ABSTRACT: Neutral glycolipids (NGL) are promising diagnostic markers of human gliomas, but differences in NGL with age and sex have not been examined. Previous work demonstrated that ceramide dihexosides (CDH) levels in mouse kidney are age- and sex-dependent, probably due to levels of sex hormones. We quantitated CDH in 181 human gliomas and found significant differences with sex and age, particularly menopause and male puberty. This emphasizes the importance of assessing results of studies on glycolipids in disease states with respect to age and sex in order to avoid erroneous conclusions concerning the relationship of glycolipid composition with diagnosis and pathogenesis.

Paper no. L8027 in *Lipids 34,* 1–4 (January 1999).

Neutral glycolipids (NGL) are ubiquitous within the animal kingdom. Although the specific biological functions of most NGL are unknown, evidence exists that specific ones function as receptors for microorganisms and some bacterial toxins (1–3), and that sialylated glycolipids (gangliosides) can modulate the activities of several receptors (4). Additional evidence for the biological importance of glycolipids is that they undergo major compositional changes with growth, differentiation, and many disease processes including malignant transformation (5–11). The NGL of some tissues also differ between males and females. Such differences have been most extensively studied in murine kidney, in which the most consistent change is that males have more ceramide dihexosides (CDH) than females (12,13), a difference most pronounced after puberty (14). A similar difference occurs in normal human thyroid (15). Although it is well documented that many types of tumors have NGL compositions different from those of the normal tissues from which they were derived (11), we are unaware of reports of a difference in NGL composition within the same tumor type that correlates with patient sex or age. In an ongoing comprehensive study of NGL in human brain tumors, we found a striking sex-related difference in the amount of CDH within these tumors. This novel finding forms the basis of this communication.

Abbreviations: CDH, ceramide dihexosides; CDH-L, lower band of CDH; CDH-T, total of upper and lower bands of CDH; CDH-U, upper band of CDH; GalCer, galactosylceramide; $GaOse_2Cer$, galabiglycosylceramide, Gal(α1-4)Gal(β1-1)Cer; H and E, hematoxylin and eosin; Hfa, Hydroxy fatty acid; HPTLC, high-performance thin-layer chromatography; LacCer, lactosylceramide; Nfa, nonhydroxy fatty acid; NGL, neutral glycolipids; Sph, sphingosine.

EXPERIMENTAL PROCEDURES

Tissues were removed at surgery and frozen in liquid nitrogen, in most cases within 30 min of excision. To be certain that it consisted of tumor, a small portion of this tissue was processed for microscopy as a frozen section, stained with hematoxylin and eosin (H and E) for histological study by a neuropathologist (AJY). Other portions of the tumor were prepared for diagnostic histology by formalin fixation, paraffin embedding, and staining with H and E and other methods as required. Three neuropathologists (BWS, PCB, and AJY) independently examined representative slides of all tumors. With respect to diagnosis and grade, the majority opinion was accepted.

Frozen tissues were thawed, weighed, lyophilized overnight, desiccated for 1 h, and then weighed again. Dried samples were homogenized in 20 vol of chloroform/methanol/water (1:2:0.75) and insoluble materials removed by centrifugation. The supernatant was removed, the pellet rehomogenized in chloroform/methanol/water (1:1:0.1), and the homogenate centrifuged. The supernatant was pooled with the first supernatant after which the pooled sample was dried under nitrogen and reconstituted in chloroform/methanol/water (30:60:8). Neutral lipids were first separated from acidic lipids on a DEAE-Sephadex column (3-mL bed volume) by eluting them with 30 mL chloroform/methanol/water (30:60:8) and then taken to dryness. NGL were purified using an acetylation technique based on that of Saito and Hakomori (16) with two modifications: neutralization was with 0.01 N HCl; neutralized samples were then taken to dryness, dissolved in chloroform and desalted by centrifugation from chloroform. Total NGL content was estimated using the orcinol method of Neskovic *et al.* (17) with galactose serving as a standard. Individual NGL were separated on silica gel 60 high-performance thin-layer chromatography (HPTLC)

Copyright © 1999 by AOCS Press

plates in chloroform/methanol/water (65:25:4), visualized with diphenylamine (18), and quantitated by scanning densitometry at 580 nm in reflectance mode. Values for NGL were corrected based on external standards carried through the entire extraction, purification, and quantitation procedure.

RESULTS

The total number of tumors studied was 181, including 45 oligodendrogliomas, 92 astrocytomas, 15 oligo-astrocytomas, and 29 other primary brain tumor types. The last consisted of 9 primitive neuroectodermal tumors, 4 ependymomas, 4 anaplastic ependymomas, 1 subependymoma, 1 gangliocytoma, 1 ganglioglioma, and 9 unclassifiable primary brain tumors. Of all specimens, 69 arose in females and 112 in males.

On HPTLC the CDH from all tumors ran as a doublet, the more rapidly migrating upper band (CDH-U) frequently constituting more than half of the total CDH (CDH-T) (Fig. 1). Data regarding the amounts of CDH-U (expressed as μg hexose/mg tissue dry weight) for all tumors showed that the median values for males (16.9) were twice those of females (8.3). There were similar differences between median values for the lower band of CDH (CDH-L) in males (17.2) and females (10.3), and for CDH-T in males (35.4) and females (16.4). However, these sex differences vary among different age groups (Table 1). CDH levels are equal in both sexes at ages less than 14 yr. After that, CDH levels increase in males but not in females until after 50 yr of age (Table 1). Expressed on a log scale, values for CDH-T were subjected to an analysis of variance with the least squares difference post hoc test and an experiment-wise error rate of less than 5%. This showed that there was significantly more CDH-T in males over 50 yr than in each of the other age–gender groups. Furthermore, females 14 to 50 yr of age had significantly less CDH-T than either 14- to 50-yr-old males, or females over 50 yr of age. All other pair-wise differences were not statistically significant. A similar pattern of statistically significant differences was seen for CDH-U, CDH-L (Table 1) for all tumors and for CDH-T (Table 2) in astrocytomas. The same trend occurred in the remaining three diagnostic categories (oligodendrogliomas, oligo-astrocytomas, and other tumors), but there were too few patients under 14 and over 50 yr in these groups to permit a meaningful statistical analyses.

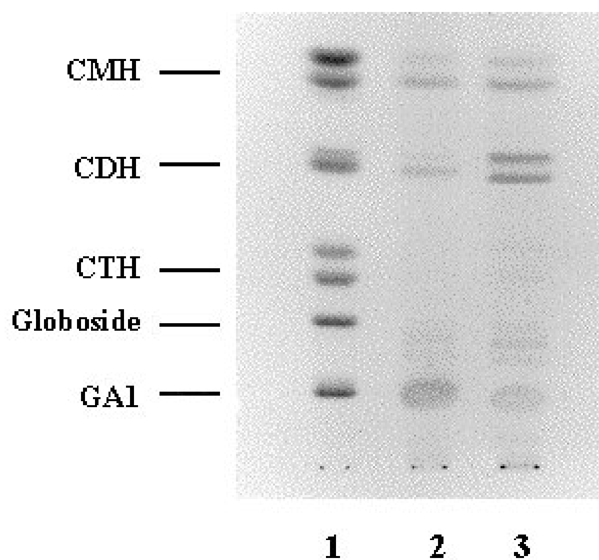

FIG. 1. Total neutral lipids isolated from glioblastoma multiforme tissues separated by high-performance thin-layer chromatography and detected by diphenylamine reagent. Each lane contains a total of 6 μg total hexose. Lane 1, standards; lane 2, female 69 years of age; lane 3, male, 83 years of age. CMH, ceramide monohexoside; CDH, ceramide dihexosides; CTH, ceramide trihexoside; GA1, asialo-GM1.

DISCUSSION

In the TLC solvent system used in our study, galabiglycosylceramide ($GaOse_2Cer$) and lactosylceramide (LacCer) co-migrate (15). Owing to limited amounts of specimens, we were unable to determine the relative contributions of these to the CDH in either the upper or lower bands, which separated on the basis of fatty acid content. However, evidence exists that in some tissues the contents of both types of CDH are greater in postpubertal males than in females either before or after puberty (14). In some mouse strains the CDH in kidney is $GaOse_2Cer$, whereas in others it is LacCer (12,14). Regardless of which type of CDH is present, a sex-related difference exists in the amount of CDH in the kidneys of all mouse strains studied (12–14). Although prior to puberty the CDH content of mouse kidney is the same in both sexes, postpubertal males had considerably larger amounts of CDH than females (14). The amount of galabiglycosylceramide in kidney cells cultured from C57BL/6J male mice is also greater than in cells cultured from females (19). Experimental evidence indicates that these sex-related differences are due to sex hormones. Administration of testosterone to adult female C3H/He, C57/BL, and C57BL/6J mice induced a marked increase in total kidney NGL, especially CDH (13,20). In kidneys of C57BL/6J mice there was a significant increase in $GaOse_2$-Sph-Nfa, a "male-specific glycolipid" (13). In the solvent system we used, this glycolipid migrates in the upper band of CDH (CDH-U), the CDH we found to be present in the largest amounts in tumors from postpubertal males. Estrogen administration to male rats also affected the NGL of kidney, thus indicating that it too can affect glycolipid metabolism (21). Perhaps this explains the increase in CDH in tumors from postmenopausal females (Tables 1 and 2). Whether or not there is a gender-related difference in sex hormone receptors in human gliomas is not known, but there is no gender-related difference in histological appearance of human gliomas.

The sex-related differences in CDH appear to be the result of differences in the activities of glycosyltransferases responsible for the synthesis of GalCer and CDH (22). With respect to our work, it is significant that the following were all elevated in male kidneys: glucosylceramide:UDP-Gal galactosyltransferase; Nfa-Ceramide:UDP-Gal galactosyltrans-

TABLE 1
Sex- and Age-Related Difference in Upper and Lower Bands of CDH

			CDH-U[a]		CDH-L[a]		CDH-T[a]	
Age (yr)	Sex[b]	N[c]	Median	Mean ± SE	Median	Mean ± SE	Median	Mean ± SE
Under 14	F	16	8.2	14.0 ± 4.8	6.8	10.9 ± 3.6	15.6	20.6 ± 5.2
	M	17	8.5	10.8 ± 2.0	5.9	7.8 ± 1.4	14.8	20.2 ± 4.2
14–50	F	33	6.8	12.3 ± 3.2[f]	8.2	11.4 ± 2.6[f]	15.0	22.3 ± 4.8[g]
	M	47	16.0	20.6 ± 3.2	15.5	18.6 ± 2.7	29.6	34.2 ± 4.3
Over 50	F	20	14.4	24.7 ± 6.7	19.1	24.3 ± 6.2	37.2	48.6 ± 11.9
	M	48	29.4	33.2 ± 3.7[d]	26.6	28.0 ± 3.2[e]	55.3	61.9 ± 5.9[d]

[a]CDH-U (probably Nfa-LacCer) and CDH-L (probably Hfa-LacCer) refer to the upper and lower bands, respectively, of ceramide dihexosides (CDH) that separated on thin-layer chromatography in chloroform/methanol/water (65:25:4). CDH-T is the total of these two bands. Values are in mg hexose/mg tissue dry weight.
[b]F and M are female and male, respectively.
[c]N is the number of individual tumors analyzed.
[d]Significantly greater values than all other age–sex groups (experiment-wise $P < 0.05$).
[e]Significantly greater values than all other age–sex groups except females >50 (experiment-wise $P < 0.05$).
[f]Significantly ($P < 0.05$) lower values than males 14–50 yr of age and marginally significantly ($P \approx 0.06$) lower than females >50.
[g]Significantly ($P < 0.05$) lower values than males 14–50 yr of age and females >50.

ferase; Hfa-Galcer: UDP-Gal galactosyltransferase. These differences in enzyme activities would cause an increase in the synthesis of both Hfa-CDH and Nfa-CDH by males, with an even greater synthesis of the latter. A similar sex-related difference in enzyme activities could be responsible for our finding of greater amounts of CDH (more pronounced for CDH-U than CDH-L) in tumors from males than of females. Also consistent with our findings are reported sex-related differences in CDH of human thyroid (15). Male thyroid contains significant amounts of both $GaOse_2Cer$ and LacCer, whereas female thyroid has only small amounts of the former. Although there is very little CDH in normal human brain, most of it is LacCer (23). To our knowledge there has been no study comparing amounts and types of CDH in brains of males and females. Seyfried *et al*. (24) have found that infiltrating inflammatory cells can alter the glycolipid composition of brain tumors implanted into the flank of animals, but they did not report studying differences based on the sexes of the host animals. Nevertheless, attempts to identify the cellular location of glycolipids in tumors growing *in vivo* must take their findings into account.

TABLE 2
Sex- and Age- Related Differences in Total CDH in Astrocytomas[a]

Age (yr)	Sex	N	Median	Mean ± SE
Under 14	F	10	14.7	24.0 ± 8.3
	M	7	14.1	20.9 ± 8.7
14–50	F	12	12.4	22.23 ± 7.0[c]
	M	17	41.8	45.6 ± 7.5
Over 50	F	14	54.2	66.1 ± 14.5[d]
	M	32	67.8	72.8 ± 7.2[b]

[a]Abbreviation and units are as in Table 1.
[b]Significantly greater values than all other age–sex groups except females >50 (experiment-wise $P < 0.05$).
[c]Significantly ($P < 0.05$) lower values than males 14–50 yr of age and females >50.
[d]Significantly ($P < 0.05$) greater values than females <14 and marginally significantly ($P \approx 0.06$) greater than males <14.

There have been few investigations of NGL in primary tumors of the human central nervous system, but those published report that CDH is frequently increased in such neoplasms. Based on small series of astrocytic tumors, Eto and Shinoda (25) and Wiegandt and colleagues (26,27) found CDH to be increased in those of higher histological grade. Singh *et al*. (28) performed glycolipid analyses on 98 primary human brain tumors of several types. The only significant association they found was that anaplastic astrocytomas had higher concentrations of CDH-U, CDH-L, and CDH-T than any of the other tumor types. In none of these studies did the investigators report a difference in the amounts of CDH between tumors from males and females. In contrast, our findings underscore the importance of analyzing such data for sex- and age-related differences in that they may mask important differences in glycolipid composition among tumor types.

n-3 and n-6 Fatty Acid Enrichment by Dietary Fish Oil and Phospholipid Sources in Brain Cortical Areas and Nonneural Tissues of Formula-Fed Piglets

[a]Institut National de la Recherche Agronomique, Laboratoire de Nutrition et Sécurité Alimentaire, Jouy-en-Josas, France, and [b]CIRDC, Le Plessis-Robinson, France

ABSTRACT: Sufficient availability of both n-3 and n-6 long-chain polyunsaturated fatty acids (LCPUFA) is required for optimal structural and functional development in infancy. The question has been raised as to whether infant formulae would benefit from enrichment with 20 and 22 carbon fatty acids.To address this issue, we determined the effect of fish oil and phospholipid (LCPUFA) sources on the fatty acid composition of brain cortical areas and nonneural tissues of newborn piglets fed artificially for 2 wk. They were fed sow milk, a control formula, or the formula enriched with n-3 fatty acids from a low-20:5n-3 fish oil added at a high or a low concentration, or the formula enriched with n-3 and n-6 fatty acids from either egg yolk- or pig brain-phospholipids. Both the fish oil- and the phospholipid-enriched formula produced significantly higher plasma phospholipid 22:6n-3 concentrations than did the control formula. The 22:6n-3 levels in the brain, hepatic, and intestinal phospholipids were significantly correlated with plasma values, whereas cardiac 22:6n-3 content appeared to follow a saturable dose-response. Feeding sow milk resulted in a much higher 20:4n-6 content in nonneural tissues than did feeding formula. Supplementation with egg phospholipid increased the 20:4n-6 content in the heart, red blood cells, plasma, and intestine in comparison to the control formula, while pig brain phospholipids exerted this effect in the heart only. The addition of 4.5% fish oil in the formula was associated with a decline in 20:4n-6 in the cortex, cerebellum, heart, liver, and plasma phospholipids, whereas using this source at 1.5% limited the decline to the cerebellum, liver, and plasma. Whatever the dietary treatment, the phosphatidylethanolamine 20:4n-6 level was 10–20% higher in the brain temporal lobe than in the parietal, frontal, and occipital lobes in the temporal lobe by administering the formula enriched with egg or brain phospholipids.

In conclusion, feeding egg phospholipids to neonatal pigs increased both the 22:6n-3 content in the brain and the 20:4n-6 content in the temporal lobe cortex. This source also increased the 22:6n-3 levels in nonneural tissues with only minor alterations of 20:4n-6. These data support the notion that infant formulae should be supplemented with both 22:6n-3 and 20:4n-6 rather than with 22:6n-3 alone.

Paper no. L7972 in *Lipids 34,* 5–16 (January 1999).

Long-chain polyunsaturated fatty acids (LCPUFA) with 20 and 22 carbon atoms, mainly 20:4n-6 and 22:6n-3, are integral constituents of the central nervous system and are thought to play a major role in the development of neural functions during the late fetal and early postnatal periods (1). LCPUFA are necessarily provided by the diet, either directly or in the form of their precursors with 18 carbon atoms, i.e., 18:2n-6 and 18:3n-3. The developing brain prefers preformed 22:6n-3 over 18:3n-3 for fatty acid uptake from blood and brain phospholipid synthesis (2), suggesting that preformed LCPUFA in the diet may be better for securing optimal brain function.

Human milk contains both precursors and LCPUFA (3), whereas conventional infant formulae are almost free of LCPUFA, owing to the fact that their lipid component is essentially constituted by vegetable and oleo oils which naturally contain only fatty acids up to 18 carbons. The need to supplement infant formulae with preformed LCPUFA from other lipid sources continues to be debated vigorously.

Preferential depletion of 22:6n-3 has been found in the cerebral cortex of infants who died from sudden death syndrome fed conventional formulae (4–6), and clinical trials have reported that the addition of preformed LCPUFA in the formula may improve performance on early mental development tests in comparison to conventional formula feeding (7,8). Blood 22:6n-3 content and visual acuity both correlate with the dietary supply of preformed 22:6n-3 (9), although normal visual development also occurs when the formula is fortified solely with 18:3n-3 at the level of at least 2% by weight of total fatty acids (10,11). Both preterm and full-term infants can synthesize LCPUFA from their 18-carbon precursors through the Δ6- and Δ5-desaturation pathways (12–14). However, formula-fed full-term infants are unable to match the n-3 and n-6 LCPUFA status of breast-fed full-term infants until at least 2 mon after birth (15), and adding preformed

22:6n-3 to formulae is undoubtedly more effective than increasing 18:3n-3 to maintain blood phospholipid 22:6n-3 levels similar to those in breast-fed infants (16). Moreover, an adverse effect of lowering the 18:2n-6 to 18:3n-3 ratio on the weight gain of term infants has been recently reported (17), showing that the physiological results of high 18:3n-3 intake in early infancy has to be more accurately evaluated. Dietary LCPUFA may be considered indispensable nutrients for the formula-fed neonate if it is admitted that the lipid status of breast-fed infants is significant.

Enrichment of term infant formulae with preformed LCPUFA at typical breast milk levels has been recently acknowledged as a goal by the Commission of the European Union (18). The question of the nature of the lipid source to use, and whether both 20:4n-6 and 22:6n-3 must be added, remains partly unsolved. Two options may be considered: supplementing either with n-3 LCPUFA only or with both n-6 and n-3 LCPUFA. With this perspective, we studied the effects of adding LCPUFA from different dietary sources, in amounts similar to those found in average human milk, upon the LCPUFA status in the piglet model (19).

We have experimented with two types of LCPUFA enrichment: either by supplementing n-3 without n-6 LCPUFA using fish oil triglycerides, or by supplementing both n-3 and n-6 LCPUFA using animal phospholipids. In the first case, a low-20:5n-3 fish oil was chosen in an attempt to circumvent the competing effect between 20:5n-3 and 20:4n-6 for phospholipid acylation and metabolic conversion. The effect of an excess supply of n-3 LCPUFA was also examined by adding the fish oil in higher amounts than needed. In the second case, we compared two different phospholipid sources purified either from hen egg yolks or from pig brains. The direct supply of the LCPUFA found in natural phospholipids could be particularly beneficial. The developing brain preferentially uses 22:6n-3 from plasma lysophosphatidylcholine (lyso-PC) over unesterified 22:6n-3 for the synthesis of brain phospholipids (20). Some activity of dietary phosphatidylserine on memory retrieval and exploration in mice has been found (21), and the use of this phospholipid has been considered for treating memory loss in later life (22). In infant nutrition, the main advantage of dietary phospholipids would be the simultaneous supply of LCPUFA from both series. Eggs produced by hens reared in free-range conditions have almost equal amounts of 20:4n-6 and 22:6n-3 and are therefore particularly suited to infant feeding (23). The LCPUFA from egg lipids are absorbed as effectively as from human milk (24).

A conventional infant formula was supplemented with the low-20:5n-3 fish oil (ratio of 20:5n-3/22:6n-3 < 1) added either at a low or high concentration (n-3 LCPUFA < 1% and > 1%, respectively), or with the phospholipid concentrate containing similar levels of 20:4n-6 and 22:6n-3 (n-6 LCPUFA < 2%, n-3 LCPUFA < 1%, 20:5n-3/22:6n-3 < 1). After 2 wk, we analyzed the phospholipid fatty acid compositions of the red blood cells (RBC), blood plasma, liver, intestine, heart, cerebellum, whole cerebral cortex, and individual cortical areas of the piglets.

MATERIALS AND METHODS

Animals and milk replacer diet. Official French regulations (Nos. 87 848 and 03 056) for the care and use of laboratory animals were followed. Nonlittermate piglets (Pietrain × Large White) were fed from birth to 14 d of age with either sow milk (group SM), a conventional infant formula (group F), or an LCPUFA-enriched formula, according to the environmental conditions previously described (25). The weight of the newborn piglet brain gains 40% within 2 wk after birth, whereas the same relative gain requires 9 wk in the human term infant. On the basis of this single criterion, one might say that the 2 wk-postpartum period in piglet is comparable to the 9 wk-postpartum period in the term infant, the latter period corresponding to the mean duration of breast-feeding in France.

Seven nonlittermate piglets were fed sow milk (group SM). Five to eight nonlittermate piglets were randomly assigned to one of the five formula-feeding groups after receiving the colostrum for 12 h. Standard sow milk contained LCPUFA of both the n-6 and n-3 series: the major n-6 LCPUFA was 20:4n-6, and 22:5n-3 was the major LCPUFA of the n-3 family (Table 1).

The basic milk-replacer powder was manufactured by Diépal-nsa (Steenvoorde, France). It was similar to an infant formula, but the nutrient formulation was adapted to meet the specific energy requirement of the piglets, i.e., 4200 kJ/L. The formula fat was composed of a blend of palm, coconut, sunflower, and soybean oils. The LCPUFA enrichments were obtained by adding either the low-20:5n-3 fish oil (groups R and R+), egg yolk phospholipids (group E), or pig brain phospholipids (group P). Total lipids in all formulae accounted for 30% by weight of the dry matter. The final fatty acid compositions are given in Table 1. The different formulae supplied similar amounts of 18:2n-6 and 18:3n-3, i.e., 16.5 to 18% and 1.1 to 1.3% of total fatty acids, respectively.

Low-20:5n-3 fish oil supplementation (groups R and R+). A 22:6n-3-rich marine oil product (gift from Produits Roche, Neuilly-sur-Seine, France), with a low 20:5n-3 to 22:6n-3 ratio, was added to the formula in the proportion of either 1.5% by weight of total lipids (group R) or 4.5% (group R+). The final 22:6n-3 and 20:5n-3 contents were 0.3 and 0.1% in formula R, and 0.9 and 0.3% in formula R+, respectively. Arachidonic acid was detectable only in formula R+ (20:4n-6 < 0.1% of total fatty acids).

Egg yolk phospholipid supplementation (group E). Egg yolk lipids have been suggested as a source of LCPUFA in infant feeding (23). Eggs were harvested from hens fed a diet containing 4% by weight of rapeseed oil (26). The yolk phospholipids were prepared by Institut Yves Ponroy (Bailly, France). The phospholipid concentrate was composed of 67% PC, 24% phosphatidylethanolamine (PE), 6% phosphatidylinositol (PI), and 3% sphingomyelin, after class separation using high-performance liquid chromatography and detection by light scattering (see below). It was stored at −80°C under nitrogen until use. The 20:4n-6, 22:6n-3, and 20:5n-3 con-

[a]SM, sow milk, mean values from colostrum (first value of pair, $n = 8$ samples) to mature milk (second value, $n = 3$ samples).
[b]F, standard infant formula containing a mixture of vegetable oils.
[c]P, formula F enriched with pig brain phospholipids (8.5% of total lipids).
[d]E, formula F enriched with egg phospholipids (17% by weight of total lipids).
[e]R, formula F enriched with low-eicosapentaenoic acid fish oil (1.5% by weight of total lipids).
[f]R+ formula F enriched with low-eicosapentaenoic acid fish oil (4.5% by weight of total lipids). Abbreviation: MUFA, monounsaturated fatty acids.

tents in the phospholipid concentrate were 5.5, 4.9, and 0.1% by weight of total fatty acids, respectively. It was added to the formula fats in the proportion of 17% by weight of total lipids. The egg phospholipid-supplemented formula contained 0.5 and 0.4% by weight of total fatty acids as 20:4n-6 and 22:6n-3, which is close to the mean values generally found in the mature milk of European women (27–29).

Pig brain phospholipid supplementation (group P). Although brain phospholipids cannot currently be considered an edible product acceptable for infant nutrition (owing to prion diseases), we have tested this "endogenous" source as a possible nutritional reference concerning the specific needs of the developing brain for its own structural LCPUFA. Cerebral phospholipids (prepared by the Institut Yves Ponroy) were purified from pig brains and adsorbed onto an aerosyl (silica powder) matrix according to the method previously described (30). The brain phospholipids were composed of PC (43% by weight of total phospholipids), PE (31%), phosphatidylserine (15%), sphingomyelin (8%), and PI (3%). In the supplemented formula, the added brain phospholipids accounted for 8.5% of total dietary fats. Arachidonic acid and 22:6n-3 were present at the same concentration, i.e., 0.4% of total fatty acids.

Collection of tissues. After the 2-wk feeding period, piglets were fasted overnight, with water *ad libitum*, and then killed. Ten milliliters of blood were collected with heparin as anticoagulant and centrifuged. The plasma was drawn off, and the RBC were washed twice with 20 mmol/L Tris HCl, 150 mmol/L NaCl, 1 mmol/L EDTA (pH 7.4). The plasma and RBC were lyophilized.

The whole brain was excised, rinsed with 9 g/L NaCl, drained, and weighed. The whole fresh brain weighed 39.9 ± 1.4 g (mean ± sd) whatever the type of feeding. The brains in groups R and R+ weighed on average 8% less than those of group SM, but this difference was not significant (data not shown). The cerebellum was detached, rinsed, drained, and weighed. The cerebral cortex was entirely excised from the right hemisphere, whereas the left cerebral cortex was dissected into the four main cerebral areas, i.e., frontal, parietal, temporal, and occipital lobes. Preliminary experiments showed that the right and left cerebral hemispheres were not different in terms of phospholipid fatty acid composition (data not shown). Thus, the right hemispheres were used to determine the fatty acid composition in the whole cortex, whereas the left hemispheres from the same animals were used to specify the fatty acid distribution in the four cortical areas. The frontal, parietal, temporal, and occipital lobes represented 32.7 ± 1.0, 33.3 ± 1.9, 16.6 ± 0.8, and 17.4 ± 1.4% (mean ± sd) of the total cortical weight, respectively.

All samples were lyophilized, weighed and thoroughly homogenized before extraction of total lipids. Other organs (liver, heart, and proximal jejunal cells) were collected and prepared as previously described (25) for extraction of total lipids.

Determination of fatty acid composition. Total lipids were extracted from the blood and tissue samples (31). The plasma total phospholipids were separated from neutral lipids by filtration through silica cartridges (Waters, Milford, MA) (32). The plasma phospholipids, composed of 90% PC, were not further purified. The two major phospholipid classes in the different tissue samples, PC and PE, were separated by high-performance liquid chromatography coupled with a light-scattering detector (33,34). The total lipids were loaded onto a 25 cm × 7.5 mm silica column (Lichrosorb SI 60, Merck, Nogent-sur-Marne, France), and the isolation of PC and PE was carried out at a flow rate of 2.5 mL/min using a linear gradient of solvents that began with 100% of the first eluent composed of hexane/isopropanol/chloroform/water (42:44.6:10.4:3, by vol) and ended with 100% of the second eluent, composed of hexane/isopropanol/chloroform/water (32:49.6:10.4:8, by vol).

Fatty acid methyl esters were produced by reacting PC with 10% BF_3 in methanol at 90°C (20 min) (35), and PE with 10% HCl and 4% dimethoxypropane in methanol at 70°C (4 h). After adding 2 mL of distilled water, the methyl esters were extracted twice with 1 mL hexane, washed with distilled water to neutralization, dried under nitrogen, and finally taken up in 100–200 µL isooctane for gas chromatography. An aliquot of 1 µL was injected through the on-column injector of a 9001 gas chromatograph (Chrompack, Middleburg, The Netherlands) equipped with a retention gap and a CP WAX 52 CB bonded fused-silica capillary column of 0.3 mm i.d. and 50-m length. The oven temperature was programmed for 79–140–205°C, at a heating rate of 9°C/min for the first step, and 3°C/min for the second step. The instrument responses attributable to fatty acid methyl esters were automatically integrated, and their factor response and equivalent chain length were compared to standard compounds. The lower limit acceptable for 20:4n-6 and 22:6n-3 factor responses was set at 90%. All compositions were expressed as a percentage by weight of total fatty acids.

Statistical treatment. The significance of fatty acid composition differences between diet groups was evaluated using Statview SE™ (Abacus Concepts Inc., Berkeley, CA) for one-way analysis of variance followed by Fisher's test. The significance was tested at the level of $P < 0.05$ in each tissue (Fig. 1) and in each individual cortical area (Fig. 4). The area effect in the cortical fatty acid composition was specifically tested by one-way analysis of variance and Fisher's test. In this case, the diet groups were confounded and the area location was taken as the grouping factor. An area effect for a given fatty acid was considered as significant when the fatty acid level in one specific area was significantly different from its value in each of the three other areas, at least at the level of $P < 0.05$. When P values lower than 0.05 were found, the data are reported in the text.

RESULTS AND DISCUSSION

Fatty acid composition in SM-fed piglets, general considerations. Tables 2 and 3 give the fatty acid composition in PE and PC from neural and nonneural tissues in group SM. The main observation was that n-3 LCPUFA were three- to fourfold more abundant in the cortical and cerebellum PE than in nonneural tissues (excluding the liver). As already mentioned (25,26) the major n-3 LCPUFA in SM is 22:5n-3 (Table 1). The physiological significance of this particularity of SM is unclear, since 22:5n-3 in SM cannot be considered as equivalent to dietary 22:6n-3 in terms of 22:6n-3 accretion in piglet tissues (26). It should be remembered that achieving a high 22:6n-3 concentration in SM (greater than that of 22:5n-3) required the use of sow rearing diets specially enriched with soybean, canola, and fish oils (36). There was no accumulation of 22:5n-3 in neural tissues from group SM in spite of its substantial incorporation in plasma phospholipids and in nonneural tissues, notably in the heart (Table 2). Thus, n-3 LCPUFA uptake and/or phospholipid esterification was mostly restricted to 22:6n-3 in neural tissues. With respect to n-6 LCPUFA, 20:4n-6 was present in very high concentration (40% of total fatty acids) in the myocardial PE of SM-fed piglets (Table 2). This 20:4n-6 level was the highest that we have found among the different phospholipid fractions examined. In terms of double-bond index, the unsaturation level brought about by n-6 fatty acids in the PE fractions was higher in the heart than in all other tissues (192 vs. 72 to 140, see Table 2), whereas the myocardial n-3 double-bond index (DBI = 55) was among the lowest in comparison to other tissues. On the contrary, the cortical and cerebellum PE presented the highest n-3 double-bond index, essentially generated by their high 22:6n-3 status. Lastly, note that RBC phospholipids had the lowest status in LCPUFA from both n-6 and n-3 series (Tables 2 and 3), the major fatty acids in RBC being 18:1n-9 and 16:0 in PE and PC, respectively. The phospholipid fatty acid composition in piglet RBC was therefore only slightly representative of that of other tissues.

Status of 22:6n-3 in nonneural tissues. The lowest 22:6n-3 level in plasma and nonneural tissues was found in piglets fed the standard formula without preformed LCPUFA (group F). Compared to SM feeding, giving the standard formula lowered the 22:6n-3 status by 27% to 65% in the two phospholipid classes from the different tissues. The major alteration (65%) was observed in the myocardial PE (Fig. 1). Both types of supplementation, fish oil or phospholipids, restored the 22:6n-3 status or significantly increased the 22:6n-3 levels in nonneural tissues and plasma (Fig. 1). Compared to SM feeding, the egg phospholipid supplementation resulted in the significant increase of PE 22:6n-3 levels in all nonneural fractions, whereas pig brain phospholipids caused this level to increase significantly only in the liver (Fig. 1). Overall, formula E can be considered more efficient than formula P, all the 22:6n-3 levels in nonneural tissues being higher in group E than in group P (Fig. 1). This difference between both phospholipid sources could be mainly due to the adsorption of the dietary pig brain phospholipids onto the aerosyl matrix (while egg phospholipids were simply emulsified in the formula) leading to the lower intestinal absorption of dietary 22:6n-3 from formula P than from formula E. In neural tissues (see below), the higher efficiency of formula E compared with formula P was found in the cerebellum PE (Fig. 1). However, the difference between the two phospholipid sources did not reach a significant level in the cortex or the retina [as seen in our previous study (26)]. We also noted that groups E and R did not show a significant difference in their 22:6n-3 status either in plasma phospholipids or in PE from nonneural tissues (Fig. 1). These data suggest that, at equivalent amounts of dietary 22:6n-3, the incorporation of 22:6n-3 into nonneural tissues was not determined by the triglyceride or phospholipid nature of the dietary source. However, the different pattern obtained for 22:6n-3 enrichment in the heart compared to other nonneural tissues (see Fig. 1) led us to test LCPUFA nature (triglycerides or phospholipids) as a statistical factor for determining the 22:6n-3 status in myocardial PE. Two groups were therefore worked out, joining up groups

[d]Including odd-numbered and branched-chain fatty acids.

SM, R and R+ on the one hand, and groups P and E, on the other, excluding group F which did not receive preformed LCPUFA. The mean 22:6n-3 level was 1.3-fold higher ($P < 0.03$) in the myocardial PE from piglets fed phospholipids than in that from piglets fed triglycerides. Thus, it appears that the 22:6n-3 status in myocardial PE depended on the nature of the lipid source at least as much as on the total amount of dietary 22:6n-3. It has been suggested that dietary fatty acids provided as phospholipids are predominantly incorporated into intestinal very low density particles, whereas fatty acids from dietary triglycerides are incorporated into chylomicrons (37). Differences in the intestinal handling of dietary LCPUFA could influence the bioavailability of dietary LCPUFA, but the reason why the distribution of 22:6n-3 to the heart was specifically affected remains unclear.

Inasmuch as the 22:6n-3 levels in tissue and plasma phospholipids were spread among the different groups (see Fig. 1), it was interesting to relate the changes in whole tissues to those in circulating phospholipids. Plasma phospholipid fatty acid composition reflected what had actually been absorbed and metabolized from the dietary fatty acid pool and, above all, gave an indication of the bioavailability of circulating LCPUFA for their uptake by whole tissues. Plotting the hepatic and intestinal-PE 22:6n-3 levels against those of plasma phospholipids showed that 22:6n-3 changes in liver and intestine were linearly correlated with their plasma counterparts, whereas the myocardial PE responded in a saturable manner (Fig. 2A). Comparison of data from formula F-fed piglets with those from group R+ indicated that 22:6n-3 increased by 152 and 195% in hepatic and intestinal PE at the same time that it increased by 172% in plasma phospholipids. In the myocardial phospholipids from group F, 22:6n-3 accounted for only 0.6 and 2.5% of total fatty acids in PC (not shown) and PE (Fig. 2A), respectively. The myocardial PE

[a]Including odd-numbered and branched-chain fatty acids. See Table 2 for abbreviations.

22:6n-3 level increased twofold from group F to group SM, then plateaued to around 6% in the other groups, independent of the 22:6n-3 levels in plasma (Fig. 2A).

22:6n-3 status in brain. A linear relationship was also found between brain PE-22:6n-3 and plasma 22:6n-3 (Fig. 2B), although the amplitude of variation was 6- to 10-fold lower in cortex and cerebellum than in the PE fractions from nonneural tissues. The changes in brain phospholipids were not large enough to produce significant differences between all the groups (as shown in Fig. 1). However, from group F to group R+, the 22:6n-3 status significantly increased, by 18 and 23% in the cortical- and cerebellum-PE, respectively (Fig. 2B). The mean PE-22:6n-3 levels in the cortex were 1.25 ± 0.04 times those in cerebellum (mean ratio from the six groups ± sd), showing that the 22:6n-3 status in brain cortex and cerebellum developed concurrently whatever the dietary treatment.

The examination of the individual areas (Fig. 3) highlighted some regional particularities. As found in the whole cortex (Fig. 2B), the accretion of 22:6n-3 in the frontal and parietal lobes paralleled that of plasma phospholipids ($P < 0.003$). However, the occipital lobe exhibited a lower response ($P < 0.01$) to the increasing 22:6n-3 plasma levels than did frontal and parietal lobes, and the temporal area appeared to be unrelated to plasma phospholipids. Thus, the linear relationship between cortical and plasma levels of 22:6n-3 exhibited in Figure 1 was mainly generated by the frontal and parietal lobes and, to a lesser extent, by the occipital lobe. The data as a whole could suggest that 22:6n-3 accretion in the different brain structures is regulated through similar pathways, although specific regional requirements cannot be excluded (38).

The main objective of this regional study was to determine whether the occipital lobe, involved in visuospatial processing and in discrimination of color and movement (39), contained higher amounts of 22:6n-3, known to play a role in the process of visual development, than other cortical lobes. Our results do not support this hypothesis, at least not in the piglet model. The temporal lobe, which is involved in the primary organization of sensory input in humans, such as hearing ability and visual and verbal memories (40), was richer in 22:6n-3 than the other areas (except in group SM), but this difference reached statistical significance in groups F and P only. In humans, the frontal lobe controls motor activities, emotional response, and expressive language and is involved in many aspects of social behavior (41), while the parietal lobe

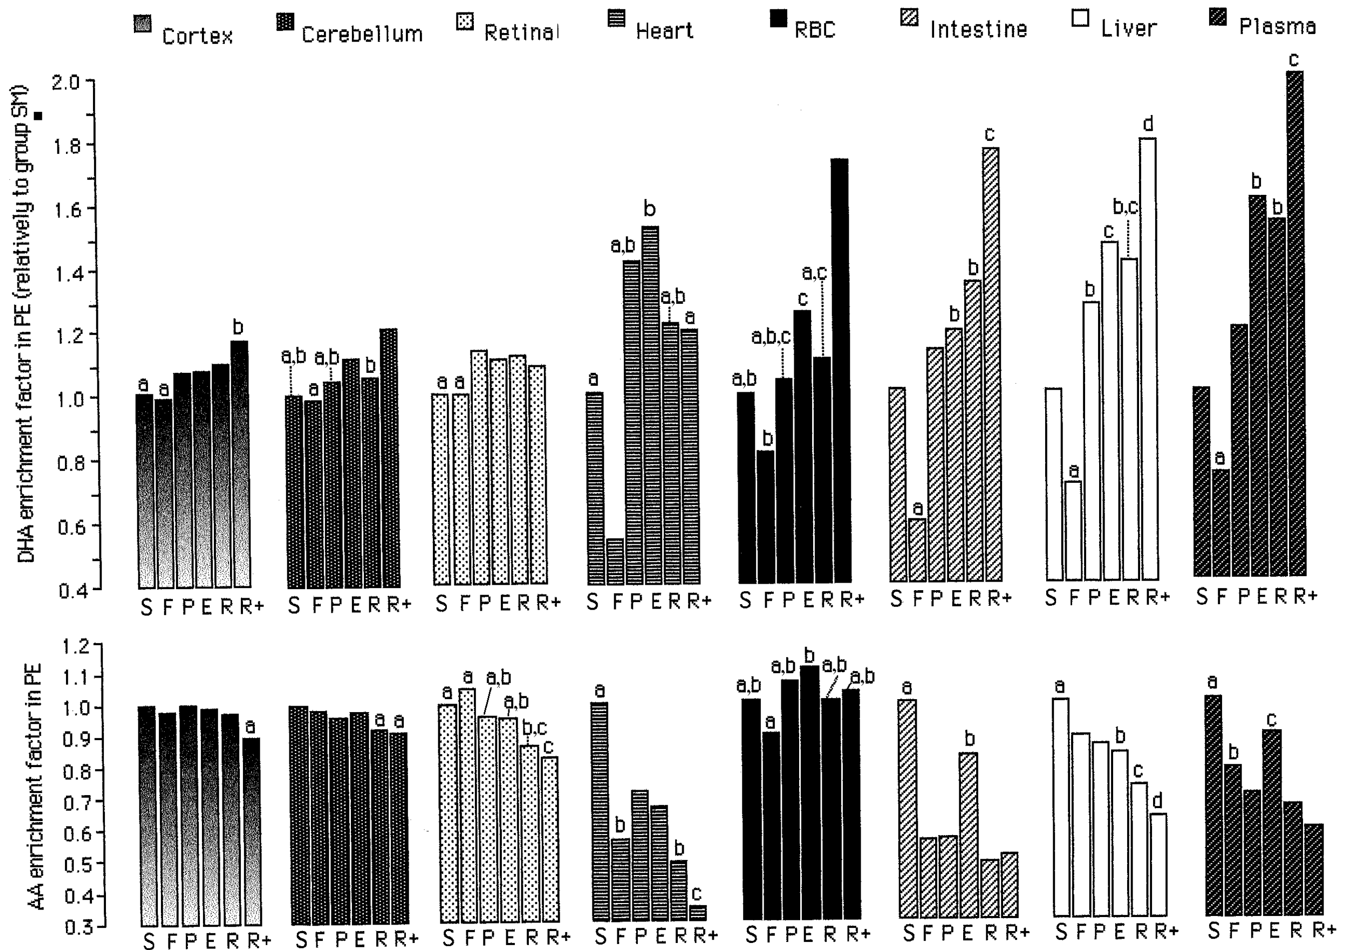

FIG. 1. Enrichment factor for long-chain polyunsaturated fatty acids (LCPUFA) in the phosphatidylethanolamine (PE) fractions from the five formula feeding groups. Upper panel: 22:6n-3 (docosahexaenoic acid, DHA), lower panel: 20:4n-6 (arachidonic acid, AA). The DHA and AA levels were expressed relative to those of the corresponding tissue from the sow milk-fed group, which are indicated in Table 2. The retina values were drawn from the data reported in Reference 26. Differences between diet groups were tested at the level of $P < 0.05$. The histograms with common superscripts are not significantly different. S: sow milk-fed group (0.1% dietary DHA) with an assigned value of 1.0; F: formula-fed group (0% dietary DHA); P: pig brain phospholipid-supplemented group (0.4% dietary DHA); E: egg phospholipid-supplemented group (0.4% dietary DHA); R: fish oil-supplemented group (0.3% dietary DHA); R+: fish oil-supplemented group (0.9% dietary DHA).

is concerned with integrating sensory input and perception of sensory information (39). Behavioral changes, learning impairment, and altered responses to drugs have been described in rodents fed diets deficient in n-3 fatty acids (review in 42). Besides these studies of total deprivation of n-3 fatty acids, the suboptimal provision of n-3 LCPUFA to the rat brain for multiple generations alters spatial learning ability (43). Moreover, breast feeding, or formula supplementation with egg phospholipids, can transiently benefit term infants in neurodevelopmental performance as opposed to standard formula feeding without LCPUFA (8). The question arises whether frontal and parietal lobes, which seem to respond to the bioavailability of dietary 22:6n-3, may be particularly involved in the improvement of some brain functions.

Among the nervous tissues we have examined, the cerebellum, involved in the coordination of voluntary motor movements, equilibrium and muscle tone, had the lowest 22:6n-3 content. These data could suggest that cerebellum functions were poorly affected by dietary supplies of preformed 22:6n-3. Total deprivation of n-3 fatty acids in mice diminished learning capacities without altering motor coordination (44).

20:4n-6 and 20:5n-3 status in nonneural tissues. In comparison to SM feeding, 20:4n-6 levels were significantly reduced in the nonneural phospholipids from piglets receiving any of the formula diets, except in the RBC PE (Fig. 1). Dietary supplementation with egg yolk phospholipids reduced the 20:4n-6-lowering effect in the heart, plasma, and intestine, whereas fish oil used at levels of 4.5% of total lipids (group R+) considerably accentuated the 20:4n-6 decline in the cardiac, plasma, and hepatic phospholipids (Fig. 1). The 20:4n-6 decline was also more marked ($P < 0.0001$) in the plasma and hepatic phospholipids from piglets fed the low concentration of fish oil (group R) than from those fed the standard formula. Thus, in the presence of dietary 22:6n-3 without 20:4n-6, a low 20:5n-3 intake (<0.1% of total fatty

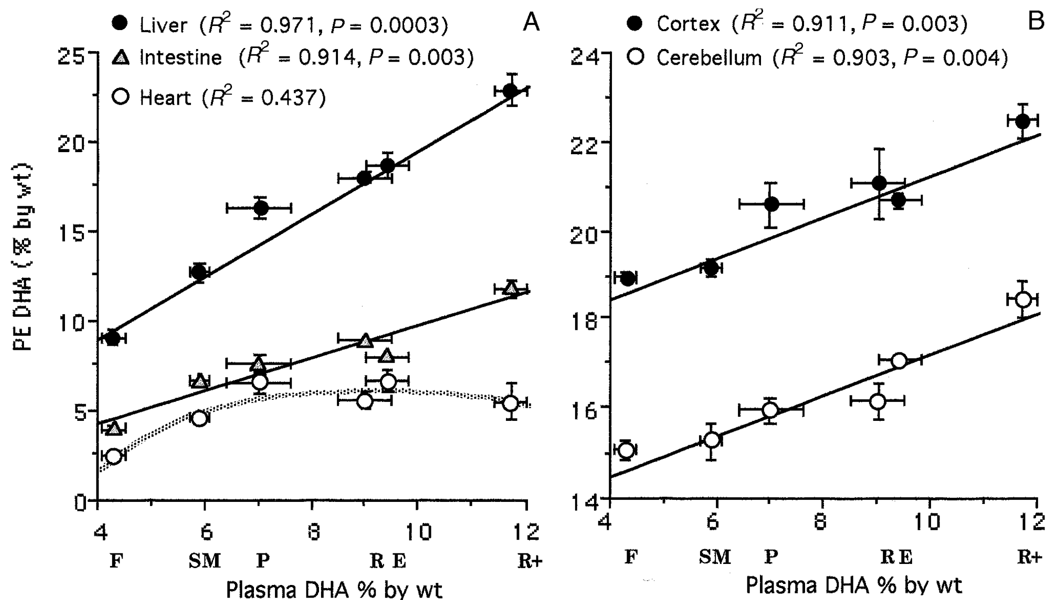

FIG. 2. Correlation between PE DHA levels in nonneural tissues (A) or brain (B) and DHA levels in plasma phospholipids. Each point is the mean value (± se) for DHA levels in the liver, intestine, heart, whole cortex, or cerebellum and plasma from one group assigned to one of the six dietary treatments. Each group is indicated along the abscissa by and positioned according to its plasma DHA value. F: formula-fed group (0% dietary DHA); SM: sow milk-fed group (0.1% dietary DHA), P: pig brain phospholipid-supplemented group (0.4% dietary DHA); R: fish oil-supplemented group (0.3% dietary DHA); E: egg phospholipid-supplemented group (0.4% dietary DHA); R+: fish oil-supplemented group (0.9% dietary DHA). The R^2 and P values testing for linear regression are indicated. For abbreviations see Figure 1.

acids) did not prevent a drop in the 20:4n-6 status in nonneural tissues. The data shows that a decrease in 20:4n-6 contents was not necessarily related to a reciprocal increase in 20:5n-3 contents. Indeed, using the fish oil at a low concentration was effective in maintaining the 20:5n-3 status similar to that in SM-fed piglets (Table 4). In contrast, giving the high concentration of fish oil induced the 20:5n-3 levels to increase significantly (P < 0.0001) in all of the nonneural tissues (Table 4). This resulted in higher levels of 20:5n-3 than 22:5n-3 in group R+, in contrast to what was found in group SM and in all other groups. However, the sum of both fatty acids in group R+ (and in all formula feeding groups) never exceeded the values found in group SM (Table 4).

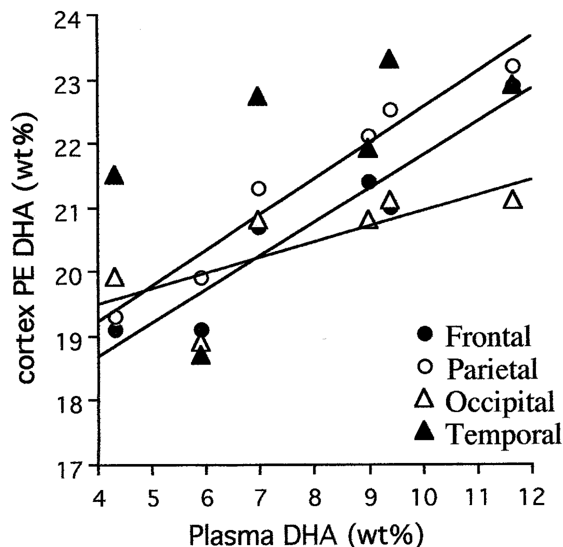

FIG. 3. Correlation between PE DHA levels in the frontal, parietal, occipital, and temporal lobes and DHA levels in plasma phospholipids. Each point is the mean value for DHA levels in cortical lobe and plasma from one group assigned to one of the six dietary treatments (as shown in Fig. 2). The R^2 and P values testing for linear regression were as follows: frontal lobe, R^2 = 0.914, P = 0.003; parietal lobe, R^2 = 0.957, P = 0.0007; occipital lobe, R^2 = 0.546, P = 0.09; temporal lobe, R^2 = 0.34, P = 0.2. For abbreviations see Figure 1.

The 20:5n-3 levels in neural tissues remained very low (<0.1% of total fatty acids) whatever the dietary treatment (data not shown).

The largest fall in 20:4n-6 was observed in myocardial phospholipids, in which the PE- and PC-20:4n-6 levels decreased by 65 and 73%, respectively, in group R+ relative to group SM. It also decreased by 43% in the myocardial PE of group F, and by 33 and 28% in groups E and P (Fig. 1). Decreases in 20:4n-6 of 74 and 44% in cardiac PC and PE were also reported in 16-d-old piglets fed a canola oil-enriched formula as opposed to piglets fed SM (45). In the present study, we found that both phospholipid supplementations improved the cardiac 20:4n-6 status relative to feeding of the control formula, but failed to match the high levels resulting from SM feeding. However, the sum of total n-6 fatty acids in myocardial PE (mainly including 18:2n-6) was not markedly altered by the different dietary treatments (data not shown). This apparent compensation within the n-6 family suggests that the molecular replacement of 20:4n-6 by dietary 18:2n-6 was the main factor responsible for the decrease in 20:4n-6 in the my-

ocardial PE of piglets fed milk replacer diets, even though the formula contained substantial amounts of 20:4n-6 from phospholipid sources.

We found that the cardiac 20:4n-6 content was greatly reduced by formula feeding. This alteration could be limited but not totally prevented under our conditions of phospholipid supplementation, and it was further accentuated when the formula contained high amounts of n-3 LCPUFA without 20:4n-6. It can be hypothesized that such modifications in the proportions of 20:4n-6, 20:5n-3 and 22:6n-3 may have the potential to modify the myocardial eicosanoid balance or the state of cardiomyocyte excitability (46).

20:4n-6 status in brain. The global 20:4n-6 decline in nonneural tissues resulting from the different formula diets had low effects on the 20:4n-6 status in brain phospholipids (Fig. 1). Only group R+ had its 20:4n-6 status altered, by around 10%, in the two phospholipid classes of both the whole cortex and the cerebellum (Fig. 1). At the regional level, the decrease was significant in the frontal, parietal, and occipital lobes, the temporal lobe being apparently more preserved (Fig. 4). In addition, the 22:5n-6 level was significantly reduced in the different areas from group R+, including the temporal one (Fig. 4). Thus, alteration of n-6 LCPUFA occurred in neural tissues from piglets fed fish oil from the moment that it accounted for more than 1.5 to 4.5% by weight of total dietary lipids.

Feeding formula without preformed LCPUFA led to the same 20:4n-6 levels in brain phospholipids as SM feeding, whereas the 20:4n-6 contents of all the nonneural tissues from group F were greatly reduced (except in the RBC-PE in which 20:4n-6 levels remained almost unchanged with diets, as in the brain). The data obtained from the piglet brain confirmed its homeostatic 20:4n-6 properties, as shown in humans by postmortem analysis of cortical samples from infants who died from sudden death syndrome, whose 20:4n-6 levels were not altered through feeding with conventional formulae, as opposed to those of 22:6n-3 (5,6). However, our data from the fish oil-fed groups showed that maintaining the 20:4n-6 status in neural tissues was limited to the condition that, in the absence of dietary preformed 20:4n-6, the sum of total n-3 long-chain fatty acids (20 to 22 carbons) remained between 0.6 and 1.2% of total dietary fatty acids. Beyond this threshold, brain 20:4n-6 levels were slightly but significantly reduced, and this alteration could occur even though the dietary 22:6n-3 to 20:5n-3 ratio was greater than 1.

Whatever the dietary treatment, the 20:4n-6 level was 10 to 20% higher (according to groups) in the temporal PE than in the PE from parietal, frontal and occipital lobes ($P < 0.0001$, grouping together the dietary treatments), and the decrease of 20:4n-6 in the temporal lobe PE of group R+ was not significant in comparison to group SM (Fig. 4). Moreover, the temporal PE was the sole fraction to be enriched with significant amounts of 20:4n-6 when both dietary 22:6n-3 and 20:4n-6 were supplied, since piglets fed the phospholipid-supplemented formulae gained 9 and 7% of 20:4n-6 in groups E and P relative to group SM (Fig. 4). There was no other appreciable increase of 20:4n-6 in all the neural tissue samples examined. None of the other n-6 LCPUFA present in the cortical PE samples, i.e., 20:3n-6, 22:4n-6 and 22:5n-6, were found to be preferentially distributed among the different areas, although the 22:5n-6 levels in all groups were slightly lower ($P < 0.05$) in the temporal lobe than in the other lobes (Fig. 4). Higher levels of 20:4n-6 and lower levels of 22:5n-6 resulted in higher 20:4n-6 to 22:5n-6 ratios in temporal lobes ($P < 0.0001$, grouping together the dietary treatments, data not shown). These data suggest that n-6 metabolism in the temporal lobe was preferentially turned to synthesis, accumulation, or sequestration of 20:4n-6 over other n-6 LCPUFA.

In brief, the PE-20:4n-6 content of temporal lobe appeared not to be altered by the high n-3 intake (group R+). Among all the cortical lobes the temporal lobe seemed to be the preferential target for the additional incorporation of 20:4n-6 into PE

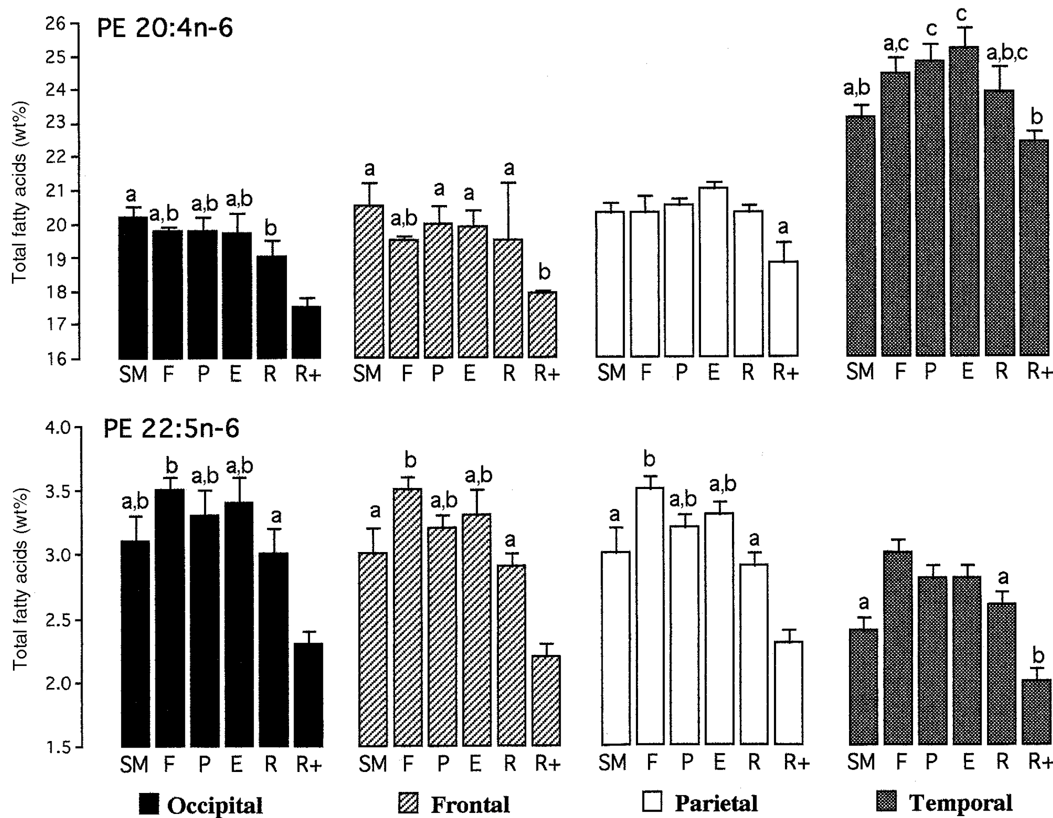

FIG. 4. Levels of n-6 LCPUFA in the brain PE from occipital, frontal, parietal, and temporal lobes (mean ± se). Upper panel: 20:4n-6, lower panel: 22:5n-6. Significant differences between diet groups within the same area are indicated by different superscripts ($P < 0.05$). All areas from group R+ contained less 20:4n-6 and 22:5n-6 than those from group SM, with the exception of the temporal 20:4n-6 level which was reduced only in comparison to groups F, P, and E. Confounding dietary treatments, the mean 20:4n-6 level in the temporal area was significantly higher than the mean value in the other areas ($P < 0.0001$), while the 22:5n-6 level was slightly lower ($P < 0.05$). For abbreviations see Figure 1.

when this fatty acid was provided as a phospholipid (groups E and P). A higher level of 20:4n-6 in the temporal lobe, as compared with frontal or occipital lobes (+21 and +43%, respectively), was also found in the brain microsomal lipids of one macaque monkey (47). It is tempting to suggest that the specific retention of 20:4n-6 in the temporal lobe could be significant from a functional point of view, possibly in terms of signal transduction or eicosanoid synthesis modulation through the cyclooxygenase pathway (reviewed in Ref. 48).

In summary, we evaluated the effects of LCPUFA supplementation upon the fatty acid status in formula-fed piglets. Fortification of formula with a conventional fish oil (with high 20:5n-3 content) has already been shown to increase the 22:6n-3 status in the brain and nonneural tissues of piglets (49). In the present study, we showed that the low-20:5n-3 fish oil, used at concentrations of 1.5% by weight of total lipids, was as efficient as conventional fish oil in increasing the 22:6n-3 status in neural and nonneural tissues; the advantage over conventional fish oils was that, at this concentration, the enhancement of 22:6n-3 occurred without increasing 20:5n-3 levels. However, fish oil supplementation resulted in an overall decrease of 20:4n-6 status, even though the oil contained low amounts of 20:5n-3. The 20:4n-6 decline affected the neural phospholipids, including the retina (26), bearing in mind that the n-3 LCPUFA accounted for more than 0.6% of total fatty acids in the formula deprived of preformed 20:4n-6. Thus, the fortification of formulae with 22:6n-3 without the concomitant incorporation of 20:4n-6 does not result in maximal 20:4n-6 status in neural and nonneural tissues, even though the dietary amount of 22:6n-3 exceeds that of 20:5n-3, the metabolic competitor of 20:4n-6. It may even generate a risk of alteration in the frontal, parietal and occipital lobes of the cortex, the temporal lobe apparently being more efficiently preserved. However, the corresponding short- and long-term effects on cognitive development have yet to be determined. Finally, the heart appeared to be highly sensitive to 20:4n-6 reduction in the absence of dietary preformed 20:4n-6, especially when n-3 LCPUFA from fish oil were added at a higher concentration than 0.6% by weight of total fatty acids. These data also argue in favor of the cosupplementation with both n-6 and n-3 LCPUFA, rather than with n-3 LCPUFA alone. Phospholipid supplementation allowed brain 22:6n-3 to increase and could prevent changes in the 20:4n-6 status to some extent. Nevertheless, richer LCPUFA sources should be used in infant nutrition to imitate the lipid composition of human milk and to circumvent their absence

in vegetable oils. With this in mind, raising both 20:4n-6 and 22:6n-3 levels in the ratio of around 1.3 seems reasonable.

ACKNOWLEDGMENTS

We gratefully acknowledge Jacqueline Thévenoux and Alain Linard for their technical assistance, Jean-Pierre Richard for the management of the rearing unit, and Anne-Marie Wair for revising the English manuscript. Bénédicte Goustard received a joint grant from the Institut National de la Recherche Agronomique and the Groupe Danone, Villefranche sur Saône, France. The work was supported by grants from the Ministère de l'Enseignement Supérieur et de la Recherche ("Aliment Demain," program N° 94G0080), the Groupe Danone, and the Institut de Recherche Biologique Yves Ponroy. The low-20:5n-3 fish oil was a gift from Produits Roche, and the phospholipids were specially prepared by the Institut de Recherche Biologique Yves Ponroy. The basic formula powder was donated by Diépal nsa.

ABSTRACT: Lysophosphatidylcholine (LPC) and lysophosphatidic acid (LPA) mediate various kinds of biological activities and play an important role in cellular signal transduction. We analyzed serum phospholipids obtained from 16 multiple myeloma (MM) patients and observed that serum LPA level was significantly higher in MM patients (5.3 ± 0.5 nmol/mL) than in normal controls (1.7 ± 0.3 nmol/mL). LPC level was also higher than that in normal controls, and it correlated significantly with the concentration of LPA ($r = 0.678$, $P < 0.01$). In MM patients, palmitic acid/linoleic acid ratios in phosphatidylcholine and LPC were higher than those in normal controls. In the 12-mon follow-up study of two patients with the immune globulin G type, we recognized that the increase of LPC, LPA, and arachidonic acid/linoleic acid ratio in phosphatidylinositol corresponded with a decline in the serum albumin level and choline esterase activity.

Paper no. L7899 in *Lipids 34,* 17–21 (January 1999).

Multiple myeloma (MM) is characterized by malignant monoclonal lymphoplasmacytic cells that increase in bone marrow and produce an M-component [a specific immune globulin (Ig) produced by malignant cells in myeloma patients]. It is known that many kinds of malignancies involve abnormal lipid metabolism. Many MM patients have an impaired immune response, which causes a secondary high blood triglyceride level. These lipid-mobilizing activities are caused by cytokine-induced suppression of lipoprotein lipase (1) as well as by suppression of the enzyme related to the alteration of phospholipid compositions.

Lysophosphatidylcholine (LPC) and lysophosphatidic acid (LPA) mediate various kinds of biological activities and play an important role in cellular signal transduction. LPA activates its own GTP-binding protein (G-protein)-coupled receptor to trigger phospholipase C-mediated Ca^{2+} mobilization and other effector pathways such as induction of smooth muscle contraction (2), cell proliferation mediated by G-protein (3), and mediation of tumor cell invasion (4). LPC in oxidized low density lipoprotein stimulates proliferation of foam cells, which are derived from macrophages and are linked to atherosclerosis progression (5). In producing these lysophospholipids by phospholipase A_2 or C, arachidonate is released from membrane phospholipids and interacts with a G-protein (6). Arachidonate is a precursor of eicosanoids, which promote Ca^{2+} mobilization and activate protein kinase C (7).

Mills *et al.* (8) found that ascites from an ovarian cancer patient strongly induced proliferation of ovarian cancer cells. Recently, Okita *et al.* (9) found higher LPC levels in ascites from ovarian cancer patients. In this study, we analyzed serum phospholipids in MM patients and recognized increased levels of lysophospholipid levels compared to those in normal subjects.

EXPERIMENTAL PROCEDURES

Sera from 16 MM patients were obtained at the Third Department of Internal Medicine of Toyama Medical and Pharmaceutical University (Toyama, Japan). Diagnosis of MM was based on histological increase of myeloid cells on bone marrow biopsy and monoclonal hyperglobulinemia. Clinical data are shown in Table 1. Control subjects were two healthy men and 11 healthy women. Serum lipids were extracted and separated by two-dimensional thin-layer chromatography according to the procedure reported previously (9). Transmethylation of the phospholipids was carried out at 90°C for 2 h in acetylchloride/methanol (5:50 vol/vol). Fatty acid methyl esters were analyzed by gas–liquid chromatography (model GC-14A; Shimadzu, Kyoto, Japan) using margaric acid (17:0) as an internal standard. The results are expressed as the mean ± SE. For comparison of two groups of individuals, the Mann-Whitney U test was used. The coefficient of correlation (r) was calculated by the Spearman R test. P-values were two-tailed and considered significant at less than 0.05.

RESULTS AND DISCUSSION

Serum phospholipids and fatty acid compositions of the phospholipids were analyzed for each type of MM patients and compared with those of controls. No significant differences were

TABLE 1
Clinical Data of the Study Group[a]

	Control	Myeloma IgG	Myeloma Bence-Jones	Myeloma IgA
Number (sex)	2(M),11(F)	2(M),8(F)	1(M),3(F)	1(M),1(F)
Age (yr)	51 ± 1	65 ± 3	63 ± 9	53
BMI		22.2 ± 1.0	22.1 ± 1.8	21.4
Total protein (g/dL)		9.4 ± 0.5[ab]	6.3 ± 0.2[b]	6.7[a]
Albumin (g/dL)	4.5 ± 0.1	3.6 ± 0.2[a]	4.1 ± 0.1	4
A/G		0.7 ± 0.1	1.9 ± 0.1	1.4
Immune globulin (Ig)				
IgG (mg/dL)		4043 ± 384	1599 ± 1234	415
IgA (mg/dL)		36 ± 14	42 ± 32	1317
IgM (mg/dL)		22 ± 8	16 ± 11	46
RBC (× 10^4/μL)		325 ± 28	266 ± 25	297
WBC (/μL)		4079 ± 831	4563 ± 516	5160
Platelets (× 10^4/μL)		15.7 ± 3.2	22.1 ± 1.4	12

[a]BMI, body mass index; A/G, albumin/globulin ratio; RBC, red blood cells; WBC, white blood cells. Data reported as mean ± SE. [a], $P < 0.01$; [b], $P < 0.05$.

recognized in the serum phospholipid concentrations and fatty acid compositions among the types of disease. Serum LPC levels were significantly higher in MM (193.2 ± 17.3 nmol/mL) than in controls (135.0 ± 8.4, Fig. 1). Serum LPA levels were also significantly higher in MM (5.3 ± 0.5 nmol/mL) than in controls (1.7 ± 0.3 nmol/mL). Serum LPC concentrations correlated with those of LPA ($r = 0.678$, $P < 0.01$, Fig. 2). There were no significant differences in the serum phosphatidylcholine (PC), phosphatidylethanolamine, and phosphatidylinositol concentrations between controls and MM patients.

The Ig type differs with each MM type. Malignancy induces monoclonal Ig production and suppression of other Ig types. The serum albumin level decreases in the IgG and IgA types but not in the Bence-Jones (BJ) type. To indicate the progression of each type of disease, we calculated the albumin/globulin (A/G) ratio. The ratio decreased in the IgG type but increased in the BJ type with disease progression. In the IgG type, LPC concentration and A/G correlated negatively ($r = -0.685$, $P < 0.05$) and positively in the BJ type ($r = 1.000$, $P = 0.05$, Fig. 3).

Fatty acid composition of phospholipids is shown in Table 2. In MM sera, the percentages of the saturated palmitic acid (16:0) in PC and stearic acid (18:0) in phosphatidylethanolamine were higher than those in normal subjects. However, linoleic acid (18:2n-6) in PC and LPC, and arachidonic acid (20:4n-6) in phosphatidylinositol were lower in MM. In comparing the palmitic acid/linoleic acid molar ratio in phospholipids, the ratio in MM patients was significantly higher for PC and LPC than in controls (Fig. 4).

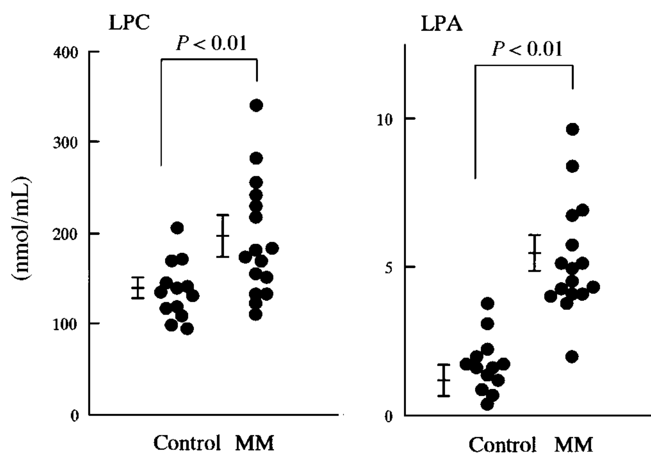

FIG. 1. Serum lysophosphatidylcholine (LPC) and lysophosphatidic acid (LPA) levels in multiple myeloma (MM) patients and control subjects. Significant differences are recognized in LPC ($P < 0.01$) and LPA concentrations ($P < 0.01$). Vertical lines show mean ± SE for 13 controls and 16 MM patients.

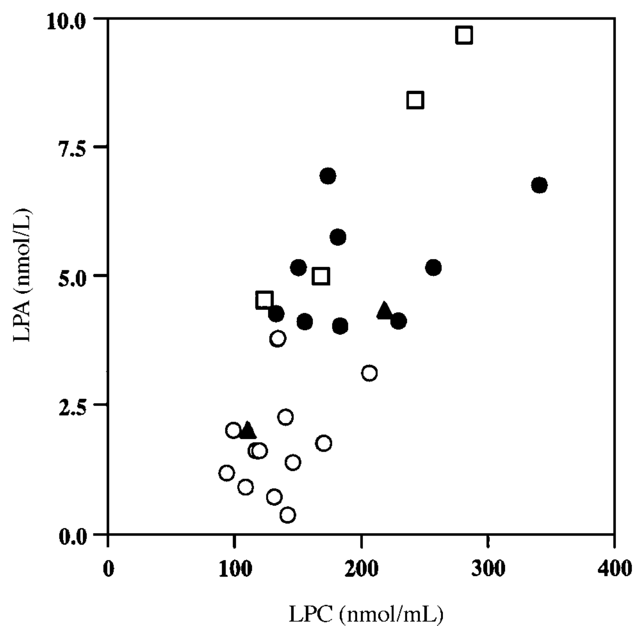

FIG. 2. Correlation of LPC and LPA concentrations. Data points indicated are controls (○), immune globulin G (IgG) type (●), Bence-Jones type (□), and IgA type (▲). Significant correlations are recognized between LPC and LPA concentrations ($r = 0.678$, $P < 0.01$). For abbreviations see Figure 1.

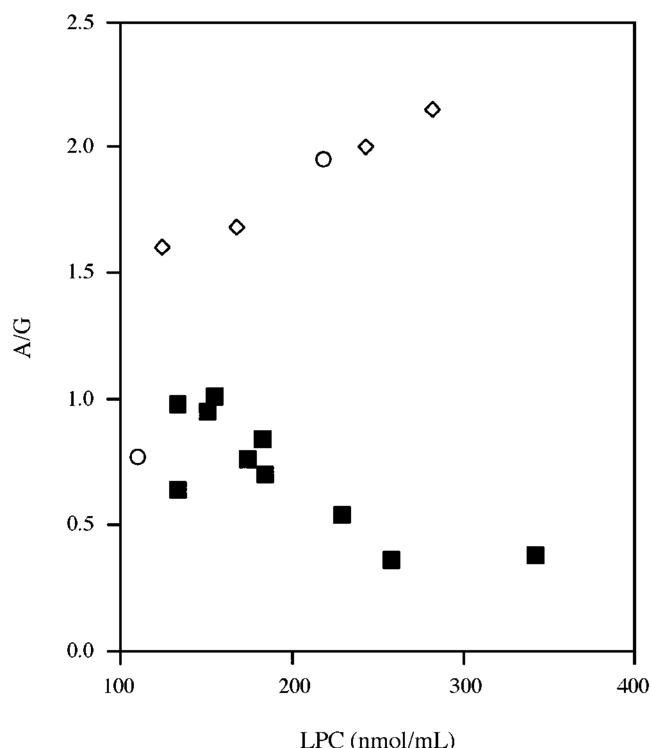

FIG. 3. Correlation of LPC concentration and albumin/globulin (A/G) ratio. Data points indicated are IgG type (■), Bence-Jones type (◇), and IgA type (○). In the IgG type, LPC and A/G ratio correlated negatively ($r = -0.685$, $P < 0.05$) and they correlated positively in the Bence-Jones type ($r = 1.000$, $P = 0.05$). For other abbreviations see Figures 1 and 2.

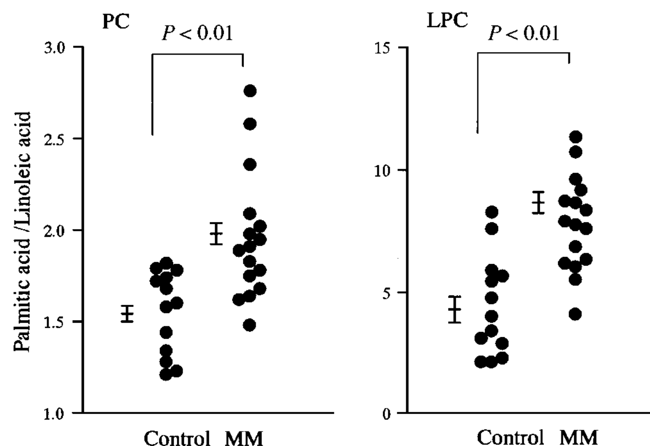

FIG. 4. Palmitic acid/linoleic acid ratio in serum phosphatidylcholine (PC) and LPC. Significant differences are recognized between the palmitic acid/linoleic acid ratio in PC ($P < 0.01$) and LPC concentrations ($P < 0.01$). Vertical lines show mean ± SE for 13 controls and 16 MM patients. For abbreviations see Figure 1.

We observed two patients with the IgG type (61- and 64-yr-old females) for 12 mon. Markedly higher levels of LPC and LPA were observed at the start of follow-up compared with those of normal subjects. These levels increased slightly after 12 mon, corresponding to a decline in serum albumin and choline esterase activity. The arachidonic acid molar ratio in phosphatidylinositol increased with disease progression (Fig. 5).

LPA was produced rapidly in thrombin-activated platelets (10). LPA concentration in heparinized plasma, compared to that in serum, was 3.21 and 6.39 nmol/mL, respectively, in a MM patient with IgG type, whereas these values averaged 0.29 and 1.45 nmol/mL, respectively, in three controls (data not shown). Therefore, LPA production in MM may be higher than that in controls during blood clotting. LPA has been reported to be produced from phosphatidic acid by phospholipase A_2 (PLA_2) (11). LPA plays a role in the growth of ovarian and breast cancer cells (3). LPA stimulates proliferation of Jurkat cells in serum-free medium or in a low concentration of fetal bovine serum. Biological activities differ in each LPA species: oleoyl-LPA has a higher activity, followed by arachidonoyl-LPA, and linoleoyl-LPA which constitute the unsaturated group. LPA can mobilize cellular Ca^{2+}, and palmitoyl-LPA induces maximal activity, on the order of 10^{-6} M (12). LPA concentrations in both serum and plasma in MM are considered sufficient to induce Ca^{2+} mobilization *in vitro*. LPA induces mitogenic responses in fibroblasts, or inhibition of proliferative activity of myeloma cells (13). Imagawa *et al.* (14) reported that LPA induced varying degrees of cell proliferation in different cell types, mediated through pertussis toxin-sensitive or -insensitive G-protein. On the basis of these facts (this research; 3,12–14) we suggest that LPA may be potentially active in the plasma of MM patients.

Okita *et al.* (9) showed that the percentages of palmitoyl- and stearoyl-LPC species in plasma and ascites from ovarian cancer patients were significantly higher than those of con-

TABLE 2

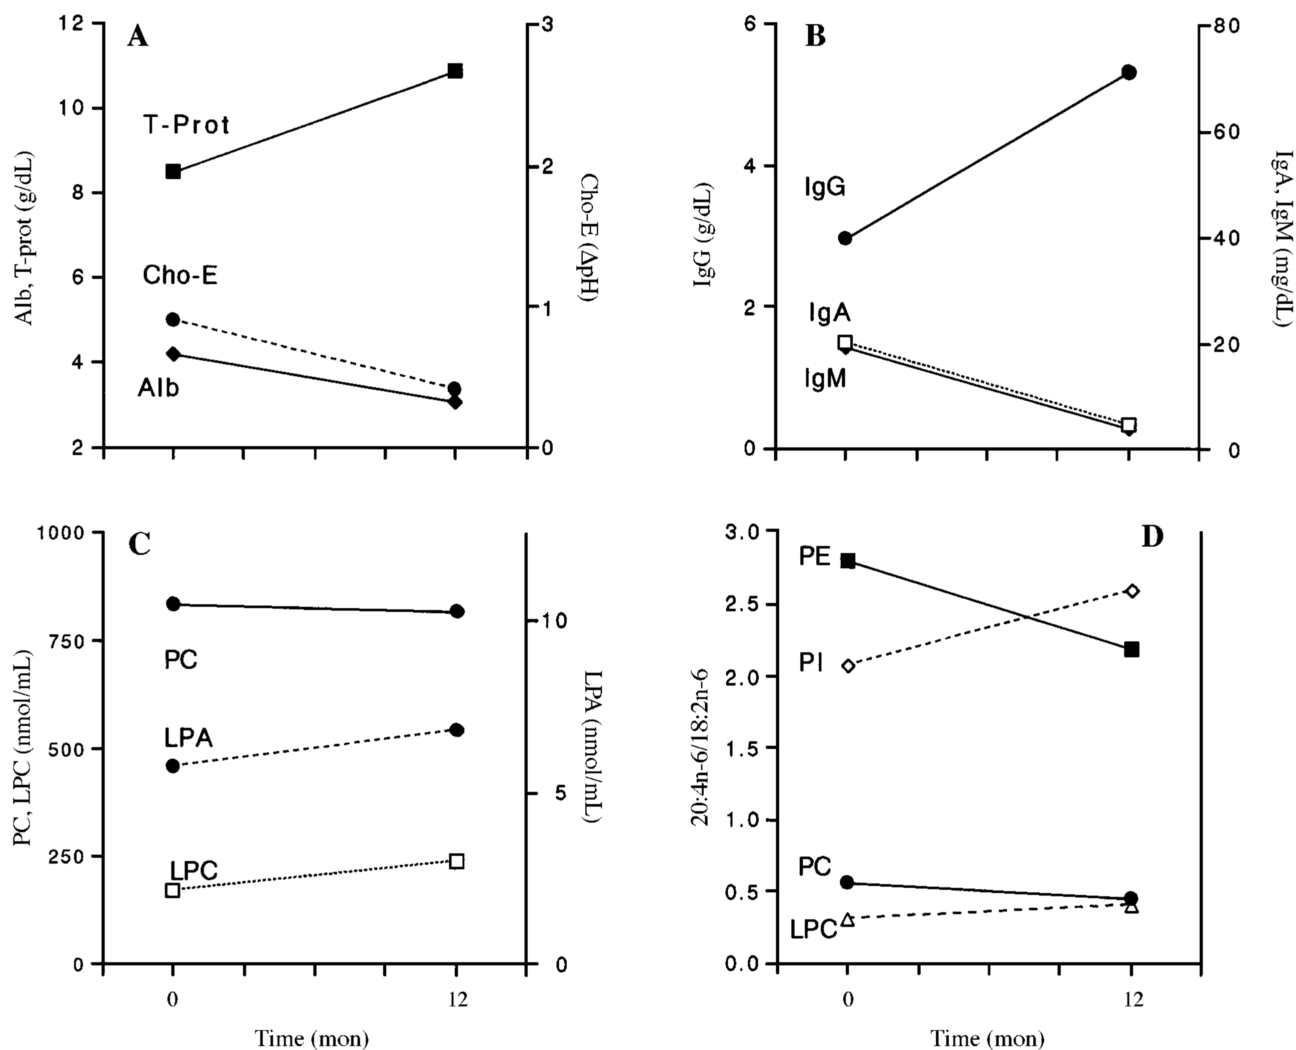

FIG. 5. Follow-up study of two patients of IgG type for 12 mon. Averages of clinical data and serum phospholipid levels are shown at 0 and 12 mon. Abbreviations: T-Prot, total protein; Alb, albumin; Cho-E, choline esterase; PE, phosphatidylethanolamine; PI, phosphatidylinositol. For other abberviations see Figures 1–3.

trols. Our data showed a higher palmitic/linoleic acid ratio of PC and LPC in serum phospholipids of MM patients compared to that in the controls (Fig. 4). Moreover, we recognized an abnormal serum albumin/globulin ratio in MM patients, a decrease in IgG type and an increase in BJ type, and a significant correlation of this ratio with the serum LPC level (Fig. 3). These results may suggest that elevated serum LPC level in MM indicates a progression of the disease. Several biological functions of LPC have been studied. Sakai *et al.* (5) reported that macrophage proliferation occurred following the LPC uptake of oxidized low density lipoprotein through the scavenger receptor. Other investigators (15,16) reported that LPC enhanced T-lymphocyte proliferation and potentiated protein kinase C activation in other cell lineages.

The source of LPC is fatty acid release from PC by PLA_2 and phospholipase A_1. Secretory group II PLA_2 ($sPLA_2$) and cytosolic group IV PLA_2 ($cPLA_2$) regulate extra- or intracellular arachidonic acid release with cross reactivity (17,18). In malignant tissue, phospholipid fatty acid remodeling was regulated through PLA_2 and acyltransferase, and this process leads to increased use of arachidonic acid (18). Another LPC-producing pathway involves transacylation of PC by lecithin cholesterol acyltransferase. Kuliszkiwicz-Janus and Baczynski (19) reported that high density lipoprotein and lecithin cholesterol acyltransferase levels decreased in MM patients, and our data also indicated decrement of these levels. From our present results, a close relation between the formations of two lysophospholipids, LPA and LPC, was observed. It may indicate involvement of lysophospholipase D in the production of LPA (20). Further investigation is needed to determine the relationship between tumor progression and lysophospholipids.

ABSTRACT: The effect of *N*-ethyl-maleimide (NEM) on Δ5- and Δ6-desaturase activities and the incorporation of substrates and products into different microsomal lipid classes and phospholipid (PL) subclasses were studied in human fetal liver microsomes, obtained after legally approved therapeutic abortion. Desaturase activities were measured by a radiochemical method using reversed-phase high-performance liquid chromatography (HPLC). After nonphospholipid (NPL) and PL separation on silica cartridges, the radioactivity in different lipids of the NPL group was assessed by two-dimensional thin-layer chromatography, and their fatty acid (FA) composition by gas–liquid chromatography. The PL subclasses were separated, and the distribution of radioactivity between products and substrates was determined in PL subclasses. NEM inhibited the Δ5- and Δ6-desaturase activities in the n-6 series of FA but not the Δ6-desaturase activity in the n-3 series, which suggests the existence of two distinct Δ6-desaturases, one for the n-6 series and another for the n-3 series. Whether NEM was present or absent, most of the radioactivity was recovered in the free FA form (about 80%). The desaturation products, obtained in the presence or absence of NEM, were preferentially incorporated into PL, suggesting a channeling of the newly synthesized FA toward microsomal PL. The comparison of the distribution of substrates and products incorporated into the different PL classes showed that most of the labeled FA were incorporated into phosphatidylcholine and to a lesser degree into phosphatidylethanolamine.

Paper no. L8026 in *Lipids 34,* 23–30 (January 1999).

Polyunsaturated essential fatty acids (PUFA) are required during fetal development as constituents of membrane phospholipids (PL) and precursors of eicosanoids. In addition to autonomous synthesis by the fetal liver, essential fatty acids (EFA) are provided to the fetus from the mother's blood through the placenta (1), the placenta itself being devoid of PUFA synthesis capacity (2). The accretion of PUFA during the fetal period results in a gradient of concentration between maternal plasma and fetal tissues, reported as biomagnification (3). The biosynthesis of PUFA occurs essentially in liver from C_{18} EFA through a sequence of alternating desaturation and chain-elongation reactions.

The desaturation steps are dependent on the Δ5- and Δ6-desaturases, key enzymes localized in the endoplasmic reticulum (4). The Δ6-desaturase catalyzes the conversion of linoleic acid (18:2n-6) into γ-linolenic acid (18:3n-6) and of α-linolenic acid (18:3n-3) into stearidonic acid (18:4n-3). In this pathway, Δ6-desaturation is considered to be the rate-limiting step (5). The last step in the biosynthesis of arachidonic acid (20:4n-6) involves the Δ5-desaturation of eicosatrienoic acid (20:3n-6). Both the Δ5- and Δ6-desaturases are highly dependent on numerous nutritional and hormonal factors (4).

These enzymes were described in fetal rat (6). The data suggested that, close to term, the fetus is capable of supplying some of its arachidonic acid requirements, and thus relies less on the availability from the maternal organism than during early pregnancy. Another study showed that human fetal liver microsomes are able to desaturate fatty acids (FA) (2). However, the desaturase activities observed in the fetal microsomes were low compared to other mammals (7), and they are probably unable to satisfy the PUFA requirements of the fetus, at least between the 17th and 36th gestational weeks (8).

PL are the main lipid components in biological membranes, and their properties are greatly influenced by the types of FA they contain. PL FA composition is known to be one of the major factors in the regulation of membrane stability, fluidity, permeability, and membrane enzyme activity. Both exogenous FA supply and desaturation–elongation processes are responsible for the maintenance of the PUFA membrane status.

In contrast to the growing body of information on EFA desaturation and its regulation, very little is known about the immediate metabolic fate of neosynthesized PUFA *in situ* in microsomal membranes. Yet this is of special interest since neosynthesized FA are supposed to appear in the free form. Indeed, except for one report showing Δ5-desaturation using PL

as substrate in rat liver (9), it is generally considered that the actual substrate of desaturases in vertebrates is fatty acylCoA. This implies that the FA substrate is released from the PL precursor, then reincorporated after enzymatic modifications.

FA incorporation into membranes is dependent on several enzymatic reactions. As previously shown (10), FA desaturation and FA incorporation into microsomal PL are two simultaneous, but independent, processes. Thus, competition may occur between esterification and desaturation in the endoplasmic reticulum. This may explain in part the weak desaturation rate observed in human fetal liver *in vitro*.

The aim of the present study was to investigate the metabolic fate of neoconverted FA by comparing the distribution and incorporation of substrates and desaturation products into the different lipid classes. To do so, we also studied the influence of *N*-ethyl maleimide (NEM), a sulfhydryl reagent, on both the microsomal desaturase activities and the metabolic fate of desaturated FA, more particularly the PL reacylation by either substrate or desaturation product.

MATERIALS AND METHODS

Biological samples. Biological samples were obtained from the Fetal Pathology Centers of CHU Lapeyronie-Arnaud de Villeneuve, Montpellier, France, and CHU Robert Debré, Paris, France, after legally approved medical abortion according to French law. These therapeutic abortions were obtained by both oral dose of Myfegyne® (mifepristone, 600 mg) and/or Misoprostol® (cytotec, 200 mg/4 h) from Roussel-UCLAF, Paris, France, and Syntocinon® drip from Sandoz, Rueil-Malmaison, France. The abortions were permitted for three reasons: fetal unviability, polymalformations, and 18 or 21 trisomy. The three fetuses were 24-, 24-, and 25-wk old, and the liver samples (4–5 g each) were obtained 1–4 h after fetal death.

Preparation of microsomes. The microsomal suspension was prepared as previously described (8) from liver samples deep-frozen in liquid nitrogen. The microsomal protein concentrations were estimated by the method of Layne (11) with FA-free crystalline bovine serum albumin as standard.

Enzyme assays. Enzyme activities were measured by the radiochemical method previously described (12) using [1-^{14}C]linoleic acid ([1-^{14}C]18:2n-6), [1-^{14}C]α-linolenic acid ([1-^{14}C]18:3n-3), and [1-^{14}C]eicosatrienoic acid ([1-^{14}C]-20:3n-6) (40–60 mCi/mmol, 99% pure; NEN Life Science Products–France S.A., Le Blanc Mesnil, France) as substrates. For each substrate, we used concentrations that allowed the highest desaturase activity, i.e., 28.6, 19, and 57 μM for 18:2n-6, 20:3n-6, and 18:3n-3, respectively. These concentrations were determined in a previous study (12). All reactions were started by the addition of 3 mg of microsomal proteins.

In a second set of experiments, the conditions of incubation were essentially the same, except that we added 0.52 mM NEM to the reaction medium before adding microsomal proteins.

PL and nonphospholipid (NPL) separation. The analytic schema is shown in Figure 1. This separation was performed on pooled lipid extracts obtained from two microsome incubations for enzyme measurement. According to a modified method from Juadena and Rocquelin (13), the PL and NPL fractions of fetal hepatic microsomes were separated using Sep-Pak Plus® silica cartridges (silica cartridges, Waters). The lipid extracts were evaporated to dryness under nitrogen stream and kept in 200 μL of methanol/chloroform (1:2, vol/vol) (Prolabo, Paris, France). The cartridges were rinsed with 8 mL of chloroform, and the samples were injected at the top of the cartridge. After adsorption of sample, 7 mL of chloroform, and then 6 mL of acetone were pushed through the cartridge, and the corresponding eluted fractions containing the NPL fraction were collected. Then, 24 mL of methanol was added, and the fraction containing PL was eluted. Each fraction was evaporated to dryness under nitrogen stream and kept in 300 μL of methanol/chloroform (1:2, vol/vol). The radioactivity of each fraction was measured by liquid scintillation counting (Picofluor; Packard Instruments, Rungis, France) in Packard Tri-Carb Model 2425.

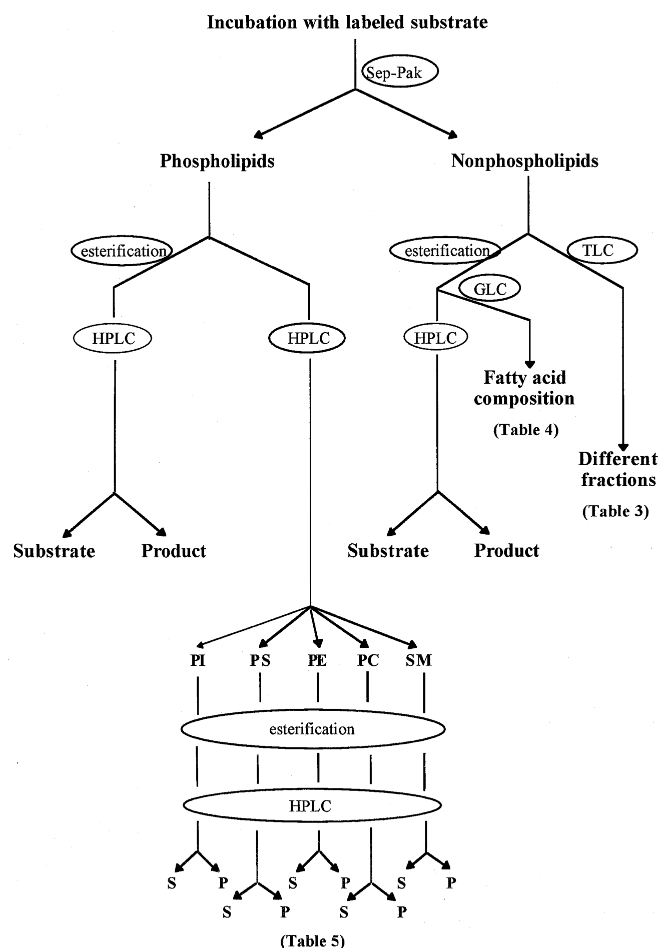

FIG. 1. Analytic scheme: GLC, gas–liquid chromatography; HPLC, high-performance liquid chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; SM, sphingomyelin; TLC, two-dimensional thin-layer chromatography; P, product; S, substrate.

Determination of distribution of radioactivity between substrates and products in the PL and NPL fractions. After

the PL and NPL fractions were transesterified (14), the radioactivity distribution between substrate and desaturation product was determined by a reversed-phase HPLC (15) using a Beckman model 110 A pump (Fullerton, CA) and a Nova-Pack C18 column (60 Å, 4 µm, 3.9 × 150 mm) (Waters, Milford, MA). Activity was expressed as the percentage of converted substrate.

FA composition in the NPL fractions. The FA composition of the NPL fractions was determined by gas–liquid chromatography of methyl esters. After NPL transesterification, the FA methyl esters were analyzed using a DELSI DI 200 chromatograph (Delsi Nermag, Argenteuil, France) and a fused-silica capillary column (50 m × 0.32 mm, C.P. Sil 88; Chrompak, Les Ulis, France). Conditions were as follows: ionization detector, 250°C; injector, 230°C; and oven program, 3.5°C/min from 115 to 230°C. Hydrogen was used as the carrier gas with a flow rate of 1 mL/min^{-1}. Quantitative analysis was achieved with reference to the internal standards using a DELSI ENICA 10. The percentage of total FA was given by weight for the FA of main interest.

Two-dimensional separation of NPL classes. The standard mixture contained equal amounts (80 µg) of triglycerides, cholesterol, and ceramides (Type IV with α-hydroxy FA and Type III with normal FA), equal amounts (90 µg) of 1,2-diacylglycerol and monoglycerides, 70 µg of free fatty acids (FFA), and 60 µg of cholesteryl esters. All standard lipids were purchased from Sigma (St. Louis, MO). Standard lipid mixture was mixed with an aliquot of the microsomal NPL fraction eluted from Sep-Pak. After evaporation to dryness under nitrogen, the samples were kept in 50 µL of methanol/chloroform (1:1, vol/vol). Lipids were applied at the lower left-hand corner of the 20 × 20 cm thin-layer chromatography (TLC) plate (Kieselgel 60 F_{254}; Merck, Darmstadt, Germany). The plate was developed in the first dimension (15 cm) in solvent system I [4 mL of acetic acid (commercial solution at 96%; Merck) and 96 mL of a mixture containing *tert*-butyl-methyl-ether/hexane, 70:30, vol/vol (Prolabo)]. The solvent was allowed to run up to 3 cm from the top. After drying the plate in air, it was developed in the second dimension (15 cm) (see Fig. 2) in solvent system II [ethyl ether/petroleum spirit/acetic acid (commercial solution at 96%), 90:10:1, by vol (Merck, Prolabo)]. The solvent was allowed to run up to 3 cm from the top. The plate was then removed, air-dried, and sprayed with 2′,7′-dichlorofluoroscein (Merck). The separated lipid spots were identified under ultraviolet light and were scraped into counting vials. The gel was mixed with 10 mL of Picofluor 30 scintillation fluid. Radioactivity was determined as indicated above.

Separation of PL classes. The PL classes were separated by HPLC using a Beckman model 110 A pump and a Lichrospher Si-60 column (5 µm, 4 × 125 mm) (Merck), according to the method described by Niessen and Kreysel (16) and adapted as follows: the solvent mixture contained acetonitrile (solvent A) (Carlo Erba, Val de Reuil, France) and H_2O/NH_4OH (0.2%) (commercial solution at 30%) (solvent B) (Carlo Erba), using a flow rate of 1 mL/min^{-1}. The multiphasic elution gradient is shown in Figure 3 (the solvent B percentage varied from 2 to 25%). The separation was in the following order: phosphatidylinositol, phosphatidylserine, phosphatidylethanolamine (PE), phosphatidylcholine (PC), and sphingomyelin. Fractions were collected and stored under nitrogen at −20°C. The fractions obtained during the species separation were dried under a nitrogen stream, saponified, and methylated (14). The distribution of radioactivity between the

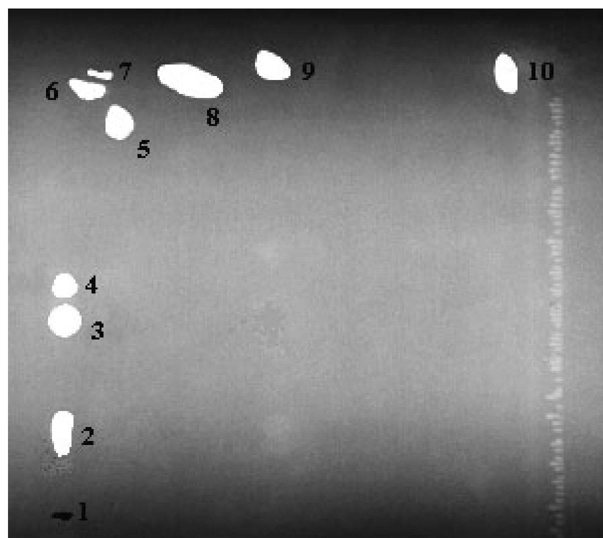

FIG. 2. Representative example of a TLC of radioactive lipids diluted with standard lipids from liver microsomes. 1: origin; 2: ceramide type IV Sigma (St. Louis, MO) with α-hydroxy fatty acids; 3: monoglyceride (MG), 4: ceramide III Sigma with usual fatty acids; 5: cholesterol; 6: 1,2-diacylglycerol (DAG); 7: 1,3-DAG; 8: free fatty acid (FFA); 9: triglyceride (TG); 10: cholesteryl esters (CE). Additionally, 1,3-DAG and 1,2-DAG are well separated from cholesterol. But we have considered the 1,3-DAG and 1,2-DAG together. See Figure 1 for other abbreviation.

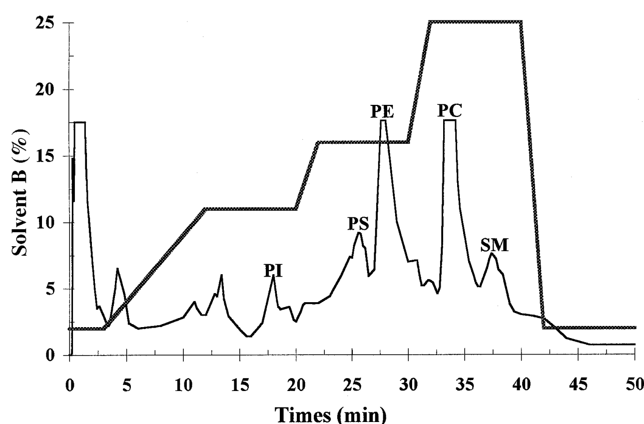

FIG. 3. Separation of phospholipid classes from human fetal liver. The column (4 × 125 mm) was packed with silica (LiChrospher Si 60). Extraction of lipids, application to the column, and elution conditions were as described in the Materials and Methods section. The absorbance of the eluate was measured at 214 nm. PI, phosphatidylinositol; PS, phosphatidylserine; PE, phosphatidylethanolamine; PC, phosphatidylcholine, and SM, sphingomyelin. For the compositions of solvents A and B see the Materials and Methods section.

substrate and the desaturation product in each PL class was determined by reversed-phase HPLC as described above for total PL and NPL fractions.

Statistics. Results are expressed as the mean ± SD for n = 3 fetal liver and were analyzed statistically using a Mann-Whitney nonparametric test (StatView™; Alsyd, Meylan, France). The differences between groups were considered significant at 0.05.

RESULTS

Figure 4 compares the effect of NEM on n-6 Δ6-, n-6 Δ5- and n-3 Δ6-desaturase activities of fetal liver microsomes, showing that 0.52 mM NEM significantly decreased (P < 0.05) linoleic and eicosatrienoic acid conversion: 79 and 69.8% for n-6 Δ5- and n-6 Δ6-desaturase activities, respectively. In contrast, n-3 Δ6-desaturase was not inhibited by NEM but, surprisingly, it increased (49.8%). These results suggest that NEM specifically inhibits Δ6-desaturase activity in the n-6 series but not in the n-3 series. When measured in the incubation medium, the endogenous substrate concentrations were 0.21 µM for 18:2n-6; 0.09 µM for 20:3n-6, and ≤0.004 µM for 18:3n-3 (12). Notably the actual endogenous substrate concentrations were only 0.73, 0.47, and ≤0.007% of the exogenous labeled substrate concentrations. In these experimental conditions, the dilution of exogenous substrate with endogenous substrate was negligible and was not able to interfere significantly in enzyme activity measurements.

Table 1 shows the respective incorporation of substrates and desaturation products into the PL and NPL fractions.

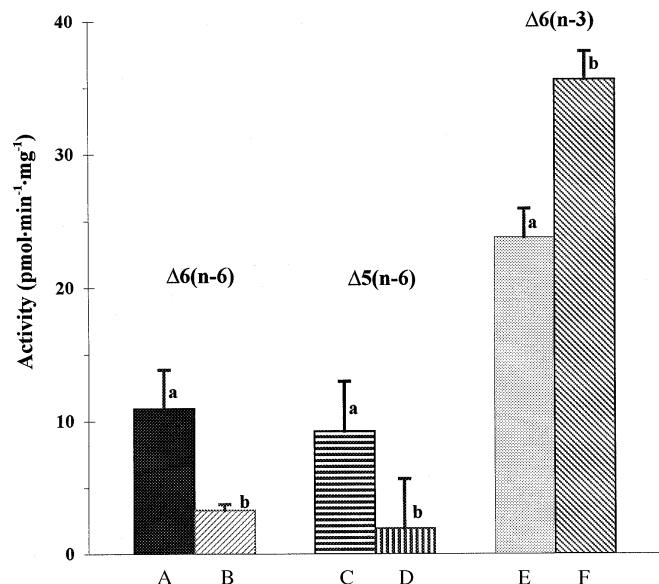

FIG. 4. Comparison of Δ5- and Δ6-desaturase activities in the presence or absence of *N*-ethyl-maleimide (NEM; 0.52 mM). Results are expressed as the mean ± SD for n = 3 fetal liver (age = 24, 24, and 25 wk). The differences between groups were considered significant at P < 0.05 (Mann-Whitney nonparametric test) [A, 18:2n-6 (28.6 µM); B, 18:2n-6 (28.6 µM) + NEM; C, 20:3n-6 (19 µM); D, 20:3n-6 (19 µM) + NEM; E, 18:3n-3 (57 µM); and F, 18:3n-3 (57 µM) + NEM].

TABLE 1
Distribution (%) of Total Radioactivity Between the Phospholipid and Nonphospholipid Fractions from Incubations Carried Out in the Presence and in the Absence of NEM[a]

	A 18:2n-6		B 20:3n-6		C 18:3n-3	
		+NEM		+NEM		+NEM
Phospholipid	11.1	22.2	11.1	8.4	8.6	9.6
Nonphospholipid	88.9	77.8	88.9	91.6	91.4	90.4

[a]The distribution of incorporated radioactivity is expressed as percentage of total radioactivity recovered as phospholipid (PL) plus nonphospholipid (NPL): 30636, 22833, and 66092 cpm in the absence of *N*-ethyl-maleimide (NEM) for A, B, and C incubations, respectively, and 37306, 28564, and 84252 cpm in the presence of 0.52 mM of NEM for A, B, and C incubations, respectively.

Whatever the substrate and in the presence or absence of NEM, most of the radioactivity was recovered in the NPL fraction. When 20:3n-6 and 18:3n-3 were used as substrates (incubations B and C), the distribution varied little in the presence or absence of NEM. When 18:2n-6 was used as substrate, the radioactivity recovered in the PL fraction in the absence of NEM was half that recovered in the presence of NEM.

The radioactivity distribution between substrates and desaturation products in the PL and NPL fractions is shown in Table 2. The incorporation of labeled substrates was clearly higher than that of products in both fractions, in the presence and absence of NEM. In addition, the proportion of recovered products was three- to fivefold higher in PL than in NPL. The percentage of 18:3n-6, 20:4n-6, and 18:4n-3 recovered in microsomal PL was about 3.9-, 5.2- and 3.7-fold higher, respectively, than in microsomal NPL. The highest PL or NPL incorporation was observed for 18:4n-3. This was in accordance with the total enzyme activities observed (Fig. 4). Arachidonic acid was also strongly integrated in the PL fraction despite a lower biosynthesis.

TABLE 2
Distribution (%) of Total Radioactivity Between the Phospholipid and Nonphospholipid Fractions from Incubations Carried Out in the Presence and in the Absence of NEM (0.52 mM)[a]

		Phospholipid		Nonphospholipid	
			+NEM		+NEM
A	18:2n-6	96.1	97.6	99.0	99.2
	18:3n-6	3.9	2.4	1.0	0.8
B	20:3n-6	94.2	96.7	98.9	99.3
	20:4n-6	5.8	3.3	1.1	0.7
C	18:3n-3	90.4	88.4	97.4	97.4
	18:4n-3	9.6	11.6	2.6	2.6

[a]The distribution of incorporated radioactivity is expressed as percentage of total radioactivity recovered as substrate plus product: 5023, 5240, and 6071 cpm in PL and 51622, 36084, and 116684 cpm in NPL in the absence of NEM for A, B, and C incubations, respectively and 7539, 1953, and 5586 cpm in PL and 52017, 36303, and 109380 cpm in NPL in the presence of 0.52 mM NEM for A, B, and C incubations, respectively. See Table 1 for abbreviations.

TABLE 3
Distribution (%) of Total Radioactivity into Different Classes of the Nonphospholipid Fraction from Incubations Carried Out in the Presence and in the Absence of NEM[a]

	A 18:2n-6		B 20:3n-6		C 18:3n-3	
		+NEM		+NEM		+NEM
Origin	4.29	0.89	2.99	0.95	9.62	0.93
Ceramide IV	2.41	0.78	2.40	1.37	3.35	0.25
Ceramide III	2.95	0.56	2.90	1.11	3.75	0.12
Monoglycerides	0.78	ND	1.57	0.72	1.56	ND
Cholesterol	1.07	0.28	2.27	1.37	1.89	0.82
DAG (1,2- + 1,3-)	ND	1.20	7.22	7.52	8.13	3.09
FFA	76.7	90.14	74.38	84.63	63.04	91.79
TG	4.17	0.49	3.83	0.26	5.31	0.22
CE	3.13	0.33	0.52	0.15	0.67	0.18

[a]Data are means of three countings. The distribution of incorporated radioactivity is expressed as percentage of total radioactivity recovered as substrate plus product: 40900, 33600, and 105000 cpm in the absence of NEM for A, B, and C incubations, respectively, and 195500, 140000, and 833239 cpm in the presence of 0.52 mM NEM for A, B, and C incubations, respectively. DAG, diacylglycerol; FFA, free fatty acid; TG, triglycerides; CE, cholesteryl esters. ND, nondetectable. See Table 1 for other abbreviation.

Figure 2 shows a typical two-dimensional TLC of lipids from liver microsomes. Data are reported in Table 3. Whatever the substrate, most of the total radioactivity was found in the FFA fraction. The percentage of total radioactivity (substrate plus product) recovered in the FFA fraction increased in the presence of NEM: 90.2% vs. 76.7%, 84.6% vs. 74.4%, and 91.8% vs. 63% in incubations A, B, and C, respectively. The second-highest radioactivity incorporation was found in diacylglycerol (1, 2- plus 1, 3-) for B and C, but was undetectable in incubation A, in the absence of NEM.

In triglyceride, monoglyceride and ceramide III and IV fractions, the percentage of radioactivity distribution was in the same range whatever the substrate, but decreased with NEM.

Surprisingly, some radioactivity was detected in the cholesterol fraction, but it was also lower when incubations were conducted in the presence of NEM.

The NPL fractions were esterified and analyzed by gas–liquid chromatography (Table 4). The comparison of FA composition in these different fractions obtained from incu-

[a]Results are expressed as percentage of total identified fatty acids. *The bold characters refer to the fatty acid composition resulting from the addition of exogenous radioactive fatty acid substrates in the medium and their conversion products. Other values report the endogenous microsome fatty acid composition in each incubation condition. For abbreviations see Tables 1 and 3.

TABLE 5
Distribution (%) of Radioactive Precursors and Products in Phospholipid Classes[a]

	PI	PS	PE	PC	SM
18:2n-6	5.6	7.8	12.9	70.1	2.2
18:3n-6	Trace	Trace	Trace	1.4	
20:3n-6	18.0	10.25	21.0	60.2	2.7
20:4n-6	Trace		1.7	4.2	
18:3n-3	9.3	5.8	16.1	65.6	1.9
18:4n-3			Trace	1.2	

[a]The distribution of incorporated radioactivity is expressed as percentage of total radioactivity. Data are means of three countings. PI, phosphatidylinositol; PS, phosphatidylserine; PE, phosphatidylethanolamine; PC, phosphatidylcholine; SM, sphingomyelin.

bations in the presence and in the absence of NEM showed that 18:2n-6, 20:3n-6, and 18:3n-3 contents (radioactive plus endogenous substrates in heavy characters) were, respectively, about 3-fold, 15.5-fold, and ≫15-fold higher than the concentration of the corresponding endogenous substrate. Compare for instance 18:2n-6 (heavy characters) in incubation A with 18:2n-6 (endogenous) in incubations B and C. This shows that the FFA of the NPL fraction (the actual substrate of mammalian desaturases) was mainly constituted with exogenous substrate. The desaturation products were distributed among different classes, but at substantially lower levels. The high 18:4n-3 content reflected a high conversion rate.

Table 5 shows the distribution of labeled substrates and products among the different PL classes. They were essentially incorporated into PC and to a lesser extent into PE. The highest percentage of incorporated desaturation product was observed with arachidonic acid.

DISCUSSION

Liver samples were obtained from fetuses having anatomic malformations, but none of the fetuses came from mothers affected with metabolic disorders. No therapeutic interventions were reported in the antecedents except for the expulsion protocol. The low frequency of legally approved medical abortions that provide good conditions for sampling considerably reduced the number of usable livers. In addition, due to the multiplicity of studies on the same human material, the available biological material was limited. To ensure that enzyme activities remained unaltered, livers were immediately frozen in liquid nitrogen and processed as soon as possible. The difference in desaturase activities before and after deep-freezing remained in the range of the experimental variation (17).

The n-6 Δ6-, n-6 Δ5-, and n-3 Δ6-desaturase activities were 10.9, 9.3, and 23.8 $pmol \cdot min^{-1} \cdot mg^{-1}$, respectively (Fig. 4) in the absence of NEM. These values are within the range of the data previously obtained in fetuses of the same gestational age and at the same substrate concentration (8). The Δ6-desaturase activity in the n-3 series was higher than the Δ6- and Δ5-desaturase activities in the n-6 series. All these activities in human fetal liver were lower than in human adults or animals, especially rodents (12).

Some *in vitro* studies suggested that substrate FA incorporation into microsomal lipids may compete with the desaturation reaction (10,18,19). According to this hypothesis, the FA substrate would be preferentially incorporated into PL and only the nonincorporated substrate would be desaturated. In order to verify this hypothesis, we blocked the acyltransferase activity by means of NEM, an SH reagent that was reported to inhibit this activity (20). In this condition, the desaturase activities were expected to increase due to the inhibition of the competing acyltransferase activity. In the presence of NEM, a significant increase in n-3 Δ6-desaturase activity was observed (49%, $P < 0.025$) in accordance with the hypothesis. In contrast, n-6 Δ6- and Δ5-desaturase activities were strongly decreased by 79 and 69.8%, respectively (Fig. 4). It should be noted that this result is consistent with that of Yamaoka *et al*. (21), who showed that NEM inhibited n-6 Δ5-desaturase activity by 46% of control in rat liver. However, this was never reported for Δ6-desaturase. It could be hypothesized that alteration of endogenous substrate concentration under the NEM influence could be responsible for enzyme activity variation by diluting the exogenous substrate. However, notably the actual substrates of desaturases in mammals are not PL FA but only acylCoA. In our experimental conditions, the concentrations of endogenous unesterified FA are much lower than exogenous substrate concentrations and account only for 0.007 to 0.7% of exogenous substrate (cf. Results and Ref. 12). In these conditions, it is very unlikely that endogenous substrate concentration variation could significantly alter the measurement of desaturase activity.

The fact that NEM inhibited the Δ5- and Δ6-desaturase activities of the n-6 series, but not the Δ6-desaturase activities of the n-3 series, may be due to a direct interaction with the enzymes and/or membrane environment modifications. In any case, these results suggest the existence of two distinct Δ6-desaturases, one for the n-6 series and another for the n-3 series. Another study has suggested this by reporting that sesame oil specifically inhibited n-6 Δ5-desaturase of rat liver but not n-3 Δ5-desaturase (22).

We investigated the distribution in the different lipid classes and PL subclasses of [1-^{14}C]18:2n-6, [1-^{14}C]18:3n-3, and [1-^{14}C]20:3n-6 and their desaturation products [1-^{14}C]-18:3n-6, [1-^{14}C]18:4n-3, and [1-^{14}C]20:4n-6, respectively, after *in vitro* Δ5- or Δ6-desaturation. In the presence or absence of NEM, the substrate and product radioactivity was recovered mainly in the NPL fraction (Table 1). Two hypotheses could explain why NEM did not clearly alter the FA radioactivity distribution between the PL and NPL fractions: either the incubation conditions and/or the microsome preparation that were adapted to desaturase measurement were inadequate for acyltransferase activity, or the acyltransferase system was overloaded by exogenous substrate. The first hypothesis is unlikely since it was recently shown that acyltransferase and Δ6-desaturase activity can be evaluated using the same liver microsome preparation and the same incubation

conditions (23). Overloading of the acyltransferase system is more likely. It should be recalled as indicated above, that in the incubation medium, the FFA concentration resulting mainly from addition of exogenous radioactive substrate was higher than the FA concentration in endogenous membranes and considerably higher than the endogenous FFA concentration. Recently, the activity ratio of acyltransferase/Δ6 n-6 desaturase was estimated to be about 10:1 in rat liver (23). The amount of substrate transformed by the fetal hepatic desaturase, in 15 min in the incubation medium, can be calculated from the specific activity measured for instance for Δ6-linoleic desaturase. If the ratio of acyltransferase/Δ6 n-6 desaturase would be in the same range as in the rat liver, the amount of linoleic acid reacylated would be 10 times higher. When calculated, this theoretical amount of reacylated linoleic acid accounts for only 10% of the exogenous substrate. This interpretation is supported by the observation that about 90% of the exogenous radioactive substrate remained in the NPL fraction, and about 80% was recovered in the FFA form (Tables 1 and 3).

Considering the distribution of the neoconverted FA, it is noteworthy that they tended to be incorporated more into the PL fraction than in the NPL fraction (Table 2), both in the presence and absence of NEM. This preferential PL incorporation of products suggests channeling of the neoconverted PUFA toward the PL of microsomal membrane. This could be of special importance for the control of the desaturation level of the constitutive lipids, a critical parameter for the maintenance of membrane functions.

In the presence of NEM, we observed that the percentage of recovered radioactivity was lower in all lipid fractions, with the exception of FFA, in all incubation conditions (Table 3). This indicates a shift in the radioactivity toward the FFA fraction in the presence of NEM, in agreement with a limited lowering of the acyltransferase activity by this compound. Surprisingly, traces of radioactivity were detected several times in the cholesterol or sterol fraction. Contamination with the radioactivity from another fraction is an unlikely explanation. The liver is a major site of cholesterol biosynthesis, and it should be noted that our incubation medium offered all the conditions for sterol synthesis: liver microsomes had very active HMGCoA reductase; the crude microsomal preparation carried some light mitochondria and/or mitochondrial fragments able to perform β-oxidation; a few cytosols were added to the incubation medium that also contained the cofactors of sterol synthesis, NADPH and ATP; and the incubation duration was 15 min.

The PL-incorporated substrates and products showed that most of the labeled FA were incorporated into PC and to a lesser extent into PE (Table 5). This observation is in agreement with the accepted notion that PC and PE are the main PL classes synthesized at the outer surface of the endoplasmic reticulum (24). Regarding the desaturation products, PC again appears to be the main acceptor. It is interesting to note that the proportion of substrate converted into 20:4n-6 and incorporated into PC and PE was about twice that of 18:4n-3 and 18:3n-6. This result suggests that direct incorporation of arachidonic acid into PC and PE could very efficiently contribute to the maintenance of the high level of this FA in these PL classes. This observation is in agreement with our data obtained in total PL and confirms that a different channeling may be involved in human liver microsomes for the processing of desaturation substrates and products. Such a channeling would give some priority to the neoconverted FA toward the exogenous PUFA.

Dietary α-Linolenate Suppresses Endotoxin-Induced Platelet-Activating Factor Production in Rat Kidney

Kentaro Oh-hashi, Tetsuya Takahashi, Akiko Tanabe, Shiro Watanabe, and Harumi Okuyama*

Department of Biological Chemistry, Faculty of Pharmaceutical Sciences, Nagoya City University, Nagoya 467-8603, Japan

ABSTRACT: In comparison with dietary high-linoleate safflower oil, high α-linolenate perilla oil decreased alkylacyl- and alkenylacyl-glycerophosphocholine (GPC) content in rat kidney by roughly 30 and 25%, respectively. The fatty acid composition was also modified by high α-linolenate oil; arachidonic acid (AA) level in alkylacyl-GPC, a platelet-activating factor (PAF) precursor, decreased by 30% along with concomitant increases in the n-3 fatty acid levels. PAF contents under resting conditions were similarly low in the two dietary groups. Fifteen minutes after endotoxin administration, PAF and lyso-PAF contents increased significantly, and the PAF content in the high α-linolenate group was 60% lower than in the high linoleate group; the lyso-PAF contents also tended to be lower. Lyso-PAF acetyltransferase and CoA-independent transacylase activities in kidney microsomes increased significantly after endotoxin administration, while PAF acetylhydrolase activity in the cytosol was relatively unchanged. The lyso-PAF acetyltransferase and PAF acetylhydrolase activities did not differ between the two dietary groups, but the CoA-independent transacylase activity was roughly 30% lower in the high α-linolenate group. In agreement with *in vitro* study, our present study demonstrates that dietary high α-linolenate suppresses PAF production in rat kidney during systemic endotoxemia, and which is mainly due to the decrease in alkylacyl-GPC content, altered fatty acid compositions of the precursor lipids and lower CoA-independent transacylase activity.

Paper no. L7952 in *Lipids 34*, 31–37 (January 1999).

1-*O*-Alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (platelet-activating factor, or PAF) and PAF analogs are potent proinflammatory mediators produced by stimulated phagocytes and endothelial cells. They cause a wide range of biological responses including platelet aggregation, activation of leukocytes, broncho-constriction, increased vascular permeability, and systemic hypotension (1–6). PAF is associated with many pathological states, particularly with endotoxic shock, as noted by increased plasma PAF levels in gram-negative sepsis and experimental endotoxemia. Results of the administration of PAF to experimental animals mimic many pathophysiological features of endotoxic shock, and PAF receptor antagonists have been shown to ameliorate endotoxin-induced hypotension and prolong survival time (7–9).

A number of studies have shown that dietary n-3 fatty acids are effective in reducing arachidonic acid (AA) in membrane phospholipids, attenuating the production of biologically active eicosanoids and PAF, and ameliorating inflammatory diseases (10–14). We have demonstrated that dietary supplementation with perilla oil, having high α-linolenate (18:3n-3) and low linoleate (18:2n-6) contents, suppresses PAF production in rat peritoneal polymorphonuclear leukocytes (PMN) as compared with high linoleate safflower oil, and we have proposed a possible mechanism of the reduction of PAF synthesis in PMN by feeding perilla oil (15,16). In rat kidney, Yeo *et al.* (17) reported that dietary eicosapentaenoate- and docosahexaenoate-rich fish oil reduced the lyso-PAF acetyltransferase activity in microsomes. Furthermore, Park *et al.* (18) showed that dietary high α-linolenate perilla oil decreased the alkylacyl-glycerophosphocholine (GPC) content in rat kidney. However, the dietary effects of these n-3 fatty acids on PAF biosynthesis in kidney *in vivo* have not been evaluated directly by measuring PAF levels because of its presence in low concentrations and rapid hydrolysis to lyso-PAF *in vivo*. Furthermore, we noted no significant differences in alkylacyl-GPC contents in PMN of rats fed perilla oil or safflower oil (15).

The purpose of the present study was (i) to evaluate whether dietary high α-linolenate perilla oil changes the PAF precursor content in rat kidney compared with dietary high linoleate safflower oil and (ii) to quantify and compare PAF biosynthesis *in vivo* using an endotoxemia model.

MATERIALS AND METHODS

Reagents. 1-*O*-Alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (PAF) was purchased from Avanti Polar Lipids Inc. (Birmingham, AL). [^{3}H]PAF was prepared by treating 1-*O*-[^{3}H]octadecyl-2-lyso-*sn*-glycero-3-phosphocholine ([^{3}H]-lyso-PAF, 148 MBq/mmol) (Amersham Co., Buckinghamshire, England) with acetic anhydride/pyridine. [^{14}C]Acetyl-CoA (3.6

MBq/mmol) was purchased from American Radiolabeled Chemicals Inc. (St. Louis, MO). Endotoxin (lipopolysaccharide, *E. coli* 026: B6) and phospholipase C (*Bacillus cereus*) were obtained from Sigma Chemical Co. (St. Louis, MO). Sep-Pak silica cartridges were purchased from Waters Co. (Milford, MA). Silica gel 60 thin-layer chromatography (TLC) plates were obtained from Merck (Darmstadt, Germany). 3,5-Dinitrobenzoyl chloride (DNBC) was obtained from Dojindo (Kumamoto, Japan).

Animals and diets. Male Sprague-Dawley rats (SLC Co., Shizuoka, Japan) at 3 wk of age were divided randomly into two groups and fed a diet supplemented either with linoleate-rich (18:2n-6) safflower oil or with α-linolenate-rich (18:3n-3) perilla oil *ad libitum* for 5 wk. These diets were prepared by supplementing a semipurified fat-free diet (Clea Japan Co., Tokyo, Japan) with 10% (w/w) safflower oil or perilla oil (Ohta Oil Mill Co., Okazaki, Japan). The diets were stored at −20°C. The fatty acid composition of the test diets is shown in Table 1.

Animal treatment. Following anesthesia with sodium pentobarbital (50 mg/kg body weight, i.p.), endotoxin (5 mg/kg) or vehicle (phosphate-buffered saline, 2.5 mL/kg) was injected intravenously. After 15 min, 0.8 mL of whole blood was collected by heart puncture in EDTA and immediately mixed with 3 mL of chloroform/methanol (1:2, vol/vol). Tissue samples (kidney and lung) were harvested, quickly frozen with liquid nitrogen, and stored at −80°C until use.

Measurement of PAF and lyso-PAF. For the PAF and lyso-PAF assays, frozen tissues were thawed and homogenized in 20 mL chloroform/methanol/water (1:2:0.8, by vol). Total lipids were extracted from whole blood and tissue homogenates using the methods of Bligh and Dyer (19). After evaporation of the solvent under N_2 gas, the residue was dissolved in chloroform. The extracted total lipids were applied to a Sep-Pak silica cartridge, which was sequentially washed with 10 mL chloroform, 10 mL acetone, 10 mL acetone/methanol (1:1, vol/vol), and 10 mL chloroform/methanol (7:3, vol/vol) (20). A 10-mL chloroform/methanol/water (1:2:0.8, by vol) eluate was collected, and the lipids were extracted again using the method of Bligh and Dyer. Individual phospholipids were separated by silica gel TLC with chloroform/methanol/water (65:35:6, by vol) as a developing solvent. The areas corresponding to PAF and lyso-PAF were scraped off the plates, and the lipids were extracted as described above. After evaporation of the solvent under N_2 gas, the residue containing PAF was dissolved in Tyrode's solution (3.8 mM HEPES; 2.7 mM KCl; 0.4 mM NaH_2PO_4; 137 mM NaCl; 0.5 mM $MgCl_2 \cdot 6H_2O$; 1.8 mM $CaCl_2$; 5.6 mM glucose; 0.25% gelatin, pH = 7.35) containing 0.25% bovine serum albumin. The residue containing lyso-PAF was chemically acetylated to PAF using acetic anhydride/pyridine (5:1, vol/vol) (21) and dissolved as described above. PAF was quantified by measuring the aggregation of washed rabbit platelets as described previously (22). Briefly, 100 µL of platelet suspension (2.5×10^8/mL) in Tyrode's solution was prewarmed to 37°C and stirred at 1000 rpm. Platelet aggregation was recorded as the percentage change in light transmission after the addition of 10 µL of test sample. PAF concentration was calculated based on a calibration curve obtained with known concentrations of authentic PAF. The recovery of [^{3}H]PAF, which had been spiked into total lipids, in the eluates from Sep-Pak cartridge was more than 95%, and that from TLC was about 75% as estimated using a PAF standard. Total recovery measured by the addition of [^{3}H]PAF to the tissue homogenates was more than 70%. The platelet aggregation-inducing activity of PAF was blocked completely by CV6209, a PAF receptor antagonist (23).

Fatty acid analysis. The total lipids in kidney were extracted as described above. The individual phospholipids were separated by silica gel TLC with chloroform/methanol/acetic acid/water (25:15:4:2, by vol). The area corresponding to cholinephospholipids (PC) was scraped off the plates, and PC were extracted as described above. The fatty acid compositions of PC subclasses were measured according to the method of Nakagawa *et al.* (24). Briefly, PC were hydrolyzed with phospholipase C, and the resultant diradylglycerols (DG) were treated with acetic anhydride and pyridine. The samples were dried under N_2 gas and separated by TLC using petroleum ether/diethyl ether/acetic acid (90:10:1, by vol) and then with toluene. The area corresponding to each DG subclass was scraped from the plates, heptadecanoic acid was added as an internal standard, and the lipids were extracted as described above. Fatty acid methyl esters were obtained by treating the total lipids with 50 mg/mL hydrogen chloride in methanol for 1 h in a boiling water bath, and were analyzed by gas–liquid chromatography as described previously (25). Alternatively, PC subclass contents were determined according to the method of Kito *et al.* (26) with slight modifications. Briefly, alkylacyl-GPC (PAF) was added as an internal standard to the PC residue and hydrolyzed with phospholipase C as described above. The resultant DG were treated with DNBC (25 mg/0.5 mg DG) in pyridine and incubated for 10 min at 60°C to yield the dinitrobenzoyl (DNB) esters of DG. The DNB esters of DG were applied to a Sep-Pak C18 car-

TABLE 1
Fatty Acid Composition of Test Diets[a]

Fatty acid	Safflower oil	Perilla oil
	% (w/w) of total fatty acids	
16:0[b]	6.6	6.4

18:1	14.6	21.0
18:2n-6	75.9	13.4
18:3n-3	0.4	57.2
18:2n-6/18:3n-3 ratio	190	0:23

[a]All components for the preparations of test diets were supplied by Clea Japan Inc. (Tokyo, Japan). The test diets consisted of 44.5% cornstarch, 23.3% casein, 1.9% α-starch, 7.6% cellulose powder, 4.7% sucrose, 1.9% vitamin mixture, 5.7% mineral mixture, 0.4% *dl*-methionine, and 10% each oil. The fatty acid composition of each diet was analyzed by gas–liquid chromatography.
[b]Fatty acids are designated by the carbon chain: the number of double bonds. The position of the first double bond numbered from the methyl terminus is designated as n-6 or n-3.

tridge, and methanol eluates were dried and dissolved in methanol. An aliquot of the solution was applied to high-performance liquid chromatography (HPLC) on a normal-phase HPLC column (Rainin Silica, 4.56 × 250 mm; Rainin Instrument Co. Inc., Woburn, MA) using the mobile phase of hexane/diethyl ether/ethanol (87.5:12.5:0.05, by vol), and the DNB esters of DG were quantitated at 254 nm. The DNB derivatives of alkylacylglycerol, alkenylacylglycerol, alkylacetylglycerol (an internal standard), and diacylglycerol were eluted in order. The phosphorus contents of PC and ethanolaminephospholipid (PE) were determined using the method of Bartlett (27).

Lyso-PAF acetyltransferase, PAF acetylhydrolase and CoA-independent transacylase activities. For lyso-PAF acetyltransferase assay, frozen kidney was thawed and homogenized in 10 vol of 0.25% sucrose, 20 mM Tris-HCl, 10 mM EDTA, 5 mM mercaptoethanol, 50 mM NaF (pH 7.4) using a glass homogenizer (10 strokes). The homogenate was first centrifuged at 450 × *g* for 10 min to remove cellular debris and nuclei. After further centrifugation at 15,000 × *g* for 10 min, membrane pellets were prepared from the supernatant fraction by centrifugation at 100,000 × *g* for 60 min. The microsomes were resuspended in 0.25 M sucrose/1 mM dithiothreitol/20 mM Tris-HCl (pH 7.4). Lyso-PAF acetyltransferase activities were measured by incubating 200 µg of microsomal proteins in 0.8 mL of 0.1 M Tris-HCl (pH 6.9) containing 200 µM [^{14}C]acetyl-CoA and 25 µM lyso-PAF for 10 min at 37°C as described by Lee (28). The total lipids were extracted, and the radioactivity corresponding to PAF on TLC was determined using a liquid scintillation counter. PAF acetylhydrolase was assayed according to the method of Blank *et al.* (29). Briefly, kidney was homogenized in 10 vol of 0.25% sucrose and fractionated as described above. PAF acetylhydrolase activities in cytosolic fractions were measured at 37°C after incubation for 10 min in 0.3 mL 0.1 M phosphate buffer (pH 8.0) containing 25 µg cytosol protein and 10 µM [^{3}H]PAF. After the extraction of total lipids, PAF and lyso-PAF were separated and their radioactivities were counted. For the determination of CoA-independent transacylase activities, incubation was carried out at 37°C for 3 min in 0.4 mL 0.1 M Tris-HCl buffer (pH 7.4) containing 100 µg microsomal protein and 2 µM [^{3}H]lyso-PAF (30). After the extraction of total lipids, PC, lyso-PAF, and neutral lipids were separated and their radioactivities were quantified.

Statistical analysis. Statistical analysis was performed using the Student's *t*-test and two-way analysis of variance (StatView–4.02, Abacus Concepts Inc., Berkeley, CA), and probability (P) values below 0.05 were considered significant.

RESULTS

Fatty acid composition of PC in rat kidney. There were no significant differences in body and kidney weights between the two dietary groups (data not shown). The most abundant phospholipid in kidney was PC, and its content was not different between the high linoleate safflower oil group and the high α-linolenate perilla oil group (9.59 ± 0.25 and 9.35 ± 0.22 µmol/g tissue, respectively).

TABLE 2
Subclass Composition of PC in Rat Kidney[a]

Subclass	Safflower oil group	Perilla oil group
	(mol %)	
Experiment 1		
Diacyl	96.20 ± 0.53	97.40 ± 0.26**
Alkylacyl	1.47 ± 0.09	1.04 ± 0.07*
Alkenylacyl	2.32 ± 0.49	1.60 ± 0.18
Experiment 2		
Diacyl	96.71 ± 0.20	97.48 ± 0.18*
	(9.28 ± 0.25)	(9.11 ± 0.22)
Alkylacyl	1.48 ± 0.11	1.07 ± 0.10*
	(0.14 ± 0.01)	(0.10 ± 0.01)
Alkenylacyl	1.81 ± 0.10	1.45 ± 0.10*
	(0.17 ± 0.01)	(0.13 ± 0.01)

[a]The compositions of cholinephospholipid (PC) subclasses in rat kidney were analyzed by gas–liquid chromatography (Experiment 1) and high-performance liquid chromatography (Experiment 2) as described in the Materials and Methods section. Values are the means ± SEM (n = 5–7). Values in parentheses denote the amounts expressed as µmol/g wet tissue. Statistical analysis was performed by Student's *t*-test; *$P < 0.05$ and **$P < 0.10$.

The molar proportions of PC subclasses are shown in Table 2. When determined using the gas–liquid chromatography method, the alkylacyl and alkenylacyl forms were minor components of the total PC fraction in rat kidney (<3%), in contrast to the reported values of 10–25% (18). However, a significant decrease in alkylacyl-GPC content (by 30%) was reproducibly observed in the perilla oil group as compared with the safflower oil group. In view of the importance of accurately determining the content of PAF precursor, we applied the HPLC method. Again, the alkylacyl-GPC and alkenylacyl-GPC contents in the perilla oil group were significantly lower than in the safflower oil group by 27 and 20%, respectively.

The acyl chain compositions of PC subclasses are presented in Table 3. In regard to alkylacyl-GPC content, the major polyunsaturated fatty acid (PUFA) in the high linoleate safflower oil group was AA, but the AA content was more than 50% lower, which was compensated for by marked increases in eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) contents in the high α-linolenate perilla oil group. The dietary oil-induced changes in fatty acid compositions were qualitatively similar among the three PC subclasses. Despite a very low linoleate/α-linolenate ratio (0.23) in the perilla oil diet, the linoleate content was significantly higher than in the safflower oil group, and α-linolenate was a relatively minor component of the three PC subclasses. The compositions of dimethyl acetal derived from alkenylacyl-GPC did not differ between the two dietary groups (data not shown).

The content of another major phospholipid, PE, did not differ between the two dietary groups, and the differences in the fatty acid compositions of PE between the two dietary groups were also similar to those of the PC subclasses (data not shown).

[a]Values represent means ± SEM (n = 5). Statistical significance of the differences (*P < 0.05) between the safflower (SAF) and perilla (PER) oil groups were evaluated by Student's t-test. EPA, eicosapentaenoic acid; AA, arachidonic acid; for other abbreviation see Table 2.

Endotoxin-induced PAF production in vivo. In preliminary experiments on rats fed a conventional diet, kidneys contained 0.82 ± 0.11 pmol PAF/g tissue (n = 5). The PAF levels 15 min after i.v. injection of endotoxin increased significantly to 14.60 ± 1.70 pmol/g tissue (n = 5), but values 30 min after endotoxin injection decreased markedly, to 2.77 ± 1.01 pmol/g tissue (n = 3) although they were still higher than the basal values. Therefore, we compared the PAF levels in whole kidney homogenates of the two dietary groups at 15 min after endotoxin treatment.

As shown in Figure 1, PAF levels in whole kidney homogenates of endotoxin-treated rats in the high linoleate safflower oil group were significantly higher than in the high α-linolenate perilla oil group. On the other hand, PAF levels in kidney homogenates of vehicle-treated rats were quite low and did not differ between the two dietary groups. In contrast, the lyso-PAF levels in kidney were remarkably higher than the PAF levels even under control conditions, and increased further and significantly 15 min after endotoxin administration. Lyso-PAF levels in the high α-linolenate group were

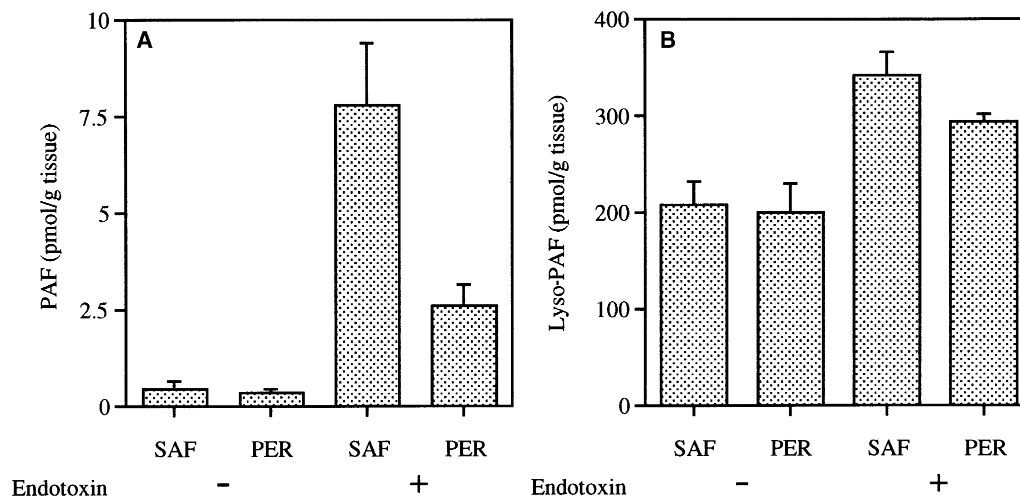

FIG. 1. Effect of dietary fatty acids on platelet-activating factor (PAF) and lyso-PAF contents in rat kidney. Endotoxin (5 mg/kg) or vehicle was injected i.v. into anesthetized rat. Fifteen minutes after injection, kidneys were harvested and stored at −80°C. PAF and lyso-PAF contents were measured as described in the Materials and Methods section. Each value represents the mean ± SEM from 7–8 rats. PAF and lyso-PAF contents in the endotoxin-injected rats were significantly higher than those in the phosphate-buffered saline-injected control rats (P < 0.05). PAF content in rat kidney from the high α-linolenate group (perilla oil, PER) was significantly lower than that from the high-linoleate group (safflower oil, SAF) (P < 0.05). Statistical analysis was performed by two-way analysis of variance.

TABLE 4
Effect of Dietary Fatty Acid on Lyso-PAF Acetyltransferase, PAF Acetylhydrolase and CoA-Independent Transacylase in Rat Kidney[a]

	Control		Endotoxin		ANOVA		
	SAF	PER	SAF	PER	Endotoxin	Diet	Endotoxin × Diet
Lyso-PAF acetyltransferase (nmol/min/mg protein)	0.13 ± 0.00 (5)	0.13 ± 0.00 (5)	0.17 ± 0.01 (6)	0.19 ± 0.02 (6)	$P < 0.01$	N.S.	N.S.
PAF acetylhydrolase (nmol/min/mg protein)	1.76 ± 0.13 (5)	1.68 ± 0.21 (5)	1.82 ± 0.22 (7)	1.53 ± 0.18 (7)	N.S.	N.S.	N.S.
CoA-independent transacylase (pmol/min/mg protein)	20.5 ± 0.7 (5)	15.4 ± 1.1 (5)	24.8 ± 1.0 (5)	18.6 ± 2.0 (5)	$P < 0.02$	$P < 0.01$	N.S.

[a]Endotoxin (5 mg/kg) or phosphate-buffered saline was injected into the tail vein of anesthetized rats. Fifteen minutes after injection, kidneys were harvested and stored at −80°C. Each enzymatic activity was measured as described in the Materials and Methods section. Each value represents the mean ± SEM. Numbers in parentheses represent the number of rats used. Statistical analysis was performed by two-way analysis of variance (ANOVA); N.S., not significant. PAF, platelet-activating factor; for other abbreviations see Table 3.

30% lower (45.3 pmol/g tissue) than those in the high linoleate group following endotoxin administration.

Because Chang *et al.* (9) had reported that blood and lung PAF levels increase within 20 min after intraperitoneal injection of endotoxin, we also measured PAF levels in whole blood and lung homogenates of the two dietary groups. The blood PAF levels in the two dietary groups 15 min after PBS or endotoxin administration were below detection (<0.02 pmol/mL whole blood). The PAF levels in the lung homogenates of both the dietary groups were significantly higher than those of the kidney under resting conditions [2.39 ± 0.29 pmol/g tissue in the high linoleate group (n = 3) and 1.99 ± 0.47 pmol/g tissue in the high α-linolenate group (n = 3)]. PAF levels following endotoxin administration showed no increase over the control values in either dietary group [1.74 ± 0.36 pmol/g tissue in the high linoleate group (n = 5) and 2.26 ± 0.47 pmol/g tissue in the high α-linolenate group (n = 5)].

Lyso-PAF acetyltransferase, PAF acetylhydrolase and CoA-independent transacylase activities in rat kidney. Microsomes of the rats after endotoxin administration showed significantly higher lyso-PAF acetyltransferase activity compared with those of vehicle-treated rats (Table 4). However, the activity of this enzyme was not affected by dietary oils. PAF acetylhydrolase activity in the cytosolic fraction was about 10-fold higher than the lyso-PAF acetyltransferase activity in microsomes. Neither endotoxin treatment nor dietary manipulation affected the PAF acetylhydrolase activity in the cytosolic fraction. The CoA-independent transacylase activity in microsomes of the high α-linolenate group was about 30% lower than that from the high-linoleate group. When the microsomes were prepared from endotoxin-treated rats, the CoA-independent transacylase activity increased slightly but significantly ($P < 0.05$), and the 25% difference was maintained between the two dietary groups.

DISCUSSION

A number of investigations have shown that dietary n-3 fatty acids are effective in reducing the AA content in membrane phospholipids and attenuating PAF production (10–13), but these effects have been evaluated only in isolated cells *in vitro* (14,15). Because the amounts of PAF produced in most tissues are remarkably small and PAF is rapidly degraded by PAF acetylhydrolase *in vivo* (31), it is not clear whether dietary n-3 fatty acids really decrease PAF production in tissues *in vivo*. In the present study, we found that PAF content in rat kidney significantly increases within 15 min after endotoxin administration and that the high α-linolenate diet decreases PAF production in kidney during systemic endotoxemia compared with the dietary high linoleate diet. Among the kidney cells, mesangial cells in glomeruli synthesize PAF in response to several stimuli including endotoxin (32). Pirotzky *et al.* (33) reported that glomerular and medullary cells in the isolated kidney are capable of forming PAF. Recently, we found that dietary high α-linolenate oil suppresses PAF production in rat resident macrophages in peritoneum and lung (Takahashi, T., Oh-hashi, K., Tanabe, A., Watanabe, S., and Okuyama, H., unpublished data) as well as in PMN (15,16). Therefore, mesangial cells may be responsible for the reduced production of PAF in the high α-linolenate group compared with that in the high-linoleate group.

Moreover, we observed that the high α-linolenate diet decreases alkylacyl- and alkenylacyl-GPC contents in rat kidney compared with the high linoleate diet, which is consistent with the previous report of Park *et al.* (18). Yeo *et al.* (34) showed that dietary fish oil decreases the rate of alkylacyl-GPC biosynthesis in rat kidney by using [^{3}H] glycerol, but the precise mechanism remains to be determined. The lower proportion of ether-linked PC in rat kidney in our study (<3%) was consistent with the observation of Blank *et al.* (30), but was much lower than that (10–20%) reported by Park *et al.* (18). We considered that differences in strains, oils, and experimental conditions could be the causes for these inconsistent observations.

As compared with the high linoleate group, the AA content in alkylacyl-GPC in kidney decreased along with concomitant increases in the linoleate (18:1); EPA (20:5n-3), and DHA contents in the high α-linolenate group. The higher content of 18:1 in perilla oil (Table 1) may be the cause of the increased 18:1 content in kidney PC and PE (Table 3). Alternatively, competitive inhibition by α-linolenate and feedback inhibition by EPA and DHA derived from α-linolenate could be the causes for the increased linoleate levels in PC

and PE in the high α-linolenate group (35). Suga *et al*. (36) showed the important role of AA at the *sn*-2 position of alkylacyl-GPC for the PAF biosynthesis *in vitro*. Moreover, cytosolic phospholipase A_2 has been shown to be relatively specific for AA and EPA, but not for DHA (37). Therefore, the decreases in not only AA content but also the sum of AA and EPA content in alkylacyl-GPC in the high α-linolenate group would contribute to the decreased production of PAF.

Some investigators have suggested that the activities of several enzymes responsible for PAF biosynthesis *via* the remodeling pathway were attenuated by dietary n-3 fatty acids. Yeo *et al.* (17) reported that lyso-PAF acetyltransferase activity in kidney microsomes from fish oil-fed rats was lower than that of the high linoleate oil-fed rats. We previously reported that CoA-independent transacylase activity in rat PMN homogenates from the high α-linolenate group was lower than that from the high linoleate group (16). Blank *et al*. (30) also showed that fish oil supplementation decreased CoA-independent transacylase activity in rat spleen microsomes. In our present study, lyso-PAF acetyltransferase and CoA-independent transacylase activities in kidney microsomes, but not PAF acetylhydrolase activity in the cytosolic fraction, increased 15 min after endotoxin injection, implying that the enhanced PAF synthesis in rat kidney during endotoxemia was catalyzed mainly *via* the remodeling pathway. We also found no significant changes in PAF acetyltransferase and acetylhydrolase activities in rat kidney by dietary α-linolenate. Narahara *et al.* (38) reported that endotoxin inhibited the release of PAF acetylhydrolase by macrophages, but PAF acetylhydrolase activity in rat kidney was not affected by endotoxin injection. In the present experiments, quickly frozen samples of rat kidney were used after homogenization to measure PAF acetylhydrolase. Therefore, we cannot exclude the possibility that the endotoxin treatment has some influence on the release of certain kidney cell types as Narahara *et al.* (38) observed in cultured macrophages.

The lower CoA-independent transacylase activities in kidney microsomes in the high α-linolenate group, compared to those in the high linoleate group, would contribute to lower PAF levels in rat kidney. In the present study, we measured the transacylase activity in microsomes following the acylation of the exogenously added acyl acceptor, 1-alkyl-2-lyso-GPC, with endogenous acyl donors in the absence of CoA according to the method of Blank *et al.* (30). Sugiura *et al.* (39) reported that CoA-independent transacylase was relatively specific for C20 and C22 PUFA without discrimination between n-6 and n-3 PUFA. The total C20 and C22 PUFA contents in PC and PE in the high α-linolenate group were significantly lower than in the high linoleate group, which would contribute to the lower CoA-independent transacylase activity in the high α-linolenate group.

In the present study, the alterations of fatty acid composition and subclass composition of PC and CoA-independent transacylase activity in rat kidney by dietary high α-linolenate oil were found to lead to decreased PAF production in rat kidney during systemic endotoxemia, although the observed changes in biochemical parameters may not account for the whole mechanism by which dietary oils affect PAF production in kidney. Because PAF is reported to be associated with renal failure in endotoxemia (40,41), further studies will be required to determine whether high α-linolenate oil would be beneficial for such pathological states.

ABSTRACT: The aim of the present study was to assess the effect of vegetal oils obtained from *Pinus pinaster* and *P. koraiensis* seeds on plasma lipoprotein levels and apolipoprotein (apo) gene expression in rats. These oils contain two particular fatty acids of the Δ5-unsaturated polymethylene-interrupted fatty acid (Δ5-UPIFA) family: all-*cis*-5,9,12-18:3 (pinolenic) and/or all-*cis*-5,11,14-20:3 (sciadonic) acids. Rats were fed for 28 d a diet containing 5% (w/w) oil supplement. Two control diets were prepared to match the fatty acid composition of *P. pinaster* or *P. koraiensis* oils with the exception of Δ5-UPIFA, which were replaced by oleic acid. *Pinus pinaster* seed oil decreased serum triglycerides by 30% ($P < 0.02$), very low density lipoprotein (VLDL)-triglycerides by 40% ($P < 0.01$), and VLDL-cholesterol by 33% ($P < 0.03$). *Pinus koraiensis* seed oil decreased serum triglycerides by 16% [not statistically significant (ns)] and VLDL-triglycerides by 21% (ns). Gel permeation chromatography and nondenaturating polyacrylamide gel electrophoresis showed a tendency of high density lipoprotein to shift toward larger particles in pine seed oil-supplemented rats. Finally, *P. pinaster* seed oil treatment was associated with a small decrease of liver apoC-III ($P < 0.02$) but not in apoE, apoA-I, or apoA-II mRNA levels. The levels of circulating apo were not affected by pine seed oil supplementation. In conclusion, *P. pinaster* seed oil has a triglyceride-lowering effect in rats, an effect that is due to a reduction in circulating VLDL.

Paper no. L8036 in *Lipids 34,* 39–44 (January 1999).

Fatty acids have unequal lipid-lowering properties (1). Certain classes of plants, marine invertebrates, and insects contain unusual unsaturated polymethylene-interrupted fatty acids (UPIFA). Particularly, UPIFA with a *cis*-5 ethylenic bond, named Δ5-UPIFA, are characteristic and systematic components of Gymnosperm seed oils (2–4). In conifer seeds, some of the following acids may be present, depending on the botanical family considered: all-*cis*-5,9,12-18:3, all-*cis*-5,9,12,15-18:4, all-*cis*-5,11-20:2, all-*cis*-5,11,14-20:3, and all-*cis* 5,11,14,17-20:4. The lipid-lowering potential of oils containing these fatty acids is currently under investigation. *Biota orientalis* (arborvitae, a Chinese Cupressaceae) is used in traditional Chinese medicine. *Biota orientalis* seed oil decreased the concentration of serum cholesterol, high density lipoprotein (HDL)-cholesterol, and phospholipids as compared to a linoleic acid-enriched diet in hypercholesterolemic rats (5). *Pinus koraiensis* (China pine) seeds, another source of Δ5-UPIFA, are consumed in Asia as condiment for various dishes. Supplementation of cholesterol-fed rats with this oil is associated with the lowering of serum triglycerides as compared to linseed and safflower oils (6). It appears from these studies that conifer oils have different lipid-lowering potentials, which may be related in part to differences in their fatty acid composition. Therefore, a detailed analysis of the properties of conifer oils and a comparison of their effects to commercially available oils are necessary before recommending their use in the population at large. *Pinus pinaster* (maritime pine) seeds are harvested in France on a multiton scale for reforestation. The oil extracted from the seeds of this pine contains an average, 16% Δ5-UPIFA that differ in fatty acid composition from previously described pine seed oils (3).

Presently the lipid-lowering potential of *P. pinaster* seed oil is unknown. Moreover, the effect of pine seed oils on circulating lipoprotein has not been explored in detail. Therefore, the aim of our study was to assess the impact of oils extracted from *P. pinaster* and *P. koraiensis* on circulating lipoprotein fractions in rats. Since fatty acids exert part of their effect on lipoprotein levels by modulating the expression of a number of apolipoprotein (apo) genes (7), we evaluated whether any lipid-lowering effect was associated with an effect on apo gene expression and circulating levels.

EXPERIMENTAL PROCEDURES

Animals and diets. All studies were performed with 50-d-old, 200 g, male Wistar rats purchased from IFFA CREDO (L'Arbresle, France). The animals were acclimatized for 1 wk under conditions of controlled temperature (20 ± 1°C) and lighting (dark from 8 P.M. to 8 A.M.) in a room of low background noise. Rats were allowed free access to water and standard rodent chow (Rat and Mouse diet 113; UAR, Villemoisson-sur-Orge, France) during this period. Rats were then separated into

four groups of six rats fed *ad libitum* different diets prepared from a fat-free semipurified diet (UAR) supplemented with: (i) 5% (w/w) *P. pinaster* seed oil; (ii) 5% (w/w) of a mixture (Control-P) prepared with safflower, oleic acid-enriched sunflower, and linseed oils: 66.5, 31, and 2.5%, respectively; (iii) 5% (w/w) *P. koraiensis* seed oil; and (iv) 5% (w/w) of a mixture (Control-K) prepared with safflower, oleic acid-enriched sunflower, and linseed oils: 55, 44.7, and 0.3%, respectively. *Pinus pinaster* and *P. koraiensis* differed with respect to their fatty acid composition. *Pinus pinaster* contains less 18:1 and more 18:2 and 18:3 than *P. koraiensis*. In order to assess the potential lipid-lowering effect of Δ5 fatty acid, two control diets were prepared to match the fatty acid composition of *P. pinaster* or *P. koraiensis* and to replace the Δ5 fatty acids by oleic acid. Oleic acid was chosen because it is a monounsaturated fatty acid with properties intermediate between those of saturated and polyunsaturated fatty acids. In addition, monounsaturated fatty acids are widely recommended in the diet of dyslipidemic patients (8). The oils were provided by Society BERTIN (Lagny le Sec, France) and by R.L. Wolff for *P. pinaster*. The fatty acid compositions of these diets, as determined by gas–liquid chromatography of the methyl esters, are presented in Table 1. *Pinus pinaster* and *P. koraiensis* seed oils used in these studies contained 15.7 and 17.7%, respectively, of Δ5-UPIFA. Other dietary components were carbohydrate (63%), casein (22.5%), cellulose (6%), salt mixture (7%), and vitamin mixture (1%). Weight gain was monitored throughout the study. After 4 wk, the rats were fasted and then exsanguinated under ether anesthesia. Liver tissue and epididymal adipose tissues were removed immediately and frozen in liquid nitrogen for biochemical analysis.

Extraction of liver lipids, phospholipid isolation, fatty acid methyl ester (FAME) preparation, and analysis. Liver lipids were extracted according to Folch *et al.* (9). Phospholipids were separated by thin-layer chromatography on silica gel plates. FAME from phospholipids were prepared essentially according to Morrison and Smith (10). FAME were analyzed by gas–liquid chromatography using Varian 1400 and 940 chromatographs (Palo Alto, CA) equipped with flame-ionization detectors. Peaks were identified by comparison of their relative retention times to those of commercially available standards. Δ5-UPIFA were identified by their equivalent chain lengths according to Wolff *et al.* (11). The use of equivalent chain lengths was supported by gas–liquid chromatography–mass spectrometry of appropriate derivatives (12).

Lipoprotein separation and measurements. Blood was collected from the carotid artery in dry tubes. Serum was separated by centrifugation (630 × *g*) for 20 min at 4°C. Very low density lipoproteins (VLDL) were separated by ultracentrifugation by using a Beckman TL100 ultracentrifuge (Beckman Instruments France SA, Gagny, France), from 0.5 mL of serum by a single spin at density 1.006 × *g* mL^{-1}. Briefly, 0.5 mL of a 0.9% NaCl solution was added to 0.5 mL of serum and spun in a polycarbonate tube (400,000 × *g*, 10°C) with a Beckman TLA-100.2 rotor (Beckman Instruments France SA) for 2.5 h (13). The tube was sliced, and the remaining 0.5 mL infranate fraction ($d > 1.006$ g mL^{-1}) was analyzed for lipids. Lipids in the VLDL fraction ($d < 1.006$ g mL^{-1}) were determined by subtracting infranate values from total serum values according to the Lipid Research Clinic protocol (14).

Serum $1.019 < d < 1.21$ g mL^{-1} fraction was also separated by sequential ultracentrifugation using a Beckman TLA-100.3 rotor (Beckman Instruments France SA) at 480,000 × *g* and 10°C. Two mL of serum was adjusted at $d = 1.019$ g mL^{-1} with potassium bromide and spun for 4 h. The supernate fraction was discarded, and the infranate fraction was spun at the same density for 3.5 h. Then the infranate fraction was adjusted at $d = 1.21$ g mL^{-1} and spun twice for 4 h. The resulting serum $1.019 < d < 1.21$ g mL^{-1} density fraction was dialyzed against a 10 mM phosphate buffer containing 0.01% EDTA and 0.01% sodium azide.

Lipids were determined enzymatically using commercially available kits for triglycerides (Triglycerides GPO-PAP; Boehringer Mannheim, Mannheim, Germany), cholesterol (Cholesterol C System; Boehringer Mannheim), and phospholipids (Phospholipids PAP 150; BioMérieux, Lyon, France).

Measurements of apo. Rat lipoproteins apoA-I, apoA-II, and apoE were measured by a noncompetitive enzyme-linked immunosorbent assay (sandwich ELISA). Briefly, polystyrene microtiter plates were coated with affinity-purified polyclonal antibodies to rat apoA-I, apoA-II, or apoE (1 mg/mL). Duplicate serum samples were diluted with 100 mM phosphate buffered saline (PBS) containing 1% albumin. The samples were added to the wells along with the standards and controls and incubated for 2 h at 37°C. After incubation, the plates were washed four times with PBS 100 mmol/L, and the corresponding polyclonal antibody conjugated to peroxidase was added. The plates were incubated for 2 h at 37°C and then washed. Color development was performed in 30 min by the addition of peroxidase substrate (*o*-phenylenediamine dichloride; Sigma Chemical Co., St. Louis, MO). The plates were read at 492 nm

on an automated microplate reader model EL340 (Bio-Tek Instruments, Inc., Winooski, VT). ApoC-III was measured by nephelometry using a Behring automated analyzer (Behring Nephelometer Analyser; Behring Diagnostics, Rueil Malmaison, France) and rabbit polyclonal anti apoC-III antibody.

Gel filtration chromatography. The ultracentrifugally isolated serum fraction of density $1.019 < d < 1.21$ g mL^{-1} was further separated using a Superdex 200HR 10/30 column to assess lipoprotein heterogeneity. The gel was allowed to equilibrate with PBS (10 mM) containing 0.01% EDTA and 0.01% sodium azide; 200 µL of serum was eluted with the buffer at room temperature at a flow rate of 0.2 mL min^{-1}. Elution profiles were monitored at 280 nm and recorded with an analog-recorder chart tracing system (Pharmacia LKB Biotechnology, Uppsala, Sweden). The effluents were collected in 0.24-mL fractions. Calibration was carried out with bovine albumin Fraction V (Sigma-Aldrich Chimie SARL, Saint Quentin Fallavier, France). Cholesterol was measured in each collected fraction using commercially available enzymatic kits (Cholesterol C System; Boehringer Mannheim).

Nondenaturing polyacrylamide gel and agarose gel electrophoresis. Lipoprotein sizes were identified by nondenaturing gel electrophoresis using a ready-to-use discontinuous 2–3% polyacrylamide gel LIPOFILM (Sebia, Issy-les-Moulineaux, France). Sera (10 µL) were prestained with Sudan black for 30 min at room temperature. Prestained serum aliquots (5 µL) were applied to the gel, and electrophoresis was run for 45 min at 170 V, 12 mA. The gels were scanned using an appropriate scanner (Intégrateur Lipofilm, Préférence SEBIA, HIT-HR Software 2XX, Issy-les Moulineaux, France). In order to assess whether seed oil supplementation affects lipoprotein electrophoretic mobility, agarose gel electrophoresis was performed according to Noble (15) with a Beckman Paragon system (Beckman Instruments France SA). Briefly, serum (5 mL) was applied on a 0.5% agarose gel (Paragon LIPO lipoprotein electrophoresis; Beckman Instruments France SA). Electrophoresis was performed for 30 min in a barbital buffer (pH 8.6) at 100 V. Gels were stained with Sudan black B.

RNA analysis. Total cellular RNA was isolated from liver tissue by the acid guanidinium thiocyanate/phenol–chloroform method (16). Northern and dot-blot hybridizations were performed exactly as described previously (17). The rat apoA-I, apoA-II, apoC-III, and apoE cDNA probes were described previously (18,19). All probes were labeled by random primed labeling (Boehringer Mannheim). Filters were hybridized to 1×10^6 cpm mL^{-1} of each probe as described (17). They were washed in 300 mL of 75 mM NaCl, 7.5 mM sodium citrate, pH 7.4, and 0.1% sodium dodecyl sulfate for 10 min at room temperature and twice for 30 min at 65°C and subsequently exposed to X-ray film (Kodak X-OMAT-AR; Eastman Kodak Co., Rochester, NY). Autoradiograms were analyzed by quantitative scanning densitometry (Bio-Rad GS670 Densitometer; Bio-Rad Laboratories, Richmond, CA) as described elsewhere (17).

Statistical analysis. Unpaired *t*-tests were used to compare the experimental to the control diets. Whenever a covariable (weight) explained part of the variability of the biological variable, the adjusted error term was calculated for the *t*-test using the LS-Means procedure of SAS software (SAS Institute Inc., Cary, NC).

RESULTS

The body weight, food intake, liver, and epididymal fat tissue weights were not significantly different between rats treated with *P. pinaster* or *P. koraiensis* seed oils and their respective controls (data not shown). *Pinus pinaster* and *P. koraiensis* seed oils ingestion was associated with the appearance of all-*cis*-5,11,14-20:3 and all-*cis*-5,9,12-18:3 fatty acids in liver phospholipids (Table 2). These changes were associated with a concomitant decrease of all-*cis*-9,12-18:2 and all *cis*-5,8,11,14-20:4 in *P. pinaster* seed oil-supplemented rats and with a decrease of all *cis*- 9,12-18:2 in the *P. koraiensis*-fed rats.

The effects of pine seed oil supplementation on serum lipid and lipoprotein levels were assessed after 4 wk of supplementation. The results are presented in Table 3. The levels of serum triglycerides were decreased significantly (by 30%, $P < 0.02$) in the group supplemented with *P. pinaster* seed oil compared to its respective control group. This reduction was accounted for by a decrease in the VLDL fraction, resulting in significantly lower levels of VLDL-triglycerides (–40%,

[a]Unpaired *t*-test: *P* values for pine seed oil vs. control group.
[b]Values adjusted for weight.
[c]Very low density lipoprotein (VLDL) serum $d < 1.006$ g mL^{-1} density fraction. See Tables 1 and 2 for other abbreviations.

$P < 0.01$) and VLDL-cholesterol (–33%, $P < 0.03$). Total cholesterol, cholesterol in the serum $d > 1.006$ g mL^{-1} serum density fraction, and serum phospholipid levels were not statistically significantly (ns) different between the two groups. Although there was a tendency to lower levels of serum total triglycerides (–16%, ns) and VLDL-triglycerides (–21%, ns) in rats treated with *P. koraiensis* seed oil as compared to its control group, these differences did not reach the level of statistical significance. In order to further assess the potential impact of pine seed oil supplementation on lipoprotein metabolism, the compositions of VLDL and serum $1.019 < d < 1.21$ g mL^{-1} fraction were determined (data not shown). There were no statistically significant differences in lipid composition of the various lipoproteins between treated and control rats with the exception of a moderate increase in VLDL-phospholipid ($P < 0.004$) in *P. koraiensis*-treated rats. Agarose gel electrophoretic patterns of serum lipoproteins were not different among groups (data not shown).

In order to investigate the changes in serum lipid distribution in more detail, lipoproteins were separated by gel permeation chromatography. Cholesterol was determined in the gel filtration elution fractions of the serum $1.019 < d < 1.21$ g mL^{-1} density fraction (Fig. 1). *Pinus pinaster* and *P. koraiensis* supplementation resulted in a slight shift of the HDL peak toward larger particles (Fig. 1A and B). This observation was confirmed by nondenaturing gel electrophoresis that showed a tendency, although ns, to smaller HDL relative mobility (R_f) values in the *P. pinaster* (29.8 ± 2.4 vs. 31.8 ± 2.3, ns) and *P. koraiensis* (30 ± 4 vs. 31.8 ± 4.1, ns) seed oil-supplemented rats than in controls.

Finally, we determined whether pine seed oil treatment has an effect on apo gene expression and apo levels. To this end, the liver mRNA levels of various apo were measured. The results are presented in Table 4. *Pinus pinaster* seed oil-supplemented rats had significantly lower levels of liver apoC-III mRNA than control ($P < 0.04$). This change, however, was not associated with a decrease in the concentration of serum apoC-III (*P. pinaster* 0.038 ± 0.015 vs. control 0.021 ± 0.006 g/L; ns). ApoA-I, apoA-II, and apoE liver mRNA and serum levels (A-I: 0.47 ± 0.08 vs. 0.47 ± 0.08, ns; A-II: 0.37 ± 0.10 vs. 0.45 ± 0.04, ns; E: 0.004 ± 0.003 vs. 0.002 ± 0.001, ns g/L) were not different between animals treated with *P. pinaster* seed oil and control regimen-treated rats. *Pinus koraiensis*

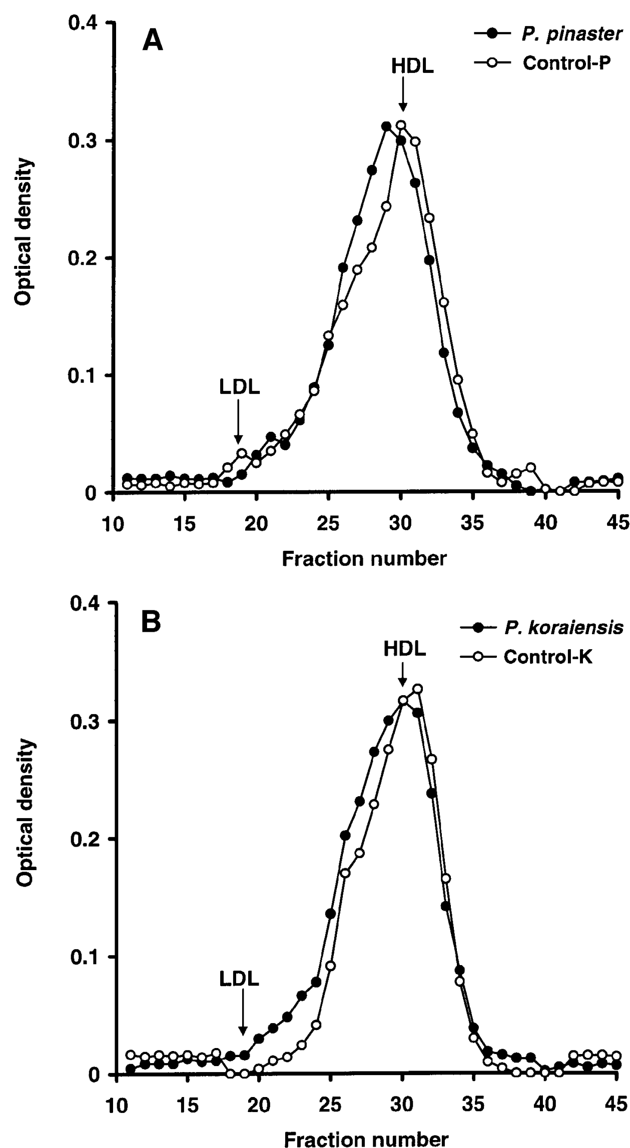

FIG. 1. Cholesterol profile of serum density fraction $1.019 < d < 1.21$ g mL^{-1} of *Pinus pinaster* (A) and *P. koraiensis* (B) supplemented rats and their respective controls. Values are medians of four profiles. The $1.019 < d < 1.21$ g mL^{-1} serum fraction was fractionated on a Superdex 200HR 10/30 column (Pharmacia LKB Biotechnology, Uppsala, Sweden). Pine seed oil and control treatments are presented with closed and open circles, respectively. HDL, high density lipoprotein; LDL, low density lipoprotein.

TABLE 4
Liver Apolipoprotein mRNA Levels (mean ± SEM) in Treated and Control Rats[a]

	P. pinaster	Control-P	P^b	*P. koraiensis*	Control-K	P^b
ApoA-I	100 ± 8	100 ± 15	ns	88 ± 9	100 ± 3	ns
ApoA-II	92 ± 3	100 ± 5	ns	105 ± 6	100 ± 5	ns
ApoC-III	85 ± 4	100 ± 5	0.04	103 ± 5	100 ± 5	ns
ApoE	100 ± 2	100 ± 6	ns	100 ± 4	100 ± 6	ns

[a]Units are percentage of controls.
[b]Unpaired *t*-test: *P* values for pine seed vs. control group; apo, apolipoprotein. See Tables 1 and 2 for other abbreviations.

seed oil supplementation had ns effect on any apo liver mRNA (apo A-I, A-II, C-III, and E) and apo levels (A-I: 0.51 ± 0.07 vs. 0.44 ± 0.07, ns; A-II: 0.37 ± 0.06 vs. 0.39 ± 0.07, ns; C-III: 0.024 ± 0.004 vs. 0.024 ± 0.005, ns; E: 0.002 ± 0.001 vs. 0.003 ± 0.003, ns g/L) compared to control diet.

DISCUSSION

The major finding of the present study is the lowering of triglycerides, VLDL-triglycerides, and VLDL-cholesterol levels in rats treated with *P. pinaster* seed oil compared to rats treated with control regimen, in which oleic acid replaced Δ5-UPIFA. In contrast, *P. koraiensis* seed oil treatment had ns effect on lipid or on lipoprotein and apo levels compared to oleic acid-enriched diet.

Recent studies analyzed the effects of two conifer seed oils on circulating total cholesterol and triglyceride levels in rats. Ikeda *et al*. (5) found lower levels of serum cholesterol and triglycerides in hypercholesterolemic rats treated for 24 d with a diet supplemented with *B. orientalis* oil compared with a diet supplemented with linoleic acid. Similarly, Sugano *et al*. (6) observed lower levels of serum triglycerides in rats supplemented with *P. koraiensis* seed oil compared with linseed and safflower oils. In the latter studies, however, the results were confounded by the addition of 0.5% cholesterol and 0.125% sodium cholate to the diet. In the present study, all-*cis* 5,11,14-20:3 and/or all-*cis* 5,9,12-18:3 fatty acids were replaced by 18:1 in the control regimens, and no cholesterol or cholate was added to the diet, suggesting that Δ5-UPIFA has a triglyceride- and VLDL-lowering effect as compared to oleic acid. This effect is more pronounced for *P. pinaster* than for *P. koraiensis* seed oil, suggesting that sciadonic acid (all-*cis*-5,11,14-20:3), which is more abundant in *P. pinaster* seed oil, has a greater VLDL-lowering potential than pinolenic acid (all-*cis*-5,9,12-18:3). However, notably oils, not fatty acids, were used in the present study. This fact has potential implications in the interpretation of the data since factors other than fatty acids may be present in the oil and could interfere with lipoprotein metabolism.

Eicosapentaenoic acid (5,8,11,14,17-20:5) is present in marine oils and, similar to sciadonic acid (5,11,14-20:3) of *P. pinaster* seed oil, has 20 carbon atoms and *cis* double bonds in positions Δ5, Δ11, and Δ14 (Scheme 1). Eicosapentaenoic acid has a major impact on triglyceride levels (20). It is difficult to compare the results of the present study with those of previous publications on marine oils (21–24) because of differences among studies such as the amount of fat or cholesterol consumed, the length of treatment, and the type of control diet. Although the effects of *P. pinaster* seed oil on lipid and lipoprotein levels appear to resemble those of fish oils, no evidence exists that proves that *P. pinaster* oil, like fish oils, could be used safely and efficiently in man.

Clearly, evidence exists that apo have a crucial role in lipid metabolism. ApoA-I and apoA-II are key proteins of HDL metabolism (25). ApoE is necessary for lipoprotein remnant clearance (26). ApoC-III is a major component of triglyceride-rich lipoparticles and interferes with VLDL lipolysis (27–30) and uptake by cellular receptor (31–34). Evidence also exists that fatty acids exert part of their lipid-lowering effects by altering the expression of various apo genes (35). As a first indication of a possible effect of pine seed oil on apo gene expression, the mRNA levels of apoA-I, apoA-II, apoC-III, and apoE were measured in the liver of supplemented rats. Although a decreased expression of apoC-III gene in the *P. pinaster*-supplemented rats existed, this effect was modest and not associated with a decrease in serum apoC-III levels, suggesting a marginal impact of *P. pinaster* on apoC-III metabolism. Therefore, mechanisms other than a direct effect of *P. pinaster* on apo metabolism may have contributed to the triglyceride-lowering properties of *P. pinaster* seed oil, such as (i) decreased *de novo* lipid synthesis, (ii) reduced substrate availability for lipoprotein formation, or (iii) changes in VLDL physicochemical properties. Further studies are necessary to assess the mechanism of triglyceride reduction by *P. pinaster* in rats.

In the present study, *P. pinaster* seed oil supplementation reduced triglycerides and VLDL levels in rats, suggesting a potential benefit for *P. pinaster* in lowering high blood triglyceride levels. However, additional investigations in other animal models as well as controlled studies in humans are necessary before recommending the use of *P. pinaster* oil as an alternative source of oil in patients with dyslipidemia.

Differences in the Sterol Composition of Dominant Antarctic Zooplankton

Anneke Mühlebach, Carola Albers, and Gerhard Kattner*

Alfred Wegener Institute for Polar and Marine Research, D-27570 Bremerhaven, Germany

ABSTRACT: The composition of free sterols was determined in Antarctic zooplankton species with various feeding behaviors. In the Southern Ocean, the dominant calanoid copepods *Calanoides acutus, Calanus propinquus, Metridia gerlachei*, and *Euchaeta antarctica* were investigated during different seasons and compared with the euphausiids *Euphausia superba, E. crystallorophias*, and *Thysanoessa macrura*. In addition, the Arctic copepods *Calanus hyperboreus, C. glacialis*, and *C. finmarchicus* were studied for comparison. Analyses were performed using gas chromatography and mass spectrometry. The zooplankton species exhibited a simple sterol content of up to six sterols. In the copepods, cholest-5-en-3β-ol (22.1 to 60.5%, range of sample means), cholesta-5,24-dien-3β-ol (22.3 to 45.2%), and cholesta-5,22*E*-dien-3β-ol (4.3 to 33.4%) contributed most, while in euphausiids the sterol composition was less complex with cholest-5-en-3β-ol always accounting for more than 75% of the total. Although sterols are membrane constituents and are expected not to vary considerably, differences in the abundance of sterols were observed between the species and the seasons. In herbivorous copepods, cholesta-5,24-dien-3β-ol increased by a factor of 1.5 to about 45% during the main feeding period in summer; this sterol is a metabolic precursor of cholest-5-en-3β-ol in the process of the dealkylation of dietary C-24 alkylated phytosterols. Cholest-5-en-3β-ol decreased by the same proportion. Omnivorous and carnivorous copepods showed average levels of cholesta-5,24-dien-3β-ol below 25%. These changes in sterol composition between copepod species seem to reflect their different feeding modes.

Paper no. L7959 in *Lipids 34*, 45–51 (January 1999).

In high Antarctic waters, primary production is extremely seasonal. Zooplankters generally accumulate large lipid deposits as energy reserves to survive the periods of low productivity and to reproduce (1,2). Apart from lipids stored as reserves, lipids such as phospholipids and sterols are major components of the membranes. Sterols are especially abundant in the plasma membranes of eukaryotic organisms. It is generally believed that they modulate membrane fluidity by interaction with the phospholipid components (3). These structural elements maintain the functionality of membranes even in extreme environments such as the cold polar oceans.

Sterols are present in the form of cholest-5-en-3β-ol in nearly all animals. However, marine invertebrates, whether or not they are sterol auxotrophs, discriminate much less among their dietary sterols than do mammals. Therefore, these marine animals may exhibit compositions reflecting the general availability of these compounds in their food (3). Among marine invertebrates, the crustaceans have the simplest sterol compositions (4–6). It is well established that crustaceans are incapable of *de novo* sterol biosynthesis from acetate or mevalonic acid. Their sterols originate either directly from the diet or by dealkylating dietary C-24 alkyl-substituted phytosterols (6–9). However, we know little about the content and the variation of sterols in zooplankton from the polar oceans (10,11).

The herbivorous copepods *Calanoides acutus, Calanus propinquus*, the omnivorous *Metridia gerlachei*, and the carnivorous *Euchaeta antarctica* contribute substantially to zooplankton biomass in the Southern Ocean (12–14). Among the euphausiids, the herbivorous *Euphausia superba* is the key species with biomass estimates of hundreds of millions of tons (15). *Euphausia crystallorophias* and *Thysanoessa macrura* are also major components of the Antarctic macrozooplankton biomass (12). The dominant herbivorous Arctic copepods *Calanus glacialis, C. hyperboreus*, and *C. finmarchicus* were considered for comparison, since they exhibit life strategies similar to those of the Antarctic *C. acutus*.

In this study, the dominant zooplankton species of the polar oceans were investigated for sterols in order to gain information about species-specific compositions and possible metabolic processes. In the Antarctic copepods, seasonal changes in the sterol compositions were studied to elucidate the influence of the feeding behavior on sterols in organisms coping with the extreme environment of the high latitudes.

MATERIALS AND METHODS

Zooplankton sampling was carried out in the Antarctic Weddell Sea during several expeditions of RV *Polarstern* (Table 1). Samples were collected during austral spring (November/December 1986 and November/December 1997), summer (January/February 1985), and fall (April/May 1992 and

TABLE 1
Zooplankton Samples from Various *Polarstern* Cruises to the Southern (ANT) and to the Arctic Ocean (ARK)

Cruise	Region	Season	Species
ANT III/3 Jan./Feb. 1985	Southern Weddell Sea	Summer	*Calanoides acutus, Calanus propinquus, Metridia gerlachei, Euchaeta antarctica Thysanoessa macrura, Euphausia crystallorophias, Euphausia superba*
ANT V/3 Nov./Dec. 1986	Central Weddell Sea	Spring	*C. acutus, C. propinquus*
ANT X/3 April/May 1992	Eastern Weddell Sea	Fall	*T. macrura, E. crystallorophias, E. superba*
ANT XIII/4 March/April 1996	Central Weddell Sea	Fall	*C. acutus, E. superba, T. macrura*
ANT XIV/2 Nov./Dec. 1997	South Shetland Region	Spring	*C. acutus, M. gerlachei*
ARK XI/2 Sep./Oct. 1995	Greenland Sea	Fall	*Calanus hyperboreus, Calanus glacialis, Calanus finmarchicus*

March/April 1996). For comparison, some Arctic copepods were obtained from the Greenland Sea (September/October 1995). According to species, stage, and season, the copepods and euphausiids were sampled by vertical bongo net hauls and various plankton and nekton net hauls, respectively. The specimens were sorted in a cooled container-laboratory and stored deep-frozen in glass vials at −80°C. Arctic samples were kept in dichloromethane/methanol (2:1, vol/vol) at −30°C. Samples of euphausiids consisted of single individuals; up to 200 copepods were pooled for each sample. Sterols in the gut content are regarded as negligible. With respect to gut pigments in copepods during spring (16), the ratio of sterols to pigments in algae (17), and the sterol content in copepods (18), the sterols in the gut were estimated to contribute less than 2% to total sterols.

Total lipid was extracted as described by Folch *et al.* (19). Preparative separation of lipid classes was performed by thin-layer chromatography on silicic acid (60H; Merck, Darmstadt, Germany). A mixture of *n*-hexane/diethyl ether/formic acid (65:35:0.04, by vol) was used as eluting solvent. According to their R_f values, the bands of the different lipid classes were identified, scraped off, and eluted with dichloromethane/methanol (2:1, by vol). Steryl esters contributed less than 1% to the total of sterols in copepods (Albers, C., unpublished data).

The solutions containing free sterols were evaporated under a stream of nitrogen and dried over silica gel for 15 h. Sterols were converted into their corresponding trimethylsilyl ethers applying *N,O*-bis-(trimethylsilyl)-trifluoroacetamide (BSTFA; Macherey-Nagel, Düren, Germany) at 60°C for 2 h. After the evaporation of excess BSTFA, the steryl ethers were redissolved in *n*-hexane and analyzed by a Chrompack 9002 gas chromatograph equipped with a fused-silica capillary column (HP5-MS, 30 m × 0.25 mm I.D.) and a flame-ionization detector. Helium was used as carrier gas. A splitless injection mode was employed. The oven temperature was raised from 55 (1.6 min) to 200°C at 30°C/min, then to 325°C at 6°C/min, and held for 15 min. Gas chromatography–mass spectrometry (GC–MS) analyses were performed with an HP 5890II gas chromatograph directly coupled to a VG AutoSpec mass spectrometer. Electron impact mass spectra were acquired at an ionization energy of 70 eV and a mass resolution of 1000. A range from *m/z* 600 to *m/z* 35 was monitored at a rate of 1 scan/s. Sterols were identified by comparison of GC retention indices, mass spectra, and the use of authentic reference substances (20).

Cholesta-5,24-dien-3β-ol and 24-methylcholesta-5,22*E*-dien-3β-ol have only slightly different GC retention times. Cholesta-5,24-dien-3β-ol always dominated in the samples; quantification by GC–MS showed that even in summer the amount of 24-methylcholesta-5,22*E*-dien-3β-ol was at least 10 times smaller than that of cholesta-5,24-dien-3β-ol. For species that were sampled during the same season, but not analyzed by GC–MS, a similar ratio of cholesta-5,24-dien-3β-ol to 24-methylcholesta-5,22*E*-dien-3β-ol was assumed. The stereochemistry of C-24 epimers is not discussed in this work, since they could not be separated.

RESULTS

The zooplankton investigated never contained more than six sterols (Fig. 1). The percentage distribution of these sterols in copepods showed species-specific (Fig. 2) and seasonal variabilities (Table 1). Sterol patterns of euphausiids were simpler than those of the copepods and were strongly dominated by cholest-5-en-3β-ol. No difference occurred between copepodite stages CIV–CV and adult females; thus, these samples were discussed together.

Antarctic Copepoda. In *C. acutus* cholest-5-en-3β-ol was the major sterol observed in spring (49.4% of total free sterols); cholesta-5,24-dien-3β-ol and cholesta-5,22*E*-dien-3β-ol followed next in abundance. In summer, an increased abundance of cholesta-5,24-dien-3β-ol of up to 45.2% was

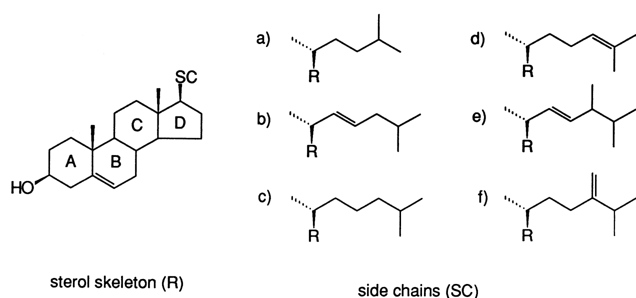

FIG. 1. Structure of sterols found in Antarctic crustaceans (R ring skeleton, SC side chain). (a) 24-Norcholesta-5,22*E*-dien-3β-ol, (b) cholesta-5,22*E*-dien-3β-ol, (c) cholest-5-en-3β-ol, (d) cholesta-5,24-dien-3β-ol, (e) 24-methylcholesta-5,22*E*-dien-3β-ol, and (f) 24-methylcholesta-5,24(28)-dien-3β-ol.

striking, while levels of cholest-5-en-3β-ol exhibited a respective decrease. Cholesta-5,22*E*-dien-3β-ol contributed considerably to the sum of sterols both in spring and in summer. The very low level of 24-methylcholesta-5,24(28)-dien-3β-ol had increased to 2.5% in summer. During fall, 60.5% of cholest-5-en-3β-ol was measured, a proportion higher than during spring and summer. The abundance of cholesta-5,24-dien-3β-ol was comparable to that found during spring, whereas the proportion of cholesta-5,22*E*-dien-3β-ol (6.6%) was least in the fall (Table 2).

In *C. propinquus* cholest-5-en-3β-ol constituted 40.5% of the total in spring; cholesta-5,24-dien-3β-ol and cholesta-5,22*E*-dien-3β-ol yielded about 30 and 20%, respectively. As observed for *C. acutus*, cholesta-5,24-dien-3β-ol was the major sterol in the summer specimens; its level had increased by a factor of about 1.5 in comparison with the spring animals. In summer, nearly equal proportions of cholest-5-en-3β-ol and cholesta-5,22*E*-dien-3β-ol were measured (Table 2).

In *M. gerlachei* collected during spring, cholest-5-en-3β-ol was most abundant, followed by cholesta-5,22*E*-dien-3β-ol and cholesta-5,24-dien-3β-ol. Cholesta-5,24-dien-3β-ol exhibited a stronger variation than cholesta-5,22*E*-dien-3β-ol (relative standard deviation of 40 vs. 20%). Besides, 24-nor-cholesta-5,22*E*-dien-3β-ol contributed to the sum of sterols with a proportion (9.4%) considerably higher than in *C. acutus* and *C. propinquus*. During summer, the main sterol found in *M. gerlachei* was cholesta-5,22*E*-dien-3β-ol (33.4%). This observation was in contrast to the summer specimens of *C. acutus* and *C. propinquus*, which contained cholesta-5,24-dien-3β-ol as main component. Cholest-5-en-3β-ol and cholesta-5,24-dien-3β-ol were detected in similar percentages of about 25%. 24-Methylcholesta-5,24(28)-dien-3β-ol showed an increase in abundance by a factor of about 5.5 (Table 2).

In summer, the predatory *E. antarctica* exhibited about 1.5–2 times more cholest-5-en-3β-ol than the herbivorous and omnivorous species; *E. antarctica* contained cholesta-5,24-dien-3β-ol and cholesta-5,22*E*-dien-3β-ol in similar proportions (Table 2).

Arctic Copepoda. In the fall, *C. hyperboreus* and *C. glacialis* contained similar proportions of cholest-5-en-3β-ol and cholesta-5,24-dien-3β-ol (about 40%). *Calanus finmarchicus* exhibited a higher abundance of cholest-5-en-3β-ol (56.7%), but less cholesta-5,24-dien-3β-ol (24.4%). In contrast

[a](*n*), number of samples; sd, sample standard deviation; N.D., not detectable.
[b]Coeluting cholesta-5,24-dien-3β-ol and 24-methylcholesta-5,22*E*-dien 3β-ol; the proportion of 24-methylcholesta-5,22*E*-dien-3β-ol is suspected not to exceed 10% of the sum.

to the Antarctic copepod species, the abundance of cholesta-5,22*E*-dien-3β-ol was low (4.3–10.2%) in all Arctic species, but comparable to that of *C. acutus* in the fall (6.6%) (Table 3).

Antarctic Euphausiacea. All euphausiid species showed a similar sterol pattern with cholest-5-en-3β-ol as the dominant sterol followed by cholesta-5,24-dien-3β-ol and cholesta-5,22*E*-dien-3β-ol (Table 4). Proportions of cholest-5-en-3β-ol were always higher than in the copepods. In all euphausiids, 24-norcholesta-5,22*E*-dien-3β-ol and C_{28} phytosterols were only found in traces or were below the detection limit. Summer and fall samples exhibited very similar sterol compositions. Because of the limited number of samples we did not discriminate between seasons.

DISCUSSION

Polar zooplankton have developed various solutions for adaptation to the cold environment. The biosynthesis and storage of lipids with a large variety of fatty acids and alcohols is especially pronounced in these species (21). Lipid levels and compositions depend on life cycle strategies and trophic preferences. It is well known that not only herbivorous polar copepods but also euphausiids are capable of accumulating large amounts of lipid deposits (1,22,23). In contrast to lipids accumulated as energy reserves, membrane lipids such as phospholipids and sterols have to fulfill basic physiological demands. They guarantee the functionality of membranes and modulate the fluidity. The hydroxy function at position C-3 of ring A of the ring skeleton (Fig. 1) permits the orientation of the planar and rigid sterol molecule in the bilayer. Sterol molecules are able to separate or laterally displace both the acyl chains and polar head groups of membrane phospholipids (3).

All copepods and euphausiids analyzed in this study exhibited simple sterol patterns. The dominant sterol in vertebrates, cholest-5-en-3β-ol, is also a major sterol in copepods

TABLE 3
Sterol Compositions of Arctic Copepods (fall)[a]

Sterol		Percentage composition (of total free sterols)

[a]For abbreviations see Table 2.

and euphausiids. This is in accordance with observations of Goad (4) and Teshima (6) and references therein. It is well established that crustaceans must obtain sterols either directly from their diet or by dealkylating dietary C-24 alkyl-substituted phytosterols (6–8). The production of cholesta-5,24-dien-3β-ol as an intermediate in this dealkylation process provides an attractive explanation for the occurrence of considerable amounts of this sterol in many crustaceans (4,24). The mechanisms of the dealkylation of 24-ethylcholest-5-en-3β-ol operating in insects—like the crustaceans, they belong to the Arthropoda—have been studied in detail; 24-ethylcholesta-5,24(28)-dien-3β-ol, its 24,28-epoxide, and cholesta-5,24-dien-3β-ol have been identified as intermediates (4,25). Baker and Kerr (9) described the dealkylation of 24-methylcholesta-5,24(28)-dien-3β-ol and 24-ethylcholesta-5,24(28)-dien-3β-ol to cholesta-5,24-dien-3β-ol and cholest-5-en-3β-ol in marine sponges, indicating a mechanism parallel to that observed in phytophagous insects.

Thus, cholesta-5,24-dien-3β-ol may be accumulated during summer, when phytoplanktonic food is abundant. Indeed, an increased proportion of cholesta-5,24-dien-3β-ol was observed in the herbivorous *C. acutus* and in *C. propinquus* during summer, whereas the abundance of cholesta-5,24-dien-3β-ol in the fall was similar to that in spring; cholesta-5,24-dien-3β-ol may have been converted to cholest-5-en-3β-ol. The North Atlantic *C. finmarchicus* and the Arctic *C. glacialis* also exhibited a higher content of cholest-5-en-3β-ol than cholesta-5,24-dien-3β-ol in the fall. A higher abundance of cholesta-5,24-dien-3β-ol in the Arctic *C. hyperboreus* may be explained by differences in the food availability.

Direct uptake of cholesta-5,24-dien-3β-ol from the diet is regarded as negligible since this sterol is not a common major component in algal sterol profiles (26). This compound was a minor constituent of the particulate sterols found in the surface of the Weddell Sea in spring (27); in the fall, its mean abundance was only 3.1% of all free sterols in particulate matter of surface waters (28).

Findings similar to this study were described by Serrazanetti *et al.* (29) for mixed zooplankters from the Adriatic Sea. These authors observed that levels of cholesta-5,24-dien-3β-ol were higher by a factor of about three during algal blooms than later in the year. Our data revealed a decrease of cholest-5-en-3β-ol compared to cholesta-5,24-dien-3β-ol, whereas they also found increased abundances for cholest-5-en-3β-ol in bloom situations. In zooplankters from the Gulf of Trieste cholesta-5,24-dien-3β-ol exhibited the lowest proportion in winter when sterols from phytoplankton are scarce (30). However, the higher percentage of cholest-5-en-3β-ol in Adriatic zooplankters during bloom situations is difficult to evaluate, since sterols in mixed zooplankton were analyzed.

In contrast to the herbivorous copepods, the sterol pattern of the omnivorous *M. gerlachei* changed to a higher proportion of cholesta-5,22*E*-dien-3β-ol in summer. This finding may be attributed to the deviating feeding behavior and to differences in metabolic pathways. *Metridia gerlachei* feeds not only on phytoplankton but also on zooplankton and detritus (31) containing this sterol. Cholesta-5,22*E*-dien-3β-ol is a frequent sterol in marine particulate matter (27,28). In *Fragilariopsis (Nitzschia) cylindrus*, a diatom common in the Weddell Sea, cholesta-5,22*E*-dien-3β-ol contributed to about 70% to the total sterols (32). Virtue *et al.* (10) demonstrated that the proportion of cholesta-5,22*E*-dien-3β-ol in the digestive gland of *E. superba* decreased by an order of magnitude during short-term starvation, suggesting an algal origin of this sterol. Thus, high abundances may be indicative of a high dietary input. However, the herbivorous species did not exhibit enhanced levels of cholesta-5,22*E*-dien-3β-ol. A difference in the metabolic pathway cannot be excluded. It has been noted, that some arthropods are not able to convert cholesta-5,22*E*-dien-3β-ol to cholest-5-en-3β-ol (33).

In *M. gerlachei* a distinct increase of the C_{28} phytosterol 24-methylcholesta-5,24(28)-dien-3β-ol was observed in summer, which may be explained by a higher uptake. Other copepods also exhibited a slightly higher proportion of this sterol in summer. However, even in summer levels were still low; thus, dealkylation probably takes place soon after ingestion.

Nearly all copepods contained 24-norcholesta-5,22*E*-dien-3β-ol, it being most abundant in *M. gerlachei* with almost 10%.

Since this sterol is common in marine invertebrates, it seems likely that the primary producer may be an organism early in the food chain (4). According to Minale and Sodano (34), 24-norcholesta-5,22*E*-dien-3β-ol may be formed from 24-methylcholesta-5,22*E*-dien-3β-ol by side-chain dealkylation. Boutry and Barbier (35) suggested that C_{26} sterols can be produced through degradation of C_{28} precursors.

Euchaeta antarctica is a planktonic predator. In contrast to the herbivorous and omnivorous species, its major sterol was the zoosterol cholest-5-en-3β-ol in summer. The proportion of cholesta-5,24-dien-3β-ol was only half of that observed for copepods feeding on phytoplankton. Changes in the sterol composition may reflect the trophic preference of *E. antarctica*.

All euphausiid species showed a similar and very simple sterol composition. Although the species investigated have been described to feed omnivorously or even herbivorously (36,37), cholest-5-en-3β-ol was more dominant than in the copepods. For example, *E. superba* is known to feed mainly as an herbivore (1); nevertheless, the content of cholesta-5,24-dien-3β-ol was almost nine times less than that of cholest-5-en-3β-ol and was always less than in the copepods. Although copepods contained C-24 alkylated phytosterols in abundances up to 8%, their proportions were even smaller in euphausiids with levels below 2%. In contrast to copepods, 24-norcholesta-5,22*E*-dien-3β-ol could not be detected in euphausiids. These observations suggest a faster and/or more complete metabolic conversion of phytosterols to cholest-5-en-3β-ol in euphausiids than in copepods.

Not only the sterol compositions of copepods and euphausiids differed but also the compositions of their phospholipids. The Antarctic krill *E. superba*, *T. macrura,* and *E. crystallorophias* exhibited higher proportions of 18:1n-9 and 20:5n-3 and lower levels of 22:6n-3 fatty acids in their phospholipids (38–40) than are reported in copepods (41). Farkas *et al.* (42) found that the molecular species composition of membrane lipids plays a decisive role in membrane adaptation. In accordance with these observations the deviating sterol compositions suggest different ways of cold adaptation in the membranes of copepods and euphausiids attained by specific interactions of the various membrane components.

In summary, the zooplankters investigated exhibited simple sterol compositions. The copepods showed clear species-specific differences. The patterns observed in euphausiids were dominated to a greater extent by cholest-5-en-3β-ol than those in the copepods, suggesting a faster or more complete metabolic conversion of phytosterols in euphausiids. In Antarctic copepods, differences in the abundance of sterols were noticed during the seasons in which samples were collected, which may have been caused by the trophic preferences of these animals. While herbivorous copepods contained enhanced levels of cholesta-5,24-dien-3β-ol during the phytoplankton blooms in summer, the carnivorous *E. antarctica* demonstrated a high percentage of the zoosterol cholest-5-en-3β-ol. The characteristic sterol composition of the zooplankton may be accounted for by the existence of specific physiological mechanisms of accumulation and elimination.

ACKNOWLEDGMENTS

We thank Wilhelm Hagen, Corinna Dubischar, and Victor Spiridonov for providing zooplankton material and Lars Klöhn for his excellent analytical work. We thank Kurt Weber for advice regarding mass spectrometric procedures and useful comments on a draft version of this paper. We are grateful for the support of captain and crew of the RV *Polarstern* during several expeditions. The manuscript benefited from comments of three anonymous reviewers. This paper is AWI-contribution No. 1446.

Mitochondrial Membrane Composition of Two Arctic Marine Bivalve Mollusks, *Serripes groenlandicus* and *Mya truncata*

Todd E. Gillis[a] and James S. Ballantyne[b,*]

[a]Cardiac Membrane Research Laboratory, School of Kinesiology, Simon Fraser University, Burnaby, British Columbia V5A 1S6, and [b]Department of Zoology, University of Guelph, Guelph, Ontario, N1G-2W1 Canada

ABSTRACT: The phospholipid and fatty acid composition of gill mitochondria membranes from two Arctic marine bivalve mollusks, *Mya truncata* and *Serripes groenlandicus*, were examined. These animals were collected from the Arctic Ocean, where waters remain below 0°C throughout the year. In both species, the primary membrane phospholipids were phosphatidylcholine, and phosphatidylethanolamine. Although a low ratio of bilayer-stabilizing phospholipids to bilayer-destabilizing phospholipids is frequently associated with cold acclimation in temperate species, this ratio is very different between the two species. The monounsaturated fatty acid 20:1 was abundant in the membranes of both Arctic species equaling 13.0% of the fatty acid composition in *S. groenlandicus*, and 17.7% in *M. truncata*. Polyunsaturated fatty acids were relatively low in the Arctic species, equaling 35.9% of total membrane fatty acids compared to that of temperate zone mollusks. It is suggested that monoenes are common in the tissues of Arctic species since they play a role in maintaining membrane function at subzero temperatures.

Paper no. L7759 in *Lipids 34*, 53–57 (January 1999).

Polar marine environments are among the most thermally stable regions of the world. Such stability resulted in many organisms becoming highly specialized to function at subzero temperatures (1). The properties of biological membranes in particular must be adapted to function under these conditions. The composition of cellular membranes can be manipulated to maintain membrane properties and function. Membrane phospholipid and fatty acid composition are two of the components that can be altered to maintain membrane function (2–4). Study of temperate, ectothermic species demonstrated that the bilayer-destabilizing phospholipid phosphatidylethanolamine (PE), as well as long-chain polyunsaturated fatty acids (PUFA) accumulate within cellular membranes upon acclimation to low temperatures (2,3,5–9). Such manipulation of membrane composition aids in maintaining membrane properties (2–4,6,9).

Several studies indicate that the lipids of polar organisms differ from those of temperate zone organisms. In particular, whole tissue lipids of Arctic and Antarctic copepods contain unusually high amounts of monounsaturated fatty acids (monoenes) (10). It is not known if these differences apply to membrane lipids. Chronic exposure to very low temperature such as occurs in polar organisms may require membrane adaptational strategies previously unidentified by thermal acclimation studies of temperate species.

The purpose of this study is to characterize the mitochondrial membranes of the two Arctic bivalve mollusk species *Serripes groenlandicus* and *Mya truncata*. As a result of their limited ability for locomotion, these species remain in subzero waters throughout the year in the Canadian Arctic. By comparing the membrane composition of these animals to those of cold-adapted temperate species, it may be possible to establish if mollusk species from the Arctic and Temperate zones utilize similar methods of membrane modification in overcoming the challenge of living at low temperatures.

MATERIALS AND METHODS

Experimental animals. Serripes groenlandicus and *M. truncata* were collected by scuba divers in depths of 7–18 m from the waters of the Arctic Ocean surrounding Igloolik Island (81°45′ W, 69°23′ N), Northwest Territories. The water temperature was −1.5–0.0°C, and the animals were observed to be feeding at time of capture. The animals were held in an aerated marine aquarium, maintained below 0°C for a maximum of 24 h prior to tissue processing.

Mitochondrial isolation. The gills were excised and placed in ice-cold isolation medium consisting of 400 mM sucrose, 1 mM EDTA, 2 mM EGTA, 10 mM HEPES pH 7.4 at 20°C, and 1% bovine serum albumin (essentially fatty acid-free). The gills of two animals were pooled to obtain a sufficient mass of tissue. The tissue was then weighed, minced, and suspended in ice-cold isolation medium in a ratio of 1 g of tissue to 5 mL of isolation medium. This mixture was homogenized

with three passes of a loosely-fitting Teflon pestle in a Potter-Elvehjem homogenizer. The homogenate was then centrifuged for 15 min at 1200 × *g*. The resulting supernatant was centrifuged for 15 min at 13600 × *g*, the pellet was removed and resuspended in 1 mL isolation medium, stored at −20°C for 3–7 d, and transported to the laboratory at the University of Guelph where it was stored at −80.0°C until further processing.

Measurement of marker enzymes. Marker enzymes were measured in both the initial homogenate and in the mitochondrial preparation. The following were used as markers for cellular membranes: cytochrome C oxidase (mitochondrial membrane), glucose 6-phosphatase (endoplasmic reticulum), Na^+,K^+-ATPase (plasma membrane), and peroxidase (peroxisomes). The activities of these marker enzymes were measured as described by Gillis and Ballantyne (11).

Analysis of mitochondrial membrane phospholipid composition. The mitochondrial membrane phospholipids were extracted, separated, and analyzed as described by Gillis and Ballantyne (11)

Protein determination. Protein was determined by the method of Bradford (12) using bovine serum albumin as a standard. Mitochondrial and tissue protein was determined by measuring the difference between the protein concentration in the isolation medium and the mitochondrial suspension.

Chemicals. The lipid standard used (Nu-Chek-Prep., Inc. Elysian, MN) was augmented by the addition of menhaden oil extract. Menhaden oil contains fatty acids not found in the commercial standard, but which are present in the lipids of most marine and freshwater organisms. Solvents were obtained from Fisher Scientific Ltd. (Whitby, Ontario) and were of American Chemical Society-certified grade. All other chemicals were obtained from Sigma Chemical Co. (St. Louis, MO) and were of the highest purity available.

RESULTS

Characterization of mitochondrial membrane purity. The isolation procedure used results in a substantial enrichment of the mitochondrial membrane marker cytochrome C oxidase in relation to the other marker enzymes for plasma membrane, peroxisomes, and endoplasmic reticulum (Table 1), indicating little contamination of the mitochondria with these cellular membranes. A second indication of membrane purity was the almost complete absence of sphingomyelin (SPH) (<1.0%). This phospholipid is found in trace amounts in the mitochondrial membrane (1%) while it is prevalent in lysosomes, plasma membranes, and Golgi membranes, representing as much as 20, 16, and 8%, respectively, of total phospholipid in these membranes (13). The very low proportion of this phospholipid is further evidence that there was minimal contamination of the membrane preparations by these organelles in the present study.

Phospholipid composition. In *M. truncata,* PE was the dominant phospholipid, representing 47.8% of the total membrane phospholipids, while phosphatidylcholine (PC) and phosphatidylinositol (PI) made up 22.4 and 19.5%, respectively, of the membrane phospholipid composition (Table 2). In *S. groenlandicus*, PE and PC were the two most abundant phospholipids, equaling 38.4 and 40.4% of the total membrane phospholipids, while PI represented 13.3% (Table 2). Cardiolipin (CL) and phosphatidylserine (PS) were minor components in the membrane phospholipids of both bivalve species. The ratio of bilayer-stabilizing (PC) to bilayer-destabilizing phospholipids (PE, CL) equaled 1.01 in *S. groenlandicus* and 0.45 in *M. truncata*. The phospholipid SPH was present in trace amounts in the mitochondrial membranes of both species but in all preparations represented less than 1% of total membrane phospholipid.

Gill mitochondrial membrane fatty acid composition. The predominant fatty acids in the cumulative fatty acid composition of membrane phospholipids in both bivalve species were 16:0, 20:1, and 20:5n-3 (Table 3), equaling a combined total of 45.9% in *S. groenlandicus* and 56.1% in *M. truncata*. Saturated fatty acids (SFA) were the most prevalent class of fatty acids equaling 42% in *S. groenlandicus* and 38% in *M. truncata* (Table 3).

In both species of mollusk, SFA, monoenes, and PUFA represented similar proportions of the fatty acids in the phospholipid PE (Table 4). The main individual fatty acids in this phospholipid from both species were 20:0 and 20:1. In *S. groenlandicus,* 20:0 equaled 24.3 ± 3.2% of total fatty acid content while 20:1 equaled 23.1 ± 3.3%. In *M. truncata* these fatty acids equaled 18.5 ± 4.7 and 29.4 ± 3.6%, respectively.

In mitochondrial PC of *S. groenlandicus*, SFA and PUFA were the prevalent classes of fatty acids (Table 4); this was

[a]Values are presented as means ± SEM.
[b]Not detectable.
[c]Three or more values expressed in mean were not detectable therefore included as zeroes.
[d]Unsaturation index = $\Sigma m_i \pm n_i$, where m_i is the mole percentage and n_i is the number of C-C double bonds of the fatty acid$_i$.
[e]Mean chain length = $\Sigma f_i \pm c_i$, where f_i is the mole fraction and c_i is the number of carbon atoms of the fatty acid $_i$.

due to the large proportions of 14:0, 16:0, and 20:5n-3, equaling 17.8 ± 1.3, 21.0 ± 1.1, and 18.4 ± 4.4%, respectively, of the fatty acids in this phospholipid. In *M. truncata* PUFA represented the largest class of fatty acids in PC due to the high levels of 20:5n-3 (33.7 ± 0.6%) in this phospholipid (Table 4).

PUFA was the largest class of fatty acids in CL from *S. groenlandicus* (Table 4). This was due to 20:5n-3, equaling 28.7 ± 3.9% of the fatty acids in this phospholipid. The monoene 20:1 was also prominent in this phospholipid, equaling 19.9 ± 6.5% of the fatty acid content. SFA and PUFA were the most common fatty acids in CL from *M. truncata* due to the high levels of 16:0 and 20:5n-3. These two fatty acids equaled 26.6 ± 1.4 and 24.9 ± 1.2%, respectively.

In PS from *S. groenlandicus*, SFA and PUFA were the dominant fatty acids (Table 4) as a result of the levels of 18:0 and 20:5n-3. These two fatty acids equaled 30.5 ± 2.2 and 17.9 ± 2.5%, respectively. In *M. truncata*, SFA was the most common class of fatty acids in this phospholipid due to the levels of 16:0 and 20:0. These two fatty acids equaled 19.6 ± 3.8 and 13.3 ± 1.2%, respectively. The monoene 20:1 was also prominent in PS, equaling 16.0 ± 2.6% of the fatty acid content.

In the phospholipid PI, SFA was the prevalent class of fatty acids in both species (Table 4). This result is due to the high levels of 16:0 in this phospholipid, equaling 53.7 ± 1.5% in *S. groenlandicus* and 71.2 ± 3.8% in *M. truncata*.

DISCUSSION

In the mitochondrial membranes of both *S. groenlandicus* and *M. truncata,* PE and PC were the main phospholipids, typical of most mitochondrial membranes (13). These two phospholipids play an important role in regulating membrane properties in the biological membranes of temperate zone organisms (2,6,14). The ratio of PC to PE decreases in many ectothermic animals acclimated to lower temperatures (2). PC stabilizes the bilayer as it favors the formation of a laminar bilayer, while PE destabilizes the bilayer by keeping the membrane close to the phase transition between laminar and hexagonal (H_{II}) phase conformations (15). For example, acclimation of trout *Salmo gairdneri* from 20 to 5°C lowered the ratio of PC/PE from 1.71 to 0.78 (16). Mitochondria contain a second bilayer-destabilizing phospholipid, CL. This phospholipid adopts the H_{II} phase conformation in the presence of Ca^{2+} (17,18) and the membrane protein cytochrome C oxidase (19), both of which are associated with the inner mitochondrial membrane. The ratio of PC/(PE + CL) in *M. truncata* was about half that of *S. groenlandicus.* This difference is as a result of twofold higher proportion of PC in the membranes of *S. groenlandicus*. Such interspecific differences in this ratio are not uncommon in temperate marine bivalves. In the oyster, *Crassostrea virginica,* this ratio is twice that of the quahog, *Mercenaria mercenaria* (11,20), and similar to that of *S. groenlandicus* in the present study. These results suggest that a low PC/(PE + CL) ratio is not a unique characteristic of Arctic marine mollusks.

The monounsaturated fatty acid (monoene) 20:1 was one of the three primary fatty acids in the cumulative totals of the mitochondrial membrane phospholipids in both bivalve species. Accordingly, this fatty acid was dominant in the phospholipids PE, CL, and PI in both species as well as in PS of *M. truncata*. This is different from the fatty acid composition of temperate marine bivalves where the predominant fatty acids are SFA and PUFA (11,20). Other cold-water organisms have high levels of monoenes. The monoene 18:1 is reported to be prevalent in red muscle mitochondrial membranes of Arctic char *Salvelinus alpinus* sampled from 4°C waters of the Arctic Ocean (21). The monoenes 20:1 and 22:1 were also reported in unusually high proportion in the whole tissue lipids of Arctic and Antarctic copepods (10).

The combination of the monoene 18:1 in the *sn*-1 position and a long-chain PUFA in the *sn*-2 position in the phospho-

lipid PE in cold-adapted and acclimated teleosts was suggested to play a role in fluidizing the biological membrane (13,22). These authors suggest that the presence of these specific fatty acids in PE is at least partially responsible for the increased disorder and lower transition temperatures of membranes of fish either evolutionarily or seasonally adapted to low temperatures. In PE of *S. groenlandicus,* the monoene 20:1 was the predominant fatty acid while in *M. truncata* it and 20:0 were of equally high proportion. Compared to the levels in PE of the temperate marine bivalve *C. virginica*, 20:1 was at least five times as abundant while PUFA content was one-half in this phospholipid in the Arctic species (20). This result suggests that this monoene is of particular importance to this phospholipid in the membranes of Arctic organisms.

While monoenes are in abundance in the mitochondrial membranes of the Arctic bivalves, PUFA are not. The PUFA content in the mitochondrial membranes of the Arctic animals is at least one-third less than that reported for the mitochondrial membranes of the temperate marine bivalve species acclimated to either −1, 10, or 12°C (11,20). It is the comparatively low levels of the fatty acid 22:6n-3 in a number of the membrane phospholipids of the Arctic bivalve species that can account for this difference. This PUFA was demonstrated to be accumulated in the membranes of both cold-adapted and cold-acclimated teleost fish (6,14,22) and is the primary fatty acid in the mitochondrial membranes of *S. alpinus* caught from 4°C water of the Arctic Ocean (21). The low level of 22:6n-3 in the Arctic bivalves is not due to a limited supply of its n-3 precursors as the level of the fatty acid 20:5n-3 is similar to that of temperate species (20). This implies that high levels of 22:6n-3 are not required for optimal membrane function at low temperatures.

The SFA content in the mitochondrial membranes of the Arctic bivalves is higher than any reported values for the mitochondrial membranes of marine and freshwater teleost fish (8,21,23), or of tissue phospholipids of marine and freshwater crustaceans (5,7). However, this finding is similar to what has been reported for the gill mitochondrial membranes of the temperate marine bivalves *C. virginica* and *M. mercenaria* acclimated to either −1.5, 10, or 12°C (4,11). This suggests that high concentrations of SFA, in particular 16:0, in mitochondrial membranes may be a common characteristic of marine mollusks. Having high proportions of SFA in the membranes of animals from very cold temperatures does not conform to what is predicted by acclimation studies of teleost fish (2,8, 9,22). As membrane fluidity was not measured in our study, the thermotropic phase transition temperatures of the membranes are unknown. However, as the Arctic species were active and feeding at time of capture, their membranes must have been sufficiently fluid to be functioning.

Diet plays a role in determining the fatty acid composition of biological membranes (24). The prevalence of monoenes in the tissues of Arctic copepod plankton (10) indicates that these fatty acids are common in the Arctic food chain. These fatty acids would be of adaptive value to the copepods, and when transferred to the mollusks feeding on them would require little modification to confer optimal membrane properties of the mollusks.

Overall the membranes of the Arctic species are very different from what would be expected based on previously published studies of animals acclimated to the cold. This may be due to the chronic lower temperatures faced by Arctic organisms. High levels of monoenes appear to be characteristic of polar animals and may play a functional role in the maintenance of membrane fluidity. The high proportion of 20:1 in PE may support the fluidizing effect of this phospholipid on the membrane. The low levels of PUFA, specifically 22:6n-3, compared to temperate species in the Arctic bivalves suggest that these fatty acids are not essential to membrane function at low temperature.

Influences of Subzero Thermal Acclimation on Mitochondrial Membrane Composition of Temperate Zone Marine Bivalve Mollusks

Todd E. Gillis[a] and James S. Ballantyne[b,*]

[a]Cardiac Membrane Research Laboratory, School of Kinesiology, Simon Fraser University, Burnaby, British Columbia V5A 1S6, and [b]Department of Zoology, University of Guelph, Guelph, Ontario, N1G-2W1 Canada

ABSTRACT: The phospholipid and phospholipid fatty acid composition of gill mitochondrial membranes from two temperate zone marine bivalve mollusks, the quahog, *Mercenaria mercenaria,* and the American oyster, *Crassostrea virginica,* were examined after acclimation to 12 and −1°C. Cardiolipin (CL) was the only phospholipid with proportions altered upon acclimation to −1°C, increasing 188% in the mitochondrial membranes of *M. mercenaria*. Although the ratio of bilayer stabilizing to destabilizing lipids is frequently associated with cold acclimation in ectothermic species, no change was found in this ratio in either of the species. Polyunsaturated fatty acids (PUFA) were found only to increase in *C. virginica* with cold acclimation, with total n-3 PUFA increasing in the phospholipid phosphatidylethanolamine, total n-6 PUFA increasing in CL, and total PUFA increasing in phosphatidylinositol. Monounsaturated fatty acids, not PUFA, were found to have increased in *M. mercenaria,* with 18:1n-9 increasing by 150% in CL, and 20:1 increasing in both CL and phosphatidylcholine, by 146 and 192%, respectively. These manipulations of membrane phospholipid and fatty acid composition may represent an attempt by these species to help maintain membrane function at low temperatures.

Paper no. L7751 in *Lipids 34,* 59–66 (January 1999).

Ectothermic animals alter the phospholipid and fatty acid composition of their cellular membranes in order to defend membrane function from the effects of lowered environmental temperature. This is accomplished by strategies which include alterations in the proportions of membrane phospholipids and the fatty acid composition of membrane phospholipids (1,2).

While there are numerous studies of the effects of thermal acclimation on marine fishes, to date, no study has been made of membrane acclimation in ectothermic species below 5°C. Adaptation to subzero temperatures may demand previously unidentified changes to membrane composition. Changes in the physical properties of subzero water, such as pH, density, as well as the large impact of very low temperature on the kinetic properties of biological membranes may pose a significant challenge to the maintenance of membrane function. Many temperate zone species are exposed to subzero temperatures during the winter. Marine mollusks, owing to their limited mobility, are unable to migrate to warmer temperatures and are therefore seasonally exposed to such low temperature. Only limited study has been done of thermal effects on the fatty acid composition of bivalve mollusks (3–5).

To determine how marine mollusks utilize phospholipid composition to help maintain membrane function at subzero temperatures, we examined the mitochondrial membranes of two common species of temperate zone mollusk: the American oyster, *Crassostrea virginica*, and the quahog, *Mercenaria mercenaria* with acclimation to 12 and −1°C. These two species demonstrate tissue growth during the winter (4,6), suggesting that cellular activity and therefore membrane function are maintained during this time. The animals used in this study were obtained from waters which range in temperature from 12°C in the summer to −1.5°C in the winter. The acclimation temperatures used therefore resemble those to which the animals are accustomed.

MATERIALS AND METHODS

Quahogs, *M. mercenaria,* and American oysters, *C. virginica,* cultured in Prince Edward Island, were obtained from a local seafood supplier in September. The animals were held at 12.0 ± 0.7°C in a flow-through seawater system (32‰) at the University of Guelph for a period of 2 mon prior to any temperature manipulation in 250-L tanks. A blended mixture of frozen krill was fed to the animals three times a week prior to and during the experimental period. The photoperiod of the holding facilities in which the bivalves were kept was 12 h dark/12 h light. Individuals of each species were randomly assigned to one of two experimental tanks. One tank was maintained at 12.0°C for the entire experimental period, while the temperature of the other tank was lowered to −1.0°C over a period of 26 d by decreasing the temperature by 1°C every 2 d using a water chiller (Ramco Inc., Columbus, OH). Once −1.0°C was achieved in the cold tank, both tanks were kept at

their respective temperatures for 65 d. Both acclimation tanks remained in the flow-through biological filtration system throughout the experimental period.

Mitochondrial isolation. The gills were excised and placed in ice-cold isolation medium consisting of 400 mM sucrose, 1 mM EDTA, 2 mM EGTA, 10 mM HEPES pH 7.4 at 20°C, and 1% bovine serum albumin (essentially fatty-acid free). The gills of two animals were pooled to obtain a sufficient mass of tissue, which was then weighed, minced, and suspended in ice-cold isolation medium in a ratio of 1 g of tissue to 5 mL of isolation medium. This mixture was homogenized with three passes of a loosely fitting Teflon pestle in a Potter-Elvehjem homogenizer. The homogenate was then centrifuged for 15 min at $1,200 \times g$. The resulting supernatant was centrifuged for 15 min at $13,600 \times g$; the pellet was removed and resuspended in 1 mL isolation medium, frozen in liquid nitrogen, and then stored at −80°C.

Analysis of mitochondrial membrane phospholipid composition. Mitochondrial lipids were extracted by a modification of the method of Bligh and Dyer (7) as described by Glemet and Ballantyne (8). The thin-layer chromatography method used for the separation of phospholipids from each other and from neutral lipids is essentially that of Holub and Skeaff (9). The lipid samples dissolved in 25 µL of a 2:1 mixture of chloroform/methanol were run on Merck silica gel 60 glass precoated 20×20 cm plates with a 0.25-mm layer thickness (British Drug House, Toronto, Canada). Phospholipid standards were run in separate lanes on the plates with the membrane lipids in separate lanes for reference. The solvent system used to develop the plates consisted of chloroform/methanol/acetic acid/water in a 50:37.5:3.5:2 (by vol) mixture. Once the solvent system had run within 0.5 cm of the top of the plate, the plate was removed and allowed to air dry then sprayed with a saturated solution of 2,7-dichlorofluorescein in methanol/water, 1:1 (vol/vol). The plate was then placed in a raised-bottom developing chamber containing 50–100 mL of 25% ammonium hydroxide for 5 min. The phospholipid bands were then visualized under ultraviolet light at a wavelength of 366 nm. This method is effective in completely separating the phospholipids: phosphatidylethanolamine (PE), phosphatidylcholine (PC), cardiolipin (CL), phosphatidylinositol (PI), phosphatidylserine (PS), and sphingomyelin (SPH) (9).

The preparation of fatty acid methyl esters from the separated phospholipids followed the method of Holub and Skeaff (9). The individual phospholipid bands were scraped into glass Kimax tubes containing 2 mL of 6% H_2SO_4 in methanol and 10 µg of heptadecanoic acid (17:0) as an internal standard. The sealed tubes were then mixed and incubated at 80°C for 2 h. Upon completion, the tubes were cooled to room temperature, 2 mL of petroleum ether was added, and the tubes were then vortexed for 60 s. Double-distilled H_2O (1 mL) was added, and the tubes were vortexed for a further 30 s. The upper petroleum ether phase containing the eluted fatty acid methyl esters was removed and transferred to a glass vial and stored at −20°C until further processing. These samples were than analyzed as described by Glemet and Ballantyne (8), using a Hewlett-Packard (Mississauga, Ontario, Canada), HP5890 series II gas chromatograph fitted with a flame-ionization detector, an automatic injector (7673A; Hewlett-Packard) and an electronic pressure control program. Fatty acid methyl esters were analyzed on DB 225 megabore fused-silica column (Chromatographic Specialties Inc., Brockville, Ontario, Canada). Chain lengths shorter than C:14 were not resolved and therefore were not reported. Phospholipid content was calculated by summing the concentrations of fatty acids for each phospholipid, taking into account the number of fatty acids esterified to each phospholipid. The quantitative recovery of a known PI standard following these methods of thin-layer chromatography, methylation, and gas chromatography is 95% (9).

Extraction and quantification of total lipids from frozen krill. Total lipids of the frozen krill fed to the animals throughout the thermal acclimation study were extracted and quantified by the same methods used for the mitochondrial preparations.

Measurement of marker enzymes. Marker enzymes were measured in both the initial homogenate and in the mitochondrial preparation. The following marker enzymes were used: cytochrome C oxidase (mitochondrial membrane), glucose 6-phosphatase (endoplasmic reticulum), Na^+,K^+-ATPase (plasma membrane), and peroxidase (peroxisomes). A temperature-controlled Hewlett-Packard HP8452 diode array spectrophotometer maintained at 10°C by a Haake D8 circulating water bath (Haake Buchler Instruments Inc., Saddlebrook, NJ) was used for all enzyme assays. The methods for the specific enzyme measurements were as follows:

(i) Cytochrome C oxidase. The oxidation of fully reduced cytochrome C (50 µM) by the sample in 50 mM imidazole buffer (pH 7.5) at $\lambda = 550$ nm was measured by the method as described by Stuart and Ballantyne (10).

(ii) Glucose 6-phosphatase. The method used to measure the activity of the sample was modified from that of Aronson and Touster (11). The assay conditions were as follows: 50 mM imidazole (pH 6.5), 2 mM NAD, 20 mM glucose-6-phosphate, 9.6 units glutamate dehydrogenase, and 0.2 units malate dehydrogenase. Phosphorus production after 1 h incubation was measured at $\lambda = 820$ nm.

(iii) Na^+,K^+-ATPase. The method used to measure the activity of the sample was modified from that of Chen *et al*. (12). The sample was suspended in an environment of: 50 mM imidazole buffer (pH 7.5), 80 mM NaCl, 20 mM KCl, 6 mM $MgCl_2$, 1.5 mM EGTA, 10 mM NaF, and 3 mM ATP. Phosphorus production after 1 h of incubation was measured at $\lambda =$ 820 nm. Background ATPase activity was measured by comparing the rates of the enzyme in the presence to that in the absence of ouabain (10 mM). As ouabain acts to inhibit Na^+,K^+-ATPase, the difference in activity between measurement with and without ouabian equals the activity of Na^+,K^+-ATPase.

(iv) Peroxidase. Activity of the sample in 50 mM imidazole buffer (pH 7.5) was measured after the addition of 3 mM H_2O_2 at $\lambda = 240$ nm (10).

Protein determination. Protein content was determined by the method of Bradford (13) using bovine serum albumin as a standard. Mitochondrial and tissue protein was determined by measuring the difference between the protein concentration in the isolation medium and the mitochondria suspension.

Chemicals. The lipid standard used (Nu-Chek-Prep., Inc., Elysian, MN) was augmented by the addition of menhaden oil extract. Menhaden oil contains fatty acids not found in the commercial standard but which are present in the lipids of most marine and freshwater organisms. Solvents were obtained from Fisher Scientific Ltd. (Whitby, Ontario, Canada) and were of American Chemical Society-certified grade. All other chemicals were obtained from Sigma Chemical Co. (St. Louis, MO) and were of the highest purity available.

Statistical analysis. Differences between the percentages of individual phospholipids and fatty acids from phospholipids were tested using a one-factor analysis of variance followed by Bonferroni's *posthoc* test. Statistical comparisons were only made with fatty acids which represented greater than 1.0% of the total. In all cases, the assumptions of parametric tests were verified and a $\log_{10}$ or square root transformation was used when necessary to normalize the data (14).

RESULTS

Characterization of mitochondrial membrane purity. The isolation procedure used resulted in a substantial enrichment of the mitochondrial membrane marker cytochrome-C-oxidase in relation to the other marker enzymes for plasma membrane, peroxisomes, and endoplasmic reticulum (Table 1), indicating little contamination of the mitochondria with these cellular membranes. A second indication that the membranes recovered were not significantly contaminated by other membranes was the almost complete absence of SPH (<1.0%). This phospholipid is found only in trace amounts in the mitochondrial membrane (1%) while it is prevalent in lysosomes, plasma membrane, and Golgi membrane, representing as much as 20, 16, and 8%, respectively, of total phospholipid in these membranes (15). The very low proportion of this phospholipid in these membranes is evidence that there was minimal contamination of the membrane preparations by these organelles in the present study.

Phospholipid composition. The most prevalent phospholipid in the mitochondrial membranes of both acclimation groups of *M. mercenaria* was PE equaling 41–42% of total membrane phospholipid (Table 2). In *C. virginica* PE and PC were the most prevalent phospholipids, equaling a cumulative 75% of membrane phospholipid in both acclimation groups (Table 2). The phospholipid SPH was present in trace amounts in the mitochondrial membranes of both species but in all preparations represented less than 1% of total membrane phospholipid. The proportion of CL increased in *M. mercenaria* with cold acclimation but not in *C. virginica* (Table 2). There was no change in the ratio of bilayer stabilizing- (PC) to bilayer-destabilizing phospholipids (PE, CL) in either of the two species with cold acclimation.

Gill mitochondrial phospholipid fatty acids. Polyunsaturated fatty acids (PUFA) were the predominant fatty acids in the mitochondrial membranes of both species from either acclimation group (Table 3), resulting from the high proportions of 22:2n-6 and 22:6n-3 in the membranes of *M. mercenaria* and 20:5n-3 and 22:6n-3 in *C. virginica* (Table 3). The saturated fatty acid (SFA) 16:0 represented the largest proportion of individual fatty acids in the membranes of both species (Table 3). The only effect of cold acclimation on the cumulative fatty profile of either species was a decrease in 22:4n-6 in *M. mercenaria* by 33.6% (Table 3).

Acclimation of *M. mercenaria* to −1°C caused alteration in the fatty acid composition of mitochondrial membrane PE, PC, and CL while PE, CL, PS, and PI were altered in *C. virginica*. In mitochondrial membrane PE of both species, PUFA were the dominant class of fatty acid constituting from 67.0–71.4% of the fatty acids in this phospholipid in both species (Table 4). With cold acclimation there was a decrease in the n-6 PUFA content in PE from the mitochondrial membranes of *M. mercenaria.* SFA in PE were found to increase with cold acclimation in *M. mercenaria* caused by a compositional increase in the fatty acid 16:0 (Fig. 1). In *C. virginica* there was an increase in n-3 PUFA content and unsaturation index in PE caused by increased proportions of the fatty acid 22:6n-3 (Fig. 1).

PUFA were the most prevalent fatty acids in mitochondrial membrane PC in both species ranging from 52.5–60.3% (Table 4). Cold acclimation of *M. mercenaria* increased the proportion of monounsaturated fatty acids (monoenes) due to an increase in the fatty acid 20:1 (Fig. 2); 22:4n-6 was found to decrease in this phospholipid. The fatty acid composition of PC from the mitochondrial membranes of *C. virginica* was not affected by cold acclimation.

[a]Values are presented as means ± SEM. PS, phosphatidylserine; PI, phosphatidylinositol; SFA, saturated fatty acids; monoenes, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids. See Table 2 for other abbreviations.
[b]Statistically significant difference between treatment groups of the species in this column.
[c]Unsaturation index (unsat. ind.) = $\Sigma m_i \cdot n_i$, where m_i is the mole percentage and n_i is the number of C–C double bonds of the fatty acid *i*.

In mitochondrial CL, PUFA were the predominant fatty acids in both species, representing from 47.0–60.6% of the fatty acids in this phospholipid (Table 4). Cold acclimation of *M. mercenaria* increased the proportion of monoenes in CL (Table 4) due to increased levels of 18:1n-9 and 20:1 (Fig. 3). Additionally, there was a decrease in n-6 PUFA in this phospholipid (Table 4). Cold acclimation of *C. virginica* caused an increase in the content of n-6 PUFA as well as in 20:5n-3 while the level of the fatty acid 16:1 was found to decrease (Fig. 3).

PUFA were the most prevalent fatty acids in mitochondrial membrane PS in both species, ranging from 35.7–53.8% of total fatty acid content. This phospholipid was not affected by cold acclimation in *M. mercenaria*; however, there was an increase in the content of 20:4n-6 in this mitochondrial membrane phospholipid in *C. virginica* increasing from 0.57 ± 0.16 to 2.48 ± 0.96%.

In mitochondrial membrane PI, SFA were the predominant fatty acids in both species equaling 70–90%. This result is due to the 16:0 content in this phospholipid (Fig. 4). Cold acclimation of *M. mercenaria* did not affect the fatty acid content of this phospholipid. In *C. virginica*, cold acclimation caused a decrease in SFA content due to a decrease in 16:0. Total PUFA content of PI as well as n-3 PUFA content, n-6 PUFA content, and the unsaturation index were found to increase in

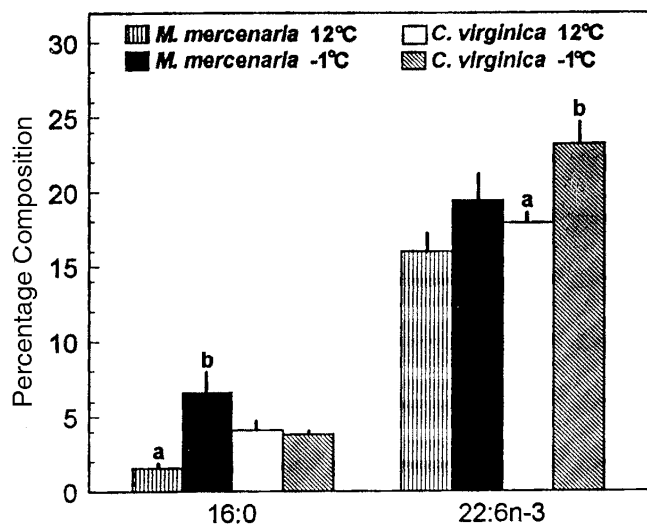

FIG. 1. Percentages of the fatty acids 16:0 and 22:6n-3 in the mitochondrial membrane phospholipid phosphatidylethanolamine of the bivalve mollusks, quahog clam, *Mercenaria mercenaria,* and American oyster, *Crassostrea virginica,* acclimated to either 12 or –1°C. Values, within species, are statistically different if they are marked with the letters a and b. Values presented as means ± SEM.

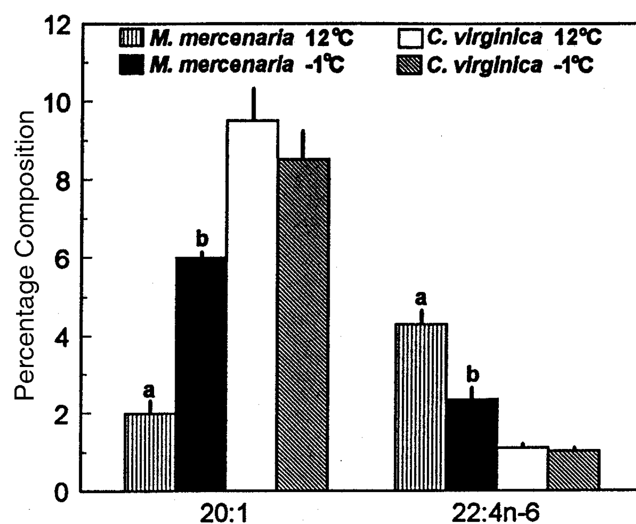

FIG. 2. Percentages of the fatty acids 20:1 and 22:4n-6 in the mitochondrial membrane phospholipid phosphatidylcholine of the bivalve mollusks, quahog clam, *Mercenaria mercenaria,* and American oyster, *Crassostrea virginica,* acclimated to either 12 or –1°C. Values, within species, are statistically different if they are marked with the letters a and b. Values presented as means ± SEM.

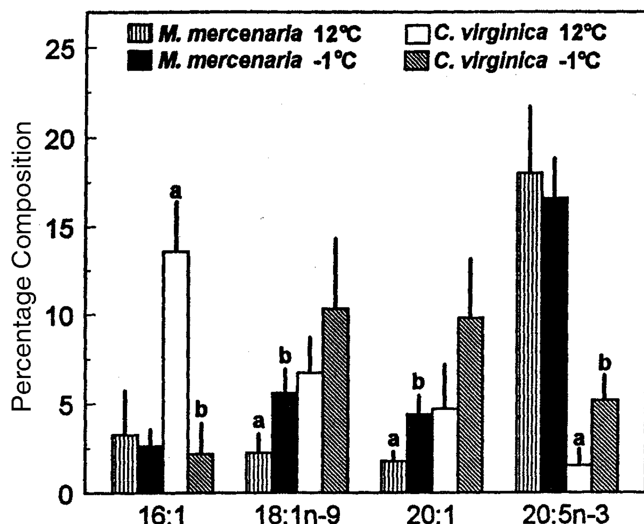

FIG. 3. Percentages of the fatty acids 16:1, 18:1n-9, 20:1, and 20:5n-3 in the mitochondrial membrane phospholipid cardiolipin of the bivalve mollusks, quahog clam, *Mercenaria mercenaria,* and American oyster, *Crassostrea virginica,* acclimated to either 12 or −1°C. Values, within species, are statistically different if they are marked with the letters a and b. Values presented as means ± SEM.

C. virginica with cold acclimation (Table 4). These results were due to increases in the fatty acids 20:2n-6 and 20:5n-3 (Fig. 4). The monoene 20:1 was also found to increase with cold acclimation in this phospholipid with cold acclimation (Fig. 4).

Fatty acid composition of krill. SFA were the most abundant fatty acids in the total lipid equaling 52%, PUFA composed primarily of 20:5n-3 and 22:6n-3 represented 32% of total fatty acid content (Table 5).

Mitochondrial protein. No change occurred in the concentration of mitochondrial protein with cold acclimation in either of the two species. In *M. mercenaria* mitochondrial protein was 6.43 ± 0.81 mg/g gill in animals acclimated to 12°C and 7.02 ± 0.92 mg/g gill in animals acclimated to −1°C. In *C. virginica*, mitochondrial protein was 10.14 ± 1.37 mg/g gill and 11.03 ± 1.52 mg/g gill in animals acclimated to 12 and −1°C, respectively. All protein values presented are from an *n* of 4.

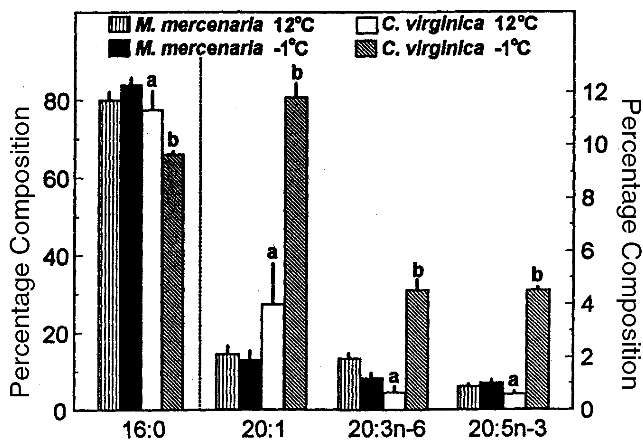

FIG. 4. Percentages of the fatty acids 16:0, 20:1, 20:3n-6, and 20:5n-3 in the mitochondrial membrane phospholipid phosphatidylinositol of the bivalve mollusks, quahog clam, *Mercenaria mercenaria,* and American oyster, *Crassostrea virginica,* acclimated to either 12 or −1°C. Values, within species, are statistically different if they are marked with the letters a and b. Values presented as means ± SEM.

TABLE 5
Percentages of Individual Fatty Acids in the Total Lipids Extracted from the Frozen Krill Used to Feed Both Species of Mollusk During the Thermal Acclimation Study

Fatty acid	mol%
14:0	13.70
14:1	0.97

n-6 Polyunsaturated fatty acids	0.67
n-3/n-6	45.57
Unsaturation index[a]	173.05

[a]Unsaturation index = $\sum m_i \cdot n_i$, where m_i is the mole percentage and n_i is the number of C–C double bonds of the fatty acid *i*.

DISCUSSION

Many of the observed changes in the composition of the mitochondrial membranes in the marine mollusks in the present study differ from what was previously reported in other ectothermic species during thermal acclimation. Previous laboratory studies demonstrated that the ratio of bilayer-stabilizing to bilayer-destabilizing lipids decreases in the cellular membranes of ectothermic animals with cold acclimation (16–18). As in other cellular membranes, PC stabilizes the bilayer in mitochondrial membranes as it favors the formation of a laminar bilayer, while PE destabilizes the bilayer by keeping the membrane close to the phase transition between laminar and hexagonal (H_{II}) phase conformations (16,19). Mitochondria contain a second bilayer-destabilizing phospholipid, CL. This phospholipid adopts the H_{II} phase conformation in the presence of Ca^{2+} (20,21) and the membrane protein cytochrome C oxidase (22), both of which are associated with the inner mitochondrial membrane. Cold acclimation of either species of mollusk in the present study did not alter the ratio of PC/(PE + CL), indicating that alterations of membrane-stabilizing to

-destabilizing lipids are not used by either of these animals to maintain membrane function at low temperatures.

The increase in the proportion of CL in the mitochondrial membranes of *M. mercenaria* with cold acclimation represents an acclimatory response to lowered environmental temperature. No change occurred in the ratio of PC/(PE + CL), therefore the likelihood that this alteration would affect bilayer stability is slight. Since CL is a required component for the function of several mitochondrial proteins (15), the observed changes may relate to shifts in metabolic organization. Previous studies demonstrated that the proportion of PUFA increases at the expense of SFA in the tissue lipids upon the acclimation of ectothermic animals to low temperatures (1,16,18,23–25). Compared to SFA, PUFA have lower melting points and, when included in a membrane, disrupt the monolayer due to their permanently "kinked" acyl chain (16,23,26). These two characteristics of PUFA increase the fluidity of a biological membrane and, it is suggested, enable the membranes of cold-acclimated animals to remain fluid and functioning (1,16,23,). In the present study no increase of PUFA took place in the mitochondrial membranes of *M. mercenaria* with cold acclimation, while the fatty acid 22:4n-6 actually decreased, suggesting that this species of marine mollusk is not utilizing PUFA to maintain membrane function at low temperatures and therefore may be utilizing a different strategy. Only in *C. virginica* were PUFA found to increase with cold acclimation, with n-3 PUFA increasing in PE, n-6 PUFA increasing in CL, and total PUFA increasing in PI. This response indicates that these animals are actively manipulating membrane composition and that PUFA may be important to membrane function at low temperatures at least in this mollusk.

While PUFA levels in the membranes of *M. mercenaria* did not increase with cold acclimation, monoene levels did. The fatty acid 18:1n-9 increased in CL while 20:1 was found to increase in PC and CL. Monoenes also were demonstrated to increase in tissue phospholipids and cellular membranes of other ectothermic animals with cold acclimation (18,25,27, 28). However, in these previous studies, PUFA increased in parallel with monoenes. Only in PI from the gills of *C. virginica* in the present study was such a result noted. An increase in monoenes in animals acclimated to cold temperatures may be related to the maintenance of membrane fluidity. The presence of the monoene 18:1 in the *sn*-1 position of PE of cold-acclimated or adapted fish was suggested to increase the influence of that phospholipid on the membrane (27). This would act to increase the fluidity of the membrane and therefore help maintain membrane function at low temperatures. The results of the present study suggest that *M. mercenaria* is increasing monoene content, not PUFA, to help maintain membrane function at low temperatures.

In both marine bivalves, the SFA 16:0 constitutes 66–84% of the fatty acids in PI. High levels of 16:0 were previously demonstrated to occur in gill mitochondrial membranes of *C. virginica* (8); therefore, the levels reported in the current study are not unexpected. The increase in 16:0 found in PE from the membranes of cold-acclimated *M. mercenaria* would act to stabilize the membrane at low temperature. The significance of this particular finding is not known at this time.

Limited study has been made of the metabolism of dietary fatty acids in bivalve mollusks. It was demonstrated that the oyster, *C. virginica*, and the yellow clam, *Mesodesma matroides*, are capable of elongation and desaturation of fatty acids (29–31). The fatty acid composition of the diet (krill) fed to these animals throughout the experiment has a higher proportion of SFA and lower proportion of PUFA and monoenes than the fatty acid composition of the membrane phospholipids of both species used in this study. Both mollusks therefore accumulated these fatty acids in their membranes in a higher proportion to what is found in the diet. The long-chain PUFA 22:6n-3 is lower in the krill-based diet than in the mitochondrial membranes. Long-chain n-3 fatty acids such as 22:6n-3 can only be made from other shorter n-3 fatty acids which are all synthesized from the precursor 18:3n-3. This fatty acid must be obtained from the diet. The diet used contained sufficient concentrations of all precursors for the synthesis of longer-chained PUFA.

The ratio of n-3 to n-6 fatty acids (n-3/n-6) of the mitochondrial membrane phospholipids of the marine mollusks in the present study is lower compared to those of previously published values for marine teleost fish. This ratio is 1.0 in *M. mercenaria* and 2.0 in *C. virginica* at 12°C, while it is 16 in the winter flounder *Pseudopleuronectes americanus*, acclimated to 10°C (32), and 76 in Arctic char, *Salvelinus alpinus*, caught from 4°C seawater (33). This is due to the lower levels of n-6 fatty acids in the phospholipids in the marine teleosts compared to that of the marine bivalves. Within wild populations of marine organisms, low levels of n-6 fatty acids are common when compared to similar freshwater species. This difference was attributed to fatty acid precursors available in the diet (34). However, the diet fed the mollusks throughout the current study had an n-3/n-6 ratio of 45. This is much higher than that of the marine bivalves due to the low content of n-6 fatty acids This indicates that n-6 fatty acids are being concentrated in the mitochondrial membrane, suggesting a functional significance of these fatty acids in the membrane.

The seasonal temperatures experienced by most temperate zone marine organisms in northern latitudes range from −1.5°C in winter to 12°C in summer. The large alterations of membrane phospholipid composition seen in previous thermal acclimation studies were in response to correspondingly large changes in environmental temperature for example: 5 vs. 30°C (35), 7 vs. 27°C (24), and 10 vs. 32°C (25). The results of the present study indicate that during thermal shifts such as those occurring during seasonal changes in environmental temperature changes in membrane phospholipids do occur in mollusks.

Unlike thermal acclimation in fishes and some other organisms, the ratio of membrane-stabilizing phospholipids to membrane-destabilizing phospholipids was not altered. Most of the acclimation response is due to changes in phospholipid fatty acids such as alterations in PUFA content (*C. virginica*) or monoene levels (*M. mercenaria*).

Biosynthesis and Localization of Phosphatidyl-*scyllo*-Inositol in Barley Aleurone Cells

Sven Carstensen[a], Gay Pliska-Matyshak[b], Narasimhan Bhuvarahamurthy, Kim M. Robbins[c], and Pushpalatha P.N. Murthy*

Department of Chemistry, Michigan Technological University, Houghton, Michigan 49931

ABSTRACT: A novel isomer of phosphatidylinositol (PI), phosphatidyl-*scyllo*-inositol, was characterized in the aleurone cells of barley seeds. In this investigation, the subcellular localization of *scyllo*-PI and the relative rates of biosynthesis and accumulation of [^{32}P]phosphoric acid ([^{32}Pi])-labeled *scyllo*- and *myo*-phosphoinositides in the plasma membrane and intracellular membrane pools were investigated. About 25% of the [^{32}Pi]-labeled phospholipids were present in plasma membrane and 75% in intracellular membranes. Incorporation of [^{32}Pi] into *scyllo*-PI was greater than into *myo*-PI in both the plasma membranes and intracellular membranes at all time points investigated, thus suggesting a higher rate of biosynthesis; however, the data do not preclude reduced breakdown of labeled *scyllo*-PI as a contributing factor. *In vitro* studies were conducted to investigate the presence of cytidinediphosphate diacylglycerol (CDP-DG):*scyllo*-inositol 3-phosphatidyltransferase (*scyllo*-PI synthase) and to optimize enzymatic activity. The inclusion of nonionic detergents (Brij 58 and Triton X-100) effected significant enhancement in the biosynthesis of *scyllo*-PI, whereas anionic, cationic, and zwitterionic detergents had little or no effect. This is the first evidence for CDP-DG:*scyllo*-inositol 3-phosphatidyltransferase activity.

Paper no. L7940 in *Lipids 34,* 67–73 (1999).

Phosphoinositides, a group of negatively-charged phospholipids, are important constituents of cell membranes. The critical role that *myo*-inositol-containing phosphoinositides play in signal transduction is well established. Plasma membrane-bound *myo*-phosphatidylinositolbisphosphate undergoes hormone-triggered hydrolysis to generate two second messengers, diacylglycerol and *myo*-inositol(1,4,5)trisphosphate (1). Numerous investigations aimed at understanding the role of phosphoinositides in plant cells have been published (2–4). Spatially and metabolically distinct pools of phosphoinositides occur in cells (1,2); therefore, a complete and accurate understanding of the role of phosphoinositides requires information on the biosynthesis, transport, and accumulation of phospholipids in cell membranes.

During seed development, the outer endosperm cells differentiate into functionally and morphologically distinct cells called the aleurone cells (5). Mature aleurone cells of common cereals, including barley, are packed with protein bodies, phytin grains, and lipid bodies. During germination, the aleurone layer plays a major role in the mobilization of reserves to the developing seedling by its involvement in the hormone-controlled synthesis and secretion of hydrolytic enzymes including α-amylase, β-galactosidase, phytase, and proteases. Rapid proliferation of the protein-synthesizing apparatus and intracellular membranes also occurs soon after imbibition (5,6). The ready availability of viable aleurone layers has made this a good model system for the study of plant hormone action (5–7).

We have described our efforts to characterize phosphoinositides in the aleurone tissue of barley (8,9), including the structural characterization of a novel phosphoinositide, *scyllo*-phosphatidylinositol (PI), in barley seeds (10,11). We are interested in the biosynthesis and accumulation of *myo*- and *scyllo*-phosphoinositides in the plasma membrane and intracellular membrane pools and the incorporation of [^{32}P]phosphoric acid ([^{32}Pi]) into these phosphoinositides. Toward this end, our first step (12) was to investigate the fractionation of membrane vesicles from barley aleurone cells, starting with the isolation and assessment of purity of plasma membrane and intracellular membrane vesicles using the aqueous polymer two-phase method (13,14). Whereas [^{32}Pi]-labeled monophosphorylated PI (PIP) and bisphosphorylated PI were clearly evident only in the plasma membrane (if present in intracellular membranes, they occur in undetectably low amounts), *myo*-PI and *scyllo*-PI are present in the intracellular membranes as well as in the plasma membrane. In this paper, results on the biosynthesis of *scyllo*- and *myo*-phosphoinositides by *in vivo* and *in vitro* studies are presented. Data on *in vivo* [^{32}Pi] labeling of the spatially distinct pools of phosphoinositides in plasma membrane and intracellular membranes are presented. Finally, the consequence of these results on signal transduction studies are discussed.

EXPERIMENTAL PROCEDURE

***Plant material*.** Barley seeds (*Hordeum vulgare* L. cv. Himalaya, 1991 harvest) were purchased from Seed Technology, Department of Agronomy and Soil, University of Washington, Pullman, WA.

Labeling with radioactive precursors. Aleurone layers were isolated from barley seeds (15). Aleurone layers were incubated at 25°C in a solution (1 mL/10 layers) containing succinate buffer (20 mM, pH 5), $CaCl_2$ (20 mM), chloramphenicol (30 μM), and [^{32}Pi], as indicated in figure legends; the [^{32}Pi], dissolved in 0.02 M HCl (DuPont/NEN, Boston, MA), was neutralized just before use with 0.02 M NaOH (9). To double-label with [^{32}Pi] and ^{14}C, the layers were incubated with [^{32}Pi] (20 μCi per five layers) and *myo*-[^{14}C(U)]inositol (from American Radiolabeled Chemicals Inc., St. Louis, MO; 2.5 μCi per five layers). After 20 to 26 h the layers were freed of excess isotope by washing three times with media without isotope (8). To separate the plasma membrane and intracellular membrane vesicles, the aleurone layers were homogenized in a cold mortar and pestle with 25 mL of homogenization buffer containing sucrose (0.5 M), Hepes-KOH (50 mM, pH 7.5), ascorbic acid (5 mM), dithiothreitol (1 mM), and polyvinylpyrrolidone (0.6%, wt/vol) and the separation was carried out as described previously (13,14). The concentration of both polymers, Dextran T500 and polyethyleneglycol 3350, in the aqueous polymer two-phase method was 6.2%.

Extraction and separation of phospholipids. Phospholipids were extracted from aleurone layers or from membrane pellets by a modified acidic Bligh-Dyer method (10,11). The washed aleurone layers were homogenized in a mortar and pestle with a small amount of sand and water (1 mL), and the slurry was transferred to a test tube. With membrane pellets, water (1 mL) was added and mixed well with a vortex mixer. To the suspension was added 3 mL of CH_3OH, 2.5 mL of $CHCl_3/CH_3OH$ (2:1, vol/vol), 0.75 mL of 2.4 N HCl, and 2.1 mL of $CHCl_3$. The solution was vortex-mixed and centrifuged, and the lower organic phase was removed. The aqueous phase was reextracted with 1.7 mL of $CHCl_3$. The combined organic extract was washed twice with 0.75 mL of 2.4 M HCl and 3.0 mL of CH_3OH/H_2O (1:1, vol/vol). Unlabeled phospholipids (0.075 mg) from soybean were added to the organic extract and separated on a high-performance thin-layer chromatography (HPTLC) plate [using a modified Folch solvent system, $CHCl_3/CH_3OH$/aqueous NH_4OH, 28–30% of NH_3 in H_2O, w/w (90:90:20, by vol)] as described previously (10). In some experiments the phospholipids were converted to glycerophospholipids by deacylation using methylamine and then separated by high-voltage paper electrophoresis or high-performance liquid chromatography (10).

Isolation of PI synthase. Barley seeds (300–400) were imbibed for 60–63 h at 30°C (15). The seeds were homogenized in a cold mortar and pestle in Tris/MES [2-(*N*-morpholino)ethanesulfonic acid] buffer (pH 7.5) containing Tris (25 mM), sucrose (0.30 mM), KCl (10 mM), $MgCl_2$ (1.0 mM), dithiothreitol (10 mM), and polyvinylpyr-rolidone (6.0%). The homogenate was centrifuged for 10 min at 750 × *g*. The supernatant was removed and centrifuged at 50,000 × *g* for 30 min. (Initial studies were conducted with 18,000 × *g* and 100,000 × *g* pellets, and the 50,000 × *g* pellet was used for all subsequent experiments.) The microsomal pellet was suspended in Tris/HCl buffer (pH 8.0) containing Tris (40 mM), sucrose (0.46 mM), and KCl (15 mM). A homogeneous suspension was obtained with difficulty, after repeated efforts to break up the pellet with a flattened glass rod.

PI synthase assay. PI synthase activity was assayed at 30°C in a solution containing 20 mM Tris/HCl (pH 8.0), 0.23 M sucrose, 7.5 mM KCl, 1 mM cytidinediphosphate diacylglycerol (CDP-DG) made from egg phosphatidylcholine (Doosan Serdary Research Laboratory, Englewood Cliffs, NJ), 5mM $MnCl_2$, 1 mM *myo*-[2-^{3}H(N)]inositol (40,000 to 200,000 cpm per assay) or *scyllo*-[^{3}H(N)]inositol (100,000 to 200,000 cpm per assay (American Radiolabeled Chemicals Inc.), and 0.03% Brij 58 (polyoxyethylene 20 cetyl ether) or 0.2% Triton X-100 in a total volume of 0.4 mL. CDP-DG was added to the solution containing Tris/HCl, sucrose, and KCl and sonicated for 30–60 s. After the solution appeared homogeneous, inositol and $MnCl_2$ were added. The reaction was initiated by addition of the PI synthase enzyme (150–300 μg protein) and was terminated after 3 h by the addition of 3.3 mL $CHCl_3/CH_3OH/H_2O$ (1:2:0.3, by vol). The phospholipids were extracted by the acidic Bligh-Dyer method (10).

RESULTS AND DISCUSSION

In vivo *[^{32}Pi] labeling of plasma membrane and intracellular membrane phosphoinositides.* To monitor the relative rates of incorporation of phosphoinositides in the plasma membrane and intracellular membrane pools, we followed the incorporation of [^{32}Pi] into phospholipids as a function of

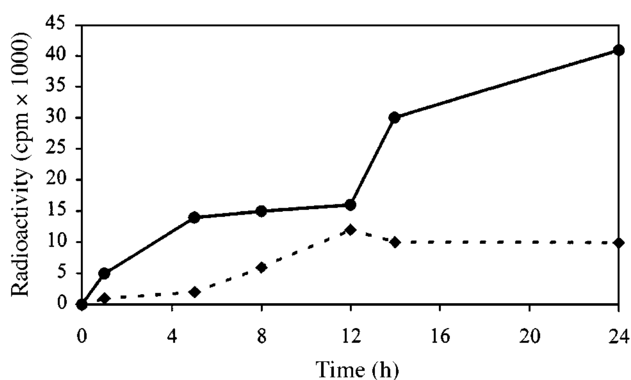

FIG. 1. Incorporation of [^{32}P]phosphoric acid ([^{32}Pi]) into the phospholipids of plasma membranes (◆)and intracellular membranes (●) in barley aleurone layers. Aleurone layers were incubated in media containing 75 μCi [^{32}Pi]/10 layers for the indicated time period. Plasma membranes and intracellular membranes were isolated and phospholipids were extracted from the membrane vesicles. The content of radioactivity in the phospholipid extracts was determined by liquid scintillation counting. This graph represents two independent experiments.

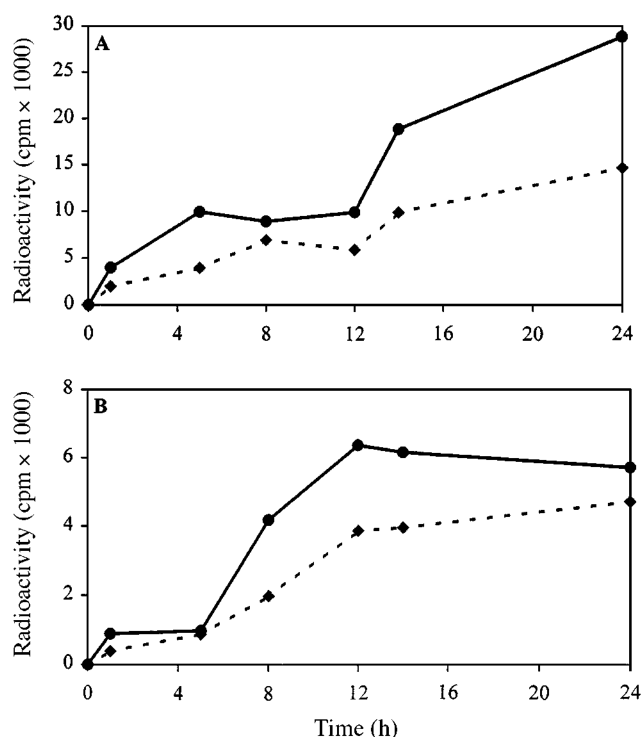

FIG. 2. Incorporation of [^{32}Pi] into *myo*-phosphatidylinositol (PI) and scyllo-PI of (A) intracellular membranes and (B) plasma membranes in barley aleurone layers. Aleurone layers were incubated in media containing 75 µCi [^{32}Pi]/10 layers for the indicated time period. Plasma membranes and intracellular membranes were isolated by aqueous polymer two-phase separation. The phospholipids from membrane vesicles were extracted, deacylated to glycerophospholipids, and separated by high-performance liquid chromatography. The content of radioactivity in the fractions corresponding to *myo*-glycerophosphoinositol (GPI: ◆) and *scyllo*-GPI (●) (7) was determined by liquid scintillation counting.

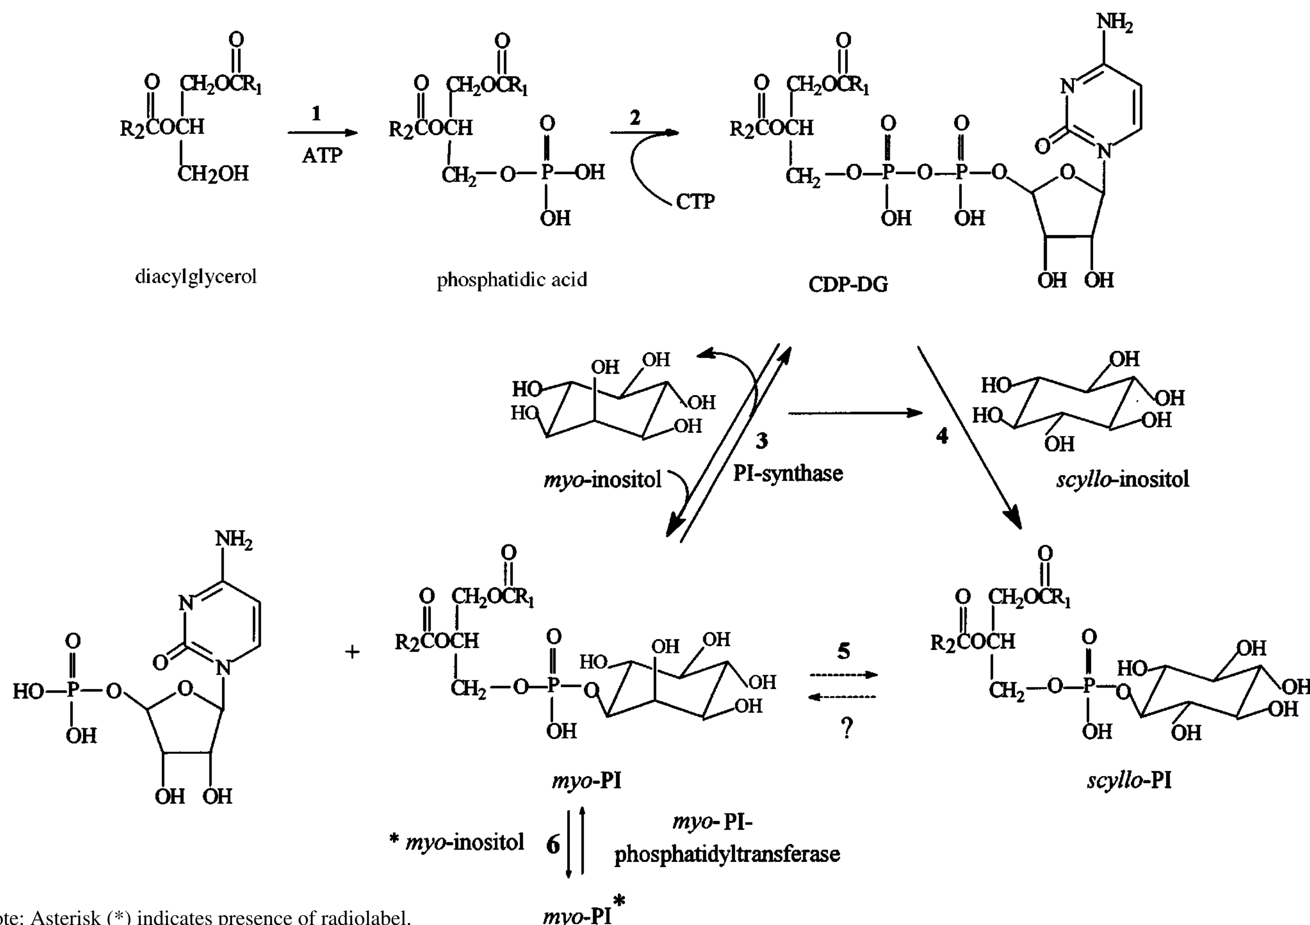
time. Incorporation of [^{32}Pi] into lipid extract increased for the first 24 h (Fig. 1). Figure 1 illustrates that phospholipids in intracellular membranes incorporate radioactivity faster than phospholipids in plasma membranes possibly due to the fact that phospholipids are biosynthesized in the endoplasmic reticulum and subsequently transported to the plasma membrane. After 14 h, about 75% of the radiolabeled cellular phospholipids was present in intracellular membranes and 25% in plasma membranes. [^{32}Pi] incorporation into the phospholipids of the plasma membranes had reached isotopic equilibrium in about 10–12 h, whereas incorporation into intracellular membranes continued to increase. To determine the relative rate of biosyntheses of *scyllo*-PI and *myo*-PI, incorporation of [^{32}Pi] into *scyllo*-PI and *myo*-PI was monitored by extracting phospholipids from plasma membranes and intracellular membranes, converting to glycerolipids, and separating by HPLC. The preferential incorporation of [^{32}Pi] into *scyllo*-PI compared to *myo*-PI in intracellular membranes as well as in plasma membranes was evident as early as 1.5 h and at all subsequent time points studied (Fig. 2A,B). In addition, whereas the rate of biosynthesis of *myo*-PI and *scyllo*-PI in the intracellular membranes continued to increase for 24 h (Fig. 2A), incorporation into both isomers had reached isotopic equilibrium in the plasma membranes in about 14 h (Fig. 2B).

These results indicate that in barley aleurone cells only 25% of the total [^{32}Pi]-labeled phospholipids is present in the plasma membrane. In addition, these data indicate that the times required to label the plasma membrane and intracellular membrane pools to isotopic equilibrium are different. The rapid rate of incorporation of [^{32}Pi] into *scyllo*-PI compared to *myo*-PI, in both plasma membranes and intracellular membranes, at all times points studied could reflect relative rates of turnover. A high turnover rate is characteristic of lipids that play a role in signal transduction, such as *myo*-PIP and *myo*-bisphorylated PI (1,2).

Biosyntheses of myo- *and* scyllo-*PI:* in vivo *studies*. The biosynthesis of *myo*-PI occurs *via* CDP-DG (Scheme 1). The reaction of CDP-DG with *myo*-inositol to yield *myo*-PI and cytidine monophosphate is catalyzed by CDP-DG:inositol 3-phosphatidyltransferase (EC 2.7.8.11), also called *myo*-PI synthase. This reaction is localized in the endoplasmic reticulum (16).

An enzyme that catalyzes the exchange of the head group, inositol, or *myo*-PI:*myo*-inositol phosphatidyltransferase (Scheme 1, Step **6**), has been observed in a number of cells including plant cells (16,17). The exchange enzyme is believed to be localized in the endoplasmic reticulum and the Golgi apparatus (16). Two forms of exchange activity, CMP-dependent and CMP-independent, have been characterized (17). It has been suggested that the CMP-dependent exchange activity may be due to the reversal of PI synthase activity (Step **3**) and incorporation of free inositol, whereas the CMP-independent exchange activity is due to the presence of a second enzyme (Step **6**). Recent cloning studies in mammalian cells indicated that a single polypeptide exhibits both the synthase and exchange activities (17), thereby providing evidence that, in mammalian cells, the CMP-dependent exchange activity is due to PI synthase catalyzing the reverse and forward reactions sequentially. The physiological significance of the exchange reaction is unknown. Analogous to the biosynthesis of *myo*-PI, *scyllo*-PI could be produced by the reaction of CDP-DG with *scyllo*-inositol (Step **4**). Alternatively, the head group of *myo*-PI, *myo*-inositol, could be exchanged with *scyllo*-inositol to form *scyllo*-PI (Step **5**).

Our [^{32}Pi] incorporation experiments indicate that preferential incorporation of ^{32}P into *scyllo*-PI compared to *myo*-PI occurred at all time points studied. Increased ^{32}P radioactivity in *scyllo*-PI could be due to the higher rate of biosynthesis of *scyllo*- PI compared to *myo*-PI, slower rate of subsequent metabolic degradation of *scyllo*-PI compared to *myo*-PI, or both. Although subsequent metabolism of *myo*-PI occurs rapidly, we currently have no information on subsequent metabolism of *scyllo*-PI. However, the increased rate of incorporation of [^{32}Pi] at all time points investigated strongly points to a higher rate of biosynthesis of *scyllo*-PI rather than the possibility that *scyllo*-PI was produced from *myo*-PI by the



Note: Asterisk (*) indicates presence of radiolabel.

SCHEME 1

exchange reaction (Step **5**). Evidence in favor of the latter possibility would have suggested a possible cellular role for the CMP-independent exchange enzyme for which there is currently no known biological role. A double-labeling experiment using [^{32}Pi] and *myo*-[^{14}C(U)]inositol was conducted to monitor the incorporation of both the phosphate and the head group inositol moieties. We chose to use *myo*-[^{14}C(U)]inositol rather than *myo*-[2-^{3}H]inositol for the double-labeling experiments to avoid the possibility of losing the ^{3}H at the C-2 position of *myo*-inositol during the isomerization of *myo*-inositol to *scyllo*-inositol, as this involves the epimerization of the C-2 carbon (10,18). Aleurone layers were incubated with [^{32}Pi] and *myo*-[^{14}C(U)]inositol for 24 h at 25°C, and the radiolabeled phospholipids were extracted and separated by HPTLC. The data in Table 1 indicate that, in contrast to the [^{32}Pi] studies, the amount of *myo*-[^{14}C(U)]inositol incorporated into *myo*-PI was much greater (eightfold) than that incorporated into *scyllo*-PI. (The region between *scyllo*-PI and *myo*-PI on the HPTLC plate contained very little radioactivity, about 60 dpm [^{14}C], which is the background value, thus indicating that the radioactivity in *scyllo*-PI is not due to tailing of *myo*-PI.) The low incorpora-

tion of ^{14}C from *myo*-[^{14}C(U)]inositol into *scyllo*-PI compared to *myo*-PI is probably due to the low rate of conversion of *myo*-inositol to *scyllo*-inositol (18).

Biosynthesis of myo- *and* scyllo-*PI:* in vitro *studies.* To investigate the presence of *scyllo*-PI synthase in aleurone cells, *in vitro* experiments were conducted with microsomal membrane vesicles. Previous research has shown that *myo*-PI synthase enzyme is located in the microsomal pellet, which contains membrane vesicles from endoplasmic reticula, Golgi membranes, and plasma membranes (15). In initial experiments, the presence of *myo*-PI synthase and the formation of *myo*-PI were monitored by using *myo*-[2-^3H(N)]inositol as the precursor and measuring the ^3H content in the organic layer following enzymatic reaction and phospholipid extraction. Unreacted *myo*-[2-^3H(N)]inositol partitions into the aqueous phase and the *myo*-[2-^3H(N)]inositol that is incorporated into phospholipids partitions into the organic phase; consequently, the content of radioactivity in the organic phase is indicative of the extent of conversion. The microsomal pellet isolated after centrifugation of the cellular suspension at 18,000 × *g* did not catalyze the production of *myo*-PI in the presence of detergent whereas the 50,000 × *g* pellet did, thus suggesting that the membrane vesicles containing *myo*-PI synthase were not pelleted at 18,000 × *g*. The 100,000 × *g* microsomal pellet did not affect increased biosynthesis of *myo*-PI compared to the 50,000 × *g* pellet, therefore the 50,000 × *g* pellet was used as the source of enzyme in subsequent experiments. To confirm the formation of *myo*-PI, comigration with standard phospholipids was used to characterize the structure of the labeled product. The ^3H-labeled products were spotted alongside [^{32}Pi]-labeled phospholipids (obtained from an *in vivo* experiment) on an HPTLC plate. The results (Fig. 3, left lane) indicate that the radiolabeled product had the same migratory properties as *myo*-PI thereby providing evidence that *myo*-PI was produced in the *in vitro* experiment *via* the PI-synthase pathway. The presence of radiolabeled product in the PIP region suggests that the microsomal pellet also contains PI kinase that converts PI to PIP.

To detect the presence of *scyllo*-PI synthase (CDP-DG:*scyllo*-inositol transferase) we conducted the experiment with *scyllo*-[2-^3H(N)]inositol. When the *scyllo*-[2-^3H(N)]inositol was checked for purity by paper chromatography, the radiolabeled precursor used contained both *myo*-[^3H]inositol and *scyllo*-[^3H]inositol in tritium ratio of 1:2, respectively). Radioactivity was detected in the organic layer when Brij 58 or Triton X-100 was included in the reaction medium, suggesting that enzymatic conversion of *scyllo*-inositol to phospholipids had occurred. To confirm the formation of *scyllo*-PI, comigration with standard phospholipids was used to obtain structural information of the radiolabeled product. The ^3H-labeled products were spotted alongside [^{32}Pi]-labeled phospholipids (obtained from an *in vivo* experiment) on an HPTLC plate. As illustrated in Figure 3, right lane, radioactivity was detected in regions corresponding to both *scyllo*-PI and *myo*-PI, thereby indicating the presence of *scyllo*-PI synthase in the microsomal pellet.

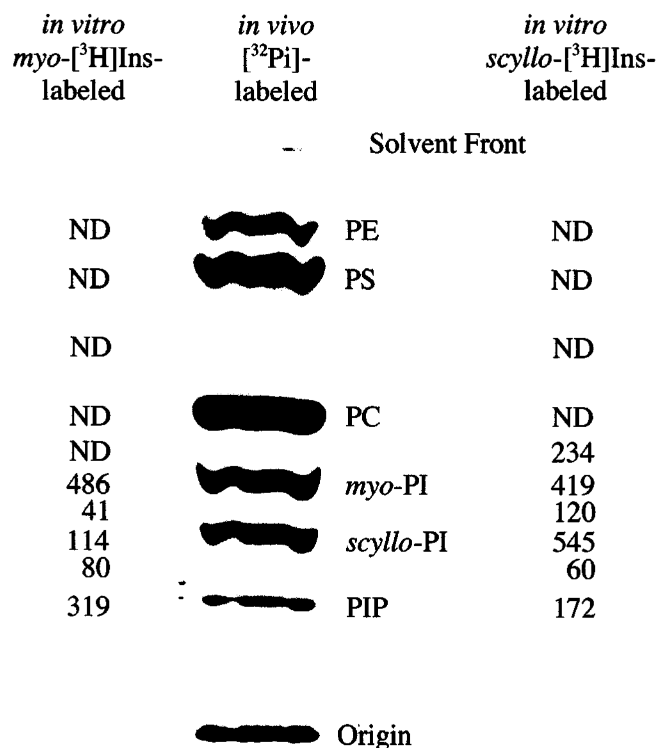

FIG. 3. Separation of *in vivo* [^{32}Pi]-labeled phospholipids (middle lane) alongside *in vitro myo*-[2-^3H(N)]inositol-labeled (left lane) and *scyllo*-[^3H(N)]inositol-labeled (right lane) phospholipids from PI-synthase assay. The *in vitro* assays were incubated with *myo*-[2-^3H(N)]inositol (200,000 cpm) or *scyllo*-[^3H(N)]inositol (400,000 cpm), and the labeled phospholipids were extracted. Aliquots of the [^{32}Pi]- and [^3H]-labeled phospholipids were mixed with carrier phospholipids and separated on a high-performance thin-layer chromatography plate. The *in vivo* [^{32}Pi]-labeled phospholipids (in the middle lane) were localized by autoradiography and silica gel (left and right lanes) corresponding to *myo*- and *scyllo*-PI, PC, and PIP; other regions of the plate were scraped and the [^3H] contents determined by liquid scintillation counting. The numbers in the left and right lanes indicate [^3H] values above background. ND, areas in which radioactivity above background (10–15 cpm) was not detected. These data are representative of two experiments. Abbreviations: PC, phosphatidylcholine; PE, phosphatidylethanolamine; PIP, phosphatidylinositol-monophosphate; PS, phosphtidylserine; Ins, inositol; for other abbreviations see Figures 1 and 2.

Effect of detergent on PI synthase activity. Investigations of membrane-bound enzymes are conducted in the presence of detergents to facilitate solubilization of either substrate or enzymes or both (19). Detergents can be divided into four categories on the basis of charge: cationic, anionic, nonionic, and zwitterionic. The best detergent and the optimal concentrations required for maximal enzymatic activities vary with enzyme and cell type. A number of different types of detergents were included in order to determine the best detergent for the reaction. Deoxycholate, an anionic detergent, cetylpyridinium bromide, a cationic detergent, cholamidopropyldimethylammonio-1-propanesulfonate, a zwitterionic detergent, and two nonionic detergents, Brij 58 and Triton X-100, were included in our experiments. The data (Fig. 4) indicate that, consistent

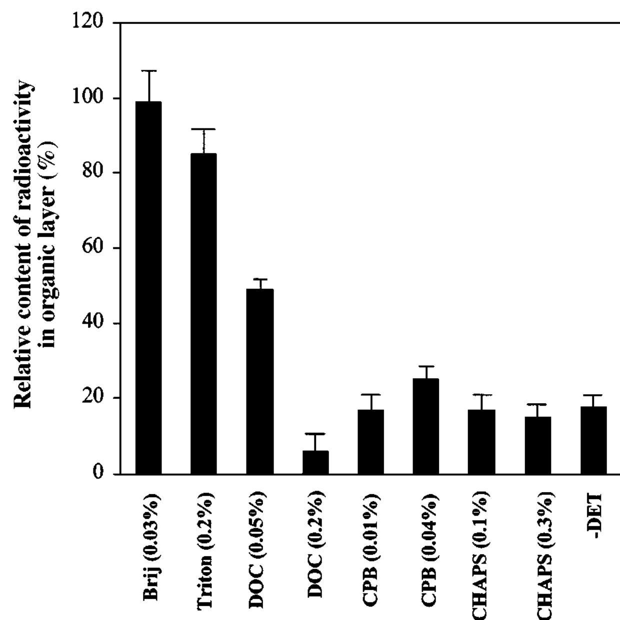

FIG. 4. Effect of various detergents on the biosynthesis of *myo*-PI. Barley seeds (350–400) were imbibed (60 h) and homogenized, and aliquots from the microsomal pellet were added to buffer containing *myo*-[2-^{3}H(N)]inositol (about 100,000 cpm) and various detergents, as indicated, to initiate the PI-synthase reaction. Reactions were terminated after 3 h by the addition of $CHCl_3/CH_3OH/H_2O$ (1:2:0.3, by vol), and the phospholipids were extracted, concentrated, and the content of radioactivity determined by liquid scintillation counting. All experiments was performed in duplicate; error bars represent the standard deviation. The amount of radioactivity at 100% corresponds to about 3,200 cpm. This graph is representative of three independent experiments. Abbreviations: DOC, deoxycholate; CPB, cetylpyridinium bromide; CHAPS, cholamidopropyldimethylammonio-1-propanesulfonate; –DET, no detergent. For other abbreviation see Figure 2.

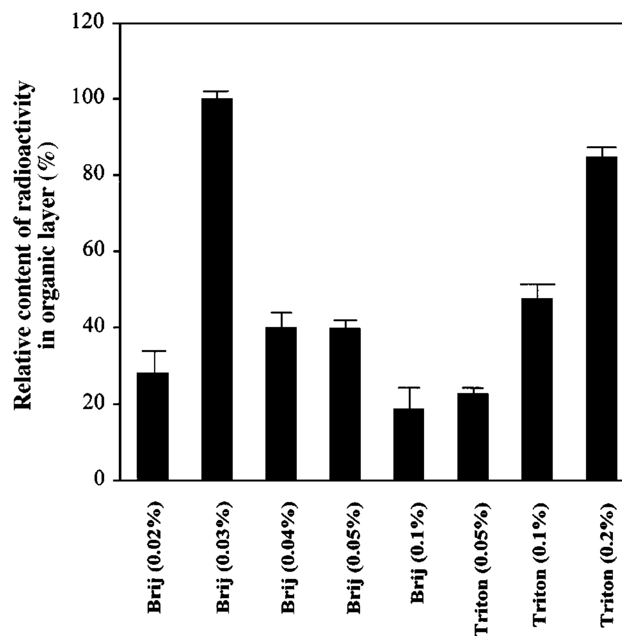

FIG. 5. Effect of Triton X-100 and Brij 58 on the biosynthesis of *myo*-PI. Barley seeds (350–400) were imbibed (60 h) and then homogenized, and aliquots from the microsomal pellet were added to buffer containing *myo*-[2-^{3}H(N)]inositol (about 100,000 cpm) and detergents, as indicated. Reactions were terminated after 3 h by the addition of $CHCl_3/CH_3OH/H_2O$ (1:2:0.3, by vol), and the phospholipids were extracted, concentrated, and the content of radioactivity in the organic phase determined by liquid scintillation counting. All experiments were performed in duplicate; error bars represent the standard deviation. The amount of radioactivity at 100% corresponds to about 4,200 cpm. This graph is representative of three independent experiments.

with previous experiments in soybeans and castor beans (20,21), Brij 58 and Triton X-100 gave the best yield of *myo*-PI. The biosynthesis of *myo*-PI in the presence of Brij 58 increased fivefold compared to the conversion in the absence of detergent. The inclusion of Triton X-100 in the reaction mixture stimulated biosynthesis fourfold compared to the absence of detergent. The inclusion of deoxycholate (0.05%) showed an increase in biosynthesis (2.5-fold) as compared to the absence of detergent, but was only about half as effective as Brij 58. Cetylpyridinium bromide and cholamidopropyldimethylammonio-1-propanesulfonate had no significant effect on the biosynthesis of *myo*-PI. The dependence of the formation of *myo*-PI and *scyllo*-PI on the concentration of Brij 58 and Triton X-100 was investigated. The formation of *myo*-PI in the presence of various concentrations of Brij 58 (0.02 to 0.1%) and Triton X-100 (0.05 to 0.2%) is illustrated in Figure 5. The optimal concentration of Brij 58 was clearly 0.03% while Triton X-100 proved to be 90% as effective at 0.2%. In contrast to *myo*-PI biosynthesis, the presence of Triton X-100 effected increased formation (150%) of *scyllo*-PI as compared to Brij 58. [The concentrations of Triton X-100 (0.2%, 3.3 mM) and Brij 58 (0.03%, 0.27 mM) in the assay were above the critical micelle concentration of both detergents: Triton X-100 (0.30 mM) and Brij 58 (0.19 mM)]. The differences in activity could be due to the unique response (or responses) of one (or two) enzyme(s) located on the same or different membranes.

In summary, *in vivo* and *in vitro* studies indicate that *scyllo*-PI is biosynthesized by CDP-DG:*scyllo*-inositol transferase. Like CDP-DG:*myo*-inositol transferase enzyme, CDP-DG:*scyllo*-inositol transferase activity is stimulated by the addition of the nonionic detergents Triton X-100 and Brij 58. This is the first report of CDP-DG:*scyllo*-inositol transferase activity in cells; however further work is required to demonstrate clearly that head group transfer activity is not involved.

Hormone-induced changes in phosphoinositides are often investigated by monitoring changes in the radioactive content of bulk, *in vivo*-labeled cellular phospholipids that are at isotopic equilibrium. The discovery of *scyllo*-PI and the difficulty in separating the many closely related *myo*- and *scyllo*-phosphoinositides and *myo*-inositol phosphates in plant cells complicate the analysis of phosphoinositides (10). In addition, spatially and metabolically distinct pools of phosphoinositide lipids are present in cells (1–3) and only phosphoinositides in plasma membranes are involved in the initial hormone-trig-

gered events. The hormone-sensitive pool in the plasma membrane is small and exhibits a high turnover rate compared to the hormone-insensitive pool, which includes the rest of the cellular phospholipids. This study shows that the hormone-sensitive plasma membrane pool in barley aleurone cells is less than 25% of the total cellular phospholipids, since all, or indeed most, of the phosphoinositides in the plasma membrane are not hormone sensitive, and 75% of the labeled phospholipids would not be expected to undergo any hormone-triggered change. Moreover, this investigation indicates that the incubation periods required for the plasma membrane and intracellular membranes to achieve isotopic equilibrium are different. Therefore, changes in plasma membrane phosphoinositides could be masked and/or lead to misleading conclusions when changes in ^{32}P content of total cellular phosphoinositides are monitored in signal transduction studies. Information on the subcellular localization of labeled phospholipids is essential for a more complete and accurate understanding of the role of phosphoinositides in signal transduction.

Department of Chemistry, Michigan Technological University, Houghton, Michigan 49931

ABSTRACT: Examination of organelle- and membrane-specific processes such as signal transduction necessitates the use of plasma membrane vesicles with cytoplasmic side-in orientation. We are interested in the structural identity and subcellular localization of *in vivo* [^{32}P]phosphoric acid ([^{32}Pi])-labeled phosphoinositides, including the recently discovered phosphatidyl-*scyllo*-inositol, for signal transduction studies. In the first part of this investigation, plasma membrane vesicles from barley aleurone cells were isolated employing the aqueous polymer (Dextran and polyethylene glycol) two-phase partition method. The membrane vesicles that partitioned into the upper and lower phases of the aqueous polymer two-phase system were characterized and the purity of the vesicles ascertained by assaying for two marker enzymes, K^+-stimulated, Mg^{2+}-dependent adenosine triphosphatase (EC 3.6.1.3, ATPase), localized in the plasma membranes, and cytochrome c oxidase, localized in the mitochondria. Inhibitors for ATPases such as azide, molybdate, and vanadate were used to distinguish between plasma membrane-associated and intracellular membrane-associated ATPases. These inhibitor studies suggest that the plasma membrane preparation contained about 7% of intracellular membrane vesicles and the intracellular membrane fraction contained about 6% of plasma membrane vesicles. Orientation of the plasma membrane vesicles was ascertained by measuring the latent ATPase activity. These latency studies suggest that about 95% of the plasma membrane vesicles were of cytoplasmic side-in orientation. In the second part of this investigation, intracellular distribution and *in vivo* [^{32}Pi] labeling of phosphoinositides in the plasma membranes and intracellular membranes were investigated. Preferential accumulation of [^{32}Pi]-labeled phosphatidyl-*myo*-inositol monophosphate (*myo*-PIP) and phosphatidyl-*myo*-inositol bisphosphate (*myo*-PIP_2) was observed in the plasma membrane. However, *scyllo*-phosphatidylinositol (*scyllo*-PI) was detected in both the plasma membrane and the intracellular membranes. The cellular concentration of *myo*-phosphoinositides was determined, and, after 24 h of labeling with [^{32}Pi], the ratio of radiolabel in *myo*-PI, PIP, and PIP_2 paralleled the relative concentrations in aleurone cells.

Paper no. L7941 in *Lipids 34*, 75–82 (1999).

Biochemical processes in living cells are compartmentalized. A number of fundamental processes such as signal perception, message transduction, ion uptake, and cell wall biosynthesis are localized in the plasma membrane. Plasma membrane vesicles of right-side-out orientation are essential for investigation of plasma membrane-specific processes such as signal transduction and ion transport. Many features of barley aleurone tissue make it particularly attractive for the study of plant hormone action, hence, gibberellin- and abscissic acid-regulated cellular events have been extensively studied in this model system (1,2). However, our understanding of the molecular mechanism of hormone perception, signal transduction, and biochemical regulation remains incomplete. In recent reports from this laboratory, we described our efforts to characterize phosphoinositides in the aleurone tissue of barley seeds (3,4, and references therein). We are interested in the structural identity of *in vivo*-labeled phosphoinositides including the subcellular localization of the recently discovered phosphatidyl-*scyllo*-inositol (3,4). To this end, our first step was to investigate the fractionation of membrane vesicles from barley aleurone cells.

Fractionation of intracellular organelles from aleurone tissue has presented problems. Previous attempts to isolate intracellular organelles, such as phytin bodies and endoplasmic reticulum, from aleurone tissue of wheat (5,6) and barley (7) indicated that the commonly used density centrifugation and differential centrifugation methods could not be easily applied to aleurone cells because of the tendency of intracellular organelles in aleurone cells to swell and aggregate. Aqueous polymer two-phase partitioning method has been successfully used to isolate plasma membrane vesicles from a number of plant tissues (8) including aleurone cells from wild oats (9). A solution containing Dextran, polyethylene glycol, water, and salts separates into two phases, each with unique ionic and hydrophobic properties, and these properties are dependent on salt composition, pH, and temperature (10–12). Plasma membrane and intracellular membrane vesicles fractionate by differential partitioning between the two phases based on their hydrophobicity and other surface properties

(10,11). In this paper, we will present results on the isolation, characterization, and assessment of purity of plasma membrane vesicles from barley aleurone cells using the aqueous polymer two-phase method (10,13). In addition, information regarding the orientation of the plasma membrane vesicles isolated by the aqueous polymer two-phase method will be presented. Then, characterization of *in vivo*-labeled phosphoinositides and the intracellular distribution of *scyllo*-phosphatidylinositol (*scyllo*-PI) will be discussed.

EXPERIMENTAL PROCEDURES

Plant material. Barley seeds (*Hordeum vulgare* L. cv. Himalaya, 1991 harvest) were purchased from Seed Technology, Department of Agronomy and Soil, University of Washington, Pullman, Washington. Fresh spinach leaves for preliminary studies on fractionation were purchased from a local grocery.

Preparation of microsomal fraction from aleurone layers for aqueous polymer two-phase partitioning (10). Plant material was maintained at 4°C throughout the experiment. Barley aleurone layers were isolated from barley half-seeds as described previously (3,4,14). Layers were homogenized in a cold mortar and pestle with 25 mL of homogenization buffer containing sucrose (0.5 M), Hepes-KOH (50 mM, pH 7.5), ascorbic acid (5 mM), dithiothreitol (1 mM), and polyvinylpyrrolidone (0.6%, wt/vol). The homogenate was filtered through cheesecloth and centrifuged at 10,000 × *g* for 10 min. The supernatant was centrifuged at 50,000 × *g* for 30 min to obtain the microsomal pellet.

Separation of intracellular membranes from plasma membranes by aqueous polymer two-phase partitioning. As suggested by Larsson *et al*. (10), preliminary experiments were conducted with spinach leaves, as partitioning of intracellular membranes, which include chloroplast membranes, can be ascertained visually. Successful separation was easily indicated by a green lower phase and a pale white upper phase. The following concentrations of both polymers, Dextran T500 and polyethylene glycol 3350, were tried: 5.8, 6.0, 6.2, 6.4, and 6.5% (wt/vol). In agreement with previous results, aqueous polymer solution containing 6.2% of both polymers gave the best separation. However, in our experience, the concentration of polymers necessary for partitioning into two phases and for providing the best separation varied with the manufacturer and batch.

The microsomal pellet from aleurone layers was suspended in buffer containing sucrose (0.33 M), KCl (3 mM), and potassium phosphate (5 mM, pH 7.8) to a total volume of 1.667 mL. Suspended membrane vesicles (1.5 g) were added to a test tube containing 4.5 g of aqueous polymer two-phase mixture containing the following: Dextran T500 (11.16 g of 20% w/w solution), polyethylene glycol 3350 (5.58 g of 40% w/w solution), sucrose (3.05 g), potassium phosphate buffer (0.675 mL of 0.2 M, pH 7.8 solution), KCl (0.041 mL of 2 M solution), and sufficient water to a final weight of 27.00 g. This aqueous polymer mixture was prepared the night before to allow adequate time for phase separation. The final concentration of polymer after the addition of membrane suspension was 6.2%. Final concentrations of the other reagents in the mixture were sucrose (0.33 mM), KCl (3 mM), and potassium phosphate (5 mM, pH 7.8). The test tube was inverted 20 to 30 times to ensure thorough mixing. Separation of the phases was facilitated by centrifugation at 1,100 × *g* for 5–10 min. The upper and lower phases were removed and washed, two times each, with equal volumes of fresh lower- and upper-phase solutions from the bulk solution B that was prepared as follows: Bulk phase solution B containing Dextran T500 (93.00 g of 20% w/w solution), polyethylene glycol 3350 (46.5 g of 40% w/w solution), sucrose (33.89 g), potassium phosphate buffer solution (7.50 mL of 0.2 M solution, pH 7.8), KCl (0.45 mL of 2 M solution), and sufficient water to a final weight of 300 g was prepared the night before, and the two phases were used for washing phase-partitioned membranes. The washed solutions were diluted with Tris-Mes buffer (300 mM, pH 6.5); the upper, plasma membrane-containing fraction was diluted twofold and the lower, intracellular membrane-containing fraction was diluted 10-fold, and the membrane pellets were obtained by centrifugation at 50,000 × *g* for 1 h. Protein was assayed by the BioRad protein assay (15) using bovine serum albumin as the standard.

Adenosine triphosphatase (ATPase) assay. ATPase activity was determined by monitoring the inorganic phosphate released during the reaction, which was assayed by a colorimetric method (16–18). The reaction mixture contained $MgSO_4$ (5 mM), KCl (50 mM), sucrose (125 mM), ATP (5 mM), Tris-Mes buffer (30 mM, pH 6.5 unless indicated otherwise), Triton X-100 (0.05% wt/vol), protein (10–50 µg), and activators or inhibitors as indicated, in a total volume of 500 µL. The reaction was initiated by the addition of ATP. The reaction mixture was incubated at 37°C for 20 min and the reaction stopped with the addition of 1.0 mL of a solution containing H_2SO_4 (0.5 M), sodium dodecylsulfate (5% wt/vol), and ammonium molybdate, $(NH_4)Mo_7O_{24}\cdot H_2O$ (0.5% wt/vol). Total inorganic phosphate released from ATP hydrolysis was determined spectrophotometrically by the addition of ascorbic acid (50 µL of 10% wt/vol). The reaction was allowed to proceed for 20 min and absorbance measured at 820 nm. Enzyme assays were performed in duplicate and mean values ± standard error of the mean are given. Specific activity of ATPase is µmol of total inorganic phosphate released/mg protein/min. A solution of sodium vanadate was prepared by the method of Gallagher and Leonard (19).

Cytochrome c oxidase assay. Cytochrome c oxidase activity was determined, at room temperature, by measuring the oxidation of reduced cytochrome c (17,20–22). The reduced form of cytochrome c shows characteristic absorption at 550 nm. Prior to the assay, cytochrome c from horse heart was reduced using sodium dithionite, $Na_2S_2O_4$. Excess dithionite was removed by air oxidation to SO_2. This oxidation can be achieved by passing air through the solution for a few minutes (17). Removal of excess reducing agent is necessary to prevent the reduction of oxidized product formed during enzymatic reaction.

The reaction mixture contained phosphate buffer (2.7 mL, 50 mM, pH 7.5), digitonin [100 μL, 0.3% (wt/vol)], membrane suspension (100 μL, 10–50 μg protein), and reduced cytochrome c from horse heart (100 μL, 0.45 mM in phosphate buffer). All reagents were added to a sample cuvette, and the reaction was initiated by the addition of reduced cytochrome c. Decrease in absorbance of the reaction mixture at 550 nm was monitored over time. Change in absorbance per minute was obtained from the initial slope of the curve using a millimolar extinction coefficient of 29.5 at 550 nm. Enzyme assays were performed in duplicate, and mean values ± standard error of the mean are given. Specific activity of cytochrome c oxidase is μmol of product produced/min/mg protein.

Labeling with radioactive precursors. Aleurone layers were isolated from barley seeds as previously described (3,4). Aleurone layers were incubated at 25°C in a solution (1 mL/10 layers) containing succinate buffer (20 mM, pH 5), $CaCl_2$ (20 mM), chloramphenicol (30 μM), and ^{32}P-labeled phosphoric acid ([^{32}Pi]) {the [^{32}Pi] in 0.02 M HCl (Dupont/NEN, Boston, MA) was neutralized just before use with 0.02 M NaOH} (3,4). After 24 h, the layers were freed of excess isotope by washing three times with media without isotope, and the plasma membrane and intracellular membranes were separated as described above.

Extraction and separation of phospholipids. Phospholipids were extracted from aleurone layers or from membrane pellets by a modified acidic Bligh-Dyer method (3,4). The washed aleurone layers were homogenized in a mortar and pestle with a small amount of sand and water (1 mL), and the slurry was transferred to a test tube. With membrane pellets, water (1 mL) was added and mixed well with a vortex mixer. To the suspension was added 3 mL of CH_3OH, 2.5 mL of $CHCl_3/CH_3OH$ (2:1 vol/vol), 0.75 mL of 2.4 N HCl, and 2.1 mL of $CHCl_3$. The solution was vortex-mixed and centrifuged, and the lower organic phase was removed. The aqueous phase was reextracted with 1.7 mL of $CHCl_3$. The combined organic extract was washed twice with 0.75 mL of 2.4 M HCl and 3.0 mL of CH_3OH/H_2O (1:1 vol/vol). Unlabeled phospholipids (0.075 mg) from soybean were added to the organic extract, converted to glycerophospholipids by deacylation using methylamine, and the products separated by high-voltage paper electrophoresis (HVE) (3,4).

Concentration of phosphoinositides in barley aleurone layers. The concentration of phosphoinositides was calculated by determining the phosphate content. Phosphoinositides from 225 aleurone layers were extracted, deacylated and the glycerophosphoinositides separated by high-voltage paper electrophoresis (HVE). The regions corresponding to *myo*-glycerophosphoinositol (GPI), -glycerophosphoinositolmonophospate (GPIP), and -glycerophosphoinositolbisphosphate ($GPIP_2$) were extracted from the paper with 1 mL of water, 5 times. The resulting solution was concentrated and the phosphate content determined according to Ames (16). The background phosphate content of an equivalent sheet of paper was determined at the same time (15 nmol) and subtracted from the phosphate content. The phosphate content in *myo*-phosphatidylinositol (PI), -phosphatidylinositolmonophosphate (PIP), and -phosphatidylinositolbisphosphate (PIP_2) was 330, 66, and 12.2 nmol per 200 layers, respectively. By assuming that there are 110,000 cells per aleurone layer and that the volume of each cell is 33 μL (23) the concentrations of *myo*-PI, -PIP, and -PIP_2 were found to be 0.8 ± 0.1, 0.08 ± 0.03, and 0.01 ± 0.005 mM, respectively.

RESULTS AND DISCUSSION

Fractionation of aleurone vesicles by aqueous polymer two-phase method: Assay of marker enzymes. Barley aleurone layers were homogenized and the microsomal pellet was separated by the aqueous polymer two-phase partition method of Larsson *et al.* (10). The membrane pellet from the lower phase contained approximately 80% of the recovered protein, and the pellet from the upper phase contained approximately 20%. About 70% of the protein in the microsomal pellet was recovered in the two phases. The protein recovery increased to 75% when the phases were centrifuged at 100,000 × *g*. We did not observe significant loss of membrane vesicles in the 10,000 × *g* pellet with barley aleurone cells, as was observed with wheat aleurone cells (9).

To ascertain the subcellular origin of the membrane vesicles that partition into the two phases, two marker enzymes, ATPase and cytochrome c oxidase, were assayed. We chose to assay ATPase activity because, in addition to providing information on the subcellular origin, the dependence of ATPase activity on factors such as detergent (24) and freeze/thaw treatment (25,26) provides information on the orientation (sidedness) of plasma membrane vesicles. ATPase activity is found in multiple locations in plant cells, such as mitochondria, plasma membrane, plastids, tonoplast, Golgi apparatus and endoplasmic reticulum. However, ATPase from different locations can be distinguished by differences in pH optima; susceptibility to inhibition by azide, molybdate and vanadate; and activation by K^+ ions (19). A marker widely used for plasma membrane is the K^+-stimulated, vanadate-inhibited, ATPase with optimal pH of 6.5 (10,11,19). ATPase activity of detergent-permeabilized membrane vesicles from the upper and lower phase was measured at pH 6.5, the optimal pH for plasma membrane-associated ATPase (11,17). ATPase activity in the upper phase was relatively insensitive to azide (1 mM), a mitochondrial ATPase inhibitor, and ammonium molybdate (0.1 mM), an acid phosphatase inhibitor (7% inhibition), whereas the addition of vanadate (0.1 mM), a plasma membrane ATPase inhibitor, either alone or in the presence of azide and molybdate, inhibited ATPase activity by 83 ± 1%, clearly indicating the sensitivity of ATPase in the upper phase to vanadate (Table 1). In contrast, ATPase in the lower phase was markedly sensitive to azide and molybdate (88% inhibition) and insensitive to vanadate (6% inhibition), as reported by Gallagher and Leonard (19) and confirmed by subsequent investigators (10,18,28).

Although vanadate is not a specific inhibitor of plasma

TABLE 1
Distribution of Marker Enzymes Before and After Aqueous Polymer Two-Phase Partitioning

Marker enzyme	Microsomal pellet Specific activity (μmol/mg protein/min)/(% control)	Upper phase Specific activity (μmol/mg protein/min)/(% control)	Lower phase Specific activity (μmol/mg protein/min)/(% control)
ATPase			
Control[a]	1.00 ± 0.03 (100)	0.55 ± 0.022 (100)	0.81 ± 0.03 (100)
Control + azide[b] + molybdate[c]	0.52 ± 0.02 (52)	0.51 ± 0.024 (93)	0.10 ± 0.02 (12)
Control + azide[b] + molybdate[c] + vanadate[d]	0.34 ± 0.04 (34)	0.10 ± 0.04 (18)	0.09 ± 0.04 (11)
Control + vanadate[d]	—	0.09 ± 0.04 (16)	0.76 ± 0.03 (94)
Cytochrome c oxidase	0.21 ± 0.013	0.080 ± 0.007	0.48 ± 0.024

[a]ATPase assay mixture contained $MgSO_4$ (5 mM), KCl (50 mM), sucrose (125 mM), ATP (5 mM), Tris-Mes buffer (30 mM, pH 6.5), Triton X-100 (0.05% wt/vol), protein (10–50 μg), and activators or inhibitors as indicated.
[b]Sodium azide (1 mM).
[c]Ammonium molybdate (0.1 mM).
[d]Sodium orthovanadate (0.1 mM). Abbreviation: ATPase, adenosine triphosphatase.

membrane ATPase and, at concentrations above 500 μM, does inhibit mitochondrial ATPase, previous investigations (19) showed that vanadate inhibits plasma membrane ATPases at concentrations (100 μM) which do not have a significant effect on mitochondrial ATPases. Our observations of ATPase inhibition at low vanadate concentrations (100 μM) were consistent with previous reports and suggest that the upper-phase fraction consists predominantly of plasma membrane vesicles.

The activity of a second marker enzyme, cytochrome c oxidase, located in the mitochondria, was determined. Specific activity in the lower-phase membrane fraction was six times that in the upper-phase membrane fraction, indicating that the lower phase was enriched in mitochondrial vesicles (Table 1). The specific activity of cytochrome c oxidase was similar to the value observed in wild oats (9).

ATPase activity in plasma membrane vesicles (upper phase fractions) is stimulated by K^+ ions, and the K^+-stimulated component is sensitive to vanadate inhibition (19). In the assay mixture described in the Experimental Procedures section detergent-permeabilized vesicles were assayed for vanadate-sensitive ATPase activity in the presence and absence of KCl. The addition of 50 mM KCl stimulated ATPase specific activity threefold, from 0.17 ± 0.01 to 0.49 ± 0.006 μmol (mg protein)$^{-1}$ min^{-1}. The addition of vanadate in the presence of KCl suppressed ATPase activity to 0.10 ± 0.005 μmol (mg protein)$^{-1}$ min^{-1}, whereas the addition of vanadate in the absence of KCl had no effect; the specific activity was 0.18 ± 0.007 μmol (mg protein)$^{-1}$ min^{-1}. The data illustrate that the inhibitory action of vanadate occurs only in the presence of K^+ ions and suggest that vanadate inhibits the K^+-stimulated component of plasma membrane ATPase, thus providing further proof that ATPase activity in the upper phase is due to the K^+-stimulated, vanadate-sensitive ATPase of the plasma membrane.

The pH dependence of ATPase activity in the vesicles in the upper phase was investigated. ATP-hydrolyzing activity at pH 6.5, the optimal pH of plant plasma membrane-associated H^+-pump, was 10 times the activity at pH 8.0, the optimal pH of mitochondrial and tonoplast ATPase (Table 2) (19). In fact, very little ATPase activity was observed at pH 8.0.

Taken together, the data (Table 3) demonstrate that the plasma membrane marker, the vanadate-sensitive component of ATPase, is enriched ninefold in the upper phase compared

TABLE 2
Effect of pH on ATPase Activity in the Upper-Phase Fraction

Treatment	Specific activity at pH 6.5 (μmol/mg protein/min)	Specific activity at pH 8.0 (μmol/mg protein/min)
Control[a]	0.55 ± 0.04	0.015 ± 0.01
Control + azide[b] + molybdate[c]	0.49 ± 0.03	0.02 ± 0.01
Control + azide[b] + molybdate[c] + vanadate[d]	0.14 ± 0.04	0.03 ± 0.01

[a]ATPase assay mixture contained $MgSO_4$ (5 mM), KCl (50 mM), sucrose (125 mM), ATP (5 mM), Tris-Mes buffer (30 mM, pH 6.5 or 8.0), Triton X-100 (0.05% wt/vol), protein (10–50 μg), and inhibitors as indicated.
[b]Sodium azide (1 mM).
[c]Ammonium molybdate (0.1 mM).
[d]Sodium orthovanadate (0.1 mM). See Table 1 for abbreviation.

TABLE 3
Relative Enrichment or Depletion of Enzymes in the Two Phases

Enzyme	Specific activity of enzyme (μmol/mg protein/min)		
	Microsomal fraction[a]	Upper phase	Lower phase
K^+,Mg^{2+}-ATPase, Vanadate-sensitive[b]	0.66	0.45	0.05
K^+,Mg^{2+}-ATPase, Azide and molybdate sensitive[c]	0.48	0.04	0.71

to the lower phase. In contrast, the intracellular markers, the azide- and molybdate-sensitive components of ATPase, are depleted 18-fold. The assay of cytochrome c oxidase, a mitochondrial marker, provided additional confirmation that mitochondrial membrane was enriched in the lower phase and intracellular membranes were depleted in the upper phase. The low inhibition of upper-phase membrane vesicles by azide and molybdate (7%, Table 1) and of lower-phase membrane vesicles by vanadate (6%, Table 1) suggests that the plasma membrane fraction contains about 7% contamination from intracellular membranes and that the intracellular membrane fraction contains about 6% contamination from the plasma membrane.

Orientation of plasma membrane vesicles. When membrane vesicles are formed during tissue homogenization, two orientations are possible; cytoplasmic side in, or right-side out, and cytoplasmic side out, or inside out. ATPase activity in cytoplasmic side-in vesicles is latent, as the active site and ATP-binding domain of ATPase in the plasma membrane are located on the inner, cytoplasmic side of the plasma membrane and therefore inaccessible to ATP (27). Latent ATPase activity can be unmasked in the presence of detergents, which render membranes more permeable to ATP. Thus, latent ATPase activity is an indication of the percentage of cytoplasmic side-in vesicles in plasma membrane preparations. An estimate of the latent ATPase activity can be determined by (i) increase in ATPase activity in the presence of a detergent that increases the permeability of membranes to ATP (18,24,25) and (ii) increase in ATPase activity when membrane vesicles are subjected to freeze/thaw treatment, whereupon cytoplasmic side-in membrane vesicles burst and reform (26,28). During revesiculation, the potential exists for the formation of a higher proportion of vesicles of cytoplasmic side-out orientation.

To unmask the latent ATPase sites two nonionic detergents were employed: Triton X-100 was selected because it is widely used in such studies and therefore allows for comparison, and Brij 58 [$C_{16}H_{33}(OCH_2CH_2)_{20}OH$] was chosen because it is able to permeabilize plasma membranes at low concentrations with minimal activating or inhibitory effects (24). The effect of varying concentrations of Triton X-100 and Brij 58 on ATPase activity at pH 6.5 was investigated (Fig. 1). ATPase activity was maximal when the concentration of Brij 58 was 0.005% (wt/vol), and further increases in the concentration of Brij 58 were inhibitory. When Triton X-100 was employed, 10 times as much detergent [0.05% (wt/vol)] was required to produce the same ATPase activity. However, the maximal ATPase activity observed in the presence of Triton X-100 (10 times that observed without detergent) was 150% that in the presence of Brij 58. Both Brij 58 and Triton X-100 were inhibitory at high concentrations. These data illustrate that a major portion of ATPase activity at pH 6.5 is latent in plasma membrane vesicles, suggesting a high proportion of cytoplasmic side-in vesicles. Brij 58 showed latency of about 84% [ratio of latent activity, (i.e., difference in activity measured ± detergent) to total activity, (i.e., activity measured with detergent)], whereas, with Triton X-100, a latency of 90% was observed.

Latent ATPase activity is dependent on the nature and concentration of the detergent. Use of detergents to determine ATPase latency is complicated by the fact that detergents, in addition to permeabilizing membrane vesicles, may have stimulatory or inhibitory effects (24–26) due to incorporation of detergents into the lipid bilayer of vesicles and consequent conformational changes in the ATPase molecule. The differ-

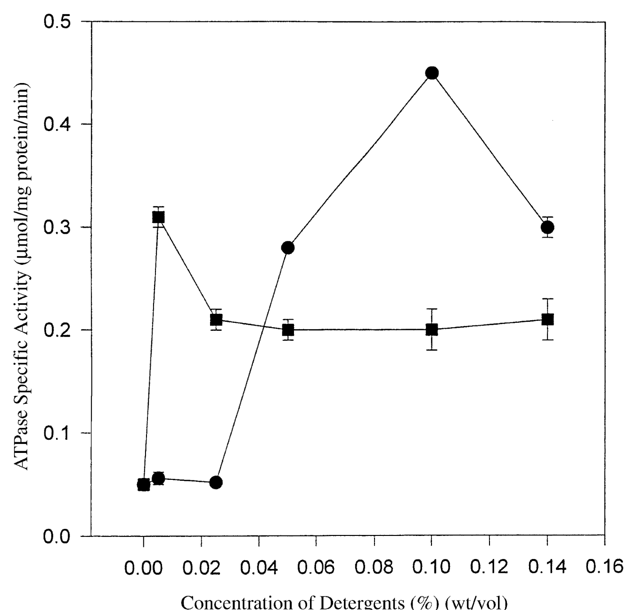

FIG. 1. Effect of varying concentrations of two nonionic detergents, Triton X-100 (●) and Brij 58 (■), on adenosine triphosphatase (ATPase) activity (pH 6.5) associated with the upper phase of the aqueous polymer two-phase partitioning method. All experiments were performed in duplicate. Error bars represent standard deviation about the mean. This graph is representative of three separate experiments.

ence in the maximal ATPase activity produced could be due to inhibition of ATPase at optimal concentration of Brij-58 or to activation of plasma membrane ATPase by Triton X-100. In contrast to our observations, others observed that Brij 58-permeabilized membranes exhibited higher ATPase activity than Triton X-100 and that Triton X-100 was inhibitory at higher concentrations (24,28).

The orientation of the isolated plasma membrane vesicles was investigated by freeze/thaw treatment. The vesicles were frozen in liquid nitrogen (for 2 min) and then thawed (in water at 25°C) to induce vesicle breakage and reformation, possibly with the opposite orientation. The freeze/thaw cycle was carried out four times, and ATPase activity assayed in the presence and absence of detergents (Table 4). ATPase activity increased dramatically (10-fold) after the freeze/thaw cycle. Interestingly, ATPase activity after freeze/thaw treatment was similar to that observed in the presence of Triton X-100. When Triton X-100 was added to vesicles that had been subjected to freeze/thaw treatment, a further increase (twofold) in ATPase activity was observed.

That freeze/thaw treatment significantly increased ATPase activity suggests that, when vesicles reform after cleavage during freezing, a higher proportion of inside-out vesicles are formed. A 10-fold increase after four freeze/thaw cycles is significantly greater than the fourfold increase reported previously (25). Further doubling of ATPase activity upon addition of Triton X-100 to plasma membrane vesicles that have been subjected to freeze/thaw treatment suggests that 50% of the reformed vesicles are cytoplasmic side in, and therefore sidedness during revesiculation of barley aleurone cells is a random event. The freeze/thaw data suggest that approximately 95% of ATPase activity is latent, and therefore 95% of the vesicles are cytoplasmic side in. This observation also suggests that Triton X-100 did not unmask all the latent ATPase activity. An alternative explanation could be that freeze/thaw treatment disturbs the integrity of the membranes, and the additional increase upon addition of Triton X-100 is due to activation of the enzyme and is not related to unmasking of latent activity.

Previous investigations have shown that upon homogenization, vesiculation with cytoplasmic side-in orientation is strongly favored (24,25,29). This preference could be due to (i) higher negative charge density of the outer surface compared to the inner surface, affecting membrane curvature, and (ii) the remaining inner cytoskeleton attached to the plasma membrane, affecting curvature (25). Since cytoplasmic side-in and cytoplasmic side-out vesicles can be expected to have different surface properties, the aqueous polymer two-phase partitioning method, in which separation is based on surface properties, can discriminate between these orientations. Indeed, plasma membrane vesicles isolated by the aqueous polymer two-phase partition method yield predominantly cytoplasmic side-in vesicles (25,26,30), and our investigations with barley aleurone cells are consistent with these observations.

In summary, we have demonstrated that the aqueous polymer two-phase partitioning method separates plasma membrane vesicles in barley aleurone cells from intracellular membrane vesicles. The assaying of K^+-stimulated, Mg^{2+}-dependent ATPase with activators and inhibitors and cytochrome c oxidase as marker enzymes suggests that the plasma membrane vesicles isolated by this method are over 90% pure and predominantly (95%) cytoplasmic side in.

Identification of phospholipids in the plasma membrane and intracellular membranes. To identify the phospholipids that are labeled in the plasma membrane and intracellular membranes pools, aleurone cells were incubated in [^{32}Pi] for 24 h, and the *in vivo*-labeled phospholipids were extracted from whole cells, plasma membranes, and intracellular membranes. Radioactivity in the lipid extract from intracellular membranes was three times that in plasma membranes. The phospholipids were converted to glycerophospholipids and separated by HVE. Comparison of the autoradiograms (Fig. 2) indicates that there are significant differences. In whole-cell extract, the ratio of radioactivity in *myo*-PI:-PIP:-PIP_2 (Bands 3, 5, and 7) after incubating the aleurone cells for 24 h was 100:11:3 (10,928:1236:340 cpm). In plasma membranes, the ratio of radioactivity in *myo*-GPI:-GPIP:-$GPIP_2$ was 100:30:15 (1000:295:153 cpm). The lack of radioactivity in the regions corresponding to *myo*-GPIP (Band 5) and *myo*-$GPIP_2$ (Band 7) in intracellular membranes is clearly evident and suggests the undetectably low concentration or lack of *myo*-PIP and *myo*-PIP_2 in intracellular membranes. The pres-

TABLE 4
Effect of Freeze/Thaw Treatment on ATPase Activity in the Upper Phase

Treatment	Specific activity (µmol/mg protein/min) (% of control)
Control[a] (without freeze/thaw) – Triton X-100	0.05 ± 0.002 (100)
Control subjected to freeze/thaw treatment[b] – Triton X-100[c]	0.5 ± 0.03 (1000)
Control + Triton X-100[c]	0.560 ± 0.03 (1120)
Control subjected to freeze/thaw treatment[b] + Triton X-100[c]	1.11 ± 0.013 (2220)

[a]ATPase assay mixture contained $MgSO_4$ (5 mM), KCl (50 mM), sucrose (125 mM), ATP (5 mM), Tris-Mes buffer (30 mM, pH 6.5), protein (10–50 g) and Triton X-100 as indicated.
[b]The vesicles in the upper phase were subjected to freeze/thaw cycle (four times) as described in Experimental Procedures section (26).
[c]Concentration of Triton X-100 was 0.10% (wt/vol). See Table 1 for abbreviation.

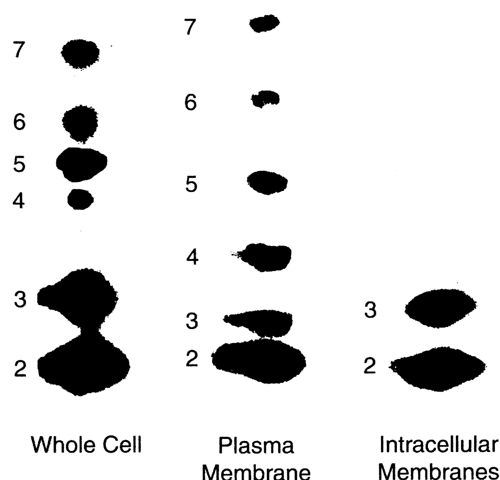

FIG. 2. Separation of anionic [^{32}P]phosphoric acid ([^{32}Pi])-labeled phospholipids from whole cells, plasma membranes and intracellular membranes. Aleurone layers from barley seeds of 1991 harvest were radiolabeled with [^{32}P]phosphoric acid (50 μCi/10 layers) for 24 h at 25°C. Total cellular phospholipid was extracted from 10 aleurone layers. Plasma membrane and intracellular membrane fractions were isolated from 40 aleurone layers using the aqueous polymer two-phase partitioning method, and phospholipids were extracted from the separated membranes. Phospholipids were deacylated, separated by high-voltage paper electrophoresis, and the radioactive compounds were detected by autoradiography. Data are representative of five independent experiments. Compounds 2, 3, 5, and 7 were identified as *scyllo*-glycerophosphoinositol (GPI), *myo*-GPI, *myo*-glycerophosphoinositolmonophosphate, and *myo*-glycerophosphoinositolbisphosphate. Compounds 4 and 6 are unidentified. See Narasimhan *et al.* (3) and references therein for more details.

ence of *scyllo*-PI (Band 2) in both intracellular and plasma membranes is also clear. In addition, radioactivity in *scyllo*-PI is greater than in *myo*-PI in whole-cell extract (2:1), plasma membrane (4:1), and intracellular membranes (2:1). The data suggest that preferential labeling of *scyllo*-PI, *myo*-PIP, and *myo*-PIP_2 occurs in the plasma membranes compared to intracellular membranes. The relative accumulation of labeled *myo*-PIP and *myo*-PIP_2 is consistent with that observed in other studies. Rincón and Boss (30) found that 90% of the labeled *myo*-PIP and *myo*-PIP_2 in prelabeled carrot cells was located in the plasma membranes and 10% in intracellular membranes. Sandelius and Sommarin (31,32) assayed *myo*-PI-kinase and *myo*-PIP-kinase in wheat seedlings and concluded that both of these enzymes are localized predominantly in the plasma membranes. The data presented above indicate that *myo*-PIP and -PIP_2 in plasma membranes incorporate more [^{32}Pi] than intracellular membranes. This could be due either to enhanced activity of PI-kinase and PIP-kinase in plasma membrane compared to intracellular membranes or to greater translocation of *myo*-PIP and *myo*-PIP_2 and *scyllo*-PI to plasma membrane.

Information on the chemical quantities of phosphoinositides in plant cells by direct determination of phosphoinositides is, to our knowledge, unavailable (33). Molar ratios of phosphoinositides is estimated from radiolabeling studies on the assumption that the relative ratio of radioactivity reflects chemical quantities after isotopic equilibrium has been reached. To obtain information on the molar amounts, we extracted phosphoinositides from barley aleurone layers, deacylated them to glycerophosphoinositols, separated by HVE, and determined the phosphorus content. After accounting for the differences in the number of phosphate groups (one, two, and three in *myo*-PI, *myo*-PIP and *myo*-PIP_2, respectively) the concentrations of *myo*-PI, -PIP, and PIP_2 were found to be 0.8 ± 0.1, 0.08 ± 0.03, and 0.01 ± 0.005 mM, respectively. The molar ratio of *myo*-PI:-PIP:-PIP_2 is therefore 100:10:1.25. Comparison of the ratios of chemical amount and [^{32}Pi]-labeling suggests that the ratio of radioactivity in phosphoinositides after 24 h of labeling is similar to chemical amounts. This is in contrast to animal cells where the quantitatively minor PIP and PIP_2 incorporate a disproportionate amount of the radiolabel, suggesting that these phospholipids are turning over rapidly (34). If one assumes that the [^{32}Pi] label in the whole cell reflects the chemical amounts and that the PI in plasma membranes is 25% of that found in the whole cell, whereas most or all of the *myo*-PIP and -PIP_2 are located in the plasma membrane, then the ratio of the chemical amounts of *myo*-PI:-PIP:-PIP_2 is 0.2:0.08:0.01 mM, or 100:40:5, which is comparable to the ratio of radiolabel (100:30:15).

In summary, the distribution of phosphoinositides in plasma membranes differed from that in intracellular membranes. Preferential accumulation of [^{32}Pi] label in *myo*-PIP and -PIP_2 was observed in the plasma membrane, and the amount found in the intracellular membranes was undetectably low. Both isomers of PI, *myo*- and *scyllo*-PI, were present in the plasma membranes as well as the intracellular membranes.

Principal Component Analysis of Measured Quantities During Degradation of Hydroperoxides in Oxidized Vegetable Oils

Károly Héberger[a,*], Ágnes Keszler[a], and Michael Gude[b]

[a]Chemical Research Center, Institute for Chemistry of the Hungarian Academy of Sciences, H-1525 Budapest, Hungary, and [b]Unilever Research Laboratory, NL-3130 AC Vlaardingen, The Netherlands

ABSTRACT: Decomposition of hydroperoxides in sunflower oil under strictly oxygen-free conditions was followed by measuring peroxide values against time, absorbance values at 232 and 268 nm, *para*-anisidine values, and by quantitative analyses of volatile products using various additives. The results were arranged in a matrix form and subjected to principal component analysis. Three principal components explained 89–97% of the total variance in the data. The measured quantities and the effect of additives were closely related. Characteristic plots showed similarities among the measured quantities (loading plots) and among the additives (score plots). Initial decomposition rate of hydroperoxides and the amount of volatile products formed were similar to each other. The outliers, the absorbance values, were similar to each other but carried independent information from the other quantities. *Para*-anisidine value (PAV) was a unique parameter. Since PAV behaved differently during the course of hydroperoxide degradation, it served as a kinetic indicator. Most additives were similar in their effects on the mentioned quantities, but two outliers were also observed. Rotation of the principal component axes did not change the dominant patterns observed. The investigations clearly showed which variables were worth measuring to evaluate different additives.

Paper no. L7878 in *Lipids 34,* 83–92 (January 1999).

Oxidation of edible oils causes serious flavor and taste problems in the food industry. During oxidation, hydroperoxides are formed which decompose into volatile organic compounds such as alcohols, aldehydes, ketones, and acids (1). These volatile end-products can lead to off-flavor of foods (2–4). Polyunsaturated vegetable oils heated or exposed to light in the presence of oxygen may undergo partial autoxidation resulting in hydroperoxides. During oxidation the decomposition of hydroperoxides is the most important process, which produces secondary initiation, leads to hydroxyl, alkoxyl and peroxyl radicals, propagating the chain, attacking the hydroperoxides and bulk triglycerides.

For characterization of oil oxidation and of hydroperoxide degradation, the following data are used generally: peroxide value (POV), absorbance values at 232 and 268 nm (E232 and E268, respectively), *para*-anisidine value (PAV), and concentrations of volatile products formed during the process. These data are termed "variables," "measured quantities," or "factors" later on. Different kinds of additives can accelerate and/or inhibit the decomposition of hydroperoxides. Herewith we limited our examinations to study solely the decomposition of hydroperoxides and to examine the effect of 10 additives or their combinations. Therefore oxygen-free conditions were applied. The hydroperoxide amount formed from radical-induced decomposition of hydroperoxides is far below the detection level under the circumstances applied.

Such a multicomponent–multivariable problem calls for a detailed multivariate analysis. Hence application of a multivariate technique to characterize the hydroperoxide decomposition seems to be appropriate. Principal component analysis (PCA), factor analysis, and related techniques became popular because they can offer information otherwise not accessible (5–7). This information includes, e.g., classification, searching similarities, finding relationships, outlier detection, modeling, data reduction, and finding physical significance to abstract factors.

PCA was successfully applied to various fields of chemistry especially in chromatography and spectroscopy (6). The usefulness of the technique was proved recently by its extension to quantitative structure–activity relationships (8,9), to reaction kinetics (10,11), and to chemical engineering (12). In food chemistry multivariate approaches are normally applied to correlate instrumental data and food components. The most commonly used multivariate techniques in food chemistry are PCA, discriminant analysis, cluster analysis, and their various combinations. These approaches are mainly used for classification and pattern recognition purposes (13–16). Classification of beer aroma volatile compounds is also reported (15). Multivariate statistical methods are routinely applied for authenticity control of edible oils (16,17),

or they can be applied to discover adulteration of vegetable oils (18). Cluster analysis and PCA were also carried out for feature selection and validation problems (19,20). It might be quite interesting to find out whether the application of PCA can be extended to other fields as well.

To our knowledge this is the first attempt to characterize measured quantities (factors) and additives by PCA for the deterioration of oils.

The aims of the present investigation were as follows: (i) to determine which measured quantities (factors) bear the same information and which are independent ones (what kinds of characteristics are worth measuring?); (ii) to classify the measured quantities and additives according to their similarities; (iii) to compare the results of hydroperoxide decomposition at 180 and 240 min; and (iv) to assess differences in additives. This paper was primarily concerned about the degradation products of vegetable oils and about the analysis of decomposition products. Secondarily, it was considered as a chemometrics paper having application of known principles and methods. The information extracted by PCA is used mainly useful for food chemists.

EXPERIMENTAL PROCEDURES

Standard refined (neutralized, bleached, deodorized) sunflower oil was mildly oxidized by oxygen under controlled conditions. The POV of the oxidized oil was measured to be 21. The oil was provided by Unilever Research Laboratory (URL), Vlaardingen, The Netherlands. All experiments of hydroperoxide decomposition were carried out under strictly oxygen-free conditions at 140°C using deoxygenated nitrogen atmosphere and sealed ampoules (21).

POV, PAV, and absorbances at 232 and 268 nm were determined by standard methods: POV {ISO 3960 or DGF C-VI 6a (84)}, PAV {DGF C-VI 6e (84)}, and ultraviolet absorptivity {AOCS Ch 5-91 (93)}. Volatile contents of sunflower oils were analyzed by headspace solid-phase microextraction (22–24) using a Finnigan MAT GCQ GC/MS apparatus (San Jose, CA) having a quadrupole ion-trap mass analyzer. Separation was carried out (21,25) on a CP WAX 52CB (ChromPack) column (Middleburg, The Netherlands) (30 m long with 0.25 mm i.d. and 0.25 µm film thickness). Electron impact mass spectra were taken by full-scan mode in 10–650 amu mass range. Detected components were identified by matching electron impact spectra against the NIST library containing about 100,000 compounds. Samples were inserted into the injection port by headspace solid-phase microextraction method using 100 µm poly(dimethylsiloxane) fiber (Supelco Inc., Bellefonte, PA). Optimal conditions were: 45 min adsorption time at 40°C from a 4-mL vol closed vial containing 1 mL of oil. A narrow (0.75 mm i.d.) inlet liner was applied in order to detect fairly sharp and well-defined peaks. Desorption time was 1 min at 275°C. Column temperature setting was programmed from 40 to 220°C (hold for 5 min) with 4°C/min increase rate. The carrier gas was helium at 35 cm/s constant velocity.

Variables PAV, absorbance, and amount of volatiles were measured at two time points: after 3 h and 1 h later. The time was determined by the average rate of hydroperoxide decomposition. The majority of hydroperoxides were decomposed at the end of the experiments. The initial rate of hydroperoxide decomposition (w) was calculated from the beginning of POV vs. time curves using 6–7 time points. The POV was measured by iodometric titration {ISO 3960 or DGF C-VI 6a (84)}.

All measurements concerning any quantities were repeated several times (at least twice, on average four, at maximum seven times), and only the averages were used later on. The following data pretreatment was applied: The data were arranged in a matrix form. The mean of each column was subtracted from the corresponding matrix elements. Then, every matrix element was divided by the variance of its own column. Thus, the data were centered to zero mean and scaled to unit variance. The approach presented here is called "finite population" approach in some scientific fields. On each entity the measurement can be considered as fairly accurate with little repetition error such that the observed variance related to PCA is entirely between additives, i.e., there is little within additive uncertainty. In other words, if the experiments are repeated, nearly the same results are expected.

THEORY

In the course of defining principal components, the original variables are transformed into new ones. The principal components are, in fact, linear combinations of the original variables. Their values are the component scores. The linear coefficients are called the component score coefficients. The linear coefficients of the inverse relation are the loadings, i.e., in our case the correlation coefficients between the original variables and the principal components. The algorithms for PCA can be found in standard chemometrics books and tutorials (5–7). The principal components are orthogonal (independent), in other words uncorrelated. Further on, they are ordered in such a way that the variance of the first principal component is the greatest, the variance of the second is second-greatest, and so on, whereas that of the last one is the smallest. The solution is obtained by an eigenvalue calculation.

The columns of data matrices are intercorrelated, i.e., the data are redundant. The method of PCA (5–7) makes use of the intercorrelations by starting from the correlation matrix of the variables, and it eliminates the redundancy from the data, i.e., it reduces their dimensionality by revealing several underlying components. The underlying components are represented by new variables called principal components.

A basic assumption in the use of PCA is that the score and loading vectors corresponding to the largest eigenvalues contain the most useful information relating to a specific problem and that the remaining ones constitute mainly noise, i.e., for a practical problem it is sufficient to retain only a few components accounting for a large percentage of the total variance (7).

Arrangement of Matrices to be Analyzed (notations are in parentheses)[a]

Column designees		Row designees	
No.	Measured quantities	No.	Additives
1	Initial decomposition rate of hydroperoxides: (*w*)	1	Without any additive
2	Absorbance value at 232 nm (E232)	2	Butyl hydroxyanisol (BHA)
3	Absorbance value at 268 nm (E268)	3	Butyl hydroxytoluol (BHT)
4	*para*-Anisidine value (PAV)	4	*tert*-Butyl hydroquinone (TBHQ)
5	Amounts of hexanal (HEX)	5	Propylgallate (PRG)
6	Amounts of 2-*trans*-heptenal (HEP)	6	Lecithin (LEC)
7	Amounts of *cis,trans* 2,4-decadienal (TCDEC)	7	α-Tocopherol (TOC)
8	Amounts of *trans,trans* 2,4-decadienal (TTDEC)	8	Tocopheryl acetate (TAC)
9	Sum of all aldehyde amounts (SALD)	9	β-Carotene (CAR)
10	Sum of all acid amounts (SAC)	10	Additive 2 + 7: TOC + BHA
		11	Additive 4 + 7: TOC + TBHQ

[a]The measured quantities (reactivity values) are taken as variables (columns) and the various additives as mathematical–statistical cases (rows).

Each data set to be analyzed was essentially a data matrix containing the measured quantities. The arrangement of matrices is summarized in Table 1.

First, the correlation matrix of the original variables was computed (this matrix contained the correlation coefficients of each original variable with the others). Then, the component loadings were calculated from the eigenvectors and eigenvalues of the correlation matrix. Finally, the component scores were obtained from the component loadings and the original variables. The computer program used (26) furnishes the variances accounted for by the principal components, the loading patterns, the score coefficients for the standardized variables at mean zero and standard deviation one, and the component scores.

Three sets of data were analyzed: Data Set I was a matrix of 10×11; all the data referred to 180 min. The letter "A" and number "1" at the end of notations indicated the reaction time (180 min). The 10 measured quantities constituted the columns. The data points in 11 rows of the matrix represented measurements on oils with differing additives added. The first row corresponded to the results without any additives. All the other additives were denoted by numbers 2–11 (see Table 1). They were all conventional antioxidants. The last two entries showed an eventual synergistic effect since additives No. 10 and 11 were composites from additives No. 2 and 7 as well as 4 and 7, respectively.

Data Set II showed the results after 240 min. This was again a 10×11 matrix. The same measured quantities were used at 240 min (except *w* values which were identical to the ones in Data Set I). Only the notations differed a little: E232B and E268B instead of E232A and E268A as well as PAV2, HEX2, HEP2, etc. instead of PAV1, HEX1, HEP1, . . ., etc. indicated the time period of 240 min. The same additives were used as in Data Set I.

Data Set III consisted of a joined data set, i.e., Data Set I + Data Set II. It consisted of a 19×11 matrix using the same measured quantities and additives as above. (The initial decomposition rate was identical for the first two data sets, which is why only 19 measured variables were analyzed instead of 20.)

RESULTS AND DISCUSSION

Generally, it can be established for all sets of data that three principal components explain about 89–97% of the variance in the data. The selection of the number of principal components is somewhat arbitrary. Empirical rules suggest the involvement of components with eigenvalue larger than 1 or 0.5. Considering the above empirical rules, even two principal components to be retained are enough in the case of Data Set II. Analyzing the loading values of Data Sets I and II, a grouping can be seen immediately (Figs. 1 and 2).

Not only are the amounts of different aldehydes correlated with each other but also the initial decomposition rates of hydroperoxides: the decomposition reaction is kinetically controlled. The larger the initial decomposition rate is, the more volatile products are formed. The alternative would be the formation of some intermediates, and hence no direct link would be observed between decomposition rate and product formation. The absorbance values are outliers beyond doubt in both figures: the amount of conjugated dienes and trienes in the system carries independent information from the volatile compounds formed. Therefore, it is inappropriate to characterize the oil deterioration processes alone by measuring the volatile products and initial rates of hydroperoxides (as followed by POV).

PAV, characteristic of the conjugated oxo-diene content of the oil, is an outlier in Figure 1 (at 180 min, Data Set I), but its point is included in the cluster of product amounts (and *w*) in Figure 2 (at 240 min, Data Set II). From this observation it follows that α,β-unsaturated aldehydes "behave differently" within the time interval studied. Since after the degradation of hydroperoxides PAV is not an outlier anymore, this quantity can be used as a kinetic indicator.

The observations involve some far-reaching conclusions. For example, it is not worthwhile to quantify all the volatile products present in the system. Their values are related to each other at both time points. Naturally, it is expedient to measure the aldehyde present in the largest amount. The quantification of products can be avoided in case of quick

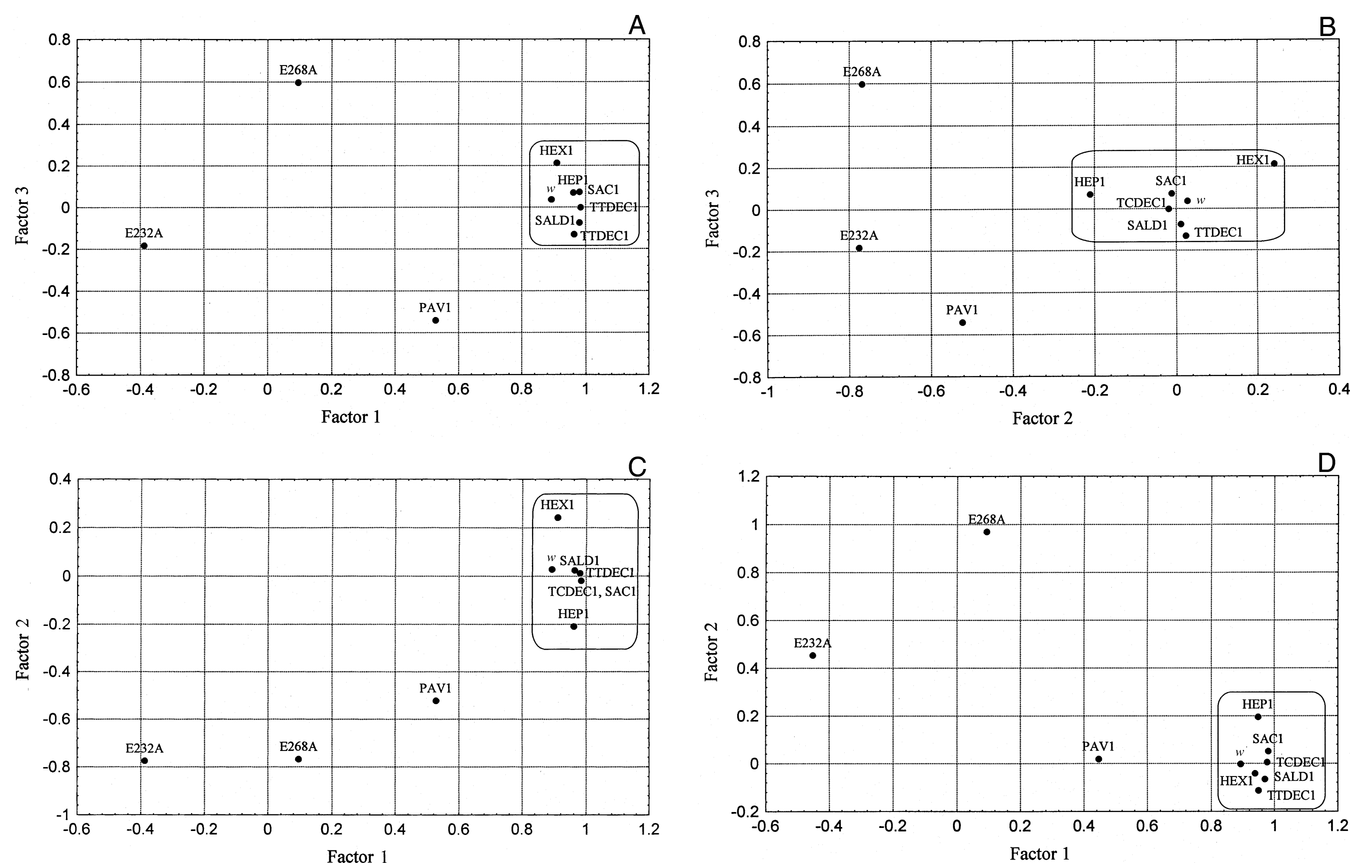

FIG. 1. Characterization of measured quantities. Factor loadings for Data Set I (at 180 min, 140°C). Parts A, B, and C are plots of unrotated loading values in three dimensions. Part D is the plot of rotated loading values. "A or 1" at the end of abbreviations means a reaction time of 180 min. HEX, hexanal; *w*, initial decomposition rate of hydroperoxides; SALD, sum of all aldehyde amounts; TTDEC, *trans,trans* 2,4-decadienal; TCDEC, *cis,trans* 2,4-decadienal; SAC, sum of all acid amounts; HEP, 2-*trans*-heptanal; PAV, *para*-anisidine value; E268A, absorbance value at 268 nm; E232A, absorbance value at 282 nm.

characterization of the decomposition process because *w* holds approximately the same information as the amounts of volatile products. Of course, gas chromatography/mass spectrometry measurements provide much useful information on the quality and quantity of the products formed. However, all amounts of aldehydes are similar to each other and to *w* from the point of view of additive effects on the decomposition of hydroperoxides. In other words, if one of the additives causes a slow decomposition rate of hydroperoxides, then the amounts of aldehydes will similarly be low and, on the contrary, large *w* involve large amounts of volatile aldehydes formed. This statement is relative. If we need the absolute values of products, the gas chromatography/mass spectrometry analysis (quantification) cannot be avoided.

The loading values of the first three principal components are provided in a table form for Data Set III (Table 2) instead of a loading plot.

The above tendencies are expressed even stronger if analyzing the joined data set. Correlation coefficients larger than 0.7 are indicated by bold in Table 2. It can be seen immediately that the first principal component is closely related to the "*w*" and to the amounts of products (both at 180 and 240 min). The initial decomposition rate of hydroperoxides carries the same information as the volatile products formed during degradation of hydroperoxides.

The second principal component closely resembles the absorbance values (E268A and E232B), whereas the third principal component correlates well with PAV at 180 min. Although the absorbance values show close similarity according to the second abstract factor, in a three-dimensional space of factors the points for absorbance values do not coincide. The absorbance values are proportional to the amounts of conjugated dienes and trienes. The amounts of dienes and trienes were correlated well [the corresponding absorbance values (E268A, E232B, and E268B) formed the second principal component almost exclusively]; nevertheless they also differ to some extent. This suggests that the absorbance values should be measured at both wavelengths and at different time points. Notably two absorbance values behave oppositely during the degradation process. At the earlier stage (180 min), absorbance at 268 nm correlates better with the second principal component, whereas at the later stage (240 min) absorbance at 232 nm does the same.

The third principal component is composed mainly of PAV1 and E232A. The correlation of the third principal component with other variables is almost always negligible, usu-

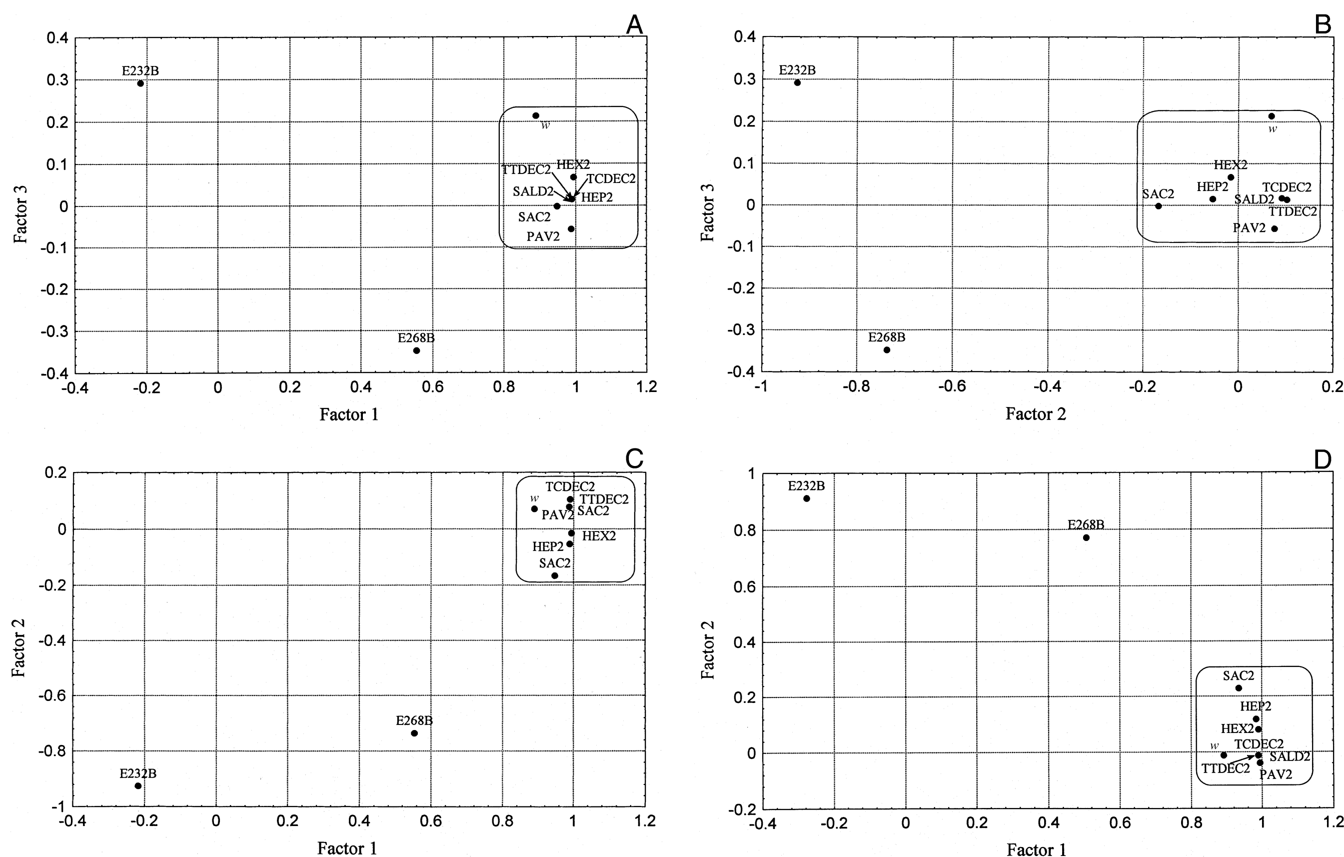

FIG. 2. Characterization of measured quantities. Factor loadings for Data Set II (at 240 min, 140°C). Parts A, B, and C are plots of unrotated loading values in three dimensions. Part D is the plot of rotated loading values. "B or 2" at the end of abbreviations means reaction time 240 min. See Figure 1 for abbreviations.

[a]Loading values (unrotated), i.e., the correlation coefficients between the original and new variables. Values larger than 0.7 are indicated in bold. For abbreviations see Table 1 in the paper ("A or 1" and "B or 2" at the end of abbreviations means reaction times 180 and 240 min, respectively).

ally less than 0.3, and its absolute value reaches a maximum of 0.334 for HEX1. This behavior is quite common in the field of PCA. The most dominant pattern is expressed by the first two principal components, whereas PAV's "uniqueness" is in the third one.

This can help in the interpretation of the influence of additives. The score values are plotted in Figure 3.

Two outliers can be observed beside a grouping on the most informative Score 1 vs. Score 2 plots (Fig. 3C and D). Additive No. 6 (lecithin) is an outlier according to the first principal component, whereas additive No. 7 (α-tocopherol) is according to the second (the absorbance values). All the other additives are similar to each other. Although the third abstract factor can differentiate among them, it must be kept in mind that this factor explains only about 7% of variability in the data. The outlying observations suggest that, in all probability, lecithin and α-tocopherol react with different mechanisms than the other antioxidants. Lecithin causes a high initial rate of decomposition and a large amount of volatile products. α-Tocopherol differs from the other additives in the amounts of conjugated dienes and trienes.

Rotation of the principal component axes can help in the identification of abstract factors. Moreover, if the dominant pattern remains after rotation, the reliability of the pattern found is enhanced. There are many ways to rotate the axes.

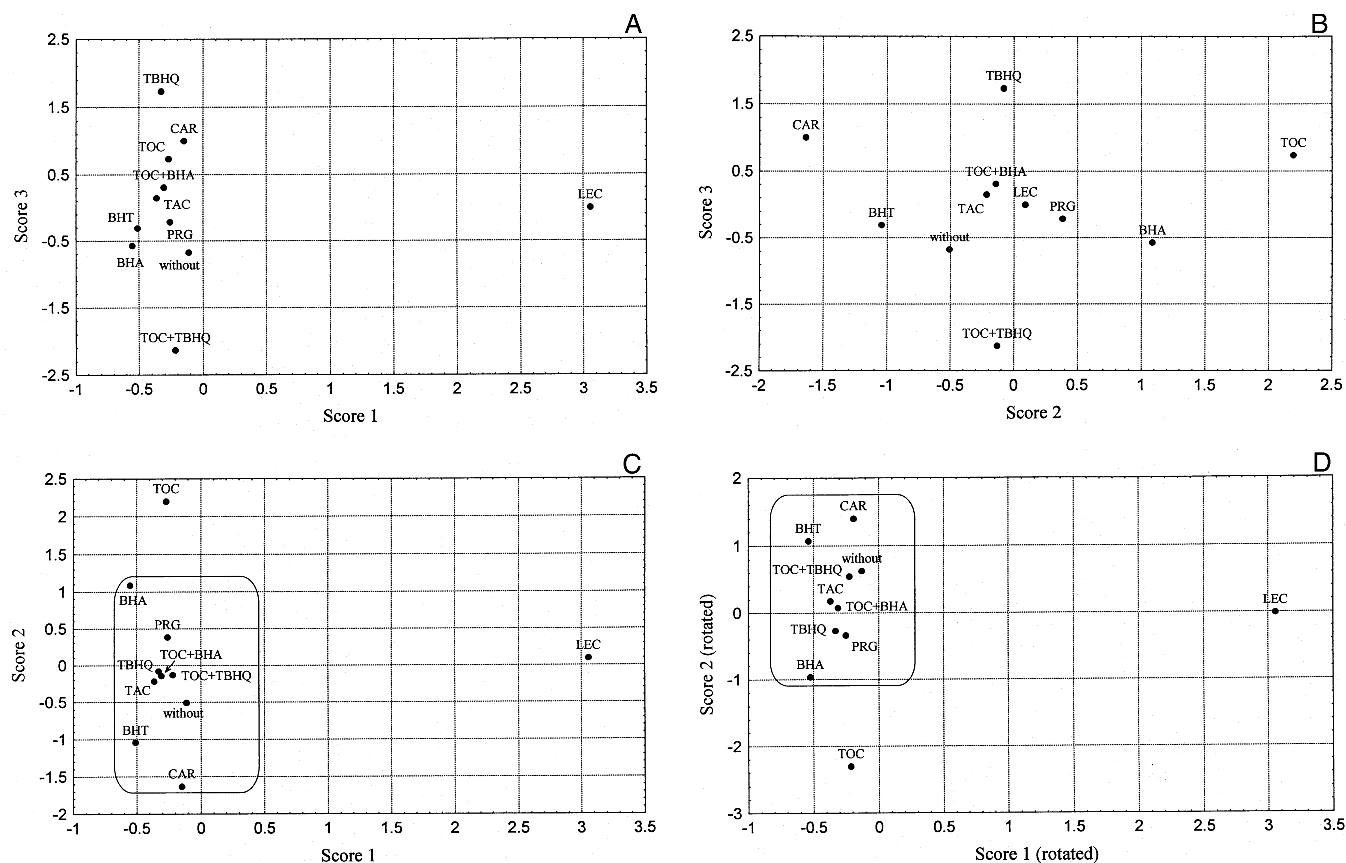

FIG. 3. Characterization of additives. Score plots for Data Set III (joined data for 180 and 240 min, at 140°C). Parts A, B, and C are plots of unrotated scores in three dimensions. Part D is the plot of rotated scores. TOC, α-tocopherol; BHA, butylated hydroxyanisole; PRG, propylgallate; TBHQ, *tert*-butyl hydroquinone; TAC, tocopheryl acetate; BHT, butyl hydroxytoluol; CAR, β-carotene; LEC, lecithin.

We have chosen the varimax rotation (normalized) which preserves the orthogonality of the axes. Varimax rotation of the factor axes enhances the role of the third factor, slightly decreasing the role of the first two abstract factors. The role of PAV1 becomes more expressed if analyzing Data Set I. Although E232A and PAV1 replace each other in their loading values (Data Set III), PAV2 will not correlate with the third abstract factor, influencing rotation and suggesting that the different behavior of PAV1 and PAV2 is not an artifact. Lack of influence of rotation on the dominant patterns strengthens our conclusion, suggesting that the effects are real and not the result of random effects or calculation artifacts.

It should be mentioned that during the reviewing process some additional measurements were made. Although the numbers in the input matrix changed a little, all the conclusions drawn remained the same. This again supports the reliability of the findings.

Naturally, all these statements are valid within the scope of the investigation, i.e., within the measured quantities and additives applied. However, in the case of new additives or additive combinations, the calculations can easily be extended.

The experimental error, as usual, can affect the data and hence the statements. However, PCA has a favorable characteristic: it is not sensitive on the error level or small changes of experimental errors. The underlying philosophy of PCA is that the "noise" comprises the last principal components not even considered and discussed here.

The input matrices (Data Sets I–III; Supplementary Table 1), all results of calculations [tables of loading and score values (Supplementary Tables 2–7 and Supplementary Tables 8–13, respectively) and their plots] are available from the authors upon request.

In conclusion, PCA of measured quantities (and additives) unambiguously shows a close similarity among measured quantities (and additives). Although the findings are applicable exclusively to the additives studied, no doubt similar analysis can be carried out on other, even different type of, additives. Three abstract factors explain 89–97% of variances present in the data. A definite cluster is observed on the loading plots, i.e., initial decomposition rate of hydroperoxides and amounts of volatiles measured by gas chromatography/mass spectrometry are closely related. The outliers are the absorbance values. That is, they are different from the variables in the cluster and carry independent information. PAV is unique at 180 min. It is different from all other quantities, and from the value at 240 min. This latter value fits into the cluster of other quantities. The analysis makes differences in ad-

ARTICLE

Lymphatic Fatty Acid Absorption Profile During 24 Hours After Administration of Triglycerides to Rats

Trine Porsgaard, Ellen Marie Straarup, and Carl-Erik Høy*

Department of Biochemistry and Nutrition, Technical University of Denmark, 2800 Lyngby, Denmark

ABSTRACT: In this study we determined in rats the complete 24-h lymphatic fatty acid profile after administration of either rapeseed oil (RO) or rapeseed oil interesterified with 10:0 (RO/C_{10}) with special emphasis on the transition from absorptive to postabsorptive phase. Rats were subjected to cannulation of the main mesenteric lymph duct and the next day oils were administered through a gastric feeding tube. Lymph was collected in 1-h fractions for the following 24 h. The time for maximum lymphatic transport of fatty acids was at 4 h with fast changes in fatty acid composition from the fatty acids of endogenous origin to those of the administered oils. Seven to eight hours after administration the transport was significantly lower than maximum, indicating the change from absorptive to postabsorptive phase. At 24 h after administration of either oil the transport of total fatty acids, palmitic acid (16:0), and linoleic acid (18:2n-6) together with oleic acid (18:1n-9) after RO had not returned to the transport at baseline. In contrast, the transport of decanoic acid (10:0) and α-linolenic acid (18:3n-3) returned to baseline values between 12 and 15 h. This indicated that the absorption of purely exogenous fatty acids (illustrated by 10:0 and 18:3n-3) was complete at 15 h and that the fatty acids transported between 15 and 24 h were derived mostly from endogenous stores.

Paper no. L8024 in *Lipids 34,* 103–107 (February 1999).

Dietary triacylglycerols are hydrolyzed by preduodenal lipases and pancreatic lipases (1–3). By the action of these lipases the triacylglycerols are hydrolyzed to 2-monoacylglycerols and free fatty acids prior to absorption (3–5). Triacylglycerols are resynthesized from monoacylglycerols and long-chain fatty acids in the enterocyte (6) and are assembled together with phospholipids, cholesterol, cholesterol esters, and apolipoproteins to form chylomicrons secreted to the lymph (7–9). After reaching the circulation the triacylglycerols are degraded in the extrahepatic tissues by lipoprotein lipase and the resulting fatty acids are absorbed by most tissues for triacylglycerol synthesis or for energy provision (10,11). Short- and medium-chain fatty acids are absorbed to a higher degree through the portal vein and transported in the blood bound to albumin (12).

Bollman *et al.* (13) developed a rat model, used by many other research groups as well, to investigate the lymphatic absorption of fatty acids. Researchers often observe the absorption for 24 h with frequent collections of lymph samples during the absorptive phase and a pooled sample in the phase supposed to be postabsorptive (14–18), while some concentrate on investigating the absorptive phase (19–21). Others collect samples less frequently during the 24-h experiment (22) or only one sample from 0 to 24 h (23). To our knowledge, nobody has examined in detail the changes in fatty acid profile during the postabsorptive phase.

In the present study we determined the complete fatty acid absorption profile after administration of rapeseed oil (RO) or rapeseed oil interesterified with 10:0 (RO/C_{10}) to lymph-cannulated rats by collecting 1-h lymph samples throughout a period of 24 h. The purpose was to investigate in more detail the phase from maximal absorption to baseline in order to decide the optimal time to finish a lymph absorption study. This was performed partly to report the most correct results and partly from an ethical point of view, i.e., to reduce the collection time for the animals involved.

EXPERIMENTAL PROCEDURES

Animals and surgery. The following experiment was approved by the Danish Committee for Animal Experiments. Male albino Wistar rats were obtained from Møllegaard Breeding and Research Centre, Ll. Skensved, Denmark. They were fed a standard rat chow diet (Altromin No. 1324, Chr. Petersen A/S, Ringsted, Denmark) and weighed 250–280 g at the time of surgery. Nonfasted rats (6 in each group) were anesthetized intraperitoneally with pentobarbital (approximately 0.05 mg/g body weight) and were subjected to cannulation of the main mesenteric lymph duct (13) with a clear vinyl tube (o.d. 0.8 mm, i.d. 0.5 mm; Critchley Electrical Products Pty. Ltd., NSW, Australia). A feeding silicone tube (o.d. 3.0 mm, i.d. 1.0 mm; Polystan, Værløse, Denmark) was inserted into the fundus region of the stomach and fixed with a purse-string suture. Following surgery the rats were placed in individual restraining cages (24) with tap water freely

available, no food, but a steady infusion of physiological saline (0.9% NaCl) at 3 mL/h through the feeding tube.

Administration of oil and collection of lymph. The next day, the experiment was started by collection of a baseline fraction of lymph from −1 to 0 h. At time zero 0.3 mL of oil was injected through the feeding tube followed by 0.5 mL saline, and the infusion of saline was continued at 3 mL/h. For the following 24 h, lymph was collected in 1-h fractions in tubes containing 100 μL of a 10% (wt/vol) $Na_2EDTA \cdot 2H_2O$. They were frozen immediately after collection and kept at −20°C until analysis.

Oils and lipid analysis. RO (Aarhus Olie, Aarhus, Denmark) and RO/C_{10} (manufactured at the Department of Biotechnology, DTU, Lyngby, by random interesterification of rapeseed oil with tri-10:0 using sodium methoxide as catalyst) were used for the experiment. The fatty acid profile of triacylglycerols was determined by gas–liquid chromatography after methylation with KOH in methanol (25). The resulting fatty acid methyl esters were analyzed using a Hewlett-Packard 5890 chromatograph with a fused-silica capillary column (SP-2380, 60 m, i.d. 0.25 mm), flame-ionization detection (FID), and helium as a carrier gas. Initial oven temperature was 70°C followed by temperature programming: 15°C/min until 160°C, followed by 1.5°C/min until 200°C which was maintained for 15 min, and finally the temperature was raised to 225°C and maintained for 5 min. Peak areas were calculated using a Hewlett-Packard computing integrator and were used to calculate the mol% of fatty acids following correction for response factors based on calibrated standards (Nu-Chek-Prep, Elysian, MN).

Analysis of lymph lipids. Total lipid was extracted from lymph fractions according to the method by Folch *et al.* (26) after addition of internal standards (13:0 and 17:0 methyl esters). After methylation with KOH in methanol the fatty acids were analyzed by gas–liquid chromatography as described above. The internal standards were used to calculate the amounts of fatty acids transported in lymph, 13:0 for chain lengths up to C_{14} and 17:0 for chain lengths of C_{16} and above.

Statistics. Results were expressed as mean ± standard error of the mean (SEM). Differences between lymphatic transport at different time points were determined by paired *t*-test using the Jandel SigmaStat statistical package (Jandel Corporation, Erkrath, Germany). The level of statistical significance was taken as $P < 0.05$.

RESULTS

Fatty acid composition of oils (Table 1). The major fatty acids (in mol%) in RO were oleic acid (18:1n-9, 55.3%), linoleic acid (18:2n-6, 21.8%), and α-linolenic acid (18:3n-3, 9.7%), while those in RO/C_{10} were decanoic acid (10:0, 40.8%), 18:1n-9 (33.0%), 18:2n-6 (12.7%), and 18:3n-3 (5.8%).

Lymphatic transport. The peak of total fatty acid lymphatic transport was at 4 h, reaching values of 15.7 ± 1.9 mg/h after RO and 20.1 ± 4.2 mg/h after RO/C_{10}, and thereafter declining toward baseline values (Fig. 1). The average lymph flow after administration of RO was 3.0 ± 0.8 mL/h and 3.0 ± 0.7 mL/h after RO/C_{10}. The fatty acids of lymph lipids [mainly palmitic (16:0), stearic (18:0), linoleic (18:2n-6), and arachidonic acid (20:4n-6) (not shown)] changed quickly after administration of oils to reflect the administered oils. A particularly steep rise in the content of 18:1n-9 was observed between 1 and 4 h (Fig. 2A and 2B). The lymphatic transport at baseline differed between fatty acids with transport values close to 0 for 10:0, 18:1n-9, and 18:3n-3, indicating that these fatty acids were not present in the fasting animal in appreciable amounts.

Considering the lymphatic transport of total fatty acids after administration of RO and RO/C_{10} (Fig. 1) significantly higher values ($P < 0.05$) were observed at 24 h compared with 0 h, indicating that the transport had not returned to baseline at the end of the experiment. After administration of RO significant differences were observed between the transport at 24 h and the values from 2 to 10 h. After administration of

TABLE 1
Fatty Acid Composition (mol%) of Oils[a]

Fatty acid	Rapeseed oil (RO)	Rapeseed oil/10:0 (RO/C_{10})
10:0	0.0	40.8
16:0	5.4	2.9
18:0	1.7	1.1
18:1n-9	55.3	33.0
18:1n-7	3.5	1.9
18:2n-6	21.8	12.7
18:3n-3	9.7	5.8
20:0	0.6	0.3
20:1n-9	1.1	0.7
Others	0.9	0.8

[a]Values represent the mean of three determinations.

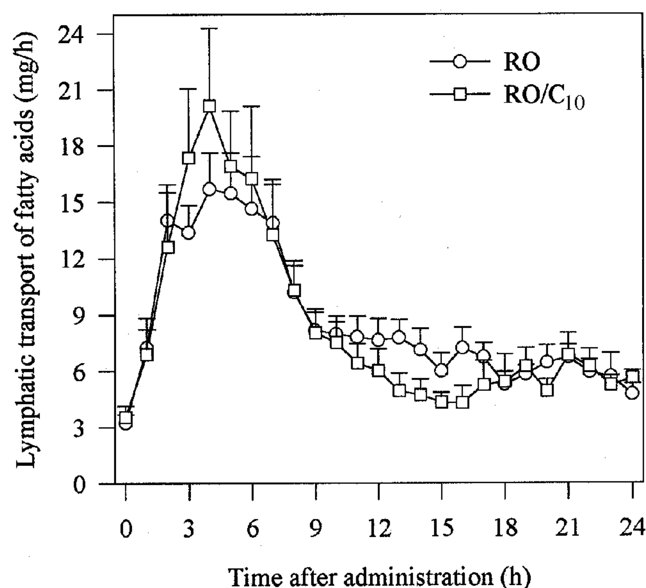

FIG. 1. Lymphatic transport of total fatty acids following intragastric administration of rapeseed oil (RO) and rapeseed oil interesterified with decanoic acid (RO/C_{10}). Values are means ± SEM (n = 6).

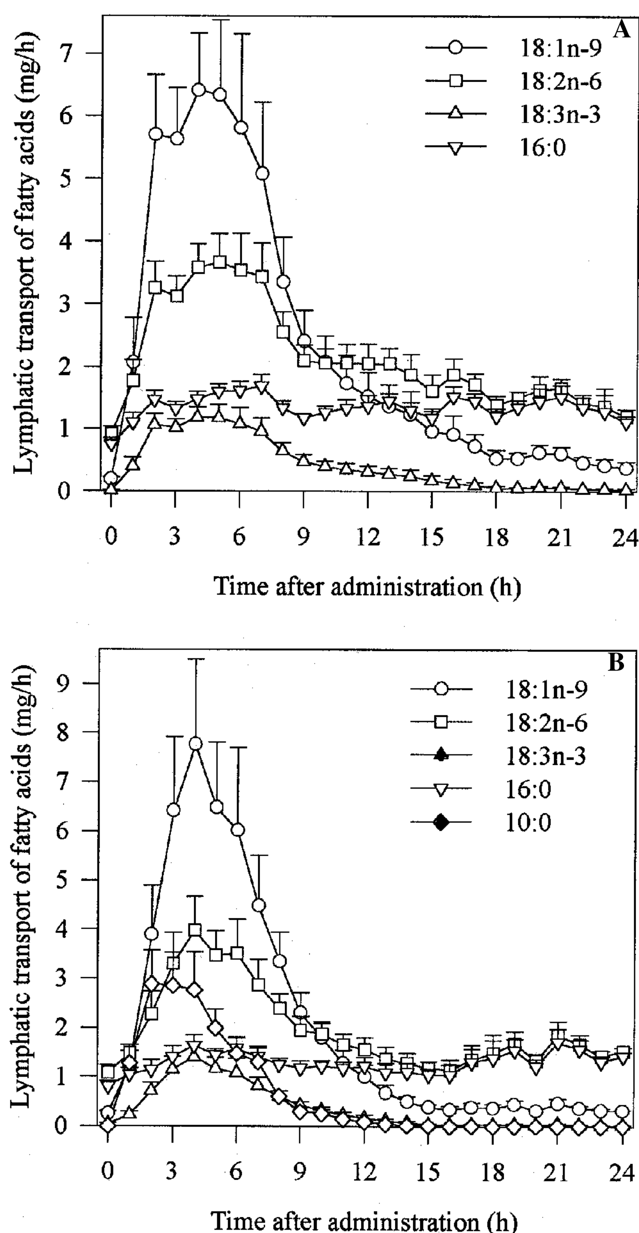

FIG. 2. Lymphatic transport of fatty acids (10:0, 16:0, 18:1n-9, 18:2n-6 and 18:3n-3) following intragastric administration of (A) RO and (B) RO/C_{10}. Values are means ± SEM ($n = 6$). See Figure 1 for abbreviations.

RO/C_{10}, differences were observed between values at 24 h and the values at 3 to 7 h, indicating a more rapid decline from maximal transport toward baseline after this oil compared with RO, although not reaching baseline.

The lymphatic transport of 16:0 and 18:2n-6 after administration of both oil, and of 18:1n-9 after administration of RO (Fig. 2) had not returned to baseline at 24 h (significantly higher than the value at 0 h; $P < 0.05$). There was no difference ($P > 0.05$) between 0 h and 15 to 24 h values for lymphatic transport of 18:3n-3 after RO. After RO/C_{10} no differences were observed between baseline and 15- to 24-h values for 10:0, 14- to 24-h values for 18:1n-9, and 12- to 24-h values for 18:3n-3, indicating that the transport of these fatty acids had returned to baseline before the end of the experiment.

The value at the time for maximal transport of fatty acids after RO administration was significantly higher than the transport values from 8 to 24 h ($P < 0.05$) for total fatty acids and for C_{18}-fatty acids. After RO/C_{10} administration the maximal transport was significantly higher ($P < 0.05$) than the values from 7 to 24 h for 18:1n-9, 18:3n-3, and total fatty acids, and higher than the values from 8 to 24 h for 10:0 and 18:2n-6. There was no difference between the transport at 8 h and the values at 9 to 14 h for total fatty acids and for 18:2n-6, and between the values at 8 h and 9 to 11 h for 18:1n-9 and 18:3n-3 after RO. Compared with this, no differences were observed after RO/C_{10} administration between the return from maximal transport and the values at 8 h for 18:1n-9 and 18:3n-3, 9 to 10 h for 10:0, 9 to 11 h for 18:2n-6, and 8 to 11 h for total fatty acids.

DISCUSSION

The profiles of fatty acid transport were similar for total fatty acids after administration of RO and RO/C_{10} with maximal lymphatic transport at 4 h and thereafter decreasing toward the transport at baseline. The return toward baseline was slower for total fatty acids, 16:0 and 18:2n-6, after both oils together with 18:1n-9 after RO (significant differences between 0 and 24 h), than for 18:3n-3 after RO and for 10:0, 18:1n-9, and 18:3n-3 after RO/C_{10} (no significant differences). This indicates that the fatty acid composition of lymph at 24 h does not necessarily parallel the fatty acid composition at baseline, and if a complete return to baseline is considered important for the interpretation of an experiment, it must exceed 24 h. Furthermore, the absorption profiles for fatty acids like 10:0 and 18:3n-3 show that these fatty acids are exclusively exogenous fatty acids with transport values close to 0 in the fasting state and a return to baseline between 12 and 15 h after administration. Thus, 10:0 and 18:3n-3 could act as markers for total absorption of exogenously administered fat, indicating that the transport of fatty acids after 15 h is almost purely endogenously derived.

For practical reasons, a collection period of 15 h is not very suitable and the performed experiments will be a compromise between acceptable recoveries and reasonable collection periods. From our data it is possible to calculate the underestimate if the experiment is brought to an end before 24 h. Ending the experiment after RO/C_{10} administration at 8 or 10 h would give a 10:0 recovery compared with 24 h values of 95 and 98%, respectively. The same values for 18:3n-3 are 81 and 90%, respectively. Compared with this, RO administration leads to 18:3n-3 recovery of 73 and 81% at 8 and 10 h, respectively. From these calculations it is obvious that RO/C_{10} is absorbed more rapidly than RO and that 18:3n-3 is absorbed at a slower rate compared with 10:0. Furthermore, ending the experiment 8 h after oil administration leads especially to a considerable underestimate of 18:3n-3 absorption.

There are marked differences in the way different researchers perform lymph absorption experiments concerning the frequency with which samples are collected and the duration of the total period of collection. From our experiment it is evident that remarkable changes can happen during 1-h collections, especially during the absorptive phase. Collection of lymph with frequency less than 1 h is not advisable if the purpose is a detailed analysis of the changes in fatty acid composition during absorption or concerns individual fatty acids. Depending on the aim of the experiment, less frequent sampling could suffice, like Nilsson *et al.* (15), Ikeda *et al.* (18), and Reicks *et al.* (22), primarily investigating the recovery of fatty acids.

Because of differences in fatty acid compositions, administered fats give rise to different absorption profiles and thereby return toward baseline values at different times, as seen in this experiment when comparing the absorption of RO and RO/C_{10}, and as seen by Degrace *et al.* (17), Rayo *et al.* (20), and Bergstedt *et al.* (27). It is therefore important to cover the entire absorption process in time when absorption of different dietary fats is compared. In our experiment, transport values significantly lower than maximal values were not reached until 7 to 8 h after administration, indicating the transition from absorptive to postabsorptive phase. This means that it is necessary to collect frequent samples for 8 h after the administration in order to identify and pass the absorption maximum. Investigators like Degrace *et al.* (17) and Chernenko *et al.* (21) stop the frequent collection of lymph samples 6 h after administration of fat. Although absorption of different fats results in different absorption profiles, 6 h after administration could not be considered the end of the absorptive phase. On the other hand, nothing is gained in continuing the frequent collection of samples beyond this point because in this experiment no differences were observed between the transport at 7 and 8 h (values significantly lower than maximum) and the transport until 11 to 14 h for most fatty acids, the only exceptions being 18:1n-9 and 18:3n-3 after RO/C_{10} (values at 9 h significantly lower than values at 7 h).

The results from this experiment led to the conclusions that collection of lymph samples for 8 h after administration of fat is sufficient to cover the major part of the absorptive phase. From an ethical point of view, the animals could be killed after this period because a fatty acid composition of lymph at 24 h, similar to that of the fasting animal, will not be obtained anyway. On the other hand, collection of lymph for more than 8 h is necessary to estimate the recovery of administered fat, because the absorption of exogenous fat has not been completed at 8 h after administration, as illustrated by the 10:0 and 18:3n-3 absorption profiles. Continuing the collection for 24 h leads to a higher degree of mixing exogenous fatty acids with endogenously derived fatty acids.

ACKNOWLEDGMENTS

The authors wish to thank Flemming Kejser and Bente Pedersen for technical assistance, and Steen Balchen, Department of Biotechnology, DTU, for making the chemical interesterification of rapeseed oil and 10:0. Dietary Effects of Conjugated Octadecatrienoic Fatty Acid (9 *cis*, 11 *trans*, 13 *trans*) Levels on Blood Lipids and Nonenzymatic *in vitro* Lipid Peroxidation in Rats

P. Dhar, S. Ghosh, and D.K. Bhattacharyya*

Department of Chemical Technology, University Colleges of Science and Technology, Calcutta University, Calcutta - 700009, West Bengal, India

ABSTRACT: The present study examined the antioxidant activity of conjugated octadecatrienoic fatty acid (9 *cis*,11 *trans*,13 *trans*-18:3), α-eleostearic acid, of karela seed *(Momordica charantia)*, fed to rats for 4 wk. The growth pattern of rats and the effect on plasma cholesterol and high density lipoprotein (HDL) cholesterol and peroxidation of plasma lipid, lipoprotein, eryhrocyte membrane, and liver lipid were measured. Rats were raised on diets containing sunflower oil mixed with three different levels of conjugated trienoic fatty acid (9*c*,11*t*,13*t*-18: 3) 0.5, 2, and 10% by weight; the control group was raised with sunflower oil as dietary oil as the source of linoleic acid (9*c*,12*c*-18:2). The growth pattern of the three experimental groups of rats showed no significant difference compared to the control group of rats, but the group with 10% 9*c*,11*t*,13*t*-18:3 had slightly higher body weight than the control group of rats. Concentrations of total cholesterol, HDL-cholesterol, and non-HDL-cholesterol in plasma were similar in all four groups. Plasma lipid peroxidation was significantly lower in the case of 0.5% 9*c*,11*t*,13*t*-18:3 group than the control group and the 2 and 10% 9*c*,11*t*,13*t*-18:3 dietary groups as well. Lipoprotein oxidation susceptibility test with 0.5, 2, and 10% 9*c*,11*t*,13*t*-18:3 dietary groups was significantly less susceptible to lipoprotein peroxidation when compared with sunflower oil dietary group, and the dietary group with 0.5% 9*c*,11*t*,13*t*-18:3 showed least susceptibility. There was significant lowering in erythrocyte ghost membrane lipid peroxidation in the 0.5, 2, and 10% 9*c*,11*t*,13*t*-18:3 dietary groups compared to the sunflower oil groups. Nonenzymatic liver tissue lipid peroxidation was significantly lower in the group of rats raised on 0.5% 9*c*,11*t*,13*t*-18:3, but the groups on 2 and 10% 9*c*,11*t*,13*t*-18:3 acid did not show any significant difference compared with the control group of rats.

Paper no. L7967 in *Lipids 34*, 109–114 (February 1999).

Polyunsaturated fatty acids (PUFA) are susceptible to autoxidation giving rise to peroxyl free radical. Peroxidation takes place both in *in vivo* (1) and *in vitro* (2) conditions. *In vivo* lipid peroxidation takes place either by free radicals or enzymatically (2). Growing evidence exists that the oxidation of lipids plays a significant role in the development of atherosclerosis (3). Free radicals are constantly being generated, and antioxidant defense mechanism neutralizes them, making them ineffective (4). When the free-radical generation exceeds the scavenging capacity of the antioxidant defenses, the result is oxidative stress; there is a preponderance of free radicals that initiate *in vivo* peroxidation of PUFA of membrane lipids (5). There are currently four nutrients—ascorbic acid (5); conjugated linoleic acid (CLA) (6); one food preservative (butylated hydroxytoluene); and one drug (probucol) (7)—that function as *in vivo* antioxidants. The latter two also are antiatherosclerotic in animal models (7,8).

Growing interest exists in dietary conjugated fatty acids, especially CLA, which was shown by several workers to be an effective agent in reducing the incidence of chemically induced cancers and to act as chemoprotective agent (9). Anticarcinogenic effects of CLA might be attributed to their antioxidant activity (10) that serves as an *in-situ* defense mechanism against membrane attack by free radicals. However, recent reports from Van den Berg *et al*. (11) and Chen *et al.* (12) raised some doubts regarding the antioxidant property of CLA.

Conjugated linolenic acid (α-eleostearic acid: 9*c*,11*t*,13*t*-18:3) commonly found in karela seed (*Momordica charantia*) was nutritionally evaluated in our laboratory (13). However, its role as an antioxidant was not established.

In the present study, an attempt was made to determine the antioxidant effects of α-eleostearic acid 9*c*,11*t*,13*t*-18:3 supplemented at three different percentages (0.5, 2, 10%) in the diet by measuring plasma lipid, lipoprotein, erythrocyte membrane (EM), and liver lipid peroxidations. We also studied the growth rate and lipid profile of plasma using the same rat model.

EXPERIMENTAL PROCEDURES

Dietary fat sources. Authentic karela seeds, obtained from the local market of Calcutta, India, were crushed into fine particles,

and the oil was extracted in a Soxhlet apparatus with *n*-hexane (40–60°C boiling point range). The free fatty acids present in the oil were then removed by miscella refining process (14). The extracted oil containing hexane, known as miscella (hexane/oil, 2:1) was mixed with 10% NaOH solution (20% excess of the theoretical amount required) at 40°C for 30 min to neutralize the free fatty acids. The soap formed was removed by centrifugation and the organic phase was washed with water. Deacidified oil was recovered after removing the solvent under vacuum distillation and drying under vacuum.

The refined oil was then bleached with tonsil earth optimum (1% w/w) (15) obtained from P.T. Sud-Chemic (Jakarta, Indonesia) and activated carbon (0.2% w/w), supplied by E. Merck India Pvt. Ltd. (Bombay, India) at 60°C under vacuum for 20 min. After the bleaching operation, the oil was recovered by vacuum filtration and stored at −20°C under nitrogen.

Dietary fat blends. Sunflower oil (trade name Sundrop) was obtained from I.T.C., Ltd. (Hyderabad, India). Sunflower oil was mixed with 1, 4, and 20% karela oil to give a final oil mixture containing 0.5, 2, and 10% by weight eleostearic acid, respectively; see Table 1 for fatty acid composition of the dietary oil mixtures.

Analysis of fat products. Gas chromatography was used as described previously (16). Fatty acid methyl esters were prepared following published procedures (17). Briefly, approximately 50 mg of oil was dissolved in 0.5 mL of diethyl ether, and 1.0 mL of 0.5 N methanolic KOH solution was added. The reaction mixture was shaken for 10 min at room temperature, and shaken vigorously after the addition of 1.0 mL of 1 N HCl. Methyl esters were extracted with 3 × 1 mL portions of petroleum ether. The extracts were combined and the solvent removed by a flow of nitrogen in a screw-capped test tube.

Conjugation of α-eleostearic acid present in karela seed oil was determined by ultraviolet spectrophotometric analysis at 262, 268, and 274 nm (18).

Feeding experiment. Animal experiments were designed and carried out as reported previously (19). Male albino rats of Charles Foster strain were housed in individual cages and were fed the dietary oils and fresh water *ad libitum*. Daily food consumption and weekly body weight gain were recorded. The feeding experiment was conducted to evaluate the antioxidant effect of α-eleostearic acid supplementation at three different levels.

Thirty-two rats (70–80 g body weight) were divided into four groups each consisting of eight rats having equal average body weight. The rats were fed experimental diets composed of fat-free casein, 18%; fat, 20%; starch, 55%; salt mixture, 4% [composition of salt mixture No. 12 (in g): NaCl, 292.5; KH_2PO_4, 816.6; $MgSO_4$, 120.3; $CaCO_3$, 800.8; $FeSO_4 \cdot 7H_2O$, 56.6; KCl, 1.66; $MnSO_4 \cdot 2H_2O$, 9.35; $ZnCl_2$, 0.5452; $CuSO_4 \cdot 5H_2O$, 0.9988; $CoCl_2 \cdot 6H_2O$, 0.0476] (20); cellulose, 3%; one multivitamin capsule [vitamin A I.P. (Indian Pharmacopia) 10,000 units; thiamine mononitrate I.P. 5 mg; vitamin B I.P. 5 mg; calcium pantothenate USP 5 mg; niacinamide I.P. 50 mg; ascorbic acid I.P. 400 units; cholecalciferol USP 15 units; menadione I.P. 9.1 mg; folic acid I.P. 1 mg, vitamin E USP 0.1 mg] per kg of diet. The diets were adequate in all nutrients.

Rats were maintained on the above diets *ad libitum* for 4 wk. For each rat the amount of daily diet consumed and weekly body weight gain were noted. Rats were killed while under mild anesthesia, blood was collected, and liver was immediately excised, blotted, and stored at −40°C before analysis.

Lipid analysis. According to the standard methods, the lipid components such as total cholesterol (21) and high density lipoprotein (HDL)-cholesterol (22) of plasma were analyzed using enzymatic kits supplied by Ranbaxy Diagnostics Ltd. (New Delhi, India).

Plasma lipid peroxide was measured by the assay of thiobarbituric acid-reactive substances (TBARS) according to the standard method (23). The amount of malondialdehyde formed was calculated by taking the extinction coefficient of malondialdehyde to be 1.56×10^5 M^{-1} cm^{-1}.

Lipoprotein oxidation susceptibility (LOS) test. Non-HDL-cholesterol oxidation was carried out by precipitating apoB-containing lipoprotein (low density lipoprotein and very low density lipoprotein) according to Bachorik and Albers (24). The LOS test was carried out according to the method described by Phelps and Harris (25).

Preparation and oxidative sensitivity of EM ghost. After plasma separation, the erythrocytes were washed three times with 3 vol of a cooled isotonic solution containing 0.15 M NaCl, 10^{-5} M EDTA. The buffy coat was removed by aspiration after each wash. Finally the EM ghosts were prepared by using hypotonic solution of NaCl according to the method of Rose and Oklander (26).

A modification of the 2-thiobarbituric acid test (27) was used to measure lipid peroxides. A 0.5-mL aliquot of the red blood corpuscle membrane suspension was mixed with 1.0 mL of 10% trichloroacetic acid and 2.0 mL of 0.67% 2-thiobarbituric acid. The mixture was heated at 95°C for 15 min, cooled, and centrifuged. The absorbance of the supernatant was measured at 534 nm in a Shimadzu spectrophotometer (Tokyo, Japan), and the relative amounts of lipid peroxides were expressed in absorbance units, A_{534} nm (28).

Liver tissue lipid peroxidation. For lipid peroxide measurement, *ca.* 1 g of liver tissue was homogenized and extracted using the method of Bligh and Dyer (29).

2-Thiobarbituric acid test for liver lipid peroxidation. The present test was performed according to the method described by Schmedes and Hølmer (30).

RESULTS

Antioxidant property of conjugated octadecatrienoic fatty acid, α-eleostearic (9*c*,11*t*,13*t*-18:3) acid was investigated.

The fatty acid composition of the dietary oils and oil blends are shown in Table 1. The oleic (18:1) and linoleic (18:2) contents were generally similar in all the dietary fats.

The mean body weight gain of rats fed the 0.5, 2, and 10% 9*c*,11*t*,13*t*-18:3 dietary groups for 4 wk showed no statistically significant difference when compared with the sun-

[a]As determined by gas chromatography. 9*c*,11*t*,13*t*-18:3, α-eleostearic acid. $n = 8$.

TABLE 2
Plasma Cholesterol Profile of Rats Fed Sunflower Oil and Sunflower:Karela Seed Oil Blended Products Containing 0.5, 2, and 10% α-Eleostearic Acid (9*c*,11*t*,13*t*-18:3)

Diets	Total cholesterol (mg/dL)	HDL-cholesterol (mg/dL)	Non-HDL-cholesterol (mg/dL)
Sunflower oil	46.3 ± 7.3[a]	23.3 ± 2.4	23.01 ± 6.7
0.5% 9*c*,11*t*,13*t*-18:3	35.8 ± 2.5	18.1 ± 1.7	17.8 ± 3.2
2% 9*c*,11*t*,13*t*-18:3	40.1 ± 3.7	20.1 ± 2.2	20.0 ± 5.2
10% 9*c*,11*t*,13*t*-18:3	44.3 ± 4.8	19.9 ± 4.6	24.3 ± 2.4

[a]All values are means of eight rats/diet. HDL, high density lipoprotein.

flower oil control group (Fig. 1). Although statistically insignificant, the dietary group with 10% 9*c*,11*t*,13*t*-18:3 showed maximal gain in weight at the end of week 4. In a previous nutritional experiment (13) the mean body weight gain was shown to be significantly more in rats raised on 51.1% 9*c*,11*t*,13*t*-18:3 compared to rats raised on 9*c*,12*c*,15*c*-18:3 dietary fat, which would support our present observation.

The amounts of plasma total cholesterol, HDL-cholesterol, and non-HDL-cholesterol of the rats raised on 0% 9*c*,11*t*,13*t*-18:3 (sunflower oil) and 0.5, 2, and 10% 9*c*,11*t*,13*t*-18:3 diet are included in Table 2. A comparison of the plasma total cholesterol of rats fed 0.5, 2, and 10% 9*c*,11*t*,13*t*-18:3 and 0% 9*c*,11*t*,13*t*-18:3 (sunflower oil) showed that there was a trend of greater amount of plasma total cholesterol in the 0% 9*c*,11*t*,13*t*-18:3 diet compared to the other three 0.5, 2, and 10% 9*c*,11*t*,13*t*-18:3 diets. The total cholesterol was minimal in the group fed 0.5% 9*c*,11*t*,13*t*-18:3 and increased gradually as the level of 9*c*,11*t*,13*t*-18:3 was raised. There was no significant difference between the 0% 9*c*,11*t*,13*t*-18:3 and three 0.5, 2, and 10% 9*c*,11*t*,13*t*-18:3 dietary groups. HDL-cholesterol content in the plasma (Table 2) was maximal in the 0% 9*c*,11*t*,13*t*-18:3 dietary group, but there was no significant difference between the four dietary groups.

Table 3 includes the *in vitro* plasma lipid peroxidation and LOS of the 0, 0.5, 2, and 10% 9*c*,11*t*,13*t*-18:3 diet. It is evident that 9*c*,11*t*,13*t*-18:3 supplementation effectively reduced the susceptibility of the plasma lipid to peroxidation; the minimal susceptibility was achieved with 0.5% 9*c*,11*t*,13*t*-18:3 along with the gradual increase of 9*c*,11*t*,13*t*-18:3 supplementation (2%, 10%). The 0% 9*c*,11*t*,13*t*-18:3 group (sunflower group) showed maximal peroxidation of plasma lipid. Increasing the level of 9*c*,11*t*,13*t*-18:3 in the diet from 0.5 to 2% resulted in 25% increase in sensitivity to *in vitro* plasma lipid peroxidation. When the dietary level of 9*c*,11*t*,13*t*-18:3 was further increased to 10%, the sensitivity to *in vitro* plasma peroxidation increased by an additional 29%, but this change was not significant.

The oxidative sensitivity of the EM ghost and liver lipid

[f]2% 9*c*,11*t*,13*t*-18:3 group vs. sunflower group $P < 0.01$; $P < 0.05$.
[g]10% 9*c*,11*t*,13*t*-18:3 group vs. sunflower group $P < 0.05$.

peroxidation of the four dietary fat groups of rats are presented in Table 4. TBARS production in EM ghosts from the 0% 9*c*,11*t*,13*t*-18:3 group was significantly higher when compared with TBARS production in the EM ghosts of the 0.5, 2, 10% 9*c*,11*t*,13*t*-18:3 dietary groups. But there was no significant difference between the 9*c*,11*t*,13*t*-18:3 supplemented groups.

Liver lipid peroxidation results showed that *in vitro* production of TBARS in liver tissue of dietary group supplemented with 0.5% 9*c*,11*t*,13*t*-18:3 was significantly lower than the 0, 2, and 10% 9*c*,11*t*,13*t*-18:3 dietary groups. Thus the TBARS formation in the *in vitro* condition was lowest in the dietary group that was supplemented with least amount of 9*c*,11*t*,13*t*-18:3.

DISCUSSION

The study showed that 0.5 and 2% 9*c*,11*t*,13*t*-18:3 fatty acid in dietary oil had no effect on the body growth of rats, but there was an improved weight gain with 10% 9*c*,11*t*,13*t*-18:3, though not significant. The previous nutritional experiment (13) showed that 20% 9*c*,11*t*,13*t*-18:3 in the diet improved the body weight gain of rats in comparison with the rats raised on 9*c*,12*c*,15*c*-18:3 dietary fat which supports the present observation. Chin *et al*. (31) studied the effect of CLA on rat growth and development. Pups that continued to receive the CLA-supplemented diet after weaning had significantly greater body weight gain compared to control animals.

For assessment of the effect of 9*c*,11*t*,13*t*-18:3 on atherosclerosis in rats, total cholesterol, HDL-cholesterol, and non-HDL-cholesterol were estimated in plasma. There was no evidence of significant difference in the total cholesterol and various forms of cholesterol between the experimental and the control groups of rats. It can be concluded that the four dietary groups were nutritionally equivalent since the PUFA content of the four dietary fats was more than adequate, generally equal in content, and the levels of 9*c*,11*t*,13*t*-18:3 were low. A diet supplemented with 0.5 g CLA for 12 wk reduced low density lipoprotein-cholesterol and triglycerides markedly (32).

Plasma lipid peroxidation and LOS were maximally reduced at 0.5% of dietary 9*c*,11*t*,13*t*-18:3, and peroxidation increased gradually with the increased levels of 9*c*,11*t*,13*t*-18:3 in the diet group. Therefore, the antioxidant efficacy of 9*c*,11*t*,13*t*-18:3 is maximal at 0.5% in the diet. Ip *et al*. (33) showed that 0.25% CLA in the diet had maximal antioxidant effect, and CLA lowered mammary tissue malonaldehyde formation.

EM lipid peroxidation data indicate that 9*c*,11*t*,13*t*-18:3 had reduced lipid peroxidation possibly after being incorporated into the lipids of red blood cell membrane. Sunflower oil containing high levels of linoleic acid and no 9*c*,11*t*,13*t*-18:3 showed increased membrane lipid peroxidation. Cunningham *et al.* (34) observed that supplementation of linoleic acid increased intracellular lipid peroxide concentrations in normal human mammary epithelial cells. Ha *et al.* (10) from his investigations concluded that CLA might serve as an *in situ* defense mechanism against membrane attack by free radicals which may explain the anticarcinogemic properties of CLA.

Liver tissue lipid peroxidation also reduced at 0.5% 9*c*,11*t*,13*t*-18:3 which may have been due to incorporation of this conjugated linolenic acid. Belury and Kempa-Steczko (35) showed that dietary CLA was incorporated in neutral and phospholipids at the expense of linoleic acid in the diet.

Normally conjugated fatty acids are more rapidly oxidized than the nonconjugated PUFA (11). Various investigators showed that the linolenates oxidize approximately twice as fast as the linoleates (36). According to Swern (37) conjugated triene esters oxidize more rapidly than nonconjugated triene esters. In compounds with more than two conjugated double bonds, conjugation increased the rate of oxidation (38). Thus, in the *in vivo* study conjugated trienoic fatty acids are also likely to be more rapidly oxidized than linoleates by picking up more free radicals, thereby eliminating or reducing the formation of hydroperoxides. CLA in higher concentrations

acts as prooxidant rather than antioxidant (9). At 0.5%, 9*c*,11*t*,13*t*-18:3 showed antioxidant property that decreased with increase in its level. At higher concentrations it could have possibly acted as a prooxidant similar to CLA, also reported to act as a prooxidant at higher concentration (9).

Another possible mechanism could be that oxidation of conjugated trienoic fatty acid resulted in the formation of conjugated dienoic fatty acids (CLA) that acted as antioxidants (9). Brauer and Steadman (38) measured the oxidation of β-eleostearic acid by means of ultraviolet spectrophotometry and observed that the conjugated triene decreased as oxidation proceeded, while the absorption due to conjugated diene increased. This also occurred during oxidation of α-eleostearic acid (39). Allen and Kummerow (40) found that the amount of triene conjugation lost and the amount of diene conjugation formed were proportional to the amount of oxygen absorbed. Thus it may be possible that in the *in vivo* conditions these conjugated linolenic fatty acids may have reduced the formation of hydroperoxides by lowering the generation of free radicals and peroxidation of PUFA occurring in EM and other lipids.

ABSTRACT: This investigation was carried out to characterize the effects of specific dietary marine oils on tissue and plasma fatty acids and their capacity to generate metabolites (prostanoids, lipid peroxides). Young male guinea pigs were fed nonpurified diet (NP), or NP supplemented (10%, w/w) with menhaden fish oil (MO), harp seal oil (SLO), or corn oil (CO, control diet) for 23 to 28 d. Only the plasma showed significant n-3 polyunsaturated fatty acid (PUFA)-induced reductions in triacylglycerol (TAG) or total cholesterol concentration. Proportions of total n-3 PUFA in organs and plasma were elevated significantly in both MO and SLO dietary groups (relative to CO), and in all TAG fractions levels were significantly higher in MO- than SLO-fed animals. The two marine oil groups differed in their patterns of incorporation of eicosapentaenoic acid (EPA). In guinea pigs fed MO, the highest levels of EPA were in the plasma TAG, whereas in SLO-fed animals, maximal incorporation of EPA was in the heart polar lipids (PL). In both marine oil groups, the greatest increases in both docosahexaenoic acid (22:6n-3, DHA) and docosapentaenoic acid (22:5n-3, DPA), relative to the CO group, were in plasma TAG, although the highest proportions of DHA and DPA were in liver PL and heart TAG, respectively. In comparing the MO and SLO groups, the greatest difference in levels of DHA was in heart TAG (MO > SLO, $P < 0.005$), and in levels of DPA was in heart PL (SLO > MO, $P < 0.0001$). The only significant reduction in proportions of the major n-6 PUFA, arachidonic acid (AA), was in the heart PL of the SLO group (SLO > MO = CO, $P < 0.005$). Marine oil feeding altered *ex vivo* generation of several prostanoid metabolites of AA, significantly decreasing thromboxane A_2 synthesis in homogenates of hearts and livers of guinea pigs fed MO and SLO, respectively ($P < 0.04$ for both, relative to CO). Lipid peroxides were elevated to similar levels in MO- and SLO-fed animals in plasma, liver, and adipose tissue, but not in heart preparations. This study has shown that guinea pigs respond to dietary marine oils with increased organ and plasma n-3 PUFA, and changes in potential synthesis of metabolites. They also appear to respond to n-3 PUFA-enriched diets in a manner that is different from that of rats.

Paper no. L7939 in *Lipids 34*, 115–124 (February 1999).

It has been suggested that diets containing moderate levels of oily fish, which are enriched in n-3 polyunsaturated fatty acids (PUFA), have a variety of health benefits, including prevention of fatal cardiac arrhythmias (1,2 and references therein) and support of normal brain and retinal development (3). The molecular mechanisms underlying these effects of n-3 PUFA are not fully understood, but before we can understand them, we need to know the extent to which individual n-3 polyenes are incorporated into different body organs. It will be important also to know whether incorporation varies with the source and PUFA composition of the dietary oil, an issue that has been studied to only a limited extent (4,5).

Dietary studies, which have been done primarily with n-6 PUFA, have demonstrated that guinea pigs are closer to humans than are the more commonly used laboratory animal species, including rats, in terms of their lipid and fatty acid metabolism. Examples include their lipid profiles in some organs, particularly heart (6,7), their plasma lipoprotein profile (8) and its response to dietary fat saturation (9), and their distribution of hepatic cholesterol pools (10). Also, a small number of studies have suggested that guinea pigs fed a standard laboratory diet are relatively n-3 PUFA deficient (5,11). This condition appears to be be readily reversed by diets containing n-3 PUFA, although the effects produced in major organs and blood have not yet been fully characterized.

The low levels of n-3 PUFA in the guinea pig also make this species a good model for determining whether the dietary source of n-3 PUFA (e.g., oils from fish *vs.* oils from marine mammals) influences any change that may occur with respect to organ/blood lipid and fatty acid profiles. A little-appreciated fact regarding marine oils is that their chemical composition and structure can vary significantly. One difference is in the relative proportions of their major n-3 PUFA, eicosapentaenoic (EPA, 20:5n-3) and docosahexaenoic (DHA, 22:6n-3) acids (12). Also, oils from marine mammals, but not fish, contain substantial amounts of the less well-known n-3 long-chain PUFA, docosa-

pentaenoic acid (DPA, 22:5n-3). It constitutes approximately 5% of the total fatty acids in seal oil, which was the dominant fat in the diet of Greenland Eskimos (13), the population in which an association was first made between a low incidence of cardiovascular disease and high dietary intake of n-3 PUFA. Another potentially important difference between oils from marine mammals and fish is the positional distribution of these PUFA in triacylglycerols (TAG). In fish oils, n-3 PUFA are esterified primarily at the *sn*-2 position, whereas in seal oil they are found mainly at *sn*-1 and *sn*-3 (14–16). This structural difference could result in differences in absorption, distribution, and systemic metabolism of the n-3 PUFA, although its significance regarding organ/cell structure and function remains unknown.

For the representative fish oil in this study, we used menhaden oil (MO). It contains ≈30% (by wt) n-3 PUFA, of which EPA is 13.4% and DHA is 9.9%. The U.S. Food and Drug Administration recently approved its use as a human food supplement (17), and as such, it is quantitatively the most important fish oil in North America. Harp seal oil (SLO) contains ≈21% n-3 PUFA, has DHA (8%) ≥ EPA (7%), and has a relatively high proportion of DPA (4–6%). SLO is also of interest since there is little information regarding its effects on organ structure and metabolite production, and particularly since it is being investigated for use in the food and pharmaceutical industries (16).

This investigation was undertaken to determine the effects of marine oil-enriched diets on organ-specific uptake, metabolism, and incorporation of n-3 PUFA into polar lipids (PL) and/or TAG in guinea pig organs (heart, liver, brain, adipose tissue) and plasma. Effects of the diets on the *ex vivo* generation of select prostanoids and lipid peroxide (LPO) markers were also determined.

MATERIALS AND METHODS

Materials. The marine oils used were refined menhaden fish (*Brevoortia tyrannis*) oil (MO), a gift of the United States Department of Commerce, National Marine Fisheries Services, Southeast Fisheries Science Center (Charleston, SC), and harp seal (*Phoca groenlandicus*) oil (SLO), a gift of Gateway Maritime Inc. (Brigus, Newfoundland, Canada). Corn oil (CO) was obtained commercially (Best Foods Canada Inc., Etobicoke, Ontario). Reagents for fatty acid analyses and colorimetric assays and α-tocopherol were purchased from Sigma Chemical Co. (St. Louis, MO) or Diagnostic Chemicals (Charlottetown, Prince Edward Island, Canada).

Animals and diets. The diets were prepared with a standard nonpurified guinea pig diet (NP; PROLAB Guinea Pig Formula, Agway Inc., Syracuse, NY). It was ground, mixed with the marine oils or CO (10 g/100 g diet), and reconstituted into pellets in a California pelletizer at the Laboratory of Fisheries and Oceans Canada (Halifax, Nova Scotia, Canada). Antioxidant (100 mg α-tocopherol/kg diet) was added to each of the oil-enriched diets. The diets were made up at the beginning of the study and were stored at –20°C under N_2 in 100-g portions. The fatty acid compositions of the diets were reported in detail previously (5). Ten- to 14-d-old male albino guinea pigs (Harlan, Indianapolis, IN) weighing 120–240 g were fed the diets (4–9/dietary group) for 23–28 d. The animals were given free access to food and to water supplemented with ascorbic acid (200 mg/L, wt/vol) and kept in 12-h light:dark cycles in the Animal Care Quarters of the Sir Charles Tupper Medical School, Dalhousie University (Halifax, Nova Scotia, Canada). They were fed at the same time each day, at which time uneaten food was weighed and discarded, and the cups were washed thoroughly. The guinea pigs were weighed every 2 to 3 d throughout the feeding period. They were killed with an overdose of euthanol, and blood was taken by cardiac puncture into 10 mL syringes that contained EDTA (19 mg) and indomethacin (7.2 mg). Plasma and red blood cells were separated by centrifugation. Organs were quickly removed, weighed, flash frozen and stored at –86°C. These studies were carried out in full compliance with the regulations of the Canadian Council on Animal Care.

Lipid extraction and fatty acid analysis. Lipids were extracted from hearts, livers, brains, and adipocytes using chloroform/methanol (2:1, vol/vol) under an N_2 atmosphere, according to the method of Bligh and Dyer (18). On the day of extraction, tissues were brought to room temperature, weighed, and homogenized in a Sorvall Omni-mixer (Mandel Scientific Co., Guelph, Ontario, Canada) using double volumes of solvents relative to tissue weights to ensure complete homogenization. The chloroform phase was allowed to settle overnight in a glass separatory funnel. The solvent was removed under water aspirator vacuum in a rotary evaporator and finally under mechanical vacuum. For extraction of plasma lipids, 10 vol of chloroform/methanol (2:1, vol/vol) were added to the samples, the solutions were vortexed vigorously for 2 min, and 1 vol of 0.9% saline was added. The mixture was centrifuged, and the bottom chloroform layer was removed by Pasteur pipette. The upper phase was reextracted with chloroform/methanol (2:1, vol/vol), and the chloroform layers were pooled and dried over sodium sulfate under N_2. Where indicated, lipid classes (PL, TAG) were isolated by thin-layer chromatography on Soft Layer Adsorbosil Plus-1 plates (Mandel Scientific) using the solvent system hexane/anhydrous ethyl ether/glacial acetic acid (85:15:1, by vol). Lipids were recovered from the appropriate bands by extraction with chloroform/methanol (2:1, vol/vol). The methyl esters of fatty acids of the individual lipid classes were prepared using the method described previously (19). Methyl esters were separated by gas–liquid chromatography (GLC) with a 30 m × 0.25 mm Omegawax 320 column (Supelco Sigma-Aldrich Canada Ltd., Oakville, Ontario, Canada) in a Perkin-Elmer AutoSystem gas chromatograph (Perkin-Elmer, Norwalk, CT) equipped with a flame-ionization detector. Fatty acids were identified by comparison with authentic standards, and peak areas were converted to weight percentages with flame-ionization detector response correction.

Prostanoid analyses. Frozen tissue samples were analyzed for prostanoids essentially as described by Abeywardena *et al.* (20). Briefly, the samples (approximately 100 mg) were minced, washed several times in Tris-EDTA with the washes removed by rapid centrifugation, and the washed tissues were reconstituted in a modified Tyrode's solution. This preparation was in-

cubated at 37°C for 45 min on a shaking water bath, after which the tubes were cooled on ice for 5 min and centrifuged. The supernatants were acidified with 1 N HCl, extracted with ethylacetate, and analyzed for prostanoids as described below. Plasma samples (stored at −86°C in the presence of EDTA and indomethacin) were also acidified and extracted with ethylacetate. The samples were first purified and concentrated by passage through either C2 or C18 Amprep™ Minicolumns (Amersham Canada Ltd., Oakville, Ontario, Canada). Levels of prostaglandin (PG) E_2, thromboxane (TX) A_2 (measured as TXB_2), and prostacyclin (PGI_2, measured as 6-keto-$PGF_{1\alpha}$) were determined in sample aliquots by enzyme immunoassay; $PGF_{2\alpha}$ was measured using radioimmunoassay. All assays were done with kits from Amersham, and color intensities in wells of the enzyme immunoassay plates were read using a Bio-Rad Model 3550 Microplate Reader (Bio-Rad, Mississauga, Ontario, Canada). It was appreciated that there could be some cross reactivity of the antibodies with the trienoic prostanoids.

Quantitation of lipid peroxide products. Tissue levels of LPO were quantitated using a combination of colorimetric and high-performance liquid chromatography (HPLC) methods, essentially as described by Wong *et al.* (21). Organ homogenates or plasma were incubated under acidic conditions with thiobarbituric acid (TBA) to form TBA-reactive substances (TBARS). LPO-specific TBARS were isolated and quantitated using a Varian high-performance liquid chromatograph (Model 9010) equipped with a 25 cm C_{18} column that was attached to a 2 cm LC-18 guard column, frit filter and 50 µL sampling loop. The eluting solvent was methanol/50 mM phosphate buffer (pH 6.8; 2:3, vol/vol), which was filtered and degassed prior to use. Flow rate was 1.5 mL/min. After the columns had been equilibrated for 30 min with methanol/buffer, samples were injected and absorbance was monitored at 532 nm for 10 min. Mean elution time for the LPO-TBARS was 3.6 min. Products were quantitated by comparison with peak heights of TBARS products of known amounts of the standard, 1,1,3,3-tetramethoxypropane.

Colorimetric analyses. Protein was analyzed according to Lowry *et al.* (22) using bovine serum albumin as a standard. Total cholesterol (TC) and TAG were quantitated using kits from Sigma Chemical Co. and Diagnostic Chemicals, respectively.

Statistical analysis. Data are expressed as mean ± SEM. They were analyzed for statistical significance by a one-way analysis of variance using a Bonferroni correction factor for multiple testing. Differences were considered to be significant when $P < 0.05$.

RESULTS

Growth and diet tolerance. Weight gains and growth rates were similar for all dietary groups, as we had found in an earlier study (5), although guinea pigs fed the nonsupplemented NP diets ate approximately 30% more food each day than did those in the oil-supplement feed groups. As the NP and oil-supplemented diets differed in caloric densities, and since animals fed the latter ingested lower amounts of other nutrients (e.g., vitamins, protein,

[a]Data are the means of values from analyses of 3-4 different food lots, each of which was analyzed in duplicate following the same procedure as that given for the tissue samples.
[b]PUFA, polyunsaturated fatty acids; CO, corn oil; MO, menhaden fish oil; SLO, harp seal oil; SFA, saturated fatty acids; MUFA, monounsaturated fatty acids. Fatty acids are abbreviated as number of carbons:number of double bonds. The n-x refers to the position of the first double bond, relative to the methyl terminus of the fatty acid.

fiber), comparisons between them are not valid. However, data for the NP group are included in the tables and figures, as there are very few reports of lipid and fatty acid profiles for guinea pigs on standard laboratory diets. Based on the average food consumption per day and the proportions of fatty acids in the diets (Table 1), the MO- and SLO-fed guinea pigs ingested approximately 1.8 and 1.2 g n-3 PUFA/kg/d, respectively. Those fed CO consumed <0.05 g of n-3 PUFA/d. The levels of antioxidants and cholesterol consumed with each diet are shown in Table 2. The animals tolerated the oils well, and there was no evidence of diarrhea. The only difference in overall appearance between the groups was that the guinea pigs fed the seal oil-enriched diets had particularly healthy coats and long, hard nails. Under light microscopy, the hearts and livers showed no evidence of pathological effects attributable to the diets, including very little fatty steatosis. On autopsy, the only tissue that appeared to be affected by diet was the epididymal fat. There were significant differences between the relative weights of the fat pads, as those from the MO-fed guinea pigs were significantly lighter (0.35% of total body weight) than those from either the SLO- or CO-fed groups (0.44–0.49% of total body weights) ($P < 0.0001$). Physically, the MO fat pads were amorphous and very sticky, resembling those of the NP animals, whereas those of the SLO and CO groups were much more solid and cohesive.

Diet effects on plasma and organ TAG and TC levels. Only in the plasma were TAG and TC levels significantly altered by diet (Table 3). The TAG were significantly higher in the CO-fed guinea pigs than in those fed either MO ($P < 0.005$) or SLO ($P < 0.0001$). The highest levels of plasma TC were also in the animals fed CO, although differences were significant only relative to the MO group ($P < 0.02$). Values for plasma TAG or TC were not significantly different between the MO and SLO groups.

Effects of the diets on fatty acid class profiles. Fatty acid analyses were carried out on the total PL and/or TAG fractions of tissues and plasma (Table 4). The only significant difference in total saturated fatty acids was in the heart, where their proportions in the TAG of MO-fed animals were significantly (≈25%) higher than those in either the SLO or CO groups (data not shown). With the exception of the plasma PL, levels of monounsaturated fatty acids (MUFA) in the SLO-fed guinea pigs were all significantly higher than those in both MO and CO groups (Table 4). This may have reflected the higher levels of MUFA in the SLO diet (Table 1). Proportions of n-6 PUFA were consistently ≥2-fold higher in the animals fed CO, and differences between these and marine oil-fed animals were greatest in the TAG. In heart and adipose TAG, n-6 PUFA were significantly higher with MO than with SLO feeding ($P < 0.001$). Not surprisingly, total n-3 PUFA were elevated significantly in plasma and in all organs of marine oil-fed guinea pigs (Table 4), including brain (not shown). Levels of n-3 PUFA in the MO group were significantly higher than those of SLO-fed animals in the TAG of heart, plasma, and adipose tissue (all $P < 0.001$).

TABLE 2
Antioxidant and Cholesterol Contents, and Peroxide Values, of Dietary Oils

[a]Data represent percent, relative to total fatty acids.
[b]Male albino guinea pigs, 10 to 14 d of age and weighing 120–240 g, were fed NP or NP supplemented (10%, w/w) with MO, SLO, or CO for 23 to 30 d. The animals were killed with an overdose of euthanol, and organs and blood were taken as quickly as possible as described the Materials and Methods section. Lipid classes were separated by thin-layer chromatography and methylated, and the fatty acid methyl esters were separated and quantitated as described in the text. Data are the means ± SEM of values obtained from 4 to 9 animals. For each data group in a column, differences in roman superscript letters indicate statistical significance. PL, polar lipid; TAG, triacylglycerol; Adipose, epididymal fat. For other abbreviations see Table 1.

Effects of the diets on major n-3 and n-6 PUFA. Literature reports have suggested that EPA, DHA, 22:5n-3DPA and arachidonic acid (AA, 20:4n-6) have distinct biologic functions (see Discussion). Accordingly, a major objective in this study was to determine whether the MO and SLO diets resulted in differences in the organ/plasma levels of each of these fatty acids. As shown in Table 5, MO-fed guinea pigs had maximal incorporation of EPA into plasma TAG, where levels were significantly higher than they were for SLO-fed animals ($P < 0.0001$). Indeed, EPA levels in all TAG fractions were consistently higher in the MO group than in the SLO group. In contrast, relative to the CO group, SLO-fed animals had the greatest increase in EPA in the heart PL. With both MO and SLO feeding, the greatest increases in DHA, relative to the CO group, were in plasma TAG, although liver PL had the highest DHA content (≈17% of total fatty acids) in both marine oil groups. As with EPA, proportions of DHA were consistently higher in the MO-fed group than those in SLO-fed animals in the TAG fractions of plasma

[a]Data represent percent, relative to total fatty acids. nd, Not detected; for other abbreviations see Tables 1 and 3.
[b]Male albino guinea pigs, 10 to 14 d of age and weighing 120–14 d of age and weighing 120–240 g, were fed NP or NP supplemented (10%, w/w) with MO, SLO, or CO for 23 to 30 d. The animals were killed, and organs and blood were taken as quickly as possible, flash frozen and stored at −86°C (see Methods section). Lipids were extracted as described in the Materials and Methods section, and lipid classes were separated by thin-layer chromatography. Lipids were transmethylated and the fatty acid methyl esters were separated by gas–liquid chromatography, and identified by comparison with authentic standards. Data are the means ± SEM of values obtained from 4 to 9 animals. For each data group in a column, differences in superscript roman letters indicate statistical significance.

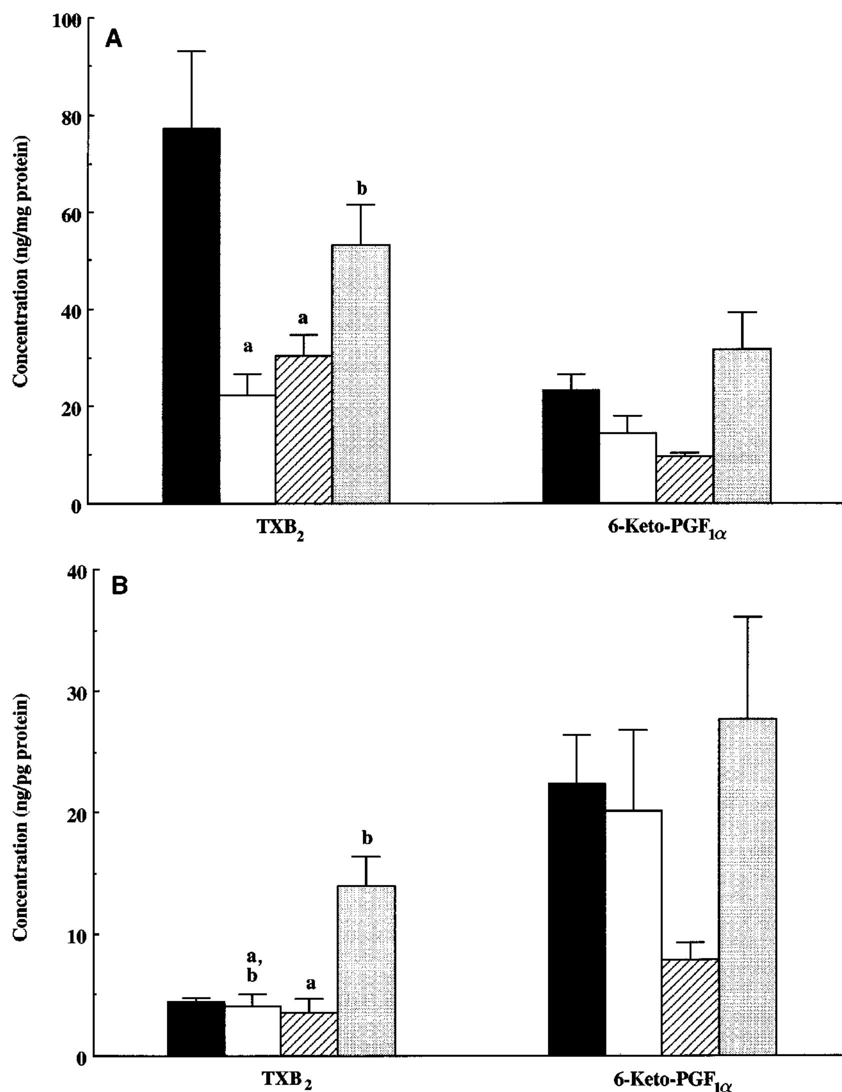

FIG. 1. Levels of thromboxane B_2 (TXB_2) and (6-keto-prostaglandin $F_{1\alpha}$ ($PGF_{1\alpha}$) in heart (A) and liver (B) of guinea pigs fed nonpurified diet (NP, solid block) supplemented (10%, wt/wt) with menhaden fish oil (MO, open block), seal oil (SLO, cross-hatched block) or corn oil (CO, stripped block). The guinea pigs were fed the diets for 23-28 d, after which they were killed. Organs were quickly harvested, flash-frozen, and stored at −86°C. Prior to analysis they were minced and incubated as described in the Materials and Methods section. The samples were purified by passage through Amprep™ minicolumns (Amersham Canada Ltd., Oakville, Ontario, Canada), and analyzed by enzyme immunoassay. The data are the means ± SEM of values obtained from 4–9 animals from two different dietary studies. Differences in letters above data bars indicate differences are statistically significant by student's *t*-test with Bonferroni correction factor.

($P < 0.05$), heart ($P < 0.005$), and adipose tissue ($P < 0.005$). Although its levels are often not reported, DPA can be present in appreciable amounts in mammals, particularly in heart and plasma. Remarkably, it was the major n-3 PUFA in heart PL of CO-fed guinea pigs. In both MO- and SLO-fed guinea pigs, the greatest increases in DPA were in the plasma TAG (22- to 25-fold increases, relative to CO), although its highest proportions were in the heart TAG. In all PL there were significant differences between levels of DPA in the MO vs. SLO groups, as exemplified in the heart PL, where values for the SLO animals were 63% higher than those for animals fed MO.

The effects of the marine oil diets on proportions of AA in plasma and organs were very surprising, as the only decrease in AA levels (relative to values with CO-fed animals) was in the heart PL of SLO-fed guinea pigs (Table 5). Otherwise, all samples and fractions had proportions of AA that were either unchanged or even increased; for example, the AA content of plasma PL and TAG of MO-fed animals was ≥3-fold higher than in the CO group. In all samples but plasma and liver, values for AA in the MO group were significantly higher than those for the SLO group.

Prostanoid levels in MO-, SLO-, and CO-fed guinea pigs. The effects of the diets on synthesis of TXA_2, PGI_2, PGE_2, and $PGF_{2\alpha}$ were determined in heart, liver, plasma, and brain. TXA_2 and PGI_2 were measured as TXB_2 and 6-keto-$PGF_{1\alpha}$, respectively. The only appreciable effects of the marine-oil diets on

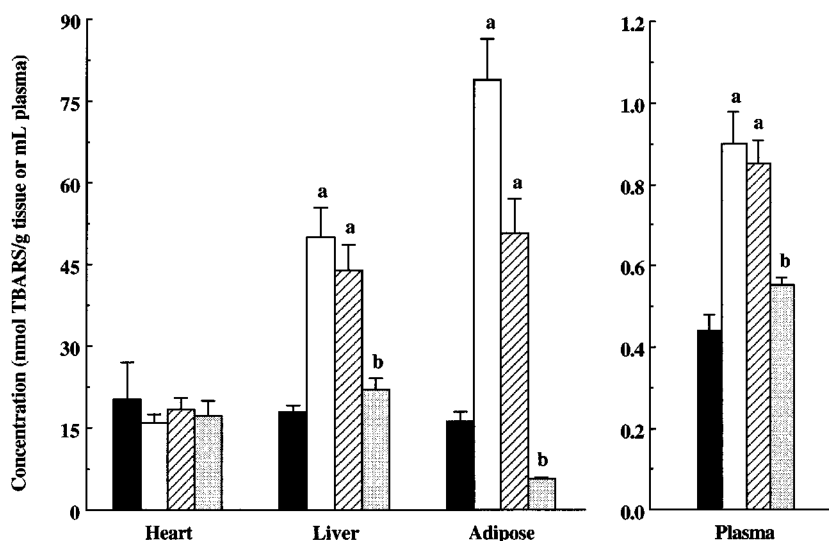

FIG. 2. Levels of thiobarbituric acid-reactive substances (TBARS) in organs and plasma of guinea pigs fed NP supplemented with MO, SLO, or CO (10%, w/w) for 23–28 d. The guinea pigs were killed with euthanol, after which organs were quickly harvested and plasma separated from whole blood. All samples were flash-frozen and held at −86°C prior to analysis. Data are the means (± SEM) of values obtained from 4 to 9 different animals. For each data bar, differences in letters above data bars indicate that differences are statistically significant.

the prostanoid synthesis associated with organ harvesting were in the hearts and livers. In the hearts (Fig. 1A), levels of TXB_2 in guinea pigs fed MO or SLO were consistently lower than those in CO-fed animals, although differences reached statistical significance only between the MO and CO groups ($P <$ 0.03). 6-Keto-$PGF_{1\alpha}$ measured in the heart preparations was also lower in the marine oil-fed animals, and was lowest in those fed SLO. As shown in Figure 1B, levels of TXB_2 were approximately threefold lower in liver homogenates from marine oil-fed than in CO-fed guinea pigs, although differences were statistically significant only between the SLO and CO groups ($P <$ 0.03). Liver homogenate 6-keto-$PGF_{1\alpha}$ was also lowest in the SLO-fed animals. There were no apparent differences in levels of PGE_2 or $PGF_{2\alpha}$ in preparations from either the hearts or livers (not shown). In plasma and brain, measured levels of prostanoidwere not altered significantly by dietary marine oils.

Effects of the diets on TBARS levels. One concern regarding ingestion of high levels of n-3 PUFA is that they could increase concentrations of potentially harmful LPO. As shown in Figure 2, there were no diet-related differences in levels of TBARS in the guinea pig heart homogenates. There also were no significant differences between TBARS in brain homogenates, although values for brain homogenates from SLO-fed animals were only about 75% of those in either the MO or CO groups (not shown). By contrast, homogenates of livers and adipose tissue, as well as plasma from guinea pigs fed either MO or SLO, were all higher in TBARS than were those from the CO-fed animals. There were no significant differences between values for the MO and SLO groups, although those for the SLO group were consistently lower, possibly reflecting a lower total dietary PUFA content. It was of interest that TBARS levels were appreciably higher in adipose homogenates from animals fed the NP diet than in those from the CO group.

DISCUSSION

This study provides a comprehensive analysis of the effects of dietary n-3 PUFA on guinea pig organ and plasma fatty acid and lipid profiles, and on generation of biologically active prostanoids and lipid peroxides in tissue homogenates. It confirms previous suggestions that when this species is maintained on standard laboratory diet it is relatively deficient in n-3 PUFA (11) and demonstrates that relatively short periods of marine oil feeding dramatically increase the n-3 PUFA content of major organs and plasma. It has been pointed out that relative n-3 PUFA deficiencies are appearing in an increasingly large sector of the Japanese population, and also in North Americans (23). The ability to reverse such deficiencies biochemically raises the question of the importance of the source of the marine oil, and this is one of very few studies to address this.

Much of the current interest in dietary marine oils concerns their effect on circulating levels of TAG and cholesterol. In the guinea pigs, only the plasma exhibited n-3 PUFA-dependent changes in quantities of these lipids (Table 3). The MO- and SLO-fed groups exhibited similar reductions in plasma TAG (≈55%) and TC (≈25%) levels, relative to levels in animals fed the CO diet. A significant hypotriglyceridemic effect has been reported to occur also in rats and swine but in few other species (see 24 for refs.), and the effect in rats may depend on the source of marine oil (4). Humans whose diets were supplemented with fish or flaxseed oils have been reported to have an average 25% reduction in circulating TAG (25,26), which is

less than that which we observed in the guinea pigs. There are several possible explanations for the more pronounced hypotriglyceridemic effect in the guinea pigs. First, we calculated the reductions relative to animals fed diets high in CO, and the comparator diets in humans probably did not contain similarly high proportions of n-6 PUFA. It may also reflect interspecies variability in the extent to which n-3 PUFA regulate metabolic events that determine circulating TAG levels, including the degree of inhibition of hepatic TAG synthesis (25). Data from the recent study of Ikeda *et al.* (26) support the idea of species differences, since rats fed either squid (fish-type oil) or seal oil had levels of liver TAG that were >20% lower than levels in safflower-fed controls (27), whereas in the guinea pigs, liver TAG levels actually increased slightly relative to the CO controls (Table 3). As with the TAG, discrepancies between humans and animals in the effects of n-3 PUFA on plasma cholesterol may reflect differences in comparator diets and/or interspecies differences. In humans, fish oils appear either to have no effect or even to increase TC slightly (24,26), whereas most commonly used laboratory species (4,24, and refs.), and the guinea pigs (Table 3) have reduced levels of TC with n-3 PUFA feeding. With respect to marine oil specificity in altering plasma lipids, we did not find any significant differences between the MO and SLO groups in terms of their effects on TAG or TC levels. By contrast, one of the first studies to compare the effects of seal and whale oils vs. fish oil in healthy humans found that, relative to control subjects who were not given oil supplements, serum TAG levels were reduced significantly by cod liver oil but not by SLO or whale oil (26). The authors proposed that the more pronounced effect of the fish oil was due to its specific *sn*-2 positioning of EPA, the n-3 PUFA that has been suggested as being specifically responsible for reducing circulating TAG (28). However, it could also reflect the 40% higher proportion of EPA in the cod liver oil. MO also has a higher proportion of EPA (relative to SLO) and it is in the *sn*-2 position, yet in the guinea pigs, plasma TAG levels were the same for both groups. Again, this could reflect a species-specific difference in the extents to which marine mammal oils and fish oils regulate lipid metabolism.

Data from two Norwegian studies indicated that the relative proportions of total n-3 PUFA in serum lipids of humans fed seal, whale, or cod liver oils reflect the relative content of these PUFA in the different diets (26,29). Similarly, the higher proportions of total n-3 PUFA in the plasma lipids of MO-fed guinea pigs (relative to SLO, Table 4) were consistent with the higher proportions of total n-3 PUFA in the MO diet (Table 1). This apparent dose response relationship for total n-3 PUFA was true only of the tissue TAG (heart, adipose), which we (5) and others (30) have proposed is a good indicator of dietary fat intake. This may not be true of rats, since Ikeda *et al.* (27) reported that, when two groups of rats were fed different marine oils that had equivalent levels of total n-3 PUFA, the resulting total n-3 PUFA levels were equivalent in liver phospholipids but were very different in liver TAG.

One n-3 PUFA that warrants brief mention is the frequently ignored DPA (22:5n-3). Although it constituted less than 3 and 2% of the SLO and MO diets, respectively (Table 1), DPA accounted for ≥10% of total n-3 PUFA of heart PL and ≥20% of total n-3 PUFA in the TAG of heart in animals fed these diets (Table 5). Even more surprising was the fact that it was quantitatively the most important n-3 PUFA in heart lipids of animals fed CO. This apparent concentrating of DPA in heart lipids was also seen in rats fed MO (4,31) or soybean oil (4), which tempts us to speculate that it plays a specific role in cardiac function. To date, however, the only property that has been attributed specifically to DPA is an antiatherogenic one (32).

Strong support for the concept that there are species-specific differences in regulation of fatty acid metabolism came from our observation that marine oil diets affected plasma and organ levels of AA in guinea pigs in a very different manner from that in rats. For example, although standard laboratory diets for rats and guinea pigs both contain high levels of n-6 PUFA, levels of AA in plasma phospholipids from rats (14–27 mol%) (4,27,33,34) are considerably higher than those of guinea pigs (4–8 mol%) (35; Table 5). Lower levels (4–10 mol%) are also reported for humans (26,29,33,36). Feeding fish-oil has been shown consistently to reduce AA levels in rats, whereas in humans and guinea pigs (e.g., Table 5) they either remain the same or even increase, as can be seen in the plasma PL of the MO-fed animals. However, we cannot rule out the possibility that reductions in plasma AA are dose and/or time dependent (37). The lack of change or increases in levels of AA in n-3 PUFA-fed guinea pigs occurred in all tissues with the exception of heart (Table 5). The consistently lower levels of AA in SLO-fed animals could be the result of a more effective inhibition by SLO of the Δ-6 desaturase that converts linoleic acid (18:2n-6) to AA (38). In some samples (e.g., plasma, liver) this is supported by the observation that levels of linoleate in the SLO group were significantly higher than they were in MO-fed animals, in spite of the fact that both marine oil diets had the same linoleate levels (Table 1). Regardless of mechanism, the importance of species- and/or oil-specific differences in effects on AA levels has been attributed their ability to modifiy endogenous eicosanoid production (39).

Although differences in experimental approaches make it difficult to compare literature data in a meaningful manner, it appears that dietary n-3 PUFA generally lower levels of TXA_2 in blood/vascular components of both rats (27,33,34) and humans (29,33,37,40) and have less effect on PGI_2 (34,40). In the present study, the fact that there were no appreciable diet-dependent differences in prostanoid levels in the guinea pig plasma (not shown) could be due to a true species-dependent difference in n-3 PUFA regulation of prostanoid synthesis, including an undetected compensatory increase in TXA_3 production. Previous studies have suggested that there is a species difference in ability to form PGI_3 from EPA (33). Alternatively, it could merely reflect the lack of difference between substrate availability in the marine oil and CO diets, since in the heart homogenates where AA levels were reduced by marine oil feeding, TXA_2 and PGI_2 were both reduced by 40–70% in the MO- and SLO-fed animals (Fig. 1A). Similar n-3 PUFA-dependent reductions in these

PG have been observed in marmoset monkey heart (20,41) and in rat heart (42,43) and cardiomyocytes (44). These demonstrations that n-3 PUFA modulation of cardiac eicosanoids may be physiologically relevant, as Leaf and colleagues recently demonstrated that TXA_2 induces arrhythmic activity in cultured neonatal rat myocytes, whereas PGI_2 attenuates beat rate and arrhythmic activity (45).

The role of dietary fat in tissue injury, due to increased LPO and free radical formation, has generated considerable interest and controversy, since the high degree of unsaturation of n-3 PUFA could theoretically promote cardiovascular disease and cancer (46,47). An interesting finding in the present study was that, although the marine oil-dependent increases in n-3 PUFA in the heart were of approximately the same magnitude as those in the plasma and adipose tissue (Table 4), there were no increases in TBARS in hearts of guinea pigs fed MO or SLO (Fig. 2). Similar types of discrepancies between organs and oxidative stress markers have been described in rats (48). Studies done with guinea pigs suggest that discrepancies may be related to numerous factors, including organ-specific differences in antioxidant enzyme levels (49) or activities (50), and/or in levels of antioxidants such as ascorbate and α-tocopherol (51). The effects of different dietary PUFA on any of these factors could also vary between organs (52), although data from the present study suggest that in organs (and plasma) where there are increases in TBARS levels in response to n-3 PUFA-rich marine oils (e.g., in liver), the increases are independent of the type of oil fed.

In summary, this study has provided new information regarding the effects of dietary marine oils on the lipid profiles and fatty acid metabolite levels in plasma and homogenates of major organs of the guinea pig. We found that in several respects, feeding seal oil produces metabolic profiles that differ from those produced with feeding fish oil. Equally significant, our data lend support to Harris' earlier suggestion (24) that there are potentially important species differences in fatty acid and lipid metabolism, and that in many respects responses of humans to dietary n-3 PUFA can be mimicked better in guinea pigs than in rats.

ACKNOWLEDGMENTS

The authors would like to thank Gateway Maritime Inc., Brigus, Newfoundland, Canada, for the seal oil and the U.S. Department of Commerce, National Marine Fisheries Services, Southeast Fisheries Science Center, Charleston, SC, for the MO. We also thank Dr. Geoff Rowden for the microscopy, Dr. F.B. Palmer for use of the platereader for the prostaglandin analyses, and Ms. J. Evans for careful reading of the manuscript. This investigation was supported by the New Brunswick Heart and Stroke Foundation and Gateway Maritime Inc.

Docosahexaenoic Acid in the Infant and Its Mother

Sir:

The potential role of 22:6n-3 (docosahexaenoic acid, or DHA) as a necessity for the development of the central nervous system, especially in the third trimester of gestation of the full-term human infant, is widely recognized (1–5). This has led to suggestions that either formulas (6) or maternal blood, and hence milk, should be enriched with DHA (7–9). Even a short period (2–4 mon) of supplementation may have long-term (~12 mon) benefits (10,11).

In many studies with fish oils, popular and reputable products such as MaxEPA® (Seven Seas Health Care Ltd., Hull, United Kingdom), with 180 mg/g of eicosapentaenoic acid (EPA) and 120 mg/g of DHA (12), have been used as sources of DHA. In one study the excess of EPA was presumed to have interfered briefly with the growth of preterm infants by competing with 20:4n-6 (arachidonic acid, or AA), also essential for infant health (2,13). Innis *et al*. (3) concluded, based on comparison with breast-feeding, that healthy term-gestation infants do not require DHA if the precursor 18:3n-3 (α-linolenic acid) is fed in a formula at 2.1% w/w (~10% of energy).

Carlson (2) mentioned that DHA and AA decline in infant plasma and erythrocyte phospholipids following birth. The work of Harzer *et al*. (14) clearly illustrates (Table 1) a similar phenomenon for whole human milk in Germany. Over 36 d AA dropped by nearly half, EPA 12-fold, and DHA by a third. The ratio of EPA to DHA at 36 d was 1:3. Table 2 gives comparable figures from Makrides *et al*. (4) for human milk in Australia; after 16 wk (112 d) the EPA to DHA ratio also stabilized at 1:3, and that ratio was maintained to 30 wk. Similar ratios are seen for milks from the United States collected at 42 d (15) and are also confirmed by Hoffman and Uauy (16) for human milk at day 200 and by Dotson *et al*. (17) for the mean of 30 samples collected at 4, 6, and 8 wk postpartum. An excellent collection of data by Jensen (18) provides other examples of this ratio in countries with dietary fatty acid patterns as diverse as France and Finland. Higher proportions of DHA in particular are recorded, for example by Boersma *et al*. (19) for milks on the island of St. Lucia, and by Jørgensen *et al*. (20) for both EPA and DHA in human milk in Denmark, although the approximately 1:3 ratio for EPA to DHA was observed in the Danish milks over 3 mon. The latter authors reported two cases of the relative concentration of DHA suddenly increasing during the study period for no obvious reason. Excluding these, the DHA proportion declined as expected, the median figures being 0.49, 0.40, and 0.32% at 1, 2, and 4 mon, respectively (*cf*. Table 2). It can be inferred that marine foods are involved in these instances, much as has been recently suggested for the fatty acids of human milks from different parts of China (21). It is of interest that this 1:3 ratio was also employed in the special preterm formula used by Carlson and Werkman (10).

The stabilization of the EPA to DHA ratio in the milk of mothers not receiving special diets may be compared to the data of Henderson *et al*. (9) condensed in Table 3. The mothers were given a diet supplement of a total of 1080 mg of EPA and 720 mg of DHA each day (six fish oil capsules), and this included 6 mg of vitamin E per day. The percentage of EPA increased sixfold in the fatty acids of milk and in the fatty acids of maternal and infant erythrocytes. DHA increased by about 25% in both erythrocyte samples, but only doubled in the milk. Possibly these two n-3 fatty acids displaced saturated acids from phospholipids in erythrocytes; importantly, the EPA increase did not seriously affect the AA level in those lipids. Fatty acid chain length may be a selection factor in the enzymatic processes involved (22).

TABLE 1
Total Fatty Acids (w/w%) of Human Milk[a]

	Day after parturition					
Fatty acid	1	3	5	8	22	36
18:2n-6	9.70	10.30	9.97	10.76	9.96	11.78
18:3n-3	0.60	0.70	0.62	0.69	0.70	0.71

[a]Recorded by Henderson *et al.* (9).
[b]Two weeks postpartum.

The constancy of the EPA to DHA ratio in normal human milk from different parts of the world and its relatively low level after approximately 30 to 40 d of lactation lead to the conclusion that the origins of EPA and DHA are specific and quite unconnected to an obligation on the part of the mother to supply preformed DHA to the infant. Tables 1–3 suggest that the EPA and DHA of human milk are derived from the same source, phospholipids. Neville and Walsh (23) clearly illustrated that the milk fat globule is secreted from the mammary alveolar cell by a "pinching off" process in which the triacylglycerol globule is encapsulated in actual cell membrane. This process is well understood (24,25). This cell membrane phospholipid, which amounts to at least 20% of the human milk fat globule membrane (26), presumably continues to incorporate EPA and DHA under normal conditions in a stable 1:3 ratio after lactation has been active for at least 30 d (Tables 1 and 2). Phospholipid content and some details about fatty acid of human milk globule membranes are shown in Table 4. The total for C_{22} acids is selective and somewhat higher, relative to AA, than the C_{22} acids in the detailed breakdown of whole milk lipids given by Jensen (18). However, in the same review, more of the C_{20} AA was present in the milk triacylglycerols, at about 0.3% of fatty acids. One can conclude that the long-chain n-3 fatty acids, both C_{20} and C_{22}, are derived from the maternal cell wall phospholipids. Bitman *et al.* (28) emphasized that class percentages of phospholipids in milks from mothers giving birth either prematurely or at term are remarkably constant. The origin of the higher levels of polyunsaturated fatty acids at earlier times of lactation (Table 1) is not readily explained, but the recent comments of Al *et al.* (29) that essential and long-chain polyunsaturated fatty acids (AA, DHA) in maternal plasma phospholipids increase considerably during normal gestation are possibly relevant. In maternal plasma phospholipids the total n-3 fatty acids then declined after the 18th wk of gestation (30), presumably as fetal brain development accelerated. Spear *et al.* (31) noticed no EPA at all in fatty acids of full-term human colostrum, but 0.32% of the fatty acids were DHA. These figures reflected respective maternal serum fatty acid EPA and DHA percentages of 0.06 and 1.80%. Colostrum figures are thus quite different from that of the milk at day 1 in Table 1. The subsequent decline in maternal DHA reserves (29) is of concern. Interestingly, the fatty acids of the infant plasma phospholipid fraction of preterm infants fed expressed breast milks had EPA to DHA ratios of 1:7 and 1:5 at the first and fifth week of life, respectively (6). This change was thought to reflect the development of the ability of the infant after 5 wk of life to convert α-linolenic acid to DHA, because maternal milk EPA to DHA should then be stabilized at 1:3.

TABLE 4
Phospholipid Classes and Long-Chain Polyunsaturated Fatty Acids of Human Milk Globule Membrane[a]

	Lipid class					
	PE	PC	SPH	LPC	PI	PS
Percentage of total phospholipids	36.6	29.7	26.2	1.9	4.6	1.0
20:4n-6 (w/w%)	1.0	1.7	1.6	—	—	—
C-22 (w/w%)	3.2	—	5.0	3.9	4.1	6.1

[a]As published by Bracco *et al.* (27). PE, phosphatidylethanolamine; PC, phosphatidylcholine; SPH, sphingomyelin; LPC, lysophosphatidylcholine; PI, phosphatidylinositol; PS, phosphatidylserine.

The ability of the young rat to convert α-linolenate to DHA is not influenced in the short term by linoleic acid (32), an interesting point in view of dietary research in human infants not involving preformed DHA (3,33). When rats were given human breast milk with an EPA/DHA ratio (actual w/w%) of 0.8:1.1, the lymph triacylglycerols had the same ratio (0.5:0.7) while the lymphatic phospholipids had a ratio of 0.8:1.8 (34). One would not expect this to have the 1:3 ratio of human milk, but the phospholipids of the lymph duct wall endoplasmic reticulum seem to show enrichment with respect to DHA relative to EPA when "pinched off" to enclose the basic triacylglycerol-rich part of the chylomicrons (35). The human milk given to the rats (34) came from a woman in the eighth month of lactation. Possibly the low proportion of DHA relative to EPA in her milk confirms the views of Al *et al.* on DHA depletion with lactation time (30).

Few of these concepts are new. Harris *et al.* (36) demonstrated enrichment of human milk with fish oil-derived polyunsaturated fatty acids in 1984. Hall (37) made the point that fatty acids of human milk collected during active feeding are generally uniform in composition (confirmed by Gurr [38]). Many changes outlined in Tables 1 and 2 are not peculiar to human milk. Bitman and Wood (39), for Holstein cows, may be quoted:

> The changes that occurred in milk total fatty acids were reflected in phosphatidyl phospholipid fatty acid compositions: an increase in medium-chain fatty acids and a decrease in polyunsaturated fatty acids of 18, 20 and 22 carbon atom chain lengths as lactation progressed. These changes are consistent with the theory that milk phospholipids are synthesized *de novo* entirely in the mammary gland.

That dietary fatty acids (including fish oil supplements) can modify total milk fatty acid composition through the triacylglycerol fatty acids is well known. In ruminants this ef-

fect is also demonstrable in the fatty acids of the milk fat globule membrane (25).

Bitman *et al*. (28) concluded for human milk that "core lipids are surrounded by a milk fat globule membrane which was identical in the milk of mothers of premature and term infants in all stages of lactation." However, modifying the maternal diet with regular amounts of supplemental DHA increased the amount of DHA in milk as shown in Table 3, counteracting the normal decrease with time shown in Tables 1 and 2. It is not known if this result reflects changes in fatty acids of triacylglycerols, smaller milk globules with a higher proportion of membrane phospholipid, or a modification of the fatty acids of that membrane. Effects of dietary fats on human milk are usually considered to be short-term. However, an important distinction has been noted for EPA and DHA. After fish oil ingestion these two fatty acids remain elevated in milk for up to 3 d (40). Because of uncertainty about temporary storage of EPA and DHA in adipose tissue and about mobilization (41), one cannot state with certainty that this retention of EPA and DHA is due to changes in the maternal cell phospholipids. The proportions and positions of additional DHA in milk triacylglycerols seemingly have not been reported, although obtaining this information is technically feasible.

The erythrocytes of both mother and nursing infant are accessible models for studying changes in DHA proportions in milk phospholipids (4,9). Recently Jørgensen *et al*. (20) compared EPA and DHA in the phosphatidylcholine and phosphatidylethanolamine of infant erythrocytes from 1 to 4 mon postpartum. These two fatty acids declined slightly, but in parallel, in the phosphatidylcholine from breast-fed and formula-fed groups. This confirms the report for the latter lipid published by Innis *et al*. (42) for very low birthweight infants. When term infants were fed α-linolenic acid (no DHA) at varying levels (33) DHA was observed to decrease in total erythrocyte phospholipids over 21 to 120 d, while EPA doubled in the same period. Because of controversies over digestion in the neonate, more comparisons of phospholipid fatty acids of erythrocytes with those of milk membranes are urgently required to determine how closely this parallel can be extended (5). Consideration should also be given to the route by which supplemental DHA in formulas is digested and distributed in the infant body because it may differ between triacylglycerols and phospholipids and because not all currently available fish oils or other sources of DHA supplementation are "natural" in the distribution of DHA on glycerol (43,44). Finally, it is now obvious that the emphasis on long-chain n-3 fatty acids for the development of the neonate cannot be separated from the nutritional aspects of the same fatty acids in the mother, particularly in view of the increasing prevalence of breast-feeding.

SYMPOSIUM

PUFA in Infant Nutrition: Consensus and Controversies

Susan E. Carlson[a], Berthold Koletzko[b], and Robert A. Gibson[c]

[a]Schools of Nursing and Medicine, University of Missouri-Kansas City, Kansas City, Missouri 64108, [b]Division of Metabolic Diseases and Nutrition, Kinderklinik and Kinderpoliklinik, Dr. von Haunersches Kinderspital, University of Munich, Germany, and [c]Child Nutrition Research Centre, Flinders Medical Centre, Bedford Park (Adelaide), SAS 042, Australia

The AOCS-sponsored meeting on "PUFA in Infant Nutrition: Consensus and Controversies" was held November 7–9, 1996, in Barcelona, Spain. A total of 375 technical registrants from 39 countries attended. The focus of the meeting was on polyunsaturated fatty acid (PUFA) status of mothers and infants, PUFA metabolism, visual and neural development as related to long-chain (LC) PUFA status, safety, and other industry issues. One session included a review of the status of LCPUFA regulation and recommendations that have come from different committees. No attempt was made to reach a consensus on need, as such an attempt would have been inappropriate for a research meeting. Over 100 abstracts and posters were presented within the broad category of LCPUFA and infant development.

The meeting was conducted as an advanced workshop using a "new" concept that mandated more discussion than usual in scientific symposia. The regular sessions were 2 h long, and the time was divided equally between state-of-the-art lectures (to bring participants to some common ground on the topics) and discussion (to enhance communication on the topics among scientists from academia, government, and industry). By providing an opportunity for dialog among these groups, the intent was to encourage them to reach a consensus on the state of the field and to share perceived needs on directions for new work.

At the meeting, the first two sessions provided essential new information about brain development relative to LCPUFA and neonatal PUFA metabolism. These were followed by sessions devoted to studies of LCPUFA and visual and neurodevelopment, especially to critical analyses of the randomized trials that were published before the meeting. A session was devoted to biological effects of LCPUFA other than neural function during development. The consensus was that there is a need for balance between n-3 and n-6 LCPUFA for optimal biological function, with the understanding that the definition of optimal balance and the role that intake of essential fatty acids and LCPUFA play in achieving it may only be defined by further research. The last session was devoted to issues of industry and regulatory groups, especially the issue of safety.

In addition to the regular sessions, workshops provided technical direction for investigators and sponsors planning new work within the broad area of PUFA in infant nutrition. Some of these were directly related to regular sessions, but most of the workshops had a clinical orientation. The organizers were aware that larger trials with infants were a perceived need and realized that many working in the LCPUFA area had little experience with randomized clinical trials (RCT). For those planning new exploratory studies of LCPUFA and development, one workshop dealt with confounding and mediating variables in studies of human neurodevelopment. Another discussed issues essential to the conduct of RCT, particularly how to design studies with sufficient statistical power to reject or accept the null hypothesis. Other workshops provided directions for new studies to explore the basic or mechanistic effects of LCPUFA. Papers from the discussion leaders and workshop directors are included in this issue of *Lipids,* and they provide a state-of-the-art summary of the topics introduced above.

There is a need to look at more outcomes that can be related to n-3 fatty acid deficiency in human infants with different n-3 LCPUFA status. RCT designed to study outcomes affected by LCPUFA status in smaller clinical trials are also needed. Study designs, methods, and populations need to be carefully chosen in future clinical studies and related to the smaller published trials. A study that adheres strictly to RCT methodology, but that is poorly designed or based upon a lack of understanding of the biology of LCPUFA, may be technically excellent but have no biological meaning and value. Because the published effects of feeding LCPUFA on behavior have been small, an additional need for RCT is that they account for evaluator differences, which may mask differences in neural function if adjustments are not made in calculating the statistical power for the study. Because the design of better clinical trials was a major goal of the meeting, the organizers agreed that the true success of the meeting could not be evaluated until the design, methods, and results of new clinical trials are available.

Finally, it was noted that mechanistic studies of the effects of LCPUFA in neural development and in other physiological functions are needed. There appears to be an increased interest in conducting such studies since the meeting was held. We hope that some bases for the physiological actions of LCPUFA and new exploratory and clinical work can be available for presentation at the time of the second international meeting in the Fall 2000 in Kansas City, Missouri.

Brain Development and Assessing the Supply of Polyunsaturated Fatty Acid

M.T. Clandinin

Nutrition and Metabolism Research Group, Department of Agricultural, Food and Nutritional Science and Department of Medicine, University of Alberta, Edmonton, Alberta, Canada

ABSTRACT: Membrane lipids are necessary for structure and function of the developing nervous system. Rapid synthesis of brain tissue occurs during the last trimester of development of the human brain and the early postnatal weeks. This synthesis of brain structure involves the formation of complex lipids, many of which contain significant quantities of chain-elongated desaturated homologs of essential fatty acids. The present report discusses the implications of change in nutritional status on processes of brain development and metabolic events that involve lipids.

Paper no. L7958 in *Lipids 34,* 131–137 (February 1999).

EARLY STAGES

In adult vertebrates, the form of nervous system brain development at early stages is remarkably similar. The distinct character of the neural plate and neural tube, from which the nervous system originates in all vertebrates, suggests that development of the central nervous system occurs through similar overall mechanisms. The cells, regions, and various structures of the brain do not develop uniformly, as in other tissues and organs (1–3). Characteristic, well-defined stages of growth occur anatomically and biochemically (4,5) and result in significant growth spurts or critical periods during fetal and neonatal life. The development of any part of the brain occurs in stages: induction of the neural plate, localized proliferation of cells in different regions, migration of cells, formation of identifiable parts of the brain by cell aggregation, differentiation of immature neurons, formation of connections, selective cell death, and modification of connections (6). These changes within the developing nervous system proceed in a caudal (brain stem) to rostral sequence (7). Caudal brain structures include phylogenetically older brain structures, whereas rostral structures are phylogenetically newer (8). Structural changes in the brain during development result in an increase in weight and size. These increases are not necessarily parallel: the greatest growth in size occurs prior to the greatest gain in weight (9). Different parts of the brain grow at different speeds, and not all regions reach their fastest rates at the same time. In this respect, the "growth spurt" and velocity curves as defined by Dobbing (1,10,11) represent rates of change in total brain weight over time and not individual regions of the brain. The early concepts developed by Dobbing did not encompass the developmental processes that are now understood to be critical periods of growth and highly susceptible to insult. As well, they do not reflect the interrelationships of growth occurring in subregions of the developing brain (12).

Neurogenesis. Most neurons are generated in or close to the ventricular zone of the neural tube. A complex set of factors including neuron type, position in the mitotic gradients, and phylogenetic status determines the time of neuronal origin (7). The number of neurons initially formed in any brain region is determined by three factors: the duration of the proliferative period (which may last a few days to several weeks), the duration of the cell cycle (which in a young embryo is a few hours and increases to 4 or 5 d as development progresses), and the number of precursor cells (6).

Depending on the region of the nervous system (13) and neuron type (7), production of neurons occurs over varying lengths of time with different time schedules for formation. Neurons born first in any given region of the mature nervous system are the phylogenetically older neurons and the larger neurons (7). Large neurons apparently become postmitotic early because they have the longest axons and must reach their targets while the embryo is still small. Neurogenesis peaks around the 14th week of gestation and is completed by the 25th week when the adult number of neurons is present (14). In rats these developmental events occur at about 18 and 20 d of gestation, respectively. Known exceptions that continue to proliferate postnatally include some neurons of the hippocampus and the cerebellum. It is important to recognize that the timetable of neuronal differentiation cannot be simply deduced from its time of origin. The type of neuron, its regional situation, and the timing of the arrival of axons with which synapses will form are factors that also affect neuronal differentiation.

Gliogenesis. Glial cells tend to originate after neurons in any particular region of the brain. Formation of glia differs from neuronal formation in three main ways. First, many of the proliferative cells that generate glia lie outside the neuroepithelium, at or near the site where they will be located in the adult (15). Second, the production of glial cells continues throughout

adult life (7). Gliogenesis is primarily a postnatal event (16); however, in some brain regions it is detected before birth (16,17). Early gliogenesis is completed by the 15th week of gestation in humans and the 16th day of gestation in rats (12). Third, damage to the glial population is rarely permanent (18–20). However, it is known that a qualitative unbalance or quantitative deficit of food intake produces alterations in the ontogeny and function of the nervous system (21–24).

Making connections with function. Because most nerve cells are generated at or close to the inner, proliferative surface of the neural tube, they subsequently migrate past other cells to their final locations. The temporal origin of neurons may be related to later establishment of anatomical connections (15). There are two spatiotemporal gradients for neuron migration. In nuclear regions of the brain (such as the thalamus and hypothalamus), the oldest neurons produced by the neuroepithelium are pushed farther out as the younger neurons are generated. In these regions, cells accumulate in an "outside-in" or "pushing" gradient (25). The "inside-out" or "passing" gradient occurs in regions of the brain that have a laminar structure (such as the cerebral and cerebellar cortices). Cell accumulation in these regions occurs as younger neurons migrate past the older neurons, which remain closest to the neuroepithelium (26). Despite the heterogeneity of the cell population in the nervous system, the development of the system's complex form is reliable. The developmental program of the nervous system must contain mechanisms for neurons to migrate to their proper destination. This arrangement of neurons must be completed successfully for normal functioning to result.

Functional connections in the nervous system are established through growth of neurites (axons and dendrites) and formation of synapses. Synaptogenesis is the contact between axons and target cells that starts before neurogenesis is completed (27) and follows a cell-specific, region-specific timetable. Most neurons generate and receive many processes, producing many more synaptic connections. A period of programmed cell death and synapse reorganization follows as the final stages of brain morphogenesis. Stages of brain morphogenesis ensue in each brain region in a specifically timed series of events. Each period becomes a critical basis for development of the next (28). Time scales occurring in each brain region are further complicated by migration of cells between regions. Due to the brain's general lack of regeneration potential and its dependence on specialized interactions, any misdirected, mistimed, or absent developmental cues can lead to structural aberrations (29). These structural changes are irreversible and result in functional deficits if future developmental changes are unable to compensate for these structural changes. Thus, insults that alter brain development in the fetus or neonate may permanently alter a myriad of functions in later stages of infant development.

BRAIN LIPIDS AND NUTRITION

Second only to adipose tissue, the brain is the most lipid-concentrated organ in the body. Nervous tissue contains 50% lipid on a dry weight basis, or 10% lipid on a weight/weight basis (30). This lipid plays a role in modifying the structure, fluidity, and function of brain membranes (31–36). A variety of complex lipids exists in the brain, and the composition and metabolism of these lipids change with development and age (37–39).

Fatty acid accretion in the brain. One approach to determining the fatty acid needs of the developing infant is to determine the fatty acid composition during infant growth and quantitate the accretion of fatty acids in body tissues. Although this approach seems simple, it may be hampered by not knowing whether fetal development is the optimal model for the assimilation of fat accretion during the extrauterine growth of infants born prematurely. It should be noted that a difference in the deposition and net absorption of fat exists between perinatal and postnatal growth (40). Accretion of essential fatty acids in adipose tissue during the last trimester of intrauterine development was estimated by using data on net fatty acid accretion and values for adipose tissue fatty acid composition (41). The average accretion rates determined are consistent with the fat deposition estimated by indirect calorimetry for preterm infants fed 120 kcal/kg/d (42). Based on the assumption that tissues not quantitatively analyzed have a total fat and essential fatty acid content similar to that of skeletal muscle (41), minimum values for essential fatty acid utilization in tissue synthesis during the last trimester of intrauterine growth were estimated. Estimates for utilization in *de novo* synthesis of tissues were approximately 522 mg/d of n-6 fatty acids and 67 mg/d of n-3 fatty acids (41). These values are minimal levels, as consideration was not made for the amounts of fatty acids oxidized to meet the energy requirements for tissue accretion. More information about the proportion of fatty acids used in energy metabolism and tissue synthesis is needed before information about body composition can be applied to a practical feeding situation. Proportions of major dietary fatty acids consumed may potentially affect the net contribution of fat oxidation to total energy production (43). This observation was made in adult males; however, it suggests that changing the balance of nonessential to essential fatty acids in the diet affects how fat oxidation is partitioned for energy production.

Analyses of whole-body fat content (44,45) indicate that preterm infants, with an appropriate weight for gestational age of 1300 g at birth, have a total body fat content of about 30 g compared with the term infant of 3500 g with a total body fat content of 340 g. Clandinin *et al.* (46) estimated that approximately 2783 mg of n-6 fatty acids and 387 mg n-3 fatty acids accrue in adipose tissue each week *in utero*. Birth after only a few more weeks of intrauterine development would dramatically increase the potential reserve of fatty acids in adipose tissue both for total fatty acids used for energy production and for essential fatty acids used for synthesis of structural tissues. These estimates also support the body of research by Van Houwelingen *et al.* (47) suggesting that the growing fetus represents a large draw upon maternal essential fatty acid stores and perhaps that a limitation in the size of the maternal essential fatty acid stores may be critical to fetal growth and development.

TABLE 1
Fatty Acid Accretion Rates in Infant Brain and Cerebellum (mg/wk)[a]

	Intra-uterine (26–41 weeks: preterm)	Extra-uterine (0–10 weeks: term)
Total n-6	32.8	82.4
Total n-3	14.6	5.5
Total n-9	31.2	65.5

[a]Data from References 48 and 49.

During the third trimester of human development, n-3 and n-6 fatty acids accrue in fetal tissues as an essential component of structural lipids, and rapid synthesis of brain tissue occurs. This rapid synthesis causes increases in cell size, cell type, and cell number (48). Brain lipid levels increase rapidly during this period. Levels of 18:2n-6 and 18:3n-3 were consistently low in the brain during the last trimester of pregnancy (48). However, accretion of long-chain essential fatty acid desaturation products 20:4n-6 and 22:6n-3 occurred, and the absolute accretion rates of the n-3 fatty acids, specifically 22:6n-3, were greater in the prenatal period compared with the postnatal period (Table 1; 48, 49). It is apparently critical that the developing fetus obtain the correct types and amounts of fatty acids to ensure complete and proper development of the brain. Timing of the availability of these fatty acids is also a factor. Collectively, this quantitative information indicates that large amounts of docosahexaenoic acid (22:6n-3) and arachidonic acid (20:4n-6) are required during development of neural tissue when cellular differentiation and active synaptogenesis are taking place.

Development of the visual system. The entire visual system spans caudal to rostral regions of the brain and includes some lateral areas of the brain. The visual pathway involves a chain of visual processing events that only begin with the retina in the eye. During visual processing, incoming light strikes the photoreceptors and generates electrical signals, which are sent to bipolar cells and ganglion cells. These networks in turn send visual information along the optic nerve to the visual cortex. “Funneling” of information within the eye is the result of an individual neuron receiving, converging, and combining impulses from several incoming nerve fibers. Thus, the separate signals of each nerve fiber are integrated into an entirely new message based on all the inputs. The retinal content of 22:6n-3 normally increases during development, and this change in lipid composition is apparently important to the function of the visual system although it cannot be easily distinguished functionally from the simultaneous increase in 22:6n-3 in the entire visual pathway.

SOURCES OF ESSENTIAL FATTY ACIDS FOR THE FETUS AND NEONATE

The developing fetal brain can synthesize saturated and monounsaturated fatty acids (50,51). High rates of lipogenesis in fetal liver (52) may act as a source of fatty acids for the fetus. Initially the placenta, by controlling the passage of 20:4n-6 and 22:6n-3, determines the amount of these fatty acids available to the fetus, but then the fetus (by its own metabolism) starts to synthesize its own 20:4n-6 and 22:6n-3 (53). The age at which this progression may begin and be completely achieved is not defined. As synthesis of long-chain polyenoic fatty acids by fetal liver has not been clearly demonstrated under physiological conditions, this progression remains hypothetical (53). Thus, the contribution of fatty acid synthesis to 20:4n-6 and 22:6n-3 accumulation by the neonate would be affected by the age of the infant at birth. While *in utero*, it is clear that the fetus relies on the mother for its supply of many fatty acids, particularly the essential fatty acids.

Biomagnification. Crawford *et al.* (54) describe a process in which, compared with parent essential fatty acids, the relative percentage of 20:4n-6 and 22:6n-3 increases in phosphoglycerides progressively from maternal blood to placenta and to fetal blood, liver, and brain. By this process, termed biomagnification, specific mechanisms within the placenta hypothetically result in sequestration and release of specific fatty acids to the fetal circulation. Neuringer *et al.* (55) also reported that, in monkey and human fetuses, the levels of 22:6n-3 and 20:4n-6 are higher in fetal blood compared with maternal blood, whereas the opposite is true for their precursors. Thus, the importance of these long-chain polyunsaturated fatty acids is evident in their preferential, active transfer across the placenta to the fetus in a lipid form normally impermeable to the placental barrier. It has recently been proposed that a more likely mechanism of biomagnification is selective sequestering of long-chain polyunsaturated fatty acids on the fetal side of the placenta (56). King *et al.* (57) found that, when comparing adipose tissue triglyceride between infants and mothers, infants have greater levels of palmitic and palmitoleic acids. The predominance of these two fatty acids in newborns indicates that glucose plays an important role in fetal fat synthesis. Embryonic and fetal lipids in early gestation are derived from maternal fatty acids that cross the placenta, but with advancing gestational age, there is a gradual shift to *de novo* synthesis from glucose in fetal tissue (58).

It is evident that some fatty acids are transferred to the fetus across the placenta. It also appears that the degree of placental and fetal synthesis of fatty acids varies with gestational age (58,59). Clandinin *et al.* (48) reported that 80% of human fetal brain 22:6n-3 accrues between 26 and 40 wk of gestation. These authors also observed that infants born prior to 32 wk gestation have low concentrations of brain 22:6n-3. Early in pregnancy, there is apparently a great dependence on maternal fatty acids to provide the fetus with lipids. This may have important implications for the low-birthweight, premature infant and for the shift of essential fatty acid from maternal stores to fetal tissues during fetal growth.

Altering n-6 to n-3 fatty acid balance in premature infants. Human milk contains both n-6 and n-3 fatty acids. One percent 18:3n-3 and 10 to 15% 18:2n-6 are typical amounts of essential fatty acids in the breast milk fat of North American and European women (41,60). The need to balance n-6 and n-3 fatty acids fed to infants to reflect the overall fatty acid

balance in human milk was proposed by Clandinin *et al.* (61). Moreover, a balance between the levels of very-long-chain C20 and C22 n-6 and n-3 polyunsaturated components was recommended to be 1.4 (61). Based on quantitative analysis of 24-h milk collections, the n-3 long-chain polyenes are present at 0.3–0.6% and n-6 long-chain polyenes at 0.5–1.5% (41,60). Recommended ratios of n-6 to n-3 fatty acids in infant formula have also been suggested to be within the range of 4 to 1 and 10 to 1 (Health and Welfare Canada, 1991) or 5 to 1 and 15 to 1 (62). The concern surrounding an appropriate n-6 to n-3 fatty acid ratio stems from the competition that exists between the n-6 and n-3 series for the Δ-6 and Δ-5 desaturase enzymes. There is also the desire to mimic the composition of fats present in human milk and the effect of feeding this fatty acid balance on the fatty acid composition of various phospholipids in the developing neonatal brain or tissues (61). Studies that have attempted to increase only the n-3 intake by adding marine oil sources to diets have reported a predictable decrease in arachidonate levels in various cellular phospholipids (63–67).

Arachidonic acid status is an important factor in the growth of the fetus and premature infant (41,68). In the fetus and newborn, birthweight is significantly correlated to plasma triglyceride content of arachidonic acid (69). An important consideration in using marine oil sources is that fish oil contains both eicosapentaenoic and docosahexaenoic acid and results in higher levels of n-3 long-chain fatty acids compared with n-6 long-chain polyenes. This produces an unbalanced n-6 to n-3 ratio. Eicosapentaenoic acid may have a greater effect than docosahexaenoic acid on the reduction of arachidonate levels (63,70), which may be due in part to the inhibition of Δ-5 desaturation and competition for insertion into phospholipids. Mohrhauer and Holman (71) reported that the precursor n-3 fatty acid, 18:3n-3, also reduces arachidonate levels. Other groups studying both humans and rats (66,72,73) have since reported this observation. Dyer and Greenwood (32) examined neural long-chain fatty acids in weanling rats in response to a range of 18:2n-6 and 18:3n-3 fatty acid ratios between 1.8 and 165 and concluded that the dietary 18:2n-6 to 18:3n-3 ratio affected membrane fatty acid profile. The level of brain arachidonic acid did not appear to be significantly affected by lower 18:2n-6 to 18:3n-3 ratios.

Effect of dietary 18:2/18:3 ratios on long-chain polyene content of brain. Research on the effect of dietary fat on brain development has generally been limited to undernutrition, malnutrition, or essential fatty acid deficiency and study of animal models. Within what are believed to be essential fatty acid-adequate diets, studies that have focused on altering n-6/n-3 fatty acid ratios have been limited to analyzing the brain as a whole or to considering the response at only one time period. Research in this area has not examined the effect of changes in dietary fat content on lipid composition of different brain regions or different cell types during one of the initial developmental periods. To date, most research has examined the effects of diet on brain composition and inferred effects on neuronal function from behavior. Much less is known about glial cell responsiveness to alterations in nutrient supply in the absence of malnutrition (22). Studies of brain regions have focused primarily on the cerebrum, brainstem, and cerebellum. Few studies have examined the hippocampus, despite the relative ease of isolation and removal of this structure and the fact that it completes development during the postnatal period.

In a recent experiment (74), the fatty acid composition of rat brain cells in different brain regions was examined over time in response to feeding diets varying in fat composition. Diets of similar 18:2n-6 and 18:3n-3 content, with and without small amounts of arachidonic and/or docosahexaenoic acid, were fed to nursing dams. The n-6 to n-3 fatty acid ratios were within the recommended range for infant formulas and varied between 4 to 1 and 7.3 to 1. The cerebellum and the frontal and hippocampal brain regions were excised from rat pups at birth and at 1, 2, 3 and 6 wk of age. Neuronal and glial brain cells were isolated from each brain region. By analysis of the fatty acid composition of ethanolamine-, choline-, serine- and inositolphosphoglycerides, it was apparent that the diets fed altered neuronal and glial cell composition differently and in a region- and time-specific manner. It is thus clear that analysis of whole brain cannot reflect the complexity of changes occurring during development of individual brain regions.

It can be concluded that the temporal development of brain regions is different—the cerebellum and the hippocampus are among two of the regions to complete development postnatally; the timing of development differs between the brain cells—the majority of neurogenesis is complete prior to completion of gliogenesis; and physiological changes in dietary fat affect the fatty acid composition of brain regions and of cell types. The functional implications of these changes in brain structural lipids are still unknown. However, it is certain that feeding small amounts of 20:4n-6 and/or 22:6n-3 will produce remarkable transitions in the fatty acid composition of individual membrane phospholipids during the postnatal growth and development of the brain.

SPECULATIVE RELATIONSHIPS AND COGENT QUESTIONS

The brain is an incredibly complex organ. Connections within the nervous system may exhibit a high degree of variability between individuals and change during the lifetime of each individual (75). These anatomical connections influence learning and memory and ultimately affect how an individual interacts with and adapts to an environment. Confounding variables influencing an individual's interactions are genetics and environmental factors, including nutrition. In addressing possible later behavioral differences resulting from a nutritional insult, such as low 20:4n-6 or 22:6n-3 status during development, consideration of both genetic and environmental factors is relevant. Comparisons of one without the other will not clearly reveal consistent insights, as both factors affect the development of an individual and the expression of traits in later life.

It is difficult to establish conclusive links between the functional and behavioral effects of nutritional insults when many of the methods for testing behavior cannot be clearly or easily related to human functioning (76). Other methods attempt to correlate the appearance of a behavior with the development of specific indices, such as neurotransmitter systems. However, to prove cause-and-effect relationships in this way would be limiting, as no one event occurs independently in the developing brain or whole animal. Thus, the appearance of a behavior, or the lack thereof, may also be correlated with other events, such as postnatal development and maturation of cells, myelination, endocrine system maturation, or skeletal muscle development. Subsequently, modifications produced by behavior or cognition involve not just a single cell and its connections but many cells and their connections. In this regard, it may not be reasonable to expect to identify a clear relationship between n-6 and n-3 fatty acid imbalance and the exhibition, or lack thereof, of a single behavior or functional impairment.

One important challenging question that remains to be addressed is the effect(s) arising from nutritional imbalances or deficiency in availability of long-chain essential fatty acids. If long-chain n-6 and n-3 fatty acids are so important in function and development of the brain, why are specific characteristics not evident in large populations? To answer this question, we need to understand how the lack of or imbalance of 20:4n-6 and 22:6n-3 during development may be manifested in terms of characteristics or behaviors in later life. These "effects" have not been defined, although suggestions have been made that depression, visual development, and perhaps "intelligence" are adversely affected, at least initially. It has been demonstrated that visual function is slow to develop if adequate docosahexaenoic acid is not supplied. However, visual function is improved with the addition of this fatty acid. This does not imply that the individual will never catch up or adapt, nor does it imply that the individual will not be as "smart." Visual function is not related to an individual's intellectual capacity, as evidenced by visually impaired individuals who are not intellectually impaired. Intellect is the "faculty of knowing and reasoning; understanding." Intelligence is acquired through exposure to the environment and experience, which occur in many forms. In this respect, testing intelligence by present methods is limiting and perhaps inappropriate in some situations. These views regarding vision and intellect are no doubt provocative, but until further research is conducted in this area, and until appropriate measures of intelligence are developed and confounding variables carefully analyzed, care should be taken in drawing conclusions and making speculations. Many questions remain unanswered.

Future directions should focus on establishing functional and/or behavioral implications caused by varying the n-6 to n-3 fatty acid ratio within the ranges recommended by experts and by including or omitting long-chain polyunsaturated fatty acids, namely, docosahexaenoic and arachidonic acids. A discrepancy remains regarding the degree to which a newborn human infant is capable of desaturating and elongating 18:2n-6 and 18:3n-3 to their longer-chain homologs. That is, immediately after birth there is no significant accretion of chain elongation–desaturation products. This suggests that the limiting factor may initially exist in liver synthesis of these products or that mobilization of these long-chain polyunsaturated fatty acids from the liver exceeds the capacity of the liver to synthesize them from dietary precursors (61). If the capability for desaturation exists, is it sufficient to support the requirements of the developing nervous system? If it is sufficient, in what instances, diseases, or dietary circumstances may it be compromised? Premature or very-low-birthweight infants are likely candidates in this category. Is the full-term infant also a likely candidate in certain circumstances? What factors are likely to affect this activity? Maternal nutritional status during pregnancy may be one example. Another example is the occurrence of fatty acids in the diet. Fatty acids do not occur individually but with other fatty acids and are associated with vitamins and other nutrients. These clusters of nutrients likely also affect how individual fatty acids are metabolized.

Little quantitative evidence is available to indicate the sources of 20:4n-6, 22:4n-6, 22:5n-3, and 22:6n-3 in the fetus. During intrauterine development, does the fetus rely entirely on placental synthesis and a transfer mechanism to obtain these essential structural long-chain fatty acids or are they synthesized by the fetus or in specific tissues? Because development of the brain is not uniform and many vulnerable periods exist prenatally and postnatally, the use of whole-brain analyses is conceptually quite limiting. In the same regard, because phospholipids vary in fatty acid composition, analyses of total brain phospholipids are also limiting. In terms of correlating functional deficits with morphological alterations, Vitiello and Gombos (21) noted that these can occur only in some cases. These authors point out that relationships between structure and function in brain are not always well defined. Thus, a single morphological structure cannot always be identified as the structure essential for a certain function (21). The need exists to focus our efforts on developing innovative tests to dissect out functions of the central nervous system that are interpretable in terms of brain regions, groups of neurons, or transmitter activity and function. These tests would need to be applicable in some form for use in infants and children and would then lead to the means to develop meaningful markers of essential fatty acid status during fetal and infant development.

ABSTRACT: The importance of n-6 and n-3 polyunsaturated fatty acids (PUFA) in neonatal development, particularly with respect to the developing brain and retina, is well known. This review combines recent information from basic science and clinical studies to highlight recent advances in knowledge on PUFA metabolism and areas where research is still needed on infant n-6 and n-3 fatty acid requirements. Animal, cell culture, and infant studies are consistent in demonstrating that synthesis of 22:6n-3 involves C24 PUFA and that the amounts of 18:2n-6 and 18:3n-3 influence PUFA metabolism. Studies to show that addition of n-6 fatty acids beyond Δ6-desaturase alters n-6 fatty acid metabolism with no marked increase in tissue 20:4n-6 illustrate the limitations of analyses of tissue fatty acid compositions as an approach to study the effects of diet on fatty acid metabolism. New information to show highly selective pathways for n-6 and n-3 fatty acid uptake in brain, and efficient pathways for conservation of 22:6n-3 in retina emphasizes the differences in PUFA metabolism among different tissues and the unique features which allow the brain and retina to accumulate and maintain high concentrations of n-3 fatty acids. Further elucidation of the Δ6-desaturases involved in 24:5n-6 and 22:6n-3 synthesis; the regulation of fatty acid movement between the endoplasmic reticulum and peroxisomes; partitioning to acylation, desaturation and oxidation; and the effects of dietary and hormonal factors on these pathways is needed for greater understanding of neonatal PUFA metabolism.

Paper no. L7785 in *Lipids 34,* 139–149 (February 1999).

The fatty acids currently recognized as essential dietary components (nutrients) are linoleic acid (18:2n-6) of the n-6 series and α-linolenic acid (18:3n-3) of the n-3 series. Once consumed, these fatty acids can be converted to longer-chain, more highly unsaturated fatty acids of the same series, including arachidonic acid (20:4n-6) from 18:2n-6 and docosahexaenoic acid (22:6n-3) from 18:3n-3 (1). Considerable controversy exists over how much and, in particular, which n-6 and n-3 fatty acids are needed in the diet of young infants. Indeed, the literature contains many studies to suggest that groups of infants who are breast-fed may have a developmental advantage and subsequently higher scores on psychometric tests than infants who are not breast-fed (2). These observations have fostered interest in the possible role of human milk nutrients in providing for optimal neurodevelopment. The presence of high concentrations of 20:4n-6 and 22:6n-3 in select regions of the brain and retina (3,4), and of small amounts of these same fatty acids in human milk (5) has raised questions about the potential need for a dietary source of 20:4n-6 and 22:6n-3 during development. Adequate levels of 20:4n-6 and 22:6n-3 in membrane phospholipids (PL) are crucially important to many different functions, for example, 20:4n-6 as a precursor for formation of eicosanoids and 22:6n-3 in normal visual function (2).

This session on neonatal polyunsaturated fatty acid (PUFA) metabolism was designed to review current information, specifically focusing on important unanswered questions about the synthesis and pathways of tissue assimilation of 20:4n-6 and 22:6n-3 in the newborn. Information about the pathways involved in the biosynthesis of 20:4n-6 and 22:6n-3 in liver; the steps involved in committing fatty acids to acylation, partial (peroxisomal) or complete oxidation or further desaturation and elongation, as well as potential differences between the metabolism of n-6 and n-3 fatty acids; and the regulation of n-6 and n-3 fatty acid metabolism in brain, eye, and other organs compared with that in the liver are being actively explored. The findings of recent research on these topics were summarized as described below. Several groups have used recent advances in stable isotope technology to provide evidence that term- and preterm-gestation infants are able to convert 18:2n-6 to 20:4n-6 and 18:3n-3 to 22:6n-3 (6–8). One important aspect of these studies, which are based on measures of isotopic enrichment of fatty acids in plasma lipids, is how to use the data to obtain quantitative information on the effects of various diets on 20:4n-6 and 22:6n-3 synthesis in relation to the tissues' needs for optimal function. A summary of studies focusing on the effect of age and dietary 18:2n-6 and 18:3n-3 quantity and ratio on conversion of 18:2n-6 and

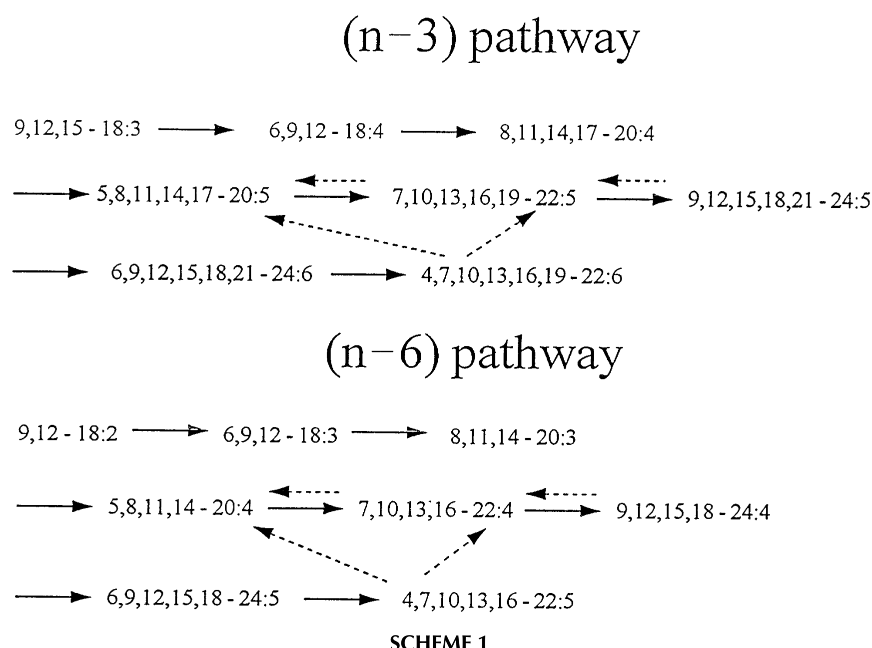
18:3n-3 to 20:4n-6 and 22:6n-3, respectively, forms the second part of this review. This theme is continued in a review of studies using the gastrostomy-reared rat fed with lipids containing stable isotopes to explore the highly selective ways by which the brain controls the supply of saturated and unsaturated fatty acids and cholesterol during growth and development. This is followed by discussion of the unique aspects of PUFA metabolism and of specific pathways for conservation of 22:6n-3 in retina. Although these important studies illustrate unique aspects of PUFA metabolism in the central nervous system, many basic questions about the digestion and absorption of dietary fatty acids by young infants remain unanswered. The consideration of some of these issues forms the final section of this review.

DIFFERENCES IN REGULATION OF BIOSYNTHESIS OF 5,8,11,14-ARACHIDONIC ACID AND 4,7,10,13,16,19-DOCOSAHEXAENOIC ACID

The biosynthesis of 20:4n-6 from dietary 18:2n-6 takes place in the endoplasmic reticulum. The liver is the major site for the production of PUFA, both for synthesis of its own membrane PL and for export and uptake by most other cells. The incorporation of unsaturated fatty acids into membrane PL is also a process that is localized primarily in the endoplasmic reticulum. Most PL contain large amounts of 18:2n-6 and 20:4n-6 but only relatively small amounts of 18:3n-6 or 20:3n-6. Studies with rat liver microsomes have shown that desaturation at position 6 is rate-limiting for the conversion of 18:2n-6 to 20:4n-6 (9). This finding implies that the addition of fatty acids to the diet beyond the reaction catalyzed by a 6-desaturase (e.g., 18:3n-6) should increase the amount of 20:4n-6 that is produced and incorporated into tissue lipids. To address this, a series of cross-over feeding studies was conducted in which unlabeled or deuterium-labeled 18:3n-6 or 20:3n-6 was added to a diet containing a constant amount of either labeled or unlabeled 18:2n-6 (10). These studies found that the addition of fatty acids beyond the 6-desaturase step did not markedly increase the amount of 20:4n-6 that was esterified in heart, liver, or kidney PL. However, there was an increase in the specific activity of esterified 20:4n-6 when the contributions of deuterium-labeled 18:2n-6 plus the other deuterium-labeled n-6 fatty acid were calculated. It was also observed that the specific activities of 20:4n-6 esterified in heart, kidney, and liver PL were all modified differently when n-6 fatty acids were added to a diet with a constant amount of 18:2n-6. The results of these studies showed that individual tissues process unsaturated fatty acids in different ways. Another important conclusion was that simply measuring the amount of 20:4n-6 in a tissue PL did not completely describe how a dietary fat supplement modifies fatty acid metabolism. In addition, the results also implied that measuring one pool of lipids (for example, liver phosphatidylcholine) does not adequately describe what takes place in any other pool [for example, heart phosphatidylcholine or liver triglyceride (TG)]. It is also important to stress that much of what we know about the regulation of PUFA biosynthesis has come from studies with rats. It remains to be determined if there are major differences among species and which animal most closely mimics what takes place in humans.

The evidence to show that 22:4n-6 (7,10,13,16-22:4) and 22:5n-3 (7,10,13,16,19-22:5) are not converted to 22:5n-6 (4,7,10,13,16-22:5) and 22:6n-3 (4,7,10,13,16,19-22:6), respectively, by a microsomal acyl-CoA-dependent 4-desaturase has been summarized recently (1). Instead of a microsomal 4-desaturase, the pathways, as shown in Scheme 1, re-



SCHEME 1

quire that when they are produced in the endoplasmic reticulum, 24:5n-6 and 24:6n-3 must move to a site for partial β-oxidation. Solid arrows denote reactions taking place in the endoplasmic reticulum, dashed arrows show fatty acids that are partially degraded, with subsequent esterification of the indicated chain-shortened metabolites into membrane lipids. This site is most likely peroxisomes. These pathways raise several new questions about both microsomal fatty acid biosynthesis and the intracellular movement of fatty acids between microsomes and peroxisomes. Two fatty acids in each of the n-6 and n-3 fatty acid pathways are desaturated at position 6 of the carbon chain. Although there is no conclusive evidence for multiple forms of a Δ6-desaturase (11), it seems highly unlikely that the enzyme previously assumed to catalyze the rate-limiting step, i.e., desaturation of 18:2n-6 and 18:3n-3, would also desaturate 24:4n-6 and 24:5n-3 at position 6. How many chain-elongating enzymes are present in the endoplasmic reticulum is also unknown (12). The revised pathways of fatty acid biosynthesis require three, rather than two, chain elongation steps, and two of these reactions now take place in sequence. It remains to be determined whether a single chain-elongating system can accept three n-6 and three n-3 fatty acids as substrates.

The pathways in Scheme 1 imply that when 24-carbon unsaturated fatty acids are produced in the endoplasmic reticulum they move to a site for partial β-oxidation. It is generally accepted that, once initiated, mitochondrial β-oxidation proceeds to completion (13). It is also generally recognized that peroxisomes partially degrade fatty acids (14). What regulates the transfer of fatty acids to a site for partial β-oxidation, rather than to mitochondria for complete oxidation, and whether they move as free fatty acids or acyl-CoA are not yet known. Some insight as to what terminates peroxisomal β-oxidation has been gathered from studies comparing the rates of β-oxidation of [3-^{14}C]-labeled 9,12,15,18,21-24:5 (24:5n-3) with 6,9,12,15,18,21-24:6 (24:6n-3). When [1-^{14}C] 4,7,10,13,16,19-22:6 (22:6n-3) was produced from [3-^{14}C] 24:6n-3, it was preferentially transported out of peroxisomes for use in membrane lipid biosynthesis by microsomes, rather than serving as a substrate for continued β-oxidation. The next cycle of β-oxidation of 22:6n-3 requires NADPH-dependent 2,4-dienoyl CoA reductase, which has been shown to be a slow step. Conversely, two cycles of β-oxidation of 24:5n-3 require only the enzymes of saturated fatty acid degradation, and indeed, the preferred metabolic fate of [1-^{14}C]-labeled 7,10,13,16,19-22:5 (22:5n-3) was continued β-oxidation rather than transfer from the peroxisomes back to microsomes for esterification (15).

This short review of current information on the regulation of 20:4n-6 and 22:6n-3 is confined to metabolism in the liver. Other types of controls are operative in other tissues. For example, brain and other tissues contain small amounts of very long chain unsaturated fatty acids with up to 40 carbon atoms with four, five, and six double bonds (16). When 24-carbon chain n-6 and n-3 fatty acids are produced in these tissues, they do not simply move to peroxisomes for partial degradation; they may also serve as precursors for the production of very long chain fatty acids. In addition, the differences in PL fatty acid composition, for example the presence of very long chain n-6 and n-3 fatty acids in some tissues, suggest that the activity and/or specificity of chain-elongating enzymes in some tissues may differ from those of liver.

STABLE ISOTOPE TRACERS AS PROBES TO STUDY PUFA BIOCHEMISTRY AND PHYSIOLOGY

The human infant requires an adequate supply of n-6 and n-3 fatty acids in order to sustain development of neurological structures of the brain and retina and to support normal growth and development of other tissues. The goals of the stable isotope studies were to validate the role of 24-carbon PUFA in the synthesis of 22:6n-3, to quantify levels of PUFA metabolites present in serum PL, to measure the enrichment of various PUFA isotopomers, and to devise kinetic models to quantify rates of synthesis of 20:4n-6 and 22:6n-3.

The role of 24-carbon chain PUFA in the metabolism of 18:2n-6 and 18:3n-3 to 22:5n-6 and 22:6n-3, respectively, is widely accepted. Whether these pathways occur in humans, and what the capacity is for conversion of dietary 18:2n-6 to 20:4n-6, and particularly of 18:3n-3 to 22:6n-3, are of particular interest with respect to the lipid composition of infant formulas and the effect of age and postnatal development on PUFA metabolism. However, the very low concentration of some n-6 and n-3 fatty acids, especially the 24-carbon PUFA, in tissue lipids hinders the design of metabolic studies aimed at quantifying the elongation and desaturation of n-6 and n-3 fatty acids. Several studies have now been reported on human infants, neonatal piglets, and pregnant baboons (6,17,18). The consensus is that infants are able to elongate and desaturate 18-carbon precursors to form 20:4n-6 and 22:6n-3. However, to establish whether the capacity of these metabolic systems proceeds at a sufficient rate to meet tissue needs for 20:4n-6 and 22:6n-3 will require developmental tests with a finer capability to discriminate between populations of normal infants on various diets.

In one series of studies, [U-^{13}C]-18:2n-6 (25–40 mg/kg) and [U-^{13}C]-18:3n-3 (15–25 mg/kg) were emulsified in formula and given orally to 4-mon-old infants. Blood was collected at 8, 12, and 24 h (8,18). In a study in neonatal piglets, [U-^{13}C]-18:2n-6 (25 mg/kg) and [U-^{13}C]-18:3n-3 (15 mg/kg) were emulsified in intravenous lipid and given i.v. *via* an indwelling catheter; 15 blood samples were then collected over a 3–5 d period. Plasma lipids were extracted with hexane/2-propanol, separated into TG and PL fractions on silica columns, and saponified with methanolic KOH. Pentafluorobenzyl (PFB) esters were then prepared. Samples were analyzed by methane negative chemical ionization (NCI)–gas chromatography–mass spectrometry (GC–MS) on both 60 m × 0.32 mm Omegawax and 60 m × 0.32 mm SP-2380 capillary columns to completely resolve all of the putative metabolites.

Several approaches have been employed recently to quantify the stable isotopic enrichment of PUFA. Emken and coworkers used methyl esters and positive chemical ionization GC–MS to study fatty acid metabolism in adults (19,20). Their studies were among the first to show direct synthesis of 20:4n-6 and 22:6n-3. More recently, Carnielli *et al.* (17), Demmelmair *et al.* (6), and Greiner *et a*l. (21) used high-precision, GC-combustion-isotope ratio mass spectrometry (GCC-IRMS) for analysis of fatty acid methyl esters. The chief advantage of GCC-IRMS is its ability to quantify much lower levels of enrichment accurately than is possible with GC–MS. However, GCC-IRMS is unable uniquely to detect and to quantify minor fatty acids present at very low concentrations in a complex biological matrix. To overcome these limitations, Sauerwald *et al.* (8,18,22–24) and Salem *et al.* (7,25) employed the PFB ester and NCI GC–MS to study PUFA metabolism. The PUFA-PFB esters have three desirable attributes: this derivative affords extraordinary attomole sensitivity, it possesses good chromatographic resolution of *cis/trans* and positional isomers, and it gives unambiguous assignment of chain length and degree of unsaturation (8,24). Moreover, the dominant ion in the mass spectrum is the carboxylate anion caused by scission of the PUFA-PFB ester bond, thus $[^{13}C]$- and $[^{2}H]$-PUFA are readily quantified because the carbon skeleton remains intact during ionization (18,22). The molar response factors were determined using a commercial standard with 31 fatty acids of C10 to 24. The concentration of various PUFA in infant plasma PL was determined by comparison of GC–MS peak areas relative to the concentration of 18:3n-3 and 22:6n-3 determined by capillary GC. The mole percentage and concentration of n-3 series PUFA in plasma PL from infants fed a formula with 16% 18:2n-6 and 3.2% 18:3n-3 are summarized in Table 1. The C24 PUFA were present in plasma PL at 0.003 to 0.012 mol% of total fatty acids, and the plasma concentration was 0.087 to 0.38 nmol/mL.

Figure 1 shows a total ion chromatogram for the C24 PUFA region and the selected ion recordings for the [M + 18] isotopomers of the elongation products (18). The n-3 series lipids are clearly enriched, whereas neither the C22 nor the C24 n-6 series had detectable levels of enrichment, although 20:4n-6 was labeled. The enrichment data for one infant, including both n-6 and n-3 series lipids, are shown in Figure 2. The peak enrichment in the precursor PL was achieved in under 8 h, consistent with studies in adult humans (19,20). Simulation of kinetic tracer studies reveals that enrichment flows from high to low as the isotope traverses the metabolic path of the system (26,27). These data show that the C24 n-3 PUFA possess a greater enrichment than 22:6n-3, thus they must arise at an earlier stage of biosynthesis than 22:6n-3. The results are also consistent with *in vitro* studies which show that the final steps in synthesis of 22:5n-6 and 22:6n-3 involve elongation to 24:5n-6 and 24:4n-3, rather than direct 4-desaturation of 22:4n-6 and 22:5n-3, respectively (1). The extent to which the 4-desaturase alternate pathway, rather than other pathways, is utilized for synthesis of 22:5n-6 and 22:6n-3 *in vivo,* however, cannot be determined unambiguously from the tracer data.

Studies employing NCI GC–MS with term and preterm infants have also assessed the effect of age and dietary 18:2n-6 and 18:3n-3 amounts and ratios on the endogenous conversion of 18:2n-6 and 18:3n-3 as well as variability among individual infants (7,18,24). The studies were performed in term infants fed formulas with 16% of total fatty acids as

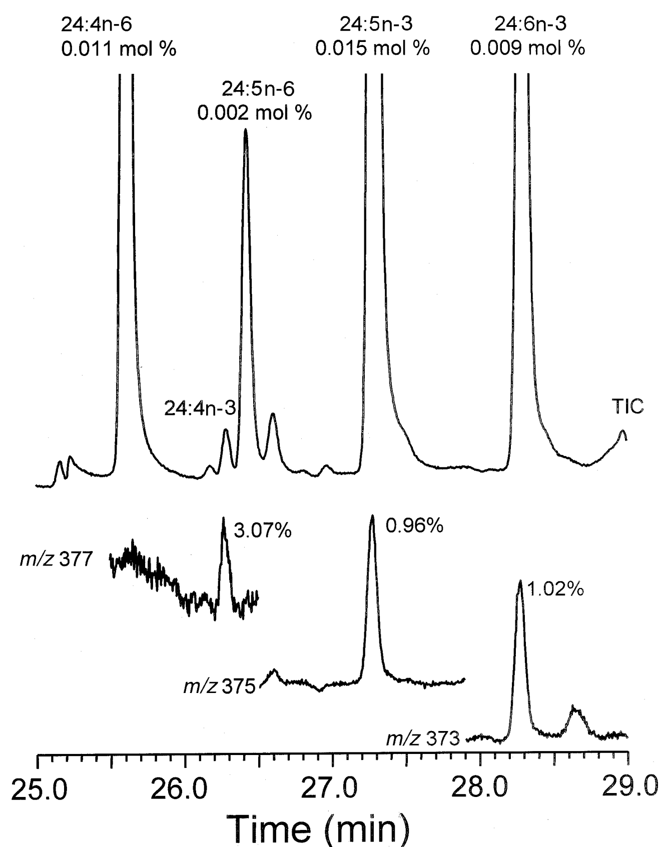


FIG. 1. Selected ion chromatograms showing incorporation of $[U-^{13}C]$-18:2n-6 and $[U-^{13}C]$-18:3n-3 into serum 24-carbon phospholipid polyunsaturated fatty acids.

TABLE 1
Composition and Concentration of Selected Plasma Phospholipid PUFA Determined by Capillary GC and NCI–GC-MS

PUFA	Mol%	Concentration (nmol/mL)
18:3n-3[a]	0.32 ± 0.12	9.95 ± 4.23
18:4n-3	0.002 ± 0.001	0.067 ± 0.070
20:4n-3	0.62 ± 0.76	18.4 ± 20.1
20:5n-3	1.69 ± 1.23	46.1 ± 35.8
22:4n-3	0.023 ± 0.022	0.69 ± 0.60
22:5n-3	0.81 ± 0.64	25.0 ± 17.7
22:6n-3[a]	2.93 ± 0.82	93.3 ± 31.4
24:5n-3	0.003 ± 0.002	0.087 ± 0.047
24:6n-3	0.012 ± 0.011	0.38 ± 0.29
24:5n-6	0.006 ± 0.004	0.14 ± 0.11

[a]Determined by capillary gas chromatography (GC). PUFA, polyunsaturated fatty acid; NCI, negative chemical ionization; MS, mass spectrometry.

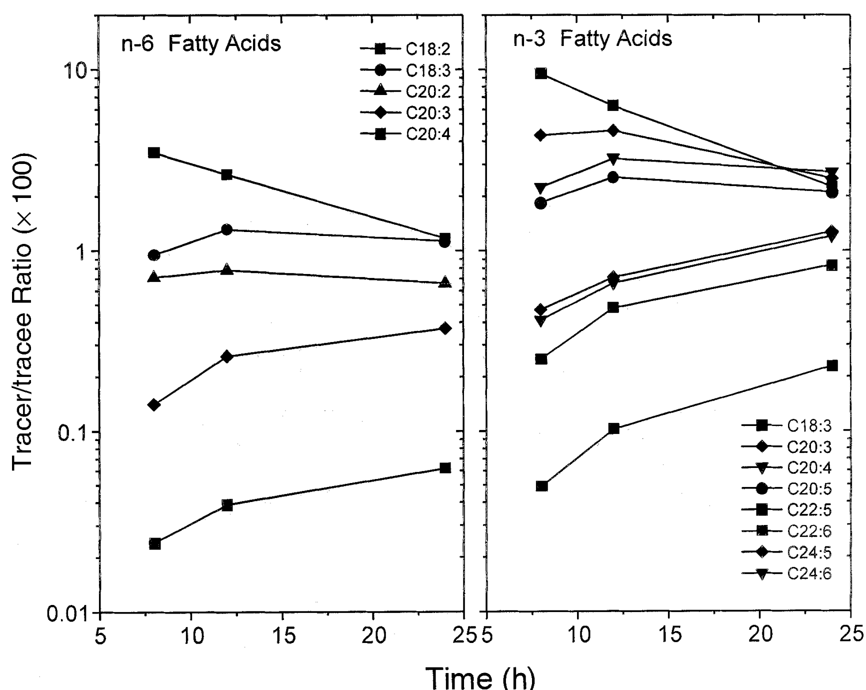

FIG. 2. Incorporation of [U-^{13}C]-18:2n-6 and [U-^{13}C]-18:3n-3 and various elongation and desaturation products into serum phospholipids in formula-fed infants over 24 h.

18:2n-6; with 0.4, 1.0, 2.0, or 3.2% 18:3n-3; and in premature infants fed formulas with 1 or 3.2% 18:3n-3. The formulas were fed from shortly after birth until 56 wk postmenstrual age. Bolus doses of [UL-^{13}C]-18:2n-6 and [UL-^{13}C]-18:3n-3 were given with a feeding at 43 and 56 wk postmenstrual age. Blood samples were taken 8, 12, and 24 h later for determination of concentrations and isotopic enrichments of all detectable n-6 and n-3 fatty acids in plasma lipids. Fractional rates of conversion of 18:2n-6 and 18:3n-3 as well as fractional rates of synthesis and incorporation of 20:4n-6 and 22:6n-3 into plasma lipids were calculated from the data using a simple precursor–product compartmental model (Fig. 3). Precursor–product models are widely used in kinetic studies and have been systematically validated (27,28). These studies confirm that both term and preterm infants synthesize 20:4n-6 and 22:6n-3 and that synthesis of 22:6n-3 proceeds *via* C24 PUFA metabolites, which utilizes a Δ6-desaturase. The fractional rates of endogenous conversion of 18:2n-6 and 18:3n-3, however, were highly variable among individual infants and were not higher in term than in preterm infants. Furthermore, rates of conversion did not increase with increasing postnatal age. These studies also found that increasing 18:3n-3 intake from 0.5 to 3.2% fatty acids increased the incorporation of 22:6n-3 into plasma lipids but inhibited the fractional conversion of 18:2n-6 and incorporation of 20:4n-6 into plasma lipids. Across all infants, the fractional rates of conversion of 18:2n-6 and 18:3n-3, as well as the fractional rates of 20:4n-6 and 22:6n-3 incorporation, were highly correlated ($r^2 = 0.5$). This suggests marked individual differences in desaturase and elongase activities.

The physiology and biochemistry of PUFA are sufficiently complex that they demand more invasive studies than are possible in human infants. A series of studies in neonatal piglets quantified individual steps in the elongation and desaturation of 18-carbon PUFA precursors using the techniques described

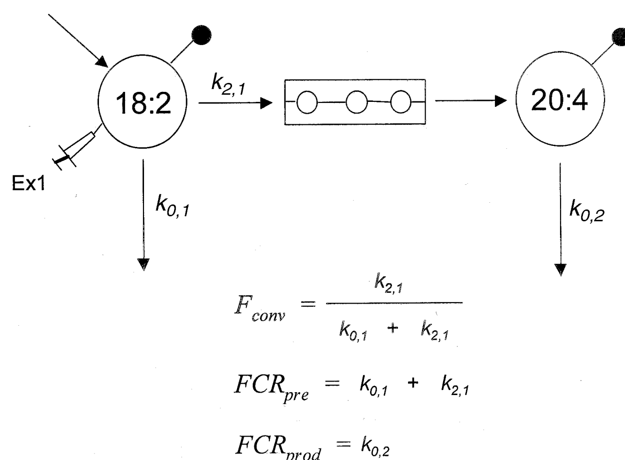

FIG. 3. Simple precursor product compartmental model used to estimate rates of synthesis of arachidonic acid and docosahexaenoic acid in human infants. The compartments are labeled "18:2" and "20:4" inside the large circle. The symbol (•—) emanating from the side of the large circles is the kinetic notation for the site of sample measurements. The subscripts 1 and 2 refer to the precursor compartment 18:2 and product compartment 20:4, respectively. Ex1 is the "external input of tracer" into compartment 1; F_{conv} is the fraction of compartment 1 converted to product in compartment 2; FCR_{pre} is the fractional catabolic rate of material in precursor compartment 1; FCR_{prod} is the fractional catabolic rate of material in product compartment 2.

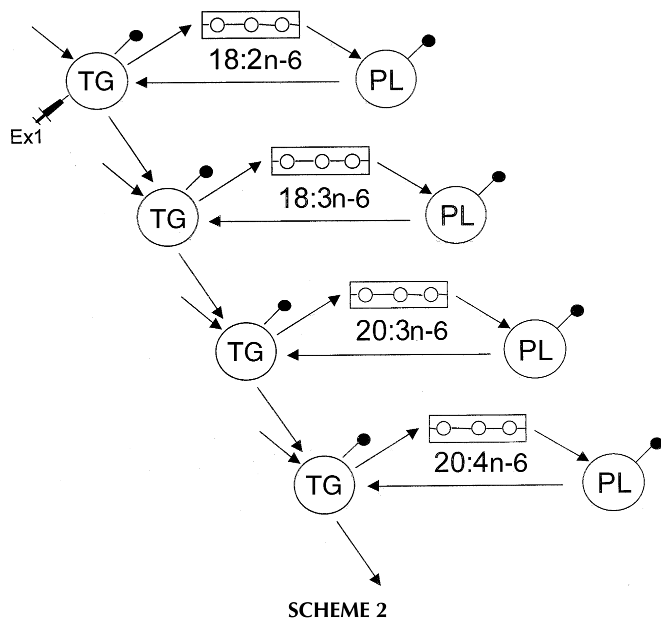

SCHEME 2

above (22,23). A tentative model for the synthesis from [U-^{13}C]-18:2n-6 of 20:4n-6 in a neonatal piglet is shown in Scheme 2 (22), where FCR = fractional catabolic rate. This model incorporates two aspects of physiology and biochemistry not possible with the simple precursor–product model. The model partitions the fatty acids into separate TG and PL compartments, and it incorporates separate compartments for each step in the desaturation and elongation sequence. To model this system adequately, four pieces of information are required; separate concentration measurements of the various PUFA in TG and PL fractions, and measurement of isotopic enrichment in each polyunsaturate in TG and PL. The studies are demanding in terms of the number of analytical measurements required, especially for the n-3 series fatty acids, which have twice the number of metabolites as the n-6 series fatty acids. A model determined to fit the data is shown in Figure 4. The median fractional error estimate of the rate constants in the model was 7% (range: 2.5–35%). The model confirms that the rate-limiting step is the initial Δ6-desaturase (18:2n-6 to 18:3n-6) and that accumulation of 20:4n-6 is due to a slow fractional catabolic rate. As intricate as this model is, it does not reflect the true complexity of the system, e.g., no attempt was made to quantify cholesterol esters nor to incorporate transport *via* lipoproteins. Moreover, the model does not consider that biochemical conversions take place *via* unesterified fatty acids in intracellular compartments.

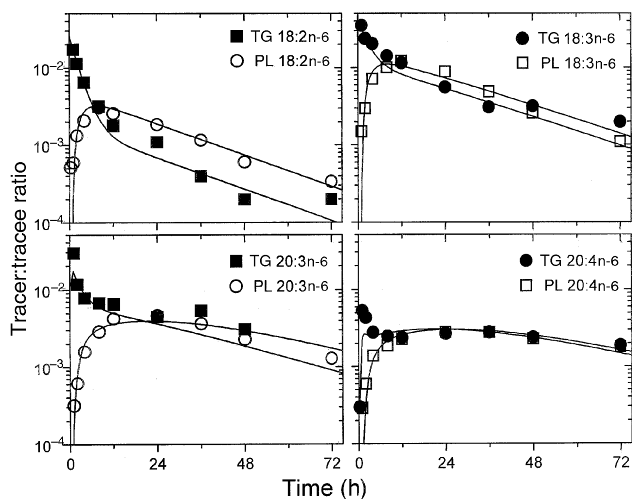

FIG. 4. Incorporation of [U-^{13}C]-18:2n-6 into n-6 series polyunsaturated fatty acid metabolites in a neonatal piglet. Model parameters and fit were obtained using the model shown in Scheme 2. TG, triglycerides; PL, phospholipids.

In the neonatal piglet (22), the rate of conversion was extraordinarily rapid compared to what was anticipated from studies in the human infant. Indeed, high levels of enrichment were observed in 20:4n-6 in TG as early as 60 min after the tracer was administered, whereas the 20:4n-6 in PL did not peak until 24 h, as observed in the infant studies. Thus, the kinetics observed in the infant studies may have been dominated by slow rates of PL synthesis and probably do not reflect the underlying kinetics of desaturation and elongation. Refinements in the model may identify kinetic parameters with a finer ability to discriminate between subject populations and thus permit more reliable evaluation of the effects of diet on PUFA metabolism. Kinetic analysis of the PUFA system is in an early stage of development compared to that of other complex kinetic systems, such as cholesterol metabolism or the lipoprotein transport system (29). The kinetic tools are available to model complex physiologic systems, but investigators working in this area should come to some consensus on the most appropriate model structure in order to design and implement tracer studies.

The studies described above, together with those of others (6,17,18), provide firm evidence that term and preterm infants synthesize 20:4n-6 and 22:6n-3 from their respective dietary precursors, 18:2n-6 and 18:3n-3. The relative amounts of 18:2n-6 and 18:3n-3 in the diet, however, appear to be important determinants of this conversion. In summary, NCI GC–MS measures of stable isotopically labeled fatty acids can be used to study (i) pathways and (ii) the effects of diet, age, or various clinical conditions on the conversion of n-6 and n-3 fatty acids and their incorporation into plasma and tissue lipids. Results of studies completed with term and preterm infants confirm that 18:2n-6 and 18:3n-3 compete for desaturation and elongation, and that n-6 and n-3 fatty acid metabolism involves 24-carbon chain intermediates. The results obtained dispel the assumptions that 18:2n-6 and 18:3n-3 conversion is lower in preterm- than term-gestation infants and increases with postnatal age. The results also show that dietary 18:2n-6 and 18:3n-3 intake determines the conversion 18:2n-6 and 18:3n-3 to 20:4n-6 and 22:6n-3, respectively. Further studies employing these techniques are likely to provide important information on the effects of dietary supplementation with 20:4n-6 and 22:6n-3 in term and preterm infants.

METABOLISM, SOURCES, AND UTILIZATION OF PUFA BY THE DEVELOPING BRAIN: LESSONS LEARNED FROM AN ANIMAL MODEL

The brain is a unique organ and not subject to the same conditions as nearly all the other organs of the body. The management of lipids for the brain must be a highly specialized process equated to its development, structure, and function. Studies with rat pups reared on defined diets *via* gastrostomy tube feeding (gastrostomy-reared rat) have provided basic evidence that the brain is autonomous in providing the bulk of its lipids, entirely by *de novo* synthesis (30–32). Neither cholesterol nor 16:0 nor 18:0 nor 18:1 is supplied from exogenous (diet/plasma) sources. All are provided within the brain. Because of this, synthesis can be directed to supply needs in the specified regions and compartments as required to meet the demands for their dynamic growth and specialized development. The essential features are that this commitment to lipid synthesis is site-directed, efficient, and avoids problems of redundancy in supply that an organ like the brain must avoid.

Studies using gastrostomy-reared rat pups have taken advantage of lipids containing stable isotopes with characteristic mass to study which fatty acids can enter the brain at the most dynamic period in brain development, the primary brain growth spurt and onset of white matter formation (34,35). The artificially reared rat pups were pulse-fed *via* gastrostomy (36–38) for 20 or 30 min in each hour throughout each 24-h day beginning at day 6 postnatal with a rat milk subtitute containing fats of defined composition. The rat pups were fed over 7–10 d periods, long enough to ensure that labeled lipids reached all organs to which they have access. Results of these studies showed that deuterated cholesterol, D_7 -cholesterol (mw 393, compared to 386 for D_O-cholesterol), even when fed to produce a hypercholesterolemic state, does not enter the brain (30). In contrast, other tissues, for example, liver, red blood cells and lung, contained D_7-cholesterol in excess of 55% of their total cholesterol. Subsequent studies using the same methodology demonstrated that deuterated 16:0, either the D_3 or D_{31} perdeuterated form (mw 273 and 301, compared to mw 270 for D_0-16:0 on quantitation as their methyl esters), when fed in the fat blend of the milk substitute, did not gain entry to the brain; organs such as liver and lung contained both isotopomers in the relative proportions in which they were fed (31).

The above studies have now been expanded to determine the transport and utilization of dietary essential and nonessential fatty acids. In these more recent studies, gastrostomy-reared rat pups were fed a rat milk substitute containing the perdeuterated (97 atom% D) fatty acids 16:0, 18:0, 18:1, 18:2n-6, and 18:3n-3 from day 7 to day 14 after birth (32,33). Fatty acids in lipid extracts of the liver, lung, kidney, and brain were subjected to GC–MS analysis to determine their content of each of the deuterated fatty acids (301 vs. 270, 16:0; 333 vs. 298, 18:0; 329 vs. 296, 18:1; 325 vs. 294, 18:2n-6; and 321 vs. 292,18:3n-3), and were quantitated from the abundance of these respective ions; the exception was oleate, which was determined as stearate (331 vs. 298) after oleate was separated from the fatty acid mixture and converted to stearate by hydrogenation. The uptake and metabolism of perdeuterated fatty acid leads to the appearance of three distinct groups of isotopomers: the intact perdeuterated, the newly synthesized [with recycled deuterium from the oxidation of fatty acids to the water-soluble metabolites acetoacetate and hydroxybutyrate, which are used for *de novo* lipogenesis (39)], and the natural unlabeled (D_0) fatty acid. The quantitation of these isotopomers permits the estimation of uptake and *de novo* synthesis of these fatty acids. Intact perdeuterated 16:0, 18:0, and 18:1 from the diet were found in liver, lung, and kidney but not in brain. By contrast, perdeuterated 18:2n-6 was found in all these organs; in the brain the perdeuterated 18:2n-6 equaled the natural form in its abundance. Isotopomers of fatty acids from *de novo* synthesis as measured by the increase in mass over natural abundance in their respective (M + 1) and (M + 2) ions were observed in 16:0, 18:0, and 18:1 in all tissues. The highest enrichment of isotopomers with recycled deuterium was found in the brain. As an example, from the data it could be calculated that the relative rate of synthesis of 18:1 in brain was sixfold greater than the relative rate of 18:1 synthesis in the liver at this age (33). The data indicate that during the brain growth spurt and the prelude to myelination, the major nonessential fatty acids (and cholesterol) in lipids in brain are exclusively produced locally by *de novo* biosynthesis. These results suggest essential fatty acids must be transported and delivered to the brain by highly specific mechanisms capable of distinguishing between, for example, 18:1 and 18:2n-6. In the studies discussed in this section it was found that 18:1 is excluded from brain whereas 18:2n-6 passed readily into brain, indicating the mechanism for transport/transfer has the sophistication and selectivity to distinguish between 18-carbon monocarboxylic acids which differ by one double bond.

The conclusions from the studies with the gastrostomy-reared rat are that there are essentially no contributions of saturated or monounsaturated fatty acids or cholesterol to brain from a plentiful extraneural supply of these lipids. By extrapolation, this means that those fatty acids that do need to enter the brain, especially the n-6 and n-3 fatty acids, must be processed in a unique manner. From studies to date one can hypothesize that there must be a stringent approach to how the brain deals with its need for the PUFA. An extension of the information gathered on saturated and monounsaturated fatty acids, and cholesterol is that the brain exercises exclusive control on the content of these PUFA, and by analogy, this control would dictate that the brain produces 20:4n-6 and 22:6n-3 as needed in the specific regions and compartments on demand, as required to meet the needs for dynamic growth and specialized development. These conditions would imply that the optimal arrangement calls for a controlled and selective uptake of their precursors, 18:2n-6 and 18:3n-3, which are delivered (uniquely again) for *in situ* conversion to the products, or for specific and regulated uptake of 20:4n-6 and

22:6n-3 as commissioned by, and specifically required within, the brain.

SYNTHESIS, UTILIZATION AND CONSERVATION OF PUFA IN THE CENTRAL NERVOUS SYSTEM

Tissues of the nervous system and reproductive organs are unique in that their membrane PL contain large amounts of n-3 fatty acids. The rod outer segments (ROS) of the retina have up to 50% n-3 PUFA, most of which is 22:6n-3. These membranes contain light-sensitive photopigments that absorb light and initiate visual excitation. Biochemical events that lead to the generation of the electrical signals that are transmitted to the occipital cortex occur in these membranes on a millisecond time scale. These rapid changes evidently require the presence of 22:6n-3, as evidenced by changes in retinal function in rats fed n-3 fatty acid-deficient diets (40–42). Similar functional changes have been demonstrated in guinea pigs (43), monkeys (44), and human infants (45). Given the important role of 22:6n-3 in retinal function, it is not surprising that the nervous system has developed mechanisms for conservation of n-3 fatty acids during times of dietary deprivation. In fact, it is rather difficult to reduce the retinal levels of 22:6n-3 in a rat, even when the diet is started at weaning (46). The largest changes in retinal 22:6n-3 levels can be made by depriving female rats of n-3 fatty acids during the last trimester of pregnancy and throughout the nursing period (47). ROS are dynamic structures whose membrane components are constantly being replaced. The distal 10% of mammalian ROS is shed daily and phagocytized by the retinal pigment epithelium (RPE); new membranes are synthesized and incorporated into the base of the ROS to maintain a constant length of the outer segment. This process is not affected by n-3 fatty acid status (48). Since 22:6n-3 is present in the shed tips (49,50), the RPE must metabolize it and return it to the retina for incorporation into new membranes. This is accomplished by a shuttle system that is not well understood but involves transient storage of 22:6n-3 in the RPE as TG and possibly 22:6n-3 specific-binding and transport proteins. The efficiency of 22:6n-3 conservation by the retina was demonstrated (48). Labeled 22:6n-3 injected into the vitreous cavity was rapidly incorporated into retinal PL, but no label could be detected in 22:6n-3 in the circulation (51).

In addition to its efficient uptake and conservation mechanisms, the retina is also supplied with 22:6n-3 derived from synthesis from appropriate n-3 precursors by cells within the eye. The RPE can convert 18:3n-3 and 22:5n-3 to 22:6n-3 *via* the Sprecher pathway (52). Recently, it was demonstrated that retinal capillary endothelial cells can also synthesize 22:6n-3 from 22:5n-3 (53). Interestingly, these cells released 24:5n-3, 24:6n-3, and 22:6n-3 into the medium, suggesting that they may be responsible for supplying these long-chain PUFA to retinal cells.

In summary, the retina conserves 22:6n-3 during n-3 fatty acid deprivation by recycling between the retina and RPE. In addition, RPE and capillary endothelial cells can synthesize 22:6n-3 from precursors and release it into the intercellular space. Both mechanisms of conserving 22:6n-3 ensure that the retina maintains a high level of this fatty acid in ROS membranes.

UNANSWERED QUESTIONS ON THE DIGESTION AND ABSORPTION OF PUFA

Breast-fed infants receive a dietary source of 20:4n-6 and 22:6n-3, and the fetus probably receives 20:4n-6 and 22:6n-3 by placental transfer. One important as yet unanswered question is whether the dietary essential fatty acid requirements of infants born early in the third trimester of gestation are the same as those of infants born after full-term gestation. Several studies on the essential fatty acid requirements of young infants have been done with premature infants, generally of birthweight less than 1500 grams. Infants born early in the third trimester of gestation are often more vulnerable to nutritional deficiencies, including essential fatty acid deficiency, than healthy term infants (54). For example, premature infant formulae with higher concentrations of protein and minerals than in term infant formulae produce a major advantage in neurodevelopment (55). The much earlier stage of brain maturation at birth, suggesting greater developmental need, as well as minimal stores of n-6 and n-3 fatty acids in adipose tissue (which often represent only 1–2% bodyweight in a 1,000 g premature infant), indicate that n-6 and n-3 fatty acid requirements may be higher than, or different from, term infants. Results of recent studies with stable isotopes of 18:2n-6 and 18:3n-3, however, suggest that premature infants do not have a lower ability (immaturity) to form 20:4n-6 and 22:6n-3 when compared with their term counterparts (6,17,18). Despite this, it is important to recognize that there are many differences in the clinical care, rate of growth, and composition of developing tissues in premature infants which could influence fatty acid metabolism and thus requirement and tissue assimilation. As a result, caution is needed before extending results of studies with premature infants to the needs of term gestation infants and vice versa.

Because breast-fed infants and the developing fetus receive preformed 20:4n-6 and 22:6n-3, it seems reasonable to consider providing an exogenous (dietary) source of 20:4n-6 and 22:6n-3 for infants who are bottle-fed or fed intravenously. Several potential sources of 20:4n-6 and 22:6n-3 are available for supplementation of infant formula. These include fish and other marine oils, egg total lipids or PL, and oils derived from micro-algae and fungi (single-cell organisms). These oils provide 20:4n-6 or 22:6n-3, as well as other fatty acids, unusual TG configurations, and potentially sterols and pigments native to the oil. Simply matching the composition of the major fatty acids in a formula with that in human milk, however, may not provide assurance that individual fatty acids are absorbed and assimilated in the same way as from human milk. For example, a recent study with rats found that 22:6n-3 from fish oil was preferentially transported in lymph TG, rather than in lymph PL as when fed as human

milk (56). Unfortunately, very little is as yet known about the pathways of digestion, absorption, and transport of n-6 and n-3 fatty acids from human milk TG and PL. Some studies have led to the suggestion that the milk enzyme, bile salt-stimulated lipase, which is present in human milk but not in infant formula, may be involved in the digestion of long-chain PUFA (57). Studies on the increase in blood lipid 20:4n-6 and 22:6n-3 in infants fed formulae supplemented with egg lipids and/or fish oils, however, clearly show 20:4n-6 and 22:6n-3 are digested and absorbed (58–60), even in the absence of this enzyme.

Current information suggests that 20:4n-6 and 22:6n-3 in human milk TG are distributed between the 2- and 3-positions of the glycerol (61). Studies with TG with varying saturated and unsaturated fatty acid distributions have suggested that dietary TG fatty acid distribution is important in determining the efficiency of fatty acid absorption, the pathway of absorption (as unesterifed fatty acids or as 2-monoglycerides), and subsequent routes of intravascular transport and tissue clearance (62–65). A better understanding of the physiological significance of milk fat fatty acid distribution seems fundamental to the design of fat blends which more closely mimic human milk lipids.

Some studies have found that adding fish oils with 22:6n-3 with either high or low 20:5n-3 to formula can reduce growth in premature infants (66,67) and possibly some aspects of neural function related to language in term infants (68). The levels of 22:6n-3 used in these studies did not, however, exceed those usually found in human milk. The absence of information on the usual pathways of digestion and absorption, transport, and tissue uptake of long-chain n-6 and n-3 fatty acids and on the specific roles these fatty acids play in development makes it difficult to understand the mechanism of possible adverse effects on growth and development. Studies with animals, however, have found evidence of reduced visual function (43) and decreased brain weight and performance on some tasks (69) as a result of feeding large amounts of fish oil with 20:5n-3 and 22:6n-3, or of single cell TG sources of 22:6n-3. Potential reasons for these problems could include oxidative problems in membrane lipids or effects secondary to reduced 20:4n-6. The findings, however, suggest that the balance of 20:4n-6 and 22:6n-3 is an important nutritional consideration for optimal growth and neural development.

Another important question is whether the composition of saturated and monounsaturated fatty acids, and the levels of 18:2n-6 and 18:3n-3 in a formula, influence the metabolism of either 18:2n-6 or 18:3n-3, or of any supplemental 20:4n-6 and 22:6n-3. Studies with formula-fed piglets have shown that dietary saturated fatty acid chain length influences tissue levels of 22:6n-3, 20:4n-6, and 18:2n-6 as well as other fatty acids (70,71). Recent studies in preterm infants also reported that the chain length of saturated fatty acids in formula influences plasma lipid levels of 22:6n-3 (72). Whether this is due to changes in β-oxidation of n-6 and n-3 fatty acids for energy vs. direct acylation or desaturation and elongation is not known. However, the findings suggest that studies on the appropriate levels of n-6 and n-3 fatty acids for infant diets should consider the composition of nonessential fatty acids as well as the amounts and balance of 18:2n-6 and 18:3n-3 levels and of any other n-6 and n-3 fatty acids in the diet fed.

This review has provided information from basic science and clinical studies that should be considered in future work on neonatal PUFA metabolism, and has indicated areas where research is needed to advance understanding on infant n-6 and n-3 fatty acid requirements. Animal, cell culture, and infant studies are consistent in demonstrating that synthesis of 22:6n-3 involves C24 PUFA and that the amounts of precursor n-6 and n-3 fatty acids influence PUFA metabolism. Studies have shown that addition of n-6 fatty acids beyond the Δ6-desaturase step alters n-6 fatty acid metabolism, with the effect differing among different tissues and with no marked increase in tissue 20:4n-6; this underscores the limitations of measures of tissue fatty acid compositions with respect to the effects of diet on fatty acid metabolism. The studies that show the brain has highly selective pathways for uptake of n-6 and n-3 fatty acids and that the retina has efficient pathways for conservation of 22:6n-3 further emphasize the differences in PUFA metabolism among different tissues and unambiguously confirm that many unique features are present to allow the brain and retina to accumulate and maintain high levels of n-3 fatty acids. Greater understanding of n-6 and n-3 fatty acid metabolism will be obtained with further elucidation of the Δ6-desaturases involved in the synthesis of 24:5n-6 and 22:6n-3, and the biochemistry of regulation of movement of fatty acids between the endoplasmic reticulum and peroxisomes, partitioning to acylation, desaturation–elongation and oxidation, and the effects of other dietary and hormonal factors on these pathways.

Assessment of Long-Chain Polyunsaturated Fatty Acid Nutritional Supplementation on Infant Neurobehavioral Development and Visual Acuity

Sandra W. Jacobson*

Department of Psychiatry and Behavioral Neurosciences, Wayne State University School of Medicine, Detroit, Michigan 48201

ABSTRACT: The aims of this paper are (i) to consider how best to examine effects of long-chain polyunsaturated fatty acid nutritional supplementation or deficiency on infant neurobehavioral development, after controlling for other factors that might influence outcome, including maternal demographic, intellectual, and personality characteristics, and (ii) to present new findings on the relation between visual acuity and processing speed and the effects of prenatal alcohol exposure and visual acuity on infant information processing. The following topics are also addressed: (i) breastfeeding and intelligence, (ii) criteria for the selection and control of potential confounding variables, and (iii) new infant information processing measures.

Paper no. L7742 in *Lipids 34,* 151–160 (February 1999).

The aims of this paper are twofold: (i) determination of how best to examine effects of long-chain polyunsaturated fatty acid (LCPUFA) nutritional supplementation or deficiency on infant neurobehavioral development, after controlling for other factors that might influence outcome, including maternal demographic, intellectual, and personality characteristics, and (ii) presentation of new findings on the relation between visual acuity and processing speed and the effects of prenatal alcohol exposure and visual acuity on infant information processing.

Much of the data presented is drawn from one of two prospective longitudinal studies: our Detroit study on effects of prenatal exposure to alcohol on infants (1) and our Michigan study on effects of pre- and postnatal exposure to polychlorinated biphenyls (PCBs) (2), an environmental contaminant found at elevated levels in contaminated Lake Michigan sportsfish. Findings from these studies are reviewed because they generated data about the sensitivity and predictive validity of new information processing and sensory measures also used in LCPUFA supplementation studies. These assessments include the Fagan Test of Infant Intelligence (FTII) (3) and the Teller Acuity Card Procedure (4). The findings on alcohol-related deficits on FTII processing speed and visual acuity may be particularly relevant for researchers who have found enhanced fixation and acuity effects of LCPUFA on these instruments. Recent studies linking chronic alcohol exposure to altered levels of LCPUFA concentrations in the feline brain and retina suggested that infants of women who abuse alcohol during pregnancy may be potentially at risk for reduced levels of these essential fatty acids (5).

LCPUFA STUDIES

The research design used to study the effects of adding LCPUFA to formula in many studies of preterm and full-term infants involves a clinical trials approach in which nonbreast-fed newborns are randomly assigned to different supplementation groups (e.g., 6–10). Comparison with a breast-feeding reference group is also often included in the study; and between-group differences in infant growth, visual acuity, and cognitive development are subsequently assessed. In that event, strictly speaking, random assignment is no longer complete because the mothers self-select on whether or not to breast-feed, a decision known to distinguish them (e.g., 11). Although comparisons of the randomly assigned newborn groups with the breast-feeding reference group could be omitted, this comparison seems useful in order to determine how well bottle-fed infants fare in contrast to those receiving maternal milk. Similar comparisons have been made in other developmental research areas, such as in longitudinal studies of low birthweight preterms or substance-exposed newborns in comparison with normal, full-term, nonexposed newborns. Intervention studies can randomly assign newborns to different experimental conditions, but subsequent follow-up studies have assessed group performance in comparison with full-term or nonexposed infants to determine degree of catch-up.

BREAST-FEEDING AND IQ

There has been considerable interest in the finding by Lucas *et al.* (12) that children who had been breast-fed as infants

had significantly higher IQ scores at 7.5 to 8 yr of age than those not breast-fed. This finding and the high rate of accumulation of LCPUFA in the retina and cortex during the last trimester of pregnancy and postnatally have been used to suggest that bottle-fed infants may miss some of the nutritional benefits of exposure to LCPUFA found in mother's milk (e.g., 6,8). However, human milk contains many components not present in infant formula, and comparisons of these groups cannot provide evidence for a single dietary component. Similarly, although an IQ difference remained after control for social class and maternal education in the Lucas *et al.* study, we found that the decision to breast-feed may reflect other factors, such as parenting skills, maternal personality characteristics and IQ, that may be responsible for the higher IQ scores in the children.

In an earlier study, we compared cognitive and personality correlates of breast-feeding in two independent cohorts: (i) 137 African-American inner-city mothers and (ii) 50 predominantly white lower-class mothers receiving WIC (Women, Infants, and Children, a U.S. government program to provide dietary assistance to financially disadvantaged families with small children) support (11). The decision to breast-feed and the duration of breast-feeding were positively related to maternal verbal IQ on the Peabody Picture Vocabulary Test-Revised (PPVT-R) (13) and ego development (14) in both samples (see Table 3 in Ref. 11). Two earlier studies also reported that breast-feeding mothers had higher verbal IQs and provided a more enriched home environment (15,16). We have since found that differences in maternal IQ and intellectual stimulation may account for the reported association between breast-feeding and childhood IQ (17).

Since 1980 we have been conducting a longitudinal study on the effects of prenatal exposure to PCBs (18). The data presented here are from this Michigan cohort of 323 white, predominantly middle-class 4-yr-old children. Although prenatal PCB exposure is associated with subtle cognitive deficits, no PCB-related cognitive deficits have been found in relation to postnatal exposure from breast milk (2,19,20). Data on feeding were collected at 2, 4, 5, and 7 mon, and infants were classified in one of five categories ranging from exclusively breast-fed to exclusively bottle-fed. These detailed estimates were highly correlated with duration of nursing ($r = .94$) and suggest that weeks of nursing can be used to indicate amount of breast milk consumed (21).

The children were administered the McCarthy Scales of Children's Abilities and the PPVT-R in the child's home at a mean age of 4.1 yr. The McCarthy Scales yield a General Cognitive Index that is highly correlated ($r = .81$) with IQ. Socioeconomic status (SES) was assessed on the Hollingshead Scale (22), an index that is more strongly related to early childhood cognitive functioning than other indices of SES (23). Maternal verbal IQ was assessed on the PPVT-R. Quality of parenting was evaluated on the Home Observation for Measurement of the Environment (HOME; 24), a semistructured maternal interview and observation of mother–child interaction. (The PPVT-R and HOME will be described in greater detail later.)

The majority (73.4%) of the mothers breast-fed for an average of 28.1 wk (SD = 27.7). As in the two other cohorts described above (11), breast-feeding was related to higher social class and education in this cohort, and mothers who breast-fed scored higher on the PPVT-R and had better parenting skills on the HOME.

Children who were breast-fed scored significantly higher on the McCarthy and PPVT-R tests at 4 yr, confirming the findings of the Lucas *et al*. (12) study (Table 1). The beneficial effect of breast-feeding remained significant after inclusion of social class and education in the regression analyses, but addition of maternal IQ and the HOME parenting score in the next step reduced the breast-feeding, social class, and educational influences to nonsignificant levels.

When the Michigan cohort was assessed at 11 yr on the Wechsler Intelligence Scale for Children-III (WISC-III) (21), the same pattern of effects was detected, namely, that breast-feeding was associated with higher IQ scores in the older children, but the effect disappeared again when maternal IQ and the HOME score were included in the regression analyses (25). At 11 yr, achievement tests were also administered to the children. No between-group differences were found on the Wide Range Achievement Test-Revised (WRAT-R) Spelling and Arithmetic subtests (Ps > .6). By contrast, achievement scores on the Woodcock Word, Passage, and Reading Comprehension tests were higher for breast-fed than bottle-fed children. As with the IQ scores, the relations between breast-feeding and achievement scores were significant after inclusion of social class and maternal education but not after inclusion of maternal IQ and the HOME scores.

These findings confirm those of the Lucas *et al*. (12) study regarding the IQ advantage shown by children who were breast-fed as infants and extend them to a full-term sample. However, our study included direct measures of maternal IQ and parenting skills. After these more direct measures of parental input were controlled statistically, breast-feeding no

longer appeared to affect childhood IQ. The mother's decision to breast-feed presumably reflects her concern with her infant's health and her motivation and ability to stimulate and enrich her child's subsequent development, which are at least partly independent of social class and education.

POTENTIAL CONFOUNDING VARIABLES

As already indicated, ethnic, socioeconomic, parenting, and intellectual differences associated with incidence of breast-feeding are known to influence infant outcome (11). In laboratory animal studies, random assignment can control for individual differences in genetic make-up, and cross-fostering for poor parenting. Given that complete random assignment will not necessarily occur in LCPUFA supplementation studies, it is important to compare experimental and breast-feeding reference groups in order to rule out any other group differences that might account for the observed differences. In fact, failure to control for measures, such as maternal IQ or quality of parenting, may underplay the positive role of the nutritional supplement and result in Type II error, the failure to recognize a true effect or, in this case, to understate the magnitude of the effect. If, as shown above, offspring of breast-feeding mothers consistently test at slightly higher developmental or IQ levels, a lower score for a supplementation group may be due to lower maternal IQ scores that are transmitted genetically and/or environmentally to their offspring rather than to a lack of an LCPUFA effect. Maternal IQ in these instances acts as a suppressor of the true effect.

Socioenvironmental influences. Measures selected to represent the potential confounders must be both reliable and valid because measurement error in the control variables can threaten the validity of any causal inferences drawn from the data. Although SES and maternal education have been used to assess socioenvironmental influences in some studies, these variables assess environmental effects on child performance less adequately than direct measures of quality of parenting and parental intelligence (17). A standard instrument for evaluating quality of parenting is the HOME Inventory (24), which combines a semistructured parental interview with informal observation of parent–child interaction to assess quality of parental intellectual stimulation and emotional responsiveness. The validity and sensitivity of the HOME as an indicator of socioenvironmental influences on development have been demonstrated by evidence that it explains significant variance in childhood cognitive functioning over and above that attributable to socioeconomic status (SES) and maternal education (17,25,26). Its validity for use with African-American samples has also been established (27). Although designed to be administered in the home, considerations of personal safety may preclude home visits in certain neighborhoods. The validity of administering the HOME in the laboratory has been demonstrated at 12 and 24 mon (28,29).

Because it is often not possible to perform a full IQ test on parents and because vocabulary is the strongest single correlate of IQ, a standardized vocabulary test, such as the PPVT-R (13), can be used to assess parental intelligence. The PPVT-R is a brief vocabulary recognition test that (i) is strongly correlated with more comprehensive measures of adult IQ, such as the Wechsler Adult Intelligence Scale, median $r = .72$, (ii) is highly stable over a 1-yr period, median $r = .72$ (13), and (iii) has been shown to be valid for use with various populations (11).

A parental vocabulary test assesses two sources of extraneous influence on child cognitive performance, genetic endowment and quality of stimulation, both of which may need to be controlled. Standardized vocabulary tests may not be valid, however, for minority or at-risk populations. Adult vocabulary scores are very low in most economically disadvantaged samples, averaging 75 on tests standardized to a mean of 100 (SD of 15), for example, in both inner-city Cincinnati (30) and Detroit (11). In Detroit, more than one-third of the mothers scored below 70 on the PPVT-R, even though few if any appeared to be functionally retarded. The mothers' scores were higher on two Performance IQ scales from the Wechsler Adult Intelligence Score; scores normalized to a mean of 100 (SD of 15) averaged 82.5 (SD = 9.6) and 85.4 (SD = 9.7) for Block Design and Picture Completion, respectively. The PPVT-R was, nevertheless, more strongly correlated with other relevant maternal demographic and personality variables than the Performance IQ scores (11). Although the low vocabulary scores were misleading, presumably owing to the limited educational opportunities available to these inner-city mothers, the PPVT-R apparently rank-ordered them appropriately within the cohort.

SAMPLE SELECTION AND ATTRITION BIAS

Exclusionary criteria. In evaluating the effects of LCPUFA supplementation or deficiency, infant exclusionary criteria should include major chromosomal anomalies or neural tube defects or multiple births, conditions known to have a major impact on cognitive outcome. Inclusion of a cognitively impaired child in one of the experimental groups may bias the findings and result in another instance of Type II error. Similarly, unless maternal instruments are translated into the mother's primary language and there are interviewers who are fluent in the mother's language, inclusion of mothers who do not speak English may lead to a considerable amount of missing or poor data. Data from infants or children who are "untestable" or refuse or are unable to cooperate may also need to be excluded from the data set or from analyses of specific outcomes for which most of the data are missing. An analysis should, however, be conducted to see whether such children are found more often in one experimental group or another, since a specific type of supplement may be responsible for their inability to perform.

It is important to test that random assignment to condition has been successful by comparing maternal demographic, intellectual, and parenting characteristics, as well as gestational age, gender, parity, and birth size of the infant for the supplementation groups at the outset of the study. Similarly, in any

long-term follow-up, it is important to test for attrition bias since it is possible that demographic or other socioenvironmental differences that may influence neurobehavioral or physical outcome may affect which infants are brought back for reassessment. For example, working mothers or mothers whose infants are ill are sometimes less likely to return for follow-up, thereby affecting outcome. If such a systematic difference between groups is detected, it can be controlled in the multivariate analyses.

It is also important to ensure that there is sufficient power (a large enough *n*) in each experimental group both at the onset and at follow-up to assess the desired outcomes (31). In our alcohol research, we demonstrated that an insufficient number of moderately to heavily exposed children in a follow-up cohort can result in a lack of alcohol-related effects on the Bayley Scales of Infant Development (see below for description) that would otherwise be found were enough such children represented in the long-term sample (32). In the case of alcohol exposure, we found that 45 moderately to heavily exposed infants proved sufficient to detect a subtle alcohol effect in our Detroit cohort, whereas another large study conducted in Cleveland with only seven moderately to heavily exposed infants did not. When all but seven of the infants whose mothers drank above a moderate threshold (5 oz. AA/d or more, where AA is absolute alcohol) were randomly deleted from the Detroit data, the zero-order correlation of alcohol with the Bayley dropped from −.17 to −.05, similar to the −.06 correlation reported in the Cleveland study. If we had not overrepresented moderate to heavy alcohol users in our cohort, we would have failed to detect a true relation between prenatal exposure and infant outcome.

Statistical analysis. In multivariate analysis, the coefficient assessing the magnitude of the experimental effect is likely to be unreliable if the ratio of subjects to independent variables is too low; a minimum of 20 subjects per independent variable is recommended (33). In addition, the inclusion of control variables unrelated to the developmental outcome is likely to increase the error term, that is, make the statistical analysis less accurate, which can make it more difficult to detect significant effects (34).

For these reasons, control variables are usually prescreened to determine which ones to include in the multivariate analyses. This prescreening is based on the premise that a control variable cannot be the true cause of an observed deficit unless it is related to both predictor and outcome (35). In our Detroit alcohol study, all control variables that were at least weakly related to the outcome being evaluated (at $P < .10$) were included as potential confounders. The $P < .10$ criterion is conservative in this context because it includes even weak potential confounders. Control variables are usually selected based on their relation to outcome because their inclusion will reduce the error term, thereby improving the chances of detecting real effects (34). Control variables can be selected either by examining their univariate relations with each outcome or simultaneously by stepwise multiple regression (e.g., 30). A group effect is inferred only if the relation between the predictor and outcome is significant at $P < .05$ after controlling for the potential confounders.

Confounders that are too highly correlated with each other ($r = .70$ or more) should also not both be included in multivariate analyses at the same time since they may be too confounded to determine which is the true predictor of the outcome being studied (36). For example, since pre- and postnatal drinking by the mother are moderately correlated, statistical analyses that include both may obscure true effects of prenatal exposure and lead to the conclusion that only the postnatal social environment is influencing the child's performance. A similar problem in LCPUFA research occurs when both docosahexaenoic and eicosapentaenoic acids, two highly correlated fatty acids, are included in the same multivariate analysis with the former usually obscuring the role of the latter.

NEW INFANT INFORMATION PROCESSING OUTCOME MEASURES

Virtually all prospective studies of the effects of teratogenic exposure or medical or socioenvironmental at-risk conditions have used the Bayley Scales of Infant Development (37) to assess neurobehavioral function in infancy. The Bayley is an apical, multidomain test, which provides both a Mental Development Index (MDI) and a Psychomotor Development Index (PDI) score. In our research, we have tried to include infant information processing tests with better predictive validity than the more traditional assessments, such as the Bayley. We hoped to detect effects early in development and expected that more focused, narrow-band tests would provide more information about the specific domain affected. We found, as predicted (3), that these information processing tests were less influenced by socioenvironmental factors than the Bayley measures (see Table 2 in Ref. 1).

Several new paradigms for assessment of infant information processing have been advanced in recent years (see Ref. 8 for an excellent review of infant tests used in LCPUFA supplementation studies). Traditional infant tests, such as the Bayley Scales, focus on rate of progress through developmental milestones, an approach also taken by measures from the Uzgiris-Hunt (38) Scales and complexity of play tasks (e.g., 39,40). Other tests based on habituation and paired comparison paradigms focus more directly on information processing capabilities (41). Some investigators (3,42) have emphasized measurement of novelty preference in the paired comparison paradigm, whereas others have recommended assessment of duration of attention and inattention during familiarization (43). Newer infant information processing tests, such as the FTII, appear to be especially sensitive to specific deficits, enabling researchers to detect deficits in memory, attention, or processing speed previously seen only in older children (e.g., 1,2).

Furthermore, novelty preference has been found to have markedly better predictive validity for later performance on standardized intelligence tests than the Bayley (3,44), and three studies have shown that shorter fixation duration during

infancy also predicts better childhood performance (45–47). Shorter fixation duration, which has been related to superior performance on numerous infant tasks (e.g., 43), may indicate more efficient information processing (48), which is often measured by reaction time (RT) paradigms in older children and adults. We have recently reported a direct relation of fixation duration on the FTII and cross-modal transfer test to infant RT using this paradigm (49).

DETROIT PROSPECTIVE LONGITUDINAL PRENATAL ALCOHOL EXPOSURE STUDY

We have been studying the effects of prenatal alcohol and cocaine exposure in a cohort of 480 inner-city infants. In this study visual recognition memory was assessed at 6.5 and 12 mon using the FTII novelty preference test developed by Fagan and Singer (3). The infant was seated on the mother's lap in front of a portable observation chamber containing a pivoting stimulus presentation "stage," on which were located two stimulus plaques. Infant fixation to the stimuli was judged from corneal reflections of the stimulus targets observed through a 0.64-cm peephole located halfway between the two plaques and recorded on a Zenith PC computer. The stimuli consisted of 10 pairs of faces, measuring approximately 14.5 cm from crown to chin and mounted on a 20.0 × 17.5 cm white posterboard. In the 6.5-mon test, the familiar targets were shown until the infant had fixated them for a total of 20 s. The familiar target was then paired with a novel target for two 5-s periods, reversing left-right positions from one period to the next. The same pairs of photos were used in the 12-mon test, but the initial study time was shortened to 12 s and the test period to 3 se on each side.

Preference for novelty on the FTII is computed separately for each problem by dividing duration of fixation to the novel stimulus by total time fixating the novel and familiar stimuli and then averaging across the 10 problems. Mean preference for novelty was calculated by averaging percentage of novelty preference for the 10 problems at each age and then, to increase reliability, across the two ages (see 43,50).

Following Colombo *et al*. (43), mean fixation length or duration was computed for each problem by dividing the total duration looking time by the number of looks and averaging these across the 10 problems and then across the two ages. It is also possible to compute length of look for the familiarization or test period only by dividing duration looking time for that period by number of looks during that period. Since we found basically the same pattern of results when looking at mean duration looking time for the total or for the familiarization period only, we have usually presented the findings in terms of the mean duration fixation for the combined familiarization and test periods. FTII data were used in our study only if available for both visits and were omitted for a few infants who completed fewer than three problems, whose mothers interfered throughout testing, who were sick during the visit or refused to look at the photos, or because of computer failure.

Age at time of testing was adjusted for infants born at less than 38 wk gestational age. For the FTII, for example, infants should be seen for the 6.5-mon assessment within 1 wk of the conceptual rather than the chronological age. Since the Bayley Scales are standardized, a broader testing window is permissible, and age at testing does not need to be as closely adjusted.

Prenatal alcohol exposure sample. The sample described here consists of the 403 black infants (233 males, 170 females) for whom there are complete FTII data. They were born to women recruited antenatally based on their consumption of alcohol during pregnancy. The women were recruited at their first visit (mean = 23.3 wk of pregnancy, SD = 8.0) to the prenatal clinic of a large, inner-city maternity hospital serving primarily (92%) black women. In using the protocol described in Jacobson *et al*. (51), each gravida was interviewed regarding her alcohol consumption both currently and at conception. All women reporting alcohol consumption at conception averaging at least 0.5 oz of AA/d (about one drink per day), a random sample of approximately 5% of the women who drank at lower levels or abstained, and 57 high-cocaine (at least 2 d/wk), low alcohol (<0.5 oz AA/d) users were invited to participate. The high-cocaine/low-alcohol users were included to reduce the risk that alcohol would be confounded with cocaine exposure in this sample.

The sample was predominantly lower lower class (mean = 19.8, SD = 8.5 on the Hollingshead Four Factor Index (22), with 84.4% receiving welfare. Mean maternal age was 26.9 yr (SD = 6.1), with 3.5% of the women between 14 and 17 yr of age. Only 10.7% were married. Maternal education was low (M = 11.7 yr, SD = 1.6, range = 6–18); 42.7% had not completed high school. Mothers averaged 5.3 prenatal clinic visits (SD = 3.2), with 13.2% having only one prenatal visit. Infant exclusionary criteria included birthweight less than 1500 g, gestational age (GA) less than 32 wk, major chromosomal anomalies or neural tube defects, and multiple births. About one-third of the infants (35.0%) were first-borns. Mean birthweight was 3088 g (SD = 530); mean GA was 39.4 (SD = 1.6). Seven newborns (1.8%) weighed less than 2000 g. Age of testing was corrected for the 11.4% of the infants born between 32.5 and 38.0 wk gestation by testing them at the conceptual age equivalent to that of the full-terms.

Processing speed effects. The most consistent neurobehavioral effect of prenatal alcohol exposure in older children relates to attention. Poorer accuracy and slower reaction times have been reported in a Seattle cohort of 4- and 7.5-yr-old children exposed prenatally to alcohol at moderate levels (52,53), an effect also detected in children with fetal alcohol syndrome (54). These findings led Streissguth (52,53) to suggest an alcohol-related deficit in "speed of central processing."

In our Detroit longitudinal study we included three tests that assess processing speed in infancy: the FTII, a test of cross-modal transfer, and Haith's Visual Expectancy Paradigm (VExP; 55), which for the first time assesses RT in infancy. Processing speed was assessed in the FTII recognition memory and cross-modal tests in terms of length of visual fix-

ation. Short looks on the FTII and cross-modal tests are associated with more rapid information processing and are predictive of higher childhood IQ (43,47,56).

We found that prenatal alcohol exposure, like LCPUFA (9), is unrelated to novelty preference in these infant tests (Table 2). Prenatal alcohol was, however, related to slower processing speed on the FTII and cross-modal transfer test and longer latencies to respond on the VExP (1,57). This pattern of impairment seems specific to alcohol exposure and is different from that seen in infants exposed to environmental contaminants, such as PCBs (2,58), or other prenatal substance exposure, such as heavy maternal cocaine use (59). These deficits, which can already be detected in infancy, were consistent with speed of processing deficits seen in older alcohol-exposed children (52,53). Early deficits in play and symbolic development were also related to prenatal alcohol exposure (1).

By contrast to pregnancy drinking, postpartum drinking by the mother or primary caregiver did not relate significantly to any of the outcomes tested (all $P > .15$, after adjustment for the potential confounders) (Table 2), suggesting that these effects are related to prenatal exposure rather than a consequence of being raised by a drinking mother.

Predictive validity. Several studies have documented the predictive validity of new infant information processing measures by looking at the association between the infant measures and childhood IQ assessed on the WISC-III or other tests (56,59–62). In addition to a Full Scale IQ, the WISC-III provides a Verbal IQ score which summarizes performance on the more verbally mediated subtests, including Vocabulary, Information, and Similarities, and a Performance IQ, which is based on subtests that assess more perceptual organization tasks, such as Block Design, Object Assembly, and Picture Organization. Analyses of the data from the first 94 Detroit children seen at follow-up visits (47) indicate that the FTII recognition memory measure appears to be a stronger predictor of 7-yr Verbal IQ on the WISC-III than the Bayley MDI, and 12-mon fixation duration was related to poorer Performance IQ scores (Table 3). Whereas the Bayley PDI was not significantly related to either Verbal or Performance IQ at 7 yr, level of play, assessed on the Belsky play scale (39), was moderately predictive of Verbal IQ.

A regression analysis indicated that the MDI did not contribute independently to Verbal IQ (Table 4). By contrast, fixation duration, a measure of processing speed, and the 13-mon MDI, which is composed largely of fine-motor manipulation and spatial ability items, were independently associated with 7-yr Performance IQ. When play was included in the Verbal IQ regression, it provided an additional independent dimension of verbal cognitive function, probably because it assesses early symbolic development. These effects remained virtually unchanged when the Infant HOME and maternal verbal IQ from the PPVT-R were included in the regressions. These data are among the first to demonstrate these associations in a highly disadvantaged, inner-city sample. These

findings provide further support for the hypothesis that memory/attention (as assessed by novelty preference) and processing speed (fixation duration) represent separate underlying components of intellectual function in infants and children. These data are consistent with findings from two studies of infant monkeys, which also found evidence for independent effects on visual recognition memory/novelty preference and fixation duration of taurine and LCPUFA, respectively (63,64). In addition, symbolic play, assessed on the Belsky play scale (39), appears to reflect yet a third independent component of intellectual function (Table 4).

VISUAL ACUITY

Procedure. To ensure that the alcohol-related infant deficits detected in our research reflect cognitive rather than perceptual difficulty, infants were screened at 6.5 and 12 mon on the Teller Acuity Card Procedure (4), a test commonly used in LCPUFA studies to assess the effects of LCPUFA supplementation on visual acuity in infants. The infant is seated on the mother's lap in front of a gray screen designed by Vistech, Inc. (Dayton, Ohio). A shield suspended in front of the screen prevents the mother from viewing the stimuli and inadvertently influencing the infant's gaze. In this procedure, based on infant fixation of patterned stimuli, the infant is shown a visual target with vertical black and white stripes, which appears alternately on the right and left side of the gray screen. An examiner notes side preferred by observing the infant's gaze through a peephole in the center of the screen. Over successive trials, progressively narrower stripes are displayed. Acuity is defined by the smallest grating size (spatial frequency) the infant fixates and the distance of the infant from the stimuli.

Visual acuity effects. All but four infants in the cohort scored in the normal range at both ages. Two with low scores at 6.5 mon scored within the the normal range at 12 mon; two with marginal scores at 12 mon performed well on the cognitive tests at 12 and 13 mon. There was therefore no evidence that visual acuity problems interfered with the assessment of cognitive performance.

Although acuity was unrelated to prenatal exposure to marijuana, opiates, or smoking (*r* ranged from .03 to .08, n.s.), alcohol exposure was associated with poorer infant visual acuity, after control for potential confounders (Table 5). This relation was not mediated by GA or birth size since acuity was unrelated to GA, birthweight, length, or head circumference (*r* ranged from .01 to .08, n.s.). As can be seen in Table 5, the alcohol effect on acuity was particularly strong for infants of mothers 30 yr or older. This effect is consistent with our finding that maternal age appears to be a moderator for several of the alcohol-related neurobehavioral deficits we have detected in infancy (65). Performance on the Bayley Scales, processing speed on the FTII and cross-modal transfer, and elicited play were more severely affected in infants born to older moderate-to-heavy drinking mothers (at least 30 yr of age).

A Pearson correlation analysis indicated a significant relation between visual acuity and the FTII mean length of gaze and infant reaction time on the Haith VExP (Table 6). Poorer acuity was associated with slower processing speed. Regression analyses show, however, that, although correlated, the effect of prenatal alcohol exposure and visual acuity on mean fixation duration and the infant RT measures are independent, even after control for potential confounders (Table 7). Thus,

the alcohol-related processing speed deficits were not mediated by acuity.

CONCLUSIONS

There has been considerable recent interest regarding the advisability of adding LCPUFA to infant formula. The issue was first examined in studies such as those conducted by Neuringer and colleagues. The findings of Lucas *et al*. (12) that children who had been breast-fed as infants had higher IQ scores than those not breast-fed, and the concern that preterms and bottle-fed infants may lack some of the nutritional benefits of exposure to LCPUFA found in mothers' milk, have also been noted. The findings presented here suggest that any comparisons between breast-fed and supplemented groups should include measures of maternal IQ and quality of parenting on which these groups tend to differ. Failure to control for maternal IQ or quality of parenting may underplay the potentially positive role of the nutritional supplement.

Although our data raise doubt about whether higher IQ in full-terms can be attributed to the nutritional benefits of breast-feeding, they have no bearing on evidence of the medical and psychological benefits of breast-feeding, which have been extensively demonstrated in other studies, or on the need to provide nutritionally adequate formula for preterm or other nutritionally-deprived or at-risk infants. Nor do our findings detract from the potential benefits of LCPUFA supplementation to infant formula. By contrast to prenatal alcohol exposure, which is related to poorer acuity and longer fixations on the FTII, animal (63,64) and human studies (7–9) suggest that LCPUFA supplementation may result in enhanced acuity and shorter, more optimal fixation duration patterns, which have been found to be predictive of more optimal cognitive function and higher IQ in children.

Given the alcohol-related deficits in infant visual acuity and fixation duration found in our Detroit sample, maternal report of prenatal alcohol use should also be considered a potential confounding variable for human studies of LCPUFA supplementation on these outcomes. A brief screening of alcohol use during pregnancy at the time of recruitment may help identify women whose infants may be affected. Failure to control for the impact of moderate to heavy prenatal alcohol exposure (>.05 oz AA/d) in an LCPUFA study may mask true effects of the supplement on these outcomes.

As noted earlier, chronic alcohol exposure has recently been linked to altered levels of LCPUFA concentrations in the feline brain and retina, leading the authors to note that women who abuse alcohol during pregnancy may be especially at risk for reduced levels of essential fatty acids and may need to supplement their diets in order to ensure an adequate neural supply of 22:6n-3 (5). In our research, we found a relation between visual acuity and processing speed. Our findings suggest, however, that although prenatal alcohol exposure is related to both poorer infant visual acuity and processing speed, these appear to be relatively independent alcohol-related deficits. Thus, animal and human studies indicating a relation between LCPUFA supplementation and enhanced visual acuity and shorter visual fixations may, in fact, represent relatively independent effects of supplementation on both acuity and cognitive processing speed.

ACKNOWLEDGMENTS

This research was supported by grants RO1-AA06966 and P50-AA07606 from the National Institute of Alcohol Abuse and Alcoholism, with supplemental support from a Minority Access to Research Careers grant No. T34-GM08030 and a Minority Biomedical Research Support grant No. SO6-RR08167 from the National Institutes of Health and a research grant from the Joe Young, Sr. Fund from the state of Michigan. I would like to thank Joseph L. Jacobson and Robert J. Sokol, my collaborators on the Detroit alcohol study, and Lisa M. Chiodo, Renee Berube, Sonia Narang, and Susan Martier, all of whom have worked on major aspects of this study. I would also like to thank Greta Fein and Pamela Schwartz, who together with Joseph Jacobson were collaborators on the infant PCB study, supported by a grant from the U.S. Environmental Protection Agency. Follow-up PCB studies conducted in collaboration with Joseph Jacobson were funded by the National Institute of Environmental Health Sciences. Lastly, my sincere appreciation goes to Susan Carlson and Martha Neuringer, who introduced me to the LCPUFA research area.

Effects of Dietary Polyunsaturated Fatty Acids on Neuronal Function

John D. Fernstrom*

Departments of Psychiatry, Pharmacology, and Neuroscience,
University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania 15213

ABSTRACT: Diets deficient in linoleic acid (18:2n-6), or that have unusual ratios of linoleic acid to α-linolenic acid (18:3n-3) induce changes in the polyunsaturated fatty acid (PUFA) composition of neuronal and glial membranes. Such changes have been linked to alterations in retina and brain function. These functional effects are presumed to follow from the biochemical consequences of modifying membrane PUFA content; known effects include modifications in membrane fluidity, in the activities of membrane-associated, functional proteins (transporters, receptors, enzymes), and in the production of important signaling molecules from oxygenated linoleic and α-linolenic acid derivatives. However, despite the demonstration that central nervous system function changes when dietary PUFA intake is altered, and that in general, membrane PUFA content influences membrane functions, little work has focused specifically on brain and retina to reveal the underlying biochemical bases for such effects. This review examines this issue, looking at known effects of dietary PUFA on neurons in both the central and peripheral nervous systems, and attempts to identify some approaches that might promote productive investigation into the underlying mechanisms relating changes in dietary PUFA intake to alterations in neuronal and overall nervous system functioning.

Paper no. L7646 in *Lipids 34*, 161–169 (February 1999).

Over the past 30 yr, evidence has accumulated showing that modification of the dietary intake of linoleic (18:2n-6) acid or of the proportion of linoleic to α-linolenic (18:3n-3) acids, particularly during development, influences the content of these and related polyunsaturated fatty acids (PUFA) in the membrane lipids of cells (1,2). Modification of the PUFA content of cell membranes has a large impact on membrane fluidity and the functioning of a variety of membrane-associated proteins (transporters, enzymes, receptors) (3,4). As a result, cell functions are altered, such as glucagon-stimulated adenylate cyclase activity in liver (5) and insulin binding and insulin-stimulated glucose transport and lipogenesis in adipocytes (6).

The central nervous system (CNS) is not immune to such effects. Indeed, modifications in the dietary intake of linoleic acid or in the proportion of linoleic to α-linolenic acids were repeatedly shown to influence neuronal and glial membrane contents of several PUFA, including arachidonic acid (AA, 20:4n-6), eicosapentaenoic acid (EPA, 20:5n-3), and docosahexaenoic acid (DHA, 22:6n-3) (1,2,7,8). The most carefully studied CNS effects of dietary PUFA relate to the visual system, where DHA is a major constituent of photoreceptor membranes (2). Photoreceptor DHA abundance in these (as well as in retinal and occipital cortex) membranes is modified by dietary PUFA content and is associated with changes in the electroretinogram and in visual acuity tests in humans and nonhuman primates (2,9–12). These findings indicate that functional effects occur at several levels of the visual system, including the photoreceptor, the retina, and the visual areas of the brain (13). [A separate literature source also describes dietary PUFA effects on learning and memory, but the complexity of the models examined and the effects obtained suggest that further work is required before a clear linkage emerges (14).]

Given reported effects of dietary fat intake on the nervous system, both with regard to membrane fatty acid composition and complex CNS functions, it would be of interest to identify underlying mechanism(s) in brain and retina that link these effects. (Presumably, the functional changes are causally related to the alterations in membrane composition.) Apart from studies that reach to the molecular level to illuminate DHA function in phototransduction (15,16), few attempts have been made to evaluate the potential connections. Occasional studies have looked for effects of dietary PUFA on brain membrane-associated activities that influence neurotransmitter function, such as acetylcholinesterase (17), or the presynaptic norepinephrine (NE) reuptake transporter (which is embedded in the presynaptic membrane, and rapidly removes the amine from the synaptic cleft, once it has been released) (18). Conceivably, dietary PUFA-induced changes in membrane functions such as these could modify neurotransmission across affected synapses in visual circuits in retina and/or brain and contribute to the observed visual changes.

A priori, to the neuropharmacologist, no obvious reason is apparent why studies have not progressed in brain and retina. The starting points for hypotheses are clear: diet-related

changes in membrane PUFA composition should modify membrane (and thus cellular) function, based on changes in (i) membrane fluidity, which could be expected to influence membrane-associated cellular functions (e.g., transporters, enzymes, receptors) (3) and, (ii) the production of second messengers (notably prostaglandins), which influence many important cell-associated functions in response to specific, external signals (4,19). Indeed, reported effects of dietary PUFA on acetylcholinesterase activity (17) and NE reuptake (18) in brain are consistent with such a hypothesis. Given the broadness of the postulated PUFA effects (to modify an array of membrane-associated functions in essentially any neuron), it is remarkable that exploratory studies identifying dietary PUFA effects on neurotransmitter systems in brain/retina (20,21) were not followed up to elucidate the biochemical mechanisms of such effects. As one example, given the existence of dopamine (DA) interneurons in the retina, their known function, the wealth of biochemical tools for studying DA neurons and receptors, and the known actions of several DA drugs on the electroretinogram (22–28), it is surprising that biochemical studies of retinal DA were not conducted under dietary conditions that alter retinal membrane PUFA content. If reuptake mechanisms, receptors, and second-messenger systems for neurotransmitters are targets of dietary PUFA action in brain and retina, many such neurotransmitter-specific effects should be awaiting discovery.

Peripheral nerves and synapses: a known site of dietary PUFA action. Although few data exist regarding dietary PUFA actions on neuronal functions inside the brain, data describing effects on neurons outside the CNS do exist. While these studies show some dietary naiveté by present standards (while they focus on manipulation of linoleic acid, they do not appreciate that α-linolenic acid content is also being modified), they are neurochemically and neuropharmacologically thoughtful, and thus offer insight into general approaches that can be taken to examine this dietary-neuronal linkage inside as well as outside of the brain.

Diet-related changes in neuronal (and glial) membrane PUFA content could affect either (or both) of two broad categories of neuronal function: conduction or transmission. Conduction describes the movement of nerve impulses along the axon from cell body to nerve terminal, while transmission is the transfer of an electrical impulse across the synapse from one neuron to the next. Both processes are complicated membrane functions: conduction requires a continuous depolarization and repolarization process to move the signal along the axon and utilizes membrane-associated enzymes (e.g., Na^+,K^+ATPase) and ion pores. Transmission first involves an electrical–chemical transduction, during which the electrical signal, on reaching the nerve terminal, causes a chemical (neurotransmitter) to be released into the synapse (the small space between a nerve terminal and an adjacent neuron). The neurotransmitter molecules move into the synaptic space, where some quickly occupy specific receptors on nearby neurons. Finally, a chemical–electrical transduction occurs, for the appropriate receptor type, and depolarization of the neuron occurs. (Some receptors do not cause depolarization, when occupied, but instead initiate other functions, such as the activation of enzymes and various cellular processes.) Like conduction, transmission thus involves many membrane-associated events, including the release of transmitter through the terminal membrane (or from vesicles that join with the membrane), its association with membrane-bound receptors (and attendant ion pores or second-messenger systems), and its rapid removal from the synapse either by a process of reuptake into the terminal (involving membrane-associated transporters) or destruction by membrane-associated enzymes (e.g., for acetylcholine, acetylcholinesterase) (Fig. 1). Events such as these occur in most neurons (although some neurons make direct membrane contact, and thus do not require neurotransmitters to share electrical signals), suggesting that dietary PUFA-associated changes in neuronal membranes and functions might be widespread.

A few studies have examined the influence of the diet on peripheral nerve membrane PUFA profile and on conduction. Yao *et al.* (29) fed weanling rats 5% fat diets consisting of either hydrogenated coconut oil (n-3 and n-6 fatty acid-deficient) or corn oil (n-3 fatty acid-deficient). After 8 mon, most phospholipids in sciatic nerve myelin of rats fed the coconut oil diet contained considerably lower levels of the n-6 fatty acids than was the case in rats ingesting the corn oil diet. Moreover, following nerve crush, the regenerating sciatic nerve in coconut oil-fed rats did not experience the large increase in AA observed in the regenerating nerves of corn oil-fed rats (perhaps suggesting that the nerves would not regenerate normally). In a functional study of like dietary design, similar effects were observed on myelin phospholipids, but no impact of these differences was noted on nerve conduction velocity, the compound action potential, or on the morphological features of nerve regeneration that follow injury (30). Conceivably, functional effects on nerve conduction properties might emerge in animals made linoleic acid-deficient during pre- and postnatal development, rather than postweanling, but no data are available that evaluate this possibility.

Bourre *et al.* (31) also looked at peripheral nerves under conditions of dietary PUFA deficiency but focused solely on membrane fatty acid composition (there were no functional measures). Nevertheless, it is an interesting study, showing a marked membrane deficiency in DHA (and a large excess of 22:5n-6) in rats fed 1.5% sunflower oil for three–four generations, when compared to animals ingesting 1.5% soybean oil. Such PUFA abnormalities were corrected by changing n-3-deficient rats (sunflower oil-fed) to a soybean oil diet (high in 18:3n-3), but the reversal required nearly 2 mon. An evaluation of nerve conduction properties in this paradigm would be interesting.

In contrast to the scarcity of studies of nerve conduction in animals fed diets varying in n-3 and n-6 fatty acids, more information is available showing clear changes in neurotransmission in the peripheral nerves of animals consuming a linoleic acid-deficient diet. The nerves most carefully studied are the postganglionic sympathetic neurons (for which NE is

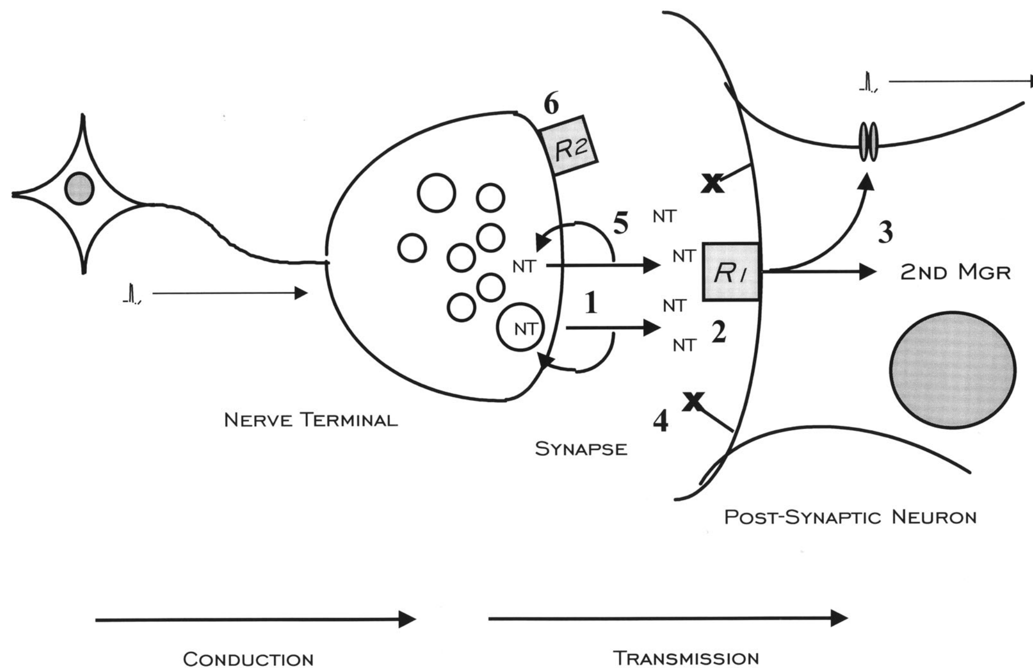

FIG. 1. Neuronal conduction and transmission. The depolarization wave moves along the axon from cell body to nerve terminal (conduction). On reaching the nerve terminal, neurotransmitter (NT) is released into the synapse (1), where it quickly diffuses, some molecules reaching postsynaptic receptors [R_1] (2), with which they bind, leading to postreceptor events that promote neuronal depolarization and/or second-messenger-mediated cellular events (3). Other NT molecules interact with catabolic enzymes (4) and are destroyed, with presynaptic reuptake transporters (5), or with presynaptic receptors [R_2] (6). X = membrane-bound catabolic enzyme; 2nd mgr = second messenger (e.g., cyclic AMP).

the neurotransmitter) that innervate the heart. The heart rate (beats/minute) and force of contraction are stimulated by the firing of the sympathetic nerves that innervate it, effects that are mediated primarily *via* β adrenergic receptors on the heart (pacemaker and muscle cells). When most sympathetic nerves fire, therefore, they release NE, which interacts with postsynaptic (i.e., heart cell) β-receptors to increase the heart rate (chronotropic action) and force of contraction (inotropic action). Since β-receptors are adenylate cyclase-linked (32), the chronotropic and inotropic effects on the heart are cyclic AMP-mediated. Once the sympathetic nerve has released NE, the transmitter is removed from the synapse by a reuptake mechanism located on the nerve terminal. This mechanism ensures that the synaptic dwelling time of NE will be short, thus enabling the synapse to be quickly "reset" for the next firing. One other relevant feature of sympathetic nerve endings is that their surface contains a "presynaptic" α_2 receptor (also adenylate cyclase-linked), which can be occupied by NE, once released. Activation of this receptor exerts a negative feedback effect on nerve firing and NE release. These relationships are summarized in Figure 2.

The dietary paradigm involved the *ad lib* feeding of pregnant rats (from day 10 of gestation) a semipurified, casein-based diet containing either 16% (by weight) coconut (n-3 and n-6 fatty acid-deficient) or sunflower oil (n-3 fatty acid-deficient) (18). [A third group remained on the standard laboratory rat diet (4–5% fat).] The rats continued receiving their respective diets at parturition, and the pups were weaned onto the same diets. The newborn animals were studied at intervals from birth to young adulthood (postnatal days 60–65), a time during which the sympathetic innervation of the heart continues to develop and mature (33). Since the sunflower oil and coconut oil diets were of similar composition, containing equivalent amounts of fat, while the regular diet was of different composition and much lower fat content, the most meaningful comparisons are between the two experimental diets. Because the heart can be removed with the sympathetic nerve trunk and endings intact, all biochemical and physiological measurements could be made using just the heart, greatly simplifying experimental design and interpretation of results (since complex physiological feedback loops were no longer present).

Several interesting dietary effects were found to occur on both the sympathetic nerve terminals and the heart tissue itself. When the sympathetic endings to the heart were electrically stimulated *in vitro,* NE release was much lower from the hearts of rats that had ingested the coconut oil diet compared to those that had consumed the sunflower oil diet. This effect was noted from postnatal day 14 into adulthood. A reduction in NE release from nerve endings could follow from several effects: the nerve endings might contain less NE (and thus release less), the activity of the reuptake carrier for removing

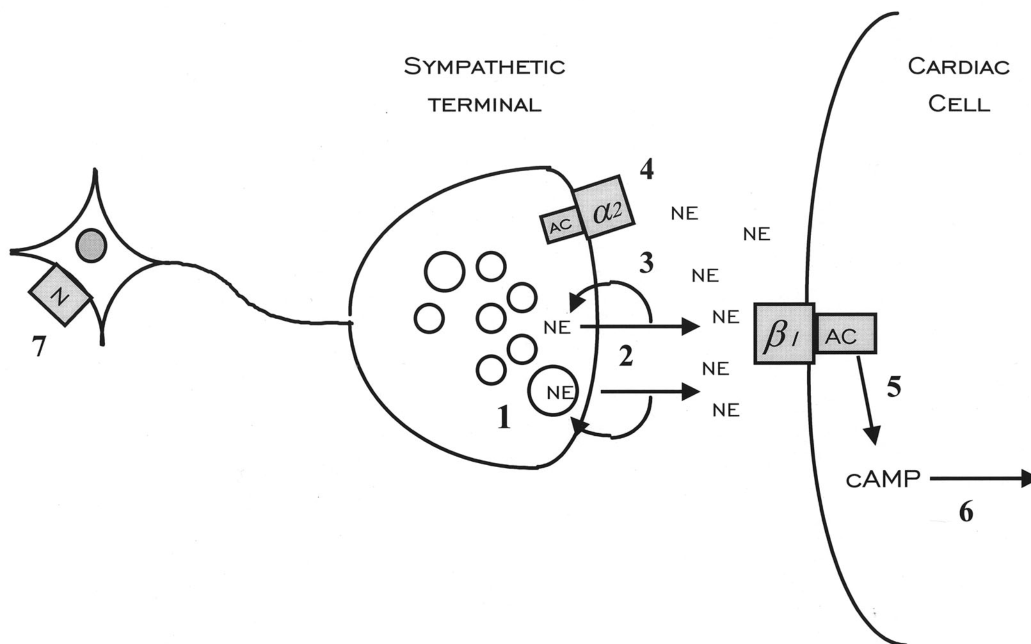

FIG. 2. Postganglionic norepinephrine synapse on heart tissue: modification by dietary polyunsaturated fatty acids (PUFA). Norepinephrine (NE) is released into the synapse, where it can interact with β (β_1) receptors on cardiac cells (leading to stimulation of cyclic AMP (cAMP) production, and thus enhanced cellular functions), with α_2 receptors on the presynaptic terminals [the receptor is also adenylate cyclase (AC) linked and causes a reduction in NE release when stimulated] or with presynaptic reuptake carriers. The postganglionic NE neuron is stimulated by preganglionic sympathetic neurons, which release acetylcholine onto nicotinic receptors (N). Changes in the NE neuron caused by dietary PUFA modifications include: (i) an increase in stored NE; an apparent reduction in NE release; (ii) (see text), an enhancement of NE reuptake, and (iii), an increase in the sensitivity of presynaptic NE α_2 receptors and increase in cAMP production (5), and (iv) an enhanced sensitivity of cardiac cells to cyclic AMP (6). Some data also indicate that PUFA can influence the sensitivity of nicotinic receptors (7), which might also modify sympathetic neurotransmission; not shown, changes in prostaglandin release by cardiac cells, which may also influence NE synaptic functions (see text).

NE from the synapse might be greatly increased, and/or the sensitivity of the inhibitory presynaptic α_2 receptors may have increased. A difference in NE content did not account for the difference in release. However, NE reuptake was greater from birth until adulthood in rats consuming the coconut oil diet vs. that in animals ingesting the sunflower oil diet (34). In addition, α_2 receptors were more sensitive to NE in coconut oil-fed than in sunflower oil-fed rats (35). Hence, the relatively lower rate of NE release from sympathetic nerve endings of coconut oil-fed rats vs. sunflower oil-fed animals could have been produced by an enhancement in the reuptake of released NE and a reduction in the release of NE secondary to the release-inhibiting action of α_2-receptor stimulation.

The heart's responsiveness to NE was also altered by diet. First, the number of β receptors on the heart was found to be greater at postnatal day 60 in rats ingesting the coconut oil diet than in those ingesting the sunflower oil diet (36). In addition, the inotropic and chronotropic efficacies of NE and isoproterenol (a β agonist) became greater as adulthood approached in the coconut oil-fed vs. the sunflower oil-fed rats (36,37). Finally, NE-stimulated cyclic AMP (cAMP) formation in heart membrane preparations was greater in coconut oil-fed than in sunflower oil-fed rats (36). Together, these results suggest that the heart's sensitivity to NE becomes greater in rats ingesting the coconut oil diet than in animals consuming the sunflower oil diet. The effects emerge by the time the animals reach postnatal days 60–65, and thus follow temporally the changes in NE release by sympathetic nerve endings. This sequence suggests a causal link, namely that in animals releasing less NE (coconut oil-fed rats), the heart compensates by becoming supersensitive to the reduced exposure to neurotransmitters. If correct, this assessment indicates that the primary effects of the dietary difference in fat source are on the nervous system (possibly the NE neuron), not the heart. However, Wince *et al.* (37) obtained data indicating that cAMP efficacy in promoting the heart's contractile force was directly affected by the diets: when hearts were exposed to dibutyryl cAMP (which crosses cell membranes) or agents that directly increase endogenous cAMP levels, the tension developed was greater in tissue from coconut oil diet-fed than sunflower oil-fed rats, indicating that the proportion of saturated to unsaturated fat in the diet directly influences cellular sensitivity to the second messenger. From these data one might suggest that the primary effect of the diets is to modulate cAMP action. If the coconut oil diet produces an enhanced cAMP response in the end-organ (the heart), and

the heart therefore pumps blood more efficiently, possibly feedback circuits that monitor and control blood pressure would adjust, in part by reducing sympathetic activity to the heart. Arguing against this possibility, however, is the view that to envision a reduction in sympathetic firing enhancing NE reuptake is difficult. Hence, the change in dietary fat may influence more than one biochemical point in the sympathetic neurons and cardiac cells. By way of summary, some of the possible sites of action for these dietary effects are indicated in Figure 2.

Only a few other studies have examined the heart's sensitivity to β-receptor stimulation. Hoffmann *et al.* (38) fed postweanling rats for 10 wk, diets either rich [12% (weight) sunflower oil, 2% lard] or poor (14% palm oil) in linoleic acid. While the strength of contraction of the heart muscle from the linoleic acid-adequate rats exceeded that from the linoleic acid-deficient rats, the inotropic effect of isoproterenol (a β agonist) was lower in linoleic acid-adequate vs. the linoleic acid-deficient heart muscle. This latter effect is thus similar to that described above. However, Rulka and Hamm (39) fed weanling rats for 4–5 wk diets containing 10% fat (weight), either as corn oil, butterfat, or a 1:9 corn oil/butterfat mix. They observed that the *in vivo* responsivity of the heart to a β agonist or antagonist was greater in the corn oil-fed than the butterfat-fed rats. This finding thus seemingly contrasts with the results above, although, as the authors point out, the diets in these studies had quite different fatty acid compositions. This latter point reveals a significant impediment to more rapid progress in this area, namely, the absence of a standardized dietary paradigm. In addition, the dietary treatment periods in all of the above studies only partly overlapped. Regardless, the important point should not be obscured that in all cases the difference in dietary fat produced a difference in the responsivity of a postsynaptic receptor for a neurotransmitter, as well as to specific receptor agonists and antagonists.

The heart represents only a single terminus for the sympathetic nervous system. Various other organs receive sympathetic fibers, including the blood vessels. Panek *et al.* (40) examined the impact of feeding weanling rats coconut oil- vs. sunflower oil-containing diets on NE release from sympathetic terminals to blood vessels, and on the vessels' responsivity to NE. Using the tail artery preparation, they observed that, like the heart, the sympathetic terminals of coconut oil-fed rats contain more NE than their counterparts in sunflower oil-fed rats, and release less NE on stimulation. When the sympathetic fibers to the tail arteries were stimulated electrically, the increments in pressure were smaller in the arteries from coconut oil-fed rats than in those from sunflower oil-fed rats, a finding consistent with diminished sympathetic NE release in the coconut oil-fed rats. However, unlike the heart, which developed enhanced sensitivity to NE under like conditions in coconut oil-fed rats, the tail artery blood vessels in these animals became less sensitive to NE (relative to that seen in the sunflower oil-fed rats). This difference appears not to have been resolved and suggests that the changes in the sensitivity of sympathetic end organs to NE that accompany alterations in dietary PUFA intake are not uniform.

Together, these studies of peripheral nerve function indicate that (i) the fatty acid composition of neuronal/myelin membranes differs markedly as a function of dietary PUFA content, (ii) nerve conductance does not appear to be influenced by differences in dietary PUFA intake, and (iii) the transmission properties of at least one class of peripheral nerve (NE-containing sympathetic neurons) are remarkably modified by changes in dietary PUFA intake.

Several points seem worthy of comment regarding these conclusions. First, too few data are available to conclude convincingly that nerve conduction is not modified by alterations in membrane PUFA profile. Further work is clearly warranted, since, for example, the activity of a key enzyme in the maintenance of the sodium and potassium gradients across neuronal membranes, Na^+K^+ATPase, has been shown by some to be altered by membrane PUFA profile (3,4,41). Second, the results described for NE (i.e., sympathetic) transmission in the heart, while indicating the possibility of quickly reaching significant biochemical detail in studies of dietary PUFA effects on neurotransmission, do not adequately investigate the range of possible mechanisms. It should be possible to use the heart preparation (or indeed, other sympathetic end-organ models) to go into greater detail in identifying dietary PUFA actions on NE neurotransmission. For example, the prostaglandins have notable effects on the sympathetic nervous system and on end-organ responsivity to NE: NE release by sympathetic nerve terminals can be inhibited by prostaglandins, which are released during nerve stimulation (by both nerve and end organ); the response of the heart and blood vessels to NE is also influenced by prostaglandins (42,43); and nicotinic cholinergic receptors that reside on and activate postganglionic sympathetic neurons may be influenced by local PUFA availability (44). Because prostaglandin release in the hearts of rats fed high- or low-linoleic acid diets differs substantially, both basally and in response to isoproterenol stimulation (38), possibly some (or all) of the NE effects on cardiac function discussed above relate ultimately to dietary PUFA-induced changes in the membrane content of relevant prostaglandin precursors and/or in their rate of conversion to prostaglandins. This issue has not been examined, although some data are available, using patch-clamping techniques, showing that PUFA (AA, DHA) directly modify voltage-activated sodium currents and membrane electrical excitability in cardiac myocytes (45,46). This technique might be productively applied to the study of cardiac excitability and responsivity to NE in several dietary PUFA paradigms.

Insights gleaned from studies of the peripheral nervous system should stimulate and guide studies on retinal, brain, and other peripheral neurons. But how might such studies proceed? As indicated above, if NE neurotransmission can be affected by dietary PUFA differences, there is no reason to think that other catecholamine neurons might not also be affected. The most immediate example would be retinal DA neurons, because of the known effects of dietary PUFA manipulations on retinal and visual function. A very interesting series of studies could be undertaken to determine, among

other things, if light-induced activation of retinal DA neurons (and tyrosine hydroxylase), the functional state of retinal DA receptors (and second-messenger responsiveness), and the modification of the electroretinogram by DA drugs (agonists, antagonists) are modified by dietary PUFA treatment. As another example, one could simply use the results obtained from the sympathetic nerve–heart studies discussed above as a guide to similar biochemical studies in brain (are NE receptors, reuptake transporters, and biosynthetic enzymes modified?). Interesting findings might also result from the application of a well-studied neurophysiological paradigm for measuring the sensitivity of primary motor neurons in brain to NE boutons that terminate on them [the electrical activity of neurons of the facial motor nucleus and their responsivity to glutamate are influenced by local NE terminals (47)]. Variations in dietary PUFA intake might be found to alter this relationship in a manner similar to that observed for the sympathetic NE neurons innervating the heart.

A related approach would be to study neurons that utilize noncatecholamine neurotransmitters, such as serotonin (5HT). If changes in dietary PUFA intake modify membrane functions in catecholamine neurons (transporters, receptors, biosynthetic enzymes), they might also have similar effects in other neurons. Exploratory studies to identify biochemical effects on brain 5HT neurons would be straightforward. If positive results were obtained, good models exist to examine functional consequences [e.g., 5HT neurons, like NE neurons, project to the facial motor nucleus and influence motor neuron function (47); they also project into the hypothalamus, and predictably modify the secretion of pituitary hormones such as prolactin, which is readily studied (48,49)].

In general, this focus of study begins with postulated membrane effects of dietary PUFA manipulations, attempts first to identify specific neurochemical consequences (i.e., changes in how the neuron "handles" NE or 5HT), and then, based on much literature linking CNS functions to such transmitters, searches for specific functional consequences. Such an approach may more quickly identify links between alterations in dietary PUFA intake and CNS function than an approach that begins with an effect on a global brain function (e.g., visual function), for which few neurochemical/neuropharmacological links are currently known, and attempts to identify underlying mechanisms (although the hopeful exception may be the retinal DA neurons). If so, the findings would at least establish the principle and ultimately aid in the search for underlying explanations for dietary PUFA-induced changes in very complex CNS functions, such as vision.

PUFA models. Several current ambiguities of experimental design no doubt impede neurochemists, neuropharmacologists, and neurophysiologists who might otherwise become interested in exploring for CNS effects of dietary PUFA. First and foremost is the diet. No commonly-agreed-upon dietary formulations exist that the nonnutritionist can easily identify for study. The neurophysiological, neurochemical, and neuropharmacological paradigms that can be brought to bear on this issue are often complicated, time- and labor-intensive, and are unlikely to be applied to this area of investigation if the "treatment" is not clear. Reference to a selection of nervous system-focused studies reveals diets of a wide range of fat contents (e.g., 1→20% by weight) and fat sources (e.g., sunflower oil, safflower oil, corn oil, lard, butter, red fish oil, "fish oil," coconut oil, hydrogenated coconut oil, soybean oil, rapeseed oil, menhaden oil), almost all of undescribed purity (7,11,17,18,29,31,38,39,50,51). The occurrence of such an extensive variety of fat sources makes it difficult (for the neuroscientist) to know which is (are) the accepted standard(s) in the field. The most important contemporary issues relevant to brain PUFA composition and function suggest that the specification of perhaps five standardized diets might eliminate this dietary confusion. Such diets might be (i) a linoleic acid/α-linolenic acid "control" diet, (ii) a linoleic acid-deficient diet, (iii) an α-linolenic acid-"deficient" diet, (iv) a "breast-milk" diet (i.e., one containing appropriate amounts of longer-chain PUFA, such as arachidonate, eicosapentaenoate, and docosahexaenoate), and (v) an "infant formula" diet (which lacks the longer chain PUFA) (1). In the absence of such recommendations, for example, a neuroscientist might simply refer to the work of Yao *et al.* (29) or Brenneman and Rutledge (18) (discussed above) and choose a corn oil or sunflower oil diet as a "control" diet. The results of studies using such a "control diet" might later be discounted by some investigators, since the control diet would not be accepted as a true control (though containing adequate amounts of linoleic acid, it would be deficient in α-linolenic acid). The better choice might be a soybean oil-based diet, containing both linoleic and α-linolenic acids. Such problems are avoided by the existence of an agreed-upon selection of PUFA diets.

As a second issue, it would be extremely useful to specify the membrane PUFA changes that should be expected with such diets and to encourage their quantitation. The current database suggests, for example, that linoleic acid-deficient diets should reduce the membrane levels of 20:4n-6 (arachidonate) (29), and diets with high ratios of linoleic acid to α-linolenic acid should diminish the levels of one or more long-chain n-3 PUFA (e.g., DHA) while raising n-6 PUFA levels (e.g., 22:5n-6) (8,31,52). By specifying expected membrane PUFA changes associated with the use of a particular dietary formulation, the investigator new to dietary PUFA research has a basis for validating his/her ability to set up the model, and others have a reference point for comparing results across laboratories and disciplines.

A third issue is the age(s) at which the animals should be studied. Many animal studies involve institution of the diets during gestation and examination of the animals at different postnatal timepoints through single or multiple generations of dietary exposure (8,18). Other studies focus on early postnatal development (34,35). Indeed, a good deal of interest currently revolves around the question of what fatty acids to feed a baby in order that its brain and retina undergo proper postnatal development (1). Breast milk contains certain PUFA that infant formulas do not (e.g., AA, DHA, eicosapentaenoic acid), and an important question is if these fatty acids should

be added to infant formulas (1,53,54). Still other studies institute diets at or after weaning and explore for membrane effects several weeks or months later (7,17,29,38,55–57); a variation examines the reversibility of dietary PUFA deficiency produced during gestation and early postnatal life by provision of a diet adequate in PUFA at or after weaning (31). While sound reasons exist for employing each of these temporal designs, good arguments also may exist for further refining the time periods during which dietary PUFA modifications are provided and their effects examined. For the neurochemist or neuropharmacologist, the basis for such refinement might be related to the selection of a particular neuron for study. For example, NE neurons first appear in rat brain around gestational day 12; the multiplication of this cell population ends by gestational day 16. Axonal proliferation then occurs, and major projections are present at birth. However, NE and tyrosine hydroxylase contents in almost all brain regions undergo their largest increases postnatally, with adult values being reached by postnatal day 40 (58,59). These facts suggest that a treatment provided before gestational day 16 might conceivably influence the population size of the NE neuronal pool, while a treatment instituted at and after day 16 might influence axonal extensions and neuronal connectivities of these neurons. A treatment provided after postnatal day 40 would not be expected to affect the number of NE neurons or their fundamental connections but might influence their functional properties *via* membrane remodeling. A similar case can be made for autonomic NE neurons (33). Developmental data are also available for other chemically specific neurons in brain (e.g., 5HT, DA); a similar argument could be made for each. Agreement on such time posts for treatment would minimize ambiguity in the interpretation and comparison of NE findings, such as when a study is somewhat vague as to the gestational age at which diets were instituted (days 13–18) (18), or when one study institutes the diets in "weanling rats" (presumably postnatal days 17–21) (39), and another almost 2 wk later (100 g rats) (38). The timing of treatment could be an important source of variability within and among such studies.

And fourth is the issue of animal model. The neurochemist/neuropharmacologist usually prefers the rat because of its size and cost and because it has proven itself to be a good model (more often than not) for humans. Indeed, most of the neuroscience literature is based on this animal. Hopefully, the rat can be used as the focus of exploration for dietary PUFA effects on the nervous system. If not, the preferred model will have to be characterized neurochemically and pharmacologically for its similarity to the more familiar rat model before results obtained with it will be widely accepted. As an example, we recently conducted studies of the influence of dietary cholesterol intake on the synthesis and turnover of 5HT in brain, to evaluate the hypothesis that lowering serum cholesterol enhances suicidal and violent thoughts in humans by reducing 5HT function in brain (60). The rat is the standard model for studying the neuropharmacology and "nutrition" of 5HT. But the rat is not an acceptable model for the study of biological effects of dietary cholesterol, since serum cholesterol levels are minimally responsive to diet in this species; the gerbil is the animal of choice (61). Very few studies are present in the literature dealing with 5HT function in gerbil brain. Hence, whatever the outcome of cholesterol–5HT studies in this species, their relevance would be unknown, since there is no basis for determining if results obtained in gerbils are neurochemically applicable to rats (and thus ultimately to humans). In conducting gerbil studies, therefore, we were compelled to include a set of basic pharmacological experiments to establish if 5HT neurons in gerbil brain respond in the expected manner to treatments known to influence these neurons in rats. This approach turned out to be particularly important: the pharmacological studies showed that gerbil and rat 5HT neurons behave alike, while the ultimate outcome of the cholesterol studies was that 5HT synthesis and turnover are unaffected in gerbil brain over an enormous range of serum cholesterol levels (and thus did not support the original hypothesis) (62).

Hopefully, with the recognition that changes in dietary PUFA intake can influence neuronal membranes and neurotransmission, as well as the definition of standard dietary paradigms, neuroscientists will become more involved in the exploration for the neurochemical effects of dietary PUFA that underlie functional effects in both the CNS and the peripheral nervous system.

ACKNOWLEDGMENTS

Some of the studies described were supported by a grant from the National Institutes of Health (HD24730) and the National Dairy Council.

Polyunsaturated Fatty Acid Status and Neurodevelopment: A Summary and Critical Analysis of the Literature[1]

Susan E. Carlson[a,]* and Martha Neuringer[b]

[a]Schools of Nursing and Medicine, The University of Missouri-Kansas City, Kansas City, Missouri, and [b]Oregon Health Sciences University, Portland, Oregon, and Oregon Regional Primate Research Center, Beaverton, Oregon

ABSTRACT: The rationale for randomized trials designed to measure the effects of variable docosahexaenoic acid (DHA) status on neurodevelopment in human infants came from earlier studies of neurodevelopment in animals that were deficient in DHA owing to diets low in α-linolenic acid. The session on neurodevelopment looked at the results of these animal studies and discussed outcomes that appear to be analogous in human infants with variable DHA status. Presentations focused mainly on measures of development that may be attributed to more specific developmental domains (e.g., visual attention, recognition memory, problem-solving), some of which have been shown to be affected by long-chain polyunsaturated fatty acid (LCPUFA) status. This paper derives from discussions that took place during the session and reviews subsequent developments in this area. Although more difficult to interpret, global measures of infant development (e.g., the Bayley Scales of Infant Development, and Brunet-Lezine) can only suggest a relationship to specific developmental domains, but they have been applied in some randomized trials of LCPUFA and infant development. Those results are also summarized here.

Paper no. L7961 in *Lipids 34,* 171–178 (February 1999).

The session on polyunsaturated fatty acids (PUFA) and neurodevelopment/infant behavior began with short presentations by Neuringer, Jacobson, Willatts, and Morley. Neuringer focused on the effects of n-3 fatty acid deficiency on primate behavior, including effects on visual attention that appear to be analogous to those found in preterm infants with lower docosahexaenoic acid (DHA) status. Jacobson gave an overview of similar and of differing effects of toxic agents such as alcohol, cocaine, and polychlorinated biphenyls on visual attention of human infants. Willatts presented evidence that infant problem-solving is affected by n-3 fatty acid status. Morley demonstrated what normal variability is among infants on the Bayley Scales of Infant Development in relation to the number of infants that must be studied to determine if a variable influences global development. The paper that follows is based on the presentations and discussion in this session and summarizes work from other scientists on points crucial to the design of future studies of neurodevelopment.

Animal studies of n-3 deficiency, particularly those in nonhuman primates, have provided the rationale to study the functional effects of varying DHA status of human infants. The animal studies of development deliberately provided little α-linolenic acid, that is, they were designed to be n-3 fatty acid deficient. These n-3 fatty acid-deficient diets led to lower retinal and brain DHA, which could be interpreted as the cause of changes in behavior.

These studies were done with rhesus monkeys fed vegetable oils containing large amounts of linoleic acid and very small amounts of α-linolenic acid. Because the diets contained good amounts of n-6 fatty acids, the n-3 fatty acid-deficient animals grew normally and accumulated amounts of long-chain polyunsaturated fatty acid (LCPUFA) like n-3 fatty acid fed animals. Had these factors been affected by n-3 fatty acid deficiency, additional control groups would have been required. Instead, there was only a qualitative change in LCPUFA in retina and brain, with DHA replaced by docosapentaenoic acid (22:5n-6) synthesized from linoleic acid. Consequently, changes in behavior could be attributed to this change in composition. The underlying mechanism for changes in behavior is not known. Studies to learn the mechanism(s) by which variable amounts of neural LCPUFA influence behavior are currently being done in a number of laboratories using several approaches and are likely to become a topic for discussion at future meetings on PUFA and development.

In contrast to animal studies of n-3 fatty acid deficiency, the human studies of PUFA have asked if α-linolenic acid, at either low or high levels as present in standard feedings, provided optimal DHA for brain and retina of infants. These studies have sometimes varied α-linolenic acid in infant formula, but more frequently have included an experimental formula with some amount of DHA. The latter type of study has been used to test the hypothesis that DHA is a "conditionally essential" nutrient for rapidly growing infants, especially infants who, because of preterm birth, have been deprived of the normal DHA accumulation that occurs in the last intrauterine trimester.

One may conceptualize the difference between the animal and human infant studies of development as one of degree of

[1]This manuscript is based on the session on neurodevelopment held at the AOCS sponsored meeting on PUFA in Infant Nutrition: Consensus and Controversies, in Barcelona, Spain, in November 1996.

depletion of tissue DHA, especially neural DHA. The animal studies, which provided little n-3 fatty acids of any kind, are more likely to result in greater tissue DHA depletion than studies in humans, who are not deliberately fed n-3 fatty acid-deficient diets (estimates of the degree of depletion in brain have been made by some investigators and are included later in the paper). Consequently, studies in human infants addressed here and in the paper by Gibson and Makrides (1) on visual development have reported outcome measures analogous to those affected by reduced neural DHA accumulation in nonhuman primates.

These studies differ in background and design from a separate body of literature focused on the developmental differences between breast-fed and formula-fed infants (for example, Ref. 2). Studies of DHA supplementation in formula-fed infants are sometimes compared or confused with studies comparing breast milk and formula, because of the recognized differences in DHA status between these groups. This confusion is unfortunate, because effects of human milk feeding cannot be attributed to DHA alone but are likely to be related to a host of other nutritional or environmental factors. Comparisons of breast-fed and formula-fed infant development have focused almost exclusively on cognitive development (as distinct from other domains of development such as sensory, temperament, motor, or social). However, as discussed by Jacobson in this issue (3), recent studies that have controlled for all of the parental variables associated with the choice to breast-feed do not show a cognitive advantage of breast-feeding over formula-feeding using standardized tests of intelligence. Moreover, as will be pointed out in the following section, the animal literature suggests that even extreme reductions in neural DHA do not affect learning or memory directly, although they do affect other developmental domains that may indirectly influence cognitive function.

DHA DEFIENCY AND ANIMAL DEVELOPMENT

Caldwell and Churchill in 1966 (4) and Paoletti and Galli in 1971 (5) were the first to report effects of essential fatty acid deficiency (combined deficiency of both n-6 and n-3 fatty acids) on behavior, implying effects of low brain LCPUFA on neural function. These and other early animal studies found differences in performance on learning tasks that were interpreted as evidence of lower ability to learn. More recent studies of n-3 fatty acid-deficient rodents and primates (6–8) suggest that lower performance on some tasks of learning is secondary to effects on other behavioral domains (9,10). As Wainwright and Ward (9) and Neuringer and Reisbick (10) indicated, effects on other behavioral domains such as sensory, motivation/arousal, motor or social are not less interesting or important than primary effects of deficiency on learning. Although lower performance on learning tasks can occur secondary to a primary effect on some domain other than cognition, it is important to identify the primary domain affected so that attention can be focused on outcomes more likely to demonstrate true effects in studies involving observation or intervention.

Sometimes an unambiguous assignment of function to a specific neural domain (e.g., sensory, cognitive/learning, motivational, motor or social) is not possible in studies of behavior. Wainwright and Ward (9) highlighted the importance for behavioral research of construct validity, i.e., the correspondence between what is measured and the ultimate interpretation of the findings. This is not to imply that a positive or negative meaning may not be assigned to a given effect on behavior, only that the neural domain responsible for the effect on behavior may not be clear. By analogy, Wainwright and Ward (9) suggested that there is generally little concern about construct validity for biochemical measures, such as tissue DHA.

In animal studies, those that involve feeding deficient diets to the mother or through several generations generate the highest degree of concern about attributing changes in behavior to a specific neural domain. This is because the diet may affect the behavior of the mother as well as the newborn, and both effects have the potential to influence the quality of maternal care and the ultimate behavior of the offspring. These and other excellent points are raised by Wainwright and Ward (9) in their chapter "Early Nutrition and Behavior: A Conceptual Framework for Critical Analysis of Research." Because n-3 fatty acid-deficient animals have normal growth and physical health, it may not be apparent that maternal behavior could be a mediating variable. In contrast, n-6 fatty acid deficiency has obvious effects on growth and physical health, mediating variables that are routinely monitored in nutrition research and for which the need for control is understood.

Studies in nonhuman primates have been particularly critical for the human studies of LCPUFA and development. Neural DHA accumulation is higher and neural function of newborn monkey infants is more mature than in newborn human infants. For this reason, rhesus monkeys were exposed to n-3 fatty acid-deficient diets both *in utero* and after birth, effectively producing different degrees of DHA depletion in retina and brain (11). In the course of these studies, a number of behavioral effects of n-3 fatty acid deficiency in rhesus monkeys were identified.

Monkeys exposed to n-3 fatty acid-deficient diets *in utero* and postnatally had lower n-3 LCPUFA accumulation in retina and brain (11,12) and abnormal retinal function (11). Smaller a-wave amplitudes seen with n-3 fatty acid deficiency were corrected by 2 yr of age, but differences from the control group in implicit time and relative refractory periods actually became more pronounced with age (13). Moreover, these differences were not corrected even when the retina and cerebral cortex DHA were returned to normal at 10 mon of age or later by feeding n-3 LCPUFA (14). Monkeys that were n-3 fatty acid-deficient also had lower visual acuity during the period after birth when grating acuity increases most rapidly (12). Infant monkeys fed diets deficient in α-linolenic acid after birth also developed abnormal electroretinograms compared to monkeys with a high intake of α-linolenic acid (15).

Deficiency of n-3 fatty acids in monkeys also led to longer look duration in a test of visual attention relative to monkeys with higher brain DHA accumulation (16). This could have

been due to lower visual function, although look duration was not related to concurrent visual acuity (17). Look duration decreases with age, and this maturational effect has been attributed to faster processing speed (a cognitive effect) (18,19). However, there are alternative explanations for relatively shorter look duration such as increased ability to disengage attention (20) and lower reactivity (8). Any of these explanations might apply to animals developing with higher neural DHA; and each of these possible explanations suggests a positive effect of higher neural DHA on development. Whatever the neural domain affected, the difference in attention has the potential to provide insights into the effects of n-3 LCPUFA on cognitive development.

In addition to the effects of n-3 fatty acid deficiency already noted, deficient monkeys had polydipsia and polyuria but with normal renal function, growth, and physical health (21). Reisbick *et al.* (8,22) also described a higher frequency of stereotyped behavior, locomotor activity, and general behavioral reactivity in n-3 fatty acid-deficient monkeys than in a control group fed α-linolenic acid.

Not all of the neural domains investigated in studies of n-3 fatty acid-deficient primates have been affected, however. For example, Reisbick *et al.* (8) measured performance on several kinds of learning tasks in monkey infants and adults. Based on these studies, they concluded that even severe, long-term n-3 fatty acid deficiency did not cause general deficits in learning or memory.

Wainwright and Ward (9) put forth the theory that vulnerability to insults such as poor health and environmental deprivation could interact with poor n-3 LCPUFA status to create adverse effects on behavior even in the absence of a main effect of fatty acid status on behavior. In their studies of stereotyped behavior, activity and reactivity, Reisbick *et al.* (8,22) compared laboratory-reared, randomized groups to a nonrandomized group of "standard" monkeys that were breast-fed as infants, fed food containing DHA after weaning, and raised in a social group until at least 2 yr of age. At 4 yr of age, standard monkeys had lower frequencies of whole body activity, and stereotyped behavior and lower reactivity to a variety of social and nonsocial stimuli than the controls fed α-linolenic acid, who in turn had lower scores (a positive finding) than n-3 fatty acid-deficient monkeys.

One possible explanation for the lower scores on these measures by standard monkeys was that they accumulated more neuronal DHA than monkeys fed α-linolenic acid in the early months of life, because they were nursed by the mother and received a postweaning diet with DHA. At 2 yr of age (the only age data available other than at birth), however, DHA in the retina and frontal cortex of standard and soybean oil-fed monkeys did not differ (8). Alternatively, Reisbick *et al.* (22) suggested that partial social deprivation (social experience with agemates but not with mothers) heightened the behavioral response to n-3 fatty acid deficiency.

Given the large amount of n-3 and n-6 LCPUFA in neural membranes, and the relatively few behavioral outcomes that have been studied, it seems likely that many effects of low brain n-3 LCPUFA accumulation on neural function remain to be discovered.

DHA INTAKE AND DEVELOPMENT OF HUMAN INFANTS

Human infants cannot be fed diets that are deficient in any required nutrient, but studies to optimize the intake of required nutrients are permissible, indeed desirable, if a plausible case for a meaningful difference in function can be made. Human infants fed formula rather than human milk have lower red blood cell and plasma lipid DHA (23–26). The assumption was made that this might represent lower accumulation of DHA in the retina and/or brain with possible effects on infant behavior analogous to those observed in n-3 fatty acid-deficient animals.

Although declines were larger in infants fed a low-linolenic acid formula (24), they still occurred when the control groups were fed formulas containing soybean oil that contributed very large amounts of α-linolenic acid and a good ratio (~7:1) of linoleic acid to α-linolenic acid (27,28).

Recent analyses of DHA in infant brains (29,30) confirmed that infants fed DHA from human milk accumulated more DHA than infants fed formula. Infant formulas with greater than 1% of energy from α-linolenic but no DHA led to 20 to 25% less DHA in brain phospholipids than human milk. An even greater reduction of 35 to 45% compared to human milk was calculated for term infants fed formulas low in α-linolenic acid without DHA (29). One preterm infant fed α-linolenic acid-containing formula had a 60% reduction in brain phospholipid DHA compared to term, human milk-fed infants (29). These reductions can be compared to n-3-fatty acid-deficient monkeys that have approximately 75% lower DHA than n-3-fatty acid-sufficient monkeys at birth (11). Because the degree of reduction in brain DHA increased with age in both human infants and monkeys, the relative reduction in brain DHA among preterm infants may be comparable in some cases to that of monkeys deprived of n-3 fatty acids *in utero* (31).

All of the clinical trials of DHA supplementation conducted in the United States have compared a group of infants fed formula with n-3 LCPUFA to a group of infants fed at least 1% of energy from α-linolenic acid, an amount recently recommended for preterm infants (32). This was true of the first published trials in preterm infants (28,33,34) as well as three recent studies in term infants (35–37), although one of the earlier preterm studies (33) also included a group that was fed a formula with corn oil (a fat low in α-linolenic acid). Because the control groups in all but this one case were fed α-linolenic acid, observations of higher neural functions in the groups fed experimental formulas with DHA compared to formulas without DHA are evidence that DHA is a conditionally essential nutrient for preterm infants (38).

Some randomized studies of term infants performed outside the United States compared formulas with n-3 LCPUFA (with or without n-6 LCPUFA) to formulas containing less

than 1% of energy (~2.0% of total fatty acids) from α-linolenic acid. Importantly, even when formulas with DHA resulted in higher neural function, the studies cannot be used to conclude that DHA *per se* is a conditionally essential nutrient when the control formula contained low α-linolenic acid. However, such studies have contributed to evidence that there are functional effects of low neural DHA accumulation.

To be fair to investigators who have compared commercially available low α-linolenic acid formulas to experimental formulas with DHA, one should note that investigators (33,39–41) have only recently demonstrated effects of low dietary α-linolenic acid on human infant development. Because functional information in human infants prior to these reports was absent, recommendations for α-linolenic acid in artificial infant feeds were necessarily provisional. Frequently, the composition of formulas was based on human milk, in which α-linolenic acid is typically much less than 1% energy (42,43), and ignored the fact that human milk, unlike formula, provided DHA and arachidonic acid (ARA).

Effects of DHA on sensory function. Of the13 reported randomized trials that were designed to study the effects of variable DHA status on neurodevelopment, 11 trials (28,33–37, 40,41,44–46) measured sensory development, in particular, visual or retinal development. At the meeting, studies of visual and retinal development were presented in a different session from studies of other neurodevelopmental domains, despite the fact that some studies measured both types of outcomes. Gibson and Makrides (1) summarized the session on visual development. This paper will not address visual development except to note when effects on sensory development could be an explanation for differences in behavior related to lower n-3 LCPUFA status.

Are there effects of n-3 LCPUFA status on cognition/learning ability? Other than sensory effects, the neurodevelopmental outcomes measured in human infants with variable n-3 LCPUFA status have been more limited than those employed in animal studies. Despite reports of altered performance on tests often used to assess these functions, neither animal nor human studies have provided convincing evidence that the primary effect of n-3 LCPUFA status is on learning ability or memory. Performance differences are more likely to be attributable to sensory, motivational or other behavioral differences rather than to changes in cognitive ability. For example, past studies of malnutrition and development found an apparent poorer ability to learn. However, most of these effects were secondary to the effects of malnutrition on infant responsiveness and temperament, which influenced the caretaker's interactions with the infant (for example, see Ref. 47). There could be an analogy between these studies and those that varied LCPUFA status during development.

Several studies have used the Fagan Infantest (FTII) to assess visual recognition memory in infants with different DHA status (46,48,49). In this test the infant is presented with a series of photographs of human faces. For most of the test items, the infant is allowed to gaze at a face [or two identical copies of the same face] for a predetermined number of seconds of cumulative looking time, and then is shown the now familiar face paired with a novel one. Consistent preference for the novel pictures is an index of memory for the pictures that are familiar and, therefore, that attract less attention. Only one study found an effect on recognition memory (46). In that preliminary report, term infants fed human milk and LCPUFA-containing formula had normal visual recognition memory on the test, whereas infants fed a commercially available formula of undefined composition had abnormally low recognition memory. The lower scores in that group suggested that the control diet could have interacted with some other variable to influence outcome.

In addition to its designed use to assess visual recognition memory, the FTII has been used experimentally to measure the average duration of individual looks during both the familiarization and paired comparison phases of the test. An analogous test was developed for monkey infants. Both monkey (16) and human infants (48,49) with relatively higher DHA status had shorter look duration without effects on visual recognition memory. Using a classical habituation paradigm (exposure to a single visual stimulus until attention wanes), Forsyth and Willatts (50) also found shorter look duration in 9-mon-old term infants with higher DHA and ARA status. However, the reduction in look duration with DHA and ARA occurred only in a subgroup with lower birthweight, who may have accumulated less DHA *in utero*. The control formula contained only 0.35% energy from α-linolenic acid (51), and the effect might not have been observed had the control contained more α-linolenic acid.

Longer look duration may be used to infer an undesirable effect of lower n-3 LCPUFA status on brain function. Longer look duration in infancy correlates moderately well with poorer performance on later tests of cognitive ability (52–54). The usual interpretation has been that longer look duration represents slower information processing speed (a cognitive function) (18,19). More recent studies have led to the alternative suggestion that longer look duration could represent an inability to disengage or shift attention from the stimulus (20) or higher reactivity to visual stimuli (8,10). Differences in sensory function are also a possible explanation for differences in look duration in the animal and human studies, because groups with higher DHA status were shown to have higher visual acuity either concurrently or earlier in development. Neither concurrent visual acuity in monkey infants (17) nor earlier visual acuity in preterm infants (55) was correlated with look duration, however, making this explanation somewhat less likely.

More advanced infant problem-solving ability and language development have also been used as indices of higher cognitive function, and some early tests of both have been related to higher performance on tests of development in childhood. Willatts *et al.* (51) reported higher means-end problem-solving scores in 10-mon-old term infants fed a formula with DHA and ARA. Because the control formula provided only 0.35% energy from α-linolenic acid, these data, in conjunction with studies of brain composition (29,30), bolster the

case for positive effects of higher brain DHA accumulation on infant development. Again, however, they cannot be used to conclude that DHA is a conditionally essential nutrient for term infants.

Janowsky *et al.* (56) reported lower language scores at 14 mon in term infants fed formula with DHA throughout the first year of life in comparison to infants fed human milk, formula without n-3 or n-6 LCPUFA, or formula with both DHA and ARA. However, at 3.25 yr of age, cognitive and language scores of these same infants were unaffected by their early diet (57). It is not entirely clear how the early language data from this study should be interpreted. On one hand, the data could be used to suggest that feeding only LCPUFA of the n-3 fatty acid family created an imbalance of n-3 and n-6 LCPUFA. On the other hand, an inverse relationship has been reported between productive vocabulary at 16 mon of age and nonverbal memory performance, with the difference emerging over longer delays between 1 and 12 mon (58).

Effects of n-3 LCPUFA on global tests of mental and physical development. Several reports of higher global development among infants fed formulas with n-3 (or n-3 and n-6) LCPUFA have appeared, although the numbers of infants per group have been relatively small. Two scales of global development have been employed, the Brunet-Lezine Test (59) and the Bayley Scales of Infant Development (60). Both have elements of the Gesell Developmental Schedules (61), the first system developed to assess behavioral development in infants. Global tests of development were designed to assess current abilities, not to predict long-term outcomes, which are susceptible to many intervening variables. Some studies have shown modest relationships between infant performance on global tests and performance on tests later in childhood, but the relationships generally are weaker than more specific measures such as look duration and recognition memory in infancy.

Agostoni *et al.* (62) compared psychomotor development of term infants fed a formula with 0.3% DHA and 0.44% ARA to those fed formula containing 0.35% energy from α-linolenic acid. At 4 mon, infants fed LCPUFA had higher psychomotor development scores. Effects of diet were not found when the groups were compared again at 12 and 24 mon of age, although blood LCPUFA at those ages did correlate with development (63). Damli *et al.* (44) compared preterm infants fed formulas with LCPUFA (0.2% DHA and 0.3% ARA) to a formula without LCPUFA, but with an unspecified amount of α-linolenic acid. They found higher performance scores on the 6-mon Bayley Mental Developmental Index in the group of infants who were fed LCPUFA-supplemented formula. It was not clear if infants were assessed after 6 mon of age, and, therefore, if these effects persisted. Janowsky *et al.* (56) also measured Bayley Scales of Infant Development scores of term infants at 12 mon and found no effect of supplementing formula with DHA on performance at that age.

Preterm infants fed formula with DHA compared to formula with at least 1% energy from α-linolenic acid but no DHA had higher scores on the 12-mon Bayley Mental Developmental Index (MDI) in one of two randomized trials conducted in the same center (64). Lucas (65) pointed out that a higher mean developmental score in one trial could represent a Type I error, a possibility that cannot be ruled out. However, differences in design between the trials might also have been influential. In particular, both control and experimental groups in the study that resulted in higher 12-mon Bayley MDI scores with DHA supplementation received formulas with higher concentrations of most nutrients (designed for preterm infants) until they were 2 mon corrected age (28). In contrast, infants in the study that found no effect of dietary DHA on the Bayley MDI were fed a lower nutrient (term) formula beginning approximately 1 mon before expected term delivery (34).

The developmental scores for the control groups in both trials were similar despite the differences in nutrient densities of the formulas. As well, the scores of both groups were similar to the historical scores for preterm infants in the same center. This suggested that the higher Bayley MDI in DHA-supplemented infants in the second trial could have been the result of an interaction between higher nutritional status and higher DHA status (38). Marginal nutritional status may be an unreported mediating variable in many developmental studies, especially those involving preterm infants, who have been reported to have low indices of many nutrients that can continue for months after discharge from the hospital. Unfortunately, published articles rarely provide information about the nutrient content of the diet fed in studies of infant development, much less provide measurements of nutritional status.

Bronchopulmonary dysplasia (BPD), characterized by periods of hyperoxemia and hypoxemia, may adversely influence development of the central nervous system. The diet groups in the second randomized trial, in which n-3 LCPUFA led to higher scores on the Bayley MDI, were subsequently divided into infants with and without BPD. The already higher mean score in the experimental group increased even more and was equivalent to breast-fed term infants from the same study population when infants without BPD were excluded. On the other hand, DHA-supplemented infants with BPD and infants with and without BPD who consumed the control formula had scores that were similar to each other and lower than DHA-supplemented infants without BPD (66). These results suggested that something about the condition of BPD prevented infants from experiencing the benefit of n-3 LCPUFA—on this test of global mental development—in the presence of higher nutrient intakes. The infants in these studies were not followed after 12 mon of age, so whether any effects of diet on behavior persisted is unknown.

DISCUSSION

As reviewed here, some but not all randomized trials have found effects of an experimental formula with DHA on some aspects of infant behavior. The tests employed in most of these studies have been used to infer effects on intellectual development. However, studies in n-3 fatty acid-deficient monkeys

suggest that lower brain accumulation of DHA may influence neural domains such as sensation, motivation or temperament, but not cognition (8). The most consistent effect identified to date in human and animal studies has been in one specific measure, that of look duration in tests of visual attention.

Although data on brain composition from infants fed a variety of infant diets are very limited, those that are available support the premise that variations in n-3 fatty acid intake (especially dietary DHA) affect DHA accumulation in brain (29,30). Preterm infants appear to accumulate less DHA relative to term infants, and infants fed little α-linolenic acid accumulate less brain DHA relative to infants fed at least 1% of energy from α-linolenic acid (29,30).

There are now a few examples in which effects of higher DHA status on early performance in a specific neural domain are not found later; e.g., early effects on visual acuity may not be found later in infancy (1). Although such results could be taken as evidence of functional recovery with time, it cannot be accepted that the effects of higher early DHA status are transient without further testing. For most tests of infant development, their sensitivity to developmental influences is highly age dependent. The dilemmas are (i) that there are not straightforward tests to sample the same or analogous abilities continuously from infancy through childhood, and (ii) that effects on one function at an early age may affect the development of other related functions at later ages. Before it can be concluded that a neural domain does not show long-term functional effects, it will be necessary to determine test(s) that sample that domain at the later age and show that it is unaffected by early DHA status. For the most part, there is an absence of evidence (studies have not been done) rather than evidence of absence of an effect on later development (studies that show transient effects on a specific domain of neural development).

Factors other than early birth and n-3 fatty acid intake may also influence the accumulation of DHA in developing brain. Some variables that have been suggested are intrauterine growth retardation (67), maternal alcohol use (68,69), maternal tobacco use (68,69), zinc status (70), *trans* fatty acid intake (71–73), and preeclampsia/ hypertension (74). As yet, no study has controlled for all of these possible variables, and differences in their occurrence among populations could be responsible for some variability in clinical studies that have been reported.

In addition to these variables, Wainwright and Ward (9) have suggested effects of socioeconomic status (SES) and/or health that could interact with DHA status to influence behavior. For example, poor DHA status may have little or no effect on development of healthy term babies or babies going to high SES homes but contribute to developmental risk in sick preterm or low-SES infants (9). The degree of formal education received by low-SES parents affected look duration in the same way and to the same degree as DHA-supplemented formula (55), perhaps an example of an interaction between SES and PUFA. Had all parents in the study been highly educated, DHA-supplemented formula might have had little additional effect on look duration.

In summary, only a limited number of behavioral studies in animals and humans address the question of neural DHA accumulation and developmental measures other than vision. It is encouraging that the human studies found several effects of n-3 LCPUFA status that appear analogous to those found in nonhuman primates. Such parallels add validity to the idea that lower neural DHA is responsible for the differences in behavior found in human infants fed diets with compared to without DHA. However, the optimal concentration of neural DHA and the optimal ratio of n-3 and n-6 LCPUFA in neural membranes are still not known. Moreover, they are not likely to be discovered until basic structure/function studies in animals identify the mechanism(s) by which LCPUFA act on the developing central nervous system and clinical studies more clearly identify variables that influence neural DHA accumulation in specific populations.

Polyunsaturated Fatty Acids and Infant Visual Development: A Critical Appraisal of Randomized Clinical Trials

Robert A. Gibson[a,*] and Maria Makrides[b]

[a]Child Nutrition Research Centre, Flinders Medical Centre, Bedford Park (Adelaide), SA 5042, Australia, and [b]Department of Obstetrics and Gynecology, University of Adelaide, Women's and Children's Hospital, North Adelaide, SA 5006, Australia

ABSTRACT: At the Consensus and Controversies Conference held in Barcelona in November 1996, one of the sessions focused on an evaluation of the effects of dietary polyunsaturated fatty acids (PUFA) on infant visual development. The intervention trials in preterm and term infants were reviewed and discussed in detail. Results of these trials, particularly those in term infants, were inconsistent; much discussion occurred concerning the causes of these diverse results. We attempt to reflect, rather than report exactly, the discussion relating to these issues and address the clinical trials according to recently published guidelines for conduct and reporting of randomized clinical trials (RCT). Compared with these recent guidelines, the published papers of RCT involving PUFA and visual function are often incomplete, making it difficult to assess if we can have a high degree of confidence in the reported effects (or lack of effects). Despite this, valuable data relating to the effect of diet on the visual development of infants were obtained. Our evaluation of the trials to date suggests that the definitive answer to the degree to which dietary long-chain PUFA is likely to influence visual development may only be resolved with impeccably conducted RCT.

Paper no. L8071 in *Lipids 34*, 179–184 (February 1999).

The AOCS conference entitled "PUFA in Infant Nutrition: Consensus and Controversies" held in Barcelona in 1996 included a session entitled PUFA and Infant Visual Function Development. The purpose of this session was to review the evidence relating to a role for n-3 polyunsaturated fatty acids (PUFA) in infant visual development. While it is well established that n-3 PUFA are important and even essential for visual development (1,2), the debate is now focused on the possibility that an adequate level of the precursor PUFA, α-linolenic acid (18:3n-3, ALA) is sufficient or the possibility that docosahexaenoic acid (22:6n-3) is also required in the infant diet. Speakers included Eileen Birch, who reviewed the visual maturation process; Maria Makrides, who reported on clinical trials involving acuity as an outcome measure; Martha Neuringer, who reviewed electroretinogram studies; and Bob Gibson, who made general comments about the use of randomized clinical trials (RCT) in nutrition (Tables 1 and 2). Discussion was extensive, facilitated by many questions from the floor. Most of the vocal participants were eager for an explanation of the fact that some trials report effects of n-3 long-chain LCPUFA on visual development while others do not.

In the field of PUFA research, we have become used to conducting and reporting relatively small, carefully designed studies that often have specific biochemical outcomes. Only recently have studies been reported that were designed to determine functional outcomes, particularly in the area of visual development. These newer outcome measures bring a new level of complexity to study design and conduct because the differences expected are often small and may be influenced by a range of factors other than diet, and special testing skills and equipment are required. Given these facts, not surprisingly, variation appears in the reported visual responses of infants to changes in dietary LCPUFA. In other words, the fact that some investigators report an improvement in acuity while others conducting a similar trial can report no effect may have a lot more to do with the complexity of the development of the visual process in infants than any shortcomings in the design and conduct of the study. Clinical trials with infants, particularly preterm infants, are extremely difficult to conduct. Recognition of this fact is pivotal to our understanding of the field. The following discussion is designed to help the general reader understand some of the complex issues relating to the conduct of clinical trials with particular reference to issues relating to detecting effects of dietary n-3 PUFA on visual development in infancy.

Although many reports exist of differences between breast- and formula-fed infants, the only way to test if an ingredient of breast milk causes a reported difference is to conduct a RCT. In the case of LCPUFA, a RCT cannot be conducted in breast-fed infants with a zero LCPUFA treatment since LCPUFA are always present in breast milk. Thus, most RCT reported to date were conducted in formula-fed infants. However, testing the effect of a range of LCPUFA doses in breast-fed infants by supplementation of breast-feeding mothers is possible (3,4).

Rationale for studies. The underlying hypothesis of all studies involving n-3 PUFA and neural/developmental out-

TABLE 1
Visual Outcomes of Randomized Clinical Trials (published in full) of PUFA Supplementation in Preterm Infants

Reference	Diet	Test	Age	Results
5,18,30	HM (supplemented with	Rod ERG	36 wk PCA	HM and FO > LA/ALA 24:0.5
	FO formula)		57 wk PCA	No difference with diet
	LA/ALA 24:0.5	Cone ERG	36, 57 wk PCA	No difference with diet
	LA/ALA 21:2.7	Steady-state VEP	36, 57 wk PCA	HM and FO > LA/ALA 24:0.5
	LA/ALA 20:1.4 + FO	Acuity cards	57 wk PCA	HM and FO > LA/ALA 24:0.5
6	SF, LA/ALA 33:4.8	Acuity cards	48, 57 wk PCA	FO > SF
	+ FO		68, 79, 93 wk PCA	no difference with diet
7	SF, LA/ALA 21.2:2.4	Acuity cards	2 mon CA	TO > SF, if no BPD
	+ TO		4, 6, 9, 12 mon CA	No difference with diet
8	HM	ERG latencies	52 wk PCA	No difference with diet
	SF, LA/ALA 18:0.3	ERG amplitudes	52 wk PCA	No difference with diet
	+ egg PL	Flash VEP latency	52 wk PCA	N4: HM and +eggPL < SF

Abbreviations: PUFA, polyunsaturated fatty acid; HM, human milk; SF, standard formula; LA, linoleic acid; ALA, α-linolenic acid; PL, phospholipid; FO, fish oil; TO, tuna oil; VEP, visual-evoked potential; ERG, electroretinogram; PCA, postconceptional age; CA, corrected age; BPD, bronchopulmonary dysplasia.

comes is that the demonstrated effects on development of visual acuity may reflect an underlying, more widespread difference in neural maturation that might affect other (perhaps many) aspects of brain function. This hypothesis, although often stated, has not been adequately tested by measuring a range of developmental outcomes. Visual acuity is the only functional outcome that has received repeated attention in trials of LCPUFA supplementation, largely because earlier work in monkeys demonstrated an effect of dietary ALA and because it is the only visual ability for which there are standardized, validated, and readily available tests for infants. This does not mean that other visual, nonvisual sensory, cognitive, or behavioral outcomes might be equally or more sensitive to effects of early LCPUFA intake.

Treatments. The RCT of n-3 PUFA and vision reported thus far vary in their dietary treatments (5–16). Differences are present both in the level and type of PUFA supplementation and in the background or placebo formulas (17). Only two trials have formally addressed the issue of 18 carbon PUFA levels and examined the effect of linoleic acid (18:2n-6) to ALA ratios on visual performance (13,18). In terms of n-3 LCPUFA, the source used varied and has included high-eico-sapentaenoic acid (20:5n-3) fish oil, low-eicosapentaenoic acid fish oil, egg phospholipids, and unicellular oils (17). Some recent trials included sources of arachidonic acid (20:4n-6) as well as n-3 LCPUFA. The spread of treatment fatty acids and doses encouraged workers to speculate about dose-dependent effects. For example, studies using relatively

TABLE 3
Summary of Full-Published Reports of Randomized Clinical Trials Involving PUFA

Study	Method of allocation	Placebo	Blinded outcome assessment	Losses to follow-up	Power calculation	Notes
Preterm infants						
5,18,30	Random, method not stated	Yes	Not reported	40%	Not reported	?Coinciding of blood sample and visual assessment
6	Random, method not stated	Yes	Partial	28%	Yes	13% (10/79) infants were replaced post-randomization
7	Random, method not stated	Yes	Yes	46%	Yes	Infants were replaced (more controls than supplemented) postrandomization
8	Random, method not stated	Yes	Not reported	Not clear	Not reported	Inappropriate visual assessment
Term infants						
10	Random, method not stated	Yes	Yes	11%	Yes	Uneven randomized group due to unavailability of test formula
11	Random, method not stated	Yes	Yes	38%	Yes	
31	Three-site trial with separate randomization at each center method of allocation not stated	Yes	Yes	28%	Not reported	Each of the three sites had different assessment protocols.
13	Random and masked assignment	Yes	Not clear	29%	Yes	Inappropriate visual assessment
12	Random and masked assignment	Yes	Yes	2%	Yes	Formula fed infants were initially breast-fed. Formula feeding began ≈25 day postpartum
16	Random and masked assignment	Yes	Yes	24%	Yes	

high levels of n-3 LCPUFA supplementation (>0.5% total fatty acids) have more often found beneficial effects than those providing lower levels. In addition, Heird *et al.* (19) proposed that visual effects of dietary supplementation with n-3 LCPUFA were seen only in studies where the placebo diet contained less than 2% ALA. However, this hypothesis is not consistent with the current literature. Presently, two trials exist with <2% ALA in the placebo diet which demonstrate no effect of LCPUFA treatment (12,15) and four trials with >2% ALA in the placebo formula which demonstrate beneficial effects of n-3 LCPUFA supplementation on the measures of visual function (6,7,11,16). The issue of dietary treatment was reviewed in detail elsewhere (17,19).

Another issue related to the source of LCPUFA is the type of lipid (triglycerides or phospholipids) in which the LCPUFA are esterified. The exact source of dietary LCPUFA (triglycerides, phospholipids) may be irrelevant to the recipient infant provided that docosahexaenoic acid is present, since there is much reconstruction of dietary lipids postdigestion. Because the varied treatments used in many of the studies generally result in similar LCPUFA status in the infant, we believe that the source of LCPUFA may not be a cause of the disparate results. Other issues relating particularly to the design and conduct of RCT as well as the small size of the anticipated differences in visual development may be more important.

Methodology. By far the most common measure used to assess visual function is acuity, assessed either by electrophysiological or behavioral methods. The specific methods for visual acuity and retinal function assessment were extensively documented and reviewed elsewhere (20). Most trials used standardized and widely accepted visual assessment methods to assess the effect of n-3 PUFA on visual outcome. However, two trials used inappropriate methods (8,13) (Table 3). Faldella *et al.* (8) used an electroretinogram method to assess retinal function that did not involve the pupil being dilated or the use of a contact lens electrode, two test conditions considered necessary by the international standard for clinical visual electrophysiology (20). In a similar vein, Jensen *et al.* (13) measured visual-evoked potential in response to a single high-contrast checkerboard pattern (30-min arc), which provides information about waveform amplitude and latency but cannot be used to evaluate acuity. Therefore, lack of effect in these trials cannot be interpreted as treatment having no influence on visual development, as the specific outcomes sensitive to LCPUFA were not assessed.

The size of the effect. If we assume, for the sake of argument, that all the reported trials were unaffected by any limitations in study design and conduct and that all papers report true effects, effects on visual development (where seen) were generally modest and close to the limit of clinical significance. Because the anticipated effect of dietary LCPUFA on

some outcome measures is likely to be small, not surprisingly some trials report effects while others do not. Some of the apparent inconsistent effects reported in the PUFA field, especially in term infants, may derive from this fact. Having said that, one must not dismiss effects simply because they are small, particularly when global developmental effects are monitored. Effects of small size may be significant when considered on a population basis. Thus, a shift of 1 or 2% in test scores in a whole population can translate to a large increase in those individuals falling below the threshold of normal.

Some studies have aimed to increase the power of the study by enrolling large numbers of infants at multiple sites. Crucial to obtaining a valid result is the need to have absolute consistency between operators (or testers) at all the study sites. The results from each of the operators should be monitored and the separate results examined statistically for variation between sites and then presented in any report of the overall findings. Statistical procedures may be necessary to combine data that show site differences, or variation in testing procedures may result in small diet-induced effects being masked. Operator–operator error may be due to different sites or simply due to more than one operator carrying out an assessment at one site; nevertheless, it may contribute to a larger variance than estimated at the start of the study. The reader should therefore do simple power calculations on data that purport to demonstrate no effect, as operator error could have reduced the power of the study to a degree that a type II error was introduced.

Post hoc analysis of data can easily determine if either insufficient numbers in the groups existed or excessive noise (or variance) was present in the data for an effect to be seen (type II error). However, no test is available for detecting if confounding influences (parental smoking, socio-economic variables) or unintentional bias as a result of nonadherence to the randomization code had a major influence on the final result. For this reason, the remainder of this paper concentrates on study design and conduct issues that can possibly infuence the outcome of trials (21–26).

Clinical trial issues: (i) Bias in RCT. The word "bias" often raises connotations of deliberate intent, as this is the general usage in a social sense. This is not the meaning of the word in regard to RCT. Essentially, it refers to any influences that have the potential to distort group comparisons other than the assigned treatment. Most commonly, such influences or biases occur as a result of trial design or conduct (27). The sources of bias can stem from the initial randomization (selection bias), the loss of study participants (attrition bias), and the way participants are assessed during the trial (performance and detection bias).

(ii) Method of allocation. The purpose of a randomized study is to ensure that any event that arises has an equal (or random) chance of arising in both the treatment and the placebo groups unless it is influenced by the treatment (treatment effect). This can be ensured only if the groups of the trial are assembled in a truly random way and not in a way that is at all influenced (even accidentally) by the investigators. Random assignment is vital because unless everything except the treatment effects is distributed equally among the groups, the true effect of the treatment cannot be accurately determined. This will be due to two inherent problems: first, an unequal variance or confounding in the data sets exists such that an effect can be obscured or created and second, the use of basic statistical procedures will be invalidated.

Many ways of allocating subjects into a trial are possible, and some forms of allocation are better than others. For this reason, great emphasis has been placed on the method of allocation in recent publications that aims to improve the quality and reporting for randomized clinical trials (22,27). For example, to use an open list of random numbers of assignment or other methods of allocation such as odd and even medical record numbers or dates of birth is insufficient. These allocation procedures are transparent before assignment, and now evidence suggests that transparent allocation is associated with selection bias (28,29). This bias is best avoided by using a method that prevents foreknowledge of treatment assignment and is often referred to as allocation concealment (27). For example, when allocating infants into a trial of placebo or LCPUFA-supplemented formula, the person responsible for recruiting participants should determine the eligibility of the infant, speak to the family, and gain consent before contacting an independent person in the research team to obtain the next formula allocation or opening a sealed, opaque envelope containing the next allocation. In such a process the person recruiting participants can in no way influence the allocation.

Ideal allocation practice also necessitates no deviation from the predetermined randomization schedule, and following assignment, it should not be possible to alter the assignment or the decision about eligibility (27). In the n-3 PUFA field, examples exist of deviations from ideal practice in the trials reported to date. In an RCT reported by us in 1995, a greater number of infants was recruited into the control group compared with the supplemented formula group (10). This occurred because we were supplied with an inadequate amount of the LCPUFA supplement, and we continued recruiting into the control group until the appropriate number of infants was enrolled, resulting in only 13 infants in the n-3 LCPUFA-supplemented formula-fed group and 19 infants in the placebo formula-fed group (10). Other examples exist of studies that have involved deviation from the predetermined assignment schedule by replacement of infants lost to follow-up that may have resulted in an unintended selection bias, hence affecting the outcome of the trial (6,7). While authors clearly do not consciously select better infants for one group than another, any deviation from the randomization schedule means that the process is no longer random, raising the possibility of an imbalance in the groups that can override or enhance treatment effects.

(iii) *Blinded outcome assessment.* As this is one of the areas in which investigators are most aware of the possibility of unintentional biases, many of the authors may in fact have conducted blinded outcome assessments but failed to report them (Table 3).

(iv) Losses to follow-up. Many of the clinical trials in the areas of n-3 PUFA and infant visual function have had large dropout rates (Table 3). Indeed, it is extremely difficult to conduct relatively long-term trials in the real world of mothers and their babies, and intense emphasis and energy are required to assess as many infants as practically possible. Loss of participants from the trial postrandomization may be due to withdrawal of consent, failure to attend clinic appointments, or exclusions made by the investigative team. These losses may result in systematic differences between groups, especially if greater numbers are lost from one group relative to another. The systematic differences between groups that result because of loss to follow-up are referred to as attrition bias. The new guidelines for reporting of RCT emphasize that it is vital that authors attempt to better describe the characteristics of all the subjects enrolled, those lost to follow-up as well as those of the subjects completing the trial in each treatment group. In that way, any major aberrations in characteristics between groups that may result in attrition bias will be evident.

In conclusion, valuable data relating to the effect of diet on the visual development of infants has been obtained from the published papers of RCT involving PUFA. However, details about the conduct of the trials are often incomplete, making it difficult to assess if we can have a high degree of confidence in reported effects or lack thereof. Power calculations suggest that many of the studies were of sufficient size to detect differences in visual acuity due to dietary treatment. Variations in reported results could possibly be due to unintentional bias as a result of accidental inclusion of confounders, deviations from the randomization code, or loss to follow-up. A definitive answer to the degree to which dietary LCPUFA are likely to influence visual development may only be resolved with RCT that are impeccably conducted and that are of sufficient size to avoid potential perturbations from unreported confounders. Evaluation of a more comprehensive range of outcomes initiated to more completely assess the global implications for infant development would be valuable.

Statistical Considerations in Infant Nutrition Trials

Sheila M. Gore*

MRC Biostatistics Unit, Cambridge CB2 2SR, United Kingdom

ABSTRACT: Infant nutrition trials usually require developmental follow-up, often to 18 mon, and sometimes beyond reading ability at age 7 yr. They are therefore logistically complex and costly, and should be conducted to a high statistical standard. With examples, we focus on: good practice in nutrition trials and the goal of a common protocol; how to set plausible trial targets and to work out trial size accordingly; statistical observations on assessing visual maturation; and methods of randomization, including the method known as minimization, which can be adapted to select more appropriately a comparison cohort of breast-fed infants. We end with discussion of analysis and reporting standards, including the give-aways (or tell-tale signs) to be on the look out for. A Cochrane Collaboration for systematic review of randomized trials of infant nutrition is proposed.

Paper no. L7990 in *Lipids 34,* 185–197 (February 1999).

CONSULTATION OF "GOOD PRACTICE" DOCUMENTS

Randomized controlled trials (RCT) in infant nutrition should be conducted to a high statistical standard. Investigators may therefore find it instructive to consult two excellent "good practice" documents: Guidelines for Standard Operating Procedures for Statistical Practice in Clinical Research (1) and Biostatistical Methodology in Clinical Trials in Applications for Marketing Authorizations (2) (Scheme 1). The first has 12 practical sections ranging from clinical development plans and clinical trial protocol through to randomization and blinding, interim analysis plans, and quality assurance. Infant nutrition trials usually entail developmental follow-up, often to 18 mon and sometimes beyond reading ability at age 7 yr. They are therefore logistically complex, and costly. Longer-term follow-up is unlikely to be funded unless predicated upon evidence of early benefit for, say, short-term anthropometry. Choosing wisely the infant nutrition trials in which to invest both intellectually and financially needs careful attention to basic scientific rationale and to rigorously presented short-term results.

BIOSTATISTICAL METHODOLOGY IN CLINICAL TRIALS IN APPLICATIONS FOR MARKETING AUTHORIZATIONS . . .

SCHEME 1

COMMON PROTOCOL AS A GOAL

A goal for investigators of polyunsaturated fatty acids (PUFA) in infant nutrition should be a common protocol to which all can refer.

At the very least, in any protocol, sample size should be clearly specified and justified in terms of trial objectives. The methods used to arrive at trial size should be referenced and documented, as should estimates of any quantities used in trial size calculations. I shall give some examples of how to do this in a later section. Plans for sample size reviews, to alter the planned number of patients—up (for example, because variability is greater than had been anticipated) or down (for example, because of poor accrual)—should be conducted blinded and noncomparatively: that is, without breaking the code for treatment assignments.

Multiplicity should be addressed in the protocol. By multiplicity I mean any or all of: multiple trial objectives, multiple measures of the same endpoint, or multiple endpoints. Priorities should be set, or an appropriate hierarchical analysis

strategy should be set out explicitly, which safeguards against false positive inferences. More generally, generic statistical analysis plans should outline the methods of analysis for all aspects of the trial data. Before actual analysis, these plans should be developed into a comprehensive description and set of statistical programs.

Rules to determine the evaluability of patients should be laid out in the protocol, especially in the case of protocol violations, withdrawal of patients from study by the investigator, or patient drop-outs. An off-study form might be completed in such cases to explain the circumstances.

DETERMINING TRIAL SIZE: PRELIMINARIES

How do we determine *a priori* a rational target difference for each major outcome variable on which infants randomized to different diets/supplements/formulas will be assessed in the course of follow-up?

The effect size (or estimated difference) in animal studies or in related randomized trials on other formulas may suggest the size of differential that is reasonable and prudent to expect with a new formulation in infants. Epidemiological studies, especially those which have reported covariate-adjusted comparisons of outcome for breast-fed vs. formula-fed infants, may suggest an upper bound for plausible effect size.

Target differentials may be set relative to the gender or gestational age effect on outcome. How much better do female infants perform than males? Could the new formulation achieve as much? Is it reasonable to target the new formulation to achieve more than the gender differential, or more than the effect on outcome of one additional week of gestational age?

Do we need to consider a differential effect of the new formula? For example, is its effect likely to be greater in preterm than in term infants, or less in infants who receive the new formulation only as supplement to mother's own milk rather than as sole nutrition? An example follows.

Also, consideration needs to be given to whether the new formulation has a persistent or transient effect. If its effect is thought to be transient, when in the course of follow-up do investigators expect that the maximum effect is likely to occur, and why so? They should ensure that assessments are timed for the period of maximum effect and, if scientifically important, document its transience.

EXPLAINING TARGET DIFFERENTIALS BY REFERENCE TO OUR MULTICENTER LOW-BIRTHWEIGHT FEEDING TRIAL

Design outline. Our five-center low-birthweight (<1850 g) feeding trial was designed in the early 1980s as follows. Three centers [Cambridge, Ipswich, Kings Lynn (CIK)] had donor milk banks, but in the other two centers [Norwich, Sheffield (N&S)] the control diet was term formula rather than donor milk. Pilot studies around Cambridge showed that two-thirds of mothers of low-birthweight infants chose to express breast milk: the infants of these mothers were to be randomized in the so-called supplement trial—that is, they would receive the trial diet (control = banked milk or term formula according to center; or special pre-term formula) only as supplement to mother's own milk if mother was not providing enough. Other low-birthweight infants, those whose mothers elected not to express breast milk, were to be randomized in the primary trial—that is, they would receive the trial diet as sole nutrition.

Major outcome variables. Outcome variables were ordered in time and prioritized as follows. First, we were interested in the effects of the preterm formula on short-term anthropometry: days to regaining birthweight, steady-state weight gain in g/kg/d, length gain, head circumference, and skinfold thickness. Steady-state weight gain was the major short-term outcome. The last three were to check that babies did not just put on weight but also grew in length and head circumference and did not become excessively fat. The first was important because it entailed a careful definition of the day of regaining birthweight: from that date until discharge was the period over which steady-state weight gain was assessed using linear regression of the natural logarithm of weight on day. A secondary economic variable was also reported: days to discharge from special care, irrespective of survival status—a harsh outcome to contemplate.

Second, we were interested in the effect of the special preterm diet on developmental outcome, as assessed by Bayley scores at 18 mon. A longer horizon stretching from reading ability at age 7 and beyond was not formally part of our trial size considerations in 1982, when the reality was that unless the preterm formula had a significant effect on short-term anthropometry, it was unlikely that industry or the Medical Research Council would underwrite continued randomization to achieve the trial size that would be necessary to powerfully discern (by the benchmark of statistical significance) moderate effects on developmental scores, if such effects pertained.

Research strategy. Our research strategy was therefore a four-group sequential design allowing up to three formal interim analyses when recruitment was 1/4, 1/2, and 3/4 complete. This design was selected to allow early reporting of major effects on steady-state weight gain, but randomization continued to ensure that sufficient infants were randomized to discern moderate effects on Bayley scores at 18 mon. In effect, we assumed that publication of results on short-term anthropometry would encourage funders to underwrite the continued randomization and more costly, actual follow-up to 18 mon and Bayley assessments.

This plan differed from the usual reason for a group sequential design, which is to curtail randomization to the inferior treatment if important effects are soon seen. With a four-group sequential design—each group of size s and half the infants per group having been randomized to the preterm formula—analysis at a more extreme significance level than the 5% level is made after s, $2s$, $3s$, and $4s$ infants have been recruited: up to four analyses. But if, at any of the three planned interim analyses, the design-specific significance

level is met, then randomization may cease and the significant differential between preterm and control diet can be reported with confidence that false positive inference, so-called Type 2 error, has been appropriately controlled. Type 1 error occurs when statistical significance is observed but there is truly no difference between treatments. Type 2 error is when there is truly an important difference between treatments but statistical significance is not achieved.

How were target differentials determined? Going back a stage, how were rational target differentials determined for steady-state weight gain and for Bayley developmental scores? Professor Alan Lucas will forgive me, I hope, for paraphrasing the then process as: he provided the differentials and I provided the rationale!

(i) Steady-state weight gain. From prospective pilot studies and also from analysis of data from case-notes of low-birthweight babies, we estimated the standard deviation (sd) for steady-state weight gain as 6 g/kg/d and the mean as 16 g/kg/d. Professor Lucas was confident that the effect would be large. A large target was set (3.8 g/kg/d), about two-thirds of a standard deviation in the primary trial; that is, twice as large as would nowadays be considered to constitute a moderate effect.

The rationale that I imposed on this exuberance was that a more modest target (set at two-thirds of the target in the primary trial = 2/3 × 3.8 g/kg/d = 2.5 g/kg/d) should be used for the supplement trials in which babies would receive the trial diets only as supplement to mother's own milk, and hence could receive anything from 0 to 100% of their nutrition from the randomized diet. In the event, and regrettably, data which we had not obtained from a formal pilot study before the start of the main trials, infants in the supplement trials received about half their nutrition from mother's own milk, and so—on crude proportionality—the second target should perhaps have been smaller still.

(ii) Bayley developmental scores. Bayley developmental scores, like IQ scores, have a published mean of 100 and standard deviation of 15.

For the 18-mon assessments, it was prudent to set a more modest, but still confident-that-early-dietary-effects-would-persist, 5-point differential in the primary trials, equivalent to one-third of the then-published standard deviation. For the supplement trials, the same shrinkage to two-thirds effect was applied as for short-term anthropometry, giving a target 3.3-point difference between preterm diet and control.

Simple trial size sums. Using the simple trial size sum illustrated in Scheme 2, we calculate that for the primary trials to have 80% power to discern a 5-point differential by the benchmark of statistical significance at the 5% level, 140 infants whose mothers elected not to breast feed should be randomized to the control group and 140 to preterm diet. Thus, for primary trials,

$$A1 = 2 \times 15 \times 15/(5 \times 5) = 18 \quad [1]$$

and, for 80% power and 5% significance level,

$$\text{number per dietary group} = 8 \times A1 = 8 \times 18 = 144 \quad [2]$$

Trial size (ratio 1:1)

Step 1. Rational target difference ... *science, not arithmetic*
Step 2. Literature, historical or pilot data . . . standard deviation (SD)
Step 3. Back-of-envelope sum, as follows:

Compute:
A = 2 × SD × SD/(target difference × target difference)

For 80% power[a] and 5% significance level:
number per treatment group = 8 × A

For 50% power[a] and 5% significance level:
number per treatment group = 4 × A
[= *half the number required for 80% power*]
$= (1.96 + 0.84)^2 = (Z_{1-\alpha/2} + Z_{1-\beta})^2$.

[a]For 80% power, multiplier 8 (actually, 2.8 × 2.8 = 7.84)
For 50% power, 4 = approximately (1.96 × 1.96) with $Z_{1-\beta} = 0$.

SCHEME 2

How did these requirements measure up to the numbers of infants (4 groups of 32 each) to be randomized in the CIK (4 × 32 = 128 babies) and N&S (also 4 × 32 = 128 babies) four-group sequential primary trials? The answer is: not well for the primary trials separately (less than 50% power each, see Scheme 2), but comfortably for the CIK + N&S primary trials combined. The combined primary trial thus addressed powerfully a generalized question: whether the special preterm formula improved upon the control diet (be it term formula or banked human milk) as sole early nutrition in respect of Bayley developmental scores at 18 mon.

For each of the supplement trials we needed to randomize 330 per dietary group for 80% power and 5% significance level per trial. The numbers to be randomized in the CIK (288) and N&S (also 288) supplement trials afforded less than 50% power per trial but approached 80% power for the combined supplement trials to answer the generalized question: as measured by Bayley developmental scores at 18 mon, did the special preterm formula improve upon control diet (be it term formula or banked human milk) as supplement to mother's own milk up to discharge from special care?

Our low-birthweight feeding trials therefore had adequate power to answer the same generalized question at 18 mon separately for infants randomized in the pair of primary trials and for those randomized to receive the trial diet as supplement to mother's own milk.

Best laid plans of mice and men . . . . But, the best laid plans of mice and men gang aft agley. In practice, the sd of Bayley scores in this population of children was around 18, nearer 20 than 15, in other words. When the above calculations are repeated with a sd of 18 rather than 15, the number to be randomized per dietary group in the combined primary trials becomes 210; the combined primary trials have only just over 50% power when the sd is as high as 18.

And similarly for the combined supplement trials, the number to be randomized per dietary group becomes 520.

In consequence, our five-center low-birthweight feeding

trials' program had adequate power in practice, rather than in concept, to answer only a single global question: does the special preterm formula confer advantage in terms of Bayley developmental score at 18 mon over the control diet (be it term formula or banked human milk) whether the infants received the trial diet as sole or only as part of early nutrition?

The original trial-specific target differentials translated to a "pooled-across-all-four-trials" 3.8 differential $[(128 \times 5 + 288 \times 3.3)/(128 + 288) = 3.8]$ between preterm and control diets, where 128 = number randomized to preterm in both primary trials; 5 = primary trial target differential (preterm formula vs. nursery standard) 228 = number randomized to preterm in both supplement trials; and 3.3 = supplement trial target differential (preterm formula vs. nursery standard). With sd of 18, for 80% power and 5% significance level, for the combined trials

$$A3 = 2 \times 18 \times 18/(3.8 \times 3.8) = 45 \quad [3]$$

$$\text{number per dietary group} = 8 \times A3 = 360 \quad [4]$$

at 18 mon, which the program achieved!

Sample size review because of change in variability. This example illustrates one context—change in anticipated variability—in which sample size review becomes necessary, but it is also an example in which nothing, practically, could be done about it, because by the time the first 50 or so infants had had their 18-mon developmental assessment, randomization had practically ceased.

AS WELL AS sd, TIME PER ASSESSMENT AND LIKELY ACCRUAL MATTER

Before turning to another, and successful, example of trial size determination I want to draw attention to Table 1 which shows four hypothetical visual acuity protocols A to D. Protocol D has the smallest sd (= 1), but it takes 4 h to test a single baby. For 80% power to discern—at the 5% significance level—a visual acuity difference of 0.5, 130 babies would need to be randomized and 520 observer hours committed for asessment of their visual acuity.

Protocol A has the second-largest sd in assessments of visual acuity (sd = 2) but it requires only 1 h to test one baby. Thus, although four times as many infants have to be randomized, the observer hours are the same as for Protocol D.

TABLE 1
Choice of Acuity Protocol[a]

Visual acuity protocol	SD	Time to test one baby (h)	Number of infants to be randomized	Observer hours
A	2	1.0	500	500
B	4	1.0	2000	2000
C	3	0.5	1150	575
D	1	4.0	130	520

[a]Assume target acuity difference = 0.50.

As well as sd of assessments, practicalities, such as time taken per assessment and number of babies available for recruitment per month, matter. If only 20 babies could be recruited per month it would take over 8 yr to complete accrual if protocol B were selected!

ELICITING PRIOR BELIEFS

Clinical trials should be designed with at least 80% power to detect *a priori* plausible treatment differences and probably should not start if they are unlikely to achieve 50% power. Also, if the only difference that is *a priori* plausible is so small that it would not affect clinical practice, the proposed trial should be vetoed and research conducted on a more promising theme in order to waste neither patient nor physician effort.

What differences are *a priori* plausible? Answers can be attained by eliciting prior beliefs, using a method which I call trial roulette.

TRIAL ROULETTE: HOW TO ELICIT, AND HOW TO FORM PRIOR BELIEFS

British Randomized Evaluation of Artificial Lung Expanding Compound (ALEC) Therapy (BREATHE) was a randomized evaluation of surfactant prophylaxis to reduce the mortality of babies born at 25–29 wk of gestation. BREATHE addressed the question: does ALEC therapy at birth reduce neonatal mortality of very premature infants? Elicitation of prior beliefs proceeded as follows.

A collaborators' meeting was held in Cambridge in June 1984. Neonatal units had forwarded their neonatal statistics for the previous 2 yr, which showed that 36% of babies born at 25–29 wk of gestation died within 28 d.

With 36% control mortality as their reference, participants were asked to place 20 bets in the betting streets illustrated in Figure 1 to indicate their prior belief in the likely mortality of ALEC-treated infants of 25–29 wk of gestation. More bets would be placed in the avenues or betting streets in which they thought it more plausible that the neonatal mortality of ALEC babies would lie. A spread of belief would be expected from most participants, indicating their uncertainty.

ALEC mortality	15%	20%	25%	30%	35%	40%	Recorded by
Centered on: 28%	4%	15%	22%	31%	25%	3%	Peers ($n = 12$)
Centered on: 22%	28%	30%	25%	10%	7%	0%	Cambridge team ($n = 3$)
Centered on **27%**	9%	18%	23%	27% ***	21% *****	2%	Pooled prior belief ($n = 15$)

FIG. 1. Prior beliefs about ALEC mortality from placing 20 bets per person. Trial roulette on the plausibility of Artificial Lung Expanding Compound (ALEC) mortality. Control mortality: 36%. Range of equivalence [*********] from 30 to 37% ALEC mortality.

Also, it is usual to elicit the so-called "range of equivalence" within which participants would be indifferent between use of ALEC and control: for example, a range of equivalence of 30 to 37% for neonatal mortality might have been cited. This would mean, for example, that if ALEC resulted in low neonatal mortality for which the upper 95% confidence limit excluded the range of equivalence, then ALEC therapy should certainly be adopted into neonatal practice forthwith.

Figure 1 also shows the total bets placed by 12 non-Cambridge peers, by the Cambridge team of three, which included me, and all bets pooled. What data and other sources were available in June 1984 on which to base opinions? Firstly, there was the rationale for artificial surfactant therapy: making up for a deficiency of natural surfactant without introducing foreign protein. Secondly, colleagues will have been aware of two small randomized trials in Oxford of ALEC which were then unpublished, and they may have inferred—rightly—"no significant difference" and concluded—wrongly—that "no significant difference" meant there was no difference. Remember that what is reported from RCT depends upon the power of the trial as well as upon the true superiority of one treatment over another. The Oxford trials were wholly inadequate in power, and hence almost completely uninformative.

Colleagues were also aware of a 1981 paper by Morley *et al*. (3) which reported zero deaths out of 22 ALEC-treated babies under 33 wk of gestation but 24% mortality in 33 control babies whose consultant was not Professor Colin Morley. This paper was received critically, not least because of confounding of consultant with therapy.

My first exercise in statistical caution in respect of Morley *et al*. (3) was to halve the difference "to adjust" for publication bias: the likelihood that the investigators had been keeping informal track of the results and rushed into print when the differential was fortuitously high. The lack of a planned stopping rule is suggested by the number of children studied being 55 rather than divisible by 2 and either 50 or 60, say. And indeed, the same design continued with recruitment of a further 76 babies prior to the start of randomization and the differential shrank from 24 to 14%.

My second exercise of statistical caution was for selection bias: I halved the differential again because the infants were not randomized to ALEC therapy vs. control and so, to me, the nonrandomized data from Cambridge were consistent with a one-third drop in mortality such as from 21% (in the under-33-wk gestational age-group) to 14%.

The foregoing description is how I formed my prior belief that a one-third reduction in neonatal mortality was plausible with ALEC. Also available at the time were randomized results by Halliday *et al*. (4) for a subgroup of 30 babies under 29 wk gestation that showed a dramatic fall in neonatal mortality from 43% in 14 controls to 25% in surfactant-treated infants. These Belfast data were consistent with interim, not fully checked data for 25–29-wk-old babies in the ongoing Cambridge-Nottingham trial (21% ALEC-treated vs. 38% control neonatal mortality, each out of 47 infants) to which only the Cambridge team was privy.

The pooled prior belief centered on 27% ALEC-treated mortality, which the two-stage trial (5) was designed with nearly 80% power to discern, given the results in hand. Ultimately, 328 babies were randomized in BREATHE, 164 to ALEC, of whom 35 (21%) died in the neonatal period compared to 59 controls (36%).

Figure 2 provides some betting streets to use to elicit prior beliefs about the impact of some long-chain polyunsaturated fatty acids (LCPUFA) on outcomes such as visual acuity (Teller acuity) at 7 mon, head circumference at 3 mon, Bayley Mental Developmental Index at 18 mon and Wechsler Intelligence Scale for Children (Wisc-R) at 7 yr (The Psychological Corp., San Antonio, TX). Notice that on each graph is documented the mean for formula-fed controls, and the standard deviation of measurements.

VISUAL MATURATION: SOME STATISTICAL OBSERVATIONS

Before leaving the topic of trial size, I want to make a series of statistical observations about visual maturation and their implications for assessment times and for analysis of visual acuity.

Since visual maturation is linked to postconceptional age rather than to postnatal age, care has to be taken that assessments are made at the intended postconceptional age and appointments booked appropriately. Visual maturation is rapid: for example, stereoacuity apparently matures to within 0.5 log of adult level by 6 to 8 mon of age. It is therefore desirable to document that bias in assessment times has been avoided, for example by reporting mean and sd of (intended – actual assessment time) per dietary group. Clearly, if the control group were seen on average at a younger age, then their visual maturation could be less on that account alone.

It is also necessary to avoid observer bias in assessing visual maturation: in particular, the assessor should be masked as to the pattern size and grating being used at all times during her/his assessment of the infant's visual maturation.

Time per test is important (Table 1). It is worth remembering that stereoacuity has been assessed on 2000 three-year-olds in the United Kingdom: it can be done.

Finally, exclusion of infants from analysis is not infrequent, for example, because of strabismus or noncompliance. The former should mean that there is a protocol for detecting strabismus that is employed for every child. The second reason for exclusion is more problematic: for example, if noncompliant children are those who see less well, such exclusions could bias the comparison between control and experimental diet by excluding from analysis precisely the controls which a successful dietary intervention might have helped!

Scheme 3 was compiled to discover something about the statistical properties of the Teller Acuity Card (TAC) assessment. Within each study, the sd is substantially lower in

Table 1: Mean Teller acuity (TAC) at 7 mon on formula is 10.0, standard deviation (sd) = 3. Place your bets (20) on change in mean with LCPUFA

–2.0	–1.8	–1.6	–1.4	–1.2	–1.0	–0.8	–0.6	–0.4	–0.2	NIL	+0.2	+0.4	+0.6	+0.8	+1.0	+1.2	+1.4	+1.6	+1.8	+2.0

Range of equivalence = ...

Table 2: Mean head circumference at 3 mon on formula is 40 cm, sd = 2 cm. Place your bets (20) on change in mean with LCPUFA

–2.0	–1.8	–1.6	–1.4	–1.2	–1.0	–0.8	–0.6	–0.4	–0.2	NIL	+0.2	+0.4	+0.6	+0.8	+1.0	+1.2	+1.4	+1.6	+1.8	+2.0

Range of equivalence = ...

Table 3: Mean Bayley Mental Development Index at 18 mon on formula is 100, sd = 16. Place your bets (20) on change in mean with LCPUFA

–20	–18	–16	–14	–12	–10	–8	–6	–4	–2	NIL	+2	+4	+6	+8	+10	+12	+14	+16	+18	+20

Range of equivalence = ...

FIG. 2. Betting streets for use to record prior beliefs about long-chain polyunsaturated fatty acids (LCPUFA).

breast-fed infants, which may be a clue to bias in their selection with, for example, replacements being drafted in for breast-fed babies with anomalous results. Typically, mean Teller acuity (cy/cm) is 2.6 times sd, an indication for logarithmic transformation of the data before analysis and when computing trial size. Notice that 3-mon adjusted visual acuity is less for preterm than for healthy term infants with between-study differentials of the order of 0.25 to 1.0 (one-eighth to one-half sd); within-trial differentials between breast- and formula (FM)-fed infants are of the same order. Thus, for 80% power to discern a modest diet-related differential of 0.25 [mean TAC (cy/cm) at 3 mon of 3.50 vs. 3.75] when sd = 1.5 requires 1200 infants to be randomized. To discern a moderate differential of 0.5, if that were *a priori* plausible, would require 300 infants to be randomized (see Scheme 2 for how to compute trial size).

Teller Acuity Card (TAC) visual acuity: statistical properties?

TAC test at 3 mon: healthy term infants
Breast-fed ~ mean TAC (cy/cm) = 3.54, SD = 1.2, n = 45
FM + PUFA ~ mean TAC (cy/cm) = 3.52, SD = 1.8, n = 32
FM . . . . . . ~ mean /tac (cy/cm) = 4.28, SD = 1.7, n = 21

TAC at 3 mon adjusted age: preterm infants
Breast-fed ~ mean TAC (cy/cm) = 4.08, SD = 1.5, n = 19
FM + PUFA ~ mean TAC (cy/cm) = 4.52, SD = 2.8, n = 18
FM . . . . . . ~ mean TAC (cy/cm) = 4.50, SD = 2.6, n = 19

(i) SD is low in breast-fed babies: *selection bias*?
(ii) Typically, mean TAC is 2.6 times SD, an indication for logarithmic transformation?
(iii) Is visual acuity less for preterm than for healthy term infants? The differential is of the order of 0.25 to 1.0.
(iv) Differential of 0.25, e.g., 3.50 vs. 3.75, SD = 1.5 leads to: for 80% power, $2n$ = 1200 infants randomized.

SCHEME 3

Critical remarks on infant habituation protocols from a statistical standpoint are inevitable. The setup is that independent observers are behind opaque screens to right and left of baby and up to 10 trials are made with the habituation stimulus. Trial j ends when baby fixates away from habituation stimulus for 2 s or more: this defines the duration of trial j.

Baseline duration of fixation is defined as (trial 1 + trial 2) duration/2 = B. Habituation criterion is reached if [trial j + trial (j + 1)] duration < B, such as in consecutive trials 3 and

4, or 4 and 5, or . . . , or 9 and 10. Baby is excluded from analysis if she or he fails to reach habituation criterion within 10 trials. Such exclusions may constitute a serious analysis bias by removing infants who are slow at recognition or are not easily bored!

Four novelty preference tests are then presented. But, inexplicably, the test order is predetermined and systematic,

*H on left, Novelty on right

+Novelty on left, H on right

*H on left, Novelty on right

+Novelty on left, H on right.

and presumably is known to the observers who assess the infant's preference. If such observers also know to which dietary group the infant has been randomized, the potential for observer bias—conscious or otherwise—would be extremely high. Moreover, bright children may habituate to the alternation! There can be no excuse for not randomizing the order in which the two * and two + sequences appear, as randomization of the order of appearance is security against observer bias.

RANDOMIZATION

Simple randomization, the equivalent of tossing a coin, is not recommended because unequal numbers per treatment group readily result, and the imbalance can be severe in small studies or for individual centers within a multicenter trial, or at interim analyses.

Balanced randomization using permuted blocks. Balanced randomization can be achieved using tables of random permutations of fixed length (for block length 8, say, ignore numbers 9 to 16 in printed permutations of length 16). Block length 8 means that after every eighth patient has been randomized—that is, after patients 8, 16, 24, 32, . . .—an equal number of patients will have been assigned between treatments, to control, and to LCPUFA, for example. In assuming a randomization ratio of 1:1 and block length 8, the maximum imbalance at any time would be 4, which is half the block length.

If treatments cannot be made double-blind, there is a serious drawback to using permuted blocks of fixed length, namely, that a proportion of assignments is knowable in advance, as illustrated below for block length 4. Knowable-in-advance assignments are shown in boldface and constitute one-third of assignments. For longer block lengths, the proportion is lower, and so there is a trade-off between maximum imbalance and the percentage of assignments that can be determined.

cc**LL** . . . . LL**cc**

cLc**L** . . . . LcL**c**

cLL**c** . . . . Lcc**L**

When treatments are not double-blind, the solution is to use permuted blocks of variable length (6 or 8 or 12, say) with the length of the first, second, third block and so on being chosen at random so that the investigator never knows when the balance will fall next.

When there is one major prognostic factor, or perhaps two, such as gestational age or gender, investigators may wish to ensure that treatments are evenly assigned to patients who differ in respect of this prognostic factor. Thus, randomization in BREATHE was stratified by center and by gestational age within each center (25–26 wk or 27–29 wk) to ensure that equal numbers of very premature babies were assigned to ALEC and to control within each center (5).

Minimization. Minimization is a method of randomization which achieves balanced treatment allocation in respect of marginal frequencies for several covariates, for example, gestational age, gender, maternal education. Thus, preterm babies would be assigned equally between control and LCPUFA, as would term babies. Male babies would be assigned roughly 50:50 between control and LCPUFA, as would female infants. Assignment would be made similarly for three levels of maternal education, but the method would not guarantee equal numbers per formula group for each cross-classification, such as: preterm female infant born to mother who completed higher education.

In multicenter studies, the choice will often be between balanced randomization within center or balanced randomization across centers (for trial as a whole, that is) or minimization. A central randomization office would usually be needed for the second and third options even though formula supplies were locally held and numbered serially such as for Barcelona in Scheme 4. The Barcelona investigators would

Randomization

Central randomization office:

Baby	Center (covariates)	Minization assignment	Local serial
1.	Flinders (female, preterm, maternal educ. 1)	A	. . .
2.	Cambridge (female, term, maternal educ. 2)	A	. . .
3.	Barcelona (male, preterm, maternal educ. 1)	B	#2 . .

.

Local supplies: BARCELONA . . . *record randomization date and to whom allocated, for example.*

1 A
2 B . . . 961102 to Baby Fernando, trial number 003: supplies B 02
3 A
4 B
5 B
6 B
7 B
8 B
etc.

*Randomization ratio: 1:1 or 2:1 or . . . , e.g., twice as many babies randomized to experimental formula.

*Randomization leaks: unblinded because . . . ; substitutions?

SCHEME 4

TABLE 2
Minimization Assignments So Far

Formula	A	B
Totals	2	0
Male	0	0
Preterm	1	0
Maternal education, level 1	1	0
Barcelona	0	0

not know that local supplies 1, 3, 11, and 12 were the A formula; that information would, however, be known by the central randomization office.

Scheme 4 shows that the first baby randomized in the trial was from Flinders, a female preterm baby whose mother achieved level 1 education. Minimization is being used at the central randomization office to achieve marginal balance in respect of center, gender, gestational age, and maternal educational level. The first baby is assigned by simple randomization to formula A. The second baby to enter the trial is from Cambridge, also female but a term infant whose mother attained education level 2. To maintain balance for female infants, it would be preferable if this second child were allocated formula B. Simple randomization is used with probability 0.8 for the assignment which minimizes the imbalance, but with probability 0.2 the imbalance is exaggerated. As it happens, the Cambridge baby was assigned to formula A. The third infant notified to the central randomization office is Baby Fernando, a preterm male from Barcelona whose mother is at educational level 1. The central randomization office checks each margin which applies to this baby as follows (Table 2). It would be preferable to assign this baby to formula B to reduce the imbalance (see Totals: 2 vs. 0), and this assignment is made using simple randomization with probability 0.8. Baby 3 is indeed assigned to formula B. The central randomization office now has to instruct Barcelona which local supplies should be assigned to Baby Fernando. The office does this by selecting a serial number at random from the first 10 which contain supplies of formula B. As luck would have it, Baby Fernando is to receive local supplies #2, but there is only a 1 in 9 chance that the next Barcelona baby who has been assigned to formula B will receive #4 as his or her supplies. Re-randomization in use of local supplies is to confound deductive disclosure such as would occur if supplies were used in sequence, Thus, used in sequence, the assignments #2, #4, #1—that is, going back to #1—would allow the local team to deduce that two babies receiving local supplies #4 and #1 were in fact receiving different diets! Re-randomization makes such deductions impossible and is a precaution that should be taken to confuse the intelligence of participants.

The randomization ratio may be different from 1:1. For example, there may be good reasons to wish twice as many babies to be assigned to the experimental formula. Some randomization give-aways (tell-tale signs) are listed in Scheme 5. Scheme 6 shows what Consolidation of Standards for Reporting of Trials (CONSORT) (6) expects investigators to detail about how assignments were made in RCT and about masking. The CONSORT flowchart, which is to be a feature of all RCT published in leading medical journals from 1 January 1997 on, is reproduced as Figure 3.

Randomization give-aways

Single-center studies
*Number randomized is not divisible by number of diets.
(more generally: does not accord with randomization ratio)
At best: untidy
At worst: clue to unplanned trial size, opportunistic stopping, exclusions from analysis

*Imbalance in numbers assigned per formula exceeds the maximum imbalance for reported permuted block lengths.

*Accrual *(number randomized per month)* does not accord with historical data on number eligible per month.

Multicenter studies
As above on a per-center basis, unless randomization was balanced only across centers.

SCHEME 5

CONSORT on Assignment

Describe:
*Unit of randomization (e.g., individual, cluster—such as twins or litters, geographic)
*Method used to generate the allocation schedule
*Method of allocation concealment, and timing of assignment
*Method to separate the generator from the executor of assignment

CONSORT on Masking (blinding)

Describe:
*Mechanism (e.g., capsules, tablets, packets of formula)
*Similarity of formula characteristics (e.g., appearance, taste, weight of packets/contents, ease of deductive biochemical or other analysis: docosahexaenoic acid in serum?)
*Allocation scheme control [location(s) of code during trial and when broken—individual breaches and across-trial]
*Evidence for successful masking of mother/baby; doctor who assigned diet to baby; outcome assessors; data analysts.

SCHEME 6

COHORT MINIMIZATION TO SELECT BREAST-FED INFANTS FOR PARALLEL STUDY

Before moving on to analysis, I'd like to suggest a novel use of minimization to select the sort of parallel cohort of breast-fed infants which features as a nonrandomized control group in many nutrition studies. Whether it is generally useful to study such nonrandomized cohorts is debated elsewhere.

If the aim is to select breast-fed infants for study so that they have the same center distribution, and same gestational age distribution, same maternal education distribution as the

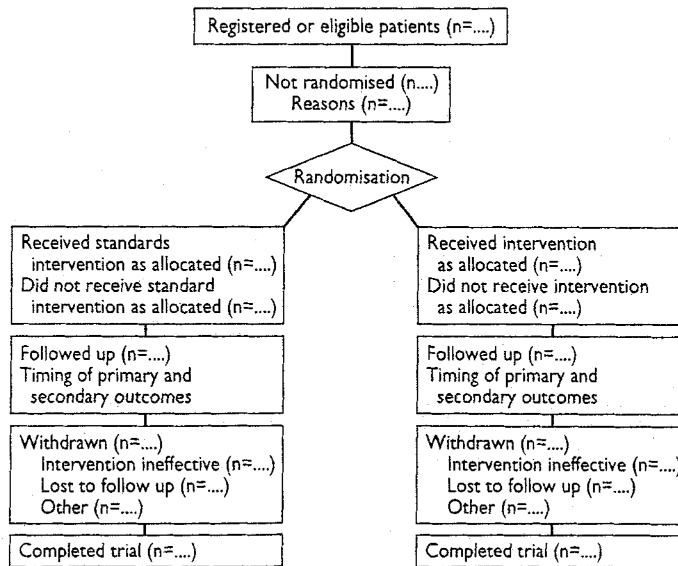

FIG. 3. Flow chart to be used in describing patient progress through randomized trials. This flow chart is intended to produce better reporting of randomized control trials and is designated as the Consolidation of Standards for Reporting of Trials (CONSORT) statement. Flow chart reprinted with permission from *JAMA,* 1996, *276* (8), 637–639. Copyright 1996, American Medical Association.

infants randomized to formula (FM vs. FM + LCPUFA), then for each breast-fed infant who is potentially eligible for study, compute its "cohort score."

Cohort score is shown in Scheme 7 for a 30–32 wk preterm infant born in Cambridge to a university-educated mother. In respect of the covariates of interest (gestational age, center, and maternal education) the cohort score basically works out whether recruitment of this baby would tend to equalize, or to imbalance, the number of Cambridge babies randomized per formula group as compared to the average of cohorted plus randomized babies from Cambridge, and likewise for the other two covariates that apply to this potentially eligible breast-fed baby. The cohort score sums the discrepancies over the three covariates of interest for this potential recruit.

If the baby's cohort score ≥ 0, then the infant is recruited into the cohort with probability 0.8 because its recruitment will make for a better balance between randomized and cohorted babies. But, if its cohort score < 0, baby is cohorted with probability 0.1 only because its recruitment exaggerates the existing imbalance.

Such design considerations can thus aid selection of a more appropriate breast-fed cohort. There is also the assurance that since all potential recruits are notified and detailed to the central randomization office, there is minimal opportunity for untoward selection bias on investigators' part. Recall that previously low sd for Teller acuity was a clue to such untoward selection bias.

Cohort minimization

Selection of breast-fed infants for study so that they have same center distribution, same gestational age distribution, and same maternal education distribution as the infants randomized to FM or FM + PUFA.

Centers = Adelaide, Barcelona, Cambridge
Gestation = 27–29 wk preterm, 30–32 wk preterm, or term
Education = school to age 16, high school, or university

Next eligible breast-fed baby: 30–32 wk preterm infant born in Cambridge to university-educated mother. Its cohort score:

#RCT(Cambridge)/2 − [#RCT(Cambridge) + #Breast(Cambridge)]3 +
#RCT(30–32 wk)/2 − [#RCT(30–32 wk) + #Breast(30–32 wk)]/3 +
#RCT(university)/2 − [#RCT(university) + #Breast(university]/3
That is, Cohort score = sum of Observed − (expected marginal)

If Cohort Score ≥ 0, baby is cohorted with probability of 0.8.
If Cohort Score < 0, baby is cohorted with probability of 0.1.

If All (expected marginals) = 0, cohort with probability of 0.5.

SCHEME 7

ANALYSIS AND REPORTING STANDARDS

Cochrane Collaboration and systematic reviews. Consideration should be given to establishing a Cochrane Collaborative Center to conduct systematic reviews of RCT of infant nutrition according to the standards expected of Cochrane Collaborations and to update them regularly.

Statistical overview, or meta-analysis, of a series of clinical trials requires from each: integrity of design, analysis and reporting. The goal of a common protocol available to all investigators would assist in ensuring adequacy of trial design, including plausible target differentials, sufficient trial size to ensure not less than 50% power and ideally at least 80% power, randomization and masking to CONSORT standards,

and attention to the timing of visual acuity measurements and assessment protocol.

Integrity of analysis concerns the avoidance of untoward stopping and careful consideration of potential biases, for example in the handling of protocol deviations. Particular care is needed in the conduct and reporting of regression analyses. Some analysis give-aways include the following: too little variation; *n* not divisible by number of formulas; NS without 95% confidence interval; inconsistency between outcome measures or across observation times; selective emphasis in results/discussion on comparisons which were not of prior interest; *P*-values rather than clinically meaningful data summaries/results; effect sizes which are *a priori* implausible; subgroup analyses without formal tests of interaction; and interactions which influenced neither randomization nor trial size considerations.

Factorial treatment structure or dose response studies. The interplay between design and analysis is pre-eminent when randomized treatments have a factorial structure such as: group 1, FM; group 2, FM + DHA (0.35%); group 3, FM + arachidonic acid (AA) (0.70%); and group 4, FM + DHA (0.35%) + AA (0.70%); this structure allows the main effect of DHA (0.35%) to be estimated efficiently by comparison of groups 2 and 4 vs. 1 and 3 and of AA (0.70%) by comparison of groups 3 and 4 vs. 1 and 2.

If it is considered *a priori* likely, for example, that AA (0.70%) may potentiate the effect of DHA (0.35%), then this interaction can be assessed by comparing the effect of DHA (0.35%) in the absence of AA (0.70%) (group 2 minus group 1 differential) with the effect of DHA (0.35%) in the presence of AA (0.70%) (group 4 minus group 3 differential). Factorial treatment structure is the only way to address the question of potentiation, but answering it powerfully requires that trial size sums be done in respect of plausible magnitudes for the interaction, that is, for the differential effect of DHA (0.35%) in the presence vs. absence of AA (0.70%). Statistical collaboration is advisable. However, a factorial treatment structure has much to commend it, specifically when no such interaction is anticipated, because the four-way randomization we have been discussing effectively allows two trial questions to be answered for the price of one.

Another design feature related to analysis occurs when treatments are selected so that dose response can be estimated as in comparison of 7-mon visual acuity between infants randomized to formulas differing only in α-linolenic acid content (e.g., 0.4, 0.8, 1.6, 3.2% of fatty acids). The objective at analysis is to model the dose-response relationship. Is it significantly nonlinear to an important degree?

Reporting standards: adjusted vs. unadjusted analyses. Whenever regression methods are used there should be a statistical strategy for doing so. This requires consideration both of the coding of covariates [one coding would be simply an indicator variable for preterm (vs. term) babies; a more informative coding might be number of weeks before or after 40 wk of gestation at which the babies were born, namely, (gestational age − 40 wk); the reader can think of others] and the prioritizing of covariates. Some covariates relate to trial design: randomized treatment allocation, center, randomization stratum such as birthweight <1200 g or 1200–1849 g. They should be fitted for that reason. Other covariates are widely recognized to be prognostic and could be expected to be in the regression model, whether they are formally statistically significant in these data or not, such as gender, maternal education, ... Yet others may have been recorded speculatively, and the statistical strategy should be designed to guard against false positive signals in trawling through this set of speculative covariates. This applies *a forteriori* to trawling for interactions. Finally, there may be some specific objective of analysis such as to explore dose-response, whether in a randomized or nonrandomized context. Consider our multicenter feeding trials: does the percentage of its nutrition that an infant receives from the trial diet explain developmental outcome at 18 mon for babies randomized in the supplement trials? Another specific objective of analysis may be to check out an interaction that affected trial size considerations or a lesser one that influenced randomization, say, as a stratification or minimization factor. The trial size considerations for our multicenter feeding trials anticipated a quantitative interaction by assuming a smaller effect size but benefit from preterm formula nonetheless as in the supplement vs. primary trials. We did not expect a so-called qualitative interaction, wherein the direction of effect switches from benefit to harm.

In preparing tables and figures for publication, investigators should ensure that readers can follow how covariates have been recoded and that they are provided with descriptive statistics for the recoded covariates. Standard errors for regression effects should be cited, and also the residual standard deviation. The tables or text should also allow readers to follow the investigators' statistical thinking by documenting the regression chi-square (or equivalent other statistic) and degrees of freedom for salient intervening models by which the end simplification was arrived at.

Readers should expect to see justification of linearity, for example by indicator variables having been fitted for quartiles of the data and the regression coefficients for these showing a suitably linear progression, or because a quadratic term had been fitted to check for nonlinearity, or otherwise.

Readers should be wary of specious (that is: wrong!) statistical reasoning such as "covariate does not differ significantly between treatment groups, therefore no need to adjust for it." Differences between properly randomized groups in the distribution of a highly prognostic covariate may influence the comparison between treatments and therefore need to be adjusted for, despite the distributional difference not being statistically significant. Contrariwise, a highly significant distributional difference in an irrelevant covariate, that is, one which does not affect outcome, while it might lead to checks that there had not been some breach of the randomization procedure, would be unlikely to alter estimation of the treatment effect.

Reporting standards: an example. Table 3 is taken from a much-quoted *Lancet* paper (7) on breast milk and subsequent IQ in children born preterm. Only 11% of infants who re-

TABLE 3
Breast Milk and Subsequent IQ in Children Born Preterm

Factors relating to IQ	Increase in IQ	95% Confidence interval
Received mother's milk	8.3	4.9 to 11.7
Social class[a]	−3.5 per class[b]	−5.5 to −1.5
Mother's education[a]	2.0 per group[c]	0.5 to 3.5
Female gender	4.2	1.0 to 7.4
Days of ventilation[a]	−2.6 per wk	−3.7 to −1.5

[a]Full descriptive data given in Lucas and Morley (7).
[b]Classes 1 and 2; 3 nonmanual; 3 manual; 4 and 5.
[c]5-point scale from 1 = no qualifications to 5 = degree or higher.

ceived no mother's milk were from social class 1 or 2 compared to 30% of the 210 infants whose mothers intended to breast-feed. Of these 210, 17 mothers failed to express any breast milk. Of the mothers who were unsuccessful, 24% were from social class 1 or 2 compared to 31% of mothers who successfully expressed breast milk, a difference which was not statistically significant. Nonetheless, social class is a major correlate of IQ and so should feature anyway in regression analyses. The investigators chose to exclude the 17 from analysis of factors relating to IQ, perhaps because their overall IQ was closer to that of the 90 whose mothers opted not to express breast milk, and despite their social class 1 or 2 advantage. Leaving that decision aside, the published paper clearly explains the covariate coding that was adopted and cites 95% confidence intervals, which go roughly from 2 standard errors (se) below to 2 se above the estimated regression coefficient. Less clear is the distribution of covariate codes for the 90 vs. 193 infants who feature in the analysis. And linearity has not been clearly demonstrated. However, the regression model presented here is that which the investigators had used in a previous publication, and there is much to be said for a consistent literature.

Further analyses were summarized in the text as follows without the actual results being shown: "When % diet as mother's milk was regressed against IQ, while adjusting for the above confounders, there was a significant linear relation ($P < 0.05$)—a finding that was greatest for the verbal scale ($P < 0.01$) with a 9-point advantage [95% CI from 6 to 12]."

Notice that we are left to work out for ourselves that the 9-point advantage was associated with 100% mother's milk; the linearity of the relationship has not been justified; and the adjusted advantage for overall IQ has not been cited. Can we deduce it?

We may apply some statistical thinking to the deduction task as follows: (i) unadjusted se for verbal IQ is 8% higher than for overall IQ [see Table II in (7)]; (ii) assume that the same holds for the adjusted comparisons; (iii) verbal IQ advantage = 9, significant at 1% level, which implies [by statistical reasoning]: $2.58 \times$ se (verbal) = 9, that is, se (verbal) = 9/2.58 = 3.5, which implies (using i and ii) that se (overall) = 3.5/1.08 = 3.2; (iv) overall IQ advantage, we were told, was significant at 5% level, hence $1.96 \times$ se (overall) = overall IQ advantage = $1.96 \times 3.2 = 6.3$ (associated with 100% mother's milk). Recall that median %diet as mother's milk was around 50% in the low-birthweight feeding trial, and so the typical adjusted overall IQ advantage might have been of the order of 3. Future investigators, of LCPUFA for example, should bear in mind the typical IQ rather than the greatest differential (which happened to be in verbal IQ).

Analysis and other give-aways in published trials. Analysis give-aways listed earlier include NS = not statistically significant, but without appropriate qualification such as by quoting se or 95% confidence interval. I interpret NS as a non-statement in such contexts.

Beware, also, of selective emphasis in Results or Discussion on comparisons that were not of prior interest. Subgroup analyses without formal tests of interaction, which are the statistical equivalent of the drunk man who leans on a lamp post for support rather than illumination, are often paraded in desperate defense of selective emphasis. Beware also flaunted interactions which are *post hoc* in that they influenced neither trial design through stratified randomization nor trial size considerations. Also be concerned about inconsistency of inference between outcome measures or across observation times unless transience of effects was postulated *a priori*.

Another give-away is claimed effect sizes in trial size calculations which have not been authenticated and are not *a priori* plausible.

Too little variation is another give-away, which alerts the reader to possible exclusions from analysis; and, if the number randomized is not divisible by the number of treatments when permuted block randomization was used, there should be some explanation given thereof in the text.

Worst of all are abstracts and text which cite only *P*-values without giving a single clinically meaningful data summary.

SUMMARY

Recommended reading are: Guidelines for Standard Operating Procedures for Statistical Practice in Clinical Research (1), Biostatistical Methodology in Clinical Trials in Applications for Marketing Authorizations (2), and the CONSORT recommendations (6) on randomization, masking, and flow-diagram on accrual and follow-up (Scheme 6, Fig. 3).

Scheme 8 is an *aide memoire* to data sources and considerations to be taken into account in determining rational tar-

Rational target difference for each major outcome variable?

Animal studies
Related randomized studies on other formulas
Epidemiological studies, e.g., breast-fed vs. formula

Order of magnitude: relative to gender effect or effect per extra week of gestation?

Differential effect: greater in preterm than in term infants; less in infants who receive formula only as supplement to mother's own milk?

Transient or persistent effect: maximum impact when (and why so)?

SCHEME 8

get differences for each major outcome variable. Prior opinion of participants in the Clinical Trials Workshop was elicited about the likely change in Bayley developmental scores at 18 mon for infants randomized to LCPUFA-enriched formula vs. control formula. The mean *a priori* plausible differential was 3.3. By assuming sd of 16 for the revised Bayley test, this means (see Scheme 2) that $A4 = 2 \times 16 \times 16/(3.3 \times 3.3) = 47$ and, for 80% power and 5% significance level, number to be randomized per formula $= 8 \times 47 = 376$ and hence some 800 infants in total.

Figure 4 shows the corresponding sum when the outcome variable is binary (success/failure, necrotizing enterocolitis (NEC)/no NEC) rather than continuous or measured (weight gain or Bayley developmental score), for which use Scheme 2. If a meta-analysis of several RCT, or a single study, wanted to have 80% power to detect a doubling in the incidence of NEC with control vs. experimental diet, how many infants would need to be studied? The answer depends upon the nursery incidence of NEC which in Cambridge, for example, is nearer 1% than 5%. To detect a doubling in incidence from 1% to 2% requires: $A5 = 99 \times 1 + 98 \times 2/[(2 - 1) \times (2 - 1)] = 295$. The number per treatment group $= 8 \times 295 = 2360$, and hence requires some 5000 infants in total.

If other serious infections were added to NEC, the nursery incidence in Cambridge would rise to about 5%, but detecting a doubling in incidence of "NEC and other serious infections" from 5 to 10% requires randomization of only some 1000 infants in total.

If, however, the randomized trials are sited in nurseries which have an incidence of "NEC and other serious infections" of around 15%, then detecting a doubling in incidence from 15% to 30% requires only 250 randomized infants. It would therefore be scientifically efficient to focus attention on such nurseries because an answer can be obtained more quickly.

Compute:

$$A = \frac{\text{success} \times \text{failure rate on control diet} + \text{success} \times \text{failure rate on experimental diet}}{\text{(target difference in failure rates} \times \text{target difference in failure rates)}}$$

For 80% power and 5% significance level:
number per treatment group = 8 × A

For 50% power and 5% significance level:
number per treatment group = 4 × A

(= half the number required for 80% power)

Table: Necrotizing enterocolitis (NEC) example

Nursery incidence of NEC (%)	For 80% power to discern doubling in nursery incidence of NEC on experimental diet, number of infants randomized (ratio 1:1) needs to be
15	250
5	1,000
1	5,000
0.5	10,000

FIG. 4. Trial size when comparing failure rates.

Long-Chain Polyunsaturated Fatty Acids and Eicosanoids in Infants–Physiological and Pathophysiological Aspects and Open Questions

Alois Sellmayer[a],* **and Berthold Koletzko**[b]

[a]Institut für Prophylaxe und Epidemiologie der Kreislaufkrankheiten und Medizinische Klinik, and [b]Division of Metabolic Diseases and Nutrition, Dr. von Haunersches Kinderspital, Klinikum Innenstadt, University of Munich, Germany

ABSTRACT: Eicosanoids are highly active lipid mediators in physiologic and pathologic processes, with their effects ranging from cytoprotection and vasoactivity to modulation of inflammatory and proliferative reactions. Generation of eicosanoids can be affected by changes in the pools of their precursors, the long-chain polyunsaturated fatty acids (LCPUFA). Thus, dietary interventions such as supplementation of infant formula with specific n-3 and n-6 LCPUFA will alter formation as well as activity of the eicosanoids produced. This report summarizes the results and discussion of the workshop on "Eicosanoids and Polyunsaturated Fatty Acids in Infants." The intention of the workshop organizers was to give an overview of the role of eicosanoids in physiological and pathophysiological processes in infants, to discuss the implications that an increased n-3 and n-6 LCPUFA intake may have on eicosanoid generation, and to point out open questions and controversies for future research.

Paper no. L7615 in *Lipids 34*, 199–205 (February 1999).

The term eicosanoids was coined to describe collectively the oxygenated derivatives of long-chain polyunsaturated fatty acids (LCPUFA) containing 20 carbon atoms that can be formed either enzymatically or by nonenzymatic (per)oxidation. Arachidonic acid is the predominant precursor fatty acid, owing to its high abundance in phospholipids. Other fatty acids serve as precursors for enzymatically oxygenated fatty acids with 20 carbon atoms, such as dihomo-γ-linolenic acid (20:3n-6) and eicosapentaenoic acid (20:5n-6). PUFA with 18 or 22 carbon atoms, such as linoleic acid (18:3n-6) or docosahexaenoic acid (22:6n-3), are also oxygenated by some but not all of the enzymes of the arachidonic acid cascade. Because the role of these metabolites in physiologic processes is not understood, the workshop focused on the metabolites with 20 carbon atoms.

Abbreviations: CNS, central nervous system; HETE: hydroxyeicosatetraenoic acid; LCPUFA: long-chain polyunsaturated fatty acid; LT: leukotriene; PG: prostaglandin; Tx, thromboxane.

THE ARACHIDONIC ACID CASCADE

Arachidonic acid can be oxygenated by three different enzymatic systems: cyclooxygenases, lipoxygenases, and cytochrome P450 monooxygenases (Scheme 1, where FA = fatty acid; for review, see Refs. 1–3). The expression of these enzymes can be rather specific for a certain cell lineage, as, for example, expression of the 5-lipoxygenase in cells of myeloid origin.

After release of arachidonic acid from its storage site in cellular phospholipids or after its transcellular exchange, metabolism by cyclooxygenases leads to the formation of prostaglandins (PG) and thromboxane A_2 (TxA_2), whereas 5-, 12-, or 15-lipoxygenase activity results in the formation of the respective monohydroxylated fatty acids (mono-HETE). Production of leukotrienes (LT) is initiated by 5-lipoxygenase, whereas subsequent oxidation by the 5-lipoxygenase and 12- or 15-lipoxygenases results in the formation of trihydroxylated compounds, the lipoxins. Metabolism of arachidonic acid by cytochrome P450 monooxygenases gives rise to epoxides, the epoxyeicosatrienoic acids, and ω-hydroxylated derivatives of the precursor fatty acids or other eicosanoids. Cross-talk between these different enzymatic systems leads to the formation of additional eicosanoids, e.g., 15-epilipoxins, which are generated by the subsequent metabolism of as-

pirin-inhibited cyclooxygenase-2 and 5-lipoxygenase (4).

Eicosanoids are highly active lipid modulators of a multitude of physiologic and pathologic processes (1,2,5). Among their most important properties are cytoprotective effects, modulation of renal function, mediation of allergic and inflammatory reactions, induction and inhibition of thrombotic processes, and regulation of smooth muscle cell tone leading, for example, to vaso- and bronchoconstriction or -relaxation and to the postnatal closure of the *ductus arteriosus Botalli*. *In vitro* observations further indicate that eicosanoids may have a multitude of additional biochemical and physiologic effects; the most important ones are outlined in Table 1. Apart from being intercellular mediators, arachidonic acid and eicosanoids also have been identified as novel intracellular second messengers in inflammatory and mitogenic signaling (6). However, since we are just beginning to understand this role of eicosanoids, it was beyond the intention of this workshop to discuss possible effects of PUFA on intracellular signaling by eicosanoids.

EICOSANOID SYNTHESIS FROM ALTERNATIVE PUFA

In addition to arachidonic acid, dihomo-γ-linolenic acid (20:3n-6) and eicosapentaenoic acid (20:5n-3) also serve as precursors for eicosanoids. Dr. Howard R. Knapp, University of Iowa, gave an overview of the *in vivo* generation and detection of eicosanoids derived from these alternative fatty acid precursors. He pointed out that the metabolism of these PUFA to PGE_3 or LTB_5, which has been observed *in vitro*, does not necessarily correspond to an abundant generation of these compounds *in vivo*. Dihomo-γ-linolenic acid is principally converted to the 1-series PG and the 3-series LT. However, *in vivo* formation of these eicosanoids is barely detectable, with the exception of PGE_1 in seminal fluid. In contrast, eicosapentaenoic acid is readily metabolized to PG of the 3-series such as PGI_3 or TxA_3 and to LT of the 5-series such as the peptidoleukotrienes LTC_5 and LTD_5. This is of physiologic importance, since some eicosapentaenoic acid-derived eicosanoids have different activities from those of the respective arachidonic acid-derived compounds (7,8). Thus, TxA_3 has a much lower potency to activate platelets or to induce vasoconstriction than TxA_2, and LTB_5 is much weaker in stimulating neutrophil activation than LTB_4, although a reduction of its generation by n-3 LCPUFA has not yet been proven *in vivo* (9). In contrast, PGI_3 inhibits platelet activation and aggregation to the same degree as does PGI_2 and has equal vasodilatory activity. Furthermore, the proallergic and proinflammatory effects of the peptidoleukotrienes LTC_5/LTD_5 are also equal to the effects of LTC_4/LTD_4. Despite *in vitro* observations suggesting that PGE_3 may be as active as PGE_2, its physiologic relevance remains to be determined, since formation of PGE_3 has not yet been detected in abundant amounts *in vivo* after supplementation with n-3 PUFA.

In addition to conversion to PG and LT, dihomo-γ-linolenic acid, eicosapentaenoic acid, and other LCPUFA can also be oxygenated *in vitro* to various monohydroxylated or epoxide derivatives by lipoxygenase and cytochrome P450 monooxygenase activities, respectively. However, the physiologic effects of these compounds *in vivo* are just being elucidated.

TABLE 1
Physiological and Biochemical Effects of the Most Physiologically Important Eicosanoids[a]

Eicosanoid	Effects	
PGE_2	Vasculature	Vasodilation (arterial), vasoconstriction (venous)
	Airways	Bronchodilation
	Pain	Hyperalgesia
	Stomach	Cytoprotection
	Kidney	Reduction of water or NaCl reabsorption, increase in renin secretion
	Neutrophils	Reduction of activation
	Lymphocytes	Reduction of apoptosis, reduction of cytokine production
	Bone	Increase in osteoblast activity
	Reproductive system	Uterus contraction, induction of ovulation
	Body temperature regulation	
$PGF_{2\alpha}$	Vasculature	Vasoconstriction
	Reproductive system	Uterus contraction, induction of ovulation
PGI_2	Vasculature	Vasodilation, reduction of platelet aggregation and activation
	Airways	Bronchodilation
TxA_2	Vasculature	Vasoconstriction, platelet aggregation and activation
	Airways	Bronchoconstriction
LTB_4	Neutrophils	Chemotaxis, superoxide anion generation, degranulation, increased expression of adhesion molecules, aggregation
	Monocytes	Increase in cytokine production
	Lymphocytes	Induction of T-suppressor cells, reduction of apoptosis in premature cells, increase in cytokine production
LTC_4/LTD_4	Vasculature	Vasoconstriction, vascular leakage, plasma extravasation
	Airways	Bronchoconstriction, mucus secretion

EICOSANOIDS AND DISEASES IN INFANTS

Most of the physiologic and pathophysiologic effects of eicosanoids have been established *in vitro* and in animal models and have been confirmed in adults. Less is known about the actions of eicosanoids in infants. Many basic physiologic effects of eicosanoids may be similar in infants and adults, such as activation or inhibition of platelet aggregation, vasorelaxation or vasoconstriction, stimulation of inflammatory and allergic reactions or cytoprotection. Dr. Ricardo Uauy, University of Santiago de Chile, discussed the potential role of eicosanoids in the manifestation and/or progression of several diseases in infants. Some of these are listed in Table 2. Clear proof that the suggested pathophysiological mechanisms are active *in vivo* and underlie the disease process exists for only a few diseases, such as the effects of cyclooxygenase inhibition on the occlusion of patent ductus arteriosus (10). In infants with congenital heart diseases that depend hemodynamically on an aortopulmonary shunt, the ductus can be kept open by continuous infusion of a PGE_1 mimetic (10). Furthermore, decreased urinary excretion of 6-keto-$PGF_{1\alpha}$, the stable metabolite of PGI_2, and of PGE metabolites has been observed in the first days of life (11). Whether the decrease in vasodilatory PG formation in the newborn period underlies additional changes of physiologic processes during the first days of life remains to be examined. However, in most examples listed, only an association between eicosanoid levels in biological fluids or tissue samples and a certain disease has been made, without demonstration of a clear causal relationship.

Effects of supplementation with dihomo-γ-linolenic acid or n-3 LCPUFA on eicosanoid formation related to the course of diseases have not yet been studied in infants. Given the observations in adults, it may be expected that n-3 LCPUFA could modulate immunologic, inflammatory, vascular, and thrombotic responses in infants. Indeed, marine oil supplementation in preterm infants led to a significant increase in bleeding time vs. infants fed nonsupplemented control formula (12). However, the bleeding times remained in the normal range (below 5 min) and were not associated with an increase in bleeding complications.

SPECIAL ASPECTS OF DIETARY MODULATION OF EICOSANOID GENERATION IN INFANTS

Whereas in many physiological or pathological processes modification of eicosanoid synthesis by n-3 and n-6 LCPUFA may lead to the same responses that have already been identified in adults, some effects which have not yet been sufficiently investigated may be of special importance in infants and merit further consideration. Thus, possible effects on the maturation and activity of the immune system and the modulation of growth responses may be of special importance.

Maturation and activity of the immune system. Eicosanoids, especially PGE_2 and LTB_4, have been implicated as modulators of proliferation, differentiation, and cytokine synthesis in cells involved in the immune response (13–16). PGE_2 and LTB_4 have been found to reduce apoptosis of premature thymocytes (13,15), whereas apoptosis is increased by TxA_2 (13,15). Furthermore, LTB_4 induces formation of $CD8^+$ T-suppressor cells while inhibiting proliferation of $CD4^+$ T-helper cells (16). PGE_2 also inhibits proliferation of T-helper cells (15,16). Both eicosanoids may also affect B-cell function by increasing immunoglobulin synthesis and modulating B-cell differentiation and growth (14,16). In addition, cytokine synthesis in lymphocytes and monocytes is greatly inhibited by PGE_2, whereas LTB_4 in most studies had a stimulatory effect (Table 3; Refs. 15,16). Although most of these observations have been made in lymphocytes or prelymphocytes of different animal species and although they do not yet definitively link the action of either PGE_2 or LTB_4 to a specific immune response, they support the view that the generation of eicosanoids can modulate the maturation and activity of immunocompetent cells.

These observations raise the question whether supplementation with n-3 LCPUFA may alter the maturation and activity of an infant's immune system. In particular, the observed decrease in overall PGE formation [reduced generation of PGE_2 and PGE_1 without abundant synthesis of PGE_3 (17)] after supplementation with n-3 LCPUFA may affect proliferation and differentiation of lymphocytes and cytokine production. In accordance with such an effect, Dr. Jane Carver, University of South Florida, reported preliminary data indicating that sup-

TABLE 3
Modulation of Immune Responses by PGE_2 and LTB_4[a]

Response		PGE_2	LTB_4
Apoptosis of prelymphocytes		+	+
Proliferation of T-helper cells		—	—
Proliferation of T-suppressor cells		?	+
Proliferation of B-cells		—	+
Immunoglobulin synthesis of B-cells		±	+
Migration of T-cells		+	+
Cytokine synthesis			
T-helper cells	IL-3	—	?
	GM-CSF	—	?

T-suppressor cells	IFN-γ	?	—
Monocytes	IL-1	—	+
	TNF-α	—	+

[a]+, stimulation; —, inhibition; ?, effect not yet determined; IL, interleukin; GM-CSF, granulocyte/macrophage colony stimulating factor; IFN-γ, interferon-γ; TNF-α, tumor necrosis factor α. For other abbreviations see Table 1. For references see 13–16.

plementation with n-3 PUFA in rat pups increased thymocyte differentiation to a $CD4^+CD8^-$ cell type while reducing $CD4^+CD8^+$ prelymphocytes. Since LTB_4 has been found to induce $CD8^+$ suppressor cells, these observations also point to the necessity to determine whether the activity of LTB_4 differs after n-3 LCPUFA increases. Thus, supplementation with eicosapentaenoic acid ameliorated the clinical state in children with cystic fibrosis (18), and this was correlated with an upregulation of LTB_4 receptor activity (19). In contrast, a reduction in the *in vivo* production of LTB_4 has not been observed after supplementing adults suffering from allergic rhinitis with moderate doses of n-3 LCPUFA (9).

Observations and experiences in populations with a traditionally high fish intake seem to argue against a strong immunosuppressive effect of dietary n-3 LCPUFA, since no increase in immunodeficiencies or decreases in the success of vaccination programs have been reported so far in these populations. Supplementation with n-3 LCPUFA has been observed to slow the progression of adult diseases that potentially involve autoimmunity, such as rheumatoid arthritis (20) and immunoglobulin A nephropathy (21). In contrast, n-3 LCPUFA had no effect on graft rejection after renal transplantation (22,23) and did not delay the decrease in renal function in patients with lupus nephritis (24), but they had a clearly beneficial effect on autoimmune-induced kidney diseases in rodent models (25,26). Whether these positive effects of n-3 LCPUFA are related to a decrease in the immune response or to a decrease in the accompanying inflammatory reaction, both of which may result from the well-documented reduction in cytokine formation by n-3 LCPUFA, is not known (27). Therefore, controlled trials should be performed in infants to clearly determine whether infant formulas that decrease n-6 LCPUFA or increase n-3 LCPUFA levels alter the immune response.

Modulation of the growth response. The effects of eicosanoids and LCPUFA on growth are not yet fully established. Taken together, epidemiological as well as animal studies indicate that increased consumption of n-3 LCPUFA is associated with a decrease in pathologic and hyperproliferative growth responses such as in tumor progression or chronic proliferative disorders (28,29). In studies of adult humans and of other mammals no adverse growth-inhibiting effects of n-3 LCPUFA on physiologic (i.e., regenerative) growth, such as of hematopoietic stem cells or intestinal epithelial cells, have been reported. In addition, supplementation of pregnant women with n-3 LCPUFA had no effect on growth and weight of the newborns, although gestational length increased slightly but significantly (30). Furthermore, lower levels of arachidonic acid in red blood cell phospholipids in term infants fed formulas containing different amounts of n-3 and n-6 LCPUFA were not associated with reduced growth at 3 (31) or 12 (32) mon after birth. In contrast, feeding term infants a formula containing either high or low levels of α-linolenic acid while linoleic acid content was kept constant resulted in a significant reduction in plasma levels of phospholipid arachdonic acid and in body weight during the first 4 mon of life in the infants receiving the high α-linolenic acid formula (33). Similar observations were made in preterm infants: Reduced growth was observed after supplementation with a fish oil rich in the n-3 LCPUFA eicosapentaenoic acid (34), and lower arachidonic acid status in preterms was associated with lower first-year growth even among infants who were fed formula without n-3 LCPUFA (35). In several other studies in premature infants, depletion of n-6 LCPUFA has been associated with reduced growth (36–38). Although these data from feeding studies are still controversial, a number of these studies suggest that levels of n-6 LCPUFA, especially of arachidonic acid, may correlate with growth. This assumption is further supported by *in vitro* observations demonstrating that cellular arachidonic acid metabolism stimulates and promotes cell growth (39,40).

On a cellular and molecular level, various eicosanoids have been found either to stimulate or to inhibit the mitogenic

response. Thus, PGE_2, TxA_2, $PGF_{2\alpha}$, or LT in the main increased cell growth (41), whereas PGI_2, PGA_2, and in certain cell types also PGE_2 inhibited cell growth. In a recent *in vitro* study, we further demonstrated that the mitogenic response in mouse 3T3 fibroblasts was induced by the cellular metabolism of arachidonic acid to PGE_2, whereas n-3 LCPUFA antagonized mitogenic stimulation with arachidonic acid by reducing PGE_2 formation (42). Dr. Bruce A. Watkins from Purdue University indicated that PGE_2 may have a biphasic effect on bone formation, increasing osteoblast activity and bone formation at low concentrations but reducing bone formation at high concentrations by increasing osteoclast activity as well. n-3 LCPUFA decreased PGE_2 levels and increased bone formation in animals.

These observations indicate that a delicate balance between pro- and antiproliferative effects of eicosanoids is likely to exist and that the superimposed effects of n-3 LCPUFA will likely add further complexity. Observations in various organs and tissues in populations with a traditionally high intake of n-3 LCPUFA detected neither growth retardation of term infants at birth nor growth delay of infants and children, suggesting that other factors also must come into play such as the balance of n-3 and n-6 LCPUFA achieved *in utero* and beyond. Further research is required to determine which amounts of n-3 and n-6 LCPUFA have to be supplied to pregnant women and infants for optimal physiologic balance between these two classes of PUFA.

EICOSANOIDS IN THE CENTRAL NERVOUS SYSTEM

The role eicosanoids have in the maturation of the central nervous system (CNS) and related functions such as cognitive processes, visual acuity, or behavioral responses is difficult to establish. However, observations in animals and in a few clinical trials in infants indicate that eicosanoids may be important signaling molecules in the CNS. That PGE_2 regulates body temperature (43) and modulates nociception of pain, mainly by inducing hyperalgesia, is well documented. Prostaglandins and hydroperoxy derivatives of arachidonic acid have been suggested to influence synaptic plasticity through their effects on long-term potentiation and depression of neuronal function (44). PGE_1 has also been suggested to increase behavioral activation and to exert antidepressant activity (45). Furthermore, PGD_2 (46) and to a lesser degree lipoxins and LT (47) have been found to promote sleep in rodents, an activity which is counteracted by PGE_2 (48). In support of a potential role of PUFA in regulating sleep, it has been observed that slow-wave sleep is reduced in children maintained on a totally fat-free parenteral nutrition for months as compared to children whose parenteral nutrition was supplemented with essential fatty acids (49).

Taken together, these observations indicate that eicosanoids modulate important processes in the maturation of the CNS as well as in behavioral responses. Further work is required to characterize more clearly the role of eicosanoids in the CNS and to delineate the effects of LCPUFA supplementation on these processes.

OPEN QUESTIONS

Apart from clearly determining the effects of n-3 and n-6 LCPUFA supplementation on the maturation and the activity of the immune system and on physiological growth patterns, several other issues related to these items await further research and clarification in infants.

One central issue is the determination of the amount of n-3 and n-6 LCPUFA which can be supplied to infants without provoking severe adverse effects due to a shift in eicosanoid generation from these LCPUFA. This implies that individual needs may differ, as various diseases and disorders may benefit from different eicosanoid levels. In some situations (e.g., in thrombotic conditions or in inflammation) a higher ratio of n-3 over n-6 fatty acids may be more beneficial than merely supplying LCPUFA for a balanced nutrient intake. In contrast, individuals with bleeding disorders may profit from a formula with a reduced n-3 LCPUFA content. These considerations may be extended to inflammatory disorders, pulmonary hypertension, or patent ductus arteriosus. Basic to such concepts is, of course, the determination of *in vivo* eicosanoid synthesis in infants and the effects of LCPUFA supplementation. Dr. Margaret Craig-Schmidt, Auburn University, reported that neonatal piglets fed infant formula enriched with 20:4n-6 had higher formation of PGI_2 and TxA_2 in lung tissue than piglets fed no arachidonic acid, whereas dietary 22:6n-3 decreased the levels of both eicosanoids (50). These observations indicate the importance of investigating the effects of single n-3 and n-6 LCPUFA in animal models. Preparations now available allow the addition of a single LCPUFA to experimental formulas, as well as combinations of LCPUFA. In the appropriate animal model, studying these effects on eicosanoid formation can be useful in helping design strategies for formula supplementation.

Finally, the sources and the form of the LCPUFA supplied may be of importance for eicosanoid formation. Thus, it may be necessary to determine whether n-3 LCPUFA extracted from single-cell oils have effects on eicosanoid formation that are identical to those of n-3 LCPUFA from marine oils. Furthermore, the lipid class containing the LCPUFA may be of importance. It has to be ruled out whether the different forms in which LCPUFA can be supplied, either the free ethyl esters which allow a highly concentrated supply of the respective fatty acids, LCPUFA esterified in phospholipids, or LCPUFA supplied as triglycerides, have different biological activities and, if so, the form of supplementation which is the most suitable must be determined.

CONCLUSION

The workshop on eicosanoids in infants and their modulation by LCPUFA supplementation made evident that eicosanoids are important physiologic and pathophysiologic mediators in

infants. Various diseases in infants are asssociated with a change in eicosanoid formation. Further research is needed to better define the effect of LCPUFA supplementation, especially that of n-3 LCPUFA on eicosanoid formation and its impact on the modulation of physiologic processes including growth and immune responses as well as their effects on pathologic conditions.

ABSTRACT: The purpose of this workshop at the American Oil Chemists' Society Symposium, "PUFA in Infant Nutrition: Consensus and Controversies," was to enumerate the safety issues raised by the prospect of supplementing infant formulas with long-chain polyunsaturated fatty acids (LC-PUFA), to evaluate the evidence that these concerns are problematical, or theoretically problematical, and to identify the safety issues most in need of resolution. This was approached by reviewing briefly the known biological effects of LC-PUFA and how these effects might give rise to concerns about safety of LC-PUFA as components of infant formulas. Some of these issues were then discussed in more detail by invited participants, all of whom had submitted abstracts concerning the issue discussed. The pertinent aspects of all issues discussed during the workshop are summarized. In addition, since the symposium was held over 2 yr ago, an addendum summarizing additional data reported since the symposium that either support or refute issues discussed during the workshop also is included.

Paper no. L7757 in *Lipids 34,* 207–214 (February 1998).

Considerable evidence exists that a dietary source of long-chain polyunsaturated fatty acids (LC-PUFA) during infancy may be beneficial with respect to subsequent visual and neural development. This evidence is based on comparisons of relatively short-term visual and neurodevelopmental outcomes of breast-fed vs. formula-fed infants as well as infants fed formulas with LC-PUFA vs. without LC-PUFA. These data, as well as the methods used to obtain them, were evaluated in other sessions of this conference and are reviewed in the summaries of the respective sessions.

At the outset, it is important to note that the described benefits of LC-PUFA are subtle. Formulas without LC-PUFA have been fed to infants for decades and have not resulted in epidemics of either poor vision or neurodevelopmental delays. This highlights the importance of questions that have been raised concerning the immediate and long-term safety of LC-PUFA intake during infancy. For example, it is logical to ask, as several have, if addition of bioactive substances such as LC-PUFA to infant formulas for their perhaps beneficial but, nonetheless, subtle effects on visual and neural development might result in undesirable effects on other systems that, on balance, negate any beneficial effects on visual and/or neural development. Within this context, even the largely theoretical concerns that have been raised represent problems that must be resolved before widespread supplementation of infant formulas with LC-PUFA can be unconditionally recommended.

BIOLOGICAL EFFECTS OF LC-PUFA AND SAFETY ISSUES RAISED BY THESE EFFECTS

Addition of LC-PUFA to infant formulas is known to influence the fatty acid pattern of both plasma and erythrocyte membrane lipids, and it is assumed that the fatty acid pattern of tissue membranes is similarly influenced. The fatty acid pattern of membrane lipids, in turn, is thought to affect the characteristics of the membrane. In fact, the beneficial effects of LC-PUFA on visual and central nervous system development are usually attributed to this general effect. LC-PUFA also are known to affect eicosanoid metabolism; for example, increased availability of the major n-3 precursor of eicosanoids [i.e., eicosapentaenoic acid (EPA)] relative to the major n-6 precursor [i.e., arachidonic acid (AA)] results in decreased synthesis of eicosanoids derived from AA and, perhaps, increased synthesis of those derived from n-3 precursors (see summary of the session devoted to eicosanoid metabolism, Ref. 1). These two general effects of LC-PUFA have been known for years. More recently, both n-3 and n-6 LC-PUFA have been shown to influence the rate of transcription of a number of genes including genes controlling hepatic lipogenic and lipolytic enzymes (2).

Any or all of these effects, of course, could result in both beneficial and undesirable effects. For example, the better visual and central nervous system development of breast-fed vs. formula-fed infants and of infants fed formulas supplemented with docosahexaenoic acid (DHA) vs. unsupplemented formulas have been attributed to a greater content of retinal and central nervous system DHA secondary to dietary intake of DHA. However, supplementation of formulas with DHA, particularly supplementation with sources of DHA that also have a high content of EPA (e.g., fish oil), is associated with a lower content of AA in plasma and erythrocyte phospholipids and this, in turn, has been associated with lower rates of growth (3).

This effect on growth could be mediated by the expected effects of n-3 LC-PUFA intake on eicosanoid metabolism, i.e., a

[1]Summary of workshop "Biological Effects and Safety Aspects of PUFA Related to Infants," held at the AOCS symposium: PUFA in Infant Nutrition: Consensus and Controversies, November 7–9, 1996, Barcelona, Spain.

decrease in eicosanoids derived from AA. Alternatively, it could be mediated by changes in hormone sensitivity and/or binding of hormones to receptors secondary to changes in membrane fatty acid pattern and, hence, changes in membrane characteristics. Altered transcription of genes controlling enzymes involved in metabolism of energy substrates also could affect substrate metabolism and, hence, growth. Unfortunately, data to distinguish among these theoretical mechanisms for lower growth and/or to implicate any or all mechanisms are not available.

Changes in eicosanoid metabolism secondary to LC-PUFA intake might also affect a number of other systems, e.g., hemostasis, and immune function. Uauy *et al.* (4) reported that infants receiving formula supplemented with high-EPA fish oil have longer bleeding times than infants receiving an unsupplemented formula; however, the mean bleeding times of both groups were within normal limits. Inflammatory responses also are affected by LC-PUFA; in general, n-6 LC-PUFA are proinflammatory and n-3 LC-PUFA are antiinflammatory. While an antiinflammatory effect obviously may be beneficial in some circumstances (e.g., autoimmune disorders), such an effect may be undesirable in others (e.g., infection).

In addition to alterations in hormone sensitivity and/or binding to receptors, changes in the fatty acid pattern of membranes might enhance the likelihood of oxidative damage. For example, increasing the unsaturation index of membranes, as is assumed to occur with an increased intake of LC-PUFA, might well increase the likelihood of peroxidation. This, in turn, could contribute to development of a variety of conditions that are thought to be caused and/or aggravated by peroxidative damage; in the infant, such conditions include bronchopulmonary dysplasia and necrotizing enterocolitis (NEC).

EVIDENCE FOR SAFETY CONCERNS

Unfortunately, available studies provide little definitive information concerning the extent to which the safety concerns incident to the known biological effects of LC-PUFA are warranted. Exceptions include the aforementioned difference in bleeding times of infants receiving a formula supplemented with fish oil vs. an unsupplemented formula and the effects of the same type of supplement on growth.

Several participants cited a presentation at a recent symposium in which data from a recent study of Carlson *et al.* (5) were reanalyzed to show that preterm infants who received formula supplemented with low-EPA fish oil had a higher combined incidence of NEC plus sepsis than control infants—an outcome that was not analyzed by the investigators. In this study, 94 infants were randomized to either an unsupplemented formula ($n = 45$) or the same formula with 0.2% of total fatty acids as DHA and 0.06% as EPA ($n = 49$); linoleic (LA) and α-linolenic acid (ALA) contents of both formulas were 21.2 and 2.4% of total fatty acids, respectively. Three infants assigned to the control formula (6.7%) and nine infants assigned to the supplemented formula (18.4%) developed NEC. Two assigned to the control formula (4.4%) and five assigned to the supplemented formula (10.2%) developed sepsis. The difference in incidence of neither condition between infants fed control vs. supplemented formulas was statistically significant. Further, power analysis suggested that 100 subjects per group would have been required to detect statistically significant differences of the magnitude observed in rates of either NEC or sepsis between supplemented and unsupplemented infants. Equally important, the incidence of neither condition in the supplemented group differed significantly from the incidence of that condition within the total nursery population. However, the incidence of the two conditions combined, which was not evaluated by Carlson *et al.* (5), apparently was significantly greater in the supplemented group.

Overall, the incidence of sepsis in both groups was lower than the roughly 20% incidence observed in the late 1980s among 1,765 infants (birthweight < 1500 g) delivered at the seven centers participating in the National Institute of Child Health and Human Development Neonatal Intensive Care Network (6). The 6.7% incidence of NEC observed in the unsupplemented group was similar to that reported among the same 1,765 infants (6). The 18.4% incidence of NEC observed in the supplemented group was high, although not higher than the incidence of this condition at some of the centers making up the National Institute of Child Health and Human Development Neonatal Network (6). Nonetheless, the n-3 LC-PUFA supplement theoretically could result in an increased incidence of NEC by decreasing eicosanoids derived from AA and/or by increasing eicosanoids derived from EPA, thereby decreasing the enteric cytoprotective effects of prostaglandins derived from AA and, perhaps, the ability to mount an effective inflammatory response against invading pathogens. Theoretically, the supplement also could have increased unsaturation of enterocyte lipid membranes, thereby increasing the likelihood of peroxidative damage which also could contribute to development of NEC. However, more information than provided in the report of Carlson *et al.* (5) is necessary to conclude that the difference in incidence of NEC and/or the difference in the combined incidence of NEC and sepsis between the two groups was statistically significant.

Discussion of this anecdotal report, as occurred during the session, is included to illustrate the need for studies with sufficient power to determine if formulas supplemented with LC-PUFA increase the incidence not only of NEC and sepsis but also the myriad other conditions that are common in preterm infants and, theoretically, might be increased by LC-PUFA. Unfortunately, studies of the effects of formulas with a variety of combinations, amounts, and sources of LC-PUFA are likely to be necessary.

In contrast to the lack of data concerning the safety of 3 LC-PUFA in human infants, some data are available from studies conducted in animals. Such studies are particularly useful because relatively large doses of LC-PUFA can be given, thereby identifying potential problems that subsequently can be evaluated in human infants receiving more reasonable LC-PUFA intakes.

Data from a study in rats that examined the effects of maternal diet during pregnancy and lactation on auditory brain stem response, excitoxic neural injury, hypoxic ischemic injury, and immune response of the offspring were presented at the symposium by Carver *et al.* (7). In this study, dams were fed a control

chow diet, a diet supplemented with corn oil (22% of energy), or a diet supplemented with fish oil (22% of energy). The expected effects of the diets on the fatty acid patterns of the dams' plasma and milk as well as the pups' plasma were observed. The latency component of the auditory brain stem response of the offspring of dams fed the fish oil diet was longer at 16, 19, and 29 d of age suggesting a slower rate of conduction. However, cerebral edema 4 d following injection of methyl aspartate into the left ventricle of the cerebrum (to produce excitoxic damage) was less in the offspring of dams fed the fish oil diet, suggesting a protective effect. Hypoxic ischemic injury produced on day 3 of life by ligation of the right carotid artery followed by 2 h in an 8% oxygen environment delayed developmental milestones in all groups, but the delays were more marked in the fish oil group. Contrary to theoretical expectations, mortality following injection of Group B streptococci was lower, not higher, in offspring of dams assigned to the fish oil diet. The percentage of immature CD4+/CD8+ thymocytes also was lower in the offspring of dams fed the fish oil diet while the percentage of mature CD4/+CD8+ thymocytes was higher. Studies addressing at least some of these issues in infants are badly needed.

AMOUNTS OF LC-PUFA THAT SHOULD BE ADDED TO INFANT FORMULAS

Many believe that some of the theoretical problems discussed above can be avoided by supplementing formulas with both AA and DHA. Most also believe that high intakes of EPA should be avoided. Unfortunately, few published data exist either to support or to refute these beliefs. Representatives from several formula manufacturers cited preliminary data from just-completed or soon-to-be-completed multicenter studies showing no difference in either growth or morbidity between infants assigned to an unsupplemented formula and those assigned to the same formula supplemented with DHA and AA. However, the amounts and sources of DHA and AA differed considerably among the studies, highlighting concerns regarding the amounts and sources of fatty acids that should be added to formulas.

Regulatory agencies usually condone addition of components of human milk to formula in the same amounts that are present in human milk. However, there are nutrients for which this guideline clearly is not appropriate. For example, more vitamin D than is present in human milk appears to be desirable. In addition, iron and zinc are more bioavailable from human milk than formula. Thus, modern infant formulas contain more vitamin D, iron, and zinc than human milk.

Although advocated by many, it is not clear that the amounts of the various LC-PUFA in human milk are the appropriate guidelines for the amounts that should be present in formulas. First, these fatty acids may be conditionally essential for some infants, but they are not essential nutrients in the traditional sense. Further, the amount of LA and ALA, the precursors for endogenous synthesis of AA and DHA, respectively, as well as the amounts of all longer-chain, more unsaturated n-3 and n-6 fatty acids in human milk are quite variable (8); coefficients of variation are at least 50% for most. This variation in part reflects the maternal plasma fatty acid pattern which, in turn, reflects the fatty acid content of the mother's diet rather than regulation of the fatty acid content of human milk fat at the level of the mammary gland. In contrast, the ratio of AA and DHA in human milk appears to be somewhat less variable than the absolute amount of either (the coefficient of variation of the ratio is roughly half that of either AA or DHA). Thus, it has been argued that the ratio of these two fatty acids is more important than the absolute amount of either.

Another potential problem in adopting either the amounts of AA and DHA or the ratio of these two fatty acids in human milk as a guideline for the amounts of each that should be in formula is that human milk contains LA and ALA as well as LC-PUFA other than AA and DHA. Since infants can synthesize DHA and AA (9–12), the amounts of these fatty acids that are produced endogenously are likely to be influenced by the amounts of the precursors as well as the amounts of other fatty acids in human milk that, once ingested and absorbed, can be converted to AA and DHA and/or compete with other fatty acids for conversion. According to data presented at the symposium by Sauerwald *et al.* (13), intake of DHA and AA decreases endogenous synthesis of both fatty acids. In this study, enrichments of plasma lipid DHA and AA following administration of uniformly ^{13}C-labeled ALA and LA were considerably lower in breast-fed infants and infants fed formulas supplemented with AA and DHA than in infants fed an unsupplemented formula.

Thus, even though formulas are supplemented with the same amounts of AA and DHA and/or the same ratio of AA/DHA present in human milk, there is no *a priori* reason to expect that such supplementation will result in the same plasma and tissue patterns of these fatty acids observed in breast-fed infants. For this to occur, one would predict that the amounts of the precursors of n-6 and n-3 LC-PUFA, i.e., LA and ALA, as well as the content of all n-6 and n-3 polyunsaturated fatty acids in formula must be the same as in human milk.

An alternative and more reasonable strategy is to supplement formula with a mixture of fatty acids that results in a plasma lipid pattern of fatty acids similar to that of breast-fed infants. However, the plasma lipid fatty acid pattern of breast-fed infants, although not as variable as the fatty acid pattern of human milk, also is quite variable. Moreover, application of this strategy clearly will require considerable time and effort.

Four posters presented at the symposium included plasma and/or erythrocyte phospholipid fatty acid contents of preterm infants fed formulas supplemented with varying amounts of AA and DHA. Two of these as well as an additional poster also included data from infants fed formulas supplemented with only DHA—an algal triglyceride in one study and a low-EPA fish oil in the other two. All studies included a group of preterm infants fed human milk. Combinations of AA and DHA (% of total fatty acids), respectively, of 0.50:0.35, 0.6:0.4, 0.72:0.36, and 0.75:0.6 all resulted in plasma and/or erythrocyte contents of AA and DHA similar to those observed in infants fed preterm human milk. The amount of DHA was similar in all studies of only DHA supplementation (0.35, 0.36, and 0.37% of total fatty acids; the latter, the low-

EPA fish oil, also included 0.07% of total fatty acid as EPA). The algal triglyceride DHA supplements resulted in plasma or erythrocyte phospholipid contents of DHA similar to those observed in infants fed preterm human milk. The low-EPA fish oil supplement resulted in higher contents of both DHA and EPA than observed in infants fed preterm human milk. In all studies, the AA content of plasma or erythrocyte phospholipid was lower than observed in infants fed preterm human milk.

Thus, despite the considerations discussed above, it appears that supplementing preterm infant formulas with ratios of AA/DHA from 1.4–2.0 (with AA ranging from 0.5–0.75% of total fatty acids) results in plasma and erythrocyte phospholipid contents of AA and DHA similar to those observed in infants fed preterm human milk. Although all studies were small, were performed by investigators from three continents, and included measurements of the fatty acid contents of different lipid fractions using different methods, the data are reassuring.

AVAILABLE SOURCES OF LC-PUFA

In addition to the issues discussed above concerning the amounts of LC-PUFA that should be added to formulas, there are issues concerning the source(s) of supplementation to be used. Currently, three general sources are available. The first, fish oil, contains large amounts of n-3 LC-PUFA but minimal amounts of n-6 LC-PUFA; further, some fish oils contain at least 1.5 times as much EPA as DHA, and the high EPA content has been implicated as the cause of adverse effects on growth. Some fish oils contain considerably less EPA but one such oil also was shown to have an adverse effect on growth of preterm infants (5), although a smaller effect than high-EPA fish oil. All fish oils, theoretically, are subject to contamination with heavy metals and, perhaps, other components; however, it should be relatively easy to ensure that such contamination is minimal.

Other sources of LC-PUFA include egg yolk lipid, or phospholipid, and triglycerides, usually derived from algae or other single-cell organisms. Egg yolk lipid, of course, contains large amounts of cholesterol; for example, the amount necessary to supply even the lowest amounts of AA and DHA in human milk will result in a formula with considerably more cholesterol than is usually present in human milk. For this reason, egg yolk phospholipid is a more logical choice. Although egg yolk phospholipid contains AA and DHA, the proportions of the two are not necessarily the same as the proportions of these fatty acids in human milk. However, the proportions of AA and DHA in egg yolk phospholipid can be modified by alterations in the diet of the hens. There is some concern, although no evidence, that egg yolk lipid or phospholipid may contain allergens. Of more concern is the possible difference in intestinal digestion/absorption and/or metabolism of phospholipid vs. triglyceride sources of LC-PUFA.

Both phospholipid and triglyceride sources of LC-PUFA contain fatty acids other than the LC-PUFA, including unusual fatty acids. These sources also may contain toxins, pigments, and/or other contaminants from fermentation or extraction processes utilized in their manufacture but, again, this theoretical concern should be easily allayed. The algal triglycerides contain positional distributions of LC-PUFA different from those of human milk triglycerides; whereas AA and DHA in human milk triglycerides are present primarily in the *sn*-1 and *sn*-2 positions, they are present in all three positions in the algal oils. Further, while human milk triglycerides rarely contain more than one molecule of AA and/or DHA, some algal triglycerides contain two, even three, molecules of AA and/or DHA. Whether this is a problem—or, perhaps, a desirable attribute—remains to be determined.

COMPARISON OF PHOSPHOLIPID AND TRIGLYCERIDE SOURCES OF LC-PUFA

Carnielli *et al.* presented data at the symposium (14) from a study in preterm infants showing that absorption of DHA was better at 1 mon of age in infants who received DHA as a component of phospholipid than in infants who received this fatty acid as a component of triglyceride (i.e., 91.6 ± 1.5% of intake in infants who received the phospholipid source vs. 80.4 ± 2.1% of intake in infants who received the triglyceride source). Absorption of AA from the phospholipid vs. triglyceride source also was higher (i.e., 84.7 ± 1.7% vs. 80.4 ± 2.3% of intake), but this difference was not statistically significant. Absorption of DHA and AA by infants fed human milk was 78.4 ± 4.4% and 81.1 ± 3.6% of intake, respectively. In this study, the intake of DHA and AA from the phospholipid source was lower than the intake of these fatty acids from the triglyceride source, i.e., 13.6 ± 0.1 and 19.4 ± 0.2 mg/kg/d of DHA and AA, respectively, in infants who received the phospholipid source vs. 37.8 ± 0.7 and 49.7 ± 1.0 mg/kg/d of DHA and AA, respectively, in infants who received the triglyceride source. This raises the question of whether the apparently better absorption of DHA from the phospholipid source is secondary to the known physiological differences in digestion and absorption of phospholipid vs. triglyceride or simply reflects the usual greater percentage absorption of lower intakes. Despite apparently poorer absorption of DHA and AA from the triglyceride source, the amounts of the two fatty acids absorbed were higher in infants who received the triglyceride vs. the phospholipid source of these fatty acids, i.e., 30.6 ± 1.1 vs. 12 ± 0.3 mg/kg/d of DHA and 40.0 ± 1.4 vs. 16.4 ± 0.4 mg/kg/d of AA in infants who received the triglyceride and phospholipid sources, respectively.

Questions arose concerning the effect of calcium supplementation of human milk on absorption of both fatty acids from human milk as well as the effect of the calcium content of formulas on absorption of both as components of phospholipid vs. triglyceride. No information concerning the specific questions was available. However, recent data of Schanler *et al.* (15) show that addition of a commercially available human milk fortifier (protein, calcium salts, and other mineral salts) to human milk markedly decreases total fat absorption.

Despite evidence that human infants absorb DHA better from phospholipid than from triglyceride sources, Goustard *et al.* presented data at the symposium (16) showing that the DHA content of retinal phosphatidylethanolamine was similar in piglets fed formulas enriched with egg yolk (phospholipid),

salmon oil (high-EPA triglyceride) or low-EPA fish oil (triglyceride), i.e., 40–42% of total fatty acids, the same as in sow-fed controls, vs. only 35% of total fatty acids in animals fed a formula with no LC-PUFA. However, interpretation of these findings is complicated by the fact that the egg yolk (phospholipid) supplement contained more DHA than either triglyceride supplement [0.4% of total fatty acid vs. 0.2% of total fatty acids in the salmon oil supplement (plus 0.3% 20:5n-3 and 0.1% 22:5n-6) and 0.3% in the low-EPA fish oil supplement].

EFFECT OF POSITIONAL DISTRIBUTION OF DHA

Data presented at the symposium by Christensen *et al.* (17) provide some insight into the biological significance of the positional distribution of DHA. In this study, newborn rats were fed dietary supplements of either specifically structured or randomized oils. Both oils had the same total content of DHA but, in the structured oil, DHA was present exclusively in the *sn*-2 portion whereas, in the randomized oil, it was equally distributed among *sn*-1, -2, and -3 positions. At 12 wk of age, the liver and brain DHA contents of both supplemented groups were higher than the content of the control group which was suckled and then fed chow. Liver DHA content was higher in animals supplemented with the randomized vs. structured oil. Brain content of DHA, on the other hand, was highest in the group supplemented with the structured oil. In both tissues, the increase in DHA was accompanied by a decrease in n-6 LC-PUFA. Fatty acid profiles of the retina did not differ among the three groups. Despite the apparent differences in metabolism and distribution of DHA as a result of positional distribution within the oils, there were no differences among groups in learning ability and only minor differences in electroretinograms and auditory brain responses.

LC-PUFA AND INSULIN SENSITIVITY

Data from extensive studies in both animals and human volunteers showing statistically significant positive correlations between the content of various LC-PUFA in skeletal muscle membrane and insulin sensitivity (18) were reviewed by Baur. Specifically, there are statistically significant positive correlations between insulin sensitivity and the content of AA, DHA, the sum of all n-3 LC-PUFA and the sum of all n-3 and n-6 LC-PUFA in skeletal muscle phospholipid. In adults, these relationships are thought to be important with respect to development and/or progression of diseases linked to insulin resistance—i.e., obesity, coronary heart disease, hypertension. Although it has not been conclusively established that diet during infancy and childhood is an important antecedent for development of these adult diseases, there is concern that this may be the case. Thus, these relationships may be equally, perhaps even more, important in children.

Altered insulin sensitivity secondary to the fatty acid pattern of skeletal muscle membranes also may affect the rate as well as the composition of weight gain during infancy. For example, greater insulin sensitivity should be associated with a lower plasma insulin concentration and, hence, less marked effects of insulin on skeletal muscle and adipose tissue. This, as well as eicosanoid-mediated effects on growth, is a rational explanation of the lower rate of weight gain observed by Carlson *et al.* (3) in low-birthweight infants supplemented with a high-EPA fish oil and the lower weight-for-length Z-scores observed in a subsequent study by the same group in low-birthweight infants supplemented with a low-EPA fish oil (5). Greater insulin sensitivity could also explain the lower rates of weight gain observed by Jensen *et al.* in both low-birthweight (18) and term infants (20) fed formulas with a high (i.e., 3.2% of total fatty acids) vs. a low (i.e., 0.4–1.0% of total fatty acids) content of ALA.

Baur also reviewed her group's more recent studies in children (21). In these studies, the fatty acid pattern of muscle membranes obtained at elective operation was related to diet as well as to fasting glucose concentrations. Infants who were breast-fed vs. formula-fed at the time of operation had higher muscle phospholipid contents of DHA as well as total n-3 and n-6 LC-PUFA. Plasma insulin concentrations of the two groups did not differ, but the breast-fed infants had lower fasting plasma glucose concentrations, suggesting greater insulin sensitivity (or less insulin resistance). Moreover, among the total study population, there was a wide range of skeletal muscle phospholipid contents of DHA and other LC-PUFA and, as observed in adults, there was an inverse correlation between fasting plasma glucose concentration and the percentage of DHA ($r = -0.47$) as well as the sum of n-3 and n-6 LC-PUFA ($r = -0.38$) in skeletal muscle phospholipid. Baur concluded that diet and probably genetics determine the fatty acid composition of the muscle membranes of children as well as adults and that this pattern affects insulin sensitivity and hence regulation of glucose metabolism.

Whether insulin sensitivity and/or resistance secondary to LC-PUFA intake and the resulting effect on the fatty acid content of skeletal muscle membrane are responsible for or contribute to the lower rates of weight gain observed in infants fed formula supplemented with n-3 LC-PUFA or containing a high content of the precursor of these fatty acids remains to be established. In the initial study of Carlson *et al.* (3), there was a positive correlation between weight at 1 yr of age and the plasma phosphatidylcholine content of AA early in infancy, i.e., those with higher AA contents early in life weighed more at 1 yr of age. Jensen *et al.* (20) also observed a positive correlation between weight of term infants at 120 d of age and the plasma phospholipid content of AA as well as the plasma phospholipid content of other n-6 LC-PUFA at the same age. The AA content of cord plasma lipid also has been related to the size of infants at birth (22).

As discussed elsewhere, this apparent relationship between AA status and growth might also be explained by an imbalance in eicosanoids derived from AA vs. EPA. Recent studies showing that growth of infants supplemented with both AA and DHA is not lower than that of infants fed unsupplemented formulas tend to support this possibility. However, a role of insulin sensitivity cannot be discounted. If LC-PUFA increase insulin sensitivity, infants supplemented with these fatty acids should de-

posit less fat. Hence, the impression that the lower rate of growth of infants fed formulas supplemented with n-3 LC-PUFA or formulas with a high content of ALA is "bad" may need to be reevaluated. In other words, this current safety concern may prove to be a reason for adding LC-PUFA to formulas. Clearly, much more data are needed concerning this issue.

RESEARCH NEEDS

As discussed throughout this summary, much more data are needed concerning all of the safety issues discussed above. While a number of posters presented data from studies with formulas containing a variety of LC-PUFA supplements, few of these studies included outcome variables related specifically to the safety issues of concern. Moreover, most were reasonably short-term studies and included relatively few subjects. Virtually no data are available concerning the effects of feeding formulas supplemented with LC-PUFA for the entire first year of life, as is likely to occur if such formulas become generally available. The extent to which formulas supplemented with LC-PUFA are "safe" for all groups of preterm infants is even more problematical. In these infants, LC-PUFA theoretically could interfere with host defense mechanisms, leading to an even greater incidence of infection. These fatty acids also could exacerbate effects of oxidant stress secondary to increased unsaturation of lipid membranes and, if oxidant stress is an etiological factor in development of such conditions as NEC, bronchopulmonary dysplasia and retrolental fibroplasia, as some suggest, supplemented formulas could result in an even higher incidence of these conditions. Effects on hemostasis theoretically, could also result in an increased incidence of intraventricular hemorrhage and/or other bleeding disorders; however, intraventricular hemorrhage usually occurs during the immediate neonatal period, frequently before infants are fed. As noted above, longer bleeding times, although still within normal limits, were observed in preterm infants supplemented with fish oil (4).

Although large, possibly multicenter, studies will be required, data concerning the extent to which these theoretical safety issues are real should be relatively easy to obtain and, until such data are available, questions concerning the safety of LC-PUFA are likely to persist. Data concerning the purity of various sources of LC-PUFA should be even easier to obtain and some such data, in fact, are available. On the other hand, the data required to answer questions concerning the bioavailability and metabolic consequences of LC-PUFA from various sources will be more difficult to obtain, and these data are needed to determine both the optimal amounts of n-3 and n-6 LC-PUFA that should be added to formula and the optimal sources of these fatty acids. However, with respect to amounts of LC-PUFA with which formulas should be supplemented, it is somewhat reassuring that a variety of levels of supplementation with both DHA and AA appears to result in plasma and/or erythrocyte lipid contents of these fatty acids similar to those of breast-fed infants.

Manufacturers of LC-PUFA supplements and infant formulas are urged to address at least some of the outstanding safety issues at the same time issues concerning the efficacy of LC-PUFA supplementation of infant formulas are being addressed. However, manufacturers should not be expected to assume responsibility for resolving all the issues that have been raised. Many of these issues also should be of sufficient concern to governmental health and research agencies to warrant greater investment in studies to help resolve them. Until some of the outstanding questions concerning safety are resolved, there is likely to be resistance to adding LC-PUFA to formula. This might be unfortunate if these fatty acids, indeed, are important for optimal visual and central nervous system development.

ADDENDUM

Some of the data presented in this session of the symposium in November 1996 (and reviewed above) have since appeared in peer-reviewed publications. These include the study of Carnielli *et al.* (23) showing more efficient intestinal absorption of DHA from a phospholipid vs. a triglyceride source and the study of Baur *et al.* (24) concerning differences in insulin sensitivity of breast-fed vs. formula-fed infants. Other peer-reviewed publications and abstracts addressing biological effects and safety issues related to LC-PUFA in infants also have appeared since November 1996 and some of the more pertinent of these are discussed below.

Recent data from both animals and infants suggest that balanced intakes of AA and DHA do not result in altered eicosanoid metabolism. Huang and Craig-Schmidt (25) found that the tissue contents of eicosanoids derived from n-6 LC-PUFA were lower, and those derived from n-3 LC-PUFA were higher, in piglets fed a diet supplemented with only DHA, whereas eicosanoids derived from n-6 and n-3 LC-PUFA were not deranged in piglets fed diets supplemented with both AA and DHA. Stier *et al.* (26) found no difference in mean urinary excretion of stable metabolites of prostaglandin E_2, thromboxane A_2, and prostacyclin among groups of preterm infants fed a standard formula, a formula supplemented with AA and DHA (~0.35 and 0.20% of total fatty acids, respectively) or human milk. However, the urinary prostanoid excretion of all groups was quite variable.

Additional data also are available concerning the amounts of AA and DHA with which formulas should be supplemented. Clandinin *et al.* (27) reported the fatty acid contents of erythrocyte membrane phospholipid of preterm infants who were assigned randomly to be fed an unsupplemented formula or a formula supplemented with one of three combinations of AA and DHA for the first 6 wk of life, i.e., 0.32 and 0.24, 0.49 and 0.35%, or 1.1 and 0.76% of total fatty acids, respectively, as AA and DHA. A clear dose response between intake and the AA and DHA contents of erythrocyte membrane phospholipid was observed. Based on these data, AA and DHA intakes of 0.6 and 0.4% of total fatty acids, respectively, appeared adequate and, perhaps, optimal with respect to achieving an erythrocyte phospholipid pattern of fatty acids similar to that of breast-fed infants.

A considerable amount of data concerning the safety of preterm infant formulas supplemented with AA and DHA

produced by single-cell organisms also has become available since November 1996. In addition, the manufacturer of the supplements and infant formula manufacturers have reported additional data concerning both the safety and toxicology of the supplements in animals (28,29). The latter show no untoward effects of doses of AA and DHA from single-cell source orders of magnitude higher than likely to be added to infant formula. I am not aware of similar published data concerning other LC-PUFA sources.

Unfortunately, the major sets of data concerning the biological effects and safety issues related to LC-PUFA in infants have been published only as Abstracts (30,31). These data are from two randomized, double-blind, controlled clinical trials of LC-PUFA-supplemented *vs.* unsupplemented formulas in preterm infants. The specific details of the two studies differed somewhat, but both included a relatively large number of infants as well as a reference group fed human milk and both included follow-up at least through 57 wk postmenstrual age.

The two studies plus two smaller published studies (27,32) provide data from roughly 175 preterm infants fed formulas containing 0.32–1.1% of total fatty acids as AA and from 0.24–0.76% of total fatty acids as DHA, both from a single-cell source and produced by the same manufacturer. The combined data show that formulas containing approximately 0.6% of total fatty acids as AA and 0.3–0.4% of total fatty acids as DHA result in plasma and erythrocyte lipid levels of these fatty acids similar to those observed in either preterm or term infants fed human milk. More important, these data suggest that formulas supplemented with AA and DHA from single-cell organisms are safe. In no study was the incidence of any adverse outcome or all adverse outcomes combined greater in the supplemented group than in the control group. Further, in no study was growth of infants receiving a supplemented formula less than that of infants receiving the control formula (a standard preterm formula fed to preterm infants for a number of years). In fact, one study suggests that infants fed a formula supplemented with both DHA and AA grow better than infants fed either the control formula or a formula supplemented with only DHA.

Despite the lack of specific data concerning the effects of preterm formulas supplemented with LC-PUFA on eicosanoid metabolism, peroxidation, etc., these recent data suggest that these concerns may be more hypothetical than real. Certainly, the incidence of diseases which might be related to these biological effects of LC-PUFA (e.g., NEC, bronchopulmonary dysplasia, and retrolental fibroplasia sepsis) did not differ between supplemented and unsupplemented groups enrolled in these studies. A caveat, of course, is that this conclusion applies only to formulas containing the sources of AA and DHA used in the studies evaluated. Also, since data concerning the safety of formulas supplemented with only DHA are limited, this conclusion may not apply to such formulas.

Much less information is available concerning the safety of preterm formulas supplemented with other sources of AA and DHA. One exception is a recent study of Carlson *et al.* (33) in which preterm infants (birthweight, 725–1375 g) were randomly assigned to be fed a control formula without LC-PUFA until 12 mon corrected age, this formula until discharge and, then, a formula containing egg yolk phospholipid (75% phosphatidylcholine; 0.4% of total fatty acids as AA and 0.13% as DHA) until 12 mon corrected age or the latter formulas through 12 mon corrected age. Only one infant fed the formula supplemented with egg yolk phospholipid during hospitalization developed NEC (2.9%) whereas 15 fed the control formula during hospitalization developed this condition. The incidence of sepsis, bronchopulmonary dysplasia and retrolental fibroplasia did not differ between groups.

The extent to which conclusions concerning the safety of preterm formula containing AA and DHA are applicable to all preterm and low-birth-weight infants remains to be addressed. While all studies cited above included a few infants who weighed less than 1000 g at birth, none included an appreciable number of these infants who, theoretically, are more likely to require an exogenous source of LC-PUFA and also more likely to be vulnerable to the potential adverse effects of these fatty acids. Thus, lack of such data, although understandable, is unfortunate.

Long-Chain Polyunsaturated Fatty Acids in Diets for Infants: Choices for Recommending and Regulating Bodies and for Manufacturers of Dietary Products

Berthold Koletzko[a,*] **and Andy Sinclair**[b]

[a]Department of Paediatrics, Ludwig-Maximilians-University of Munich, Germany, and [b]Department of Food Science, Royal Melbourne Institute of Technology University, Australia

ABSTRACT: While the scientific evaluation of the physiologic effects, potential benefits, and risks of dietary preformed long-chain polyunsaturated fatty acids (LCPUFA) for infants have been discussed elsewhere, this manuscript addresses some of the resulting consequences and challenges of interpreting the available knowledge from the perspective of recommending and regulating bodies, and of manufacturers of dietary products and their ingredient materials. Traditionally human milk composition has served as a reference point for infant formula design. With respect to the use of LCPUFA in infant formula, much more emphasis than ever before invested for any other group of micronutrients has been put on clinical studies investigating the potential advantages and disadvantages of LCPUFA in infant foods, including growth, safety aspects, and a variety of other outcome measures.

Paper no. L8070 in *Lipids 34*, 215–220 (February 1999).

CURRENT NATIONAL AND INTERNATIONAL RECOMMENDATIONS AND REGULATIONS ON THE LONG-CHAIN POLYUNSATURATED FATTY ACID (LCPUFA) SUPPLY WITH INFANT DIETS

It is common knowledge that the nutritional and metabolic requirements of children differ from that of adults, and age-specific dietary guidelines are particularly important in infancy (1) However, current recommendations of national and international bodies on the LCPUFA supply with infant diets, and the respective legal regulations, show considerable variation.

With respect to national recommendations, no formal comment of a scientific society in the United States on this question has been made. The U.S. Food and Drug Administration (FDA) has not approved any commercial preterm or term infant formula with added LCPUFA for sale in the United States. The FDA commissioned the Life Sciences Research Office to convene an expert panel in order to review the need for nutrients supplied with formulas for healthy, full-term infants, and the report has recently become available (2,3). This North American expert panel followed the general concepts of previous European recommendations (4) and regulations (5,6) with regard to increasing the minimum required fat content in infant formulas to 40% of energy, adding α-linolenic acid (U.S. recommendation 1.75–5% of total fatty acids), limiting the linoleic/α-linolenic acid ratio (U.S. recommendation 6–16:1), as well as avoiding a high exposure to *trans* fatty acids and to myristic acid. However, the committee "did not recommend the addition of arachidonic acid (AA) or docosahexaenoic acid (DHA) to infant formulas at this time." The committee considered the evidence available at present insufficient to warrant a recommendation for adding LCPUFA to formulas, but advised that the potential short- and long-term effects of LCPUFA should be further characterized and "the question of requiring the addition of specific LCPUFAs to infant formulas be reassessed within five years" (2,3).

Similarly, the Canadian Paediatric Society, the Dieticians of Canada, and the government department Health Canada concluded in a recent joint statement on the nutrition of healthy term infants: "Although it is reasonable to presume that infants not fed breast milk might benefit from dietary sources of AA and DHA, until the safety and efficacy of the sources of these fatty acids and of the formulas supplemented with them have been established, the routine addition of these nutrients to formulas designed for full-term infants is not recommended" (7).

National regulations in Asian countries on PUFA in infant formulas are mostly restricted to linoleic acid content, e.g., in Japan (linoleic acid > 0.3 g/100 kcal), the People's Republic of China (linoleic acid in special grade formula > 3 g/100 g, first-grade > 2 g/100 g, passed > 1.5 g/100 g), and Taiwan (linoleic acid > 0.3 g/100 kcal). Thailand regulates not only linoleic acid content (> 0.3 g/100 kcal) but also acknowledges the addition of LCPUFA up to an upper limit of no more than 1% of dietary energy. Several term formulas with added LCPUFA are commercially available in Japan, Thailand, and other Asian countries as well as Australia.

In the United Kingdom the British Nutrition Foundation issued a report providing a recommendation of the authors for the PUFA supply per day and kg body weight (8). The numbers given for preterm as well as for term infants are 280–1130 mg linoleic acid, 50 mg α-linolenic acid, 20 mg docosahexaenoic acid (DHA) and "some" arachidonic acid (AA).

International recommendations were provided by a joint expert consultation of the Food and Agriculture Organization (FAO) of the United Nations and the World Health Organization (WHO) (9). It was stated that infant formulas for term infants should contain preformed DHA and AA. Recommendations for Europe were issued by the Committee on Nutrition of the European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) (4). For preterm and term infant formulas as well as follow-on formulas, the committee recommended a linoleic acid content of 0.5–1.2 g/100 kcal and a linoleic acid/α-linolenic acid ratio in the range of 5–15. With respect to LCPUFA it was stated: "The Committee feels that enrichment with metabolites of both linoleic and α-linolenic acids approximating levels typical for human milk lipids (n-6 LCPUFA 1%, n-3 LCPUFA 0.5% of total fatty acids) is desirable for formulas for low birthweight infants. LCPUFA supplementation to infant formulas, i.e., for infants born at term, might be of advantage but further data on this question are required prior to a definite recommendation." It was also recommended that n-3 and n-6 LCPUFA contents of formula should not exceed 1 and 2%, respectively, of total formula fatty acids.

The Commission of the European Union issued regulations on infant formula composition, including permission for addition of LCPUFA up to 1 and 2%, respectively, of total fat content as n-3 and n-6 LCPUFA (6).

In Europe, several term and particularly preterm infant formulas are commercially available (since the early 1990s) as a consequence of the recommendations and regulations issued (Tables 1 and 2). In addition, two phenylalanine-free dietary products for the treatment of infants with phenylketonuria with added LCPUFA were introduced (10,11). Interestingly, even though numerous infants were fed with such LCPUFA-enriched formulas, no observations of LCPUFA-related adverse effects have been reported with the enriched formulas available on the market.

IS HUMAN MILK COMPOSITION A SUITABLE MODEL FOR FATTY ACID CONTENT OF INFANT FORMULAS?

In view of the differences of recommendations to include or not include LCPUFA, and of the practice of infant formula manufacturers, the question arises to what extent guidance on infant formula design may be derived from human milk composition. From a historical perspective, the aim of making infant formula similar to human milk appears logical and valid. Unmodified animal milks were widely used for infant feeding well into the nineteenth century, when results of biochemical investigations on human milk composition sparked first efforts to modify the nutrient content of cows' milk preparations (12). During the twentieth century, improved understanding of human milk composition and infant physiology led to a dramatic development from only slightly modified animal milks to modern sophisticated infant formulas. Many infant formulas approached a composition that was much more similar to human milk, with respect to energy density, protein quantity and composition, relative contents of saturated and unsaturated fats, carnitine, and taurine.

In 1977 the Commitee on Nutrition of the ESPGHAN (then still named ESPGAN) summarized some of the underlying basic concepts by stating that "Breast feeding is superior to any other feeding system for infants . . ." while infant formula was considered a supplement to or substitute for breast feeding (13). The compositional and quality requirements for infant formula are higher than for any other food product because it is "intended to cover, by itself, all the nutritional needs during the first 4–6 months . . ." It was further concluded that infant formula "should resemble human milk as far as is possible" (13).

The conclusion that human milk composition should be the model for infant formula, however, has a number of limitations. The nutrient supply with breast feeding is rather variable, since milk composition varies within and between individuals, with duration of lactation, during a day, within one nursing and with changes of maternal diet (14,15), even though recent stable isotope studies indicate that the effects of short-term changes of dietary PUFA intake on milk composition are metabolically buffered (16). For example, average total LCPUFA content of human milk falls from about 3% of total fatty acids in the first week of lactation to about 1.8% at 1 mon (17). Moreover, breast-milk volumes consumed by the exclusively breast-fed infant vary markedly, even in well-nourished populations between some 550 to 1100 mL per day. Hence, it is rather difficult to define reference nutrient intakes of breast-fed babies. Furthermore, the bioavailability and metabolism of nutrients may differ considerably between breast- and formula-fed infants, and they can be influenced by a complex interaction of several components in human milk. The absorption and metabolism of LCPUFA from human milk lipids cannot be assumed to be identical to different forms of LCPUFA added to formula. As another example, the linoleic/α-linolenic acid ratio in human milk may not necessarily be the best guidance for the ratio in formula, not only because it is markedly influenced by maternal diet but also because the linoleic/α-linolenic acid ratio may have a fundamentally different importance in formula- than in breast-fed infants. In babies fed conventional vegetable oil-based infant formula without LCPUFA, an unbalanced ratio of the two precursor fatty acids may have untoward effects on the synthesis of AA or DHA (18). In contrast, this is probably of little relevance in breast-fed infants who receive sufficient amounts of preformed LCPUFA with human milk lipids to cover their needs for growth of membrane-rich tissues (19). It is also well known that contents of some human milk ingredients are markedly influenced by maternal intakes, and in some cases suboptimal supplies to breast-fed infants may

occur, for example of the vitamins K, D, B_{12}, the trace elements iodine, zinc, fluorine, and iron (14,15,20). In conclusion, there is no scientific basis to presume that average fatty acid and LCPUFA contents in human milk found under given dietary and living conditions in a population would represent the ideal substrate supply either of the breast-fed or the formula-fed infant.

The concept that infant formula should resemble human milk as closely as possible is further challenged by the identification of a several bioactive components in breast milk (15). With the developments of biotechnology, it appears technically feasible in the foreseeable future to also add several of these bioactive compounds found in human milk to infant formulas. In addition to LCPUFA, nonpeptide and peptide hormones, lactoferrin, oligosaccharides, polyamines, a variety of different nucleotides and nucleosides, and enzymes such as bile salt-stimulated lipase might theoretically be incorporated into formulas, particularly into products with special indications for defined subgroups of infants. However, at present the addition of a number of these compounds may not be economically affordable. In fact, the introduction of some modifications of standard infant formula that may be technically

TABLE 1
Commercial Low Birthweight Infant Formulas with Metabolites of Linoleic and α-Linolenic Acid in Europe, Based on Manufacturers' Data[a]

Manufacturer	Product	Major metabolites (% of fatty acids)	Raw materials used
Alete (Munich, Germany)	Aletemil preterm formula	0.3 GLA, 0.1 AA, 0.3 DHA	Marine oil, black currant seed oil, egg lipids
Cow & Gate (Trowbridge, United Kingdom)	Nutriprem LBW	0.4 GLA, 0.4 AA, 0.35 DHA	Borage oil, marine oil, egg lipids
Friesche Flag (Leeuwarden, Netherlands)	Frisopre	0.35 GLA, 0.2 EPA, 0.3 DHA	Borage oil, marine oil
Farley (Nottingham, England)	OsterPrem with LCPUFA	0.9 GLA, 0.1 EPA, 0.5 DHA	Borage oil, marine oil
Gallia (Paris, France)	PreGallia au DHA	0.1 EPA, 0.4 DHA	Marine oil
Humana (Herford, Germany)	Humana 0, Humana 0 HA	0.2 GLA, 0.2 DHA	Borage oil, egg lipids
Laboratorios Ordesa (Barcelona, Spain)	Bleviprem	0.3 AA, 0.15 DHA	Egg lipids
Milupa (Friedrichsdorf, Germany)	Prematil	0.2 GLA, 0.4 AA, 0.2 DHA	Evening primrose oil, egg lipids
Nestlé (Vevey, Switzerland)	Beba preterm formula, Pre Nidal + LCPUFA	0.3 GLA, 0.1 AA, 0.3 DHA	Marine oil, black currant seed oil, egg lipids
Nutricia (Zoetermeer, Netherlands)	Nenatal	0.6 AA, 0.4 DHA	Single-cell oils
Nutricia (Zoetermeer, Netherlands)	Premilon (for preterm infants after hospital discharge)	0.45 AA, 0.3 DHA	Single-cell oils
SMA Nutrition (Taplow, United Kingdom)	SMA Low Birthweight	0.6 AA, 0.4 DHA	Single-cell oils

[a]GLA = γ-linolenic acid, AA = arachidonic acid, EPA = eicosapentaenoic acid, DHA = docosahexaenoic acid. Modified from Reference 25.

TABLE 2
Commercial Infant Formulas for Healthy Term Infants with Metabolites of Linoleic and α-Linoleic Acid in Europe and New Zealand, Based on Manufacturers' Data[a]

Manufacturer	Product	Major metabolites (% of fatty acids)	Raw materials used
Alete	Aletemil preterm formula	0.3 AA, 0.15 DHA	Egg lipids
Humana	Humana ES	0.2 DHA	Marine oils
Laboratorios Ordesa	Blemil 1 plus	0.3 AA, 0.15 DHA	Egg lipids
Milupa	PreAptamil	0.2 GLA, 0.4 AA, 0.2 DHA	Evening primrose oil, egg lipids
Nestlé	Beba Start HA	0.3 AA, 0.15 DHA	Egg lipids
Nutricia Ltd. (Auckland, New Zealand)	Karicare	0.4 AA, 0.2 DHA	Single-cell oil, tuna oil
Wander (Bern, Switzerland)	Adapta 90 Inicio	0.2 EPA, 0.2 DHA	Marine oil

[a]See Table 1 footnote for company source locations and abbreviations.

possible could absorb so much resources that other modifications, which might confer as much or even greater benefits for the recipient infant, would not be affordable any more. Hence, one needs both to set priorities and to select some of the possible multitude of formula modifications, based on a thorough evaluation of possible benefits and disadvantages.

EVALUATION OF FORMULA MODIFICATIONS

An important question is how the incorporation of new concepts or new ingredients into an infant formula and its nutritional and clinical effects should be assessed. An expert committee in the United Kingdom recently provided guidelines for such evaluations (21). The committee concluded that nutritional assessment should be performed if modifications that aim at a functional or other clinical benefit are applied to infant formula. If modifications are introduced for other reasons than these two benefits, for example for economic, technological or commercial reasons, these products should at least be subjected to studies of acceptability. In these cases it should also be assessed whether the modification might have nutritional implications, and that the new product is no less satisfactory than the product that went before. The committee further concluded that results of clinical studies should be interpreted in the light of outcomes of healthy infants exclusively breast-fed for 4–6 mon. If adequate data on breast-fed populations are not available, the inclusion of breast-fed groups in clinical studies should be considered as the reference. Some further recommendations of the committee on the design and conduct of clinical studies evaluating formula modifications, as provided by the Working Group on Nutritional Assessment of Infant Formulas, are: (i) At the outset of a nutritional study there should be a clear hypothesis of functional or clinical benefit with defined selection criteria and outcome measures. (ii) Appropriate preclinical studies should be performed for previously untested components of infant formula. (iii) A pilot study should be considered to provide the information necessary to design an adequate study. (iv) Nutritional, including metabolic, outcome measures should be justified as relevant to the modification under test. (v) The need for continuing follow-up to 2 yr or beyond, and the consequent ethical and practical implications, should be considered in all studies. (vi) Studies to assess infant formulas should comply with the principles of Good Clinical Practice and Good Laboratory Practice. (vii) The possibility of unpredicted adverse outcomes should be addressed by adequate clinical monitoring of the participants and by independent scrutiny of the accumulating data. (viii) Results from clinical studies of infant formula, including those partly completed which have been abandoned, should be published.

SPECIFIC ISSUES RELATED TO LCPUFA INCORPORATION INTO INFANT FORMULAS

Following are several specific questions and concerns with regard to LCPUFA incorporation into infant formula.

(i) *What evidence of benefit, and of benefit/cost ratio, is required for incorporation of LCPUFA into infant formula?* A far more detailed evaluation of LCPUFA effects, and of the relationship between benefit and risk as well as cost, has been performed by manufacturers, scientific bodies, and regulatory agencies than was previously applied with respect to decision making on the addition of other nutrients to infant formula, e.g., taurine. This detailed evaluation that is more similar to the approach of evaluating pharmaceutical products is generally welcomed. Nonetheless, no consensus has been reached on the criteria and evidence base required to make decisions regarding formula composition. This lack of consensus is underlined by the differences in strategies that have been applied by various manufacturers and regulatory bodies in different parts of the world. Some experts feel that any change of product design would only be justified by conclusive scientific evidence on biologically relevant long-term benefits, such as improved neurodevelopmental outcome at school age or even in adulthood. In contrast, others raise concern that such conclusive long-term evaluation would not be available for almost any of the components of current infant diets. Based on the lack of such long-term outcome data and the limited feasibility to perform intensive studies lasting more than a decade, decisions on dietary composition in many cases need to be based on considerations of nutritional physiology. Furthermore, the question was raised whether the use of very rigid evaluation criteria might not unduly delay the application of any product innovation, with potential disadvantages for recipient infants who might then be excluded from the potential benefits of scientific and technological progress.

(ii) *Effects of LCPUFA on growth.* Some studies in which preterm infants were fed with formulas supplying high amounts of n-3 LCPUFA relative to n-6 LCPUFA found reduced growth, which has been associated with poor AA status (22). Results of studies without impairment of infant AA status did not show adverse effects on growth. There is general agreement that modifications of infant formula lipid composition should be tested for potential effects on growth, and that sufficient sample sizes need to be achieved for this purpose.

(iii) *Effects of LCPUFA on antioxidant status and interaction with other formula components.* The potential of enhanced peroxidation by added LCPUFA both in products and in the infant *in vivo* has been discussed. Higher dietary supplies of PUFA and LCPUFA may increase the need for antioxidants such as vitamin E, which was addressed in a recent comment by the ESPGHAN Committee on Nutrition (23). Therefore, one should evaluate effects of each approach of LCPUFA incorporation into infant formula on formula stability and peroxide contents as well as infant antioxidant status. Recent results also indicate the potential of an interaction between LCPUFA and selected amino acids (24).

Moreover, one must consider that effects of LCPUFA contents in formulas may potentially be influenced by other aspects of formula composition, such as the content of precursor essential fatty acids linoleic and α-linolenic acids, the

linoleic/α-linolenic acid ratio, and factors modulating endogenous LCPUFA synthesis such as general nutritional status, trace element status, or infant age (25,26).

(iv) *Efficacy and safety of different LCPUFA sources.* The bioavailability, metabolic effects, and safety of the various LCPUFA sources used for the production of infant formula may differ and need to be characterized. Cost is an important consideration for a manufacturer in the choice of raw materials. It has been concluded that related to kg DHA content, fish oil tends to be the cheapest and egg phospholipids the most expensive choice, whereas the price per kg AA tends to be most reasonable for single-cell oils and most expensive for phospholipids.

Some food sources of LCPUFA such as fish, eggs, and some of the plants providing oils rich in γ-linolenic acid (e.g., black currants) have been part of the human diet for a very long time and are generally regarded as safe. However, the provision of extracted and at times fractionated lipids from such foods in relatively high amounts per kg body weight to newborn infants is a new development, and its safety needs to be documented.

Concern was expressed that the early feeding of diets containing fish oils or egg lipids might sensitize infants and induce a risk for development of allergic reactions against fish or egg proteins. However, manufacturers of raw materials emphasized the purity of extracted lipids without appreciable protein residues. So far, no case of fish or egg allergy caused by sensitization with the feeding of an LCPUFA-enriched formula is known. Quality assurance programs should consider testing oils for residual protein contents.

Single-cell oils with high concentrations of LCPUFA that can be produced with fermentation technology are novel food sources in the human diet, and their safety for use in infant feeding requires thorough evaluation (27–29). Concern was raised that some organisms used for single-cell oil production may produce biotoxic substances and novel sterols (27,30–32). Some scientists proposed that single-cell oils used for infant formula production should preferably be derived from nonpathogenic microorganisms and be free of contaminating substances.

Labeling, health claims and advertisements. In Europe, the available commercial products with LCPUFA may state the content of these fatty acids on the package, but no health claim indicating possible advantages for the infant may be made. The question was raised whether information on the LCPUFA content appearing on the label would be understood by the persons responsible for the feeding of infants, and whether these persons would be induced to ask more information from health workers such as doctors or nurses. Scientists working in industry emphasized that it would be very important that health claims of effects in the recipient infant be based on solid scientific evidence. They felt that the consumer had a right to be informed on scientific results, and the opportunity for such claims would stimulate manufacturers to invest more in product improvements, even if they were costly, and in their scientific investigation. Questions were raised as to what criteria claims could and should be based on, and which body would control and follow up such claims and their implementation, as well as ingredients and safety. There are intense scientific efforts to investigate functional effects of early feeding (33) and these may strengthen the basis for establishing governmental regulations on health claims related to food ingredients.

It was also discussed that even though no health claims related to LCPUFA contents in infant formulas are presently permitted in Europe, advertisements are made on product labels and with parent informations that imply improved visual function, brain development, and cognitive outcome. Representatives of regulatory bodies felt that there is a strong need to control these developments in the consumer interest.

Even though scientific knowledge is universal, the interpretation of the available knowledge as well as the conclusions drawn by recommending and regulating bodies and by the dietary industry varies within and between different parts of the world. This is influenced not only by some difference in the emphasis put on different aspects of basic concepts, but even more so by differences in legal systems, issues of patent protection, and economic aspects. Compared with the LCPUFA issue, the decision to add taurine to infant formulas made several years ago by many manufacturers was relatively easy, since this ingredient was not very expensive. In contrast, the incorporation of LCPUFA into infant formula increases production costs considerably. This increase in cost may be compensated for by an increased retail price in affluent countries with a free market economy, such as Europe, particularly if a proven benefit can be communicated to the consumer. In contrast, it may be a much more difficult decision to make for producers in the United States, where a major proportion of formula is sold to the individual states at low bid for distribution through the Special Supplemental Food Program for Women, Infants and Children (WIC). Hence, the implementation of a costly innovation might considerably reduce the profit of the manufacturers under these circumstances. A particular ethical dilemma might arise for a manufacturer with international presence if a costly innovation with a proven benefit for the recipient infant would be affordable for consumers in affluent countries but not for the majority of consumers in a developing country. How could a company justify selling a "second-class" infant product with a perceived reduced health benefit to a poorer population?

For the time being, the available information indicates the potential of some benefit of a balanced dietary LCPUFA intake for term and particularly preterm infants, but great gaps of knowledge remain with respect to both the possible benefits and safety of different PUFA supplies and the potential dependance of LCPUFA effects on other dietary and biological varaibles. Therefore, it appears reasonable that no unanimous conclusion was reached but a variety of different choices are being followed until further information is accumulated.

ABSTRACT: Major advances in understanding cholesterol dynamics and the role that cholesterol plays in vascular disease have recently been made. The brain is an organ that is highly enriched in cholesterol, but progress toward understanding brain cholesterol dynamics has been relatively limited. This review examines recent contributions to the understanding of brain cholesterol dynamics, focusing on extracellular and intracellular lipid carrier proteins, membrane cholesterol domains, and emerging evidence linking an association between cholesterol dynamics and Alzheimer's disease.

Paper no. L8057 in *Lipids 34*, 225–234 (March 1999).

Cholesterol is a molecule that is essential for cellular function. In biological membranes cholesterol contributes to the structure of the membrane, and cholesterol is involved in regulating activity of certain integral proteins. Cholesterol is the precursor of steroids and bile salts. Major advances have been made in understanding how cholesterol contributes to both normal and pathological cell function, particularly with respect to vascular function (1). There has been extensive interest in the dynamics of cholesterol transport, both extracellular and intracellular transport (2–6). Progress has also been made in discerning the structural and functional roles of cellular cholesterol domains (5–7). Liver is the major organ of cholesterol metabolism and the primary site for the synthesis of lipid transport proteins. Brain is highly enriched in cholesterol but brain cholesterol dynamics such as transport and the role of cholesterol domains, are not well understood. Work by Kabara and others in the 1960s and 1970s established the fact that cholesterol was synthesized in brain *in situ* and readers are referred to a review of that work on brain cholesterol metabolism (8). Prior to that time there had been disagreement as to whether cholesterol was synthesized in brain or if brain cholesterol was metabolically stable (8). Subsequent studies have shown that the rate of cholesterol synthesis is high in the fetus and newborn animal and that as the animal matures, brain cholesterol synthesis is very low (9,10). Several recent advances have been made in understanding brain cholesterol dynamics such as identification and potential functional roles of different cholesterol transport proteins, structural and functional properties of membrane cholesterol domains, and the association between alterations in brain cholesterol dynamics and neuropathophysiology. The purpose of this review is to examine recent studies of brain cholesterol dynamics and to discuss the potential role(s) of cholesterol in neuropathophysiology, focusing on Alzheimer's disease.

LIPID TRANSPORT PROTEINS

Lipid transport and the proteins involved in such transport have been studied extensively in systems outside the brain and recently reviewed (3,11,12). While studies of lipid transport in the brain are relatively few when compared with work outside of the central nervous system, there has been an emerging database on both extracellular and intracellular lipid carrier proteins in the brain; those studies are discussed below.

Intracellular proteins. Brain tissue has at least three families of intracellular proteins that may be involved in cholesterol trafficking: the sterol carrier protein-2 (SCP-2) (13,14), caveolin (15,16), and fatty acid binding proteins (17,18). These proteins occur in multiple forms: alternate transcription sites, posttranslational modification, and separate genes. The SCP-2 gene has two initiation sites giving rise to two translation products, a 58 kDa sterol carrier protein-X (SCP-x) and a 15 kDa pro-sterol carrier protein-2 (pro-SCP-2) (17,19). In most tissues, pro-SCP-2 is posttranslationally cleaved by proteolysis to yield the mature 13 kDa SCP-2. A putative 30 kDa SCP-2 gene product arising from alternate mRNA splicing was recently shown not to be present in rat or mouse tissue (19). While SCP-2 was detected in brain tissue by immunoblotting earlier (20), this did not establish whether the brain SCP-2 immunoreactive protein was the

same as that expressed in other tissues. Recently a cDNA encoding SCP-2 isolated from a mouse brain library, demonstrated for the first time that the brain form of SCP-2 was identical to that found in liver and other tissues (13). Furthermore, it was shown that SCP-2 was present in pinched off nerve endings or synaptosomes (13).

While SCP-2 markedly facilitates transfer of cholesterol as well as other molecules (oxysterols, phospholipids, glycolipids, etc.) between membranes *in vitro*, establishment of ligand binding by this protein has been difficult due to the poor solubility of lipids such as cholesterol. Nevertheless, increasing evidence from ^{3}H-cholesterol, fluorescent [dehydroergosterol, NBD-cholesterol {22-[N-(7 nitrobenz-2-oxa-1,3-diazol-4-yl)amino]-23,24-bisnor-5-cholen-3β-ol}, and ^{13}C-cholesterol binding studies demonstrate that SCP-2 binds cholesterol with high affinity (K_d as low as 6 nM) and equimolar stoichiometry (6). Whether the other SCP-2 gene products, SCP-x and pro-SCP-2, also bind sterols is not known. All three SCP-2 gene products do enhance intermembrane sterol transfer *in vitro*.

Until recently, there was very little physiological evidence demonstrating that SCP-2 gene products modulated cellular cholesterol uptake and intracellular trafficking. However, increasing data from transfected cell lines overexpressing the SCP-2 gene products are highly supportive of these roles. For example, overexpression of 15 kDa pro-SCP-2 in several cell lines (CHO and L-cells) led to increased levels of 13 kDa SCP-2 and increased many aspects of cholesterol metabolism including the following: cholesterol uptake, cellular cholesterol mass, cholesterol esterification, cellular cholesteryl ester mass, transfer of plasma membrane cholesterol to endoplasmic reticulum, and mitochondrial cholesterol oxidation (21–23). The functional role of SCP-2 in brain has not been determined.

Three other intracellular proteins have been identified in brain. Caveolins (a multimember family) are usually thought of as an integral plasma membrane protein (24). However, recent evidence has demonstrated that caveolin forms homo- and hetero-oligomers that bind cholesterol (25) and that caveolin is both membrane-bound and in the cytosol (26). Caveolin is involved in cholesterol trafficking from the endoplasmic reticulum to the plasma membrane (24). Caveolins 1, 2, and 3 have been identified in brain endothelial cells and astrocytes (15,16). A clear role for caveolin in brain cholesterol intracellular trafficking remains to be demonstrated. Finally, two members of the fatty acid binding protein family have recently been isolated from brain: the heart and brain fatty acid binding proteins (H-FABP and B-FABP) (17). Both proteins are found in synaptosomes and, although, these proteins do not bind cholesterol, they do inhibit intermembrane sterol transfer *in vitro* (18).

In summary, the brain contains at least four different proteins (SCP-2, caveolin, H-FABP, and B-FABP) that may play a role in intracellular cholesterol trafficking. Such a role may involve the transport of cholesterol from the neuronal cell body to projecting nerve terminals. Research has shown that phospholipids are synthesized in axons of cultured rat sympathetic neurons but that cholesterol is synthesized only in the cell body and transported to the axon by some unidentified mechanism (27). SCP-2, caveolin, H-FABP, and B-FABP may be part of such a transport mechanism. SCP-2 expression increased significantly in the brain tissue of chronically alcohol-treated mice (13). H-FABP and B-FABP expression in brain tissue significantly decreased with increasing age in mice (18). Changes in the levels of these proteins correlate with chronic ethanol-induced (28,29) and age-related (30) alterations in synaptosomal plasma membrane cholesterol domains and structure. This issue is discussed in the Cholesterol domains section elsewhere in this review.

Apolipoproteins. Apolipoproteins such as apoA-I, apoA-II, apoB, and apoE bind cholesterol, esterified cholesterol, phospholipids, and triglycerides, forming lipoproteins that are the primary means by which cholesterol is transported systemically. The main apolipoprotein of low density lipoproteins (LDL) is apoB. ApoA-I, apoA-II, and apoE are the apolipoproteins associated with high density lipoproteins (HDL). Apolipoproteins in brain include apoA-I, apoA-IV, apoD, apoE, and apoJ (31–33). There has been great interest in the role of apoE in brain as a result of studies indicating an association between the apoE4 allele and Alzheimer's disease (34,35). ApoE is thought to be synthesized in astrocytes and released from there to transport cholesterol and other lipids to neurons (36). ApoE-enriched lipoproteins bind to the low density lipoprotein-receptor (LDL-R), the low density lipoprotein receptor-related protein (LRP), and the apolipoprotein E receptor 2 (apoER2) and these receptors also have been identified in brain tissue (32,37–41). ApoE has been proposed to be an important factor in maintaining the stability of the neuron during aging and brain injury (42–45). In support of that hypothesis was the finding that there was a loss of brain nerve terminals in apoE-deficient mice and that aged apoE-deficient mice displayed the greatest loss of neuronal structure compared to younger apoE-deficient mice and wild-type mice (42). Both apoE3 and apoE4 have been found to increase neurite length in primary cultures of developing rat hippocampal neurons (46). Lesioning of the hippocampus increased apoE expression and increased binding of fluorescent-labeled LDL to hippocampal brain slices (37). That study led to the conclusion that apoE and the LDL receptor were necessary for recycling neuronal cholesterol for membrane biogenesis. Mechanisms of membrane biogenesis and the recycling of cholesterol in neuronal membranes are not known. In skin fibroblasts it was shown that LDL-derived cholesterol is transported by cholesterol carrying "rafts" from the *trans*-Golgi network to the plasma membrane (3). Whether such a mechanism is present in brain tissue is yet to be determined.

ApoE may be required for brain neuronal homeostasis but apoE is not necessary for peripheral nerve homeostasis. Peripheral nerve regeneration and the reutilization of cholesterol occurred in mice that were deficient in apoE and apoA-I (47). Another study reported that axonal regeneration occurred in rat-sympathetic neurons when cholesterol was added alone or with lipoproteins (48). Neither apoE nor apoA-I was necessary for axonal growth. Comparisons between brain tissue

and peripheral neural tissue may not be appropriate with respect to physiological function. Activity of apoE and apoA-I in peripheral nerves may differ when compared with brain tissue. Moreover, there may be other proteins that can efficiently replace the function of apoE and apoA-I in peripheral nerve reutilization.

ApoJ (clusterin) is a sulfated glycoprotein that is found in several different tissues including brain (49). The function of this protein is not well understood but there is evidence suggesting that apoJ may be involved in lipid transport and remodeling, sperm maturation, programmed cell death, and complement activation (50). ApoJ may also be involved in the removal of cholesterol from cells (50). Cholesterol, cholesteryl esters, and phospholipids were removed from foam cells incubated with apoJ. There is some evidence to suggest that apoJ may be associated with certain types of brain lesions. Expression of messenger RNA for apoJ was increased in neurons, glia, and choroid plexus following lesioning of the rat hippocampus (51). In the same study apoE expression increased but mRNAs of LDL-R, LDL-R protein, receptor-associated protein, glycoprotein 330/Megalin, and very low density lipoprotein receptor were not affected.

It is reasonable to conclude that brain apolipoproteins are probably involved in transporting cholesterol to neurons *in vivo.* However, what is not clear is the role of such cholesterol compared to cholesterol that is synthesized in the neuron. For example, could cholesterol incorporated into the neuron by apoE be used to form new membranes in addition to the cholesterol that is synthesized in the neuron? It is possible that neuronal injury might actually result in a net increase in cholesterol content resulting from neuronal cholesterol synthesis and apoE transport of cholesterol into the neuron. However, it has been reported that following entorhinal cortex lesions in 3-mon-old Fisher 344 rats there was an accumulation of nerve terminal-derived cholesterol in both astrocytes and neurons and a reduction in 3-hydroxy-3-methylglutaryl CoA reductase (HMG-CoA reductase), the key enzyme in regulating synthesis of cholesterol (37). It was suggested that the cholesterol taken up by the neurons was then used for membrane biogenesis. What is not clear is the fate of the cholesterol contained in the apoE-lipoprotein complex that is incorporated into the neuron by the LDL-R, LDL-R-related protein, or apoER2 receptors. Moreover, how cholesterol that has been internalized by the neuron is transported to the membrane has not been determined. Raft-mediated transport was discussed earlier. An alternative mechanism is that an intracellular cholesterol carrier protein such as SCP-2 may transport the newly arrived cholesterol into the neuronal membrane. Another intracellular protein, the Niemann-Pick protein (NPC1), whose function appears to be to transport cholesterol within the cell, may also interact with cholesterol derived from lipoproteins (52,53). Further discussion of this protein is contained in the section on Neuropathophysiology and Cholesterol.

MEMBRANE CHOLESTEROL DOMAINS

Cholesterol plays an important role with respect to the physical structure of the membrane. Modification of membrane cholesterol content can alter membrane fluidity, lipid packing, and interdigitation (54,55). Another important role of cholesterol is its interaction with membrane proteins. This interaction has been described in both neuronal and nonneuronal tissue (56–58). Plasma membranes are highly rich in cholesterol; in both erythrocyte membranes and synaptic plasma membranes, cholesterol accounts for over 40 mol% of the total membrane lipid (59,60). Cholesterol in the plasma membrane is not evenly distributed throughout the membrane but is located in different pools or domains (7,61).

Cholesterol lateral domains. Lateral domains of cholesterol have been described and these domains have been identified in neuronal tissue (62–64). To our knowledge, a microscopic picture of cholesterol lateral domains in biological membranes has not appeared. Instead, the existence of lateral domains of cholesterol is based largely on the removal of cholesterol from membranes, kinetic studies of cholesterol exchange, and cholesterol oxidase treatment (6). The large amount of work on lateral cholesterol domains in nonneuronal cells and model membranes has been reviewed previously (6).

Two lateral cholesterol pools that were associated with the acetylcholine receptor (62) were shown in the electroplax membranes of *Torpedo californica*. Approximately 40% of the cholesterol could be easily depleted by incubation with small unilamellar vesicles, whereas the remaining membrane cholesterol was resistant to depletion even at longer incubation periods (62). The pool of cholesterol that was easily removed was thought to be a contributor to the bulk fluidity of the membrane, while the pool that was resistant to depletion may have been closely associated with the acetylcholine receptor (62). Forty percent of cholesterol could be removed from electroplax membranes—results that are similar to what we observed in studies of mouse synaptosomal membranes. We found that there was an exchangeable pool of cholesterol that accounted for 50% of the total synaptosomal membrane cholesterol (63,64) when experiments were conducted at 37°C. Not surprisingly, at 25°C, the size of the exchangeable pool was significantly reduced and the rate of cholesterol exchange was much slower. Chronic ethanol consumption also significantly reduced the rate of cholesterol exchange (64). Another treatment that modified the rate of cholesterol exchange in synaptosomes was the hydrolysis of sphingomyelin. It has been proposed that sphingomyelin may be involved in determining the distribution of cholesterol in membranes (65,66). Sphingomyelin in the exofacial leaflet of the synaptosomal membrane was hydrolyzed by sphingomyelinase. The rate of cholesterol exchange was significantly slower than the rate of exchange in control synaptosomes but the size of the cholesterol exchangeable pool was not affected (63,64). The reduction in the rate of cholesterol exchange that we observed in sphingomyelinase-treated

synaptosomes may have been due to movement of cholesterol from the membrane surface to deeper in the synaptosomal membrane. This idea is supported by data showing that depletion of sphingomyelin by sphingomyelinase in cultured fibroblasts resulted in movement of cholesterol from the cell surface to the intracellular environment (65). It may simply require a longer period of time to move cholesterol from deep within the membrane to the membrane surface where exchange takes place.

There is little known regarding the structure and role of cholesterol lateral domains in brain tissue. Modification of cholesterol lateral domains can alter activity of certain integral proteins (67), and such domains may be important with regard to neuronal functions such as ion transport and receptor function. Mechanisms that regulate cholesterol lateral domains and their contribution to neuronal homeostasis have yet to be determined.

Transbilayer cholesterol domains. Two other important cholesterol domains are the outer or exofacial leaflet and the inner or cytofacial leaflet of the plasma membrane. The two leaflets that make up the bilayer differ in their fluidity, lipid distribution, electrical charge, and active sites of certain proteins (6,68,69). We have shown that the SPM cytofacial leaflet contains over 85% of the total SPM cholesterol (28,30,70). This large difference in the transbilayer distribution of cholesterol is associated with differences in the fluidity of the two leaflets. The cytofacial leaflet that contains almost seven times as much cholesterol as the exofacial leaflet is markedly less fluid compared to the exofacial leaflet (30,70,71). The two leaflets differ in their susceptibility to perturbation. Whereas 25 mM ethanol significantly fluidizes the exofacial leaflet, ethanol at a concentration as high as 400 mM had no effect on the fluidity of the cytofacial leaflet (29,71). Increasing temperature also had a greater effect on fluidity of the exofacial leaflet compared with the cytofacial leaflet (71). It is well known that membrane fluidity is inversely correlated with the cholesterol-to-phospholipid ratio and that increasing the ratio reduces fluidity. We attribute the differences in effects of ethanol and temperature on the two leaflets to the differences in the transbilayer distribution of cholesterol.

SPM transbilayer cholesterol distribution is not fixed or immobile but can be modified *in vivo*. Chronic ethanol consumption altered the transbilayer distribution of cholesterol in SPM of C57BL/6J mice (28). There was approximately a twofold increase in exofacial leaflet cholesterol in the chronic ethanol-treated mice compared with the pair-fed control group. Total amounts of SPM cholesterol did not differ between the ethanol-treated and control groups. We also observed that the exofacial leaflet of the ethanol group was significantly less fluid and the cytofacial leaflet was significantly more fluid than the corresponding leaflets of the control group (29). Increasing age is another condition in which the transbilayer cholesterol distribution of SPM is significantly modified (30). Twenty-five-month-old C57BL/6NNIA mice had approximately 30% of cholesterol in the SPM exofacial leaflet in contrast to mice 14–15 mon and 3–4 mon of age that had approximately 23 and 14% of cholesterol in the exofacial leaflets, respectively. We did not detect a change in the total amount of SPM cholesterol among the three different age groups. Differences in fluidity of the exofacial and cytofacial leaflets were abolished in SPM of the 24–25-mon-old mice. The exofacial leaflet became less fluid. However, fluidity of the cytofacial leaflet of the aged mice was not altered despite a reduction in the amount of cholesterol. Regulation of fluidity in the cytofacial leaflet of aged mice may involve other factors in addition to cholesterol.

Research has consistently indicated that either increasing or decreasing membrane cholesterol can modify membrane proteins. For example, varying the amount of cholesterol in SPM and synaptosomes has had an effect on sodium-dependent γ-aminobutyric acid (GABA) (72). A reduction of cholesterol in the membranes produced a loss in GABA uptake, and the uptake was restored by the addition of cholesterol. Choline uptake was not affected by changes in cholesterol content in that study. Removing or adding cholesterol to the membrane not only modifies the total amount of cholesterol but such procedures would also alter the transbilayer distribution of cholesterol. The transbilayer distribution of cholesterol may be important with respect to regulating the activity of certain membrane-bound proteins; however, this is a topic that has received little attention. Cholesterol enrichment of the erythrocyte exofacial leaflet increased protein sulfhydryl group exposure and antigen exposure (73). We have shown that oxidation of cholesterol in the exofacial leaflet of synaptosomes significantly reduced Ca^{2+} + Mg^{2+}-ATPase activity (74). Na^{+} + K^{+}-ATPase activity was not affected by modification of exofacial leaflet cholesterol. On the other hand, in murine L-cell fibroblasts transfected with liver fatty acid binding protein (L-FABP), Na^{+} + K^{+}-ATPase activity was significantly reduced in the transfected cells (75). This reduction in enzyme activity was associated with a doubling in the percentage of cholesterol in the exofacial leaflet of the transfected cells relative to the control cells. However, there was a marked reduction in the total amount of cholesterol in the L-cell membrane of the transfected cells that may have also contributed to the differences in enzyme activity between the transfected and control cell lines. Changing the distribution of cholesterol between the two leaflets of the membrane could alter the interdigitation or thickness of the two leaflets, which in turn could affect protein activity. Addition of cholesterol to model membranes reduced interdigitation (76). Ca^{2+} + Mg^{2+}-ATPase has been shown to require an optimal thickness or interdigitation and that modification of interdigitation by phosphatidylcholines of different carbon lengths modified enzyme activity (77).

Mechanisms that regulate the transbilayer distribution of cholesterol are poorly understood. There is evidence (78–80) that membrane phospholipid asymmetry is protein-regulated but there has been little progress in understanding the regulation of membrane cholesterol asymmetry. As mentioned in the preceding paragraph, L-cells transfected with the cDNA for L-FABP differed in their transbilayer distribution of cholesterol when compared with control cells. We have not been

able to detect L-FABP in mouse brain although there have been some reports suggesting that L-FABP may be present in rat brain (81). SCP-2 expression was increased in synaptosomes of chronic ethanol-treated mice (13). B-FABP and H-FABP levels were significantly lower in synaptosomes of 25-mon-old mice compared with 4-mon-old mice (18). Changes in the expression of SCP-2, B-FABP, and H-FABP in brain are associated with modification of the transbilayer distribution of cholesterol and fluidity in SPM of chronic ethanol-treated mice and aged mice. These proteins may act on cholesterol that enters the neuron by lipoproteins or contribute to cholesterol transport from the cell body.

SCP-2, B-FABP, and H-FABP are intracellular proteins. Regulation of the transbilayer distribution of cholesterol could involve factors associated with the cell surface such as apolipoproteins, their receptors, and sphingomyelin. We have recently reported that apoE and the LDL-R may play a role in regulating the distribution of cholesterol in the exofacial and cytofacial membrane leaflets (70). The SPM exofacial leaflets of apoE-deficient and LDL-R-deficient mice had two times more cholesterol than the exofacial leaflets of the control mice. These differences in cholesterol distribution were not accounted for by differences in the total amount of SPM cholesterol. ApoE may either add cholesterol by coupling with the LDL-R or other receptors or apoE may remove cholesterol from the membrane which in turn could alter the transbilayer distribution of cholesterol. Worth noting is the fact that although there was a doubling of cholesterol in the exofacial leaflets of the “knockout” mice, cholesterol remained asymmetrically distributed between the two leaflets of the bilayer. While apoE and the LDL-R may be involved in regulating the transbilayer distribution of cholesterol there must be other factors, e.g., apoJ, SCP-2, apoD, NPC1, or sphingomyelin that contribute to maintaining membrane cholesterol asymmetry. Some investigators have proposed that sphingomyelin contributes cholesterol to the distribution of membranes (65,82). Hydrolysis of sphingomyelin in Leydig tumor cells and fibroblasts has resulted in the movement of cholesterol from the cell surface to the cell interior where cholesterol was esterified. Sphingomyelin may be involved in regulating cellular cholesterol distribution, but this regulation may involve exofacial leaflet cholesterol but not cytofacial leaflet cholesterol. Sphingomyelin is primarily if not exclusively located in the exofacial leaflet of erythrocytes and SPM (63,64,83). Sphingomyelin accounts for approximately 2 to 4% of the total SPM phospholipid (29,63,64) but is not present in the SPM cytofacial leaflet (63). In erythrocytes, sphingomyelin content is approximately 25% of total phospholipid (84) content, and the amount in the exofacial leaflet was reported to be between 82 and 100%, depending on the species (83). The percentage of cholesterol in the SPM exofacial leaflet is approximately 13–15% of total SPM cholesterol. Cholesterol content in the erythrocyte exofacial leaflet is approximately 25% of the total membrane cholesterol (59). Thus increasing sphingomyelin content in the exofacial leaflet is positively associated with increasing cholesterol content in that leaflet. The interaction of sphingomyelin and cholesterol might involve binding, complex formation, or changes in membrane structure such as fluidity and lipid packing.

NEUROPATHOPHYSIOLOGY AND CHOLESTEROL

Cholesterol plays a major role in coronary heart disease. The incidence of coronary heart disease is inversely correlated with the distribution of cholesterol in the HDL fraction. In brain, an association between altered cholesterol dynamics and pathophysiology is not as well understood. A notable exception is Niemann-Pick C disease (NP-C), an inherited lipid disorder that is manifest in marked problems in cholesterol homeostasis with the central nervous system a prime target of the disease (52,53). Unesterified cholesterol accumulates in the cells leading to cell dysfunction and cell death. Cells of Niemann-Pick patients are impaired in the capacity to regulate cholesterol, including insertion and deletion of cholesterol from the plasma membrane. Recently it has been shown that mutations in a gene identified as NPC1 are the cause of NP-C (85,86). This gene encodes a protein that would appear to be important in cellular cholesterol transport. Another protein that may be involved in NP-C is apoD. Levels of apoD were significantly increased in brain of NP-C mice, an animal model of NP-C (33). ApoD was also secreted from astrocytes, and the level of apoD was lower in NP-C mice than in the control mice (33). Secretion of apoD may be important in the removal of cholesterol from cells.

NP-C is a disease in which cholesterol homeostasis is clearly disrupted. Alzheimer’s disease (AD) may be a disease in which cholesterol homeostasis is altered. The strongest evidence for such an association is the epidemiological data indicating a relationship between the apoE4 allele and the occurrence of AD. This topic has been examined in several recent reviews (45,87–89). Briefly, the apoE4 allele is a risk factor in late-onset familial and sporadic AD. Individuals with the apoE2 and apoE3 alleles may be at lower risk for AD. There is also evidence to indicate that apoE4 may be more neurotoxic compared with apoE2 and apoE3 (44).

Cholesterol content was slightly but significantly increased in frontal cortex gray matter of AD patients with the apoE4 genotype when contrasted with control subjects who also had the apoE4 genotype (89). The means ± SEM of cholesterol levels were expressed as mg/g wet tissue weight and were 2.04 ± 0.18 and 2.65 ± 0.14 for the control and AD subjects, respectively. However, another study has concluded that brain cholesterol content may actually be lower in AD patients than the cholesterol content in nondemented subjects (90). The cholesterol to phospholipid ratio was decreased by 30% in the temporal gyrus of autopsied brains from AD patients compared to control brains (90). There were no differences in the cholesterol to phospholipid ratio in cerebellum of the two groups. This reduction in the cholesterol to phospholipid ratio was attributed to a reduction of cholesterol content because the phospholipid to protein ratio was similar in brains from Alzheimer’s patients and control subjects. The amounts of

cholesterol were not reported in that study. Much more work is needed to establish if brain cholesterol amounts are affected by AD. Future studies should examine subcellular brain fractions, e.g., synaptic plasma membranes, that would provide important and necessary information about specific lipid changes. In addition, it is possible that there are regions of the brain that are more susceptible to changes in cholesterol homeostasis potentially induced by AD; the data discussed above are consistent with such an interpretation. Differences in the amounts of cholesterol in brain regions could result from cholesterol synthesis, degradation, or transport.

The amount and distribution of membrane cholesterol are important factors that modulate membrane fluidity and in turn affect activity of various proteins (69,91). Reducing the amount of cholesterol in the membrane increases fluidity of the membrane. There have not been any published studies on fluidity of brain membranes of AD patients. However, platelet membranes of AD patients were more fluid than control membranes; differences in fluidity may have resulted from a reduction in membrane cholesterol of AD patients (92,93). One might infer from that study that neuronal membranes of AD patients may be more fluid than membranes of age-matched control individuals and such changes in fluidity could affect protein activity.

Neuritic plaques and neurofibrillary tangles in brain are characteristic neuropathological features of AD (94). The main component of neuritic plaques are aggregates of the amyloid-beta peptide (Aβ). The Aβ peptide is 39–43 amino acids long and is derived from the transmembrane region of the amyloid precursor protein (95,96). There have been an extensive number of studies on the effects of Aβ on membranes, cell function, and behavior (45,97–99). Moreover, recent work has shown that there is an association between Aβ and cholesterol. Using fluorescent-labeled lipids, we have shown that aggregated Aβ binds lipids with an affinity for cholesterol > saturated fatty acids > phosphatidylcholine (100). Aβ was preincubated for different time periods (0, 1, 3, 6, 21, 24 h) and the fluorescent-labeled lipids were then added and fluorescence intensity measured. Binding of lipids was dependent on aggregation of the peptide, particularly with respect to formation of peptide polymers. Lipid binding was not observed in Aβ that had been preincubated for ≤3 h and is similar to an earlier study that reported that cholesterol and phosphatidylcholine did not bind to Aβ that had been incubated for 3 h (101). Cholesterol esterification was inhibited by different amyloid species ($A\beta_{25-35}$, $A\beta_{1-42}$, $A\beta_{1-40}$) in B12 cells and rat neuronal cortex cultures (102). In the same study, Aβ stimulated the removal of cholesterol from rat hippocampal neurons in the presence of 2-hydroxypropyl-β-cyclodextran.

Modification of cholesterol content alters APP and Aβ metabolism. Increasing the cholesterol content in APP 751 stably transfected HEK 293 cells reduced levels of soluble amyloid precursor protein (103). A conclusion of that study was that increased cholesterol levels may be a risk factor for AD, that cholesterol interferes with proteases that act on amyloid precursor proteins (APP), and that such an effect may contribute to neuronal pathology in AD. Whether there is a change in the total amount of brain cholesterol in AD patients has not been demonstrated unequivocally. Administration of cholesterol to mice expressing APP holoprotein and human Aβ-peptide produced a reduction in amounts of brain APP metabolites including $A\beta_{1-40}$ and $A\beta_{1-42}$ (104). In that study it was concluded that changes in cholesterol levels can affect APP metabolism. However, the changes in the total amounts of cholesterol were relatively modest when compared with mice on the control diets. There were no significant differences in the total amount of brain cholesterol between the two groups. In the same study it was found that the frontal cortex of the cholesterol group contained 16 mg of cholesterol, the frontal cortex of the control group contained 13.3 mg of cholesterol, and that this difference was statistically significant. Furthermore, there was more than a twofold increase in frontal cortex apoE in mice on the cholesterol diet compared with the control mice (104). Levels of apoE and not cholesterol per se may be the determining factor in Aβ metabolism. Whereas, increasing cholesterol reduced amounts of brain APP metabolites including $A\beta_{1-40}$ and $A\beta_{1-42}$, it was reported that depletion of cholesterol inhibited the production of Aβ formation in hippocampal neurons (105). Cholesterol was reduced using lovastatin and methyl-β-cyclodextrin. It is apparent that there is disagreement as to the effects of modification of cholesterol amounts on Aβ metabolism. Differences in the procedures to modify cholesterol and the biological systems employed are obvious, and potential explanations for the different effects of cholesterol on Aβ metabolism. However, an alternative explanation is that cholesterol homeostasis differs in different brain regions and/or that Aβ metabolism is brain region-dependent. What is clear is that modification of bulk cholesterol, regardless of the method employed, alters Aβ metabolism.

There is an association between cholesterol and AD, but the role of cholesterol in AD is not understood. Certainly the apoE4 allele data imply that cholesterol transport and possibly other lipids may be modified in brain of some AD patients. Metabolism of brain cholesterol may be altered in AD patients but much more data are needed to establish such a conclusion. APP and Aβ metabolism are affected by cholesterol content; however, the direction of the effect is in dispute.

Cholesterol is absolutely necessary for optimal brain function. Either too much cholesterol or too little can disrupt neuronal structure and function. An understanding of brain cholesterol dynamics is at an early stage of development. For example, it is not known how cholesterol is transported from the cell body of the neuron to the axon and what mechanisms are involved in inserting cholesterol into the plasma membrane. Cholesterol synthesis and degradation are not well understood in brain. There are some data showing that synthesis of brain cholesterol is low compared to other organs and that synthesis is high during development and then synthesis is quite low or stable (9). The half life of cholesterol in a rat brain slice preparation was calculated to be approximately 6 mon (106). Earlier work had indicated a faster turnover of cholesterol in rat (107). It is not known if cholesterol synthesis is the same

for different brain areas. Areas of the brain differ in their lipid composition, including cholesterol; however, an explanation for those differences has not been forthcoming (108). Either differences in the rate of cholesterol synthesis or differences in cholesterol transport mechanisms could explain brain regional differences in cholesterol distribution. Brain cholesterol degradation is another process in which there is little data. Outside of brain, most of the cholesterol is degraded by the liver. Degradation of brain cholesterol may involve transport from brain to the liver or there may be specialized cells in brain that catabolize cholesterol. A conclusion in an earlier review of brain cholesterol was that the sterol was not degraded in brain (109). Recently, a metabolite of cholesterol, 24S-hydroxycholesterol (24-OH-Chol), was identified as being primarily derived from brain cholesterol in both human subjects and Sprague-Dawley rats (110). Much more work is needed on brain cholesterol metabolism.

The function of brain apolipoproteins is only beginning to be understood. Much attention has focused on apoE. It is not clear if transport of cholesterol by apoE to neurons occurs only in response to injury or if such transport is required for normal neuronal cholesterol homeostasis. Involvement of other apolipoproteins in brain has not been characterized well. Another important topic that has not been examined is the role of brain lipoproteins in cellular cholesterol efflux. HDL have been shown to remove cholesterol from peripheral cells (111) and this mechanism of "reverse cholesterol transport" may be another factor involved in the regulation of cholesterol homeostasis in brain. Lipoproteins from human cerebrospinal fluid reduced cholesterol levels in fibroblasts loaded with cholesterol (112). It has been reported, however, that lipoproteins of the cerebrospinal fluid and those secreted by rat astrocytes differ in shape and lipid composition (113). Whether lipoproteins of the cerebrospinal fluid and those present in brain cells are similar in shape and composition from the same species has not been determined. Differences in lipoproteins could alter lipid transport. Optimal membrane structure and integral protein function require that cholesterol as well as other lipids be asymmetrically distributed between the two leaflets. Mechanisms that are involved in regulating the transbilayer distribution of brain membrane lipids including cholesterol are poorly understood.

The association between brain cholesterol and Alzheimer's disease is intriguing. While epidemiological data indicate that apoE4 allele may be a risk factor for AD, the molecular role of cholesterol in AD is yet to be determined. There is an interaction among APP, Aβ, and cholesterol. It has not been convincingly demonstrated whether too much or too little cholesterol drives this interaction. Areas of brain that differ in their cholesterol content may be more or less susceptible to the neurotoxic effects of Aβ.

ARTICLE

Evidence That the *trans*-10,*cis*-12 Isomer of Conjugated Linoleic Acid Induces Body Composition Changes in Mice

Yeonhwa Park, Jayne M. Storkson, Karen J. Albright, Wei Liu, and Michael W. Pariza*

Food Research Institute, Department of Food Microbiology and Toxicology, University of Wisconsin-Madison, Madison, Wisconsin 53706

ABSTRACT: We investigated the effects of conjugated linoleic acid (CLA) preparations, which were enriched for the *cis*-9,*trans*-11 CLA isomer or the *trans*-10,*cis*-12 CLA isomer, on body composition in mice. Body composition changes (reduced body fat, enhanced body water, enhanced body protein, and enhanced body ash) were associated with feeding the *trans*-10,*cis*-12 CLA isomer. In cultured 3T3-L1 adipocytes, the *trans*-10,*cis*-12 isomer reduced lipoprotein lipase activity, intracellular triacylglycerol and glycerol, and enhanced glycerol release into the medium. By contrast, the *cis*-9,*trans*-11 and *trans*-9,*trans*-11 CLA isomers did not affect these biochemical activities. We conclude that CLA-associated body composition change results from feeding the *trans*-10,*cis*-12 isomer.

Paper no. L8045 in *Lipids 34,* 235–241 (March 1999).

CLA is the acronym for a class of positional and geometric conjugated dienoic isomers of linoleic acid. The term originated in 1987 when we reported biological activity (i.e., anticarcinogenic activity) associated with CLA isolated from grilled ground beef or produced from linoleic acid by base-catalyzed isomerization (1). Since then substantial interest has developed in the biochemical actions of CLA and its potential application to foods, feeds, and pharmaceuticals (2; for a current listing of the scientific literature on CLA since 1987, see http://www.wisc.edu/fri/clarefs.htm).

Dietary CLA has been shown to affect body composition (reduction in body fat, enhancement of fat-free mass) in mice (3,4), rats (5,6), and pigs (7–10). Previously we (3) reported that CLA exerts direct effects on adipocytes, which are the principal sites of fat storage, and skeletal muscle cells, which are the principal sites of fat combustion. We found that adding CLA to the culture medium of mouse 3T3-L1 adipocytes produced a dose-dependent reduction in lipoprotein lipase (LPL) activity and apparently induced lipolysis as well in this cell line. Additionally, skeletal muscle from mice fed CLA exhibited elevated carnitine palmitoyltransferase (CPT) activity. Evidence was also presented indicating that CLA enhanced whole body protein accretion. Based on these findings we proposed that the physiological mechanism of body fat reduction in mice by CLA involved inhibition of fat storage in adipocytes coupled with both elevated β-oxidation in skeletal muscle and an increase in skeletal muscle mass (3).

A central question concerns the biochemical mechanism(s) whereby CLA induces these physiological effects on adipocytes and skeletal muscle. This complex matter logically begins with the issue of CLA metabolism. The CLA preparations used to date in this research consisted principally of two isomers present in similar amounts: *cis*-9,*trans*-11 CLA, and *trans*-10,*cis*-12 CLA (1,3,11–13). Hence it is possible that either, or both, of these isomers could be involved in inducing body composition change. Previously (14) we provided evidence indicating that the *trans*-10,*cis*-12 CLA isomer decreased the expression of hepatic stearoyl-CoA desaturase mRNA in mice.

We now report on the effects, on body composition in mice, of feeding CLA preparations that contained both *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA in approximately equal amounts, and preparations that were enriched for one or the other of these isomers. Body composition change was associated with the *trans*-10,*cis*-12 CLA isomer content of the preparations. A commercial preparation that was highly enriched for the *trans*-10,*cis*-12 isomer was also active in reducing LPL activity in cultured 3T3-L1 adipocytes and enhancing triacylglycerol release from these cells. By contrast, commercial preparations highly enriched for either the *cis*-9,*trans*-11 or *trans*-9,*trans*-11 CLA isomers did not affect these biochemical activities.

MATERIALS AND METHODS

Materials. Linoleic acid was purchased from Nu-Chek-Prep Corporation (Elysian, MN); triolein, [9,10-^{3}H(N)], (specific activity 12 Ci/mmol) from American Radiolabeled Chemicals (St. Louis, MO); and [1-^{14}C]linoleic acid (specific activity 55 mCi/mmol) from Amersham Life Science (Arlington

Heights, IL). The isomer contents of the CLA preparations used in this study are presented in Table 1. UW-CLA was prepared as described (12). UW-CLA-1 and UW-CLA-2 were prepared by low-temperature crystallization of UW-CLA as described below. Natural Lipids (Hovdebygda, Norway) kindly provided CLA-SF (prepared by base isomerization of safflower seed oil), CLA-DC (prepared from dehydrated castor oil), and *trans*-10,*cis*-12 CLA. The *cis*-9,*trans*-11 CLA and *trans*-9,*trans*-11 CLA preparations were purchased from Matreya Inc. (Pleasant Gap, PA). 3T3-L1 preadipocytes were purchased from American Type Culture Collection (Rockville, MD).

Low temperature crystallization. Low-temperature crystallization of UW-CLA was performed as described (15) with slight modification. Methyl esters of UW-CLA were prepared with 4% HCl in methanol (12). The CLA methyl esters were dissolved in acetone, and the solution was cooled to a range of −60 to −70°C. The solvent was removed by evaporation from the supernatant fluid. The supernatant fluid was redissolved in methanol and subjected again to recrystallization; the resulting supernatant fluid, which was enriched for *cis*-9,*trans*-11 CLA, was designated UW-CLA-1. The crystalline fraction from the first crystallization was redissolved in acetone and recrystallized at the same temperature; this preparation, which was enriched for the *trans*-10,*cis*-12 CLA isomer, was designated UW-CLA-2. UW-CLA-1 and UW-CLA-2 were hydrolyzed with 1 M KOH in methanol and extracted with hexane after acidification. Fractions were analyzed with gas chromatography (GC); the extent of methylation or hydrolysis was determined with thin-layer chromatography. GC was conducted with a Hewlett-Packard 5890 series II (Wilmington, DE) fitted with a flame-ionization detector and 3396A integrator. A Supelcowax-10 fused-silica capillary column (60 m × 0.32 mm i.d., 0.25 µm film thickness) (Bellefonte, PA) was used, and oven temperature was programmed from 50 to 200°C with an increase of 20°C per min, held for 50 min, increased 10°C per min to 225°C, and held for 20 min.

TABLE 1
Isomer Distribution of the Conjugated Linoleic Acid (CLA) Preparations Used in this Study[a]

	Fatty acid (%)			
	c-9,*t*-11[b]	*t*-10,*c*-12	*t*-9,*t*-11/*t*-10,*t*-12	Other CLA isomers[c]
UW-CLA[d]				
(used in Exp. 1)	41.1	43.5	10.0	3.04
(used in culture)	45.7	47.6	1.71	2.79

[c]Mostly *cis*-9,*cis*-11 or *cis*-10,*cis*-12 isomers.
[d]CLA, prepared as described in Ref. 12; for preparation of UW-CLA-1 and UW-CLA-2 see the Materials and Methods section.
[e]Purchased from Matreya, Inc. (Pleasant Gap, PA).
[f]Materials and analysis provided by Natural Lipids (Hovdebygda, Norway). CLA-SF and CLA- DC were made from safflower seed oil and dehydrated castor oil, respectively.
[g]N.D., not detected.
[h]*trans*-9,*trans*-11 isomer only.
[i]Additionally includes 8,10 and 11,13 isomers.

Animal studies and body composition analyses. Weanling ICR mice (females for experiment 1, males for experiment 2) and semipurified diet (TD94060, 99% basal mix) were purchased from Harlan Sprague-Dawley (Madison, WI). The diet was composed as follows (ingredient, g/kg): sucrose, 476; casein, "vitamin-free" test, 210; corn starch, 150; DL-methionine, 3; corn oil, 60; cellulose, 50; mineral mix, AIN-76, 35; vitamin mix, AIN-76A, 10; calcium carbonate, 4; choline bitartrate, 2; and ethoxyquin, 0.1. For the treatment diets, 5 g UW-CLA, 3 g UW-CLA-1, or 2.5 g UW-CLA-2 (for Experiment 1), 5 g CLA-SF, 5 g or 9 g CLA-DC (for Experiment 2) were added at the expense of corn oil to maintain 6% fat. Diet was stored at −20°C until use. Mice were housed individually in a windowless room with a 12-h light-dark cycle in strict accordance to guidelines established by the Research Animal Resources Center of University of Wisconsin-Madison. Diet and water, available *ad libitum*, were freshly provided three times per week. After a 5-d adaptation period mice were randomly separated into groups and fed control diet, or diet supplemented with 0.5% UW-CLA, 0.3% UW-CLA-1, or 0.25% UW-CLA-2 (Experiment 1); or 0.5% CLA-SF, 0.5% CLA-DC, or 0.9% CLA-DC (Experiment 2).

For body composition analyses, animals were sacrificed, gut contents were removed (to obtain empty carcass weight), and the carcasses frozen at −20°C. Frozen carcasses were chopped and then freeze-dried to determine water content. Each dried carcass was ground to give a homogeneous sample before further analysis. Total nitrogen was analyzed by the Kjeldahl method (16). Carcass fat content was measured by extraction with diethyl ether overnight using a Soxhlet apparatus. Total ash content was determined by incineration (500–600°C, overnight).

Adipocyte cell culture. 3T3-L1 preadipocytes were cultured as described (17). Briefly, 3T3-L1 preadipocytes were grown to confluence at 37°C in Dulbecco's Modified Eagle's Medium (DMEM) with 10% fetal bovine serum (FBS). At 2-d postconfluence (designated "day 0") cell differentiation was induced with a mixture of methylisobutylxanthine (0.5 mM), dexamethasone (0.25 µM), and insulin (1 µg/mL) in DMEM containing 10% FBS. On day 2 this medium was replaced with DMEM medium containing 10% FBS and insulin only. On day 4 and thereafter the medium consisted of DMEM plus 10 %FBS only; this medium was subsequently replaced with fresh medium at 2-d intervals. Fatty acid–albumin complexes were prepared as described (3). All culture media including control had a final concentration of 100 µM albumin.

Free and esterified glycerol were determined using a Sigma Diagnostic Kit (Sigma Chemical Co., St. Louis, MO).

Heparin-releasable LPL activity (EC 3.1.1.34, 10 U heparin/mL media for 1 h at 37°C) was measured as described (18). Recovery of free fatty acid was estimated at 71% by using [^{14}C]linoleic acid. Protein was determined using Bio-Rad DC Protein assay kit (Hercules, CA).

Statistical analyses. Data were subjected to analysis using the Statistics Analysis System (SAS Users Guide: Statistics, SAS Institute Inc., Cary, NC). Data in Tables 2–4, and Figures 1 and 2 were analyzed with one-way analysis of variance (ANOVA). Two-way ANOVA (treatments and experiments) were performed on data as log values for Figures 3 and 4. If the interaction between treatment and experiment was significant, this interaction was then used as the error term in the Least Square Means analysis. For Figure 4, standard errors were computed using a nested model including variability between experiments and variability among dishes with an experiment as described (19).

RESULTS

Table 1 shows the relative isomer content of the CLA preparations employed in this study. UW-CLA was characterized primarily by two peaks with retention times corresponding to the *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA isomers. UW-CLA-1 was enriched for the *cis*-9,*trans*-11 isomer, whereas UW-CLA-2 was enriched for the *trans*-10,*cis*-12 CLA isomer. Preparations designated *cis*-9,*trans*-11 CLA, *trans*-10,*cis*-12 CLA, and *trans*-9,*trans*-11 CLA, respectively, contained more than 90% of the indicated isomer. CLA-SF was similar to UW-CLA. CLA-DC contained a number of CLA isomers including the *cis*-9,*trans*-11 isomer, but very little of the *trans*-10,*cis*-12 isomer.

In Experiment 1, mice were fed control diet, or diet containing 0.5% UW-CLA, 0.3% UW-CLA-1, or 0.25% UW-CLA-2. Body weight gains during the course of this experiment are shown in Figure 1; total feed intake is shown in Table 2. Mice fed diets supplemented with UW-CLA-2 gained significantly less body weight than controls. Mice fed diets supplemented with UW-CLA or UW-CLA-1 appeared to gain less weight than controls, but the differences were not statistically significant (however, the mean empty carcass weight of mice fed diet supplemented with UW-CLA was significantly different from controls, see Table 3). Feed intake was significantly reduced for mice fed UW-CLA and UW-CLA-2, but there was no difference in feed intake between controls and mice fed diet supplemented with UW-CLA-1.

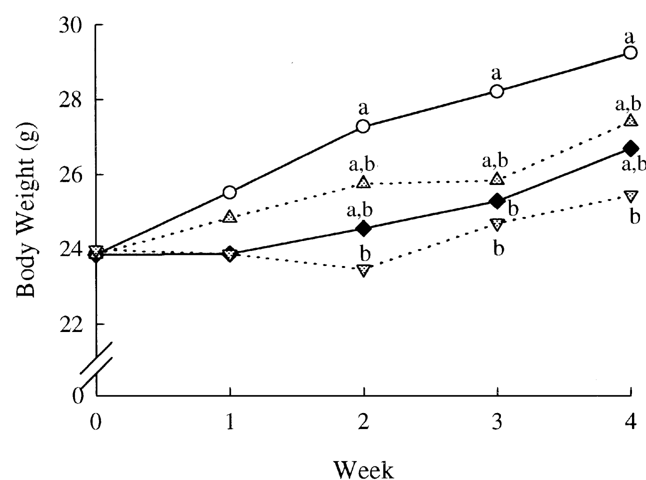

FIG. 1. Body weights, Experiment 1. Animals were fed one of the following diets for 4 wk: control (circle); UW-CLA, 0.5% (diamond); UW-CLA-1, 0.3% (triangle); UW-CLA-2, 0.25% (inverted triangle). Reported values are means ± SE for 5 or 6 animals. At each time point, means with different roman letters are significantly different at $P < 0.05$. UW-CLA, diet devised at University of Wisconsin containing conjugated linoleic acid (Ref. 12). For preparation of UW-CLA-1 and UW-CLA-2, see the Materials and Methods section.

TABLE 2
Food Intake[a]

	Food Iintake (g/mouse/4 wk)
Experiment 1	
Control	129.2[a] ± 2.5
UW-CLA	110.6[b] ± 4.5
UW-CLA-1	131.7[a] ± 1.5
UW-CLA-2	113.9[b] ± 6.8
Experiment 2	
Control	129.5[a] ± 2.0
CLA-SF	112.9[c] ± 1.7
CLA-DC 0.5%	117.9[b,c] ± 5.2
CLA-DC 0.9%	122.8[a,b] ± 1.8

[a]Female (Experiment 1) or male (Experiment 2) mice were fed treatment diet for 4 wk. Reported values are mean ± SE (n = 5 or 6 for Experiment 1, and 7 or 8 for Experiment 2). For each experiment, means with different superscript roman letters are significantly different ($P < 0.05$).

Body composition results from Experiment 1 are shown in Table 3. The percentage of body fat of the mice fed diet supplemented with UW-CLA was reduced by 70% relative to controls, whereas the percentages of whole body water, protein, and ash were significantly increased. This is consistent with our previous observations (3). A similar reduction in percentage of whole body fat, accompanied by increased percentages of whole body water, protein, and ash, was observed for mice fed diet containing UW-CLA-2. By contrast, mice fed diet containing UW-CLA-1 exhibited a smaller reduction in percentage of body fat, and smaller increases in percentages of whole body water, protein, and ash relative to controls.

In Experiment 2, mice were fed control diet or diet containing 0.5% CLA-SF, 0.5% CLA-DC, or 0.9% CLA-DC. Feeding CLA-DC at 0.9% of the diet provided an amount of the *cis*-9,*trans*-11 isomer that was equivalent to that in diet supplemented with 0.5% CLA-SF; however, the diet supplemented with 0.5% CLA-SF contained about 10 times more *trans*-10,*cis*-12 CLA than diet supplemented with 0.9% CLA-DC (Table 1).

Body weight changes during the course of this experiment are shown in Figure 2; feed intake data are indicated in Table 2. Animals fed diet containing CLA-SF exhibited reduced body weight gain relative to controls, whereas mice fed diet supplemented with CLA-DC at 0.5% or 0.9% exhibited

TABLE 3
Body Composition, Experiment 1[a]

	ECW (g)[b]	Fat (%)	Water (%)	Protein (%)	Ash (%)
Control	27.43[a] ± 1.21	22.27[a] ± 1.80	54.30[a] ± 1.35	16.26[a] ± 0.49	3.29[a] ± 0.13
UW-CLA	24.28[b] ± 0.76	6.69[c] ± 0.86	65.59[c] ± 0.68	19.04[b] ± 0.24	3.78[b] ± 0.10
UW-CLA-1	25.53[a,b] ± 0.59	13.08[b] ± 1.66	60.99[b] ± 1.14	18.09[b] ± 0.50	3.54[a,b] ± 0.13
UW-CLA-2	23.44[b] ± 0.92	6.80[c] ± 1.26	65.35[c] ± 1.13	19.33[b] ± 0.29	3.83[b] ± 0.08

[a]Female mice were fed treatment diet for 4 wk. Reported values are means ± SE (n = 5 or 6). In each column, means with different superscript roman letters are significantly different ($P < 0.05$).
[b]ECW, empty carcass weight.

TABLE 4
Body Composition, Experiment 2[a]

	ECW (g)[b]	Fat (%)	Water (%)	Protein (%)	Ash (%)
Control	31.4[a] ± 0.4	15.31[a] ± 1.66	58.3[a] ± 1.2	19.57[a] ± 0.41	3.35[a] ± 0.11
CLA-SF	27.6[b] ± 0.6	4.78[c] ± 0.57	66.1[c] ± 0.4	22.59[c] ± 0.17	3.84[b] ± 0.11
CLA-DC 0.5%	30.7[a] ± 1.3	12.27[a,b] ± 1.84	60.5[a,b] ± 1.5	20.58[a,b] ± 0.47	3.32[a] ± 0.08
CLA-DC 0.9%	30.4[a] ± 0.9	10.06[b] ± 0.99	61.9[b] ± 0.7	20.93[b] ± 0.24	3.31[a] ± 0.09

[a]Male mice were fed treatment diet for 4 wk. Reported values are mean ± SE (n = 7 or 8). In each column, means with different superscript roman letters are significantly different ($P < 0.05$).
[b]ECW, empty carcass weight.

similar weight gain to controls. Mice fed CLA-SF ate significantly less feed than controls. Mice fed a diet supplemented with 0.5% CLA-DC also appeared to eat significantly less feed than controls, but this difference was not evident for mice fed diet supplemented with 0.9% CLA-DC.

The data of Table 4 indicate that the mice fed a diet supplemented with CLA-SF exhibited significantly greater changes in body composition relative to controls than mice fed diet supplemented with CLA-DC at either 0.5 or 0.9%.

We previously reported (3) that CLA inhibited heparin-releasable LPL activity in 3T3-L1 adipocytes. Using this model,

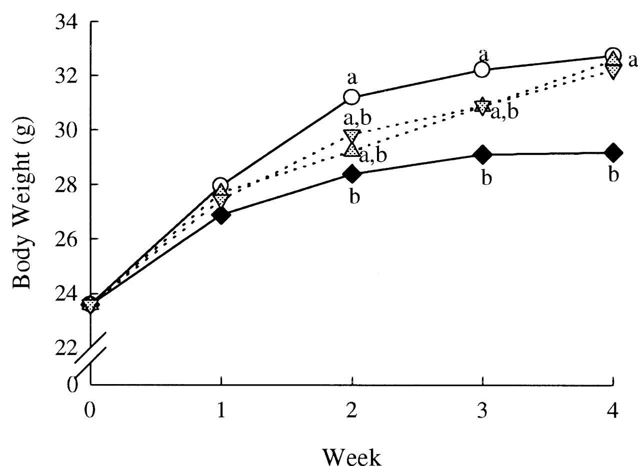

FIG.2. Body weights, Experiment 2. Animals were fed one of the following diets for 4 wk: control (circle); CLA-SF, 0.5% (diamond); CLA-DC, 0.5% (triangle); CLA-DC, 0.9% (inverted triangle). Reported values are means ± SE from 7 or 8 animals. At each time point, means with different roman letters are significantly different at $P < 0.05$. CLA-SF diet (Natural Lipids, Hovdesygda, Norway), prepared by base isomerization of safflower seed oil; CLA-DC (Natural Lipids), prepared from dehydrated castor oil.

we studied the effects of UW-CLA, *cis*-9,*trans*-11 CLA, *trans*-10,*cis*-12 CLA, and *trans*-9,*trans*-11 CLA on LPL activity (Fig. 3). UW-CLA and *trans*-10,*cis*-12 CLA significantly reduced LPL activity, whereas *cis*-9,*trans*-11 CLA and *trans*-9,*trans*-11 CLA were without effect (Fig. 3A). UW-CLA and *trans*-10,*cis*-12 CLA also significantly enhanced glycerol release (Fig. 3B), and significantly reduced intracellular triacylglycerol (Fig. 3C) and glycerol (Fig. 3D). By contrast, *cis*-9,*trans*-11 CLA and *trans*-9,*trans*-11 CLA appeared to produce no effect on intracellular triacylglycerol (Fig. 3C) or glycerol (Fig. 3D). Both *trans*-9,*trans*-11 CLA and *cis*-9,*trans*-11 CLA appeared to induce significant enhancements in glycerol release at the concentrations tested (Fig. 3B).

We determined the dose-response for *trans*-10,*cis*-12 CLA on LPL activity and intracellular triacylglycerol (Fig. 4). Both of these biochemical markers were reduced in a dose-dependent fashion with addition of *trans*-10,*cis*-12 CLA.

Previously (3) we published data on the inhibition of LPL activity in 3T3-L1 adipocytes by CLA. The CLA preparation employed in that study (3) was identical to UW-CLA in this study; accordingly, it was not possible to determine which isomer was responsible for the inhibitory effect. Figure 5 shows these previously published data (3) plotted as total CLA (top axis) or normalized for the *trans*-10,*cis*-12 or *cis*-9,*trans*-11 isomer content of UW-CLA (bottom axes) (the scales of the bottom axes are similar because the concentrations of the *trans*-10,*cis*-12 and *cis*-9,*trans*-11 isomers in UW-CLA are similar—Table 1). Figure 5 also includes the new data from Figure 4, which were obtained with *trans*-10,*cis*-12 CLA, and additional new data which were obtained with *cis*-9,*trans*-11 CLA. It is clear from this plot of data from independent experiments that the inhibition of LPL activity is effected by the *trans*-10,*cis*-12 isomer, not the *cis*-9,*trans*-11 isomer.

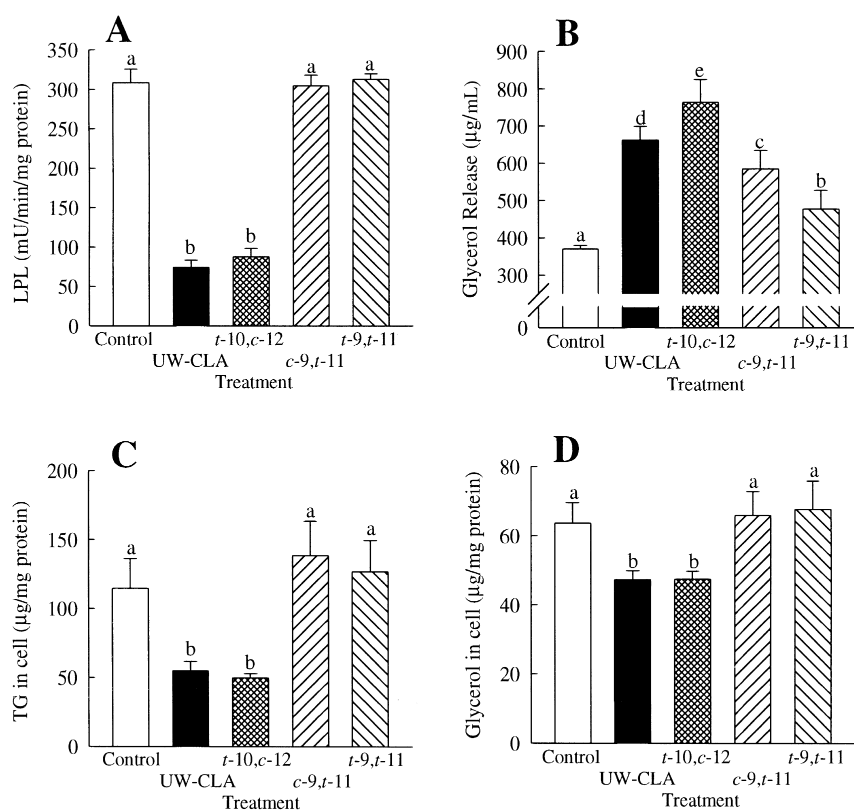

FIG. 3. Effects of CLA on heparin-releasable lipoprotein lipase (LPL) activity (A), glycerol release (B), cellular triacylglycerol (TG) (C), and cellular glycerol (D) in 3T3-L1 adipocytes. Final concentrations are 100 μM for UW-CLA, 43.6 μM for *trans*-10,*cis*-12 isomer (*t*-10,*c*-12), 44.0 μM for *cis*-9,*trans*-11 isomer (*c*-9,*t*-11), and 40.0 μM for *trans*-9,*trans*-11 isomer (*t*-9,*t*-11). Albumin (100 μM) was included in all cases, and incubations were for 48 h. Reported values are mean ± SE (n = 12–16, collected from three independent experiments). Data were analyzed as log value with a two-way analysis of variance using fatty acid (as treatments) and experiment. If the interaction between treatment and experiment was significant, this interaction was used as the error term. Means with different roman letters are significantly different ($P < 0.05$). For other abbreviation see Figure 1.

DISCUSSION

Our present results indicate that the effects of CLA on body composition are associated with the *trans*-10,*cis*-12 CLA isomer. Enrichment of dietary supplements for the *cis*-9,*trans*-11 isomer was not correlated with body composition change. The small amounts of *trans*-10,*cis*-12 CLA in UW-CLA-1 and CLA-DC (Table 1) are most likely responsible for the modest effects of these CLA preparations on body composition (Tables 3,4). In addition, in cultured 3T3-L1 mouse adipocytes, a preparation that was highly enriched for *trans*-10,*cis*-12 CLA significantly reduced LPL activity and enhanced triacylglycerol release. By contrast, preparations highly enriched for either the *cis*-9,*trans*-11 or *trans*-9,*trans*-11 CLA isomers did not affect these biochemical activities (Fig. 3–5). Accordingly, we conclude that CLA-associated body composition change is effected by the *trans*-10,*cis*-12 isomer. It is important now to determine if the 20-carbon metabolites of *trans*-10,*cis*-12 CLA identified by Sebedio *et al.* (20) will induce body composition changes in mice and other species. We have presented preliminary data indicating that conjugated eicosadienoic acid is biologically active in this regard (21).

Our working hypothesis (3) is that the CLA-induced changes in body composition are largely the result of effects of CLA on adipocytes (the major site of fat storage) and skeletal muscle cells (the major site of fat oxidation), although CLA-induced reductions in feed intake (Table 2) may also play an important role. Although the exact relationship between these different factors is unclear, they appear to correlate closely with other CLA-induced effects on lipid metabolism (14,22), indicating that hepatocytes may also be affected by CLA. Indeed, we have already demonstrated that UW-CLA (but not enzymatically synthesized *cis*-9,*trans*-11 CLA) decreased the expression of hepatic stearoyl-CoA desaturase mRNA in mice (14). Accordingly, the conclusion now that body composition changes are effected by the *trans*-10,*cis*-12 CLA isomer indicates a central role for this isomer in mediating many (but not necessarily all) of the biochemical effects attributed to CLA. Given the array of reported

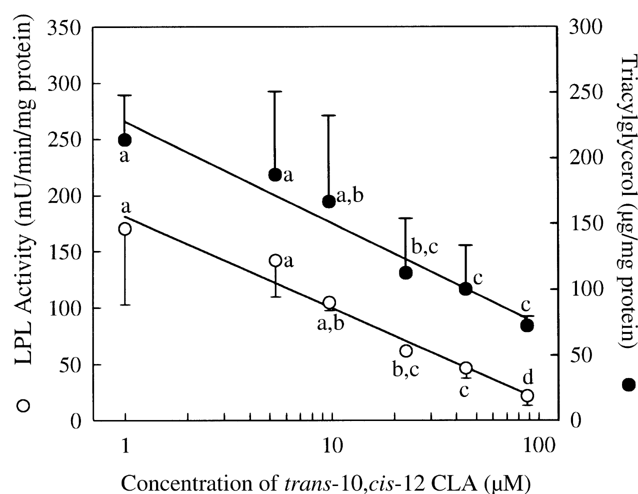

FIG. 4. Dose-response of *trans*-10,*cis*-12 CLA on heparin-releasable LPL (open circle) and amount of cellular TG (closed circle) in 3T3-L1 adipocytes. Albumin (100 μM) was included in all cases, and incubations were for 48 h. Reported values are mean ± SE (n = 4–8, collected from two independent experiments). Data were analyzed as log value with a two-way analysis of variance using fatty acid (as treatments) and experiment. If the interaction between treatment and experiment was significant, this interaction was used as the error term. Means with different roman letters are significantly different ($P < 0.05$). (To avoid zero values of log, the value of 1 was added to all data.) For abbreviations see Figures 1 and 3.

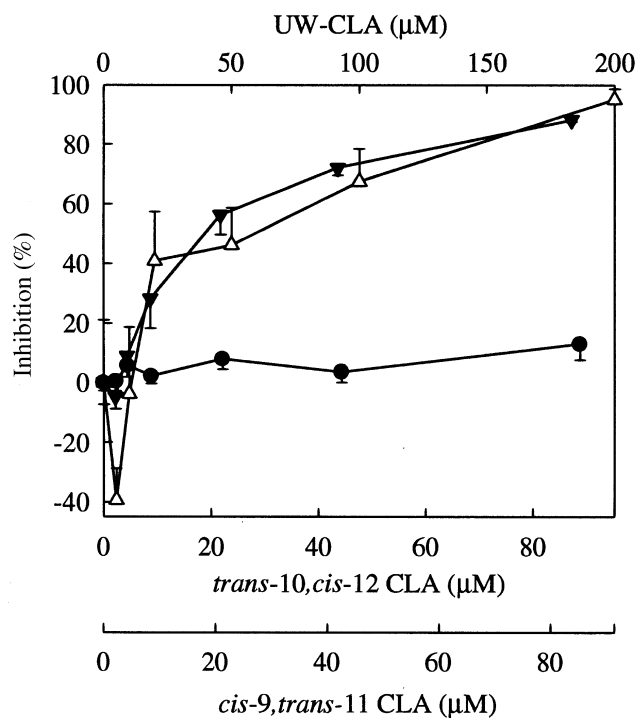

FIG. 5. Effect of UW-CLA, *trans*-10,*cis*-12 CLA, and *cis*-9,*trans*-11 CLA on heparin-releasable LPL activity in 3T3-L1 adipocytes. The top axis indicates the concentration of total CLA and refers to previously published data (3) using UW-CLA (open triangle). The bottom axis indicates the *trans*-10,*cis*-12 isomer concentration, or the *cis*-9,*trans*-11 isomer concentration and refers to data obtained with *trans*-10,*cis*-12 CLA (closed inverted triangle, data from Fig. 4), *cis*-9,*trans*-11 CLA (closed circle), or UW-CLA normalized for *trans*-10,*cis*-12 or *cis*-9,*trans*-11 isomer content. Albumin (100 μM) was included in all cases, and incubations were for 48 h. Reported values are means ± SE of 3–16 culture dishes, normalized against control.

physiological and biochemical effects of CLA, it is likely that the *cis*-9,*trans*-11 CLA isomer (and possibly other CLA isomers as well) will also be found to exert significant biological effects.

ACKNOWLEDGMENTS

We thank Professor E. Nordheim for assistance with statistical analysis. This research was supported in part by gift funds administered through the University of Wisconsin-Madison Food Research Institute. Two of the authors (YP, MWP) are inventors of CLA use patents that are assigned to the Wisconsin Alumni Research Foundation.

ABSTRACT: Two experiments were conducted. In Experiment 1, 8-wk-old mice were fed control diet or diet supplemented with 0.5% conjugated linoleic acid (CLA) to study the effect of CLA on body composition (CLA: 40.8–41.1% *c*-9,*t*-11 isomer, 43.5–44.9% *t*-10,*c*-12 isomer). The data for CLA-fed mice vs. controls described parallel but significantly distinct responses for both absolute and relative changes in body fat mass (reduced in CLA-fed mice) and for relative changes in whole body protein and whole body water (both of which were increased in CLA-fed mice). In the CLA-fed mice, the effect on whole body protein appeared to precede the reduction in body fat mass. In Experiment 2, weanling mice were fed control diet or diet supplemented with 0.5% CLA for 4 wk (test group), at which time all mice were fed control diet devoid of added CLA. The test group exhibited significantly reduced body fat and significantly enhanced whole body water relative to controls at the time of diet change. Time trends for changes in relative body composition were described by parallel lines where the test group exhibited significantly less body fat but significantly more whole body protein, whole body water, and whole body ash than controls. Tissue CLA levels declined following the withdrawal of CLA from the diet. In skeletal muscle of mice fed CLA-supplemented diet, the *t*-10,*c*-12 isomer was cleared significantly faster than the *c*-9,*t*-11 CLA isomer.

Paper no. L8012 in *Lipids 34*, 243–248 (March 1999).

CLA is the acronym for a class of positional and geometric conjugated dienoic isomers of linoleic acid. The term dates from 1987 when we reported biological activity (i.e., anticarcinogenic activity) associated with CLA produced from linoleic acid by base-catalyzed isomerization (1). Since then substantial interest has developed in the biochemical actions of CLA and its potential application to foods, feeds, and pharmaceuticals (2; for a current listing of the scientific literature on CLA since 1987, see our web page [http://www.wisc.edu/fri/clarefs.htm).]

Dietary CLA has been shown to affect body composition (reduction in body fat, enhancement of fat-free mass) in a number of animal species including mice (3,4), rats (5,6), and pigs (7–10). Previously we (3) reported that CLA exerts direct effects on adipocytes, which are the principal sites of fat storage, and skeletal muscle cells, which are the principal sites of fat combustion. We found that adding CLA to the culture medium of mouse 3T3-L1 adipocytes produced a dose-dependent reduction in lipoprotein lipase activity, and apparently induced lipolysis as well in this cell line. Additionally, skeletal muscle from mice fed CLA exhibited elevated carnitine palmitoyltransferase activity. Evidence was also presented indicating that CLA enhanced whole body protein accretion. Based on these findings we proposed that the physiological mechanism of body fat reduction in mice by CLA involved inhibition of fat storage in adipocytes coupled with both elevated β-oxidation in skeletal muscle and an increase in skeletal muscle mass (3).

We now report the results of two experiments designed to confirm and expand upon these previous observations. Experiment 1 was designed to study body composition at various times after initiating CLA feeding. Experiment 2 was conducted to determine the effect on body composition of subsequently withdrawing CLA from the diet.

The findings confirm that mice fed CLA-supplemented diet exhibited enhanced whole body protein and whole body water content, coupled with reduced fat mass. The effect on whole body protein appeared to precede body fat reduction in mice fed diet supplemented with CLA. Changes in body composition were still evident 8 wk after the cessation of CLA feeding, by which time tissue CLA levels had returned to control levels.

EXPERIMENTAL PROCEDURES

Animals and Diets. Female ICR mice were purchased from Harlan Sprague-Dawley (Madison, WI) and housed in a windowless room on a 12-h light/dark cycle, in strict accordance with guidelines established by the Research Animal Resources Center of the University of Wisconsin-Madison. Fresh diet was provided *ad libitum* three times per week; body weights were determined weekly. Diet ingredients [Composition (ingredient, g/kg): sucrose, 500; casein, "vitamin-free" test, 200; corn starch, 150; DL-methionine, 3; corn oil, 55; cellulose, 50; mineral mix, AIN-76, 35; vitamin mix, AIN-76A, 10; choline bitartrate, 2; ethoxyquin, 0.1. The foregoing diet was used in Experiment 1 (11). The diet in Experi-

ment 2 was identical except for sucrose (481 g/kg diet), casein (210 g/kg) and calcium carbonate (4 g/kg). When the diet was supplemented with conjugated linoleic acid (CLA), it contained 5 g CLA plus 50 g corn oil.] or semipurified diet (TD 94060) were purchased from Harlan-Teklad (Madison, WI). Control diets contained 5.5% corn oil whereas CLA-supplemented test diets contained 0.5% CLA plus 5% corn oil. CLA was prepared by alkali isomerization (12,13) of linoleic acid purchased from Nu-Chek-Prep Corporation, Elysian, MN. CLA produced by this method has been extensively characterized (12–14). The preparation used in this investigation was distinguished primarily by two peaks with retention times corresponding to the *c*-9,*t*-11 (40.8–41.1%) and *t*-10,*c*-12 (43.5–44.9%) CLA isomers, with other CLA isomers containing double bonds at the delta 9,11 or 10,12 positions as minor components (*t*-9,*t*-11/*t*-10,*t*-12, 4.6–10.0%).

Determination of body composition. Animals were sacrificed by CO_2 suffocation, and gut contents were removed prior to determining empty whole body weight. The whole bodies were then frozen at −20°C, chopped, ground, and freeze-dried to determine water content. Total protein was calculated by the Kjeldahl method (15). Whole body fat was measured following extraction overnight with diethyl ether using a Soxhlet apparatus. Total body ash was determined by incineration (500–600°C, overnight).

Fatty acid analyses. In Experiment 2, tissues (muscle, liver, and fat pad) were collected from two animals at each time point and subjected to fatty acid analysis as described previously (13). Fatty acid methyl esters were prepared by reaction with 4% HCl in methanol for 20 min at 60°C and identified by comparison with standards (Sigma Chemical Co., St. Louis, MO, and Nu-Chek-Prep Corporation) by gas chromatography (GC). GC analysis was conducted with a Hewlett-Packard 5890 series II gas chromatograph fitted with a flame-ionization detector and 3396A integrator. A Supelcowax-10 fused-silica capillary column (60 m × 0.32 mm i.d., 0.25 μm film thickness) was used, and oven temperature was programmed from 50 to 200°C, increased 20°C per min, held for 50 min, increased 10°C per min to 230°C, and held for 20 min.

Statistics. Data in Figures 1 and 4 were subjected to analysis of variance (ANOVA) using the General Linear Models procedure of the SAS Institute (SAS Users Guide: Statistics, SAS Institute Inc., Cary, NC). For Figures 2, 3, 5, 6, and 7, data were subjected to ANOVA using the mixed procedure which included a two-factor ANOVA with factors of time and diet (for Figs. 2 and 3, data from week 0 were excluded). The resulting ANOVA table contains three portions for treatments, one for diet, one for time, and one for the interaction between diet and time. The sum of squares for time was further divided into two portions, the first representing a linear time trend and the second reflecting time effects beyond the linear. The sum of squares for the treatment and time interaction was similarly divided, with the first piece representing the difference in linear trends for the two diets and the second piece representing the difference in effects beyond the linear between the two diets. In all analyses in which data were obtained on individual mice within a cage, we used PROC MIXED to explore the significance of cage effects. If such effects were not significant for all response variables of interest within an experiment, the cage term was dropped from the analysis of that experiment. If cage effects were significant for at least some response variables within an experiment, the PROC MIXED results were used for all analyses. However, in a small number of cases, we determined that *P*-values for comparisons of particular interest differed when the cage effect was included vs. when it was excluded. If for the variable in question the cage effect was not significant, we report the *P*-value for the situation with the cage effect excluded.

RESULTS

We previously established that mice fed diet supplemented with 0.5% CLA exhibited significantly reduced body fat and significantly increased whole body protein relative to mice fed a control diet (3). To confirm and expand upon these findings we conducted two experiments. The first (Experiment 1) was designed to study body composition at various times after initiating CLA feeding. The second (Experiment 2) was conducted to determine the effect on body composition of subsequently withdrawing CLA from the diet.

Figure 1 shows body weight and feed intake over the course of Experiment 1. In comparison with controls, the mice fed diet supplemented with CLA exhibited slightly reduced body weight gain. The CLA-fed mice also ate significantly less feed than control mice ($P < 0.0001$). These findings are in agreement with our previous report (3).

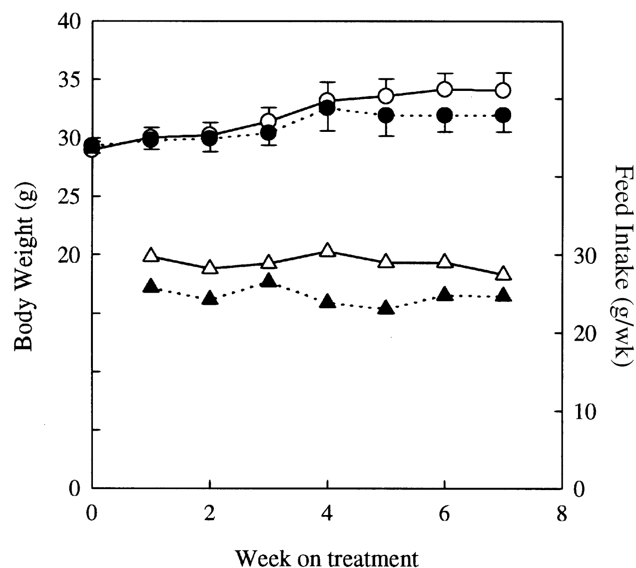

FIG. 1. Body weights and feed intake of mice in Experiment 1. Closed symbols, conjugated linoleic acid (CLA)-fed mice; open symbols, control mice. Circles, mean body weight/mouse ± S.E.; there was no cage effect ($P > 0.20$ for all points). Triangles, mean feed intake/mouse/wk determined from 3–10 cages each holding 1–3 mice; feed intakes for the CLA-fed and control groups were significantly different ($P < 0.0001$).

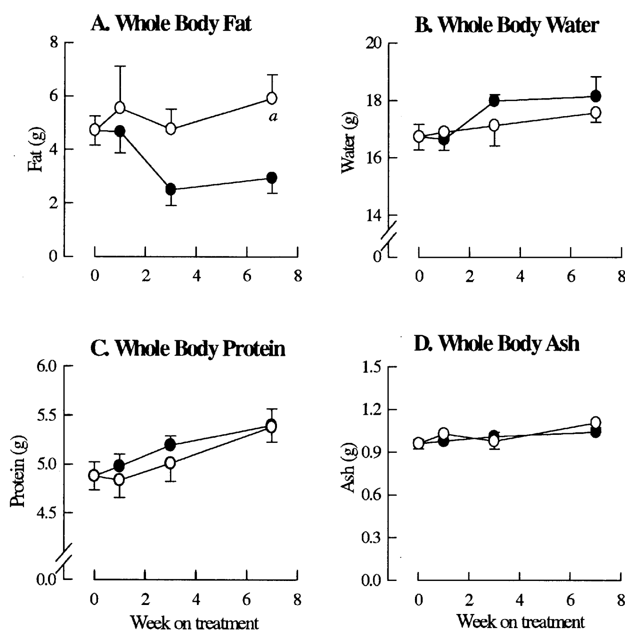

FIG. 2. Absolute changes in whole body fat, whole body water, whole body protein and whole body ash for mice of Experiment 1. Closed circles, CLA-fed; open circles, controls. Each data point represents the mean ± S.E. of 6 animals. $^aP < 0.05$ when compared to control at the same time point when cage effects, which were not significant, were ignored. For abbreviation see Figure 1.

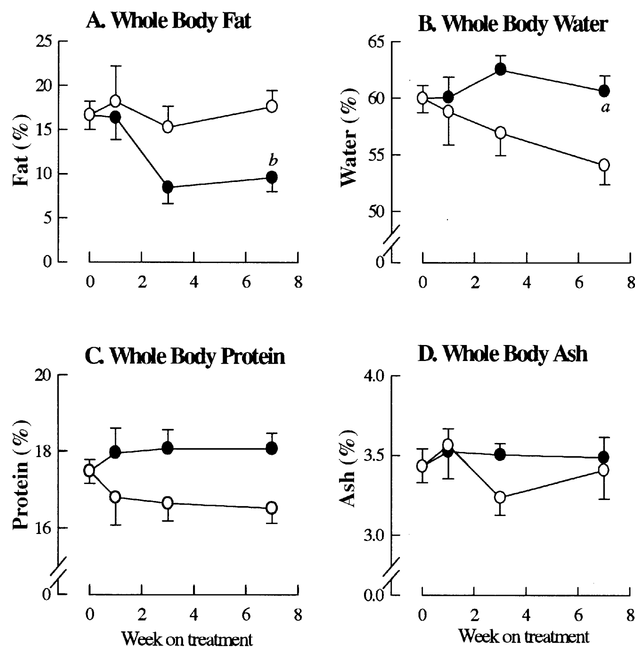

FIG. 3. Relative changes in whole body fat, whole body water, whole body protein, and whole body ash for mice of Experiment 1. Closed circles, CLA-fed; open circles, controls. Each data point represents the mean ± S.E. of 6 animals. $^aP < 0.05$ when compared to control at the same time point. $^bP < 0.05$ when compared to control at the same time point when cage effects, which were not significant, were ignored. See Figure 1 for abbreviation.

Figure 2 shows changes in absolute body composition over the course of Experiment 1. At 3 wk a reduction in whole body fat was evident in the CLA-fed mice relative to controls (Fig. 2A); the difference was significant at week 7. Overall, the whole body fat data for CLA-fed vs. controls (Fig. 2A) were described by parallel but significantly distinct responses ($P = 0.0274$). There were no significant differences in whole body water (Fig. 2B), whole body protein (Fig. 2C), or whole body ash (Fig. 2D), at any time studied. However, the CLA-fed mice appeared to exhibit small though nonsignificant elevations in whole body water (Fig. 2B) and whole body protein (Fig. 2C) at some of the time points.

To explore further the possible biological significance of the data on Figure 2, we calculated the changes in relative body composition of the mice of Experiment 1. The data are shown in Figure 3. Differences in both the percentage whole body fat (Fig. 3A) and whole body water (Fig. 3B) were apparent at week 3 and significant at week 7. At 1, 3, and 7 wk, respectively, differences in relative whole body protein (Fig. 3C) between CLA-fed and control animals approached significance ($P = 0.186$, $P = 0.109$, and $P = 0.085$, respectively). When the data for CLA-supplemented mice at these times (1, 3, and 7 wk, respectively) were summed and compared with the summed control data for the same time period, the difference in percentage whole body protein was highly significant (18.0 ± 0.3% for CLA-fed, and 16.7 ± 0.3% for controls, $P = 0.0045$). No significant differences in whole body ash between controls and mice fed CLA-supplemented diet were observed (Fig. 3D).

An analysis of overall time trends for the data of Figure 3 indicated that the slopes of the data for CLA-fed and control mice were not different. However, for whole body fat (Fig. 3A), whole body water (Fig. 3B), and whole body protein (Fig. 3C), the linear intercepts for CLA and control data were significantly different from each other ($P = 0.0251$ for whole body fat, $P = 0.0207$ for whole body water, and $P = 0.0125$ for whole body protein). This indicates that in each instance the data describe parallel but significantly distinct responses. No time trend was observed for the whole body ash data (Fig. 3D).

In Experiment 2, CLA-supplemented diet was fed for 4 wk and then withdrawn. At times thereafter body compositions were determined and compared with mice fed control diet throughout the study.

Figure 4 shows body weight and feed intake over the course of Experiment 2. During the time when CLA was fed, the mice fed diet supplemented with CLA exhibited significant reductions in feed intake (weeks 1 and 3) which were possibly accompanied by small nonsignificant reductions in body weight gain relative to controls. After withdrawal of dietary CLA, no significant differences in feed intake or body weight were evident although at week 6 and thereafter the test animals that had previously been fed CLA-supplemented diet appeared to eat slightly more feed than controls that had never been fed CLA-supplemented diet.

The absolute changes in body composition following withdrawal of dietary CLA are shown in Figure 5. For body fat (Fig. 5A), the overall time trends for the data of the CLA-fed

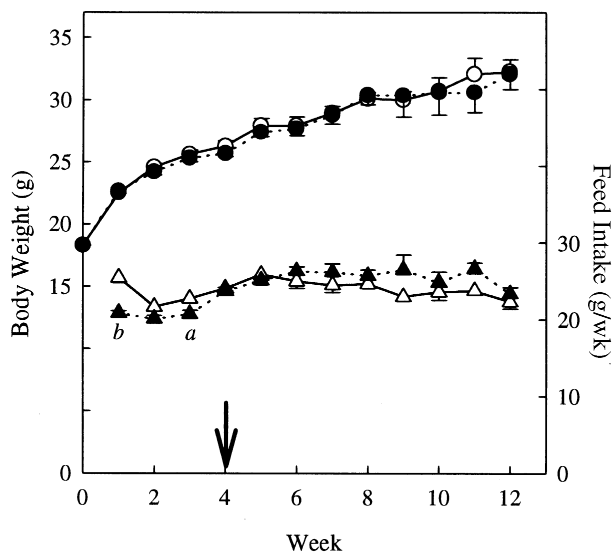

FIG. 4. Body weights and feed intake of mice in Experiment 2. Female ICR mice were fed either control or CLA-supplemented diet for 4 wk, then switched to control diet (arrow). Closed symbols, CLA-fed mice; open symbols, control mice. Circles, mean body weight/mouse ± S.E.; triangles, mean feed intake/mouse/wk ± S.E. determined from 2–10 cages each holding 5 mice under the assumption that each mouse acted independently. $^{a}P < 0.05$; $^{b}P < 0.0001$. For abbreviation see Figure 1.

and control mice exhibited parallel but significantly distinct responses ($P = 0.0016$), indicating that body fat increased in both groups but remained lower in the mice that had been fed CLA-supplemented diet. There appeared to be no significant differences in the overall time trends for whole body protein (Fig. 5B), whole body water (Fig. 5C), or whole body ash (Fig. 5D) between controls and mice that had been fed CLA-supplemented diet. However, whole body water and protein appeared to remain elevated in the mice that had been fed CLA-supplemented diet.

Figure 6 shows the relative body composition for the mice of Experiment 2. The group that had been fed diet supplemented with CLA exhibited increased whole body protein, which was significant at 1 and 2 wk (Fig. 6C), as well as increased whole body water and reduced body fat, which were significant at 0, 1, 2, and 8 wk (Fig. 6B and 6A). Relative whole body ash appeared to be higher in the CLA-fed group at every time point but the differences were not significant at any time point (Fig. 6D).

The overall time trends for the data of Figure 6 can be statistically described as parallel lines where the mice that had been fed CLA exhibited significantly less body fat ($P = 0.0001$) (Fig. 6A) and significantly more whole body protein ($P = 0.0014$) (Fig. 6C), whole body water ($P = 0.0001$) (Fig. 6B), and whole body ash ($P = 0.0448$) (Fig. 6D).

Figure 7 shows the changes in the amounts of the *c*-9,*t*-11 and *t*-10,*c*-12 CLA isomers in liver, fat pad, and muscle dur-

Each data point represents the mean ± S.E. of 7 or 8 animals. $^{a}P < 0.05$; $^{b}P < 0.01$, when compared to control at same time point. $^{c}P < 0.05$ when compared to control at the same time point when cage effects, which were not significant, were ignored. For abbreviations see Figure 1.

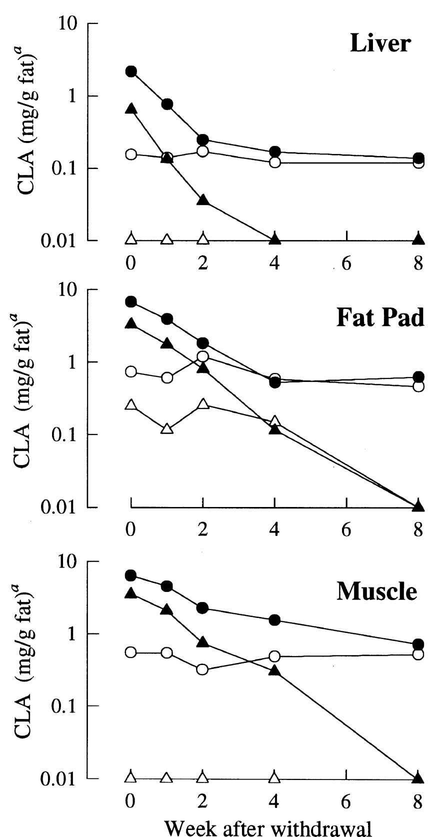

FIG. 7. CLA concentration of liver, fat pad, and muscle from animals in Experiment 2. Closed symbols, mice that had been fed CLA; open symbols, controls. Circles, *c*-9,*t*-11 CLA isomer; triangles, *t*-10,*c*-12 CLA isomer. Ten control and 10 CLA-fed animals were sacrificed as indicated (2 each per time point). [a]To avoid a zero log value when tissue CLA was undetectable, 0.01 was added to data points. For abbreviation see Figure 1.

ing the CLA withdrawal period of Experiment 2. In mice fed CLA, the levels of these CLA isomers in muscle and fat pad were similar and about three times greater than the levels in liver. Following CLA withdrawal from the diet, the *c*-9,*t*-11 isomer was virtually undetectable above background in liver after 2 wk, in fat pad after 4 wk, and in muscle after 8 wk, whereas the *t*-10,*c*-12 isomer was virtually undetectable in liver after 1 wk, fat pad after 2 wk, and muscle after 4 wk. In skeletal muscle, the *t*-10,*c*-12 CLA isomer was cleared significantly faster than the *c*-9,*t*-11 CLA isomer ($P = 0.0001$) (Fig. 7).

The CLA preparation that was fed contained both of these isomers in about equal amounts. It is noteworthy, then, that in all three tissues from mice fed CLA, the *t*-10,*c*-12 isomer was initially present at about half the concentration of the *c*-9,*t*-11 isomer.

DISCUSSION

Dietary CLA affects body composition in several animal species (3–10). Direct effects are found in adipocytes and skeletal muscle cells (3). Specifically we (3) reported that adding CLA to the culture medium of 3T3-L1 adipocytes produced a dose-dependent reduction in lipoprotein lipase activity (lipoprotein lipase hydrolyses fatty acids from circulating triacylglycerides; the free fatty acids are then taken up by the adipocytes and re-esterified). Adding CLA to the culture medium also appeared to induce lipolysis in this cell line. Additionally, skeletal muscle from mice fed CLA exhibited elevated carnitine palmitoyltransferase activity (carnitine palmitoyltransferase is the rate-limiting enzyme in fatty acid β-oxidation). Evidence was also presented indicating that CLA enhanced whole body protein accretion in mice.

Accordingly, we proposed that the physiological mechanism of body fat reduction in mice by CLA involved inhibition of fat storage in adipocytes coupled with both elevated β-oxidation in skeletal muscle and an increase (both relatively and absolutely) in skeletal muscle mass. The data presented in the present report are consistent with this model.

In addition to confirming and expanding upon our previous findings, the data of Experiment 1 provide limited evidence that an effect on whole body protein may precede body fat reduction in mice fed diet supplemented with CLA. At 1 wk of CLA feeding an apparent increase in (or maintenance of) whole body protein as percentage of body mass was evident (Fig. 3C). By contrast, reduced body fat was not clearly evident until 3 wk of CLA feeding (Fig. 2A, 3A). It is possible that the CLA-induced effect on whole body protein (relative to controls) is causally related to the (subsequent or accompanying) reduction in body fat, in that skeletal muscle is the principal site of fat combustion. The issue of energy balance may also be complicated by an apparent reduction in feed intake in CLA-fed animals, which occurred in Experiment 1 (Fig. 1) but to a much lesser extent in Experiment 2 (Fig. 4). In this regard it should be noted that fat free mass is conserved in direct proportion to food intake, e.g., more lean is conserved as more food is consumed (16). Further research is indicated to fully resolve these issues.

The data of Experiment 2 indicate that upon cessation of CLA feeding the percentage of whole body fat increased in the mice that had been fed CLA-supplemented diet (Fig. 5A and 6A). However, during the 8-wk study period, the overall level of body fat in the test group appeared to remain consistently lower than the body fat of control animals that had not been fed CLA, even though feed intake was virtually identical between the control and test mice (Fig. 4). Additionally, during this time, whole body protein (Fig. 6C) and whole body water (Fig. 6B) tended to remain elevated in the mice that had been fed the CLA-supplemented diet. Hence CLA appears to induce effects on body composition that continue for at least some time after clearance of the supplemental dietary CLA from tissue, presumably as a result of CLA metabolism (Fig. 7).

The data of Figures 4, 5A, and 6A do not appear to be consistent with the proposal (5, 17) that CLA induces adipocyte differentiation in rodents. If CLA had induced adipocyte differentiation (and, thereby, adipocyte number), then following CLA withdrawal, at which time feed intake was also similar for test and control mice (Fig. 4), we would have expected that in mice previously fed the CLA-supplemented diet, body fat accumulation would have achieved and possibly even sur-

passed control levels. This would have been expected because, if the hypothesis were correct, there would have been more fat cells in the CLA-fed mice than in the control mice, owing to the hypothetical stimulation of adipocyte differentiation by CLA and to the fact that energy would not be limiting in the mice that had been fed CLA (Fig. 4). Clearly, however, excessive body fat accumulation was not observed (Fig. 5A, 6A). To the contrary, body fat accumulation in the mice previously fed CLA lagged behind the controls and did not appear to return to control levels even after 8 wk (Fig. 6A), indicating that CLA may actually have blocked adipocyte differentiation during the time when CLA-supplemented diet was fed. Alternative explanations are possible, of course, indicating the need for further research.

The data of Figure 7 indicate that the levels of both the *c*-9,*t*-11 and *t*-10,*c*-12 CLA isomers decline at similar rates in liver and fat pad when supplemental CLA is withdrawn from the diet. However, in skeletal muscle, the *t*-10,*c*-12 CLA isomer was cleared significantly faster than the *c*-9,*t*-11 CLA isomer. The data of Figure 7 also indicate that in liver, fat pad, and muscle, the *t*-10,*c*-12 isomer was initially present at about half the concentration of the *c*-9,*t*-11 isomer, even though the CLA preparation that was fed contained both of these isomers in about equal amounts. The difference between tissue and dietary levels of these isomers could be due at least in part to the apparent preferential metabolism of *t*-10,*c*-12 CLA by skeletal muscle and possibly other tissues sites as well.

ACKNOWLEDGMENTS

We thank Professor E. Nordheim for assistance with statistical analysis, and Drs. Joseph Scimeca and Eric Hentges for discussions and support. This research was supported in part by a grant from the National Cattlemen's Beef Association and by gift funds administered through the University of Wisconsin-Madison Food Research Institute. Three of the authors (YP, MEC, MWP) are inventors of CLA use patents that are assigned to the Wisconsin Alumni Research Foundation.

ABSTRACT: We developed an oleic acid oil-in-water (o/w)-type emulsion of a new tacrolimus formulation that presented an improvement in the delivery of the drug for oral absorption. This investigation was undertaken to assess a sustained release drug delivery system and selective drug transfer into the lymphatic system. The whole blood concentration profiles after oral administration at a dose of 2mg/kg and bone marrow, spleen, liver, lung, small intestine, kidney, brain, and whole blood distribution after oral administration at a dose of 1 mg/kg of o/w emulsion formulation of tacrolimus (O/W group) were compared with those of commercially available formulation (T group) in the rat. The mean diameter of the o/w emulsion droplets was 0.47 μm immediately after preparation. The tacrolimus entrapping efficiency of o/w emulsion was 71.3 ± 5.0% in 12 h and did not change for 2 d. The area under the whole blood concentration-time curve (AUC) in the O/W group was significantly higher ($P < 0.01$) than that in the T group. In contrast, the values of constant elimination rate and total clearance in the O/W group were significantly lower ($P < 0.01$) than those in the T group, with a comparative bioavailability of 115.9%. The tissue concentration of tacrolimus in the O/W group was significantly higher levels in the bone marrow, spleen, liver, lung, and small intestine, and significantly lower in the brain and kidney, relative to the T group. The o/w emulsion of tacrolimus may be an improved dosage form *via* the enteral route.

Paper no. L7956 in *Lipids 34,* 249–254 (March 1999).

Tacrolimus has become an established immunosuppressant in the management of organ transplant patients. Tacrolimus has a molecular weight of 822, and is highly lipophilic. It is very soluble in methanol, ethanol, chloroform, and propyleneglycol and this seems to be associated with a markedly variable bioavailability and pharmacokinetics following oral administration (1). Much of this variability appears to result from poor absorption (1). We have been particularly interested in the development of sustained release drug delivery systems (2,3) and in selectively transferring drugs into the lymphatic system (4). Oil-in-water (o/w)-type emulsions are a system of dispersed-oil drops containing lipophilic drugs in aqueous fluids. There have been a few applications of this type of emulsion as a drug carrier *via* the enteral route. Sandimmune Neoral (5) (Sandoz Pharma Ltd., Basel, Switzerland) has been developed in an attempt to incorporate cyclosporine into a microemulsion to improve intestinal absorption. Compared to standard formulation, the absorption rate and systemic availability of cyclosporine were greater for Sandimmune Neoral at several dose levels (5). On the other hand, tacrolimus as well as cyclosporine causes adverse effects beyond systemic immunosuppression, including neurotoxicity and nephrotoxicity (6). The neurotoxicity and nephrotoxicity of tacrolimus appear to be dose-dependent (7,8).We proposed that o/w emulsion of tacrolimus was unlikely to be distributed in the brain and kidney, with their poor reticuloendothelial system (RES), and was likely to be distributed in the bone marrow and spleen, with their rich RES. To reduce the adverse effects of tacrolimus while enhancing the immunosuppressive efficacy to the site of the target organs, we developed a new emulsion formulation of tacrolimus. In the present study, an o/w emulsion based on oleic acid was used as a model for the delivery of tacrolimus. The pharmacokinetic advantages and potential usefulness of the emulsion as a carrier were evaluated.

Abbreviations: α, constant distribution rate; AUC, area under the whole blood concentration-time curve; AUC_{tr}, AUC calculated by trapezoidal rule; C_{max}, peak level; CL_{tot}, total clearance; F, extent of bioavailability; FEBA, comparative bioavailability; k_{21}, intercompartmental transfer rate constant; ka, rate constant of absorption; Kel, constant elimination rate; o/w, oil-in-water; RES, reticuloendothelial system; T_{max}, peak time; Vc, apparent volume of the central compartment; Vd(β), apparent volume of distribution.

MATERIALS AND METHODS

Materials. Both tacrolimus and oleic acid were purchased from Fujisawa Pharmaceutical Company Ltd. (Osaka, Japan). Tween 20 (Wako Pure Chemical Ltd., Osaka, Japan) and casein sodium (Katayama Chemical Ltd., Osaka, Japan) were used as surface agents.

Preparation of emulsion. This study used tacrolimus solution (100 mg/1 mL) in ethanol. Tacrolimus solution (100 mg/1 mL) was diluted with 9 mL oleic acid. To prepare the o/w emulsion, 2 mL of the tracrolimus solution diluted with oleic acid (100 mg/10 mL) was blended with a mixture of 189 mL distilled water, 2 mL Tween 20, 2 g casein sodium, and 5

Copyright © 1999 by AOCS Press

g glycerol and stirred for about 15 min in an ice bath using an ultrasonic homogenizer (V-Level 200, Nippon Seiki Co., Tokyo, Japan). O/W emulsions were checked microscopically by microphotography. The diameter of the o/w emulsion droplets was measured by a Shimazu Laser Diffraction Particle Size Analyzer, SALD-2001 (Kyoto, Japan). We measured the particle diameters of the emulsions once immediately after and then again 24 h after preparation of the emulsions to find out the variability between batches. We administered the o/w emulsion formulation within 24 h after preparation. To determine the entrapping efficiency of tacrolimus in the oil phase of o/w emulsion, o/w emulsion was dialyzed. The dialyzer used was hemofiltration FH-66D (Gambro Co., Germany). The external water of the dialyzer was prepared using o/w emulsion without tacrolimus. The dialysis was continued at room temperature for 12 h ($n = 3$) and 24 h ($n = 3$). The tacrolimus concentration in the external water of dialyzer was assayed by microparticle enzyme immunoassay (9), which is described subsequently in the Measurement of tacrolimus levels section. The entrapping efficiency was calculated by the equation

$$\text{entrapping efficiency (\%)} = 100 \cdot (1 - C_{\text{ext}} \cdot V \cdot R/A) \qquad [1]$$

where A represents the value of total amount of tacrolimus in the o/w emulsion, C_{ext} represents the value of tacrolimus concentration in the external water of dialyzer, V represents the volume of o/w emulsion and the external water of the dialyzer, and R represents the dilution rate of the external water of the dialyzer.

Animals. All animals were housed, fed, and handled in accordance with the Guidelines for Animal Experimentation of Hamamatsu University School of Medicine, with approval of the institution review board for animal experiments. Male DA/Slc rats weighing 180–220 g (SLC, Shizuoka, Japan) were used. The experiments described in this report were conducted according to the *Guide for the Care and Use of Laboratory Animals*, in strict adherence to the Declaration of Helsinki.

Experimental design. Animals were separated into two experimental groups. The first (O/W group) consisted of rats given the o/w emulsion of tacrolimus. The second group contained rats given the commercially available formulation (solid dispersion formulation containing 20% active ingredient, 20% hydroxypropyl methylcellulose, 20% croscarmellose sodium, and 40% lactose), which was dispersed with isotonic sodium chloride solution (T group). Tacrolimus was administered orally without sedation into the stomach at a dose of 2.0 mg/kg (O/W group; $n = 6$, T group; $n = 6$) and 1.0 mg/kg (O/W group, $n = 45$; T group, $n = 45$). The animals were fasted from 24 h before administration until 48 h afterward in both groups. The test solution contained 0.1 mg tacrolimus in 1.0 mL in each group. Venous blood samples were obtained predose and then 15 min, 30 min, and 1, 2, 4, 8 12, 24, and 48 h after 2.0 mg/kg tacrolimus administration. Venous blood samples and tissue samples were obtained predose ($n = 5$) and then 15 min ($n = 5$), 1 h ($n = 5$), 3 h ($n = 5$), 6 h ($n = 5$), 9 h ($n = 5$), 12 h ($n = 5$), 24 h ($n = 5$), and 48 h ($n = 5$) after 1 mg/kg tacrolimus administration. The blood samples (50 μL) were taken from blood vessels of the tail at each time point and were collected in EDTA-containing tubes. At the end of the experiment, bone marrow, brain, liver, spleen, kidney, small intestine, and lung samples were excised. These samples were immediately frozen at −20°C.

Measurement of tacrolimus levels. Concentration of tacrolimus in whole blood and tissue samples was assayed by microparticle enzyme immunoassay method (9) using anti-tacrolimus monoclonal antibody. This assay for the IMx analyzer (Dainabot Co., Tokyo, Japan) utilizes four reagents: a precipitation reagent to extract tacrolimus from whole blood; a capture reagent consisting of latex microparticles to which tacrolimus antibodies have been attached; a tacrolimus alkaline phosphatase conjugate reagent; and an enzyme substrate reagent consisting of 4-methylumbelliferyl phosphate. Rat whole blood standard and tissue samples standards in the range of 1.5–30 ng/mL were prepared using blank rat whole blood and homogenates of tissue samples. Several tacrolimus metabolites formed in the systemic circulation are not detected by this microparticle enzyme immunoassay allowing kinetic analysis of distribution of tacrolimus alone. SOFT max PRO, which is a program made by Molecular Devices Corp. for a personal computer, is used for collection and analysis of data. The standard curves were shown by a four-parameter fitting equation:

$$\mathrm{Y} = (\mathrm{A} - \mathrm{D})/[1 + (\mathrm{X}/\mathrm{C})^{\mathrm{B}}] + \mathrm{D} \qquad [2]$$

where Y represents the value of optimal density; X represents the value of concentration of tacrolimus; and A, B, C, and D represent the values of each parameter. The correlation coefficients for the standard curves of whole blood and tissue samples were more than 0.995 in both the free and emulsion forms of tacrolimus, in the range of 1.5–30 ng/mL. Precision analysis gave coefficients of variance of 13.3, 4.9, and 8.1% for quality control samples in intraassay of 5, 10, and 20 ng/mL. The accuracy for 5, 10, and 20 ng/mL samples was 93.3, 97.7, and 98.5% of their values, respectively. The detection range was 3–30 ng/mL judging from the intravalidation data. For the determination of tissue levels of tacrolimus, tissue samples were homogenized in 10 vol of isotonic sodium chloride solution and analyzed. Tissue tacrolimus levels were calculated as the amount of tacrolimus in 1 g of tissue sample. Whole blood tacrolimus concentration profiles were analyzed by population pharmacokinetic modeling. Nonlinear multiple regression analysis was performed using MULTI 2 (10). The tacrolimus concentration (C) to time (t) data were fitted to the following equation:

$$\begin{aligned} C = &-[F \cdot k_a \cdot D \cdot (k_a - k_{21})/V_c \cdot (\alpha - k_a) \cdot (k_{el} - k_a)] \cdot \exp(-k_a \cdot t) \\ &+ [F \cdot k_a \cdot D \cdot (k_{21} - \alpha)/V_c \cdot (k_a - \alpha) \cdot (k_{el} - \alpha)] \cdot \exp(-\alpha \cdot t) \\ &+ [F \cdot k_a \cdot D \cdot (k_{21} - k_{el})/V_c \cdot (k_a - k_{el}) \cdot (\alpha - k_{el})] \cdot \exp(-k_{el} \cdot t) \qquad [3] \end{aligned}$$

where F, V_c, k_a, k_{21}, α, k_{el}, and D are extent of bioavailability, apparent volume of the central compartment, rate constant of

absorption, intercompartmental transfer rate constant, constant distribution rate, constant elimination rate, and oral administration dose of 2 mg/kg, respectively. Pharmacokinetic parameters—peak time (T_{max}), peak level (C_{max}), apparent volume of distribution [$V_{d(\beta)}/F$], area under the whole blood concentration–time curve (AUC), and total clearance (CL_{tot})—were estimated by MULTI 2. Area under the whole blood concentration–time curve (AUC_{tr}) was also calculated by the trapezoidal rule for the mean whole blood levels. Therefore, the values of AUC estimated from MULTI 2 were used for further analysis. Comparative bioavailability (F_{EBA}) was calculated by the following equation:

$$F_{EBA} = (CL_{tot}^{O/W} \cdot AUC_{tr}^{O/W}/D)/(CL_{tot}^{T} \cdot AUC_{tr}^{T}/D) \quad [4]$$

where superscripts O/W and T represent the O/W group and T group, respectively.

Statistics. Tacrolimus levels are presented as means ± standard deviation, and compared between the groups using the unpaired Student's *t*-test and *F*-test. The analysis of variance for the particle diameters of the emulsions was performed by *F*-test. $P < 0.05$ was considered significant.

RESULTS

The mean diameters of the o/w emulsion droplets were 0.47 µm immediately after preparation and 0.49 µm 24 h afterward. The particle distributions in the emulsion immediately after preparation and 24 h afterward were not significantly different (Table 1). The entrapping efficiency of tacrolimus in emulsion formulation was 71.3 ± 5.0% in 12 h and 71.9 ± 3.2% in 24 h. The stability of o/w emulsion formulation did not change when the emulsion was stored at room temperature for 2 d.

Concentration of tacrolimus in blood. Whole blood concentration profiles of drug after oral administration of O/W group and T group at a dose of 2.0 mg/kg are shown in Figure 1. Whole blood profiles were best accommodated by a two-compartment model for both O/W group and T group. Table 2 lists the pharmacokinetic parameters based on whole blood concentration. The value of AUC calculated by the trapezoidal rule in the O/W group was significantly higher ($P < 0.01$) than in the T group. In contrast, the values of k_{el} and CL_{tot} in the O/W group were significantly lower ($P < 0.01$) than those in the T group. There were no significant differences in C_{max}, T_{max}, $V_{d(\beta)}/F$, and V_c values between the O/W group and T group. The value of F_{EBA} was 115.9%. The interindividual variabilities for pharmacokinetic parameters of O/W group were not significantly reduced compared with the T group.

Tacrolimus levels of organs. As shown in Table 3, the tacrolimus levels of the bone marrow in the O/W group were significantly higher (15 min, 1 h, 3 h, and 6 h: $P < 0.05$; 9 h, 12 h, 24 h, and 48 h: $P < 0.01$) than in the T group. The tacrolimus levels in the spleen at 12, 24, and 48 h were significantly higher ($P < 0.01$) in the O/W group than in the T group. The tacrolimus levels of the liver in the O/W group were also significantly higher (15 min, 9 h, and 48 h: $P < 0.05$; 6 h: $P < 0.01$) than in the T group. The small intestinal concentrations of tacrolimus at 15 min, 1, 12, 24, and 48 h were significantly higher ($P < 0.01$) in the O/W group than in the T group. The lung concentrations at 12, 24, and 48 h were significantly higher ($P < 0.01$) in the O/W group than in the T group. In contrast, the tacrolimus levels in the brain were quite low compared with the levels in other organs. The brain concentrations of tacrolimus were significantly lower (6 and 9 h: $P < 0.05$; 15 min, 1, 3, and 12 h: $P < 0.01$) in the O/W group than in the T group. The tacrolimus levels in the kidney in the O/W group were significantly lower (6 and 9 h: $P < 0.05$; 12 and 24 h: $P < 0.01$) than in the T group. There were no significant differences between the whole blood concentrations of tacrolimus at the dose of 1.0 mg/kg.

[b]$P < 0.05$. The values are not statistically different from that immediately after the preparation within a batch.
[c]$P < 0.05$.

DISCUSSION

This is the first study to document the pharmacokinetic advantages of an orally administered oleic acid o/w emulsion incorporating tacrolimus. An o/w emulsion was used as a carrier of tacrolimus *via* the enteral route since numerous emulsions for oral administration have already been studied (11), and lipophilic drugs can be incorporated easily and efficiently within emulsions. The behavior of an emulsion is largely dependent on the lipid that constitutes the oil phase (12). If the emulsion is composed of unsaturated fatty acids, an absorption-promoting action may be obtainable (13). Emulsions enter the lymphatic system easily (4). However, we have no data to show that the drug could reach the systemic circulation incorporated in the oil-in-water-type emulsion.

Following oral administration, tacrolimus is absorbed erratically and incompletely (1). Tacrolimus is fairly stable in the gastrointestinal juice and is absorbed predominantly from the upper part of the small intestine (14). Oleic acid mixed

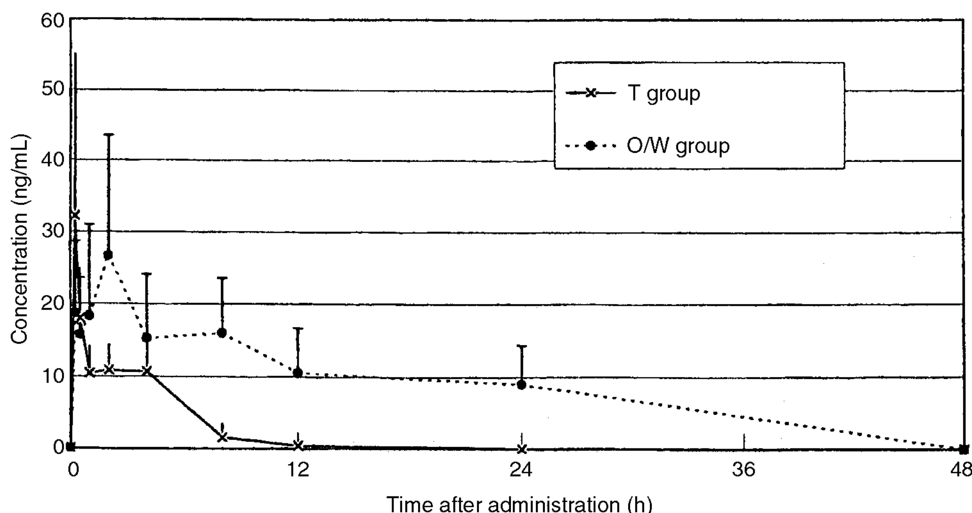

FIG. 1. Whole blood tacrolimus concentration profiles of O/W group (rats given the oil-in-water emulsion of tacrolimus) and T group (rats given the commercially available formulation) following orally administered doses of 2 mg/kg to rats. (●), O/W group (n = 6); (X), T group (n = 6). Each point represents the mean ± SD of six rats.

micelles markedly increase the mucosal membrane permeability to drugs and enhance their intestinal absorption (12). The oleic acid o/w emulsion of tacrolimus we obtained had very small particle size and good stability *in vitro*. However, no significant difference was seen in whole blood tacrolimus concentrations between O/W group and T group after oral administration at a dose of 1.0 mg/kg because whole blood tacrolimus concentrations were low in both groups, compared with the assay detection range of more than 3.0 ng/mL. On the other hand, pharmacokinetic parameters based on whole blood tacrolimus concentrations after 2.0 mg/kg oral administration in the O/W group indicated increased bioavailability relative to the T group.

In our view, some of the most important criteria of a good sustained release formulation are a bioavailability of at least 80% relative to the commercially available formulation (15), higher value of AUC, and lower values of k_{el} and CL_{tot} than in the commercially available formulation, whereas the V_c and $V_{d(\beta)}$ values should not be different between two formulations. In the present study, when an oleic acid o/w emulsion formulation of tacrolimus was administered orally at a dose of 2.0 mg/kg, the bioavailability of tacrolimus from the O/W group was 115.9%, the AUC value was significantly higher, and the k_{el} and CL_{tot} values were significantly lower compared to those from the commercially available formulation. There were no significant differences in V_c and $V_{d(\beta)}$ values between the O/W group and T group. Increased bioavailability appears to result from reduced CL_{tot} and smaller first-pass effect. The variability was much larger in the O/W group, in part due to inadequate precision in the delivered dose. The release pattern of a sustained release preparation should be independent of pH, enzyme, agitation, and any other variables that might be encountered in the gastrointestinal tract. Further, *in vitro* evaluation of these parameters is needed.

[a]Values represent mean ± SD of five animals. The values of whole blood level were calculated as ng/mL alone. See Table 2 for abbreviations.
[b]Tacrolimus (1 mg/kg) was administered as each formula. The value is significantly different from T group.
[c]$P < 0.05$.
[d]$P < 0.01$.

The present pharmacokinetic study of the O/W group of emulsion demonstrated significantly increased tacrolimus levels in the bone marrow, spleen, liver, lung, and small intestine, and significantly decreased tacrolimus levels in the brain and kidney, compared to the T group. This suggests that the main site of o/w emulsion uptake after oral administration was the RES; brain and kidney are known to contain little in the way of RES elements. Increased delivery of oleic acid o/w emulsion incorporating tacrolimus into the lymphoid organs may markedly alter alloantigen presentation, proliferation and differentiation of allosensitive lymphocytes, thereby increasing the effectiveness of this drug in delaying graft rejection. From the viewpoint of adverse effects, decreased tacrolimus levels in the brain and kidney with this emulsion formulation of tacrolimus may logically be expected to result in less tendency to cause neurotoxicity and nephrotoxicity but this point was not addressed in the present study. The evaluation of the host's systemic immune function as well as the effect of local immunosuppression on tolerance induction and the avoidance of neurotoxicity and nephrotoxicity by the use of an o/w emulsion formulation need to be explored.

In conclusion, our o/w emulsion formulation of tacrolimus has very small particle size, good *in vitro* stability, a sustained release of drug, and selective drug transfer into the lymphatic system comparable to the characteristics of a commercially available formulation. It is considered that o/w emulsion might have advantages as an alternative oral dosage form for tacrolimus.

Susceptibility of Serum Lipids to Copper-Induced Peroxidation Correlates with the Level of High Density Lipoprotein Cholesterol

ABSTRACT: As a first step in evaluating the significance of our recently developed method of monitoring the kinetics of copper-induced oxidation in unfractionated serum, we recorded the kinetics of lipid oxidation in the sera of 62 hyperlipidemic patients and analyzed the correlation between oxidation and lipid composition of the sera [high density lipoprotein (HDL) cholesterol, low density lipoprotein (LDL) cholesterol, and triglycerides]. We used six factors to characterize the kinetics of oxidation, namely, the maximal absorbance of oxidation products (OD_{max}), the maximal rate of their production (V_{max}), and the time at which the rate was maximal (t_{max}) at two wavelengths (245 nm, where 7-ketocholesterol and conjugated dienic hydroperoxides absorb intensely, and 268 nm, where the absorbance is mostly due to dienals). The major conclusions of our analyses are that: (i) Both OD_{max} and V_{max} correlate positively with the sum of concentrations of the major oxidizable lipids, cholesterol, and cholesteryl esters. (ii). The value of t_{max}, which is a measure of the lag preceding oxidation and therefore reflects the resistance of the serum lipids to copper-induced oxidation, exhibits a negative correlation with HDL cholesterol. Although this finding accords with the observation of shorter lags for HDL than for LDL, it is apparently inconsistent with the role of HDL as an antirisk factor in coronary heart diseases.

Paper no. L7984 in *Lipids 34*, 255–259 (March 1999)

Oxidation of low density lipoprotein (LDL) in the subendothelial space of major arteries is believed to play a key role in atherogenesis (1–3). The possible involvement of high density lipoprotein (HDL) in this process is not clear. On one hand, several *in vitro* studies have shown that HDL is more susceptible to oxidation than LDL (4–6) and that in mixtures of HDL and LDL the lag preceding oxidation of LDL lipids is longer than the lag preceding the oxidation of pure HDL but shorter than the lag preceding the oxidation of pure LDL (6). On the other hand, in several other studies HDL appeared to be less susceptible to oxidation than LDL and to protect LDL against copper-induced oxidation, presumably owing to the activity of the HDL-associated enzymes platelet-activating factor-acetyl hydrolase (PAF-AH) and paraoxonase (7–10).

Previously we developed a method for monitoring the kinetics of copper-induced lipid oxidation in unfractionated serum (6,11). Although this optimized assay is only slightly dependent on the experimental processing of the serum, we do not know whether the recorded kinetic profiles, measured under nonphysiological conditions, are relevant to *in vivo* oxidation. As a first step in evaluating the possible significance of our assay, we investigated the relationship between the kinetics of lipid oxidation and the lipoprotein composition of hyperlipidemic patients, for whom lipid composition, as measured routinely by clinical laboratories, varies markedly with respect to the concentrations of triglycerides (TG), LDL-cholesterol, and HDL-cholesterol (Table 1). Specifically, we recorded continuously the time course of copper-induced oxidation of serum samples of 62 patients and analyzed the correlations between the characteristics of oxidation of the sera and the concentrations of TG, HDL-cholesterol and LDL-cholesterol. Because the patients differed in their dyslipidemia, treatment, sex, and age, we did not expect the results to yield any conclusion regarding the correlation between the kinetics of oxidation and the treatment given to the patients. Nonetheless, given the large variation of the serum lipid concentrations we attribute significance to the correlations described below between the concentrations of the different components of the serum and the factors that can be used to characterize its copper-induced oxidation *in vitro*.

MATERIALS AND METHODS

The study is based on the lipid composition and oxidizability of the serum of 62 randomly chosen, nonobese, hyperlipidemic patients of the lipid outpatient clinic of Rabin Medical Center. It was carried out according to the principles of the Declaration of Helsinki approved by the Human Experimentation Committee of the Hospital. All participants gave their written informed consent. Obese patients and patients suffering from inflammatory conditions (white blood cell count ≥ 12,000 per dL) were excluded from the study. Nine of the participating patients suffered from insulin–independent diabetes. Eleven of the patients were smokers. Venous blood was drawn after 12 h of fasting, as part of the regular checkup examinations. Serum was prepared by centrifugation (at 1000

TABLE 1
Composition and Parameters of Oxidation Kinetics in Sera of Hyperlipidemic Subjects[a]

Treatment	Diet	Fibrates	Statins	All
Number (M/F)	17 (7/10)	15 (8/7)	30 (16/14)	62 (31/31)
Age (yr)	50.47 ± 9.73	55.67 ± 9.25	57.30 ± 10.64	55.03 ± 10.33
Cholesterol (mg/dL)	245.5 ± 41.0	232.1 ± 40.9	243.3 ± 64.9	241.2 ± 53.5
LDL cholesterol (mg/dL)	129.7 ± 51.3	121.2 ± 35.7	150.6 ± 57.0	137.8 ± 51.9
HDL cholesterol (mg/dL)	47.4 ± 14.4	41.1 ± 11.5	54.1 ± 12.1	49.1 ± 13.5
Triglycerides	342.0 ± 256.1	340.7 ± 142.2	180.4 ± 68.2	263.5 ± 175.0
Kinetics at 245 nm				
OD_{max}[a]	0.631 ± 0.108	0.641 ± 0.149	0.585 ± 0.109	0.611 ± 0.120
V_{max} (OD/min)	0.0054 ± 0.0013	0.0050 ± 0.0011	0.0058 ± 0.0016	0.0055 ± 0.0014
t_{max} (min)	86.8 ± 21.7	94.2 ± 20.2	78.1 ± 19.0	84.4 ± 20.8
Kinetics at 268nm				
OD_{max}[a]	0.379 ± 0.053	0.396 ± 0.064	0.381 ± 0.060	0.384 ± 0.059
V_{max} (OD/min)	0.0026 ± 0.0005	0.0026 ± 0.0005	0.0029 ± 0.0006	0.0027 ± 0.0006
t_{max} (min)	91.5 ± 19.1	100.0 ± 18.3	80.5 ± 13.7	88.2 ± 18.1

[a]OD_{max} denotes the (nearly constant) optical density (OD) level, as measured after 5 h of exposure of the serum to copper (see the Materials and Methods) section. Statin, hydroxymethylglutaryl-CoA-reductase inhibitor; M/F, male/female; LDL, low density lipoprotein; HDL, high density lipoprotein; V_{max}, maximal rate of oxidation products accumulation, *t*, time.

× *g*) of the blood (collected into vacutainers) at 4°C, 30 min after collection. Isolation of serum lipoproteins was performed by sequential ultracentrifugation according to our earlier report (6). The cholesterol and TG concentrations in the serum and isolated lipoproteins were determined using commercially available kits (Boehringer-Mannheim, Mannheim, Germany).

The kinetics of lipid oxidation in each serum was monitored through continuous recording of the absorbance at two wavelengths (245 and 268 nm) following 50-fold dilution of the serum in a phosphate-buffered saline containing sodium citrate (0.72 mM) and $CuCl_2$ (0.1 mM) (6,11). Figure 1 depicts the results of a typical time course of the absorbance under these conditions. The time-dependent increase of absorbance at 268 nm, to which dienals make the major contribution, lags only slightly behind the increase of absorbance at 245 nm, to which the major contribution is that of lipid hydroperoxides and 7-ketocholesterol (12). Each of these time dependencies was characterized by three factors, namely, the maximal absorbance (OD_{max}), the maximal rate of increase of absorbance (V_{max}), and the time at which the rate was maximal (t_{max}). The last factor has been shown previously to correlate with the more commonly used lag time (13). Because t_{max} can be unequivocally determined from the first derivative of the time course of accumulation (Fig. 1, lower panel), we prefer using this factor (rather than the lag) to characterize the resistance of serum lipids to oxidation.

Data analysis was performed by the standard procedures provided by Microsoft Excel 7 (Redmond, WA) and Microcal Origin 4.0 (Northampton, MA) software.

RESULTS

Of the 62 patients that participated in this study, 17 were treated for hyperlipidemia by a low-fat diet only, 15 were treated with fibric acid derivatives (fibrates), and 30 were treated with hydroxymethylglutaryl-CoA-reductase inhibitors (statins) at varying doses. The concentrations of serum lipids

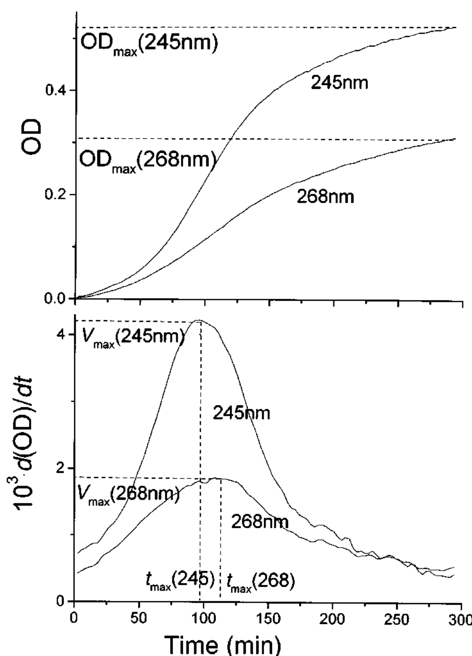

FIG. 1. Time course of lipid peroxidation in unfractionated serum, as monitored by continuous recording of absorbance at 245 and 268 nm. A serum sample (30 µL) was added to a phosphate-buffered solution (pH 7.4) containing 150 mM NaCl, 0.72 mM sodium citrate, and 0.1 mM $CuCl_2$, preequilibrated at 37°C. The absorbance, recorded at intervals of 3 min, using a Kontron (Model 933) spectrophotometer equipped with an automated cell changer, is depicted in the upper panel. The lower panel depicts the derivative of the time dependencies given in the upper panel. The values of OD_{max} were derived from the time dependencies of accumulation (upper panel). The values of V_{max} (in OD units/min) and of t_{max} (in min) were derived from the respective coordinates of the peaks in the time courses of rate (lower panel). OD, optical density; V_{max}, maximal rate of oxidation products accumulation.

in these three groups of patients (Table 1) differed accordingly. The lipid compositions of the sera of those patients who were treated by diet or fibrates were very similar with respect to both cholesterol and TG. Furthermore, the total cholesterol content of the sera of the hypercholesterolemic patients treated with statins was not significantly different from that of the sera of the other two groups. However, both the experimentally determined HDL cholesterol and the calculated LDL cholesterol levels were somewhat higher in the statin group than in the other two groups ($P < 10^{-2}$). By contrast, the patients of the statin groups had much lower TG levels than those of the other two groups ($P < 10^{-3}$).

Also presented in Table 1 are the results of our kinetic studies, given in terms of the mean values and standard deviations of V_{max}, t_{max} and OD_{max}, as measured both at 245 and 268 nm for the sera of patients of the three groups. These data indicate that oxidation of the serum of statin-treated patients was preceded by somewhat shorter lag times than the oxidation of the other patients ($P < 0.02$). Interestingly, even the largest mean value of t_{max}, as measured at 245 nm for the group of hyperlipidemic patients treated by fibrates (94.2 min), was shorter than that observed for 15 normolipidemic individuals as determined by the same assay (107 ± 17 min; Fainaru, O., Pinchuk, I., Fainaru, M., Assali, A. and Lichtenberg, D., in preparation). The question remains whether these results relate to the lipid composition and/or to the treatment. The following analyses concerning the correlation between the oxidation parameters and serum composition for all the tested sera provide a partial answer to this question.

Figure 2 presents the correlations observed between the various kinetic factors and the composition of the individual sera. Because peroxidation of serum lipids depends on many factors, it is not surprising that none of these correlations was very high. Nonetheless, the following correlations were highly statistically significant ($P < 10^{-3}$). (i) Both OD_{max} (observed range of values 0.369–0.948 OD units) and V_{max} (observed range of values 0.0024–0.0101 OD units/min), as measured at 245 nm, depended linearly on the cholesterol concentration (range of values 138–457 mg/dL). (ii) The correlations between cholesterol level and either OD_{max} (observed range of values 0.260–0.517 OD units) or V_{max} (observed range of values 0.0017–0.0042 OD units/min) at 268 nm were statistically significant but somewhat weaker. (iii) The value of OD_{max} at 245 nm (but not at 268 nm) correlated negatively with the concentration of HDL cholesterol (range of values 22–80 mg/dL). (iv) The value of t_{max}, as measured at either 245 (observed range of values 48–135 min) or 268 nm (observed range of values 54–135 min) correlated negatively with the level of HDL cholesterol.

Before evaluating these results we tested whether the correlations observed for the whole population exist for subgroups of the 62 patients studied. First, we analyzed separately the data on the 31 male and 31 female patients who participated in the study and found the same trends as those obtained for all the sera taken together. Second, we repeated these analyses for the group of 53 nondiabetic patients as well

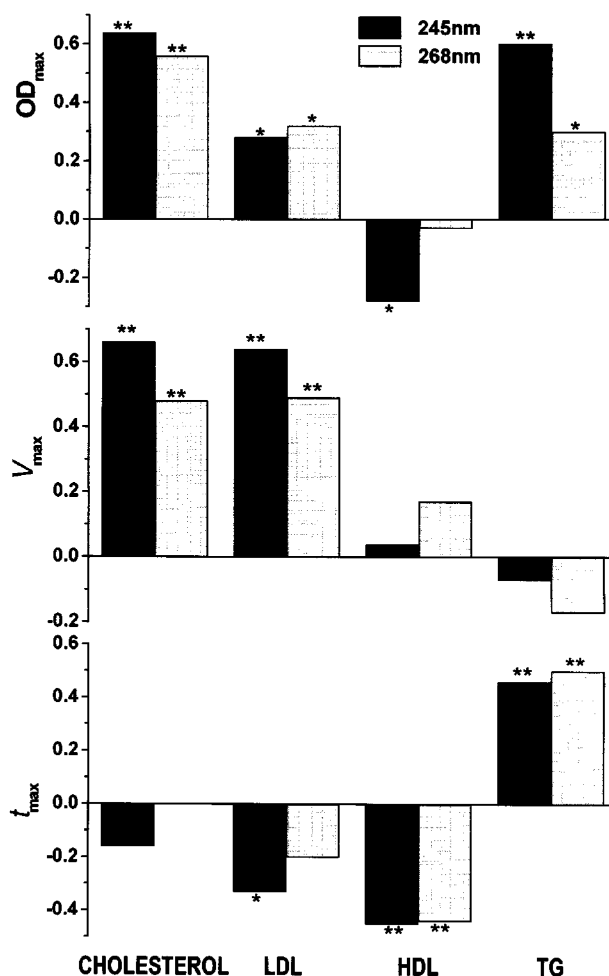

FIG. 2. The relation between serum composition and oxidation parameters. Correlation coefficients are given between the serum concentrations of cholesterol (total), low density lipoprotein (LDL) cholesterol, high density lipoprotein (HDL) cholesterol, and total triglycerides (TG), on one hand, and the oxidation parameters, OD_{max}, V_{max} and t_{max}, on the other. The black bars relate to oxidation kinetics as recorded at 245 nm, whereas the gray bars relate to the kinetics as recorded at 268 nm. The symbol (*) corresponds to a P-value smaller than 0.05; the symbol (**) corresponds to P-values smaller than 10^{-3}.

as for the group of 51 nonsmokers among the studied patients and found in both cases the same correlations observed for all the patients, with comparable correlation coefficients. These analyses showed that in each of these groups both V_{max} and OD_{max} correlated with the lipid composition of the serum as described above. Furthermore, the positive correlation between t_{max} and TG was similar for each of the studied groups.

By contrast, the correlation between t_{max} and HDL in the statin-treated group differed markedly from that observed for the patients of the two other groups. Linear regression analyses of the dependence of t_{max} on HDL exhibited negative correlations for each of the three groups, but the influence of HDL on t_{max} was less pronounced for the statin-treated patients than for the other groups. Specifically, for the statin group the dependence of t_{max} on HDL did not reach the 5% limit of significance, the correlation coefficient was very low

($R = -0.13$), and the computed slope of the dependence was -0.21 min/mg% HDL cholesterol. By contrast, in the other two groups the same analysis indicated that the dependence of t_{max} on HDL is very significant ($R = -0.59$, $P = 4 \times 10^{-4}$) and much stronger (-0.94 min/mg% HDL cholesterol). This difference may possibly indicate that the HDL of patients treated by statins is different from that of patients of the two other groups, as a result either of the difference in the dyslipidemia or of the statin treatment. We are unaware of any data that may either support or rule out any of these possibilities.

DISCUSSION

The dependencies of both OD_{max} and V_{max} on serum composition can be interpreted as follows: (i) The linear dependence of OD_{max}, measured at 245 nm after 5 h of exposure to copper, on the total cholesterol is expected because hydroperoxides are intermediates in the time course of oxidation (12,14). Hence, oxidized cholesterol is likely to make the major contribution to the maximal level of OD at 245 nm, as measured after most of the cholesterol in the lipoproteins had already oxidized while most of the hydroperoxides had already decomposed. Furthermore, V_{max}, expressed in terms OD units per minute, is proportional to the concentration of the major oxidizable lipids (cholesterol and cholesteryl esters); its correlation with the total cholesterol level is not surprising. (ii) To explain the correlation between cholesterol level and either OD_{max} or V_{max} at 268 nm, it should be noted that much of the polyunsaturated fatty acids (PUFA), from which dienals are formed (*via* hydroperoxides) is esterified with cholesterol. However, this correlation was weaker, probably because free PUFA and PUFA esterified into phospholipids and TG, which do not necessarily correlate with the level of cholesterol, also contribute to the production of dienals. (iii) The negative correlation between OD_{max} at 245 nm (but not at 268 nm) and the concentration of HDL cholesterol can be understood as being a result of the significant correlation between OD_{max} at 245 nm and total cholesterol, on one hand, and the negative correlation between HDL cholesterol and the total cholesterol level, on the other. By contrast, no correlation could have been expected between OD_{max} at 268 nm and HDL cholesterol because the contribution of cholesterol oxidation products to the absorbance at this wavelength is marginal.

The most intriguing result of this study is the negative correlation between t_{max} (as measured either at 245 or at 268 nm) and HDL cholesterol concentration. This correlation accords with our previous finding that the lag obtained in the time course of oxidation of mixtures of HDL and LDL decreases upon increasing the concentration of HDL in the mixture (6), although it is apparently inconsistent with the observations of other authors that oxidative changes in LDL–HDL mixture occur later than in isolated LDL (10).

The pathological relevance of these results, as well as those of any other *in vitro* assay of lipid oxidation of either LDL or unfractionated serum or plasma, is questionable. In fact, HDL is an established anti-risk factor in coronary heart diseases. Hence, our results may imply that the significance of the reverse transport of cholesterol by HDL exceeds its enhancing effect on the rate of oxidation. In addition, HDL oxidation may have a more direct effect on oxidation-induced atherogenesis in the subendothelial space, where LDL oxidation is involved in foam cell formation and the concentration of HDL is smaller than that of LDL (15,16). First, HDL may play a protective role by being oxidized prior to LDL (17,18). Second, oxidized HDL itself may either be atherogenic (19) or anti atherogenic, possibly owing to the activity of the HDL-associated enzymes paraoxonase and/or PAF-AH (16,20,21).

Further effort will be devoted to elucidate these possibilities.

Activation of Acyl-CoA Cholesterol Acyltransferase: Redistribution in Microsomal Fragments of Cholesterol and Its Facilitated Movement by Methyl-β-Cyclodextrin

Donghui Cheng* **and Carl L. Tipton**

Department of Biochemistry and Biophysics, Iowa State University, Ames, Iowa 50011

ABSTRACT: Acyl-CoA cholesterol acyltransferase (ACAT) (EC 2.3.1.26) in the yolk sac membrane of chicken eggs plays an important role in the transport of lipids, which serve as both structural components and as an energy source during embryogenesis. ACAT from the yolk sac membrane of chicken eggs 16 d after fertilization has higher activity and better stability than its mammalian liver counterpart. During our study of the avian enzyme, ACAT was found to be activated up to twofold during storage at 4°C. The activation was investigated, and data suggest that redistribution of cholesterol within microsomal vesicles leads to the increase. Methyl-β-cyclodextrin (MβCD) increases activation an additional twofold, possibly by facilitating the movement of cholesterol within microsomal fragments and allowing redistribution of cholesterol in lipid bilayers to a greater extent. Treatment of microsomes with MβCD removes cholesterol from the membranes. Controlled amounts of cholesterol can be restored to the membranes by mixing them with cholesterol-phosphatidylcholine liposomes in the presence of MβCD. Under these conditions, the plot of ACAT vs. cholesterol mole fraction in the liposomes is sigmoidal. The finding that MβCD can enhance cholesterol transfer between liposomes and microsomes and reduce the limitation of slow movement of nonpolar molecules in aqueous media should make cyclodextrins more useful in *in vitro* studies of apolar molecule transport between membrane vesicles.

Paper no. L7830 in *Lipids 34,* 261–268 (March 1999).

Acyl-CoA cholesterol acyltransferase (ACAT) (EC 2.3.1.26) catalyzes intracellular esterification of cholesterol with long-chain fatty acyl coenzyme A. ACAT is an integral membrane protein and resides in the cytoplasmic side of the rough endoplasmic reticulum (ER) (1). ACAT activity has been observed in many kinds of tissues and plays an important role in the maintenance of intracellular cholesterol homeostasis. In the liver, the production and secretion of lipoproteins, which deliver various lipid molecules to peripheral tissues, require a lipid core of triacylglycerols and cholesteryl esters. Dietary absorption of cholesterol requires the function of intestinal ACAT, which controls the rate-limiting step of absorption (2). Overaccumulation of cholesteryl esters in macrophages and smooth muscle cells in large arteries leads to formation of fatty streaks and atherosclerosis. During embryogenesis, ACAT of the yolk sac membrane of chicken eggs functions significantly in providing essential lipid nutrients to the developing embryo (3,4). More than fivefold higher ACAT activity was observed at day 16 in the yolk sac membrane compared with that in the liver or intestine (3). Despite its biological significance, ACAT has not been isolated in pure form, and study of the enzyme is limited to microsomal preparations or detergent extracts.

It is known that cellular membranes are not homogeneous structures of randomly distributed lipids with embedded proteins. Rather, they contain microorganizations that differ from each other by the size of domains, by lipid and protein compositions, and by the kinetic properties of each component (5). Cholesterol-rich and cholesterol-poor domains have been shown to exist in the plane of the membrane, and the distribution of the sterol in the two leaflets of the bilayer and among different membrane compartments is known to be asymmetrical (5). In an early study, Hashimoto and Fogelman (6) showed that ACAT in rat liver microsomes is concentrated in the RNA-rich fraction, whereas the bulk of the cholesterol ester is found in smooth microsomes. When acyl-CoA was added to mixtures of the two kinds of membranes, a disproportionate amount of the cholesterol ester formed was in the smooth membrane fraction. It was suggested that cholesterol in the smooth microsomes may have been esterified by ACAT on the surface of the RNA-rich membranes; neither cholesterol nor cholesterol ester needed to be transported between the membranes. Transport of cholesterol among different membrane structures and maintenance of concentration gradients require lipid carrier proteins and transporting vesicles. Cholesterol oxidase susceptibility indicates that about 90% of cellular free cholesterol is associated with the plasma membrane (7); and many studies have shown that, under physiological conditions, ACAT is not saturated with cholesterol. Therefore, transfer of the sterol from other cellular fractions

to the ACAT substrate pool can be a limiting factor in the activity of the enzyme.

Cyclodextrins are a family of cyclic molecules composed of varying numbers of glucose units. Among the commercially available cyclodextrins, β-cyclodextrin and its derivatives have been found to be the most efficient molecules in extracting cholesterol from lipid bilayers (8,9). Atger *et al.* (10) showed that cyclodextrins can facilitate the transfer of cholesterol from cells to phospholipid vesicles. A complex of cholesterol with methyl-β-cyclodextrin (MβCD) can be used as an efficient delivery tool to provide cells or other biological systems with cholesterol (11).

In this paper the effect of prolonged incubation of microsomes and the addition of a cyclodextrin derivative, both allowing cholesterol redistribution, on ACAT activity are reported.

MATERIALS AND METHODS

Materials. Chicken eggs, 16 d after fertilization, were obtained from Hy-Vac (Adel, IA). 2-[*N*-Morpholino]ethanesulfonic acid (MES), cholic acid sodium salt, Triton X-100, 4-aminoantipyrine, sodium 3,5-dichloro-2-hydroxybenzene sulfonate, MβCD, cholesterol, oleoyl coenzyme A, horseradish peroxidase, and cholesterol oxidase were all from Sigma (St. Louis, MO). Phosphatidylcholine, 20 mg/mL in chloroform, was prepared from chicken eggs following a procedure by White *et al.* (12). *p*-Methylaminophenol sulfate was purchased from Aldrich Chemical Co. (Milwaukee, WI). Tris(hydroxymethyl)aminomethane Na_2EDTA, sucrose, sodium bisulfite, sodium sulfite, perchloric acid, and 7-mL polyethylene scintillation vials were obtained from Fisher Scientific (Fair Lawn, NJ). Bovine serum albumin, fatty acid poor, was purchased from Calbiochem Co. (La Jolla, CA). Ecolume scintillation fluid was obtained from ICN Pharmaceuticals, Inc. (Costa Mesa, CA). 1-^{14}C-Oleoyl CoA was from DuPont NEM (Boston, MA). [1α,2α(n)-^{3}H] Cholesteryl oleate was from Amersham Life Science, Inc. (Arlington, IL). Silica gel (40–140 mesh) was a product of J.T. Baker, Inc. (Phillipsburg, NJ). Plates for thin-layer chromatography, silica gel 60 precoated, 20 × 20 cm, were from Merck (Darmstadt, Germany). Packard Tri-carb 1600TR liquid scintillation analyzer with a dual radioisotope counting program was used for radioactivity counting. LiposoFast extrusion device from Avestin, Inc. (Ottawa, Canada) was employed for liposome preparation.

Preparation of yolk sac membrane microsomes from fertilized chicken eggs. The procedure described by Shand *et al.* (3) was followed. Yolk sac membranes were isolated from 15- or 16-d-old chick embryos, which were reported to have maximal ACAT activity (3). The membrane was washed in ice-cold NaCl (0.9 wt%) four or five times to remove excess yolk. The following steps were performed at 4°C. Yolk sac membrane was homogenized by a mechanical homogenizer in about 3 vol of medium I (0.25 M sucrose, 1 mM EDTA, 10 mM Tris-Cl, pH 7.4), and then was centrifuged at 10,200 × *g* for 15 min. The reddish supernatant was then centrifuged at 106,500 × *g* for 30 min. The pellet was suspended in medium II (50 mM MES, 50 mM Tris-Cl, pH 7.2) and centrifuged at 106,500 × *g* for another 30 min. The new pellet was resuspended in medium II. The microsomes had protein concentrations of 20 to 50 μg/μL and were stored in aliquots at –70°C.

Protein concentration was determined by the method of Lowry *et al.* (13).

ACAT assay. The assay for ACAT followed procedures reported by Doolittle and Chang (14) and Chautan *et al.* (15). Microsomes (160 μL) containing 15 to 250 μg protein were preincubated at 37°C for 10 min. To start the esterification reaction, 40 μL of ^{14}C-oleoyl CoA solution (250 μM ^{14}C-oleoyl CoA, 25 dpm/pmole and 12.5 mg/mL BSA,) was added to the assay mixture. After 5 min, 2 mL of hexane/2-propanol (3:2, vol/vol) was added, followed by 10 μL of cholesteryl-^{3}H-oleate (about 20,000 dpm), serving as an internal standard. The organic layer was separated and dried under a stream of N_2. The solid residue was redissolved in 200 μL hexane/diethyl ether (98:2, vol/vol) and applied to a column of 0.7 g silica gel (40–140 mesh) that had been prewashed with 3 mL hexane/diethyl ether. The cholesteryl oleate was eluted from the column with 6 mL hexane/diethyl ether and counted by a dual channel radioisotope counter.

Quantitation of synthesis of cholesteryl ester (CE), triacylglycerol (TAG), and phospholipids (PL) Microsomes (5 μL) containing 220 μg protein were incubated with 155 μL medium II or MβCD- medium II at room temperature for 30 min. The mixture was incubated at 37°C for 10 min prior to the addition of 40 μL ^{14}C-oleoyl CoA. Two milliliters chloroform/MeOH (2:1, vol/vol) was added to the mixture after a 5-min reaction time at 37°C followed by the addition of 10 μL ^{3}H-cholesteryl oleate. The top aqueous layer was extracted one more time with chloroform/MeOH (2:1, vol/vol), and the organic extracts were combined and dried under N_2. The solid residue was redissolved in 50 μL chloroform/MeOH (2:1, vol/vol) and applied onto a thin-layer chromatographic plate that had been prewashed in MeOH for 5 min and air-dried completely. For the quantitation of neutral lipids, the plate was developed in petroleum ether/diethyl ether/acetic acid (80:20:0.5, by vol) (16), and for complex lipids in chloroform/methanol/water/acetic acid (70:30:4:2, by vol) (17). Following comparison with standards, the spots corresponding to CE, TAG, or PL were scraped into a scintillation vial and counted for radioactivity.

Cholesterol depletion. Microsomes (1 mL) were mixed with 5 mL MβCD solution and stirred slowly at 4°C for 1 h. The amount of protein in the microsomes was 44 mg. The mixture was centrifuged at 106,500 × *g* at 4°C for 30 min. The pellet was suspended in 1.3 mL medium II and subjected to the same treatment with MβCD two more times and one wash with medium II. Gentle homogenization was sometimes needed during resuspension, and the final microsomes were prepared in a small volume of medium II to have a concentrated protein solution.

Preparation of liposomes. The liposomes were prepared

following the procedure of MacDonald *et al.* (18). Cholesterol was recrystallized twice from methanol and dissolved in chloroform. A solution of phosphatidylcholine (PC), 20 mg/mL in chloroform, was mixed with different amounts of cholesterol in chloroform so that varying mole ratios of cholesterol to PC were obtained. The combined solution was dried first under a stream of N_2 and then under vacuum at 40–45°C for 30 min. The waxy residue was suspended in medium II, and the final PC concentration was 10 mg/mL. The mixture was then frozen and thawed 10 times, using a dry ice–ethanol bath and a room temperature water bath, respectively. The multilamellar vesicles were extruded 19 times through two polycarbonate membranes (100-nm pore size) mounted on an extrusion device. The unilamellar liposomes were stored under N_2 at 4°C and used within 2 d. The concentrations of cholesterol and PC were determined for each liposome preparation.

Determination of cholesterol concentration. The procedure described by Sale *et al.* (19) was followed with moderate modification. Cholesterol was extracted three times from microsomes or liposomes using hexane/2-propanol (3:2, vol/vol). The solvent was evaporated under N_2, and the solid residue was redissolved in ethanol. Reagent A contained 822 μM 4-aminoantipyrine, 1.9 mM Na 3,5-dichloro-2-hydroxybenzene sulfonate, 200 IU/L peroxidase, and 50 mM phosphate buffer (3 mM Na cholate–0.5 vol% Triton X-100, pH 7.0), and was prepared on the day of the assay. To a 200-μL sample or standard containing 5 to 20 μg cholesterol in ethanol was added 1 mL reagent A. After a 10-min incubation at 37°C, the absorbance at 505 nm was measured and taken as blank. Ten microliters of 25 IU/mL cholesterol oxidase dissolved in 50 mM phosphate buffer was added to the sample prior to a second incubation at 37°C for 15 min. The absorbance at 505 nm was measured again, and the difference between the two readings was used to calculate the amount of cholesterol.

Determination of PL concentration. PL concentration was determined according to Harris and Popat (20), and the assumption was made that the majority of PL in the microsomes or liposomes had 1 mol of phosphorus per mol of PL. An aliquot of microsomes or liposomes in a final volume of 120 μL was mixed with 1 mL 70% perchloric acid. For the supernatant in the cholesterol depletion experiment, a larger volume of sample, e.g., 500 μL, was used to ensure a large enough sample of phosphorus, and the sample was first evaporated to dryness and then redissolved in 120 μL water. After digestion, 200 μL of digest was diluted with 1.7 mL H_2O followed by 200 μL 5 wt% ammonium molybdate and 400 μL Elon reducing reagent (20). Absorbance at 795 nm was measured 10 min later.

RESULTS

ACAT of yolk sac membrane was found to be quite tolerant of repeated freezing and thawing: specific activity (SA) of 753 ± 4.4 pmole/min/mg after the first cycle vs. 842 ± 16.0 after the sixth cycle, an increase of 12%. Freezing and thawing is generally destructive of protein structure, and enzymes tend to become inactive after repeated freezing and thawing. To investigate this phenomenon further, microsomes were thawed and stored at 4°C for 10 d. The ACAT activity was measured on the day the membrane preparation was thawed (d 0) and every other day thereafter. The experiment was carried out three times: the first experiment started the next day after the microsomes were prepared, the second experiment was after 3.5 wk storage at −70°C, and the third after 7 wk storage at −70°C. The results of these three experiments are shown in Figure 1. Storage of microsomes at −70°C slowly inactivated ACAT. When the microsomes were newly made and stored at −70°C overnight, the ACAT SA was 504 ± 6.4 pmole/min/mg (100%) (value at d 0). After 3.5 wk storage at −70°C, the SA decreased to 466 ± 7.9 pmole/min/mg (92%). After 7 wk at −70°C, the SA decreased to 395 ± 11.2 pmole/min/mg (78%). During storage at 4°C, the activity first increased, then slowly declined. Control experiments (not shown) showed that protease inhibitors had no effect on the initial rise in activity during 4°C storage although they slowed the later loss in activity. Oxidation with H_2O_2 or O_2 plus Cu^{2+} also had no appreciable effect on ACAT activity, nor did addition of various lipid hydrolysis products.

Incubation of microsomes with MβCD at concentrations up to 1 mM stimulated the enzyme activity: ACAT SA was 1088 ± 33.7 (1 mM) vs. 278 ± 4.6 (0 mM) pmole/min/mg, a 3.9-fold increase (Fig. 2). The synthesis of CE, TAG, and PL in the presence of 1 mM MβCD was measured (Fig. 3). The synthesis of CE was elevated 3.8-fold: 1782 ± 5.4 vs. 471 ± 24 pmole/min/mg, whereas synthesis of TAG and PL did not change significantly: TAG: 64.7 ± 2.2 vs. 92.6 ± 12

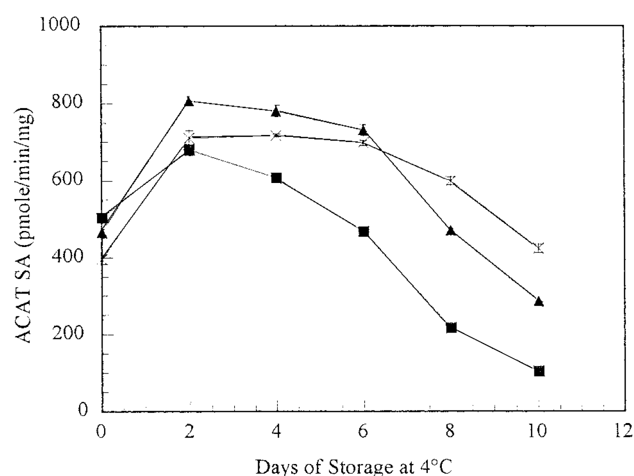

FIG. 1. Effect of storage at 4°C on acyl CoA-cholesterol acyltransferase (ACAT) activity. The microsomes were taken out of −70°C freezer, thawed, and stored at 4°C. ACAT activity was measured on the day they were thawed (day 0) and every other day thereafter. The line with ■ represents the experiment carried out the next day after the microsomes were prepared, and the lines with ▲ and × represent experiments done 3.5 and 7 wk later, respectively. Each value is a mean of duplicates with a bar showing the range; where no bar is shown, it is smaller than the symbol.

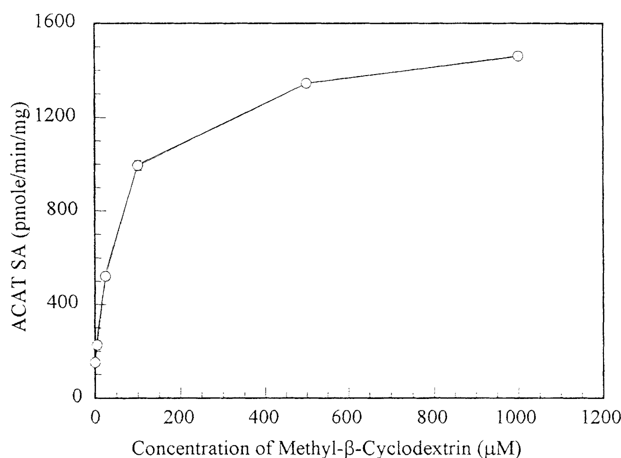

FIG. 2. Effect of methyl-β-cyclodextrin (MβCD) on ACAT activity. Microsomes (5 μL) containing 220 g protein were incubated with 155 μL MβCD-medium II (50 mM MES, 50 mM Tris-Cl, pH 7.2) at room temperature for 30 min followed by the regular ACAT assay. Each value is a mean of duplicates with a bar showing the range; where no bar is shown, it is smaller than the symbol. For abbreviation see Figure 1.

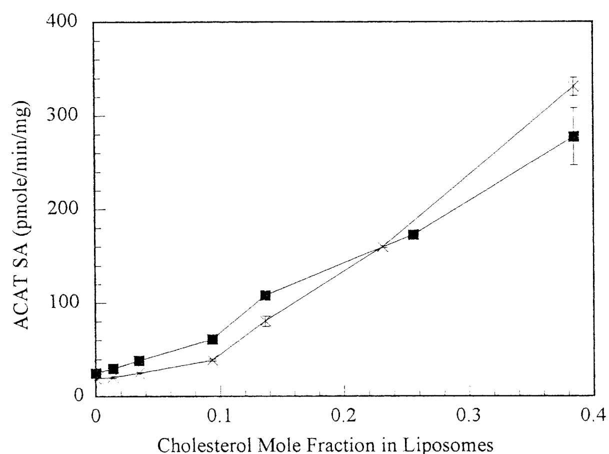

FIG. 4. Effect of cholesterol mole fraction on ACAT activity. Microsomes were taken out of the −70°C freezer and stored at 4°C for 2 d before the depletion experiment. Treated microsomes (5 μL) were incubated with 155 μL cholesterol–phosphatidylcholine liposomes of different mole fractions prior to the regular ACAT assay. In the experiment represented by the line with solid squares, microsomes were treated with 25 mM MβCD three times and incubated with liposomes at room temperature for 30 min. In the experiment represented by the line with ×, microsomes were treated with 25 mM MβCD twice and stored at 4°C overnight followed by the third treatment and wash, and the treated microsomes were incubated with liposomes at 4°C overnight. Each value is a mean of duplicates with a bar showing the range; where no bar is shown, it is smaller than the symbol. For abbreviations see Figures 1 and 2.

dpm/min/μg, and PL: 76.2 ± 1.2 vs. 57.5 ± 9.6 dpm/min/μg in the presence and absence, respectively, of MβCD.

Cholesterol in the microsomes was depleted by treatment with 25 mM MβCD, from initial levels of 0.067 to 0.016 μg/μg protein (Expt. 1) and 0.062 to 0.015 μg/μg protein (Expt. 2). The ACAT activity in the microsomes was assayed in the presence of increasing cholesterol mole fraction in PC-cholesterol liposomes (Fig. 4). In the control assays, the depleted microsomes were mixed with liposomes containing only PC, so the residual cholesterol from the microsomes represented mole fractions of 0.0018 and 0.0015 in the two experiments. Cholesterol in the liposomes stimulated ACAT activity 11-fold in the first experiment: 278 ± 30.6 (0.38 cholesterol mole fraction) vs. 25 ± 1.1 (zero cholesterol mole fraction) pmole/min/mg, and 17-fold in the second experiment: 331 ± 9.9 (0.38 cholesterol mole fraction) vs. 19 ± 1.1 (zero cholesterol mole fraction) pmole/min/mg (Fig. 4). Despite the substantial increase in the specific activity, the enzyme was not saturated with cholesterol at the highest cholesterol concentration used in the experiments.

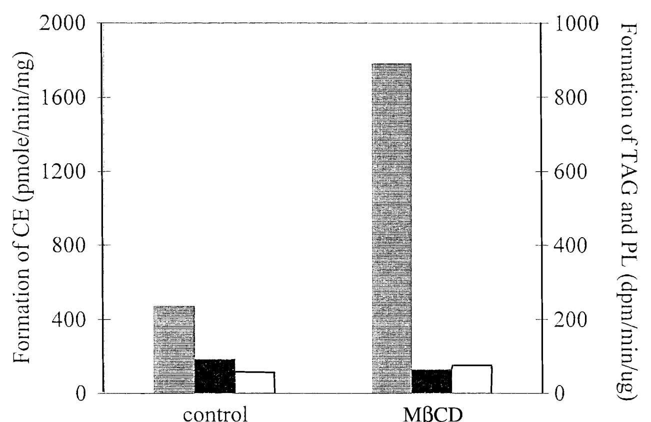

FIG. 3. Effect of MβCD on the synthesis of cholesteryl ester (CE: gray bar), triacylglycerol (TAG: black bar), and phospholipids (PL: open bar). Microsome preparations with 220 μg protein were incubated with 1 mM MβCD at room temperature for 30 min. The formation of CE, TAG, and PL was quantitated by a thin-layer chromatographic method as described in the Materials and Methods section. In all cases, the range is less than 17% of the mean. For abbreviation see Figure 2.

Cholesterol in microsomes was depleted to 0.007 μg/μg protein by treatment with 50 mM MβCD (final amount 0.0012 mole fraction in the ACAT assay when the microsomes were mixed with liposomes containing no cholesterol). The enzyme was again assayed in the presence of liposomes with varying amounts of cholesterol, with or without MβCD (Fig. 5). In the absence of MβCD, cholesterol stimulated ACAT activity 14-fold: 338 ± 5.1 (0.54 cholesterol mole fraction) vs. 24 ± 0.4 (zero cholesterol mole fraction) pmole/min/mg, but in the presence of MβCD, cholesterol stimulated the enzyme activity 63-fold: 1395 ± 7.3 (0.39 cholesterol mole fraction) vs. 22 ± 0.1 (zero cholesterol mole fraction) pmole/min/mg, and saturation of ACAT was observed.

DISCUSSION

The function of ACAT in the yolk sac membrane is to convert cholesterol and fatty acids in the yolk to CE, which can be packaged into lipoproteins and stabilize the assembly and structure of the particles secreted into circulation (4). Experiments with chicken embryos indicate that CE are synthesized extensively (about 80% of the free cholesterol is converted to

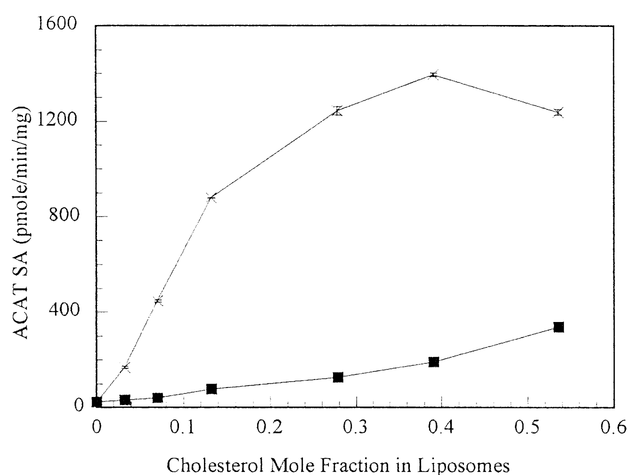

FIG. 5. Effect of cholesterol mole fraction on ACAT activity in the absence or presence of 1 mM MβCD. Microsomes were thawed and stored at 4°C for 2 d. After being depleted with 50 mM MβCD three times, 5 μL of the microsomes was incubated at room temperature for 30 min with cholesterol–phosphatidylcholine liposomes of different mole fractions in the absence or presence of 1 mM MβCD followed by the regular enzyme assay. The line with solid squares represents the assay in the absence of MβCD and the line with × represents the assay in the presence of 1 mM MβCD. Each value is a mean of duplicates with a bar showing the range; where no bar is shown, it is smaller than the symbol. For abbreviations see Figures 1 and 2.

CE) in the yolk sac membrane, and that esterification of cholesterol, which exists primarily as the free sterol in the yolk, facilitates the absorption of free fatty acids as well as cholesterol and contributes importantly to the absorption and transportation of lipid from yolk to embryos (4). Thus, ACAT plays an important role in the supply of lipid molecules as structural components and energy sources during embryo development (3,4). The properties of the avian enzyme were found to be comparable to those of the mammalian counterpart, including catalytically related histidine and cysteine residues and detergent-extractable activity (data not shown). The higher specific activity found in the yolk sac membrane (3) and better stability upon storage (data not shown) make this an attractive system for the study of ACAT.

Recent progress in molecular cloning of human macrophage ACAT (21) has accelerated the process of ACAT investigation, but study of the enzyme is still limited to microsomal preparations or detergent extracts because the enzyme has resisted purification. During the study of the avian ACAT, a nearly twofold activation of the enzyme was observed during storage at 4°C for 10 d (Fig. 1), and the following series of experiments was designed to investigate this phenomenon.

Mounting evidence suggests that under physiological conditions ACAT is not saturated with substrate cholesterol and that addition of exogenous cholesterol to microsomes can increase the synthesis of CE. It has been shown that cholesterol-rich and -poor domains are present in lipid bilayers inside the cell, and transport of the sterol among different membrane structures and the maintenance of the gradient of cholesterol require lipid carrier proteins and transporting vesicles (5). Upon break-up of the cell and subsequent cellular fractionation, the nonequilibrium condition of cholesterol is disrupted, and redistribution of the sterol among membrane fragments may now be able to proceed. Without adding cholesterol exogenously, Corton and Hardie (22) showed that redistribution of endogenous cholesterol among microsomal vesicles could increase ACAT activity and, in this case, that sterol carrier proteins possibly induced and facilitated the redistribution. The activation of ACAT observed in the 4°C storage experiment could be due to a redistribution of cholesterol in the microsomes during the storage period, with the redistribution leading to an increase in the ACAT substrate pool and resulting in the activation seen in the first 2 d of the experiment. To test the hypothesis, a means of systematically varying the cholesterol concentration in the substrate pool was required.

Cyclodextrins are macrocyclic molecules composed of varying numbers of glucose units. With a hydrophilic surface and hydrophobic interior, cyclodextrins can form inclusion complexes with hydrophobic molecules and enhance the solubility of lipophiles in aqueous solutions (23). Utilization of cyclodextrins in delivery of nonpolar drug molecules and supplementation of natural lipid carriers in circulation and cell cultures has been very important in pharmaceutical, clinical, and basic research (24–27), and the usefulness of these lipid-solubilizing sugar oligomers in cholesterol research is increasing. Studies of reverse cholesterol transport and intracellular cholesterol trafficking use cyclodextrins as effective cholesterol acceptors (28–31). Among the commercially available cyclodextrins, β-cyclodextrin with seven glucose units is the most effective molecule to solubilize cholesterol from lipid bilayers (8,9). Cyclodextrins themselves are quite toxic to animals, and their solubilities in aqueous solutions are limited. Derivatives of cyclodextrins have been synthesized chemically and found to be much less toxic and more soluble (25). In their study of reverse cholesterol transport, Kilsdonk *et al.* (28) found that the methyl derivative of β-cyclodextrin was more effective than the 2-hydroxypropyl derivative or β-cyclodextrin itself in extracting cholesterol from the plasma membrane of mouse L-cell fibroblasts. Not only are cyclodextrins used as acceptors in cholesterol depletion experiments, but also complexes of cholesterol with cyclodextrins can efficiently provide the sterol to membranes or cells in cholesterol repletion experiments (11,32).

Addition of MβCD to microsomes enhanced ACAT activity greatly, nearly a fourfold increase in ACAT SA (Fig. 3). The results of these experiments suggest that MβCD can shuttle cholesterol among microsomal fragments, from cholesterol-rich microdomains to cholesterol-poor microdomains, or from non-ACAT substrate pools to the ACAT substrate pool, and the enhanced redistribution of cholesterol results in increased enzyme activity. Other membrane-associated activities, synthesis of PL and TAG, did not increase in the presence of MβCD, strengthening the conclusion that enhanced access to cholesterol is the basis for the stimulation of ACAT. Thus, redistribution of cholesterol among microsomal vesicles during the storage period was very likely the mechanism

that increased ACAT activity seen in the first 2 d of the experiments (Fig. 1). During the course of this study, Liza *et al.* (33) reported an approximately fourfold activation of rat liver microsomal ACAT in the presence of 6 mM 2-hydroxypropyl-β-cyclodextrin and explained the activation as a result of the facilitated redistribution of cholesterol in the presence of the cyclodextrin molecule. Therefore, increases in ACAT activity because of cholesterol redistribution may be quite general. An increase in ACAT activity during storage of mammalian microsomes may not be apparent because the mammalian enzyme is less stable than the one from egg yolk membrane used in this study and loses activity even though cholesterol redistribution is occurring. In one instance, Cheng *et al.* (34) observed a nearly twofold increase in ACAT activity when they compared cell extracts incubated for 30 min at 37°C or at 4°C. It is plausible to suggest that a faster redistribution of cholesterol at the higher temperature was the factor leading to the increase. The activation of ACAT by redistribution of cholesterol in the absence of MβCD did not exceed twofold, whereas in the presence of the cyclodextrin, a nearly fourfold increase in the activity was observed (Fig. 2). ACAT remained fully active for about 4 d before beginning to lose activity. Thus, different extents of activation of the enzyme do not depend upon loss of enzyme under the same conditions.

To study the effect of cholesterol concentration on avian ACAT activity, microsomes of yolk sac membrane were depleted of cholesterol by repeated treatments with MβCD and then assayed with liposomes with varying ratios of cholesterol to PC. As shown in Figure 4, ACAT activity increases progressively with increasing cholesterol mole fraction, without reaching a plateau. At the highest concentration used, 0.38 mole fraction, and with overnight incubation with the liposomes, ACAT was not saturated with cholesterol. According to Yeagle (35), plasma membranes normally contain about 0.45 mole fraction of cholesterol, and ER membranes have 0.10–0.12 mole fraction of the sterol. The cholesterol mole fraction in microsomes of yolk sac membrane was measured to be from 0.099 to 0.12, in very good agreement with the literature. At around 0.10 mole fraction of cholesterol, the human macrophage ACAT activity was shown to reach a plateau (34), but the mouse liver enzyme reached a plateau at a higher cholesterol mole fraction (about 0.3) (36). Perhaps the avian enzyme has a very high K_m, or a change in membrane properties caused by increasing concentrations of cholesterol prevents saturation of the enzyme. A third possibility is that the transfer of cholesterol from cholesterol–PC liposomes to microsomes is slow, limiting the access of the sterol to the ACAT substrate pool. Since MβCD is capable of facilitating cholesterol redistribution among microsomal vesicles, it should enhance the transfer of cholesterol from liposomes, the source of substrate, to the microsomes, the site of enzyme catalysis. Indeed, when the depleted microsomes were assayed with liposomes of increasing cholesterol mole fractions in the presence of 1 mM MβCD, the enzyme activity reached a maximum around 0.4 cholesterol mole fraction (Fig. 5). Thus, failure to saturate the enzyme with a high concentration of cholesterol (Fig. 4) is the result of limitation of substrate movement, and the use of MβCD accelerated the transfer of cholesterol from liposomes to the enzyme substrate pool and minimized that restraint.

The usefulness of MβCD in the study of ACAT is clearly seen in Figure 5 where the enzyme shows saturation kinetics in the presence of the cyclodextrin but not in its absence. The ACAT assay solution was a mixture of microsomal vesicles and small unilamellar liposomes (in the extrusion device used to prepare liposomes, the membrane pore size was 100 nm). Cholesterol in the microsomal membranes was depleted to about 1/10 of the usual content in the ER membrane, so that the major supply of the sterol was from liposomes. Encounter of cholesterol in the liposomes with ACAT on the ER membrane could be achieved in two ways. It could diffuse through the aqueous medium, but desorption of the sterol from lipid bilayers and aqueous diffusion would be very slow considering the solubility of the sterol in aqueous solution. In pure water, the solubility of cholesterol is 1.8 μg/mL or 4.7 μM (37). Or, movement of the sterol between membranes could be promoted by collision or contact of ER membranes with liposomes, and the efficiency of cholesterol transfer from one bilayer to another may very well depend on the duration and distance of the contact and may not be high. Cholesterol transport inside the cell among different membrane compartments is proposed to proceed through three possible mechanisms: aqueous diffusion, vesicle-mediated transport, and soluble protein or lipid carriers. Vesicular transport and cytosolic carriers are most likely the major mechanisms (38,39). Artificial vesicles like liposomes lack the possible protein and lipid factors that mediate cellular lipid transfer between bilayers or vesicle–membrane fusion, so artificial vesicles may not function effectively in some *in vitro* studies (5). The access of cholesterol to the ACAT substrate pool is a problem in the study of regulation of ACAT, which the use of MβCD can mitigate.

Very recently, Chang *et al.* (40) reported purification of the recombinant ACAT of human origin and the sigmoidal response of ACAT specific activity toward cholesterol concentration. An allosteric effect of the sterol on the enzyme was proposed. In his book, however, Segel (41) described another kinetic mechanism in which a sigmoidal profile of activity vs. concentration does not associate cooperative substrate binding. In this mechanism, the enzyme catalyzes a Random Bi Bi reaction, and the formation of the complex—enzyme-substrate 1-substrate 2—is much slower than the conversion to products and one route to products is favored over the other. The possibility of a slow formation of ACAT-cholesterol-acyl-CoA complex is not unlikely and may be worth investigation.

ABSTRACT: The effects on bile acid and sterol transformation of clostridia (fusiform bacteria), the dominant intestinal bacteria in rodents (*ca.* 10^{10} counts per g wet feces) were examined in Wistar rats. After inoculation of clostridia into germ-free rats and into rats previously inoculated solely with *Escherichia coli*, most of the endogenous bile acids were deconjugated, and cholic acid and chenodeoxycholic acid were 7α-dehydroxylated to deoxycholic acid and lithocholic acid, respectively. Tauro-β-muricholic acid, another major bile acid in rats, was deconjugated, but only part of it (*ca.* 30%) was transformed into hyodeoxycholic acid. Cholesterol and sitosterol were also reduced to coprostanol and sitostanol, respectively. *Escherichia coli* transformed neither bile acids nor sterols. These data suggest that clostridia play an important role in the formation of secondary bile acids and coprostanol in rats.

Paper no. L8023 in *Lipids 34,* 269–273 (March 1999).

Intestinal bacteria biotransform bile acids (1,2). Deconjugation, dehydroxylation, oxidation–reduction, and epimerization are the major reactions in bile acid metabolism, whereas deconjugation and 7α-dehydroxylation are the most important. Since the major bile acids found in human feces are deconjugated and 7α-dehydroxylated, deoxycholic acid and lithocholic acid arise from taurine- or glycine-conjugated primary bile acids. In the case of rats and mice, taurine-conjugated cholic acid and β-muricholic acid are major bile acids synthesized in the liver. Cholic acid is transformed to deoxycholic acid, and β-muricholic acid to β-hyocholic acid (previously called as ω-muricholic acid) and further to hyodeoxycholic acid by intestinal bacteria.

Deconjugation activity is found in many species of intestinal bacteria (3) but those possessing 7α-dehydroxylation activity are limited. 7α-Dehydroxylating activity is found in *Clostridium* (4–7), *Bacteroides* (8), *Lactobacillus* (9), *Eubacterium* (4,5,10,11) and in as yet unclassified intestinal bacteria (4,5). The population of these 7α-dehydroxylating bacteria is not large, and their counts are only 10^5–10^6 per g wet feces, while the counts of dominant intestinal bacteria possessing no 7α-dehydroxylation activity (12) are around 10^{11}–10^{12} per g wet feces.

Previously, we found that fecal deoxycholic acid and coprostanol formed from cholesterol by intestinal bacteria were markedly decreased in cecectomized (13) or totally colectomized rats (14). Eyssen *et al*. (15) also reported that production of coprostanol is abolished in cecectomized rats. On the other hand, clostridia, or fusiform bacteria, grow only in the cecum of rats and mice, and the population is 10^{10} counts or more per g feces (16).

Therefore, we suspected that clostridia participated in the biotransformation of bile acids and cholesterol in rats, and found that a significant formation of secondary bile acids and coprostanol was achieved in the clostridia monoassociated germ-free rats.

MATERIALS AND METHODS

Animals and treatments. Germ-free Wistar rats (*ca*. 4 mon old) bred in our laboratory (Shionogi Aburahi Laboratories, Shiga, Japan) were housed individually under germ-free conditions and inoculated orally with clostridia (fusiform bacteria) and *Escherichia coli* isolated from conventional rats kept in our laboratory.

Clostridia were collected from the large intestinal content after treatment with chloroform (only spores survive) by procedures described previously (16). Since a culture system for clostridia has not yet been established, the chloroform-treated intestinal contents were suspended in Trypticase Soy Broth (BBL, Cockeysville, MD) and directly administered to rats. *Escherichia coli* was cultured for 72 h at 37°C in GAM semifluid media (Nissui Co., Tokyo, Japan). After thorough mixing, a 1-mL aliquot containing *ca*. 10^8 bacteria was administered to each rat.

Germ-free rats were divided into three groups, each consisting of two males and two females. The first group was inoculated with clostridia, the second group was with *E. coli* and then clostridia 1 wk after the inoculation of *E. coli*, and the third group was given the feces of conventional rats.

The rats were fed a commercially available chow diet (CMF Diet; Oriental Kobo Co., Tokyo, Japan) sterilized by

γ-irradiation at 50 kGy. The feces were collected every day for 6 wk after inoculation of clostridia. At the end of the experiment, the rats were killed and the numbers of viable bacteria in the fresh feces were examined (16,17).

Determination of fecal bile acid and sterols. A portion of feces (usually *ca*. 1 g) was extracted three times with 20 mL ethanol at 85–90°C for 1 h. After filtration, a portion of the extract was subjected to ion-exchange chromatography on a piperidinohydroxypropyl Sephadex-LH-20 (PHP-LH-20, Shimadzu, Kyoto, Japan) gel column (18) to obtain the fractions of free, glycine-conjugated, taurine-conjugated, and sulfated bile acids. The sulfate fraction was hydrolyzed using sulfatase and β-glucuronidase (19) and then subjected to piperidinohydroxypropyl Sephadex-LH-20 column chromatography to obtain the fractions of free, glycine-conjugated, and taurine-conjugated bile acids. The bile acids were analyzed by high-performance liquid chromatography on a reversed-phase column (Develosil ODS-HG-5, 15 cm × 4.6 mm i.d.; Nomura Chemical, Seto, Japan) at room temperature and quantified using an immobilized 3α-hydroxysteroid dehydrogenase column with postcolumn fluorescent detection (19,20). Tauro-23-nordeoxycholic acid was used as an internal standard.

Fecal sterols were reextracted with *n*-hexane from the ethanol extract, converted to trimethylsilyl ether derivatives with trimethyl silyl imidazole, and quantified by a Shimadzu gas–liquid chromatograph Model GC-14A (Shimadzu, Kyoto, Japan) equipped with a methylsilicon capillary column (Hicap CBP-1, 25 m × 0.25 mm i.d., Shimadzu), a flame-ionization detector, a solventless injector, and a Chromatopak C-R4A integrator (Shimadzu). The column temperature was kept at 260, the injector port at 305, and the detector at 300°C.

RESULTS

Bacterial counts in the feces after 6 wk of inoculation are shown in Table 1. Only clostridia were detected in the first group; *E. coli* and clostridia were detected in the second group, and a usual pattern of intestinal flora was established in the third group. The counts of clostridia reached on the order of 10^{10} per g feces in all the rats.

[a]Rat number.
[b]N.D., not detected (less than 10^2 counts/g feces).
[c]Log counts/g feces, 6 wk after inoculation.

The bile acids were analyzed after fractionating into free, glycine-conjugated, taurine-conjugated, and sulfated bile acids; but only a trace amount of bile acids, less than 0.01 μmol/g feces, was detected in the glycine-conjugate and sulfate fractions.

The fecal bile acids were composed of taurine-conjugated primary bile acids under germ-free conditions (0 wk), but most of the bile acids (>97%) were deconjugated and the secondary bile acids were formed as early as 1 wk after the inoculation of clostridia. The composition ratio of fecal bile acids remained almost unchanged thereafter, resembling that in the ex-germ-free rats given conventional rat feces 6 wk before.

In the second experiment, clostridia were inoculated 1 wk after the first inoculation with *E. coli*. This action was expected to enhance the growth of clostridia by making the intestinal lumen more anaerobic. *Escherichia coli* caused neither deconjugation nor formation of secondary bile acids, but the changes in the fecal bile acid composition after inoculation of clostridia were very similar to those in clostridia monoassociated rats.

Since no difference was found between the first and second experiments in the changes of the fecal bile acid composition after clostridia inoculation, both data were combined and are shown in Table 2. Three days after inoculation, most of the bile acids were deconjugated, and considerable amounts of unconjugated primary bile acids, such as cholic acid and β-muricholic acid, were detected. Unconjugated cholic acid decreased markedly 1 wk after inoculation, but unconjugated β-muricholic acid remained high. Secondary bile acids such as deoxycholic, lithocholic, and β-hyocholic acids were at relatively low levels after 3 d, but, after at least a week, the levels increased. 7-Oxo-deoxycholic acid levels were high after 3 d but decreased thereafter.

Table 3 shows the fecal bile acid composition in male and female germ-free rats, those inoculated with clostridia (with and without an *E. coli* preinoculation) and those with rat feces 6 wk before. The fecal bile acid composition in the clostridia-inoculated rats was very similar to that in the conventional rats, suggesting that clostridia are primarily responsible for the formation of secondary bile acids in rats.

Subsequently, changes in the composition ratio of deoxycholic acid in 12α-hydroxyl bile acids (cholic acid group), of coprostanol in C-27 sterols (cholesterol plus coprostanol), and of sitostanol in C-29 sterols (sitosterol plus sitostanol) in the feces after clostridia inoculation were examined. As shown in Figure 1, the formation of deoxycholic acid increased to values of 60–75% after 1 wk in rats inoculated with only clostridia and with *E. coli* plus clostridia together, and remained at these levels thereafter. However, the formation of coprostanol and also that of sitostanol were somewhat delayed compared with that of deoxycholic acid, especially in clostridia monoassociated rats. *Escherichia coli* did not form coprostanol or sitostanol by itself, but previous inoculation of *E. coli* enhanced the formation of these sterols by clostridia.

[a]Mean ± SE (*n* = 4 rats). T, taurine conjugated; U, unconjugated. Compound designation: substituted 5β-cholan-24-oic acids. Greek letters denote configuration of hydroxyl groups at C-3, C-6, C-7, or C-12.

Coprostanol was not found in the diet, but sitostanol was present. A considerable amount of sitostanol was detected in the feces of germ-free rats (Fig. 1C).

DISCUSSION

The present data showed that clostridia, or fusiform bacteria, are capable of biotransforming bile acids and cholesterol in rats as do the usual intestinal microflora in conventional rats. The bacterial counts were 10^{10} per g wet weight feces in ex-germ-free rats after inoculation of clostridia, and this level was comparable to that in conventional rats.

Clostridia are found in rodents and comprise over 50 biovars (16). They grow in the cecum and are believed to require highly anaerobic conditions for growth. Since no *in vitro* culture systems have yet been fully established, we examined the

[a]Mean ± SE (*n* = 4 rats).
[b]Mean ± SE (*n* = 2 rats. For abbreviations see Table 2.

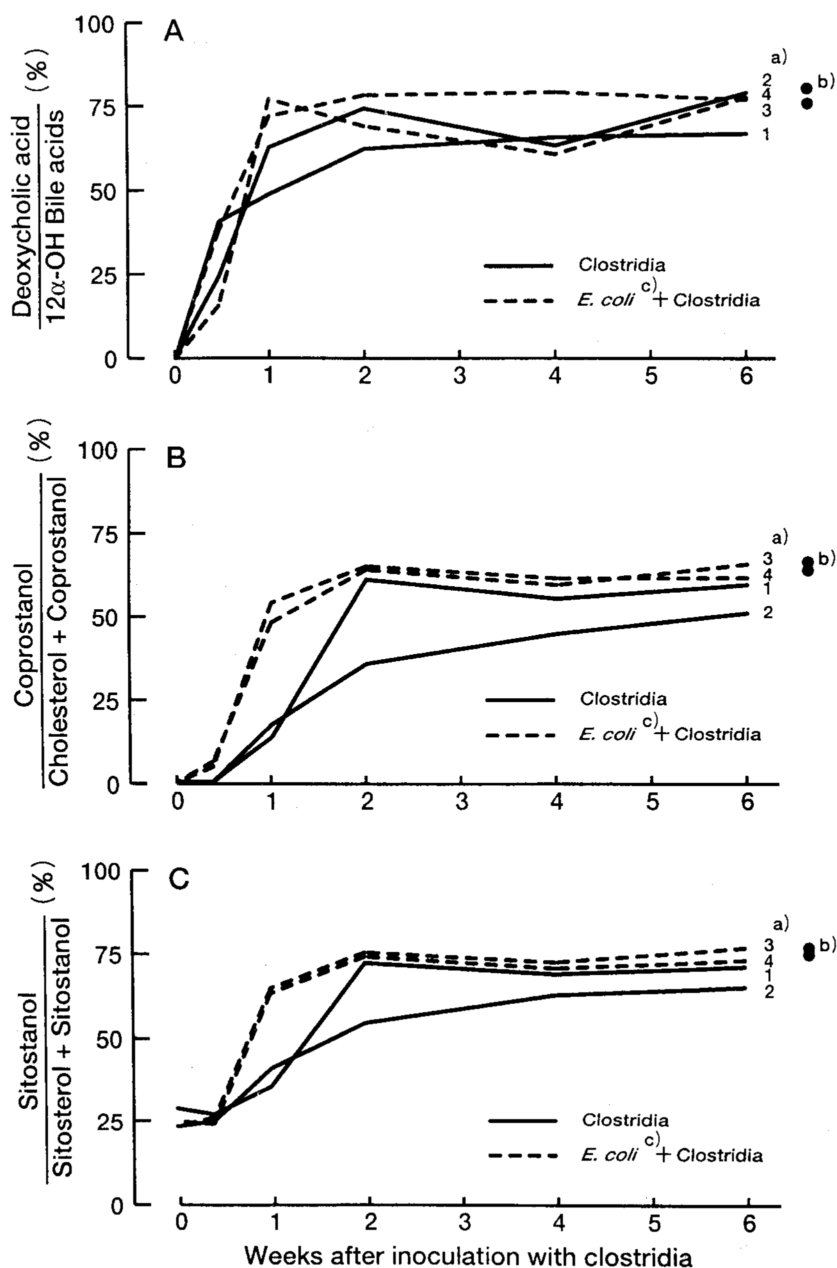

FIG. 1. Changes in the composition ratios of deoxycholic acid in 12α-hydroxyl bile acids (A), coprostanol in C-27 sterols (B), and sitostanol in C-29 sterols (C) in the feces of male germ-free rats inoculated with clostridia with and without preinoculation of *Escherichia coli.* [a]Rat #; [b]rats given conventional rat feces; [c]*E. coli* preinoculated 1 wk before the inoculation of clostridia.

effect of clostridia in germ-free rats and in *E. coli* preinoculated rats because *E. coli* does not biotransform bile acids (12) and its presence was expected to increase the anaerobic conditions in the intestinal lumen.

Escherichia coli did not affect the fecal bile acid or sterol composition in these experiments, and no differences were found for the effect of clostridia on fecal bile acids between germ-free and *E. coli* preinoculated rats, suggesting that clostridia grow in germ-free and *E. coli*-monoassociated rats. However, the formation of coprostanol and sitostanol after clostridia inoculation was delayed in germ-free rats compared with *E. coli* preinoculated rats (Fig. 1). These observations suggest that the growth of clostridia biovars responsible for coprostanol formation is enhanced by *E. coli* pre-inoculation, and these biovars may be different from those responsible for deoxycholic acid formation.

Major bile acids found in germ-free rats were taurine-conjugated cholic and β-muricholic acids. Both bile acids were deconjugated after clostridia inoculation, and most cholic acid was further transformed to secondary bile acids, but

β-muricholic acid was rather resistant to biotransformation by clostridia. Low conversion of β-muricholic acid was also noted in germ-free rats after implantation of human microflora (21).

Which bacteria in human intestinal microflora correspond to the present clostridia in rats is not yet known but some species of human intestinal bacteria have been reported to have 7α-dehydroxylation activity (4–11), although the counts of 7α-dehydroxylating positive bacteria were as low as 10^5–10^6 counts per g wet weight feces. Stellwag and Hylemon (7) reported that the 7α-dehydroxylation activity of mixed fecal bacteria was 0.06–0.012 μmol/h·mg protein for cholic acid in an *in vitro* system. Most cholic acid is 7α-dehydroxylated in human and also in rats. This formation of deoxycholic acid *in vivo* seems not to be achieved by the activity reported for cholic acid *in vitro*. On the other hand, 7α-dehydroxylation activity and also 7β-dehydroxylation activity of *Eubacterium* were reported to be enhanced by the presence of *Bacteroides,* which exhibits no activity by itself (10). These data suggest that a mechanism as yet unknown enhances 7α- and 7β-dehydroxylation activities.

ABSTRACT: Alpine marmots (*Marmota marmota*) were maintained on a laboratory diet, and the fatty acid composition of gonadal and subcutaneous white adipose tissues (WAT) was studied during a yearly cycle. Fatty acids (FA) released from isolated adipocytes were also identified after stimulation of *in vitro* lipolysis. Analysis of the FA composition of WAT depots showed that marmot WAT mainly contained monounsaturated FA (65%, mostly oleic acid, 18:1n-9) although laboratory food contained 45% of linoleic acid (18:2n-6) and only 21% of 18:1n-9. During stimulated lipolysis, saturated FA were preferentially released from isolated adipocytes whereas unsaturated FAs were retained. Despite this selective release of FA from isolated WAT cells *in vitro*, and despite the FA composition of the food, marmots maintained a constant FA composition in both WAT depots throughout the year. Six months of hibernation and fasting as well as an intense feeding period did not affect this composition. The potential adaptive benefit of such regulation of WAT composition, based on a high level of monounsaturated FA, might be to maintain fat with appropriate physical properties allowing animals to accommodate to and survive the wide range of body temperatures experienced during hibernation.

Paper no. L7978 in *Lipids 34*, 275–281 (March 1999).

Alpine marmots (*Marmota marmota*) exhibit a marked yearly rhythm of food intake, with a feeding period during summer and a fasting period during hibernation, which can last 5 to 6 mon depending on geographic and climatic conditions (1,2). During hibernation, marmots alternate long torpor bouts [lasting 10–15 d with a body temperature (Tb) regulated a few degrees above 0°C] with short euthermic phases [lasting 1–2 d with a Tb of 37°C (3)]. Rewarming during arousal mainly depends on brown and white fat lipid oxidation (4–6). Large hibernating mammals such as marmots therefore rely mainly on their large fat deposits, which can reach 50% of their body mass prior to hibernation (reviewed in Ref. 7). Nearly 80% of this stored fat can be used during hibernation (8).

In small rodents, such drastic depletion in fat mass may affect the lipid composition of adipose tissue because of the known differential mobilization of fatty acids (FA) during fasting (9). Therefore, after several days of starvation in the rat, the relative distribution of the remaining FA in white adipose tissue (WAT) is profoundly altered (9). If such change in lipid composition occurs in long-term fasting hibernators, it may in turn have marked effects on hibernation. Indeed, it was shown that diet-induced changes in lipid composition of WAT affect hibernation characteristics. Deficiency in essential FA (linoleic acid, 18:2n-6; and α-linolenic acid,18:3n-3) led to marked changes in the hibernation pattern of marmots (10,11). Similarly, feeding a high polyunsaturated acid diet to chipmunks (*Tamias amoenus)* altered their hibernation bout lengths and the minimum Tb reached during deep hibernation (12). These physiological effects may be due to changes in the FA composition of cell membranes and fat stores, which would alter physical properties such as fluidity at low Tb. Although of likely functional importance, WAT lipid composition during an annual cycle with regard to preferential mobilization of FA released by lipolysis has not been investigated in marmots.

The aim of the present study was to investigate the FA composition of two WAT depots (subcutaneous and abdominal) throughout an entire annual cycle in captive marmots maintained on identical laboratory diets. Furthermore, isolated adipocytes from these two depots were stimulated *in vitro* so that we could analyze the composition of the FA released during the annual cycle.

MATERIAL AND METHODS

Animals. Marmots were trapped in the French Alps (Bonneval-sur-Arcs, Savoie). The study was performed on 12 adults (6 males and 6 females). Marmots were cared for under the French Code of Practice for the Care and Use of Animals for Scientific Purpose, and the experimental protocols were approved by the French Ministry of Agriculture Ethics Committee (Animals). They were caged in pairs under outdoor conditions of photoperiod and ambient temperature (Ta) during the summer (Ta ranged from 15 to 25°C) and during the hibernation season in a cold room (Ta = 6 ± 1°C, light/dark 0:24). Standard food (rodent chow pellet, Genthon, Cheyssieu,

France) was given to the animals. Food and water were provided *ad libitum* after the emergence from hibernation (April) and were removed when the animals ceased to feed in late fall. The mean body mass loss during hibernation was 29.4% for males and 34.0% for females (6.8 kg *vs.* 4.8 kg and 5.8 *vs.* 3.8 kg, respectively) and was not significantly different between genders.

Sequencing of the cycle. The marmot cycle was studied for 15 mon, beginning in October and finishing in late December of the following season (see Fig. 1). In the first part of the cycle, the period of hibernation occurred within the fasting period. During the second part of the study, marmots reduced their food consumption in mid-September, somewhat earlier than in the previous year. This drop in food consumption coincided with a sudden drop in the outdoor temperature, which was a few degrees above 0°C during the night. During the study, animals were kept alive and sampled at least twice during the experimental cycle (except for marmot #4 which was sampled once, see Fig. 1). The sampling frequency was approximately one animal every 15 d. Because marmots did not start fasting at the same time prior to the first and second hibernation season, we decided to consider only the periods in which all the animals were both hibernating and fasting (Fasting period) or both active and eating (Food Intake period). Among the 12 marmots we used in this study, 7 were sampled once at both periods (marmots #1, 5, 6, 7, 8, 9, 11) and then data on these 7 were used to perform the statistical analysis.

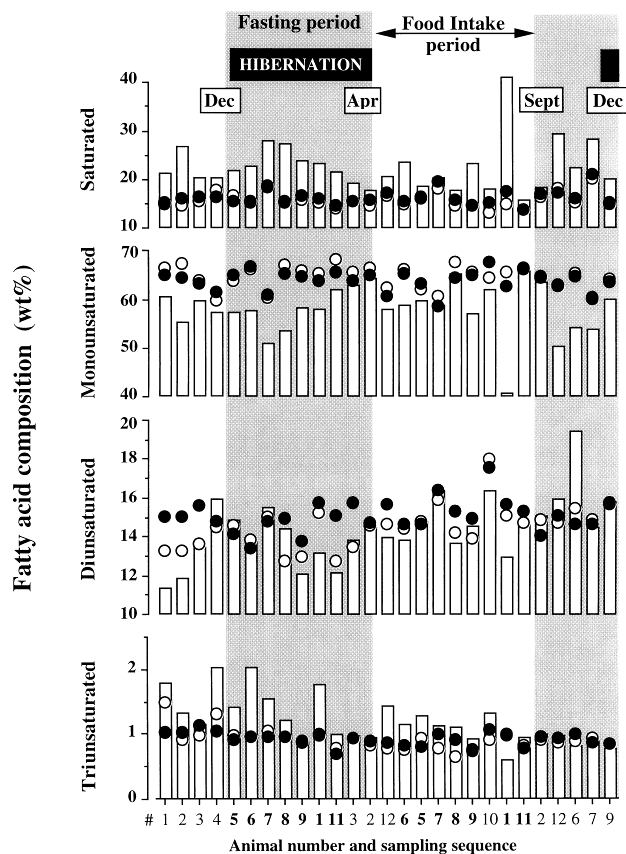

FIG. 1. Fatty acid composition of gonadal (open circles) and subcutaneous white adipose tissue (closed circles) compared to the composition of the fatty acids released *in vitro* (open bars) from gonadal isolated adipocytes over the annual cycle of marmots. The sampling sequence was approximately one animal every 15 d. The identification number of the marmots is reported on the abscissa and the numbers in bold indicate marmots used for statistics; for comments see the paragraph on "Sequencing of the cycle" in the Materials and Methods section.

Adipose tissue samplings. Gonadal and inguinal subcutaneous WAT was surgically removed from marmots during the active and hibernating periods. In summer, nonhibernating marmots were fasted overnight before being anesthetized the next morning with zoletil 100 (Virbac, Carros, France; 100 mg/kg) and a fat biopsy performed (4–5 g). In winter, fasting hibernating marmots were removed from the cold room 24 h before surgery and allowed to arouse at room temperature (Ta = 21°C) without any food being available. Marmots were then anesthetized and biopsies were performed as described above. Fat samples were either immediately frozen at −30°C until lipid extraction and analysis or else minced in a collagenase buffer and incubated at 37°C for adipocyte isolation. Rodent pellet samples were collected four times over the food intake period to analyze the lipid composition of the diet.

To investigate whether the diet could similarly influence the WAT composition in another species, we also analyzed the FA composition of gonadal WAT from 6-mon-old rats fed the same diet. Gonadal WAT samples from rats were treated as described above for marmot WAT samples.

Composition of fatty acids released after in vitro *stimulated lipolysis.* At different times during the yearly cycle, the FA composition found in the fat depots was compared with the composition of the FA released *in vitro* after stimulated lipolysis of gonadal and subcutaneous WAT (feeding period only). This was achieved by preparing a suspension of 30–35 mg of isolated adipose cells per milliliter of buffer as described previously (13) with slight modifications. The pieces of gonadal and subcutaneous WAT were subjected to collagenase P digestion (0.3 mg/mL, Boehringer-Mannheim Chemicals, Meylan, France) in a Krebs-Hepes buffer (10 mM, pH = 7.4) containing 5% (wt/vol) of FA free bovine serum albumin and 6 mM glucose. An aliquot of the cell suspension was incubated at 37°C (shaking water bath) in polypropylene microcentrifuge tubes, and lipolysis was stimulated with adrenocorticotropic hormone (ACTH, from Sigma Chemicals, Saint Quentin Fallavier, France). ACTH was as effective as norepinephrine in stimulating FA release from isolated marmot adipocytes as noted in rats (14) and in rabbits (15,16). After 1 h incubation, samples were centrifuged and cells were removed by vacuum suction. Fatty acids in the medium were recovered with chloro-form/methanol (2:1, vol/vol) containing 50 mg/L of butylated hydroxytoluene (BHT) and stored immediately at −30°C under nitrogen prior to lipid extraction and analysis.

FA analysis. WAT samples were homogenized in chloroform/methanol (2:1, vol/vol) containing 50 mg/L of BHT, extracted, and purified according to the procedure of Folch *et al.* (17). Lipids were evaporated to dryness under a stream of

nitrogen, taken up in an appropriate volume of chloroform/methanol, and stored in glass tubes at −30°C under nitrogen. The methylation was performed according to Slover and Lanza (18) with minor modifications. A known amount of heptadecanoic acid (17:0) was added as an internal standard, transmethylation was achieved by heating at 80°C for 150 min in methanol/sulfuric acid (98:2, vol/vol). After neutralization with a 5% K_2CO_3 solution, methyl esters were extracted in hexane and dried on anhydrous sodium sulfate. Samples were analyzed by gas–liquid chromatography at constant oven temperature (180°C) over the whole run, using a Chrompack CP-9001 (Chrompack, Middelburg, The Netherlands) equipped with a silica 50 m × 0.25 mm i.d. capillary column coated with CP SIL88, using nitrogen as the carrier gas. FA standards were run periodically to determine correct retention times for the FA identification. Peaks were measured using Maestro Chromatography data system software (Chrompack).

Statistics. The composition of FA from both depots (gonadal and subcutaneous) and of FA released from gonadal WAT were compared over the same period and between food intake and fasting periods using a one repeated factor two-way-analysis of variance with Bonferoni/Dunnett *post-hoc* tests ($P < 0.03$). Before calculations, percentage values were transformed into angular values [arcsin root of (value/100)].

RESULTS

Marmot gonadal and subcutaneous WAT composition did not change significantly over the year (Fig. 1). It is clear from this figure that no profound variation in the saturated FA (SFA), monounsaturated FA (MUFA), and polyunsaturated FA (PUFA) composition occurred in either of the depots in either the feeding or fasting period. In addition, no significant difference between depots was observed between the food intake/fasting periods (Table 1). Within depots, small though significant differences in MUFA and PUFA (mainly diunsaturated and triunsaturated) composition were observed between the food intake and fasting periods. The unsaturation index was similar in both depots and did not change during the year.

Marmot WAT FA composition differed markedly from that

[a]Fatty acids (mean ± SEM) are expressed in wt% of the total fatty acids identified. WAT, white adipose tissue.

of the diet (Table 2). The linoleic acid (18:2n-6) content of marmot gonadal and subcutaneous WAT depots (13–15%) was three times lower than that found in the rodent diet (45%, Tables 1 and 2), whereas oleic acid (18:1n-9) content (55–57%) was three times higher in both marmot fat depots as compared with the diet (21%, Tables 1 and 2). The total SFA content in marmot WAT was decreased by 7% in comparison with the diet, and the linolenic content by 2%.

In rats, the WAT composition reflected more closely the laboratory diet composition than in marmots. In rat WAT (Table 2), the 18:2n-6 content was 35.5% (diet was 45%). This decrease in the percentage of 18:2n-6 was balanced by high SFA and MUFA content, and the relative percentage of α-linolenic acid (18:3n-3, 1.7%) was nearly 50% of that ingested and presumably absorbed from the diet (3%).

The composition of FA released into the medium was quite different from that found in WAT, as indicated by the lowering of the UI of the total FA identified in the medium after *in vitro* lipolysis (compare Tables 1 and 3). The main differences observed were for 14:0, 16:0, and 18:0. Bars in Figure 1 also

[a]Fatty acids (mean ± SEM; gonadal, *n* = 7; subcutaneous, *n* = 4) are expressed in wt% of the total.
[b]Release of fatty acids from subcutaneous WAT isolated adipocytes taken from animals during the fasting period was not determined.
[c]Significant difference between Food Intake and Fasting periods within a same depot ($P < 0.05$).
[d]Significant difference between gonadal WAT composition and fatty acids released from gonadal WAT after an *in vitro* lipolysis.
[e]—, below the detection limit. For abbreviations see Tables 1 and 2.

show the clear difference between the FA released from gonadal adipocytes *in vitro* and gonadal WAT composition. This suggests a preferential release of SFA throughout the whole cycle whereas MUFA appeared to be retained. However, we do not know how the absolute concentration of each FA changes but only how each FA changes as a percentage of the total. It follows that the increased release of one FA species will result in an apparent decreased release of other FA species.

In the case of fasting, the same general results were observed in gonadal WAT as seen during the feeding period (Tables 1 and 3), although slight differences emerged between the relative mobilization rates of FA in gonadal WAT for the two periods.

DISCUSSION

The main finding of the present study is that, despite fasting and refeeding periods and a differential mobilization of FA during *in vitro* lipolysis, alpine marmots maintain a surprisingly stable WAT FA composition throughout the yearly cycle.

Numerous studies have reported that the FA composition of WAT is largely influenced by the dietary FA intake, both in nonhibernating mammals (19,20) and hibernators (10,21–24). However, the FA profile of captive alpine marmot WAT (Table 1) exhibited greater differences from the diet than that of the rat (Table 2), indicating that the pattern of the FA storage may be species-specific. Present results indicate that, in marmots, a preferential accumulation of MUFA occurs at the expense of PUFA, although the latter are known to have beneficial effects on hibernation (10–12,25). Surprisingly, this FA composition is maintained throughout the annual cycle, during the intense feeding period, when marmots rapidly reconstitute their fat stores, as well as during the fasting period, when marmots metabolize most of these fat stores. In the rat, by contrast, several days of starvation profoundly alter the distribution of the FA remaining in WAT (9).

As previously observed in rats (9,26,27), the composition of the FA mobilized from marmot white adipocytes (bars in Fig. 1) did not exactly reflect the composition of WAT. However, the pattern appeared to differ somewhat between rats and marmots. The conclusions drawn from rat studies are that short-chain and unsaturated FA, with a double bond close to the methyl end of the chain, are preferentially mobilized during *in vitro* lipolysis. In marmots, however, FA mobilization seems directed toward a preferential release of SFA rather than PUFA, whereas MUFA are retained within the tissue (Fig. 1 and Table 3). Previous results with marmots *in vivo* correlate well with the present *in vitro* data, *i.e.*, SFA amount to 60% of the FA found in plasma during deep hibernation, rewarming, and arousals (28). Moreover, contrary to rats, this preferential mobilization of FA does not lead to changes in WAT composition after several months of fasting.

The mechanism(s) underlying this process may involve hormone-sensitive lipase specificity and/or differential reesterification by analogy with the situation in rats. In mammals, hormone-sensitive lipase preferentially hydrolyses the first and the third ester bonds of triacylglycerols (29) where SFA are frequently found. However, in spite of this specificity, lipolysis in the rat (26,30) is directed toward the preferential release of PUFA. Wilson *et al.* (31) reported the presence of high amounts of messenger RNA for hormone-sensitive lipase in marmot WAT during fall and winter, but the activity and the specificity of this enzyme on triacylglycerols were not determined. Another mechanism could be FA reesterification which has been shown to occur *in vitro* in rats, even under stimulated lipolysis (32,33), and could explain the unchanged FA composition in marmot in spite of a nonramdom FA mobilization. However, during hibernation of *M. flaviventris*, under nonstimulated conditions the venous blood of gonadal fat shows a molar ratio FA/glycerol of 3:1 (10), which is not in favor of reesterification within WAT. Whatever the mechanism, it appears that, owing to a marked repletion/depletion of fat stores during the yearly cycle of marmots and because of the preferential release of FA by adipose tissue (as shown by *in vitro* lipolysis), the FA composition should markedly change throughout the year. Because we did not observe such changes, it is likely that the composition of fat depots is actively regulated in marmots. Such regulation has never been described before in either hibernators or nonhibernators.

Apart from the unresolved problem of the mechanisms allowing the constancy of FA composition throughout the yearly cycle of marmots, the question arises as to what could be the role of such regulation of FA composition. It is tempting to suggest that a particular FA composition may play a major role during hibernation and particularly during periodic arousals. When body temperature has to change rapidly within a 35°C range, i.e., from a few degrees above zero to +37°C and back in a period of few days, some physical properties of fat may be necessary to maintain the optimal functions of the tissue. Because such dramatic change in tissue temperature is likely to affect fluidity of membranes and triglyceride stores, a given FA composition may ensure a low WAT melting point. Supporting this interpretation, WAT melting temperature is −4.3°C in the adult California ground squirrel (*Spermophilus beldingi*) before hibernation (34). Similarly, differential fluidity of outer and inner sides of subcutaneous fat depots in cattle (19) and polar bear (35) is also achieved through regulation of FA composition.

In this way, a high UI, an estimate of the amount of unsaturated FA in a tissue (36), is usually associated with high fluidity at low temperature. Present results in marmots suggest that the apparent regulation of the FA composition of WAT, and possibly fluidity, is primarily achieved through the regulation of the MUFA content. This is in accord with the well-established fact that the introduction of the first double bond in SFA chains has the maximal effect on the decrease in melting point and thus fluidity of WAT, whereas the introduction of further double bonds affects physical properties less (36–38). In agreement with this point is the observation that the decrease in WAT melting point in the ground squirrel (*S. beldingi*) before hibernation is more highly correlated with the content of MUFA, which increases from 25 to 44%, than with the content of PUFA, which decreases from 54 to 38%

(34). Similarly, physiological differences were reported in chipmunks fed with a diet supplemented in either 18:0, 18:1, or 18:2 (22). Geiser *et al*. (22) demonstrated that the addition of 18:1 to the food caused the greatest change in the pattern of torpor (minimum Tb reached during torpor and duration of torpor bouts), and these observations were highly correlated with the increase of MUFA in the WAT of chipmunks (22). In captive yellow-bellied marmots, it was also observed that, relative to free-ranging animals, the drastic lowering of 18:3n-3 was compensated by an increase in 18:1n-9 rather than 18:2n-6, despite the high availability of the latter in the lab food (10,11).

It therefore appears that the preferential storage of MUFA may be a general feature of hibernating animals, enabling the constitution of fat with appropriate physical properties for deep hibernation and periodic arousals. The synthesis of MUFA, which does not depend on the diet, may be an efficient and simple adaptive mechanism allowing marmots and possibly other hibernators to survive rapid and frequent large changes in body temperature without further FA chain restructuration. In captive marmots (present study) fed a laboratory diet low in n-3 PUFA, it appears that the regulation of WAT optimal fluidity leads to a steady FA composition during the yearly cycle. The importance of MUFA in hibernating marmots may be in relation with the preferential release of SFA by isolated adipocytes (present study), contrary to what is observed in nonhibernating rodents such as the rat (26,30). The precise physical characteristics and thus biological activity which are to be preserved in hibernating animals by such precise regulation now needs to be determined.

ACKNOWLEDGMENTS

This research is a part of the program "Dynamics of space occupation by Alpine marmot" supported by the French Ministry of Environment (EGPN 90-294) and "Programme Environnement, PIREN" supported by CNRS-France. The authors specially thank Professor M. Lagarde (INSERM unity 352, INSA-Villeurbanne, France) for his help in fatty acid identification, the "Laboratoire de Socioécologie and Ethoécologie" (Université LYON I) for providing us marmots, Professor C. Duchamp for helpful discussion, and C. Moulin and B. Georges for their assistance with experimental procedures.

ABSTRACT: The emperor penguin (*Aptenodytes forsteri*) is an Antarctic seabird feeding mainly on fish and therefore has a high dietary intake of n-3 polyunsaturated fatty acids. The yolk is accumulated in the developing oocyte while the females are fasting, and a large proportion of the fatty acid components of the yolk lipids are derived by mobilization from the female's adipose tissue. The fatty acid composition of the total lipid of the yolk was characterized by high levels of n-3 polyunsaturated fatty acids. However, it differed in several respects from that of the maternal adipose tissue. For example, the proportions of 14:0, 16:1n-7, 20:1n-9, 22:1n-9, 20:5n-3, and 22:6n-3 were significantly greater in adipose tissue than in yolk. Thus adipose tissue lipids contained 7.6 ± 0.3% and 8.0 ± 0.3% (wt% of total fatty acids; mean ± SE; *n* = 5) of 20:5n-3 and 22:6n-3, respectively, whereas the yolk total lipid contained 1.6 ± 0.1 and 5.5 ± 0.3% of these respective fatty acids. The proportions of 16:0, 18:0, 18:1n-9, 18:2n-6, and 20:4n-6 were significantly lower in the adipose tissue than in the yolk lipids. The proportions of triacylglycerol, phospholipid, free cholesterol, and cholesteryl ester in the yolk lipid were, respectively, 67.0 ± 0.2, 25.4 ± 0.3, 5.3 ± 0.2, and 1.8 ± 0.2% (wt% of total yolk lipid). The proportions of 20:4n-6, 20:5n-3, 22:5n-3, and 22:6n-3 were, respectively, 5.7 ± 0.3, 2.8 ± 0.2, 1.4 ± 0.1, and 11.7 ± 0.5% in phospholipid and 0.4 ± 0.0, 1.2 ± 0.1, 0.8 ± 0.1 and 3.6 ± 0.3% in triacylglycerol. About 95% of the total vitamin E in the yolks was in the form of α-tocopherol with γ-tocopherol forming the remainder. Two species of carotenoids, one identified as lutein, were present.

Paper no L8051 in *Lipids 34*, 283–290 (March 1999).

The prime importance of yolk lipid as a nutrient source for the avian embryo is illustrated by the fact that over 90% of the energy required for development is generated by β-oxidation of yolk-derived fatty acids (1). In addition, the rapid rate of cell proliferation during development is dependent on the provision of yolk-derived lipid components for the synthesis of membrane phospholipids (1). A feature of particular interest is the role of C_{20-22} polyunsaturated fatty acids of both the n-3 and n-6 series in the functional differentiation of certain embryonic tissues (2). Most notably, the phospholipids of the developing brain (3) and retina (4) of the avian embryo are characterized by very high proportions of docosahexaenoic acid (22:6n-3). Studies on mammals, including humans, have indicated that inadequate provision of 22:6n-3 to the neural tissues during fetal/neonatal life can result in a range of behavioral, cognitive, and visual impairments (2,5–8). With regard to birds, the importance of 22:6n-3 for neurological development is emphasized by the expression of a series of mechanisms in the embryonic chicken which selectively promote the transfer of this n-3 polyunsaturate from the lipids of the yolk to the target tissues of the embryo (9). For example, 22:6n-3 is preferentially taken up from the yolk (10) and is also selectively mobilized from the adipose tissue of the chicken embryo (11). The n-6 polyunsaturate, arachidonic acid (20:4n-6), also has important functions in the developing tissues of the chick embryo, with roles in signal transduction and eicosanoid synthesis (9). Thus it may be envisaged that the successful development of the avian embryo may be promoted by the availability in the yolk of an appropriate balance of n-3 and n-6 polyunsaturates. The profile of polyunsaturated fatty acids in the yolk lipids is profoundly influenced by the fatty acid composition of the diet of the parent hen (9). In particular, supplementation of chicken diets with fish oil produces major elevations in the 22:6n-3 content of the yolk lipid (4,12–15). The yolk fatty acid composition, particularly with regard to the proportions of 22:6n-3 and 20:4n-6, is also markedly affected by genetic differences between avian species (9).

The purpose of the present work was to determine the fatty acid composition of the yolk lipids of a bird with a very high natural intake of C_{20-22} n-3 fatty acids. The emperor penguin (*Aptenodytes forsteri*) is an Antarctic seabird feeding on fish, krill, and squid (16) and thus ingests large amounts of n-3 polyunsaturates and also of very long chain monounsaturates, as can be inferred from its adipose tissue fatty acid composition (17). The defining feature of the life cycle of this species is that feeding only occurs while at sea whereas activities as-

sociated with breeding (courtship, egg laying, incubation of eggs, chick brooding) take place ashore at colony sites which may be many kilometers from the sea (18). Thus breeding activities are associated with prolonged periods of fasting during which the birds are sustained mainly by extensive stores of subcutaneous adipose tissue which were accumulated during the previous sojourn at sea (19). The most extreme period of fasting (90–120 d) is endured by the male, which assumes responsibility for incubating the eggs throughout the winter, losing 40% of its initial body mass and 80% or more of its lipid reserves (17). In the case of the female, egg laying is preceded by about 6 wk of total fasting during courtship and pairing (17,20). On arrival at the breeding colony, the ovary is relatively undeveloped and weighs only a few grams compared with about 100 g 4 wk later and about 200 g just prior to laying (18,20). The egg yolk is therefore almost entirely formed while the female is fasting, and consequently the yolk fatty acids are derived largely from the mobilization of adipose tissue lipid (20).

These exceptional circumstances relating to the diet, metabolism, and reproductive cycle of the emperor penguin provided the opportunity for: (i) determining the fatty acid composition of the yolk lipids of a high n-3 consumer; (ii) relating this composition to that of the potential precursor lipids, i.e. the maternal adipose tissue; and (iii) evaluating if a high degree of unsaturation of yolk lipids is associated with a high content of yolk antioxidants.

MATERIALS AND METHODS

Egg collection and adipose tissue sampling. Biological samples were obtained from emperor penguins breeding within 1 km of the Dumont d'Urville Station (Adelie Land, Antarctica, 66°40′S, 140°01′E) in 1996. About 3000 pairs breed there each year. Five females were caught in early April on arrival at the breeding colony and after the pre-breeding fattening period at sea. Their body weights averaged 29.5 kg. A subcutaneous adipose tissue biopsy (about 1 g) was immediately taken under local anesthesia (xylocain, 1%), and the birds were then released into the colony. Adipose samples were rinsed with saline, blotted dry, and extracted with chloroform/methanol (2:1, vol/vol) according to the method of Folch *et al.* (21). The extracts were stored at −20°C in the presence of butylated hydroxytoluene (0.5% wt/vol) prior to analysis.

The emperor penguin is a protected species and for ethical reasons we collected only eggs which had been abandoned. By checking the colony daily in May, we were able to collect 6 abandoned eggs within 1 d of laying. Since the ambient temperature was around −20°C at this time of year, the eggs were rapidly frozen on being abandoned and were therefore well-preserved. The mass of these eggs averaged 460 g, which is close to the mean mass of 470 g in this species (17). The eggs were partly thawed and the yolk was collected. The wet mass of the yolks was 115 ± 3 g, which is similar to the reported 120-g average yolk mass (17). Approximately 3 g of each yolk was extracted for lipid analysis as described for the adipose tissue. The preparation of the lipid extracts of adipose tissue and yolk was performed at the Antarctic Field Station. The extracts were maintained at −20°C during transport to the authors' laboratories in France and Scotland.

Lipid analysis. The fatty acid compositions of the total lipid of the yolks and of the adipose tissue were determined following the transmethylation of aliquots of the extracts to form the fatty acid methyl esters (22). Analysis of the fatty acid methyl esters was performed by gas–liquid chromatography using a capillary column (Carbowax, 30 m × 0.25 mm, film thickness 0.25 μm; Alltech, Carnforth, United Kingdom) in a CP9001 Instrument (Chrompack, Middleburg, The Netherlands) connected to an EZ Chrom Data System (Scientific Software Inc., San Ramon, CA). The Data System enabled the expression of the fatty acid compositions in terms of wt%. The peaks were quantified by comparison with a 19:0 standard. The identification of the peaks was confirmed by comparison with the retention times of standard fatty acid methyl ester mixtures (Sigma, Poole, United Kingdom).

Portions of the extracts of the yolks were subjected to thin-layer chromatography on silica gel G using a solvent system of hexane/diethyl ether/formic acid (80:20:1, by vol) in order to isolate the major lipid classes [triacylglycerols (TAG), phospholipids (PL), free fatty acids (FFA), cholesteryl ester (CE), and free cholesterol (FC)]. Visualization of the bands and elution of the lipid classes from the silica were performed as described previously (22). The isolated PL fraction was further fractionated by thin-layer chromatography on silica gel D using a solvent system of chloroform/methanol/acetic acid/water (25:15:4:2, by vol). The major PL classes present [phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), and sphingomyelin (Sph)] were visualized and eluted from the silica (22). The isolated acyl-containing lipid and PL classes were transmethylated, and the fatty acid methyl esters were analyzed by gas–liquid chromatography as described above. The amounts of each lipid and PL class present in the yolk extracts were calculated from the amount and composition of the fatty acyl groups derived from each class, together with the acyl group contribution to the molecular weights of these compounds. FC was determined using an enzymatic-colorimetric assay kit (Boehringer Mannheim, Lewes, United Kingdom).

Analysis of vitamin E and carotenoids. Vitamin E was measured in the yolk extracts by high-pressure liquid chromatography using a Spherisorb S30DS2 3μ C_{18} reversed-phase column, 150 mm × 4.6 mm (Phase Separations Ltd., Clwyd, United Kingdom) with a mobile phase of methanol/water (97:3, vol/vol) and fluorescence detection as previously described (23). Calibration was performed using standard solutions of the vitamin E forms (α-, β-, δ-, and γ-tocopherols and tocotrienols; Sigma, and Merck, Darmstadt, Germany). Carotenoids were analyzed by high-pressure liquid chromatography using a Spherisorb S30DS2 3μ C_{18} reversed-phase column, 250 mm × 4.6 mm (Phase Separations Ltd.) with a mobile phase of acetonitrile/dichloromethane/methanol (7:2:1, by

vol) and detection by absorbance at 445 nm as described previously (24). Carotenoid standards (lutein, zeaxanthine, canthaxanthin, β-cryptoxanthin, lycopene, α-carotene, β-carotene, and citranaxanthin obtained from Fluka, Gillingham, United Kingdom; Apin, Abingdon, United Kingdom; and Hoffman-La Roche, Basel, Switzerland) were used for calibration and identification of the peaks.

Statistical analysis. Statistical significance of differences in fatty acid composition between yolk and adipose tissue was assessed by unpaired Student's t-test after arcsin transformation of the percentage values in order to make the variance independent of the mean (25).

RESULTS

Fatty acid composition of total lipids of yolk and of maternal adipose tissue. There were significant differences in detail between the fatty acid profiles of yolk and adipose tissue (Table 1). The total lipid from both sources contained oleic (18:1n-9) and palmitic (16:0) acids as the major fatty acids with substantial levels of 22:6n-3 also present. However, of the 17 fatty acids listed in Table 1, 14 differed significantly in relative content between the two sources. In several cases, the magnitude of these differences was considerable. For example, the proportions of myristic (14:0), gondoic (20:1n-9) and eicosapentaenoic (20:5n-3) acids were, respectively, 6.9, 4.0, and 4.8 times higher in adipose tissue than in yolk. The proportion of 22:6n-3 was 1.5 times higher (8.0% vs. 5.5%, $P < 0.001$) in adipose tissue compared with yolk. Also, palmitoleic (16:1n-7) and docosapentaenoic (22:5n-3) acids were represented to a greater extent (1.8 and 1.4 times, respectively) in adipose tissue than in yolk. Erucic (22:1n-9) acid was a significant constituent of adipose tissue lipid but was not detected in the yolk samples. On the other hand, the proportions of stearic acid (18:0) and 20:4n-6 were, respectively, 3.2 and 4.3 times greater in yolk than in adipose tissue. The yolk lipids also exhibited greater proportions of 16:0, 18:1n-9, and linoleic acid (18:2n-6) than were present in adipose tissue lipids. As a consequence of the enhanced proportions of 18:2n-6 and 20:4n-6 and the reduced proportions of 20:5n-3, 22:5n-3, and 22:6n-3 in the yolk relative to the adipose tissue, the n-3/n-6 ratio was far higher in adipose tissue than in yolk. Similarly, the 22:6n-3/20:4n-6 ratio was very high in adipose tissue but much lower in yolk (Table 1).

Lipid and PL classes of the yolk. TAG was by far the major lipid class present in the yolk (67.0 ± 0.2 wt% of total yolk lipid; mean ± SE, n = 6 yolks) with PL also making a substantial contribution (25.4 ± 0.3 wt%). Much lower proportions of FC, CE, and FFA were present (5.3 ± 0.2, 1.8 ± 0.2, and 0.5 ± 0.0 wt%, respectively). The proportions of these lipid classes showed little variation among the six replicate eggs that were analyzed. The very low and constant proportion of FFA suggests that little or no hydrolysis of complex lipids had occurred in the eggs prior to collection or in the lipid extracts prior to analysis. PC (45.9 ± 8.0 wt% of total PL; mean ± SE, n = 6 yolks) and PE (34.3 ± 4.8 wt%) were the main constituents of the total PL although relatively high proportions of PS and Sph were also present (9.3 ± 1.8 and 10.5 ± 1.8 wt%, respectively). However, there was a considerable degree of inter-egg variation in the proportions of these PL classes.

Fatty acid composition of the major lipid and phospholipid classes of the yolk. The two major fatty acyl constituents of the TAG, PL, CE, and FFA were 18:1n-9 and 16:0 (Table 2). A key feature was the presence of high proportions of 22:6n-3 in all of these classes. Although PL displayed the highest proportions of 22:6n-3, a substantial level of this polyunsaturate was also present in the TAG fraction. The minor lipids, CE and FFA, also contained high proportions of 22:6n-3. The four lipid classes contained 20:5n-3 at lower levels than 22:6n-3. The highest proportion of 20:4n-6 was found in the PL fraction. The C_{18} polyunsaturate, 18:3n-3, was a very minor component of all the lipid classes.

Very high proportions of 22:6n-3 were present in the PE and PS fractions of the yolk PL, forming the major acyl component of these two fractions (Table 3). PE and PS were also rich in 20:4n-6, 20:5n-3, and 22:5n-3, whereas lower proportions of these C_{20-22} polyunsaturates were found in PC and Sph. With regard to the saturated and monounsaturated fatty acids, 16:0 and 18:1n-9 were the major components of PC whereas 18:0 predominated in PE and PS. Sph consisted mainly of saturated and monounsaturated fatty acids although 22:6n-3 also made a significant contribution.

Vitamin E and carotenoids of the yolk. There was considerable inter-egg variation in the yolk content of vitamin E and carotenoids. The major form of vitamin E in the yolk was α-tocopherol (206.9 ± 46.6 μg/g lipids mean ± SE, n = 6 yolks)

with much smaller amounts of γ-tocopherol also present (11.3 ± 2.0 μg/g lipid). No tocotrienols were detected. The total carotenoid content was almost entirely accounted for by two compounds, lutein (3.9 ± 0.3 μg/g lipid; mean ± SE, *n* = 6 yolks) and an unidentified component (4.7 ± 0.6 μg/g lipid), with retention times of 2.3 and 17.8 min, respectively, at a flow rate of 1.5 mL/min. The unidentified carotenoid did not correspond to any of the standards used (see the Materials and Methods section), which all had retention times of less than 10 min.

DISCUSSION

The fatty acid composition of the subcutaneous adipose tissue of the female penguins at the time of arrival at the breeding colony is consistent with the prior consumption of a diet based on fish and other marine organisms during the prebreeding fattening period at sea (16). This is typified by the presence of high proportions of the long-chain n-3 polyunsaturates, 20:5n-3 and 22:6n-3, and of the long-chain monounsaturates, 20:1n-9, 22:1n-9 and 24:1n-9, in the adipose tissue lipids. The results from previous studies comparing the fatty acid composition in penguins of the adipose depots with that of the diet suggest that the stored fatty acids are mainly of dietary origin and are probably incorporated into adipose TAG without major transformation (26).

In the emperor penguin, the processes of yolk formation and the deposition of lipids in the developing oocyte are almost entirely restricted to the period following arrival at the breeding colony, a time of stringent fasting and extensive mo-

bilization of the maternal adipose tissue reserves (17,18,20). It is therefore very likely that fatty acids released from adipose tissue TAG are the predominant precursors for yolk lipid assembly. The yolk components of the avian egg are initially assembled in the maternal liver and then secreted into the bloodstream, mainly in the form of a specialized type of very low density lipoprotein (VLDL) which is then delivered *via* the circulation to the ovary and taken up by the oocyte (9). As a result, the lipid composition of the yolk is almost identical to that of the precursor VLDL and is therefore dependent on metabolic events in the maternal liver (9). It may be envisaged that, in the specialized circumstances encountered by the female emperor penguin, yolk lipid formation results from an interplay between the adipose tissue and liver, with the former tissue releasing large amounts of FFA into the circulation for delivery to the hepatocytes where the fatty acids are esterified to form TAG and PL which are incorporated into the yolk-precursor VLDL.

The fatty acid composition of the total lipid of the yolk shared certain general features with that of the maternal adipose tissue, as befits the idea of a precursor–product relationship. In particular, the proportions of $C_{20–22}$ n-3 polyunsaturated fatty acids in the yolk lipids of the emperor penguin were far higher than the values reported for the eggs of terrestrial birds (1,9). By contrast, the C_{18} polyunsaturates were very minor components of both the yolk and the adipose tissue of the penguin. This observation represents a major contrast with birds such as the chicken, duck, goose, and ostrich, where 18:2n-6 or 18:3n-3 are the major polyunsaturated fatty acids of yolk lipid as a result of maternal consumption of seeds (rich in 18:2n-6) or of green plant material (rich in 18:3n-3) (9,27).

There were, however, extensive differences, both qualitative and quantitative, between the fatty acid profiles of the yolk and the maternal adipose tissue of the emperor penguin. We suggest these differences arise from a combination of three factors. The first factor is that a proportion of the yolk fatty acids possibly may be derived from *de novo* lipogenesis in the liver, using glucose as the precursor. A previous study using radioactively labeled precursors indicated that the liver of the emperor penguin has the ability to synthesize fatty acids, mainly 16:0 and 18:0 and to a lesser extent 16:1n-7 and 18:1n-9 (17). This could partly explain the higher proportions of 16:0, 18:0, and 18:1n-9 in the yolk compared with the adipose lipids. On the other hand, the possibility that the liver could synthesize significant amounts of fatty acid from glucose during an extensive period of fasting is questionable and *de novo* lipogenesis may make only a minor contribution to the yolk fatty acid content.

The second factor that could affect the fatty acid profile of the yolk is the differential mobilization of the various fatty acids from the maternal adipose TAG. Studies using rat (28,29) and human (30) adipocytes incubated *in vitro* in the presence of lipolytic agonists have shown that certain fatty acids are preferentially released into the incubation medium whereas others are selectively retained as components of the TAG of the cells. These investigations established the general rule that the relative mobilization of a fatty acid was positively correlated with the number of double bonds and negatively correlated with the chain length (28). Thus, highly polyunsaturated C_{16}, C_{18}, and C_{20} fatty acids including 20:4n-6 and 20:5n-3 were preferentially mobilized whereas long-chain saturated and monounsaturated fatty acids such as 22:0, 20:1n-9, 22:1n-9 and 24:1n-9 displayed a high degree of resistance to mobilization. In the case of 22:6n-3, the promobilization effect of the six double bonds was effectively counterbalanced by the long chain length, resulting in an intermediate rate of release (28). These principles of differential mobilization were subsequently demonstrated to apply to mammals *in vivo* during fasting (31) and following hormonal stimulation of lipolysis (32). It was proposed that TAG molecular species that contain fatty acids such as 20:4n-6 and 20:5n-3 are excellent substrates for the hormone-sensitive lipase of the adipocytes, whereas those TAG species that contain fatty acids such as 24:1n-9 are very poor substrates for this enzyme (28). These differences in susceptibility to hydrolysis by hormone-sensitive lipase are not due to differences in the positional distribution of highly and weakly mobilized fatty acids on the glycerol backbone of the TAG (33). Rather, it seems that the more polar TAG species (i.e., those that contain the highly polyunsaturated shorter-chain fatty acids) partition to a greater extent at the lipid–water interface at the surface of the lipid droplet and are thus more accessible to the enzyme (28,34).

Preliminary results suggest that the emperor penguin is no exception to these features of differential mobilization of fatty acids (19). The fatty acid composition of subcutaneous adipose tissue of the male emperor changes markedly during the course of the breeding fast, consistent with the preferential release of 18:4n-3, 20:4n-6, and 20:5n-3 and the selective retention of long-chain monounsaturates. The *in vitro* release of fatty acids from adipose tissue slices also suggests that the relative mobilization of different fatty acids occurs in accordance with the same dependence on chain length and unsaturation exhibited by mammalian adipocytes (19). In the present work, the low relative mobilization of 20:1n-9, 22:1n-9, and 24:1n-9 from the maternal adipose tissue could at least partly explain the low levels of these monounsaturates in the lipids of the yolks. Also, the preferential mobilization of 20:4n-6 from the adipose tissue may contribute to the enhanced proportion of this fatty acid in the yolk lipid. However, several prominent features of the yolk fatty acid profile cannot be explained solely on the basis of the differential mobilization of fatty acids from the maternal fat stores. In particular, the proportion of 20:5n-3 in the yolk was about five times lower than in the adipose tissue despite the very high relative mobilization of this fatty acid.

A third determinant of the yolk fatty acid profile is the acyl-substrate specificity of the acyltransferases responsible for TAG and PL synthesis in the maternal liver. Presumably, such specificity would represent a mechanism to ensure that the fatty acid composition of the yolk is suited to the needs of

the embryo and is not simply a passive reflection of the pattern of fatty acids released from the maternal fat stores. In the case of the domestic chicken, feeding the laying hen with a fish oil-supplemented diet in which the ratio of 20:5n-3/22:6n-3 was 1.5 resulted in eggs in which this ratio was only 0.3 (4). Thus, there appears to be a relative discrimination against the incorporation of 20:5n-3 into egg lipids which could, in the case of the penguin, explain the low proportion of this fatty acid in the yolk compared with that in the maternal adipose tissue.

Species of birds that exhibit the precocial developmental mode produce well-developed hatchlings capable of independent feeding and thermoregulation whereas hatchlings of altricial species are relatively helpless and dependent on the parents for food provision and warmth (35). The proportions of the different lipid classes in the yolk also differ markedly between the two developmental modes. For example, the egg lipids of the chicken, a precocial species, consist of 70% TAG, 21% PL and 1% CE (3) whereas in an altricial species such as the pigeon these proportions are 58, 31, and 5%, respectively (36). The higher proportion of TAG in the eggs of precocial birds will provide the embryo with a greater amount of energy in order to achieve the more advanced state of development before hatching. Since, by most criteria, the hatchlings of the emperor penguin are altricial (for example, they depend on the parents for warmth for 2 mon posthatching), it may appear surprising that the lipid class profile of the eggs is typical of the precocial pattern. However, studies on eggs of the king penguin and the gentoo penguin have revealed that the changes in embryonic oxygen consumption during development follow the precocial rather than the altricial pattern (37). Thus, the developmental energy needs of these penguin embryos may require an energy-rich yolk with a high proportion of TAG.

As a proportion of total yolk PL, the penguin egg contained relatively less PC and relatively more PE and PS than the chicken egg (1). Because PE and PS are the main repositories for 22:6n-3 in eggs of both these avian species (1), the higher proportions of these two PL classes in the penguin egg may represent a means of facilitating the accommodation of the high levels of 22:6n-3 within the yolk lipid. It should also be noted that very high proportions of 22:6n-3 are present in the PE and PS fractions of the avian embryo brain (3). The large inter-egg variation in the proportions of the PL classes was surprising given that there was little inter-egg variation in the proportion of total PL in the yolk lipid. This degree of variation cannot be explained by the analytical methodology since replicate analyses ($n = 5$) of a single yolk sample indicated coefficients of variation of 4–5% in the estimation of the proportions of the PL classes. Future work, using measurements on a larger number of eggs, would help to resolve this point.

The very high proportion of 22:6n-3 in the yolk lipid of the emperor penguin in comparison with the levels of this polyunsaturate in the eggs of birds such as the chicken has already been commented upon. A further finding relates to the distribution of 22:6n-3 between the main acyl-containing lipid classes, TAG and PL. In the yolk of the domestic chicken, and of many other species of captive and wild birds that have been studied (3,9,27), 22:6n-3 is almost entirely confined to the PL fraction, with only trace levels present in TAG. The relative amount (mg of 22:6n-3 in PL per g total yolk lipid) of this n-3 polyunsaturate in the PL fraction is three times greater in the penguin yolk than in that of the chicken; however, an equivalent amount of 22:6n-3 was also present in the TAG fraction of the penguin yolk (Fig. 1). Thus, in the penguin eggs, 22:6n-3 is almost equally distributed between PL and TAG. This arises because, although the proportion (wt% of fatty acids) of 22:6n-3 is higher in PL than in TAG, the amount of TAG in the yolk exceeds that of PL. It may be suggested that, during the assembly of yolk lipid in the maternal liver, the supply of 22:6n-3 in the form of FFA mobilized from the maternal adipose tissue far exceeds the capacity for incorporation into PL, resulting in a "spillover" into TAG. In other words, there may be a limit on the proportion of this fatty acid that can be accommodated in PL, possibly to avoid compromising the role of PL in stabilizing the yolk–precursor VLDL structure (9).

It has been suggested that the commercial grain-based diets provided to herbivorous domestic or captive birds (e.g., duck, pheasant, goose, ostrich) may contain an imbalance in the proportions of n-6 vs. n-3 polyunsaturates with the result that the eggs and possibly the embryonic neural tissues may exhibit a degree of deficiency in 22:6n-3 (9). Clearly, the penguin embryo in the natural state is at no such risk. On the contrary, the penguin embryo may face the opposite problem: a relative limitation in the availability of 20:4n-6. The concentrations of 20:4n-6 in the PL and TAG of the penguin eggs are, however, very similar to those present in eggs of the chicken (Fig. 1). Possibly the preferential mobilization of 20:4n-6 from the maternal adipose tissue may help to achieve adequate levels of this fatty acid in the yolk lipid, although

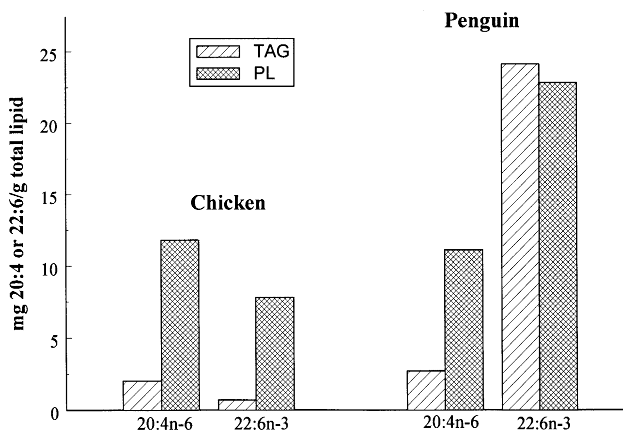

FIG. 1. Distribution of arachidonic (20:4n-6) and docosahexaenoic (22:6n-3) acids between triacylglycerol (TAG) and phospholipid (PL) of the yolk: comparison between chicken and penguin eggs. The mg of each acid present in each lipid class per g total yolk lipid is shown. Chicken data calculated from Reference 9. Penguin data calculated from the means in the Results section and in Table 2.

other mechanisms such as the acyl substrate specificity of acyltransferases in the maternal liver could also be involved.

It may be envisaged that the exceptional content of highly polyunsaturated n-3 fatty acids in the penguin eggs will require a considerable degree of antioxidant protection in order to prevent peroxidative damage during the development of the embryo (24). Thus, the concentrations of two major types of lipid-soluble antioxidants, vitamin E and carotenoids, were determined. The concentration of total vitamin E in the penguin yolks was very similar to that measured in free-range chicken eggs, which were found to contain 200–300 µg vitamin E/g lipid (Surai, P., unpublished data) and in eggs of the feral Canada goose, which contained 180–280 µg vitamin E/g lipid (38). It has been estimated that the amount of vitamin E in the chicken's egg is twice the steady-state level of this vitamin in the maternal liver, emphasizing the importance of continuous dietary provision to support egg production (39). In the emperor penguin, the fact that the yolk contents are deposited in the oocytes during a period of fasting may therefore place limitations on the amount of vitamin E that can be accumulated in the yolk. The concentration of carotenoids in the penguin yolks was very low, approximately a tenth of the concentration measured in the free-range chicken egg (Surai, P., unpublished data) and in eggs of the feral Canada goose (38). The unidentified carotenoid peak would appear from its retention time to be a very hydrophobic molecule and is presumably derived ultimately from phytoplankton at the base of the penguins' food chain. Vitamin E and carotenoids, together with the trace element selenium, are the main antioxidant components present in the avian yolk (23,24). It would appear that the yolk of the emperor penguin is only moderately provisioned with antioxidants, despite the very high levels of polyunsaturated fatty acids.

ABSTRACT: Evidence suggests that differences in fatty acid composition among various fish species may be due to differences in diet or to environmental factors such as temperature, salinity, and depth at which the fish are caught. The beneficial effects of a diet containing fish on cardiovascular or other diseases have been associated with their high content of eicosapentaenoic (20:5n-3) and docosahexaenoic (22:6n-3) acids. In this study we analyzed the fatty acid composition of the flesh of 18 different species of marine fish and of cultured rainbow trout. The fish were obtained from the Black and the Marmara Seas, both of which have unique biological and ecological systems as well as eutrophication and pollution. The contents of 20:5n-3 and 22:6n-3 in the marine fish ranged from 4.2 to 13.3 wt% of total fatty acids, and from 6.6 to 40.8 wt%, respectively. The most important differences from other studies on oceanic fish were the tendencies toward higher percentages of 16:0 and 22:6n-3. The n-3 series of polyunsaturated fatty acids were present as 32.4 ± 1.9% of the total fatty acids. The present study suggests that mature and immature *Pomatomus saltator* as well as *Engraulis encrasicolus, Mullus surmuletus, Sardina pilchardus, Mugil cephalus,* and *Sarda sarda* may be preferred for the Turkish diet as a result of their high 20:5 n-3 and 22:6 n-3 contents. The cultured rainbow trout *Oncorhynchus mykiss* is not as good a source of n-3 fatty acids as are the marine fish.

Paper no. L7859 in *Lipids 34,* 291–297 (March 1999).

Consumption of fish oil has beneficial effects on growth and development, coronary heart disease, blood lipids and lipoprotein levels, platelet aggregability, hypertension, inflammation, Crohn's disease, arthritis, autoimmune disorders, and cancer (1–10). Consumption of modest amounts of n-3 fatty acids (FA), as little as one meal of fatty fish per week, is associated with reduced incidence of fatal coronary heart disease and decreased vulnerability to ventricular fibrillation, perhaps because the fish provide an essential amount of long-chain n-3 polyunsaturated fatty acids (PUFA), or some still-unidentified nutrient (11–14). The evidence of reduced incidence of cardiovascular disease in Eskimos, a population with a high dietary intake of n-3 FA derived from fish, suggests that dietary supplementation with n-3 FA may be beneficial in the reduction of cardiovascular risk (15).

Proximate fat composition of fish varies considerably from species to species and also for individual fish or lots of fish of the same species taken at different times or under different conditions. The FA composition of fish lipids, especially PUFA, varies according to the FA profile of the lipids consumed by the fish. The FA composition also varies in response to water temperature changes, salinity, and depth through adaptive mechanisms. Most studies related to the proximate composition of fish have been carried out on fish obtained from oceanic waters. There is little information on the FA composition of fish species commonly consumed in Turkey. As a basis for possible nutritional and health benefits, we have determined the FA composition of some fish commonly available for consumption.

MATERIALS AND METHODS

All the fish, which were caught from the Black Sea and the Marmara Sea, were collected from a local fish market between September and November, 1994, when the fat content of wild fish tended to be at its maximum. The mean total weight and standard length showed that the fish were mature at the time of capture (Table 1). Only *Pomatomus saltator* was immature and did not have its maximal fat content at that time. Rainbow trout was purchased from a trout farm.

The freshly caught fish were scaled, and 2–3 g samples were taken from the edible portion of the dorsal muscle between the dorsal fin and the head. Sampling was always done by one of the authors (E. Şener) from the Faculty of Aquatic Products. The number of fish examined is included in Table 1. Tissue samples were stored at −70°C until analyzed.

FA analysis. Tissue FA profiles were prepared by a slight modification of a method previously described by Yazıcı *et al.* (16). The frozen tissue sample was thawed, weighed (200–300 mg taken from the whole sample), and homogenized in cold 154 mM NaCl. Total lipids, added internal standard (heptadecanoic acid), and butylated hydroxytoluene (an antioxidant, 20 gr L^{-1}) were extracted with chloroform/methanol (2:1). The extracted lipids were then saponified with 2% KOH in

[a]*n*, number of specimens analyzed. BS, Black Sea; MS, Marmara Sea; F, freshwater. Weight and length data presented as mean ± SEM.

methanol, and finally the FA were methylated with 20% BF_3 in methanol. The FA methyl esters were extracted with hexane and analyzed by capillary gas chromatography (column: 50 × 0.25 mm WCOT fused silica, CP-Sil 88; flame-ionization detection temperature 300°C; carrier gas, N_2, 16 mL min^{-1}; splitter injector temperature 290°C; oven temperature programmed from 150 to 240°C at 2°C min^{-1}); Perkin-Elmer 8420 capillary gas chromatograph (Gouda, The Netherlands).

A mixture of FA standards (Sigma Chemical Co., St. Louis, MO), containing the following methyl esters of all-*cis* or of saturated FA, was used to determine the total FA profiles: lauric, 12:0; myristic, 14:0; palmitic, 16:0; palmitoleic, 16:1n-7; stearic, 18:0; oleic, 18:1n-9; *cis*-vaccenic, 18:1n-7; linoleic, 18:2; linolenic, 18:3; 6,9,12,15-octadecatetraenoic, 18:4; arachidic, 20:0; eicosenoic, 20:1n-9; 1,14-eicosadienoic, 20:2; 11,14,17-eicosatrienoic, 20:3; arachidonic, 20:4n-6; 5,8,11,14,17-eicosapentaenoic (EPA), 20:5; behenic, 22:0; erucic, 22:1n-9; 13,16-docosadienoic, 22:2; 7,10,13,16-docosatetraenoic, 22:4; 7,10,13,16,19-docosapentaenoic, 22:5; 4,7,10,13,16,19-docosahexaenoic (OHA), 22:6; lignoceric, 24:0; and nervonic, 24:1n-9.

The values of FA are presented as percentage of total FA mass.

Data are presented as mean ± SEM, unless otherwise stated. Analysis of variance test was used to determine the significance of levels of FA in various fish species. The Student-Newman-Keuls test was used to compare FA of each fish with the FA of other fish species.

RESULTS

The total lipid contents of the edible muscle in different species of fish were compared. When the fish were grouped by fat levels, the high-fat (>8%) species were blue fish (*Pomatomus saltator,* mature and immature), red mullet (*Mullus surmuletus*), sardine (*Sardina pilchardus)*, striped mullet (*Mugil cephalus),* horse mackerel (*Trachurus trachurus),* and bonito (*Sarda sarda)* (17). The fish with medium fat content (4–8%) were anchovy (*Engraulis encrasicolus),* Atlantic mackerel (*Scomber scombrus), garfish (Belone belone),* common sole (*Solea vulgaris),* comber (*Serranus cabrilla),* Spanish mackerel (*Scomber japonicus),* and rainbow trout (*Oncorhynchus mykiss).* On the other hand, sea bream (*Pagellus erythrinus),* sand smelt (*Atherina boyeri),* whiting (*Merlangius merlangus euxinus),* scorpion fish (*Scorpaena scrofa)*, gurnard (*Trigla lucerna*), and round goby (*Neogobius melanostomus)* could be classified as low-fat (2–4%) fish.

Analysis of the compositions of FA from different species of fish revealed significant differences (Tables 2 and 3). The most abundant individual FA in our study were palmitic, oleic, eicosapentaenoic, and docosahexaenoic acid. Palmitic and stearic acids were the most abundant saturated FA, and oleic acid was the dominant monounsaturate. Of the PUFA EPA and DHA were the major n-3 FA.

There was some variation in the FA composition of different fish species. The levels of each FA in individual fish that were significantly different compared to those of other fish

[a]Figures are given as percentage of the total amount of fatty acids (FA). Data presented as mean ± SEM. Values across rows not sharing a common superscript letter are significantly different from each other, $P < 0.05$. Sat./unsat., ratio of contents of saturated to unsaturated FA. N.D., not detected. For other abbreviations see Table 1.
[b]g/100 g tissue (wet weight basis).

species are given in Table 2. The content of EPA, a precursor of the third series of eicosanoids varied in marine fish between 4.2 and 13.3% (mean: 7.8 ± 0.6%), with the highest content of 20:5n-3 found in striped mullet. On the other hand, 20:5n-3 contents in mature and immature blue fish, garfish, and Atlantic mackerel were relatively low, but immature and mature blue fish had the highest calculated amount of EPA (1.8 g and 1.5 g/l00 g of fish muscle, respectively) among other fish. Whiting had the lowest saturated/unsaturated FA ratio. Whiting also had the highest percentage content of DHA; whereas, amounts of DHA were highest in the young of the blue fish (5.1 g /100 g). The following fish all had DHA levels >15% of total FA: comber, round goby, gurnard, Spanish mackerel, scorpion fish, Atlantic mackerel, sea bream, common sole, anchovy, red mullet, sand smelt, garfish, and rainbow trout. The highest percentage of myristic acid was found in sardine and immature and mature blue fish as well as anchovy. Palmitic acid content was very high in all the fish examined and was highest in sea bream. The stearic acid content was high in comber, round goby, horse mackerel, scorpion fish, Spanish mackerel, red mullet, sardine, Atlantic mackerel, sea bream, sand smelt, and common sole. Horse mackerel, blue fish, red mullet, and common sole had high 16:1n-7 percentage levels, and horse mackerel had the highest 18:1n-9 percentage content. With regard to the ratio of saturated to unsaturated FA content, the highest values were found in anchovy, sea bream, and sardine. The percentage contents of 18:0 and 24:1n-9 were significantly higher in fish caught from the Marmara Sea as compared to those from the Black Sea (6.8 ± 0.5 vs. 4.6 ± 0.1%, $P = 0.002$; 0.9 ± 0.1 vs. 0.66 ± 0.1%, $P = 0.05$, respectively). When pelagic fish species caught from the Black Sea were compared with pelagic species from the Marmara Sea, none of the FA differed significantly. However, when demersal fish from either sea were compared, the percentage content of 20:5n-3 and the calculated amount of 22:6n-3 were higher in fish from the Black Sea (11.2 ± 1.9 vs. 7.5 ± 2%, $P = 0.05$, and 1.26 ± 0.1 vs. 0.74 ± 0.08 g, $P = 0.02$, respectively). On the other hand, 18:0 and 24:1n-9 were higher in demersal fish species caught from the Marmara Sea (6.8 ± 1 vs. 4.8 ± 0.3%, $P = 0.006$; 0.87 ± 0.10 vs. 0.49 ± 0.0%, $P = 0.03$). Demersal fish species from the Black Sea had higher percentages of 20:5n-3 than pelagic species from the Marmara Sea (11.2 ± 1.1 vs. 7.4 ± 1.1%, $P = 0.05$).

Fish classified as carnivorous had significantly higher proportions of 20:0, 20:1n-9, and 24:1n-9 than omnivorous fish (0.5 ± 0.0 vs. 0.4 ± 0.0%, $P = 0.03$; 2.8 ± 1.8 vs. 0.7 ± 0.0%, $P = 0.001$; 0.9 ± 0.3 vs. 0.5 ± 0.1%, $P = 0.04$, respectively). Percentages of 18:3n-3 and 20:0 were lower in omnivorous than in planktivorous fish (0.6 ± 0.1 vs. 1.5 ± 0.1%, $P = 0.01$; 0.4 ± 0.0 vs. 1.1 ± 0.0%, $P = 0.001$, respectively).

DISCUSSION

The FA compositions of 18 commonly eaten fish species caught from the Black Sea and the Marmara Sea and of cultured rainbow trout (freshwater fish) were determined. In our study, marine fish, such as comber, whiting, round goby, horse mackerel, anchovy, red mullet, sardine, sand smelt, and striped mullet contained levels of 20:5n-3 at a mean of 7.8 ± 0.6% (range: 8.3–13.3%). Levels of 20:5n-3 were found to average 10.1% in marine fish by Ackman (18) , 5.3% by van Vliet and Katan (19), 8.07% by Castell (20), 4.3% by Belling *et al*. (21), and 11.7% in marine and freshwater fish by Puustinen *et al*. (22). Despite the presence of a relatively lower percentage of 20:5n-3 in our study, EPA was abundant in most of the fish, especially in immature and mature blue fish and in bonito *(Sarda sarda)*. Compared to other food, the lipids of fish are particularly rich in long-chain n-3 PUFA, e.g., EPA and DHA. Tissue FA of fish are derived from two sources, namely, the diet and *de novo* biosynthesis. Furthermore, fish can incorporate 18:2n-6 or 18:3n-3 acids, which may be in their diet, into PUFA, such as 20:4n-6, 20:5n-3, 22:5n-3 and 22:6n-3 (23). However, this ability differs from one species to another. The biosynthesis of 22:6n-3 and 22:5n-3 has recently been evaluated. Voss *et al*. (24) and Aveldaño *et al*. (25) showed that 24:5n-3, 24:6n-3, 24:4n-6, and 24:5n-6 are intermediates in the conversion of the C_{18} FA to 22:6n-3 and 22:5n-6 in the rat, which also may represent what occurs in fish.

Most of the fish analyzed in our study had high levels of 22:6n-3, averaging 21.1 ± 1.9% of the total FA. A survey of North European fish showed that several species also had high levels of 22:6n-3, for example, 11.2% in seven marine fish and 8.6% in six freshwater fish (20); 3.9% in Atlantic herring, 12.7% in Atlantic cod (18); 15% in wild trout, 4% in wild eel, 10% in wild salmon (19); and 15.6% in 11 species of Australian fish (21). Taking into consideration that the Turish fish examined in this study had low 20:1 contents and high DHA levels, one may speculate that the proportion of phospholipids was higher than that of triglycerides in muscle lipids of their fish (26).

The variation in FA composition of different fish species in our study may be explained by the unique features of the seas from which our fish were obtained. Studies concerning the composition of FA of fish living in these two seas are very few and limited. Among European semienclosed and coastal seas, the Black Sea is the most isolated from the deep oceans (Fig. 1). The biological consequence of the excess nutrient runoff from incoming rivers is the most intense eutrophication in the world, thus transforming the Black Sea ecosystem (27). The recent consequence of this phenomenon has been an increase of some small phytoplanktonic species, and of pi-

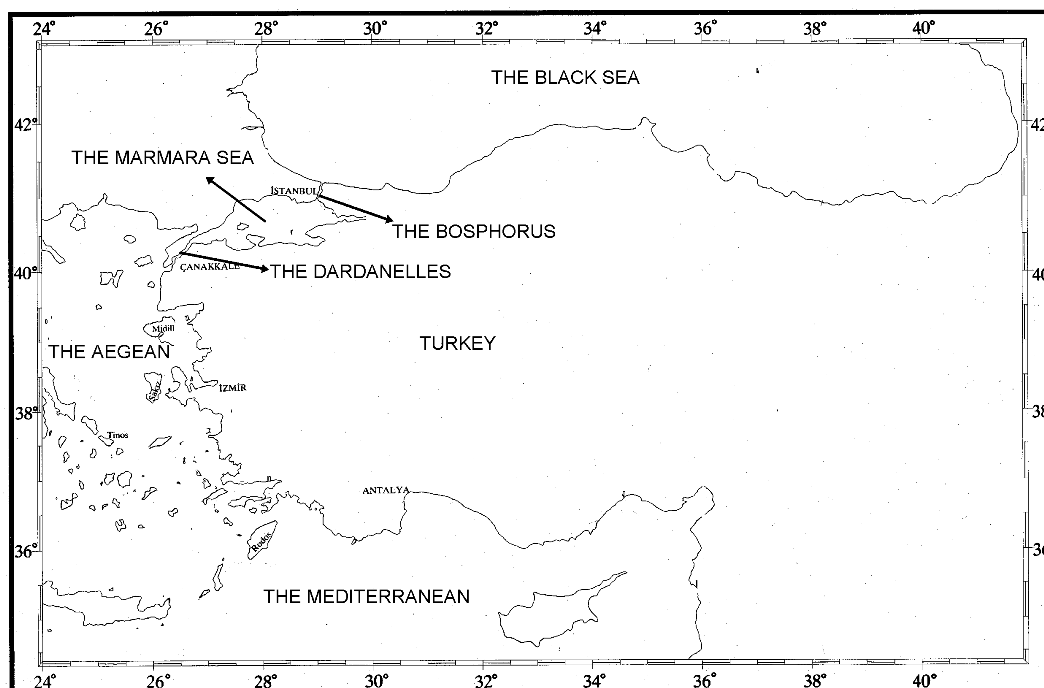

FIG. 1. Map of Turkey showing fishing areas discussed in text.

coplankton and zooplankton species. In addition, populations of some large planktonic species, especially *Phyllaphora* fauna, large pelagic carnivorous crustaceans, and mixotrophs have declined (28,29). Other important aspects of eutrophication have been the increase in water turbidity, which diminishes photosynthesis by bottom-dwelling algae, and the sedimentation of large amounts of dead and decomposing phytoplankton, causing hypoxia in the near-bottom layers of water and limiting the vertical range of different species of fish (30). In addition, a bloom or *Mnemiopsis leidyi* in the late 1980s reduced the biomass of copepods and other zooplankton almost tenfold, diminishing these important food species in the Black Sea (30). Because of the decline in populations of zooplankton and the increase of phytoplankton mass, especially of the dinoflagellates, as a response to the immense eutrophication in the Black Sea, the fish in our study (excluding *P. saltator*) had low levels of 20:1n-9 (mean, 2.5 ± 0.4% by wt) and high levels of n-3 PUFA (32.4 ± 1.9% of the total FA). This situation leads to FA compositions like those of marine fish found elsewhere in lower latitudes (31). Although the levels of 20:5n-3. In contrast, the low EPA to DHA ratio of 0.4 ± 0.07 was due to the higher 22:6n-3 content.

Another source of our marine fish was the Marmara Sea, which also has special biological and ecological features because of its enclosed configuration and estuarine characteristics. The importance of the Marmara Sea is emphasized by its location on the migratory path of large numbers of fish. While the surface waters of the Marmara Sea are affected by the Black Sea, deeper waters remain under the influence of the Mediterranean (32). In winter, nutrient-rich waters of the Black Sea enter the Marmara Sea from the surface, but in the spring and summer, the nutrient flow decreases. The temperature and the salinity in the Marmara Sea vary with depth and the distance from both seas and affect the phytoplankton biomass (33). The currents from the Black Sea bring in nutrients, leading to significant eutrophication that affects fish populations migrating into the system (34). Pelagic fish species enter the Marmara Sea during the spring for feeding, then migrate back to the Black Sea, then return to the Marmara Sea toward winter. The proportions of 18:0 and 24:1n-9 in total FA were significantly higher in those demersal and pelagic fish species caught from the Marmara Sea. Pelagic species of fish from either the Black Sea or the Marmara Sea had significantly higher percentage contents of 14:0, 18:1n-9, 20:0, 20:1n-9, saturated FA, total FA, and DHA compared to demersal species, whereas the proportions of 22:5n-3 and other minor unsaturated FA were considerably lower than those of demersal fish species. However, more importantly, there was no significant difference in the FA compositions between the pelagic species of fish either from the Black Sea or the Marmara Sea, which showed that the upper layer of the Marmara Sea was greatly influenced by the nutrients gained from the Black Sea. However, when demersal fish species from these seas were compared, 20:5n-3 as percentages of FA and the approximate amounts of 22:6n-3 (g/100 g) were significantly higher in fish from the Black Sea (11.2 vs. 7.5% and 1.2 vs. 0.7 g, respectively). Whiting, which belongs to the demersal group, is an exceptional fish since it usually spends the winter in the Black Sea although it may occasionally be caught in the Marmara Sea all year around. We found that this fish had the lowest percentage contents of 14:0, 16:0 (second-lowest), 16:1n-7, and 18:4n-3 FA and the highest percentages of

22:6n-3 and n-3 PUFA among the 18 fish species. These findings suggest that there is a need for further studies to determine how the ecosystem of the Black Sea affects the FA composition of fish that are endemic inhabitants to the Black Sea.

The mean level of 18:3n-3 was 1.09 ± 0.17% in Turkish marine fish, which, while low, was similar to other food fish such as Chinook salmon (1% by wt), mackerel (1.3% by wt), and wild salmon (1% by wt) (19,20). In our study, the contents of 18:2n-6 and 18:3n-3 FA in Turkish marine fish were low as expected. Although the levels of 20:4n-6 would be expected to be low, similar to 18:2n-6 and 18:3n-3 in marine fish, the levels of arachidonic acid were spuriously higher than expected, probably due to technical error. However, 22:1n-(13+11) isomers may be eluted in exactly the same position as 20:4n-6 on the capillary columns that were employed in our study (Ackman, R.G., personal communication). This source of error may be responsible for spuriously elevated levels of arachidonic acid, which are therefore not discussed. It should also be mentioned that palmitic acid levels, with a mean content of 24.9 ± 0.6%, was one of the highest among the FA examined in the present study, generally differing from other studies (17,18,22) although with some exceptions (20). Stearic acid content in marine fish in the present study was higher compared to North European fish species (mean: 6.1 vs. 3.1% by wt), possibly owing to moderately higher water temperatures. The levels of 16:1n-7 and 18:1n-9 in Turkish marine fish were not high, probably because they are confined to relatively shallow waters owing to bottom hypoxia or anoxia.

The only freshwater fish in our study was cultured rainbow trout. Although its saturated/unsaturated FA ratio was moderate, it had the lowest percentage of EPA and relatively low percentage content of DHA, but a very high percentage of 18:2n-6, which was up to almost 10 times that of marine fish.

Epidemiological data suggest that a decrease in coronary heart disease mortality occurs in people consuming relatively small amounts of fish and/or fish oils, as little as 0.4 g n-3 FA per day (14). The beneficial effect of a fish diet has been suggested to be mediated by the amount of EPA in fish (35,36). In this respect, the present study suggests that mature or immature blue fish, sardine, anchovy, horse mackerel, red mullet, sand smelt, striped mullet, and bonito may be preferred in the diet because of their relatively high EPA contents (>0.4 g/100 g) compared to other Turkish marine fish. Some studies have shown that an adequate DHA supply is essential for normal eye and brain development in infants and in children (37,38). In this regard, our study showed that DHA was present in measurable high amounts (>1 g/100 g) in blue fish, anchovy, red mullet, sardine, whiting, Atlantic mackerel, striped mullet, Spanish mackerel, bonito, garfish, comber, and rainbow trout.

In conclusion, there is a need for prospective epidemiological studies to determine whether the beneficial effects of fish consumption might be due to some specific nutrient or to the FA composition of each species of fish, before the reduction in cardiovascular diseases is attributed solely to high levels of EPA and DHA. In this respect, fish from Turkish waters, with their unique FA compositions, may be interesting to study.

ABSTRACT: We prepared model Schiff bases from 2-[9-oxo]nonanoyl glycerol (2-MAG-ALD) and various amino compounds. 2-MAG-ALD was obtained by pancreatic lipase hydrolysis of trioleoyl glycerol and reductive ozonolysis of the resulting 2-monooleoyl glycerol. The reaction products were purified by thin-layer chromatography. Schiff bases were synthesized in greater than 50% yield by reacting 2-MAG-ALD with twofold molar excess of valine, *N*α-acetyl-L-lysine methyl ester and the tripeptides glycyl-glycyl-glycine, glycyl-glycyl-histidine, and glycyl-histidyl-lysine in aqueous methanol and with 1-palmitoyl-2-stearoyl glycerophosphoethanolamine (PE) in chloroform/methanol for 16 h at room temperature. Prior to analysis the bases were reduced with sodium cyanoborohydride in methanol for 30 min at 4°C. Reaction products were analyzed by high-performance liquid chromatography/electrospray ionization/mass spectrometry (HPLC/ESI/MS). Reduced Schiff bases of 2-MAG-ALD with PE and amino acids were analyzed by normal-phase HPLC/ESI/MS and those with peptides by reversed-phase HPLC/ESI/MS. Single adducts were obtained in all cases and both the α-amino group of valine and the ε-amino group of *N*α-acetyl-L-lysine methyl ester were reactive. Molecular ions of reaction products were the only detected ions in the negative ionization mode, whereas in the positive ion mode sodiated molecular ions were also detected. The present study suggests that 2-MAG-ALD may form Schiff base adducts with amino compounds in other aqueous media, such as the intestinal lumen and in the hydrophobic environment of cell membranes.

Paper no. L8072 in *Lipids 34*, 299–305 (1999).

Oxidation of unsaturated triacylglycerols leads to the formation of low- and high-molecular-weight aldehydes as secondary products (1). Low-molecular-weight aldehydes have been studied extensively whereas investigation of high-molecular weight aldehydes is fairly recent. It has been shown that α,β-unsaturated aldehydes originating from oxidation of polyunsaturated fatty acids are absorbed from the gut and excreted in urine as C-3 mercapturate conjugates in rats (2). Reactions of low-molecular-weight aldehydes with various amino compounds have been described, with the most reactive aldehydes being the bifunctional compounds, malonaldehyde and 4-hydroxynonenal. Malonaldehyde forms eneamines (3), *N*-substituted 3-iminopropenals (4), and *N*,*N*′-disubstituted 1-amino-3-iminopropenes (5) with amino acids and also reacts with amino groups of proteins (5,6) and deoxynucleosides (7) *in vitro* forming various adducts. A glycerophosphoethanolamine-malonaldehyde-glycerophosphoserine Schiff base conjugate was identified in rabbit lens oxidized *in vitro*, and similar reactions are believed to occur in human cataract (8). Schiff base formation between peptide- mimicking the hemoglobin β–chain N-terminus and acetaldehyde has been reported (9). Acetaldehyde is the major oxidation product of ethanol *in vivo,* and its adducts with hemoglobin can serve as markers of ethanol intake (10). High-molecular-weight aldehydes of cholesteryl esters have been prepared (11) and isolated from oxidized human plasma lipoproteins (12). These aldehydes form complexes with proteins (13). Schiff bases of glycerophosphocholine core aldehydes and aminophospholipids, amino acids, and myoglobin have been prepared (14) as well as the Schiff base adducts of triacylglycerol core aldehydes and aminophospholipids (15). The formation and metabolic reactivity of acylglycerol core aldehydes are of potential interest to studies of digestion and absorption of food. Food systems contain complex mixtures of lipids, amino compounds, and other nutrients. Edible oils are mainly unsaturated triacylglycerols, the oxidation of which produces triacylglycerol core aldehydes and low-molecular-weight aldehydes. Triacylglycerols are hydrolyzed to free fatty acids and 2-monoacylglycerol by pancreatic lipase. Pancreatic lipase hydrolysis of oxidized unsaturated triacylglycerols would be anticipated to produce 2-[9-oxo]nonanoyl glycerol (2-MAG-ALD). The objective of the present study was to investigate if 2-MAG-ALD forms Schiff bases with model amino compounds and to determine their chromatographic and mass spectrometric characteristics in anticipation of the isolation of such compounds during digestion and absorption of oxidized dietary oils.

L-lysine methyl ester, glycyl-glycyl-glycine (GGG), glycyl-glycyl-histidine (GGH), glycyl-histidyl-lysine (GHK), and sodium cyanoborohydride were purchased from Sigma Chemical Co. (St. Louis, MO). 2,4-Dinitrophenylhydrazine (DNPH) and triphenylphosphine were obtained from Aldrich Chemical Company Inc. (Milwaukee, WI). Pancreatic lipase was a crude preparation (Steapsin), obtained from Nutritional Biochemicals Corporation (Cleveland, OH). All solvents were high-performance liquid chromatography (HPLC) grade, when available, otherwise reagent grade and were purchased from Caledon Chemicals (Toronto, Canada). All chemicals used were of reagent grade or better quality.

Preparation of 2-MAG-ALD. Trioleoyl glycerol was hydrolyzed by pancreatic lipase in borate–gum arabic buffer to obtain 2-oleoyl glycerol. Buffer (0.1 M, $[Ca^{2+}] = 5 \times 10^{-3}$ M) contained 1 g gum arabic/mL and pH was adjusted to 8 by adding 0.1 N NaOH solution. Hydrolysis was carried out in a mechanical shaker (38°C), and the mixture contained 10 mg substrate/mL buffer, whereas the amount of pancreatic lipase preparation used in hydrolysis was 20% of the amount of the substrate. After 1 h reaction time the hydrolysis products were extracted with diethyl ether and dried by anhydrous Na_2SO_4. 2-Oleoylglycerol was isolated by thin-layer chromatography using boric acid-impregnated silica gel G plates. A slurry of silica gel (0.5 g/mL) was prepared in 2.4% (wt/vol) boric acid solution and a layer of 500 μm spread on 20 × 20 cm glass plates. Before use the plates were air-dried and activated at 120°C for 1 h. Plates were developed in chloroform/acetone (88:12, vol/vol), and lipid bands were visualized by spraying with 2′,7-dichlorofluorescein. The 2-oleoyl glycerol-containing band was scraped off the plate, and lipids were extracted with diethyl ether. 2-MAG-ALD was prepared by ozonization of the 2-oleoyl glycerol and reduction of the resulting ozonide by triphenylphosphine as described previously (16,17). The method was modified slightly by using acetone as ozonization solvent instead of hexane to obtain better solubility. 2-MAG-ALD was purified by thin-layer chromatography as described above, except the aldehyde-containing bands were visualized by spraying part of the band with Schiff base reagent (17), which gave a purple color in the presence of aldehydes. Two bands corresponding to *sn*-1/3 (R_f 0.07) and *sn*-2 (R_f 0.12) isomers of 9-oxononanoyl glycerol were detected as a result of isomerization during ozonization. The *sn*-2 isomer was recovered, and no further isomerization was observed. The structure of 2-MAG-ALD was further confirmed by preparing its dinitrophenylhydrazone (2-MAG-ALD DNPH) derivative as described for aldehydes (18) and analyzing the free aldehyde and the DNPH derivative by HPLC-electrospray ionization-mass spectrometry (HPLC/ESI/MS).

Preparation of reduced Schiff bases of PE and 2-MAG-ALD. Reduced Schiff base of 2-MAG-ALD and PE was prepared as previously described for aminophospholipids (14). 2-MAG-ALD (1 mg) and a twofold molar excess of PE (6 mg) were dissolved in 4 mL chloroform/methanol (2:1, vol/vol) and allowed to react at room temperature for 16 h. After reaction, freshly prepared $NaCNBH_3$ in methanol was added to a final concentration of 70 mM and the mixture kept at 4°C for 30 min to allow reduction of the imine bond of Schiff base. Excess reducing reagent was removed by washing the organic phase with water and passing it through anhydrous Na_2SO_4. The reduced Schiff base was identified by HPLC/ESI/MS.

Preparation of reduced Schiff bases of amino acids and peptides with 2-MAG-ALD. Reduced Schiff bases of valine, *N*α-acetyl-L-lysine methyl ester, and tripeptides (GGG, GGH, and GHK) with 2-MAG-ALD were obtained using a modification of the method previously described for preparation of reduced Schiff bases of amino acids with phosphatidylcholine core aldehydes (14). 2-MAG-ALD (1 mg) was dissolved in 2 mL methanol, and a twofold molar excess of amino acid or peptide dissolved in 2 mL water was added. The reaction and reduction were done as described above except no washing was performed. After reduction 5 mL of $CHCl_3$ was added and the phases were allowed to separate. Schiff base adducts of amino acids were recovered from the organic phase and Schiff bases of peptides from the aqueous phase.

HPLC/ESI/MS. The HPLC/ESI/MS system consisted of a Hewlett-Packard (Palo Alto, CA) 1090 Liquid Chromatograph connected to a Hewlett-Packard 5989A quadrupole mass spectrometer equipped with a nebulizer-assisted electrospray interface. HPLC effluent was split 1:50 using a commercial splitter (LC Packings) to deliver suitable flow to the electrospray interface. The capillary exit voltage was +160 V in positive and −160 V in negative ion mode. The capillary, end plate, and cylinder voltages were 3500, 3000, and 3500 V, respectively, in negative and −4000, −3500 and −5000 V, respectively, in positive mode. The mass range scanned as total ion current was *m/z* 200–1100. A minimum of 5 μg of total sample was injected. 2-MAG-ALD and its reduced Schiff bases with PE and amino acids were analyzed on a silica column (Supelcosil LC-Si, 5 μm, 250 × 4.6 i.d., Supelco Inc., Bellefonte, PA). The solvent system consisted of solvent mixture A (chloroform/methanol/30% ammonium hydroxide, 80:19.5:0.5, by vol) and B (chloroform/methanol/water/30% ammonium hydroxide, 60:34:5.5:0.5, by vol) (19). The column was eluted at a flow rate of 1 mL/min with a linear gradient starting from 100% solvent A and changing to 100% solvent B in 14 min after holding the starting composition for 3 min. The final composition was held for 10 min. Reduced Schiff bases of 2-MAG-ALD and peptides were analyzed using a reversed-phase column (ODS Hypersil, 5 μm, 100 × 2.1 i.d., Hewlett-Packard) with a flow rate of 0.5 mL/min. The mobile phase composition changed from 0.5% ammonium hydroxide in water/methanol/hexane (12:88:0, by vol) to (0:88:12, by vol) in 17 min after holding the starting composition for 3 min (20). The final composition was held for 5 min.

RESULTS

2-MAG-ALD. Figure 1 shows the total negative ion current chromatogram (A) of 2-MAG-ALD and single-ion chromatograms of ions *m/z* 281 (B) and *m/z* 261 (C). Table 1 lists

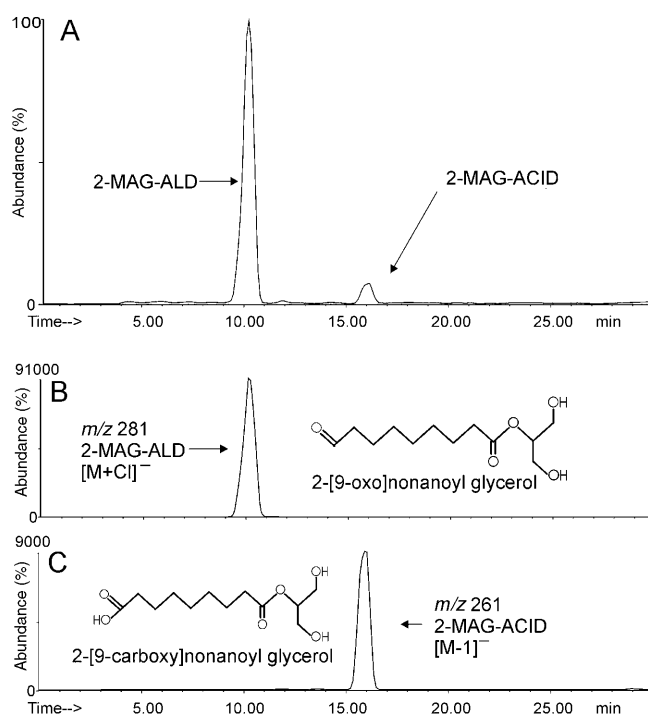

FIG. 1. Normal-phase high-performance liquid chromatography/electrospray ionization/mass spectrometry (HPLC/ESI/MS) of 2-[9-oxo]nonanoyl glycerol (2-MAG-ALD). Total negative ion current chromatogram (A) and single-ion chromatograms of ions *m/z* 281 (B) and *m/z* 261 (C). Ions are identified in figures and discussed further in text. The HPLC/ESI/MS instrumentation is described in Materials and Methods section. The solvent system consisted of solvent mixture A (chloroform/methanol/30% ammonium hydroxide, 80:19.5:0.5, by vol) and B (chloroform/methanol/water/30% ammonium hydroxide, 60:34:5.5:0.5, by vol) with a linear gradient starting from 100% solvent A and changing to 100% solvent B in 14 min after holding the starting composition for 3 min.

TABLE 1
Retention Times of Oxoacylglycerols and Reduced Schiff Bases and Yields of the Bases As Calculated by Using Ion Abundance in HPLC/ESI/MS

Compound	Retention time (min)	Yield (%)
2-MAG-ALD	10.2[a]	—
2-MAG-ALD DNPH	4.1[a]	—
2-MAG-ACID	15.9[a]	—
2-MAG-ALD + PE	13.1[a]	60
2-MAG-ALD + Lysine	11.2[a]	>50[c]
2-MAG-ALD + Valine	10.9[a]	>50[c]
2-MAG-ALD + GGG	2.2[b]	76
2-MAG-ALD + GHK	2.1[b]	74
2-MAG-ALD + GGH	2.0[b]	71

[a]Normal-phase HPLC/ESI/MS. See Figure 1 for conditions.
[b]Reversed phase HPLC/ESI/MS. See Figure 3 for conditions.
[c]Yield approximated by comparing with ion abundance of Schiff bases of peptides since the unreacted amino acids were lost in aqueous phase before analysis. Abbreviations: 2-MAG-ALD, 2-[9-oxo]nonanoyl glycerol; 2-MAG-ACID, 2-[9-carboxy]nonanoyl glycerol; DNPH, dinitrophenylhydrazine; GGG, glycyl-glycyl-glycine; GHK, glycyl-histidyl-lysine; GGH, glycyl-glycyl-histidine; PE, phosphatidylethanolamine; HPLC/ESI/MS, high-performance liquid chromatography/electrospray ionization/mass spectrometry.

the normal-phase HPLC retention times for these compounds. The ion at *m/z* 281 eluting at 10.2 min corresponds to the $[M + Cl]^-$ ion of 2-MAG-ALD (MW 246.3). The peak at 15.9 min (*m/z* 261) is due to the $[M - 1]^-$ ion of 2-[9-carboxy]nonanoyl glycerol. As shown in the single-ion chromatograms the abundance of 2-[9-carboxy]nonanoyl glycerol is about 10% of the abundance of 2-MAG-ALD. In comparison to the flame-ionization response in the gas chromatograph, the acid gave about four times higher response than the aldehyde. Thus, the amount of the 2-[9-carboxy]nonanoyl glycerol in the 2-MAG-ALD preparation was 2–3%. The DNPH derivative of 2-MAG-ALD eluted at 4.1 min (Table 1), and the total mass spectrum averaged over the peak showed no other ions than the $[M - 1]^-$ ion of the derivative at *m/z* 425 (mass chromatogram not shown). The alternative method for preparing 2-MAG-ALD, where trioleoyl glycerol or sunflower oil was ozonized before pancreatic lipase hydrolysis, was also tested. The final products of lipase hydrolysis of the triacylglycerol core aldehydes were 2-MAG-ALD for trioleoyl glycerol and 2-MAG-ALD and 2-monoacylglycerols for sunflower oil. Diacylglycerols and diacylglycerol core aldehydes were also detected as intermediate hydrolysis products.

Schiff bases of amino acids. Figure 2 shows the total positive ion current chromatogram of the reduced Schiff base of valine and 2-MAG-ALD (A) and the full mass spectrum averaged over the Schiff base peak (B). Figure 2 also shows the corresponding total mass spectrum of Schiff base peak (C) obtained from negative ion HPLC/ESI/MS. Valine Schiff

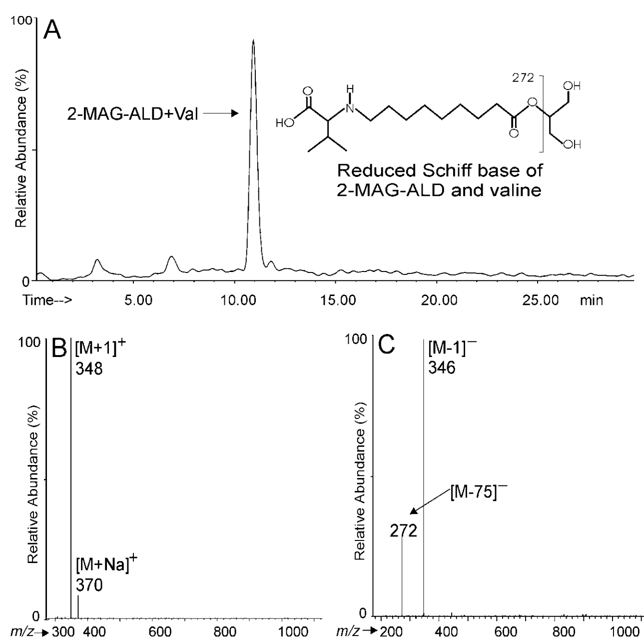

FIG. 2. Normal-phase HPLC/ESI/MS of sodium cyanoborohydride-reduced Schiff base of 2-MAG-ALD and valine. Total positive ion current chromatogram (A) and total mass spectrum averaged over Schiff base peak from positive (B) and negative (C) total ion current chromatogram. Ions are identified in figures and described in text. See Figure 1 for HPLC/ESI/MS conditions and abbreviations.

base eluted at 10.9 min (Table 1) and the $[M + 1]^+$ ion of the adduct (MW 347) at *m/z* 348 was the major ion in the positive ion mode (B). In addition to the molecular ion a sodium adduct of the Schiff base was detected at *m/z* 370. The molecular ion of the adduct also was detected in the negative ionization mode at *m/z* 346 (C), as well as a fragment ion $[M - 75]^-$ at *m/z* 272 which was formed by loss of glycerol as marked in Figures 2A and 2C. The reduced Schiff base of 2-MAG-ALD and *N*α-acetyl-L-lysine methyl ester also was analyzed by HPLC/ESI/MS in negative and positive ionization mode. The elution time of *N*α-acetyl-L-lysine methyl ester adduct was 11.2 min (Table 1), and the $[M - 1]^-$ molecular ion was the only ion detected in the negative ionization mode at *m/z* 467. The total mass spectrum of the reduced Schiff base peak obtained from the positive ion chromatogram showed $[M - 36]^+$ as a major ion (mass chromatogram not shown). This ion was formed by loss of the $[CH_3\text{-CO-}NH_2]$ group from the α-carbon of sodiated Schiff base adduct of *N*α-acetyl-L-lysine methyl ester and 2-MAG-ALD. The fragmentation pattern was confirmed by analyzing the pure *N*α-acetyl-L-lysine methyl ester, which also yielded the $[M + Na - CH_3\text{-CO-}NH_2]^+$ fragment as a major ion.

Schiff bases of peptides. Figure 3 shows the total positive ion current chromatogram obtained by reversed-phase HPLC/ESI/MS for the reduced Schiff base of triglycine (GGG) and 2-MAG-ALD (A) and the full mass spectrum averaged over the Schiff base peak (B). The Schiff base adduct of GGG eluted at the beginning of the run (2.2 min) although not in the solvent front (Table 1). The adducts of GGH and GHK eluted at 2.0 and 2.1 min, respectively (Table 1). The total mass spectrum averaged over the cyanoborohydride-reduced Schiff base peak of GGG and 2-MAG-ALD showed the $[M + 1]^+$ molecular ion to be the major ion of reaction products at *m/z* 420 (B). The monosodium adduct of the reduced Schiff base was detected at *m/z* 442 with approximately half of the intensity of the molecular ion, whereas the intensity of the ion for disodiated adduct at *m/z* 464 was even smaller. Ions representing the unreacted triglycine were *m/z* 190, 212, and 234, corresponding to $[M + 1]^+$, $[M + Na]^+$, and $[M + 2Na]^+$ ions, respectively, the sodiated ion being the most intense (B). For reduced Schiff bases of peptides GHK and GGH with 2-MAG-ALD the $[M + 1]^+$ molecular ion was the main ion in the positive ionization mode. Sodiated ions were also detected as in the case of GGG. For unreacted peptides the main ion was monosodiated adduct ion, but molecular ion and disodiated adducts were also present. Figure 4 shows the total negative ion chromatogram of the reduced Schiff base of GHK and 2-MAG-ALD (A) and the total mass spectrum averaged over the Schiff base peak (B), where deprotonated molecular ions for the reduced Schiff base of GHK and 2-MAG-ALD (*m/z* 569) and unreacted peptide (*m/z* 339) were the only ions detected. The schematic structure in Figure 4 represents the most probable structure for the reduced Schiff

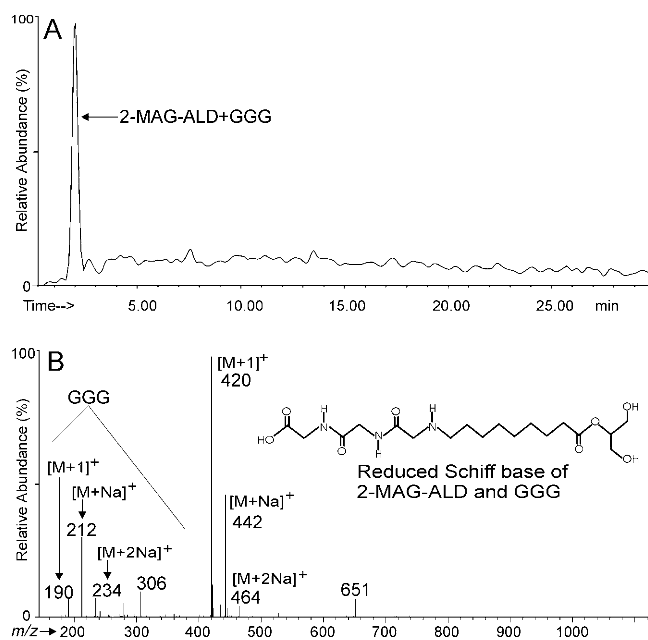

FIG. 3. Reversed-phase HPLC/ESI/MS of sodium cyanoborohydride-reduced Schiff base of 2-MAG-ALD and triglycine (GGG). Total positive ion current chromatogram (A) and total mass spectrum of Schiff base peak (B). Ions are identified in figures and discussed further in text. HPLC/ESI/MS instrumentation is described in Materials and Methods section. The mobile phase composition changed from 0.5% ammonium hydroxide in water/methanol/hexane (12:88:0, by vol) to (0:88:12, by vol) in 17 min after holding the starting composition for 3 min. For abbreviations see Figure 1.

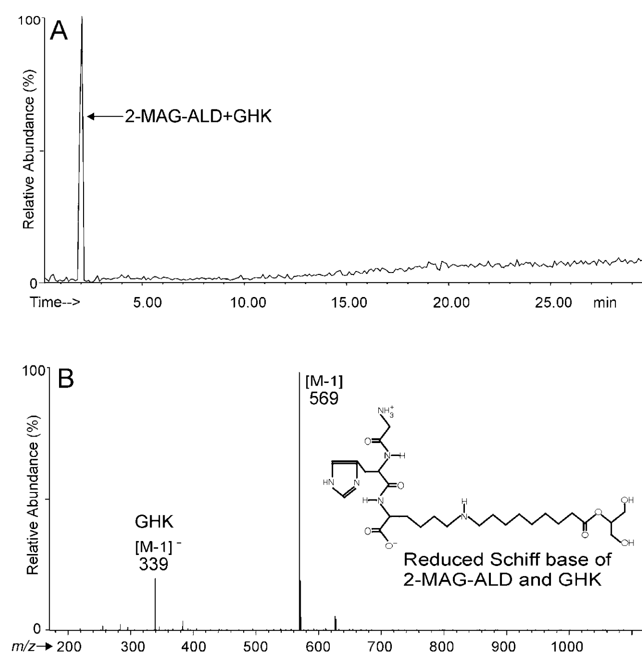

FIG. 4. Reversed-phase HPLC/ESI/MS of sodium cyanoborohydride-reduced Schiff base of 2-MAG-ALD and glycine-histidine-lysine (GHK). Total negative ion current chromatogram (A) and total mass spectrum of Schiff base peak (B). Ions are identified in figures and discussed further in text. See Figure 3 for HPLC/ESI/MS conditions and Figure 1 for abbreviations.

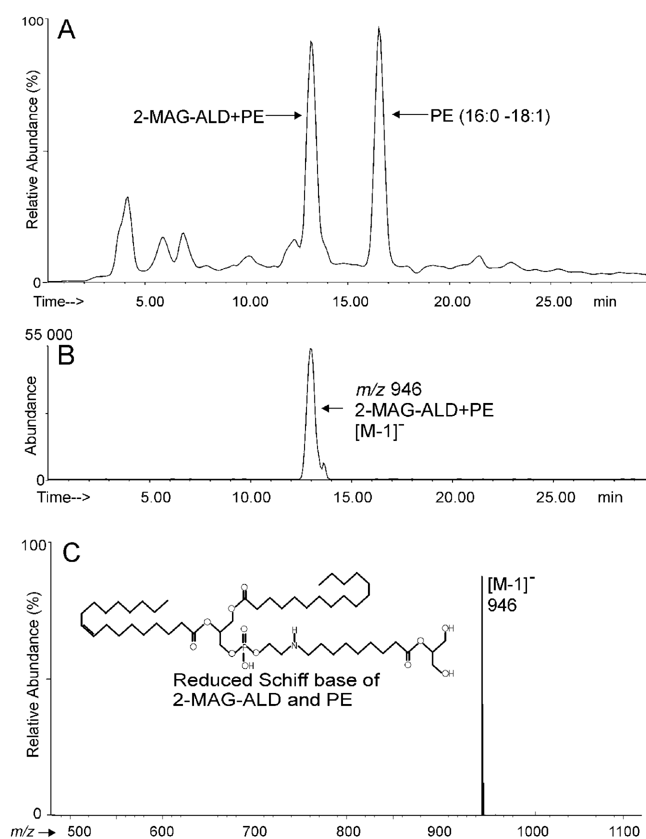

FIG. 5. Normal-phase HPLC/ESI/MS of sodium cyanoborohydride-reduced Schiff base of 2-MAG-ALD and 1-palmitoyl-2-oleoyl glycerophosphoethanolamine (PE). Total negative ion current chromatogram (A), single-ion chromatogram of Schiff base adduct (*m/z* 946) (B), and total mass spectrum averaged over Schiff base peak (C). Ions are identified in Figures. See Figure 1 for HPLC/ESI/MS conditions and abbreviations.

base adduct, although reaction with the α-amino group of glycine is also possible as will be discussed later. Deprotonated molecular ions were also the only detected ions in negative ionization mode for reduced Schiff base adducts of 2-MAG-ALD with GGG (*m/z* 418) and GGH (*m/z* 498) as well as for the unreacted peptides at *m/z* 188 and *m/z* 268, respectively (ion chromatograms not shown).

Schiff bases of PE. Figure 5 shows the total negative ion current chromatogram obtained for the reduced Schiff base of 2-MAG-ALD and PE (16:0–18:1) by normal-phase HPLC/ESI/MS (A), the single-ion chromatogram for Schiff base adduct (*m/z* 946) (B), and the total mass spectrum averaged over the Schiff base peak (C). The Schiff base adduct and PE were clearly resolved in the chromatographic system used, the former eluting at 13.1 min (Table 1) and the latter at 16.4 min. The total mass spectrum of the Schiff base peak averaged from 12.6 to 13.7 min shows no other ions than $[M-1]^-$ ion for the reduced Schiff base of PE and 2-MAG-ALD at *m/z* 946. It was estimated by using the integrated peak areas of PE and its Schiff base that the yield of the adduct is 60% (Table 1), assuming that there are no major differences in ionization efficiency between these compounds.

DISCUSSION

The present study shows that 2-MAG-ALD readily reacts with amino groups in amino acids, peptides, and aminophospholipids in hydrophobic and aqueous media. The reaction products are shown to be of Schiff-base type by reducing the adducts with sodium cyanoborohydride and analyzing the reduced reaction products by HPLC/ESI/MS. The results are consistent with Schiff base formation reported earlier between lipid ester core aldehydes and amino compounds (13–15,21). Bifunctional 4-hydroxy-2-nonenal has been shown to react with proteins preferentially *via* the Michael addition (22–24), and some low-molecular weight aldehydes have been demonstrated to undergo secondary reactions in complexing with amino groups (25,26). However, the main reaction products between 2-MAG-ALD and amino compounds in the present study were Schiff base adducts. The amino acids used to prepare Schiff base adducts in this work were valine and *N*α-acetyl-L-lysine methyl ester. Since the α-amino group of *N*α-acetyl-L-lysine methyl ester is blocked by an acetyl group, the only possible site for Schiff base formation is the ε-amino group in the side chain, whereas valine contains only an α-amino group. Both amino acids investigated formed Schiff bases with 2-MAG-ALD and no clear difference was observed in the reactivity between α- and ε-amino groups. However, the kinetics of the reaction between L-lysine and hexanal has been studied (27), and the ε-amino group of lysine has been shown to be two times more reactive than the α-amino group. A higher reactivity of the primary amino group compared to the secondary group has also been observed for free lysine and the core aldehyde of glycerophosphocholine (14). Two of the three peptides used (GGG and GGH) in the reaction contained only one free α-amino group at the end of the chain and thus possessed only one possible site for Schiff base formation. The ε-amino group of lysine in a third peptide (GHK) gave rise to another possible reaction site. Owing to the greater reactivity of the primary amino group, 2-MAG-ALD is assumed to react mainly with the ε-amino group in the side chain, without excluding the possibility of a reaction with the α-amino group. Theoretically both α- and ε-amino groups of GHK could react with 2-MAG-ALD, resulting in an adduct with two aldehyde groups attached to the peptide. Such double adducts were not detected nor were significant differences observed in reactivity among the peptides.

The reactions with amino acids and peptides were carried out at room temperature in aqueous solutions and at close to neutral pH. Since the reaction products were obtained in high yields under mild reaction conditions it may be suggested that 2-MAG-ALD could also react with amino compounds in foods and during fat absorption. 2-MAG-ALD is the final product of pancreatic digestion of oxidized triacylglycerols (15). The 2-MAG-ALD are formed by oxidation of unsaturated 2-monoacylglycerols present in food or food additives. The oxidation of triacylglycerols produces triacylglycerol core aldehydes as secondary oxidation products (1,28,29),

and these compounds have been identified in oxidized sunflower oil (30) and fish oil (31). Moreover, it has been shown that primary oxidation products, linoleic acid hydroperoxides (32), and trilinoleoylglycerol hydroperoxides (33) decompose to aldehydes in the stomach. During fat absorption 2-MAG-ALD may react with amino acids and peptides in the gastrointestinal tract and be partly responsible for impaired utilization of dietary protein. The structure of 2-MAG-ALD is identical to that of 2-monoacylglycerol, the normal hydrolysis product of triacylglycerols, which is absorbed from the intestine and metabolized further. In addition the α,β-unsaturated aldehydes originating from polyunsaturated fatty acids are absorbed, metabolized, and excreted in experimental animals (2). Therefore, the 2-MAG-ALD would be anticipated to be absorbed by the micro villus cells, where it could become acylated to triacylglycerol, as well as react with the cell protein. The rapid reaction of 2-MAG-ALD with PE in a hydrophobic environment suggests that 2-MAG-ALD might react with the aminophospholipids present in the cell membrane, where hydrophobic conditions would also be expected to prevail. The Schiff base adducts prepared in the present study should serve as reference compounds when investigating the intestinal uptake of 2-MAG-ALD during fat absorption.

Synthetic Routes to Lipidic Diamines and Amino Alcohols: A Class of Potential Antiinflammatory Agents

George Kokotos[a,*], Violetta Constantinou-Kokotou[b], Caterina Noula[a], and Dimitra Hadjipavlou-Litina[c]

[a]Department of Chemistry, University of Athens, Panepistimiopolis, Athens 15771, Greece, [b]Chemical Laboratories, Agricultural University of Athens, Athens 11855, Greece, and [c]Pharmaceutical Chemistry, University of Thessaloniki, Greece

ABSTRACT: Simple and efficient methods for the synthesis of lipidic amino alcohols and diamines are described in this paper. Lipidic 2-amino alcohols and 1,3-diamines can be synthesized starting from synthetic lipidic α-amino acids. Alternatively, commercially available lipidic 1,2-diols may be used as starting material for the synthesis of 2-amino alcohols. Initial experiments on the *in vivo* antiinflammatory activity of the compounds synthesized gave promising results.

Paper no. L8052 in *Lipids 34,* 307–311 (March 1999).

Currently available nonsteroidal antiinflammatory drugs (NSAID) are widely used in the treatment of inflammatory conditions including rheumatoid arthritis (1). However, long-term NSAID use has been associated with gastrointestinal ulceration, bleeding and nephrotoxicity (2). On the other hand, the use of antiinflammatory steroids can cause systematic suppressive effects on adrenal function and the immune system. As a result, the discovery of novel antiinflammatory agents as an alternative to the conventional steroids or nonsteroidal compounds is in demand.

Recently we have been involved in the synthesis of lipidic amino acids and derivatives and the investigation of their biological properties. The lipidic α-amino acids (LAA) are synthetic α-amino acids with saturated or unsaturated long aliphatic side chains (3). A general approach to enantioselective synthesis of saturated LAA is based on the oxidative cleavage of amino diols obtained by the regioselective opening of enantiomerically enriched 2,3-epoxy alcohols (4). We have recently published the synthesis of optically active unsaturated LAA, including α-amino arachidonic acid, through a Wittig reaction on the suitable glutamate semialdehyde (5). LAA amides and esters with long-chain amines and alcohols, respectively, as well as lipidic dipeptide derivatives, inhibit phospholipase A_2 (6,7). On the other hand, the palmitic acid derivative *N*-(2-hydroxyethyl)hexadecanamide has been reported to have antiinflammatory activity (8), correlating with its ability to down-modulate mast cell activities *in vivo* (9). The interaction of this derivative with the peripheral cannabinoid CB_2 receptor has been demonstrated by *in vitro* studies (9). The aim of this paper is to develop synthetic routes to lipidic 2-amino alcohols and 1,3-diamines. These compounds, which can be called lipid mimetics because they resemble lipids either structurally or functionally, may have potentially useful biological activities.

Abbreviations: Ac, acetyl; Boc, *tert*-butoxycarbonyl; ^{t}Bu, *tert*-butyl; DMF, *N,N*-dimethylformamide; EtOAc, ethyl acetate; FAB, fast atom bombardment; LAA, lipidic α-amino acid; MS, mass spectrometry; NMR, nuclear magnetic resonance; THF, tetrahydrofuran.

EXPERIMENTAL PROCEDURES AND RESULTS

tert-Butoxycarbonyl (Boc)- or acetyl (Ac)-protected LAA were prepared as described elsewhere (3,10) and reduced to amino alcohols in high yield as described in Scheme 1. N-Protected amino acids **1a–d** were converted into their corresponding fluorides **2a–d** by treatment with cyanuric fluoride in the presence of pyridine. Acyl fluorides **2a–d** were reduced in situ to primary alcohols by sodium borohydride with dropwise addition of methanol at room temperature. Boc or Ac protective groups remained inert under the conditions described. The present method for the conversion of N-protected LAA into alcohols gave products in higher yields in comparison with the previously reported mixed anhydride–$NaBH_4$ method (10). 2-Butoxycarbonylamino-hexadecanoic acid (**1a**) was used in both the racemic and the optically active *S* form; all the other derivatives of LAA were racemic mixtures. As indicated by comparison of the specific rotation values of the *S*-enantiomer of **3a** with that reported in the literature (4), the present reductive method proceeded with retention of optical purity. In addition, the preparation of the corresponding (+) and (−) Mosher esters of *S*-**3a** and ^{1}H nuclear magnetic resonance (NMR) analysis confirmed enantiomeric excess >95% due to the absence of any diastereomeric proton signal. The free lipidic amino alcohols **4a,b** were obtained by removal of the Boc group of **3a,c** using HCl in tetrahydrofuran (THF).

N-Protected amino alcohols **3** can be converted into lipidic 1,2-diamines (10) and 1,3-diamines. The hydroxyl group of **3a** was activated as the mesylate, and the methanesulfonate was converted directly into the nitrile **5** by treatment with sodium cyanide in *N,N*-dimethylformamide (DMF) at 60°C

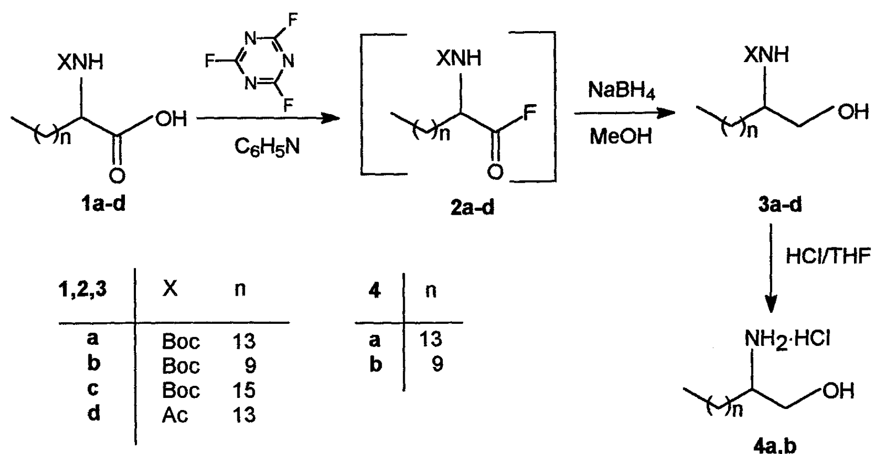

SCHEME 1

(Scheme 2). Reduction of the cyano group of **5** with sodium borohydride–transition metal system ($NiCl_2$ or $CoCl_2$) gave the N^3-monoprotected diamine **6**. Free 1,3-diamine **7** was obtained by treatment of **6** with HCl in THF.

Lipidic 2-amino alcohols can be also prepared using long-chain 1,2-diols as starting material (Scheme 3). Selective protection of the primary hydroxyl group of 1,2-hexadecanediol (**8**) by the *tert*-butyl (^{t}Bu) group was achieved in good yield by treatment with ^{t}Bu-trichloroacetimidate in the presence of a catalytic amount of boron trifluoride etherate. The secondary hydroxyl group of **9** was activated as the mesylate and converted directly into the azido group by treatment with sodium azide in DMF at 60°C in high yield. The reduction of **10** was carried out using sodium borohydride in the presence of 10% palladium-charcoal at room temperature. The ^{t}Bu group of **11** was removed by treatment with trifluoroacetic acid.

The compounds synthesized were characterized by elemental analysis, mass spectrometry, ^{1}H NMR and ^{13}C NMR spectroscopy. ^{13}C NMR spectra using DEPT pulse sequence were also recorded.

Melting points were determined on a Buchi micro melting point apparatus and are uncorrected. Specific rotations were determined with a Perkin-Elmer 141 polarimeter using a 10-cm cell. ^{1}H NMR and ^{13}C NMR spectra were run on a Bruker AM-200 spectrometer. Fast atom bombardment (FAB) spectra were obtained on a VG Analytical ZAB-SE instrument. THF was passed through a column of aluminum oxide and distilled over CaH_2. All solvents and chemicals were of reagent grade and used without further purification. Silica gel 60 (70–230 mesh, Merck) was used for column chromatography.

General procedure for the preparation of alcohols **3a–d**. Pyridine (80 μL, 1 mmol) and subsequently cyanuric fluoride (180 μL, 2 mmol) were added to a stirred solution of N-protected amino acid **1a–d** (1 mmol) in CH_2Cl_2 (2.5 mL), kept under a N_2 atmosphere, at –20 to –10°C. Precipitation of cyanuric acid occurred and increased gradually as the reaction proceeded. After the mixture was stirred at –20 to –10°C for 1 h, ice-cold water was added along with 15 mL of additional CH_2Cl_2. The organic layer was separated, and the aqueous layer was extracted once with CH_2Cl_2 (5 mL). The combined organic layers were washed with ice-cold water (10 mL), dried (Na_2SO_4), and concentrated under reduced pressure to a small volume (2 mL). $NaBH_4$ (76 mg, 2 mmol) was added in one portion and MeOH (2 mL) was then added dropwise over a period of 10–15 min at room temperature. The reaction mixture was neutralized with 0.5 M H_2SO_4, and the organic solvents were evaporated under reduced pressure. The residue was treated with CH_2Cl_2 (10 mL) and H_2O (5 mL), the organic layer was separated, and the aqueous layer was extracted with CH_2Cl_2 (2 × 8 mL). The combined organic layers were washed consecutively with 0.5 M H_2SO_4 (5 mL) and H_2O (2 × 10 mL), dried (Na_2SO_4), and the solvent was evaporated under reduced pressure. The residue was purified by

2-Acetylaminohexadecanol **3d**. Yield 74%; m.p. 84–85°C [lit. (10): 83–85°C].

*3-(*tert*-Butoxycarbonylamino)heptadecane nitrile* **5**. To an ice-cooled solution of N-protected amino alcohol **3a** (0.36 g, 1 mmol) in CH_2Cl_2 (40 mL), triethylamine (0.21 mL, 1.5 mmol) and methanesulfonyl chloride (0.12 mL, 1.5 mmol) were added together dropwise. The reaction mixture was stirred for 30 min at 0°C and for 30 min at room temperature. The organic phase was washed consecutively with brine, 1 M HCl, brine, 5% aqueous $NaHCO_3$ and brine, dried (Na_2SO_4), and the solvent was evaporated under reduced pressure. The crude methanesulfonate ester obtained was dissolved in DMF (2 mL); sodium cyanide (0.12 g, 2.5 mmol) was added and the reaction mixture was heated for 3 h at 60°C. After cooling, water (12 mL) was added and the precipitated product was filtered and dried. The crude product was purified by column chromatography using EtOAc/hexane (2:8, vol/vol) as eluent: Yield 0.27 g (74%); m.p. 55–56°C; ^1H NMR ($CDCl_3$) δ 0.87 (3H, *t*, *J* = 7 Hz, CH_3), 1.20–1.40 (24H, *m*, 12 × CH_2), 1.44 [9H, *s*, $C(CH_3)_3$], 1.59 (2H, *m*, CH_2CHCH_2CN), 2.51 (1H, *dd*, *J* = 4 Hz, *J* = 17 Hz, C*H*HCN), 2.75 (1H, *dd*, *J* = 5 Hz, *J* = 17 Hz, CH*H*CN), 3.78 (1H, *m*, α-CH), 4.60 (1H, *d*, *J* = 8 Hz, OCONH); ^{13}C NMR ($CDCl_3$) δ 14.1 (C-17), 22.7 (C-16), 23.7 and 25.9 (C-4 and C-5), 28.3 [$(CH_3)_3$], 29.3–29.6 (C-6–C-14), 31.9 (C-15), 33.4 (C-2), 47.2 (C-3), 80.1 [$C(CH_3)_3$], 117.4 (CN), 155.0 (OCO); FAB MS: *m/z* 367 ($M + H^+$, 10%), 311 (100), 267 (25), 226 (34). Calc. for $C_{22}H_{42}N_2O_2$: C 72.08; H 11.55; N 7.64; MW 366.59. Found: C 71.91; H 11.51; N 7.32.

*3-(*tert*-Butoxycarbonylamino)heptadecanamine* **6**. To a stirred solution of **5** (0.37 g, 1 mmol) in methanol (8 mL) nickel chloride hexahydrate (1.18 g, 5 mmol) was added at 0°C, followed by $NaBH_4$ (0.30 g, 8 mmol) in small portions. After stirring for 30 min at room temperature, water was added, the mixture was neutralized with 0.5 M H_2SO_4 and the organic solvent was removed under reduced pressure. The aqueous phase was extracted with EtOAc (5 × 10 mL). After drying (Na_2SO_4), the solvent was evaporated to dryness to give **6**. Yield 0.27 g (74%); m.p. 112–114°C; ^1H NMR ($CDCl_3$) δ 0.84 (3H, *t*, *J* = 7 Hz, CH_3), 1.00–1.60 [35H, *m*, $C(CH_3)_3$, 13 × CH_2), 2.10 (2H, *m*, $CH_2CH_2NH_2$), 2.90 (2H, *m*, NH_2), 3.20 (2H, *m*, CH_2NH_2), 3.59 (1H, *m*, α-CH), 4.50 (1H, *d*, *J* = 8 Hz, OCONH); ^{13}C NMR ($CDCl_3$) δ 14.1 (C-17), 22.7 (C-16), 25.9 (C-5), 28.3 [$(CH_3)_3$], 29.3–29.6 (C-6–C-14), 31.9 (C-15), 33.6 (C-4), 35.6 (C-2), 37.1 (C-1), 47.8 (C-3), 80.3 [$C(CH_3)_3$], 157.0 (OCO); FAB MS *m/z* 371 (M + H, 100%), 315 (74), 271 (20), 226 (20). A mixture of the purified oil (0.51 g, 1.3 mmol) in DMF (2.6 mL) and NaN_3 (0.34 g, 5.20 mmol) was stirred under heating at 60°C for 24 h. The solvent was evaporated, and water (20 mL) and EtOAc (20 mL) were added. The organic phase was washed with brine, dried (Na_2SO_4), concentated, and purified by column chromatography using EtOAc/petroleum ether (4:96, vol/vol). Yield 0.43 g (96%) of colorless oil; ^{1}H NMR ($CDCl_3$) δ 0.82 (3H, *t*, J = 7 Hz, CH_3), 1.0–1.5 (35H, *m*, $C(CH_3)_3$, 13 × CH_2), 3.42 (3H, *m*, CH_2O, CH); ^{13}C NMR ($CDCl_3$) δ 14.1 (C-16), 22.7 (C-15), 26.1 (C-4), 27.3 [$(CH_3)_3$], 29.4–29.6 (C-5–C-13), 30.9 (C-3), 31.9 (C-14), 62.2 (C-2), 65.1 (C-1), 73.3 [*C*$(CH_3)_3$]; infrared (cm^{-1}) 2927, 2856, 2103, 1467, 1364, 1097; FAB MS *m/z* 340 (M + H^+, 5%), 312 (13), 256 (66). Calc. for $C_{20}H_{41}N_3O$: C 70.74; H 12.17; N 12.37; MW 339.57. Found: C 70.67; H 12.22; N 12.19.

*1-*tert*-Butoxy-2-hexadecyl amine* **11**. To a mixture of **10** (0.33 g, 1 mmol), 10% palladium on charcoal (66 mg) and $NaBH_4$ (113 mg, 3 mmol) in THF (4 mL), methanol (8 mL) was added dropwise under cooling at 10°C. After 10 min, the catalyst was filtered off, and the filtrate was neutralized with 0.5 M H_2SO_4 and concentrated to a smaller volume to remove the organic solvents. Water (10 mL) was added and the product was extracted with EtOAc (3 × 10 mL). The organic phase was washed with brine, dried (Na_2SO_4), concentrated, and the product was purified by column chromatography using $CHCl_3$/MeOH (93:7, vol/vol) as eluent. Yield 0.30 g (95%); m.p. 67–69°C; ^{1}H NMR ($CDCl_3$) δ 0.88 (3H, *t*, J = 7 Hz, CH_3), 1.30 [33H, *m*, 12 × CH_2, $C(CH_3)_3$], 1.72 (2H, *m*, C*H*$_2$CHCH$_2$O), 3.18 (1H, *m*, α-CH), 3.40 (1H, *dd*, J = 10 Hz, J = 9 Hz, C*H*HO), 3.55 (1H, *dd*, J = 5 Hz, J = 10 Hz, CH*H*O); ^{13}C NMR ($CDCl_3$) δ 14.1 (C-16), 22.7 (C-15), 25.7 (C-4), 27.4 [$(CH_3)_3$], 29.4–29.7 (C-5–C-13), 30.0 (C-3), 31.9 (C-14), 52.4 (C-2), 61.2 (C-1), 73.7 [*C*$(CH_3)_3$]; FAB MS *m/z* 315 (M + H^+, 100%), 259 (88), 227 (20). Calc. for $C_{20}H_{43}NO \cdot 1.5H_2O$: C 70.53; H 13.61; N 4.11; MW 340.59. Found: C 70.72; H 13.58; N 4.09.

2-Aminohexadecanol trifluoroacetate **12**. A solution of **11** (0.10 g, 0.3 mmol) in trifluoroacetic acid (0.9 mL) was stirred at room temperature for 1 h. The reaction mixture was diluted with CH_2Cl_2 (5 mL), and the excess acid and solvent were removed under reduced pressure. Dichloromethane (5 mL) was added to the residue, and the solvent was evaporated. The process was repeated once more. A white solid was formed upon the addition of dry ether, which was filtered, yielding 96 mg (86%); m.p. 107–109°C; ^{1}H NMR (CD_3OD) δ 0.88 (3H, *t*, J = 7 Hz, CH_3), 1.10–1.40 (24H, *m*, 12 × CH_2), 1.48 [2H, *m*, C*H*$_2$(CH$_2$)$_{12}$CH$_3$], 3.02 (1H, *m*, α-CH), 3.40 (1H, *m*, CH*H*OH), 3.63 (1H, *m*, C*H*HOH); ^{13}C NMR (CD_3OD) δ 14.5 (C-16), 23.8 (C-15), 26.5 (C-4), 30.5–30.8 (C-5–C-14), 33.1 (C-3), 54.6 (C-2), 62.1 (C-1); FAB MS *m/z* 259 (M + H^+ – CF_3COOH, 100%), 227 (12). Calc. for $C_{16}H_{35}NO \cdot CF_3COOH$: C 58.20; H 9.77; N 3.77; MW 371.49. Found: C 57.95; H 9.93; N 3.53.

A sample of 2-aminohexadecanol, isolated as hydrochloride salt, was identical to that prepared as described (10).

DISCUSSION

Initial experiments on the potential *in vivo* antiinflammatory usefulness of these compounds were carried out using the rat carrageenin-induced paw edema assay as a model for acute inflammation. Preliminary results were obtained for lipidic 1,2- and 1,3-diamines, containing at least one free amino group, as well as for 2-amino alcohols. For example, 2-aminohexadecanol (**4a**) and 1,2-hexadecanediamine (10) caused, respectively, 85.6 ± 0.38% and 93.5 ± 0.36% inhibition of paw edema at a high dose of 0.15 mmol/kg, while 1,3-heptadecanediamine (**7**) inhibited the edema by 70.7 ± 2.02% at a dose of 0.04 mmol/kg.

In conclusion, this paper described facile and efficient methods for the synthesis of biologically important lipidic diamines and amino alcohols. *In vivo* studies of the antiinflammatory activity of the compounds presented in this paper are in progress.

ARTICLE

Docosahexaenoic Acid Ingestion Inhibits Natural Killer Cell Activity and Production of Inflammatory Mediators in Young Healthy Men[1]

D.S. Kelley[a,*], P.C. Taylor[a], G.J. Nelson[a], Perla C. Schmidt[a], Aldo Ferretti[b], Kent L. Erickson[c], Rina Yu[d], Ranjit K. Chandra[e], and B.E. Mackey[f]

ABSTRACT: The purpose of this study was to examine the effects of feeding docosahexaenoic acid (DHA) as triacylglycerol on the fatty acid composition, eicosanoid production, and select activities of human peripheral blood mononuclear cells (PBMNC). A 120-d study with 11 healthy men was conducted at the Metabolic Research Unit of Western Human Nutrition Reach Center. Four subjects (control group) were fed the stabilization diet throughout the study; the remaining seven subjects were fed the basal diet for the first 30 d, followed by 6 g DHA/d for the next 90 d. DHA replaced an equivalent amount of linoleic acid; the two diets were comparable in their total fat and all other nutrients. Both diets were supplemented with 20 mg D α-tocopherol acetate per day. PBMNC fatty acid composition and eicosanoid production were examined on day 30 and 113; immune cell functions were tested on day 22, 30, 78, 85, 106, and 113. DHA feeding increased its concentration from 2.3 to 7.4 wt% in the PBMNC total lipids, and decreased arachidonic acid concentration from 19.8 to 10.7 wt%. It also lowered prostaglandin E2 (PGE2) and leukotriene B4 (LTB4) production, in response to lipopolysaccharide, by 60–75%. Natural killer cell activity and *in vitro* secretion of interleukin-1β and tumor necrosis factor α were significantly reduced by DHA feeding. These parameters remained unchanged in the subjects fed the control diet. B-cell functions as reported here and T-cell functions that we reported previously were not altered by DHA feeding. Our results show that inhibitory effects of DHA on immune cell functions varied with the cell type, and that the inhibitory effects are not mediated through increased production of PGE2 and LTB4.

Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; HPLC, high-performance liquid chromatography; IL, interleukin; IR, immune response; LTB4, leukotriene B4; LPS, lipopolysaccharide; NK, natural killer; PBMNC, peripheral blood mononuclear cells; PBS, phosphate buffered saline; PGE2, prostaglandin E2; PUFA, polyunsaturated fatty acids; TLC, thin-layer chromatography; TNFα, tumor necrosis factor α.

The low incidence of mortality from coronary heart disease among the Eskimos was initially attributed to the relatively large proportion of n-3 fatty acids from fish in their diet (1). Subsequent human and animal experimental studies also demonstrated the beneficial effects of n-3 fatty acids on cardiovascular health. Fish oils may improve cardiovascular health because of their antiinflammatory effects, lowering of serum triglyceride, and inhibition of platelet aggregation.

The n-3 polyunsaturated fatty acids (PUFA) from marine and plant sources inhibit several aspects of human immune response (IR), including the production of inflammatory cytokines tumor necrosis factor α (TNFα) and interleukin 1β (IL-1β), natural killer (NK) cell activity, and lymphocyte proliferation (2–16). Most of the studies with n-3 PUFA neither held total fat intake constant nor provided extra antioxidant nutrients to meet the need for increased oxidative stress. Both these factors may alter human IR (11,17–19). Thus it is not clear whether the inhibition of IR in previous studies was due to n-3 PUFA, increased total fat intake, increased oxidative stress, or a combination of these factors.

Fish oils contain a variable mixture of eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA), along with many other fatty acids. It is not known whether the decline in IR caused by the fish oils is due to EPA, DHA, both, or other fatty acids. Purified esters of EPA lowered several aspects human IR (9,10,15). *In vitro* addition of DHA to human (20) and rat lymphocytes (21) inhibited their proliferation. Similar results were also obtained in a DHA feeding study conducted with rats (22). Addition of EPA or DHA to human peripheral blood mononuclear cells (PBMNC) in culture indicates that different mechanisms may mediate the alteration of lymphocyte function by these two fatty acids (20,23).

Dietary fatty acids may alter IR by altering eicosanoid production and the fatty acid composition of the participating cells. Prostaglandin E2 (PGE2) and leukotriene B4 (LTB4), both derived from arachidonic acid (20:4n-6), are considered to be some of the most important eicosanoids that alter immune cell functions. PGE2 inhibited a number of lymphocyte

Copyright © 1999 by AOCS Press

functions such as proliferation and IL-2 secretion in a dose-dependent manner, while the LTB4 was stimulatory at low concentrations and inhibitory at higher concentrations (24). The n-3 fatty acids, EPA and DHA, may reduce the arachidonic acid concentration within the immune cells and thus reduce the production of inflammatory eicosanoids.

The effect of dietary DHA on production of inflammatory mediators or other aspects of human IR has not been published. This is because until recently, purified DHA was not available for human consumption. Such studies are now possible with the availability of DHASCO™ oil, which contains 40% DHA as natural triacylglycerol. Studies with DHA are important, because it is the major n-3 fatty acid in tissues, and the body tends to conserve it more than EPA. The purpose of this study was to examine the effect of a moderately high intake (6 g/d) of DHA, in the absence of EPA, on select parameters of human IR, including inflammatory cytokine production, NK cell activity, and *in vivo* antibody production. Possible mechanisms by which DHA may alter immune cell functions were determined by examining PBMNC fatty acid composition, *in vitro* eicosanoid production, and the serum concentrations of apoprotein E and antioxidant vitamins. We held total fat intake constant and supplemented diets with D α-tocopherol acetate (20 mg/d) to avoid increased oxidative stress from DHA consumption.

MATERIALS AND METHODS

Subjects and study design. Twelve healthy men between the ages of 20–40 yr were selected from the San Francisco Bay area through local advertisements. They passed a physical examination given by a licensed physician, and had body weights within 20% of ideal body weights based on 1983 Metropolitan Life Insurance tables. They were all nonsmokers and nondrug users. Mean body weights, age, and body mass index (BMI) for the study subjects are given in Table 1. Body weights of the subjects were maintained within 2% of their initial weights throughout the study by adjusting their energy intake when necessary.

The study protocol was approved by the Human use committee of the University of California at Davis and the United States Department of Agriculture committee at Houston, Texas. The study lasted for 120 d (April 1 to July 29, 1996) although no immunological tests were conducted after day 113, because of other scheduled procedures. All subjects were immunized on day 85 with a trivalent 1995–1996 influenza vaccine (Connaught Laboratories Inc., Swiftwater, PA). Subjects lived at the Metabolic Research Unit (MRU) of the Western Human Nutrition Research Center for the duration of the study, except when going for daily walks (2 × 2 miles) or other scheduled outings. They consumed only those foods prepared by the staff of the MRU and were under constant supervision. Subjects were divided into two groups. Four subjects (control group) were fed the control or stabilization diet throughout the study. The remaining eight subjects (DHA group) were fed the control diet for the first 30 d of the study and a DHA-supplemented diet for the last 90 d. One subject from the DHA group did not complete the study, so data from only seven subjects were evaluated. More subjects were included in the DHA group than in the control group, because most of the DHA effects were evaluated by comparing the pre- and post-DHA indices in the DHA group.

TABLE 1
Physical Characteristics of Study Subjects[a]

Index	DHA group (*n* = 7)	Control group (*n* = 4)
Age, yr	33.1 ± 1.8	33.3 ± 3.1
Weight, kg	78.6 ± 4.2	74.7 ± 4.2
BMI, kg/m^2	23.7 ± 0.8	23.1 ± 1.1

[a]DHA, docosahexaenoic acid; BMI, body mass index. Mean ± SEM.

Diets. Diets were made up of natural foods, except DHA and vitamin E, and were fed in a 5-d rotating menu, comprising three meals and a postdinner snack. Dietary composites from each of the 5-d menus for both diets were analyzed for macronutrients. In both diets, protein, fat, and carbohydrates provided approximately 15, 30, and 55% energy, respectively (Table 2). The micronutrient contents of the diets were calculated by using *USDA Handbook 8* (25); all nutrients were at or above the recommended dietary allowances (RDA) and were identical in the two diets. Diets contained about one RDA of vitamin E from natural foods (calculated using values from *USDA Handbook 8*) and were supplemented with an additional 20 mg/d of D α-tocopherol acetate (Bronson Pharmaceutical, St. Louis, MO).

DHA diet contained 15 g of DHASCO™ oil (a gift from Martek Corporation, Columbia, MD), which was incorporated by replacing an isocaloric amount of safflower oil; all other foods were identical in the two diets. The main effect of incorporating DHASCO™ oil into diet was the replacement of 6 g linoleic acid (18:2n-6) with an equivalent amount of DHA. Fatty acid composition of the two diets is given in Table 3. The DHASCO™ oil was kept in sealed containers at –20°C, and all open bottles were flushed with nitrogen before

TABLE 2
Nutrient Composition of Experimental Diets[a]

	Energy %	
Nutrient	DHA diet	Control diet
Protein	15.2 ± 0.6	14.6 ± 0.5
Carbohydrate	53.9 ± 3.0	56.4 ± 3.1
Fat, total	30.9 ± 2.1	29.0 ± 1.8
Saturated	8.9 ± 0.4	8.1 ± 0.4
Monounsaturated	9.2 ± 0.3	9.2 ± 0.3
n-6 Polyunsaturated	6.5 ± 0.3	8.5 ± 0.3
n-3 Polyunsaturated	2.8 ± 0.1	1.1 ± 0.1
trans	1.9 ± 0.1	2.1 ± 0.1
P/S ratio	1.2	1.1
Cholesterol (mg/d)	360	360

[a]Mean ± SEM (*n* = 5). Dietary composites were prepared for each 5-d rotating menu. Both diets were supplemented with D α-tocopherol acetate, 20 mg/d. P/S, polyunsaturated fatty acid/saturated fatty acid. See Table 1 for other abbreviation.

[b]Significantly different between two diets ($P < 0.05$).

being returned to the refrigerator. It was served only in cold foods such as yogurt, dips, or salads. Thus the chances of DHA oxidation were minimized.

Laboratory procedures. Blood samples were collected between 7: 00 and 8:00 A.M. after an overnight fast on study days 23, 30, 78, 85, 106, and 113. Samples were collected by antecubital venipuncture into evacuated tubes without anticoagulants (for sera preparation) or containing heparin (for cell culture experiments). For both dietary groups two determinations of cytokine production, NK cell activity, and serum antioxidant vitamins were made at the end of stabilization, middle, and end of the intervention periods (days 23, 30, 78, 85, 106, and 113). Means of the two measurements are shown in the results section. PBMNC fatty acid composition and eicosanoid production were determined only on study days 30 and 113. Influenza antibody titers were determined in the sera prepared from blood samples drawn on days 30, 85, 106, and 113.

Isolation and culture of PBMNC for cytokine and eicosanoid secretion. PBMNC were isolated using Histopaque-1077 as previously reported (26) and cultured with or without lipopolysaccharide (LPS, 1.0 mg/L) in 24-well flat-bottom culture plates (5×10^5 PBMNC/mL/well). The culture medium used was RPMI-1640 (Gibco, Grand Island, NY), containing 10% autologous serum and L-glutamine (2 mmol/L), penicillin (100 KU/L), streptomycin (100 mg/L) and gentamicin (20 mg/L). The tissue culture media were collected by centrifugation 24 h after stimulation with LPS and stored frozen at −70°C until the cytokine and eicosanoid concentrations were determined. Enzyme-linked immunosorbent assay (ELISA) kits for cytokine assays were purchased from Immunotech (Miami, FL) and those for LTB4 from Cayman Chemical Company (Ann Arbor, MI).

PGE2 concentration in the media was determined by gas chromatography–mass spectrometry (GC–MS) as the methoxime-pentafluorobenzyl ester-trimethylsilyl ether derivative. Analyte and internal standard were extracted from 200 µL culture media with C_{18} Sep-Pak cartridges after dilution with 10 mL acidified (pH 3.0) water, and addition of 1 ng of (3,3,4,4-$^2H_4$) PGE2 internal standard. They were eluted with methyl formate/petroleum ether (1:1) after sequential rinsing first with acidified water, then with methyl formate/petroleum ether (5:95). The prostaglandins were esterified with pentafluorobenzyl bromide in CH_3CN, then were treated with methoxylamine hydrochloride in pyridine. The PGE2-pentafluorobenzyl ester-methoxime derivative was purified on silica gel thin-layer chromatography plates and finally converted to trimethylsilyl ether derivative with *N,O*-bis(trimethylsilyl)-trifluoroacetamide (BSTFA) in pyridine (1:1). Gas chromatography–mass spectrometry in the electron capture chemical ionization (ECCI) mode was carried out with a Finnigan-MAT TSQ-70B instrument operated at 70 eV with methane as the moderating gas. The ions monitored were m/z 524 (M − 181) for the endogenous analyte and m/z 528 for the tetradeuterated internal standard.

Determination of NK cell activity. NK cell activity was determined by using the nonadherent PBMNC and the ^{51}Cr labeled K-562 cells at effector/target cell ratios of 50:1, 25:1, 12.5:1, 6.2:1, and 3.1:1 as previously reported (26). Six wells were used for each effector cell concentration and for the spontaneous and maximal release (caused by 3% centrimide) of ^{51}Cr. After 4 h incubation at 37°C in 5% CO_2, the plates were centrifuged and aliquots of supernatant collected to determine the amount ^{51}Cr released.

Percent lysis was calculated as follows:

$$\%\ \text{lysis} = \frac{(\text{experimental CPM} - \text{spontaneous CPM})}{(\text{maximum CPM} - \text{spontaneous CPM})} \times 100 \quad [1]$$

Serum antibody titers. The antibody titers for the viral strains A/TEXAS/36/91, A/Johannesburg/33/94, and B/Harbin/7/94 (strains included in the vaccine) were determined by using the hemagglutination inhibition assay (27). Results for antibody titers are expressed as the geometric mean (GM) of the antibody titers and 95% confidence intervals.

PBMNC fatty acid composition. PBMNC for fatty acid analysis were isolated using Histopaque-1077 as discussed above. Cells were further washed twice with Dulbecco's phosphate buffered saline (PBS) resuspended in 1 mL PBS and layered over 1.5 mL Histopaque-1077. The tubes were centrifuged for 15 min at 1000 × *g* to remove contaminating erythrocytes. PBMNC were washed with PBS, mixed with 0.8 mL LYMPHO-KWIK (Canoga Park, CA) and incubated for 15 min at 37°C. The PBMNC were then overlaid with 0.2 mL PBS and centrifuged for 2 min at 2000 × *g*. The cell pellet was washed one more time with PBS and stored frozen at −20°C until fatty acid analysis. This isolation procedure removed most of contaminating platelets and erythrocytes, and yielded cells containing 90–95% mononuclear cells as determined by differential cell counting.

PBMNC lipids were extracted by the procedures previously described by Nelson (28,29) using chloroform/

methanol (2:1, vol/vol). The total lipid extract was transmethylated with methanolic HCl (7%, w/w) by the procedures described previously (30,31). The impurities extracted into the hexane phase after termination of the reaction were removed by thin-layer chromatography (29). We have described the conditions of the capillary gas-liquid chromatography (GLC) previously (30). Briefly, the column was a 30-m × 0.025 mm fused-quartz column coated with SP-2340 (Supelco, Inc., Bellefonte, PA). The GLC data were processed with a Hewlett-Packard ChemStation software running on an IBM compatible desktop computer.

Serum antioxidant vitamins. Fasting blood samples were collected from all subjects and sera were separated by centrifugation at 1000 × *g* for 15 min at 4°C. Aliquots of sera were stored under liquid nitrogen until antioxidant analysis. For the analysis of α-tocopherol and retinol in sera, 100 µL of each of the internal standards retinyl acetate and α-tocopherol acetate were transferred into disposable glass tubes and mixed vigorously with 200 µL of sera. For extraction of the antioxidants 400 µL of hexane was added and the contents were mixed vigorously for 1 min. The tubes were centrifuged and the solvent layer was transferred to a centrifuge tube and the contents were evaporated under a stream of nitrogen. The antioxidants in the tube were dissolved in 25 µL of diethyl ether followed by 75 µL of methanol, and 20 µL of the sample solution was injected for high-performance liquid chromatography (HPLC) analysis. The HPLC conditions for α-tocopherol and retinol were as follows: A Waters LC with a stainless steel column packed with microBondapak C18 (10 µm, 300 mm × 3.9 i.d.) as the solid phase was used. The mobile phase was methanol/water (97:3, vol/vol) at a flow rate of 1.0 mL/min. The eluate was monitored with an ultraviolet (UV) detector at 280 nm.

For ascorbic acid, serum proteins were precipitated with 60% methanol in water and 1 mM EDTA. Serum (50 µL) was mixed with 200 µL of 60% methanol/water/ EDTA, incubated for 10 min on ice, centrifuged at 12,000 × *g* at 4°C for 8 min, and then filtered. A 20 µL sample of filtrate was immediately analyzed for L-ascorbic acid. A stainless steel column packed with Inersil-ODS (5 mm, 150 mm × 4.6 mm i.d., Gaskurokogyo Ltd., Japan) was used. The mobile phase was methanol/phosphate buffer containing 0.005 M tetra-*n*-butylammonium bromide (20:80, vol/vol) at a flow rate of 0.5 mL/min. The eluate was monitored at 265 nm with a UV detector.

For serum β-carotene, serum was twice deproteinized with ethanol and then extracted with hexane. The extract was centrifuged, the hexane layer removed, and then evaporated with nitrogen. The dried extracts were dissolved in isopropanol for HPLC with a Nova-pak C_{18}. The mobile phase was acetonitrile/methanol/acetone (40:40:20, by vol). The eluate was monitored with a UV detector at 450 nm.

Data analysis. A repeated measure of analysis of variance model was used to determine the effects of DHA on the indices of IR tested. A univariate, split-plot approach was taken using SAS PROC Mixed (32). Contrasts were constructed for within-group comparisons among the stabilization and intervention periods. Paired *t*-test was used to compare PBMNC fatty acid composition and eicosanoid secretions. Changes in the parameters examined are considered significant for $P < 0.05$, unless otherwise stated.

RESULTS

Effect of DHA feeding on NK cell activity. Figure 1 contains the data for NK cell activity for the DHA group determined at the effector/target cell ratio of 50:1 on study days 30, 85, and 113. NK cell activity was not altered by dietary DHA within the first 55 d (study day 85) of its feeding ($P = 0.82$). However, DHA feeding for 83 d (study day 113) caused a 20% decrease in NK cell activity as compared to the activity found prior to the start of DHA feeding (day 30). This decrease in NK cell activity associated with DHA feeding was statistically significant ($P = 0.004$). NK cell activity for the control group did not change throughout the study. Similar results were obtained at the effector/target cell ratios of 25:1, 12.5:1, 6.2:1, and 3.1:1 (data not shown).

Effect of DHA feeding on the secretion of proinflammatory cytokines. The concentrations of IL-1β and TNFα secreted by PBMNC from the subjects in the DHA group are shown in Figures 2 and 3, respectively. DHA feeding caused a reduction in the secretion of both IL-1β and TNFα within 55 d (study day 85), although it was not statistically significant at that time ($P = 0.093$ for IL-1β and 0.31 for TNFα). With the continued feeding of DHA, the secretion of these cytokines continued to decrease. By the end of the study, their concentrations were reduced by approximately 40–45% as compared to the concentrations before DHA was fed ($P = 0.0004$ for IL-1β and 0.0002 for TNFα). In the control group, the secretion of these two cytokines did not change during the study.

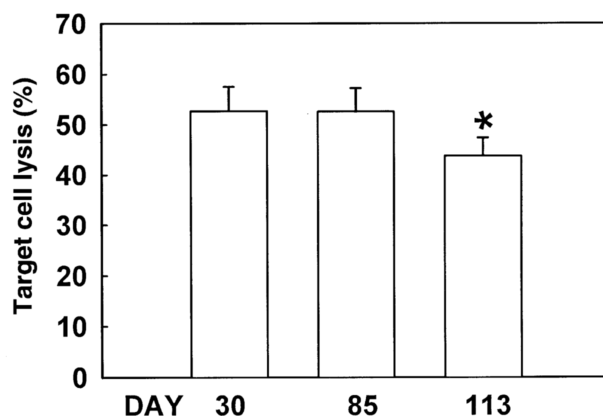

FIG. 1. Docosahexaenoic acid (DHA) feeding decreased natural killer (NK) cell activity. NK cell activity was determined with an effector/target cell ratio of 50:1 and data shown are the mean ± SEM ($n = 7$). NK cell activity was significantly reduced on day 113, compared to the value at day 30 ($P = 0.004$), but not on day 85. The corresponding values for percentage target cell lysis in the control group on days 30, 85, and 113 were 38.5 ± 14.0, 39.0 ± 14.0, and 41.0 ± 18.0, respectively.

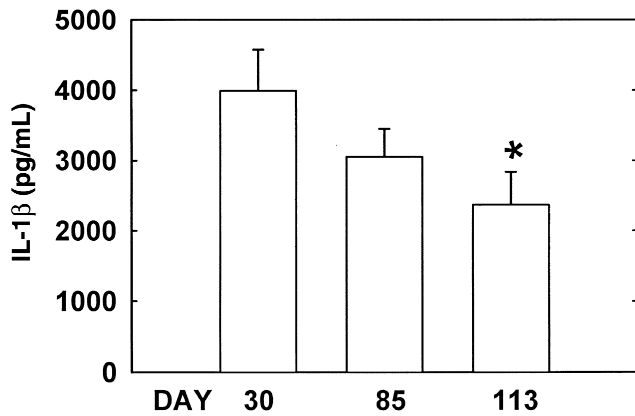

FIG. 2. DHA feeding reduced *in vitro* secretion of interleukin-1β (IL-1β). Peripheral blood mononuclear cells (PBMNC) were cultured with lipopolysaccharide (1.0 mg/L) for 24 h, and the IL-1β secreted was quantified with an enzyme-linked immunosorbent assay (ELISA). Data shown are the mean ± SEM (n = 7). DHA feeding reduced IL-1β secretion, when compared to the value at day 30 (P = 0.093 for day 85 and P = 0.0004 for day 113). The corresponding values for IL-1β secretion in the control group on days 30, 85, 113 were 2912 ± 294, 3104 ± 201 and 2981 ± 678, respectively. See Figure 1 for abbreviation.

DHA feeding and serum influenza antibody titers. The pre- (day 30) and postimmunization (day 113) antibody titers against the three strains of influenza virus for both groups of subjects are shown in Table 4. The preimmunization (day 30) mean titers for A/Johannesburg and B/Harbin strains between the two groups were not different, while the titer for A/Texas strain was about fourfold higher in the DHA group than in the control group. Immunization caused a significant increase (three- to tenfold) in the mean titers for all three strains in both the groups. The postimmunization titers for all three strains were not different between the two dietary groups. However, the differential increase between the two dietary groups after immunization by the A/Texas strain was almost significant (P = 0.059). This difference was most likely due to the higher initial antibody titer for this strain in the DHA group. Antibody titers for all three strains in both dietary groups on day 106 were not significantly different from titers on day 113 (data not shown).

TABLE 4
Effect of DHA Feeding on Serum Influenza Antibody Titers[a]

		DHA group (n = 7)		Control group (n = 4)	
Strain	Day	GM	CI	GM	CI
A/Texas	85	195	98–389	57	23–141
	113	585	278–1234	640	257–1596
A/Johannesburg	85	27	13–56	34	13–88
	113	109	51–234	135	51–354
B/Harbin	85	54	27–109	40	16–101
	113	148	70–311	160	63–405

[a]GM, geometric mean; CI, 95% confidence interval. For other abbreviation see Table 1. All subjects were immunized on day 85. Immunization significantly (P < 0.05) increased the antibody titers for all three strains in both groups. The difference in the increase between the DHA and control group was almost significant (P = 0.059) for A/Texas, but not for the other two strains.

Influence of DHA feeding on the fatty acid composition of PBMNC. Table 5 contains data regarding the major fatty acids of the PBMNC isolated on study days 30 and 113 for both dietary groups. PBMNC fatty acid composition on day 30 was not different between the two dietary groups. Dietary DHA increased the concentration of DHA in the PBMNC from 2.3 wt% on day 30 to 7.4 wt% on day 113. The arachidonic acid content of the PBMNC decreased from 19.8 to 10.7 wt% with DHA feeding. The EPA concentration in PBMNC lipids was 1.3 wt% and it did not change with DHA feeding (not shown). The concentration of major fatty acids in the PBMNC from control group (Table 5), as well as that of other trace fatty acids in both groups (data not shown), did not change during the study.

DHA feeding and eicosanoid secretion. The concentrations of PGE2 and LTB4 secreted into the tissue culture media by the PBMNC stimulated with LPS from both dietary groups are shown in Table 6. DHA feeding caused a 60–75% reduction in the secretion of both these eicosanoids when compared to the concentrations on day 30. Eicosanoids secreted by the PBMNC from control group did not change during the study.

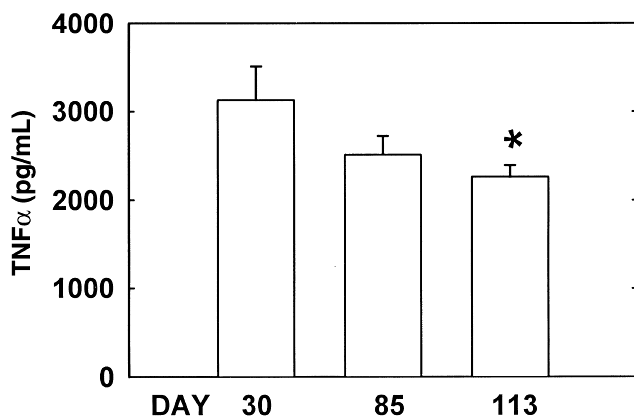

FIG. 3. DHA feeding reduced tumor necrosis factor α (TNFα) secretion. PBMNC culture and TNFα analysis procedures were similar to those given in Figure 2. DHA feeding reduced the secretion of TNFα, with P values of 0.31 and 0.0002, for days 85 and 113, respectively. The corresponding values for TNFα secretion in the control group on days 30, 85, and 113 were 2611 ± 526, 2834 ± 480, and 2648 ± 348, respectively. See Figures 1 and 2 for abbreviations.

TABLE 5
Major Fatty Acids (wt%) of Peripheral Blood Mononuclear Cells[a]

	DHA group (n = 7)		Control group (n = 4)

LTB4, pg/10^6 PBMNC	140 ± 30	34 ± 10*	118 ± 41	92 ± 28

[a]Eicosanoids secreted into the medium (mean ± SEM) in 24 h after LPS (1 mg/L) addition. Abbreviations: PGE2, prostaglandin E2; LTB4, leukotriene, B4; PBMNC, peripheral blood mononuclear cells. For other abbreviation see Table 1. PGE2 was quantified by gas chromatography–mass spectrometry and LTB4 by enzyme-linked immunosorbent assay (ELISA). For each eicosanoid, comparisons were made between day 30 and 113 within each group, and those with the asterisk (*) are significantly different ($P < 0.01$).

TABLE 7
DHA Feeding and Serum Antioxidant Vitamins[a]

	DHA group (n = 7)		Control group (n = 4)	
Vitamin	Day 30	Day 113	Day 30	Day 113
Retinol, μg/mL	0.52 ± 0.06	0.48 ± 0.19	0.40 ± 0.08	0.44 ± 0.06
β-Carotene, μg/mL	78.2 ± 17.1	84.4 ± 17.3	95.3 ± 28.6	113.7 ± 19.9
α-Tocopherol, μg/mL	2.20 ± 0.12	1.82 ± 0.19*	2.37 ± 0.42	1.92 ± 0.44*
Ascorbate, mg/dL	0.48 ± 0.20	0.61 ± 0.28	0.36 ± 0.20	0.52 ± 0.32

[a]Mean ± SEM. *α-Tocopherol concentration on day 113 was lower in both groups than the corresponding values on day 30 ($P < 0.04$); the concentrations of other three vitamins did not change. For abbreviation see Table 1.

In both groups, the concentrations of PGE2 secreted by 1×10^6 PBMNC was about 100-fold higher than that of LTB4.

Effect of DHA feeding on the serum concentration of antioxidant vitamins. The concentrations of retinol, β-carotene, α-tocopherol, and ascorbate in the sera of the subjects in both dietary groups on study days 30 and 113 are shown in Table 7. None of these antioxidant vitamins except α-tocopherol changed during the study in either group. The concentration of α-tocopherol on day 113 was significantly decreased ($P < 0.04$) in both dietary groups when compared to the corresponding values on day 30.

DISCUSSION

This study was conducted to determine whether DHA feeding would inhibit select indices of human IR that have previously been reported to be inhibited with dietary EPA, fish, or flax seed oils. In contrast to most of the previous studies with fish oils, we maintained total fat intake constant, supplemented diets with D α-tocopherol acetate at 20 mg/d, and used diets devoid of EPA. All these factors are important in evaluating the effects of n-3 PUFA on human IR. In an attempt to determine the possible mechanisms underlying the effects of DHA feeding, we examined the fatty acid composition of PBMNC, the production of eicosanoids, the serum concentrations of apoprotein E and antioxidant vitamins.

DHA feeding caused a significant decrease in NK cell activity and the secretion of proinflammatory cytokines, IL-1β, and TNFα by monocytes stimulated with LPS. The time required for the decrease in these functions after DHA feeding was different. After 55 d of DHA feeding, cytokine production was inhibited, but not NK cell activity. However, the NK cell activity was decreased within 83 d of DHA feeding. Our results showing reduction in NK cell activity and the secretion of proinflammatory cytokines by dietary DHA are consistent with the results from earlier human studies involving EPA, fish, or flax seed oils (2–16). Reduction in NK cell activity may lower resistance to cancer and viral infections.

DHA feeding did not alter B-cell functions (Table 4). Nor did it change T-cell functions in this study, as previously reported by us (33). The amount of DHA fed was equivalent to 15–20 g fish oils, which has been found to inhibit T- and B-cell responses within 90 d of its feeding (8–14). Our dietary protocol differed from those used in previous investigations, because we held total fat constant and provided extra vitamin E. These factors may be responsible for our lack of an observed change in T- and B-cell functions.

Dietary DHA increased DHA concentration in PBMNC lipids from 2.3 to 7.4 wt%. It was incorporated into PBMNC lipids primarily by replacing arachidonic acid. Although DHA can be converted back to EPA by humans (34,35), and the serum concentration of EPA in the DHA group of our study subjects increased from 0.38 to 3.39 wt% (36), the concentration of EPA in PBMNC lipids was not altered by DHA feeding (data not shown).

Reduction in PBMNC arachidonic acid concentration with DHA feeding was associated with a concomitant decrease in the production of PGE2 and LTB4. Since PGE2 inhibits NK and macrophage cell functions (24), the decrease in NK cell activity and proinflammatory cytokine production could not be due to reduction in PGE2 production. These results are consistent with the results from other studies using inhibitors of eicosanoid synthesis (37–41). The decrease in immune cell functions was probably not due to increased oxidative stress either, because the serum concentration of retinol, β-carotene, and ascorbic acid were not altered by DHA feeding. The serum concentration of tocopherol decreased in both groups; therefore, it could not be attributed to DHA feeding.

Serum concentration of apoprotein E was not different between the two groups on study day 30 and did not change throughout the study in the control group (not shown). However, its concentration increased from 7.7 ± 1.6 (mean ± SEM) on day 30 to 12.0 ± 1.7 mg/dL on day 113 in the DHA group. Because apoprotein E has been reported to inhibit lymphocyte and monocyte functions (45), it is possible that it contributed to the reduction in NK cell activity and cytokine production in the DHA group. These alterations in immune cell functions may also result from a reduction in LTB4 production, which has been shown to enhance these functions *in vitro* (42,43).

It is possible that some of the effects observed in this study were due to a reduction in linoleic acid intake rather than the increase in DHA intake. The intake of linoleic acid was de-

creased by about 7 g/d in the high-DHA diet compared to the basal diet. The subjects on the high-DHA diet still received more than 20 g/d linoleic acid, an amount of substrate in excess of that required for the fatty acid metabolic acid pathways. It was well above any known requirements for linoleic acid. The plasma linoleic acid content in the basal and high-DHA diets fed subjects was 39 and 36% of total fatty acids, respectively, and was not significantly different (36). The basal diet provided less than 50 mg/d of DHA , and the high-DHA diet provided 6 g/d. Thus it is unlikely that any of the change in immune cell function or eicosanoid production was due to a 20% reduction in linoleic acid intake. These were most likely the result of an increase in DHA intake.

Results from this study show that feeding DHA to humans inhibited select immune cell functions, but it seems to be a less potent and selective inhibitor than that predicted by previous results obtained with fish oils. Although the subjects in the DHA group in our study did not show increased incidence of infections, they may be potentially at a higher risk. The risk for infections may further increase with the increased duration of DHA feeding, increased total fat intake, or increased oxidative stress. The antiinflammatory effects of DHA may be useful in the management of autoimmune disorders; however, such benefits need to be balanced with the increased risk of infections.

ACKNOWLEDGMENTS

The authors are appreciative of the support provided by the dietary and nursing staff of the Metabolic Research Unit in conducting this study. We thank the volunteers who participated in the study, the bioanalytical laboratory for sample processing, Health Services Department of California in Berkeley for determining influenza antibody titers, and the Martek Corporation for donating the DHASCO oil.

ABSTRACT: Lipoprotein (a) [Lp(a)] is a low-density lipoprotein (LDL) particle with an additional apolipoprotein named apo(a). The concentration of Lp(a) in plasma is determined to a large extent by the size of the apo(a) isoform. Because elevated Lp(a) concentrations in plasma are associated with risk for premature coronary heart disease it is important to determine whether variations in production or catabolism mediate differences in Lp(a) concentration. We determined metabolic parameters of Lp(a) in 17 patients with heterozygous familial hypercholesterolemia or severe mixed hyperlipidemia by fitting a monoexponential function to the rebound of Lp(a) plasma concentration following LDL-apheresis. In 8 of those 17 patients this was done twice following two different aphereses. Although this approach allows one to estimate metabolic parameters without the use of a tracer, it requires several major assumptions such as that apheresis itself does not change production or catabolism of Lp(a) and that Lp(a) metabolism can be described by a single compartment. One apheresis decreased Lp(a) concentration by 59.1 ± 8.3%. The fractional catabolic rate (FCR) was 0.16 ± 0.12 d^{-1} and production rate 6.27 ± 5.26 $mg \cdot kg^{-1} \cdot d^{-1}$. However, observed (concentration before first apheresis) and predicted steady-state concentrations differed considerably (more than 20%) in 9 of 17 patients, indicating that not all assumptions were fulfilled in all patients. Production rate but not FCR was correlated with Lp(a) plasma concentration (r^2 = 0.43, P = 0.004) and molecular weight of apo(a) (r^2 = 0.48, P = 0.011), which confirms radiotracer experiments showing that variations in Lp(a) plasma concentrations are due to differences in production not catabolism. When parameters were estimated twice in a subgroup of eight patients, satisfactory reproducibility was observed in six patients. Although parameters determined on two occasions correlated well, only FCR was concordant (intraclass correlation coefficient). Thus, despite the limitations arising from the assumptions implicit to this method, metabolic parameters of Lp(a) can be estimated from the rebound of plasma concentration following apheresis.

Paper no. L7904 in *Lipids 34*, 325–335 (April 1999).

Abbreviations: apo, apolipoprotein; CAD, coronary artery disease; FCR, fractional catabolic rate; LDL, low density lipoprotein; Lp(a), lipoprotein (a); PR, production rate.

Lipoprotein (a) [Lp(a)] is a low density lipoprotein (LDL) particle with an additional apoprotein [apo(a)] linked with a disulfide bridge to apolipoprotein B (apoB) (1,2). An elevated Lp(a) concentration is an independent risk factor for coronary artery disease (CAD), and it has been shown that the Lp(a) concentration in plasma is to a large extent determined genetically with apo(a) polymorphism accounting for more than 50% of the variation observed (3). More than 20 different apo(a) isoforms varying in molecular weight from 300 to over 800 kD have been described, and it has been shown that the smaller isoforms are associated with higher Lp(a) concentrations in plasma (4,5).

Because elevated Lp(a) concentrations in plasma are associated with risk of premature CAD it is important to determine factors that control Lp(a) concentration. Furthermore, knowledge of the underlying metabolic mechanism could indicate possible therapeutic approaches to lower elevated Lp(a) concentrations. Theoretically, an increased concentration in plasma could be the result of an increased production and/or a decreased catabolism.

In studies using radio-iodinated Lp(a) it has been shown that the concentration of Lp(a) in plasma is almost exclusively determined by its production rate (PR) (6,7). Furthermore, it could be shown that the variation of Lp(a) concentrations between subjects characterized by the same apo(a) isoforms is also the result of differences in production and not catabolism (8). However, this method involves the use of radioactive tracers and results may be confounded by the fact that the metabolism of tracer and tracee particles are not identical as it has been shown for other lipoprotein particles (9). An additional disadvantage of radiotracer experiments is that they usually cannot be repeated in the same subjects, thus, intra-individual variability cannot be determined.

Alternatively, Lp(a) metabolism can be determined without the use of a tracer by applying nonsteady-state kinetics (10). This approach is based on the concept that a steady state upset by a defined perturbation will ultimately be restored and that the dynamics of steady-state restoration will only depend on the PR and the rate of catabolism. Lp(a) concentration can be perturbed by selective apheresis of apoB-containing lipoproteins, and the rebound of plasma Lp(a) concentrations can be described by a monoexponential function in which the exponent defines the fractional catabolic rate (FCR) and by

Copyright © 1999 by AOCS Press

which a steady-state concentration is predicted. However, this approach implies two essential assumptions: (i) that the perturbation itself has no impact on the metabolic parameters characterizing the steady-state and (ii) that Lp(a) metabolism can be described by a one-pool model. From the form of the rebound curve one cannot deduce whether these assumptions are fulfilled. However, if these assumptions are valid, observed (concentration before first apheresis) and predicted steady-state concentrations should be the same. A particular advantage of this approach is that metabolic parameters can be determined repeatedly in the same subjects.

We evaluated Lp(a) metabolism with this methodology in 17 patients with heterozygous familial hypercholesterolemia or severe mixed hyperlipidemia treated with regular apheresis and compared predicted to observed steady-state concentrations. Furthermore, in eight patients we determined Lp(a) metabolism on two different occasions to determine intraindividual variability.

MATERIALS AND METHODS

Seventeen patients with heterozygous familial hypercholesterolemia or severe mixed hyperlipidemia were included. Inclusion criteria were regularly performed apheresis (weekly or biweekly) for more than 3 mon and steady-state Lp(a) concentration > 10 mg · dL^{-1}. The characteristics of the patients are shown in Table 1. All but three patients (patients #2, #5, #8 in Table 2) were on concomitant hydroxymethylglutaryl-CoA (HMG-CoA) reductase inhibitor therapy (lovastatin, simvastatin, atorvastatin). Patients were treated with three different LDL-apheresis techniques [immunoadsorption—Therasorb (Baxter, Unterschleissheim, Germany); heparin-induced precipitation—HELP (B. Braun, Melsungen, Germany); and adsorption to dextran-sulfate—(Kanegafuchi, Osaka, Japan)], as indicated in Table 2. Details concerning the apheresis protocol are outlined elsewhere (11). During the index apheresis preceding the observed rebound of Lp(a) concentration 3683 ± 1324 mL plasma was processed.

Lp(a) concentration was determined prior to the first apheresis (observed steady-state concentration). After regular apheresis was performed for at least 3 mon Lp(a) concentration in plasma was determined before, immediately after, and then daily for 1 wk following a typical apheresis (index apheresis). In some of the patients Lp(a) concentrations were determined at additional time points for up to 4 wk. In these cases the regular rhythm of weekly or biweekly apheresis was interrupted and the first apheresis following the index apheresis was delayed for up to 4 wk. However, this schedule could not be applied in all patients. Thus, different numbers of data points (between 6 and 12) were used to define the rebound of Lp(a) concentration in plasma following the index apheresis. The number of data points used to define the rebound is indicated in Table 3.

In a subgroup of eight patients metabolic parameters of Lp(a) were determined twice following two different aphereses. The index aphereses following which the parameters were determined were at least 6 mon and up to 10 yr apart.

Lp(a) concentrations were determined in duplicate at each time point by radio immunoassay (until 1997) or nephelometry (since 1998, patients #9, #10, #12, #14, and for all repeated analysis performed in eight patients). For radioimmunoassay a commercially available test kit (intra- and interassay variation of 5 and 9%, respectively; Pharmacia Diagnostics, Uppsala, Sweden) was used as described before (12). Nephelometric determinations were performed using a Behring nephelometer and material (intra- and interassay variation of <2.0 and <3.5%, respectively; Behring, Marburg, Germany). Lipid concentrations were determined by commercially available enzymatic tests (Boehringer Mannheim, Mannheim, Germany). Apo(a) phenotypes were determined with sodium dodecylsulfate polyacrylamide gel electrophoresis followed by immunoblotting and categorized as previously described (5,13).

By using the SAAM-II program (version 1.1, SAAM Institute, Seattle, WA) a curve defined by the following monoexponential equation

$$\text{Lp(a)} = A + [B\cdot(1 - e^{-k\cdot t})] \quad [1]$$

was fitted to the observed Lp(a) concentrations, where Lp(a) = concentration at time t after apheresis, A = Lp(a) concentration immediately after apheresis, B = difference between postapheresis concentration and steady-state concentration, thus: $A + B$ = predicted steady-state Lp(a) concentration, k = FCR. PR is estimated by multiplying the FCR with the pool size at steady-state. Pool size of Lp(a) was determined by multiplying the measured Lp(a) concentration by the estimated plasma volume (0.04 · body weight). Predicted steady-state concentrations were compared to observed steady-state concentrations (concentration before first apheresis), and correlations between kinetic parameters and steady-state concentrations as well as Lp(a) phenotypes were tested.

Fitting a monoexponential equation to Lp(a) concentrations following apheresis to determine kinetic parameters implies that Lp(a) plasma metabolism can be described by a one-pool model, which implies that plasma Lp(a) is kinetically homogenous. This methodology furthermore assumes that apheresis does not alter Lp(a) metabolism, thus that apheresis does not induce a change in FCR or PR.

TABLE 1
Characteristics of Patients (n = 17)

Parameter	Value
Age (yr)	54 ± 11
BMI (kg·m^{-2})	26.2 ± 3.5
Cholesterol[a] (mg·dL^{-1})	360 ± 130
LDL-cholesterol[a] (mg·dL^{-1})	285 ± 127
HDL-cholesterol[a] (mg·dL^{-1})	50 ± 9
Triglycerides[a] (mg·dL^{-1})	126 ± 59
Lp(a)[a] (mg·dL^{-1})	110 ± 71
	(median 110; range 11–245)

[a]Determined prior to first apheresis. Values represent means ± SD. SMI, body mass index; LDL, low density lipoprotein; HDL, high density lipoprotein; Lp(a), lipoprotein (a).

[c]Not applicable.

In the subgroup of patients in whom parameters were determined twice, parameters from the two analyses were tested for correlation and concordance (intraclass correlation coefficient). The intraclass correlation coefficient was calculated according to the method of Kramer and Feinstein (14). A coefficient value (R_i) of above 0.73 was considered to indicate concordance.

Correlation analysis tests for interdependence or linear relatedness between two parameters, however, it does not test to which extent the two approaches yield the same result. For quantitative comparisons between the results of the two approaches a concordance index such as the intraclass correlation coefficient is preferable (14,15).

Values are expressed as mean ± SD; in addition Lp(a) concentrations are given as median and range. Correlations were calculated using the Minitab program (Minitab, State College, PA).

[a]Observed Lp(a) concentration refers to Lp(a) concentration determined before first apheresis.
[b]Number of data points used to fit the monoexponential function. FCR, fractional catabolic rate; PR, production rate; for other abbreviation see Table 1.

RESULTS

Lp(a) concentrations determined before the first apheresis (observed steady-state concentration) as well as before and after the index apheresis are shown in Table 2. On average LDL-apheresis decreased Lp(a) plasma concentration by 59.1 ± 8.3%. This decrease was independent of the apheresis method. These patients were treated regularly with apheresis at weekly or biweekly intervals. Since rebound to steady-state is not complete within this period preapheresis concentrations decrease over time and are usually lower than steady-state concentrations.

In Figure 1 Lp(a) concentrations following apheresis are shown in three patients, representing a wide range of FCR. A monoexponential function (solid line) was fitted to observed Lp(a) concentrations (symbols). Predicted steady-state concentration (dotted line) and Lp(a) concentration prior to the first apheresis (observed steady-state concentration—dashed line) are also shown. There is good agreement between observed and predicted steady-state concentration in one patient (Fig. 1A) whereas these values were different in the other two patients (Figs. 1B and 1C). In Figure 2 Lp(a) concentrations are shown for three of the eight patients in whom Lp(a) metabolism was determined twice. In two of the three patients (patterns C–F) the rebound is similar, whereas in the other patient (pattern A and B) rebound curves were different on the two occasions.

Table 3 shows the calculated metabolic parameters. The estimated FCR (0.16 ± 0.12 d^{-1}) and PR (6.27 ± 5.26 $mg \cdot kg^{-1} \cdot d^{-1}$) varied over a wide range. Metabolic parameters

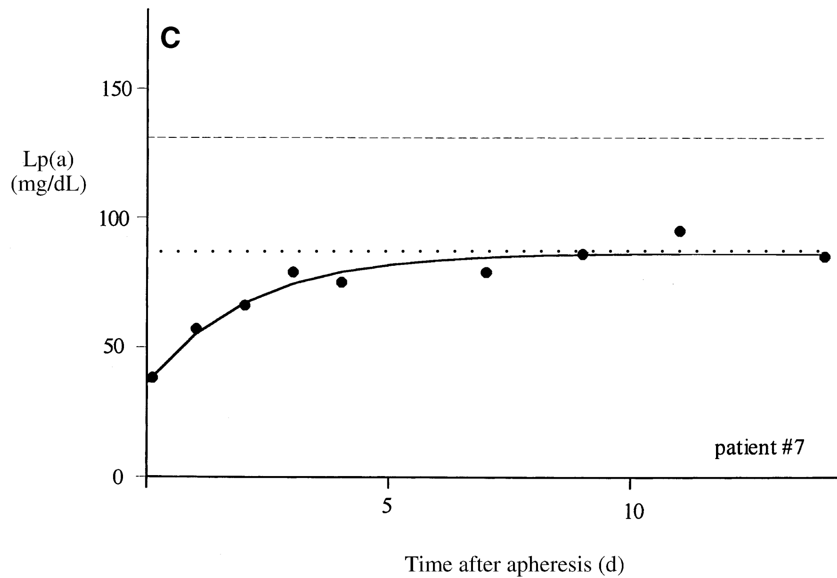

FIG. 1. Time course of lipoprotein (a) [Lp(a)] plasma concentration in three patients representing a wide range of fractional catabolic rate (A, patient #4: 0.16 d^{-1}; B, patient #15: 0.07 d^{-1}, C, patient #7: 0.48 d^{-1}). Symbols represent observed concentrations during rebound, solid line (—) indicates the fit of the monoexponential function and dashed and dotted lines correspond to observed (concentration before first apheresis) and predicted steady-state concentration, respectively.

were not related to the apheresis technique used (data not shown). The analysis predicted steady-state Lp(a) concentrations, which in 9 out of 17 patients were considerably different (more than 20%) from observed steady-state concentrations (concentration before first apheresis). Whether or not predicted and observed steady-state concentrations were similar did not depend on whether one or two apo(a) isoforms were detectable and did not depend on the Lp(a) concentration.

Figure 3 shows observed steady-state Lp(a) concentrations as dependents of Lp(a) PR. PR (r^2 = 0.43, P = 0.004) but not FCR (r^2 = 0.03, P = 0.5) was correlated with plasma Lp(a) concentration. Similarly, PR (r^2 = 0.41, P = 0.005) but not FCR (r^2 = 0.13, P = 0.15) was correlated with the molecular weight of the apo(a), thus the apo(a) isoform (Fig. 4). Furthermore, in the subgroup of five patients with the apo(a) isoform S2, Lp(a) concentration was correlated with Lp(a) production (r^2 = 0.98, P = 0.002) but not with Lp(a) FCR (r^2 =

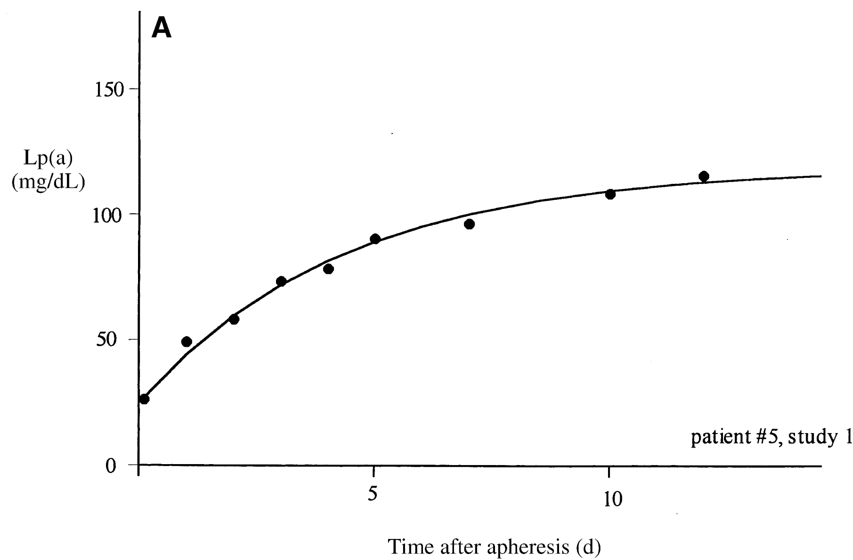

FIG. 2. (continued)

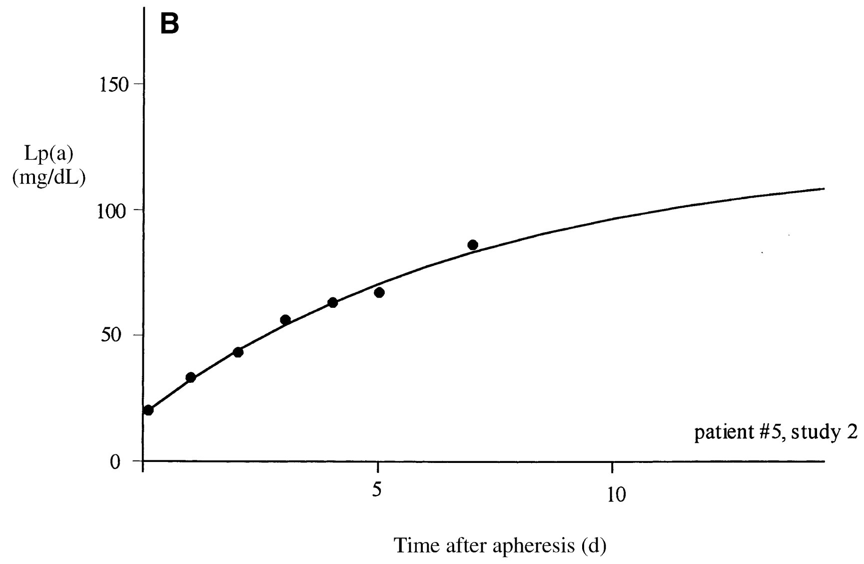

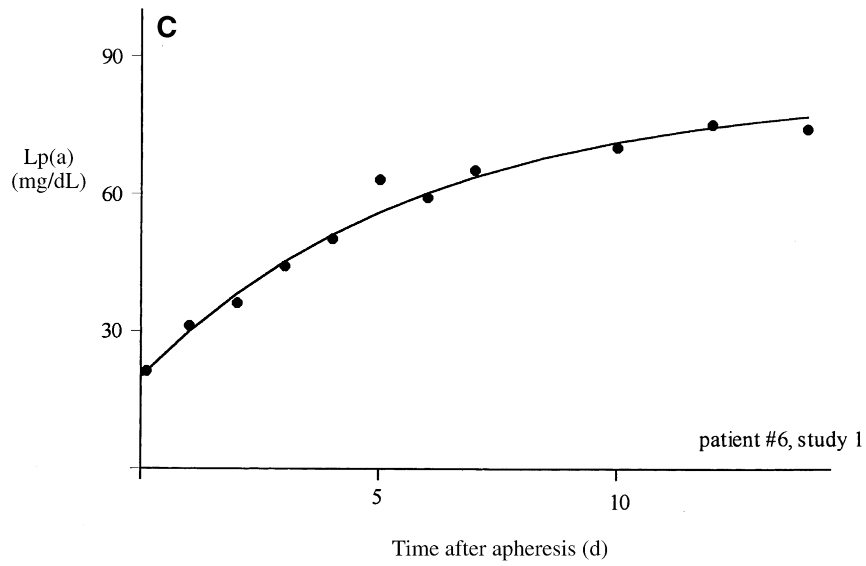

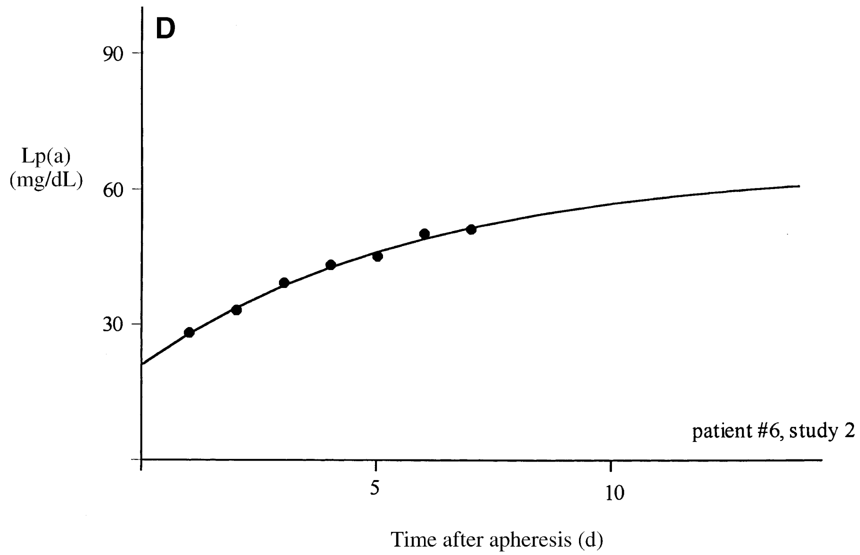

FIG. 2. (continued)

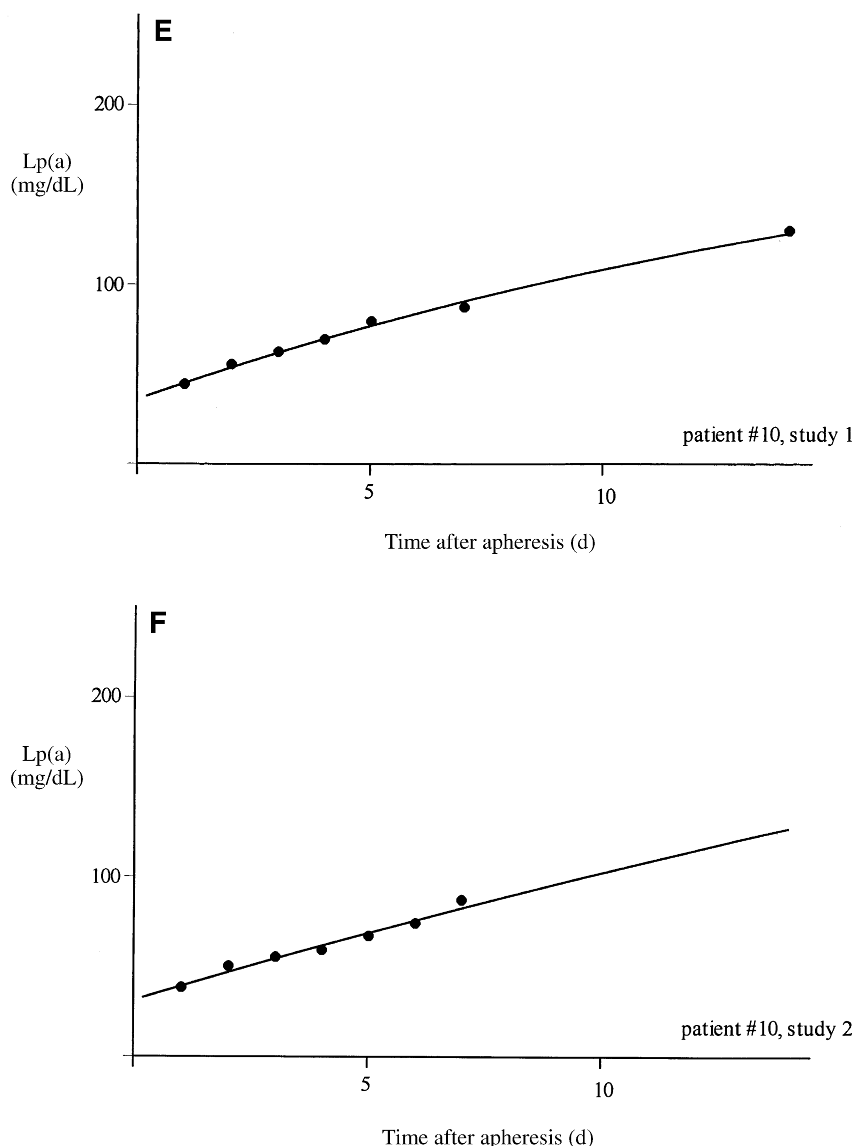

FIG. 2. Time course of Lp(a) plasma concentration in three patients (#5, #6, #10) in whom Lp(a) metabolism was determined twice following two different aphereses. Symbols represent observed concentrations during rebound and the solid line indicates the fit of the monoexponential function. While in two patients (#6, patterns C and D; #10, patterns E and F) the rebound curves are similar, there is some variation between the two analyses in the other patient (#5, patterns A and B). For abbreviation see Figure 1.

0.25, $P = 0.39$). In patients with more than one isoform the smaller isoform (major isoform) was used for these analyses, since the smaller isoform is predominantly associated with the plasma Lp(a) concentration (4,5).

In eight patients Lp(a) metabolism was determined twice (Figs. 2 and 5, Table 4). PR and FCR determined independently following two different aphereses up to 10 yr apart correlated well (PR, $r^2 = 0.883$, $P = 0.0005$; FCR, $r^2 = 0.856$, $P = 0.001$), but only FCR was concordant ($R_i = 0.731$), while PR was not ($R_i = -1.14$). When the parameters were looked at by pairwise comparison (Fig. 5), PR and FCR were each reproducible in six patients, although we observed some random variation in two subjects (FCR: #5 and #11; PR: #5 and #7).

DISCUSSION

Because elevated Lp(a) concentration in plasma is associated with the risk for premature CAD it is important to determine factors that control its concentration. We determined parameters of Lp(a) metabolism in a group of 17 hyperlipoproteinemic patients without the use of a tracer by estimating the FCR from the analysis of the rebound of Lp(a) plasma concentra-

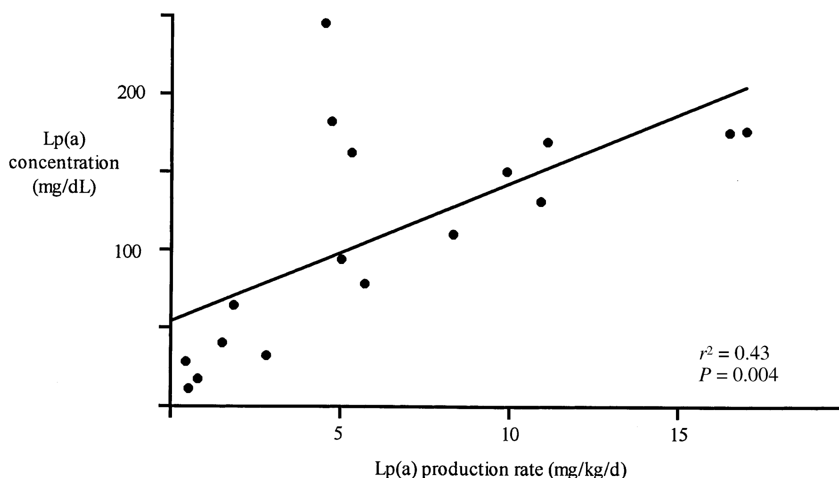

FIG. 3. Correlation (linear regression analysis) of plasma Lp(a) concentration and Lp(a) production rate. For abbreviation see Figure 1.

tion following apheresis. The metabolic parameters obtained by this approach are similar but not identical to those reported from studies using radioactive tracers. As reported in tracer studies we found that (i) Lp(a) production and not catabolism determines plasma concentrations, (ii) the inverse association of Lp(a) concentrations with apo(a) isoforms is due to differences in production and not catabolism, and (iii) differences in Lp(a) concentrations among individuals with the same apo(a) isoform are due to differences in production and not catabolism. Furthermore, in a subgroup of eight patients parameters were determined twice following two different aphereses. Pairwise comparison of FCR and PR determined on both occasions revealed that parameters were similar in six patients but showed some degree of random variation in two patients.

In a series of studies using radiolabeled material Rader *et al.* (6,8) reported FCR of Lp(a) of $0.30 \pm 0.06\ d^{-1}$ (compared to $0.16 \pm 0.12\ d^{-1}$ in our study) and production rates of 2.1 ± 2.7 mg·kg^{-1}·d^{-1} (compared to 6.25 ± 5.26 mg·kg^{-1}·d^{-1} in our study). However, these subjects had considerably lower Lp(a) concentrations (average 18.5 ± 27.5 compared to 98 ± 73 mg·dL^{-1} in this study). A consistent finding in both studies was the observation that PR and not FCR determines Lp(a) concentrations. Despite some discrepancies with regard to absolute values the overall conclusions are very similar: PR and not FCR determines Lp(a) concentrations, the inverse association of Lp(a) concentrations with apo(a) isoforms is due to differences in PR and not catabolism, and finally differences in Lp(a) concentrations among individuals with the same apo(a) isoform seem to be due to differences in production and not catabolism (6,8).

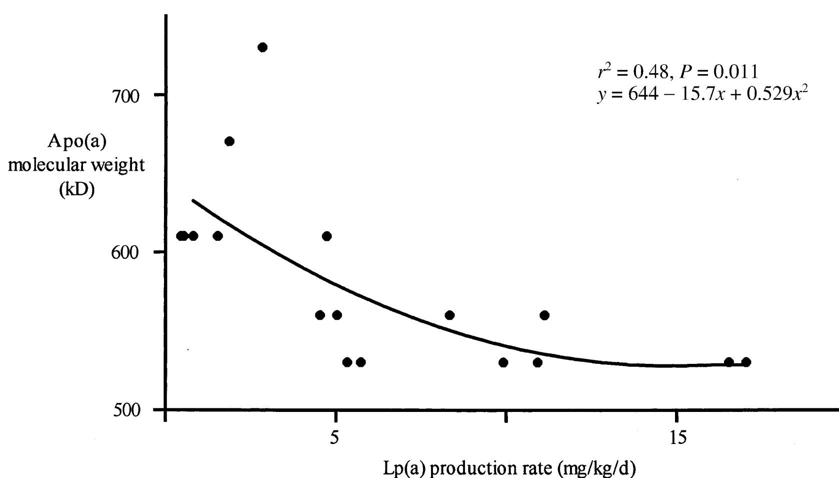

FIG. 4. Correlation (quadratic regression analysis) of the molecular weight of the predominant apoprotein (a) [apo(a)] isoform and Lp(a) production rate. In patients with more than one isoform the molecular weight of the smaller isoform (predominant isoform) was used for analysis. For abbreviation see Figure 1.

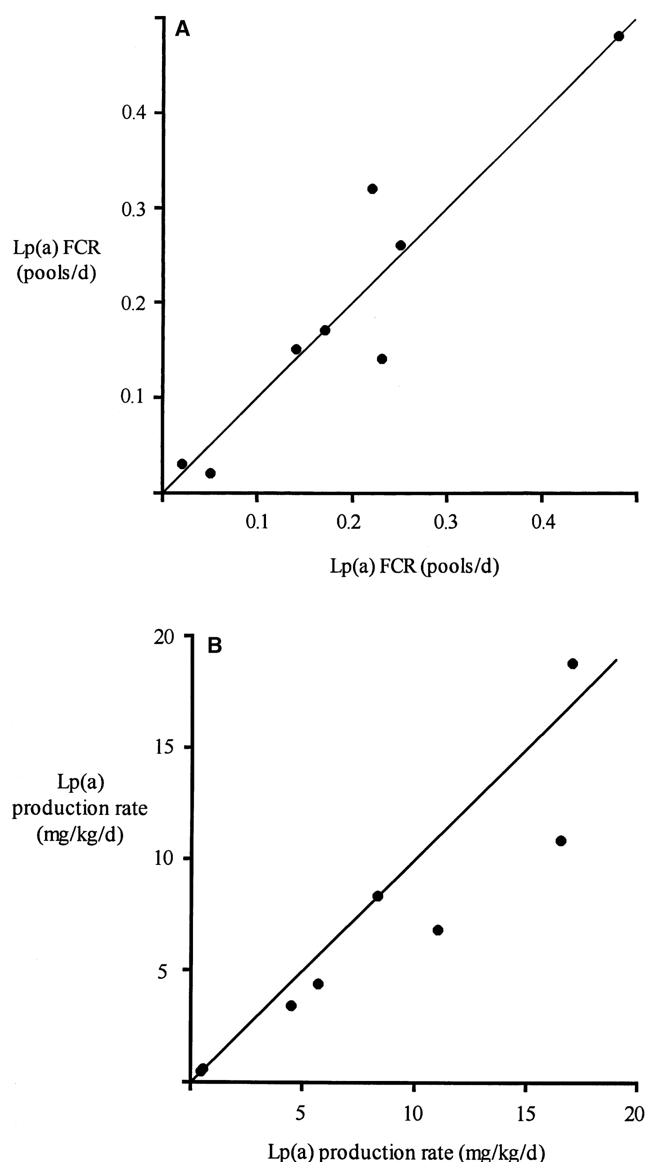

FIG. 5. Fractional catabolic rate (FCR) (A) and production rate (B) estimated on twp different occasions following two different aphereses (between 6 mon and 10 yr apart), with line of equality.

Compared to the parameters published by Rader *et al.* (6,8) the FCR obtained in this study vary over a wider range (0.02–0.48 d^{-1} as compared to 0.22–0.39 d^{-1}). The reason for this variance is unknown, but may be related to several aspects. First, there may be a wide natural variation particularly in such a heterogeneous group of patients as studied here. This heterogeneity is probably further enhanced by the fact that most patients were on concomitant hydroxymethylglutaryl-CoA (HMG-CoA) reductase inhibitor therapy, although such therapy does probably not significantly affect Lp(a) metabolism. Second, in some patients apheresis may affect parameters more than in others. In this respect it is interesting that in the eight patients in whom observed (concentration before first apheresis) and predicted steady-state concentrations were close to each other FCR varied less (FCR, 0.15 ± 0.06 d^{-1}) than in the nine patients in whom predicted and observed steady-state concentrations were different (FCR, 0.18 ± 0.16 d^{-1}). Finally, heparin, which is given as anticoagulant in apheresis, can be considered a further modifying factor perturbing lipoprotein metabolism to some extent.

Our Lp(a) FCR are in better accordance with results published by Armstrong *et al.* (10) who used a similar experimental approach. Values were in the range of 0.05 to 0.18 d^{-1} in a group of five patients with heterozygous familial hypercholesterolemia using a similar approach. Similar to our patients, Lp(a) concentrations were relatively high, but it is unclear whether the analysis predicted steady-state concentrations similar to the observed values.

Our study confirms that metabolic parameters of Lp(a) can be estimated without the use of a tracer. The methodology is based on the concept that metabolic parameters can be estimated from the dynamics by which a steady-state is restored after it has been perturbed by apheresis. However, it is important to understand the limitations of such an approach, which may explain why metabolic parameters obtained with tracer studies and those obtained with this approach differ and why observed (concentration before first apheresis) and predicted steady-state concentrations do not coincide in 9 of 17 patients. The use of the methodology presented here implies several assumptions.

First, this approach implies that apheresis does not alter Lp(a) metabolism, i.e., that apheresis does not affect the production and/or catabolism of this particle. While it has been shown that LDL-apheresis does not alter apoB metabolism in the long term (16), it has been demonstrated *in vivo* (17) and *in vitro* (18) that LDL-receptor activity is increased immediately after apheresis. However, no studies are available examining the effect of apheresis on Lp(a) metabolism. Although Lp(a) is an LDL particle with an additional apoprotein [apo(a)], its metabolism is very different from regular LDL and it is known that the LDL-receptor is not necessary for normal Lp(a) catabolism (19). Whether apheresis changes Lp(a) metabolism is unknown at present. If Lp(a) FCR increases following an acute reduction of pool size (plasma concentration), this would considerably limit the validity of this approach. This could not be overcome by replacing the monoexponential function by a multiexponential one. Such an increase in FCR after apheresis could be observed, if the catabolic pathways operate at saturation before apheresis. For LDL-apoB metabolism it has been pointed out that the rebound analysis does not provide direct information whether LDL-apoB FCR is affected by pool size (20).

Second, the use of a monoexponential equation to describe the rebound of Lp(a) concentration in plasma implies that Lp(a) metabolism can be described by a one-compartment model, with all Lp(a) in plasma being kinetically homogenous. In the case of patients with more than one apo(a) isoform this assumption necessarily represents a simplification, since each Lp(a) contains only one molecule of apo(a) and it is unlikely that Lp(a) particles with different apo(a) moieties behave iden-

tically in kinetic terms. If Lp(a) is not kinetically homogenous a sum of exponentials would be necessary to describe the rebound of Lp(a) following apheresis. However, the concentration data defining the rebound are not sufficient to define a second compartment (second exponent) with sufficient accuracy.

Whether these assumptions are correct cannot be deduced from this study. The observations that the rebound analysis does not predict steady-state concentrations correctly in half of our patients (Table 3) and that there is a discrepancy between the parameters found here compared to those defined by tracer studies indicate that some of these assumptions are not entirely fulfilled in some patients.

Estimating kinetic parameters of Lp(a) metabolism from the rebound following apheresis offers the particular advantage that analyses can repeatedly be performed in the same subject. Up till now, Lp(a) metabolism has not been determined more than once in a given subject, and therefore data on intra-individual variation are not available. We determined Lp(a) metabolism on a second occasion following a different apheresis in eight patients and found, as expected, parameters to be highly correlated. However, the intraclass correlation coefficient may be a more appropriate statistical method to test for concordance and thus reproducibility (14,15). Although both parameters correlated well, only FCR but not PR estimated at the two occasions were concordant. Pairwise comparison revealed satisfactory reproducibility in six out of eight patients (Fig. 5). In two patients (#5 and #11) FCR and in two patients (#5 and #7) PR differed between the two studies. Several explanations are possible: first, some variance in Lp(a) metabolism may exist. The period between the two analyses was longest in those patients in whom parameters differed. Second, the observed difference may be related to the method used for determination of Lp(a) concentration. The estimation of the parameters is obviously dependent on the quality of the concentration measurement and is very sensitive to the data obtained early after the index apheresis. It is well known that the determination of Lp(a) concentration is associated with a considerable error when performed with a radioimmunoassay. The variation coefficients determined in our laboratory (intra-/interassay variation of 5/9% and <2.0/<3.5% for the radio immunoassay and the nephelometric determination, respectively), however, indicate that the differences may not be solely due to the different methods to measure Lp(a) concentration.

Although tracer studies performed in steady state represent the gold standard to determine metabolic parameters, the injection of radiolabeled material is not without problems. Results may be confounded by nonuniform labeling (9), by changes of particle properties by iodination, and by problems associated with the Lp(a) used for labeling (6). Furthermore, a recently published study (21) examining renovascular arteriovenous differences in Lp(a) plasma concentrations indicated much higher production rates of Lp(a) than suggested by the exogenous tracer studies or by the present study. However, studies (22,23) using endogenous labeling with amino acids labeled with stable isotopes, which are now considered gold standard for the evaluation of lipoprotein metabolism (24,25), indicate that Lp(a) production is not as high as suggested from the renal arteriovenous concentration difference.

Given the limitations of the different methods applied, the conclusions from tracer studies and from our own study are remarkably similar.

We conclude that metabolic parameters of Lp(a) can be estimated from the rebound of Lp(a) concentrations following apheresis without the use of a tracer. This approach also allows repeated measurements of Lp(a) metabolic parameters, which in eight patients showed similar albeit not identical results on two occasions. Furthermore, in this group of hyperlipoproteinemic patients differences in Lp(a) plasma concentration are due to differences in production and not in catabolism. Our study also indicates the limitations of such a nonsteady-state approach.

ACKNOWLEDGMENT

We appreciate the help of our apheresis patients and the staff of the Apheresis Unit at Ludwig Maximilians University's Medical Department II. We are indebted to Christa Ueblacker for technical assistance.

Fatty Acid Profile of Buccal Cheek Cell Phospholipids as an Index for Dietary Intake of Docosahexaenoic Acid in Preterm Infants

Dennis R. Hoffman[a,b,*], Eileen E. Birch[a,c], David G. Birch[a,c], and Ricardo Uauy[a,d]

[a]Retina Foundation of the Southwest, Dallas, Texas 75231; Departments of [b]Pediatrics and [c]Ophthalmology, University of Texas Southwestern Medical Center at Dallas, Texas; and [d]Clinical Nutrition Unit, Institute of Nutrition and Food Technology (INTA), University of Chile, Santiago, Chile

ABSTRACT: Cheek cells (buccal epithelia) were utilized as a noninvasive index of fatty acid status in a study of the effects of n-3 long chain polyunsaturated fatty acid supplementation on visual function in preterm infants. The fatty acid profile of cheek cell phospholipids was directly correlated with the dietary docosahexenoic acid (DHA) intake of infants receiving: (i) primarily human milk; (ii) n-3 fatty acid-deficient, corn oil-based, commercial formula (CO); (iii) α-linolenic acid-enriched, soy oil-based, commercial formula; or (iv) experimental formula enriched with soy and marine oils providing a DHA level equivalent to that in human milk. In a subset of infants with complete cheek cell fatty acid profiles and visual function assessments, preterm infants at both 36 wk ($n = 63$) and 57 wk ($n = 45$) postconceptional age had significantly ($P < 0.0005$) reduced cheek cell phospholipid DHA levels in the n-3-deficient, CO-fed group compared to the other diet groups. The DHA content in cheek cell phospholipids was highly correlated ($P < 0.0005$) with that of both red blood cell lipids and plasma phospholipids at the 36- and 57-wk time points. The DHA content in cheek cell lipids of infants at 36 wk was significantly correlated with electroretinographic responses ($r = -0.29$; $P < 0.03$) and visual acuity ($r = -0.31$; $P < 0.02$) as measured by visual-evoked potentials (VEP). Cheek cell DHA was highly correlated ($r = -0.57$; $P < 0.0005$) with VEP acuity at the 57-wk time point. These results suggest that the fatty acid profile of cheek cells is a valid index of essential fatty acid status, can be monitored frequently, and is associated with functional parameters in infants.

Paper no. L8077 in *Lipids 34,* 337–342 (April 1999).

Recently, a number of randomized and nonrandomized clinical trials have been conducted to assess the impact of enrichment of formulas with long chain polyunsaturates (LCP) on the biochemical and functional development of both term and preterm infants. Most investigations have utilized either plasma or red blood cell (RBC) lipid profiles to document compliance and to provide indices of tissue fatty acid status. Typically, infant blood samples are obtained from either the antecubital vein or by heel stick; both methods are painful and can be traumatic for the infant and attending parent. As an alternative, human cheek cells (buccal epithelia) can be isolated by noninvasive procedures and represent an accessible tissue for investigating the influence of diet on the infant's fatty acid nutritional status (1,2). Subsequent extraction of lipids and separation of cheek cell phospholipids provide a lipid fraction representative of fatty acids in cellular membranes.

Buccal cheek cells were collected during a clinical trial designed to evaluate the role of the dietary essential n-3 fatty acid, α-linolenic acid (LNA; 18:3n-3), and its long chain metabolite, docosahexaenoic acid (DHA; 22:6n-3), in early visual development in preterm infants. Details of the infant cohort, diets, and methods have been presented previously (3–8). We report here on the utility of cheek cell phospholipids to accurately reflect the impact of fatty acid modifications to formula on cell membrane composition. A second goal was to determine whether, as for RBC and plasma lipids (3–8), these fatty acid modifications are correlated with visual development in preterm infants.

MATERIALS AND METHODS

Subjects. Preterm infants born at 27–33 wk postconception participated in this prospective, randomized clinical trial conducted between 1987 and 1991. Inclusion and exclusion criteria and additional clinical details for the study have been previously reported (3,8).

The current report includes a subset of infants, tested at 36 wk postconception ($n = 63$) and at 57 wk ($n = 45$), that had fatty acid measurements of cheek cell phospholipids, RBC total lipids, and plasma phospholipids as well as complete visual function data.

Diets. Infants were randomized to one of three formula groups or belonged to a reference group whose mothers chose to provide primarily human milk (HM). One group received a standard commercial preterm infant formula based on corn oil (CO) with a relatively low content of n-3 fatty acids [i.e., 24.2% linoleic acid (LA; 18:2n-6); 0.5% LNA; no DHA; and

an n-6/n-3 fatty acid ratio of 48.2]. The formula enriched with soy oil (SO) supplied 20.8% LA, 2.7% LNA, no DHA, and had an n-6/n-3 ratio of 7.7. The formula enriched with soy and marine oils (MO) provided 20.4% LA, 1.4% LNA, 0.35% DHA, and had an n-6/n-3 ratio of 8.5. The latter formula was designed to provide a fatty acid profile closer to HM (i.e., 12.7% LA, 0.8% LNA, 0.29% DHA, with an n-6/n-3 ratio of 11.4). The "reference standard" HM-fed group received their own mother's milk following Parkland Hospital (Dallas, TX) nursery procedures (including hepatitis B and HIV screening of mothers); an Egnell pump (Lact-e; Hollister, Inc., Libertyville, IL) was used for milk collection with aseptic handling and storing. If milk was intended for use within 24 h, it was refrigerated; otherwise it was frozen and used within 3 wk. This subgroup of six HM-fed infants received more than 75% of their energy intake from HM by 36 wk and 63% through 57 wk. During periods of limited milk supply, formula MO was provided because its fatty acid profile most closely matched that of HM. Details of the diet composition have been published (3,6).

Biological sampling and analysis. Blood samples were obtained by venipuncture from a small arm vein. Cheek cells (buccal mucosal epithelia) were obtained by scraping the inside of the cheek (about 10 strokes) with a sterile wooden spatula (6 × 125 mm) after gently cleaning the mucosa with a gauze soaked in saline. Cells were suspended in 8 mL sterile saline and the process repeated on the second cheek. Cheek cells were precipitated from the suspension by centrifugation at 3,000 × g for 10 min. Lipids from plasma, RBC, and the cheek cell pellet were extracted as previously described (6) within 2–4 hours of harvest, stored in solvent containing 0.02% butylated hydroxytoluene, and kept under N_2 at −20°C for a maximum of 1 wk. Collection of blood and cheek cell samples coincided with visual function measurements at both 36- and 57-wk time points. Both plasma and cheek cell phospholipids were isolated by thin-layer chromatography using a hexane/diethyl ether/acetic acid (80:20:1, by vol) solvent system. Analysis of the phospholipid fraction of buccal cheek cells eliminated contamination of the sample by fatty acids derived from formula present in the mouth during sampling. Fatty acid methyl esters prepared from plasma, RBC, and cheek cell lipids were analyzed by capillary gas chromatography as previously described (6). Data for plasma phospholipids and RBC fatty acids have been published (6,7).

Visual function tests. Electroretinography (ERG) measures the summed electrical response of the retina to a light stimulus and reflects the overall health of the neural retinal layer. Pattern-reversal visual-evoked potential (VEP) visual acuity is a measure of the neural integrity of the pathway from the retina to the primary visual cortex. These procedures have been described in detail elsewhere [ERG (3,4); VEP (5)] and will be summarized briefly here.

Full-field ERG responses to short- and long-wavelength stimuli over an extensive range of retinal illuminances were evaluated at 36- and 57-wk postconceptional age. The ERG response to short wavelength stimuli was used to help isolate rod photoreceptor function. Naka–Rushton plots were computed from rod responses to graded illuminances to derive rod thresholds, defined as the light intensity required to produce a 2 μV response. Thus, lower threshold values reflect healthy, more mature retinal photoreceptors.

VEP were assessed using black-and-white checkerboard stimuli presented on a video monitor with pattern reversals at a rate of 3.8 per second. Responses from three electrodes pasted on the scalp were recorded on tape and subsequently filtered digitally and analyzed. The VEP acuity was derived from peak-to-peak amplitude responses to variations in spatial frequencies of the grating pattern. Visual acuities are reported as Snellen equivalents; the average for normally sighted adults is 20/20 and the average for normally sighted full-term infants at 57 wk postconception is 20/70 (5).

Data analysis. Analysis of variance was used to analyze the effects of the four diets on fatty acid levels of infant groups at each time period. Nonparametric multiple comparison analysis of diet group results was conducted using the Newman–Keuls procedure at an α of 0.05. Visual function data were log transformed prior to Pearson correlation analysis.

RESULTS

Cheek cell fatty acids as a dietary index. Fatty acid profiles in cheek cell phospholipids obtained from infant study groups are presented for the 36- and 57-wk time points in Tables 1 and 2, respectively. Significant differences among infant groups were found for numerous individual fatty acids, fatty acid ratios, and summation data. Of particular importance, LA levels in cheek cells at the 36-wk time point were significantly lower in the HM-fed infants than formula-fed infants, reflecting the 40 to 50% lower level of LA in HM compared to the formulas. Elevated levels of arachidonic acid (20:4n-6), the n-6 end-product docosapentaenoic acid (DPA; 22:5n-6), and the sum of n-6 LCP in the essentially n-3 fatty acid-deficient CO group compared to the infant groups receiving n-3 fatty acid-enriched formula are consistent with competition for incorporation into phospholipids between the n-6 and n-3 series of fatty acids. Furthermore, reduced levels of the n-3 fatty acids and the n-3-to-n-6 LCP ratio in the CO diet group at 36 wk were consistent with the n-3 fatty acid composition of the formulas. The n-6 and n-3 LCP profiles in the experimental MO formula group were nearly identical to those of the HM-fed group with the only exception being the eicosapentaenoic acid level (20:5n-3); this n-3 fatty acid is typically present in menhaden fish oil at twice the concentration of DHA. Second-generation formulas used in current clinical trials to evaluate efficacy of LCP supplementation use DHA sources such as marine algae, egg yolk phospholipids, or select fish oils, all with little or no eicosapentaenoic acid and preferable to menhaden fish oil.

At 57 wk postconception (Table 2), differences in monounsaturates and LA among groups were no longer evident. However, significant differences in major n-3 LCP persisted such that the cheek cell level of DHA and the DHA/DPA ratio

See Table 1 for footnote information.

(an index of n-3 fatty acid sufficiency) in the CO group differed from that in the MO and HM groups by 6- to 12-fold.

Correlations between blood and cheek cell fatty acid profiles. Numerous fatty acids and major indexing values were significantly correlated between cheek cell phospholipids and both total RBC lipids and plasma phospholipids at the 36- and 57-wk time points [see Table 3; RBC and plasma lipid data given previously (6,7)]. The DHA content, as well as the n-3 LCP-to-n-6 LCP ratio (Table 3), in cheek cells was significantly correlated with that in both RBC lipids and plasma phospholipids at 36 and 57 wk postconception (Fig. 1A,B). At this later time point, cheek cell/RBC and cheek cell/plasma phospholipid correlation coefficients (r = 0.72 and 0.83, respectively) were higher than that found for RBC vs. plasma phospholipid DHA (r = 0.58; P < 0.0005). At 36 wk, the arachidonic acid content in cheek cells did not correlate with that in RBC and plasma phospholipids. However at 57 wk, the r value between cheek cells and both blood components was significant (r = 0.40; P < 0.01) but not to the extent of the association between arachidonic acid in RBC lipids and plasma phospholipids [r = 0.51; P < 0.0005; RBC and plasma fatty acid data previously reported (6, 7)].

DHA and visual function. Results of the trial have been reported in detail regarding the impact of n-3 fatty acid nutri-

[b]RBC and plasma phospholipid fatty acid data reported previously (6,7).

tional intervention on ERG (3,4), visual acuity (5), total RBC and plasma lipid fatty acid distribution (6), and growth (8) of the entire preterm infant cohort. Data presented here are for the 36- and 57-wk subsets of infants with complete visual function, cheek cell, RBC, and plasma lipid data (Fig. 2). Retinal function was less mature in the n-3-deficient CO formula group as evident from elevated rod ERG thresholds at 36 wk postconception (Fig. 2B). By 57 wk, significant differences in rod ERG thresholds are no longer apparent (Fig. 2E) and may be attributable to the inability to record functional differences during a plateau in development of retinal tissues (3,4). Maturation of visual function was delayed in both the 36-wk and 57-wk CO-infant groups as determined electrophysiologically using VEP responses (Fig. 2C,F). Visual acuities in the MO and HM infants were nearly equivalent whereas the SO group (receiving ample LNA) had intermediate values.

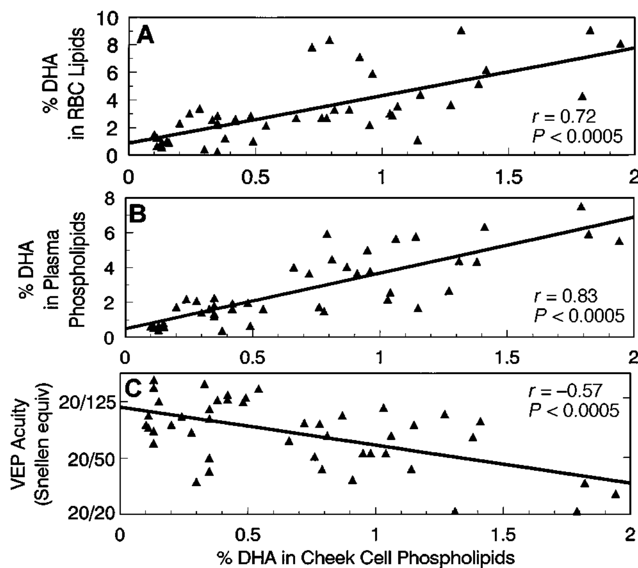

FIG. 1. Correlations between docosahexenoic acid (DHA) in cheek cell phospholipids and DHA in total red blood cell (RBC) lipids (A), DHA in plasma phospholipids (B), and with visual-evoked potential (VEP) acuity (C) at 57 wk postconception. VEP visual acuity given as Snellen equivalents where 20/20 is the average value for normally sighted adults. Equations defining the regression lines in A, B, and C are $y = 0.21 + 0.72x$ ($r^2 = 0.52$), $y = 0.11 + 0.83x$ ($r^2 = 0.68$), and $y = 0.76 - 0.57x$ ($r^2 = 0.33$), respectively. Fatty acid results for RBC and plasma fatty acids reported previously (6,7).

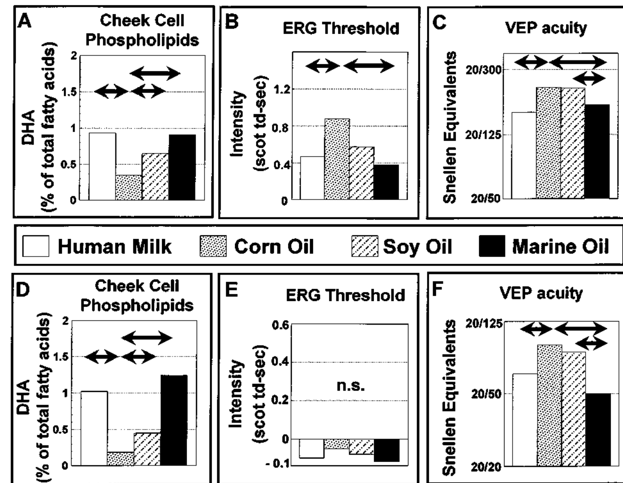

FIG. 2. Cheek cell DHA levels and visual function results of preterm infant subgroups (see Materials and Methods section) at 36 wk (A, B, C) and 57 wk (D, E, F). Rod electroretinography (ERG) thresholds given as light intensity (log scotopic troland-seconds) necessary to obtain a 2 μV response. Comparison of Snellen equivalents for VEP visual acuity on the *y*-axes of (C) vs. (F) demonstrate maturation of visual processes between 36-wk and 57-wk infants; higher Snellen equivalents (e.g., 20/20) are associated with better visual function. Arrows indicate significant differences ($P < 0.05$) between diet groups using Newman–Keuls multiple comparison analysis. n.s., not significant. See Figure 1 for other abbreviations.

At 36 wk postconception, DHA in cheek cell phospholipids was correlated with both rod ERG threshold and VEP acuity (ERG: $r = -0.29$, $P = 0.03$; VEP: $r = -0.31$, $P = 0.02$). Similarly, DHA in plasma phospholipids was correlated with these electrophysiologic functions (ERG: $r = -0.45$, $P < 0.0005$; VEP: $r = -0.38$, $P = 0.002$); however, the association between total RBC lipid DHA values and either ERG thresholds or VEP acuities at 36 wk was not significant (4,5) ($P > 0.09$). At 57 wk, rod ERG thresholds were no longer associated with cellular fatty acid levels; however, VEP acuity was correlated ($P < 0.0005$) with DHA in total RBC lipids ($r = -0.50$) (5), plasma phospholipids ($r = -0.61$) and cheek cell phospholipids ($r = -0.57$; see Fig. 1C). VEP acuity was also correlated with the n-3 sufficiency index (DHA/DPA ratio) in cheek cell phospholipids at both 36 wk ($r = -0.26$, $P < 0.05$) and 57 wk ($r = -0.50$, $P < 0.001$). Thus, elevations in both blood and cheek cell DHA levels were associated with maturation of visual function, based on electrophysiological measurements.

DISCUSSION

In order to better understand the cellular biochemistry associated with early development or pathology of the human visual system, it would be preferable to analyze tissue from the eye, retina, or visual cortex. However, since this is impractical, an alternative source is necessary to provide a fatty acid index for studies of development, disease, or dietary intake. In addition, biochemical sampling permits direct monitoring of compliance in clinical trials instead of relying on self-reporting measures. Blood lipids are commonly used for this purpose and, as reported previously (3–5), provide excellent correlations between fatty acid levels and developing visual function in infant trials. Nevertheless, in some clinical trials, blood samples may not be available or scheduling of repeated sampling may be excessively invasive. The present results suggest that phospholipids from cheek cells (buccal mucosal epithelia) may provide a suitable alternative or supplemental index to the individual's fatty acid status.

Increasing attention has recently been given to buccal cheek cells as a source for identifying various biological characteristics in individuals. Cheek cell preparations are now commonly used in DNA screening to detect gene mutations for diseases such as cystic fibrosis (9) and more recently, Alzheimer's disease (10). Other clinical investigations have utilized cheek cells to evaluate the vitamin E nutritional status in newborns, children, and adults (11–13). For example, Yokota *et al.* (11) found that α-tocopherol levels in buccal cheek cells were closely correlated with both RBC and plasma α-tocopherol levels in young adults when expressed on a per g cellular lipid basis.

Two previous clinical studies have employed cheek cell phospholipids as an index for fatty acid status during nutritional intervention. McMurchie *et al*. (1) reported a significant elevation in the proportion of LA in cheek cell phospholipids in subjects consuming a diet enriched with LA [polyunsaturate-to-saturate (P/S) ratio of 1.0] compared to those receiving a low P/S diet (P/S = 0.4). These authors also noted that vegetarians with low saturated fatty acid intakes compared to omnivores had significantly lower levels of saturates in cheek cell lipids. As part of a larger nutritional study, Sampugna *et al*. (2) evaluated cheek cell lipids as indicators of fatty acid status in women on high (1.0) or low (0.3) P/S diets for 4 mon. The authors reported no significant differences in individual cheek cell fatty acids from subjects on the two diets. The results of our studies are consistent with the studies of McMurchie *et al.* (1) but differences in subject ages, degree of maturation (preterm infants vs. adults), and strict regulation of the nutritional intervention (use of liquid diets in the current study) may have led to a more sensitive response in our study. Variations in sample preparation may also contribute to different results among studies; for example, centrifugation of cheek cells at 12,000 × *g* for 30 min (2), 6,000 × *g* for 10 min (1), or 3,000 × *g* for 10 min (current study) may result in analysis of different cell populations. Furthermore, cell storage may influence the outcome measure; McMurchie *et al.* (1) stored cells frozen at −20°C for 2 wk prior to lipid isolation, Sampugna *et al.* (2) stored cells briefly overnight at −80°C, and we extracted the lipids immediately and stored the extracts for up to 1 wk under N_2 at −20°C before analysis on the chromatograph. These technical variations among laboratories would need to be standardized before cheek cells become a routine measure of fatty acid status in the body.

The fatty acid profiles of cheek cell phospholipids in the present study were found to reflect intake of dietary fatty acids. At 36 and 57 wk postconception, diet-associated differences in several major fatty acids and indices were found in cheek cell phospholipids including numerous individual n-3 and n-6 LCP, total n-3 and n-6 LCP, DHA/DPA ratios, and n-3-to-n-6 LCP ratios.

An elevation in arachidonic acid and other n-6 LCP in cheek cell lipids of the SO formula group at 57 wk also was observed in total plasma lipids (6) and plasma phospholipids (data not shown) but not in RBC lipids (6). Thus a greater association between plasma and cheek cell lipid metabolism is suggested by these data together with: (i) a high correlation between cheek cell-DHA and plasma phospholipid-DHA, and (ii) similar correlations of VEP acuity with DHA in cheek cells ($r = -0.57$) and plasma phospholipids ($r = -0.61$) at 57 wk compared to that in RBC lipids. A common factor to both may be the relatively rapid turnover rates of plasma lipids (7–8 d) (14) and cheek cells (5 d) (15) in comparison to RBC (108–135 d) (15). Considering the different origins, environments, and characteristics of RBC, plasma phospholipids, and cheek epithelial cells, distinct fatty acid profiles may be expected for each entity. None of these indices should be expected to totally reflect the fatty acid profile of brain or retinal tissue, both of which vary regionally. Cheek cells may, however, provide a supportive role along with RBC and/or plasma phospholipids as indices to neural fatty acid status based on significant correlations between visual function and cheek cell, RBC, and plasma phospholipid DHA content. These results support the validity of cheek cells as an index for essential fatty acid status and may be of importance for investigators who need a noninvasive procedure to support blood lipid analysis data in clinical trials.

Acyl-CoA Synthetase Activity in Liver Microsomes from Calcium-Deficient Rats

Carlos A. Marra* and María J.T. de Alaniz

Instituto Nac. de Investigaciones Bioquímicas (INIBIOLP), Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), y Cátedra de Bioquímica, Facultad de Ciencias Médicas de la UNLP (Universidad Nacional de La Plata), La Plata, Argentina

ABSTRACT: A study on the kinetic properties of the nonspecific acyl-coenzyme A (CoA) synthetase activity in liver microsomal vesicles from both normal and calcium-deficient Wistar rats was carried out. After a 65-d treatment, the calcium-deficient diet reflected a 75% increase in the synthetase activity with respect to control animals. The apparent Vm was significantly enhanced, while the Km remained unchanged. We also provided experimental evidence about various fatty acids of different carbon length and unsaturation which depressed the biosynthesis of palmitoyl-CoA following different behaviors in control or calcium-deprived liver microsomes. In addition, we studied in detail the inhibition reflected by stearic, α-linolenic, or arachidonic acids, in the biosynthesis of palmitoyl-CoA in microsomal suspensions either from control or hypocalcemic rats. In control microsomes, stearic acid produced a pure competitive effect, while the other fatty acids followed a mixed-type inhibition. The competitive effect of stearic acid was not observed in calcium-deprived microsomes. At the same time, a mixed-type inhibition produced by either α-linolenic or arachidonic acid was diminished in deprived microsomes due to an increase in the noncompetitive component (αKi). These changes observed in apparent kinetic constants (Km, Vm, Ki, and αKi), as determined by Lineweaver-Burks and Dixon plots, were attributed to the important alterations in the physicochemical properties of the endoplasmic reticulum membranes induced by the calcium-deficient diet. The solubilization of the enzyme activity from both types of microsomes demonstrated that the kinetic behavior of the enzyme depends on the microenvironment in the membrane, and that the calcium ion plays a crucial role in determining the alterations observed.

Paper no. L8054 in *Lipids 34,* 343–354 (April 1999).

The importance of long-chain acyl-coenzyme A (CoA) derivatives as intermediates and regulators of lipid metabolism has prompted a number of investigators to study the long-chain acyl-CoA-synthetase (ACS) AMP-forming (EC 6.2.1.3), which was first demonstrated by Kornberg and Pricer (1) in particulate preparations from guinea pig liver. Subsequent works extended research to different sources such as rat tissues (2–9), yeasts (10,11), infected erythrocytes (12), murine T lymphocytes (13), and various human cells and tissues (14–16). In rat livers, ACS is located in microsomes (1,17–19), outer mitochondrial membranes (20,21), and peroxisomal membranes (22,23). Purified ACS from these three different organelles are identical regarding all molecular and catalytic properties (2,24). The identity of the enzymes was also confirmed immunologically (25). Wilson *et al.* (14) and Laposata *et al.* (16) demonstrated the occurrence of an arachidonic acid-specific enzyme activity, and they suggested its potential role in regulating free arachidonic acid within the cell. Another enzyme activity requiring GTP instead of ATP was reported to occur in the mitochondrial fraction (26), though the significance of this enzyme reaction is controversial (27,28). More recently, Sugiura *et al.* (29) have suggested that certain types of fatty acyl chains of membrane lipids are continuously being converted transiently into acyl-CoA esters by an ATP-independent acyl-CoA synthetase. In any case, it is clear that the long chain acyl-CoA synthetase activity existing in liver microsomes is attributed to a well-characterized protein different from other enzyme activities (12,13,16,30). This enzyme, called nonspecific ACS, is very important because it catalyzes the initial reaction for the overall fatty acid metabolism, and it further regulates the rate of fatty acid biosynthesis (31,32). It has been recently demonstrated that acyl-CoA is necessary for the thyroid hormone receptor function (33), the budding of transport vesicles from Golgi cisternae (34), and the modulation of several enzyme activities such as Na^+,K^+-ATPase (35), Ca^{2+}-ATPase (36), and protein kinase C (37). In addition, three recent reports have indicated that acyl-CoA esters are involved in the intracellular handling of Ca^{2+} (38–40). We should also bear in mind that acyl-CoA have substantial, complex, and differing effects on Ca^{2+} movements in rat liver microsomes. These facts led us to study the relationship between calcium availability and the ACS activity in liver microsomal vesicles from both normal and calcium-deficient Wistar rats. In subsequent experiments, the catalytic properties of this enzyme were also examined under a calcium-deprived diet and the results obtained were discussed in terms of their kinetic significance.

MATERIALS AND METHODS

Fatty acids and other chemicals. All the unlabeled fatty acids were obtained from Nu-Chek-Prep. (Elysian, MN). ATP (disodium salt), dithiothreitol, coenzyme A (lithium salt), and Triton X-100 were purchased from Sigma Chemical Co. (St. Louis, MO). [1-^{14}C]Palmitic (58.0 mCi/mmol, 99% radiochemically pure) and [1-^{14}C]stearic acids (56.5 mCi/mmol, 98% radiochemically pure) were supplied by Amersham International (Buckinghamshire, United Kingdom). Other chemicals used were of analytical or chromatographic grade, and they were provided by commercial sources. The concentration and purity degrees of fatty acids were routinely checked by liquid-scintillation counting and gas–liquid chromatography of fatty acid methyl esters prepared in the presence of internal standards. Fatty acids were dissolved in ethanol and stored in the dark at −20°C under an atmosphere of N_2 until they were used.

Animal treatment. Female Wistar rats from Comisión Nacional de Energía Atómica (Buenos Aires, Argentina) weighing 170 ± 10 g were bred and maintained on a control diet (Cargill type "C", Rosario, Argentina) throughout gestation and lactation. The dams were housed in plastic cages (one animal per cage) in a vivarium kept at 22 ± 1°C with a 12-h light/dark cycle and a relative humidity of 60 ± 10%. After weaning, 24 female pups (weighing 47 ± 4 g/animal) were randomly divided into two groups of 12 animals each, and fed *ad libitum* either on a calcium-deficient diet (group CD), or on a balanced diet (group S). The composition of the calcium-deficient diet prepared in our laboratory is shown in Table 1. The Ca^{2+} content (0.5 g/Kg) was determined by a Shimadzu Atomic Absorption Spectrophotometer AA-630-12 (Kyoto, Japan) following the mineralization procedure described elsewhere (41). Control animals were fed on a standard balanced diet supplemented with 5.0 g/Kg calcium in order to supply the mineral at a level equivalent to that recommended by The American Institute of Nutrition (AIN)-93 Purified Diets for Laboratory Rodents (42). The content of Ca^{2+} in drinking water (given *ad libitum*) was determined either by atomic absorption or by calcium-selective electrode Orion model 93-20, Orion Research Inc. (Cambridge, MA), and it was generally below 5 ppm. During the feeding period, body weights, water consumption, and food intakes were determined every day. Samples of blood were collected in order to determine plasma calcium levels. The food intake and water consumption relative to body weights were not significantly different between both groups of animals at the time the rats were killed, after 60 d of feeding. Calcium-deficient animals grew at a rate similar to the control group during the initial 20 d of feeding, then they grew at a reduced rate until day 59 when differences between groups became significant. In order to avoid individual differences among animals that might have resulted from *ad-libitum* feeding, on day 59 all the rats were fasted for 24 h, refed with the corresponding diet for 2 h, and then killed by decapitation without prior anesthesia 12 h after the refeeding period.

TABLE 1
Composition of Calcium-Deficient Diet

Ingredients	g/kg
Casein, high protein (free of calcium)	200.0
Sucrose	505.9
Corn starch	150.0
Cellulose	50.0
Corn oil[a]	50.0
Mineral mixture (calcium-deficient)[b]	13.4
Sodium phosphate, monobasic	8.9
Potassium phosphate, monobasic	8.8
Vitamin mixture[c]	10.0
DL-Methionine	3.0

[a]Contained 11.5% 16:0, 2.1% 18:0, 26.6% 18:1, 57.3% 18:2n-6, 1.4% 18:3n-3, 0.2% 20:3n-6, 0.2% 20:4n-6, 0.2% 20:1, and other fatty acids as trace amounts (<0.2%).
[b]Contained (g/kg mix): NaCl, 183.7; potassium citrate, 576.0; K_2SO_4, 136.1; MgO, 62.8; $MnCO_3$, 9.2; ferric citrate, 16.7; $ZnCO_3$, 4.2; $CuCO_3$, 0.80; KIO_4, 0.03; $Na_2SeO_3 \cdot 5H_2O$, 0.03; $CrK(SO_4) \cdot 12H_2O$, 1.40.
[c]Contained (g/kg mix): choline dihydrogen citrate, 349.7; ascorbic acid, 101.7; vitamin E acetate, 24.2; p-aminobenzoic acid, 11.0; inositol, 11.0; niacin, 9.9; panthothenate, 6.6; menadione, 5.0; vitamin A palmitate, 4.0; vitamin B_{12}, 3.0; pyridoxine HCL, 2.2; riboflavin, 2.2, thiamine, 2.2; vitamin D_3, 0.44; folic acid, 0.2; biotin, 0.04; and corn starch, 466.7.

All the diet components used were purchased from Carlo Erba (Milan, Italy) or Mallinckrodt Chem. Works (NY). The casein was deprived of calcium by EGTA treatment and then defatted with boiling acetone. The calcium content in the extracted casein was negligible. Animal maintenance and handling were in accordance with the National Institutes of Health guide for the care and use of laboratory animals (43).

Preparation of liver microsomal suspensions. Livers were rapidly excised and immediately placed in an ice-cold homogenizing medium (44). The homogenate from each liver was processed individually at temperatures varying from 0° through 2°C, and the microsomal fractions were separated by differential centrifugation at 110,000 × *g*, as described previously (44). Microsomal pellets were resuspended in a cold homogenizing solution up to a final protein concentration of 30–40 mg/mL.

Assay of long-chain fatty acyl-CoA synthetase activity. The enzyme activity was radiochemically determined basically following the method of Tanaka *et al.* (2), consisting of the enzymatic conversion of heptane-extractable radioactively labeled fatty acid into water-soluble acyl-CoA esters. The standard reaction mixture contained 0.1 M Tris-HCl buffer (pH 8.0), 5 mM dithiothreitol, 0.15 M KCl, 15 mM $MgCl_2$, 10 mM ATP(Na_2), 1 mM CoA (lithium salt), and the substrate (1 mM palmitic acid, in a final volume of 0.2 mL.). To prepare the palmitic acid solution, labeled and unlabeled acids were dissolved in ethanol and mixed to obtain 200,000 dpm/incubation tube. The solvent was evaporated to dryness under N_2 and the fatty acids resuspended by sonication in 375 mM Tris-HCl buffer, pH 8.0, containing 1% polyethyleneglycol. The reaction was started by adding 0.04 mg liver microsomal protein in a solution of 10 mM Tris-HCl (pH 8.0), 1 mM dithiothreitol, and 1 mM EDTA. After 3 min of incubation, the reaction was stopped by adding 2.25 mL of a mixture of isopropanol/heptane/2 M-sulfuric acid (40:10:1, vol/vol). Then 1.5 mL heptane and 1 mL distilled water were added and the

upper layer was discarded. The lower layer was washed 3 times with 2 mL heptane containing 1 mg/mL of carrier palmitic acid to remove the unreacted radioactive fatty acid. The radioactivity of the aqueous phase was counted in a Wallac 1214 Rackbeta Liquid Scintillation Counter (Turku, Finland). In some experiments, different amounts of unlabeled fatty acids (tested as enzyme inhibitors) were added to the incubation mixture at the concentration indicated in the figures, while in other experiments palmitic acid was replaced by stearic acid under the incubation conditions described above. Blanks were routinely run in all incubations. These blanks consisted of tubes in which boiled microsomes (10 min at 100°C) were added. In preliminary experiments using different experimental conditions, the recovery of radioactivity from the aqueous phase (labeled acyl-CoA) of the blanks did not exceed 1 to 2% of the added radioactivity. The aqueous extract from the reaction mixture was reacted with neutral hydroxylamine, and the hydroxamate derivative was chromatographed on silica gel G with chloroform/methanol/water (95:5:0.5, vol/vol), following the procedure described elsewhere (10). The reaction products were identified by means of authentic standards. Ninety percent of the radioactivity in the reaction product was found in palmitoyl-CoA and *ca.* 3% in free palmitic acid; the remaining 7%, which migrated below the acyl-CoA ester, may be in oxidation products (5).

Solubilization of enzyme activity. The ACS activity was solubilized from the microsomal membrane of control or calcium-deficient rat livers as described by Nagamatsu *et al.* (30) with minor modifications. Briefly, microsomes were diluted in Tris-HCl buffer (50 mM, pH 8.0) containing 5 mM dithiothreitol (instead of 2-mercaptoethanol as indicated in the original method) and 1 mM EGTA, so that the protein concentration was 4.0 mg/mL. A solution of Triton X-100 was added to make the final detergent concentration 5 mM (various detergent concentrations were previously tested). The mixture was allowed to stand at 0–2°C for 60 min and centrifuged at $105{,}000 \times g$ for 1 h. The enzyme activity was partially purified by ammonium sulfate precipitation as described elsewhere (2). The excess of Triton X-100 was removed by washing the pellet three times with 10 vol of the ammonium sulfate solution. The washed pellet was dialyzed overnight at 2°C against 0.02 M sodium phosphate buffer (pH 7.0), 130 mM NaCl, and 1 mM EGTA. This enzyme preparation had a specific activity of 177 ± 6 nmol of palmitoyl-CoA synthesized per milligram of protein per minute, which was similar to that reported by other authors (45) in the presence of residual amounts of Triton X-100. Solubilization of the ACS was also performed by means of the modified method of Juarez *et al.* (46). The extraction was carried out using a high ionic strength solution of KCl. The liver microsomal pellet was resuspended in a buffer containing 0.05 M K_2HPO_4 (pH 7.00), 1.50 M KCl, 2 mM EDTA, and 0.5 mM dithiothreitol. The suspension (4.0 mg protein/mL) was incubated with stirring at 2°C for 30 min in the presence of 10% glycerol. At the end of this period, the solubilized enzyme was separated from the pellet by centrifugation in the cold at $110{,}000 \times g$ for 60 min.

Diphenylhexatriene labeling of microsomes and steady-state fluorescence anisotropy determinations. The $110{,}000 \times g$ microsomal pellet from either control or calcium-deficient diets was washed according to the method of Glaumann *et al.* (47) with minor modifications (48). Fluorescence anisotropy was determined in these washed microsomal suspensions, as previously described (49). All measurements were performed at 37°C in an Aminco-Bowman spectrofluorometer equipped with two glan prism polarizers. Both methodology and calculations were described in a previous paper (48).

Other analytical determinations and statistical treatment of the data. The fatty acid composition of lipids from microsomal suspensions was determined as described previously (48). Total lipids were extracted from microsomes according to the procedure of Folch *et al.* (50), and determined gravimetrically after evaporating aliquots to constant weight (48). The cholesterol content was measured by the method of Allain *et al.* (51). Phospholipid and neutral lipid fractions were isolated from the total lipid extract by silicic acid microchromatography (Bio-Rad Lab., Richmond, CA) according to the method of Hanakan *et al.* (52). Phosphorus analysis was performed following the method of Chen *et al.* (53). Protein content was determined by the micromethod of Lowry *et al.* (54) with crystalline bovine albumin as standard. Samples for gas–liquid chromatography analysis were transesterified as previously described (48), and they were analyzed in a Hewlett-Packard 5840-A gas–liquid chromatography apparatus (Avondale, PA) equipped with a 5840-A terminal computer integrator system and with a 6-ft glass column packed with 10% SP-2330 on a 100–200 mesh Chromosorb WAW-DMCS (Supelco Inc., Bellefonte, PA). Eicosa-11-monoenoic acid (1 μg/tube) was used as an internal standard.

All values represented the mean of 3 to 6 individual determinations (assayed in triplicate) ± 1 standard error of the mean (SEM). In order to test the statistical significance of numerical differences in results, data were analyzed by either the Student's *t*-test or by ANOVA (analysis of variance), with the aid of the GB-STAT Professional Statistics Program (version 4.0) from Dynamic Microsystems, Inc. (Silver Springs, MD). Data were plotted using Sigma Plot Scientific Graphing Software (version 2.0) from Sigma Chem. Co., (St. Louis, MO).

RESULTS

In the present experiments, the ACS activity was studied in liver microsomal suspensions from both normal and calcium-deprived rats. At weaning, CD animals were fed on a diet whose calcium content was 10-fold lower than that recommended for animal breeding (42). During the feeding experimental period, calcium levels in the serum of the CD-group progressively decreased up to 1.8 times lower than those of the S-group (1.44 ± 0.10 vs. 2.60 ± 0.10 mmol/L, respectively). Using this kind of microsomal suspension, we optimized the assay design with respect to protein concentration and incubation time. Previous studies with ACS from rat liver microsomes had shown that the interpretation of experimen-

TABLE 2
ACS Activity for Palmitic Acid from Control (S) or Calcium-Deficient (CD) Rat Liver Microsomes[a]

Microsomes	Specific activity (nmol/min·mg)
S	150.1 ± 3.1
CD	261.4 ± 4.0*

[a]Results were obtained as described in the Materials and Methods section and they are given as nmoles of product formed per min per mg of microsomal protein. Each value represents the mean ± 1 SEM of six animals assayed in triplicate.
*Significantly different from S-group, $P < 0.001$.

tal results could become complicated by a high ratio of endogenous fatty acid to enzyme protein, or to an excessively lengthy incubation period (55). Thus, following the procedure of Tanaka *et al.* (2), we verified that the enzyme activity with palmitic acid as substrate (1.0 mM concentration) was completely linear as a function of a microsomal protein up to 0.40 mg/tube or 2 mg/mL (constant incubation time 10 min), and to time for up to 15 min (constant protein concentration of 0.50 mg/mL). Under the experimental conditions stated in the Materials and Methods section, the activity of nonspecific ACS was measured at initial velocity conditions using palmitic acid as substrate. Therefore, the resulting rate of formation of the product was directly proportional to the enzyme activity. As indicated in Table 2, the activity of nonspecific ACS increased *ca.* 75% over control values in animals fed on the calcium-deficient diet.

Then we examined the effect of the calcium-deficient diet on the apparent kinetic parameters by determining the values of Vm and Km for palmitic acid through double reciprocal plots according to the method of Lineweaver and Burk (56). Figure 1 shows that the apparent Vm for the calcium-deficient control or calcium-deficient microsomes, evoked by the presence of varying amounts of different fatty acids, labeled palmitate was used as substrate—at a saturated concentration of 1 mM—while another fatty acid was simultaneously added as an alternative substrate within the range 0.05 to 0.40 mM. The results obtained are illustrated in Figure 2A for control microsomes and Figure 2B for calcium-deficient ones. In control microsomes, the sole saturated fatty acid tested as alternative substrate (stearic acid) evidenced a weak inhibitory effect only at concentrations greater than 0.3 mM. Unsaturated fatty acids derived from linoleate or α-linolenate showed a greater inhibition capacity of nonspecific ACS activity than that observed for fatty acids of the n-9 family. In calcium-deficient microsomes the pattern of the inhibitory effects displayed by the tested fatty acids was less noticeable than that observed in control microsomes. Moreover, in the case of the

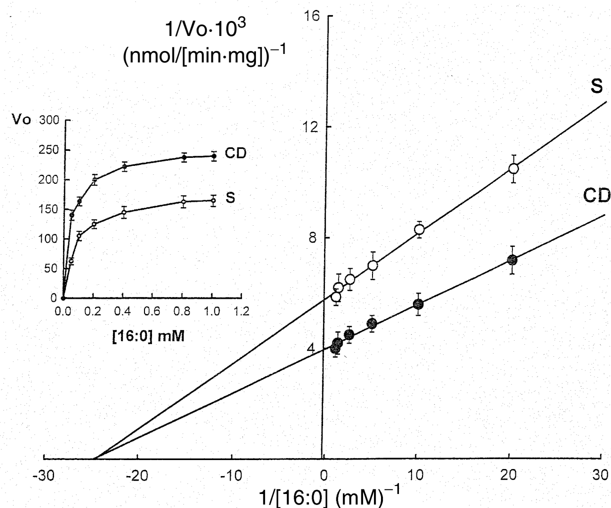

FIG. 1. Linear regressions for the Lineweaver-Burk plots of acyl-coenzyme A-synthetase ACS activity for palmitic acid from control or calcium-deficient rat liver microsomes. Enzyme activity was assayed as described in the Materials and Methods section. Typical Michaelis-Menten plots are shown in the insert. Each point represents the mean ± 1 standard error of the mean (SEM) of three different incubations assayed in triplicate.

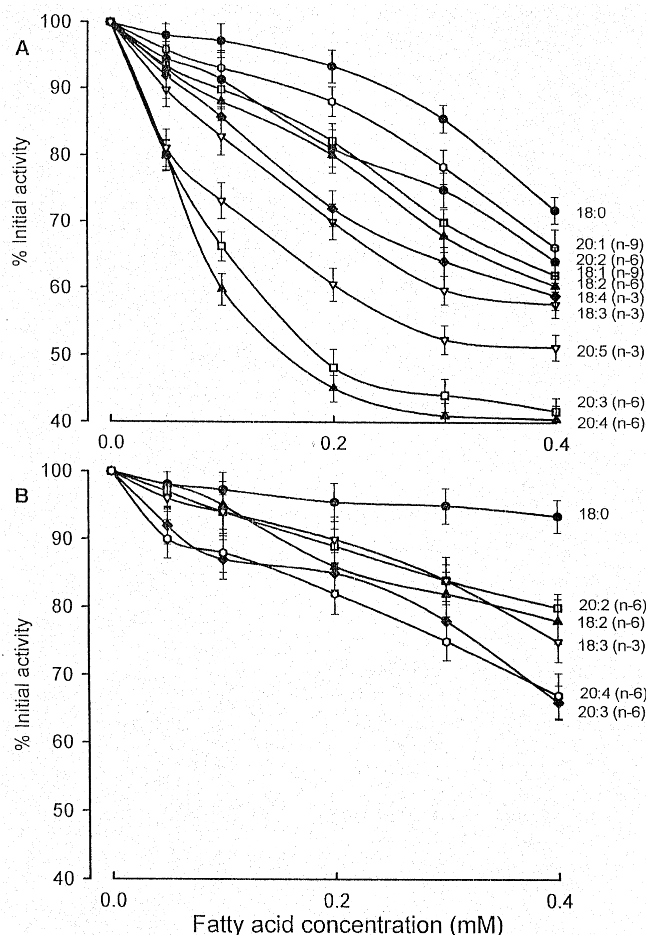

FIG. 2. Inhibition of nonspecific ACS activity for palmitic acid from control (A) or calcium-deficient (B) microsomes in the presence of various fatty acids. The enzyme was assayed as described in the Materials and Methods section. The reaction mixture contained saturated amounts of labeled palmitic acid as the main substrate and varying amounts of unlabeled inhibitor fatty acids at the concentrations indicated. Basal activity was 143.5 ± 4.0 and 271.1 ± 4.4 nmol·min^{-1}(mg protein)$^{-1}$ in control and calcium-deficient microsomes, respectively. Each point represents the mean ± 1 SEM of three different incubations using microsomes from three animals. For abbreviations, see Figure 1.

saturated fatty acid (stearic), there was no inhibitory effect within the range of concentrations assayed. In spite of the quantitative differences observed, the relative capacity shown by the alternative substrates to reduce palmitate activation was the same in both types of microsomal preparations.

In order to further investigate the type of inhibition provoked by the alternative substrates and the calcium-induced modifications in the lipid composition of the endoplasmic reticulum membranes, we carried out a series of experiments using palmitic acid as substrate with stearic, α-linolenic, and arachidonic acids, as weak, medium, or strong inhibitors, respectively, of the nonspecific ACS activity. In these incubations, for each concentration of palmitic acid studied (0.05 to 1.00 mM), various concentrations of inhibitors were tested (stearic acid: 0 to 0.36 mM or 0 to 0.40 mM in either control or calcium-deficient microsomes; α-linolenic acid: 0 to 0.12 mM or 0 to 0.20 mM; and arachidonic acid: 0 to 0.08 mM or 0 to 0.20 mM). In all instances initial velocities were measured and plotted according to the method of Lineweaver and Burk (56) (Figs. 3 and 4 for control or calcium-deficient microsomes, respectively). The analysis of the double reciprocal plots shown in Figure 3 indicates that the stearic acid displayed a competitive behavior only at relatively high fatty acid concentrations, whereas α-linolenic and arachidonic acids evidenced a mixed-type inhibition consisting of uncompetitive and competitive components (57). In calcium-deficient microsomes (Fig. 4) the stearic acid was not effective as a competitive inhibitor even at higher concentrations tested. Although α-linolenic and arachidonic acids showed a mixed-type inhibition pattern, the extent of their effects was significantly lower than that observed in control preparations. To estimate quantitatively the magnitude of these inhibitory effects on nonspecific ACS activity, data from Figures 3 and 4 were re-plotted as the inverse of the initial velocities vs. inhibitor concentrations (Dixon plots). Dixon plots are frequently used to identify the type of inhibition and to determine Ki values. The velocity equation for competitive inhibition may be converted into a linear form in which the varied ligand is [i]. The straight lines obtained at different substrate concentrations have positive slopes. Drawing a horizontal line at a height of 1/Vm, these lines can be intercepted at the −[i] value representing the kinetic parameter "αKi". This parameter considers the noncompetitive component of a linear-mixed-type inhibition (57). Figures 5 and 6 show the results obtained for control or calcium-deficient microsomes, respectively. The slopes of these plots are given by Km/−[S].Vm.Ki. Since Km [S] and Vm are constants, the slope is inversely proportional to Ki. Comparing the plots obtained for both types of microsomal preparations, relative Ki and αKi values were obtained. These data were consistent with the apparent kinetic parameters obtained from the Lineweaver-Burk plots shown in Figures 3 and 4. All these kinetic data are summarized in Table 3. These results clearly indicate that the calcium-deficient diet produced a significant decrease in the inhibitory effects presented by all the tested fatty acids. In the case of the stearic acid, Vm was increased *ca.* 80% over control values, while

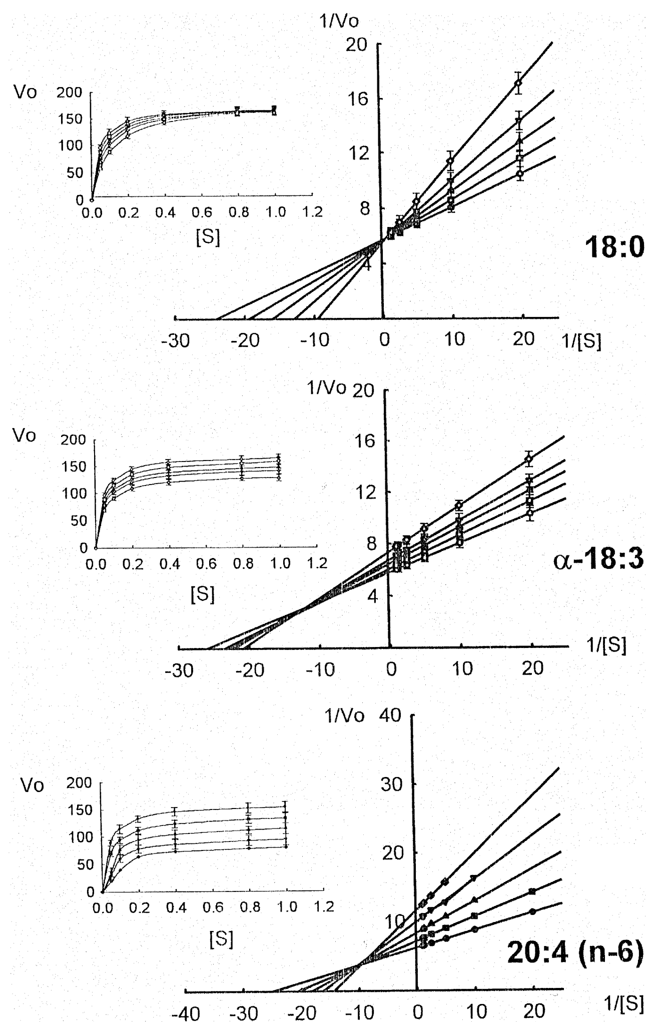

FIG. 3. Linear regressions for Lineweaver-Burk plots of ACS activity for palmitic acid from control microsomes in the presence of various concentrations of inhibitory fatty acids. The enzyme was assayed as described in the Materials and Methods section. The reaction mixture contained saturated amounts of labeled palmitic acid and varying amounts of the unlabeled inhibitory fatty acid as indicated. Typical Michaelis-Menten plots are given in the inserts. 1/Vo was expressed as $[\text{nmol}/(\text{min}\cdot\text{mg})]^{-1}\cdot 10^3$ and 1/[S] was given as $(\text{mM})^{-1}$. Each point represents the mean ± 1 SEM of six different incubations assayed in duplicate. For abbreviations, see Figure 1.

its competitive effect disappeared at the concentrations assayed. The increase in Vm values observed with hepatic microsomes of the CD-group, even in the presence of the α-linolenic or arachidonic acids as inhibitors, was produced through a decrease in the competitive component. Although this finding was markedly evident in the case of arachidonic acid, Ca deficiency significantly raised both Ki and αKi in all the studied fatty acids.

We also studied the linear regressions for Lineweaver-Burk plots of nonspecific ACS activity using either palmitic or stearic acid as substrate (Fig. 7). It was observed that the Km value for stearic acid (a pure competitive inhibitor) increased in calcium-deficient microsomes, compared to controls, while Km for palmitic acid remained unchanged in both

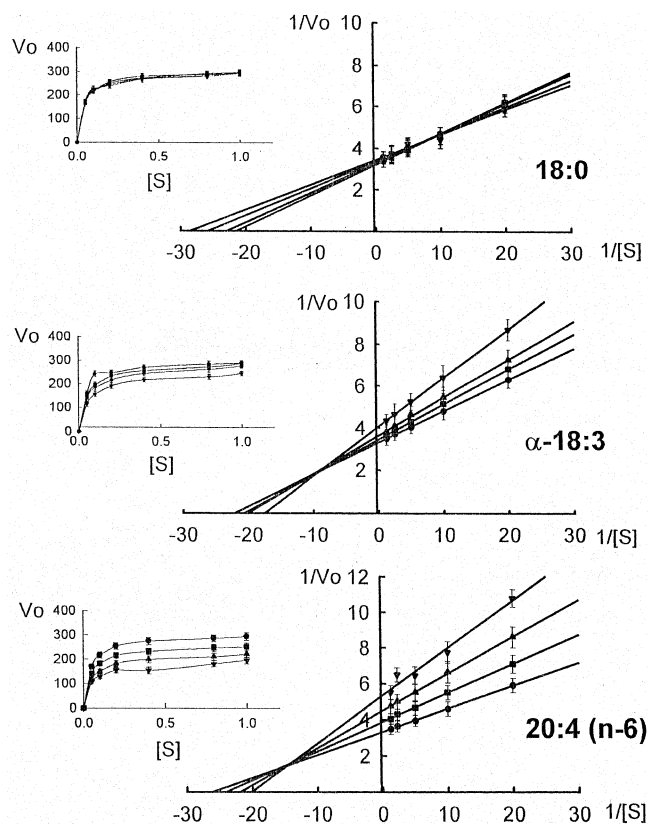

FIG. 4. Linear regressions for Lineweaver-Burk plots of nonspecific ACS activity for palmitic acid from calcium-deficient microsomes in the presence of various concentrations of inhibitory fatty acids. The enzyme was assayed as described in the Materials and Methods section. The reaction mixture contained saturated amounts of labeled palmitic acid and varying amounts of the unlabeled inhibitory fatty acid as indicated. Typical Michaelis-Menten plots are given in the inserts. 1/Vo was expressed as $[nmol/(min \cdot mg)]^{-1} \cdot 10^3$ and 1/[S] was given as $(mM)^{-1}$. Each point represents the mean ± 1 SEM of six different incubations assayed in duplicate. For abbreviations, see Figure 1.

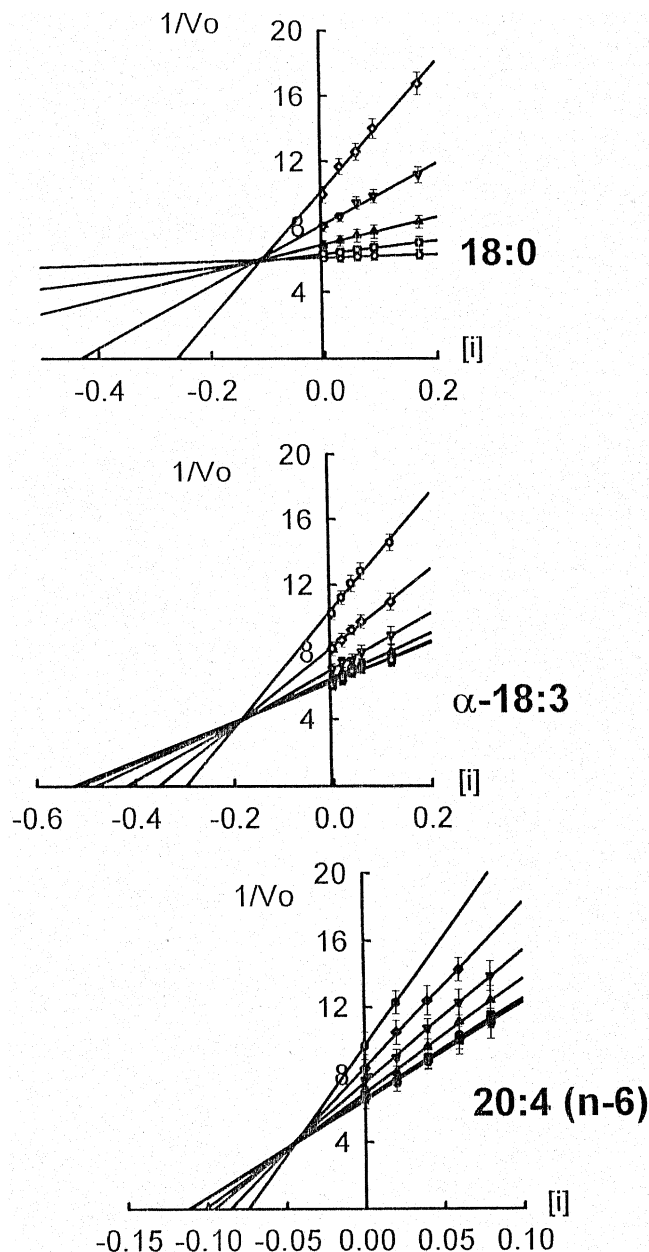

FIG. 5. Linear regressions of Dixon plots from control microsomes. Data were taken from the reciprocal plots shown in Figure 3. 1/Vo was expressed as $[nmol/(min \cdot mg)]^{-1} \cdot 10^3$ and [i] was given as mM. Each point represents the mean ± 1 SEM of six different incubations assayed in duplicate. For abbreviations, see Figure 1.

kinds of microsomes.

Table 4 shows the interlipid relationships and fluorescence anisotropy of liver microsomal membranes from either control or calcium-deficient rats. The results clearly indicate that in fact the lipid bilayer of the endoplasmic reticulum membrane was significantly modified by calcium deficiency. The relative content of lipids was decreased at the time that the neutral lipid was significantly raised. The proportion of cholesterol and phospholipids was diminished by calcium deficiency. On the other hand, Table 5 shows that the fatty acid composition of the different lipid fractions was significantly modified by calcium deprivation. The amounts of saturated fatty acids significantly increase in both triglyceride and phospholipid fractions, while a concomitant decrease was observed in the content of phospholipid polyunsaturated fatty acids. The decrease produced in the unsaturation index suggested that the quality and/or quantity of the fatty acid chains acylated to the lipid structures were substantially modified in the microsomes of the CD-group. These modifications in the physicochemical state of the lipid bilayer, induced by calcium deficiency, could be closely associated with the difference found in the nonspecific ACS activity, and with the altered response of this enzyme to the fatty acid tested as inhibitors. Taking into account these considerations, we investigated the ACS activity deprived of its microenvironment in the biomembrane. The linear regressions for Lineweaver-Burk plots of the solubilized enzyme from control or calcium-deficient microsomes are shown in Figure 8. It is evident that the kinetic behavior exhibited by nonspecific ACS between control and calcium-deficient microsomal preparations was the same after solubilization procedures either with Triton X-100 or

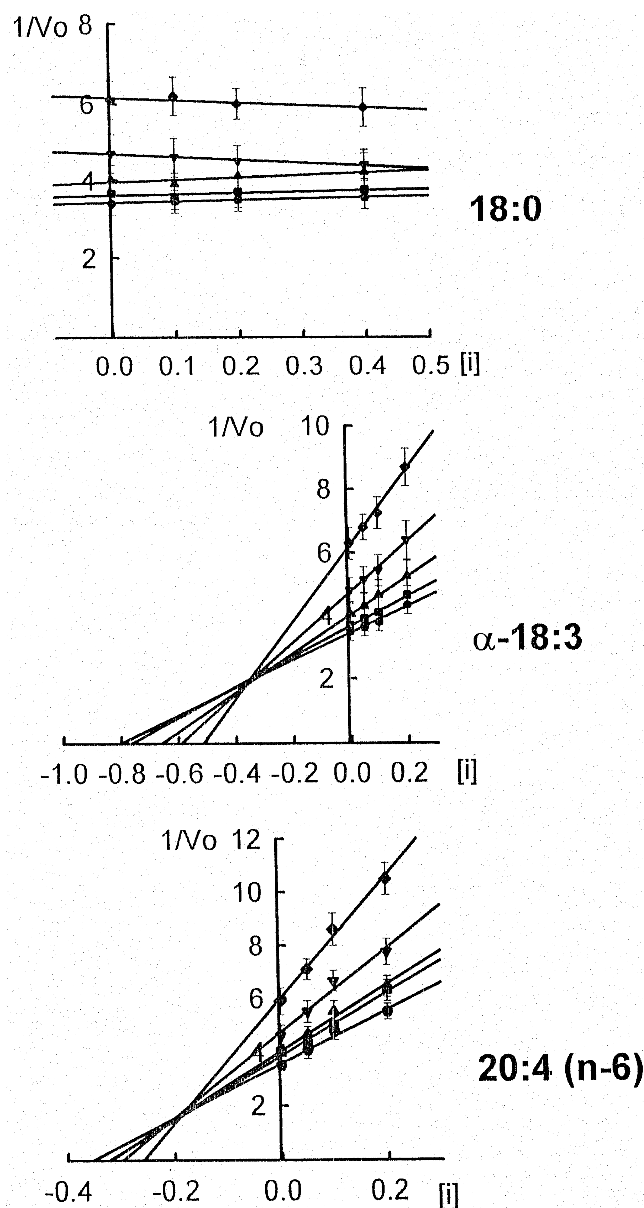

FIG. 6. Linear regressions of Dixon plots from calcium-deficient microsomes. Data were taken from the reciprocal plots shown in Figure 4. 1/Vo was expressed as $[\text{nmol}/(\text{min}\cdot\text{mg})]^{-1}\cdot 10^3$ and [i] was given as mM. Each point represents the mean ± 1 SEM of six different incubations assayed in duplicate. For abbreviations, see Figure 1.

KCl. These apparent kinetic parameters calculated from Figure 8 are summarized in Table 6.

DISCUSSION

An examination of the nonspecific ACS activity in liver microsomal suspensions from both normal and calcium-deprived rats using palmitic acid as substrate revealed that calcium deprivation promotes a significant increase in this enzymatic activity measured at initial velocity conditions. To our knowledge, this is the first experimental evidence of the regulatory effect caused by calcium deprivation on the palmitoyl-CoA synthesis in liver microsomes. Previous studies by other authors clearly indicate that the formation of palmitoyl-CoA causes a significant increase in the release of Ca^{2+} from microsomal vesicles (38–40). Based on these findings, it is reasonable to speculate that in calcium-deficient rats the stimulation observed in the biosynthesis of palmitoyl-CoA would preserve calcium levels within the cells.

From the results shown in Figure 1, we can assume that, under calcium-deficient conditions, the increased Vm resulted from an increment in the specific activity of the enzyme, whereas the substrate affinity remained unchanged. Previous studies from other laboratories showed that ACS seems to be largely dependent on the extent of substrate unsaturation and the carbon chain length (2–5,8,12). On the other hand, studies on the fatty acid composition carried out in platelets (4), lymphocytes (13), rat brain microsomes (5), and plasmodium-infected erythrocytes (12) demonstrated that the activation of palmitic acid is markedly decreased in the presence of unlabeled unsaturated fatty acids.

The interpretation of the competition studies shown in Figures 2–4 is rather difficult because of unknown factors, such as fatty acid solubility, critical micellar concentration of the different fatty acids, and the form in which fatty acids are present in the incubation medium. However, it was shown that in calcium-deficient microsomes the pattern of the inhibitory effects displayed by the tested fatty acids was similar but less noticeable than the one observed in control microsomes (Fig. 2A,B). The highest inhibitory capacity of unsaturated fatty acids provoked in the activation of palmitic acid (especially the polyunsaturated fatty acids of the n-6 or n-3 series), compared with the other fatty acids studied, may be due to their relatively easy accessibility and higher affinity for the membrane-bound enzyme. This explanation was first suggested by Reddy *et al.* (5) to justify the fatty acid specificity of long chain ACS from rat brain microsomes and mitochondria. Thus the minor response obtained for each fatty acid in calcium-deficient microsomes would be the consequence of some alterations in the physical and/or chemical state of these membranes.

The different kinetic behavior induced by calcium deficiency seems to be the consequence of a change in the concentration range at which the inhibitory effects are produced. In this regard, the kinetic pattern in both types of microsomes (Figs. 3 and 4) was similar, having a minor response in the CD-microsomal suspensions despite the highest concentrations of the fatty acids used as inhibitors. Taking into account that the three fatty acids studied exhibited special variations in their inhibition mechanisms, we may presume that there exist at least two binding sites in the nonspecific liver ACS. α-Linolenate, which behaves like arachidonate, would be activated at the same site and would have a better affinity for polyunsaturated species, whereas palmitate and stearate would be activated at the other site. The results summarized in Table 3 would support this hypothesis because of the differential effect on the palmitoyl-CoA synthesis caused by the unsaturated inhibitors, compared to stearic acid. On the other

TABLE 3
Apparent Kinetic Parameters of ACS for Palmitic Acid from Control or Calcium-Deficient Microsomes[a]

	Control			Calcium-deficient			Change (%)		
	18:0	α-18:3	20:4	18:0	α-18:3	20:4	18:0	α-18:3	20:4
Km	41 ±3	39 ±4	43 ±2	39 ±4	43 ±5	37 ±5	−5	10	−14
Vm	176 ±11	170 ±8	163 ±9	306* ±18	308* ±16	312* ±21	74	81	92
Ki	117 ±9	178 ±13	47 ±3	∞*	292* ±17	189* ±11	∞	64	302
αKi	—	537 ±22	113 ±7	—	789* ±53	347* ±29	—	48	207

[a]Apparent kinetic parameters are expressed as mean ± 1 SEM of six different incubations assayed in duplicate using at least five different substrate concentrations and four inhibitor concentrations (see Figures 3 and 4 for control or calcium-deficient diet, respectively). Km, Ki , and αKi are given in μM concentrations. Vm was expressed as nmoles/min.mg.protein. The inhibition constants (Ki for the competitive and αKi for the noncompetitive component) of the linear-mixed-type inhibition were calculated as described in the text. Percent changes were calculated with respect to the corresponding value of the control group. —, no inhibition observed; ∞, too high to be calculated; *significantly different with respect to control ($P < 0.01$).

hand, if saturated fatty acids had been activated at the same molecular site, the Km value of stearic acid as substrate would have had a value similar to its Ki in inhibiting the activation of palmitate. As shown in Figure 7, the Km for stearic acid, a pure competitive inhibitor, was 52.0 ± 4.1 and 101.3 ± 6.5 μM for control and CD-microsomes, respectively, whereas the Km for palmitic acid in both kinds of microsomes remained unchanged (41.6 ± 3.3 vs. 40.9 ± 4.1 μM). This finding indicates that, under calcium-deficient conditions, the affinity for stearic acid significantly declines; consequently, this acid works as a bad competitor for other substrates. It is worth noticing that the abnormal changes introduced by calcium deficiency only imply a significant increase in the Vm for palmitic acid, with no substantial modifications in Km values. On the contrary, in the case of stearic acid, Vm modification was less important than that observed in Km val-

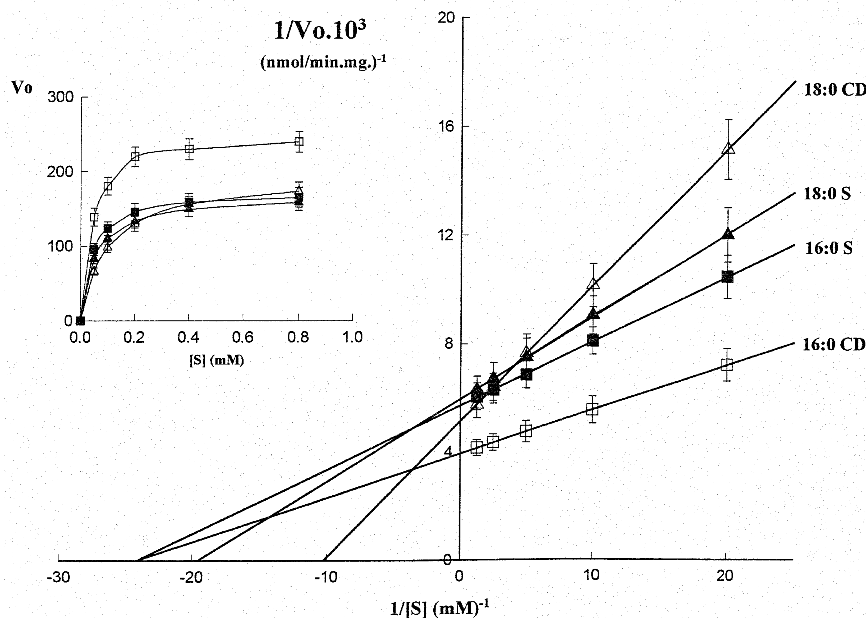

FIG. 7. Linear regressions for Lineweaver-Burk plots of ACS activity using palmitic acid (squares) or stearic acid (triangles) as substrates, from control (S) (solid symbols) or calcium-deficient (CD) (open symbols) microsomes. Enzyme activities were assayed as described in the Materials and Methods section. Typical Michaelis-Menten plots are shown in the insert. Each point represents the mean ± 1 SEM of three different incubations assayed in triplicate. For abbreviations, see Figure 1.

TABLE 4
Interlipid Relationships and Fluorescence Anisotropy of Liver Microsomal Membranes from Control or Calcium-Deficient Rats[a]

	Control	Calcium-deficient	*n*	*P* <
Cholesterol/phospholipid (μmol/μmol)	0.31 ± 0.02	0.23 ± 0.01	3	0.02
Total lipid/phospholipid (mg/μmol)	0.79 ± 0.03	0.98 ± 0.04	3	0.02
Total lipid/cholesterol (mg/μmol)	2.48 ± 0.02	3.00 ± 0.03	4	0.001
Phospholipid/protein (μmol/mg)	0.45 ± 0.03	0.30 ± 0.01	3	0.01
Neutral lipid/protein (μg/μg)	0.06 ± 0.003	0.11 ± 0.01	3	0.01
Neutral lipid/polar lipid (μg/μg)	0.13 ± 0.01	0.36 ± 0.02	5	0.01
Fluorescence anisotropy (r_s)	0.1405 ± 0.0010	0.1112 ± 0.0008	6	0.01
Unsaturation index	3.80 ± 0.05	2.90 ± 0.1	4	0.001

[a]Results were expressed as the mean ± 1 SEM of the experiments indicated as "*n*". For details see the Materials and Methods section. Unsaturation index was calculated as the total double bonds in total unsaturated fatty acids/mol saturated fatty acids. *P* <, indicates the value at which calcium-deficient results are significantly different from the respective control value.

ues (Fig. 7). Whether changes in affinity and/or in the number of active enzyme molecules are the consequence or the cause of calcium-induced alterations in the lipid bilayer awaits further clarification.

Previous studies have demonstrated that the lipid domain fluidity is determined by the cholesterol/phospholipid molar ratio, lipid/protein ratio, and degree of unsaturation of lipid acyl chains (58,59). Such changes were reflected in our experimental system through a modification in the diphenylhexatriene steady-state fluorescence anisotropy (r_s) (Table 4), as detected by an increase in the rotational mobility of the probe within the membrane lipid phase when compared to those values observed in the microsomal membranes from control animals. As previously reported, this parameter depends on the overall membrane lipid mobility (60) and earlier studies with diphenylhexatriene have demonstrated that this probe is a useful tool to estimate membrane fluidity (61). Storch and Schachter (62) reported that an increase in calcium ion evokes a decrease in lipid fluidity of isolated rat hepatocyte plasma membranes by the activation of phospholipase A_2, demonstrating that the cation decreased the arachidonic acid content and the overall double bond index of membrane lipids. The effect of calcium deficiency on the physicochemical state of the microsomal membrane has not been shown until now, and further investigation on the precise role of this ion seems to be needed.

Previous studies carried out with long-chain ACS from rat liver microsomes showed that Triton X-100 enhanced fourfold the Vm value without affecting Km (5). Taking this fact into account, it seemed vital to investigate the ACS activity deprived of its microenvironment in the biomembrane.

Our results demonstrated that the enzyme preparation obtained after a solubilization with Triton X-100 exhibited a similar specific activity as compared with the one shown by a fraction solubilized with KCl. In accordance with data previously reported by other authors (45,63), the results presented

[a]Results are expressed as the mean ± 1 SEM from six animals assayed in duplicate. Asterisks indicate significantly different (*P* < 0.01) with respect to the corresponding control value. GLC analyses were performed as described in the Material and Methods section. Only relevant fatty acids were included.

TABLE 6
Apparent Kinetic Parameters of Solubilized ACS Activity for Palmitic Acid, from Control (S) or Calcium-Deficient (CD) Microsomes[a]

	Treatment			
	KCl		Triton X-100	
	S	CD	S	CD
Km (μM)	42.6 ± 4.1	39.2 ± 5.2	56.8 ± 4.3	60.4 ± 5.5
Vm (nmol/min·mg)	177.1 ± 8.7	176.9 ± 6.6	167.3 ± 9.8	158.6 ± 5.5

[a]Results were obtained from the linear regressions shown in Figure 8. Data are given as the mean ± 1 SEM of four different incubations assayed in triplicate.

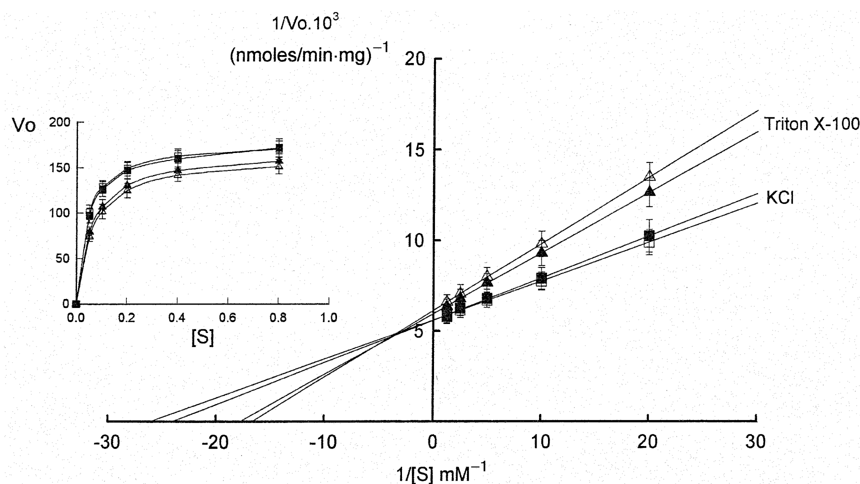

FIG. 8. Linear regressions for Lineweaver-Burk plots of solubilized ACS activity for palmitic acid, from control (open symbols) or calcium-deficient (solid symbols) microsomes. Both types of microsomes were treated with Triton X-100 (triangles) or a buffer with KCl (squares). After partial purification, the activity was assayed as described in the Materials and Methods section. Michaelis-Menten plots are shown in the insert. Each point represents the mean ± 1 SEM of four different incubations assayed in triplicate. For abbreviations, see Figure 1.

in this paper also show that residual amounts of Triton X-100 have no significant effect on the palmitoyl-CoA synthetase activity, but they promote an increase in Km values without affecting Vm (Table 5).

Considering that membrane enzymes such as ACS interact with surrounding lipids and proteins in the membrane, it is conceivable that the configuration of the molecule would be altered if its microenvironment changed. It is important to remark that the different behavior exhibited by ACS between S- and CD-microsomal preparations was eliminated after solubilization procedures. From the results shown in Figure 8 and Table 5, we may assume that both modifications in the specific activity of the enzyme and the differential response observed in competition experiments were the consequence of the alterations in the reticulum membranes induced by the calcium-deficient diet.

In conclusion, this work shows experimental evidence of the role of calcium ions in relation to fatty acid activation. These studies would indicate an alteration in the physicochemical state of the lipid bilayer, evoked by calcium deficiency, that indirectly modifies the kinetic properties of the enzyme. The results presented here would be of interest when examining the intracellular regulation of acyl-CoA synthesis, from the lipid metabolism as well as cell biology and physiology points of view.

The Inhibitory Guanine Nucleotide-Binding Protein $G_{i2}\alpha$ Induces and Potentiates Adipocyte Differentiation

Kjerstin E. Høvik*, Pengfei Wu[1], and Jan O. Gordeladze

Institute of Medical Biochemistry, University of Oslo, Oslo, Norway

ABSTRACT: The present study further elucidates the involvement of the α-subunit of the GTP-binding protein G_{i2} in the differentiation of murine 3T3-L1 cells. Control and vector-transfected cells attained a fully differentiated adipocyte phenotype showing ample lipid droplets. Cells expressing wild type (WT)-$G_{i2}\alpha$ or the constitutively active R179E-$G_{i2}\alpha$, however, became enlarged, less confluent, and produced large amounts of lipids. Differentiation consistently increased the triglyceride (TAG) content in control cells. In both WT-$G_{i2}\alpha$ and R179E-$G_{i2}\alpha$ clones, a marked increase in TAG could be detected even prior to insulin/dexamethasone/isobutyl methylxanthine exposure. The activity of palmitoyl-CoA synthetase (PCS) and glycerophosphate acyltransferase (GPAT) also increased upon differentiation. WT-$G_{i2}\alpha$ and R179E-$G_{i2}\alpha$ overexpression also enhanced PCS and GPAT activities even before differentiation medium was added. The total amount of phospholipids (PL) generally increased upon differentiation; however, pre- and postdifferentiation values were insignificantly different in cells expressing WT-$G_{i2}\alpha$ and R179E-$G_{i2}\alpha$. Differentiation altered the PL profile with a relative shift from phosphatidylcholine and phosphatidylethanolamine to phosphatidylinositol (PI) in differentiated cells. Finally, differentiation yielded a general increase in the activity of basal PI-phospholipase-C activity. Again, cells expressing WT-$G_{i2}\alpha$ and R179E-$G_{i2}\alpha$ demonstrated elevated enzyme activity and enhanced second messenger accumulation subsequent to differentiation. In summary, cells with the R179E-mutants of $G_{i2}\alpha$ exhibited stimulated lipid turnover and accumulation in both undifferentiated and differentiated cells.

Paper no. L8014 in *Lipids 34,* 355–362 (April 1999).

The G-proteins (guanine nucleotide-binding proteins) were discovered in 1971 (1). Since then, more than 20 α-subunits have been described (2,3), which constitute four distinct classes or families (i.e., G_s, G_i, G_q, and G_{12}). The G-proteins, which are more or less ubiquitous (3), are able to communicate with each other (4,5), and there is also extensive cross-talk between G-protein-mediated and several other signaling systems (5,6). Malfunctions of G-proteins may result in altered communication within cells, leading to aberrations in hormonal signalling (6,7). In turn, endocrine diseases like acromegaly may result (8). Therefore, naturally occurring mutations in G-proteins have been sought and discovered in different endocrine tumors and osteosarcoma cells (9,10). This has led to speculations about G-proteins as possible proto-oncogenes, implicating them as discriminant factors in both cellular growth and differentiation (11,12).

Murine 3T3-L1 cells are preadipocytes that differentiate to mature adipocytes (13,14) after 5 to 7 d of treatment with insulin, dexamethasone, and the phosphodiesterase inhibitor isobutyl methylxanthine. G_{i2} of the G_i-subspecies has previously been implicated in the modulation of DNA-synthesis and transcription rates (15,16), and has also been shown to couple to the insulin-like growth factor (IGF) type-II receptor (17). We recently transfected 3T3-L1 cells with the stimulatory R179E- and Q205L-$G_{i2}\alpha$ [constitutively activated (GTPase deficient) $G_{i2}\alpha$ mutant] constructs, which reduced the rate of DNA-synthesis prior to cell confluence (16). These missense mutations strongly affected the differentiation process measured by increased hormone-sensitive lipase mRNA, increased isoprenalin- and corticotropin-elicited adenylate cyclase activity, and elevated 2-deoxy glucose uptake (16).

The goal of the present work is to elucidate to what extent $G_{i2}\alpha$ influences deposition of triglycerides (TAG), fat-metabolizing enzymes, and phospholipid (PL) content and turnover as markers of the differentiation process.

Abbreviations: DAG, diacylglycerol; G204A-$G_{i2}\alpha$, constitutively inactivated (receptor dissociated) $G_{i2}\alpha$ mutant; GPAT, glycerophosphate acyltransferase; GPDH, glycerophosphate dehydrogenase; IGF, insulin-like growth factor; IP_3, 1,4,5-inositol trisphosphate; MAPK, mitogen-activating protein kinase; PBS, phosphate-buffered saline; PCS, palmitoyl-CoA synthetase; PI, phosphatidylinositol; PIP_2, phosphatidylinositol 4,5-bisphosphate; PI-PLC, phosphatidylinositol phospholipase-C; PKC, protein kinase C; PL, phospholipid; pZipNeo, pZipNeo(SX)V (retroviral vector); R179E- and Q205L-$G_{i2}\alpha$, constitutively activated (GTPase deficient) $G_{i2}\alpha$ mutant; TAG, triglyceride; WT, wild type.

MATERIALS AND METHODS

Site-directed $G_{i2}\alpha$ mutations and construction of expression vectors. The insert of plasmid DJG18, encoding a rat α_{i2} cDNA (provided by Reed, R., Johns Hopkins University, Baltimore, MD) was subcloned into M13mp19, and site-directed mutagenesis was performed by a modification of the method of Nakamaye and Eckstein (18). The mutagenic oligonucleotide had the following sequences: R179E-α_{i2}, 5′-GC-

Copyright © 1999 by AOCS Press

CTGTGGTCTTCACTTCGGTC-CGCAGCACATC-3′, and G204A-α_{i2}, 5′-CCGCTCAGATCGCTGGGCGCCCACAT-CAAACAT-3. Mutations were confirmed by dideoxy sequencing. Wild type (WT) and mutant α_{i2} cDNA were ligated into the EcoRI site of a shuttle vector pSP72NotI and then into the NotI site of a modified retroviral vector, pZipNeoSV(X) (19). In the latter constructs, the transcription of α_{i2} cDNA and the G418-resistance gene is directed by the Moloney murine leukemia virus long terminal repeat.

Transfection and clone selection. Cell lines were transfected with 1.0 µg of linearized DNA per 10-cm plate by calcium phosphate precipitation. Twenty-four hours after transfection, cells were grown in selective medium containing G418 (0.60 mg/mL) for at least 3 wk. G418-resistant clones were selected by serial dilution. Ten clones were selected for each construct, and the studies described here were performed with one of the three clones demonstrating the highest level of $G_{i2}\alpha$ expression.

Cell culture. 3T3-L1 cells were grown in monolayer cultures in petri dishes 6 cm in diameter, obtained from Costar (Cambridge, United Kingdom). Dulbecco's modified Eagle medium (DMEM) with high glucose, purchased from GibcoBRL (Grand Island, NY), was used as growth medium. To this medium were added 10% fetal calf serum, penicillin-streptomycin (50 µg/mL), fungizone (2.5 µg/mL), and anti-pleuropneumonia-like organisms agent (10 µg/mL) from GibcoBRL. The cells were grown in a humidified atmosphere of 5% CO_2 and 95% air at 37°C. Medium was changed three times a week. Differentiation was accomplished with insulin (10 µg/mL), dexamethasone (10 nM), and isobutyl methylxanthine (0.5 mM) present in the growth medium for 7 d after cell confluence. The hormones were obtained from Sigma Chemical Company (St. Louis, MO). Growth medium was changed every 24 h for the last 3 d before the cells were fully differentiated. Cells were prewashed with 2 × 1.0 mL phosphate-buffered saline (PBS), pH 7.4, and then finally harvested in 2.0 mL PBS.

Measurement of DNA content. The DNA content was measured by the method of Labarca and Paigen (20).

Analysis of protein level. The protein amount was measured by the method of Lowry *et al.* (21) using bovine serum albumin (BSA) as a standard.

Determination of TAG. For the determination of TAG amounts, a commercial kit delivered by Boehringer (Mannheim, Germany), was used. The assay is based on spectrophotometric end point glycerol measurements subsequent to hydrolysis.

Assay of palmitoyl-CoA synthetase (PCS). The enzyme velocity was assayed as described by Krisans *et al.* (22). Washed cells were homogenized using an Ultra-Turrax for 10 s and centrifuged for 30 min at 27,000 × *g*. The supernatant was discarded. The reaction was started by the addition of crude, resuspended membrane protein (20–50 µg) to ice-cold incubation mixture. The mixture had a final volume of 400 µL and consisted of 150 mM Tris-HCl, pH 7.4, 6.2 mM $MgCl_2$, 0.5 mg/mL Triton X-100, 2 mM ATP, 600 mM CoA, 1 mM dithiothreitol, and 100 µM [1-^{14}C]-palmitic acid ($5 \cdot 10^4$ dpm). After 6.5 min incubation at 37°C, the reaction was terminated by addition of 3.0 mL of methanol/chloroform/heptane (1.4:1.25:1.0) and 1.0 mL of 0.1 M sodium acetate, pH 4. After vortexing and centrifugation for 5 min at 270 × *g* at room temperature, 1.0 mL of the aqueous phase was mixed with 10 mL of scintillation fluid, and radioactivity was determined by counting in a Packard counter for 5 min.

Assay of glycerophosphate acyltransferase (GPAT). The enzyme activity was essentially assayed as described by Sooranna and Saggerson (23). Crude membrane protein was prepared as indicated above. Crude membrane protein (0.5 mg) was incubated in a total volume of 1.0 mL for 7.5 min at 30°C. The incubation mixture contained 0.1 M Tris-HCl, pH 7.4, 0.7 mM L-[U-^{14}C]-glycerol 3-phosphate (0.06 mCi/mmol), 2 mM $MgCl_2$, 2 mM KCN, 0.7 mM dithiothreitol, bovine serum albumin (1.2%, wt/vol) and 70 µM palmitoyl-CoA. The reaction was stopped by the addition of 4.0 mL of 6% $HClO_4$. After vortexing and centrifugation at 12,100 × *g* for 10 min, the supernatant was decanted. The walls of the incubation tubes were wiped with tissue paper before the pellet was redissolved in 1.6 mL distilled water and shaken for 1 h. Butanol (1.0 mL) was added, followed by vortexing, the addition of 4.0 mL $HClO_4$, and repeated vortexing. After centrifugation for 5 min at 480 × *g*, 0.5 mL of the supernatant butanol layer was mixed with 10 mL scintillation fluid and radioactivity determined in a Packard counter.

Measurement of PL. The growth medium was removed from the cell culture dishes after 7 d of treatment subsequent to confluency. Growth medium containing 10 µCi/mL of [^{32}P]-labeled phosphate was added to the dishes and the cells were incubated for 2 h. Finally, the medium was removed, and the cells were washed twice with PBS, pH 7.4. Then the cells were harvested in 1.0 mL PBS, the lipids were extracted using the procedure of Folch *et al.* (24), and the organic layer was dried under a stream of N_2. The lipid residues were dissolved in 100 µL of chloroform and applied to thin-layer chromatography plates delivered by Merck (Darmstadt, Germany). The plates were chromatographed for 2 h in a tank containing 65 mL methanol, 35 mL chloroform, 5.0 mL 40% methylamine, and 5.0 mL distilled water (25). The radiolabeled PL were visualized by autoradiography. Autoradiographic film was delivered by Amersham International (Buckinghamshire, United Kingdom). The spots representing the different PL were scraped, 4.5 mL of Insta-Gel II was added, and the vials were counted in a Packard scintillation counter for 5 min.

Assay of diacylglycerol (DAG). The assay was performed using a commercial kit (RPN200) furnished by Amersham, and designed to analyze tissue and cellular levels of DAG. The assay procedure is based on a radioenzymatic assay, employing the enzyme DAG kinase which quantitatively converts DAG to phosphatidic acid in the presence of [^{32}P]-γ-ATP.

Phosphatidylinositol phospholipase C (PI-PLC) assay. This method was adapted from Jackowski *et al.* (26).

Aliquots (30 μL) of diluted crude membrane suspensions (35 μg protein) in 10 mM Tris-HCl, pH 7.4, 1 mM EDTA, were mixed with 10 μL incubation mixture (100 mM Tris-HCl, pH 6.5, 400 μM GTP, 2.2 mM $CaCl_2$, 1.0 mM $MgCl_2$ in 2.4-mL microfuge tubes on ice. Three microliters (42,000 cpm) of a $[^3H]$phosphatidylinositol 4,5-bisphosphate (PIP_2) (New England Nuclear, Boston, MA) stock solution in 2% sodium cholate was added to each tube, and incubations were carried out at 35°C for 5 min. The reaction was stopped by adding in succession 150 μL $CHCl_3/CH_3OH/HCl$ (1:2:0.02), 50 μL $CHCl_3$, and 50 μL 2 M KCl. After vortexing and phase separation at 5000 × *g* in a microfuge, 100-μL aliquots of the aqueous layers were counted in a Packard liquid scintillation counter. In the assay blanks, some 2% of the radioactivity was retained in the aqueous phase.

RESULTS

The gross appearance of the 3T3-L1 cells changed markedly subsequent to differentiation (Fig. 1). Cells, transfected with the retroviral vector pZipNeoSV(X), attained the characteristics of fully mature adipocytes upon differentiation. However, the WT-$G_{i2}\alpha$ and the activating mutant R179E-$G_{i2}\alpha$ cell clones became larger upon transfection and accumulated much larger lipid droplets subsequent to differentiation. The inactivating mutant G204A-$G_{i2}\alpha$ did not affect the 3T3-L1 preadipocytes significantly (not shown).

Consistent with the profile of lipid droplet deposition seen in the light microscope, differentiation increased the TAG contents in control and vector-transfected cells as well as in cells expressing WT-$G_{i2}\alpha$ and R179E-$G_{i2}\alpha$. However, the differentiation medium did not enhance ($P > 0.05$) TAG contents in G204A-$G_{i2}\alpha$ transfected cells (Fig. 2). Characteristically, a distinct elevation of TAG content could be detected in WT-$G_{i2}\alpha$- and R179E-$G_{i2}\alpha$-expressing clones even before differentiation ($P < 0.05$).

To further elucidate the impact of $G_{i2}\alpha$ on TAG accumulation, the two lipid-synthesizing enzymes PCS (Fig. 3A) and GPAT (Fig. 3B) were studied. The activity of each enzyme exhibited the same pattern as the TAG deposition profile. The

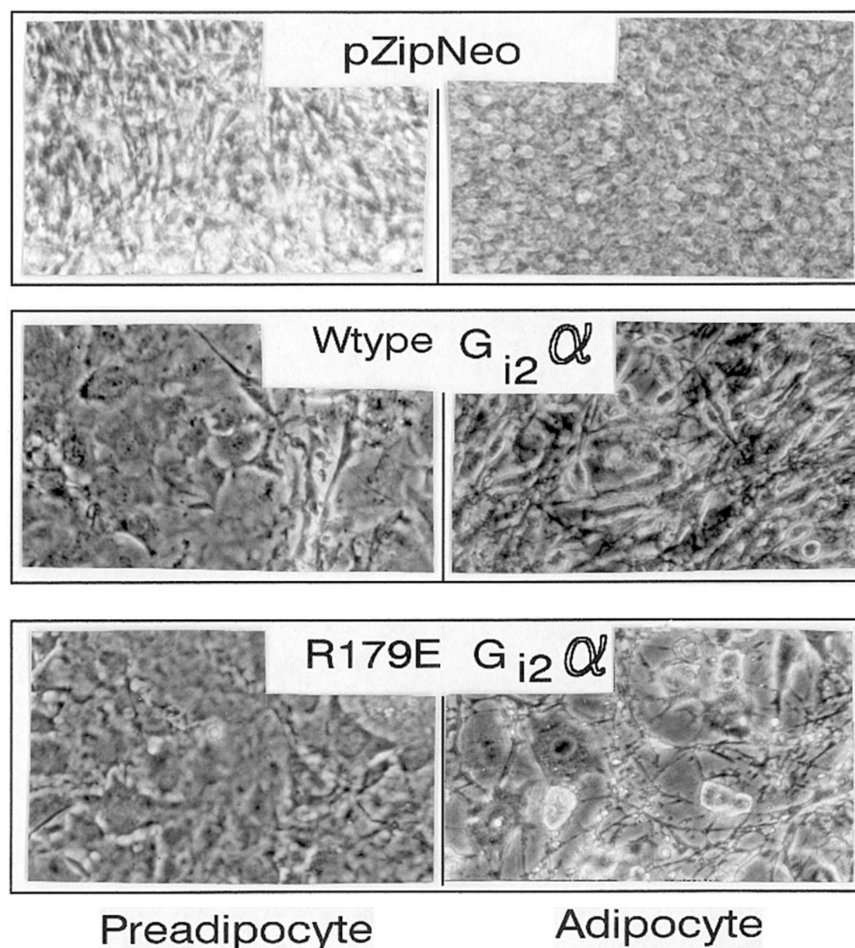

FIG. 1. Stably $G_{i2}\alpha$-transfected 3T3-L1 cells at confluence subsequent to 7 d of treatment with insulin (10 μg/mL), dexamethasone (10 nM), and isobutyl methylxanthine (0.5 mM). All clones were grown in Dulbecco's modified Eagle medium containing 10% fetal calf serum and standard penicillin-streptomycin, with antipleuropneumonia-like organisms agent and fungizone supplementation. Abbreviations: pZipNeo = pZipNeo(SV)X (retroviral vector); Wtype $G_{i2}\alpha$ = wild type $G_{i2}\alpha$; R179E-$G_{i2}\alpha$ = constitutively activated (GTPase deficient) $G_{i2}\alpha$ mutant.

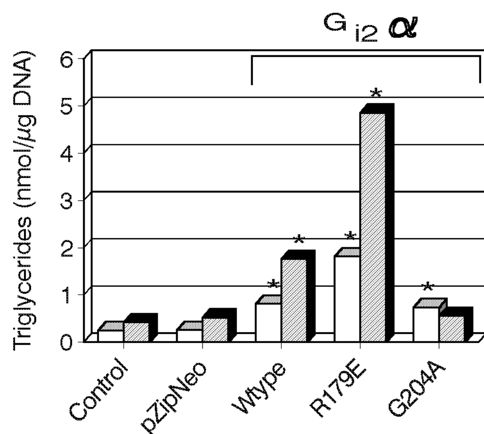

FIG. 2. Triglyceride contents (nmol/µg DNA) in stably $G_{i2}\alpha$-transfected 3T3-L1 preadipocytes (open bars) and adipocyte (cross-hatched bars) measured before and after 7 d of incubation in Dulbecco's modified Eagle medium supplemented with 10% fetal calf serum, insulin (10 µg/mL), dexamethasone (10 nM), and isobutyl methylxanthine (0.5 mM). Washed cells were harvested in phosphate-buffered saline, pH 7.4, and homogenized for 10 s. Lipids were extracted at room temperature by the procedure of Folch *et al.* (24), and triglyceride content assayed using a commercial kit from BioMerrieux. *Significant differences ($P < 0.05$) from nontransfected control cells. (Student's *t*-test, $n = 6$). Average coefficient of variation (CV) for this study equaled 13.4%. G204A: G204A-$G_{i2}\alpha$, constitutively inactivated (receptor dissociated) $G_{i2}\alpha$ mutant. For other abbreviations see Figure 1.

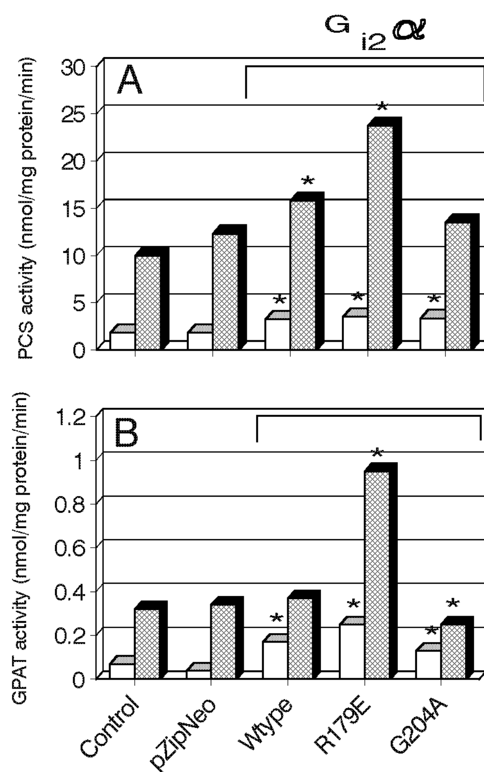

FIG. 3. (A) Palmitoyl-CoA synthetase (PCS) activity measured as nmol · min^{-1} · mg^{-1} in membranes from stably $G_{i2}\alpha$-transfected undifferentiated cells and cells treated with insulin (10 µg/mL), dexamethasone (10 nM), and isobutyl methylxanthine (0.5 mM). Cells harvested in 1.0 mL of phosphate-buffered saline (PCS), pH 7.4, were homogenized for 10 s and centrifuged for 30 min at 27,000 × *g* to isolate membranes. PCS was determined according to the method of Krisans *et al.* (22). Protein (20–50 µg) was incubated for 6.5 min at 37°C in a mixture of 150 mM Tris-HCl, pH 7.4, 6.2 mM $MgCl_2$, 0.5 mg/mL Triton X-100, 2 mM ATP, 600 mM CoA, 1 mM dithiothreitol, 100 µM [1-^{14}C]-palmitic acid (5 × 10^4 dpm) in a total volume of 400 µL. *Significant differences ($P < 0.05$) from nontransfected control cells (Student's *t*-test, $n = 6$). Average CV for this study equaled 17.2%. (B) Glycerophosphate acyltransferase (GPAT) activity (nmol · min^{-1} · mg^{-1}) measured in undifferentiated 3T3-L1 cells and after treatment with insulin (10 µg/mL), dexamethasone (10 nM), and isobutyl methylxanthine (0.5 mM). GPAT was determined essentially according to Sooranna and Saggerson (23). Membrane protein fractions were incubated in a total volume of 1.0 mL at 30°C for 7.5 min. The incubation solution contained 0.1 M Tris buffer, pH 7.4, 0.7 mM of L-[U-^{14}C]-glycerol 3-phosphate (0.06 mCi/mmol), 2 mM $MgCl_2$, 2 mM KCN, 0.7 mM dithiothreitol, bovine serum albumin (1.2 %, wt/vol), and 70 µM palmitoyl-CoA ester. *Significant differences from nontransfected control cells (Student's *t*-test, $n = 4$). Average CV for this study equaled 14.7%. Open bars: preadipocytes; cross-hatched bars, adipocyctes. Abbreviation: Wtype-$G_{i2}\alpha$ = wild type $G_{i2}\alpha$. For other abbreviations see Figures 1 and 2.

activating enzyme PCS showed a marked rise after differentiation in both control and transfected cells ($P < 0.05$). Not unexpectedly, the most notable increase was elicited by the R179E-$G_{i2}\alpha$ construct. A similar phenomenon with increased enzyme activity subsequent to differentiation ($P < 0.05$) was also observed for GPAT. Again the highest rate of activity was exhibited by cell cultures expressing R179E-$G_{i2}\alpha$. The somewhat unexpected finding that G204A-$G_{i2}\alpha$ mutant also brought about changes of PCS and GPAT activities in 3T3-L1 cells is discussed later.

The documented two- to fourfold stimulation of the lipid-synthesizing machinery, induced by R179E-$G_{i2}\alpha$, stimulated speculations as to whether the total amount of PL was also augmented to the same extent. As can be interpreted from Figure 4, preadipocyte cell transfection and differentiation led to a marked elevation in total amount of PL ($P < 0.05$). Compared to control and vector-transfected cells, the R179E-$G_{i2}\alpha$-expressing clones exhibited the most striking increase, both before and after differentiation. Despite elevation of predifferentiation contents of PL in G204A-$G_{i2}\alpha$-expressing cells, enhancement of PL accumulation upon incubation in differentiation medium was not observed ($P < 0.05$). Figure 5 portrays the percentage shift in the PL profile subsequent to 7 d of attempted differentiation. All the clones transfected with activating $G_{i2}\alpha$-containing constructs reduced ($P < 0.05$) their relative phosphatidylethanolamine (PE) and phosphatidylcholine (PC) contents, while relative phosphatidylinositol (PI) levels were enhanced ($P < 0.05$).

Increased steady-state amounts of PI moieties (i.e., PI, phosphatidylinositol 4-phosphate PIP_2) may signify chronically enhanced protein kinase (i.e., protein kinase C = PKC; calmodulin-dependent protein kinase = CamPK) activities. Hence, analyses of accumulated DAG and rate of 1,4,5-inositol trisphosphate (IP_3) synthesis were conducted (see Fig. 6A and B, respectively). The cells expressing the R179E-$G_{i2}\alpha$-activating mutant exhibited much higher levels of DAG and

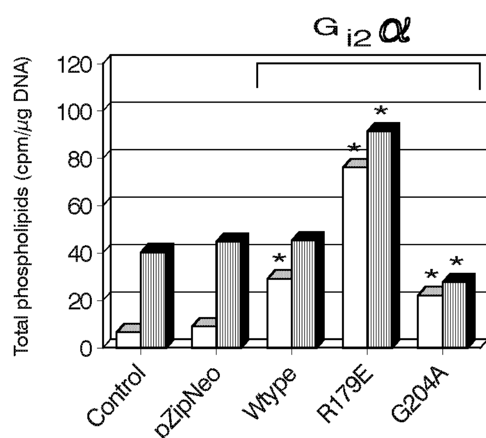

FIG. 4. Total amounts of phospholipids measured as [^{32}P]-cpm/µg DNA in undifferentiated cells and after treatment with insulin (10 µg/mL), dexamethasone (10 nM), and isobutyl methylxanthine (0.5 mM). The cells were incubated for 2 h in 0.5 mL of Dulbecco's modified Eagle medium supplemented with 10 µCi/mL [^{32}P]-labeled phosphate. The cells were washed twice in 1.0 mL phosphate-buffered saline (PBS), pH 7.4. Then the cells were harvested 1.0 mL PBS, pH 7.4 and the lipids extracted at room temperature using the procedure of Folch *et al.* (24) and dried under a stream of N_2. The lipids were dissolved in 100 µL of $CHCl_3$ and applied to thin-layer chromatographic (TLC) plates. After chromatography and autoradiography were completed, the TLC plates were cut and counted in a Packard scintillation counter for 5 min. *Significant differences ($P < 0.05$) from nontransfected control cells (Student's *t*-test, $n = 4$). Average CV for this study equaled 12.0%. Open bars, preadipocytes; lined bars, adipocytes. For abbreviations see Figures 1–3.

rate of IP_3 production after differentiation ($P < 0.05$). No other construct modulated the differentiation process in terms of DAG amounts and IP_3 production to a significant extent ($P > 0.05$).

DISCUSSION

According to Wang *et al.* (27,28), differentiation of 3T3-L1 preadipocytes can be enhanced by insulin or by dexamethasone and a methyl xanthine; however, insulin is the main anabolic hormone taking part in regulation of metabolism in the liver, muscle, and adipose tissue (29). *In vivo*, insulin also plays a role in cellular proliferation (30). GTP-binding proteins (G-proteins) mediate transmembrane signaling from receptors on the cell surface to different effector units (2–6). The levels of G-proteins often change upon cell differentiation (31–34). However, we (16) and others (27,28,35) have previously shown that $G_s\alpha$ inhibits, whereas $G_{i2}\alpha$ enhances the extent to which 3T3-L1 cells differentiate. In this work, we assess the impact of $G_{i2}\alpha$ on the differentiation process in terms of actual TAG deposition, fat-metabolizing enzymes, PL accumulation, PL profile, and second messengers derived from PI-PLC-elicited turnover of PI trisphosphate (PIP_2).

Generally, this paper demonstrates that overexpression of constitutively active $G_{i2}\alpha$ enhanced TAG-synthesizing enzyme activities as well as TAG steady-state levels. However, inconsistent data with regard to lipid synthesis rate and accumulation in the G204A-$G_{i2}\alpha$ expressing clones were observed. These may be due to an inherent variability of the 3T3-L1 cells to respond to differentiation stimuli (27,35). In a previous report, we showed that the inactive G204A-$G_{i2}\alpha$ construct completely inhibited 3T3-L1 cell differentiation in terms of isoproterenol- and corticotropin-susceptible adenyl-

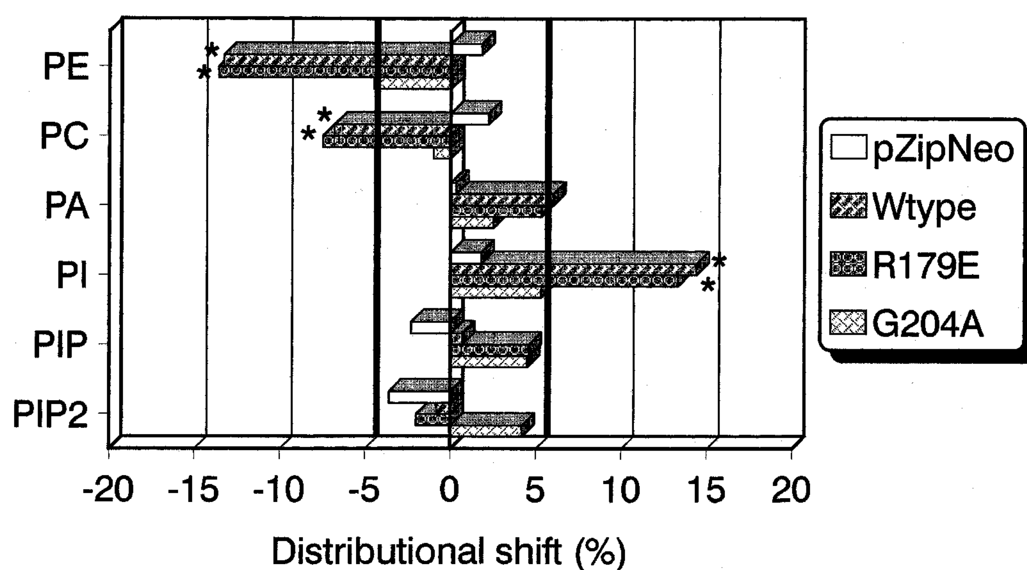

FIG. 5. Changes in phospholipid profile in 3T3-L1 cells after treatment for 7 d with insulin (10 µg/mL), dexamethasone (10 nM), and isobutyl methylxanthine (0.5 mM) as compared to control. The figure shows percentage (%) distribution of different phospholipids. *Significant differences ($P < 0.05$) from nontransfected control cells (Student's *t*-test, $n = 6$). Average CV for this study equaled 12.0%. Abbreviations: PE = phosphatidylethanolamine; PC = phosphatidylcholine; PA = phosphatidic acid; PI = phosphatidylinositol; PIP = phosphatidylinositol 4-monophosphate; PIP_2 = phosphatidylinositol 4,5-bisphosphate. ate cyclase activation and hormone-sensitive lipase mRNA levels (16). Finally, overexpression of constitutively active $G_{i2}\alpha$ enhanced the overall contents of phosphatidyl moieties, as well as steady-state levels of the second messengers DAG and IP_3.

Differentiation of the preadipocytes has been linked to insulin or IGF type I (IGF-I) activation of the mitogen-activating protein kinase (MAPK) cascade (2,36). Since the G_{i2} heterotrimer was shown to couple to the IGF-II receptor subtype (17), the impact of $G_{i2}\alpha$ probably also involves MAPK activation through *raf*- and *ras*-proteins (36,37). However, this model of preadipocyte differentiation presents a similar G-protein profile as adipocytes from obese mice (38,39) and from hypothyroid rats (40), where the $G_{i2}\alpha/G_s\alpha$ ratio is enhanced. Contrastingly, no difference in the $G_{i2}\alpha/G_s\alpha$-ratio could be detected in adipocytes from insulinopenic diabetic rats (41), thyroidectomized patients suffering from papillary carcinoma (42), or obese subjects (42). Nonetheless, evidence has been published that $G_i\alpha$ in adipocytes from streptozocin-induced diabetic rats display far less efficient coupling to prostaglandin E_1- and A_1-receptors (43). All in all, the recent literature indicates that enhanced differentiation of adipocytes by $G_{i2}\alpha$ involves enhanced growth factor receptor coupling to the MAPK pathway with a concomitant reduction in basal cAMP production.

Others have demonstrated that preadipocytes enhance their levels of acetyl-CoA carboxylase, fatty acid synthetase, and glycerophosphate dehydrogenase (GPDH) activity (44–46) upon differentiation. The activities of these and other enzymes, including PCS and GPAT, are also augmented in adipocyte differentiation *in vivo* (14). Hence, it may be asserted that $G_{i2}\alpha$ plays a major role in the phenotypic change of fibroblast-like cells to mature adipocytes, both as a solitary signal and as an amplifier of insulin.

Like the TAG, the steady-state level of PL rose as a consequence of the differentiation process induced by $G_{i2}\alpha$. When the cells enter their resting state as adipocytes, their content of PI, PIP, and PIP_2 increases markedly. It has been reported that insulin stimulates the activity of PI 3-kinase, thus leading to an increased amount of PIP_2 (47). As PI 3-kinase can be considered a key enzyme in the polyphosphoinositide cycle (48,49), changes in the content of other PL in this cycle may be a result of PI 3-kinase modulation. Apparently, enhanced $G_{i2}\alpha$ activity may have induced PI 3-kinase by itself and potentiated the stimulatory effect of insulin. Interestingly, wortmannin, which inhibits PI 3-kinase activity, was demonstrated also to reduce 3T3-L1 lipid deposition and GPDH activity (50). Furthermore, pioglitazone, which normally interferes with cAMP-dependent pathways, was shown to obliterate the isoproterenol-induced reduction in PI 3-kinase activity (51). In summary, the relative increase in PI-derived moieties over the levels induced by insulin itself may reside with $G_{i2}\alpha$-elicited potentiation of the insulin effect or also may be due to inhibition of basal adenylate cyclase activity in the preadipocytes.

DAG has been reported to be generated in response to insulin in the 3T3-L1 clone and in many other cell types (52,53). DAG is a signal molecule and is made from the same precursor (PIP_2) as IP_3 through hydrolysis by PI-PLC. Thus, this pathway is bifurcate, as the external message is split into two second messengers. DAG is lipophilic and induces translocation of PKC. After stimulation, DAG kinase removes DAG by converting it to phosphatidic acid. IP_3 is water-soluble and is released into the cytosol where its role is

to mobilize Ca^{2+}. Recently, it was demonstrated that pertussis toxin treatment of 3T3-L1 cells reduced insulin-elicited DAG release, GPDH activity, and 2-deoxy glucose uptake (54). Hence, $G_{i2}\alpha$-induced adipocyte differentiation involves chronically enhanced PIP_2 turnover. It was shown that PKC seeks to attenuate PI-PLC activity in differentiated 3T3-L1 cells (55); however, it seems that basal PI-PLC activity in cells expressing the constitutively activated $G_{i2}\alpha$ stays at a 2.5-fold higher level. Phorbol-12-myristate-13-acetate and the ionophore ionomycin synergistically counteract adipocyte marker gene expression (56). Since PKC is known to inactivate $G_{i2}\alpha$ (6), it seems that a reduction in $G_{i2}\alpha$ during normal adipocyte differentiation is a natural mechanism used by the preadipocyte to counteract excessive phenotype alteration. In fact, treatment of mature 3T3-L1 adipocytes with pertussis toxin reduced the level of GPDH activity by 50% after 7 d of exposure (54). The introduction of a constitutively active $G_{i2}\alpha$ that escapes inactivation by PKC thus accounts for the preservation of the two- to fourfold enforcement of 3T3-L1 adipocyte characteristics reported in this paper.

PLC also degrades other phosphatidylinositides into inositol phosphates, DAG, and 1-alkyl,2-acyl glycerol (57,58). By this action, the enzyme takes part in the regulation of the amount of substrate(s) available for the kinases (e.g., PI 3-kinase) in the polyphosphoinositide cycle and also yields bioactive acyl glycerols. According to recent reports (59,60), PI-PLC activity seems to be regulated by several G-proteins such as $G_{q/11}$ and G_o. Hence, G_{i2} may also be instrumental in modulating the steady-state level of adipocyte differentiation by restraining the impact of PKC activation.

ACKNOWLEDGMENTS

We hereby commend the expertise rendered by professor Jon Bremer, Institute of Medical Biochemistry, University of Oslo, Oslo, Norway, in making the analyses of PCS and GPAT possible. This work was supported by Novo Nordisk, the Norwegian Society for Fighting Cancer, and the Anders Jahre Foundation.

ABSTRACT: Although a novel brain-specific fatty acid-binding protein (B-FABP) was recently cloned, the identity of a second fatty acid-binding protein detected with antibodies to the heart (H-FABP) has not been clearly resolved. The present investigation, using matrix-assisted laser desorption mass spectrometry, showed that this protein was a form of H-FABP whose N-terminal amino acid was neither methionine nor was it acetylated. Furthermore, isoelectric focusing revealed two major isoforms, a major band pI 7.4 and a minor band pI 6.4, in a distribution pattern opposite to that observed for H-FABP in the heart. Tryptic peptide mass maps of the in-gel digested SDS polyacrylamide gel electrophoresis protein bands showed that the two isoforms differed only in a single peptide corresponding to residues 97–106 of the heart H-FABP sequence. This peptide had an $[M + H]^+$ ion of either 1205.62 (pI 7.4) or 1206.53 (pI 6.4), consistent with a single amino acid substitution, Asp98 or Asn98. Whereas it is well established that both H-FABP and B-FABP interact with polyunsaturated fatty acids, we showed that they also significantly alter plasma membrane cholesterol dynamics in a manner opposite to that of another brain lipid-binding protein, sterol carrier protein-2. In summary, the data demonstrated for the first time that the H-FABP from brain, while nearly identical to H-FABP from heart, differed significantly in isoform distribution and in amino terminal structure from heart H-FABP. This suggests that the brain and heart H-FABP may not necessarily function identically in these tissues.

Paper no. L7998 in *Lipids 34,* 363–373 (April 1999).

Western and Northern blottings indicate that brain cytosol contains at least four members of the fatty acid-binding protein (FABP) family, with the brain-specific (B)-FABP (1–3) and a protein crossreactive to heart (H)-FABP being the most prominent (4–7). Comparison of the cDNA sequences reveals that B-FABP shares only about 65% sequence homology with H-FABP (1–3). FABP bind a wide variety of hydrophobic ligands involved not only in lipid metabolic and structural pathways but also in cellular signaling and differentiation (4–6,8–10). B-FABP preferentially binds polyunsaturated fatty acids (e.g., arachidonic acid and docosahexaenoic acid, K_d ~ 10 nM) (11), fatty acyl CoA, and lysophosphatidic acid (4). H-FABP from mouse heart also preferentially binds polyunsaturated fatty acid such as arachidonic acid (4). Finally, some intracellular proteins that bind fatty acids also interact with cholesterol and modulate membrane cholesterol dynamics (12–18). Whether the brain FABP acts similarly is not known.

In contrast to B-FABP, almost nothing is known regarding the cDNA or amino acid sequence, isoform pattern, definitive structural identification, or function of the protein crossreactive to anti-H-FABP. Structural identification of this protein is especially important for several reasons: First, H-FABP is present in vascular muscle (19,20), suggesting that H-FABP detected in brain may in part originate from vascular tissue. Although the quantitative contribution of the latter is most likely small given the neural/glial volume relative to vascular, noncapillary volume, the contribution of vascular vs. neural/glial derived H-FABP may influence the isoform pattern of H-FABP in brain. Second, the presence of polymorphism (21) and impurities in native FABP preparations (22–24) has made it difficult to resolve the identity of anti-H-FABP crossreactive proteins. For example, a mammary gland FABP (originally identified as a new protein differing only slightly from H-FABP) was recently shown to be a mixture of H-FABP and another FABP, rather than being a new protein or H-FABP isoform (22–25). Third, native FABP often display isoform patterns not evident from cDNA sequence analysis alone (reviewed in Ref. 26). Fourth, the different isoforms may have distinct functions. For example, the two H-FABP isoforms present in bovine heart have distinct intracellular localization in mitochondria and cytosol, respec-

tively (reviewed in Ref. 24). Similarly, two rat liver (L)-FABP isoforms differentially modulate microsomal fatty acyl CoA incorporation into phosphatidic acid (26,27). The primary purpose of the present work was to isolate the B-FABP immunoreactive to anti-heart H-FABP, resolve its isoform pattern, mass map the peptide sequence to resolve its identity, and examine the effect of H-FABP as well as B-FABP on plasma membrane cholesterol dynamics.

MATERIALS AND METHODS

Materials. Tris base, SDS, urea, acrylamide, bis-acrylamide, bovine serum albumin, glycine, Tween 20, 20% Nonidet P-40 (octylphenol-ethylene oxide condensate), Ponceau S, dibasic potassium phosphate, monobasic potassium phosphate, EDTA, phenylmethylsulfonyl fluoride, leupeptin, pepstatin, sodium azide (NaN_3), dithiothreitol, ammonium persulfate, *N,N,N′,N′*-tetramethylethylenediamine, ammonium sulfate $(NH_4)_2SO_4$, 2-(*N*-morpholino)ethanesulfonic acid, piperazine-*N,N′*-bis(2-ethanesulfonic acid), and cholesterol were obtained from Sigma Chemical Company (St. Louis, MO). Trifluoroacetic acid (TFA), acetonitrile [high-performance liquid chromatography (HPLC) grade], β-mercaptoethanol, glycerol, and methanol were from Fisher (Pittsburgh, PA). Polyvinylidene difluoride (PVDF) membranes were purchased from Millipore Inc. (Bedford, MA). Horseradish peroxidase-conjugated goat-anti-rabbit-immunoglobulin and Brilliant Blue G were from Bio-Rad (Richmond, CA). Murine recombinant H-FABP and affinity-purified antibody against this protein were prepared as described (25). Murine recombinant B-FABP and affinity-purified antibodies against this protein were prepared as described (28). Amicon stirred ultrafiltration cell (Model 8050) and Amicon Centriprep 10 concentrator tubes were obtained from Amicon (Beverly, MA). Ampholytes pH 3.5–9.5, Sephadex G-25 (coarse), Sephadex G-50 (superfine), diethylaminoethyl (DEAE) CL-4B Sepharose, and carboxymethyl Fast Flow Sepharose were purchased from Pharmacia (Piscataway, NJ). C4 reversed-phase HPLC column was from Vydac (Hesperia, CA).

Animals. Swiss Webster mouse brains, purchased frozen and shipped on dry ice, were obtained from Hazleton Research Products (Denver, PA). In order to remove plasma proteins that bind fatty acids (e.g., albumin) and may interfere with isolation of the H-FABP, blood was removed by rinsing the brains with phosphate-buffered saline prior to freezing. Blood does not normally contain H-FABP as a contaminant since this is an intracellular protein expressed in skeletal or vascular muscle. The experimental protocols for the use of laboratory animals were approved by the appropriate institutional review committee and met guidelines of the American Association for Accreditation of Laboratory Animal Care.

Purification of H-FABP from mouse brain. The H-FABP was isolated at 4°C from mouse brain by a modification of an earlier described protocol (4). In addition to removing extraneous proteins, the purification procedure had to remove B-FABP copurifying in the early steps of the procedure. Purification was monitored by Coomassie Blue stain/silver stain, and Western blotting using affinity-purified specific antibodies against recombinant mouse H-FABP and recombinant mouse B-FABP.

Briefly, the procedure was as follows: Frozen mouse brains (700) brains were thawed, rinsed, and homogenized in 50 mM phosphate buffer, pH 7.4, with 1.0 mM EDTA, 0.02% NaN_3, 0.5 mM phenylmethylsulfonyl fluoride, 0.5 μg/mL leupeptin, and 1.5 μg/mL pepstatin using 10 strokes with a tight-fitting glass Dounce homogenizer. The homogenate was centrifuged at $12{,}000 \times g$ for 30 min, and the supernatant was reserved. Powdered ammonium sulfate was added to this supernatant to a concentration of 25, 50, 75, and 90% saturation. The suspension was centrifuged at $3{,}000 \times g$ for 30 min, the 90% saturation pellet was taken up in 50 mM phosphate buffer and was loaded on a G-25 Coarse Sephadex desalting column (50 mm, 36 cm), equilibrated with 50 mM phosphate buffer, pH 7.4, 0.02% NaN_3, and eluted with the same buffer. Eluant absorbance was monitored at 280 nm. Ammonium sulfate in the fraction was detected by spot tests using barium chloride in HCl. In the initial salt fractionation procedure both H-FABP and B-FABP were mainly precipitated in the 90% ammonium sulfate saturation pellet. Some lower and higher molecular weight contaminants were removed in the other ammonium sulfate pellets and 90% ammonium sulfate saturation supernatant. After removal of ammonium sulfate, the sample was concentrated and loaded onto a G-50 Sephadex size exclusion column (30 mm, 87 cm). Fractions that were immunoreactive with anti-H-FABP and anti-B-FABP were collected, concentrated, buffer-exchanged with 20 mM triethanolamine buffer, pH 7.8, concentrated again, then loaded on a DEAE-Sepharose column (15×3 cm) equilibrated with 20 mM triethanolamine buffer, pH 7.8, eluted with a linear gradient of 0 to 1 M NaCl in 20 mM triethanolamine buffer, pH 7.8. Fractions immunoreactive with only anti-H-FABP and fractions immunoreactive with both anti-H-FABP and anti-B-FABP were collected separately. The latter were concentrated, buffer-exchanged with 20 mM acetate buffer, pH 4.6, concentrated, loaded on a CM-Fast Flow Sepharose (15×3 cm) column, and eluted as for the DEAE-Sepharose to yield additional purified H-FABP. Fractions immunoreactive with only anti-H-FABP from the two columns were maintained separate. Final purity was achieved by C4 reversed-phase (Vydac) HPLC using an aqueous phase (with 0.1% TFA) in a linear gradient with organic phase (0.1% TFA in acetonitrile) from 10 to 80% organic phase over 60 min.

Tricine SDS-polyacrylamide gel electrophoresis (SDS-PAGE), Western blotting, Coomassie Blue staining, and silver staining. H-FABP purity was determined by Tricine SDS-PAGE, followed by blotting on PVDF membranes (Millipore Inc.), and detection with affinity-purified anti-H-FABP as described earlier (4,29,30). Protein concentration was determined as described earlier (31).

Isoelectric focusing and pI determination. Isoelectric focusing (IEF) electrophoresis was carried out basically as de-

scribed earlier (32) with the following modifications. IEF gels were cast as 1.5-mm thick polyacrylamide gels [30% T, 5.7% C, where T denotes the total percentage concentration of both monomers (acrylamide and bis-acrylamide), and C denotes the percentage concentration of the crosslinker relative to the total concentration T] containing 9 M urea, 2% (vol/vol) Nonidet P-40, 5% (vol/vol) Pharmacia ampholytes, pH 3.5–9.5, using a Mini Protean II electrophoresis Unit (BioRad). Duplicate gels were run essentially according to published procedures (33). Gels were prefocused at 300 V for 15 min. Samples (20 μL) of H-FABP from the HPLC purification and pH marker were then loaded on the gels. Gels were run at 100 V for 20 min, followed by 300 V for 16 h, in the cold room. One gel was stained with Coomassie stain (0.1% Brilliant Blue R-250), another was transferred onto PVDF membrane to develop a Western blot. Isoelectric points were determined by calibration using Pharmacia broad range (pI 3–10) Isoelectric Point Calibration Kit. IEF gel bands of interest were cut and loaded onto the second dimension 16% SDS-polyacrylamide gel (1-mm thick). The latter was run at 75 V for about 30 min, then at 100 V for about 2 h, and then silver stained as described (34) and submitted to Smith Kline Beecham Pharmaceuticals (King of Prussia, PA) for in-gel digestion and amino acid sequencing by mass spectrometric analysis.

In-gel digestion and mass spectrometric analysis of tryptic peptides. Silver staining of 1-mm thick SDS-PAGE gels in preparation for subsequent mass spectrometric analysis was carried out as described (34). The procedure for the digestion of proteins in polyacrylamide gels was a modification of a published procedure (35). Briefly, the silver-stained band of interest was excised from the gel, equilibrated in 100 mM NH_4HCO_3, and then reduced and alkylated using dithiothreitol and iodoacetamide. Following reduction and alkylation, the gel slice was removed and washed in 50% acetonitrile/100 mM NH_4HCO_3, cut into small pieces, and lyophilized. Modified trypsin in 50 mM NH_4HCO_3 was added to the gel pieces, and the sample was incubated overnight at 37°C. An aliquot of the crude digest supernatant was removed, for direct analysis by matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) mass spectroscopy.

Samples were prepared by mixing the crude digest supernatant with an equal volume of matrix solution containing 200 fmol/μL of adrenocorticotropic hormone peptide 18–39 ($[M + H]^+ = 2465.199$) as an internal standard and allowing 0.5 μL of this sample/matrix to dry on the MALDI target. The matrix solution was 10 μg/mL α-cyano-4-hydroxycinnamic acid in 50:50 ethanol/acetonitrile. MALDI mass spectra were recorded on a Micromass (Manchester, United Kingdom) TofSpec SE single-stage, reflectron time-of-flight mass spectrometer. A three-element ion source provided a variable ion extraction region and utilized the time lag focusing principle (36). The instrument had a 3.4-m effective path length. Samples were irradiated by 337 nm photons from a pulsed Laser Science (Cambridge, MA) nitrogen laser at a frequency of 5 Hz. Between 25 and 50 laser shots were averaged per spectrum.

Monoisotopic peptide $[M + H]^+$ values were assigned based on an internal calibration derived from a matrix ion (*m/z* 379.350) and adrenocorticotropic hormone peptide 18–39 (*m/z* 2465.199). Peptide molecular weights were searched against the European Molecular Biology Laboratory nonredundant protein database using the Peptide Search Program (37).

Fluorescence polarization measurement. (i) *Sterol exchange assay*. The exchange of dehydoergosterol for cholesterol was monitored by an assay based on a method (38) modified to determine molecular sterol transfer (18). The plasma membrane lipid composition (17,18) was the same for donors and acceptors except for the nature of the sterol (total sterol in both cases was 35 mol%; 12 mol% of total cholesterol was replaced by dehydroergosterol in the donor membranes). Donor plasma membranes were diluted in piperazine-*N,N′*-bis(2-ethanesulfonic acid) (10 mM, pH 7.4) to 3.5 μg protein/mL. Effector proteins, lyophilized H-FABP or B-FABP were dissolved in sterile distilled water prior to use and were added at this stage. Tenfold excess of acceptor plasma membrane was added to give a final volume of 2 mL and final membrane concentration of 38.5 μg protein/mL. During the exchange assay the sample was continuously stirred at 37°C using a resident micro stir bar (Fisher Scientific Inc., Pittsburgh, PA) in the cuvette. The extent of sterol transfer was monitored by contin-uous measurement of dehydroergosterol polarization for 3–4 h in the T-format with an ISS photon-counting fluorometer (ISS Inc., Champaign, IL) equipped with a 300 watt Xe-arc lamp. Excitation wavelength was 324 nm. Light scattering was reduced through use of KV-389 emission cutoff filters (Schott Glass Technologies Inc., Duryea, PA). The inner-filter effect was made negligible by use of dilute membrane suspensions (absorbance at 324 nm <0.1). Previous studies showed that photobleaching did not occur under these conditions (39). Data were collected automatically every 20 s by a Compaq PC computer through an ISS analog-to-digital interface.

(ii) Dehydroergosterol standard curve for plasma membrane sterol exchange assays. The dependence of polarization, p, on dehydroergosterol concentration can be described in standard curves for plasma membranes with the following polynomial:

$$p = mx_d^2 + n \qquad [1]$$

where x_d is the dehydroergosterol concentration in donor membranes. Parameters $m = 0.1207$ and $n = 0.3187$ for plasma membranes were obtained using computer nonlinear regression.

(iii) Data analysis. Light scatter contributions from the acceptor membranes were subtracted from the entire curve prior to computer analysis. Initial rates were determined from the first 10 min of exchange for both spontaneous and protein-mediated exchange. Earlier results from this laboratory using model membrane systems suggested that sterol exchange occurs *via* kinetics that can be described by the following biexponential equation:

$$x_d = A_2 \exp(-k_{E1}t) + B_2 \exp(-k_{E2}t) + C_2 \qquad [2]$$

When Equation 2 is inserted into Equation 1, we obtain:

$$p = m\,[A_2^2 \exp(-2k_{E1}t) + 2\,A_2B_2 \exp(-k_{E1}t - k_{E2}t) + B_2^2 \exp(-2k_{E2}t) + 2A_2C_2 \exp(-k_{E1}t) + 2B_2C_2 \exp(-k_{E2}t) + C_2^2] + n \quad [3]$$

where A_2, B_2, and C_2 represent the two exchangeable and nonexchangeable fractions, respectively, k_{E1} and k_{E2} represent the corresponding rate constants of exchangeable fractions, and the constants m and n are from Equation 1. Equation 3 was used to fit experimental curves with four fitted parameters, k_{E1}, k_{E2}, A_2, and B_2. C_2 must satisfy the condition that $A_2 + B_2 + C_2 = 1$.

RESULTS

Purification of H-FABP from mouse brain. After separation of the combined FABP from brain cytosol as described in the Materials and Methods section, the key step allowing resolution of H-FABP from B-FABP was ion exchange chromatography. DEAE anion exchange column elution (Fig. 1A) showed fractions immunoreactive to affinity-purified anti-H-FABP eluting with low salt elution (demonstrated by a – sign), whereas fractions immunoreactive to affinity-purified anti-B-FABP were eluted with increasing NaCl (demonstrated by + sign). The remaining fractions immunoreactive to both anti-H-FABP and anti-B-FABP were further separated by CM Sepharose fast flow cation exchange column chromatography (Fig. 1B). In contrast to DEAE anion exchange chromatography, fractions immunoreactive to anti-B-FABP were eluted with no salt and/or low salt (+ symbol, Fig. 1), whereas fractions immunoreactive to anti-H-FABP were eluted with increasing NaCl (– symbol, Fig. 1).

Final purity of H-FABP was achieved by reversed-phase HPLC. The anti-H-FABP immunoreactive fractions obtained from the DEAE anion exchange column and the CM Sepharose cation exchange column were injected separately on a C4 reversed-phase HPLC column and eluted with a stepwise acetonitrile (0.1% TFA) gradient from 10 to 70% in aqueous solution (H_2O, 0.1% TFA) within 35 min. Under the HPLC elution conditions utilized, the H-FABP was eluted at 60% acetonitrile with relative retention time of 30 min (Fig. 2A). The final purity of H-FABP was shown by Western blot (Fig. 2B) and silver staining (Fig. 2C). In contrast, under identical HPLC conditions, B-FABP eluted with relative retention time of 26 min (data not shown).

Two-dimensional electrophoresis. The first dimension of IEF electrophoresis (Fig. 3A) showed that H-FABP from brain (lane 1) migrated primarily as two bands. The major band had an apparent pI 7.4, and the minor band had an apparent pI 6.4. Western blot analysis showed that only the bands pI 7.4 and 6.4 were immunocrossreactive to anti-H-FABP (Fig. 3B). The silver-stained second-dimension SDS-PAGE gel showed primarily a single band for both the pI 7.4 (lane 1) and pI 6.4 (lane 2) isoforms (Fig. 3C). A faint band corresponding to the mass of the dimer was also detectable.

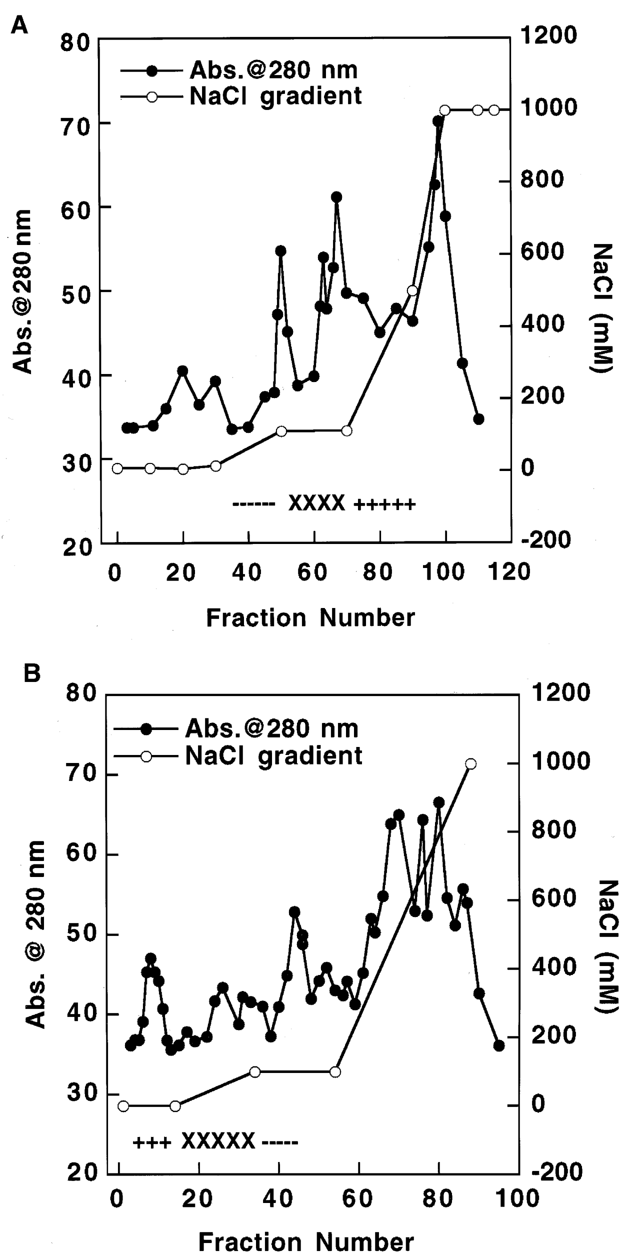

FIG. 1. Ion exchange chromatographic profiles for the separation of heart fatty acid-binding protein (H-FABP) from brain-specific (B)-FABP. Solid circles represent the absorbance at 280 nm, and open circles represent the step gradient of NaCl used to elute the proteins. The minus (–) signs represent the fractions only immunocrossreactive with anti-H-FABP. The × signs represent the fractions immunocrossreactive with both anti-H-FABP and anti-B-FABP. The plus (+) signs represent the fractions only immunocrossreactive with anti-B-FABP. (A) Diethylaminoethyl anion exchange chromatographic profiles. (B) Carboxymethyl cation exchange chromatographic profiles.

Identification of H-FABP from mouse brain by mass spectrometry. The identity of the H-FABP from brain was determined by in-gel digestion of the second-dimension SDS-PAGE bands with trypsin and subsequent MALDI mass spectrometry of resultant peptides (Fig. 4). The pattern of tryptic digest peptides revealed almost complete identity to that ob-

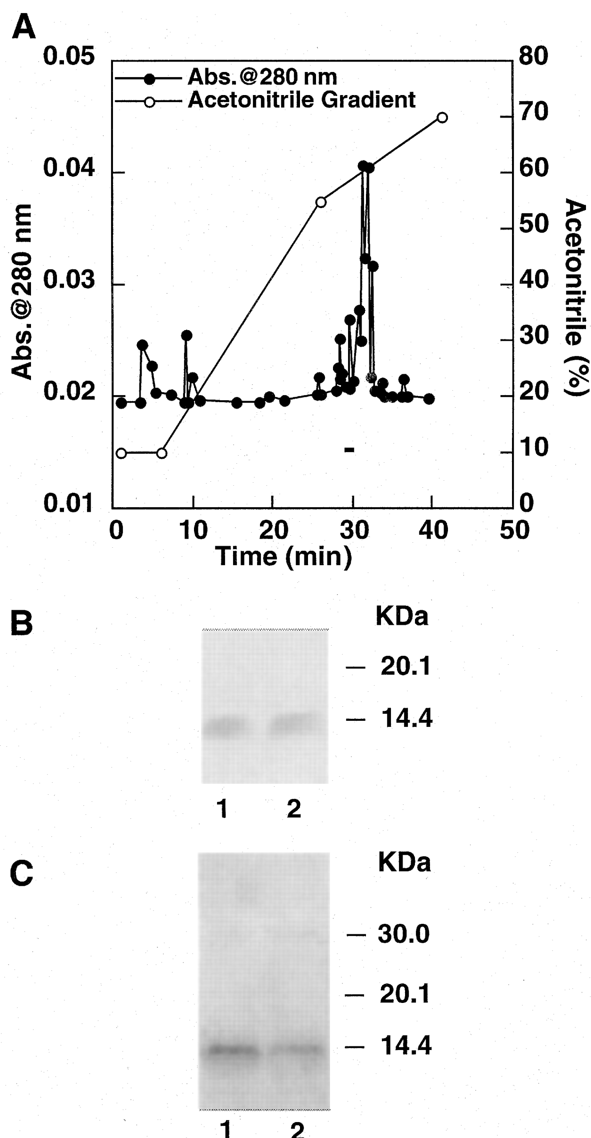

FIG. 2. (A) High-performance liquid chromatographic (HPLC) profile of final purification of H-FABP from mouse brain. A C4 reversed-phase HPLC column was equilibrated with 90% H_2O (0.1% trifluoroacetic acid)/10% acetonitrile (0.1% trifluoroacetic acid). A stepwise gradient to 30% H_2O (0.1% trifluoroacetic acid)/70% acetonitrile (0.1% trifluoroacetic acid) (open circles) was run within 35 min to elute H-FABP. The closed circles represent the absorbance at 280 nm. The final purities of H-FABP from mouse brain are shown in (B), Western blot; (C) silver staining of SDS-polyacrylamide gel electrophoresis (SDS-PAGE) gel. Lanes 1 and 2 represent samples from two different vials collected in series. For other abbreviation see Figure 1.

tained from the H-FABP sequence (Table 1) and recombinant H-FABP (not shown). The only difference was in the N-terminus of the H-FABP of brain vs. heart origin. In contrast to the masses of N-terminal peptides from heart H-FABP, the brain H-FABP did not contain either an acetyl group or a methionine at the N-terminus as revealed by mass of the N-terminal peptide T1 (Table 1).

Identification of native heart H-FABP isoforms from mouse brain by mass spectrometry. There is considerable debate whether true FABP isoforms actually exist or whether they are simply due to posttranslational modifications, degree of ligand binding, or conformation (reviewed in Ref. 26). Therefore, it was important to determine if the H-FABP from brain separated by IEF in the preceding section are true isoforms. As described above and in Figure 3, IEF of the H-FABP from brain revealed two bands. In-gel digestion of the second-dimension SDS-PAGE bands with trypsin and subsequent MALDI mass spectrometry of resultant peptides showed that the pattern of tryptic digest peptides for H-FABP band 1 (Fig. 4A) and band 2 (Fig. 4B) from IEF were almost completely identical between calculated and observed masses (Table 1). The only difference between these two isoforms was noted in peptide T13 (Table 1). The masses of the T13 peptide from band 1 and band 2 of native H-FABP from mouse brain were 1205.62 and 1206.53, respectively (Table 1). A 1-Da difference in the mass of peptide T13 is consistent with a single amino acid substitution, either Asn98–Asp98 or Gln100–Glu100. The partial published amino acid sequence predicted from the cDNA of heart H-FABP was aligned to the partial amino acid sequence of native brain H-FABP (40,41) in Table 2. The Asp/Asn substitution (labeled in bold) is that found in the heart H-FABP (reviewed in Ref. 26). In summary, these data are consistent with the brain H-FABP isoforms resolved by IEF as being true isoforms and not simply altered proteins due to bound ligand or posttranslational modifications as has been observed for several other putative FABP isoforms (reviewed in Ref. 26).

Fluorescence polarization measurement. As described in the introduction, although the fatty acid specificity of both the B-FABP and H-FABP are known, there is evidence that some FABP can also modulate intermembrane sterol transfer. Therefore, this possibility was tested with H-FABP and B-FABP, using a fluorescence polarization assay to examine sterol transfer between isolated plasma membrane vesicles. Sterol carrier protein-2 (SCP-2), a protein that binds cholesterol and increases sterol transport, was used as a positive control in the assay. Both recombinant H-FABP and recombinant B-FABP functionally affected sterol transfer between plasma membranes but in a manner very different from SCP-2. In contrast to SCP-2, which stimulated intermembrane sterol transfer (Fig. 5), H-FABP (Fig. 6A) and B-FABP (Fig. 6B) inhibited intermembrane sterol transfer. Furthermore, analysis of the exchange data as described in the Materials and Methods section showed that the effect of the B-FABP on individual exchange parameters was not simply the reverse of that observed with SCP-2 (Table 3). Although all three proteins increased the size of the exchangeable sterol domain, the effect of both H-FABP and B-FABP was greater than that of SCP-2 (Table 3). In contrast to SCP-2, which decreased the half-time of exchange, both H-FABP and B-FABP increased the half-time of sterol transfer (Table 3). Finally, whereas SCP-2 doubled the initial rate of sterol transfer, H-FABP and B-FABP had no effect on the initial rate of sterol exchange. In summary, both H-FABP and B-FABP may modulate intermembrane sterol transfer.

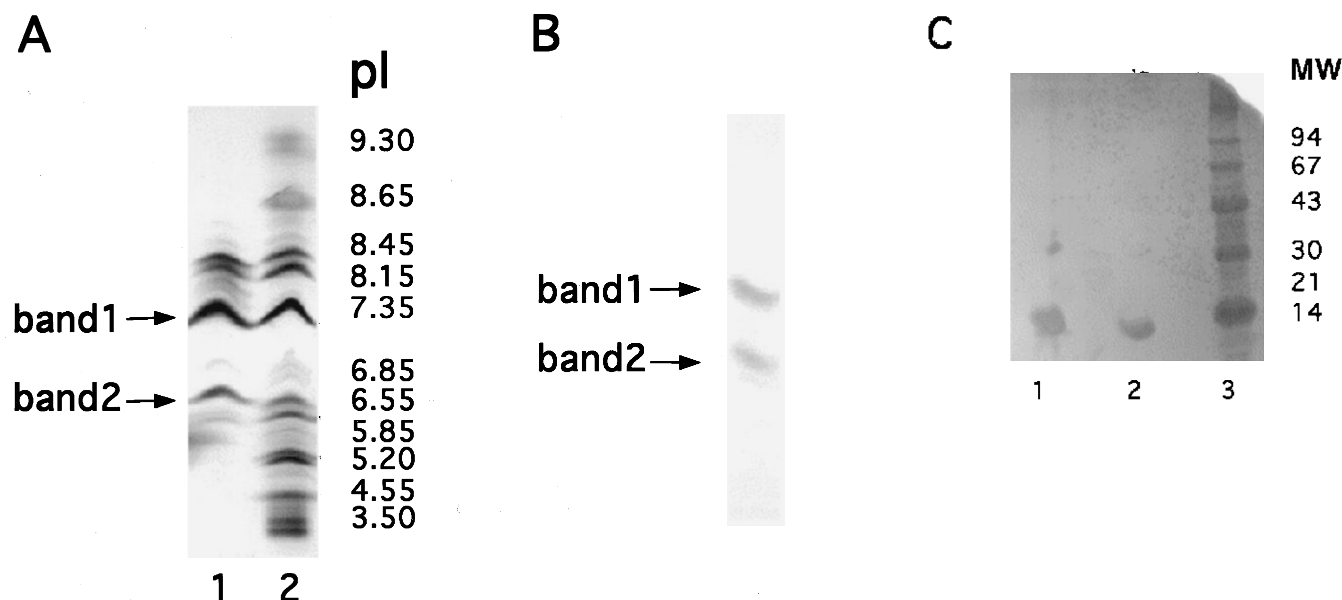

FIG. 3. (A) Isoelectric focusing (first dimension) gel. Isoelectric focusing and Coomassie staining were used to determine the isoelectric points of the H-FABP from mouse brain. Lane 1 is 15 ng of H-FABP from brain. Lane 2 is Pharmacia Broad Range pI Calibration Kit markers, the pI values of which are listed along the right edge of the gel. The isoform pI 7.4 was labeled as band 1, and the isoform pI 6.4 was labeled as band 2. (B) Western blot shows both band 1 and band 2 of H-FABP from brain were immunocrossreactive with anti-H-FABP. (C) Silver staining of second-dimension (SDS-PAGE) gel. Band 1 (pI 7.4) and band 2 (pI 6.4) of H-FABP from brain were cut from isoelectric focusing gel and loaded in lanes 1 and 2 of an SDS-PAGE gel. Lane 3 is Gibco (Grand Island, NY) prestained molecular weight markers. For abbreviations see Figures 1 and 2.

DISCUSSION

Increasing evidence for roles of fatty acids in differentiation and function of brain tissues has stimulated interest in proteins that may be involved in the uptake and/or intracellular trafficking/targeting of fatty acids in nervous system cells. Western and Northern blotting has suggested that brain contains at least four cytosolic FABP (4–7,24) and one integral plasma membrane FABP (42). Prior to the present investigation, only one of these had been structurally identified (B-FABP primary amino acid sequence was predicted from the cDNA cloned from a brain library). In brain, the identity of the second major FABP, which is crossreactive to anti-H-FABP from heart, has not been established. This is a significant problem in view of previous difficulties in identifying FABP based only on cross reactivity with antisera (see introduction and Ref. 4). Results of the present investigation made several important contributions to our understanding of FABP from brain.

First, isolation of the native H-FABP from mouse brain and subsequent mass spectroscopic analysis revealed that it was essentially identical to H-FABP from mouse heart. The major difference was that tryptic peptide data of the native H-

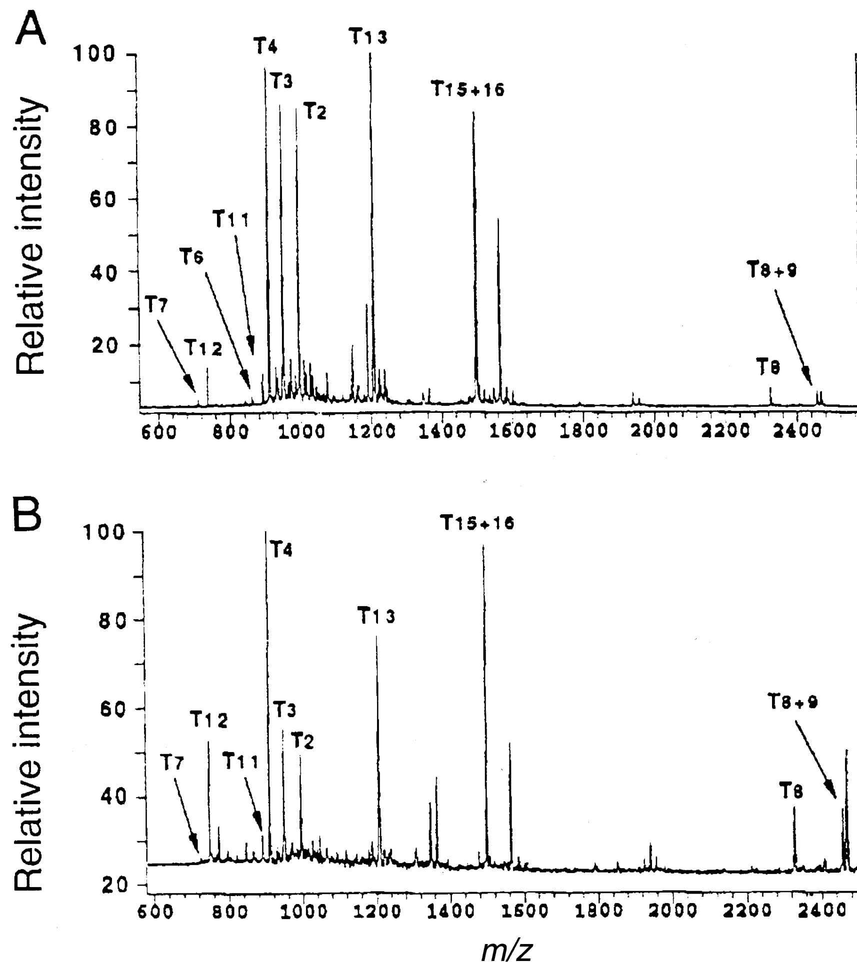

FIG. 4. Delayed-extraction MALDI-reflectron time-of-flight mass spectra of tryptic digest peptides from band 1 (pI 7.4) (A), and band 2 (pI 6.4) (B) of H-FABP from brain after two-dimensional electrophoresis purification. MALDI, matrix-assisted laser desorption ionization; for other abbreviation see Figure 1.

FABP from mouse brain had an N-terminal Ala, unlike native heart H-FABP (43) or the cDNA-derived amino acid sequence (44). This difference in amino terminus is primarily responsible for the major difference in IEF behavior between the native H-FABP and native H-FABP. The isoelectric points, pI 7.4 and 6.4, of native H-FABP from mouse brain were more basic than those of human H-FABP, pI 5.3 and bovine H-FABP, pI 4.9 and pI 5.1 (45). Both pI of native mouse H-FABP were also more basic than the pI 5.82 calculated from the cDNA encoding mouse heart H-FABP (44) and the pI 6.0 of rat mammary epithelial cell heart H-FABP (46). Since the native H-FABP from mouse brain was not N-terminal acetylated, its pI was more basic. In contrast, the isoforms of native H-FABP from human heart, bovine heart, and rat heart have an acetyl group at the N-terminal, which give a more acidic pI. The functional significance of H-FABP with or without N-terminal acetylation is thus far not clear. However, it was recently observed that another cytosolic lipid-binding protein, acyl-CoA-binding protein, isolated from murine cells was N-terminal acetylated and exhibited a 2.1-fold greater stimulation of microsomal phosphatidic acid synthesis than did recombinant rat ACBP which was not N-terminal acetylated (47).

[a]Amino acids corresponding to position 98 are in bold. See Table 1 for abbreviation.

Second, the mass spectroscopic data clarified another problem, i.e., whether the two forms of native anti-heart H-FABP immunoreactive proteins from mouse brain represented true isoforms. As shown herein, mass spectroscopic analysis revealed that these bands were true isoforms due to an amino acid substitution. Peptide mass mapping of the two native H-FABP proteins from mouse brain revealed that they differed by only 1 Da in a single tryptic peptide, 97–106. Based on the cDNA-derived amino acid sequence of this peptide, the observed mass difference between the two isoforms

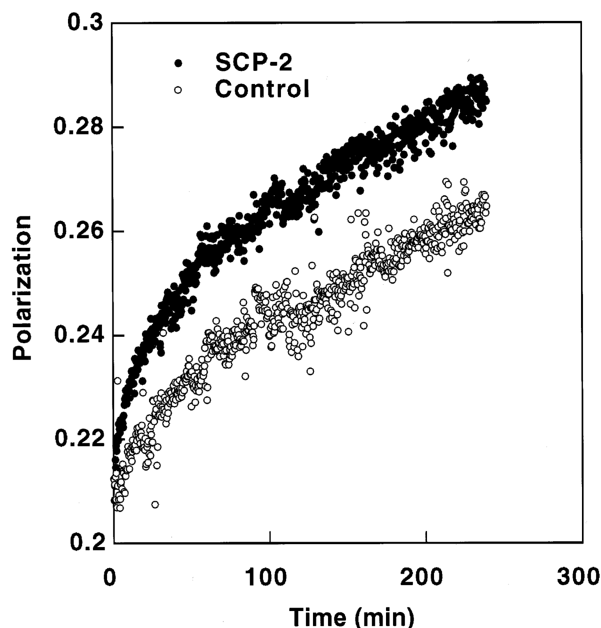

FIG. 5. Effect of sterol carrier protein-2 (SCP-2) on plasma membrane sterol exchange. Plasma membrane sterol exchange was determined as described in the Materials and Methods section. The lower curve represents spontaneous exchange whereas the upper curve was obtained with 1.5 μM SCP-2 present in the assay medium.

could be accounted for by either an Asn exchange with Asp at residue 98 or by a Gln exchange with Glu at residue 100. Asp/Asn exchange seems to be a common event in several members of the FABP family (26,48–50). Two isoforms of native H-FABP from bovine heart have been isolated and shown to result from an Asp/Asn exchange at residue 98 (43). Because the Asn at residue 98 in both bovine heart and mouse brain H-FABP is present in a sequence (Asn–Gly) which is subject to facile nonenzymatic deamination, it is possible that the two forms of H-FABP are an artifact. However, it was shown that in bovine heart, the Asp98 and Asn98 isoforms are coded by distinct mRNA, and that the protein product of the Asn98 gene did not convert to Asp98 over time (48).

Third, the pattern of brain H-FABP isoforms suggests that these altered protein forms may be functionally significant. The most important observation in this regard was that the proportions of the two native H-FABP isoforms from brain differed significantly from those found in heart. For example, in bovine heart the more acidic isoform of H-FABP represents a larger portion of the total (43,48,51). Based on the observation that one of the H-FABP isoforms was exclusively found associated with mitochondria, the latter investigators suggested an important role for this isoform in mitochondrial fatty acid oxidation, the most important energy source for the heart. In contrast, brain acquires most of its energy from glycolysis. Consistent with this, the pattern of the brain H-FABP isoforms was shifted away from that predicted to be associated with mitochondria. While this correlative explanation is appealing, future work is needed to reveal the physiological significance of brain H-FABP isoforms.

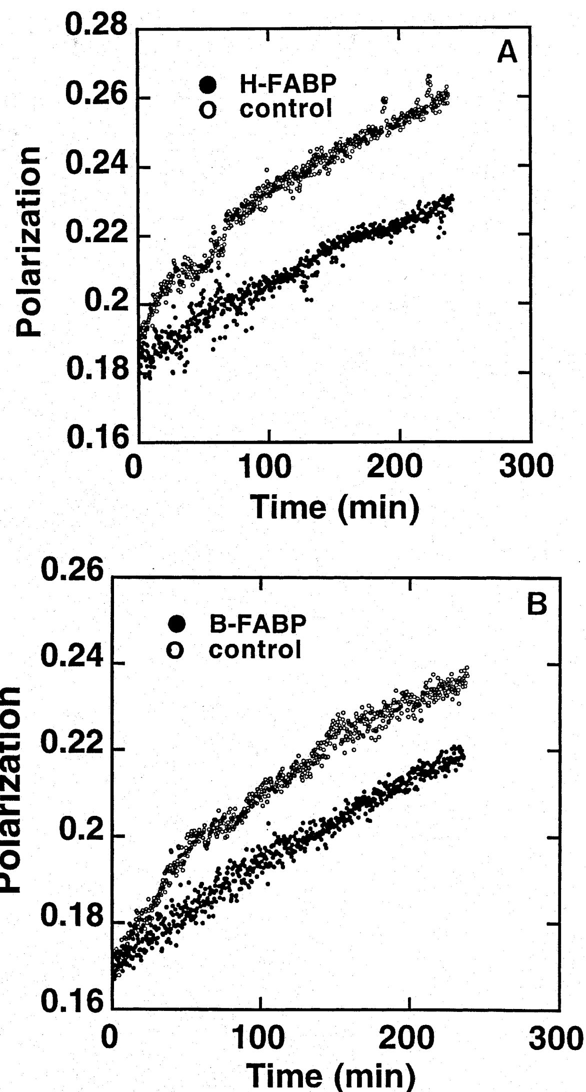

FIG. 6. Effect of H-FABP and B-FABP on plasma membrane sterol exchange. (A) The top curve (○) represents spontaneous exchange, and the bottom curve (●) was obtained with 1.5 μM H-FABP present in the assay medium. (B) The top curve (○) represents spontaneous exchange and the bottom curve (●) was obtained with 1.5 μM B-FABP present in the assay medium. All exchanges were performed at 37°C in 10 mM piperazine-*N,N′*-bis(2-ethane sulfonic acid) (pH 7.4). For abbreviations see Figure 1.

Fourth, native brain H-FABP as well as B-FABP may participate in intracellular sterol trafficking and modulation of membrane sterol domains/membrane function. Another FABP, the liver L-FABP, was shown to alter intracellular cholesterol trafficking, plasma membrane cholesterol domains, and plasma membrane Na^+,K^+-ATPase activity (12,13,18,52). Both B-FABP and H-FABP increased exchangeable sterol domain size, concomitantly increased the half-time of sterol transfer, but did not alter the initial rate of sterol transfer from isolated plasma membranes. The net effect was that H-FABP and B-FABP inhibited intermembrane sterol transfer. This inhibition may be correlated with recent observations that increasing age alters transbilayer fluidity and cholesterol asym-

TABLE 3
Kinetic Parameters of Spontaneous and Protein-Mediated Sterol Transfer Between Plasma Membranes[a]

Samples	Fractional domains f_1 (%)	Fractional domains f_2 (%)	Halftime $t_{1/2}$ (min)	Initial rate (ΔP, 10^{-4} min^{-1})
Control	0.47 ± 0.03	0.53 ± 0.03	137 ± 5	5.13 ± 0.89
SCP-2	0.56 ± 0.11	0.44 ± 0.11	99 ± 1*	11.10 ± 1.10**

metry in synaptic plasma membranes (53) and that the content of both H-FABP and B-FABP decreases dramatically in brains of aged mice (54). Many of the brain FABP also change quantitatively with brain differentiation and development to adulthood (5,7,42). The effects of these brain FABP on intermembrane sterol transfer were specific in contrast to other brain lipid-binding proteins, SCP-2 and acyl-CoA-binding protein, also found in synaptosomes. As shown herein, SCP-2 stimulated intermembrane sterol transfer while acyl CoA-binding protein was ineffective (not shown). Consequently, the two brain H-FABP have opposing effects to SCP-2 on intermembrane sterol trafficking, and the ratio of these proteins as well as their cellular and subcellular localization may be important to regulation of several functional processes in brain.

Finally, H-FABP and B-FABP appear to be differentially expressed in brain. Although H-FABP is also highly expressed in skeletal and vascular smooth muscle, in brain H-FABP is also localized to neurons. For example, H-FABP was enriched 3.5- and 7-fold in synaptosomal cytosol as compared to brain homogenate and synaptosomal nerve endings, respectively (54). Furthermore, immunohistochemical studies show cerebellar neuronal staining with antisera to H-FABP (9) while *in situ* hybridization histochemistry demonstrated H-FABP mRNA expression in hippocampal neuronal layers and in cerebral cortex neurons (7,55). In contrast, B-FABP was enriched only 2.6- and 6-fold in synaptosomal cytosol as compared to brain homogenate and synaptosomal nerve endings. This, taken together with immunohistochemical (1) and *in situ* hybridization (55) data, suggests that B-FABP is primarily a glial protein.

In summary, the data presented herein show that with the exception of the N-terminal amino acid, the native H-FABP from mouse brain is identical to that derived from mouse heart. Two true isoforms were observed, most likely due to an amino acid Asp98/Asn98 or Gln100/Glu100 exchange. However, the isoform pattern of H-FABP in brain was distinct from that previously reported for heart. These data as well as the results of intracellular localization, fatty acid binding, and intermembrane sterol exchange studies indicate that H-FABP and B-FABP may be functionally involved in membrane lipid trafficking and distribution in brain, albeit in different cell types.

Metabolic Profile of Linoleic Acid in Stored Apples: Formation of 13(*R*)-Hydroxy-9(*Z*),11(*E*)-octadecadienoic Acid

Till Beuerle and Wilfried Schwab*

Lehrstuhl für Lebensmittelchemie, Universität Würzburg, D-97074 Würzburg, Germany

ABSTRACT: During our ongoing project on the biosynthesis of *R*-(+)-octane-1,3-diol the metabolism of linoleic acid was investigated in stored apples after injection of [1-^{14}C]-, [9,10,12,13-^{3}H]-,$^{13}C_{18}$- and unlabeled substrates. After different incubation periods the products were analyzed by gas chromatography–mass spectroscopy (MS), high-performance liquid chromatography–MS/MS, and HPLC-radiodetection. Water-soluble compounds and CO_2 were the major products whereas 13(*R*)-hydroxy- and 13-keto-9(*Z*),11(*E*)-octadecadienoic acid, 9(*S*)-hydroxy- and 9-keto-10(*E*),12(*Z*)-octadecadienoic acid, and the stereoisomers of the 9,10,13- and 9,12,13-trihydroxyoctadecenoic acids were identified as the major metabolites found in the diethyl ether extracts. Hydroperoxides were not detected. The ratio of 9/13-hydroxy- and 9/13-keto-octadecadienoic acid was 1:4 and 1:10, respectively. Chiral phase HPLC of the methyl ester derivatives showed enantiomeric excesses of 75 % (*R*) and 65 % (*S*) for 13-hydroxy-9(*Z*),11(*E*)-octadecadienoic acid and 9-hydroxy-10(*E*),12(*Z*)-octadecadienoic acid, respectively. Enzymatically active homogenates from apples were able to convert unlabeled linoleic acid into the metabolites. Radiotracer experiments showed that the transformation products of linoleic acid were converted into (*R*)-octane-1,3-diol. 13(*R*)-Hydroxy-9(*Z*),11(*E*)-octadecadienoic acid is probably formed in stored apples from 13-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid. It is possible that the *S*-enantiomer of the hydroperoxide is primarily degraded by enzymatic side reactions, resulting in an enrichment of the *R*-enantiomer and thus leading to the formation of 13(*R*)-hydroxy-9(*Z*),11(*E*)-octadecadienoic acid.

Paper no. L8069 in *Lipids 34,* 375–380 (April 1999).

Biosynthesis in fruits of aroma compounds, such as alcohols and esters, is directly associated with the metabolism of fatty acids and lipids (1). During our ongoing project on the biosynthesis of *R*-(+)-octane-1,3-diol in stored apples we observed that linoleic acid is the most efficient precursor for this antimicrobial diol (2).

Galliard (3) measured 880 and 947 mg of lipids, respectively, in 1 kg of pulp in pre- and postclimacteric Cox's Orange Pippin apples. Phospholipids constituted the largest category with amounts of 405 and 395 mg/kg fresh weight in pre- and postclimacteric apples, respectively. Recently, the lipid metabolism of ripening apples was investigated by Bartley (4). Fatty acids are generally esterified, and are found in very small amounts in the free state. The most abundant saturated and unsaturated fatty acids in apples are, respectively, hexadecanoic acid and linoleic acid, which represent 31 and 53% of total acids, respectively (5).

Previous experiments with homogenates of various plant materials with linoleic and linolenic acid have demonstrated that enzyme systems specifically degrading unsaturated fatty acids in the presence of oxygen are widely distributed in plant tissues (6). The key step is the dioxygenation of unsaturated fatty acids by lipoxygenase (7). The initial products of lipoxygenase action, i.e., hydroperoxides, are relatively unstable and cytotoxic. Fatty acid hydroperoxides are susceptible to nonenzymatic reactions such as isomerization, reduction, cleavage and radical polymerization and also to a variety of enzymatic processes catalyzing their further metabolism (8). Conversion of the hydroperoxide by, e.g., hydroperoxide lyases, hydroperoxide-dependent epoxygenases and allene oxide synthase results in the formation of compounds important for plant defense and as precursors of phytohormones (9).

The objective of the present study was the isolation and identification of the primary transformation products of linoleic acid in stored apples in order to understand the first steps of the biosynthesis of (*R*)-octane-1,3-diol.

MATERIALS AND METHODS

Materials. Linoleic acid and soybean lipoxygenase (LOX: Type I-S) were purchased from Sigma (Deisenhofen, Germany); linoleic acid-$^{13}C_{18}$ from Isotec (Miamisburg, OH), [1-^{14}C]linoleic acid (58 mCi/mmol) from DuPont (Boston, MA), [9,10,12,13-^{3}H]linoleic acid (60 Ci/mmol) from Biotrend (Köln, Germany), silica gel thin-layer chromatography (TLC) plates (0.25 mm, 60 F254) from Merck (Darmstadt, Germany). Solvents and reagents were of analytical or high-performance liquid chromatography (HPLC) grade. Fresh, ripe apple fruits (cv. Douce Moen) were kindly provided by Pernod Ricard, Créteil Cedex, France.

Synthesis of reference material. 13(*S*)-Hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid (13*S*-HPOD) was obtained

by incubating linoleic acid with soybean lipoxygenase (EC 1.13.11.12) (10–11) whereas 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid (9*S*-HPOD) was prepared using tomato lipoxygenase (12). Reduction of 13*S*-HPOD and 9*S*-HPOD with sodium borohydride afforded 13(*S*)-hydroxy-9(*Z*),11(*E*)-octadecadienoic acid (13*S*-HODE) and 9(*S*)-hydroxy-10(*E*),12(*Z*)-octadecadienoic acid (9*S*-HODE), respectively (13). 13-Keto-9(*Z*),11(*E*)-octadecadienoic acid (13-KODE) and 9-keto-10(*E*),12(*Z*)-octadecadienoic acid (9-KODE) were synthesized by the method of Andre and Funk (14). Reduction of 13-KODE and 9-KODE yielded racemic 13*R,S*-HODE and racemic 9*R,S*-HODE, respectively.

Application of fatty acids. Ethanolic solutions (100 µL) of [1-^{14}C]linoleic acid (5 µCi), [9,10,12,13-^{3}H]linoleic acid (50 µCi), linoleic acid $^{13}C_{18}$ (1 mg), and unlabeled linoleic acid (1 mg) were injected subepidermally with a syringe into ripe apples (*ca.* 40 g). Ten 10-µL aliquots were applied. The needle of the syringe was almost totally stuck into the apple, and the needle was carefully drawn back while the substrate was injected. The solution filled the space formed by the needle during the insertion into the apple. Apples were stored at 4°C while connected to a hood.

Isolation and identification of transformation products. Apples (*ca.* 40 g) were cut into small pieces and homogenized with 100 mL of water. After centrifugation (4000 × *g*, 15 min), the solid residue was extracted with 100 mL of water (3×). The supernatants were combined and passed through a conditioned XAD (polystyrene resin; Aldrich, Steinheim, Germany) column. After rinsing the column with 500 mL of water the products were eluted with 500 mL of diethyl ether and then 750 mL methanol. The diethyl ether extract was concentrated and was analyzed either by HPLC with ultraviolet (UV) and radiodetection or UV and evaporative light-scattering detection (ELSD). For the structural characterization two types of volatile derivatives were prepared: (i) samples were methylated by ethereal diazomethane solution and (ii) methyl esters were trimethylsilylated with a mixture of 1-(trimethylsilyl)-imidazole/pyridine (1:4 vol/vol) for at least 1 h at room temperature. After separation by RP18 (octadecyl reversed phase) chromatography, characterization of the stereoisomers of trihydroxy-octadecenoic acid was performed according to Hamberg (15,16). Separation of *cis*- and *trans*-1,4-diol isomers of methyl 9,10,13- and 9,12,13-trihydroxyoctadecenoates was achieved by TLC on silica gel and a solvent system consisting of diethyl ether/methanol 10:1 (15,16). Products were visualized by spraying with vanillin/H_2SO_4. For preparative TLC the products were applied as a band on the plate. After development a small strip of the aluminum TLC foil was cut off and sprayed with vanillin/H_2SO_4. The strip was used to localize the compounds on the plate. The bands were scraped off. Diastereomeric *cis*- and *trans*-1,4-diol isomers were silylated and separated by capillary gas chromatography–mass spectrometry (GC–MS) analysis on a DB 5 capillary column (15,16). Solid residues were dried at 80°C for 24 h. Aliquots of liquid samples were added to 10 mL of scintillation cocktail (Emulsifier-Safe: Packard, Groningen, The Netherlands). Solid samples were combusted in a biological oxidizer. The $^{14}CO_2$ formed was absorbed in 12 mL of the scintillation cocktail, Oxysolve 400 (Zinsser, Frankfurt, Germany). Recoveries of ^{14}C as $^{14}CO_2$ from test combustions fortified immediately before combustion with ^{14}C standards were greater than 90%. All measurements were carried out by means of liquid scintillation counting using corrections for chemiluminescence.

Stereochemical analysis of 13-HODE and 9-HODE. A mixture of ^{14}C- and a mixture of ^{3}H-labeled 13-HODE, 13-KODE, 9-HODE, and 9-KODE was obtained by semipreparative RP18-HPLC analysis, collecting the peaks eluting from 30–33 min (Fig. 1). The eluate was extracted (3×) with 3 mL of diethyl ether, and the combined organic phase was dried (Na_2SO_4) and concentrated. Individual compounds were separated by normal phase HPLC analysis (13). After methylation of 13-HODE and 9-HODE, separation of the enantiomers was achieved by chiral phase HPLC analysis. The enantiomers were collected and the radioactivity was determined by liquid scintillation counting.

Homogenate. Apples were homogenized in 600 mL 0.1 M acetate buffer pH 4.5 containing 2 mM ascorbic acid and 2 mM $Na_2S_2O_5$. An ethanolic solution (5 mL) of linoleic acid (150 mg) was added, and aliquots were withdrawn after 1, 2, 4, 6, 24, and 48 h. Samples were filtered and directly analyzed by HPLC analysis.

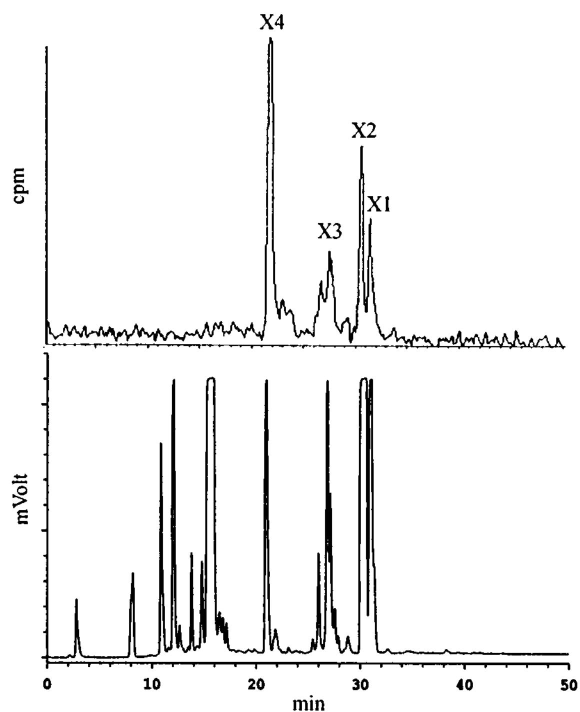

FIG. 1. Reverse-phase high-performance liquid chromatographic separation of the diethyl ether extract obtained by XAD (polystyrene resin) solid phase extraction from an apple incubated with [1-^{14}C]linoleic acid for 12 h. The upper panel shows the signal of the radiodetector and the lower panel depicts the evaporative light-scattering detector signal. Compounds eluting between 0 and 20 min are endogenous apple constituents.

GC–MS analysis. Analysis of the methylated and/or silylated products was performed by using a Fisons MD 800 Quadrupol mass spectrometer coupled to a Fisons GC 8000 with split injector (1:20) equipped with Fisons MassLab software (version 1.3). A J&W (Folsom, CA) DB5 fused-silica capillary column (30 m × 0.25 mm i.d.; film thickness, 0.25 µm), which was programmed from 60 to 300°C at 5°C/min, was used with helium gas at a flow rate of 3 mL/min. The MS operating parameters were: ionization voltage, 70 eV (electron impact ionization); ion source and interface temperature, 280 and 290°C, respectively.

HPLC analysis. Reverse-phase HPLC was carried out on a Eurospher 100 C-18 column (250 × 4 mm, 5 µm; Knauer, Berlin, Germany) using a flow rate of 1 mL/min, employing a Knauer HPLC pump MaxiStar coupled on-line to a Knauer multiwavelength UV/visible detector (205, 234, or 254 nm) and an ELSD (Sedere, Alfortville Cedex, France) at 40°C and 2.4 bar compressed air. Data acquisition was achieved using Eurochrom 2000 software (Knauer). Radio-HPLC was conducted using a Waters HPLC system equipped with a variable wavelength detector and a Canberra Packard A100 radioactivity detector with a 300 µL YSi scintillation tube. The following gradient was applied: solvent A (0.05% formic acid), solvent B (CH_3CN): 0–30 min, 5–80% B, 30–40 min, 80–100% B, 40–45 min, 100% B.

Normal phase HPLC analysis was performed on a Eurospher Si 100 column (250 × 4.6 mm, 5 µm, Knauer) using a mixture of isohexane/isopropanol/acetic acid (98:2:0.5 by vol) at a flow rate of 1 mL/min. Chiral phase HPLC analysis was carried out on a Chiralcel OB-H (250 × 4.6 mm, 5 µm) (Daicel) using a mixture of isohexane/isopropanol (100:7) at a flow rate of 0.5 mL/min.

Liquid chromatography (LC)–MS analysis. Analysis of the products and isolates was performed using a triple-stage quadrupole TSQ 7000 LC–MS/MS system with electrospray ionization (ESI) interface (Finnigan MAT, Bremen, Germany) in the positive mode. The temperature of the heated capillary was 220°C. ESI capillary voltage was set to 3.5 kV, resulting in 6.6 µA current. Nitrogen served both as sheath (70 psi) and auxiliary gas (10 L/min). Data acquisition and evaluation were carried out on a Personal DECstation 5000/33 (Digital Equipment, Unterföhring, Germany) and ICIS 8.1 software (Finnigan MAT).

Nuclear magnetic resonance (NMR). ^{1}H and ^{13}C NMR spectra were recorded on a Bruker WM 400 spectrometer with $CDCl_3$ (Merck) as solvent.

RESULTS

Identification of transformation products. Linoleic acid-$^{13}C_{18}$, [1-^{14}C], and [9,10,12,13-^{3}H]linoleic acid were injected subepidermally into ripe apples cv. Douce Moen. The fruits were stored up to 4 d at 4°C, extracted with water, and the extract subjected to solid phase extraction. Tables 1 and 2 show the ^{14}C and ^{3}H recovery data, respectively, for the different fractions as a percentage of the applied radioactivity. A high amount of $^{14}CO_2$ is produced within 24 h, indicating a rapid degradation of linoleic acid by β-oxidation. The slight increase in $^{14}CO_2$ production after the first day is probably caused by the degradation of the oxyfunctionalized transformation products formed from linoleic acid. This hypothesis is supported by the fact that at day 4 the diethylether extract contained almost no ^{14}C radioactivity but still had ^{3}H activity. Therefore, linoleic acid has lost the labeled carbon by β-oxidation while degradation products carrying the tritium label are still available (Table 2).

TABLE 1
Distribution of Recovered ^{14}C (expressed as percentage of total uptake) in Different Fractions After the Application of [1-^{14}C]Linoleic Acid to Apples

	Days

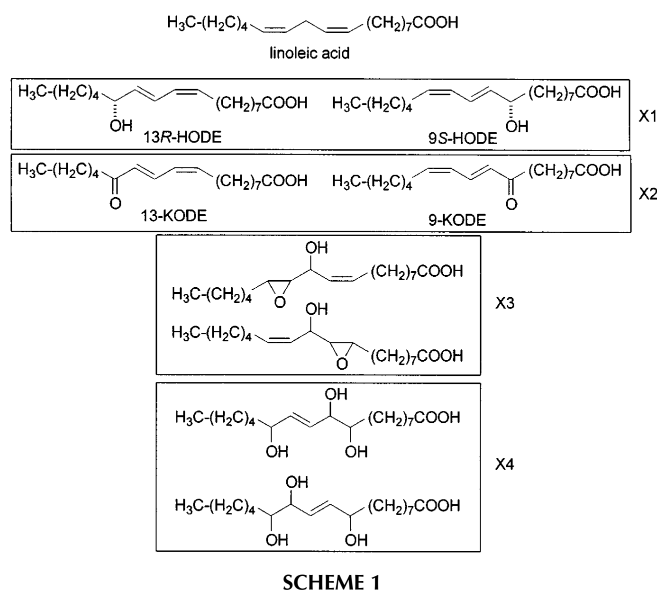
Analysis of the diethyl ether extracts obtained by XAD (polystyrene resin) solid phase extraction was performed by HPLC (Fig. 1). After 12 h applied linoleic acid was already completely degraded. Four new compounds (Fig. 1: X1–X4) were detected by radiodetection and ELSD. Product X1 was identified as a mixture of 13-KODE and 9-KODE (ratio 10:1) after methylation by GC–MS analysis and by comparison with the synthesized reference compounds (Scheme 1). LC–MS analysis of X1 showed characteristic ions at *m/z* 295 $[M + H]^+$, *m/z* 312 $[M + NH_4]^+$, and *m/z* 317 $[M + Na]^+$. GC–MS analysis of X1 formed after application of linoleic acid-$^{13}C_{18}$ showed the typical pattern for uniformly labeled 13-KODE and 9-KODE in addition to the unlabeled derivatives. Product X2 consisted of a mixture of 13-HODE and 9-HODE (ratio 4:1) (Scheme 1). The mass spectral data of derivatized X2 were in accordance with those for the reference material. Uniformly labeled and unlabeled 13-HODE and 9-HODE were detected after the application of linoleic acid-$^{13}C_{18}$. On the basis of the mass spectrum of its methyl ester trimethyl silyl (TMS) ether derivatives, X3 was tentatively



SCHEME 1

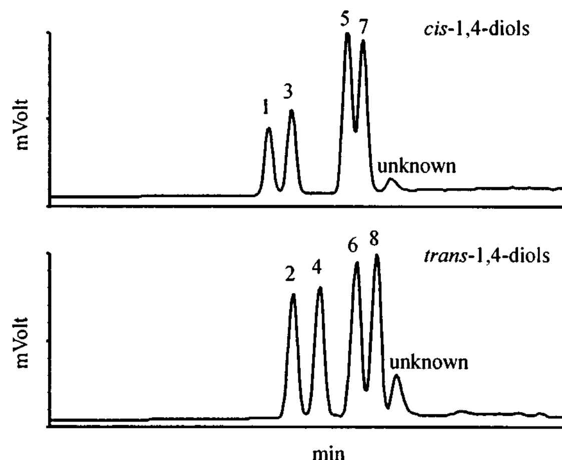


FIG. 2. Gas chromatographic separation of trimethyl silyl derivatives of trihydroxy-methyl esters obtained by incubation of linoleic acid with apples. Peak 1: 9,10,13-trihydroxy *threo/cis*-1,4-diol; peak 2: 9,10,13-trihydroxy *threo/trans*-1,4-diol; peak 3: 9,10,13-trihydroxy *erythro/cis*-1,4-diol; peak 4: 9,10,13-trihydroxy *erythro/trans*-1,4-diol; peak 5: 9,12,13-trihydroxy *threo/cis*-1,4-diol; peak 6: 9,12,13-trihydroxy *threo/trans*-1,4-diol; peak 7: 9,12,13-trihydroxy *erythro/cis*-1,4-diol; peak 8: 9,12,13-trihydroxy *erythro/trans*-1,4-diol.

assigned as a mixture of 11-hydroxy-12,13-epoxy-9-octadecenoic acid and 11-hydroxy-9,10-epoxy-12-octadecenoic acid (17–19) (Scheme 1). The assumption is supported by the LC–MS analysis displaying ions of *m/z* 330 $[M + NH_4]^+$ and *m/z* 335 $[M + Na]^+$. Product X4 was separated by preparative RP18 chromatography, and nuclear magnetic resonance analysis revealed the occurrence of positional isomers of trihydroxy-octadecenoic acids (Scheme 1). LC–MS analysis displayed pseudomolecular ions at *m/z* 348 $[M + NH_4]^+$ and *m/z* 353 $[M + Na]^+$. Product X4 was methylated, and the derivatives were resolved on silica gel-coated TLC plates into *cis*-1,4- and *trans*-1,4-diol according to Hamberg (15). Each fraction was converted into the TMS derivative and analyzed by GC–MS (Fig. 2). A mixture of the positional isomers was obtained. Since all isomers showed almost the same intensity it was expected that the trihydroxy-octadecenoic acids are formed by chemical transformation during the long incubation period (16). Therefore, steric analysis of trihydroxy-octadecenoic acids was not performed. Many plants contain a hydroperoxide peroxygenase/epoxygenase system. In that case one positional isomer of the trihydroxy-octadecenoic acids is enriched (16). Hence, we have no indication for a peroxygenase pathway.

Steric analysis of 13-HODE and 9-HODE. Although lipoxygenase from apples has been investigated by several authors (3,20), the stereochemistry of the products formed by this enzyme is still unknown. Despite intensive LC–MS analysis according to Schneider *et al.* (11), linoleic acid hydroperoxides (HPOD) were not detected as primary products during the metabolism study in apples (Fig. 1). One reason might be the long incubation period of 12 h. However, high amounts of 13-HODE and 9-HODE, formed by enzymatic reduction of HPOD, have been identified. In order to quantify the enantiomers of 13-HODE and 9-HODE, ^{14}C- and ^{3}H-labeled alcohols were purified by semipreparative reverse-phase HPLC analysis followed by semipreparative normal phase HPLC analysis according to Wu *et al.* (13). Separation of the enantiomers was achieved on a Chiralcel OB-H HPLC column. Unlabeled synthesized 13*S*-HODE, 9*S*-HODE, 13*R*,*S*-HODE, and 9*R*,*S*-HODE were added as carrier. The individual enantiomers were collected and quantified by liquid scintillation counting. The enantiomeric ratios of 13-HODE and 9-HODE obtained in the experiments with the ^{14}C- and ^{3}H-labeled substrates were very similiar. 13-HODE and 9-HODE exhibited an enantiomeric excess of *ca.* 75% (*R*) and 65% (*S*), respectively (Fig. 3).

Homogenate. Apples were homogenized in acetate buffer of pH 4.5, and unlabeled linoleic acid was added. Although the solution was analyzed after 1 h of incubation, major products (9-HODE, 13-HODE, 9-KODE, 13-KODE) were detected by ELSD only after 2 h. Trihydroxy-octadecenoic acids were the main metabolites after 48 h.

DISCUSSION

Lipoxygenase from apples has always been studied in relation to its formation of C6 aldehydes such as hexanal and (3*Z*)- and (2*E*)-hexenals, important flavor compounds of apples. A lipoxygenase was extracted from apples and partially purified (21,22). The enzyme belongs to the LOX II type but shows a relatively high specificity toward the dioxygenation of position 13 (82% 13-HPOD:18% 9-HPOD) (21,22). Stereochemical analysis of the products has not been performed until now.

During our investigation on the metabolism of linoleic acid in stored apples we identified 13-HODE, 9-HODE, 13-KODE, and 9-KODE as major metabolites. At first glance the formation of these compounds can be explained by oxidation

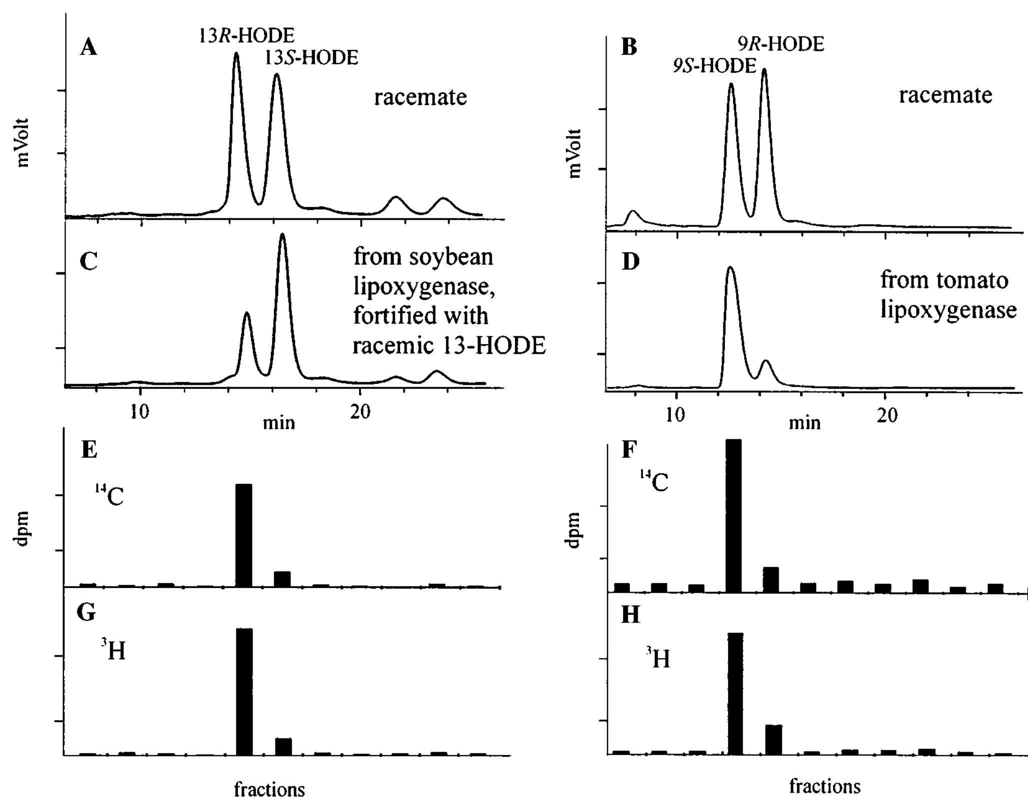

FIG. 3. Ultraviolet (UV) detection of the separation of racemic standards (A, B); UV detection of the separation of soybean lipoxygenase products, fortified with racemic 13-hydroxy-octadecadienoic acid (13-HODE) (C) as well as the separation of tomato lipoxygenase products (D). ^{14}C and ^{3}H in 13*R*- and 13*S*-HODE (E, G) as well as in 9*R*- and 9*S*-HODE (F, H) obtained from apple fruits incubated with labeled linoleic acid.

and reduction of the respective linoleic acid hydroperoxides (HPOD) formed by the action of LOX. Although we could not detect any hydroperoxides in apples we revealed the stereochemistry of the major metabolite 13-HODE to be *R*. Almost all plant LOX so far studied catalyze the formation of *S*-configured hydroperoxides. Only LOX from peas and the LOX type II enzymes from soybean seeds have been reported to form *R*-hydroperoxides (23). However, enzymes from several species of invertebrate, such as sea urchin, starfish and coral, express LOX which produce *R*-hydroperoxides (24,25). Recently, an arachidonic acid (8*R*)-LOX was cloned and sequenced (24), and the formation of (13*R*)-hydroperoxy-(9*Z*,11*E*)-octadecadienoic acid (13*R*-HPOD) by manganese LOX from the fungus *Gäumannomyces graminis* was demonstrated (25). In apples, 13*R*-HODE might be formed either by a (*R*)-LOX followed by enzymatic reduction of the hydroperoxide or by a bisallylic oxidation catalyzed by a cytochrome P450 monooxygenase followed by double-bond migration (26). As lyases degrade predominantly 13*S*-HPOD, 13*R*-HODE might also be generated by reduction of the remaining 13*R*-HPOD (27–29).

The linoleic acid metabolites 11-hydroxy-12,13-epoxy-9-octadecenoic acid and 11-hydroxy-9,10-epoxy-12-octadecenoic acid, tentatively identified in this report, have been described as nonenzymatic degradation products of 13-HPOD (17,19,30), but they have also been reported to be free-radical decomposition products of 13-HPOD through formation of alkoxyl radicals (19). Nevertheless, the occurrence of the epoxy fatty acids gives a strong hint to the existence of hydroperoxides as their metabolic precursors in apples.

An indication for the nonenzymatic formation of the trihydroxy-octadecenoic acids is given by the observation that equal amounts of the stereoisomers were formed. This is not surprising, as apples have an internal pH of 3.5, sufficient to catalyze the rearrangement of unstable epoxides. In summary, the metabolic profile of linoleic acid in stored apples resembles the pattern obtained for the metabolism of linoleic acid in porcine leukocytes (31) and wheat (32) for which a predominant formation of LOX-derived products at position C-13 could be demonstrated.

Homogenates prepared from apples showed in principle the same product pattern after incubation with unlabeled linoleic acid as the intact apples. After prolonged incubation periods high amounts of trihydroxy acids accumulated, probably by chemical transformations, like the homolysis of hydroperoxides and autoxidation of linoleic acid. However, in apples the trihydroxy acids are probably further degraded by β-oxidation as can be seen by comparison of the recovery data for ^{14}C and ^{3}H in the diethyl ether extracts (Table 1 and 2). Radiotracer experiments showed that the transformation

products of linoleic acid were converted into (*R*)-octane-1,3-diol. However, the incorporation of the oxylipids into (*R*)-octane-1,3-diol was lower than the incorporation of linoleic acid (Beuerle, B., and Schwab, W., unpublished results).

Metabolism of *Trans* Fatty Acids by Hepatocytes

Manuel Guzmán[a], Wil Klein[b], Teresa Gómez del Pulgar[a], and Math J.H. Geelen[b,*]

[a]Department of Biochemistry and Molecular Biology I, School of Biology, Complutense University, 28040-Madrid, Spain, and [b]Laboratory of Veterinary Biochemistry, Utrecht University, 3508 TD Utrecht, The Netherlands

ABSTRACT: The present work was undertaken to study the metabolism of fatty acids with *trans* double bonds by rat hepatocytes. In liver mitochondria, elaidoyl-CoA was a poorer substrate for carnitine palmitoyltransferase I (CPT-I) than oleoyl-CoA. Likewise, incubation of hepatocytes with oleic acid produced a more pronounced stimulation of CPT-I than incubation with *trans* fatty acids. This was not due to a differential effect of *cis* and *trans* fatty acids on acetyl-CoA carboxylase (ACC) activity and malonyl-CoA levels. Elaidic acid was metabolized by hepatocytes at a higher rate than oleic acid. Surprisingly, compared to oleic acid, elaidic acid was a better substrate for mitochondrial and, especially, peroxisomal oxidation, but a poorer substrate for cellular and very low density lipoprotein triacylglycerol synthesis. Results thus show that *trans* fatty acids are preferentially oxidized by hepatic peroxisomes, and that the ACC/malonyl-CoA/CPT-I system for coordinate control of fatty acid metabolism is not responsible for the distinct hepatic utilization of *cis* and *trans* fatty acids.

Paper no. L8053 in *Lipids 34*, 381–386 (April 1999).

Trans fatty acids are geometrical isomers of unsaturated fatty acids that adopt a saturated fatty acid-like configuration. Human diets contain *trans* fatty acids derived from animal sources (e.g., dairy products and ruminant meats), but most are supplied by products containing industrially hydrogenated vegetable oils (e.g., margarines, shortenings, and baked goods) (1–3). A number of clinical studies have shown that, in contrast to *cis*-monounsaturated fatty acids (e.g., oleic acid), *trans*-monounsaturated fatty acids (e.g. elaidic acid) increase plasma levels of total cholesterol, total triacylglycerols, and low density lipoprotein (LDL) cholesterol, whereas they decrease plasma levels of high density lipoprotein (HDL) cholesterol (1–3). In addition, *trans* fatty acids may tend to increase the plasma concentration of the atherogenic lipoprotein (a) (1–3). Thus, intake of *trans* fatty acids may have an adverse effect on the plasma lipid profile, which represents an increased risk for cardiovascular diseases (1–4). On the basis of this evidence, claims have been made that the *trans* fatty acid content should be included on food labels (5). Other studies, however, have concluded that *trans* fatty acids do not significantly affect plasma cholesterol and triacylglycerol levels, and therefore the effect of dietary *trans* fatty acids on the plasma lipid profile remains controversial (1–4).

In spite of the important body of evidence showing that dietary *trans* fatty acids have a negative impact on plasma lipids, the mechanism responsible for this effect is as yet unknown. Since the liver is a major site of plasma lipoprotein generation, a possibility would be that inherent differences in the metabolism of *cis* and *trans* fatty acids occur in the liver. Indeed, it has been put forward that a distinct partitioning of *cis* fatty acids and saturated fatty acids between hepatic esterification and oxidation may be a factor responsible for the different effects of these two types of fatty acids on plasma lipid levels in the hamster (6). The present study was therefore designed to investigate the metabolic fate of *trans* fatty acids compared to *cis* fatty acids in hepatocytes. Special emphasis was put on two key enzymes of hepatic fatty acid metabolism, *viz.*, carnitine palmitoyltransferase I (CPT-I) and acetyl-CoA carboxylase (ACC), which catalyze the pace-setting steps of mitochondrial fatty acid oxidation and of fatty acid synthesis *de novo*, respectively (7–9).

EXPERIMENTAL PROCEDURES

Materials. [1-^{14}C]Elaidic acid and [1-^{14}C]oleic acid were supplied by ARC (St. Louis, MO). The various unlabeled fatty acids were supplied by Sigma (St. Louis, MO). Tetradecylglycidic acid (TDGA) was kindly donated by Dr. J.M. Lowenstein (Brandeis University, Waltham, MA).

Isolation and incubation of hepatocytes. Male Wistar rats (200–250 g) which had free access to food and water were used throughout this study. Hepatocytes were isolated and incubated as described in Reference 10.

Assay of CPT-I activity. CPT-I activity was determined as the incorporation of radiolabeled carnitine into acylcarnitine by two previously described procedures.

(*i*) CPT-I activity was determined in isolated mitochondria with elaidoyl-CoA or oleoyl-CoA as substrate (11). Mitochondrial preparations were obtained from rat hepatocytes and were practically devoid of peroxisomes, as judged from the low recovery (<5%) of catalase activity (11). The assay mixture consisted of 25 mM Tris-HCl, pH 7.4, 150 mM su-

crose, 60 mM KCl, 1 mM EDTA, 1 mM dithioerythritol, 2 mg/mL defatted and dialyzed bovine serum albumin, 0.5 mM L-[*Me*-^{3}H]carnitine (1 Ci/mol) and varying concentrations of acyl-CoA. Reactions were carried out at 30°C for 2 min (the assay proceeds at a linear rate up to 4 min). Carnitine palmitoyltransferase (CPT) activity that was insensitive to 100 μM malonyl-CoA was always subtracted from the CPT activity experimentally determined. This malonyl-CoA-insensitive CPT activity routinely accounted for 5–10% of the total CPT activity experimentally determined.

(*ii*) CPT-I activity was determined in digitonin-permeabilized hepatocytes with palmitoyl-CoA as substrate exactly as described in Reference 12. Reactions were carried out at 37°C for 1 min (the assay proceeds at a linear rate up to 1.5 min). Evidence has been presented showing that the contribution of CPT-I to the total TDGA-sensitive CPT pool is very high (>85%); in contrast, microsomal CPT and peroxisomal CPT together only make a minor contribution (<15%) to the TDGA-sensitive CPT pool under the same assay conditions (12,13). Therefore, determination of CPT-I activity by the permeabilized-hepatocyte procedure is not prone to substantial error.

Assay of ACC activity. ACC activity was determined as the incorporation of radiolabeled acetyl- CoA into fatty acids in a reaction coupled to the fatty acid synthase reaction by two previously described procedures.

(*i*) ACC activity was determined in cytosolic fractions that were prepared from rat hepatocytes as described in References 14 and 15. The assay mixture consisted of 78 mM Hepes, pH 7.5, 125 mM mannitol, 2.5 mM 2-mercaptoethanol, 3 mM EDTA, 1 mM citrate, 5 mM $MgCl_2$, 2 mM ATP, 20 mM $KHCO_3$, 1 mg/mL defatted and dialyzed bovine serum albumin, 0.5 mM dithioerythritol, 0.5 mM NADPH, 0.062 mM butyryl-CoA, 0.062 mM [1-^{14}C]acetyl-CoA (4 Ci/mol), 3.2 mU fatty acid synthase, and, optionally, 150 μM acyl-CoA. Reactions were carried out at 37°C for 1 min (the assay proceeds at a linear rate up to 1.5 min). The rest of this procedure was performed as in Reference 16.

(*ii*) ACC activity was determined in digitonin-permeabilized hepatocytes exactly as described in Reference 16. Reactions were carried out at 37°C for 4 min (the assay proceeds at a linear rate up to 9 min). Although a large fraction (50–70%) of total hepatocellular ACC does not leak out from the hepatocytes under the permeabilization conditions used (15,16), evidence has been presented showing that ACC activity remaining inside the permeabilized hepatocytes is also measured (16).

Rates of fatty acid metabolism. (*i*) The rate of [^{14}C]fatty acid oxidation was determined as the formation of acid-soluble products (which mostly constitute ketone bodies) and CO_2 (17). Briefly, incubations were carried out at 37°C in the presence of 0.5 mM albumin-bound [1-^{14}C]fatty acid (0.1 Ci/mol) and stopped with 0.3 mL 2 M $HClO_4$ after 30 min (reactions proceed at a linear rate up to 45 min). At the same time, 0.15 mL of benzethonium hydroxide (1 M in methanol) was injected in a center well containing filter paper. Samples were allowed to equilibrate for an additional hour at 4°C, and the center well (with the CO_2 fixed as bicarbonate) was transferred to vials for radioactive counting. The cell precipitate was spun down, and supernatants were washed three times with light petroleum ether. Acid-soluble products were subsequently extracted from the samples as the aqueous phase of the Bligh and Dyer lipid extraction procedure (18). In some experiments, acetoacetate and 3-hydroxybutyrate produced from unlabeled fatty acids were quantified by standard spectrophotometric methods (19).

TDGA, a specific inhibitor of CPT-I and therefore of mitochondrial long-chain fatty acid oxidation, was used to determine separately the mitochondrial and peroxisomal oxidation of [^{14}C]fatty acids. Thus, the former was calculated as TDGA-sensitive oxidation, whereas the latter was measured as TDGA-insensitive oxidation (12). This method does not take into account the fact that peroxisomes degrade fatty acids only partially. However, the use of specific inhibitors of CPT-I to determine peroxisomal fatty acid oxidation, although it may yield overestimated values, is a widely valuated procedure (*cf.* 12,20).

(*ii*) The rate of [^{14}C]fatty acid incorporation into cellular and very low density lipoprotein (VLDL) lipids was monitored as described before (21). Briefly, incubations were carried out at 37°C in the presence of 0.5 mM albumin-bound [1-^{14}C]fatty acid (0.1 Ci/mol). Reactions were stopped after 60 min (reactions proceed at a linear rate up to 90 min for cellular lipid synthesis, and between 30 and 90 min for VLDL lipid secretion). Then, cells were transferred to centrifuge tubes and separated from the incubation medium, from which VLDL were isolated. Cellular and VLDL lipids were extracted (18) and subsequently resolved by thin-layer chromatography (21).

Malonyl-CoA concentration. Intracellular levels of malonyl-CoA were determined in neutralized perchloric acid cell extracts by a radioenzymatic method (21).

Statistical analysis. Results shown represent the means ± SD of the number of animals indicated in each case. Cell incubations and/or enzyme assays were always carried out in triplicate. Statistical analysis was performed by the Student *t* test.

RESULTS

Effect of trans *fatty acids on the ACC/malonyl-CoA/CPT-I system.* Experiments were conducted to ascertain the effect of elaidic acid (*trans*-9-octadecenoic acid) compared to that of its *cis* counterpart oleic acid (*cis*-9-octadecenoic acid) on CPT-I activity. In isolated hepatic mitochondria, elaidoyl-CoA was a poorer substrate for CPT-I than oleoyl-CoA over a broad range of acyl-CoA concentrations (Fig. 1A). Similar results were observed when bovine serum albumin was excluded from the assay mixture (Fig. 1B), indicating that the observed differences in CPT-I activity were not due to different binding affinities of the two acyl-CoA molecules for bovine serum albumin. When bovine serum albumin was absent from the assays, concentrations of the two acyl-CoA

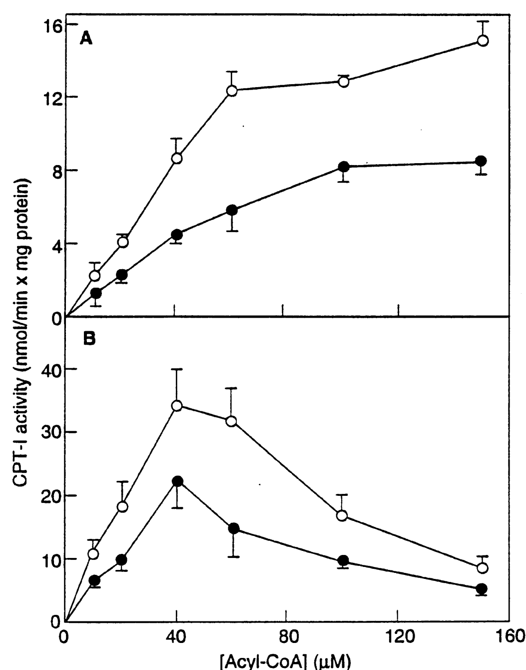

FIG. 1. Carnitine palmitoyltransferase I (CPT-I) activity in liver mitochondria with elaidoyl-CoA and oleoyl-CoA as substrates. Isolated liver mitochondria were incubated in the presence (Panel A) or absence (Panel B) of 2.0 mg/mL defatted and dialyzed bovine serum albumin, and CPT-I activity was determined with oleoyl-CoA (○) or elaidoyl-CoA (●) as substrate. Results correspond to four (Panel A) or three (Panel B) different experiments.

molecules higher than about 40 μM were inhibitory (Fig. 1B), possibly owing to detergent action.

CPT-I activity was subsequently determined in digitonin-permeabilized hepatocytes. As shown in Table 1, CPT-I activity increased when isolated hepatocytes were preincubated with a number of monounsaturated C_{18} nonesterified fatty acids. The maximal stimulation of CPT-I activity was evident after 10 min of cell exposure to the fatty acids. This maximal stimulation kept constant for up to at least 30 min (results not shown). Interestingly, CPT-I became much more activated by oleic acid than by the three *trans* acids tested, namely, elaidic acid, petroselaidic acid (*trans*-6-octadecenoic acid), and *trans*-vaccenic acid (*trans*-11-octadecenoic acid). Peroxisomal CPT activity was not affected by the different fatty acids tested (results not shown). Although a number of cellular modulators have been shown to exert stable short-term modifications of CPT-I activity (e.g., 7,11), the stimulatory effect of the C_{18} fatty acids on CPT-I was labile, since it did not survive extensive washing of the permeabilized cells prior to the assay of enzyme activity (results not shown).

The different stimulatory effects of *cis* and *trans* fatty acids on CPT-I might be due to their different effects on the activity of ACC, the enzyme that catalyzes the formation of malonyl-CoA, a well-established physiological inhibitor of CPT-I (7–9). However, when hepatocytes were incubated with either *cis* or *trans* fatty acids, a quantitatively similar decrease of ACC activity and intracellular malonyl-CoA levels ensued (Table 1). Likewise, elaidoyl-CoA and oleoyl-CoA exerted similar inhibitory effects on ACC activity as determined in a cytosolic fraction. Thus, ACC activity (in nmol/min × mg protein) was 1.25 ± 0.16 with no additions, 0.39 ± 0.05 with 150 μM oleoyl-CoA, and 0.44 ± 0.06 with 150 μM elaidoyl-CoA (n = 3). Hence, a malonyl-CoA-independent mechanism seems to be responsible for the differential stimulation of CPT-I by *cis* and *trans* fatty acids.

Metabolism of [^{14}C]elaidic acid in hepatocytes. The metabolism of [^{14}C]elaidic acid was subsequently studied in isolated hepatocytes. Although CPT-I is generally considered to play a key regulatory role in the control of fatty acid oxidation by hepatic mitochondria (7–9), Table 2 shows that the formation of acid-soluble products was surprisingly higher with [^{14}C]elaidic acid than with [^{14}C]oleic acid as substrate. CO_2 production was also higher from [^{14}C]elaidic acid than from [^{14}C]oleic acid (Table 2).

The contribution of the mitochondrial and the peroxisomal compartment to total hepatocellular fatty acid oxidation was determined. As shown in Table 2, [^{14}C]elaidic acid was a better substrate than [^{14}C]oleic acid for both mitochondrial and peroxisomal oxidation. Interestingly, the contribution of peroxisomal oxidation was significantly higher for [^{14}C]elaidic acid than for [^{14}C]oleic acid (Table 2). In order to corroborate that mitochondrial acid-soluble product formation actually reflects ketogenesis, the mass of ketone bodies (acetoacetate plus 3-hydroxybutyrate) was enzymatically determined. Sim-

TABLE 1
Effect of *Cis* and *Trans* Fatty Acids on ACC Activity, Malonyl-CoA Levels, and CPT-I Activity in Hepatocytes[a]

Addition	ACC activity (nmol/min × mg protein)	Malonyl-CoA (pmol/mg protein)	CPT-I activity (nmol/min × mg protein)
None	0.38 ± 0.04	64 ± 11	1.32 ± 0.22
Oleic acid	0.19 ± 0.03*	30 ± 7*	2.62 ± 0.16*

Total	1.69 ± 0.51	1.64 ± 0.51
Triacylglycerols	0.97 ± 0.21	0.59 ± 0.20**
Phospholipids	0.31 ± 0.17	0.39 ± 0.19
Cholesterol esters	0.09 ± 0.06	0.07 ± 0.03
Total [^{14}C]fatty acid metabolized	32.43 ± 3.77	42.57 ± 3.79*

[a]Hepatocytes were incubated with 0.5 mM [^{14}C]oleic acid or [^{14}C]elaidic acid except for the determination of ketone bodies, for which incubations contained 0.5 mM of the unlabeled fatty acids. In the latter case endogenous ketone body production was subtracted. The rates of oxidation, esterification, and VLDL lipid production were determined. Results correspond to three different experiments. Compared to the corresponding incubations with oleic acid: *$P < 0.01$; **$P < 0.05$. VLDL, very low density lipoprotein.

ilar results were obtained as with acid-soluble product formation, i.e., elaidic acid was observed to be a better substrate for ketogenesis than oleic acid (Table 2).

Since the fatty acid concentration may influence the relative contributions of mitochondria and peroxisomes to hepatic fatty acid oxidation (22), experiments were subsequently performed with different doses of the fatty acids. Figure 2 shows that mitochondrial and—especially—peroxisomal oxidation of [^{14}C]elaidic acid was higher than that of [^{14}C]oleic acid in the range of 0.2–0.8 mM fatty acid.

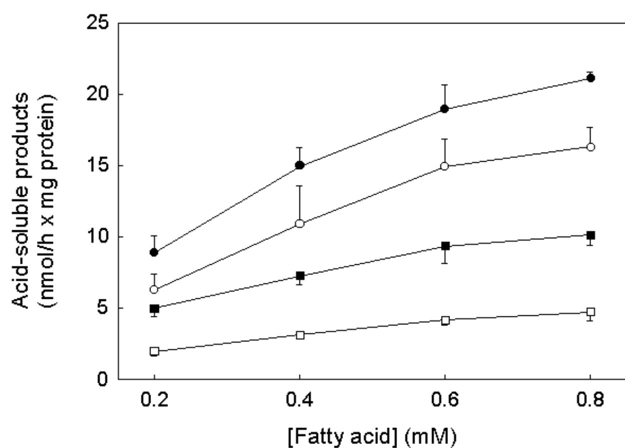

FIG. 2. Mitochondrial and peroxisomal oxidation of [^{14}C]elaidic acid and [^{14}C]oleic acid in hepatocytes. Cells were incubated with varying concentrations of [^{14}C]oleic acid (○,□) or [^{14}C]elaidic acid (●,■), and the formation of mitochondrial (○,●) and peroxisomal (□,■) acid-soluble products was quantified. Results correspond to three different experiments.

The incorporation of [^{14}C]elaidic acid into both cellular and VLDL triacylglycerols was lower than that of [^{14}C]oleic acid (Table 2). In contrast, an increase in the incorporation of [^{14}C]elaidic acid into phospholipids was evident (Table 2). Table 2 also shows that the total amount of [^{14}C]elaidic acid metabolized by hepatocytes was higher than that of [^{14}C]oleic acid, indicating that factors in addition to the modulation of the balance between oxidation and esterification may be involved in the different utilization of *cis* and *trans* fatty acids by the liver.

DISCUSSION

Liver peroxisomes exhibit a preference for oxidizing trans *fatty acids rather than* cis *fatty acids*. Although there is general agreement that the fatty acids that are more abundant in a normal diet are preferentially oxidized in mitochondria rather than in peroxisomes, some types of fatty acids (e.g., very long chain, branched-chain, and dicarboxylic fatty acids) are mostly oxidized in peroxisomes (22,23). The present report shows that the rate of peroxisomal oxidation of elaidic acid is about 2.5-fold that of oleic acid. Since the entry of long-chain acyl-CoA into peroxisomes is independent of a CPT system (22,23), this preferential utilization of trans fatty acids by peroxisomes may reflect a substrate specificity of the peroxisomal β-oxidation equipment.

Elaidic acid was shown to be a poorer substrate than oleic acid for the synthesis of both cellular and VLDL triacylglyc-

erols in rat hepatocytes. If these observations could be extrapolated to the *in vivo* situation, other mechanisms should be responsible for the putative hyperlipidemic effect of *trans* fatty acids. In addition, a preferential incorporation of elaidic acid into hepatic phospholipids was observed, in line with data obtained by Fukuda *et al.* (24) on the metabolism of *trans*, *trans*-9,12-octadecadienoic acid in the perfused rat liver. The regulation of liver phospholipid biosynthesis involves a number of mechanisms distinct from those acting in liver triacylglycerol formation (25,26). However, the reason for the diversion of *trans* fatty acids into phospholipid synthesis is as yet unknown.

The ACC/malonyl-CoA/CPT-I system is not responsible for the distinct oxidation of cis *and* trans *fatty acids by liver mitochondria*. Short-term changes in CPT-I activity are usually accompanied by parallel changes in the rate of long-chain fatty acid oxidation (7). In addition, under pathophysiological situations in which long-chain fatty acid oxidation is induced, CPT-I activity increases, and vice versa (8,9). These short- and long-term changes in CPT-I activity usually (though not always) occur in concert with reciprocal changes in ACC activity and malonyl-CoA levels (7–9). The ACC/malonyl-CoA/CPT-I system is therefore considered to play a central role in the control of the flux through the fatty acid-oxidative pathway (7–9). However, the ACC/malonyl-CoA/CPT-I system is not responsible for the distinct hepatic utilization of *cis* and *trans* fatty acids. This assumption is mainly based on the observation that incubation of hepatocytes with oleic acid produces a much more pronounced stimulation of CPT-I than incubation with various *trans* fatty acids, in spite of the quantitatively similar depressive effect of oleic acid and the *trans* fatty acids on ACC activity and malonyl-CoA levels. In addition, although in isolated hepatocytes mitochondrial oxidation is more active toward elaidic acid than toward oleic acid, elaidoyl-CoA is a poorer substrate than oleoyl-CoA for CPT-I in isolated liver mitochondria. Our data therefore indicate that one or more steps involved in the intramitochondrial oxidation of fatty acids exert(s) preference for elaidic acid over oleic acid. This is also suggested by the observation that the total utilization of elaidic acid by hepatocytes is higher than that of oleic acid, i.e., the increased mitochondrial oxidation of elaidic acid is not simply due to a preferential shift of this fatty acid from esterification to oxidation. Hence, enhanced intramitochondrial utilization of elaidic acid would overcome the lower entry of this fatty acid into mitochondria through the CPT-I system.

The reason for which oleic acid is more potent activator of CPT-I than *trans* fatty acids is not obvious. Data clearly indicate that this effect is independent of malonyl-CoA. Recent evidence from our laboratories has put forward a novel malonyl-CoA-independent mechanism of acute control of hepatic CPT-I, which involves modulation of the interactions between CPT-I and cytoskeletal components (13,27,28). However, changes in CPT-I activity mediated by that mechanism survive extensive washing of the permeabilized hepatocytes prior to determination of enzyme activity, and this is not the case for the fatty acids used in the present study. It should be kept in mind that in our experiments hepatocytes were preincubated with the C_{18} fatty acids and then CPT-I activity was determined by the permeabilized-cell procedure with palmitoyl-CoA as substrate. This supports the notion that long-chain fatty acids exert a labile, malonyl-CoA-independent allosteric stimulation of CPT-I. The existence of an allosteric site for long-chain fatty acyl-CoA in liver CPT-I, although previously suggested (29), has still to be demonstrated.

ABSTRACT: Introduction of liposomes into target cells is important for drug delivery systems. For this purpose, the surface of the liposome is equipped with ligand peptides, which may bind to specific receptors on the cell membrane. An artificial novel lipopeptide (MSH-C4A2) containing the α-melanocyte-stimulating hormone (α-MSH) sequence and two long alkyl chains was designed and synthesized, and the liposome, composed of egg phosphatidylcholine (EPC) and MSH-C4A2, was prepared. The stability of the liposome was estimated by measuring calcein leakage from the liposome inner phase. The stability of the liposome decreased upon addition of MSH-A4C2, which seemed to be attributable to the amphiphilic property of the peptide moiety (α-MSH) of MSH-A2C4. The stability was, however, recovered fairly well upon addition of cholesterol (Ch) or phosphatidylglycerol (PG). It was concluded therefore that the ternary system, MSH-C4A2/Ch/EPC or MSH-C4A2/PG/EPC, is suitable for preparing the functional liposome.

Paper no. L8028 in *Lipids 34,* 387–394 (April 1999).

Liposome has been extensively studied as a carrier of drugs (1), proteins (2), and nucleic acids (3,4) for drug delivery systems (DDS). Since liposome is usually entrapped by reticuloendothelial systems by nonspecific endocytosis or phagocytosis (5), the liposome cannot remain in the organs long enough to be introduced into the target cell. To solve this problem, the specificity toward target cells should be improved. One promising method may be to equip the surface of liposome with ligand peptides which can bind to the specific receptors on cell membrane. In this study we have designed an artificial novel lipopeptide with α-melanocyte-stimulating hormone (α-MSH) and have prepared the liposomes including the lipopeptide in the bilayer membrane. This type of covalently bound lipopeptide has two advantages. One is that we can use the solid phase synthesis method, which makes procedures such as a deprotection step easier, and the other is that we can attach the peptide moiety onto the liposome surface more efficiently than by incorporating it after liposomes have been formed. The α-MSH peptide has 13 amino acid residues that can bind to the α-MSH receptor found on the melanocyte and melanoma cell surface (6). As the first step of the liposome study toward DDS, we have estimated its stability by measuring calcein leakage from the inner aqueous phase of liposome. This estimation is important for developing DDS because we have no knowledge of the stability of the present novel liposome; the efficiency of targeting toward cells would be decreased if the liposome membranes are not stable and active substances leak from the inner phase. We have been also interested in the captured volume of liposomes, which is ordinarily used as an index of the efficiency of liposome formation (7–9).

EXPERIMENTAL PROCEDURES

Materials. t-Butoxylcarbonyl-aspartic acid (Boc-Asp) and *N*-α-9-fluorenylmethoxycarbonyl (Fmoc) amino acids were purchased from Watanabe Chemical Ind., Ltd. (Hiroshima, Japan). TGR resin was commercially available from Calbiochem Novabiochem Corp. (La Jolla, CA). Egg phosphatidylcholine hydrogenated (EPC) and 1,2-dipalmitoyl-*sn*-glycero-3-[phospho-*rac*-(1-glycerol)] sodium salt (phosphatidylglycerol: PG) were obtained from Avanti Polar Lipids, Inc. (Alabaster, AL). 5-Cholesten-3β-ol (Ch) was purchased from Sigma Chemical Co. (St. Louis, MO). Calcein was obtained from Kanto Chemical Co., Inc. (Tokyo, Japan). All other reagents were of the highest grade commercially available.

Instruments. Proton nuclear magnetic resonance (NMR) spectra (270 MHz) were recorded on a Jeol JNM EX-270 FT spectrometer. Time-of-flight (TOF) mass spectra were acquired on a Kratos Analytical Kompact Maldi III spectrome-

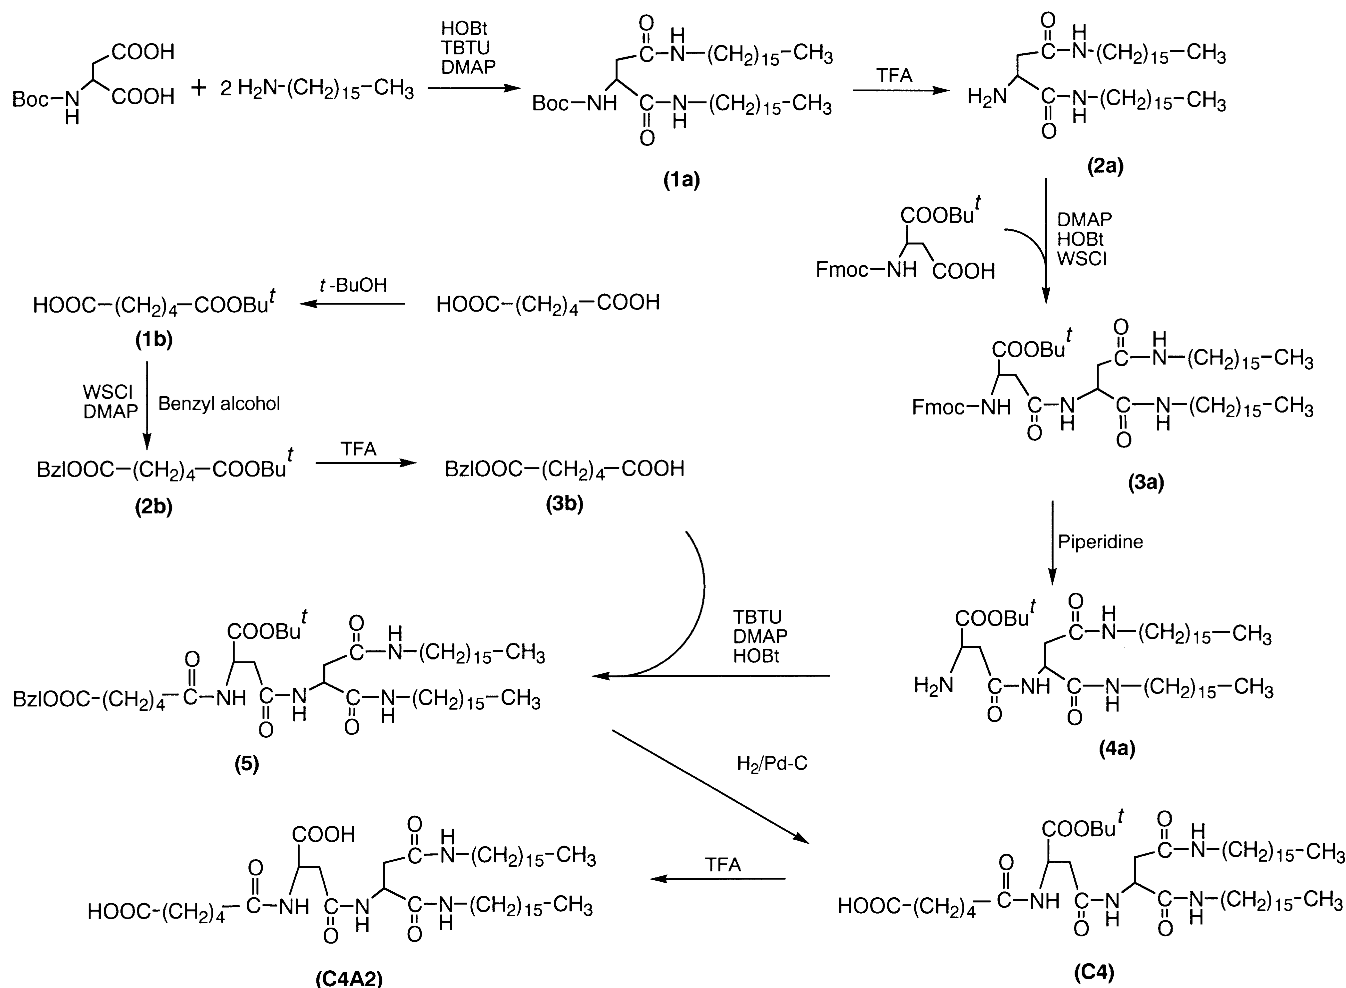
ter, and fast-atom bombardment (FAB) mass spectra were measured on a Jeol JMS-SX102A mass spectrometer. Peptides were synthesized with a PerSeptive Pioneer (Framingham, MA) peptide synthesizer. Measurement of fluorescence was carried out on a Jasco FP-777 spectrometer.

Synthesis of lipid. The synthetic route for the following compounds is shown in Scheme 1.

*(i) **1a***: *t*-Butoxylcarbonyl-aspartic acid (3.00 g, 12.9 mmol) was dissolved in a mixture of dimethylformamide (DMF) (15 mL) and $CHCl_3$ (15 mL). 1-Hydroxybenzotriazole (HOBt: 4.74 g, 31.0 mmol) (10) in DMF (30 ml) and 2-(1H-benzotriazole-1-yl)-1,1,3,3-trimethyluronium tetrafluoroborate (TBTU) (9.94 g, 31.0 mL) (11,12) in DMF (60 mL) were added to the above mixture. Hexadodecylamine (6.23 g, 25.8 mmol) was dissolved in $CHCl_3$ (15 mL), into which 4-dimethylaminopyridine (DMAP: 3.78 g, 31.0 mmol) in $CHCl_3$ (20 mL) was added. This solution was further added to the above DMF solution and stirred for 3 h at room temperature. The reaction mixture was washed with water (*ca.* 150 mL × 3), and the $CHCl_3$ phase was dried over Na_2SO_4. The Na_2SO_4 was filtered off, and the filtrate was condensed. The resultant residue was purified by column chromatography on silica gel (i.d., 7 × 11 cm; eluant, 3% $MeOH/CHCl_3$) to form a white solid. Yield: 7.16 g (10.5 mmol, 81.4%). ^1H NMR ($CDCl_3$) δ 6.94 (*s* br, 1H, N*H*CH_2), 6.21 (*d*, 1H, N*H*CH, J = 6.6 Hz), 5.95 (*s* br, 1H, N*H*CH_2), 4.39 (*ddd*, 1H, NHC*H*, J = 4.0, 6.6 and 6.6 Hz), 3.1–3.3 (*m*, 4H, $2NHCH_2$), 2.83 (*dd*, 1H, CH_AH_BCO, J = 4.0 and 14.8 Hz), 2.48 (*dd*, 1H, CH_AH_BCO, J = 6.6 and 14.8 Hz), 1.4–1.55 (*m*, 4H, $2NHCH_2CH_2$), 1.45 [*s*, 9H, $C(CH_3)_3$], 1.25 [*s* br, 52H, $2CH_3(CH_2)_{13}$], 0.88 [*t*, 6H, $2CH_3(CH_2)_{13}$, J = 6.5 Hz]. Anal. calcd. for $C_{41}H_{81}N_3O_4$: C, 72.41; H, 12.00; N, 6.18. Found: C, 72.58; H, 12.06; N, 6.07. FAB mass spectrometry (MS) calcd.: 680.6 (MH^+), found: 681.

*(ii) **2a***: Compound **1a** (7.03 g, 10.6 mmol) was dissolved in $CHCl_3$ (90 mL) and trifluoroacetic acid (TFA)/$CHCl_3$ (3:7, vol/vol, 27 mL) (13), and the solution was stirred for 4 h at room temperature. Then 5 N NaOH aqueous solution (22 mL) was added to the above solution to neutralize it. The reaction mixture was then washed with water (*ca.* 100 mL × 3), and the $CHCl_3$ layer was dried over Na_2SO_4. After filtering off the Na_2SO_4, the filtrate was condensed and purified by column chromatography on silica gel (i.d., 7 × 12 cm; eluant: 3% $MeOH/CHCl_3$) to form a white solid. Yield: 5.84 g



SCHEME 1

(10.1 mmol, 95.3%). ^{1}H NMR ($CDCl_3$) δ 7.48 (*t*, 1H, N*H*CH_2, *J* = 5.0 Hz), 6.12 (*t*, 1H, N*H*CH_2, *J* = 5.0 Hz), 3.65 (*dd*, 1H, NH_2C*H*, *J* = 5.0 and 6.5 Hz), 3.15–3.3 (*m*, 4H, 2NHCH_2), 2.59 (*dd*, 1H, C$H_A$$H_B$CO, *J* = 5.0 and 14.5 Hz), 2.56 (*dd*, 1H, $CH_A$$H_B$CO, *J* = 6.5 and 14.5 Hz), 1.86 (*s* br, 2H, NH_2), 1.4–1.55 (*m*, 4H, 2NHCH_2CH_2), 1.26 [*s* br, 52H, 2(CH_2)$_{13}$$CH_3$], 0.88 (*t*, 6H, 2$CH_2CH_3$, *J* = 6.4 Hz). Anal. calcd. for $C_{36}H_{73}N_3O_2$: C, 74.55; H, 12.69; N, 7.25. Found: C, 74.49; H, 13.01; N, 7.16. FAB MS calcd.: 580.6 (MH^+), found: 581.

*(iii) **3a***: Compound **2a** (0.94 g, 1.63 mmol) was dissolved in $CHCl_3$ (80 mL), into which DMAP (0.53 g, 2.93 mmol) in $CHCl_3$ (2 mL) was added. Fmoc-Asp-OBu^t (1.00 g, 2.44 mmol) (14) was dissolved in $CHCl_3$ (5 mL), and HOBt (0.45 g, 2.93 mmol) in DMF (2 mL) was added to this $CHCl_3$ solution. The mixture was further added to the **2a**-DMAP solution, into which 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride (WSCI) (0.56 g, 2.93 mmol) (15) in $CHCl_3$ (3 mL) was added, and the mixture was stirred for 3 h at room temperature. The reaction mixture was washed with water (*ca*. 100 mL × 3), and the $CHCl_3$ layer was dried over Na_2SO_4. The Na_2SO_4 was filtered off, the filtrate was condensed, and the residue was purified by silica gel column chromatography (i.d., 7 × 20 cm; eluant, 3–5% MeOH/$CHCl_3$ vol/vol) to form a white solid. Yield: 1.50 g (1.54 mmol, 94.5%). ^{1}H NMR ($CDCl_3$) δ 7.75 (*d*, 2H, fluorene, *J* = 7.6 Hz), 7.60 (*d*, 2H, fluorene, *J* = 7.6 Hz), 7.35–7.45 (*m*, 3H, N*H*CH and fluorene), 7.30 (*t*, 2H, fluorene, *J* = 7.6 Hz), 7.21 (*t*, 1H, N*H*CH_2, *J* = 5.8 Hz), 5.84 (*s* br, 2H, N*H*CH_2 and N*H*CH), 4.63 (*ddd*, 1H, NHC*H*, *J* = 3.0, 7.3 and 7.3 Hz), 4.45–4.6 (*m*, 1H, NHC*H*), 4.35–4.45 (*m*, 2H, CH_2O), 4.22 (*t*, 1H, C*H*CH_2O, *J* = 6.8 Hz), 3.1–3.3 (*m*, 4H, NHCH_2), 2.81 (*dd*, 1H, C$H_A$$H_B$CO, *J* = 3.0 and 14.8 Hz), 2.72 (*dd*, 1H, $CH_A$$H_B$CO, *J* = 5.0 and 16.2 Hz), 2.63 (*dd*, 1H, C$H_A$$H_B$CO, *J* = 7.3 and 16.2 Hz), 2.40 (*dd*, 1H, $CH_A$$H_B$CO, *J* = 7.3, and 14.8 Hz), 1.47 [*s* br, 13H, 2NHCH_2CH_2 and C(CH_3)$_3$], 1.26 [*s* br, 52H, 2CH_3(CH_2)$_{13}$], 0.88 [*t*, 6H, 2CH_3(CH_2)$_{13}$, *J* = 6.6 Hz]. *(iv) **4a***: Compound **3a** (0.291 g, 0.299 mmol) was dissolved in $CHCl_3$ (50 mL), and piperidine (3 mL) (16) was added, which was then stirred for 3 h at room temperature. The reaction mixture was purified by silica gel column chromatography (i.d., 7 × 14 cm; eluant, 3–5% MeOH/$CHCl_3$ vol/vol) to form a white solid. Yield: 0.209 g (0.278 mmol, 93.0%). ^{1}H NMR ($CDCl_3$) δ 8.12 (*d*, 1H, N*H*CH, *J* = 7.9 Hz), 7.47 (*t*, 1H, N*H*CH_2, *J* = 5.6 Hz), 6.06 (*t*, 1H, N*H*CH_2, *J* = 5.8 Hz), 4.69 (*ddd*, 1H, NHC*H*, *J* = 3.6, 6.3, and 7.9 Hz), 3.75 (*dd*, 1H, NH_2C*H*, *J* = 5.0 and 8.3 Hz), 3.1–3.3 (*m*, 4H, 2NHCH_2), 2.89 (*dd*, 1H, C$H_A$$H_B$CO, *J* = 3.6 and 14.8 Hz), 2.67 (*dd*, 1H, $CH_A$$H_B$CO, *J* = 5.0 and 15.0 Hz), 2.48 (*dd*, 1H, C$H_A$$H_B$CO, *J* = 8.3 and 15.0 Hz), 2.46 (*dd*, 1H, $CH_A$$H_B$CO, *J* = 6.3 and 14.8 Hz), 1.72 (*s*, 2H, NH_2), 1.47 [*s* br, 13H, C(CH_3)$_3$ and 2NHCH_2CH_2], 1.25 [*s* br, 52H, 2CH_3(CH_2)$_{13}$], 0.88 [*t*, 6H, 2CH_3(CH_2)$_{13}$, *J* = 6.6 Hz]. Anal. calcd. for $C_{44}H_{86}N_4O_5$: C, 70.35; H, 11.54; N, 7.46; found: C, 70.23; H, 11.99; N, 7.27. FAB MS calcd.: 751.7 (MH^+), found: 752.

*(v) **1b***: 2-Methyl-2-propanol (10 mL, 106 mmol), WSCI (1.30 g, 6.8 mmol) in $CHCl_3$ (10 mL), and DMAP (0.83 g, 6.8 mmol) in $CHCl_3$ (10 mL) were added to adipic acid (1.0 g, 6.8 mmol), and the mixture was stirred for 9 h at room temperature. It was then diluted with diethyl ether (100 mL) and washed with 0.05 N HCl (3 times) and water (3 times). The $CHCl_3$ layer was dried over Na_2SO_4 and condensed. Purification of the residue by silica gel column chromatography (i.d., 7 × 11 cm; eluant, AcOEt/hexane 4:6 vol/vol) gave liquid product. Yield: 0.4 g (1.97 mmol, 29%). ^{1}H NMR ($CDCl_3$) δ 2.38 (*t*, 2H, CH_2CO, *J* = 7.1 Hz), 2.24 (*t*, 2H, CH_2CO, *J* = 6.9 Hz), 1.6–1.7 (*m*, 4H, COCH_2CH_2C$H_2$$CH_2$CO), 1.44 [*s*, 9H, C($CH_3$)$_3$]. Anal. calcd. for $C_{10}H_{18}O_4$: C, 59.39; H, 8.97. Found: C, 59.40; H, 9.14. FAB MS calcd.: 203.1 (MH^+), found: 203.

*(vi) **2b***: CH_2Cl_2 (5 mL), benzyl alcohol (97.3 mg, 0.90 mmol) in CH_2Cl_2 (3 mL), WSCI (229 mg, 1.2 mmol) in CH_2Cl_2 (2 mL), and DMAP (101 mg, 0.83 ml) in CH_2Cl_2 (3 mL) were added to **1b** (166.2 mg, 0.82 mmol), and the reaction mixture was stirred for 2 h at room temperature. It was washed with water and the CH_2Cl_2 layer was dried over Na_2SO_4. The Na_2SO_4 was filtered off, and the filtrate was condensed and the residue was purified by silica gel column chromatography (i.d., 3 × 8 cm; eluant, AcOEt/hexane 1:9 vol/vol) to form a liquid product. Yield: 156 mg (0.53 mmol, 65.0%). ^{1}H NMR ($CDCl_3$) δ 7.35 (*m*, 5H, C_6H_5), 5.11 (*s*, 2H, PhCH_2), 2.38 (*t*, 2H, OCCH_2, *J* = 6.9 Hz), 2.22 (*t*, 2H, OCCH_2, *J* = 6.9 Hz), 1.6–1.8 [*m*, 4H, CH_2(CH_2)$_2$$CH_2$], 1.43 [*s*, 9H, C($CH_3$)$_3$]. Anal. calcd. for $C_{17}H_{24}$: C, 69.84; H, 8.27. Found: C, 69.59; H, 8.14.

*(vii) **3b***: To **2b** (64.2 mg, 0.22 mmol) was added $CHCl_3$ (5 mL) and TFA (1 mL), and the mixture was stirred for 3 h at room temperature. It was washed with water, and the $CHCl_3$ layer was dried over Na_2SO_4. The Na_2SO_4 was filtered off, the filtrate was condensed, and the residue was purified by column chromatography on silica gel (i.d., 3 × 8 cm; eluant, AcOEt/hexane 4:6 vol/vol) to form a liquid product. Yield: 44.5 mg (0.19 mmol, 85.6%). ^{1}H NMR ($CDCl_3$) δ 7.35 (*m*, 5H, C_6H_5), 5.12 (*s*, 2H, PhCH_2), 2.3–2.5 (*m*, 4H, OCCH_2), 1.6–1.8 [*m*, 4H, CH_2(CH_2)$_2$$CH_2$]. Anal. calcd. for $C_{13}H_{16}O_4 \cdot 0.2H_2O$: C, 65.10; H, 6.89. Found: C, 65.38; H, 7.13.

*(viii) **5***: Compound **4a** (0.114 g, 0.152 mmol) was dissolved in $CHCl_3$ (30 mL), into which TBTU (0.0964 g, 0.300 mmol) in DMF (3 mL) and DMAP (0.0246 g, 0.201 mmol) in $CHCl_3$ (1 mL) were added. **3b** (0.0418 g, 0.201 mmol) was dissolved in $CHCl_3$ (1 mL), into which HOBt (0.0460 g, 0.3 mmol) in DMF (1 mL) was added. The mixture was stirred for 4.5 h at room temperature and washed with water three times. The $CHCl_3$ layer was dried over Na_2SO_4, the filtrate was condensed, and the residue was purified by column chromatography on silica gel (i.d., 7 × 12 cm; eluant, 3–5% MeOH/$CHCl_3$) to form a white solid. Yield: 133 mg (0.143 mmol, 93.1%). ^{1}H NMR ($CDCl_3$) δ 7.3–7.45 (*m*, 7H, N*H*CH,

N*H*CH_2, and phenyl), 6.65 (*d*, 1H, N*H*CH, J = 8.1 Hz), 6.01 (*t*, 1H, N*H*CH_2, J = 4.3 Hz), 5.11 (*s*, 2H, PhCH_2), 4.74 (*dt*, 1H, NHC*H*, J = 5.3 and 8.1 Hz), 4.62 (*ddd*, 1H, NHC*H*, J = 3.4, 6.9, and 6.9 Hz), 3.1–3.3 (*m*, 4H, 2NHCH_2), 2.81 (*dd*, 1H, CH_AH_BCO, J = 3.4 and 15.1 Hz), 2.73 (*d*, 2H, CH_2CO, J = 5.3 Hz), 2.40 (*dd*, 1H, CH_AH_BCO, J = 6.9 and 15.1 Hz), 2.38 (*t*, 2H, COCH_2CH_2, J = 6.9 Hz), 2.24 (*t*, 2H, COCH_2CH_2, J = 6.8 Hz), 1.68 (*s* br, 4H, 2COCH_2CH_2), 1.45 [*s* br, 13H, $C(CH_3)_3$ and 2NHCH_2CH_2], 1.25 [*s*, 52H, $2CH_3(CH_2)_{13}$], 0.88 (*t*, 6H, $2CH_3(CH_2)_{13}$, J = 6.6 Hz). Anal. Calcd. for $C_{57}H_{100}O_8N_4$: C, 70.62; H, 10.40; N, 5.78. Found: C, 70.61; H, 10.97; N, 5.59. FAB MS calcd.: 969.8 (MH^+), found: 970.

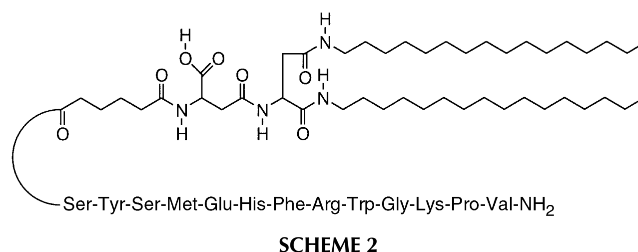
(ix) ***C4***: Compound **5** (0.133 g, 0.137 mL) was dissolved in CH_2Cl_2 (20 mL) and 2-propanol (10 mL). Then 10% Palladium/Aktivkohle (0.040 g; Merck, Schucherdt, Germany) was added to the reaction mixture and hydrogen gas was introduced for 1 h (17). After the reaction, Palladium/ Aktivkohle was removed by a polytetrafluoroethylene membrane. Purification of the reaction mixture by silica gel column chromatography (i.d., 3 × 2 cm; eluant, 8% MeOH/$CHCl_3$) gave a white solid. Yield: 99.3 mg (0.113 mmol, 82.4%). ^{1}H NMR ($CDCl_3$) δ 7.39 (*d*, 1H, N*H*CH, J = 6.9 Hz), 7.33 (*t*, 1H, N*H*CH_2, J = 5.8 Hz), 6.65 (*d*, 1H, N*H*CH, J = 7.9 Hz), 5.99 (*s* br, 1H, N*H*CH_2), 4.75 (*dt*, 1H, NHC*H*, J = 5.3 and 7.9 Hz), 4.63 (*ddd*, 1H, NHC*H*, J = 3.3, 6.9, and 6.9 Hz), 3.1–3.3 (*m*, 4H, 2NHCH_2), 2.09 (*dd*, 1H, CH_AH_BCO, J = 3.3 and 15.2 Hz), 2.74 (*d*, 2H, CH_2CO, J = 5.3 Hz), 2.41 (*dd*, 1H, CH_AH_BCO, J = 6.9 and 15.2 Hz), 2.33 (*t*, 2H, COCH_2CH_2, J = 6.8 Hz), 2.34 (*t*, 2H, COCH_2CH_2, J = 5.4 Hz), 1.66 (*s* br, 4H, 2COCH_2CH_2), 1.46 [*s* br, 13H, $C(CH_3)_3$ and 2NHCH_2CH_2], 1.25 [*s* br, 52H, $2CH_3(CH_2)_{13}$], 0.88 [*t*, 6H, $2CH_3(CH_2)_{13}$, J = 6.3 Hz]. FAB MS calcd.: 879.7 (MH^+), found: 880.

(x) ***C4A2***: Compound **C4** (64.2 mg, 0.073 mmol) was dissolved in $CHCl_3$ (1 mL). After adding TFA (1 mL), the mixture was reacted for 5 h at room temperature. After the solvent was evaporated and the residue was dried *in vacuo* for 12 h at 70°C, a white solid was obtained. Yield: 60 mg (0.072 mmol, 99%). ^{1}H NMR ($CDCl_3$ and CD_3OD) δ 4.7–4.8 (*m*, 1H, CH), 4.6–4.7 (*m*, 1H, CH), 3.1–3.2 (*m*, 4H, 2NHCH_2), 2.79 (*dd*, 1H, CH_ACH_B, J = 5.9 and 15.7 Hz), 2.75 (*dd*, 1H, CH_ACH_B, J = 6.6 and 15.7 Hz), 2.63 (*dd*, 1H, CH_ACH_B, J = 5.9 and 15.2 Hz), 2.54 (*dd*, 1H, CH_ACH_B, J = 6.3 and 15.2 Hz), 2.33 (*t*, 2H, CH_2CH_2CO, J = 6.9 Hz), 2.27 (*t*, 2H, CH_2CH_2CO, J = 7.3 Hz), 1.6–1.7 (*m*, 4H, 2CH_2CH_2CO), 1.4–1.55 (*m*, 4H, 2NHCH_2CH_2), 1.2 [*s* br, 52H, $2(CH_2)_{13}CH_3$], 0.89 (t, 6H, $2CH_2CH_3$, J = 6.6 Hz). Anal. calcd. for $C_{44}H_{82}N_4O_8$·0.5CF_3COOH: C, 64.13; H, 9.91; N, 6.37. Found: C, 63.83; H, 9.83; N, 6.13. FAB MS calcd.: 823 (MH^+), found: 824.

Synthesis of α-MSH. Peptide α-MSH was synthesized in an ordinary Fmoc method (18) by a peptide synthesizer (PerSeptive Biosystems, Pioneer Peptide Synthesis System). The major conditions were as follows: TGR resin, 1 g (0.2 mmol); Fmoc amino acid, 0.8 mmol in DMF; coupling reagents, HOBt (0.5 M)/TBTU (0.5 M)/diisopropylethylamine (1.0 M) in DMF; deblocking reagent, 20% piperidine in DMF; washing solvent, DMF; condensation reaction time, 20 min; deblocking reaction time, 5 min. The peptide was cleaved from the resin by the reaction in TFA (2.5 mL), 1,2-ethanedithiol (EDT) (62.5 μL), triisopropylsilane (62.5 μL), and H_2O (125 μL) for 5 h at room temperature. After filtering off the resin, ethyl ether was added to the filtrate and a white precipitate formed. After centrifugation (4°C, 3500 rpm, 20 min), the supernatant was removed, ethyl ether was added again, and the same procedure was repeated. The white precipitate obtained was dissolved in water and purified by high-performance liquid chromatography (HPLC) (YMC pack ODS column; i.d., 10 × 250 mm; eluant, 0.08% aq. TFA/MeCN = 100:0 → 50:50 during 30 min; flow rate, 2 mL/min). The retention time of the separated peak was 14.9 min. The purified peptide was finally obtained after lyophilization. Yield: 49.9%. FAB MS calcd.: 1623 (MH^+), found: 1624.

Synthesis of MSH-C4A2 (Scheme 2). The peptide (α-MSH sequence) on the resin was reacted with **C4**: *viz*., the peptide on resin, **C4**, HOBt, and *N,N′*-diisopropylcarbodiimide (molar ratio 1:1:10:10) were mixed in *N*-methylpyrrolidione (NMP) and reacted for 12 h at 60°C. After filtering off the resin, washing it with *N*-methylpyrrolidione (2 mL × 10) and MeOH (2 mL × 10) and drying it for 10 min, TFA (2.5 mL), 1,2-ethanedithiol (62.5 μL), triisopropylsilane (62.5 μL), and H_2O (125 μL) were added to the resin and reacted for 5 h at room temperature in order to obtain the free lipopeptide. The resin was filtered off, and ethyl ether was added to the filtrate to obtain a white precipitate, which was then centrifuged (4°C, 3500 rpm, 20 min). After removing the supernatant, diethyl ether was added again, and the centrifugation was repeated. The white precipitate was dissolved in 20% acetate solution and purified by high-performance liquid chromatography (YMC pack C4; i.d., 10 × 250 mm; eluant:, 0.08% aq. TFA/MeCN = 100:0 → 50:50 during 30 min; flow rate, 2 mL/min). The retention time of the separated peak was 11.7–12.3 min. The final product was obtained after lyophilization. Yield: 12.6%. Time-of-flight MS calcd.: 2410 (MH^+ – 17), found: 2410.

Preparation of lipid thin film. (i) EPC. Solution **A** was prepared by dissolving EPC (18.35 mg) in $CHCl_3$ (5 mL). One hundred microliters of solution **A** was put into a 10-mL test tube. Lipid thin film was prepared by evaporating the solvent by a N_2 gas stream as the test tube was rotated. The



SCHEME 2

resultant EPC thin film was dried in a desiccator under vacuum for 2 h.

(ii) EPC/MSH-C4A2. Solution **B** was prepared by dissolving MSH-C4A2 (1.455 mg) in 20% acetic acid (250 µL). Solution **A** (100 µL) and solution **B** (10 µL or 20 µL) were put into a 10-mL test tube. After adding MeOH to prevent phase separation, lipid thin film was prepared in a similar manner as EPC lipid thin film. The film was then dried in a desiccator overnight, since it was somewhat difficult to remove the solvent when the synthetic lipids were contained. The molar ratios of EPC/MSH-C4A2 were 20:1 and 10:1, respectively.

(iii) EPC/Ch. Solution **C** was prepared by dissolving Ch (1.16 mg) in MeOH/$CHCl_3$ (20:80 vol/vol, 200 µL). Solution **A** (100 µL) and solution **C** (10 µL) were put into a 10-mL test tube. Lipid thin film was prepared in a similar manner, which was then dried in a desiccator for 2 h. The molar ratio of EPC/Ch was 10:3.

(iv) EPC/MSH-C4A2/Ch. Solution **A** (100 µL), solution **B** (20 µL) and solution **C** (10 µL) were put into a 10-mL test tube. MeOH was added to make the solution homogeneous. After lipid thin film was prepared in a similar manner, it was dried in a desiccator overnight. The molar ratio of EPC/MSH-C4A2/Ch was 10:1:3.

(v) EPC/PG. Solution **D** was prepared by dissolving PG (1.841 mg) in MeOH/$CHCl_3$ (20:80 vol/vol, 200 µL). Solution **A** (100 µL) and solution **D** (10 µL) were put into a 10-mL test tube. Lipid thin film was prepared in a similar manner and dried in a desiccator for 2 h. The molar ratio of EPC/PG was 10:3.

(vi) EPC/MSH-C4A2/PG. Solution **A** (100 µL), solution **B** (20 µL), and solution **D** (10 µL) were put into a 10-mL test tube. MeOH was added to make the solution homogeneous. Lipid thin film was prepared in a similar manner and dried in a desiccator overnight. The molar ratio of EPC/MSH-C4A2/PG was 10:1:3.

(vii) EPC/MSH-C4A2/Ch/PG. Solution **A** (100 µL), solution **B** (20 µL), solution **C** (10 µL), and solution **D** (10 µL) were put into a 10-mL test tube. MeOH was added to make the solution homogeneous. After lipid thin film was prepared in a similar manner, it was dried in a desiccator overnight. The molar ratio of EPC/MSH-C4A2/Ch/PG was 10:1:3:3.

(viii) EPC/C4A2. Solution **E** was prepared by dissolving C4A2 (1.4 mg) in MeOH/$CHCl_3$ (20:80 vol/vol, 3.4 mL). Solution **A** (100 µL) and solution **E** (100 µL) were put into a 10-mL test tube. Lipid thin film was prepared in a similar manner and dried in a desiccator overnight. The molar ratio of EPC/C4 was 10:1.

Preparation of liposomes. One milliter of calcein solution (20 mM, pH 7.15, containing 120 mM NaCl) was put into a test tube containing lipid thin film, and the solution was stirred for 5 min. After the freeze-thaw procedure (19) was repeated five times, liposomes with homogeneous size (<0.1 µm) were obtained by the extrusion method.

Measurement of calcein leakage from liposome. Stability of the liposomes was estimated by using calcein as a fluorescence probe in a manner similar to that of using carboxyfluorescein (20). Liposomes and calcein were separated by gel filtration (Sephadex G-75; i.d., 10 × 285 mm) eluted with HEPES buffer (10 mM HEPES, 150 mM NaCl, pH 7.2). Two milliters of liposome solution including calcein were obtained. After the liposome solution had been put in a water bath (37°C) for 5 min, 24 µL of the solution was transferred to a cuvette and diluted by HEPES buffer to the total volume of 2.4 mL. When calcein molecules are located inside liposomes, fluorescence is depressed by self-quenching of calcein. If calcein passes through liposome membranes and reaches the bulk phase, however, the fluorescence increases because the self-quenching disappears by dilution. The time course of calcein leakage from liposomes was measured on a fluorescence spectrometer (λ_{ex} = 490 nm, λ_{em} = 520 nm) (21). Calcein leakage (%) was calculated by Equation 1,

$$\text{leakage (\%)} = \frac{F(t) - F(0)}{F(\text{triton}) - F(0)} \times 100 \quad [1]$$

where $F(0)$, $F(t)$, and F(triton) are the fluorescence intensity at time 0, t, and after collapsing liposomes by triton X-100 (final concentration was 0.3%), respectively. Here it was assumed that after adding triton X-100 liposomes were completely collapsed and all calcein molecules were in the bulk phase. In the measurement using α-MSH peptide as a free form, 1 mL of α-MSH solution (Hank's buffer) was added to the calcein-included liposome solution, whose final molar ratio was 10:1 (EPC/MSH).

Calculation of captured volume ratio. Captured volume ratio, which is the quantity giving the relative size of liposomes, was calculated by Equation 2,

$$\text{captured vol ratio (\%)} = \frac{F(\text{triton:MSH-C4A2 / EPC})}{F(\text{triton:EPC})} \times 100 \quad [2]$$

where F(triton:MSH-C4A2/EPC) and F(triton:EPC) are the fluorescence intensities, respectively, in MSH-C4A2/EPC liposome and in EPC liposome after addition of triton X-100.

RESULTS

Calcein leakage from liposome. The degree of calcein leakage through liposome membranes was used as an index of the stability of liposomes perturbed by lipopeptide MSH-C4A2. Figure 1 shows the time course of calcein leakage in different concentrations of MSH-C4A2. It is apparent that MSH-C4A2 makes liposome unstable; that is, calcein leakage was increased by 2.9 times for 5 mol% MSH-C4A2 and by 3.8 times for 10 mol% MSH-C4A2 compared to the control experiment. In order to determine which part of the MSH-C4A2 molecule primarily contributes to the instability of liposome, we compared calcein leakage among liposomes of MSH-C4A2 free (control), 10 mol% MSH-C4A2, 10 mol% MSH, and 10 mol% C4A2 (Fig. 2). α-MSH and C4A2 were used to estimate the individual contribution from the peptide part and the lipid part. As mentioned already MSH-C4A2 increased the calcein leakage from 1.6 to 6.3%. Similarly to MSH-C4A2, free MSH obviously made liposomes unstable,

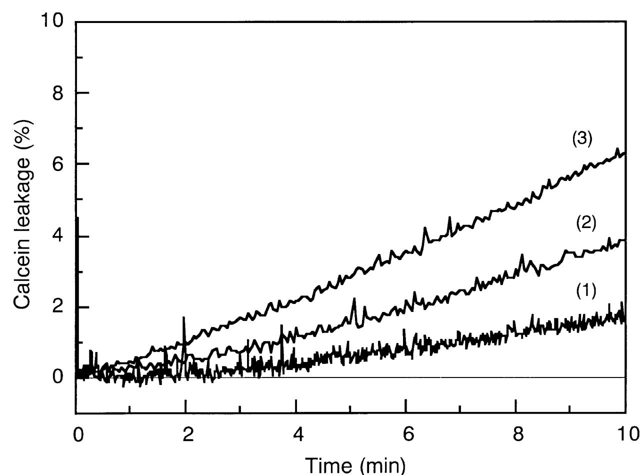


FIG. 1. Time course of calcein leakage from liposomes containing (1) 0% MSH-C4A2 (control), (2) 5 mol% MSH-C4A2, and (3) 10 mol% MSH-C4A2. MSH-C4A2, melanocyte-stimulating hormone .

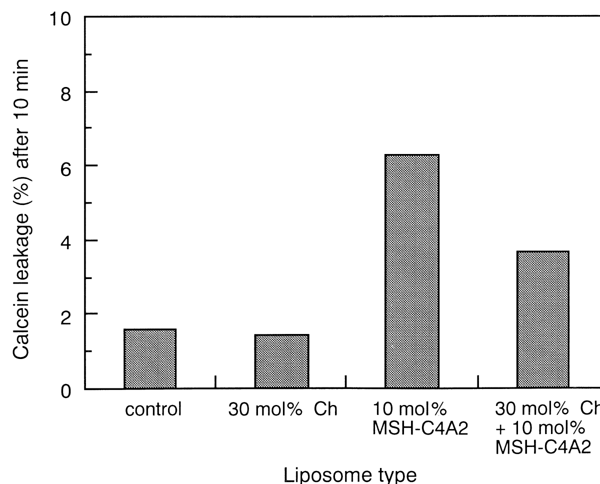

FIG. 3. Effect of cholesterol (Ch) on calcein leakage from MSH-C4A2/EPC liposome; control liposome is composed of only EPC. For abbreviations see Figures 1 and 2.

since calcein leakage increased from 1.6 to 7.7%. Contrary to MSH-C4A2 and MSH, C4A2, which corresponds to the lipid skeleton of MSH-C4A2, had little effect on liposome stability (*viz*., calcein leakage increased by only 0.4%).

Effect of Ch and PG. Some kinds of lipids like Ch and PG are known to have special functions to stabilize lipid membranes (22,23). To recover the stability of MSH-C4A2-liposome, we added Ch and/or PG to liposome membranes. In Figure 3 the calcein leakage after 10 min is compared in four systems: control, Ch (30 mol%), MSH-C4A2 (10 mol%), and Ch (30 mol%) + MSH-C4A2 (10 mol%). When Ch alone was present in liposome membrane, the stability increased a little. When MSH-C4A2 alone was present, the stability was much reduced (*viz*., calcein leakage increased). It should be noted, however, that the stability recovered considerably (*viz*., the calcein leakage was reduced by 42%) when both Ch and MSH-C4A2 were introduced to liposome membranes. Another promising stabilizer is PG (24), whose effect on calcein leakage is shown in Figure 4. Although PG (30 mol%) did not have a large effect on the control liposome, it largely stabilized MSH-C4A2 (10 mol%) liposome (*viz*., calcein leakage was reduced by 37%). It was expected then that addition of both Ch and PG should reduce calcein leakage to a greater extent than when either of them was present individually. Contrary to our expectation, however, calcein leakage was at a level similar to that of the Ch or PG system (Fig. 5).

Captured volume ratio. Captured volume ratio was obtained from the measurement of calcein leakage (data not shown). The ratio is reduced to 72 and 32% as the content of MSH-C4A2 increases to 5 and 10 mol%, respectively, which means that MSH-C4A2 inhibits liposome formation or reduces the liposome size (7–9).

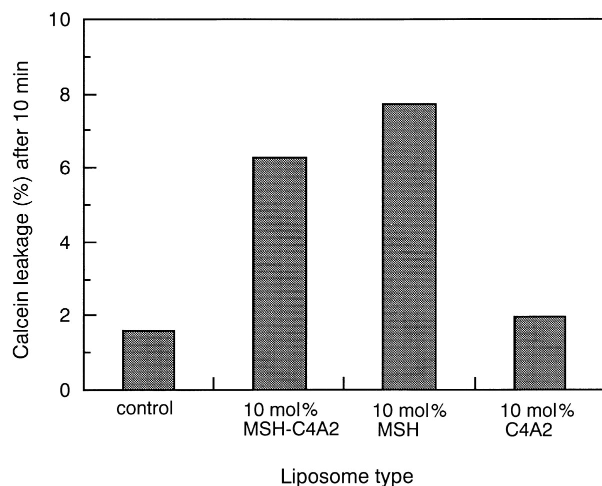

FIG. 2. Effect of MSH peptide ligand moiety and lipid skeleton part on calcein leakage from MSH-C4A2/EPC liposome; control liposome is composed of only EPC. EPC, egg phosphatidylcholine hydrogenated; for other abbreviations see Figure 1.

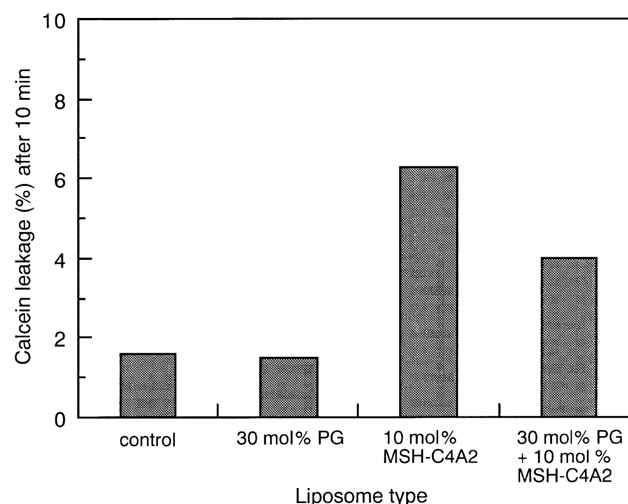

FIG. 4. Effect of phosphatidylglycerol (PG) on calcein leakage from MSH-C4A2/EPC liposome; control liposome is composed of only EPC. For abbreviations see Figures 1 and 2.

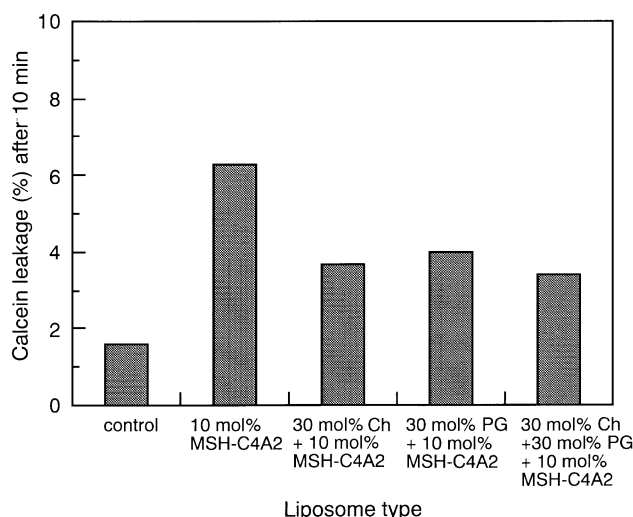

FIG. 5. Effect of coexistence of Ch and PG on calcein leakage from MSH-C4A2/EPC liposome; control liposome is composed of only EPC. For abbreviations see Figures 1–4.

DISCUSSION

The results of calcein leakage shown in Figure 1 suggest that the peptide ligand (α-MSH sequence) of MSH-C4A2 greatly influences the stability of liposome. It is predicted from the amino acid sequence that α-MSH should have an amphiphilic property. Amphiphilic peptides generally have a tendency to make liposome unstable (25). As free α-MSH peptide probably forms an α-helix, it may act as an amphiphilic reagent with its hydrophobic side being embedded in liposome membranes. With respect to the effect of charge of the membrane components on liposomes, the expected charges in the neutral pH region are +2 for α-MSH, −2 for calcein, −1 for PG, −2 for C4A2, +2 for MSH-C4A2, and 0 for EPC. Since the degree of the calcein leakage was similar in the control experiment (Fig. 2), 10 mol% C4A2 (Fig. 2), 30 mol% Ch (Fig. 3), and 30 mol% PG (Fig. 4), we concluded that the anionic charge does not affect liposome stability.

One Ch molecule and two phospholipid molecules can form a cluster in lipid membranes in the range of 30–50 mol% of Ch, and thus the membranes become more stable (26,27). The stabilization of MSH-C4A2 liposome by 30 mol% Ch observed in Figure 3 must be accounted for by the foregoing mechanism. Although the detailed mechanism of the stabilization by PG is unknown, there may be some electrostatic repulsion between calcein with a −2 charge and PG with a −1 charge, leading to the suppression of calcein leakage from liposomes. The effects of both Ch and PG were much smaller when they were present in liposome without MSH-C4A2 (*viz*., control liposome). Probably the membrane of the control liposome was stable enough even if Ch and PG were not present, so the effect of Ch and PG was not noticeable.

The decrease in the captured volume ratio may be due to the inhibition of liposome formation by MSH-C4A2. Since MSH-C4A2 is a lipid bearing a peptide moiety, its properties related to molecular size and hydrophilic-hydrophobic balance must be different from those of EPC. MSH-C4A2 may affect the orientation of EPC by intermolecular interactions such as steric hindrance. Since liposome with larger captured volume is capable of holding more bioactive compounds in its inner phase, such a liposome is appropriate for DDS. As captured volume primarily depends on the method of preparing liposome (9,19), the freeze-thaw method used here seems to be the best in terms of the efficiency of capturing bioactive compounds.

We have designed and synthesized the novel lipopeptide MSH-C4A2. Although the liposome composed of EPC is not so stable in the presence of MSH-C4A2, its stability is largely restored by addition of the third component, Ch or PG. The test of whether the liposome containing MSH-C4A2 can bind to melanoma cells will be performed by flow cytometry.

ABSTRACT: Recently we described a block in bile acid synthesis in cerebrotendinous xanthomatosis (CTX), a lipid storage disease related to an inborn error of bile acid metabolism. In this disease a defect in hepatic microsomal (24*S*) hydroxylation blocks the transformation of 5β-cholestane-3α,7α,12α,25-tetrol into (24*S*) 5β-cholestane-3α,7α,12α,24,25-pentol and cholic acid. Mitochondrial cholesterol 27-hydroxylation has also been reported to be abnormal in CTX subjects, but the relative importance of the enzymatic defect in this alternative microsomal pathway (namely, the 24*S* hydroxylation of 5β-cholestane-3α,7α,12α,25-tetrol relative to the abnormality in mitochondrial 27-hydroxylase) has not been established in CTX. To delineate the sequence of side-chain hydroxylations and the enzymatic block in bile acid synthesis, we synthesized the (23*R* and 23*S*) 24-nor-5β-cholestane-3α,7α,12α,23,25-pentols utilizing a modified Sharpless asymmetric dihydroxylation reaction on 24-nor-5β-cholest-23-ene-3α,7α,12α-triol, a C_{26} analog of the naturally occurring C_{27} bile alcohol, 5β-cholest-24-ene-3α,7α,12α-triol. Stereospecific conversion of the unsaturated 24-nor triol to the corresponding chiral compounds (23*R* and 23*S*), 24-nor-5β-cholestane-3α,7α,12α,23,25-pentols, was quantitative. However, conversion of the unsaturated 24-nor triol to the chiral nor-pentols had absolute stereochemistry opposite to the products predicted by the Sharpless steric model. The absolute configurations and enantiomeric excess of the C_{26} nor-pentols and the C_{27} pentols (synthesized from 5β-cholest-24-ene-3α,7α,12α-triol for comparison) were confirmed by nuclear magnetic resonance and lanthanide-induced circular dichroism Cotton effect measurements. These results may contribute to a better understanding of the role of the 24*S*-hydroxylation vs. 27-hydroxylation step in cholic acid biosynthesis.

Paper no. L8043 in *Lipids 34,* 395–405 (April 1999).

In normal human physiology, biosynthesis of the primary bile acids, cholic and chenodeoxycholic acids, from cholesterol involves conversion of 5β-cholestane-3α,7α,12α-triol and 5β-cholestane-3α,7α-diol, respectively, to 27-hydroxylated products (1–3). This reaction is catalyzed by a mitochondrial cytochrome P_{450} enzyme, 27-hydroxylase (previously termed “26-hydroxylase”) (4,5). An alternative biosynthetic pathway which was discovered in our laboratory and which does not involve mitochondrial or peroxisomal enzymes proceeds *via* microsomal 25-hydroxylation of 5β-cholestane-3α,7α,12α-

triol to give 5β-cholestane-3α,7α,12α,25-tetrol (6) followed by stereospecific 24*S*-hydroxylation to yield 5β-cholestane-3α,7α,12α,24*S*,25-pentol. The pentol is then oxidized to 3α,7α,12α-trihydroxy-5β-cholestan-24-one, which is degraded by cytosolic enzymes to give cholic acid and acetone (7–9). Although this "alternative" 25-hydroxylation pathway is responsible for less than 5% of the cholic acid produced in normal individuals, it becomes a major pathway in cerebrotendinous xanthomatosis (CTX), an autosomal recessive inborn error of bile acid metabolism (7,10,11). CTX is characterized by the accumulation of the cholesterol metabolite, 5α-cholestanol, in various tissues including the nervous system, arteries, and tendons, leading to the diverse clinical manifestations of this disease (7–12).

Further studies by Skrede *et al.* (13) and Cali and Russel (4) demonstrated that a major enzymatic defect in CTX is the presence of an abnormal sterol 27-hydroxylase (EC 1.14.13.15). The molecular genetics in North African Jewish families exhibiting CTX indicated three separate gene mutations, of which the most recently described is a missense mutation that results in a methionine for threonine substitution (15–17).

To investigate further the sequence of side-chain hydroxylations and the quantitative importance of this metabolic defect in CTX, we developed methods for efficient and stereospecific large-scale syntheses of (23*R* and 23*S*) 24-nor-5β-cholestane-3α,7α,12α,23,25-pentols as model substrates. We utilized a nonenzymatic method for enantioselective hydroxylations recently developed by Sharpless *et al.* (17–19) utilizing a modified phthalazine (PHAL) class of cinchona alkaloid-based chiral ligands. In this report, we describe methods for synthesis, purification, and identification of these isomeric (23*R* and 23*S*) 24-nor-5β-cholestane-3α,7α,12α,23,25-pentols. These experiments will be important not only in yielding stereoisomeric compounds of interest in our current work but also in serving as model substrates for the synthesis of other isomers of potentially important biologic interest.

EXPERIMENTAL PROCEDURES AND RESULTS

Melting points. Melting points were determined on a model MP-12600 Thermolyne apparatus (Thermolyne Corp., Dubuque, IA) and are uncorrected.

Thin-layer chromatography (TLC). All tri- and tetrahydroxy bile alcohols and their corresponding isomers were separated on silica gel G plates (Uniplates; Analtech, Newark, NJ, 0.25-mm thickness) in the solvent system $CHCl_3/(CH_3)_2CO/CH_3OH$, 70:50:10 (by vol). For pentahydroxy sterols and their corresponding isomeric analogs, the solvent system $CHCl_3/(CH_3)_2CO/CH_3OH$, 70:50:15 (by vol) was used (9,20,21). The spots were detected by spraying the plates with phosphomolybdic acid (3.5% in isopropanol), sulfuric acid (10%), and heating for 1 min at 110°C.

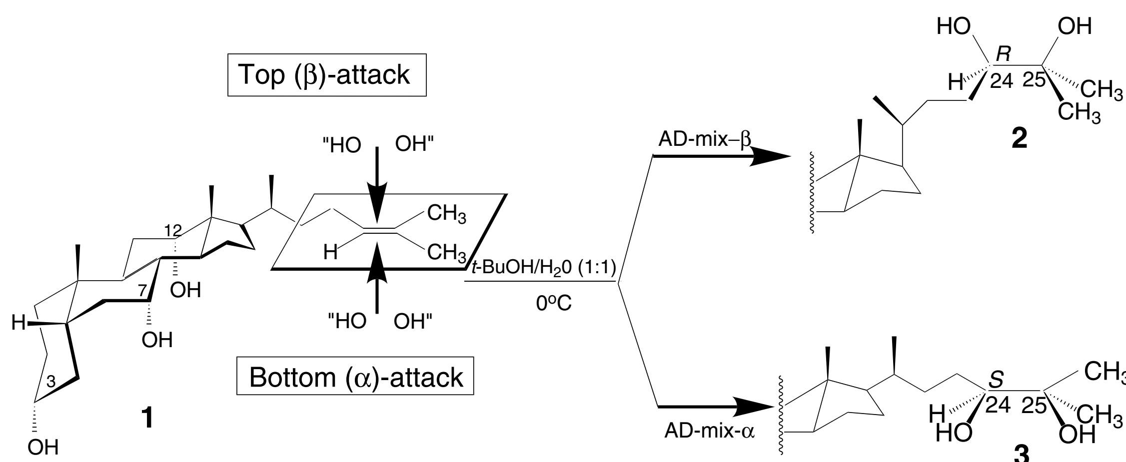
(^1H and ^{13}C) Nuclear magnetic resonance (NMR) spectrometry. NMR spectra (^1H and ^{13}C) were recorded on a Varian XL-400 (400 MHz) spectrometer equipped with Fourier transform mode. All NMR spectra were taken in (CD_3OD) solution or $CDCl_3$with Me_4Si as the internal standard. In addition, the nature of each carbon in 24-nor-5β-cholestane-3α,7α,12α,23,25-pentols was deduced through distortionless enhancement by polarization transfer (DEPT) spectra (in $CDCl_3$) performed by using a polarization pulse of 90 and 135°, respectively, obtaining in the first case only signals for CH groups, and in the second case positive signals for CH and CH_3 and negative signals for CH_2 groups. All these data were recorded on an XL-400 spectrometer at 100 MHz for ^{13}C nuclei (9,20–23).

Optical measurements. Circular dichroism (CD) measurements were carried out on a Jasco-500A spectropolarimeter at 24°C, under a stream of high-purity dry N_2. The coefficient of dichroic absorption, $\Delta\varepsilon$, was calculated from the molar ellipticity (θ) by the following equation: molar ellipticity (θ) = 3300$\Delta\varepsilon$. Both molar ellipticity (θ) and $\Delta\varepsilon$ are expressed in degree $\times$ $cm^2 \times dmol^{-1}$ (9,24–26).

Positive ion fast atom bombardment–mass spectrometry (FAB–MS). Direct probe mass spectrometric analysis of the C_{26} bile alcohols (24-nor-5β-cholestane-3α,7α,12α,23,25-pentols) and the C_{27} series of bile alcohols (25-tetrol/pentol) was performed by FAB–MS using a ZAB-IF mass spectrometer (VG, Manchester, United Kingdom) equipped with a standard FAB source as described previously (9,27,28). The FAB technique has emerged as a simple and extremely versatile ionization process that is particularly well suited to biomedical applications. Although negative ion FAB–MS is much more satisfactory than the positive ion mode, this was not available at that time. In the FAB mode (positive ions) the sample was dissolved in thioglycerol, and a small aliquot (1–2 μL) placed on the mass spectrometer direct probe. After insertion into the mass spectrometer, the sample was bombarded with a neutral atom beam of xenon having approximately 6 kV of translational energy.

Electron ionization mass spectra (EI–MS). EI–MS of the bile alcohols were obtained with a Varian MAT-5 and Varian MAT-III gas chromatograph–mass spectrometer as described previously (29).

Gas–liquid chromatography (GLC). Capillary GLC analysis of bile alcohols (as their trimethylsilyl derivatives) was performed on Hewlett-Packard model No. 4890 (equipped with a flame-ionization detector) and a split column injector using a CPsil 5 (CB) WCOT capillary column (25 m × 0.22 mm with 0.13-mm film thickness) (23). Helium was used as a carrier gas at a flow rate of 20.2 mL/min (135 kPa).



SCHEME 1

Preparation of asymmetric dihydroxylation (AD)-mix-α and AD-mix-β. This procedure has been adequately described by Sharpless and associates (17–20,30–42). AD-mix-β consists of a mixture of potassium ferricyanide, potassium carbonate, and a catalytic quantity of potassium osmate blended with the chiral dihydroquinidine ligand, $(DHQD)_2$-PHAL and AD-mix-α has the chiral dihydroquinine-derived ligand, $(DHQ)_2$-PHAL.

*(i) Synthesis of 5β-cholestane-3α,7α,12α, 24*S *(or 24β),25-pentol (Scheme 1, compound* **3***)* via *asymmetric dihydroxylation of 5β-cholest-Δ^{24}-3α,7α,12α-triol (Scheme 1, compound* **1***).* To a well-stirred mixture of AD-mix-α (1.8 g) in 20 mL of 1:1 *tert*-butanol/water (10 mL each) and $MeSO_2NH_2$ (0.19 g, 2 mmol) at 0°C was added 5β-cholest-Δ^{24}-3α,7α,12α-triol (0.509 g, 1.22 mmol) (20,29,43). The mixture was stirred at 0°C overnight, then 6 g of solid Na_2SO_3 was added and stirred at room temperature for 1 h. The *tert*-butanol layer was separated, and the aqueous layer was extracted with EtOAc (3 × 25 mL). The combined organic layers were washed with water and saturated NaCl solution, dried over Na_2SO_4, concentrated under a stream of N_2 at room temperature, and the residue subjected to flash column chromatography (EtOAc/$CHCl_3$, 90:10 vol/vol) to give pure 5β-cholestane-3α,7α,12α, 24*S* (or 24β),25-pentol (**3**, Scheme 1) (455 mg, 89%). ^{1}H NMR (400 MHz, $CDCl_3$ + CD_3OD): δ 0.70 (*s*, 18-CH_3), 0.90 (*s*, 19-CH_3), 1.0 (*d*, 21-CH_3, 6 Hz), 1.2/1.17 (26 CH_3 + 27 CH_3), 3.32 (*dd*, 24-H, 10 Hz), 3.45 (*m*, H-3), 3.86 (*br, s*, H-7), 4.0 (*br, s*, H-12) (Table 1). GLC: relative retention times (24*S*) pentol, 2.70 min, and retention time of 5α-cholestane, 12.90 min. The CD spectrum of the 24*S*,25-pentol in the presence of $Eu(fod)_3$ showed $\Delta\varepsilon_{307}$ = +9.4 degrees × cm^2 × $dmol^{-1}$ (first Cotton effect) and $\Delta\varepsilon_{284}$ = −5.9 degrees × cm^2 × $dmol^{-1}$ (second Cotton effect) (20,44,45). These positive Cotton effects measured at its maximum value, around 310 nm, were found to correlate with the chirality of the two hydroxyl groups (20,44,45) having a 1,2-glycol system in the side chain, and thus the chirality at C-24 hydroxyl group in this pentol was assigned as *S* (20,21).

By using a similar protocol, 5β-cholestane-3α,7α,12α, 24*R* (or 24α),25-pentol (Scheme 1, compound **2**) was synthesized from AD-mix-β: ^{1}H NMR for 24*R*,25-pentol (400 MHz, $CDCl_3$ + CD_3OD): δ 0.70 (*s*, 18-CH_3), 0.90 (*s*, 19-CH_3), 1.0 (*d*, 21-CH_3, 6 Hz), 1.2/1.17 (26-CH_3 + 27-CH_3), 3.25 (*t*, 24*H*), 3.41 (*m*, H-3), 3.83 (*s*, H-7), 4.0 (*br, s*, H-12) (Table 1). GLC: relative retention time (24*R*) pentol, 2.66

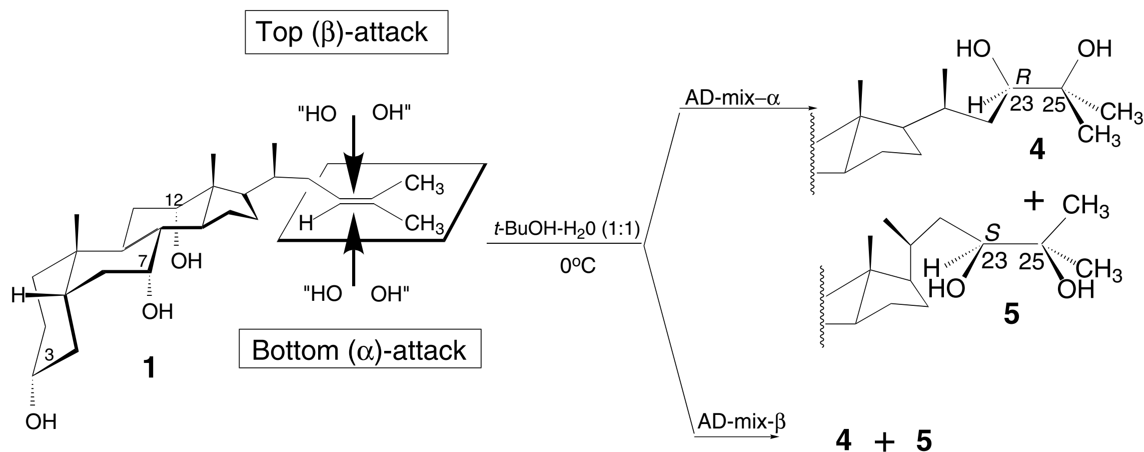

SCHEME 2

min, and retention time of 5α-cholestane 12.90 min. The CD spectrum of the 24*R*,25-pentol in the presence of Eu(fod)$_3$ showed $\Delta\varepsilon_{307} = -5.83$ degrees × cm^2 × dmol^{-1} (first Cotton effect) and $\Delta\varepsilon_{284} = +409$ degrees × cm^2 × dmol^{-1} (second Cotton effect) (20,44). These negative Cotton effects measured at its maximum value, around 310 nm, were found to correlate with the chirality of the two hydroxyl groups having a 1,2-glycol system in the side chain and thus the chirality at the C-24 hydroxyl group in this pentol was assigned as *R* as described previously (20,21).

The FAB mass spectra of both *R* and *S* isomers provided protonated and sodium-adduct molecular ions at *m/z* 453 and 475, respectively, and a weak signal at *m/z* 905 which corresponded to $[2M + H]^+$. In addition, the mass spectra displayed a number of fragment ions representing successive losses of

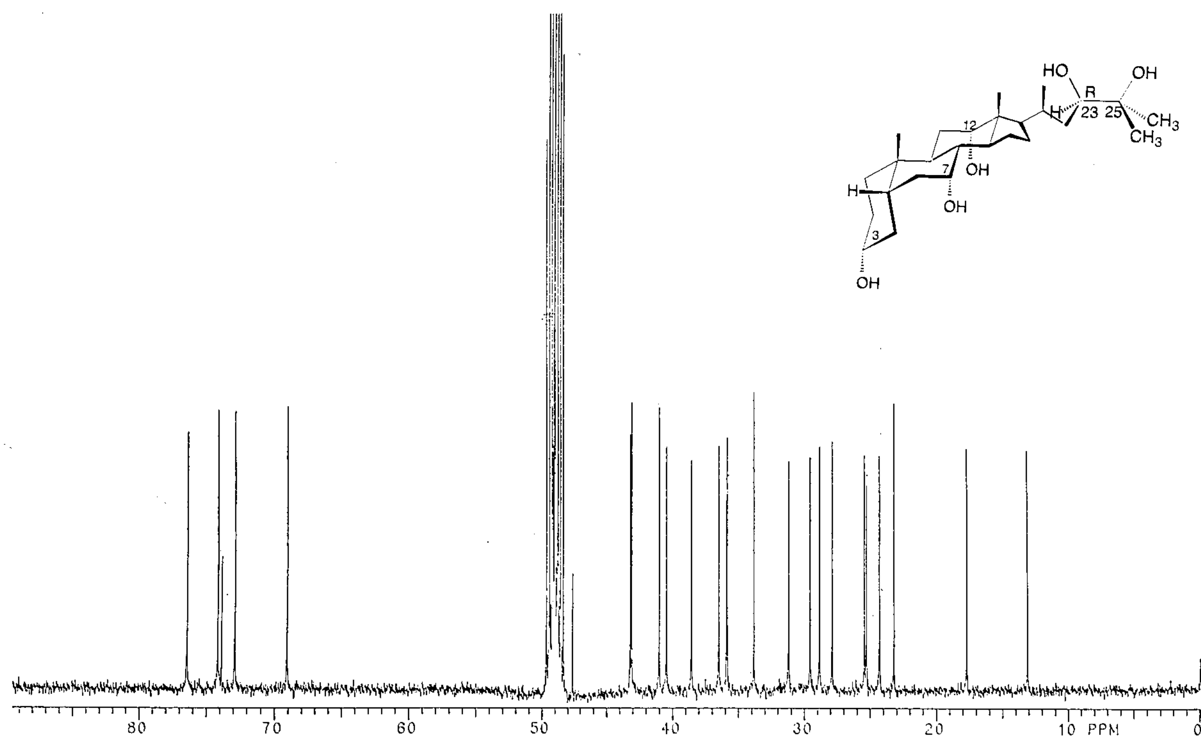

FIG. 3. ^{13}C NMR [^{1}H-decoupled, expanded version of Figure 2 distortionless enhancement polarization transfer (DEPT)] spectrum of 24-nor-5β-cholestane-3α,7α,12α-23*R*,25-pentol. See Figure 1 for abbreviation.

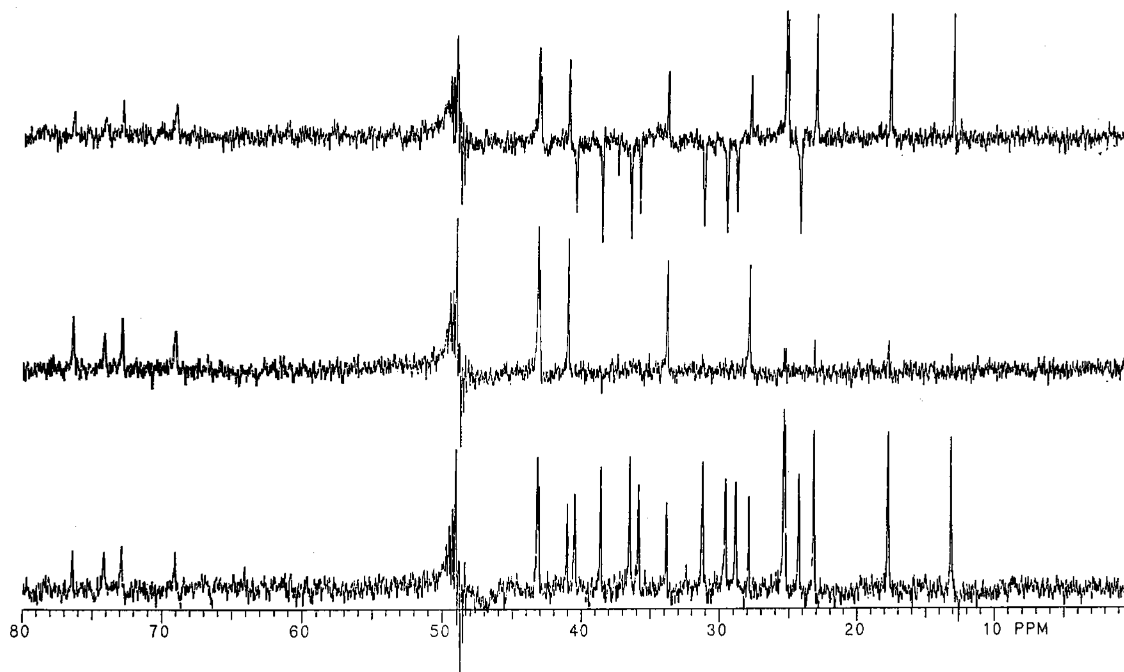

FIG. 4. ^{13}C NMR (^{1}H-decoupled, DEPT) spectrum of 24-nor-5β-cholestane-3α,7α,12α-23*R*,25-pentol. See Figures 1 and 3 for abbreviations.

H_2O molecules from the protonated molecular ions at *m/z* 435 $[M + H - H_2O]^+$, 417 $[M + H - 2H_2O]^+$, 399 $[M + H - 3H_2O]^+$, 381 $[M + H - 4H_2O]^+$, and 363 $[M + H - 5H_2O]^+$.

*(ii) Synthesis of 24-nor-5β-cholestane-3α,7α,12α, 23*R*,25-pentol (Scheme 2, compound* **4***)* via *asymmetric dihydroxylation of 24-nor-5β-cholest-Δ^{23}-3α,7α,12α-triol (Scheme 2, compound* **1***).* To a well-stirred mixture of AD-mix-α (450 mg) in 10 mL of 1:1 *tert*-butanol/water (5 mL each) and $MeSO_2NH_2$ (0.19 g, 2 mmol) at 0°C was added 24-nor-5β-cholest-Δ^{23}-3α,7α,12α-triol (100.0 mg, 0.25 mmol); TLC, $R_f = 0.69$, solvent system chloroform/acetone/methanol, 70:50:15 (by vol) (46,47). The mixture was stirred at 0°C overnight, then 0.5 g of solid Na_2SO_3 was added and stirred at room temperature for 1 h. The *tert*-butanol layer was separated, and the aqueous layer was extracted with EtOAc (3 × 25 mL). The combined organic layers were washed with water and brine, dried over Na_2SO_4, concentrated, and the residue subjected to flash column chromatography (ethyl acetate/chloroform, 90:10, vol/vol) to give pure 24-nor-5β-cholestane-3α,7α,12α, 23*R*,25-pentol (**4**, Scheme 2) (55.0 mg, 55%). TLC: $R_f = 0.32$ (upper spot, solvent system: chloroform/acetone/methanol, 70:50:15, by vol). ^{1}H NMR, 23,25-pentol (400 MHz, CD_3OD): δ 0.75 (*s*, 18-CH_3), 0.92 (*s*, 19-CH_3), 1.03 (*d*, 21-CH_3, 6 Hz), 1.12/1.14 (26-CH_3 + 27-CH_3), 3.45 (*dd*, 10 Hz, 23-H), 3.32 (*m*, H-3), 3.80 (*br, s*, H-7), 4.0 (*br, s*, H-12) (Fig. 1, Table 1). ^{13}C NMR (^{1}H-decoupled spectrum, Fig. 2; ^{1}H-decoupled spectrum, expanded version, Fig. 3; and ^{1}H-decoupled, DEPT spectrum, Fig. 4).

The CD spectrum of the 24-nor-5β-cholestane-23,25-pentol in the presence of $Eu(fod)_3$ showed $\Delta\varepsilon_{308} = -8.48$ degrees × cm^2 × $dmol^{-1}$ (first Cotton effect) and $\Delta\varepsilon_{284} = +5.90$ degrees × cm^2 × $dmol^{-1}$ (second Cotton effect) (Fig. 5). These negative Cotton effects measured at its maximum value, around 310 nm, were found to correlate with the chirality of the two hydroxyl groups (20,44,45) having a 1,2-glycol system in the side chain and thus the chirality at the C-23 hydroxyl group in 24-nor-5β-cholestane3α,7α,12α,23,25-pentol (Scheme 2, compound **4**) was assigned as *R* (Fig. 5).

Further elution of the flash chromatography column with ethyl acetate/chloroform (90:10, vol/vol) gave pure 24-nor-5β-cholestane-23,25-pentol (Scheme 2, compound **5**, lower isomer, 35 mg). TLC analysis: $R_f = 0.24$ (solvent system: chloroform/acetone/methanol, 70:50:15, by vol). ^{1}H NMR showed an isomer of 23,25-pentol (400 MHz, CD_3OD): δ 0.75 (*s*, 18-CH_3), 0.92 (*s*, 19-CH_3), 1.03 (*d*, 21-CH_3, 6 Hz), 1.12/1.14 (26-CH_3 + 27-CH_3), 3.45 (*d*, 23-H), 3.35 (*m*, H-3), 3.80 (*s*, H-7), 4.0 (*br, s*, H-12) (Table 1). The CD spectrum of this 23,25-pentol in the presence of $Eu(fod)_3$ showed $\Delta\varepsilon_{307} = +2.73$ degrees × cm^2 × $dmol^{-1}$ (first Cotton effect) and $\Delta\varepsilon_{285} = -1.36$ degrees × cm^2 × $dmol^{-1}$ (second Cotton effect) (20). These positive Cotton effects measured at its maximum value, around 310 nm, were found to correlate with the chirality of

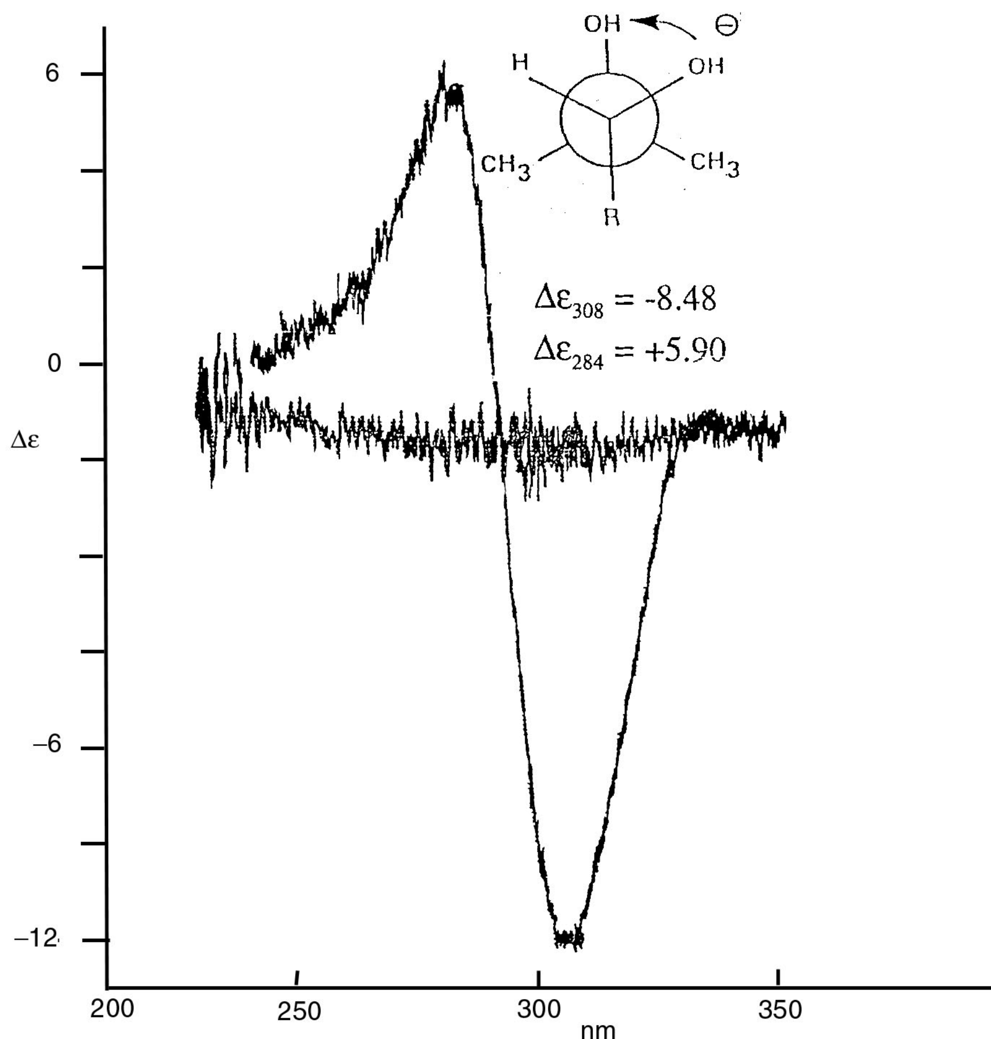

FIG. 5. Circular dichroism of 2×10^{-4} M 24-nor-5β-cholestane-3α,7α,12α-23*R*,25-pentol and 2×10^{-4} M tris-1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-octane-4,6-dionato) europium(III) in dry $CHCl_3$ at ambient temperature within 30 min after mixing.

the two hydroxyl groups having a 1,2-glycol system in the side chain and thus the chirality at the C-23 hydroxyl group in this pentol was assigned as *S* (44,45). The isomeric mixture in 24-nor-5β-cholestane-3α,7α,12α,23 (*R* and *S*),25-pentols was present in the ratio of (55:35, *R/S*).

The FAB mass spectra of both *R* and *S* isomers provided protonated and sodium-adduct molecular ions at *m/z* 439 and 461, respectively, and a weak signal at *m/z* 877 which corresponded to $[2M + H]^+$. In addition, the mass spectra displayed a number of fragment ions representing successive losses of H_2O molecules from the protonated molecular ions at *m/z* 421 $[M + H - H_2O]^+$, 403 $[M + H - 2H_2O]^+$, 385 $[M + H - 3H_2O]^+$, 367 $[M + H - 4H_2O]^+$, and 349 $[M + H - 5H_2O]^+$.

EI–MS displayed a number of fragment ions representing successive losses of H_2O and CH_3 molecules from the parent molecular ions at *m/z* 402 $[M - 2H_2O]^+$, 387 $[M - 2H_2O - CH_3]^+$, 384 $[M - 3H_2O]^+$, 271 $[M - 2H_2O - \text{side chain}]^+$, and 253 $[M - \text{side chain} - 3H_2O]^+$.

*(iii) Synthesis of (23*R *and 23*S*) 24-nor-5β-cholestane-3α,7α,12α,23,25-pentols (Scheme 2, compounds* **4** *and* **5***)* via *asymmetric dihydroxylation of 24-nor-5β-cholest-Δ*^{23}*-3α,7α,12α-triol (Scheme 2, compound* **1***).* To a well-stirred mixture of AD-mix-β (450 mg) in 10 mL of 1:1 *tert*-butanol/water (5 mL each) plus $MeSO_2NH_2$ (0.19 g, 2 mmol) at 0°C was added 24-nor-5β-cholest-Δ^{23}-3α,7α,12α-triol (100.0 mg, 0.25 mmol) (46,47). The mixture was stirred at 0°C overnight, then 0.5 g of solid Na_2SO_3 was added and stirred at room temperature for 1 h. The *tert*-butanol layer was separated, and the aqueous layer was extracted with EtOAc (3 × 25 mL). The combined organic layers were washed with water and brine, dried over Na_2SO_4, concentrated, and the residue subjected to flash column chromatography (ethyl ac-

etate/chloroform, 90:10) to give pure 24-nor-5β-cholestane-23*R*,25-pentol (80.0 mg, 80%). TLC: $R_f = 0.31$ (upper isomer, solvent system: chloroform/acetone/methanol, 70:50:15 (by vol). ^{1}H NMR, 23*R*,25-pentol (400 MHz, CD_3OD): δ 0.75 (*s*, 18-CH_3), 0.92 (*s*, 19-CH_3), 1.03 (*d*, 21-CH_3, 6 Hz), 1.12/1.14 (26-CH_3 + 27-CH_3), 3.45 (*dd*, 10 Hz, 23H), 3.32 (*m*, H-3), 3.80 (*br, s*, H-7), 4.0 (*br, s*, H-12). The CD spectrum of the 24-nor-5β-cholestane-23*R*,25-pentol in the presence of $Eu(fod)_3$ showed $\Delta\varepsilon_{308} = -7.65$ degrees × cm^2 × dmol^{-1} (first Cotton effect) and $\Delta\varepsilon_{284} = +5.40$ degrees × cm^2 × dmol^{-1} (second Cotton effect) (20,44). These negative Cotton effects measured at its maximum value, around 310 nm, were found to correlate with the chirality of the two hydroxyl groups (20,44,45) having a 1,2-glycol system in the side chain and thus the chirality at the C-23 hydroxyl group in this pentol was assigned as *R* (Scheme 2, compound **4**). TLC analysis using silica gel G plates and a solvent system of chloroform/acetone/methanol 70:50:15 (by vol) revealed a component with $R_f = 0.21$ (lower spot on TLC, minor isomer, 20%). TLC and ^{1}H NMR showed an isomer of 23,25-pentol (400 MHz, $CDCl_3$ + CD_3OD): δ 0.70 (*s*, 18-CH_3), 0.90 (*s*, 19-CH_3), 1.0 (*d*, 21-CH_3, 6 Hz), 1.2/1.17 (26-CH_3 + 27-CH_3), 3.48 (*d*, 23-H), 3.41(*m*, H-3), 3.86 (*s*, H-7), 4.0 (*br, s*, H-12). The CD spectrum of this 23,25-pentol in the presence of $Eu(fod)_3$ showed $\Delta\varepsilon_{308} = +5.8$ degrees × cm^2 × dmol^{-1} (first Cotton effect) and $\Delta\varepsilon_{285} = -5.3$ degrees × cm^2 × dmol^{-1} (second Cotton effect) (44). These positive Cotton effects measured at its maximum value, around 310 nm, were found to correlate with the chirality of the two hydroxyl groups having a 1,2-glycol system in the side chain and thus the chirality at the C-23 hydroxyl group in this pentol was assigned as *S* (Scheme 2, compound **5**) (9,20,45).

DISCUSSION

A defect in mitochondrial cytochrome P_{450} enzyme 27-hydroxylase, in which the conversion of 5β-cholestane-3α,7α,12α-triol to the 5β-cholestane-3α,7α,12α,26 (or 27)-tetrol is blocked, is considered by many to be the major inherited abnormality in the formation of cholic acid in CTX (4,11,13–16). Recent results from our laboratory have described an alternative microsomal pathway for the cleavage of the side chain in this triol starting with microsomal 25-hydroxylation followed by 24-hydroxylation to yield 5β-cholestane-3α,7α,12α,24*S*,25-pentol (6–12,48). This pathway is involved in synthesis of cholic acid but not in the chenodeoxycholic acid pathway (4,8,9,12,13).

Despite the interest of many laboratories in this pathway, which involves neither mitochondrial nor peroxisomal enzymes, its importance relative to the 27-hydroxylase block in CTX is still controversial (4,8,11,12,43,48–50).

In this report, we synthesized both the C_{27}- and the C_{26}-analogs of naturally occurring C_{27}-bile alcohols by means of the new Sharpless' chiral ligands dihydroquinidine $(DHQD)_2$-PHAL and dihydroquinine $(DHQ)_2$-PHAL (17–20, 30–35,39,51,52). With the proper choice of the chiral reagent, this reaction permitted the preparation of the enantiomerically pure (24*R* and 24*S*) 5β-cholestane-3α,7α,12α,24,25-pentols (Scheme 1, compounds **2** and **3**) from the prochiral substrate, 5β-cholest-Δ^{24}-3α,7α,12α-triol (Scheme 1, compound **1**). The absolute stereochemistry (24*R*/24*S*) of 5β-cholestane-3α,7α,12α,24,25-pentols was established *via* NMR and lanthanide-induced CD Cotton effect measurements, and thus the AD reaction in the 5β-cholestane-24,25-pentols was confirmed as predicted by the face selection rule of Sharpless and coworkers (17–21). Moreover, we observed an anomalous enantioselectivity in the Sharpless catalytic AD reaction (36–42) of 24-nor-5β-cholest-Δ^{23}-3α,7α,12α-triol (Scheme 2, compound **1**) to yield the isomeric (23*R*) and (23*S*) 24-nor-5β-cholestane-3α,7α,12α,23,25-pentols in high yield (80–87%) and with moderate to good stereoselectivity (30–80%) (Scheme 2, compounds **4** and **5**).

The absolute configuration at C-23 of 24-nor-5β-cholestane-3α,7α,12α,23,25-pentols was further established by lanthanide-induced CD analysis experiments (20,21). Our results in the nor series show that the stereoselective nature of the AD reaction is only partial and that the preexisting stereogenic center at C-20 affects the stereochemical outcome of the reaction. Indeed, the absolute configuration of the nor-pentols is dictated by the overwhelming asymmetric induction of the stereogenic center at C-20 and not by the chiral ligands used. However, one cannot predict the interplay of the steric or polar hydrogen-bond effects of the molecule over the sterically demanding osmium-ligand complexes. In this case, both chiral ligands afforded the expected pentols, but an anomalous enantioselectivity of the AD reaction was observed (30–42).

Using AD-mix-α, we obtained 65% *R* isomer and 35% *S* isomer (Scheme 2, compounds **4** and **5**), and with AD-mix-β, 80% *R* isomer and 20% *S* isomer. These results clearly indicate that the Sharpless AD reaction of nor compounds is not controlled by the chiral reagent and that maybe some asymmetric induction of C-20 exerts a directional effect. Clearly, all these results emphasize the need for exercising great caution when applying the Sharpless face-selection rule to the 24-nor-series of steroids (30–42).

The configuration at C-23 of 24-nor-5β-cholestane-3α,7α,12α,23,25-pentols was established by NMR experiments and verified by CD analysis as previously described for (24*R* and 24*S*) 5β-cholestane-3α,7α,12α,24,25-pentols (20,21). The results of ^{1}H and ^{13}C NMR studies are summarized in Table 1. In (24*R*) 5β-cholestane-3α,7α,12α,24,25-pentol, the C-*24H* showed a triplet at δ 3.4 and in (24*S*)-pentol showed a doublet at δ 3.2. The ^{13}C NMR spectra for (24*R*

and 24*S*) 5β-cholestanepentols (in CD_3OD) exhibited 30 signals between 140 and 10 ppm and analyzed by DEPT-135 spectra in CD_3OD which allowed the identification of seven quaternary carbons, ten CH, nine CH_2, and five CH_3 (20,21). In 24-nor-5β-cholestane-3α,7α,12α,23,25-pentols the C-*23H* in both (23*R* and 23*S*) pentols showed a doublet at δ 3.45 and 3.48. A standard ^{13}C NMR DEPT spectrum in CD_3OD was used to delineate the multiplicity of each carbon resonance in 24-nor-5β-cholestane-3α,7α,12α,23*R*,25-pentol. A complete analysis with respect to quaternary carbons and CH, CH_2, and CH_3 groups using spectral editing with the DEPT pulse sequence (signals between 80 and 10 ppm) is shown in Figure 4. However, these ^{13}C data could not differentiate the isomeric pairs of (23*R* and 23*S*) 24-nor-5β-cholestane-3α,7α,12α,23,25-pentols. Therefore, the signal assignments were further confirmed by comparison of the expanded version of ^{13}C NMR spectra of 23*R* pentol with that of the ^{13}C NMR DEPT spectra of model compounds, namely 5β-cholestane-3α,7α,24β (24β carbon absorptions, 79.66 ppm)25-tetrol and 5β-cholestane-3α,7α,24α (24α carbon absorptions, 78.86 ppm)25-tetrol as described previously (20,21). Since these sharp signals were unequivocally identified and separated completely from each other, the shielding data provided a straightforward identification of each isomer, as well as an estimate of purity.

FAB–MS data of (23*R* and 23*S*) 24-nor-5β-cholestanepentols and (24*R*)- and (24*S*)-pentols in the presence of NaCl (9,23,27,28) provided very intense molecular ions, 461 = $[M + Na]^+$ and 475 = $[M + Na]^+$, respectively, as base peaks in the spectra of these molecules. Since the fragmentation pattern was similar for both samples as discussed above, these data could differentiate neither 24*S*-pentol from the 24*R*-pentol nor 23*R*-pentol from the 23*S*-pentols.

The synthesis and characterization of 24-norpentols described in these studies will be helpful in studying the stereospecificity of the hepatic enzymes that promote oxidation of the cholesterol side chain, and in determining whether these compounds that contain one less carbon atom in their side chains are capable of undergoing the same reaction sequences as the normally occurring C_{27} bile alcohols.

METHOD

Improved Separation of Conjugated Fatty Acid Methyl Esters by Silver Ion–High-Performance Liquid Chromatography

ABSTRACT: Operating from one to six silver ion–high-performance liquid chromatography (Ag$^+$–HPLC) columns in series progressively improved the resolution of the methyl esters of conjugated linoleic acid (CLA) isomeric mixtures from natural and commercial products. In natural products, the 8 *trans*, 10 *cis*-octadecadienoic (18:2) acid was resolved from the more abundant 7 *trans*, 9 *cis*-18:2, and the 10 *trans*, 12 *cis*-18:2 was separated from the major 9 *cis*, 11 *trans*-18:2 peak. In addition, both 11 *trans*, 13 *cis*-18:2 and 11 *cis*, 13 *trans*-18:2 isomers were found in natural products and were separated; the presence of the latter, 11 *cis*, 13 *trans*-18:2, was established in commercial CLA preparations. Three Ag$^+$–HPLC columns in series appeared to be the best compromise to obtain satisfactory resolution of most CLA isomers found in natural products. A single Ag$^+$–HPLC column in series with one of several normal-phase columns did not improve the resolution of CLA isomers as compared to that of the former alone. The 20:2 conjugated fatty acid isomers 11 *cis*, 13 *trans*-20:2 and 12 *trans*, 14 *cis*-20:2, which were synthesized by alkali isomerization from 11 *cis*, 14 *cis*-20:2, eluted in the same region of the Ag$^+$–HPLC chromatogram just before the corresponding geometric CLA isomers. Therefore, CLA isomers will require isolation based on chain length prior to Ag$^+$–HPLC separation. The positions of conjugated double bonds in 20:2 and 18:2 isomers were established by gas chromatography–electron ionization mass spectrometry as their 4,4-dimethyloxazoline derivatives. The double-bond geometry was determined by gas chromatography–direct deposition–Fourier transform infrared spectroscopy and by the Ag$^+$–HPLC relative elution order.

Paper no. L8079 in *Lipids 34*, 407–413 (April 1999).

Recently we reported for the first time the separation of a complex mixture of conjugated linoleic acid (CLA) isomers by silver ion–high-performance liquid chromatography (Ag$^+$–HPLC) as their methyl esters using 0.1% acetonitrile in hexane as the mobile phase (1). With this method, a commercial CLA mixture was separated into three groups of *trans,trans*, *cis/trans*, and *cis,cis* octadecadienoic acid (18:2) isomers. Each of the three groups of geometric isomers was shown to contain four major positional CLA isomers 8,10-18:2, 9,11-18:2, 10,12-18:2, and 11,13-18:2. Application of Ag$^+$–HPLC to the separation of natural products revealed additional CLA peaks, including several that were not resolved. For instance, 7 *trans*, 9 *cis*-18:2 was reported for the first time to be present in cow and human milk, cheese, beef and human adipose tissue, but it coeluted with 8 *trans*, 10 *cis*-18:2 (2). Furthermore, it was reported recently that mouse liver microsomes elongated 9 *cis*, 11 *trans*-18:2 to 11 *cis*, 13 *trans*-20:2 (3). The longer-chain 20:2 conjugated fatty acids (CFA) were synthesized by alkali isomerization of 11 *cis*, 14 *cis*-20:2, but no supporting evidence was provided (3). Therefore, it was not known where longer-chain CFA such as 20:2 eluted relative to CLA on Ag$^+$–HPLC columns. Based on the elution order of saturated fatty acid methyl esters (FAME) or their triacylglycerols by Ag$^+$–HPLC using a similar acetonitrile in hexane mobile phase, an inverse relationship of retention volume and chain length was expected (4).

In the present communication, we report the markedly improved resolution of the CLA isomers, and the separation of the 18:2 from the 20:2 CFA isomers, by using two to six Ag$^+$–HPLC columns in series. This resulted in the separation of several previously coeluting pairs of CLA isomers found in foods and biological systems.

MATERIALS AND METHODS

The polyunsaturated fatty acids (PUFA) linoleic acid (9 *cis*, 12 *cis*-18:2) and 11 *cis*, 14 *cis*-eicosadienoic acid (11 *cis*, 14 *cis*-20:2) were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). CLA standards (9 *cis*, 11 *trans*-18:2 and 10 *trans*, 12 *cis*-18:2) were obtained from Matreya, Inc. (Pleasant Gap, PA). A 10% solution of trimethylsilyldiazomethane in hexane was obtained from TCI America (Portland, OR). 2-Amino-2-methyl-1-propanol (95%) was purchased from Aldrich Chemical Company, Inc. (Milwaukee, WI). All solvents and chemicals were reagent grade.

The two PUFA 9 *cis*, 12 *cis*-18:2 and 11 *cis*, 14 *cis*-20:2 were isomerized according to published procedures (5,6). Briefly, 20 mL of ethylene glycol was placed in a three-necked round-bottom flask (100 mL) equipped with a magnetic stirrer, a condenser, and a thermostatically controlled heater, and heated to 110°C. Argon was passed through the reaction flask throughout the heating process. KOH (5 g) was carefully added to the flask, and the temperature was raised to 160°C after the KOH had dissolved. At this point, a PUFA was added and heated for 40 min at 160 ± 5°C. The flask was allowed to cool to room temperature, and the liquid was transferred into a 500-mL separatory funnel containing 100 mL of 6 N HCl; final pH 1–2. The liquid was extracted with two portions of 40 mL petroleum ether/diethyl ether (1:1). The combined organic phase was washed with 80 mL distilled water and dried over Na_2SO_4.

The 4,4-dimethyloxazoline (DMOX) derivatives of the CFA were prepared directly from the free fatty acids by reaction with a threefold excess of 2-amino-2-methyl-1-propanol at 170°C for 0.5 h in a 1-mL vial (7). The DMOX derivatives were analyzed by gas chromatography–electron ionization mass spectrometry (GC–EIMS) (1). The CFA were methylated with trimethylsilyldiazomethane according to Hashimoto *et al.* (8). The FAME were then analyzed by GC using a 100-m CP-Sil 88 column (9). FAME were also measured by GC–direct deposition–Fourier transform infrared (GC–DD–FTIR) (10). A Bio-Rad (Cambridge, MA) Tracer™ GC–FTIR 60A spectrometer system was used. This system was used with a 50-m CP-Sil 88 capillary column as described earlier (11).

Ag^+–HPLC separation of the CFA methyl esters was carried out using an HPLC (Waters 510 solvent delivery system; Waters Associates, Milford, MA), equipped with a 100-µL injection loop (Waters 600E, System Controller), a photodiode array detector (Waters 996) operated at 233 nm, and an operating system (Waters Millennium™ version 2.15). Two to six ChromSpher 5 Lipids analytical silver-impregnated columns (each 4.6 mm i.d. × 250 mm stainless steel; 5 µm particle size; Chrompack, Bridgewater, NJ) were used in series. The mobile phase was 0.1% acetonitrile in hexane and operated isocratically at a flow rate of 1.0 mL/min; a flow rate of 2.0 mL/min sharpened all the peaks but led to less resolution in the *trans,trans* and *cis/trans* regions. The flow was initiated 0.5 h prior to sample injection. Typical injection volumes were 5–15 µL. The column head pressure increased from about 350 psi to about 750, 1050, 1300, and 2000 psi as the number of columns in series increased from one to two, three, four, and six, respectively. The silica LC-Si, phenyl LC-DP, and diol LC-Diol columns, each 4.6 mm i.d. × 250 mm stainless steel, 5 µm particle size, were obtained from Supelco Inc. (Bellefonte, PA).

RESULTS AND DISCUSSION

The separation of CLA isomers progressively improved by increasing the number of Ag^+–HPLC columns connected in series (up to six) as demonstrated with a beef lipid mixture in Figure 1. This is the first chromatographic separation of peaks attributed to the minor CLA isomers 8 *trans*, 10 *cis*-18:2 and 10 *trans*, 12 *cis*-18:2 in natural products, which were previously unresolved (2). The use of three columns in series was sufficient to begin resolving 8 *trans*, 10 *cis*-18:2 from 7 *trans*, 9 *cis*-18:2 and 10 *trans*, 12 *cis*-18:2 from 9 *cis*, 11 *trans*-18:2. The presence of these minor CLA isomers was previously confirmed in cheese lipids by GC–EIMS even though they had not been resolved with a single Ag^+–HPLC column (2,12). Further examples of three-column separation of total CLA methyl esters are presented for cheese (Fig. 2A) and cow milk (Fig. 2B). In a recent publication, the presence of the 10 *trans*, 12 *cis*-18:2 isomer in cheese was indirectly deduced by using partial hydrazine reduction and GC techniques (13).

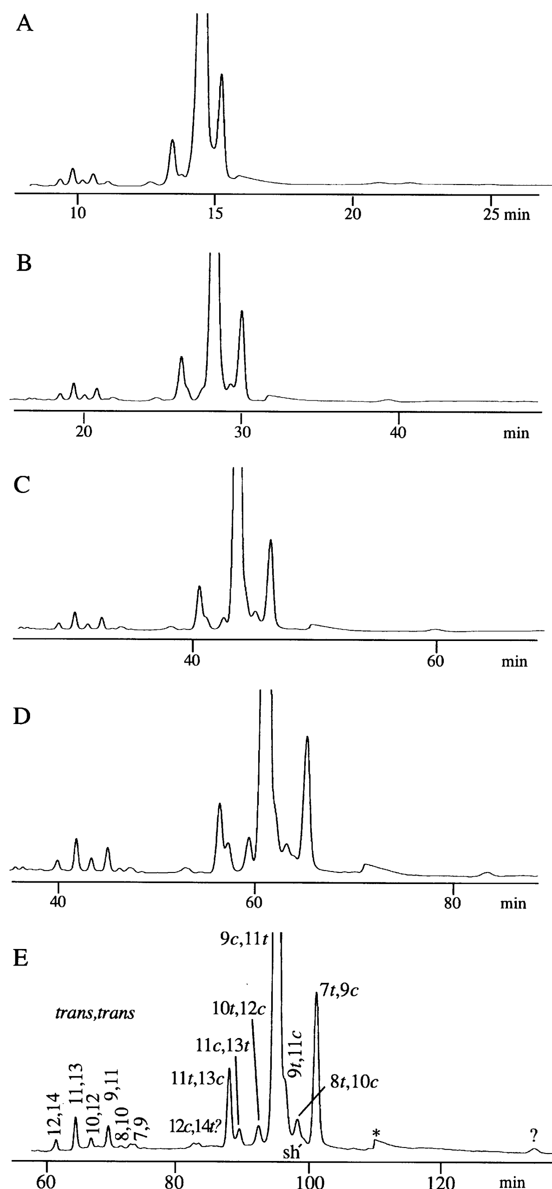

FIG. 1. Separation of total beef conjugated fatty acids using one (A), two (B), three (C), four (D), and six (E) silver ion–high-performance liquid chromatography (Ag^+–HPLC) columns in series. The asterisk (*) denotes an ultraviolet absorption at 233 nm due to methyl oleate. A shoulder after the 8*t*,10*c* peak was abbreviated "sh."

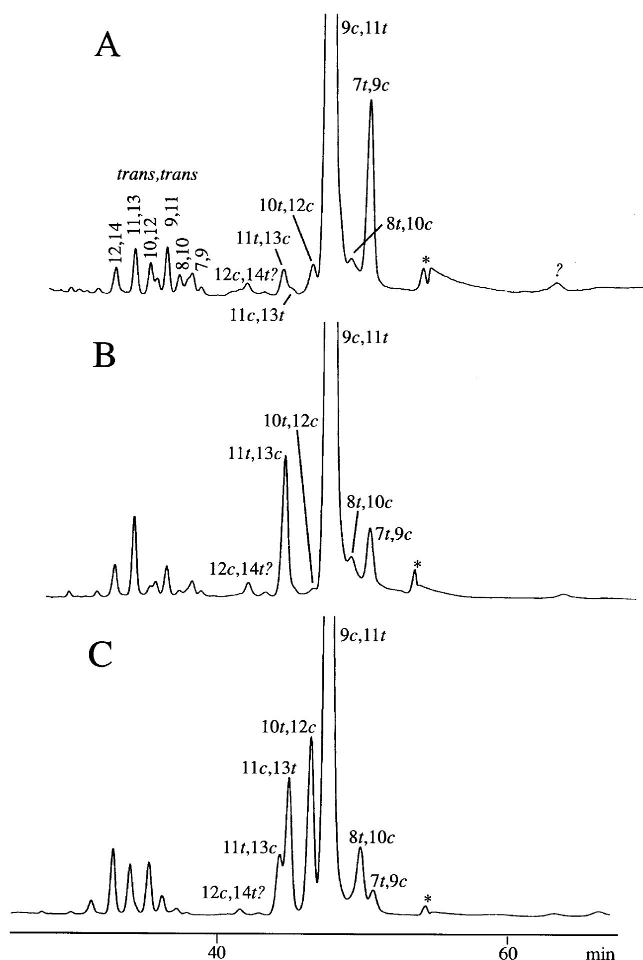

FIG. 2. Ag^+–HPLC profiles of cheese (A) and cow milk (B) using three silver-ion columns in series. Profile for coinjected mixtures of cow milk (C) with a commercial preparation from Nu-Chek-Prep (Elysian, MN). The extra peaks in the *trans,trans* region have not been identified. For asterisks and abbreviation see Figure 1.

Furthermore, the use of two to six Ag^+–HPLC columns in series clearly resolved the two 11,13-18:2 geometric isomers (Fig. 1B–E). The identification of these two isomers was achieved by coinjection of each of the natural product mixtures investigated with a known Nu-Chek-Prep commercial preparation of CLA; the resulting chromatogram for the mixture of cow milk plus Nu-Chek-Prep is shown in Figure 2C. The geometric configuration of the 11,13-18:2 isomer in the commercial CLA preparation was previously established as 11 *cis*, 13 *trans*-18:2 based on its chromatographic elution order by GC and Ag^+–HPLC (2,12,14). Therefore, the first-eluting major 11,13-18:2 isomer in cow milk (Fig. 2B) was tentatively assigned to be 11 *trans*, 13 *cis*- 18:2. The 11 *trans*, 13 *cis*-18:2 isomer was also found to be the most abundant 11,13-18:2 isomer in beef (Fig. 1), cheese (Fig. 2A), and human adipose tissue (data not shown), unlike the human milk that we examined which showed about equal amounts of the 11,13-18:2 pair of isomers.

A shoulder on the tail of the 9 *cis*, 11 *trans*-18:2 peak, tentatively attributed to the 9 *trans*, 11 *cis*-18:2 isomer, was observed only when the separation was carried out with six columns connected in series (Fig. 1E). A similar partial resolution of the *cis/trans* 9,11-18:2 pair of isomers was recently reported by using two Ag^+–HPLC columns in series under different experimental conditions, namely, 0.5% acetonitrile in hexane and detection at 206 nm (4); 9 *trans*, 11 *cis*-18:2 eluted as a shoulder on the leading edge of the 9 *cis*, 11 *trans*-18:2 peak in that case (15). The presumed reversal of the elution sequence of this pair of *cis/trans* geometric isomers may be an effect of mobile phase composition and is being investigated further.

The relative proportion of the different minor CLA isomers varied slightly in the different biological matrices investigated. For example, the 7 *trans*, 9 *cis*-18:2 was more abundant than 11 *trans*, 13 *cis*-18:2, except for cow milk, whereas 11 *trans*, 13 *cis*-18:2 was more abundant than 11 *cis*, 13 *trans*-18:2, except for human milk. These findings probably are not general characteristics but may be attributed to the limited number of test samples investigated. Also unclear is the dependence on diet of these variations in CLA distribution in human tissue lipids.

In using the previously identified Nu-Chek-Prep commercial mixture as reference (1), the separation of CLA mixtures was further investigated by joining several normal-phase HPLC columns, such as silica, phenyl, and diol columns, before or after a silver-ion column in series. In general, a degradation in resolution was obtained. The best combination of all of these columns was achieved by using a silica column followed by a silver-ion column (Fig. 3A). However, this result did not match the excellent separation obtained by using even two Ag^+–HPLC columns in series (Fig. 3B).

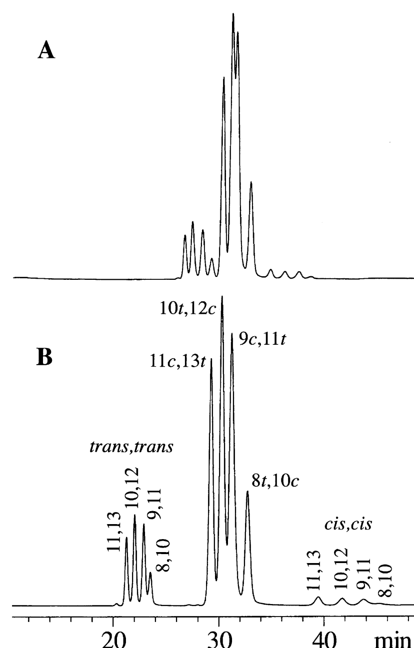

FIG. 3. Separation of a commercial conjugated linoleic acid preparation (Nu-Chek-Prep, Elysian, MN), using a combination of a silica column followed by a silver-ion column (A), and two silver-ion columns in series (B).

The resolution of synthetic C_{18} and C_{20} CFA mixtures was also enhanced with multiple Ag^+–HPLC columns. The isomerized FAME products of either 9 *cis*, 12 *cis*-18:2 (Fig. 4A) or 11 *cis*, 14 *cis*-20:2 (Fig. 4B) gave rise to two peaks in each of the *trans,trans*, *cis/trans*, and *cis,cis* regions of the Ag^+–HPLC chromatogram. The major CFA peaks were due to the *cis/trans* isomers. In using two Ag^+–HPLC columns in series, the retention times (volumes) for these two *cis/trans* pairs of CFA were close, as seen from the analysis of a mixture of these CFA mixtures (Fig. 4C). In each case, the three pairs of C_{20} CFA eluted before the corresponding C_{18} CFA in the *trans,trans*, *cis/trans*, and *cis,cis* regions, respectively. By comparison, using a single Ag^+–HPLC column was inadequate (Fig. 4D). A similar partial resolution was previously reported (16) for some positional C_{18} and C_{20} monounsaturated fatty acid isomers, using a single Ag^+–HPLC column. Furthermore, the inverse relationship between elution order and chain length was similar to that reported for saturated FAME and their triacylglycerols (4). These conjugated C_{18} and C_{20} products were also analyzed by GC. The two *cis/trans* C_{18} CFA isomers eluted at the same GC retention times as those of the standards 9 *cis*, 11 *trans*-18:2 and 10 *trans*, 12 *cis*-18:2 on the 100-m CP-Sil 88 column. The two *cis/trans* C_{20} CFA isomers eluted shortly after arachidonic acid. Their equivalent chain lengths were 22.48 and 22.57 for 11,13-20:2 and 12,14-20:2, respectively; the equivalent chain length of arachidonic acid on this GC column was 22.40.

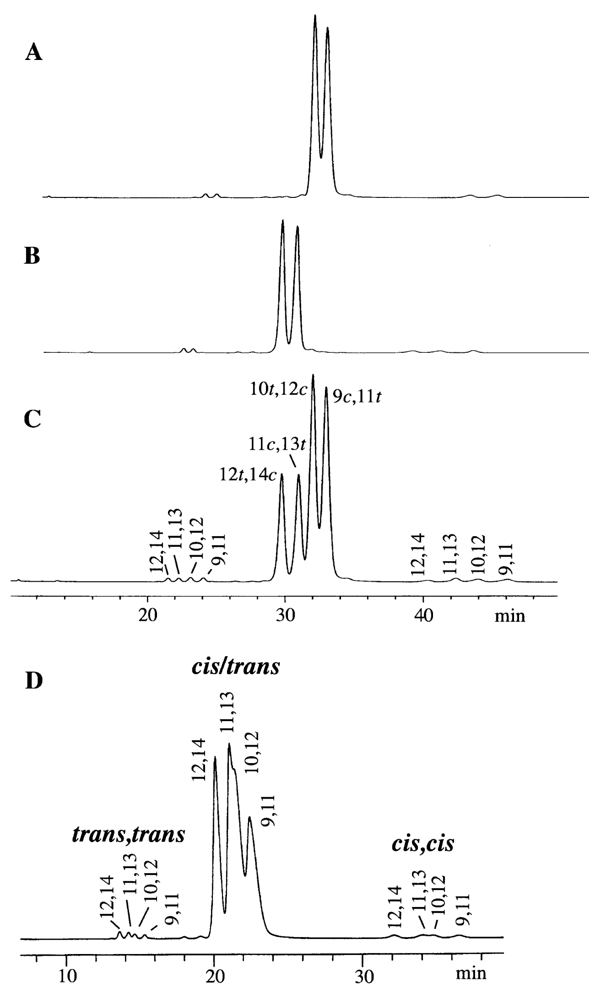

FIG. 4. Ag^+–HPLC separation using two silver-ion columns in series for (A) a CLA mixture obtained by alkali isomerization of linoleic acid (9 *cis*, 12 *cis*-18:2), (B) a conjugated fatty acid mixture obtained by alkali isomerization of 11 *cis*, 14 *cis*-20:2, and (C) coinjection of mixtures (A) and (B). Chromatogram (D) shows the separation obtained by analyzing a mixture of (A) and (B) on a single Ag^+–HPLC column. Different amounts of conjugated 18:2 and 20:2 mixtures were analyzed in (C) and (D). For abbreviations see Figures 1–3.

The isomerization products of 9 *cis*, 12 *cis*-18:2 were identified as 9,11-18:2 and 10,12-18:2 (data not shown), and those of 11 *cis*, 14 *cis*-20:2 were found to be 11,13-20:2 and 12,14-20:2 by GC-EIMS as the DMOX derivatives (Fig. 5). The characteristic fragment ions due to the double bond occurred at *m/z* 224, 236, 250, and 262 for 11,13-20:2 (Fig. 5A), and at *m/z* 238, 250, 264, and 276 for 12,14-20:2 (Fig. 5B). Favorable allylic cleavages occurred at *m/z* 210 and 290 for 11,13-20:2 and *m/z* 224 and 304 for 12,14-20:2. In addition, the ion that was 14 mass units greater than the higher- mass allylic ion was also abundant, i.e., *m/z* 304 and 318, for 11,13-20:2 and 12,14-20:2, respectively.

The *cis/trans* geometries of the C_{18} and C_{20} CFA methyl ester isomers were established by GC–DD–FTIR (Fig. 6). These compounds exhibited characteristic =C-H stretching vibrations at 3020 and 3002 cm^{-1} and deformation bands at 985 and 946 cm^{-1}, as previously described for *cis/trans* conjugated dienes (10). The relative intensities of the C-H stretching vibrations for *cis/trans* C_{18} and C_{20} CFA methyl esters were compared in Figure 7 after normalization relative to the ester carbonyl band. The results showed that, whereas the asymmetric C-H stretch (2952 cm^{-1}) for the CH_3 group in these two CFA isomers was similar, the asymmetric (2924 cm^{-1}) and symmetric (2853 cm^{-1}) CH_2 stretching vibration bands were more intense in C_{20} than in C_{18} CFA. These data were consistent with the formation of 11 *cis*, 13 *trans*-20:2 and 12 *trans*, 14 *cis*-20:2, respectively.

The results of the present study demonstrated the improved resolution of CLA isomers observed by using two or more Ag^+–HPLC columns in series. It would appear that the use of three Ag^+–HPLC columns was the best compromise to achieve, in a timely manner, resolution of most CLA isomers in biological matrices. More than three columns should only be used to resolve specific critical pairs of isomers. Furthermore, this method resolved the 11,13-18:2 pair of geometric CLA isomers. No improvements or advantages were gained by combining a silver-ion column with any of the normal-phase columns, such as silica, phenol, or diol.

In addition, the results show that the CFA with different chain lengths eluted in the same region of the Ag^+–HPLC chromatogram. Therefore, for future investigations of CLA metabolites a prior isolation based on chain length, such as reversed-phase HPLC (17,18), may be required.

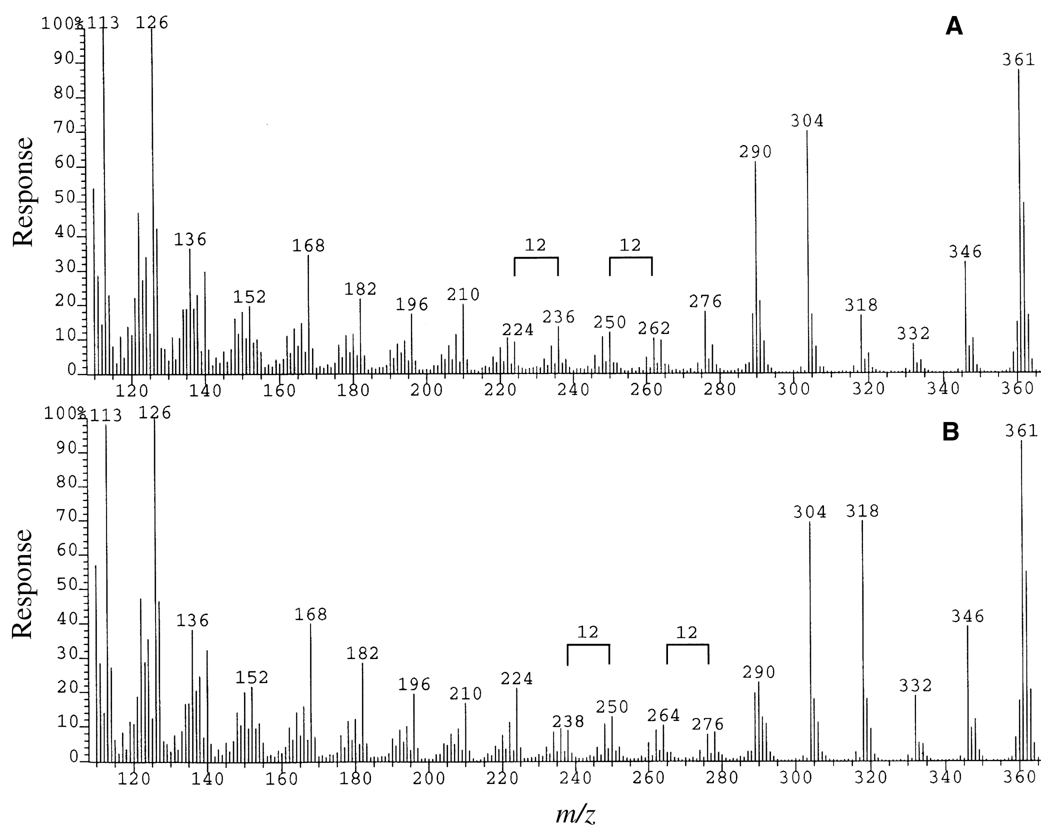

FIG. 5. Gas chromatography–electron ionization mass spectrometry of the 4,4-dimethyloxazoline derivative of isomerized 11 *cis*, 14 *cis*-20:2. The two major *cis/trans* isomers were 11,13-20:2 (A) and 12,14-20:2 (B).

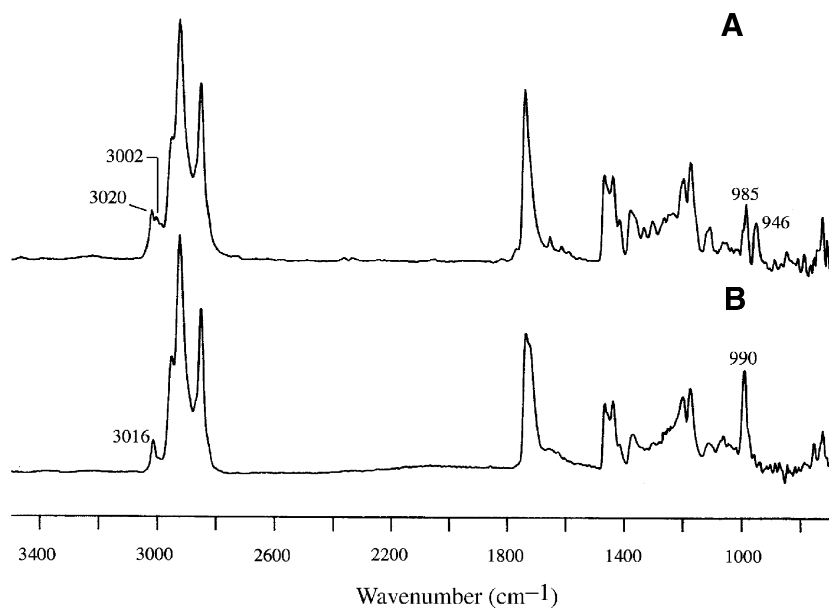

FIG. 6. Characteristic gas chromatography–direct deposition–Fourier transform infrared spectral regions, indicating *cis/trans* (A) and *trans,trans* (B) conjugated double bonds in 20:2 fatty acid methyl esters.

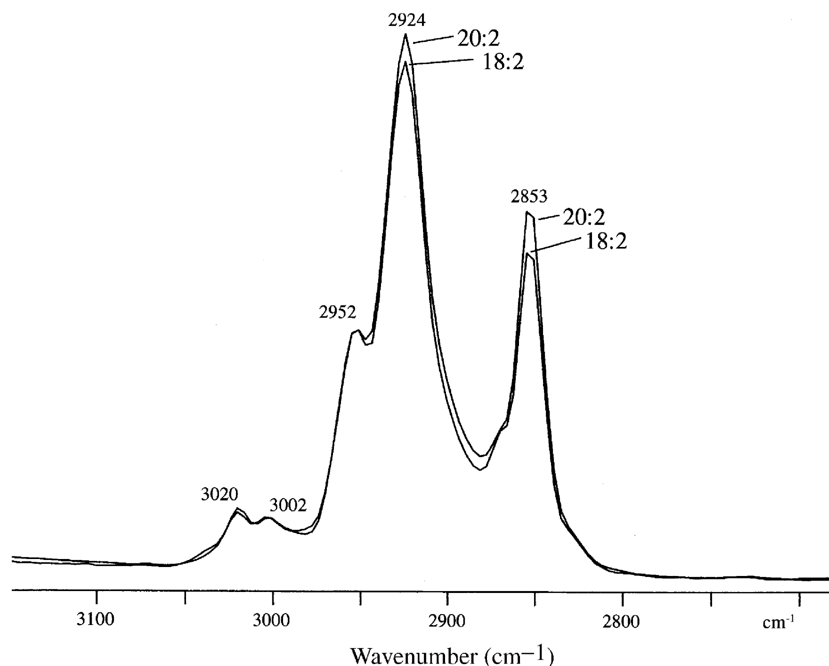

FIG. 7. Comparison of the relative intensity of C-H stretching vibrations for *cis/trans* C_{18} and C_{20} conjugated fatty acid methyl esters after normalization relative to the ester carbonyl band: asymmetric C-H stretch for the CH_3 group at 2952 cm^{-1}, asymmetric (2924 cm^{-1}) and symmetric (2853 cm^{-1}) C-H stretch for the CH_2 groups.

ABSTRACT: We established a method to simultaneously determine *RRR*- and *SRR*-α-tocopherol (α-Toc) and their quinones in biological samples by chiral-phase high-performance liquid chromatography (HPLC). α-Toc had a shorter retention time than α-tocopherylquinones (α-TQ), and 2-*ambo*-α-Toc was completely separated into two peaks; the first peak was *RRR*-α-Toc and the second *SRR*-isomer by chiral HPLC connected Chiralcel OD-H column and Sumichiral OA4100 column. In contrast, of the two peaks of α-TQ, the first was the *SRR*-isomer. We also investigated differences in the distribution of *RRR*- and *SRR*-α-TQ in rat tissues after oral administration of 2-*ambo*-α-Toc by the above HPLC method. Rats deficient in vitamin E were divided into two groups, control and experimental, and tissues were collected at 3, 6, and 24 h after oral 2-*ambo*-α-Toc administration. The concentrations of *RRR*- and *SRR*-α-Toc and their quinones in plasma and each tissue were determined. The concentration of *SRR*-α-TQ in plasma and adrenal glands was not significantly different from *RRR*-α-TQ. However, the concentration of *SRR*-α-TQ in liver up to 6 h after oral administration was higher than that of *RRR*-α-TQ, and *SRR*- and *RRR*-α-TQ levels were similar at 24 h after oral administration. Therefore, we may assume that the formation of α-TQ *in vivo* was not different between *RRR*- and *SRR*-isomer and that it was not affected by the presence of α-Toc stereoisomers.

Paper no. L7991 in *Lipids 34*, 415–422 (April 1999)

Vitamin E, especially α-tocopherol (α-Toc), is known to be a major antioxidant protecting cellular membranes (1). There are two types of α-Toc, natural and synthetic. Synthetic α-Toc (all-*rac*-α-Toc), which is used in many types of medical preparations and food additives, is composed of equal amounts of the eight stereoisomers of α-Toc arising from the three asymmetric carbons (2-position in chroman ring and 4′ and 8′ positions in side chain). Among the eight stereoisomers, only the 2*R*,4′*R*,8′*R* (*RRR*) stereoisomer occurs naturally. Biological activities of the eight stereoisomers of α-Toc were determined by the rat fetal resorption–gestation assay, as follows: *RRR* = 100%, *RRS* = 90%, *RSS* = 73%, *SSS* = 60%, *RSR* = 57%, *SRS* = 37%, *SRR* = 31%, and *SSR* = 21% (2). 2-*ambo*-α-Toc is composed of equal amounts of *RRR*- and *SRR*-α-Toc.

In 1987, Ingold *et al.* (3) synthesized deuterium-substituted *RRR*- and *SRR*-α-Toc, in which the substituted numbers of deuterium were varied for purposes of differentiation, and elucidated their absorption, transportation, and biodiscrimination of *RRR*- and *SRR*-α-Toc. In their study, the ratio of *RRR*-α-Toc to *SRR*-α-Toc in every tissue except the liver was higher than 1.0, showing that biodiscrimination may occur in the liver. Traber *et al.* (4) had elucidated the differentiation of *RRR*- and *SRR*-α-Toc in the lipoprotein subfraction of human blood by using the same methodology and concluded that biodiscrimination of the α-Toc isomers might occur when very low density lipoprotein (VLDL) is excreted to transport lipids with α-Toc from liver (4). Furthermore, we have examined the distribution and biodiscrimination of α-Toc stereoisomers (especially 2*R*- and 2*S*-isomers) in rats and humans (5–10) by a chiral high-performance liquid chromatography (HPLC) method (11), and we found that the ratios of α-Toc stereoisomers in the lymph of rats dosed with all-*rac*-α-Toc were the same as the ratio of α-Toc stereoisomers administered: 2*R*-isomers constituted approximately 50% of α-Toc. The uptake of α-Toc stereoisomers into small intestinal cells was measured by using Caco-2 cell lines. The concentration of *RRR*-α-Toc in Caco-2 cells was not significantly different from that of *SRR*-α-Toc. This finding suggested that the discrimination of α-Toc stereoisomers does not occur during absorption in small intestine and indicated the contribution of the liver to this discrimination (8). Moreover, we had investigated changes in the concentrations of the stereoisomers of α-Toc in serum and lipoproteins in healthy humans who were dosed orally with synthetic α-Toc acetate. α-Toc stereoisomers detected in the serum of all subjects administered 100 mg all-*rac*-α-Toc acetate/day were all 2*R*-isomers; no 2*S*-isomers were found (9). Weiser *et al.* (12) reported the

measurements of all eight stereoisomers of α-Toc in rat plasma and tissues and concluded that the configuration at C-2 of the α-Toc molecule is of major importance with regard to uptake and storage of α-Toc stereoisomers, whereas the chiral centers of the phytyl side chain have less influence. Furthermore, Hosomi *et al.* (10) examined the structural characteristics of vitamin E analogs required for recognition by α-Toc transfer protein (α-TTP). Relative affinities (*RRR*-α-Toc = 100%) calculated from the degree of competition were as follows: γ-Toc, 9%; *SRR*-α-Toc, 11%; and so on. From this result, they proposed that the affinities of vitamin E analogs for α-TTP, which may determine their plasma levels, are a major determinant of their biological activity.

According to these reports, orally administered α-Toc stereoisomers (especially *RRR*- and *SRR*-isomer) are absorbed equally from the small intestine without discrimination. After uptake into intestinal cells, α-Toc stereoisomers are secreted into chylomicrons. Chylomicron remnants are catabolized during the circulation by the lipoprotein lipase. After uptake of chylomicron remnants by the liver, α-Toc stereoisomers are discriminated by α-TTP in liver, which transports *RRR*-α-Toc preferentially over *SRR*-α-Toc into VLDL during assembly. VLDL rich in *RRR*-α-Toc is then circulated in plasma and transported to each tissue. On the other hand, *SRR*-α-Toc remained in liver. Kayden and Traber (13) discussed in a review that the different *RRR*-α-Toc remaining in liver (such as γ-Toc or *SRR*-α-Toc) will probably be excreted in the bile. Thus we can note the difference in the metabolism of *RRR*- and *SRR*-α-Toc *in vivo*.

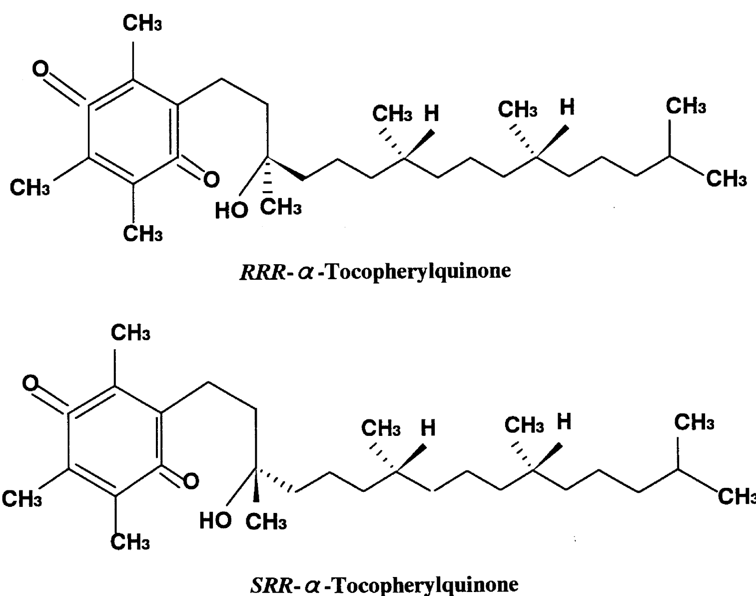
The first metabolite of α-Toc is assumed to be α-tocopherylquinone (α-TQ). Stereoisomerism of α-TQ arises from an asymmetric carbon at the 2-position on the chroman ring similar to α-Toc (Scheme 1). Regarding the determination of α-TQ, Hughes and Tove (14) reported that rat liver contained 124 nmol/g of α-TQ (the amount of α-TQ was determined spectrophotometrically). In contrast, Bieri and Tolliver (15) reported that 1–4 nmol/g of α-TQ was present in the liver of rats fed low and high levels of dietary α-Toc [the amount of α-TQ was determined by thin-layer chromatography (TLC) and HPLC]. Moreover, Koskas *et al.* (16) reported the determination of α-TQ by the reverse-phase HPLC method, and Vatassery and Smith (17) reported the determination of it in biological samples by using the reverse-phase HPLC method. Their results showed that the concentration of α-TQ in normal human serum was extremely small, only 0.02–0.05% of the α-Toc concentration. In this brief review we show that there have been many reports on the determination of the amounts of α-TQ in biological samples, but no reports on the determination of α-TQ stereoisomers, and that an HPLC method to separate *RRR*- and *SRR*-α-TQ has not yet been developed.

Therefore in this study we devised a method to determine *RRR*- and *SRR*-α-TQ in biological specimens by chiral phase HPLC so that we could estimate the amounts of *RRR*- and *SRR*-α-TQ present *in vivo*. Furthermore, we examined the distribution of *RRR*- and *SRR*-α-TQ in rat tissues after oral administration of 2-*ambo*-α-Toc.

EXPERIMENTAL PROCEDURES

Materials. *RRR*-α-Toc, 2-*ambo*-(2*RS*,4′*R*,8′*R*) α-Toc, and 2,2,5,7,8-pentamethyl-6-hydroxychroman (PMC) as an internal standard were donated by Eisai Co. (Tokyo, Japan).

Preparation of 2-ambo-*α-TQ.* Mixed in the separation funnel were 200 mL of ethanolic 2-*ambo*-α-Toc solution (2-*ambo*-α-Toc, 6 mg/mL) and 100 mL of ethanolic $FeCl_3$ solution ($FeCl_3$ 50 mg/mL), and the funnel was shaken vigorously for 3 min. Next, the solution was shaken with 100 mL of *n*-hexane and 100 mL of water for 1 min. After shaking, the solution was



RRR-α-Tocopherylquinone

SRR-α-Tocopherylquinone

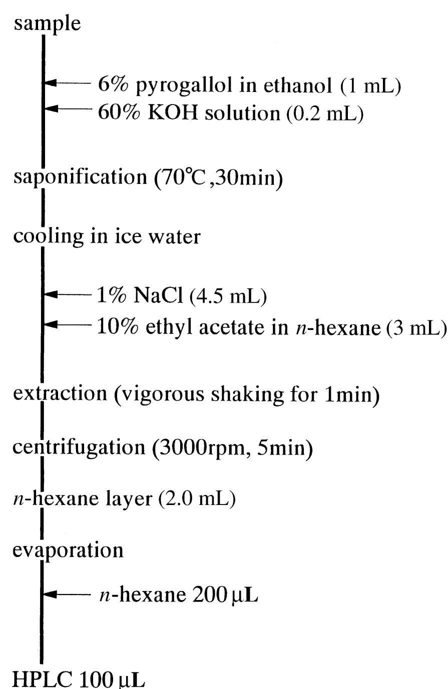
SCHEME 1

permitted to stand for a few minutes, and the water phase was removed. Water was again added to the *n*-hexane layer and shaken for 1 min. This process was repeated three times. The washed hexane layer was dehydrated by filtration through Na_2SO_4. The 2-*ambo*-α-TQ in hexane was purified by using silica gel column chromatography. The mobile phase used was 10% chloroform in hexane, and the concentration of chloroform was raised gradually to 50%. A few fractions of the purified 2-*ambo*-α-TQ solution were extracted, and 2-*ambo*-α-TQ in each fraction was confirmed by TLC. The mobile phase of TLC was benzene/chloroform (15:1, vol/vol). The standard used for TLC was α-tocopherol quinone (purchased from ICN Nutritional Biochemicals, Cleveland, OH). The purity of 2-*ambo*-α-TQ was checked by HPLC and was found to be greater than 97%. *RRR*-α-TQ was also prepared in a method similar to the one described above. The identification of 2-*ambo*-α-TQ was performed by liquid chromatography–mass spectrometry (LC–MS).

Vitamin E-deficient rats. Male Sprague-Dawley strain rats (3 wk of age) were purchased from Nippon Clea Co (Tokyo, Japan). They were initially fed a commercial diet (CE-2; Nippon Clea Co.) for a week to allow them to adapt to the new environment. These rats were then fed a diet deficient in vitamin E (AIN-76; Eisai Co.) for 8 wk. This diet was composed of 23.68% sucrose, 23.68% glucose, 18.95% vitamin-free casein, 14.21% cornstarch, 4.74% filter paper, 3.32% mineral mixture, 0.95% vitamin mixture except vitamin E, 0.28% DL-methionine, 0.19% choline bitartrate, and 10% stripped corn oil. Animals were housed individually in cages at 22°C and 55% humidity with a 12 h light/dark cycle. The feed and water were supplied *ad libitum.*

Determination of RRR- *and* SRR-*α-Toc and their quinones in rats.* Corn oil, stripped of vitamin E, was used as a vehicle. After 18 h fasting overnight, the vitamin E-deficient rats were divided into four groups; one was a control group and the others were experimental groups. The experimental groups of six rats each were given a dosage of 0.5 mL corn oil preparation containing 50 mg of 2-*ambo*-α-Toc per rat. One group was killed under anesthesia at 3 h after oral administration, and the other groups were killed after 6 and 24 h. The control group was given a dosage of 0.5 mL stripped corn oil (depleted of vitamin E) per rat, then killed at 24 h after oral administration. Plasma was separated from heparinized blood by centrifugation. Each of the tissue and the plasma were stored at −80°C until analysis of α-Toc and α-TQ stereoisomers.

Extraction of α-Toc and-TQ stereoisomers from the biological specimens. Plasma (0.2 mL) was pipetted into a 10-mL centrifuge tube. About 0.5 g of each tissue, cut into small pieces, was placed in a 10-mL centrifuge tube. Then 0.1 mL of 1% NaCl (wt/vol) solution was added to the tubes to accelerate the saponification by dispersion of the samples. Ethanolic pyrogallol solution (1 mL, 6%, wt/vol) was added to each tube during stirring. After 0.2 mL of 60% (wt/vol) KOH solution had been added to each tube, the contents were saponified with occasional shaking at 70°C for 30 min. After the saponified solution was cooled in ice water, 4.5 mL of 1%



SCHEME 2

NaCl solution was added to it and the medium was shaken vigorously with 3 mL of 10% ethyl acetate in hexane for 1 min. The mixture was centrifuged at 600 × *g* for 5 min, and 2 mL of the upper layer was collected and evaporated. The residue was dissolved in 200 μL of hexane for the determination by HPLC. Scheme 2 shows the simultaneous extraction procedure for α-Toc and α-TQ stereoisomers.

Chromatographic apparatus and conditions. The HPLC system consisted of a Water's LC Module 1 (Japan Millipore Ltd., Tokyo, Japan) and an SK-25 column oven (Nihon Seimitsu Kagaku, Co., Ltd., Tokyo, Japan). The analysis of α-Toc and α-TQ stereoisomers was performed at 30°C by using Chiralcel OD-H column (250 × 4.5 mm i.d., Daicel Chem. Ind., Tokyo, Japan) and Sumichiral OA4100 column (250 × 4.5 mm i.d., Sumika Chemical Analysis Service, Ltd., Tokyo, Japan) connected in series. The mobile phase was hexane/isopropyl alcohol (97.3:2.7, vol/vol) at a flow rate of 0.3 mL/min. The detection wavelength was 268 nm.

Statistical analysis. All results are expressed as mean ± SD. Student's *t*-test was used for a comparison of *RRR*- and *SRR*-isomer of α-Toc and for α-TQ in each tissue. Differences were considered significant at $P < 0.05$.

RESULTS AND DISCUSSION

Separation of standard samples. Figure 1 shows HPLC chromatograms of standard samples of 2-*ambo*-α-Toc, 2-*ambo*-α-TQ, and PMC as the internal standard. Both 2-*ambo*-α-Toc and 2-*ambo*-α-TQ were separated into two peaks each (peak area ratio, 1:1) by chiral HPLC. For α-Toc, the first peak was *RRR*-α-Toc and the second *SRR*-α-Toc; the first peak of α-TQ was the *SRR*-isomer and the second was *RRR*. The con-

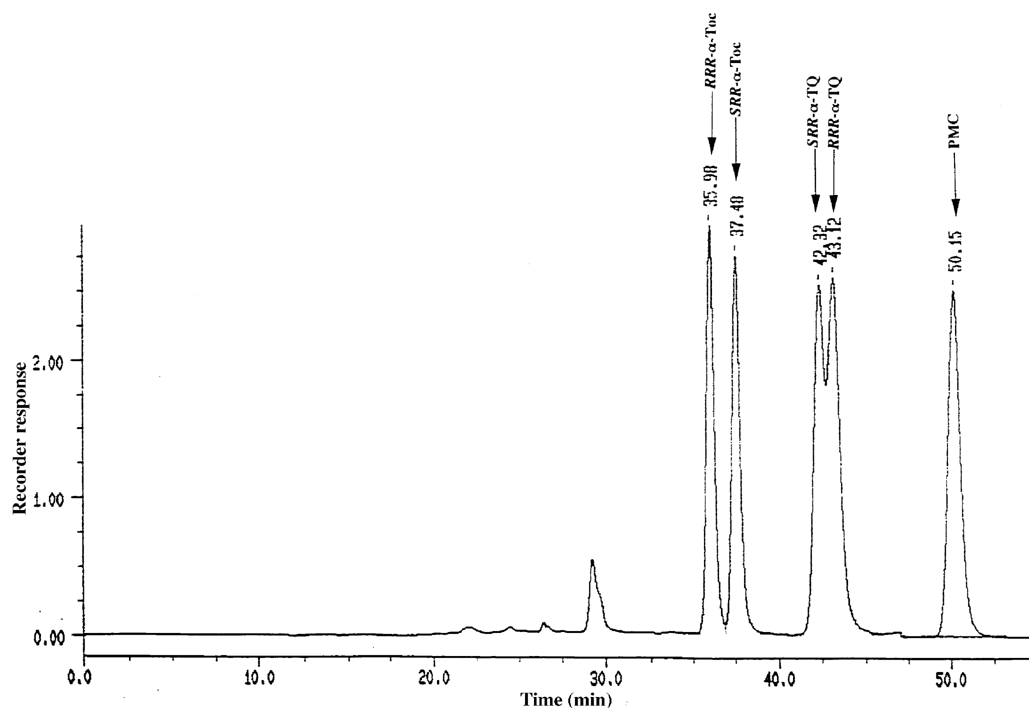


FIG. 1. A high-performance liquid chromatogram of 2-*ambo*-α-tocopherol (Toc), 2-*ambo*-α-tocopherylquinone (TQ), and 2,2,5,7,8-pentamethyl-6-hydroxychroman (PMC) as an internal standard.

firmation of each peak was performed by comparing the retention time with *RRR*-α-Toc and *RRR*-α-TQ.

The detection wavelength used in this method was determined to be 268 nm, the ultraviolet-absorption maximum wavelength for 2-*ambo*-α-TQ. Because α-TQ content compared with α-Toc might be a small amount *in vivo*, and because the ultraviolet absorption wavelength of 2-*ambo*-α-TQ may overlap those of 2-*ambo*-α-Toc and PMC, we used an analytical wavelength of 268 nm in this study (Fig. 2).

Calibration curves (Fig. 3). Calibration curves were prepared to evaluate the appropriate quantitative analysis of this methodology with authentic samples of 2-*ambo*-α-Toc, 2-*ambo*-α-TQ, and PMC as the internal standard.

One milliliter of 5.0, 10.0, 20.0, or 40.0 μg/mL ethanolic 2-*ambo*-α-Toc or 1 mL of 0.5, 1.0, 2.0, or 4.0 μg/mL ethanolic 2-*ambo*-α-TQ solutions was saponified with 5.0 μg/mL PMC. The extracts were analyzed by chiral HPLC. The correlation between the concentration ratio (x) and the peak area ratio (y) to the internal standard of each peak was determined. Concerning the results, the linear regression equation of *RRR*-α-Toc were $y = 1.43 \times 10^6x + 9.58 \times 10^4$ (correlation coefficient: $r = 0.999$, $P < 0.05$); that of *SRR*-α-Toc was $y = 1.45 \times 10^6x + 5.35 \times 10^4$ (correlation coefficient: $r = 1.000$, $P < 0.05$) (Fig. 3A); that of *RRR*-α-TQ was $y = 1.87 \times 10^6x + 5.13 \times 10^4$ (correlation coefficient: $r = 0.996$, $P < 0.05$); and that of *SRR*-α-TQ was $y = 1.52 \times 10^6x + 4.54 \times 10^4$ (correlation coefficient: $r = 0.996$, $P < 0.05$) (Fig. 3B).

Recoveries of 2-ambo-*α-Toc and -TQ added to rat plasma and tissues.* The standard samples of 2-*ambo*-α-Toc and -TQ

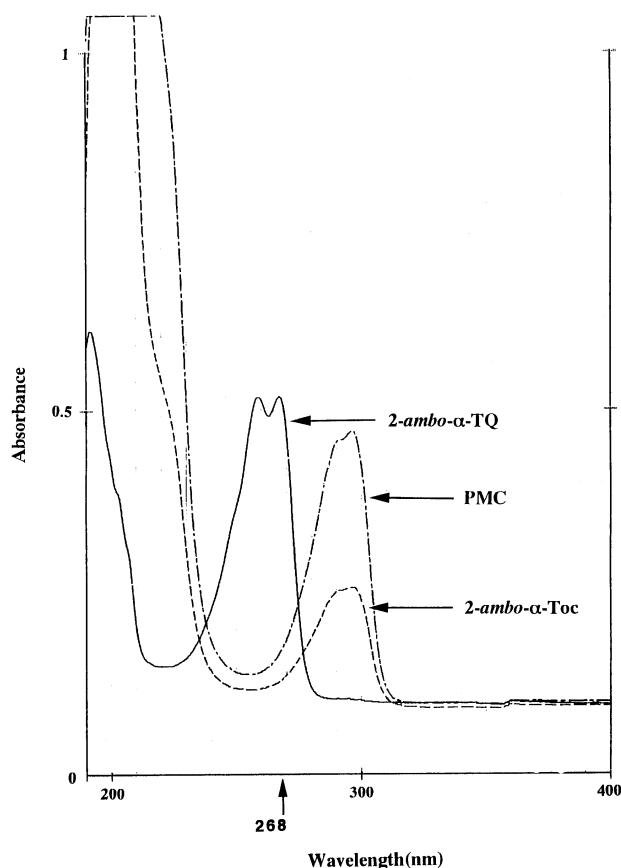

FIG. 2. Ultraviolet absorption spectra of 2-*ambo*-α-Toc, 2-*ambo*-α-TQ, and PMC in hexane. For abbreviations see Figure 1.

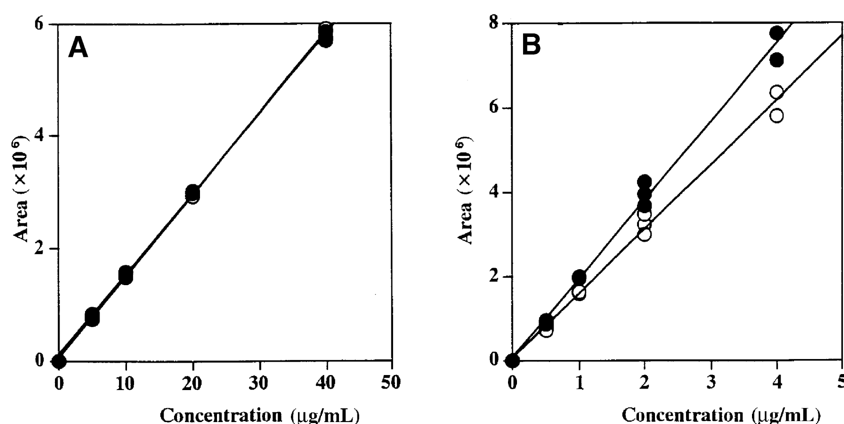

FIG. 3. Calibration curves of *RRR*- and *SRR*- α-Toc and -TQ. (A) Calibration curves of *RRR*- (●) and *SRR*- (○) α-Toc. One milliliter of 5.0, 10.0, 20.0, or 40.0 μg/mL ethanolic 2-*ambo*-α-Toc solution was saponified with PMC and each concentration of α-TQ. These extracted solutions were analyzed by chiral high-performance liquid chromatography (HPLC). (B) Calibration curves of *RRR*- (●) and *SRR*- (○) α-TQ. One milliliter of 0.5, 1.0, 2.0, or 4.0 μg/mL ethanolic 2-*ambo*-α-TQ solution was saponified with PMC and each concentration of α-Toc. These extracted solutions were analyzed by chiral HPLC. For abbreviations see Figure 1.

was added to plasma or tissues of rats, and the analytical recoveries of *RRR*- and *SRR*-α-Toc and their quinones were measured by this method. Pipetted into a 10-mL centrifuge tube was 0.2 mL of rat plasma. About 0.1 g of rat liver, cut into small pieces, was placed in a 10-mL centrifuge tube. Then 0.1 mL of 1% NaCl (wt/vol) solution was added to the tubes to accelerate the saponification by dispersion of the samples. One milliliter of ethanolic standard solution contained 2.0 μg of 2-*ambo*-α-TQ (1.0 μg each of *RRR*- and *SRR*-α-TQ) and 20 μg of 2-*ambo*-α-Toc (10 μg each of *RRR*- and *SRR*-α-Toc), and 20 μg/mL PMC solution and 1 mL of 6% (wt/vol) ethanolic pyrogallol solution were separately added to each tube during stirring. The samples added to each ethanolic 2-*ambo*-α-Toc and -TQ were saponified and extracted, similar to the method described above, and the analytical recoveries of *RRR*-, *SRR*-α-Toc and *RRR*-, *SRR*-α-TQ were determined by this method. According to this method of standard addition, the analytical recoveries of *RRR*-, *SRR*-α-Toc and *RRR*-, *SRR*-α-TQ exceeded 95% (Table 1). Moore and Ingold (18) demonstrated *in vivo* that orally administered α-TQ is converted to α-Toc in human plasma; from our results, this conversion *in vitro* was not observed.

In this examination, we used an antioxidant agent, pyrogallol, during saponification of the samples. Vatassery and Smith (17) reported the effect of antioxidant combinations by determining α-Toc and α-TQ in human red blood cells. According to their results, antioxidant combinations effectively inhibited the oxidation of α-Toc and the "artificial" formation of α-TQ (as a result of the saponification process). Therefore, we used only pyrogallol as an antioxidant in this study, and we found that by this method the simultaneous recoveries of α-Toc and α-TQ stereoisomers (*RRR*- and *SRR*-isomer) in each tissue to which a standard solution had been added exceeded 95%. Furthermore, artificial α-TQ resulting from the extraction procedure itself was scarcely formed in this method.

Distribution of α-Toc and α-TQ stereoisomers in rat tissues. We next investigated by this HPLC method changes of the distribution of *RRR*-, *SRR*-α-Toc and their quinones in rat plasma and tissues after oral administration of 2-*ambo*-α-Toc. The corn oil preparation (100 mg/mL of 2-*ambo*-α-Toc) was checked by HPLC, and 2-*ambo*-α-TQ was not detected.

The α-Toc and α-TQ stereoisomers in tissues were not detected 3 h after oral administration. Figure 4 shows that changes in the concentrations of α-Toc and α-TQ stereo-

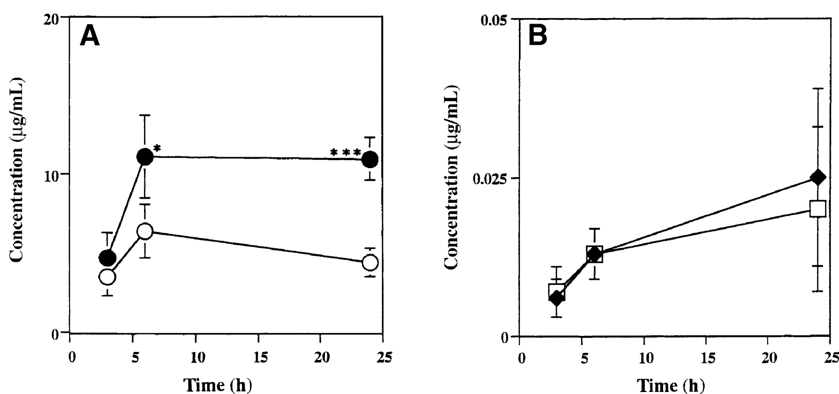

FIG. 4. Concentrations of α-Toc and α-TQ stereoisomers in rat plasma. Values are mean ± SD of 5–6 rats. (A) Change in concentration of *RRR*- (●) and *SRR*- (○) α-Toc in rat plasma after oral administration of 2-*ambo*-α-Toc. Values with asterisks mean a significant difference between *RRR*- and *SRR*-isomer; *** $P < 0.001$; * $P < 0.05$ (by *t*-test). (B) Change in concentration of *RRR*- (◆) and *SRR*- (□) α-TQ in rat plasma after oral administration of 2-*ambo*-α-Toc. For abbreviations see Figure 1.

isomers did occur in rat plasma after oral administration. The concentration of *RRR*-α-Toc was significantly higher than that of *SRR*-α-Toc up to 6 h, and remained at a similar level until 24 h. The total α-TQ content in plasma was approximately 0.2% of total α-Toc. The concentration of both *RRR*- and *SRR*-α-TQ gradually increased after oral administration, but no significant difference was found between *RRR*- and *SRR*-isomers. On the contrary, the concentration of *SRR*-α-Toc in liver was higher than that of *RRR*-α-Toc from 6 h to 24 h after oral administration. Concerning α-TQ, total α-TQ content in liver was <1% of total α-Toc in liver. As to *RRR*- and *SRR*-isomers, the concentration of *SRR*-α-TQ was higher than that of *RRR*-α-TQ up to 6 h after oral administration. The concentration of *SRR*-α-TQ at 24 h after oral administration had decreased in comparison with the level after 6 h, and *RRR*-α-TQ at 24 h had slightly increased in comparison. However, the concentration of α-TQ in liver was not significantly different between *RRR*- and *SRR*-isomer at all times (Fig. 5). In adrenal glands, the increases of *RRR*- and *SRR*-α-Toc contents continued until 24 h after oral administration; then the concentration of *RRR*-α-Toc became significantly higher than that of *SRR*-α-Toc. The concentration of α-TQ also gradually increased until 24 h after oral administration, but no significant difference was noted between *RRR*- and *SRR*-α-TQ (Fig. 6). The total α-TQ content in adrenal glands was approximately 0.2% of total α-Toc. In brain, only *RRR*-α-Toc was found in small amounts up to 24 h; no *SRR*-α-Toc or α-TQ stereoisomers were detected until 24 h.

We studied α-TQ, the first product of α-Toc oxidation, because the differentiation of the turnover for α-Toc stereoisomers *in vivo* has been investigated. Howell and Smith (19) and others (15,17) established the measurement of α-TQ in the biological specimens, but reports of separation and determination of *RRR*- and *SRR*-α-TQ had not yet been made. In

(B) Change in concentration of *RRR*-(◆) and *SRR*- (□) α-TQ in rat liver after oral administration of 2-*ambo*-α-Toc. For abbreviations see Figure 1.

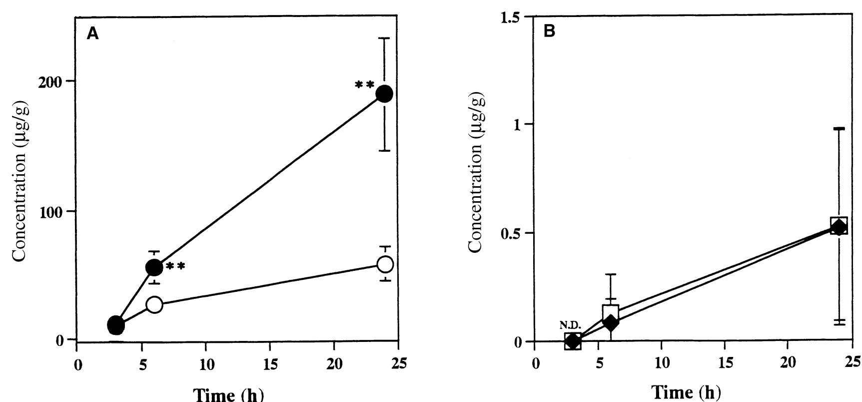

FIG. 6. Concentrations of α-Toc and α-TQ stereoisomers in rat adrenal glands. Values are mean ± SD of 5–6 rats. (A) Change in concentration of *RRR*-(●) and *SRR*- (○) α-Toc in rat adrenal glands after oral administration of 2-*ambo*-α-Toc. Values with asterisks mean a significant difference between *RRR*- and *SRR*-isomers; $^{**}P < 0.01$ (by *t*-test). (B) Change in concentration of *RRR*- (◆) and *SRR*- (□) α-TQ in rat adrenal glands after oral administration of 2-*ambo*-α-Toc. For abbreviations see Figure 1.

this experiment, we established the determination of α-Toc and α-TQ stereoisomers in biological specimens by chiral HPLC. In plasma and adrenal glands, the concentration of *RRR*-α-TQ was not significantly different from that of *SRR*-α-TQ, but the *SRR*-α-TQ content in liver was higher than that of *RRR*-α-TQ up to 6 h after oral administration (Fig. 4). Therefore, we suggested that the turnover of *SRR*-α-Toc was more rapid than that of *RRR*-α-Toc in rat liver.

The mechanism of α-Toc metabolism is suggested as follows: α-Toc is oxidized to α-TQ first; then it is reduced to α-TQH, which is followed by degradation of the side chain. Finally, these are produced as the Simon metabolites. The Simon metabolites were first found in the urine of rabbits (20), in which they are present mainly as glucuronide conjugates. Dutton *et al.* (21) suggested that Simon metabolites are oxidation products derived from α-TQ. In this study, we investigated the distribution only of α-TQ stereoisomers *in vivo*, not of α-TQH stereoisomers. However, because the total α-TQ content in liver was less than 1% of the total α-Toc content, we assumed that a part of α-Toc might be metabolized into other types of metabolite (e.g., the degradation of the side chain without oxidative splitting of the chroman ring). Schultz *et al.* (22) reported that 2,5,7,8-tetramethyl-2-(2′-carboxyethyl)-6-hydroxy-chroman (α-CEHC) was the major urinary metabolite of α-Toc. They suggested that α-Toc can undergo ω-oxidation without oxidation and opening of the chroman ring, and that this pathway will be responsible for generation of the major urinary α-Toc metabolite in healthy humans.

In conclusion, we established a procedure to simultaneously determine *RRR*- and *SRR*-α-Toc and their quinones in rat plasma and tissues by chiral HPLC and investigated the distributions of α-Toc and α-TQ stereoisomers *in vivo*. We found that *RRR*- and *SRR*-α-TQ were present in very low concentrations in tissues, compared with *RRR*- and *SRR*-α-Toc. However, the concentrations of *RRR*- and *SRR*- α-TQ in each tissue were not significantly different. Therefore, we suggest that the formation of α-TQ *in vivo* is not different from the *RRR*- and *SRR*-isomers of α-Toc and that the formation of α-TQ had no effect on the proportion of α-Toc stereoisomers present *in vivo*. Furthermore, we conjecture that the *SRR*-isomer is rapidly metabolized into other types of metabolites, except α-TQ.

Using *SRR*-α-[5-methyl-^{14}C]Toc, we are now studying the differences in metabolism of *RRR*- and *SRR*-α-Toc in the rat.

COMMUNICATION

The Occurrence and Possible Significance of Diacylglyceryl Ether Lipids in Abalone

Matthew M. Nelson[a,*], **Peter D. Nichols**[b], **and David L. Leighton**[a,c]

[a]Department of Biology, San Diego State University, San Diego, California 92182, [b]CSIRO Marine Research, and Antarctic Co-operative Research Centre, Hobart, Tasmania, 7001, Australia, and [c]Marine Bioculture, Leucadia, California 92024

ABSTRACT: Gonadal and foot tissues of the green abalone, *Haliotis fulgens,* raised on artificial diets, were analyzed for lipids using thin-layer chromatography/flame-ionization detection and gas chromatography–mass spectrometry (GC–MS). Diacylglyceryl ether (DAGE) was 0.7% of total lipids in the gonad. The major alkyl constituents of the glyceryl ether diols in the gonad (as % of total diols) were 16:0 (38%) and 18:1 (36%). While levels of DAGE in the abalone foot were below flame-ionization detection limits, glyceryl ether diols from them were detected using the more sensitive GC–MS procedure. The major diol components in the foot were 18:0 (39%) and 18:1 (32%). To our knowledge, this is the first report of DAGE in abalone tissues. Although the precise role of DAGE in abalone remains to be determined, a possible structural role may exist.

Paper no. L8034 in *Lipids 34,* 423–427 (April 1999).

Knowledge of lipid composition provides a basis for understanding trophodynamic interactions and thereby possible nutritional requirements, energy storage, and buoyancy strategies of marine organisms. The most common lipids and those most often studied have been fatty acids, sterols (ST), triacylglycerols (TAG), phospholipids, and wax esters (WE). Research and identification of ether-containing phospholipids in molluscs include studies performed by Koizumi *et al.* (1) on the oyster *Crassostrea gigas* and by Sugiura *et al.* (2) on a number of invertebrate species. Earlier pertinent studies on ether-containing phospholipids include those of the aquatic snail *Lymnaea stagnalis* (3) and two species of terrestrial slug (4). Diacylglyceryl ether (DAGE) is generally an uncommon neutral lipid in marine organisms, which is reflected in the paucity of literature concerning it. DAGE has recently been reported to occur in pteropod molluscs at 28% of the total lipid (5).

Lipid studies performed on abalone, a commercially important fishery and mariculture family (6), include those by Uki *et al.* (7–10), Dunstan *et al.* (11), and other authors (12, 13). Except for the suggestion that glyceryl ether phospholipids may be present in the abalone *Haliotis midae* (14) and discussion in a study by Floreto *et al.* (15), all previous studies have neither reported nor quantified the wider complex lipid class composition, including DAGE, in abalone. This work reports on lipid class distributions, including the occurrence of DAGE, in the gonad and foot of the green abalone, *H. fulgens*.

MATERIALS AND METHODS

Sample description. Female green abalone, *H. fulgens*, were supplied during December, 1996, by Marine Bioculture, Leucadia, California. Ovary tissue from two fully ovigerous individuals was carefully ablated from the underlying hepatopancreas. Foot columellar tissue (partly cartilagenous) was obtained from the same individuals. Samples were immediately frozen in a −70°C Kelvinator freezer and lyophilized in a Virtis Freezemobile II lyophilizer at the Scripps Institution of Oceanography, California, in the laboratory of Dr. V. Vacquier.

Lipid extraction. During March, 1997, lipid analyses were conducted on the lyophilized tissues. Samples were homogenized with a mortar and pestle and subsamples taken for analysis. Tissues were rehydrated with the addition of water and left standing for 1 h. Rehydration prior to extraction results in improved lipid yields in comparison to nonrehydrated lyophilized samples (16). Samples were quantitatively extracted overnight using a modified Bligh and Dyer one-phase methanol/chloroform/water extraction (17).

Lipid classes. Lipid classes were determined with an Iatroscan MK V TH-10 thin-layer chromatograph–flame-ionization detector (18), utilizing two solvent systems for lipid separation. The primary solvent system was hexane/diethyl ether/acetic acid (60:17:0.1 by vol), a mobile phase resolving nonpolar compounds such as WE, TAG, free fatty acids, and ST. A second nonpolar system of hexane/diethyl ether (96:4, vol/vol) resolved hydrocarbons, WE, TAG, and DAGE. The flame-ionization detector was calibrated for each lipid class with phosphatidylcholine, cholesterol, cholesteryl oleate, oleic acid, squalene, triolein, and DAGE that had been purified from shark liver oil; 0.1–10 µg range. Glyceryl ether diol composition (1-*O*-alkyl glycerols) was determined using a Fisons MD 800 gas chromatograph–mass spectrometer (GC–MS) (Manchester, United Kingdom). The GC–MS was fitted with an on-column injector and operated in scan mode

with an ionization voltage of 70 eV. Techniques used to isolate and analyze these components are described further by Bakes and Nichols (19).

RESULTS

Lipid classes. TAG was the major lipid class in the abalone gonadal tissue (62.9%, as percentage of total lipid, Table 1). The foot was dominated by polar lipids, essentially all phospholipids (74.8%), whereas TAG were low (<0.05%). ST were also abundant in the foot tissue (23.5%). All samples contained WE, although the gonad (4.3%) contained on average 43 times that in the foot (0.1%). Gonad contained small amounts of DAGE (0.7%, 0.9 mg/g, dry mass) and long-chain alcohol (0.2%). Free fatty acids were present (1–4%) in all samples (Table 1).

1-O-alkyl glycerols. In abalone gonad the major alkyl glyceryl ether diols (GE) were 16:0 (38.1%, as percentage of total GE, Table 2) and 18:1 (36.1%); minor GE included 16:1, 17:1, 18:0, 20:1, and 20:0. The abalone foot tissue also contained GE, with 18:0 (39.4%) and 18:1 (31.5%) most prominent, as well as 16:1, 16:0, 20:1, and 20:0 (Table 2). A representative mass spectrum of the 17:1 diol and a plot of the ion *m/z* 205 characteristic of the diols are shown in Figure 1. A [M − 147] ion (e.g., *m/z* 327, 17:1 GE) provided additional information on the alkyl chain length (20). Methoxyethers were not detected.

Sterols. In gonad tissue, the main ST was cholesterol (97.4%, as percentage of total ST, Table 3), with small amounts of cholestanol and desmosterol. The foot lipids were dominated by cholesterol (97.9%), and minor ST included dehydrocholesterol, cholestanol, desmosterol, 24-methylenecholesterol, and fucosterol (Table 3).

DISCUSSION

The high proportions of polar lipid (essentially phospholipids) and of ST in the foot signify that it is composed mostly of membrane lipid, whereas the markedly high abundance of TAG in abalone gonad tissue suggests an energy storage function for transference to larvae. The main energy reserves for adult abalone (*H. cracherodii*) are stored in the foot tissue as glycogen, rather than lipid (21). Our results indicate the same energy storage pathway is also used by *H. fulgens*. In addition, the gonad is a temporally variable tissue, which at times is almost nonexistent. Therefore, TAG may function as an energy reserve in the yolk in lecithotrophic larvae of this mollusc. Observations on six California species of abalone (*H. corrugata*, *H. cracherodii*, *H. fulgens*, *H. kamtschatkana*, *H. rufescens*, and *H. sorenseni*) provided evidence that pigments in free swimming (veliger) larvae are derived from the parental lipids in the yolk (22). If fat-soluble carotenoids are passed to larvae, it follows that other lipids would be as well. The presence of WE in abalone and their macroalgal diet (Nelson, M., unpublished data) suggests a dietary source, and it appears that WE are selectively incorporated into the gonads. WE may also be transferred to larvae, although this lipid class has low metabolic activity and typically serves as a long-term energy reserve. The presence of small proportions of DAGE in ovary tissue is intriguing. DAGE has been suggested to have a buoyancy role in some molluscs (5) and in other selected marine organisms (23). However, in abalone the role of DAGE observed at such low levels is unclear, although a buoyancy role is not anticipated. Other molluscs reported to contain DAGE include sea mussels (24) and *Octopus dofleini* (25).

The detection of GE in abalone foot lipids confirms the presence of DAGE, which was present at only trace

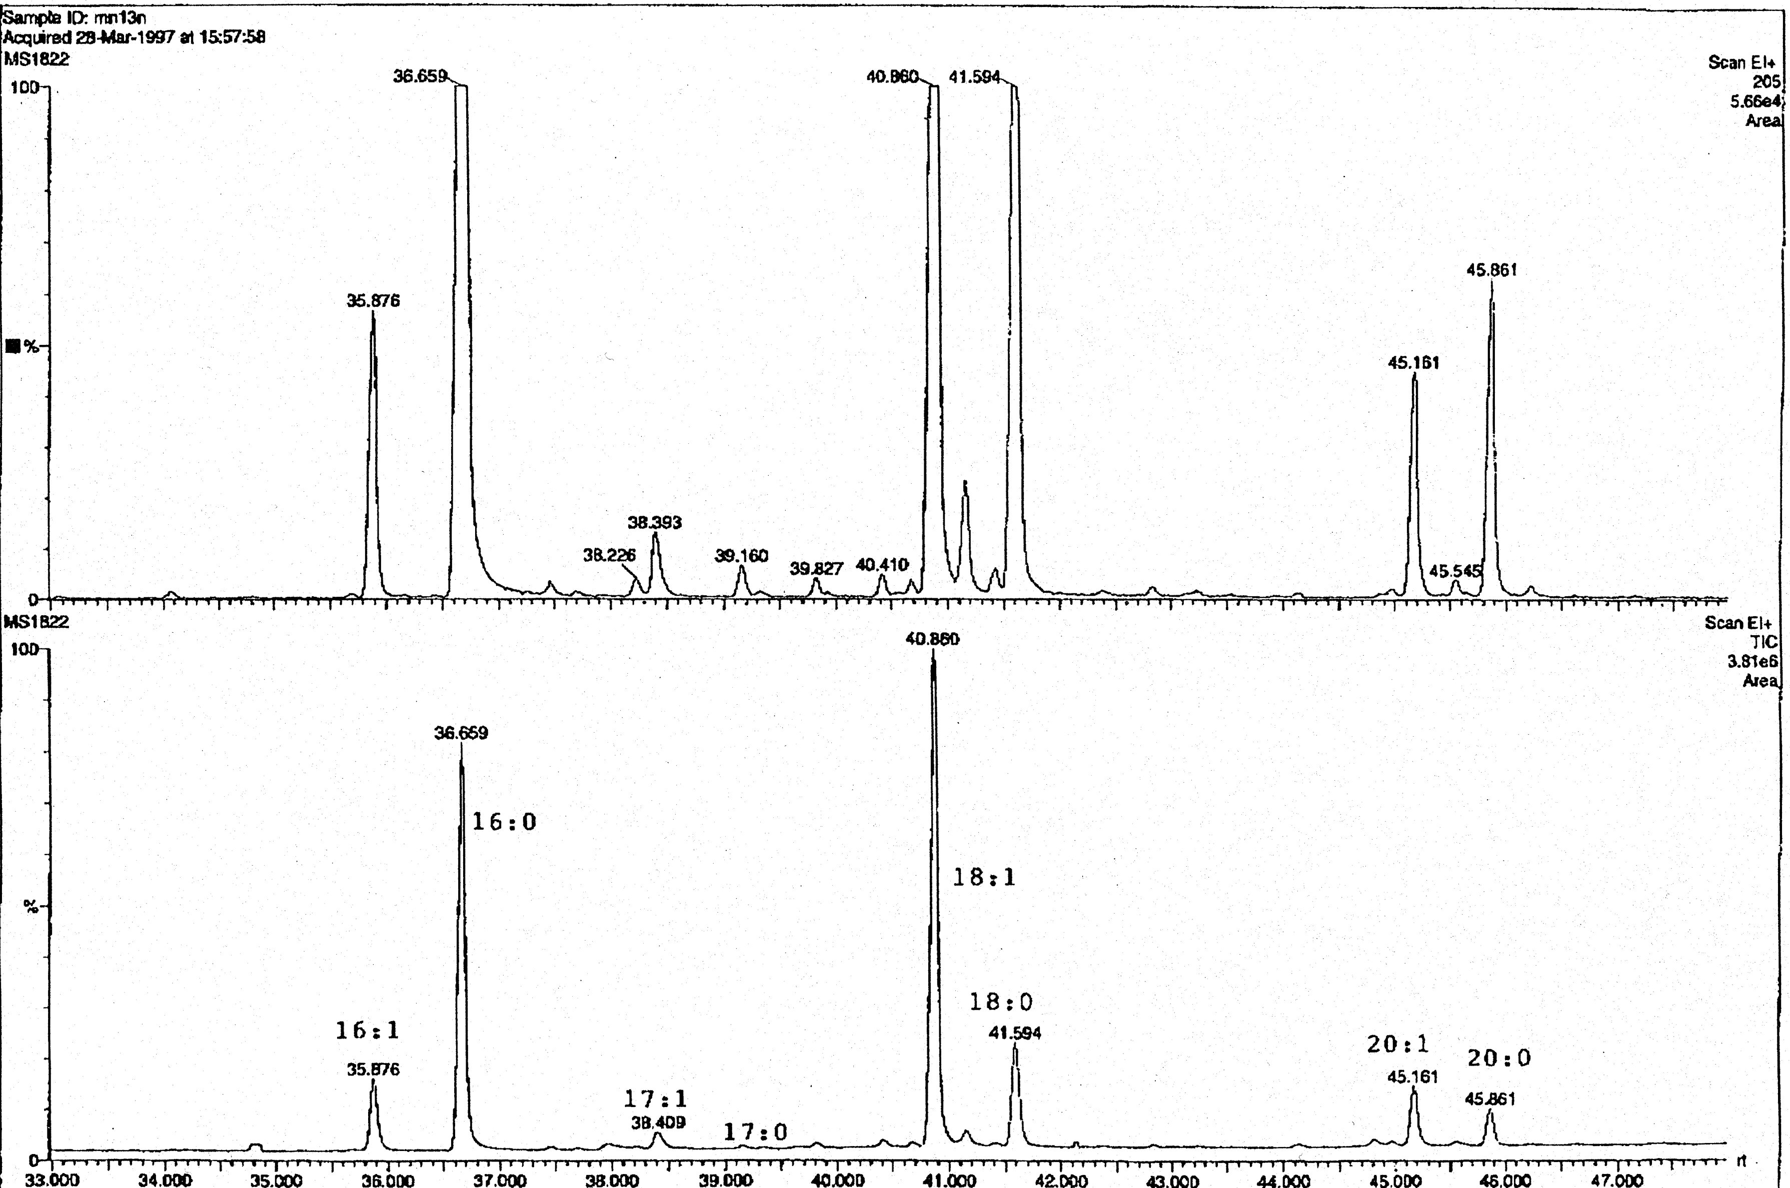

FIG. 1. (Below) Partial total recombinant ion chromatogram of glyceryl ether fraction from *Haliotus fulgens* as diol *O*-trimethylsilyl ethers. (Above) Partial recombinant ion chromatogram for *m/z* 205.

amounts(<0.05%), and was therefore not detected by thin-layer chromatograph–flame-ionization detector. A comprehensive taxonomic study by Isay *et al.* (26) revealed the occurrence of α-glyceryl ethers in 22 molluscs, including several species of limpets (*Collisella dorsuosa*, *Collisella* sp., and *Acmaea pallida*), which are archaeogastropods. This order also includes *Haliotis*. The major DAGE alkyl diol detected in abalone foot tissue in the present study was 18:0 (39.4%). In contrast to the foot, the dominant DAGE alkyl diol in abalone gonad was 1-hexadecylglyceryl ether (16:0; 38.1%), which was also found at high levels in three species of pteropods (5). Almost equally abundant in abalone gonad was the DAGE with 18:1 alkyl diol (36.1%). High proportions of 16:0 and octadec-9-enyglyceryl ether [18:1n-9c] were also found in the deep sea squid, *Moroteuthis robusta* (27). Furthermore, the ovaries of two asteroids were reported to contain 18:0, 20:1, and 16:0 as predominant DAGE diol components (28). The reasons for the difference between tissues in alkyl chain profiles are unknown, however these findings may provide insight to diet of and biosynthetic pathways in *H. fulgens*.

The major ST detected was cholesterol. The high proportions of phytol in algae (Nelson, M., unpublished data) is reflected in the very high proportions of cholesterol (Table 3) in sterols of abalone tissue, supporting the suggestion that abalone can convert phytosterols into cholesterol (29). The fucosterol common in algal diets was likely also converted to cholesterol or desmosterol, an intermediate.

Although only present in small quantities, the occurrence of DAGE in abalone tissue implies a possible structural requirement for it. These observations provide an impetus to clarify its function. DAGE may be synthesized by the abalone or it may be of dietary origin. However, it is noteworthy that neither DAGE nor GE were detected in macroalgae which are commonly part of the farmed abalone diet (Nelson, M., unpublished data). These data suggest that artificial diets for abalone culture may benefit from inclusion of small amounts of DAGE. Future research will examine the presence of DAGE in abalone larvae and juveniles, as well as in young adults undergoing gonad development. Their diet will also be examined, including macroalgae and epiphytic organisms associated with the macroalgae. These and other experiments will assist in elucidating the role of DAGE in abalone.

ARTICLE

Fatty Acid Metabolism in Marine Fish: Low Activity of Fatty Acyl Δ5 Desaturation in Gilthead Sea Bream *(Sparus aurata)* Cells

Douglas R. Tocher* **and Cristina Ghioni**

Unit of Aquatic Biochemistry, Institute of Aquaculture, University of Stirling, Stirling FK9 4LA, Scotland

ABSTRACT: Marine fish have an absolute dietary requirement for C_{20} and C_{22} highly unsaturated fatty acids. Previous studies using cultured cell lines indicated that underlying this requirement in marine fish was either a deficiency in fatty acyl Δ5 desaturase or $C_{18–20}$ elongase activity. Recent research in turbot cells found low $C_{18–20}$ elongase but high Δ5 desaturase activity. In the present study, the fatty acid desaturase/elongase pathway was investigated in a cell line (SAF-1) from another carnivorous marine fish, sea bream. The metabolic conversions of a range of radiolabeled polyunsaturated fatty acids that comprised the direct substrates for Δ6 desaturase ([1-^{14}C]18:2n-6 and [1-^{14}C]18:3n-3), $C_{18–20}$ elongase ([U-^{14}C]18:4n-3), Δ5 desaturase ([1-^{14}C]20:3n-6 and [U-^{14}C]20:4n-3), and $C_{20–22}$ elongase ([1-^{14}C]20:4n-6 and [1-^{14}C]20:5n-3) were utilized. The results showed that fatty acyl Δ6 desaturase in SAF-1 cells was highly active and that $C_{18–20}$ elongase and $C_{20–22}$ elongase activities were substantial. A deficiency in the desaturation/elongation pathway was clearly identified at the level of the fatty acyl Δ5 desaturase, which was very low, particularly with 20:4n-3 as substrate. In comparison, the apparent activities of Δ6 desaturase, $C_{18–20}$ elongase, and $C_{20–22}$ elongase were approximately 94-, 27-, and 16-fold greater than that for Δ5 desaturase toward their respective n-3 polyunsaturated fatty acid substrates. The evidence obtained in the SAF-1 cell line is consistent with the dietary requirement for C_{20} and C_{22} highly unsaturated fatty acids in the marine fish the sea bream, being primarily due to a deficiency in fatty acid Δ5 desaturase activity.

Paper no. L8113 in *Lipids 34,* 433–440 (May 1999).

The essential fatty acid (EFA) requirements of freshwater and marine fish have long been known to differ qualitatively, for in freshwater fish 18:3n-3 and/or 18:2n-6 can satisfy the EFA requirement, whereas marine species require the longer-chain highly unsaturated fatty acids (HUFA) 20:5n-3 and 22:6n-3 to be supplied by the diet for optimal growth (1–3). This suggested that there was a difference between freshwater and marine fish in the fatty acid desaturation/elongation pathway (4,5). Dietary conversion studies performed on turbot *in vivo* indicated that marine fish were unable to produce 20:4n-6 and 20:5n-3 from dietary 18:2n-6 and 18:3n-3, respectively (6–8). However, the *in vivo* experiments were unable to locate precisely any potential deficiency in the fatty acid desaturation/elongation pathway.

The difference in fatty acid metabolism between freshwater and marine fish observed *in vivo* was also present in cultured cell lines (9). Studies involving supplementation of turbot fin (TF) cells in culture, compared to both rainbow trout cells (RTG-2) and Atlantic salmon cells (AS), with various n-3 and n-6 polyunsaturated fatty acids (PUFA) showed that a relative deficiency in the desaturase/elongase pathway in TF cells was located either at the C_{18} to C_{20} elongase ($C_{18–20}$ elongase) multienzyme complex or the fatty acyl Δ5 desaturase (9,10). To establish more precisely a deficient step in the desaturase/elongase pathway, the direct substrates for all the component enzymes in the pathway are required so that each activity can be assayed and determined in isolation from the influence of preceding activities in the pathway. However, isotopes for two crucial fatty acid substrates, 18:4n-3 (the direct substrate for $C_{18–20}$ elongase) and 20:4n-3 (the direct substrate for Δ5 desaturase) were not available commercially. Recently, Ghioni *et al.* (11) biosynthesized high-purity [U-^{14}C]18:4n-3 and [U-^{14}C]20:4n-3 and provided good evidence that the deficiency in TF cells was located at the $C_{18–20}$ elongase and not the Δ5 desaturase.

To date, a deficiency in marine fish fatty acid metabolism has been characterized in only one species, turbot. Results from various *in vivo* studies involving injection of radiolabeled fatty acid precursors such as [1-^{14}C]18:3n-3 and [1-^{14}C]20:5n-3 into other species such as gilthead sea bream (*Sparus aurata*) and golden grey mullet (*Liza aurata*) confirmed that an apparent deficiency in the desaturation/elongation pathway was present in those species and supported the view that it was common to all marine fish (12–14). However, as with the *in vivo* studies in turbot, Mourente and Tocher (12–14) were unable to identify the specific enzymic location responsible for a deficiency in the pathway. Recently, the

availability of a cell line from sea bream, SAF-1, combined with the availability of [U-^{14}C]18:4n-3 and [U-^{14}C]20:4n-3 isotopes, has enabled the deficiency in the pathway to be characterized in another marine fish. We report here that, in contrast to TF cells, the primary deficiency in the desaturation/elongation pathway in SAF-1 cells from gilthead sea bream was clearly identified at the level of the fatty acyl Δ5 desaturase.

MATERIALS AND METHODS

Cell line and culture conditions. The gilthead seabream (*S. aurata* L.) cell line, SAF-1, developed from fin tissue without immortalization, was kindly provided by Dr. M.C. Alvarez (Department of Cell Biology and Genetics, University of Malaga, Spain) (15). The cell line displays fibroblast-like morphology and had been subcultured approximately 120 times over a 2-yr period. Karyotype and DNA content indicate a predominantly euploid and stable cell population. The cells were routinely maintained in Leibovitz L-15 medium supplemented with 2 mM glutamine, antibiotics (50 I.U. mL^{-1} penicillin and 50 mg·mL^{-1} streptomycin) and 10% fetal bovine serum (FBS). Cells were cultured at 22°C in 75 cm^2 sealed plastic tissue culture flasks (Corning Costar, High Wycombe, United Kingdom) and were routinely subcultured within 24 h of reaching confluence at a seeding density of 1×10^5 cells·cm^{-2}. Unless otherwise stated, for each experimental sample, 3×75 cm^2 flasks were seeded and this experiment was repeated three times to obtain the replicates. Therefore, all results are means ± SD of three such experiments.

Cell harvesting and lipid extraction. Medium was aspirated and the cultures washed twice with 20 mL of ice-cold Hanks' balanced salt solution without calcium and magnesium (HBSS). Cells were harvested by trypsinization with 0.05% trypsin/0.5 mM EDTA, washed with 5 mL ice-cold HBSS; and samples were taken for cell counting (16) and protein determination according to the method of Lowry *et al.* (17) after incubation with 0.25 mL of 0.25% (wt/vol) sodium dodecyl sulfate/1 M NaOH for 45 min at 60°C. The cells were washed with 5 mL HBSS containing 1% fatty acid-free bovine serum albumin (FAF-BSA), and total lipid was extracted from the cell pellets with 5 mL ice-cold chloroform/methanol (2:1, vol/vol) containing 0.01% butylated hydroxytoluene (BHT) as antioxidant, according to Folch *et al.* (18) as described in detail previously (19). Lipid content was determined gravimetrically after 1 h vacuum desiccation; lipid was resuspended in chloroform/methanol (2:1, vol/vol) containing BHT at a concentration of 10 mg·ml^{-1}, and samples were stored at −20°C prior to analyses.

Lipid class analysis. Lipid classes were separated by one-dimensional, double-development high-performance thin-layer chromatography (HPTLC) using methyl acetate/propan-2-ol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:9, by vol) and hexane/diethyl ether/acetic acid (85:15;1.5, by vol) as developing solvents as described previously (20). Lipid classes were quantified by charring (21) followed by scanning densitometry using a Shimadzu CS-9000 dual wavelength flying spot scanner and DR-2 recorder (22).

Fatty acid analyses. Fatty acid methyl esters (FAME) were prepared from total lipid by acid-catalyzed transmethylation at 50°C for 16 h (23) and extracted and purified as described previously (20). FAME were analyzed in a Carlo Erba Vega GC6000 gas chromatograph (Carlo Erba Strumentazione, Milan, Italy) equipped with a CP Wax 51 fused-silica capillary column (50 m × 0.32 mm i.d., Chrompack U.K. Ltd., London), with on-column injection using hydrogen as carrier gas and a biphasic thermal gradient from 50 to 225°C. FAME were identified by comparison with known standards and a well-characterized fish oil and by reference to published data as described previously; they were quantified using a Carlo Erba DP800 data processor (20). All solvents contained 0.01% BHT as an antioxidant.

Incubation of cultures with ^{14}C-labeled PUFA and incorporation of radioactivity into total lipid. Cell cultures were routinely grown in 75 cm^2 flasks in medium containing 10% FBS and subcultured into medium containing 2% FBS 24 h prior to experimentation. All experiments were performed in triplicate with three flasks for [1-^{14}C]PUFA and one flask for [U-^{14}C]PUFA per sample per experiment. The medium was aspirated, cultures were washed with Dulbecco's phosphate-buffered saline (PBS), and fresh Leibovitz L-15 medium, as above, was added. The [1-^{14}C]PUFA (18:2n-6, 18:3n-3, 20:3n-6, 20:4n-6, and 20:5n-3) (0.25 µCi per flask; concentration, 0.35 µM) were added to the cell cultures bound to FAF-BSA in medium (24). The [U-^{14}C]PUFA (18:4n-3 and 20:4n-3) were both obtained as methyl esters and because of the low yield that characterized their production, with little mass available, these substrates were added directly as methyl esters in 50 µL of ethanol) (0.25 µCi per flask; concentration approximately 0.1 µM), to avoid the losses associated with saponification, purification of unesterified fatty acid, and sterile filtration (11). Preliminary experiments incubating cells with 25 µM unlabeled 18:4n-3 as fatty acid salt/BSA complex and as methyl ester in ethanol showed no difference in the metabolism to 20:4n-3, after 6 d of culture, and no accumulation of methyl ester in cellular lipids (11). Therefore, these two ways of presenting and delivering radiolabeled PUFA to the cells in culture can be considered equivalent under the conditions used in this study.

After addition of isotope, incubation continued for 6 d at 22°C. Cells were harvested, lipid extracted as above and the radioactive content of total lipid determined in three aliquots of 5 µL in mini-vials containing 2.5 mL scintillation fluid (Ecoscint A; National Diagnostics, Atlanta, GA) using a Tri-Carb 2000CA liquid scintillation spectrophotometer (United Technologies Packard). Results were corrected for counting efficiency and quenching using an appropriate calibration curve. All solvents contained 0.01% BHT as antioxidant.

Incorporation of radioactivity into glycerophospholipid classes. Samples of total lipid (100 µg) were applied as 1-cm streaks to HPTLC plates, and lipid classes separated by the one-dimensional, double-development method described

above (20). After desiccation, the lipid classes were visualized by brief exposure to iodine vapor, and areas corresponding to phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine, phosphatidylinositol, phosphatidic acid/cardiolipin, and total neutral lipid (the combined free fatty acid, triacylglycerol, and steryl ester areas) were scraped into scintillation vials containing 2.5 mL scintillation fluid and radioactivity determined as above.

Incorporation of radioactivity into PUFA. Total lipid extracts were transmethylated overnight at 50°C in methanolic sulfuric acid (23) and FAME extracted and purified as described above. TLC plates were impregnated by spraying with 2 g silver nitrate in 20 mL acetonitrile and activated at 110°C for 30 min. FAME were applied as 1-cm streaks and plates developed with toluene/acetonitrile (95:5, vol/vol) to separate PUFA (25). Autoradiography was performed using Kodak MR2 film for 7 d at room temperature. Silica corresponding to individual FAME was scraped into scintillation vials containing 2.5 mL scintillation fluid and radioactivity determined as described above.

Preparation of [U-^{14}C]18:4n-3 and [U-^{14}C]20:4n-3. [U-^{14}C]18:4n-3 was prepared as described in detail by Ghioni *et al*. (11). Briefly, the unicellular marine alga *Isochrysis galbana* (Parke) (S.M.B.A. strain No. 58 C.C.A.P. strain 927/1) was incubated with sodium [^{14}C]bicarbonate and total lipid extracted. The 18:4-rich glycerolipids (mono- and digalactosyldiacylglycerols) were purified by TLC, transmethylated, and FAME extracted as described previously (11,20). FAME were separated by argentation TLC, individual FAME identified by autoradiography; and the [U-^{14}C]18:4n-3 methyl ester was eluted and quantified (11). [U-^{14}C]20:4n-3 was biosynthesized from [U-^{14}C]18:4n-3 as described by Ghioni *et al*. (11). Briefly, AS cells were incubated with [U-^{14}C]18:4n-3 methyl ester; total lipid was extracted and transmethylated, and FAME were separated by argentation TLC as above. Both [U-^{14}C] isotopes had specific activities of approximately 12 mCi/mmol and were >99% pure, determined by radio-gas chromatography as described by Buzzi *et al*. (26).

Materials. Sodium [^{14}C]bicarbonate (~50 mCi·mmol^{-1}) was purchased from ICN Biomedicals Ltd. (Thame, United Kingdom). [1-^{14}C] PUFA (all 50–55 mCi·mmol^{-1} and >98% pure) were obtained from NEN Life Science Products (Hounslow, United Kingdom). Leibovitz L-15 medium, HBSS, Dulbecco's modification phosphate-buffered saline (wtihout Ca^{2+} and Mg^{2+}), glutamine, penicillin, streptomycin, FBS, trypsin/EDTA, FAF-BSA, and BHT were obtained from Sigma Chemical Co. Ltd. (Poole, United Kingdom). TLC plates (20 cm × 20 cm × 0.25 mm) and HPTLC plates (10 cm × 10 cm × 0.15 mm), pre-coated with silica gel 60, were obtained from Merck, (Darmstadt, Germany). All solvents were of high-performance liquid chromatography grade and were obtained from Rathburn Chemicals (Walkerburn, Peebleshire, Scotland).

Statistical analysis. All results are means ± SD of three experiments. Where indicated, data were subjected to one-way analysis of variance, and where appropriate the significance of differences was determined by Tukey's test. When necessary, data were subjected to arc-sin transformation prior to statistical analysis. Differences are reported as significant when $P < 0.05$ (27).

RESULTS

The lipid content and class composition of SAF-1 cells cultured in 10% FBS are shown in Table 1. Nearly 75% of the total lipid was polar lipid with almost 30% PC, 19% PE, 7.3% phosphatidylinositol, and 6.3% phosphatidylserine, whereas the neutral lipid was predominantly cholesterol (20.3%). The fatty acid composition of total lipid of SAF-1 cells contained over 41% monounsaturated fatty acids, with 18:1n-9 constituting 25.2%, and approximately 25% saturated fatty acids, predominantly 16:0 (15%) and 18:0 (8.5%) (Table 2). The PUFA were characterized by 10% n-9 PUFA (90% of which was 18:2n-9, the single most abundant PUFA in the cells), 11.1% n-3 PUFA (mainly 22:6n-3 and 20:5n-3), and 9.5% n-6 PUFA (primarily 20:4n-6).

The recovery of radioactivity in total lipid from SAF-1 cells incubated with [1-^{14}C]20:5n-3 was significantly greater than any of the other PUFA investigated (Table 3). There were numerical differences between the other PUFA but, irrespective of the way that the recovery data were presented, few were statistically significant although there was a trend for the recovery of radioactivity from cells incubated with [1-^{14}C]18:2n-6, [1-^{14}C]18:3n-3, and [1-^{14}C]20:4n-6 to be higher than the recovery of radioactivity from incubations with [1-^{14}C]18:4n-3, [1-^{14}C]20:3n-6, and [1-^{14}C]20:4n-3. All the PUFA were predominantly esterified into the main glycerophospholipid classes with between 88 and 98% of radioactivity being recovered in these classes (Table 4). Higher in-

corporation into the glycerophospholipids was generally observed with the C_{20} PUFA compared to the C_{18} PUFA. Both [1-^{14}C]20:4n-6 and [1-^{14}C]20:5n-3 were predominantly incorporated into PE whereas all the other PUFA were incorporated predominantly into PC, these differences being statistically significant (Table 4). Significantly more [U-^{14}C]18:4n-3 and [U-^{14}C]20:4n-3 were incorporated into PC compared to the other PUFA; and significantly greater proportions of [1-^{14}C]20:4n-6 and, to a lesser extent, [1-^{14}C]20:3n-6 were incorporated into phosphatidylinositol compared to the other PUFA.

The main metabolic product of [1-^{14}C]18:2n-6 recovered from SAF-1 cells was 18:3n-6 (over 35% of radioactivity recovered in this fraction) whereas the main metabolic products of [1-^{14}C]18:3n-3 were 18:4n-3 and 20:4n-3 (almost 41 and 21% of radioactivity recovered in these products, respectively) (Table 5). With all the other PUFA, over 80% of the radioactivity was recovered in the form of the fatty acid originally added to the cells. With [U-^{14}C]18:4n-3, the only major products were the elongation products 20:4n-3 (13.2%) and 22:4n-3 (5.1%), with only 0.7% being desaturated to 20:5n-3. Similarly, with [1-^{14}C]20:3n-6, elongation products constituted almost 85% of the total metabolized. The main products of the metabolism of [U-^{14}C]20:4n-3 in SAF-1 cells were 22:4n-3 and the chain-shortened product, 18:4n-3 (Table 5). Both [1-^{14}C]20:4n-6 and [1-^{14}C]20:5n-3 were mainly elon-

gated with only a small fraction of radioactivity being recovered as 22:6n-3 in [1-^{14}C]20:5n-3-supplemented cells. Table 6 is a summary of the results obtained in the isotope experiments and is derived from the data contained in Table 5 but presented as sums of products of each individual step in the desaturation/elongation pathway taking into account all the fatty acids that are derived from that step, irrespective of subsequent conversions. The results obtained for each enzyme activity when incubating the cells with the fatty acid which is its direct substrate (i.e., 18:4n-3 for $C_{18–20}$ elongase and 20:4n-3 for Δ5 desaturase) are of particular interest as they show the potential of each activity independent of the previous enzymes. Table 6 shows that considerable amounts of radioactivity are recovered as Δ6 desaturase products in SAF-1 cells incubated with the main fatty acid substates for Δ6 desaturase, [1-^{14}C]18:3n-3 and [1-^{14}C]18:2n-6. Although the majority of the [1-^{14}C]18:3n-3 and [1-^{14}C]18:2n-6 metabolized to Δ6 desaturase products was not further metabolized, about 27 and 9% of the total radioactivity recovered in the case of [1-^{14}C]18:3n-3 and [1-^{14}C]18:2n-6, respectively, were elongated by $C_{18–20}$ elongase. Very little radioactivity from [1-^{14}C]18:2n-6 and, especially, [1-^{14}C]18:3n-3, was recovered in Δ5 desaturated products. When SAF-1 cells were incubated with the direct n-3 substrate of $C_{18–20}$ elongase, [U-^{14}C]18:4n-3, 19% was elongated but only 0.7% was recovered in Δ5 desaturated products. The very low activity of fatty acyl Δ5 desaturase in SAF-1 cells was confirmed using direct substrates for Δ5 desaturase, [1-^{14}C]20:3n-6 and

TABLE 6
Products of Desaturase and Elongase Activities in SAF-1 Cells Incubated with Various ^{14}C-Labeled PUFA[a]

Fatty acid added	Δ6 desaturase products	$C_{18–20}$ elongase products	Δ5 desaturase products	$C_{20–22}$ elongase products
[1-^{14}C]18:2n-6	43.2 ± 1.5	8.9 ± 0.5	4.3 ± 0.8	1.8 ± 0.3
[1-^{14}C]18:3n-3	66.1 ± 1.1	27.1 ± 0.6	Trace	4.5 ± 0.3
[U-^{14}C]18:4n-3	—	19.0 ± 2.1	0.7 ± 0.5	5.1 ± 0.2
[1-^{14}C]20:3n-6	—	—	2.5 ± 0.2	13.9 ± 0.7
[U-^{14}C]20:4n-3	—	—	0.7 ± 0.4	5.2 ± 1.7
[1-^{14}C]20:4n-6	—	—	—	6.6 ± 1.9
[1-^{14}C]20:5n-3	—	—	—	10.9 ± 0.8

[a]Results are presented as percentages of total radioactivity recovered and are means ± SD (n = 3). All fatty acid metabolites for a given step in the pathway were summed, irrespective of subsequent metabolism by another activity (e.g., for [1-^{14}C]18:2n-6, "Δ6 products" represents the sum of radioactivity recovered as 18:3n-6, 20:3n-6, 20:4n-6, and 22:4n-6). Trace, <0.05%.

[U-^{14}C]20:4n-3, where little radioactivity was recovered in Δ5 desaturated products (Table 6). $C_{20–22}$ elongase products were found in the cells with all the fatty acids used and in higher percentages compared to Δ5 desaturation products.

DISCUSSION

The results of the present study indicate that the sea bream cell line has a deficiency in the desaturation/elongation pathway similar in effect to that observed in turbot and sea bream *in vivo* and TF cells *in vitro*. Specifically, the results show, first, that the lipid and fatty acid compositions of cell lines derived from marine fish have several features that distinguish them from cell lines from freshwater fish; second, that one of the main factors underpinning these differences is a relative deficiency in the pathway for the desaturation and elongation of EFA in marine fish cells; and third, that although the effect of the deficiency is similar in different marine fish, its location in the pathway is different.

The first feature distinguishing cells from a marine fish was the lipid class composition. The SAF-1 cells cultured in 2% serum displayed a lipid content (59.8 ± 4.7 μg/10^6 cells) comparable to levels previously reported in other fish cell lines cultured in 2% serum, being similar to that observed in AS cells (50.4 ± 10.0 μg/10^6 cells) but slightly higher than that found in another marine fish cell line, TF, (41.4 ± 3.3) and lower than that found in RTG-2 (87.2 ± 6.0) (9,28). However, the proportion of neutral lipids in SAF-1 cells (25.8%) was very similar to that found in TF cells (27.3%), both of which were much lower than the levels found in the freshwater fish cell lines, 37.2 and 39.2% for AS (cell line prepared from freshwater fry stage) and RTG-2 cells, respectively, which were characterized by higher percentages of triacylglycerols (9,28).

Importantly however, the fatty acid composition of SAF-1 cells was characterized by the presence of substantial amounts of n-9 PUFA, 90% of which was 18:2n-9, the most abundant PUFA in SAF-1 cells. This is an identical feature to

that observed in TF cells, in which 18:2n-9 was also the most abundant PUFA and its level was increased to over 22% by reducing the serum supplement to 2% (9). In contrast, 18:2n-9 is a relatively minor PUFA in AS and RTG-2 cells, amounting to only 1.2 and 1.8%, respectively, in cells cultured in 2% serum (9,28). The presence of large amounts of this unusual PUFA (18:2n-9) in marine fish cells, compared to freshwater fish cells and mammalian cell lines, on its own strongly suggests a deficiency in fatty acid desaturation/elongation as a principal factor responsible for the differences in EFA requirements between marine and freshwater fish.

The higher level of total n-9 PUFA in TF cells compared to AS and RTG-2 cells was hypothesized to be due to the marine fish cells having a higher requirement for n-3 HUFA (4,29) and thus experiencing a greater EFA deficiency when grown in relatively n-3 HUFA-deficient, n-6 PUFA-rich mammalian serum (9). This, combined with the specific location of the apparent deficiency in the EFA desaturation/elongation pathway in marine fish, resulted in the specific accumulation of 18:2n-9 in TF cells. Although the level of 18:2n-9 is lower than in TF cells, the present data in SAF-1 cells support this hypothesis and indicate that high levels of 18:2n-9 may be a characteristic fatty acid marker for all marine fish cells in culture. Consistent with the hypothesis that marine fish cells require higher levels of n-3 HUFA, the two marine fish cell lines retained the highest proportions of n-3 PUFA in their total lipid, with n-3 PUFA accounting for 54 and 45% of total PUFA (not counting n-9 PUFA) in SAF-1 and TF cells, respectively, but only 38 and 34% in AS and RTG-2 cells, respectively (9,28). These observations in cell lines derived from marine fish are supported by the dietary traits of the marine species with both sea bream and turbot being carnivorous, specifically piscivorous, species with diets consisting almost entirely of smaller fish. As such their natural diets are rich in the long-chain n-3 HUFA, 20:5n-3 and 22:6n-3 (5,29,30). In contrast, freshwater salmonids, such as rainbow trout, have diets richer in C_{18} PUFA and much lower long-chain HUFA (4,29,31).

In contrast to the lipid and fatty acid composition data, the fatty acid incorporation data show surprisingly little difference between marine and freshwater cell lines. The data in Table 3 suggest (i) that the SAF-1 cells retained [1-^{14}C]20:5n-3 in their lipids to a greater extent than any other PUFA studied and (ii) that the PUFA, which are present normally in only very small amounts in fish lipids and are generally regarded as more transient intermediates in the PUFA pathway, specifically 18:4n-3, 20:3n-6 and 20:4n-3, were retained the least. This is consistent with the observed fatty acid composition of fish in general, with 20:5n-3 and 22:6n-3 being the major PUFA. However, these data represent the net recovery of radioactivity in the cells after incubation with the fatty acid isotopes. The radioactivity recovered will depend on the amount of fatty acid initially taken up by the cells, less the amount of fatty acid lost due to other metabolic processes such as oxidation or conversion to eicosanoids. Owing to the limited amount of pure U-^{14}C-labeled isotopes available, they were not used at exactly the same concentration as the 1-^{14}C-labeled isotopes, thereby possibly affecting the amount initially taken up by the cells. In addition, the 1-^{14}C-labeled isotopes lose the radiolabel after one round of β-oxidation whereas the U-^{14}C-labelled isotopes will not, also affecting the relative recoveries of radioactivity from the differently labeled isotopes. Therefore, some caution is required in directly comparing the data in Table 3. Previously, we have shown in several fish cell lines that there was little difference between the recovery of radioactivity when incubated with the 1-^{14}C-labeled isotopes of 18:2n-6, 18:3n-3, 20:4n-6, and 20:5n-3 (10).

The pattern of incorporation of the PUFA into lipid classes was very similar to that reported previously in AS, RTG-2, and TF cell lines (10). In that earlier study, 86–94%, and 96–98% of radioactivity from C_{18} PUFA and C_{20} PUFA, respectively, were recovered in polar lipids compared with figures of 88–92% for C_{18} PUFA and 92–98% for C_{20} PUFA obtained with SAF-1 cells in the present study (10). The preferential incorporation of C_{18} PUFA into PC was also observed in the earlier study as was the preferential incorporation of 20:4n-6 into PI and 20:5n-3 into PE (10). The present study has shown that the pattern obtained with 20:3n-6 was basically as expected for a C_{20} PUFA in general, but particularly similar to 20:4n-6, whereas the incorporation of 20:4n-3 was more similar to that for C_{18} PUFA. However, there was no major difference between the freshwater fish cell lines, AS and RTG-2, and the marine fish cell lines, TF and SAF-1, in the incorporation of PUFA into lipid classes. These results appear to indicate that the ability of the cells to metabolize the fatty acids *via* desaturation and elongation does not greatly influence their uptake, retention or distribution in cell lipids, at least at the low concentrations used in the present study.

The primary aim of the present study was to determine if the deficiency in the desaturase/elongase pathway, established in C_{18-20} elongase in TF cells (11), was identical in another marine fish cell line. The results obtained using the direct substrates for each individual enzymic activity in the pathway enabled the deficient step in SAF-1 cells to be identified. The fact that 43.2 and 66.1% of added [1-^{14}C]18:2n-6 and [1-^{14}C]18:3n-3, respectively, were desaturated showed that SAF-1 cells expressed a highly active Δ6 desaturase. In addition, 19% of the direct substrate for C_{18-20} elongase, [U-^{14}C]18:4n-3, was elongated. In contrast, only 2.5 and 0.7% of added [1-^{14}C]20:3n-6 and [U-^{14}C]20:4n-3 were recovered as Δ5 desaturation products. Almost 7 and 11% of [1-^{14}C]20:4n-6 and [1-^{14}C]20:5n-3, respectively, were C_{20-22} elongated. In summary, the apparent activities of Δ6 desaturase, C_{18-20} elongase, and C_{20-22} elongase were approximately 94-, 27-, and 16-fold greater than that for Δ5 desaturase toward their respective n-3 PUFA substrates. These results showed that, in contrast to TF cells, fatty acyl Δ5 desaturation was the step with the lowest activity in the pathway biosynthesizing 20:5n-3 (or 20:4n-6) in the SAF-1 cells.

The Δ5 desaturase activity in SAF-1 cells was particularly ineffective toward the n-3 substrate. This was unexpected, as

desaturases in general are normally more active toward n-3 fatty acids in mammals (32,33) and fish cells (10,11,34). Furthermore, the other enzymes in the pathway, Δ6 desaturase and the C_{18-20} and C_{20-22} elongases, showed greater activity toward n-3PUFA in SAF-1 cells.

Deficiencies in fatty acyl desaturase activities have precedents in terrestrial carnivores such as cats in which Δ6 and Δ5 desaturase activities may both be very low (35–38). It has been hypothesized that this situation may be an evolutionary adaptation to carnivorous diets rich in preformed C_{20} and C_{22} HUFA. This may be paralleled in fish because, as described above, the diets of the generally more herbivorous/omnivorous freshwater fish are rich in C_{18} PUFA and do not contain much C_{20} or C_{22} HUFA, whereas marine fish that are predominantly carnivorous consume diets rich in 20:5n-3 and 22:6n-3 (30,31). Therefore, the differences in the fatty acid desaturase/elongase pathways between fish species may be an evolutionary response to dietary differences. However, this cannot explain the why turbot should have low C_{18-20} elongase and sea bream low Δ5 desaturase.

In both cases of marine fish studied, Δ5 desaturase in SAF-1 cells and C_{18-20} elongase in TF cells, there is not a complete lack of the enzyme activity responsible for the deficiency in the pathway. This is now also known to be the case in cats. In early studies, a complete lack of Δ6 desaturation enzymatic activity in felines was originally reported (35–38), although recent and more sensitive studies conducted with deuterated fatty acids showed that a low level of Δ6 desaturase is present in the cat (39).

The present study provides good evidence that SAF-1 cells have a deficiency in fatty acyl Δ5 desaturase activity in contrast to TF cells in which C_{18-20} elongase is deficient. Both of these relative deficiencies in the fatty acid desaturation/elongation pathway are entirely consistent with the known EFA requirements of marine fish. However, it is important to determine if this is a reflection of the situation *in vivo* and if the cell lines are a model for the whole animal. Studies with mammalian cell lines have shown that three out of six expressed little Δ6 desaturase activity, Δ5 desaturase activity appeared to be absent in four cell lines, and only one cell line expressed any desaturation activity beyond Δ5 (40). An apparent loss of stearoyl-CoA Δ9 desaturase has been reported in cultured murine T lymphocytes (41). Therefore, experiments with stable isotopes, similar to those performed by other authors in felines (39) and humans (42,43) are required to confirm the deficiencies in fatty acid desaturation and elongation in marine fish *in vivo*.
