestyramine caused a dose-related increase of the cholesterol 7α-hydroxylase activity and the activity was 6.2 times that of the control values (2.96 ± 0.59 pmol/min/mg protein) when 10% cholestyramine was fed. In contrast, the serum 7α-hydroxycholesterol levels did not increase in a dose-dependent manner and were practically unchanged compared with the control level (322 ± 58 pmol/mL), although a statistically significant decrease was observed in the 2% cholestyramine group. There was no correlation between the serum 7α-hydroxycholesterol level and the hepatic cholesterol 7α-hydroxylase activity (data not shown).

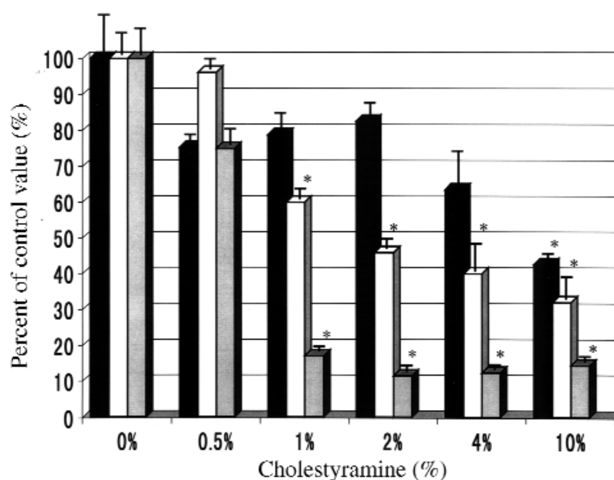

FIG. 1. Effect of cholestyramine on tissue lipid concentrations in the hamster, dose-dependent study. Variable dose of cholestyramine (0, 0.5, 1, 2, 4, and 10% in chow) was fed to 4 hamsters in each group for 4 wk. Values are expressed as percent of the control value. Closed column, light column, and gray column indicate serum triglyceride, serum total cholesterol, and hepatic total cholesterol, respectively. Vertical bar indicates SEM of 3 to 4 hamsters. *$P < 0.01$ vs. the controls.

Time-dependent study. The body and liver weights of the hamsters, which were administered 2% cholestyramine for 1 to 28 d are listed in Table 2. The animals gradually gained weight until day 14 and then the body weight was stable. The liver weight was essentially unchanged throughout the experiment. However the liver weight on the day 28 was significantly less than that of animals fed only chow (refer to Table

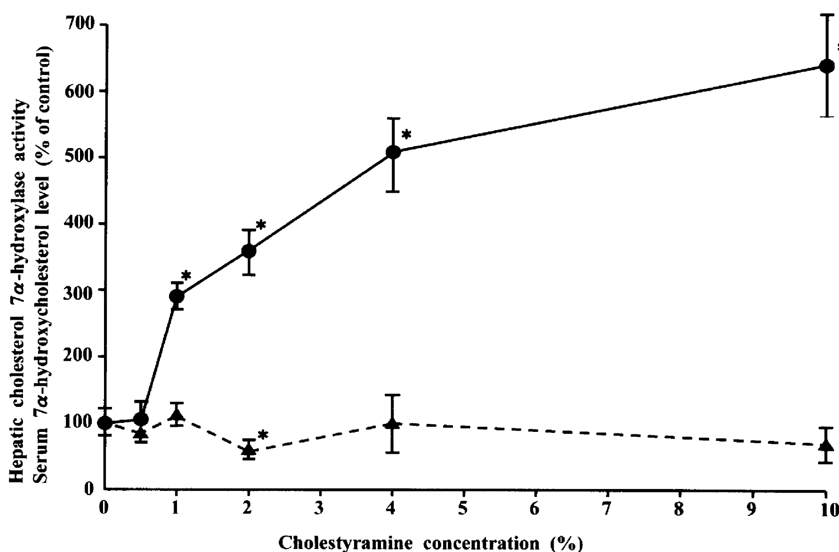

FIG. 2. Effect of cholestyramine on hepatic microsomal cholesterol 7α-hydroxylase activity and serum 7α-hydroxycholesterol level in the hamster, dose-dependent study. Variable dose of cholestyramine (0, 0.5, 1, 2, 4, and 10% in chow) was fed to hamsters for 4 wk and the hepatic enzyme activity (●) and the serum 7α-hydroxycholesterol level (▲) were determined. Values are expressed as percent of the control value. Vertical bar indicates SEM of three to four hamsters. *$P < 0.01$ vs. the controls.

[a]Cholestyramine (2% in chow) was administered for 1, 3, 7, 14, 21, and 28 d to five to six hamsters in each group. Values are expressed as mean ± SEM and figure in parentheses indicates number of animals.
[b]$P < 0.05$ and [c]$P < 0.01$, significantly different from the value of the control group (day 0).

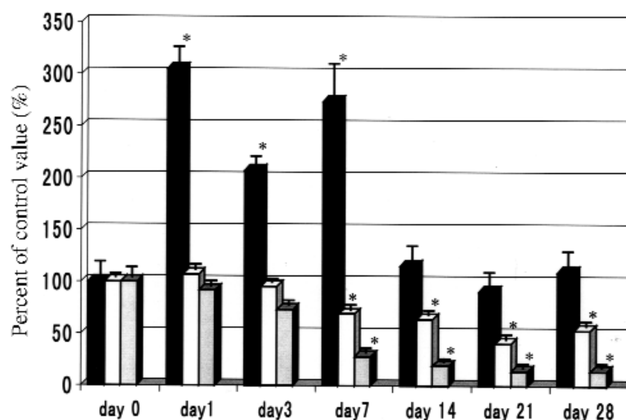

FIG. 3. Effect of cholestyramine on tissue lipid concentrations in the hamster, time-dependent study. Cholestyramine (2% in chow) was administered for 1, 3, 7, 14, 21, and 28 d to five to six hamsters in each group. Values are expressed as percent of the control value. Closed column, light column, and gray column indicate serum triglyceride, serum total cholesterol, and hepatic total cholesterol, respectively. Vertical bar indicates SEM of five to six hamsters. *$P < 0.01$ vs. the controls.

1). Figure 3 shows serum triglyceride, serum cholesterol, and liver cholesterol concentrations of the animals in the time-dependent study. Serum triglyceride increased significantly on day 1, had significantly higher levels until day 7, and then decreased. The level on day 28 was not statistically different from the pretreatment level. Serum cholesterol level was not significantly changed during the first 3 d and then significantly decreased. Serum cholesterol became about 50% of the pretreatment level on day 28. The liver cholesterol level significantly decreased from day 7 and kept the significantly low level until day 28. The liver cholesterol on day 28 was only 14% of the pretreatment value.

Hepatic cholesterol 7α-hydroxylase activities and serum 7α-hydroxycholesterol levels after feeding 2% cholestyramine for various periods are shown in Figure 4. The cholesterol 7α-hydroxylase activity increased significantly as early as day 1, and reached the maximal level on day 7, keeping significantly higher values than the basal value until day 28. The serum 7α-hydroxycholesterol level increased significantly on day 1, was significantly higher than the pretreatment value until day 7, and then decreased. The levels between day 14 and day 28 were not significantly different from the pretreatment value.

The correlation between the serum 7α-hydroxycholesterol levels and the serum cholesterol levels is shown in Figure 5. There was a significant positive correlation between the serum 7α-hydroxycholesterol level and the serum cholesterol levels ($n = 28$, $r = 0.58$, $P < 0.01$). There also was a significant positive correlation between the serum 7α-hydroxycholesterol levels and the serum triglyceride levels (Fig. 6, $n =$

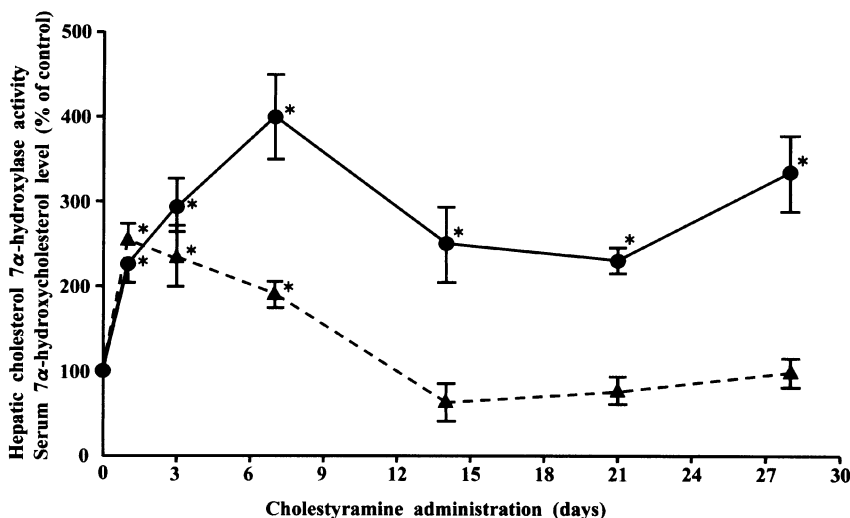

FIG. 4. Effect of cholestyramine on hepatic microsomal cholesterol 7α-hydroxylase activity and serum 7α-hydroxycholesterol level in the hamster, time-dependent study. Cholestyramine (2% in chow) was administered for 1, 3, 7, 14, 21, and 28 d and the hepatic enzyme activity (●) and the serum 7α-hydroxycholesterol level (▲) were determined. Values are expressed as percent of the control value. Vertical bar indicates SEM of five to six hamsters. *$P < 0.05$ vs. day 0.

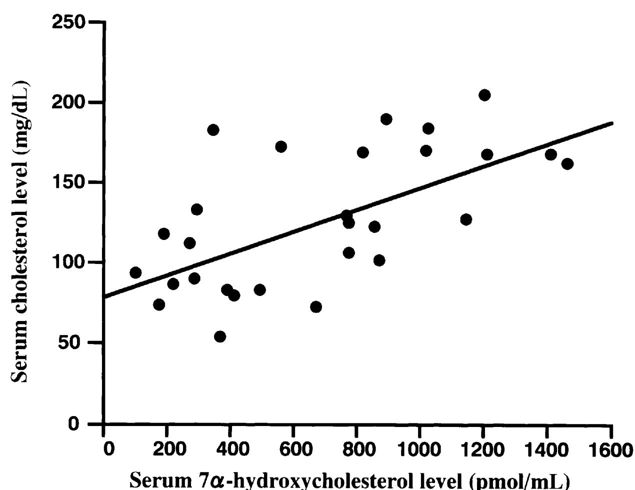

FIG. 5. Correlation between the serum 7α-hydroxycholesterol level and the serum cholesterol level, time-dependent study. A significant positive correlation was observed ($y = 0.07x + 80.8$, $n = 28$, $r = 0.58$, $P < 0.01$).

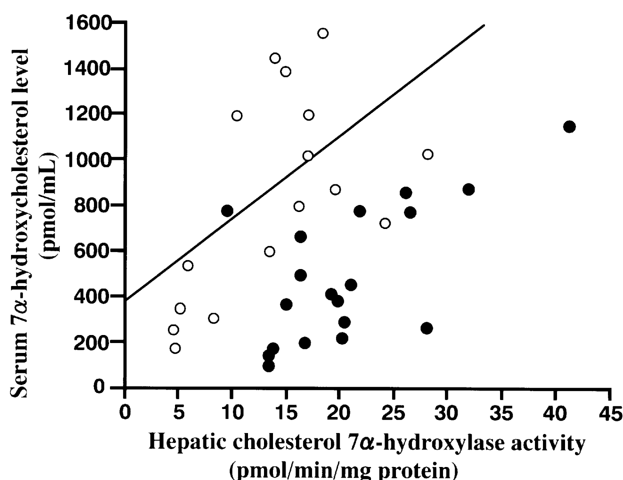

FIG. 7. Relationship between the hepatic cholesterol 7α-hydroxylase activity and the serum 7α-hydroxycholesterol level, time-dependent study. Open circles (○) indicate animals fed 2% cholestyramine for 0–3 d (16 animals). There was a significant positive correlation between the two parameters ($y = 36.4x + 379$, $n = 16$, $r = 0.58$, $P < 0.01$). Closed circles (●) indicate animals fed 2% cholestyramine for 7 to 28 d (19 animals). There was no significant correlation in all animals ($n = 35$, $r = 0.264$, $P = 0.126$).

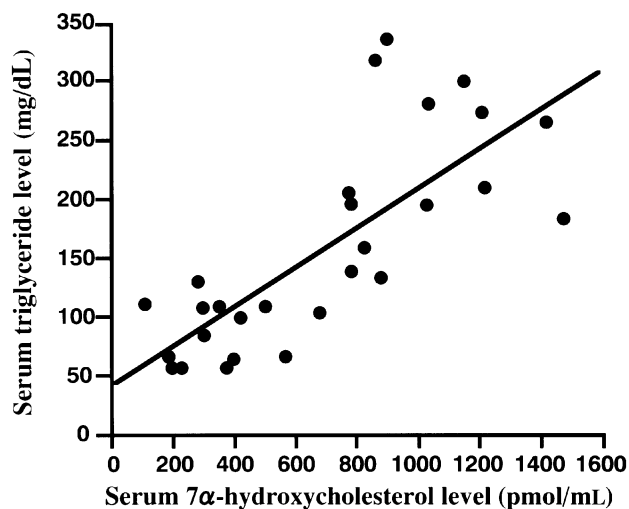

FIG. 6. Correlation between the serum 7α-hydroxycholesterol levels and the serum triglyceride levels, time-dependent study. A significant positive correlation was observed ($y = 0.17x + 43.4$, $n = 28$, $r = 0.78$, $P < 0.01$).

28, $r = 0.78$, $P < 0.01$). The relationship between the hepatic cholesterol 7α-hydroxylase activities and the serum 7α-hydroxycholesterol levels in the time-dependent study is shown in Figure 7. There was no significant correlation between the hepatic cholesterol 7α-hydroxylase activities and the serum 7α-hydroxycholesterol levels in all animals (open and closed circles). However, there was a significant positive correlation between the enzyme activities and the serum 7α-hydroxycholesterol levels during the first 3 d (Fig. 7, open circles, $n = 16$, $r = 0.58$, $P < 0.01$), when serum and hepatic cholesterol levels were not decreased significantly (Fig. 3).

DISCUSSION

Cholestyramine is an ion exchange resin that binds anions such as bile acids (9). Because bile acids play an important role in the absorption of cholesterol (21), the binding of bile acids by cholestyramine decreases intestinal cholesterol absorption (9). Interruption of the enterohepatic circulation of bile acids by cholestyramine decreases bile acid concentration in the portal blood and increases bile acid synthesis by a negative feedback mechanism (15,22). It is generally accepted that the hepatic cholesterol 7α-hydroxylase activity increases several fold by cholestyramine feeding (23–27). As a result, elimination of cholesterol from the body is greatly accelerated by cholestyramine. Although the liver may respond to compensate for the situation by increasing *de novo* cholesterol synthesis (28–30), the serum and liver cholesterol concentrations are decreased by the oral administration of cholestyramine in experimental animals (31) as well as in humans (32).

As cholestyramine is not absorbed by the intestine, it is considered to be a safe hypocholesterolemic agent. In the present study, however, animals fed extraordinarily high concentrations of cholestyramine (10%) did not gain weight, and some of them died. The liver was apparently atrophic, and cholesterol concentrations of the liver and serum were dramatically decreased. Serum transaminase levels were not measured in this study, however, it is not likely that cholestyramine has direct hepatotoxicity, as we previously showed unchanged serum transaminase levels when 2% cholestyramine was fed to hamsters for 5 wk (33). The cholesterol metabolism of the hamster is known to be very sensi-

tive to dietary cholesterol manipulation when compared to rats and humans (31). The administration of high concentrations of cholestyramine to hamsters is reported to decrease the body cholesterol pool by extensive losses of bile acids and cholesterol into the feces (31). Humans are reported to be less sensitive to cholesterol load (34) and cholestyramine (32,35) and the toxic effect of cholestyramine observed in the present study may not be directly applicable to humans. However, it should be pointed out that there might be a possible toxicity of cholestyramine treatment in patients with disturbed cholesterol synthesis, such as those with liver cirrhosis (35).

In the dose-dependent study, the activity of hepatic cholesterol 7α-hydroxylase significantly increased in hamsters when more than 0.5% of cholestyramine was fed. In contrast to the increase in the enzyme activity, the concentrations of serum 7α-hydroxycholesterol did not increase. No correlation between the cholesterol 7α-hydroxylase activity and the serum 7α-hydroxycholesterol level was found. The result was not expected from the previous report in which cholestyramine increased both the enzyme activity and the serum 7α-hydroxycholesterol level in rats (15). We also reported the increased serum 7α-hydroxycholesterol levels in cholestyramine-fed humans (35). We hypothesized that the serum 7α-hydroxycholesterol level may increase from a short-term cholestyramine feeding and then decrease to the pretreatment levels after a prolonged administration of cholestyramine. Thus, the time-dependent study was conducted.

For the time-dependent study, 2% cholestyramine was selected. At this dose, serum and liver cholesterol levels began to decrease significantly on day 7 after the administration of cholestyramine. The activity of cholesterol 7α-hydroxylase increased significantly as early as the first day, reached the maximum level on day 7, and remained high thereafter.

As hypothesized above, the serum 7α-hydroxycholesterol levels did not respond as hepatic cholesterol 7α-hydroxylase activity did after the 2% cholestyramine feeding. The time-dependent study has clearly shown that the serum 7α-hydroxycholesterol levels significantly increased for the first 7 d and then decreased to the pretreatment levels between the 14th and 28th days, when hepatic cholesterol 7α-hydroxylase activity remained significantly higher than the pretreatment value.

This is the first report to reveal the inconsistent behaviors of the cholesterol 7α-hydroxylase activity and the serum 7α-hydroxycholesterol level. In our previous study, we reported that the serum 7α-hydroxycholesterol level reflects the enzyme activity in humans and rats under various conditions (12–17). In the present study, however, there was no correlation between the cholesterol 7α-hydroxylase activities and the serum 7α-hydroxycholesterol levels. It should be noted, however, that there was a significant positive correlation between the two parameters during the first 3 d after 2% cholestyramine feeding, when serum and hepatic cholesterol concentrations were not altered significantly. These results suggest that the serum level of 7α-hydroxycholesterol could still be an indicator of hepatic cholesterol 7α-hydroxylase activity when tissue cholesterol levels are not significantly affected. However, these results do not reflect the hepatic enzyme activity under a severely disturbed cholesterol metabolism.

The key to solving the mystery of inconsistent serum 7α-hydroxycholesterol behavior may be the participation of low density lipoprotein (LDL) receptors. It has been well documented that LDL receptors on the surface of the hepatocytes increase in animals treated with cholestyramine (28,29,36). Because most of serum 7α-hydroxycholesterol is present in the LDL fraction (37), the increased uptake of serum LDL *via* LDL receptors should result in the elimination of serum 7α-hydroxycholesterol. The statistically significant positive correlation between the serum cholesterol or serum triglyceride levels and the serum 7α-hydroxycholesterol levels shown in the present study (Figs. 5 and 6) support the mechanism.

In summary, the activity of hepatic microsomal cholesterol 7α-hydroxylase increased in relation to time and dose in cholestyramine fed hamsters. Also, we found that the serum 7α-hydroxycholesterol level does not always reflect the activity of hepatic cholesterol 7α-hydroxylase, when cholesterol metabolism is severely affected

ABSTRACT: Oleate is one of the most abundant dietary fatty acids, and much remains to be learned about its metabolism in fat cells. We studied the incorporation of exogenous [1-^{13}C]-oleate into triglycerides (TG) in differentiating 3T3L1 preadipocytes using ^{13}C NMR spectroscopy. The quantity of oleate incorporated into TG was found to increase as preadipocytes differentiated into fat cells. The ratio of unesterified [1-^{13}C]oleate to total stored fatty acids was higher in less differentiated cells, and declined at later stages of differentiation as cells accumulated fatty acids through *de novo* synthesis. When added as the only exogenous fatty acid, oleate was largely esterified at the *sn*-2 position. When equimolar unlabeled linoleate was co-provided at the same time, the ratio of [1-^{13}C]oleate esterified at the *sn*-1,3 position increased, implying competition between linoleate and oleate for esterification, especially at the *sn*-2 position. When cells pre-enriched with [1-^{13}C]oleate (esterified to TG) were treated with isoproterenol, a lipolytic agent, most of the [1-^{13}C]oleate was still found in TG, despite a high rate of lipolysis determined by measuring glycerol release. This implies extensive re-esterification of the oleate released by lipolysis.

Paper no. L8102 in *Lipids 34,* 825–831 (August 1999).

Oleic acid is present in a variety of acylated lipids, including phospholipids, cholesteryl esters, and triglycerides. The metabolism of oleate plays an important role in a number of diseases, particularly obesity and atherosclerosis (1–6). As adipose tissue is the major organ for fatty acid storage and release, elucidation of how oleate is metabolized in adipocytes and how this is affected by other fatty acids is of considerable importance.

^{13}C nuclear magnetic resonance (NMR) spectroscopy has proven very useful for investigating the metabolism of fatty acids in adipocytes, particularly for identifying esterification products (7–12). A ^{13}C NMR analysis of perfused cultured 3T3L1 adipocytes showed the utility of [1-^{13}C] labeled fatty acids for monitoring incorporation of exogenous fatty acids and their release through lipolysis (8). Cellular enzymes tended to esterify saturated fatty acids to the *sn*-1,3 positions and unsaturated fatty acids to the *sn*-2 position of glycerol. Under basal conditions, the rate of fatty acid release was the same from both carbonyl positions. When stimulated by a lipolytic agent, the rate of fatty acid release was greater from the *sn*-1,3 position than from the *sn*-2 position (8). Such studies employing perfused cells can detect cell metabolic products, providing valuable information about cellular events. However, perfusion experiments have to be completed in relatively short periods of time.

We recently used a different strategy to study the incorporation of exogenous fatty acids into cellular lipids (9). Cells maintained in monolayer culture were incubated with fatty acids at appropriate stages of differentiation for various periods of time. Cultures were terminated and the cellular lipids were extracted for NMR analysis. A known amount of [1-^{13}C]methyl myristate was added before extraction to serve as an internal integration reference. This method is advantageous for its optimal spectral resolution, sensitivity for a given mass of lipid, and flexible cell incubation conditions. We applied this method to study the incorporation of palmitate in rat preadipocytes, and found that palmitate could be esterified into both phospholipids (particularly at the *sn*-1 position) and triglycerides (with even distribution between *sn*-1,3 and *sn*-2 positions). As cells became more differentiated, the incorporation of palmitate into phospholipids decreased, whereas incorporation into triglycerides increased (9).

In this work, we used a similar strategy to study the incorporation of oleate into lipids in 3T3L1 cells at different stages of differentiation and to study the effects of lipolysis on the esterified oleate.

EXPERIMENTAL PROCEDURES

Cell culture and sample preparation. NIH-3T3L1 cells were cultured in basal medium [DMEM, fetal bovine serum (10%), penicillin (100 units/mL), and streptomycin (100 μg/mL)] until 2 d post confluency. To induce differentiation, cultures were exposed to basal medium supplemented with MDI [methylisobutylxanthine (120 μg/mL), dexamethasone (0.39 μg/mL), and insulin (100 μU/mL)]. Two days later, cells were

incubated in basal medium supplemented with insulin (25 μU/mL). Medium was changed every 2–3 d. Multiple, small intracellular lipid droplets were visible by phase contrast microscopy 2 d after MDI treatment.

Sample preparation. A stock solution containing [1-^{13}C]-oleate complexed to bovine serum albumin (BSA) was added to the cell culture medium [concentration of [1-^{13}C]oleate = 1 mM, BSA = 0.2 mM, at the beginning of free fatty acid (FFA) incubation] during a regular medium change. Incubations were terminated at various time points by removing the medium. Cells were washed three times with phosphate buffer saline solution (pH = 7.4), scraped off into methanol, and Folch-extracted as described previously (9). Lipids were dissolved in deuterated chloroform and stored at 4°C under dry N_2 to prevent oxidation until the NMR experiments were performed. For each sample preparation, cells were harvested from one 100-mm culture dish. All cultures used were treated with MDI 2 d post confluency. As cells differentiated, confluency was maintained. Within the time frame of our experiment, we did not notice significant loss of cells (>5%). The total DNA value was 136 ± 10 μg/culture. Incubation with 1 mM of fatty acids complexed to BSA solution with a 5:1 molar ratio did not affect cell viability. We measured DNA instead of protein as the index for cell number because cellular protein levels change as cells differentiate, whereas the total DNA level generally remains constant after MDI treatment.

Chemicals. [1-^{13}C]oleate and deuterated solvent ($CDCl_3$) were purchased from CIL (Cambridge, MA), [1-^{14}C]oleate from NEN (Boston, MA), glycerol analysis reagent from Sigma Chemical Co. (St. Louis, MO), unlabeled linoleate and all other organic solvents were HPLC grade and purchased from Aldrich (Milwaukee, WI). [1-^{13}C]methyl myristate was prepared as described previously (9).

NMR spectroscopy. ^{13}C NMR spectra were obtained at 125 MHz on a Bruker DMX-500 spectrometer (Billerica, MA) with a 5-mm triple resonance probe. A 90° pulse width (12 μs), ^{1}H decoupling with the inverse-gated Waltz-16 sequence, and a pulse interval of 7.0 s were used for generating all spectra. The T_1 effects on integrated intensities were calibrated as described before (9). All NMR experiments were performed at 12°C to minimize solvent evaporation. The center peak of $CDCl_3$ in the spectrum was used as an internal chemical shift reference (77.0 ppm). All spectra were acquired with 4000 scans and processed without linebroadening to optimize resolution.

Determination of total triglycerides (TG) by densitometry. After the NMR experiments, thin-layer chromatography was performed to quantitate total TG (labeled plus unlabeled). About 10 μg of the total lipid mixture were spotted on a 10 × 10 cm HPTLC-GHL silica gel plate (Analtech, Newark, DE) and eluted in a solvent mixture for neutral lipids (hexane/ethyl ether/acetic acid, 70:30:1). The plate was sprayed with sulfuric acid and charred. The plate was then scanned and the volume of the TG component in each sample was quantified on a Diversity pdi 420oe™ scanner (Huntington Station, NY) with a reference to a known external thin-layer chromatograph reference standard (18-5A; Nu-Chek-Prep, Elysian, MN) eluted on the same plate. The total amount of TG so measured was converted to molar scale by assuming an average molecular weight of 887 (triolein).

Isotope tracing of [1-^{14}C]oleate in the culture medium. At appropriate stages of differentiation, cells were incubated with 1 mM unlabeled oleate/BSA complex containing a trace amount of [1-^{14}C]oleate (~3 μCi). Aliquots of the culture medium were taken at various time points and acidified to expel dissolved CO_2. Then the sample was mixed with 10 mL scintillation liquid and counted on a Wallace 1217 Rackbeta liquid scintillation counter (Gaithersburg, MD). Samples prepared in this way could contain minor amounts of soluble metabolites. However, other investigators have reported that exogenous long-chain fatty acids are exclusively (>98%) used for TG synthesis in differentiating preadipocytes (13). We also found that the amount of $^{14}CO_2$ produced from ^{14}C-labeled exogenous long-chain fatty acids in cells prepared under our conditions was negligible (unpublished results). Hence, we assumed that the amount of isotope remaining in the medium represented the amount of residual fatty acids.

Measurement of lipolysis. Lipolysis was measured by assaying glycerol released into the incubation medium. Briefly, cells at appropriate stages of differentiation were incubated with [1-^{13}C]oleate for 5 h to enrich the intracellular TG pool. Control cultures were terminated at this point to prepare samples for NMR and total TG measurement. Parallel cultures were washed three times with PBS and incubated with lipid-free, serum-free, and BSA-free DMEM containing ISO (10 μM) with and without insulin (100 μU/mL). At the end of the incubation, the medium was aspirated and assayed enzymatically for glycerol (Sigma Procedure No. 337) (14). Because fat cells do not have glycerol kinase, glycerol released from lipolysis cannot be metabolized (31), and is thus generally used as an index for lipolysis (24). Cellular lipids were extracted as described above.

RESULTS

^{13}C NMR spectral features. A complete ^{13}C NMR spectrum of the total lipid extract from cells incubated with [1-^{13}C]-oleate is illustrated in Figure 1. Signals in the upfield region (10–40 ppm) represent the background of the naturally abundant acyl chain carbons and are similar to those observed in pure triglycerides (8,10). Peaks in the region of 60–70 ppm are from glyceryl carbons, and those at ~130 ppm are from olefinic carbons. Compared to these naturally abundant signals, the carbonyl region (172–175 ppm) is dominated by two intense peaks with chemical shifts corresponding to the carbonyls at the *sn*-1,3[TG(1,3)] and *sn*-2 [TG(2)] positions in the TG molecules. Signals from *sn*-1 and *sn*-3 carbonyls are not discriminated in this spectrum. The farthest downfield signal (174.5 ppm) is from added [1-^{13}C]methyl myristate that serves as an internal integration reference.

Signals from phospholipids or other acylated lipids were not detected in this spectrum, indicating that TG was the main labeled component in the lipid mixture. In principle, [1-^{13}C]-

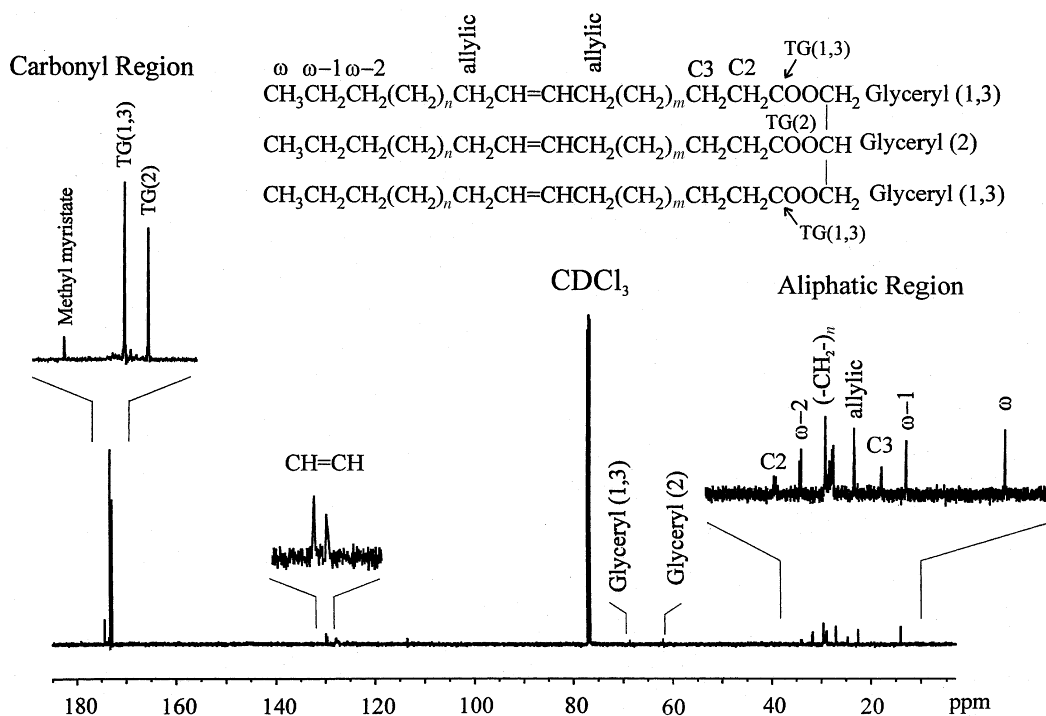

FIG. 1. The full ^{13}C nuclear magnetic resonance spectrum of a lipid extract from differentiated 3T3L1 cells incubated with [1-^{13}C]oleate for 1 h. After longer periods, signals in the aliphatic region became insignificant compared to the carbonyl signals as accumulation of esterified [1-^{13}C]oleate increased. In this spectrum, 50 μL (1 mg/mL) of internal standard solution was added. For all other samples studied, 50–200 μL of the same standard solution was added to the cells before the Folch extraction. The amount of standard added was based on the cellular TG content estimated by microscopy before cell harvesting, so as to minimize any integration error due to large differences between the intensities of the reference signal and the lipid signals.

oleate could be β-oxidized to produce [1-^{13}C]acetylCoA for *de novo* synthesis of long-chain fatty acids. If this occurred to a significant extent, ^{13}C enrichment would appear in the aliphatic carbons, and signal enhancement would have been detected in the aliphatic spectral region. The absence of such signals indicated that utilization of acetylCoA derived from the β-oxidation product of [1-^{13}C]oleate was not significant. Therefore, the incorporation of exogenous [1-^{13}C]oleate into TG can be determined by the integrated intensity of [TG(1,3) + TG(2)], and the distribution of [1-^{13}C]oleate between the *sn*-1,3 and *sn*-2 positions can be determined by the peak intensity ratio of TG(1,3)/TG(2).

Incorporation of [1-^{13}C]oleate increases as cells differentiate. Treatment with MDI stimulates differentiation of 3T3L1 cells (15). Using the NMR method described above, we measured the incorporation of exogenous [1-^{13}C]oleate into TG in cells at different stages of differentiation (Table 1). In essentially undifferentiated cells (day 0), total cellular TG content was very low (Table 1), and the exogenous [1-^{13}C]-oleate incorporated into TG (within 5 h incubation) accounted for ~30 mol% of the total stored fatty acids. This ratio decreased to ~10% when cells were highly differentiated (Table 1), probably because *de novo* synthesis from glucose also provides a significant quantity of fatty acids for storage

TABLE 1
Total Free Fatty Acid Content, [1-^{13}C]Oleate Incorporated Into TG, Esterification at TG(1,3)/(TG(2), and Ratio of [1-^{13}C]Oleate to Free Fatty Acid[a]

	Days					
	0	2	3	4	5	7
Total FFA (μmol)	0.54 ± 0.2	1.2 ± 0.3	5.1 ± 1.5	16.2 ± 2.4	23.5 ± 2.7	27 ± 1.1
[1-^{13}C]Oleate (μmol)	0.15 ± 0.03	0.2 ± 0.03	0.5 ± 0.07	1.5 ± 0.2	2.1 ± 0.2	2.4 ± 0.2
TG(1,3)/TG(2)	2.0 ± 0.1	1.8 ± 0.1	1.7 ± 0.1	1.3 ± 0.1	1.22 ± 0.1	1.2 ± 0.1
[1-^{13}C]Oleate/stored FFA (%)	28 ± 1	17 ± 2	10 ± 3	9 ± 2	8.9 ± 1	8.9 ± 1

[a]Results are presented as ±SE per culture (n = 3). Readings were taken from lipids extracted from cells after a 5-h incubation with [1-^{13}C]oleate on different days after MDI treatment. FFA, free fatty acid; MDI, methylisobutylxanthine (120 μg/mL), dexamethasone (0.39 μg/mL), and insulin (100 μU/mL); TG, triglyceride.

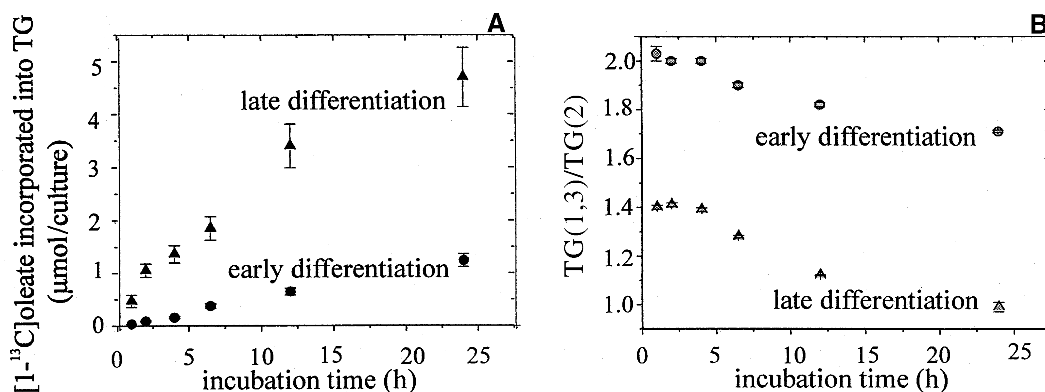

FIG. 2. (A) The incorporation of [1-^{13}C]oleate into triglycerides (TG) in cells at early [2 d after 120 μg/mL methylisobutylxanthine, 0.39 μg/mL dexamethasone, 100 μU/mL insulin (MDI) treatment] and late (6 d after MDI treatment) stages of differentiation as a function of incubation time. (B) The ratio of [1-^{13}C]oleate esterifed at the TG(1,3)/TG(2) positions as a function of incubation time. Data are presented as mean ± SE, *n* = 3.

(16). Palmitate, as the major end product of *de novo* synthesis (17), may have become increasingly available. Previous studies showed that palmitate is more likely than oleate to be esterified at the *sn*-1,3 position (8). Probably for these reasons, more [1-^{13}C]oleate was directed toward *sn*-2 position, resulting in a net decrease of the TG(1,3)/TG(2) ratio (Table 1).

Incorporation of [1-^{13}C]oleate increases with incubation time. To study the time-dependent incorporation (0–24 h) of [1-^{13}C]oleate into cellular lipids, we incubated cells at early (day 2) and advanced (day 6) stages of differentiation. Figure 2A shows that the incorporation of [1-^{13}C]oleate was dependent on incubation time, and total incorporation was greater in cells at advanced stages of differentiation. At the end of a 24-h incubation, the amount of [1-^{13}C]oleate detected in cellular TG was about 21% (2 d after MDI) and 72% (6 d after MDI) of the total [1-^{13}C]oleate added.

Analogous to the results shown in Table 1, we found that the incorporation of [1-^{13}C]oleate was similar at the TG(1,3) and TG(2) positions [TG(1,3)/TG(2) ≅ 2] in cells at early stages of differentiation. However, oleate was more likely to be esterified in the TG(2) position in cells at the advanced stage of differentiation. There was a gradual decrease in the TG(1,3)/TG(2) ratio as incubation time increased (Fig. 2B). This indicates that rearrangement of [1-^{13}C]oleate from the *sn*-1,3 to the *sn*-2 position may occur when the incubation time increases or the concentration of exogenous [1-^{13}C]-oleate decreases.

To determine the rate of substrate utilization, we incubated cells with unlabeled oleate (1 mM) and a trace amount of [1-^{14}C]oleate. We then measured the [1-^{14}C]oleate remaining in the medium to determine the concentration of exogenous oleate at different time points over a 24-h period (Fig. 3). The clearance of exogenous oleate was faster in cells at advanced stages of differentiation, and the labeled oleate was about 30% (2 d) and 85% (6 d) depleted at the end of a 24-h incubation. Both values are slightly greater than the amount of [1-^{13}C]oleate recovered in cellular TG (see above).

As previously reported (13), and as is evident from our data, the major metabolic fate of exogenous oleate is esterification into TG. Hence, the net rate of oleate usage can be approximately described by:

$$3 \text{ oleate} + \text{glycerol-3-phosphate} \rightarrow \text{TG} \qquad [1]$$

Because the cells used in this study were at a relatively early stage of differentiation compared to mature fat cells, the extent of accumulation of fatty acids into TG was far less than that of typical adipocytes (10). Hence, we can assume that there is no product inhibition in the reaction (Eq. 1), and the equilibrium constant is very large, so that the integrated form of the Henri-Michaelis-Menten equation (18) is applicable to describe the kinetics of oleate usage:

$$V_{max} = 2.3K_m \log \{[S_o]/[S]\} + ([S]_o - [S]) \qquad [2]$$

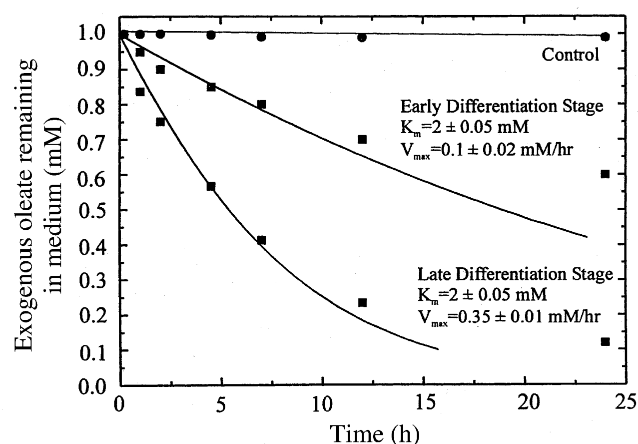

FIG. 3. The concentration of residual oleate in the culture medium after different incubation time intervals. Total oleate concentration was 1 mM at the beginning of incubation. Solid lines are the nonlinear least squares fit to the Henri-Michaelis-Menten equation. The last data point (24 h) was not included in the fit because the reaction mechanism might not be applicable after extended incubation.

TABLE 2
The Effects of Incubation with Linoleate (1 mM) and [1-^{13}C]Oleate (1 mM) on Differentiating 3T3L1 Adipocytes at Mid-Stage of Differentiation (4 d after MDI treatment)[a]

	Oleate	Oleate + linoleate
Total TG-derived FFA (μmol)	25.5 ± 5.1	26.7 ± 4.5
TG-incorporated [1-^{13}C]oleate (μmol)	2.6 ± 0.06	1.9 ± 0.04
% [1-^{13}C]Oleate /total TG-fatty acids	10.2 ± 0.3	7.1 ± 0.4
TG(1,3)/TG(2), ($P < 0.001$)	1.6 ± 0.2	2.7 ± 0.1

[a]Cells were incubated with the listed fatty acids in DMEM containing 10% FBS and insulin (100 μU/mL) for 5 h. The results are presented as mean ± SE per culture ($n = 3$). For abbreviations see Table 1.

where $[S]$ is the substrate (oleate) concentration with $[S]_o = 1$ mM, K_m is the pseudoequilibrium constant, and V_{max} is the limiting maximal velocity. Using a nonlinear least square-root fitting program, we calculated the values of K_m and V_{max} as indicated in Figure 3. For cells treated on day 2 and day 6, the K_m values were the same (~2 mM). V_{max} was substantially higher in the more differentiated cells. This is in accord with the general observations that both the mass and activities of lipogenic enzymes increase as cells progress to more advanced stages of differentiation (19).

Effects of linoleate on the incorporation of [1-^{13}C]oleate. As shown above, [1-^{13}C]oleate is more likely to be esterified at the *sn*-2 than *sn*-1,3 position, especially in cells at more advanced stages of differentiation or after longer periods of incubation. By exposing cells simultaneously to equimolar [1-^{13}C]oleate and linoleate (unlabeled), we found that the TG(1,3)/TG(2) ratio increased significantly in the presence of linoleate (Table 2). This alteration in positional labeling suggests competition between oleate and linoleate for storage in TG, especially into the *sn*-2 position.

Lipolysis and the reesterification of [1-^{13}C]oleate in cellular TG. We measured glycerol release in parallel with ^{13}C NMR lipid analysis in cells treated with lipolytic (ISO) and antilipolytic (insulin) agents. During 1–2 h incubations with ISO, glycerol release ranged from 1.1 to 5.3 μmol/culture (Table 3). During the first hour of incubation with ISO, addition of insulin suppressed glycerol release. Cells incubated with ISO lost about 10% of stored [1-^{13}C]oleate (Table 3, column A), whereas those incubated with ISO and insulin lost only ~1% (Table 3, column C). A second exposure to ISO stimulated glycerol release to the same extent in the presence or absence of insulin (cf. columns B and D). However, insulin still promoted slightly more retention of [1-^{13}C]oleate at both the *sn*-1,3 and *sn*-2 positions (Table 3, columns B and D). In all cases, free [1-^{13}C]oleate was not detected, and the retention of [1-^{13}C]oleate was higher at the *sn*-2 than *sn*-1,3 positions. In looking at the percent of [1-^{13}C]oleate in total stored FFA, we found that total TG contents before and after lipolytic treatment were similar (3.3 ± 0.4 mg/culture), implying active TG synthesis with simultaneous TG hydrolysis.

DISCUSSION

In the presence of high concentrations of glucose, most of the fatty acids stored in 3T3L1 adipocytes are synthesized *de novo*. These are mainly saturated and monounsaturated C_{14}–C_{18} fatty acids (20). In cells at early stages of differentiation, exogenous [1-^{13}C]oleate was the major substrate for TG synthesis (Table 1) when *de novo* synthesis was not yet very active (15). Additionally, at the beginning of incubation with oleate (Fig. 2B), the ratio of [1-^{13}C]oleate incorporated at the *sn*-1,3 and *sn*-2 positions was close to 2.0. Under conditions in which the quantity of *de novo* synthesized fatty acids would be predicted to increase (as incubation time increased, or in cells at more advanced stages of differentiation), relatively more [1-^{13}C]oleate became esterified at the *sn*-2 position (Table 1, Fig. 2B).

The greater propensity for [1-^{13}C]oleate to be esterified at the *sn*-2, rather than *sn*-1,3 position, could be a mechanism through which cells maintain an unsaturated acyl chain at the *sn*-2 position. Fatty acids with a higher extent of unsaturation than oleate appear to compete with oleate for esterification at the *sn*-2 position. When unlabeled linoleate was added to cells in combination with an equimolar amount of [1-^{13}C]oleate, we found that the incorporation of [1-^{13}C]oleate into TG was reduced by ~20%. However, the ratio of TG(1,3)/TG(2) increased by 69% (Table 2). This suggests that linoleate has a greater probability than oleate of being esterified at the *sn*-2 position. The total amount of stored TG did not change significantly, probably because the incubation was only for a rel-

TABLE 3
[1-^{13}C]Oleate Incorporation into TG Following Exposure to ISO and ISO/Insulin[a]

	Control	A	B	C	D

[a](A) [1-^{13}C]Oleate incorporation into TG in cells following exposure to ISO for 1 h; (B) after exposure for 2 h with a second dose of ISO at the end of the first hour; (C) following exposure to ISO/insulin for 1 h; (D) following exposure to ISO/insulin for the first hour, plus a second dose of ISO at the end of the first hour, and incubation extended for an additional hour. Results are presented as mean ± SE per culture ($n = 3$).
[b]Cells used were collected 3 d after MDI treatment.
[c]Control cultures were terminated at the beginning of lipolysis experiments, thus with no measurement of glycerol release. Basal glycerol release (without ISO) was 0.3 ± 0.1 μmol/culture after a 2-h incubation. See Table 1 for abbreviations.

atively short period after most of the stored TG had already been acquired from *de novo* lipid synthesis.

Incorporation of exogenous oleate into TG may occur from direct esterification into TG or degradation and reacylation of existing TG. While we are not able to discriminate between these two processes, we expect that the former plays an important role because of the rapid TG synthesis in differentiating cells and their relatively low net TG storage compared to mature fat cells. Biosynthesis of TG (and also phospholipids) begins with the acylation of glycerol-3-phosphate to lysophosphatidate and then to phosphatidate, which is further hydrolyzed into diacylglycerol (21). Diacylglycerol is the common precursor for both TG and phospholipids. The esterification at the *sn*-2 position by lysophosphatidate acyltransferase is relatively selective for unsaturated fatty acids (21). For these reasons, most phospholipid molecules contain palmitate or stearate in the *sn*-1 position and primarily unsaturated fatty acids in the *sn*-2 position (22). However, this selectivity is not absolute, and the fatty acid composition of the newly synthesized TG depends on the fatty acids available in the cell. Unsaturated fatty acids, when present, are more likely than saturated fatty acids to be esterified to the *sn*-2 position. They can also be esterified to *sn*-1,3 positions, especially when they are the major fatty acids available for TG synthesis. Our results agree with this paradigm, and further indicate that polyunsaturated fatty acids are more likely than monounsaturated fatty acids to be esterified at the *sn*-2 position.

When cells preincubated with [1-^{13}C]oleate were subjected to lipolysis stimulated by ISO, the extent of glycerol release (Table 3) indicated that about 55% of the stored TG was hydrolyzed after a 1-h incubation, about eightfold above basal glycerol release. This was somewhat greater than the typical four- to fivefold stimulation by ISO reported previously (23,24). This discrepancy is probably related to the different compositions of the basal media used in the different studies. A second exposure to ISO further increased glycerol release. It must be pointed out that the amount of glycerol released represents the amount of TG molecules that have been hydrolyzed. In the meantime, new TG molecules are being constantly synthesized from both endogenous and exogenous fatty acids and glucose. The endogenous fatty acids include those released from TG hydrolysis or obtained *via de novo* synthesis.

In these experiments, BSA was removed after incubation, and lipolysis proceeded in the absence of an extracellular "sink" for the released fatty acids [i.e., BSA (8,25)]. This condition prevents the removal of the released fatty acids. The NMR determination of esterified [1-^{13}C]oleate represents the sum of molecules that have not been cleaved and those that have been cleaved and reesterified. With the presence of a high concentration of glucose, utilization of fatty acids for oxidation is limited (26). Our finding that 83–96% of [1-^{13}C]-oleate remained esterified in TG indicates that a majority of the released fatty acids were reesterified. The continuous recycling of fatty acids maintains or even increases substrate availability for lipolysis.

The addition of insulin during the first hour of lipolysis reduced glycerol release by ~50%. [1-^{13}C]Oleate was found at both *sn*-1,3 and *sn*-2 positions with little change compared to the control. Taken together, these results suggest that the rate of TG hydrolysis was reduced and nearly all the released fatty acids were rapidly reesterified. A second dose of ISO overcame the inhibitory effect of insulin on lipolysis, resulting in glycerol release to an extent similar to that found in cells incubated in the absence of insulin. The amount of [1-^{13}C]-oleate in the TG molecules was still higher than in cells incubated without insulin (Table 3), suggesting that although the insulin/ISO ratio was not sufficient to suppress TG hydrolysis, it still enhanced the reesterification of released fatty acids.

Another interesting observation shown in Table 3 is that the loss of [1-^{13}C]oleate from the *sn*-1,3 position was always greater than that from the *sn*-2 position, in agreement with a previous report (8). The chance of having all three glycerol carbons in the same molecule esterified with [1-^{13}C]oleate is rather low, especially when other fatty acids are obtained through *de novo* synthesis (15). GC analysis of selected samples showed that palmitate in cellular TG (in cells incubated with oleate for 5 h) accounts for ~30% of the total stored fatty acids (not shown). Palmitate has a lower affinity for the *sn*-2 position compared to oleate (8). Therefore, for those TG molecules with [1-^{13}C]oleate at the *sn*-2 position, the *sn*-1,3 position would have a high probability of being occupied by a saturated acyl chain such as palmitate. If this is true, our observation and the observation of others (8) that [1-^{13}C]oleate at the *sn*-1,3 position was hydrolyzed rapidly indicates that unsaturated *sn*-1,3 chains are hydrolyzed more rapidly than saturated *sn*-1,3 chains. This is in accord with the prediction that TG molecules containing acyl chains with high polarity are hydrolyzed more rapidly than those with lower polarity (27,28). Because the hydrolysis of *sn*-1,3 chains is the rate-limiting step in lipolysis (29,30), cellular TG enriched with unsaturated fatty acids may have a higher fatty acid turnover rate than those enriched with saturated fatty acids, reducing the probability of fat cell hypertrophy.

In this work, we found that oleate was preferentially esterified into TG at the *sn*-2 position. The extent to which it was esterified was dependent on the stage of differentiation and incubation time. When linoleate was added together with oleate, more oleate was found to be esterified to the *sn*-1,3 position, probably as a result of competition between oleate and linoleate for the *sn*-2 position. Without providing albumin to remove fatty acids during lipolysis, most of the [1-^{13}C]oleate was found to be re-esterified into TG, especially when insulin was present. These results provide new insights concerning the incorporation of oleate into acylated lipids, and contribute to the general understanding of fatty-acid metabolism and energy storage in fat cells.

ABSTRACT: Short-term effects of physiological concentrations of conjugated linoleic acid (CLA) on membrane integrity, metabolic function, cellular lipid composition, lipid peroxidation, and antioxidant enzymes were examined using rat hepatocyte suspension cultures. Incubation with CLA (5–20 ppm) for 3 h decreased the ability of hepatocyte plasma membranes to exclude trypan blue by approximately 25%, and caused leakage of cytosolic lactate dehydrogenase (LDH) into the medium. The significant decrease ($P < 0.02$) in hepatocyte viability as measured by LDH leakage during cell incubation with 10 and 20 ppm CLA was not associated with significant changes in cellular ATP content. Protein synthesis in hepatocytes was elevated ($P < 0.05$) in the presence of 5 and 10 ppm CLA, but at a higher concentration (20 ppm), protein synthesis was similar to that of control cells. Gluconeogenesis was maintained in cells incubated with lower concentrations of CLA (5 and 10 ppm) but was decreased ($P < 0.02$) at the higher concentration. Incubation with 20 ppm CLA for 3 h did not affect the specific activity of 3-hydroxy-3-methylglutaryl coenzyme A reductase, the rate-limiting enzyme of cholesterol synthesis. Both *cis*-9,*trans*-11/*trans*-9,*cis*-11, and *cis*-10,*trans*-12/*trans*-10,*cis*-12 isomers of CLA were incorporated to a similar level into hepatocytes. Levels ranged from 3.9 to 4.1%, respectively, of total fatty acids in neutral lipids, and from 0.7 to 0.8%, respectively, of total fatty acids in phospholipids. Cellular lipid peroxidation remained unchanged in the presence of CLA (5–20 ppm), despite significant inhibition ($P < 0.05$) of superoxide dismutase. Catalase activity was maintained near control levels in the presence of 5 and 10 ppm CLA but was significantly decreased in the presence of 20 ppm CLA. Glutathione peroxidase activity was significantly decreased in the presence of 10 ppm CLA. The apparent sensitivity of the antioxidant enzyme defense system of liver cells to CLA, coupled with the lack of effect of CLA on lipid peroxidation in cells, suggests that cytotoxic effects of CLA as described by LDH leakage and decreased gluconeogenesis were not mediated by a prooxidant action in hepatocytes.

Abbreviations: CLA, conjugated linoleic acid; FAME, fatty acid methyl ester; GLC, gas–liquid chromatography; GPx, gluthathione peroxidase; HBSS, Hanks' balanced salt solution; HMGCoA reductase, 3-hydroxy-3-methylglutaryl coenzyme A reductase; LDH, lactate dehydrogenase; PBS, phosphate-buffered saline; PUFA, polyunsaturated fatty acids; SOD, superoxide dismutase; TBARS, thiobarbituric acid-reactive substances.

Conjugated linoleic acid (CLA) refers to a group of positional and geometric isomers of linoleic acid that exist naturally in dairy products and meat (1). Of the various CLA isomers detected in the lipid fractions of many different kinds of food, the *cis*-9,*trans*-11 isomer is the most abundant, constituting up to 90% of the total CLA content of dairy products (1). A quantitative comparison of the isomeric distribution of CLA in tissue lipids following the feeding of a commercial mixture of CLA isomers to pigs revealed that liver and heart tissues accumulated approximately 50% of total dietary CLA in the form of triglycerides and phospholipids with *cis*-9,*trans*-11 CLA being the primary isomer incorporated into liver phospholipids, as well as into liver and heart triglycerides with *cis*-11,*trans*-13 CLA as the primary isomer incorporated into heart phospholipids (2,3).

Administration of CLA to animal models of carcinogenesis has been shown to delay and reduce the onset of chemically induced tumors at various sites such as skin (4), mammary glands (5), colon (6), and forestomach (7). Experiments carried out in laboratory animals have shown CLA can inhibit chemically initiated cancer at several stages of the carcinogenic process (8,9). CLA has therefore prompted considerable interest as a potentially powerful cancer chemopreventive agent that possesses the ability to prevent carcinogenesis in different tissues by interfering either with mutagenesis or subsequent postmutagenic steps.

None of the animal feeding studies, some of which involved feeding high doses of CLA for prolonged periods, produced any signs of toxicity. A recent toxicological assessment of CLA in male rats based on determination of organ weights and hematological profiles of control and CLA-fed rats indicated a lack of toxicity and supported the determination of its generally-regarded-as-safe status (10).

An important aspect of the toxicological assessment of CLA must be determination of its effect on liver metabolism and the key role the liver plays in its uptake and metabolism. Mechanisms of toxicity induced by a variety of hepatotoxins include free-radical formation, covalent binding, reduction in cellular glutathione pools, disruption of Ca^{2+} homeostasis, disruption of tissue-repair mechanisms, and inhibition of cellular energy production (11). Current methods to evaluate such hepatotoxicity include measurement of the synthesis and secretion of albumin by liver, synthesis of cholesterol and

lipoproteins, gluconeogenesis, cellular ATP content, membrane leakage of cytosolic enzymes such as lactate dehydrogenase (LDH), DNA, and protein synthesis (11).

Data on the impact of CLA on organs such as the liver, the major organ of lipid metabolism, are only now beginning to emerge (12,13). Despite an initial claim that feeding rats CLA produced no observable effects on the amount of thiobarbituric acid-reactive substances (TBARS) in liver (5), a recent study has predicted a possible hepatocarcinogenic effect of this dietary fatty acid in mice (13). Dietary CLA induced the accumulation of peroxisome-specific enzymes and ornithine decarboxylase activity in the liver in a manner suggesting a role for CLA as a peroxisomal proliferator in mice. The importance of CLA in hepatocarcinogenesis awaits a study of its effect on the steroid hormone receptor, peroxisome proliferator-activated receptor α (PPARα). Hepatocytes are a useful model for evaluating hepatotoxicity, PPARα-regulated growth responses, and hepatocarcinogenesis (14).

Owing to the involvement of oxidative events in carcinogenesis, protection against hepatic oxidative stress is an important aspect for considering both the safety and the cancer chemopreventive potential of CLA. Cancer chemopreventive agents that reduce the rate at which mutations arise are effective largely through their ability to induce the expression of antioxidant and detoxification proteins (15). Such an adaptive response enables the cell to eliminate metabolic damage caused by oxidative or chemical stress. The aim of this study was to determine if acute exposure of normal rat hepatocytes to physiological concentrations of CLA altered the specific activities of the antioxidant enzymes, superoxide dismutase, catalase, and glutathione peroxidase.

MATERIALS AND METHODS

Materials. CLA, a synthetic mixture comprising four positional isomers [29.5% *cis*-9,*trans*-11/*trans* 9,*cis*-11; 29% *cis*-10,*trans*-12/*trans*-10,*cis*-12; 21.7% *cis*-11,*trans*-13/*trans*-11,*cis*-13; 12.3% *cis*-8,*trans*-10/*trans* 8,*cis*-10, and minor amounts of all *trans* (3.6%) and all *cis* (2.9%) isomers (1)] was purchased from Nu-Chek-Prep (Elysian, MN). Waters silica Sep-Pak cartridges were purchased from AGB Scientific (Dublin, Ireland). Collagenase from *Clostridium histolyticum* type 1A, Hanks' balanced salt solution (HBSS), Hams F12, Percoll, trypan blue solution, glucose oxidase enzyme kit 510-DA, hydrogen peroxide, thiobarbituric acid, trichloroacetic acid, and hydroxymethylglutaryl coenzyme A were purchased from Sigma Ltd. (Poole, United Kingdom). 3-Hydroxy-3-methyl [3-^{14}C] glutaryl coenzyme A reductase (HMGCoA) (50 mCi/mmol), [5-^{3}H] mevalonic acid lactone (33 Ci/mmol), and [4,5-^{3}H] leucine (45–85 Ci/mmol) were purchased from Amersham Life Science Ltd. (Amersham, United Kingdom). Ransod and Ransel kits for the determination of superoxide dismutase (SOD) and gluthathione peroxidase (GPx) activity, respectively, were purchased from Randox Laboratories Ltd. (Armagh, Northern Ireland). All other reagents were purchased from BDH (Poole, United Kingdom).

Isolation of hepatocytes. Hepatocytes were isolated from male Sprague-Dawley rats according to a method recommended by the European Center for the Validation of Alternative Methods (16) and the Hepatocyte User Group. Animals were sacrificed by cervical dislocation and the liver was perfused *in situ* with a Ca^{2+}-free solution of HBSS, pH 7.4, containing 0.1 mM EGTA. The second step of the perfusion employed a solution of collagenase [0.03% (wt/vol)] in HBSS, pH 7.4 containing 1 mM calcium. The liver was excised and then passed through a sieve to separate the cells and to remove extracellular material. After centrifugation ($50 \times g$, 2 min) and Percoll treatment to remove damaged cells (17), the viable cell yield was determined using 0.1% (vol/vol) trypan-blue exclusion and LDH leakage (17).

CLA incubations. A 2000 ppm solution of CLA was prepared in ethanol and aliquots representing 5, 10, and 20 ppm CLA (equivalent to 17.8, 35.5, and 71 μM) as final concentrations in culture medium were transferred to empty and dry six-well plates. Ethanol was evaporated from wells prior to the addition of hepatocytes (~10^6 viable cells) for incubation in Ham's F12 nutrient medium for 3 h at 37°C, 5% CO_2, and >80% relative humidity. Control wells to which only ethanol was added were treated similarly.

CLA uptake into liver lipid fractions. Total lipids of hepatocytes were extracted using the extraction method of Folch *et al.* (18). Hepatocyte cultures were centrifuged at $800 \times g$ for 5 min and the supernatant was discarded. Chloroform/methanol solution [20 mL of 2:1 (vol/vol)] was added prior to sonication and after filtration through Whatman No. 1 filter paper; 5 mL of distilled water was added to the extract which was then centrifuged at $800 \times g$ for 20 min. The upper aqueous phase was discarded, and the lower organic phase containing the lipid fractions was evaporated to dryness. The lipids were redissolved in 1 mL of chloroform in preparation for the separation of the lipid fractions.

Separation of lipid fractions and fatty acid analysis. The extracted lipids were injected onto a Waters Sep-Pak silica cartridge and the neutral lipids eluted with 20 mL chloroform at a flow rate of 25 mL/min, followed by 10 mL of a 98:2 (vol/vol) chloroform/methanol solution to elute the monoglycerides. Finally, the phospholipids were eluted with 30 mL methanol. These fractions were dried under nitrogen, resuspended in 1 mL chloroform and stored at −80°C under nitrogen until required for analysis. Fatty acid methyl esters (FAME) of neutral and phospholipid fractions were prepared using acid-catalyzed methanolysis as described previously (19). Fatty acids were separated using a Supelcowax-10 capillary column (19) (Supelco Inc., Bellefonte, PA) (60 m × 0.32 mm i.d., 0.25 μm film thickness) and analyzed using a Varian 3500 gas–liquid chromatograph (GLC) (Varian, Harbor City, CA) fitted with a flame-ionization detector. CLA was identified by retention time with reference to a CLA mix, generously provided by the Food Research Institute, University of Wisconsin (Madison, WI). Fatty acids (other than CLA) were identified by their retention times with reference to standard FAME (Sigma Chemical Co., St. Louis, MO) and quantified

as described previously (20). The quantity of each fatty acid was expressed as a percentage of total fatty acids.

ATP measurement. Cellular ATP was determined using a coupled hexokinase/glucose 6-phosphate dehydrogenase enzyme assay (21).

Gluconeogenesis activity. After isolation of hepatocytes, 1×10^6 cells from fasted rats were incubated for 3 h at 37°C, 5% CO_2, and 80% relative humidity in 5 mL of a glucose-free medium containing 78.8 mM NaCl, 3.1 mM KCl, 0.8 mM KH_2PO_4, 0.8 mM $MgSO_4$, 1.7 mM $CaCl_2$, 16.7 mM $NaHCO_3$, 0.5% bovine serum albumin, 20 mM lactate, and 2 mM pyruvate. Glucose was measured using glucose oxidase enzyme assay kit (Sigma).

Protein synthesis. After isolation of hepatocytes, 1×10^6 cells were pulsed with L-[4,5-^{3}H]leucine (5 µCi) for 3 h at 37°C and 5% CO_2. Following incubation, cells were washed three times with phosphate-buffered saline (PBS) and the supernatant was discarded. One milliliter of trichloroacetic acid (TCA) [10% (wt/vol)] was added, and the samples were maintained on ice for 15 min. After centrifugation for 10 min at 750 × *g*, the pellet was washed three times with TCA [10% (wt/vol)] and finally resuspended in 100 µL of Protosol tissue solubilizer (Amersham Pharmacia Biotech, Little Chalfont, Bucks, United Kingdom). These solutions were digested for 30 min at 60°C before transfer to scintillation vials with 3 mL methanol and 10 mL scintillation fluid and counted in a Beckman LS-6500 scintillation counter.

Determination of enzyme activity. SOD and GPx activity were determined using Ransod and Ransel kits (Randox Laboratories Ltd., Armagh, Northern Ireland) respectively. The units of GPx activity are defined as µmol NADPH oxidized/min at pH 7.4 and 30°C. One unit of SOD activity is that quantity of enzyme that inhibits by 50% the conversion of xanthine to a formazon dye by xanthine oxidase. Catalase activity was determined as described (22) and expressed in Bergmeyer units which are defined as µmol [H_2O_2] decomposed min^{-1} mL^{-1} at pH 7 and 25°C.

Determination of lipid peroxidation using the TBARS method. Measurement of TBARS was performed according to Esterbauer and Cheeseman (23) and reported as nmol MDA/mg protein.

Statistical analysis. All experiments were performed in triplicate. Mean and standard error of triplicate assays performed on three to four animals (where indicated) were analyzed by Student's *t*-test.

RESULTS

Viability. The effect of CLA on hepatocyte viability as determined by both trypan blue exclusion and measurement of LDH activity in medium after 3 h is shown in Figure 1. Approximately 20–25% of the CLA-treated hepatocyte population was unable to exclude trypan blue. In using LDH leakage as an enzymatic-based measure, a significant decrease in viability ($P < 0.02$) was observed in cells treated with 10 and 20 ppm CLA.

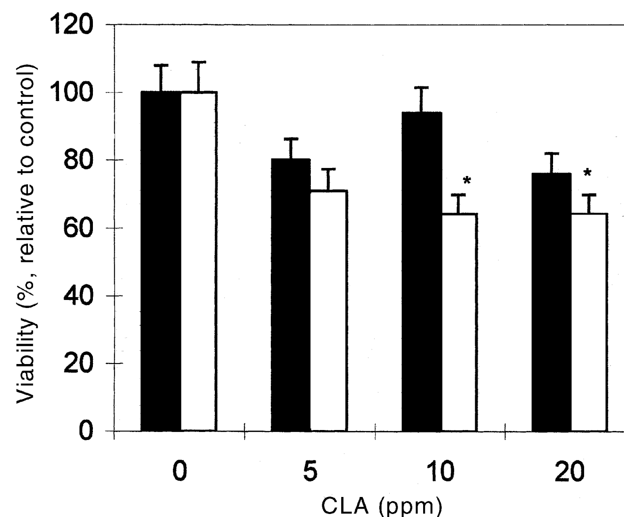

FIG. 1. The effect of conjugated linoleic acid (CLA) (5–20 ppm) on hepatocyte viability. Data are expressed as mean value ± SEM (n = 3). *$P < 0.02$ relative to control. ■, Trypan blue; □, lactate dehydrogenase.

CLA uptake into liver lipid fractions. The effect of short-term incubation of hepatocytes with 20 ppm CLA on the quantity of each fatty acid in neutral lipid and phospholipid fractions is shown in Table 1. Both neutral lipids and phospholipids contained similar amounts of palmitic and *trans*-18:1 acids. Phospholipids contained significantly higher ($P <$ 0.05) amounts of stearic and arachidonic acid and lower amounts of oleic, linoleic, and CLA isomers *cis*-9,*trans*-11/*trans* 9,*cis*-11 and *cis*-10,*trans*-12/*trans*-10,*cis*-12, compared with neutral lipids. No effect was seen on palmitic, stearic, oleic, *trans*-18:1, linoleic, linolenic, and arachidonic acids of neutral lipid fractions after exposure of hepatocytes to CLA (20 ppm). Incubation with 20 ppm CLA led to an approximate 2.4-fold increase in the quantity of *cis*-9,*trans*-11/*trans*-9,*cis*-11 (4.1 ± 0.4% total fatty acids, $P < 0.01$), and an

TABLE 1
Effect of Short-Term Incubation of Rat Hepatocytes with CLA (20 ppm) on Fatty Acid Concentrations in Lipid Fractions[a]

	Neutral lipids		Phospholipids

$20:4^{\Delta 5,8,11,14}$	9.2 ± 1.0	9.1 ± 1.1	26.0 ± 2.4[a]	20.7 ± 1.7

[a]Values are means ± SEM (n = 3) expressed as percentage total fatty acid. Means with different superscript roman letters are significantly different from control, where [a]$P < 0.05$ relative to corresponding control; [b]$P < 0.01$ relative to corresponding control; *not detected in measurable quantities. Palmitic 16:0; stearic 18:0; oleic $18:1^{\Delta 9}$; linoleic $18:2^{\Delta 9,12}$; linolenic $18:3^{\Delta 9,12,15}$; CLA isomers *c,t/t,c*-10,12-18:2 and *c,t/t,c*-9,11-18:2; arachidonic acid $20:4^{\Delta 5,8,11,14}$; CLA, conjugated linoleic acid.

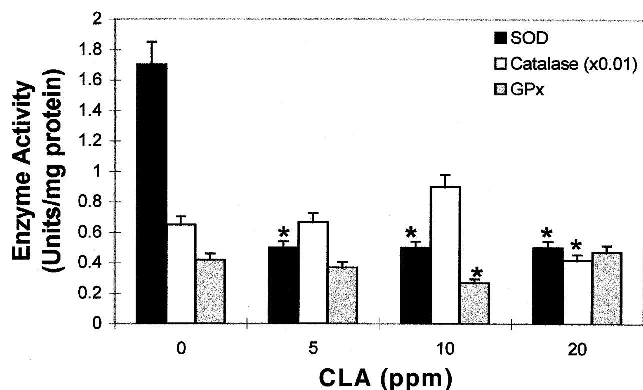

FIG. 2. The effects of CLA (5–20 ppm) on specific activities of superoxide dismutase (SOD), catalase, and glutathione peroxidase (GPx) in rat hepatocytes. Data are expressed as mean value ± SEM (n = 4). *P < 0.05 relative to control. See Figure 1 for other abbreviation.

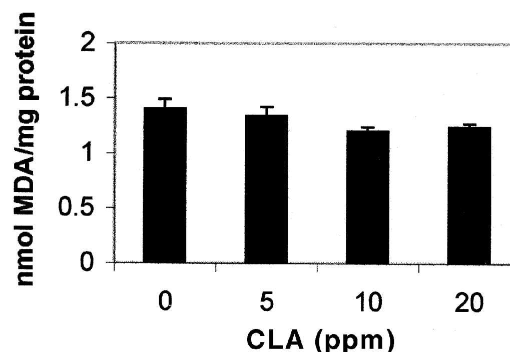

FIG. 3. The effect of CLA (5–20 ppm) on lipid peroxidation level as measured by thiobarbituric acid-reactive substances (TBARS, ■). Data are expressed as a mean value ± SEM (n = 4). MDA, malondialdehyde; see Figure 1 for other abbreviation.

approximate 2.8-fold increase in the quantity of *cis*-10, *trans*-12/*trans*-10,*cis*-12 isomer (3.9 ± 0.6% total fatty acids, $P < 0.05$) in neutral lipid fractions. Despite lower uptake of both CLA isomers into phospholipid fractions (0.7–0.8% total fatty acids), there was a trend toward a reduced level of phospholipids containing linoleic, linolenic, and arachidonic acids in hepatocyte suspension cultures exposed to CLA.

ATP, gluconeogenesis, protein and cholesterol synthesis. The data showing the effects of CLA on functional metabolic activities of liver cells are shown in Table 2. Cellular ATP levels were not significantly altered in cells exposed to increasing concentrations of CLA despite an apparent increase upon incubation with 10 ppm CLA. Gluconeogenesis was significantly reduced (25 ± 1 µg/mg protein, $P < 0.02$) in cells exposed to 20 ppm CLA relative to control cells, but there was no effect at lower concentrations of CLA. Incubation of cells with 5 and 10 ppm CLA led to approximate 1.6- and 2-fold increases, respectively, in protein synthesis ($P < 0.05$) relative to control cells. At 20 ppm CLA, however, the rate of ^{3}H-leucine uptake into protein (240 ± 50 dpm $h^{-1} \cdot 10^5$ cells^{-1}) was similar to that of the control (180 ± 5 dpm $h^{-1} \cdot 10^5$ cells^{-1}). The specific activity of HMGCoA reductase in CLA-treated cells (60 ± 5 pmol mevalonate formed min^{-1}·mg protein^{-1}) was similar to that of control cells (55 ± 10 pmol mevalonate formed min^{-1}·mg protein^{-1}).

The effect of CLA on antioxidant enzymes and lipid peroxidation. The effect of CLA on specific activities of SOD, catalase, and GPx is shown in Figure 2. Cellular SOD activity was significantly decreased from 1.7 ± 0.2 U/mg to approximately 33% of control levels (0.5 ± 0.01 U/mg , $P < 0.05$) upon exposure of cells to CLA in the range 5–20 ppm. While incubation with 5 and 10 ppm CLA had no significant effect on the specific activity of catalase, activity was decreased ($P < 0.05$) by approximately 36% in the presence of 20 ppm CLA. Incubation with 10 ppm CLA resulted in decreased GPx activity ($P < 0.05$) relative to the control (Fig. 2). CLA in the range 5–20 ppm was found to have no significant effect on lipid peroxidation as measured by TBARS (Fig. 3).

DISCUSSION

Hepatocyte suspension cultures were used as a model for short-term studies on the effects of CLA on membrane integrity and a number of liver cell "housekeeping" functions.

TABLE 2
Effect of CLA on ATP, Gluconeogenesis, Protein, and Cholesterol Synthesis[a]

		CLA (ppm)		
	Control	5	10	20
ATP (pmol/10^5 cells)	4.1 ± 1.0	1.9 ± 1.1	14.1 ± 9.4	4.0 ± 0.42
Glucose (µg/mg protein)	40 ± 2	45 ± 3	54 ± 10	25 ± 1[a]
Protein (dpm ^{3}H leucine incorporation $h^{-1} \cdot 10^5$ cells^{-1})	180 ± 5	300 ± 40[b]	350 ± 40[b]	240 ± 50
HMGCoA reductase (pmol ^{14}C mevalonate·min^{-1} mg^{-1})	55 ± 10	n.d.	n.d.	60 ± 5

[a]Values are means ± SEM (n = 3). Means with different superscript roman letters are significantly different from control. [a]$P < 0.02$; [b]$P < 0.05$. n.d., Not determined; HMGCoA reductase, 3-hydroxy-3-methylglutaryl coenzyme A reductase; see Table 1 for other abbreviation.

Measurement of trypan blue exclusion and LDH leakage are alternative means of measuring the viability of cells. Trypan blue exclusion is the quickest method for identifying cell damage, but it does have serious limitations. Uneven cell distribution over the slide, statistically small samples, and albumin binding of the dye may give misleadingly low values for percentages of cells stained with trypan blue. Our study showed an increase in dye uptake by cells that were incubated with CLA, suggesting a decline in viability. However, the decline did not reach statistical significance. In view of the relatively large standard error of the mean ATP values reported, it would be imprudent to predict that the extent of dye exclusion observed was the result of an energy-dependent maintenance of plasma membrane potential. For this reason, the extent of enzyme leakage (LDH) from the cytoplasm of isolated hepatocytes into culture medium occurring over a 3-h incubation period was considered. This approach to viability testing avoids the statistical problems with the trypan blue technique arising from the small number of cells examined and the possibility of dye binding caused by increased protein synthesis (Table 1). An increase in leaked-LDH activity in medium as a percentage of total LDH activity of the extract was observed when cells were incubated with 10 and 20 ppm CLA, indicating approximately 35% cellular disruption.

An examination of the metabolic competency of the CLA-treated cells showed some anabolic activity, as was evident from the increased radiolabeled precursor uptake into protein in the presence of 5 and 10 ppm CLA. At 20 ppm CLA, the increase in protein synthesis was not as remarkable and may have been a metabolic index of a decreased buffering capacity by cells when exposed to 20 ppm CLA. Protein synthesis is pH dependent, with leucine incorporation into protein being depressed by lower pH levels (17). Particular metabolic pathways such as gluconeogenesis are widely believed to be far more susceptible to toxic agents than processes maintaining plasma membrane integrity. We observed a maintenance of gluconeogenic capacity in cells treated with 5 and 10 ppm CLA, suggesting a lack of toxicity upon exposure of hepatocytes to 5 and 10 ppm CLA. By contrast, a significant decrease in gluconeogenesis was observed only when cells were incubated with 20 ppm CLA, which, in association with LDH leakage, may be evidence that the higher concentration of CLA mediated a decline in cellular integrity. However, in view of the lack of effect on the activity of HMGCoA reductase, the rate-limiting enzyme of cholesterol biosynthesis, it is obvious that more *in vitro* tests should be carried out to examine further the toxicity profile of CLA at concentrations of 20 ppm or more in hepatocytes.

Despite recent findings that diets containing 1.0 and 1.5% CLA were associated with hepatic peroxisome proliferation and induction of ornithine decarboxylase (13), no study has yet shown cytotoxic effects of CLA in liver cells comparable to those observed in some cancer cell lines (24–26). The observed effects of CLA on gluconeogenesis, protein synthesis, ATP status, lipid oxidation, and antioxidant enzymatic activity must be considered as relative only to the control incubations carried out in the absence of CLA. A definitive conclusion of the effects of CLA on these end points should await the inclusion of a positive control (equimolar concentration of linoleic acid) in the experimental design.

The concentrations of CLA (5–20 ppm) used in this study (equivalent to 17.8–71 μM) were similar to those used by Shultz *et al.* in an earlier cell culture study (26). A previous *in vivo* study carried out by Belury *et al.* (13) showing the effects of CLA on hepatic metabolism in mice was conducted using doses of 0.5–1.5% CLA in diet. The addition of 1.5% CLA to rat diets is equivalent to administering ~225 mg CLA (assuming an average daily intake of 15 g of food). Allowing for 55% absorption of CLA into lymph, as estimated by Sugano *et al.* (31), this would suggest up to 124 mg CLA may be taken up by the liver in the portal vein. In our study, 1×10^6 cells representing approximately 10 mg whole liver were exposed to 100 μg CLA (a 20-ppm dose in a 5-mL well plate). In taking into account the total weight of rat liver (10 g), this was approximately 100 mg CLA, and was therefore close to physiological concentrations.

Previous studies reported trace levels of CLA in phospholipid (0–0.1%) and neutral lipid (0.06–0.2%) fractions of mammary glands and mouse liver (12,27,28). Ip *et al.* (27) showed that feeding rats a 1% CLA diet increased the CLA content of mammary tissue phospholipids to 0.4%, and of neutral lipids to 3.5% total fatty acids (27). Similar levels of incorporation were observed in liver fractions from CLA-fed mice (12,28). Of the two predominant CLA isomers present in synthetic CLA mixtures used in animal-feeding studies to date, the *cis*-9,*trans*-11/*trans*-9,*cis*-11 isomer was incorporated to a greater extent (up to 0.4%) than the *trans*-10,*cis*-12 isomer (up to 0.3%) into the liver phospholipids of pigs (3), rats (27), and mice (12,28). Our *in vitro* study showed not only approximate equal distribution of both isomers, but substantially more of both isomers in hepatocyte phospholipids (up to 0.8%) and in neutral lipids (up to 4.1%), compared with dietary-feeding studies. In light of evidence that CLA isomers may be metabolized by desaturation and elongation (29, 30), the equal distribution of *cis,trans/trans,cis* -9,11 and *cis,trans/trans,cis*-10,12 isomers in hepatocytes suggests that both isomers, while having accumulated to a similar extent, were slowly metabolized under the experimental conditions described.

In view of the myriad of beneficial biological effects attributed to CLA observed *in vivo* and *in vitro*, it is plausible that protection against lipid peroxidation may be a mechanism by which CLA preserves the phospholipid milieu of cell membranes for subsequent eicosanoid metabolism or membrane-mediated signaling events. In this study, we have shown that both CLA isomers were readily incorporated into cell membrane phospholipids and neutral lipids. It is of note that short-term incubations of hepatocytes with 20 ppm CLA resulted in detectable levels of both *cis*-9,*trans*-11/*trans* 9,*cis*-11 and *cis*-10,*trans*-12/*trans*-10,*cis*-12 isomers in the phospholipid fraction, in addition to slightly higher levels of stearic and oleic acids compared with control incubations

while lowering levels of oxidation-susceptible linoleic, linolenic, and arachidonic acids. As an antioxidant, the presence of CLA in phospholipid membranes would be expected to reduce or at least maintain the amount of TBARS produced in cells during culture. In our study, the level of lipid peroxidation in CLA-treated cells was found to remain similar to control levels [1.4 ± 0.09 nmol malondialdehyde (MDA)/mg protein]. These data are consistent with a previous study (32), where rat liver was reported to have 1.1 ± 0.18 nmol MDA/mg protein.

However, the apparent insensitivity of liver cells to CLA-mediated changes in lipid peroxidation may be a reflection of the ample antioxidant status of hepatocytes. Induction of oxidative stress is expected to lead to an increase in the level of activity of the antioxidant defense enzymes and finally to lipid peroxidation if the endogenous defense system is overloaded. SOD is known to be the first line of antioxidant defense dismuting superoxide radicals to H_2O_2 and water. In this study, SOD was decreased in cells exposed to CLA suggesting that generation of $O_2^{\cdot -}$, the major initiator of the oxygen radical cascade that feeds into the lipid peroxidation chain reaction, did not occur in CLA-treated cells. The observation that 20 ppm CLA caused a significant decrease in catalase activity while having no significant effect on GPx activity may be supportive of a possible quenching effect of CLA on potential reactive oxygen species generated as a result of CLA metabolism in liver cells. Although this study has shown an antioxidant enzyme-sparing effect in hepatocytes, it does not exclude possible effects of CLA in maintaining levels of other membrane-bound antioxidants such as α-tocopherol as reported previously (33). The apparent sensitivity of the antioxidant enzyme defense system of liver cells to CLA coupled with the lack of effect of CLA on lipid peroxidation in cells serve as indirect evidence that CLA may not be a prooxidant in normal liver cells. Longer-term incubations of hepatocyte suspension cultures with physiological concentrations of CLA or of spheroid aggregate-culture systems for between 48 and 96 h may be useful to investigate the effects of chronic exposure to CLA by diet.

ABSTRACT: We have characterized the gene encoding fatty acid α-hydroxylase, a cytochrome P450 (P450) enzyme, from *Sphingomonas paucimobilis*. A database homology search indicated that the deduced amino acid sequence of this gene product was 44% identical to that of the *ybdT* gene product that is a 48 kDa protein of unknown function from *Bacillus subtilis*. In this study, we cloned the *ybdT* gene and characterized this gene product using a recombinant enzyme to clarify function of the *ybdT* gene product. The carbon monoxide difference spectrum of the recombinant enzyme showed the characteristic one of P450. In the presence of H_2O_2, the recombinant *ybdT* gene product hydroxylated myristic acid to produce β-hydroxymyristic acid and α-hydroxymyristic acid which were determined by high-performance liquid chromatography (HPLC) and gas chromatography–mass spectrometry. The amount of these products increased with increasing reaction period and amount of H_2O_2 in the reaction mixture. The amount of β-hydroxyl product was slightly higher than that of α-hydroxyl product at all times during the reaction. However, no reaction products were detected at any time or at any concentration of H_2O_2 when heat-inactivated enzyme was used. HPLC analysis with a chiral column showed that the β-hydroxyl product was nearly enantiomerically pure *R*-form. These results suggest that this P450 enzyme is involved in a novel biosynthesis of β-hydroxy fatty acid.

Paper no. 8255 of *Lipids 34,* 841–846 (August 1999).

β-Hydroxy fatty acids are usually found as their CoA derivatives in the fatty acid β-oxidation pathway, where β-hydroxy acyl-CoAs are produced from the corresponding acyl-CoAs by sequential reaction of acyl-CoA dehydrogenase and Δ2-enoyl-CoA hydratase. Gram-negative bacteria have β-hydroxy fatty acids as acyl moieties of cell wall lipids such as lipid A and ornithine lipid (1), whereas gram-positive bacteria such as *Bacillus* produce acylpeptides containing β-hydroxy fatty acid, as antibiotic compounds (2). Whether this acyl moiety is derived from the β-hydroxy intermediate in the β-oxidation pathway or is produced in another metabolic pathway is unclear.

In contrast, α-hydroxy fatty acids are components of sphingolipids of various species. We have studied fatty acid α-hydroxylase from *Sphingomonas paucimobilis*, a bacterium with large amount of sphingoglycolipid containing α-hydroxymyristic acid as an acyl moiety. Fatty acid α-hydroxylase is a unique enzyme which introduces an oxygen atom from H_2O_2 into fatty acid to produce α-hydroxy fatty acid (3). We recently cloned the fatty acid α-hydroxylase gene from this bacterium (4). Sequence analysis of the cloned gene and spectral analysis of the recombinant enzyme indicated that fatty acid α-hydroxylase from *S. paucimobilis* was a cytochrome P450 (P450) enzyme, which is designated as $P450_{SP\alpha}$ here. P450 enzymes have several highly conserved regions in their amino acid sequences associated with their secondary structure (5). $P450_{SP\alpha}$ also has the conserved sequences, especially in helix-K. However, a few sequences of $P450_{SP\alpha}$ are unique as compared to other bacterial P450s: (i) the conserved Thr in helix-I, which is believed to be important for O_2 activation (6), was absent; (ii) the presence of an aromatic region (7); and (iii) the consensus sequence in the heme-binding region, which was modified by insertion of amino acids (4).

Recently, the complete genome sequence of *B. subtilis* (8) was released into the DDBJ/GenBank/EMBL database. By homology search, we found that the deduced amino acid sequence of the *ybdT* gene (accession number, AB006424) product, which is a 48-kDa protein of unknown function, was significantly homologous to that of $P450_{SP\alpha}$. Moreover, the *ybdT* gene product appeared to have sequences highly homologous to those of $P450_{SP\alpha}$ in helix-I, aromatic region, and heme-binding region. Thus, we hypothesized that *ybdT* encodes fatty-acid hydroxylating P450, and in this study, we characterized its gene product.

MATERIALS AND METHODS

Materials. Bacillus subtilis IFO14144 was obtained from the Institute for Fermentation (Osaka, Japan). *Escherichia coli* BL21 and KOD DNA polymerase were purchased from Toyobo Co., Ltd. (Tokyo, Japan). The expression plasmid pGEX-4T-1 and glutathione-Sepharose 4B were purchased from

Amersham-Pharmacia. 9-Anthryldiazomethane (ADAM) was purchased from Funakoshi Co., Ltd. (Tokyo, Japan). 3-[(3-cholamidopropyl)-Dimethylammonio]-1-propanesulfonate (CHAPS) was purchased from Nakarai Tesque (Kyoto, Japan). Diazomethane was synthesized from *N*-nitroso-*N*-methylurea (Sigma Chemical Co., St. Louis, MO). α-Hydroxymyristic acid and β-hydroxymyristic acid were purchased from Sigma Chemical Co. Other reagents was purchased from Wako Pure Chemicals (Osaka, Japan).

Cloning of the ybdT *gene, and expression and purification of a glutathione* S*-transferase-*ybdT *gene product fusion protein. Bacillus subtilis* was cultured in Luria broth at 37°C. Genomic DNA was isolated by standard procedure (9). The *ybdT* gene was amplified by polymerase chain reaction (PCR) using the following primers: 5′-CGGGATCCATGAATGAGCAGATTCCACATG-3′ (the sense primer including the start codon of *ybdT* gene) and 5′-CCGCTCGAGGACAACAAAATGGTATCAGAAG-3′ (the antisense primer, complementary to the sequence downstream from the *ybdT* gene). After amplification, a 1.4 kbp single band was determined by agarose-gel electrophoresis. The amplified DNA fragment was isolated from the agarose gel and digested by *Bam* HI and *Xho* I. The *Bam* HI-*Xho* I fragment was ligated into a *Bam* HI-*Xho* I-digested pGEX4T-1, and the resulting expression plasmid including the *ybdT* gene was transfected into *E. coli* BL21. Sequencing of the cloned polymerase chain reaction fragment indicated that the nucleotide sequence of the isolated gene from *B. subtilis* IFO14144 was completely identical to the reported sequence of *ybdT*. Expression and purification of a glutathione *S*-transferase-*ybdT* gene product fusion protein were performed by a modification of the method previously described (4). Briefly, cells were disrupted with sonication in 0.1 M Tris-HCl (pH 7.5), 20% glycerol, and 1 mM dithiothreitol, and the supernatant was obtained by centrifugation at 100,000 × *g* for 60 min. Glutathione *S*-transferase-*ybdT* gene product fusion protein was bound to glutathione-Sepharose and eluted with 0.1 M Tris-HCl (pH 7.5), 20% glycerol, 0.1% 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate (CHAPS), 10 mM reduced glutathione, and 1 mM dithiothreitol.

Enzyme assay and determination of reaction product. Fatty acid hydroxylation activity was determined by a modification of the method for assaying $P450_{SP\alpha}$ activity (4). The reaction mixture contained 0.1 M potassium phosphate buffer (pH 5.9), 0.2 mM H_2O_2, 60 μM myristic acid, and the enzyme preparation in a total volume of 0.2 mL. Incubation was carried out at 37°C for the indicated periods. The reaction was terminated by the addition of 20 μL of 2 N HCl, and then the products and the substrate were extracted with ethyl acetate. The extract was washed with distilled water, and the ethyl acetate layer was evaporated. For high-performance liquid chromatography (HPLC) analysis, the resulting residue was treated with ADAM. HPLC analysis of ADAM-derivatized fatty acids was performed by a minor modification of the method described previously (10).

For gas chromatography–mass spectrometry (GC–MS), the products were treated with diazomethane and then sequentially treated with *N,O*-bis(trimethylsilyl)trifluoroacetamide. GC–MS was performed essentially as described previously (3). For GC, samples (1 μL) were introduced onto the column which was operating at 250°C. A GC oven temperature program was then applied: the initial temperature of 150°C was held for 4 min, and then the temperature was increased linearly to 270°C by 4°C/min. Helium was used as the carrier gas at a flow rate of 0.5 mL/min. The GC–MS interface temperature was 250°C. Electron-impact MS was performed with an ion source temperature of 250°C, emission current of 0.37 mA, and electron energy of 40 eV.

Analysis of optical configuration of α-hydroxy fatty acids. The optical configuration of the hydroxyl products was determined by HPLC with an OA-3100 column (Sumika, Osaka, Japan) according to the method of Nakagawa *et al*. (1). After the reaction, the hydroxymyristic acids were treated with 3,5-dinitrophenyl isocyanate (Sumika) in the presence of a small amount of dry pyridine at room temperature overnight. The solvents used for the HPLC analysis was methanol containing 50 mM ammonium acetate and 10% distilled water. Flow rate was 0.5 mL/min.

RESULTS AND DISCUSSION

As shown in Figure 1, the amino acid sequence of the *ybdT* gene product indicated as BSβ showed significant homology to that of $P450_{SP\alpha}$ (overall identity, 44%). Helix-I, helix-K to the aromatic region, and the heme-binding region were highly homologous. As described in the introduction, many P450 have the conserved Thr in helix-I. However, both the *ybdT* gene product and $P450_{SP\alpha}$ lack the conserved Thr, suggesting that the *ybdT* gene product does not require O_2 activation for its catalytic activity, as $P450_{SP\alpha}$ does not (4). In helix-K, the Glu-Xaa-Xaa-Arg motif which is conserved in all P450 was also conserved in the *ybdT* gene product. The aromatic region was proposed by Gotoh and Fujii-Kuriyama (7). This region was originally found in eukaryotic P450, but not in bacterial P450 with a few exceptions, one of which was $P450_{SP\alpha}$. The *ybdT* gene product also has an aromatic region similar to that of $P450_{SP\alpha}$ (75% identical). Moreover, the consensus motif of the heme-binding region was modified by insertion of amino acids, similar to $P450_{SP\alpha}$ (4), although the heme-binding Cys was found at position 363. On the basis of these observations, we assumed that the *ybdT* gene product would show similar enzymatic properties to $P450_{SP\alpha}$, and thus characterized the *ybdT* gene product using a recombinant enzyme.

We constructed a fusion gene of glutathione *S*-transferase gene and the *ybdT* gene in pGEX 4T-1, and then the fusion protein was expressed in *E. coli*. The CO difference spectrum of the fusion protein is characteristic of P450, which showed a peak at 446 nm (Fig. 2). Thus, we refer to the *ybdT* gene product as $P450_{BS\beta}$ (fatty acid β-hydroxylating cytochrome P450 from *B. subtilis*) below. Next, we investigated whether the recombinant $P450_{BS\beta}$ enzyme could hydroxylate fatty acid in the presence of H_2O_2 similarly to $P450_{SP\alpha}$. HPLC analysis of products using myristic acid as the substrate

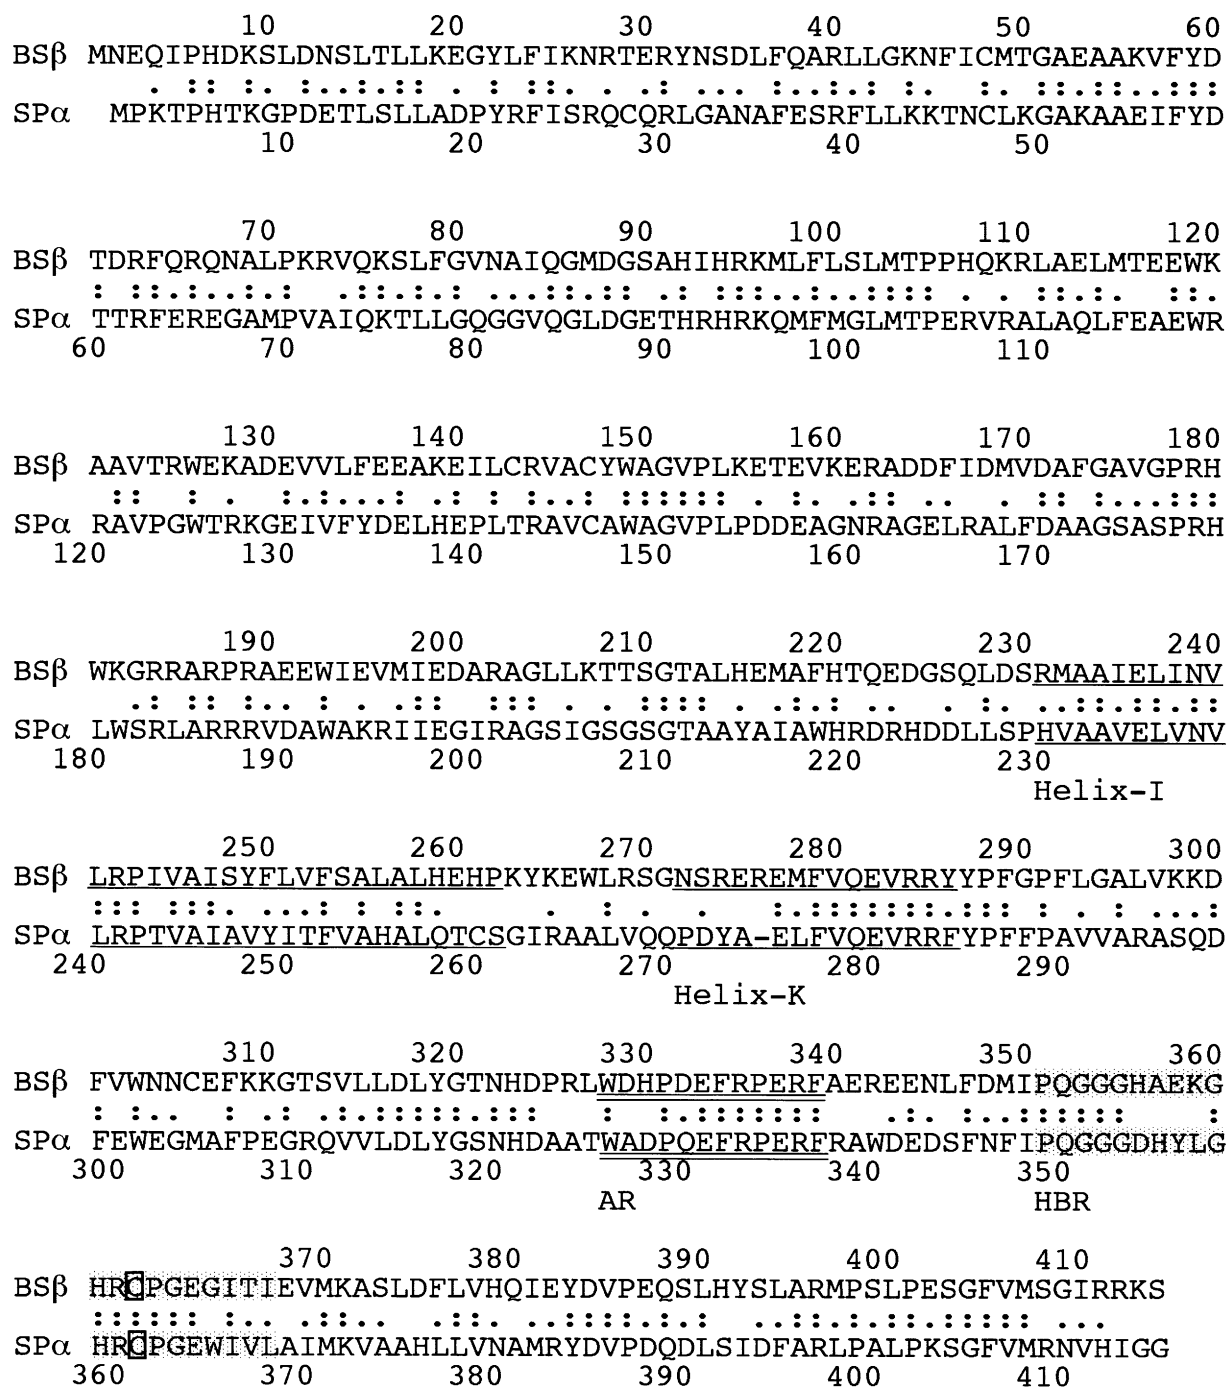

FIG. 1. Comparison of amino acid sequences of fatty acid β-hydroxylating cytochrome P450 from *Bacillus subtilis* ($P450_{BS\beta}$) and fatty acid α-hydroxylating cytochrome P450 from *Sphingomonas paucimobilis* ($P450_{SP\alpha}$). $P450_{BS\beta}$ and $P450_{SP\alpha}$ are indicated as BSβ and SPα, respectively. Helix-I and helix-K are underlined. The aromatic region (AR) is double-underlined. The heme-binding region (HBR) is shaded. Heme-binding cysteines are boxed. Dots and double dots indicate similar amino acids and identical amino acids between $P450_{BS\beta}$ and $P450_{SP\alpha}$, respectively.

showed newly produced peaks at retention times of 12.5 and 15.2 min after reaction (compare Fig. 3A and 3B). The retention times of these peaks corresponded with those of authentic β-hydroxymyristic acid (12.5 min) and α-hydroxymyristic acid (15.2 min), respectively. To further characterize these products, we performed GC–MS analysis for methyl, trimethylsilyl (TMS)-products. One of these products showed a fragmentation pattern of the methyl, TMS-derivative of β-hydroxymyristic acid (Fig. 4A). The ions at m/z 175 and 257 are formed by cleavage between C_3 and C_4 and between C_2 and C_3, respectively. The ion at m/z 175 is characteristic for the hydroxylation of fatty acid at the C_3-position. The ion at m/z 315 (M − 15) is formed by cleavage between CH_3 and Si of the TMS moiety. The fragmentation pattern of the other prod-

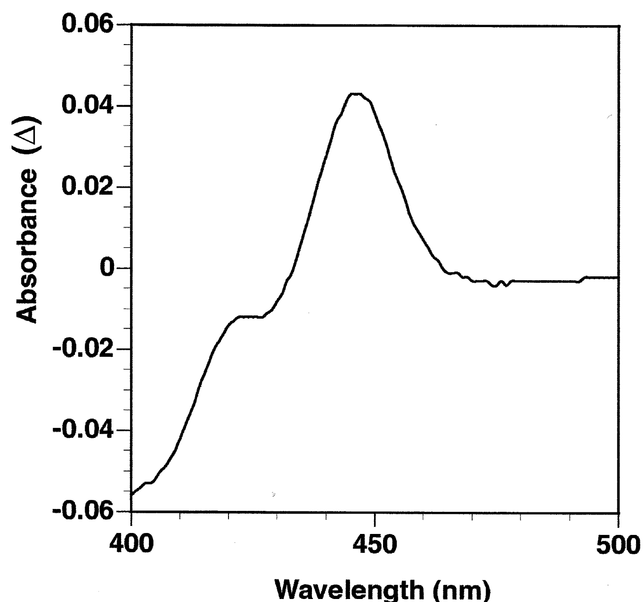

FIG. 2. CO difference spectrum of $P450_{BS\beta}$. $P450_{BS\beta}$ was dissolved in 0.1 M potassium phosphate buffer (pH 7.2) containing 20% glycerol and 1 mM dithiothreitol. The final concentration of protein was 0.28 mg/mL. For abbreviation see Figure 1.

uct corresponded to that of the methyl, TMS-derivative of α-hydroxymyristic acid (Fig. 4B). The ion at *m/z* 315 also was seen. The ion at *m/z* 271 is the characteristic fragment ion of an α-hydroxy fatty acid that has lost the carboxylmethyl group of *m/z* 330 (M). Furthermore, fragmentation patterns of these products were nearly identical to those of methyl, TMS-derivatives of authentic α-hydroxymyristic acid and β-hydroxymyristic acid (data not shown). Based on these results, we concluded that the reaction products were β-hydroxymyristic acid and α-hydroxymyristic acid.

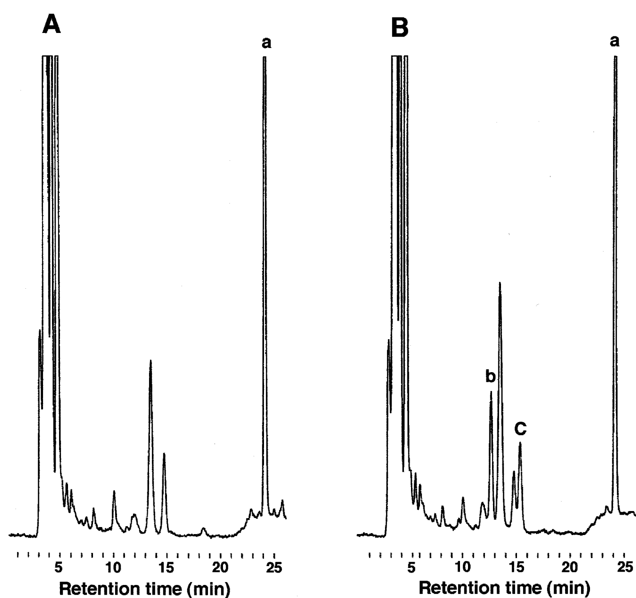

FIG. 3. Identification of products by high-performance liquid chromatography (HPLC). Incubation periods were 0 min (A) and 4 min (B). Peak **a** is that of myristic acid as the substrate. The retention times of peaks **b** and **c**, newly produced after the reaction, corresponded with those of β-hydroxymyristic acid and α-hydroxymyristic acid, respectively.

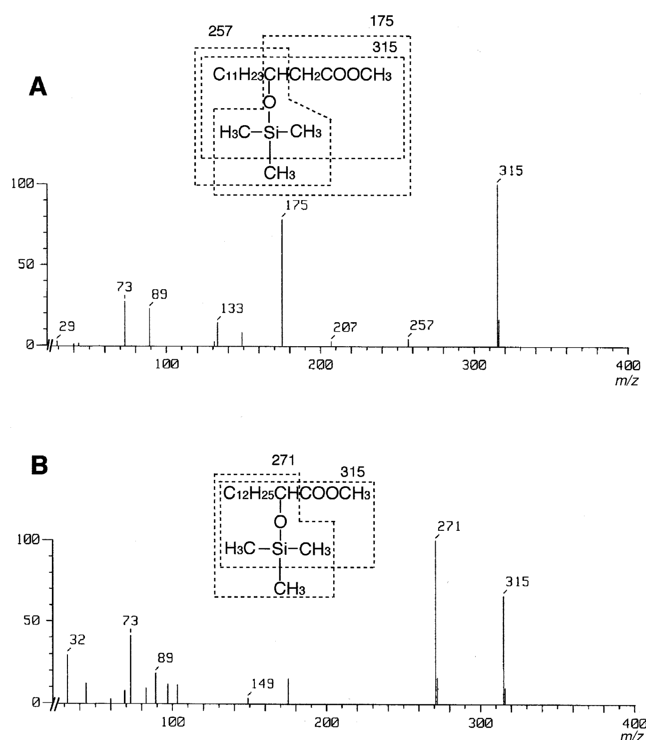

FIG. 4. Determination of methyl, trimethylsilyl (TMS)-derivatives of products by gas chromatography–mass spectrometry. Methyl, TMS-derivatives of two products found in Figure 3 showed fragmentation patterns of β-hydroxymyristic acid (A) and α-hydroxymyristic acid (B).

To determine whether these products were formed enzymatically, we investigated the effects of incubation period, the amount of H_2O_2 added to the reaction mixture, and heat treatment of the enzyme on the amount of products formed. As shown in Figure 5A, the total amount of products increased in a time-dependent manner. The amount of β-hydroxymyristic acid was slightly greater than that of α-hydroxymyristic acid at all sampling times. The amounts of β-hydroxymyristic acid, α-hydroxymyristic acid, and total products increased with the concentration of H_2O_2 in the reaction mixture and approached a plateau at a concentration of 200 μM (Fig. 5B). Other peroxides such as cumene hydroperoxide, *t*-butylhydroperoxide, *t*-butylperoxybenzonate, and *m*-chloroperoxybenzoic acid had no effect on the activity of $P450_{BS\beta}$ (data not shown). Conversely, no product was detected at any time or at any concentration of H_2O_2 when heat-treated enzyme was used. Turnover rate was approximately 300 nmol/min/nmol P450, which was comparable to that of $P450_{SP\alpha}$ (4). These results indicated that formation of these products was due to an enzymatic reaction of $P450_{BS\beta}$.

We demonstrated that $P450_{BS\beta}$ showed fatty acid β-hydroxylation and α-hydroxylation activities and specifically required H_2O_2 for its activity, similar to $P450_{SP\alpha}$ (11). Based on the specific requirement for H_2O_2 and high turnover rate in the pres-

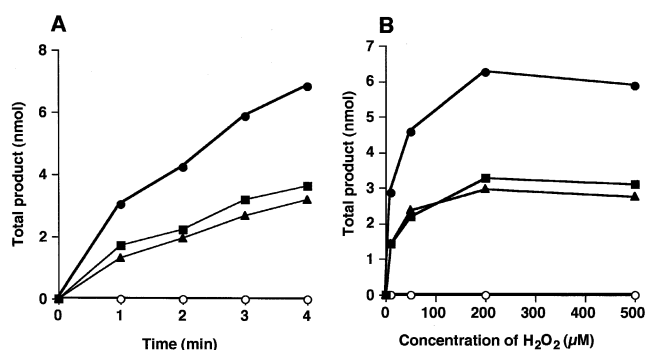

FIG. 5. Changes in the amount of product formed as a result of varying the incubation period (A) and varying the amount of H_2O_2 (B). Amount of the enzyme preparation in the reaction mixture was 1.5 μg (containing 5.7 pmol of P450). (A) Closed and open circles represent the amounts of product formed during the indicated incubation periods when nontreated and heat-treated (100°C, 10 min) enzyme were used, respectively. The concentration of H_2O_2 was 0.2 mM. Closed squares and triangles represent the amounts of β-hydroxyl product and α-hydroxyl product, respectively, when nontreated enzyme was used. (B) The amounts of products formed in the presence of various concentrations of H_2O_2 were measured. The incubation period was 4 min. Symbols are the same as those in (A).

ence of H_2O_2, it may be more appropriate to refer to $P450_{SP\alpha}$ and $P450_{BS\beta}$ as "peroxygenases" (12) rather than "monoxygenases." To our knowledge, this is the first direct evidence that β-hydroxy fatty acid is produced by such a "peroxygenase."

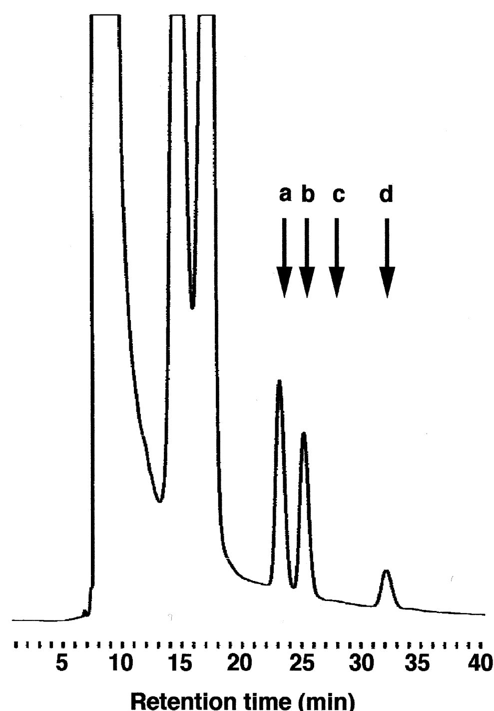

FIG. 6. HPLC analysis of optical configuration of the products. Arrows show the retention times of authentic *R*-enantiomer (**a**, 23.5 min) and *S*-enantiomer (**c**, 28.0 min) of β-hydroxymyristic acid and authentic *R*-enantiomer (**b**, 25.7 min) and *S*-enantiomer (**d**, 32.6 min) of α-hydroxymyristic acid, respectively. For abbreviation see Figure 3.

Configuration analyses indicated that β-hydroxymyristic acid of this acylpeptide was an *R*-enantiomer (D-enantiomer) (13). This configuration is due to favoring the *R*-enantiomer as the fatty acid substrate in acyltransferation step of the acylpeptide biosynthesis (14,15). By HPLC analysis using a chiral column, we observed that β-hydroxymyristic acid formed by the reaction of $P450_{BS\beta}$ is nearly enantiomerically pure *R*-form (Fig. 6). *S*-Form of β-hydroxymyristic acid could not be detected, but *S*-form of α-hydroxymyristic acid was about 22% of the total amount of α-hydroxyl product. In yeast, Venter *et al.* (16) demonstrated that 3-hydroxy-polyenoic fatty acid was *R*-form and suggested that the *R*-form of β-hydroxy fatty acid is formed by other metabolic reactions such as direct oxygenation by P450, because the normal β-hydroxyl intermediate in β-oxidation is the *S*-form. Thus, at least β-hydroxy fatty acid produced by the reaction of $P450_{BS\beta}$ may be utilized to synthesize acylpeptides, antibiotic compounds produced by *Bacillus* species, although the physiological roles of α-hydroxyl fatty acid in this bacterium remain to be elucidated.

Identification of Acylated Glycoglycerolipids from a Cyanobacterium, *Synechocystis* sp., by Tandem Mass Spectrometry

Young Hwan Kim[a,c,*], Jong-Soon Choi[b], Jongki Hong[a], Jong Shin Yoo[a], and Myung Soo Kim[c]

[a]Mass Spectrometry Analysis and [b]Biomolecular Analysis Teams, Korea Basic Science Institute, Taejon 305-600, Korea, and [c]Department of Chemistry, Seoul National University, Seoul 151-742, Korea

ABSTRACT: Acylated glycoglycerolipids were identified in the total lipid extract from cyanobacterium *Synechocystis* sp. PCC 6803. These compounds have a palmitoyl group esterified to the hydroxyl group at the C-6 position of the terminal glycosyl moiety of digalactosyl monoacylglycerol and digalactosyl diacylglycerol. Their structural elucidation was accomplished by tandem mass spectrometry coupled with fast atom bombardment ionization. Acylated digalactosyl monoacylglycerol has a structure of 1-hydroxy-2-palmitoyl-3-*O*-[(6-*O*-palmitoyl)-α-D-galactopyranosyl-(1→6)-β-D-galactopyranosyl]-*sn*-glycerol. This compound has not been reported previously.

Paper no. 8063 in *Lipids 34*, 847–853 (August 1999).

Glycoglycerolipids, such as monogalactosyl, digalactosyl, and sulfoquinovosyl diacylglycerols (MGDG, DGDG, and SQDG, respectively), have been regarded as the major lipid components of the photosynthetic membrane in plants, algae, and various bacteria (1,2). These glycoglycerolipids account for more than 90% of the total glycerolipids in the intact cells of *Synechocystis* sp. PCC 6803 (3). They may also play a critical role in photosynthesis owing to their exclusive distribution in the chloroplasts. Furthermore, glycoglycerolipids possessing pharmacological activity (4,5) or unique structural features (6–10) have been isolated and characterized from various organisms.

Cyanobacteria provide excellent models for the study of oxygenic photosynthesis (3). Recently, the structural identification of individual molecular species of major glycerolipids, such as MGDG, DGDG, SQDG, and phosphatidylglycerol, which were purified from the total lipid extract of cyanobacterium *Synechocystis* sp. PCC 6803, was accomplished using tandem mass spectrometry (MS/MS) coupled with fast atom bombardment (FAB) (11). Collision-induced dissociation (CID) of sodium-adducted molecular ions ($[M + Na]^+$ or $[M + 2Na - H]^+$) gives rise to numerous product ions that provide information on the structure of a polar head and fatty acyl groups, including the double-bond positions in fatty acyl chains and regiospecificity of the acyl linkages (11,12). Additionally, four *sn*-2 acyl lysoglycerolipids corresponding to their monoacylglycerolipids, which contain exclusively a palmitoyl group at the *sn*-2 position, were also isolated simultaneously.

Here we describe the structural characterization of acylated digalactosyl monoacylglycerol (DGMG) and DGDG isolated from *Synechocystis* sp. PCC 6803, using FAB–CID–MS/MS. To our knowledge, acylated DGMG has not been reported previously, although acylated DGDG, MGDG, and monogalactosyl monoacylglycerol (MGMG) were isolated from leaf homogenates and nitrogen-fixing cyanobacteria before (6–9).

EXPERIMENTAL PROCEDURES

Isolation of acylated DGMG and DGDG. Cyanobacterium *Synechocystis* sp. PCC 6803 was cultured as described previously (11). Briefly, the cells in BG11 medium were cultivated at 28°C for 3 to 4 d and illuminated continuously at an intensity of 1000 lux with a fluorescent lamp. The culture was harvested in the mid-log phase of growth by centrifugation at 12,000 × *g* and 4°C for 15 min. The harvested cells were homogenized in 300 mL of chloroform/methanol/water (1:1:1, by vol). Total lipids were extracted from the homogenized cells by the method of Bligh and Dyer (13). The extracted lipids were separated by two-dimensional thin-layer chromatography on silica plates (Whatman, Hillsboro, OR) according to the method of Douce *et al.* (14). The solvent systems were chloroform/methanol/water (65:25:4, by vol) as solvent for dimension I and chloroform/acetone/methanol/acetic acid/water (10:4:2:2:1, by vol) for dimension II. Lipids were located by spraying the plate with a solution of 0.01% primuline in 80% acetone, followed by visualization under ultraviolet light. Two spots corresponding to unknown lipids A and B were detected between MGDG and MGMG and recovered in small quantities.

Mass spectrometry. All mass spectrometric analyses were performed using a JMS-HX110/110A tandem mass spectrometer (JEOL, Tokyo, Japan) of four-sector instrument with an E_1B_1-E_2B_2 configuration as described previously (15). Briefly, the ion source was operated at 10 and −10 kV accelerating voltages in the positive- and negative-ion modes, respectively. Ions were produced by FAB using the cesium ion beam, which was generated from the ion gun and accelerated to 12 keV. The sample was dissolved in chloroform/methanol (1:1, vol/vol) at about 5 μg/μL and then mixed with 1 μL 3-nitrobenzyl alcohol (Sigma, St. Louis, MO) for the positive-ion spectra and triethanolamine (BDH, Poole, Dorset, United Kingdom) for the negative-ion spectra on the FAB probe tip. CID of the sodium-adducted and deprotonated molecular ions (i.e., $[M + Na]^+$ and $[M - H]^-$) selected with first mass spectrometer (MS-1; E_1B_1) occurred in the collision cell located between B_1 and E_2 and floated at 3.0 and −3.0 kV, respectively. The resultant product ions were analyzed by B/E scan method of second mass spectrometer (MS-2; E_2B_2). The collision gas, helium, was introduced into the collision chamber at a pressure sufficient to reduce the precursor ion signal by 70%.

RESULTS AND DISCUSSION

Positive-ion FAB mass spectra of unknown lipids A and B, which were found between MGDG and MGMG on two-dimensional thin-layer chromatography shown in Figure 1, display abundant peaks corresponding to $[M + Na]^+$ ions at *m/z* 915 and 1175, as shown in Figure 2A and 2B, respectively. Also, their negative-ion FAB mass spectra (not shown) show deprotonated molecular ions ($[M - H]^-$) at *m/z* 891 and 1151. Thus, their molecular masses are 892 and 1152 Da. Exact mass measurements for the ions of *m/z* 915 and 1175 revealed the elemental compositions $C_{47}H_{88}O_{15}Na$ (observed, 915.6019: theoretical, 915.6021) and $C_{65}H_{116}O_{16}Na$ (observed, 1175.8145: theoretical, 1175.8161), respectively. The negative-ion FAB–CID–MS/MS spectra of glycoglycerolipids were helpful in determining the fatty acid composition in previous work (12). Namely, as shown in Figure 3A, the CID–MS/MS spectrum of $[M - H]^-$ ion of lipid A indicates a dominant carboxylate ion at *m/z* 255 corresponding to a palmitate (16:0). Furthermore, the neutral loss of a palmitoyl group as the ketene analog (R=C=O) and free fatty acid (RCOOH) yields abundant peaks at *m/z* 653 and 635, respectively. Also, further loss of another palmitoyl group of the ion at *m/z* 653 results in the product ions at *m/z* 415 and 397. The ion of *m/z* 397 can also be generated by further loss of another palmitoyl group of the product ion at *m/z* 635 as the ketene analog. This fragmentation pattern is similar to that observed in the negative-ion CID spectrum of DGDG, which was investigated in our previous work (12).

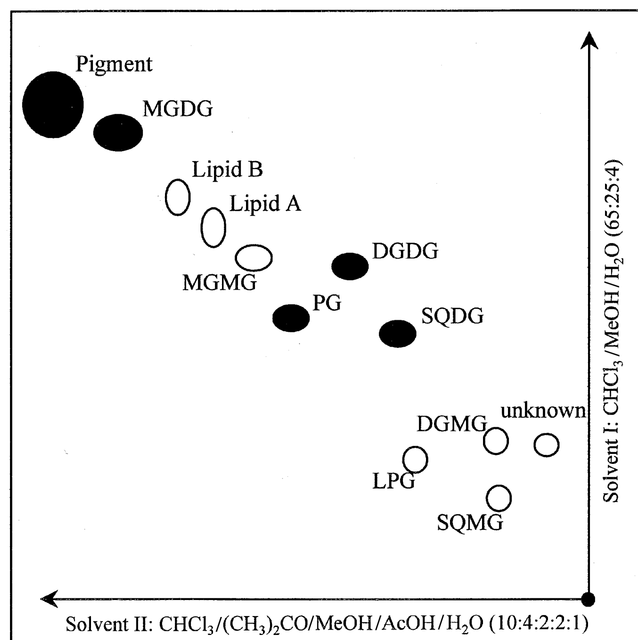

FIG. 1. A schematic picture of separation of total lipids from *Synechocystis* sp. PCC 6803 by two-dimensional thin-layer chromatography (TLC). Dark circles indicate the four major diacylglycerolipids. The four minor *sn*-2 acyl lysoglycerolipids corresponding to their monoacylglycerolipds are also represented. White circles labeled as Lipid A and B correspond to unknown lipids in small amounts. Their structural determination is described in the text.

From these results, the unknown lipid A is established as containing two palmitoyl groups and a disaccharide as a polar head group. From the dominant carboxylate anions at *m/z* 255 and 277 appearing in the negative-ion CID spectrum of an unknown lipid B, this compound contains palmitoyl and 18:3 acyl groups. The product ions formed by the neutral losses of carboxylic acid and ketene analog of these fatty acyl groups are also observed. However, by comparing the fragmentation pattern observed in the CID–MS/MS spectra of $[M + Na]^+$ ions (*m/z* 915 and 1175) of unknown lipids A and B as shown in Figure 4A and 4B, respectively, with that of DGDG reported previously, the structural difference between unknown lipids and DGDG was identified. To confirm this difference more explicitly, we compared the feature of these spectra with that of the CID spectrum of $[M + Na]^+$ ion (*m/z* 677) of DGMG species, which was isolated from the same cyanobacterium and contained a palmitoyl group at the *sn*-2 position. Figure 4C shows the positive-ion CID spectrum of the $[M + Na]^+$ ion of DGMG. Although the CID–MS/MS spectrum of $[M + Na]^+$ ion was very complicated owing to a variety of fragmentations, they were helpful in determining the structure of unknown lipids, based on the comparison between these spectra.

In the CID spectrum of the $[M + Na]^+$ ion (*m/z* 915) of lipid A, charge-remote fragmentation occurring along a palmitoyl chain yields a series of homologous product ions from *m/z* 899 to 731 ($^3I_2$), due to consecutive loss of C_nH_{2n+2} from the terminus of a palmitoyl group. The product ions resulting from the cleavage within the terminal sugar ring occur at *m/z* 543 ($^{1,5}X_1$) and 557 ($^{0,2}X_1$). These are very informative about the structural feature. As shown in Figure 4C, the same product ions in the CID–MS/MS spectrum of $[M + Na]^+$

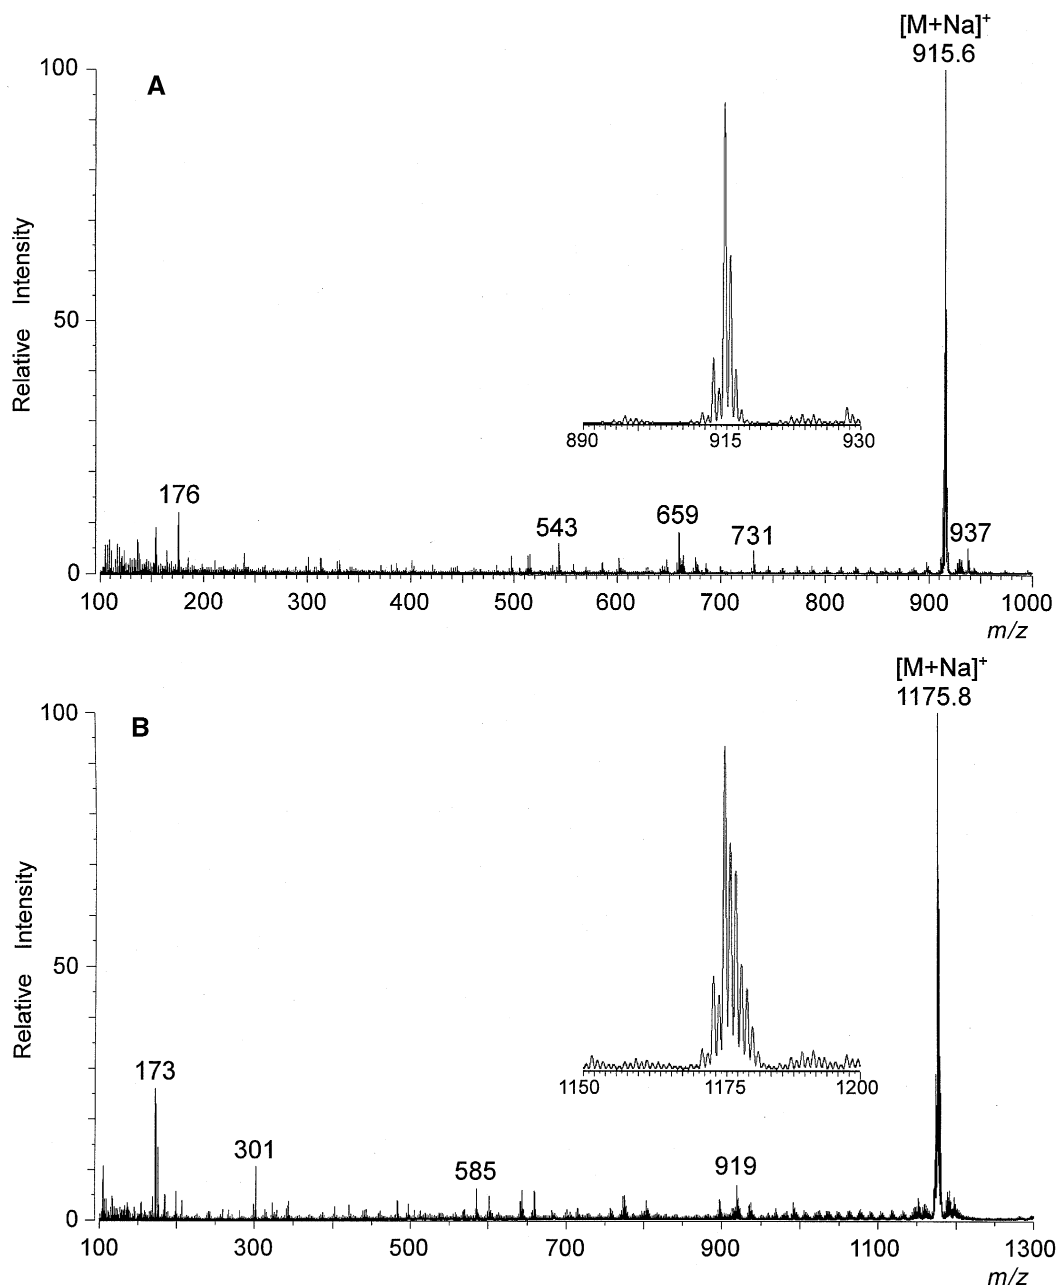

FIG. 2. Positive-ion fast atom bombardment (FAB) mass spectra of unknown (A) lipid A and (B) lipid B isolated from the cyanobacterium *Synechocystis* sp. PCC 6803. The inserts indicate the expanded region in which the sodium-adducted molecular ions are observed. The ions of *m/z* 915 and 937 in A correspond to $[M + Na]^+$ and $[M + 2Na - H]^+$ of lipid A, respectively, whereas the ion of *m/z* 1175 in B is the $[M + Na]^+$ ion of lipid B.

ion of DGMG are observed at the same *m/z* value. These results lead to the conclusion that one of two palmitoyl groups in lipid A is attached to the glycerol backbone and the other to the carbon on the terminal sugar ring. Fragmentation of the glycosidic bond, with loss of the nonreducing terminal portion as a neutral fragment, which is observed at *m/z* 513 ($Y_1 - 2H$) and 515 (Y_1), provides further evidence for this result. On the other hand, the concomitant loss of two groups, which are linked to the C-4 and C-5 positions of a terminal sugar unit, *via* 1,2-elimination, produces the common product ion at *m/z* 629 in both spectra. Thus, a palmitoyl group must be esterified to a hydroxyl group of the C-4 or C-6 position on the sugar ring. The remainder of the peaks except for those at *m/z* 169 and 185 in Figure 4A are up-shifted by 238 Da in comparison with the corresponding one observed in Figure 4C, including the $^{0,4}A_2$ and $^{3,5}A_2$ ions which provide information on the 1→6 linkage between the two sugar rings. The product ions of *m/z* 169 and 185 may be formed by second fragmentation of the B_1' and B_1 ions *via* the ketene loss of the palmitoyl group on the terminal sugar ring, respec-

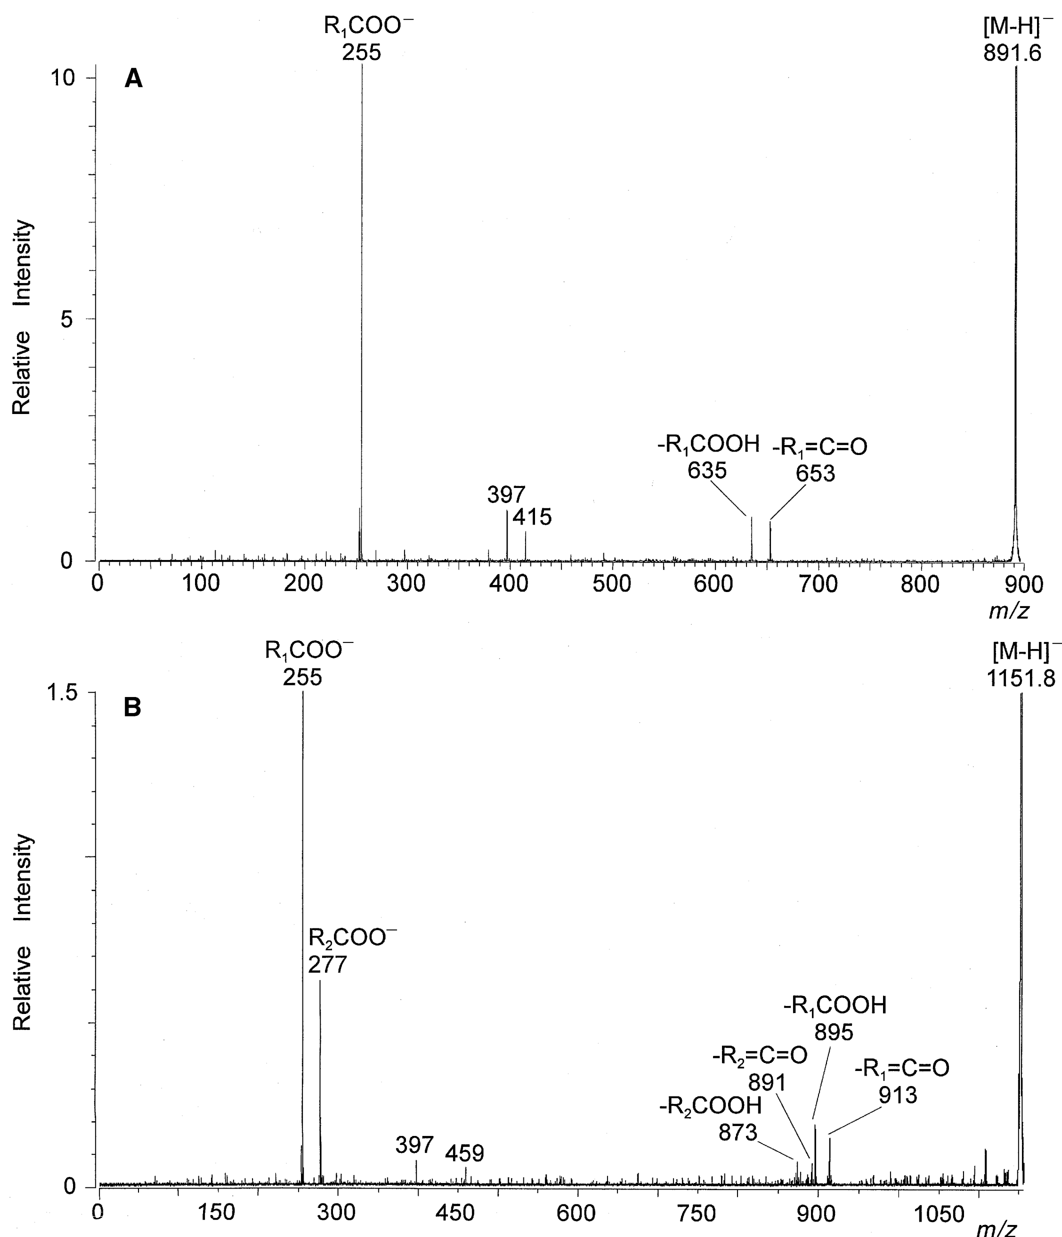

FIG. 3. Negative-ion FAB collision-induced dissociation (CID) tandem mass (MS/MS) spectra of $[M - H]^-$ ions of unknown (A) lipid A and (B) lipid B. The ions at *m/z* 255 and 277 correspond to a palmitate (16:0) and 18:3 carboxylate anions, respectively. For abbreviation see Figure 2.

tively. The fragmentation pathways observed in CID of the sodium-adducted molecular ion are illustrated in Figure 5.

All of the acylated DGDG, MGDG, and MGMG that have been found so far had a fatty acyl group linked to the C-6 position of the terminal sugar ring (5–8). Consequently, the palmitoyl group of this new acylated galactolipid is also linked to the C-6 position. Thus, since DGMG isolated from the same cyanobacterium was synthesized by specific enzymatic hydrolysis of the *sn*-1 fatty acyl group of DGDG species and then had a structure of 1-hydroxy-2-palmitoyl-3-*O*-[α-D-galactopyranosyl-(1→6)-β-D-galactopyranosyl]-*sn*-glycerol, as mentioned in a previous work (11), acylated DGMG has a structure of 1-hydroxy-2-palmitoyl-3-*O*-[(6-*O*-palmitoyl)-α-D-galactopyranosyl-(1→6)-β-D-galactopyranosyl]-*sn*-glycerol. This compound is a novel lipid which has been not reported previously.

When the CID spectrum of $[M + Na]^+$ ion (*m/z* 1175) of lipid B shown in Figure 4B is compared with that of lipid A shown in Figure 4A, the product ions such as A, B, B′, C-2H and E, which do not contain the fatty acyl groups on glycerol backbone, are observed at the same *m/z*. Thus, lipid B also contains a palmitoyl group on the C-6 position of the terminal sugar ring. However, the product ions such as X, Y-2H, Y, G_2 and $^3I_2$ are up-shifted by 260 Da corresponding to a mass difference of an 18:3 acyl group ester-linked on the glycerol backbone. Furthermore, the spectral pattern of a series of ho-

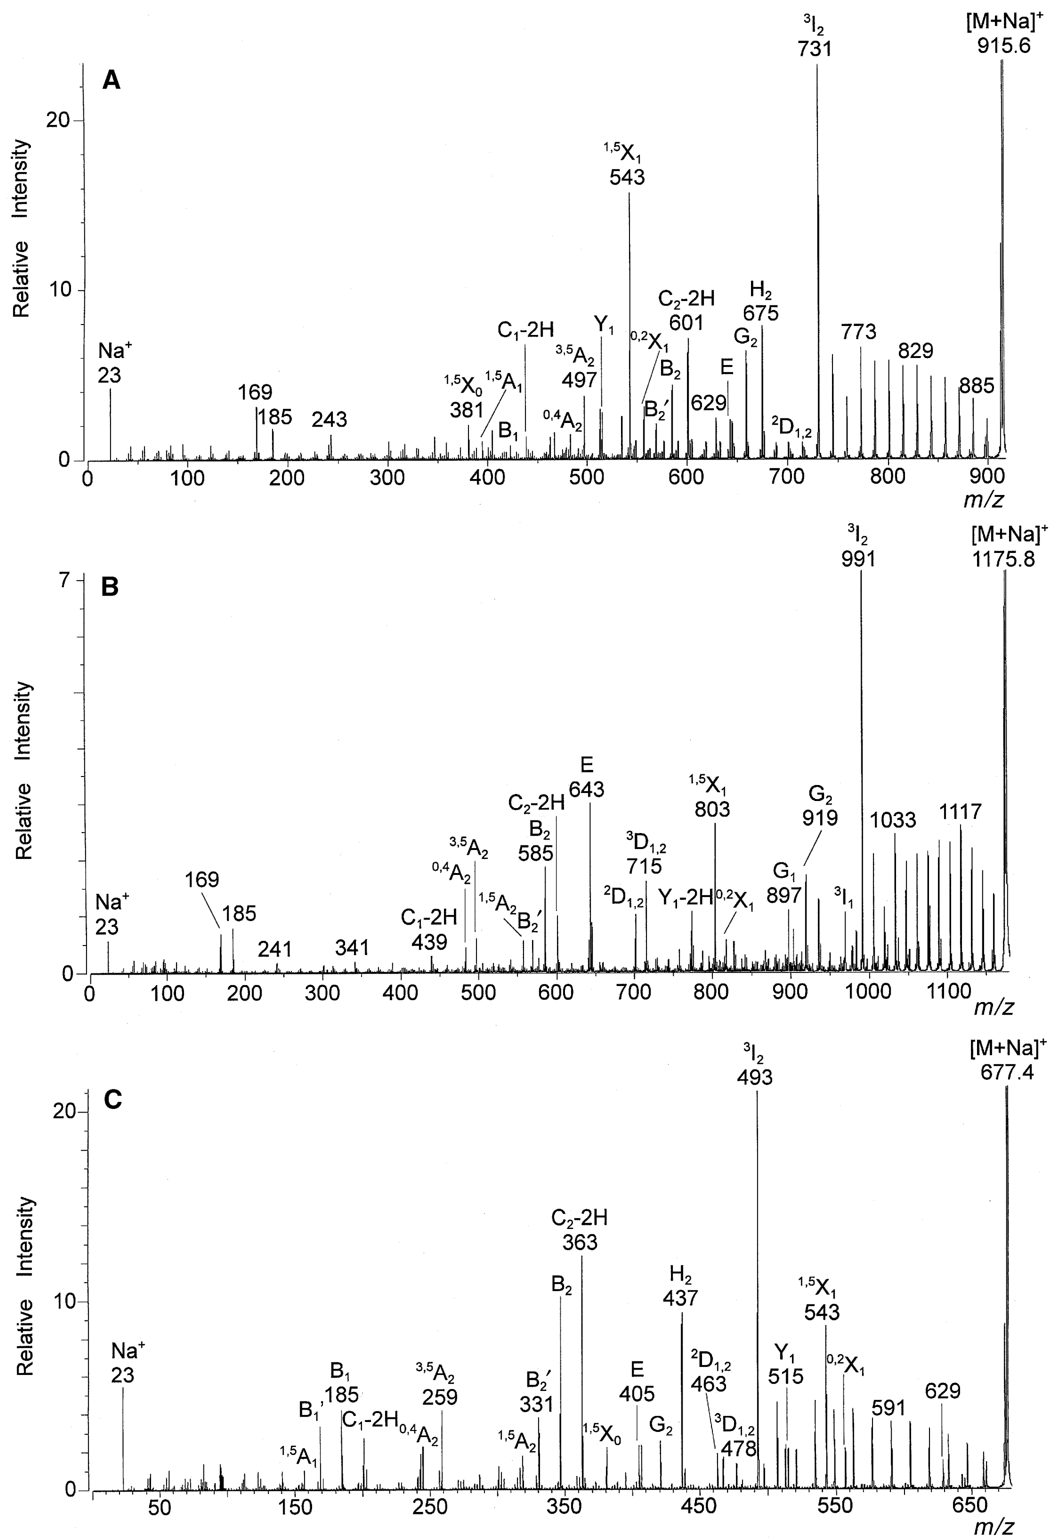

FIG. 4. Comparison of positive-ion FAB–CID–MS/MS spectra of [M + Na]$^+$ ions; (A) an unknown lipid A of *m/z* 915, (B) an unknown lipid B of *m/z* 1175, and (C) digalactosyl monoacylglycerol of *m/z* 677.

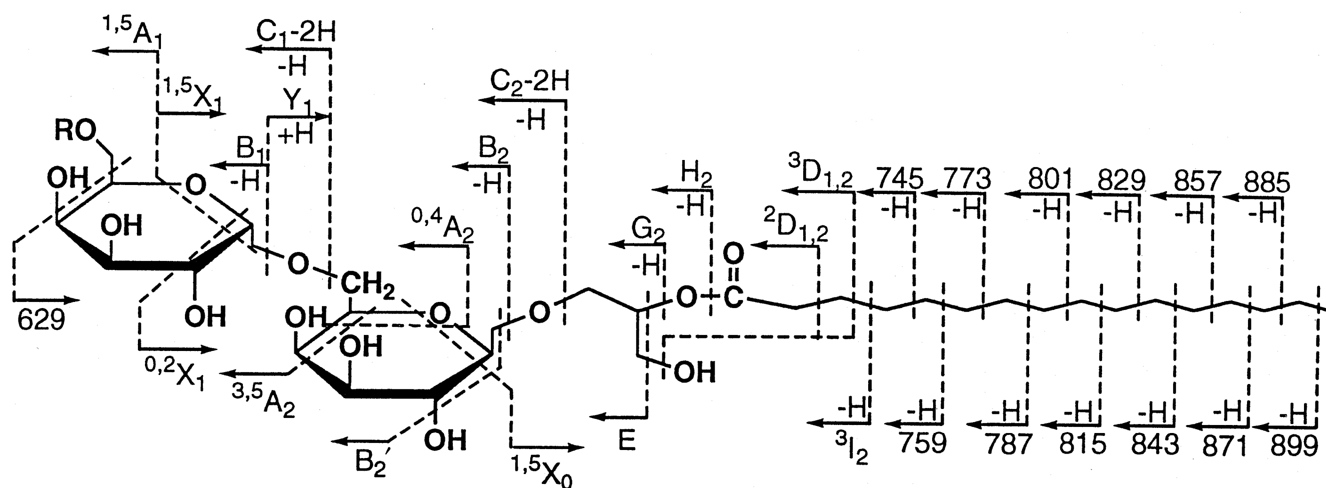

FIG. 5. Proposed structure of a new glycoglycerolipid. The fragmentation pathways are also shown. The nomenclature proposed by Domon and Costello (16) was adopted with minor changes and addition of the new notation for the cleavages of the fatty acyl groups, as described previously (3,11). R is a palmitoyl group at the C-6 position of the terminal sugar unit. The resultant product ions contain a sodium ion.

mologous ions appearing in high-mass region provides information about the double-bond positions in the fatty acyl groups. The homologous ions can be divided into two groups: *m/z* 1089, 1075, 1061, 1047, 1033, 1019, 1005, and 991 ($^3I_2$), due to the saturated palmitoyl chain (16:0), and *m/z* 1091(=, where = represents the double-bond position), 1077, 1063, 1051(=), 1037, 1023, 1011(=), 997, 983 and 969 ($^3I_1$), due to the triply unsaturated γ-linolenoyl chain (18:3). The ions at *m/z* 1159, 1145, 1131, 1117, and 1103 are common to the cleavage of both fatty acyl groups. Also, based on the previous result that the G_2 ion due to the loss of *sn*-2 fatty acyl group was always larger than the G_1 ion due to the loss of an *sn*-1 fatty acyl group (11), γ-linolenoyl and palmitoyl groups are positioned at *sn*-1 and *sn*-2, respectively. Thus, since corresponding DGDG species ($[M + Na]^+ = 937$) isolated from the same cyanobacterium had a structure of 1-γ-linolenoyl-2-palmitoyl-3-*O*-[α-D-galactopyranosyl-(1→6)-β-D-galactopyranosyl]-*sn*-glycerol, acylated DGDG of *m/z* 1175 has a structure of 1-γ-linolenoyl-2-palmitoyl-3-*O*-[(6-*O*-palmitoyl)-α-D-galactopyranosyl-(1→6)-β-D-galactopyranosyl]-*sn*-glycerol. In addition, according to the results obtained by the same structural analyses for other molecular species, the species of *m/z* 1177 and 1179 have the same structure as a species of *m/z* 1175 except for containing linoleoyl (18:2) and oleoyl (18:1) groups at the *sn*-1 position, respectively. The distribution and fatty acid compositions of these molecular species are similar to those of DGDG molecular species, which was reported previously (11).

As proposed by Heinz and coworkers (7,8), the synthesis of acylated DGMG and DGDG involves the transfer of an acyl group catalyzed by an enzyme such as acyltransferase. Furthermore, they concluded that this enzyme had no positional specificity with respect to transferring the acyl group from the *sn*-1 or *sn*-2 positions of the donor molecules but specifically transferred the acyl group to the C-6 position of the acceptor molecule (6,7). However, as described previously (11), the majority of glycerolipids isolated from *Synechocystis* sp. PCC 6803 contained a palmitoyl group at the *sn*-2 position. Moreover, since the positive-ion FAB mass spectra shown in Figure 2A and 2B indicate the exclusive presence of *m/z* 915 and molecular ion distributions similar to that of DGDG, respectively, these new acylated DGMG and DGDG should be formed by specifically transferring the palmitoyl group from the *sn*-2 position of other galactolipids to the C-6 position of the terminal sugar ring of DGMG and DGDG.

ACKNOWLEDGMENT

Δ5-Olefinic Acids in the Seed Lipids from Four *Ephedra* Species and Their Distribution Between the α and β Positions of Triacylglycerols. Characteristics Common to Coniferophytes and Cycadophytes

Robert L. Wolff[a,*], William W. Christie[b], Frédérique Pédrono[a], Anne M. Marpeau[c], Nanzad Tsevegsüren[d], Kurt Aitzetmüller[d], and Frank D. Gunstone[b]

[a]ISTAB, Université Bordeaux 1, Talence, France, [b]Scottish Crop Research Institute, Dundee, Scotland, [c]Laboratoire de Chimie des Substances Végétales, Institut du Pin, Talence, France, and [d]Institute for Chemistry and Physics of Lipids, BAGKF, Münster, Germany

ABSTRACT: The fatty acid compositions of the seed lipids from four *Ephedra* species, *E. nevadensis, E. viridis, E. przewalskii,* and *E. gerardiana* (four gymnosperm species belonging to the Cycadophytes), have been established with an emphasis on Δ5-unsaturated polymethylene-interrupted fatty acids (Δ5-UPIFA). Mass spectrometry of the picolinyl ester derivatives allowed characterization of 5,9- and 5,11-18:2; 5,9,12-18:3; 5,9,12,15-18:4; 5,11-20:2; 5,11,14-20:3; and 5,11,14,17-20:4 acids. Δ5-UPIFA with a Δ11-ethylenic bond (mostly C_{20} acids) were in higher proportions than Δ5-UPIFA with a Δ9 double bond (exclusively C_{18} acids) in all species. The total Δ5-UPIFA content was 17–31% of the total fatty acids, with 5,11,14-20:3 and 5,11,14,17-20:4 acids being the principal Δ5-UPIFA isomers. The relatively high level of *cis*-vaccenic (11-18:1) acid found in *Ephedra* spp. seeds, the presence of its Δ5-desaturation product, 5,11-18:2 acid (proposed trivial name: ephedrenic acid), and of its elongation product, 13-20:1 acid, were previously shown to occur in a single other species, *Ginkgo biloba,* among the approximately 170 gymnosperm species analyzed so far. Consequently, Ephedraceae and Coniferophytes (including Ginkgoatae), which have evolved separately since the Devonian period (~300 million yr ago), have kept in common the ability to synthesize C_{18} and C_{20} Δ5-UPIFA. We postulate the existence of two Δ5-desaturases in gymnosperm seeds, one possibly specific for unsaturated acids with a Δ9-ethylenic bond, and the other possibly specific for unsaturated acids with a Δ11-ethylenic bond. Alternatively, the Δ5-desaturases might be specific for the chain length with C_{18} unsaturated acids on the one hand and C_{20} unsaturated acids on the other hand. The resulting hypothetical pathways for the biosynthesis of Δ5-UPIFA in gymnosperm seeds are only distinguished by the position of 11-18:1 acid. Moreover, ^{13}C nuclear magnetic resonance spectroscopy of the seed oil from two *Ephedra* species has shown that Δ5-UPIFA are essentially excluded from the internal position of triacylglycerols, a characteristic common to all of the Coniferophytes analyzed so far (more than 30 species), with the possibility of an exclusive esterification at the *sn*-3 position. This structural feature would also date back to the Devonian period, but might have been lost in those rare angiosperm species containing Δ5-UPIFA.

Paper no. L8247 in *Lipids 34,* 855–864 (August 1999).

Gymnosperms are generally divided into two main taxonomic groups: the Coniferophytes and the Cycadophytes (1,2). Despite the fact that not all authors agree on this classification, what is important is that extant species belonging to these two distinct groups have evolved independently since the Devonian period for approximately 300 million years (1,2). The monophyletic taxon status of gymnosperms is doubtful (1). Takagi and Itabashi (3) have analyzed in detail the seed lipids from 21 gymnosperm species, including two Cycadophytes, whereas Wolff and coworkers have established the fatty acid composition of seed lipids from approximately 170 Coniferophyte species of the families Pinaceae, Cupressaceae, Taxodiaceae, Sciadopityaceae, Taxaceae, Cephalotaxaceae, Podocarpaceae (4–14; Wolff, R.L., Pédrono, F., and Marpeau, A.M., unpublished results), and more recently, of the family Araucariaceae (Wolff, R.L., Christie, W.W., Pédrono, F., and Marpeau, A.M., unpublished results).

Both Japanese and European researchers agreed on the systematic presence of Δ5-unsaturated polymethylene-interrupted fatty acids (Δ5-UPIFA or Δ5-olefinic acids) in all analyzed gymnosperm seeds. The same peculiarity would also hold true for gymnosperm leaves (15). The following structures of Δ5-UPIFA have been characterized in gymnosperm plants: 5,9-18:2 (taxoleic); 5,11-18:2; 5,9,12-18:3 (pinolenic); 5,9,12,15-18:4 (coniferonic); 5,11-20:1; 5,11,14-20:3 (sciadonic), and 5,11,14,17-20:4 (juniperonic) acids, all ethylenic bonds being in the *cis* configuration. The content and profile of individual Δ5-UPIFA depend on the family, the genus, or even the species considered (5–8). The same Δ5-UPIFA (and others, e.g., 5,13-22:2 acid) have been observed in the seeds of about a dozen angiosperm species, which may additionally

contain Δ5-monoenoic acids, and *trans* Δ5-UPIFA are known in two or three angiosperm species (16–26).

The first report on the fatty acid composition of the seed lipids from a Cycadophyte species was probably that of Kleiman *et al*. (27), which was published more than 30 yr ago. The species under analysis was *Ephedra campylopoda*, and it was shown that the seeds contained several Δ5-UPIFA, i.e., 5,11-18:2; 5,11-20:2; 5,11,14-20:3, and 5,11,14,17-20:4 acids. The position of the ethylenic bonds as established by a complex combination of preparative or analytical gas–liquid chromatography (GLC) of the fatty acid methyl esters (FAME), fractionation according to the number of ethylenic bonds by argentation thin-layer chromatography (Ag-TLC), partial hydrazine reduction, and ozonolysis. The double bond location in eicosatetraenoic acid was later confirmed by GLC–mass spectrometry (MS) of its monomethoxy eicosanoates (28). With few discrepancies, the Δ5-olefinic acids identified in *E. campylopoda* seed lipids were the same as those characterized a few years earlier by Schlenk and Gellerman (29) in *Ginkgo biloba* seeds and leaves. Litchfield (30) analyzed the seed lipids from another Ephedraceae, *E. nevadensis* (known as Nevada Mormon tea), at approximately the same time, and though the exact location of the ethylenic bonds in each acid was not determined, he concluded that *E. nevadensis* seed fatty acids apparently resembled those identified in *E. campylopoda* by Kleiman *et al*. (27).

In the 1980s, some authors published supplementary data for the seeds and/or leaves of a few other Cycadophytes, i.e., *Welwitschia mirabilis* (31), *Gnetum scandens* (32), *Gnetum gnemon* (33), and *Macrozamia communis* (34). No Δ5-olefinic acids were reported for these species, but surprisingly, some of them were found to contain cyclopropene acids. Takagi and Itabashi (3) found several Δ5-UPIFA in the seeds of *Cycas revoluta*, though in low amounts, as in *E. sinica* dried stalks.

In the present study, FAME were prepared from *E. nevadensis*, *E. viridis*, *E. przewalskii*, and *E. gerardiana* seed lipids and analyzed by capillary GLC on three fused-silica capillary columns with different polarities, one coated with a 100% cyanopropyl polysiloxane stationary phase (CP-Sil 88; Chrompack, Middelburg, The Netherlands), a second one with a polyethylene glycol stationary phase (DB-Wax; J&W Scientific, Folsom, CA), and a third one with a 1:1-cyanopropyl-phenyl polysiloxane stationary phase (Silar-5CP; Chrompack). Identifications of peaks were performed by comparison of their equivalent chain lengths on the DB-Wax column (isothermal) or their retention times on the CP-Sil 88 and the Silar-5CP columns (temperature programming) with the corresponding parameters of FAME prepared with known sources of individual Δ5-UPIFA. However, owing to the botanical and taxonomic distance between Coniferophytes and Cycadophytes, the absolute FAME structures were also established by GLC–MS of the picolinyl esters prepared from *E. nevadensis* seed lipids.

Additionally, we studied the seed oil from the latter species and from *E. viridis* by ^{13}C nuclear magnetic resonance (NMR) spectroscopy, which allows differentiation of Δ5-UPIFA present in the α and β positions of the triacylglycerols (TAG) because it is known that in all Coniferophyte families analyzed so far, the Δ5-UPIFA are almost completely excluded from the internal position of seed TAG (3,11,12, 35–43). It was therefore interesting to verify whether this structural feature had remained unchanged in the two "branches" of gymnosperms, even after a gap of 300 million years.

MATERIALS AND METHODS

Seeds, oil extraction, and FAME preparation. *Ephedra nevadensis* and *E. viridis* (green jointfir ephedra) seeds were purchased from Lawyer Nursery, Inc. (Plains, MT). Seeds from *E. przewalskii* were collected in the vicinity of Ulan Bator, Mongolia, and seeds from *E. gerardiana* were from the Botanical Garden, University of Hamburg. The extraction of lipids from whole seeds and the preparation of FAME were performed as described in detail elsewhere for other gymnosperm seeds (4,5). All FAME preparations were done in duplicate and analyzed twice on the DB-Wax column and once on the CP-Sil 88 and the Silar-5CP columns. As a rule, FAME were prepared and analyzed on the DB-Wax column immediately after lipid extraction.

Analytical GLC. FAME were analyzed in a Carlo Erba 4130 chromatograph (Carlo Erba, Milano, Italy) equipped with a DB-Wax column (30 m × 0.32 mm i.d., 0.5 µm film; J&W Scientific). The oven temperature was 190°C and the inlet pressure of the carrier gas (helium) was 140 kPa. Alternatively, a CP-Sil 88 column (50 m × 0.25 mm i.d., 0.2 µm film; Chrompack) was operated with temperature programming in a Carlo Erba HRGC chromatograph from 150 to 185°C at 4°C/min with H_2 at 100 kPa. The injector (split mode) and flame-ionization detector were maintained at 250°C for both columns. Quantitative data were calculated by SP 4290 integrators (Spectra Physics, San Jose, CA). Additionally, all FAME samples were analyzed on a Silar-5CP column (Chrompack) using a temperature program standardized for seed oil fatty acid "fingerprints" as described elsewhere (44).

Identification of FAME peaks. The seed lipids from selected conifer species (45) and from Ranunculaceae such as *Cimicifuga* spp. (46) were used as sources of Δ5-olefinic acid methyl esters with known structures to identify fatty acids from *Ephedra* seed lipids by GLC, either by coinjection, comparison of the equivalent chain lengths (DB-Wax column), or retention times (CP-Sil 88 and Silar-5CP). FAME prepared from meadowfoam seed oil were used to locate Δ5-monoenoic (16:1, 18:1, 20:1, and 22:1) acids on chromatograms.

Preparation of picolinyl esters (47). The free acids (1 mg), prepared by hydrolysis with 0.1 M ethanolic potassium hydroxide, were converted to acid chlorides by reaction with oxalyl chloride (0.5 mL) at ambient temperture overnight. Excess reagent was removed in a stream of nitrogen, and the product was reacted immediately with a solution (0.5 mL) of 3-hydroxymethylpyridine in dichloromethane [20 mg/mL; stored over beads of molecular sieve type 4A (Fisher Scien-

tific, Loughborough, United Kingdom)]. After 1 h at ambient temperature, the solvent was evaporated, the product taken in isohexane (5 mL), and washed with water (2 × 2 mL). The isohexane solution was dried over anhydrous sodium sulfate and evaporated; the product was dissolved in isohexane containing butyl-hydroxytoluene (50 ppm) for analysis by GLC–MS.

GLC–MS. The picolinyl ester derivatives were submitted to GLC–MS with a Hewlett-Packard 5890 Series II plus gas chromatograph attached to an HP model 5989 mass spectrometer. The latter was used in the electron impact mode at 70 eV with a source temperature of 250°C. The chromatograph was fitted with on-column injection and equipped with a capillary column of fused silica coated with Supelcowax 10 (25 m × 0.25 mm i.d., 0.25 μm film; Supelco UK, Poole, United Kingdom). After holding the temperature at 80°C for 3 min, the column was temperature programmed at 20°C/min to 160°C, then at 2°C/min to 280°C, where it was held for 5 min. Helium at 1 mL/min was the carrier gas.

^{13}C NMR spectroscopy. ^{13}C NMR spectra were obtained on a Bruker AM 300 spectrometer (Karlsruhe, Germany) operating at a frequency of 75.47 MHz. Samples were prepared in 5-mm tubes with approximately 100 mg of oil (from *E. nevadensis* and *E. viridis* seeds) in 0.5 mL deuteriochloroform that contained tetramethylsilane as reference and $Cr(acac)_3$ as relaxation agent (0.025 M). Spectra were acquired by a nuclear Overhauser effect-suppressed, inverse-gated, proton-decoupling technique and employed a 90° excitation pulse, a 5-s pulse delay, and a sweep width of 20 kHz (32 K data points). The 90° pulse width was 3.9 μs. The number of scans was 1000 per spectrum.

RESULTS AND DISCUSSION

The phyletic position of Ephedraceae. A hypothetical phyletic relationship between Ephedraceae and Conipherophytes is shown in Figure 1 (adapted from Ref. 2). This figure is only intended to help visualize and emphasize the considerable distance between these plant groups on a geological time scale. It is believed that the Gnetatae, to which the Ephedraceae would belong along with the Gnetaceae and the Welwitschiaceae (with only one species, *W. mirabilis*), are the closest living relatives of the angiosperms, though they have common roots with the Coniferophytes (1,26,48). However, the extant Gnetatae might not be the ancestors of angiosperms, because no fossil records of this group have been found before the Tertiary period, while angiosperms certainly existed in the Jurassic (49). Yet, as mentioned above, Δ5-olefinic acids are also present in the seeds of a few rather archaic angiosperm families (22–24).

Fatty acid characterization and composition. Fatty acids are most easily identified by MS in the form of picolinyl esters or 4,4-dimethyloxazoline derivatives (50,51), and the former were used here. Some key diagnostic ions are listed in Table 1. As picolinyl esters, conventional monoenoic and methylene-interrupted dienoic fatty acids are recognized by characteristic gaps of 26 amu in the mass spectra for fragmentation on either side of the double bond and by abundant ions adjacent to the double bond. Picolinyl esters of fatty acids with a 5,9-double bond system can be recognized by a prominent ion at m/z = 219, representing cleavage between carbon atoms 7 and 8; other ethylenic bonds are located as for more conventional unsaturated fatty acids (50,51). An isolated double bond in position 5 can be located by the appropriate gap of 26 amu, but a prominent ion at m/z = 232 for a fragmentation adjacent to the double bond is often a more useful diagnostic guide. For example, spectra of picolinyl esters of 5-20:1 and 5,13-22:2 acids have been published previously (52). Mass spectra of 4,4-dimethyloxazoline derivatives of the same Δ5-UPIFA prepared from the seed lipids of various conifer species and of *Cimicifuga* spp. have been published previously (45,46).

11,14,17-20:3	397 (36)	368 (10), 328 (24), 288 (14)
5,11,14,17-20:4	395 (31)	232 (15), 286 (17), 326 (21)

With regard to Δ5-UPIFA, all species analyzed here have seed lipids that contain the whole series of such acids (Tables 1 and 2). No Δ5-monoenoic acids were observed on routine chromatograms of FAME (the three capillary columns used here allow distinction of the isomeric *cis*-5 and *cis*-9 18:1 acids; results not shown). With the possible exception of *E. sinica* stalk lipids (3), this appears to be a general feature of gymnosperm lipids. However, in a few species distinct from *Ephedra*, small peaks with the same retention time of 5-18:1 acid have been observed on Silar-5CP columns, which require further investigation and identification (Aitzetmüller, K., unpublished observations). In contrast to most gymnosperm species, Δ5-monoenoic acids have been observed in the seeds of a number of angiosperm families, sometimes in great amounts (22,53), and 5,11,14-20:3 acid also has been observed at levels up to 30% in a few angiosperm seed oils (53).

Our results clearly show that 5,9- and 5,11-18:2 acids, though in minor amounts, coexist in *Ephedra* spp. seed lipids (Table 2), with a higher level of the latter as compared to the former. As dicussed elsewhere for FAME prepared from *G. biloba* seed lipids (13), analyses of FAME prepared from *Ephedra* seed lipids on the DB-Wax capillary column allow only a partial resolution of the 5,9- and 5,11-18:2 acids, whereas baseline resolution of these two isomers is obtained on the CP-Sil 88 and Silar-5CP capillary columns. Identification (by their retention times) and quantitation of these acids were thus made with the latter columns. These identifications were supported by MS of the picolinyl esters separated on a Supelcowax capillary column (similar to the DB-Wax) (Table 1).

The same octadecadienoic acids that were formally identified in *G. biloba* seeds (13) were identified by GLC–MS of the picolinyl esters, and our observations confirm the tentative identifications of these acids by Takagi and Itabashi (3) in *E. sinica* dried stalks, based on calculated equivalent chain lengths. In the study by Kleiman *et al*. (27) on *E. campylopoda* seed lipids, only the 5,11-18:2 isomer was identified by chemical means. For practical purposes, it would appear that *Ephedra* seeds are more useful than *G. biloba* seeds in preparing 5,11-18:2 acid, because their oil content is *ca*. 11%

(relative to undehulled seeds) instead of only 1.5–2%, respectively. The 5,9,12-18:3 and 5,9,12,15-18:4 acids, which are the Δ5-desaturation products of linoleic and α-linolenic acids, are present in small amounts (0.1–0.5%), and were not reported previously in *Ephedra* seeds (27,28). However, an isomeric 18:3 acid (unknown structure) was noted on the chromatogram of FAME prepared from *E. nevadensis*, and published by Litchfield (30). The 5,11-20:2 acid (derived from 11-20:1 acid) also occurs in the seed lipids of the four *Ephedra* species (1.1–1.6%), but we could not detect the Δ5-desaturation product of 13-20:1 acid, the elongation product of *cis*-vaccenic acid. Both the 9,12-18:2 and the 9,12,15-18:3 acids are elongated to 11,14-20:2 and 11,14,17-20:3 acids, respectively, but none of these acids accumulated to a large extent (3.3% at most). They are apparently actively Δ5-desaturated to 5,11,14-20:3 and 5,11,14,17-20:4 acids, which are present at levels in the range 4.4–7.5% and 8.8–19.2%, respectively. The total Δ5-UPIFA reached 17.3% in *E. przewalskii*, 21.9% in *E. nevadensis*, 23.1% in *E. viridis*, and 30.8% in *E. gerardiana*. The latter value compares well with the proportion determined in *E. campylopoda* (30.5%) (Table 2). It is interesting to note that total Δ5-UPIFA is less than 33% in the five *Ephedra* species analyzed so far, such as the Conipherophyte species. For the latter species, this was explained by the fact that all Δ5-UPIFA are mostly esterified to only one position of TAG, the *sn*-3 position (37).

Among "habitual" fatty acids, the main component was oleic (9-18:1) acid (17–34%), accompanied by fairly high levels of 11-18:1 (*cis*-vaccenic or asclepic) acid (*ca*. 7–12%). Among Coniferophytes, only *G. biloba* seeds present a higher level of *cis*-vaccenic acid (17–18%) (3,54,55); other species generally contain less than 2% of this acid in their seed lipids. Following the octadecenoic acids, and in more or less equal abundance, are linoleic (9,12-18:2) and α-linolenic (9,12,15-18:3) acids (9–13% and 8–17%, respectively). The level of α-linolenic acid was between that present in Pinaceae and Taxaceae on the one hand, and that in Taxodiaceae and Cupressaceae on the other hand. The saturated fatty acids, principally 16:0 and 18:0 acids, were quite low (less than 10% in the species analyzed here), which is an habitual feature of most Coniferophytes. Other minor fatty acids were 14:0, possibly 15:0, 17:0, 9-17:1 [identified by its mass spectrum (Table 1)], and 22:0 acids. 14-Methylhexadecanoic acid, which is an ubiquitous branched fatty acid in Pinaceae seeds (56), and also present in *G. biloba* seeds (55), could not be positively identified in *Ephedra* seeds.

Hypotheses on Δ5-desaturases in gymnosperms. A metabolic pathway for the synthesis of habitual fatty acids and of Δ5-UPIFA was proposed initially by Itabashi and Takagi (57), who analyzed the fatty acid composition of *Taxus cuspidata* (Japanese yew) seed, aril, and leaf lipids. Later, Wolff *et al*. (5) proposed a similar scheme based on the analysis of the seed fatty acids from 28 species belonging to the families Pinaceae, Taxaceae, Taxodiaceae, Sciadopityaceae, and Cupressaceae. Both groups of researchers postulated the existence of a Δ5-desaturase that would use 9-18:1, 9,12-18:2, 9,12,15-18:3, and their elongation products, 11-20:1, 11,14-20:2, and 11,14,17-20:3 acids, as substrates. Additionally, in *G. biloba* seed lipids (13) and in *Ephedra* spp. (this study), the 11-18:1 acid also is visibly a substrate for the Δ5-desaturase and gives 5,11-18:2 acid. With regard to this acid, we propose the trivial name "ephedrenic" acid, to recall that it is a widespread fatty acid in *Ephedra* spp. seeds, though it also occurs in *G. biloba* seed lipids.

Our observations suggest that there might exist two Δ5-desaturases in Coniferophyte and Ephedraceae seeds, one specific for unsaturated fatty acids with a Δ11-ethylenic bond, and another one specific for unsaturated fatty acids with a Δ9 double bond (Figure 2). In the particular case of *Ephedra* spp. seeds, the former would present a high activity, whereas the latter would be considerably less active: Fatty acids with a 5,11-ethylenic pattern are considerably higher than those containing a 5,9 system. For example, an opposite situation is observed in Pinaceae and in some Taxaceae [e.g., *Taxus* species (11)], where the 5,9-system is generally prominent. *Pinus edulis* (9) and other pines from the subsection *Cembroides* (10) are exceptions. In these species, the proportion of 5,11,14-20:3 acid may be higher than that of the 5,9,12-18:3 acid, though both acids are exceptionally low in this subsection of *Pinus*. On the other hand, the 5,11-dienoic arrangement predominates in some other families such as Sciadopityaceae [with the single extant species *Sciadopitys verticillata* (58)], Cupressaceae, and Taxodiaceae (3,5,7,14). If one ignores the existence of the 5,11-18:2 acid in *G. biloba* and *Ephedra* spp. seeds, then one can also hypothesize that there may exist two desaturases, one specific for unsaturated C_{18} acids, and the other specific for unsaturated C_{20} acids (Fig. 2). A third possibility—at least in some Cycadophytes—would depend on different chain-elongation activities (from C_{18} to C_{20}), prior to Δ5-desaturation by only one Δ5-desaturase, which generally prefers Δ11- and/or C_{20} substrates over Δ9- and/or C_{18} substrates. This model could also explain the observed different Δ5-UPIFA levels. The Δ5-UPIFA would then simply depend on the relative amounts of the preformed Δ11- (e.g., 11-18:1) or C_{20} acid substrates that were available to attack a single Δ5-desaturase.

The problem in making a decision regarding these possibilities is linked to the existence of 5,11-18:2 acid, issued from 11-18:1 acid, which is both a C_{18} acid and a Δ11-unsaturated acid. Moreover, the 13-20:1 acid, a C_{20} monoenoic acid without a Δ11-ethylenic bond, is apparently not a substrate for the Δ5-desaturase(s). These two exceptions would favor the first hypothesis, i.e., a specificity of the Δ5-desaturases for either the Δ9- or the Δ-11 ethylenic bond. In view of the fact that no Δ5-monoenoic acids are present, one ethylenic bond in the latter positions is apparently necessary for the introduction of a Δ5-ethylenic bond. Whatever the number of Δ5-desaturases and their substrate specificities, it is likely that they exist in both "branches" of gymnosperms. This is clearly demonstrated for *Ephedra* spp. and *Cycas revoluta* (3), another Cycadophyte. Except for the elongation of 5,9,12-18:3 acid to 7,11,14-20:3 (bishomopinolenic) acid,

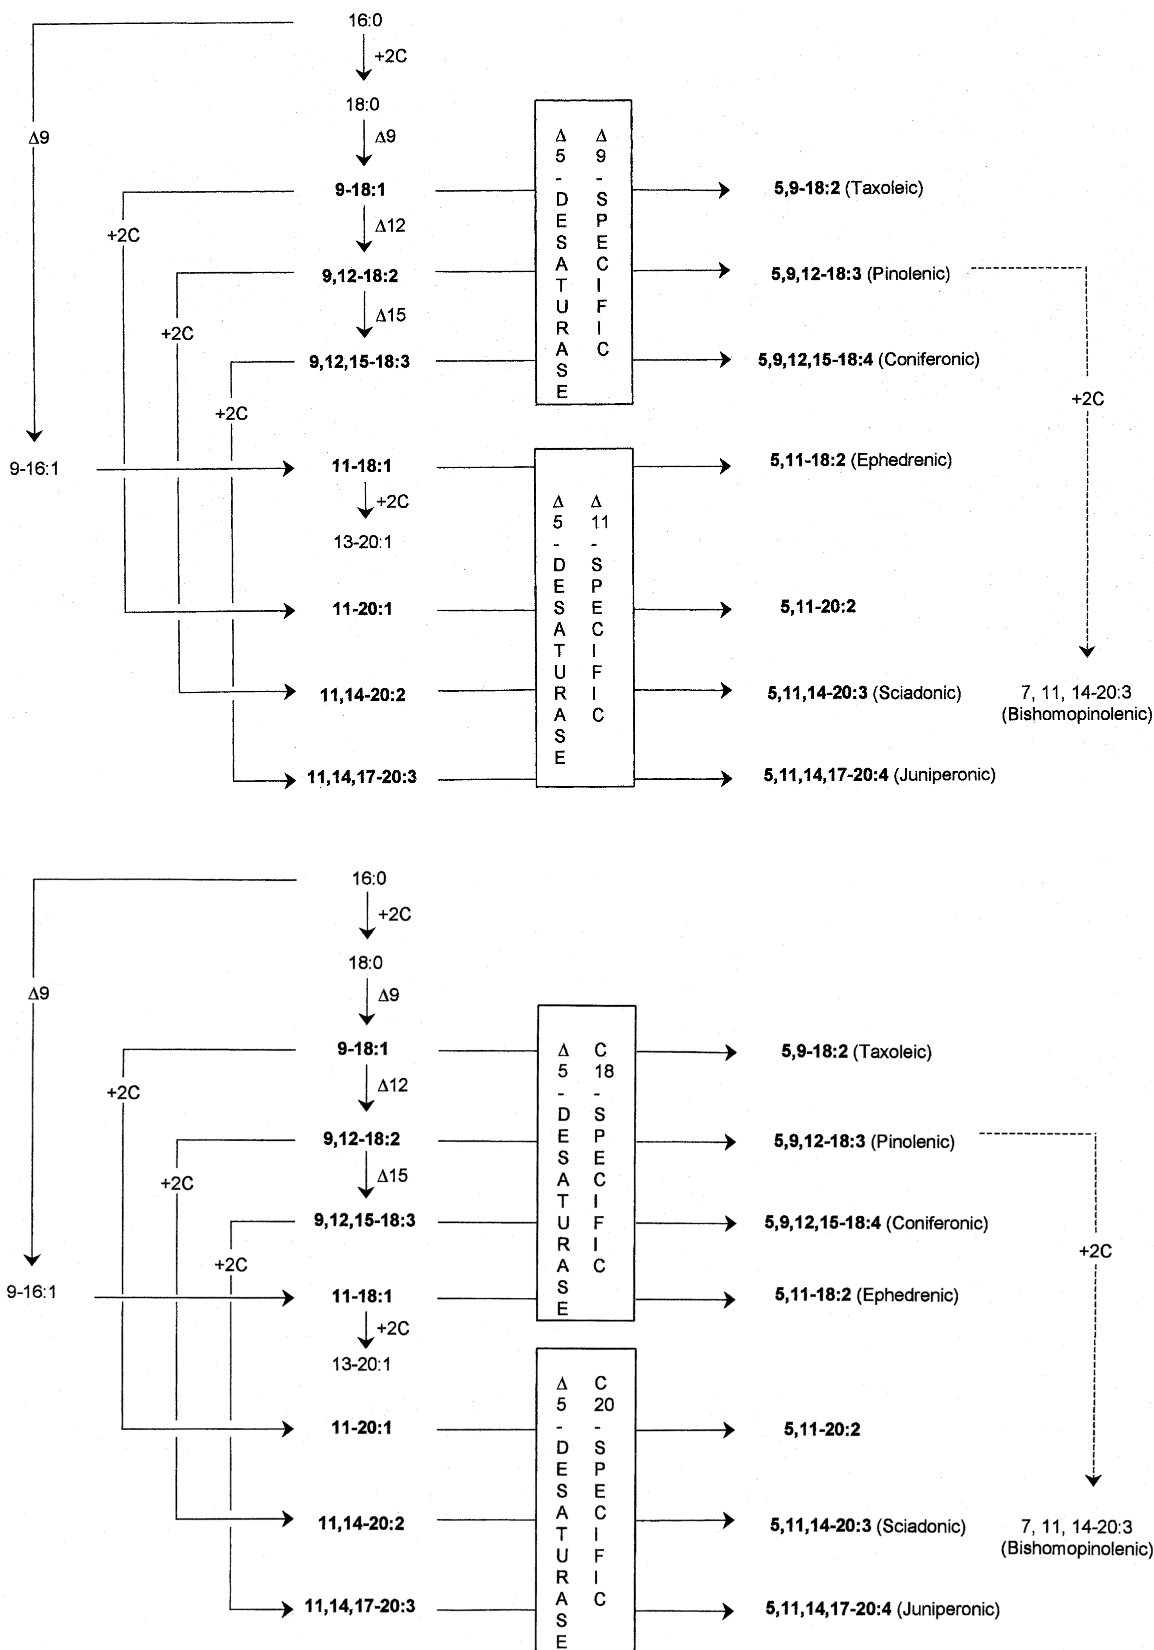

FIG. 2. Possible metabolic pathways for the biosynthesis of known unsaturated fatty acids occurring in gymnosperm seeds, and particularly in *Ephedra* spp. seeds. The upper figure is based on a specificity of Δ5-desaturases for the first ethylenic bond (Δ9 vs. Δ11), and the lower figure is based on a specificity for the chain length (C_{18} vs. C_{20}). The reaction symbolized by a dotted arrow is apparently limited to Pinaceae species, and does not seem to take place in *Ephedra* spp. seeds.

which was shown to occur in many species, but exclusively in the Pinaceae family (59), all other reactions shown in Figure 2 would occur simultaneously in *Ephedra* spp. seeds. The end products as well as the intermediate fatty acids have all been characterized in the present study.

When considering the ancestors of gymnosperms, possibly an extinct group of Pteridophytes (or derived from them, e.g., the "seed ferns"), or some still more remote ancestors, it is interesting to note that some extant species of the latter plant group (e.g., ferns) can synthesize arachidonic (5,8,11,14-20:4) and eicosapentaenoic (5,8,11,14,17-20:5) acids in their green parts (29). This implies that they contain one Δ6-desaturase specific for polyunsaturated C_{18} acids and one Δ5-desaturase specific for polyunsaturated C_{20} acids, which is a feature common to the more ancient group Bryophytes [e.g., mosses (29,60,61) and liverworts (61)], many microalgae and algae, some molds, and to most animals. However, the simultaneous presence of both Δ5- and Δ6-acids also has recently been observed in an angiosperm at levels between 3 and 5% of each (Aitzetmüller, K., unpublished results). The passage from Pteridophytes (or a related plant group) to gymnosperms might thus have been accompanied by a change of the C_{18}-specific (or Δ9-specific) Δ6-desaturase to a C_{18}-specific (or Δ9-specific) Δ5-desaturase, whereas the C_{20}-specific (or Δ11-specific) Δ5-desaturase would have kept its specificity. No fatty acids with a Δ6-ethylenic bond have been reported in any of the gymnosperm families analyzed so far, but conclusive results supported by MS indicate that the seeds from at least one species of the Araucariaceae family would contain both the Δ6-desaturase specific for polyunsaturated C_{18} acids and the Δ5-desaturase specific for polyunsaturated C_{20} acids. Their lipids contain γ-linolenic, stearidonic, arachidonic, and eicosapentaenoic acids, in addition to C_{20} Δ5-olefinic acids characteristic of other Coniferophytes (Wolff, R.L., W.W. Christie, F. Pédrono, and A.M. Marpeau, unpublished results). Because the interfamily relationships of Araucariaceae among Conipherophytes are mostly obscure, and because little is known as to which family could be more primitive, it is unclear whether the original status of polyunsaturated fatty acids in gymnosperms was a Δ6-unsaturated C_{18} status or a Δ5-unsaturated C_{18} status.

The possibility of the simultaneous presence of a C_{18}-specific Δ6-desaturase and of a C_{20}-specific Δ5-desaturase in a Spermaphyte is more than of academic interest. The logical metabolites of the combined action of both desaturases, with the intermediate intervention of a C_{18}-C_{20} elongase, are arachidonic and eicosapentaenoic acids. Surprisingly enough, arachidonic acid has been characterized in a few rare angiosperm species that are not known to contain the metabolic precursor γ-linolenic acid, whereas species containing the latter acid would not contain arachidonic acid (62). It is noteworthy that garlic and virgin wheat germ oil, have been reported to contain arachidonic acid (62).

Distribution of Δ5-UPIFA between the α- and β-chains of TAG. Several studies, using either chemical or enzymatic degradative procedures (3,36–39,43) or ^{13}C NMR spectroscopy (11,12,35,36,40–43), have shown that in all Coniferophyte seed lipids analyzed so far (more than 30 species belonging to 8 families and 15 genera; Table 3), Δ5-UPIFA are practically excluded from the β-position of TAG. This was corroborated by two studies, indicating that TAG molecular species with two Δ5-UPIFA were scarce [*Pinus pinaster* and *P. koraiensis* (63)] or undetectable [*P. koraiensis* (64)]. A more detailed study of the stereodistribution of Δ5-UPIFA has shown that they were principally esterified (more than 90%) to the *sn*-3 position [in *Taxus baccata*, *Larix decidua*, *Sciadopitys verticillata*, *Juniperus communis*, and the two preceding *Pinus* species (37)]. This results in a maximum observed content of Δ5-UPIFA in TAG of 33% of total fatty acids [in *Larix sibirica* seeds (65)], supporting the hypothesis that these acids would be exclusively esterified to the *sn*-3 position of TAG from

[d]Erroneously reported earlier as a species of the Taxodiaceae family (58).

Coniferophyte seeds.

One aim of the present study was to determine whether the systematic and specific esterification of Δ5-UPIFA to the *sn*-3 glycerol hydroxyl observed in the Coniferophyte branch also occurred in the Cycadophyte branch, even after a separation of 300 million years. As a first approach, ^{13}C NMR spectroscopy was applied to *E. nevadensis* and *E. viridis* seed crude oils. As detailed elsewhere (35,41), this technique not only allows calculation of Δ5-acid levels, but also distinction of Δ5 acids esterified to the α (*sn*-1/3) and β (*sn*-2) positions of TAG with specific reference to carbon atoms 1 (acyl) and 2. The *E. nevadensis* oil has three signals for both C_1 and C_2 corresponding to Δ5 acids in the α position and to the remaining acids in the α and β positions. *Ephedra viridis* oil shows the same major signals accompanied by some small signals which cannot be assigned with certainty. One of these may relate to Δ5 acids in the β position. The results are set out in Table 4. The levels of Δ5 acids measured by NMR (mol%)—both C_1 and C_2 signals—are in good agreement with the more accurate levels measured by GLC (wt%). Consequently, the Δ5 acids occur wholly or mainly in one or both of the α positions in *Ephedra* spp. seed TAG, and the level of these acids in the β position does not exceed 3% (experimental limit detection level).

Because ^{13}C NMR spectroscopy does not distinguish between the *sn*-1 and *sn*-3 positions, our conclusion is thus limited to the α positions. At this molecular level, Coniferophytes and Cycadophytes (at least those species containing Δ5-UPIFA) share in common the distribution of Δ5 acids in TAG. The present study provides some evidence that the unusual role for Δ5 unsaturation [or of the Δ5-desaturase(s)] in the acylation (or desaturation) of glycerol esters in gymnosperm seed lipids is of great antiquity. Apparently, the stereospecific distribution of Δ5-UPIFA in the seed TAG from species of the two gymnosperm branches has remained unchanged during the past 300 million years.

Few data are available for the intraglyceride distribution of Δ5-UPIFA in angiosperm species presenting such acids in their seed lipids. The best documented species are apparently *Limnanthes* species, i.e., *L. douglasii* (66) and *L. alba* (67). The former species was subjected to complete stereospecific analysis, and it was observed that Δ5-olefinic acids (mostly 5-20:1, 5-22-1, and 5,13-22:2 acids, none of which occur in gymnosperm seeds) were esterified to all three glyceride positions, although not in equal amounts. Δ5-Olefinic acids were more abundant in the α positions (almost equally distributed between the *sn*-1 and *sn*-3-positions) than in the β position (66). The TAG species in *L. alba* seeds have been investigated, and almost 51% of them contained three Δ5-olefinic acids (67).

From the absence of 5-18:1 and 5-20:1 acids in reports on gymnosperm seed lipids (which is a distinctive feature as compared to some angiosperms containing Δ5 acids), it may be inferred that the Δ5-desaturase(s) acts as a final step in the biosynthesis of C_{18} Δ5-UPIFA, that is after the introduction of Δ9-, Δ12-, and Δ15-ethylenic bonds, and of the C_{20} Δ5-UPIFA after elongation of oleic, linoleic, and α-linolenic to the corresponding bishomo derivatives. However, it cannot be decided whether the introduction of the Δ5-ethylenic bond occurs before or after incorporation of C_{18} and C_{20} unsaturated acids into TAG. In both cases, one should postulate the existence of either Δ5-desaturase(s) or an acylase specific for the *sn*-3 position of glycerol. This emphasizes some major differences between gymnosperms and angiosperms with regard to the biosynthesis of Δ5-acylated TAG. Within the Gnetatae, the Ephedraceae seed TAG composition and structure are gymnospermous biochemical characteristics apparently not shared by Gnetaceae and Welwitschiaceae (48), which may help clarify the much controversed taxonomy and phylogeny of Gnetatae (1).

We also have found a different tentative classification of gymnosperms by Meyen (68). This author suggests another taxonomic and phyletic position for the family Ephedraceae, which he includes in the order Ephedrales. This order is grouped with Ginkgoales and seven other extinct orders in the class Ginkgoopsida. The reason for this grouping is the primary platyspermy of the seeds, possibly "of utmost importance for tracing gymnosperm phylogeny" (1). Coincidentally, *Ephedra* (this study) and *Ginkgo biloba* (13) are the two single genera among the 170 gymnosperm species we analyzed that contain both taxoleic and ephedrenic acids in sig-

TABLE 4
Total Content of Δ5 Acids in the Seed Oil from Two *Ephedra* Species as Determined by ^{13}C NMR Spectroscopy and by GLC, and Their Content in the α and β Positions[a]

		Fatty acid content[b]					
		α and β positions				Total

Positional Analysis of Triglycerides and Phospholipids Rich in Long-Chain Polyunsaturated Fatty Acids

L. Amate[a,*], M. Ramírez[a], and A. Gil[b]

[a]Research and Development Department, Ross Product Division, Abbott Laboratories, 18004 Granada, Spain and [b]Department of Biochemistry and Molecular Biology, University of Granada, 18071 Granada, Spain

ABSTRACT: Four sources of long-chain polyunsaturated fatty acids (LCP) differing in their chemical structure (triglycerides or phospholipids) and in their origin (tuna triglycerides, fungal triglycerides, egg phospholipids, and pig brain phospholipids) were analyzed to determine the distribution of the component fatty acids within the molecule. Lipase and phospholipase A_2 hydrolysis was performed to obtain 2-monoacylglycerols and lysophospholipids, respectively, which allowed us to determine the distribution of fatty acids between the *sn*-2 and *sn*-1,3 positions of triglycerides or between the *sn*-1 and *sn*-2 position of phospholipids. Fatty acids in the LCP sources analyzed were not randomly distributed. In tuna triglycerides, half of the total amount of 22:6n-3 was located at the *sn*-2 position (49.52%). In fungal triglycerides, 16:0 and 18:0 were esterified to the *sn*-1,3 (92.22% and 91.91%, respectively)18:1 and 18:2 to the *sn*-2 position (59.77% and 62.62%, respectively), and 45% of 20:3n-6 and only 21.64% of 20:4n-6 were found at the *sn*-2 position. In the lipid sources containing phospholipids, LCP were mainly esterified to the phosphatidylethanolamine fraction. In egg phospholipids, most of 20:4n-6 (5.50%, *sn*-2 vs. 0.91%, *sn*-1) and 22:6n-3 (2.89 vs. 0.28%) were located at the *sn*-2 position. In pig brain phospholipids, 22:6n-3 was also esterified to the *sn*-2 (13.20 vs. 0.27%), whereas 20:4n-6 was distributed between the two positions (12.35 vs. 5.86%). These results show a different fatty acid composition and distribution of dietary LCP sources, which may affect the absorption, distribution, and tissue uptake of LCP, and should be taken into account when supplementing infant formulas.

Paper no. L8041 in *Lipids 34*, 865–871 (August 1999).

Long-chain polyunsaturated fatty acids (LCP) play an important role in the structure and function of cellular membranes and are precursors of important lipid mediators. Moreover, some LCP, especially 22:6n-3, account for a large proportion of the polyunsaturated fatty acids in neuronal membranes. Studies with animals have shown an association between very low levels of 22:6n-3 in the retina and central nervous system and measures of visual and behavioral outcomes (1,2). Therefore, several studies have been carried out in preterm and term infants to evaluate the influence of dietary 22:6n-3, and both 20:4n-6 and 22:6n-3 on visual acuity and cognitive development (3). These reports and the observation that infants fed conventional formula have lower erythrocyte and plasma levels of the n-6 and n-3 LCP led us to consider that infants may benefit from dietary supplementation with 22:6n-3 or both 20:4n-6 and 22:6n-3.

A number of highly unsaturated dietary lipid sources are currently available for supplementing infant formulas with LCP, namely: egg yolk lipids, fish oils, and oils from unicellular organisms (i.e., fungi and algae). These lipid sources differ in their structure [triglycerides (TG) or phospholipids (PL); position of fatty acids in their backbone], fatty acid composition, and the presence of other components.

Lipase-catalyzed hydrolysis of triglycerides (TG) occurs in the mouth, stomach, and small intestine. The products of hydrolysis are free fatty acids (FFA) from the *sn*-1 and *sn*-3 positions and *sn*-2-monoacylglycerols (2-MG), which are readily absorbed, reesterified into triglycerides, and secreted into the lymph in the form of chylomicrons (4). The distribution of fatty acids in the outer and *sn*-2 positions within the molecule governs the lumenal partition between the free and 2-MG forms (5). Under normal dietary conditions, dietary PL constitute a minor portion of the PL presented to the gut for intestinal absorption; the majority are of biliary origin. Biliary PL (primary phosphatidylcholine, PC) are absorbed from the lumen as lysophosphatidylcholine (lysoPC) and are reacylated to PC for the formation of chylomicrons (6). A number of studies have focused on the importance of fatty acids esterified to the *sn*-2 position of TG (7–9). Fat and mineral absorption was higher in rat and infants fed diets containing structured triglycerides with 16:0 mainly in the *sn*-2 position (7). Linoleic acid was also better absorbed when it was esterified to the *sn*-2 position (8). Palmitic acid in the *sn*-2 position may also have some effects on cholesterol metabolism (9). Little information is available about the positional distribution of fatty acids in PL sources and its influence on the absorption and distribution of fatty acids. Recent studies carried out in preterm infants fed breast milk or formula with LCP derived from PL or from TG showed that absorption of 22:6n-3 and n-3 LCP was greater from PL-

LCP formula than from breast milk or TG-LCP formula (10). On the other hand, data from animal studies suggest that in the enterocytes, dietary fatty acids provided as TG are predominantly incorporated into chylomicrons, whereas dietary fatty acids provided as PL seemed to be predominantly incorporated into intestinal very low density lipoproteins. If such differences exist, the LCP source could influence the distribution and bioavailability of dietary LCP (11).

Stereospecific analysis of TG has received much attention by many authors in the last few years (12–14). Some methods involving chemical and enzymatic reactions have been reported to analyze positional fatty acid distribution. The chemical method using the Grignard degradation is one of the most reliable methods for obtaining representative diacylglycerols, but it does not give reliable results for the composition of 2-MG because of acyl migration during the reaction (13). Therefore, this method is usually combined with an alternative procedure to obtain the *sn*-2 composition, such as lipase hydrolysis, hydrolysis of PL derived from diacylglycerides, and separation of chiral isomers (15,16). This means *sn*-1, *sn*-2, and *sn*-3 fatty acid composition can be determined separately. Lipase hydrolysis does not give the complete structure of the TG molecule, but it offers reliable information about the *sn*-2 position, which is physiologically the most important. It has been reported that LCP such as 20:4n-6, 20:5n-3, and 22:6n-3 are resistant to lipase hydrolysis when linked to the outer position of the glycerol molecule (13). However, when prolonged incubation times are used, leading to nearly complete hydrolysis, representative 2-MG are obtained (12). Phospholipase A_2 hydrolysis has been used not only to study positional distribution of fatty acids in fungi (17) and bacteria (18) but also to analyze TG structure together with the Grignard reaction (12).

In the present study, we measured lipid and fatty acid composition and fatty acid distribution between the inner and outer positions of TG and PL molecules in four LCP dietary lipid sources currently available for use in infant formulas.

EXPERIMENTAL PROCEDURES

Samples. Two sources of LCP-enriched TG were analyzed: fungal TG and tuna TG. In addition, two sources of LCP-enriched PL were analyzed: one from egg lipids (egg PL) and the other from pig brain (pig brain PL).

Materials. *Rhizopus arrhizus* lipase (EC 3.1.1.3) and bee venom phospholipase A_2 (EC 3.1.1.4) were obtained from Boehringer Mannheim (Mannheim, Germany). TLC plates coated with a 0.25-mm thin layer of silica gel G60 and acetyl chloride were purchased from Sigma Chemicals Co. (St. Louis, MO). High-performance thin-layer chromatography (HPTLC) precoated silica gel 60 plates were purchased from Merck (Darmstadt, Germany).

HPTLC analysis. HPTLC was used to analyze the lipid composition of each lipid source. Plates were washed with chloroform/methanol/water (60:35:1.5, by vol) and activated by heating for 30 min at 100°C. Five µg of oils was placed on the HPTLC plates and developed using chloroform/methanol/acetic acid/water (65:50:1:4, by vol) for polar lipids (19), and hexane/isopropyl ether/acetic acid (75:25:1.5, by vol) for neutral lipids (20). After migration, plates were treated with a solution of 3% copper acetate in 8% *o*-phosphoric acid and heated at 180°C for 10 min. The relative percentage of each lipid was measured by photodensitometry in a Shimadzu CS 9000 scanning densitometer (Kyoto, Japan).

Fatty acid composition of oils. The total fatty acid compositon of the lipid sources were obtained by direct transmethylation according to the method of Lepage and Roy (21). The fatty acid composition of the main PL classes in the sources containing PL were measured after separation of species by TLC (developing solvent: chloroform/methanol/acetic acid/water, 60:40:1:2, by vol) and methylation.

Lipase hydrolysis of TG. The lipase reaction method of Fischer *et al.* (22), with minor modifications was used to hydrolyze the TG sources. Six mg of the lipid sources was sonicated for 10 min with Tris-HCl buffer (40 mM, pH 7.2) containing 50 mM sodium borate (to reduce positional migration of fatty acids) and 0.5% sodium taurocholate. One hundred to 120 units of lipase was added to the mixture and incubated at 22°C for up to 1 h with continuous shaking. The reaction was stopped by the addition of 0.5 mL 0.1 N acetic acid. Lipids were extracted from the assay with chloroform/methanol (2:1, vol/vol). After evaporation of the solvent under N_2, lipid extracts were applied to TLC plates and developed with hexane/isopropyl ether/acetic acid (75:25:1.5, by vol). Bands were visualized by iodine vapors and the band corresponding to 2-MG (*sn*-2) was scraped into test tubes. The lipid fractions were methylated as above (21).

Phospholipase A_2 hydrolysis of phospholipids. Phospholipase A_2 reaction was performed according to a modified procedure of Griffith *et al.* (23). Five mg of the sample was dissolved in 1 mL of diethylether, and 1 mL borate buffer (100 mM, pH 8.9) was added. The mixture was then sonicated for 15 min. Eighty to 200 units of phospholipase A_2 was added to the mixture and incubated with continuous shaking for 30 min at 37°C. Diethylether was then evaporated under N_2, and samples were extracted with chloroform/methanol (2:1, vol/vol). To obtain the different lipid fractions, lipid extracts were subjected to single-dimension double development with hexane/isopropanol/acetic acid (75:25:1.5, by vol) followed by chloroform/methanol/acetic acid/water (65:50:1:4, by vol). The spots were visualized with iodine vapors and the bands corresponding to lysoPC, lysophosphatidylethanolamine (lysoPE), and free fatty acids (FFA) were scraped and collected into tubes and methylated (21). Bee venom phospholipase A_2 hydrolyzes not only PC but also phosphatidylethanolamine (PE), phosphatidylinositol, and phosphatidylserine (24).

Gas–liquid chromatography. Fatty acid methyl esters were separated and quantified by gas–liquid chromatography, using a Hewlett-Packard 5890 gas chromatograph (Hewlett-Packard Co., Palo Alto, CA) equipped with a flame-ionization detector and a 60 m × 0.32 mm internal diameter SP-2330 capillary column (Supelco, Bellefonte, PA). Nitrogen at a flow rate of 1 mL/min was used as the carrier gas, and the

split ratio was 1:40. Temperature programming started at 165°C for 3 min, then was raised 2°C/min to 195°C, held for 2 min at 195°C, increased again at 3°C/min to 211°C, held for 6 min at 211°C, and then decreased at 15°C/min to return to 165°C. The injector and detector temperatures were 275°C. Peaks were identified by comparison with known standards (Sigma, St. Louis, MO).

Calculation. Results were expressed as the means of three replicates in mole percentage of total fatty acids. The fatty acid composition of the *sn*-1,3 position in tryglycerides was calculated from the overall fatty acid composition, and from that of the *sn*-2 position, using the formula: [*sn*-1,3] = 1.5[TG] − 0.5[*sn*-2]. The fatty acid composition of the *sn*-2 position in PL was calculated from the overall fatty acid composition of each PL class and from that of the *sn*-1 position using the formula: [FFA] = 2[PL] − [LysoPL]. The contribution of each PL class to the FFA fractions was corrected by their percentage in the original source. Both *sn*-1,3 in TG and *sn*-2 in PL were calculated from the other positions because they were obtained in the FFA fraction after the corresponding hydrolysis. We verified that, by means of structured standards, the composition of this fraction was less reliable because it was contaminated by acyl migration.

RESULTS AND DISCUSSION

Characterization of the lipid sources. The percentage of each lipid fraction in the original dietary lipid sources was assessed by HPTLC. Tuna TG and fungal TG were composed mainly of TG (>99%), and therefore were subjected to lipase hydrolysis without previous purification. Egg PL was composed of 86.76% PC and 11.13% PE. Pig brain PL was a complex mixture of PL in which PC and PE represented 24.43 and 43.75% of the total PL, respectively.

The overall fatty acid compositions of these lipid sources are shown in Figure 1 and in Tables 1–3. Tuna TG were characterized by a high content of 22:6n-3 and a low ratio of 20:5n-3 to 22:6n-3 (0.29). Saturated and monounsaturated fatty acids were also present, with percentages exceeding 30 and 20% mol of the total fatty acids, respectively. On the contrary, fungal TG contained a high proportion of 20:4n-6, without detectable amounts of 22:6n-3. The availability of oils containing a high proportion of n-6 and n-3 LCP, separately, provides the advantage of varying the n-6/n-3 ratio in infant formulas. Egg PL had a 20:4n-6/22:6n-3 ratio of 1.36. Pig brain PL contained a higher proportion of LCP compared to the egg PL source, with a 20:4n-6/22:6n-3 ratio of 1.31.

Positional analysis of TG. Table 1 gives the fatty acid composition of the TG molecule in the lipid sources containing LCP and that of the *sn*-2 and *sn*-1,3 positions. Likewise, Figure 2 shows the percentages of the total amount of selected fatty acids which were located at the *sn*-2 position (calculated according to the formula % *sn*-2 = [(*sn*-2) × 100]/3 TG). If random distribution among the three positions of the TG molecule was expected, 33.33% of the total amount of a considered fatty acid would be located at the *sn*-2 position. How-

[a]TG, fatty acid composition of the total triglyceride; *sn*-2, fatty acid composition of the *sn*-2 monoglycerides obtained after lipase hydrolisis; *sn*-1,3, fatty acid composition of *sn*-1 and *sn*-3 positions obtained as followed [*sn*-1,3] = 1.5[TG] – 0.5[*sn*-2]; LCP, long-chain polyunsaturated fatty acids.

ever, the *sn*-2 position in tuna TG contained 49.52% of the total 22:6n-3. Eicosapentaenoic acid and palmitic acid were almost equally distributed between the *sn*-2 and *sn*-1,3 positions. In fungal TG, 16:0 and 18:0 were mainly esterified to the *sn*-1,3 positions, whereas the opposite was found for 18:1 and 18:2. Forty-five percent of 20:3n-6 and only 21.64% of 20:4n-6 were found at the *sn*-2 position.

Only one work is available on the stereospecific distribution of highly unsaturated oils (12). This study showed the analysis of six polyunsaturated oils containing triglycerides, two of which were quite similar in the total fatty acid and *sn*-2 fatty acid composition to the tuna TG and fungal TG reported here, and were also of tuna and fungal origin.

It has been reported that polyunsaturated fatty acids are distributed within the TG molecule of human milk in a highly specific manner, with 20:4n-6 and 22:6n-3 being located at the *sn*-2 and *sn*-3 positions (13). Although LCP linked to the outer position of the TG molecule are resistant to pancreatic hydrolysis, breast-fed infants may efficiently hydrolyze TG containing LCP due to gastric lipase and bile salt-stimulated lipase. In contrast to human milk, infant formulas do not contain any lipase activity, and consequently the hydrolysis of the *sn*-1 and *sn*-3 ester bonds of TG may decline. In the case of appropriate lipase hydrolysis, LCP absorbed as 2-MG or FFA may undergo different metabolic processes (25). Some researchers suggest a possible substantial blood absorption pathway for polyunsaturated fatty acids with reference to their hydrosolubility properties (26). On the other hand, it has been reported that 20:5n-3 and 22:6n-3 were more readily and efficiently absorbed when the TG administered had a specific intramolecular structure, with medium-chain fatty acids located in the *sn*-1 and *sn*-3 positions and n-3 LCP located in the *sn*-2 position, compared with TG having a random fatty acid distribution among the three positions (27). Our results showed that nearly 50% of 22:6n-3 and more than 20% of 20:4n-6 were esterified to the *sn*-2 position. Fatty acids in the *sn*-2 position may have some unique properties in terms of facilitating fatty acid intestinal absorption and improving

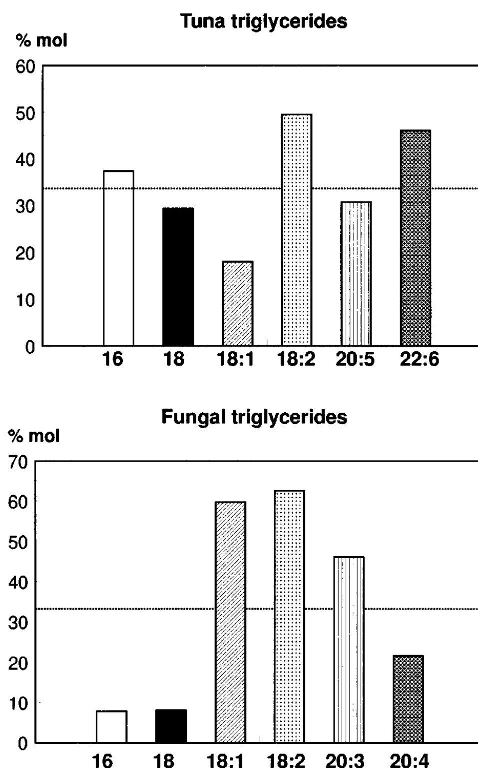

FIG. 2. The *sn*-2 fatty acid composition in triglyceride LCP-enriched lipid sources. The horizontal broken line indicates the proportion of each fatty acid expected (33.33%) on the basis of random distribution. See Figure 1 for abbreviation.

mineral balance (7). However, the influence of this fatty acid distribution on LCP absorption and metabolic fate when supplementing infant formulas needs further research.

Positional analysis of phospholipids. Tables 2 and 3 give the fatty acid composition of intact PL, the fatty acid composition of the major PL fractions, and the fatty acid composition of the products after phospholipase A_2 hydrolysis in egg PL and pig brain PL. The fatty acid composition of lysoPC and lysoPE represents that of the *sn*-1 position in PC and PE, respectively. The fatty acid composition of FFA represents that of the *sn*-2 position in the complete PL. As shown in Tables 2 and 3, the PC fraction contained more 16:0 and 18:1n-9 and less 18:0 than PE in PL from eggs. In pig brain PL, PC contained more 16:0, 18:1n-9, and 18:0 than PE. LCP were mainly esterified to the PE fraction of PL sources, both from egg and pig brain, and were located at the *sn*-2 positions, because they were nearly absent from lysophospholipids. Arachidonic acid in pig brain PL was also present in the *sn*-1 position. On the contrary, saturated fatty acids were mainly esterified to the *sn*-1 position, but oleic acid to the *sn*-2. These results agree with the general assumption that, in tissues, saturated fatty acids were linked to the *sn*-1 and polyunsaturates to the *sn*-2 position of PL.

As far as we know, no study has been made about the positional distribution of PL in sources currently used in infant nutrition. Henderson *et al.* (18) and Kendrick and Ratledge (17) used similar methods to analyze the positional distribution of fatty acids in PL isolated from species of bacteria and fungi which contained LCP. Phospholipids enriched in LCP are an available source of these fatty acids and some of them are used currently to supplement infant formulas. Data of animal studies suggest that in the enterocyte, dietary fatty acids provided as TG are predominantly incorporated into chylomicrons. On the contrary, fatty acids provided as PL seem to be predominantly incorporated into very low density particles synthetized at the enterocytes (28). It has been recently reported that infants fed LCP-supplemented formula from egg PL absorbed 22:6n-3 as efficiently as did breast-fed infants (10,11), and better than did infants fed a formula containing LCP-TG (10).

In conclusion, there are many differences in the chemical structure and fatty acid composition and distribution of the currently available dietary sources of LCP for infant formulas. These differences may affect the absorption, distribution, and tissue uptake of these important fatty acids and should be taken into account when supplementing infant formulas.

ABSTRACT: Conjugated linoleic acid (CLA) mixtures were isomerized with *p*-toluenesulfinic acid or I_2 catalyst. The resultant mixtures of the eight *cis/trans* geometric isomers of 8,10-, 9,11-, 10,12-, and 11,13-octadecadienoic (18:2) acid methyl esters were separated by silver ion–high-performance liquid chromatography (Ag^+–HPLC) and gas chromatography (GC). Ag^+–HPLC allowed the separation of all positional CLA isomers and geometric *cis/trans* CLA isomers except 10,12-18:2. However, one of the 8,10 isomers (8*cis*,10*trans*-18:2) coeluted with the 9*trans*,11*cis*-18:2 isomer. There were differences in the elution order of the pairs of geometric CLA isomers resolved by Ag^+–HPLC. For the 8,10 and 9,11 CLA isomers, *cis,trans* eluted before *trans,cis*, whereas the opposite elution pattern was observed for the 11,13-18:2 geometric isomers (*trans,cis* before *cis,trans*). All eight *cis/trans* CLA isomers were separated by GC on long polar capillary columns only when their relative concentrations were about equal. Large differences in the relative concentration of the CLA isomers found in natural products obscured the resolution and identification of a number of minor CLA isomers. In such cases, GC–mass spectrometry of the dimethyloxazoline derivatives was used to identify and confirm coeluting CLA isomers. For the same positional isomer, the *cis,trans* consistently eluted before the *trans,cis* CLA isomers by GC. High resolution mass spectrometry (MS) selected ion recording (SIR) of the molecular ions of the 18:1, 18:2, and 18:3 fatty acid methyl esters served as an independent and highly sensitive method to confirm CLA methyl ester peak assignments in GC chromatograms obtained from food samples by flame-ionization detection. The high-resolution MS data were used to correct for the nonselectivity of the flame-ionization detector.

Paper no. L8226 in *Lipids 34*, 873–877 (August 1999).

The distribution of conjugated linoleic acid (CLA) isomers was examined in a number of natural products, including milk, cheese, meat, adipose tissue, and tissues from animals fed commercial CLA mixtures, using the newly developed silver ion–high-performance liquid chromatography (Ag^+–HPLC) system (1–4). The resolution of the CLA isomers was further enhanced by using up to six Ag^+–HPLC columns in series (5). The initial results indicated that Ag^+–HPLC resolved positional *cis/trans* CLA isomers, but not pairs having the same double-bond positions with opposite geometrical configuration. In cheese lipids, however, we observed what appeared to be two 11,13-octadecadienoic (18:2) acids with *cis,trans* and *trans,cis* double-bond configurations through gas chromatography–electron ionization mass spectrometry (GC–EIMS) (4).

It is occasionally difficult to match the Ag^+–HPLC data based on ultraviolet (UV) detection at 234 nm with GC results obtained using 100-m polar capillary columns and a flame-ionization detector (FID) for some lipid extracts. Extraneous peaks may arise in the Ag^+–HPLC chromatogram from conjugated fatty acids of different chain lengths eluting in the same region (5), or in the GC chromatogram from non-CLA fatty acid methyl esters (FAME). These two methods are complementary, but peculiar results should be thoroughly investigated using additional techniques to avoid misidentifications.

To confirm the identity of positional and geometrical CLA isomers, we have prepared all possible *cis/trans* CLA isomers of 8,10-, 9,11-, 10,12- and 11,13-18:2 by reaction of a commercial CLA mixture with *p*-toluenesulfinic acid (6) or I_2 (7). The mixture of isomers was then evaluated by GC and Ag^+–HPLC under optimal chromatographic conditions. High resolution GC–EIMS was used to deal with the problem of extraneous peaks in GC–FID chromatograms.

MATERIALS AND METHODS

A commercial CLA mixture containing four major positional CLA isomers as their methyl esters was purchased from Nu-Chek-Prep Inc. (Elysian, MN). The methyl esters of 9*cis*,11*trans*-18:2 (98%), 10*trans*,12*cis*-18:2 (98%) and technical grade 9*cis*,11*trans*-18:2 (75–78%) were obtained from

Matreya Inc. (Pleasant Gap, PA). *p*-Toluenesulfinic acid, I_2, and 2-amino-2-methyl-1-propanol (95%) were purchased from Aldrich Chemical Company Inc. (Milwaukee, WI). Hexane and acetonitrile were UV grade.

The 10*trans*,12*cis*-18:2 FAME was reacted with *p*-toluenesulfinic acid as previously described (6). Each of the commercial mixtures of CLA isomers and 9*cis*,11*trans*-18:2 was isomerized in the presence of I_2 as catalyst (7). Briefly, the CLA isomers were dissolved in hexane, a crystal of I_2 was added, and the mixture was allowed to stand in sunlight for 5 h. The reaction products were washed with 0.1 M sodium thiosulfate solution and the hexane solution was washed with water, dried with sodium sulfate, followed by removal of hexane using a rotary evaporator.

Ag^+–HPLC analyses were performed using a Waters 510 solvent delivery system (Waters Associates, Milford, MA), a Waters 717 plus Autosampler with a 200 µL injection loop, a Waters 486 tunable absorbance UV detector set at 234 nm, and a Waters software program (Millennium™ version 2.15.01). ChromSpher 5 Lipids analytical (4.6 mm i.d. × 250 mm stainless steel; 5 µm particle size) silver-impregnated columns were used (Chrompack, Bridgewater, NJ). The solvent flow was set at 1.0 mL/min. The best resolutions were obtained with isocratic operation and a mobile phase of 0.1% acetonitrile in hexane. The mobile phase mixture was prepared fresh each day, stirred vigorously before use, and stirred continuously with a magnetic stirrer. The flow was started for 0.5 h prior to sample injection. Typical injection volumes were 5–15 µL.

The GC (model 5890; Hewlett-Packard, Palo Alto, CA) was equipped with a flame-ionization detector (FID) and an automatic injection system (model 1090, Hewlett-Packard). Analyses were performed using a fused-silica capillary column (CP-Sil 88; 100 m × 0.25 mm i.d. × 0.2 µm film thickness; Chrompack Inc., Raritan, NJ). The column was held at 70°C for 4 min after injection, the temperature was programmed at 13°C/min to 175°C, held at 175°C for 27 min, then temperature programmed at 4°C/min to 215°C, and held at 215°C for 31 min. Hydrogen was used as the carrier gas, at a split ratio of 20:1. The detector and injector were set at 250°C.

A high-resolution mass spectrometer (Autospec Q, Micromass, Wythenshawe, England) coupled through a line-of-sight interface to a GC (model 5890 series II GC, Hewlett-Packard) provided GC–MS data. The static resolution of the instrument was adjusted to 10,000 at the *m/z* 293 ion of perfluorokerosene. Data acquisition recorded the selected ion profiles of *m/z* 292.2402, 294.2559, 296.2715 for 200 ms per scan using *m/z* 292.9824 of perfluorokerosene as the lock mass. Total scan time was 0.8 s/scan. Data were acquired from 35 to 60 min during the GC–MS analysis.

The hydrogen carrier gas at a head pressure of 25 psi resulted in a measured linear velocity of 35 cm/s through a 100 m × 0.2 mm i.d. 0.2 µ phase cyanopropyl polysiloxane capillary column (CP-Sil 88, Chrompack) with the septum purge set at 3 mL/min and the split flow at 100 mL/min. Injector and transfer line temperatures were 220°C, while the ion source temperature was 250°C. The GC oven was initially held at 75°C for 2 min after splitless injection. This was followed by temperature programming to 180°C at 5°/min, held at 180° for 30 min and then increased to 220°C at 5°/min, and held at 220°C for 20 min.

RESULTS AND DISCUSSION

Isomerization of CLA. Both *p*-toluenesulfinic acid and I_2-catalyzed isomerization of CLA led to the formation of extensive *trans,trans* and all possible *cis,trans* and *trans,cis* 8,10-, 9,11-, 10,12-, and 11,13-18:2 isomers; the ratio of the two geometric *cis/trans* isomers formed was 1:1 (Table 1). The *p*-toluenesulfinic acid-catalyzed isomerization conditions (dioxane, 105°C) resulted in less than 0.5% double-bond migration (6). The I_2-catalyzed isomerization reaction was generally complete after 2 h (Fig. 1). Thereafter, the isomer distribution remained unchanged. Isomerization led to a marked increase in the *trans,trans* content at the expense of both the *cis/trans* and *cis,cis* CLA isomers. For example, the composition of the original 75–78% technical grade 9*cis*,11*trans*-18:2 from Matreya Inc. was 79.2% *cis/trans*, 15.1% *cis,cis,* and 5.7% *trans,trans*. After isomerization, the composition of the product mixture was 13.4% *cis,trans*, 13.4% *trans,cis*, 2.4% *cis,cis*, and 70.8% *trans,trans*. Similar changes in CLA isomer distribution were observed with the other CLA mixtures investigated.

Ag^+–HPLC separation of the isomerized CLA mixture. Ag^+–HPLC, using three columns in series, separated the 11,13-, 9,11-, and 8,10-18:2, but not the 10,12-18:2 geometric isomers (Fig. 2B) in contrast to the original CLA mixture known to contain only four *cis/trans* CLA isomers (1–5) shown in Figure 2A. Using up to six Ag^+–HPLC columns in series gave essentially the same elution sequence as that observed using three Ag^+–HPLC columns, except with improved resolution; the 10,12-18:2 geometric isomers still remained unresolved (data not shown). The separation of the 9,11-18:2 geometric isomers and the lack of separation of the 10,12-18:2 geometric isomers were further demonstrated by

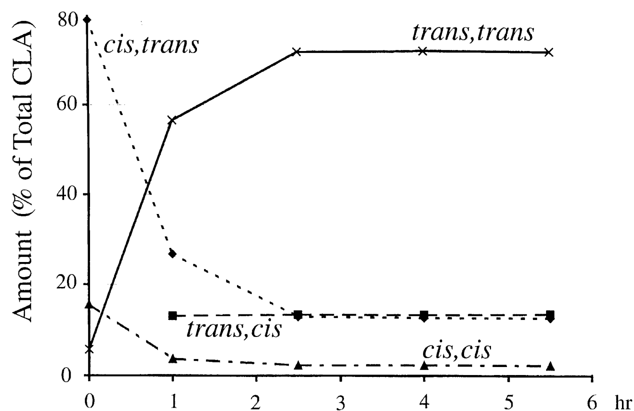

FIG. 1. Variation in the relative concentrations of the 9,11-18:2 geometric isomers during I_2-catalyzed isomerization. Equilibrium was reached in less than 3 h.

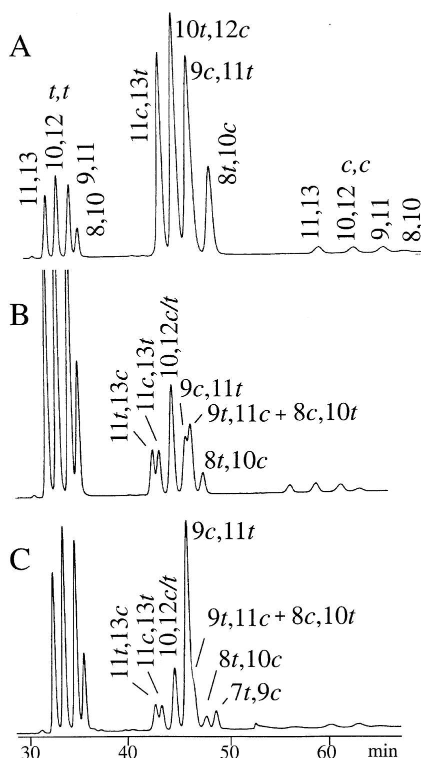

FIG. 2. Silver ion–high performance liquid chromatographic (Ag$^+$–HPLC) separation of a commercial conjugated linoleic acid (CLA) fatty acid methyl ester (FAME) mixture (A) before, and (B) after isomerization using three Ag$^+$–HPLC columns. (C) The same isomerized commercial CLA FAME mixture spiked with the total FAME mixture from a cheese test sample.

isomerization followed by Ag$^+$–HPLC analysis of the individual commercially available CLA isomers (data not shown). Individual 8,10- and 11,13-18:2 could not be tested separately, because these CLA isomers were not commercially available. The separation of the 8,10-18:2 geometric isomers was demonstrated by quantitative consideration of the Ag$^+$–HPLC chromatogram (Table 1). Isomerization resulted in an equal abundance of geometric *cis/trans* CLA isomers from any given pair of positional CLA isomers; the sum of both geometric *cis/trans* isomers compared well with the relative composition present in the original CLA mixture. The exception was 8,10-18:2. One of the 8,10-18:2 *cis/trans* isomers was well resolved and present at only half the relative concentration in the original mixture, whereas the 9*trans*,11*cis*-18:2 peak was greater by the amount of half the 8,10-18:2 isomer concentration (Table 1). This clearly suggested that one of the 8,10-18:2 *cis/trans* isomers coeluted with 9*trans*,11*cis*-18:2.

The elution order of the geometric *cis/trans* CLA pairs was established by comparison of the isomerized mixture (Fig. 2B) with the original CLA mixture (Fig. 2A) and by co-injection of the isomerized commercial CLA mixture with cheese lipids (Fig. 2C). The 9*cis*,11*trans*-18:2 isomer, known to be the major CLA isomer in cheese (3,4,9), eluted before the opposite 9*trans*,11*cis*-18:2 isomer (Fig. 2C). The two geometric *cis/trans* isomers of 11,13-18:2 also separated as two peaks,

TABLE 1
Relative Concentration of *cis/trans* CLA Isomers in the Commercial CLA Preparation and Its Isomerized Products

CLA isomer	Isomerized CLA	Commercial CLA
11*trans*,13*cis*	0.121	
11*cis*,13*trans*	0.122	
Total 11,13	0.244	0.238
Total 10,12	0.320	0.322
9*cis*,11*trans*	0.159	
9*trans*,11*cis*	0.213[a]	
Total 9,11	0.372	0.312
8*trans*,10*cis*	0.064	0.128

[a]The contribution of the 9*trans*,11*cis* is 0.149 if the assumed contribution for 8*cis*,10*trans*-18:2 of 0.064 (as indicated by the relative concentration of 8*trans*,10*cis*-18:2) is subtracted from the found relative concentration (0.213 – 0.064 = 0.149). CLA, conjugated linoleic acid.

but the elution order was reversed compared to that of the 9,11-18:2 pair. The second 11,13-18:2 peak corresponded to 11*cis*,13*trans*-18:2 shown previously to be present in commercial CLA preparations (1–5; see also Fig. 2), while the first eluting 11,13-18:2 peak, 11*trans*,13*cis*-18:2, was generally more abundant in natural dairy products (4). The identity of the resolved 8,10-18:2 isomer was 8*trans*,10*cis*-18:2 based on comparison to the commercial CLA mixture which is known to contain this geometric isomer (1–5). The other 8,10 geometric *cis/trans* isomer, 8*cis*,10*trans*-18:2, coeluted with 9*trans*,11*cis*-18:2 (Table 1). Therefore, the elution order of the 8,10- and 9,11-18:2 geometric *cis/trans* isomers (*cis,trans* before *trans,cis*) was observed to be opposite to the elution order of the 11,13-18:2 geometric *cis/trans* isomers (*trans,cis* before *cis,trans*). The reason for the difference in elution order of the geometric *cis/trans* CLA isomers, or the nonresolution of the 10,12-18:2 isomer under identical conditions is not known. There may be a structural difference, which is reminiscent of the alternating physical properties, such as melting point, of monounsaturated fatty acids (10).

In a recent report, an opposite elution order for the 9,11-18:2 *cis/trans* isomers was shown using two Ag$^+$–HPLC columns and a mobile phase of 0.5% acetonitrile in hexane (8). These two separations differed essentially in the concentration of acetonitrile. Furthermore, a claim was made in that report (8) that the resolution of CLA isomers could be improved by increasing the acetonitrile in hexane. Both concerns were investigated further.

Increasing the content of acetonitrile to 0.2, 0.3, and 0.4% reduced the retention time (volume) for the *cis/trans* CLA isomers from 40 min to 23, 19, and 16 min, respectively, using three Ag$^+$–HPLC columns in series. The peaks became sharper but their resolution was degraded. At 0.2% acetonitrile, the *cis/trans* 11,13-18:2 isomers did not resolve any longer, and at 0.3% acetonitrile, the *cis/trans* 9,11-18:2 isomer pair appeared as one broad peak (data not shown). Reducing the acetonitrile content to 0.05% improved the separation of the 11,13-18:2 pair but not that of the 9,11-18:2 pair, with a concomitant doubling of the elution time. There was no indication of a reversal of the elution sequence of the 9,11-18:2 *cis/trans* isomers with changes in the content of acetoni-

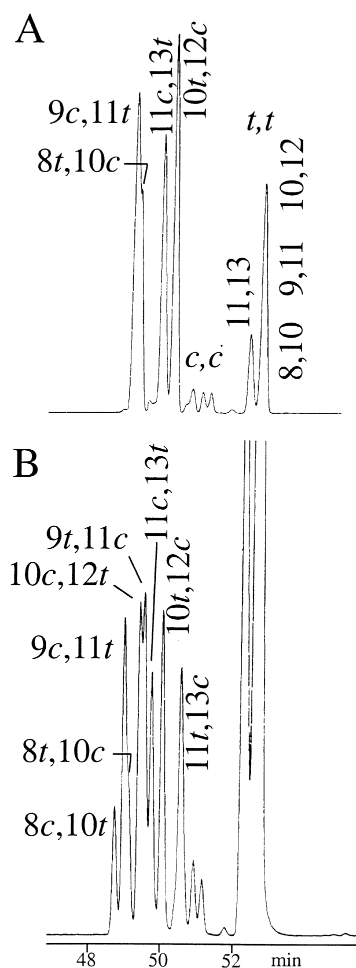

FIG. 3. Partial gas chromatographic profile of the CLA region of a commercial CLA FAME mixture (A) before and (B) after isomerization. For abbreviations see Figure 2.

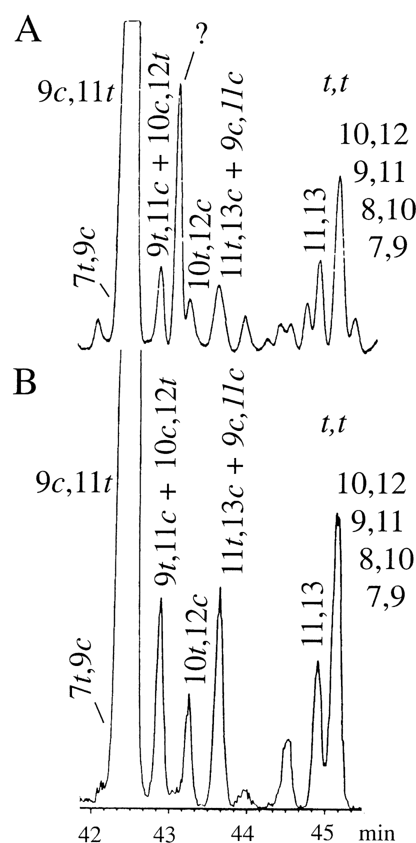

FIG. 4. Partial gas chromatographic profile of the CLA FAME region for a cheese test sample (A) obtained using flame-ionization detection, and (B) analyzed by high-resolution selected ion recording of the molecular ion of CLA FAME at *m/z* 294.2559. For abbreviations see Figure 2.

trile in the mobile phase, and as indicated previously (1–5), the 0.1% acetonitrile in the hexane solvent system was found to give the best resolution of CLA isomers.

GC separation of the isomerized CLA mixture. A comparison of the original and isomerized CLA mixture separated by GC using a 100-m CP-Sil 88 fused-silica capillary column is shown in Figures 3A and 3B, respectively. The individual CLA isomeric peaks are labeled in Figure 3. As is evident, the total *trans,trans* content was high in the isomerized mixture, and the peak attributed to 11,13-18:2 separated from that of the remaining three coeluting *trans,trans* CLA isomers (8,10-18:2, 9,11-18:2, and 10,12-18:2).

The individual CLA isomers were identified by coinjection with known CLA isomers. Coinjection of the isomerized mixture with cheese lipids identified 9*cis*,11*trans*-18:2. Isomerized 9,11-18:2 and 10,12-18:2 were coinjected separately with the total isomerized CLA mixture to confirm their identities. The identities of all the CLA positional isomers were also confirmed by GC–EIMS after derivatization to 4,4-dimethyloxazolines (DMOX). Characteristic mass spectral patterns were previously published for CLA DMOX isomers (1,3,4). The first-eluting CLA isomer was established as 8,10-18:2, while 11*trans*,13*cis*-18:2 coeluted with the minor *cis,cis* CLA isomers in the mixture (see Fig. 3B). For all geometric pairs, the *cis,trans* eluted before the *trans,cis* CLA isomer. These results confirm previous reports (8) and the prediction of the GC elution order of CLA isomers (4).

Inspection of Figure 3B indicates that the relative amounts of the *cis/trans* geometric isomers in the isomerized commercial CLA mixture separated by GC were fairly similar. By contrast, the corresponding distributions found for natural products were vastly different, as shown for cheese in Figure 4A. The large abundance of 9*cis*,11*trans*-18:2 in natural products obscured the possible presence of adjacent minor CLA isomers, such as 8*trans*,10*cis*-18:2 and 7*trans*,9*cis*-18:2 (3). Furthermore, the higher Δ CLA *cis/trans* isomers would elute in the retention time window of the minor *cis,cis* CLA isomers, as observed for 11*trans*,13*cis*-18:2 (Figs. 3 and 4). In cases where CLA isomers were obscured by the large abundance of another CLA isomer, GC–EIMS of the DMOX derivatives with reconstructed ion chromatograms was used to identify and confirm coeluting CLA isomers (3,4).

The occurrence of non-CLA FAME in the CLA methyl

ester region of the GC is a concern in the identification of CLA isomers. Generally, this region of the gas chromatogram is relatively free of other FAME, except for 21:0 (2) and an unknown peak eluting just after 9*trans*,11*trans*-18:2 (Adlof, R.O., unpublished results). We recently observed, however, a peak by FID in the GC chromatogram of cheese lipids, which we tentatively identified as 11*trans*,13*cis*-18:2 (4). We were unable to relate this large FID response to any peak in the Ag^+–HPLC chromatogram, and therefore placed a question mark next to that GC–FID peak (Fig. 4A) (4). We have subsequently developed a high resolution mass spectrometric method to distinguish between CLA and non-CLA signals in the CLA methyl ester region.

High-resolution MS. High-resolution selected-ion recording (SIR) is a useful tool to verify GC peak assignments based on nonselective FID data. The high-resolution SIR mode of GC–MS analysis increases the sensitivity of the instrument for the monitored ions more than 80-fold vs. the signals recorded for the same ions at low resolution with mass scans of 368 to 66 Da at 1 s/decade. This technique is suitable for the analysis of the same test portions examined by GC–FID. A high-resolution SIR of the FAME mixture from the same cheese test sample shown in Figure 4A is presented in Figure 4B. The molecular ion of CLA FAME at *m/z* 294.2559 was used. Comparison of Figures 4A and 4B indicates that the peak identified in the FID data with a question mark was not a CLA methyl ester. The other CLA isomers in the GC–FID trace of cheese FAME were found to have been correctly identified (4).

For the purpose of this GC–MS check on FID detection, the high-resolution SIR data record is intentionally limited to molecular ion information to maximize sensitivity. Thus, the potential for misinterpretation of the SIR data does exist. The molecular ions of 18:0, 18:1, 18:2, 18:3, and 18:4 congeners contribute, to a limited extent, to each other's signals with isotope cluster contributions and losses of H_2. The contributions of 18:1 and 18:3 to any 18:2 signal are recognized by comparing the absolute abundances of the *m/z* 292, 294, and 296 signals. A more interesting *m/z* 294 response is provided by artifacts of methylation with acid catalyst (11). The artifacts elute just beyond the CLA methyl ester region and fragment in several ways, including expulsion of the elements of methanol, to form *m/z* 294.

ABSTRACT: Linoleic acid was efficiently converted into the two major components of conjugated linoleic acid, 9*Z*,11*E*-octadecadienoic (**1a**) and 10*E*,12*Z*-octadecadienoic acid (**1b**) using either the superbase (*n*-butyllithium/potassium *tert*-butoxide) or by simply refluxing with KOH in 1-butanol. In turn, **1a** and **1b** were separated from each other using the lipase from *Aspergillus niger via* stereoselective esterification in 1-butanol. This enzyme has a preference for the 9*Z*,11*E* isomer, **1a**, and has excellent selectivity. This method has allowed the ready preparation of gram quantities of **1a** and **1b** in their highly purified forms, which are not readily accessible by current methods.

Paper no. L8215 in *Lipids 34,* 879–884 (August 1999).

Conjugated linoleic acid (CLA) is a general term used to describe a mixture of octadecadienoic acids (18:2) that possess a conjugated double-bond system. In 1987 Pariza and coworkers (1) at the University of Wisconsin isolated an anticarcinogenic principle from extracts of grilled ground beef and established that it consisted of a series of conjugated dienoic isomers of linoleic acid. Since that time, the mixture has been referred to as CLA. In the last decade, interest in CLA has risen with reports that dietary CLA reduced atherosclerosis (2), carcinogenesis (3–5), and body fat (6) in laboratory animals. However, commercial synthetically derived CLA samples, prepared *via* alkali isomerization of linoleic acid (7), are a complex mixture of CLA isomers, some of which still remain to be identified. Consequently, at the present time, there is no definitive evidence as to which isomers are the biologically active components and whether different isomers are responsible for different bioactivities.

Using silver ion-impregnated high-performance liquid chromatography (HPLC), Sehat *et al.* (8) reported a clear separation of CLA isomers into three groups related to their *E,E*; *Z,E* or *E,Z*; and *Z,Z* configurations of the conjugated double-bond system. Application of this method to the analysis of a commercial CLA mixture revealed the presence of 12 isomers. The four major positional isomers—11,13; 10,12; 9,11; and 8,10—with *Z,E* and/or *E,Z* double-bond configurations accounted for 92.5% of the mixture. To establish which isomers are associated with which types of biological activities, it is necessary to prepare the CLA isomers in their pure forms for in-depth biological studies. In a preliminary communication (9), we recently disclosed a chemoenzymatic method for the synthesis of two of the major components, 9*Z*,11*E*, **1a**, and 10*E*,12*Z*, **1b**, of CLA (10). We now report the experimental details which allowed the successful preparation of these two major CLA components, free of geometric isomers.

MATERIALS AND METHODS

Linoleic acid (99%) and an isomeric mixture of CLA were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). *Candida rugosa* (MY) and *Alkaligenes* sp. (PL) lipases were products of Meito Sangyo Ltd. (Nagoya, Japan). Novozym 435 (*C. antarctica*) was obtained from Novo Nordisk (Danbury, CT). The following lipases were purchased from the Amano Co. (Troy, VA): *Aspergillus niger* (APF-12); *Candida* sp. (AY); *Geotrichum candidum* (GC4). Hexane and acetonitrile (HPLC grade) were products from Aldrich Chemical Co. (Milwaukee, WI). All other chemicals were of reagent grade. General experimental techniques and analytical measurements were applied as previously described (11).

HPLC. HPLC analysis was performed with a Hitachi L-6200 solvent delivery system (Tokyo, Japan), a Hitachi L-3000 photo array detector (233 nm) and a Hewlett-Packard integrator (Palo Alto, CA). An analytical silver-impregnated column (4.6 mm i.d. × 250 mm stainless steel; 5 µm particle size) was used (Chrompack, Bridgewater, NJ). The solvent flow rate was 1 mL/min. The mobile phase was 0.1% acetonitrile in hexane and prepared fresh daily. The flow was commenced for 0.5 h prior to sample injection. Typical injection volumes were 5–15 µL.

*Preparation of 9*Z*,11*E *and 10*E*,12*Z *CLA isomeric mixture using Schlosser base.* To a −78°C solution of *n*-butyllithium (14.2 mL of a 2.5M solution in hexane, 35.5 mmol) in tetrahydrofuran (THF) (150 mL) was added potassium *tert*-butoxide (35.4 mL of a 1 M solution in THF, 35.4 mmol). After 5 min, a solution of linoleic acid (3.1 g, 11.1 mmol) in THF (10 mL + 10 mL) was added. The resulting solution was stirred at

–78°C for another 30 min and poured into 150 mL of 6 N HCl at 0°C. The aqueous layer was extracted with ether (150 mL × 3), and the combined organic layers were washed with a saturated sodium chloride solution, dried over magnesium sulfate, filtered, and concentrated under reduced pressure.

The crude extracts were dissolved in anhydrous diethyl ether (45 mL) and methanol (5 mL). To this solution was added diazomethane (ether solution) until the solution turned yellow, and the mixture was stirred at 24°C for 30 min to yield the methyl esters. Excess diazomethane was evaporated with a stream of nitrogen. The reaction mixture was concentrated under reduced pressure and then purified by $AgNO_3$-silica gel chromatography using hexane/ethyl acetate (60:1) as eluent to afford a mixture of 9*Z*,11*E* and 10*E*,12*Z* CLA methyl esters, **2a** and **2b** (2.5g, 77%). Analysis of this mixture using silver ion-impregnated HPLC showed the presence of only two peaks in a ratio of 1:1.5, corresponding to the retention times of **2a** and **2b** (Fig. 1), respectively (Scheme 1).

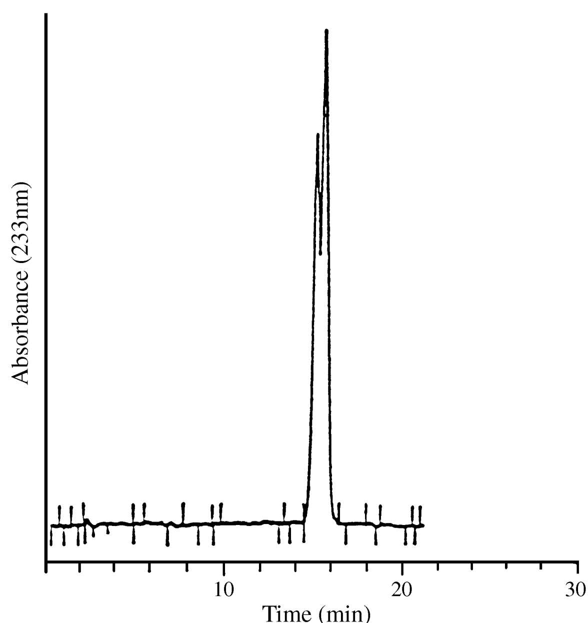

FIG. 1. Silver-ion high-performance liquid chromatography (HPLC) profile of a conjugated linoleic acid (CLA) mixture obtained from *n*-BuLi/*t*-BuOK isomerization. The conditions are described under the Materials and Methods section.

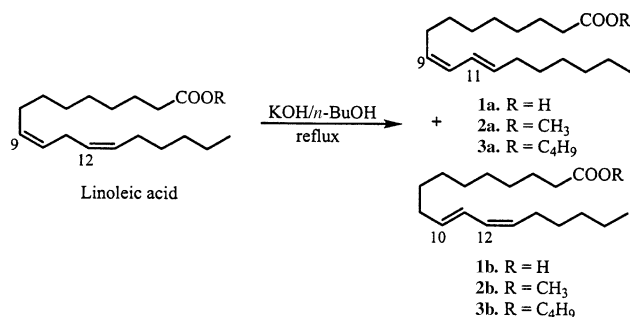

SCHEME 1

Base-catalyzed isomerization of linoleic acid. To a solution of linoleic acid (30 g, 0.107 mol) in 1-butanol (100 mL) was added KOH (30 g, 0.47 mol). The mixture was refluxed for 12 h and then was poured into water. The solution was acidified to pH 1.0 with HCl and extracted with hexane. The combined organic extract was washed with brine, dried over $MgSO_4$, and concentrated to dryness under reduced pressure to yield an isomeric mixture of CLA (29 g, 97%). The silver ion-impregnated HPLC profile is shown in Figure 2.

*Representative procedure for lipase-catalyzed selective hydrolysis of **2a** and **2b**.* To a solution of *A. niger* (APF-12) lipase (5 mg) in 2 mL of 0.1 M phosphate buffer, pH 7.0, was added 22 mg of **2a** and **2b** in 0.24 mL of acetone, and the mixture was stirred at 24°C for 3 h. After acidification of the mixture with 10% HCl, the aqueous layer was extracted with ether (10 mL × 3). The combined organic extracts were washed with a saturated sodium chloride solution and dried over magnesium sulfate. After evaporation of the solvent under reduced pressure, the residue was chromatographed over a silica gel column. The column was eluted first with ethyl acetate/hexane (30:1) followed by methanol/methylene chloride (5:95) to yield **2a** and **2b** in a ratio of 18:82 and **1a** and **1b** in a ratio of 87:13, respectively (46% conversion).

*Representative procedure for lipase-catalyzed selective esterification of **1a** and **1b**.* To a solution of **1a** and **1b** (19 mg) in 0.2 mL of 0.1 M phosphate buffer, pH 7.0, was added 0.2 mL of l-butanol and 1 mg of *A. niger* (APF-12) lipase. After stirring at 24°C for 2.5 h, the mixture was acidified with 10% HCl (1 mL) and extracted with ether (3 mL × 3). The combined organic extracts were washed with a saturated solution of sodium chloride, dried over $MgSO_4$, filtered, and concentrated to dryness under reduced pressure. The crude products were dissolved in 5 mL of diethyl ether and 1 mL of methanol. To this solution was added an ethereal solution of diazomethane until the solution turned yellow, and the mixture was left standing for 30 min. Excess diazomethane was evaporated with a stream

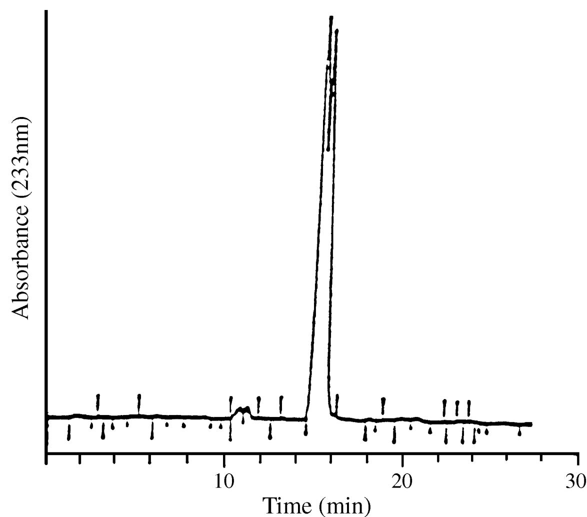

FIG. 2. Silver-ion HPLC profile of a CLA mixture derived from KOH isomerization. Conditions and abbreviations are the same as for Figure 1.

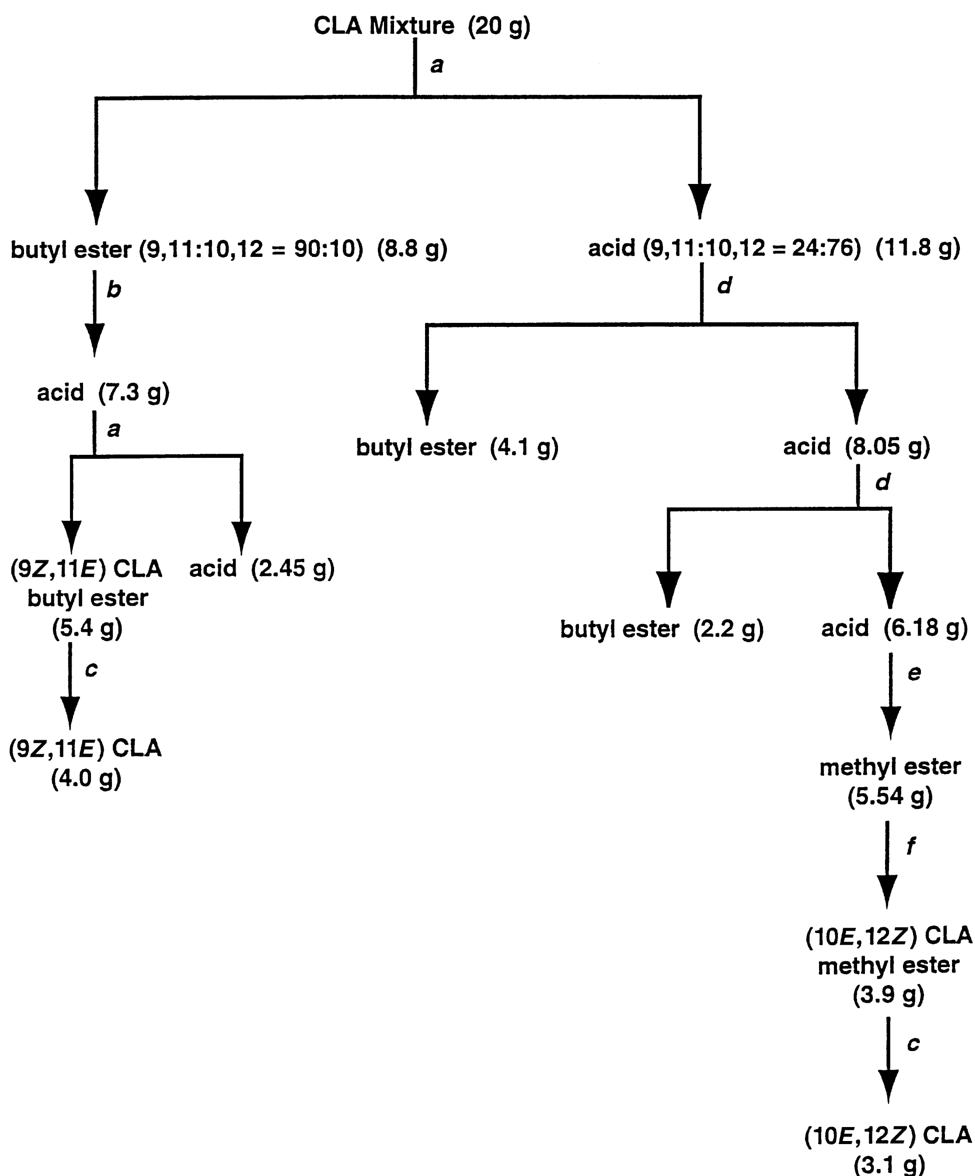
of nitrogen, and the reaction mixture was concentrated to dryness under reduced pressure. Silver ion-impregnated HPLC of this mixture showed the presence of 9*Z*,11*E* and 10*E*,12*Z* butyl esters, **3a** and **3b**, in a ratio of 95:5 and **2a** and **2b** in a ratio of 31:69, respectively (29% conversion).

General procedure for the separation of butyl esters from free acids. To a mixture (5 g) of butyl esters, **3a** and **3b**, and free acids, **1a** and **1b**, in 100 mL of hexane was added 100 mL of 1 M NaOH. After mixing, a mixture of 100 mL of ether, 100 mL of methanol, and 5 mL of *tert*-butanol was added to this solution, the mixture was shaken well, and the upper layer was decanted. To the lower layer was added 50 mL of hexane and 50 mL of methanol, and the mixture was shaken and the layers were separated again. The two upper layers were combined and washed successively with 50 mL of 1 M NaOH, 50 mL of methanol, water, and brine. After drying the solvent with $MgSO_4$, the solvent was removed under reduced pressure to give the butyl esters, **3a** and **3b**. The combined lower layers were acidified with HCl and extracted with ether. The extract was washed with brine, dried over $MgSO_4$, and concentrated to yield the free acids, **1a** and **1b**.

*Enzymatic separation of **1a** and **1b**.* To a mixture of 20 g of **1a** and **1b** in 200 mL of 1-butanol and 80 mL of water was added 4 g of *A. niger* (APF-12) lipase. The mixture was shaken on a rotary shaker (120 rpm) at 24°C for 10 h and then extracted with hexane three times. The combined organic extract was washed with brine, dried over $MgSO_4$, and concentrated to dryness under reduced pressure. The residue was subjected to the above procedure to yield 8.8 g of butyl ester (**3a** and **3b**)



SCHEME 2

and 11.8 g of free acids (**1a** and **1b**) (step *a*; Scheme 2). The butyl ester was dissolved in methanol; KOH (3.5 g) was added to the solution. After stirring at 24°C for 24 h, the reaction mixture was poured into water, acidified to pH 1.0, and extracted with ether. The ethereal extract was washed with brine and evaporated to dryness under reduced pressure to give 7.3 g of **1a** and **1b** (step *b*) which was again incubated with 1.5 g of the APF-12 lipase in 75 mL of 1-butanol and 30 mL of water. After incubation on a rotary shaker for 10 h, the butyl ester and free acid were separated to 5.4 g of **3a** and **3b** and 2.45 g of **1a** and **1b** (step *a*). This free acid fraction was reincubated with the lipase, and the resulting butyl ester was again hydrolyzed with KOH. Two crystallizations of the crude **1a** from methanol afforded 4 g of pure **1a** (step *c*).

To the acid fraction from the first enzymatic incubation, dissolved in 120 mL of 1-butanol and 48 mL of water, was added 2.4 g of the APF-12 lipase. The reaction mixture was incubated at 24°C in a rotary shaker for 18 h, and then was separated to give 8.05 g of acid and 4.1 g of butyl ester (step *d*). The acid (8.05 g) was subjected to APF-12 lipase esterification again to yield 6.18 g of the acid (**1a** and **1b**) (step *d*), which was dissolved in 100 mL of methanol and incubated with 1 g of Novozym 435 for 48 h to afford 5.54 g of a mixture of the methyl esters **2a** and **2b** (step *e*). The methyl esters were crystallized with urea (16.6 g) in methanol (110 mL) (step *f*). The mother liquor fraction was acidified with 200 mL of 2 M HCl and then extracted with hexane three times. The combined organic extract was washed with brine, dried, and concentrated to give 3.9 g of the 10*E*,12*Z* methyl ester, **2b**, which was hydrolyzed with KOH in methanol to afford crude **1b** (step *c*). Recrystallization of **1b** from methanol (65 mL) afforded 3.1 g of pure 10*E*,12*Z* acid, **1b** (Scheme 2).

RESULTS AND DISCUSSION

Since diallylic protons generally have pK values around 30 (12), it occurred to us that the superbasic mixture of *n*-butyllithium and potassium *tert*-butoxide (Schlosser base) would be a suitable reagent for the metalation of linoleic acid (13). In fact this organometallic reagent has been successfully used for the deprotonation of 1,4-pentadienyl systems with excellent selectivity (14). When linoleic acid was reacted with this superbase at −78°C in THF, only two major products were formed (Scheme 1), which accounted for more than 99% of the material recovered. After treatment of the reaction mixture with diazomethane, the resulting methyl esters were analyzed using silver ion-impregnated HPLC (8), which revealed the presence of only two peaks in a ratio of 4:6, corresponding to the retention times of methyl 10*E*,12*Z*- and 9*Z*,11*E*-octadecadienoates (**2a** and **2b**), respectively (Fig. 1).

For larger-scale preparations, we found it more convenient to use an alternative procedure by simply refluxing linoleic acid with NaOH in 1-butanol for 12 h. After treatment of the reaction mixture with diazomethane, the resulting methyl esters were again analyzed by silver ion-impregnated HPLC. The profile in Figure 2 shows the presence of two major peaks corresponding to the retention times of the 9*Z*,11*E* and 10*E*,12*Z* CLA isomers but in a ratio of 1:1, accompanied by about 2.5% of *trans* isomers (9*E*,11*E* and 10*E*,12*E*) and a trace (<1%) of the *cis* isomers (9*Z*,11*Z* and 10*Z*,12*Z*).

To our knowledge no current analytical techniques are available to separate the 9*Z*,11*E* and 9*E*,11*Z* isomers. Consequently, it was necessary to establish more definitely the position and geometric configurations of double bonds in the synthetic CLA preparation. This was carried out following a published procedure (15): (i) the double bonds of the CLA isomers were partially reduced with hydrazine; (ii) the resulting *E* monoene fraction, isolated by silver-impregnated silica gel column chromatography, was subjected to oxidative ozonolysis followed by methylation (16); and (iii) the diesters were isolated by silica gel column chromatography and their structures were verified by mass spectral analyses. When this procedure was applied to the synthetic CLA isomers, only dimethyl-1,10-decanedioate and 1,11-undecanedioate were obtained (17). These results showed the absence of geometric isomers and demonstrated the remarkable selectivity of the deprotonation–protonation procedure. This supposition was further confirmed by the ^{13}C nuclear magnetic resonance (NMR) spectra of pure **1a** and **1b**, which exhibited signals free of geometric isomers.

Because the regioisomers of CLA are difficult to separate from each other using chromatographic methods, we resorted to the use of enzymatic methods for the separation of the 9*Z*,11*E* from the 10*E*,12*Z* isomer. It is well documented that the lipase from *G. candidum* has a proclivity for unsaturated fatty acids possessing a 9*Z* double bond (18). That is, esters of 9*Z* unsaturated fatty acids are attacked more rapidly than other types of unsaturated fatty acid esters (19). However, when the synthetic CLA methyl esters **2a** and **2b** (1:1) were incubated with this lipase at pH 7.0 in 0.1 M phosphate buffer, the 9*Z*,11*E* isomer, **2a**, was preferentially hydrolyzed with a selectivity factor (*S*) (20) of only about 9. For systems containing two competing regioisomers, the selectivity factor $S = \ln[(1 - c)(1 - \mathrm{SE})]/\ln[(1 - c)(1 + \mathrm{SE})]$, where *c* denotes the extent of conversion and SE is the excess of one remaining substrate divided by the total remaining substrate at conversion *c*. See References. A 1:1 mixture of regioisomers (**1a** and **1b** or **2a** and **2b**) was used for the determination of *S*. Since the selectivity may often be improved by conducting the reverse reaction in organic solvents (21), we incubated the synthetic CLA isomers with the same lipase in 1-butanol for esterification. Indeed, the enzyme preferentially esterified the 9*Z*,11*E* isomer, **1a**, but the selectivity (factor *S*) was enhanced to only 12. This moderate improvement encouraged us to examine other lipase preparations for improved selectivities.

The results in Table 1 clearly show that the only enzyme that was more selective than the *G. candidum* lipase was the *A. niger* lipase (APF 12, Amano), which has the same stereochemical preference but the selectivity factor was enhanced to 25. In contrast, most of the other lipases exhibited low selectivities with *S* in the range of 1–3. In contrast to all the other lipases examined, immobilized lipase from *C. antarc-*

[e]1 g CLA, 50 mg lipase in 10 mL of 1-butanol, 24°C; 10,12-CLA was preferentially esterified.

tica exhibited an opposite stereochemical preference in that it preferentially attacked the 10*E*,12*Z* CLA isomer, but the selectivity factor was low (*S* = 3.3).

To test the applicability of this methodology for the preparation of pure CLA isomers, we exposed 20 g of a 1:1 mixture of 9*Z*,11*E* and 10*E*,12*Z* isomers to the *A. niger* lipase in *n*-butanol for selective esterification. After 10 h of incubation, the ester fraction consisted of a mixture of 9*Z*,11*E* and 10*E*,12*Z* butyl esters in a ratio of 9:1 as determined by silver ion-impregnated HPLC and ^{13}C NMR. The remaining acid fraction consisted of 9*Z*,11*E* and 10*E*,12*Z* acids in a ratio of 24:76. To obtain the pure 9*Z*,11*E* isomer, the butyl ester fraction was hydrolyzed with methanolic KOH back to the free acid, which was subjected again to esterification to provide 5.4 g of the butyl ester, which upon base hydrolysis and crystallization from methanol afforded 4 g of pure 9*Z*,11*E* CLA, **1a**: ^{1}H NMR ($CDCl_3$, 300 MHz) δ 0.88 (3H, *t*, *J* = 6.1 Hz), 1.20–1.50 (16H, *m*), 1.63 (2H, *m*), 2.12 (4H, *m*), 2.34 (2H, *t*, *J* = 7.6 Hz), 5.28 (1H, *m*), 5.65 (1H, *m*), 5.94 (1H, *t*, *J* = 10.8 Hz), 6.29 (1H, *dd*, *J* = 15 Hz, 11 Hz); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 180.5 (C1), 134.8 (C12), 129.8 (C9), 128.7 (C10), 125.6 (C11), 34.1 (C2), 32.9 (C13), 31.8 (C16), 29.7, 29.4, 29.1, 29.0, 28.9 (C4, C5, C6, C7, C14, C15), 27.6 (C8), 24.6 (C3), 22.6 (C17), 14.1 (C18). The remaining acidic fraction consisted of a mixture of **1a** and **1b** and could be recycled to obtain additional quantities of pure **2a**.

To secure the pure 10*E*,12*Z* CLA, **1b**, it was necessary to remove **1a** completely. This was achieved by subjecting the initial acid fraction to two cycles of enzymatic esterification in 1-butanol. The remaining acid fraction (6.18 g) was then subjected to selective esterification using the lipase of *C. antarctica*, which preferentially attacks the 10*E*,12*Z* isomer, to yield the methyl ester, **2b**. HPLC analysis of the methyl ester fraction revealed that **2b** was present as the main component, contaminated with small quantities of 9*Z*,11*Z*, 10*Z*,12*Z*,9*E*,11*E*, and 10*E*,12*E* CLA methyl esters. These impurities were removed by urea fractionation (7) to yield pure **2b**, which was subjected to base hydrolysis to afford **1b**; recrystallization from methanol gave the pure 10*E*,12*Z* CLA, **1b**: ^{1}H NMR ($CDCl_3$, 300 MHz) δ 0.89 (3H, *t*, *J* = 6.3 Hz), 1.20–1.50 (16H, *m*), 1.63 (2H, *m*), 2.12 (4H, *m*), 2.34 (2H, *t*, *J* = 7.5 Hz), 5.30 (1H, *m*), 5.65 (1H, *m*), 5.94 (1H, *t*, *J* = 10.9 Hz), 6.30 (1H, *dd*, *J* = 15 Hz, 11Hz); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 180.5, 134.5, 130.1, 128.6, 125.7, 34.1, 32.9, 31.5, 29.4, 29.3(8), 29.3, 29.1(8), 29.1(5), 29.0, 27.7, 24.7, 22.6, 14.1. The results of this fractionation procedure are summarized in Scheme 2.

In conclusion, we have shown that linoleic acid was transformed into the two major components of CLA, **1a** and **1b**, by reaction with the Schlosser superbase (*n*-butyllithium/potassium *tert*-butoxide) or by simply refluxing with KOH in 1-butanol. In turn, **1a** and **1b** were separated from each other using the lipase from *A. niger via* selective esterification in 1-butanol. This enzyme has a preference for the 9*Z*,11*E* isomer, **1a**, and has excellent selectivity. This method has allowed the preparation of gram quantities of **1a** and **1b** in their highly purified forms, which are not readily accessible by current methods (22–25). The availability of these pure CLA isomers allows one to conduct in-depth experiments to determine which isomer is responsible for the reported biological activities.

ABSTRACT: The objective of this study was to determine if the positional structure of dietary triacylglycerol affected lipidemic responses. Thirty healthy adults (16 men and 14 postmenopausal women) with low-density lipoprotein cholesterol (LDL-C) concentrations >3.37 mM (130 mg/dL) enrolled in a prospective, single-blind, cross-over outpatient clinical trial that consisted of two 5-wk dietary phases. After baseline screening, subjects were instructed to follow individualized meal plans (weight maintenance diets with 36% of total energy from fat, half of which was from a test oil) and randomized to receive either butter (B) or an interesterified mixture (IM) of butter, medium-chain triacylglycerol (MCT), and safflower oils. Blood drawn during weeks 5 and 10 of feeding was analyzed for total cholesterol (TC), high density lipoprotein cholesterol (HDL-C),LDL-C, and triacylglycerols (TAG). Mean plasma levels of TC (B, 6.98 ± 1.06 mM; IM, 7.09 ± 1.20 mM), HDL-C (B,1.30 ± 0.35 mM; IM, 1.29 ± 0.34 mM), and LDL-C (B, 4.91 ± 0.95 mM; IM, 4.92 ± 1.10 mM) were not significantly different between the two dietary treatments. Mean TAG levels were higher for the interesterified B–MCT mixture (B, 1.75 ± 0.72 mM; IM, 1.96 ± 0.86 mM, $P < 0.05$). We conclude that an IM of B, MCT, and safflower oils as compared to native B has no appreciable effect on plasma cholesterol concentrations but is associated with a modest rise in plasma TAG.

Paper no. L7698 in *Lipids 34*, 889–894 (October 1999).

Traditionally, the cholesterolemic effect of dietary lipids has been thought of in terms of their degree of saturation (1,2). However, work with *trans* unsaturated fatty acids has suggested that geometric isomers of unsaturated fatty acids affect cholesterol metabolism differently from their *cis* counterparts (3). Over the years, data have been reported which demonstrate a differential effect of the cholesterolemic response from native or interesterified dietary triacylglycerols (TAG) (4–8). Interesterification or randomization is a process frequently used in the food industry to harden liquid oils. It alters the physical properties of a dietary fat by redistributing the fatty acids randomly, so that all three positions of the TAG molecule contain equal portions of the fatty acids (9). During interesterification of vegetable oils, the unsaturated fatty acids that commonly occupy the *sn*-2 position may move to the *sn* -1 or *sn*-3 positions that typically carry saturated fatty acids. In the small intestine, dietary fatty acids in the *sn*-2 position are preferentially absorbed as monoacylglycerols, whereas those esterified to the *sn*-1,3 positions are absorbed as free fatty acids (10). Thus, an interesterified fat may be metabolized differently from native fat. A recent intravenous study demonstrated slower clearance of a TAG that had stearic acid (as opposed to oleic or linoleic acid) in the number 2 position (11). Christophe *et al.* (8) reported that randomized butter (B) does not give the same hypercholesterolemic response as native B. Subjects fed 84 g/d of randomized or interesterified B oil for 20 d had an 11% reduction in mean serum cholesterol levels compared to when they were fed the same amount of native B.

In a series of experiments designed to determine the cholesterolemic effect of individual fatty acids, McGandy *et al.* (6) reported inconsistent effects of stearic acid. The authors hypothesized that the discrepancies were due to the position of the fatty acid on glycerol and that stearic acid esterified to the *sn*-2 position raised cholesterol concentrations more than when it was esterified to *sn*-1,3 positions. They also reported that mean serum cholesterol concentrations fell by 13.6 ± 5.1 mg/dL when subjects consumed a transesterified mixture of 50% medium-chain triacylglycerols (MCT)/myristic (60% MCT/40% trimyristin) and 50% safflower oil. When the amount of MCT/myristic was lowered to 20% and safflower was increased to 80%, mean serum cholesterol levels rose by 31.6 ± 7.0 mg/dL. Other studies have reported a neutral effect of MCT on blood cholesterol concentrations (12–14). Medium-chain fatty acids have been effective in treating individuals with fat malabsorption. Although most medium-chain fatty acids bypass the lymphatics and enter directly into the portal circulation where they are readily oxidized in the liver for energy, recent work in animals (15,16) has shown that medium-chain fatty acids in the *sn*-2 position can be absorbed into the lymphatics, and human studies have demonstrated they can be incorporated into chylomicron TAG (17).

If the positional arrangement of fatty acids on the glycerol molecule does indeed influence cholesterol metabolism, interesterification would conceivably be favorable if it moved cholesterol-raising fatty acids out of the *sn*-2 position and neutral fatty acids in. It would also be unfavorable, as in some vegetable oils, if the concentration of saturated fatty acids on the middle carbon increased. Palmitic acid is the most abundant saturated fatty acid in the diet. In animal fats such as pork and dairy fat, palmitic acid is largely in the *sn*-2 position, unlike plant oils such as palm oil where it is most often esterified to the first and third carbons (18). One recent study addressed the question of what effect interesterification of palm oil would have on blood lipoprotein concentrations in humans and reported little effect (19). Another study investigated whether interesterification of a high palm oil margarine would have harmful effects on plasma lipids and also demostrated no significant effect from interesterification (20).

The present study was designed to investigate whether an IM of B (60%), MCT (35%), and safflower oils (5%), when incorporated into baked goods and then fed to healthy hypercholesterolemic adults, would show a differential lipidemic response when compared to butter.

EXPERIMENTAL PROCEDURES

Subjects. Adults were recruited by advertising in local Boston newspapers. All subjects underwent a medical history evaluation and physical examination. They were eligible for the study if their plasma low-density lipoprotein cholesterol (LDL-C) was >3.37 mM and they were free of any diseases (cardiac, renal, thyroid, or hepatic) or medications (hypolipidemic drugs, beta-blockers, diuretics, estrogens, progestins, or thyroxine) capable of influencing plasma lipid levels. They were required to maintain their body weight within a 2-kg range and to avoid extremes in dietary or exercise habits throughout the study period. Two subjects smoked cigarettes (each <5 per day). The study was approved by the Institutional Review Board on Human Studies at the Deaconess Hospital. Written informed consent was obtained from all subjects at the time of enrollment.

Of the 226 people who were screened *via* a telephone interview, 106 were eligible to receive written medical history questionnaires. Of these mailed questionnaires, 53 were returned from which 49 individuals were selected for baseline clinical screening. Of these 49 people who came to the clinic, six were ineligible as their plasma LDL-C was below the cut-off point and 10 were unable or unwilling to comply with the study protocol. Three subjects were dropped during the study: one completed phase 1, but due to a change in work schedule was unable to continue into phase 2; one developed a cardiac arrhythmia during phase 2 and was started on atenolol; and one violated the weight criterion.

Study design. The study followed a single-blind, randomized, two-phase, cross-over design. Baseline plasma lipid levels were determined after a 12-h fast on the first clinic visit. After a 2–3 wk screening period to confirm eligibility, establish the test diet, teach food recording and fat gram counting techniques and to document stable weight, subjects were randomized to receive either regular B oil or an interesterified B–MCT oil mixture. Subjects were fed one of the fats for 5 wk and immediately crossed over to the alternate fat after fasting-blood samples were taken on three separate days during week 5. Plasma lipids have been reported to stabilize by week 4 of fat-modified diet consumption (21). In each treatment phase of this study, all subjects followed the test diets for 5 wk in order to allow for triplicate fasting-blood sampling during week 5. They were required to report to the clinic each week in order to monitor their health status, weight, and food records, and to pick up their supply of baked goods for the subsequent week.

Diet. The test diet was designed to simulate a typical American diet with an energy distribution of 15–49–36% of each subject's total weight maintenance energy from protein, carbohydrates, and fats, respectively, and a cholesterol concentration of 35 mg/kJ (22). Energy requirements were estimated by the Harris–Benedict equation and from energy intakes reported in the 3-d food records. In each dietary phase, the test oil was designed to provide 18% of total daily energy and was baked into muffins (18 g of fat each) and cookies (8 g of fat each). Stepan Company Inc. (Maywood, NJ) provided the test oils; their fatty acid composition and positional TAG distribution are listed in Tables 1 and 2, respectively. The muffins and cookies were made by the Dietary Department of Deaconess Hospital and frozen until ready for use.

Subjects were instructed by the research coordinator (CEM, a registered dietitian) to follow a low-fat, exchange-style meal plan (18% fat energy) supplemented with high-fat baked goods in amounts that provided 18% of the subjects' energy from the test oil. Three-day food records were completed each week. In an attempt to minimize the error and variability associated with dietary-assessment protocols, food intake was recorded on two nonconsecutive weekdays and one weekend day (23). Subjects also were taught to count and record the grams of fat in the foods they reported in their records. As there was variability in food preferences and subsequently in food choices among the subjects, it was impossible to precisely control the specific fatty acid profile of the diet. However, as each person served

[a]Percentage of triacylglycerol in *sn*-2 position determined by Grignard procedure; see Table 1 for abbreviations.

as his/her own control, the test fat was the only significantly different dietary component between each phase.

The 3-d food records from baseline and from weeks 2 and 4 of each dietary phase were analyzed for mean daily totals of energy and nutrients using Minnesota Nutrition Data System© (24).

Anthropometric data. Height was measured to the nearest 0.5 cm and weight to the nearest 0.1 kg using a Seca™ scale (8920A RT. 108; Columbia, MD). Body fat was measured by bioelectrical impedance using a Quantum BIA-101Q™ (RJL Systems Inc., Clinton Township, MI) as previously described by Lukaski (25).

Test oils. The B used in the study was clarified B oil which contained 99.48% (by weight) fat and 0.24% water. The interesterified B-MCT mixture was made by blending clarified B oil (60% by weight), MCT oil (35%), and safflower oil (5%) in a stainless steel batch reactor and heating the mixture to 75–80°C under nitrogen as per the method described by Sreenivasan (9). Sodium methoxide was used as a catalyst. After 30–60 min, the resulting product was washed, dried, deodorized, and filtered to give the final interesterified product.

Test oil TAG structure (Grignard degradation). The dietary oils (10 mL) were dissolved in 1 mL of hexane and methylated using KOH in methanol (26). The fatty acid methyl esters were analyzed with a Hewlett-Packard 5890 series II gas chromatograph equipped with a fused-silica column (SP2380, 60 m, 0.25 mm i.d., Supelco Inc., Bellefonte, PA). Helium was the carrier gas with a split ratio of 1:20. The mixture was heated to 75°C for 0.5 min, and the temperature was then increased as follows: 15°C/min until 160°C was reached, followed by 30°C/min until 225°C was reached. This was maintained for 5 min. The fatty acid methyl esters were identified and quantified by internal standards added prior to the methylation (Nu-Chek-Prep Inc., Elysian, MN).

The distribution of the fatty acids within the TAG was determined using Grignard degradation (27). The *sn*-2 monoacylglycerol fractions were then isolated and the fatty acid composition was determined in the same manner as the total TAG.

Blood collection, preparation, and analyses. Fasting (14-h) blood samples were collected in tubes containing EDTA (0.1%). Plasma was separated by centrifugation at 3000 rpm at 4°C. Total cholesterol (TC) and TAG were analyzed with an Abbott Diagnostics Spectrum CCX bichromatic analyzer (Abbott Park, IL) using enzymatic reagents. High-density lipoprotein cholesterol (HDL-C) was measured in the supernatant fraction after precipitation of other lipoproteins by a dextran sulfate-magnesium procedure as described elsewhere (28). LDL-C was separated directly using a reagent kit from Genzyme Corp.© (Cambridge, MA) which precipitates very low-density lipoprotein and high-density lipoprotein with antibodies to apolipoproteins A-I and E, as previously described (29).

Plasma TAG structure (Grignard degradation). The total lipid fraction from the plasma samples was extracted according to the method of Folch *et al.* (30). Methanol (1.5 mL) was added to 200 mL of plasma. Then, 3 mL of chloroform and 0.2× the volume of saline (0.73 wt% NaCl) were added and the mixture was shaken vigorously. The mixture was left to separate into two phases and the aqueous phase was discarded. The organic phase was filtered through a column of anhydrous Na_2SO_4 and the column was washed twice with 1 mL of chloroform. The solvent was evaporated and the lipid fraction redissolved in 2 mL of chloroform/methanol (95:5, vol/vol) containing 0.005% butylated hydroxytoluene (Kock-Light Laboratories, England). One milliliter of the lipid extract was applied on thin-layer chromatographic plates and developed using heptane/propanol-1/acetic acid (95:5:1, by vol). The plates were sprayed with 2,7-dichlorofluorescein and the lipid classes visualized under an ultraviolet lamp. The TAG fractions were scraped off for fatty acid analysis. The TAG fraction was extracted from the plate material using 3 × 1 mL of ether which was evaporated and the TAG fraction was redissolved in 0.5 mL of hexane and methylated using KOH in methanol. The phospholipid fraction was saponified and methylated using BF_3 (31). The 2-monoglyceride band was scraped off the plate, since 2-monoglyceride yields the best results in a regiospecific analysis (27). The 2-monoglyceride was extracted from the silica gel with 3 × 1 mL diethyl ether, the ether was evaporated under nitrogen, and the glycerides were dissolved in hexane.

Statistical analysis. All statistical analyses were carried out using Systat® (32). Paired *t*-tests were used to compare the averaged plasma lipid and lipoprotein values between the B and interesterified B-MCT phases. An α level of 0.05 was used. Dietary variables were expressed as a percentage of total energy, and paired *t*-testing was used to determine if any differences existed. Carryover effects of the previous diet were determined by comparing the differences between the plasma lipid values averaged over the entire study with those subjects who received B first and those who received the interesterified B-MCT mixture first.

RESULTS

The sample consisted of 16 men and 14 postmenopausal women whose mean age was 59 ± 11 yr (women, 64.3 ± 7.4 yr; men, 54.3 ± 12.3 yr) and body-mass index (kg/m^2) was 27.2

± 5.3 (women, 27.9; men, 26.7). The women weighed 69.2 ± 16.1 kg and men 80.4 ± 12.7 kg. The mean blood pressure (mm Hg) was 129/80 (women, 137/80; men, 122/80). The mean percent body fat was 26.7 ± 9.7 (women, 34.0; men, 20.4). As such, the patient population was, on average, both hypercholesterolemic and obese, and less responsive to dietary changes in unsaturated fatty acids. Food records from weeks 2 and 4 of each dietary phase were averaged together and analyzed for mean energy and selected nutrient concentrations. Nutrients were expressed as a percentage of total energy and, as *t*-tests revealed no significant differences for any of the nutrients between men and women, the data were combined. There were no significant differences seen in any mean nutrient intakes from diet alone between the two dietary phases. However, when the test foods were added to the nutrient data file, paired *t*-tests revealed the expected differences that are reported in Table 3. During the B phase, significantly more butyric (4:0), myristic (14:0), palmitic (16:0), stearic (18:0), and oleic (18:1n-9) acids were consumed, while in the interesterified phase more caprylic (8:0) and capric (10:0) acids and less cholesterol were consumed. The overall energy distribution was slightly higher in carbohydrates (4%) and lower in protein (2%) and fats (4%) than the intended goal.

Mean intake of alcohol (per 1000 kJ) was 0.7 ± 1.3 g during baseline, and dropped to 0.4 ± 1.0 g and 0.4 ± 0.8 g during the B and IM phases, respectively. Subjects were instructed to abstain from alcohol intake during the weeks of blood sampling. Mean fiber intakes were stable throughout the study.

Table 4 shows the plasma lipid concentrations at baseline and during the two treatment phases of the study. The subjects were moderately hypercholesterolemic and hypertriglyceridemic upon entry. There were no significant differences in plasma cholesterol concentrations between the two dietary treatments. The interesterified B-MCT mixture resulted in a significantly ($P < 0.05$) higher fasting plasma TAG concentration. Statistical comparisons were not made with baseline measurements given unknown dietary intakes prior to screening. Analysis showed that there was no effect due to the order of treatment.

TAG molecular structure. As shown in Table 2, the more common fatty acids in the *sn*-2 position in the B were myristic and palmitic acids, accounting for 66 and 55%, respectively, of these fatty acids relative to the *sn*-1,3 position. In the IM, the most common fatty acids in the *sn*-2 position were caprylic and capric acids, accounting for 49 and 50%, respectively, of these fatty acids relative to the *sn*-1,3 position. The latter distribution is essentially what would be predicted from the random distribution of the fatty acids in the oils used in the manufacturing of the interesterified oil. Unfortunately, during the Grignard procedure, the shorter-chain fatty acids were volatilized, accounting for the lower values, as compared to those in Table 1.

Table 5 shows the fatty acid composition seen in the subjects' plasma TAG. Subjects had significantly more capric, stearic, and dihomo-γ-linolenic acid, and less oleic acid when they consumed the IM as compared to B.

TABLE 3
Mean Nutrient Intakes and Percent Energy Distribution (diet plus test foods) for Baseline and Dietary Phases[a]

Nutrient	Baseline	Butter	Interesterified butter + MCT

DISCUSSION

The results of this study demonstrate that the mean plasma cholesterol concentrations did not differ significantly when subjects consumed the interesterified oil vs. the B oil. This finding is interesting in view of the composition and molecular structure of the test oil. Medium-chain fatty acids accounted for 50% of the fatty acids in the test oil as compared with 6% in the B oil. Caprylic and capric acids in the *sn*-2 position of the IM appear to have the same potential to increase plasma cholesterol concentrations as the longer-chain saturated fatty acids, such as myristic and palmitic acids, which were of greater concentrations in the B oil. We cannot, however, definitely conclude this since interesterification of the oil mixture was performed, rather than merely feeding the oil mixture.

After a 20-yr hiatus, there has been a renewed interest in the effect of interesterified fat on serum lipid levels. Unlike results from earlier studies that reported interesterified fats had different effects on serum lipids, the present study and studies by Zock *et al.* (19) and Nestel *et al.* (20) have found little or no difference with interesterified fats.

The majority of research on MCT and cholesterol metabolism was conducted in the 1960s. Beveridge *et al.* (12) reported no significant change in serum cholesterol levels in healthy students when an MCT-containing formula replaced a fat-free regime. When coconut oil formula was substituted for MCT, slight increases in serum cholesterol levels occurred, whereas a B-containing formula produced a marked elevation of serum cholesterol levels.

Roels and Hashim (14) compared liquid formulae containing MCT, corn oil, or B as the sole source of dietary fat (50% of total energy). In comparison with corn oil, MCT induced a slight rise in serum cholesterol levels, whereas serum cholesterol increased when B followed MCT and fell when MCT replaced B.

McGandy *et al.* (6) reported that mean serum cholesterol concentrations decreased by 3.2 ± 8.4 mg/100 mL in a group of 10 men and by 11.0 ± 4.3 mg/100 mL in a group of nine men when these groups consumed a diet that provided 38% of total energy as fat of which 5.7 total energy % was added from MCT.

In the present study, there was a significant rise in fasting TAG levels when subjects were consuming the test oil. Uzawa *et al.* (33) substituted MCT for long-chain saturated or unsaturated fatty acids in a diet (45% of energy from fat) and reported an increase of serum TAG levels of 100% or more. Resumption of long-chain fatty acid intake resulted in an immediate drop of serum TAG concentrations to previous levels. The study is limited, however, as two of the three subjects were diabetic.

McGandy *et al.* (6) reported a significant ($P < 0.01$) increase in mean serum TAG concentrations of 61.1 ± 17.8 mg/100 mL when MCT provided 38% of the total dietary energy in a group of 10 institutionalized men. In another group of nine given the same diet, the mean increase in TAG was 20.1 ± 3.0 mg/100 mL. This effect was diminished in both groups when the MCT was mixed with trimyristate and safflower oil.

Kuo and Huang (34) also reported a significant increase in serum TAG concentrations in a group of patients with cystic fibrosis when they were given a formula supplemented with MCT. However, the ranges of variation were large and the level of significance was marginal ($P < 0.10$).

In summary, there appears to be consistency in the reporting of increased TAG concentrations when subjects consume MCT. Even though cholesterol levels were unaffected, interesterified TAG can influence the atherosclerotic process as shown by Kritchevsky *et al.* (4). Other studies emphasize alterations in lipoprotein composition after different types of dietary fats (35,36).

ACKNOWLEDGMENTS

The authors gratefully acknowledge the unselfish contributions of all the subjects involved in this study. Additionally, we thank Dondeena Bradley (Stepan Company), Judy McNamara, Lenny Markowitz, and Vicky Huang for expert technical assistance; and Eugenie Coakley (Harvard School of Public Health) for expert assistance with statistical analysis. This research was supported in part by Medical Foods Inc. (Toronto, Canada).

Mechanisms Mediating Lipoprotein Responses to Diets with Medium-Chain Triglyceride and Lauric Acid

Yu-Hwai Tsai, Sunmin Park, Jeffery Kovacic, and Jean T. Snook*

Department of Human Nutrition and Food Management, The Ohio State University, Columbus, Ohio 43210

ABSTRACT: Medium-chain triglycerides (MCT) are often used in specialized formula diets or designer fats because of their special properties. Yet their influence on lipid metabolism is not completely understood. In this two-period cross-over study, the effects of MCT (8:0 + 10:0) in contrast to a similar saturated fatty acid (12:0) were compared. Eighteen healthy women ate a baseline diet [polyunsaturated (PUFA)/saturated fat = 0.9] for 1 wk. Then, they consumed test diets (PUFA/saturated fat = 0.2) for 4 wk. Monounsaturated fat and cholesterol were constant in baseline and treatment diets. MCT and 12:0, substituted for part of the PUFA, provided 14 energy (en)% of the test diets. In comparison to the PUFA baseline diet, a 16% increase in mean serum low density lipoprotein (LDL)-cholesterol (C) on the 12:0 diet was accompanied by a 21% decrease in mean receptor-mediated degradation of LDL by freshly isolated mononuclear cells (MNC) *in vitro*. The MNC assay theoretically gives an indication of receptor-mediated degradation of LDL. In contrast, the MCT diet raised mean receptor-mediated degradation of LDL by 42%, a finding out of line with the mean 11% increase in serum LDL-C. Perhaps MCT, by increasing the rate of LDL-C production, overcame the rate of LDL-C clearance. The 12:0 diet enhanced some factors involved in reverse cholesterol transport (e.g., high density lipoprotein fractions) while MCT had a different or less pronounced effect. The overall effects of MCT on cholesterol metabolism may or may not be desirable, whereas those of 12:0 appear largely undesirable as previously reported.

Paper no. L7996 in *Lipids 34,* 895–905 (September 1999).

Medium-chain triglycerides (MCT) are composed of fatty acids (FA) with 6–12 carbons (1). Although they are found in several natural fats and oils, FA with 8 and 10 carbons, henceforth referred to as MCT, are not present in high amounts in fats and oils produced in the United States. Yet they play an important role in certain American diets. For example, because they are easily digested and absorbed, they have been incorporated into nutritional products developed for patients with diseases of fat malabsorption (2). Very low birth-weight infants are often given formulas with MCT to improve absorption of fat and calcium (3). MCT are on a list of supplements frequently used by body builders (4), sometimes in large amounts (5). Gene manipulation can be employed to modify the MCT content of oils such as canola (6) and so might be used to enhance the MCT content of food products if this should prove desirable.

MCT, in addition to being more digestible, are metabolized somewhat differently from long-chain triglycerides (LCT) (7). For example, [^{13}C]trioctanoate, in contrast to [^{13}C]trioleate, is oxidized more rapidly after both oral and parenteral administration. This rapid oxidation may amount to 50% of the dietary energy use in very low birth-weight infants (3,7). There is evidence of incorporation of label from orally administered [^{13}C]octanoate into myristic and palmitic acids in plasma triglycerides (TG), a result suggestive of chain elongation of a portion of the medium-chain FA (3). In addition, MCT are metabolized to other, less usual compounds compared to LCT. More ketones (3-hydroxybutyrate) are recovered in plasma and more dicarboxylic acid is found in urine of low birth-weight infants when MCT constitute 50% rather than 0% of formula fat (8). Not all dietary MCT are metabolized immediately. Infants may store up to 12% of the medium-chain FA they consume in adipose tissue (9). These metabolic data suggest that MCT can have a somewhat different effect on energy and lipid metabolism from that of LCT. In fact, excess dietary energy in the form of MCT, in contrast to LCT, seems to increase postprandial thermogenesis, as assessed by indirect calorimetry, possibly because of enhanced lipogenesis in the liver and reduced efficiency of energy storage (10). As regards effects on lipid metabolism, the multiple regression coefficients compiled by Hegsted *et al*. (11) suggest that 10:0 has a slightly elevating effect on serum cholesterol concentrations in contrast to oleic, linoleic, and stearic acids, which have different degrees of negative effect. In a two-study series conducted by Wardlaw *et al*. (12), a structured TG made of randomly distributed 8:0, 10:0, and 22:0 had the same cholesterolemic properties as the comparison diets that were high in 12:0, 14:0, and 16:0, as provided by butter or a mixture of palm oil/palm kernel oil. Even though the structured TG had reduced metabolizable energy

content compared to the natural products, there was no evidence in this study that it could be used as a heart-healthy substitute for animal fats or tropical oils.

Since MCT have the potential for extensive use in specialized formulas and designer TG, it is important to know more about their metabolic effects. In this study, the effects of diets high in MCT were compared to the changes in lipid metabolism produced by a diet high in lauric acid (12:0), which has consistently been demonstrated to raise serum cholesterol concentrations compared to a neutral diet, whether fed in a natural oil (palm kernel oil) or as a synthetic TG (11,13,14).

METHODS AND MATERIALS

Subjects. Eighteen healthy, premenopausal women were randomized into this two-period cross-over study, the minimal number needed to detect a 10% mean difference with an 8% standard deviation by a power of 0.9. Since one subject left the study after period one, 17 subjects consumed the MCT (8:0 + 10:0) diet and 18 subjects finished the lauric acid (12:0) diet. The average age of all subjects was 24 ± 4 yr (mean ± SEM), range 19 to 33 yr; the average weight was 62.2 ± 11.7 kg, range 40.5 to 91.8 kg; and the average height was 161.9 ± 7.7 cm, range 147.9 to 176.5 cm. The fasting serum cholesterol concentration at screening was 167 ± 22 mg/dL (mean ± SEM) with a range between 143 and 237 mg/dL. The health of subjects was verified by blood chemistry and a health questionnaire. Anyone taking medications influencing lipid metabolism was not recruited into this study. The ethnic background of subjects was 10 Caucasians, seven Asians, and one African American. Apolipoprotein E (apoE) phenotype of subjects was 12 apoE 3/3, three apoE 4/3, and three apoE 3/2. Each subject signed a consent form approved by The Ohio State University Biomedical Human Subjects Committee.

Design. In this two-period and two-sequence design involving 18 subjects, nine subjects ate the MCT diet in the first period, and the other nine received the lauric acid diet. Then, in the second period, all subjects consumed the alternate diet. In order to standardize nutrient intake prior to the experimental treatments and provide a comparison base, the subjects were given a baseline diet designed to be higher in polyunsaturated fatty acids (PUFA) and lower in saturated fatty acids (SFA) than the treatment diets for the initial week of each period. The experimental diets were given during the following 4 wk. A 7-wk washout period was held between periods. The study was designed so that blood samples were obtained at the same phase of each subject's menstrual cycle. Blood samples were collected twice during the last 3 d of baseline and twice during the last 3 d of experimental feeding, and the two data points were averaged. The blood samples were drawn into vacutainers with or without anticoagulant depending on the tests to be run. For lipoprotein analyses, serum was obtained by centrifuging at 500 × *g* for 20 min. Some serum samples were used immediately for procedures requiring fresh blood. The remaining samples were frozen at –80°C for later analysis.

Diets. All diets were prepared in a metabolic kitchen in the Department of Human Nutrition and Food Management. The subjects ate breakfast and dinner in the metabolic dining room and carried out lunch during weekdays. Except for Saturday night dinner, they took out weekend meals. According to the nutrient analysis by Food Processor II software (ESHA Research, Salem, OR), the baseline diet contained 40 en% total fat, 11.9 en% saturated fat, 14.9 en% monounsaturated fat, and 10.5 en% polyunsaturated fat, and 323 mg cholesterol

TABLE 1
Daily Energy and Nutrient Intake on Two Saturated Fat Diets and Baseline Diet[a] (mean ± SEM)

Dietary variable	Baseline (*n* = 35)	MCT (*n* = 17)	Lauric acid (*n* = 18)
Energy (MJ)[b]	8.1 ± 0.1	8.3 ± 0.1	8.4 ± 0.1

[a]Values in parentheses are calculated values for percentage of food energy provided by the nutrient.
[b]Analyzed from daily dietary records using Food Processor II Analyses Software (ESHA Research, Salem, OR).
[c]As determined by gas–liquid chromatography. MCT, medium-chain triglyceride; SFA, saturated fatty acid; MUFA, monounsaturated fatty acid; PUFA, polyunsaturated fatty acid; P/S, ratio of PUFA to SFA.

(Table 1). The MCT and lauric diets provided 40 en% total fat, 19.8 en% saturated fat, 14.8 en% monounsaturated fat, and 3.4 en% polyunsaturated fat, and 316 mg cholesterol (Table 1). The test fats furnished over two-thirds of the saturated fat. Dietary fat was present in lean beef (56 g), turkey breast (56 g), and an experimental fat/oil blend. In the baseline diet, the fat/oil blend was 32.7% high-oleic safflower oil, 30.9% safflower oil, 10.9% coconut oil, 12.7% sheanut oil, and 12.7% butter. Commercial miglyol (a 8:0 + 10:0 TG) or trilaurin (42% of the fat blend), obtained from HULS America Inc. (Piscataway, NJ), was the main fat in the experimental fat blends, which also contained 46% high-oleic safflower oil, 6% butter, and 6% coconut oil. The fat blends were used as spread on bread and added to the main dishes at dinner. They were also incorporated into cakes and cookies. The basal menu initially provided 8.1 MJ. The subjects, who were weighed daily, were given extra food energy with the same fat composition to maintain their initial body weight. Food Processor II software was used to calculate the components of the diets by adding data on FA composition in each menu to the software database. (Table 1). The specific FA composition of 1-d composites of each menu was analyzed by gas–liquid chromatography (Table 1).

Biochemical procedures. (i) Serum lipoprotein cholesterol. Total cholesterol (TC) and free cholesterol (FC) in previously frozen serum samples were analyzed by enzymatic assays (Sigma procedure No. 352, St. Louis, MO) (15). Total high density lipoprotein-cholesterol (HDL-C), HDL_2-C (by difference) and HDL_3-C concentrations were determined by the same enzymatic method after precipitation of very low density lipoprotein (VLDL) and low density lipoprotein (LDL) portions with dextran sulfate-Mg^{2+} solution followed by removal of HDL_2-C with a stronger dextran sulfate-Mg^{2+} solution (16). Serum TG concentration was assayed enzymatically (Sigma procedure No. 339). LDL-cholesterol (in mg/dL, LDL-C) was calculated as TC minus [HDL-C and 0.2 (TG)] (17). Data for cholesterol and TG concentrations from two pre- and two postperiod measurements were averaged. The coefficients of variation, evaluated for the assay using previously frozen pool samples, were 0.9% for TC, 1.2% for total HDL-C, 3.2% for HDL_3-C, and 1.6% for TG levels.

(ii) Apolipoprotein (apo) concentration. ApoA-1 and apoB were assayed by a turbidimetric procedure (Raichem, San Diego, CA) in one pre- and one postperiod blood sample which was frozen at −80°C immediately after the blood draw. The coefficient of variation of two control sera provided in the kits was 2.9 and 1.9% for apoA-I and 2.5 and 2.5% for apoB.

(iii) LDL receptor activity. LDL binding and degradation mediated by LDL receptors in mononuclear cells (MNC) were determined as in previous studies (18,19). Briefly, LDL was iodinated 3 d before the blood drawing day using pooled blood obtained from a constant group of donors consuming self-selected diets. The composition of LDL was assumed to be constant throughout the whole study. Pooled serum treated with 0.1% disodium EDTA was used to isolate the LDL fraction from density 1.019 to 1.063 by sequential ultracentrifugation after KBr layering. Then, LDL was radioiodinated after dialysis against phosphate buffer saline to produce a specific activity of 100–600 cpm/ng protein. Free iodine content was less than 3%.

MNC were isolated by centrifugation (800 × *g* for 20 min at 25°C) from blood anticoagulated with sodium citrate and diluted 1:1 with NaCl (0.9%), and the dilute blood was layered over Nycoprep™ (Mediatech, Inc., Herndon, VA). Freshly isolated MNC were then counted and incubated with ^{125}I-LDL (20 μg/mL) in the presence and absence of a 20-fold excess of unlabeled LDL at 37°C for 5 h, a period determined to be suitable for demonstrating differences in ^{125}I-LDL degradation if they existed among treatments (18). After incubation, trichloroacetic acid was added to the samples to achieve a final concentration of 20% in the presence of bovine serum albumin to precipitate undegraded, protein-bound iodotyrosine. The precipitate then was sedimented by centrifugation to obtain supernatant, which was counted in a gamma counter to determine the amount of LDL degraded. Specific degradation was expressed as the difference in degradation in the presence and absence of 20-fold excess unlabeled LDL.

The specific and nonspecific binding activity of LDL receptors was determined by incubating MNC at 4°C with 5, 10, 20, 40, and 80 μg/mL ^{125}I-LDL in the presence and absence of excess unlabeled LDL. After incubation, cells were washed three times with RPMI 1640 medium, collected by centrifugation at 12,000 × *g*, and counted in a gamma counter.

(iv) Lecithin cholesterol acyl transferase (LCAT) and cholesterol ester transport protein (CETP) activity. Endogenous cholesterol esterification (LCAT) and transfer (CETP) were measured by an isotopic method (20). In order to determine esterification rate, fresh serum was preincubated at 4°C for 1 h with ^{3}H-cholesterol-albumin emulsion, and the mixture was incubated at 37°C for 3 h after equilibration of the added cholesterol and endogenous cholesterol. Then lipids were extracted, separated by thin-layer chromatography, and cholesterol ester (CE) and FC spots were scraped and counted by liquid scintillation. To determine CETP, transfer of radiolabeled CE into apoB-containing lipoproteins was measured first by precipitating these lipoproteins from the incubation media with dextran sulfate followed by counting total radioactivity in the incubate, in the HDL-containing supernatant, and in the apoB-containing lipids by liquid scintillation. From these data the rate of CE transfer was calculated.

(v) ApoE phenotype. ApoE phenotype was determined by an isoelectric focusing (IEF) method (21,22) using whole serum samples. After delipidating serum with a dithiothreitol solution overnight, the apoE isoforms were separated in gels of 7.5% polyacrylamide/3 M urea, containing 1:2 ampholine to pharmalyte on an IEF machine (Bio-Rad Bio-Phoresis Horizontal electrophoresis cell, Hercules, CA) with NaOH (1 M) and H_3PO_4 (1 M) as cathode and anode solutions, respectively. After isoelectrofocusing, each lane of apoE phenotype was identified by Western blot using goat anti-human apoE as first antibody, rabbit anti-goat as second antibody, and visualization

with color-developing solution containing β-naphthyl phosphate and Fast Blue BB and $MgSO_4$ in boric acid developer.

(vi) Lipoprotein isolation. A single-spin density gradient ultracentrifugation method (23,24) was used to separate VLDL, LDL, HDL_2, and HDL_3 fractions from whole serum. After blood drawing, 2 mL fresh serum was pipetted into the bottom of a cellulose-nitrate centrifuge tube containing 0.77 g KBr to make a density of 1.25 g/mL, followed by sequentially overlaying with equal amounts of density 1.225 g/mL KBr solution and density 1.1 g/mL KBr solution and, finally, distilled water. Then the tubes were placed in a SW41 rotor (L7-65 Beckman) and centrifuged at 39,000 rpm at 10°C. After 24 h, samples were taken out carefully without shaking and each fraction of lipoprotein was withdrawn by Pasteur pipet.

(vii) LDL size and composition. The composition of LDL isolated as described above was analyzed to estimate the average diameter of LDL obtained from analysis on the two experimental diets. LDL particle diameters were calculated from the core to surface volume ratio using the following formula (25):

$$r = \{[1.093(TG) + 1.044(CE)]/[0.968(FC) + 0.97(PL) + 0.705(PRO)]\} \times 3 \times 21.5 \text{ Å} \quad [1]$$

where $d = 2r + 2 \times 21.5$ Å and r = radius of the particle, d = diameter, PL = phospholipid mass, TG = triglyceride mass, CE = cholesterol ester mass, FC = free cholesterol mass, and PRO = protein mass; 21.5 Å is the assumed thickness of the lipoprotein surface layer; 1.093, 1.044, 0.968, 0.97, and 0.705 are the corresponding specific volumes (26).

LDL-C, TC, and FC concentrations were analyzed by an enzymatic assay (15). LDL-CE value was calculated by difference. LDL-TG concentration was determined by the same assay as the serum TG level. LDL-PL concentration was assayed by an enzymatic colorimetric method (Biochemical Diagnostics reagent, Edgewood, NY). The concentration of LDL-PRO was quantified by total protein reagent (Sigma). The core to surface ratio was calculated as:

$$\text{core/surface} = (4/3\pi r^3)/(4\pi r^2 \times 21.5) = \{[1.093(TG) + 1.044(CE)]/[0.968(FC) + 0.97(PL) + 0.705(PRO)]\} \quad [2]$$

(viii) Fatty acid analysis. Fat was extracted from the blended menu composites with hexane and isopropanol (3:2), and the extracted fat was saponified and methylated with 10% methanolic HCl (27). After heating at 90°C for 2 h, the samples were cooled on ice, and hexane and K_2CO_3 were added. Then a small amount of sodium sulfate and charcoal was added to the extracted hexane fraction followed by centrifugation. The clean hexane layer was analyzed for fatty acyl contents by gas–liquid chromatography (GLC).

Statistical analysis. All data from the beginning and the end of each period and the changes from the baseline produced by the experimental diets were analyzed statistically by MINITAB (Minitab Inc., State College, PA). Differences between the baseline and experimental values were analyzed by paired t-test. Differences between the two diets were analyzed by two-sample t-test. Significance level was set at $\alpha = 0.05$. Relationships among relevant variables were determined by Pearson correlation analysis.

RESULTS

Diet composition. According to computer (Food Processor II) analysis, the experimental diets provided almost the same amount of monounsaturated fatty acids and cholesterol as the baseline diet. There were no significant differences in energy intake between the two preperiods and between the two postperiods. The protein, carbohydrate, and fat intakes as percentages of total energy intake were the same among baseline and the two experimental diets (Table 1). According to the gas–liquid chromatographic analysis, the baseline diet provided three times more PUFA than the experimental diets and only about three-fifths as much SFA (Table 1). Therefore, the PUFA/SFA ratio of the baseline diet was five times higher than the experimental diets. Except for MCT and lauric acid, the contents of all other SFA in the experimental diets were lower than in the baseline diet. Because the carbon chain length of the experimental FA in this study was 12 or less, it was assumed that the absorption of major dietary fats was the same. Therefore, fecal excretion of FA was not measured.

Serum lipoprotein-cholesterol and apo concentrations. The mean ± SEM serum cholesterol concentration of the subjects at screening and representing their usual diet was 167 ± 22 mg/dL. This value was reduced by 10 ± 3 mg/dL after the subjects had consumed the baseline diet for 1 wk during the first period. In comparison to the baseline diet, both MCT (P = 0.032) and lauric acid (P = 0.0001) diets raised mean serum TC concentrations. The 12:0 diet produced higher postperiod values for mean serum TC than the MCT diet (P = 0.021) (Table 2), which tended to return serum cholesterol to levels observed on the subjects' usual, self-selected diet. Among the 18 subjects who consumed the 12:0 diet, TC concentrations were raised in 16 women compared to baseline (Fig. 1), whereas on the MCT diet TC rose in 12 out of 17 subjects (Fig. 2). There was no correlation between changes produced by the two diets (r = −0.058), meaning that individual subjects did not have uniform responses to the two treatments. There was no difference (P > 0.05) in changes in TC among the three different apoE phenotypes represented in this study on either diet.

Both diets increased LDL-C values (P = 0.05 for MCT, P = 0.0016 for 12:0) from baseline value (Table 2). Fifteen out of 18 subjects had increased LDL-C levels after eating the 12:0 diet, in agreement with the changes in TC except for one subject (Fig. 3), and 12 out of 17 subjects had LDL-C increases after consuming the MCT diet, which was also in agreement with the changes in TC except for one subject (Fig. 4). The correlation between changes in LDL-C pro-

[a]Significant difference between pre- and postperiod values (P < 0.05). NS, nonsignificant; S, significant; LDL, low density lipoprotein; HDL, high density lipoprotein. For other abbreviation see Table 1.

duced by two experimental diets was small (r = −0.267). There was no significant difference in LDL-C changes among the three apoE phenotypes on either diet, even though LDL-C was increased in all three subjects with apoE 4/3 phenotype compared to values on the baseline diet.

Total HDL-C (P = 0.0017), HDL_2-C (P = 0.026), and HDL_3-C (P = 0.0019) all increased on the 12:0 diet, whereas on the MCT diet, HDL_2-C decreased (P = 0.0031), HDL_3-C increased (P = 0.0002), but total HDL-C did not change (Table 2). At the end of treatment, values for serum HDL_2-C differed (P = 0.04) between MCT and 12:0, and values for total HDL-C concentrations appeared lower on MCT than 12:0, suggesting that MCT and 12:0 had different effects on certain parameters of reverse cholesterol transport (RCT). There were no significant differences in TG concentration either on the MCT or on the 12:0 diet or in changes from baseline (Table 2). ApoA-I and apoB concentrations did not change significantly on either diet (Table 2).

Changes in variables associated with RCT. Both serum FC (P = 0.002) and CE (P = 0.003) concentrations increased on the 12:0 diet, but not on the MCT diet (P > 0.05) (Table 3). At the end of the period serum CE concentration was higher on 12:0 than MCT (P = 0.023). The rate of cholesterol esterification (LCAT) rose on the 12:0 diet (P = 0.0003) but was

TABLE 4
Saturated Fat and LDL Receptor Activity in MNC (mean ± SEM)

MNC variable	MCT (n = 17)	Lauric acid (n = 18)	Difference between diets
Receptor-mediated degradation of ^{125}I-LDL (ng/10^6 MNC/h)			
Preperiod	12 ± 1	14 ± 1	NS (P = 0.19)
Postperiod	17 ± 2	12 ± 1	S (P = 0.033)
Difference	5 ± 1[a]	−3 ± 1[a]	S (P = 0.0001)
Nonspecific degradation of ^{125}I-LDL (ng/10^6 MNC/h)			
Preperiod	7.3 ± 1.1	5.2 ± 0.9	NS (P = 0.14)
Postperiod	7.9 ± 1.3	9.0 ± 1.7	NS
Difference	0.6 ± 1.5	3.7 ± 2.0	NS
Receptor-mediated ^{125}I-LDL binding (ng/10^6 MNC)			
Preperiod	16 ± 2	18 ± 1	NS
Postperiod	21 ± 2	16 ± 1	NS (P = 0.056)
Difference	4 ± 1[a]	−2 ± 1	S (P = 0.0023)

[a]Significant difference between pre- and postperiod values (P < 0.05). MNC, mononuclear cell; for other abbreviations see Tables 1 and 2.

not altered significantly on the MCT diet. However, differences in cholesterol esterification at postperiod were not significant between the two diets. The rate of cholesterol ester transfer (CETP) from HDL to apoB-containing lipoproteins also increased on the 12:0 diet (P = 0.0002). In addition, differences in cholesterol transfer rates at postperiod were significant between the two diets (P = 0.0041). The correlation between changes in CETP and LCAT was moderate on MCT (r = 0.667) and was small on 12:0 (r = 0.452).

Changes in LDL receptor activity in MNC. The rate of receptor-mediated degradation of ^{125}I-LDL increased on the MCT diet (P = 0.0018) (Table 4) although the increase was inconsistent with the rise in serum LDL-C. However, the reduced rate of specific LDL degradation on the 12:0 diet (P = 0.0088) was consistent with the increased serum LDL-C. Postperiod values for specific LDL degradation by MNC were higher on MCT than 12:0 (P = 0.033). The rate or changes in the rate of nonspecific degradation of ^{125}I-LDL (degradation not involving the LDL-receptor) was not significant between the two diets (Table 4). The relationship between ^{125}I-LDL concentration in the incubation media and ^{125}I-LDL binding by MNC is shown in Figure 5 for the baseline and the two experimental diets. Differences among treatments were apparent when the incubation media contained 20 μg ^{125}I-LDL/mL, a concentration at which MCT increased receptor-mediated LDL binding (P = 0.0069). This result was in line with the increased receptor-mediated LDL degradation but not with the increased serum LDL-C levels. Receptor-mediated LDL binding decreased but not significantly (P = 0.14) on the 12:0 diet, a tendency consistent with the decreased receptor-mediated LDL degradation and increased serum LDL-C values. Changes in specific LDL binding induced by the two dietary treatments differed (P = 0.0023), and the lower value for specific binding of LDL by MNC on 12:0 compared to MCT approached significance (P = 0.056). In

TABLE 3
Saturated Fat and Rates of Cholesterol Esterification and Transfer in Serum (mean ± SEM)

Serum variable	MCT (n = 17)	Lauric acid (n = 18)	Difference between diets

[a]Significant difference between pre- and postperiod values (P < 0.05). For abbreviations see Tables 1 and 2.

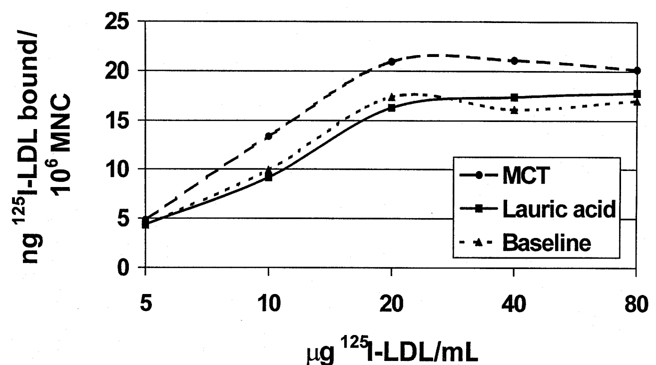

FIG. 5. Binding of ^{125}I-LDL to LDL receptors when freshly isolated mononuclear cells (MNC) obtained from subjects eating two saturated fat mixtures were incubated with different amounts of ^{125}I-LDL. (Baseline n = 35, MCT n = 17, lauric acid n = 18). For abbreviations see Figures 1 and 3.

addition, the correlation between changes in receptor-mediated LDL degradation and binding was small on 12:0 (r = 0.422) and was not demonstrated on MCT (r = –0.153).

The associations of changes in LDL-C with mechanisms of LDL removal were various. Except for the moderate correlations between changes in LDL-C concentration and specific LDL (r = 0.528) and nonspecific LDL (r = 0.499) degradation on MCT, the changes in serum LDL-C concentration were not correlated with changes in receptor-mediated binding on either diet.

Effect of different SFA on LDL size and composition. Although no significant LDL diameter changes were observed after either dietary treatment, and the postperiod LDL diameters were not different, there was a slight tendency for LDL diameter to increase in subjects fed MCT (P = 0.069) and 12:0 (P = 0.11) (Table 5). There were some compositional changes in LDL that occurred during the treatment periods, but the changes effected by the two diets were not different (P > 0.05). LDL-FC concentration increased on 12:0 (P = 0.028) but was not significantly different on MCT. LDL-TG (P = 0.0008) and PL (P = 0.0092) concentrations increased but LDL-PRO (P = 0.028) decreased on the MCT diet. Furthermore, although the core to surface ratio was not altered significantly on either diet, the ratio tended to increase on MCT (P = 0.069) and 12:0 (P = 0.11) compared to the PUFA baseline diet.

DISCUSSION

This is the most thorough study to date of the effects of MCT on lipoprotein metabolism in humans. The objective was to compare the effects of diets providing MCT (8:0 + 10:0) or lauric acid (12:0) with each other and with a baseline diet having half as much saturated fat, three times as much polyunsaturated fat, and the same amount of total fat, monounsaturated fat, and cholesterol. Because MCT and lauric acid are normally obtained from imported tropical oils, they were fed in greater amounts (14 en%) in this study than are typically consumed in the United States, except possibly by persons consuming certain formula diets or taking supplements. The major findings were (i) that both MCT and 12:0 raised serum LDL-C concentrations compared to the more polyunsaturated baseline diet. The effect of MCT was about two-thirds that of 12:0. (ii) Lauric acid produced higher levels of serum TC than MCT partly because of its effect on HDL_2. (iii) The MCT diet suppressed or did not affect some measures of RCT in many subjects whereas 12:0 consistently enhanced the same parameters compared to the PUFA diet. (iv) Increases in serum LDL-C in subjects consuming MCT were positively associated with higher rates of specific LDL degradation, not lower rates as might be expected. These results suggest that MCT and 12:0 have somewhat different effects on lipoprotein metabolism despite their closeness in chain length and the fact that MCT and at least some 12:0 enter the blood *via* the portal circulation (28).

The influence of MCT and lauric acid on LDL-C concentration. The effect of MCT on blood TC and LDL-C concentrations is somewhat controversial. Several human feeding trials with MCT, dating back to 1959, are summarized in Table 6. These studies differed considerably in the amount of MCT fed (5–40 en%), in the type of fat fed along with the MCT (none or a blend of different fats), in the type of diet fed (conventional foods vs. liquid formula diets), in the comparison fat (linoleic acid, oleic acid, other SFA, or a fat-free diet), in the length of the feeding period (5–28 d), and in the type of subject used (healthy vs. hospital patients, men vs. women).

In early studies (29,30), in which MCT or comparison fats were usually fed alone and in high amounts, MCT appeared to be considerably less cholesterolemic than butter or coconut oil. Total blood cholesterol levels were measured in these studies, not HDL-C or LDL-C. In more recent studies (12,31, 32, and this one), diets providing MCT in varying amounts (5–43 en%) had similar effects on blood cholesterol and LDL-C levels as the subjects' usual (presumably not heart-healthy) diets or a baseline diet high in butter or tropical oils. Either the latter studies were short in duration (31) or the MCT diets contained the minimum recommended levels of 18:2 in addition to MCT and other FA (12,32, and this study). These more recent studies consistently indicated that in con-

TABLE 6
Summary of Studies on the Effect of Diets with MCT on Blood Total and LDL-Cholesterol Levels[a]

Investigator, date (ref. no.)	Subjects	Baseline diet	Treatment or comparison diets	Results	Comments
Hashim *et al.*, 1960 (29)	8 middle-aged male and female hospital patients	Regular hospital diet	40 en% corn oil, butter, or MCT diets for 2 wk (butter) or 4 wk (MCT, corn oil). Patients consumed 2 of the 3 test fats.	In corn oil–MCT comparisons, MCT produced 8–9% higher TC; in butter–MCT comparisons, butter produced 20–50% higher TC.	MCT diet was devoid of POLY; it took up to 4 wk to establish a steady-state response to the MCT diet.
Beveridge *et al.*, 1959 (30)	83 college males and females	Fat-free diet was fed for 8 d to all subjects	One of 8 treatment diets was fed for 8 d and replaced 30 en% of carbohydrate in the baseline diet. Treatments were MCT, coconut oil, and distilled fractions of butter with or without added cholesterol.	MCT diets raised TC 5–7% compared to the fat-free diet. Coconut oil raised TC by 17%. Butter diets raised TC up to 60%.	MCT was not neutral contrasted with the fat-free diet, but it was considerably less cholesterolemic than coconut oil or the butter fractions. Treatment diets were low in or devoid of 18:2. Periods were short.
Snook *et al.*, 1985 (33)	12 college-age males and females	Conventional food, butter-based diet providing 42 en% fat was fed for 1 wk.	Liquid formula diets, with 32 en% fat, were fed for 1 wk in a cross-over design. Corn oil was the sole fat in Diet 1. MCT replaced some POLY in Diet 2.	Compared to the butter-based diet, Diet 1 lowered TC by 24% in 1 wk. Diet 2 lowered TC by 12% in 1 wk.	Replacement of some of the POLY in the formula diet with MCT reduced the cholesterol-lowering properties of the formula. Study periods were short.
Hill *et al.*, 1990 (31)	10 healthy males	Usual diet	Liquid formula diets with 40 en% fat were fed for 5 d in a cross-over design. Fat was soybean oil or MCT.	Soybean oil lowered TC by 15% in 5 d while MCT produced no change compared to usual diet.	POLY diet lowered TC compared to usual diet while MCT did not. The study was short. The MCT diet was devoid of 18:2.
Cater *et al.*, 1997 (32)	9 males with documented coronary artery disease	Outpatient *ad libitum* diet	Diets with 53 en% fat, 43 en% of which was palm oil, high-oleic sunflower oil or MCT, were given for 3 wk periods in cross-over design. All diets had at least 3 en% PUFA. Palm oil diet provided 20 en% 16:0.	TC and LDL-C were 12 and 15% higher, respectively, on MCT than MONO diet. Effects of MCT and palm oil did not differ.	MCT raised TC and LDL-C compared to MONO diet. According to authors, cholesterol-raising potency of MCT appeared to be half that of 16:0. All diets provided at least 3 en% 18:2. Periods were of adequate length.
Wardlaw *et al.*, 1995 (12)	34 males (study 1) and 14 males (study 2) with mildly elevated cholesterol	Diets had 38–41 en% total fat and 15–17 en% 12:0–16:0 provided by palm oil/palm kernel oil (study 1) or butter (study 2) and were fed for 3 wk.	MCT + 22:0 replaced about 10 en% of the 12:0–16:0 for 6 wk in diets of half the men. The other half continued on the baseline diet.	TC and LDL-C were not altered; HDL was higher on palm kernel oil than on the MCT + 22:0 diet.	MCT, butter, and palm oil/palm kernel oil had equivalent effects on TC when about 5 en% 18:2 was in all diets. Cholesterolemic effect of 22:0 is not known.
Tsai *et al.*, 1999 (this paper)	17–18 healthy, premenopausal females	40 en% fat diet with 10 en% PUFA and 10 en% saturated fat was fed for 1 wk.	40 en% fat diets with 3.4 en% PUFA and 14 en% MCT or 12:0 were fed for 4 wk in cross-over design.	MCT raised TC and LDL-C by 7 and 11%, respectively. 12:0 raised TC and LDL-C by 12 and 16%, respectively.	When substituted for the POLY baseline diet, MCT had about 2/3 the cholesterol-raising potency of 12:0.

[a]TC, total cholesterol; POLY, dietary polyunsaturated fat; MONO, dietary monounsaturated fat; LDL-C, LDL-cholesterol; 12:0–16:0, dietary content of lauric, myristic, and palmitic acids, the saturated fatty acids considered to be the most cholesterolemic; for other abbreviations see Tables 1 and 2.

trast to diets high in PUFA, MCT diets produced 8–15% higher levels of TC in serum or plasma (29,31,33, and this study). Furthermore, an MCT diet resulted in 12 or 8–9% higher levels of TC than a high monounsaturated FA diet (32) or a fat-free diet (29), respectively. One of the multiple regression equations developed by Hegsted *et al*. (11) predicted the effects of seven FA and dietary cholesterol on serum concentrations of TC. The positive partial regression coefficient describing the effect of 10:0 was about two-thirds that of 12:0 and was positive in contrast to the negative coefficients for 18:0, 18:1, and especially 18:2. In a companion study to the one reported herein (34), mean serum concentrations of TC and LDL-C were the same on the PUFA baseline diet as on a diet with 14 en% 18:0, suggesting, as did the work of Hegsted *et al*. (11), that 18:0 is less cholesterolemic than MCT. In summary, in this study, MCT was more cholesterolemic than 18:2 and less so than 12:0, which has been shown to raise blood cholesterol concentrations in previous studies (11,13, 14). In addition, reports in the literature suggest MCT is more cholesterolemic than 18:1 and 18:0 and may not lower blood cholesterol levels in some cases when substituted for self-selected diets or for 12:0–16:0 SFA. Thus, when an effect on serum cholesterol or LDL-C concentrations is the criterion, MCT is not a convincing heart-healthy substitute for other saturated fats. However, MCT do have some unique effects on lipoprotein metabolism that merit further attention.
