Growth regulation by ceramide. Ceramide accumulates in response to several different inducers such as cytokines [tumor necrosis factor α (TNFα), interleukin β1 (ILβ1), interferon-γ (Infγ) and Fas], cytotoxic agents (chemotherapeutic agents, irradiation), and finally stressful conditions (such as serum deprivation and heat shock) (13). The general response to these stresses is a growth-suppressed condition which can be due either to cell cycle arrest or to apoptosis. The choice between the two fates is determined mostly by the cell type. Cellular treatments with exogenously added short-chain ceramide analogs (C2-, C6-ceramide) mimic the same biological effects observed when natural stress inducers are used. The effects of ceramide on cell cycle arrest were studied mostly in response to serum deprivation (14). This condition induced elevation of intracellular ceramide level with time, a progressive arrest of cell cycle in the G0-G1 phase and dephosphorylation of the retinoblastoma gene product (Rb). Treatment with exogenously added ceramides also induced dephosphorylation of Rb (15). On the other hand, ceramide-mediated apoptosis was studied upon treatment with several different agonists, in particular with TNFα and after addition of short-chain ceramide analogs. The latter treatment was able to induce DNA fragmentation similar to TNFα treatment (16). Also recent studies established the involvement of pro-interleukin-1 converting enzyme (ICE) family members upstream (such as FLICE) and downstream (such as caspase 3) to ceramide signaling (17). Interestingly, activation of the PKC pathway by treatment with phorbol esters seems to enhance viability and thus to counteract ceramide mediated apoptosis (16). Importantly, treatment with exogenous ceramide increased proliferation of quiescent Swiss 3T3 fibroblasts, indicating that eventually ceramide may positively regulate cell proliferation (18).

Regulation by sphingosine and sphingosine-1-P. Sphingosine was first discovered to be a PKC inhibitor (11), and in line with this observation it has been shown to inhibit cell growth (19). Moreover, sphingosine was implicated as endogenous me-

diator of apoptosis during phorbol ester-induced differentiation of HL-60 cells (20). On the other hand, sphingosine stimulated the proliferation of growth-arrested Swiss 3T3 (21) and Rat-1 fibroblasts (22). The mitogenic effects exerted by sphingosine may be due to its conversion to sphingosine-1-P (23). One of the mechanisms by which sphingosine and sphingosine-1-P may elicit mitogenic effects could be the induction of phosphatidic acid accumulation (19). This accumulation could be the result of diacylglycerol (DAG) kinase activation (24), inhibition of phosphatidic acid phosphohydrolase (25), and most importantly activation of phospholipase D (26).

Other metabolites. Other sphingolipid metabolites, such as ceramide 1-P (8) and GD3 gangliosides (27), seem to be also bioactive molecules in the regulation of cellular proliferation and/or apoptosis, but further investigations are in process.

The web of sphingolipid signaling. In addition to the general paradigm that ceramide negatively regulates cell growth, it is clear that there are several interrelated events, such as competing functions of ceramide, sphingosine, sphingosine-1-P, ceramide-1-P, gangliosides and DAG, which create a more complex picture. The emerging scenario is best understood as an intricate web of interconnected metabolic reactions, which modulate the relative intracellular concentrations of the several different species. These metabolic pathways may play a critical role in the fate of a signaling pathway by differential regulation of the key enzymes. So, in order to better understand the biological behavior of a given pathway as part of a more general picture, it becomes extremely important to study and seriously characterize each enzymatic activity and try to relate it to the cellular environment, in terms of inhibitors or activators.

ENZYMES OF SPHINGOLIPID SIGNALING

Until now, great efforts have been spent in order to better understand the biological functionality of the sphingolipid pathway. On the other hand, this approach cannot replace investigations directed to study the biochemical characteristics of the reactions themselves, and thus of their regulatory enzymes. Researchers normally find several obstacles when approaching the problem. First, sphingolipid metabolism is based on a number of interconnected reactions; different enzymes may share the same precursor or lead to the same product, possibly influencing each other. In this case it is difficult to discriminate between enzymatic activities. Second, very few enzymes of the pathway have been purified and cloned; thus most of the studies conducted *in vitro* use mixed preparations (homogenates or membrane pools) which may yield misleading results. The involvement of different enzymes regulating the levels of specific sphingolipid species in response to external stimuli is becoming more and more evident. In this report, we will be focusing on a few of them, such as ceramide synthase, sphingomyelinases (SMase), ceramidases, and SM synthase.

CERAMIDE SYNTHASE

Ceramide synthase catalyzes the acylation of long-chain sphingoid bases by transfer of a fatty acid from the CoA thioester (28). This activity is localized in the endoplasmic reticulum, with the catalytic site thought to face the cytosol and an *in vitro* pH optimum of 7.4 (29). The most popular approach followed to study the role and biological importance of ceramide synthase is the use of specific inhibitors. Since ceramide synthase is one of the early enzymes involved in sphingolipid *de novo* synthesis, eventual *in vivo* experimental manipulations of this activity may result in a general alteration of sphingolipid metabolism. One may predict that inhibition of ceramide synthase activity would lead either to sphinganine accumulation and/or loss of complex sphingolipids. In many cell types both free sphinganine and specific inhibition of sphingolipid metabolism are growth inhibitory and cytotoxic. It follows that results obtained by altering/inhibiting ceramide synthase activity may not be easy to interpret. Among the inhibitors, fumonisin B1 is the best studied (29). Treatment with fumonisin B1 mainly induces accumulation of sphinganine, which is then partially phosphorylated to sphinganine-1-P. The most rapid intracellular effect of fumonisin B1 treatment is sphinganine elevation rather than depletion of complex sphingolipids, but the relative magnitudes of these two effects vary between cell types (30). Fumonisin B1 treatment alters the behavior of cell-surface proteins and changes cell morphology, inhibits PKC, and induces Rb dephosphorylation and cell cycle arrest (29). On the other hand, fumonisin B1 was shown to induce cell proliferation in growth-arrested Swiss 3T3 cells (28). Moreover, fumonisins were recognized to play an important role in the induction of different diseases such as esophageal cancer, equine leukoencephalomalacia, and porcine pulmonary edema (31).

SMASE

SMase is a SM-specific phospholipase C (PLC)-type activity, hydrolyzing SM phosphodiester bond and yielding ceramide and phosphorylcholine. Evidence for the importance of SMase activity arose with the discovery of the so-called "sphingomyelin cycle." Several different inducers (TNFα, INFγ, IL-1β, nerve growth factor, Fas ligand, dexamethasone, and others) were found to cause SM hydrolysis in a variety of cell types (monocytes, lymphocytes, fibroblasts, glioma cells) (13). SM hydrolysis leads to ceramide production which mediates at least part of the biological effects exerted by these inducers. SM is then regenerated by the action of the SM synthase. So far, five types of SMases have been described: a lysosomal acid SMase (A-SMase), a plasma membrane-bound neutral magnesium-dependent (N-SMase), a cytosolic neutral magnesium-independent, a zinc-stimulated acid SMases and finally an alkaline SMase. At least two of these SMases, the A-SMase, and the N-SMase, may regulate ceramide intracellular levels (32).

N-SMase. The N-SMase activity can be detected in a variety of organs even if its distribution is not uniform. For example, in rat, the highest activity can be found in brain; less activity is found in testis, adrenal gland, liver, spleen, and kidney (9). Subcellular fractionation studies showed that N-SMase is a plasma-membrane bound enzyme with a possible intracellular

orientation (33). Its activity requires the presence of magnesium and its optimal pH values range between 6.0 and 8.5. Phospholipids (in particular phosphatidylserine (34)) and free arachidonic acid can stimulate N-SMase activity (35). *In vitro* (direct enzymatic assay) and *in vivo* (changes in SM and ceramide levels) measurements of N-SMase activity showed enzyme activation after cellular treatments with inducers of the SM cycle (9). The N-SMase time-course activation varies between cell lines, such that after TNFα treatment of monocytic U937 cells, human skin fibroblasts and mesangial cells a peak of activity is reached after few minutes (2–60 min), while in murine L929 fibro-blasts a significant increase is evident only after several hours (12 h) (13). Studies conducted using a potent ICE inhibitor (crm A) seem to suggest a possible role of this family of proteases in the events that lead from TNFα/receptor interaction to N-SMase activation (17). Recently another forwarding step toward a better understanding of the biochemical/biological N-SMase regulation has been made. Remarkably, glutathione (GSH), at concentrations similar to intracellular levels, was shown to actively modulate N-SMase activity (36). *In vitro* studies on a partially purified N-SMase showed that physiologic intracellular GSH concentrations (1–20 mM) were inhibitory of the enzymatic activity, whereas at lower GSH concentrations, N-SMase activity was recovered. The GSH inhibitory effect was not due to the sulfhydryl group as other general reducing agents used (dithiothreitol, β-mercaptoethanol) were ineffective. Instead, the γ-glutamyl-cysteine moiety of GSH seems to be required. Moreover, cellular treatment with L-buthionine-(*SR*)-sulfoximine, a GSH synthesis inhibitor, caused, as expected, intracellular GSH depletion and induced the SM cycle. Since GSH depletion is a general cellular phenomenon observed in response to stressful conditions, it can be an important mechanism of N-SMase activation, while under physiological conditions GSH would control N-SMase activity. GSH/N-SMase model is also a useful example of a regulatory system involving cross-talk between different cellular areas implicated in stress signaling. Finally, the recent reported cloning of the enzyme will be extremely helpful in the near future to get a better understanding of the processes just discussed (37).

A-SMase. A-SMase is distributed in all mammalian tissues analyzed, and compared to the N-SMase, A-SMase activity is much higher (except for the brain) (32). Its pH optimum sets around 5.0, and its activity localizes with the lysosomal fraction (9). A-SMase was the first of the SMases to be described, purified, and cloned (38). A-SMase defect was found to be the biochemical determinant of Type A and Type B Niemann-Pick disease, resulting in SM accumulation and causing neurological disorders (32). Divalent ions and chelating agents do not affect the activity of this enzyme, while dithiothreitol and AMP are inhibitors (9). On the other hand, ApoC-III, an apolipoprotein from human very low density lipoprotein and a group of proteins named saposins (sphingolipid activator proteins), in particular saposin D, stimulate A-SMase activity (9). The biological role of A-SMase, and in particular its importance in the regulation of the apoptotic signal, is still controversial. Schutze *et al.* (39) reported A-SMase activation after TNFα treatment: through the activation of a putative PC-specific PLC, TNFα induced DAG release, turning on A-SMase. A-SMase has been proposed also to mediate Fas-induced apoptosis (40). On the other hand, evidences against the involvement of A-SMase in the TNFα and IL-1β induced SM cycle were reported by other authors (41). Finally, A-SMase knock-out mice have reproduced a phenotype similar to the type A Niemann-Pick disease and they showed resistance to radiation-induced apoptosis (62).

CERAMIDASES

Ceramidase activity hydrolyzes ceramide into free sphingoid base (sphingosine) and fatty acid. Therefore, it may represent a very important tool in order to modulate the switch between ceramide- and sphingosine-regulated biology. In spite of this potential major role, not much is known about their biochemical and biological regulation even if some of the forms have been purified and cloned. In the literature, different forms of ceramidases have been reported, mainly based on different pH profiles.

Acid ceramidase. Acid ceramidase activity is assumed to be ubiquitous (rat brain, liver, kidney, and human skin fibroblasts, spleen, kidney, brain, leukocytes) and to play a housekeeping role being localized in the lysosomes (42). Its optimal pH ranges between 4.0 and 5.0. This type of activity was the first ceramidase to be purified and cloned (43). Acid ceramidase activity does not seem to be affected by phospholipid addition, while saposin D was shown to activate *in vivo* and less clearly *in vitro* (44). On the other hand, *N*-oleoylethanolamine is recognized as an acid ceramidase inhibitor even if its inhibitory effect is rather weak and at very high concentrations (44). Substrate specificity studies showed preference for ceramides with unsaturated fatty acids (45); moreover, the preferred fatty acyl chain would carry 12 carbons, while increasing or decreasing chain length would result in loss of activity (46). The main biological significance for acid ceramidase is its association with lipogranulomatosis or Farber's disease, evolving when this ceramidase activity is impaired (42). Interestingly, this kind of disease is also observed when normal saposin D is absent (47).

Alkaline ceramidase. Less is known about alkaline ceramidase. Its activity was reported in rat cerebellum and liver, in human fibroblasts and brain, in guinea pig skin, and porcine epidermis (44). It is a membrane-bound enzyme, possibly localized in the plasma membrane, with an *in vitro* pH optimum ranging between 8.0 and 9.0 (44). Nowadays, two alkaline ceramidases were purified from guinea pig skin (48): the first one (CDase I) purified to homogeneity with pH optimum around 7–10, the second (CDase II) partially purified with pH optimum around 8–9. Contrary to acid ceramidase, saposin D, as well as the A, B, and C forms, do not have any effect on alkaline activity (49). On the other hand, a ceramide analog (1*S*,2*R*)-D-erythro-2-(*N*-myristoylamino)-1-phenyl-1-propanol was shown to be a potent inhibitor of alkaline ceramidase in HL-60 cells (at lower concentrations than *N*-oleoylethanolamine), with no effect on acid ceramidase activity (50). The implication of alkaline ceramidase in mediating sphingolipid signaling became evident when the cellular response to growth factors ([Platelet Derived Growth

Factor (PDGF), Fibroblast Growth Factor (FDF), Epidermal Growth Factor (EDF)] was investigated in Swiss 3T3 and vascular smooth muscle cells (44). In this model, ceramide degradation and sphingosine accumulation accompanied the growth factor- induced proliferative effect. Induction of alkaline ceramidase by growth factors seems to be subsequent to tyrosine kinase phosphorylation (44). Cytokines (TNFα, IL-1β), on the other hand, are more directly involved in SMase induction and do not stimulate ceramidases activation.

Neutral ceramidase. Neutral ceramidase activity is poorly characterized from every point of view. Ceramidase activity, ranging in neutral pH, is reported in rat liver plasma membrane and microsomes and rat intestinal brush border membrane (44). One problem in studying neutral and alkaline ceramidases is the rather broad range of pH in which these enzymes work, so that it is difficult to discriminate between the two forms considering only this parameter. On the other hand, the high affinity shown by the neutral ceramidase toward very short- (C2) or long-chain ceramides (C16) represents a tool which can be efficiently used for this purpose (51). Until now, there are no reports on neutral ceramidase involvement in signal transduction events.

SM SYNTHASE

Mechanisms of *in vivo* SM biosynthesis have been somewhat controversial over the past years, and different biochemical routes have been proposed. At first, CDP-choline was suggested to be the donor of the phosphocholine moiety to ceramide (52); then, the acylation by stearoyl-CoA of sphingosylphosphorylcholine was considered (53). Finally, *in vitro* (5,6) and most importantly *in vivo* cellular labeling studies (6,54) established the existence of a preferred biochemical pathway which transfers the phosphorylcholine unit directly from PC to ceramide. This reaction is catalyzed by the PC:ceramide phosphocholine transferase (SM synthase) and leads to SM and DAG formation. SM synthase activity has been reported in mouse and rat kidney, lung, liver, and spleen and in monkey liver and heart (5,32,55); on the other hand, in the brain, SM synthesis may pass through phosphatidylethanolamine instead of PC (5). Subcellular fractionation studies characterized SM synthase as a membrane-bound enzyme with an intracellular orientation of the active site (56). In liver most of the activity seems to be localized in the Golgi apparatus (>80%), with the remainder mainly distributed between plasma membrane and endoplasmic reticulum (55). On the other hand, SM synthase localization in cellular models shows more variability. For instance, it was reported that in SV40-transformed fibroblasts (57), oligodendrocytes (58), and BHK cells (59), plasma membrane SM synthase shows a higher relative activity compared to the one that resides in the Golgi. *In vitro* studies indicated no strong dependency of the activity on the presence of divalent cations in the incubation mixture (6). The enzyme shows a pH optimum around 7.4 when Tris buffer is used and around 6.5 in the presence of imidazole buffer (5). SM synthase is one of the less-studied enzymes along the sphingolipid pathway, and little is known about its involvement in ceramide-mediated signal transduction events. On the other hand, because of the direct regulation of ceramide and DAG levels, its biological importance in directing a cell toward cell cycle progression or growth arrest is more than reasonable. Elevation of SM synthase activity (seven- to ninefold) was recently observed in malignant conditions, such as Morris hepatomas (60). Moreover, recent studies (60) showed that SV40-transformation induced a significant increase of SM synthase activity in human lung fibroblasts. *In vivo* metabolic labeling with a short-chain ceramide analog and *in vitro* measurements showed a twofold increase of SM synthase activity in SV40-transformed fibroblasts compared to the normal counterpart. Interestingly, when elevation of a specific pool of cellular ceramide, localized in the plasma membrane, was induced by bacterial SMase treatment, normal fibroblasts were completely unable to produce SM from it, while the SV40-transformed cells actively metabolized this ceramide, converting it back to SM. These results may suggest the possibility that SV40 transformation would induce a form of SM synthase that resides in the plasma membrane or in functional proximity to it. This would indicate that different forms of SM synthase may have different targets and eventually different biological effects (*de novo* synthesis for the enzymatic activity in the Golgi and signal transduction for the one in the plasma membrane). As a consequence of the elevated SM synthase activity in SV40-transformed cells, a decrease of the intracellular ceramide levels and an increase of DAG levels occurred. The regulation of intracellular ceramide/DAG ratio makes SM synthase an important "biostat" in the regulation of cell viability/cell death. Another important feature of this enzyme is its reported inhibition by the putative PC-PLC specific inhibitor, D609 (60). PC-PLC is thought to play an active role in signal transduction events regulating DAG formation (39). On the other hand, no genuine evidence of the real existence of the PC-PLC has been produced. Interestingly, SM synthase and PC-PLC share several biochemical and biological characteristics (DAG formation from PC, increased activity in transformed phenotype (61), inhibition by D609); thus, these considerations raise the question whether the biological events that until now have been attributed to the PC-PLC may be partially due to the SM synthase.

CONCLUSIONS

In conclusion, the study of signaling and cell regulation through ceramide has now evolved to the biochemical level by focusing on specific enzymes of ceramide metabolism. A general hypothesis can be presented whereby individual enzymes of ceramide metabolism serve as input points in the regulation of ceramide levels (Scheme 1). For example, activation of SMases or ceramide synthase would elevate ceramide levels and activate ceramide-induced responses. On the other hand, activation of enzymes of ceramide degradation or incorporation such as ceramidases or SM synthase decreases and attenuates ceramide levels. Also, as an important

corollary, some of these enzymes may play an additional fundamental role in interconverting lipid signals. For example, SM synthase has the capacity of interconverting a ceramide signal into a DAG signal, whereas ceramidases can transform a ceramide signal into a sphingosine or sphingosine-phosphate signal. This area of research promises great future insight into important areas of cell studies.

Lipids in Vascular Function

Alois Sellmayer*, Nina Hrboticky, and Peter C. Weber

Institut für Prophylaxe und Epidemiologie der Kreislaufkrankheiten, Klinikum Innenstadt, University of Munich, 80336 Munich, Germany

ABSTRACT: Physiological and pathological vascular responses depend on the action of numerous intercellular mediators, ranging from hormones to gases like nitric oxide, proteins, and lipids. The last group consists not only of the different types of lipoproteins, but also includes a broad array of other lipophilic signaling molecules such as fatty acids, eicosanoids, phospholipids and their derivatives, sphingolipids and isoprenoids. Due to space limitations, it is impossible to discuss all the vascular effects of lipophilic mediators or compounds. Therefore, we will focus on one of the most important lipid-mediated diseases, atherosclerosis. Lipoproteins and especially their native or oxidized lipid compounds affect vascular function in many different ways, and these effects do not only modulate atherogenesis but are of paramount physiological and pathophysiological importance in other diseases, such as inflammation, tumor metastasis, or normal wound healing.

Hypercholesterolemia, as defined by increased levels of low density lipoproteins (LDL), was found to alter vascular function in an atherogenic way. This includes disregulated endothelium-dependent vasodilation or contraction, hypercoagulability, enhanced platelet reactivity, as evidenced by increased *in vivo* formation of thromboxane A_2 and increased recruitment of inflammatory cells into the vessel wall. Lowering cholesterol not only reverses these adverse effects but also reduces the incidence of major cardiovascular events, demonstrating a key role for LDL and/or its oxidized derivatives mildly modified LDL (mmLDL) and thoroughly oxidized LDL (oxLDL) in atherosclerotic vascular dysfunction. On the cellular level, a complex network of molecular processes associated with plaque formation and progression is activated by LDL and oxidatively modified LDL, and their bioactivity can at least in part be mimicked by native or oxidized lipid components present in these lipoproteins.

LDL and intracellular arachidonic acid. Native LDL, which is taken up by almost all cell types *via* receptor-mediated endocytosis, induces the activation of key intracellular signaling pathways, such as protein kinase C (PKC), mitogen-activated protein (MAP) kinases, and the transcription factors activating protein-1 (AP-1) and nuclear factor κB (NFκB). These in turn trigger the expression of proatherosclerotic factors and cellular responses (for reviews, see Refs. 1–4). The most relevant are the increased synthesis of platelet-derived growth factor (PDGF) and of the adhesion molecule intracellular adhesion molecule 1 (ICAM-1) by endothelial cells, which stimulate growth of endothelial and smooth muscle cells and increase monocyte adhesion, respectively. In parallel, production of the vasodilator nitric oxide (NO) is reduced, whereas formation of superoxide anion (O_2^-) is increased, shifting the vascular response to a more contractile state.

In addition to these cellular processes, native LDL also delivers polyunsaturated fatty acids (PUFA), especially linoleic acid and arachidonic acid, to cells. These fatty acids can be incorporated and stored in membrane phospholipids, serve as precursors for eicosanoids, or may act as intra- or intercellular messengers, modulating inflammatory, atherogenic and mitogenic responses. Accordingly, arachidonic acid derived from intracellular stores or from extracellular sources was found to enhance O_2^- generation in monocytic cells by increasing the assembly of the NADPH oxidase (5). In fibroblasts, the 5-lipoxygenase products of arachidonic acid were implicated in the transduction of growth factor-induced cytoskeletal rearrangements and possibly in cell migration by the activation of rho (6). Arachidonic acid and its enzymatically oxygenated derivatives, the eicosanoids, were also found to modulate the activity of other important intracellular signaling pathways, such as adenylate and guanylate cyclases, G-proteins, or various protein kinase pathways including PKC, MAP kinases, tyrosine kinases, and protein kinase A (PKA; for reviews, see Refs. 7,8). Downstream of these signaling pathways, transcription factors such as AP-1, NFκB or the peroxisome proliferator-activated receptors (PPAR) are activated (9). These transcription factors may then stimulate expression of the immediate early response genes c-fos, c-jun or Egr-1 or late response genes, coding for tumor necrosis factor-α, the receptor for the macrophage colony-stimulating

factor (M-CSF) or interleukin-8 (7). Increased expression of c-fos and Egr-1 by cellular as well as extracellular arachidonic acid was linked to the induction of cell growth in fibroblasts (10), whose increased proliferative response may be associated with the early restenosis of atherosclerotic vessels after deep injury of the vascular wall by angioplasty.

Eicosanoids. LDL-derived or cellular arachidonic acid can be enzymatically oxygenated by cyclooxygenases, lipoxygenases, or cytochrome P450 monooxygenases, resulting in the formation of eicosanoids. These are highly active local mediators which affect vascular responses in often complex and opposing ways (for reviews, see Refs. 11–14). Depending on the cell types involved and on the transcellular exchange of precursors, eicosanoids may promote and increase inflammatory and atherogenic responses or may inhibit them. The classical vasoactive eicosanoids are the endothelium-derived antiaggregatory and vasodilatory prostacyclin and its direct platelet- or monocyte-derived counterpart thromboxane A_2 which induces platelet aggregation and vasoconstriction. In addition, prostaglandin E_1 (PGE_1) and PGE_2 have vasodilatory effects, whereas $PGF_{2\alpha}$ and the leukotrienes C_4 and D_4 are vasoconstrictors. Formation of leukotriene C_4 (LTC_4) was not only observed in monocytes or macrophages, but also in endothelial cells after transcellular uptake of the epoxide precursor LTA_4 produced in neutrophils. The other main leukotriene, LTB_4, is synthesized in activated neutrophils and monocytes and is a primary mediator of inflammatory processes, stimulating neutrophil degranulation, chemotaxis, and O_2^- generation. LTB4 also facilitates neutrophil adhesion to the endothelium by increasing the expression of the granulocyte adhesion molecule CD11b/CD18 (MAC-1; for review, see Ref. 13) and by enhancing the binding affinity of the endothelial counterreceptor ICAM-1 (15). Increased adhesion of neutrophils to endothelial cells is the first step in neutrophil extravasation into the subendothelial space such as in inflammatory responses and enables transcellular arachidonic acid metabolism.

A novel group of lipoxygenase-derived eicosanoids whose vascular activity was only recently identified is the lipoxins, LxA_4 and LxB_4 (for review, see Ref. 16) These trihydroxylated derivatives of arachidonic acid are generated through the dual oxygenation by 15- and 5-lipoxygenases or 5- and 12-lipoxygenases, respectively. Since these lipoxygenases are usually expressed in different cell types, Lx synthesis depends mainly on the transcellular exchange of intermediates between monocytes and neutrophils or neutrophils and platelets. Such cellular interactions will arise in inflammatory or atherogenic activation and after endothelial wounding. Lx are vasodilatory and anti-inflammatory, since they reduce neutrophil activation, expression of CD11b/CD18, and neutrophil transmigration across the endothelium. In contrast, they were found to be chemotactic for monocytes and to increase monocyte adherence, a response which may be important in early atherogenesis.

Another not yet well-characterized group of eicosanoids, the cytochrome P450 monooxygenase-derived metabolites epoxyeicosatrienoic acids (EET) and 19- or 20-hydroxyeicosatetraenoic acids (19- or 20-HETE), also deserve brief discussion because of their putative vascular effects. Apart from their enzymatic generation by the cytochrome P450 monooxygenase system, EET may also be formed by a free radical attack of arachidonic acid. Furthermore, LDL in atherogenic concentrations stimulated EET synthesis in endothelial cells (17) and EET were detected in LDL (18). EET were found to induce vasodilation (19) and to reduce platelet aggregation (20), but also to enhance monocyte adhesion to the endothelium (21) and to increase cell growth in nonvascular cells (22). 19- and 20-HETE, which can also be formed by nonenzymatic oxidative modification of arachidonic acid, function as vasoconstrictors in different animal models (for review, see Ref. 23). Further investigation is required to definitely delineate the vascular effects of these compounds *in vivo*, but it is indicated that they may exert an important modulatory role in inflammation and atherogenesis, especially with regard to their formation by free radical attack of lipoproteins or cellular phospholipids.

n-3 PUFA. Epidemiologic studies indicate that long-chain n-3 PUFA reduce cardiovascular events and possibly atherosclerosis. Given the important roles of prostacyclin and thromboxane A_2 in vascular function and the observations that n-3 PUFA reduce the formation of active thromboxanes while not altering the production of prostacyclins (as PGI_2 and PGI_3 are equally active), this shift in prostanoid synthesis may be one decisive mechanism through which n-3 PUFA protect from cardiovascular disease. Additional studies revealed that n-3 PUFA do not only affect the vascular tone and platelet aggregation (for reviews, see Refs. 24–26). They reduce the formation of cytokines and growth factors in monocytes, decrease the expression of adhesion molecules and of PDGF in endothelial cells, and subsequently also reduce adhesion of monocytes to endothelial cells (27). They increase NO production in endothelial cells and inhibit mitogenesis in smooth muscle cells and fibroblasts. Similar to arachidonic acid, n-3 PUFA were also found to act as intracellular second messengers (for review, see Refs. 8,28). They are at least in part antagonistic to arachidonic acid and reduce the activation of cellular signaling pathways involved in inflammatory and mitogenic responses, such as the formation of inositol phosphates, release of intracellular calcium, activation of PKC and growth-related early gene expression (29). On the other hand, activation of the NADPH oxidase and generation of superoxide anion are stimulated by both n-3 and n-6 PUFA in monocytic cells. In addition, when incorporated into LDL at high levels, n-3 PUFA may render LDL more susceptible to oxidation and thus may trigger proatherogenic responses. Whether this effect is relevant *in vivo* depends on cellular and plasma antioxidant status (30). Thus, n-3 PUFA may have the potential to reduce atherogenic vascular dysfunction as long as they are in balance with other protective factors, especially with lipid-soluble antioxidants.

Oxidized LDL. LDL deposited in the subendothelial space are oxidatively modified by cell-derived oxygen free radicals or cellular enzymes such as monocytic 15-lipoxygenase, re-

sulting in the oxidation of cholesterol and the esterified PUFA. The oxidative modification of LDL can be mimicked *in vitro*, leading to the formation of either mmLDL or thoroughly oxLDL. It was suggested that in the early stages of atherogenesis, primarily mmLDL may be generated, whereas in later stages with a pronounced inflammatory reaction, oxLDL will be formed. Although mmLDL binds to the LDL receptor and oxLDL to a member of the scavenger receptors, their effects on vascular cells are very similar and result in the activation of prothrombotic, proinflammatory, and mitogenic responses (Table 1; for review, see Refs. 1–4). Through the activation of intracellular protein kinase systems and transcription factors such as NFκB or AP-1, they induce the expression of cellular adhesion molecules on endothelial cells and monocytes, and stimulate the synthesis of monocyte chemoattractant protein-1, as well as of cytokines and growth factors, in particular PDGF, and procoagulant factors like tissue factor or plasminogen activator inhibitor-1 in vascular cells. Oxidized LDL induces a vasoconstrictive state, reducing the formation of the endothelium-derived vasodilators NO and PGI_2, while enhancing the production of the vasoconstrictor endothelin. In the subendothelial space, the unregulated uptake of oxLDL by monocyte-derived macrophages reduces macrophage migration and leads to their transformation to one of the hallmarks of atherosclerotic lesions, the foam cells. In low concentrations, oxLDL induces smooth muscle cell growth, whereas in high concentrations it is cytotoxic. Furthermore, oxLDL is chemotactic for monocytes and T-cells. Monocytes or macrophages may then present antigenic epitopes of oxLDL to B-cells, inducing the formation of anti-oxLDL antibodies and an immune reaction toward deposited oxLDL.

Vasoactive components of oxidatively modified LDL. The vascular effects of oxidized LDL, well-characterized *in vitro* and to a great part *in vivo*, clearly delineate key pathophysiological events leading to atherosclerotic lesions. However, it is not yet well-understood which components present in mmLDL or oxLDL activate these processes. During oxidation of LDL, the apolipoproteins, cholesterol, and the unsaturated fatty acids esterified in phospholipids or present as cholesterol-esters can be modified. Whereas modification of the apolipoproteins seems to play only a minor role in the vascular responses, oxidized lipid components of LDL were found to activate cellular responses similar to those of mmLDL or oxLDL. Oxidatively modified LDL contains various oxidized derivatives of cholesterol, the oxysterols 7-hydroxycholesterol, 7-ketocholesterol or 5α,6α-epoxycholesterol, as well as a number of highly active oxidation products of PUFA, such as aldehydes, monohydroxylated fatty acids, epoxides or isoprostanoids (31–33). During oxidation of LDL, endogenous phospholipase A_2 activity is increased, leading to the cleavage and release of these oxidized vasoactive metabolites and to the formation of lyso-phosphatidylcholine. In addition, vasoactive platelet-activating factor (PAF)-like phospholipids (34) and phosphatidylcholine derivatives in which arachidonic acid in the *sn*-2 position was oxidized to oxovaleric or glutaric acid were detected in oxidatively modified LDL (35). Table 2 summarizes important vascular effects of oxidized lipid components in mmLDL or oxLDL. Taken together, most of these derivatives activate endothelial cells, smooth muscle cells and monocytes, resulting in increased monocyte and endothelial cell adhesiveness, the generation of proinflammatory mediators and growth factors, and in the induction of cell growth. They also facilitate vasoconstriction, thrombosis, and platelet aggregation and thus stimulate *in vitro* many of the processes associated with atherogenesis.

Statins and isoprenoids. Lowering cholesterol by any kind of intervention will reduce the incidence of cardiovascular events not only in hypercholesterolemic subjects but also in normocholesterolemic persons with additional risk factors. The most effective drugs available today are the statins, which inhibit HMG-CoA reductase and thus cholesterol and also isoprenoid synthesis. It is assumed the beneficial effects of statins derive from the reduction in cholesterol levels alone. However, additional clinical and laboratory investigations demonstrated that statins modulate vascular responses by other mechanisms as well (for review, see Refs. 36,37). Statins reduce the expression of the monocyte adhesion molecule CD11b and monocyte adhesion to endothelial cells; they inhibit cell growth in smooth muscle cells and induce differentiation of monocytic cells. In hepatic and monocytic cells, statins increase desaturation and elongation of n-6 and

TABLE 1
Vascular Effects of mmLDL and oxLDL[a]

Cell type	mmLDL	oxLDL
Endothelium	Increased expression of CAM, MCP-1, M-CSF, G-CSF, tissue factor	Increased expression of CAM, MCP-1, tissue factor, PAI-1, endothelin cytotoxicity
		Reduced formation of NO, PGI_2, t-PA
Smooth muscle	Increased expression of MCP-1 cell retraction	Increased expression of MCP-1, PDGF, tissue factor
		Cell growth or cytotoxicity, chemotaxis
Monocytes	Increased expression of CD11b, IL-1 cytokines	Increased expression of CD11b, MCP-1, tissue factor, TNF-α chemotaxis
Plateles	Aggregation	

[a]CAM, cellular adhesion molecules; MCP-1, monocyte-chemoattractant protein-1; M-CSF, monocyte colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; PAI-1, plasminogen activator inhibitor 1; t-PA, tissue-type plasminogen activator; PDGF, platelet-derived growth factor; IL-1, interleukin 1; TNF-α, tumor necrosis factor-α; NO, nitric oxide; PG, prostaglandin; LDL, low density lipoprotein; oxLDL, oxidized LDL; mmLDL, mildly modified LDL.

TABLE 2
Vascular Effects of Oxidized Lipid Components in Oxidatively Modified LDL[a]

Oxidized lipid	Vascular effects
Oxysterols	Apoptosis in endothelial cells
Aldehydes (e.g., 4-hydroxynonenal)	Mitogenic for vascular smooth muscle cells; cytotoxic for endothelial cells; chemotactic for neutrophils and monocytes; stimulation of platelet aggregation and foam cell formation
19- or 20-HETE	Vasoconstriction
9- or 13-HODE	Increased eNOS expression, vasorelaxation
Epoxides	Vasodilation; induction of cell growth; increased monocyte adhesion
Isoprostanoids	Vasoconstriction; induction of smooth muscle cell and fibroblast growth; stimulation of platelet activation; priming platelet aggregation
Lyso-phosphatidylcholine	Increased expression of adhesion molecules, PDGF, MCP-1 and COX-2 in endothelial cells; increased expression of CD11b in monocytes; monocyte chemotaxis; induction of smooth muscle cell growth
PAF-like phospholipids	Increased neutrophil adhesion to endothelial cells
Oxidized phosphatidylcholine	Increased monocyte adhesion to endothelial cells

[a]HETE, hydroxy-eicosatetraenoic acid; HODE, hydroxy-octadecadienoic acid; PAF, platelet-activating factor. See Table 1 for other abbreviations.

n-3 PUFA, increasing the formation and cellular availability of arachidonic acid (38). Statins also decrease the expression of the scavenger receptors type I and II and of CD36 in monocytic cells, reduce the expression of tissue factor in macrophages, and inhibit superoxide anion generation in macrophages. *In vivo*, treatment with statins reduces platelet aggregation and plasma fibrinogen levels, and normalizes endothelial dysfunction, the latter probably by increasing NO formation. Many of these effects are most likely secondary to the lowering of serum cholesterol levels. However, some may be a consequence of a reduced generation of isoprenoids. Isoprenoids, such as all-*trans*-geranylgeranyl or all-*trans*-farnesyl moieties, bind to proteins, making the latter more lipophilic and enabling their interaction with lipophilic molecules (for review, see Ref. 39). Isoprenylation of signaling molecules such as heterotrimeric G-proteins or small G-proteins of the *ras* family allows for their translocation to the plasma membrane and transduction of receptor-dependent signals to the cytosol and nucleus. Accordingly, it was found that the growth inhibitory effects of statins in mesangial cells are based on reduced isoprenoid formation, since only all-*trans*-farnesol and all-*trans*-geranylgeranyl which are not precursors of cholesterol were able to overcome the inhibition (40). Since a reduction in cardiovascular events by statins is often observed already after a few months of therapy and not after some years as would be expected by plaque regression, altered cell activation by reduced isoprenylation of signaling molecules may be an additional mechanism underlying the protective effects of statins in vascular function.

HDL. HDL play a protective role in cardiovascular disease. This has been mainly attributed to their involvement in reverse cholesterol transport, enabling the removal of cholesterol from peripheral cells and the reduction of LDL entry into the vessel wall. However, HDL was found to have additional beneficial effects on vascular function. HDL reduces LDL oxidation and cellular responses to oxidized LDL, such as generation of PAF (41) or adhesion molecule expression in endothelial cells (42), while restoring prostacyclin synthesis (43). Further research will probably uncover additional molecular mechanisms which may explain the protective effects of HDL.

Other vasoactive lipids. In addition to the lipids discussed above, numerous other lipid molecules modulate vascular function either on an intercellular or intracellular level. Two other atherogenic lipoproteins, lipoprotein (a) [Lp(a)] and triglycerides in very low density lipoproteins or chylomicrons were found to directly affect vascular responses. Lp(a) was suggested to inhibit fibrinolysis due to its kringel-like domains which resemble plasminogen (for review, see Ref. 44). Lp(a) can compete with plasminogen for its activation by tissue-type plasminogen activator and increases endothelial cell expression of plasminogen activator inhibitor. Lp(a) also induces the expression of ICAM-1 on endothelial cells (45), and oxidized Lp(a) stimulates adhesion of monocytes to the endothelium (46), effects which may explain in part its role in atherogenesis. Similar effects were observed for triglycerides in endothelial cells. They induce expression of the adhesion molecules vascular cell adhesion molecule 1 and E-selectin and increase monocyte adhesion (47). Interestingly, triglyceride levels are lowered by n-3 PUFA *in vivo*. A further important mediator in vascular processes, in particular in inflammation, is the PAF (for review, see Ref. 48). PAF does not only stimulate platelet activation and aggregation but also induces vasoconstriction, expression of endothelial cell adhesion molecules, and the activation of neutrophils and monocytes as evidenced by their formation of LTB_4, O_2^- and cytokines and their adhesion to endothelial cells. Furthermore, saturated fatty acids or *trans* fatty acids also modulate vascular responses by as yet not well-characterized mechanisms. At the intracellular level, signaling in vascular cells is not only affected by PUFA or isoprenoids but also by the classical lipid second messengers inositolphosphates or by the activation of the sphingomyelin/ceramide pathway, leaving room for additional mechanisms for lipids to modulate vascular function.

Concluding remarks. Lipids in their broadest sense can affect vascular responses and vascular function in numerous ways, stimulating or inhibiting cellular processes which are associated with atherogenesis, inflammation, wound healing, or tumor metastasis. These effects of lipids help to maintain the physiologic vascular responses or restore normal vascular function after injury, but may also promote vascular damage if additional factors, such as hypercholesterolemia and oxidation of lipoproteins, are active. Further delineation of mechanisms underlying the vasoactivity of lipids will help to better understand pathophysiological mechanisms and to design effective therapeutic or preventive strategies in vascular diseases.

Dietary Fatty Acids and Coronary Heart Disease

Arne Nordøy
Department of Medicine, Institute of Clinical Medicine, University of Tromsø, N-9038 Tromsø, Norway

ABSTRACT: The effects of dietary fats have been established in epidemiological and intervention studies and through relationship to risk factors for development of coronary heart disease (CHD). During a period where the impressive effects of hydroxymethylglutaryl-CoA reductase inhibitors on the mortality of CHD dominate the medical journals, it is important to realize the major effects of dietary fatty acids on a series of events included in the multifactorial disorder of CHD.

During the last few years, four secondary and primary prevention studies on the morbidity and mortality of coronary heart disease (CHD) documented the effects of statins, the hydroxymethylglutaryl-CoA reductase inhibitors (1–4). A meta-analysis on the effects of cholesterol reduction after the introduction of statins predicts that for every 10 percentage points of cholesterol lowering, CHD mortality risk is reduced by 15% ($P <$ 0.001) and total mortality risk by 11% (5).

During the last 50 yr, many dietary intervention studies (for review see Ref. 5) were designed to establish potential effects on CHD by modulating the dietary intake of fatty acids and cholesterol. In summary, these studies showed that by reducing the intake of saturated fatty acids and cholesterol in the diet and partly substituting them with mono- or polyunsaturated fatty acids, both serum cholesterol and the risk for developing CHD are reduced. In the present situation, the question arises. Do the new potent hypocholesterolemic drugs make dietary intervention less important? This question is certainly relevant in a period where both patients and physicians are overwhelmed by the impressive results of the drug intervention trials.

It is important to stress that CHD still is the most common cause of death globally in both males and females. Less than 40% of the fatalities, however, can be associated with traditional coronary risk factors, including high levels of serum cholesterol. Also the statin intervention studies suggest that even with these drugs effects other than cholesterol lowering may be of significance. The reduction in mortality could not be explained on the basis of only cholesterol. Furthermore, looking upon the geographical distribution of CHD and relating that to dietary traditions, the Seven Countries Study clearly indicates that the risk associated with a certain cholesterol level is much higher in the northern European countries than in the countries in southern Europe and even more so in Japan (6). This study clearly indicates that factors other than cholesterol may be heavily involved in the pathogenesis of CHD.

Dietary fats and CHD. Only anecdotal reports associated dietary fats with development of atherosclerosis and cardiovascular disease until after World War II (7). The fall and subsequent rise in CHD mortality during and after the war in Norway were correlated with lower consumption of animal fats and higher consumption of cereals, vegetables, and fish during the war years (8). This change was also associated with the fall and rise in the frequency of postsurgical venous thrombosis, probably indicating a relationship between the occurrence of venous thrombosis and arterial vascular disease. During the following years, a series of studies associating dietary fats with serum cholesterol levels initiated by the studies of Keys and the Framingham Study later confirmed a close relationship between intake of dietary fats and the occurrence of CHD (9,10). Also the dietary changes among the Japanese due to westernization of the traditional diet or to emigration to areas with different dietary habits support these associations (11). More than 20 yr ago the studies by Dyerberg *et al.* (12) in the Greenland Eskimos suggested that the intake of n-3 polyunsaturated fatty acids was significant in preventing CHD. In more recent studies, the development in eastern European countries was of special interest. The morbidity and mortality of CHD were increased, and at the same time diets rich in fats from animals sources were dominant in regard to nutrition (13).

Recently, the Nurses Health Study including more than 80,000 nurses confirmed the association between intake of saturated fatty acids and also of *trans* unsaturated fatty acids and CHD, whereas monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFA) had the opposite effect (14). Also other studies showed a similar pattern; however, the protective relationship with MUFA was not confirmed in all studies; the beneficial effects of very high intake of n-6 PUFA were questioned (15). Of special interest are the epidemiological studies suggesting that intake of small amounts of n-3 fatty acids in certain populations seems to have a protective effect against development of CHD, whereas in other populations with a traditionally high intake of n-3 fatty acids no such relationship was established. These last epidemiological observations certainly indicate that the interplay between the various dietary fatty acids is of prime importance for understanding the relationship between dietary fatty acids and CHD (for review see Ref. 16).

It has been estimated that at least half of the deaths caused by CHD result from electrical instability of the heart, culminat-

Lipids 34, S19–S22 (1999).

Abbreviations: CHD, coronary heart disease; MUFA, monounsaturated fatty acid; PUFA, polyunsaturated fatty acid.

ing in ventricular fibrillation. Studies in cardiac myocytes and in animals following partial occlusion of coronary arteries indicate that saturated fatty acids could promote ventricular arrhythmia, whereas n-3 and n-6 PUFA have antiarrhythmogenic effects (17,18); n-3 PUFA seem to be more potent. A population-based case–control study including 334 patients with primary cardiac arrest and 493 control subjects seems to confirm the experimental studies (19). Compared with no intake of n-3 PUFA, an intake of 5.5 g/mon or one fatty fish meal per week was associated with a 50% reduction in the risk of primary cardiac arrest. Compared with the red blood cell membrane n-3 PUFA levels of 3.3% of total fatty acids, a level of 5.0% of total fatty acids was associated with a 70% reduction in the risk of primary cardiac arrest. Two dietary intervention studies seem to confirm this observation (20,21).

Intervention studies. The intention of all the intervention studies performed to date in humans was to determine whether reduction in CHD can be produced by modulation of the diet. No distinction was made as to whether thrombosis, athersclerosis, or both or other factors were altered. As thrombosis was shown to be present in more than 90% of patients with acute coronary events, the results of the intervention studies may reflect effects on atherosclerosis, thrombosis, and possibly also on other factors like inflammation and myocardial vulnerability.

The dietary intervention studies included reduction in blood cholesterol as secondary endpoints. An analysis of randomized trials evaluating the effect of the dietary-induced cholesterol reduction on total mortality and incidence of CHD concluded that for 1% reduction in cholesterol an estimated 2.5% reduction in CHD incidence was observed (5). The subjects were included from both secondary and primary prevention trials. Many of these trials were designed on the use of combined drug and dietary interventions.

A large multiple risk factor intervention trial was designed to reduce over a period of 6 yr three major risk factors in middle-aged men who were at increased risk for CHD: elevated serum cholesterol, increased blood pressure, and excessive cigarette smoking (22). A significant reduction in risk factors was accomplished in the intervention group, but there was also a less-pronounced reduction in the control group. In both groups the survivors had a greater reduction in serum cholesterol than in those participants who ultimately died from CHD, suggesting that the reduction of serum cholesterol induced by changes in the diets was associated with a lower mortality from CHD. However, the MRFIT study was inconclusive in respect to overall mortality from CHD (22). The primary intervention trial carried out by the Oslo Study Group lasted 8.5 yr and included 1,200 high-risk men (23,24). This trial showed that the reduction of total fat intake from 41 to 28% of calories and an assumed change in the polyunsaturated/saturated ratio from 0.4 to approximately 0.7 reduced CHD events, including CHD death and sudden death by approximately 50%. The reduction in polyunsaturated/saturated ratio was caused mainly by a reduction of saturated fatty acids. Approximately 75% of the beneficial effects observed in the Oslo Study appeared to be due to the changes in long-term dietary habits of the participants, whereas 25% were related to changes in smoking habits.

In most dietary intervention studies, saturated fat was replaced by an increased intake of PUFA of the n-6 family. Subsequent analysis, however, indicated that most of the beneficial effects of these dietary manipulations were related to a reduced intake of saturated fats. The Diet and Reinfarction Trial (DART) including 2,033 men who had recovered from myocardial infarction showed that subjects advised to eat fatty fish had a 29% reduction in 2 yr all causes mortality compared with those not so advised or advised to reduce fat intake only (20). The incidence of sudden death plus death rate from CHD was not significantly affected. The Lyon Study including 605 survivors of a recent first myocardial infarction (303 controls and 302 study patients) who were followed over a period of 27 mon (21). Those in the study group had been on a Mediterranean-type diet which included less than 10% of energy as saturated fat, less than 5% of energy as linoleic acid, and more than 0.6% of energy as α-linolenic acid. When primary and secondary end points were combined, the study showed a risk reduction of 76%. Interestingly, no significant reduction in cholesterol levels was observed compared with the control group.

Finally, dietary intervention with n-3 fatty acids on graft potency in patients undergoing coronary artery bypass and followed by angiographic evaluation showed more open grafts 1 yr after the procedure in a study, including 600 patients given 4 g of 85% eicosapentaenoic acid and docosahexaenoic acid (ethylester) in addition to aspirin or warfarin. No conclusive evidence indicates that supplement with n-3 fatty acids prevents the occurrence of restenosis after percutaneous transluminal coronary angioplasty (for review see Ref. 16).

Dietary fatty acids and risk factors for CHD. It has been well documented not only that dietary fatty acids may modify well-established coronary risk factors like blood lipid levels, blood pressure, and hemostatic variables associated with increased tendency to thrombosis but also that a high intake of saturated fatty acids in the diet has been documented as an independent risk factor for CHD.

In the present context it is significant that, whereas lipid-lowering drugs like the statins lower low density lipoprotein cholesterol levels, increase high density lipoprotein-cholesterol, and reduce triglycerides, modulation of the dietary fatty acids with reduction in saturated fatty acids and eventually an increase in MUFA and/or PUFA particularly of the n-3 family may induce similar or occasionally even more pronounced changes in blood lipid levels. In addition these fatty acids have metabolic effects which may reduce blood pressure in patients with hypertension, reduce the consequences of postprandial hyperlipemia which in itself represents an independent risk factor, and modulate cell structure and function leading to metabolic consequences in every cell in the body. It may turn out that these cellular adaptations to nutrition may be of greater importance for the development of coronary events than the reduction of traditional risk factors.

The combined effect of n-3 fatty acids and statins. In recent studies the combined effects of long chain n-3 fatty acids from

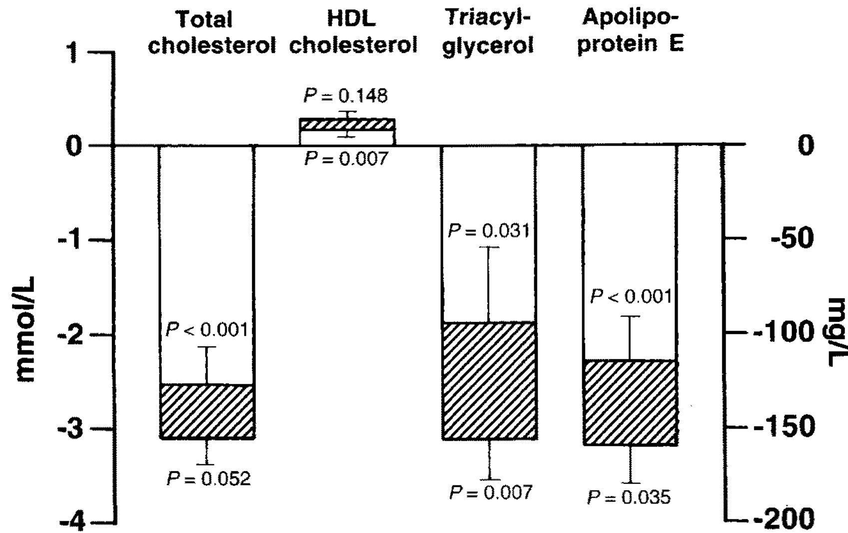

FIG. 1. Effects of Simvastatin (20 mg/d) and additional effects of n-3 fatty acids (Omacor[R]) (4 g/d) in 21 patients with combined hyperlipemia treated for 5-wk periods compared to 20 patients treated with Simvastatin plus placebo (corn oil) on serum total cholesterol, high density lipoprotein (HDL)-cholesterol, triglycerides, and apolipoprotein E (Ref. 26); open box, effect Simvastatin; cross-hatched box, additional effect of n-3 fatty acids.

fish oil and simvastatin in patients with combined hyperlipemia were evaluated (25,26). As can be observed from Figure 1, 4 g/d of n-3 fatty acids given as ethylesters of eicosapentaenoic acid and docosahexaenoic acid (Omacor[R]; Pharmacia & Upjohn K/S; Oslo, Norway) in addition to 20 mg/d of Simvastatin reduced serum total cholesterol and triglycerides more than Simvastatin only. In addition, apolipoprotein E levels were further reduced. The postprandial hyperlipemia after a standardized fatty meal was similarly reduced. Also risk factors related to the hemostatic system were modulated by the supplement of n-3 fatty acids. This study indicates that even minor changes in the intake of n-3 fatty acids may efficiently reduce the risk profile in addition to what can be induced by the statins in this patient group with a very high risk for development of CHD.

Concluding remarks. In a period where secondary but also primary prevention for development of CHD is dominated by the new potent cholesterol-lowering drugs, it is imperative not to forget the traditional interventions related to lifestyle and dietary habits. It is definitely easier to swallow one tablet a day than to interfere with dietary preferences and tradition. Thus, in the 4S Scandinavian Simvastatin Study, dietary advice was followed by a $^1/_2$% decrease in total cholesterol (Pedersen, T., personal communication). It should be stressed that dietary changes may have profound structural and metabolic effects, interfering with a series of risk factors not modulated by statins. CHD definitely is a multifactorial disorder involving atherosclerosis and thrombosis in addition to inflammation, cell proliferation, and a disharmony in the orchestra of cytokines and eicosanoids. A reappraisal of good dietary habits and further research evaluating the effects of the individual fatty acids separately and in combination with other fatty acids are mandatory.

Antioxidant and Other Activities of Phenolics in Olives/Olive Oil, Typical Components of the Mediterranean Diet

Claudio Galli* and Francesco Visioli

University of Milan, Institute of Pharmacological Sciences, 20133 Milan, Italy

The impact of the environment on human physiology and pathology has been recognized for decades. In this respect, the diet certainly plays a major role, as indicated by the well-known observation that the incidence of certain diseases is quite different in geographical areas where populations have traditionally been exposed to somewhat unique diets. "Niches" characterized by distinct dietary conditions maintained throughout the centuries can be recognized throughout the world, such as those of populations in the Far East, or living on sea coasts, where fish is a major component of the diet, and those in the Mediterranean area. In the Mediterranean basin, several components of the diet are derived from plants and fruits and, among them, olives and grapes have been, at least originally, rather unique to this area.

Due to the particular climate, plants in the Mediterranean basin are subjected to prolonged exposure to sunlight. Thus, many fruits, including olives and grapes, have developed an array of protective compounds that limit the effects of ultraviolet light and the subsequent oxidative damage. Accordingly, the levels, dependent upon the rates of synthesis, of anthocyanins, flavonoids, and phenols in dark-colored fruits are enhanced by sunlight. Wine and olive oil, which originate from the Mediterranean area, are obtained by pressure techniques from ripe fruits; the compounds, responsible for the organoleptic and other properties of the fruits are thus transferred to the fluids.

The observation of a lower incidence of coronary heart disease (CHD) (1,2) and of certain types of cancers (3,4) in the Mediterranean area lead to the hypothesis that a diet rich in grain, legumes, fresh fruits and vegetables, wine in moderate amounts, and olive oil had beneficial effects on human health. To date, this effect has been mainly attributed to the low saturated-fat intake of the Mediterranean diet and to its high monounsaturates proportion, which indeed may favorably affect the plasma lipid/lipoprotein profiles. Nevertheless, other components of the diet, such as fiber, vitamins, flavonoids and phenols, may play an important role in disease prevention, acting on different cardiovascular variables.

Olive oil, in particular, is the principal source of fat of the Mediterranean diet. The production of olive oil for 1997–1998 in the European Community is estimated to be 1,941,000 tons, which represents 85% of the world production. Due to the increasing popularity of the Mediterranean diet, its consumption is expanding to nonproducer countries such as the United States, Canada, and Japan. Abundance of oleic acid, a monounsaturated fatty acid, is the feature that sets olive oil apart from other vegetable oils. In particular, oleic acid (18:1n-9) ranges from 56 to 84% of total fatty acids, while linoleic acid (18:2n-6), the major essential fatty acid and the most abundant polyunsaturate in our diet, is present in concentrations between 3 and 21%. Depending on its chemical and organoleptic properties, olive oil is classified into different grades (5) that also serve as guidelines for the consumer's preference. In many producing countries, extra virgin olive oil, i.e., the one with the highest quality, accounts for just 10% of the whole production. In addition to triglycerols and free fatty acids, olive oil contains a variety of nonsaponifiable compounds that add up to 1–2% of the oil and are important for its stability and unique flavor and taste. In contrast, other edible seed oils lose most of their minor compounds during the refining stages.

The absolute concentration of phenols in olive oils is the result of a complex interaction between several factors, including cultivar, degree of maturation, and climate. It usually decreases with overmaturation of olives, although there are some exceptions to this rule. For instance, olives grown in warmer climates, in spite of a more rapid maturation, yield oils that are richer in phenols. Analysis of the "minor constituents" is very important for the identification of the area of production of each batch and allows the disclosure of possible adulterations. Most phenols confer a very bitter and pungent zest to the oil. The effect of bitterness and pungency is the result of complex interactions between the "minor constituents" and the taste buds. In particular, phenolic acids, such as phenol and cinnamic acid, are responsible for the bitter sensation felt on the lateral and posterior areas of the tongue, while secoiridoids confer a peculiar pungency. As a result, organoleptic feelings that remind one of pepper or chili peppers can be found in phenols-rich

TABLE 1
Inhibition of Superoxide Anion Formation Rates by Olive Oil Phenolics

	Superoxide-producing system	
	Xanthine-xanthine oxidase	PMN + PMA[a]
Hydroxytyrosol (EC_{50})	9.1 μM	3.2 μM
Oleuropein (EC_{50})	14.3 μM	29.3 μM

[a]PMN, phorbol 12-myristate 13-acetate; PMA, polymophonucleate.

olive oil, which is most favored by gourmets. This is confirmed by the higher scores usually obtained in panel tests by oils produced from greener olives (6) because of the "fruity" and complex aroma provided by their high phenol content. Conversely, "sweet" oils are almost devoid of phenols. Notably a very high load of phenols may result in an excessive and unpleasant bitterness and is not synonymous with quality. The continuous systems employed to extract the oil sampled in the panel test reported by Cimato *et al.* (6), in spite of removing a portion of phenols, prevented the development of off-flavors that can derive from dirty fiber mats or molds and hence lower the percentage of defective oils. In turn, phenol-rich virgin olive oils very likely exhibit greater stability and a strong, fruity flavor, indicating a high, but not necessarily the most preferred, organoleptic quality of the oil.

The presence of phenolic compounds confers on olive oil a particular resistance to the development of rancidity, and the major contributor to this effect has been attributed to hydroxytyrosol (3,4-dihydroxyphenylethanol), an orthodiphenol that derives from the secoiridoid oleuropein (OE), the bitter principle of olives. In contrast, tyrosol appears to contribute very little, if any, to the stability of olive oil.

Thanks to the recent availability of pure compounds, we investigated the biological activities of some olive oil phenols including, but not limited to, their antioxidant capacity. Both hydroxytyrosol (HT) and OE potently inhibit copper sulfate-induced oxidation of low density lipoprotein (LDL) in a dose-dependent manner, when incubated from 10^{-6} to 10^{-4} M (7,8). The protective effects of HT and OE are demonstrated through the assessment of various markers, such as a reduced formation of short-chain aldehydes (evaluated as thiobarbituric acid-reacting substances) and of lipid peroxides, by the persistence of a higher vitamin E content in the residual LDL (indicating sparing of endogenous antioxidants), and by a reduced formation of malondialdehyde-lysine and 4-hydroxynonenal-lysine adducts, indicating protection of the apoprotein moiety (7,8). Although the antioxidant activity of olive oil phenols on LDL oxidation was observed mainly when copper sulfate was used as the oxidative agent, suggesting that these compounds at least acted as metal chelators, they also prolonged the lag phase of conjugated diene formation when LDL oxidation was induced by a metal independent oxidative process, such as the use of free radical generators (7). This suggests that additional activities of HT and OE, among the antioxidant properties, may include chain-breaking in radical propagation and/or radical scavenging (9).

More recent studies focused on the scavenging activities of olive oil phenols with respect to various free radicals (10). In particular, OE and HT were shown to potently inhibit superoxide production by either a cell-free system or by activated human neutrophils (Table 1 and Fig. 1). Superoxide is an oxygen-centered radical that is produced by enzyme sys-

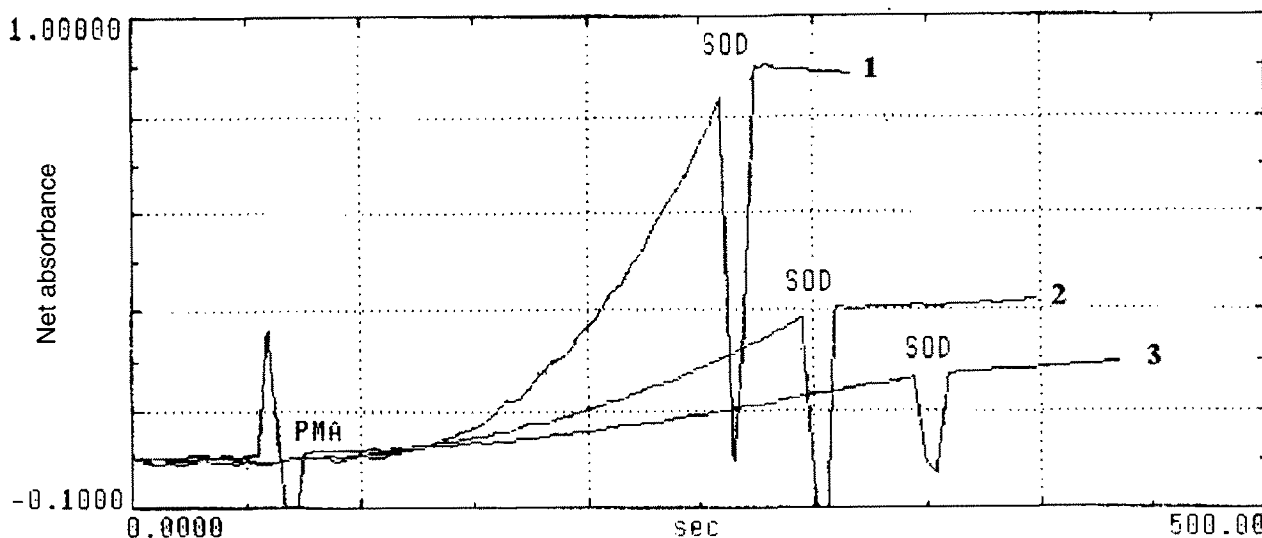

FIG. 1. Phorbol 12-myristate 13-acetate-induced superoxide production by human neutrophils. Samples were as follows: (1) control; (2) hydroxytyrosol 10^{-5} M; (3) hydroxytyrosol 10^{-4} M. SOD, superoxide dismutase 50 ng/mL.

tems, by autoxidation reactions, and by univalent oxygen reduction caused by electron transfers. It is highly reactive (half-life 10^{-5} s) and, in biological systems, can oxidize ascorbic acid and reduce cytochrome C. It is also a key factor in the Haber-Weiss reaction from which it generates the highly reactive hydroxyl radical. Superoxide dismutase dismutases superoxide to hydrogen peroxide and molecular oxygen. It is noteworthy that vitamin E and the established synthetic antioxidant butylated hydroxytoluene do not scavenge superoxide, suggesting that olive oil phenols are better antioxidants than the above-mentioned molecules in processes involving Haber-Weiss reactions.

Also, olive oil phenols were shown to scavenge hypochlorous acid (Fig. 2). HOCl is produced at the site of inflammation by activated neutrophils, through activation of the enzyme myeloperoxidase. Among other actions, hypochlorous acid inactivates α-1-antiproteinase, the major inhibitor of proteolytic enzymes in human plasma, such as elastase. Therefore, since elastase is also released by activated neutrophils, chlorination and oxidation of α-1-antiproteinase may greatly potentiate tissue damage (11). HOCl is also a component of household bleaches. This particular aspect may bear some relevance to industrial application of phenolic antioxidant, since bleaches are often employed to disinfect items with which food comes into contact.

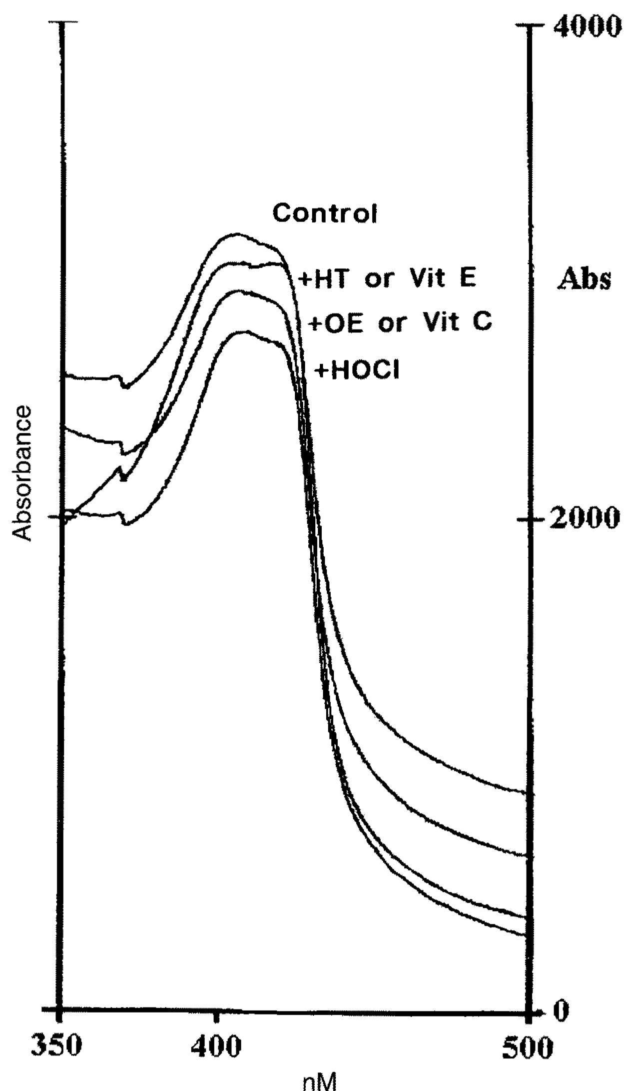

FIG. 2. Absorption spectra of catalase incubated with HOCl and the compounds under investigation. HOCl was 80 μM, whereas the compounds under investigation were added at the final concentration of 10^{-5} M. Abbreviations: OE, oleuropein; HT, hydroxytyrosol; Vit C, vitamin C; Vit E, vitamin E.

Finally, as demonstrated by chemiluminescence, both OE and HT were able to inhibit phorbol ester-induced neutrophil respiratory burst, a process involved in bronchoconstriction and airways inflammation.

HT and OE were also tested for other biological activities, namely, the effects on cells which appear to be involved in various functions in the cardiovascular systems, such as platelets and polymorphonuclear leukocytes. As to the activity on platelets, they exerted marked inhibition of the aggregation induced by various agonists, with an IC_{50} of the same order (10^{-5} M range) of magnitude as that of aspirin, and they also inhibited the accumulation of the proaggregatory compound thromboxane in serum which takes place during blood clotting obtained under controlled conditions. In human leukocytes, HT and OE markedly inhibited the production of the proinflammatory molecule leukotriene B_4, an eicosanoid generated from arachidonate through a 5-lipoxygenase, following activation with a calcium ionophore (12). The potent inhibitory effects of HT and OE toward these parameters suggest that they are able to interfere with cellular oxygenases, thus disclosing unpredicted biological activities in addition to the antioxidant activities.

Finally, when added to murine macrophages together with a bacterial lipopolysaccharide, OE increases the functional activity of these immune-competent cells, as evaluated by a significant increase (+58.7 ± 4.6%) in the production of the bactericidal and cytostatic factor nitric oxide (NO) (Table 1). A tonic effect of OE on the inducible form of the enzyme nitric oxide synthase (iNOS) was demonstrated by Western blot analysis of cell homogenates and by the use of the iNOS inhibitor L-nitromethylarginine methyl ester (Table 1) (13). On the other hand, OE alone was unable to affect the production of NO and the expression of iNOS, indicating that it behaves as a modulator of the NO system, and not as a direct activating agent.

Macrophage-derived NO during acute sepsis and inflammation represents an adaptive response of the organism that reacts to the endotoxin challenge by increasing the production of this mediator. In fact, NO inhibits platelet aggregation and adherence to vessel walls, and it maintains a proper perfusion rate through increased vasorelaxation. The protective effects of NO on cardiovascular function are further documented by the observation that inhibition of NO synthesis during sepsis increases cellular damage and animal mortality (14).

In conclusion, the interest in minor components, providing a vast array of different chemical structures, in plants and veg-

etables is rapidly growing in the areas of both nutrition and pharmacology and pharmaceutics. From the point of view of nutrition, it should be pointed out that minor compounds in cells and tissues, which are components of our diet, may play important functions, and their activities may thus be transferred to the recipient organisms.

This applies to the complex mixture of minor components, including those of phenolic nature, that are present in olives and consequently in the oil.

Although they all play a role in the drupe, it should be recognized that not all of them appear to be active, at least in the biological assays devoted to test the antioxidant and cellular activities. Accurate evaluations of the composition of minor components, affected by cultivars, climate, ripeness and processing, indifferent oil batches, and of the relationships between structure and biological activities (nature and potency) are essential for the characterization of different oils in terms of organoleptic and nutritional properties.

The biological activities disclosed in *in vitro* studies need obviously to be confirmed after administration, and information on the absorption, distribution, and metabolism of these compounds in animals and humans is an essential prerequisite. Notably, however, possible interactions at different steps in the kinetics (intestinal lumen, hepatic metabolism, cardiovascular and peripheral tissues and organs), with endogenous lipid and water-soluble antioxidants, considering the amphiphilic nature of phenolics, represent an area of additional important research.

Fatty Acids, Antioxidants, and Coronary Heart Disease from an Epidemiological Perspective

D. Kromhout*

Division of Public Health Research, National Institute of Public Health and the Environment, 3720 BA Bilthoven, The Netherlands

ABSTRACT: Oxidized low density lipoproteins (LDL) play a major role in the development of atherosclerosis. Saturated fatty acids, especially fatty acids with 12–16 carbon atoms, are the most important determinants of the LDL cholesterol level. The LDL lipoprotein fraction can be oxidized by, e.g., smoking. Oxidative damage of LDL lipoproteins can be prevented by nutritive, e.g., vitamin E, and nonnutritive antioxidants, e.g., flavonoids. It can therefore be hypothesized that fatty acids and antioxidants are important determinants of coronary heart disease (CHD). There is a large body of evidence from prospective studies that LDL cholesterol-lowering is associated with a lower CHD risk. The evidence for a protective effect of antioxidants on CHD risk is much weaker and is most promising for vitamin E and flavonoids. The Seven Countries Study showed that at the population level saturated fat, cigarette smoking, and flavonoids are important determinants of long-term CHD mortality. These results suggest that a diet low in saturated fat and rich in antioxidants in combination with no smoking is associated with low CHD risk.

In research carried out since the 1950s it became clear that dietary fatty acids are important determinants of serum total and low density lipoprotein (LDL) cholesterol. More recently evidence is accumulating that not native LDL but oxidized LDL is of major importance in the development of atherosclerosis. This raised the interest in a possible protective role of antioxidants in the occurrence of atherosclerotic complications like coronary heart disease (CHD). This presentation will give an overview of the associations between dietary fatty acids, antioxidants, and the occurrence of CHD from an epidemiological perspective.

FATTY ACIDS AND CHD

In 1952 Keys (1) hypothesized that serum cholesterol was a major determinant of CHD. At that time it was thought that dietary cholesterol and total fat were the major determinants of serum cholesterol (1,2). Later on it became clear that not dietary cholesterol and total fat but individual fatty acids, especially saturated fatty acids with 12–16 carbon atoms, were the most important determinants of serum cholesterol (3). These fatty acids have a strong cholesterol-elevating effect.

Recently a meta-analysis was published of 395 controlled dietary experiments among 129 groups of individuals with an average duration of 1 mon (4). In these metabolic ward studies, the effect of different dietary fatty acids and cholesterol on blood lipids and lipoproteins was studied using dietary carbohydrates as a reference. This meta-analysis confirmed the strong serum cholesterol-elevating effect of saturated fatty acids on serum total and LDL cholesterol. Monounsaturated fatty acids were neutral, and polyunsaturated fatty acids had a mild total and LDL cholesterol-lowering effect compared with carbohydrates. Dietary cholesterol had a slight total and LDL cholesterol-elevating effect. Dietary fatty acids also have an effect on high density lipoprotein (HDL) cholesterol. This lipoprotein fraction has in contrast to LDL cholesterol a protective effect on CHD occurrence. All major classes of fatty acids have an HDL cholesterol-elevating effect. The strongest effect is observed for saturated fatty acids. Thus saturated fatty acids elevate both LDL and HDL cholesterol. Because of their strong LDL, cholesterol-elevating effect, saturated fatty acids in the diet should be replaced by a mixture of unsaturated fatty acids and carbohydrates.

Clarke and coworkers (4) quantified the effect of changes in dietary fatty acid and cholesterol composition of the diet on total cholesterol. If 5% of the energy intake of saturated fat is replaced by polyunsaturated fat and another 5% by monounsaturated fat and the intake of dietary cholesterol is reduced by 200 mg, total cholesterol will be lowered by 0.76 mmol/L. If a Western population has an average serum cholesterol level of 6 mmol/L, the cholesterol level can be lowered by about 13% if this population changes to a low saturated fat–low cholesterol diet.

During the hardening process of polyunsaturated fat in margarine production, so-called *trans* fatty acids are formed. Controlled dietary experiments showed that especially the *trans* fatty acid elaidic acid has a total and LDL cholesterol-elevating effect and an HDL cholesterol-lowering effect (5). Presently, it is not clear whether there is a dose-response relationship between the intake of elaidic acid in the diet and total

Lipids 34, S27–S31 (1999).

Abbreviations: AA, arachidonic acid; CHD, coronary heart disease; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; HDL, high density lipoprotein; LDL, low density lipoprotein.

Copyright © 1999 by AOCS Press

and LDL cholesterol level in the blood. The HDL cholesterol-lowering effect of elaidic acid seems to be confined to high intake levels. More information is needed to make definite statements about the relationships between the intake of *trans* fatty acids and different lipoprotein fractions. However, it can be concluded that the *trans* fatty acid elaidic acid also has a total and LDL cholesterol-elevating effect at the lower levels of intake.

Serum total cholesterol-lowering is associated with a reduction of risk in the occurrence of CHD. Truswell (6) reviewed in a meta-analysis the results of 14 dietary intervention trials in which the effect of serum total cholesterol-lowering on the occurrence of CHD was studied. This included primary and secondary intervention trials and both uni- as well as multifactorial interventions. In all 14 trials an average serum total cholesterol reduction of 10% was obtained by replacing saturated fat by polyunsaturated fat. This was associated with a 13% reduction in CHD events and a 6% reduction in all-cause mortality. The five trials with the largest serum total cholesterol reduction showed on average a decrease in serum cholesterol of 13%. This decrease in serum total cholesterol was associated with a 30% decrease in CHD events and an 11% decrease in mortality from all causes. These results suggest that the stronger the reduction in serum total cholesterol, the larger the reduction in CHD events and all-cause mortality.

Polyunsaturated fatty acids are not a homogeneous category of fatty acids. They consist of two parent compounds: linoleic acid (LA), a fatty acid of the n-6 family with 18 carbon atoms and two double bonds, and α-linolenic acid, a fatty acid of the n-3 family with 18 carbon atoms and three double bonds. These fatty acids have different metabolic effects. LA can be elongated to arachidonic acid (AA), a fatty acid with 20 carbon atoms and four double bonds. α-Linolenic acid can be elongated to either eicosapentaenoic acid (EPA), a fatty acid with 20 carbon atoms and five double bonds, or docosahexaenoic acid (DHA), a fatty acid with 22 carbon atoms and six double bonds. The fatty acids with 20 carbon atoms, AA and EPA, play an important role in prostaglandin metabolism and may influence the thrombotic process.

In case-control studies carried out in Finland and Scotland in the 1980s, an inverse association was observed between the LA concentration in phospholipids or adipose tissue and CHD risk (7,8). At that time the LA intake in these population was low (<4% of energy). In cultures with a higher intake of LA, such an association was not observed.

In the case-control study from Finland an inverse relationship also was observed between the phospholipid concentration of α-linolenic acid and myocardial infarction (7). Also in an intervention trial among cardiac patients. a strong protective effect was observed of an α-linolenic acid-enriched Mediterranean diet on coronary and all-cause mortality (9). These data suggest that α-linolenic acid may play an important role in the prevention of CHD. However, more information is needed before definite statements can be made about the possible protective effect of α-linolenic acid.

Fish is an important source of the n-3 fatty acids EPA and DHA. We found in two prospective studies carried out in The Netherlands that a small amount of fish may be protective against CHD mortality (10,11). This association was observed in several prospective studies but not in all (12). The association was observed in cultures with a low fish intake especially if persons were compared who did not consume fish with those who consumed fish once a week. The association also depends on the end point. Associations are observed for hard end points, e.g., coronary mortality or cardiac arrest, but not for softer end points, e.g., CHD incidence.

The protective effect of fish, especially fatty fish, was shown in a secondary prevention trial carried out in Wales (13). About 2,000 cardiac patients were randomized, and members of the experimental group were advised to eat fatty fish three times a week. The average fish intake of the control group was about once a week. The difference in EPA intake between the two groups was about 200 mg/d. After 2 yr of follow-up, the cardiac mortality was reduced by 34% and the all-cause mortality by 29% among the patients who got the fish advice compared with the control group. Also in this trial no effect of the fish advice was found on the soft end point of CHD incidence. It can be concluded the fish is protective in relationship to CHD mortality.

ANTIOXIDANTS AND CHD

Research on antioxidants has traditionally focused on (pro-) vitamins with antioxidant properties, e.g., tocopherols (vitamin E), carotenoids (β-carotene), and vitamin C. Besides these so-called nutritive antioxidants, there are also nonnutritive antioxidants. Nonnutritive substances are compounds in foods without nutritional value. Recently it became clear that plant foods especially contain numerous compounds with strong antioxidant properties, e.g., polyphenols. Important examples are flavonoids, e.g., quercetin which is present in onions and apples, and catechins, e.g., epigallocatechin which is present in tea. The associations between (non)nutritive antioxidants and CHD will be summarized.

In large epidemiological studies, blood samples are stored for future analyses of blood parameters. In this context, associations are studied in so-called nested case-control studies. In these studies, antioxidant concentrations are measured retrospectively in stored blood samples of persons who developed CHD and in controls. This is an efficient study design because only the blood samples of the persons who developed the disease and a limited number of controls have to be analyzed.

In The Netherlands and Finland, three nested case-control studies were carried out studying the association between vitamin E levels in blood and cardiovascular diseases (14). No association was observed. In a case-control study carried out in Scotland, plasma vitamin E was inversely associated with angina pectoris in limited multivariate analyses (15). However, when the LA content of adipose tissue and the EPA content of platelets also were taken into account in the multivari-

ate model, the association between plasma vitamin E and angina pectoris was no longer statistically significant. Also no association was observed between the α-tocopherol concentration in adipose tissue and myocardial infarction in the multicenter EURAMIC case-control study (16).

In five prospective studies, inverse associations were observed between vitamin E intake and CHD risk (17–21). However, in three studies, this association was noted for supplement users (17–19) and in two studies for the vitamin E content in the diet (20,21). This means that the results of these cohort studies suggest a protective effect of vitamin E on CHD risk. However, it is unclear what level of intake provides protection.

In the CHAOS trial, the hypothesis was tested whether vitamin E supplementation among cardiac patients could prevent the risk of reinfarction and mortality (22). There was a reduction in nonfatal myocardial infarction in the patients supplemented with vitamin E. However, no association was observed with respect to hard end points, e.g., cardiovascular and all-cause mortality. Similar results in relationship to hard end points were observed in the ATBC trial carried out in Finland among 30,000 smokers (23). These results suggest that vitamin E supplementation is not effective in preventing hard end points, e.g., cardiovascular and all-cause mortality.

In the EURAMIC case-control study, an inverse association was found between β-carotene concentration in adipose tissue and myocardial infarction (16). This association was, however, confined to smokers. In four prospective studies, no association between β-carotene intake and CHD was observed (18,20,21). An exception was the inverse association between β-carotene intake and CHD in smokers as observed in the Health Professionals Follow-up Study (18).

Three large intervention trials were carried out, one in Finland and two in the United States, to study the effect of β-carotene supplementation on lung cancer and other causes of death (23,25,26). These trials took place among smokers, asbestos workers, and physicians. In spite of the hypothesized protective effect, these studies showed a detrimental effect of β-carotene supplementation on lung cancer. In the ATBC and CARET trials, β-carotene supplementation was also associated with a higher cardiovascular and all-cause mortality. In the Physical Health Trial, significant associations were not observed between β-carotene supplementation and cardiovascular and all-cause mortality. The data of the Physicians Health Trial suggest that the effect of β-carotene supplementation on myocardial infarction may be related to smoking status. An odds ratio of 0.88 [95% confidence interval (CI) 0.72–1.07] was observed among nonsmokers and of 1.08 (95% CI, 0.80–1.48) among smokers.

In six prospective studies the association between vitamin C intake and CHD was studied (18–21,24,27). No association was observed. An exception was the inverse association between vitamin C intake and CHD among nonsmokers noted in the Western Electric Study (24). Controlled trials on the association between vitamin C intake and CHD have not been carried out.

In 1993 we published a paper showing an inverse relationship between the intake of flavonols and the 5-yr mortality from CHD in the Zutphen Elderly Study (28). This association was also present when the follow-up period was extended to 10 yr (29). Besides in The Netherlands this association was also studied in three prospective studies carried out in Finland, the United States, and Wales (30–32). An inverse association was also observed in the study from Finland but not in those from the United States and Wales. It can be concluded that the association between flavonol intake and CHD is promising, but more data are needed before definite conclusions on this association can be drawn.

If we try to summarize the results on the associations between the intake of different antioxidants and CHD risk we can conclude that: (i) vitamin E is related to CHD risk in prospective cohort studies but not in case-control and intervention trials; (ii) β-carotene is related to CHD in case-control studies only in smokers but not in prospective cohort studies and intervention trials; (iii) vitamin C is not related to CHD risk in prospective cohort studies; and (iv) flavonols are related to CHD risk in some but not all prospective cohort studies.

FATTY ACIDS, ANTIOXIDANTS AND CHD FROM A PUBLIC HEALTH PERSPECTIVE

Within Europe large differences exist in mortality from CHD. Historically there was a marked North-South gradient with high rates in the North and low rates in the South. Over the last two decades, CHD mortality rates decreased in most northern European countries and the differences between northern and southern Europe became less pronounced (33). Nowadays, the highest CHD mortality rates are observed in eastern Europe. From a public health point of view, it is necessary to know what the major determinants of population CHD mortality rates are. If these determinants are known, preventive measures can be taken in order to reduce the burden of CHD mortality in populations.

The question why CHD mortality rates differ between population was asked in the 1950s by Professor Ancel Keys, University of Minnesota, Minneapolis, Minnesota. He carried out pilot studies in the United States, Europe, and Japan in the early 1950s (34). In 1958 he started the Seven Countries Study, a population-based survey in 16 cohorts of men originally aged 40–59 yr. Between 1958 and 1964, 12,763 men were examined. These men were re-examined after 5 and 10 yr of follow-up and were followed for mortality during 25 yr. During that period, about 6,000 men died and the underlying cause of death was adjudicated in a standardized way. About 1,500 men died from CHD.

Information on smoking habits was collected in all men in a standardized way in the baseline survey. Detailed dietary data were collected in small samples of the cohorts (35) The 7-d record was used as dietary survey method, and duplicate portions of the foods eaten were collected and chemically analyzed. In the 1960s it was possible to determine total fat and

the major classes of fatty acids, e.g., saturated, monounsaturated, and polyunsaturated fatty acids but not n-3 polyunsaturated and *trans* fatty acids. Therefore, it was decided in 1986 to recode the original dietary data of the 16 cohorts in a standardized way. These data were summarized in 16 major food groups, and the average consumption for each cohort was calculated (36). In 1987 food composites were collected representing the average food intake of the 16 cohorts in the 1960s. These food composites were chemically analyzed, and different nutritive and nonnutritive substances were determined.

Univariate analyses showed that the intake of saturated fatty acids was the strongest determinant of 25-yr CHD mortality rates of the 16 cohorts (37). Also the *trans* fatty acid elaidic acid was strongly related to CHD mortality, but this association was not independent from saturated fat intake. Therefore, only saturated fat was included in the multivariate model. In univariate models the dietary antioxidants vitamin E, β-carotene, and vitamin C were not related to long-term CHD occurrence (38). However, flavonoids were inversely related to 25-yr CHD mortality (39). No association was observed between cigarette smoking and CHD mortality, due to the high smoking and low CHD mortality rates in the two Japanese cohorts. However, after multivariate analysis, saturated fat intake and cigarette smoking were positively related with CHD mortality and flavonoid intake inversely. These results suggest that populations characterized by diets low in saturated fat and high in flavonoids and low smoking rates have low mortality rates from CHD. In general terms this means that a diet low in animal foods and hard margarines and high in plant foods is protective in relationship to CHD mortality.

These results from cross-cultural analyses do not prove that changes in diet and smoking habits are directly related to changes in the occurrence of CHD. In primary and secondary prevention trials, it is shown that changes in diet (e.g., lowering of saturated fat intake and increasing consumption of fish, vegetables, and fruits) and antismoking intervention lower not only the risk of (sudden) cardiac death but also of all-cause mortality (9,13,40,41). Together with the increasing evidence from basic research, showing the importance of oxidized LDL in the atherosclerotic process, it can be concluded that interventions on diet and smoking have a large impact on the rate of CHD occurrence in populations.

ABSTRACT: The purpose of the present research was to clarify the effect of docosahexaenoic acid (DHA) intake on behavior and plasma catecholamines (CA). In Study 1, 42 students took either DHA-rich oil capsules containing 1.5–1.8 g DHA/d or control oil capsules containing 97% soybean oil plus 3% of another fish oil for 3 mon in a double-blind fashion. They took a psychological test (PF Study) at the start and end of the study. This study started at the end of summer vacation and ended just before the final exams. In the control group, external aggression (aggression against others) in PF Study was significantly increased at the end of the study as compared with that measured at the start (+8.9%), whereas it was not significantly changed in the DHA group (−1.0%). In a similar double-blind study (Study 2), we measured external aggression under nonstressful conditions. External aggression slightly decreased in the control group, whereas there were no significant changes in the DHA group. In Study 3 with 14 students, plasma CA were measured at the start and end of capsule administration period of 2 mon. Subjects were under continuous stress of the final exams that lasted throughout the whole study period. The ratio of plasma epinephrine to norepinephrine concentrations was significantly increased in the DHA group (78%), whereas it stayed at the same level in the control group. In Study 4, mice were fed either DHA-deficient diet or -sufficient diet for 4 wk, and their rearing frequency (an anxiety index) was measured. In the DHA-sufficient group, the rearing frequency was significantly less than in the other group. These effects of DHA intake may be applied to people in an attempt to ameliorate stress-related diseases.

Docosahexaenoic acid (DHA) is the major n-3 polyunsaturated fatty acid (PUFA) in the brain phospholipid fraction. The depletion of n-3 PUFA affects the brain functions of rats. Yamamoto *et al.* (1) fed rats either an n-3 PUFA-deficient diet or an n-3-sufficient diet for two generations and tested the higher functions of the brain. They found that the correct response ratio in a brightness-discrimination-learning test was better in the n-3-sufficient group than in the n-3-deficient group. However, the total responses, irrespective of their correctness, were 50% greater in the n-3-deficient group than in the n-3-sufficient group by the 25th session when rats were thoroughly trained for the test. The differences seen in the total responses were observed both in Wistar Kyoto rats and SHR (1). Mice fed an n-3-deficient diet and n-3-sufficient diet for two generations had different behavior and also different sensitivities to behavior-affecting medicines (2). These animal experiments suggest that DHA deficiency affects behavior of animals.

Investigating 6- to 12-yr-old boys, Stevens *et al.* (3) showed that boys with lower total n-3 PUFA concentrations in the plasma phospholipid fraction had a greater number of behavior problems, temper tantrums, and sleep problems. n-3 Fatty acid concentrations in blood are also associated with depression. Adams *et al.* (4) showed that the ratio of red blood cell (RBC) phospholipid arachidonic acid to eicosapentaenoic acid (EPA) correlates significantly with severity of depression. Furthermore, Hibbeln (5) recently noted that a high consumption of fish was significantly correlated with a lower annual prevalence of major depression.

From these studies we thought that it was necessary to test the effects of DHA on normal human behavior. In the present paper, we show the effects of DHA in nonsmoking students and also report on our related studies on mice.

MATERIALS AND METHODS

Study 1 (6): Subjects. Fifty-three students (19–30 yr of age) were recruited from two universities: one was a fourth-year class of Toyama Medical and Pharmaceutical University, and the other was a second-year class of Yokkaichi University. The subjects had been judged healthy by physical examination and blood tests 3–4 mon before the entry to the study.

Lipids 34, S33–S37 (1999).

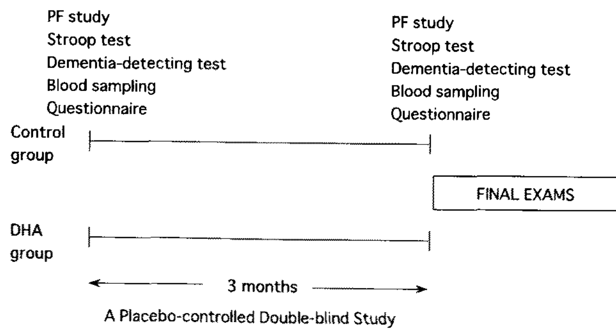

FIG. 1. Design of Study 1.

Study design and oils. The design of the study is shown in Figure 1. The study took place in the two universities with the same protocol. Subjects were asked to complete food frequency questionnaires and questionnaires about adverse effects of oil-containing capsules. At the end of the study another questionnaire was prepared to ask subjects to guess whether they had been taking DHA or control capsules. As shown in Figure 1, the final exams were scheduled a few days after the end of the study as a stressor component. Fasting blood was taken for fatty acid analysis. Mental and psychological tests were performed at the start and end of the study. All subjects were asked to keep their body weights and physical activity levels, and to consume their habitual diets during the study. They were also asked to take 10–12 capsules (according to subjects' body weights) containing either DHA-rich fish oil or control oil for 3 mon for the DHA and control groups, respectively. Each capsule contained 300 mg of oil and 0.3% α-tocopherol. The DHA-rich fish oil contained 49.3% DHA, 6.7% EPA, and 9.0% palmitic acid, 7.3% oleic acid and 3.3% arachidonic acid. Consequently, in the DHA group, subjects ingested 1.5–1.8 g DHA/d from capsules. The control oil was a mixture of 97% soybean oil and 3% of another fish oil. The purpose of the inclusion of another fish oil in the control oil was to camouflage fish odor of DHA capsules. The composition of the control oil was 54.1% linoleic acid, 22.3% oleic acid, 10.8% palmitic acid, 6.8% α-linolenic acid, 3.7% stearic acid, and 0.5% DHA.

PF Study, and Stroop and dementia-detecting tests. PF Study was originally developed by Rosenzweig (7). This psychological test consisted of 24 pictures illustrating frustration. Subjects were asked to look at pictures and describe their first reactions. Their reactions were analyzed according to their direction. If the direction of reactions was against others, the reactions were diagnosed external aggressive. Stroop test checked accuracy and speed of discrimination of color-meaning words written in different colors. Dementia-detecting test required two kinds of ability at a time, namely to pick out certain indicated letters (usually three kinds of letters) from a few sentences and put a circle on every indicated letter while understanding the sentences.

Study 2 (8). The protocol of Study 2 was essentially the same as Study 1. The only major difference was that there was no stressor component in Study 2. Minor differences were: (i) fatty acid composition was determined with the total phospholipid fraction of RBC; (ii) subjects ingested 10 DHA or placebo oil-containing capsules instead of 10–12 capsules/d. Another group of 59 nonsmoking volunteers was recruited from Toyama Medical and Pharmaceutical University and Kogakkan University.

Study 3. Plasma catecholamine (CA) concentrations were measured in a similar 2-mon study with another group of volunteers (medical students). In this study, subjects were asked to take 10 capsules of DHA-rich fish oil as in Study 2 or mixed plant oil. The major difference between Studies 1 and 3 was the presence of continuous psychological stress throughout the study period, during which subjects underwent more than 20 stressful final exams. The placebo oil was a mixture of 47% olive oil, 25% rapeseed oil, 25% soybean oil, and 3% of DHA-rich fish oil. At the start and end of the study, fasting subjects were asked to sit quietly with an indwelling needle in an antecubital vein for 30 min. Then blood was taken for plasma CA concentrations and for the fatty acid composition in red blood cells (RBC).

Study 4. Male ddY mice were group-fed either a DHA-rich diet (90% lipid-free diet + 8% lard + 2% DHA ethyl ester) or a control DHA-deficient diet (DHA was replaced with soybean oil) for 4 wk with the reversed day/night cycle (dark, 9:00–21:00; light 21:00–9:00). At the end of diets, locomotor activity (rearing) was measured with an animal movement analyzer (Scanet SV-10, MATYS, Toyama) during a dark cycle.

Statistical analysis. Data are expressed as means ± SD. Intragroup and intergroup differences were analyzed by paired and unpaired t-tests (comparing intragroup differences of the two groups), respectively.

RESULTS

Study 1. Noncompliant subjects such as those taking less than 70% of capsules, changing their body weights by more than 3 kg, smoking, and dropping out for personal reasons were excluded before the double-blind code was broken. Subjects did not complain of any serious adverse effects in either group. The questionnaires performed at the end of the study showed that subjects could not guess the kind of their own capsules more correctly than by chance. This was also the case for Studies 2 and 3.

Because two DHA subjects whose DHA concentrations in blood did not increase were excluded before analysis by one of the authors who did not know the results of PF Study, DHA concentrations in all the analyzed DHA subjects increased (3.1 ± 0.5 to 6.1 ± 1.6%, theoretically $p = 0$) in the total serum phospholipid fraction, whereas those in the control group did not change significantly (3.6 ± 1.3 to 3.5 ± 1.1%). The final numbers of subjects analyzed were 20 (7 males and 13 females) and 22 (5 males and 17 females) for the control group and DHA group, respectively. As shown in Figures 2 and 3, no significant differences were observed between the two groups in Stroop and dementia-detecting tests, respectively.

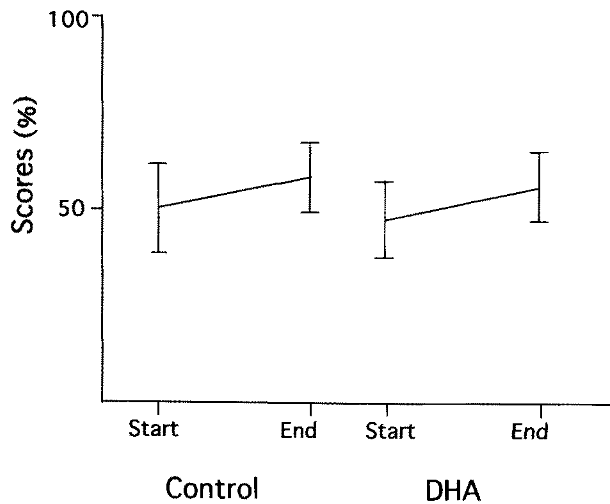

FIG. 2. Stroop Test (Study 1). Stroop test was performed at the start and end of 3 mon of capsule administration. There were no significant differences between the two groups. n = 19 for the control group and 22 for the DHA group.

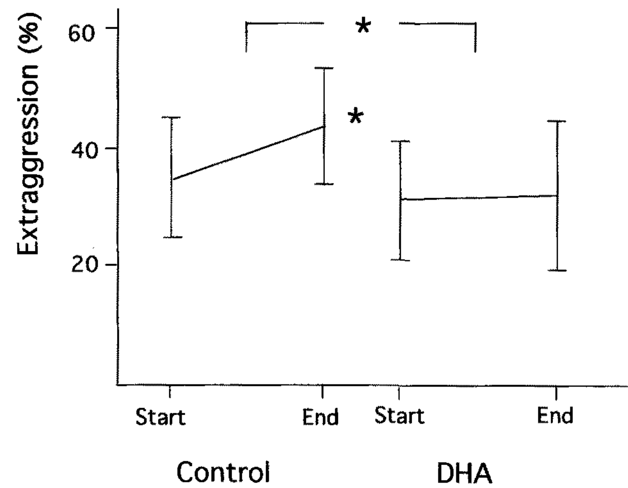

FIG. 4. Changes in external aggression (Study 1). External aggression was measured at the start and end of 3 mon of capsule administration. n = 19 for the control group and 22 for the DHA group. $^{*}P < 0.007$.

However, as shown in Figure 4, there were highly significant differences between the two groups in PF Study. In the control group, external aggression increased significantly, but in the DHA group, it stayed unchanged. The increase in external aggression in the control group was set off by a decrease in extraggression (aggression against nobody). The average daily intake of DHA from food was about 220 ± 90 mg in the control group and 230 ± 90 mg in the DHA group.

Study 2. Noncompliant subjects were excluded as in Study 1. Twenty-four control subjects (11 males and 13 females) and 22 DHA subjects (13 males and 9 females) were selected for analysis. DHA in the total phospholipid fraction of RBC in the %DHA group increased from 4.8 ± 0.9% to 7.0 ± 1.0% (theoretically $p = 0$), and arachidonic acid decreased from 9.4 ± 1.0 to 8.8 ± 0.6% ($P < 0.001$). In the control group, linoleic acid significantly increased from 8.3 ± 0.7 to 9.0 ± 0.9% ($P < 0.001$). As shown in Figure 5, external aggression decreased slightly but significantly ($P < 0.005$). However, the intergroup difference was only marginally significant ($p = 0.05$).

Study 3. DHA in the total phospholipid fraction of RBC increased in every DHA subjects from 5.8 ± 1.1 to 8.2 ± 1.1% ($P < 0.002$), whereas in the control group there were no significant changes in any fatty acids between the start and end of the study. The plasma norepinephrine (NE) decreased in the DHA group (2.3 ± 0.8 to 1.6 ± 0.5 nmol/L, −31%, $P < 0.03$), whereas it did not significantly change (2.0 ± 0.7 to 1.8 ± 0.7 nmol/L) in the control group. Epinephrine (EP) levels

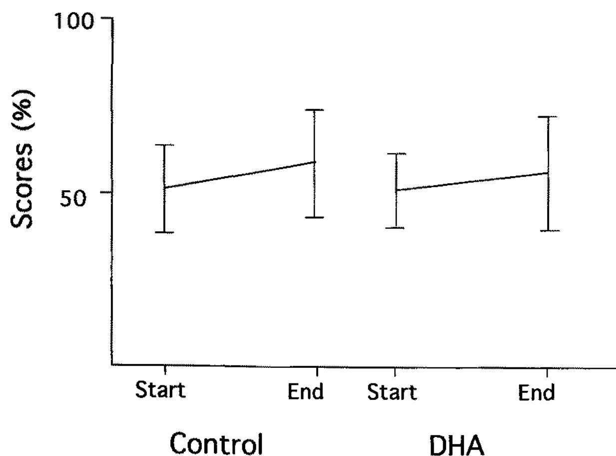

FIG. 3. Dementia-detecting test (Study 1). Dementia-detecting test was performed at the start and end of 3 mon of capsule administration. There were no significant differences between the two groups. n = 20 for the control group and 22 for the DHA group.

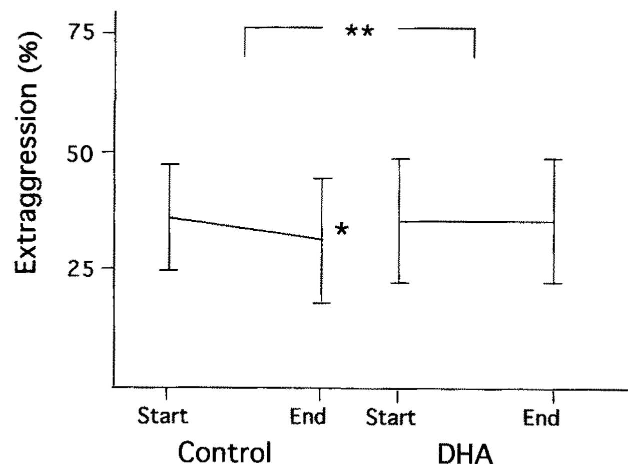

FIG. 5. Changes in external aggression (Study 2). External aggression was measured at the start and end of 3 mon of capsule administration. n = 24 for the control group and 22 for the DHA group. $^{*}P < 0.005$, $^{**}p = 0.05$.

decreased in the control group (187 ± 121 to 166 ± 177 pmol/L) and increased in the DHA group (197 ± 149 to 224 ± 156 pmol/L), although not significantly in either group. Consequently, the ratio of plasma EP to NE increased in all DHA subjects by 78% (Fig. 6).

Study 4. As shown in Figure 7, the locomotor activity, rearing frequency, was significantly higher in the control diet group than in the DHA group.

DISCUSSION

Study 1. We started this study on September 4, around the end of summer vacation, and terminated the study on December 4. In Toyama there were final exams in pathology for all subjects just a few days after the end of the study. These university exams were probably the toughest of all for Toyama subjects. In Yokkaichi, all subjects had to finish their graduation thesis (also the toughest trial for them) by the middle of December. Consequently, December 4 was one of the busiest and most frustrating days for both Toyama and Yokkaichi subjects. External aggression was naturally increased in the control group, considering the situations of subjects. Why, then, was external aggression in the DHA group stable? n-3 PUFA-depleted mice had different behavior (2), and n-3-depleted rats were more aggressive (1). Our control subjects might have suffered from DHA deficiency, while DHA subjects were not. With enough DHA intake, those final exams as stressor might not have been strong enough to provoke external aggression.

Enhanced aggression was once recognized as a risk factor of coronary heart disease (CHD) (9). But now one of the aggression components, hostility, is recognized as a more reliable risk factor for CHD and likely all-cause mortality as well (10).

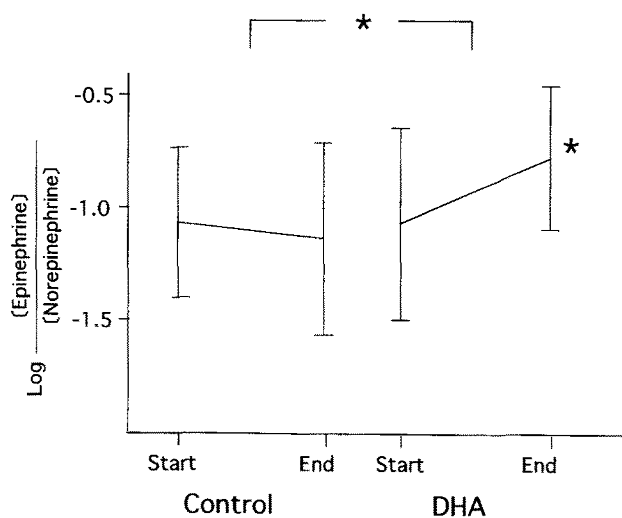

FIG. 6. Changes in the ratio of epinephrine to norepinephrine (Study 3). Catecholamines were measured at the start and end of 2 mon of capsule administration. Data were log-transformed for normalization. The averaged increase in the DHA group was 78%. $n = 7$ for each group; $^*P < 0.03$.

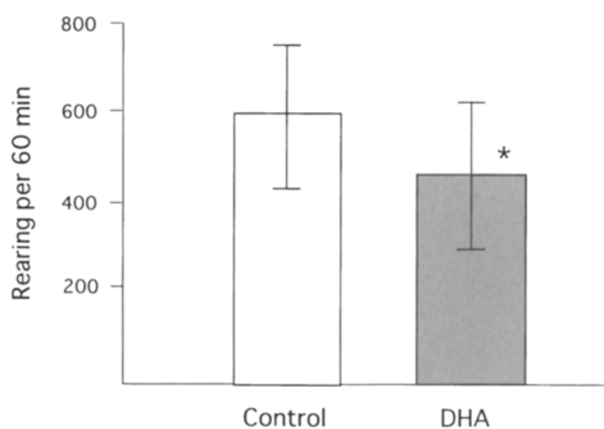

FIG. 7. The rearing frequency of rats (Study 4). The rearing frequency was measured after 4 wk of diets. $n = 20$ for each group. $^*P < 0.01$.

The preventive effects of fish oils on CHD death are well-known (11–13). In this context, the aggression-controlling effects of DHA may be one of the mechanisms of CHD prevention by fish oils.

Stroop and dementia-detecting tests did not show any differences at all. Performance at the final exams carried out a few days after the end of the study was essentially the same between the two groups (data not shown). These points indicate that capsules did not affect deep concentration and quick judgments.

Study 2. External aggression in the control group decreased contrary to Study 1, in which controls exhibited increased external aggression at the end of the study (Figs. 4 and 5). The major difference between these two studies consisted in the absence of extremely important university exams at the end of the study period in Study 2. Because we carefully planned the timing of psychological testing, any important university exams were not scheduled within 30 d from any checkpoints. It is likely that stress levels for students were alike between the two checking points. Then, why did measured external aggression decrease in the control group? Habituation to testing could account for such a decline, but this would not explain the failure of a drop in measured external aggression in the DHA group.

In general, the presence of a stressor increases the degree of aggression (14,15). Hostility scale measured with the Multiple Affect Adjective Checklist and aggression scale with the Adjective Rating Form of nondrinkers were higher than those of moderate drinkers when subjects were not provoked, whereas, after provocation, both scales increased in the two groups, those of moderate drinkers becoming higher than for nondrinkers (15). Thus, it is possible that the results of the psychological test without stressor as performed in Study 2 were different from Study 1. The results of Study 2 therefore do not necessarily contradict the finding of Study 1 that DHA reduced external aggression in a normal population under significant stress.

Study 3. What does an increase in the ratio of EP to NE mean? Christensen *et al.* (16) measured basal plasma CA lev-

els of 412 males of 70 yr of age and followed them for 7 yr. Analysis of plasma CA levels revealed that only 10% of the subjects with high plasma EP levels and low NE had died during the 7-yr follow-up period, but 50% of the subjects with low plasma EP and high NE had died during the same period. Psychological stress in patients with duodenal ulcer does not increase plasma EP levels but NE levels (17). Consequently, it is likely that subjects in the DHA group adapted with chronic psychological stress more favorably than for the control group in terms of CA levels.

Study 4. We still do not know how DHA works on human behavior. A simple animal model may be useful in answering this question. The models with rats (1) and mice (2) might be interesting. However, those models were definitely different from our human studies in the following two points: first, the dietary intervention period was too long compared with ours (two generations instead of 2–3 mon); second, in those studies (1,2), n-3 PUFA-deprived animals and n-3-sufficient animals were compared, whereas our human controls were not n-3 PUFA-deprived at all. In this context our animal model was very similar to our human study situations. Our control mice had some n-3 PUFA in their diet (soybean oil contained 6% α-linolenic acid); the experimental diet period was only 1 mon. Nevertheless, we were able to find a difference in behavior between the two groups. Mechanistic studies using this animal model are now underway.

ACKNOWLEDGMENTS

This work was partly supported by the Nissin Seifun Foundation, the Japan-U.S. Cooperative Medical Science Program, the Shorai Foundation for Science and Technology, and the Special Coordination Funds for Promoting Science and Technology of the Science and Technology Agency of the Japanese Government. The authors are grateful to students who voluntarily joined our very stressful studies.

ABSTRACT: The African savanna ecosystem of the large mammals and primates was associated with a dramatic decline in relative brain capacity associated with little docosahexaenoic acid (DHA), which is required for brain structures and growth. The biochemistry implies that the expansion of the human brain required a plentiful source of preformed DHA. The richest source of DHA is the marine food chain, while the savanna environment offers very little of it. Consequently *Homo sapiens* could not have evolved on the savannas. Recent fossil evidence indicates that the lacustrine and marine food chain was being extensively exploited at the time cerebral expansion took place and suggests the alternative that the transition from the archaic to modern humans took place at the land/water interface. Contemporary data on tropical lakeshore dwellers reaffirm the above view with nutritional support for the vascular system, the development of which would have been a prerequisite for cerebral expansion. Both arachidonic acid and DHA would have been freely available from such habitats providing the double stimulus of preformed acyl components for the developing blood vessels and brain. The n-3 docosapentaenoic acid precursor (n-3 DPA) was the major n-3-metabolite in the savanna mammals. Despite this abundance, neither it nor the corresponding n-6 DPA was used for the photoreceptor nor the synapse. A substantial difference between DHA and other fatty acids is required to explain this high specificity. Studies on fluidity and other mechanical features of cell membranes did not reveal a difference of such magnitude between even α-linolenic acid and DHA sufficient to explain the exclusive use of DHA. We suggest that the evolution of the large human brain depended on a rich source of DHA from the land/water interface. We review a number of proposals for the possible influence of DHA on physical properties of the brain that are essential for its function.

THE INVERTEBRATES, REPTILES, AND MAMMALS

The origin of air-breathing animals. For the first 2.5 billion yr of life on the planet, the blue-green algae dominated the proto-oceans. The photosynthesis of the algae produced complex molecules, including proteins, carbohydrates, and lipids that were rich in n-3 fatty acids. Based on the explosion of the phyla in the fossil record, oxidative metabolism became predominant about 600 million yr ago. Thus animals, visual, nervous systems, and brains evolved in a docosahexaenoic acid (DHA)-rich environment (1).

Mammals. The dominance of n-3 fatty acids in the early oceans was associated with fish and reptiles requiring n-3 fatty acids for their reproduction. This dominance persisted until the end of the Cretaceous period, 70 million yr ago. In the wake of the extinction of the giant reptiles, cycads, ferns and their allies, and the flowering plants appear in the fossil record. They stored lipids, for energy during germination, containing seed oils rich in n-6 fatty acids. Then, a new set of species, the mammals, evolved: it may not be a coincidence that they required n-6 fatty acids for their reproduction.

Mammalian brain size is larger in relation to body size compared to the previous egg-laying amphibians, reptiles, and fish. The difference could be explained by the evolution of the placenta. The placenta enables nutrients and energy to be focused continuously on the development of one or a small number of progeny throughout the critical time of brain development. In the human, 70% of the calories used at this time are devoted to brain growth. The placenta is a rapidly growing vascular system with a high requirement for n-6 fatty acids, especially arachidonic acid (AA). In 42 species so far studied, AA and DHA are major acyl constituents of the brain, with the precursors being virtually absent. So the emergence of the n-6 fatty acids may have added the missing biochemical link, liberating genetic potentials for vascular development and hence the evolution of the placenta, mammary gland, and the larger brains of the mammals.

The difference between species is not the chemistry but the extent or size to which the brain is developed (1). The manner of these differences is so large as to imply that the availabilities of AA and DHA were limiting factors in the evolution of the brain (1,2). Indeed, the need for both n-6 and n-3 fatty acids for development and health of the vascular system and brain has long been recognized (3).

EVIDENCE FROM PALEONTOLOGY

The evolution of the modern human brain. The accepted dogma regarding the evolution of *Homo sapiens* is that he was originally a hunter and gatherer on the African savanna. A study of savanna and other African species shows that as they evolved larger and larger bodies, the relative size of the brain diminished logarithmically with increase in body weight (1,4). A cebus monkey of 0.9 kg body weight has 2.3% of its body weight as brain, a 60 kg chimpanzee 0.5%. The larger gorilla, at 110 kg, has only 0.25% brain, which is physically smaller than the chimpanzee's brain. At the extreme, the one-ton rhinoceros has <0.1% with its brain weighing only 350 g. It reaches that massive one-ton body weight at 4 yr of age.

Why do size and velocity of growth matter? The reason is that the biosynthesis of AA and DHA is relatively slow and may not be able to keep up with body growth in fast-growing animals. Rats and mice desaturate and chain-elongate the parent essential fatty acids to produce larger amounts of AA and DHA than their precursors. Stepping up in size from the guinea pig to the wild pig, the impact of velocity of growth results in a progressive decline in AA and DHA while the precursors linoleic and α-linolenic acids become more dominant in liver lipids (1). Instead of DHA, the n-3 docosapentaenoic acid (n-3 DPA) precursor is now the major metabolite of α-linolenic acid (5).

So the faster an animal grows, the larger it becomes and the greater is the constraint of the biosynthesis of AA and DHA. The large savanna mammals of Africa all shared the same fate: DHA and brain capacity declined as body size accelerated. The important issue is that desaturation and elongation in these large mammals peter out at the n-3 DPA with relatively little DHA being synthesized. What little DHA is synthesized is used in the brain and photoreceptor. The abundant n-3 DPA is not found here. Brain size was sacrificed, not brain DHA (1,6). This fact raises two issues: (i) The savanna food chain on which *H. sapiens* is supposed to have evolved is fairly devoid of DHA so how did *H.* evolve a large brain? (ii) Why was the more readily available n-3 DPA not used for the brain instead of DHA?

Modern human intellect and brain-specific nutrition. Australopithecus spp. are unremarkable in their apparent encephalization throughout their evolutionary history as far as can be deduced from the fossil record. No australopithecine has a cranial capacity much over 500 cm^3 (7), despite the existence of the genus for over 3 Myr. Contrast this to genus *Homo*, whose cranial capacity doubled from *H. erectus* to *H. sapiens* in a span of at most 1 Myr (Table 1). The *Homo* spp. fossil evidence and encephalization quotient values do not support a slow, linear Darwinian progression toward modern intelligence, but rather a sudden, exponential growth of relative brain size in the last 200,000 yr or so.

The earliest evidence for modern *H. sapiens* is found in Africa. *Homo* spp. in general are associated with lakeshore (lacustrine) environments in the East African Rift Valley, while australopithecines are associated more with forested areas (8,9). Thus far, evidence for precocious cultural development of *H. sapiens* is exclusively confined to lacustrine and coastal marine environments. Lakeshore sites in the Rift Valley yielded fairly sophisticated stone tools as old as 260 kyr associated with *H. sapiens* remains. The implications of this land/water habitat providing brain-specific nutrients have largely been overlooked.

TABLE 1
Mean Brain Volumes and Encephalization Quotients (EQ) for Selected Hominoid Species[a]

Species	Brain volume (cm^{-1})	EQ1	EQ2
Australopithecus afarensis	384	1.23	1.45
A. africanus	420	1.31	1.62
A. boisei	488	1.37	1.72
A. robustus	502	1.49	1.92
Homo habilis	579–597	1.74–1.79	2.10–2.29
H. rudolfensis	709	1.41	2.11
H. erectus	820–844	1.59–1.63	2.38–2.44
H. sapiens	1,250	3.05	4.26
Pan troglodytes	410	1.25	1.57

[a]EQ1 from the calculations of Martin (Ref. 4); EQ2 from the calculations of Harvey and Clutton-Brock (Ref. 47).

Fossils from coastal sites on the southern Cape of South Africa are widely regarded as the earliest modern human fossils (10–12). At numerous sites along the Cape, hominid occupation is evidenced dating from 120 to 60 kyr before now. Modern human fossils dating to about 100 kyr and recovered at Klasies River Mouth and Border Cave are found associated with incontrovertible evidence for the consumption of seafood dating to the time of rapid cerebral expansion (10,13–15).

Parkington (15) points out that in coastal hunter–gatherer cultures women are responsible for collecting shellfish. So Stone Age women could have easily provided themselves with a plentiful source of brain-specific nutrition, even when strength/mobility are compromised during pregnancy and lactation. Children would have naturally participated in exploitation of, at that time, this extremely rich resource. Early consumption of shellfish is also present in the archaeological record on the Mediterranean coast of Africa. It is likely to have occurred elsewhere as well; however, most possible coastal sites which could be investigated have been obliterated by the higher sea levels of the current interglacial era.

Successful early Homo *spp. were tropical coastal migrants.* Both *H. erectus* and *H. sapiens* successfully colonized areas outside of Africa. There is all but unanimous agreement among paleoanthropologists that *H. sapiens* originated in Africa and then spread throughout the world (16–19). Recently, stone tools of 0.8–0.9 Myr were found on the island of Flores, one of the Wallacean Islands lying between Java and Timor in Indonesia (20). The antiquity of the specimens suggests they were manufactured by *H. erectus*, not *H. sapiens*. Although Java and Bali were periodically connected to the mainland during the Pleistocene glaciation, even at times of lowest sea level, reaching Flores would have required a sea crossing of at least 19 km. This implies that at least in Indone-

sia, *H. erectus* had already reached the cognitive capability to build and use watercraft repeatedly.

Previous to the recent discovery by Morwood *et al.* (20), the earliest evidence for the use of watercraft dates from about only 40 kyr or slightly earlier with the migration of *H. sapiens* from the Wallacean Islands to Australia. That initial colonization of Australia, Tasmania, and New Guinea was accomplished by modern *H. sapiens*. Similar to the movements of *H. erectus*, these early migrants are considered to have followed a tropical coastal route. Therefore, both the earliest occurrence of modern *H. sapiens*, the earliest use of watercraft, and successful colonization of Southeast Asia were intimately associated with the utilization of food resources from the marine food chain.

We consider this association neither accidental nor coincidental, but a reflection of the dramatic influence of brain-specific nutrition on the evolutionary process. We do not accept the postulate that *H. sapiens a priori* evolved a large, complex brain, then began to hunt in order to maintain it—the brain must come first.

Our thesis is that there must have been enough long-chain polyunsaturated fatty acids (LC-PUFA) available in the diet to: (i) provide many generations of hominids with fuel for fetal/infant development as well as childhood and adult needs for the cardiovascular system and the brain, (ii) allow for substantial amounts of 18-carbon PUFA which would have been oxidized for energy requirements (21,22), and (iii) explain and allow for our inefficient conversion of linoleic acid to AA and linolenic acid to DHA [which is illustrated by preferential incorporation of DHA in the infant brain (23) and improved problem solving in infants fed DHA which persisted beyond the period of supplementation (24)].

THE STRUCTURE OF DHA VS. n-3 AND n-6 DPA

Global three-dimensional energy-minimized structures of DHA, n-3 DPA, n-6 DPA, and various phospholipids containing these LC-PUFA were constructed with MOPAC software (Alchemy 2000 v. 2.0; Tripos Inc., St. Louis, MO). MOPAC (molecular orbital package) calculates the steric energy and energy-minimized configuration of a given molecule by successive approximation and is considered to be reasonably accurate

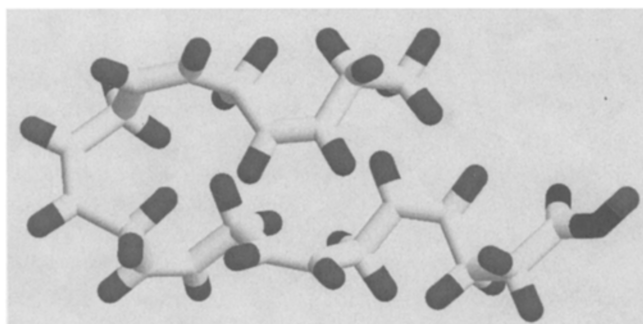

FIG. 1. 3-D energy-minimized structure of docosahexaenoic acid (DHA). This and following figures are energy minimized and drawn with molecular orbital package (MOPAC) software as described in the text.

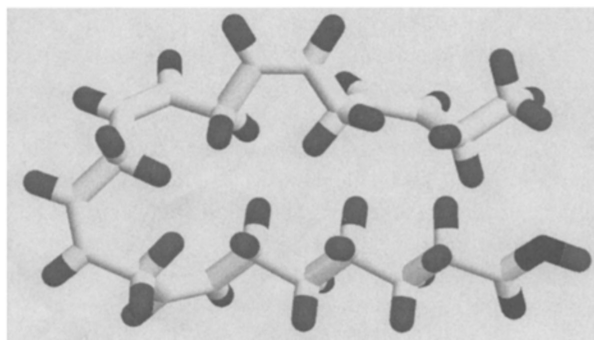

FIG. 2. n-3 Docosapentaenoic acid (n-3 DPA).

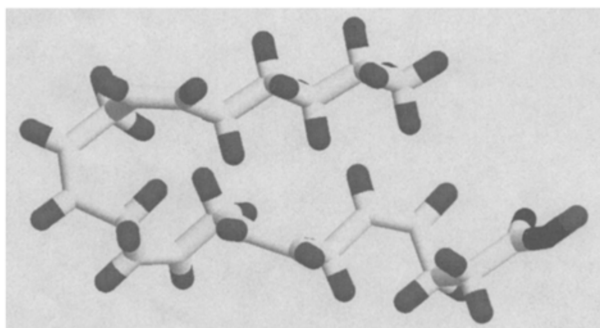

FIG. 3. n-6 Docosapentaenoic acid (n-6 DPA).

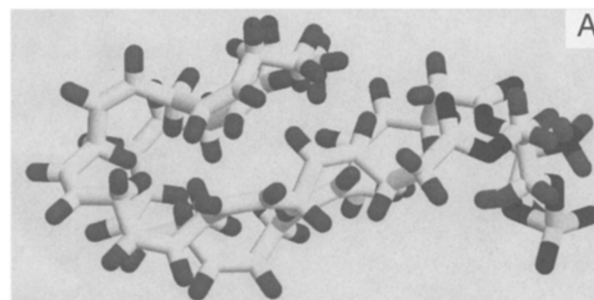

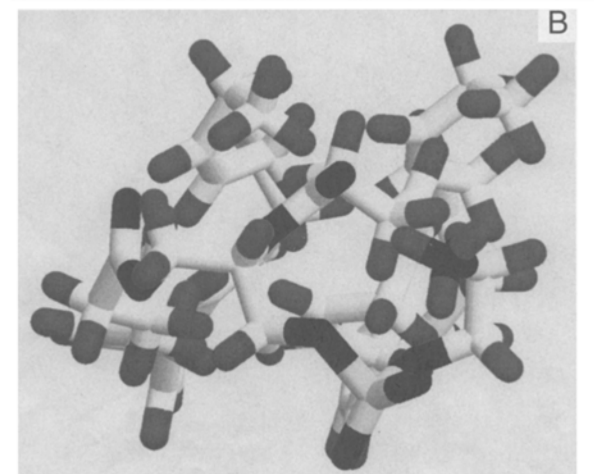

FIG. 4. (A) 3-D Energy-minimized structure of phospholipid with ethanolamine, DHA, DHA. Side view. (B) Ethanolamine, DHA, DHA. End view; note position of phosphate group. See Figure 1 for abbreviation.

as compared to known structures. The free fatty acids DHA, n-3 DPA, n-6 DPA are shown in Figures 1 to 3, respectively. The sixth ethylenic bond in DHA changes the character of the free fatty acids, completing the methylene-interrupted sequence along the carbon chain and conferring a folded, slightly spiral nature to the molecule. In n-3 DPA, the side of the chain closest to the terminal methyl is essentially ethylenic, while the other side is essentially saturated. The opposite is seen in the n-6 DPA, where the side of the chain closest to the methyl group is saturated, and the other side unsaturated. The DPA lack the full methylene-interrupted sequence of double bonds throughout the carbon chain, which could be the basis of why they apparently do not have the functionality required by retinal and brain tissue.

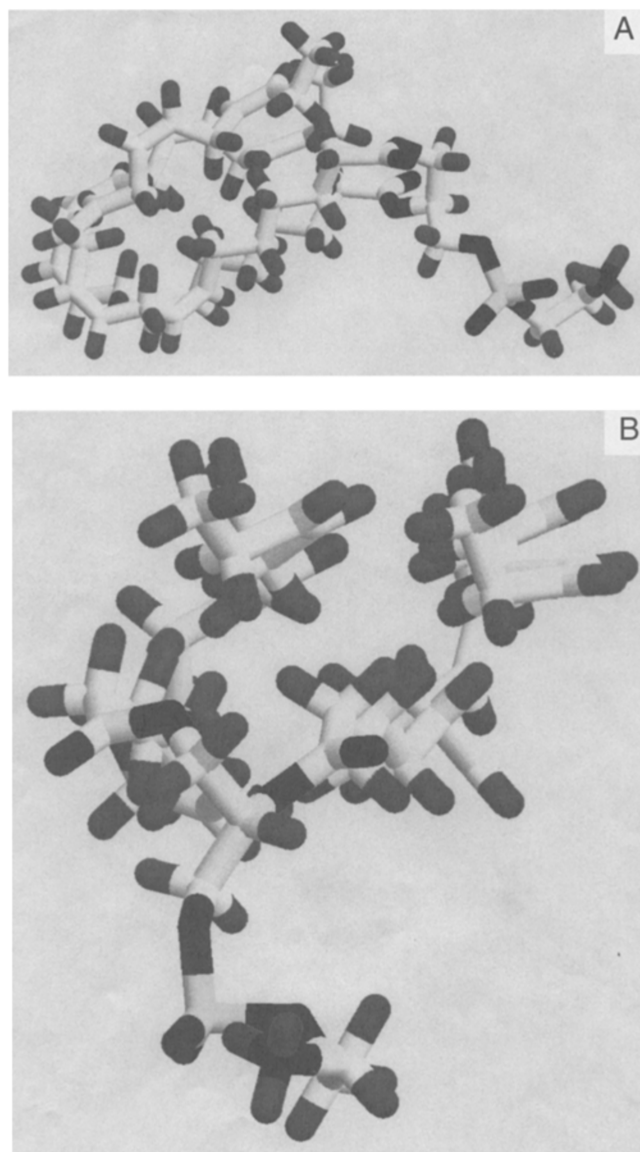

FIG. 5. (A) 3-D Energy-minimized structure of phospholipid with ethanolamine, n-3 DPA, n-3 DPA. Side view. (B) Ethanolamine, n-3 DPA, n-3 DPA. End view; note position of phosphate group. See Figure 2 for abbreviation.

The energy-minimized ethanolaminephosphoglyceride structures with DHA (Fig. 4) and n-3 DPA (Fig. 5) dramatically illustrate the significance of the missing double bond in DPA vs. DHA. The final (C_{19}) double bond in DHA constrains the position of the phosphoethanolamine headgroup, pulling it in and maintaining the spiral structure. This reduces the molecular volume and may facilitate communication between the headgroup and the esterified lipid chains. In contrast, the headgroup in n-3 DPA is far less constrained and in fact moves away from the lipid ester chains. This structure would be more typical of phospholipids in general since most fatty acids are less polyunsaturated than DHA. The cell membrane is in constant fluid motion so these structures only represent the preferred orientations of the molecules.

The evidence on the extensive coastal and lacustrine exploitation implies LC-PUFA were consistently abundant in the food supply as we evolved. *Homo* did not, however, go as far as the obligate carnivores in which the desaturation process is barely detectable (25). If *H. sapiens* had developed his intellect by evolving into a primate which can make heroically efficient use of 16- and 18-carbon PUFA from vegetarian sources, we would see an obvious signature in our current PUFA metabolism, since we are only a 300–100-kyr-old species. Instead we see the opposite. We might hypothesize that *Australopithecus* spp. could not mount this heroic metabolic effort either, which explains why their brain capacity was constrained by their land-based diet at 400–500 cc for 3 Myr and explains why exploitation of coastal foods fits with the rapid and recent cerebral expansion to 1.3 kg after 3 Myr of a static brain size (9,15).

CONTEMPORARY EVIDENCE

The human brain requires a rapidly developing heart and vascular system to meet the prodigious energy and nutrient demand during its development. The vascular system itself has a high requirement for AA (26). Hence the principles of vascular development were *sine qua non* vital for the final evolution of the large human brain.

If we now examine the contemporary evidence on cardiovascular disease, we find that land-based animal fats have been causally linked to heart disease since the Seven Countries Study of the 1950s and even earlier (27). Saturated fats and vascular degeneration would be incompatible with central nervous system expansion. Also, there is increasing evidence that cardiovascular disease has its origin in poor fetal nutrition (28), consistent with our hypothesis of long-term, multigeneration effects operating on vascular and central nervous system evolution. Those forces can act for expansion or degeneration.

Worldwide diets and cardiovascular risk factors show that marine fats, especially DHA, are cardioprotective (29–31). It is well known that people living on seafood have low cardiovascular risk factors. The diet of contemporary populations beside East African lakes (Lake Nyasa and Lake Turkana) is still largely based on fish rich in n-3 and n-6 LC-PUFA. From Table 2, calculated intakes of n-3 LC-PUFA are 1–4 g/d and AA 0.5–1.0 g/d, compared with n-3 LC-PUFA 0.2–0.3 g/d

and AA 0.1–0.2 g/d for populations consuming Western diets. Total dietary fat in the African populations was similar at 10–15% of the dietary energy (32).

We compared East African lakeshore, mainly vegetarian, and European cardiovascular risk factors (Table 3). Blood cholesterol, blood pressure, and lipoproteins [Lp(a)] are lower in the contemporary Africans living on lakeshores of Turkana and Nyasa compared to their vegetarian cousins and Europeans. Plasma AA, eicosapentaenoic acid, and DHA are highest in the fish-eating, lakeshore people and lowest in the vegetarian or omnivorous inland cousins. Furthermore, comparison of children from the lakeshore vs. European children living in East Africa showed that the two populations can be separated on the basis of blood cholesterol at the age of 6 yr! While the European children's blood pressure and cholesterol continue to rise, the Africans remain stable, illustrating the compatibility of the lacustrine diet with good cardiovascular performance compatible with the needs of fetal brain expansion. Interestingly, the Turkana have the highest mitochondrial DNA diversity of any ethnic group. In fact, 36 Turkana people have a higher diversity than the worldwide population database. The simplest explanation is that humans date back to the East African Rift Valley (33).

These unique conditions of the Rift Valley lakeshores replicate the contrast in the high mortality from vascular disease and high prevalence of mental disease among Americans and Europeans vs. the low risk for Japanese, Greenland, and Inuit Indians living on a rich fish and seafood diet (34). Similarly, comparison of fish-eating populations in the Faroes compared to their genetically similar mainland Denmark contemporaries shows that the high intake of fish and seafood results in higher birth weights and a lower proportion of preterm deliveries (35). The advantage of longer gestations is the greater exposure of the fetus and its developing vascular system and brain to the placental biomagnification of AA and DHA (36). The conclusion is that land-based diets led increasingly in this century to cardiovascular disease being the number one killer in Western consumers, and which would have made cerebrovascular expansion *in utero* difficult and incompatible with expansion of the hominid brain.

Experimental support for the above case came in an unexpected result from studies on diabetes by our colleagues, Professor Lucilla Poston and others at St. Thomas's Hospital Medical School. Pregnant rats were subjected to high saturated fat diets similar to those consumed in Western countries, and blood vessel function tested in mothers and newborn offspring. The results from small vessel myography described arterial dysfunction specifically associated with the high-fat Western-type diet. Vascular function tests on the 15-d-old pups from mothers on the high-fat (30%) diet exhibited reduced vascular endothelium-dependent relaxation to acetylcholine, with evidence of constrictor responses to noradrenaline and the thromboxane mimetic U46619. The vascular dysfunction was still observable at 120 d of age despite rearing on a normal diet. Thus the high-fat diet fed to the mother changed the intrauterine milieu, which caused persistent vascular dysfunction in the newborn animals without any genetic predisposition. Diabetes imposed on the high-fat diet made vascular function worse. Biochemical analysis of the tissues from the control low-fat and high saturated fat animals revealed the high-fat diet selectively depressed liver DHA of the pups. Here is experimental evidence of the negative influence of land-based animal fats fed to the mother on the next generation, emphasizing the importance of long-term nutritional forces (37).

TABLE 2
The Fatty Acid Composition Data of the Fish from Lakes Nyasa and Turkana (wt%)[a]

	Turkana Tilapia species	Turkana Tilapia? species 2	Nyasa Mfui	Nyasa Kambale	Nyasa Carp	Nyasa Mbelele catfish
Fat g (wt%)	2.3	2.6	1.1	1.8	4.9	10.3
20:4n-6	8.4	7.7	8.0	5.8	5.8	4.3

22:5n-3	3.2	3.8	3.7	5.2	5.0	1.8
22:6n-3	15.7	18.1	19.1	13.3	7.8	8.6

THE SPECIFICITY OF DHA

The question which arises from this discussion is: What is so special about DHA? Why has DHA been chosen so overwhelmingly for photoreceptor and synaptic membranes, despite the availability of similar molecules which would be less difficult to obtain and are less vulnerable to oxidative damage (38,39)? In particular, what advantage does it convey relative to the very closely related n-3 and n-6 DPA, each of which differs from DHA only in the absence of one double bond (between carbons 4–5, and 19–20, respectively)?

As described above, nature's preference for DHA in the brain is strikingly demonstrated in large land mammals, in which DPA is the dominant n-3 metabolite, yet neural membranes still retain the DHA-rich composition observed in other species (possibly at the expense of gross brain size, since DHA is in such limited supply). Significant quantities of the n-6 form of DPA are observed only in situations of artificial n-3 deficiency, yet even here brain membranes are resistant to decreases in their DHA levels. Nature is thus highly sensitive to the slight difference between DHA and DPA molecules; the presence of DHA's full complement of six double bonds is for some reason an important priority in neural membranes.

What is the cause of such specificity in membrane composition? It is understood that biological membranes, while always having the form of a fluid lipid bilayer, have detailed distributions of lipid and protein molecules that reflect the interactions between lipids and integral membrane proteins (40). It seems that the one missing double bond in DPA species renders them unsuitable for whatever lipid–protein interaction favors DHA's inclusion in membranes of the brain.

Tight regulation of membrane lipid composition extends to differentiation between polyunsaturated species. We recently investigated the relationship between DHA and AA levels in plasma and red cell membranes of maternal and fetal

TABLE 3
Comparison of Cardiovascular Risk Fatty Factors, Plasma and Fish Fatty Acid Composition of Lakeshore, Fish-Eating Vegetarian and European, Communities in the Rift Valley and East Africa[a]

		Populations		
		Largely vegetarian	Lakeshore	significance of differences (P)
Plasma lipids (mg/dL)				
Plasma TC		136.3 ± 39.8 n = 686	121.6 ± 30.9 n = 622	<0.05
Plasma TG		105.3 ± 53.1	80.6 ± 40.7	<0.001
Lp(a)		32.3 ± 22.4	19.9 ± 17.7	<0.001

[a]P < 0.001 for LA, AA, and DHA in El Molo compared to all others. n, number of subjects; TC, total cholesterol; TG, triglycerides; FA, fatty acids; LA, linoleic acid; LNA, α-linolenic acid; AA, arachidonic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid. Values are the average ± SD. Adapted from Ref. 32. El Molo live on a lava desert which runs down to the eastern shore of Lake Turkana, North Kenya (Ref. 48). The Bantu were Baganda and Bunyoro people of central Uganda. The Europeans were living in East Africa, mainly Kampala Uganda (data from Ref. 49). The slow conversion of linoleic to AA and α-linolenic to DHA is illustrated in the equilibrium of the higher linoleic content of the plasma lipids and the lower AA and DHA in the vegetarian and European plasmas compared to the fish-eating people where preformed AA and DHA are consumed in the diet and appear as higher levels in the plasma. Such data reflect the rate limitations of the conversion process, especially Δ6 desaturase which is involved twice in the synthesis of DHA (50). The higher circulating levels of AA and DHA would favor their incorporation into the developing brain, where their incorporation is an order of magnitude greater than their synthesis from precursors (51).

blood samples. While these studies revealed only a modest correlation in levels of the two PUFA species in plasma choline phosphoglycerides (r = 0.62, P < 0.001, n = 74), a strong positive correlation was revealed between DHA and AA in the maternal red cell membrane (r = 0.85, P < 0.0001, n = 74), and a still tighter relationship in the red cells of preterm infants (r = 0.88, P < 0.00005, n = 24) (41). Bearing in mind the very different dietary origins of these two PUFA, such significant correlations indicate that some powerful mechanism exists to regulate their relative abundances in the membrane.

Possibly, specific esterification processes could explain the correlations. The phosphatidylethanolamine (PE) and serine phosphoglycerides have the highest content of DHA. In the brain there is an active base-exchange reaction for serine and ethanolamine. Other fatty n-3 fatty acids do not esterify easily with PE and serine phosphoglycerides. So specificity of composition could be brought about by DHA–serine phosphoglycerides or DHA–PE formation. Nonetheless, the double bonds in positions 4–5 and 19–20 would still have to be relevant for the esterification, to explain why the n-6 and n-3 DPA might not match these conditions.

Nuclear magnetic resonance and fluorescence studies attempted to differentiate the membrane properties conferred by PUFA. In another paper (42), we discuss some of the constraints of such approaches and review the results obtained to date. Holte *et al.* (43) conducted a thorough nuclear magnetic resonance investigation of the effects of polyunsaturation on

lipid acyl chain orientational order which revealed significant changes as the number of double bonds increased from one to three, but little difference as further double bonds were introduced. Ehringer *et al.* (44) directly compared the effects of 18:3 and 22:6 on membrane physical properties and observed considerably higher permeability and perhaps vesicle fusibility in the samples containing DHA.

In summary, numerous studies were conducted on the physical effects of polyunsaturation on membranes, in which DHA was compared to a range of other unsaturated chains having from one to five double bonds. Thus far, however, all differences that were measured were matters of degree, and none provide a compelling explanation for the striking specificity with which DHA is selected for membranes of the eye and brain. In addition, to our knowledge, no study has compared DHA to either species of DPA to search for whatever property it is that causes neural membranes to discriminate so clearly between these seemingly similar molecules. The minimized energy structures presented here (see above) represent a preliminary step in this direction.

Where, then, can we hope to find an explanation of DHA's preferred status in neural membranes? An obvious starting point is in protein–lipid interactions: some way in which DHA favorably affects any of the myriad integral membrane proteins that are so important to neural membrane function. Such an effect could conceivably involve either a specific, molecular interaction between lipid and protein or some modulation of bulk properties of the bilayer which alters protein function. We believe that specific binding interactions between lipid and protein molecules in a biological membrane are unlikely, since the membrane's fluid state means that individual lipid molecules will be undergoing rapid translational diffusion within the bilary and thus will never be in prolonged contact with any one protein. Furthermore, Brown's studies (45) on the rod photoreceptor outer segment membrane revealed that specific chemical-type interactions could not be the cause of DHA's established role in supporting rhodopsin function. It was found that full rhodopsin efficiency could be obtained by substituting other lipid mixtures designed to mimic the bulk mechanical properties of the physiological, DHA-rich membrane. This gave rise to a model in which DHA's role was to promote mechanical conditions in the membrane suitable to stabilize certain critical conformational changes undergone by rhodopsin in the course of photoactivation. These models do not fully reconstitute the structure of the photoreceptor cell and its synaptic function, the ten thousand-fold adaptive capability of which is still unexplained. However, should this model be valid to conditions *in vivo*, it could be potentially be extended to other G-protein systems elsewhere in the central nervous system.

In applying this reasoning to the problem of distinguishing DHA from DPA, we must find a way in which the difference of one double bond might have a large enough impact on some bulk membrane property. The simulated structures shown in the figures are encouraging in this respect, as they show considerable differences between the minimized-energy conformations of di-DHA PE and di-DPA PE (perhaps the first results which show a difference of sufficient magnitude to account for nature's longstanding, clear discrimination between the two). It must be stated, though, that these simulations were carried out in vacuum and report only the lowest energy state; their applicability to lipid molecules in a fluid bilayer at physiological temperatures is thus open to question.

Another, more speculative, possibility is that DHA *in vivo* plays a more direct role in neuronal signaling, in which some special properties conferred on the membrane by DHA chains exert an influence on membrane electrical phenomena. These might include distinctive dielectric or polarizability properties arising from the unique periodic and symmetric arrangement of double bonds in the DHA chain (which would be disrupted in DPA). Conceivably, some polarization of π-electron clouds might occur and perhaps even be transmitted from one double bond to another (either within a given chain, or between neighboring chains in the membrane). It must be emphasized that this model is strictly speculative, and there is no evidence, experimental or theoretical, to support it. An experiment to measure the dielectric response of lipid systems at a broad range of applied frequencies is currently being developed. In a similar vein, Penrose (46) postulated that some brain functionality may arise due to quantum coherence in the microtubules of neurons (46); it may be worthwhile to look for a similar phenomenon in membranes containing DHA.

There is much still to be learned about the physical properties of membranes containing DHA. The extremely high degree of specificity with which it is selected for membranes of the brain (and has been, since very early evolutionary times) cannot be explained on the basis of the conventional measurements that have been made thus far. DHA's special role may relate either to undefined interactions with integral membrane proteins or, more speculatively, to some role in neuronal signaling arising from unusual electrical properties. Nature's sharp discrimination between DHA and the nearly identical DPA species may give guidance to further inquiries into DHA's putative role, by focusing attention on the importance of the full complement of six periodic double bonds.

ACKNOWLEDGMENTS

New Developments in Phospholipase A_2

Brigitte Chaminade, François Le Balle, Olivier Fourcade, Michel Nauze, Claire Delagebeaudeuf, Ama Gassama-Diagne, Marie-Françoise Simon, Josette Fauvel, and Hugues Chap*

Institut Fédératif de Recherche en Immunologie Cellulaire et Moléculaire, Université Paul Sabatier and Centre Hospitalo-Universitaire de Toulouse, INSERM Unité 326, Phospholipides Membranaires, Signalisation Cellulaire et Lipoprotéines, Hôpital Purpan, F 31059 Toulouse Cedex, France

ABSTRACT: Some of the most recent data concerning various phospholipases A_2, with special emphasis on secretory, cytosolic, and calcium-independent phospholipases A_2 are summarized. Besides their contribution to the production of proinflammatory lipid mediators, the involvement of these enzymes in key cell responses such as apoptosis or tumor cell metastatic potential is also discussed, taking advantage of transgenic models based on gene invalidation by homologous recombination. The possible role of secretory and cytosolic platelet-activating factor acetyl hydrolases is also briefly mentioned. Finally, the ectopic expression in epididymis of an intestinal phospholipase B opens some novel issues as to the possible function of phospholipases in reproduction.

General interest for phospholipases A_2 (PLA_2) comes mainly from their role in the liberation of arachidonic acid, which is an obligatory and limiting step for the synthesis of eicosanoids (1). In this respect, other lipid mediators also deserve attention and include platelet-activating factor (PAF) produced by acetylation of the lysophospholipid 1-*O*-alkyl-*sn*-glycero-3-phosphocholine (1), and lysophosphatidic acid, which is now considered as a novel phospholipid mediator with diverse biological activities (2,3). In recent years, the field of PLA_2 has rapidly grown, essentially because several enzymes were characterized at a molecular level following molecular cloning of the corresponding cDNA. Even though new and powerful tools were used to further explore the biological function of these enzymes, the complexity of the subject increased. Numerous recent reviews (1,4–7) shed some light on this complex field and cover the various types of PLA_2 which have been the object of a classification proposed by Dennis (8). The aim of this short review is not to cover exhaustively all the literature data presently available on PLA_2 but to present some recent concepts emerging in our understanding of PLA_2.

Abbreviations: MAP kinase, mitogen-activated protein kinase; mPLB, membrane phospholipase B; PAF, platelet-activating factor; PLA_2, phospholipase A_2; mPLB, phospholipase B; $cPLA_2$, cytosolic PLA_2; $iPLA_2$, calcium-independent PLA_2; $sPLA_2$, secretory PLA_2, TNFα, tumor necrosis factor α.

CLASSIFICATION OF PLA_2

The main families of PLA_2 are presented in Table 1, taking into account the classification of Dennis (8), assigning a specific number to each enzyme. The most abundant family is represented by secretory PLA_2 ($sPLA_2$). These include the digestive pancreatic PLA_2 (type IB PLA_2), snake and bee venom enzymes, and the type IIA $sPLA_2$, which has been the object of numerous studies based on its expression during inflammatory reactions. All of them are characterized by a low molecular mass, the presence of at least five disulfide bridges, and a requirement for calcium in the μM range, in agreement with the fact that these secreted enzymes are expected to exert their catalytic activity in an extracellular medium. Cytosolic PLA_2 ($cPLA_2$) displays a constitutive and ubiquitous expression and is activated by μM calcium concentrations achieved in the cytoplasm of cells stimulated with various agonists. In contrast, calcium-independent PLA_2 ($iPLA_2$) was initially recognized in heart cytosol as a 40 kDa protein able to associate with phosphofructokinase (9), whereas cDNA molecular cloning revealed that $iPLA_2$ are actually homotetramers of an 85-kDa protein (10). Despite an identical subcellular localization, $iPLA_2$ differs from $cPLA_2$ by the absolute lack of calcium requirement for its enzymatic activity. We will not describe in detail the properties of PAF acetyl hydrolases able to remove the acetyl group esterifying the *sn*-2 position of PAF and belonging, like $cPLA_2$ and $iPLA_2$, to the large group of serine esterases. For further information, the reader is referred to the review of Stafforini *et al.* (7) and to the recent cloning of intracellular PAF acetyl hydrolase II (11). We should also add to the list a 26-kDa lysosomal PLA_2 active at acidic pH (12). Finally, we have included in the classification of PLA_2 a peculiar enzyme initially purified from guinea pig intestine (13) and displaying, in addition to PLA_2, a high lysophospholipase activity allowing a total deacylation of glycerophospholipids, although the same hydrolytic activities were also reported against neutral glycerolipids (14). The cDNA coding for this brush-border hydrolase acting as an ectoenzyme has now been cloned from rabbit (15), rat (16), and guinea pig (17) intestine. Although all the available evidence indicates a digestive function for membrane phospholipase B (mPLB), we shall discuss at the end of this review novel ex-

TABLE 1
Different Phospholipases A_2[a]

PLA_2	Type	Molecular mass	Disulfide bridges	Calcium requirement	Localization
$sPLA_2$	I, II, III, V, IX, X	13–15 kDa	5–8	mM	Secreted
$cPLA_2$	IV	85 kDa	0	μM	Cytosolic
$iPLA_2$	VI	4 × 85 kDa	0	0	Cytosolic
Secreted PAF acetyl hydrolase	VII	45 kDa	?	0	Secreted
Intracellular PAF acetyl hydrolase Ib	VIII	29, 30 kDa (+45 kDa)	0	0	Cytosolic
Intracellular PAF acetyl hydrolase II	?	40 kDa	0	0	Cytosolic and membrane-bound
Lysosomal PLA_2	?	26 kDa	?	0	Lysosomal
mPLB	?	170 kDa	Yes (?)	0	Membrane (extracellular)

[a]$cPLA_2$, cytosolic PLA_2; $iPLA_2$, calcium-independent PLA_2; PAF, platelet-activating factor; PLA_2, phospholipase A_2; mPLB, membrane phospholipase B; $sPLA_2$, secretory PLA_2.

pression data indicating a role of this enzyme in reproduction. But some of the specific points recently evolved in the fields of $sPLA_2$, $cPLA_2$, and $iPLA_2$ will be discussed first.

SECRETORY PLA_2

The main interest has been brought to type IIA $sPLA_2$, which appears as the major enzyme produced in response to proinflammatory cytokines and accumulates in inflammatory fluids as well as in the serum of patients suffering from septic shock (18). The situation might actually be more complex than previously anticipated, owing to the fact that novel $sPLA_2$ are involved as well, such as type V $sPLA_2$ in P388 macrophages (19) and mastocytes (20) or the recently cloned type × $sPLA_2$ expressed in a number of immune cells (21).

When considering type IIA $sPLA_2$ itself, at least five points deserve some attention: (i) the promoter of the human gene has been isolated, allowing investigation of the factors regulating enzyme expression, among which is single-strand DNA-binding proteins (22); (ii) combinatorial oligonucleotide synthesis led to the isolation of aptamers able to bind to type II $sPLA_2$ at nM concentrations, resulting in inhibition of the enzyme and opening interesting issues for the design of specific inhibitors with potential use as anti-inflammatory drugs (23); (iii) the enzyme displays potent bactericidal activity, even in the absence of cofactors such as bactericidal permeability-increasing protein when used against *Staphylococcus aureus*, for instance (24,25); (iv) a number of cells undergoing apoptosis were described as selective substrates of type II $sPLA_2$, in contrast to intact cells remaining insensitive to membrane attack by the enzyme (26); and (v) phosphatidic acid was found as the best substrate for the enzyme, site-directed mutagenesis giving some partial explanation for a behavior typical of type IIA $sPLA_2$ (27).

The latter two observations are interesting to discuss in the light of our previous study showing that type IIA $sPLA_2$ is only able to act on membranes whose transverse phospholipid asymmetry has been modified, allowing the exposure of phospholipids, such as phosphatidylethanolamine and phosphatidylserine, normally present in the internal leaflet (28). Since redistribution of phospholipids between the two halves of the plasma membrane is one of the earliest events occurring during apoptosis (29), this offers an explanation to the mechanism by which cell membranes could present a suitable substrate to $sPLA_2$. On the other hand, since phosphatidic acid is also translocated from the cytoplasmic to the extracellular side of the membrane, type II $sPLA_2$ could also be involved in the production of the novel phospholipid mediator lysophosphatidic acid (28), although other pathways should still be considered (3).

Another interesting field is the relationship between $sPLA_2$ and cancer. For instance, genetic studies provided evidence that $sPLA_2$ protected mice against the development of multiple intestinal neoplasia due to mutations in the adenomatous *polyposis coli* gene (30,31). Although we ignore whether the enzyme is able to selectively destroy malignant cells, those studies revealed that several mouse strains such as C57BL/6 actually carry a homozygous mutation-abolishing type IIA $sPLA_2$ expression (30). Further evidence that this enzyme could play a protective role in tumor development comes from the interesting observation that injection of phospholipase-activating protein induces regression of malignant gliomas (32). This has stimulated a number of genetic studies in man; however, no clear situation similar to that observed in the mouse has yet emerged (33–40). In contrast, there are a number of observations reporting an increased expression of type II $sPLA_2$ during cancer, reflecting an inflammatory reaction induced by the tumor as well as a consequence of cell malignancy (see Refs. 41 and 42 for an example).

To discuss whether type II $sPLA_2$ might modulate tumor cell proliferation or the reaction of surrounding tissues by promoting the formation of lipid mediators such as lysophosphatidic acid, as mentioned above, will be interesting. Another possible involvement of $sPLA_2$ in cancer might be *via* interactions with their specific membrane receptors, as recently shown for pancreatic PLA_2, which stimulates extracellular matrix invasion by normal and cancer cells (43). We will not discuss herein all the data accumulated on the characterization of $sPLA_2$ high-affinity receptor, which was the object of an important review (44). The molecular structure of $sPLA_2$ receptor, which displays a large extracellular domain containing carbohydrate recognition domains, is suitable to have the role of this membrane protein to be endocytic removal of $sPLA_2$ (45). Internalization of $sPLA_2$ might allow its nuclear translocation, opening some interesting issues as to the mechanism underlying its proliferative effects (46). Fi-

nally, a recent study reported a significantly decreased lethality of endotoxin shock in mice bearing an homologous disruption of $sPLA_2$ high-affinity receptor gene (47). Other membrane proteins such as heparan sulfates could also contribute to the interactions of $sPLA_2$, especially type IIA enzyme, with cell membrane (48). This will be discussed later on, when considering the complementarily observed between $sPLA_2$ and $cPLA_2$.

TYPE IV CYTOSOLIC PLA_2

As recently reviewed (5,49), a number of structural features revealed by molecular cloning of the cDNA coding for $cPLA_2$ have allowed us to understand the function and regulation of this enzyme. Three main points can be mentioned: (i) This serine esterase specific for arachidonic acid esterifying the *sn*-2 position of glycerophospholipids displays a nonclassical catalytic triad with apparently an arginine instead of an histidine residue; (ii) The N-terminal end is a calcium-phospholipid binding domain similar to the C2 domain present in protein kinase C; its crystal structure was recently resolved (50), and it is thought to direct association of the enzyme with its membrane phospholipid substrate in the presence of physiological μM calcium concentrations (51); (iii) the protein contains two serine residues (505 and 727) probably phosphorylated by various mitogen-activated protein kinases (MAP kinases) (see Ref. 52 for an up-to-date discussion). More recently, a pleckstrin homology domain was identified in the sequence of $cPLA_2$ and found to promote association of the protein to phosphatidylinositol 4,5-bisphosphate, resulting in a dramatic increase of its enzymatic activity (53).

Based on numerous studies including site-directed mutagenesis experiments, these features have promoted a rather broad consensus, indicating that $cPLA_2$ is activated by two complementary events, i.e., calcium-dependent translocation of the protein to the membrane, and phosphorylation *via* classical MAP kinases of Ser 505, which promotes increased activity of the enzyme (5,49). However, such a simple scheme should certainly be revisited for several reasons: (i) $cPLA_2$ phosphorylation might also involve stress-activated kinases such as p38, which does not result necessarily in enzyme activation, at least in platelets (54); and (ii) the site of $cPLA_2$ action might not be the plasma membrane, but instead the nuclear membrane, where lipoxygenase and cyclo-oxygenase 2 might also be located under conditions leading to eicosanoid production (55–58). In some cells, nuclear or cytosolic localization of $cPLA_2$ might even depend on cell density (59). Whether the lack of nucleus is in some way related to the apparently different regulation of $cPLA_2$ in platelets is unknown but would deserve some attention (54).

However, very new data from two independent groups might completely change our views about the so-called calcium-dependent translocation of $cPLA_2$, which appeared by immunocytochemical methods to display a punctuate labeling pattern all over the cytoplasm, without any evidence for a change in localization upon cell activation (60,61). These troubling observations should draw our attention to particular cytoplasmic structures called lipid bodies where both $cPLA_2$ and MAP kinases could be localized (61).

As to the most recent data concerning $cPLA_2$, five points justify a particular mention: (i) Gene invalidation was achieved by two independent groups, providing strong evidence for a nonredundant role of $cPLA_2$ in female reproduction, eicosanoid synthesis, allergic reactions, and postischemic brain injury (62,63); (ii) evidence was given for a direct involvement of $cPLA_2$ in apoptosis promoted by tumor necrosis factor α (TNFα) in a mechanism implicating enzyme activation *via* caspase-mediated proteolysis (64–68); (iii) $cPLA_2$ is an obligatory intermediate in the activation pathway of phagocyte NADPH oxidase (69); (iv) $cPLA_2$ displays an altered regulation in cystic fibrosis, suggesting a possible role of this enzyme in the pathophysiology of this disease (70); and (v) there is some genetic evidence for a possible involvement of $cPLA_2$ in the pathogenesis of schizophrenia, thus opening very fascinating issues on the role of $cPLA_2$ in brain (71,72). However, further studies are still required since a calcium-independent PLA_2 might also be involved (73).

Finally, as discussed above, the role of $cPLA_2$ cannot be considered without reference to $sPLA_2$, both enzymes acting in a complementary manner. For instance, numerous reports agree with the fact that $cPLA_2$ would be responsible for the immediate, rapid phase of arachidonate liberation, $sPLA_2$ being involved in a sustained and delayed phase of eicosanoid production. A recent study also showed that $cPLA_2$ is an obligatory intermediate for the cytokine-induced expression of $sPLA_2$ (74). However, the reverse order might be true as well, as elegantly shown by Hernandez *et al.* (75) in cultured astrocytes. Beside showing that type II $sPLA_2$ promotes MAP kinase and $cPLA_2$ activation probably *via* both specific-$sPLA_2$ receptor and membrane-bound heparan sulfates, the latter authors discuss available literature data illustrating the complementary nature of the two enzyme types. At the same time we finished this review, a remarkable study of Murakami *et al.* (76) appeared, fully clarifying the respective roles of $sPLA_2$ and $cPLA_2$, as well as $iPLA_2$, the latter one being discussed below.

TYPE VI CALCIUM-INDEPENDENT PLA_2

The last review devoted to $iPLA_2$ (4) described in detail the structure of this 85-kDa protein, characterized by the presence of eight ankyrin repeats possibly involved either in self-association of $iPLA_2$ as an homotetramer or in specific interactions with, for instance, cytoskeletal proteins. Balsinde and Dennis (4) also discussed very carefully the specificity of $iPLA_2$ inhibitors such as the bromoenol lactone currently used as a suicide substrate. The selectivity of the compound is not absolute, giving some doubt about a number of functions previously suspected for the enzyme. These include, for instance, arachidonic acid liberation (77), insulin secretion, as discussed in Reference 78, or long-term potentiation (79). Probably the use of antisense strategies will allow reevalua-

tion of some of the previous suggestions concerning the possible function of $iPLA_2$; this has indeed been the case for the proposal that $iPLA_2$ plays a main role in membrane phospholipid remodeling (80). Of course, clearer conclusions will certainly become available after gene targeting by homologous recombination, which does not seem to have been achieved.

When focusing on more recent findings on $iPLA_2$, molecular cloning of the cDNA coding for the human enzyme reveals a similar structure but also a great diversity in the gene expression pattern (81). For instance some splice variants containing the ankyrin motifs but lacking the catalytic triad are able to associate with and to inhibit the full-length enzyme (81). Another characteristic feature of the enzyme is its highest activity toward phosphatidic acid, as shown with the recombinant enzyme (10). Whether this could imply a contribution of $iPLA_2$ in the generation of lysophosphatidic acid still remains to be established (3). Also, the fact that $iPLA_2$ can be activated upon depletion of intracellular calcium pools might appear at first glance as a paradoxical observation but suggests that the enzyme could also be regulated in relation to calcium signaling (77). Finally, a very recent study indicated that Fas-mediated apoptosis is accompanied by an increased liberation of arachidonic and oleic acids by $iPLA_2$, $cPLA_2$ being inactivated by caspase-3-mediated cleavage (82). How this relates to the cleavage promoted by TNFα (66) will require special attention.

MEMBRANE ECTO-PHOSPHOLIPASE B

Molecular cloning of cDNA from three different species (15–17) revealed a good conservation of this enzyme, which is also apparently present in humans, as revealed from systematic search of sequence data (Gassama-Diagne, A., unpublished data). The protein is anchored in the membrane by a single hydrophobic segment followed by a short C-terminal cytoplasmic tail. Enzymatic activity is supported by the large heavily glycosylated (83) extracellular domain, which contains four homologous repeats. Despite the fact that two serine residues are included in a lipase consensus sequence present in domains II and IV (17), recent evidence indicates that the only active site is located in domain II and involves another serine residue (Table 1) (16,84,85).

The enzyme thus belongs to the group of brush-border hydrolases expressed upon enterocyte differentiation (13–17, 83–85) and is the first ecto-phospholipase so far characterized. By facing the intestinal lumen, mPLB thus appears obviously as a digestive enzyme able to fully deacylate glycerophospholipids as well as neutral glycerides such as diacylglycerol and monaoacylglycerol (14). However, additional sites of expression were recently identified, including testis (16) and epididymis (17). As discussed in our previous study (17), the latter observation agrees with the fact that spermatozoa lose up to 50% of their phospholipids upon their transit through epididymis, which is also the major source of glycerophosphocholine present in seminal plasma at mM concentrations. We thus suggest that mPLB might play a very critical role in sperm maturation. However, mPLB activation requires proteolytic cleavage by trypsin (17). This is easily achieved in the intestinal lumen (84) but still awaits further studies to identify which protease might be active in the male genital tract. Obviously, the precise role of mPLB in reproduction will be better defined after gene invalidation by homologous recombination.

CONCLUSION

This short review allowed us to summarize some of the most recent data available in the field of PLA_2. Molecular cloning of a number of cDNA provided novel and efficient tools to better understand the function of this complex family of proteins. However, as clearly illustrated for $cPLA_2$ (62,63), this might be only the first step of more-efficient strategies such as gene invalidation, which clearly appears as the most selective way to delineate PLA_2 function. In the case of $sPLA_2$, one can even more easily take advantage of the existence of spontaneous disruption of the gene, as recently illustrated for the role of $sPLA_2$ in gut infection by *Helicobacter felis* (86).

ACKNOWLEDGMENT

Thanks are due to Liliane Vranken for her help in collecting documentation.

Changes in Membrane Microdomains and Caveolae Constituents in Multidrug-Resistant Cancer Cells

Yaakov Lavie, Giusy Fiucci, Malgorzata Czarny, and Mordechai Liscovitch*

Department of Biological Regulation, Weizmann Institute of Science, Rehovot 76100, Israel

ABSTRACT: Cancer chemotherapy often fails because of the development of tumors which are resistant to most commonly used cytotoxic drugs. This phenomenon, multidrug resistance (MDR), is usually mediated by overexpression of P-glycoprotein (P-gp), an ATPase that pumps out the drugs used in chemotherapy, thereby preventing their accumulation in cancer cells and greatly reducing their cytotoxic efficacy. A large body of work indicates that MDR is associated also with marked changes in membrane lipid composition. Most notably, elevated levels of cholesterol, glycosphingolipids (e.g., glucosylceramide), and sphingomyelin have been reported. These lipids are enriched in caveolae and in membrane microdomains termed detergent-insoluble glycosphingolipid-enriched complexes (DIGs). Recently we demonstrated that in multidrug-resistant tumor cells there is a dramatic increase in the number of caveolae and in the level of caveolin-1, an essential structural constituent of caveolae. Another constituent of membrane microdomains, phospholipase D, is also elevated in MDR cells. These findings may be related to the fact that a significant fraction of cellular P-gp is associated with caveolin-rich membrane domains. The possible role of DIGs and caveolae in the acquisition and/or maintenance of the multidrug resistant phenotype is discussed.

MULTIDRUG RESISTANCE (MDR): DEFINITION, SIGNIFICANCE, CELLULAR MODELS

Anticancer drug resistance is the primary reason for the failure of chemotherapy in cancer patients (1,2). The resistance of human malignancy to chemotherapeutic intervention has a multifactorial etiology which falls into two categories: first, host-mediated resistance, with all the characteristics of tumor–host tissue interactions (e.g., tumor-immune system interactions); second, cellular resistance, which can be either intrinsic (inherent or natural) or acquired. It may be generally stated that as tumors progress in time and size, they become increasingly resistant to chemotherapy. Both of the above-mentioned forms of resistance are responsible for this development (2). Thus, clinical improvement of cancer therapy critically depends on understanding and controlling drug resistance.

One form of drug resistance, termed MDR, has been most studied, and was extensively characterized utilizing *ex vivo* models of multidrug resistant cancer cells in culture (3). Such model cell lines are generated by growing cancer cells under progressively higher concentrations of a given cytotoxic drug. Selection over many generations results in drug-resistant cell lines that can grow in the presence of drug concentration orders of magnitude higher than those tolerated by the parental cells (e.g., Ref. 4). The degree of resistance can be determined in different drug-sensitive and -resistant cell lines by using cell proliferation/survival assays like the MTT assay [based on conversion of 3(4,5-dimethylthiazol-2-yl)2,5-diphenyl tetrazolium bromide (MTT) to formazan by living cells] (5). EC_{50} values for cell killing can also provide a quantitative tool for comparing different cytotoxic drug potencies and for assessing the effectiveness of compounds that can reverse the MDR phenotype. It was repeatedly observed that selection for resistance to one particular drug is accompanied by resistance to a variety of other drugs. This general characteristic of cancer cells defines the MDR phenomenon. Drugs known to induce MDR include Vinca alkaloids (e.g., vincristine), anthracyclins (e.g., doxorubicine), actinomycin D, etopside, paclitaxel, and colchicine. Although, in general, these drugs are structurally and functionally unrelated, they have two common broad structural features, a planar hydrophobic ring and a tertiary amine (3). Presently many cell lines serve as models for MDR, including murine leukemia P388-Adr (adriamycin), and P388-VCR (vincristine) cells; chinese hamster ovary (CHO)-emetine cells; breast cancer MCF-7-AdrR; and MCF-7-VCR cells, and many more.

MOLECULAR MECHANISMS OF MDR

Many cellular changes have been described that accompany the multidrug-resistant phenotype. However, most studies have focused on the so-called "classical" MDR protein termed P-glycoprotein (P-gp), which is the product of the MDR1 gene (6,7). P-gp is a membrane-bound glycoprotein that belongs to the protein family of ABC transporters. P-gp acts as an ATP-dependent drug efflux pump and is believed to mediate drug resistance by actively extruding drugs from

Lipids 34, S57–S63 (1999).

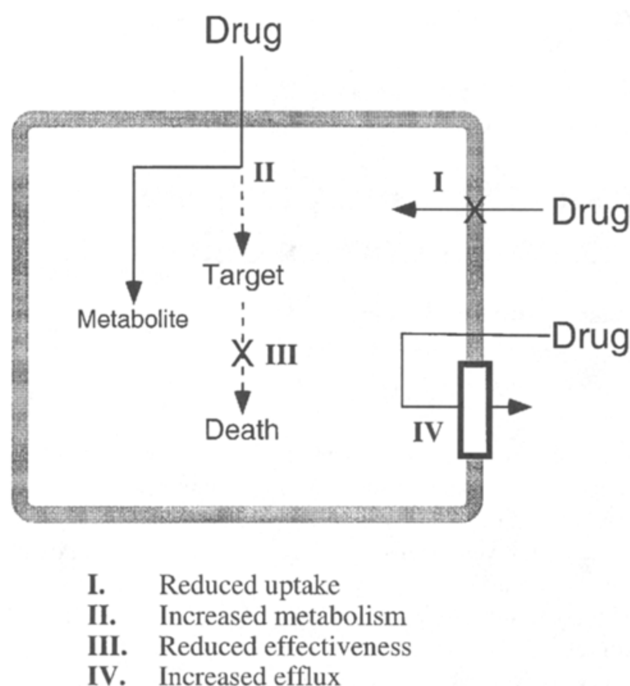

FIG. 1. Mechanisms of drug resistance in cancer cells. A schematic representation of a multidrug-resistant cell and four possible mechanisms that reduce a cytotoxic drug efficacy (and increase cellular drug resistance). Mechanisms I and IV occur at the plasma membrane and may be modulated by membrane lipid changes as detailed in the text.

the cells. A large body of work documents the modulation of P-gp activity by control mechanisms such as phosphorylation and the regulation of its expression on the transcriptional level (6). In additon to MDR1/P-gp, MDR1-like proteins were isolated that are overexpressed in various drug-resistant tumor cell lines. To date, the MDR1-like protein family includes multidrug resistance-associated protein (MRP) and its homologs (8). P-gp and MRP belong to the ATP-binding cassette (ABC) super-family of transporters, and despite having a differential substrate specificity, all operate by facilitating efflux of chemotherapeutic drugs.

Clearly, however, P-gp and related ABC transporters are not the sole determinants of drug resistance in MDR cells. Rather, cells seem to adopt multiple strategies in order to survive the lethal effects of chemotherapeutic drugs (2), and the various cellular mechanisms that contribute to the existence and degree of cross-resistance displayed by MDR cells are suggested to act simultaneously. Thus, in addition to the accelerated outward transport of drugs, mediated by overexpression of ABC transporters, there are additional cellular mechanisms for drug adaptation (for review see Ref. 2). These include: (i) altered cellular pharmacokinetics of drug uptake, that may be attributed to changes in membrane permeability, probably *via* changes in membrane lipid composition; (ii) increased inactivation of drugs, due either to overexpression of glutathione-*S*-transferase and elevated intracellular glutathione concentrations; or altered drug metabolism, e.g., by the cytochrome P-450 enzyme system (responsible for reducing quinone-containing anticancer drugs in tumor cells); or by aldehyde dehydrogenase, which detoxifies nitrogen mustard compounds; (iii) increased DNA repair *via* alterations in DNA topoisomerase-II enzyme activity. Together, these mechanisms result in a major decrease in intracellular drug accumulation and effectiveness (Fig. 1). In the present review we will focus on cellular and biochemical changes that occur at the level of the cell plasma membrane in multidrug-resistant cancer cells.

MEMBRANE LIPIDS CHANGES IN MULTIDRUG-RESISTANT CELLS

Studies on membrane alterations associated with anticancer drug resistance began to appear in the early 1980s. Cell resistance was suggested to be accompanied by changes in membrane microviscosity (lipid bilayer structural order or membrane fluidity). Whereas most studies reported that drug-resistant cells exhibit an increase in membrane fluidity, other studies suggested the opposite (see Ref. 9 and citations therein). An elegant study, dating to 1982, showed that adriamycin coupled to insoluble agarose matrix was almost as cytotoxic to L1210 cells as the unconjugated drug (10). It was concluded that the drug's cytotoxic action can solely be attributed to its interaction with the cell surface. Thus, it is safe to say that membrane composition and structure are important factors in drug action and cell resistance.

In this context, lipids are likely to fulfill multiple and complex functions in MDR, by influencing drug transport across the plasma membrane and by modulating the activity of drug transporters. Lipids determine cell membrane fluidity, which was shown to be a factor in the capacity of MDR cells to accumulate drugs (11). Higgins and Gottesman (12) proposed that P-gp substrates initially interact with the lipid bilayer, by partitioning into the lipid phase, before gaining access to P-gp. This view was corroborated by recent three-dimensional structural data showing a gap within the transmembrane region of P-gp through which drugs can enter the hydrophilic core of the protein (13). Additionally, a large body of data demonstrates the effect of the lipid environment of P-gp on its function. Like other membrane-bound ATPases, P-gp requires phospholipids for its ATPase activity. Using a partially purified preparation of P-gp, Doige *et al.* (14) showed that unsaturated phosphatidylcholine and phosphatidylserine are crucial for restoring P-gp ATPase activity, while saturated phosphatidylethanolamine is most effective in activating the ATPase. Urbatsch and Senior (15) suggested that in addition to the significant influence of the lipid environment on the characteristics of purified, reconstituted P-gp-ATPase activity, lipids may have a role in the coupling between drug-binding sites and catalytic sites of P-gp.

Indeed, chemical analyses of cell lipids and quantitative comparison of various lipid types in drug-sensitive and drug-resistant cells indicated that the acquisition of MDR is associated with significant changes in their membrane lipids. Such

changes can be attributed mainly to altered lipid uptake from the medium, or alterations in cell lipid synthesis and metabolism. Vrignaud *et al.* (16) have shown a twofold increase in fatty acid uptake by doxorubicine-resistant rat glioblastoma cells compared to the drug-sensitive wild-type clone. Other workers demonstrated a much higher amount of triglycerides in drug-resistant P388 leukemia cells (17). This work showed also that, in the resistant cells, the ratio of sphingomyelin to phosphatidylcholine is significantly higher (17). Another study showed that the incorporation of [^{3}H]palmitic acid into sphingomyelin was up to 3.5-fold higher in adriamycin-resistant MCF-7 cells in comparison with the drug-sensitive control cells (18). May *et al.* (19) utilized a purified plasma membrane preparation of leukemic T-lymphoblasts to show that upon development of drug resistance, there is a very significant elevation of cell ether-lipid content. In addition they demonstrated that lipid-to-protein ratio, in general, is increased. The role of fatty acids, triglycerides, or ether lipids in MDR cells is not specified; however, these elevations of lipid content might account for changes in MDR cell-membrane properties and may affect drug uptake, transport, and extrusion.

Patterns of glycosphingolipid expression are known to change profoundly upon oncogenic transformation of cells (20). Intriguingly, more recent work has indicated that such changes occur also in association with the MDR phenomenon. Lavie *et al.* (18) showed that the precursor of all glycosphingolipids, glucosylceramide (GlcCer), is markedly elevated in various MDR cell lines, including MCF-7-AdrR, KB-V, and NIH:OVCAR-3, as compared to their wild-type counterparts. It was further demonstrated that higher activity of GlcCer synthase is the principal cause of this alteration in MDR GlcCer level (18). These results are consistent with prior studies demonstrating a biosynthetic block at the point of gangliosides production, which was shown to accompany the acquisition of resistance to daunorubicine and vincristine in DC-F3 Chinese hamster lung cells (21). Together these results indicate that a general change of membrane glycosphingolipids occurs in MDR cells.

Mountford and Wright (22) compared several drug-sensitive and drug-resistant cell lines with respect to lipid composition of their purified plasma membrane. These authors found a significant elevation in free cholesterol level in vinblastine-resistant T lymphoblasts as compared with the vinblastine-sensitive parental cells. Similarly, human ovarian MDR cells exhibit higher membrane cholesterol levels compared with their wild-type counterpart, when cultured under conditions of cholesterol deprivation (23). These data indicate that cholesterol metabolism is modified in the MDR cells and suggest that MDR cells are better able to maintain high cholesterol levels. In conclusion, reports from studies carried over the last 30 yr in different MDR cells demonstrate significant changes in membrane lipid composition; in particular, fatty acids, ether lipids, triglycerides, glycosphingolipids, sphingomyelin, and cholesterol are affected. However, it is not known at this time how these alterations do contribute to the development or maintenance of MDR in cancer cells.

It is known that sphingolipids (sphingomyelin and glycosphingolipids) and cholesterol are highly enriched in distinct membrane microdomains termed detergent-insoluble glycosphingolipid-enriched complex (DIGs) that have received much attention in recent years (see below). The elevated levels of GlcCer, sphingomyelin and cholesterol, independently reported in different types of MDR cells, suggest that MDR might be associated with increased formation of these microdomains in the plasma membrane. In the following paragraphs we shall discuss the properties of membrane microdomains and review the evidence for their involvement in mediating MDR in cancer cells.

DIGs AND CAVEOLAE: MICRODOMAINS IN BIOLOGICAL MEMBRANES

There is growing evidence for the existence in biological membranes of microdomains that are laterally segregated in the plane of the bilayer and that are enriched in sphingolipids and in cholesterol (Fig. 2; Refs. 24,25). Such microdomains have been variously termed DIGs (26), GEMs (glycosphingolipid-enriched membranes; 27), LDTI (low density Triton-insoluble) membranes; 28), or rafts (29). As can be inferred from some of these terms, DIGs can be distinguished from the bulk of cellular membranes by their insolubility in certain nonionic detergents such as Triton X-100. Because of their low buoyant density, the detergent-insoluble microdomains can readily be separated from other cell constituents by flotation in a sucrose density gradient (30). Analysis of the lipid composition of DIGs, isolated in this manner from MDCK cells, revealed that they are highly enriched in cholesterol and sphin-

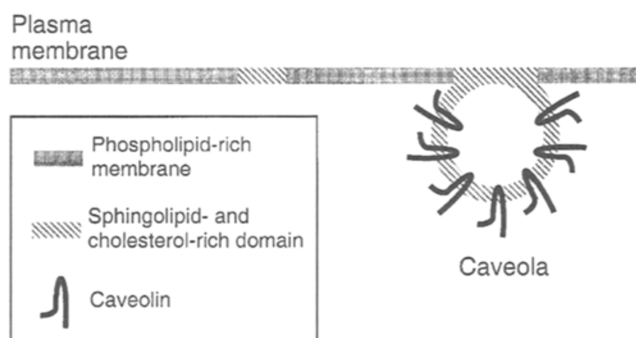

FIG. 2. Membrane microdomains and caveolae. Membrane microdomains detergent-insoluble glycosphingolipid-enriched complex [(DIGs); shaded areas] have a characteristic lipid composition, rich in sphingolipids and cholesterol, that is significantly different from the bulk phospholipid-rich membrane (solid areas). DIGs are laterally segregated in the plane of the membrane and exhibit a liquid-ordered (L_o) phase behavior, as opposed to the liquid crystalline phase of bulk membranes. Caveolae have a similar lipid composition and can be co-isolated with DIGs as detergent-insoluble particles with low buoyant density. Caveolae have a characteristic coat protein called caveolin—a 21-kDa integral membrane protein with a unique hairpin loop structure—and are present mainly in epithelial cells, adipocytes, and fibroblasts (see text for more details and references).

golipids. About 25% of cellular cholesterol was insoluble in Triton X-100, and cholesterol was nearly threefold enriched in the detergent-insoluble membranes as compared to the whole cell lysate (30). The sphingolipids sphingomyelin and lactosylceramide were virtually insoluble in Triton X-100, while other sphingolipids were only 50–60% soluble; as a class, sphingolipids were enriched nearly sevenfold in the DIGs (30). The results of this seminal study were confirmed by subsequent experimentation in other cell types (see Ref. 24 for review). The property of detergent insolubility is conferred upon DIGs by their specific lipid composition. This was demonstrated in experiments in which sphingolipid- and cholesterol-rich liposomes (SCRL) were largely resistant to detergent solubilization. Furthermore, detergent resistance was conferred upon glycosylphosphatidylinositol-anchored proteins incorporated into SCRL (31,32). Detergent insolubility correlates with the presence of liquid ordered (L_0) phase domains in either artificial or biological membranes (see Ref. 24 for review).

DIGs have been isolated from many cell types, and their biochemical analysis has provided important clues as to their biological functions. Numerous signaling proteins are enriched in DIGs (28,33), implicating these microdomains as platforms on which multimolecular signaling complexes are assembled and from which signal cascades aimed at intracellular effectors are launched. DIGs have been envisioned also as sphingolipid-cholesterol "rafts" which function in the sorting and subsequent transport of glycosylphosphatidylinositol-anchored and other membrane proteins destined for apical membranes of polarized cells (29). Finally, DIGs were hypothesized to serve as building blocks for assembly of caveolae (34).

DIGs are related, in their lipid composition and their resistance to detergent solubilization, to specific, morphologically and biochemically well-defined cellular structures called caveolae (35). Caveolae are nonclathrin-coated plasma membrane invaginations, 50–100 nm in size, that have a characteristic striated coat structure (36,37). A major caveolar coat protein is caveolin-1, a 21-kDa integral membrane protein (37,38). Caveolin-1 forms high molecular weight homo-oligomers and acts as a scaffolding protein for various other proteins (34). Because of their similar lipid composition, DIGs and caveolae are co-purified as low density, Triton-insoluble membrane particles on discontinuous sucrose density gradients (30,39). However, while DIGs are present in most if not all cell types, caveolae are found mostly (though not exclusively) in epithelial cells (38). Caveolae have been implicated in transport processes such as nonclathrin-mediated endocytosis (Ref. 40 and citations therein), as well as cholesterol efflux (41). In addition, recent work strongly suggests that, like DIGs, caveolae play an important role in cellular signal transduction (34,42).

COORDINATE UP-REGULATION OF CONSTITUENTS OF DIGs AND CAVEOLAE IN MDR CANCER CELLS

The functions assigned to DIGs and caveolae, namely, endocytosis, signaling, and cholesterol efflux, share a common cellular localization in the plasma membrane. Together, the data suggest that, depending on circumstances, both DIGs and caveolae microdomains act to sequester or recruit specific membrane and cytosolic proteins into large, multimolecular functional complexes. The MDR transporters are known also to be localized and function in the plasma membrane. It was therefore of interest that analysis of cell membranes from MDR cells showed marked changes in sphingolipids and cholesterol, both of which are characteristic constituents of DIGs and caveolae. The accumulation of GlcCer in various MDR cells seems to be of particular significance because it is associated with, and depends on, elevated GlcCer synthase activity (18). This suggests that MDR is associated with a regulated modification of membrane lipid biosynthetic pathways.

We have therefore examined whether other constituents of DIGs and caveolae are up-regulated in MDR cancer cells. DIGs and caveolae were prepared from HT-29 human colon carcinoma cells and from a colchicine-resistant HT-29-derived cell line (HT-29-MDR) by flotation of Triton X-100-insoluble membranes on a sucrose density gradient (30,39). Analysis of the gradient fractions by Western blotting with antibodies to caveolin-1 revealed a dramatic, over 10-fold increase in caveolin-1 levels in the MDR cells (43,44). To confirm the generality of this finding, we examined the expression of caveolin-1 in an adriamycin-resistant variant cell line derived from MCF-7 human breast adenocarcinoma cells (MCF-7-AdrR). Whereas in the parental MCF-7 cells caveolin-1 expression was nearly undetectable, the expression of caveolin-1 in MCF-7-AdrR cells was very high (43,44). The up-regulation of caveolin-1 expression in the HT-29-MDR cells was accompanied by a fivefold increase in the number of juxtamembrane, 50 to 100 nm noncoated invaginations, with the characteristic flask shape morphology of caveolae. Confirming previous results in other MDR cells (18), sphingolipid analysis revealed elevated levels of GlcCer in the HT-29-MDR cells cells, compared to the parental HT-29 cells; GlcCer levels returned to "normal" wild-type levels upon treatment of the MDR cells with the GlcCer synthase inhibitor 1-phenyl-2-decanoylamino-3-morpholino-1-propanol (PDMP) (43,44).

TABLE 1
Up-Regulation of Lipid and Protein Constituents of DIGs and Caveolae in MDR Cells[a]

Lipid/protein	Relative change	Reference
Cholesterol	↑	22, 23
Sphingomyelin	↑	17, 18
Glucosylceramide	↑↑	18
Caveolin-1	↑↑↑	44
Phospholipase D	↑↑	Fiucci, G., Czarny, M., Lavie, Y., Zhao, D., Berse, B., Blusztajn, J.K., and Liscovitch, M., unpublished data

[a]MDR, multidrug resistance; DIGs, detergent-insoluble glycosphingolipid-enriched complex.

DIGs and caveolae are enriched in phosphatidylinositol 4,5-bisphosphate (PIP_2) and in the lipid kinases that synthesize it (45–49). PIP_2 is a cofactor of phospholipase D (PLD) (50), and it is required for PLD activation by small GTPases such as ADP-ribosylation factor (51). More recent work has indicated that PLD directly interacts with PIP_2 in *in vitro* liposome-binding assays (52,53). The localization of PIP_2 in DIGs and caveolae raised the possibility that PLD might also be present there. Indeed, a PLD activity was found to be enriched in these domains in a variety of cell types, including HaCaT human keratinocytes, COS-7 cells, U937 promonocytes, and NIH-3T3 fibroblasts (54,55). The PLD activity found in DIGs and caveolae was not the ADP ribosylation factor-dependent PLD1 isoform, and likely represents a product of the PLD2 gene. These data suggest that PLD is a normal constituent of DIGs and caveolae. As MDR is accompanied with an up-regulation of other constituents of DIGs and caveolae, we compared the domain-associated PLD activity in parental and MDR cells. This analysis revealed that PLD activity in the DIGs and caveolae fraction was markedly elevated in both multidrug-resistant variants of HT-29 and MCF-7 cells, compared to their respective parental lines (54; Fiucci, G., Czarny, M., Lavie, Y., Zhao, D., Berse, B., Blusztajn, J.K., and Liscovitch, M., unpublished data).

In conclusion, our recent results indicate that caveolin-1 expression and PLD activity are greatly elevated in MDR cancer cells. Together with previous data showing increased levels of cholesterol and sphingolipids (Table 1), it may be concluded that acquisition of the multidrug-resistant phenotype by human cancer cells is accompanied with a coordinate up-regulation of plasma membrane DIGs and caveolae. The functional significance of this dramatic membrane modification is discussed below.

SUMMARY AND CONCLUSIONS: ARE MEMBRANE MICRODOMAINS INVOLVED IN MDR?

Acquisition of MDR is clearly a multifactorial process. Whereas expression of P-gp (and other ABC transporters) is a major factor, additional biochemical changes that are associated with MDR may make significant contributions to the drug-resistant phenotype. The results summarized above imply that there is a coordinated program for up-regulation of constituents of caveolae and related membrane microdomains in MDR cells. The lipids that seem to be involved in this phenomenon are GlcCer, sphingomyelin, and cholesterol. A structural protein of caveolae, caveolin-1, is also dramatically elevated, and so is a novel DIGs and caveolae-resident enzyme, PLD (Table 1). Indeed, the number of caveolae is greatly increased in MDR cells. Future studies may reveal that additional lipids (e.g., PIP_2) and proteins (e.g., flotillin), previously localized to DIGs and caveolae, are up-regulated in MDR cells. These results raise a number of interrelated and potentially important questions. First, how is the formation of DIGs and caveolae regulated? Second, is there a relationship between the expression of P-gp and these membrane changes? Third, do DIGs and caveolae contribute to MDR and, if yes, how?

A plausible mechanism for the coordinate up-regulation of the various lipid and protein components of caveolae may involve the greater number of caveolae found in MDR cells. If caveolae are required for, or contribute to drug resistance, cells that have more caveolae may be positively selected under the drug treatment regimen that results in establishment of an MDR cell line (see below). The elevated levels of lipid and protein constituents of caveolae may thus be a consequence of the fact that there are more caveolae in those cells. An alternative mechanism, i.e., that overexpression of P-gp somehow drives the up-regulation of caveolae, seems consistent with our preliminary results showing that P-gp is localized in part in DIGs/caveolae (43,44). The overexpression of P-gp in MDR cells may thus drive the increased synthesis of building blocks required for formation of these membrane microdomains. However, this mechanism is inconsistent with our findings, showing that there is no change in caveolin-1 expression in MCF-7 cells transfected with recombinant P-gp (44).

What might be the relationship between caveolae and MDR? Of the various functions assigned to caveolae, their proposed role in mediating cholesterol efflux seems most relevant in the context of MDR. Fielding and Fielding (56,57) showed that caveolae act as plasma membrane terminals for the outward transport of cellular cholesterol and thus act to reduce cellular cholesterol levels. Furthermore, caveolin-1 expression is under the control of free cholesterol, acting through the sterol regulatory element-binding protein (SREBP) pathway (58,59). The SREBP pathway has been implicated in the transcriptional activation of enzymes and proteins involved in biosynthesis or uptake of cholesterol (60). In contrast, and consistent with the proposed role of caveolae in free cholesterol efflux, SREBP has a suppressive effect on caveolin-1 expression (59). While the molecular mechanism of free cholesterol efflux through caveolae is not known, it is possible that caveolae may be capable of mediating or facilitating the export of certain lipophilic drugs (probably at relatively low efficiency). If such a capability does exist, during early stages of drug exposure cells may be under a selective pressure that favors cells with more caveolae and hence high expression of caveolin-1.

Interestingly, oncogenic transformation of cells is accompanied by decreased expression of caveolin-1 and a greatly reduced number of caveolae (61). Expression of caveolin-1 has a growth-inhibitory effect on transformed cells (62,63). Our results, showing an up-regulation of caveolin-1 in MDR cells, suggest that the acquisition of a multidrug-resistant phenotype is associated with a reversal of at least one aspect of oncogenic transformation. The slower rate of proliferation that must ensue may afford some protection to caveolin-expressing cells against the action of cytotoxic drugs, and thus possibly contribute to their selective growth advantage under chemotherapy.

In summary, a fairly large body of work indicates that significant membrane lipid alterations occur in MDR cells. Of

particular interest, several constituents of DIGs and caveolae—cholesterol, sphingolipids, caveolin-1, and PLD—are up-regulated in multidrug-resistant cancer cells. We propose that caveolae may be involved in drug efflux and thus be selected for during cell exposure to chemotherapeutic drugs. This hypothesis is amenable to experimental scrutiny and is currently under study in our laboratory.

ACKNOWLEDGMENTS

We thank Yona Eli and Tova Harel for excellent technical assistance. This work was supported in part by grants from the Levine Fund for Applied Research, the United States–Israel Binational Science Foundation (BSF; Jerusalem), the Israel Science Foundation, the Minerva Foundation (München), and the Forchheimer Center for Molecular Genetics. [a]Department of Molecular Cell Biology and [b]Centre for Biomembranes and Lipid Enzymology, University of Utrecht, NL-3584 CH Utrecht, The Netherlands

The 85-kDa Ca^{2+}-dependent cytosolic phospholipase A_2 ($cPLA_2$) is of special interest since it selectively hydrolyzes glycerophospholipids at the *sn*-2 position, generating arachidonic acid, which plays an important role in various cellular processes. In many cell types, $cPLA_2$ can be activated by various stimuli, such as cytokines and growth factors. Growth factors stimulate $cPLA_2$ activity by activating the mitogen-activated protein kinase (MAPK) cascade, resulting in a phosphorylation of $cPLA_2$ by MAPK on Ser-505. $cPLA_2$ is fully activated when it is translocated to membranes in a Ca^{2+}-dependent manner. Localization studies of endogenous $cPLA_2$ revealed a punctate pattern randomly distributed throughout the cytoplasm. Recent evidence suggests that reactive oxygen species (ROS), such as superoxide and hydrogen peroxide (H_2O_2), function as intracellular second messengers. Furthermore, exogenously H_2O_2 could mimic growth factor-induced tyrosine phosphorylation in A431 cells. Recently we demonstrated that epidermal growth factor (EGF) induced a twofold $cPLA_2$ activation in Her 14 fibroblasts. This activation is mediated by the MAPK isoforms ERK-1 and ERK-2, which are phosphorylated and thus activated upon EGF stimulation. Because ROS are thought to function as intracellular second messengers, we investigated whether H_2O_2 is also able to activate MAPK and $cPLA_2$ in Her 14 fibroblasts. To this extent cells were stimulated for 30 min with 0.1, 0.5, 1, 2, or 5 mM H_2O_2, respectively, in phosphate-buffered saline containing 0.9 mM Ca^{2+}, 0.5 mM Mg^{2+}, and 5 mM glucose, whereafter the cells were scraped in buffer (50 mM HEPES pH 7.4; 0.25 M sucrose; 50 mM NaF; 250 μM Na_3VO_4; 1 mM EGTA; 10 μM leupeptin; 1 μM pepstatin; 1 mM phenyl methylsulfonyl fluoride). The proteins were separated on SDS-polyacrylamide gel electrophoresis and stained with a phospho-specific antibody for MAPK. H_2O_2 was found to phosphorylate ERK-1 and ERK-2 MAPK in a dose-dependent manner with a maximal effect at 5 mM. Under these conditions, no release of lactate dehydrogenase was detected, indicating that they are still viable. Subsequently, the time course of ERK-1 and ERK-2 phosphorylation induced by 5 mM H_2O_2 was examined, showing a rapid phosphorylation, with a maximal effect at 10 min. We then investigated the effect of H_2O_2 on $cPLA_2$ activity. $cPLA_2$ activity was measured by the release of radiolabeled arachidonic acid from the *sn*-2 position of 1-stearoyl-2-[1-^{14}C]arachidonoyl-glycero-3-phosphocholine *in vitro*. H_2O_2 stimulated $cPLA_2$ activity in a dose-dependent way with a maximum at 1 mM. $cPLA_2$ activity was already maximal after 5 min and remained increased up to 40 min. In EGF-induced signal transduction, MAPK is activated by MAPK kinase (MEK) which in turn is activated by Raf. In order to establish whether in H_2O_2-stimulated cells MAPK as well as $cPLA_2$ is activated through this pathway, we preincubated the cells with the MEK inhibitor PD98059 which inhibits the phosphorylation of MEK by Raf. Preliminary results using this inhibitor in H_2O_2-stimulated cells showed that ERK-1 and ERK-2 phosphorylations were significantly reduced as well as the H_2O_2-induced activity of $cPLA_2$. Here we show that H_2O_2 induces ERK-1 and ERK-2 phosphorylation dose- and time-dependently. In addition, $cPLA_2$ is also activated by H_2O_2 in a dose- and time-dependent manner. These phosphorylations of ERK-1, ERK-2, and $cPLA_2$ were inhibited by the MEK inhibitor, suggesting that MEK activates in part ERK-1 and ERK-2 and that these MAPK mediate $cPLA_2$ phosphorylation.

Targeting of Cytosolic Phospholipase A_2 to Plasma Membrane Inhibits Its Activation by G-Protein Coupled Receptors

Elsa Klapisz, Mouloud Ziari, Kamen Koumanov, Dominique Wendum, Corinne Brachet, Jean Luc Olivier, Gilbert Béréziat, and Joëlle Masliah*

UPRESA CNRS 7079, CHU St-Antoine, 75012 Paris, France

The 85 kDa Ca^{2+}-sensitive cytosolic phospholipase A_2 ($cPLA_2$) specifically hydrolyzes arachidonic acid-containing phospholipids, thus initiating the biosynthesis of inflammatory mediators under the stimulation of membrane receptors. Two main mechanisms regulate $cPLA_2$ activation: its calcium-dependent translocation to membrane phospholipids and its phosphorylation by several Ser/Thr kinases, including MAPKinases. In order to investigate the respective importance of these two mechanisms in the activation of $cPLA_2$ by G protein-coupled receptors, we constitutively targeted $cPLA_2$ to plasma membrane, therefore bypassing calcium-dependent translocation.

We constructed a chimeric $cPLA_2$ constituted by the full-length $cPLA_2$ and containing at its C-terminal end the 18 last amino acids of K-Ras4B. This motif targeted cytosolic proteins to plasma membrane. Chinese Hamster ovary (CHO) cells permanently expressing α_{2B}-adrenergic receptor were stably transfected with the cDNA encoding for the chimeric $cPLA_2$-Ras. Immunofluorescence of one stable transfectant, the 2B7 clone, demonstrated that $cPLA_2$-Ras localizes to the plasma membrane. We demonstrated by gas chromatography/mass spectrometry that $cPLA_2$-Ras is enzymatically active on endogenous membrane phospholipids. Stimulation of the 2B7 clone with epinephrine induces a gel shift of $cPLA_2$-Ras, resulting from its phosphorylation on Ser505 by MAPKinases. However, treatment of 2B7 clone with epinephrine, calcium ionophore A23187, or both agonists leads to an inhibition of stimulation of arachidonic acid release in comparison with parental CHO-α_{2B} cells. In contrast with this inhibition, overexpression of wild-type $cPLA_2$ at the same level has no effect on arachidonic acid release induced by epinephrine and/or calcium ionophore.

These results suggest that the presence of $cPLA_2$-Ras at the plasma membrane inhibits the activation of endogenous $cPLA_2$ in CHO-α_{2B} cells.

In order to verify the level of activation of $cPLA_2$-Ras, we expressed the chimera in the baculovirus-*Sf9* cell system. Sf9 cells do not contain endogenous $cPLA_2$ and perform the same posttranslational modifications as in mammalian cells. We constructed two recombinant viruses, allowing the expression of either wild-type $cPLA_2$ or $cPLA_2$-Ras.

In these cells, the expression of wild-type $cPLA_2$ leads to an important stimulation of arachidonic acid release from prelabeled cells in response to A23187 or to okadaïc acid, a Ser/Thr phosphatase inhibitor. In contrast, the expression of $cPLA_2$-Ras leads to a dramatic decrease of arachidonic acid release in response to these agonists. This lack of activation of $cPLA_2$-Ras is not due to a lack of phosphorylation. Indeed, okadaïc acid induces the same increase of [^{32}P] incorporation in $cPLA_2$-Ras as compared to wild-type $cPLA_2$.

These results indicate that, in spite of constitutive membrane localization and agonist-induced phosphorylation, the chimeric $cPLA_2$-Ras is enzymatically active but is not activated in response to stimuli. Moreover its plasma membrane targeting inhibits endogenous $cPLA_2$ activation in CHO-α_{2B} cells.

Inhibition of Ca^{2+}-Independent Phospholipase A_2 Affects Arachidonate-, Not Docosahexaenoate-, Phospholipid Remodeling in U_{III} Cells

H. Birbes, C. Luquain, J.F. Pageaux, M. Lagarde, and C. Laugier*

INSERM U 352, Laboratoire de Biochimie & Pharmacologie, INSA-Lyon, 69621 Villeurbanne Cedex, France

The phospholipase A_2 (PLA_2) enzymes are now recognized to play a central role in cellular signaling mechanisms by regulating the synthesis of lipids mediators and the remodeling of phospholipid (PL) fatty acyl chains. We previously showed in rat uterine stromal cells (U_{III}) a very specific pattern in arachidonic acid (AA) and docosahexaenoic acid (DHA) distribution between PL classes. $[^3H]$ AA was mainly incorporated in the diacyl subclasses of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) and in phosphatidylinositol, while $[^3H]$ DHA was principally recovered in PE plasmalogens. At low concentrations, AA appears to be incorporated in selected PL classes *via* the deacylation/reacylation cycle. Thus, in resting cells, availability of lysophospholipid acceptor provided by a PLA_2 activity is a limiting factor for incorporation of AA into PL. In this report, we describe the involvement of PLA_2 enzymes involved in the esterification of AA and DHA in unstimulated U_{III} cells. The extent of $[^3H]$ AA and $[^3H]$ DHA esterification into PL of cells incubated in Ca^{2+}-free medium supplemented with EGTA and BAPTA, the latter being an intracellular Ca^{2+} chelator, was the same as that in the presence of Ca^{2+}, suggesting that the PLA_2 responsible for supplying the lysophospholipid acceptor for AA and DHA esterification was Ca^{2+}-independent. A Ca^{2+}-independent PLA_2 activity was detected in U_{III} cell homogenates with 1,2-dipalmitoyl-glycerophosphocholine as substrate. One common feature of the best characterized Ca^{2+}-independent PLA_2 is their irreversible inhibition by a selective inhibitor bromoenol-lactone (BEL). Preincubation of U_{III} cells with increasing amounts of BEL resulted in a dose-dependent inhibition of Ca^{2+}-independent PLA_2 activity with an apparent IC_{50} of about 7 μM. Cells treated with BEL for 30 min and then exposed to exogenous $[^3H]$ AA for 30 min showed a partial inhibition (about 20%) of $[^3H]$ AA esterification into PL, affecting mainly arachidonate-containing PC. The cellular amount of lysophosphatidylcholine (lysoPC) isolated by thin-layer chromatography in cells prelabeled with $[^3H]$ choline was also reduced by BEL treatment. Maximal inhibition of lysoPC levels never exceeded 20%, even with BEL at doses higher than 50 μM. This decrease is in accordance with inhibition by BEL of AA esterification into PL and demonstrates that a PLA_2 activity is involved. By contrast, $[^3H]$ DHA esterification was not affected by BEL treatment. These results suggest that the pathways for AA and DHA esterification into U_{III} cells PL are at least partially different. We also studied the effects of BEL on the remodeling of PL fatty acyl chains. Cells were prelabeled with $[^3H]$ AA or $[^3H]$ DHA, and the transfer of radioactive fatty acid between PL classes was analyzed after an additional incubation of 4 h without the label, in the absence or presence of BEL. In control cells, the transfer of AA occurs mainly from diacyl-glycerophosphocholine (diacyl-GPC) to alkenylacyl-glycerophosphoethanolamine (alkenyl-acyl-GPE) and at a lesser extent from diacyl-GPC to diacyl-GPE. In BEL-treated cells, the redistribution of AA between diacyl-GPC and -GPE was completely inhibited, indicating that a BEL sensitive Ca^{2+}-independent PLA_2 controls this pathway. By contrast, BEL treatment did not affect the transfer of AA from diacyl-GPC to alkenylacyl-GPE as well as the remodeling of DHA. These last results suggest that the esterification of AA and DHA into plasmalogens involves another PLA_2, which is Ca^{2+}-independent but BEL-insensitive.

Hormonal Regulation of Phosphatidylcholine Metabolism and Transport

D. Coletti[a], S. Palleschi[b], S. Adamo[a,*], and L. Silvestroni[b]

[a]Department of Histology and Medical Embryology, and [b]Department of Medical Physiopathology, University "La Sapienza," Rome, Italy

Phosphatidylcholine (PC), a major membrane phospholipid, is involved in a wide variety of cell functions. Involvement of PC in signal transduction [i.e., phospholipase D (PLD)-mediated PC hydrolysis] is a well-characterized process, but very little is known about its metabolism after hormonal stimulus. We investigated this process in a well-characterized experimental system, consisting of L6 myogenic cells stimulated by Arg^8-vasopressin (AVP), which rapidly activates PLD, inducing measurable PC hydrolysis in the plasma membrane (PM) (1).

Pre-loaded L6 cells were stimulated with 30 nM AVP, PM were purified by centrifugation in a sucrose discontinuous gradient, and [^{3}H-choline/^{14}C-arachidonate]-labeled PC was separated by thin-layer chromatography. Vesicle traffic was investigated by transmission electron microscopy and fluorescence measurements of trimethylammonium diphenylhexatriene (TMA-DPH) and acridine orange (AO).

A marked decrease of [^{3}H-choline]-PC (87 ± 4% of control) after 1 min of AVP stimulation was measured in PM isolated from L6 cells, followed by a return to the pre-stimulus level (98 ± 8% of control) within the following 4 min. Preincubating the cells with hexadecylphosphocholine (HePC) did not affect PC hydrolysis but selectively inhibited its *de novo* synthesis and the restoration of labeled PC in PM. In other experiments, unlabeled cells were incubated with ^{14}C-arachidonate along with AVP (or vehicle). In these conditions, AVP stimulated incorporation of the label into PC separated from purified PM (300 ± 12% of control after 1 min, and 174 ± 6% of control after 3 min).

Ultrastructural quantitative analysis revealed a significant vesicle traffic, rapidly stimulated after AVP treatment. Hormone-induced vesicle transport consisted mainly of exocytosis, as evidenced by the AVP-induced release of AO. The kinetics of this traffic (measurable after 1 min of hormonal treatment and returning to the basal level within a few minutes) is consistent with the previous data and confirmed also by TMA-DPH fluorescence measurements of vesicle traffic. The latter measurements allowed us to better characterize AVP-induced vesicle traffic: this depended both on PC hydrolysis (since it was sensitive to Zn^{2+} inhibition of PLD) and on PC neosynthesis (since it was inhibited by HePC). Moreover, vesicle traffic was on a direct route from the endoplasmic reticulum to the PM, since it was not inhibited by Brefeldin A, and it required the integrity of the microtubule-microfilament network. We observed also a hormone-induced vesicle traffic with the same features in a different experimental system, namely in endothelin-1 (ET1)-stimulated rat peritubular myoid cells.

These data demonstrate that hormone-induced plasma membrane PC hydrolysis is immediately followed by stimulation of its neosynthesis and by its return to the PM, thus restoring the pre-stimulus level. These experimental systems allow us to distinguish which one of the known PC biosynthetic pathways (2) is involved in restoring the plasma membrane PC pool after PLD activation. It is worth noting that both AVP-stimulated myogenic cells and ETl-stimulated myoid cells are not specialized secretory cells. This excludes the involvement of the membrane cycling process characteristic of secretory cells in the observed phenomenon and it allows us to assign a role to hormone-stimulated exocytosis in nonsecretory cells.

Abnormalities in Sarcolemmal Phospholipase D and Phospholipase C Isoenzymes and in Their Interactions in Post-Infarcted Failing Hearts

V. Panagia*, P.S. Tappia, C. Yu, N. Takeda, and N.S. Dhalla

Institute of Cardiovascular Sciences, St. Boniface G.H. Research Centre and Departments of Human Anatomy and Cell Science and Physiology, Faculty of Medicine, University of Manitoba, Winnipeg, Canada

Phospholipase D (PLD) activity associated with the myocardial cell membrane (sarcolemma, SL) specifically hydrolyzes phosphatidylcholine to form phosphatidic acid (PtdOH). As reported for other cells, SL PLD is coupled to a PtdOH phosphohydrolase for the coordinate production of a *sn*-1,2-diacylglycerol (DAG) pool originating from phosphatidylcholine (1). PLD is part of the SL signaling system (2). Its importance for the heart function is shown by PtdOH-induced changes in cellular Ca^{2+} movements and contractile performance, as well as by its potential involvement in the development of cardiac hypertrophy (2). We reported biochemical evidence for the presence, at the SL level, of a *cis*-unsaturated fatty acid (UFA)-sensitive PLD activity (*cis* UFA-PLD); arachidonic, oleic and docosahexaenoic acids being the most efficient stimulants among the fatty acids tested) (3,4) which is affected by oxidants and thiol modifiers (5). SL phosphoinositide-phospholipase C (PLC), which participates in many different physiological processes of the cardiac cell (6), is also inhibited by the oxidative stress (7). Oxidants generation, which alters functional protein thiols, is an important feature of congestive heart failure (CHF) following myocardial infarction (8). Therefore, *cis* UFA-PLD and PLC β_1, γ_1 and δ_1, which are the most relevant and well-characterized variants of PLC in mammalian cells, were studied in SL membranes purified from the surviving left ventricle of rats at 8 wk after occlusion of the left-anterior descending coronary artery, when the animals were in a moderate stage of CHF (9).

A significant reduction of the SL level of signaling PtdOH was observed in CHF, due to the imbalance between increased PtdOH synthesis (124% of controls) by *cis* UFA-PLD and comparatively higher PtdOH dephosphorylation (135% of controls) by PtdOH phosphohydrolase. As expected, the specific DAG pool derived from *cis* UFA-PLD/PtdOH phosphohydrolase combined activities was significantly augmented in CHF.

Abbreviations: CHF, congestive heart failure; DAG, diacylglycerol; PLC, phospholipase C; PLD, phospholipase D; PtdOH, phosphatidic acid; SL, sarcolemma; UFA, unsaturated fatty acid.

The rank order of PLC isoenzymes hydrolytic activity toward phosphatidylinositol 4,5-bisphosphate in control SL was PLC δ_1 > PLC γ_1 > PLC β_1, while that of the protein mass was PLC γ_1 > PLC δ_1 > PLC β_1. CHF resulted in a drastic reduction of PLC γ_1 and δ_1 activity (11 and 14% of controls, respectively) and protein mass (7 and 18% of controls, respectively), in direct contrast with a significant increase of both PLC β_1 parameters. *In vivo* treatment with the angiotensin-converting enzyme inhibitor imidapril, instituted 4 wk post-infarct, significantly improved the contractile function of the 8-wk postinfarcted failing hearts with partial correction of the PLC isoenzymes parameters and normalization of *cis* UFA-PLD and PtdOH phosphohydrolase activities.

PtdOH stimulates the total SL PLC activity in normal hearts (2). As the level of *cis* UFA-PLD-derived PtdOH was diminished in CHF, we investigated whether or not the response of PLC isoenzymes to PtdOH was also altered in this disease state. In controls, *in vitro* stimulation by exogenous PtdOH (30 μM) was limited to the γ_1 and δ_1 variants. In CHF, these PtdOH-stimulated PLC activities were significantly lower than the correspondent control values. We also showed that PLC is one of the mechanisms for PtdOH-induced increase in intracellular Ca^{2+} ($[Ca^{2+}]_i$) and contractile performance of the normal heart (10). In CHF, PtdOH-mediated rise of cardiomyocytal $[Ca^{2+}]_i$ was significantly reduced; this might have been caused, at least partly, by the attenuated response of PLC γ_1 and δ_1 to PtdOH.

Our results indicate that, in post-MI CHF: (i) the bioprocesses mediated by the SL PtdOH and DAG pool originating from the *cis* UFA-PLD/PtdOH phosphohydrolase pathway may be impaired; (ii) SL PLC β_1-dependent function is amplified with almost complete loss of the PLC γ_1 and δ_1-related signaling; this event would impact negatively on the complex second-messenger response of PLC-linked receptors; and (iii) the possibility of valid interactions between SL *cis* UFA-PLD and PLC signaling pathways may be hampered by the diminished level of SL PtdOH as well as by the striking decrease of PLC γ_1 and δ_1 and their insufficient response to PtdOH, with possible consequences for $[Ca^{2+}]_i$ homeostasis and contractile performance of the post-infarcted failing

Copyright © 1999 by AOCS Press

heart. Moreover, the reversibility of PLC, *cis* UFA-PLD, and PtdOH phosphohydrolase pathological changes by the imidapril therapy may confer pathophysiological significance to these enzymes and may be related to the mechanism of the beneficial action of this angiotensin-converting enzyme inhibitor.

Role of Sphingosine in Induced Apoptosis

A.V. Alessenko* and A.V. Khrenov

Institute of Biochemical Physics of the Russian Academy of Sciences, Moscow, 117977, Russia

Apoptosis is a programmed cell death shown to play a key role in normal development, differentiation, glandular atrophy following hormonal withdrawal, and maturation of the immune system. Its hallmark biochemical feature is endonuclease activation, giving rise to internucleosomal DNA fragmentation. Internucleosomal cleavage of DNA is a result of a apoptotic-specific signal transduction which involves protein kinases, protein phosphatases, proteases, oncoproteins, and lipid second messengers. Utilization of the sphingomyelin (SM) pathway for induction of the apoptotic response has now been demonstrated in a large number of mammalian cells. The role of ceramide in apoptotic signal transduction is widely presented in literature, while the highly toxic product of its hydrolysis sphingosine does not get the appropriate attention. Our investigation was devoted to more precise study of the role of sphingosine in the apoptotic signal transduction, induced by both tumor necrosis factor-α (TNF-α) and other agents, including protein synthesis inhibitor cycloheximide (CHI) and mycotoxin fumonisin B_1.

Relation of sphingosine accumulation in murine liver with biological activity of mutant forms of recombinant human TNF-α. The inflammatory cytokine TNF-α has been shown to initiate apoptotic cell death and DNA fragmentation in several mammalian cell lines. Biological action of TNF has been associated in part with enhanced SM turnover. To determine the role of sphingosine in TNF cytotoxicity, TNF mutants differing in their toxicity to L929 cells were produced and studied. We showed that TNF-α administration to mice produced a rapid (<30 min) increase in free sphingosine level. Wild-type TNF-α and the mutant with deleted residues 67–70 exhibited the highest toxicity and caused accumulation of sphingosine exceeding its control level 5.5 times in murine liver. TNF-α variants with single-point mutation (E127Q, I155L, or V150I) and double mutations (V150I and I155L) caused moderate increases in sphingosine content and were significantly less toxic. The observed relationship between toxicity of TNF-α mutants and the extent of sphingosine accumulation in murine liver provides evidence to suggest that sphingosine may be mediator of TNF-α -induced cell damage and death.

Apoptosis in rat liver induced by CHI. CHI is a well-known inhibitor of protein synthesis and synergistically increases TNF-α cytotoxicity. Regulation of apoptosis differs with cell type and stage of differentiation and does not always require protein synthesis. Herein we demonstrate that CHI in sublethal doses (0.3 mg/100 g) causes an apoptosis in liver cells *in vivo.* Inhibition (95%) of protein synthesis by sublethal dose of CHI induced short-term superexpression of *c-myc, c-fos, c-jun,* and *p53* genes which are involved directly in programmed cell death detected by electron microscopy and gel electrophoresis of DNA. We examined changes in free sphingosine level in liver cell and nuclei during treatment of rats by different doses of CHI (0.01, 0.05, and 0.3 mg/100 g). Sphingosine level in the liver cells increased concomitantly with an increasing of *c-myc* and *c-fos* genes expression after injection of sublethal dose of CHI. On the other hand, the level of free sphingosine in liver isolated from rats after injection of CHI at doses which did not sharply increase gene expression did not show any increase. Sphingosine functions as an inhibitor of protein kinase C (PKC). Other PKC inhibitors strongly induce apoptosis in certain cell types. Our results suggest that sphingosine may function as an endogenous mediator of apoptotic signaling.

Fumonisin B1-induced apoptosis in vivo. Fumonisin B1, a mycotoxin, is an inhibitor of ceramide synthase, a key enzyme in *de novo* sphingolipid biosynthesis and reacylation of free sphingosine. We found correlation between accumulation of intracellular free sphingoid basis and DNA degradation in liver cells after injection of fumonisin B1 in doses of 5 and 20 μg per mouse.

Sphingosine- induced apoptosis in vivo. Injection of sphingosine to mice in doses of 20 and 50 μg per mouse induced large-scale fragmentation of DNA in liver, spleen, and thymus comparable with TNF action in doses of 20 μg per animal. Sphingosine-enchanced TNF-α-induced DNA degradation in thymus to oligonucleosomal fragmentation. Sphingosine can

dramatically potentiate apoptotic events induced by TNF even if the cytokine is used in subtoxic doses. Thus this natural compound, along with TNF-α, might fill a prominent place in contemporary pharmacology. The details of the apoptotic pathway downstream of sphingosine are not known, although several targets for sphingosine action were identified, including PKC, casein kinase II, Rb, and bcl-2 proteins which play the key role in transmission of apoptotic signal.

Sphingosine Kinase: Assay Conditions, Tissue Distribution in Rat, and Subcellular Localization in Rat Kidney and Liver

S. Gijsbers, C. Causeret, G. Van der Hoeven, and P.P. Van Veldhoven*

Katholieke Universiteit Leuven, Campus Gasthuisberg, Afdeling Farmakologie, B-3000 Leuven, Belgium

The phosphorylation of sphingoid bases is the penultimate step in the breakdown of sphingolipids. Sphingenine-1-phosphate (SeP), a product of this reaction, however is also bioactive and was proposed as a second messenger (1). Sphingosine kinase, the enzyme catalyzing the formation of SeP, is poorly characterized. Often it was reported to be cytosolic, but evidence for a membrane-bound activity also exists and it is not known whether catabolic SeP and bioactive SeP are formed by the same enzyme. The aim of this study was therefore to get a better insight in the subcellular distribution of sphingosine kinase(s).

Using D-erythro-[^{3}H-4,5]sphinganine as substrate, assay conditions were optimized in rat liver homogenates, taking care of inhibiting sphingosine-phosphate lyase (2) and sphingosine-phosphatase (3), two membrane-bound activities present in biological samples that destroy the reaction product.

A tissue distribution study in rat revealed the highest kinase activities in testis, followed by kidney and intestine.

Based on subcellular fractionation of rat liver and kidney homogenates, the presence of (at least) two kinase activities is deduced, a membrane-bound and a cytosolic one. The latter one accounts only for about 20% of the total tissue activity. Further separation of the membrane vesicles by means of density gradient centrifugation showed that a portion of the kinase activity is associated with the plasma membrane.

It is tempting to speculate that the cytosolic sphingosine kinase is responsible for the formation of catabolic SeP that subsequently will be cleaved at the cytosolic site of endoplasmic reticulum by the sphingosine-phosphate lyase (2). The plasma membrane-bound sphingosine-kinase would act on sphingenine formed in or near the plasma membrane and be involved in the generation of bioactive SeP.

α2-Adrenergic Receptor-Mediated Release of Lysophosphatidic Acid by Adipocytes: A Paracrine Signal for Preadipocyte Growth

Céline Pagès, Philippe Valet, Olivier Jeanneton, Alexia Zakaroff-Girard, Pierre Barbe, Michel Record, Claude Wolf, Françoise Chevy, Max Lafontan, and Jean Sébastien Saulnier-Blache*

INSERM U317, Institut Louis Bugnard, Université Paul Sabatier, CHR Rangueil, 31403 Toulouse Cedex 4, France

Lysophosphatidic acid (LPA) is a bioactive phospholipid able to generate several cellular responses (proliferation, rearrangement of the cytoskeleton, ion exchanges) by interaction with specific G protein-coupled receptors. LPA is produced by aggregating platelets constituting the main source of serum LPA. Our study brings evidence for a local production of LPA in white adipose tissue (WAT) exposed to α2-adrenergic agonists. This α2-adrenergic-dependent production of LPA could play an important role in the control of adipogenesis.

WAT is composed of nonproliferating mature adipocytes storing triglycerides, and of preadipocytes which can proliferate and differentiate into new fat cells. An excess of adipose tissue is due to adipose cell hypertrophy accompanied, in most severe obesities, by adipose tissue hyperplasia. Formation of mature fat cells from preadipocytes (adipogenesis) can take place throughout life in rodents and humans. It can be regulated not only by circulating factors but also by autocrine/paracrine factors produced locally in WAT. Determining the identity of the factors regulating adipogenesis is a major point in understanding normal and pathologic growth of adipose tissue.

α2-Adrenergic receptors are highly expressed in adipocytes, particularly human adipocytes, and mediate some specific biological responses induced by circulating catecholamines (epinephrine and norepinephrine) in WAT such as antilipolysis in mature adipocytes, and growth and cytoskeletal rearrangements in preadipocytes.

We report that conditioned media from isolated adipocytes increase spreading (reflecting regulation of actin cytoskeleton) and proliferation of 3T3F442A preadipocytes. These effects were amplified when an α2-adrenergic agonist was present during the obtention of the conditioned media. This α2-adrenergic-dependent trophic activity was completely abolished by pretreatment of the conditioned media with a lysophospholipase (phospholipase B), or a specific desensitization of LPA-responsiveness of 3T3F442A preadipocytes (generated by previous chronic treatment with high concentration of LPA). Among the different lysophospholipids tested, only LPA was able to induce spreading and proliferation of 3T3F442A preadipocytes. α2-Adrenergic stimulation also leads to a rapid, sustained, and pertussis-toxin-dependent release of [^{32}P]LPA from [^{32}P]-labeled adipocytes. Identity of LPA was confirmed by mass spectrometry after derivatization of the phospholipids of the conditioned media with 1-pyrenyldiazomethane.

α2-Adrenergic-dependent release of LPA was also demonstrated *in vivo* by *in situ* microdialysis. This technique allows analysis of the extracellular fluid composition of intact adipose tissue. Microdialysis probes were implanted in human subcutaneous adipose tissue and perfused with physiological solution supplemented or not with an α2-adrenergic agonist. Microdialysates were collected and tested for their ability to generate LPA-like responses on preadipocytes. Microdialysates obtained in the presence of the α2-adrenergic agonist exhibited a higher spreading effect as compared to microdialysates obtained in the absence of agonist. The additional spreading effect was completely abolished by pretreatment with phospholipase B and by previous desensitization of LPA-receptors. Based upon these results, it was proposed that stimulation of α2-adrenergic receptors provokes the extracellular release of LPA from adipocytes, both *in vitro* and *in vivo*.

Because of the close proximity of adipocytes and preadipocytes in the adipose tissue, and because of the ability of LPA to regulate preadipocyte growth, the α2-adrenergic-dependent local production of LPA could play an important role in the process of adipogenesis.

Phosphatidic Acid-Dependent Activation of Adenosine-3′,5′-cyclic-monophosphate-phosphodiesterase Is Necessary for Arg-Vasopressin Induction of Myogenesis

F. Naro[a], E. Vicini[a], C. Sette[b], M. Grange[c], A.-F. Prigent[c], R. Curci[a], M. Lagarde[c], G. Némoz[c], and S. Adamo[a,*]

[a]Dip. Istologia Embriologia Med., Univ. di Roma "La Sapienza", [b]Dip. San. Pubbl. Biol. Cell., Univ. di Roma "Tor Vergata", Rome, Italy, and [c]Lab. Biochimie-Pharmacologie, INSERM U352, INSA-Lyon, France

Arg^8-Vasopressin (AVP) stimulates differentiation of L6 myoblasts (1) likely through activation of phospholipase D (PLD) and generation of phosphatidic acid (PA) (2). Conversely, high intracellular adenosine-3′,5′-cyclic monophosphate (cAMP) levels and protein kinase A (PKA) activation inhibit myoblast differentiation (3). Intracellular cAMP level is not only regulated by activation of adenylyl cyclase but also by its hydrolysis due to phosphodiesterase (PDE) activity. We reported that PA can activate specific isoforms of type IV cAMP-phosphodiesterase (PDE4) *in vitro* (4). Here, we investigate whether AVP-induced differentiation of L6 myoblasts involves activation of PDE4 isoforms by PA.

PLD activity was assessed measuring [^{3}H]-myristate phosphatidylethanol production (2). PDE4 expression and activity in L6 cells were investigated by RNase-protection assay, immunoprecipitation, Western blot (WB), and PDE assay. PKA activity was evaluated by measuring kemptide phosphorylation in the presence of protein kinase inhibitor. L6 cell differentiation was assessed by creatin kinase activity and nuclear localization of the specific muscle transcription factor myogenin by immunofluorescence (1).

RNase-protection assay, immunoprecipitation, and Western blot analyses indicated that only one isoform of PDE4 with apparent M.W. of 100 kDa is expressed in L6 myoblasts, and it is responsible for 75% of the cAMP hydrolyzing activity of these cells. Incubation of L6 cells with 12-*O*-tetradecanoylphorbol 13-acetate (a potent activator of PLD) stimulated a significant and sustained increase of PDE4 activity of about 50%, similar to the activation observed after direct addition of exogenous PA to L6 cell homogenate. AVP stimulation of L6 cells induced a biphasic increase of PDE activity with a first rapid peak occurring after 2 min (150% over controls), followed by a slower increase, reaching a maximum after 15 min (150% over controls) and subsequently declining. On the contrary, insulin-like growth factor I [a cofactor—in our experimental conditions—of L6 cell differentiation which is unable by itself to induce differentiation (1)] did not stimulate PLD nor PDE activity. Treatment of L6 cells with propranolol (an inhibitor of PA-phosphohydrolase) before AVP stimulation led to an increase of PA accumulation and inhibition of diacylglycerol formation. These effects led to parallel modifications of AVP-induced PDE4 activation with an increase of the first phase and a decrease of the late phase. This suggests that the two phases of AVP-dependent PDE activation are mediated by PA and, respectively, by its conversion product, diacylglycerol. Protein kinase C downregulation obtained with long-term 12-*O*-tetradecanoylphorbol 13-acetate treatment (24 h) selectively abolished AVP-dependent PLD activation and PDE activation. Preliminary results indicate that PKA activity is lowered by L6 stimulation with AVP by about 50% after 3 h of hormonal treatment. Experiments performed with selective inhibitors for different PDE families (rolipram, RS 25344 for PDE4, milrinone for type III PDE, and zaprinast for type V PDE) demonstrated that only inhibition of PDE4 results in complete suppression of the AVP-induced differentiation. This result is confirmed by immunofluorescence experiments which showed inhibition of myogenin translocation into the cell nucleus. Taken together, these results suggest that PA can act as a cross-talk molecule between the PLD and the cAMP pathways by stimulating PDE4 activity in L6 cells and decreasing PKA activity. This event may play a crucial role in the control of the physiological process of myoblast differentiation induced by AVP.

Many hormones and growth factors stimulate the production of the putative second messenger phosphatidic acid (PA) in various cell types (fibroblasts, lymphocytes, myoblasts, etc.). In turn, this phospholipid alters the function of several effector proteins playing major roles in cell signal transduction, such as protein kinases, phosphatases and phospholipases. We previously showed that PA selectively stimulates in an acellular system some isoforms of cyclic AMP phosphodiesterases (PDE) belonging to the type 4 family (1), i.e., the enzymes hydrolyzing specifically cAMP and inhibited by the reference inhibitor rolipram. This family of enzymes plays a critical role in controlling the cAMP levels in several cell systems, in particular lymphocytes and myoblasts. The PA-sensitive PDE 4 isoforms are characterized by the presence of conserved regulatory sequences in the N-terminal region (1). We also observed that only acidic phospholipids are able to activate type 4 PDE, and among them PA, especially the stearoyl-arachidonoyl species, is the most potent activator (2). Since this PA species is preferentially synthesized in thymic lymphocytes in response to a mitogenic stimulation (2), we have proposed the hypothesis that the regulation of PDE 4 activity by PA may have a physiological relevance.

Methods and Results. To demonstrate the physiological relevance of PDE 4 regulation by PA in intact cells, we used transiently transfected MA10 Leydig tumor cells overexpressing different isoforms of PDE 4 and studied the influence of an accumulation of endogenous PA induced by propranolol, an inhibitor of the PA-degradating enzyme PA-phosphohydrolase. In MA10 cells overexpressing PDE4D3, an isoform of PDE 4 sensitive to PA-activation, PA accumulation induced a strong stimulation of PDE activity (threefold), peaking at 45 min. By contrast, when the overexpressed PDE was PDE4D1, a PA-insensitive isoform, PA accumulation did not modify PDE activity. Furthermore, the treatment of PDE4D3-transfected cells by propranolol induced significant decreases of both intracellular cAMP levels and cAMP-dependent protein kinase activity.

To determine the mechanism of PDE stimulation by PA, MA10 cells overexpressing PDE4D3 were preincubated with ^{32}P-orthophosphate, to label phospholipids. After treatment by propranolol, the cells were homogenized, and PDE was immunoprecipitated by a specific antibody. Lipids present in the immunopellet were extracted and analyzed by thin-layer chromatography. Autoradiography of the thin-layer chromatography plates showed that PA was the major phospholipid bound to PDE4D3, which supports the hypothesis that endogenous PA activates PDE4D3 by means of direct binding to the protein.

A preliminary characterization of the PA binding site on PDE4D3 was performed by engineering deletions of selected regions in the regulatory domain. Three regions particularly rich in basic and/or hydrophobic aminoacid residues were deleted. Deletion of amino acids 2 to 19 had no effect, while deletion of amino acids 31 to 59, or amino acids 99 to 130 suppressed PA-activating effect, suggesting that these last regions might be involved in the binding of PA to PDE4D3.

Conclusions. These results show that intracellular PA can regulate PDE 4 activity in intact cells by direct binding of the phospholipid to some PDE 4 isoforms, and thus modulate cAMP levels. This conclusion reinforces the concept that PA has a role of second messenger, and defines type 4 PDE as new effector enzymes for its intracellular actions. The observed cross-talk between the cAMP pathway and phospholipid metabolism is likely to be of importance in various physiological processes submitted to regulation by cAMP, such as lymphocyte proliferation and differentiation of skeletal myoblasts.

Tumor Necrosis Factor-α and Ceramides in Insulin Resistance

David N. Brindley*, Chuen-Neu Wang, Jie Mei, James Xu, and Atef N. Hanna

Department of Biochemistry (Signal Transduction Laboratories), University of Alberta, Edmonton, Alberta T6G 2S2, Canada

ABSTRACT: The present studies tested the hypothesis that some effects of tumor necrosis factor-α (TNF-α) are mediated by activation of sphingomyelinases and the production of ceramides. Differentiated 3T3-L1 adipocytes were incubated with short-chain ceramide analogs, (C_2- and C_6-ceramides: *N*-acetyl- and *N*-hexanoyl-sphingosines, respectively), and this treatment increased 2-deoxyglucose uptake in the absence of insulin progressively from 2–24 h. This effect was inhibited by blocking the activations of mitogen-activated protein kinase, phosphatidylinositol 3-kinase (PI 3-kinase), and ribosomal S6 kinase which mediated an increase in GLUT1 concentrations. Long-term increases in PI 3-kinase activity associated with insulin receptor substrate-1 (IRS-1) increased the proportion of GLUT1 and GLUT4 in plasma membranes. These events explain the increases in noninsulin-dependent glucose uptake and incorporation of this glucose into the fatty acid and glycerol moieties of triacylglycerol. The mechanisms by which TNF-α and ceramides increase PI 3-kinase activity were investigated further by using rat2 fibroblasts. Incubation for 20 min with TNF-α, bacterial sphingomyelinase, or C_2-ceramides increased PI 3-kinase activity by about fivefold, and this effect depended upon a stimulation of tyrosine kinase activity and an increase in Ras-GTP. This demonstrates the existence of a novel signaling pathway for TNF-α that could contribute to the effects of this cytokine in stimulating basal glucose uptake. By contrast, treating the 3T3-L1 adipocytes for 2–24 h with C_2-ceramide diminished insulin-stimulated glucose uptake by decreasing the insulin-induced translocation of GLUT1 and GLUT4 to plasma membranes. This inhibition was observed when there was no increase in basal glucose uptake, and it occurred downstream of PI 3-kinase. Our work provides further mechanisms whereby TNF-α and ceramides produce insulin resistance and decrease the effectiveness of insulin in stimulating glucose disposal from the blood. Conversely, TNF-α and ceramides increase the ability of adipocytes to take up glucose and store triacylglycerol in the absence of insulin.

Insulin resistance (defined as decreased ability of insulin to stimulate glucose uptake) is an important component of Type 2 diabetes (1). It is caused by a postreceptor defect in insulin signaling which normally leads to glucose transport into cells. This involves activation of the insulin receptor (IR) by phosphorylation of tyrosine residues, which then causes the tyrosine phosphorylation of insulin receptor substrate-1 (IRS-1). Activated IRS-1 then binds phosphatidylinositol 3-kinase (PI 3-kinase) which itself becomes activated and stimulates the movement of glucose transporters (mainly GLUT4) to the cell surface. The increase in GLUT4 at the plasma membrane is then responsible for insulin-dependent glucose uptake. Insulin resistance results from a decreased efficiency to stimulate this cascade. It can occur in sepsis, advanced cancer, and trauma, partly as a result of tumor necrosis factor-α (TNF-α) action. TNF-α is also secreted by adipose tissue and is implicated in insulin resistance associated with obesity (2,3).

Incubation of 3T3-L1 adipocytes (4) or hepatoma cells (5) with TNF-α was reported to decrease the insulin-induced tyrosine phosphorylation of IR and IRS-1. TNF-α increases the serine phosphorylation of IRS-1, which inhibits the tyrosine kinase activity of IR (6) and impairs the association of IRS-1 with PI 3-kinase (7). In rat hepatoma Fao cells, changes in IRS-1 were seen after 1 h (7), whereas incubations of 2 to 4 d were used in 3T3-F442A adipocytes (6). By contrast to these results, incubation of 3T3-L1 adipocytes with TNF-α for 30–60 min had the opposite effect of increasing the tyrosine phosphorylation of IRS-1 and its binding of PI 3-kinase (8). Other work with 3T3-L1 adipocytes ascribed the long-term effects of TNF-α in producing insulin resistance to a decreased expression of IRS-1 and GLUT4 rather than decreased tyrosine phosphorylation of IRS-1 (9). TNF-α activates several signaling cascades, including a stimulation of sphingomyelinases and consequent ceramide production (10). Exogenous sphingomyelinase and cell-permeable (short-chain) ceramides were shown to mimic some effects of TNF-α in decreasing the insulin-dependent tyrosine phosphorylation of IRS-1 (11,12) and activation of phosphoprotein phosphatase-1 (13). The present studies investigated further the nature of the insulin resistance that is produced by TNF-α and determined which effects of TNF-α were mediated by ceramides.

METHODS

3T3-L1 fibroblasts were cultured in Dulbecco's minimum essential medium (DMEM) supplemented with 10% fetal

bovine serum, differentiated and maintained in DMEM containing 10% fetal bovine serum (14). Experiments were performed 9–10 d after induction of differentiation, when greater than 90% of the cells expressed the adipocyte phenotype. Glucose transport was determined over 10 min after adding [^{3}H]2-deoxyglucose. Lipid synthesis from [^{14}C]glucose was determined by extraction of the triacylglycerol, saponification, and separation of the fatty acid and glycerol moieties. Western blot analysis was performed by the enhanced chemiluminescence method (14). In other work, rat2 fibroblasts were grown to confluence and were used to study the mechanisms by which TNF-α, bacterial sphingomyelinase, or C_2-ceramide stimulates PI 3-kinase activity.

RESULTS AND DISCUSSION

Treatment of 3T3-L1 adipocytes with 100 μM C_2-ceramide for 2, 6, and 24 h increased basal glucose transport by 1.6, 4.3- and 7.6-fold, respectively (Table 1). C_2-ceramide decreased insulin-stimulated glucose uptake by 53 to 60% after 2, 6, and 24 h. C_2-ceramide also decreased the subsequent insulin-dependent incorporation of glucose into the fatty acid and glycerol of triacylglycerols by about 80 and 33% after 2 h, respectively. However, C_2-ceramide increased these incorporations in the absence of insulin by about 4- and 12-fold, respectively, after 24 h (Brindley, D.N., Wang, C.-N., Mei, J., Xu, J., and Hanna, A.N., unpublished). Cells incubated for 6 and 24 h with 100 μM dihydro-C_2-ceramide, which is unable to mimic several biological effects of C_2-ceramide, showed relatively little increase in basal glucose transport or incorporation into lipids. The effects of C_2-ceramide on glucose transport were therefore relatively specific.

Incubation with C_2-ceramide for 24 h increased (P < 0.001) the total amount of GLUT1 by fivefold compared to control cells (Fig. 1A). C_2-ceramide treatment for 24 h increased GLUT1 concentrations by ninefold in the plasma membrane fraction (14). Insulin increased the amount of GLUT1 in plasma membranes of control and C_2-ceramide treated cells by about 260 (P < 0.001) and 10%, respectively (14). C_2-ceramide treatment therefore blocked the insulin-in-

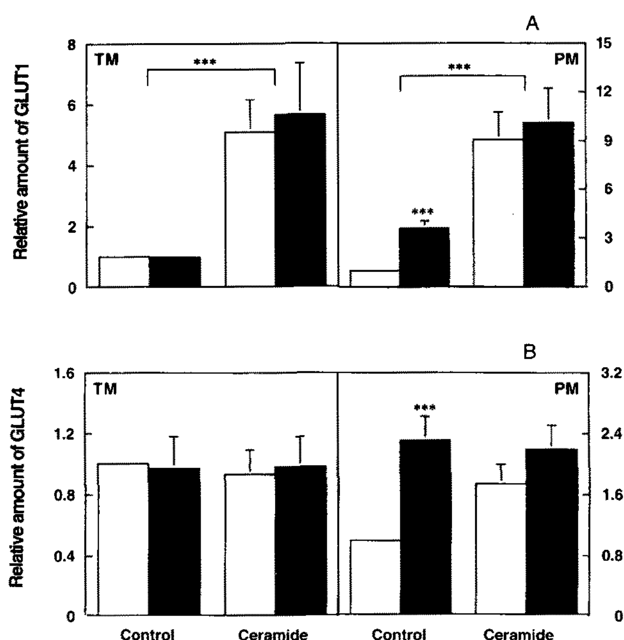

FIG. 1. Effect of C_2-ceramide on the distribution of glucose transporter 1 (GLUT1) and GLUT4 in subcellular membrane fractions. 3T3-L1 adipocytes were incubated with 100 μM C_2-ceramide for 24 h. Cells were then treated with or without 20 nM insulin for 30 min as indicated and subjected to subcellular fractionation. Results are shown for the total membrane (TM) and plasma membranes (PM) fractions. The figure shows the relative level of GLUT1 in membrane fractions prepared from unstimulated cells (open bars) or cells stimulated with 20 nM insulin (solid bars). Results are means ± SD (where large enough to be shown) from five independent experiments and are expressed relative to control cells under basal condition in each fraction. Significant differences between control and ceramide-treated cells or between control and insulin treatment are indicated by ***, $P \leq 0.001$.

Procedure 2			
Control	200 ± 4	1516 ± 71	1315 ± 72
C_2-ceramide (2 h)	320 ± 20*	848 ± 152***	526 ± 139***

[a]In Procedure 1, cells were incubated for 24 h or for the final 6 h in the absence or presence of 100 μM C_2-ceramide or dihydro-C_2-ceramide. Basal 2-deoxyglucose transport and that induced by 20 nM insulin were measured, and the difference between these values gave insulin-stimulated glucose transport. In Procedure 2, a different series of cells were treated with C_2-ceramide for 2 h. Glucose uptake was measured as above except that the Krebs'-Ringer buffer contained 0.5% bovine serum albumin. Results are means ± SD from three independent experiments. Significant differences between control and treated cells are indicated by *, $P \leq 0.01$; **, $P \leq 0.05$; and ***, $P \leq 0.001$. The results are reproduced from Reference 14, with permission.

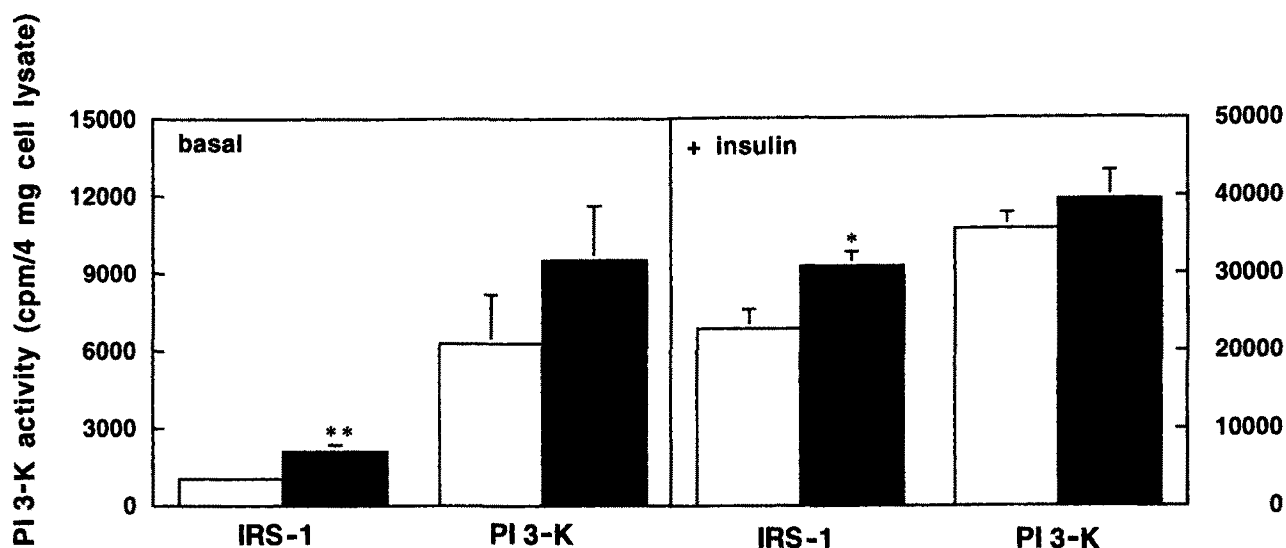

FIG. 2. Effects of C_2-ceramide on the activity and association of phosphatidylinositol 3-kinase (PI 3-K) with insulin receptor substrate-1 (IRS-1). Differentiated 3T3-L1 adipocytes were treated with 100 μM C_2-ceramide for 12 h and the cells were then stimulated with 100 nM insulin for 10 min as indicated. PI 3-K was then precipitated from cell lysates with antibodies against IRS-1 or the 85 kDa subunit to measure activity associated with IRS-1 or total activity, respectively. PI 3-K activity was determined by the phosphorylation of PI in control cells (open bars), or ceramide-treated cells (solid bars). Results are means ± SD from three independent experiments. Significant differences between control and ceramide-treated cells are indicated by: *, $P \leq 0.05$ and **, $P \leq 0.01$. The results are reproduced from Reference 14 with permission.

duced translocation of GLUT1 to plasma membranes after incubation for 2 or 24 h.

Treatment with C_2-ceramide (Fig. 1B) for 2 or 24 h did not affect GLUT4 levels in the total membrane fraction significantly. However, C_2-ceramide increased the level of GLUT4 in plasma membranes by 1.7-fold. Insulin increased GLUT4 levels in plasma membranes by 2.3-fold in control cells. However, the increase was only 1.26-fold in C_2-ceramide-treated cells. Consequently, C_2-ceramide also inhibited the insulin-induced increase in the translocation of GLUT4 to plasma membranes.

Incubation of 3T3-L1 adipocytes for 24 h with C_2-ceramide did not alter significantly the masses of IR or IRS-1, nor their tyrosine phosphorylations after insulin stimulation (14). The amount of PI 3K (85 kDa subunit) that was coimmunoprecipitated with IRS-1 in the presence or absence of insulin was also not significantly decreased after incubation with C_2-ceramide. By contrast, incubation for 24 h with 10 ng/mL TNF-α decreased the mass of IR by about 20%, and there was an equivalent decrease in its tyrosine phosphorylation. The mass, tyrosine phosphorylation, and association of IRS-1 with PI 3-kinase were decreased by about 60, 75, and 60%, respectively. These results indicate that TNF-α decreases the activation of IRS-1 by pathways that are independent of ceramide action. The effects of C_2-ceramide on PI 3-kinase were investigated in greater detail by determining its activity after coimmunoprecipitation with IRS-1, or by using an anti-p85 antibody to assess the total PI 3-kinase activity. C_2-ceramide treatment for 12 h did not change the total PI 3-kinase activity significantly in the absence of insulin, or the stimulation of activity by insulin (Fig. 2). However, C_2-ceramide had an insulin-like effect in increasing the PI 3-kinase activity associated with IRS-1 in the presence or absence of insulin.

In order to determine further the mechanism for this increase in PI 3-kinase activity, we treated rat2 fibroblasts with 10 ng of TNF-α/mL, 0.1 units of bacterial sphingomyelinase/mL, or 40 μM C_2-ceramide. These treatments increased the activity of PI 3-kinase by about five- to sixfold after 20 min (15). The increases in PI 3-kinase activity produced by these agonists involved a stimulation of tyrosine kinase activity since the effects were blocked by the tyrosine kinase inhibitors, genistein and PP1. Also the stimulation of PI 3-kinase activity was dependent upon an increase in the concentration of Ras-GTP after 5 min. which interacted with the p110 subunit of PI 3-kinase. Furthermore, the stimulation of PI 3-kinase activity by TNF-α, sphingomyelinase, and C_2-ceramide did not occur in fibroblasts expressing dominant/negative (N17) Ras (15). The increase in PI 3-kinase activity in the rat2 fibroblasts resulted in the stimulation of MAP kinase activity since this effect was blocked by compound, Ly 290024. The activation of PI 3-kinase and MAP kinase activities by ceramides and TNF-α was much more rapid than that observed in 3T3-L1 adipocytes.

Treatment of 3T3-L1 adipocytes with insulin stimulates both MAP kinases, and IRS-1-associated PI 3-K, which in turn activates pp70 S6 kinase (1). These events increase GLUT1 synthesis (16,17) and thus contribute to increased basal glucose transport. Our results show that the increase in GLUT1 concentrations and the stimulation of glucose uptake that is produced by C_2-ceramide is inhibited by PD 98059, Ly294002, or with rapamycin (14). These compounds block the activity of MAP kinase, PI-3K, and the stimulation of

pp70 S6 kinase, respectively. Cell-permeable ceramides therefore mimic some effects of TNF-α, and ceramides have insulin-like effects especially in stimulating basal glucose uptake. We identified a novel inhibition of insulin-stimulated glucose uptake that is downstream of PI 3-kinase which may result from an effect of ceramides in inhibiting the movement of GLUT4-containing vesicles to the cell surface.

The observations that TNF-α increased GLUT1 concentrations and basal glucose uptake (Refs. 18–20 and our unpublished work) are compatible with the effect of TNF-α in stimulating the peripheral uptake of glucose *in vivo* (21). Furthermore, GLUT1 expression in plasma membranes prepared from skeletal muscle of obese diabetic SHR rats is increased by 40% compared to the lean genotype (22). The idea that TNF-α and ceramides exacerbate insulin resistance may seem paradoxical if these agents, on their own, stimulate glucose uptake and lipid synthesis. However, the problem with TNF-α is that despite an increase in noninsulin-stimulated (basal) glucose uptake, the insulin-resistant tissue is unable to respond with sufficient glucose uptake to dispose of a post-prandial glucose load effectively. This may predispose to hyperglycemia and hyperinsulinemia after meals. It is interesting to speculate that the increased glucose uptake in adipocytes that is produced by TNF-α is designed to enable the cells to store lipids effectively in conditions of semistarvation when insulin concentrations are low. This may have provided an evolutionary advantage when food is in limited supply during many seasons of the year. However, this condition with its attendant insulin resistance becomes a health risk in obesity and type 2 diabetes in affluent societies. Our work provides further mechanisms for explaining the effects of TNF-α and ceramides in decreasing the importance of insulin as a regulator of metabolic balance in adipose tissue.

Magnetic Resonance Imaging-Based Balance Analysis of Linoleate Utilization During Weight Loss in Obese Humans

S.C. Cunnane[a,*], R. Ross[b], J.L. Bannister[a], and D.J.A. Jenkins[a]

[a]Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, and [b]School of Physical and Health Education, Queens University, Kingston, Ontario, Canada

Fatty acid balance analysis in animals demonstrates that, despite apparently adequate linoleate intake (>2% of energy), impaired weight gain due to energy deficit selectively impairs whole-body accumulation of linoleate by increasing its β-oxidation (1). No methods have been described by which linoleate balance could be measured in living humans, but this would be helpful in determining how energy balance affects metabolism and β-oxidation of polyunsaturates. Exercise increases fat oxidation (2) and reduces skeletal muscle phospholipid content of linoleate (3), but weight loss does not appear to affect the adipose tissue content of linoleate (4). In this study, we assessed the potential application of magnetic resonance imaging (MRI) to indirectly measure whole-body changes in linoleate levels in humans in order to estimate whole body β-oxidation of linoleate during weight loss.

Adipose tissue needle biopsies and whole-body MRI scans were obtained before and after voluntary weight loss averaging 12 kg over 16 wk in obese humans (starting body mass indexes of 33–34). Weight loss was achieved by diet only (n = 11) or diet plus exercise (n = 9). Linoleate intakes were determined from food records maintained throughout the study. Whole body linoleate content was determined from the percentage of linoleate in the biopsies plus literature values for linoleate in lean tissue multiplied by actual whole-body lean and adipose tissue weights obtained by MRI (5). Linoleate excretion and the density and water content of adipose tissue were also measured.

Average linoleate intake across both groups was 6 g/d or 3.2% of energy intake. Linoleate excretion was 4% of intake. During weight loss, whole-body linoleate depletion exceeded linoleate intake by about 60% in both groups leading to net β-oxidation of linoleate (Table 1). Despite similar weight loss in both groups, the percentage of linoleate in adipose tissue was significantly lower after weight loss only in the diet plus exercise group (12.0 vs. 12.8% before weight loss; $P < 0.05$), leading to 35% higher β-oxidation of linoleate in the diet plus exercise group compared to the diet only group (Table 1). The percentage of n-6 long chain polyunsaturates in adipose tissue did not change during weight loss. Linoleate intake during weight loss did not predict adipose tissue linoleate values (percentage or kg) or β-oxidation of linoleate. Linoleate in adipose tissue (final percentage or change in percentage during weight loss) also did not predict the measured change in body linoleate content during weight loss.

TABLE 1
Whole-Body Linoleate Balance (kg) (over 16 wk) in Obese Humans Undergoing Weight Loss by Diet Alone or by Diet plus Exercise[a]

	Diet only (kg)	Diet plus exercise (kg)
Intake	0.54 ± 0.20	0.76 ± 0.20
Excretion	0.02 ± 0.01	0.03 ± 0.02
Accumulation[b]	−0.90 ± 0.46	−1.18 ± 0.76
β-Oxidation[c]	−1.42 ± 0.44	−1.91 ± 0.69

[a]Values are mean ± SD kg linoleate; n = 11 (Diet only), n = 9 (Diet plus exercise); no statistically differences between groups.
[b]The negative values indicate a loss from body stores. These measurements assume negligible desaturation of linoleate to longer chain n-6 polyunsaturates during energy deficiency (6).
[c]Calculated by difference (intake −[excretion + accumulation]).

Thus, β-oxidation of linoleate during weight loss in obese humans was not related to linoleate intake but was directly proportional to weight loss if accompanied by exercise. Adipose tissue levels of linoleate were reduced only if exercise was a component of energy deficiency. These results suggest that exercise contributes to selective linoleate depletion from adipose tissue during weight loss. This methodology involving a combination fatty acid analysis of fat biopsies and MRI scanning of whole-body changes in total lean and adipose tissue permits analysis of the utilization of linoleate in living humans.

Diabetes Puts Myocardial n-3 Fatty Acid Status at Risk in the Absence of Supplementation in the Rat

P.L. McLennan[a,]* and D. Raederstorff[b]

CSIRO Division of Human Nutrition, Adelaide, Australia; [a]Smart Foods Centre, Department of Biomedical Science, University of Wollongong, NSW 2522, Australia, and [b]F. Hoffmann-La Roche, Basel, Switzerland

Diabetes is associated with high cardiovascular disease morbidity and mortality. Excess incidence of myocardial infarction and heart failure includes not only components of vascular disease and hypertension but also an independent diabetic cardiomyopathy (1). Polyunsaturated fatty acid (PUFA) metabolism is also perturbed in diabetes with inhibition of desaturase activity (2), resulting in reduced desaturation of linoleic acid (18:2n-6) to its long-chain derivative arachidonic acid (20:4n-6). The long-chain n-3 PUFA eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA) are increasingly being associated with reduced cardiovascular disease mortality (3). The n-3 PUFA are subject to the same metabolic pathways as the n-6 PUFA in a competitive manner and since the provision of adequate long-chain n-3 PUFA from shorter-chain precursors is only poorly met under normal conditions, diabetes may impact adversely upon n-3 PUFA composition of the heart, thereby putting the heart and heart function at risk (4).

This study investigates the effect of diabetes on myocardial membrane fatty acids and the ability of purified PUFA to modify incorporation and influence ischemia-induced cardiac arrhythmias, a physiological endpoint that varies with myocardial membrane composition (4).

METHODS

Male rats (Hooded Wistar, 10-wk-old) made diabetic with streptozotocin (50 mg/kg i.p.) were fed diets with 5% total fat as olive oil (OO) or 4.5% OO plus 0.5% (1.1% energy) of purified PUFA ethyl esters (18:3n-6, γ-linolenic acid; EPA; or DHA; or a mix containing 26% EPA + 37% DHA (n-3 Mix). Ischemia was produced by acute coronary artery ligation (4)

RESULTS

After 5 wk of diabetes, little change was seen in membrane levels of arachidonic acid or linoleic acid, but DHA fell to almost half its control level ($P < 0.0001$, analysis of variance, Bonferroni) in OO-fed rats (Table 1). The ratio of n-6/n-3 PUFA was significantly elevated in diabetes to almost double that of nondiabetic OO-fed animals.

All n-3 diets lowered arachidonic acid, raised EPA levels, and markedly raised DHA levels in myocardial membranes of nondiabetic animals, and the n-6/n-3 ratio was reduced to less than half the level found in OO-fed animals (all $P < 0.0001$). DHA levels were significantly higher with the DHA and n-3 Mix diets than with purified EPA ($P < 0.001$).

Arrhythmias were significantly inhibited by DHA (arrhythmia score 2.08 ± 0.62, $n = 12$) and n-3 Mix diet (2.25 ± 0.58, $n = 12$) compared with the OO diet (4.77 ± 0.52, $n = 13$) in control animals ($P < 0.01$).

In diabetes, the level of DHA incorporation into myocardial membranes fell in the EPA group to the level seen in nondiabetic OO-fed animals, and DHA also fell significantly with the n-3 Mix diet ($P < 0.0001$). The DHA diet maintained high myocardial DHA levels in diabetes. Arrhythmia severity was depressed during acute myocardial ischemia in diabetic animals (OO: 3.00 ± 0.39, $n = 12$), and arrhythmia severity was further reduced only with the DHA diet (1.09 ± 0.58, $n = 11$, $P < 0.01$).

CONCLUSIONS

The changes in fatty acid incorporation into myocardial membranes that occurred with acute diabetes in this study were indicative of depressed PUFA desaturation. However this was largely confined to the long-chain n-3 PUFA, DHA. Anti-arrhythmic effects of n-3 PUFA diets were associated with elevated DHA levels. It is concluded that perturbed PUFA metabolism in diabetes puts myocardial n-3 PUFA status at high risk which may have important implications for heart function and that this may be prevented by low-level supplementation with purified DHA.

Neuroprotective Effect of Fish Oil in Diabetic Neuropathy

A. Gerbi[a,b,*], J.-M. Maixent[b], O. Barbey[b], I. Jamme[c], M. Pierlovisi[a], T. Coste[a], G. Pieroni[d], A. Nouvelot[c], P. Vague[a], and D. Raccah[a]

Diabetic neuropathy is a degenerative complication of diabetes accompanied by an alteration of nerve conduction velocity and Na,K-ATPase activity. This decrease in Na,K-ATPase activity has been implicated in the pathogenesis of electrophysiological abnormalities characterizing neuropathic complication in different animal models and in humans (1). Na,K-ATPase is a membrane-bound enzyme consisting of three catalytic isoenzymes ($\alpha 1$, $\alpha 2$, $\alpha 3$) and a large lipid core (2). It plays a fundamental role in Na^+ and K^+ transport by maintaining the ionic gradients necessary for nervous excitability. A decrease in this process leads to an increase in the intracellular concentration of sodium and a corresponding decrease in membrane sodium potential. The mechanism responsible for impairment of Na,K-ATPase during hyperglycemia is still unclear, but alterations of the kinetic parameters of the enzyme and/or of subunit expression are likely (3,4). In recent years there has been great interest in the effect of n-3 essential fatty acids, found particularly in fish oil, on the prevention of atherosclerosis and hypertension in animal models and patients with vascular disease (5). Fish oil treatment as MaxEPA was recently reported to improve vascular function in diabetic patients (6), and prevent $\alpha 2$ isoenzyme activity of Na,K-ATPase in diabetic cardiomyopathy (7).

Aim of the study. The present study in rats was designed, first, to measure diabetes-induced abnormalities in Na,K-ATPase acyivity, isoenzyme expression, fatty acid content in sciatic membranes, and nerve conduction velocity and second, to assess the preventive ability of a fish-oil rich diet (rich in n-3 fatty acids) on these abnormalities.

Methods. Diabetes was induced by intravenous streptozotocin injection. Diabetic animals (D) and nondiabetic control animals (C) were fed the standard rat chow either without supplementation or supplemented with either fish oil (DM, CM) or olive oil (DO, CO) at a daily dose of 0.5 g/kg by gavage during 8 wk.

Results. Analysis of the fatty acid composition of purified sciatic nerve membranes from diabetic animals showed a decreased incorporation of 16:1n-7 fatty acid and arachidonic acid. Fish oil supplementation changed the fatty acid content of sciatic nerve membranes, decreasing 18:2n-6 fatty acid and preventing the decrease of arachidonic acid and 18:1n-9 fatty acid. Protein expression of Na,K-ATPase α-subunits, Na,K-ATPase activity, and ouabain affinity were assayed in purified sciatic nerve membranes from CO, DO, and DM. Na,K-ATPase activity was significantly lower in sciatic nerve membranes of diabetic rats and significantly restored in diabetic animals that received fish oil supplementation. The Na,K-ATPase activity correlated with the nerve conduction velocity. Diabetes induced a specific decrease of $\alpha 1$ and $\alpha 3$ isoform activity and protein expression in sciatic nerve membranes. Fish oil supplementation restored partial activity and expression to varying degrees depending on the isoenzyme. These effects were associated with a significant beneficial effect on nerve conduction velocity.

Conclusion. These findings suggest that the lipid metabolism which is affected by diabetes and fish oil supplementation modulates the activity and level of the $\alpha 1$ and $\alpha 3$ isoenzymes. This study indicates that fish oil has beneficial effects on diabetes-induced alterations in sciatic nerve Na,K-ATPase activity and function.

Hyperglycemia Inhibits Liver Fatty Acid Oxidation and Increases Triacylglycerol Secretion in Humans

S. Sidossis, B. Mittendorfer, E. Walser, D. Chinkes*, and R. Wolfe
University of Texas Medical Branch and Shriners Burns Institute, Galveston, Texas

Hypertriglyceridemia is the most common abnormality associated with insulin resistance and a strong predictor of coronary heart disease mortality in NIDDM patients. Other pathological responses, such as alterations of the coagulation system and pancreatitis, have also been attributed to hypertriglyceridemia. However, the mechanisms responsible for the development of hypertriglyceridemia in insulin-resistant states remain unclear. The goal of the present study was to investigate the role of moderate hyperglycemia in the development of hypertriglyceridemia.

METHODS

Five healthy volunteers were studied in the post-absorptive state (basal) and, on a different occasion, during a 15-h dextrose infusion (hyperglycemic clamp). Catheters were inserted in a peripheral vein for tracer infusion and a femoral artery and a hepatic vein for determination of splanchnic fatty acid kinetics and oxidation. [U-^{13}C]-fatty acids were infused to measure fatty acid appearance and oxidation, whereas *in vivo* labeled [^{13}C] very low density lipoprotein–triglycerides (VLDL–TG) were infused to measure the rate of TG secretion. The VLDL–TG tracer was produced 3–4 d prior to the infusion studies by ingestion of [U-^{13}C]-glycerol followed by plasmapheresis 4 h later. VLDL–TG were isolated out of ~450 cc of plasma, under sterile conditions, and were stored until the day of the study. Lipids and heparin were infused in the clamp experiments only to maintain plasma fatty acid concentration constant. Splanchnic blood flow was measured by infusion of Indocyanin Green.

RESULTS

Plasma glucose concentration increased from 4.8 ± 0.2 in the basal to 8.8 ± 0.5 mM during the clamp ($P < 0.05$), whereas insulin increased from 5.5 ± 1.1 to 35.8 ± 11.4 μU/mL ($P < 0.05$). Glucose balance across the splanchnic region switched from net release (basal; 9 ± 1 mg/dL) to net uptake (clamp; 36 ± 12 mg/dL, $P < 0.05$). The rate of appearance of fatty acids was maintained constant in the basal and clamp experiments (4.8 ± 0.6 and 4.4 ± 0.6 $\mu mol \cdot kg^{-1} \cdot min^{-1}$, respectively). This is crucial, as the primary goal of the present study was to isolate the effects of hyperglycemia on splanchnic fatty acid kinetics and oxidation and the rate of TG secretion. Splanchnic fatty acid oxidation decreased significantly during the clamp (0.38 ± 0.04 and 0.2 ± 0.05 $\mu mol \cdot kg^{-1} \cdot min^{-1}$ during basal and clamp, respectively; $P < 0.05$). The decrease in splanchnic fatty acid oxidation was not related to a decline in free fatty acid (FFA) availability, as the absolute FFA uptake by the splanchnic region was similar in the basal and clamp experiments (0.7 ± 0.3 and 0.7 ± 0.5 $\mu mol \cdot kg^{-1} \cdot min^{-1}$, respectively). Ketone production was 1.5 ± 0.3 $\mu mol \cdot kg^{-1} \cdot min^{-1}$ in the basal state but dropped to undetectable levels during the clamp, suggesting complete inhibition of ketone body production during hyperglycemia. Interestingly, ketone body production was nearly completely inhibited during hyperglycemia even though splanchnic fatty acid oxidation to CO_2 was proceeding at a significant rate.

The rate of VLDL–TG appearance in plasma increased from 0.35 ± 0.07 in the basal state to 0.53 ± 0.11 $\mu mo \cdot kg^{-1} \cdot min^{-1}$ during the clamp ($P < 0.05$). Plasma-derived fatty acids contributed 91 ± 10% of the fatty acids for VLDL–TG formation in the basal state and 70 ± 22% during the clamp ($P < 0.05$). Nonplasma-derived fatty acids contributed the remaining FFA. Plasma VLDL–TG concentration increased from 0.28 ± 0.06 to 0.43 ± 0.05 mM ($P < 0.05$). The increase in plasma VLDL–TG concentration during the clamp appeared to be mostly due to the increased VLDL–TG secretion as the clearance of VLDL–TG did not change significantly.

DISCUSSION

It is concluded that moderate hyperglycemia increases glucose uptake and oxidation across the splanchnic region. Increased glucose oxidation, in turn, inhibits hepatic fatty acid oxidation even in the setting of constant fatty acid uptake. Inhibition of fatty acid oxidation increases the availability of fatty acids for TG synthesis, resulting in accelerated TG production rate.

These data provide a potential mechanism for the observed hypertriglyceridemia in conditions where glucose uptake and oxidation by the liver are enhanced (e.g., upper body obesity, NIDDM, and high-carbohydrate diets). In all of the above-mentioned conditions, increased availability of glucose for oxidation is coupled with normal or elevated systemic fatty acid availability, thereby creating a metabolic profile favoring enhanced incorporation of fatty acids into TG.

Effects of 3-Thia Fatty Acids on β-Oxidation and Carnitine Palmitoyltransferase-I Activity in Cultured Hepatocytes

Jowita Sleboda*, Kari Anne Risan, Øystein Spydevold, and Jon Bremer

Institute of Medical Biochemistry, University of Oslo, Blindern, Oslo, Norway

3-Thia fatty acids are fatty acid analogs in which an S atom replaces the β-methylene group in the chain. Consequently, they cannot be β-oxidized. When fed to rats, they induce a decrease in plasma triglycerides and cholesterol already after 3 h, mainly by stimulating mitochondrial β-oxidation and decreasing triacylglycerol secretion, followed by an increase in activity of peroxisomal β-oxidation enzymes after ~12 h.

When 3-thia fatty acids are added to isolated hepatocytes, they are shown to stimulate fatty acid oxidation and to inhibit fatty acid synthesis. The strength of this effect depends on the chain length of 3-thia fatty acid used. Dodecylthioacetic acid (DTA) and tetradecylthioacetic acid are most potent, shorter and longer 3-thia fatty acids having reduced effects. Hepatocytes from both fasted and fasted-carbohydrate refed rats are responsive toward 3-thia fatty acids, although the effect is more pronounced in the latter.

When hepatocytes are transferred to cell culture, both their palmitic acid oxidation rate and carnitine palmitoyltransferase-I (CPT-I) activity (the rate-limiting enzyme in β-oxidation pathway) decrease rapidly. Addition of DTA increases the oxidation rate of palmitate, but not of shorter fatty acids like octanoate. CPT-I activity is stimulated by DTA in a similar manner as palmitate oxidation. Normal fatty acids, e.g., palmitic acid, have some effect on CPT-I activity, but only when added in high concentration. This activation is most likely caused by free DTA, and not by its CoA ester. The activation of CPT-I is very fast (maximum is reached after 5–10 min), and if the thia fatty acid is removed from the medium the CPT-I activity returns to the low level within 2 h.

We conclude that the 3-thia fatty acids activate a latent CPT-I enzyme since the activation is too fast to be explained by enzyme synthesis (gene transcription). Apparently we can exclude the involvement of malonyl-CoA, because of the similarity between hepatocytes from fasted and fasted-refed animals.

Polyunsaturated Fatty Acids and Breast Cancer

P. Bougnoux*, E. Germain, F. Lavillonnière, S. Cognault, M.L. Jourdan, V. Chajès, and C. Lhuillery
Laboratoire de Biologie des Tumeurs, EA 2103, Université François-Rabelais, Tours; LNSA, INRA, Jouy-en-Josas, France

To address the role of dietary lipids in mammary carcinogenesis and in breast cancer and metastases development, we studied the lipid composition of adipose breast tissue as an indicator of past dietary fatty acid intake in patients with benign or malignant breast tumors. Using a case-control approach, we found α-linolenic acid (18:3n-3) to be inversely related to the risk of breast cancer. We confronted the lipid profile to breast cancer clinical presentation and posttreatment evolution. We found that the level of 18:3n-3 was inversely related to risk of developing metastases in breast cancer patients. The potential role of conjugated isomers of 18:2n-6 (CLA) in breast cancer is currently being evaluated with similar observational method. Preliminary data indicate a strong protective effect of CLA against breast cancer.

Using an animal system of *N*-methylnitrosourea-induced mammary tumors, we found that dietary 18:3n-3 (rapeseed oil) or n-3 polyunsaturated acid (PUFA) (fish oil) inhibited tumor development and growth only in the absence of the antioxidant vitamin E. This inhibition was even more pronounced in the presence of prooxidants. Such effects were not found when lipid diet was low in PUFA. Tumor cell loss may be involved, because tumor cell proliferation was not affected. These data suggest that PUFA inhibit tumor growth because they are lipid substrates to peroxidation, an intermediate step toward cell death.

Similar studies were made to address the effect of PUFA on tumor response to anticancer agents. We found that the responsiveness of breast malignant tumors to induction chemotherapy was high when the level of docosahexaenoic acid (DHA, 22:6n-3) in stored lipids of patients was elevated. Using cultured breast cancer cell lines, we observed that addition of DHA to medium increased the toxicity of anticancer drugs that generate an oxidative stress and also increased cell lipid peroxides. The effect was lost when antioxidant was added. *In vivo*, rat mammary tumors were sensitized to epirubicin when fish oil and oxidants were provided in the rat diet. We believe that tumor growth-inhibiting lipoperoxides are generated during drug action, provided that DHA substrate is available to tumor cells, thus leading to increased drug efficacy.

These studies demonstrate the importance of dietary components in the genesis and development of breast cancer. Precise identification of their role should permit their use as nutritional targets in therapy and prevention of cancers.

Altered Lipid Metabolism Associated with the Progression of Premalignant Lesions in Rat Liver

S. Abel[a],*, C.M. Smuts[b], and W.C.A. Gelderblom[a]

[a]Programme on Mycotoxins and Experimental Carcinogenesis, and [b]National Research Programme for Nutritional Intervention, Medical Research Council, Tygerberg, 7505, South Africa

Altered lipid metabolism has been associated with cellular growth, altered cell function, and the development of premalignant lesions in rat liver. Fatty acid (FA) changes have a wide range of effects regarding the integrity of cellular membranes that are known to affect the membrane structure, the activity of membranal enzymes, and the affinity of growth factor receptors. Membranal FA also play a role as second messengers during signal transduction and cell regulation *via* the activation of protein kinase C (PKC), mitogen-activated protein kinase (MAP kinase), and generation of ceramide. FA also play a determining role in the regulation of prostaglandin production and decreased lipid peroxidative activity generally observed in tumor tissue. In the present study, alterations in lipid metabolism were monitored in rat hepatocyte nodules by comparing the lipid profiles of nodular tissue with surrounding and control tissue as a function of time by harvesting the nodules (1, 3, 6, and 9 mon after induction) as well as the surrounding and control tissue. As cellular proliferation is an important determinant in cancer development, tissue fractions obtained from hepatectomized rats were included as a control for normal liver regeneration. In the nodular tissue, the concentrations of phosphatidylethanolamine (PE) and cholesterol increased significantly compared to control and surrounding tissue. Phosphatidylcholine (PC) was also increased, but only significantly at 1 mon. This resulted in a decrease of the PC/PE ratio. Similar changes were observed in the regenerating liver, with the exception of PC which tended to decrease. The nodular membrane fluidity was significantly decreased at months 1, 3 and 6, but increased at month 9. In the regenerating liver, the membrane fluidity was significantly increased at days 1, 2, and 7. The levels of the different n-6 and n-3 FA in PC and PE were analyzed quantitatively and qualitatively. In the nodular tissue, 18:1n-9 and 18:2n-6 increased in PE and PC while 20:4n-6 decreased in PC and increased quantitatively in PE only over the 9-mon period. 22:5n-6 and 22:6n-3, the end products of the n-6 and n-3 metabolic pathways, respectively, decreased qualitatively and quantitatively in PE and PC. The FA profiles of PC and PE of the surrounding tissue reflected the pattern of the untreated control rat livers. In the regenerating liver, the FA profiles of PC and PE showed the same pattern as described for the hepatocyte nodules, except for a qualitative and quantitative decrease of 18:1n-9 in PC and PE. These results indicated that the lipid parameters associated with increased cellular proliferation in hepatocyte nodules closely mimic normal regeneration in the liver. However, a determining event is the persistence of the lipid changes associated with the nodules compared to the reversion of these changes in regenerating liver. This implies that nodular lipid metabolism escapes the normal regulatory mechanisms required for controlled regeneration and homeostasis. The above changes in the nodule lipid parameters suggest various paths in which FA can play a role in the persistent cellular proliferation known to prevail in these lesions. The increase in nodular PE led to an increase in the level of 20:4n-6 which, in its capacity as second messenger, can influence cellular proliferation *via* increased levels of prostaglandin E_2, cAMP, activation of PKC and phosphorylation of phospholipase A_2 *via* MAP kinase. 20:4n-6 can also play a role in apoptosis *via* ceramide generation and indirectly through the deregulation of c-myc expression; however, in hepatocyte nodules the FA appears to be one of the major players in the progression of these lesions into neoplasia. The increased level of 18:1n-9, a FA with antioxidative properties, as well as the decreased levels of the PUFA have been associated with the decreased lipid peroxidation level in hepatocyte nodules. The resultant decrease in peroxidative metabolites, which are known to induce apoptosis, could affect the apoptotic process in the nodular environment. The altered phospholipid and FA profiles in the hepatocyte nodules could provide a unique opportunity to alter the lipid parameters by dietary manipulation in order to modulate the increased cellular proliferation and the progression of these lesions into neoplasia.

Reversal of Tumor Cell Drug Resistance by Essential Fatty Acids

U.N. Das*

Division of Internal Medicine, Clinical Immunology and Biochemistry, L.V. Prased Eye Institute, Banjara Hills, Hyderabad-500 043, India

Tumor cell drug resistance is a major problem in cancer chemotherapy. Several tumors initially respond favorably to chemotherapy, but subsequently develop multidrug resistance (MDR). The development of this MDR state is due to increased efflux and decreased influx of anticancer drugs into the tumor cells. This leads to a decrease in the accumulation of anticancer drugs inside the tumor cells and hence decreased response to their cytotoxic action. Further, the antioxidant status of the tumor cells and the efflux and influx of anticancer drugs which depends on the cell membrane properties can also be related to tumor cell drug resistance. It is known that cell membrane properties depend on their lipid composition.

It is known that essential fatty acids and their metabolites are cytotoxic to a variety of tumor cells *in vitro* and *in vivo* (1–5). But the effect of these fatty acids on tumor cell drug resistance is not well documented.

In our study, it was noted that γ-linolenic acid (GLA) and eicosapentaenoic acid (EPA) potentiated the cytotoxicity of anticancer drugs vincristine, *cis*-platinum, and doxorubicin on human cervical carcinoma cells *in vitro* by enhancing the uptake of anticancer drugs. In addition, docosahexaenoic acid (DHA), EPA, GLA, and dihomo γ-linolenic acid were found to by cytotoxic to both vincristine-sensitive and -resistant human cervical carcinoma cells *in vitro*. These fatty acids enhanced the uptake and inhibited the efflux of vincristine and thus enhanced the intracellular concentration of the drug. Further, these fatty acids could decrease the levels of various antioxidants in the tumor cells. In an extension of this study, it was also noted that pre-incubation of vincristine-resistant cells with suboptimal doses of fatty acids enhanced the cytotoxic action of vincristine. Fatty acid analysis showed that vincristine-resistant tumor cells have low amounts of α-linolenic acid, GLA, and DHA in comparison to the sensitive cells. These results suggest that essential fatty acids and their metabolites can reverse and/or inhibit tumor cell drug resistance at least *in vitro*.

Protection from Chemotherapy-Induced Alopecia by Docosahexaenoic Acid

Kyoya Takahata[a,*], Mikirou Tada[a], Kazunaga Yazawa[b], and Takahiko Tamaki[c]

[a]Faculty of Agriculture, Okayama University, Okayama 700-8530, Japan, [b]Sagami Chemical Research Center, Kanagawa, Japan, and [c]First Department of Surgery, Okayama University Medical School, Okayama, Japan

Chemotherapy-induced alopecia is a common side effect of many chemotherapeutic drugs used for the treatment of cancer. Several methods currently utilized to prevent chemotherapy-induced alopecia are unsatisfactory. Research of new treatments has been hampered, in part, by the lack of a suitable and reproducible experimental animal model to determine the cellular target of anticancer drugs in the hair follicle and how the interaction of these drugs with that target leads to hair loss. Recently made observations in the young rat model (1) have provided a new insight into this problem and opened new avenues for further investigation. Using this model, Cece *et al.* (2) reported that chemotherapy treatment induced apoptosis in a hair follicle cell. Thus we examined whether docosahexaenoic acid (DHA), which had been found to have a modulator effect on neural apoptosis, could prevent chemotherapy-induced alopecia in this model.

Lactating Sprague-Dawley rats with 10 newborns/mother were purchased. In these experiments, 8-d-old rats were used for cytosine arabinoside (Ara-C)-induced alopecia, and 11-d-old rats were used for etoposide (VP-16)-induced alopecia. All chemotherapy was given i.p., and DHA was given p.o. Degree of alopecia was assessed on the 17-d-old (Ara-C) or 20-d-old (VP-16) animals.

The results are as follows: (i) all rats in the chemotherapy-treated group became totally alopecia; (ii) in these alopecia-induced groups, apoptosis was detected by TUNEL staining method in skin sections; (iii) in contrast, most rats in the DHA-treated group were protected from chemotherapy-induced alopecia; (iv) recombinant human interleukin1α (rhIL1α) or intrinsic IL1 inducer, lipopolysaccharide, also could strongly protect alopecia; and (v) the effect of DHA could not be neutralized by IL1-receptor antagonist.

In conclusion, it is suggested that DHA protection against chemotherapy-induced alopecia could be mediated either directly or indirectly through apoptosis modulation without involving IL1 systems.

Proliferation and Types of Killing of Leukemia Cell Lines By Very Long Chain Polyunsaturated Fatty Acids

Hanne S. Finstad, Hilde Heimli, Svein O. Kolset, and Christian A. Drevon*

Institute for Nutrition Research, University of Oslo, Oslo, Norway

Polyunsaturated fatty acids (PUFA) may reduce cell multiplication in cultures of normal (1) as well as transformed (2,3) white blood cells. We assessed the sensitivity of 14 different leukemia cell lines to PUFA by measuring cell number after 3 d of incubation. Ten of the examined cell lines were sensitive to 30, 60, and/or 120 mM of arachidonic, eicosapentaenoic (EPA), and docosahexaenoic acid (DHA), whereas four cell lines were resistant. The sensitivity to PUFA was not associated with any particular cell lineage, clinical origin, or specific mRNA pattern of bcl-2 and c-myc. Effects on cell viability were assessed by studying cell membrane integrity, DNA fragmentation, and cell morphology. The sensitive cell lines Raji and Ramos died by necrosis and apoptosis, respectively, during incubation with EPA, whereas the viability of the resistant U-698 cell line was unaffected. The effects of EPA on Raji cells were counteracted by vitamin E, indicating that lipid peroxidation may be involved. However, apoptosis induced by EPA in Ramos cells was unaffected by vitamin E as well as eicosanoid synthesis inhibitors. Thus, our results indicate that a majority of leukemia cell lines are sensitive to PUFA. This sensitivity may be caused by induction of apoptosis or necrosis by very long-chain PUFA.

For further analyses the monoblastic cell line U-937-1 was cultured in the presence of EPA or oleic acid (OA, 18:1n-9). EPA caused a dose-dependent inhibition of cell growth, whereas OA was not inhibitory at any concentration tested. At the highest EPA concentrations used, 120 and 240 mM, inhibition of cell growth was accompanied by initiation of apoptosis, as shown by microscopy after staining with propidium iodide and Hoechst 33342. At 60 mM concentration, EPA caused a 35% reduction in cell proliferation without inducing apoptosis and was therefore used for further studies. The addition of antioxidants or inhibitors of eicosanoid synthesis had no influence on the reduced cell growth with EPA. Furthermore, the inhibition required the continuous presence of EPA in the incubation medium. The cells resumed a normal proliferation rate when they were placed in EPA-free medium. The inhibition of proliferation was not accompanied by differentiation of the cells into macrophage-like cells, as the expression of serglycin and the ability to perform respiratory burst were not affected by EPA. The expression of mRNA for CD23 increased with EPA, but to a smaller extent than after incubation with retinoic acid or phorbol myristate acetate. Furthermore, the cell surface expression of the antigens CD36 and CD68 was lower in cells treated with EPA or OA compared to untreated cells. The cell cycle distribution of U-937-1 cells was similar in cells treated with EPA and phorbol myristate acetate, whereas retinoic acid-treated cells accumulated in the G1 phase of the cell cycle. However, when the cells were subjected to side scatter and forward scatter analyses during flow cytometry, those treated with EPA and OA showed an increased side scatter. Accumulation of lipid droplets could be demonstrated by electron microscopy, and the number of droplets per cell was higher in cells exposed to EPA than OA. The cells showed 5.5- and 15.5-fold increases in the content of triacylglycerol after OA and EPA treatment, respectively, whereas there was no difference in the cellular content of cholesterol. The triacylglycerol fraction in EPA-treated cells contained high amounts of EPA, and OA-treated cells had high levels of OA. No inhibition of cell growth or accumulation of lipid droplets was observed in U-937-1 cells treated with a sulfur-substituted EPA. The accumulation of EPA-rich triacylglycerols with 60 mM EPA was correlated to inhibition of cell growth and was unaffected by antioxidants or eicosanoid inhibitors, and without any initiation of apoptosis. This may indicate the existence of other mechanisms for regulation of cell behavior than the well-established lipid peroxide and eicosanoid pathways.

Cytotoxic Drug Efficacy Correlates with Adipose Tissue Docosahexaenoic Acid Level in Locally Advanced Breast Carcinoma

P. Bougnoux[a,*], V. Chajès[a], E. Germain[a], B. Hubert[b], C. Lhuillery[c], O. Le Floch[a], G. Body[a], and G. Calais[a]

[a]Laboratoire de Biologie des Tumeurs et Clinique d'Oncologie-Radiothérapie, et Service de Gynécologie (UPRES-EA2103), [b]Service d'Information Médicale et d'Hygiène, Hôpital Bretonneau, Tours, and [c]LNSA, INRA, Jouy en Josas, France

Experimental studies indicated that long chain n-3 polyunsaturated fatty acids (PUFA) may increase sensitivity of mammary tumors to several cytotoxic drugs. No data in humans are available concerning the potential influence of dietary fatty acids on chemosensitivity of tumors to cytotoxic drugs. In a previous study in breast cancer patients, we found that a decreased level of α-linolenic acid in adipose tissue, used as a biomarker of past qualitative dietary fatty acids, was associated with subsequent development of visceral metastases, suggesting that the type of fatty acids available to tumor cells may have influenced the outcome of breast cancer, by alterating the response of cancer cells to the initial treatment. The aim of the study was to examine the association between the level of individual fatty acids in the adipose breast tissue and the response of the breast tumor to primary chemotherapy, in 56 patients with locally advanced breast carcinoma.

Adipose breast tissues were obtained at the time of biopsy, and individual fatty acids were measured as a percentage of total fatty acids, using capillary gas chromatography. Patients then received primary chemotherapy, combining mitoxantrone, vindesine, cyclophosphamide, and 5-fluorouracil every 4 wk. Tumor size was reassessed after three cycles of chemotherapy. Tumor response was evaluated according to World Heath Organization criteria.

Complete or partial response to chemotherapy was achieved in 26 patients. Level of n-3 PUFA was higher in the group of patients with complete or partial response to chemotherapy than in patients with no response or with tumor progression ($P < 0.004$). Among n-3 PUFA, only docosahexaenoic acid (22:6n-3) was significantly associated with tumor response ($P < 0.005$). In a logistic regression model taking into account age, body mass index, and tumor size, 22:6n-3 level proved to be an independent predictor for chemosensitivity ($P = 0.03$).

These results suggest that, in breast cancer, 22:6n-3 may increase the response of the tumor to the cytotoxic agents used. Thus, dietary intervention could provide an effective means to increase 22:6n-3 availability in tumor tissues and thereby may affect chemosensitivity of tumors.

Effects of Eicosapentaenoic and Docosahexaenoic Acids Dietary Supplementation on Cell Proliferation and Apoptosis in Rat Colonic Mucosa

Gabriella Calviello[a], Paola Palozza[a], Nicola Maggiano[b], Piergiorgio Franceschelli[a], Fiorella Di Nicuolo[c], Maria Elena Marcocci[c], and Gianna Maria Bartoli[c,*]

[a]Institute of General Pathology and [b]Institute of Pathology, Catholic University, and [c]Department of Biology, Tor Vergata University, Rome, Italy

n-3 Polyunsaturated fatty acids (PUFA) have been shown to inhibit chemical-induced carcinogenesis of colon in rats (Reddy, B.S., and Maruyama, H., *Cancer Res. 46*:3367–3370, 1986) and to normalize altered proliferative patterns of the colonic mucosa in human subjects at high risk for colon cancer (Anti, M., *Gastroenterology 103*, 883–891, 1992 and *Gastroenterology 107*, 1709–1715, 1994). To determine whether n-3 PUFA also influence the normal cellular turnover, we investigated the effects of dietary supplementation with eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), the two major n-3 PUFA, on cell proliferation, apoptosis, and crypt morphology in normal colonic mucosa. Moreover we analyzed some metabolic pathways such as fatty acid incorporation into membrane phospholipids and peroxisomal β-oxidation involved in the effects of n-3 PUFA. Sixty male inbred ACI/T rats were randomly divided into three groups of 20 each, receiving oleic acid (control), EPA, or DHA (1 g/kg body wt/d) as ethyl esters by gastric gavage for 10 d. Cell proliferation and apoptosis were examined by bromodeoxyuridine and by *in situ* nick end labeling staining, respectively; fatty acid composition of phospholipid (PL) classes by thin-layer chromatography and gas–liquid chromatography and the activity of palmitoyl-CoA oxidase, the limiting enzyme of peroxisomal β-oxidation, were measured fluorimetrically by a coupled peroxidase reaction in mucosal homogenate. Both EPA and DHA inhibited cell proliferation and induced apoptosis in normal colonic mucosa of rats, but they did not modify crypt morphology and the total number of cells per crypt. EPA and DHA treatment decreased arachidonic acid content in phosphatidylethanolamine (PE) and increased EPA in all PL classes. After DHA treatment, DHA itself increased in phosphatidylcholine (PC) and PE but not in phosphatidylinositol (PI). As a consequence of the modifications in fatty acid composition, n-6/n-3 PUFA ratio decreased in total PL, in PC and PE fractions of both EPA and DHA groups. On the contrary, n-6/n-3 PUFA ratio did not change in the PI fraction. Unsaturation index was not modified in total PL as well as in PL classes. A significant increase in peroxisomal β-oxidation (140% in EPA and 170% in DHA rats) was observed after both EPA and DHA supplementation. The increase in this metabolic pathway resulted in an overproduction of hydrogen peroxide. The changes in cell proliferation and apoptosis were related to changes in the composition of membrane PL and in fatty acid peroxisomal metabolism. The observation that arachidonic acid level is not affected in PC and PI suggests that eicosanoids are not involved in n-3 PUFA effects. Moreover, the induction of peroxisomal β-oxidation with a consequent increase in hydrogen peroxide production suggests that a mild increase in reactive oxygen species could be implicated in the inhibition of cell proliferation and in the induction of apoptosis by n-3 PUFA. Our finding that EPA and DHA did not modify crypt morphology and the total number of cells per crypt, although they altered cell proliferation and apoptosis in normal colonic mucosa, suggests a possible use of these fatty acids as dietary chemopreventive agents.

Fatty Acid Composition in Serum Phospholipids and Risk of Breast Cancer: A Prospective Cohort Study in Northern Sweden

V. Chajès[a,*], K. Hultèn[b], A.L. Van Kappel[a], A. Winkvist[b], R. Kaaks[a], G. Hallmans[b], P.G. Lenner[b], and E. Riboli[a]

[a]Unit of Nutrition and Cancer, International Agency for Research on Cancer, Lyon, France, and [b]University of Umeå, Umeå, Sweden

Data derived from animal experiments indicated that diets rich in n-3 polyunsaturated fatty acids (PUFA) from marine origin inhibited tumor growth and metastasis. Prospective cohort studies generally provided weak support for the hypothesis that dietary intake of n-3 PUFA might protect against breast cancer. Conclusive evidence for a role of individual fatty acids in breast cancer risk may be precluded by the many methodological limitations in measurements of dietary intake of fatty acids. In this regard, the use of reliable markers of dietary fatty acids would be of major interest. Serum phospholipid fatty acid composition is known to reflect dietary concentrations for PUFA. Thus, the aim of the study was to evaluate the hypothesis of a possible protection of n-3 fatty acids against breast cancer in women, using fatty acid concentrations in serum phospholipids as a marker of dietary intake of PUFA, in a prospective cohort study in Umeå, Sweden.

Patients were selected from three cohort studies in the town of Umeå and its surroundings in northern Sweden. We examined the fatty acid composition of phospholipids in prediagnostic sera of 196 women who developed breast cancer, and of 388 referrents matched for age at recruitment, age of blood sample, and sampling center. Individual fatty acids were measured as a percentage of total fatty acids, using capillary gas chromatography.

Conditional logistic regression model was performed to obtain odds ratio and 95% confidence intervals, while adjusting for weight and height. Quartile cut points for fatty acids were determined based on the referrents, and the lowest quartile was used as the reference category.

We found no association between n-3 PUFA in serum phospholipids and risk of breast cancer. In the subgroup of postmenopausal women, we found an inverse association between the ratio stearic acid (18:0)/oleic acid (18:1n-9), which reflects Δ-9 desaturase activity, and risk of breast cancer. The adjusted relative risk of breast cancer for postmenopausal women in the highest quartile of the ratio 18:0/18:1n-9 was 0.38 compared to women in the lowest quartile (*P* trend = 0.019).

Our data do not support the hypothesis that dietary intake of n-3 PUFA might protect against breast cancer. The inverse association between the ratio 18:0/18:1n-9 and risk of breast cancer in postmenopausal women may suggest an increase in breast cancer in women with high activity of the enzyme Δ-9 desaturase, which may reflect an underlying metabolic profile, characterized by insulin resistance and chronic hyperinsulinemia.

Essentiality of Docosahexaenoic Acid in Retina Photoreceptor Cell Development

N.P. Rotstein, M.I. Aveldaño*, and L.E. Politi
Instituto de Investigaciones Bioquímicas de Bahía Blanca, UNS-CONICET, 8000 Bahía Blanca, Argentina

Unless docosahexaenoic acid (DHA, 22:6n-3) is added, retina photoreceptor cells in culture undergo a degeneration process that leads to their massive death in 2 wk (1). We recently showed that this occurs by the activation of an apoptotic pathway and that DHA provides against such event, postponing the onset of apoptosis and slowing down its progression (2). Our objective in this project is to investigate the factors associated with this action of DHA. Here we present the effect of diverse fatty acids including DHA on lipid composition and metabolism and on the apoptosis and differentiation of photoreceptors.

Rat retina neuronal cultures prepared from 1–2-d-old rats (1,3) were incubated in a chemically defined serum-free medium, in the absence and in the presence of DHA and other fatty acids (20:4, 18:1, 16:0), unlabeled and radioactive. Cells were identified by morphological and immunocytochemical techniques, and apoptosis was determined using nuclear markers (2).

In cells incubated with DHA, its proportion in lipids increased four- to sixfold, in contrast to other fatty acids whose addition did not affect the cell lipid composition. However, all labeled fatty acids were actively incorporated and esterified in neuronal lipids, particularly in phosphatidylcholine, showing that efficient mechanisms exist for the uptake of each. Apart from this common feature the distribution of radioactivity among lipids varied, showing a characteristic profile for each fatty acid. The addition of unlabeled DHA to cells did not affect the incorporation of labeled 16:0 or 18:1 in phosphatidylcholine but significantly decreased that of 20:4. Retinal neurons thus have specific mechanisms for handling fatty acids of different length and unsaturation, the incorporation of DHA taking priority in this phase of development. This may contribute to the high proportion of DHA-enriched phospholipids found in retinal neurons. Furthermore, neurons may have specific mechanisms for handling DHA. While there was a net uptake of all fatty acids tested when added as radioactive substrates, only DHA was able to modify the lipid acyl chain composition when supplied as unlabeled fatty acid. This suggests that, whereas other fatty acids are incorporated by deacylation–reacylation of preexisting phospholipid molecules, DHA is also used for the synthesis of new molecular species of phospholipids.

Of all fatty acids tested, DHA was not only the only one effective in preventing apoptosis but also the most competent in promoting photoreceptor cell differentiation. In control cultures, photoreceptors have a small round body, a single neurite and some of them develop a *cilium*, but none show the characteristic outer segment these cells have *in vivo*. DHA supplementation led to the formation of new apical processes: after 6–7 d, over one-third of the photoreceptors showed these processes at the end of their cilium, looking like the first steps in the assembly of their outer segment. DHA also led to an increase in the expression of opsin: over 40% more photoreceptors expressed this protein in DHA-treated than in control cultures. Even more striking was the redistribution of opsin induced by DHA. Immunocytochemical studies using Rho4-D2, a monoclonal antibody against rhodopsin, showed that without DHA opsin was uniformly distributed over the entire neurolemma, as is found in immature photoreceptors. Addition of DHA stimulated the correct localization of the protein in the newly formed apical processes, as it occurs in mature photoreceptors. Accretion of DHA entails the formation of the DHA-containing phospholipid molecules that are necessary for the assembly of the disk membranes where (rhod)opsin is to be embedded. The availability of these molecules may be essential for a timely formation of photoreceptor outer segments with proper localization of the newly formed opsin, this enhanced differentiation in turn, delaying photoreceptor apoptosis.

A Role for Cerebral and Retinal Endothelial Cells in the Supply of Docosahexaenoic Acid to the Brain and the Retina?

I. Delton-Vandenbroucke[a,b], P. Grammas[c], and R.E. Anderson[a,b,*]

Departments of [a]Ophthalmology and [c]Pathology, Oklahoma Center for Neuroscience, University of Oklahoma Health Sciences Center; and [b]Dean A. McGee Eye Institute, Oklahoma City, Oklahoma

Docosahexaenoic acid (DHA, 22:6n-3), the most highly polyunsaturated n-3 fatty acid in animals, is derived from a series of elongation and desaturation reactions originating from linolenic acid (18:3n-3). DHA is found in abundant proportion in neuronal tissues such as brain and retina. The reason for such high levels of DHA is not clearly understood although changes in cerebral and retinal functions were reported in animals and humans fed diets deficient in n-3 fatty acids. Because of its functional importance, more information is needed about the delivery of DHA to these structures. DHA is primarily synthesized in the liver from dietary linolenic acid and distributed to target organs *via* the circulation. The brain and the retina can also form DHA; astrocytes and retinal pigment epithelium were respectively involved. In the present study, we examined whether cerebral and retinal microvascular endothelial cells could produce DHA.

Confluent bovine retinal and rat cerebral endothelial cells (EC) were incubated with 1 μCi of [3-^{14}C]22:5n-3 for 24 h. At the end of incubation, media and cells were harvested. Total lipids were extracted; fatty acid phenacyl esters were prepared and analyzed by high-performance liquid chromatography (HPLC), and radioactivity measured by continuous scintillation counting. In both cerebral and retinal EC, the primary product of 22:5n-3 metabolism, which includes retroconversion, elongation and desaturation reactions, was 20:5n-3, followed by 22:6n-3, 24:5n-3, and 22:6n-3. The formation of 24-carbon metabolites is consistent with the proposal of Voss *et al.* (1) that the conversion of 22:5n-3 to 22:6n-3 is independent of a δ4-desaturase. Interestingly, all of these metabolites were recovered in the medium. Thin-layer chromatography analyses revealed that 80–90% of the radioactivity found in the medium was associated with the free fatty acid fraction. The HPLC profiles obtained from the free fatty acid fractions did not differ from that obtained from media total lipids, indicating that the metabolites were released as free fatty acids. The distribution of metabolites between cells and medium shows that except for 20:5n-3 in retinal EC, each n-3 metabolite was recovered in the medium three to five times more than in the cells. Moreover, for retinal cells, there seems to be a chain-length specificity in the α-release process, the release being greater for longer-chain fatty acids (medium/cell ratio: 8.3 for 24:5n-3 > 5.0 for 24:6n-3 > 1.2 for 22:6n-3 > 0.6 for 20:5n-3). No apparent specificity was found for cerebral EC (medium/cell ratio about 4 for each metabolite). In the next experiments, we examined whether n-6 metabolites would also be released in high proportion by cerebral and retinal EC. The conversion of labeled linoleic acid ([1-^{14}C]18:2n-6) and the esterification and release of its metabolites were determined. In both cells, the major product formed by desaturation and chain elongation was 20:4n-6. Some further elongation of 20:4n-6 to 22:4n-6 was observed as well as accumulation of 20:3n-6, an anticipated intermediate between 18:2n-6 and 20:4n-6. The elongation/desaturation products, with the exception of 18:3n-6, were all preferentially retained in the cells (three to five times more than in the medium). Because the longer-chain n-6 fatty acids, such as 22:5n-6 and 24-carbon fatty acids, were not detected in our conditions, it is difficult to distinguish between fatty acid series (n-3 vs. n-6) and chain-length specificity in the release process. However, since 18:3n-6 was actually more released than the longer-chain n-6 fatty acids (medium/cell ratio: 2 vs. 0.25), and since there is no chain-length specificity in cerebral EC, these results rather suggest a preferential release of n-3 over n-6 fatty acids. This may contribute to the enrichment of 22:6n-3 in the brain and the retina. Moore (2) previously proposed a pathway in which cerebral endothelium forms and releases 20:5n-3, which is then converted by astrocytes to 22:6n-3, which is released for uptake by neurons. Since cerebral EC can also release 22:6n-3 and 24-carbon fatty acids in high proportion, we suggest that they could cooperate in supplying 22:6n-3 to neurons. Based on such a model, retinal endothelium could cooperate with retinal pigment epithelium in supplying 22:6n-3 to rod outer segments.

Effects of Dietary Oils and Cholesterol Supplement on Fluidity and Enzyme Activities of Liver Microsomes in the Rat

Mariane Lutz*, Julio Alvarado, Paola Barraza, Silvia Bonilla, and Leticia Luna
Escuela de Química y Farmacia, Universidad de Valparaíso, Casilla 5001, Valparaíso, Chile

Dietary fats affect the lipid composition of membranes. As a consequence of this chemical change, dynamic properties of membranes such as fluidity may be modified, affecting various biological functions, including the activity of enzymatic systems involved in the metabolism of endogenous substances and xenobiotics.

The aim of this study was to investigate a possible relationship between the ability of dietary lipids to modify liver microsomal fluidity and the activity of integral membrane enzymes participating in the metabolism of xenobiotics in rats submitted to standardized dietary conditions. We aimed to answer this question by investigating the effects of the intake of corn (C), olive (O), or fish (F) oil, and of a dietary supplement of 1% cholesterol (Ch), on microsomal fluidity, cytochrome P450 content, and the activities of phase I enzymes aniline hydroxylase (AH) and aminopyrine-*N*-demethylase (AD) and phase II enzyme UDP-glucuronyltransferase (UDP-GT).

Male Sprague-Dawley rats ($n = 6$ per group), *ca.* 100 g initial body weight, were fed semipurified diets containing 15% each oil, without or with Ch supplement.

After 20 d of feeding each of the six experimental diets, feed intake and efficiency were lower in rats fed F ($P < 0.01$) and did not differ in groups fed any of the vegetable oils, which is associated to a lower acceptability of the diet containing marine oil. Relative liver weight of rats fed with C or O oil augmented after Ch supplementation, while in F + Ch group the size of the organ was diminished compared with the nonsupplemented F group ($P < 0.001$). This is likely to be related to the accumulation of cholesterol esters in the liver in animals fed vegetable oils.

F oil intake increases n-3 polyunsaturated fatty acids in microsomal phospholipids, resulting in a higher degree of membrane unsaturation that explains the increase in fluidity. A relationship between microsomal fluidity and enzyme activity was observed: rats fed F oil exhibited the highest microsomal fluidity, cytochrome P450 content, and enzyme activities vs. groups fed C or O oils ($P < 0.001$).

A high fluidity allows the mixed function oxidases system to have an adequate structural disposition, flexible enough to facilitate the electron transport required for their optimal functioning. The intake of Ch supplement decreased membrane fluidity in all groups. The decrease in AH activity in rats fed F + Ch ($P < 0.05$) or C + Ch ($P < 0.01$) may be associated with the packing effect of this lipid. UDP-GT activity was higher in rats fed F oil vs. all vegetable oils ($P < 0.001$) and decreased after the intake of Ch ($P < 0.01$). AD was less affected by Ch supplement intake, and only F + Ch group showed lower activity ($P < 0.01$). Ch diminished the physical and functional parameters measured in animals fed F oil and, to a lesser extent, C oil. The rigidizing effect of Ch is reflected mainly on very fluid membranes, rich in long chain polyunsaturated fatty acids.

The marine oil intake exerts the most significant effects upon liver microsomal properties, which prevail over the intake of high amounts of Ch. These results also indicate that although AH and AD act in the same microsomal metabolic pathway (phase I), their localization into the membrane may be determinant of their activity and the response to dietary lipids, and also confirm that dietary lipid intake is an important factor to be taken into account when evaluating the individual response of different subjects to drug therapy and/or exposure to environmental chemicals or other xenobiotics.

The Effect of Palmitic Acid on Lipoprotein Cholesterol Levels and Endogenous Cholesterol Synthesis in Hyperlipidemic Subjects

M.T. Clandinin[a,b,c,*], S.L. Cook[a,b], S.D. Konrad[a,b], Y.K. Goh[a,b], and M.A. French[a,b]

[a]Nutrition and Metabolism Research Group, [b]Department of Agricultural, Food and Nutritional Science, and [c]Department of Medicine, University of Alberta, Edmonton, Canada T6G 2P5

ABSTRACT: The present study assesses the effect of high vs. low palmitic acid intakes on plasma lipoprotein cholesterol levels and on rates for endogenous synthesis of cholesterol in healthy and hyperlipidemic subjects. Four diets were formulated to provide combinations of 16:0 at two levels of 18:2n-6. Subjects received each diet treatment for 21 d, followed by washout periods of 21 d. On day 21 of each diet treatment, a fasting blood sample was drawn for lipoprotein determination and to provide a measure of the background level of deuterium. A priming dose of deuterium was consumed and a second blood sample obtained 24 h after the first sample. Isotope ratio mass spectrometry was used to determine the incorporation of deuterium into the newly synthesized cholesterol molecule, and fractional synthetic rates were calculated. Serum total cholesterol and low density lipoprotein-cholesterol was not significantly affected by the high level of 16:0 when diets also contained a high level of 18:2n-6. There was no effect of dietary 16:0 on high density liproprotein-cholesterol at either the high or low levels of intake. The results indicate that 16:0 has no effect on serum lipoprotein profiles in the presence of recommended intakes for 18:2n-6.

According to the original Keys (1,2) hypothesis, palmitic acid should increase blood cholesterol levels. These commonly cited equations fail to separate the effect of three saturated fatty acids (12:0, 14:0, and 16:0), defining these as equally hypercholesterolemic. When the Keys equation is modified to treat palmitic acid as neutral (similar to stearic acid), the equation is a better predictor of changes observed in serum cholesterol levels. This observation was supported by Hayes *et al.*, who hypothesized that 16:0 is a neutral fatty acid (3). In a study which exchanged 5% of energy from 12:0 plus 14:0 for 16:0 in healthy young men consuming a low-cholesterol diet, the dietary combination of 12:0 plus 14:0 produced significantly higher serum cholesterol levels than did 16:0 (4). Other studies failed to demonstrate elevated plasma cholesterol following palmitic acid consumption. Ng *et al.* (5), compared the effects of palmitic acid and oleic acid in normocholesterolemic subjects (5).

Recently we reported a study of normal subjects in which we investigated the effect of dietary palmitic acid levels fed in high- or low-linoleic acid diets on plasma lipoprotein cholesterol content and on the rate of endogenous synthesis of cholesterol (6). Using the deuterium-uptake method, the fractional synthetic rate was assessed. When palmitic acid was exchanged for dietary 18:2n-6, plasma cholesterol levels increased. When high vs. low palmitic acid was exchanged for 18:1n-9 and was fed at both high dietary intake levels of 18:2n-6, no effect on plasma cholesterol level or the endogenous cholesterol synthesis rate was observed, thus, indicating that dietary palmitic acid has no effect on serum lipoprotein profiles in the presence of recommended dietary intakes of 18:2n-6. The present study utilized a similar dietary comparison to determine if plasma cholesterol levels can be increased in modestly hypercholesterolemic subjects by increased consumption of 16:0 when the diet contains >10% 18:2n-6.

MATERIALS AND METHODS

All procedures were approved by the Faculty of Agriculture, Forestry and Home Economics Human Ethics Review Committee. Subjects were recruited from advertisements posted at the University of Alberta campus. An in-depth questionnaire was completed by all subjects to screen for medical problems known to affect lipoprotein levels, and to characterize the subjects' activity level and sleep patterns. Subjects were nonsmokers and were not taking any medication or vitamin supplements during the study.

Subjects and diets. Moderately hyperlipidemic male and female subjects ($n = 6$) were recruited (Table 1). Caloric requirements were determined and maintained as described earlier (6). The study consisted of 21-d treatments, each consisting of a 3-d menu. All meals were prepared in the Metabolic Research kitchen and consumed at fixed times. For female subjects, diet treatments were coordinated with their menstrual cycles such that lipogenesis was measured during the luteal phase in order to be comparable to rates measured in

TABLE 1
Subject Description Information

Age (yr)	45.2 ± 4.2
Body weight (kg)	74.5 ± 4.9
Height (cm)	169 ± 3.3
Body mass index	25.9 ± 1.4
Initial total cholesterol (mmol/L)	6.07 ± 0.34

male subjects (7). Diets were formulated using published nutrition composition tables (8) to contain an average of 30.6 ± 1.6% of energy from fat, 55.3 ± 1.8% of energy from carbohydrate and 15.4 ± 0.8 energy from protein. The diets were designed to provide low (2% energy) or high (8% energy) levels of palmitic acid (16:0) and approximately 10% energy as linoleic acid (18:2) (Table 2).

Experimental design. Subjects were randomly given either the low 16:0 or the high 16:0 diet and fed for 21 d. After a washout period, the next diet treatment was fed for 21 d. On day 21 of each treatment, a fasting blood sample (30 mL) was taken as described earlier (6). Subjects then consumed a priming dose of deuterium oxide (6) and a maintenance dose over the next 24 h (6). Exactly 24 h later (day 22), a second fasting blood sample (30 mL) was collected.

Serum was analyzed for lipoprotein cholesterol as described earlier (9). The remaining blood from days 21 and 22 was centrifuged at 3000 rpm for 15 min at 4°C (Jouan refrigerated centrifuge, CR 4.11) to obtain plasma. Day 21 plasma was used to determine background deuterium enrichment. Day 22 plasma was used to measure deuterium enrichment at 24 h (6) and the cholesterol fractional synthesis rate. Each diet treatment was balanced for n-3 fatty acids, cholesterol, and fiber content (6). All other analytical methods were as described earlier.

RESULTS AND DISCUSSION

Subject compliance in consuming all food provided from the metabolic research kitchen was high. Weight changes were minimal throughout the study period.

There were no significant differences between diets in regard to total fat intake. The analyzed 16:0 content of the diet varied little from the formulated values. There were no significant differences between diet treatments in regard to dietary fiber, n-3 fatty acid, and cholesterol content (Table 2). The arachidonic, eicosapentaenoic, and docosahexaenoic acids were negligible in each of the diet treatments (0.016 ± 0.006, 0.002 ± 0.012, and 0.30 ± 0.011% of fatty acids, respectively). The analyzed fat content of meals in each diet treatment was close to the formulated values and was consistent within each diet treatment.

Total cholesterol. During the entire study period, normalized total cholesterol values were between 3.17 and 4.02 mmol/L in normal subjects (Fig. 1). Feeding high 16:0 increased levels of total cholesterol from 3.30 to 3.61 mmol/L ($P < 0.001$) when the diet was low in 18:2n-6. When the diet was high in 18:2n-6, raising the level of 16:0 did not have a significant effect on total plasma cholesterol level in normal or hypercholesterolemic subjects.

Low density lipoprotein (LDL)-cholesterol. Throughout the study period, normalized LDL-cholesterol values ranged from 1.76 to 2.48 mmol/L in normal subjects, within the low range of normal (Fig. 1). Plasma LDL-cholesterol level was higher ($P < 0.0001$) when subjects consumed the higher level of 16:0 (2.18 mmol/L) at the low 18:2n-6 intake level. LDL-cholesterol levels decreased ($P < 0.01$) at the high levels of 18:2n-6 consumption (1.92 mmol/L) as compared to the lower levels of 18:2n-6 (2.12 mmol/L). Similar to the total cholesterol response, when the diet was high in 18:2n-6, raising the level of 16:0 did not have a significant effect on plasma LDL-cholesterol levels in normal or hypercholesterolemic subjects.

High density lipoprotein (HDL)-cholesterol. Throughout the study period, normalized HDL-cholesterol values varied only minimally, ranging from 1.08 to 1.24 mmol/L (Fig. 1) in normal subjects. No significant main effects of diet on HDL-cholesterol levels were observed in hypercholesterolemic subjects. At high levels of 18:2n-6, high 16:0 leads to significant reductions in HDL-cholesterol levels (1.21 vs. 1.08 mmol/L) ($P < 0.003$) in normal subjects.

Cholesterol synthesis. The diet treatments did not alter the fractional synthesis rates for cholesterol (Table 3).

In North America, palmitic acid is the predominant saturated fatty acid in the diet, contributing to approximately 7–8% of the total energy intake. Current dietary recommendations suggest that no more than 30% of the total energy be derived from fat. Of this, at least one-third, or 10% of energy, is suggested to be obtained from 18:2n-6. The diets in this study designated as high in linoleic acid contained 18:2n-6 at levels currently recommended. Clearly, the presence of adequate linoleic acid is of primary importance and cannot be overlooked. The finding that palmitic acid does not exert a cholesterol-raising effect in the presence of adequate linoleic acid has practical applications to the food industry as well as to nutritionists.

TABLE 2
Nutrient Composition of Diets Consumed by Hypercholesterolemic Subjects[a]

	Low 16:0 diet	High 16:0 diet
Energy (MJ)	12.50	12.49
Protein (energy)	16.9 ± 2.3	16.1 ± 2.1
Carbohydrate (% energy)	57.0 ± 3.3	53.5 ± 2.6
Total fat (% energy)	27.6 ± 1.1	31.1 ± 0.5
Saturated fat (% energy)	4.7 ± 0.3	10.2 ± 0.7
MUFA (% energy)	7.5 ± 0.1	8.1 ± 0.3
18:2n-6 (% energy)	12.0 ± 1.4	12.1 ± 0.6
16:0 (% energy)	2.9 ± 0.2	9.9 ± 0.2
n-3 FA (% energy)	0.5 ± 0.1	0.4 ± 0.0
Cholesterol (mg)	176.7 ± 77.5	148.8 ± 22.5
Dietary fiber (g)	32.7 ± 8.5	32.9 ± 5.3

[a]Values represent means ± SD; $n = 3$ for each diet treatment. Diet averages are based on the average calculated from each menu cycle. All values are derived from Food Processor II data, except for 16:0 and 18:2n-6 which are derived from published food composition tables. The detailed nutrient composition of diets consumed by normal subjects has been published (Ref. 6). MUFA, monounsaturated fatty acids; FA, fatty acids.

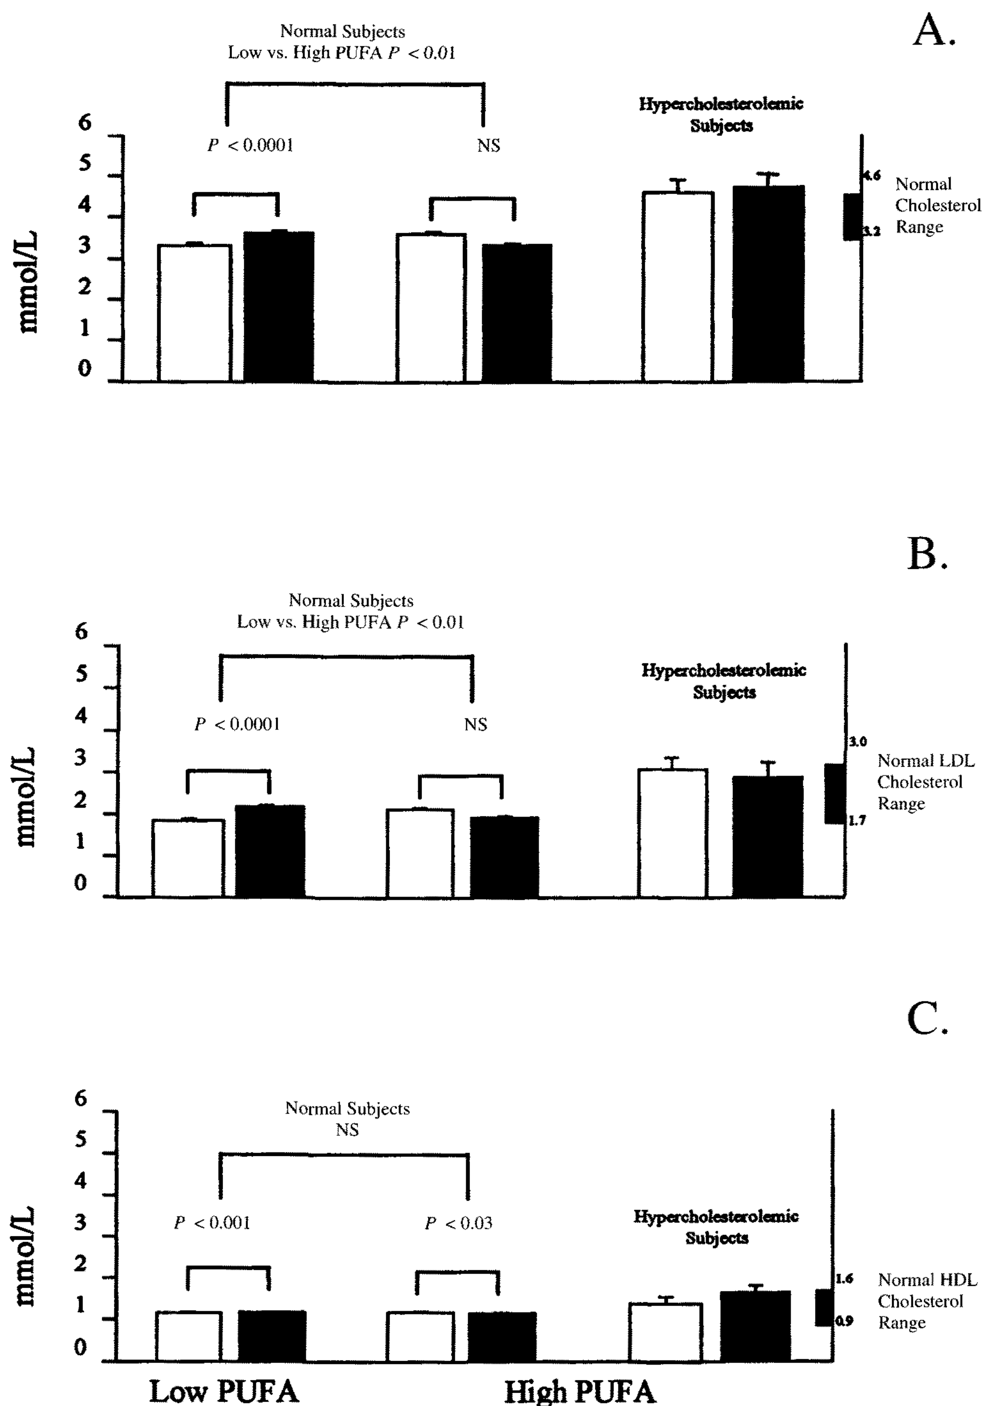

FIG. 1. Plasma lipoprotein cholesterol values. (A) Total cholesterol, (B) low density lipoprotein (LDL)-cholesterol, and (c) high-density lipoprotein (HDL)-cholesterol for subjects. Values represent means ± SEM for all subjects. NS, nonsignificant ($P > 0.05$); PUFA, polyunsaturated fatty acids. □, low 16:0; ■, high 16:0. Significant effects of diet treatments in hypercholesterolemic subjects were not found.

It is concluded that for normolipidemic and mildly hypercholesterolemic subjects who typically consume a relatively low-fat diet (30% energy from fat and containing the recommended intake of n-6 polyunsaturated fat) the consumption of palmitic acid is unlikely to have an appreciable effect on lipoprotein profiles. Furthermore, it can be inferred that an adequate amount of palmitic acid is necessary to promote a more favorable serum cholesterol response. Epidemiological data suggest that as intake of saturated fatty acids is decreased to about 10% of energy, there is a progressive fall in mortality due to cardiovascular disease. Evidence for lowering the level of saturated fat in the diet below this level is lacking, leading one to question the benefit of reductions beyond this point. Palmitoylation of protein is required for the function of receptors and in combination

TABLE 3
Fractional Synthesis Rates for Plasma Cholesterol Synthesis in Subjects Consuming Experimental Diets[a]

Number	Acid	Mean
6	Low 16:0, low 18:2	0.04 ± 0.008
6	Low 16:0, high 18:2	0.03 ± 0.008

with the finding that 16:0 intake may not be cholesterolemic suggests the potential for a suboptimal intake of saturated fat if intake is lower than a level that may be needed for essential processes. This finding may be of particular importance as low and even negligible levels of dietary saturated fat are frequently recommended by health professionals to promote lowered lipid levels. Because palmitic acid is an abundant fatty acid in palm oil, meat and dairy products, and food items also high in nutritive value in other ways, reevaluation of the recommendations to limit consumption of these food items is warranted.

Postprandial Hypertriglyceridemia Induced by Saturated vs. Monounsaturated Fatty Acids Is Related to Reduced Hepatic Lipoprotein Receptors Binding in NZW Rabbits

A. Harbis, C. Juhel, M. Senft, and D. Lairon*

Unit 476-INSERM (National Institute of Health and Medical Research), 13009 Marseille, France

Ingestion of fat is characterized by plasma accumulation of chylomicrons and very low density lipoprotein, which represent the triglyceride-rich lipoprotein (TRL). TRL accumulation depends on endovascular lipolysis by lipoprotein lipase and hepatic lipase and lipoprotein receptor-mediated uptake by the liver. The low density lipoprotein (LDL) receptor (LDL-R) and LDL R-related protein could be the major candidates implicated in this process. More recently, it was suggested that the lipolysis-stimulated receptor (LSR) could also play a role in the TRL uptake. As defect of TRL clearance generates the formation of atherogenic remnants, postprandial hypertriglyceridemia eventually leads in the long term to the development of arteriosclerosis. This study aimed to evaluate if the postprandial triglyceride response induced by saturated fatty acid or monounsaturated fatty acids is related to hepatic LDL-R and LSR activities.

MATERIALS AND METHODS

Rabbits (28 NZW) were fed during 2 or 4 wk, with either a control diet (2.7% vegetable fat) or 10%-fat diet providing either saturated fatty acid (SFA) (coconut oil) or monounsaturated fatty acid (MUFA) (olive oil).

Rabbits had a fat test-meal containing either SFA or MUFA and [^{14}C]triglycerides. Control rabbits ingested the SFA and the MUFA test-meal. Chronically coconut oil-fed rabbits for 2 or 4 wk were given a SFA-rich meal at the end of the dietary experiment. Following the same protocol, olive oil-fed rabbits were given a MUFA-rich meal. Plasma triglyceride and radiolabeled dietary triglyceride concentrations were assayed. Postheparin plasma lipoprotein lipase and hepatic lipase were checked. Lipoprotein binding to low density lipoprotein (LDL) receptor (LDL-R) and lipolysis-stimulated receptor (LSR) in control and fat-fed rabbits was measured. Hepatocyte plasmic membranes were isolated with a sucrose-gradient method. Then, ^{125}I-LDL were incubated with hepatocyte plasmic membrane in two conditions: (i) with $CaCl_2$ (binding to LDL-R calcium-dependent) and (ii) with EDTA (prevent the binding to LDL-R) and oleate (LSR activated by free fatty acids).

RESULTS

As compared to control rabbits, postprandial triglyceridemia as well as plasma dietary [^{14}C]triglyceride accumulation was slightly altered in olive oil-fed rabbits. On the contrary, postprandial plasma triglyceride and [^{14}C]triglyceride concentrations were significantly higher in rabbits fed the coconut oil-rich diet for 4 wk, as compared to control and olive oil-fed rabbits.

Chronic ingestion of the MUFA diet did not alter hepatic lipase activity, while the SFA diet decreased it after 2 wk and increased it after 4 wk. The two experimental diets did not modify lipoprotein lipase activity as compared to the control diet.

Binding of lipoprotein to the LDL-R and to the LSR is expressed as μmol ^{125}I-LDL/mg plasma membrane protein. As compared to control rabbits, the SFA diet decreased lipoprotein binding to LDL-R, while the MUFA diet significantly increased lipoprotein binding to LDL-R. As compared to control rabbits, the MUFA diet increased lipoprotein binding to LSR. On the contrary, the SFA diet decreased LSR binding activity after 2 wk.

CONCLUSIONS

As compared to a low-fat control diet, chronic ingestion of a SFA diet increased postprandial lipemia, did not noticeably modify lipoprotein lipase and hepatic lipase activities, and decreased binding activities to LDL-R as well as LSR. On the contrary, a MUFA-rich diet did not alter postprandial lipemia,

had no effect on lipase activities, but increased binding activities to LDL-R and to LSR measured on hepatocyte plasmic membrane. In both cases, postprandial triglyceridemia and accumulation of triglycerides from dietary origin were inversely correlated to LDL-R and LSR binding activities.

The reduced LDL-R as well as LSR binding activities could explain the postprandial hypertriglyceridemia observed in rabbits chronically ingesting SFA. MUFA could prevent postprandial accumulation of TRL by accelerating their hepatic uptake mediated by LDL-R and LSR.

Effects of Age and Dietary n-3 Fatty Acids on the Metabolism of [^{13}C]-α-Linolenic Acid

S.H.F. Vermunt, R.P. Mensink*, A.M.G. Simonis, and G. Hornstra
Department of Human Biology, Maastricht University, 6200 MD Maastricht, The Netherlands

Conversion of α-linolenic acid into longer-chain polyunsaturates (LCP) may be influenced by physiological and nutritional factors. For instance, desaturation may decrease with aging (1), and conversion of linoleic acid and α-linolenic acid may be inhibited by dietary linoleic acid (2). These findings, however, are mainly based on *in vitro* and rat studies using radioactive isotopes. We have therefore investigated *in vivo* the effects of age and diets rich in α-linolenic acid or eicosapentaenoic acid/docosahexaenoic acid (EPA/DHA) vs. an oleic acid-rich diet on the oxidation of uniformly labeled [^{13}C]-α-linolenic acid and its conversion into LCP in healthy human subjects.

SUBJECTS AND METHODS

Fifteen men and women participated in this study. The elderly volunteers (age > 60 yr) received a diet rich in oleic acid (n = 5), α-linolenic acid [6.8 g/d (n = 2)], or EPA/DHA [1.0 g EPA/d plus 0.6 g DHA/d (n = 3)] for 7 wk. Five younger subjects (age < 35 y) received the α-linolenic acid-rich diet. Fatty acids were provided as margarine from which pies, cakes, and chocolate paste were prepared. After 6 wk, subjects came to the department after a fasting period of 12 h. After a blood sample (t = 0), subjects were given 45 mg of uniformly labeled [^{13}C]-α-linolenic acid as methyl ester (Martek Biosciences Corporation, Columbia, MD) dissolved in 8 g of olive oil. Breath was sampled and CO_2 production was measured each hour for 12 h. Furthermore, blood samples were collected at t = 5, 11, 24, and 96 h. Subjects then returned to their home diets, and 1 wk later a final fasting blood sample was taken at t = 336 h. ^{13}C enrichments in plasma and breath samples were analyzed with a gas chromatograph-combustion-isotope ratio mass spectrometer, while fatty acid composition of plasma total lipids was measured by gas chromatography/flame-ionization detection.

RESULTS

In plasma, ^{13}C enrichments in α-linolenic acid, EPA, docosapentaenoic acid, and DHA were detected. The ^{13}C enrichments of all fatty acids were lower on the n-3-rich diets compared to the oleic acid group. Plasma concentrations of α-linolenic acid were higher in both α-linolenic acid groups than in the oleic acid group. Hardly any ^{13}C enrichment of LCP was observed in the EPA/DHA group, while plasma concentrations of EPA and DHA were highest in this group. After 336 h, plasma ^{13}C enrichments of α-linolenic acid, EPA, and docosapentaenoic acid had almost returned to baseline, while DHA was still enriched.

From the ^{13}C enrichment in breath and CO_2 production, the oxidation of ^{13}C α-linolenic acid was calculated. The mean proportion of labeled α-linolenic acid oxidized after 12 h was about 18%, and was slightly higher in the EPA/DHA group compared to the oleic acid group.

CONCLUSION

We conclude that ^{13}C α-linolenic acid is converted into its LCP. The conversion of α-linolenic acid into its LCP appears to be inhibited on diets rich in EPA/DHA, while it appears not to be influenced by age. In addition, oxidation of α-linolenic acid is not dependent on age or dietary α-linolenic acid, but may be slightly increased on diets rich in EPA/DHA.

Carbon Recycling from Linoleate During Severe Dietary Linoleate Deficiency

K. Belza, M.J. Anderson, M.A. Ryan, and S.C. Cunnane*
Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto M5S 3E2, Canada

A significant portion of the ß-oxidized carbon skeleton of polyunsaturated fatty acids can be recycled into *de novo* lipogenesis (DNL), i.e., cholesterol, saturates, and monounsaturates (1–3). In the present study, we quantitated the DNL pathway in severely linoleate (18:2n-6)-deficient rats to determine whether it is a function of redundancy or is obligatory. If there is minimal recycling during severe linoleate deficiency, it will suggest that recycling from linoleate is mainly a function of linoleate intake in excess of requirement; if not, it will support the obligatory nature of this component of linoleate utilization.

Weanling male Sprague-Dawley rats consumed a semipurified diet containing linoleate at 2 en% (control) or 0.01 en% (deficient). After 13 wk, 7 μCi [1-^{14}C]-linoleate was given by gavage, and the rats were killed 48 h later. Fatty acid profiles and distribution of ^{14}C in liver sterols and individual fatty acids were determined.

In the linoleate-deficient group, fatty acid profiles reflected extreme n-6 polyunsaturated fatty acids depletion (4). In the deficient group, 69% less ^{14}C was recovered as $^{14}CO_2$ than in the control group (11 vs. 36% of the dose, $P < 0.01$; 4). ^{14}C (dpm/g) in total lipids of liver, brain, and perirenal fat of deficient rats was 2–6 times higher than in control rats (all $P < 0.01$). In livers of the linoleate-deficient group, ^{14}C (dpm/g) was 13-fold higher in linoleate, 2.7-fold higher in arachidonate (20:4n-6), and 3.5-fold higher in products of DNL (Fig. 1; all $P < 0.01$). In livers of control rats, ^{14}C distribution was: 41% arachidonate, 29% linoleate, 22% sterols, 3% oleate (18:1n-9), 3% palmitate (16:0), and 2% stearate (18:0). In liver total lipids of the controls, as much ^{14}C (dpm/g) was recovered in products of DNL as in linoleate (Fig. 1; 29–30%). In livers of the linoleate-deficient rats, ^{14}C distribution was: 63% linoleate, 19% arachidonate, 11% sterols, 4% oleate, 2% palmitate, and 1% stearate. Thus, in the deficient rats, the proportion of ^{14}C that was recovered in liver DNL was equivalent to being converted to arachidonate (Fig. 1; 18 vs. 19%).

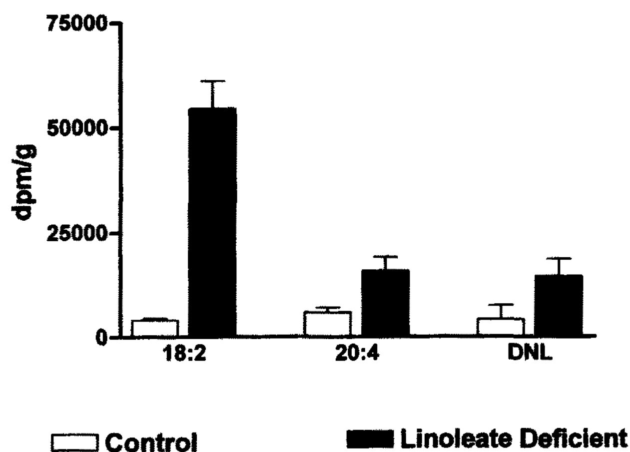

FIG. 1. Recovery of ^{14}C in liver linoleate (LA), arachidonate (AA), and the main products of *de novo* lipogenesis (DNL—cholesterol, palmitate, oleate and stearate combined) 48 h after an oral dose of [1-^{14}C]-linoleate. Values are the mean ± SD of $n = 6$/group; (□), controls; (■), linoleate-deficient; each pair of values is significantly different between the controls and deficient group.

Thus, in linoleate-deficient rats, although less ^{14}C-linoleate was expired as CO_2 (4) and more was retained in the liver pool of n-6 polyunsaturates, more ^{14}C was also recovered in DNL. Hence, linoleate deficiency shifted metabolism of ^{14}C-linoleate toward both greater conservation of n-6 polyunsaturates and toward more carbon recycling but less linoleate ß-oxidation to CO_2. We conclude that in addition to ß-oxidation to CO_2, carbon recycling into DNL accounts for a significant, obligatory component of linoleate metabolism even during severe linoleate deficiency.

A Chronic Ethanol-Feeding Study in Rhesus Monkeys

Robert J. Pawlosky[a,]* and Norman Salem Jr.[b]

[a]U.S. Department of Agriculture, Human Nutrition Research Center, Beltsville, Maryland, and [b]National Institute on Alcoholism and Alcohol Abuse, National Institutes of Health, Rockville, Maryland 20852

ABSTRACT: This study describes the effect of chronic ethanol-feeding in rhesus monkeys. Animals which were maintained on a diet containing 18:2n-6 and 18:3n-3 as 1.4 and 0.08% of the calories, respectively, and consumed alcohol (mean 2.6 g kg^{-1} d^{-1}) had decreased amounts of 20:4n-6 and 22:6n-3 in their livers and plasma lipids compared with controls. Alcohol consumption did not appear to effect the absorption of $^2H_5$-18:2n-6 and 18:3n-3 esters into the blood following an oral dose. There was an increase in $^2H_5$ enrichment in plasma 20:4n-6 and 22:6n-3, indicating that alcohol may have increased production of these fatty acids. There was a greater concentration of 4-hydroxynonenal in the plasma of alcohol-exposed monkeys compared to controls.

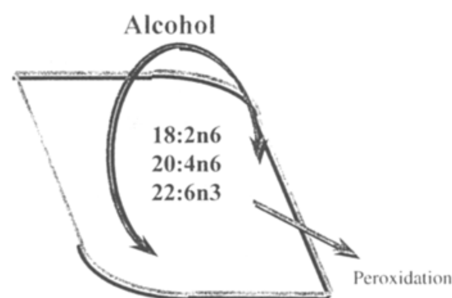

FIG. 1. Alcohol consumption causes decreases in tissue polyunsaturated fatty acids through increased catabolism.

Among its various effects, alcohol consumption alters the fatty acid (FA) composition of membrane phospholipids, causing a decrease in the concentration of tissue polyunsaturated fatty acids (PUFA) (1). The mechanism by which alcohol depletes tissues of PUFA, *in vivo*, is unknown. Evidence from *in vitro* studies suggests that alcohol may decrease Δ-6 and -5 desaturase activity (2). Other evidence suggests that ethanol does not act uniformly across desaturase systems, leaving these findings open to other interpretations. The metabolism of ethanol through P450IIE1 produces hydroxyl radicals which may react with FA-forming oxygenated compounds. The effect of chronic alcohol consumption on lipid peroxidation, the absorption of 18-carbon FA, and the *in vivo* production of 20:4n-6 and 22:6n-3 was studied in monkeys which consumed alcohol over 18 mon (Fig. 1).

METHODS

Ten adult male rhesus monkeys were maintained on a semipurified diet (3) and given access to food twice a day. Six animals were given 24 h access to an artificially-sweetened 7% ethanol solution for 18 mon. Control animals were maintained on the same diet and provided with the same amount of food as the alcohol-exposed animals (540 kcal/d). The fat content (14 en%) of the diet consisted of a 2:1 ratio of olive oil/hydrogenated coconut oil. There were 8.9 g of 18:2n-6 and 0.5 g of 18:3n-3 per 100 g of fat. Pieces of liver (20–30 mg) and plasma (1 mL) were analyzed for their FA content by gas chromatography–flame-ionization detector. The uptake and metabolism of $^2H_5$-18:2n-6 and $^2H_5$-18:3n-3 were determined in both groups by gas chromatography–mass spectrometry (4). Animals were fasted and anesthetized with ketamine-hydrochloride/acepromazine (10:1). A nasogastric tube was inserted into the stomach, and animals were given a bolus dose of 100 mg of $^2H_5$-18:2n-6 and 10 mg $^2H_5$-18:3n-3 ethyl esters. Blood (2 mL) was collected at 0, 4, 24, 130, 168, and 216 h.

RESULTS AND DISCUSSION

In the livers of animals that consumed alcohol, the concentration of nonessential FA was about 15% higher compared to controls. In particular, there were higher concentrations of 18:1n-9 (66%) and 20:3n-9 (45%) and lower concentrations of several PUFA which included 18:2n-6 (–20%), 20:4n-6 (–14%), and 22:5n-3 (–36%). There was a lower (–56%) concentration of liver 22:6n-3. In the plasma there were higher percentages of 16:1n-9 (82%), 18:1n-9 (14%), 18:1n-7 (62%), 20:3n-9 (100%), and 24:1n-9 (40%) in monkeys consuming alcohol compared with controls. There were lower percentages of 18:2n-6, 20:4n-6, 18:3n-3, and 22:6n-3 in the plasma in the alcohol group compared to the controls. The total integrated amounts of the plasma concentrations of $^2H_5$-18:2n-6 and $^2H_5$-18:3n-3 were similar in both groups over the 9 d. The total concentrations calculated as area under the curve for $^2H_5$-20:4n-6, $^2H_5$-20:5n-3, and $^2H_5$-22:6n-3 were not found to be significantly different between the two groups. However, the enrichment of deuterium into plasma 20:4n-6 and 22:6n-3 was greater in monkeys consuming alcohol compared to controls. Alcohol consumption caused a

Lipids 34, S131–S132 (1999).

Abbreviations: FA, fatty acid; PUFA, polyunsaturated fatty acid.

Copyright © 1999 by AOCS Press

marked increase in the concentration of 4-hydroxynonenal in the plasma. There was a significant ($P < 0.02$) increase in 4-hydroxynonenal in the plasma of monkeys consuming alcohol (mean 1440 ± 441 pg/mL) compared to controls (68 ± 23 pg/mL). Alcohol exposure did not appear to decrease the absorption of the 18-carbon essential FA from the diet into the blood. The hypothesis that alcohol inhibits desaturases, and therefore, the *in vivo* formation of long-chain PUFA predicts that a lower concentration of $^2H_5$-20:4n-6 and 22:6n-3 should follow from oral doses of the labeled 18-carbon precursors. Finding of similar total accumulations of labeled long-chain PUFA in the plasma suggests that ethanol metabolism may not be directly linked to an inhibition of desaturase activities. However, evidence from this study does suggest that alcohol exposure had a significant impact on lipid peroxidation and suggests that alcohol may lower tissue levels of long chain essential FA primarily through increases in catabolism and not by decreases in anabolic processes.

The Metabolism of Essential Fatty Acids in Rat Liver Is Influenced More by Dietary Fat Than Dietary Ethanol

Kjetil Retterstøl*, Anne-Marie Lund, Siri Tverdal, and Bjørn O. Christophersen
Institute of Clinical Biochemistry, University of Oslo, Rikshospitalet, N-0027 Oslo, Norway

Ethanol ingestion has been shown to influence fatty acid composition and metabolism of cellular and subcellular membranes in various mammalian tissues (1,2). A rather consistent finding is a decrease in 20:4n-6 in rat liver after ethanol exposure, but the specific mechanism of the altered lipid composition still remains unresolved. Shorter essential fatty acids are elongated and desaturated to longer and more unsaturated fatty acids. Ethanol may influence these pathways at several levels.

MATERIALS AND METHODS

We used the Lieber DeCarli Liquid Rat diet with ethanol and the corresponding control diet. Ethanol and water were added to the diet according to the manufacturer giving an energy percentage (E%) of 36% from ethanol. This diet had a high triglyceride content, but the n-6/n-3 ratio of 132 may be capable of inducing a selective n-3 deficiency. The low-fat diet was a standard rat and mouse chow diet with an n-6/n-3 ratio of 13, and ethanol was mixed into this diet giving an E% of ethanol of 50%. The rats fed ethanol had a slower weight gain than the controls. From week 3 to week 4 after ethanol exposure (7 d), the rats fed the high-fat diet increased from 161 ± 5 g to 178 ± 6 g (mean ± SD). The control rats increased from 197 ± 4 to 251± 6 g at the same time. Parenchymal liver cells were prepared according to the method of Seglen (3). Lipids were extracted by the method of Folch *et al.* (4). Separation in lipid classes and phospholipid classes was performed by thin-layer chromatography. Separation of fatty acid was performed by reverse-phase high-performance liquid chromatography and radio gas chromatography. Separation in phospholipid molecular species was performed by reverse-phase high-performance liquid chromatography.

RESULTS

In the low-fat diet group, 32.7% of the [1-^{14}C]20:5n-3 was elongated to [3-^{14}C]22:5n-3, decreasing to 6.0% after ethanol feeding (P = 0.002) and to 16.7% after incubating control hepatocytes with ethanol *in vitro* (P = 0.048). The high-fat diet itself decreased the elongation of [1-^{14}C]20:5n-3 to 17.0%. The elongation of 20:4n-6 was 6% when fed the high-fat diet and 8% when fed the low-fat diet (not significantly different) and not affected by ethanol.

Ethanol feeding decreased the esterification of [1-^{14}C]22:6n-3 in phospholipids. After 90 min of incubation, esterification decreased from 4.6 ± 0.2 (mean ± SD) to 3.3 ± 0.1 nmoles (P = 0.001) and after 200 min incubation, from 4.9 ± 0.6 to 2.3 ± 0.1 nmoles (P = 0.001) in rats fed the low-fat diet.

Using [1-^{14}C]22:6n-3, ethanol feeding increased the ratio of esterification in phosphatidylethanolamine (PE) and phosphatidylcholine (PC). However, using [1-^{14}C]20:5n-3, the high-fat diet itself increased the PE/PC ratio compared to the low-fat diet.

Ethanol feeding decreased the relative amount of molecular species containing 18:0 compared to species containing 16:0 in PC of rats fed the low-fat diet. The 18:0/16:0 ratio was lowered by ethanol from 0.94 to 0.62 using [1-^{14}C]20:4n-6 and from 0.75 to 0.40 using [1-^{14}C]20:5n-3 after 200 min of incubation. Ethanol led to formation of species in which the labeled substrates were paired with 18:1n-9 in rats fed the low-fat diet, a species not formed in detectable amounts in these rats without ethanol in the diet.

DISCUSSION

Ethanol feeding inhibited the elongation of 20:5n-3 to 22:5n-3 in animals fed a low-fat diet. To our knowledge this observation has never been published. If this elongation was a rate-limiting step in the synthesis of 22:6n-3 in the liver, one would expect to find a decreased amount of endogenous 22:6n-3 after ethanol feeding, which we did not find. The high-fat diet itself also inhibited the elongation of 20:5n-3 compared to the low-fat diet.

A recent study concluded that the synthesis of PC was reduced by chronic ethanol treatment and that synthesis of PE and phosphatidylserine was increased (5). In agreement with this, the ratio of esterification in PE compared to PC increased when using [1-^{14}C]22:6n-3 as substrate in present study. However, the PE/PC ratio was not altered by ethanol using [1-^{14}C]20:4n-6 and [1-^{14}C]20:5n-3 as substrates. These find-

ings seem interesting since in guinea pigs with fetal ethanol syndrome a reduced amount of both PE and of 22:6n-3 in liver and brain was observed (6).

In conclusion, we demonstrated that ethanol exerts selective and different effects on the metabolism of 20:4n-6, 20:5n-3, and 22:6n-3 provoked by a low-fat diet.

Effects of n-3 and n-6 Polyunsaturated Fatty Acids on 3-Hydroxy-3-methylglutaryl-CoA Reductase in Liver and Mammary Glands of Low Density Lipoprotein-Receptor Knockout Mice

Ahmed El-Sohemy and Michael C. Archer

Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Canada

Marine fish oils provide one of the richest sources of long chain n-3 polyunsaturated fatty acids (PUFA) in the diet. Consumption of these fatty acids is associated with a reduced risk of developing breast cancer as well as cardiovascular disease. The inhibitory effects of n-3 PUFA on breast cancer development were supported by animal studies and cell culture experiments, but the molecular mechanisms are still unclear. We recently showed that 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase is down-regulated in the mammary glands of rats fed n-3 PUFA and proposed this as a possible mechanism by which tumorigenesis is inhibited (1). HMG-CoA reductase is the rate-limiting enzyme in cholesterol biosynthesis that catalyzes the formation of mevalonate which is required for cell-cycle progression and was implicated in cancer development. Competitive inhibitors of HMG-CoA reductase (e.g., lovastatin and simvastatin) inhibit rat and mouse mammary tumorigenesis *in vivo* and the proliferation of human breast cancer cells *in vitro*. The mevalonate-derived metabolite that is required for cell-cycle progression has not yet been identified, but is known not to be cholesterol.

Cellular uptake of cholesterol-rich lipoproteins such as low density lipoprotein (LDL) is mediated through the LDL receptor (LDL-R) as well as a receptor-independent pathway. When uptake is enhanced, intra cellular cholesterol levels rise, and HMG-CoA reductase is down-regulated to prevent excessive accumulation of cholesterol. As a result, the synthesis of mevalonate that is required for cell proliferation is reduced.

In this study, we used mice with a targeted disruption of the LDL-R gene to determine whether the LDL-R mediates the down-regulation of HMG-CoA reductase by n-3 PUFA. Female mice lacking the LDL-R (–/–) and wild-type (+/+) mice were fed a 7% (wt/wt) fat diet rich in either n-3 (menhaden oil) or n-6 (safflower oil) PUFA for 1 wk. The effects of dietary n-3 PUFA were compared to those of n-6 PUFA. Total serum cholesterol was reduced by n-3 PUFA to the same extent in +/+ (43%) as in –/– (41%) mice. Serum triglyceride levels were reduced by 34% in the +/+ group and by 50% in the –/– group. n-3 PUFA also reduced serum LDL-cholesterol, but to a greater extent in the +/+ (6-fold) than in –/– mice (2-fold). HDL-cholesterol levels were reduced in +/+ mice but not in –/– mice. The specific activity of HMG-CoA reductase was measured using a radiochemical assay and expressed as pmol/mg/min. In +/+ mice, the specific activity of HMG-CoA reductase was lower in the livers (109 ± 25 vs. 336 ± 80) and mammary glands (36 ± 10 vs. 20 ± 9) of mice fed n-3 PUFA compared to those fed n-6 PUFA. In –/– mice, HMG-CoA reductase was also lower in the livers (65 ± 38 vs. 123 ± 27) of those fed n-3 PUFA, but was surprisingly greater in the mammary glands (19 ± 6 vs. 10 ± 2).

When the data were analyzed by two-way analysis of variance, there was a significant diet-genotype interaction. This indicates that not only were the effects of diet on measures of lipid metabolism dependent on LDL-R genotype, but the effects of LDL-R status were dependent on the PUFA in the diet. For example, when mice were fed n-3 PUFA, serum LDL-cholesterol was 27-fold higher in –/– than in +/+ animals, but only 10-fold greater in those fed n-6 PUFA. HDL-cholesterol levels were lower in –/– than in +/+ mice only when n-6 PUFA were fed and did not differ when n-3 PUFA were the major source of fat. With either diet, hepatic HMG-CoA reductase was lower in –/– than in +/+ mice, but the magnitude of this effect was greater in animals fed n-6 PUFA (>3-fold) than in those fed n-3 PUFA (<2-fold). +/+ Mice fed n-6 PUFA had considerably higher levels of HMG-CoA reductase in the mammary gland than –/– mice, but no differences were observed among those fed n-3 PUFA.

These results show that the LDL-R is required for n-3 PUFA to down-regulated mammary gland HMG-CoA reductase, but is not required for the reduction in serum lipids or the down-regulation of hepatic HMG-CoA reductase. The diet-genotype interactions we observed suggest that the composition of dietary fat should be considered in future studies on cholesterol metabolism using knockout or transgenic mice.

Dietary Fatty Acids and the Immune System

P.C. Calder*

Institute of Human Nutrition, University of Southampton, Bassett Crescent East, Southampton SO16 7PX, United Kingdom

An effect of dietary fatty acids upon the immune system was suggested by early epidemiological studies of the incidence of multiple sclerosis and by the observations that the blood, cells, and tissues of patients with multiple sclerosis are deficient in long-chain polyunsaturated fatty acids (PUFA) (1). This suggestion was supported by observations that linoleic (18:2n-6) and arachidonic (20:4n-6) acids inhibit mitogen-stimulated proliferation of human peripheral blood lymphocytes in culture (see Ref. 2) and that subcutaneous injections of these fatty acids prolong the survival of skin allografts in mice (3). These studies focused on the n-6 family of PUFA, but more recently there has been intense interest in the effects of the n-3 PUFA. An immunomodulatory effect of these latter fatty acids is suggested by epidemiological studies which show that populations such as Greenland Eskimos, who consume large quantities of marine mammal and fish oils which are rich in eicosapentaenoic (20:5n-3) and docosahexaenoic (22:6n-3) acids, have a very low incidence of inflammatory and autoimmune disorders (4). Furthermore, a number of clinical studies reported that fish oil supplementation has some beneficial effects in rheumatoid arthritis, psoriasis, lupus, and inflammatory bowel disease and prolongs the survival of grafts (see Refs. 5,6). The potential clinical use of oils rich in n-6 or n-3 PUFA has given rise to a number of investigations of the effects of fatty acids and dietary oils upon immune cell functions (see Ref. 7).

Dietary fatty acids and immunity: An overview. A number of studies showed that feeding rats, mice, rabbits, or chickens diets rich in fish oil results in suppressed *ex vivo* lymphocyte proliferation (8–13), interleukin-2 (IL-2) production (14), natural killer (NK) cell activity (12,15–17), cytokine [(IL-1, IL-6, tumor necrosis factor (TNF)] production by inflammatory macrophages (18–20), and macrophage-mediated cytotoxicity (20–22). Recent studies indicate that relatively low levels of n-3 PUFA are required to bring about some of these suppressive effects (23,24), that dietary eicosapentaenoic and docosahexaenoic acids both inhibit lymphocyte proliferation (14,23), and that dietary eicosapentaenoic acid but not docosahexaenoic acid inhibits NK cell activity (23). Feeding laboratory animals diets containing high levels of linseed oil [rich in α-linolenic acid (18:3n-3)] also brings about suppressive effects (10,16,25,26). A recent study indicates that the precise effect of α-linolenic acid on lymphocyte functions depends on the level of linoleic acid and the total PUFA content of the diet (27). Investigations which have directly compared the effects of n-3 PUFA-rich oils indicate that fish oil is more suppressive than linseed oil. Diets rich in n-6 PUFA are less suppressive than those containing n-3 PUFA or, in some studies, without effect (see Ref. 7). Other fatty acids also appear to influence lymphocyte functions, with the levels of palmitic and oleic acids appearing to modulate the effect of linoleic acid (28,29).

Supplementation of the diet of healthy human volunteers with fish oil-derived n-3 PUFA (1.2 to 14 g/d) results in decreased lymphocyte proliferation (30–32), monocyte and neutrophil chemotaxis (33–36), and production of IL-1, IL-2, IL-6, and TNF (30–33,37). A high dose of α-linolenic acid (approx. 15 g/d) was reported to suppress human IL-1 and TNF production (37). The inverse relationship between the eicosapentaenoic acid content of mononuclear cell lipids and production of TNF and IL-1 was recently described (37).

n-PUFA decrease the expression of some adhesion molecules on the surface of cultured endothelial cells, monocytes, and lymphocytes (38–40). Addition of fish oil-derived n-3 PUFA to the diet of laboratory animals or healthy humans also appears to modulate adhesion molecule expression on the surface of monocytes and lymphocytes (12,41–43) and alters the ability of such cells to bind to ligand-bearing cells (43).

The *ex vivo* observations described above indicate that consumption of diets containing n-3 PUFA, particularly diets rich in fish oil, should result in protection against the damaging effects of inflammatory challenges, which are mediated in part by overproduction of the proinflammatory cytokines TNF, IL-1, and IL-6 (44). This would be a clinically beneficial effect of n-3 PUFA. Certainly rats or guinea pigs given large amounts of fish oil either intravenously or through the diet show markedly enhanced survival following the administration of a high dose of bacterial endotoxin (45,46) and a reduction in the anorexia which accompanies administration of IL-1 or TNF (47,48).

Fish oil feeding also ameliorates the symptoms of some animal models of autoimmune disease such as lupus-prone mice (e.g., 49), so increasing the lifespan of such animals

(50). These changes are associated with abolition of proinflammatory cytokine production and the induction of antiinflammatory cytokines and antioxidant enzymes (51).

Mechanisms of action. Several possible mechanisms by which n-3 PUFA influence immune cell function have been suggested (see 5,52,53). These mechanisms include modulation of eicosanoid synthesis, alteration of intracellular signaling pathways, regulation of transcription factor activity, and altered antioxidant status. These are not necessarily exclusive, and different effects of n-3 PUFA might be exerted through different mechanisms.

Some eicosanoids, such as prostaglandin E_2, are important regulators of the development and functions of T and B lymphocytes, NK cells, monocytes, and macrophages and modulate the synthesis of inflammatory and immunoregulatory cytokines (54). Other eicosanoids, such as leukotriene B_4, are potent chemoattractants and also have a role in the regulation of inflammation and cytokine synthesis. High levels of prostaglandin E_2 are present during acute and chronic inflammation and during infections, and the 4-series leukotrienes have been implicated as playing a role in a number of inflammatory diseases (55,56). Under normal conditions most eicosanoids are derived from arachidonic acid (20:4n-6). However, when high levels of n-3 PUFA are consumed in the diet, less arachidonic acid-derived eicosanoids are produced (55,57). Instead, eicosanoids are formed from eicosapentaenoic acid. This may be functionally significant, since the eicosanoids produced from eicosapentaenoic acid are usually less biologically potent than those formed from arachidonic acid (55,57). Thus, an n-3 PUFA-induced change in the amounts and types of different eicosanoids produced will have a significant influence on the functioning of immune and inflammatory cells and might partially account for the antiinflammatory and immunomodulatory actions of fish oils.

Although some of the effects of n-3 PUFA may be brought about by modulation of the amount and types of eicosanoids made, these fatty acids might elicit some of their effects by eicosanoid-independent mechanisms, including actions upon intracellular signaling pathways and transcription factor activity (see Refs. 59,60 for reviews). Recent studies showed that n-3 PUFA reduce agonist-stimulated diacylglycerol and ceramide production (14), phospholipase Cγ1 activation and subsequent inositol-1,4,5-trisphosphate production (58) and phosphatidic acid generation (59) in lymphocytes. Thus, n-3 PUFA appear to influence the generation of a range of lipid-derived second messengers in lymphocytes, and perhaps other immune and inflammatory cell types. This might account for the widespread effects of these fatty acids on the functioning of these cells.

Dietary Fat Influences the Production of Th1- but Not Th2-Derived Cytokines

F.A. Wallace, P. Yaqoob, E.A. Miles, and P.C. Calder*

Institute of Human Nutrition, University of Southampton, Southampton SO16 7PX, United Kingdom

Diets enriched in long-chain n-3 polyunsaturated fatty acids decreased the production of interleukin-2 (IL-2) by murine and human lymphocytes (1,2). IL-2 and interferon-γ (IFN-γ) are produced by the Th1 class of lymphocytes involved in cell-mediated immunity, macrophage and natural killer cell activation, transplant rejection, and inflammation. There is little information about the effects of dietary fatty acids on the production of IFN-γ or on the production of cytokines such as IL-4 which are produced by the Th2 class of lymphocytes involved in antibody-dependent responses and allergic reactions. Therefore, in the current study the effect of feeding mice diets enriched in different types of fatty acids upon IL-2, IFN-γ, and IL-4 production by spleen lymphocytes was investigated.

Male C57Bl/6 mice (n = 6 per diet) were fed for 6 wk on diets containing 200 g/kg of either coconut oil (CO), olive oil (OO), safflower oil (SO), or fish oil (FO). Spleen lymphocytes were prepared by standard procedures (3) and 2×10^6 cells were cultured for 24 h in the presence of 2.5 μg/mL concanavalin A, a T-cell mitogen; the final culture volume was 2 mL and the cultures contained 5% (vol/vol) fetal calf serum. The concentrations of the cytokines IL-2, IFN-γ, and IL-4 in the culture medium were measured by commercially available ELISA kits (Biosource International, Camarillo, CA). Lymphocyte proliferation was assessed as concanavalin A-stimulated [^{3}H]thymidine incorporation over the final 18 h of a 66-h culture period (3).

Each of the diets rich in unsaturated fatty acids (OO, SO, FO) decreased lymphocyte proliferation (i.e., thymidine incorporation) and IL-2 production compared with feeding the CO diet (Table 1). IFN-γ production was reduced by SO or FO feeding compared with feeding the CO- or OO-rich diets (Table 1). IL-4 production was not significantly affected by the type of fat in the diet, although production was lowest by cells from FO-fed mice (Table 1).

The effects of the unsaturated fatty acid-rich diets on spleen lymphocyte proliferation are in agreement with those published previously in a variety of species (3). Furthermore the reduced IL-2 production by spleen lymphocytes from FO-fed mice, at least compared with CO-fed mice, agrees with previous studies (1,2). However, this study shows that SO and FO feeding also decrease IFN-γ production. It is concluded that, compared with saturated fatty acids, polyunsaturated fatty acids decrease Th1 lymphocyte responses and that dietary fatty acids do not markedly influence Th2 lymphocyte responses. Since the Th1 response is involved in transplant rejection, autoimmunity, and inflammation, these observations might at least partly account for the beneficial effects of FO observed in these situations (see 1).

TABLE 1
Effect of Dietary Fats on Murine Spleen Lymphocyte Proliferation and Cytokine Production

Diet	Thymidine incorporation (cpm/well)	IL-2 (pg/mL)	IFN-γ (pg/mL)	IL-4 (pg/mL)
CO	34632 ± 651[a]	231 ± 44[a]	9.1 ± 1.0[a]	57 ± 10
OO	12484 ± 983[b]	127 ± 9[b]	8.5 ± 0.9[a]	70 ± 8
SO	16438 ± 6795[b]	106 ± 8[b]	3.1 ± 1.3[b]	67 ± 12
FO	10402 ± 1499[b]	137 ± 19[b]	1.3 ± 1.0[b]	48 ± 13

[a]Data are mean ± SEM for six animals fed on each diet. Values in a column indicated by different superscript letters are significantly different from one another ($P < 0.05$; one-way analysis of variance). CO, coconut oil; OO, olive oil; SO, safflower oil; FO, fish oil; IL-2, interleukin-2; IFN-γ, interferon-γ; IL-4, interleukin 4.

Very Low Dietary Intake of n-3 Fatty Acids Affects the Immune Function of Healthy Elderly People

S. Bechoua, M. Dubois, G. Némoz, P. Chapuy, E. Véricel, M. Lagarde, and A.F. Prigent*

INSERM U 352, Biochimie et Pharmacologie, INSA-Lyon, Villeurbanne, France

The aging process, characterized by decreased antioxidant defenses, is usually accompanied by a moderate decline of immune functions. The n-3 polyunsaturated fatty acids (PUFA), abundant in fish oil, are associated with diverse human health benefits and offer some protection against cardiovascular, inflammatory, and autoimmune diseases. The efficacy of dietary n-3 PUFA in disorders involving overreactive immune responses is very likely to be due to their immunomodulatory effects (1,2). The n-3 PUFA are immunomodulatory both *in vitro*, when added to lymphocyte culture medium, and *in vivo*, after oral administration to animals and humans. In humans, most supplementation studies showing an immunomodulatory effect of n-3 PUFA used high fatty acid dosages, usually more than 2 g fatty acids per day. In these conditions of high supply, n-3 PUFA might have increased the cell susceptibility to lipid peroxidation, as both docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), the main components of fish oil, are highly prone to peroxidation. Paradoxically, very low doses of n-3 PUFA were shown to protect cells, mainly platelets, from peroxidative stress and to exhibit some antioxidant properties (3,4). Thus, we sought to investigate the influence of a very low daily dose of n-3 PUFA on immune function in human healthy elderly people.

Healthy elderly subjects and experimental design. Twenty healthy elderly subjects (over 70 yr) were randomly assigned to a placebo group (600 mg/d sunflower oil, vitamin E 0.6 mg/g oil) or to a group consuming 600 mg/d RO-PUFA (Roche) (150 mg DHA + 30 mg EPA, Vitamin E 2 mg/g oil) for 6 wk. At the beginning of the study, all subjects had normal blood cell counts, normal cholesterolemia and triglycerides, and normal systolic and diastolic blood pressure. Blood samples were drawn by venipuncture before (on day 0) and after supplementation with either placebo or RO-PUFA (on day 42). Plasma was recovered after platelet sedimentation, and peripheral blood mononuclear cells were isolated by gradient density centrifugation. Several biochemical and immune parameters were assayed.

Abbreviations: ConA, concanavalin A; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; OKT3, antioD3m Ab; PHA, phytohemagglutinin; PUFA, polyunsaturated fatty acid.

RESULTS AND DISCUSSION

Although no drastic modification in the fatty acid composition of plasma lipids was observed after supplementation with either the placebo or RO-PUFA, the proliferative responses of lymphocytes to several mitogens were significantly decreased in the RO-PUFA group as compared with controls (ConA: –45%, PHA: –31%, OKT3: –32%). The decreased proliferative response was accompanied by a slight lowering of their cytosolic cyclic nucleotide phosphodiesterase activity, a marked and significant increase of their particulate phosphodiesterase activity (+50%) and a slight but significant increase of cyclic nucleotide intracellular levels. In the same time, the glutathione peroxidase activity of mononuclear cells was markedly and significantly depressed in the RO-PUFA group. None of these modifications could be seen in the placebo group.

On the whole, these results demonstrate that even very low doses of n-3 fatty acids are sufficient to affect the immune responses of elderly subjects. The decreased lymphoproliferative responses observed after supplementation with RO-PUFA might be due to the modest but significant increase of cyclic nucleotide levels in mononuclear cells, cAMP being a well-recognized negative effector of the proliferative response.

On the other hand, we observed a marked decrease in the glutathione peroxidase activity of mononuclear cells, which may be interpreted as a marker of a lower peroxidative stress, as it was found, in the same study, in platelets of elderly people supplemented with RO-PUFA.

The Effect of Dietary Fat on Cytokine Production by Murine Macrophages in Different Activation States

F.A. Wallace, E.A. Miles, and P.C. Calder*

Institute of Human Nutrition, University of Southampton, Southampton SO16 7PX, United Kingdom

Some studies report that diets rich in n-3 polyunsaturated fatty acids such as fish oil (FO) decrease pro-inflammatory cytokine production by macrophages (MØ), whereas other studies report that such diets increase production of these cytokines (1). It has been hypothesized that the use of MØ in different activation states may explain some of the contradictions in the literature (1). Thus, in this study we compared the effects of different high-fat diets on the production of pro- and anti-inflammatory cytokines by lipopolysaccharide (LPS)-stimulated resident and thioglycolate-elicited peritoneal MØ.

Male C57Bl/6 mice were fed for 8 wk on a low-fat (LF) diet (25 g/kg corn oil) or on diets containing 200 g/kg of either coconut oil (CO), safflower oil (SO), or FO. Resident MØ were collected by lavaging the peritoneal cavity with phosphate-buffered saline and were purified by adherence to tissue culture plates. Inflammatory MØ were elicited with an intraperitoneal injection of thioglycolate broth and collected from the peritoneal cavity by lavage 4 d postinjection. Purified MØ (1×10^6 cells) were cultured for 24 h in the presence of 10 μg/mL bacterial LPS; the total culture volume was 2 mL and the cultures contained 5% (vol/vol) fetal calf serum. The concentrations of the cytokines tumor necrosis factor-α (TNF-α), interleukin (IL)-1β, IL-6, and IL-10 in the culture medium were measured by commercially available ELISA kits (Biosource International, Camarillo, CA).

Inflammatory MØ from LF-fed mice produced higher concentrations of all cytokines measured than did resident MØ (Tables 1 and 2). Inflammatory MØ from FO-fed mice showed significantly decreased production of TNF-α and IL-1β compared to those from mice fed the other diets (Table 1). Resident MØ from mice fed FO had increased TNF-α production compared to those from CO-fed mice (Table 2). IL-6 production was higher from resident MØ from SO-fed mice than from those fed the LF or FO diets (Table 2). IL-10 production by both types of MØ was lowest following CO feeding (Tables 1 and 2). Diets rich in polyunsaturated fatty acids (SO, FO) significantly increased IL-10 production by resident MØ (Table 2).

TABLE 1
Effect of Dietary Fats on Cytokine Production by LPS-Stimulated Inflammatory MØ[a]

	Cytokine concentration (ng/mL)			
Diet	TNF-α	IL-1β	IL-6	IL-10
LF	3.1 ± 0.6^a	0.15 ± 0.03^a	14.9 ± 2.2	0.13 ± 0.02^a
CO	2.0 ± 0.3^a	0.13 ± 0.01^a	19.9 ± 1.5	0.08 ± 0.01^b
SO	0.7 ± 0.1^b	0.11 ± 0.02^a	16.8 ± 1.7	0.11 ± 0.01^a
FO	0.12 ± 0.02^c	0.06 ± 0.01^b	14.9 ± 1.7	0.11 ± 0.02^a

[a]Data are mean ± SEM for six mice fed on each diet. Values in a column indicated by different superscript letters are significantly different ($P < 0.05$; one-way analysis of variance). LF, low fat; CO, corn oil; SO, safflower oil; FO, fish oil; LPS, lipopolysaccharide; TNF, tumor necrosis factor-α; IL, interleukin; MØ, macrophages.

TABLE 2
Effect of Dietary Fats on Cytokine Production by LPS-Stimulated Resident MØ[a]

	Cytokine concentration (ng/mL)			
Diet	TNF-α	IL-1β	IL-6	IL-10
LF	$0.25 \pm 0.03^{a,b}$	0.05 ± 0.01	8.0 ± 1.6^b	0.09 ± 0.01^b
CO	0.14 ± 0.06^b	0.04 ± 0.01	$11.6 \pm 1.8^{a,b}$	0.07 ± 0.04^b
SO	$0.30 \pm 0.06^{a,b}$	0.03 ± 0.01	16.1 ± 3.1^a	0.19 ± 0.03^a
FO	0.35 ± 0.03^a	0.04 ± 0.01	9.9 ± 1.9^b	0.18 ± 0.03^a

[a]Data are mean ± SEM for six mice fed on each diet. Values in a column indicated by different superscript letters are significantly different ($P < 0.05$; one-way analysis of variance). See Table 1 for abbreviations.

It is concluded that dietary fat influences cytokine production by MØ but that the precise effects of dietary fat differ according to the activation state of the MØ studied. This may explain some of the contradictions in the literature (1). The significant reduction in pro-inflammatory cytokine (i.e., TNF-α, IL-1β) production by inflammatory MØ from FO-fed mice might at least partly account for the beneficial effects of FO observed in acute and chronic inflammatory conditions (1,2).

Phospholipid Modulation of Monocyte Oxidative Activity Measured by Luminol-Enhanced Chemiluminescence

A. Tonks[a], K.P. Jones[a], and S.K. Jackson[b,*]

[a]School of Biomedical Sciences, University of Wales, Institute Cardiff, and [b]Department of Medical Microbiology, University of Wales College of Medicine, Cardiff, Wales

The lung is susceptible to inflammatory and oxidative injury leading to tissue damage and decreased function. Infiltrating neutrophils and monocytes and resident macrophages are a likely source of the damaging molecules. It is hypothesized that pulmonary surfactant rich in phospholipid may modulate the cytotoxic and inflammatory function of alveolar macrophages. Changes in membrane lipid composition may alter the immunological responses of monocytes to infection, including endotoxin (lipopolysaccharide, LPS). The present study was undertaken to determine the role of phospholipids in the modulation of monocyte respiratory burst activity.

Materials and methods. Human monocyte-derived cell line (MonoMac 6) was from the German Cell and Tissue Culture Collection, Braunsweig, Germany. Phospholipid species luminol and LPS were from Sigma Chemical Co. (Poole, United Kingdom). Phospholipids (10–500 μg/mL) were dissolved in RPMI 1640 medium and added to 1×10^6/mL MonoMac 6 cells with or without 100 ng/mL LPS for 12 h at 37°C. The cells were then washed three times, and the respiratory burst was triggered by the addition of zymosan in the presence of luminol. The production of reactive oxygen species was measured by chemiluminescence using an automated luminometer. Cells not preincubated with LPS to prime them produced little superoxide and acted as controls.

Results. The phospholipid species investigated all had effects on the priming of monocytes for superoxide production in the respiratory burst. At the concentrations used (10–500 mg/mL), they had no direct effect on the triggering of the respiratory burst with zymosan or phorbol 12,myristate 13,acetate. Therefore the phospholipids altered the monocyte responses to LPS, resulting in a primed state for enhanced superoxide generation.

Mixed lipid species of phosphatidylcholine inhibited the LPS-induced priming of the monocyte respiratory burst in a dose-dependent manner from 100–500 μg/mL. However, dipalmitoylphosphatidylcholine, the major phospholipid species in pulmonary surfactant, was stimulatory at 100–500 μg/mL but was inhibitory at concentrations below this. Mixed species of phosphatidylethanolamine had a suppressive effect on the respiratory burst in a dose-dependent manner up to 100 μg/mL, whereas at high concentrations (250–500 μg/mL) sphingomyelin had a stimulatory effect. The effects of other molecular species of the phospholipids are currently being investigated.

Conclusions. This study shows that phospholipids can modulate the respiratory burst in monocytes and that this is at the level of monocyte priming. The effect of the phospholipids was dependent both on the lipid acyl composition and on the polar headgroup composition. These results suggest that phospholipid species may regulate monocyte and macrophage oxidative responses *in vivo*, and alterations in cellular phospholipid content and composition may affect the host responses to infection. Manipulation of the extracellular lipid content may be a novel strategy in the treatment of inflammatory lung diseases.

Novel, Selective Δ6 or Δ5 Fatty Acid Desaturase Inhibitors as Antiinflammatory Agents in Mice

M. Obukowicz*, D. Welsch, W. Salsgiver, C. Martin-Berger, K. Chinn, K. Duffin, A. Raz, and P. Needleman

G.D. Searle, Discovery Pharmacology, St. Louis, Missouri 63198

Aim. The antiinflammatory properties of essential fatty acid deficiency or n-3 polyunsaturated fatty acid supplementation have been attributed to a reduced content of arachidonic acid (AA). A novel antiinflammatory approach would be to deplete AA by decreasing its endogenous synthesis *via* inhibition of the Δ5 and/or Δ6 fatty acid desaturase.

Methods. Mixed Δ6/Δ5 or selective Δ6 or Δ5 desaturase inhibitors were identified during the screening of chemical and natural product libraries. The antiinflammatory properties of CP-24879, a *p*-hydroxyaniline derivative that is a mixed Δ6/Δ5 desaturase inhibitor and SC-26196, a piperazine derivative that is a selective Δ6 desaturase inhibitor, were further evaluated *in vitro* and *in vivo*. CP-24879 was utilized for mechanism validation *in vitro* using mouse mastocytoma ABMC-7 cells. SC-26196 was nontoxic and had pharmacokinetic and pharmacodynamic profiles that allowed for the evaluation of chronic inhibition of desaturase activity *in vivo*. Effects of desaturase inhibition on eicosanoid levels were measured by enzyme-linked immunosorbent assay, while changes in lipid/fatty acid composition of liver, plasma, and peritoneal cells were quantified by gas chromatography and tandem mass spectrometry. Inflammation was quantified by measuring edema and myeloperoxidase activity in the carrageenan-induced paw edema model in the mouse.

Results. In ABMC-7 cells cultured chronically with CP-24879, there was a concentration-dependent inhibition of desaturase activity that correlated with the degree of depletion of AA and decreased production of leukotriene C_4. In mice dosed with SC-26196, there was a dose-dependent decrease in paw edema and a corresponding decrease in the level of AA in liver, plasma, and peritoneal cells. At the highest dose of SC-26196 administered (100 mpk, ip, bid, for 9 d), mitigation of edema was similar to that obtained with essential fatty acid deficiency or acute dosing with indomethacin (10 mpk, ig). In liver and plasma, AA was selectively decreased while linoleic acid was selectively increased in phosphatidylcholine, phosphatidylserine, and cholesteroyl ester lipid species. The antiinflammatory properties of SC-26196 were consistent with its proposed mechanism of action. Firstly, dose-dependent inhibition of liver Δ6 desaturase activity correlated with decreased paw edema. Secondly, the onset of edema was time-dependent, indicating that AA first had to be decreased in the target tissue. Thirdly, the AA content in liver, plasma, and peritoneal cells decreased dose-dependently. Lastly, in the presence of SC-26196, dietary AA, but not dietary oleic acid, reversed the antiinflammatory effects of desaturase inhibition; AA increased in peritoneal cells and was accompanied by dose-dependent increases in both edema and myeloperoxidase activity.

Conclusions. These results suggest that Δ5 and/or Δ6 desaturase inhibitors manifest an antiinflammatory response by decreasing the level of AA. Either desaturase may be a target for the development of antiinflammatory drugs whose mechanism of action is unique.

In Vitro Interactions of γ-Linolenic Acid and Arachidonic Acid with Ceftazidime on Multiresistant *Pseudomonas aeruginosa*

E.J. Giamarellos-Bourboulis[a,*], P. Grecka[a],
A. Dionyssiou-Asteriou[b], and H. Giamarellou[a,*]

[a]1st Department of Propedeutic Medicine, and [b]Department of Biological Chemistry, Athens Medical School, Athens, Greece

γ-Linolenic acid (GLA) inhibits the growth of *Escherichia coli* (1), and when applied in combination with arachidonic acid (AA) it acts bactericidally on *Pseudomonas aeruginosa* susceptible to a variety of antibiotics (2). Multiresistant *P. aeruginosa* is today a common cause of nosocomial infections accompanied by high morbidity due to the lack of active antibiotics (3). We applied the combination of GLA and AA on such strains studying also whether the presence of GLA or of AA might render them susceptible to ceftazidime since the latter is the most potent antipseudomonal agent (3).

MATERIALS AND METHODS

Nineteen isolates resistant to ceftazidime, imipenem, ciprofloxacin, and amikacin were exposed over time to GLA and/or AA at a 150 or 300 μg/mL concentration with/without ceftazidime. Acid ethyl esters (Sigma, St. Louis, MO) were dissolved in ethanol 99% (Merck, Darmstadt, Germany) (1) and added into tubes of a 10 mL final volume containing Mueller-Hinton broth (Oxoid Ltd., London, United Kingdom) and a 5×10^6 CFU/mL log-phase inoculum of each strain. Ceftazidime was applied at a concentration of 16 μg/mL which is equal to its mean serum levels. Bacterial growth was determined in each tube at 0 time, 3, 5, and 24 h of incubation. Growth in the presence of ethanol 99% and of ceftazidime served as control, and a total of 190 killing curves were performed. As for antibiotics, bactericidal effect was considered any $\geq 3 \log_{10}$ decrease of viable cells compared to controls.

RESULTS AND DISCUSSION

Mean $\log_{10}$ changes by the tested combinations are shown in Figure 1. A killing effect was found by the 300 μg/mL GLA + 300 μg/mL AA combination on 9 (47.4%) isolates. Our findings signify that GLA combined *in vitro* to AA acts bactericidally on a considerable number of multiresistant *P. aeruginosa* at a concentration of 300 μg/mL. The percentage of the achievable killing effect is significant when considering that these isolates are resistant to all antibiotics (3). It is important to state that either GLA or AA augments the activity of ceftazidime, an effect also observed in the presence of a 150 μg/mL concentration of each acid (Fig. 1).

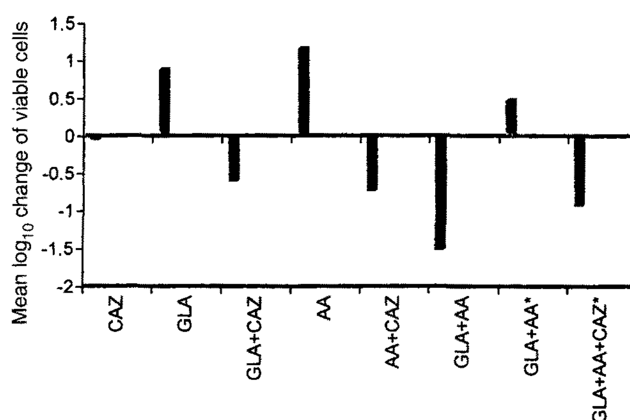

FIG. 1. Mean changes of the starting inoculum (6.69 $\log_{10}$) after 24 h of incubation. Acids were applied at a 300 μg/mL concentration. CAZ, ceftazidime; *, acids applied at a 150 μg/mL concentration; GLA, γ-linolenic acid; AA, arachidonic acid.

The clinical significance of the presented findings is supported by the fact that both the 150 μg/mL concentration of each acid and the 16 μg/mL concentration of ceftazidime are easily achievable in serum (3). The future perspectives of our study are supported by studies where the intravenous administration of GLA in patients with advanced human immunodeficiency virus (HIV) infection resulted in a moderate decrease of their HIV load and an increase of their CD4(+) count (4).

The most probable explanation of the action of GLA and AA might be lipid peroxidation, as it was found by our study group that their bactericidal activity on susceptible isolates was accompanied by the production of thiobarbiturate-reactive substances and limited in the presence of vitamin E (2). Since mul-

tiresistant *P. aeruginosa* is characterized by an impermeable cell wall, limiting the entrance of antibiotics in the bacterial cell (3), these peroxides might attack the cell wall and render the resistant bacterial cell susceptible to ceftazidime (Fig. 1).

Regulation of the Biosynthesis of 22:5n-6 and 22:6n-3: A Complex Intracellular Process

Howard Sprecher*, **Qi Chen, and Feng Qin Yin**

The Department of Medical Biochemistry, The Ohio State University, Columbus, Ohio 43210

ABSTRACT: Both 22:4n-6 and 22:5n-3 are synthesized from n-6 and n-3 fatty acid precursors in the endoplasmic reticulum. The synthesis of both 22:5n-6 and 22:6n-3 requires that 22:4n-6 and 22:5n-3 are metabolized, respectively, to 24:5n-6 and 24:6n-3 in the endoplasmic reticulum. These two 24-carbon acids must then move to peroxisomes for partial degradation followed by the movement of 22:5n-6 and 22:6n-3 back to the endoplasmic reticulum for use as substrates in membrane lipid biosynthesis. Clearly an understanding of the control of intracellular fatty acid movement as well as of the reactions carried out by microsomes, peroxisomes, and mitochondria are all required in order to understand not only what regulates the biosynthesis of 22:5n-6 and 22:6n-3 but also why most tissue lipids selectively accumulate 22:6n-3.

During the past three or four decades the results of numerous investigators led to the general concept that microsomes contain position-specific acyl-CoA-dependent 5- and 6-desaturases, but there was no evidence for the presence of an analogous 4-desaturase (1). In 1973 Ayala *et al.* (2) reported that testes and liver microsomes were unable to desaturate 7,10,13,16-22:4. We subsequently showed that neither 7,10,13,16,19-22:5 nor 7,10,13,16-22:4 was desaturated at position 4 (3,4). Instead these two 22-carbon acids were chain elongated to yield acids with their first double bond at position 9. These acids were then desaturated at position 6, but it is not known if the 6-desaturase that recognizes 24-carbon substrates is different from the enzyme that desaturates linoleate and linolenate (5). The implications of these findings were that 24-carbon acids are produced in the endoplasmic reticulum, but they must then move to another intracellular site for partial degradation. When [3-^{14}C]labeled 22- and 24-carbon unsaturated fatty acids were incubated with fibroblasts, [1-^{14}C]labeled acids were incorporated into membrane lipids. When identical experiments were carried out with fibroblasts from patients with Zellweger's syndrome, who lack peroxisomes, no chain-shortened metabolites were esterified. These studies establish that partial β-oxidation is a peroxisomal event (6,7).

The biosynthesis of 22-carbon fatty acids, with their first double bond at position 4, is thus not a process that is confined to microsomes, but rather the synthesis of these compounds requires considerable movement of fatty acids within the cell. The diagram in Figure 1 depicts an overview of some of these processes. The diagram implies that when 24-carbon fatty acids are produced in the endoplasmic reticulum they may be used for membrane lipid biosynthesis. Alternatively, they may potentially move as either acyl-CoA or free fatty acids to either mitochondria or peroxisomes. Presumably they would be completely degraded by mitochondria but only partially β-oxidized by peroxisomes. The diagram further implies that there must be structural features in the fatty acid molecule so that when 22:5n-6 or 22:6n-3 is produced, its pre-

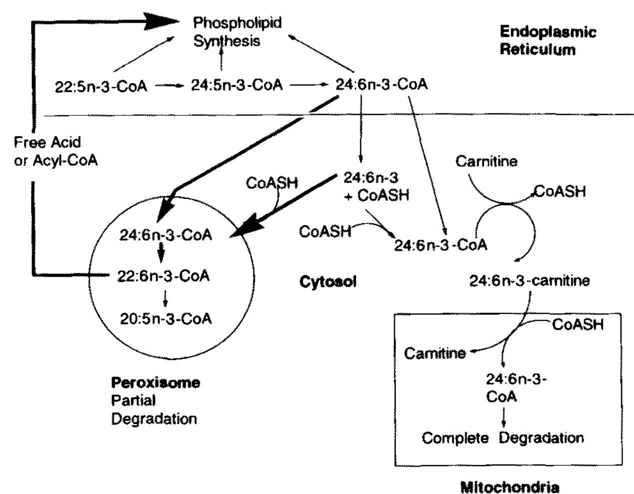

FIG. 1. The intracellular movement and metabolism of unsaturated fatty acids. The diagram implies that when 24:6n-3 is produced in the endoplasmic reticulum, it may be used as a substrate for phospholipid synthesis. Its preferred metabolic fate in liver, however, is to move to another subcellular particle. It is not established whether it moves directly as the acyl-CoA, or whether the acyl-CoA is hydrolyzed in the cytosol, followed by the reactivation of 24:6n-3 at the subcellular site, where it is to be metabolized. The diagram implies that if 24:6n-3 is degraded by mitochondria, the process would probably proceed to completion. In liver, this is a minor pathway. The dark arrows in the diagram show that the preferred metabolic fate of 24:6n-3 is to move to peroxisomes, and after one cycle of degradation, the 22:6n-3 moves back to the endoplasmic reticulum, where it is used as a substrate for phospholipid synthesis.

ferred metabolic fate is to move out of peroxisomes rather than to serve as substrates for continued degradation. If 22:5n-6 and 22:6n-3 are to be used preferentially for membrane lipid biosynthesis, it would seem likely that they should primarily move back to the endoplasmic reticulum rather than serve as substrates for complete degradation by mitochondria. The objective of this brief review is evaluate, and indeed to speculate, as to what controls some of the processes depicted in Figure 1.

INCORPORATION OF FATTY ACIDS INTO MEMBRANE LIPIDS

If 24-carbon acids produced in the endoplasmic reticulum in liver were good substrates for membrane lipid biosynthesis, their movement to peroxisomes for partial degradation would be curtailed. When [3-^{14}C]labeled 24:5n-3 and 24:6n-3 (3) and the analogous n-6 fatty acids (4) were incubated with hepatocytes, only very small amounts of these compounds were incorporated directly into phospholipids. When these acids were converted to their acyl-CoA and incubated with microsomes and 1-acyl-*sn*-glycero-3-phosphocholine, their rates of acylation were either not detectable or very low when compared with 20- and 22-carbon acyl-CoA (8,9). These findings suggest that in liver when 24-carbon acids are produced they are neither further chain-elongated nor incorporated into phospholipids. Instead the 24-carbon acids preferentially move to another cellular compartment for subsequent metabolism. The phospholipids of many tissues contain small amounts of very long chain fatty acids with up to 40 carbon atoms and six double bonds (10,11). Clearly when 24-carbon acids are produced in the endoplasmic reticulum, in these tissues, they have other fates than to move to another cellular compartment. It is not known how many chain-elongating enzymes are found in liver or whether additional enzymes are expressed in extrahepatic tissues (12). Clearly when these long-chain compounds are produced, they are, in part, esterified, but again little is known about the numbers of enzymes that carry out these reactions or what differences exist in tissue-specific enzyme expression.

MOVEMENT OF FATTY ACIDS WITHIN THE CELL

In some cases the substrates and the products of microsomal chain elongation and desaturation are the acyl-CoA (13,14). Although it was not established, when 24-carbon acids are produced in the endoplasmic reticulum, they are likely acyl-CoAs and not free fatty acids. However, it is not known whether acyl-CoA can move directly from one cellular compartment to another or whether they are hydrolyzed by cytosolic acyl-Co hydrolyases (15). Microsomes, peroxisomes, and mitochondria all have a long-chain acyl-CoA synthetase, while a second enzyme, referred to as a very long chain activating enzyme, is not found in mitochondria, but it is present in microsomes and peroxisomes (16). It seems likely that when acyl-CoA are produced, as a product of metabolism in a cellular compartment, they are subsequently hydrolyzed in the cytosol, followed by reactivation where they are to be metabolized.

MITOCHONDRIAL FATTY ACID METABOLISM

It is generally accepted that, under normal physiological conditions, once mitochondrial fatty acid β-oxidation is initiated it proceeds to completion (17). If 24-carbon acids moved from microsomes to mitochondria and were used as substrates for total β-oxidation, they would have the potential of reducing the production of both 22:5n-6 and 22:6n-3. Rates of palmitic acid and linoleic acid activation by mitochondria were between 50–60 nmol/min/mg of mitochondrial protein. Rates of 24:4n-6 and 24:5n-6 activation were only 1–2 nmol/min/mg of mitochondrial protein. Rates of acylcarnitine synthesis, using 16:0-CoA and linoleoyl-CoA as substrates, were 10–15 nmol/min/mg of mitochondrial protein, while the rates of acylcarnitine synthesis using the 24-carbon acyl-CoA derivatives were less than 2 nmol/min/mg of mitochondrial protein. When 16:0-CoA and linoleoyl-CoA were incubated with mitochondria, 35–40 ng atoms of oxygen/min/mg of mitochondrial protein were used. When the CoA derivatives of 24:4n-6 and 24:5n-6 were used, these values were, respectively, 2 and 1.8. Collectively these studies show that 24-carbon n-6 acids were poor substrates for acyl-CoA synthesis, acylcarnitine synthesis, and mitochondrial β-oxidation (Chen, Q., and Sprecher, H., unpublished data). These results suggest that when 24-carbon n-6 and n-3 fatty acids are made in the endoplasmic reticulum, they are preferentially channeled to peroxisomes for further metabolism, rather than being degraded by mitochondria.

PEROXISOMAL FATTY ACID METABOLISM

Peroxisomes are able to activate 24-carbon acids although at a somewhat lower rate than was found for 20- and 22-carbon fatty acids. Rates of activation for the n-3 acids, 20:5, 22:5, 22:6, 24:5, and 24:6 were, respectively, 126, 72, 37, 20, and 16 nmol/min/mg of peroxisomal protein from rats whose diets contained 0.5% clofibrate (8). Similar values were obtained for the corresponding n-6 fatty acids (9). The relative contribution of the long chain and the very long chain acyl-CoA synthetase in activating these fatty acids is not known. Since 24-carbon fatty acids were very poor substrates for activation in mitochondria, the results suggest that the very long chain enzyme probably is used for activating these fatty acids in peroxisomes. All of our studies were thus carried out by generating fatty acids *in situ*, which may well be what takes place *in vivo*.

When any fatty acid is produced in the microsome, it has the potential of moving to peroxisomes for partial degradation. It is generally accepted that peroxisomes partially degrade long-chain fatty acids and that the chain-shortened products are channeled to mitochondria to complete the degradative process (18). The synthesis of 22:5n-6 and 22:6n-3, respectively, from 24:5n-6 and 24:6n-3 implies that there must be some structural feature in 22:5n-6 and 22:6n-3, so that when they are produced

they are preferentially used for membrane lipid synthesis rather than as substrates for continued degradation. Peroxisomes are unable to esterify 1-acyl-*sn*-glycero-3-phosphocholine (19). When 22:5n-6 and 22:6n-3 are produced in peroxisomes, the diagram in Figure 1 implies that they must move to microsomes where they are used as substrates for membrane lipid synthesis. We carried out a series of experiments that we termed "mixing experiments" that have as their objective to determine what structural features in a fatty acid make it a preferred substrate for movement to microsomes for acylation rather than continued peroxisomal β-oxidation. In this protocol we compare the amount of acid-soluble radioactivity produced when peroxisomes are incubated alone with labeled fatty acids vs. what is obtained when microsomes and 1-acyl-*sn*-glycero-3-phosphocholine are included in the incubation. With the later incubations, phospholipids are isolated and the amounts of metabolites esterified into the acceptor are quantified. After a 30-min incubation, using 100 nmol of [3-^{14}C]labeled 24:4n-6 or 24:5n-3, 30–40 nmol of acid-soluble radioactivity was produced. When microsomes and 1-acyl-*sn*-glycero-3-phosphocholine were added to the incubations, there was only about a 10% decrease in the production of acid-soluble radioactivity. Two cycles of fatty acid β-oxidation of [3-^{14}C]labeled 9,12,15,18-24:4 and 9,12,15,18,21-24:5 yield, respectively, arachidonate and 20:5n-3 with loss of label. These two degradative cycles require only the enzymes of saturated fatty acid degradation. When [3-^{14}C]labeled 6,9,12,15,18-24:5 and 6,9,12,15,18,21-24:6 were incubated alone with peroxisomes, only about 8–10 nmol of acid-soluble radioactivity was produced after 30 min. When microsomes and 1-acyl-*sn*-glycero-3-phosphocholine were included in the incubations, there was an approximate 50% decrease in the production of acid-soluble radioactivity. The first cycle of 24:5n-6 and 24:6n-3 degradation also only requires the enzymes of saturated fatty-acid degradation. As soon as [1-^{14}C]labeled 4,7,10,13,16-22;5 and 4,7,10,13,16,19-22:6 are produced, their continued degradation requires both NADPH-dependent 2,4-dienoyl-CoA reductase and Δ^3,Δ^2-enoyl-CoA isomerase which is a component part of the peroxisomal trifunctional enzyme (20). In all of our studies, when an acid with its first double bond at position 4 is incubated with peroxisomes, or when an acid is produced with its first double bond at position 4, metabolites with their first two double bonds at the 2-*trans*-4-*cis*-positions always accumulate (8,9,21,22). These results suggest that the reaction catalyzed by the reductase is a control step in the peroxisomal degradation of unsaturated fatty acids. As a corollary the preferred metabolic fate of a fatty acid, with its first double bond at position 4, is to move out of peroxisomes to microsomes for use in membrane lipid synthesis rather than to serve as a substrate for continued peroxisomal degradation. This general hypothesis is supported by comparing the amounts of metabolites that were esterified into the acceptor when the four 24-carbon n-3 and n-6 fatty acids were incubated with peroxisomes in the presence of microsomes and 1-acyl-*sn*-glycero-3-phosphocholine. As shown in Table 1, only small amounts of all four 24-carbon acids were esterified. Most importantly, the amounts of [1-^{14}C]labeled 22:4n-6 and 22:5n-3 that were produced, respectively, from [3-^{14}C]labeled 24:4n-6 and 24:5n-3 and esterified were much less than was found for the two 22-carbon acids with their first double bond at position 4, which are produced from [3-^{14}C]labeled 24:5n-6 and 24:6n-3.

TABLE 1
Incorporation of Radioactive Acids into Phospholipids When Peroxisomes Were Incubated with Microsomes and 1-Acyl-*sn*-glycero-3-phosphocholine[a]

	Substrate			
	24:4n-6	24:5n-6	24:5n-3	24:6n-3
	(nmols of esterified radioactive fatty acids)			
24:4n-6	3			
22:4n-6	9			
24:5n-6		2		
22:5n-6		32		
24:5n-3			3	
22:5n-3			6	
24:6n-3				6
22:6n-3				41

[a]Peroxisomes (300 μg of protein) were incubated with 100 μM each of [3-^{14}C]labeled fatty acids and 1-acyl-*sn*-glycero-3-phosphocholine along with 300 mg of microsomal protein. After 30 min the labeled acids in phospholipids were quantified.

Once 22:5n-6 and 22:6n-3 are produced in peroxisomes, they presumably must be transported back to the endoplasmic reticulum for use as substrates in membrane lipid biosynthesis. It remains to be determined in what form fatty acids are transported out of peroxisomes, i.e., acyl-CoA or free fatty acids. The production of 22:5n-6 and 22:6n-3 from dietary linoleate and linolenate is a lengthy process. It would seem likely that the primary metabolic fate of these 22-carbon acids is to serve as precursors for phospholipid synthesis. However, both of these acids must also be degraded. When we incubated [3-^{14}C]labeled 24:5n-6 and 24:6n-3 with peroxisomes in the presence of microsomes and 1-acyl-*sn*-glycero-3-phosphocholine, the production of acid-soluble radioactivity was depressed but not abolished, showing that under these conditions some 22:5n-6 and 22:6n-3 were degraded (8,9). The relative contribution of peroxisomes vs. mitochondria in degrading 22:5n-6 and 22:6n-3, however, is not established. We found that 22:5n-6 was a poor substrate for β-oxidation by liver mitochondria (Chen, Q., and Sprecher, H., unpublished data), but Nada and his colleagues (23) reported that 22:6n-3 was readily degraded by heart mitochondria. Clearly, more studies are required not only to determine the intracellular site for the degradation of long-chain polyunsaturated fatty acids but also whether there might be tissue-specific differences.

The Growing Family of Peroxisomal Thiolases

V.D. Antonenkov*, P.P. Van Veldhoven, and G.P. Mannaerts

Katholieke Universiteit Leuven, Campus Gasthuisberg, Afdeling Farmacologie, B-3000 Leuven, Belgium

Thiolases catalyze the reversible thiolytic cleavage of different fatty 3-oxoacyl-CoA. Animal tissues contain two classes of thiolase: acetoacetyl-CoA specific thiolases and 3-oxoacyl-CoA thiolases that possess a broad substrate specificity and act on medium and long straight-chain 3-oxoacyl-CoA. Thiolases participate in different catabolic (fatty acid oxidation and bile acid formation) and anabolic (cholesterogenesis, ketone body synthesis, fatty acid elongation) processes. Peroxisomes play a role in most of these pathways and harbor different thiolases.

The aim of the present study was to elucidate the functional significance of multiple thiolases in mammalian peroxisomes. Methods for the purification of peroxisomal thiolases were based on the alteration in their chromatographic properties in presence or absence of low concentrations of CoA. In peroxisomes from normal rat liver, four main thiolases were detected: 3-oxoacyl-CoA thiolase A (thiolase A), sterol carrier protein 2/3-oxoacyl-CoA thiolase (SCP-2/thiolase), and two new enzymes: acetoacetyl-CoA thiolase and a long chain 3-oxoacyl-CoA thiolase (LC-thiolase).

Purified preparations of thiolase A and 3-oxoacyl-CoA thiolase B (thiolase B, the enzyme was isolated from clofibrate-treated rat liver) reacted with antibodies raised against thiolase A, but could be distinguished by their isoelectric points, their N-terminal amino acid sequences and their stability, the latter being higher for thiolase A. Thiolase A displayed a substrate specificity that is roughly similar to that of thiolase B. Both enzymes reacted with short, medium, and long straight-chain 3-oxoacyl-CoA (1).

Purified preparation of SCP-2/thiolase consisted of a 58 and a 46 kDa polypeptide. Internal peptide sequencing and immunoblot analysis revealed that the 46 kDa polypeptide is the N-terminal (thiolase) domain of SCP-2/thiolase. The enzyme exists *in vivo* as a mixture of three isoforms consisting of homo- and heterodimeric combinations of the 58 and 46 kDa subunits. SCP-2/thiolase is active with medium and long straight-chain 3-oxoacyl-CoA but also with 2-methyl-branched 3-oxoacyl-CoA and the 24-oxoacyl-CoA derivative of trihydroxycoprostanic acid (2).

Acetoacetyl-CoA thiolase is a homotetrameric protein with a subunit molecular mass of 42 kDa. The enzyme cleaves only acetoacetyl-CoA as substrate and is also active in the reverse direction (condensation of two molecules of acetyl-CoA). Kinetic analysis, internal peptide microsequencing, immunological, and some other data indicate that the peroxisomal, cytoplasmic, and mitochondrial acetoacetyl-CoA thiolases are three closely related but distinct proteins. Acetoacetyl-CoA thiolase from peroxisomes most probably catalyzes the initial step of cholesterol synthesis in these organelles.

Peroxisomal LC-thiolase has an unusual substrate specificity that distinguishes it from other known mammalian thiolases. After subfractionation of peroxisomes, the enzyme activity was recovered in the membrane fraction.

α-Oxidation of 3-Methyl-branched Fatty Acids: A Revised Pathway Confined to Peroxisomes

K. Croes*, P.P. Van Veldhoven, G.P. Mannaerts, and M. Casteels
Katholieke Universiteit Leuven, Campus Gasthuisberg, Afdeling Farmakologie, B-3000 Leuven, Belgium

α-Oxidation of phytanic acid (3,7,11,15-tetramethylhexadecanoic acid), a 3-methyl-branched isoprenoid-derived fatty acid, was generally believed to consist of a hydroxylation in the 2-position, followed by an oxidative decarboxylation generating CO_2 and a fatty acid shortened by one carbon. Until recently, however, the α-oxidation process has remained a matter of debate as to its subcellular localization, the reaction intermediates, and the cofactors involved (1). The observation that formate is formed during α-oxidation of phytanic acid in human skin fibroblasts (2) has been the basis for the recent unraveling of the α-oxidation process.

For our study, we used synthetic 3-methyl-branched fatty acids that were shown to be valid substitutes for phytanic acid in the study of the α-oxidation process.

As in human fibroblasts, formate was formed during α-oxidation of 3-methyl-branched fatty acids in intact rat hepatocytes (3) and was shown to be the first product which is then converted to CO_2, presumably in an NAD^+-dependent cytosolic process (4). Consequently, α-oxidation was assessed by the sum of formate and CO_2 in all further experiments.

When studied in permeabilized rat hepatocytes and rat liver homogenates, the α-oxidation process required ATP, CoA, Mg^{2+}, Fe^{2+}, ascorbate, and 2-oxoglutarate (4). Subsequent experiments in subcellular fractions of rat liver demonstrated that this set of cofactors reflects two steps: first, activation by an acyl-CoA synthetase requiring ATP, CoA, and Mg^{2+} and then 2-hydroxylation of the resulting 3-methylacyl-CoA by a 3-methylacyl-CoA hydroxylase requiring Fe^{2+}, ascorbate, and 2-oxoglutarate (4). The whole α-oxidation pathway up to the formation of formate was clearly a peroxisomal process (4). Mihalik *et al.* (5) came to the same conclusion using a different approach. Furthermore, our results suggest that the 2-hydroxylation is a membrane-bound process (4). The 2-hydroxy-3-methylacyl-CoA is cleaved into formyl-CoA and a 2-methyl-branched fatty aldehyde by a 2-hydroxy-3-methylacyl-CoA lyase, probably located in the peroxisomal matrix and requiring no additional cofactors. In peroxisomes formyl-CoA is actively converted to formate (6), while the 2-methyl-branched fatty aldehyde is converted to a 2-methyl-branched fatty acid in the presence of NAD^+ (7). After activation to its CoA-ester, the 2-methyl-branched fatty acid can be degraded by peroxisomal β-oxidation.

Our studies show that in rat liver the whole α-oxidation process up to the formation of formate and a 2-methyl-branched fatty acid consists of five enzymatic steps, which are all confined to peroxisomes.

Adipose Peroxisome Proliferator-Activated Receptor γ mRNA Expression in Insulin-Resistant Obese Patients: Relationship with Adipocyte Membrane Phospholipids

Nezha Zeghari[a], Hubert Vidal[b], Sophie Perche[b], Laurent Meyer[c], Olivier Ziegler[c], Bruno Guerci[c], Mireille Donner[a,*], and Pierre Drouin[c,d]

[a]EA 2402, Université Henri-Poincaré-Nancy 1, 54500, Vandoeuvre les Nancy, France; [b]INSERM U449, Faculté de Médecine Laënnec, 69000, Lyon, France; [c]Département de Diabétologie, Maladies Métaboliques et Nutrition, CHU de Nancy, and [d]CIC Inserm-CHU, 54520, Dommartin les Toul, France

Peroxisome proliferator-activated receptors (PPARs) control the expression of genes implicated in the metabolism of intra- and extracellular lipids. The subtype PPARγ is also an essential factor for adipocyte differentiation, and it has now become clear that it plays a crucial role in the action of insulin. Thiazolidinediones enhance the sensitivity of obese patients and patients with non-insulin-dependent diabetes mellitus (NIDDM) to insulin by activating PPARγ. As the amount of adipose tissue PPARγ mRNA tends to increase in response to activators and/or ligands, several attempts have been made to find disregulation of PPARγ in the tissues of obese and NIDDM patients. The results are not clear-cut, and there is no definite evidence that PPARγ expression in the skeletal muscle and adipose tissue of normal, obese, and diabetic subjects differs. Besides their role on lipid metabolism, there is also an indication of a relationship between PPAR and phospholipid metabolism. Clofibrate, a peroxisome proliferator, inhibits the synthesis of all major cellular phospholipids in cultured human fibroblasts. In a previous study, we found that changes in the phospholipid composition of the plasma membranes of adipocytes from abdominal subcutaneous fat biopsies are linked to insulin resistance in obese patients. Multivariate analysis showed that the membrane sphingomyelin (SM) content was the major independent predictor of insulin resistance markers [fasting plasma insulin and homeostasis model assessment (HOMA) values]. We have therefore examined the association between the phospholipid composition of adipocyte membranes and the expression of the PPARγ gene. This was done by assaying classes of phospholipids in adipocyte plasma membranes and by determining the PPARγ mRNA levels in a group of obese nondiabetic subjects with variable degrees of insulin resistance.

Abbreviations: FPI, fasting plasma insulin; HOMA, homeostasis model assessment; NIDDM, non-insulin-dependent diabetes mellitus; PPAR, peroxisome proliferator-activated receptor; SM, sphingomyelin.

Abdominal subcutaneous fat tissue was obtained from 23 obese nondiabetic patients: age: 43.7 ± 10.7 yr, body mass index: 36.3 ± 10.5 kg/m^2, fasting blood glucose: 5.10 ± 1.14 mmol/L. The fasting plasma insulin concentrations (FPI: 142.0 ± 70.5 pmol/L) and the HOMA estimates: 4.6 ± 2.8 were used as markers of insulin resistance. PPARγ mRNA levels were measured by a reverse transcription-competitive polymerase chain reaction method. Eighteen of the 23 biopsies contained enough fat (>5 g) to allow isolation of adipocyte plasma membranes. The lipids were extracted, and the phospholipid composition of the membranes was analyzed by high-performance liquid chromatography.

FPI and HOMA values were positively correlated with membrane SM (FPI $r = 0.744$, $P < 0.0005$; HOMA: $r = 0.667$, $P < 005$), phosphatidylethanolamine (FPI: $r = 0.506$, $P < 0.05$; HOMA: $r = 0.531$, $P < 0.05$), and phosphatidylcholine (FPI: $r = 0.589$, $P < 0.01$; HOMA: $r = 0.480$, $P < 0.05$). The amounts of PPARγ mRNA were positively correlated with phosphatidylinositol ($r = 0.512$, $P < 0.05$) and negatively with phosphatidylcholine ($r = -0.303$, $P < 0.05$) and SM ($r = -0.551$, $P < 0.05$). Lastly, the PPARγ mRNA concentration was negatively correlated with the fasting plasma insulin ($r = -0.433$, $P < 0.05$) and HOMA values ($r = -0.496$, $P < 0.05$).

Changes in the phospholipid composition of the adipocyte plasma membranes are linked to insulin resistance in obese nondiabetic patients. The membrane SM content is strongly positively correlated with the two markers of insulin resistance studied. Although SM may accumulate in membranes for other reasons, the negative correlation between PPARγ mRNA levels and the membrane SM content supports the hypothesis that PPARγ could play a role in phospholipid metabolism. Tumor necrosis factor-α which down-regulates PPARγ and affects the SM pathway may also be important. Finally, low PPARγ mRNA levels are associated with high fasting plasma insulin and HOMA values. These results suggest that those obese women with lower insulin sensitivity are also characterized by a lower PPARγ gene expression in their subcutaneous adipose tissue.

Mitochondrial 3-Hydroxy-3-methylglutaryl CoA Synthase and Carnitine Palmitoyltransferase II Are Potential Control Sites of Hepatic Ketogenesis Under Conditions of Peroxisome Proliferation

Rolf K. Berge[a,*], Alexis Garras[a], Guillermina Asins[b], Dolors Serra[b], Fausto G. Hegardt[a], and Lise Madsen[a]

[a]Department of Clinical Biochemistry, Haukeland Hospital, University of Bergen, Bergen, Norway, and the [b]Unit of Biochemistry, School of Pharmacy, University of Barcelona, Barcelona, Spain

3-Thia fatty acids are potent hypolipidemic fatty acid derivatives and mitochondrion and peroxisome proliferators. They increase the transport of fatty acids into the mitochondria and increase the capacity of the β-oxidation process. Administration of 3-thia fatty acids to rats was followed by a significantly increased production of acid-soluble products and ketone bodies. The levels of nonesterified fatty acids in plasma were decreased, whereas the hepatic mRNA levels of fatty acid-binding protein were increased. Increased mitochondrial carnitine palmitoyltransferase (CPT)-II and 3-hydroxy-3-methylglutaryl (HMG)-CoA synthase activities, immunodetectable proteins, and mRNA levels were also observed in the liver. In contrast, the mitochondrial CPT-I mRNA levels were unchanged, and CPT-I enzyme activity was slightly reduced. The immunodetectable CPT-I protein, however, was increased. An increase in immunoreactive protein, which is not essential for catalytic function or sensitivity to malonyl-CoA, is possible due to formation of a 3-thia fatty acid CoA-ester which *inhibits* the CPT-I activity. Acetoacetyl-CoA thiolase and HMG-CoA lyase activities involved in ketogenesis were increased. The citrate synthase activity was decreased. We conclude that under conditions of peroxisome proliferation by 3-thia fatty acids, HMG-CoA synthase and CPT-II may be regulatory sites of ketone bodies formation.

Suspicion of Latent Δ5-Desaturase and Peroxisomal β-Oxidation Deficiency in Elderly Women over 75 Years of Age

F. Babin[a], M. Abderrazik[b], F. Favier[b], J.P. Cristol[a], C.L. Léger[a], L. Papoz[b], and B. Descomps[a,]*

[a]Laboratoire de Biologie et Biochimie des Lipides, EA 2033, Institut de Biologie, Université de Montpellier I, CHU de Montpellier, and [b]INSERM U 500, Montpellier, France

The aim of the present study was to compare the plasma and erythrocyte fatty acid (FA) status in a cohort of 200 women over 75 yr of age living at home with that of a control group of 50 young female volunteers aged 20–48 yr. The data were related to the dietary habits and food intakes which were evaluated by two different methods of dietary investigation. The FA composition of total plasma lipids, plasma triglycerides, cholesterol esters (CE), and erythrocytes were determined by capillary column gas–liquid chromatography using H_2 as carrier gas.

The n-6 series precursor linoleic acid (18:2n-6) was significantly lower in elderly women (EW) than in the control group in plasma triglycerides and CE ($P = 0.029$ and $P = 0.014$, respectively), suggesting that dietary intake of this essential fatty acid was lower in this group than in the control group. This is supported by the high correlation we observed between linoleic acid in CE and vegetables, vegetal fat, polyunsaturated fatty acid and vitamin E intakes ($P < 0.001$ each). In CE, the n-3 series precursor α-linolenic acid (18:n-3) was also lower in EW ($P < 0.04$) and was highly correlated to carbohydrates, bread, fibers, and vegetal protein intakes ($P < 0.0001$ each), suggesting again a lower dietary supply. In agreement with this observation, palmitoleic acid (16:1n-7) in CE was higher in the EW group ($P < 0.0001$), an observation supported by logistic regression analysis showing that higher 16:1n-7 values were associated with the EW group in all plasma lipid fractions. These data show a tendency to EFA deficiency in the EW group.

The 20:4n-6/20:3n-6 ratio was lower in CE and phospholipids ($P < 0.02$ and $P < 0.005$, respectively) for EW, suggesting some impairment in the Δ5 desaturation, whereas 18:3n-6/18:2n-6 ratio was not reduced in EW, supporting an unaltered Δ6-desaturase activity. Contrasting with the suspected lower linoleic acid intake and Δ5-desaturase activity, no difference was observed in arachidonic acid levels. Dietary investigations suggested that high dietary protein intakes largely contributed in EW to 20:4n-6 supply by diet meat.

In PL, 22:6n-3/20:5n-3 was lower in EW ($P < 0.002$), suggesting impairment in the apparent "Δ4-desaturase" pathway. Since Δ6-desaturase capacity seemed unchanged, alteration of the peroxisomal retroconversion could be implicated. Such a peroxisomal defect has been observed in aging rodents (1,2), whereas increased Δ4-activity was observed in fibrate-treated rats (3). A fragile equilibrium largely dependent on exogenous supply of long chain FA characterizes the essential fatty acid status of the group of EW studied. It is suggested that (i) the high protein intake contributing to 20:4n-6 homeostasis in free living EW should be maintained and (ii) caution is required before dietary supplementation with large amounts of very long chain polyunsaturated fatty acids in these populations until potential peroxisomal β-oxidation deficiency can be ruled out.

The Mitochondrion Is the Principal Target for Nutritional and Pharmacological Control of Plasma Triglyceride

L. Madsen[a], L. Frøyland[a], H. Kryvi[b], J. Auwerx[c], B. Staels[c], and R.K. Berge[a,*]

[a]Department of Clinical Biochemistry, N-5021 Haukeland Hospital, Norway, [b]Institute of Zoology, University of Bergen, N-5007 Bergen, Norway, [c]U 325 INSERM, Département d'Athérosclérose, Institut Pasteur, 59019 Lille, France

Fish oil polyunsaturated fatty acids, fibrates, and the 3-thia fatty acid analog tetradecylthioacetic acid (TTA) are potent hypotriglyceridemic agents, which act by increasing fatty acid catabolism and decreasing triglyceride synthesis and secretion by the liver. A major unresolved issue is whether this hypotriglyceridemic effect can occur independent of induction of peroxisomal β-oxidation mediated *via* peroxisome proliferator-activated receptor (PPAR). The main n-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), are still mostly referred to as fish oils without any further distinction. However, studies performed in the recent years demonstrated that they possess different metabolic properties. The present study was undertaken to determine which component of fish oil, EPA or DHA, is responsible for its hypotriglyceridemic effect. We demonstrate that EPA, not DHA, is the hypotriglyceridemic component of fish oil and that only EPA feeding induces mitochondrial proliferation in rat liver. However, our data show that DHA, not EPA, is the fatty acid responsible for the observed peroxisomal proliferating effect of fish oil. EPA feeding also led to a decrease in hepatic fat droplets, whereas DHA, which increased the peroxisomal β-oxidation, actually increased the volume fraction of hepatic fat droplets. We therefore conclude that the mitochondria, not the peroxisomes, are the principal targets for nutritional and pharmacological control of triglyceride metabolism. Interestingly, fenofibrate and TTA seem to operate by the same mechanism as EPA, i.e, by increasing the mitochondrial β-oxidation capacity. In the rat model, the mitochondrial β-oxidation increased significantly, although not to the same extent as the peroxisomal β-oxidation system. In the rabbit model, however, the increase in the mitochondrial β-oxidation was more evident than the peroxisomal. And finally, in the dog model, the mitochondrial β-oxidation was increased, whereas the peroxisomal was unaffected. This is an interesting finding, as the fibrates have a modest effect on peroxisome proliferation in humans but possess a hypotriglyceridemic effect. In contrast to fibrates and TTA, EPA did not affect hepatic apolipoprotein C-III gene expression. We conclude that increased mitochondrial β-oxidation with a concomitant decrease in triglyceride synthesis is the primary mechanism underlying the hypotriglyceridemic effect of EPA, fibrates, and TTA in rats, rabbits, dogs, and possibly also in humans. In addition, these data show that the hypotriglyceridemic action of nutritional (such as fish oil) and pharmacological agents (such as fibrates and TTA) can be dissociated from any deleterious effects from peroxisome proliferation.

Cellular Fatty Acid Transport in Heart and Skeletal Muscle as Facilitated by Proteins

J.J.F.P. Luiken[a,b], F.G. Schaap[b], F.A. van Nieuwenhoven[b], G.J. van der Vusse[b], A. Bonen[a], and J.F.C. Glatz[b,*]

[a]Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1, and [b]Department of Physiology, Cardiovascular Research Institute Maastricht (CARIM), Maastricht University, Maastricht, The Netherlands

ABSTRACT: Despite the importance of long-chain fatty acids (FA) as fuels for heart and skeletal muscles, the mechanism of their cellular uptake has not yet been clarified. There is dispute as to whether FA are taken up by the muscle cells *via* passive diffusion and/or carrier-mediated transport. Kinetic studies of FA uptake by cardiac myocytes and the use of membrane protein-modifying agents have suggested the bulk of FA uptake is due to a protein component. Three membrane-associated FA-binding proteins were proposed to play a role in FA uptake, a 40-kDa plasma membrane FA-binding protein ($FABP_{pm}$), an 88-kDa FA translocase (FAT/CD36), and a 60-kDa FA transport protein (FATP). In cardiac and skeletal myocytes the intracellular carrier for FA is cytoplasmic heart-type FA-binding protein (H-FABP), which likely transports FA from the sarcolemma to their intracellular sites of metabolism. A scenario is discussed in which $FABP_{pm}$, FAT/CD36, and H-FABP, probably assisted by an albumin-binding protein, cooperate in the translocation of FA across the sarcolemma.

Long-chain fatty acids (FA) are an important source of energy for most mammalian cells. In addition, FA serve as building blocks for phospholipids, forming the structural compounds of biological membranes. Newer functions attributed to FA include altering protein function by protein acylation and serving as messenger in certain signal transduction pathways (Fig. 1).

In heart and oxidative skeletal muscle, FA are the predominant substrates. In heart, it was observed that more than 30% of FA in the vascular space was extracted upon a single pass perfusion (1), indicating that FA uptake is fast, i.e., on the metabolic time scale. Since the energy demands of both heart and muscle can vary rapidly and markedly, it is important that FA delivery to these tissues is rapid, efficient, and subject to regulation. In contrast with other substrates such as glucose and lactate, the aqueous solubility of FA is extremely low (nanomolar range), and would impose theoretical problems on the observed uptake rate by heart and skeletal muscles without the presence of specific proteins to increase their aqueous solubility and to facilitate their transport (2). In the blood and interstitial space, FA are bound to albumin, while the intracellular carriers for FA are members of a family of small cytoplasmic fatty acid-binding proteins (FABP).

Cellular uptake of FA requires passage through the sarcolemmal lipid bilayer which can be divided into three stages: (i) adsorption to the outer leaflet of the sarcolemma, (ii) translocation across the sarcolemma, and (iii) desorption from the cytoplasmic leaflet of the sarcolemma. The involvement of a protein component in either one of these steps, however, is heavily disputed. Proponents of passive diffusion as the likely mechanism base their arguments on the physicochemical properties of FA and their ability to readily dissolve in and diffuse through membranes (3). This view is strengthened by observations that flip-flop of FA across artificial bilayers, as monitored with the pH-sensitive fluorophore pyranin, was extremely fast (3,4), although these findings were disputed by others (5). On the other hand, those who are in favor of a facilitated, carrier-mediated FA transport argue that cellular FA uptake is saturable, subject to competitive inhibition, and sensitive to proteases and to heat treatment (6). As will be discussed in more detail below, our own experiments using either cardiac myocytes or sarcolemmal vesicles derived from these cells, where unidirectional influx is studied either in the presence (7) or absence (8) of ongoing metabolism, demonstrated that FA uptake could be inhibited by up to 80% in the presence of protein-modifying agents (trypsin, phloretin) or highly reactive FA derivatives such as sulfo-*N*-succinimidyl-oleate (SSO) (Fig. 2). The observation that none of these agents, either alone or in combination, can fully inhibit FA uptake (Fig. 2), suggests that for cardiac myocytes there is a noninhibitable component contributing to *ca.* 20% of cellular FA uptake and likely due to passive diffusion (7). Thus, it appears that, at least in muscle, the mechanisms of passive and facilitated diffusion of FA co-exist, whereby their relative

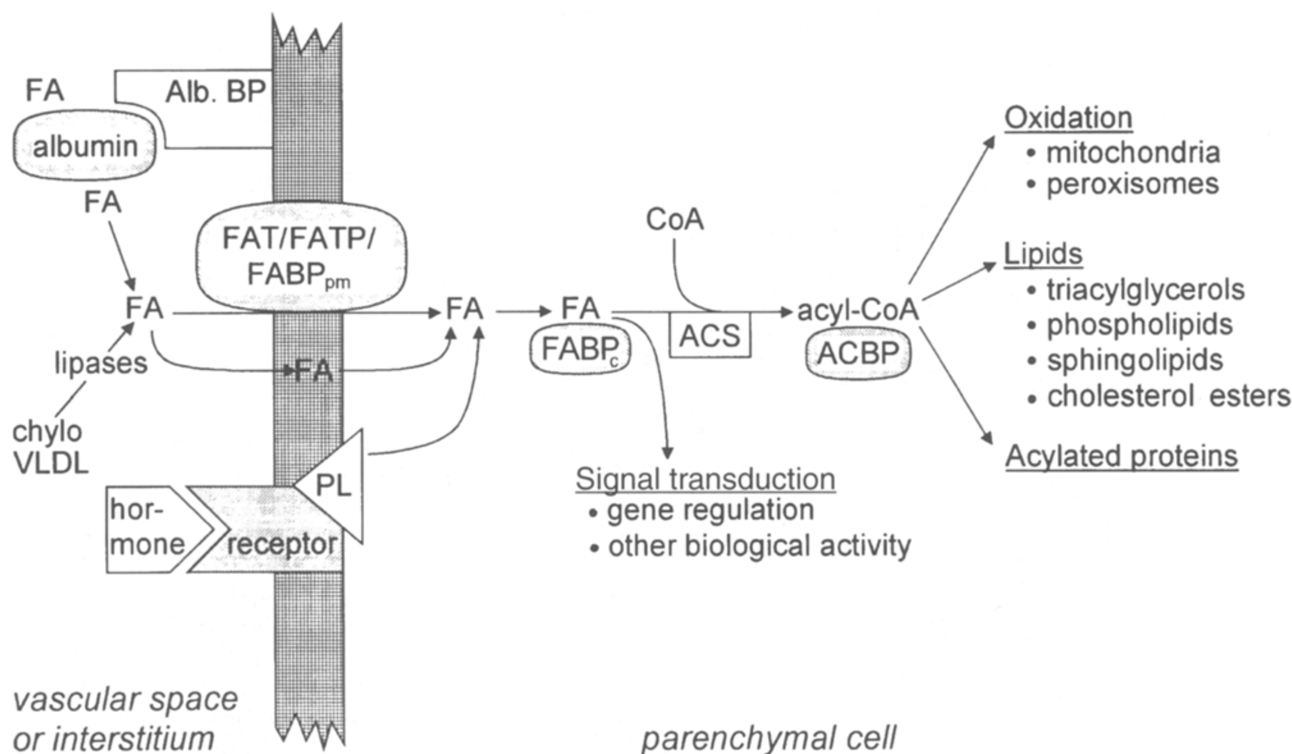

FIG. 1. Schematic presentation of the uptake and utilization of long-chain fatty acids (FA) by parenchymal cells, with emphasis on the assumed or proposed roles of various lipid-binding proteins in this process. Transmembrane translocation of FA presumably takes place by passive diffusion through the phospholipid bilayer and/or facilitated by membrane-associated proteins ($FABP_{pm}$, FAT/CD36, FATP). Intracellularly, FA are bound by cytoplasmic FABP and, after activation to fatty acyl-CoA, by ACBP. In addition, the binding of specific hormones to its cell-surface receptor may trigger the release of FA from membrane phospholipids (PL), which then act as signaling compounds (second messenger) modulating certain cellular functions. Abbreviations: chylo, chylomicrons; VLDL, very low density lipoproteins; Alb. BP, albumin-binding protein; $FABP_{pm}$, plasmalemmal fatty acid-binding protein; FAT, fatty acid translocase (CD36); FATP, fatty acid-transport protein; $FABP_c$, cytoplasmic fatty acid-binding protein; ACS, acyl-CoA synthetase; ACBP, acyl-CoA binding protein.

contribution to overall FA uptake is likely to depend on the metabolic demands of the tissue.

Driving force for FA uptake in heart and muscle. Experimental studies in heart and skeletal muscle in which the vascular and intracellular concentration of FA (sum of protein-bound and nonprotein-bound FA) was determined indicated the existence of an inwardly directed FA gradient with an extracellular FA concentration in 10–20-fold excess over the intracellular content (1,9). This gradient is regarded as the driving force for FA uptake. The intracellular (unesterified) FA concentration in cardiac myocytes is maintained at a low level of 6–8 μM by rapid metabolic conversion of the FA into fatty acyl-CoA followed by β-oxidation or esterification, which makes FA metabolism an important factor of the rate of FA uptake (7). Observations supporting this notion include the findings that (i) initial FA uptake is depressed by inhibitors of FA-metabolizing enzymes and by competitive substrates (7), (ii) in electrically stimulated cardiac myocytes, the increased metabolic demands cause an enhancement of initial uptake of FA (Luiken J.J.F.P., unpublished observations), and (iii) during the initial uptake phase (3 min) more than 50% of the sequestered FA is esterified (7).

The study of FA uptake in the absence of their subsequent metabolism has recently become possible by the introduction of giant sarcolemmal vesicles as an experimental model (8,10). These vesicles (diameter *ca.* 15 μm) are oriented fully right-side-out, and substrate metabolism is completely absent. Importantly, the vesicles contain cytoplasmic FABP that serves as an intravesicular sink for FA.

Comparison of FA uptake by cardiac myocytes and giant sarcolemmal vesicles from heart has yielded insight into the question as to what is the rate-limiting step in cellular FA uptake and metabolism. Both in myocytes and giant vesicles, i.e., in the presence and absence of FA metabolism, respectively, FA uptake showed similar saturation kinetics (7,8). Moreover, with myocytes it was observed that at high, externally added palmitate concentrations, when the initial uptake becomes saturated, there is no drastic increase in the cellular steady-state levels of (unesterified) FA, which were found to remain *ca.* 8 μM (7). Such an increase is likely to be expected when palmitate metabolism would be rate-limiting. Together these observations suggest that the translocation of FA across the sarcolemma might be a primary control point of cellular FA uptake. This notion implies that either there is an overcapacity of

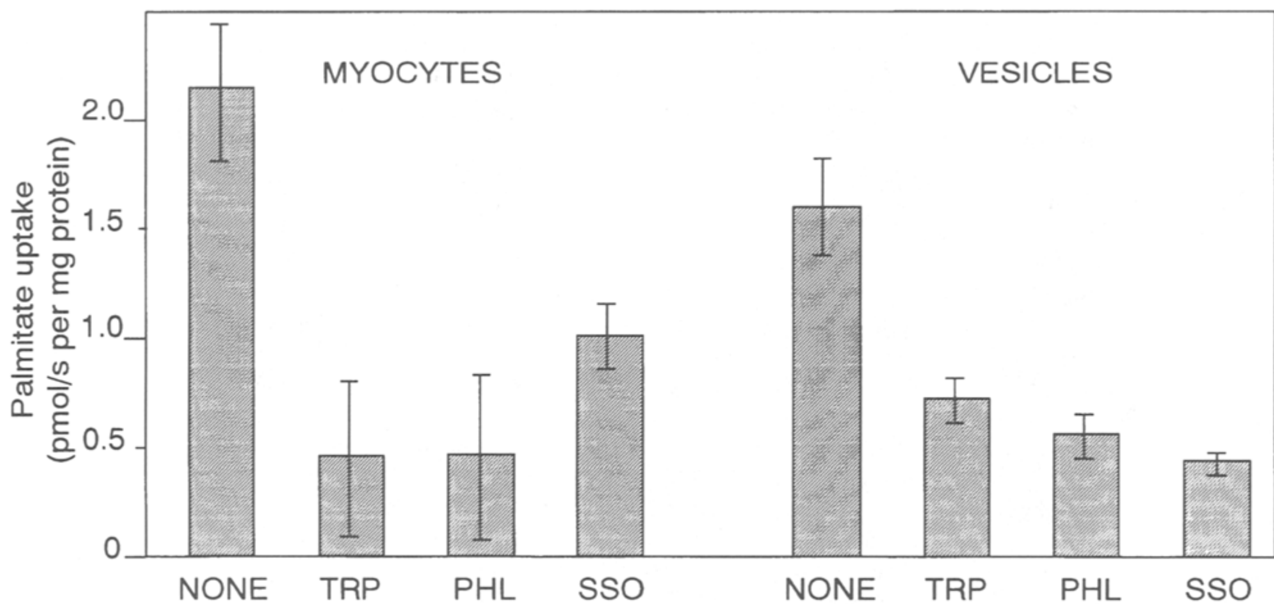

FIG. 2. Influence of plasma membrane-acting agents on palmitate uptake by isolated rat cardiac myocytes (left) or by rat heart giant sarcolemmal vesicles (right). Cells or vesicles were pretreated with trypsin (TRP) or sulfo-*N*-succinimidyloleate (SSO) or incubated in the presence of phloretin (PHL), and the uptake of ^{14}C-labeled palmitate (90 μM) complexed to albumin (300 μM) was monitored at 37°C for 3 min (myocytes) or 15 s (vesicles). Values are expressed as nmol palmitate sequestered per second and per milligram total protein and represent means ± SD for 3–5 experiments. Data obtained from References 7 and 8.

FA metabolism over the capacity of the sarcolemma to translocate FA, or that FA uptake and subsequent metabolism are finely tuned. The ability of metabolism to influence the initial uptake rate (7) strongly argues for this latter fine-tuning. It is important to maintain a low intracellular concentration of FA because these compounds are potentially detrimental for cells if allowed to accumulate (1).

The Na^+ gradient across the plasma membrane, which is the driving force for uptake of a number of nutrients, plays a role in FA uptake into neither heart nor muscle, as this process was unaffected by ouabain (11). This finding is in contrast to liver, where ouabain markedly inhibits FA uptake (12).

Membrane-associated FABP. The identification of several membrane-associated FABP during the last decade provides strong additional evidence for a facilitated transport mechanism. While the kinetic evidence in favor of facilitated transport is still explainable by passive diffusion (13,14), the evidence obtained more recently using molecular biological techniques is convincing for a role of these membrane proteins in the mechanism of cellular FA uptake. Together with the cytoplasmic FABP, these proteins, and their presence in heart and skeletal muscle, form the further focus of this review (Table 1).

Plasma membrane FABP ($FABP_{pm}$). Stremmel and coworkers (15) were the first to isolate a 43 kDa protein from hepatocyte plasma membranes that displayed a high affinity for oleate. This protein appeared to be ubiquitously present in most mammalian tissues, but most prominently in heart, skeletal muscle, brain, liver, and kidney (for review, see Ref. 16). Antibodies raised against this protein inhibited FA uptake in liver (12) and heart (17) up to 70%, providing functional evidence for an involvement in this process. Surprisingly, the amino acid sequence of this protein is homologous to mitochondrial aspartate aminotransferase (mAAT, 16). However, 3T3 fibroblasts transfected with mAAT cDNA demonstrated a plasma membrane localization of this protein rather than a mitochondrial localization. Another important finding was that overexpression of mAAT resulted in augmented FA uptake (16), again in agreement with an important role in cellular FA uptake. The finding that high salt treatment of membranes leads to the extraction of this protein (16) indicates that it is a peripheral membrane protein which therefore most likely acts in the trapping of extracellular FA.

TABLE 1
Proteins Involved in Muscular Long-Chain Fatty Acid Binding and Transport[a]

Protein	Current designation	Molecular mass (kDa)
Extracellular		
Albumin	Albumin	68
Membrane-associated		
Albumin-binding protein	ABP (Alb. BP)	18,31,60
Plasmamembrane FABP	$FABP_{pm}$	43
FA transport protein	FATP	60
FA translocase	FAT (CD36)	88
Intracellular		
Cytoplasmic FABP[b]	H-FABP	14.5
	E-FABP	15
Acyl-CoA binding protein	ACBP	10

[a]Abbreviations: FA, long-chain fatty acid; FABP, fatty acid-binding protein. [b]In muscles both heart-type FABP (H-FABP) and epidermal-type FABP (E-FABP) occur.

FA translocase (FAT)/CD36. The first step toward the identification of a putative FA transporter in adipocytes was made by labeling a highly glycosylated 88 kDa membrane protein with radiolabeled succinimidylesters of FA under conditions whereby these compounds inhibited FA uptake by adipocytes up to 70% (18). The nonglycosylated form of this protein was found to have a molecular mass of 54 kDa. This protein was designated as FAT, and its cloning (from rat) revealed a high degree of amino acid homology (85%) with human platelet glycoprotein IV, also referred to as CD36 (19), suggesting that these proteins are species homologs (20). CD36 is supposed to be involved in platelet aggregation and signal transduction (19). Besides its presence in platelets and endothelial cells (19), FAT/CD36 mRNA is expressed in tissues with a high lipid-metabolizing capacity such as heart, oxidative muscle and fat, but is absent in liver, brain, and kidney (20–22). Differentiation of preadipocytes into adipocytes showed an induction of FAT which was paralleled with an increase in FA uptake (20). In platelets, CD36 was demonstrated to be an integral membrane protein with one or two membrane-spanning regions (23,24). Extrapolation of these findings to the rat implies that FAT is also an integral membrane protein. Strong evidence for a functional role in cellular FA transport was again provided by a transfection study, whereby overexpression of rat FAT/CD36 in fibroblasts resulted in a significantly increased FA uptake rate (25). However, in another study FAT/CD36 was expressed in a heart muscle cell line (H9c2) normally lacking this protein, but this did not lead to altered FA uptake kinetics (26). This discrepancy is discussed below.

FA-transport protein (FATP). Few data are available regarding the most recently discovered candidate for facilitating the transmembrane transport of FA. This transporter, designated as FATP, was identified *via* expression cloning of an adipocyte cDNA library in COS7 cells and subsequent screening for cells exhibiting elevated uptake of a fluorescent FA analog (27). FATP has a molecular mass of 63 kDa and is an integral membrane protein with multiple transmembrane sequences, as predicted from hydropathy plots. The mRNA for FATP is present in most mammalian tissues tested with highest expression levels observed in brain, oxidative skeletal muscle, heart, and fat cells (22,27).

Mode of action of membrane-associated FABP. On the mRNA level, all three membrane-associated FABP are present in heart and muscle tissue. When comparing FA uptake in different muscle tissues using giant sarcolemmal vesicles, uptake was highest in heart, was lower in red oxidative skeletal muscle, and was lowest in white glycolytic skeletal muscle, in agreement with the oxidative capacities of these muscle tissues (8,10). The relative protein contents of both $FABP_{pm}$ and FAT/CD36 in these vesicles paralleled the observed FA uptake rates. On the other hand, the FATP content was lower in heart than in muscle. These observations, together with findings that antibodies against $FABP_{pm}$ as well as SSO, a specific inhibitor for FAT/CD36, were able to block FA uptake by heart and muscle sarcolemmal vesicles, indicate that for FA uptake into muscle both $FABP_{pm}$ and FAT/CD36 might be physiologically important (8,10). Interestingly, the inhibitory actions of SSO and anti-$FABP_{pm}$ antibodies were nonadditive (8), suggesting that $FABP_{pm}$ and FAT/CD36 may cooperate to translocate FA across the sarcolemma. This raises the attractive hypothesis that the peripheral membrane protein $FABP_{pm}$ located at the extracellular leaflet could act as a scavenger of FA in order to facilitate FA adsorption (Step I) while the integral membrane protein FAT/CD36 would function as a translocase (facilitation of Step II).

Analogous to the short-term regulation of glucose uptake into adipose tissue and muscle by insulin, which is due to translocation of GLUT4 from intracellular stores to the plasma membrane, we recently obtained evidence that FA uptake could also be regulated by a translocation event (Bonen, A., personal communication). In sarcolemmal vesicles from muscles that are electrically stimulated for 25 min, there is an increase in FA uptake concomitant with an increase in FAT/CD36, but not $FABP_{pm}$. FAT/CD36 appears directly responsible for the increased FA uptake since SSO can block this increased uptake completely. Since the duration of the period of muscle contraction is too short for *de novo* protein synthesis, this increase in sarcolemmal FAT/CD36 could only be explained by protein translocation. Interestingly, there are two independent reports claiming that rat FAT (at one extracellular site; Ref. 28) or human CD36 (at two cytoplasmic sites; Ref. 24) are palmitoylated in a reversible manner. Since acylation of proteins is often associated with a change in subcellular localization, one might speculate that muscle contractions induce signaling pathways stimulating protein-acylating enzymes to palmitoylate CD36, which in turn is translocated to the sarcolemma where it accepts FA from $FABP_{pm}$. A candidate intracellular store could be the caveolae, because in platelets this is the primary subcellular fraction where CD36 is located (29). FAT/CD36 being possibly translocated while $FABP_{pm}$ is not makes FAT/CD36 the primary site of control in the FA uptake process.

It must be stressed, however, that FATP, although probably not involved in FA uptake by muscle tissues, could be of functional importance in tissues other than heart and skeletal muscle, for instance in adipose tissue which is involved both in uptake and delivery of FA from and to the bloodstream, or otherwise in brain and liver which lack FAT/CD36.

Intracellular FABP. The intracellular FABP consist of a family of 14–15 kDa proteins with the property to bind hydrophobic ligands such as FA with high affinity. There are at least 13 members of this protein family, including four retinoic acid-binding proteins, which mutually display amino acid sequence homologies of 15–70% (for review, see Refs. 2 and 30). However, their tertiary structures share a remarkable similarity and consist of a clam shell-like structure with the lipid ligand bound in between the two halves of the clam. Each type of FABP displays a specific tissue distribution pattern, which likely relates to the specific FA metabolic needs of the respective tissues. In heart and skeletal muscle cells the most predominantly present FABP isoform is referred to as heart-type FABP (H-FABP). Myocytes also contain, in con-

siderably lesser amounts, a second FABP type which is also found in epidermal cells, and therefore designated as epidermal-type FABP (E-FABP). There is a positive correlation between the occurrence of H-FABP and the oxidative capacity of the muscle tissue (heart > red muscle > white muscle), indicating a functional involvement of these proteins in muscle lipid metabolism (2). Intracellularly also occurs an acyl-CoA binding protein, which binds the FA after activation to their acyl-CoA esters (Fig. 1 and Table 1) (2).

Functions of intracellular FABP. The proposed primary function of cytoplasmic FABP is to serve as transport vehicle for FA from the sarcolemma, through the cytoplasm to their site of metabolic conversion, i.e., acyl-CoA synthetase at the cytoplasmic leaflet of the outer mitochondrial membrane or endoplasmic reticulum. This notion is based on three independent lines of evidence. First, intracellularly sequestered fluorescent FA were found to be bound by FABP (31). Second, theoretical studies demonstrated that the aqueous solubility of FA is enhanced about 700-fold in the presence of FABP which leads to a 17-fold increased diffusional flux of FA (32). Third, studies monitoring the transfer of fluorescent FA between FABP and phospholipid bilayers indicate that FABP interacts with membranes through collisional transfer, thus without the FA being exposed to an aqueous environment (33). Furthermore, when in similar studies FABP was used as FA donor and phospholipid vesicles as acceptor, it appeared that the presence of acidic phospholipids within these vesicles enhanced the transfer rate of FA, which compounds likely interact with positive lysine residues in the portal region of the FABP molecule (34). Because the mitochondrial membrane is enriched in cardiolipin, these negatively charged phospholipids could be important in directing the intracellular transport of FA by FABP toward mitochondria.

Other functions of cytoplasmic FABP, but related to the former, may include the enhancement of cellular FA uptake by (i) extracting FA from the sarcolemma (desorption) and by (ii) trapping FA that are taken up by cells in order to maintain their intracellular nonprotein bound concentration at a low level (1,2). Transfection studies in which liver-type FABP was expressed in fibroblasts normally lacking this protein resulted in an enhanced FA uptake (35). However, expression of H-FABP in COS7 cells did not affect FA uptake rates (27). Currently, the transgenic mouse model is being used to elucidate the function of FABP. The first FABP to be knocked out was the adipocyte-type lipid-binding protein, but this resulted in a compensatory expression in adipose tissue of E-FABP (36). More recently, an H-FABP knock-out mouse was generated by Binas and coworkers (37). In contrast to the adipocyte-type lipid-binding protein knock-out mice, no compensatory upregulation of other types of cytoplasmic FABP was observed in the H-FABP knock-out model. An initial search for a phenotype revealed that these mice died with great frequency upon strenuous exercise (37). Studying FA utilization by heart homogenates showed no alteration of the tissue capacity for β-oxidation. However, in intact cardiac myocytes, both FA uptake and oxidation were depressed by about 50% when compared to cardiac myocytes isolated from hearts of control rats, strongly suggesting that H-FABP is required for an efficient intracellular utilization of FA (38).

There is also evidence that H-FABP is involved in cell growth and differentiation and in certain signal transduction pathways. For a further discussion of these putative functions, the reader is referred to recent reviews (2,30).

Molecular mechanism of cellular FA uptake. It is becoming increasingly evident that myocytes, and also other mammalian cells, govern passage of FA across the plasma membrane *via* distinct protein–protein interactions. In a first step of the putative mechanism, FA are captured from the albumin–FA complex by $FABP_{pm}$. This process could be facilitated by assistance of albumin-binding proteins which may serve as docking place for the albumin–FA complex and may accelerate the dissociation of FA (Fig. 1). The sarcolemma of cardiac myocytes is known to contain high-affinity albumin-binding sites (39). More detailed investigations led to the identification of three proteins, gp18, gp30 and gp60, showing high affinity for modified albumin species and which could function as albumin receptors (39,40). Because studies on the kinetics of palmitate uptake demonstrated a K_m for albumin of 23 μM (7), it is unlikely that *in vivo*, i.e., at physiological albumin concentrations of 300–600 μM, albumin-binding proteins could be of regulatory importance. However, they could play a permissive role by assisting the FA–albumin complex to diffuse through the unstirred fluid layer surrounding the cells. This increase in concentration of the FA–albumin complex either would lead to an increase in the concentration of unbound FA which are then extracted by $FABP_{pm}$ or would enable the direct transfer of FA from albumin to $FABP_{pm}$ without the need for these FA to enter into the aqueous phase. Subsequently, $FABP_{pm}$ might transfer the FA to FAT/CD36 which, in turn, mediates the translocation of FA across the membrane and possibly also their binding to cytoplasmic FABP. This latter concept is supported by the observation of a physical contact between FAT/CD36 and FABP (41).

A protein-mediated transport of FA across the membrane could be of importance in directly and efficiently targeting FA to their site(s) of intracellular processing, and also in protection of cells against the potentially toxic effects of (unesterified) FA. Such controlled FA uptake presumably would be more difficult to realize in case FA would partition between albumin and membrane phospholipids based on their physicochemical properties, then translocate by flip-flop to the inner leaflet of the bilayer before being bound by cytoplasmic FABP. Thus, while passive diffusion of FA into cells contributes to the mechanism of cellular FA uptake, in muscle the bulk of sarcolemmal FA translocation most likely occurs by involvement of membrane-associated FABP, possibly assisted by albumin-binding protein(s) without regulatory function.

It will be a challenge in the coming years to investigate the nature of the interactions between the various proteins involved in muscle FA uptake: albumin-binding proteins, $FABP_{pm}$, FATP, FAT/CD36, and H-FABP. Issues to be solved

include whether at some stage during the FA uptake process these proteins actually are in physical contact with each other, and whether yet other proteins are involved. Another matter worthy to be investigated in more detail is the nature of the intracellular translocation of FAT/CD36 and to what extent extracellular factors can influence this translocation.

ACKNOWLEDGMENTS

Studies performed in the authors' laboratories were supported by a Collaborative Grant from the Natural Sciences and Engineering Research Council of Canada (NSERC), by the Medical Research Council of Canada, and by the Netherlands Heart Foundation (grant NR. 95.190).

Extracellular fatty acid-binding protein (Ex-FABP) is a 21-kDa protein developmentally regulated in chick embryo, first observed *in vitro* in chondrocytes at a late stage of differentiation as a protein secreted into the culture medium (1). Immunolocalization performed in cartilage tissues with polyclonal antibodies obtained against the purified protein showed that the protein is present *in vivo* in chicken embryo tibia in hypertrophic chondrocytes of the growth plate at the border between hypertrophic cartilage and newly formed bone, in the cartilage surrounding marrow cavities and blood vessels, and in the epiphysial prearticular cartilage. The complete amino acid sequence of the protein, obtained by combining protein and nucleotide sequence data, assigned the protein to the superfamily of lipocalins or lipophilic molecules carrier proteins (2). The recombinant protein was obtained in the baculovirus system, and studies were performed to identify a possible ligand. By lipidex binding assay with radioactive lipophilic compounds, a specific fatty acid binding to the protein was shown and a preferential binding of long-chain unsaturated fatty acids was observed (3). Calculated dissociation constant was 2×10^{-7} M for unsaturated fatty acids and 5×10^{-7} M for stearic acid. Short-chain fatty acids did not bind to the protein. Other hydrophobic molecules as retinoic acid, retinol, progesterone, prostaglandins, and long-chain alcohols and aldehydes did not bind to the protein. It is widely accepted that free fatty acids in blood are transported by albumin. Ex-FABP is present in chicken serum and represents the first extracellular protein able to selectively bind and transport fatty acids in extracellular fluid and serum. Ex-FABP could represent in blood the high-affinity, low-capacity, specific binding protein that transports fatty acids to target organs while albumin could represent a low-affinity, high-capacity storage protein for fatty acids. Ex-FABP is also produced by peripheric granulocytes. We performed studies aimed to elucidate a possible role of the protein during chicken embryo development, and we observed that Ex-FABP is expressed in the forming myotubes both *in vitro* and *in vivo*. The presence of the protein and of the mRNA was observed in newly formed myotubes at early stages of chick embryo development by immunohistochemistry and by *in situ* hybridization. At later stages of development, myofibers still expressed both the mRNA and the protein. Ex-FABP expression was observed also in the developing myocardium and in the muscular layer of large blood vessels. In agreement with these findings, an initial expression of the mRNA and protein secretion by cultured chicken myoblasts were observed only after the onset of myoblast fusion. Double immunofluorescence staining of these cultured cells revealed that multinucleate myotubes were stained by antibodies directed against both the Ex-FABP and the sarcomeric myosin, whereas immature myotubes and single myoblasts were not. When added to cultured myoblasts, antibodies against the Ex-FABP induced a strong enhancement of the production of the same protein. In all experiments some cell damage and a transient impairment of myotube formation were also observed. The finding that the continous removal of the Ex-FABP from the culture medium of myoblasts, due to the formation of immune complexes, resulted in an overproduction of the protein suggests a feedback (autocrine) control during myotube differentiation and maturation. We propose that the requirement for increased transport and metabolism of free fatty acid released from the membrane phospholipids and storage lipids, mediated by Ex-FABP, may be essential during differentiation of multinucleated myotubes, or that an increased local amount of fatty acids and metabolites may act as a local hormone in tissues differentiating and undergoing morphogenesis.

Molecular Modeling and Experimental Confirmation of Selective Mobilization of Polyunsaturates from Triacylglycerols

C.L. Broadhurst[a,*], W.F. Schmidt[a], and S.C. Cunnane[b]

[a]NMR and Environmental Chemistry Laboratories, U.S. Department of Agriculture ARS, Beltsville, Maryland 20705 and [b]Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, Ontario M5S 3E2, Canada

Research has shown that polyunsaturated fatty acids (PUFA) are selectively mobilized from adipose tissue during energy deprivation or weight cycling. In rats, weight cycles of 24 h fasting followed by 72 h refeeding resulted in stochastic loss of both linoleate and α-linolenate (1). These two fatty acids (FA) are oxidized at levels greater than intake (2). Very low calorie diets in obese female humans were found to result in selective loss of α-linolenate, despite supplementation with this FA (3,4). *In vitro* and *in vivo* studies of relative mobilization of FA from adipose tissue led Raclot and Groscolas (5,6) to formulate the following empirical observations: relative mobilization of FA from triacylglycerols (TG) increases with (i) decreasing chain length at a given degree of unsaturation; (ii) increasing unsaturation at a given chain length; and (iii) double bond(s) closer to the methyl end of the carbon chain.

Apparently more saturated, longer-chain TG structures are more likely to be stored but less likely to be mobilized, i.e., "first in, last out," but there is no rigorous physical chemical model which accounts for these observations. We present nuclear magnetic resonance (NMR) data from obese and normal mouse lipids and 3-D energy-minimized TG structures that demonstrate that storage of more saturated FA and mobilization/oxidation of PUFA are energetically favorable from a molecular standpoint.

Obese and normal mice were fed identical standard diets with 10% fat containing equal proportions of saturated fat (SFA), monounsaturated fat (MUFA), and PUFA. Extracted lipids were examined by gas chromatography and 2-D $^{13}C/^{13}C$ NOESY chemical exchange NMR spectroscopy. Normal mouse fat contained almost entirely linoleate, oleate, and palmitate in a 1:1:1 LOP (linoleate, oleate, palmitate) ratio. Obese mouse fat was enriched in oleate by a factor of two compared to normal mouse fat (i.e., 1:2:1 LOP), and obese mouse fat was more densely packed. All 27 3-D energy-minimized TG structures of palmitate, oleate, and linoleate were calculated. For *Z*α,*Z*β,*E* palmitate is strongly preferred in *E*, followed by linoleate, and then oleate. Obese mice had more oleate and less linoleate in *Z*α than normal mice. The lowest energy average structure for 1:1:1 LOP was a mixed TG with *Z*α,*Z*β,*E*, linoleate, oleate, and palmitate, respectively. At 100 ms mixing time in the 2-D NMR exchange experiment, obese mouse fat showed characteristic cross peaks. These cross peaks and the modeling both indicated that a head-foot-head-foot TG tetramer is the most likely base unit for extended adipose storage.

We constructed 3-D energy-minimized TG model structures to test the results of References 5 and 6. We considered that higher steric energies would lead to an increased tendency toward mobilization/oxidation as opposed to storage. The summed energies of three free FA (FFA) were much higher than those of the TG structures, especially for SFA, and in general FFA were not good test models. Pure SFA TG energies decreased uniformly from 8- to 20-carbon chain lengths (24.2–15.0 kcal/mol). Increasing from 2 to 6 double bonds in 22:xn-3 led to little change in energy in the FFA (19.6–21.5 kcal/mol). However, various TG structures with 18:0 and 22:6n-3 docosahexaenoic acid (DHA) increased in energy from *Z,Z,E* 18:0, 18:0, 22:6n-3 to *Z,Z,E* 22:6n-3, 22:6n-3, 18:0 (33.5–49.9 kcal/mol). DHA is a spiral molecule, and the structure/energy relationships of TG with DHA are complex and not predictable from simple progressions based on the chemistry of the FFA involved. The *Z,Z,E* 18:0, 18:0, PUFA structure is fairly realistic for adipose storage in humans consuming normal diets, and in models using α-linolenate (18:3n-3) instead of DHA, 18:0, 18:0, 18:3n-3 ac-

tually had a higher energy than 18:0, 18:0, 22:6n-3. This might account for the observed preferential loss of α-linolenate (1–4).

The double bond in 18:1 was placed in the n-3, n-6, and n-9 positions. Again, the energies for even a single FFA were nearly as high as the TG high were very dissimilar, but in TG *Z,Z,E* 18:0, 18:0, 18:1, energies increased from n-3 to n-9 (18.5 to 24.9 kcal/mol), opposite the trend from References 5 and 6. However, the structure of 18:1n-9 is unique in that the MUFA chain folds back on itself, allowing for packing nearly as efficient as a pure SFA TG in tetramer units. This may account for the prevalence of oleic acid in the obese mouse fat, as well as in storage lipids in plants.

It is concluded that the energetics of TG tetramers as a mimimum structural unit play a fundamental role in relative mobilization of FA from adipose tissue. Describing FA mobilization and kinetics of lipolysis without considering the extended 3-D structure of adipose and the packing of TG chains is likely to provide results which are too simplistic.

Albumin Interferes with the Uptake Metabolism of Arachidonic Acid by Human Leukocytes

Marina Dadaian* **and Pär Westlund**
Department of Woman and Child Health, Division of Reproductive Endocrinology, Karolinska Hospital, S-171 76 Stockholm, Sweden

Arachidonic acid in human neutrophils is metabolized primarily *via* the 5-lipoxygenase (5-LO) pathway which leads to the formation of leukotriene A_4 (LTA_4), the precursor of the potent chemotactic factor for leukocytes, leukotriene B_4 (LTB_4), formed in neutrophils. The release of arachidonic acid through the action of phospholipases within the cells is believed to be a limiting step in the production of LTB_4. Another source of arachidonic acid or LTA_4 for the biosynthesis of LTB_4 in neutrophils might be through transcellular metabolism of the precursors released from other cells.

Little is known about how arachidonic acid or other intermediates such as LTA_4 enter the cells. Albumin together with the plasma lipoproteins is the major carrier of fatty acids in the circulation, and in the present study we addressed the question of how albumin influences the conversion of arachidonic acid to LTB_4 in human neutrophils.

Polymorphonuclear leukocytes (PMNL), obtained from buffy coat, were incubated with 10 μM [1-^{14}C]arachidonic acid in phosphate buffered saline in the presence or absence of 600 μM albumin and with or without stimulation by the calcium ionophore A23187 for 1 h. In another set of experiments, the cells were prelabeled with arachidonic acid for 1 h and then incubated for another 60 min using the conditions described above. The product profile was recorded both by two-dimensional thin-layer chromatography in combination with autoradiography and by high-performance liquid chromatography with ultraviolet and radioactivity monitoring.

When the cells (1×10^7 PMNL per mL) were stimulated in the absence of albumin, both LTB_4 and ω-hydroxy-LTB_4 were formed. However, in the presence of albumin, no 5-LO metabolites were detected and around 75% of the added arachidonic acid was found to be unmetabolized compared to 3% in the absence of albumin. The incorporation of arachidonic acid into cellular phospholipids and triglycerides was not influenced by albumin.

When a concentrated suspension of neutrophils (10^9 PMNL per mL) was incubated under the same conditions, we observed a different metabolic pattern of arachidonic acid. Under all conditions, negligible amounts of free arachidonic acid were found. With unstimulated cells in the presence of albumin, the major part of the radioactivity was found in the fraction containing phospholipids and triglycerides. Some formation of 12-hydroxyeicosatetraenoic acid (12-HETE) was also observed due to contaminating platelets. When the cells were stimulated with ionophore, the major part (63%) of the arachidonic acid was converted to 12-HETE, indicating that 12-LO has a higher capacity to utilize exogenous arachidonic acid compared to the 5-LO. In this case 12-LO might act as a drainage pool for excess amount of arachidonic acid.

Since albumin seems to have a major influence on the conversion of exogenously added arachidonic acid, it was of interest to study if albumin also interfered with arachidonic acid release and metabolism if the source of arachidonic acid was cellular lipids. Leukocytes prelabeled with arachidonic acid were incubated for 1 h under the same conditions as described above. The main part of the radioactivity was associated with cellular lipids under all conditions. However, the level of free arachidonic acid was doubled when calcium ionophore and albumin were present in the incubations.

It is known that the synthesis of LT occurs in the nuclear envelope, and upon activation 5-LO translocates from the cytosol to the nuclear membrane to associate with 5-lipoxygenase-activating protein. Moreover, the cytosolic phospholipase A_2 was reported to translocate to the nuclear membrane and the endoplasmic reticulum upon activation. The source from which arachidonic acid arises during the activation was not elucidated. However, a number of authors report a rapid remodeling of arachidonic acid when the cells are stimulated. From our experiments, it is clear that exogenous arachidonic acid bound to albumin cannot serve as a precursor for LT synthesis in the leukocytes. However, it seems to be a good substrate for the 12-LO in platelets during the same conditions. Furthermore, prelabeling of the cells with arachidonic acid and stimulation of the cells without any addition of exogenous arachidonic acid did not give any detectable amounts of radioactive LTB_4 and LTB_4 metabolites. This further points out the importance of albumin as a regulator of the availability of arachidonic acid as a substrate for LT biosynthesis.

Elongation and Trafficking of Arachidonate in Lipids of Vascular Smooth Muscle Cells

M. Breton, A. Cane, K. Koumanov, and O. Colard*

UPRES-A CNRS 7079, Biochimie, CHU Saint-Antoine, 75012 Paris, France

Inflammatory cells surrounding vascular smooth muscle cells (VSMC) in atherosclerotic lesions are susceptible to release, in addition to arachidonate metabolites, high amounts of free arachidonic acid (20:4). It was then of interest to analyze the capacity of VSMC to protect themselves against excess 20:4. The A7r5 VSMC line, derived from rat embryo aorta, was cultured in Dulbecco modified Eagle medium-fetal calf serum 10% (control cells) or supplemented with 15 and 45 μM 20:4. The fatty acid composition of triacylglycerols and phospholipids was analyzed by gas chromatography–mass spectrometry after alkaline hydrolysis. The phospholipid subclasses were separated by thin-layer chromatography after benzoylation of their di-radylglycerol derivatives. Metabolic transformation of $[^3H]$20:4 into $[^3H]$22:4 and their release in chase medium were investigated using high-performance liquid chromatography on line with a radioactive counter.

The 20:4 content of phospholipids increased by 2–3 times when cells were supplemented with 15 μM 20:4 and did not change very much with higher 20:4 concentration. The 22:4, the elongated product of 20:4, incorporated in phospholipids represented around 10% of esterified 20:4. Among the phospholipids, the 22:4 fatty acid was preferentially incorporated into phosphatidylethanolamine, particularly the alkylacyl species. The 20:4 and 22:4 increases in phospholipids were at the expense of other unsaturated fatty acids, the total amount of phospholipids being not modified. The 20:4 fatty acid was not incorporated into phosphatidylcholine as di-20:4 species by *de novo* pathway, in contrast with migrating inflammatory cells, although its content in polyunsaturated fatty acids (PUFA) was fourfold increased. It then appears that, in VSMC, 20:4 and 22:4 are incorporated into phospholipids only by the remodeling pathway

The amount of triacylglycerols did not change with 15 μM 20:4 and increased by 2.5 times when cells were supplemented with 45 μM 20:4. In these newly synthesized triacylglycerols, the elongation product represented more than 30% of esterified 20:4, and PUFA content of triacylglycerols was then higher than PUFA content of phospholipids from control cells. It is likely that di- or tri-PUFA species are synthesized through *de novo* pathway involving fatty acid esterification into phosphatidic acid and diglyceride formation. The incorporation of 20:4 into triacylglycerols only in the presence of high 20:4 concentration is consistent with triacylglycerols being a storage pool protecting cells from 20:4 that is in excess. However, 20:4 can also be transferred from triacylglycerols to phospholipids and utilized as precursor of lipid mediators. Therefore, we investigated the fate of 20:4 and its elongation product, from triacylglycerols. Cells were prelabeled with 45 μM $[^3H]$20:4, then chased. The 20:4 decreased rapidly in triacylglycerols and was not transferred to phospholipids. The 20:4 is thus released directly from triacylglycerols probably by triacylglycerol lipase activity, which is specific for 20:4, as the elongation product was retained a longer time than 20:4 in triacylglycerols.

The elongation of 20:4 into 22:4 and high synthesis of triacylglycerols, together with incorporation of 20:4 into phospholipids only by the remodeling pathway, and absence of PUFA transfer from triacylglycerols to phospholipids appear to be specific ways for VSMC to protect themselves against excess 20:4.

The Effect of n-3 Fatty Acids on Leukotriene Formation from Neutrophils in Patients on Hemodialysis

K. Løssl[a], H.A. Skou[a], J.H. Christensen[b], and E.B. Schmidt[a,*]

[a]Department of Medicine, Hjørring/Brønderslev Hospital, DK-9800 Hjørring, Denmark, and [b]Department of Nephrology, Aalborg Hospital, DK-9000 Aalborg, Denmark

Dietary intake of long chain n-3 polyunsaturated fatty acids, derived from fish, modulates several measures of leukocyte reactivity in healthy volunteers and in various patient groups. In the present study we evaluated the effect of dietary supplementation with n-3 fatty acids on *ex vivo* formation of leukotrienes B_4 and B_5 from stimulated neutrophils in patients with chronic renal failure. Sixteen patients treated with maintenance dialysis therapy three times a week at the Department of Nephrology, Aalborg Hospital, were included. Eight patients (five men and three women with a mean age of 53 yr) were randomized to daily supplementation with 5.2 g of n-3 fatty acids, while eight subjects (four men and four women with a mean age of 56 yr) were randomized to a similar amount of olive oil used as placebo. The oils were delivered in identical capsules, and the patients received 8 capsules/d for 12 wk in a double-blind study design. Neutrophils were isolated from whole blood before and after the supplements and were stimulated with calcium-ionophore. Leukotrienes B_4 and B_5 were measured in the supernatants by high-performance liquid chromatography. The two groups of patients were well-matched and had similar baseline levels of leukotrienes. In the placebo group there was a 2% increase in leukotriene B_4 formation, while in contrast n-3 fatty acids led to a 34% decrease in formation of leukotriene B_4. Comparisons between changes in the two groups revealed a highly significant statistical difference ($P < 0.001$, Mann-Whitney U-test). Similarly, production of leukotriene B_5 was unaltered by olive oil and increased by more than five times in the patients randomized to n-3 fatty acids ($P < 0.001$, Mann-Whitney U-test). Dietary supplementation with n-3 polyunsaturated fatty acids thus significantly reduces formation of leukotriene B_4 from activated neutrophils at the expense of leukotriene B_5. This is of potential interest because leukotriene B_4 has very powerful proinflammatory effects, with leukotriene B_5 possessing less than 10% of such effects. Introducing n-3 fatty acids into the diet may therefore lead to important antiinflammatory effects in patients treated with dialysis. Furthermore, increasing evidence exists for the role of inflammation in atherogenesis, and n-3 fatty acids may therefore reduce the risk of atherothrombotic complications in this patient group known to be at a very high risk of vascular disease. Clinically controlled trials are, however, necessary to document such a possible clinical benefit of n-3 fatty acids.

n-3 Fatty Acids in the Prevention of Cardiac Arrhythmias

Alexander Leaf[a,*], Jing X. Kang[a], Yong-Fu Xiao[b], and George E. Billman[c]

Departments of Medicine, [a]Massachusetts General Hospital, [b]Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, Massachusetts, and Department of Physiology, [c]The Ohio State University, Columbus, Ohio

ABSTRACT: In animals and probably in humans n-3 polyunsaturated fatty acids (PUFA) are antiarrhythmic. A report follows on the recent studies of the antiarrhythmic actions of PUFA. The PUFA stabilize the electrical activity of isolated cardiac myocytes by inhibiting sarcolemmal ion channels, so that a stronger electrical stimulus is required to elicit an action potential and the relative refractory period is markedly prolonged. This appears at present to be the probable major antiarrhythmic mechanism of PUFA.

McLennan *et al.* reported (1,2) that feeding rats a diet in which the fat content was largely saturated or monounsaturated fats resulted in a high incidence of irreversible ventricular fibrillation (VF) when their coronary arteries were subsequently experimentally ligated. When vegetable oils were the major source of the dietary fat, there was a reduction in arrhythmic mortality by some 70%. With tuna fish oil, however, they reported irreversible ventricular arrhythmias to be completely prevented with or without reflow to the ischemic myocardium. They confirmed their findings in marmosets (3). These striking observations led us to pursue the possible mechanism(s) for such an antiarrhythmic action of the fish oil.

To see first if we could confirm their findings, we studied a canine model of sudden cardiac death. A surgically induced myocardial infarction was produced by ligating the left main coronary artery, and an inflatable cuff was placed around the left circumflex artery. The dogs were allowed about a month to recover from the surgery and their myocardial infarction during which they were trained to run on a treadmill. The animals were then screened for susceptibility to a fatal ventricular arrhythmia when the left circumflex artery was occluded while they were running on a treadmill. About 60% of animals were found susceptible and these were the dogs studied. Once an animal is "susceptible," it remains susceptible on further exercise-ischemia trials. In 10 of the 13 such dogs, infusion of an emulsion of a concentrate of the fish oil free fatty acids, polyunsaturated fatty acids (PUFA) infused intravenously just prior to the exercise-ischemia test prevented the fatal VF ($P < 0.005$) (4). In the control exercise-ischemia tests 1 wk prior to the test with the infusion of the PUFA, and 1 wk following that test all animals developed ischemia-induced VF, requiring prompt defibrillation. In additional studies, we found that pure eicosapentaenoic acid (20:5n-3) or docosahexaenoic acid (22:6n-3), or α-linolenic acid (18:3n-3) are apparently equally antiarrhythmic in this dog preparation. We purposely infused the n-3 fatty acids rather than fed the dogs fish oil to be certain exactly what ingredient of the fish oil prevented the fatal VF. In dietary studies invariably several things must change. When the free fatty acids were infused intravenously just prior to producing the ischemia and preventing the fatal VF, then that effect convincingly results from what has been just infused.

Having confirmed directly the findings of the earlier workers, we wanted to determine the mechanism of this striking antiarrhythmic effect of n-3 PUFA. To have a simple, available model to study in which we could visualize the production of arrhythmias and possible prevention of the arrhythmias by the PUFA, we studied cultured neonatal rat cardiac myocytes (5). Hearts are quickly removed from 1- to 2-d-old decapitated rat pups. The cardiac cells are separated with trypsin digestion, and the cells are plated on microscope cover slips. By the second day of culture, one sees clumps of growing myocytes of a few to several hundred cells. Each group of cells is contracting spontaneously, rhythmically, and synchronously. With a microscope, a video camera, and an edge monitor we can focus on a single myocyte in a clump of cells and see and record the rate and amplitude of contractions. With this *in vitro* model we produced arrhythmias with a number of chemicals known to produce fatal VF in humans: elevated extracellular [Ca^{2+}] toxic levels of the cardiac glycoside ouabain (5), excessive β-adrenergic agonist isoproterenol (6), lysophosphatidylcholine, acylcarnitine, and even the calcium inophore A23187 (7). With each agent a tachyrhythmia was induced. If the PUFA were added to the fluid perfusing the isolated myocytes before the arrhythmogenic toxins were administered, they would in every instance prevent the expected arrhythmia. If the arrhythmia was first induced by the toxin and the PUFA added to the superfusate in the continued presence of the toxin, within a short time the arrhythmia would be terminated and the cells would commence beating again regularly. Then in the continued presence of the toxin, the PUFA can be extracted from the cells with delipidated bovine serum albumin and the

arrhythmia promptly resumes. These results indicated that it was only the free PUFA partitioning into the membrane phospholipids that prevented the arrhythmias. If the fatty acid had been covalently bound to any constituent in the membrane, we would not have been able to extract them from the membrane. When the ethyl ester or the triglyceride of the PUFA was tested, they were not antiarrhythmic in this model; the free carboxylic acid group is essential for this antiarrhythmic action.

We then tested which PUFA were antiarrhythmic (5). Both the n-3 and n-6 classes of PUFA are antiarrhythmic, but arachidonic acid (20:n-6) was anomalous. Cyclooxygenase metabolites of arachidonic acid cause arrhythmias (8). For this reason we have recommended that only the n-3 PUFA should be tested in clinical trials as antiarrhythmic agents.

The structural requirements for an antiarrhythmic compound that acts in the manner of these PUFA are a long acyl or hydrocarbon chain with two or more C=C unsaturated bonds and a free carboxyl group at one end. With this guideline we found all-*trans*-retinoic acid also to be specifically antiarrhythmic (9).

The antiarrhythmic action of the PUFA results from their effects on the electrophysiology of cardiac myocytes (10). They cause slight hyperpolarization of the resting or diastolic membrane potential and an increase in the threshold voltage for the opening of the Na^+ channel. This results in an increased depolarizing stimulus of about 50% required to induce an action potential. In addition, the relative refractory period, phase 4 of the cardiac cycle, is prolonged by some threefold. These two effects on every myocyte in the heart would account for the increased electrical stability and resistance of the heart to lethal arrhythmias.

These effects in turn result from an action of the PUFA to modulate the conductance of ion channels in the plasma membranes of the heart cells. By whole-cell voltage clamp measurements, we found that the PUFA inhibit the voltage-dependent Na^+ (I_{Na}), (11), K^+ (the transient outward current, I_{to}, and the delayed rectifier current, I_K, but not the inward rectifying current, I_{K1}) (Xiao *et al.*, unpublished results), as well as the L-type Ca^{2+} current, $I_{Ca,L}$, (12). In the case of the Na^+ channels we showed that only the antiarrhythmic PUFA displace ^{3}H-batrachotoxinin-20-α-benzoate bound to the sodium channel pore protein noncompetitively (13). This is similar to our finding that PUFA noncompetitively displaced ^{3}H-nitrendipine (a specific L-type calcium channel antagonist) from its binding site at the external pore of the calcium channel protein (14). Because the displacement in each case, though specific, was noncompetitive, we cannot resolve the urgent question of whether the PUFA bind specifically and primarily to ion channel proteins directly or interact primarily with the phospholipid of the cell membranes to allosterically change the conformation of transmembrane protein channels.

In the cultured neonatal rat heart cells, the PUFA shifted the steady-state potential for inactivation of the Na^+ channels to more hyperpolarized potentials (11). A recent study of the effects of the PUFA on the Na^+ currents in α-subunits of the human myocardial Na^+ channel expressed in human embryonic kidney cells (15) showed no effect on the activated opening of the Na^+ channel. The only effect seen was a large shift in the hyperpolarization of the membrane potential necessary to close the Na^+ channel. Attaining a closed resting, but activatable, state is required before the channel is again susceptible to initiation of a new action potential. This makes the I_{Na} voltage-dependent in the presence of the PUFA, as we found (11,15). Myocytes apparently must maintain their normal resting membrane potentials in order to avoid the inhibitory actions of the PUFA on I_{Na}.

These effects primarily on inhibition of the Na^+ and Ca^{2+} currents, we now think, may account for the potent antiarrhythmic effects of these PUFA. In ischemic myocardium, myocytes become slightly depolarized due to functional reduction of the Na,K-ATPase pump. These cells become "hyperexcitable" and subject to induction of premature action potentials and arrhythmias. Their resting membrane potential is more positive and closer to the threshold for the gating of the I_{Na} so that any small depolarizing current may elicit a premature action potential and initiate an arrhythmia. Because they have a reduced resting membrane potential, it is just these ischemic "hyperexcitable" myocytes that are eliminated quickly from further mischief by PUFA. After their first activation, the necessity for a more negative resting potential in order to revert the channel to an activatable resting state makes the channel unresponsive and eliminates it as an arrhythmogenic risk.

The potent inhibitory action of the PUFA on L-type Ca^{2+} currents, $I_{Ca,L}$ (12), complements this action on I_{Na}. Significant inhibition of $I_{Ca,L}$ is observed at 10 nM Ca^{2+} in the medium, bathing the human cardiac Na^+ channel (15). This effect prevents triggered arrhythmias induced by overload of cytosolic Ca^{2+} and increased cytosolic Ca^{2+} fluctuations. Most arrhythmogenic cardiotoxins may induce fatal ventricular tachycardia (VT) or VF by triggered after-potentials from excessive cytosolic Ca^{2+} which are prevented by the PUFA., e.g., cardiac glycosides, lysophosphatidylcholine, excessive catecholamines, thromboxane A_2, etc.

Evidence that PUFA will prevent lethal arrhythmias in patients is slim, but two secondary prevention trials, which unexpectedly showed prevention of ischemia-induced sudden cardiac death, are encouraging. One dietary study (16) was a prospective, randomized, single-blinded, secondary prevention trial which compared the effect of a Mediterranean α-linolenic acid-rich diet to the usual "prudent" diet. The subjects on the more fat-restricted experimental diet receiving the α-linolenic acid (18n-3) showed a remarkable reduction in mortality and morbidity of some 70%, including prevention of sudden death. The other study (17) was also a randomized, prospective, secondary prevention trial in which advice to eat oily fish two or three times weekly was compared with no such advice. This study did not record arrhythmic deaths. It, however, found no reduction in new events but a 29% reduction in mortality, suggesting a reduction in sudden deaths which constitute 50 to 60% of the acute mortality from heart attacks (18). In both studies the survival curves showed a very

early beneficial separation of the experimental vs. control groups, quite unlike the 2 yr required in the cholesterol-lowering trial (19) before the lower mortality was significant. A case-control study (20) reported an inverse relationship between fish consumption and sudden cardiac death, suggesting an antiarrhythmic effect from ingestion of fish. The Indian infarct survival study reported a significant reduction in arrhythmic and total cardiac deaths in a randomized, blinded, controlled study in patients fed fish oil 1.08 g/d for 1 yr (21). Reanalysis of the Physicians Health Study (22) reported a 52% reduction of risk of sudden cardiac death in subjects eating fish at least once a week.

In conclusion, it is apparent that there exists a basic control of cardiac function by common dietary fatty acids which has been largely overlooked. The n-3 PUFA have been part of the human diet for some 2–4 million yr (23), while our genes were adapting to our diet as hunter-gatherers. With some 250,000 sudden cardiac deaths annually largely due to VF in the US alone (18) there may be a potential, large public health benefit from the practical application of this recent understanding. Carefully planned and executed clinical trials are now needed to determine the antiarrhythmic effectiveness of these fatty acids in humans at high risk of fatal arrhythmias.

ABSTRACT: Dietary long-chain fatty acids (FA) may influence pathological processes involving endothelial activation and leukocyte-endothelial interactions, such as inflammation and atherosclerosis. We previously showed that the n-3 FA docosahexaenoate (22:6n-3, DHA) inhibits cytokine-stimulated expression of endothelial-leukocyte adhesion molecules and soluble cytokines in the range of nutritionally achievable plasma concentrations. More recently we assessed structural determinants of VCAM-1 inhibition by FA. Cultured endothelial cells were incubated first with various saturated, monounsaturated, n-6 or n-3 polyunsaturated FA alone and then together with interleukin-1 or tumor necrosis factor. Saturated FA did not inhibit cytokine-induced endothelial activation, while a progressive increase in inhibitory activity was observed, for the same chain length, with the increase in double bonds accompanying the transition from monounsaturates to n-6 and, further, to n-3 FA. Comparison of various FA indicated no role of the double-bond position or configuration; the greater number of double bonds could explain the greater inhibitory activity of n-3 vs. n-6 FA. In order to ascertain mechanisms for these effects, we demonstrated inhibition of nuclear factor-κB (NF-κB) activation by DHA in parallel with a reduction in hydrogen peroxide (a critical mediator of NF-κB activation) released by endothelial cells either extracellularly or intracellularly. This suggests that a property related to fatty acid peroxidability (the presence of multiple double bonds) is related to inhibitory properties of hydrogen peroxide release and, consequently, of endothelial activation.

Highly unsaturated fatty acids (FA) and, particularly, n-3 FA, are receiving increasing attention as potential anti-atherogenic and antiinflammatory agents. This paper will summarize our recent research line in attempting to provide some mechanistic explanations for their preventive or therapeutic use to this regard.

n-3 FA AND ATHEROGENESIS

The epidemiological association between dietary n-3 polyunsaturated fatty acids (n-3 FA) and protection from cardiovascular disease (1–8) results at least in part from a decreased incidence of atherosclerosis. Apart from numerous animal studies showing decreased atherosclerosis in animals treated with n-3 FA (reviewed in Ref. 9), recent evidence has been obtained about such effects in humans, through autopsy studies in Alaskan natives (consuming high amounts of fish-derived products) and nonnatives, mostly consuming Western-type diets. In the study by Newman and coworkers, reporting decreased percentage of intima covering with fatty streaks and raised lesion in Alaskan natives [with a high n-3 FA dietary intake (6)], vs. nonnatives, the magnitude of difference in fatty streak development appears larger in younger age groups (10), suggesting an effect of diet mainly in the early events leading to fully developed atherosclerotic lesions. A recent study of n-3 FA supplementation after coronary bypass surgery indicates that such a treatment significantly reduces vein graft stenosis (11), a process which may be regarded as an accelerated form of atherosclerosis.

We therefore hypothesized that n-3 FA may modulate atherogenesis by affecting processes of early atherosclerotic development leading to the formation of fatty streak. Such processes are mostly comprised under the name of "endothelial activation."

ENDOTHELIAL ACTIVATION AS AN EARLY CONTROLLING STEP IN ATHEROGENESIS

Atherosclerosis and inflammation share similar basic mechanisms involving the adhesion of leukocytes to vascular endothelium in their early phases. Multiple protein families, each with a distinct function, provide "traffic signals" for leukocytes. These include (i) the "selectin" family of adhesion molecules; (ii) chemoattractants, some of which ("classical" chemoattractants), such as *N*-formyl peptides, complement components, leukotriene B_4 and platelet-activating factor, act broadly, on neutrophils, eosinophils, basophils and monocytes, while more recently described "chemokines," such as monocyte chemoattractant protein-1 and interleukin (IL)-8, have selectivity for

Copyright © 1999 by AOCS Press

leukocyte subsets; (iii) the immunoglobulin superfamily members on the endothelium (ICAM-1, ICAM-2,ICAM-3, and VCAM-1), recognizing "integrin" ligands on the leukocyte surface. For neutrophil and, probably, lymphocyte adhesion, selectins mediate initial tethering of the circulating leukocyte over the endothelium, allowing it to roll over the endothelium, considerably slowing down its speed, and allowing leukocytes to "sense" the presence of chemotactic gradients. Final firm attachment of leukocytes to endothelium requires the interaction of integrin ligands on the leukocyte surface with immunoglobulin superfamily members expressed on the endothelium, such as ICAM-1, ICAM-2, and VCAM-1. The multiple molecular choices available for each of these ligand–ligand interactions provide great combinatorial diversity in signals, allowing the selective responses of different leukocyte classes to inflammatory agents, the preferential recirculation patterns of lymphocyte subpopulations, or the selective binding of monocytes to arterial endothelium during early phases of atherogenesis.

Since monocyte recruitment into the intima of large arteries is specific for atherosclerosis as compared to other forms of leukocyte-endothelial interactions, it was hypothesized that these localized monocyte–endothelium interactions reflect specific molecular changes in the adhesive properties of the endothelial surface, leading to endothelial surface expression of "athero-ELAMs," i.e., endothelium-leukocyte adhesion molecules expressed in the early phases of atherosclerosis. The first such protein, originally identified in the rabbit hypercholesterolemic model, is VCAM-1, a member of the immunoglobulin superfamily, expressed on human vascular endothelium at least in two molecular forms. Both forms are able to bind a heterodimeric integrin receptor, VLA4, whose leukocyte selectivity of expression, on monocytes and lymphocytes, but not on neutrophils, can explain the selectivity of monocyte recruitment in early atherogenesis (12). Endothelial cells express VCAM-1 early during cholesterol feeding in the rabbit, before the appearance of macrophages/ foam cells in the intima of developing fatty streak, in a temporal pattern consistent with its pathogenetic role in lesion develoment. Pathophysiologically relevant stimuli for VCAM-1 expression in atherogenesis could include minimally oxidized low density lipoprotein or β-very low density lipoprotein, the advanced glycation end products associated with diabetes, lipoprotein (a), or perhaps homocysteine, elevated in homocysteinuria and in subtler forms of congenital or acquired enzyme defects in its biosynthetic pathway. In addition to these humoral stimuli, VCAM-1 endothelial gene expression also responds to hemodynamic forces, thus potentially explaining the localization of atherosclerosis in particular points of the arterial vasculature. For a general review on these issues, see Reference 12.

EVIDENCE THAT n-3 FA MAY CONTROL ENDOTHELIAL ACTIVATION

We used human adult saphenous vein endothelial cells activated by cytokines, in an *in vitro* model of these early steps in atherogenesis, first assessing the effects of various fatty acids on the surface expression of endothelial leukocyte adhesion molecules, and subsequently characterizing mechanisms and functional relevance of such effects. One n-3 fatty acid, docosahexaenoic acid (DHA), when added to cultured endothelial cells hours to days before the stimulation with cytokines, early enough to allow a significant incorporation of this fatty acid in cell membrane phospholipids, significantly inhibited events connected with endothelial activation, including the expression of adhesion molecules such as VCAM-1, E-selectin and, to a lesser extent, ICAM-1 after stimulation with virtually any stimulus able to elicit the coordinated expression of such genes (13,14). Thus, this inhibition could be demonstrated with IL-1α and β, tumor necrosis factor α (TNFα), IL-4, and lipopolysaccharide. Inhibition of adhesion molecule expression occurred in a range of DHA concentrations compatible with nutritional supplementation of this fatty acid to normal Western diet, occurred at any time point after the appearance of cytokine effect, modifying the specific kinetics of surface expression of adhesion molecules, and was strictly related in its magnitude to the extent of incorporation into total cell lipids. Indeed, the extent of VCAM-1 inhibitory effect paralleled the incorporation of DHA and the overall increase in incorporation of n-3 FA and was inversely related to the content of n-6 FA. Experiments following the fate of ^{14}C-labeled DHA into cell phospholipids showed a significant incorporation of DHA into the phosphatidylethanolamine pool, i.e., in a specific and not the most abundant phospholipid pool, likely in the inner plasma membrane, and therefore in a possibly strategic position to alter intracellular signal transduction pathways. This effect was not limited to the expression of transmembrane molecules involved in leukocyte recruitment but appeared to be true for other cytokine-activated products, such as the soluble proteins IL-6 and IL-8 involved either in the amplification of the inflammatory response (IL-6) or in specific chemoattraction for granulocytes (IL-8), and was accompanied by a functional counterpart, i.e., reduced monocyte or monocytoid cell adhesion to cytokine-activated endothelium. Compared to DHA, eicosopentaenoic acid was a weaker inhibitor of the expression of these molecules and of monocyte adhesion, although still more potent than other fatty acids. We also showed that DHA's effects on VCAM-1 expression are accompanied by parallel reductions in VCAM-1 mRNA steady-state levels, as assessed by Northern analysis (see Refs. 13,14). Similar results, in experiments with remarkably similar design, were later reported by Weber *et al.* (15). These authors also carried these investigations one step further, demonstrating, by electrophoretic mobility shift assay, an inhibition by DHA of the activation of the nuclear factor-κB (NF-κB) system of transcription factors (15), which controls the coordinated expression of adhesion molecules and of leukocyte-specific chemoattractants upon cytokine stimulation (16,17).

THE DOUBLE BOND AS THE MINIMAL NECESSARY AND SUFFICIENT REQUIREMENT FOR THE INHIBITION OF ENDOTHELIAL ACTIVATION BY FA

We further analyzed endothelial effects of various FA differing in chain length, number, position (n-3 vs. n-6 vs. n-9) and

cis/trans configuration of the double bonds. From a large number of such experiments, using VCAM-1 surface expression (by enzyme immunoassay or flow cytometry) as a readout, we concluded that (i) saturated FA are inactive; (ii) potency of polyunsaturated FA increases with the number of unsaturation; (iii) potency does not depend on chain length; (iv) the single double bond present in the monounsaturated fatty acid oleic acid is indeed sufficient to produce all the effects obtainable with higher unsaturated FA, albeit at higher concentrations; (v) for such an effect to occur even the configuration (*cis* vs. *trans*) of the double bond does not really matter, since oleic acid (19:1n-9 *cis*) and its *trans* stereoisomer elaidic acid are of equal potency (18). Indeed, inhibition of NF-κB activation could also be reproduced upon incubation of endothelial cells with oleic acid (19).

POSSIBLE MECHANISMS BY WHICH UNSATURATED FA MAY INHIBIT ENDOTHELIAL ACTIVATION

In order to ascertain mechanisms for these effects, we demonstrated inhibition of NF-κB activation by DHA (the most potent FA inhibitor of endothelial activation) in parallel with measurements of production of hydrogen peroxide by cultured endothelial cells. This reactive oxygen species (or one of more of its downstream unstable products) appears to be a critical mediator of NF-κB activation, because of our previous demonstration that treatment of endothelial cells with polyethylene glycol-complexed superoxide dismutase (a cell membrane-permeable form of this enzyme catalyzing the conversion of superoxide anion to hydrogen peroxide) does not much affect VCAM-1 mRNA production, contrary to a treatment with polyethylene glycol-catalase, which acts by accelerating the degradation of hydrogen peroxide, and which clearly diminished VCAM-1 mRNA levels (20). These results suggested that some specific reactive oxygen species (hydrogen peroxide or some downstream products) are involved more directly than others (e.g., superoxide anion) in the activation of NF-κB. We assessed the production of extracellular hydrogen peroxide by endothelial cells stimulated with the cytokine-transforming growth factor-β and, more pertinent to results described above, the production of intracellular hydrogen peroxide (and/or its downstream products) by measuring the intracellular fluorescence after endothelial cell loading with dichloro-fluoresceine before or after stimulation with IL-1 or tumor necrosis factor. In both these experimental systems we could document (preliminary results) a decrease in baseline production of hydrogen peroxide (or some of its downstream products) after cell membrane enrichment with DHA, and an even more pronounced dampening of the increase produced by stimulation with cytokines. Saturated FA served as a negative control in these experiments. This suggests that a property related to FA peroxidability (the presence of multiple double bonds), and usually regarded as a detrimental consequence of polyunsaturated FA enrichment of cell membranes, is indeed also directly related to inhibitory properties in the release of some reactive oxygen species crucial for cell responsiveness to cytokines.

CONCLUSIONS AND OPEN QUESTIONS

These results have led to a reappraisal of how FA may act on endothelial cells in modulating general phenomena such as atherogenesis (mostly investigated by our experimental systems), but also, potentially, inflammation or some immune responses. Since all these effects could be confirmed to occur even in the presence of inhibitors of metabolic conversion of FA to eicosanoids, they provide a novel explanation for the modulating effect of n-3 FA in atherogenesis, distinct from the "classical" hypothesis of substrate substitution (21). The results with oleic acid might also be an explanation for at least some of the beneficial effects of olive oil-rich ("Mediterranean") diets on atherogenesis (19). It is noteworthy, to this regard, that oleic acid mostly appeared to incorporate to the expense of saturated FA, thus disclosing the possibility of additive effects with n-3 FA, which mostly substitute less unsaturated FA in the membrane phospholipid pools. If extended to cell types different from endothelial cells, such as the monocyte-macrophage, also undergoing "activation" phenomena upon cytokine or LPS stimulation, they may provide a coherent explanation for a number of previous observations such as the inhibition of cytokine formation from lipopolysaccharide-activated macrophages (22). As to the mechanism(s) involved, these effects might be intrinsically linked to polyunsaturated FA peroxidability, usually regarded as a detrimental effects of higher unsaturated FA, but which could simply be the other side of the same coin. Future research will have to further elucidate molecular aspects of these phenomena as well as the greater scope of this research line to help explain other many biological effects of unsaturated FA as modulators of biological responses to cytokines.

Dietary Fish Oil Promotes Positive Inotropy and Efficiency of Digitalis

M. Bernard[a,*], A. Gerbi[b], O. Barbey[b], I. Jamme[b], P.J. Cozzone[a], and J.-M. Maixent[b]

[a]Centre de Résonance Magnétique Biologique et Médicale, UMR CNRS 6612, and [b]Laboratoire de Recherche Cardiologique, Université de Médecin, Marseille, France

Digitalis is clinically effective in heart failure, but it has an extremely narrow therapeutic index. Inclusion of fish oil (FO) in the diet may have cardioprotective effects by different mechanisms (1,2): decreased heart rate and occurrence of arrhythmias, increased mechanical activity, and ejection fraction. The aim of this study was to investigate if dietary FO with incorporation of n-3 polyunsaturated fatty acids in membranes could promote positive inotropy of ouabain.

Methods. Twenty-five male Wistar rats were fed for 60 d: (i) supplemented with FO concentrate [180 mg eicosapentaenoic acid (EPA) + 120 mg docosahexaenoic acid (DHA)/g oil] at a dose of 0.5 g/kg/d (group FO), (ii) without supplementation (group C). Inotropic and toxic responses to cumulative doses of ouabain (from 100 nM to 0.3 mM) were evaluated in the isolated perfused rat heart and the relative variations in cardiac energetic metabolism, and pH were obtained using ^{31}P magnetic resonance spectroscopy. Activity, contribution, affinity, and expression of Na,K-ATPase isoforms were determined on purified membrane-bound Na,K-ATPase. Fatty acid composition of cardiac membrane fractions was analyzed by gas chromatography.

Results. The rat is the only mammalian species with a well-characterized biphasic inotropic response to ouabain which is coupled to consecutive inhibition of the $\alpha 2$- and $\alpha 1$-isoforms of high and low affinity for ouabain, respectively. Results show that (i) there is a twofold increase in the low-affinity response to ouabain (0.1 mM) (% inotropy = 40 ± 3 in group C vs. 79 ± 7 in group FO, $P < 0.001$), (ii) there is a lower inhibition of $\alpha 1$ Na,K-ATPase activity ($IC_{50} = 7.2 \pm 2.0 \times 10^{-5}$ M in group C and $3.4 \pm 0.8 \times 10^{-4}$ M in group FO, $P < 0.05$), (iii) the higher inotropic response to ouabain is not associated with significant changes in energetics, (iv) alteration of function and energetics in response to the toxic dose of 0.3 mM is delayed in the FO group, (v) there are no differences in overall Na,K-ATPase activity or in the proportion of its isoforms, and (vi) fatty acid composition of rat hearts submitted to FO diet shows that the proportion of EPA and DHA had significantly risen.

In conclusion, improving ouabain efficacy may represent an additional mechanism whereby FO exert their cardioprotective action in rats and possibly in humans.

n-3 Fatty Acids and the Risk of Sudden Cardiac Death Assessed by 24-Hour Heart Rate Variability

J.H. Christensen*, J. Dyerberg, and E.B. Schmidt

Department of Nephrology, Aalborg Hospital, Medi-Lab A/S, Copenhagen, and Department of Medicine, Hjørring Hospital, Denmark

Dietary n-3 polyunsaturated fatty acids (PUFA) may reduce the incidence of sudden cardiac death (SCD) in humans possibly due to an antiarrhythmic effect. However, only sparse information exists on such an effect in humans. Therefore, we performed three double-blinded intervention trials with n-3 PUFA in three different groups: in patients with a previous myocardial infarction (MI) (1,2), in patients with chronic renal failure and at high risk of SCD (3), and in healthy volunteers (Christensen, J.H., Christensen, M.S., Dyerberg, J., and Schmidt, E.B., unpublished data). The end point in the trials was 24-h heart rate variability (HRV), and the clinically important HRV parameter SDNN [standard deviation of all normal RR intervals during a 24-h electrocardiogram (ECG) recording] was used. HRV is a powerful predictor of mortality and of arrhythmic events in humans.

The relationship between fish consumption, the content of n-3 PUFA in platelets, and 24-h HRV was examined in 55 post-MI patients (mean age 63 ± 7 yr) with left ventricular dysfunction (mean ejection fraction 0.33 ± 0.05). The patients were divided into three groups: (i) Those who never ate fish, (ii) those who ate fish once a week, and (iii) those eating fish at least twice a week. A close positive correlation was observed between fish intake and the cellular content of n-3 PUFA. HRV tended to be higher among those who consumed one fish meal per week compared to no fish (122 vs. 103 ms, $P = 0.07$). Furthermore, a significant positive correlation was found between the cellular content of n-3 PUFA and HRV ($r = 0.30$, $P < 0.05$). These post-MI patients were now randomly allocated to receive either 5.2 g of n-3 PUFA daily or placebo oil for 12 wk. After dietary supplementation, HRV increased from 115 to 124 ms (significant compared to baseline and to placebo, $P = 0.01$).

The relationship between the cellular content of n-3 PUFA and HRV was also examined in patients with chronic renal failure. Twenty-nine patients (mean age 52 ± 15 yr) received 5.2 g of PUFA or olive oil daily for 12 wk. After dietary supplementation, a close positive correlation was found between the cellular content of n-3 PUFA and HRV ($r = 0.71$, $P < 0.01$).

Finally, 60 healthy subjects (25 women, mean age 38 yr; 35 men, mean age 38 yr) were randomized to either (i) 2.0 g of n-3 PUFA daily, or (ii) 6.6 g of n-3 PUFA daily, or (iii) placebo for 12 wk. At baseline, a close positive correlation was found between n-3 PUFA in granulocytes and HRV. Furthermore, the subjects with a low HRV at baseline had a dose-dependent increase in HRV after n-3 PUFA supplementation.

In conclusion, the results showed a beneficial effect of n-3 PUFA on HRV in three different populations, strongly indicating an antiarrhythmic effect of n-3 PUFA. Our data may explain the findings from other studies, namely that a low occurrence of SCD is observed in subjects with and without coronary heart disease who regularly eat fish.

Stearic Acid-Rich Diets Do Not Increase Thrombotic Risk Factors in Healthy Males

F.D. Kelly[a], N.J. Mann[a], A.H. Turner[b], and A.J. Sinclair[a,*]

[a]Department of Food Science and [b]Medical Laboratory Science, RMIT University, VIC, 3001, Australia

Stearic acid is a saturated fatty acid found in meat fat and chocolate. Studies from more than 30 yr ago indicated that stearic acid might promote blood clotting through increased platelet aggregation (1). More recent studies have indicated that stearic acid is unique as a saturated fatty acid in that it does not cause an increase in blood cholesterol levels (2). Several recent studies indicate that stearic acid might not be a thrombotic-promoting fatty acid; however, the data have not been convincing to all observers. Five intervention studies carried out (between 21–40 d for each dietary intervention) with a range of 10–18 subjects (mean age 23–37 yr) gave varying results regarding the cholesterolemic and thrombogenic influences of stearic acid. In one of the studies (3), the stearic acid-rich diet increased the thrombosis potential (increased factor VIIc); however, since the study did not compare stearic acid with another saturated fatty acid, this reduced the importance of this result. A second study found a nonsignificant rise in this parameter (4), while a third study showed there was a decreased factor VIIc activity (5). The study by Schoene *et al.* (6) showed that stearic acid-rich diets decreased mean platelet volume, which indicates a reduced platelet activation (less thrombotic) and Tholstrup *et al.* (4) showed that platelet aggregation induced by low levels of collagen and ADP was lowered 24 h after consumption of stearic acid.

The aim of this study was to compare the thrombotic risk factors of two diets rich in saturated fatty acids, palmitic acid, and stearic acid. Palmitic is a very common saturated fatty acid in foods including meat fats. In this study, 13 male subjects consumed each test fat for 4 wk with a 7-wk wash-out between test diets in a random cross-over design. The test fats were supplied to the subjects in the form of baking and spreading margarines, cakes, and biscuits. The mean intake of stearic acid was 19.4 g/d in the high stearic acid period compared with 7.3 g/d in the baseline period. For palmitic acid, the baseline level was 13.6 g/d compared with 22.5 g/d in the test period. The diets led to significant ($P < 0.05$) increases in palmitic (8%) or stearic acids (17%) in the platelets during the test diet periods. Despite this, there were no significant differences in platelet aggregation, fibrinogen levels, or Factor VIIc activity between the two test diets. The main difference was in mean platelet volume (MPV) which was significantly reduced ($P < 0.05$) on the stearic acid diet (–6%, $-0.57 \pm 0.09\ 10^{-15}$ L) compared with the palmitic acid diet which increased MPV (+2%). Reduced MPV values are an index of reduced platelet activity, and this supports the data of Schoene *et al.* (6) who also reported that stearic acid-rich diets reduce MPV. These data indicate that an additional 12 g/d of stearic acid is not pro-thrombotic over a 4-wk period in men. Additional studies should be conducted using more sophisticated markers of platelet reactivity as well as consideration to use stearic acid in the food industry to provide the appropriate physical properties for various food stuffs. There is reported interest in increasing the stearic acid content of soybeans through the use of plant breeding techniques, as indicated by several papers presented at the 1998 annual meeting of the American Oil Chemists' Society.

The 3-Thia Fatty Acid, a Novel Bioactive Compound, Which Changes the Plasma Profile from Atherogenic to Cardioprotective

Rolf Kristian Berge*, Lise Madsen, and Livar Frøyland

Department of Clinical Biology, Division of Biochemistry, N-5021 Haukeland Hospital, Bergen, Norway

The hypolipidemic effect of sulfur-substituted long chain fatty acids (tetradecylthioacetic acid, TTA), where sulfur substitution prevents the β-oxidation of TTA, is well-documented in rats, rabbits, dogs, and possibly also in humans. The hypotriglyceridemic properties of TTA which activates peroxisome proliferator-activated receptor α are probably due to increased mitochondrial β-oxidation with a concomitant decreased triglyceride synthesis. Therefore, the mitochondria and not the peroxisomes are the principal targets for this effect. The lowering of low density lipoprotein (LDL)-cholesterol is possibly due to inhibition of 3-hydroxy-3-methylglutaryl-CoA reductase and acyl-CoA cholesterol acyltransferase. TTA possesses a sulfur atom, and it is therefore expected to have reducing properties. TTA was a potent compound in inhibiting the human LDL oxidative modification induced either by Cu^{2+} ions or azo-compounds. The electrophoretic mobility of LDL returned to normal values in the presence of TTA. This fatty acid analog was effectively able to reduce, in a dose-dependent manner, the formation of 8-hydroxydeoxy guanosine from 2-deoxy guanosine. TTA also changed the antioxidant defense system in plasma in a beneficial way, i.e., reduced glutathione levels increased. The total antioxidant status elevated, and thiobarbituric acid-reactive substances were decreased. An additional "olive oil" effect of TTA was seen as LDL purified from TTA-treated rats and dogs were protected from oxidation. The LDL from TTA-treated animals were enriched with 18:1n-9 and a Δ^9-desaturated metabolite of TTA, probably due to upregulated Δ^9-desaturase gene expression. Antioxidants were suggested to reduce restenosis. In a preliminary study, TTA reduced proliferation of smooth muscle cells. Data from a study of oral administration with TTA suggest that it is effective reducing the development of restenosis on rabbit artery after balloon injury (overstretching). The exact mechanism is not known, but it seems possible to modulate the injury response pharmacologically. The pharmacological properties of the 3-thia fatty acids suggest that TTA may be of potential interest for a new therapeutic approach to atherosclerosis.

Dietary n-3 Polyunsaturated Fatty Acids and Oxidants Increase Rat Mammary Tumor Sensitivity to Epirubicin Without Change in Cardiac Toxicity

E. Germain[a], F. Lavandier[a], V. Chajès[a], V. Schubnel[b], P. Bonnet[b], C. Lhuillery[c], and P. Bougnoux[a,*]

[a]EA 2103 and [b]UMR-CNRS 6542, Université de François-Rabelais, F-37044 Tours, and [c]LNSA, INRA, F-78350 Jouy-en-Josas, France

We previously reported that polyunsaturated fatty acids (PUFA) and oxidants (OX) increased *in vitro* efficacy of anticancer drugs that generate reactive oxygen species, through an increase in lipid peroxides formation (1). The aim of the study was to examine whether n-3 PUFA and OX modulate *in vivo* the antitumor activity and cardiotoxicity of epirubicin, an anthracyclin that stimulates oxidative stress.

Thirty-six rats with *N*-methyl nitrosourea-induced mammary tumors were fed a basal diet supplemented with n-3 PUFA and separated in three groups receiving n-3 PUFA alone (15% sardine oil, control group) or with lipid peroxidation inhibitor (vitamin E, 100 IU/kg, vit E group) or with lipid peroxidation inducers (dehydroascorbate + menadione, respectively, 20 and 0.2 mg/d, OX group). When the target tumor reached 1 cm in diameter, epirubicin (3 mg/kg; i.p.) was administered weekly for 3 wk. Tumor response was assessed in two ways: the change in tumor area and the score of new tumors occurring after chemotherapy. Four weeks after the end of treatment, cardiac functioning was evaluated by measuring the left ventricular end-diastolic pressure at basal conditions or during volume expansion.

During a 6-wk period, the growth of the target tumor was totally inhibited in the OX group by the epirubicin treatment, while it kept going in the control and in the vit E groups. Similarly, the number of newly appeared tumors was reduced three times in the OX group in comparison to both the other groups. No difference in the cardiac pressures measured at rest or during volume expansion was observed between the dietary groups. However, almost 10% of rats in all dietary groups were found to present an elevated left ventricular end-diastolic pressure, which is characteristic of the cardiotoxicity induced by anthracyclin.

It is concluded that dietary n-3 PUFA in the presence of OX increased the antitumor activity of epirubicin *in vivo*, without affecting cardiac toxicity. This observation suggests that supplementing the diet with n-3 PUFA plus OX increases the cytotoxicity of epirubicin toward tumor cells rather than toward normal cardiac cells. A phase I-II is now contemplated in metastatic breast cancer patients in Tours.

Roles of Lipid-Activated Receptors in the Adipogenic Action of Fatty Acids

Paul A. Grimaldi*

INSERM U470, Centre de Biochimie, UFR Sciences, Parc Valrose, UNSA, 06018 Nice Cedex 2, France

Fatty acids are precursors of triglycerides, phospholipids, and eicosanoids. In addition to their role as substrates, fatty acids affect many cell functions acting either indirectly, *via* arachidonic acid metabolites, or directly by modulating various cellular signaling pathways (1–3). During the past years, it has been demonstrated that fatty acids play a central role in the control of gene expression in many tissues and participate in the control of adipose tissue development. *In vivo* studies showed that high-fat diets lead to hypertrophic and hyperplastic development of adipose tissue in adult rodents (4,5). These nutritional obesities occur within weeks and are preceded by a proliferation of preadipose cells taking place a few days after the shift to high-fat diet. The finding that diets containing saturated fat are more active than polyunsaturated fat-enriched diets (6) suggested a direct action of fatty acids on adipose tissue rather than involvement of fatty acid metabolites such as eicosanoids. During the last few years, the use of preadipose cell lines has greatly improved our knowledge on the cellular and molecular mechanisms which are behind the adipogenic effects of fatty acids. Particularly, these studies led to the identification of nuclear receptors activated by fatty acids and related molecules and to the description of their roles in adipogenesis. These findings were an important step in the understanding of the control of adipose differentiation and have provided a molecular explanation of the relationships between the amount of fat in diet and adipose tissue development.

ADIPOGENIC ACTION OF FATTY ACIDS

The action of fatty acids has been extensively investigated in our laboratory using the Ob1771 preadipose cell line. These cells, established from genetically obese mouse, undergo a typical adipose conversion process when maintained in appropriate conditions. Adipose differentiation is a complex process that corresponds to transcriptional activation of numerous genes and occurs in a sequential manner (6,7). The first step occurs just at growth arrest and is characterized by transcriptional activation of "early genes," such as pOb24, CAAT enhancer-binding protein (CEBP) β and δ, and lipoprotein lipase (8). These committed preadipose cells undergo several rounds of mitosis which are critical for terminal differentiation. This last step is characterized by expression of a large set of genes, including those involved in triglyceride synthesis such as glycerophosphate dehydrogenase (GPDH), adipocyte lipid-binding protein (ALBP), fatty acid transporter (FAT), or acylCoA synthetase (ACS). Notably, in standard culture conditions, terminal differentiation occurs only in a limited proportion of the cells leading to the formation of colonies of adipose cells separated from each other by cells resting in the preadipose state, i.e., cells expressing only the early markers of adipose differentiation. Adipose tissue from adult animals contains such dormant preadipose cells capable of proliferation and terminal differentiation throughout the life. Adipose differentiation is under multihormonal control involving circulating hormones and factors such as insulin, growth hormone, triiodothyronine, retinoids and prostacyclin, which activate adipose marker expression and lipid deposition.

Exposure of Ob1771 cells to fatty acid-enriched medium during the course of differentiation leads at the end of the process to a tremendous increase of adipose cell number due to an enhancement of the percentage of differentiated cells and an amplification of the proliferation of preadipose cells that occurs after confluence. This morphological adipogenic action of fatty acid supplementation is characterized at the biochemical level by an increase of triglyceride amount per cell (fivefold increase when compared to cells maintained in standard differentiation medium) and is not a passive filling-up of the cells as accompanied by increase of specific activities of enzymes of lipid metabolism such as GPDH and ACS and enhancement of adipose differentiation program expression. Interestingly, saturated and unsaturated long-chain fatty acids (LCFA) were found to be equally potent, whereas middle- and short-chain fatty acids were ineffective on adipose differentiation of Ob1771 cells. Furthermore, 2-bromopalmitate, as compared to palmitate, exerted its adipogenic action at lower concentrations (half-maximal effect observed at 10 μM vs. 75 μM)(9). As 2-bromopalmitate was shown to be less metabolized than palmitate in Ob1771 cells (10), this last observation suggested that adipogenic effect of LCFA is likely related to a direct effect of the molecule rather than to an increase in substrate availability for triacylglycerol synthesis.

Lipids 34, S205–S208 (1999).

Copyright © 1999 by AOCS Press

In order to further characterize this adipogenic action of LCFA, some efforts were devoted to determine the differentiation step affected by 2-bromopalmitate. These experiments showed that chronic exposure to the compound was not required for maximal effect as treatment from confluence to day 5 exerted similar effects on adipose differentiation. By contrast, treatments delayed to day 5 were found to be ineffective (9). These findings led to the conclusion that an increase in intracellular concentration of unprocessed LCFA occurring in preadipose cells, i.e., not terminally differentiated cells, acts as a trigger for terminal differentiation events.

TRANSCRIPTIONAL EFFECTS OF LCFA IN PREADIPOSE CELLS

The effects of LCFA on the pattern of gene expression were investigated in preadipose Ob1771 cells just after confluence (11–13). At this stage, genes related to terminal differentiation, including those involved in fatty acid metabolism, are completely unexpressed, and the cells are not able to synthesize fatty acids and triglycerides. Treatment of such cells by LCFA led to potent transcriptional activation of genes encoding proteins directly involved in fatty acid metabolism, such as ALBP, FAT, ACS and lipoprotein lipase, whereas the other adipose-related genes remained transcriptionally inactive. In such transcriptional effect, saturated and unsaturated LCFA as well as nonmetabolized LCFA derivatives were found to be active, while middle- and short-chain fatty acids were less effective. Time-course experiments revealed that LCFA effects occurred within hours and were rapidly and completely reversible upon their withdrawal from culture medium (11,12). The use of 2-bromopalmitate and serum-free culture medium allowed the conclusion that this LCFA derivative exerted its transcriptional effect at intracellular concentrations ranging from 10 to 100 nanomolar.

Taken together, these findings indicated that accumulation of very low amounts of unprocessed LCFA led to transcriptional activation of genes directly involved in fatty acid uptake and activation and that these short-term effects of LCFA resulted, after several days, in an amplification of the terminal differentiation process. Direct extrapolation of these results to *in vivo* situation remains hazardous, but the demonstration that LCFA act as transducing molecules in preadipose cells favors the hypothesis of a direct link between the LCFA amount of the diet and adipose tissue development and could explain, at least partially, the hypertrophic and hyperplasic action of high-fat diets.

ROLE OF NUCLEAR RECEPTORS IN FATTY ACID GENE REGULATION

It is now fully established that fatty acids and fatty acid metabolites exert some of their transcriptional effects through activation of nuclear receptors, namely PPAR (peroxisome proliferator-activated receptors). So far, three different PPAR isoforms have been identified in mammals. Various authors have showed that PPAR exerted their transcriptional effects by heterodimerization with retinoid × receptors and binding to a responsive element, called peroxisome proliferator-responsive element. These regulatory sequences, first identified in the acyl-CoA oxidase promoter (14), are imperfect 6-base pair direct repeats of the sequence RGGTCA spaced by a single variable nucleotide. Additional peroxisome proliferator-responsive elements have been identified in regulatory sequences of various genes, and especially those encoding proteins involved in lipid metabolism (15).

The differential expression of PPAR isoforms suggested specific regulatory functions. PPARα (16), mainly expressed in liver and brown adipocytes, could play a central role in fatty acid catabolism as suggested by the finding that targeted disruption of this isoform in mice resulted in abolishment of liver peroxisomal proliferation and fatty acid oxidation (17). PPARγ is predominantly expressed in adipose cells and plays, in combination with other transcription factors, a crucial role in activation of genes of adipose differentiation process and adipogenesis (18). PPARδ, also called FAAR (fatty acid-activated receptor), shows high level of expression in various lipid-metabolizing tissues such as adipose tissue, small intestine, and muscles and could play a role in the process of fatty acid uptake and activation as suggested by transfection experiments, demonstrating that its ectopic expression in fibroblasts confers fatty acid responsiveness to FAT, ALBP, and ACS genes (19).

Despite intense efforts, the identification of physiological ligands and activators of the various PPAR isoforms still remains an open question. By using transactivation assays, it has been shown that PPAR are activated by a large variety of molecules including fatty acids, arachidonate metabolites, and pharmaceutical compounds. These studies carried out with different recipient cells and with different reporters genes led to contradictory results. However, from the most recent data, it can be proposed that PPARα is activated by unsaturated LCFA and fibrates; that PPARγ is activated by 15-deoxy-Δ12-prostaglandin J_2 (PGJ_2), thiazolidinediones or hydroxy-LCFA and insensitive to native LCFA. LCFA, carbaprostacyclin ($cPGI_2$), or 2-bromopalmitate activates FAAR.

From the numerous studies performed in recent years, it can be concluded that PPAR play a central role in the control of expression of genes involved in lipid metabolism of various tissues. These lipid-activated nuclear receptors are probably very important actors in the processes of adaptation of the organism to high-fat feeding by increasing expression of enzymes of fatty acid catabolism in certain tissues such as liver and brown adipose tissue, and increasing the capacity of storage of fatty acids in white adipose tissue.

FATTY ACIDS, PPAR, AND ADIPOGENESIS

PPARγ and FAAR are induced during adipose differentiation. FAAR is a very early marker of differentiation occurring during the preadipose state whereas PPARγ is induced later during terminal differentiation (19,20). A regulatory role for PPARγ in adipogenesis has been established by ectopic ex-

pression experiments. Expression of physiological level of this nuclear factor by retroviral vector promotes activation of an adipose differentiation program and adipogenesis in fibroblasts upon treatment by PPARγ activators (21). A cooperative process between PPARγ and other transcription factors of the C/EBP family in induction of adipogenesis has also been described (22). However, the recent demonstration that fatty acids do not activate PPARγ (23) argues against its direct implication in development of obesity induced by high-fat feeding. Very recent data from our laboratory suggested that activation of FAAR by fatty acids could be the first event involved in adipogenic action of LCFA. Stable 3T3-C2 cell lines expressing the FAAR protein (3T3-C2/FAAR) and control cell lines (3T3-C2/Biz) have been isolated by retroviral infection and their response to various cocktails of fatty acids and other adipogenic agents has been investigated. Exposure of 3T3-C2/FAAR cells to FAAR activators such as LCFA, 2-bromopalmitate, or $cPGI_2$ led within hours to a strong activation of FAT and ALBP genes and, after a few days, to a delayed accumulation of PPARγ mRNA. At that stage, addition of PPARγ activators, such as thiazolidinediones or 15-deoxy-$\Delta 12$–PGJ_2 resulted in lipid accumulation and expression of the overall adipose differentiation program. By contrast, treatment by PPARγ activators of cells not previously exposed to FAAR activators did not promote adipogenesis. Furthermore, the finding that control 3T3-C2/Biz cells remained unresponsive to the various treatments confirmed that this new phenotype is related to FAAR expression. These data strongly suggest that a direct FAAR activation by LCFA leads to PPARγ gene induction and that, in turn, PPARγ activation by its specific activators promotes adipogenesis.

How fatty acids promote obesity *in vivo* remains an open question. However, keeping in mind that it has been clearly established that adipose tissue from adult animals contains some preadipose "dormant" cells expressing the early markers of adipose differentiation including FAAR, it is tempting to speculate that under conditions leading to an increase of fatty acid supply, such as high-fat feeding, FAAR activation could promote PPARγ gene expression and subsequent adipose conversion. Further studies are clearly required to validate such a model. In that respect, PPAR gene disruption experiments could provide very interesting animal models for these studies.

In conclusion, fatty acids act as transducing molecules and behave as adipogenic hormones. These effects are, at least in part, mediated by activation of nuclear receptors of the PPAR subfamily. The characterization of the mode of action of these lipid-activated nuclear receptors could be useful to define new pharmaceutical strategies in the treatment of nutritional obesities.

Dietary Polyunsaturated Fatty Acids and Hepatic Gene Expression

Donald B. Jump*, Annette Thelen, and Michelle Mater
Departments of Physiology, Biochemistry, and Animal Science, Michigan State University, East Lansing, Michigan 48824

ABSTRACT: Dietary polyunsaturated fatty acids (PUFA) have profound effects on hepatic gene transcription leading to significant changes in lipid metabolism. PUFA rapidly suppress transcription of genes encoding specific lipogenic and glycolytic enzymes and induce genes encoding specific peroxisomal and cytochrome P450 (CYP) enzymes. Using the peroxisome proliferator-activated receptor α (PPARα)-null mouse, we showed that dietary PUFA induction of acyl CoA oxidase (AOX) and CYP4A2 require PPARα. However, PPARα is not required for the PUFA-mediated suppression of fatty acid synthase (FAS), S14, or L-pyruvate kinase (L-PK). Studies in primary rat hepatocytes and cultured 3T3-L1 adipocytes showed that metabolites of 20:4n-6, like prostaglandin E_2 (PGE_2), suppress mRNA encoding FAS, S14, and L-PK through a G_i/G_o-coupled signal transduction cascade. In contrast to adipocytes, 20:4n-6-mediated suppression of lipogenic gene expression in hepatic parenchymal cells does not require cyclooxygenase. Transfection analysis of S14CAT fusion genes in primary hepatocytes shows that peroxisome proliferator-activated PPARα acts on the thyroid hormone response elements (−2.8/−2.5 kb). In contrast, both PGE_2 and 20:4n-6 regulate factors that act on the proximal promoter (−150/−80 bp) region, respectively. In conclusion, PUFA affects hepatic gene transcription through at least three distinct mechanisms: (i) a PPAR-dependent pathway, (ii) a prostanoid pathway, and (iii) a PPAR and prostanoid-independent pathway. PUFA regulation of hepatic lipid metabolism involves an integration of these multiple pathways.

Understanding the molecular basis for dietary fatty acid regulation of cell function and how dietary fat contributes to human health is a central issue in modern nutrition research (1–4). First, it is important to understand how dietary fat affects specific biochemical events under normal physiological conditions and then to determine whether these pathways contribute to the onset and/or progression of specific chronic diseases. Our studies have focused on defining how dietary fat affects gene expression under normal physiological conditions, with an emphasis on understanding the role dietary fat plays in the control of hepatic lipid synthesis and metabolism (5–10).

The liver plays a central role in whole-body lipid metabolism. Fatty acids originating from the diet (as triglycerides) or extrahepatic tissues enter hepatocytes and are rapidly converted to fatty acid CoA esters (FA-CoA). These FA are processed to complex lipids, such as triacylglycerols and phospholipids or are diverted to oxidation in mitochondria (β-oxidation), peroxisomes (β-oxidation), or microsomes (cytochrome P450, CYP). Complex lipids are assembled into lipoprotein complexes and secreted in the form of very low density lipoproteins (VLDL) for export to extra-hepatic tissues. The liver also carries out *de novo* FA synthesis (lipogenesis), which involves the conversion of carbohydrate to palmitate. In rodent liver (and probably humans), lipogenesis is induced by high-carbohydrate fat-free diets, triiodothyronine (T_3), and insulin and is inhibited by starvation, streptozotocin-induced diabetes, or treatment with hormones that elevate hepatocellular cAMP levels (4).

In addition to these endocrine regulatory mechanisms, hepatic lipogenesis and triacylglycerol synthesis are suppressed in rats fed diets containing polyunsaturated fatty acids (PUFA), particularly highly unsaturated n-3 PUFA found in fish oil (see Refs. 3,4). PUFA suppression of lipogenesis may be linked to fuel partitioning. Suppressing lipogenesis keeps malonyl CoA low. Malonyl CoA is an inhibitor of carnitine palmitoyl transferase I (11). Thus, by suppressing lipogenesis, mitochondrial FA oxidation is favored. Another explanation for this effect is that newly synthesized FA might facilitate triglyceride assembly into VLDL. Certainly, feeding rats fish oil has profound inhibitory effects on lipogenesis and suppresses hepatic VLDL secretion leading to diminished circulating VLDL-triglyceride (12–15).

Studies described here focus on the effects of dietary fat on the transcription of the hepatic gene encoding the S14 protein. The S14 protein is thought to play a role in orchestrating the glucose/insulin regulation of hepatic FA synthase (FAS), malic enzyme, and ATP-citrate lyase (16). These studies will show that FA activate multiple mechanisms to influence hepatic gene transcription.

PUFA regulation of S14 gene transcription is directed at the S14 proximal promoter region. n-3 and n-6 PUFA suppression of mRNA encoding hepatic lipogenic [fatty acid synthase (FAS), S14, SCD1] and glycolytic (L-PK) enzymes is due to

Lipids 34, S209–S212 (1999).

rapid inhibition of transcription of these genes (5–9). Moreover, these same effects on gene expression are seen in primary rat hepatic parenchymal cells treated with specific n-3 and n-6 PUFA, indicating that PUFA action does not require extrahepatic factors. Using a transfection approach, the proximal promoter region of the S14 gene was found to contain a *cis*-regulatory region (PUFA-RR) that was targeted by PUFA. By targeting this region, PUFA can selectively control gene expression without having broad effects on either thyroid, insulin, or glucose-regulated gene transcription. Here, we describe our current understanding of the mechanism of PUFA regulation of S14 that is directed at the PUFA-RR (−220/−80 bp) (Fig. 1).

Transfection studies showed that the S14 PUFA-response region (PUFA-RR) contains a functional Y-box at −104/−99 bp upstream from the 5′ transcription start site (17). A Y-box is an inverted CCAAT-box that can potentially bind several CCAAT-box binding proteins like c/EBP-related factors, NF1, NFY, dbpA, and dbpB (YB-1). Deletion or mutation of the S14 Y-box essentially abrogates S14 gene transcription. Gel shift analyses show that c/EBP-α or β, NF1, and NFY bind this element. Transfection analyses showed that NFY, but not c/EBP, is required for the operation of the two upstream enhancers (thyroid and glucose/insulin). Such studies suggest that PUFA might regulate the composition of the Y-box, which leads to changes in S14 gene transcription. However, direct test of this hypothesis showed that genes containing a Y-box binding only NFY are marginally sensitive to PUFA control. The 100 bp region (−220/−120 bp) immediately upstream from the Y-box also did not confer PUFA control to a *cis*-linked gene when tested without the functional Y-box. However, when both the Y-box and the C-region were together, PUFA control to the S14 gene was restored. Thus, PUFA control of S14 gene transcription requires a functional interaction between NFY and factors binding the C-region.

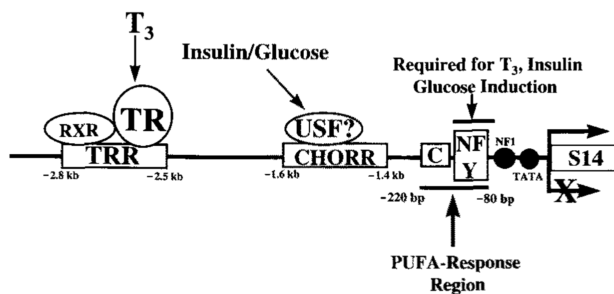

FIG. 1. Functional elements involved in the hormonal/nutrient control of the rat liver S14 protein (S14) gene. The S14 gene proximal promoter region extends to −220 bp and contains a functional TATA-box, NF1, and NFY elements. The Y-box and the C-region, (C), functionally interact to form a polyunsaturated fatty acid (PUFA)-response region (PUFA-RR) within the S14 proximal promoter. Two enhancers are found upstream. The carbohydrate-response region (CHORR) is located between −1.4 and −1.6 kb. This region contains an E-box that may bind USF-related factors. The thyroid hormone response region (TRR) is located between −2.5 and −2.8 kb and contains three thyroid hormone response elements (TRE). Each TRE binds thyroid hormone receptors (TR) and the retinoid x receptor (RXR) as heterodimers. T_3, triiodothyronine.

The identity of the factors binding the C-region is currently under investigation.

Peroxisome-proliferator-activated receptors (PPAR) regulation of hepatic gene transcription. A second mechanism for FA control of hepatic gene transcription involves PPAR (18,19). Peroxisome proliferators encompass a wide variety of compounds, including hypolipidemic drugs (WY14,643, gemfibrozil, clofibrate, etc.), plasticizers (DEHP) steroids (DHEA, DHEA-S), and dietary FA. PPAR are members of the steroid/thyroid superfamily of nuclear receptors. PPAR-mediated effects on gene transcription are achieved through the formation of PPAR-RXR heterodimers which bind DNA motifs called peroxisome proliferator response elements located in promoters of target genes.

PPAR also have inhibitory effects on gene transcription. For example, apolipoprotein CIII and transferrin gene expression are inhibited by PPAR-RXR competition for an HNF-4 binding site within the promoters of these genes (20). PPARα was also shown to interfere with thyroid hormone action by sequestering RXRα, a factor required for thyroid hormone receptor binding to DNA (19,21).

Because PPAR were reported to bind FA (22), they may potentially serve as monitors of intracellular FA levels and target the genome to control specific metabolic pathways. The fact that PPAR are activated by FA in conjunction with the known effects of PUFA (n-3) on peroxisomal and microsomal FA oxidation led us to question whether PUFA regulated peroxisomal, microsomal, glycolytic, and lipogenic pathways through a common transcriptional mediator, i.e., PPAR. While several PPAR subtypes [α, β (also known as δ , Nuc1, FAAR), γ1 and γ2] were identified in rodents, PPARα is the predominant form in rodent liver. Recent gene targeting studies clearly demonstrate that PPARα is required for the pleiotropic response to peroxisome proliferators, including an increase in hepatic mRNA encoding peroxisomal and microsomal enzymes (23).

To examine the role of PPARα in PUFA regulation of hepatic mRNA, we used the PPARα-deficient mouse. These studies included an analysis of mRNA encoding hepatic lipogenic [FAS and the S14 protein (S14)], microsomal [cytochrome P450 4A2 (CYP4A2)] and peroxisomal [acyl CoA oxidase (AOX)] enzymes (18). PUFA ingestion induced $mRNA_{AOX}$ (2.3-fold) and $mRNA_{CYP4A2}$ (8-fold) and suppressed $mRNA_{FAS}$ and $mRNA_{S14}$ and $mRNA_{L\text{-}PK}$ by >50–80% in wild-type mice. In PPARα-deficient mice, PUFA did not induce $mRNA_{AOX}$ or $mRNA_{CYP4A2}$, indicating a requirement for PPARα in the PUFA-mediated induction of these enzymes. However, PUFA still suppressed $mRNA_{FAS}$ and $mRNA_{S14}$ in the PPARα-deficient mice. These results indicate that while PPARα is required for the FA induction of AOX and CYP4A2, it is not required for PUFA suppression of L-PK, FAS, or S14.

Prostanoid regulation of hepatic gene expression. Arachidonic acid (20:4n-6) is a substrate for the synthesis of prostaglandins, leukotrienes, and related compounds (24). In cultured adipocytes, 20:4n-6 is converted to prostanoids and suppresses $mRNA_{S14}$ and $mRNA_{FAS}$ through a pertussis toxin-sensitive G_i/G_o-linked pathway (10). In liver, both 20:4n-6 and

20:5n-3 are equipotent inhibitors of glycolytic and lipogenic gene transcription. While 20:4n-6 is a precursor to prostanoids, 20:5n-3 is a poor substrate for prostanoid conversion. This finding suggested that PUFA might not go through a prostanoid pathway to affect hepatic gene expression. Thus, the mechanism of 20:4n-6 control of lipogenic gene expression in the liver and white adipose tissue is different.

To examine this issue further, primary rat hepatocytes were treated with inhibitors of 20:4n-6 conversion to prostanoids (flurbiprofen, a cyclooxygenase inhibitor) or leukotrienes [nordihydroguaiaretic acid (NGDA) a lipoxygenase inhibitor] (10). Both inhibitors failed to block the 20:4n-6-mediated inhibition of S14CAT expression. Interestingly, treatment of primary hepatocytes with prostaglandin E_2 (PGE_2) (10 μM) suppressed the mRNA encoding S14 and FAS as well as S14 CAT activity. Like PUFA regulation of S14, one of the *cis*-regulatory targets of PGE_2 action was the S14 Y-box. In adipocytes, PGE_2 suppressed S14 and FAS gene expression through a G_i/G_0 system, involving changes in intracellular free calcium (10). Whether a similar mechanism is operative in hepatic parenchymal cells awaits further investigation.

PUFA regulates hepatic gene expression through multiple mechanisms. These studies indicate that the pleiotropic effects of PUFA on hepatic gene transcription can not be attributed to a single pathway or mediator. In fact, at least three distinct pathways are operative in the liver (Fig. 2). They are: (i) PPARα-dependent; (ii) prostanoid-dependent; and (iii) PPARα and prostanoid-independent. In rat hepatic parenchymal cells, the PPARα pathway is activated by 20:5n-3, but not by 18:2n-6, 18:3n-3, 18:3n-6, or 20:4n-6. When compared to WY14,643, 20:5n-5 is a weak activator of PPARα (18). Despite this weak activation, 20:5n-3 requires PPARα to induce enzymes involved in FA oxidation, *e.g.*, AOX and CYP4A2. In contrast to FA oxidation, PPARα is not required for the PUFA-mediated suppression of lipogenic or glycolytic gene expression. An exception to this is seen with the potent peroxisome proliferator, WY14,643 (19). WY14,643-activated PPARα interferes with T_3 regulation of gene expression by sequestering RXR. RXR is a co-receptor required for heterodimer formation with thyroid hormone receptors and DNA binding. Based on these studies, we speculate that under normal dietary conditions, dietary PUFA may have little impact on PPARα-regulated gene transcription.

A second mechanism of PUFA control involves a paracrine regulatory mechanism. n-6 PUFA are not converted to prostanoids within hepatic parenchymal cells due to the lack of cyclooxygenase. However, these FA can be converted to prostanoids in nonparenchymal hepatic cells, like Kupffer or endothelial cells. Upon appropriate activation, released prostanoids, like PGE_2, can activate G-protein-coupled prostanoid receptors (*e.g.*, EP3) on hepatic parenchymal cells, initiating a signal transduction cascade that leads to a suppression of S14 and FAS mRNA. One *cis*-regulatory target for PGE_2 action of the S14 promoter is the Y-box. How this mechanism participates in the regulation of hepatic lipogenic gene expression in healthy subjects ingesting normal quantities of dietary PUFA is not clear. However, this mechanism may have a more significant impact in septic animals with hepatic inflammation.

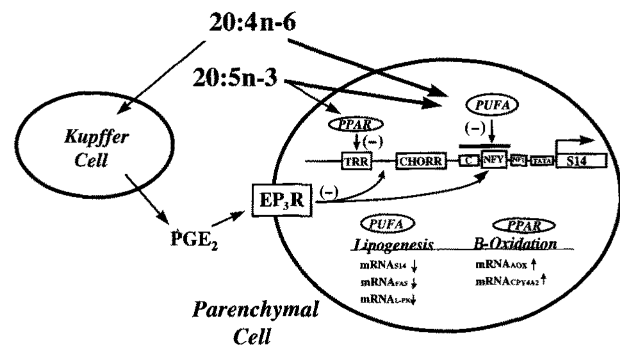

FIG. 2. Direct and paracrine regulation of S14 gene transcription by PUFA and PUFA metabolites. Hepatic parenchymal cell S14 gene transcription is suppressed by PUFA, peroxisome proliferater-activated receptor (PPARα), prostanoids (PGE_2, $PGF_{2\alpha}$);. 20:5n-3 is a weak activator of PPARα in rat liver. Activation of PPARα leads to the induction of mRNA encoding acyl CoA oxidase (AOX) and cytochrome P450 (CYP)4A2. Strong activation of PPARα by WY14,643 targets the S14 TRR leading to interference of T_3 regulation of this gene. PGE_2 is not generated in rat hepatic parenchymal cells. However, parenchymal cells respond to prostanoids through an EP3-like receptor. Thus, 20:4n-6 can be converted to a prostanoid in a nonparenchymal cell and through a paracrine mechanism activate an EP3 receptor. This leads to a suppression of mRNA encoding S14, FAS, and L-PK; 20:4n-6 and 20:5n-3 act directly on rat hepatic parenchymal cells and target the proximal promoter region of S14. Targeting this region leads to an interference with the enhancer-mediated transactivation of S14 gene transcription. FAS, fatty acid synthase; L-PK, L-pyruvate kinase; CYP, cytochrome P450. See Figure 1 for other abbreviations.

A third pathway for PUFA regulation of hepatic gene expression is independent of PPARα and prostanoids and involves the control of glycolytic and lipogenic gene transcription. In contrast to the two preceding pathways, a wide spectrum of FA activates this pathway, including 18:3n-6, 18:3n-3, 20:4n-6, and 20:5n-3. This pathway targets a *cis*-regulatory region within the S14 proximal promoter that includes the Y box, binding NFY and the C-region binding factors that remain to be identified. Based on our previous studies, this pathway is probably the operative mechanism for the control of lipogenesis under the following physiological conditions: (i) during the suckling period prior to weaning, (ii) starvation; (iii) uncompensated diabetes, and (iv) ingestion of PUFA-containing diets.

The finding that PUFA regulation of hepatic gene transcription involves multiple pathways suggests that lipogenesis, per se, may play an important regulatory role in hepatic carbohydrate/lipid metabolism. In addition to its role in the palmitate synthesis, this pathway may also function in nutrient partitioning (FA oxidation vs. storage), triglyceride assembly into VLDL, or myristate formation (25). Numerous physiological states are known to affect this pathway, like suckling/weaning, starvation/re-feeding, diabetes, high-carbohydrate fat-free diets, insulin resistance, obesity, and sepsis. With our new understanding of the pleiotropic effects of

dietary fat on gene expression, we can begin to understand how effects of dietary fat on the genome contribute to alterations in hepatic lipid/carbohydrate metabolism associated with chronic diseases like obesity and insulin resistance.

The Double Bond in Unsaturated Fatty Acids Is the Necessary and Sufficient Requirement for the Inhibition of Expression of Endothelial Leukocyte Adhesion Molecules Through Interference with Nuclear Factor-κB Activation

M. Massaro[a], M.A. Carluccio[b], C. Bonfrate[b], L. Siculella[c], G. Lazzerini[a], W. Bernini[a], G. Basta[a], and R. De Caterina[a,*]

[a]CNR Institute of Clinical Physiology, Pisa and [b]Lecce, and [c]the University of Lecce, Lecce, Italy

We previously showed that n-3 polyunsaturated fatty acids (FA) inhibit endothelial activation, i.e., early events involved in early atherogenesis and inflammation. These include the expression of endothelial leukocyte adhesion molecules, such as VCAM-1, ICAM-1, E-selectin, and endothelial chemoattractants (1). We further analyzed endothelial effects of various FA differing in chain length, number, position, and *cis/trans* configuration of the double bonds, concluding that saturated FA are inactive, while potency of polyunsaturates increases with the number of unsaturation (2). We now analyze the extent and mechanisms of modulation of endothelial activation by the monounsaturated FA oleic acid (18:1n-9), as the basis for such effects of the single double bond, and a possible contribution to healthy effects of olive oil in the Mediterranean diet.

Methods. Sodium oleate, in medium with 15% serum, was incubated with human umbilical vein endothelial cells for 24–72 h followed by coincubation of oleate with interleukin-1, *Escherichia coli* lipopolysaccharide (LPS), or phorbol myristate acetate (PMA) for a further 1–16 h. U937 monocytoid cell adhesion was measured by adhesion assays, the endothelial expression of VCAM-1, E-selectin, and ICAM-1 by cell surface enzyme immunoassays, steady-state levels of VCAM-1 mRNA by Northern analysis, and nuclear factor (NF)-κB activation by electrophoretic mobility shift assays (EMSA). Fatty acid composition of total cell lipid extracts was monitored with gas–liquid chromatography.

Lipids 34, S213–S214 (1999).

Abbreviations: EMSA, electrophoretic mobility shift assays; FA, fatty acid; LPS, lipopolysaccharide; NF-κB, nuclear factor; PMA, phorbol myristate acetate.

TABLE 1
Results for VCAM-1 Expression, After Lipopolysaccharide (for 16 h)

Sodium oleate (μM)	0	1	25	50
VCAM-1 expression	100	99 ± 3	60 ± 10*	44 ± 9*

*$P < 0.05$ vs. control (no fatty acid).

Results. At 25–100 μM, concomitant with a selective displacement of saturated FA from cell lipids, oleate inhibited U937 cell adhesion and the expression of all adhesion molecules induced by any of the stimuli used (Table 1).

The effect of oleate required a preincubation of hours before the addition of cytokines or LPS or PMA, being absent upon coincubation, and increasing up to 48–72 h. This was associated with a reduction of VCAM-1 mRNA levels at Northern analysis, and inhibition of NF-κB activation at EMSA.

Conclusions. These results indicate that the single double bond present in oleic acid is a necessary and sufficient requirement for FA inhibition of endothelial activation. Since this occurred independent of the stimuli used and was present also with PMA, bypassing membrane receptors, these results point to an interference with a common signal transduction pathway for cytokine signaling. These results are accounted for by an inhibition of NF-κB activation, here demonstrated at the same concentrations required for the inhibition of surface protein. Relevance of these observations to explaining the alleged beneficial antiatherogenic effects of the Mediterranean diet, in which oleic acid in olive oil is a major nutritional component, could lie in the relatively selective displacement of saturated FA by oleate addition to endothelial cells which was also shown to occur in our system. Thus, an increase in the unsaturation index in cell membranes by oleic acid-rich diets is theoretically additive to the effects of polyunsaturated FA. By these mechanisms, monocyte recruitment in response to atherogenic stimuli might be decreased (3).

Reduction of Scavenger Receptor Expression and Function by Dietary Fish Oil Is Accompanied by a Reduction in Scavenger Receptor mRNA

E.A. Miles, F.A. Wallace, and P.C. Calder*

Institute of Human Nutrition, University of Southampton, Southampton SO16 7PX, United Kingdom

During atherosclerosis, macrophages (MØ) within plaques take up oxidized low density lipoprotein (LDL) *via* the scavenger receptor (SR) to become lipid-laden foam cells. Dietary fish oil (FO) provides some protection against the development of atherosclerosis in a variety of species including mice, pigs, nonhuman primates, and man (1,2). We hypothesized that at least part of this beneficial effect might be due to a reduction in SR expression on MØ. Thus, in this study the effect of feeding mice high-fat diets with different fatty acid compositions upon class A SR (SRA) expression (mRNA and protein) and function [uptake of acetylated-LDL (Ac-LDL)] was investigated.

Male C57Bl/6 mice were fed for 12 wk on a low-fat (LF) diet (25 g corn oil/kg) or on diets containing 200 g/kg of either coconut oil (CO), olive oil (OO), safflower oil (SO), or fish oil (FO). Four days prior to sacrifice, the mice were injected intraperitoneally with thioglycolate broth to elicit MØ migration to the peritoneal cavity. At sacrifice the MØ were collected by lavaging the peritoneal cavity. Flow cytometry was used to assess cell surface SRA expression (staining with a fluorescently-labeled monoclonal antibody [clone 2F8; Serotec, Kidlington, United Kingdom]) and function (uptake of fluorescently-labeled Ac-LDL [Biogenesis, Poole, United Kingdom] over 1 h); flow cytometry data are expressed as % of positive cells and median fluorescence intensity (MFI). The 2F8 monoclonal antibody recognises both the type I and type II forms of the SRA (3) and both forms are involved in Ac-LDL uptake by MØ. RNA was extracted, and SRA type I and type II mRNA levels were quantified using reverse transcriptase-polymerase chain reaction (RT-PCR); mRNA levels are expressed relative to cyclophilin mRNA levels also determined by RT-PCR.

FO feeding significantly reduced the percentage of SRA-positive MØ compared with the other high-fat diets (Table 1). This was mirrored by a trend toward a reduced number of MØ able to take up Ac-LDL following FO feeding. The level of

TABLE 1
Effect of Dietary Fats on Murine Scavenger Receptor Expression and Function[a]

expression of the SRA on positive MØ, as measured by MFI, was also reduced by FO feeding, but this did not reach statistical significance. Once again, this was mirrored by a reduced level of Ac-LDL uptake by those cells which were active. MØ from OO-fed mice contained significantly lower levels of SRA type I mRNA than those from mice fed the LF and CO diets (Table 1). MØ from OO- and FO-fed mice contained significantly lower levels of SRA type II mRNA than those from LF-fed mice (Table 1).

We conclude that FO feeding reduces macrophage SRA expression by acting at the level of gene transcription and that this might contribute to the protective effect of dietary FO toward atherosclerosis.

The Effect of Eicosapentanoic Acid on Matrix Metalloproteinase Gene Expression

A.J. McCabe, J. Wallace, W.S. Gilmore, J.J. Strain, and H. McGlynn*

Northern Ireland Centre for Diet and Health (NICHE), School of Biomedical Sciences,
University of Ulster at Coleraine, Northern Ireland, BT52 1SA

Matrix metalloproteinases (MMP) are a family of serine proteases of which 21 members are known to date. The members of this gene family share a number of biochemical properties which include possession of a zinc ion in their active site, secretion in a latent form requiring proteolytic activation in the cytoplasm, and the capability of degrading at least one component of the extracellular matrix; also all members of the MMP family are inactivated by their natural inhibitors, the tissue inhibitors of matrix metalloproteinases (TIMP). Matrix metalloproteinases are involved in remodeling the extracellular matrix, which is vital to numerous cell processes including proliferation and differentiation. However, extensive remodeling of the cell matrix by MMP has been observed in a number of human disease conditions such as arthritis (1), coronary heart disease (2), and cancer (3).

MMP play a pivotal role in tumor metastasis in which excessive extracellular matrix degradation facilitates cancer cell migration to secondary sites. During the process of tumor invasion increased MMP production has been linked to an increased invasive phenotype in a number of human cancers. Dietary fats such as those comprising the polyunsaturated fatty acids, which include the n-3 and n-6 subclasses, have been reported to effect both growth and metastasis of a number of human tumors both *in vitro* and *in vivo* (4). Investigators generally report protective effects by n-3 fatty acids such as eicosapentanoic acid (EPA) and docosahexanoic acid on growth and metastasis whereas n-6 fatty acids are reported to enhance the growth and invasion of cancer cells. In this present study we investigated the effects of EPA on the gene expression of one of the most abundant metalloproteinases, MMP-2, and one of its inhibitors, TIMP-2, in a renal cell carcinoma by reverse transcription polymerase chain reaction.

Materials and Methods. Cell culture. The renal cell carcinoma, caki-1, was routinely maintained in McCoy's 5A supplemented with 10% fetal bovine serum with 5 mg/mL penicillin/streptomycin. Caki-1 were grown in a humidified atmosphere at 37°C and 5% CO_2.

Fatty acids. EPA and arachidonic acid (AA) were purchased from Sigma (United Kingdom) in 99% pure free acid form and were diluted in 100% ethanol.

Growth assay. The effect of EPA and AA on the proliferation of caki-1 cells was assessed using the MTT [3-(4,5-dimethylthiazo-2-yl)-2,5-diphenyltetrazolium bromide] assay (Boehringer Mannheim, Mannheim, Germany) according to the manufacturer's protocol.

RNA isolation. Total RNA was isolated from 1×10^6 caki-1 cells harvested by trypsinizing following culturing with fatty acids. RNA was extracted using a commercial total RNA isolation kit (Glassmax RNA isolation kit, Gibco BRL, United Kingdom). RNA was isolated according to manufacturer's protocol. Extracted RNA was measured at 260 nm, aliquoted and stored at −20°C.

Reverse transcription polymerase chain reaction (RT-PCR). RT-PCR was performed using a single tube method which utilized an enzyme mix containing both a reverse transcriptase and a polymerase enzyme (One-step RT-PCR kit, Gibco BRL). Total RNA (500 ng) was used in each RT-PCR reaction according to manufacturer's instructions. The RT-PCR conditions were as follows: 50°C for 30 min, 94°C for 3 min followed by 30 cycles of 94°C for 50 s, annealing temperature for 60 s, and 72°C for 40 s. This was followed by a final extension step of 72°C for 10 min and storage at −20°C. The annealing temperatures used for MMP-2 and TIMP-2 were 57 and 60°C, respectively. Glyceraldehyde phosphate dehydrogenase (GAPDH) was used as an internal control for the RT-PCR reactions; our GAPDH primers had an annealing temperature of 56°C. Following the RT-PCR reactions the products were visualized by agarose gel electrophoresis and analysed by one-dimensional analysis (Phoretix software package).

Results and Discussion. From data obtained from the MTT proliferation assay we were able to determine that concentrations of EPA greater than 30 μM caused a decrease in the proliferation of caki-1 cells, and concentrations of AA above 10 μM showed a similar decrease in proliferation. For this reason all subsequent experiments used concentrations of fatty acids below these levels.

FIG. 1. Reverse transcription polymerase chain reaction (RT-PCR) of matrix metalloproteinase (MMP)-2 gene. Lanes 1–5, respectively: 100 bp molecular weight marker, no fatty acid, 10 μM eicosapentaenoic acid (EPA), 20 μM EPA, 30 μM EPA.

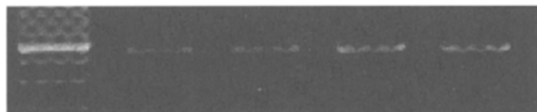

FIG. 2. RT-PCR of tissue inhibitor of metalloproteinase (TIMP)-2 gene. Lanes 1–5; respectively: 100 bp molecular weight marker, no fatty acid, 10 μM EPA, 20 μM EPA, 30 μM EPA. For other abbreviations see Figure 1.

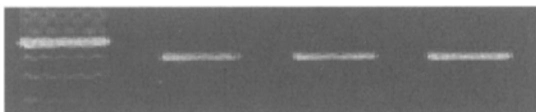

FIG. 3. RT-PCR of MMP-2 gene. Lanes 1–4, respectively, 100 bp molecular weight marker, no fatty acid, 5 μM arachidonic acid (AA), 10 μM AA. For other abbreviations see Figure 1.

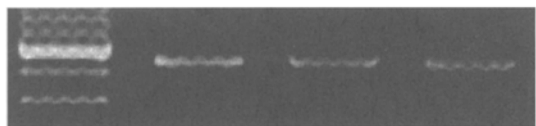

FIG. 4. RT-PCR of TIMP-2 gene. Lanes 1–4, respectively: 100 bp molecular weight marker, no fatty acid, 5 μM AA, 10 μM AA. For abbreviations see Figures 1–3.

Figure 1 shows the effect of increasing EPA concentration on the gene expression of MMP-2. Figure 1 illustrates a decrease in the MMP-2 RT-PCR bands as EPA increases to 30 μM. Figure 2 also shows a dose response effect of increasing EPA in the expression of TIMP-2, which increases with increasing EPA concentration. Caki-1 cells cultured in AA showed an increase in MMP-2 and a decrease in TIMP-2 as illustrated in Figures 3 and 4. The GAPDH gene expression did not change with treatment (data not shown). The results demonstrate alterations in the gene expression in MMP-2 and TIMP-2 which may reduce the metastatic potential of caki-1 when supplemented with n-3 fatty acids and an alteration which may enhance the metastatic potential by increasing MMP-2 and decreasing TIMP-2 when supplemented with n-6 fatty acids. The results suggest a possible role for dietary supplementation with fish oils high in n-3 polyunsaturated fatty acids for the treatment of renal cancer.

Opposite Regulation of Prostaglandin H Synthase Isoforms by Eicosapentaenoic and Docosahexaenoic Acids

M. Gilbert[a], F. Achard[a], S. Dalloz[a], J. Maclouf[b], C. Bénistant[a], and M. Lagarde[a,*]
[a]INSERM U 352, Biochimie & Pharmacologie INSA-Lyon, 69621 Villeurbanne, France, and [b]INSERM U 348, Paris, France

Long-chain n-3 fatty acids such as eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids have been described as inhibitors of platelet response by reducing prostanoid synthesis from arachidonic acid (AA), both in decreasing its availability from membrane phospholipids and its conversion by prostaglandin H (PGH) synthase (1), and at least for DHA, in reducing thromboxane receptor sensitivity (2). The effect of EPA and DHA on the other potent prostanoid, prostacyclin (PGI_2), has been however controversial as *ex vivo* experiments have suggested that PGI_2 production is preserved after fish oil intake (3), whereas its production by cultured vascular endothelial cells was inhibited (4). The latter has been reevaluated by investigating the expression of enzymes responsible for the conversion of AA into PGI_2.

Primary cultures of bovine aortic endothelial cells were incubated with 25 μM albumin-bound EPA, DHA, or oleic acid (molecular ratio fatty acid/albumin of 1.3:1) for 22 h and compared with those incubated with albumin alone (control). Under these conditions, the majority of each fatty acid tested was esterified in cell phospholipids, mainly at the expense of endogenous oleic, linoleic and arachidonic acids, except for the oleic acid-enriched cells which only lost linoleic and arachidonic acids. On the other hand, PGI_2 production from exogenous as well as endogenous AA was decreased by 50% in EPA- or DHA-rich cells but remained unchanged in oleic acid-rich ones. This indicated an inhibition of PGI_2 production downstream from phospholipase(s), i.e., at the level of PGH synthase and/or PGI_2 synthase specific activities and/or quantities. Western blotting analyses of the constitutive isoform of PGH synthase (PGHS)-1, showed a significant decreased immunoreactive amount in EPA- and DHA-rich cells but not in oleic acid-rich ones, while no alterations of PGI_2 synthase could be detected. Further investigations by Northern blotting revealed that the PGHS-1 mRNA was similarly and significantly decreased by cell preenrichment with EPA and DHA but not with oleic acid. Finally, studies on the stability of PGHS-1 mRNA in the presence of the transcription inhibitor actinomycin D failed to show any difference in the time-dependent decay in control and DHA-rich cells, strongly suggesting that the inhibition of PGHS-1 expression observed in EPA- or DHA-rich cells likely occurred at the transcriptional level (5).

Whereas the inducible isoform of PGHS, PGHS-2, could not be detected by Western blotting in any of the above-mentioned conditions, it could be measurable after 2 to 4 h incubation with phorbolmyristate acetate (PMA) used at concentrations as low as 10 nM. After 4 h incubation, the expression of PGHS-2 was already strong enough to mask any effect of cell preenrichment with DHA. However, in the weaker stimulation condition of 2-h incubation with PMA, the cell preenrichment with DHA markedly and significantly increased the expression of PGHS-2, showing a potentiation of such an expression. This indicates that PGHS-2 may be oppositely regulated by long chain n-3 fatty acids when compared to PGHS-1.

We conclude that, in addition to the well-known metabolic effect on n-3 fatty acids on prostanoid generation, a regulation of the PGHS protein expression could occur and contribute to the overall effect of those fatty acids on prostanoid homeostasis.

Effects of Fish Oil and n-3 Fatty Acids on the Regulation of Δ^9-Fatty Acid Desaturase mRNA and -Activity in Rat Liver

T. Løchsen[a], H. Ormstad[a], H. Braud[a], B. Brodal[a], E.N. Christiansen[b,*], and H. Osmundsen[a]

[a]Institute of Oral Biology, Department of Physiology and Biochemistry, University of Oslo, and [b]Institute for Nutrition Research, University of Oslo, Norway

This study was designed to study the effects of treatment with dietary fish oil, or with long-chain n-3 polyunsaturated fatty acids, on Δ^9-desaturase in rat liver. The desaturase activity was measured in isolated microsomes in parallel with measurements of liver content of Δ^9-desaturase mRNA. Fish-oil diet [20% (w/w) of dietary fat] led to 85% decrease in Δ^9-desaturase activity, while the decrease in Δ^9-desaturase mRNA was about 90%. In comparison, soybean oil-diet rich in linoleic and α-linolenic acids [20% (w/w)] decreased Δ^9-desaturase activity by 50%, and the hepatic mRNA content by about 60% (Fig. 1). Treatment with docosahexaenoic acid (DHA) *per os* decreased the Δ^9-desaturase mRNA by 70%, while treatment with eicosapentaenoic acid (EPA) decreased the mRNA level only slightly less than with palmitic acid (PMA) (Fig. 2). DHA and EPA were kindly supplied by Pronova Biocare A/S (Lysaker, Norway). Clofibrate treatment, in contrast, caused about a sixfold stimulation of Δ^9-desaturase activity and about twofold increase in mRNA concentration. At the same time the amounts of acylCoA oxidase- and acylCoA dehydrogenase mRNA did not vary significantly with high-fat diets or long-chain n-3 fatty acids, but increased 2- and 2.5-fold, respectively, with clofibrate. The experiments show that fish oil has a strong decreasing effect on the amount of Δ^9-desaturase mRNA and that docosahexaenoic acid in the oil may be a potent component in this respect.

The effect of fish oil on the transcription of Δ6- and Δ5-desaturase has not been studied because the enzymes have

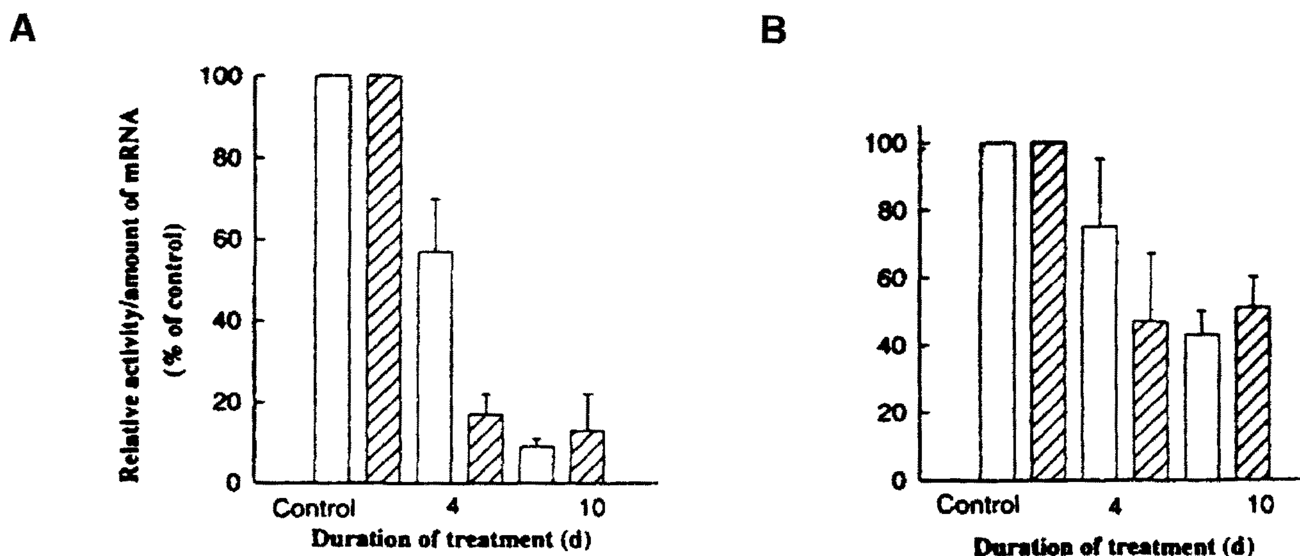

FIG. 1. Effects of fish- and soybean oil-diets on hepatic Δ^9-desaturase activity and amount of mRNA in percentage of control values. Rats were fed on high-fat diets containing 20% (w/w) fish oil (A), or soybean oil (B) for 10 d. The amounts of Δ^9-desaturase mRNA (in %) were measured, and activities of Δ^9-desaturase were assayed as described in Reference 1. Control value (pellet-fed) of Δ^9-desaturase activity was 0.15 ± 0.02 nmol/mg/min (100% activity). The values represent duplicate measurements each from four rats. Cross-hatched box; Δ^9-desaturase activity, open box; Δ^9-desaturase mRNA.

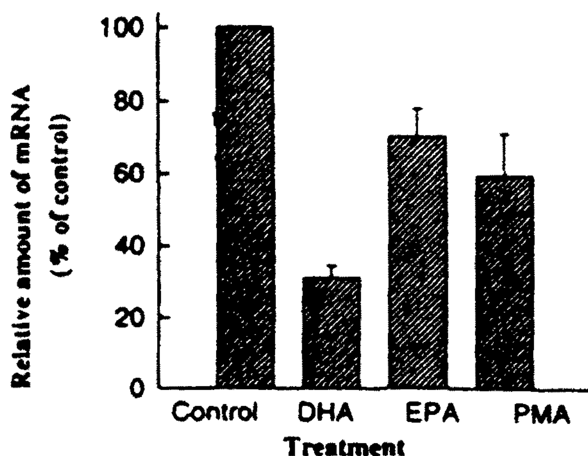

FIG. 2. Effects of ethyl-docosahexaenoate (DHA), ethyl-eicosapentaenoate (EPA), and palmitic acid (PMA) on amount of hepatic Δ^9-desaturase mRNA in percentage of control values. Rats were given the fatty acid by gastric tube delivery for 10 d as described in Reference 1. Controls were pellet-fed. The values represent duplicate measurements each from 4–8 rats.

still not been purified to satisfactory levels. However, Christiansen *et al.* (2) studied their enzymatic activities; Δ6 desaturase activity decreased 50% compared to a pellet diet and 80% compared to a sunflowerseed diet (rich in linoleic acid), while Δ5-desaturase activity did not change compared to a pellet diet and decreased 60% compared to a sunflowerseed diet. These results with fish oil compared to a sunflowerseed oil diet on Δ6- and Δ5-desaturase activities are in the same range as the presented results were when we compared fish oil with a soybeen oil diet for Δ9-desaturase activity. A clue to a possible gene-regulation of Δ6- and Δ5-desaturases was given by Kawashima *et al.* (3) who studied their regulation by clofibric acid. They found a strong stimulation on both desaturases, and inhibition by cycloheximide which is a potent inhibitor of protein synthesis.

In conclusion fish oil was found to strongly decrease the amount of Δ9-desaturase-mRNA in parallel to Δ9-desaturase activity in rat liver. This suggests that the regulation of activity is exerted either on the level of transcription or at the level of control of mRNA stability. An active component in the fish oil in this respect seems to be DHA. There are indirect indications for gene regulation of Δ6- and Δ5-desaturase activities as well; however, the direct experiment has to our knowledge still not been performed.

Fatty Acid Synthase Gene Expression in Rat Mammary Carcinoma

S. Cognault[a,*], E. Germain[b], P. Bougnoux[b], and C. Lhuillery[a]

[a]LNSA, INRA, Jouy-en-Josas, F-7835, and [b]EA 2103, Université de Tours, F-37044, France

Fatty acid synthase (FAS) [EC 2.3.1.85] is a lipogenic enzyme catalyzing *de novo* fatty acid biosynthesis. FAS is present in various mammalian tissues and at a high level in a few specific tissues, such as liver. It is well-established in these tissues that FAS activity and gene expression depend on nutritional, hormonal, and physiological parameters. We were interested in FAS because recent data showed that FAS is overexpressed in various types of human cancers, such as breast cancer, prostate cancer, and others. This abnormal expression has been associated with a poor prognosis. Yet, in contrast to normal tissues, very little study was carried out on FAS regulation mechanisms in tumoral tissues.

The objective of the present study was to investigate *in vivo* a potential dietary regulation of FAS in a rat model of breast cancer. To do so, we checked if FAS was expressed in a model of chemically induced mammary tumors. Then, we investigated if FAS gene expression was regulated by dietary factors, particularly by quantity or quality of dietary fat.

Mammary tumors were obtained by chemical induction with a direct carcinogen: *N*-methyl nitrosourea in female Sprague-Dawley rats receiving different dietary fat. To check whether FAS was expressed in this experimental model, we analyzed FAS mRNA in rat mammary tumors as compared to liver specimens from the same rat fed on a high-fat diet (15% wt). Next, to check whether FAS expression varied according to the quantity of fat in the diet, we analyzed FAS mRNA from rat mammary tumors fed either a low-fat (6% wt) or a high-fat (15% wt) diet. And then, to see if the quality of fat [degree of unsaturation, type of poyunsaturated fatty acid (PUFA)] influenced FAS expression, we tested a high level of either saturated or unsaturated fat (15% wt) and a high level of n-6 PUFA or n-3 PUFA (15% wt) on FAS mRNA level.

First, Northern blot analysis revealed that FAS gene was abundantly expressed in rat mammary tumors, but it was not detectable in the liver under these dietary conditions (high fat). Secondly, Northern blot analysis of FAS mRNA from mammary tumors of rats fed a low- or a high-fat diet has shown no difference in FAS mRNA level under the two dietary conditions. Moreover, FAS mRNA level was similar in mammary tumors whatever the degree of unsaturation of fat or the type of PUFA present in the diet.

So, the main finding of the study with the rat NMU model is that rat tumors expressed a high level of FAS, similar to previous reports on breast cancer and breast cancer cell lines. The elevated FAS level suggests that chemically induced mammary tumors are able to synthesize *de novo* fatty acid. Moreover, the level of FAS mRNA in rat mammary tumors is not regulated by dietary fat.

We conclude that this model can serve as an additional tool in evaluating *in vivo* the role of FAS in cancer development and its specific role in tumoral tissue. It can, as well, serve as a model for studying FAS regulation mechanisms in tumoral tissue.

Effects of Maternal Docosahexaenoic Acid Supplementation on Visual Function and Growth of Breast-Fed Term Infants

Craig L. Jensen[a], Thomas C. Prager[b], Yali Zou[b], J. Kennard Fraley[a], Maureen Maude[c], Robert E. Anderson[c], and William C. Heird[a]

[a]Department of Pediatrics, USDA/ARS Children's Nutrition Research Center, Baylor College of Medicine, Houston, Texas, [b]Department of Ophthalmology, Hermann Eye Center, University of Texas Health Sciences Center, Houston, Texas, and [c]Department of Ophthalmology, Oklahoma Center for Neurosciences, Dean A. McGee Eye Institute, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma

The low docosahexaenoic acid (DHA) content of the milk of women in the United States has led some to suggest DHA supplementation of breast-feeding women. However, data concerning the efficacy of supplementation are lacking. To provide such data, we determined the effects of DHA supplementation of lactating women on the visual function and growth of the recipient infants. Mothers were assigned randomly and blindly to receive ~200–250 mg of DHA daily as either algal DHA (Group 1; $n = 42$), refined high-DHA fish oil (Group 2; $n = 42$), or placebo (Group 3; $n = 42$) for 120 d after delivery. The fatty acid pattern of maternal milk and infant plasma phospholipid (PL) was determined 120 and 240 d postdelivery. Visual function of infants was assessed at the same ages by transient visual-evoked potential (VEP) latency and amplitude; visual acuity was measured at the same times by sweep VEP and the Teller Acuity Card Procedure. Growth was monitored throughout the study. At 120 d, milk total lipid DHA content of Group 1 and Group 2 was approximately twice that of Group 3 (0.37 and 0.39 vs. 0.17 mol%, respectively, of total fatty acids, $P < 0.001$); infant plasma PL DHA content was 45–48% higher ($P < 0.001$) and arachidonic acid, 22:4n-6, and 22:5n-6 contents were 11–13, 31–34, and 38–63% lower ($P = 0.04$, <0.001, and <0.001). There were no statistically significant differences among groups in VEP latency (125 ± 11 vs. 127 ± 11 vs. 122 ± 11 and 116 ± 8 vs. 117 ± 9 vs. 115 ± 8 ms in Group 1 vs. Group 2 vs. Group 3 at 120 and 240 d, respectively), sweep VEP acuity (9 ± 1.4 vs. 9 ± 1.4 vs. 9 ± 1.3 and 10.4 ± 1.7 vs. 9.6 ± 1.3 vs. 10.2 ± 1.5 cyc/deg) or Teller Card acuity (5.2 ± 2.7 vs. 5.1 ± 2.0 vs. 5.6 ± 2.6 and 11.8 ± 4.8 vs. 10.7 ± 3.9 vs. 12.9 ± 7.1 cyc/deg) at either age. Transient VEP amplitude was lower in infants whose mothers received the algal DHA supplement (Group 1) than infants in Group 2 and Group 3 at 120 d of age (22.8 ± 7.7 vs. 33.6 ± 13.5 vs. 33.1 ± 12.4 μvolts), but not 240 d of age (23.6 ± 6.6 vs. 25.0 ± 12.7 vs. 28.7 ± 11 μvolts). No measure of visual function correlated significantly with either milk DHA or infant plasma PL DHA content at 120 d of age. There were no statistically significant differences in weight, length, head circumference, or triceps skinfold thicknesses among groups at either 120 or 240 d of age. These data show that maternal DHA supplementation increases the DHA content of maternal milk as well as the plasma PL DHA content of the recipient infant but confers no detectable benefits with respect to visual function.

The Postpartum Docosahexaenoic Acid Status of Lactating and Nonlactating Mothers

Suzie J. Otto*, Adriana C. van Houwelingen, Anita Badart-Smook, and Gerard Hornstra
Department of Human Biology, Maastricht University, 6200 MD, Maastricht, The Netherlands

Results of a cross-sectional study conducted by Al *et al.* (1) indicate that the maternal docosahexaenoic acid (DHA) levels in plasma phospholipids are lower with each following pregnancy. This suggests that mothers invest DHA in the development of their infants, possibly by mobilization of their own DHA stores. This view is supported by another observation of Al *et al.* (2) that the amount of DHA in the maternal plasma phospholipids increases by more than 30% during pregnancy.

Since breast milk contains DHA, breast-feeding, in contrast to bottle-feeding, may continue to impose on the maternal DHA after delivery. Therefore, we compared the recovery of the maternal DHA postpartum between lactating and nonlactating mothers.

Methods. Healthy pregnant women in their last trimester were recruited through midwives in the area of Southern Limburg. A written inform consent was obtained from each participant before the start of the study, which was approved by the Medical Ethics Committee of the University Hospital Maastricht. Subjects were excluded if they received a blood transfusion at delivery.

Blood samples were collected into EDTA-containing tubes at week 36 of pregnancy, on the 2nd and 5th day after delivery, and at 1, 2, 4, 8, 16, 32, and 64 wk postpartum. Fatty acids were analyzed in plasma phospholipids as described previously (2). The DHA levels of the two groups were compared using multiple regression analysis, with correction for parity.

Results and conclusion. The preliminary results until 16 wk postpartum of 17 lactating mothers aged 33.1 ± 0.6 yr and 10 nonlactating mothers aged 30.0 ± 1.1 yr are reported. Both the lactating and the nonlactating mothers had uncomplicated pregnancies and delivered full-term singleton newborns (39.8 ± 0.2 vs. 39.9 ± 0.4 wk, respectively). At week 16, the mothers in the lactating group were still breast-feeding their infants.

There were no differences in the DHA levels of the two groups shortly after delivery (on the 2nd and the 5th day postpartum). The DHA levels started to decrease in both groups from week 1 postpartum. This decline became more pronounced in the lactating group, and at weeks 8 and 16 the DHA levels of the lactating mothers were significantly lower than those of the nonlactating mothers.

A comparison of the DHA levels at weeks 8 and 16 with data of 80 nonpregnant women showed that the levels of the lactating mothers were significantly lower than those of the nonpregnant women, whereas the levels of the nonlactating mothers were quite comparable with the nonpregnant group.

It can be concluded that maternal plasma DHA declines after delivery. This reduction is more pronounced in lactating as compared to nonlactating mothers. The DHA levels of lactating mothers reach values lower than in nonpregnant women. This observation suggests that lactating mothers may become DHA-depleted unless they increase their DHA intake during lactation.

The Female Docosahexaenoic Acid Status Related to the Number of Completed Pregnancies

A.C. van Houwelingen*, E.C. Hvd. Ham, and G. Hornstra
Maastricht University, Department Human Biology, 6200 MD, Maastricht, The Netherlands

Essential fatty acids (EFA) are important constituents of all cell membranes. High concentrations of the long chain polyenes (LCP) docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (20:4n-6) are present in the structural components of the brain and the retina. EFA and their LCP are therefore particularly important during fetal development, when processes like brain development and organogenesis take place. Because the fetus cannot synthesize EFA, the fetus depends on the transport of EFA from the maternal to the fetal circulation to acquire EFA. It is important that the maternal EFA status during pregnancy is adequate to cover the fetal requirement. The maternal DHA status decreases during pregnancy and seems to decrease further with each following pregnancy (1). This could imply that the maternal DHA status does not fully normalize after a mature pregnancy. To further test the suggestion that pregnancy is associated with a maternal DHA-depletion phenomenon, the existence of a relationship between the DHA status of nonpregnant women and the number of completed pregnancies has been investigated.

Materials and methods. For this purpose, the fatty acids in plasma and red blood cell (RBC) phospholipids obtained from women who completed zero ($n = 41$), one ($n = 21$), two ($n = 34$), three ($n = 26$), or four ($n = 7$) mature pregnancies have been analyzed (cross-sectional design). The average time lapse between blood sampling and last delivery was 3.7 yr (range 0.8 to 12.3 yr). Fatty acids were analyzed as described before by Al *et al.* (2). The relationships between the maternal DHA status and the number of completed mature pregnancies was estimated by means of multiple regression analysis. The influence of the time period between the different pregnancies on the maternal DHA status was also investigated. Because the total amount of fatty acids (mg/L) in the plasma and RBC phospholipids in the nulli-, primi-, and multipara was not significantly different, only the relative amounts (% w/w) of fatty acids have been considered and statistically analyzed.

Results. The amounts of plasma DHA (% w/w) in nullipara and mothers were not significantly different; a significant correlation between parity and plasma DHA did not exist either. The RBC DHA in mothers was significantly lower than that of nullipara ($P = 0.013$), but no significant correlation between RBC DHA and parity was observed. The time-interval between the different pregnancies did not influence the maternal DHA status. Because the average time lapse between blood sampling and last delivery was (rather long) 3.7 yr, we recalculated the results for a subsample of 27 mothers whose last delivery was at least 1 yr ago, but no longer than 2 yr ago. We got the same results: no differences at all.

Discussion. No relationship was found between the DHA status in blood and the number of pregnancies in nonpregnant women, by whom the last partus at the moment of research occurred at least 1 yr ago. The maternal DHA status probably normalizes within 1 yr after the last partus. Therefore, a maternal depletion phenomenon cannot be observed. The question remains why multiparous women have lower plasma DHA levels than primiparous women during pregnancy. We only can hypothesize about this. The study by Al *et al.* (1) was cross-sectional; maybe a longitudinal study will give different results. In addition, it could be that the plasma DHA levels have normalized after 1 yr, whereas tissue values (stores) have not and therefore during pregnancy, when there is a high demand for DHA, plasma levels do not rise as much as during the first pregnancy. More studies are needed to solve these questions.

Effects of Third Trimester Consumption of Eggs High in Docosahexaenoic Acid on Docosahexaenoic Acid Status and Pregnancy

Emily Borod,[a] Robin Atkinson[a], William R. Barclay[b], and Susan E. Carlson[a,*]

[a]University of Tennessee, Memphis, Tennessee, and [b]OmegaTech, Inc., Boulder, Colorado

Worldwide, maternal intakes of docosahexaenoic acid (DHA) are highly variable; however, few studies have looked at the effect of variable DHA intake on DHA in maternal and infant blood. We postulated that eggs from chickens fed DHA-rich microalgae (DHA Gold™, OmegaTech, Inc., Boulder, CO) would be accepted as a food source of DHA and increase levels of this fatty acid in blood lipids of mothers and infants. The primary aim of this study was to compare maternal third trimester DHA status and infant DHA status among women who: (i) were randomly assigned to consume up to one dozen regular eggs, each containing about 28 mg DHA, per week (regular egg); (ii) were randomly assigned to consume up to one dozen eggs from chickens fed a diet containing the dried microalgae, each containing approximately 135 mg DHA, per week (high-DHA egg); or (iii) routinely consumed few if any eggs (low egg). Secondary aims of the study were: (i) to determine the usual DHA intakes from eggs by women who delivered in our hospital, and (ii) to obtain data about pregnancy outcomes that might be relevant to safety and efficacy of the high-DHA eggs.

Methods. Pregnant women who were 24–28 wk postmenstrual age without diabetes, organ disease, or pre-eclampsia were asked to consent to the study. Blood samples (pre-study) were obtained, and the women were asked about frequency of food intake. Women who ate eggs were randomly assigned to regular or high-DHA eggs; women who ate few eggs were grouped without being randomized. The two egg groups were given one dozen eggs per week and instructed to eat as many of the eggs as they could. Egg intakes were recorded from written records and double-checked biweekly by telephone interviews.

Poststudy maternal bloods were taken at delivery. After delivery, cord bloods were obtained, the placentas and infants weighed, and infants' lengths and head circumferences measured. Plasma and red blood cells (RBC) were separated by centrifugation, and total lipids from each were extracted and separated into lipid classes by thin-layer chromatography. Plasma and RBC total phospholipids and plasma triglycerides were recovered from the plates, transmethylated with boron trifluoride–methanol, and the resulting fatty acid methyl esters analyzed by capillary gas–liquid chromatography (SP-2560, 100 m × 0.25 mm).

Results. Fifty-three women completed the study (16 low egg, 19 regular egg, 18 high-DHA egg). The respective mean pre-study DHA intakes from eggs for these groups were 5.4, 16.0, and 19.6 mg/day. The mean study DHA intakes from eggs for the same groups were 16.2, 51.2, and 205.2 mg/d based on weekly egg intakes of 2.7, 8.8, and 10.1 for 12.9, 12.6, and 12.8 wk of study, respectively.

In the control groups (low egg and regular egg), DHA decreased in each lipid class during the study while it increased in comparable lipids of the high-DHA egg group. The difference between groups did not reach statistical significance because of variable egg intakes within groups. However, regression analysis showed a significant positive relationship between study DHA intake and DHA in plasma and RBC lipids of women and infants at delivery.

The study did not have adequate power to detect an effect of high-DHA eggs on pregnancy outcome; however, several favorable outcomes were suggested. Despite the variability in number of eggs consumed, the high-DHA egg group had fewer low-birth-weight (<2500 g) (0% vs. 13 and 26%) and preterm (<37 gestation) (6% vs. 25 and 26%) infants than women from the low-egg and regular-egg groups, respectively. They also had larger placentas (760 g vs. 658 and 663 g), even after preterm infants were excluded (762 g vs. 665 and 710 g). A higher proportion of women in the control and comparison groups compared to the high-DHA group also had surgical delivery and received antibiotics in hospital. Three women in the regular-egg group but none in the high-DHA group or low-egg group developed gestational diabetes after enrollment.

Summary. High-DHA eggs appear to be a practical way to increase maternal DHA status. The data suggest that high-DHA eggs could decrease the incidence of preterm and low-birth-weight births, and this could be tested in a study with more statistical power. The neurodevelopment of infants from women fed low- and high-DHA eggs could also provide helpful information.

Essential Fatty Acid Status in Malnourished Children

Sonia Borno, María Eugenia Reymúndez, and Virgilio Bosch*

Sección de Lipidología, Instituto de Medicina Experimental, Universidad Central de Venezuela, Caracas, Venezuela

There are several hundred millions of malnourished children in the developing world. The high morbidity and mortality as well as many specific deficiencies have been extensively documented in this sad situation. On the contrary, essential fatty acid deficiency (EFAD) has only been dealt with scarcely and mainly in the extreme stages of kwashiorkor and marasmus. We report here preliminary observations in 32 cases from the hospital Instituto Clínico-Nutricional "Menca de Leoni" of Caracas (10 mild, 6 moderate, and 16 severe) and 22 controls. The staging of weight for age proposed by the World Health Organization was used (mild: <percentil 3 to −3 SD, moderate: −3 SD to −4 SD and severe: <−4 SD). None of our cases was complicated by infections. Only one reached the staging of kwashiorkor by Kanawati/McLaren index. Controls belong to the range of 90 to 10 percentile.

Biochemical methods. Three mL of blood in EDTA were obtained. Plasma phospholipids were extracted in chloroform/methanol, and then phospholipids separated by thin-layer chromatography in silica gel. Fatty acids (FA) were measured by gas–liquid chromatography in an open column of polyethylene-glycol-adipate 5% of 1.8 m at isothermal of 180°C. FA are expressed as percentage of total area of FA.

Results. Plasma phospholipid FA of the control children can be observed in Table 2. There is no major difference with what we observed in numerous analyses in the adult normal population. On the contrary, most of our malnourished children showed EFA deficiency (EFAD). In general both series, n-3 and n-6, were deficient. The extent of this problem could be very conveniently shown by calculating the index Σ non-EFA/Σ EFA in plasma phospholipids. The resulting indexes are shown in Table 3.

TABLE 1
Distribution of Malnourished Children

	N	Age (yr)	Boys	Girls

	Yes	No	*P* Fisher's exact test
Controls	2	20	
Total malnourished	27	5	<.001
Mild	9	1	<.001
Moderate	4	2	<.001

Discussion. Reported evidence of EFAD in malnourished children deals with primary severe malnutrition or with secondary deficiency related to malabsorption syndromes. Two general patterns have previously been observed. (i) The protein malnutrition prevails, so that the pool of C_{18} parent EFA cannot be elongated and unsaturated. In this case, no Mead acid is generally observed. (ii) Enzymes are preserved, but there is a very low C_{18} EFA pool. In this case Mead acid will be present and arachidonic acid will be low. Our cases belong to this second category. If the situation observed in our children is prevalent in other underdeveloped areas of the world, we can conclude that EFAD may be a very common nutritional deficiency. In general the treatment of this specific deficiency is not adequately standardized to replenish rapidly the membranes of most cells. Further research is needed in this interesting field.

A Hypothesis to Explain the Reduced Blood Levels of Docosahexaenoic Acid in Inherited Retinal Degenerations Caused by Mutations in Genes Encoding Retina-Specific Proteins

Robert E. Anderson[a–e,*], **Maureen B. Maude**[a,d,e], **Richard A. Alvarez**[a,d,e], **Gregory Acland**[f], **and Gustavo D. Aguirre**[f]

Departments of [a]Ophthalmology, [b]Cell Biology, [c]Biochemistry and Molecular Biology, and [d]Oklahoma Center for Neuroscience, University of Oklahoma Health Sciences Center, [e]Dean A. McGee Eye Institute, Oklahoma City, Oklahoma 73104, and [f]James A. Baker Institute for Animal Health, College of Veterinary Medicine, Cornell University, Ithaca, New York 14853

ABSTRACT: Some humans and animals with inherited retinal degenerations (RD) have lower blood levels of docosahexaenoic acid (22:6n-3) than controls. As a result of recent studies, clearly the low blood 22:6n-3 phenotype is found in multiple RD phenotypes and no mutation thus far identified in humans or animals is involved in lipid metabolism. Therefore, it seems reasonable to suggest that the primary defect is not in 22:6n-3 metabolism, but rather in some common convergent pathway that ultimately leads to the reduction of blood and tissue 22:6n-3 levels. One possibility is that the different mutations produce a metabolic stress that provokes structural and biochemical adaptive changes in photoreceptor cells and their rod outer segments. If the stress is oxidant, the retina could downregulate 22:6n-3 and upregulate antioxidant defenses. How such a stress could lead to changes in blood levels of 22:6n-3 is not obvious. However, the consistent finding of the 22:6n-3 phenotype in many different retinal degeneration genotypes suggests that some form of communication exists between the retina and other tissues that serves to reduce blood levels of 22:6n-3.

Retinitis pigmentosa (RP) is the name given to a group of retinal degenerations that may be inherited in an autosomal dominant, recessive, X-linked, or sporadic manner. The first symptom is usually night blindness, which is caused by the loss of rod photoreceptor cells in the peripheral retina. With time, the loss of vision slowly progresses until only "tunnel vision" remains, indicating that only cone photoreceptors in the central retina are still viable. In most cases of RP, cone photoreceptors eventually die, leading to total blindness.

Over the last 15 yr, numerous publications have appeared describing reduced levels of docosahexaenoic (22:6n-3) and other long-chain polyunsaturated fatty acids (LCPUFA) in blood lipids of patients with all types of RP (1–7). One of the most dramatic reductions in LCPUFA is in X-linked RP, where a positive correlation between blood LCPUFA levels and severity of RP was reported (7). Bazan *et al.* (8) found lower blood levels in persons with Usher's syndrome, a disease that includes loss of both vision and hearing. We (9) recently confirmed this finding and expanded it to show lower LCPUFA in persons with Usher's Type I (more profound vision and hearing loss), but not in persons with Usher's Type II (milder and slower loss of vision and hearing).

We reported that the blood level of 22:6n-3 is reduced in dogs (10) with progressive rod cone degeneration (*prcd*), an animal model of inherited retinal degeneration that closely resembles human RP (11). Interestingly, in the *prcd*-affected dog, there was also reduced 22:6n-3 levels in retinal rod outer segments (ROS) membrane lipids (12). Since there was no concomitant increase in 22:5n-6 in these membranes, the reduction was not due to n-3 deprivation. We thought at first that the primary defect in the dogs was a mutation in the gene encoding a protein involved in LCPUFA synthesis. However, we showed that affected dogs could synthesize 22:6n-3 from n-3 precursors (13). Recently, we analyzed ROS from transgenic pigs with a Pro247Leu rhodopsin mutation (Anderson, R., Maude, M., Petters, R., and Wong, F., unpublished results) and *rds* heterozygous mice with a peripherin mutation (Anderson, R., Maude, M., and Bok, D., unpublished results) and found reduced ROS levels of 22:6n-3 without an increase in 22:5n-6. Thus, in three animal models of RP, two of which have known mutations, there is a selective reduction in 22:6n-3 in the ROS membranes.

Is there a causal relationship between low-blood LCPUFA levels and retinal degeneration? The answer to this question appears to be "no." Our attempts to prevent retinal degeneration in *prcd*-affected dogs by supplementing young adults with fish oil were not successful (12). In that study, blood and ROS levels of 22:6n-3 were significantly elevated in affected

Lipids 34, S235–S237 (1999).

Copyright © 1999 by AOCS Press

and normal dogs given fish oil. However, after 5 mon, the 22:6n-3 levels in ROS of normal dogs given safflower oil (controls) were lower than those of the affected dogs given fish oil, yet the affected dogs lost photoreceptors and the normal dogs did not. In other studies, reduction in blood and ROS 22:6n-3 in rats (14,15), monkeys (16,17), and guinea pigs (18,19) can be achieved by feeding an n-3-deficient diet. However, this change is always accompanied by an elevation in n-6 LCPUFA (20). To our knowledge, there have been no reports that such fatty acid changes in ROS membranes lead to death of photoreceptor cells. Therefore, reduced ROS and blood levels of 22:6n-3, while found in animals with inherited retinal degenerations, is not sufficient to cause the degeneration.

Recently, it became clear that mutations in a number of genes encoding proteins expressed only in the retina are the cause of rod photoreceptor cell death (see RetNet™ at: http://www.sph.uth.tmc.edu/RetNet). To date, 97 genes associated with some type of retinal degeneration were mapped and 41 were cloned. Mutations were identified in the visual pigment opsin, the beta subunit of cyclic-GMP specific phosphodiesterase, RDS/peripherin, myosin type VIIa, and several other proteins. Also, different mutations within the same gene were found. There are now almost 100 different rhodopsin mutations that lead to retinal degeneration. Low blood levels of 22:6n-3 were found in patients with these known mutations, even though the proteins the genes encode are clearly not involved in lipid metabolism.

Why do humans and animals with several different, known mutations in genes encoding retina-specific proteins have reduced ROS and blood levels of 22:6n-3? To try to address this question, we have developed the metabolic oxidant stress hypothesis. Simply stated, our hypothesis is that mutations in genes encoding retina-specific proteins cause an oxidant stress that ultimately leads to the death of photoreceptor cells. Given the very high levels of 22:6n-3 in ROS membranes, the high flux of oxygen through the ROS membranes from the choriocapillaris circulation, and the constant bombardment of the ROS by light, conditions certainly exist in these membranes for lipid peroxidation. These postmitotic cells respond to the oxidant stress by undergoing a series of biochemical and morphological adaptations designed to upregulate their antioxidant defenses. This would include reducing the level of 22:6n-3, elevating the level of antioxidant protective molecules and enzymes, and perhaps reducing the ability of the cells to capture photons by either shortening their ROS or reducing the rhodopsin concentration in ROS membranes.

To achieve such changes would require a high degree of plasticity in retinal photoreceptor cells. Previous studies in our laboratory showed that rat photoreceptor cells indeed are capable of such dynamic actions (21–24). Albino rats stressed by rearing in relatively bright cyclic light from birth undergo profound structural and biochemical changes compared to animals raised in dim cyclic light. In these studies, rats were born into a controlled environment of 5, 300, or 800 lux intensity of cyclic light (12 h on/12 h off) and maintained in this environment for up to 12 wk. Compared to animals raised in 5 lux cyclic light, the following differences were found in rats raised in 800 lux cyclic light: (i) dramatic reduction in 22:6n-3 in ROS membranes without concomitant increase in 22:5n-6; (ii) relative reduction in phosphatidylethanolamine and phosphatidylserine, and increase in phosphatidylcholine; (iii) reduction in the amount of the visual pigment rhodopsin relative to phospholipid in the lipid bilayer; (iv) increase in the enzymatic activities of glutathione peroxidase, glutathione reductase, and glutathione S-transferase; (v) increase in the amounts of vitamins E and C; and (vi) shortened outer segment length and moderate disorganization of ROS disk packing.

These adaptive changes are for the most part reversible (24). If animals raised for 9 wk in 800 lux cyclic light are placed for 3 wk in 5 lux cyclic light, the level of ROS 22:6n-3 increases, the activities of the glutathione enzymes decrease, the levels of vitamins E and C decrease, and the morphological appearance of the ROS disks returns to that normally seen for these organelles. The only change that is not reversible is the loss of photoreceptor cell nuclei in the animals raised in the 800 lux cyclic light. The chronic stress of bright cyclic light rearing caused a slow loss (30%) of photoreceptor cells over a 12-wk period of time.

Our hypothesis is that mutations in photoreceptor-specific proteins cause an actual or perceived oxidant stress similar to that discussed above for albino rats raised in a bright cyclic light environment. To deal with such a stress, the retina adapts by reducing the level of 22:6n-3 in ROS membranes and upregulating the levels of antioxidant enzymes and small molecules. While this may afford some protection against retinal degeneration, the effect of the chronic stress is a slow loss of photoreceptor cells, much like that observed for the rats raised in 800 lux cyclic light.

In humans with RP and dogs with *prcd*, the initial biochemical observation was of lower blood levels of 22:6n-3 compared to controls. These results were confirmed in many different laboratories, in patients with all modes of inheritance of RP, so there is little question of their validity. We do not understand how mutations in so many different genes encoding proteins thought to be expressed primarily in the retina can lead to the systemic low-22:6n-3 phenotype. It is unlikely that each mutated gene product acts independently to affect some aspect of systemic fatty acid synthesis, transport, or uptake. We suggest that the oxidant stress caused by these different mutations induces the retina to release some signal to the liver that results in downregulation of 22:6n-3 incorporation into lipoproteins, as suggested by Bazan and Rodriguez de Turco (25), and possibly upregulation of the enzymatic oxidation of n-3 fatty acids. Alternatively, such a signal may be generated by the pineal gland, which also is capable of expressing some proteins otherwise found only in photoreceptor cells.

In order to design therapeutic strategies for RP patients, it is important to determine if their reduced blood level of 22:6n-3 is due to an adaptive response to an oxidant stress or to some other cause. If the reduction is an adaptation to an ox-

idative challenge, then supplementing RP patients with n-3 fatty acids may in fact exacerbate the loss of photoreceptor cells. On the other hand, if the lower blood levels are due to n-3 deficiency, then supplementation with LCPUFA may be of some benefit.

ABSTRACT: Studies were carried out to determine if decreased levels of central nervous system docosahexaenoic acid (DHA), a result of consuming an n-3-deficient diet, had an effect on learning- and memory-related behaviors in adult male rats. Females were reared on an n-3-deficient or n-3-adequate diet beginning at 21 d of life. Their male pups, the F2 generation, were weaned to the diet of the dam and tested at 9–12 wk of age. An olfactory-based discrimination and Morris water maze task were used to assess performance. Whole brain was collected after the behavioral experiments and central nervous system fatty acid content was analyzed in olfactory bulb total lipid extracts. F2 generation male rats consuming the n-3-deficient diet had an 82% decrease in DHA compared to rats consuming the n-3-adequate diet. The n-3-deficient animals made significantly more total errors in a 7-problem, 2-odor discrimination task compared to the n-3-adequate group. Furthermore, the escape latency in the Morris water maze task was significantly longer for the n-3-deficient rats compared to the n-3-adequate rats. These results indicate that rats with decreased DHA levels in the central nervous system perform poorer in these tasks compared to rats with higher DHA levels and suggest the presence of learning deficits in these animals.

The importance of n-3 fatty acids for the development and function of the central nervous system, particularly the visual system, has been well-established (1–3). Rats and guinea pigs maintained on diets deficient in n-3 fatty acids have abnormal electroretinograms (4–6). Human preterm infants and infant rhesus monkeys fed formulas without docosahexaenoic acid (DHA; 22:6n-3) also have abnormal electroretinograms as well as decreased visual acuity compared to infants fed formulas containing 22:6n-3 (7–10). DHA not only is found in high levels in the retinal rod outer segments but also is found in extremely high concentrations in brain synaptic membranes, suggesting it may play an important role in higher level neural function.

Previous literature describing the effects of decreased levels of brain 22:6n-3 on learning and memory in rodents has been inconsistent (11–16). In these studies, oils low in n-3 fatty acids (safflower, sunflower) were used in diets to achieve low dietary intakes of n-3 fatty acids and thus low levels of 22:6n-3 in the central nervous system. Several generations of animals maintained on the deficient diet are usually required to deplete neural 22:6n-3 (1,2). Bourre *et al.* (5) studied 60-d-old, third-generation male rats that had consumed either a sunflower oil- (low 18:3n-3) or soybean oil-based (adequate 18:3n-3) diet and found learning impairments in the safflower oil-fed rats in a shuttle box test. However, in second-generation adult mice, Wainwright found no significant differences in the Morris water maze between the n-3-deficient group and two other groups, a saturated fat group and adequate n-3 fatty acid group (17). Significantly lower rates of learning were reported in the saturated fat group (n-3 and n-6 fatty acid-deficient) compared to the n-3-adequate group. Criticisms of the animal learning and memory experiments range from improper use of statistics and experimental units to inadequate controls that would rule out sensory or motivational factors that could effect outcomes (18).

The purpose of the present experiment was to determine if decreased levels of brain 22:6n-3, achieved by an n-3-deficient diet, affected the performance of rats in an olfactory-based cognitive task and in the Morris water maze task. Rats have an exceptional ability to learn complex problems when odors are used as discriminative stimuli (19,20). Thus olfactory-based tasks may provide sensitive tests of learning and memory in the n-3-deficient rat.

MATERIALS AND METHODS

Animals. Twenty-one-day-old female, Long-Evans rats (Charles River, Portage, MI) were received at our animal facility, randomized into two groups and began consuming one of two experimental diets at this time. At 8 wk of age, these

Lipids 34, S239–S243 (1999).

females (F1 generation) were mated with chow-fed males. Their offspring, the F2 generation, were weaned to the diet of the dam and maintained on these diets throughout the study. Behavioral training of F2 generation males began when they were 68 d of age, and tissues were collected for fatty acid analysis at 12 wk of age. All animal procedures were approved by the National Institute on Alcohol Abuse and Alcoholism Animal Care and Use Committee.

Dietary treatments. The two experimental diets (Table 1), deemed "n-3-deficient" and "n-3-adequate," were based on the AIN93 diet (21) with modifications to reduce n-3 fatty acids in the basal diet components (Dyets, Bethlehem, PA). Vitamin-free casein replaced unprocessed casein, and the majority of cornstarch, which contains essential fatty acids, was replaced by maltose-dextrin. The diets were designed to contain only one primary fatty acid variable, α-linolenic acid (18:3n-3). Safflower oil contributed adequate and identical amounts of linoleic acid (18:2n-6) to both diets. A small amount of flaxseed oil, the only variable, was added to the n-3-adequate diet to provide adequate n-3 fatty acids. The fatty acid composition of the diets is shown in Table 2.

Olfactomter. A multichannel olfactometer (Model LD8; Knosys Ltd., Bethesda, MD) was used. The unit was similar in design to that described by Slotnick and Risser (22). Briefly, the unit controls air flow in eight independent channels, allowing any one of eight different odors to be presented. A special feature of the olfactometer was the use of pinch valves to control odor flow. By replacing tubing controlled by the valves when new odors were used, potential valve contamination was eliminated.

The operant conditioning chamber was similar to that described by Lu *et al.* (23). The output of the odor generator was connected to a vertically oriented 25-mm diameter glass tube attached to one wall of the chamber. A 20-mm diameter hole in the tube allowed the rat to sample odors. Snout insertions into the tube were detected by a photocell. A 13-gauge stainless steel drinking tube was located above and 50 mm to one side of the opening in the odor sampling tube. Contacts with the drinking tube were detected by a sensitive circuit. The drinking tube was connected *via* a normally closed solenoid to a water reservoir. Operation of the solenoid dispensed 0.04 mL water.

[a]n.d. = Not detected.
[b]The following fatty acids were analyzed and were not present at detectable levels: 12:1, 14:1, 20:3n-6, 20:4n-6, 20:5n-3, 22:5n-3, 22:6n-3. PUFA, polyunsaturated fatty acids.

Olfactory training and test procedures. At approximately 7.5 wk of age, F2 males were placed on a 7.0 mL/day water schedule, and beginning 12 d later, rats were trained using standard operant procedures to respond (lick) at the water delivery when it detected an odor in the odor sampling tube. The go, no-go odor discrimination procedure was described in detail (22). Testing began at about 9.5 wk of age. Each day, for 7 d, all rats were tested on a novel two-odor discrimination problem. Odors (McCormick, Hunt Valley, MD) were paired and ordered randomly. Briefly, rats were presented with two different odors each day, one designated S+ (positive stimulus) and one designated S− (negative stimulus). One hundred trials (50 S+ trials and 50 S− trials) were presented in problems 1–5, and 60 trials were presented in problems 6 and 7. Over time, rats learned that the S+ odor was associated with a water reward and the S− odor was not associated with a water reward, and subsequently the rat would only respond to the water tube after sampling the S+ odor. The endpoint was total number of errors (responding to the S− odor or not responding to an S+ odor) at the end of seven problems. Because training procedures and

discrimination tests are completely automated (computer-controlled), experimental bias was eliminated (19,20,22).

Water maze task. The Morris water maze is a more traditional method for testing spatial cognitive abilities. The water maze consists of a circular pool (4 ft diameter by 2 ft deep) containing tap water maintained at 20°C and an escape platform. The maze was in the middle of a room and was surrounded by visible cues (posters, table, door, etc.). All animals were tested two times/day in the Morris water maze. Initially, they were subjected to a visible platform test (training trial) in which the animals were placed into the water maze and allowed a maximum of 90 s to locate the visible platform. The visible test was used to test vision (sensory) and swimming ability of the animals. If the platform was not found, the rats were guided to the platform and allowed to remain there for 30 s. The following day was the first day of testing (learning trial), and a transparent (invisible) platform replaced the visible platform. The rats were allowed a maximum of 90 s to reach the platform in each trial. The times to reach the platform in both trials (escape latency) were summed to result in a total escape latency for each animal (maximal time = 180 s).

Fatty acid analysis. All rats were euthanized by decapitation and tissues removed for fatty acid analysis. Lipids were extracted by the method of Bligh and Dyer and fatty acid methyl esters prepared by a modified method of Morrison and Smith and quantified by gas chromatography as previously described (24). The fatty acid methyl ester 23:0 was used as an internal standard, and peaks were identified by comparison with standard mixtures of fatty acids (Nu-Chek-Prep, Elysian, MN).

Statistical analysis. Data are expressed as the mean plus or minus the standard error for the fatty acid values and behavioral measures. Each animal used in the olfactory testing was from a separate litter (25). Student's *t*-test was used to test for differences between the two dietary groups, and a $P < 0.05$ was considered significant. For the Morris water maze task, the Mann-Whitney U-test was used to determine significant differences between the two dietary groups.

RESULTS

F1 generation female rats began consuming an n-3-adequate or n-3-deficient diet at weaning and were mated at 8 wk of age. F2 generation pups were weaned at approximately 21 d of life. The diets had no effect on body weight of the F1 females (Fig. 1) or the F2 males (data not shown).

Fatty acid analysis. F2 generation male rats were fed the n-3-adequate or n-3-deficient diet for their entire lives. At 9.5 wk of age, rats were tested in one of several behavioral tests and subsequently euthanized, and tissues were collected for fatty acid analysis. Olfactory bulb fatty acid composition was significantly altered by the n-3-deficient diet (Table 3). DHA levels were 82% lower in the total lipid extract in the n-3-deficient olfactory bulbs compared to the n-3-adequate olfactory bulbs. The 22:6n-3 decrease was matched by an 8.4-fold increase in docosapentaenoic acid (22:5n-6) in the deficient group to maintain 22-C levels in the olfactory bulb. Brain levels of arachidonic acid (20:4n-6) and 22:4n-6 were also significantly higher, 15 and 35% respectively, in the n-3 deficient group.

[a]Percentage of total fatty acids is expressed as the mean (standard error). Values may not equal 100% due to unidentified peaks. * = $P < 0.05$; n.d. = not detected.

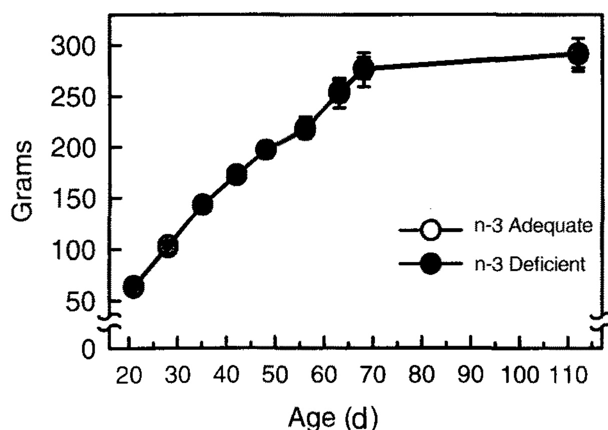

FIG. 1. The change in body weight of F1 female rats in the n-3-deficient and n-3-adequate groups over the experimental period (body weight ± SE). Only one set of data is apparent because the weights are similar at all time points.

Olfactory-based learning task. The n-3-adequate and n-3-deficient animals were tested on seven different two-odor, olfactory discrimination tasks over 7 d. Initially, all animals were testing at chance meaning 50% correct responses as they responded to both the positive and negative odor. However, there was a general trend of decreasing numbers of errors (decreases in responses to the negative odor) each day over the testing period (data not shown). The n-3-deficient rats made significantly more errors in the first two odor discriminations and more errors in all problems than did the n-3-adequate rats. However, both groups showed a gradual and progressive improvement in performance over the seven problems. The n-3-deficient animals had a significant 77% increase in total errors for the seven problems compared to the n-3-adequate group (Fig. 2). Total errors include responding to a negative odor (S−) and not responding to a positive odor (S+); however, most errors were responses to the negative odor.

Water maze task. Rats were placed into the water maze from one of two points every day and allowed 90 s to find a hidden platform (escape latency). The endpoint was total number of seconds to find the platform in two trials in the first session (day). In the first session of the learning test with the transparent platform, only 30% of the n-3-deficient animals reached the platform on both trials compared to 70% of the n-3-adequate animals. Using nonparametric statistical analysis (Mann Whitney U-test), the escape latency of the n-3-deficient group was significantly longer compared to the n-3-adequate group (Fig. 3).

DISCUSSION

In the F2 generation, the n-3-deficient brain contained 82% less 22:6n-3 compared to the n-3-adequate brain. This is a remarkable decrease in 22:6n-3 by the second generation. Many studies have reported a much less impressive decrease in this fatty acid in the second or third generation of rodents, probably due to the use of protein, carbohydrate, and fat sources that contain small, but important amounts of n-3 fatty acids (12,26). Extensive analyses were performed when preparing the diets to ensure the lowest possible n-3 content while maintaining diets that were still nutritious and palatable. This was achieved by using vitamin-free casein, a product designed to contain negligible amounts of fat-soluble vitamins, which also has a lower overall fat content compared to unprocessed casein. Some of the cornstarch was replaced with maltose-dextrin to further reduce the n-3 and n-6 fatty acids in the base diet. This is the first study to show such a marked decrease in 22:6n-3 in the second generation, using only dietary manipulations and indicating that brain 22:6n-3 levels can be lowered with diet in dam-reared rats, nearly to the extent observed in artificially-reared rats (27).

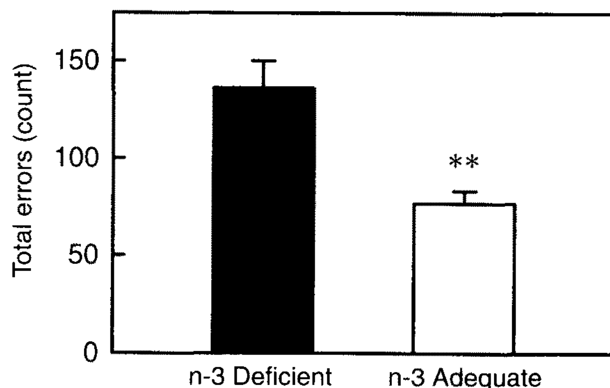

FIG. 2. Effect of the n-3-deficient and n-3-adequate diet on the total number of errors in an olfactory-based learning task (total errors ± SE), $*P < 0.02$.

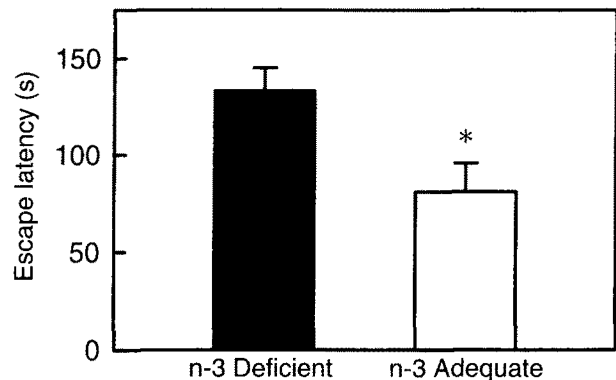

FIG. 3. Effect of the n-3-deficient and n-3-adequate diet on the escape latency in the first session of the Morris water maze task (escape latency ± SE), $*P < 0.005$.

An olfactory-based learning task was chosen to address some of the criticisms concerning rat learning experiments. Previous research in this area focused mainly on the visual system in rats. While this modality is certainly important in primates, rats are macrosmatic and rely primarily on olfactory cues. Thus olfaction may be the most appropriate modality to employ when using rats in learning experiments involving higher level neural functions. The present results indicate that n-3-deficient rats learn odor discrimination tasks more slowly than n-3-adequate rats. Additional studies will be required to determine whether this represents a sensory deficit or a deficit in making stimulus-response associations. Interestingly, rats are able to acquire a learning set when odor cues are used, and the procedures employed in the current study could easily be extended to assess learning set performance. This would be of considerable interest because acquisition of a learning set requires the subject to demonstrate a strategy or rule for responding (e.g., "win-stay, lose-shift"), and the test is widely used to assess higher-level cognitive performance (19–20,22).

The results from the Morris water maze support the results from the olfactory-based learning task. The n-3-deficient animals took longer to locate the hidden platform compared to the n-3-adequate animals, suggesting learning deficit in these animals. Both groups of animals received the same amount of

training (visible platform test), but the n-3-deficient animals had a significantly longer escape latency in session one.

These studies were conducted on adult rats (9.5–12 wk of age), and therefore, differences seen in task performance using these methods endure into maturity. Many visual deficits associated with n-3 fatty acid deficiency were reported to disappear over time and therefore could be mistakenly considered unimportant. In some cases, the behavioral task used became insensitive later in neurodevelopment. We did not examine the performance of young rats in this study, but learning differences between the n-3-adequate and n-3-deficient groups were detected in the adult rat and are thus unlikely to disappear over time. This is important when discussing the effects of n-3 deficiency on the central nervous system and demonstrates that all deficits associated with low levels of 22:6n-3 are not transient.

Low Serum Docosahexaenoic Acid Is a Significant Risk Factor for Alzheimer's Dementia

D.J. Kyle[c,*], E. Schaefer[a], G. Patton[a], and A. Beiser[b]

[a]Tufts University School of Medicine, Boston, Massachusetts 02118; [b]Boston University School of Public Health, Boston, Massachusetts 02118; and [c]Martek Biosciences, Columbia, Maryland 21045

Docosahexaenoic acid (DHA) is the major fatty acid of neurological and retinal membranes. It makes up more than 30% of the structural lipid of the neuron and is particularly enriched in synaptosomal membranes. A number of seemingly unrelated neuropathological conditions including depression, attention deficit hyperactivity disorder, and dementia have a common association in that patients exhibit a subnormal DHA status. Clinical studies in patients with adrenoleukodystrophy, long chain hydroxyacyl CoA dehydrogenase deficiency, dyslexia, and Alzheimer's dementia (AD) demonstrated improvements in visual or neurological deficits by elevating circulating DHA levels through a dietary intervention. In this study, we assessed the circulating DHA status of 1,188 elderly American subjects (mean age of 75 yr) using serum phosphatidylcholine (PC) as the biomarker. Frozen plasma samples obtained in 1985 were extracted with chloroform and methanol, and the phospholipids were separated by high-performance liquid chromatography. Purified PC fractions were collected, transesterified with methanolic base, and the fatty acid methyl esters were separated by capillary column gas chromatograpy.

Most of the serum PC fatty acids exhibited a normal frequency distribution, but there was a nonnormal distribution of the serum PC-associated DHA and eicosapentaenoic acid (EPA). This skewed distribution reflects the influence of preformed DHA and EPA in the diet, likely from fish consumption, in some members of the population. In fact, there was a significant positive correlation between serum PC-EPA and PC-DHA levels. Following the analysis of the blood samples, we undertook a blinded prospective analysis of the clinical outcomes [both AD diagnosis as well as scores on the Minimental State Exam (MMSE)] of the patients over the next 10 yr. Of those individuals who had clinically diagnosed AD at the time the blood sample was taken, there was a two-fold higher frequency (11 vs. 5) of AD in subjects from the lower half of the DHA distribution. Subjects whose serum PC-DHA was in the lower half of the distribution, but who had no AD at the time the blood sample was taken had a 67% greater ($P < 0.05$) likelihood of developing AD in the subsequent 10 yr of life. It is well known that individuals with at least one copy of the serum apolipoprotein E4 allele have a greater risk of AD, and women who had at least one apolipoprotein E4 allele had a fourfold greater risk of low scores on the MMSE in the subsequent 10 yr if they were also in the lower half of the DHA distribution. No similar relationships could be found between serum levels of other n-3 fatty acids, such as EPA or n-3 docosapentaenoic acid, and dementia.

These data suggest that low levels of circulating PC-DHA may be a significant risk factor for low scores on the MMSE, and in the development of AD in elderly patients. The inability to maintain a high level of DHA may be due to a reduced ability to synthesize DHA late in life as the result of a reduction in Δ6-desaturase activity. Moreover, the data suggest that maintaining adequate levels of serum DHA through the consumption of fish or other dietary supplements rich in DHA may be particularly important for the elderly. Intervention trials are now underway to determine the effect of dietary DHA in a triglyceride form from an algal source on the development of AD. This source of DHA was chosen because of its safety and efficacy profile, and because it contains no EPA, which may be contraindicated in otherwise healthy elderly patients.

Ethyl Docosahexaenoic Acid Administration During Intrauterine Life Enhances Prostanoid Production and Reduces Free Radicals Generation in the Fetal Rat Brain

Sabina Glozman[a], Pnina Green[a], Batia Kamensky[a], Lev Weiner[b], and Ephraim Yavin[a,]*

Departments of [a]Neurobiology and [b]Organic Chemistry, Weizmann Institute, Rehovot, Israel

Recently we demonstrated that a single intra-amniotic injection of ethyl (Et) docosahexaenoic acid (Et-DHA, 22:6n-3) reduced by 39% the ability of fetal brain slices to form Fe^{2+}-mediated lipid peroxides (LPO) measured by thiobarbituric acid reactants (TBAR), suggesting an antioxidant role for DHA (1). Under these conditions, arachidonic acid (AA) was preferentially lost from major phospholipids, suggesting a relatively greater loss of AA compared to DHA after stress (Fig. 1) in animals, 3 d following Et-DHA administration.

Since AA is the immediate precursor for most prostanoids, we examined the production of thromboxane B_2 (TxB_2) and prostaglandin E_2 (PGE_2) under these conditions. Slices taken from Et-DHA-treated and control animals were incubated in the presence of 0.1 mM Fe^{2+} and O_2. After 30 min at 37°C, medium was collected and the levels of TxB_2 and PGE_2 were determined by a radioimmunoassay technique. As shown in Figure 2A, DHA-treated slices produced more PGE_2 (182%) and TxB_2 (218%) compared to untreated ones. In contrast the levels of TBAR were lower by almost 50% compared to untreated brains. The data suggest that enhanced production of prostanoids may be an alternative pathway by which damaging hydroxyl radicals (OH˙) may be diverted to a lesser harmful metabolic route. Studies in progress are aimed to evaluate a possible activation of phospholipase A_2 and cyclooxygenase as part of this derouting process enhanced by Et-DHA administration.

An alternative mechanism by which DHA could exert its antioxidant capability against lipid peroxidation is by subserving as a direct or indirect free radical scavanger. To explore this possibility, brain homogenates and total brain lipid extracts obtained from Et-DHA-treated and control fetuses were incubated with 0.1 M DMPO (5,5-dimethyl-1-pyrroline-*N*-oxide) spin trap in the presence of 1 mM Fe^{2+} and 2 mM H_2O_2, and the changes in the electron paramagnetic resonance were examined. The appearance of DMPO-OH adducts in crude lipid extracts prepared from Et-DHA pretreated fetuses, was reduced by almost 40% in comparison to untreated fetuses (Fig 2B). No changes were found in the lipid-soluble low molecular weight antioxidant (i.e., α-tocopherol) as determined by cyclic voltammetry. Silicic acid chromatography

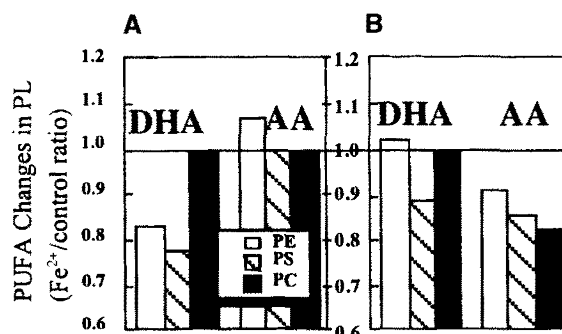

FIG. 1. Gas chromatography analysis of arachidonic acid (AA) (20:4) and docosahexaenoic acid (DHA) (22:6) content in phosphatidylethanolamine (PE), -choline (PC), and -serine (PS) after Fe^{2+}-mediated oxidative stress in fetal brain slices from (A) untreated and (B) ethyl (Et)-DHA-treated (3 d) animals. Values of each of the polyunsaturated fatty acids (PUFA) were normalized to non stress conditions. PL, phospholipids.

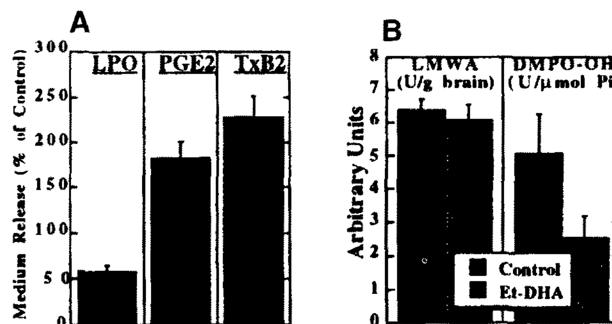

FIG. 2. Effect of Et-DHA administration on production of (A) prostaglandin E_2 (PGE_2), thromboxane B_2 (TxB_2), and lipid peroxides (LPO) and (B) free radicals (DMPO-OH) scavengers and low molecular weight antioxidant (LMWA, Fig. 2B) levels in fetal rat brain slices subjected to Fe^{2+} mediated oxidative stress. Values shown in Figure 2A are normalized to untreated brain slices and those in Figure 2B are expressed as relative units. See Figure 1 for other abbreviation.

of lipid extracts prepared from Et-DHA-treated fetal brains revealed a better capacity of an enriched phospholipid fraction to reduce, in a concentration-dependent manner, the production of DMPO-OH adducts. The antioxidant property acquired by a single intra-amniotic injection of Et-DHA may be a combined result of free radicals scavenging at the plasma membrane level and stimulation of AA release to produce prostanoids.

The Role of Docosahexaenoic Acid (22:6n-3) in Neuronal Signaling

Hee-Yong Kim* and Lisa Edsall

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, Maryland 20852

While it is believed that docosahexaenoic acid (22:6n-3) is essential for proper neuronal function, the mechanism underlying its essentiality is not clearly understood. The involvement of free arachidonic acid (20:4n-6) or phosphatidylserine (PS) in signal transduction has been demonstrated (1,2). Therefore, we hypothesized that 22:6n-3 participates in neuronal signaling through the release from the brain cells in response to neurotransmitters and/or through the modulation of the PS accumulation. The release of 22:6n-3 was investigated in comparison to 20:4n-6, using two major types of brain cells, astroglia and neuronal cells. We observed that the rat brain synaptosomes and primary cultures of hippocampal neurons did not release 22:6n-3 under the conditions where 20:4n-6 release had been established (3). However, we found that astroglia released 22:6n-3 as favorably as 20:4n-6, under the basal condition and also in response to various neurotransmitters (3,4). These data suggested that the release of 22:6n-3 may not be the mechanism for intracellular signaling in neuronal cells. One of the major functions of astroglia is to supply trophic factors to neurons for their survival. The ready release of 22:6n-3 from astroglia suggests that one of the supporting roles of astroglia may be providing 22:6n-3 to neuronal cells, probably as a trophic factor. In order to test this possibility, 22:6n-3 was added to neuronal cell culture, and apoptotic cell death induced by serum deprivation was examined using DNA fragmentation as an indicator. Neuro-2A cells exposed to 22:6n-3 for 5 h did not have any effect on cell death induced by serum deprivation. After enrichment for 48 h, however, 22:6n-3 protected Neuro-2A cells from apoptosis (Fig. 1). After 5 h of incubation, 22:6n-3 was mainly incorporated in triglycerides and phosphatidylcholines, while after 48 h, this fatty acid was primarily incorporated in aminophospholipids, phosphatidylethanolamine, and PS, suggesting that 22:6n-3 as aminophospholipids in membranes may play an important role in the survival of neuronal cells. The 22:6n-3 fatty acid is particularly enriched in PS. And PS does participate in cell signaling such as protein kinase C (2) and Raf-1 translocation (5). Since we learned that 22:6n-3 as aminophospholipids in membranes plays an important role in the survival of neuronal cells, we subsequently hypothesized that 22:6n-3 plays a role in accumulating PS, and this may be an important mechanism supporting the essentiality of 22:6n-3. Using two approaches including an n-3 deficiency animal model and a 22:6n-3 supplemented cell system, we found that PS biosynthetic activity was inhibited during n-3 deficiency but significantly increased with 22:6n-3 supplementation (6). The accumulation of PS was also significantly reduced by n-3 deficiency in rat brain microsomes (6) and pineal (7). Based on these data, we concluded that PS accumulation as well as its biosynthesis in brain is sensitive to changes of the docosahexaenoate levels in phospholipids. We postulate that 22:6n-3 may be a modulator of PS biosynthesis, which in turn, can affect neuronal signaling.

n-3 Polyunsaturated Fatty Acid Deficiency and Dopamine Metabolism in the Rat Frontal Cortex

L. Zimmer[a], G. Durand[b], D. Guilloteau[a], and S. Chalon[a,*]

[a]INSERM U316, Tours, France, and [b]LNSA, INRA, Jouy-en-Josas, France

Brain lipids are very rich in polyunsaturated fatty acids (PUFA), in particular arachidonic and docosahexaenoic acids, derived, respectively, from linoleic and α-linolenic acid. As these fatty acids are totally provided by the diet, their effects on brain functions can be studied through dietary manipulations in animal models.

It is known that a chronic dietary deficiency in α-linolenic acid in rats induces several changes, including modifications in the fatty acid composition of brain membranes, visual perturbations, and behavioral disturbances consisting of abnormal responses in several learning tests. This last finding raises the question about the mechanisms which mediate the effects of n-3 PUFA deficiency on behavior. These behavioral changes can be related to the function of the mesocorticolimbic dopaminergic systems. We therefore proposed that chronic n-3 PUFA deficiency could act on the dopaminergic functions. In order to validate this hypothesis, we used a rat model of chronic α-linolenic acid deficiency. These animals received peanut oil as an exclusive source of lipids for three generations, whereas control animals received a mixture of peanut and rapeseed oil providing both linoleic and α-linolenic acids. The male rats of the third generation, receiving the same diet as their dams, were studied at 2–3 mon of age. On this animal model, we previously measured in the prefrontal cortex a considerable decrease in the amount of n-3 PUFA, compensated for by an increase in n-6 PUFA. In addition, we found specifically in this region that the endogenous levels of dopamine were 35–40% lower in deficient rats compared to controls (1,2).

We therefore used the method of cerebral microdialysis in order to define the neurochemical mechanisms involved (3). Microdialysis allows a dynamic approach of neurotransmission processes *via* implantation of a probe in the frontal cortex on alive rats. Basal levels of dopamine released into cortical dialysates of awake rats were similar in both groups. By contrast, we measured significantly higher metabolite basal levels [dihydroxyphenyl acetic acid (DOPAC) and homovanillic acid (HVA)] in deficient rats compared to controls: DOPAC was 74 ± 37 fmol/μL of dialysate samples vs. 17 ± 10 fmol/μL, and HVA was 64 ± 13 fmol/μL vs. 26 ± 11 fmol/μL in deficient and control rats, respectively (n = 8:8). On anesthetized rats, KCl perfusion (200 mM), known to induce release of newly synthesized dopamine localized in the cytoplasmic compartment, led to a similar increase in dialysate dopamine content in deficient and control rats (n = 8:8). By contrast, tyramine perfusion (200 μM), known to release dopamine from the vesicular stores, resulted in an increase in dialysate dopamine levels three times lower in deficient rats compared to controls (n = 8:8).

These findings confirm the hypothesis of an involvement of the dopamine systems in the effects of n-3 PUFA deficiency on behavior. Our results suggest that the cortical dopamine metabolic pathway could be increased in deficient rats. The dopaminergic storage compartment could be decreased in deficient rats and then, most of the newly synthesized dopamine is not protected in vesicles from degradation by monoamine oxidase, this is in agreement with the increased metabolite production. The modification of storage compartment could be caused by lower dopamine internalization or by modifications of the structure or the number of vesicles. This inadequate storage of newly synthesized dopamine might not be enough for the maintenance of high release during stimulated cognitive processes and so could explain disturbances in cognitive performance previously observed.

In order to support our hypothesis, the study of cortical monoamine vesicles, in particular their number and structure, is now in progress. The modulatory effects of the cortical dopaminergic system on the nucleus accumbens, involved in several components of learning tasks, are also investigated.

Amount and Type of Unsaturated Aldehydes in Chicken Plasma and Tissues Depend More on Dietary Lipids Than on Vitamin E Status

H. Fuhrmann* and H.-P. Sallmann

Institute of Physiological Chemistry, Veterinary School of Hannover, Buenteweg 17, D-30559 Hannover, Germany

Free radicals are linked to a variety of neurological disorders in humans and animals. In the chicken, the feeding of n-6 fatty acids together with a vitamin E-deficient diet (1) leads to nutritional encephalomalacia (NE). Only the cerebellum is affected, leading to ataxia, prostration, and death. The subject of our research was the possible involvement of unsaturated aldehydes in the pathogenesis of experimental NE in broiler chicken. This disease serves as a model for the consequences of dietary fatty acid type on lipid peroxidation events.

Laying hens received a diet low in vitamin E. Resulting chicks were assigned to four groups fed with either linoleic (C18:2n-6, 55%) or linolenic acid (C18:3n-3, 54%) together with 1 or 50 ppm vitamin E; 9 d post-hatching NE occurred in the vitamin E-deficient group fed linoleic acid. With each chick showing NE, a healthy one from all four groups was sacrificed. Malondialdehyde (MDA), pentenal, hexenal, OH-hexenal, heptenal, octenal, and OH-nonenal were determined in plasma, liver, cerebrum, and cerebellum after derivatization with methylhydrazine (2). The aldehyde hydrazones were separated by gas–liquid chromatography (GLC) and detected with a thermoionic-specific detector (3).

Up to day 12, mortality was 50%. Nine animals showed the typical clinical signs of NE. In the brain tissues, differences in aldehyde pattern were small. An effect of the vitamin E supply was not observed. Furthermore, cerebellar damage due to NE was not accompanied by increased levels of unsaturated aldehydes.

In plasma, OH-hexenal was the most prominent aldehyde, followed by MDA and OH-nonenal in the case of linoleic acid feeding. For MDA (analysis of variance: $P = 0.0002$) and OH-nonenal (analysis of variance: $P = 0.0280$), we observed a significant increase in vitamin E deficiency. Diseased animals had high values of total aldehydes mainly due to OH-hexenal. Means were significantly different between diseased animals and those fed linoleic acid with 5 ppm vitamin E or linolenic acid.

In the liver, the concentration of total aldehydes was higher than in brain tissues. The portion of aldehydes from n-3 fatty acids was considerably lower than in the brain. MDA and OH-nonenal were the dominating aldehydes. Linoleic acid feeding resulted in a significantly higher content of total aldehydes in this tissue. Vitamin E deficiency increased the levels of pentenal ($P = 0.0379$) and hexenal ($P = 0.030$). Diseased animals in addition had increased aldehydes from n-3 fatty acids (total n-3, pentenal, hexenal, $P < 0.01$) in comparison to healthy ones from the same group.

Although NE dramatically affects the cerebellum macroscopically and microscopically, tissue aldehydes were not elevated in diseased animals. This observation is not expected in the light of earlier results on the influence of vitamin E on lipid peroxidation (4). However, in rats comparable results on the oxidative resistance of brain membranes were reported (5).

NE only occurs in animals when n-6 fatty acids like linoleic acid are fed. Evidence exists that n-6 fatty acids have a genuine prooxidative-toxic effect. Linoleic acid intake seems to be associated with increased oxidation susceptibility (6). Moreover the higher oxidizability of n-6 in comparison to n-3 fatty acids *in vitro* was reported recently (7). According to our study, the link between linoleic acid feeding and occurrence of NE is the increased concentration of lipid peroxidation products in liver and plasma when linoleic acid was fed. In plasma, we found the expected increase of aldehydes in response to vitamin E deficiency, namely OH-nonenal and MDA. Metabolism of aldehydes is supposed to be negligible in plasma, so these aldehydes may be lipid peroxidation products delivered into the plasma from tissues other than the brain.

Interactions Between Lipid Metabolism and Schizophrenia: The Biochemical Changes Which May Have Made Us Human

David F. Horrobin*

Laxdale Research, Kings Park House, Laurelhill Business Park, Stirling, Scotland FK7 9JQ

There are many aspects of human evolution which require explanation in biochemical terms. Some of the most important differences between humans and great apes are as follows: (i) the increase in brain size which began around 2.5 million yr ago and reached modern values between 0.5 and 1.0 million yr ago; (ii) the presence of subcutaneous fat, buttocks, and breasts; (iii) the surprising absence of obvious major cultural changes accompanying the increase in brain size; and (iv) the cultural explosion which began somewhere between 50,000 and 100,000 yr ago with the emergence of art, music, religion, and warfare.

The brain, like subcutaneous fat, is particularly rich in lipids, and there may be changes in lipid metabolism which differentiate humans from the great apes. The growth in the size of the brain and the development of subcutaneous fat and associated breasts and buttocks may have occurred because of changes in proteins which regulate the rate of delivery of fatty acids to tissues. Two candidate classes are lipoprotein lipases and the fatty acid-binding and transport proteins. Changes in the expression of brain fatty acid-binding proteins are known to be associated with the seasonal changes in size of part of the brain in songbirds.

Creativity is not simply related to brain size. Autistic people and Neanderthals both exhibit brain sizes greater than those of normal modern humans. Creativity is more likely to be related to the richness of connectivity between neurons. Neuronal microconnectivity is largely regulated by phospholipid synthesizing, remodeling, and degrading enzymes which are highly expressed whenever synaptic remodeling is taking place. These enzymes are therefore candidates for an association with creativity.

There is increased evidence that schizophrenia is associated with abnormalities of phospholipid breakdown and synthesis. These changes will lead to changed synaptic connectivity. Schizophrenia entered humanity prior to the separation of the races because it is found with approximately the same prevalence in all human races. Family and adoption studies show that relatives of schizophrenics have a high risk of developing schizophrenia and other psychiatric disorders. But the same studies also show that there is also an increased probability of high creativity, leadership qualities, achievements in many fields, high musical skills, and an intense interest in religion. These are precisely the qualities that entered the human race around 100,000 yr ago and ended tens of thousands of generations of cultural near-stagnation. The changes in phospholipid metabolism which are associated with schizophrenia may also be responsible for those features characteristic of our humanity.

n-3 Fatty Acids and Human Lipoprotein Metabolism: An Update

W.S. Harris

Mid America Heart Institute, St. Luke's Hospital, Kansas City, Missouri

OVERVIEW OF LIPID-ALTERING EFFECTS OF n-3 FATTY ACIDS

The impact of n-3 fatty acids (FA) on blood lipoprotein levels has been examined in many studies over the last 15 yr in both animals and humans. Studies in humans first demonstrated the potent triglyceride-lowering effect of n-3 FA, and these were followed up with animal studies to unravel the mechanism of action. To gain a perspective on the overall effects of n-3 FA on serum lipids, a meta-analysis was conducted based on 72 placebo-controlled human trials, at least 2 wk in length and providing 7 g or less of n-3 FA/d (1,2). Trials with normolipidemic subjects (triglycerides < 2.0 mM) were compared to those studying hypertriglyceridemic patients (triglycerides ≥ 2.0 mM). In the normal subjects, mean triglyceride levels decreased by 25% ($P < 0.0001$), and total cholesterol (C) levels increased by 2% ($P < 0.009$) owing to the combined increases in low density lipoprotein (LDL)-C (4%, $P < 0.02$) and high density lipoprotein (HDL)-C (3%, $P < 0.008$). In patients, triglyceride levels decreased by 28% ($P < 0.0001$), LDL-C rose by 7% ($P < 0.0001$), but neither total C nor HDL-C changed significantly. There was a clear dose–response relationship when all studies were examined together, and the triglyceride-lowering effects of n-3 FA persisted even out to more than 2 yr in placebo-controlled trials. Thus, it is well-established that n-3 FA are hypotriglyceridemic when taken in doses of 3–4 g/d.

LOW DOSE STUDIES

In stark contrast to our earliest studies with n-3 FA in which up to 25 g of eicosapentaenoic acid (EPA) + docosahexaenoic acid (DHA) were fed daily (3), we recently completed a trial comparing 1.7 vs. 3.4 g (provided as 2 vs. 4 g) of Omacor (Pronova Biocare, Oslo, Norway) in patients with severe hypertriglyceridemia (triglyceride levels between 5.65 and 22.6 mM (500 and 2,000 mg/dL). Following the completion of a 4-mon, placebo-controlled, randomized, double-blind trial of 4 g of Omacor (4), 28 patients meeting the inclusion criteria were randomized to take either 2 or 4 capsules of Omacor per day for an additional 6 mon. Compared to original baseline values, Omacor 4 g significantly reduced mean triglyceride concentrations by 45% ($P < 0.0001$), C by 15% ($P < 0.001$), very low density lipoprotein-C by 32% ($P < 0.0001$), and C/HDL-C ratio by 20% ($P = 0.0013$); and it raised HDL-C by 13% ($P = 0.014$) and LDL-C by 31% ($P = 0.0014$). The lower dose (2 g) lowered mean triglyceride levels by 25% ($P = 0.05$) and raised HDL-C by 14% ($P = 0.015$) but had no significant impact on other lipid parameters. Thus, Omacor demonstrated a dose-dependent triglyceride-lowering effect, with only two capsules per day producing a clinically meaningful, statistically significant reduction.

ANIMAL STUDIES

As discussed above, in humans, n-3 FA exert a significant hypotriglyceridemic effect that is dose-dependent and persistent. Effects on other lipoprotein fractions are relatively minimal. No animal model has yet been developed which mimics these effects (5). In several species triglyceride levels do not fall; in others, reduced atherosclerotic disease is found with n-3 FA feeding despite "adverse" changes in HDL-C and LDL-C levels (6,7). Accordingly, extreme care must be taken with these models so as to avoid inappropriate extrapolations to humans.

CLINICAL INTERVENTION STUDIES WITH n-3 FA AND CORONARY HEART DISEASE

There have been only two prospective, randomized clinical trials with n-3 FA having "hard" end points, i.e., cardiac events, and mortality: the Diet and Reinfarction Trial (8) and the Indian Experiment of Infarct Survival (9). The former study randomized 2,033 male survivors of a myocardial infarction to receive (or not receive) advice to increase their intake of oily fish by about 200–400 g/wk. This raised their EPA + DHA intakes to approximately 500–700 mg/d. Those patients randomized to the fish advice group experienced 29% fewer deaths in the ensuing 2 yr. This was the first trial to show that increasing fish oil intake could actually protect against heart attacks.

The Indian Experiment (9), although smaller in size, was designed to address more directly the question of whether marine- and/or plant-derived n-3 FA could reduce cardiac events in a secondary prevention population. Approximately 360 patients presenting to the emergency room with a suspected my-

ocardial infarction were randomized to either 2 g of EPA + DHA (6 capsules of Maxepa, Seven Seas, Ltd., Haeld, England), 2.9 g of α-linolenic acid (20 g of mustard seed oil), or placebo (capsules containing 100 mg of the inert compound aluminum hydroxide). Patients were started on one of these three treatments within 18 h of admission, and were followed for the next 12 mon for clinical events. The authors reported that total cardiac mortality was significantly decreased in both n-3 FA groups, with marked reductions in new acute myocardial infarctions, the development of new angina pectoris, arrhythmias, and heart failure. These finding provide the most compelling evidence to date that n-3 FA can have clinically important impact in preventing coronary artery disease. Additional trials are clearly called for to confirm these findings.

In summary, there is extensive and consistent documentation of the ability of marine n-3 FA to reduce serum triglyceride levels in humans by 20–30% at doses of 3–4 g per day. Smaller doses over longer periods of time may also prove clinically useful. The extent to which alterations in serum lipids and lipoproteins play a role in the new-well-documented antiatherogenic effects of n-3 FA remains to be seen.

Long-Chain n-3 Polyunsaturated Fatty Acids and Triacylglycerol Metabolism in the Postprandial State

Helen M. Roche* and Michael J. Gibney

Unit of Nutrition and Dietetics, Trinity Centre for Health Sciences, St. James's Hospital, Dublin 8, Ireland

ABSTRACT: Elevated plasma triacylglycerol (TG; triglyceride) concentrations, especially in the postprandial state, have been associated with an increased risk of coronary heart disease (CHD). Postprandial lipemia represents a complex series of reactions which occur following the ingestion of a meal containing fat and is associated with a number of adverse metabolic events including the production of atherogenic chylomicron remnants, the formation of the highly atherogenic small dense low density lipoprotein particles, a reduction in the concentration of the cardioprotective high density lipoprotein fraction and the activation of coagulation factor VII. Fish oils are a rich source of the long-chain n-3 polyunsaturated fatty acids (PUFA), eicosapentaenoic acid and docosahexaenoic acid. Long chain n-3 PUFA are effective hypotriglyceridemic agents, lowering both fasting and postprandial TG concentrations. There is a large body of evidence which shows that n-3 PUFA reduces plasma TG concentrations through reduced endogenous very low density lipoprotein production. This in turn may account for the reduced postprandial lipemic response following n-3 PUFA supplementation. However, this does not preclude a contribution of enhanced chylomicron clearance, which may be mediated through altered chylomicron size, structure or chemical composition, or altered lipoprotein lipase metabolism in terms of enzyme concentration, activity, or affinity for chylomicrons. However the precise biochemical nature of this effect remains to be established. The reduction of postprandial plasma TG concentrations by n-3 PUFA may partly explain why n-3 PUFA intake is inversely related to CHD mortality.

POSTPRANDIAL LIPID METABOLISM

Postprandial triacylglycerol (TG) metabolism refers to the series of metabolic events which occur following the ingestion, digestion, and absorption of a meal containing fat (1,2). Dietary fat is principally composed of TG, which, after digestion and absorption, stimulates the production of chylomicrons within the enterocyte (3–5). Chylomicrons are TG-rich lipoproteins (TRL) which transport exogenous dietary TG within the circulation, causing an increase in plasma TG concentrations during the postprandial response. Chylomicrons are identified by virtue of their density as well as their unique apoprotein, apo B48. Figure 1 illustrates a typical postprandial TG response to 40 g of fat (6), showing a significant transient increase in plasma TG concentrations and plasma apo B48 concentrations.

The removal of chylomicron TG is catalyzed by the enzyme lipoprotein lipase (LPL) which is present on the surface of capillary endothelial cells of adipose tissue (7). LPL is also present in other tissues with a high fatty acid requirement, including skeletal muscle, cardiac muscle, and the mammary gland (8). In the postprandial state, adipose tissue LPL is exclusively activated by insulin, which inhibits LPL activity in the other tissues. LPL is the rate-limiting hydrolytic enzyme which controls TRL removal from the circulation, and therefore LPL has a regulatory effect on the extent and duration of postprandial lipemia. During postprandial lipemia there is a significant increase in very low density lipoprotein (VLDL) TG. This occurs later in the postprandial phase (4–6 h) (9). Chylomicrons are preferentially hydrolyzed by LPL which leads to delayed VLDL removal and postprandial VLDL accumulation (10–12). The hydrolysis of chylomicron TG by LPL generates monoacylglycerol and nonesterified fatty acids (NEFA). These hydrolytic products are rapidly transported across the endothelium to parenchymal cells, where they are reesterified for storage in adipose tissue. An appreciable quantity (up to 50%) of NEFA escapes into the circulation (13), and plasma NEFA concentrations return to preprandial levels. The release of NEFA into the circulation during chylomicron lipolysis stimulates hepatic TG synthesis, thereby promoting VLDL synthesis and secretion, which in turn leads to an increase in VLDL concentrations during the postprandial response (9). The resultant delipidated chylomicron, now termed a "chylomicron remnant," is catabolized by the liver. The postprandial lipemic response lasts approximately 4 to 8

h, the magnitude and duration of which is determined by a number of physiological factors, such as age, gender, body weight and nutritional factors, which have been extensively reviewed elsewhere (1).

PLASMA TG AS A RISK FACTOR FOR CHD

Traditionally, fasting plasma TG concentrations have not been recognized as an independent risk factor for coronary heart disease (CHD) (14), but recent data suggests that the relative importance of TG as a risk factor may have been underestimated (15). The importance of TG as a risk factor for CHD has been underestimated because of the high degree of variability in plasma TG concentrations, the strong negative association which exists between plasma TG and high density lipoprotein (HDL) cholesterol concentrations, or the influence of concomitant conditions such as diabetes. Several authors have proposed that the negative correlation between plasma TG and HDL cholesterol, which reflects the physiological relationship between the lipoproteins, may explain why TG does not emerge as an independent risk factor in epidemiological studies and why low HDL cholesterol concentrations may only be a marker of plasma TG metabolism and not an independent risk factor of CHD (16,17). This hypothesis is supported by results of the Lipid Research Clinics 12-yr follow-up study (18), the Framingham Study (19) and the Caerphilly and Speedwell Collaborative Heart Disease Study (20). The results of these studies showed that high plasma TG concentrations were risk factor for CHD when HDL cholesterol concentrations were also low.

Plasma TG concentrations are highly variable, both within and between individuals. This high degree of variability leads to a low statistical power to detect significant associations in multivariate analysis. Recently, a large meta-analysis of 17 population-based prospective studies showed that increased plasma TG concentrations were associated with a significant increase in risk of CHD (21). The analysis of this large cohort (n = 57,277) showed that plasma TG concentrations were an independent risk factor for CHD, particularly in women, whereby 1 mmol/L increase in plasma TG concentration was associated with an increased cardiovascular risk of 32% in men and 76% in women (21).

A growing body of evidence shows that nonfasting or postprandial plasma TG concentrations play an important role in relation to CHD. The Physicians Heart Health Study provided prospective evidence that nonfasting serum TG concentration was a significant predictor of future myocardial infarction (22). Numerous clinical studies showed that the magnitude of postprandial lipemic response is related to the presence and progression of CHD. Patients with CHD demonstrate an elevated and delayed postprandial lipemic response compared to controls (23,24). Furthermore, Karpe *et al.* (25) showed that the concentration of postprandial chylomicron remnant apo B48 was directly related to the rate of progression of coronary lesions in postinfarction male patients.

POSTPRANDIAL TG METABOLISM AND CHD

The precise mechanism whereby postprandial TG concentrations affect the pathogenesis and progression of CHD has not been elucidated, but at least four possible mechanisms were identified. Firstly, while TG itself is not a component part of the atherosclerotic lesion, elevated postprandial TG concentrations may exert their adverse effect by promoting the production of

atherogenic chylomicron remnants (26). The "Zilversmit Hypothesis" was the first to propose that cholesteryl ester-rich chylomicron remnants were as atherogenic as low density lipoprotein (LDL) (27). An elevated postprandial response promotes the formation of small cholesteryl ester (CE)-enriched chylomicron remnants. These remnants share with LDL the ability to mediate cholesterol influx into the arterial wall intima in humans (26), thereby promoting atherogenesis.

Importantly, the postprandial lipemic response not only represents the flux of dietary TG within the circulation but it also represents a very significant period during which the composition of the cholesterol-rich lipoproteins, LDL and HDL, is changed. The extent of lipoprotein remodeling which occurs during postprandial lipemia is positively related to the magnitude and duration of the postprandial triacylglycerolemia (28). These compositional changes in turn affect the metabolic fate of HDL and LDL. Plasma TG has a major metabolic influence in the physicochemical properties of LDL; elevated postprandial lipemia stimulates the formation of small dense LDL (29). This highly atherogenic LDL subfraction has been associated with an increased risk (four- to sixfold) of CHD (30). The formation of small dense LDL represents the second mechanism underlying pathogenesis postprandial lipid metabolism.

Thirdly, elevated postprandial TG concentrations reduce the concentration of the cardioprotective HDL fraction (31). During postprandial lipemia, HDL become enriched with TG at the expense of CE, an exchange mediated by the enzyme cholesterol ester transfer protein (CETP). Pronounced postprandial triacylglycerolemia allows greater interaction and excessive lipid exchange between chylomicrons and HDL_2 (32,33). Hepatic lipase delipidates these TG-rich HDL_2 particles, converting them to HDL_3 particles, thus lowering the concentration of the cardioprotective and metabolically active HDL_2 subfraction. Finally, elevated postprandial plasma TG concentrations adversely affect the coagulation system. Postprandial TRL have the ability to activate coagulation factor VII (34). Therefore, elevated postprandial lipemia represents a proatherogenic and prothrombotic metabolic state.

Syndrome X and the atherogenic lipoprotein phenotype (ALP) are two very common metabolic syndromes of altered plasma TG metabolism which are associated with increased risk of CHD (35,36). Both refer to a cluster of metabolic abnormalities which are associated with an increased risk of CHD, including raised plasma TG concentration, low HDL cholesterol concentration, and an increased proportion of small dense LDL, raised plasma glucose concentration, and insulin resistance. Therefore, therapies which improve plasma TG metabolism could reduce the incidence of these common dyslipidemias which are associated with increased risk of CHD.

Fish oils, TG, and CHD. Eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) are the principal long chain n-3 polyunsaturated fatty acids (PUFA) derived from fish oils. Epidemiological studies have demonstrated that the incidence of CHD is inversely associated with consumption of n-3 PUFA (37,38). The DART trial provided prospective evidence that relatively low doses of n-3 PUFA reduce the risk of secondary coronary events (39). A number of biochemical mechanisms explain the cardioprotective effect of n-3 PUFA, and these include antithrombotic, antiarrhythmic, and antiinflammatory mechanisms, as well as improved plasma lipid and lipoprotein concentrations (40–44). The remainder of this review will focus on the effect of n-3 PUFA on plasma TG metabolism in the fasted and postprandial state.

In humans, n-3 PUFA exert a consistent hypotriglyceridemic effect, which is dose-dependent and persistent. In a recent review of 72 placebo-controlled human studies which supplemented a range of 1.0 to 7.0 g EPA and DHA daily for at least 2 wk, plasma TG concentrations were consistently reduced by 25–30 % (45). Several studies showed that n-3 PUFA have a dose-dependent hypotriglyceridemic effect on fasting plasma TG concentrations (46–48). When the data from these studies are pooled (Fig. 2), it emerges that the change (percentage baseline concentration) in fasting plasma TG concentration (ΔT) is related to the dose of n-3 PUFA intake (g n-3 PUFA) according to the equation $\Delta T = -7.67 - 3.05(\text{g n-3 PUFA})$ ($R^2 = 0.874$). Notably, this equation relates to doses of n-3 PUFA (1–9 g/d), which were supplemented for a relatively short period of time (4–12 wk).

The duration of supplementation is also an important factor which determines the hypotriglyceridemic efficacy of n-3 PUFA. Lower doses of n-3 PUFA supplemented for a longer time have an equivalent hypotriacylglycerolemia effect as short-term, high-dose n-3 PUFA supplementation trials. Investigations by this research group demonstrated that a low dose of fish oil (1 g/d n-3 PUFA) supplemented for 16 wk significantly reduced fasting plasma TG concentration by 21.2%, a level much greater

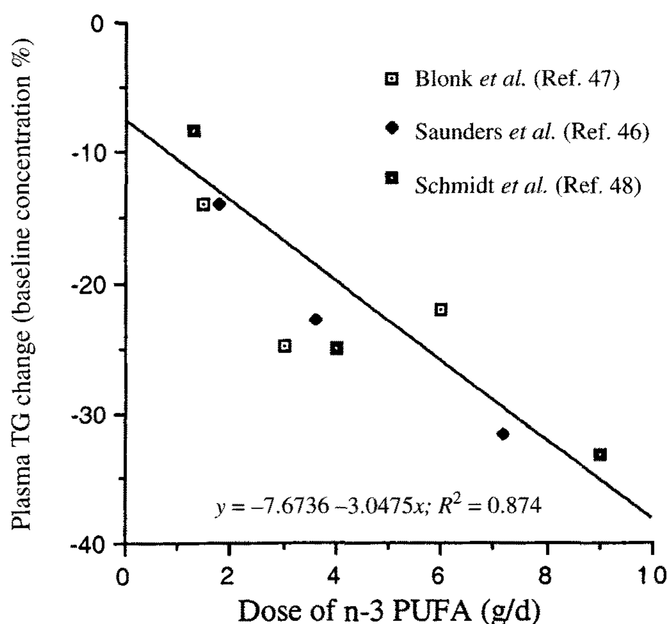

FIG. 2. The dose-dependent hypotriacylglycerolemic effect of n-3 polyunsaturated fatty acid (PUFA) supplementation. See Figure 1 for other abbreviations.

than that predicted from the above equation (–10.7%) (49). The importance of the duration of the supplementation period is supported by the results of other long-term studies. Schmidt *et al.* (50) demonstrated that daily supplementation with 4 g of n-3 PUFA was associated with a time-related reduction of plasma TG concentration during a 9-mon supplementation period (50). Saynor and Gillott (51) showed continued reduction of plasma TG levels following supplementation with 3 g of n-3 PUFA per day for 4 yr of the 7-yr intervention trial. Therefore it is reasonable to conclude that long-term n-3 PUFA supplementation is an effective hypotriglyceridemic agent.

The postprandial TG response is also significantly reduced by n-3 PUFA supplementation. A number of studies have investigated the effects of a wide range of n-3 PUFA intakes on postprandial lipemia. A summary of the results of these studies is presented in Table 1. Briefly, Harris *et al.* (52) and Weintraub *et al.* (53) demonstrated that a background diet rich in n-3 PUFA significantly reduced the postprandial response to a saturated fat test meal, compared to the postprandial response following a saturated fat diet. Williams *et al.* (54) and Agren *et al.* (55) showed that n-3 PUFA supplementation, using lower doses of n-3 PUFA for a longer time, achieved an equivalent hypotriacylglycerolemic effect. Noticeably, the long-term studies of 15 and 16 wk demonstrated the most effective reduction of postprandial TG concentrations per unit of n-3 PUFA supplemented (49,55). Therefore, the maximal hypotriglyceridemic effect on postprandial TG metabolism may be also achieved through long-term supplementation with low doses of n-3 PUFA.

Interestingly, in the same study Agren *et al.* (55) demonstrated that plasma TG concentrations were significantly reduced in another study group who received DHA-rich oil, which was free of EPA (1.68 g DHA, daily), although to a lesser extent than that shown by the group who received fish oil (1.33 g EPA and 1.95 g DHA, daily). This lesser suppression may be due to the lower dose of n-3 PUFA or a difference in the hypotriacylglycerolemic effect of EPA vs. DHA. Childs *et al.* compared EPA-rich pollock oil with DHA-rich tuna and salmon oil blends (56) and it was demonstrated that both fatty acids had equivalent hypotriacylglycerolemic effects. Conversely, another study demonstrated that DHA had no hypotriglyceridemic effect compared to EPA, when 3 g/d of either fatty acid was supplemented in humans for 3 wk. Studies in rats have shown that EPA but not DHA inhibited VLDL secretion, and this was attributed to increased mitochondrial β-oxidation of fatty acids which would reduce the supply of fatty acids for VLDL TG synthesis (58). Clearly the relative effects of both fatty acids on plasma TG metabolism need to be resolved.

The exact biochemical basis of the hypotriglyceridemic effect of n-3 PUFA on postprandial TG metabolism has not been elucidated, but it must be due to either reduced TRL synthesis, increased TRL removal, or a combination of both. Reduced chylomicron synthesis is unlikely because there is no evidence that fish oil supplementation reduces fat absorption (59). Furthermore, studies in rats demonstrated that n-3 PUFA supplementation had no effect on postprandial chylomicron synthesis and secretion (60). Therefore, it is unlikely that reduced exogenous TRL concentrations can explain the attenuated postprandial lipemic response which occurs following n-3 PUFA supplementation. However, diminished endogenous TRL, or VLDL, production does represent a possible mechanism. Animal studies showed that n-3 PUFA inhibit TG synthesis, through the inhibition of 1,2-diacylglycerol transferase (61, 62). *In vitro* studies similarly showed that the incubation of Hep G2 cells with EPA reduced VLDL output (63). Furthermore, kinetic studies in humans fed a background diet rich in n-3 PUFA, in which the protein moiety of VLDL was radio-labeled, demonstrated that n-3 PUFA inhibited endogenous VLDL synthesis and secretion (64). Chylomicrons and VLDL compete for LPL-mediated removal from the circulation (10,65). Therefore, when VLDL synthesis is diminished, chylomicron particles would have a greater opportunity to interact with LPL, thereby allowing more efficient clearance of postprandial TRL.

Enhanced TRL clearance represents another way in which n-3 PUFA exert their hypotriglycerodemic effect on postprandial TG metabolism. However, the evidence in relation to this aspect of n-3 PUFA and TG metabolism is less well understood. As described previously, LPL is the rate-limiting hydrolytic enzyme which controls TRL removal from the circulation; therefore any changes in LPL activity will affect the magnitude and duration of postprandial lipemia (7). However there is a relative paucity of information, and there are conflicting data in relation to n-3 PUFA and LPL activity. Two of the studies cited in Table 1 which investigated the effect of n-3 PUFA on postprandial TG metabolism showed that post-heparin LPL activity was not significantly affected by the presence of n-3 PUFA in the background diet (52,53). However, another study has since demonstrated that fish oil feeding

TABLE 1
Comparison of Postprandial TG n-3 PUFA Intervention Studies[a]

Study	Dose n-3 PUFA (g/d)	Duration (wk)	Fasting TG concentration (mmol/L)			TG AUC % change
			Initial	Final	% change	
Harris *et al.* (Ref. 52)	28.0	3	0.91	0.51	–43.7	–44.1
Weintraub *et al.* (Ref. 53)	7.0	3.5	1.09	0.63	–42.7	–54.0
Williams *et al.* (Ref. 54)	2.7	6	1.05	0.79	–24.8	–43.5
Agren *et al.* (Ref. 55)	2.3	15	1.21	0.89	–26.5	–31.6
Roche and Gibney (Ref. 49)	1.0	16	0.82	0.65	–21.2	–31.8

[a]TG AUC, area under the curve of the postprandial response; PUFA, polyunsaturated fatty acids; TG, triglycerides.

caused a small but significant increase in post-heparin LPL activity (66). It is important to realize that the post-heparin LPL assay measures the amount of LPL that is released from the tissue, rather than the actual physiological level of LPL activity *in vivo*. Therefore, it is unknown whether the analysis of post-heparin LPL is sensitive enough to detect any real changes in LPL activity in those studies. Recently, it was demonstrated that endogenous nonheparin-stimulated LPL activity was significantly increased following n-3 PUFA supplementation (67). Again it is unknown whether endogenous LPL activity reflects LPL activity *in vivo*. Nevertheless, the lack of a specific information in relation to LPL activity does not rule out the possibility that n-3 PUFA increase chylomicron clearance.

A number of issues in relation to n-3 PUFA and chylomicron metabolism remain unresolved. Firstly, chronic n-3 PUFA may lead to the production of chylomicrons which have a different size, structure or chemical composition, which in turn may affect chylomicron lipolysis and/or remnant disposal. Secondly, n-3 PUFA supplementation causes marked changes in membrane phospholipid fatty acid composition, which in turn could affect the affinity of membrane-bound LPL for chylomicrons. Thirdly, n-3 PUFA may increase postprandial blood flow through adipose tissue, thereby affecting the interaction between postprandial chylomicron metabolism and LPL activity. In relation to the first possibility, this hypothesis is supported by *in vitro* investigations which showed that chylomicron TG, produced following a n-3 PUFA meal, are hydrolyzed at a greater rate by LPL, than saturated fatty acid-rich chylomicron TG. Furthermore, the fatty acid composition of the acute test meal affects the composition and clearance of postprandial TRL, the degree of unsaturation of fat in the test meal was inversely related to the magnitude of the postprandial response (59). In that study, post-heparin LPL activity was significantly greater following the n-3 PUFA test meal compared to the saturated fatty acid-rich meal. Therefore, it was proposed that chylomicron TG composed of highly unsaturated fatty acids were more readily hydrolyzed by LPL. Since acute fat composition affects chylomicron removal, it is plausible that chronic or background dietary fat composition also affects the composition and catabolism of chylomicrons; however, this needs to be investigated. Furthermore, chronic n-3 PUFA consumption may affect the apoprotein composition of this chylomicron, which in turn would influence the chylomicron metabolism. Other factors which affect chylomicron lipolysis such as the geometry of the lipolytic site need to be resolved. Dietary n-3 PUFA may affect the size of the chylomicon, and TRL size affects LPL activity, whereby LPL preferentially hydrolyzes larger more TAG-rich lipoproteins (7). Clearly there is a requirement to investigate the precise effects of chronic n-3 PUFA supplementation on chylomicron metabolism.

There is a relative paucity of information in relation to the effect of n-3 PUFA on the amount, affinity, and accessibility of membrane-bound LPL for chylomicrons. Rat studies showed that fish oil leads to significantly higher expression of adipose tissue LPL mRNA (68) which suggests that n-3 PUFA supplementation increases the amount of LPL available to mediated TRL clearance. The physiological relevance of this effect and the extent to which this applies to TG in humans needs to be resolved. The n-3 PUFA chylomicrons lead to very extensive changes in membrane phospholipid composition, which in turn may affect LPL metabolism, but this effect was not investigated.

In summary, a large body of evidence shows that n-3 PUFA reduces plasma TG concentrations through reduced endogenous VLDL production. This in turn probably accounts for reduced postprandial lipemic response following n-3 PUFA supplementation; however, this does not preclude a contribution of enhanced chylomicron clearance as well; however, the precise biochemical nature of this effect remains to be solved.

Triglyceride as a Risk Factor, Epidemiology

M. Miller*

University of Maryland School of Medicine, Baltimore, Maryland

In recent years, triglyceride (TG) has emerged as an important risk factor for coronary artery disease (CAD). While earlier studies reported a positive association between TG and CAD, these effects were often attentuated after adjustment for other powerful covariates. However, a meta-analysis summarizing population-based prospective studies demonstrated a significant association between TG and CAD risk, independent of high density lipoprotein (HDL-C). For each 1 mmol/L rise in TG, CAD increased by 14% in men (n = 22,293) and 37% in women (n = 6,345) (1). A more recent follow-up of the Copenhagen Male Study reported that fasting levels of TG were independent predictors of initial cardiovascular events, even in subjects at the highest stratum of HDL-C (2).

One prevailing issue in assessing coronary risk is whether there is a designated level (or range) of TG above which CAD rates increase. For total cholesterol (TC), this level has been designated as 200 mg/dL (5.2 mmol/L). The rationale for this cutpoint is based on epidemiologic data; in Multiple Risk Factor Intervention Trial, CAD rates increased curvilinearly as TC levels exceeded 200 mg/dL (3).

A similar cutpoint for TG was established by a National Institutes of Health Consensus Panel in 1993 and subsequently adopted by the National Cholesterol Education Program (NCEP). However, there is little data to support a similar TG cutpoint for the following reasons. First, epidemiologic studies have not supported a curvilinear relationship between TG and CAD; at high TG (>1,000 mg/dL), large predominating very low density lipoprotein- and chylomicron particles are less permeable across the endothelium and consequently less atherogenic. In contrast, partially degraded and highly penetrable remnant particles that accompany mild to moderate hypertriglyceridemic states are associated with premature CAD (e.g., Type IV phenotype). Secondly, while reducing TC, and in particular LDL-C, was demonstrated to reduce CAD event rates, there were no studies evaluating the potential impact of selective TG lowering on CAD event rate. Finally, the median TC in the United States is 200 mg/dL with acceleration of CAD rates above this level. The median TG however is only 100 mg/dL, raising the possibility that TG cutpoints established by NCEP may be too high.

To explore this issue, we followed 350 men and women with arteriographic CAD for 18 yr. During this period, there were 199 new events, including CAD death, nonfatal myocardial infarction, and coronary revascularization. After controlling for other co-variates including HDL-C, an age-adjusted Cox proportional hazards model demonstrated that TG >100 mg/dL (1.13 mmol/L) was an independent predictor of new CAD events (relative risk 1.5, 95% confidence interval 1.1–2.1) (4). These data suggest that lower TG levels than previously considered (100– 199 mg/dL) may pose additional risk in CAD patients. Further studies evaluating the effect of TG lowering on CAD event rate may refine our understanding of the importance attributed to TG in atherothrombosis.

Triglyceride-Lowering Effect of n-3 Long Chain Polyunsaturated Fatty Acid: Eicosapentaenoic Acid vs. Docosahexaenoic Acid

P. Weber*

F. Hoffmannn-La Roche Ltd., Vitamins and Fine Chemicals Division, Research & Development, Human Nutrition & Health, 4070 Basel, Switzerland

It is widely accepted that fish oil decreases serum triglycerides. Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are believed to be the active components. By far the majority of animal experiments and human trials investigating the effect of n-3 long chain polyunsaturated fatty acid on serum triglyceride levels were carried out with fish oil concentrates containing both EPA and DHA. Little information exists on the effect of EPA or DHA on serum triglyceride levels as a single agent. This paper reviews the results of human studies which investigated the effect of EPA and DHA on serum triglycerides.

The results of human intervention studies investigating the effects of purified EPA and DHA on plasma triglycerides clearly demonstrate that EPA as well as DHA, given as a single agent, significantly and consistently lowers plasma triglyceride levels. In the papers reviewed, the triglyceride-lowering effect of 2.7–4.0 g EPA per day varied between 16 and 33%. A daily dose of 1.25–2.5 g of DHA resulted in a triglyceride reduction of 17–21%. Only a few studies have been published so far which were designed to investigate the effect of purified EPA vs. purified DHA on fasting triglycerides. Two recently published clinical trials investigated the triglyceride-lowering effect of 4.0 g EPA vs. 4.0 g DHA in healthy young men. These studies revealed a serum triglyceride decrease of 12 and 18% in the EPA group and of 17 and 20% in the DHA group, respectively. A study which investigated the effect of a supplementation with EPA vs. DHA on the postprandial triglyceride surge reported a marked decrease of the postprandial triglyceridemia in both the EPA and the DHA group, though this effect was more pronounced in the people who received DHA. The effect of EPA and DHA on serum lipids such as total cholesterol, low density lipoprotein-cholesterol, and high density lipoprotein, however, appears to be less consistent.

In summary, the available evidence points to the fact that both EPA and DHA have a marked hypotriglyceridemic effect in humans. As it regards the effect of purified EPA and DHA on lipoprotein subfractions, there may be some differences that warrant further clarification.

Fish Oil in Hypertriglyceridemia: Safety and Recommendations

W.E. Connor*

Oregon Health Sciences University, Portland, Oregon 97201

Fish and humans have consumed fish oil for thousands of years. The fact that these populations have survived and flourished suggests the relative safety of fish oils, which are now given to patients to prevent and treat various disease conditions. Nonetheless, certain concerns have arisen about their safety. These include excessive bleeding, thrombocytopenia, increased incidence of stroke, enhanced oxidation of fatty acids, a worsening of glucose control in diabetics, and gastrointestinal side effects such as increased gas. From an examination of extensive literature about fish oil, there is no evidence of significant toxicity. Patients undergoing elective vascular surgery and who have been consuming up to 16 g of fish oil per day have not had enhanced bleeding. The reduction in platelet count has been minimal. While early studies showed some deterioration of diabetic glucose control after fish oil, the more recent and better-controlled studies by meta-analysis showed no such effects. The benefit achieved in diabetics by lowering very low density lipoprotein and triglyceride concentrations in the plasma is considerable. Since vitamin E is included in all fish oil capsules, increased oxidation of fatty acids has not occurred. Perhaps no other therapeutic substance has undergone so much testing over the past two decades without there being significant evidence for toxicity.

This being the case, recommendations for the use of fish oil and its constituent fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), in the treatment of hypertriglyceridemia states are both logical and practical. This is particularly so for the more purified preparations of fish oil which contain 50% or more of the fatty acids EPA and DHA. This may bring the dose as low as 2 to 4 g per day of the purified components vs. 6 or more grams of the usual fish oil preparation. The use of fish oil in hypertriglyceridemia is especially important because thrombosis is a complication of this disorder, perhaps through activation of factor VII. By several actions, the EPA of fish oil is antithrombotic. The most important action is to reduce the synthesis of thromboxane A2 in platelets.

In types IV and V hyperlipidemia, fish oil can be safely utilized with other therapeutic measures such as a low-fat diet and fibrate drugs. In combined hyperlipidemia, fish oil is very helpful when given concurrently with a statin drug. Fish oil not only reduces fasting plasma triglyceride levels, but also reduces postprandial lipemia, which is both atherogenic and thrombotic. In summary, fish oil is a useful and safe therapeutic modality in the treatment of hypertriglyceridemic states, both primary and secondary.

Regulation of Cellular 15-Lipoxygenase Activity on Pretranslational, Translational, and Posttranslational Levels

Hartmut Kühn*, Dagmar Heydeck, Roland Brinckman, and Frank Trebus

Institute of Biochemistry, University Clinics Charité, Humboldt University, D-10115 Berlin, Germany

ABSTRACT: In mammalian cells, enzymatic lipid peroxidation catalyzed by 12/15-lipoxygenases is regulated by pretranslational, translational, and posttranslational processes. In rabbits, rats, and mice induction of experimental anemia leads to a systemic up-regulation of 12/15-lipoxygenases expression. In addition, interleukins-4 and -13 were identified as strong up-regulators of this enzyme in human and murine monocyte/macrophages and in the lung carcinoma cell line A549, and the interleukin-4(13) cell surface receptor as well as the signal transducer and activator of transcription 6 (STATG) appears to be involved in the signal transduction cascade. On the level of translation, 15-lipoxygenase synthesis is blocked by the binding of regulatory proteins to a characteristic gurnine-cytosine-rich repetitive element in the 3′-untranslated region of the rabbit 15-lipoxygenase mRNA, and the formation of such 15-lipoxygenase mRNA/protein complexes was identified as molecular reason for the translational inactivity of the 15-lipoxygenase mRNA in immature red blood cells. However, proteolytic breakdown of the regulatory proteins which were recently identified as hnRNP K and hnRNP E1 overcomes translational inhibition during later stages of reticulocyte maturation. For maximal intracellular activity, 12/15-lipoxygenases require a rise in cytosolic calcium concentration inducing a translocation of the enzyme from the cytosol to cellular membranes as well as small amounts of preformed hydroperoxides which act as essential activators of the enzymes. 12/15-Lipoxygenases undergo irreversible suicide inactivation during fatty acid oxygenation, and this process may be considered an element of down-regulation of enzyme activity. Suicide inactivation and proteolytic breakdown may contribute to the disappearance of functional 12/15-lipoxygenase at later stages of erythropoiesis.

Lipid peroxidation is generally considered a deleterious process which leads to the destruction of subcellular organelles and eventually to cell death (1,2). However, if lipid peroxidation proceeds in a controlled manner and when it is restricted to certain cellular compartments, it may have beneficial effects for cells and for the entire organism. Local destructive processes are an integral part of normal cellular metabolism. In particular, cell differentiation and/or maturation is characterized by a breakdown of certain cell structures and by remodeling of cellular membranes (3). Membrane remodeling and membrane fusion require local destabilization of the membrane structure, in particular a disturbance of the hydrophobic lipid–lipid and lipid–protein interaction within the lipid bilayer. Introduction of a hydrophilic peroxyl group into the hydrophobic fatty acid chains may contribute to local membrane destabilization. Membrane destabilization may not be restricted to cells which undergo differentiation and/or maturation but may also occur in cells which fulfill special tasks in the body. Phagocytosis, degranulation, antigen presentation, receptor-mediated ligand uptake etc. are among the processes associated with membrane remodeling and/or membrane fusion.

An essential precondition for a potential beneficial effect of local lipid peroxidation appears to be a tight regulation. There must be the possibility to turn on lipid peroxidation when it is needed and to switch it off when it starts to do harm to the cells. However, nonenzymatic lipid peroxidation is an autocatalytic process which is difficult to regulate. Although cells contain antioxidants and/or antioxidative enzymes which are designed to protect cells from oxidative damage, this may not be considered real regulation. In contrast, several elements of up- and down-regulation of enzymatic lipid peroxidation have been described (Table 1) and there may be others which have not yet been identified.

In this paper the recent advances in regulation of enzymatic lipid peroxidation by 12/15-lipoxygenases (LOX) are summarized, and the potential impact of enzymatic lipid peroxidation on cell structure and function will be discussed.

EXPERIMENTAL PROCEDURES

Materials and preparations. The 15-LOX was prepared from reticulocyte-rich blood cell suspensions of rabbits by fractionated ammonium sulfate precipitation and consecutive hy-

drophobic interaction and anion exchange chromatography (4). Experimental anemia was induced in rabbits or mice by repeated subcutaneous injection of a neutralized phenylhydrazine solution at a dose of 7 mg/kg body weight (rabbits) or 14 mg/kg body weight (mice). Development of anemia was followed by measuring the hematocrit, and reticulocytes were counted after staining with brilliant cresyl blue. Phospholipid hydroperoxide glutathione peroxidase (PH-GPx) was purified from pig hearts as described in Reference 5. Monocytes (human and murine) were prepared from peripheral blood by density gradient centrifugation and adherence to plastic dishes (6,7). Cells were cultured *in vitro* in the presence of recombinant interleukins for 3–5 d (5,8), and expression of the 15-LOX was tested by activity assays, immunoblotting, and quantitative reverse-transcriptase polymerase chain reaction (RT-PCR). Transgenic mice which overexpress interleukin-4 (IL-4) under the control of major histocompatibility, complex (MHC) I regulatory elements (9) were kindly provided by Dr. A. Schimpl (Würzburg). Homozygous signal transducer and activator of transcription (STAT) 6-deficient mice (10) and corresponding inbred control animals with identical genetic background were obtained from Dr. J. Ihle (Memphis).

Assay systems. The activity of 12/15-LOX was assayed either spectrophotometrically measuring the increase in absorbance at 235 nm or by high-performance liquid chromatography (HPLC) quantification of specific LOX products after incubation of a cell homogenate with exogenous arachidonic acid (100 μM). PH-GPx activity was assayed with the coupled optical test (5) using 1-palmitoyl, 2-hydroperoxylinoleyl phosphatidylcholine as substrate. Immunoblots were carried out using a polyclonal anti-rabbit-15-LOX antibody (Ig G fraction of Mono-Q FPLC). Reverse-transcriptase polymerase chain reaction (RT-PCR) of the 15-LOX mRNA was performed as described before (8): Briefly, total RNA (3 μg) was reverse-transcribed, and 2 μL of this sample was used for PCR. For amplification of the 15-LOX mRNA, the primer sequences 5′-GGGGCTGGCCGACCTCGCTATC-3′ (up) and 5′-TCCTGTGCGGGGCAGCTGGAGC-3′ (down) were selected from regions displaying minimal homology to the sequences of the human platelet-type 12- and the 5-LOX. The primers for amplification of the glyceraldehyde-3-phosphate dehydrogenase mRNA were 5′-TCGGAGTCAACGGATTTGGTCGTA-3′ (up) and 5′-ATGGACTGTGGTCATGAGTCCTTC-3′ (down). After initial denaturation for 3 min at 94°C, PCR was carried out for 23–35 cycles, and each cycle consisted of a denaturing period (40 s at 94°C), an annealing phase (30 s at 66°C for glyceraldehyde-3-phosphate dehydrogenase and at 71°C for 15-LOX) and an extension period (30 s at 72°C). The reaction mixture was a 10 mM Tris-HCl buffer, pH 8.3, containing 50 mM KCl, 2 mM $MgCl_2$, 0.1 mg/mL gelatin, 6 pmol of primer sets, 100 μM each of dNTP, 100 μg/mL albumin, and 2.5 U Taq DNA polymerase. PCR products were separated by 2% agarose gel electrophoresis. For quantification, DNA was stained with ethidium bromide and analyzed densitometrically. Densitometric data were corrected for molar equivalence and log/log plotted as function of internal standard-derived PCR products. HPLC analyses of the lipoxygenase products were carried out on a Shimadzu instrument coupled with a Hewlett-Packard diode array detector 1040 A. Reverse-phase HPLC was performed on a Nucleosil C-18 column (Macherey/Nagel, Düren, Germany; KS-system, 250 × 4 mm, 5 μm particle size). A solvent system of methanol/water/acetic acid (85:15:0.1, by vol) and a flow rate of 1 mL/min were used. Chromatograms were quantified by peak areas. The fractions containing the oxygenated polyenoic fatty acids were pooled, the solvent was evaporated, the residues were reconstituted in a mixture of *n*-hexane/2-propanol/acetic acid (100:2:0.1, by vol) and injected to straight-phase HPLC analysis which was carried out on a Zorbax SIL column (Macherey/Nagel, KS-system, 250 × 4 mm, 5 μm particle size) with a solvent system consisting of *n*-hexane/2-propanol/acetic acid (100:2:0.1, by vol) and a flow rate of 1 mL/min. For detection of the primary LOX products, the ultraviolet absorbance at 235 nm was recorded.

RESULTS AND DISCUSSION

Pretranslational regulation of 15-LOX expression. Erythrocytes of various species do not express a 12/15-LOX. However, after induction of experimental anemia in mice, rabbits (Table 2), and rats (data not shown) a 12/15-LOX activity can be measured. Experimental anemia was induced in mice and rabbits by subcutaneous injection of a neutralized phenylhydrazine solution at four consecutive days. Rabbits were treated with a dose of 7 mg phenylhydrazine/kg body weight, whereas

TABLE 2
Lipoxygenase Activity of Red Blood Cells Before and During Experimental Anemia

	LOX activity (μg HETE formation/mL of packed red cells × 15 min)	
Species	Before phenylhydrazine injection	After phenylhydrazine injection
Mouse	0[a]	210 (12*S*-HETE)[b]
Rabbit	0	91 (15*S*-HETE)

[a]In young mice we detected occasionally a 12-LOX activity in the red cells even when the animals had not been treated with phenylhydrazine.
[b]Measured 17 d after the first phenylhydrazine injection. In parentheses the chemical structure of the major product is given (see Fig. 1).

mice received 14 mg/kg body weight, 14 d after the first injection blood was withdrawn and the red cells were prepared. After washing twice with isotonic saline the cells (100 μL of packed cells suspended in 1 mL of phosphate buffered saline) were incubated for 15 min with 100 μM arachidonic acid. The reaction was stopped by addition of sodium borohydride. After acidification to pH 3, the lipids were extracted twice with 1 mL of ethyl acetate. The solvent was removed under vacuum, the lipids were reconstituted in 0.1 mL of methanol, and aliquots were injected to reverse-phase HPLC analysis with the solvent system methanol/water/acetic acid (80:20:0.1, by vol). HPLC analysis revealed that 15*S*-hydroxy-5*Z*,8*Z*,11*Z*,13*E*-[H(P)ETE] was the major product of arachidonic acid oxygenation by rabbit reticulocytes. In contrast, mainly 12-H(P)ETE was found when murine reticulocytes were incubated with arachidonic acid (Fig. 1). More detailed structural analysis indicated that rabbit reticulocytes formed a 95:5 mixture of 15*S*-H(P)ETE/12*S*-H(P)ETE, whereas this ratio was inverted for murine reticulocytes (3:97). The latter finding was quite surprising since murine peritoneal macrophages form a 12*S*-H(P)ETE/15*S*-H(P)ETE ratio of about 70:30 (11,12). If the formation of 12/15-LOX products by murine reticulocytes and murine macrophages would be catalyzed by one and the same enzyme, a more similar product pattern would have been expected. On the other hand, it was shown before that the positional specificity of the LOX reaction is not an absolute enzyme property but may depend on the reaction conditions. Thus, product analysis alone is not sufficient to answer the question of whether or not in mice two different 12/15-LOX isoforms may be expressed in a tissue-specific manner. Experiments with transgenic mice in which the gene coding for the macrophage 12-LOX was disrupted may contribute to answer this question (13).

Anemia-induced LOX expression is not restricted to the reticulocytes but was also detected in peripheral monocytes, in lung, spleen, kidney and liver, but hardly in skeleton muscle and various parts of the brain (14). At present, the mechanism of 12/15-LOX induction during experimental anemia is not known. Possibly, experimental anemia leads to the secretion of various cytokines which in turn may switch on systemic expression of 12/15-LOX.

A second element of pretranslational regulation is the induction of the 12/15-LOX by interleukins (6,15,16). Human and murine peripheral monocytes as well as the human lung carcinoma cell line A 549 do not express a 12/15-LOX. However, when the cells were cultured in the presence of IL-4 or IL-13, a functional LOX is expressed as indicated by Northern-blot analysis, RT-PCR, immunoblotting, and by activity assays. Other cytokines such as IFNγ, IL-6, IL-10, GM-CSF etc. did not exhibit this stimulatory effect. No up-regulation of 12/15-LOX expression was observed when permanent human (HL 60, THP 1, U 937, Mono-Mac 6) or murine (J 774, P 388.D1) monocytic cell lines were tested (8). These data were rather surprising since all of these cells express the IL-4 cell surface receptor. The reasons for this differential behavior of peripheral monocytes and monocytic cell lines are not clear, but it may be speculated that a high degree of maturation may be required. Most of the permanent monocytic cell lines represent rather immature precursor cells, and this may be the rea-

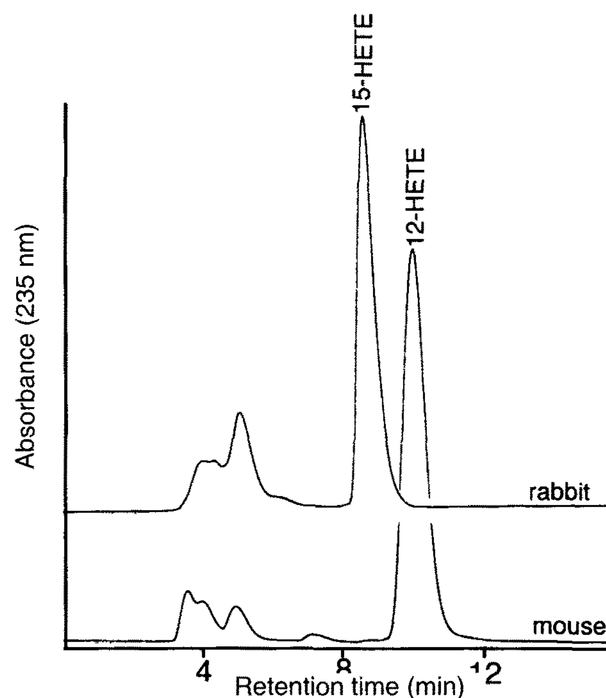

FIG. 1. Formation of specific lipoxygenase (LOX) products by rabbit and murine reticulocytes. Induction of experimental anemia, reticulocyte preparation, activity assays, and reverse-phase high-performance liquid chromatography analysis were carried out as described in the legend to Table 2. The retention times of the authentic standards are indicated above the traces. 12-HETE, 12-hydroxy-5*Z*,8*Z*,10*E*,14*Z*-eicosatetraenoic acid; 15-HETE, 15-hydroxy-5*Z*,8*T*,11*Z*,13*E*-eicosatetraenoic acid.

son for their unresponsiveness. Human alveolar macrophages (16) and murine peritoneal macrophages (7) constitutively express a 12/15-LOX. When cultured in the presence of IL-4, the level of expression is up-regulated by a factor of 2–5 (7,16). Although the mechanism of IL-4-induced up-regulation of 12/15-LOX synthesis is not completely understood, several constituents of the signal transduction cascade were identified. Competition assays with IL-4 receptor antagonists (IL-4 mutant Y124D) suggested the involvement of the IL-4(13) cell surface receptor (8). This IL-4 mutant, which is capable of binding to the receptor but does not induce the intracellular signal transduction cascade (17), inhibited the up-regulation of 15-LOX expression (8) as indicated by activity assays and immunoblot analysis.

For B-cells, IL-4 constitutes a signal for switching immunoglobulin synthesis toward immunoglobulin synthesis toward E formation, and the transcription factor STAT 6 was shown to be involved. After IL-4 binding to its cell-surface receptor, STAT 6 is phosphorylated and translocates as homodimer into the nucleus where it binds to STAT 6-responsive elements in the promoter region of IL-4-sensitive genes to activate transcription (18). In order to find out whether STAT 6 may also be involved in IL-4-induced up-regulation of 12/15-LOX expression, experiments with peritoneal macrophages were carried out which were prepared from transgenic mice in which the gene coding for STAT 6 had been inactivated by targeted gene disruption (10). We found that in these cells the expression of the 12/15-LOX was not up-regulated when cultured in the presence of IL-4 (7).

In the promoter region of the human 15-LOX gene, STAT 6 responsive elements with the consensus sequence TTC NNN(N) GAA (19) were identified, but their functionality is still unclear. Thus, the question of whether the 15-LOX gene may belong to the family of immediate early genes switched on by IL-4 cannot be answered at this time. However, the time course of 12/15-LOX expression following IL-4 stimulation (6,8) strongly suggests that the 12/15-LOX gene may not constitute an immediate early gene of IL-4 response. RT-PCR data on A 549 cells indicated that transcription of the 15-LOX gene started about 24 h after IL-4 stimulation, and expression of the functional enzyme was maximal after 3–5 d. Such a long time interval between stimulation and expression may not be typical for immediate early genes. Recently, it was reported that in human monocytes, IL-4 stimulation may induce the expression of a novel transcription factor (transcription factor X) which is capable of binding to the promoter region of the human 15-LOX gene (20). In Figure 2 the potential sequence of events involved in IL-4-induced up-regulation of 12/15-LOX expression is shown.

Translational regulation of 15-LOX expression. In young rabbit reticulocytes, the 15-LOX mRNA is present, but no functional enzyme is expressed (21). As mechanistic reasons for these biological dynamics, two regulatory proteins were identified which are capable of binding to repetitive sequences in the 3′-untranslated region of the 15-LOX mRNA which were called differentiation control elements (DICE). Protein binding to DICE prevents translation of the 15-LOX mRNA as indicated by *in vitro* translation studies (22). The regulatory proteins were purified from a lysate of rabbit reticulocytes and were identified as hnRNP K and E_1 (23). Transfection of hnRNP K and hnRNP E_1 into HeLa cells specifically silenced the translation of reporter mRNA, bearing the repetitive element of the rabbit 15-LOX mRNA in their 3′-untranslated region (23). Silenced LOX mRNA of rabbit reticulocytes specifically coimmunoprecipitated with hnRNP K. Addition of recombinant hnRNP K and/or hnRNP E_1 causes inhibition of 80S ribosome assembly on the 15-LOX mRNA. Moreover, both proteins can control cap-dependent and internal ribosome entry site-mediated translation by binding to the differentiation control elements (DICE). These data suggest a specific cytoplasmic function for hnRNP as translational regulatory proteins. In later stages of red cell maturation, these regulatory proteins may be degraded proteolytically, and the functional 15-LOX will be expressed.

Posttranslational regulation of 15-LOX activity. 12/15-LOX are not a subject of major posttranslational modification. Major glycosylation was not detected (24,25), and there are no signs for myristoylation or isoprenylation (25). Moreover, there is no experimental evidence for a regulatory phosphorylation/dephosphorylation cycle of the enzyme.

Nevertheless, 12/15-LOX require activation in order to exhibit their catalytic activity. When highly purified polyenoic fatty acids are used as LOX substrate, the reaction starts with a kinetic lag-phase which can be abolished by addition of hydroperoxy fatty acids (Fig. 3). Although the chemical nature of this activation process is not well understood, oxidation of the ferrous nonheme iron to a ferric form is involved (26). In order to find out whether such activation is also required for the oxygenation of complex substrates, we investigated the impact of a lipid peroxide-reducing enzyme on 12/15-LOX-catalyzed oxygenation of biomembranes (27). When mitochondrial membranes were incubated with the purified 15-LOX, the unsaturated phospholipids present in the membranes were oxygenated as indicated by the formation of specific LOX products. However, when the membranes were pre-incubated with phospholipid hydroperoxide glutathione peroxidase (PH-GPx), an enzyme capable of reducing esterified hydroperoxy lipids to their corresponding hydroxy derivatives, the formation of these products was prevented (27). These data may be explained by the fact that PH-GPx depletes the membranes from hydroperoxides, and thus enzyme activation becomes impossible. However, when an excess of hydroperoxy fatty acids was added, the LOX reaction did start immediately (27).

Nitric oxide also appears to be of regulatory importance for the 12/15-LOX pathway (28,29). Short-term incubations of the enzyme in the presence of nitric oxide lead to a prolongation of the kinetic lag-period, suggesting a reversible inhibition of the enzyme (29). However, after long-term incubations, the kinetic lag-phase was considerably shortened. These data suggest that during NO/15-LOX interaction an oxidation of the ferrous nonheme iron may have taken place. To

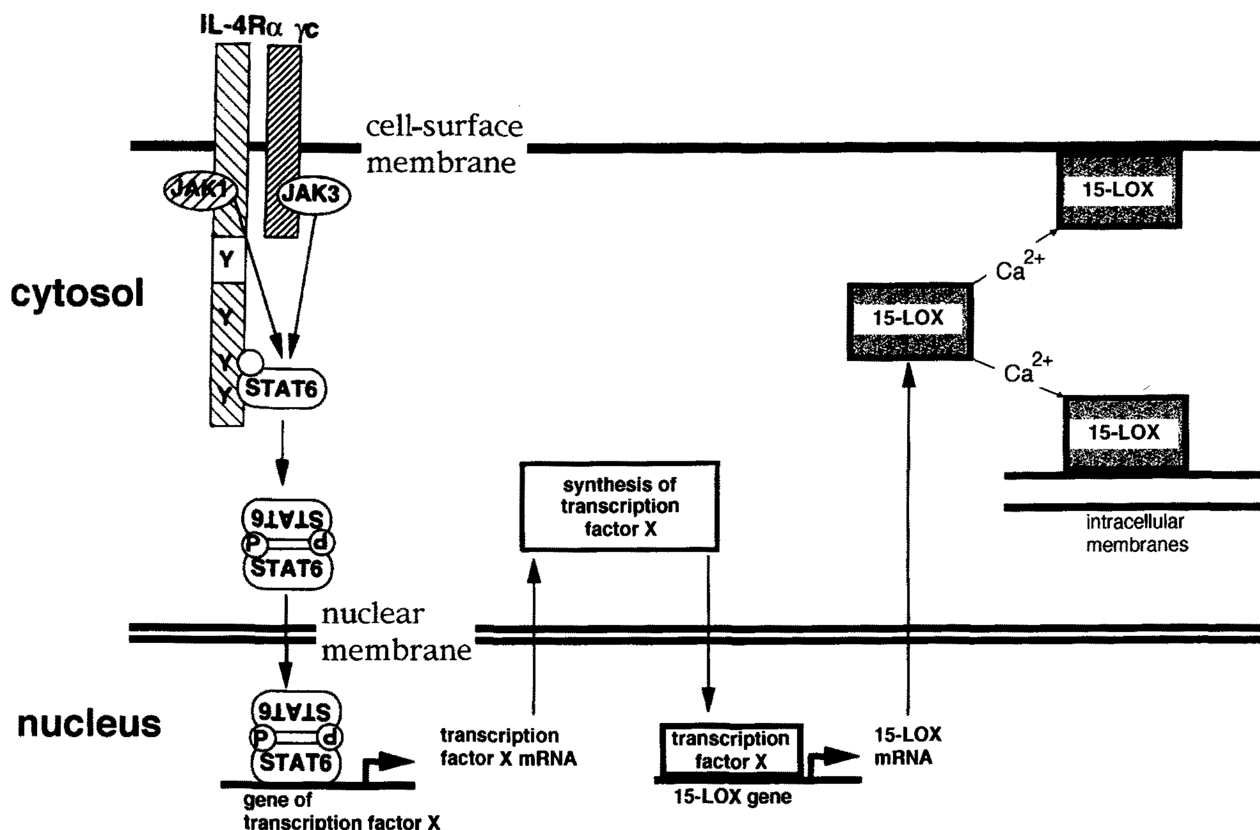

FIG. 2. Possible sequence of events involved in interleukin-4-induced up-regulation of 15-LOX expression. See Figure 1 for abbreviation.

obtain direct evidence for such an oxidation, X-ray absorption studies and electron paramagnetic resonance spectroscopy measurements were carried out (28), and with both methods we obtained evidence for the formation of ferric LOX species during 15-LOX/NO interaction.

As third element of posttranslational regulation a calcium-dependent membrane association was reported. When the purified rabbit 15-LOX is incubated with biomembranes in the presence of calcium ions, it binds to membranes as indicated by immunoblotting (30). This membrane association, which is a necessary precondition for the oxygenation of the membrane phospholipids, is paralleled by an up to 10-fold stimulation of the fatty acid oxygenase activity. Removal of calcium (complexation by EDTA) dissociates the enzyme from the membranes and prevents the oxygenation of the membrane lipids, suggesting reversibility of the membrane binding.

Many years ago it was shown that most mammalian LOX are irreversibly inhibited during oxygenation of polyenoic fatty acids, but the mechanism of this suicide inactivation is still unclear. The purified rabbit 15-LOX is rapidly inactivated when incubated with hydroperoxy linoleic acid (13*S*-HPODE), the primary product of LOX-catalyzed oxygenation of linoleic acid. Comparison of the circular dichroism spectra of the native and the 13*S*-HPODE-inactivated enzyme did not reveal major dif-

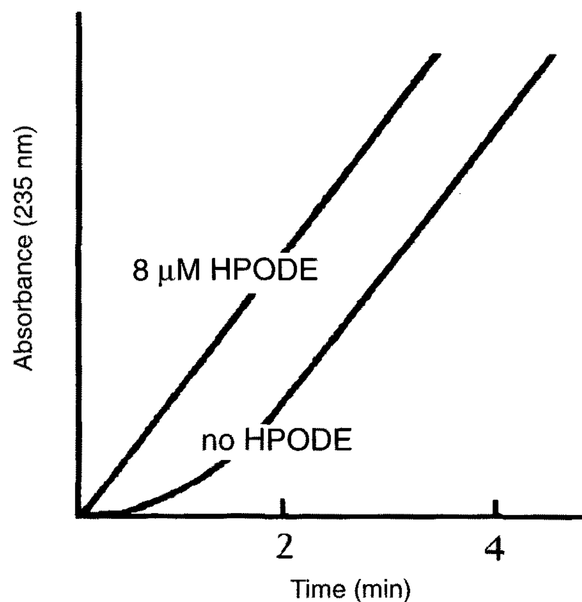

FIG. 3. Peroxide activation of rabbit 15-LOX. The rabbit 15-LOX was incubated with 0.25 mM linoleic acid in the absence and presence of hydroperoxy linoleic acid (13*S*-HPODE), and the increase in absorbance at 235 nm was assayed as a measure of linoleic acid oxygenation. See Figure 1 for other abbreviation.

ferences, suggesting that suicide inactivation may not be due to major changes in the secondary structure (Ludwig, P., unpublished data). Thus, a rather specific mechanism of suicide inactivation was proposed. Later on, it was found that suicidal inactivation was paralleled by a selective oxidation of one methionine residue to methionine sulfoxide (31). More detailed protein chemical studies identified met590 as the target amino acid (32). However, when this methionine was mutated to an oxidation-resistant leucine, the mutant enzyme species also underwent suicidal inactivation, suggesting that oxidation of met590 may not be the major molecular reason of suicide inactivation (32).

More recently the inactivation of the porcine leukocyte 12-LOX by 15-HPETE was studied (33). When radioactive 15*S*-HPETE was used as inactivating agent, the enzyme was labeled radioactively during the inactivation process. It was hypothesized that 15-HPETE is converted by the enzyme to a reactive 14,15-epoxy leukotriene intermediate which in turn reacts with the LOX protein to form a covalent adduct (33), and recent experiments with 14,15-leukotriene A_4 appear to support this hypothesis. Similar data were also obtained with the rabbit 15-LOX (Weisner, R., and Kühni, H., unpublished data).

During the publication process of this paper, it was reported (34) that IL-13-induced expression of the 15-LOX in human monocytes requires tyrosine phosphorylation of JAK2 and TYK2. These data implicate JAK and TYK kinases as additional members of the IL-4/IL-3 induced signal transduction cascade which leads to 15-LOX expression.

Fatty Acid Ethyl Esters: Nonoxidative Ethanol Metabolites with Emerging Biological and Clinical Significance

Michael Laposata*
Division of Laboratory Medicine, Department of Pathology, Massachusetts General Hospital/Harvard Medical School, Boston, Massachusetts

Despite the fact that alcoholism is a major cause of disease in society, little is known about the mechanism by which ethanol abuse induces organ damage. One increasingly compelling hypothesis is that fatty acid ethyl esters (FAEE), esterified products of fatty acids and ethanol, are at least partly responsible for the observed pattern of organ damage in alcoholics. FAEE were discovered and rediscovered on multiple occasions in different cells and tissues through the 1960s and 1970s. In the last several years *in vitro* and *in vivo* evidence emerged that FAEE contribute to ethanol-induced organ damage, with a variety of different mechanisms proposed for mediation of this toxic effect. Multiple enzymatic activities associated with FAEE formation have now been described. Independent of its role in mediating cell injury, it was very recently shown that FAEE are useful short- and long-term serum markers of ethanol intake, given their appearance in the blood rapidly after ethanol ingestion and their presence when ethanol is no longer detectable.

THE TOXIC EFFECTS OF FAEE

In 1986, a hypothetical connection was established between FAEE and ethanol abuse. Tissues obtained postmortem from humans acutely intoxicated at the time of death were tested and the organs commonly damaged by ethanol abuse, pancreas, liver, heart and brain, were found to have high levels of enzyme activity for the synthesis of FAEE and the highest concentrations of FAEE among many different organs and tissues tested (1). Adipose tissue was also found to have an accumulation of FAEE and measurable levels of FAEE synthetic activity. The organs not typically damaged by ethanol abuse showed little or no FAEE and correspondingly little ethyl ester synthase activity. FAEE were implicated as mediators of ethanol toxicity because FAEE and the enzyme(s) responsible for their synthesis were distributed primarily in organs damaged by ethanol abuse. However, there was no causal effect demonstrated between FAEE and cytotoxicity in this report.

Prior to the 1986 autopsy study, the possibility that FAEE mediate ethanol-induced organ damage had been raised. Using FAEE solubilized in emulsions and isolated heart muscle mitochondria from rabbits, a report in 1983 indicated that FAEE inhibited mitochondrial function by uncoupling oxidative phosphorylation (2). It was speculated that FAEE are hydrolyzed in cells in the mitochondrial membrane, resulting in a high concentration of free fatty acids, which impair mitochondrial function.

In 1993, Haber *et al.* (3) demonstrated that rat pancreatic lysosomes incubated for 20 min with ethyl oleate become unstable and leak their enzymes into the surrounding medium. The hypothesis was raised that increased pancreatic lysosomal fragility mediated by FAEE is associated with ethanol abuse.

Studies from my research group by Szczepiorkowski *et al.* (4) provided the first demonstration that FAEE in a physiologic particle, low density lipoprotein (LDL), exert toxic effects on an intact cell. We previously observed in human subjects that FAEE are present within LDL following ethanol ingestion (5). Therefore, in the toxicity studies, to deliver FAEE to intact cells, we synthesized radiolabeled FAEE and incorporated them into human LDL particles, which bind to LDL receptors (6). In these studies, ethyl palmitate and ethyl oleate were incorporated into LDL, yielding molar ratios of FAEE to LDL particle of 1614 ± 187 and 3154 ± 303 ($n = 6$, mean $\pm$ SE), respectively. LDL reconstituted with FAEE (rLDL) was not oxidatively modified, and native LDL markedly decreased the uptake of ethyl oleate in rLDL by HepG2 cells. Cultured HepG2 cells were incubated with LDL containing FAEE (either ethyl oleate or ethyl arachidonate), and cell proliferation was measured by [methyl-^{3}H]thymidine incorporation, and protein synthesis was determined using L-[^{35}S]methionine. Incubation of cells with 600 μM ethyl oleate or 800 μM ethyl arachidonate, which permitted us to achieve intracellular FAEE concentrations found *in vivo* in the 1986 autopsy study (1), decreased [methyl-^{3}H]thymidine incorporation into HepG2 cells by 30 and 35%, respectively. rLDL with ethyl oleate (400 μM) decreased protein synthesis in intact HepG2 cells by 40%. Electron microscopy revealed signifi-

Copyright © 1999 by AOCS Press

cant changes in cell morphology, with accumulation of intracellular lipids and a distortion of the intracellular lipids and a distortion of the nuclear membrane. FAEE delivered in rLDL were rapidly hydrolyzed, and the fatty acids reesterified into phospholipids, triacylglycerols and cholesteryl esters, with preference for triacylglycerols. These findings provided evidence that FAEE are toxic for intact human hepatoblastoma cells and that they or their metabolites may be a causative agent in ethanol-induced liver damage.

Gubitosi-Klug and Gross (7) examined the effect of FAEE on a human brain potassium channel in SF9 cells expressing the recombinant channel. They found that physiologically relevant FAEE concentrations accelerated the kinetics of activation of the channel, and raised the possibility that this *in vitro* observation may be one of the pathologic consequences of ethanol abuse in the central nervous system.

The *in vitro* toxicity studies still left unanswered the question of whether FAEE are toxic *in vivo*. This led us to perform experiments to assess the toxicity of FAEE in rLDL *in vivo* in rats (8). In these studies, rats received FAEE in rLDL at FAEE concentrations which are physiologically attainable (10–30 μM) after ethanol ingestion. The FAEE were delivered as a bolus and then by continuous infusion for 1 h through a cannula placed in the carotid artery and advanced through the aorta to the superior mesenteric artery. This placement was made to maximize the likelihood for observing FAEE-induced cytotoxicity in the pancreas. The rats were sacrificed 3–24 h after infusion of FAEE, and biochemical markers of organ damage were measured. Histologic analysis was performed for multiple organs, and the wet/dry ratio of the pancreas determined to assess pancreatic edema. Control rats received LDL which was reconstituted with cholesterol ester. The wet/dry ratio for the rats receiving the LDL containing FAEE was significantly higher than that of the rats receiving rLDL with cholesterol ester. In addition by 3 h, the level of trypsinogen-activating peptide, a biochemical marker for pancreatic cell damage, was threefold higher in the animals receiving the rLDL relative to controls.

Thus, at this time many *in vitro* and *in vivo* studies show that FAEE have significant capacity to induce cell injury.

ENZYMES ASSOCIATED WITH FAEE SYNTHESIS

In 1984, an FAEE synthase enzyme was purified to homogeneity from rabbit myocardium (9).

In a 1987 study involving FAEE synthesis using a postmortem human brain (10), FAEE synthase activity was found in 10 different anatomic locations in human brain, with gray matter sites containing approximately twice the activity of white matter sites.

A study published in 1990 investigated the synthesis and degradation of FAEE by rat hepatoma cells exposed to ethanol in tissue culture (11). FAEE synthesis by cultured hepatoma cells was found to be linearly associated with the concentration of ethanol added to the culture medium. In addition, the enzymes responsible for the synthesis of ethyl esters were shown to be primarily membrane-bound and concentrated in the microsomal fraction of the hepatocytes, rather than in the cytoplasm. It was also observed in this study that FAEE can be hydrolyzed to free fatty acids and ethanol by membrane-bound enzymes in the microsomal and mitochondrial-lysosomal fractions.

A 1996 report by Treloar *et al.* (12) provided additional information on the cytosolic and microsomal forms of FAEE synthase. The cytosolic FAEE synthase activity, which uses ethanol and free fatty acid as substrates for FAEE synthesis, was designated as FAEE synthase, and the microsomal FAEE synthase activity, which uses ethanol and fatty acyl-CoA as substrates, was referred to as acyl-CoA:ethanol acyltransferase. The data indicated that the activities/g liver of these two FAEE syntheses are comparable.

Several enzymes known to catalyze other reactions were also shown to catalyze FAEE synthesis. These include carboxylesterase from adipose tissue (13) and pancreas (14), lipoprotein lipase (15,16), pancreatic triglyceride lipase (17), and possibly cholesterol esterase (18).

We reported that white blood cells (WBC) are capable of synthesizing FAEE (19). This finding is significant because it demonstrates that a blood sample rather than a biopsy can be used to quantitate FAEE synthase activity in populations. We determined that the lymphocyte–monocyte population of WBC was particularly high in FAEE synthase activity and that the natural killer cells had the highest activity among the lymphocytes. This result correlated with a report published at the same time, showing that delivery of ethanol to rats previously injected with tumor cells permitted metastasis by inhibition of natural killer cell function (20). This observation raises the possibility that, upon ethanol ingestion, FAEE synthesis in natural killer cells is a causative factor in the inhibition of immunologic activity and the promotion of tumor metastasis.

We also demonstrated in this study that FAEE synthase activity could be induced nearly twofold in the WBC fraction of humans ingesting 2 ounces of Scotch whisky for 6 d (19). This supports the conclusion that FAEE synthase is regulated to some extent by the presence of ethanol. The enzyme activity returned to baseline levels despite ingestion of 2 ounces of Scotch whisky for an additional 3 d. This report also showed that alcoholic individuals have approximately half the WBC FAEE synthase activity detected in normal controls. The lower enzyme activity observed in the WBC of alcoholics in a detoxification center may be the result of years of ethanol abuse, or it may be that alcoholics congenitally have low levels of FAEE synthase. If the latter is true, this finding may explain in part the genetic predisposition of many alcoholic individuals to ethanol abuse.

FAEE AS FATTY ACID SUPPLEMENTS

There is substantial clinical interest in fatty acid supplements as treatments for a variety of diseases. Oral preparations of FAEE are available for fatty acid supplementation. Ethyl esters and triglycerides were shown to be equally well absorbed from the gastrointestinal tract in human subjects (21). In

1992, Yamazaki and Hamazaki (22) infused emulsions of ethyl eicosapentaenoate and found an increase in the eicosapentaenoate content in the phospholipids of a variety of organs.

We recently tested the hypothesis that orally ingested supplemental FAEE are rapidly degraded in the gastrointestinal tract and blood to explain the lack of toxicity (23). Using rats given FAEE as an oil directly into the stomach or within LDL particles directly into the circulation, we demonstrated that FAEE hydrolysis in the gastrointestinal tract and blood is rapid and extensive. The fate of the fatty acid from FAEE hydrolysis was highly dependent on the organ or tissue presented with the FAEE.

FAEE AS MARKERS OF ETHANOL INTAKE

In a 1994 study with five volunteers investigating ethanol, FAEE were shown to be bound to lipoproteins and albumin in serum (5). A higher percentage of saturated fatty acids was found in the FAEE pool than in the serum free fatty acid or triacylglycerol pools. In this study, we also demonstrated that when FAEE are isolated by density gradient ultracentrifugation from the sera of intoxicated emergency room patients, 68.3% of the FAEE associate with the $d > 1.21$ fraction, which contains albumin. To assess whether FAEE in serum, like nonesterified fatty acids, are bound to albumin, sera from several emergency room patients with detectable blood ethanol were pooled, and the serum albumin in the sample was immunoprecipitated. Lipids from the immunoprecipitate were extracted, and FAEE were found in the precipitates. These data provide evidence to support the conclusion of earlier density gradient studies that a significant fraction of serum FAEE is bound to albumin.

In a series of nuclear magnetic resonance-based studies, we analyzed FAEE binding to small unilamellar phospholipid vesicles, human LDL, and bovine serum albumin by ^{13}C nuclear magnetic resonance spectroscopy using ethyl (1–^{13}C, 99%) oleate (24). The conclusions from this study were that addition of ethyl oleate to isolated human LDL resulted in ethyl oleate in the core of the lipoprotein, that albumin has a much greater affinity for oleic acid than for ethyl oleate, and that ethyl oleate rapidly transfers between LDL and phospholipid vesicles. In our report by Doyle *et al.* (5), we found that albumin transports the majority of FAEE in plasma. The accumulated observations suggest that despite its low affinity for FAEE, albumin transports most of the FAEE in the blood because it has a much greater plasma concentration than lipoprotein particles. In a separate study, we reported that as

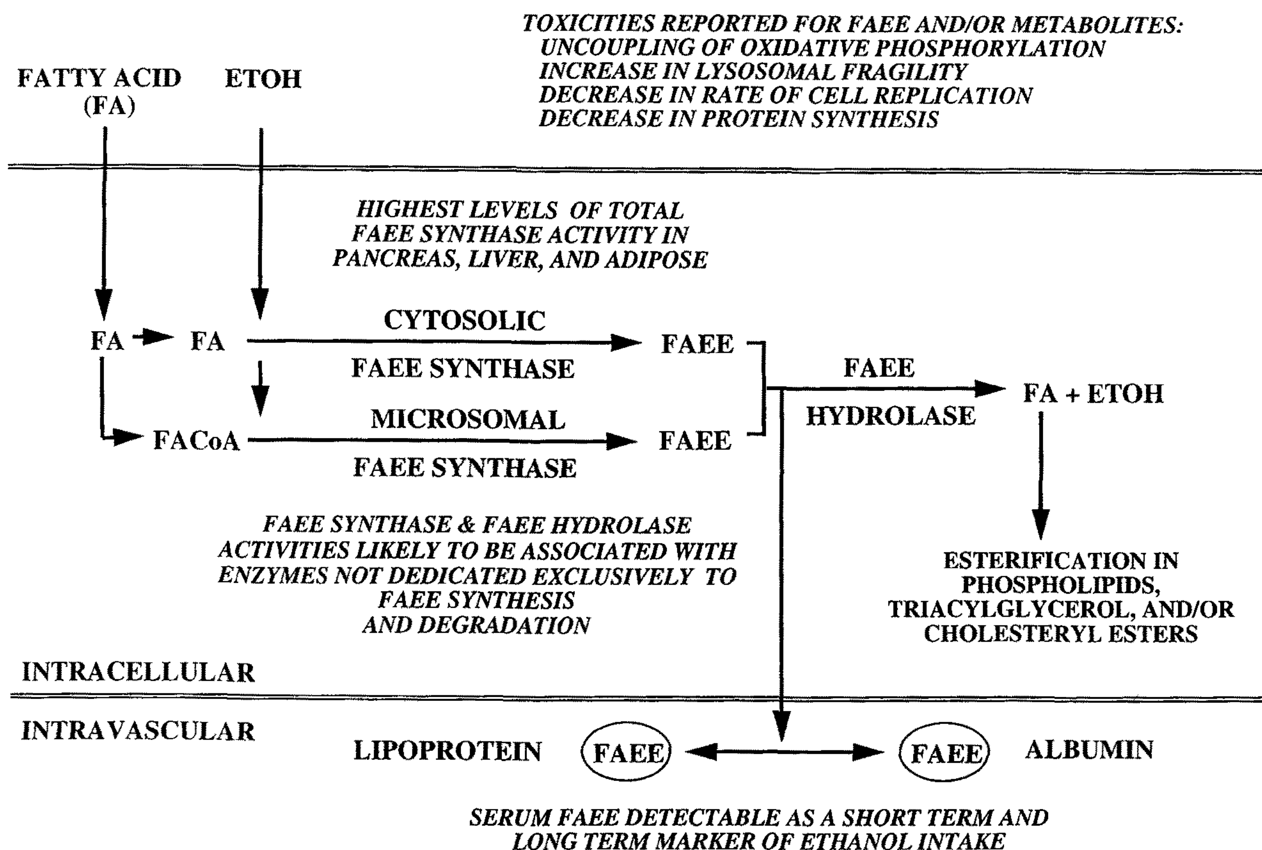

FIG. 1. A working hypothesis for the synthesis and degradation of fatty acid ethyl esters. FA, fatty acid; FACoA, fatty acyl-CoA; FAEE, fatty acid ethyl esters; ETOH, ethanol. Reprinted from *Addiction Biology*, (1998) *3*, 5–14. CARFAX Publishing Ltd., Abingdon, Oxfordshire, OX14 3UE, United Kingdom.

the serum FAEE concentration rises, the percentage of FAEE associated with lipoproteins increases and correspondingly the percentage associated with albumin decreases (25).

FAEE may be clinically important, independent of whether FAEE induce cytotoxicity, because they can serve as a marker for ethanol intake. We performed a study to determine the clinical utility of FAEE in the blood as a short-term confirmatory marker for ethanol intake and as a long-term marker for ethanol intake after ethanol is no longer detectable (26). To isolate FAEE from plasma for quantitation by gas chromatrography–mass spectrometry in these clinical studies, we developed a two-step method using solid-phase extraction with a recovery of 70 ± 3%, using ethyl oleate as a recovery marker (27).

The design for the study was a controlled clinical trial with seven healthy subjects. The subjects ingested a known amount of ethanol at a fixed rate. The concentration of FAEE in the blood after ethanol intake was determined for up to 24 h. FAEE disappearance from the blood followed a decay curve which initially resembled the decay curve for blood ethanol. However, because of a very slow secondary elimination phase, the FAEE persisted in the blood for at least 24 h after ethanol intake was completed. Also included in this report was a blinded comparison involving 48 samples that were either positive, negative, or equivocal for blood ethanol. All 20 samples positive for ethanol were positive for ethyl esters; 7 of 7 samples equivocal for ethanol and classified as negative because the amount was too low for accurate quantitation were positive for ethyl esters; and 21 of 21 samples negative for ethanol were negative for ethyl esters. These data allowed us to conclude that FAEE in the blood can serve as an excellent short-term confirmatory test for ethanol intake as well as a long-term marker of ethanol ingestion.

A summary of many of the major observations in the field is shown in Figure 1 and described in two recent reviews (28,29). The last several years have seen rapid growth of our understanding of FAEE synthesis and degradation, FAEE-induced organ damage, and the monitoring of ethanol intake with serum FAEE measurements. The years ahead could bring a mechanistic explanation for FAEE-induced cell injury and a robust clinical assay for detecting ethanol intake.

The Effects of Cigarette Smoking on the Metabolism of Essential Fatty Acids

R. Pawlosky[a,*], J. Hibbeln[b], B. Wegher[b], N. Sebring[c], and N. Salem Jr.[b]

[a]U.S. Department of Agriculture, Human Nutrition Research Center, Beltsville, Maryland, [b]National Institute on Alcoholism and Alcohol Abuse, National Institutes of Health (NIH), Rockville, Maryland, and [c]NIH Clinical Center, Bethesda, Maryland

Free radicals generated in cigarette smoke are known to deplete antioxidants and may result in increased lipid peroxidation which leads to decreased concentrations of long chain polyunsaturated fatty acids (LC-PUFA). The effect of smoking on the conversion of 18-carbon essential fatty acids to LC-PUFA has never been studied yet there is evidence that smoking alters plasma fatty acids. A stable isotope gas chromatography–mass spectrometry (GC–MS) method was used to investigate the metabolism of d_5-18:2n-6 to d_5-20:4n-6 and d_5-18:3n-3 to d_5-22:6n-3 in the plasma of smokers (n = 10) and controls (n = 10) maintained on a controlled diet. The isotopic enrichments of the plasma fatty acids pools, d_5-18:2n-6, d_5-20:3n-6, and d_5-20:4n-6, from controls and smokers were compared over 168 h. A multiple compartment model of the essential fatty acid kinetics was used to predict the percent conversion of d_5-18:2n-6 to d_5-20:3n-6 and d_5-20:3n-6 to d_5-20:4n-6 in both smokers and controls (Fig. 1). In addition, sensitive and specific GC–MS procedures were used to determine the concentration of the 4-hydroxyalkenals and 8-isoprostane-F2-α in the plasma of subjects.

METHODS

Ten subjects (five female and five male) who smoked between one and two packs of cigarettes per day and 10 volunteers (five male and five female) were placed on a controlled diet for 3 wk. The diet was low in LC-PUFA in that no fish was taken and only lean cuts of beef were eaten. In addition the primary vegetable oil used was olive oil. Beginning the third week, subjects were given a 1-g oral dose of d_5-18:2n-6 with their breakfast. Blood was collected at 0, 8, 24, 48, 72, 96, and 168 h subsequent to dosing, and the plasma was extracted and analyzed for the fatty acids and the labeled compounds by flame-ionization detector and GC–MS (1), respectively. Plasma from both groups was also subjected to analysis for 4-hydroxyalkenals and 8-isoprostane PGF2-α using appropriate derivatization procedures and GC–MS techniques (2).

The results demonstrated that the rates of disappearance of the labeled precursors from the blood were similar in both groups. Smokers had a highly significant ($P < 0.004$) increase

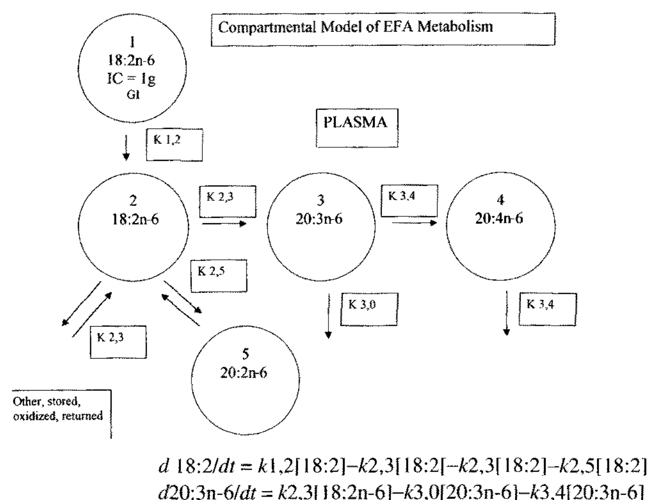

FIG. 1. Compartmental model of essential fatty acid metabolism.

(150%) in the isotopic enrichment of plasma 20:3n-6 compared to controls; however, there was no difference in the plasma pool enrichments of 20:4n-6 between the two groups. As a result, there appeared to be a 37% decrease in the conversion of 20:3n-6 to 20:4n-6. The model assessment of the essential fatty acid kinetics predicted a nearly twofold increase in the conversion of 18:2n-6 to 20:3n-6 in smokers than controls. Lipid peroxidation determinations demonstrated that there was a significantly greater concentration of 8-isoprostane-F2-α ($P < 0.001$) in the plasma of the smokers (224 ± 61 pmol/L) compared to controls (117 ± 23) and 4-hydroxynonenal ($P < 0.02$). This study showed that that cigarette smoking, which causes an oxidation in lipids, also inhibits the production of PUFA through some as yet unknown mechanism.

Impairment of Antioxidant Defense Mechanisms in Elderly Women Without Increase in Oxidative Stress Markers: "A Weak Equilibrium"

J.P. Cristol[a], M. Abderrazick[b], F. Favier[b,*], F. Michel[a], J. Castel[a], C. Leger[a], and B. Descomps[a]

[a]Biochemistry A Laboratory, University Lapeyronie Hospital,
and [b]INSERM U-500, La Colombière Hospital, Montpellier, Montpellier Cedex 5, France

The free radical theory of aging suggests that progressive defects in protection against free radicals allow tissue damage to occur. Concordant data have been observed in cell cultures or in animal models of aging. However, previous findings on antioxidant levels in human blood are somewhat conflicting according to the inclusion criteria (age, intercurrent diseases, habitus).

Oxidative metabolism was investigated in 198 elderly healthy women more than 75 yr old (81.6 ± 3.7; 75–99) living at home. Oxidative stress was evaluated by determining: the end product of lipid peroxidation, malondialdehyde (TBARS), and plasma and red blood cell (RBC) lipid content in polyunsaturated fatty acids (PUFA); nonenzymatic antioxidant system: plasma and RBC α-tocopherol (pl Vit. E and RBC Vit. E), RBC glutathione (GSH); enzymatic antioxidant: RBC superoxide dismutase (SOD) and plasma glutathione peroxidase (GPx); and trace elements (copper, zinc, selenium). Nutritional status was monitored by body mass index, caloric intake, protein and lipid markers of malnutrition (albumin, prealbumin, retinol-binding protein, cholesterol, and triglycerides). Results were compared to a control group of 50 healthy young women (age range 20–45 yr).

Despite reduced caloric intake (average 1582 kcal, range 697–3352), elderly women did not have any clinical (body mass index: 25 kg/m^2) or biological criteria of malnutrition: albumin (43.9 ± 3.4 vs. 40.5 ± 3.1 g/L; $P < 0.001$), prealbumin (0.34 ± 0.17 vs. 0.29 ± 0.1 g/L; $P < 0.01$), retinol-binding protein (44.8 ± 10 vs. 43.7 ± 11 mg/L), cholesterol (6.13 ± 1.1 vs. 5.12 ± 0.95 mmol/L; $P < 0.001$), and triglycerides (1.18 ± 0.56 vs. 0.99 ± 0.45 mmol/L) were similar or increased in elderly vs. young women, respectively. When compared to healthy volunteers, SOD activity (1.16 ± 0.23 vs. 1.28 ± 0.25 U/mg Hb, $P < 0.01$) and RBC GSH (4.32 ± 1.10 vs. 4.69 ± 1.06 nmol/mg Hb, $P < 0.05$) were significantly decreased, whereas pl Vit. E, RBC Vit. E, and GPx remained unchanged; copper (1.17 ± 0.21 vs. 1.31 ± 0.38 mg/L; $P < 0.001$) and zinc levels (0.86 ± 0.16 vs. 0.94 ± 0.16 mg/L; $P < 0.01$) were decreased; by contrast selenium levels were unaffected (75 ± 22 vs. 80 ± 17 µg/L). Despite these impairments in antioxidant defense mechanisms, we did not observe any increase in TBARS level (1.26 ± 0.36 vs. 1.34 ± 0.37 mmol/L) or a decrease in PUFA content in plasma and RBC phospholipids.

In healthy, well-nourished elderly populations, the impairment in antioxidant system did not result in an oxidative injury but in a precarious balance. This weak equilibrium could result in an increased susceptibility to reactive oxygen species and could be an underlying event for age-related diseases.

A High Linoleic Acid Diet Increases Oxidative Stress *in Vivo* and Affects Nitric Oxide Metabolism in Humans

A.M. Turpeinen[a,*], S. Basu[b], and M. Mutanen[a]

[a]Department of Applied Chemistry and Microbiology (Nutrition), University of Helsinki, Helsinki, Finland, and [b]Department of Geriatrics, Uppsala University, Uppsala, Sweden

Oxidative stress is considered to be involved in the initial stages of atherosclerosis. A hypothesis based on *in vitro* findings suggests that polyunsaturated fatty acids are a potential source of oxidative stress in humans (1–3). Oxidation products, in turn, may have an inhibitory effect on NO production (4,5) and thus on endothelium-dependent vasodilation. To study whether high-linoleic acid (LA) diets cause oxidative stress *in vivo* in a way that affects endothelial function, we measured the urinary excretion of 8-iso-prostaglandin $F_{2\alpha}$ (8-iso-$PGF_{2\alpha}$) and urinary NO metabolites as well as the plasma levels of intercellular adhesion molecule (ICAM)-1 from healthy subjects participating a controlled dietary intervention with either high-LA or high- oleic acid (OA) diets.

Subjects. Thirty-eight healthy volunteers (20 women,18 men; mean 26.6 yr) were selected from university students and employees. Exclusion criteria were serum cholesterol > 7.0 mmol/L, hypertension, anemia, glycosuria, and proteinuria. Furthermore, 13 control subjects were selected for the study. They had their habitual diets throughout the study but gave the same samples as the participating subjects.

The experiment lasted 8 wk. During the first 4 wk the subjects were given butter and advised to use other foods rich in dairy fat. For the second 4 wk 19 subjects were given a high-LA diet and 19 subjects a high-OA diet in a controlled manner. Ninety percent of daily energy intake was provided. The two diets were designed to contain similar proportions of energy from fats, carbohydrates, and proteins, similar proportions of saturated fatty acids, and similar amounts of cholesterol. They differed only in their proportions of LA and OA. At the end of each diet period the subjects gave two blood samples and collected five 24-h urine samples.

Methods. The urinary excretion of 8-iso-$PGF_{2\alpha}$ was analyzed using a newly developed radioimmunoassay (6). Concentrations of urinary NO metabolites and soluble ICAM-1 (sICAM-1) in plasma were measured with respective immunoassays (Cayman Co., Ann Arbor, MI, and R&D Systems, Minneapolis, MN).

Results. The LA diet significantly increased the excretion of 8-iso-$PGF_{2\alpha}$ (from 1.7 to 2.4 ng/μmol creatinine, $P = 0.04$) and decreased levels of urinary NO metabolites (270 vs. 166 μg/μmol creatinine, $P = 0.03$) (Table 1). No significant changes were found after the OA diet. In the control group the excretion of nitrate slightly increased ($P = 0.05$) during the study. The plasma concentration of sICAM-1 and

α-tocopherol stayed unaltered both during the dietary treatments and in the control group.

Discussion. The possibility raised by *in vitro* experiments that a high intake of LA would increase oxidative stress in the body is supported by the results of our strictly controlled human experiment: urinary excretion of 8-oxo-$PGF_{2\alpha}$ was significantly increased in these healthy subjects although their intake and plasma levels of antioxidants were within recommendations. Our results also indicate that both the synthesis of F_2-isoprostanes and NO may be modulated by dietary fatty acid composition. Whether the decrease in urinary NO metabolites in the present study was due to an increase in reactive oxygen metabolites capable of inhibiting NO cannot be answered. Dysfunction of the endothelium is unlikely due to the short duration of the study and the health status of our subjects. This is also supported by the unchanged sICAM levels. Increased levels of circulating ICAM-1 have been found in several inflammatory diseases involving leucocyte activation (7).

Although endothelial dysfunction after this short period is unlikely, even a slight decrease in NO for a longer period may be of consequence to human health.

Vitamin E Inhibition of $O_2^{\bullet -}$ Production in the Promonocyte Cell Line THP-1 Is Essentially Due to *RRR*-δ-Tocopherol

Laurence Brillant, Claude Louis Léger*, and Bernard Descomps

Laboratoire de Biologie et Biochimie des Lipides, UPRES-EA 2033 Institut de Biologie, Université Montpellier I, 34060 Montpellier, France

According to the oxidative theory of atherosclerosis, vitamin E—a potent peroxyl radical scavenger—prevents oxidation of low-density lipoprotein (LDL) which possibly explains the decrease in the risk of cardiovascular disease reported by epidemiological studies and nutritional intervention. Vitamin E also mediates cell actions. In particular, vitamin E decreases monocyte $O_2^{\bullet -}$ production that is involved in LDL oxidation. We previously found that α-tocopherol (α-Toco)-containing LDL (the main circulating form of vitamin E) decreases monocyte $O_2^{\bullet -}$ production by a cell-mediated action in a manner dependent on the LDL α-Toco content. In addition, we recently established that α-Toco impairs the assembly of the NADPH oxidase complex through cell events involving a decrease in protein kinase C (PKC)-mediated phosphorylation of $p47^{phox}$. We also showed that in monocytes vitamin E is able to decrease the membrane activity but not the membrane translocation of PKC.

We already know that antioxidant properties of vitamin E are not bound to the molecular stereostructure. Because of cell event involvement in the decrease of the monocyte $O_2^{\bullet -}$ production, we suspected that this phenomenon was stereospecifically related to the molecular structure of vitamin E. It is the reason why we decided to evaluate the inhibition potency of either a mixture of the different forms or the different forms separately of *RRR*-stereoisomers, and to more specifically compare *RRR*-α-Toco and *RRR*-δ-Toco to all-*rac*-α-Toco and all-*rac*-δ-Toco, respectively.

To do so, we chose to use the THP-1 promonocyte cell line after a 72 h differentiation through the 10^{-6} M retinoic acid, 10^{-7} M 1,25-di-OH-calciferol, and 100 U/mL interferon γ treatment. Once differentiated, cells were pre-incubated in the presence of the molecule(s) to be tested at the concentration of 20 mg/L (a physiological concentration) for 24, 48, or 72 h. They were then activated for 90 min in the presence of 0.1 μM phorbol myristate acetate. All these operations were carried out at 37°C. Lucigenin-enhanced bioluminescence was finally assessed by means of an LKB Wallac 1251 luminometer. The luminescence signal was counted for 10 s every 20 s. Results corresponded to the maximal signal value recorded with the tested molecules after a 90-min incubation in the presence of phorbol myristate acetate and expressed as percentage of the value obtained without tested molecules (but with hydrogenated soy oil as vehicle). It was verified that superoxide dismutase was able to completely depress the luminescence signal and that the tested molecules were unable to diminish the signal in a noncellular system represented by the enzyme–substrate mixture xanthine oxidase/xanthine. Measures were always carried out at least in triplicate, each incubation time on separate cell preparations.

We found that the mixture of *RRR*-α-Toco, *RRR*-β-Toco, *RRR*-γ-Toco, and *RRR*-δ-Toco (Covi-ox T-70 from Henkel, 12/2/60/21 on a weight basis, determined by high-performance liquid chromatography) depressed the THP-1 $O_2^{\bullet -}$ production during the incubation time period in a time-dependent manner, with a 54% inhibition after 72 h. *RRR*-δ-Toco was the most efficient (≈80% inhibition), whereas *RRR*-α-Toco unexpectedly had no effect. We established that *RRR*-δ-Toco had a higher inhibition potency than the all-*rac*-δ-Toco after 24-h incubation (46 vs. 17%) but not after 72-h incubation (73 vs. 72%). On the contrary, all-*rac*-α-Toco was found without effect as was *RRR*-α-Toco.

This suggests that an initial recognition step takes place in the NADPH oxidase inhibition process in these cells, involving at least one asymmetric center (possibly the C2 position). This is in accordance with the vitamin E cell transporter-receptor hypothesis. However, we totally ignore if this is a membrane or cytosolic event. Given our recent findings regarding the vitamin E inhibition of $O_2^{\bullet -}$ production in monocytes, it would be interesting first to confirm the general and physiological significance of this phenomenon and then to examine the respective effect of stereoisomers on the membrane-PKC activity and on the cytosolic-phosphorylation of $p47^{phox}$

Lipids 34, S293 (1999).

Stimulation of Platelet Aggregation in Response to Arachidonic Acid Hydroperoxide *via* Phospholipase Activation

Catherine Calzada*, Evelyne Véricel, Bérengère Mitel, and Michel Lagarde

INSERM U 352 (affiliated to CNRS), Biochimie et Pharmacologie, INSA-Lyon, 69621 Villeurbanne, France

Considerable interest exists concerning the role played by lipid peroxides in cell damage and in the development of cardiovascular diseases. Indeed, an exacerbated platelet activation, as observed in aging, was associated with an increased overall lipid peroxidation and an increased peroxidation of arachidonic acid (AA). The platelet antioxidant defenses were altered, namely, the vitamin E level and the activity of glutathione-peroxidase (GSH-Px) (1), a key enzyme reducing lipid hydroperoxides. A transient accumulation of the 12-lipoxygenase-derived product of AA, 12-hydroperoxy-eicosatetraenoic acid (12-HPETE), resulting from the decreased GSH-Px activity, is likely to activate the dioxygenases and therefore to lead to platelet hyperactivation. Considering that the biological functions of lipid hydroperoxides are not well-defined, it is of interest to determine whether low concentrations of 12-HPETE may induce platelet aggregation. Human platelets were incubated in the presence or absence of 12-HPETE for 1 min at 37°C. A subthreshold concentration (STC) of collagen—defined as the highest concentration of collagen that did not induce any platelet aggregation—was then added to the platelet suspension for another minute. Although 12-HPETE alone had no effect on platelet aggregation, the addition of nanomolar concentrations of 12-HPETE (from 10 to 100 nM) together with an STC of collagen significantly induced platelet aggregation. It was closely associated with an increased formation of thromboxane B_2, the stable catabolite of thromboxane A_2. Notably the concentration of 12-HPETE required to potentiate platelet aggregation was 50-fold lower than the one required to prime platelet aggregation in response to AA *via* an activation of the cyclo-oxygenase (2). As the activation of platelets by collagen involves the release of AA from platelet phospholipids, the concentration of unesterified AA was determined by gas chromatography. The addition of 12-HPETE to platelets co-incubated with an STC of collagen resulted in a threefold increase in the amount of unesterified AA. As it is known that the cytosolic phospholipase A_2 ($cPLA_2$) of 85 kDa is involved in the release of AA from membrane phospholipids, platelets were preincubated with a potent and selective inhibitor of the $cPLA_2$, arachidonoyl trifluoromethyl ketone ($AACOCF_3$). $AACOCF_3$ prevented the increase in the amount of unesterified AA induced by 12-HPETE and an STC of collagen, suggesting the involvement of the $cPLA_2$. In order to determine the origin of released AA, the molecular species of platelet phospholipid subclasses were measured by reversed-phase high-performance liquid chromatography (HPLC) (3). After lipid extraction, phospholipid classes were separated by thin-layer chromatography (TLC), hydrolyzed by phospholipase C, and corresponding diradylglycerols were derivatized with 3,5-dinitrobenzoyl chloride. Phospholipid subclasses were separated by TLC, and various molecular species were quantified by HPLC with ultraviolet detection at 240 nm. Among the arachidonoyl-containing molecular species of 1,2-diacyl-glycerophosphocholine (GPC), 16:0/AA and 18:0/AA species decreased in platelets incubated with 12-HPETE whereas 18:1/AA did not change significantly. Concerning the molecular species of the 1-alkyl-2-acyl-GPC subclass, 18:1/AA, 16:0/AA, and 18:0/AA tended to decrease in response to 12-HPETE. On the contrary, no difference was observed between control platelets and 12-HPETE-treated platelets in the 1,2-diacyl-glycerophosphoethanolamine pool.

In conclusion, physiologically relevant concentrations of 12-HPETE stimulate the aggregation of platelets co-incubated with nonaggregating concentrations of collagen which could be mediated *via* an activation of the $cPLA_2$. These results enlighten the physiological importance of 12-HPETE in controlling the unesterified AA level and therefore the formation of eicosanoids.

New Products from the Agri-Food Industry: The Return of n-3 Fatty Acids into the Food Supply

Artemis P. Simopoulos*

The Center for Genetics, Nutrition and Health, Washington, DC 20009

ABSTRACT: The meat from animals and fish in the wild, chicken eggs produced under complete natural conditions, and wild plants contain higher amounts of n-3 fatty acids compared to domesticated or cultivated ones. The composition of meats, fish, and eggs is dependent on animal feed. Fish-meal, flax, and n-3 from algae in animal feeds increase the n-3 fatty acid content of egg yolks and lead to the availability of n-3 fatty acid-enriched eggs in the marketplace. Research is ongoing for the production of n-3 fatty acid-enriched products from poultry, beef, lamb, pork, milk, bakery products, etc. In the case of n-3 fatty acid-enriched eggs, the egg under complete natural conditions (Greek or Ampelistra egg) can serve as a guide for proper composition. Otherwise, the amount of n-3 fatty acids is determined by the organoleptic properties of the products. It is essential in the process of returning the n-3 fatty acids into the food supply that the balance of n-6/n-3 fatty acids in the diet that existed during evolution is maintained. Clinical investigations confirm the importance of n-3 fatty acids for normal function during growth and development and in the modulation of chronic diseases. The availability of n-3 fatty acid-enriched products should lead to improvements in the food supply. Pregnant and lactating women and infants should benefit since their diet is deficient in n-3 fatty acids, especially for the vegetarians among them. Studies with n-3-enriched eggs lower cholesterol levels, platelet aggregation, and blood pressure. Since cardiovascular disease, hypertension, and autoimmune, allergic, and neurological disorders appear to respond to n-3 fatty acid supplementation, a diet balanced in n-3 and n-6 fatty acids consistent with the diet during human evolution should decrease or delay their manifestation.

The health of the individual and the population in general is the result of interactions between genetics and the environment. Nutrition is an environmental factor of major importance. Furthermore, each disease has medical and cultural components. Western culture has brought about many changes in the nutritional environment of human beings. Major changes have taken place since the agricultural revolution 10,000 yr ago and even more since the industrial revolution 200 yr ago (Fig. 1) (1). Agribusiness and the processed food industry have made it possible to increase the production and shelf life of many products, but at the same time brought about a change in the content and nutrient structure of many foods, i.e., (i) whereas human milk contains arachidonic acid (AA), eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), infant formula is devoid of these fatty acids in the United States; and (ii) the hydrogenation process led to structural changes in the double bonds of fatty acid molecules from *cis* to *trans* resulting in an increase in *trans* fatty acids found in margarine, frying oils, salad dressings, and bakery products. The increase in *trans* fatty acids in the food supply has raised concerns about their role in increasing the risk of coronary heart disease and in interfering with the desaturation and elongation of essential fatty acids (EFA) 18:2n-6 and 18:3n-3 (2). Industry is now taking measures to reduce the content of *trans* fatty acids in margarine. In the past decade, science has provided new information on the importance of the balance between n-3 and n-6 fatty acids in health and disease and in growth and development (3,4), which must be taken into consideration for a healthful food supply.

Paleolithic diet. While all these nutritional changes have taken place, our genetic profile has not changed significantly

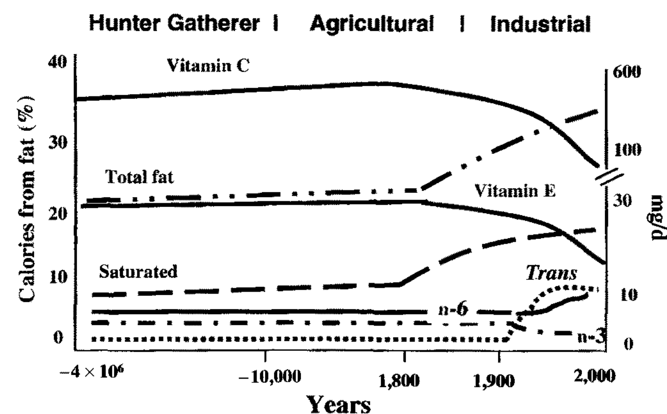

FIG. 1. Hypothetical scheme of fat, fatty acid (n-3, n-6, *trans* and total) intake (as percentage of calories from fat) and intake of vitamins E and C (mg/d). Data were extrapolated from cross-sectional analyses of contemporary hunter–gatherer populations and from longitudinal observations and their putative changes during the preceding 100 yr (Ref. 1).

EPA (n-3)	0.39	
DTA (n-6)	0.12	
DPA (n-3)	0.42	
DHA (n-3)	0.27	

[a]Data from Eaton *et al.* (6). LA, linoleic acid; LNA, linolenic acid; AA, arachidonic acid; EPA, eicosapentaenoic acid; DPA, docosapentaenoic acid; DHA, docosahexaenoic acid; DTA, docosatetraenoic acid.

over the past 40,000 yr. The Paleolithic diet is characterized by lower fat and lower saturated fat intake than Western diets; a balanced intake of n-6 and n-3 EFA; small amounts of *trans* fatty acids, contributing less than 2% of dietary energy; lots of green leafy vegetables and fruits providing higher levels of vitamin E and vitamin C and other antioxidants than today's diet; and higher amounts of calcium and potassium but lower sodium intake (1,5–7) (Fig. 1).

Today, the ratio of n-6/n-3 is between 10–20:1 in Western Europe and the United States, whereas during evolution it was 1:1 or even less (Tables 1 and 2) (1,3,5,6). Our current diet (Western diet) is characterized by an increase in total fat, saturated fat, *trans* fatty acids, and the n-6 EFA; a decrease in the n-3 EFA, the antioxidant vitamins C and E, and calcium and potassium; and an increase in sodium intake (1–8) (Fig. 1).

The change in the EFA balance came about because of the indiscriminate recommendation to substitute vegetable oils, i.e., corn oil, safflower, sunflower, and cottonseed oils, for saturated fat since 1960. These vegetable oils are very high in n-6 fatty acids and very low in n-3 fatty acids. Corn oil has a ratio of n-6/n-3 of 60:1 and safflower oil 77:1. In addition, because farm animals are grain-fed, their carcasses contain small amounts of n-3 fatty acids, but they are high in saturated fats and n-6 fatty acids unlike the composition of meat from animals in the wild (9). Eggs and poultry in agriculture, fish in aquaculture, and cultivated plants contain lower amounts of n-3 fatty acids than eggs from free-ranging chickens (Table 3) (10,11), fish in the wild (12), and wild plants (i.e., purslane) (Table 4) (13,14).

Information from archeological findings and studies from modern day hunter–gatherers suggest that the Paleolithic diet is the diet we evolved on and for which our genetic profile was programmed.

The traditional Greek diet. In addition to the information from studies on the Paleolithic diet, the studies on the traditional diet of Greece prior to 1960, and specifically Crete, provide further evidence for the higher content of n-3 fatty acids in eggs, meat, milk, cheese, and edible wild plants.

[a]Adapted from Reference 13.

Table 5 compares the fatty acid content of various U.S. and Greek cheeses (15). AA, EPA, and DHA are found in the Greek but not in the American cheeses. Since the major source of cooking oil in Greece is olive oil, providing only 6–10% linoleic acid (LA), the n-6 content of the diet is easily balanced with the high fish intake. Furthermore, the n-3 fatty acids were present in each meal, providing a good balance of the n-6 and n-3 EFA in the diet of Crete (15).

The traditional Greek diet (the diet prior to 1960) and, for that matter, the diet of the people in Crete, is characterized by a high monounsaturated fatty acid intake (olive oil), low saturated fat intake, balanced n-6 and n-3 fatty acids, less than 2% *trans* fatty acids of total energy intake, and lots of green leafy vegetables and fruits. The Greek-Crete diet is closer to the Paleolithic diet than the current Western diets (16).

The people of Crete participated in the Seven Countries Study and were shown to have lower rates of heart disease and cancer, including higher longevity, than the populations of Japan, Yugoslavia, Italy, Holland, Finland, and the United States. The people of Crete had the highest amount of 18:3n-3 (α-linolenic acid, LNA) and the lowest amount of 18:2n-6 (LA) in their serum cholesteryl esters than the other six populations (17). Closer examination of the diet of Crete, or the traditional Greek diet, showed that the n-3 fatty acids were present in every meal the people ate, either as LNA (18:3n-3) or EPA (20:5n-3) and DHA (22:6n-3) or all three. The n-3 fatty acids were present in wild plants and other green leafy vegetables, and in meat and fish, eggs, milk, cheese, and all products made from milk and eggs, such as noodles and cookies. Because the people of Crete did not use, in cooking, vegetable oils such as corn oil, safflower, sunflower, or cottonseed oils, all rich in n-6 fatty acids, their n-6/n-3 ratio was just over 1, whereas in Western diets this ratio is usually over 10–20:1 (15).

The importance of a balanced ratio of n-6/n-3, a lower saturated fatty acid intake and lower overall fat (30–33%), along with higher intakes of fruits and vegetables leading to increases in vitamins E and C, was tested in the Lyon Heart study. The Lyon study, based on a modified Crete diet, confirmed the importance of n-3 fatty acids from marine and terrestrial sources, and vitamin E and vitamin C, in the secondary prevention of coronary heart disease (18,19).

In Western diets, the current consumption of total fat, saturated fat, n-6 fatty acids, and *trans* fatty acids is not consistent with the evolutionary aspects of diet. Because health as

well as disease are the result of the interaction of genes and the environment—in this case, genes and nutrients—the presently constituted Western food supply is not appropriate for health, particularly for individuals genetically predisposed to chronic diseases such as coronary heart disease, hypertension, diabetes, arthritis, and possibly cancer. The time has come to return the n-3 fatty acids into the food supply. Human beings need both classes of fatty acids, the n-6 and n-3, and the 18 carbon (LNA) and the 20–22 carbon atoms (EPA and DHA).

The return of n-3 fatty acids into the food supply. There are now a number of products in the market that are enriched with n-3 fatty acids. They fall into the following categories:

(i) Oils. Oils rich in LNA, such as canola, flaxseed, perilla, and soybean. In addition, avoidance of vegetable oils rich in n-6 and the use of oils lower in LA such as olive oil, canola oil, and new vegetable oils rich in monounsaturated oils help bring about an improvement in the LA/LNA ratio (16).

(ii) Bakery products. Flaxseed flour and encapsulated fish oils (20) are used in bakery products, including breads.

(iii) Eggs. Changes in chicken feeds led to enrichment of n-3 fatty acids in eggs. n-3-Enriched eggs are found in many markets around the world. The chicken feeds are enriched with fish-meal, flaxseed, or DHA from algae (10,11,21,22). These eggs have a lower n-6/n-3 ratio and contain significant amounts of AA and DHA and are modeled after the "natural egg" (i.e., the egg from the Ampelistra farm in Greece listed in Table 3 as the Greek egg) which is the egg obtained under completely natural conditions (10,11).

(iv) Infant formula. Human milk contains AA, DHA and EPA, whereas infant formula based on cow milk does not. In Europe and the Far East, infant formula is now enriched with AA and DHA from various sources (23,24). However, in the United States, infant formula does not contain AA and DHA, yet.

(v) Milk. Research shows promising results in increasing DHA in cow milk (25).

(vi) Mayonnaises, margarines, and salad dressings. Hydrogenated fish oils and canola oils are used in the preparation of mayonnaise, margarines, and salad dressings (20).

(vii) Meat and poultry products. Research on how best to titrate the amount of fish oils in animal feeds without affecting stability and organoleptic properties is advancing in many parts of the world. Poultry, cattle, and pigs are being studied, and the consumption of n-3-enriched meats is not far in the future (21,26,27).

(viii) Farmed fish. There is a need to further improve the fatty acid composition of fish in aquaculture (12).

Enriched processed foods are a feasible way to increase EPA and DHA intake and bring about beneficial changes (28). Consumption of the new products modulates tissue fatty acid composition; decreases triglycerides and platelet aggregation; and reduces low density lipoprotein particle density, making it less atherogenic (22).

Issues. Research advances are solving a major problem that is the deficiency of n-3 fatty acids in Western diets. Yet at the same time a number of questions need to be answered. How much n-3 fatty acids should be in each serving? How much LNA and how much EPA, docosapentaenoic acid (DPA, 22:5n-3) and DHA? What should be the ratio of total n-6/n-3, how much LA/LNA, and what should be the proportions of the n-3 fatty acids EPA, DPA, and DHA? What are the best models—animals in the wild, fish in the wild, mother's milk from women on a paleolithic diet or a Greek/Mediterranean diet?

What can we learn from the composition of edible wild plants? We have shown that edible wild plants contain more LNA than LA. But, Guil *et al.* (29) showed that many of the edible wild plants along the Mediterranean contain AA, EPA, DPA, and DHA (Table 6). Table 6 shows that certain plants are higher in AA than EPA, DPA and DHA. The findings of Guil *et al.* are provocative and important. Although their findings need to be confirmed, they point to a need to have precise information on the fatty acid composition of traditional diets. Obviously, there is a need to investigate further edible wild plants in order to determine the terrestrial and marine sources of the 20- to 22-carbon polyunsaturated fatty acids.

Conclusion. n-3 Fatty acids must become incorporated into foods rather than be used solely as dietary supplements, which is a quasi-pharmaceutical approach. Furthermore, the development of a variety of n-3-rich foodstuffs would allow increased dietary intakes with little change of dietary habits.

n-3 Fatty acids maintain preventive and therapeutic properties when packaged in a food other than fish. Efficient use of dietary n-3 fatty acids will require the simultaneous reduction in the food content of n-6 fatty acids and their substitution with monounsaturated oils. Dietary n-3 fats give rise to

TABLE 6

[a]Data from Reference 29. See Table 1 for abbreviations.

higher tissue levels of EPA when the "background" diet is low in n-6 fats. Compared to n-6 fatty acids, olive oil increases the incorporation of n-3 fatty acids into tissues.

In the past, industry focused on improvements in food production and processing to increase shelf life of the products, whereas now and in the future the focus will be on nutritional quality in product development (30,31). This will necessitate the development of research for the nutritional evaluation of the various food products and educational programs for professionals and the public (30). The definition of food safety will have to expand in order to include nutrient structural changes and food composition (31). The dawn of the twenty-first century will enhance the scientific base for product development and expand collaboration among agricultural, nutritional, and medical scientists. This should bring about a greater involvement of nutritionists and dieticians in industrial research and development to respond to an ever-increasing consumer interest in the health attributes of foods.

n-3 Fatty Acids and Coronary Heart Disease—The Urgent Need of Clinical Trials

Erik Berg Schmidt[a] and Jørn Dyerberg[b,*]

[a]Department of Medicine, Hjørring/Brønderslev Hospital, and [b]Medi-Lab a.s., DK-1001 Copenhagen K, Denmark

Before 1970 there were only scattered reports that dietary n-3 polyunsaturated fatty acids (n-3 PUFA) might protect against coronary heart disease (CHD). However, our studies beginning in 1970 in traditionally living Greenland Eskimos with an extremely high intake of n-3 PUFA drew interest to the potential role for prevention of CHD of n-3 PUFA. Based on five expeditions to Greenland (1–4), we (Bang and Dyerberg) were able to show that this Inuit population had a remarkably low incidence of CHD, and due to their diet, an antiatherogenic lipid pattern, a strongly attenuated platelet reactivity, and favorable indices of platelet vessel–wall interaction (1–6). This made us and other scientists pursue the intriguing hypothesis that seafood, rich in n-3 PUFA, might reduce the risk of CHD.

Now, nearly 30 yr later, much more knowledge about the physiology, biochemistry, potentially preventive mechanisms of action, and other effects of n-3 PUFA has been gained. Thus, lessons from epidemiology, experimental studies, and from the effects of n-3 PUFA on established and new risk factors for CHD in humans have substantiated the existence of a beneficial effect of n-3 PUFA in the prevention and treatment of CHD (7).

In this paper we will deal with the crucial issue of clinical trials and in some detail discuss and suggest new trials and the problems associated with such studies. We will limit ourselves to studies with marine n-3 PUFA in humans and consequently not include α-linolenic acid and only discuss trials directly related to CHD.

CLINICAL TRIALS IN PATIENTS WITH CHD

Stable angina pectoris. Saynor *et al.* (8) in 1984 reported an astonishing effect of low doses (1.8 g/d) of dietary n-3 PUFA supplementation on angina symptoms in patients with stable angina pectoris in an open trial. We were, however, unable to confirm this in a larger controlled trial (9), and other studies on small groups of patients were also negative (6).

Acute myocardial infarction. There is some experimental evidence that n-3 PUFA may be beneficial in acute myocardial ischemia and reduce myocardial infarct size (10). However, no studies have been published in patients admitted with an acute myocardial infarction, unstable angina pectoris, or other acute coronary syndromes. A recent major prospective cohort study demonstrated an inverse association between fish consumption and 30-yr risk of fatal myocardial infarction (11).

Secondary prevention after myocardial infarction (MI). Burr *et al.* (12) in the diet and reinfarction trial (DART) randomized more than 2000 men with a recent MI to various dietary changes including an increased intake of n-3 PUFA by eating fatty fish twice weekly or, alternatively, using fish oil capsules (taken by approximately 20% of the participants) for 2 yr. There was a significant 29% reduction in total mortality and deaths from CHD in those given fish advice and increasing their intake of n-3 PUFA by approximately 1 g/d. However, the number of nonfatal MI increased—nonsignificantly—in the group given fish advice. This indicates that the underlying mechanism of cardioprotection is less likely to be antithrombotic, and the authors suggested an antiarrhythmic effect of n-3 PUFA as an explanation. This study was a landmark trial and still provides the best clinical evidence for a protective role of n-3 PUFA in CHD.

In the more recent Lyon study investigating the effect of a Mediterranean type of diet in post-MI patients, there was a marked effect of dietary changes in preventing coronary deaths and coronary events (13). However, in this trial an increased intake of fish was only one of several dietary changes making it impossible to know what role the (marginally) increased intake of marine n-3 PUFA had in the outcome.

Coronary bypass surgery. In a study from Norway, 610 patients undergoing coronary bypass surgery were either supplemented with approximately 3.5 g of n-3 PUFA as fish oil capsules daily or assigned to a control group (14). The primary end point was graft patency assessed by angiography 1 yr after the bypass operation. There was a significant positive effect of fish oil on venous graft patency, but not on arterial (mammary) grafts.

Restenosis after percutaneous transluminal coronary angioplasty (PTCA). An unsatisfactorily high amount of patients treated with PTCA developed restenosis. The effect of

Lipids 34, S303–S305 (May 1999).

supplementation with n-3 PUFA in the prevention of restenosis was evaluated in several trials. The results were initially promising with significant beneficial effects reported in several randomized trials: an effect that was significant, when the data were subjected to a meta-analysis (15). However, recent larger trials set up to finally prove a beneficial effect of n-3 PUFA in these patients unfortunately failed to demonstrate this (16,17).

Cardiac transplant patients. It is not known if n-3 PUFA affect graft survival, development of coronary atherosclerosis, or prognosis in cardiac transplant recipients, but some studies showed positive biochemical effects (6).

Arrhythmias and sudden cardiac death. Animal studies (18), *in vitro* experiments (19), autopsy findings (20), and—however indirectly—diet and reinfarction trial (12) suggested an antiarrhythmic effect of n-3 PUFA. In line with this, a reduced risk for sudden cardiac death was reported in recent major case control and prospective cohort studies in fish consumers compared to those not eating fish (21,22). Furthermore, we showed (23) that n-3 PUFA beneficially influence heart rate variability, a powerful predictor of sudden cardiac death.

No effect on ventricular extrasystoles of 4 g n-3 PUFA was observed in a small cross-over study of patients with CHD (24). In a pilot study we randomized patients with previous serious ventricular arrhythmias to a supplement with 5.2 g n-3 PUFA daily or matching placebo for 16 wk (25). Those given n-3 PUFA experienced a large, but nonsignificant reduction in ventricular extrasystoles. Finally, in a larger study of healthy subjects with many extrasystoles, cod liver oil (2.4 g n-3 PUFA per day for 16 wk) had some effect on the number of ventricular extrasystoles (26).

SUGGESTIONS FOR FUTURE CLINICAL TRIALS

The area of primary prevention of CHD is an important, but difficult area to study. Prospective cohort studies seem today to be the only feasible way of studying this issue. The findings from DART in the secondary prevention of CHD need to be repeated. A study from Italy (GISSI) is currently investigating the effect of supplementation with fish oil capsules in post-MI patients, and the results are eagerly awaited.

It would be of interest to study the effect of n-3 PUFA in patients with acute coronary syndromes, not least if intravenous preparations with n-3 PUFA currently under investigation turn out to be safe.

At present there is no indication for the use of n-3 PUFA to prevent restenosis after PTCA. However, approximately two-thirds of patients are now treated with stents during PTCA, which has considerably reduced the risk of restenosis. The published studies with n-3 PUFA were all performed in the pre-stent era, and it would be worthwhile to study the effect of n-3 PUFA in stented patients.

The findings from Norway (14) in patients after bypass surgery call for further studies to prove or disprove an effect of n-3 PUFA in this setting.

One of the most promising areas to pursue may be the possible effect of n-3 PUFA on sudden cardiac death due to a protective effect against malignant arrhythmias. This may be studied in patients with implantable defibrillators, because such patients often develop serious arrhythmias, and documentation for the arrhythmias are stored on computer disks.

No matter what studies are undertaken, it is extremely important to be aware that only studies with hard end points (total mortality, mortality from CHD, mortality from cardiovascular disease, and perhaps also the number of revascularizations) are likely to have impact on the treatment modalities chosen by cardiologists. Such studies have to be randomized, controlled, and must include many patients. The studies are consequently going to be expensive, and funding is an obvious problem, due to the nonpatentability of the fish oil products.

FISH VS. FISH OIL CONCENTRATES

The message of the value of an increased intake of fish by the population was well-received by nutritional experts, in part because lean fish has a low content of saturated fat. It is also to some extent accepted by the general population, but the intake of marine n-3 PUFA is still low and below 1 g/wk in many Western countries. Several, but not all, studies showed that an intake of fish providing n-3 PUFA in this order of magnitude may offer protection against CHD (10–12,21,22,27). This is puzzling, because the many biochemical effects of n-3 PUFA in general are dose-dependent and only observed at doses well above what is obtained by this amount of fish (6).

When it comes to clinical trials, studies investigating the effects of an increased intake of fish are theoretically attractive, but with some important inborn methodological problems. Replacing other food sources (rich in saturated fat) with fish should in principle be better than adding fish oil supplements on top of the usual diet. However, only low amounts of n-3 PUFA are provided by this approach, and although some support from epidemiology exists, other well-known effects supposed to be beneficial in the reduction of CHD can only be obtained by higher doses of n-3 PUFA. Also, blinding of study participants in clinical trials is not possible. Practically, it is much easier to investigate the effect of a medication (fish oil supplements) than to provide a certain amount of fish regularly for an extended period of time. Another problem is that some people dislike seafood.

Despite these reservations, we still believe that clinical trials with an increased intake of fish in the diet are of major relevance and interest. However, studies with higher doses of fish oil concentrates are equally warranted, and in evaluation of the use of fish oil concentrates in the prevention and/or treatment of CHD the same standards of evidence for fish oil supplements should be required as for other medications.

CONCLUSIONS

Data from epidemiological studies, animal experiments, and clinical trials of biochemical effects in humans lend support for

a beneficial role of n-3 PUFA in CHD. So far only a few trials of n-3 PUFA with clinical endpoints have been published. Further clinical studies in patients with acute myocardial ischemia, post-MI patients, patients undergoing coronary bypass surgery or stenting during PTCA, and patients with arrhythmias should be undertaken. Only results from controlled clinical trials with hard end points can establish whether n-3 PUFA reduce the risk of CHD and will have an impact on patient treatment.

Equal Antithrombotic and Triglyceride-Lowering Effectiveness of Eicosapentaenoic Acid-Rich and Docosahexaenoic Acid-Rich Fish Oil Supplements

Peter R.C. Howe[a,c], Peter M. Clifton[a], and Michael J. James[b]

[a]CSIRO Division of Human Nutrition and [b]Royal Adelaide Hospital, Adelaide, SA 5000, Australia, and [c]Department of Biomedical Science, University of Wollongong, NSW 2522, Australia

The relative proportions of eicosapentaenoic acid (EPA) and docosahexaenoic (DHA) acid in fish oil supplements vary between sources. With the awareness that certain health benefits of fish oil are attributable to effects of EPA on eicosanoid mechanisms, it is often assumed that EPA-rich oils are more beneficial than DHA-rich oils such as tuna oil, despite the recognized benefit of consuming DHA-rich fish. However, recent studies with purified EPA and DHA suggest that DHA may have a primary role in mediating some of the effects of fish oils. We have attempted to compare the relative efficacy of commercial DHA-rich and EPA-rich fish oil supplements on a range of health parameters.

In a 16-wk double-blind crossover trial, 32 middle-aged male volunteers were randomized to take eight 1 g capsules of either NuMega, a new DHA-rich tuna oil from Clover Corporation, Australia, providing 0.49 g EPA and 2.08 g DHA per day, or MaxEPA, providing 1.35 g EPA and 0.95 g DHA per day, for 6 wk. After a 4-wk washout period, they took the alternate oil for a further 6 wk. Initially and after 6 and 12 wk, we measured clinic blood pressure, 24-h ambulatory blood pressure, fasting plasma fatty acids, and lipids and platelet thromboxane production. Production of the inflammatory cytokines interleukin-1β (IL1β) and tumor necrosis factor-α (TNFα) was measured in mononuclear cells isolated from blood taken initially and after 6 wk.

Thirty subjects completed the trial. Their plasma EPA and DHA levels rose by 350 and 63%, respectively, with MaxEPA supplementation and by 140 and 130%, respectively, with NuMega. Despite these differences, the supplements had almost identical effects on platelet thromboxane production (reduced 40%) and on plasma lipid levels. Low density lipoprotein cholesterol rose 6%, but total and high density lipoprotein cholesterol were unaffected. Triglycerides fell 26% (from 1.96 to 1.45 mM) with both oils, the reductions being dependent on initial levels in each case. The overall increase of long chain n-3 fatty acids in plasma was less with NuMega (84%) than MaxEPA (138%), suggesting that, consistent with recent observations by Grimsgaard *et al.* and Hansen *et al.* (2) using highly purified EPA or DHA, DHA may be more efficacious than EPA in lowering both fasting and postprandial triglycerides. Conquer and Holub (3) and Nelson *et al.* (4) found that an EPA-free DHA supplement also lowered triglycerides but had no effect on thrombotic indices.

EPA and DHA may differentially affect mediators of inflammation, e.g., DHA appears to be more effective than EPA in inhibiting cytokine-induced expression of adhesion molecules (5,6). Fish oil supplementation also inhibits cytokine production in mononuclear cells, an effect which may be related to thromboxane inhibition (7). In our study, however, TNFα was unaffected, and IL 1β production fell only 29% on average, even though platelet thromboxane production was markedly reduced. MaxEPA appeared more effective than NuMega in suppressing IL1β (38 vs. 20%), but the difference was not significant.

Studies using typical EPA-rich oil supplements indicate that blood pressure can be lowered with an n-3 dose of ~3 g/d (8). If DHA is the antihypertensive mediator, we might have expected the supplementation with NuMega, providing >2 g/d of DHA, to be efficacious. However, there were no changes in clinic or ambulatory blood pressure with either MaxEPA or NuMega, even though our subjects were mildly hypertensive (150/91 mm Hg), suggesting that the increased intakes of EPA and DHA were insufficient to affect this cardiovascular risk factor.

In conclusion, it appears that various health parameters are differentially affected by DHA and EPA. Thus further comparative studies should be undertaken with EPA-rich and DHA-rich fish oils to determine appropriate supplementation strategies which will maximize specific health benefits.

Comparison of n-3 Polyunsaturated Fatty Acids from Vegetable Oils, Meat, and Fish in Raising Platelet Eicosapentaenoic Acid Levels in Humans

D. Li, N.J. Mann, and A.J. Sinclair*

Department of Food Science, RMIT University, Melbourne, VIC, 3001, Australia

Results from a recent observation study (1) showed that the n-3/n-6 ratio in plasma and platelet phospholipids (PL) was significantly lower in both ovolacto vegetarian and vegan groups compared with meat-eaters in the study population. Collagen- and ADP-stimulated whole blood platelet aggregation showed a significant opposite trend to both plasma and platelet PL n-3/n-6 ratios. Plasma 11-dehydro thromboxane B_2 (11-dehydro TXB_2), a stable metabolite of TXA_2, was found to be higher in ovolacto vegetarian and vegan groups compared with meat-eaters. That is, these data suggested that the vegetarians had a potentially greater thrombotic risk than the omnivore subjects. The aim of this study was to investigate whether male vegetarian subjects who consumed an increased dietary ratio of α-linolenic acid (ALA)/linoleic acid exhibit an increased n-3/n-6 polyunsaturated fatty acid (PUFA) ratio in platelet PL, plasma PL, and triacylglycerol (TAG), decreased plasma TX levels, and reduced platelet aggregability compared with their habitual diet. Seventeen healthy male vegetarian subjects aged 22–48 yr were recruited in Melbourne. During the study, all subjects maintained their habitual vegetarian diets, except a proportion of dietary fat was replaced with provided vegetable oils and oil-based margarines. All 17 subjects consumed a low n-3/n-6 ratio diet (safflower oil and safflower oil-based margarine) for 14 d, following which they consumed either a moderate n-3/n-6 ratio diet (canola oil and canola oil-based margarine) or a high n-3/n-6 ratio diet (linseed oil and linseed oil-based margarine) for 28 d. Subjects were requested to refrain from consuming fish during the 42 d of the intervention. Blood samples were collected at day 0 (baseline), day 14, and day 42. Collagen, ADP, and arachidonic acid (AA) stimulated whole blood platelet aggregation, plasma hemostatic factors, plasma lipid and lipoprotein lipids, plasma 11-dehydro TXB_2 and α-tocopherol, fatty acid composition of platelet and plasma PL, and plasma TAG were measured by standard methods.

Significant changes were seen in fatty acid profiles of platelet PL, plasma PL, and plasma TAG. Eicosapentaenoic acid (EPA) and total n-3 PUFA levels, and n-3/n-6 ratio were significantly increased, while the AA/EPA ratio decreased ($P < 0.05$), following either a canola or a linseed oil-based diet compared with a safflower oil-based diet. Docosapentaenoic acid was significantly increased following linseed oil-based diet compared with the safflower oil-based diet ($P < 0.05$). There was no significant increase in docosahexaenoic acid in these lipids. No statistically significant differences between the study diet period were observed on the various thrombotic risk factors. We compared these data with a previous study (2) in which 23 adult omnivore subjects consumed 350 g/d of lean red meat for 2 wk (EPA intake = 70 mg/d) or 133 g/d of Atlantic salmon for 2 wk (EPA intake = 847 mg/d) (2). These diets also led to significant changes in platelet EPA levels (0.5 to 0.7% on the red meat diet, $P < 0.001$, and 0.4 to 1.9% on the salmon diet, $P < 0.001$, as percentage of total platelet PL).

The results indicate that canola and linseed oils have similar effects on the fatty acid profile of platelet PL and plasma lipid. The greatest increases in n-3 PUFA occurred with linseed oil which had the highest ALA content. ALA from the vegetable oils (canola and linseed) used as a dietary fat for daily food preparation had a beneficial effect on alteration of fatty acid profiles of platelet PL and plasma lipids in vegetarian populations. Longer-term studies may be necessary to establish effects of plant source n-3 PUFA on hemostatic function in vegetarians. These data clearly show that dietary EPA alters platelet EPA levels more quickly and more effectively than *via* endogenous synthesis from dietary ALA. This study demonstrated that 70 mg/d of EPA was more effective than 3.7 g of ALA and almost as effective as 15.4 g/d of ALA in raising platelet EPA levels in short-term studies.

Intake of Small Amounts of n-3 Fatty Acids Decreases Platelet Lipid Peroxidation in Elderly People

Catherine Calzada[a], Paul Chapuy[b], Michel Lagarde[a], and Evelyne Véricel[a,*]

[a]INSERM U 352, Biochimie et Pharmacologie, INSA-Lyon, Villeurbanne, and
[b]Service de Gériatrie, Hôpital des Charpennes, Villeurbanne, France

Free radical damage has long been believed to be a risk factor for the degenerative processes which accompany aging (1). Reactive oxygen species initiate a wide variety of oxidative reactions, including peroxidation of lipids, and contribute to the process of aging, as well as age-related pathology such as cardiovascular diseases. Moreover, platelet activation is believed to play a role in the development of such diseases, and an increased reactivity to most aggregating agents of platelets was reported in elderly people. An exacerbated arachidonic acid metabolism was also found, as well as a significant lowered vitamin E and glutathione peroxidase activity (2). On the other hand, epidemiologic studies suggest that consumption of n-3 polyunsaturated fatty acids (PUFA) may protect against thromboembolic diseases (3). Especially, eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids could be responsible for such beneficial effects. However, an increase of n-3 PUFA in membrane phospholipids may enhance membrane susceptibility to lipid peroxidation and thus counteract these beneficial effects.

In this context, the purpose of the present study was to investigate the effects of low intake of n-3 PUFA on platelets from elderly people. In a randomized double-blind study, 20 healthy subjects (70–83 yr) were carefully selected. Ten subjects ingested one capsule of 600 mg (corresponding to 150 mg DHA and 30 mg EPA) of RO-PUFA triglyceride (Roche) per day and 10 others ingested one capsule of 600 mg sunflower oil as placebo during 42 d. RO-PUFA and placebo capsules contained 1900 and 600 ppm of α-tocopherol, respectively, representing at most 5% of the recommended daily allowance. Blood anticoagulated with ACD (acid/citrate/dextrose) was drawn before (day 0) and after oil supplementation (day 42). Platelets were isolated and several biochemical parameters were measured.

The low intake of n-3 PUFA modestly affected platelet aggregation. Indeed, a tendency to decrease the percentage of thrombin-induced aggregation in RO-PUFA group was observed. Although no modification in the composition of platelet total phospholipids appeared after the oil intake, a slight but significant increase in the proportion of DHA was found only in the phosphatidylethanolamine fraction after RO-PUFA intake. Concerning the antioxidant status, no significant changes of the platelet glutathione peroxidase activity nor of its quantity were observed. By contrast, a significant increase of both α- (+26%, from 0.85 to 1.07 nmol/10^9 platelets) and γ- (+58%, from 0.12 to 0.19 nmol/10^9 platelets) tocopherols occurred after RO-PUFA intake. Interestingly, the basal platelet thromboxane B_2 level, a marker of activation, tended to decrease (–25%). In the same way, a significant reduction of platelet malondialdehyde (–30%), a marker of the overall lipid peroxidation, was found in the RO-PUFA group. At the opposite, no significant changes for all these parameters were observed in the placebo group.

Although epidemiologic studies (3,4) indicate clearly that a low intake of fish may beneficially influence the coronary heart disease, only few experimental data are available. Our investigation indicates that platelet hyperactivity observed in elderly people could be reduced by intake of small amounts of n-3 PUFA. Such a modification was associated both with an increase of the major antioxidant vitamin E and a decrease of platelet lipid peroxidation. These data suggest that low doses of n-3 PUFA might behave as an antioxidant in a prethrombotic state as the elderly.

Docosahexaenoic Acid-Enriched Foods: Production and Effects on Blood Lipids

Lloyd A. Horrocks[a],* **and Young K. Yeo**[b]

[a]Docosa Foods, Ltd., Columbus, Ohio 43212 and Department of Medical Biochemistry, The Ohio State University, Columbus, Ohio 43210, and [b]Kyungpook National University, Taegu, Korea

Fish oil containing eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) is known to reduce human plasma triacylglycerol levels, but has little effect on high density lipoprotein (HDL)- or low density lipoprotein (LDL)-cholesterol levels (1). These changes were seen within 3 mon of beginning supplementation. The study included 26 subjects, including 15 with a low ratio of polyunsaturated to saturated fatty acids as is typical in Western diets. In this study, animal products enriched in n-3 polyunsaturated fatty acid (PUFA), primarily in DHA, were tested to determine if they have the same effects as fatty fish.

Healthy human volunteers in Taegu, Korea, consumed animal products for 4 wk. Boys, 14 yr of age, consumed 585 mL of milk per day. One group had generic milk with 3.4% fat, and the other group had Einstein milk, in which the fat contained 0.2% each of EPA and DHA. Each group contained 250 boys. The platelet aggregation values, with 5 μL of collagen (Sigma test kit), were 22.4 ± 2.1% after generic milk and 17.1 ± 1.8% after Einstein milk ($P < 0.05$). The values for DHA in the plasma fatty acids were 2.6 ± 0.1 mol% and 5.5 ± 0.2 mol%, respectively. No difference was found in the plasma cholesterol.

Women, 20 yr of age, were students at Kyungpook University (Taelgu, Korea). Groups of 100 consumed three generic eggs or three Edison eggs daily for 4 wk. Platelet aggregation values, with 5 μL of collagen) (Sigma test kit), were 26.3 ± 7.9% after generic eggs and 9.0 ± 4.3% after Edison eggs ($P < 0.05$). Total cholesterol values were 174.4 ± 11.3 mg/dL after generic eggs and 141.1 ± 9.1 mg/dL after Edison eggs ($P < 0.05$).

Groups of 20 women ate 200 g of chicken or 200 g of pork per day. Compared to values obtained before consuming the food, the subjects consuming DHA-enriched foods had significantly lower values for platelet aggregation and plasma total cholesterol. Before eating chicken, the women had 85.2 ± 6.4 mg/dL LDL-cholesterol. After 4 wk, they had 68.1 ± 4.4 mg/dL ($P < 0.05$). Before eating pork, the women had 110.0 ± 8.0 mg/dL LDL-cholesterol. After 4 wk, they had 91.8 ± 7.3 mg/dL ($P < 0.05$). They had no change in HDL-cholesterol, which was about 50 mg/dL for all subjects. The levels of plasma triacylglycerols were also lower by 30%, but this was not statistically significant. The proportions of DHA in plasma neutral and polar lipids were much higher after consuming the DHA-enriched foods than before.

Eggs enriched with n-3 PUFA are on the market in several countries. Edison 300™ eggs containing at least 300 mg DHA per 100 g of egg are now being produced in Korea by Woobang Science Co., Ltd. This company provided a feed supplement for laying hens containing fish oil, flaxseed, and a mixture that stimulates the conversion of n-3 PUFA to DHA. In tests at The Ohio State University with the feed supplement, the mole percentages of n-3 fatty acids in eggs from control and supplemented (3.75%) hens were: 0.4 and 1.2 for 18:3, 0 and 0.2 for 20:5, 0 and 0.2 for 22:5, and 0.6 and 3.0 for DHA. Thus, eggs can now be produced with relatively low increases in most n-3 fatty acids but with a fivefold increase in DHA.

Persons on a Western diet might also improve cardiovascular risk factors by consuming these DHA-enriched foods. Patients with combined hyperlipidemia were given DHA at dosages of 1.25 or 2.5 g/d or placebo. Serum triacylglycerols were reduced significantly. The LDL-cholesterol level was unchanged at the lower dose and increased at the higher dose (2). Further feeding experiments are necessary to determine whether the reduction of LDL-cholesterol levels seen with DHA-enriched foods in Korea will also be seen in subjects consuming a typical Western diet. All studies with dietary supplementation or enrichment in long-chain n-3 fatty acids showed marked reductions in serum triacylglycerol levels. The latter is an important risk factor for cardiovascular disease, so the addition of long-chain n-3 fatty acids to the diet may be clinically useful (3).

Free Radical-Scavenging Actions of Olive Oil Phenolics

Francesco Visioli* **and Claudio Galli**
Institute of Pharmacological Sciences, 20133 Milan, Italy

Exposure to environmental stress and ultraviolet light radiation enhances the synthesis of protective compounds, e.g., pigments and antioxidants, in fruits and vegetables. This results in the development of dark-colored fruits such as grapes and olives. Among the phenolic constituents of olives and extra virgin olive oil, of special interest for their biological activities are those sharing an artho-diphenolic moiety, namely hydroxytyrosol (HT) and oleuropein (OE): previous studies showed that these compounds potently inhibit low density lipoprotein oxidation. We also recently reported that OE increases nitric oxide production and inducible nitric oxide synthase expression in lipopolysaccharide-challenged murine macrophages. A net increase in nitric oxide levels may also be the result of a concomitant removal of superoxide anion, therefore preventing the formation of peroxynitrite. The present study aimed at investigating the scavenging properties of olive phenolics, that is OE and HT, with respect to superoxide anion and hypochlorous acid. The former was generated in a cell-free environment (xanthine/xanthine oxidase) and by phorbol 12-myristate 23-acetate-stimulated human neutrophils. While vitamin E was ineffective, the rate of formation of superoxide in the presence of HT and OE was greatly reduced. When superoxide was generated by the xanthine/xanthine oxidase system, EC_{50} were as follows: OE = 14.3 μM, HT = 91 μM, whereas in the case of stimulated polymorphonuclear cells they were 29.3 and 3.2 μM, respectively. A scavenging effect on physiologically feasible concentrations of hypochlorous acid was also demonstrated, as indicated by a protection of catalase integrity and by a reduced rate of oxidation of 5-thio-2-nitrobenzoic acid to 5,5′ dithiobis (2-nitrobenzoic) acid. Hypochlorous acid is produced at the site of inflammation, where it inactivates antioxidant enzymes such as catalase and glutathione peroxidase, and is a component of household bleach. These results indicate the potent *in vitro* scavenging effects of olive oil-derived compound on free radical generation. Although data on the absorption and disposition of micronutrients are still limited, there is evidence of protective effects toward oxidative stress in the laboratory animal. Also, analyses of diets rich in fruit and vegetables indicate that the daily consumption of such components reach "pharmacological" levels. Whenever demonstrated in humans, their properties would add further evidence to the observed beneficial effects of a diet rich in phenols and flavonoids, found in fresh fruits, vegetables, and olive oil.

Green Tea Extract Does Not Affect Urinary Markers of Lipid Peroxidation or Thromboxane or Nitric Oxide Synthesis During a High-Linoleic Acid Diet in Healthy Females

Riitta Freese[a,*], **Samar Basu**[b], **and Marja Mutanen**[a]

[a]Division of Nutrition, FIN-00014 University of Helsinki, Finland,
and [b]Department of Geriatrics, Uppsala University, S-75125 Uppsala, Sweden

Green tea contains polyphenolic catechins which are powerful antioxidants and cyclooxygenase inhibitors *in vitro*. We studied the effects of green tea extract on urinary 8-iso prostaglandin $F_{2\alpha}$ (8-iso-$PGF_{2\alpha}$), which is a marker of *in vivo* lipid peroxidation; urinary 2,3-dinor thromboxane B_2 (2,3-dinor-TXB_2), a marker of thromboxane production; as well as urinary nitric oxide metabolites nitrate and nitrite ($NO_3 + NO_2$) during a controlled high-linoleic acid diet.

Twenty healthy, nonsmoking, normal weight females (23–50 yr) participated in the intervention. The study consisted of a 2-wk saturated fat-rich baseline diet which was followed by a 4-wk highly controlled experimental diet period. The experimental diet was rich in linoleic acid (9 en%) and contained fat, protein, and carbohydrates: 27, 14, and 59 en%. During the experimental period, the subjects were supplemented either with encapsulated green tea extract (3 g/d) or placebo in a double-blind manner. Fasting blood samples and five 24-h urines were collected before and at the end of the 4-wk experimental period. Samples from a control group of 10 healthy women who kept their habitual diet constant were also included in the analyses. Urinary 8-iso-$PGF_{2\alpha}$ was analyzed by radioimmunoassay (Dr. Basu, Uppsala University), 2,3-dinor-TXB_2 by enzymoimmunoassay (Cayman Chemicals, Ann Arbor, MI), and $NO_3 + NO_2$ using a colorimetric kit (Cayman Chemicals).

Serum cholesterol decreased, and vitamin E/cholesterol-ratio increased similarly in the two study groups, and both study groups differed from the control group in these respects. Also serum triglyceride fatty acids showed good compliance to the experimental diet. The treatments did not differ in their effects on urinary 8-iso-$PGF_{2\alpha}$, 2,3-dinor-TXB_2, or nitric oxide metabolites (Table 1).

When the differences and 95% confidence limits of the deltas in the different groups were compared, no differences between the groups were seen (data not shown). The results show that an amount of green tea extract which corresponds to 10 cups/day did not show specific antioxidative or cyclooxygenase inhibitive effects *in vivo* during a high-linoleic acid diet in healthy female subjects in comparison with placebo treatment.

Metabolism of Anandamide and 2-Arachidonoylglycerol: An Historical Overview and Some Recent Developments

Vincenzo Di Marzo[a,*,1], Luciano De Petrocellis[b], Tiziana Bisogno[a,1], and Dominique Melck[a,1]

[a]Istituto per la Chimica di Molecole di Interesse Biologico and [b]Istituto di Cibernetica, CNR, 80072, Arco Felice, Napoli, Italy

ABSTRACT: Anandamide (*N*-arachidonoylethanolamine) and 2-arachidonoylglycerol are the two endogenous agonists of cannabinoid receptors discovered to date. Like other eicosanoids, and unlike classical neuromodulators, these two compounds are synthesized by neurons on demand, i.e., their biosynthesis, rather than release, is stimulated by Ca^{2+} influx and cell membrane depolarization. Both endocannabinoids can be produced from membrane phosphoglycerides through the action of phospholipases, although *de novo* pathways have also been suggested. Once released by cells, the action of both anandamide and 2-arachidonoylglycerol is terminated—after their diffusion through the cell membrane—by the hydrolysis of the amide or ester bonds to yield arachidonic acid, which is then immediately reincorporated into phospholipids. One enzyme, fatty acid amide hydrolase, catalyzes the hydrolysis of both endocannabinoids in nervous and nonnervous cells. This enzyme also recognizes *N*-palmitoylethanolamine, an antiinflammatory congener of anandamide, with a catalytic efficiency that depends on the cell type under study. However, the existence of different isozymes with different affinity for anandamide and *N*-palmitoylethanolamine has not been investigated. Moreover, little work has been performed on the regulation of anandamide formation and breakdown, and several open questions remain as to the possible biosynthetic and degradative mechanisms of cannabimimetic 2-arachidonoylglycerol in nucleated blood cells such as macrophages. Finally, the co-existence of both endocannabinoids in invertebrates has not been fully established. Here we briefly review the state of the art, and present new data from our laboratory, on these four largely unexplored aspects of endocannabinoid metabolism.

Abbreviations: AA, arachidonic acid; 2-AG, 2-arachidonoylglycerol; ATFMK, arachidonoyltrifluoromethane; DAG, diacylglycerol; FAAH, fatty acid amide hydrolase; GC–MS, gas chromatography–mass spectrometry; *p*-HMB, *p*-hydroxy-mercuribenzoate; HPLC, high-pressure liquid chromatography; 1-LG, 1(3)-linoleoylglycerol; MAFP, methylarachidonoylfluorophosphonate; NAE, *N*-acyl-ethanolamine; $C_{20:4}$ NAE, anandamide; NAPE, *N*-acylphosphatidylethanolamine; NArPE, *N*-arachidonoyl-phosphatidylethanolamine; NGF, nerve growth factor; PA, phosphatidic acid; PC, PE, and PI, phosphatidylcholine, -ethanolamine and -inositol; PG, phosphoglycerides; PLA_2, PLC, and PLD, phospholipases A_2, C, and D; RBL, rat basophilic leukemia; SDS-PAGE, SDS-polyacrylamide gel electrophoresis; TG, triglycerides.

The discovery that anandamide [*N*-arachidonoylethanolamine, $C_{20:4}$ NAE (1)]—a novel compound belonging to a well-known class of lipids, the *N*-acylethanolamines [NAE, (2)]—and 2-arachidonoylglycerol [2-AG (3,4)]—a widespread intermediate in tri-, di-, and phosphoglyceride metabolism—could bind and functionally activate one or both cannabinoid receptor subtypes present in mammalian tissues conclusively demonstrated the existence of an endogenous cannabinoid system (for a recent review see Ref. 5). Along with studies on the pharmacological and behavioral properties of the two compounds (recently reviewed in Ref. 6), much effort has been dedicated to the finding of the possible biochemical mechanisms underlying $C_{20:4}$ NAE and 2-AG biosynthesis and inactivation. This led to the identification of the metabolic pathways responsible for $C_{20:4}$ NAE and 2-AG biosynthesis in the central nervous system and to the understanding of the main catabolic routes for the two endocannabinoids. However, still very little is known on the regulation of these pathways or on their occurrence in peripheral cells or lower invertebrates. Progress on these subjects, with particular emphasis on recent data from our laboratory, is described here.

Biosynthesis and breakdown of $C_{20:4}$ NAE. Regulation during cell differentiation and possible isoforms of the hydrolytic enzyme. Recent evidence supports a phospholipid-mediated pathway for the biosynthesis of $C_{20:4}$ NAE, identical to that described in the 1980s for other NAE (7). According to this pathway, NAE, including the $C_{20:4}$ congener, are produced from the phospholipase D (PLD)-catalyzed hydrolysis of preformed phospholipids, the corresponding *N*-acylphosphatidylethanolamines (NAPE) (2,7). NAPE, including *N*-arachidonoylphosphatidylethanolamine (NArPE), are in turn produced from the transfer of a fatty acyl moiety from the *sn*-1 position of phospholipids to the amino group of phosphatidylethanolamine (PE) (2,8) (Fig. 1). This reaction is catalyzed by a Ca^{2+}-dependent *trans*-acylase, and it probably represents the rate-limiting step of NAE biosynthesis. This pathway explains why the formation/release of $C_{20:4}$ NAE is always accompanied by that of other more abundant NAE (7,9). In fact, very little arachidonic acid (AA) is present on the *sn*-1 position of phospholipids, and, consequently, only very little NArPE can be produced upon Ca^{2+}-influx into the cell and subsequent stimulation of the *trans*-acylase.

Copyright © 1999 by AOCS Press

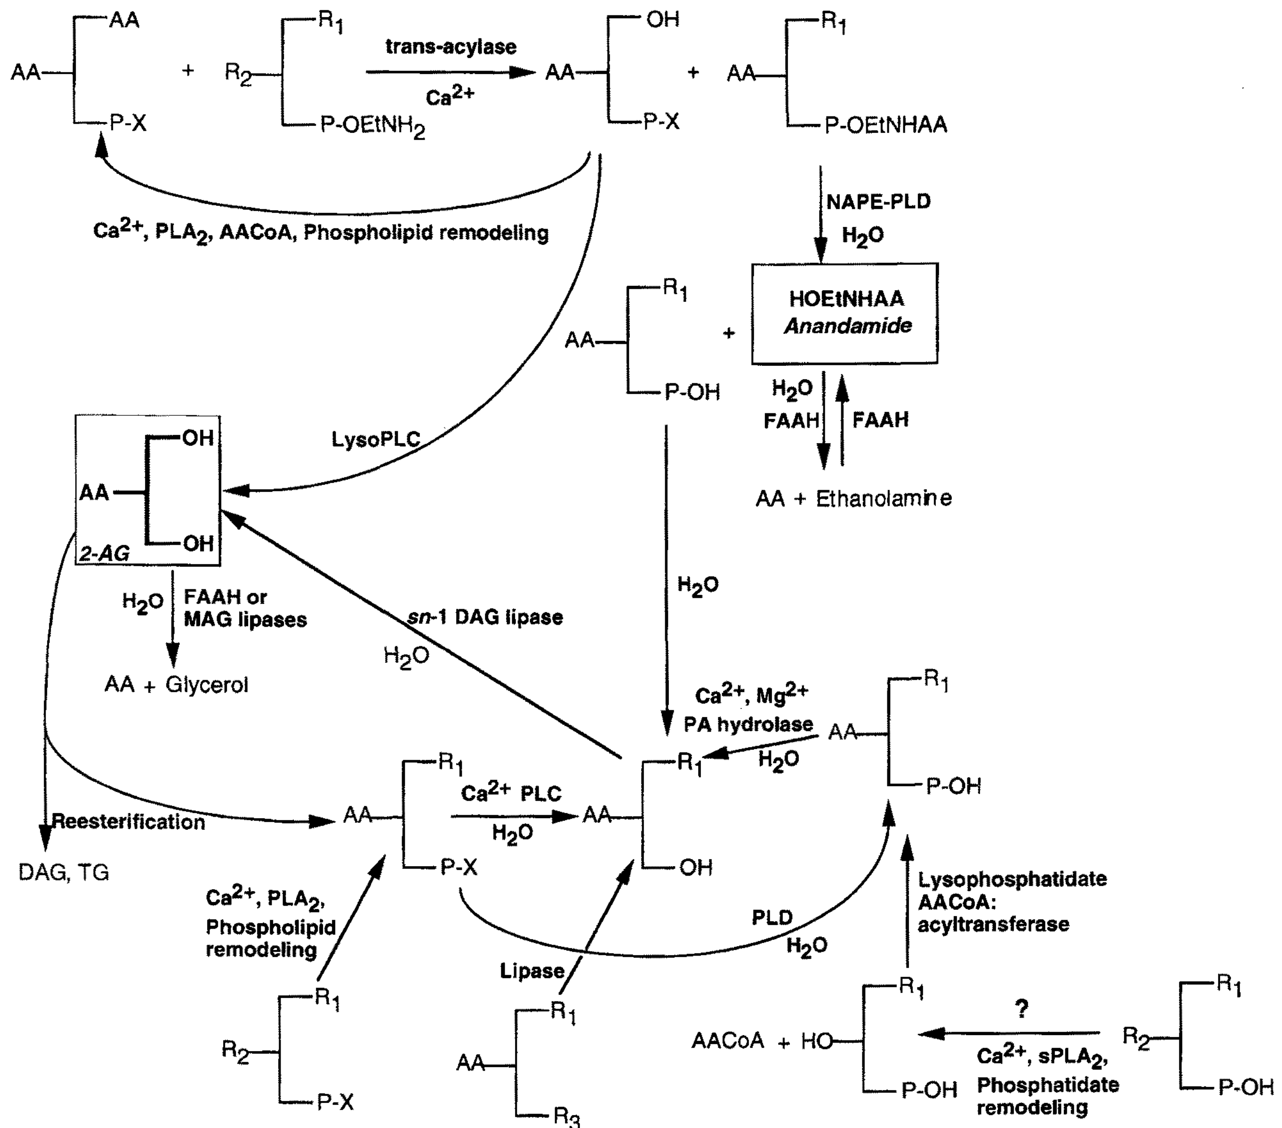

FIG. 1. Metabolic pathways for anandamide and 2-arachidonoylglycerol (2-AG) in mammalian cells. Calcium-activated phospholipid remodeling may play a role in the formation of precursors for both endocannabinoids. Data described here support the hypothesis of direct esterification of 2-AG into phospholipids and neutral lipids. AA, arachidonate; cPLA$_2$, sPLA$_2$, cytosolic or secretory phospholipase A$_2$; NAPE-PLD, phospholipase D selective for *N*-acylphosphatidylethanolamines; FAAH, fatty acid amide hydrolase; P, phosphate group; X, phospholipid base; PLC, phospholipase C; PA, phosphatidic acid; MAG, monoacylglycerol; DAG, diacylglycerols; TG, triglycerides.

There are, however, ways to stimulate the formation of NArPE over other NAPE through phospholipase A$_2$-mediated remodeling of membrane phospholipids (10). Moreover, the activity of the *trans*-acylase can be enhanced by adenylate cyclase-stimulating agonists such as the vasoactive intestinal peptide (11). We addressed the question of whether NAE and NAPE biosynthesis was upregulated following differentiation of peripheral cells, such as rat pheochromocytoma PC-12 cells, into sympathetic-like neurons. This transformation can be achieved by 2-wk treatment of PC-12 cells with the nerve growth factor (NGF). By using a gas chromatography–mass spectrometric (GC–MS) technique, we found that undifferentiated PC-12 cells contain measurable levels of $C_{20:4}$ NAE, $C_{16:0}$ NAE, and $C_{18:0}$ NAE and of the corresponding NAPE (data not shown). The production of these compounds cannot be increased by ionomycin treatment of cells or cell transformation into neurons (Fig. 2A). Moreover, transformed cells did not respond to ionomycin stimulation by producing more NAE and NAPE. Therefore, it is possible that the enzymes responsible for NAE and NAPE formation are not under control during NGF-induced peripheral cell differentiation into sympathetic-like neurons. Moreover, if NGF-transformed PC-12 cells can be taken as a model for sympathetic neurons, these data may suggest that depolarization of the latter cells may not contribute significantly to the formation of hypotensive $C_{20:4}$ NAE (see next section).

$C_{20:4}$ NAE inactivation occurs through facilitated diffusion into cells followed by enzymatic hydrolysis to AA and

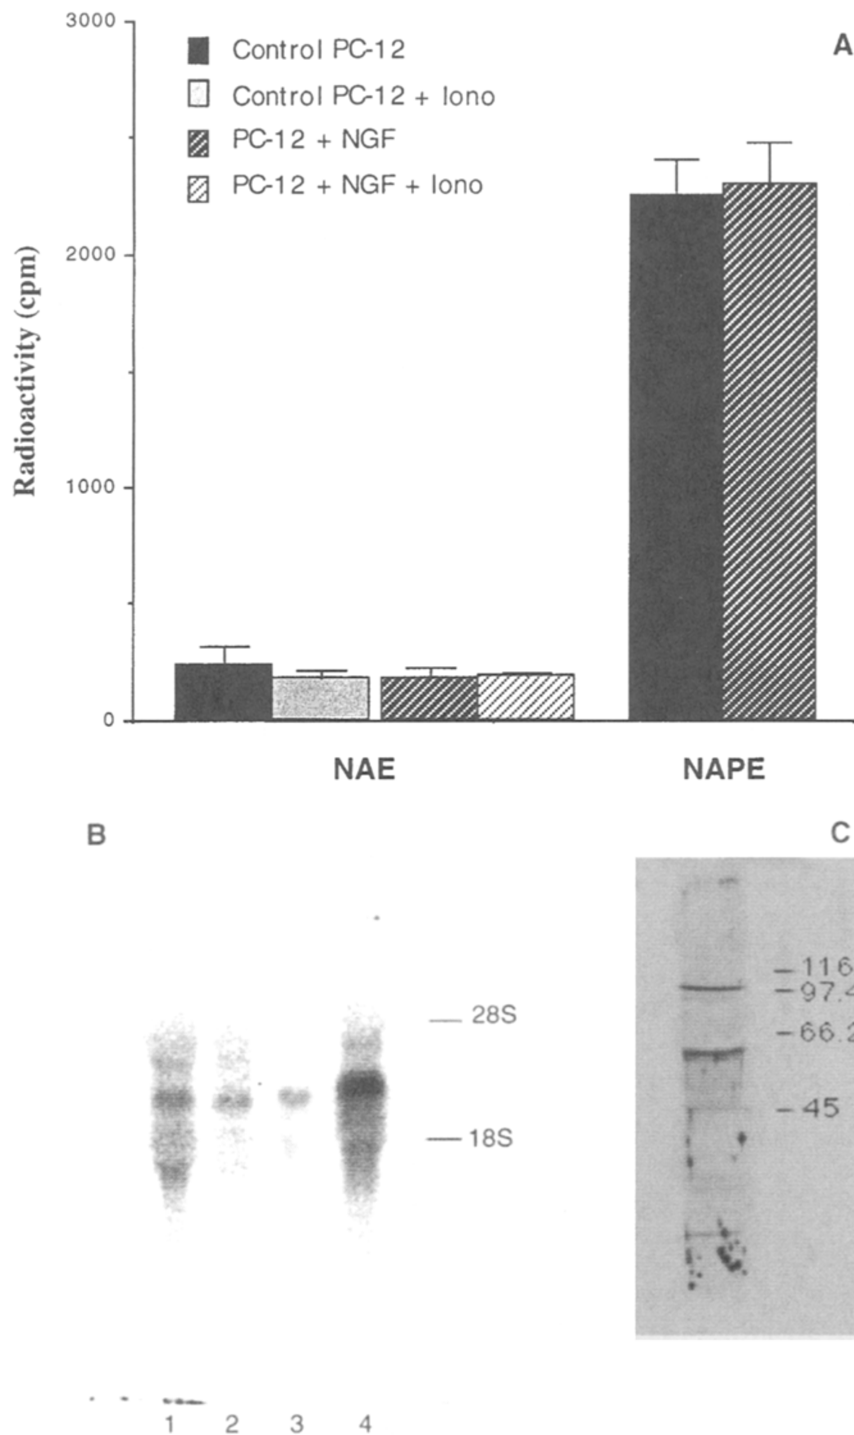

FIG. 2. Biosynthesis of *N*-acylethanolamines (NAE) and fatty acid amide hydrolase (FAAH) expression in phosphatidylcholine (PC-12) and rat basophilic leukemia (RBL)-1 cells. (A) PC-12 cells, either undifferentiated or transformed by 2-wk treatment with nerve growth factor (NGF) (50 ng/mL daily treatment), were labeled with [^{14}C]ethanolamine overnight and then stimulated with ionomycin (5 μM) or vehicle. Cells were then extracted and NAE and *N*-acylphosphatidylethanolamines (NAPE) purified as described previously (9). Their amounts are expressed as the radioactivity incorporated, measured by liquid scintillation counting of the purified compounds. The presence of $C_{20:4}$ NAE and *N*-arachidonoylphosphatidylethanolamine (NArPE) was assessed by gas chromatography–mass spectrometry (GC–MS) (9). (B) Northern blot analysis of 50 μg total RNA from either undifferentiated or differentiated PC-12 cells (lanes 1 and 2), RBL-1 cells (lane 3) and rat liver (lane 4). The blotting was performed according to the procedure described previously (24) by using an oligonucleotide probe designed from rat liver FAAH cDNA sequence. Lines indicate the mobility of 28S and 18S rRNA. Representative of four different blottings. The different band intensity in lanes 1 and 2 was not reproducible. (C) Western immunoblot analysis of proteins from RBL-1 cells with a polyclonal antibody against rat liver FAAH. Proteins were solubilized, purified by anion-exchange liquid chromatography and separated by SDS-polyacrylamide gel electrophoresis, all carried out as described previously (20). Lines indicate the mobility of molecular weight standards. Apart from the band at 62.8 kDa, another band (about 100 kDa) was also observed that did not peak with FAAH activity in chromatographic fractions.

ethanolamine (7) (Fig. 1). The enzyme responsible for $C_{20:4}$ NAE breakdown, originally named "anandamide amidohydrolase" (12), was recently cloned and expressed in COS-7 cells (13). The recombinant enzyme was found to catalyze also the hydrolysis of the sleep-inducing factor oleamide as well as other fatty acid amides and was renamed "fatty acid amide hydrolase" (FAAH) (13). This enzyme is widely distributed in membranes from rat tissues (liver > brain > gastrointestinal tract > lungs, testis > spleen) (13,24), and its expression in different brain regions fits with the distribution of the CB1 cannabinoid receptor subtype (14). Despite the fact that, of the enzymes participating in endocannabinoid metabolism, FAAH is undoubtedly the most studied one, the possibility of different FAAH isozymes and mechanisms for FAAH regulation have not been explored yet. In particular, the different substrate specificity of the enzyme from rat basophilic leukemia (RBL-1) cells as compared to the mouse neuronal enzyme (9) suggested the possible presence, in these cells, of a different FAAH isoform with a higher affinity for $C_{16:0}$ NAE. We analyzed, by Northern blotting of the total RNA from RBL-1 cells with an oligonucleotide probe obtained from the rat liver FAAH cDNA sequence, the size of FAAH mRNA in these cells as well as in PC-12 cells, either untransformed or differentiated by treatment with NGF. We found that FAAH mRNA in RBL-1 cells was undistinguishable in size from rat liver FAAH mRNA [which, in turn, is identical to rat brain FAAH mRNA (13)], and that PC-12 cell differentiation into sympathetic-like neurons does not significantly affect the levels of FAAH mRNA (Fig. 2B). Moreover, by using partially purified proteins from RBL-1 cells and a SDS-PAGE/Western immunoblotting technique exploiting a polyclonal antibody against rat liver FAAH, we analyzed the molecular size of FAAH in RBL-1 cells and found that the enzyme in these cells has an approximate molecular weight (62,800 ± 500 KDa, Fig. 2C) very similar to that calculated from rat liver FAAH amino acid sequence (i.e., 63,317 kDa). Taken together, these data do not support the presence of an FAAH isozyme in RBL-1 cells. However, the full molecular characterization of FAAH from these cells must be carried out before drawing a definitive conclusion on this issue.

Metabolism of 2-AG. Biosynthesis and catabolism in a macrophage cell line. The picture of 2-AG biosynthetic pathways is certainly more complicated than the one depicted above for $C_{20:4}$ NAE. Several routes can, in principle, contribute to 2-AG formation, all of which have as direct 2-AG precursors either *sn*-2-AA-containing diacylglycerols (DAG) or *sn*-1-lyso-2-arachidonoyl-phosphoglycerides. In the former case a *sn*-1 selective DAG lipase is responsible for 2-AG formation, whereas in the latter case a lysophospholipase C (lysoPLC) enzyme is required (Fig. 1). DAG, in turn, can be obtained through several pathways, i.e. (i) hydrolysis of triglycerides (TG) by lipases, (ii) hydrolysis of phosphatidic acid (PA) by PA hydrolase, (iii) hydrolysis of phosphatidylinositol or -choline (PI and PC) by PI- or PC-selective PLC. *sn*-2-AA-containing PA can be formed by either *de novo* synthesis and PA remodeling—through the action of lysophosphatidate AACoA:acyltransferases—or through the action of phospholipase D (PLD) and therefore also as a by-product of NAE formation. *sn*-1-Lyso-2-arachidonoyl-phosphoglycerides can be obtained from phospholipids through the action of phospholipase A_1 or as by-products of NAPE biosynthesis. In any case, there must be a Ca^{2+}-dependent, rate-limiting step since the biosynthesis and release of 2-AG, as for $C_{20:4}$ NAE, are triggered by Ca^{2+} influx into cells (15,16). Thus, in N18TG2 cells stimulated with ionomycin, DAG serving as precursors for 2-AG are probably obtained from PA formed from remodeling of nonpolyunsaturated species through pathways which may include the participation of secretory PLA_2 (15,25). Conversely, in ionomycin-stimulated rat cortical neurons and bradykinin-treated rat root dorsal ganglia, 2-AG is produced from DAG released by the action of PI-selective PLC (16,17). In platelets and other blood cells, PLC-derived intracellular 2-AG has always been regarded as the major source of AA for eicosanoid biosynthesis (18). Recently, however, platelet-derived extracellular 2-AG has been suggested to play a major role in lipopolysaccaride-induced and cannabinoid receptor-mediated hypotension (19). 2-AG was also found to be released by macrophage preparations, but since these were inevitably contaminated with platelets, it was not possible to ascertain that macrophages can produce 2-AG (19). We investigated whether a mouse macrophage/monocyte cell line, the J774 cells, once stimulated with ionomycin, could produce 2-AG. By using GC–MS for 2-AG quantitation, we found that, following such treatment, 2-AG levels in J774 macrophages can raise from 5 ± 5 mol up to 120 ± 29 pmol × 10^7 cells (about 1.1 nmol/g, means ± SD, $n = 2$) (Fig. 3A). These data provide strong evidence that stimulated macrophages can produce 2-AG.

Also 2-AG is inactivated by cells through the enzymatic hydrolysis of its ester bond, yielding AA and glycerol. Surprisingly, in both N18TG2 and RBL-2H3 cells, the enzyme mostly responsible for 2-AG hydrolysis was a protein with the same pH dependency, substrate specificity, sensitivity to inhibitors, and chromatographic behavior (after two purification steps) as FAAH (20). Conclusive evidence that this enzyme could efficiently catalyze 2-AG hydrolysis was provided by Goparaju *et al.* (21) by using recombinant FAAH overexpressed in COS-7 cells. We found that 2-AG, presumably after nonfacilitated diffusion through the plasma membrane, can also be esterified to membrane phospholipids in both N18TG2 and RBL-2H3 cells (20). We therefore decided to check whether these inactivating mechanisms also occur in living macrophages, a blood cell type whose production of vasodilatory 2-AG may play an important role during hemorrhagic- and septic shock-induced hypotension (19,22). We used again the J774 cell line and found that these macrophages can rapidly ($t_{1/2}$ = 28 min) sequester extracellular [^{3}H]2-AG from the incubation medium. Following this process, the radioactivity was time-dependently associated with 2-AG diffused into cells, free AA and DAG, TG, and membrane phospholipids (Fig. 3B). The fatty acylCoA transferase inhibitor thimerosal counteracted the formation of ra-

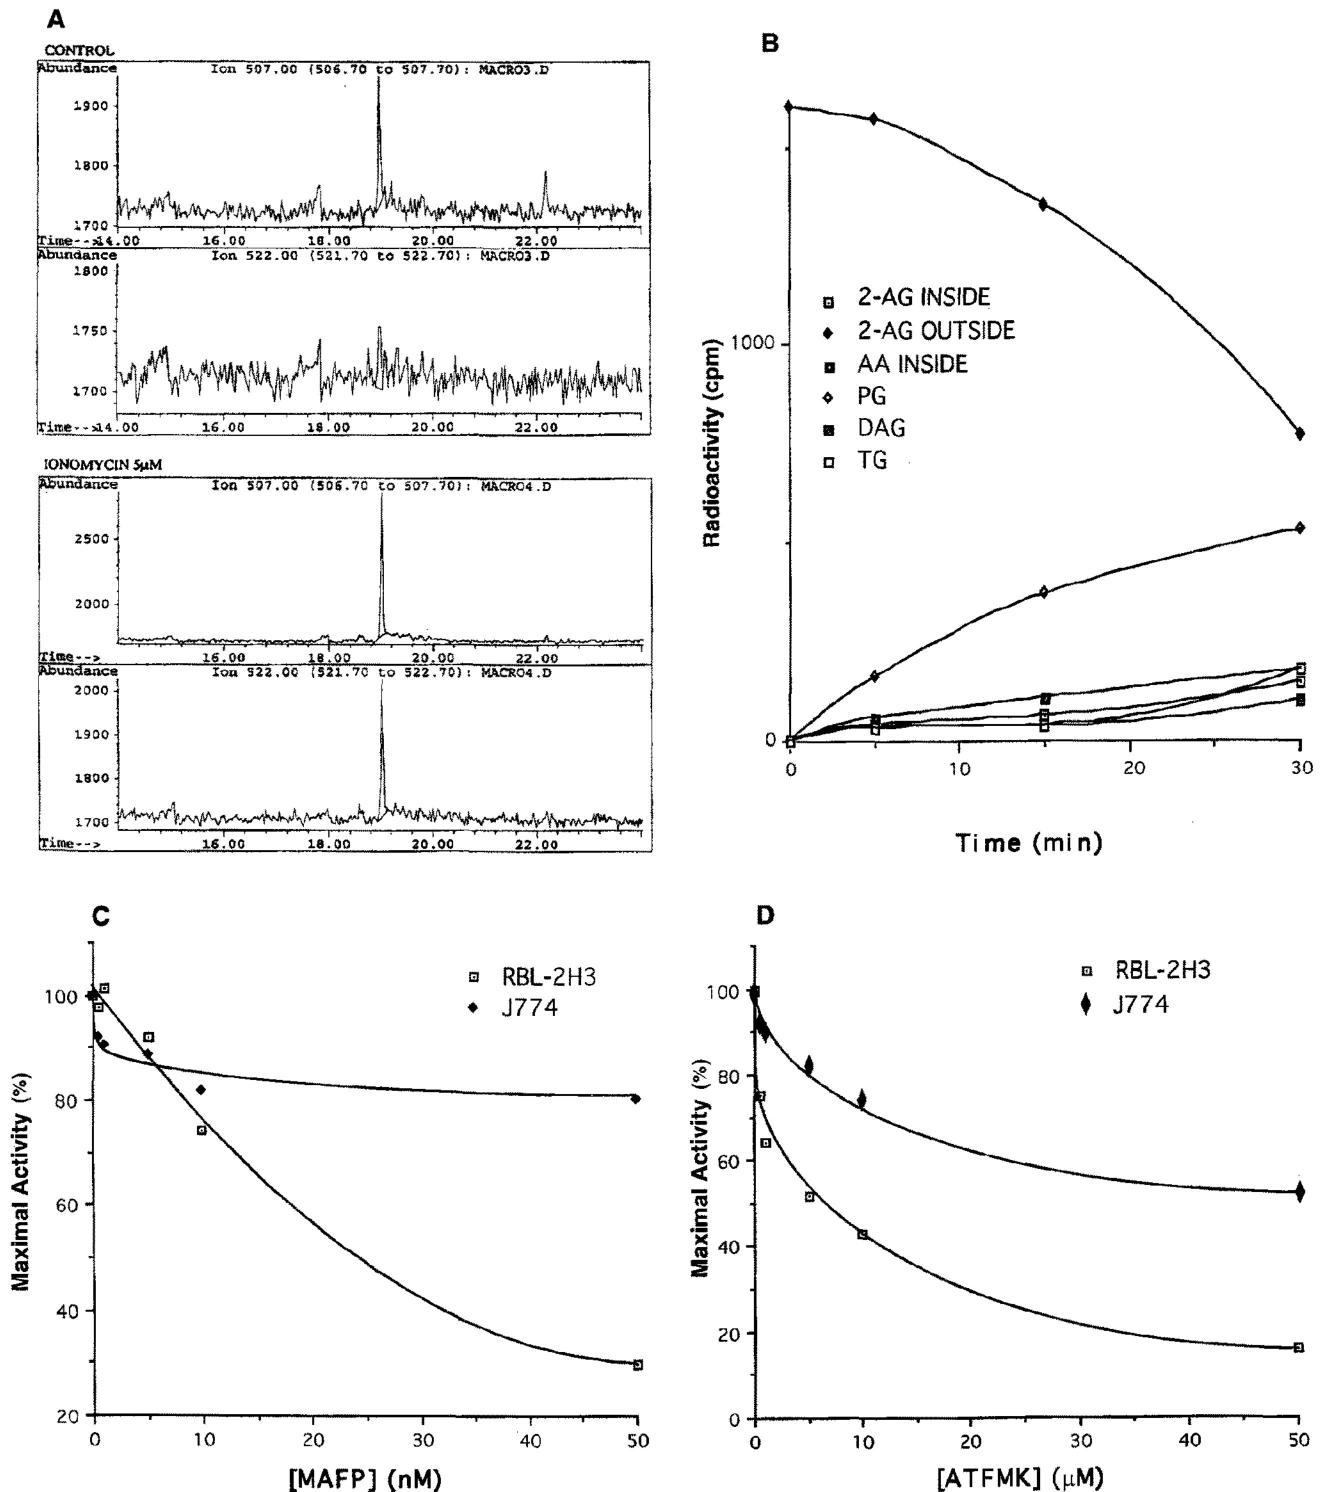

FIG. 3. Biosynthesis and catabolism of 2-AG in J774 macrophages. (A) Stimulation by ionomycin of 2-AG biosynthesis in intact J774 macrophages as detected by selected ion monitoring (SEM) GC–MS of the trimethylsilyl ether derivative. Confluent cells from twenty 100-mm Petri dishes (about 2×10^8 cells) were treated with either 5 μM ionomycin or vehicle for 20 min at 37°C. Cells plus media were then extracted in the presence of 2 nmol deuterated d_8-2-AG, and lipids processed as described previously (15). Normal-phase high-pressure liquid chromatography fractions with the same retention time as synthetic 2-AG were derivatized with 20 μL *N*-methyl-*N*-trimethylsilyl-trifluoroacetamide + 1% trimethylchlorosilane for 2 h at room temperature, prior to injection onto the GC–MS apparatus. GC was carried out as described previously (15), and selected ions monitored at $m/z = 522$ and 530 (molecular ion peaks) and $m/z = 507$ and 515 (−15, loss of methyl group). Only the fragmentograms (at $m/z = 522$ and 507) of endogenous, nondeuterated 2-AG from unstimulated (upper panel) and ionomycin-treated (lower panel) cells are shown. Representative of two experiments. (B) Catabolism of [^{3}H]2-AG in intact J774 cells. [^{3}H]2-AG (10,000 cpm/mL, 5 mCi/mmol) was added to the culture media of confluent cells in six-well dishes (about 1×10^6 cells/well) and incubated for 0, 5, 15, and 30 min. The radioactivity associated with 2-AG in the media, or with 2-AG and its metabolites in the cell extract was determined as described in the legend to Table 1. Data are means of triplicates and are representative of two separate experiments. AA, arachidonic acid; PG, phosphoglycerides . (C) and (D) Inhibition of [^{3}H]2-AG hydrolysis, catalyzed by membrane fractions from either RBL-2H3 basophils or J774 macrophages, by the two FAAH inhibitors methylarachidonoyl-fluorophosphonate (MAFP) and arachidonoyltrifluoromethane (ATFMK). Membranes were prepared and the hydrolysis of [^{3}H]2-AG (8 μM) assayed as described in (20). Data are means of triplicates and are representative of two separate experiments. See Figures 1 and 2 for other abbreviations.

diolabeled DAG, TG, and phosphoglycerides (PG) but not [^{3}H]2-AG hydrolysis to [^{3}H]AA. AA selectively inhibited the formation of [^{3}H]PG, whereas 1-linoleoylglycerol (1-LG) was also effective against [^{3}H]2-AG hydrolysis. By contrast, the other sulfhydryl group reagent, *p*-hydroxy-mercuribenzoate (*p*-HMB), inhibited [^{3}H]2-AG hydrolysis but not [^{3}H]PG formation (Table 1). These data suggest that to the formation of [^{3}H]PG contribute the re-acylation of both [^{3}H]2-AG (which is inhibited by thimerosal and 1-LG) and [^{3}H]AA (probably inhibited by AA and thimerosal), which in turn is produced from the hydrolysis of [^{3}H]2-AG (inhibited by 1-LG and *p*-HMB). Finally, we examined the 2-AG hydrolase activity in J774 cells, a cell line expressing very small amounts of FAAH (9). Unlike the enzyme in RBL-2H3 and N18TG2 cells (20), the hydrolase from J774 cells was different from FAAH in asmuch as it displayed little affinity for 2-AG (apparent K_m = 0.11 mM), and reduced sensitivity to the two FAAH inhibitors [reviewed in Ref. 6] arachidonoyltrifluoromethane (ATFMK) and methylarachidonoylfluorophosphonate (MAFP) (Fig. 3C,D). Nonetheless, the enzyme efficiently catalyzed 2-AG hydrolysis with an apparent V_{max} of 7.9 nmol min^{-1} · mg protein^{-1} at pH = 9.0. These data confirm our previous suggestion (20) that enzymes other than FAAH contribute to the inactivation of extracellular, cannabimimetic 2-AG, especially in those tissues and cells where very little FAAH is expressed, and suggest that a "cocktail" of inhibitors (for example thimerosal, *p*-HMB and ATFMK or MAFP) should always be used in biochemical and pharmacological studies on 2-AG.

Occurrence of $C_{20:4}$ NAE and 2-AG in lower invertebrates. The presence of $C_{20:4}$ NAE and NArPE in *Mytilus* and in the ovaries of sea urchins—two invertebrates which express cannabinoid receptors (6)—was previously established in our laboratory (6). However, no data exist on the presence of 2-AG in low invertebrates nor on the occurrence of the "anandamidergic" system in two widely used invertebrate models of neurobehavioral studies, i.e., *Hydra*, the first animal to have developed a neural network, and *Aplysia*. We analyzed by GC–MS (see legend to Fig. 3) the purified lipids extracted from *H. vulgaris* polyps and *Aplysia* ganglia and found that they contain measurable levels of endocannabinoids. $C_{20:4}$ NAE and NArPE contents were, respectively, 15.6 ± 1.5 and 32.4 ± 8.1 pmol/g in *Hydra*, and 10.5 ± 2.7 and 39.6 ± 7.1 pmol/g in *Aplysia* ganglia, whereas the amounts of 2-AG were 11.2 ± 1.9 and 5.7 ± 0.9 nmol/g, respectively (means ± SD, n = 2). Both endocannabinoids were accompanied by varying amounts of several congeners, including $C_{16:0}$ and $C_{18:1}$ NAE and $C_{16:0}$, $C_{18:0}$, $C_{18:1}$, $C_{20:3}$, $C_{20:5}$, $C_{22:5}$, and $C_{22:6}$ monoacylglycerols. Low levels of an FAAH-like activity were also found in both invertebrates. These data confirm that the endogenous cannabinoid system has been highly conserved during animal evolution and suggest that *Hydra* and *Aplysia* can be used for metabolic studies on $C_{20:4}$ NAE and 2-AG.

Conclusions. Although much progess has been made on the understanding of the mechanisms underlying endocannabinoid biosynthesis and degradation, still little is known on the regulation of these mechanisms, particularly in relation to some physiopathological conditions. Indeed, the two prototypical studies where a precise correlation between such conditions and $C_{20:4}$ NAE or 2-AG formation was established (19,22,23) dealt with peripheral tissues and posed further questions. Are the hypotensive endocannabinoids produced during hemorrhagic and septic shock (19,22) originated only from platelets and macrophages or also from sympathetic nervous fibers? Are they synthesized from the breakdown of phospholipid precursors? And how is the duration of their action regulated? How are produced the very high amounts of anandamide found in mouse uterus (20 nmol/g tissue, 1000 times higher than rat brain) when this organ is least receptive to embryo implantation (23)? From the phospholipid-mediated route depicted above—which can only sustain the formation of relatively low amounts of anandamide? Or through the enzymatic condensation between AA and ethanolamine (Fig. 1)—originally proposed to explain anandamide biosynthesis in cell-free systems, and then abandoned because of the high concentrations of substrates required for this reaction to occur (6)? A renewed effort from biochemists and physiologists will be required in order to provide an answer to these and other open questions on endocannabinoid metabolism.

TABLE 1
Effect of Various Inhibitors on [^{3}H]2-AG Catabolism in Intact J774 Macrophages[a]

Metabolite	[^{3}H]AA	[^{3}H]DAG	[^{3}H]TG	[^{3}H]PG
Substance				
None	100	100	100	100
p-HMB (100 μM)	39 ± 5	n.d.	n.d.	81 ± 10
MAFP (50 nM)	83 ± 4	n.d.	n.d.	84 ± 16
1-LG (100 μM)	49 ± 4	n.d.	n.d.	17 ± 7
AA (100 μM)	140 ± 6	n.d.	n.d.	23 ± 1
Thimerosal (100 μM)	89 ± 2	60 ± 9	31 ± 2	63 ± 4

[a]Intact J774 cells were incubated for 30 min at 37°C with [^{3}H]2-AG (10,000 cpm/mL, 5 mCi/mmol) in the presence of the various substances or vehicle. After the incubation, the media were removed, the cells extracted, and the lipids analyzed as previously descibed (15,20). The effect was measured as the percentage of the radioactivity found associated to each metabolite with no substance added (means ± SD, n = 3). 2-AG, 2-arachidonoylglycerol; AA, arachidonic acid; DAG diacylglycerols; TG, triglycerides; PG, phosphoglycerides; *p*-HMB, *p*-hydroxy-mercuribenzoate; MAFP, methylarachidonoylfluorophosphonate; 1-LG, 1(3)-linoleoylglycerol. The metabolites were separated by two-dimensional thin-layer chromatography using a first migration with iso-octane/ethyl acetate/water/acetic acid (50:110:100:20, by vol), to separate PG, 2-AG, and AA + DAG + TG, followed by a migration with diethyl ether/petroleum ether/ammonia (50:50:1, by vol), to separate AA, DAG, and TG (15).

ACKNOWLEDGMENTS

The authors wish to thank Dr. T. Sugiura, Teikyo University, Japan, for the gift of [^{3}H]2-AG, and Prof. S. Yamamoto and Dr. N. Ueda, Tokushima University, Japan, for the gift of FAAH antibody. The authors are also grateful to R. Turco for the artwork. This work was partly funded by a grant from the Human Frontiers in Science Program Organization (RG26/95 to VDM) and the INTAS (97/1297 to VDM).

Formation of *N*-Acyl-phosphatidylethanolamine and *N*-Acylethanolamine (including anandamide) During Glutamate-Induced Neurotoxicity

Harald S. Hansen*, Birthe Moesgaard, Henrik H. Hansen, Arne Schousboe, and Gitte Petersen

Department of Pharmacology, The Royal Danish School of Pharmacy, DK-2100 Copenhagen, Denmark

ABSTRACT: *N*-Acyl-phosphatidylethanolamine (NAPE) is present in very small amounts in mammalian tissues (less than 0.1% of total phospholipids). However, NAPE as well as its degradation product, *N*-acylethanolamine (NAE), can be formed in certain neuronal tissues in response to increased $[Ca^{2+}]_i$. A high $[Ca^{2+}]_i$ will activate the NAPE-forming *N*-acyltransferase using the *sn*-1 acyl group of a donor phospholipid as substrate in the transfer reaction. This membrane-bound enzyme seems to have no substrate specificity with respect to transfer of acyl groups; thus the fatty acids in the *N*-acyl group of NAPE are mainly 16:0 and 18:1, corresponding to the fatty acids in the *sn*-1 acyl group of the donor phospholipids. The NAPE-hydrolyzing phospholipase D also seems not to be acyl-group specific. In mouse neocortical neurons in primary culture, formation of NAPE and NAE is stimulated by glutamate *via* activation of the *N*-methyl-D-aspartate-receptor. Both NAPE and, to a lesser extent, NAE accumulate in a linear fashion for many hours while at the same time the neurons are dying. Likewise, in neurons prelabeled with ^{14}C-arachidonic acid, ^{14}C-arachidonic acid-labeled NAPE, and anandamide (= *N*-arachidonoylethanolamine) are accumulating. The formation of NAPE and NAE may represent a cytoprotective response in relation to various forms of neurotoxicity.

Formation of N-acyl-phosphatidylethanolamine (NAPE) and N-acylethanolamine (NAE). NAPE has for several decades been known to occur in a number of different plant seeds where its formation is believed to be a cytoprotective response to different stress stimuli (1). In mammals, NAPE can also be formed in certain tissues, e.g., in the brain (2). The formation is catalyzed by a membrane-associated *N*-acyltransferase that transfers an acyl group from the *sn*-1 position of a donor phospholipid to the amino group of phosphatidylethanolamine (PtdEtn) (Fig. 1). This enzyme is activated by calcium ions (ED_{50} = 0.2–0.5 mM) (2–4). The *N*-acyltransferase has been partially characterized, but it has not been purified (5). Since arachidonic acid in some cases is found in small amounts in the *sn*-1 position of phosphatidylcholine (6), formation of small amounts of *N*-arachidonoyl-PtdEtn (7–10) may occur. *N*-Arachidonoyl-PtdEtn is of special interest since it is the precursor for *N*-arachidonoylethanolamine, also called anandamide. This compound was found to be an endogenous ligand for the two types of cannabinoid receptors (11–13).

NAPE is found in very small amounts in mammalian tissues (less than 0.1% of the phospholipids), but it can accumulate during cell injury (2,5,9,10,14). This accumulation is probably caused by the activation of the *N*-acyltransferase, triggered by the increase in the concentration of intracellular Ca^{2+} that is associated with cell injury. NAPE can be hydrolyzed to phosphatidic acid plus NAE in both animal (2) and plant cells (15) by a phospholipase D (NAPE–PLD) that appears to be specific for NAPE. The mammalian NAPE–PLD does not seem to discriminate between different *N*-acyl groups (8,16,17), i.e., the acyl composition of the NAE formed appears to be identical to the *N*-acyl composition of NAPE. As opposed to the NAPE-forming *N*-acyltransferase, the NAE-forming NAPE–PLD seems to be unaffected by the calcium ion concentration (5). NAPE as well as NAE can accumulate during cell injury (2,14,18), and NAPE and NAE, including anandamide, have been found to accumulate postmortem (10,19,20).

Neuronal injury and formation of NAPE and NAE. We studied the formation of NAPE and NAE in mouse neocortical neurons in primary culture labeled with ^{14}C-ethanolamine for 22 h. In these cells, glutamate stimulated dose-dependently the formation of both NAPE and NAE *via* activation of the *N*-methyl-D-aspartate (NMDA)-subtype of glutamate receptors (14,18). The formation was linearly increasing within a time period of at least 20 h (18). However, glutamate is also known as an excitotoxic amino acid, and it can *via* the NMDA-receptor induce cell death in these cells (21). Another compound, sodium azide, which also very efficiently induces cell death *via* block of the respiratory chain, was found to be an even better stimulator of the formation of NAPE and NAE (18). The neurons were usually used after 6-7 d in culture at which developmental stage all-

Lipids 34, S327–S330 (1999).

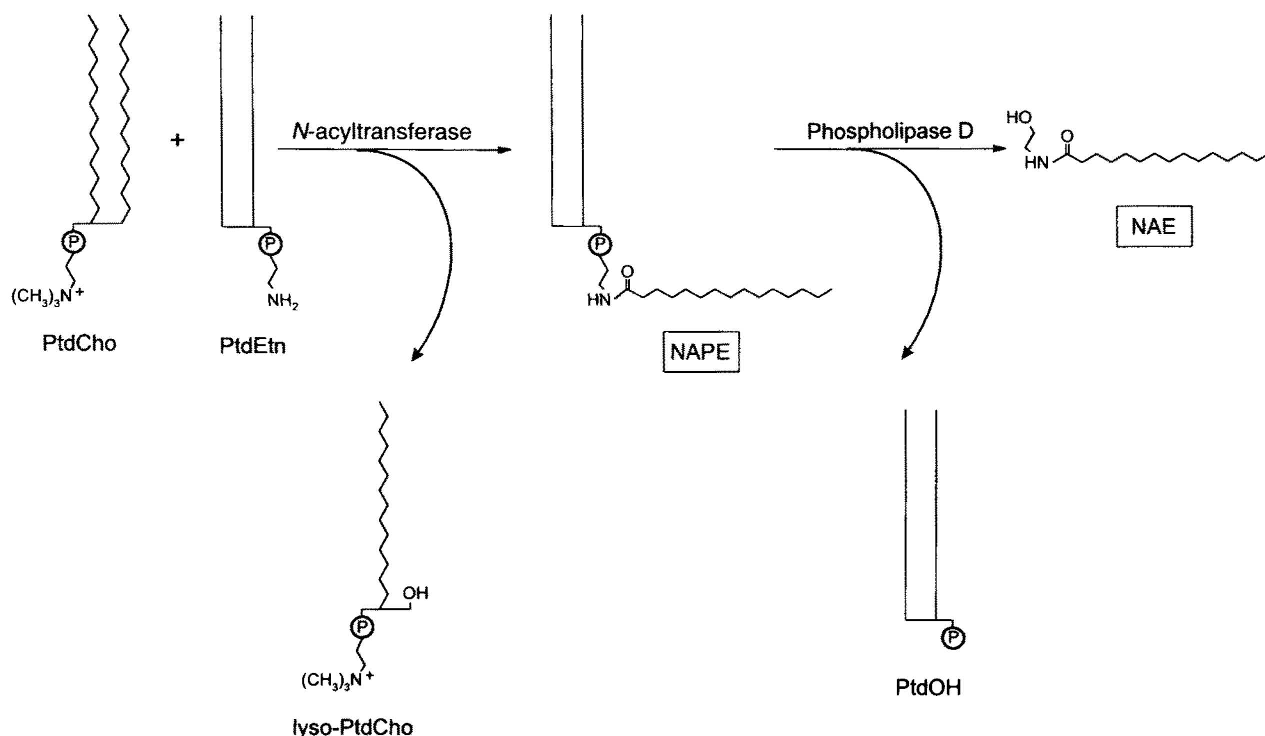

FIG. 1. The formation of *N*-acyl-phosphatidylethanolamine (NAPE) and *N*-acylethanolamine (NAE) catalyzed by the enzymes *N*-acyltransferase and NAPE-hydrolyzing phospholipase D. PtdCho, phosphatidylcholine; PtdOH, phosphatidic acid; PtdEtn, phosphatidylethanolamine.

glutamate receptor subtypes are present (22). However, as can be seen from Figure 2, the background level (= control value) of ^{14}C-ethanolamine-NAPE and ^{14}C-ethanolamine-NAE increased with time in culture, maybe indicating that the number of injured/aged cells increased with time in culture. In order to test whether ^{14}C-arachidonoylethanolamine (= anandamide) could also be formed in the neocortical neurons, the neurons were prelabeled for 22 h with ^{14}C-arachidonic acid, and then exposed to 100 μM NMDA. Figure 3 shows that ^{14}C-anandamide as well as ^{14}C-arachidonoyl-NAPE accumulated in a linear fashion with time for up to 24 h. This confirms the results of Di Marzo *et al.* (7) and extends these studies by showing that the NMDA-receptor-stimulated formation of anandamide is steadily increasing for a rather long period of time as also found for NAE in ^{14}C-ethanolamine-labeled neurons (18). These results, as well as others, (2,19,23,24) suggest that NAPE and NAE, including anandamide, are formed in response to cell injury and that anandamide accounts for less than 5–10% of the NAE formed, i.e., a rather nonspecific formation for a putative signaling molecule. This leads to the assumption that the other endogenous ligand for the cannabinoid receptors, 2-arachidonoyl-glycerol, may turn out to be a more physiologically relevant ligand for the cannabinoid receptors than is anandamide (5,24–30).

Proposed biological function of NAPE and NAE in neurotoxicity. In agreement with the original proposal of Schmid *et al.* (2) that NAPE is formed in response to cell injury, we have proposed that in neuronal tissue NAPE and NAE (including a minor amount of anandamide) are formed in response to neuronal injury and that this formation in the brain may be an indication of neurotoxicity (5,14,18). Formation of these two compounds may have a cytoprotective function in the brain. A number of the reported effects of both NAPE and NAE may be recognized as being cytoprotective, e.g., (i) NAPE can stabilize synthetic phospholipid membranes (31,32); (ii) *N*-oleoylethanolamine protects against increased calcium ion permeability of isolated damaged mitochondria (33), and *N*-palmitoylethanolamine was reported in some special cases to protect cerebellar granule neurons against excitotoxic death (34); (iii) the saturated NAE have antiinflammatory properties (2,35); (iv) anandamide can inhibit synaptic release of glutamate *via* activation of a cannabinoid receptor (36); and (v) *N*-oleoylethanolamine can potentiate staurosporine-induced apoptosis in embryonic chick neuronal cultures (37). All of these effects of NAPE and different species of NAE tend to reduce the impact of a local injury within the brain, whether acting directly on the injured neurons or by acting on neighboring cells, thereby inhibiting the spread of a local injury.

This study was supported by the Danish Medical Research Council, the Novo Nordisk Foundation, the Lundbeck Foundation, and the Danish State Biotechnology program. Grete Sørensen, Jytte Palmgren-Salomonsson, and Inge Damgaard provided excellent technical support.

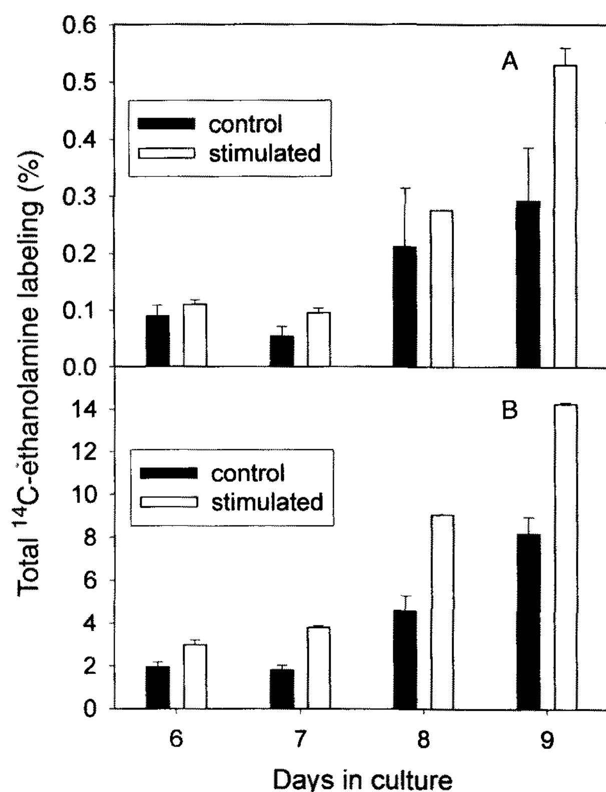

FIG. 2. N-Methyl-D-aspartate (NMDA)-induced formation of (A) ^{14}C-ethanolamine-NAE and (B) ^{14}C-ethanolamine-NAPE in neocortical neurons maintained in primary culture for different periods of time. The neurons were prelabeled with ^{14}C-ethanolamine for 22 h and then exposed to 100 μM NMDA for 2 h. Lipids were extracted and separated on thin-layer chromatography (TLC) as previously described. Results are from one of two experiments, each performed in duplicate. See Figure 1 for other abbreviations.

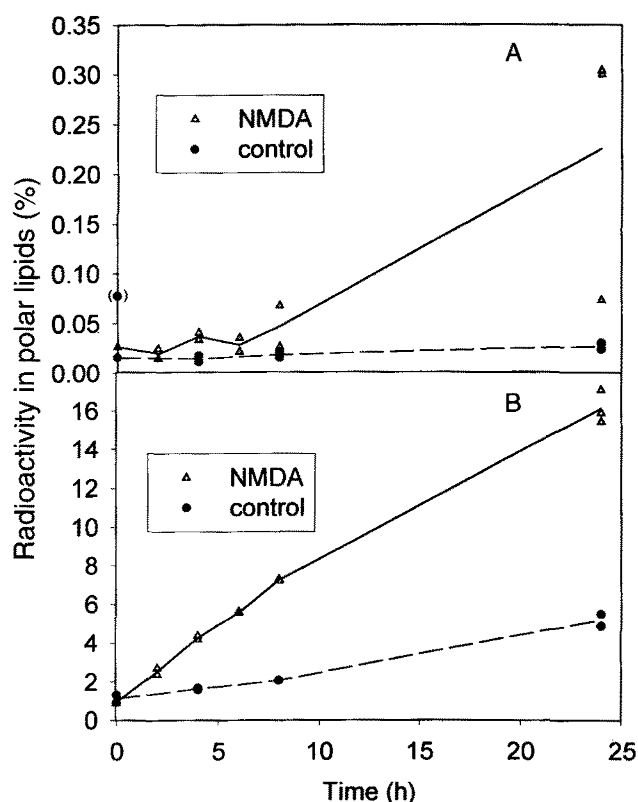

FIG. 3. NMDA-induced formation of (A) ^{14}C-anandamide and (B) ^{14}C-arachidonoyl-NAPE in neocortical neurons, day 7 in culture. The neurons were prelabeled with 1.5 μCi ^{14}C-arachidonic acid per 6×10^6 cells for 22 h and then exposed to 100 μM NMDA for various periods of time. Lipids were extracted and separated on two-dimensional TLC as previously described (14,18). Results are from one of two experiments, each performed in duplicate or triplicate. See Figures 1 and 2 for abbreviations.

The Pool of Fatty Acids Covalently Bound to Platelet Proteins by Thioester Linkages Can Be Altered by Exogenously Supplied Fatty Acids

ABSTRACT: The goals of this investigation were, first, to develop a chemical strategy to identify and quantitate the mass of fatty acid which is covalently bound to proteins by thioester linkage in unactivated platelets, and, second, to determine whether exogeneously added fatty acids can alter the fatty acid composition of thioester bound fatty acids. Studies with radiolabeled fatty acids cannot identify and quantitate the actual fatty acids bound to proteins because they permit analysis of only the radiolabeled fatty acids added and their metabolites. Therefore, in the absence of metabolic labeling by radiolabeled fatty acids, we isolated the thioester-linked fatty acids from platelet proteins using hydroxylamine at neutral pH to form fatty acid hydroxamates. The hydroxamates were subsequently converted to fatty acid methyl esters by acid methanolysis for quantitation by gas chromatography–mass spectrometry. Using platelet specimens from 14 subjects, 74% of the fatty acid recovered from the unactivated platelet proteins as thioester linked was palmitate. Importantly, however, 22% was stearic acid, and oleate was 4% of the total thioester bound fatty acid. There was minimal variability (2.6-fold at maximum) between the subjects in the amount of the thioester-linked palmitate and thioester-linked stearate. However, there was substantial variability (>100-fold at maximum) between subjects in the amount of thioester-linked oleate. We also demonstrated that incubation of platelets with exogenous fatty acids can alter the profile of fatty acids bound to platelet proteins by thioester linkages. Incubation of platelets with 100 μM palmitate for 3 h increased the amount of thioester-linked palmitate by up to 26%, and incubation of platelets with 100 μM stearate increased the amount of thioester-linked stearate up to 30%. In support of the observation that radiolabeled fatty acids other than palmitate were shown to be capable of binding to platelet proteins by thioester linkage, our results indicate that the fatty acids actually bound to unactivated platelet proteins include a significant amount of stearate, and variable amounts of oleate, as well as palmitate. In addition, the data show that palmitate and stearate can be increased, as a percentage of total protein-bound fatty acid, by incubation with exogenous palmitate and stearate, respectively.

Fatty acids can become covalently bound to proteins by three different types of linkages (reviewed in Refs. 1–4). First, fatty acids can be linked to proteins by way of an amide linkage, and the fatty acid found in this type of linkage is almost exclusively myristate (14:0). Second, fatty acids can become bound to proteins by way of thioester linkages. Fatty acids able to bind with this linkage include myristate (5), palmitate (16:0) (the most commonly studied fatty acid in thioester linkage (1–4)), stearate (18:0) (1–4), oleate (18:1) (6), arachidonate (20:4n-6) (7), docosatetraenoate (22:4n-6) (7), eicosapentaenoate (20:5n-3) (7), and docosahexaenoate (22:6n-3) (7). Fatty acids may also be bound covalently to proteins indirectly in glycosylphosphatidylinositol (GPI) anchor proteins (reviewed in Refs. 1–4). In this situation, the fatty acid is associated by an O-ester linkage with a phospholipid moiety which is linked through a variety of sugars to a protein. Although the fatty acid is not directly bound to the protein, in the isolation of total protein from the cells, the fatty acid is recovered. In trypanosomes, the common fatty acid in O-ester linkage in GPI anchor proteins is myristate (8). However, in other organisms the fatty acids in O-ester linkages of GPI anchor proteins are highly varied (3,4).

Nearly all previous studies on fatty acid acylation of proteins identified which fatty acids can become covalently bound to proteins and not the actual fatty acids that are bound to proteins in the native state. In studies with radiolabeled fatty acids, the fatty acids identified as protein-bound will only be those radiolabeled fatty acids added to the cells and their metabolites. If the radiolabeled fatty acids incorporated by the cells do not represent the fatty acids actually bound to protein, then an incorrect conclusion will be drawn concerning the identity of the fatty acids bound to the proteins. This

is a particularly important question with regard to thioester linked fatty acids because so many different fatty acids have been shown to be capable of binding to proteins in thioester linkage. If 16:0 is added to platelets, with covalent binding of the fatty acid and its metabolites to proteins, the fatty acids detectable will include 16:0, 18:0, and 18:1. This is a very limited number of fatty acids relative to the number of naturally occurring fatty acids. If 14:0 is added to platelets, the fatty acids detectable will include primarily 14:0 and 16:0. If 20:4n-6 is added to the cells, 20:4n-6 and 22:4n-6 may be detected, and if 20:5n-3 is added to the cells, 20:5n-3 and 22:6n-3 are detectable.

There are two major limitations to identifying and quantitating the fatty acids bound to cellular proteins by thioester-linkage in cells in the native state. First, the small mass of thioester-linked fatty acid presents a major limitation to identifying and quantitating the fatty acids. A second obstacle is the isolation of thioester-linked fatty acids away from O-ester-linked fatty acids in GPI anchor proteins. A common means to liberate thioester-linked fatty acids from proteins is alkaline methanolysis, which removes both thioester-linked and O-ester-linked fatty acids (1–4). Thus, this method cannot be used to selectively evaluate the thioester-linked fatty acid pool. To selectively remove thioester-linked fatty acids from proteins and allow O-ester-linked fatty acids to remain bound, it is necessary to use hydroxylamine at neutral pH. Hydroxylamine at neutral pH will specifically liberate thioester-linked fatty acids from protein (9), but it does not lead to formation of fatty acid methyl esters (FAME) which are detectable and quantifiable by gas chromatography (GC). Instead fatty acid hydroxamates are formed. Thus, the efficient chemical conversion of a very small mass of fatty acid hydroxamates to FAME is necessary for detection and quantitation of the fatty acids bound to platelet proteins in thioester linkage. We performed this analysis in the present studies, creating fatty acid hydroxamates and then FAME from the thioester-linked fatty acids bound to platelet proteins. We determined that the fatty acids actually covalently bound to platelet proteins by thioester linkage include stearate with highly variable amounts of oleate, as well as palmitate. Most importantly, however, we showed that the percentages of palmitate and stearate thioester linked to platelet proteins can be altered by incubation of the platelets with palmitate or stearate. In model membranes an increase of two carbons in fatty acid chain length greatly increases the time required for flip-flop and greatly decreases (by approximately 10-fold) the rate of dissociation of the fatty acids from the bilayer (10). This raises the possibility that proteins with the same primary amino acid sequence may be bound to membranes with different affinities because of differences in thioester-bound fatty acids which influence membrane binding.

MATERIALS AND METHODS

Isolation of the washed platelet suspension. Blood (6 mL) was collected from fasting subjects in acid citrate dextrose. Then 0.28 mM prostaglandin E_1 (PGE_1) was added to the blood, and the sample was centrifuged at 137 × *g* for 15 min at 37°C. The platelet-rich plasma (PRP) was aspirated from a total of eight samples, pooled, and subsequently centrifuged at 1230 × *g* for 15 min at 37°C. The supernatant from the centrifugation was aspirated, and the platelet pellet was resuspended in 10 ml of washing solution [36.0 mg fatty acid free bovine serum albumin (BSA) in 10 mL solution A] (10 mM HEPES, 0.14 M NaCl, 2.5 mM KCl, 0.1 mM $MgCl_2$, 0.1% glucose, 0.5 mM NaH_2P0_4, 10 mM $NaHC0_3$, pH 7.4), containing 0.28 mM PGE_1 supplemented with 50 µL 200 U/mL apyrase.). The resuspended platelet pellet was then centrifuged at 1000 × *g* for 15 min at 37°C. The supernatant from this centrifugation was aspirated, and the platelet pellet was washed an additional two times using the washing solution without bovine serum albumin.

Incubation of platelets with fatty acids. In some experiments, the platelets were incubated for 3 h at 37°C at this point with either 100 µM palmitate or 100 µM stearate in the albumin-containing washing solution described above. An aliquot was removed for a platelet count. The final pellet was resuspended in 0.5 ml SDS buffer (2.0% SDS, 62.5 mM Tris-HCl, pH 6.8). The platelet suspension in SDS was heated in boiling water for 5 min.

Removal of noncovalently bound fatty acids. To precipitate the platelet proteins and remove the lipids noncovalently associated with the proteins, the denatured platelet solution was mixed with 15 mL of $CHCl_3$/MEOH (2:1, vol/vol). The mixture was vortexed and incubated for 30 min at room temperature. The sample was vortexed again for 1 min and centrifuged at 4,468 × *g* at room temperature for 15 min. The supernatant was aspirated and discarded. At that point, 15 mL of $CHCl_3$/MEOH (2:1, vol/vol) was added to the pellet with vortexing for 1 min. The mixture was incubated for 5 min at room temperature, after which the sample was centrifuged at 4,468 × *g* at room temperature for 15 min. The supernatant was aspirated and discarded. The extraction sequence described above was repeated using 15 mL of $CHCl_3$/MEOH (2:1), $CHCl_3$/MEOH (1:2), $CHCl_3$/MEOH/H_2O (1:1:0.3) and MEOH. The final precipitate was dissolved in 1.0 mL guanidine HCl (6M) containing 20 mM TRIS-HCl and 0.02% Na_2 EDTA. An aliquot was removed for protein determination.

Release of protein-bound fatty acids and extraction of released fatty acid hydroxamates. To release the thioester-linked fatty acids from the platelet proteins by neutral hydroxylamine treatment and extract fatty acid hydroxamates, the protein precipitate from the platelets was divided into two aliquots. To one aliquot of platelets was added hydroxylamine and 4 nmol of 17:0 acyl-CoA as the thioester-linked internal standard. This was denoted as the "sample." To the second aliquot of platelet protein precipitate, 4 nmol of 17:0 acyl-CoA without hydroxylamine was added. This was denoted as the "sample blank." In place of hydroxylamine, 1 mL of 2 M TRIS-HCl was added. There were two additional blanks which contained no platelets. One blank included 1 mL of hydroxylamine with 1.0 mL of 6 M quanidine HCl to account

for any contamination introduced by hydroxylamine (the "hydroxylamine blank"). The final blank (the "TRIS blank") included 1 mL of TRIS buffer with 1.0 mL of 6 M guanidine HCl to account for any contaminating fatty acids introduced into the "sample blank" which was dissolved in 2 M TRIS-HCl rather than hydroxylamine. All tubes were vortexed gently and incubated for 18 h at room temperature. To the sample and the three blanks was added 2 mL of $CHCl_3$/ethyl acetate (1:1, vol/vol). The four tubes were then vortexed for 1 min and centrifuged at 4,468 × *g* for 15 min at room temperature. This resulted in the formation of two phases. The infranatant was removed and saved, and 2 mL of $CHCl_3$/ethyl acetate (1:1, vol/vol) was added to the remaining supernatant. The sample was vortexed for 1 min and then centrifuged at 4,468 × *g* for 15 min at room temperature. The infranatant was again collected. This process was repeated one additional time, such that for each tube, three infranatants were collected and dried completely under nitrogen. The combined dried infranatants from each tube were resuspended in 0.2 mL $CHCl_3$/ethyl acetate (1:1, vol/vol) and vortexed vigorously.

Conversion of fatty acid hydroxamates into FAME by acid methanolysis. The tube was centrifuged at 1,115 × *g* for 5 min at room temperature. The 0.2 mL supernatant was transferred to a hydrolysis tube. The original centrifuge tube was then rinsed with another 0.2 mL of $CHCl_3$/ethyl acetate (1:1, vol/vol), vortexed, and centrifuged again at 1,115 × *g* for 5 min at room temperature. The 0.2 mL rinse was added to the hydrolysis tube. The combined contents of the hydrolysis tube were dried completely under nitrogen. At that point, 1 mL of 3 M methanolic HCl was added to the hydrolysis tube which was then closed and gently agitated. The tube was then incubated at 100°C for 24 h. After cooling to room temperature, the contents of the tube were transferred to a vial for extraction three times with 1.0 mL hexane. In each 1.0 mL-extraction with hexane, the tube was vortexed vigorously. The upper hexane phase was aspirated each time and the three extracts were pooled. To these extracts was added 4 nmol of methyl 15:0 as a second internal standard to account for evaporation losses. Each specimen was then dried completely under nitrogen and resuspended in 10 μL hexane, and 1 μL of the 10 μL was then injected into a Hewlett-Packard 5890 series II model gas chromatograph-mass spectrometer (GC–MS) with a Hewlett-Packard 5971 mass spectrometer (Hewlett-Packard, Wilmington, DE). The column was a Supelcowax 10 capillary column (Supelco, Bellefonte, PA). The injector temperature was 260°C with a detector temperature of 280°C. The flow rate of the carrier gas was 0.7 ml per minute, and the carrier gas was helium. To elute the FAME from column, the GC was programmed to initiate elution at 150°C for 2 min. At that point the temperature was increased 10°C per minute to 200°C where it was held for 4 min. At that time, the temperature was increased at 5°C per minute to 240°C and held for 3 min. Finally, the temperature was ramped at 10°C per minute to 270°C where it was held for 6 min. This temperature program eluted all of the FAME. For each of the analyses, single ion monitoring using ions 55, 67, 69, 74, 79, and 91 was performed. Total ion scans were also run at 50–500 AMU. The fatty acids in thioester linkage were quantitated by determining (the pmol fatty acid in the sample) minus (the pmol fatty acid in the hydroxylamine blank) minus (the pmol fatty acid in the sample blank) minus (the pmol fatty acid in the Tris blank)/mg platelet protein. The 15:0 methyl ester blank was included to account for changes in FAME concentration as a result of evaporation, but because the recovery of the 15:0 methyl ester was found to be greater than 95% in all cases, it had a neglible impact on the calculations. The 17:0 fatty acyl-CoA, therefore, which contains a fatty acid thioester linked to CoA, was the internal standard used to account for essentially all losses in the procedure.

RESULTS

Figure 1 shows the electron-impact tracing of the GC–MS peaks which had the expected retention times for methyl palmitate and methyl stearate. The mass spectra of authentic standards of methyl palmitate and methyl stearate are shown for comparison with the fatty acid peaks eluting at the appropriate times for methyl palmitate and methyl stearate. The major ion peaks characteristic of FAME and ion peaks unique to methyl palmitate and methyl stearate were found in the methyl palmitate and methyl stearate peaks, respectively. The ions unique to methyl palmitate and methyl stearate were the molecular ions of 270 (M^+) for methyl palmitate and 298 (M^+) for methyl stearate.

Because the amount of fatty acid covalently bound to proteins by thioester linkage was expectedly low, it was important to establish the reproducibility of the measurement for thioester-linked fatty acid. To assess the precision of the analytical method, we performed five analyses on one sample of pooled platelets. For the quantitation of thioester-bound palmitate, the mean value for the sample tested was 796 pmol/mg with a standard deviation of 62 pmol/mg. The coefficient of variation was calculated to be 7.8%. A similar result was obtained for the quantitation of thioester-linked stearate. The mean value was 267 pmol/mg, and the standard deviation was 18 pmol/mg, resulting in a coefficient of variation of 7.0%. Thus, the measurement showed excellent reproducibility, and, therefore, major differences in values between subjects most likely reflect biological variability rather than analytical variability in the measurement.

The fundamental question addressed in these studies was the identity and quantitation of the mass of fatty acids covalently bound to platelet proteins by thioester linkage. Table 1 shows the results of this quantitation from 14 normal healthy subjects in pmol fatty acid/mg platelet protein, and as percentage of total fatty acid recovered. As shown in the table, the three fatty acids detected were 16:0, 18:0, and 18:1. Although palmitate was the predominant fatty acid, there was a significant amount of stearate which was thioester-linked to platelet proteins. In some subjects, oleate was also recovered, but it represented on average, less than 5% of total fatty acid. Particularly noteworthy, stearate represents a significant

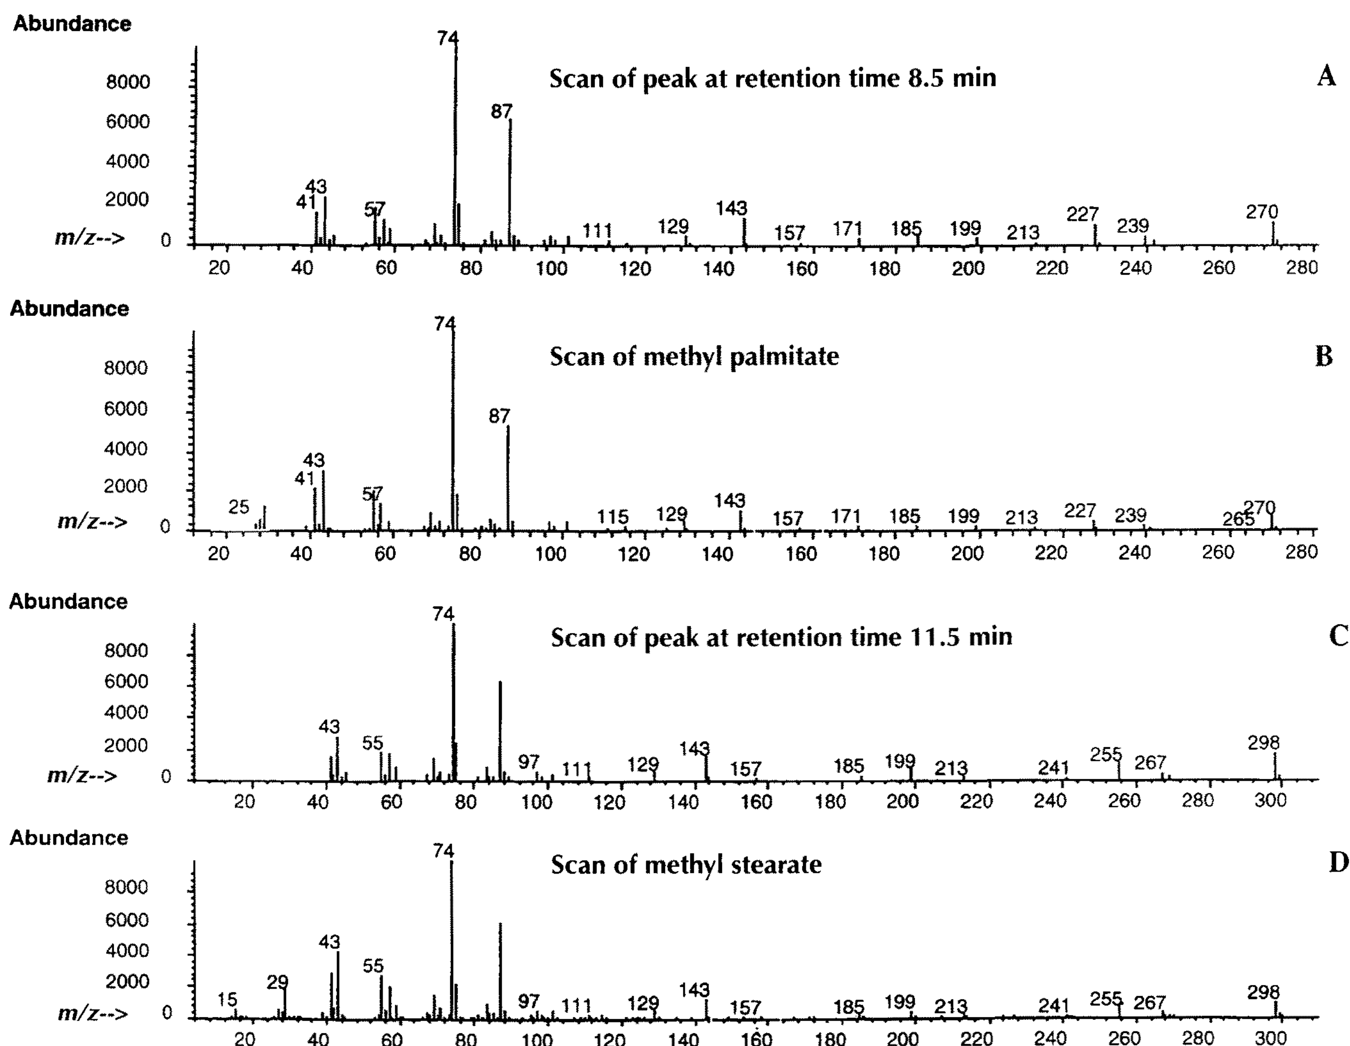

FIG. 1. Gas chromatography—mass spectrometry scans (GC–MS). Electron impact scan from GC–MS of (**A**) peak with retention time of methyl palmitate (8.5 min); (**B**) methyl palmitate standard; (**C**) peak with retention time of methyl stearate; (**D**) methyl stearate standard.

quantity of the fatty acid which is thioester-linked to protein. In studies with radiolabeled fatty acids using radiolabeled palmitate, where stearate generation is dependent on an elongase enzyme activity which converts palmitate to stearate, only trace amounts of stearate, far less than 22% of thioester-linked fatty acid, were found to be protein bound.

Table 1 also shows that there was a relatively modest amount of biological variability in the percentage of thioester-linked palmitate, and even less variability in stearate among the individual subjects. The amount of protein-bound oleate in several of the subjects (numbers 1, 3, 4, 10, and 11) was notably higher than in the others, while some subjects had undetectable levels of oleate. Although it was not possible to determine the basis for this disparity, this finding raised the possibility that the ingestion of dietary fat with a high amount of oleate, such as olive oil, may be responsible for this variability between individuals in fatty acid composition. We therefore asked whether the fatty acid composition bound to platelet proteins by thioester linkage could be modified by exogenously provided fatty acids.

To address this question, platelets were incubated for 3 h with 100 μM palmitate or 100 μM stearate to determine whether incubation with these fatty acids could alter the fatty acid composition of the thioester-linked fatty acids. Figure 2 shows the increase in thioester-linked palmitate after incubation with palmitate, and Figure 3 shows the increase in thioester-linked stearate after incubation with stearate. In each of the three samples, platelets incubated with palmitate showed an increase in the amount of covalently bound palmitate. It should also be noted, although not shown in the figure, that subjects 2 and 3 showed significant increases in the amount of protein-bound stearic acid after incubation with palmitate. This is not unexpected since platelets are able to elongate palmitate to stearate (11). Subject 1 did not show an increase in protein-bound stearate after incubation with palmitate, possibly because the platelets were less effective at elongating palmitate to stearate. The increase in stearate in subjects 2 and 3 after incubation with palmitate was, in absolute amount, less than the increase in palmitate. The increases in thioester-linked stearate after incubation of the

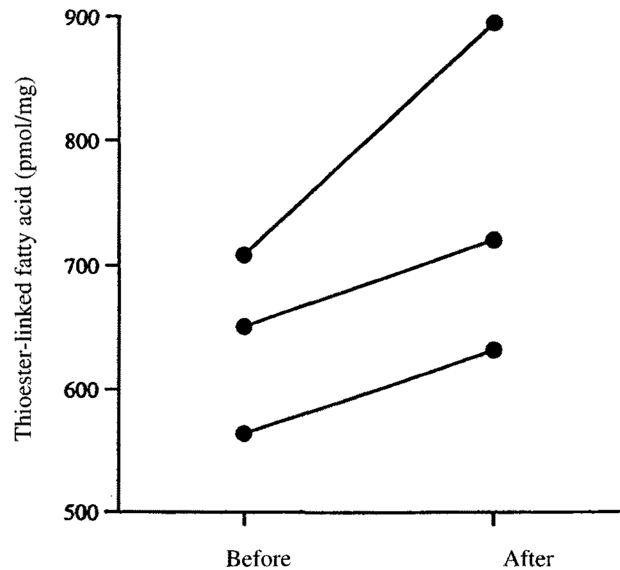

FIG. 2. Effect of palmitate (16:0) incubation on platelet protein fatty acid composition. Change in mass of thioester-linked palmitate after incubation of platelets from three subjects *in vitro* with 100 μM palmitate for 3 h at 37°C.

platelets with 100 μM stearate ranged from 10 to 30% for the three subjects. There was a decrease or no change in the amount of thioester-linked palmitate when the platelets were incubated with stearate. This was expected since incubation of platelets with stearate is unlikely to generate palmitate by retroconversion in the platelet. In some of the GC–MS tracings, arachidonate was identified as a thioester-linked fatty acid. However, the amount detected was too low to quantitate in these studies with unactivated platelets. In previous studies with radiolabeled arachidonate, we showed that arachidonate can become covalently bound to proteins by way of thioester linkages (7). These results raise the possibility that arachidonate becomes covalently bound to proteins only when the platelets are activated. In support of this hypothesis, arachidonate is liberated in substantial quantity from phospholipids upon cell activation, and the free arachidonate concentration in the platelet increases significantly at that time.

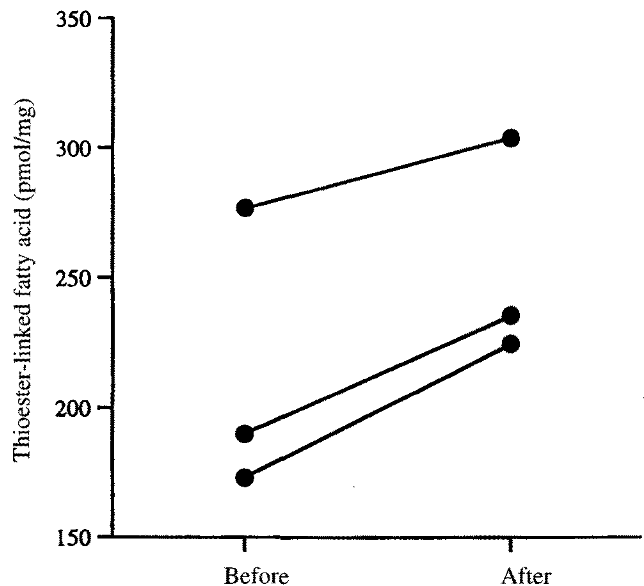

FIG. 3. Effect of stearate (18:0) incubation on platelet protein fatty acid composition. Change in mass of thioester-linked stearate after incubation of platelets from three subjects *in vitro* with 100 μM stearate for 3 h at 37°C.

DISCUSSION

The elaborate methods used in our studies, to identify and quantitate the fatty acids thioesterified to platelet proteins, were required to remove the O-ester-linked fatty acids associated with the GPI anchor proteins from the thioester-bound fatty acids. Amide-linked fatty acids do not represent a potential confounding variable because platelets have little, if any, capacity for protein synthesis, and amide-linked fatty acids are added cotranslationally. In addition, alkaline hydrolysis will remove and methylate the O-ester bound fatty acids from the GPI-linked proteins as well as thioester-bound fatty acids, but not liberate the amide-linked fatty acids (12). In addition to identifying the relative amounts of fatty acids thioester-linked to platelet proteins, these data provide a quantitation in pmol fatty acid/mg platelet protein of the actual amount of fatty acid covalently bound to platelet proteins in thioester linkages. This number is not obtainable in studies with radiolabeled fatty acids because upon incorporation into the cell, the specific activity of the radiolabeled fatty acid is decreased to an undeterminable value by dilution with an unknown amount of unlabeled precursor fatty acid already in the cell. The amount of unlabeled precursor fatty acid is unknown because the precursor fatty acid pool for thioester-linked fatty acids in the cell has not been identified. The data also permit an estimation of the stoichiometry between fatty

acids and platelet proteins. Assuming an average molecular weight of 65,000 daltons for a platelet protein, with the data from our studies showing 858 pmol of thioester-linked (palmitate + stearate + oleate)/mg platelet protein, on average 0.056 molecules of fatty acid are thioester-linked to protein if a single fatty acid is bound to a single protein. Therefore, if a single fatty acid becomes bound to a single protein molecule, approximately one out of every 20 protein molecules in the platelet would be fatty acid-acylated with a thioester linkage. It is quite possible, however, that at any given time, certain proteins are acylated with more than one fatty acid. Thus, one out of 20 protein molecules acylated with a thioester-linked fatty acid represents a maximal estimate.

The results of our studies indicate that the fatty acids thioester-linked to platelet proteins in the unactivated state include stearate and oleate as well as palmitate. The studies also demonstrate that exogenously presented fatty acids can augment the mass of thioester-linked fatty acid. There is evidence that differences in fatty acid chain length and unsaturation affect the ability of fatty acids to promote protein binding to membranes (13–15). The significance of stearate as a fatty acid bound in thioester linkage to protein is that the additional two carbons on the saturated chain relative to palmitate may enhance its ability to promote protein binding to membranes. In studies evaluating the dissociation of fatty acids from phospholipid bilayers, the rate constants (Koff $(s)^{-1}$) for fatty acid desorption from bilayers were 39.0 for myristate, 8.2 for palmitate, and 0.5 for stearate (10). Thus, there is a 16.4-fold difference in the strength of the association for the phospholipid bilayer between palmitate and stearate. Accordingly, a change from palmitate to stearate or palmitate to oleate may significantly impact the function of a protein without any alteration in the primary amino acid sequence of the protein molecule.

There are at least three studies which support our finding that stearate is not a trace fatty acid among thioester-linked fatty acids. In a study involving a single platelet protein, P-selectin was isolated from human platelets, and by GC–MS it was shown that stearate as well as palmitate was thioester-linked to the isolated P-selectin molecule (16). In work by Zeng *et al.* (17), it was demonstrated that asialoglycoprotein receptor subunits contained both thioester-linked palmitate and stearate. The relative amounts of palmitate and stearate covalently bound in thioester linkage to the asialoglycoprotein receptor could not be determined, but the data suggest that stearate is unlikely to be a trace fatty acid. Although these results were obtained with individual proteins, they are consistent with the results of this investigation which identified and quantitated the fatty acids bound to all platelet proteins. In a third study, Berthiaume and Resh (18) reported on the biochemical characterization of a palmitoyl acyltransferase activity that palmitoylates myristylated proteins. They evaluated the fatty acyl-CoA specificity of the palmitoyl acyltransferase enzyme preparation. The investigators found, as expected, that unlabeled palmitate was the most effective fatty acid at inhibiting the acylation of radiolabeled palmitate to their substrate. Importantly, however, they showed that stearate was also effective in inhibiting the acylation of radiolabeled palmitate to their substrate, indicating that stearate is an acceptable substrate for palmitoyl acyltransferase. Taken together, our results indicate that stearate, as well as palmitate, is covalently bound in thioester linkage to platelet proteins and that exogenously presented fatty acids can alter the fatty acid composition of the thioester-linked fatty acid pool.

The Influence of a Novel Antioxidant Fatty Acid on the Development of Stenosis After Balloon Injury

E. Dyrøy[a,*], K.J. Kuiper[b], R. Pettersen[b], J.E. Nordrehaug, and R.K. Berge[a]

The implantation of coronary stents reduces restenosis significantly, but it is still about 20%. Despite many studies, no pharmacological agent was found to reduce the occurrence of restenosis. Here we report that a sulfur-containing fatty acid analog tetradecylthioacetic acid (TTA) [CH_3-$(CH_2)_{13}$-S-CH_2-COOH], which has triglyceride and cholesterol-lowering effects and itself acts as an antioxidant, is effectively reducing the development of restenosis in the rabbit iliac artery after balloon injury (overstretching). Twelve rabbits in each group were re-examined 6 wk after balloon injury. Angiography showed 43% stenosis in the placebo group against 23% for the TAA-treated group. The iliac artery dilated by balloon angioplasty showed a stronger response in intima hyperplasia for the TTA group. The mean of minimal luminal diameter (MLD) in the placebo group was 1.08 whereas in the TTA group the MLD was 1.60.

We examined whether this could be a direct effect on smooth muscle cells and endothelial cells by TTA. Human smooth muscle cells and human endothelial cells were cultured in the presence and absence of TTA. We find that TTA inhibits the proliferation rate of smooth muscle cells, but not endothelial cells *in vitro.*

The data show that TTA inhibits restenosis, and this may be due to reduced proliferation of smooth muscle cells. Evidently TTA may be of potential interest for a new therapeutic approach to atherosclerosis and restenosis, as it is an antioxidant itself and influences the antioxidant dependence status.

Effects of β-Oxa and β-Thia Polyunsaturated Fatty Acids on Agonist-Induced Increase in Endothelial Cell Adhesion Molecules

B.S. Robinson[a], Z.H. Huang[a], G. Parashakis[a], C.S.T. Hii[a], J.V. Ferrante[a], A. Poulos[a], D.A. Rathjen[a], M.J. Pitt[a], C.J. Easton[b], and A. Ferrante[a,*]

Fish oils contain an abundance of n-3 fatty acids derived from linolenic acid (18:3n-3), in particular eicosapentaenoic (20:5n-3) and docosahexaenoic acids (22:6n-3). Both of these fatty acids are generally found in low concentrations in nonmarine animals although 22:6n-3 is found in high concentrations in certain specialized tissues such as retina and spermatozoa. There is increasing evidence that the beneficial effects of fish diets are related to the presence of n-3 fatty acids. Thus the ingestion of these fatty acids is thought to be responsible for the lower incidence of cardiovascular disease in certain human populations (1). It has been suggested that they may exert their antiinflammatory effects by inhibiting the 5-lipoxygenase pathway in neutrophils and monocytes. However, some fatty acids, notably *cis* monounsaturated (e.g., oleic acid) and n-6 fatty acids (arachidonic acid), stimulate superoxide production in these cells and could therefore be expected to increase the inflammatory response and cardiovascular homeostasis, resulting in myocardial injury.

Recent findings from our laboratory showed that, unlike the n-3 and n-6 polyunsaturated fatty acids (PUFA), the 15-hydroperoxy derivatives such as HPETE were much more active than the parent fatty acids in depressing tumor necrosis factor (TNF) α-induced increase in the expression of adhesion molecules in endothelial cells (2). This is interesting and of potential therapeutic importance in the treatment of intravascular inflammation since HPETE lacked leukocyte-activating properties, i.e., ability to stimulate neutrophils and macrophages to adhere to the endothelium, release oxygen radicals, and release lysosomal enzymes (3). As such these are devoid of some of the proinflammatory activities of the free fatty acids such as 20:4n-6, 20:5n-3, and 22:6n-3. However the instability of HPETE would preclude its use in any form of therapy.

We have now been able to achieve the synthesis of some compounds (4,5) which have the advantage in that they are not readily β-oxidized and show high levels of intracellular stability. Some of these have similar biological characteristics as the HPETE, such as inhibition of cytokine production and inability to stimulate neutrophil oxygen radical response. This group of novel PUFA has an oxygen atom in the β-position: β-oxa-derivatives; β-oxa-23:4n-6, β-oxa-21:3n-3, β-oxa-21:3n-6 or a sulfur atom in the β-position: β-thia-derivatives; β-thia-23:4n-6, β-thia-21:3n-2, β-thia-21:3n-6. These were examined for antiinflammatory effects in relation to activation of endothelial cell adhesion activity.

Pretreatment of human umbilical vein endothelial cells (HUVEC) with these engineered PUFA markedly reduced their ability to be stimulated by TNF-α, lipopolysaccharide (LPS), or phorbal myristate acetate for enhanced neutrophil adhesion in a time- and concentration-dependent manner, with the β-oxa-PUFA being more potent than the β-thia-PUFA. In contrast, 20:4n-6, 20:5n-3, and 22:6n-3 acids had no significant effect on the stimulus-induced adhesion of leukocytes to HUVEC. The cells remained viable throughout incubations with all fatty acids and recovered from these inhibitory effects. β-Oxa-23:4n-6 caused the greatest attenuation of TNF-α or LPS-induced neutrophil-HUVEC adhesion and was therefore used in subsequent studies. Derivatives of β-oxa-23:4n-6 (including saturated and methyl ester forms) had no inhibitory effect on TNF-α-stimulated adhesion, highlighting the importance of the parent β-oxa-23:4n-6 structure. The β-oxa-23:4n-6 inhibitory activity on adhesion was reflected in the ability of this β-oxa-PUFA to decrease the TNF-α-induced expression of the following endothelial cell adhesion molecules: intercellular adhesion molecule-1, E-selectin, and vascular cell adhesion molecule-1. TNF-α-induced increased expression of E-selectin mRNA was found to be significantly depressed by β-oxa-23:4n-6 to the three oxygenated metabolites, one being tentatively identified as a hydroxylated derivative of β-oxa-23:4n-6. β-Oxa-23:4n-6 inhibition of TNF-α-enhanced neutrophil adherence to HUVEC was abolished when the cells were preincubated with nordihydroguaiaretic acid (lipoxygen-ase inhibitor) but not with indomethacin (cyclooxygenase inhibitor). This suggests that conversion of β-oxa-23:4n-6 to an oxygenated product(s) *via*

Possible Mechanisms for the Putative Antiatherogenic and Antitumorigenic Effects of Conjugated Polyenoic Fatty Acids

A. Farquharson[a], H.-C. Wu[a], I. Grant[a], B. Graf[a], J.-J. Choung[b], O. Eremin[c], S. Heys[c], and K. Wahle[a,*]

[a]Rowett Research Institute, Bucksburn, Aberdeen, AB21 9SB, Scotland, [b]Korean Food Research Institute, Seoul, South Korea, and [c]Department of Surgery, Aberdeen University, Aberdeen, AB25 2ZD, Scotland

Conjugated polyenoic fatty acids (CPFA) are derived from the parent polyenoic acid by oxidation or hydrogenation reactions *in vivo* or *in vitro*. They occur naturally in ruminant-derived foods, due to bacterial hydrogenation in the rumen, and in chemically hydrogenated vegetable fats. The most common CPFA are those derived from linoleic acid (CLA) which occur as a mixture of *cis,trans* and *trans,cis* 9,11 and 10,12 isomers; derivatives of other PFA also occur. Originally regarded as detrimental lipid oxidation products, CLA were recently attributed with antiatherogenic and antitumorigenic properties (1). The cell mechanisms underlying these effects are not known. Our finding that CLA induced glutathione peroxidase (GPx) activity in human umbilical vein endothelial cells (HUVEC) could be important (2). This study highlights other possible beneficial mechanisms elicited by CLA in HUVEC and cancer cells.

Methods and results. HUVEC and human prostate cancer cells (PC3) were treated with 0–150 mM CLA (9, 11 and 10, 12 mix) for 24 h. mRNA expression of GPx, phospholipid GPx (PHGPx) and the adhesion molecules ICAM-1 and E-Selectin was assessed by Northern analysis; PHGPx activity by spectral analysis using an NADPH-coupled assay, and diacylglycerol (DAG) by thin-layer chromatography after incubation with ^{14}C arachidonic acid.

In HUVEC, GPx and PHGPx mRNA were increased *circa* twofold with increasing CLA concentrations although enzyme activity was unchanged. CLA (10 mM) inhibited cytokine-induced adhesion molecules (ICAM-1 and E-Selectin) by 50%. In PC3 cells, CLA increased GPx mRNA by about 50% and reduced DAG to *circa* 50% of control at 100 mM.

Conclusions. Induction of intrinsic antioxidant enzyme mRNA and suppression of adhesion molecule mRNA by CLA in vascular and/or cancer cells suggests these fatty acids are potent modulators of gene expression. These findings also emphasize the possibility that such gene modulations are important mechanisms whereby CLA elicit their reported antiatherogenic and antitumorigenic effects. Increased redox enzyme activity protects against free radical-induced cell damage and is implicated in attenuation of stress protein expression like adhesion molecules, upregulation of which are implicated in increased vascular disease. Enhanced DAG production by malignant prostate tissue was regarded as a tumor-promoting factor through protein kinase C activation similar to phorbol ester action. Inhibition of DAG in PC3 cells by CLA could explain, at least in part, their anticancer effects.

Docosahexaenoic Acid Supplementation Improves the Moderately Severe Dementia from Thrombotic Cerebrovascular Diseases

T. Terano[a,*], S. Fujishiro[b], T. Ban[c], K. Yamamoto[d], T. Tanaka[e], Y. Noguchi[e], Y. Tamura[f], K. Yazawa[g], and T. Hirayama[h]

[a]Department of Internal Medicine, Chiba Municipal Hospital, Chiba 260, [b]Kyoundou Hospital, Tokyo, [c]Kuniyoshi Hospital, Chiba, [d]Kimitsu Central Hospital, Chiba, [e]2nd Department Internal Medicine, Chiba University, Chiba, [f]Kyoundou Hiratsuka Hospital, Kanagawa, [g]Sagami Chemical Research Center, Kanagawa, and [h]Hirayama Hospital, Chiba, Japan

In Japan, the prevalence of dementia of thrombotic cerebrovascular disorders (CVD) is almost the same as that of the Alzheimer type. Supplementation of n-3 polyunsaturated fatty acids (PUFA) improves hemorrheological properties (1) and endothelial function and also might protect neuronal cells, and may result in the improvement of dementia of CVD. Docosahexaenoic acid (DHA), one of the n-3 PUFA, is rich in brain tissue and plays an antithrombotic effect. We administered DHA to the elderly with senile dementia of CVD and evaluated the effect of DHA on dementia using psychometric tests.

Methods. Male and female elderly people (average 83 yr) living in the home for the elderly with mild to moderate dementia of CVD were entered into the study. The controller randomly divided the 20 elderly in two groups according to age, baseline scores of psychometric tests [Mini-Mental State examination (MMSE) and Hasegawa's Dementia rating scale (HDS-R)] and serum fatty acid composition. All the elderly presented MMSE and HDS-R scores of 15–22. Ten elderly received 6 DHA capsules containing 0.72 g of DHA daily for 1 yr (DHA group), and other 10 elderly were registered as a control group. They ate the same food every day and lived together in the same home. Nursing staff gave DHA capsules directly to the elderly three times a day just after meals and ascertained swallowing. Prestudy assessments included clinical history, complete physical and neurological examination, standard laboratory tests, and CT or MRI of brain. All patients were assessed at baseline, and then after 3, 6, and 12 mon of continuous treatment. Assessments were based on psychometric tests (MMSE and HDS-R), as well as clinical evaluation. Serum lipid profiles, red blood cell (RBC) deformability, whole blood viscosity, RBC fragility, platelet aggregation, and fatty acid composition were also monitored after the supplementation of DHA. Informed consent was obtained from each elderly person and his or her family. For statistical analysis, F-test, paired t-test, unpaired t-test, and Wilcoxon signed-ranks tests were used.

Results. No significant pretreatment difference between the two groups emerged for scores of two psychometric tests, age, serum lipid profile, and serum fatty acid composition. In DHA group, scores of HDS-R and MMSE scale improved but in the control group, scores were unchanged or lowered as shown in Table 1 (HDS-R) and Table 2 (MMSE). There was significant difference in the dementia scores 3 to 6 mo after DHA supplementation ($P < 0.05$). In DHA group, the content of DHA and eicosapentaenoic acid (EPA) increased without altering other fatty acids compositions including arachidonic acid (AA). (DHA; before: 5.3 mol%, 3 mon: 6.8, 6 mon: 6.1, 12 mon: 9.5. EPA; before: 3.0, 3 mon: 4.2, 6 mon: 3.9, 12 mon: 5.1. DHA/AA; before: 0.96, 3 mon: 1.19, 6 mon: 1.04, 12 mon: 1.33), but no change of fatty acids compositions was observed in the control group. RBC deformability significantly improved by DHA supplementation ($P < 0.01$). Platelet aggregation by ADP and collagen did not change in both groups after treatment with DHA. There was positive correlation between serum DHA/AA and dementia scores of HDS-R ($n = 32$, $r = 0.44$, $P < 0.05$).

Discussion. In the elderly with moderately severe dementia from thrombotic cerebrovascular disorder, DHA supplementation improved the dementia scores, and this improvement was accompanied with the increase in the content of DHA. This might be mainly derived from the improvement of RBC function, and direct protective effect of DHA on neu-

Dietary 18:3n-3 and 22:6n-3 as Sources of 22:6n-3 Accretion in Neonatal Baboon Brain and Associated Organs

ABSTRACT: The bioequivalence of dietary linolenic acid (LNA) and docosahexaenoic acid (DHA) for brain DHA accretion was measured in neonatal baboons at 4–6 wk of age using stable isotope tracers. Neonates consumed a conventional U.S. term-infant formula devoid of long chain polyunsaturates and with an n-6/n-3 ratio of about 10:1. At 4 wk of age, neonates were dosed with either ^{13}C LNA or ^{13}C DHA. At 6 wk of age, neonate brain, retina, and other organs were harvested for fatty acid and isotopic analyses. The relative accretion of labeled DHA was 7-fold greater as a percentage of dose for the DHA-dosed animals compared to the LNA-dosed animals. The baboon is an omnivore that regularly consumes meat and insects; its plasma lipid profile responds similarly to humans in response to changes in feeding and living habits. These observations suggest that the baboon is a suitable model for human unsaturated fatty acid studies.

It has long been known that n-3 fatty acids cannot be synthesized *de novo* by mammals and must be acquired from the diet. From studies in rats (1,2), primates (3–6), and human infants (7–9), it is now well established that docosahexaenoic acid (DHA) is required for proper function of the brain and retina. The predominant n-3 fatty acid in terrestrial foods is α-linolenic acid (LNA), which can be converted to the functionally important long chain polyunsaturated fatty acids (LCP) eicosapentaenoic acid (EPA), and DHA primarily by a series of alternating desaturations and elongations. DHA can be acquired in the diet from marine foods and is present in all human breast milks. Only recently have commercial infant formulas begun to include preformed DHA, as it has been implicitly assumed that all infants could meet their needs for DHA through biosynthesis from LNA. However, there are no direct measurements of the bioequivalence of dietary LNA as a substrate for DHA accretion compared to dietary preformed DHA in infants or in any primate species.

Dietary fatty acids rapidly affect expression of one of the desaturases, the stearoyl-CoA desaturase (Δ-9), in the mouse (10). In addition, dietary fatty acids have specific and direct effects on gene expression (11–13). Thus, it is likely that the metabolism of tissue fatty acids depends on the mix of dietary fatty acids. Quantitative studies of fatty acid interconversion are best conducted under conditions where the diet of the subjects is controlled. There are no data available on the modulation of desaturases directly relevant to n-6 or n-3 fatty acid metabolism. In the absence of such information, it is reasonable to assume that synthesis of DHA from LNA is downregulated when DHA is present in the diet, which in turn implies that the organism's synthesis of DHA is maximal when DHA is absent from the diet. Further, the bioequivalence under conditions of dietary LNA or DHA excess is of much less practical importance than when DHA is absent and LNA is at marginal levels. It is of most interest to determine the amount of dietary DHA that could replace dietary LNA when LNA levels are low.

In part because the primate brain is more than twice as massive relative to body weight than rodents and other common laboratory species, we sought to study brain DHA accretion directly in primates. Our previous measurements in pregnant baboons showed that doses of [U-^{13}C]-LNA (LNA*) or [U-^{13}C]-DHA (DHA*) result in fetal brain DHA accretion that plateaus at about 1 4 d post-dose (14). Doses directly to a neonate are expected to equilibrate at least as quickly since the tracer enters the neonate bloodstream directly. Also, the apparent plateau observed in fetuses coupled with common experience that DHA deficiency is very difficult to produce in adult animals suggests that DHA is avidly retained by the brain.

The goal of these studies was to determine the bioequivalence of LNA and DHA as substrates for brain DHA accretion in infant primates. Commercially available infant formula, de-

void of LCP and with an n-6/n-3 ratio of about 10:1, was used as a basal diet, and ^{13}C-fatty acids were used to characterize total accretion in brain and other organs.

METHODS

All procedures were approved by the Cornell Institutional Review Board on Animal Use. Six pregnant baboons (*Papio cynocephalus*) were flown from a colony at San Antonio, Texas, to Ithaca and were immediately placed on specially prepared diets balanced in all nutrients with an n-6/n-3 ratio of 10:1 and devoid of LCP, as described in detail previously (14). Pregnant baboons remained on the diets for at least 8 wk prior to birth. Near term (182 d), a caesarean section was performed to avoid nursing, and neonates were placed in a temperature- and humidity-controlled nursery. Neonates consumed a commercial human infant formula obtained at a local supermarket. At 4 wk of age, neonates received oral doses of [U-^{13}C]-labeled fatty acids, LNA* or DHA*, loaded into formula during normal preparation. At 6 wk, brain (occipital cortex), retina, retinal pigment epithelium (RPE), liver, erythrocytes, and plasma were obtained at necropsy, and fatty acids (FA) were extracted by standard methods. Fatty acid methyl esters were prepared and analyzed by gas chromatography and by high-precision mass spectrometry as described in detail elsewhere (15,16).

Isotope ratios and quantitative profiles were used to calculate percentage of dose (dose%) and percentage of total label found in a pool at a particular time point (total%). Units of dose% are useful as normalized measures of isotope tracer relative to tracee. As long as the tracer dose does not interfere with normal physiology (i.e., it is a true tracer), dose% is interpreted as the percent of tracee that appears in a particular pool at a particular time point in a particular form. For instance, a finding that dose 1.6% appears in brain DHA after an LNA dose means that 1.6 of 100 mmol dietary LNA molecules were converted to DHA and appeared in the brain.

RESULTS AND DISCUSSION

No significant differences were found in brain and liver weights between LNA*- or DHA*-dosed neonatal baboons. Brain weight averaged about 8% of total body weight in these 6-wk-old baboons.

No statistically significant differences in FA profiles between LNA* and DHA*-dosed neonates were detected. The brain DHA composition was 9% of total FA, similar to previous findings in fetuses (8.2%) , and consistent with the figure of 7% in human infants . Retinal DHA levels were 16% of total FA again in agreement with human infant data; this tissue was the highest in DHA concentration of those investigated. DHA constituted 1 to 4% of total FA in RPE, liver, plasma, and erythrocyte.

Brain tissue had more than twice the DHA concentration per gram wet tissue (1.35 mg) than liver (0.6 mg). Erythrocytes and plasma had 0.02 and 0.05 mg DHA per mL, respectively, and there were 0.23 and 0.03 mg of DHA per retina and RPE, respectively.

Figure 1 shows the distribution of labeled FA in liver at 2 wk post-dose. DHA* was the predominant labeled FA resulting from both doses. However, the total amount of dose retained was about 2.4% for the DHA* dose compared to about 0.13% due to the LNA* dose. DHA* was overwhelmingly the bulk of the label found due to the preformed DHA* dose, while from the LNA* dose about 30% of the label was detected as 22:5n-3. The ratio of DHA* due to DHA* or LNA* doses was 27:1 in liver.

Figure 2 shows the distribution of labeled FA in brain. Preformed DHA* dose was detected at 1.71%, while 0.23% of the LNA* dose detected as DHA*. Thus preformed DHA was 7-fold more effective than LNA-derived DHA as a source for DHA accretion. The distribution of labeled FA was determined in each tissue. DHA* was >95% of labeled FA in all tissues examined, although a small amount of retroconversion to labeled docosapentaenoic acid (DPA*) and EPA* was ob-

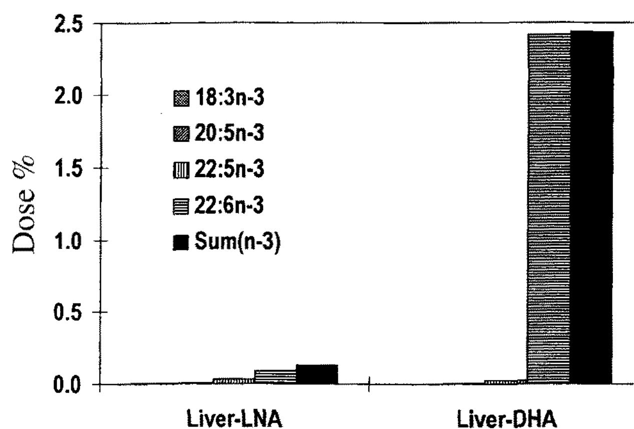

FIG. 1. Liver distribution of labeled fatty acids at 2 wk post-dose, showing (DHA) to be the predominant fatty acid due to either (LNA) or DHA dose, and that 2.4% of the DHA was retained compared to 0.13% of the LNA dose.

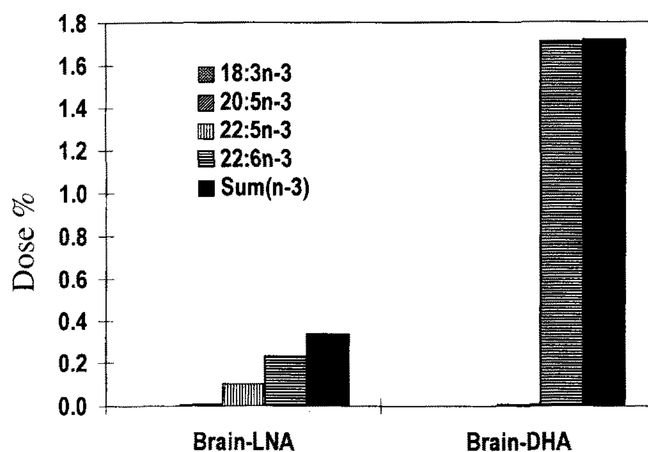

FIG. 2. Brain distribution of labeled fatty acids at 2 wk post-dose showing DHA at 1.7 and 0.23% of the DHA and LAN doses, respectively. See Figure 1 for abbreviations.

served. For the LNA*-dosed animals, the distributions of labeled FA metabolites for LNA*-dosed animals were in the order DHA>DPA>EPA>LNA, except for erythrocytes, where the order was DPA>DHA>EPA>LNA. In LNA*-dosed animals, DHA* was greater than 60% of labeled FA in tissues except erythrocytes, where DPA was 55%.

From these data we have estimated that brain DHA turnover is <5% per week between 4 and 6 wk of age . For retina and RPE, respectively, preformed DHA was found at 12- and 15-fold greater concentration than LNA-derived DHA. Liver, plasma, and erythrocytes ratios were 27, 29, and 51, respectively, showing that blood pools do not parallel tissue handling of a single dose of n-3 FA. These are the first direct measurements of the bioequivalence of DHA and LNA in neonatal primates.

There is considerable species variation in desaturation activity. Rodents are thought to be prodigious desaturators, while cats have long been known to have poor capability to synthesize 22:6 from precursors (19). In cats, this limitation is manifest in abnormal electroretinograms when young animals consume diets devoid of n-3 LCP, even though arachidonate levels are maintained (20). Presumably, this is related to the normal feline diet of meat and organs, which is rich in LCP. A trend thus emerges suggesting that biosynthesis of LCP from C_{18} precursors is species-specific and is related to the natural diet, with herbivores capable of rapid desaturation and carnivores less capable. The human is an omnivore whose conversion capability is expected to be between these extremes.

Baboons have been observed extensively in the wild. They are omnivorous primates whose diet includes insects and vertebrate small animals such as hares, birds and eggs, rodents, and newborn mammals (21,22). Baboons blood lipids, primarily plasma cholesterol and high density lipoprotein cholesterol, are known to be related to their incidence of atherosclerosis, and their responses to diets of differing FA composition parallel humans (23,24). Their feeding behaviors and endocrine responses are related to social dominance and appear to reflect social stress (25–31). Baboons frequenting a human dumpsite and consuming discarded human processed foods (including meats and high-energy desserts), gained weight rapidly, became lethargic, and reached puberty early (32). They also contracted bovine tuberculosis from infected meat (33). All these parallels to human physiology suggest that the baboon may be a highly relevant model for physiological processes that are related to dietary and environmental factors.
