ABSTRACT: The purpose of this study was to assess changes in the degree of fatty acid unsaturation in rat liver after partial hepatectomy. This is the first study in which liver fatty acid unsaturation has been analyzed over a long period of regeneration until day 28 after operation. The relationship between changes in unsaturation and fatty acid composition in the regenerating liver were also investigated in this study. Proton nuclear magnetic resonance spectroscopy revealed significantly elevated levels of unsaturation with a maximum on day 5 after partial hepatectomy, compared with untreated controls (11.72 ± 0.55 vs. 11.05 ± 0.26%, $P < 0.05$). No significant changes in unsaturation were found in day 1 regenerating liver, which is rich in absolute amounts of fatty acids. Based on gas–liquid chromatography, the relative amounts of oleic acid (18:1n-9) and linoleic acid (LA; 18:2n-6) were increased, while polyunsaturated fatty acids such as arachidonic acid (20:4n-6) and docosahexaenoic acid (DHA; 22:6n-3) were decreased on day 1. On the other hand, on day 5 of regeneration, while most fatty acids were returning to their preoperative control levels, only DHA was higher than the control value (7.69 ± 0.58 vs. 5.57 ± 0.37%, $P < 0.001$). The high levels of unsaturation on day 5 were found to be partly due to the increase in DHA. The findings suggest that some significant signals are transmitted during the regeneration process owing to alterations in the membrane structure by the high levels of fatty acid unsaturation and the increase in DHA levels on day 5 after partial hepatectomy.

Paper no. L7992 in *Lipids 35*, 445–452 (April 2000).

Much remains unknown concerning the mechanisms of liver regeneration. Regenerating rat liver is an ideal model system in which to study the mechanisms that control cell proliferation. It is now well established that some of the biochemical changes that occur during liver regeneration also occur during tumor growth. Therefore, observations about liver regeneration also will lead to a better understanding of the mechanisms of neoplastic and some liver diseases.

Fatty acids form one category of cell constituents, and among them, unsaturated fatty acids are related to membrane permeability (1–6), signal transduction (7–9), and cell proliferation (10,11). It has been reported that the composition of liver fatty acids changes during regeneration (12–16). However, there have been few studies concerning fatty acid unsaturation in the regenerating liver. Bruscalupi *et al.* (16) analyzed changes in the degree of unsaturation for up to 24 h after partial hepatectomy by gas–liquid chromatography. Many investigators have focused on the time around day 1 after hepatectomy when DNA synthesis reaches its peak and is followed by the mitotic peak (17–19). Details concerning unsaturation have not yet been fully investigated over long periods of liver regeneration.

In this study, we extended the analysis of changes in fatty acid unsaturation to day 28 after hepatectomy, at which time regeneration is essentially complete. Proton nuclear magnetic resonance (^{1}H NMR) spectroscopy shows that the degree of unsaturation of the liver fatty acids appears to increase to a maximum on day 5 after hepatectomy. In addition, gas–liquid chromatography reveals some contribution of docosahexaenoic acid (DHA; 22:6n-3) to the high degree of unsaturation at this time.

MATERIALS AND METHODS

Experiment 1 (changes in fatty acid unsaturation in the liver after partial hepatectomy). (i) Animal model. Male Wistar rats were obtained from Japan Slc Co. (Shizuoka, Japan) at the age of 12 wk and raised to 30–35 wk for experiments. All animals received humane care according to the Guideline for Animal Experimentation published by the Japanese Association for Laboratory Animal Science. Rats were housed in a windowless room with 12 h light/12 h dark and allowed free access to a standard laboratory diet and water preoperatively and postoperatively. Standard laboratory chow was obtained from Oriental Yeast Co. (Osaka, Japan). The fatty acid composition of the liver had been stabilized by the diet at the time of operation. Three groups of rats were studied. (i) Rats in group 1 were controls and underwent no treatment ($n = 6$); (ii) rats in group 2 were subjected to partial hepatectomy and sacrificed after operation on day 1, 2, 3, 5, 7, 10, 14, 21, or 28 ($n = 6$ at each time); and (iii) rats in group 3 were subjected to simple laparotomy, a so-called sham operation, and sacrificed after operation on day 1, 2, 3, 5, 7, 10, 14, 21, or 28 ($n =$

6 at each time). It is well known that surgical stress alone causes changes in the fatty acid composition of the liver (12–16). All groups of rats were given same diet both before and after surgery. The mean body weight of the rats was 390 g at the time of surgery.

(ii) Surgery. Partial (70%) hepatectomies were performed between 1200 and 1300 under light diethylether anesthesia by the method of Higgins and Anderson (20). Sham operations were carried out during the same period.

(iii) Lipid extraction. Rats were killed at various times after surgery described above. Liver samples were taken at random from one of the regenerating lobes. Minor liver lobes, corresponding to the remaining liver lobes in the hepatectomized rats, were taken from the control and sham-operated rats.

Five samples of 0.5 g tissue were taken for analysis from each rat liver, and the average of the five samples was regarded as the value from one rat by ^{1}H NMR spectroscopy analysis. A total of six animals were used from each group at each time after operation, so 30 samples were analyzed at each time.

Lipids were extracted by the method of Kwee *et al.* (21) [modified Folch *et al.* (22) method] as described below. Chloroform/methanol (4.5 mL; 2:1, vol/vol) was added to each 0.5 g piece of liver, and the lipids were extracted for 1 d under nitrogen. The solution was washed with 0.15 mL of 6 N HCl for 2 h, vortexed with 7 mL of chloroform for 2 min, then vortexed again for 2 min after the addition of 1.5 mL of 0.05 N KCl. The solution was allowed to stand for 2 h, the bottom layer was removed, and the upper phase was washed again with 3 mL chloroform. The combined organic solution was evaporated under a stream of nitrogen to prevent the oxidation of unsaturated fatty acids. This lipid sample contained the total fatty acids from all kinds of lipids (triacylglycerol, phospholipid, glycolipid, and cholesterol ester). Samples were stored under nitrogen at –40°C until ^{1}H NMR spectroscopy measurement on the following day.

(iv) ^{1}H NMR spectroscopy. The lipid extracts were redissolved in 0.7 mL of deuterochloroform and placed in 5-mm NMR tubes for ^{1}H NMR spectroscopic analysis. Spectra were taken on a VXR-400S Varian Spectrometer (Varian NMR Instruments, Palo Alto, CA) operating at a proton frequency of 399.952 MHz. All spectra were obtained using an 18° pulse, a spectral width of 6000 Hz, a repetition time of 3.7 s, 44 K data points, and a sample spinning rate of 16 Hz. Thirty-two to sixty-four acquisitions were required to attain an adequate signal. Chemical shifts are expressed with respect to residual $CHCl_3$ at 7.24 ppm. During data processing, line broadening of 0.3 Hz was applied as a noise filter. Peaks were assigned by comparison with literature data (21,23–26). Each proton on the fatty acyl chain has its own chemical shift determined by its binding character, and its assignment is shown on the spectrum in Figure 1. Peak intensity is related to the number of protons. Peak intensities were determined by computerized integration after careful baseline correction.

Values were calculated using arithmetic functions of integrated peak intensities. The degree of unsaturation was analyzed by obtaining the ratio between the double-bond peak and the sum of all peaks. Changes in unsaturation were evaluated over the time course of liver regeneration.

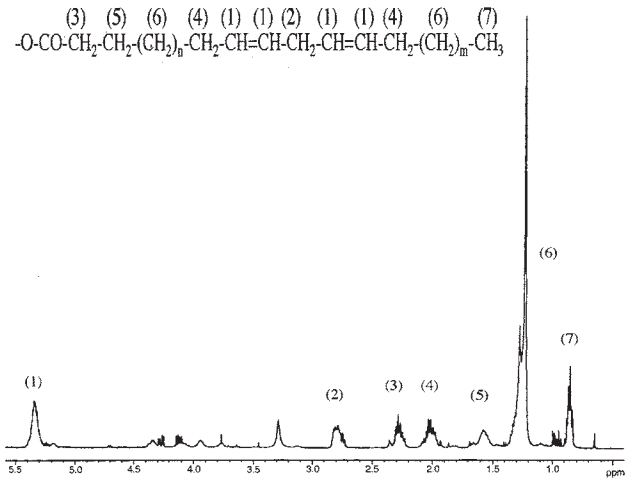

FIG. 1. Representative ^{1}H nuclear magnetic resonance (NMR) spectrum of a rat liver lipid extract. The major peaks assignable to protons in different positions on the fatty acids are indicated by numbers on the spectrum. Peak (1) represents the protons of double bonds in fatty acyl chains. Minor peaks on the spectrum from 3.0 to 4.5 ppm correspond to the remaining polar heads of phospholipids.

Experiment 2 (changes in fatty acid composition of regenerating livers). After Experiment 1, the unsaturation of the liver fatty acids after partial hepatectomy was shown to reach a maximum on day 5. The fatty acid composition was then analyzed by gas–liquid chromatography.

(i) Animal model. Male Wistar rats, age 30–35 wk, were used and surgery was performed under the same conditions as for Experiment 1. Samples from the following groups were subjected to gas–liquid chromatographic analysis: (i) untreated controls (n = 10); (ii) partial hepatectomy (n = 10 for days 1 and 5; n = 5 for days 2, 3, 7, 10, 14, 21, and 28).

(ii) Gas–liquid chromatography. Fatty acid methyl esters for gas chromatographic analysis were prepared from hepatic lipids as follows. Lipids were extracted in chloroform/methanol (2:1, vol/vol) as described for Experiment 1; the lipid sample obtained was again a mixture of all kinds of lipids. Lipid extracts were evaporated to dryness under a stream of nitrogen and then redissolved in 1 mL of dichloromethane, 2 mL of 4.5% HCl/methanol, and 0.5 mL of 1,2,3-trihydroxybenzene (pyrogallol; Sigma, St. Louis, MO). The mixtures were heated at 80°C for 1 h. After cooling, the lipids were extracted three times with hexane (5 mL × 3). The hexane extracts were combined, and 4 mL of 2% $KHCO_3$ was added. The hexane layers were separated, dried over sodium sulfate, filtered, and evaporated to dryness under nitrogen. The resulting residue was redissolved in 500 μL of hexane; then 1 μL of pentadecanoic acid methyl ester was added as an internal standard to obtain the absolute amount, and 1 μL of the total aliquot was subjected to gas–liquid chromatographic analysis.

The fatty acid methyl esters were separated in an HP5890 Series II Gas Chromatograph (Hewlett-Packard GmbH, Waldbronn, Germany) with an Omegawax 250 capillary col-

umn (Supelco Inc., Bellefonte, PA) using a flame-ionization detector. The injector, column, and detector temperatures were maintained at 250, 205, and 260°C, respectively. Helium was employed as the carrier gas at a linear velocity of 30 cm/s. The amount of each fatty acid was quantitated by automatic calculation of the peak area by an HP3396 Series II integrator (Hewlett-Packard GmbH). For identification of fatty acids, retention times were compared to a standard mixture of known composition. Fatty acid compositions are expressed in terms of mole percentages of total fatty acids and absolute amounts. Fatty acid unsaturation was also analyzed from the results of gas–liquid chromatography. The method of calculation is shown in Table 1. However, the evaluation is different from that by ^{1}H NMR spectroscopy. On the one hand, the ^{1}H NMR spectroscopy in Experiment 1 deals with the degree of unsaturation as the ratio between protons on double bonds and total protons on fatty acids, but gas–liquid chromatography deals with the unsaturation as the mean number of double bonds per one fatty acid molecule.

The percentage was then calculated for the ratio of double bonds in each major unsaturated fatty acid to total double bonds in all fatty acids in the liver. (See legend to Fig. 4.)

Statistical analysis. For Experiment 1 with ^{1}H NMR spectroscopy, two-factor factorial analysis of variance (ANOVA) was used to analyze the effects of treatment (partial hepatectomy vs. sham operation) and time after operation. The significance of differences was assessed by *post hoc* tests.

For Experiment 2 with gas–liquid chromatography, *post*

[a]Values are expressed as relative percentages of the molar amount of each fatty acid. Values in parentheses are the absolute amounts of fatty acids expressed as μg/g tissue. Mole percentages of various fatty acids were calculated on the basis of the actual amounts of fatty acids determined from the integrated peak areas on the chromatogram and the molecular weights of the respective fatty acid methyl esters. Fatty acids are designated as number of carbon atoms:number of double bonds. Unsaturation is presented as the mean number of double bonds per fatty acid molecule at the bottom. Values were calculated using the following formula: Σ (x × each fatty acid mol%/100), where x represents the number of double bonds in the fatty acid (0–6). Each number represents the mean ± SD of 10 values from 10 rats. P1: comparison of untreated control vs. day 1; P2: comparison of untreated control vs. day 5; P3: comparison of day 1 vs. day 5. NS: not significant.

hoc tests were used to analyze the significance of differences among the untreated controls and rats on days 1 and 5 after partial hepatectomy. For changes in the amounts of total fatty acids and DHA (day 0 through day 28), one-factor ANOVA and *post hoc* tests were used to analyze the effect of time after partial hepatectomy.

RESULTS

A representative ^{1}H NMR spectrum of lipid extracts from rat liver is shown in Figure 1.

Figure 2 shows changes in the degree of unsaturation after partial hepatectomy. The rat liver fatty acids after partial hepatectomy were highly unsaturated during regeneration. Unsaturation reached a maximum on day 5 after hepatectomy and then decreased gradually to control levels. As compared with the control level (11.05 ± 0.26%), unsaturation was significantly increased on day 5 and day 7 at 11.72 ± 0.55 and 11.67 ± 0.53%, respectively (vs. control, $P < 0.05$). No significant difference was observed between control and sham-operated rats at any time after operation. The degree of unsaturation after partial hepatectomy was significantly higher than that after sham operation on day 5 and day 7 ($P < 0.05$). On day 1 following partial hepatectomy, a small decrease in the level of unsaturation (10.81 ± 0.44%) was noted, but this was not statistically significant.

The fatty acid composition of livers after partial hepatectomy was analyzed by gas–liquid chromatography. As shown in Figure 3, the absolute amount of total fatty acids was increased during the early phase of regeneration from day 1 to day 3 ($P < 0.0001$), and peaked on day 2 (96.7 ± 13.5 μg/g tissue). The amount of each fatty acid reached a maximum on day 2 (data not shown).

Values from untreated control and regenerating livers on day 1 and day 5 are shown in Table 1.

The absolute amounts of most fatty acids were greatly increased during the early phase of regeneration and were returning to the preoperative control level on day 5. However, as far as the relative amounts were concerned, the individual fatty acids demonstrated different interesting characteristics. The percentages of mono- and dienoic unsaturated fatty acids such as oleic acid (OA; 18:1n-9) and linoleic acid (LA; 18:2n-6) rose to 12.27 ± 1.51 and 32.05 ± 3.29%, respectively, on day 1 (vs. control, $P < 0.001$) and then were returning to the preoperative level on day 5. This change was the same as the change in their absolute amounts. On the other hand, the relative amounts of the major polyunsaturated fatty acids (PUFA) were decreased on day 1, in contrast to their absolute amounts. Arachidonic acid (AA; 20:4n-6) decreased to 9.48 ± 1.78% on day 1 (vs. control, $P < 0.001$), then recovered but failed to reach the preoperative value by day 5. DHA, another PUFA, demonstrated a more interesting behavior. DHA decreased to 4.51 ± 0.91% on day 1 (vs. control, $P < 0.01$), like AA, but it recovered from the decrease and had increased over the preoperative control level on day 5 (7.69 ± 0.58 vs. 5.57 ± 0.37%, $P < 0.001$). Moreover, the absolute amount of

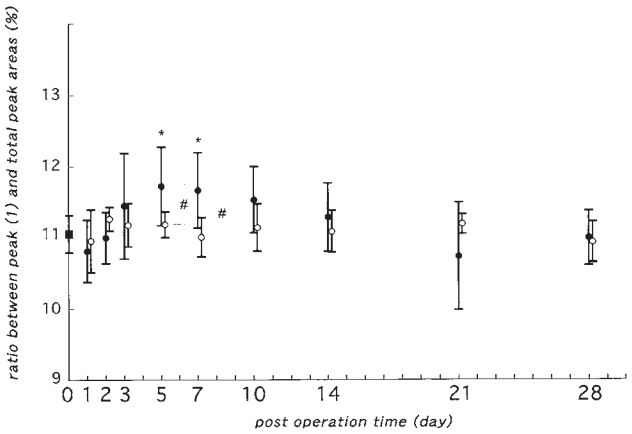

FIG. 2. Changes in the degree of unsaturation of hepatic lipids after partial hepatectomy as determined by ^{1}H NMR spectroscopy. Unsaturation is determined as the ratio between peak (1) and the total peak area (peaks are identified in Fig. 1). Values were calculated from the ratio between the integrals of peak (1) and the sum of peaks [(1) + (2) + (3) + (4) + (5) + (6) + (7)]. ■: control (n = 6), ●: partial hepatectomy (n = 6/each time after operation, day 1, 2, 3, 5, 7, 10, 14, 21, 28), ○: sham operation (n = 6/each time after operation, day 1, 2, 3, 5, 7, 10, 14, 21, 28). An average of five pieces from one liver was regarded as the value for one rat. Thirty pieces were used for analysis at each time. Each point represents the mean ± SD of 6 values from 6 rats. *$P < 0.05$, compared with the untreated control value; #$P < 0.05$ for comparisons between partial hepatectomy and sham operation. For abbreviation see Figure 1.

DHA was significantly increased on day 5, compared with the preoperative control level (3.67 ± 0.93 vs. 2.24 ± 0.27 μg/g tissue, $P < 0.001$). This is different from the change in the absolute amounts of the other fatty acids described above.

Fatty acid unsaturation was also evaluated based on the calculated values from gas–liquid chromatography. The mean number of double bonds per fatty acid molecule is also shown in Table 1. The number in day 5 regenerating liver was 1.77 ±

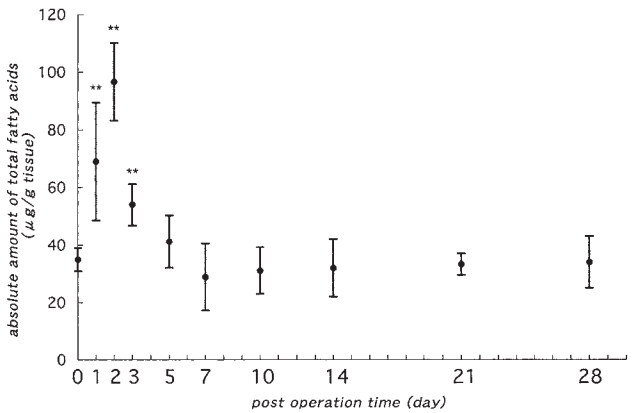

FIG. 3. Changes in the absolute amount of total fatty acids in regenerating liver plotted against time after partial hepatectomy. Each point represents the mean ± SD of 10 or 5 values from 10 or 5 rats. (n = 10 for untreated control, day 1, 5 after partial hepatectomy and n = 5 for day 2, 3, 7, 10, 14, 21, 28 after partial hepatectomy). **$P < 0.0001$, compared with the untreated control value.

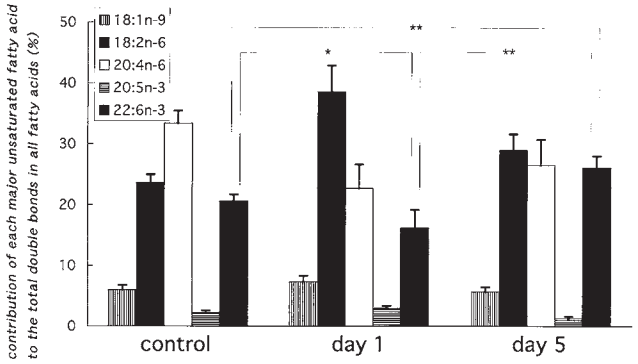

FIG. 4. Contribution of each major unsaturated fatty acid to the total double bonds in all fatty acids. Bars represent the mean ± SD of 10 values from 10 rats, calculated on the basis of the actual amounts of fatty acids determined from the integrated peak areas on the chromatogram, the respective molecular weights of the fatty acid methyl esters, and the number of double bonds in each fatty acid. Fatty acids are designated as number of carbon atoms:number of double bonds. Values were calculated from the following formula: [y × each fatty acid mol/Σ (x × each fatty acid mol)] × 100 where x represents the number of double bonds in the fatty acid (0, 1, 2, 3, 4, 5, or 6) and y represents (1, 2, 4, 5, or 6). *P < 0.001, **P < 0.0001, for comparisons of DHA among untreated control, day 1, and day 5 after partial hepatectomy.

0.03/fatty acid, higher than that in control or day 1 regenerating liver (P < 0.001). In contrast to unsaturation determined by ^{1}H NMR spectroscopy, the mean number of double bonds on day 1 was slightly higher than the control level, but no significance was found between them.

The ratio of double bonds in each major unsaturated fatty acid that contribute to the total double bonds in all fatty acids is shown in Figure 4. The value of LA was increased on day 1, then decreased on day 5 but was still higher than the control level. The decreased value of AA on day 1 compared with control was returning to but had not yet reached the preoperative level by day 5. On the other hand, the value of DHA was decreased on day 1 as in the case of AA, then increased and was higher on day 5 than the preoperative level (26.00 ± 1.96 vs. 20.58 ± 1.09%, P < 0.0001). This is different from the change in the level of AA.

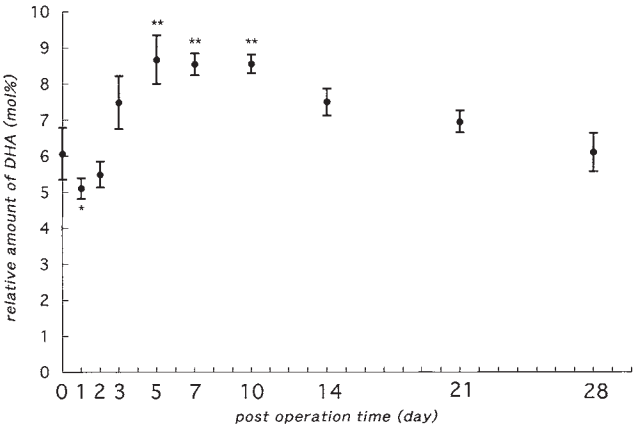

FIG. 5. Changes in the relative amount of docosahexaenoic acid (DHA) in regenerating liver plotted against various times after partial hepatectomy. Each point represents the mean ± SD of 10 or 5 values from 10 or 5 rats (n = 10 for untreated control, day 1, 5 after partial hepatectomy and n = 5 for day 2, 3, 7, 10, 14, 21, 28 after partial hepatectomy). *P < 0.001; **P < 0.0001.

The high degree of unsaturation on day 5 after partial hepatectomy was due to changes in the composition of fatty acids and found to be partly related to the increase in DHA.

Changes in the relative amount of DHA in regenerating liver are shown in Figure 5. The pattern seems to be the same as for the changes in the degree of unsaturation as analyzed by ^{1}H NMR spectroscopy (Fig. 2). The value was found to reach its highest level of 8.67 ± 0.67 mol% on day 5 (vs. control, P < 0.0001) and then remained high for several days.

DISCUSSION

One major advantage of ^{1}H NMR spectroscopy is its ability to analyze directly the protons associated with double bonds. This provides information concerning the relative ratio of fatty acyl double bonds, and thus differs from other methods such as gas–liquid chromatography. In Experiment 1, we demonstrated changes in the degree of fatty acid unsaturation, which increased during liver regeneration with a maximum on day 5 after partial hepatectomy (Fig. 2). We also evaluated fatty acid unsaturation by extrapolation from the results of gas–liquid chromatography in Experiment 2. There is a difference in the evaluation of unsaturation between the two methods as described above. Also, the definition of unsaturation is somewhat different by the two analytical methods. In any case, gas–liquid chromatography also indicates more unsaturation in day 5 than in untreated control or day 1 regenerating liver (Table 1).

Most investigators have focused their attention on the early phase of regeneration around day 1 when DNA synthesis reaches its peak and is followed by the mitotic peak (17–19). It has been reported that the total lipid content of the liver reaches a maximum around day 1 after partial hepatectomy (12–14,27–29). Total fatty acids in the liver were also greatly increased during the early phase of regeneration as shown in Figure 3. Fatty acid oxidation is the main energy source for the remnant liver when it undergoes its burst of mitotic activity around day 1 (30). Most studies have shown changes in the fatty acid composition up to day 3 after partial hepatectomy at the longest (13–15). Furthermore, there are no reports that evaluate the ratio of double bonds. Bruscalupi *et al.* (16) have shown changes in the unsaturation of membrane phospholipids of the regenerating liver by gas–liquid chromatography. However, their data extend only until 24 h after surgery, and DHA was not included in their analyses. As shown in this study, DHA has some effect on the overall degree of unsaturation (Fig. 4). Thus DHA must be included when changes in unsaturation are evaluated.

In Experiment 2, we showed changes in the hepatic fatty acid composition. These changes might be caused by changes

in the amount of food intake after surgery. Chow intake is influenced by partial hepatectomy (31–35), being depressed after operation, but restored by 3 or 4 d post-surgery. No significant difference in food intake is found on day 5 between partially hepatectomized and sham-operated animals (31). This transient decrease in the amount of chow eaten would contribute somewhat to the difference in fatty acid composition between the two populations during the early phase of regeneration. Next, hepatic fatty acid composition is influenced by the great accumulation of lipids in the liver around day 1 after partial hepatectomy caused by synthesis in the liver (29,36) and mobilization from peripheral adipose tissue (12,28).

Because of the increased amounts of hepatic lipids during the early phase of regeneration, the absolute amounts of most fatty acids are increased to maximum around day 1 (data not shown). But the relative amounts of fatty acids show very interesting differences. We show relative increases in mono- and dienoic unsaturated fatty acids such as OA and LA with decreases in PUFA such as AA and DHA on day 1 after partial hepatectomy (Table 1). The same results have been reported previously for day 1 regenerating livers (13–15,37). Ishihara *et al.* (15) have also concluded that the significant increase in OA in 28-h regenerating liver nuclei occurs at the expense of AA and DHA in the phospholipids. Carreau *et al.* (38) have demonstrated that the Δ^9-desaturase (stearyl-CoA desaturase) activity increased with a maximum on day 1 after partial hepatectomy; Δ^9-desaturase is the enzyme that transforms stearic acid (18:0) into OA. They also reported that the activities of Δ^6- and Δ^5-desaturases are least decreased on day 1; these are the enzymes related to the sequential reactions involved in the synthesis of PUFA from LA or α-linolenic acid (18:3n-3), which form C_6-C_7 and C_5-C_6 double bonds, respectively, and synthesize AA from LA or DHA from α-linolenic acid (39). These enzymes could be partly related to the relative changes in fatty acid composition (Table 1).

An increase in monoenoic fatty acids, such as OA, and a concomitant decrease in PUFA such as AA and DHA are also characteristic of membrane phospholipids in hepatomas, another model containing actively growing cells (15,40–42). Tumor cells that lack OA fail to grow because they cannot initiate chromosome DNA replication, and it has been reported that an increase in OA is essential for cell proliferation (10,15). Thus, a high level of OA accompanied by low levels of AA and DHA is suggested to be essential for the most active cell growth on day 1 after partial hepatectomy in the rat.

On the other hand, in day 5 regenerating livers, when unsaturation was at a maximum (Fig. 2), an interesting phenomenon was observed. OA and LA, whose levels were increased, and AA, whose level was decreased on day 1, were returning to their preoperative control levels at that time. But the relative amount of DHA was higher in day 5 regenerating liver than in control or day 1 regenerating liver. In addition to the fact that Δ^6- and Δ^5-desaturases are least decreased on day 1 as described above, Carreau *et al.* (39) have also reported that the Δ^6-desaturase activity increases to a maximum on day 3, and Δ^5-desaturase activity increases to its maximum level on day 4. On the other hand, the Δ^9-desaturase activity decreases gradually to a minimum on day 7 following an initial increase on day 1 (38). These enzymes might be somewhat associated with the changes in the fatty acid composition on day 5 (Table 1). As shown in Figure 4, the high degree of unsaturation in day 5 regenerating liver is partly related to an increase in DHA.

One possibility is that some significant signals might be sent to the regenerating liver owing to its high degree of unsaturation on day 5 after partial hepatectomy, since it has been suggested that changes in fatty acid unsaturation affect membrane fluidity (1–3), lipid–protein interactions, and subsequent receptor functions (4–6), and biological information is transmitted through cell membranes.

Another possibility is that DHA might have its own biological effects, for example, an inhibitory effect on liver regeneration. Regenerating liver must stop growing when it reaches its preoperative size. That is different from tumor growth which is another cell growth model that shows unlimited proliferation. There must be some complex mechanisms inhibiting liver regeneration. Day 5 is much later than the peak time in the regeneration process that occurs around day 1 when DNA synthesis reaches a maximum (17–19). In fact, Kikuchi *et al.* (43) have reported that liver mitochondrial respiratory control and ATP synthetic activity increase to maximal levels on day 1, then decrease to minimal levels on day 5 after partial hepatectomy, after which the levels return to their preoperative values.

Moreover, numerous investigations have confirmed the inhibitory effects of n-3 PUFA, including DHA, on cell proliferation (44–46). Prostaglandins, synthesized from AA, have been reported to be involved in tumor growth, and n-3 PUFA, like DHA, have inhibitory effects on prostaglandin synthesis (47–49). Prostaglandins are also associated with regenerating cell growth after partial hepatectomy (50–52).

Thus, the data suggest that some significant signals might be transmitted through the high levels of unsaturation of liver fatty acids on day 5 by altering the structure of the membrane lipid bilayer. Thus, day 5 after partial hepatectomy could be related to the inhibitory mechanism of the liver regeneration process.

In conclusion, we have demonstrated changes in the degree of unsaturation of liver fatty acids over a long period of regeneration after partial hepatectomy in the rat. Unsaturation appears to increase during the regeneration process, reaching a maximum on day 5. The high degree of unsaturation at that time is partly due to the relative increase in DHA. However, how the increased unsaturation is involved in the mechanism of liver regeneration remains poorly understood. Some significant signals, for example, inhibitory information, might be transmitted through the high levels of unsaturation and the relative increase in DHA on day 5 after partial hepatectomy. Further investigations are required concerning these possibilities.

ABSTRACT: Phospholipid (PL) compositions and fatty acid (FA) patterns of PL were determined in the erythrocytes and blood thrombocytes of a seabird, the king penguin, living in the subantarctic area and feeding on prey rich in n-3 polyunsaturated FA. Results were compared between birds in three different physiological states (breeding and molting adults, chicks) to those reported for other birds. In erythrocytes, the ratios of cholesterol to PL and of sphingomyelin to phosphatidylcholine (PC) were lower than in other birds. The PL distribution was similar to those previously reported in the hen and pigeon. In contrast to other birds, cardiolipin levels were unexpectedly high (4%). Very long chain n-3 FA were abundant (13–27%) in phosphatidylethanolamine (PE), phosphatidylserine and PC, probably in relation to the natural diet of these birds. Among n-3 FA, 22:6n-3 was the most abundant in all PL (2–20%), whereas the highest levels of arachidonic acid were observed in PE (14%). In thrombocytes, the PL distribution and FA composition of the main PL (PC, PE) differed from those of erythrocytes, and in particular, levels of n-3 FA (9–12%) were 1.5–2 times lower. The highest levels of arachidonic acid were found in phosphatidylinositol (24%). The lipid profile of penguin erythrocytes could contribute to the efficiency of blood circulation and oxygen delivery in microvascular beds, thus favoring diving capacity of these animals. Our observations do not support the hypothesis of a common origin of avian thrombocytes and erythrocytes.

Paper no. L8305 in *Lipids 35*, 453–459 (April 2000).

Knowledge of the hemostasis of birds is unfortunately limited (1–3) even in species reared for human consumption. Avian red blood cells (RBC) have aroused some interest, mainly in connection with the presence of a nucleus (4,5), but no recent publication in this field would appear to be available. The other blood cell type involved in hemostasis, the thrombocyte, performs a role similar to that of the mammalian platelet and offers a specific feature since the thrombocytes of birds are nucleated (5,6). In addition to hemostasis, these cells have been reported to play an active role in phagocytosis (7,8) but are not a component of the lymphocyte system (9). Finally, avian thrombocytes and erythrocytes share many similarities, and the two cell types are thought to be derived from a common progenitor cell line (10).

Only a few biochemical studies of avian blood cells exist, and lipids have been explored in erythrocytes but not in thrombocytes and only in hens (4,11,12) and pigeons (13). In mammalian species, studies of the lipid composition of blood cells are of great interest since there is strong evidence to suggest that diets rich in n-3 polyunsaturated fatty acids (PUFA) of marine origin are associated with a reduction in the risk of thrombosis (14,15). Thus, it was found that the incorporation of n-3 PUFA into the phospholipids (PL) of mammalian erythrocytes and platelets improved their functional properties, at the levels of peripheral blood circulation (16,17), and platelet reactivity (18,19).

The main objective of this study was to explore the lipid composition of erythrocytes and thrombocytes in a seabird, the king penguin (*Aptenodytes patagonicus)*, which has been extensively investigated on account of its unique life cycle (20,21) and its diet naturally rich in n-3 fatty acid (FA) (22). This species was also chosen for its high diving capacity (animals dive to depths of up to 300 m and for as long as 7.5 min) (23,24), which probably requires efficient protection against thrombotic risks. The physiological cycle of the king penguin is characterized by periods of fasting ashore and feeding at sea. In spring, after a fattening phase of about 4 wk at sea, the adults arrive ashore to molt, from September for early breeders to late December. During molt, the birds fast for about 1 mon and renew their whole plumage. Since feather materials (amino acids) must be drawn from tissues, this process involves high protein catabolism (25,26) and the animals lose about 40% of their body weight. On completion of the molt phase, the birds return to sea and feed heavily again for about 1 mon, before they go back to shore in the early summer for breeding. The courtship period (approximately 10 d) is followed by incubation (53 d) during which time the two mates alternate in caring for the egg, spending alternately 2 wk fasting and 2 wk feeding. Chick brooding is very long (13 mon) and is characterized by successive spells of feeding and fasting of the parents, until early autumn. If the chicks are fed

Abbreviations: CHOL, cholesterol; CL, cardiolipin; FA, fatty acid; MUFA, monounsaturated fatty acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PL, phospholipid; PS, phosphatidylserine; PUFA, polyunsaturated fatty acids; RBC, red blood cell; SAT, saturated FA; SM, sphingomyelin; TLC, thin-layer chromatography.

regularly by their parents during the first 3 mon, they are fed only episodically over the next 4 mon and thus undergo a long winter fast while losing 30 to 50% of their body weight. Thereafter, they are again regularly fed until they depart to sea and feed on their own, in late spring. The breeding and brooding fasts of the adults and the winter fast of the chicks correspond to long periods of protein sparing and are associated with use of lipids as the main metabolic fuel (26).

In the present work, we analyzed the lipid constituents of the erythrocytes and thrombocytes of the king penguin at three stages of its life cycle in the Crozet Islands: in adults during the courtship fast (breeding adults), in adults during molt, and in chicks during their winter fast. The resulting information, together with further functional studies, should contribute to a better knowledge of the relation between hemostasis, diet, and life cycle in birds.

MATERIALS AND METHODS

Animals. A total of 18 animals was selected in 1997 at Possession Island (46°26′ S and 51°52′ E) of the Crozet Archipelago, in the austral Indian Ocean. These animals were divided into three groups. The first group consisted of eight breeding, fasting adult males weighing 10–14 kg each, sampled in January during courting and after a 3–5 d fast. All were used for RBC studies and three also for thrombocyte analyses. In the second group of nine adults weighing 14–15 kg each, sampled during molt and after a 5–10 d fast, four birds were used for erythrocyte and five for thrombocyte studies. These molting birds could not be sexed, but there is no evidence for physiological, metabolic, or endocrine differences between sexes at this stage of the life cycle (25). The third group constituted five chicks weighing 3–9 kg each, sampled in September toward the end of their natural winter fast, two of which were used for erythrocyte and the other three for thrombocyte analyzes. The study was approved by the Ethical Committee of the "Institut Français pour la Recherche et la Technologie Polaires" and conformed to the Agreed Measures for the Conservation of Antarctic and Subantarctic Fauna.

Blood collection and cell preparation. Blood was drawn from a brachial vein of conscious birds into plastic syringes containing acid–citrate–dextrose anticoagulant (1:7 volume ratio) and processed within 1 h of sampling in a field station. Erythrocytes were counted and measured with a hemacytometer after a 1:200 dilution. Hematocrits were determined by centrifugation in glass capillary tubes. The mean cell volumes (μm^3) were calculated from hematocrits and red cell counts. As thrombocytes are difficult to count due to their low numbers and tendency to clump, thrombocyte counts and sizes were estimated by microscopic observation of blood smears according to Campbell (5). RBC and thrombocytes were separated by brief low-speed centrifugation (1300 × *g*, 37°C, 5 s). RBC were washed twice in physiological saline, and thrombocytes were further processed according to Cazenave *et al*. (27) with slight modifications. Thrombocyte-rich plasma was centrifuged (1000 × *g*, 37°C, 8 min), and the thrombocyte pellet was washed in Tyrode's buffer containing human serum albumin prior to lipid analyses. None of the sampled birds was in a hyperlipidemic state since plasmas were clear and yellowish but never lactescent.

Lipid analyses. Total lipids were extracted immediately from washed RBC or thrombocytes as previously described (28) and dissolved in 1 mL chloroform/methanol (2:1, vol/vol). One extract was prepared from each sample. The erythrocyte nuclear and plasma membranes were not separated because the required methodology was unavailable in the field station where blood treatment and lipid extraction were carried out. After addition of 0.3 mg/mL ethyl gallate as an antioxidant, the extracts were stored at –20°C for about 6 mon until laboratory processing in France. Cholesterol (CHOL) and PL were separated by thin-layer chromatography (TLC) using boric acid-impregnated silica gel plates with chloroform/ethanol/water/triethylamine (30:35:7:35, by vol) as eluant (29). Total PL were quantified by phosphorus estimation (30), and CHOL was measured by colorimetry (31). The FA compositions of individual PL were determined by transmethylation with BF_3/methanol reagent and gas–liquid chromatography, after addition of a known amount of heptadecanoic acid as an internal standard (29). Plasmalogens were estimated by gas–liquid chromatography from the amounts of dimethyl acetals obtained during the transmethylation process. The cardiolipin (CL) fraction was determined by running PL samples in two other eluent systems, chloroform/methanol/conc. ammonia (65:20:4, by vol) and chloroform/methanol/water (40:10:1, by vol), and by mass spectrometry using a Micromass Autospec instrument in the liquid secondary ion mass spectrometry mode. Samples were dissolved in a small quantity of chloroform/methanol (2:1, vol/vol) and mixed with 3-nitrobenzyl alcohol as a matrix.

Statistical analyses. Results are expressed as the means ± SEM of individual values. The means were examined by one-way analysis of variance, and significant differences between groups were determined by the Bonferroni post-test. When indicated, a nonparametric test (Mann-Whitney) was used.

RESULTS

Erythrocytes. Hematocrits and PL and CHOL contents of RBC in adults and chicks are given in Table 1. The mean erythrocyte count for all animals was estimated to be 2×10^6 cells/μL in whole blood, and the mean cell volume was 209 ± 17 μm^3, with dimensions of 14.7 ± 0.1 (length) and 9.2 ± 0.1 μm (width). Hematocrit ranged from 43 to 48% and did not vary significantly between the different groups. The PL content, close to 1.65 mg/mL RBC (0.46 μmol/10^9 RBC), was likewise not different between groups. The CHOL content, about 0.4 mg/mL RBC (0.23 μmol/10^9 RBC), was similar in the three groups but tended to be lower in breeding adults. Hence, the CHOL/PL ratio was lower in breeding adults, and this difference was marginally significant as compared to the other groups.

The distribution of erythrocyte PL is shown in Table 2. In all groups, phosphatidylcholine (PC, 43%) and phosphatidyl-

TABLE 2
PL Composition of Erythrocytes of King Penguins in Different Physiological States[a]

	Breeding adults (n = 8)	Molting adults (n = 4)	Fasting chicks (n = 2)
Phosphatidylcholine (PC)	43.4 ± 1.0	43.0 ± 0.7	43.7 ± 2.1
Phosphatidylethanolamine (PE)	24.1 ± 1.7	25.5 ± 1.5	29.0 ± 1.0
Phosphatidylserine (PS)	6.0 ± 0.7	6.0 ± 1.3	4.9 ± 0.7
Phosphatidylinositol (PI)	4.4 ± 0.4	3.4 ± 0.4	2.7 ± 0.5
Sphingomyelin (SM)	17.8 ± 2.5	16.1 ± 0.5	14.8 ± 0.3
Cardiolipin (CL)	4.2 ± 0.9	5.9 ± 1.3	5.0 ± 2.1

[a]Values are the means ± SEM of the molar percentage of each PL class. See Table 1 for abbreviation.

inositol (PI, 3–4%) were the most and least abundant PL, respectively. There was no significant difference between groups in the distribution of the various PL and the sphingomyelin to phosphatidylcholine (SM/PC) ratio was comparable in all three groups (close to 0.4). CL was noticeably present (4.2–5.9%) in lipid extracts from erythrocytes. Its identity was confirmed by the fact that the phosphorus-containing spot displayed chromatographic properties similar to those of a CL standard from bovine heart (Sigma-Aldrich Chimie, Saint Quentin Fallavier, France) in three TLC systems. Furthermore, mass spectrometric analysis in the LSIMS mode of the purified compound revealed four predominant groups of species, with two minor peaks at ion masses of *m/z* 1422 and 1500 and two major peaks at masses of *m/z* 1450 and 1478. These molecular weights are in accordance with the expected structures of the CL molecules present in king penguin erythrocytes as deduced from the FA composition (Table 3).

Figure 1 shows the FA composition of the total PL pool in erythrocytes, the data being restricted for clarity to the major n-3 and n-6 FA and FA classes. Monounsaturated FA (MUFA) and saturated FA (SAT) were the predominant classes, accounting for about 39 and 35% of the total FA, respectively. MUFA mainly consisted of 18:1n-9 (19.4%), 22:1n-9 (5.4%), and to a lesser extent 20:1n-9 (1.4%). Overall, the patterns did not vary greatly between the three groups, although there was a lower n-3 FA content in chicks as compared to breeding adults, the value in molting birds being intermediate. This difference was observed for both 22:6n-3 and 20:5n-3.

See Tables 1 and 2 for other abbreviations.

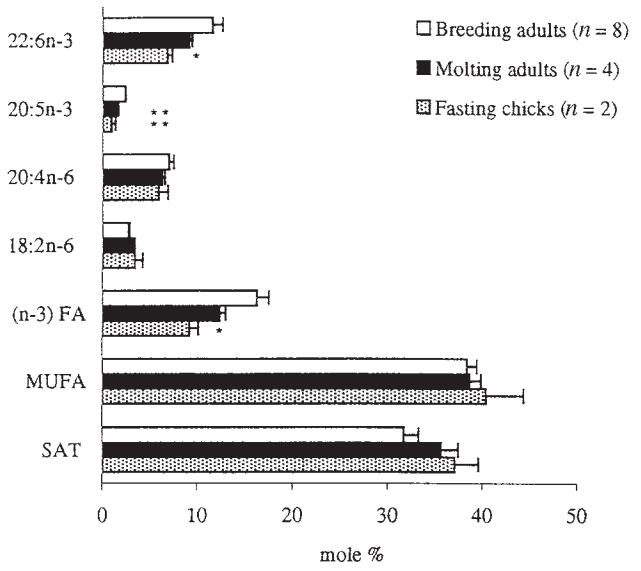

FIG. 1. Fatty acid (FA) composition of phospholipids in the erythocytes of king penguin. Values are the means ± SEM of the molar percentage of each FA. MUFA, monounsaturated FA; SAT, saturated FA. Molting adults and fasting chicks were compared to breeding adults using the Mann-Whitney test. *$P < 0.05$, **$P < 0.01$. For a FA or a FA class, asterisks indicate significant differences when compared to breeding adults. Other means were not significantly different.

Table 3 gives the FA composition of PL isolated from the erythrocytes of breeding adults, taken as a reference profile. Phosphatidylethanolamine (PE), including diacyl and plasmalogen subclasses, was the most strongly unsaturated PL having the highest levels of n-3 and n-6 FA, respectively, about 27 and 20%. The three major glycerophospholipids [PC, PE, and phosphatidylserine (PS)] had greater n-3 FA than n-6 FA contents, the n-3/n-6 ratio ranging from 1.3 to 1.7. Among n-6 FA, levels of 20:4n-6 were the highest in PE (14.4%), which represented approximately 56% of the total erythrocyte arachidonic acid, the other glycerophospholipids containing only low levels (about 5%). Among n-3 FA, 22:6n-3 was the most abundant in all PL, 3 and 24 times more abundant than 20:5n-3 in PC and PS, respectively. Among n-9 FA, the content of 22:1n-9 was remarkably high (12–17%) in PS, PI, and SM. The FA profile of CL, comparable to that of PI, displayed no dominant component, whereas SM was characterized by high proportions of molecular species containing 16:0, 22:1, or 24:1n-9.

In molting birds, the FA profiles of PL were not very different from those of breeding adults except for some significant differences in PC, PE, and PS (data not shown). Thus, PC contained less 20:5n-3, PE more plasmalogens, and PS more SAT in molting than in breeding birds ($P < 0.05$).

Fasting chicks displayed a general trend to higher PL saturation as compared to breeding adults, and this was accompanied by lower levels of n-3 FA (data not shown). The individual MUFA contents of the different PL were similar in breeding and molting adults and in chicks (data not shown).

TABLE 4
Total PL and CHOL Content of the Thrombocytes of King Penguins in Different Physiological States[a]

	Breeding adults ($n = 3$)	Molting adults ($n = 3$)	Fasting chicks ($n = 3$)
PL (mg/10^9 cells)	1.50 ± 0.41	0.83 ± 0.10	1.14 ± 0.48
CHOL (mg/10^9 cells)	1.18 ± 0.13	0.39 ± 0.16*	0.91 ± 0.20
CHOL/PL (mol/mol)	1.76 ± 0.25	0.76 ± 0.32	1.31 ± 0.35

[a]Values are the means ± SEM. Molting adults and fasting chicks were compared to breeding adults. *$P < 0.05$. For abbreviations see Table 1.

Thrombocytes. The mean thrombocyte count of king penguins was estimated to be about 18,000 cells/μL in all groups, and the cell dimensions were 7.1 ± 0.1 μm (length) and 5.9 ± 0.2 μm (width). As shown in Table 4, the PL content of thrombocytes was comparable between groups, whereas the CHOL content was lower in molting than in breeding adults ($P < 0.05$). Nevertheless, owing to a large dispersion of the results, all groups displayed a similar CHOL/PL ratio.

Table 5 gives the PL distribution of thrombocyte membranes, which was similar in the three groups. PC was the major constituent (about 31 to 41%), as in erythrocytes, while the remaining PL each contributed from 11 to 20%, in contrast to the erythrocyte profile where PI and PS did not exceed 6%.

The FA composition of the total PL pool in thrombocytes (Fig. 2) revealed some differences between groups in the distribution of the various FA classes. Unlike in erythrocytes, SAT formed the most prominent class in thrombocytes of breeding adults (46%) or chicks (39%), while MUFA amounted to only 25–30% in all three groups. It is noteworthy that n-3 FA were about two times less abundant in thrombocytes (7%) than in erythrocytes ($P < 0.001$). This was mainly due to markedly lower levels of 22:6n-3 in thrombocytes (1.5%) than in erythrocytes (11.5%) ($P < 0.001$), whereas the 20:5n-3 content was about 60% higher in thrombocytes ($P < 0.001$). The FA composition of thrombocytes was also characterized by 50% higher levels of SAT ($P < 0.001$) and by greater amounts of 20:4n-6 (about twofold, $P < 0.01$), as compared to erythrocytes. The global n-3 FA content of thrombocytes was significantly lower in molting than in breeding adults ($P < 0.01$).

Table 6 shows the FA compositions of the five PL isolated from the thrombocytes of breeding adults, which were taken

TABLE 5
PL Composition of the Thrombocytes of King Penguins in Different Physiological States[a]

	Breeding adults ($n = 3$)	Molting adults ($n = 3$)	Fasting chicks ($n = 3$)
Phosphatidylcholine	40.6 ± 0.6	36.3 ± 3.7	31.4 ± 2.7
Phosphatidylethanolamine	16.0 ± 1.7	20.1 ± 2.0	20.5 ± 2.5
Phosphatidylserine	10.6 ± 1.0	12.7 ± 1.0	15.1 ± 2.4
Phosphatidylinositol	13.5 ± 0.5	11.1 ± 0.9	15.4 ± 3.3
Sphingomyelin	17.8 ± 2.5	19.8 ± 5.2	17.6 ± 5.3

[a]Values are the mean ± SEM of the molar percentage of each PL class. See Table 1 for abbreviation.

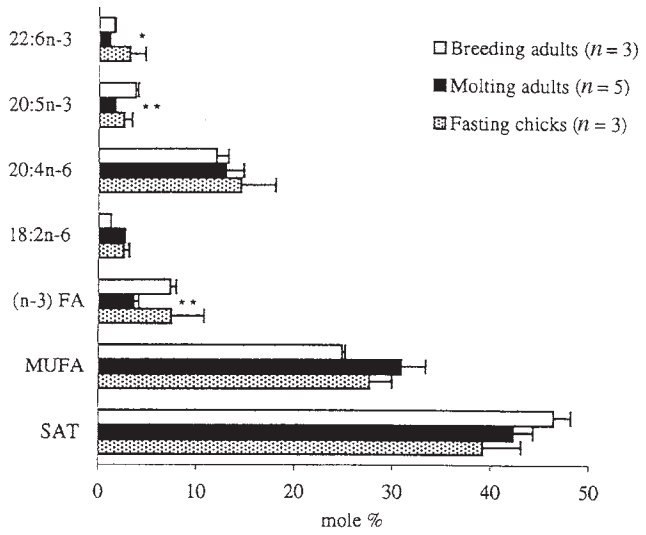

FIG. 2. Fatty acid compositions of phospholipids in the thrombocytes of king penguin. Values are the means ± SEM of the molar percentage of each fatty acid. Molting adults and fasting chicks were compared to breeding adults using the Mann-Whitney test. *$P < 0.05$, **$P < 0.01$. For a FA or a FA class, asterisks indicate significant differences when compared to breeding adults. Other means were not significantly different. For abbreviations see Figure 1.

as reference profiles. These FA compositions displayed the same general characteristics as in erythrocytes but with some specific features. Thus, PE, PS, and SM were more saturated in thrombocytes than in erythrocytes ($P < 0.05$). In all glycerophospholipids, levels of 22:6n-3 were lower (4–13 times, $P < 0.05$) and levels of 20:5n-3 higher (1.5–6 times, $P < 0.01$) in thrombocytes. The levels of 22:1n-9 in PS, PI, and SM of thrombocytes were 4.5–6 times lower than in erythrocytes ($P < 0.01$). Unexpectedly and in contrast to erythrocytes, about half the arachidonic acid pool of thrombocytes was present in PC instead of PE, another 26% being acylated in PI. Except in SM, the n-3/n-6 ratio was two to four times lower ($P < 0.01$) in thrombocytes than in erythrocytes. Thrombocyte SM exhibited a specific profile with large amounts of 16:0 (about 40%) and a long-chain FA content (22- and 24-carbon chains) several times lower than in erythrocytes.

Significant differences were observed between molting and breeding birds in the levels of PC, PI, and SM (data not shown). Thus, PC contained less 20:5n-3 ($P < 0.05$) and more 18:2n-6 ($P < 0.05$) in molting birds, and the ratio of n-3 to n-6 FA was lower in these animals. In PI, although 20:4n-6 levels were similar in both groups, 20:5n-3 levels were lower in molting than in breeding adults ($P < 0.05$). The degree of unsaturation of SM was higher in molting than in breeding birds, in relation to variations in the MUFA content ($P < 0.05$). Lastly, the FA profiles of fasting chicks and breeding adults displayed no significant differences (data not shown).

DISCUSSION

The low erythrocyte count and large cell size observed in the king penguin are in accordance with those reported for numerous bird species (32). Nevertheless, the king penguin ap-

[a]Values are the means ± SEM of three birds. For abbreviations see Tables 2 and 3.

pears to lie at the lower end of the range for cell count and at the higher end for cell size. These features also have been described in other diving seabirds, the cormorant and little penguin, in contrast to flying birds, which have higher erythrocyte counts and lower cell volumes (33,34). In the king penguin, thrombocytes were less abundant but similar in size when compared with the only reliable values reported in a bird, those for the hen (18,000 vs. 30,000 cells/μL) (35).

Comparison of our data with previously published results for the lipid composition of avian blood cells proved more difficult, as we could find only four reports, all concerning erythrocyte lipids, three in the hen (4,11,12) and one in the pigeon (13). The CHOL to PL ratio of penguin erythrocytes (0.5) was lower than those reported in other birds (0.7–0.8). As the nucleus to cell ratio in king penguin erythrocytes was similar (data not shown) to that of other avian erythrocytes (35), the nuclei could not contribute more than one-tenth of the total cell lipids (36). Thus, it may be hypothesized that the comparatively low ratios of CHO to PL and of SM to PC and likewise the high unsaturation largely characterize the plasma membrane and could confer a high deformability on king penguin erythrocytes. Despite the size of the red cells, 50% larger than those of the hen, these properties probably improve the oxygen delivery in the microvascular bed, as is required in the cooled peripheral tissues of diving penguins (24). A better knowledge of the erythrocyte plasma membrane, cell deformability, and microvascular system in penguins, as in other diving birds, is necessary before formulating a more general hypothesis.

The PL composition of penguin erythrocytes corresponded to that of pigeon erythrocytes (13), except for a higher ratio of PC to PE, and to that of hen erythrocytes (4,11), although in these studies PI and PS were not separated. The higher level of PI in penguin erythrocytes as compared to mammals (37) raises the question of the role of inositol PL in the signal transduction of these nucleated cells. Although the synthetic pathways of inositol phosphates in avian erythrocytes remain unknown (38), their well-known role in the regulation of hemoglobin function (39) would justify further investigation of the involvement of the erythrocyte inositol PL in avian respiratory function. CL, a unique phosphoglyceride known to be concentrated in mitochondria, was previously reported to be present at low levels in hen red cells (11) and chicken erythrocyte nuclei (36). Since we extracted lipids from whole RBC, our study gives no information concerning the CL distribution. Furthermore, in contrast to mammalian (40) or pigeon (41) CL, which contain large amounts of linoleic acid, no specific fatty acid pattern could be assigned to this compound, which displayed a composition similar to that of PI. This feature could be related to the scarcity of linoleic acid and the abundance of n-3 FA in king penguin prey (22). A comparison of the relative concentrations of the major FA in the erythrocytes of the king penguin and the hen, the only other bird in which FA profiles have been studied (11), shows marked differences, and these may be partly ascribed to dietary influences. In contrast to seed-based diets, marine diets are very rich in very long-chain n-3 PUFA and poor in linoleic (18:2n-6) and α-linolenic (18:3n-3) acids (42). Thus, the identical diet of adults and chicks of king penguins (myctophid fishes) contains on the average 6% 20:5n-3 and 10% 22:6n-3, but only 1% 18:2n-6 and 0.3% 18:3n-3 (22). The erythrocytes of king penguins similarly contain large amounts of very long chain n-3 PUFA but small amounts of linoleic and α-linolenic acids. On the other hand, penguin erythrocytes have a higher arachidonic acid content than hen erythocytes, which could be due to taxonomic rather than dietary differences. Hence, an assessment of the value of erythrocyte analyses to determine the nutritional status of such birds sampled in their natural environment would require further experiments, in particular in animals soon after they arrive ashore and later during their natural fast.

Although not accurately documented, the degree of unsaturation of PL acyl chains has been related to prothrombin activation in experimental models (43,44). Thus, it is possible that the higher degree of unsaturation of PS in penguin as compared to hen erythrocytes plays a definite role in the procoagulant activity of these cells in circulating blood. It would be of interest to carry out further investigations on the influence of PL unsaturation on the generation of thrombin in birds. Contrary to erythrocytes, the absence of previous studies of the lipid composition of thrombocytes in birds precludes any comparison of our findings with data for other avian species. Although thrombocytes and erythrocytes have been suggested to be genealogically closely related in birds (10), our results do not support this hypothesis since each cell type has its own PL distribution and FA composition. Although the possibility of late biochemical differentiation in the circulating blood cannot be excluded, it would seem unlikely that avian erythrocytes and thrombocytes derive from closely related cells. The recent demonstration of an aggregatory function of penguin thrombocytes (Fayolle, C., Ohlmann, P., Groscolas, R., Leray, C., and Gachet, C., unpublished data) is consistent with this conclusion.

ACKNOWLEDGMENTS

This work was supported by INSERM and the Institut Français pour la Recherche et la Technologie Polaires (Programme 119), and it received logistic support from the Terres Australes et Antarctiques Françaises. The authors would like to thank Dr. Alain Van Dorsselaer (Service de Spectrométrie de Masse, Université Louis Pasteur, URA 31, Strasbourg) for the mass spectrometric analyses and Juliette Mulvihill for revising the English of the manuscript.

METHOD

Esterification of Polyunsaturated Fatty Acids by Various Forms of Immobilized Lipase from *Rhizomucor miehei*

ABSTRACT: Ethyl esterification specificity of a lipase from *Rhizomucor miehei* for polyunsaturated fatty acids (PUFA) was compared at 1 and 100 mM to study molecular recognition of PUFA. The chemical shift of methylene adjacent to carboxyl groups in the nuclear magnetic resonance spectrum of docosahexaenoic acid (DHA) in ethanol moved to a lower magnetic field as the concentration of DHA increased, suggesting that the degree of dissociation of DHA decreased. Specificity constants or apparent second-order rate constants (V_{max}/K_m or catalytic power) for 1 mM esterification by immobilized lipases were higher than the native lipase. Immobilized hydrophobic carrier of low mass transfer resistance for the esterification substrate may improve maximal velocity and affinity for the substrate. Higher specificity constants for 1 mM substrates were observed using immobilized lipases fixed on an anion exchange resin with glutaraldehyde and on a cation exchange carrier with carbodiimide. Activity yields measured with 1 mM PUFA substrate were high. For the substrates at a concentration of 100 mM, higher specific constants with these bifunctional reagents were not observed but higher activity yields were found.

Paper no. L7917 in *Lipids 35,* 461–466 (April 2000).

Lipase attacks the ester bond that binds hydrophobic and hydrophilic residues. In an aqueous solution esters are heterogeneous with respect to charge distribution. Porcine pancreatic lipase activity is greatly increased at the water/lipid interface, suggesting interfacial activation (1). The catalytic triad (Ser-144, His-203, Asp-257) of *Rhizomucor miehei* lipase is buried completely beneath a short helical segment (residue 82-96), or lid (2). X-ray crystallographic analysis of the lipase–inhibitor complex revealed that interfacial activation is achieved by the displacement of the lid structure, which exposes the catalytic groups and creates a hydrophobic surface that stabilizes the contact between the lipase and the lipid interface (3). We previously reported that higher hydrolysis rates for 1 mM substrates were observed using immobilized lipases (on anion exchange resin with glutaraldehyde and on cation exchange carrier with carbodiimide) than for native lipase or for lipase adsorbed on weak anion exchange resin, indicating some modification of the environment of basic amino acids related to the lid of *R. miehei* lipase. Activations with these bifunctional reagents were not observed for substrates at the concentration of 100 mM, indicating that interfacial activation always occurred by formation of the aggregates of substrates at high concentrations (4).

Polyunsaturated fatty acids (PUFA) are important because of their many biological functions and utility in low-temperature adaptation of biological membranes. Amphipathic PUFA have an alkyl group in combination with a polar and/or ionizing carboxyl group, displaying an extensive range of molecular clustering patterns depending on chemical structure, concentration, and temperature (5). In a previous paper (4) we reported that at concentrations below the critical micelle concentration (CMC) of docosahexaenoic acid (DHA), 0.35 mM, the DHA sodium salt in water exists in a monomeric state. When the DHA sodium salt concentration is near the CMC, DHA salts exist in an equilibrium between the monomeric and aggregate states, where the exchange rate between a monomer and aggregate is slow. At concentrations above the CMC, DHA sodium salt exists in micelles or an aggregate state. When fatty acids are dissolved in ethanol, however, there is no interface in the homogeneous substrate at concentrations of 1 to 100 mM.

A competitive factor α is proposed for lipase specificity toward fatty acids in organic solvents (6). A specific constant $1/\alpha$ is proposed for the lipase specificity with respect to degree of unsaturation. In the earlier study, the specificity con-

stants were compared over a rather narrow range of substrate concentrations, i.e., 0.1 vs. 0.2 M and 1 vs. 2 M (7). The specificity constant of esterification has been studied for PUFA and less common fatty acids catalyzed by lipases from different sources (8,9). The present study describes polyunsaturated fatty acyl donor specificities in ethyl esterification by lipase from *R. miehei* using substrates in 1 and 100 mM concentration.

MATERIALS AND METHODS

Materials. Lipase (Lipozyme 10,000 L) from *R. miehei* was provided by Novo Nordisk (Chiba, Japan) as a liquid containing 10,000 LU/g specified by the maker. DHA was a product of Nu-Chek-Prep, Inc. (Elysian, MN). Eicosapentaenoic acid was obtained from Funakoshi Co. (Tokyo, Japan). Arachidonic, linolenic, and linoleic acids were products of Serdary Research Laboratories Inc. (London, Ontario, Canada). Sperisil C, a weakly acidic cation exchange carrier with carboxylic acid groups, was provided by Rhône-Poulenc Industry (Paris, France). Water-soluble carbodiimide of 1-ethyl-3-(3-dimethyl-aminopropyl)-carbodiimide HCl was obtained from Sigma Chemical Co. (St. Louis, MO). Dowex MWA-1, a macroporous weakly basic anion exchange resin with tertiary amine groups, was obtained from The Dow Chemical Co. (Midland, MI).

Immobilization of lipase. Lipase from *R. miehei* used in this study was prepared as previously reported (4). The flexible lipase was prepared as follows. One gram of Spherosil C was activated with the water-soluble carbodiimide as described previously (10). The activated Spherosil C and 2 g of Lipozyme 10,000L were combined with 1 mL of 0.067 M McIlvaine buffer at pH 5 (9.7:10.3, vol/vol mixture of 0.067 M citric acid and 0.133 M Na_2HPO_4), and the resultant mixture was shaken overnight at 4°C. The lipase immobilized on the cation exchange carrier was washed with water, and excess liquid was removed by suction. The adsorbed lipase was prepared as follows. One gram of Dowex MWA-1 was washed with water and mixed with 2 g of Lipozyme 10,000L and 1 mL of 0.067 M McIlvaine buffer at pH 5. The mixture was shaken at 4°C overnight and dried as described above. The rigid lipase was prepared from the above adsorbed lipase by treatment with glutaraldehyde as previously described (11).

Esterification reaction. The reaction mixture containing 1 mM fatty acid was composed of 50.0 mL ethanol, 1 mM (10–18 mg) fatty acid, and 30 mg immobilized lipase or 75 mg of Lipozyme 10,000L. The reaction mixture containing 100 mM fatty acid was composed of 1 mL of ethanol, 100 mM (20–30 mg) fatty acid, and 30 mg immobilized lipase or 75 mg of Lipozyme 10,000L. The reaction mixture was put in a round-bottomed tube saturated with nitrogen and agitated with a small magnetic stirrer at 45°C for 1–3 h. During the reaction, nitrogen was continuously blown over the surface of the reaction mixture. Three separate batches of reaction with each fatty acid were carried out under identical conditions. The standard deviation of reaction with each fatty acid was calculated and used as experimental errors.

Assay methods for esterification product. The esterification product was extracted with hexane, and the upper phase was collected after adding a small amount of water to promote the separation of two phases. The solvent was evaporated under a gentle stream of nitrogen. The esterification product was redissolved in acetone. The concentrated hydrolysate was analyzed by high-performance liquid chromatography (GL Science, Tokyo, Japan) using a refractive index detector (RI model 504; GL Science) and a chromatointegrator (D-2500; Hitachi, Tokyo, Japan). The fixed-phase column was a Superspher RP-18 (4 × 25 mm; Merck, Darmstadt, Germany), and the mobile phase was a mixture of acetone and acetonitrile (1:1, vol/vol, at a flow rate of 0.8 mL/min and pressure of 120 kg/cm^2).

Kinetic studies. The esterification rate or initial velocity was calculated from the composition of the reaction products and is expressed as the amount of ester (μmol) produced/g/min. The competitive factor α was obtained as follows. In the competitive reaction of two substrates (Ac1X and Ac2X with the same leaving group × and two different acyl groups, Ac1 and Ac2) at the same catalytically active site of the enzyme molecule, the ratio of the esterification rates for each substrate (v_1 and v_2) is given (12) by

$$v_1/v_2 = \left[\left(V_{Ac1X}/K_{Ac1X}\right)/\left(V_{Ac2X}/K_{Ac2X}\right)\right](Ac1X)/(Ac2X) \quad [1]$$

where (Ac1X) and (Ac2X) are the concentrations of the two acyl donors (two fatty acyl ethyl esters), (V_{Ac1X}) and (V_{Ac2X}) are the maximal velocities, and (K_{Ac1X}) and (K_{Ac2X}) are the Michaelis constants for each substrate. The competitive factor α is then defined as the ratio of the catalytic powers according to the following equation (6,7):

$$\left(V_{Ac1X}/K_{Ac1X}\right)/\left(V_{Ac2X}/K_{Ac2X}\right) = \alpha \quad [2]$$

The competitive factor α is calculated from the integral form of Equation 1:

$$\log\left([Ac1X]_0/[Ac1X]\right) = \alpha \log\left([Ac2X]_0/[Ac2X]\right) \quad [3]$$

From Equations 2 and 3, the specificity constant 1/α (7) can then be expressed as Equation 4

$$\left(V_{Ac2X}/K_{Ac2X}\right)/\left(V_{Ac1X}/K_{Ac1X}\right) = \log\left([Ac2X]_0/[Ac2X]\right)/\log\left([Ac1X]_0/[Ac1X]\right) \quad [4]$$

The specificity constant 1/α is an apparent second-order catalytic constant or catalytic power as log(V_{Ac2X}/K_{Ac2X}) based on the log(V_{Ac1X}/K_{Ac1X}) being equal to 1. In this paper the Ac1X is lauric acid.

Nuclear magnetic resonance (NMR) measurement. ^{1}H NMR was measured at room temperature (25°C) with 0.1–10 mM of PUFA in deuterium-labeled ethanol (C_2D_5OD) using a JEOL α-500 NMR spectrometer (499.45 Mhz; Tokyo,

Japan). The PUFA sample was poured into an NMR cell under an argon atmosphere. The standard compound was tetramethylsilane used in a C_2D_5OD capillary system.

RESULTS AND DISCUSSION

PUFA substrates. Figure 1 shows the ^1H NMR spectra of the methylene regions of DHA. The positions of methylene resonance signals (*b*, *d*, and *e* in Fig. 1) remained almost unchanged as the DHA concentration increased. However, the signal (*c* in Fig. 1) of the methylene (2-CH_2) group adjacent to the carboxylic group (–COOH) was remarkably shifted to a lower magnetic field as the concentration of DHA increased from 0.1 to 10 mM. On the other hand, as the concentration of DHA changed, all signals from DHA in chloroform solution showed neither a downfield nor an upfield shift (data not shown). This result shows that DHA does not form reversed micelles in chloroform, owing to the fact that DHA is highly soluble in chloroform. Since DHA dissolves well in ethanol too, it can scarcely form reversed micelles in ethanol. These results suggest that DHA should dissociate into ions in ethanol solution because DHA is an acid and ethanol is a polar solvent. On the other hand chloroform is nonpolar, and DHA dissociates only slightly into ions in chloroform. As the DHA concentration in ethanol increases, the degree of the dissociation decreases, which can cause the change in chemical shift of the signal of methylene group adjacent to the carboxylic one.

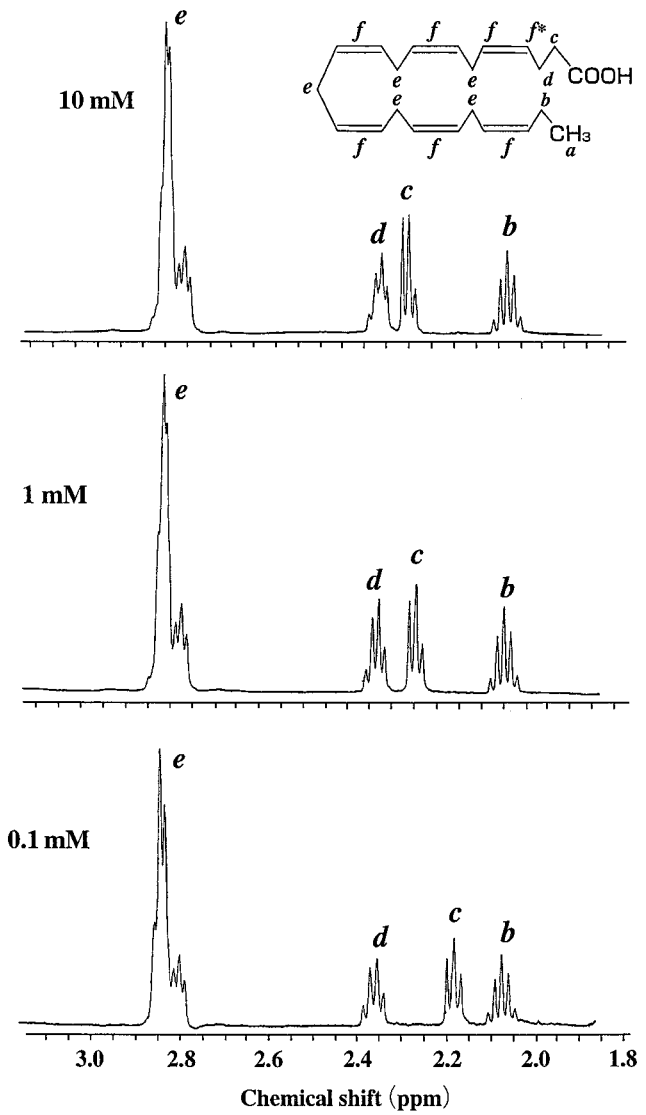

FIG. 1. ^1H Nuclear magnetic resonance spectra of the methylene regions of three concentrations of docosahexaenoic acid in C_2D_5OD. The labeled peaks (*b, c, d,* and *e*) correspond to the functional groups indicated in the structure of docosahexaenoic acid.

Immobilization of lipase. Lipase from *R. miehei,* with an isoelectric point of 4.3 (according to the manufacturer), generally does not adsorb onto a cation exchange carrier through electrostatic repulsion but rather is fixed on the carrier by covalent bonding and is called flexible lipase. The lipase also can be attached to an anion exchange resin through ionic and hydrophobic bonding and is then called adsorbed lipase. Adsorbed lipase treated with glutaraldehyde can be fixed onto an anion exchange resin through covalent bonding, ionic bonding, and hydrophobic bonding and is called rigid lipase. Native lipase and flexible lipase can easily undergo structural change, but rigid lipase undergoes little structural change despite changes in the physical conditions.

Specificity spectrum for PUFA. Lipase specificity was markedly influenced by the type of immobilization used, as shown in Figures 2–5. Esterification rates decreased with increasing substrate unsaturation as shown in Figures 2 and 4, although several exceptions existed. Higher specificity constants for 1 mM substrates were observed for flexible lipase on cation exchange carrier with carbodiimide and for rigid lipase fixed on anion exchange resin with glutaraldehyde as shown in Figure 5. Carbodiimide and glutaraldehyde attack basic amino acids such as arginine, histidine, and lysine. The enhanced activity with these bifunctional reagents was not observed using 100 mM substrates (Fig. 3). As reported previously (4), some modification may be introduced in the basic amino acids related to the lid, and some activation of esterification of the 1 mM substrate was observed. The Arg 86 in the lid of *R. miehei* lipase is exposed on the surface of molecule in the interfacial activation state (3), and the residue may be modified with these bifunctional reagents.

The substrate fatty acids used in these experiments were dissolved in ethanol. Chemical shifts of 1 and 100 mM DHA in ethanol were different, and the difference may be derived from the degree of dissociation as mentioned previously. That the lipase from *R. miehei* recognized these differences was reflected in the specific constant $1/\alpha$. The recognition is different from interfacial activation because ethyl esterification was carried out in homogeneous reactants. In our previous paper on hydrolysis, the specificity constant between 1 and 100 mM substrate was not significantly different, but differences were seen in hydrolysis rates (4). It was reported that in organic solvents, the formation and the solvolysis of the acyl enzyme occur in two independent steps. The use of competitive factor

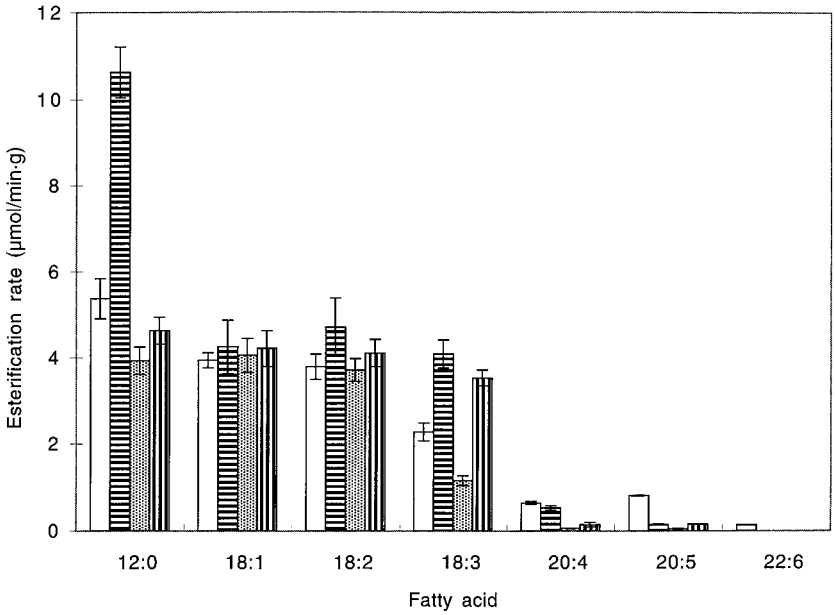

FIG. 2. Reaction rates for the esterification of 100 mM fatty acid. The columns show the data for native lipase (open bar), flexible lipase (horizontally striped bars), adsorbed lipase (stippled bars), and rigid lipase (vertically striped bars) from *Rhizomucor miehei*. The error bars represent the standard deviations obtained by more than three reaction batches.

α is not appropriate in a biphasic system where the kinetics are usually much more complex than in a organic system (6).

Higher esterification rates for 100 mM fatty acid were observed using flexible lipase and the highest esterification rate for 100 mM lauric acid as shown in Figure 2. Lower specific constants for PUFA substrates at 1 mM were observed using native lipase as shown in Figure 5. In hydrolysis, the native lipase showed a higher specific constant for PUFA substrates at 1 mM fatty acyl ester, and the highest hydrolysis rate for 100 mM linolenic acyl ethyl ester was observed using the adsorbed lipase (4). These observations show the changes occurring in the specificities of the different forms of lipase from *R. miehei* in esterification and hydrolysis.

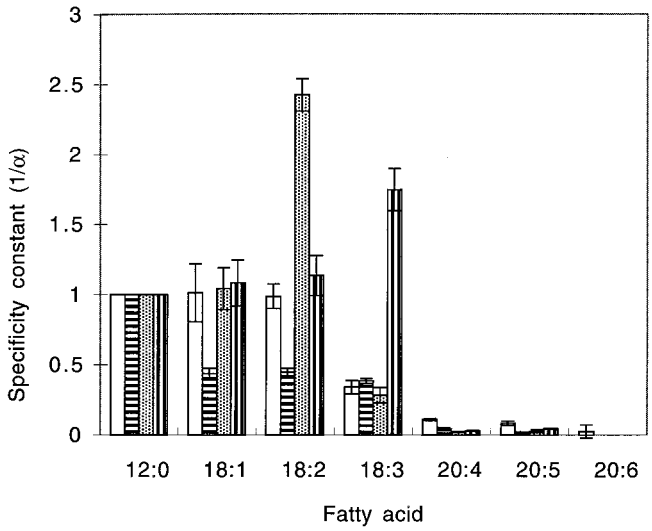

FIG. 3. Specificity constants (1/α) for the esterification of 100 mM fatty acid. For keys, error bars, and organism see Figure 2.

We observed various changes in the fatty acid specificities and competitive factors in 1 and 100 mM fatty acids as described above. However, it was reported that competition factors are not influenced by changes in the physical conditions of the reaction (water content, substrate concentration, nature of nucleophiles, etc.) (7). One simple explanation for these contradictory phenomena is that the assembling structures of the fatty acyl ethyl ester are very different between 1 and 100 mM substrate, and therefore these substrates behave as different entities. The V_{max}/K_m for fatty acid esterification of the lipase from *Candida rugosa* also changed at different concentrations of fatty acids (14).

The activity yields (immobilized lipase activity divided by used lipase activity for the nonimmobilized preparation used) using 1 mM oleic acid, linolenic acids, arachidonic acid, and eicosapentaenoic acid were extraordinarily high, as much as 150–480%. Although both 1 and 100 mM PUFA were well dissolved in ethanol, the substrate at 1 mM may be more dissociated and better suited to undergo mass transfer. Reaction rates of immobilized lipases with 1 mM PUFA were higher than that of the native lipase as shown in Figure 4 and previously observed in the hydrolysis reaction (4). The high activity yields show that immobilization results in a suitable conformation and microenvironment (13) for *R. miehei* lipase to esterify the substrates. Figure 5 shows that specificity constant 1/α of immobilized lipases was higher than that of the native lipase. Immobilized hydrophobic carriers of low mass

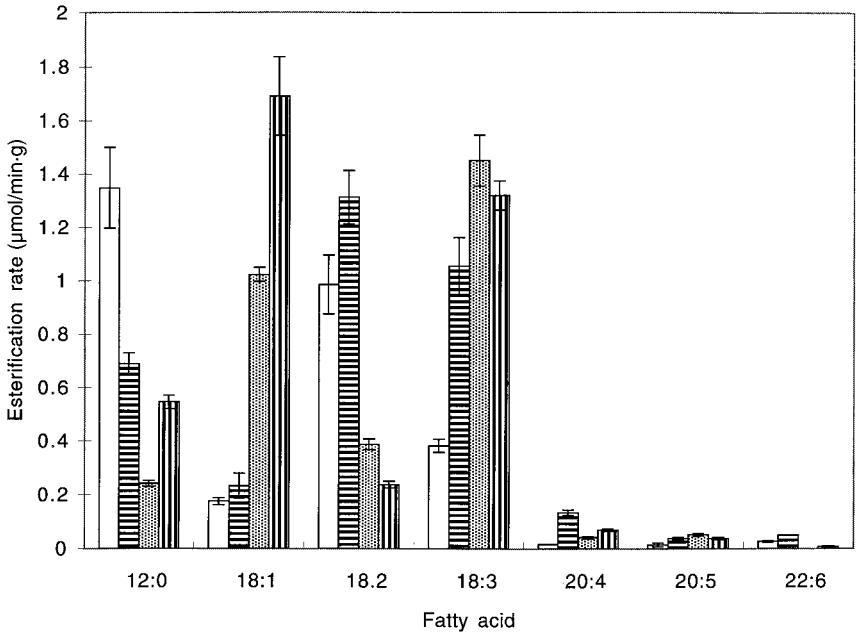

FIG. 4. Reaction rates for the esterification of 1 mM fatty acid. For keys, error bars, and organism see Figure 2.

transfer resistance for the esterification substrate improved the affinity for the substrate (Fig. 5) as well as overall rate of esterification (Fig. 4). However, the native lipase showed a higher specificity constant for the hydrolysis of 1 mM PUFA esters (4). Activity yields measured with 100 mM PUFA substrate were not extraordinary high. For the substrates at a concentration of 100 mM, higher specific constants with these bifunctional reagents were not observed but higher activity yields were found.

The "Induced Fit" theory of enzyme action says that the substrate induces conformational changes in the protein and stabilizes a new substrate–protein structure because of the new hydrophobic, hydrophilic, and electrostatic interactions formed in the binding process. The conformational flexibility

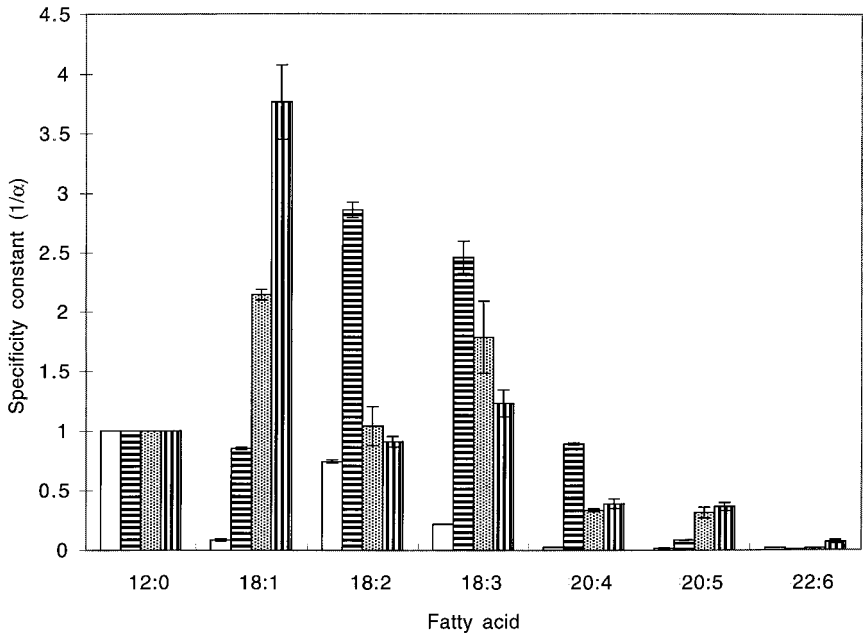

FIG. 5. Specificity constants ($1/\alpha$) for the esterification of 1 mM fatty acid. For keys, error bars, and organism see Figure 2.

of proteins appears to be a universal property that enables these molecules to be adapted to their widespread functions in the living system (15). Our conclusion is that lipase from *R. miehei* recognizes the molecular conformation of lipids even in organic solvents and that changes occur in the esterification for fatty acids under these conditions.

ACKNOWLEDGMENT

We thank Dr. Alain Roussel of AFMB-CNRS (Marseille, France) for providing the structure model of lipases.

ARTICLE

Changes in Fatty Acid Composition in Plant Tissues Expressing a Mammalian Δ9 Desaturase

Hangsik Moon[a,1], Jan Hazebroek[b], and David F. Hildebrand[a,*]

[a]Department of Agronomy, University of Kentucky, Lexington, Kentucky 40546-0091 and [b]Pioneer Hi-Bred International, Inc., Johnston, Iowa 50131-1004

ABSTRACT: Plant tissues expressing a mammalian stearoyl-CoA Δ9 desaturase were reported to accumulate Δ9 hexadecenoic acid (16:1), normally very minor in most plant tissues. The transgenic plants were thoroughly analyzed for alterations of individual lipids in different subcellular sites. Western blot analysis indicated that the animal desaturase was targeted to the microsomes. The Δ9 16:1 was incorporated into both the *sn*-1 and *sn*-2 positions of all the major membrane lipids tested, indicating that the endoplasmic reticulum acyltransferases do not exclude unsaturated C_{16} fatty acids from the *sn*-2 position. In addition to increases in monounsaturated and decreases in saturated fatty acids, accumulation of 16:1 was accompanied by a reduction in 18:3 in all the lipids tested except phosphatidylglycerol, and increases in 18:2 in phospholipids. Total C_{16} fatty acid content in the galactolipids of the transgenics was significantly higher than that in the control, but those in the phospholipids were unchanged. In transgenics, Δ11 18:1 was detected in the *sn*-1 position of the lipids tested except phosphatidylinositol and phosphatidylserine. Introduction of the animal desaturase, controlled by a seed-specific phaseolin promoter, into soybean somatic embryo resulted in a significant reduction in saturated fatty acids. Such effects were greater in cotyledons than hypocotyl-radicles. This study demonstrated that the animal desaturase can be used to decrease the levels of saturated fatty acids in a crop plant.

Paper no. L8357 in *Lipids 35,* 471–479 (May 2000).

Membrane and reserve lipids of plants contain fatty acids with different degrees of unsaturation which in part is controlled by different desaturase enzymes. The first double bond is introduced into 18:0 acyl carrier protein (ACP) by a stromal Δ9-stearoyl-ACP desaturase. The additional double bonds of polyunsaturated fatty acids are introduced into acyl chains linked to the glycerol backbone of membrane lipids (1). There are two sets of membrane-bound desaturases that catalyze the introduction of a second Δ12 and a third Δ15 double bond, resulting in linoleic (18:2) and linolenic acids (18:3), respectively. One set is located in the chloroplasts and uses ferredoxin as the electron donor (2), whereas the other set is located in microsomal membranes and receives electrons from cytochrome b_5 (3,4).

The acyl composition of lipids is determined by three factors: the substrate specificity of the acyltransferase, the pool of acyl donors available, and modifications, such as desaturation, made to the acyl group after esterification to the glycerol moiety (5). Because of the acyl-group specificity of the acyltransferases in the various organelles, lipids synthesized in the plastid have a C_{16} fatty acid on the *sn*-2 position (6), whereas lipids synthesized in the ER have a C_{18} fatty acid (7) or an unsaturated C_{16} fatty acid [when available in transgenic plants (8)] on the *sn*-2 position; the main extraplastidial C_{16} fatty acid normally present, 16:0, is confined to the *sn*-1 position (9). The fact that plant membranes are not fully unsaturated suggests a complex regulation of membrane lipid composition. The level of unsaturation may be limited by the amount of the various desaturases, or the enzymes may be subject to some form of feedback regulation. The entire system of fatty acid and glycerolipid synthesis is regulated to meet the demand for particular lipid molecular structures for optimal membrane function (5).

Many properties of fats and oils are determined by their fatty acid composition. Because of the commercial importance of seed oils both for food and industrial use, considerable attention has been given to the genetic engineering of oilseed crops. Soybean is the most important source of edible oil in the world, and also is one of the largest sources of calories in the U.S. diet. Soybean oil is relatively high in saturated fatty acids (>10% total), most of which is palmitic acid (16:0) (10). Numerous studies indicate that it is beneficial to reduce human dietary consumption of saturated fatty acids, which are undesirably abundant in many edible oils (11). Owing to the fairly well-developed understanding of lipid biosynthesis in plants, it has been possible to alter fatty acid composition in oil seeds by recombinant DNA technology. One of the many objectives for genetically engineering plant oil composition is the reduction of saturated fatty acid levels in edible oils.

Abbreviations: ACP, acyl carrier protein; BHT, butylated hydroxytoluene; C_n fatty acid(s), fatty acid(s) with *n* carbon atoms; DGD, digalactosyldiacylglycerol; ER, endoplasmic reticulum; GC, gas chromatography; KAS, 3-ketoacyl-ACP synthase; LPAAT, lysophosphatidic acid acyltransferase; MGD, monogalactosyldiacylglycerol; MS, mass spectrometry; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; RDS, rat liver stearoyl-CoA Δ9 desaturase; SDS, sodium dodecyl sulfate; X/Y, a fatty acyl group containing X carbon atoms and Y *cis* double bonds; UV, ultraviolet.

As previously reported (12), a rat liver stearoyl-CoA Δ9 desaturase (RDS) gene has been shown to be functioning in transgenic tobacco tissues, reducing the levels of saturated fatty acids. Tissues from the RDS-transgenic plants showed an accumulation of *cis* Δ9 16:1, which is normally a very minor constituent in tobacco tissues. Thus, these transgenic tissues can be useful to study plant fatty acid desaturation and glycerolipid biosynthesis. Subsequently, the RDS gene was introduced into soybean somatic embryos with a seed-specific phaseolin promoter (13). The transgenic soybean somatic embryos also showed significant conversions of saturated to monounsaturated fatty acids. Here we report the detailed investigation of the effects of the mammalian Δ9 desaturase on specific membrane lipids and reserve lipids in the transgenic plant tissues.

MATERIALS AND METHODS

Plant materials. Tobacco plants (*Nicotiana tabacum* cv. Xanthi) used in these studies were transformed with a gene encoding RDS (12). These plants were allowed to self-pollinate. Individuals with a significant amount of palmitoleic acid (*cis* Δ9 16:1) were selected from the segregating population. Plants were selected that were homozygous for palmitoleic acid accumulation. Progeny plants with the highest accumulation of 16:1 were allowed to self-pollinate again. Among the progeny, a plant with the highest level of 16:1 was selected for use in the experiments. Here we designated RDS-transgenic and control plants as plants transformed with an RDS gene under the control of the constitutive 35S promoter and those transformed with the vector only, respectively. Plants were grown in commercial potting mix in greenhouse under a 16-h photoperiod at 26 ± 2°C except as noted in the text. Leaf tissues were used for the analyses of the fatty acid composition of individual lipids, the positional analyses, and subcellular localization of RDS protein.

For soybean transformation, soybean (*Glycine max* Merill. cv. J103) somatic embryos were prepared as described by Liu *et al*. (14) and bombarded with pDGN (35*S* promoter-driven GUS::NPTII and phaseolin promoter-driven RDS) for the mammalian Δ9 desaturase expressor or pBI426 (35*S* promoter-driven GUS::NPTII only) for a control as described by Liu *et al*. (13).

Fatty acid and lipid analysis. The overall fatty acid composition of leaves and other tissues was analyzed by modifications of the procedure of Dahmer *et al*. (15). About 1–10 mg tissue samples were placed into 2 mL of 2% (vol/vol) H_2SO_4 in methanol and ground finely. The samples were then heated at 80°C until the volume was reduced to approximately 0.5 mL. One and one-half milliliters of hexane containing 0.01% (wt/vol) butylated hydroxytoluene (BHT) was added, and the mixture was vortexed vigorously. The fatty acid methyl esters in the hexane layer were separated by gas chromatography on a Hewlett-Packard (Palo Alto, CA) 0.25 mm i.d. × 0.33 μm × 10 m FFAP column and quantified using a flame-ionization detector. A Hewlett-Packard 5890A gas chromatograph was programmed for an initial temperature of 120°C for 1 min followed by increases of 12°C/min to 210°C and 50°C/min to 235°C. The final temperature was maintained for 8 min. The injector and detector temperatures were 220 and 250°C, respectively. Helium was used as the carrier gas with a flow rate of 10 mL/min.

Total lipids were extracted from leaf tissue as described by Miquel and Browse (16). Individual lipids were separated by one-dimensional thin-layer chromatography on $(NH_4)_2SO_4$-impregnated silica gel by the method of Khan and Williams (17). The $(NH_4)_2SO_4$-impregnated plates were prepared by dipping the plates (silica layer 250 μm thick; J.T. Baker Inc., Phillipsburg, NJ) in 0.15 M $(NH_4)_2SO_4$ and drying them at room temperature followed by activation for 90 min at 110°C prior to use (16). Lipids were located by spraying the plates with solution of 0.0046% primulin in 80% (vol/vol) acetone, followed by visualization under ultraviolet (UV) light. In order to determine the fatty acid composition of individual lipids, the silica gel from each lipid band was transferred to a tube containing 2 mL of 2% (vol/vol) H_2SO_4 in methanol, and fatty acid methyl esters were prepared and analyzed as described above.

Determination of position of unsaturation by gas chromatography (GC)–mass spectrometry (MS). Lipids were saponified directly, and the fatty acids were methylated by heating in 2 mL of 2% H_2SO_4 in methanol as described above. To determine double-bond positions, fatty acid methyl esters were derivatized with dimethyl disulfide (Aldrich, Milwaukee, WI) as described (18), except that the derivatization was done overnight. The dimethyl disulfide derivatives were separated by GC on a Hewlett-Packard 0.25 mm i.d. × 0.25 μm × 30 m HP-5MS column. Injections (1 μL) were made in the splitless mode with a Hewlett-Packard 7673 autosampler. A Hewlett-Packard 5890 Series II Plus gas chromatograph was programmed for an initial temperature of 50°C for 2 min, increased to 190°C at 20°C/min where it was held for 5 min, then increased to 250°C at 10°C/min where it was held for 5 min. The injector and detector temperatures were 250 and 280°C, respectively. Helium was used as the carrier gas with a constant flow rate of 1 mL/min maintained by electronic pressure control. The structure of each fatty acid was determined by an on-line Hewlett-Packard 5972 MSD mass spectrometer. A mass range of *m/z* 50–550 was scanned at a sampling rate of 1.5 scans/s. Identification of monounsaturated fatty acids was based on comparing both retention times and mass spectra of their dimethyl disulfide derivatives with those of standards.

Positional analysis. After thin layer-chromatography, silica containing each lipid band was transferred to a Pasteur pipette fitted with a glass wool filter. Lipids were extracted with 2 mL of chloroform/methanol (2:1, vol/vol) containing 0.01% BHT. Fatty acid composition at the *sn*-1 and *sn*-2 positions of individual lipids was determined using a lipase from *Rhizopus arrhizus* (Sigma) as described by Fischer *et al*. (19), except that 50 mM H_3BO_3 was added to the buffer used for lipase digestion to minimize intramolecular acyl transfer on

the lyso-lipids produced during the course of the reaction (16).

Subcellular fractionation. To examine intracellular distribution of RDS protein in the transgenic tissues, subcellular fractions were prepared by stepwise sucrose density gradients (20). This method yielded enough material to analyze fatty acid composition of the chloroplast lipids, but not the microsomal lipids. In order to study fatty acid composition of individual lipids from the microsomes, washed microsomal fractions were prepared by differential centrifugation as described by Roughan *et al*. (21). The purity of each fraction was estimated by measuring the activities of marker enzymes (22) and the chlorophyll content (23). Western immunoblotting was performed using standard procedures. For this, proteins were separated on a 10% sodium dodecyl sulfate (SDS)-polyacrylamide gel and electrophoretically transferred into a nitrocellulose membrane. The proteins in the membrane were probed with rat liver Δ9 stearoyl-CoA desaturase-specific rabbit polyclonal antibodies (24) and visualized using alkaline phosphatase-conjugated goat anti-rabbit second antibodies.

RESULTS

Fatty acid composition of different tissues of transgenic tobacco. Previously Grayburn *et al*. (12) showed that introduction of an RDS gene into tobacco resulted in altered fatty acid composition characterized by large increase in 16:1, which is normally a very minor constituent in tobacco tissues. In order to study further the effect of this animal enzyme on plant lipid biosynthesis, the RDS-transgenic tobacco plants were thoroughly analyzed. Different plant tissues showed striking differences in fatty acid composition (Table 1). Large increases in total monounsaturated fatty acid level, especially 16:1, were observed in leaves, stem, and root tissues, with corresponding decreases in 16:0 and 18:0, and 18:3 levels. However, petal and seed showed little change in fatty acid composition. Since similar low standard error values were observed for the fatty acid compositions reported in the other tables, only mean values are reported in the other tables to avoid excessive complication.

During our analysis of the fatty acid composition of the RDS-transgenic tissues, we observed a unique peak that eluted as a shoulder after Δ9 18:1. This peak was obtained from the RDS-transgenic tissues, but not from the control tissues. In order to identify its structure, dimethyl disulfide fatty acid derivatives were synthesized. Analysis of the derivatives by GC–MS demonstrated that the unknown compound was *cis* Δ11 18:1 (data not shown). The highest level of *cis* Δ11 18:1 was observed in the stem tissue (3.6% of total fatty acid), which showed the highest level of *cis* Δ9 16:1 (20.1%) as well. The *cis* Δ11 18:1 was not detected in the petals or seeds, where the levels of 16:1 were also very low.

Expression of the animal desaturase in soybean somatic embryos. In an attempt to decrease the level of saturated fatty acids in soybean seed storage lipid, the RDS gene was introduced into soybean somatic embryos with a seed-specific phaseolin promoter by particle bombardment (13). As in the case of the transgenic tobacco, RDS-transgenic soybean somatic embryos contained significantly reduced levels of saturated palmitic (16:0) and stearic (18:0) acids (Table 2). The decreased levels of saturated fatty acids were accompanied by increases in monounsaturated fatty acids including palmitoleic acid (16:1, Δ9), which does not normally accumulate in soybean seeds as well. However, the levels of polyunsaturated fatty acids, 18:2 and 18:3, were not significantly changed.

Use of the seed-specific phaseolin promoter resulted in higher accumulation of monounsaturated fatty acids and more reduction in saturated fatty acids in cotyledons than in hypocotyl-radicles (Table 2). For example, cotyledons exhibited significant reductions in 16:0 and 18:0 levels from 17.4 and 11.0% in the controls to 6.1% and undetectable level in the RDS-transgenics, respectively, whereas in hypocotyl-radicles those were from 21.7 and 7.9% to 15.4 and 4.3% of total fatty acid, respectively. The greater conversion of saturated to monounsaturated fatty acids in cotyledons than hypocotyl-radicles is apparently a consequence of the higher expression

of the RDS protein under control of the phaseolin promoter in cotyledons (Fig. 1).

Localization of mammalian Δ9 desaturase in plant tissue. Western blot analysis of subcellular fractions prepared by stepwise sucrose density gradients using transgenic soybean somatic embryos showed that the RDS protein was mainly found in the microsomal fraction (Fig. 2). From transgenic tobacco leaf tissues, the RDS protein was found to be associated mainly with microsomes as well (data not shown). These results strongly suggest an association of the RDS with the endoplasmic reticulum (ER) of the transgenic tissue, which is consistent with the enzyme's original location in the mammalian liver (25).

Fatty acid composition of individual leaf lipids. Analysis of leaf polar lipids indicated that *cis* Δ9 16:1 produced by RDS was incorporated into all the major membrane lipids, including the chloroplast lipids, monogalactosyldiacylglycerol (MGD) and digalactosyldiacylglycerol (DGD), apparently due to metabolic fluxes of fatty acids between the eukaryotic and prokaryotic pathways (Table 3). The highest level of the 16:1 was found in phosphatidylcholine (PC) (13.6%). In all the lipids examined except phosphatidylglycerol (PG), accumulation of 16:1 was accompanied by a reduction in 18:3

level, in addition to increases in the monounsaturated fatty acids, 16:1 and 18:1, and decreases in the saturated fatty acids, 16:0 and 18:0, as expected. For example, MGD, a galactolipid, and PC, a phospholipid, exhibited reductions in 18:3 levels from 84.3 to 70.9% and 37.2 to 19.7%, respectively. An increase in the 18:2 level in the phospholipids was another change.

Total C_{16} fatty acid contents in galactolipids of the RDS-transgenic leaves were significantly higher than those in the control tissues, although those in phospholipids were unchanged. In case of MGD, C_{16} fatty acids constituted 24.7% in the RDS-transgenics, compared to only 12.3% in the control plants. However, C_{16} fatty acids in PC of the RDS-transgenic and control plants were 27.9 and 25.5%, respectively.

Positional analysis. Positional analysis using the lipase from *R. arrhizus* that is specific for the *sn*-1 position of the glycerol moiety (19) indicated that the overproduced 16:1 was incorporated into both the *sn*-1 and *sn*-2 of all the lipids tested (Tables 4,5). These results are in contrast to the data obtained by Polashock *et al.* (8), in which the majority of the 16:1 overproduced by a yeast Δ9 desaturase was incorporated into the *sn*-2 position of the lipids. However, incorporation of *cis* Δ9 16:1 into the *sn*-2 position is consistent with their data in that the ER acyltransferases involved in the production of PA in the

eukaryotic pathway do not exclude 16-carbon fatty acid at the *sn*-2 position when it is unsaturated (8). The distribution of 16:1 was dependent upon individual lipids: in MGD and PC, the 16:1 was evenly distributed, while DGD contained more 16:1 in the *sn*-2 position and phosphatidylethanolamine (PE) had the majority of 16:1 in the *sn*-1 position. In both galactolipids and phospholipids except for PG, the majority of the saturated fatty acids (16:0 and 18:0) were incorporated into the *sn*-1 position.

Cis Δ11 18:1, found only in the RDS-transgenics, was detected exclusively in the *sn*-1 position of MGD, DGD, PG, PE, and PC.

Lipids of the chloroplasts and microsomes. Since fatty acid biosynthesis occurs almost exclusively in the chloroplast and the RDS enzyme appeared to be localized in the ER (Fig. 2), we determined the fatty acid compositions of lipids from the isolated chloroplasts and microsomes to examine the distribution of the *cis* Δ9 16:1 overproduced by the mammalian stearoyl-CoA desaturase and the metabolic fluxes between the eukaryotic and prokaryotic pathways.

In the lipids of the microsomal fraction, the site of RDS, the ratios of 18:1/18:0 were much higher than the ratios of 16:1/16:0, even though the levels of 16:0 were considerably higher than the levels of 18:0 (Table 6). In contrast, in the chloroplast lipids except for PG, which is known to be derived exclusively from the prokaryotic pathway (26,27), cytoplasmically produced *cis* Δ9 16:1 accumulated in large quantities while the levels of 18:1 in the RDS-transgenics were the same as in the control plants (Table 7). These results suggest that the mammalian Δ9 desaturase functioning in the ER of the transgenic plants converted 18:0 to 18:1 more efficiently than 16:0 to 16:1, and that 16:1-containing lipids were preferentially reimported into the chloroplasts. The reduction in 18:3 levels in all the microsomal and chloroplast lipids except for PG was consistent with the results from the total leaf lipids (Tables 3,6,7). Another interesting observation was that in the microsomal lipids and the chloroplast PC fraction, accumulation of monounsaturated fatty acids was accompanied by an increase in 18:2 levels, whereas most of the C_{18} fatty acids in MGD and DGD of the chloroplast were fully desaturated up to 18:3. All

these observations point to the complex and fine regulation of individual desaturases in the ER and the chloroplast.

Cis Δ11 18:1, detected in all the RDS-transgenic chloroplast lipids tested, was not found in either PI or PS of the microsomal fraction (Table 6).

DISCUSSION

The acyl-CoA desaturases are one of three groups of desaturases classified according to their specificities toward fatty acid substrates (28). The rat liver microsomal stearoyl-CoA desaturation system requires three protein components for activity: NADH-cytochrome b_5 reductase, cytochrome b_5, and the terminal desaturase (25,29). Unlike most common acyl-lipid desaturases in plants that are specific to fatty acids esterified to glycerolipids, the mammalian desaturase (RDS) *in vitro* uses acyl-CoA derivatives with chain lengths of 12 to 19 carbons (29). Introduction of the RDS into plant tissues resulted in large increase in 16:1 and 18:1 levels. Western blot analysis of the transgenic plant tissues indicates that this en-

zyme functions in the microsomes. Thus, it appears that the RDS uses both 16:0-CoA and 18:0-CoA as substrates that are exported from the chloroplast prior to their acylation into phospholipids, and that the enzyme utilizes the plant microsomal electron transport system involving cytochrome b_5 and cytochrome b_5 reductase.

Almost all the lipids examined from control tissues contained low levels of *cis* Δ9 16:1. This is not surprising because Δ9 16:1 is produced in the chloroplasts by the low activity of the soluble stearoyl-ACP desaturase toward 16:0-ACP (30). However, because the *cis* Δ9 16:1 is a very minor component in most plant tissues including tobacco, the increased level of *cis* Δ9 16:1 is a good *in vivo* measure of the mammalian desaturase activity. Furthermore, since *cis* Δ9 16:1 overproduction by RDS apparently occurs in the microsomes, the distribution of the 16:1 should be a good indicator of the metabolic flux between the eukaryotic and prokaryotic pathways.

Analysis of the lipids from the isolated microsomes showed that the conversion of 18:0 to 18:1 was greater than that of 16:0 to 16:1. These results suggest that the mammalian desaturase in the microsomes of the transgenic plant cells showed higher activity toward 18:0-CoA, as it appeared to function *in vivo* primarily as a stearoyl-CoA desaturase in rat liver (29). In contrast to the microsomal lipids, the chloroplast lipids of the transgenic plants contained higher levels of Δ9 16:1. For example, chloroplast PC contained 17.3% of *cis* Δ9 16:1 and 4.1% of Δ9 18:1, whereas the microsomal PC had 10.5% of Δ9 16:1 and 12.8% of Δ9 18:1. These data suggest that the 16:1-containing lipids are preferentially transported into the chloroplasts over 18:1-containing lipids, supporting the idea that the metabolic fluxes between the eukaryotic and prokaryotic pathways occur in a highly regulated manner (5).

Another example of fine-controlled regulation is evident from the level of desaturation. In all the lipids examined, there was no significant difference in the average number of double bonds per glycerolipid molecule between the control and the RDS-transgenic plants, in spite of increase in mono-unsaturated fatty acids and decrease in saturated fatty acids. In all the glycerolipids examined except PG, decreases in saturated fatty acids and increases in monounsaturated fatty acid were accompanied by reductions in the level of 18:3. In case of the microsomal lipids, concomitant increases in 18:2 were observed as well. The reduction in 18:3 level was also seen by Polashock *et al*. (8) in tobacco transformed with a yeast Δ9 desaturase gene. However, it is not clear how this effect is related to the increase in the ratio of monounsaturated to saturated fatty acids in the transgenic plants. A possible explanation for these results is that there might be a very fine mechanism to sense the degree of desaturation in plant cell membranes. Thus, the decreases in 18:3 level in the RDS-transgenic plant can be interpreted as a compensatory mechanism in response to the increase in the level of monounsaturated fatty acids.

The expression of a mammalian Δ9 desaturase under the control of the 35*S* promoter resulted in little change in the fatty acid composition of mature tobacco seeds. However, when the transgenic seeds were analyzed at the early stage of development, a significant amount of 16:1 was detected (data not shown). The accumulation of 16:1 appeared positively related to the level of the RDS protein as the Western blot analysis showed a significant amount of the RDS protein in the transgenic tobacco seeds at the early stage of seed development (Fig. 3). The RDS protein disappeared as seeds developed to maturity and as a result, the level of 16:1 dramatically decreased. Williamson *et al*. (31) reported that the transcript of the maize storage protein (zein) gene, when expressed under the control of 35*S* promoter in transgenic tobacco, was greatly reduced as seeds of the transgenic tobacco matured. The reduction started 15 d after pollination, and no transcript of the zein gene was detectable 25 d after pollination.

The biosynthetic pathway of *cis* Δ11 18:1 (*cis*-vaccenic acid) is not clear. Since Δ9 16:1-ACP is formed at a low level by the action of the plastid stearoyl-ACP desaturase toward 16:0-ACP (30), we cannot rule out the possibility that Δ11 18:1 could be produced from Δ9 16:1-ACP by the condensing enzyme, 3-ketoacyl-ACP synthase (KAS II), in the chloroplast. In this case, Δ11 18:1 should be detected in control plants as well. The absence of *cis*-vaccenic acid in detectable amounts in the control tissues indicates that the activities of the plastid stearoyl-ACP desaturase for 16:0-ACP and KAS II for Δ9 16:1-ACP are too low and/or that the size of 16:1 pool is too small to be available for those enzymes to produce detectable amounts of *cis*-vaccenic acid. Shibahara *et al*. (32) proposed chain elongation from palmitoleic acid and reversible enzymatic double-bond shifting of Δ9 18:1 (33) as pathways for *cis*-vaccenic acid biosynthesis based on a labeling experiment of Chinese persimmon or kaki (*Diospyros kaki* L.) pulp with deuterated fatty acids. The rat liver Δ9 desaturase in the ER of the transgenic tissue converted 16:0-CoA and 18:0-CoA to 16:1-CoA and 18:1-CoA, respectively. Accumulation of the monounsaturated fatty acyl-CoA may provide a larger size of the substrate pool for the elongase and/or isomerase to give rise to *cis* Δ11 18:1.

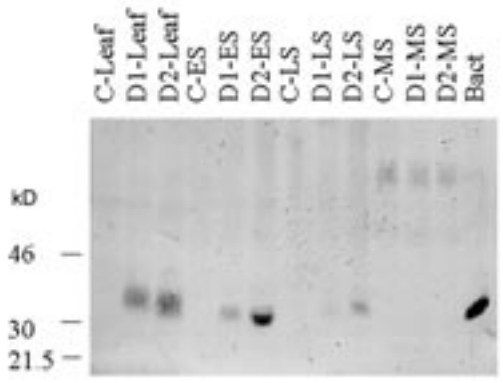

FIG. 3. Expression of RDS in *Nicotiana tabacum* seeds during development. C, control plant; D1, D2, RDS-transgenic plants; ES, seeds at early developmental stage (~10 d after pollination, DAP); LS, seeds at late developmental stage (~20 DAP); MS, mature seeds; Bact, *Escherichia coli* expressing the Δ9 desaturase.

The *cis* Δ11 18:1, which was found only in the RDS-transgenic plants, was detected exclusively in the *sn*-1 position of all the lipids tested except for PI and PS. These findings suggest that the *cis* Δ9 16:1 overproduced by the activity of the RDS was elongated to Δ11 18:1 by an ER elongase and incorporated exclusively into the *sn*-1 position of certain lipids by a specific acyltransferase. However, we cannot rule out the possibility that *cis* Δ11 18:1 is excluded from the *sn*-2 position of tobacco lipids because *cis*-vaccenic acid might be a poor substrate for lysophosphatidic acid acyltransferase (LPAAT) in tobacco leaf as Ichihara *et al*. (34) showed for the acyl-CoA specificity of the LPAAT in maturing safflower seeds.

Even though the tobacco tissues expressing RDS under the control of 35*S* promoter showed a significant reduction in the total saturated fatty acid content, very little change in seed triacylglycerol fatty acid composition was seen. Since fatty acid biosynthesis is an essential metabolic pathway in all the tissues, modification of seed oil composition may require seed-specific expression. When the rat desaturase was expressed, under the control of seed-specific phaseolin promoter, transgenic soybean somatic embryos showed significantly reduced levels of saturated fatty acids. Since the mammalian Δ9 desaturase utilizes both 16:0-CoA and 18:0-CoA as a substrate, in transgenic soybean somatic embryos, these cytoplasmic CoA, which are the main saturated fatty acyl-CoA pool for the triacylglycerol in soybean oil, were desaturated to Δ9 16:1-CoA and 18:1-CoA before being incorporated into glycerol backbones. As the seed-specific phaseolin promoter led the animal desaturase to be expressed more strongly in cotyledons than in hypocotyl-radicles, such effects on lipids of somatic embryos are expected in seeds of regenerated plants.

In conclusion, we demonstrated that a mammalian Δ9 desaturase functioned in the microsomes of plant cells, apparently using the plant's electron transport system involving cytochrome b_5 and cytochrome b_5 reductase, and reduced the levels of saturated and increased the levels of monounsaturated fatty acids in the transgenic plant tissues. The finding of *cis* Δ11 18:1 only in the *sn*-1 position of certain lipids could imply the existence of an acyltransferase with a previously undescribed function. A significant amount of the cytoplasmically produced 16:1 reenters plastids. Incorporation of *cis* Δ9 16:1, overproduced by the RDS in the microsomes of the transgenic plants, into both the *sn*-1 and *sn*-2 positions strongly indicates that the acyl-CoA-specific acyltransferases of the ER involved in production of the eukaryotic lipids do not exclude 16-carbon fatty acids at the *sn*-2 position when they are desaturated. Finally, the seed-specific expression of the RDS in soybean somatic embryos showed that the mammalian stearoyl-CoA Δ9 desaturase significantly lowered the levels of saturated fatty acids, especially in cotyledons.

ABSTRACT: We have examined the role of 2-oleoyl-PE (phosphatidylethanolamine) in the biosynthesis of triacylglycerols (TAG) by castor microsomes. In castor microsomal incubation, the label from ^{14}C-oleate of 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-phosphoethanolamine is incorporated into TAG containing ricinoleate. The enzyme characteristics, such as optimal pH, and the effect of incubation components of the oleoyl-12-hydroxylase using 2-oleoyl-PE as incubation substrate are similar to those for 2-oleoyl-PC (phosphatidylcholine). However, compared to 2-oleoyl-PC, 2-oleoyl-PE is a less efficient incubation substrate of oleoyl-12-hydroxylase in castor microsomes. Unlike 2-oleoyl-PC, 2-oleoyl-PE is not hydroxylated to 2-ricinoleoyl-PE by oleoyl-12-hydroxylase and is not desaturated to 2-linoleoyl-PE by oleoyl-12-desaturase. We have demonstrated the conversion of 2-oleoyl-PE to 2-oleoyl-PC and vice versa. The incorporation of label from 2-[^{14}C]oleoyl-PE into TAG occurs after its conversion to 2-oleoyl-PC, which can then be hydroxylated or desaturated. We detected neither PE-*N*-monomethyl nor PE-*N*,*N*-dimethyl, the intermediates from PE to PC by *N*-methylation. The conversion of 2-oleoyl-PE to 2-oleoyl-PC likely occurs *via* hydrolysis to 1,2-diacyl-*sn*- glycerol by phospholipase C and then by cholinephosphotransferase. This conversion does not appear to play a key role in driving ricinoleate into TAG.

Paper no. L8396 in *Lipids 35*, 481–486 (May 2000).

The presence of the hydroxy group on ricinoleate imparts physical and chemical properties that underlie many industrial uses such as the production of aviation lubricants, coatings, and specialty plastics. Castor (*Ricinus communis* L.) bean, the only commercial source of ricinoleate, contains the toxin ricin and potent allergens, making it hazardous to grow, harvest, and process. It is desirable to produce ricinoleate in an oilseed of a transgenic plant lacking these components.

The cDNA for oleoyl-12-hydroxylase, the key enzyme in the biosynthesis of castor oil [triacylglycerols (TAG) containing ricinoleate], has been cloned in castor and expressed in tobacco, resulting in accumulation of low levels of ricinoleate in seed lipids (1). Later, the expression of this enzyme in transgenic *Arabidopsis thaliana* plants was improved but also resulted in low levels of hydroxy fatty acids (FA; 2) compared to castor (20 vs. 90% ricinoleate in castor oil). For the purpose of developing a transgenic plant that produces castor oil, it is important to know the biosynthetic pathway and to identify the key enzymatic steps that drive ricinoleate into TAG in castor bean. We have previously used 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-phosphocholine (2-[^{14}C]oleoyl-PC) as the substrate in castor microsomal incubation to prove that 2-oleoyl-PC is the immediate substrate of oleoyl-12-hydroxylase and to identify oleoyl-12-hydroxylase, phospholipase A_2, and 1,2-diacyl-*sn*-glycerol acyltransferase in the biosynthetic pathway as the key enzymatic steps that drive ricinoleate into TAG (3). Since phosphatidylethanolamine (PE) is endogenous in castor bean and is similar to phosphatidylcholine (PC) structurally, we examine here the role of 1-acyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine (2-oleoyl-PE) in the biosynthesis of TAG containing ricinoleate in castor microsomes.

EXPERIMENTAL PROCEDURES

Preparation of the substrate. 1-Palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-phosphoethanolamine was prepared similarly to the method of Paltauf and Hermetter (4). 1-Palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-phosphocholine (6 μCi; NEN Life Science Products, Boston, MA) was dissolved in 1 mL diethyl ether. To this solution 3 mL buffer (0.2 M sodium acetate, 0.1 M calcium chloride, 20% ethanolamine, adjusted to pH 5.6 with 6 N HCl) containing phospholipase D (1 mg) was added. The mixture was vigorously stirred with a magnetic stirrer for 10 h at 40°C in a capped tube. The diethyl ether was evaporated by nitrogen flow. The aqueous phase and residue were then extracted three times with 2 mL of chloroform/methanol (2:1, vol/vol). The chloroform phase was dried and PE was purified by silica high-performance liquid chromatography (HPLC) as shown below. All commercially available phospholipase D proved unsuitable for the preparation of radioactive PE due to contamination with other lipase activities. We

Abbreviations: DAG, diacylglycerol; FA, fatty acid; FAME, fatty acid methyl ester; FFA, free fatty acid; HPLC, high-performance liquid chromatography; 2-linoleoyl-PC, 1-acyl-2-linoleoyl-*sn*-glycero-3-phosphocholine; 2-oleoyl-PC, 1-acyl-2-oleoyl-*sn*-glycero-3- phosphocholine; 2-oleoyl-PE, 1-acyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; 2-ricinoleoyl-PC, 1-acyl-2-ricinoleoyl-*sn*-glycero-3-phosphocholine; 2-ricinoleoyl-PE, 1-acyl-2-ricinoleoyl-*sn*-glycero-3- phosphoethanolamine; TAG, triacylglycerol.

used the phospholipase D of *Streptomyces antibioticus* prepared from recombinant *Escherichia coli* (5). This method was also used to prepare the nonradioactive standards, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-monomethyl and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanol-amine-*N*,*N*-dimethyl, using buffers containing 2-(methyl-amino)ethanol and 2-(dimethylamino)ethanol instead of ethanolamine.

Microsomal incubation. Microsomes from castor bean were prepared as described previously (3,6). The microsomal incubation mixture in a total volume of 1 mL included: sodium phosphate buffer (0.1 M, pH 6.3), NADH (0.5 mol), ATP (0.5 mol), $MgCl_2$ (0.5 μmol), catalase (1000 units), and the microsomal fraction of endosperm from immature castor bean (15 μL, 138 μg of protein). The radioactive substrate prepared here, 2-[^{14}C]oleoyl-PE (0.125 μCi, 2.16 nmol, 58.0 Ci/mol), in 20 μL ethanol was added last into a screw-capped tube followed by immediate mixing. The mixture was then incubated in a shaking water bath for 30 min at 22°C. The incubation was stopped by adding 3.75 mL of chloroform/methanol (1:2, vol/vol) to form a suspension. The mixture was again mixed with 0.63 mL of chloroform and 0.63 mL of water. The lower chloroform layer containing the lipid extract was dried and fractionated on a silica HPLC system for the separation of lipid classes described below. To identify the FA constituents of various lipids, lipid extracts or HPLC fractions together with NADH (0.5 μmol) as antioxidant were transmethylated in 5% HCl/methanol (1 mL) at 80°C for 1 h. The fatty acid methyl esters (FAME) formed were extracted with 2 × 1 mL of hexane. Tocopherol and butylated hydroxytoluene (also called 2,6-di-*tert*-butyl-4-methylphenol) were also used as antioxidants, but lower yields resulted.

HPLC. HPLC was carried out on a liquid chromatograph (Waters Associates, Milford, MA), using a photodiode array detector (Waters 996) detecting at 205 nm. Radioactive lipids were separated by HPLC and identified by cochromatography with lipid standards matching the retention times from ultraviolet absorbance at 205 nm and the radioactivity detector. The flow rates of eluants of different HPLC systems were 1 mL/min. The flow rate of liquid scintillation fluid (Ultima Flo M, Packard Instrument Co., Downers Grove, IL) of the radioactivity flow detector (150TR; Packard Instrument Co.) was 3 mL/min.

(i) Separation of lipid classes. Lipid classes were separated according to Singleton and Stikeleather (7) on a silica column [25 × 0.46 cm, 5 μm, Luna, silica (2); Phenomenex, Torrance, CA] with a linear gradient starting at isopropanol/hexane (4:3, vol/vol) to isopropanol/hexane/water (4:3:0.75, by vol) in 20 min, then isocratically for 20 min. A prepacked silica saturator column (3 × 0.46 cm, 15–25 μm; Phenomenex) was installed between the pump and injector to saturate the mobile phase with silica before it reached the analytical column.

(ii) Separation of molecular species of PC and PE. Molecular species of PC were separated as we reported previously (8) using a C_8 column (25 × 0.46 cm, 5 μm, Luna C8; Phenomenex) with a linear gradient of 90–100% methanol (containing 0.1% of conc. NH_4OH as silanol-suppressing agent) in 40 min. Molecular species of PE were separated with a linear gradient of 88–100% (containing 0.1% of conc. NH_4OH as silanol-suppressing agent) in 40 min.

(iii) Separation of molecular species of TAG. Molecular species of TAG were separated as we reported previously (9,10) using a C_{18} column (25 × 0.46 cm, 5 μm, Luna C18; Phenomenex) with a linear gradient starting at 100% methanol to 100% isopropanol in 40 min.

(iv) Separation of free fatty acids (FFA). FFA were separated as we previously reported (11) using a C_{18} column (25 × 0.46 cm, 5 μm, Luna C18; Phenomenex) with a linear gradient of 85–100% methanol (containing 0.05% HOAc as ion-suppressing agent) in 40 min.

(v) Separation of FAME. FAME were separated on a C_{18} column (25 × 0.46 cm, 5 m, Luna C18; Phenomenex) with a linear gradient of 90–100% methanol in 40 min (11). More rapid analyses used a short C_{18} column [5 × 0.46 cm, 3 μm, Luna C18(2); Phenomenex] with a linear gradient of 90–100% methanol in 15 min for a 10-min run (6).

RESULTS AND DISCUSSION

In the biosynthesis of TAG containing ricinoleate using 2-[^{14}C]oleoyl-PC as incubation substrate in castor microsomal incubation, we identified [^{14}C]PE as one of the metabolites (3). Given its metabolic relation and similar structure to 2-oleoyl-PC, we wanted to determine the role of 2-oleoyl-PE in the biosynthesis of TAG containing ricinoleate in castor bean. In a preliminary study we showed the conversion of oleate from 2-[^{14}C]oleoyl-PE to ricinoleate in the total lipid extract. To compare the enzyme characteristics of oleoyl-12-hydroxylase using 2-oleoyl-PE as incubation substrate to those using 2-oleoyl-PC in our earlier report (6), we examined the activities of oleoyl-12-hydroxylase as a function of pH and various incubation components that affect hydroxylase activity when oleoyl-CoA was used as incubation substrate (12–14). The total lipid extracts from the incubation mixtures at various pH values were transmethylated. The profiles of labeled FAME were similar to those we reported previously when 2-[^{14}C]oleoyl-PC was used as incubation substrate (6). The HPLC radiochromatograms showed the presence of radioactive methyl esters of oleate and its metabolites, ricinoleate and linoleate. The activities of oleoyl-12-hydroxylase using 2-[^{14}C]oleoyl-PE as incubation substrate at various pH values are shown as Figure 1. The optimal pH value is 6.3, which is the same as that of the incubations using 2-[^{14}C]oleoyl-PC as incubation substrate (6). The effects of some incubation components on the activity of oleoyl-12-hydroxylase using 2-oleoyl-PE as incubation substrate in castor microsomal incubations (30 min) were as follows: 140 pmol/30 min of [^{14}C]ricinoleate methyl ester, average of two determinations; + bovine serum albumin, 75; –catalase, 174; +CoA, 178; –ATP, 89; –NADH, +NADPH, 70; –$MgCl_2$, 95; PC incubation (the control incubations used 2-[^{14}C]oleoyl-PC as incubation substrate instead of 2-[^{14}C]oleoyl-PE), 211.

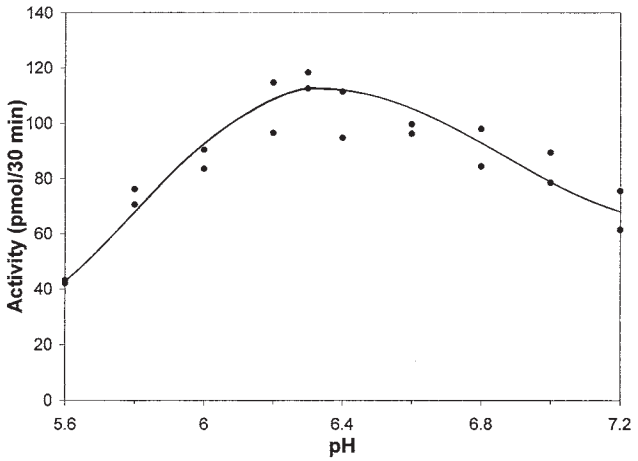

FIG. 1. Effect of pH (0.1 M sodium phosphate buffer) on the activity of oleoyl-12-hydroxylase using 1-acyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphoethanolamine (2-[^{14}C]oleoyl-PE) as incubation substrate in castor microsomal incubations (30 min). Activity is the amount of the methyl ester of [^{14}C]ricinoleate formed after the transmethylation of the total lipid. The paired dots represent the data from two determinations.

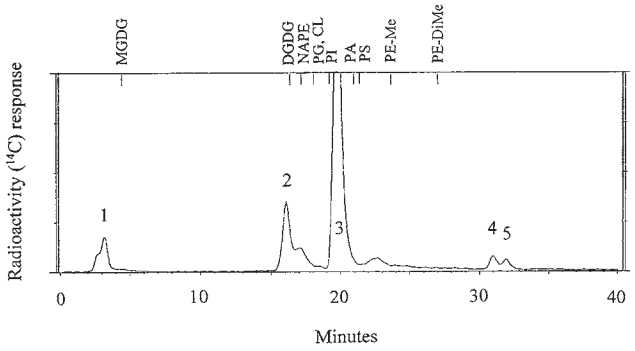

FIG. 2. Separation of lipid classes of total lipid extract from the castor microsomal incubation (60 min) with 2-[^{14}C]oleoyl-PE using a silica high-performance liquid chromatography (HPLC) system (see the Experimental Procedures section, HPLC, (i). The radioactive peaks were: (1) acylglycerols and free fatty acids (FFA) (retention time, 3.2 min); (2) the unknown (16.1 min); (3) phosphatidylethanolamine (PE) (19.8 min); (4) 1-acyl-2-oleoyl-*sn*-glycero-3-phosphocholine (2-oleoyl-PC) (30.9 min); (5) 1-acyl-2-ricinoleoyl-*sn*-glycero-3-phosphocholine (2-ricinoleoyl-PC) (31.9 min). Retention times of other lipid classes in this HPLC system are also shown in the figure. MGDG, monogalactosyl diacylglycerol; DGDG, digalactosyl diacylglycerol; NAPE, *N*-acyl-phosphatidylethanolamine; PG, phosphatidylglycerol; CL, cardiolipin; PI, phosphatidylinositol; PA, phosphatidic acid; PS, phosphatidylserine; PE-Me, PE-*N*-monomethyl; PE-DiMe, PE-*N*,*N*-dimethyl; for other abbreviation see Figure 1.

The inclusion of bovine serum albumin (1 mg) decreases the activity. The microsomal fraction was suspended in buffer containing catalase, and the further addition of catalase in the incubation did not increase the activity. The inclusion of CoA (0.5 μmol) does not significantly enhance the activity using 2-oleoyl-PE as incubation substrate. There is no effect of added CoA on the activity with 2-oleoyl-PC as incubation substrate (6). ATP (0.5 μmol) and $MgCl_2$ (0.5 μmol) enhance the activity as shown earlier using 2-oleoyl-PC as incubation substrate (6). The cofactor NADH could be replaced with NADPH but resulted in less activity than with NADH, as previously reported using 2-oleoyl-PC as incubation substrate (6). The similarity of the enzyme characteristics of oleoyl-12-hydroxylase using 2-oleoyl-PC and 2-oleoyl-PE as incubation substrates indicates the action of a single enzyme. However, 2-oleoyl-PC is a more efficient incubation substrate for oleoyl-12-hydroxylase than 2-oleoyl-PE.

Radioactive 2-oleoyl-PE was incubated with castor microsomes for various times. The total lipid extracts from the incubation mixtures were separated on a silica HPLC column for the separation of lipid classes as shown in Figure 2. The radiochromatograms (e.g., Fig. 2) showed the radioactive lipid classes of acylglycerols and FFA, the unknown, 2-oleoyl-PE (substrate), 2-oleoyl-PC, and 2-ricinoleoyl-PC (1-acyl-2-ricinoleoyl-*sn*-glycero-3-phosphocholine), which were the same lipid classes as those we reported (3) using 2-[^{14}C]oleoyl-PC as incubation substrate. The amounts of each lipid classes formed at various times are shown in Figure 3. The maximal amount of 2-ricinoleoyl-PC formed from 2-oleoyl-PE is 40 pmol, compared with 120 pmol from 2-oleoyl-PC (3), and it takes 60 vs. 30 min from the PC substrate (3). This suggests that the oleate from 2-oleoyl-PE is converted to ricinoleate after 2-oleoyl-PE is converted to 2-oleoyl-PC. The amounts of the lipid classes including acylglycerols and FFA, an unknown, and 2-oleoyl-PC increase with time at least up to 90 min. The dip at 60 min for the amount of 2-oleoyl-PC formed corresponds to the time of maximal amount of 2-ricinoleoyl-PC formed, suggesting the conversion of 2-oleoyl-PC to 2-ricinoleoyl-PC instead of the conversion of 2-ricinoleoyl-PE (1-acyl-2-ricinoleoyl-*sn*-glycero-3-phosphoethanolamine) to 2-ricinoleoyl-PC. The continuously smooth increase of the amount of unknown with time suggests that the formation of the unknown (peak 2, Fig. 3) from 2-oleoyl-PE is not on the pathway to TAG.

Figure 4 shows the HPLC separation of the molecular species of acylglycerols and FFA (peak 1, Fig. 2) from the castor microsomal incubation of radioactive 2-oleoyl-PE for 60 min. This radiochromatogram shows the presence of the same TAG and FFA as those obtained previously when the microsomes were incubated with radioactive 2-oleoyl-PC and ricinoleate (3). Oleate from 2-oleoyl-PE is incorporated into TAG containing ricinoleate by castor microsomes as shown in Figure 4. Similar to 2-oleoyl-PC, 2-oleoyl-PE is also hydrolyzed by phospholipase C in castor microsomes whereby 1-acyl-2-oleoyl-*sn*-glycerol accumulates (peak 5, Fig. 4). As shown earlier (3), the conversion of 1-acyl-2-oleoyl-*sn*-glycerol to TAG by diacylglycerol (DAG) acyltransferase is blocked when the DAG contains no ricinoleate.

We collected and transmethylated the unknown (peak 2, Fig. 2). We separated the FAME formed by a C_{18} HPLC and detected only the radioactive methyl ester of oleate. The ratio of the radioactivities of the methyl esters of oleate, linoleate, and ricinoleate was 100:0:0 in the incubation of 2-oleoyl-PE, whereas the ratio from the unknown in the incubation of 2-

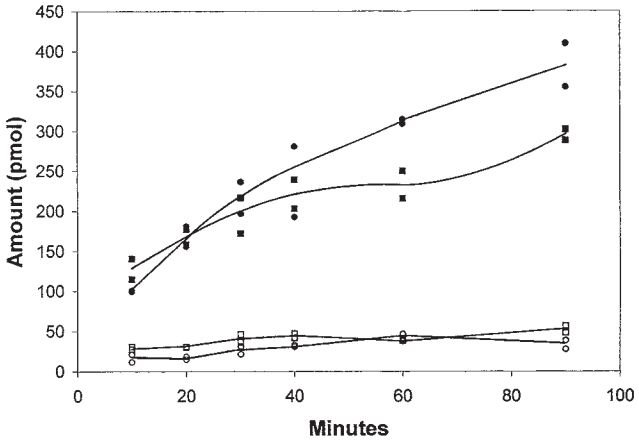

FIG. 3. Amounts of lipid classes shown in Figure 2 formed at various times of castor microsomal incubations with 2-[^{14}C]oleoyl-PE. Units for y axes are pmol of labeled fatty acids in each lipid class derived from [^{14}C]oleate of the substrate. (■), acylglycerols and FFA (including triricinolein); (●), unknown; □, 2-oleoyl-PC; (○), 2-ricinoleoyl-PC. The paired symbols represent the data from two determinations. For abbreviations see Figures 1 and 2.

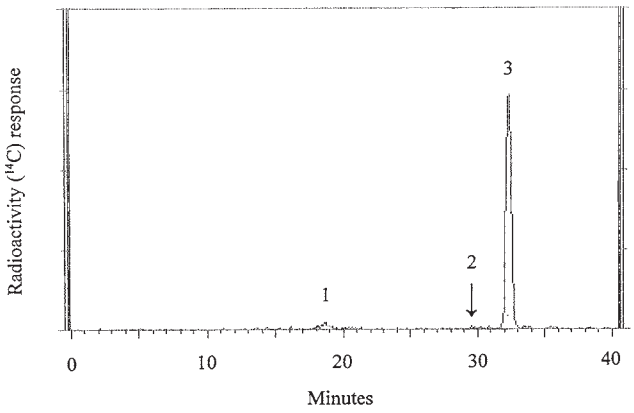

FIG. 5. HPLC radiochromatogram of phosphatidylethanolamine fraction (peak 3, Fig. 2) from the castor microsomal incubation (60 min) with 2-[^{14}C]oleoyl-PE using a reversed-phase C_8 HPLC system for the separation of molecular species of PE [see the Experimental Procedures section, HPLC, (ii)]. Peak 1, unknown (retention time, 18.6 min which is very close to that of 1-palmitoyl-2-ricinoleoyl-*sn*-glycero-3-phosphoethanolamine); arrow 2, 1-palmitoyl-2-linoleoyl-sn-glycero-3- phosphoethanolamine (retention time, 29.7 min); peak 3, 2-oleoyl-PE (32.4 min). For abbreviations see Figures 1 and 2.

oleoyl-PC was 90:4:6 which is very close to the ratio of 2-oleoyl-PC/2-linoleoyl-PC(1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine)/2-ricinoleoyl-PC, 91:3:6, in the same incubation (3). The results indicate that the unknown contains the DAG derived from the incubation substrate PE or PC, and 2-oleoyl-PE is not hydroxylated and desaturated, whereas 2-oleoyl-PC is. We are in the process of identifying this unknown lipid, which appears to be derived from PE or PC after hydrolysis by phospholipase C or D.

Figure 2 and the silica HPLC chromatogram from the incubation of 2-[^{14}C]oleoyl-PC reported earlier (3) show the presence of 2-[^{14}C]ricinoleoyl-PC, whereas 2-[^{14}C]ricinoleoyl-PE (retention time about 1 min after peak 3) is not seen in Figure 2. We hydrolyzed the PE fraction (peak 3, Fig. 2) from the microsomal incubation of radioactive 2-[^{14}C]oleoyl-PE with phospholipase A_2 (from *Naja mocambique mocambique*; Sigma P-4034, St. Louis, MO), and the FFA obtained were cochromatographed with the potential products, oleate, linoleate and ricinoleate on C_{18} HPLC [see the Experimental Procedures section, HPLC, (iv)]. The radioactive oleate (incubation substrate, 31.3 min) was present in the radiochromatogram, but radioactive ricinoleate (12.1 min) and linoleate (26.7 min) were not. We chromatographed the same PE fraction (peak 3, Fig. 2) on C_8 HPLC as shown in Figure 5 to separate the intact molecular species of PE. There are two radioactive peaks shown in Figure 5, and peak 3 (32.4 min) represents the incubation substrate 2-[^{14}C]oleoyl-PE. We hydrolyzed material in peak 1 (18.6 min) in Figure 5 with phospholipase A_2 and cochromatographed the FFA obtained with oleate, linoleate, and ricinoleate standards on C_{18} HPLC. We detected only radioactive oleate, and no radioactive ricinoleate and linoleate. 1-Palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphoethanolamine should elute at 29.7 min in Figure 5 (arrow 2) according to the HPLC run of the standard. We do not have 1-palmitoyl-2-ricinoleoyl-*sn*-glycero-3-phosphoethanolamine available as a standard; however, based on the HPLC of PC we reported recently (8), we can predict its retention time to be about 18.3 min. We have proved that peak 1 of Figure 5 is not 2-ricinoleoyl-PE. The conversions of 2-[^{14}C]oleoyl-PE to 2-[^{14}C]ricinoleoyl-PE and 1-acyl-2-linoleoyl-*sn*-glycero-3-phosphoethanolamine (2-[^{14}C]linoleoyl-PE) appear completely blocked. We have shown earlier the intact 2-[^{14}C]ricinoleoyl-PC and 2-[^{14}C]linoleoyl-PC on a C_8 HPLC radiochromatogram when the castor microsomes were incubated with 2-[^{14}C]oleoyl-PC (3). Thus, both oleoyl-

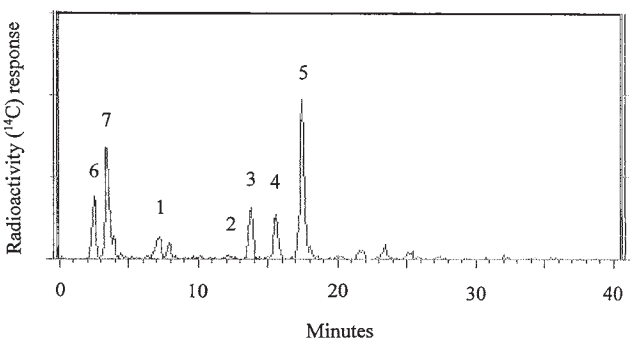

FIG. 4. HPLC identification of radioactive acylglycerols in the fraction of acylglycerols and FFA (peak 1, Fig. 3) from the castor microsomal incubation (60 min) of 2-[^{14}C]oleoyl-PE, using a C_{18} HPLC system [see the Experimental Procedures section, HPLC, (iii)]. Peak 1, triricinolein (retention time, 7.2 min); peak 2, diricinoleoyl-linolenoyl-glycerol (12.1 min); peak 3, diricinoleoyl-linoleoyl-glycerol (13.8 min); peak 4, diricinoleoyl-oleoyl-glycerol (15.6 min); peak 5, 1-palmitoyl-2-oleoyl-*sn*-glycerol (17.5 min); peak 6, ricinoleate (2.5 min); peak 7, may be 1,2-diricinoleoyl-*sn*-glycerol (3.4 min). For abbreviations see Figure 2.

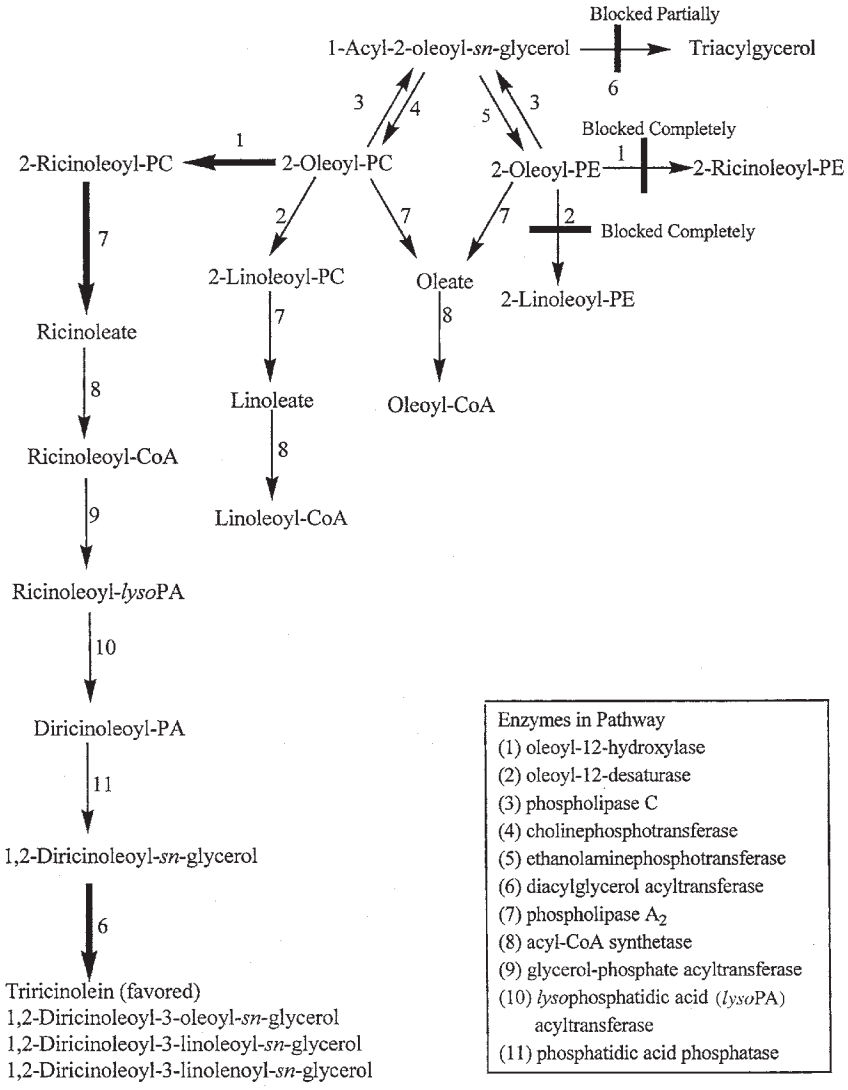

SCHEME 1

12-hydroxylase and oleoyl-12-desaturase in castor microsomes are specific for the PC head group. Since the structure of PE among the major lipid classes is similar to that of PC, and PE cannot be used as the immediate substrate of either enzyme, it is likely that 2-oleoyl-PC is the only substrate of these two enzymes.

We have synthesized 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-monomethyl and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine-*N,N*-dimethyl, the intermediate metabolites of PE to PC by N-methylation (15). Their retention times are shown in Figure 2 in a silica HPLC for the separation of lipid classes. Neither of these two compounds is detected as ^{14}C-labeled as shown in Figure 2. Even using 22-fold higher levels of labeled materials, we were unable to detect the intermediates from conversion of PE to PC by N-methylation either by silica HPLC or C_8 HPLC using the standards we synthesized.

Scheme 1 shows the biosynthetic pathway of TAG containing ricinoleate using 2-oleoyl-PE and 2-oleoyl-PC (3) as the incubation substrates in castor microsomal incubations. Enzyme 1: Oleoyl-12-hydroxylase, with cytochrome b_5, NADH, O_2, ATP (16). It is blocked completely when the substrate is 2-oleoyl-PE. Enzyme 2: Oleoyl-12-desaturase, with cytochrome b_5, NADH, O_2, ATP (16). It is blocked completely when the substrate is 2-oleoyl-PE. Enzyme 3: Phospholipase C. It is likely that 2-oleoyl-PE itself as well as 2-oleoyl-PC is hydrolyzed by phospholipase C in castor microsomes. A large amount of 1-acyl-2-oleoyl-*sn*-glycerol accumulated when 2-oleoyl-PE was incubated in castor microsomes as shown in Figure 4, and we have shown that 2-oleoyl-PE can be hydrolyzed by phospholipase C (from *Bacillus cereus*). Enzyme 4: CDP-choline:1,2-DAG cholinephosphotransferase (15). It is likely that most of the conversion of PE to PC goes *via* enzymes 3 and 4 as shown in Scheme 1, because DAG is a major metabolite of PE (Fig. 4), and it has been shown that DAG (both 1,2-diricinoleoyl-*sn*-

glycerol and 1,2-dioleoyl-*sn*-glycerol) can be efficiently converted to PC (17). There are three other possible pathways from PE to PC: (i) *S*-adenosyl-L-methionine:PE *N*-methyltransferase (15); in this study, the intermediates of the conversion from PE to PC by N-methylation were not detected; (ii) a base group exchange reaction, transfer of the phosphatidyl unit to free choline, requires Ca^{2+} (18); and (iii) conversion of 2-oleoyl-PE to lysoPE by phospholipase A_2 (enzyme step 7), conversion of the released ^{14}C-oleate to oleoyl-CoA (enzyme step 8), followed by acylation of lysoPC (13) because ATP, CoA, and Mg seem to stimulate the formation of ricinoleate from PE (see above). Enzyme 5: CDP-ethanolamine:1,2-DAG ethanolaminephosphotransferase (19). PE also could be formed from PC by a base group exchange reaction (18), transfer of the phosphatidyl unit to ethanolamine, which requires Ca^{2+}. Enzyme 6, DAG acyltransferase, with acyl CoA, is partially blocked when the DAG contain no ricinoleate (17). Because of the block, 1-acyl-2-oleoyl-*sn*-glycerol accumulated. Enzyme 7: phospholipase A_2. It is likely that 2-oleoyl-PE itself is hydrolyzed by phospholipase A_2 in castor microsomes. We have shown that 2-oleoyl-PE can be hydrolyzed by phospholipase A_2 (from *N. mocambique mocambique*). Enzyme 8: acyl-CoA synthetase, with ATP, CoA. Enzyme 9: glycerol-phosphate acyltransferase, with acyl CoA. Enzyme 10: lysophosphatidic acid acyltransferase. Enzyme 11: phosphatidic acid phosphatase.

In conclusion, the incorporation of the label from 2-[^{14}C]oleoyl-PE into TAG containing ricinoleate passes through 2-oleoyl-PC, which is then hydroxylated and desaturated. The conversion of 2-oleoyl-PE to 2-oleoyl-PC does not appear to be a key enzymatic step for driving ricinoleate into TAG, because our results indicate that 2-oleoyl-PE is not an effective incubation substrate for hydroxylation, but a precursor of 2-oleoyl-PC. In addition, the enzyme characteristics of oleoyl-12-hydroxylase using 2-oleoyl-PE as incubation substrate were shown to be the same as those using 2-oleoyl-PC, the immediate substrate (6).

ABSTRACT: Oleoyl-CoA elongase catalyzes four successive reactions: condensation of malonyl-CoA to oleoyl-CoA, reduction, dehydration, and another reduction. Evidence supporting this mechanism and the multienzymatic nature of the elongation complex are reported. A particulate membrane fraction from rapeseed is able to elongate intermediates (*R,S*) 3-hydroxy-20:0-CoA and (*E*) 2,3-20:1-CoA to very long chain fatty acids in the presence of malonyl-CoA. Studies of the 3-ketoacyl-CoA synthase activities showed that maximal activity could be measured by using 15 to 30 µM 18:1-CoA and 30 µM malonyl-CoA, and that 18:0-CoA and 18:1-CoA were the best substrates. Comparison of the condensation and the overall elongation activities indicated that condensation is the rate-limiting step of the elongation process. The 3-hydroxyacyl-CoA dehydratase activity was maximal in the presence of 75 µM Triton X-100 and 25 µg of proteins. Finally, the acyl-CoA elongase complex was solubilized and purified. During the purification process, the 3-hydroxyacyl-CoA dehydratase copurified with the elongase complex, strongly suggesting that this enzyme belongs to the elongase complex. The apparent molecular mass of 700 kDa determined for the elongase complex, and the fact that four different polypeptide bands were detected after sodium dodecyl sulfate-polyacrylamide gel electrophoretic analysis of the purified fraction, further suggest that the acyl-CoA elongase is a multienzymatic complex.

Paper no. L8414 in *Lipids 35,* 487–494 (May 2000).

Erucic acid (22:1) and its derivatives offer so many industrial applications that if an oil with about 90% 22:1 could be obtained, it would replace many petrochemical alternatives (1). Erucic acid is highly enriched in several oleaginous plants. It represents up to 60% of the total fatty acids in some varieties of rapeseed called high erucic acid rapeseed (HEAR). Higher percentages of 22:1 cannot be obtained because rapeseed lysophosphatidic acid acyl transferase cannot esterify 22:1 in the *sn*-2 position of the triacylglycerols (TAG). Recently, Lassner *et al.* (2) transformed HEAR lines with the gene of the lysophosphatidic acid acyl transferase from *Limnanthes alba,* an enzyme capable of inserting 22:1 in the *sn*-2 position of TAG. Analysis of transgenic plants showed that the total erucic acid oil content was unchanged although 22:1 was present in the *sn*-2 position of TAG. In fact, it was demonstrated that 22:1 was less abundant in the *sn*-1 and *sn*-3 positions when compared to the original HEAR lines. These results strongly suggest that the erucoyl-CoA pool is limiting, and therefore that the very long chain fatty acid (VLCFA) synthesis pathway needs to be enhanced in order to increase the total erucic acid oilseed content.

In higher plants, VLCFA are synthesized from long-chain acyl-CoA and malonyl-CoAs by membrane-bound enzymes called acyl-CoA elongases (3). From the identification of the intermediates of the elongation process (4), it has been hypothesized that four intermediate reactions occur during acyl-CoA elongation: firstly, malonyl-CoA and a long-chain acyl-CoA are condensed by a ketoacyl-CoA synthase or condensing enzyme; the resulting 3-ketoacyl-CoA is then reduced by the action of a 3-ketoacyl-CoA reductase, resulting in the synthesis of a 3-hydroxyacyl-CoA; the latter is transformed during a third step into an enoyl-CoA by a 3-hydroxyacyl-CoA dehydratase; finally, a second reduction catalyzed by (*E*) 2,3-enoyl-CoA reductase yields the elongated acyl-CoA. This scheme has recently been demonstrated in leaves using chemically synthesized intermediates (5).

Whereas the mechanism of elongation is now well characterized, the structure of the acyl-CoA elongases remains poorly understood because their membrane-bound nature has so far hindered most purification attempts. Nevertheless, several studies have provided important information. By using Triton X-100, acyl-CoA elongase complexes were successfully solubilized from various seeds (6–8). Moreover, zwitterionic detergents resulted in the solubilization of the sole condensing enzyme, indicating that the different activities may be catalyzed by independent proteins (9). Similarly, attempts to purify elongases from *Lunaria annua* seeds resulted in the

partial purification of only the first two enzyme activities (6). Finally, Créach *et al*. (10), in a preliminary work, reported the partial purification of the entire 18:1-CoA elongase from *Brassica napus* seeds.

Here we report biochemical studies of two intermediate reactions of the elongation process, i.e., those catalyzed by the 3-ketoacyl-CoA synthase and 3-hydroxyacyl-CoA dehydratase. We demonstrate that the 18:1-CoA elongase is a multienzymatic complex and that dehydratase is one of its components.

EXPERIMENTAL PROCEDURES

Plant material. HEAR plants (*B. napus* L.) were grown outdoors at INRA (Le Rheu, France). Seeds were collected 6 to 8 wk after flowering and stored at –80°C.

Chemicals. [2-^{14}C]Malonyl-CoA (2.1 GBq/mmol) was purchased from New England Nuclear (Boston, MA). (*R,S*) 3-Hydroxy-20:0-CoA, (*E*) 2,3 20:1-CoA, and (*R/S*) [1-^{14}C] 3-hydroxy-20:0-CoA (52 Ci/mol) were chemically synthesized as already described (11). All other chemicals were from Sigma Chemical Co. (St. Louis, MO).

3-Ketoacyl-CoA synthase (condensing enzyme) activity. Routinely 50 µg samples of proteins were incubated for 30 min at 30°C in the presence of 1 mM $MgCl_2$, 2 mM dithiothreitol (DTT), 9 µM [2-^{14}C]malonyl-CoA, and 30 µM acyl-CoAs in a final volume of 100 µL 0.08 M HEPES (pH 7.2). The reaction was stopped by addition of 0.8 mL of reductant buffer containing 5% (wt/vol) $NaBH_4$, 0.1 M K_2HPO_4, 0.4 M KCl, and 30% (vol/vol) tetrahydrofuran. The samples were vigorously shaken for 45 min at 37°C, the condensing products were extracted by 0.8 mL hexane, and the radioactivity was determined as reported previously (12).

Alternatively, 3-ketoacyl-CoA synthase activity was measured using the elongase assay in the absence of NADH and NADPH.

3-Hydroxyacyl-CoA dehydratase assay. Routinely, 50 µg samples of proteins were incubated for 1 h at 30°C in the presence of 1 mM $MgCl_2$, 2 mM DTT, and 11.5 µM (*R/S*) [1-^{14}C] 3-hydroxy-20:0-CoA (52 Ci/mol) in a final volume of 100 µL 0.08 M HEPES (pH 7.2). The reaction was stopped by addition of 100µL 5 N KOH in H_2O/CH_3OH (9:1,vol/vol), and saponified at 80°C for 1 h. After acidification with 100 µL 10 N H_2SO_4 containing 10% (wt/vol) malonic acid, the fatty acids were extracted and analyzed by high-performance thin-layer chromatography (HPTLC) on Merck silica gel 60F 254 plates (10 × 10 cm) eluted with hexane/diethyl ether/acetic acid (75:25:1, by vol). Under these conditions, the R_f of 3-OH fatty acids, straight-chain fatty acids (saturated or unsaturated), and methyl ketones were, respectively, 0.15, 0.7, and 0.9.

After autoradiography of the plates using DuPont NEF-485 films, the fatty acid bands corresponding to 3-hydroxy-20:0-CoAs and (*E*) 2,3-20:1-CoAs were scraped into vials, 100 µL water was added, and the radioactivity was measured using a Packard Tri Carb 2000CA liquid scintillation spectrometer. Activities were calculated as the difference between the percentage of conversion of [1-^{14}C] 3-hydroxy-20:0-CoA into (*E*) 2,3-20:1-CoA in the assay and the control (incubation time = 0) and were expressed as nmol (*E*) 2,3-20:1-CoA synthesized.

Acyl-CoA elongase assay. Routinely, 50 µg samples of proteins were incubated for 1 h at 30°C in the presence of 9 µM [2-^{14}C] malonyl-CoA, 0.5 mM NADH, 0.5 mM NADPH, 1 mM $MgCl_2$, 2 mM DTT, and 30 µM oleoyl-CoA in a final volume of 100 µL 0.08 M HEPES (pH 7.2) containing 0.02% (wt/vol) Triton X-100.

The reaction was stopped by addition of 100 µL 5 N KOH in H_2O/CH_3OH (9:1, vol/vol). The reaction mixture was saponified for 1 h at 80°C and then acidified with 100 µL 10 N H_2SO_4 containing 10% (wt/vol) malonic acid. The fatty acids were extracted with 2 mL of $CHCl_3$, washed with water (3 × 2 mL), and the radioactivity was determined. The acyl-CoA elongation was estimated as the radioactivity present in the total fatty acids.

Analysis of the reaction products. The fatty acids extracted from the elongase assay were alternatively analyzed by HPTLC using the same plates and solvent separation as in the dehydratase assay. After autoradiography of the plates using DuPont NEF-485 films, the different bands were scraped into vials, 100 µL water was added to each and the radioactivity was measured.

Preparation of the F15 fraction. The preparation of the F15 fraction was derived from the protocol published by Agrawal and Stumpf (13). Developing rapeseeds were ground with a mortar in a 0.08 M HEPES (pH 7.2) buffer containing 0.32 M sucrose, 10 mM β-mercaptoethanol, and 5% (wt/vol) polyvinylpyrrolidone. The homogenate was filtered through two layers of Miracloth and centrifuged successively at 300 × *g* (5 min) and 15,000 × *g* (25 min). The pellet from the latter centrifugation was resuspended in a 0.08 M HEPES (pH 7.2) buffer containing 10 mM β-mercaptoethanol and centrifuged again at 15,000 × *g* (25 min). The resulting pellet was resuspended in a 0.08 M HEPES (pH 7.2) buffer containing 0.32 M sucrose and 10 mM β-mercaptoethanol. This particulate fraction (F15) contained membranes from different cellular compartments and was used to characterize the condensing and dehydratase enzymes and to solubilize and purify the elongation complex.

Protein contents were determined using Bradford's method (14) with bovine serum albumin as standard.

Acyl-CoA elongase purification. Typically, 150 g of developing seeds were used per purification. The proteins of the F15 fraction (150 mg) were incubated at 4°C for 2 h with a Triton X-100 to protein ratio of 2.5 (w/w) (8). The mixture was centrifuged for 1 h at 100,000 × *g*, and after removal of the oil body-floating layer, the solubilized proteins contained in the supernatant were collected (fraction FS). FS was carefully loaded onto a palmitoyl-CoA agarose (Sigma) column (1.6 × 2 cm) which was previously equilibrated with buffer A [0.08 M HEPES (pH 7.0), Triton X-100 (0.02%, vol/vol), β-mercaptoethanol (10 mM), and ethyleneglycol (10%, vol/vol)]. After washing with the same buffer, the retained proteins were eluted with a 0–2 M NaCl gradient in buffer A. Fractions presenting the highest elongation activities were

pooled (fraction N16) and loaded on a Sephacryl S300 (Pharmacia, Uppsala, Sweden) column (1.6 × 63 cm) pre-equilibrated with buffer A. Elution was performed using a 0.25 mL/min flow rate; the fractions with the highest elongation activity were pooled (fraction S300) and loaded on a Q-Sepharose (Pharmacia) column (1.6 × 0.5 cm) previously equilibrated with buffer A. The column was washed and eluted with 1 M NaCl in the same buffer. The fractions having the highest activities were pooled and considered as the partially purified fraction (fraction Q-Seph).

Lipid stimulation. Fractions unretained on the palmitoyl-CoA agarose column (0–30 mL) were pooled and their lipids were extracted with chloroform/methanol (2:1, vol/vol). The solvent was evaporated, and the lipids were resuspended in 0.08 M HEPES (pH 7.0). Lipid analysis revealed that the major components were phospholipids, TAG, and Triton X-100 (data not shown). Usually, the proteins obtained from the different chromatographic steps were mixed with these lipids before the elongase reaction mixture was added.

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis. Protein samples were delipidated and precipitated with frozen acetone as already described by Bessoule *et al.* (15). The proteins were separated on 10% acrylamide gel using a vertical gel unit (model SE 440) from Hoefer Scientific Instrument. Fixation, staining, and destaining of the gels were carried out according to Laemmli (16).

Lipid analysis. Lipids were extracted with chloroform/methanol (2:1, vol/vol) and resolved by thin-layer chromatography. Neutral and polar lipids were separated using hexane/diethyl ether/acetic acid (90:15:2, by vol) and methyl acetate/*n*-propanol/$CHCl_3$/CH_3OH/0.1 M KCl (25:25:28:10:7, by vol), respectively. The different classes of lipids were visualized according to Macala *et al.* (17) and quantified by densitometry.

RESULTS AND DISCUSSION

Characterization of the 3-ketoacyl-CoA synthase. The specificity of the 3-ketoacyl-CoA synthase was assayed using the F15 fraction as enzyme source and different acyl-CoAs (Fig. 1A). In the presence of acyl-CoAs with 14 carbon atoms or fewer, no activity significantly different from the control (in the absence of exogenously added acyl-CoAs) was observed. Both 16:0-CoA and 16:1-CoA led to very low activities, and the highest 3-ketoacyl-CoA synthase activities were obtained in the presence of saturated and monounsaturated 18- or 20-acyl-CoAs. Surprisingly, the highest activities were measured using 18:0-CoA as the substrate, whereas the corresponding elongated product (20:0) is found only in traces in most *B. napus* seed oils. This apparent discrepancy can be explained by the fact that in plant cells, most of the 18:0-acyl carrier protein (ACP) is desaturated in the chloroplast to 18:1-ACP, which is then transformed into 18:1-CoA when entering the cytosol compartment. Owing to this *in vivo* compartmentalization, 18:0 is not accessible to the cytosolic membrane-bound elongases. Interestingly, 18:2-acyl-CoAs was a poor substrate of the condensing enzyme. These results suggest that acyl-CoA chain length seems to be the major factor, with unsaturation a secondary determinant in the specificity of 3-ketoacyl-CoA synthase. Similar results were reported for the condensing enzyme purified from jojoba (9). Finally, these results confirmed that the condensing enzyme determines the specificity of the acyl-CoA elongase demonstrated by Millar and Kunst (18).

3-Ketoacyl-CoA synthase and total elongation activities were studied as a function of time and substrate concentrations (Fig. 1B–D). The 3-ketoacyl-CoA synthesis was maximal after 15 min and remained stable or slightly decreased afterward, suggesting that condensation activity had stopped by 15 min (Fig. 1B). This may indicate that the accumulation of the reaction product of the condensing enzyme, i.e., 3-keto 20:1-CoA exerts a feedback inhibition on the enzyme. However, when NADPH and NADH were added, thereby allowing full elongation cycles to proceed, the label in fatty acids increased up to 90 min. 3-Ketoacyl-CoA synthase activity increased up to 30 µM malonyl-CoA and then plateaued, whereas the elongation increased up to 50 µM in the presence of the reducing coenzymes (Fig. 1C). The effects of oleoyl-CoA concentration on the condensation and elongation reaction were similar (Fig. 1D). Both reached maximal activity at 15–30 µM 18:1-CoA, and decreased at higher concentrations. This result could reflect an inhibition due to (i) an excess of substrate, (ii) the detergent effect of acyl-CoAs, or, most probably, (iii) the presence of enzymatic activities using the same substrate in the vicinity of the elongase as already described for leek epidermis elongases (19). Although it appeared that 3-ketoacyl-CoAs and VLCFA syntheses occurred at the same rate, the amount of 3-ketoacyl-CoAs neosynthesized was repeatedly lower than that of the VLCFA obtained after complete elongation cycles. This may indicate that the accumulation of the reaction products of the condensing enzyme, i.e., 3-ketoacyl-CoAs, exerts a feedback inhibition on this enzyme. Such an inhibition is not seen in the presence of reducing agents, thus allowing full elongation cycles to proceed. This situation has been described in *Cuphea lanceolata* where the accumulation of 3-ketoacyl-ACP retroinhibits 3-ketoacyl ACP synthase I (KAS I) (20). Fehling and Muhkerjee (4) have shown in *L. annua* that the kinetics of formation of very long chain 3-ketoacyl-CoAs and saturated acyl-CoAs are similar, therefore supporting the rate-limiting role of 3-ketoacyl-CoA synthase. Similarly, Millar and Kunst (18) showed that the accumulation and the nature of VLCFA are controlled by the 3-ketoacyl-CoA synthase. In conclusion, our data indicated that the condensing enzyme could be the rate-limiting step of the elongating process and that that 3-ketoacyl-CoAs could act as retroinhibitors.

Elongation of acyl-CoA intermediates. Elongation of (*R,S*) 3-OH-20:0-CoA and (*E*) 2,3-20:1-CoA was measured in standard conditions by incubation of 50 µg of proteins of F15 for 1 h at 30°C in the presence of 9 µM [2-^{14}C]malonyl-CoA, 1 mM $MgCl_2$, 2 mM DTT, and 30 µM of the different acyl-CoAs in a final volume of 100 µL 0.08 M HEPES (pH 7.2); the reaction stopped and activity estimated as reported in the Experimental Procedures section using the F15 fraction as the

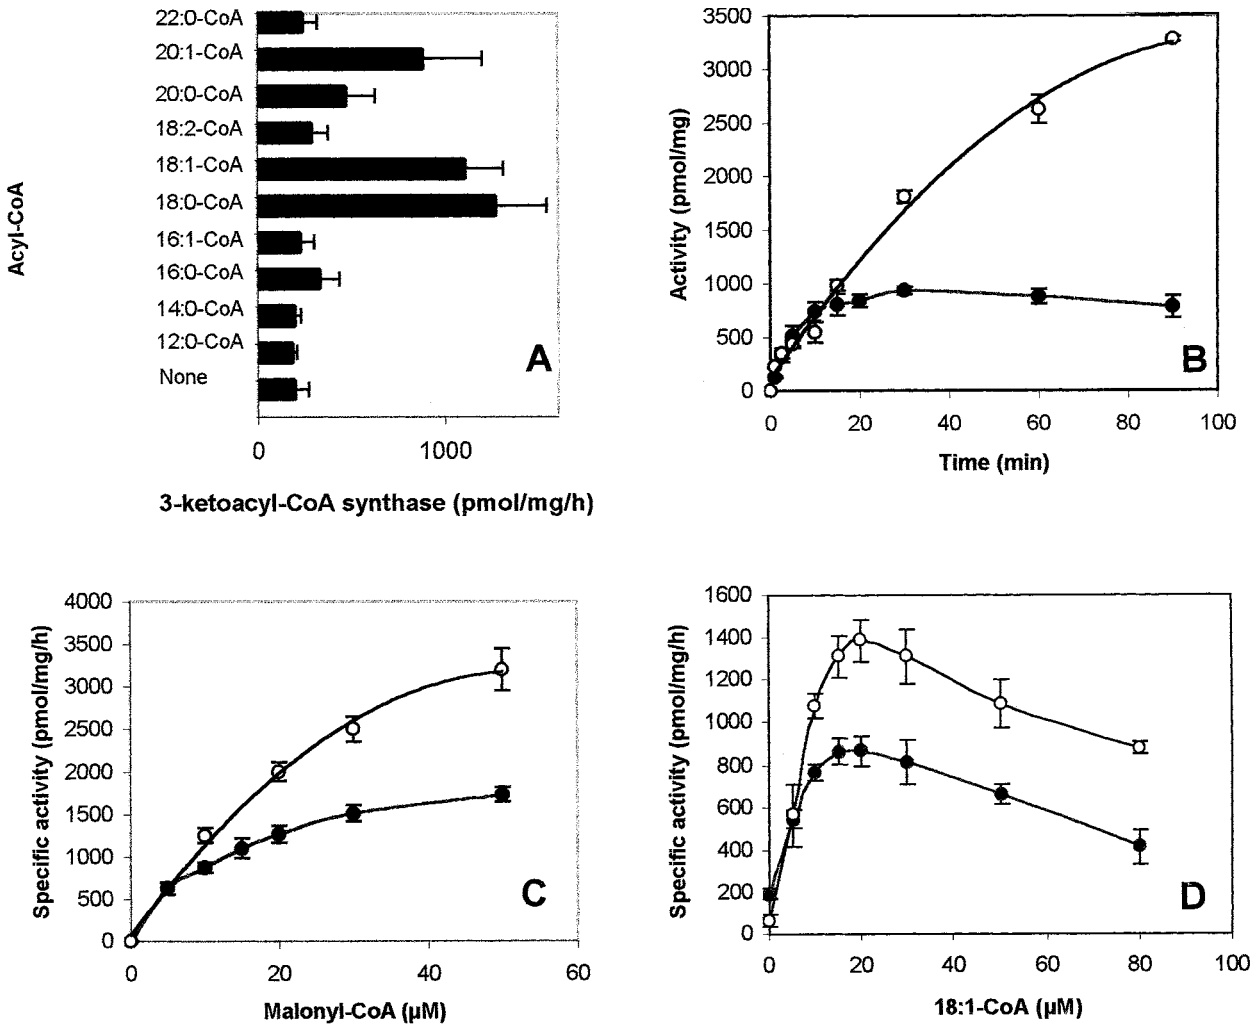

FIG. 1. Kinetic studies and specificity of condensing enzyme. (A) Condensation was measured by incubating 50 µg of proteins from fraction F15 for 30 min at 30°C in the presence 9 µM [2-^{14}C]malonyl-CoA, 1 mM $MgCl_2$, 2 mM dithiothreitol (DTT), and 30 µM acyl-CoA in a final volume of 100 µL 0.08 M HEPES (pH 7.2). The reaction was stopped and the condensing enzyme activity estimated as reported in the Experimental Procedures section. All results in this figure are expressed as mean values ± SD of three duplicate experiments. (B) Condensation (●) was measured by incubating at 30°C for various times 50 µg of proteins from F15 in the presence of 9 µM [2-^{14}C]malonyl-CoA, 1 mM $MgCl_2$, 2 mM DTT, and 30 µM oleoyl-CoA in a final volume of 100 µL 0.08 M HEPES (pH 7.2). Elongation (○) medium contained in addition 0.5 mM NADH and 0.5 mM NADPH. The reactions were stopped and the activities estimated as reported in the Experimental Procedures section. These results are expressed as mean value ± SD of three different experiments. (C) Condensation (●) and elongation (○) were measured as described in B but with an incubation time of 30 min and in the presence of increasing concentrations of [2-^{14}C] malonyl-CoA. These results are expressed as mean values ± SD of three duplicate experiments. (D) Condensation (●) and elongation (○) were measured as described in B but with an incubation time of 30 min and in the presence of increasing concentrations of oleoyl-CoA. These results are expressed as mean values ± SD of four duplicate experiments.

enzyme source. The control activity was determined using 20:0-CoA as substrate. VLCFA synthesis from 3-OH-20:0-CoA and (*E*) 2,3-20:1-CoA were 0.35 ± 0.07 and 0.37 ± 0.04 nmol/mg/h, respectively, and represented, respectively, 85 and 90% of that using 20:0-CoA as substrate (0.41± 0.03 nmol/mg/h; all results expresed as mean value ± SD of three duplicate experiments). Analysis of the reaction products showed that, irrespective of the nature of the substrate used, the label was exclusively associated with very long chain acyl-CoAs (data not shown). The absence of accumulation of intermediate products indicated that 3-OH-20:0-CoA and (*E*) 2,3-20:1-CoA entered the elongation cycle at their enzymatic sites, the dehydratase and second reductase, respectively. These intermediates were subsequently dehydrated and/or reduced during a first elongation before being condensed with [2-^{14}C]malonyl-CoA during a complete second elongation cycle (5). In good agreement with rapeseed oil composition and Figure 1A, 18:1-CoA led to the highest elongation activity (1.48 ± 0.18 nmol/mg/h).

Characterization of the 3-hydroxyacyl-CoA dehydratase. Since it was demonstrated in leek that the 3-hydroxy eicosanoyl-CoA dehydratase had a marked preference for the (*R*) 3-OH-20:0-CoA and that the inactive isomer was not inhibitory (11), dehydratase activity present in the F15 fraction was measured using the chemically synthesized [1-^{14}C] (*R,S*) 3-hydroxy-20:0-CoA. Dehydration activity was studied as a

function of the amount of protein from F15 (Fig. 2A). In the presence of 75 µM Triton, dehydration was maximal with 25 µg protein, whereas in the absence of detergent, no plateau was reached even in the presence of 90 µg protein. Time-course experiments showed that dehydration increased linearly for 15 min with a velocity of 0.45 nmol/mg/min in the presence of 75 µM Triton X-100. In the absence of detergent, dehydration velocity was only 0.05 nmol/mg/min (Fig. 2B). Altogether, these results showed that the presence of detergent induced a ninefold increase in the dehydratase activity, and it is required for maximal activity. As the dehydratase was shown to be deeply embedded within the membrane (21), it was hypothesized that Triton-X100 could improve the access of the substrate to the catalytic site.

Purification of the acyl-CoA elongase. The solubilization step allowed the recovery of 50% of the membrane proteins, while the 18:1-CoA elongation specific activity was nearly doubled and the dehydratase activity in FS was about one-fifth that in F15 (Table 1). Whereas untreated membrane synthesized mainly straight-chain acyl-CoAs, FS was unable to complete elongating cycles, and intermediates normally absent from the reaction mixture accumulated (about 80% of the total label, Table 2). In FS, 3-hydroxyacyl-CoAs were the major products of the reaction (Table 2), an observation that is in good agreement with the low dehydratase activity (Table 1).

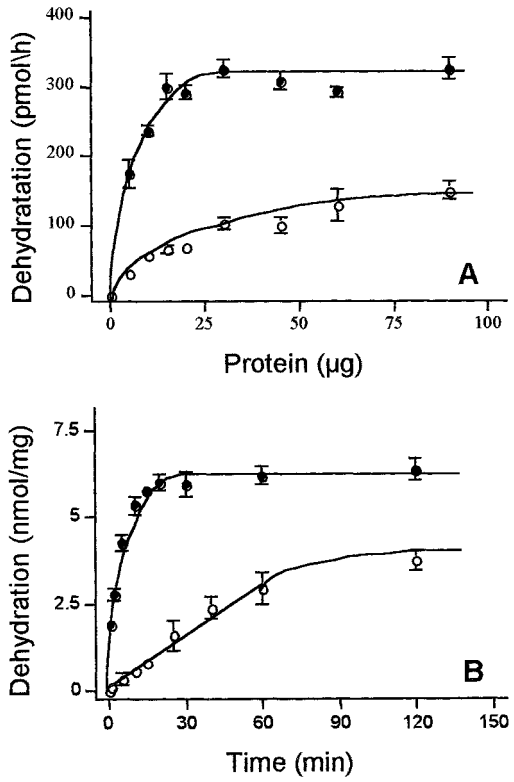

FIG. 2. Effect of Triton X-100 on dehydratase activity. (A) Dehydratase activity was measured by incubating at 30°C for 1 h different amounts of proteins from fraction F15 in the presence of 11.5 µM (*R/S*) [1-^{14}C] 3-hydroxyeicosanoyl-CoA (52 Ci/mol), 1 mM $MgCl_2$, and 2 mM DTT in a final volume of 100 µL 0.08 M HEPES (pH 7.2) buffer containing (●) or not containing (○) 75 µM Triton X-100. The fatty acids were extracted and dehydration was estimated as reported in the Experimental Procedures section. (B) Dehydratase activity was measured as in panel A but in the presence of 50 µg of proteins from F15 and over various incubation times in the presence (●) or absence (○) of 75 µM Triton X-100. Results in A and B are expressed as mean values ± SD of three duplicate experiments.

The best purification yields were obtained using the three successive chromatographic steps reported in Figure 3. FS was first subjected to affinity chromatography using a palmitoyl-CoA agarose column (Fig. 3A). Nonretained fractions contained high amounts of lipids and Triton X-100, but no elongation activity. Although some dehydratase activity was recovered in the nonretained fractions, 60% of the total activity was associated with the proteins bound to the palmitoyl-CoA agarose. These retained proteins were eluted as a single peak using a 0–1 M NaCl gradient. As shown in Figure 3A, the fractions constituting this peak contained both dehydratase and elongase activities, and they were accordingly pooled (fraction C16). Further analysis showed that this fraction contained a low lipid amount, as the lipid-to-protein ratio was four times lower in C16 than in FS (Table 2). 3-Hydroxyacyl-CoA dehydratase activity was increased threefold. This stimulation was probably due to the elimination of the excess of Triton X-100 present in FS. On the other hand, the elongase activity of N16 was one-tenth that of FS. In the presence of additional lipids, acyl-CoA elongation was stimulated threefold (Table 1), thereby demonstrating the importance of the lipid environment for these membrane-bound enzymes. Whereas straight chain acyl-CoA represented only 20% of the products synthesized in FS, they accounted for 96% in N16, in good agreement with the dehydratase activity being four times higher in N16 than in FS (Tables 1 and 2).

Figure 3B shows the elution profile obtained when N16 was loaded on a Sephacryl S300 column. The elongation and dehydration activities coeluted just after the void volume (fraction S300), indicating that the acyl-CoA elongase complex had an apparent molecular mass of 700 kDa in the presence of 0.02% (wt/vol) Triton X-100. This estimation is in good agreement with the presence of the entire elongating complex but should be taken with care, since the presence of Triton X-100 could introduce mis-estimations of molecular masses using gel filtration chromatography (22). This chromatographic step eliminated more than 90% of the proteins of N16 and lowered the lipid content. The lipid per protein ratio was one-third that of F15 (Table 2). The elongation (in the presence of lipids) and dehydration activities were increased respectively, by 12 and 3 times (Table 1). Surprisingly, 3-hydroxyacyl-CoAs accumulated although the 3-hydroxyacyl-CoA dehydratase activity was high.

The last step was a anion exchange chromatography (Fig. 3C). By using a 1 M NaCl concentration step, both activities eluted in a single peak, corresponding to the partially purified acyl-CoA elongase (fraction Q-Seph). When Q-Seph was analyzed for its lipid content, no lipid was detected (Table 2). Assuming that we were able to detect a minimum of 0.1 µg of lipid (23) and that the phospholipids-to-protein ratio was

TABLE 1
Purification of Acyl-CoA Elongase[a]

Fraction	Proteins (mg)	3-Hydroxy-acyl-CoA dehydratase (nmol/mg/h)	18:1-CoA elongase (nmol/mg/h)		Purification factor
			Control	+ Lipids (% stimulation)	
F15	142	5.01	0.46	0.67 (145)	1.0
FS	72	1.07	1.04	1.50 (144)	2.2
C16	13.9	4.25	0.09	0.26 (284)	0.4
S300	0.75	12.48	0.51	3.24 (635)	4.8
Q-Seph	0.35	3.19	0.38	3.39 (893)	5.0

[a]Protein contents were estimated using Bradford's method (Ref. 14) with bovine serum albumin as standard. The enzymatic activities were measured using 50 µL of each fraction as described in the Experimental Procedures section. The purification factor was calculated using the 18:1-CoA elongase activity in the presence of lipids.

0.27 in F15, the lipid-to-partially purified enzyme ratio could be estimated to be 0.0017. This value is at least 160-fold lower than that measured in the native membranes. Whereas neutral lipids were predominant in the F15, the phospholipid content increased during the purification process (Table 2). These results suggest that only the phospholipids strongly associated with the proteins remained after the final step. When compared to F15, the Q-Seph fraction contained 0.25% of the proteins, its elongation activity was five times higher, and its dehydratase activity was about 37% lower (Table 1). 3-Hydroxyacyl-CoAs were the major reaction products of the Q-Seph fraction, but the presence of 9% straight-chain acyl-CoAs [saturated acyl-CoAs and (*E*) 2,3-acyl-CoAs, Table 2] indicated that the partially purified fraction was able to catalyze at least the first three intermediate reactions of 18:1-CoA elongation. During each chromatographic step involved in the purification process, both elongase (condensing enzyme) and dehydratase activities co-eluted, suggesting that the 3-hydroxy dehydratase is one of the components of the partially purified oleoyl-CoA elongase.

SDS-PAGE analysis. Figure 4 shows the evolution of the protein composition of the different fractions during the purification procedure. The first chromatographic step eliminated the storage proteins (cruciferins and napins) which were present in F15 and FS (Fig. 4). The next ones led to an enrichment in four major polypeptide bands, whose apparent molecular masses were 56, 59, 61, and 63 kDa. Similar results were obtained in previous studies (6,15), and these results are compatible with the estimated molecular masses of the dehydratase (24) and of the 3-ketoacyl-CoA synthases (9,25,26). As a 700 kDa molecular mass was estimated for the entire elongating complex by filtration chromatography, it seems reasonable to suggest that the oleoyl-CoA from rapeseed is a multienzymatic complex composed of four different proteins. Each of the four polypeptide bands visualized after SDS-PAGE could correspond to one of the four enzyme activities that participate in the elongating process.

By assuming the latter hypothesis, SDS-PAGE analysis shows a higher purification factor as reported in Table 1. This discrepancy could be related to the presence of 91% 3-hydroxyacyl-CoA in the products synthesized by the purified fraction (Table 2). These products would inhibit the condensing enzyme and enable the elongase to complete its full cycle.

In summary, we have demonstrated that the acyl-CoA elongase from rapeseed is a multienzymatic complex and have characterized two of its constituents, the 3-ketoacyl-CoA synthase and the 3-hydroxyacyl-CoA dehydratase.

TABLE 2
Lipid Content and Elongation Products of Different Fractions Obtained During Purification Procedure[a]

Fractions	Lipid-to-protein ratio (a.u.)	Phospholipid content (%)	Elongation products		
			Straight-chain acyl-CoAs	3-Hydroxy-acyl-CoAs	3-Keto-acyl-CoAs
F15	1.00	19 ± 7	82	12	4
FS	1.77	25 ± 8	20	45	35
C16	0.42	33 ± 9	96	0	4
S300	0.32	55 ± 9	22	48	30
Q-Seph	ND	ND	9	91	0

[a]Lipids were extracted and analyzed as reported in the Experimental Procedures section. The lipid-to-protein ratio of F15 was normalized to 1. Elongation activities were assayed using 50 µL of each fraction, and the products were separated by thin-layer chromatography according to the Experimental Procedures section. ND, not detected; a.u., arbitrary units.

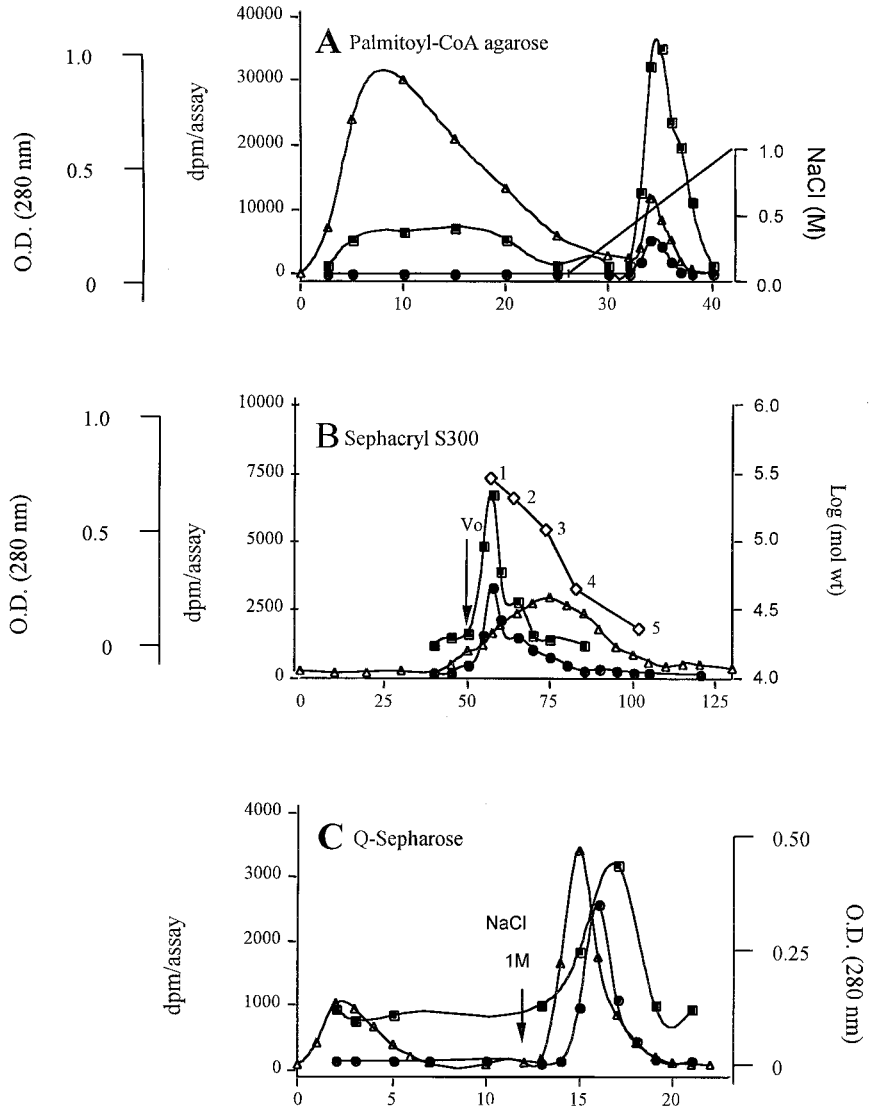

FIG. 3. Purification of acyl-CoA elongase. Symbols: (△) optical density (O.D.) (280nm), (●) elongation (dpm/assay), (■) dehydration (dpm/assay). (A) Palmitoyl-CoA agarose chromatography: Solubilized proteins (fraction FS) were applied on a palmitoyl-CoA agarose column previously equilibrated with a 0.08 M HEPES (pH 7.0) buffer containing Triton X-100 (0.02%, vol/vol), β-mercaptoethanol (10 mM), and ethylenglycol (10%, vol/vol). After washing with equilibration buffer, the elongation activity was eluted with a 0–2 M NaCl gradient in the same buffer. (B) Sephacryl S300 chromatography: Fractions eluted from the first column presenting the highest elongating activities were pooled (C16) and applied to a Sephacryl S300 column preequilibrated with the same buffer and using a 0.25 mL/min flow rate. Diamonds (◇) represent the molecular mass standards (mol wt): 1, thyroglobulin (670 kD); 2, ferritin (440 kD); 3, catalase (232 kD); 4, bovine serum albumin (66 kD); 5, α-chymotrypsinogen (28 kD). V_0 = void volume. (C) Q-Sepharose chromatography. Fractions eluted from the Sephacryl S300 column presenting the highest elongation activities were pooled (S300) and applied to a Q-Sepharose column that had been equilibrated with the same buffer. The column was washed and the activity eluted with a 1 M NaCl concentration step in the same buffer. The fractions having the highest activities were pooled and considered as the partially purified fraction (Q-Seph). Usually, elongation and dehydration activities were assayed using 50 µL of each fraction and according to the conditions described in the Experimental Procedures section.

Purification and Biochemical Characterization of a Novel Thermostable Lipase from *Aspergillus niger*

Variketta M. Haridasan Namboodiri[1] and Rajagopal Chattopadhyaya*

Department of Biochemistry, Bose Institute, Calcutta 700054, India

ABSTRACT: An extracellular 1,3-specific lipase with molecular weight of 35.5 kDa and an isoelectric point of 4.4 from *Aspergillus niger* has been purified 50-fold by pH precipitation followed by a series of chromatographic steps with an overall yield of 10%. The enzyme was homogeneous as judged by denaturing polyacrylamide gel electrophoresis and size-exclusion fast-performance liquid chromatography. It contained 2.8% sugar which was completely removed by endoglycosidase F treatment, and the deglycosylated enzyme retained full activity. The native lipase showed optimal activity between temperatures 35 and 55°C and pH 5.0 and 6.0. The amino acid composition and the N-terminal sequence were found to be different from lipases previously purified from *A. niger*. The enzyme was resistant to trypsin, chymotrypsin, endoprotease Glu-C, thrombin, and papain under native conditions but was susceptible to cleavage by the same proteases when heat-denatured.

Paper no. L8402 in *Lipids 35*, 495–502 (May 2000).

Lipases or triacylglycerol acylhydrolases (EC 3.1.1.3) are hydrolytic enzymes that catalyze reversibly the cleavage of ester bonds of triglycerides. Lipases are unique serine esterases whose catalytic activity is greatly enhanced at the lipid–water interface, a phenomenon known as "interfacial activation" (1–3). Lipases are widely distributed in animals, plants, and microorganisms (4,5). In particular, extracellular microbial lipases are regarded as important because of their potential use in biotechnology (6). Microbial lipases have been isolated, purified, and biochemically characterized from a variety of sources (5). The enzymes differ in their molecular weights, pH optima, pH and thermal stability, isoelectric points, and other biochemical properties (4,5,7).

Previous studies on the purification and biochemical characterization of fungal lipases showed one enzyme per organism (8–11). However, it was shown later that the same microbial species can secrete more than one lipase having different properties (5).

Abbreviations: BSA, bovine serum albumin; DMSO, dimethylsulfoxide; FPLC, fast-performance liquid chromatography; HPLC, high-performance liquid chromatography; PAS, periodate Schiff's stain; PITC, phenylisothiocyanate; PMSF, phenylmethylsulfonylfluoride; SDS-PAGE, polyacrylamide gel electrophoresis in sodium dodecyl sulfate; TCA, trichloroacetic acid; TLC, thin-layer chromatography.

The structures of many triacylglycerol lipases were determined by X-ray crystallography (12). All of them were found to have a similar molecular architecture with a central β-sheet and a catalytic triad consisting of serine, histidine, and a carboxylate group reminiscent of serine proteases (13).

As early as 1963, Fukumoto *et al.* reported the purification and partial characterization of a lipase from *Aspergillus niger* (9). However, its molecular weight was not reported. Tombs and Blake (14) published the purification of another lipase from a crude *Aspergillus* media concentrate obtained from commercial sources. Its molecular weight was found to be 47.8 kDa which on boiling fell to 33.8 kDa. Höfelmann (15) reported the purification of two lipases from *A. niger* with molecular weights of 31 and 19 kDa, respectively. Sugihara *et al.* (16) later reported in brief the purification of the same enzyme from the same source with a molecular weight of 35 kDa. Another acid-resistant *A. niger* lipase was reported (17) from a crude commercial preparation and was shown to be similar in biochemical properties to Sugihara's lipase.

Aspergillus niger lipase is being successfully used in traditional areas of food industry (6). Lipases with more stability and requiring improved reaction conditions for various chemical processes are required (6). Here we report the purification and characterization of a thermostable lipase from *A. niger* which was compared with previously reported lipases from the same fungus and was found to be different from them.

MATERIALS AND METHODS

Materials. The *A. niger* strain was a kind gift from Hindustan Lever Research Centre (Bombay, India). Phenyl agarose, Sephadex G75, Sephacryl HR100, corn steep liquor, protein markers, dialysis tubing, *N*, *N*, *N*′, N′-tetramethylene diamine, β-mercaptoethanol, phenylmethylsulfonylfluoride (PMSF), Coomassie brilliant blue G250, proteases, agar, ammonium persulfate, phenylisothiocyanate (PITC), triolein, 1,3-diglyceride, diolein (85% 1,3-isomer and 15% 1,2-isomer), monoolein, and sodium metabisulfite were obtained from Sigma Chemical Company (St. Louis, MO). Isoelectric focusing markers were obtained from Beckman (Fullerton, CA). The plates for thin-layer chromatography (TLC) (Kieselgel 60 WF_{254}s) were obtained from E. Merck (Darmstadt, Germany). Silver nitrate, gum acacia, isooctane, rho-

damine B, cupric acetate, calcium chloride, disodium hydrogen phosphate, magnesium sulfate, glycine, sodium dodecyl sulfate, ammonium sulfate, basic fuchsin, periodic acid, trifluoroacetic acid, trichloroacetic acid (TCA), dimethylsulfoxide (DMSO), EDTA, petroleum ether, diethyl ether, acetic acid, and 1,10-phenanthroline monohydrate were obtained from E. Merck (Calcutta, India) Ltd. Tris base, acrylamide, *N,N*-methylenebisacrylamide were obtained from Spectrochem Pvt. Ltd., (Bombay, India). Olive oil was purchased from commercial sources. Hydroxyapatite was prepared in the laboratory as described in Reference 18.

Isolation and purification. The *A. niger* strain was grown in a medium containing 0.1% $CaCl_2$, 0.1% Na_2HPO_4, 0.1% $MgSO_4$, 0.3% $NaNO_3$, 0.5% corn steep liquor, 3.0% olive oil, and 1.0% gum acacia. The pH of the medium was adjusted to 6.5 and the culture grown at 37°C for 48 h on a rotary shaker. The oil was homogenized by sonication at 300 W for 3 min. A 40-mL preculture grown for 24 h at 37°C was used to inoculate a 400-mL culture. Two liters of the media were distributed into five 1-L flasks and the cultures grown on a rotary shaker. After 48 h the cells were separated by cheesecloth filtration and the supernatant raised to pH 7.5 with 1 M NaOH. It was centrifuged at 18,000 × *g* for 20 min at 4°C and the precipitate discarded. The salt concentration of the resulting supernatant was raised to 2 M with solid $(NH_4)_2SO_4$ and charged into a phenyl agarose column (1.0 × 12.0 cm) equilibrated with 2 M $(NH_4)_2SO_4$ containing 5 mM phosphate buffer (pH 6.0). After washing the column with 300 mL of the same buffer, the bound proteins were eluted with 60 mL each of 1.9, 1.8, 1.7, 1.6, 1.5, 1.4, and 1.3 M $(NH_4)_2SO_4$. Finally, the column was eluted with 500 mL of 5 mM phosphate buffer. The final fraction was dialyzed overnight against 1 mM phosphate buffer (pH 6.0) and then loaded onto a hydroxyapatite column (1.0 × 9.0 cm) equilibrated with 1 mM phosphate buffer (pH 6.0). After washing with the same buffer, the bound proteins were eluted with 400 mL of 60 mM phosphate buffer. The eluant was concentrated roughly 50-fold in a rotary evaporator, dialyzed against water, then further concentrated to 2 mL and subsequently loaded on a Sephadex G75 column (45.0 × 1.5 cm) equilibrated with 25 mM acetate buffer (pH 5.6) at a flow rate of 12 mL/h. Active lipase fractions were pooled, concentrated, and loaded into a Sephacryl HR100 column (45.0 × 2.5 cm) equilibrated with 5 mM acetate buffer (pH 5.6) at a flow rate of 30 mL/h to get the pure lipase. All steps were performed in a 4°C cold room.

Measurement of lipase activity. Lipase activity was measured following two different assays. (i) Spectrophotometric assay: Lipase activity was measured spectrophotometrically by observing the color developed due to the liberated free fatty acids using copper acetate pyridine as the color-developing reagent (19). One unit of enzyme activity was defined as 1 μM of fatty acid liberated per minute. All assays were done by incubating the enzyme substrate mixture at 37°C for 30 min. Olive oil was used as the substrate, and the quantitation was done with a standard oleic acid curve. (ii) Plate assay: Qualitative assay to detect lipase during purification was done with rhodamine B agar diffusion assay with olive oil as the substrate (20) using 0.1% $CaCl_2$ instead of NaCl. Wells were filled with aliquots from fractions examined and incubated at 37°C. Orange fluorescence could be observed in lipase-containing fractions within 30 to 60 min under ultraviolet light.

Protein estimation. The dye-binding method of Bradford (21) was used to estimate the protein concentration. Bovine serum albumin (BSA) was used as the standard.

Polyacrylamide gel electrophoresis in sodium dodecyl sulfate (SDS-PAGE). All PAGE was performed with a Sigma mini gel apparatus (80 × 100 mm). A 12% SDS-PAGE (1.0 mm thickness) was performed as described by Laemmli (22). The molecular weight of the lipase was determined from the mobilities of known protein markers (Dalton Mark VII-L; Sigma). Nondenaturing electrophoresis was carried out with 12% gels with Tris-glycine buffer (pH 7.5). All the gels were silver-stained (23).

Isoelectric focusing. Isoelectric focusing was carried out on slab gels (80 × 100 mm) at 4°C with 5% polyacrylamide containing 2% Biolyte (3/10 ampholytes) according to the manufacturer's instructions (Bio-Rad Laboratories, Hercules, CA). RNase (pI 9.65), carbonic anhydrase (pI 5.90), and α-lactoglobulin (pI 5.10) were used as standards. Before loading the samples, prefocusing was done at 100 V for 30 min. The sample (25 μg) in each of two lanes and the standards were loaded in different lanes of the gel. Focusing was then carried out in a stepped fashion (200 V for 1 h, 300 V for 1 h, and then finally 400 V for 16 h). The portion of the gel excepting one extreme sample lane was washed with 20% TCA and then silver-stained. To check whether the band was that of lipase, the remaining gel portion was excised at the position corresponding to the lipase in the stained gel and placed on rhodamine B plates overnight for orange fluorescence.

Amino acid analysis. The purified lipase was extensively dialyzed against water before amino acid analysis. Of the sample, 25 μg was hydrolyzed with 6 N HCl for 24 h at 110°C in a nitrogen atmosphere followed by derivatization with PITC and run through a Pico-Tag high-performance liquid chromatography (HPLC) column (amino acid analysis system; Millipore Corporation, Waters Chromatographic Division, Bedford, MA) according to the manufacturer's instructions. Peaks were identified by comparing the retention times with those of known standards obtained from Sigma Chemicals.

N-Terminal sequence analysis. Of the purified lipase, 88 pmol was loaded on a biobrene-equilibrated glass fiber disk and N-terminal sequence analysis performed by automated Edman degradation using instrumentation, reagents, and protocols from Perkin Elmer (Rotkreuz, Switzerland). A model 476A gas phase sequencer equipped with an online 120A PTH analyzer and a 610A control/data analysis module was employed.

Molecular weight and Stokes' radius by size-exclusion fast-performance liquid chromatography (FPLC). The molecular weight and Stokes' radius of the native enzyme were determined by size-exclusion FPLC using a Superose 12 col-

umn (30.0 × 1.0 cm) obtained from Pharmacia Biotech (Uppsala, Sweden). The elution was carried out with 25 mM acetate buffer (pH 5.6) at a flow rate of 60 mL/h. BSA (66 kDa), egg ovalbumin (42.7 kDa), β-lactoglobulin (36.8 kDa), carbonic anhydrase (29 kDa), and bovine α-lactalbumin (14 kDa) were used as standards. Blue dextran and tryptophan were used to determine V_o, the void volume, and V_t, the total volume, respectively. The distribution coefficient K_d was calculated for each protein and was plotted against logarithm of molecular weight. From the plot, the molecular weight of the unknown lipase was determined. The Stokes' radius was also determined with the help of a calibration plot of $1000/V_e$ against the Stokes' radius of the standards (BSA: 33.9 Å, ovalbumin: 28.7 Å, carbonic anhydrase: 24.4 Å, and bovine α-lactalbumin: 20.4 Å), V_e being the measured elution volume for each protein.

Temperature and pH effects on lipase activity. The optimal temperature for activity was determined quantitatively after incubating the enzyme substrate mixture at temperatures ranging from 20 to 75°C for 30 min. Residual activity was calculated by taking the activity at 37°C as 100%. In a second set of experiments, the temperature stability was determined by preincubating the enzyme for 60 min at temperatures ranging between 20 and 75°C and then measuring the remaining activity at 37°C after adding the substrate. Residual activity was calculated by taking the activity at 37°C as 100%.

The optimal pH for enzyme activity was measured by incubating the enzyme substrate mixture at pH values ranging from 3.0 to 9.5 for 30 min at 37°C. Residual activity at various pH was calculated by taking the activity at pH 6.0 at 37°C as 100%. In another set of experiments, the pH stability was determined by incubating the enzyme in buffers from pH 3.0 to 10.0 for 60 min at 37°C. Residual activity was expressed by taking the activity at pH 6.0 as 100%. The different buffers used were citrate (pH 3.0), acetate (pH 3.5 to 5.5), phosphate (pH 6.0 to 8.0), Tris (pH 8.5 to 9.0), and glycine-NaOH (pH 9.5 to 10.0).

Effect of various chemicals on lipase activity. The effect of various salts at concentrations ranging from 10 mM to 1.0 M on the enzyme activity was checked. The reaction mixture was incubated at 37°C for 30 min and the residual activity determined quantitatively with respect to a control.

Sugar content analysis. The sugar content was determined by quantification on an SDS gel stained with periodate Schiff's stain (PAS) (24) using a gel documentation system (Gel Doc 1000; Bio-Rad Laboratories). Schiff's reagent was prepared as described in (25). Egg ovalbumin was used as the standard. As an alternative, the purified lipase was treated with endoglycosidase F (*Flavobacterium meningosepticum)* for 24 and 48 h, and the shift in mobility was observed by SDS-PAGE relative to the untreated lipase. The extent of carbohydrate removed was also checked by staining the gel with periodic acid Schiff's reagent.

Positional specificity. To determine the positional specificity of the *A. niger* lipase, the products were analyzed by TLC (26). The substrates, lipid standard [mono-, di-(85% 1,3-isomer and 15% 1,2- isomer) and triglyceride], 1,3-diglyceride (1,3-diolein), diolein (85% 1,3-isomer and 15% 1,2-isomer) and monoolein (1 monooleoyl-*rac*-glycerol) were emulsified by sonication in 0.2 M phosphate buffer (pH 6.0) containing 1% (wt/vol) gum acacia. The enzyme (10 μL of 1.2 mg/mL stock diluted to 50 μL) was added to each substrate emulsion in buffer (450 μL of emulsion prepared at the following concentrations: lipid standard mixture at 100 mg/mL; 1,3-diacylglycerol at 5 mg/mL; diolein at 50 mg/mL; or monoolein at 25 mg/mL) and incubated at 37°C for 30 min. Water was substituted for the enzyme in the respective blanks. All the mixtures were spotted on TLC plates (Kieselgel 60 WF_{254}s; E. Merck) and developed in two solvents, one after the other: solvent 1, petroleum ether/diethyl ether/acetic acid (70:30:1, by vol), and solvent 2: petroleum ether/diethyl ether (95:5, vol/vol). Plates were stained by iodine vapors.

Protease digestion. The action of typsin, chymotrypsin, and endoproteinase Glu-C, type XVII (*Staphylococcus aureus,* strain VB) on the native lipase was checked. The protein was initially dialyzed against 10 mM $NaHCO_3$ buffer (pH 8.7) and then evaporated to dryness. It was redissolved in 0.4 M $NaHCO_3$ (pH 8.7) to a final concentration of 1.6 mg/mL for trypsin and chymotrypsin digestions and 0.4 M acetate (pH 4.7) for endoproteinase Glu-C in an enzyme to substrate ratio of 1:40. The substrate was incubated with the proteases for 4, 8, 16, and 24 h at 37°C. The reaction was stopped by the addition of 30 mM PMSF in DMSO and immediately subjected to 20% SDS-PAGE. Also, the lipase was heat-denatured by boiling for 60 min, cooled, and separately treated with trypsin, chymotrypsin, papain, and thrombin for 24 h at 37°C. The conditions for reaction with papain and thrombin were similar to those for trypsin and chymotrypsin. The papain digest was stopped by adding Koshland reagent [(2-bromoacetamido)-4-nitrobenzene] to a final concentration of 4 mM while the thrombin reaction was terminated by adding PMSF to a final concentration of 3 mM. Fragments were checked on a 15% SDS-PAGE. In yet another experiment, the heat-denatured lipase was separately treated with trypsin, chymotrypsin, papain, thrombin, and endoproteinase Glu-C for 6 h at 37°C, and the fragments were purified on a preparative scale by reverse-phase HPLC on an Econosphere C18 5U column (250 × 4.6 mm; Alltech Associates Inc, Deerfield, IL). The fragments were eluted with solvent A (0.1% TFA in water) and solvent B [acetonitrile/water, 60:40 (vol/vol)] at a flow rate of 0.5 mL/min using the following gradient: 0–5 min: 0% B, 100% A; 5–45 min: 0–45% B; 45–100 min: 45–55% B; 100–145 min: 55–100% B; 145–150 min: 100% B; 150–155 min: 0% B.

RESULTS

Lipase purification. Similar activity was obtained when the fermentation was carried out at 30°C for 72 h or at 37°C for 48 h. Olive oil was used not only as an inducer but also as the major carbon source. No lipase was produced without the oil. The results of the purification protocol are shown in Table 1.

TABLE 1
Purification Table of Lipase

Step	Total activity (units)	Total protein (mg)	Specific activity (units/mg)	Yield (%)	Purification factor
Crude extract	1,200	286	4.2	100	1
pH Precipitation	1,200	156	7.7	100	1.8
Phenyl agarose	700	19.3	36.3	58.3	8.6
Hydroxyapatite	794	14.7	54	66.1	12.8
Sephadex G-75	322	2.17	148.4	26.8	35.3
Sephacryl HR 100	122	0.586	208.2	10.1	49.5

As seen from the table, the first pH precipitation step not only resulted in the removal of about 45% protein but also helped in cleaning up the medium of free fatty acids which formed the corresponding soap with NaOH. The active lipase fraction was eluted from the phenyl agarose column with a 5 mM phosphate buffer (pH 6.0) hold to speed up the elution. For the same reason elution from the hydroxyapatite column was performed with a 60 mM phosphate buffer (pH 6.0) hold instead of a gradient. The activity was found to be stable after the hydroxyapatite step. The final purified protein after Sephacryl HR 100 chromatography was homogeneous, and the elution pattern is shown in Figure 1. The purification process at different stages is shown in Figure 2. A single band was also obtained by gel electrophoresis under nondenaturing conditions (results not shown). The scheme resulted in a 50-fold purification and an overall yield of 10%. The purified lipase gave a band corresponding to 35.5 kDa in SDS-PAGE. Isoelectric focusing gave a pI of 4.4 (Fig. 3). An adjacent lane band when cut and placed on the rhodamine B plate gave an orange fluorescence, confirming that the purified protein is the lipase (results not shown).

Amino acid analysis and N-terminal sequence. The results of the amino acid analysis are shown in Table 2. The acidic amino acids (Asx and Glx) accounted for 27.1% of the total residues, while the hydrophobic residues constituted 29.1%.

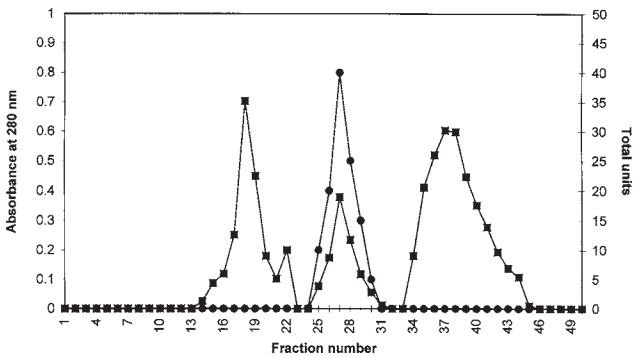

FIG. 1. Elution profile from Sephacryl HR 100. Fractions were assayed for protein content (-■-) and for lipase activity (-●-). Fractions were initially checked for lipase activity by the rhodamine B plate assay. Fractions showing orange fluorescence were then quantitated for lipase activity by the copper acetate pyridine method. Two-milliliter fractions were collected. The void volume was found to be 75 ml.

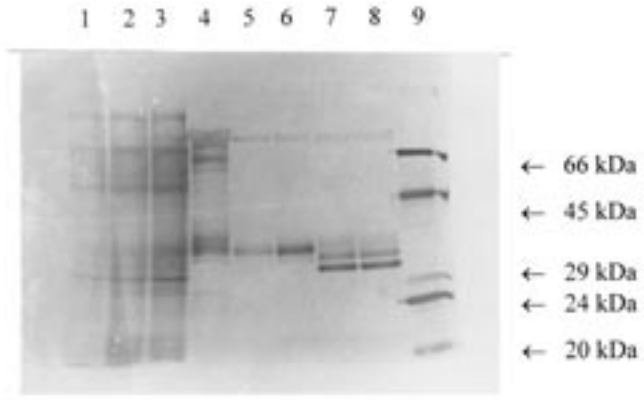

FIG. 2. Sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE) at different stages of purification. The purification at each step was monitored by SDS-PAGE (12.5%) with silver staining. Lane 1: supernatant after pH precipitation, Lane 2: fraction after phenyl agarose chromatography, Lane 3: fraction after hydroxyapatite chromatography, Lane 4: pooled fraction after Sephadex G75 chromatography, Lane 5: purified lipase after Sephacryl HR 100 chromatography, Lane 6: purified lipase (unboiled), Lane 7: purified lipase after glycosidase treatment (24 h), Lane 8: purified lipase after glycosidase treatment (48 h), Lane 9: molecular weight standards.

Glycine residue was also abundant (10.08%). The high percentage of acidic amino acids (Asp and Glu) gives the molecule a net negative charge in conformation with the pI value and is estimated to be greater than 13.59%, the total for the positively charged residues (Arg, Lys, and His). The N-terminal amino acid sequence is given below:

NH_2-Ala-Val-Leu-Asp-Phe-Trp-Leu-Asp-Asn-Leu-
Gln-Leu-Phe-Ala-Gln-Trp-Ala-Ile-Leu-Ala-

Molecular weight and Stokes' radius. The molecular weight of the native lipase by size-exclusion FPLC was calculated to be 35.5 kDa. The Stokes' radius was calculated to be 27 Å.

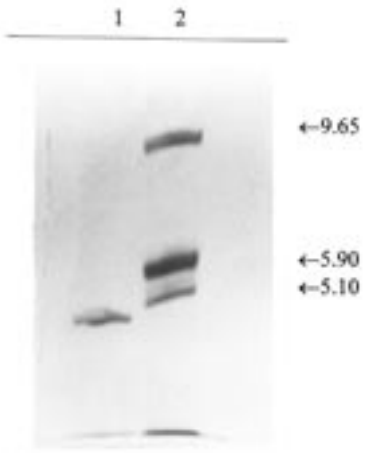

FIG. 3. Isoelectric focusing. Isoelectric focusing was carried out with 5% polyacrylamide containing 2% ampholyte (pH 3.0 to 10.0). The gel was washed with 20% trichloroacetic acid and then silver-stained. Lane 1: purified lipase, Lane 2: pI standards.

TABLE 2
Amino Acid Composition of Lipase

Amino acid	Mole percentage
Asx	8.27
Glx	18.84
Ser	8.00
Gly	10.08
His	2.86
Arg	7.26
Thr	9.00
Ala	3.00
Pro	6.57
Tyr	2.39
Val	5.35
Met	1.96
Cys	0.70
Ile	2.50
Leu	6.16
Phe	3.47
Lys	3.47

*Optimal activity and thermal stability***.** As seen from Figure 4A**,** the optimal activity for lipase was found to be in the temperature range 35 to 55°C. As seen in Figure 4B, the enzyme was stable for 60 min till 50°C beyond which the activity started falling. At 60°C it retained about 50% of the original activity (Fig. 4B).

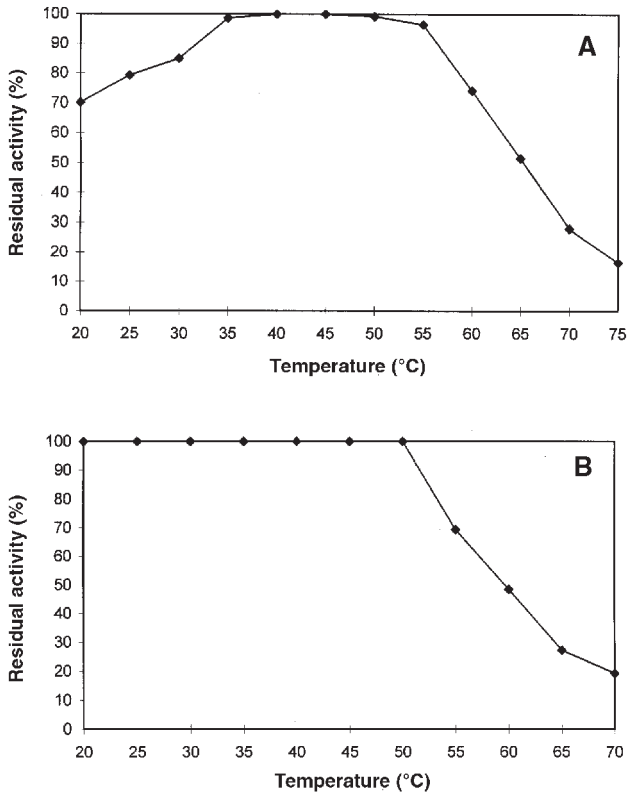

FIG. 4. Thermal activity of purified lipase. The optimal thermal activity and thermal stability of the purified lipase were quantitatively determined. (A) The optimal temperature for activity was measured quantitatively after incubating the enzyme substrate mixture at various temperatures. (B) The thermal stability was determined by incubating the enzyme alone for 60 min at a given temperature and then measuring the residual activity at 37°C. In both the cases the residual activity was calculated by taking the activity at 37°C as 100%.

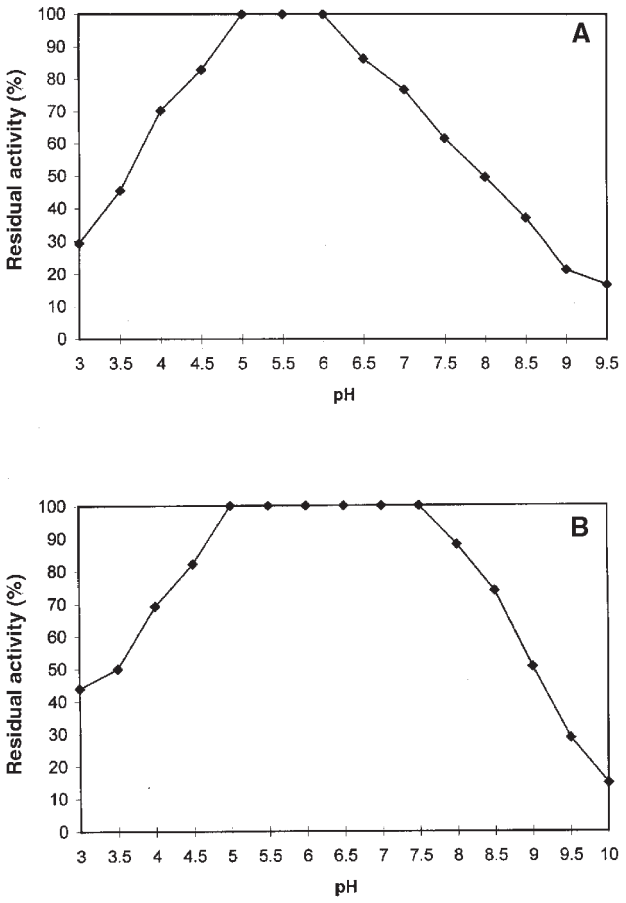

FIG. 5. pH effects of purified lipase. The optimal pH for lipase activity and the pH stability of the purified lipase were determined quantitatively. (A) The optimal pH for enzyme activity was measured by incubating the enzyme substrate mixture at pH ranging from 3.0 to 9.0 for 30 min at 37°C. (B) The pH stability was determined by incubating the enzyme alone in buffers (pH 3.0 to 10.0) for 60 min at 37°C and then by measuring the residual activity. The residual activity were calculated by taking the activity at pH 6.0 as 100%.

Optimal pH and pH stability. The optimal pH for lipase activity was found to be in the range 5.0 to 6.0 in phosphate buffer (Fig. 5A). As seen from Figure 5B, the enzyme was active in the pH range 5.0 to 7.5. Below pH 5.0 and above pH 7.5, there was a gradual loss in activity. (Fig. 5B).

Effect of various salts. Lipase activity was not found to be affected by Mg^{2+}, K^{+}, Na^{+}, Ca^{2+}, Mn^{2+}, NH_4^{+}, and Zn^{2+} up to 1.0 M, whereas strong inhibition was observed for Fe^{2+} (30% residual activity), Fe^{3+} (25% residual), and Cu^{2+} (40% residual) at 50 mM concentrations.

Carbohydrate content. The sugar content of the lipase was found to be 2.8% by densitometric scanning of the PAS-stained gel. After the protein was treated with endoglycosidase F, there was a small shift in the molecular weight as analyzed by gel electrophoresis (Fig. 2, lanes 7, 8). Their molecular weights correspond to about 34 and 32 kDa, respectively.

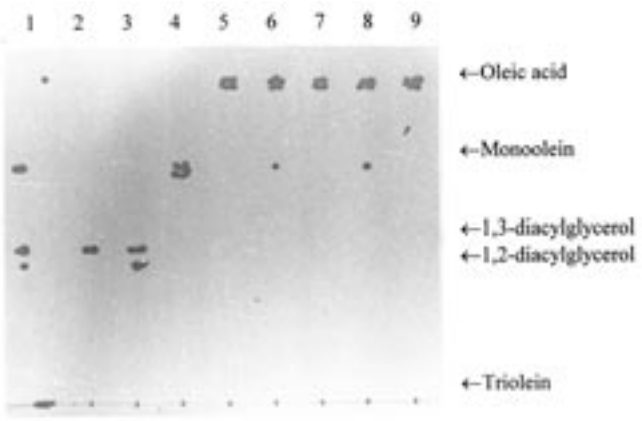

FIG. 6. Thin-layer chromatography (TLC) to determine the positional specificity of lipase. The substrates lipid standard (mixture of triolein, diolein, and monoolein), 1,3-diacylglycerol, diolein (85% 1,3-isomer and 15% 1,2-isomer), and 1-monooleoyl-*rac*-glycerol were emulsified by sonication in 0.2 M phosphate buffer (pH 6.0). Purified lipase was added to each of them separately and allowed to react at 37°C for 30 min. The products were analyzed by spotting 5–20 μL on TLC plates and developed in a solvent containing petroleum ether/diethyl ether/acetic acid (70:30:1, by vol), followed by another solvent containing petroleum ether/diethyl ether (95:5, vol/vol). The spots were identified after staining with iodine vapors. Lane 1: lipid standard, Lane 2: 1,3-diglyceride, Lane 3: diolein, Lane 4: monoolein, Lane 5: oleic acid, Lanes 6–9: reaction products after treating lipase with lipid standard, 1,3-diacylglycerol, diolein and 1-monooleoyl-*rac*-glycerol, respectively. That 2-monoolein derived from the 1,2-diolein is resistant to this lipase is evident from the 2-monoolein spots in lanes 6 and 8.

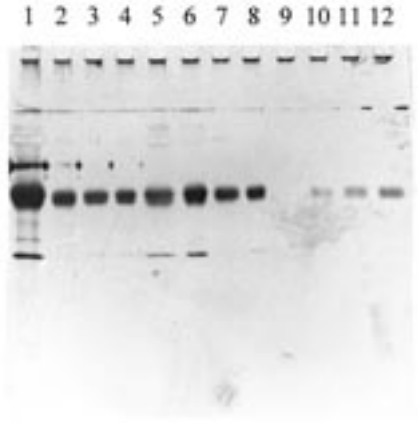

FIG. 7. SDS-PAGE of native lipase treated with proteases. The purified lipase was treated with trypsin, chymotrypsin, and endoproteinase Glu-C for 4, 8, 16, and 24 h. The samples were then analyzed in a 20% SDS-PAGE and the fragments detected by silver staining. Lane 1: untreated lipase, Lanes 2–5: lipase treated with trypsin for 4, 8, 16, and 24 h, respectively, Lanes 6–9: Lipase treated with chymotrypsin for 4, 8, 16, and 24 h, respectively, Lanes 10–12: lipase treated with Glu-C for 4, 8, 16 h, respectively. See Figure 2 for abbreviation.

We believe that the higher molecular weight species is the intact lipase without the sugar while the lower molecular weight species is a proteolytically cleaved fragment of the lipase, as it is reported that the purest forms of commercially available endoglycosidases have a metalloprotease as an impurity (29). We tried to inhibit this metalloprotease activity by adding EDTA and 1,10-phenanthroline to the digestion mixture. While 1 and 50 mM EDTA were ineffective in inhibiting the protease action, phenanthroline at 10 and 30 mM concentration was able to inhibit the protease activity to a large extent as the intensity of the lower molecular weight species was greatly reduced at the corresponding position. There was no change in the mobility of the 24 and 48 h glycosidase-treated sample, indicating complete removal of the carbohydrate moiety within 24 h (Fig. 2, lanes 7, 8). Moreover, when the glycosidase-treated samples were PAS-stained, no band was visible either for the 24 or the 48 h sample, indicating complete removal of the sugar after 24 h (results not shown). We obtained similar results when the enzyme was incubated with the glycosidase for just 2 h (results not shown).

Positional specificity. The stained TLC plate indicated that this lipase conventionally cleaves the ester bonds at the 1- and 3-positions of the triacylglycerol molecule (Fig. 6).

Protease digestion. Figure 7 shows the native lipase when treated with different proteases for different time intervals. It is evident that the tested proteases had no effect on native lipase. When the enzyme was heat-denatured by boiling at 100°C and then protease-treated for 24 h, no fragments could be detected by gel electrophoresis (results not shown). However, when the reactions were terminated after 6 h, there was restricted digestion, and the various fragments could be purified by reverse-phase HPLC (not shown).

DISCUSSION

We successfully purified a new extracellular lipase from *A. niger* involving various chromatographic steps to obtain a 50-fold purification. The molecular weight of this lipase was 35.5 kDa by SDS-PAGE and size-exclusion FPLC. There was no change in the electrophoretic mobility on boiling the pure lipase (Fig. 2, lane 5) as observed by Tombs and Blake (14). The isoelectric point was 4.4, whereas Sugihara *et al.* (16) and Torossian and Bell (17) reported a pI of 4.1 and 4.0, respectively. The purified lipase was stable for at least 8 wk when stored in 50 mM acetate buffer (pH 5.6) at 4°C.

The amino acid composition of our lipase shows a high percentage of Glx, Gly, Thr, Asx, and Ser with Thr in excess over Ser residues. In contrast the lipase of Torossian and Bell (17) and Tombs and Blake (14) contains Ser in far excess over Thr residues. As seen for other lipases there is no high hydrophobic residue content although the natural substrates of the enzyme are hydrophobic. The N-terminal amino acid sequence of our lipase is completely different from those determined by Sugihara *et al*. (16) and Torossian and Bell (17). This suggests that our lipase is novel.

The optimal thermal activity of this lipase was within the temperature range 35 to 55°C at pH 6.0, while Sugihara's enzyme had a temperature optimum of 30°C at pH 5.0 (16). The lipase purified by Tombs and Blake, was stable up to 55°C (14) while Sugihara's lipase was stable up to 65°C for 30 min

though further details were not given (16). The thermal stability profile of this lipase is given in Figure 4B.

This lipase had a pH optimum between pH 5.0 and 6.0 (Fig. 5A). Sugihara's lipase was stated to be stable between pH range 3.0 to 10.5 without further details (16). This enzyme was stable until pH 7.5. At pH 10.0, about 20% of the original activity remained (Fig. 5B).

Salt effects on activity were previously reported for *Geotrichum candidum* (7), *Penicillium simplicissimum* (26), and *Rhizopus delemar* (27) lipases as well as with another *Aspergillus* lipase (16). While these studies were conducted with millimolar salt concentrations, the present lipase was examined up to 1 M for various salts. Unlike the *R. delemar* lipase, which was inhibited by monovalent salts (27), the present lipase was not inhibited. Like the lipase of Sugihara *et al.* (16), the present lipase was inhibited by Fe^{2+} though not by Zn^{2+}. Some divalent cations like Mg^{2+}, Ca^{2+}, and Mn^{2+} also did not affect activity of the present lipase.

The carbohydrate content of fungal lipases varies from as low as 0.5% (27) to as high as 10% (28). *Aspergillus niger* lipase has been shown to contain about 7% sugar (16). In contrast, our lipase had only 2.8% oligosaccharide. The endoglycosidase F-treated enzyme resulted in the removal of all the sugar. Hence, it can be concluded that the sugars attached to the protein are exclusively Asn-linked (29). Moreover, there was no loss of enzyme activity after sugar removal.

The structure of our lipase seems to be quite compact in the native form as evident from the protease digestion experiments (Fig. 7). Another *A. niger* lipase was also shown to be trypsin- and chymotrypsin-resistant (14). Once heat-denatured, our lipase was susceptible to protease cleavage: a 24-h incubation led to complete digestion, and restricted digestion for 6 h did yield fragments detectable by HPLC.

The commercial exploitation of lipases in particular has traditionally been hampered by their inadequate stability and the limitations imposed by reaction conditions (neutral buffers, moderate temperature and pH stability, and so on) (6). However, the recent developments in biocatalysis in unconventional media, especially organic solvents (30), transformed the industrial perception of enzymes as very delicate catalysts, generally unsuitable for large-scale chemical synthesis. Most of the commercially available detergents have proteases as additives (31). The resistance of our enzyme toward proteases is another property which may be of industrial importance as there is a growing interest to engineer lipases to be protease-resistant for use in detergents. (31). The lipase purified by us may be suitable for some of the above biotransformations.

ACKNOWLEDGMENTS

This work was funded by the Council of Scientific and Industrial Research (CSIR), Government of India, Scheme No: 37(0870)/94/EMR-II. We thank Hindustan Lever Research Centre, Bombay for the *A. niger* strain, V.M.H.N. acknowledges a research fellowship from the Bose Institute and the Department of Microbiology for use of their various facilities.

Laboratory of Biochemistry, Department of Health Technology, School of Health Sciences, Faculty of Medicine, University of the Ryukyus, Okinawa 903-0215, Japan

ABSTRACT: The effects of exogenous oxidative stress due to passive smoking on cholesteryl ester (CE)-metabolizing enzymes and their regulatory kinases were examined by exposing rats to cigarette smoke (CS) for a 1-h period twice a day for 8, 12, or 20 wk. An oxidatively modified low density lipoprotein (Ox-LDL) with a high lipid peroxide was identified in three CS groups after all three exposure periods. The rat aortic acid and neutral CE hydrolases (ACEH and NCEH) were activated to similar extents by both cAMP-dependent protein kinase (PKA) and protein kinase C (PKC) in the presence of their respective cofactors. The aortic PKC activity in the three CS groups exhibited significant reductions of 72, 84, and 75% as compared with the respective controls, which coincided with the reductions in the ACEH activities (86, 71, and 80%, respectively), whereas the PKA activities increased to 121, 197, and 252% in the three CS groups, respectively. Reflecting the increase of the PKA activity, the NCEH activity exhibited increases of 112% at 8 wk and 140% until 12 wk of exposure and decreased by 50% of the control value at 20 wk of exposure, suggesting inactivation of NCEH itself. The activation of acyl-CoA:cholesterol *O*-acyltransferase activity was associated with an increase of free cholesterol in aorta. The vitamin E diet prevented the formation of Ox-LDL and the oxidative inactivation of most enzymes, especially PKC, until 12 wk, but was less effective by 20 wk. The oxidative inactivation of PKC, particularly its activated form that translocated to the membrane fraction, was confirmed in the *in vitro* exposure to active oxygen generators at an optimal concentration; this inactivation was prevented by catalase and superoxide dismutase. These results suggested that the formation of Ox-LDL and alterations in CE-metabolizing enzymes caused by passive smoking could contribute to a twofold increase in the aortic CE content, thereby contributing to one of the mechanisms for atherosclerosis associated with smoking.

Paper no. L8351 in *Lipids 35,* 503–511 (May 2000).

Accumulation of cholesteryl esters (CE) in atherosclerotic lesions could result from a variety of metabolic disturbances, including an increased influx of low density lipoprotein (LDL) cholesterol into the cells *via* the formation of oxidized LDL (Ox-LDL), imbalances between cholesterol esterification and hydrolysis, or imbalances between synthesis of cholesterol and its efflux from the cells, perhaps mediated by reduced concentrations of high density lipoprotein. The key enzymes in cholesterol metabolism as well as their regulatory enzymes in the signal transduction system may play important roles in the accumulation of CE in the arterial wall. The short-term regulation of cholesteryl ester hydrolases (CEH; EC 3.1.1.13) by reversible phosphorylation in the coordinated control of other key enzymes in cholesterol metabolism, such as 3-hydroxy-3-methylglutaryl-CoA (EC 1.1.1.34), cholesterol 7α-hydroxylase (EC 1.14.13.7) and acyl-CoA:cholesterol *O*-acyltransferase (ACAT; EC 2.3.1.26), has been well-characterized in many cell types including adipose tissue (1), macrophages (2), aorta (3,4), liver (5,6), adrenal cortex (7), and testis (8). Most studies have described the activation of CEH by cAMP-dependent protein kinase A (PKA; EC 2.7.1.37; ATP:protein phosphotransferase), followed by the initial report of neutral CEH (NCEH) activation by protein kinase C (PKC) in the rat liver (6). We recently reported the activations of rat aortic acid CEH (ACEH) and NCEH by both PKA and PKC to a similar extent in the presence of respective cofactors using selective inhibitors of two kinases (9). A cholesterol-esterifying enzyme, ACAT, is an integral membrane protein located in the endoplasmic reticulum, and evidence currently available for the involvement of phosphorylation in regulating ACAT is controversial; the dependence of ACAT activity on cholesterol availability has been documented in several studies (10,11): some evidence suggests the activation of ACAT by phosphorylation (12,13), whereas other evidence against the regulation of ACAT by phosphorylation has been presented (14,15).

We previously reported age-related decreases of the activities of lipolytic enzymes such as ACEH (16) and lipoprotein lipase (EC 3.1.1.34) (17) in mononuclear leukocytes from 214 and 158 human subjects, respectively. Inverse relations were observed between the ACEH activity and both serum cholesterol and lipid peroxide (LPO) as well as between the lipoprotein lipase activity and serum triglyceride (TG) levels.

Abbreviations: ACAT, acyl-CoA:cholesterol *O*-acyltransferase; ACEH, acid cholesteryl ester hydrolase; AO, active oxygen; BHT, butylated hydroxytoluene; CE, cholesteryl ester; CEH, cholesteryl ester hydrolase; CS, cigarette smoke; CSE, rats exposed to cigarette smoke and dietary vitamin E; CSC, control rats not exposed to cigarette smoke; G/GO, glucose/glucose oxidase; LDL, low density lipoprotein; LHPO, linoleate hydroperoxide; LPO, lipid peroxide; NCEH, neutral cholesteryl ester hydrolase; Ox-LDL, oxidized LDL; PKA, protein kinase A; PKC, protein kinase C; PP, protein phosphatase; SOD, Cu, Zn-superoxide dismutase; TBARS, thiobarbituric acid-reactive substance; TG, triglyceride; X/XO, xanthine/xanthine oxidase.

Both *in vivo* and *in vitro* inactivation of CEH in the aorta and liver was also observed in air-oxidized linoleate hydroperoxide (LHPO)-fed rats (18) and in an enzyme assay system with the addition of LHPO or LDL isolated from LHPO-fed rats (18,19), respectively. These studies suggest that oxidative inactivations of lipolytic enzymes may contribute to the extra- or intracellular increases of lipids.

Cigarette smoke (CS) contains reactive peroxy radicals that can increase lipid peroxidation (20), and the incidence of atherosclerosis in the abdominal aorta is approximately eight times higher in smokers than in nonsmokers (21). One of the mechanisms of atherosclerosis associated with smoking involves oxidative inactivation of intracellular CEH by free radicals in Ox-LDL (22). Recently, we also reported that the age-related decline of rat aortic ACEH and NCEH activities, together with their regulatory enzymes involving PKA and PKC, may be caused by long-term exposure to low levels of active oxygens such as those generated endogenously by metabolism (9). The aim of the present study was to investigate whether an exogenous oxidant burden due to passive smoking during different exposure periods generates oxidative inactivation of the aortic CEH and/or their regulatory enzymes in the signal transduction system, as had been previously observed in aging-related physiological changes that eventually led to increases of the aortic lipid content (9).

MATERIALS AND METHODS

Materials. The reagents used and their commercial sources were as follows: cholesteryl [1-^{14}C]oleate (57.0 mCi/mmol) from DuPont NEN (Boston, MA); [1-^{14}C]oleoyl-CoA (52.2 mCi/mmol) and [γ-^{32}P]ATP (25 Ci/mmol) from Amersham (Tokyo, Japan); Triton WR-1339, cholesteryl oleate, butylated hydroxytoluene (BHT), histone type III-S, ATP disodium salt, adenosine 3′,5′-cyclic monophosphate (sodium salt), diolein (18:1, *cis*-9), L-α-phosphatidyl-L-serine, xanthine oxidase (1.2 units/mg protein), glucose oxidase (178 units/mg), superoxide dismutase (4200 units/mg), and catalase (2000 units/mg) from Sigma (St. Louis, MO). Other chemicals were of analytical grade or higher. Prepacked LiChrolut RP-18 200-mg columns and the vacuum column holder unit were purchased from Merck KGaA (Darmstadt, Germany).

Animal experiments. This experiment was approved by the Animal Experiment Ethics Committee of the University of the Ryukyus. Eight-week-old male Wistar rats were housed in a room maintained on 12-h light/12-h dark cycles and a constant temperature of 20–23°C. Rats were exposed to sidestream smoke (CS) from cigarettes in an ashtray placed 10 cm below the rat cage in an exposure box (50 L × 40 W × 50 H, in cm) made of polypropylene, which was placed in a laboratory draft chamber (22). The cover of the exposure box was half opened, so that the smoke was drawn from the bottom by a fan of the draft chamber. Six groups of rats were exposed to CS for a 1-h period twice a day, once in the morning and once in the afternoon, for 8, 12, or 20 wk (two groups each). Three of these six groups, i.e., one of the two CS-exposed groups at each of the exposure periods, were given a chow supplemented with 5.1 mg DL-α-tocopherol per 100 g diet (CSE groups) and the other groups were not (CS groups). Three additional groups, control (CSC) groups for each of the exposure periods, were exposed in the same manner to atmospheric air. Both the CSC and CSE groups were given the same amount of diet intake as the CS group since the appetite of the CS groups was reduced by the nicotine in the CS (23,24). All groups consisted of 8 rats each, except that there were 10 rats in the three groups that received 12 wk of exposure. The animal experiments were started for each exposure period according to a schedule in which all rats were bled to death under anesthesia at the same time after overnight fasting.

Preparation of samples. Heparinized blood was obtained from each rat by heart-puncture under Nembutal anesthesia. Aliquots (2 mL) of plasma from each rat were pooled for each group, and LDL was fractionated from the pooled plasma in the presence of 0.002% (wt/vol) BHT and 0.01% (wt/vol) EDTA by discontinuous gradient ultracentrifugation at 4°C, 250,000 × *g* for 48 h (18). The thoracic-to-abdominal aortae (from which other tissues were removed) were kept at –80°C until assayed. Homogenates of the aorta (10%, wt/vol) were prepared in cold 0.02 M Tris-HCl buffer, pH 7.4, containing 0.25 M sucrose, 1 mM EDTA, 5 mM EGTA, 1 mM phenylmethyl sulfonyl fluoride, and 40 nM pepstatin, using a high-speed homogenizer at 25,000 rpm for 1 min. After centrifugation at 700 × *g*, 4°C for 10 min, 10-μL aliquots of the post-nuclear supernatants were used as samples in duplicate for the enzyme assays of CEH, ACAT, protein kinases, and protein determinations. The remaining part of the aortic preparation was immediately extracted twice with chloroform/methanol (2:1, vol/vol) containing 0.002% BHT. The solvent of the extract was evaporated *in vacuo*, and the residues were dissolved in an aliquot of the solvent and kept under N_2 at –20°C until analyses of lipids and LPO as thiobarbituric acid-reactive substances (TBARS). To study the effect of free radicals on the aortic PKC activity of the homogenate, cytosol, and membrane fractions, the cytosolic fraction was prepared by centrifuging the 10% aortic homogenate at 100,000 rpm (436,000 × *g*), 4°C for 15 min using a preparative micro-ultracentrifuge (HIMAC model CS120; Hitachi, Tokyo, Japan). The resulting pellet was homogenized after resuspending it in the original volume of homogenizing buffer containing 0.025% (wt/vol) Triton X-100 to make a homogeneous suspension and used for the membrane fraction. All measurements were made at least in duplicate. Statistical analyses were conducted by comparing the mean values and tested by the two-tailed *t*-test. The level of significance was set at $P < 0.05$.

Measurements of CE-metabolizing enzymes. The ACEH and NCEH activities were assayed on micellar substrates of 2.5 mM cholesteryl [1-^{14}C]oleate and 5 mM lecithin at pH 4.5 containing 1 mM β-mercaptoethanol and at pH 7.4 containing 0.15 M NaCl, respectively (9), in the absence (basal activity, Base) or the presence of the activating cofactors of 1 mM $MgCl_2$, 5 mM ATP, and 100 μM cAMP for PKA (total

activity, CoA-T) or 1 mM $MgCl_2$, 5 mM ATP, 1 mM $CaCl_2$, 20 µg/mL phosphatidylserine, and 4 µg/mL diolein for PKC (total activity, CoC-T) as described by Ghosh and Grogan (6). The difference between the basal and total activities was taken as the PKA- or PKC-activated CEH activity. After 10 µL of enzyme source was preincubated with 10 µL of cofactors, the reaction was started by adding 30 µL of the substrate, and the mixture was incubated at 37°C for 90 min as described previously (9). The enzyme activity was defined as the amount of enzyme catalyzing the release of 1 nmol oleic acid/h/mg protein. The ACAT activity was assayed as described by Billheimer (25), except that the isolation of the cholesteryl [1-^{14}C]oleate product was carried out using a prepacked reversed-phase minicolumn, LiChrolut RP-18 200 mg, according to the method of Kaluzny *et al.* (26). The recovery of cholesteryl [1-^{14}C]oleate product from the [1-^{14}C]oleate substrate was determined separately by adding authentic cholesteryl [1-^{14}C]oleate to the cold substrate in triplicate separations at every run of the ACAT assay. The recovery was usually around 60% due to the presence of Triton WR-1339, and for which the correction was made.

Assays of PKA and PKC. For the measurement of PKA activity (27), the final reaction mixture contained 50 mM Tris-HCl at pH 7, 10 mM $MgCl_2$, 20 µM [γ-^{32}P]ATP, 10 µM cAMP (cofactor for PKA, CoA), 200 µg/mL histone III-S, 0.25 mg/mL bovine serum albumin, 10 mM NaF, and 2 mM theophylline in a final volume of 50 µL. For the assay of PKC (28), the final reaction mixture consisted of 20 mM Tris-HCl at pH 7.4, 5 mM $MgCl_2$, 10 µM [γ-^{32}P]ATP, 200 µg/mL histone III-S, 0.1 mM $CaCl_2$ 25 µg/mL phosphatidylserine, 5 µg/mL diolein, and 0.3% (wt/vol) Triton X-100 in a final volume of 50 µL. The PKA and PKC reactions were started by the addition of 10 µL of the enzyme sources, containing less than 20 µg of protein, to the other components. After 5 min at 30°C, the reactions were stopped by the addition of 10 µL of 0.45 M H_3PO_4. Aliquots (45 µL) of the reaction mixture were transferred to phosphocellulose paper-P81 (dia. 2.3 cm; Whatman, Tokyo, Japan) which was placed in a vial, and the [γ-^{32}P]ATP was removed by washing three times with 10 mL of 75 mM H_3PO_4 (27). After drying for 5 min at 100°C, the scintillator was added, and the radioactivity was measured using a scintillation counter. The enzyme activity is expressed as the transfer of 1 pmol of ^{32}P to histone per min per mg of protein. Basal activity (Base) was measured in the presence of 0.5 mM EGTA and the absence of cofactors for PKC (CoC), i.e., $CaCl_2$, phosphatidylserine, and diolein. Base was subtracted from the CoC- or CoA-stimulated activity, and the difference was taken as the PKC or PKA activity. To investigate the effect of free radicals on the aortic PKC activity of the homogenate, cytosol, and membrane fractions, 10-µL aliquots of active oxygen (AO) generators, i.e., superoxide anions produced by xanthine/xanthine oxidase (X/XO) and H_2O_2 produced by glucose/glucose oxidase (G/GO), were preincubated with 10 mL of the enzyme source and 10 µL of the cofactors of protein kinases for 5 min at 30°C, and then the reaction was initiated by adding 30 µL of the substrate. Antioxidative enzymes such as Cu, Zn-superoxide dismutase (SOD) and catalase, and hydroxyl radical scavengers such as desferal and dimethylsulfoxide were first preincubated with the enzyme sources for 10 min at 30°C, followed by exposure to AO-producing systems.

Other measurements. LPO was measured fluorometrically (29) for LDL and colorimetrically (30) for the solvent extract from the aortic homogenate as TBARS after butanol extraction. Agarose gel electrophoresis was performed according to the instructions provided by the manufacturer (Ciba Corning, Palo Alto, CA), and the pattern was visualized by staining with Fat Red 7B. Lipids were measured manually using commercial clinical laboratory analysis kits (Wako, Tokyo, Japan). The CE contents were obtained by subtracting free cholesterol from total cholesterol. The amounts of proteins in the LDL and in the enzyme sources were measured by the method of Lowry *et al.* (31).

RESULTS

In vivo *formation of oxidized LDL and aortic lipid contents.* LPO expressed as TBARS values increased significantly in LDL isolated from the plasma pool of each CS group, to 143% at 8 wk, 137% at 12 wk, and 151% at 20 wk, compared to the respective control values (Table 1). The vitamin E diet prevented these increases until 12 wk of exposure, but thereafter the TBARS value in the CSE group increased to 136% relative to the control value by 20 wk. Electrophoretic exami-

CS (10)	5.45 ± 0.72*	142.9	3.82 ± 0.62	137.0	4.38 ± 0.64*	151.0
CSE (8)	3.38 ± 0.65	88.9	2.63 ± 0.51	94.3	3.93 ± 0.70	135.5

[a]Values shown are the mean of triplicates ± SD. Aliquots (2 mL) of plasma from each rat were pooled for each group, and low density lipoprotein (LDL) was fractionated as described in the Materials and Methods section. Units are expressed per gram of protein. *P < 0.05 vs. the CSC group. Abbreviations: CSC, control group, no cigarette smoke (CS) exposure; CS, exposed to cigarette smoke; CSE, exposed to CS + dietary vitamin E.

nation of LDL fractions on agarose gels revealed a typical Ox-LDL with an increase in the net negative charges in the three CS groups, as indicated by small arrows in Figure 1. Slight increases of TBARS levels were observed in the aorta of the CS groups after all three exposure periods (Table 2). The aortic CE contents of the CS groups were elevated to 236, 258, and 209% compared to the control values after 8, 12, and 20 wk exposure periods, respectively, while the increases in the CSE groups were 114, 200, and 255% for the three exposure periods, respectively. A reduction of the aortic TG content in the CS groups was observed, probably due to increased TG turnover by transient epinephrine secretion in response to the nicotine in CS (23,24,32,33).

Activations of aortic CEH by protein kinases. The aortic CEH of the control rats (CSC groups in Fig. 2) were activated to similar extents by both PKA and PKC in the presence of their respective cofactors. However, ACEH activation by PKC (224% of the basal activity) tended to be greater than that by PKA (197%), whereas the NCEH activation by PKA (169%) tended to be greater than that by PKC (142%). A similar observation in the CEH activations by two kinases was previously reported as a result of using the selective inhibitors H-7 and HA1004 of PKC and PKA, respectively (9). CS exposure significantly reduced the PKC-activated fraction of ACEH to 36% in the CS group, but the vitamin E feeding stimulated it to 218%, as compared with the value of the control CSC group. The PKA-activated fraction decreased to about 75% in two CS-exposed groups (Fig. 2A). The PKA- and PKC-acti-

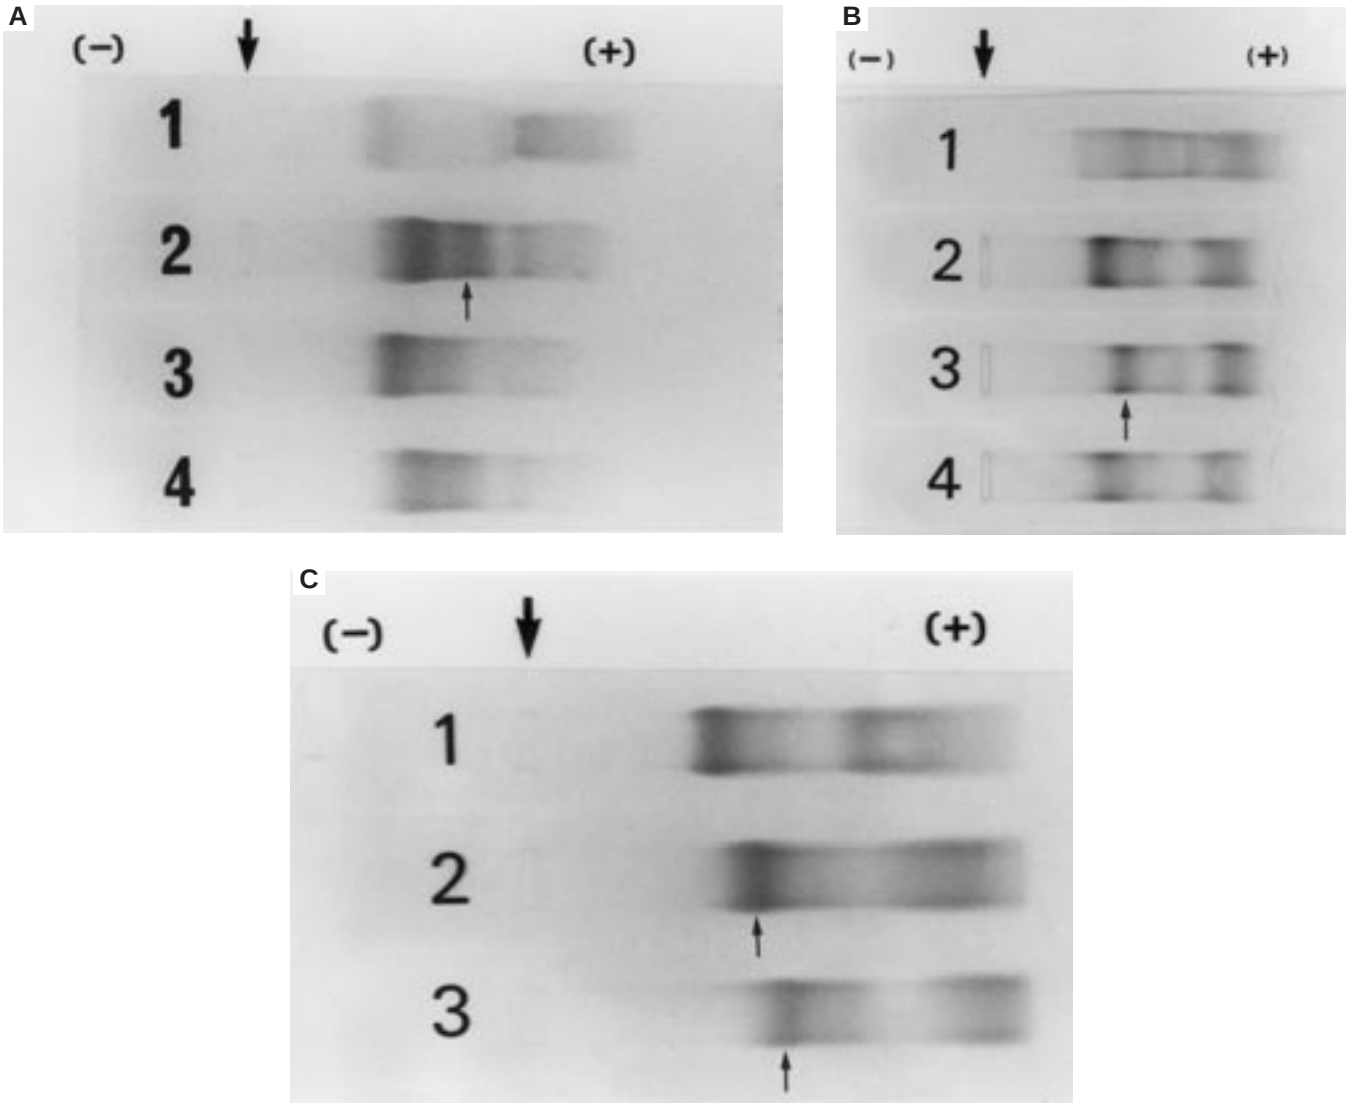

FIG. 1. Agarose gel electrophoresis of low density lipoprotein (LDL) isolated from rats exposed to cigarette smoke (CS) for 8, 12, and 20 wk. (A) 8-wk exposure. Lane 1, plasma from the CSC group (control: no CS); lanes 2, 3, and 4, LDL from the CS, CSE (CS rats fed dietary vitamin E), and CSC groups, respectively. (B) 12-wk exposure. Lane 1, plasma from the CSC group; lanes 2, 3, and 4, LDL from the CSC, CS, and CSE groups, respectively. (C) 20-wk exposure. Lanes, 1, 2, and 3, LDL from the CSC, CSE, and CS groups, respectively. The large arrow indicates the origin and the small arrow indicates the *in vivo*-modified LDL with increased net negative charges.

[a]Values shown are the means ± SD for 8–10 animals.
[b]Units are expressed per gram wet weight of tissues. *$P < 0.05$ and **$P < 0.005$ vs. the CSC control group. TBARS, thiobarbituric acid-reactive substances; for other abbreviations see Table 1.

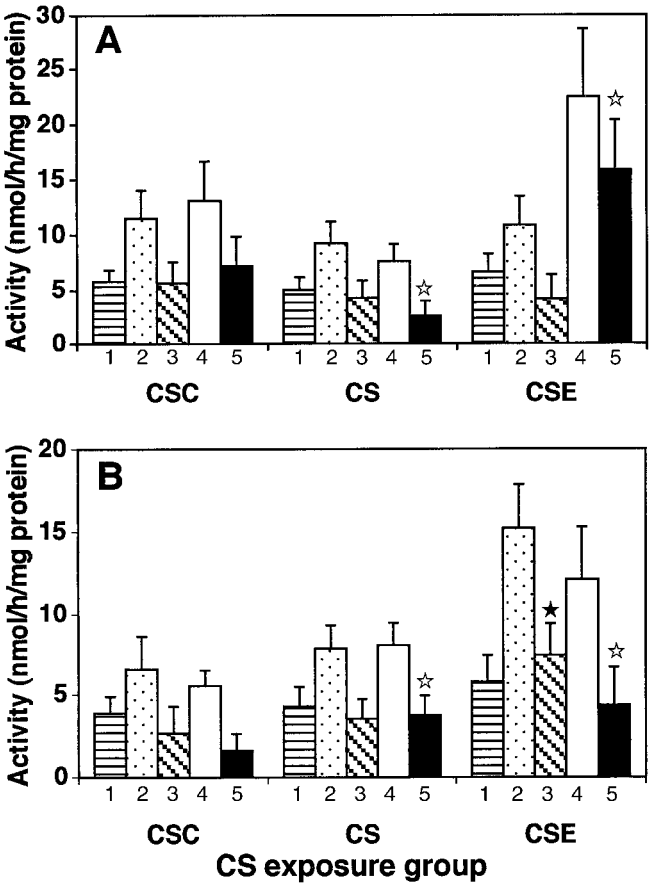

FIG. 2. The activities of aortic cholesteryl ester hydrolases (CEH) and their activations by protein kinases in rats exposed to CS for 8 wk. The activities of acid (panel A) and neutral (panel B) cholesteryl ester hydrolases were measured in the absence (Bar no. 1) and the presence of activating cofactors for protein kinase A (PKA) (CoA-T, no. 2) or protein kinase C (PKC) (CoC-T, no. 4) as described in the Materials and Methods section. The difference between the basal and the total activity was taken as the PKA (no. 3)- or PKC (no. 5)-activated CEH activity. Open stars, $P < 0.05$; solid stars, $P < 0.005$ vs. the CSC group. Values are means ± SD. For other abbreviations see Figure 1.

vated fractions of NCEH increased to 133 and 352% in the CS group and 229 and 264% in the CSE group, respectively, as compared with the values of each respective CSC group (Fig. 2B). The PKC and PKA activities were also examined on the same aortic samples of rats exposed to CS for 8 wk (Fig. 3). The two aortic kinase activities (Fig. 3) showed changes similar to those of the CS exposure-associated alterations in the CEH activities (Fig. 2): the PKC activities were significantly reduced to 72% in the CS group and increased to 118% in the CSE group compared with the activity of the CSC group (Fig. 3A), whereas the PKA activities increased in the two CS-exposed groups as follows: 121% for the CS group and 168% for the CSE group (Fig. 3B). The PKC activities in the CSC, CS, and CSE groups seem to be related to the PKC-activated fractions of ACEH (Fig. 2A), whereas the PKA activities in the three groups appear to be related to both PKA- and PKC-activated fractions of NCEH (Fig. 2B).

Activities of aortic CE-metabolizing enzymes and protein kinases in three CS-exposure periods. The CS exposure period-associated changes in the activities of CE-metabolizing enzymes and protein kinases in the rat aorta are summarized in Figure 4. The basal activities of ACEH and NCEH in Figure 2 and the PKC and PKA activities in Figure 3 are presented in Figure 4A for comparison with the other two exposure periods. The activity of aortic PKC, the regulatory enzyme of CEH, was significantly reduced to 72, 84, and 75% of the respective control values after 8, 12, and 20 wk exposure periods, respectively, while the PKA activity increased progressively to 121, 197, and 252% for the three exposure periods, respectively. The elevation of the PKA activity is probably related to a transient epinephrine secretion in response to the nicotine in CS (23,24). The ACEH activity of the CS groups remained significantly depressed, showing values of 86, 71, and 82% compared to the controls after the three exposure periods. The low ACEH activities after the three exposure periods probably reflected reduced PKC activities along with an inactivation of ACEH itself, since ACEH

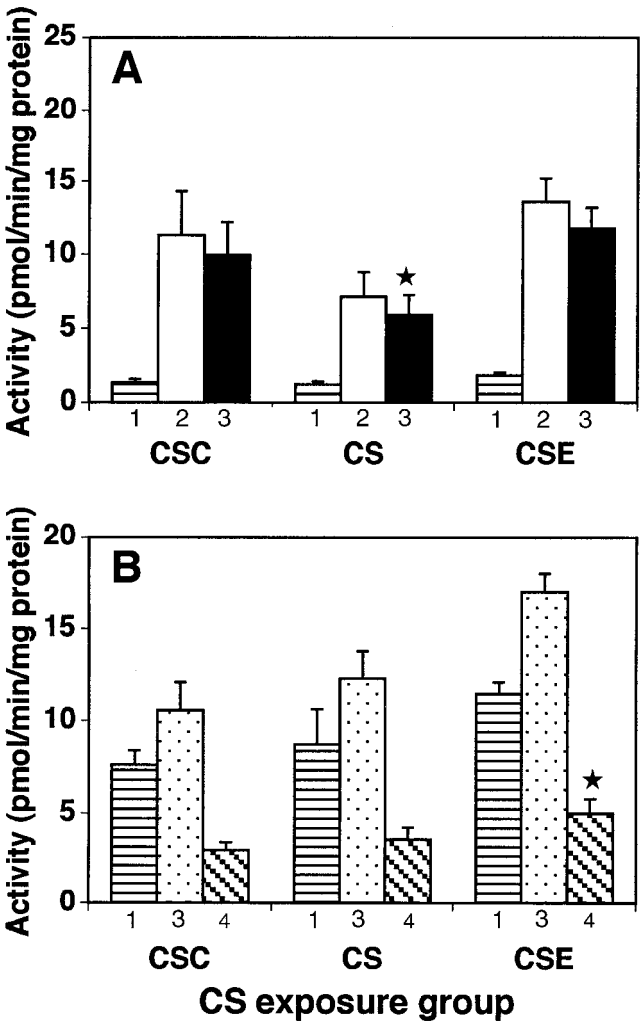

FIG. 3. The PKC and PKA activities of the aorta from rats exposed to CS for 8 wk. The difference between the activities in the absence (bar no. 1) and the presence (bar no. 2, PKC; bar no. 4, PKA) of the activating cofactors for each of the two protein kinases represents the activity of PKC (bar no. 3 in panel A) or PKA (bar no. 4 in panel B). For symbols denoting significance and other abbreviations see Figures 1 and 2. Values are means ± SD.

is activated by both types of kinases (Fig. 2; Ref. 9), and the PKA activities increased from 121 to 252 over the three exposure periods. Owing to marked elevations in the PKA activities of the CS groups, the NCEH activity continued to increase to 111% at 8 wk and 140% at 12 wk of exposure, and then decreased by 50% at 20 wk of exposure, suggesting inactivation of NCEH itself with long-term exposure to CS. The activity of cholesterol-esterifying enzyme, ACAT, exhibited significant elevations of 138% in the CS group at 12 wk and 130% in the CSE group at the 20-wk exposure; these activities were associated with increases in the aortic free cholesterol content of 116% in the CS group at 12 wk and 118% in the CSE group at 20 wk (Table 2) rather than the kinase activities. The aortic ACAT activations obtained here were roughly compatible with the hepatic microsomal ACAT reported (10), in that 25% increases of free cholesterol in microsomes increased the enzyme activity about sixfold.

Effects of antioxidants on active oxygen-mediated inhibitions of aortic PKC. The inactivation of aortic PKC by AO and its protections by antioxidants were examined. The effects of various antioxidants on the X/XO- and G/GO-mediated inhibitions of aortic PKC in the homogenate, cytosol, and membrane fractions are summarized in Table 3. The 5-min *in vitro* exposure of aortic PKC in the presence of activating cofactors to superoxide anion or hydrogen peroxide generated by X/XO or G/GO systems caused oxidative inactivation of PKC, particularly the activated form of PKC, which was translocated to the membrane as follows: 73% residual activity for the homogenate, 48% for the cytosolic fraction, and 24% for the membrane fraction, relative to the respective control PKC activities without AO exposure. Moreover, the observed inactivation of PKC in the membrane fraction was most effectively protected by catalase, and partially protected by SOD and desferal (Table 3).

DISCUSSION

The measurement of the TBARS content of LDL isolated from the plasma pool of each group showed approximately

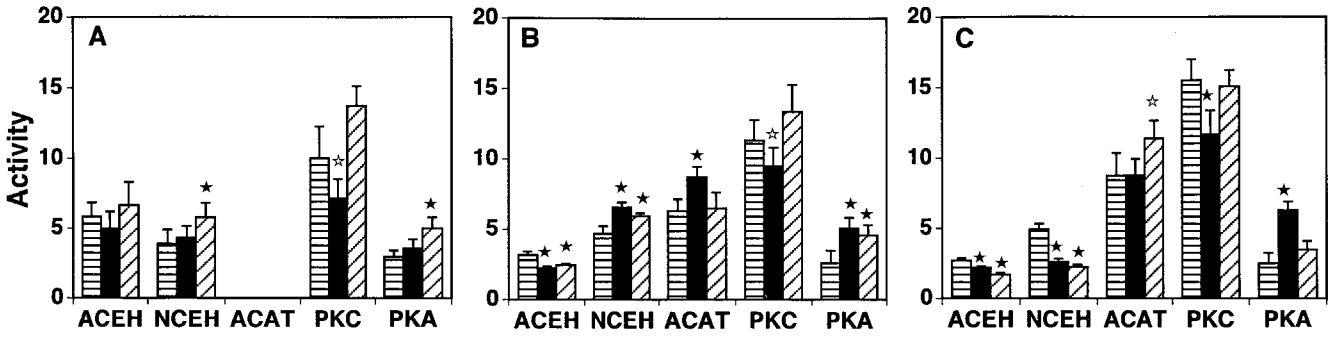

FIG. 4. Activities of cholesteryl ester-metabolizing enzymes and protein kinases in the aorta of rats exposed to CS for 8 (panel A), 12 (panel B), and 20 (panel C) wk. The height of the bars represents the specific activity in units (nmol/h for ACEH, NCEH, and ACAT; pmol/min for PKC and PKA) per mg protein for the CSC groups (horizontally striped bars), for the CS groups (solid bars), and for the CSE groups (diagonally striped bars). For symbols denoting significance, see Figure 2. Values are means ± SD. ACEH, acid cholesteryl ester hydrolase; ACAT, acyl-CoA:cholesterol *O*-acyltransferase; NCEH, neutral cholesteryl ester hydrolase; for other abbreviations see Figures 1–3.

[b]pmol/min.

150% elevation in all three CS groups (three exposure periods), indicating systemic exposure to free radicals introduced by passive smoking (Table 1). Electrophoresis of LDL revealed a typical Ox-LDL with an increase in the net negative charge in the CS groups for all three CS-exposure periods (Fig. 1). This finding suggests that AO introduced by passive smoking into the blood is incorporated into cells through Ox-LDL which then inhibits the intracellular CEH (18,19) and their activating enzymes (9), thereby resulting in an increased cellular content of CE.

In the two-compartment model of CE metabolism in macrophages (34), Ox-LDL in the circulation is taken up rapidly by specific "scavenger receptors" on macrophages and vascular smooth muscle cells (35). There are three functional enzymes in this scheme: lysosomal ACEH, which degrades blood-derived exogenous CE to cholesterol; ACAT, which esterifies cholesterol to endogenous CE as a storage form by stimulation due to an increase in the intracellular cholesterol pool; and microsomal NCEH, which hydrolyzes endogenous CE. Although we have demonstrated the loss of ACEH and NCEH activity as a result of their exposure to oxidants both *in vivo* and *in vitro* (9,18,19,22), cloning of human ACEH has revealed the presence of cysteine within the mature protein (36), and the involvement of cysteine residues in the catalytic activity of ACEH has been recently clarified (37). On the other hand, evidence currently available for the presence of cysteine residues in NCEH is scant and controversial, in that the rat hepatic NCEH has been cloned and found to be a 66 kDa protein with no cysteine residues showing great overall homology with liver carboxyesterases (38,39), while the rat hepatic microsomal NCEH has been highly purified and found to be a 106 kDa protein with 30 cysteine groups exhibiting inactivation by the free sulfhydryl-reacting reagents (40). Chemical modification studies have identified histidyl and sulfhydryl residues necessary for ACAT activity; two types of sulfhydryl groups were involved, one at the active site and the other at the regulatory site (41). The presence of histidyl and sulfhydryl residues in ACAT has also been confirmed by molecular cloning of ACAT in rat (42) as well as in other species. From evidence, CE-metabolizing enzymes seemed to be sensitive to an oxidative inactivation. In our results (discussed below), NCEH was relatively resistant to an oxidative inactivation brought about during CS-exposure periods when compared to ACEH.

We previously reported that the activities of ACEH and NCEH and their regulatory enzymes, PKC and PKA, may be modulated by the dual effects of endogenous AO: activation of CEH at low doses and inactivation at high doses; or by long-term exposure to a low level of endogenous AO, which contributes to the age-related accumulation of CE in the arterial wall (9). The present study demonstrated that a continuous burden of exogenous oxidative stress due to passive smoking can also inactivate both CEH and their regulatory enzymes (Fig. 4), thereby contributing to increases in the aortic CE content (Table 2). The aortic CEH were activated by PKA and PKC, as shown in Figure 2 and also in a previous study (9). At the short-term exposure to CS (8 wk), 28% reduction in the PKC activity of the CS group (Fig. 3A) caused 64% reduction in the PKC-activated fraction of ACEH (Fig. 2A), whereas the PKA-activated fraction of ACEH of the two CS-exposed groups showed 25% reductions (Fig. 2A) despite the 20–68% elevations in the PKA activities of the two CS groups (Fig. 3B). This indicated that both ACEH and PKC were inactivated by CS, with more damage in lysosomal ACEH which was exposed to blood-derived Ox-LDL with a high LPO content (Fig. 1, Table 1). On the other hand, the activation of NCEH by the two kinases was not much affected by the 8-wk exposure to CS (Fig. 2B), and it was consistent with the elevation in the PKA activity (Fig. 3B). By 12 wk of exposure (Fig. 4B), the longer exposure to Ox-LDL brought a significant inactivation in the ACEH activity along with a significant elevation in the ACAT activity, which was in accord with the increased substrate-cholesterol availability (10,11) in the aorta (Table 2), whereas the NCEH activity was

significantly elevated, in parallel with an increase in PKA activity which was probably related to a transient epinephrine secretion in response to nicotine in CS (4,23). After long-term exposure (20 wk), two CE-hydrolyzing enzymes were more severely inactivated than CE-esterifying enzyme, and the antioxidant effect of vitamin E did not act efficiently as protection against AO-induced inactivation of CEH, whereas it did protect the PKC activity effectively from the inactivation that occurred in the CS groups through all exposure periods. The latter finding suggested that the inactivation of PKC was caused by AO in CS. In a previous study (9), AO-mediated activation of CEH was observed in the CEH activation system by PKC at the optimal low concentration of AO. The AO-induced inactivation of PKC at the high AO concentrations and its prevention by catalase were notable for the activated form of PKC which translocated to the membrane (Table 3). This evidence suggested that the inactivation of PKC in the aortic cells may be mediated by Ca^{2+}-dependent proteases (43) *via* an elevation of intracellular Ca^{2+} (44) through calcium mobilization from the intracellular calcium store, which was caused by AO (45). The free radical species responsible for the PKC inactivation were likely hydroxyl radicals, since the PKC inactivation due to AO exposure was efficiently eliminated by antioxidative enzymes and hydroxyl radical scavengers. An intracellular increase of Ca^{2+} may also activate Ca^{2+}/calmodulin-dependent protein phosphatase (PP)2B and PP1 which inactivate PKA by at least three mechanisms (46): (i) the dephosphorylation of the regulatory subunit R II of PKA; (ii) the reduction of the cAMP levels through the activation of cAMP phosphodiesterase by dephosphorylation; and (iii) the dephosphorylation of the substrate of PKA as well as other protein kinases like PKC *via* the activation of PP1 through the dephosphorylation of inhibitor-1 by PP2B. Alterations of activities of CE-metabolizing enzymes by phosphorylation/dephosphorylation depend on the relative activities of protein kinases and PP. The alteration of the latter enzymes by passive smoking remains to be clarified, and work along this line is currently under way.

In conclusion, the present results regarding long-term exposure (20 wk) to CS demonstrated that: nicotine in CS caused elevation of the PKA activity that modulates aortic CEH, while AO in CS produced an Ox-LDL with a high LPO content that was incorporated into aortic cells, consequently inhibiting ACEH, NCEH, and PKC that regulate aortic CEH. These alterations in CE-metabolizing enzymes by passive smoking could contribute to the twofold increase in aortic CE accumulation, thereby contributing to one of the mechanisms for atherosclerosis associated with smoking.

Aggregation and Fusion of Vesicles Composed of *N*-Palmitoyl Derivatives of Membrane Phospholipids

Margarita Mora, Ferran Mir, M. Africa de Madariaga, and M. Luisa Sagristá*

Department of Biochemistry and Molecular Biology, Faculty of Chemistry, University of Barcelona, 08028-Barcelona, Spain

ABSTRACT: *N*-Acylphosphatidylethanolamines and *N*-acylphosphatidylserines have been isolated from mammalian cells and have been associated with some tissue degenerative changes, although the relationship between their synthesis and the uncontrolled sequence of events that ends in irreversible tissue damage is not completely established. Our results show that monovalent and divalent cations induce aggregation and fusion of liposomes constituted by *N*-palmitoylphosphatidylethanolamine (NPPE) and *N*-palmitoylphosphatidylserine (NPPS). The effectiveness of cations to induce the aggregation of NPPE and NPPS liposomes is $Ca^{2+} > Mg^{2+} \gg Na^{+}$. NPPS liposomes aggregate at lower concentrations of divalent cations than NPPE liposomes, but with sodium NPPE liposomes aggregate to a higher extent than NPPS liposomes. The reaction order for the aggregation processes depends on the lipid and the cation nature and range from 1.04 to 1.64. Dynamic light scattering shows an irreversible increase of the size of the aggregates in the presence of all cations tested. The irreversibility of the aggregation process and the intermixing of bilayer lipids, as studied by resonance energy transfer assay, suggest that fusion, rather than aggregation, occurs. The existence of a real fusion was demonstrated by the coalescence of the aqueous contents of both NPPS and NPPE liposomes in the presence of either monovalent or divalent cations. The different binding sensitivity of Ca^{2+} to NPPS and NPPE liposomes, determined by ζ potential measurements, agrees with the results obtained in the aggregation and fusion assays. Our results suggest that the synthesis *in vivo* of N-acylated phospholipids can introduce important changes in membrane-mediated processes.

Paper no. L8222 in *Lipids 35,* 513–524 (May 2000).

N-Acylaminophospholipids are a widespread family of membrane phospholipids in animal and plant tissues (1,2). *N*-Acyl derivatives of phosphatidylethanolamine (*N*-acylPE) have been found in cell membranes under some pathological conditions, such as the disruption of the sarcolemma, which follows myocardial infarct and ischemia, and in cells with a high catabolic activity (3,4). *N*-Acyl derivatives of phosphatidylserine have also been identified in sheep erythrocytes (5), in the central nervous system of freshwater fish (6), and in ischemic bovine brain (7). *N*-AcylPE are synthesized by N-acylation reactions carried out by a transacylase system that catalyzes the transfer of fatty acids from the *sn*-1 position of various 1,2-diacyl glycerophospholipids to the amino group of aminophospholipids. In dog heart the reaction is calcium-dependent and utilizes phosphatidylcholine, PE, and cardiolipin as main acyl donors (8). In contrast, Chapman and More (9) established that higher plants *in vivo*, under normal physiological growth conditions, and cottonseed microsomes *in vitro* synthesize *N*-acylPE by direct enzymatically catalyzed acylation of PE, without a requirement for divalent cations.

Recently, there has been a renewed interest in the study of *N*-acylPE. Their metabolism gives *N*-acylethanolamines, some of which, as the *N*-arachidonylethanolamine (anandamide), are physiologically important. For example, the latter has a role as endogenous ligand for the cannabinoid receptor in mammalian brain (10–12).

Despite the role of *N*-acylPE as putative cannabinoid precursors (13), the ability of the amides of fatty acids to act as lipid bioregulators (14), and the numerous studies carried out to ascertain completely the metabolic role of the *N*-acyl derivatives of membrane aminophospholipids, the physiological meaning of the N-acylation reactions is not yet totally established. However, the special structural characteristics of such molecules and the physicochemical properties of their aqueous dispersions show that instead of being merely the products of a high lipid catabolism, and so physiologically useless, they can be functionally useful lipids to cellular membranes. They can protect biomembranes from the high activity of some phospholipases, which easily hydrolyze PE but not their N-acyl derivatives (15). They can modulate the activity of membrane enzymes because of the decrease in the bilayer fluidity and the increase in the negative surface charge by means of their incorporation into the bilayer (16). They protect biomembranes from dehydration processes because of the increase of the hydration degree of the polar head (17). They are metabolic intermediates in the catabolism of PE, and their degradation gives *N*-acylethanolamines, which can pro-

Abbreviations: *N*-acylPE, *N*-acyl derivative of phosphatidylethanolamine; DPA, dipicolinic acid; IR, infrared; LUV, large unilamellar vesicles; MLV, multilamellar vesicle; NBD-PE, *N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-phosphatidylethanolamine; NMPE, *N*-myristoylphosphatidylethanolamine; NMR, nuclear magnetic resonance; NPPE, *N*-palmitoylphosphatidylethanolamine; NPPS, *N*-palmitoylphosphatidylserine; NTA, nitrilotriacetic acid; PCS, photon correlation spectroscopy; PE, phosphatidylethanolamine; PS, phosphatidylserine; RET, resonance energy transfer; Rh-PE, *N*-(lissamine Rhodamine B sulfonyl)-phosphatidylethanolamine; SUV, small unilamellar vesicle; TLC, thin-layer chromatography; TPE, transphosphatidylated phosphatidylethanolamine.

tect biomembrane integrity from ischemia since they inhibit calcium release, decrease the levels of lyso-PE, and inhibit phospholipase A_2 by acting as agonist (1,18). They affect the permeability and fluidity of the membrane bilayers. In this way, previous studies in our laboratory have shown (i) that the incorporation of *N*-acylPE decreases the permeability of lipid bilayers because of the rigidifying effect of the N-acylation of PE (19) and (ii) that liposomal formulations containing *N*-acyl derivatives of PE are very stable in biological media (20). Besides these considerations, their biosynthesis could have a stabilizing effect on biological membranes by reducing the effective concentration of free fatty acids, by producing a bilayer phospholipid able to form closed and stable vesicle structures by itself, and by reducing the concentration of the nonbilayer PE in membranes (9,21–23).

It has been suggested that acidic phospholipids, like phosphatidic acid and phosphatidylserine (PS), and nonbilayer lipids, like PE, contribute actively in the membrane fusion processes induced by Ca^{2+} and specific membrane proteins (24–26). In this way, Verkleij and Post (27) have shown the ability of calcium to induce a lateral phase separation of the negatively charged phospholipids, mainly located in the inner monolayer of the sarcolemma, which leads to the destabilization of the bilayer and to uncontrolled fusion events. This hypothesis could suggest a relationship between the synthesis of the negatively charged N-acylated phospholipids and the processes that lead to the degeneration of membranes.

We have previously reported the irreversible mono- and divalent cation-induced aggregation of liposomes prepared from a methylated analog of *N*-acylPE (28) and the divalent cation-induced fusion of *N*-stearoyl-PS liposomes (29). Our results have shown that the divalent cation concentrations necessary to induce the aggregation and fusion of liposomes containing *N*-acylaminophospholipids would be of physiological relevance in those pathological states in which the transient opening of calcium channels lead to an abrupt increase of calcium levels. A membrane protective role for the synthesis of *N*-acyl derivatives of PE (17,19) and PS (29) in the first stages of tissue damage has been postulated since N-acylation converts the nonbilayer unsaturated PE into a bilayer lipid and decreases the sensitivity of PS to calcium- and magnesium-induced fusion. Nevertheless, if calcium levels did not return to basal levels the degenerative changes would be favored by *N*-acyl derivatives of PE and PS.

Liposomes (phospholipid vesicles) have been used as relatively simple membrane models to investigate the molecular requirements for membrane fusion (30–33). In general, they are stable structures that do not normally fuse spontaneously. Nevertheless, a great number of references in the literature show that monovalent cations induce aggregation of liposomes containing acidic phospholipids or negative charges at the bilayer surface (34–36), whereas divalent cations are able to induce fusion processes (37–39).

All these considerations, as well as our previous results (28,29), have led us to carry out a more exhaustive study of monovalent and divalent cation-induced aggregation, lipid exchange, and aqueous content mixing of sonicated unilamellar liposomes made from *N*-palmitoylphosphatidylethanolamine (NPPE) and *N*-palmitoylphosphatidylserine (NPPS) so as to demonstrate that fusion occurs. The influence of the polar head of both lipid species on the fusogenic properties of liposomes are also considered. The electrostatic properties of NPPE and NPPS bilayers, in the absence and in the presence of calcium ions, are determined as well in order to establish the importance of electrostatic forces in the formation of stable aggregates required for vesicle fusion. The results obtained regarding the ability to fuse liposomes constituted by *N*-acyl derivatives of PE and PS can be helpful in designing drug delivery vesicles with long-circulating and fusogenic properties.

MATERIALS AND METHODS

Chemicals. Egg transphosphatidylated phosphatidylethanolamine (TPE) and the fluorophore-labeled phospholipids, *N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-phosphatidylethanolamine (NBD-PE) and *N*-(lissamine Rhodamine B sulfonyl)-phosphatidylethanolamine (Rh-PE) were obtained from Avanti Polar Lipids (Birmingham, AL). Bovine brain PS (80–85%) was a product from Sigma Chemical Co. (St. Louis, MO) and was purified by thin-layer chromatography (TLC) before use (29). Palmitoyl chloride for synthesis was from Merck (Schuchardt, Germany), and cation salts for aggregation or fusion studies were from Merck (Darmstadt, Germany). All other reagents were of analytical grade. Water was twice-distilled (Millipore Systems, Molsheim, France), and all organic solvents were redistilled before use.

Analytical TLC was performed on layers of silica gel G (Sil G-25) purchased from Macherey-Nagel (Düren, Germany). Chromatographic material for purification processes (Kieselgel 60H, 15 μm for TLC, and Kieselgel 60G and 0.1–0.2 mm for column chromatography) was obtained from Merck (Darmstadt). Samples were made visible with iodine, by spraying with ninhydrin or with ammonium molybdate in H_2SO_4, or by charring.

Synthesis of N-*acyl phospholipids*. NPPE was synthesized by condensing palmitoyl chloride with egg TPE as described previously (28). NPPS was obtained from PS, previously purified from a bovine brain extract, by means of an acylation reaction with palmitoyl chloride (29). Silicic acid column chromatography and preparative TLC-purified NPPE and NPPS were assayed for purity by TLC using two solvent systems and were identified by ^1H nuclear magnetic resonance (NMR) and infrared (IR) spectroscopy. The formation of the amide bonds was checked by means of the observation of amide I and amide II bands in the IR spectra and by ^1H NMR spectroscopy. The analysis, after chemical degradation of both products, by gas–liquid chromatography of the fatty acid methyl esters showed the incorporation of the third palmitoyl chain. Lipid concentration was determined by phosphorus analysis (40).

Preparation of liposomes. Unilamellar liposomes were prepared by using the sonication method. NPPS or NPPE was

dissolved in trichloromethane, and the organic solvent was evaporated by a stream of nitrogen gas to deposit a lipid film on the wall of a glass test tube. Final traces of residual solvent were removed under vacuum for 18 h. Multilamellar vesicles (MLV) were prepared by suspending the dried lipid film at a concentration of 0.5 mg lipid/mL of 20 mM Tris-HCl buffer (pH 7.4), containing 100 mM NaCl and 100 μM EDTA, and by vortexing for 10 min. Small unilamellar vesicles (SUV) were obtained by sonication of the MLV in a Braun Labsonics 2000 probe sonifier, equipped with a 9.5-mm titanium probe, for 15 min operating at 48 W. During sonication, the lipid suspension was kept at 45°C under a nitrogen stream. Titanium particles (arising from the progressive disintegration of the sonifier probe) and possible undispersed lipids were removed by centrifugation. It was verified by TLC that the lipids did not suffer degradation due to the sonication process. Before use, the liposome dispersion was filtered through a 0.45 μm filter.

Multilamellar liposomes for surface potential measurements were prepared by shaking the lipid film in the electrolyte for 10 min, followed by a 30-min period of sonication in a bath sonicator. The final lipid concentration in the aqueous sample was 0.5 mg/mL.

Vesicle aggregation assay. Vesicle aggregation was monitored by continuous measurements of the turbidity of SUV suspensions as a function of the monovalent (Na^+) and divalent (Ca^{2+} and Mg^{2+}) cation concentrations. The optical density changes were followed at 400 nm during 2 min, using a UV/VIS Beckman DU-70 spectrophotometer equipped with a Peltier temperature control cell and continuous stirring. The wavelength in the visible range at which our sonicated unilamellar vesicles caused maximal light scattering was found to be approximately 400 nm. For the aggregation assays, NPPE and NPPS liposomes were suspended at 0.05 mg phospholipid/mL in the same buffered salt solution used to prepare the liposomes. Measurements were performed at 20°C before and after the addition of small aliquots of the concentrated cation salt solutions to the liposome suspensions. In order to omit the initial bubbling problems or the formation of large vesicles, the results shown represent the increments of absorbance obtained 20 s after the cation addition. The threshold concentrations (c_t) for the aggregation process were calculated as the cation concentrations corresponding to the maximal increase in the rate of absorbance changes (36).

Vesicle size analysis. The aggregation of NPPE and NPPS liposomes induced by monovalent and divalent ions can also be followed by measuring the changes in size and size distribution of unilamellar phospholipid vesicles when adding the cations (32). The analysis was carried out by dynamic light scattering using a PCS41 particle sizer (Malvern Autosizer IIc) and a 5 mW He-Ne laser (Spectra Physics), at an excitation wavelength of 633 nm. The data were collected with a Malvern 7032N 72 data channel correlator, and the mean hydrodynamic diameter was calculated from a cumulant analysis of the intensity autocorrelation function. The possible reversibility of the monovalent and divalent cation-induced aggregation reaction was verified by measuring vesicle size 2 min after dilution of the aggregated vesicles up to 200 mM sodium concentration or after the addition of EDTA at six times the concentration of divalent ions to the aggregated vesicles.

Vesicle fusion assay. The fusion of NPPE and NPPS liposomes induced by monovalent and divalent cations was measured by monitoring the exchange of the bilayer lipids and the mixing of the internal aqueous contents, using fluorescent probes. Fusion of the liposomal membranes was followed by measuring lipid mixing using a modification of the fluorescence resonance energy transfer assay (RET) described by Struck *et al*. (41). SUV constituted by NPPE or NPPS were prepared without and with NBD-PE and Rh-PE at 1 and 0.5 mol%, respectively, with respect to the total lipid content (0.5 mg/mL). The fluorescent-labeled liposomes and a ninefold excess of unlabeled vesicles were mixed at 20°C to monitor the dilution of the fluorescent lipids by following continuously the decrease in energy transfer from NBD-PE to Rh-PE, using a Kontron SFM 25 spectrofluorimeter at excitation and emission wavelengths of 440 and 536 nm, respectively, using a 530-nm cut-off filter to eliminate the contribution of light scattering. The maximal fusion was determined using reference liposomes containing 0.1% NBD-PE and 0.05% Rh-PE. Light-scattering controls were performed using unlabeled vesicles. The percentage of fusion was expressed as the percentage of maximal fluorescence,

$$\%\ \text{maximal fluorescence} = \frac{\left(F_t - S_t\right)/\left(F_T - S_T\right) - \left(F_0 - S_0\right)/\left(F_T - S_T\right)}{\left(R_t - S_t\right)/\left(R_T - S_T\right) - \left(F_0 - S_0\right)/\left(F_T - S_T\right)} \times 100 \quad [1]$$

where F_t = fluorescence intensity at time t; F_0 = fluorescence intensity at time zero; F_T = fluorescence intensity in the presence of 0.7% Triton X-100. R and S represent the same measurements for reference liposomes and light-scattering controls, respectively (42). However, Equation 1 can be simplified by assuming that light-scattering values can be neglected in our experimental conditions. Thus, taking into account this consideration, we calculate the percentage of maximal fluorescence as

$$\%\ \text{maximal fluorescence} = \frac{F_t - F_0}{R_t \dfrac{F_T}{R_T} - F_0} \times 100 \quad [2]$$

A modification of the method of Nir *et al*. (43) was used for the assay of the mixing of the aqueous contents of lipid vesicles. Three populations of unilamellar vesicles (0.5 mg lipid/mL) were prepared in the following solutions: (i) 10 mM $TbCl_3 \cdot 6H_2O$/100 mM nitrilotriacetic acid (NTA)/20 mM Tris-HCl buffer (pH 7.4), (ii) 100 mM dipicolinic acid (DPA)/20 mM NaCl/20 mM Tris-HCl buffer (pH 7.4) and (iii) 5 mM $TbCl_3 \cdot 6H_2O$/50 mM NTA/50 mM DPA/10 mM NaCl/20 mM Tris-HCl buffer (pH 7.4). After vesicle preparation, the nonentrapped material was separated by gel filtration of 0.4 mL of the liposomal suspension on a Sephadex G-50 (Pharmacia Biotech, Uppsala, Sweden) column (200 × 10 mm), previously

equilibrated with 100 mM NaCl/0.75 mM EDTA/20 mM Tris-HCl buffer (pH 7.4). Liposomes were eluted by the solution used in the equilibration process; and 1.6 mL of liposomes free of nonentrapped material, containing 99% of the applied lipid, was collected. $TbCl_3$ and DPA vesicles were mixed in a 1:1 molar ratio at a final lipid concentration of 0.05 mg/mL for the fusion assay in a 100 mM NaCl/20 mM Tris-HCl buffer (pH 7.4). Fluorescence measures were performed at 20°C for 2 min after the addition of small aliquots of concentrated NaCl, $CaCl_2$, or $MgCl_2$ solutions to the liposome suspensions, in a Kontron SFM 25 spectrofluorimeter at an excitation wavelength of 276 nm. The emission fluorescence was measured at 545 nm using a 530-nm cut-off filter to eliminate the contribution of light scattering. The value for 100% fusion was determined using the reference liposomes (*R*) prepared with solution (*C*). Light scattering controls were performed using unlabeled vesicles. The percentage of fusion was calculated in the same way as for the lipid-mixing assay.

Zeta potential measurement. The zeta potential of the liposomes was measured by the commercial device ZetaSizer 4 of Malvern Instruments (Malvern, Worchestershire, United Kingdom), based on the method of photon correlation spectroscopy (PCS) (44,45). The method uses the autocorrelation function of the light scattered in a colloid solution measured by a photon counting system. The particles move in an electric field of known strength in the interference pattern of two laser beams and produce scattered light, which oscillates in time in a way that depends on the speed of the particles. The light scattered by the particles is collected by the photomultiplier and the measured autocorrelation function is first converted, using a Fourier transform, into a frequency spectrum. The frequencies are then converted successively to velocities, electrophoretic mobility and, finally, zeta potentials. The zeta potential of the liposomes is calculated by means of the Henry correction of Smoluchowski's equation (44),

$$\mu = \frac{2\varepsilon\zeta}{3\eta} f(\kappa a) \qquad [3]$$

where μ is the particle electrophoretic mobility, ε the dielectric constant, ζ the zeta potential, η the aqueous solution viscosity, and $f(\kappa a)$ is the Henry coefficient (46). The Malvern ZetaSizer 4 has an optic unit containing a 5 mW helium-neon laser; a ZET5104 electrophoresis cell, which uses a 4-mm diameter quartz capillary; a sample handling unit; and a multi-8 bit correlator with 72 data channels and 7 monitor channels with variable time expansion. The measurements of the zeta potential were performed at a fixed electrolyte concentration (50 mM NaCl in 10 mM Tris-HCl buffer of pH 7.4) and 25°C, with liposomes prepared from NPPE or NPPS, as described above. The method of liposome preparation used here gave particles with z-average diameters ranging from 300 to 400 nm. In order to check the Malvern device, a carboxy-modified polystyrene latex sample, with a zeta potential of –55 mV at 25°C, was used before each set of determinations.

Surface pressure measurements: compression isotherms. The compression isotherms were measured on a Langmuir film balance equipped with a Wilhelmy platinum plate, similar to that described by Verger and De Haas (47). The output of the pressure pick-up (Beckman LM 600 microbalance) was calibrated by recording the well-known isotherms of stearic acid and dipalmitoylphosphatidylcholine. The Teflon trough (surface area 495 cm^2, volume 330 mL) was regularly cleaned with hot chromic acid; moreover, before each experiment, it was washed with ethanol and rinsed with double-distilled water. Before each run, the platinum plate was cleaned with chromic acid and rinsed with double-distilled water. The films were spread on the aqueous surface using a Hamilton microsyringe, and at least 10 min was allowed for solvent evaporation. Films were compressed at a rate of 4.2 cm/min. Changes in the compression rate did not alter the shape of the isotherms. All the isotherms were run at least three times in the direction of increasing pressure with freshly prepared films. The accuracy of the system under the conditions in which the bulk of the reported measurements were made was ±0.5 mN/m for surface pressure.

RESULTS

Vesicle aggregation. Cation-dependent NPPE and NPPS liposome aggregation was followed by measuring the turbidity changes of lipid vesicle suspensions. Turbidities of small unilamellar NPPE and NPPS liposomes with respect to various Ca^{2+} and Mg^{2+} concentrations are shown in Figure 1A. The sharp increase in turbidity of NPPS liposomes was observed from about 1 mM Ca^{2+} and 2 mM Mg^{2+}. However, when NPPE liposome aggregation was determined, the significant increases in turbidity were observed at higher concentrations, from about 4 mM and above for both Ca^{2+} and Mg^{2+}. In this case, the slopes of the plots obtained for both divalent cations were much less steep, and thus the extent of the aggregation, measured at a given time, was smaller than that corresponding to the NPPS liposomes. The aggregation of NPPS and NPPE liposomes as a function of the lipid concentration is given in Figure 1B. A clear difference between NPPS and NPPE liposomes with regard to the sensitivity toward the aggregation processes was observed when increases in absorbance of the liposome suspensions were plotted vs. the concentration of both aminophospholipid derivatives. As in Figure 1A, the slopes of the Ca^{2+}- and Mg^{2+}-induced aggregation of NPPS liposomes as a function of the lipid concentration were considerably steeper than those obtained for NPPE liposomes. Besides this, the extent of the Mg^{2+}-induced aggregation is higher than that obtained in the presence of Ca^{2+} for either NPPS or NPPE.

In Figure 2, the sodium-induced aggregation of NPPS and NPPE liposomes is plotted vs. cation concentration (A) and vs. lipid concentration (B). The shapes of the curves corresponding to the turbidity values obtained at different Na^+ concentrations are quite different, being more sigmoidal than those obtained for NPPS. Besides this, at the lowest Na^+ concentrations, the aggregation of NPPS liposomes is delayed compared to NPPE liposomes. When turbidities were plotted

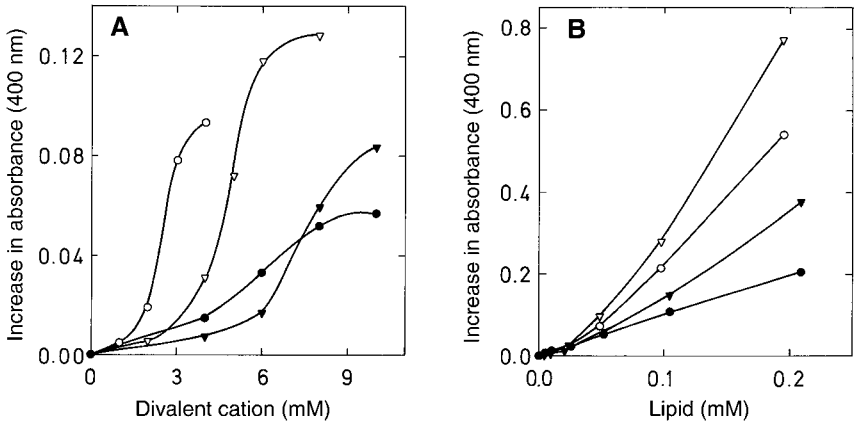

FIG. 1. Divalent cation-induced aggregation of *N*-palmitoylphosphatidylethanolamine (NPPE) and *N*-palmitoylphosphatidylserine (NPPS) unilamellar liposomes as a function of cation (A) and phospholipid (B) concentrations. (A) Influence of calcium (○,●) and magnesium (▽,▼) concentrations in the aggregation of NPPS (○, ▽) and NPPE (●,▼) liposomes. Phospholipid concentration was 0.05 mg/mL in a solution that contained 20 mM Tris-HCl buffer (pH 7.4), and 0.1 mM EDTA. (B) The dependence of the aggregation process on the phospholipid concentration was followed in 20 mM Tris-HCl buffer (pH 7.4), 0.1 mM EDTA, using $CaCl_2$ 3 mM for NPPS (○) and 8 mM for NPPE (●) or $MgCl_2$ 5.5 mM for NPPS (▽) and 8 mM for NPPE (▼). The values in the plots correspond to the average of four independent experiments. Variation coefficients ranged from 1.8 to 3.4.

vs. lipid concentrations (Fig. 2B), at a fixed Na^+ concentration of 0.5 M, great differences between both lipid species were observed. The slope corresponding to the aggregation of NPPE liposomes is very much steeper in comparison to that for NPPS liposomes. These results show a greater influence of lipid concentration in the monovalent cation-induced aggregation of NPPE liposomes in contrast with the results obtained for divalent cations, where the steeper plots were those corresponding to NPPS liposomes (Fig. 1B).

The threshold concentrations were calculated as the cation concentration corresponding to the maximal increase in the rate of absorbance change from the experimental data in Figures 1A and 2A. The calcium, magnesium, and sodium threshold concentrations were, respectively, 6.2, 7.0, and 440 mM for the aggregation of NPPE and 1.9, 4.4, and 720 mM for the aggregation of NPPS unilamellar liposomes. The results obtained show that the order of effectiveness of the cations to induce the initial spontaneous NPPE and NPPS liposomes aggregation is $Ca^{2+} > Mg^{2+} > Na^+$, although at cation concentrations above the corresponding threshold values the extent of the process is greater with Mg^{2+} ions. When comparing the threshold concentrations of divalent cations,

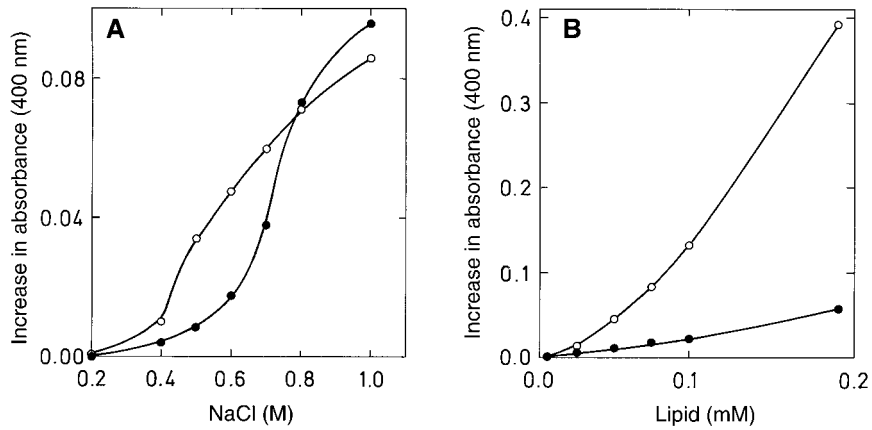

FIG. 2. Turbidity changes of NPPE and NPPS liposome suspensions measured at different sodium (A) and phospholipid (B) concentrations. Phospholipid concentration was 0.05 mg/mL in a solution that contained 20 mM Tris-HCl buffer (pH 7.4), and 0.1 mM EDTA, when the influence of the sodium concentration was studied. The dependence of the aggregation process on the phospholipid concentration was followed in 20 mM Tris-HCl buffer (pH 7.4), 0.1 mM EDTA, using NaCl 0.5 M. (○): NPPE; (●): NPPS. The values in the plots correspond to the average of four independent experiments. For abbreviations see Figure 1. Variation coefficients ranged from 2.1 to 3.8.

we observed that NPPS is more sensitive to aggregation than NPPE but, when Na^+ threshold values were considered, the sensitivity of both lipids to aggregation was reversed.

In Figure 3, the log of the initial rate of aggregation increase at a fixed cation concentration is plotted against the log of the lipid concentration for NPPS and NPPE liposomes. The data yield reasonably linear plots in the range of lipid concentrations from 25 to 200 µM. The slopes, ranging from 1.04 to 1.62, indicate the order of the aggregation reaction and show again the different behavior of NPPS and NPPE liposomes toward the aggregation processes.

Vesicle size changes. The state of aggregation of unilamellar NPPS and NPPE liposomes induced by divalent and monovalent cations was also followed by PCS. Figure 4 shows the changes in the vesicle diameter distribution of NPPS and NPPE liposomes in the presence of divalent (Ca^{2+} and Mg^{2+}) and monovalent (Na^+) cations with respect to their size without added cations. The analysis of the data shows that NPPS and NPPE liposomes, prepared by sonication in 10 mM Tris-HCl buffer media, have an average diameter of 37.8 ± 9.1 and 43.8 ± 9.3 nm, respectively, but the particle size increases in the presence of both divalent and monovalent cations. Table 1 shows the changes in vesicle size resulting from the aggregation processes. It can be seen that, when Ca^{2+} or Mg^{2+} was added to NPPE liposomes to a final concentration slightly lower than the corresponding threshold concentrations, two different-sized vesicle populations were observed. Their mean diameters were 4 and 10 times higher than those observed when the cations were not present. However, only one population of vesicles was obtained when divalent cations were added to NPPS liposomes, the mean di-

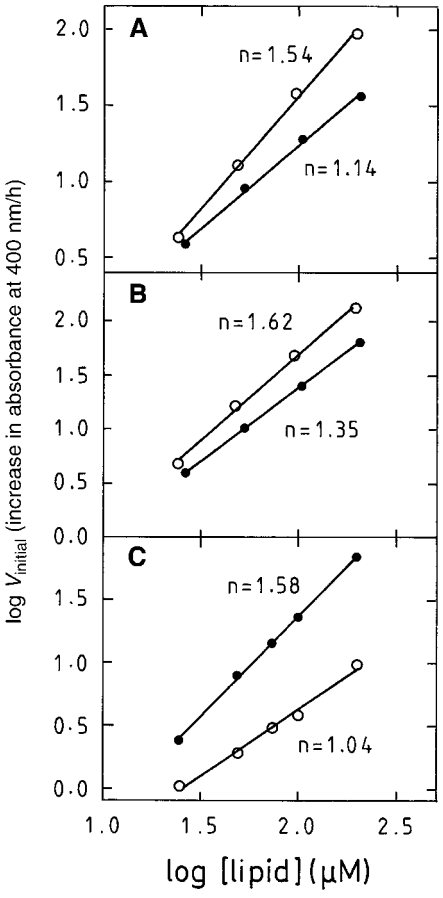

FIG. 3. Dependence of aggregation of small unilamellar liposomes on lipid concentration. Initial rates of aggregation (increase in absorbance units per hour) were plotted in a double-logarithmic manner against NPPS (○) and NPPE (●) concentrations. The aggregation was initiated by addition of: (A) $CaCl_2$ 3 mM for NPPS and 8 mM for NPPE, (B) $MgCl_2$ 5.5 mM for NPPS and 8 mM for NPPE, and (C) NaCl 500 mM for NPPS and NPPE, to liposomes at various lipid concentrations. Initial rates of aggregation have been obtained from the experimental data in Figures 1 and 2. For abbreviations see Figure 1.

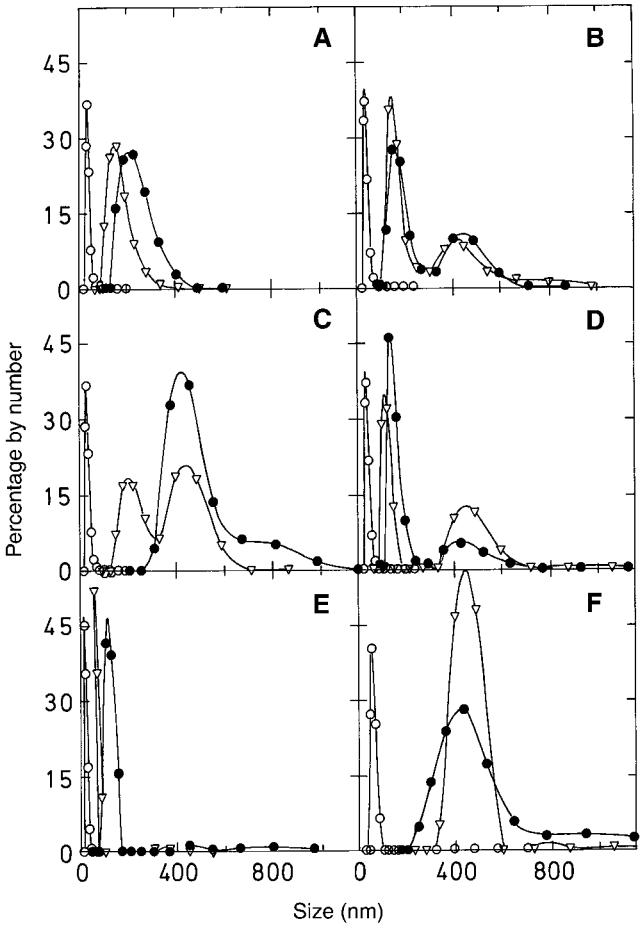

FIG. 4. Light scattering particle size analysis of NPPS (A,C,E) and NPPE (B,D,F) liposomes in the presence of calcium (A,B), magnesium (C,D), and sodium (E,F) ions. The vesicle diameter was measured before (○) and after (●) addition of the three ions. The reversibility of divalent and monovalent cation-induced aggregation was tested measuring vesicle size after EDTA addition (▽) at six times the concentration of divalent cation to the aggregated vesicles or after dilution of the aggregated vesicles up to 200 mM sodium concentration (▽). For this study, NPPS and NPPE concentrations were in all cases 0.1 mg/mL. The $CaCl_2$ concentration was 1.5 mM for NPPS and 5 mM for NPPE. The $MgCl_2$ concentration was 3.5 mM for NPPS and 5 mM for NPPE. The NaCl concentration was 480 mM for NPPS and NPPE. The values in the plots correspond to the average of three independent experiments. For abbreviations see Figure 1. Variation coefficients ranged from 4.3 to 6.2.

TABLE 1
Change in the Number-Size Distribution of NPPE and NPPS Vesicles in the Presence of Different Cations, Measured by Photon Correlation Spectroscopy[a]

Treatment	Average diameter in nm (%)			
	NPPE		NPPS	
None	43.8 ± 9.3 (100)	—	37.8 ± 9.1 (100)	—
+ $CaCl_2$	176.9 ± 36.2 (76)	449.1 ± 73.8 (24)	230 ± 59.8 (100)	—
+ $CaCl_2$ + EDTA	168.7 ± 30.0 (76)	451.7 ± 121.4 (24)	164.8 ± 48.2 (100)	—
+ $MgCl_2$	154.1 ± 25.4 (87)	435.5 ± 89.5 (13)	475.8 ± 132.8 (100)	—
+ $MgCl_2$ + EDTA	124.3 ± 17.5 (73)	474. 9 ± 77.5 (26)	212.5 ± 39.5 (52)	444.3 ± 73.7 (48)
NaCl	453.9 ± 169.9 (100)	—	123.9 ± 17.8 (97)	635.2 ± 172.7 (3)
NaCl + dilution	441.9 ± 50.5 (99)	1168.3 ± 111.8 (1)	68.1 ± 9.4 (98)	358.9 ± 114.8 (2)

[a]For conditions of the assay see Figure 4. The data are the mean diameter values calculated from the number-size distribution for each population ± SD obtained in the measure. The percentage of each vesicle population is indicated in parentheses. NPPE, *N*-palmitoylphosphatidylethanolamine; NPPS, *N*-palmitoylphosphatidylserine.

ameter after Mg^{2+} addition being twice that obtained with Ca^{2+}. After addition of 480 mM Na^+, NPPE liposomes increased their mean size up to 453.9 nm, whereas the increase in size of NPPS liposomes was less significant (mean diameter 123.9 nm).

After addition of EDTA to the divalent cation-aggregated vesicles or after dilution of the sodium-aggregated ones, only a partial reversibility of the aggregation processes occurred, since the size of liposomes did not return to the initial value in any case. These results indicate that divalent and monovalent ions would induce the formation of irreversible aggregates and suggest that vesicle fusion may occur in the presence of both cations.

NPPS and NPPE liposomes fusion. Mixing analysis for both lipid and internal aqueous contents (Figs. 5 and 6), shows that fusion rather than aggregation of NPPS and NPPE liposomes occurs in the presence of both divalent and monovalent ions, as suggested by the irreversibility of the aggregation processes. Figure 5 shows the percentage of fusion of NPPS (A–C) and NPPE (D–F) liposomes, measured as the transfer of resonance energy between NBD-PE and Rh-PE, after the addition of various concentrations of Ca^{2+} (Fig. 5A,D), Mg^{2+} (Fig. 5B,E) and Na^+ (Fig. 5C,F). The percentage of fusion depends on the nature and on the concentration of the cation and increases with time after cation addition. Lipid exchange between NPPS liposomes happened to a similar extent when Ca^{2+} (Fig. 5A) and Mg^{2+} (Fig. 5B) were added at the same concentrations, ranging from 2 to 4 mM, but the extent of this process was much less in the presence of Na^+ (Fig. 5C). In this case the concentrations needed to reach the same percentage of fusion were two orders of magnitude higher. NPPE liposomes also fuse in the presence of divalent (Fig. 5D,E) and monovalent (Fig. 5F) ions, although there are significant differences with regard to the results obtained for NPPS liposomes. Thus, the effectiveness of the divalent cations in inducing lipid mixing was higher for opposed bilayers of NPPS than for NPPE. However, NPPE liposomes were more sensitive than NPPS liposomes to sodium-induced lipid mixing, the most marked differences occurring between the two for additions of 400 and 600 mM sodium. The data obtained from the lipid exchange assays agree with the results of the aggregation studies. In order to show (i) the differences observed between NPPS and NPPE liposomes with regard to their sensitivity to aggregation and fusion in the presence of the cations and (ii) the agreement between the aggregation and fusion behavior of both lipid species, the initial velocity values of the aggregation and fusion processes at a fixed cation concentration have been compared and the ratios between the values obtained for NPPS and NPPE liposomes have been calculated (Table 2).

The data obtained when the mixing of the internal aqueous contents was monitored by the increase in the fluorescence of the Tb^{3+}-DPA complex are shown in Figure 6. Aqueous mixing was studied for both NPPS (Fig. 6 A,B,C) and NPPE (Fig. 6 D,E,F) as a function of Ca^{2+} (Fig. 6A,D), Mg^{2+} (Fig. 6B,E), and Na^+ (Fig. 6C,F). The results obtained show the coalescence of the aqueous contents of both NPPS and NPPE liposomes in the presence of either monovalent and divalent ions and demonstrate the existence of a real fusion, which has already been suggested by the irreversibility of the aggregation processes and the lipid mixing between opposed bilayers of different liposome populations. The effectiveness of divalent and monovalent cations in inducing the mixing of the aqueous contents for both types of liposomes correlates

TABLE 2
Relative Kinetics of Different Cation-Induced Aggregation and Fusion for NPPE and NPPS Small Unilamellar Liposomes[a]

Cation concentration (mM)	Initial rate of increase			
	Absorbance at 400 nm (unit increase/min)		Fluorescence (max/min, %)	
	NPPE	NPPS	NPPE	NPPS
Ca^{2+}: 4	0.044	0.281(6.39)	60	420(7)
Mg^{2+}: 4	0.020	0.093(4.65)	63	330(5.22)
Na^+: 600	0.143	0.053(0.37)	183	66(0.36)

[a]Aggregation and fusion were initiated by addition of the different cations at the concentration indicated at the table. The total lipid concentration was 0.05 mg/mL. Fusion data correspond to lipid exchange measured by the RET assay. Values in parentheses indicate the ratio of initial rates of NPPS aggregation over NPPE aggregation (column three) or the ratio of initial rates of NPPS fusion over NPPE fusion (column five). For abbreviations see Table 1.

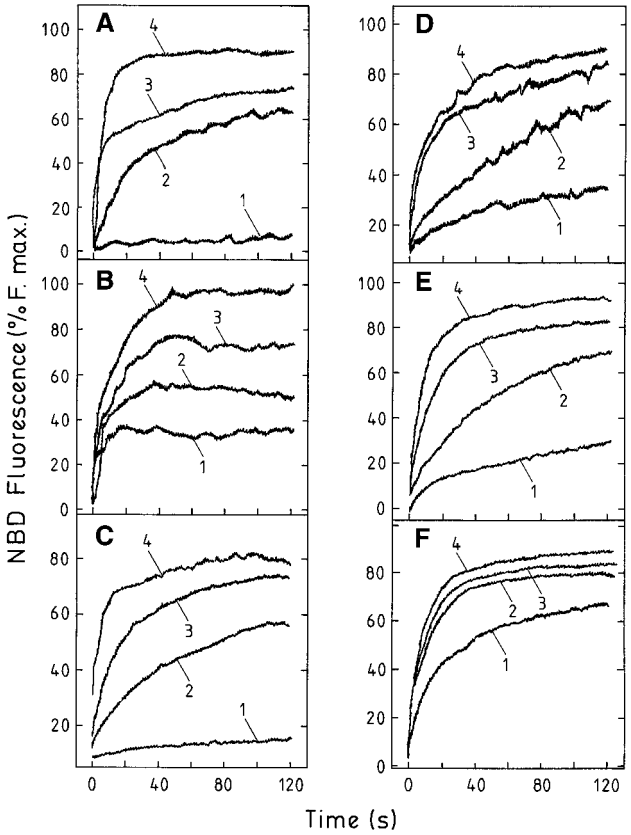

FIG. 5. Lipid mixing by the probe dilution assay of NPPS (A–C) and NPPE (D–F) liposomes, containing 0.5% Rh-PE and 1% NBD-PE, after cation addition. Percent maximal fluorescence changes were plotted vs. time at 20°C after the addition (numbered lines, 1, 2, 3 and 4, in increasing order of concentration) of $CaCl_2$ 1, 2, 3, and 4 mM (A) or 4, 6, 8, and 10 mM (D); $MgCl_2$ 1, 2, 3, and 4 mM (B) or 4, 6, 8, and 10 mM (E); and NaCl 400, 600, 750, and 1000 mM (C,F). The phospholipid concentration was 0.05 mg/mL in a solution that contained 20 mM Tris-HCl buffer (pH 7.4), and 0.1 mM EDTA, 100 mM NaCl. The values in the plots correspond to the average of four independent experiments. Variation coefficients ranged from 3.2 to 5.3. Rh-PE, *N*-(lissamine Rhodamine B sulfonyl)-phosphatidylethanolamine; NBD-PE, *N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-phosphatidylethanolamine; for other abbreviations see Figure 1.

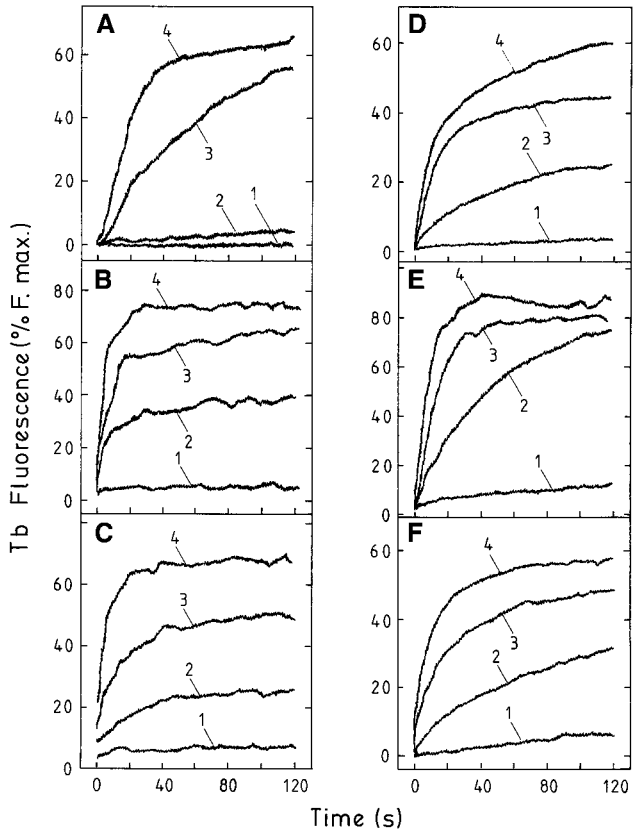

FIG. 6. Aqueous contents mixing of NPPS (A–C) and NPPE (D–F) liposomes, containing 10 mM $TbCl_3$ and 100 mM dipicolinic acid, after cation addition. Percent maximal fluorescence changes were plotted vs. time at 20°C after the addition (numbered lines, 1, 2, 3, and 4, in increasing order of concentration) of $CaCl_2$ 1, 2, 3, and 4 mM (A) or 4, 6, 8, and 10 mM (D); $MgCl_2$ 1, 2, 3, and 4 mM (B) or 4, 6, 8 and 10 mM (E); and NaCl 400, 600, 750 and 1000 mM (C,F). The phospholipid concentration was 0.05 mg/mL of 20 mM Tris buffer solution (pH 7.4). The values in the plots correspond to the average of three independent experiments. Variation coefficients ranged from 3.6 to 6.1. For abbreviations see Figure 1.

well with their effectiveness shown by the RET assay. Nevertheless, despite the fact that the extent of lipid mixing was similar using the same amounts of calcium and magnesium for both NPPS and NPPE liposomes, magnesium was more effective than calcium in inducing aqueous contents mixing. Moreover, regardless of the cation and the lipid used, at a given cation concentration, the extent of the fusion process expressed as mixing of aqueous contents was always lower than the value calculated from the lipid exchange assays.

Modification of liposome surface potential. The zeta potential changes of multilamellar NPPE and NPPS liposomes with respect to Ca^{2+} concentration are plotted in Figure 7. The results show that NPPS liposomes are slightly more negative than NPPE liposomes and that the effect of calcium in increasing the zeta potential values is more marked for NPPS liposomes. These results are in agreement with those obtained in the aggregation and fusion assays.

Compression isotherms. The molecular areas of NPPS and NPPE were estimated from studies of monolayer surface pressure. Compression isotherms were obtained after spreading 25 µL of 1 mg/mL $CHCl_3$ solutions of both lipid species on an aqueous buffered surface (pH 7.4) containing 20 mM Tris-HCl, 100 mM NaCl, and 0.1 mM EDTA. The molecular area values were calculated assuming that, in normal bilayers, the surface pressure is about 32–35 mN/m (48). The area/molecule values obtained from the plots of the compression isotherms were 99 $Å^2$ for NPPE and 106 $Å^2$ for NPPS. This result shows the similarity between the molecular areas of both *N*-acyl derivatives. On the other hand, the significant change in the molecular areas of the *N*-acyl derivatives with respect to their precursors PE and PS points out the influence of the incorporation of the third saturated (palmitic) fatty acid. The molecular areas of both aminophospholipids (PE and PS) reported in the literature range from 65 to 75 $Å^2$ (49,50).

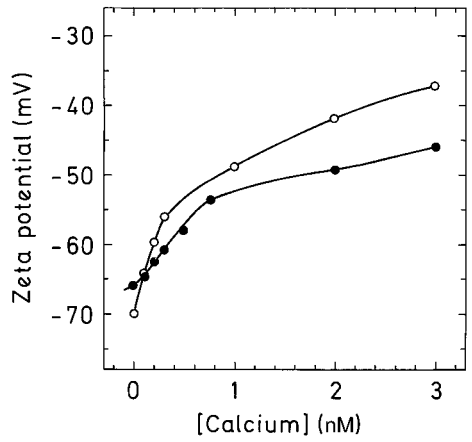

FIG. 7. Modification of the surface charge of multilamellar NPPS (○) and NPPE (●) liposomes by calcium ions at 25°C. Zeta potential variations are plotted as a function of calcium concentration. The total lipid concentration in the measurement cell was 0.5 mg/mL. Experiments were carried out in triplicate. Variation coefficients ranged from 4.4 to 6.5. For abbreviations see Figure 1.

DISCUSSION

These results show the ability of monovalent and divalent cations to induce aggregation and fusion of liposomes constituted by NPPE and NPPS and the differences that existed with regard to the nature of the cation and the nature of the lipid. The threshold concentrations for the aggregation of NPPE and NPPS unilamellar liposomes show that the order of effectiveness of the cations to induce the spontaneous aggregation of NPPE and NPPS liposomes is $Ca^{2+} > Mg^{2+} > Na^{+}$. The data also show that NPPS liposomes aggregate at lower concentrations of divalent cations than NPPE liposomes do and that the greater extent of aggregation at a given concentration of Na^{+} is obtained with NPPE liposomes. The almost linear dependence of the absorbance increases with regard to lipid concentration for NPPE liposomes in the presence of calcium and for NPPS liposomes in the presence of sodium and the exponential curves obtained with magnesium and sodium for NPPE liposomes and with calcium and magnesium for NPPS liposomes show that the reaction order for the aggregation processes depends on the lipid and the cation. The logarithmic secondary plots of the initial aggregation rates vs. lipid concentrations (Fig. 3) give the order of the aggregation reactions, which ranges from 1.04 to 1.64. An order of reaction of about 1 denotes that there is a direct relationship between the aggregation rate and the lipid concentration and that the extent of the process depends on the frequency of the collisions, which in turn depends on the concentration of vesicles. On the other hand, the initial rate of vesicle aggregation can be expected to be second order with respect to vesicle concentration if the existence of a bivesicular step in aggregation is considered (39,51). The order of the aggregation reactions near 1.5, determined in this work, could be justified by assuming that the formation of stable dimers does not occur for all the collisions between two vesicles. A reaction order of 1.5 also has been predicted for the fusion process of the dimyristoylphosphatidylcholine-myristic acid system, in which the rate-limiting step is the activation of a vesicle that remains active for several fusions with either nonactivated (without free fatty acid) or other activated (with free fatty acid) vesicles (52).

The irreversibility of the aggregation process and the intermixing of bilayer components, proved by the probe dilution assay of the RET method, suggest that vesicle fusion rather than mere aggregation occurs with both mono- and divalent cations. Cation concentrations that cause massive aggregation are those that initiate bilayer lipid mixing. Compared to NPPE liposomes, the greater tendency of NPPS liposomes to aggregate or to show lipid mixing in the presence of calcium correlates well with the higher negative surface charge of NPPS vesicles. The zeta potential values obtained by laser Doppler anemometry show the greater affinity of calcium to bind to NPPS bilayers and agree with the higher effectiveness of this cation to induce aggregation and lipid mixing of NPPS liposomes.

The zeta potential values have been calculated from the Henry correction of the Smoluchowski equation, which implies that the mobility of a phospholipid vesicle should be essentially independent of its size and shape for all charge densities. However, electrophoretic mobility depends on the size of vesicles (46) and on the salt concentration (53). In this way, O'Brien and White (54) reported that zeta potentials obtained from the application of classical electrokinetic theory might be seriously underestimated, especially at low electrolyte concentrations. The results of Egorova *et al.* (55), showing that the zeta potential as a function of the ionic strength deviates significantly from the predictions of the double-layer theory in the 1–50 mM range, and the analysis of the electrophoretic mobility by Wiersema *et al.* (56), indicating that for all experimentally accessible charge densities the mobility of a phospholipid vesicle in a 0.114 M monovalent salt solution should be independent of its size, show that in our experimental conditions (ionic strength > 60 mM) the zeta potentials obtained should not differ significantly from the theoretical values. All these considerations point out that the difference in behavior reported in this paper for the two kind of liposomes, in the presence of calcium and under conditions of equal ionic strength, is due to the different nature of their lipid constituents, which determines the different affinities to bind calcium.

The facts that the initial sizes of NPPS and NPPE small liposomes are alike and the molecular areas of both lipid species also are alike point out that the number of lipid molecules per vesicle is similar. However, the higher negative charge of the NPPS molecule, due to its carboxyl group, at physiological pH conditions would account for the differences in the zeta potential values obtained for NPPS and NPPE large liposomes, either in the absence or in the presence of calcium.

The results of the aggregation and lipid exchange studies and the above considerations suggest that the observed differences in the threshold concentrations of monovalent and di-

valent cations that induce massive aggregation and lipid mixing of NPPS and NPPE liposomes are related to the different chemical structures of the polar group of both lipid species and to differences in the negative surface charge of the bilayers.

To prove that sodium, calcium, and magnesium ions induce the fusion of liposomes constituted by NPPE and NPPS, we studied the mixing of the internal aqueous compartments of the vesicles. The assay, which relies on the formation of the fluorescent Tb/DPA complex upon mixing of the vesicle contents and allows continuous monitoring of fusion processes, meets a rigorous criterion for vesicle–vesicle fusion (39,57). Our results demonstrate the coalescence of the aqueous contents of both NPPS and NPPE liposomes in the presence of both monovalent and divalent cations and, thus, the existence of real fusion. However, in spite of the similar effectiveness of monovalent and divalent cations in inducing the mixing of the aqueous contents of NPPE and NPPS liposomes and the exchange of the lipid components of the NPPE and NPPS bilayers, the extent of the mixing of the aqueous contents was always lower than the intermixing of lipid components.

The lower extent of mixing of the internal aqueous contents can be explained in two ways. First, in lipid-mixing measurements there may be a contribution of fusion (mixing of membrane components and coalescence of aqueous contents) and hemifusion processes (merging of the contacting monolayers of opposing membranes, such that only half of each membrane's lipids can mix) (58–60); in this case the hemifusion would give structures stable enough not to develop the initial fusion pores to yield fusion. On the other hand, the lower extent of mixing of internal aqueous contents observed can be explained by a loss of fluorescence due to the leakage of the encapsulated Tb/DPA complex into the EDTA-containing medium or to the entry of EDTA. A more exhaustive study to establish the real extent and the mechanisms of the fusion processes, which includes the consideration of the possible leakage of the fluorescent complex from fused vesicles, is now in progress. On the other hand, the study of aggregation, fusion, and bilayer destabilization carried out in our laboratory with a different *N*-acylaminophospholipid (*N*-myristoylphosphatidylethanolamine, NMPE) has shown a significant Mg^{2+}- and Na^{+}-induced release either of the Tb/DPA complex or carboxyfluorescein, suggesting a vesicle destabilization after fusion; nevertheless, this event does not occur in the presence of Ca^{2+} (Mora, M., Rosell, F., and de Madariaga, M.A., unpublished results). All the same, the curves corresponding to the time course of the mixing of NMPE vesicles content were fairly different from those obtained for NPPS and NPPE with respect to the lesser extent of mixing of internal aqueous contents toward the extent of lipid exchange between the bilayers and the decrease in the fluorescence of the Tb/DPA complex 20 s after cation addition, attributable to Tb/DPA leakage (Mg^{2+}- and Na^{+}-induced fusion) or to the entry of Ca^{2+} or EDTA (Ca^{2+}-induced fusion). Despite the absence of leakage curves, the results of the Tb/DPA assays presented here show the ability of monovalent and divalent ions to induce a real fusion of NPPS and NPPE liposomes, although the percentages of fusion reported could be slightly underestimated with regard to those obtained from the RET assays in the case of a leakage of the Tb/DPA complex or an entry of EDTA happened as the result of membrane destabilization induced by monovalent and divalent cations (Mora, M., Rosell, F., and de Madariaga, M.A., unpublished results).

The differences between the abilities of Ca^{2+} and Mg^{2+} to induce NPPS and NPPE liposome fusion must be related to the effect of ions on the stabilizing hydration layer at the lipid–water interface and to the nature of the membrane surface, which will in turn be related to the conformation of the polar group of the lipid. Wilschut *et al*. (39) reported differences in the fusion of large unilamellar vesicles (LUV) and SUV, composed of pure bovine brain PS, induced by Ca^{2+} and Mg^{2+}. They showed (i) that magnesium does not induce the fusion of LUV but does induce the fusion of SUV, although the extent of this process is limited to a small increase in vesicle size, and (ii) that calcium induces rapid and extensive fusion of LUV and SUV. By contrast, our results showed the ability of Mg^{2+} to induce an extensive fusion of SUV constituted by NPPE or NPPS, that fusion is accompanied by a remarkable increase in vesicle size, and that the effect of magnesium on the NPPS liposome fusion, as measured by size increases, is greater than that of calcium. The different sensitivity of NPPS and NPPE liposomes to Ca^{2+}- and Mg^{2+}-induced fusion with regard to the data reported for PS liposomes could by justified on the basis of the structural modifications due to the N-acylation reaction. The fusion observed in the presence of the monovalent sodium ion underlines the different physical and chemical properties of the *N*-acyl derivatives of membrane aminophospholipids with regard to their precursors. To date, the ability of monovalent cations to induce fusion of liposomal membranes had been reported only by Eklund (61), who showed that sonicated vesicles consisting of acidic phospholipids with fully saturated fatty acids fuse in the presence of monovalent cations, whereas those containing unsaturated fatty acids do not. However, NPPS and NPPE synthesized in this work from natural bovine brain PS and egg TPE contain unsaturated fatty acids at the *sn*-2 position and fuse in the presence of sodium.

The results presented in this paper, together with the cited references (1,11,12,16,19–22,28,29), emphasize the fact that synthesis *in vivo* of N-acylated phospholipids can introduce important changes in membrane-mediated processes. The establishment of the real physiological meaning of the N-acylation reactions, which affect some membrane phospholipids, and the elucidation of the mechanisms by which the N-acylated constituents influence or modify the structure or dynamics of biological membranes are aims of our research. Our results to date seem to point out a protective role of *N*-acylaminophospholipids against membrane damage, as the N-acylation changes the nonbilayer PE into a bilayer lipid, with the resulting stabilization of the lipid bilayer. On the other hand, the incorporation of *N*-acyl derivatives into cell mem-

branes increases their negative charge, because of the formation of an amide bond, and makes them more sensitive to cation-induced fusion. Moreover, the facts (i) that NPPS-containing liposomes fuse to a lesser extent than PS-containing liposomes do, and (ii) that one of the suggested mechanisms for vesicle–vesicle fusion involves the formation of micellar intermediates from the nonbilayer PE, the synthesis of NPPS or NPPE from PS and PE and the resultant decrease in the bilayer levels of both aminophospholipids, would also account for the stabilizing effect of cell membranes against the sudden increases in cation concentrations that occur in some pathological situations. However, the experimental data reported here do not allow us to extrapolate to physiological conditions because the vesicles used were composed of only NPPE or NPPS. The present aggregation and fusion studies, together with our previous publications about permeability properties (19,62), bilayer fluidity (19), and polymorphic behavior (21,63,64) of *N*-acylPE-containing liposomes, have led us to consider the fusogenic characteristics of different mixed liposomes. Moreover, the fusogenic behavior of liposomes containing *N*-acyl derivatives of PE and PS could be helpful in developing drug delivery systems.

Characterization of Inositol Phospholipids and Identification of a Mastoparan-Induced Polyphosphoinositide Response in *Tetrahymena pyriformis*

George Leondaritis and Dia Galanopoulou*

Department of Chemistry, University of Athens, 15771 Athens, Greece

ABSTRACT: The unicellular eukaryote *Tetrahymena* is a popular model for the study of lipid metabolism. Less attention, however, has been given to the inositol phospholipids of the cell, although it is known that this class of lipids plays an important role in eukaryotic cell signaling. *Tetrahymena pyriformis* phosphatidylinositol was isolated, purified, and characterized by proton nuclear magnetic resonance analysis and [2-^{3}H]myo-inositol labeling. Labeling was also used for polyphosphoinositide (phosphatidylinositol phosphate and phosphatidylinositol bisphosphate) identification. *Tetrahymena* inositol phospholipids were found to belong to the diacylglycerol group, although major *Tetrahymena* phospholipids, phosphatidylcholine and aminoethylphosphonoglycerides, have been found to be mainly alkylacylglyceroderivatives. Further characterization of *Tetrahymena* phosphatidylinositol by gas chromatographic analysis indicated that 80% of fatty acids were myristic acid and palmitic acid. This is also in contrast to the fatty acid profile of *Tetrahymena* phosphatidylcholine and phosphatidylethanolamine, with respect both to the fatty acid length and degree of unsaturation, and may indicate that specific diacylglycerol species are connected with the phosphatidylinositol metabolism in this cell. Treatment of [^{3}H]inositol-labeled *Tetrahymena* cells with mastoparan, a G-protein-activating peptide, induced changes in the polyphosphoinositide levels, suggesting that inositol phospholipids may form in *Tetrahymena* a functional signaling system similar to that of higher eukaryotes. Addition of 10 μM mastoparan resulted in a rapid and transient increase in [^{3}H]phosphatidylinositol phosphate followed by a decrease in [^{3}H]phosphatidylinositol bisphosphate. Similar changes in lipids have been reported when phosphoinositide-phospholipase C pathway is activated in both animal and plant cells.

Paper no. L8411 in *Lipids 35,* 525–532 (May 2000).

Tetrahymena is a popular model for the study of various aspects of cell biology including membrane function and lipid metabolism (1). Phospholipid studies have focused on the major glycerophospholipids as well as on their ether and phosphonate derivatives (2). Less attention, however, has been given to some minor constituents like phosphatidylinositol (PI) and its phosphorylated derivatives, although these lipids are known to play a variety of specific roles in cell signaling, protein trafficking, cytoskeletal protein regulation, and secretion, at least in animal cells (3). PI has been described in several *Tetrahymena* species as a component of glycosylphosphatidylinositol (GPI)-anchored proteins which can serve as surface immobilization antigens or participate in cell differentiation (4,5). Interestingly, in *T. mimbres*, the lipid moiety of GPI-anchored proteins has been identified as an inositolphosphorylceramide (6). PI was not detected by proton nuclear magnetic resonance (NMR) analysis of lipids of *T. thermophila* (7). In contrast, using [^{32}P]phosphate labeling, PI and putative phosphatidylinositol phosphate (PIP) and phosphatidylinositol bisphosphate (PIP_2) were purported to be present in *T. pyriformis* and to change in response to hormonal (insulin) imprinting; however, a complete characterization of the [^{32}P]phosphate-labeled lipids was not done (8). In a recent report, stomatin, which induces cytodifferentiation in *T. vorax*, was found to change polyphosphoinositide levels as an early response (9).

In the present report we have isolated, purified, and characterized PI from *T. pyriformis* W cultures; we have established the presence of polyphosphoinositides by [^{3}H]inositol labeling, and we show that treatment of cells with mastoparan, a G-protein-activating peptide, induces changes in the intracellular levels of polyphosphoinositides, suggesting that these lipids may form a functional signaling pathway, as described for higher organisms. Finally, we draw attention to the potential benefits of using *Tetrahymena* as a model cell system for the study of other polyphosphoinositide-regulated cellular functions like regulated exocytosis, a pathway known to exist in *Tetrahymena*.

EXPERIMENTAL PROCEDURES

Materials. Yeast extract, phospholipid standards, PI, phosphoinositides, boron trifluoride/methanol, and mastoparan were obtained from Sigma (Steinheim, Germany, or St. Louis,

Abbreviations: AEPL, aminoethylphosphonoglyceride; 1-D, one-dimensional; 2-D, two-dimensional; DAG, diacylglycerol; GC, gas chromatography; GPI, glycosylphosphatidylinositol; GroPI, glycerophosphoinositol; GroPIP, glycerophosphoinositol phosphate; $GroPIP_2$, glycerophosphoinositol bisphosphate; NMR, nuclear magnetic resonance; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PIP, phosphatidylinositol 4-phosphate; PIP_2 phosphatidylinositol 4,5-bisphosphate; PLC, phospholipase C; PTX, pertussis toxin; TLC, thin-layer chromatography.

MO). Silica gel 60H and 60G and proteose peptone were purchased from Merck (Darmstadt, Germany). LK5D silica gel plates were from Whatman (Clifton, NJ) and Dowex AG 1-x8 Poly-Prep columns, formate form, from Bio-Rad (Hercules, CA). D-Myo [2-^{3}H]inositol (specific activity 21.0 Ci/mmol) was purchased from ICN (Irvine, CA) and phosphatidyl[2-^{3}H]inositol 4,5-bisphosphate (specific activity 1–5 Ci/mmol) from Amersham (Buckinghamshire, United Kingdom). Fatty acid methyl ester standards were obtained from Chem Service (West Chester, PA). All other chemicals and solvents were of analytical grade.

Cell cultures and labeling. Tetrahymena pyriformis, strain W was cultured at 25°C under constant shaking in an enriched proteose peptone medium consisting of 2% proteose peptone, 0.5% glucose, and 0.2% yeast extract. For the study of incorporation of [^{3}H]inositol into *Tetrahymena* lipids and for mastoparan experiments, cultures were supplemented with Fe^{2+}/EDTA 9 mM, pH 5.5 (2%, vol/vol) (10). For isolation and characterization of PI and [^{3}H]inositol phospholipid characterization, cultures grown at a slower rate were used. These cultures were generated using stock cultures of the same enriched growth medium and had a late log phase at around 70 h. [^{3}H]Inositol was added to 42-h-old cultures (25 mL, 0.4–0.6 × 10^6 cells/mL) at a final concentration of 1 μCi/mL. Cells were labeled for 24 h and then harvested by centrifugation for lipid extraction.

Lipid extraction and thin-layer chromatography (TLC). For quantitative recovery of inositol phospholipids from aliquots of cell suspensions, cells were harvested by centrifugation (1,000 × *g* for 5 min), and lipids were extracted according to Schacht (11). Briefly, 1.5 mL of ice-cold chloroform/methanol (1:2, vol/vol) was added to the cell pellet (4 × 10^6 cells or less), and after 30 min on ice and frequent vortexing, EDTA 0.1 M, HCl 2.4 N, and chloroform (0.5 mL each) were added sequentially with vortexing at room temperature. The mixture was centrifuged at 2,500 × *g* for 6 min, the lower phase was removed, and the upper phase was reextracted twice with 0.5 mL chloroform. The combined chloroform phases were washed with an equal amount of methanol/HCl 1 N (1:1, vol/vol). Lipid extraction from a whole 25-mL culture was accomplished by adding 12 mL of chloroform/methanol (1:2, vol/vol) to the cell pellet. For small lipid samples, lipids were separated by one-dimensional (1-D) TLC on oxalate-impregnated heat-activated LK5D plates (12) or, for lipid purification, on silica gel H plates, prepared my mixing silica gel H and 2.1% potassium oxalate at a ratio of 1:2.6 (wt/vol). For inositol phospholipid separation, a chloroform/methanol/ammonium hydroxide/water (86:76:6:16, by vol) solvent system was used (12). Two-dimensional (2-D) TLC was performed on silica gel G plates according to Kates (13). In this case, lipids were identified by running authentic standards on a different plate. Lipids separated by TLC were detected by exposure to iodine vapor. For the quantification of [^{3}H]inositol-labeled lipids, the silica gel was scraped off the 1-D plate in 0.3–1 cm fractions or, alternatively, bands corresponding to inositol phospholipid internal standards were scraped off. All samples were assayed for radioactivity by liquid scintillation counting using 5–10 mL of a toluene-based scintillation fluid in a Pharmacia, model 1209 RackBeta counter (Turku, Finland). For further analysis of inositol phospholipids, lipids were extracted from the silica gel according to Schacht (11) by addition of 2.4–12 mL chloroform/methanol (1:2, vol/vol) depending on the amount of silica gel. The volumes of EDTA 0.1 M, HCl 2.4 N, and chloroform were also adjusted. Lipid phosphorus determination was performed as described by Marinetti (14).

Alkaline hydrolysis of lipids and Dowex chromatography. Mild alkaline hydrolysis of 2-D TLC-purified [^{3}H]inositol-labeled PI and 1-D TLC-purified [^{3}H]inositol-labeled PIP and PIP_2 was performed according to Dittmer and Wells (15). Samples were resuspended in 0.5 mL chloroform/methanol (1:4, vol/vol) and, after addition of 0.050 mL of NaOH 1 N in methanol/water 1:1 (vol/vol), the lipids were hydrolyzed at 37°C for 10 min. Isobutanol, which was included in the subsequent partitioning, enhances the recovery of lysophospholipids in the organic phase. The resulting water-soluble products were chromatographed on Dowex AG 1-x8 columns, formate form. The aqueous phase of the hydrolysis was diluted with water (1:1), loaded onto Dowex columns, and the products were eluted batchwise with increasing concentrations of ammonium formate in formic acid (16). Glycerophosphoinositol (GroPI) was eluted with 60 mM ammonium formate/5 mM sodium borate, and the glycero-derivatives of PIP and PIP_2 were eluted with 12–14 mL of 0.4 M ammonium formate/0.1 M formic acid and 10–12 mL of 1 M ammonium formate/0.1 M formic acid, respectively. Deacylated standard phosphatidyl[2-^{3}H]-inositol 4,5-bisphosphate was used for the calibration of the columns. Total [^{3}H]inositol-labeled *Tetrahymena* lipids were deacylated with methanolic NaOH as described by Downes and Michell (16), and the water-soluble products were analyzed as above. In all cases, 2-mL fractions were collected, and the radioctivity was assayed by liquid scintillation counting using a dioxane/naphthalene/water scintillation fluid.

Proton NMR analysis. Tetrahymena PI or standard PI (approx. 15 μg of lipid phosphorus) was dissolved in 0.8 mL methanol-d_4/chloroform-d_1 (2:1, vol/vol) and transferred to 5-mm NMR tubes. Proton NMR spectra were recorded using Bruker DRX400 and AM 500 NMR spectrometers at 20°C in the Fourier transform (FT) mode with 32K data points, using a 45° detection pulse and 4.0-s acquisition time. Chemical shifts were referenced to the residual methanol resonance at 3.3 ppm.

Fatty acid analysis. Fatty acid composition of PI, phosphatidylcholine (PC), and phosphatidylethanolamine (PE) was estimated by gas chromatography (GC) of the methyl ester derivatives. The lipids were methylated by heating the samples at 70°C for 30 min in boron trifluoride/methanol (14% wt/vol), and the fatty acid methyl esters were extracted two times with diethyl ether which was then dried with sodium sulfate (17). GC was performed using a Hewlett-Packard GC (flame-ionization detector) on a BPX70-coated fused-silica capillary column (25.0 m × 0.32 mm i.d., 0.2 μm film thickness) (SGE, Ringwood, Australia), under pro-

grammed conditions from 100°C at 4°C/min to 200°C (3 min) and a post run at 250°C for 2 min. Carrier gas was He at a flow rate of 1 mL/min. Commercially obtained fatty acid methyl esters were used as standards.

Cell treatment with mastoparan. Tetrahymena cultures (25 mL) were incubated at 25°C for 48 h with [^{3}H]inositol (1.2 μCi/mL, added at the time the cells were transferred into fresh medium), and the cells were harvested by centrifugation and resuspended at 0.7×10^6 cells/mL in 0.25 M sucrose adjusted to pH 7.0. After 40 min, 1-mL aliquots were removed, placed in Eppendorf tubes and treated with 10 μM (final concentration) mastoparan or water (control samples) for the indicated times. Cells were then harvested by a 10-s centrifugation in a microfuge. After the medium was discarded, the lipids were extracted as described above and analyzed by TLC. Microscopic examination of cells revealed no visible changes in cell morphology or motility after mastoparan treatment.

RESULTS

Tetrahymena *PI isolation and identification by ^{1}H NMR spectroscopy.* Lipids of logarithmic phase *T. pyriformis* cells were extracted and separated by 1-D TLC. The spot with R_f identical to that of authentic PI was scraped off the plate and, after elution from the silica gel, lipids were subjected to a 2-D TLC separation as shown in Figure 1. In two separate experiments, isolated PI, after extraction from the silica gel and phosphorus determination, was found to account for 3.9 ± 0.3% of total lipid phosphorus.

Proton NMR analysis of 2-D TLC-purified *Tetrahymena* PI revealed the presence of an inositol moiety; the ^{1}H NMR spectrum of *Tetrahymena* PI was identical to that of standard PI (not shown), however, minor differences did occur and were attributed to structural differences of the two molecules, e.g., fatty acids esterified on the glycerol moiety. Characteristic chemical shifts corresponding to the six protons of the inositol ring (18) were observed at about 3.6 (H-4), 3.8 (H-6, a triplet), 4.0 (H-1), and 4.2 ppm (H-2) (Fig. 2) and at 3.2 and 3.4 ppm (H-5 and H-3 respectively, triplets which are not shown in the expanded version of the spectrum in Fig. 2). Peaks at 4–4.2 ppm were partially overlapped by the glycerol C-1 and C-3 proton multiplets. The signal at about 4.4 ppm (double doublets) is assigned to the glycerol C-1 proton downfield resonance (7,18). No indication of other possible contaminating lipids such as choline or ethanolamine phospholipids (singlets at 3.2 ppm or a triplet at 3.1 ppm, respectively) (7,18) was obtained from the NMR data.

Characterization of PI by [^{3}H]inositol labeling and alkaline hydrolysis. Mid-log *T. pyriformis* cells were incubated with [^{3}H]inositol, and the radioactive lipid extract was chromatographed on 1-D and 2-D TLC as described above. Under these conditions, PI was found to be labeled at a specific radioactivity of 4,500 cpm/nmol. The 2-D TLC-purified [^{3}H]inositol-labeled PI was further characterized by mild alkaline hydrolysis. By using the conditions of Dittmer and Wells (15), 98.9 ± 0.1% (n = 2) of the radioactivity was released in the aqueous phase, while the remaining chloroform-soluble radioactivity was found to consist exclusively of nonhy-

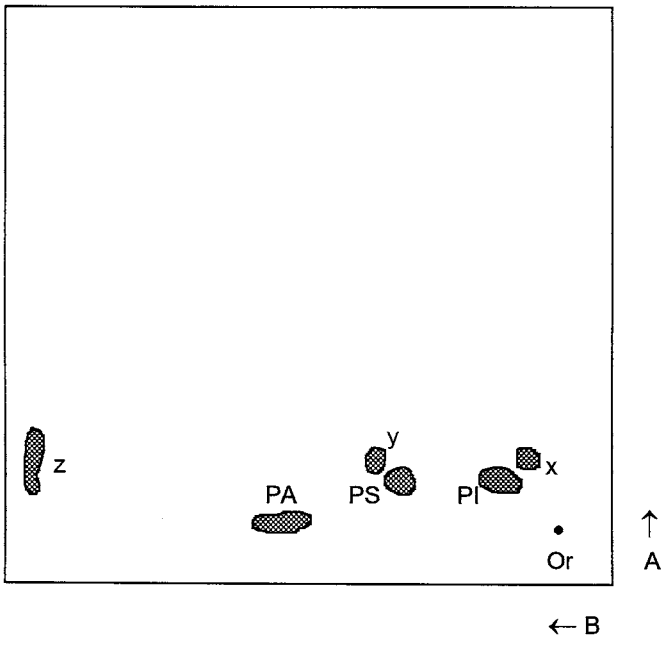

FIG. 1. Two-dimensional (2-D) thin-layer chromatography (TLC) analysis of *Tetrahymena* lipids co-chromatographed with phosphatidylinositol (PI) on 1-D TLC. Solvent systems: (A) chloroform/methanol/ammonium hydroxide (65:35:5, by vol) and (B) chloroform/acetone/methanol/acetic acid/water (14:4:2:2:1, by vol). *x, y* and *z,* unidentified lipids. PA, phosphatidic acid; PS, phosphatidylserine; Or, origin.

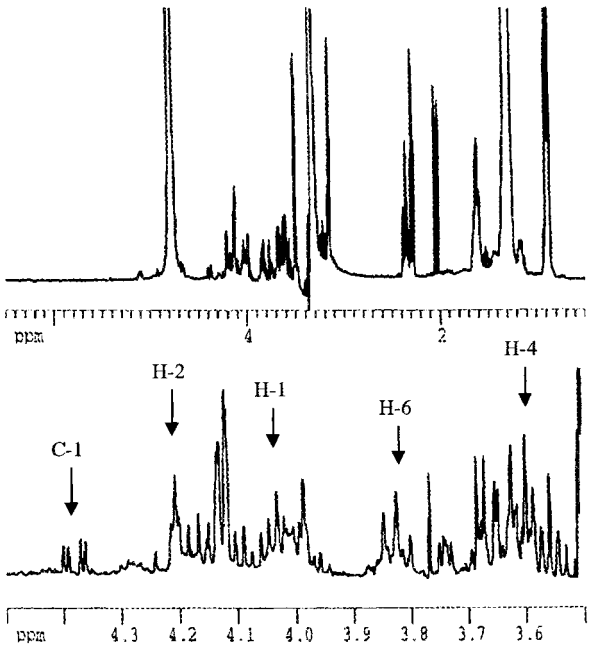

FIG. 2. Proton nuclear magnetic resonance spectrum of 2-D TLC-purified *Tetrahymena* PI. An expanded version (3.5–4.5 ppm) is shown at the lower half of the figure. C-1 and H-1, H-2, H-4, H-6 refer to glycerol and inositol ring protons, respectively. For abbreviations see Figure 1.

drolyzed PI when chromatographed on TLC. No [^{3}H]inositol-labeled lyso-PI, indicative of an alkylacyl inositol phospholipid, was detected. Furthermore, as inositolphosphorylceramide is not hydrolyzable under these conditions, its presence can be excluded as well.

The water-soluble product(s) of alkaline hydrolysis were studied by anion-exchange Dowex chromatography. As shown in Figure 3, the major product was GroPI (95%), while some inositol (3%) and inositol monophosphate (1.5%) were also detected. These results show that PI is almost exclusively a diacyl phospholipid, in contrast to other *Tetrahymena* phospholipids like PC and aminoethylphosphonoglyceride (AEPL) (19,20).

Fatty acid analysis of Tetrahymena *PI.* As the fatty acid profile of PI (and PIP and PIP_2) can give an indication of the diacyglycerol (DAG) species connected to the metabolism of these phospholipids, *Tetrahymena* PI, isolated as described above, was subjected to fatty acid analysis after preparation of the fatty acid methyl esters. PI fatty acid composition is shown in Table 1, together with the fatty acid content of the main *Tetrahymena* phospholipids, PC and PE. PC and PE were isolated from the same cell extract, by separation on silica gel G plates with a chloroform/methanol/water (65:25:4, by vol) solvent system. As shown in Table 1, the fatty acid profile of *Tetrahymena* PI was significantly different compared to that of PC and PE with respect to the fatty acid chain length and degree of unsaturation. Myristic acid (14:0) was the predominant PI fatty acid (48.1%). Myristic acid and palmitic acid (16:0) together represent about 82% of total fatty acid content of PI. Pentadecanoic acid (15:0), another saturated fatty acid, also was detected; however, stearic acid (18:0) was present only in trace amounts. Although C18 fatty acids were absent from PI, they accounted for more than 50% of PE and PC fatty acids. The fatty acid profile of PC and PE was comparable with previously published data (19,20), except that oleic acid (18:1), and not linolenic acid (18:3), was found to be the predominant C18 fatty acid. This could be attributed to the different culture growth conditions, but it also could be due to the different isolation procedure used. The absence of unsaturation in the fatty acids of *T. pyriformis* PI was confirmed by the NMR data, since no characteristic double-bond proton resonances at 5.3–5.4 and 2.8 ppm (7) were obtained (Fig. 2). Fatty acid analysis of PIP and PIP_2 was not performed due to the low content of these phospholipids.

TABLE 1
Fatty Acid Composition (wt% of total fatty acids) of *Tetrahymena* PI, PC, and PE[a]

Fatty acid	PI	PC	PE
12:0	—	1.9	6.0

[a]Values represent means of four determinations from two different cell cultures. PI, phosphatidylinositol; PC, phosphatidylcholine; PE, phosphatidylethanolamine. Fatty acids in parentheses are unidentified and have the retention times (R_T) given.

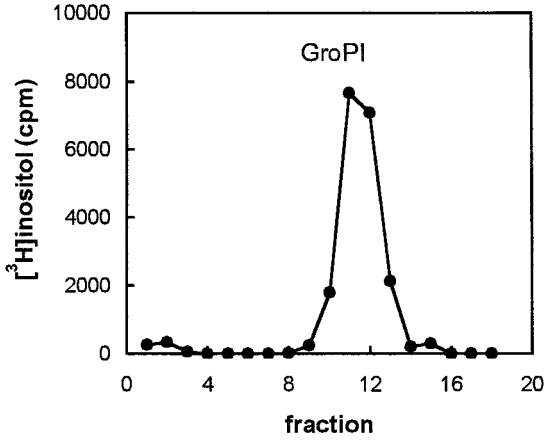

FIG. 3. Analysis of water-soluble deacylation products of [^{3}H]inositol-labeled 2-D TLC-purified *Tetrahymena* PI on Dowex AG 1-x8 columns. Deacylation was performed with methanolic NaOH as described in the Experimental Procedures section. Fractions 1–7 were eluted with water, fractions 8–14 with ammonium formate 60 mM/sodium tetraborate 5 mM, and fractions 15–18 with ammonium formate 0.2 M/formic acid 0.1 M. GroPI, glycerophosphoinositol; for other abbreviations see Figure 1.

Tetrahymena *polyphosphoinositide analysis.* Since *Tetrahymena* can readily incorporate exogenous [^{3}H]inositol into PI, we employed the same strategy to examine both the presence of polyphosphoinositides and their possible implication in cell signaling. When logarithmic phase *Tetrahymena* cells were incubated with [^{3}H]inositol, the radioactivity was incorporated not only into PI but also into PIP and PIP_2. Figure 4 shows a typical TLC separation of [^{3}H]inositol-labeled lipids of *T. pyriformis* on Whatman LK5D plates. Cells were labeled for 24 h with [^{3}H]inositol (1 μCi/mL) and extracted according to Schacht (11). The polyphosphoinositides were identified by the addition of unlabeled standard PIP and PIP_2 to the lipid extract prior to TLC. The PI/PIP/PIP_2 ratio, based on the incorporation of radioactivity, was 85:4.4:1. In fact, the PIP/PIP_2 ratio ranged between experiments from 4.4:1 to 1.3:1, depending on the labeling time. The rate of incorporation of [^{3}H]inositol into the phosphoinositides was examined using logarithmic cells labeled for 1, 4, and 18 h. Incorporation of [^{3}H]inositol into PI and PIP reached saturation after 4 h. In contrast, [^{3}H]inositol incorporation into PIP_2 had not reached saturation even after 18 h (data not shown).

In order to verify the data obtained from TLC analysis with respect to the identity of polyphosphoinositides, 1-D TLC-purified [^{3}H]inositol-labeled PIP and PIP_2 or total [^{3}H]inositol-labeled lipids were subjected to alkaline hydrolysis. The

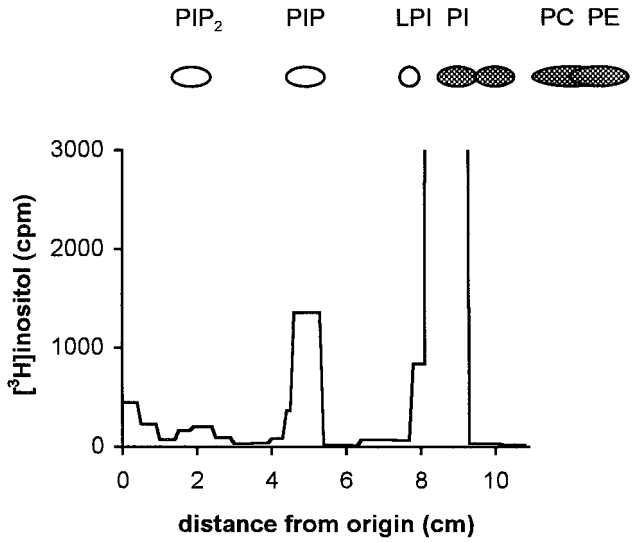

FIG. 4. TLC analysis of *Tetrahymena* [^{3}H]inositol-labeled inositol phospholipids on oxalate-impregnated Whatman LK5D plates. Solvent system: chloroform/methanol/ammonium hydroxide/water (86:76:6:16, by vol). Silica gel was scraped off the plate in 0.3–1 cm fractions and assayed for radioactivity. Unshaded spots represent inositol phospholipid internal standards and shaded spots *Tetrahymena* lipids detected by iodine vapor. PIP, phosphatidylinositol phosphate; PIP_2, phosphatidylinositol bisphosphate; LPI, lysophosphatidylinositol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; for other abbreviation see Figure 1.

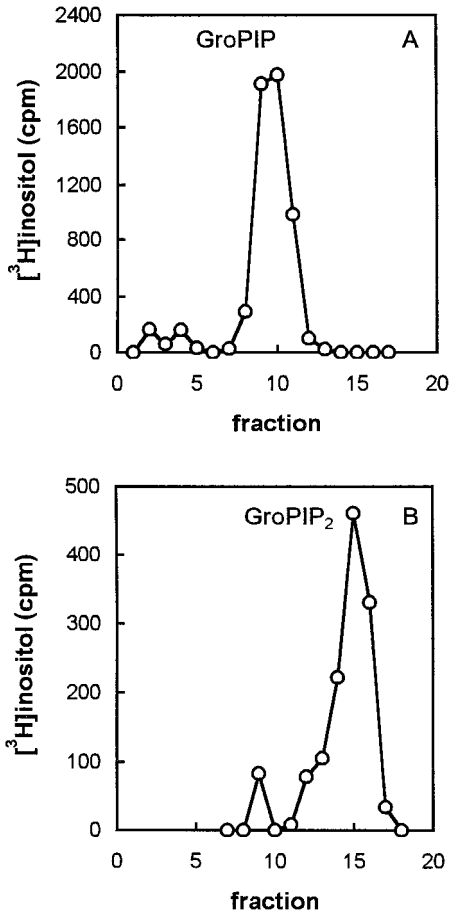

FIG. 5. Analysis of water-soluble deacylation products of [^{3}H]inositol-labeled 1-D TLC-purified *Tetrahymena* PIP (A) and PIP_2 (B) on Dowex AG 1-x8 columns. In (A), fractions 1–6 were eluted with ammonium formate 0.2 M/formic acid 0.1 M, fractions 7–13 with ammonium formate 0.4 M/formic acid 0.1 M, and fractions 13–17 with ammonium formate 1 M/formic acid 0.1 M. In (B), fractions 7–11 were eluted with ammonium formate 0.4 M/formic acid 0.1 M and fractions 12–18 with ammonium formate 1 M/formic acid 0.1 M. GroPIP, glycerophosphoinositol phosphate; $GroPIP_2$, glycerophosphoinositol bisphosphate. For other abbreviations see Figures 1 and 4.

deacylated phospholipid products were then analyzed by Dowex chromatography. Figure 5 shows the deacylation products of PIP (glycerophosphoinositol monophosphate, GroPIP; 93%) and PIP_2 (glycerophosphoinositol bisphosphate, $GroPIP_2$; 87%), eluted with 0.4 and 1 M ammonium formate/0.1 M formic acid, respectively. When total [^{3}H]inositol-labeled *Tetrahymena* lipids were deacylated, the ratio of GroPI to GroPIP to $GroPIP_2$ was very similar to that of the parent lipids (Table 2).

In order to investigate whether *Tetrahymena* PIP is the 4- and/or 3-isomer, 1-D TLC-purified [^{3}H]inositol-labeled PIP was chromatographed using the borate-based TLC system of Walsh *et al.* (21). The silica gel was scraped off the plate in 0.2–0.3 cm fractions, and the radioactivity was counted. All the [^{3}H]inositol label was found to constitute one peak with an R_f value of 0.46 corresponding to phosphatidylinositol 4-phosphate; no evidence for the presence of phosphatidylinositol 3-phosphate (expected R_f value 0.51) was obtained. We cannot, however, exclude at this point the presence of phosphatidylinositol 3-phosphate, since this isomer might be present in substantially lower amounts than phosphatidylinositol 4-phosphate. Different labeling or growth conditions may well reveal the 3-isomer.

Stimulation of polyphosphoinositide metabolism by mastoparan. As polyphosphoinositides are known to be involved in animal cell signaling, we carried out experiments to test for

TABLE 2
Percentage Distribution of [^{3}H]Inositol-Labeled *Tetrahymena* PI, PIP and PIP_2 and Their Corresponding Water-Soluble Products After Lipid Deacylation[a]

	% of total [^{3}H]inositol
TLC	
PI	93.5
PIP	5.6
PIP_2	0.87
Dowex	
GroPI	94.7
GroPIP	4.7
$GroPIP_2$	0.69

[a]The same lipid extract was analyzed by thin-layer chromatography (TLC) and by Dowex chromatography after deacylation. PIP, phosphatidylinositol-4-phosphate; PIP_2, phosphatidylinositol bisphosphate; GroPI, glycerophosphoinositol; GroPIP, glycerophosphoinositol phosphate; $GroPIP_2$, glycerophosphoinositol bisphosphate. For other abbreviation see Table 1.

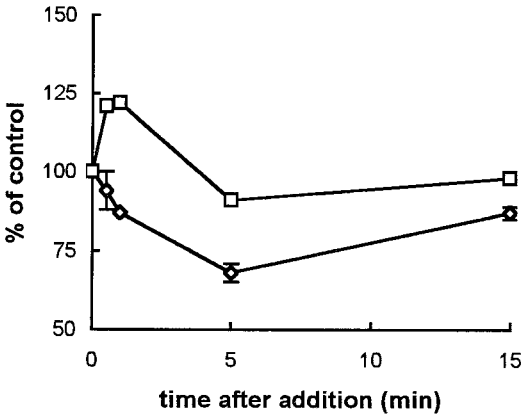

FIG. 6. Effect of 10 μM mastoparan on [^{3}H]inositol-labeled PIP (□) and PIP_2 (◇). Each value is the mean of duplicate determinations from a representative of three independent experiments. Results are expressed as percentages of their corresponding controls. In these experiments, PIP and PIP_2 accounted for 3.0–3.4 and 0.5–0.7%, respectively, of total radioactivity present in control samples (33,000–38,000 dpm). For abbreviations see Figure 4.

a similar role in *T. pyriformis*. [^{3}H]Inositol-labeled *T. pyriformis* cells were treated with 10 μM mastoparan, an effective phospholipase C (PLC) stimulator in several cell systems (22–25). Figure 6 shows mastoparan effects on both PIP and PIP_2 levels. Mastoparan increased [^{3}H]inositol-labeled PIP (20% in 0.5–1 min), which then returned to basal levels. [^{3}H]PIP_2 was decreased by 30% after a 5-min treatment. The decrease of PIP_2 was followed by a slower recovery toward control values at 15 and 30 min. In one experiment, a PIP_2 increase similar to that of PIP was observed immediately after treatment (not shown). This was followed by the PIP_2 decrease shown in Figure 6. These observations could reflect an enhanced PIP and probably PIP_2 synthesis prior to or concurrently with PIP_2 breakdown, as suggested in the case of platelet response to thrombin stimulation (26), mastoparan-treated *Chlamydomonas* cells (25), and osmostimulated *Galdieria sulphuraria* cells (27).

DISCUSSION

There are a number of reports on the utilization of PI by the unicellular *Tetrahymena* for cell surface protein anchoring (4–6), but less attention has been given to free PI which has never been convincingly shown to exist in this organism. In this report, we present for the first time structural characterization of *T. pyriformis* PI, and we also study the presence of polyphosphoinositides and their possible implication in *Tetrahymena* cell signaling.

PI was identified by ^{1}H NMR analysis, and it was found to account for about 4% of *Tetrahymena* phospholipids. In a study employing [^{32}P]phosphate labeling of *T. pyriformis* phospholipids, Kovacs and Csaba (28) reported a value of 12% for PI, but this result could be attributed to an overestimation of the PI content in the TLC or, to possible nonequilibrium labeling conditions. When we incubated *Tetrahymena* cells with [^{3}H]inositol, PI presence was confirmed. The incubation resulted in the incorporation of radioactivity not only into PI but also into PIP and PIP_2. These polyphosphoinositides were identified by co-migration with standards on TLC plates and by anion-exchange chromatography of their glyceroderivatives on Dowex columns after alkaline hydrolysis. In animal cells polyphosphoinositides are usually present in equal amounts; however, in *Tetrahymena* the PIP/PIP_2 ratio is close to that found in other unicellular organisms like the protozoa *Trypanosoma* and *Paramecium* (29,30).

Studies of the main phospholipids of *Tetrahymena* have revealed the presence of alkyl moieties in PC and AEPL (60% of the corresponding lipid) (19,20). Therefore, the presence of alkylacylphospholipids tends to be one of the cell structural characteristics. We carried out experiments to test for a possible alkylacyl content of PI isolated from *Tetrahymena* extracts, for the additional reason that other protozoa have been found to contain similar lipids (31). We found that PI is exclusively a diacylphospholipid, since mild alkaline hydrolysis resulted in a water-soluble product identified as GroPI.

Fatty acid analysis of *Tetrahymena* PI resulted in a profile that contradicts what is known for mammalian cells and other unicellular eukaryotes. For example, mammalian cell PI is rich in arachidonoyl-oleoyl-species (32), and in *Paramecium*, PI has been found to contain mainly unsaturated C18 acids and palmitic acid (30). The most striking finding, however, was the significantly different PI fatty acid profile when compared with that of PC and PE, with the high percentage of myristic acid, the absence of C18 fatty acids, and the absence of any unsaturation as the main differences. A quite similar pattern concerning these differences has been reported for *Saccharomyces cerevisiae* in which saturated fatty acids predominate in PI, whereas they are present in low amounts in PC and PE (33). The similarity in the fatty acid content of PC and PE (Table 1) can be attributed to the common biosynthetic pathways of the two lipids, as PC in *Tetrahymena* is synthesized mainly by methylation of PE (2). A possible explanation for the different PI fatty acid profile is the use of a distinct phosphatidic acid pool for the generation of CDP-DAG available for PI biosynthesis. However the existence of a fatty acid remodeling pathway after PI biosynthesis (32) cannot be excluded, since recently we have found in *Tetrahymena* an active deacylation pathway *via* phospholipase A and lysophospholipase leading from PI to GroPI (Leondaritis, G., Kapetaniou, V., and Galanopoulou, D., unpublished data). The fatty acid profiles of PI and PC/PE may well indicate the specific DAG species with which the turnover of these lipids is connected. Thus, a specific PLC activity against PI (and possibly PIP and PIP_2, since these three lipids are expected to share a common fatty acid content) would lead to the formation of DAG species with relatively short and saturated fatty acids in contrast to what is expected when a PC–PLC is considered. It is likely therefore that such DAG species may have distinct roles in the cell.

In animal cells, signaling by PIP_2 hydrolysis to DAG and water-soluble inositol 1,4,5-trisphosphate is a central path-

way in cell control mechanisms, and it often proceeds through the activation of G-proteins (34). To test for the involvement of *Tetrahymena* polyphosphoinositides in cell signaling, we investigated mastoparan effects on *T. pyriformis* PIP and PIP_2 levels. Mastoparan is a G-protein-activating peptide, and it is more potent against members of the pertussis toxin (PTX)-sensitive Gi/o family (35). The choice of mastoparan for our experiments was supported by indications for the involvement of PTX-sensitive G-proteins in the regulation of phagocytosis in *Tetrahymena* (36) and the effective use of an antibody specific for the preserved GTP-binding site of the G-protein α-subunits in the same organism (37). It is important to add, however, that, in some systems, mastoparan can increase cytosolic calcium *via* different pathways, and therefore its effects on phosphoinositide metabolism could be attributed to a calcium-regulated pathway. Results shown in Figure 6 suggest that a PLC-based signaling pathway may exist in *Tetrahymena* cells. Although the kinetics of stimulated PIP_2 depletion was slower compared to that obtained from studies in animal cells (22,38), this response could be partially explained by the observed upregulation of PIP levels, which could initially mask the breakdown of PIP_2. This kind of stimulated polyphosphoinositide metabolism has been suggested to take place in several cases of agonist or stress-induced activation of the PI cycle in animal or plant cells (25–27). However, conclusive evidence for the existence of a "PI cycle" in this lower eukaryote needs further studies aimed at elucidating different aspects of the pathway, such as the presence of inositol 1,4,5-trisphosphate and of PIP_2-specific PLC(s). Work from our laboratory and others has already shown that such components are present in *Tetrahymena* cells (39,40). Recently, Ryals *et al*. (9) have provided evidence for the activation of the PI cycle by stomatin during cytodifferentiation of *T. vorax*. It is interesting that they have observed the same early upregulation of polyphosphoinositide levels prior to the observed decrease as we had in this report (Fig. 6). They also tested the effect of mastoparan on differentiation and observed minimal stimulation. However, the concentrations of mastoparan and cells, which are important factors concerning the effectiveness of stimulation by this peptide (25), are not given and furthermore, the effects of mastoparan on phosphoinositide levels were not examined.

Among animal cell functions, in the regulation of which polyphosphoinositides play an essential, though not yet fully understood role, are regulated exocytosis and membrane trafficking events. It has been suggested that phosphorylation–dephosphorylation of the polar heads of phosphoinositides in specific intacellular compartments can regulate the function of proteins essential for these transport events (41). We find very interesting the fact that *Tetrahymena* possesses at least two different, well-characterized secretory pathways: a rather constitutive release of hydrolytic enzymes possibly of lysosomal origin (42) and a regulated exocytosis of dense core vesicles known as mucocysts, which are docked permanently at the plasma membrane (43). Therefore, it would be intriguing to examine whether polyphosphoinositides are implicated in the regulation of these secretory pathways, particularly the latter, since regulated exocytosis in *Tetrahymena* shares many common characteristics to regulated exocytosis in mammalian cells (43,44). The availability of *Tetrahymena* mutants with defects in several stages of this pathway (45) and the recent advances in genetic manipulation of *Tetrahymena* (46) will probably provide us with a simple model for the study of polyphosphoinositide involvement in the secretory pathways of animal cells.

ACKNOWLEDGMENTS

We wish to thank Dr. Emmanuel Mikros, University of Athens and Dr. Anastasios Troganis, University of Ioannina, Greece, for the NMR analysis and very helpful discussions. We also thank Dr. Cleanthis Froussios for his comments on NMR spectra. This work was partially supported by a grant (70/4/2507) from the University of Athens.

Molecular Analysis of Intact Preen Waxes of *Calidris canutus* (Aves: Scolopacidae) by Gas Chromatography/Mass Spectrometry

Marlèn H.A. Dekker[a], Theunis Piersma[b,c], and Jaap S. Sinninghe Damsté[a,*]

Departments of [a]Marine Biogeochemistry and Toxicology and [b]Marine Ecology, Netherlands Institute for Sea Research (NIOZ), Texel, The Netherlands, and [c]Centre for Ecological and Evolutionary Studies, University of Groningen, Groningen, The Netherlands

ABSTRACT: The intact preen wax esters of the red knot *Calidris canutus* were studied with gas chromatography/mass spectrometry (GC/MS) and GC/MS/MS. In this latter technique, transitions from the molecular ion to fragment ions representing the fatty acid moiety of the wax esters were measured, providing additional resolution to the analysis of wax esters. The C_{21}–C_{32} wax esters are composed of complex mixtures of hundreds of individual isomers. The odd carbon-numbered wax esters are predominantly composed of even carbon-numbered *n*-alcohols (C_{14}, C_{16}, and C_{18}) esterified predominantly with odd carbon-numbered 2-methyl fatty acids (C_7, C_9, C_{11}, and C_{13}), resulting in relatively simple distributions. The even carbon-numbered wax esters show a far more complex distribution due to a number of factors: (i) Their *n*-alcohol moieties are not dominated by even carbon-numbered *n*-alcohols esterified with odd carbon-numbered 2-methyl fatty acids, but odd and even carbon-numbered *n*-alcohols participate in approximately equal amounts; (ii) odd carbon-numbered methyl-branched alcohols participate abundantly in these wax ester clusters; and (iii) with increasing molecular weight, various isomers of the 2,6-, 2,8-, and 2,10-dimethyl branched fatty acids also participate in the even carbon-numbered wax esters. The data demonstrate that there is a clear biosynthetic control on the wax ester composition although the reasons for the complex chemistry of the waxes are not yet understood.

Paper no. L8441 in *Lipids 35,* 533–541 (May 2000).

The survival of marine birds depends on an intact and waterproof plumage kept in good shape. A key component in the maintenance systems of the feather coat of birds is the preen (or uropygial) gland, located near the tail, which produces a variety of waxes (1). Yet, we understand very little of the preen gland waxes, but they may fulfill several crucial functions: keeping feathers flexible, protecting against wetting, reducing damage (including ultraviolet protection), playing a role as antiparasitic agents, and acting as pheromones (2; and references cited therein). Preen gland secretions consist predominantly of monoester waxes (3), which are composed of a fatty acid esterified to an alcohol moiety. These moieties may possess straight-chain, monomethyl alkyl, polymethyl alkyl, or even more complex carbon skeletons. Usually a mixture of fatty acids and alcohols with varying chain lengths and degree and location of branching is used, resulting in a complex mixture composed of hundreds of individual wax esters. The pattern of the lipid constituents has been found to be quite characteristic for a species and differs markedly between various bird taxa (1,4).

The very complex wax composition is usually determined by the analysis of fatty acids and alcohols released after hydrolysis of the monoester preen waxes (2,5). This leads to a loss of information concerning the molecular distribution, which determines the physical properties of the preen wax. In this paper the preen gland wax composition of a long-distance migrating shore bird, the red knot (*Calidris canutus),* was studied in detail using an approach by which the intact waxes were analyzed by capillary gas chromatography/mass spectrometry (GC/MS) and gas chromatography/mass spectrometry/mass spectrometry (GC/MS/MS). Recent studies of the preen waxes of male and female *C. canutus* revealed significant changes over the annual cycle in the chemical composition of the preen waxes (6,7) from monoester preen waxes to diester waxes. This warranted a detailed chemical and ecological study of the structure and role of preen waxes in *C. canutus*. Here we focus on the analytical characterization of the complex monoester wax of *C. canutus*.

EXPERIMENTAL PROCEDURES

Birds. Preen wax samples were taken from the red knot, *C. canutus*, subspecies *islandica,* kept in outdoor cages at north-temperate latitudes over several annual cycles. The composition of the preen wax of *C. canutus* has been shown to vary strongly over the annual cycle (6). Here we describe the detailed chemical composition of the preen wax pattern observed in the July–March period. Knot #283 was used for this purpose. To compare the wax patterns of different species, three other species (*Limosa lapponica* 1374068, *Tringa nebularia* 1374069, and *C. alba* H227028) were captured with

mistnets on Augusts 2, 1998, on the intertidal flats near Vlieland, an island in the Dutch Wadden Sea.

Sample processing. Wax samples were taken from the living birds by softly squeezing the gland area (4). The cotton-wool was extracted with 1 mL ethyl acetate and filtered by column chromatography using Na_2SO_4 and ethyl acetate as eluent. The dried extract was analyzed directly by GC, GC/MS, and GC/MS/MS. To study the fatty acid and alcohol composition of the monoesters, wax samples of Knots #294, #382, and #389 were combined for preparative thin-layer chromatography (TLC) analysis (8). TLC bands were scraped off the TLC plate and extracted with ethyl acetate and analyzed by GC and GC/MS. The monoester fraction (representing the largest TLC fraction) was saponified (1 M KOH in 96% methanol), and the fatty acids and alcohols released from the monoesters were derivatized with diazomethane and bis(trimethylsilyl)trifluoroacetamide to their corresponding methyl esters and trimethylsilyl ether derivatives and analyzed by GC/MS.

GC. GC was performed with a Hewlett-Packard 6890 Series II instrument (Palo Alto, CA), using an on-column injector. Detection was accomplished using a flame-ionization detector. Helium was used as the carrier gas. Separation was achieved using a fused-silica capillary column (25 m × 0.32 mm i.d.) coated with CP-Sil 5CB (film thickness 0.12 µm). The samples, dissolved in ethyl acetate, were injected at 70°C, and subsequently the oven was programmed to 130°C at 20°C/min and then 4°C/min to 320°C, where it was held for 30 min. Saponified extracts were injected at 40°C, programmed to 200°C at 4°C/min, 10°C/min to 300°C where it was held for 15 min.

GC/MS. GC/MS was performed on a Hewlett-Packard 5890 Series II gas chromatograph interfaced to a VG Autospec Ultima Q mass spectrometer. GC conditions were identical as described above. Electron impact spectra were obtained at 70 eV using the following conditions: mass range *m/z* 800–50; cycle time 1.6 s; resolution 1000. For GC/MS/MS, dissociation of the parent ions was induced by collision with argon (collision energy 20 eV). The parent ion to daughter ion transitions were analyzed with 20 ms settling and 75 ms sampling periods resulting in a 1.33 s total cycle time. Separation was achieved using the same capillary column and temperature program as described for GC analyses.

RESULTS AND DISCUSSION

Analysis of intact preen waxes. Figure 1 shows the gas chromatograms of the preen gland lipids of four different species, *L. lapponica, T. nebularia, C. alba,* and *C. canutus islandica* to illustrate the complex distribution of the intact wax lipids. The preen lipids of the four species investigated are dominated by monoester waxes. The *L. lapponica* preen lipids are dominated by C_{22}–C_{38} monoester waxes, those of *T. nebularia* consist mainly of C_{23}–C_{34} monoester waxes, C_{22}–C_{33} monoester waxes for *C. alba,* and C_{21}–C_{32} monoester waxes are dominant in the preen lipids of *C. canutus*. The molecular weight, fatty acid, and alcohol moiety of the wax esters were established by GC/MS. For example, Figure 2 shows mass spectra of two C_{24} wax esters composed of a C_8 fatty acid esterified with a C_{16} alcohol and a C_{10} fatty acid esterified with a C_{14} alcohol. The base peaks result from loss of the fatty acid substituents with concomitant transfer of two hydrogen atoms (9). Together with the molecular ion, this leads to identification of the wax ester, although no specific information on the carbon skeleton of the fatty acid and alcohol is obtained.

Detailed mass spectrometric analysis. Captive *C. canutus* were used to examine the intact preen gland lipids in detail by GC/MS and GC/MS/MS analysis. Mass chromatography of the molecular ions is a useful tool to analyze individual clusters of wax esters with the same molecular weight in the preen wax. Figure 3 has been constructed on this basis and shows the mass chromatograms of C_{21}–C_{32} wax esters (*m/z* 326 + n × 14). Each individual cluster of wax esters with the same molecular weight has been normalized to the most abundant isomer present. Figure 3 shows that with increasing molecular weight the distribution of wax esters becomes increasingly complex.

To obtain information on the building blocks of the wax esters, a monoester fraction was isolated from the preen wax, hydrolyzed, and the fatty acids and alcohols formed were identified after derivatization. Fatty acids and alcohols were identified based on MS data reported in the literature (4) and the recognition of (pseudo) homologous series through linear Kovats plots (Table 1; Ref. 9). Figure 4 shows the total ion current of the hydrolyzed waxes and summed mass chromatograms of *m/z* 88 + 101 and *m/z* 199 + 213 + 227 + 241 + 255 to show the distributions of the dominant fatty acids and alcohols, respectively. Straight-chain fatty acids are present only in trace quantities and occur in the range C_{16}–C_{28} with even carbon-numbered components predominating. The abundant fatty acids are 2-methyl branched fatty acids with characteristic *m/z* 88 and 101 fragment ions (resulting from McLafferty rearrangements) in their mass spectra. They comprise C_6–C_{15} 2-methyl fatty acids and 2,6-, 2,8-, and 2,10-dimethyl fatty acids (Fig. 4B). The distribution of the C_{14}–C_{18} alcohols is exemplified by a mass chromatogram of M – 15 (Fig. 4C). The even carbon-numbered alcohols show a simple distribution composed of only the straight-chain alcohol isomers. The odd carbon-numbered alcohols have, however, a very different distribution pattern characterized by the straight-chain alcohol and ω-2-, ω-4- and ω-6-methyl and 2-methyl alcohols. These results are in general agreement with those reported by Jacob and Poltz (5), although these authors also reported 4-methyl fatty acids and 4-methyl alcohols, which were not encountered as abundant compounds in this study.

The intact C_{21} wax ester (i.e., the one peak in the mass chromatogram of *m/z* 340, Fig. 3) possesses an *m/z* 131 fragment ion in its mass spectrum, indicating that it contains a C_7 fatty acid moiety. With this information it can be identified as tetradecyl 2-methylhexanoate on the basis of the distribution of the alcohols and fatty acids formed upon hydrolysis

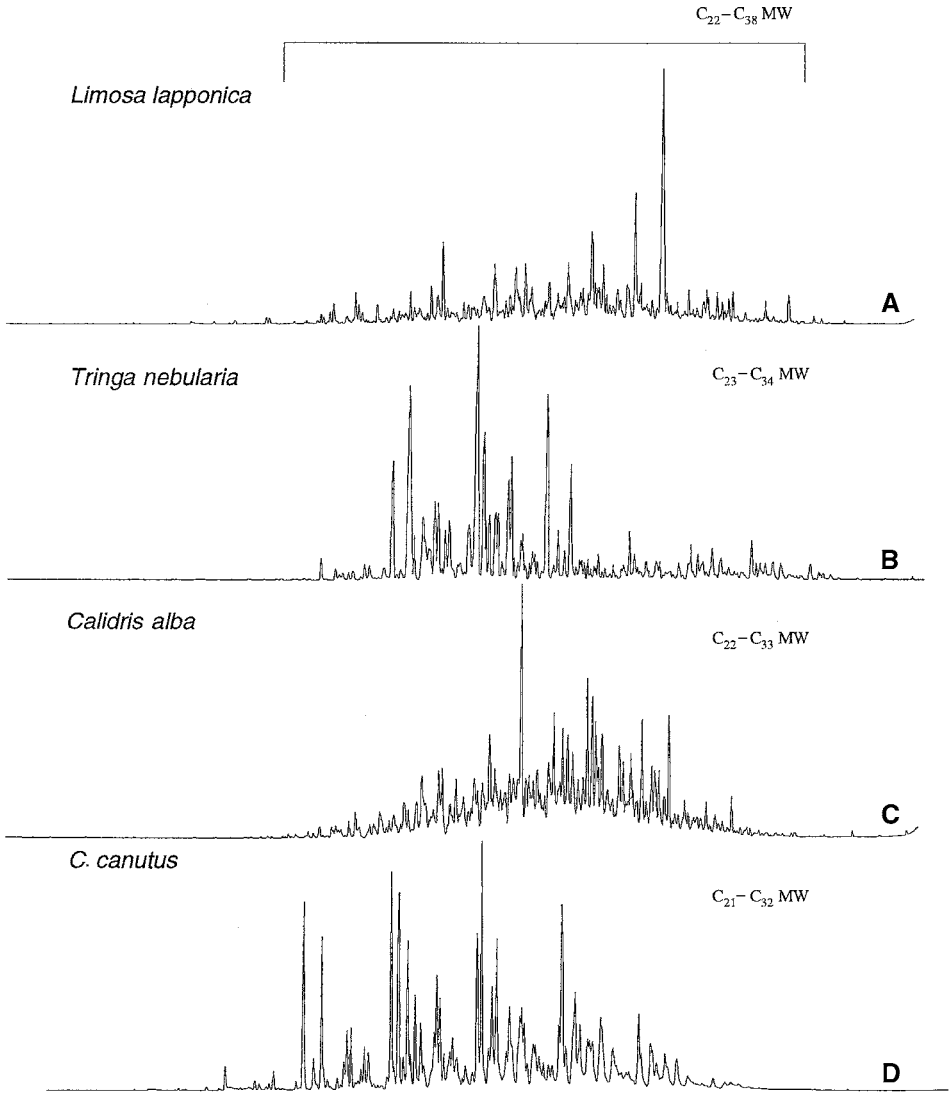

FIG. 1. Partial gas chromatography–flame-ionization detection chromatograms of the intact preen gland wax samples of several species: (A) bar-tailed godwit *Limosa lapponica*; (B) greenshank *Tringa nebularia*; (C) sanderling *Calidris alba*; (D) red knot *C. canutus*.

TABLE 1
Retention Data of Branched Fatty Acids and Alcohols

		RI[b]			
	Homologous series[a]	*a*	*b*	r^2	Range
Fatty acid	2-Methylalkanoic acid	100	0	n.a.	C_6–C_{16}
	2,6-Dimethylalkanoic acid	96	1	0.9999	C_8–C_{14}
	2,8-Dimethylalkanoic acid	93.5	44.5	0.9998	C_{10}–C_{14}
	2,10-Dimethylalkanoic acid	90.4	103.7	0.9998	C_{12}–C_{14}
Alcohol	*n*-Alkanols	100	0	n.a.	C_{12}–C_{19}
	2-Methylalkanols	99.5	–58.3	1	C_{12}–C_{19}
	2-Ethylalkanols	100	–96.2	1	C_{14}–C_{18}
	ω-2-Methylalkanols	100	–30	1	C_{15}–C_{17}
	ω-4-Methylalkanols	100.4	–55.9	0.9997	C_{14}–C_{19}
	ω-6-methylalkanols	99.5	–48.3	1	C_{15}–C_{17}

[a]Analyzed as their methyl esters or trimethylsilyl ethers.
[b]Retention index (RI) measured on CP-Sil 5CB, 130 to 320°C at 4°C/min, with the homologous series of 2-methylalkanoic acid and *n*-alcohols, respectively, as calibration standards, resulting in Kovats' plots $y = a \cdot x + b$ with correlation coefficient r^2. $RI = 100 \cdot z + 100 \cdot \{t(x) - t(z)\}/\{t(z + 1) - t(z)\}$ where $t(x)$ is retention time of compound for which RI is to be determined, $t(z)$ and $t(z + 1)$ are the retention times of the homologous which bracket the compound, and z is the number of carbon atoms. n.a., not applicable.

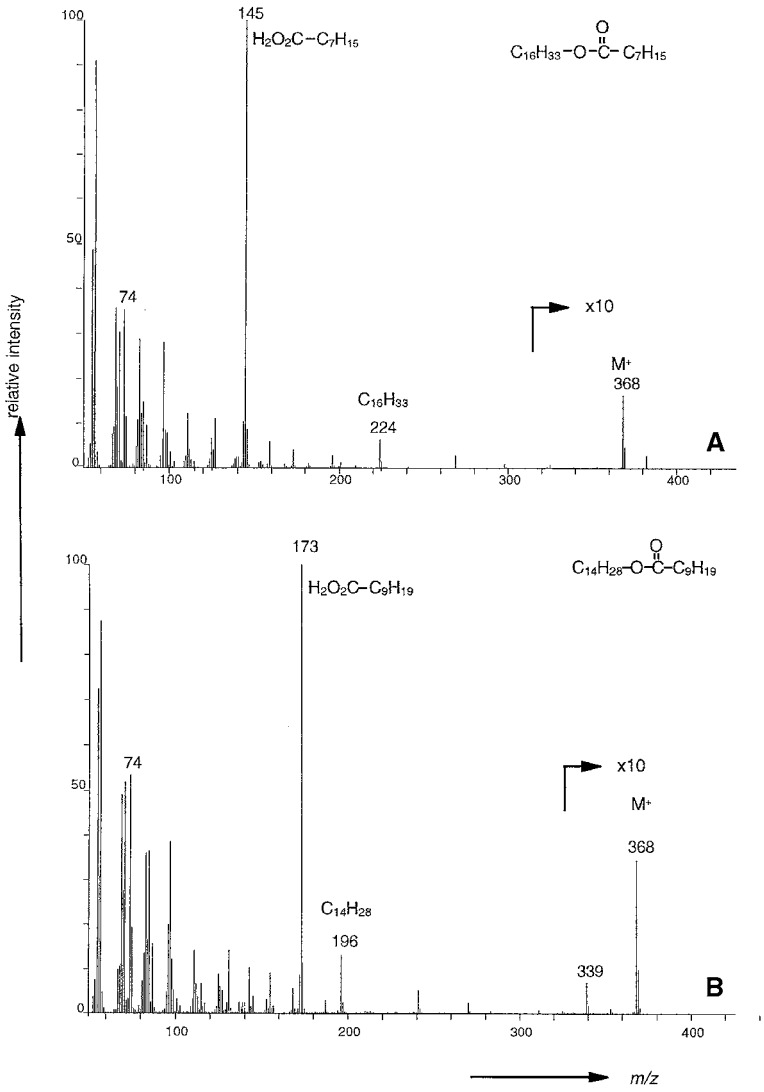

FIG. 2. Mass spectra (corrected for background) of two C_{23} wax esters: (A) hexadecyl 2-methylheptanoate (peak number 22 listed in Table 2); (B) tetradecyl 2,6-dimethyloctanoate (peak number 17 listed in Table 2).

(Fig. 4) since this represents the only possible combination of a C_7 fatty acid and C_{14} alcohol moiety to build a C_{21} wax ester. Due to the increasing complexity of the wax ester distribution pattern with increasing molecular weight (Fig. 3), these lines of argument become increasingly difficult to apply. The increasingly complex distribution with increasing molecular weight is due to: (i) the increasing number of possible combinations of fatty acids and alcohols to form a wax ester with a specific total number of carbon atoms and (ii) the increasing number of positional isomers for especially the fatty acids with increasing molecular weight (Fig. 4).

These problems in identifying intact wax esters can be partially overcome by using mass chromatograms of the characteristic fragment ion formed from the fatty acid moiety of the wax ester (i.e., *m/z* 131 + n·14) in combination with mass chromatograms of the molecular ions. However, since the clusters of wax esters with the same molecular weight partially overlap (Fig. 3), the coupling of molecular weight and specific fatty acid fragment ion becomes unreliable.

GC/MS/MS analysis. One way to overcome this problem in the identification of the intact wax esters is the application of GC/MS/MS. In this technique an ion with a specific mass (parent) is selected by the first mass spectrometer, led into the collision cell of the second mass spectrometer, and selected daughter ions, formed by collision-induced fragmentation, are collected on the second mass detector. Using this GC/MS/MS technique, it is possible to get detailed information on the composition of the preen wax. The major wax esters identified in this way are listed in Table 2.

As an example, the GC/MS/MS results for C_{24} wax esters are shown in Figure 5. These results are based on selection of the molecular ion (*m/z* 368) in the first mass spectrometer and detection of daughter ions representing the fatty acid part of the wax ester (Fig. 2) in the second mass spectrometer. Fig-

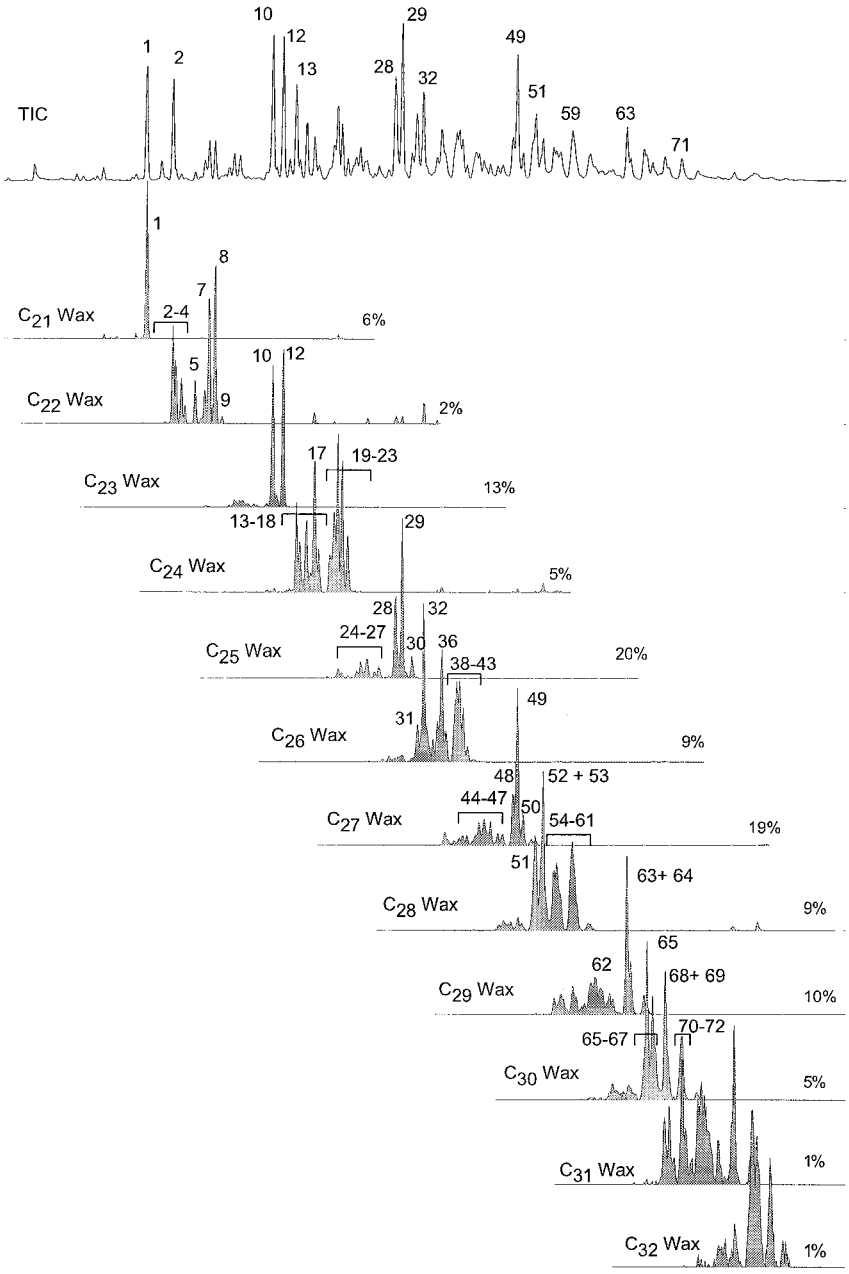

FIG. 3. Partial and mass chromatograms of the molecular ions of the C_{21}–C_{32} wax esters (*m/z* 340, 354, 368, 382, 396, 410, 424, 438, 452, 466, 480, 494) present in the nonsaponified preen wax of *C. canutus* #283. Numbers refer to specific wax ester listed in Table 2. Numbers at the end of the traces (in %) indicate the abundance based on peak height of the most abundance peak of the cluster (total set to 100%). TIC, total ion current; see Figure 1 for other abbreviation.

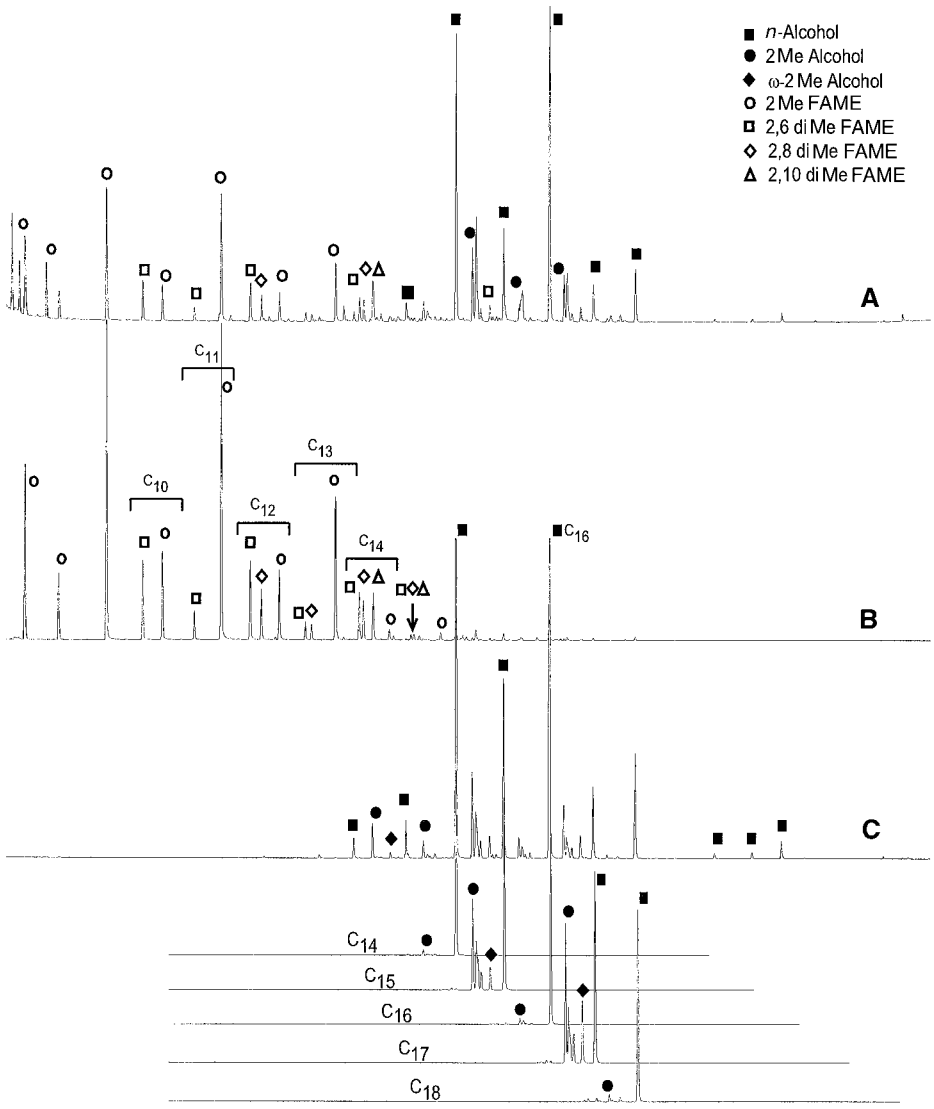

FIG. 4. Partial TIC (A) and (summed) mass chromatograms of *m/z* 88 + 101 (B) and 199 + 213 + 227 + 241 + 255 (C), showing homologous series of 2-methyl and dimethyl fatty acids and linear and methyl alcohols in the saponified monoester fraction of the preen wax of *C. canutus*. Numbers indicate the total number of carbon atoms. FAME, fatty acid methyl esters. See Figures 1 and 3 for other abbreviation.

ure 5D shows the *m/z* 368 → *m/z* 131 transition, representing C_{24} wax esters, containing a C_7 fatty acid moiety and, consequently, a C_{17} alcohol moiety. Hydrolysis has demonstrated that there is only one C_7 fatty acid (i.e., 2-methylhexanoic acid) but at least five structural isomers of the C_{17} alcohol (i.e., heptadecan-1-ol and various methyl-branched C_{17} alcohols) (Fig. 4). In fact, the distribution of peaks in the *m/z* 368 → *m/z* 131 transition is quite similar to the distribution of C_{17} alcohols in the hydrolyzed preen wax (Fig. 3). This is due to the presence of wax esters composed of 2-methylhexanoic acid esterified with all C_{17} alcohol isomers (Table 2). Due to the additivity principle (10), the retention behavior of these wax esters is similar to that of the alcohols. In this way all transitions can be analyzed. The *m/z* 368 → *m/z* 159 transition (Fig. 5F) is rather similar and shows the wax esters of 2-methyloctanoic acid with various C_{15} alcohols. In contrast, the *m/z* 368 → *m/z* 145 transition (Fig. 5E), revealing the C_{24} wax esters comprised of combinations of C_8 fatty acids and C_{16} alcohols, is dominated by one component (hexadecyl 2-methylheptanoate), in agreement with the relatively simple distribution of the C_{16} alcohols (Fig. 4). The *m/z* 368 → *m/z* 173 transition (Fig. 5G), revealing the C_{10}/C_{14} (FA/Alc.) wax esters, is comparatively simple, although in addition to tetradecyl 2-methylnonanoate another earlier-eluting wax ester is present. This is because dimethyl branched fatty acids are present in the hydrolyzed preen wax from C_{10} onward (Fig. 3). The earlier-eluting C_{10}/C_{14} wax ester was therefore identified as tetradecyl 2,6-dimethyloctanoate. The *m/z* 368 → *m/z* 187 and *m/z* 368 → *m/z* 201 transitions (Fig. 5H and 5I) revealed trace amounts of C_{11}/C_{13} and C_{12}/C_{12} wax

TABLE 2
Major Components of the Preen Gland Wax Esters from *Calidris canutus*

Peak number	MW[a]	Compound	Peak number	MW	Compound
1	326	Tetradecyl 2-methylhexanoate	35	396	Tetradecyl 2,8-dimethyldecanoate
2	340	2-Methyltetradecyl 2-methylhexanoate	36	396	Hexadecyl 2,6-dimethyloctanoate
3	340	8-Methyltetradecyl 2-methylhexanoate	37	396	14-Methylhexadecyl 2-methyloctanoate
4	340	10-Methyltetradecyl 2-methylhexanoate	38	396	Tridecyl 2-methyldodecanoate
5	340	12-Methyltetradecyl 2-methylhexanoate	39	396	Tetradecyl 2-methylundecanoate

[a]Molecular weight.

esters. The reconstructed ion current (RIC) from these seven transitions (Fig. 5B) is remarkably similar to the mass chromatogram of *m/z* 368 in the full scan mode (Fig. 5A), indicating that the GC/MS/MS technique can be used not only for qualitative but also for distributional purposes.

For the C_{25} wax esters, a quite different distribution pattern is observed by the GC/MS/MS technique (Fig. 6); components comprised of even carbon-numbered straight-chain alcohols (C_{14}, C_{16}, and C_{18}) esterified with odd 2-methyl fatty acids dominate this cluster. The transitions *m/z* 382 → *m/z* 145 and *m/z* 382 → *m/z* 173 transitions (Fig. 6D and 6F) reveal minor quantities of wax esters containing odd carbon-numbered alcohols, again comprised of various structural isomers. The distribution revealed by the latter transition is especially complex since wax esters composed of straight-chain and methyl branched C_{15} alcohols with both 2-methylnonanoic acid and 2,6-dimethyloctanoic acid occur. The RIC (Fig. 6B) shows again a good match with the mass chromatogram of *m/z* 382 in the full scan mode (Fig. 6A).

General observations. These examples are indicative of the composition of all clusters of wax esters with the same molecular weight. The odd carbon-numbered wax esters are predominantly composed of even carbon-numbered *n*-alcohols (C_{14}, C_{16}, and C_{18}) esterified predominantly with odd carbon-numbered 2-methyl fatty acids (C_7, C_9 C_{11}, and C_{13}), resulting in relatively simple distributions (Fig. 3). This is in good overall agreement with the results from the hydrolysis (Fig. 4). They show specifically that the distributions of odd carbon-numbered fatty acids and even carbon-numbered alcohols are relatively simple. The even carbon-numbered wax

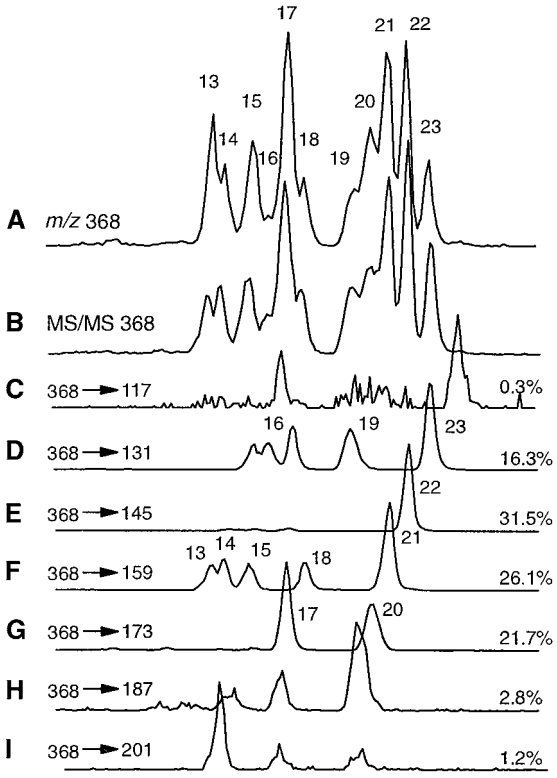

FIG. 5. Gas chromatography/mass spectrometry/mass spectrometry (GC/MS/MS) transitions (C–I) for C_{24} wax esters in the intact preen wax of *C. canutus* #283. The data were acquired by collision-induced decomposition GC/MSMS. Each trace is identified with the masses of the molecular ion (*m/z* 368) and daughter ions (i.e., C_6 fatty acid *m/z* 117, C_7 fatty acid *m/z* 131, C_8 fatty acid *m/z* 145, C_9 fatty acid *m/z* 159, C_{10} fatty acid *m/z* 173, C_{11} fatty acid *m/z* 187, C_{12} fatty acid *m/z* 201). Trace B shows the reconstructed ion current (RIC) from the measured transitions. The upper trace (A) shows a mass chromatogram of *m/z* 368 (*cf*. Fig. 3) of the GC/MS analysis in full scan mode for comparison. Numbers refer to specific wax esters listed in Table 2. Numbers at the end of the traces (in %) indicate the abundance based on peak height of the most abundance peak of the cluster (total set to 100%). See Figure 1 for other abbreviation.

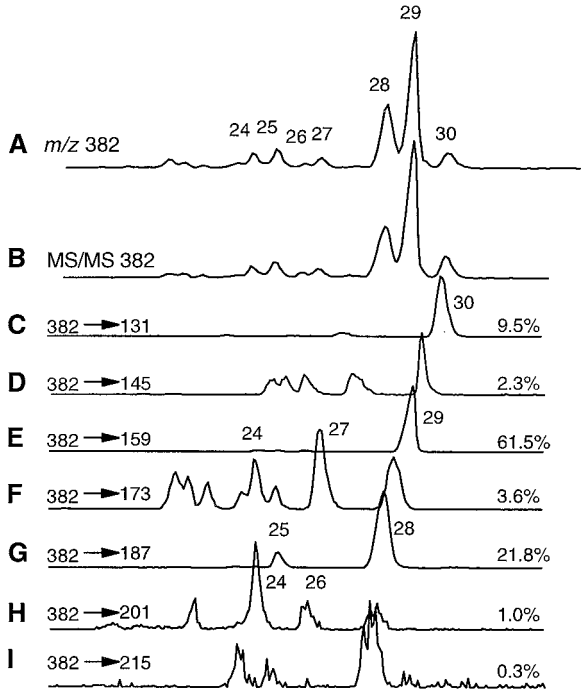

FIG. 6. GC/MS/MS transitions (C–I) for C_{25} wax esters in the intact preen wax of *C. canutus* #283. The data were acquired by collision-induced decomposition GC/MS/MS. Each trace is identified with the masses of the molecular ion (*m/z* 382) and daughter ions (i.e., C_7 fatty acid *m/z* 131, C_8 fatty acid *m/z* 145, C_9 fatty acid *m/z* 159, C_{10} fatty acid *m/z* 173, C_{11} fatty acid *m/z* 187, C_{12} fatty acid *m/z* 201, C_{12} fatty acid *m/z* 215). Trace B shows the RIC from the measured transitions. The upper trace (A) shows a mass chromatogram of *m/z* 382 (*cf*. Fig. 3) of the GC/MS analysis in full scan mode for comparison. Numbers refer to specific wax esters listed in Table 2. Numbers at the end of the traces (in %) indicate the abundance based on peak height of the most abundance peak of the cluster (total set to 100%). See Figures 1 and 5 for abbreviations.

esters show a far more complex distribution. This is due to a number of factors. First of all, the wax esters containing *n*-alcohol moieties are not dominated by even carbon-numbered *n*-alcohols esterified with odd carbon-numbered 2-methyl fatty acids, but odd and even carbon-numbered *n*-alcohols participate in approximately equal amounts. Second, odd carbon-numbered methyl-branched alcohols participate abundantly in these wax ester clusters (e.g., Fig. 5), leading to many more structural isomers. Third, with increasing molecular weight, the various isomers of the dimethyl branched fatty acids also participate in the even carbon-numbered wax esters. These fatty acid isomers are especially abundant in the clusters of even carbon-numbered fatty acids (Fig. 3), explaining why they are not so abundant in the odd carbon-numbered wax esters, which contain predominantly odd carbon-numbered fatty acid moieties. In the higher molecular weight, even carbon-numbered wax esters containing these dimethyl branched fatty acid moieties predominate as indicated by Figure 7, showing the important transitions for the C_{28} wax ester cluster. This example also reveals that even with such a powerful technique as GC/MS/MS full resolution of all structural isomers in this cluster is not obtained.

This is the first time that full structural identification of intact wax esters in complex preen waxes is achieved. In contrast to conventional techniques, which identify fatty acids and alcohols after hydrolysis, our method allows the determination of the structure of the components as they occur in the biological system. This is important if we want to understand the physiological role preen waxes play in birds, and their biosynthesis. In view of the rapid changes of the chemical composition of preen waxes in *C. canutus* over the annual cycle (6), this is most relevant, also from an ecological point of view. Our data already demonstrate that the biosynthesis of preen waxes is complex since the distribution of intact wax esters indicates that it is certainly not a random combination of available fatty acids and alcohols. It seems likely that this will influence the physical properties of the preen wax, but presently the reasons for the complex chemistry of the preen waxes are not at all understood.

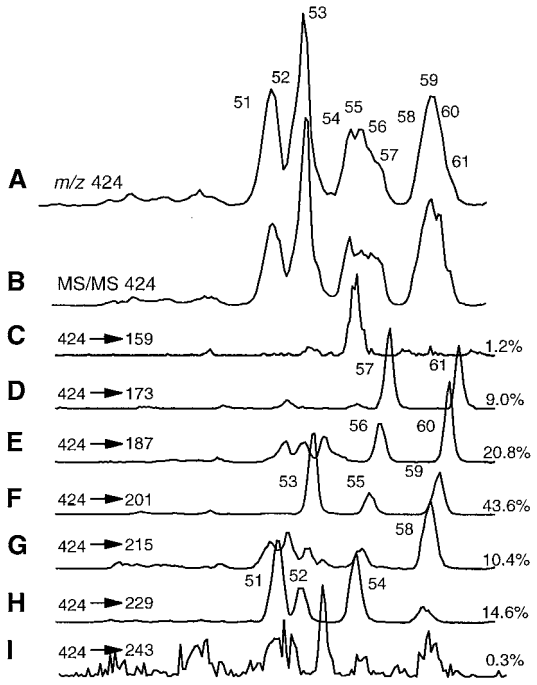

FIG. 7. GC/MS/MS transitions (C–I) for C_{28} wax esters in the intact preen wax of *C. canutus* #283. The data were acquired by collision-induced decomposition GC/MS/MS. Each trace is identified with the masses of the molecular ion (*m/z* 424) and daughter ions (i.e., C_9 fatty acid *m/z* 159, C_{10} fatty acid *m/z* 173, C_{11} fatty acid *m/z* 187, C_{12} fatty acid *m/z* 201, C_{13} fatty acid *m/z* 215, C_{14} fatty acid *m/z* 229, C_{15} fatty acid *m/z* 243). Trace B shows the RIC from the measured transitions. The upper trace (A) shows a mass chromatogram of *m/z* 424 (*cf*. Fig. 3) of the GC/MS analysis in full scan mode for comparison. Numbers refer to specific wax esters listed in Table 2. Numbers at the end of the traces (in %) indicate the abundance based on peak height of the most abundance peak of the cluster (total set to 100%). See Figures 1 and 5 for abbreviations.

ACKNOWLEDGMENTS

We thank Bernard Spaans, Anita Koolhaas, and Anne Dekinga for help in the field and with the captive birds. This work was partly supported by a PIONIER-grant to TP from The Netherlands Organization for Scientific Research (NWO). This is NIOZ-publication 3448.

Polyunsaturated Monoglycerides and a Pregnadiene in Defensive Glands of the Water Beetle *Agabus affinis*

Otmar Schaaf and Konrad Dettner*

University of Bayreuth, Department of Animal Ecology II, D-95440 Bayreuth, Germany

ABSTRACT: In addition to the C_{21} steroid 15α-hydroxypregna-4,6-dien-3,20-dione, four 1- or 2-acylated polyunsaturated monoglycerides, 1- or 2-(*cis*-5,8,11,14-eicosatetraenoyl)-glycerol and 1- or 2-(*cis*-5,8,11,14,17-eicosapentaenoyl)glycerol were identified as constituents of the prothoracic defensive gland secretion of the dytiscid beetle *Agabus affinis* by gas chromatography–mass spectrometry of trimethylsilylated gland extracts. In a feeding assay with minnows, synthetic samples of the two 2-acylated monoglycerides showed only a weak activity as a feeding deterrent. For that reason, other possible functions of the monoglycerides are discussed, such as roles as emulsifiers of cannabimimetics.

Paper no. L8304 in *Lipids 35,* 543–550 (May 2000).

Most adult dytiscid beetles (Coleoptera: Dytiscidae) contain two complex gland systems. The pygidial glands on the hindmost abdominal segment contain substantial quantities of low molecular weight aromatic substances like benzoic acid, phenylacetic acid, and *p*-hydroxybenzaldehyde (1). The beetles distribute the pygidial secretion on their surfaces using their hind legs. In addition to their antimicrobial activity, the pygidial compounds result in an increased wettability of the integument, which facilitates reentry into the water, for example after a flight (1).

Members of the dytiscid subfamilies Dytiscinae, Colymbetinae, Hydroporinae, and Laccophilinae possess an additional pair of exocrine glands located underneath the pronotum. These glands are designated as prothoracic defensive glands in order to differentiate them from the endocrine prothoracic glands of insects. When the beetles are irritated mechanically or seized by a predator, a white or yellowish milky fluid usually emerges from the anterior margin of the pronotum.

Schildknecht (2–6) was the first to show that the prothoracic defensive glands of dytiscids predominantly contain steroids of the vertebrate hormone type as active agents. In a few species, sesquiterpenes (6,7), a nucleoproteid (8), or an alkaloid (4,5) were identified as major or minor constituents of the secretion.

The constitution of the prothoracic defensive secretion of many dytiscids remains largely unknown. The present paper deals with the gas chromatography–mass spectroscopy analysis of the prothoracic defensive secretion of *Agabus affinis* (Payk.), a stenoecious (i.e., dependent on certain habitats and environmental conditions) member of the subfamily Colymbetinae. Some Colymbetinae and Dytiscinae species have already been studied (mostly common and abundant European species; reviewed in Refs. 9,10). However, knowing the defensive gland chemistry of many other rather uncommon species could contribute much to our understanding of biosynthesis of the defensive compounds or even phylogenetic correlations. *Agabus affinis* occurs exclusively in acid peat bogs in northern, eastern, and central Europe and is regularly associated with *Sphagnum* mosses. The feeding deterrence of two novel gland constituents of *A. affinis* was tested in a bioassay with minnows.

EXPERIMENTAL PROCEDURES

Beetles. Adult males and females of *A. affinis* were captured in peat bogs in the Oberpfalz and Oberfranken regions (northern Bavaria, Germany). The beetles were frozen immediately by cooling with dry ice and stored at –40°C until used.

Sample preparation. Beetles were dissected by separating the thorax from head and abdomen and by removing legs and wings with dissecting needles. The glands were freed from surrounding tissues. Gland reservoirs were detached from the pronotum with a fine needle and transferred to 40 µL ethyl acetate in a glass reacti-vial. For each sample, the reservoirs of five beetles were pooled and sonicated for 15 min. Solid residues were removed by centrifugation (2800 × *g*, 15 min). Subsequently, 30 µL of the ethyl acetate extract was transferred to a new vial. The solvent was removed, and the residue was dissolved in 30 µL pyridine/tetrahydrofuran (1:1, vol/vol). Prior to gas chromatography–mass spectrometry (GC–MS) analysis, the samples were trimethylsilylated with 30 µL *N*-mehyl-*N*-trimethylsilyltrifluoroacetamide (Fluka, Buchs, Switzerland) by heating to 40°C for 16 h; 1 µL per sample of this solution was injected into the GC–MS system.

As a control, small samples of fat body and prothoracic

Abbreviations. 1- or 2-ara-gl, 1- or 2-(*cis*-5,8,11,14-eicosatetraenoyl)glycerol (1- or 2-arachidonoylglycerol); 1- or 2-epa-gl, 1- or 2-(*cis*-5,8,11,14,17-eicosapentaenoyl)glycerol; GC–MS, gas chromatography–mass spectrometry; TMS, trimethylsilyl; TMSO, trimethylsilyloxy-.

muscular tissue were taken with fine tweezers from the dorsally opened abdomen and thorax, respectively, prior to dissection of the glands and treated and analyzed accordingly.

GC–MS analysis. Analyses were performed, and 70 eV electron ionization mass spectra were recorded with a Finnigan MAT GCQ™ GC–MS system equipped with an SGE 25QC2/HT5 capillary column; 25 m × 0.22 mm i.d., film = 0.1 µm. Samples were injected in splitless mode (1 min). Carrier gas was helium (40 cm/s; automatic flow control). Further experimental conditions: electron multiplier voltage: 1125 V, high mass adjust: 100%, injector temperature: 230°C, transfer line temperature: 275°C, ion source temperature: 150°C. The column oven temperature program consisted of an initial temperature of 60°C, a 10°C/min increase to 240°C, 3°C/min increase to 320°C, where the temperature was maintained for 5 min. Relative retention times were calculated compared to 5α-cholestane. Compounds were identified by comparing retention times and mass spectra with those of authentic standards. If no reference compounds were available, structures were proposed to comply with mass spectrometric fragmentation behavior.

Reference compounds. 15α-Hydroxypregna-4,6-dien-3,20-dione was prepared from 15α-hydroxypregn-4-en-3,20-dione (15α-hydroxyprogesterone) by selective dehydrogenation at C_6 with *p*-chloranil (11). 15α-Hydroxyprogesterone and 15β-hydroxypregna-4,6-dien-3,20-dione were gifts of Schering AG (Berlin, Germany). 2-(*Cis*-5,8,11,14-eicosatetraenoyl)-glycerol (2-arachidonoylglycerol; 2-ara-gl) and 2-(*cis*-5,8,11,14,17-eicosapentaenoyl-)glycerol (2-epa-gl) were purchased from Deva Biotech (Hatboro, PA).

Feeding assay. Agar pellets containing definite amounts of the compounds to be tested were produced similar to the method of Gerhart *et al*. (12). First, stock solutions (1.8×10^{-1} M) of the test substances in methanol were prepared. Agar (1.5%, wt/vol) was dissolved at 120°C; after the solution was cooled to 45°C, calculated amounts of agar and stock solutions were mixed, and pulverized commercial fish food (TetraMin Flockenfutter, Melle, Germany; 10 mg per mL agar solution) was added as a flavoring agent. Pellets were produced by pipetting 25 µL of the mixture per cavity in the inner surface of 96-well microplate covers and subsequent cooling to room temperature. Control pellets without addition of the test compounds were prepared similarly.

The initial amounts of the test substances per pellet (100 µg) were estimated by comparison of the GC–MS peak areas of the prothoracic gland constituents of *A. affinis* to that of authentic standards. For the second test series, a threefold amount (300 µg/pellet) compared to the natural abundance in the glands was used.

Six adult minnows (*Phoxinus phoxinus* L.) were kept in an aquarium of 60 × 30 × 30 cm at 20°C (photoperiod 8:00 a.m.–7:00 p.m). Inside the aquarium, a test area was separated by a longitudinal pane of glass and a rectangular metal grid held by a Plexiglas frame (Fig. 1). The fish were starved for 3 d before the test started. All assays were performed at 2:00 p.m. to exclude an influence of changing feeding motivation depending on the time of day. In order to minimize a susceptibility of test results to learning behavior, only one randomly selected fish per day was tested. The fish was transferred to the test area 1 h before the test started. In each test, four pellets were dropped into the test area in the same sequence in intervals of 1 min: control pellet C1 → test pellet T1 → test pellet T2 → control pellet C2; by that means, an influence to the feeding behavior by experience could have been registered through the acceptance rates of T_2 and C_2. Reactions were recorded as acceptance (pellet swallowed) or rejection (pellet spat out). Pellets that were not noticed by the fish were not scored. After each test, the fish was left in the test area until the next day in order to record possible behavioral changes due to narcotic or toxic effects. Afterward the fish was removed, and a new fish was used for the next test until every minnow was tested once; subsequently, random selection started again. The number of test repetitions ($n = 10$) was limited by the available amount of the test substances 2-ara-gl and 2-epa-gl.

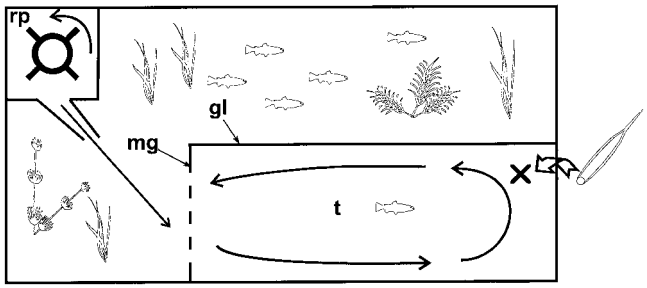

FIG. 1. Schematic drawing of experimental apparatus (view from above) for feeding assay with minnows: t = separate testing area, rp = aquarium filter with rotatory pump, gl = plane of glass, mg = Plexiglas frame with metal grid, × = insertion place for pellets. Arrows indicate the direction of water flow.

Statistics. Acceptance rates of test and control pellets were examined for significant differences employing the G-test of independence in combination with Yates' correction (13). G was calculated and compared to critical χ^2 values using statistical tables (14).

RESULTS AND DISCUSSION

Identification of prothoracic defensive gland constituents of A. affinis. During GC–MS analysis of the trimethylsilylated gland extract, the total ion current chromatogram showed five component peaks (Fig. 2). Compounds 1 and 2 as well as 3 and 4 eluted as doublet peaks with only slightly different retention times, whereas compound 5 eluted with a considerably higher retention time. Because cholesterol (C) is a ubiquitous constituent of animal cell membranes, the small amounts of it found in the ethyl acetate extracts are therefore not regarded as an original active compound of the glands but rather as a contaminant of surrounding tissues, since it was also found in comparable amounts in control extracts of fat body and prothoracic tissue.

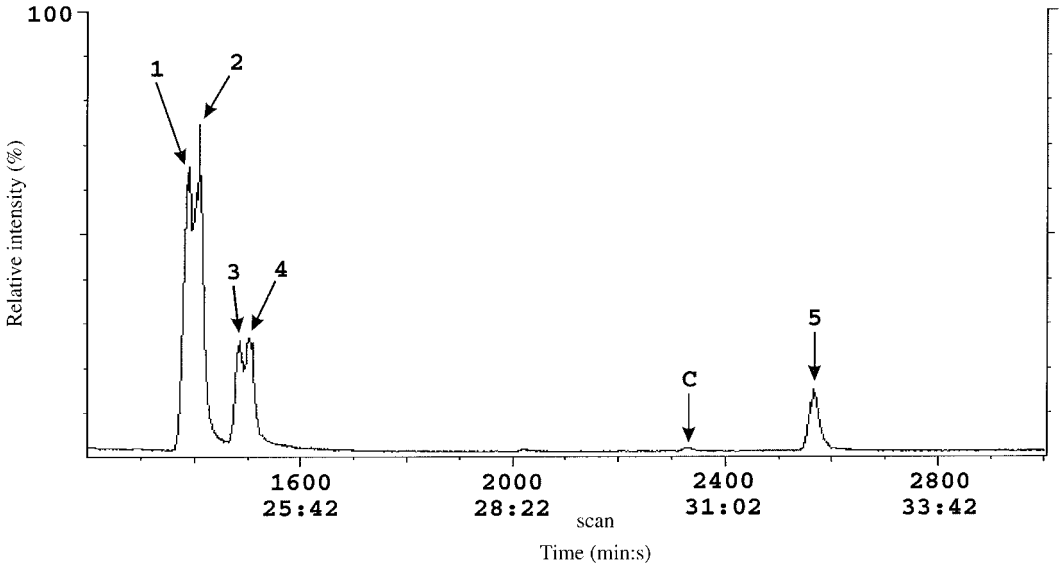

FIG. 2. Section of total ion current chromatogram of a trimethylsilylated extract of prothoracic defensive glands of *Agabus affinis* (five specimens): 1 = 2-(*cis*-5,8,11,14-eicosatetraenoyl)glycerol-bis-TMS (2-ara-gl-bis-TMS; RT = 0.94); 2 = 2-(*cis*-5,8,11,14,17-eicosapentaenoyl)glycerol-bis-TMS (2-epa-gl-bis-TMS, RT = 0.95); 3 = 1-(*cis*-5,8,11,14-eicosatetraenoyl)glycerol-bis-TMS (1-ara-gl-bis-TMS; RT = 0.97); 4 = 1-(*cis*-5,8,11,14,17-eicosapentaenoyl)glycerol-bis-TMS (1-epa-gl-bis-TMS, RT = 0.97); 5 = 15α-hydroxypregna-4,6-dien-3,20-dione-TMS (RT = 1.32); C = cholesterol-TMS. TMS = trimethylsilyl ether; RT = relative retention time (5α-cholestane = 1.00); for experimental conditions see text.

The mass spectra of compounds 1, 2, 3, and 4 showed the characteristic appearance of trimethylsilylated monoglycerides (15–17). The molecular ions of compounds 1 and 2 as well as of 3 and 4 were only of weak abundance and differed from each other in only two mass units (M^+ 520/522; see Figs. 3, 4).

The *m/z* 203 ion is formed in monoglycerides by elimination of the acyloxy radical R–COO· (+1H) from the [M – 15] fragment (*m/z* 505 or 507). The corresponding cleavage from the molecular ion, resulting in the formation of an ion at *m/z* 218, is of pronounced intensity in the mass spectra of 2-acylated monoglycerides only. In contrast, a [M – 103] fragment, which is missing in 2-acyl glycerides, is characteristic for the spectra of 1-acylated monoglycerides (16). Accordingly, compounds 1 and 2 were presumed to be 2-acylated and compounds 3 and 4 1-acylated monoglycerides (*cf*. Figs. 3, 4).

Acyl fragment $[R–CO]^+$ (–1H) at *m/z* 286 (compounds 1 and 3) and *m/z* 284 (compounds 2 and 4) indicated the acyl chain length and the number of double bonds of the acyl moiety. By comparison with authentic compounds, the structures of 1 and 2 were determined as 2-ara-gl and 2-epa-gl, respectively. Although compounds 3 and 4 were not available as authentic substances, their mass spectrometric fragmentation patterns showed high evidence for the corresponding 1-acylated monoglycerides, 1-(*cis*-5,8,11,14-eicosatetraenoyl)glycerol (1-ara-gl) and 1-(*cis*-5,8,11,14,17-eicosapentaenoyl)glycerol (1-epa-gl). Although 1- and 2-ara-gl were extracted from canine gut tissue and identified by comparison with authentic compounds in derivatized and underivatized form (18), the spectra of the trimethylsilylated monoglycerides were not published.

Only one steroid (compound 5) was found in the prothoracic defensive glands of *A. affinis*; this showed the same retention time and mass spectrum as the trimethylsilyl (TMS) ether of 15α-hydroxypregna-4,6-dien-3,20-dione. The mass spectrum of compound 5 exhibited a distinct molecular ion (M^+ 400, Fig. 5). The presence of a trimethylsilyloxy (TMSO) group was indicated by the [M – 90] ion at *m/z* 310. The base peak at *m/z* 267 = [310 – 43] is formed by subsequent elimination of the side chain (C_{20} + C_{21}). The ion at *m/z* 172, which comprises C_{15}–C_{17}, C_{20} and C_{21} together with the 15-TMSO group, is derived from D-ring cleavage and represents an important key fragment for steroids containing a 15- or 16-TMSO-20-one structure (19,20). A corresponding [M – 172] ion was also observed (*m/z* 228). The fragment at *m/z* 157 = [172 – 15] results from additional elimination of a methyl radical. The presence of a 16-TMSO group can be excluded by the absence of pronounced ions at *m/z* 109, 159, and 186 and the occurrence of an [M – 71] fragment at *m/z* 329, which is formed by C_{16}–C_{21} and promoted by a TMSO group at C_{15}. Authentic 15β-hydroxypregna-4,6-dien-3,20-dione was also analyzed by GC–MS and showed a similar fragmentation pattern, but widely differing peak intensities and a divergent retention time.

$\Delta^{4,6}$-Unsaturated C_{21} steroids were also detected in the prothoracic defensive secretion of several dytiscid species from the subfamilies Dytiscinae and Colymbetinae (9,10). The 15α-hydroxypregna-4,6-dien-3,20-dione was identified in *A. sturmi* (Gyll.) in underivatized form along with steroid isobutyric esters (21), which are obviously missing in *A. affinis*.

In contrast, the presence of considerable amounts of polyun-

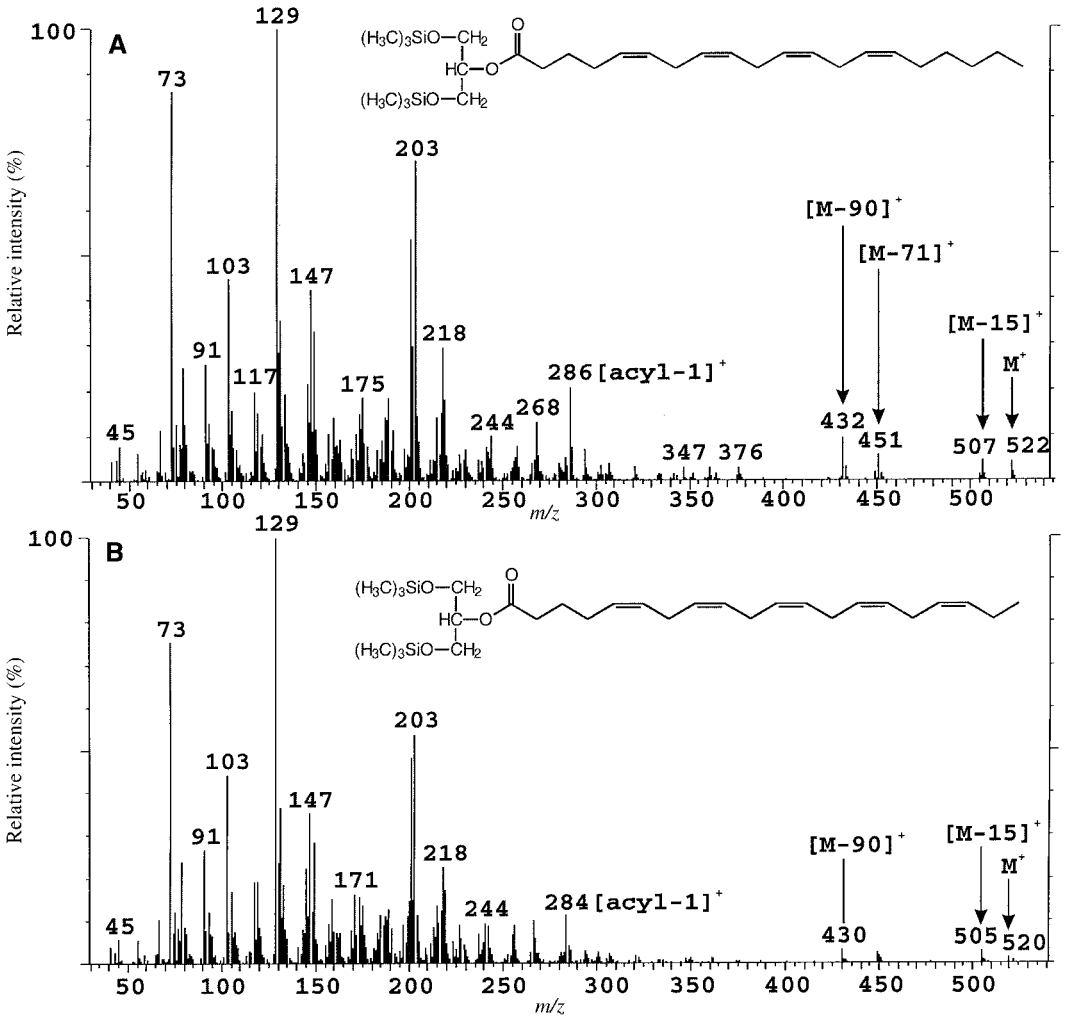

FIG. 3. Mass spectra of (A) 2-(*cis*-5,8,11,14-eicosatetraenoyl)glycerol (2-ara-gl) and (B**)** 2-(*cis*-5,8,11,14,17-eicosapentaenoyl)glycerol (2-epa-gl), derivatized as bis-trimethylsilyl ethers (compounds 1 and 2 of prothoracic defensive glands of *Agabus affinis*; *cf*. Fig. 2).

saturated monoacylglycerols as main components of the prothoracic defensive glands in *A. affinis* was a surprising result, since it was the first time that such compounds have been found to be accumulated and stored in exocrine glands, not only in water beetles but also in other insects or arthropods.

Feeding assay. Monoglycerides are common and widespread intermediates of lipid metabolism in animals and plants. In the food and cosmetics industries, they are utilized as emulsifiers. Therefore, a biological function of monoglycerides as deterring or toxic agents once appeared improbable. However, during investigation of endogenous ligands of cannabinoid receptors, Mechoulam *et al.* (18) isolated 2-ara-gl from canine gut tissues. Interestingly, 2-ara-gl not only bound to cannabinoid receptors in mouse tissue cultures but also caused the same four suppressive effects (antinociception, immobility, decrease in spontaneous activity, lowering of body temperature) induced by Δ^9-tetrahydrocannabinol. Recent studies showed that 2-ara-gl plays an important role in Ca^{2+} regulation in the central nervous system of mammals (22,23) and possibly serves as a vasomodulator in human blood vessels (24). Cannabinoid receptors (which might be 2-ara-gl receptors primarily) were detected not only in mammals but also in birds (chicken, pigeon), frogs (*Rana pipiens*), and fish (*Salmo gairdnerii*) (25); accordingly, they seem to be widespread in vertebrates. The cannabimimetic potential of 2-ara-gl in mice (16) resembles in many respects the anesthetic effects of many steroids in vertebrates.

These cannabimimetic effects have been observed thus far only upon intravenous administration of 2-ara-gl. For our purposes, an oral application of the test compounds seemed appropriate in order to match natural conditions as closely as possible. The 1-acylated monoglycerides could not be tested because of lack of the authentic compounds.

With an amount of 100 µg 2-ara-gl and 2-epa-gl each per pellet, 3 of 9 (33%) of the test pellets T1 and T2 were swallowed, whereas higher acceptance rates of the control pellets C1 (70%) and C2 (63%) were observed (Fig. 6). Thus, the pellets containing monoglycerides were consumed less fre-

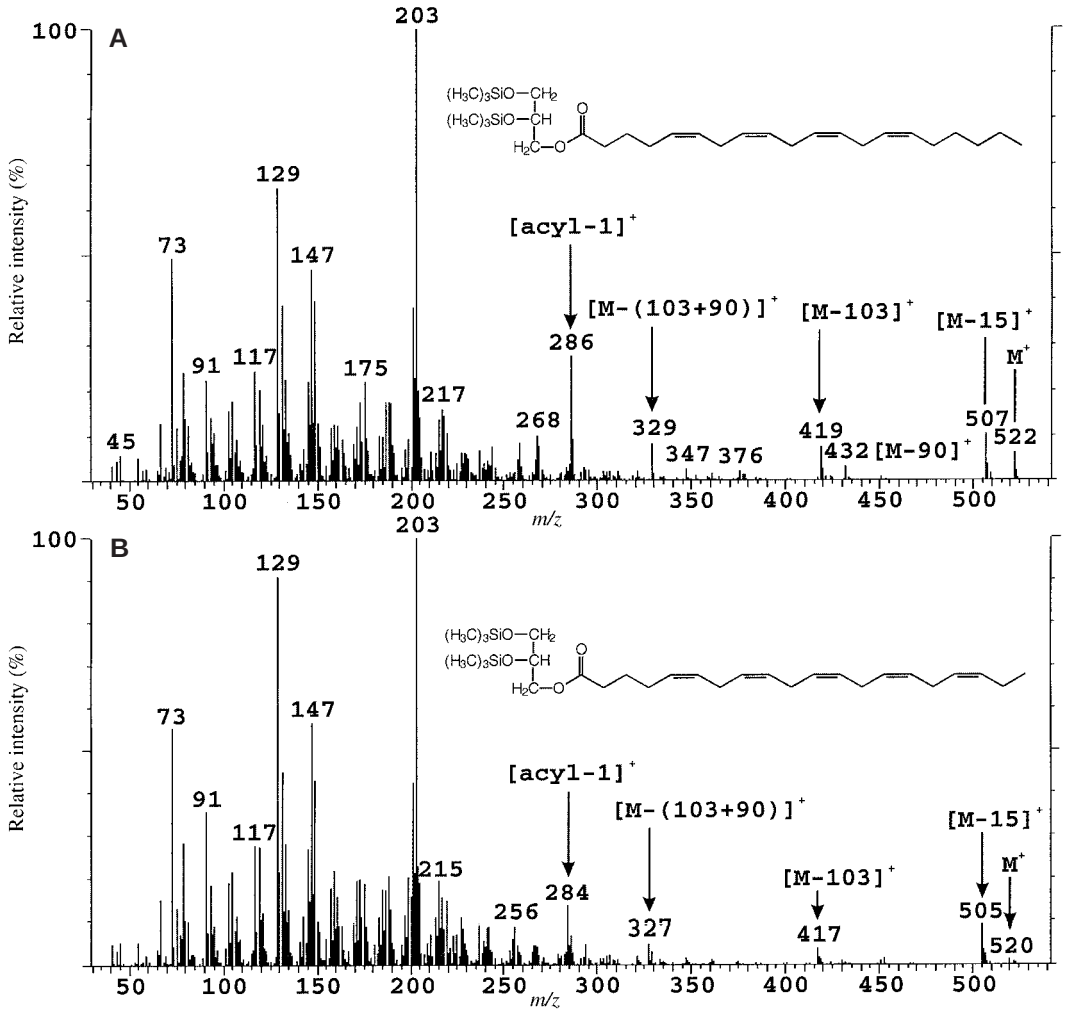

FIG. 4. Mass spectra of (A) 1-(*cis*-5,8,11,14-eicosatetraenoyl)glycerol (1-ara-gl) and (B**)** 1-(*cis*-5,8,11,14,17-eicosapentaenoyl)glycerol (1-epa-gl), derivatized as bis-trimethylsilyl ethers (compounds 3 and 4 of prothoracic defensive glands of *Agabus affinis*; *cf*. Fig. 2).

quently than the control pellets; however, statistical evaluation showed no significant differences, either between single pellet categories or upon pooling control pellets (C1 + C2) and test pellets (T1 + T2).

The threefold increase of the monoglyceride amounts per pellet (300 µg 2-ara-gl and 2-epa-gl each) led to an enhanced deterring effect (Fig. 6): the acceptance rates of the monoglyceride pellets declined to 13 (T1) and 29% (T2). In contrast, 80 (C1) and 86% (C2) of the control pellets were accepted. Upon addition of the results of T1/T2 and C1/C2, respectively, at a significance level of $\alpha = 0.01$, a significant difference between T1 + T2 and C1 + C2 as well as between T1 and C1 + C2 was calculated. T2 and C1 + C2 also differed significantly ($\alpha = 0.05$), just as T1 and C1, while the acceptance of T2 was not significantly reduced compared to C2. No significant differences were found between the first and second test and control pellets (T1 and T2, C1 and C2).

The fish bioassays showed that the monoglycerides obviously can be perceived by the fish. A deterring effect was observed; however, statistical significance occurred only after administration of amounts markedly higher than those naturally occurring in the glands of the beetles. Changes in behavior, pointing to cannabimimetic activity of the monoglycerides, were not noticed. It cannot be excluded that such effects would take place upon application of even higher amounts. On the other hand, the monoglycerides might be inactivated in the gut by lipid metabolism enzymes (lipases, acyltransferases) upon oral application.

Therefore, other functions of the monoglycerides should be considered. Analogous to the pygidial gland components of dytiscids, an improvement in the wettability of the integument is conceivable, as well as antimicrobial activity (1). Another possible role of the monoglycerides might be related to their emulsifying properties, since the prothoracic steroid of *A. affinis* is highly water-insoluble. Accordingly, the monoglycerides might serve as an emulsifier or enhance the efficacy of the steroid by influencing membrane transfer or uptake rate.

The anesthetic or toxic properties of some steroids against

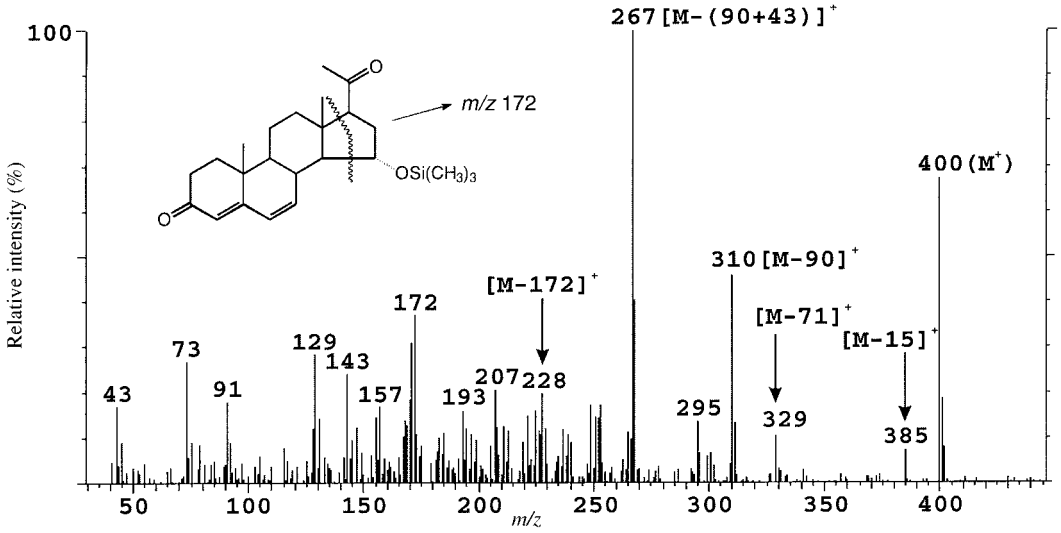

FIG. 5. Mass spectrum of 15α-hydroxypregna-4,6-dien-3,20-dione, derivatized as trimethylsilyl ether (compound 5 of prothoracic defensive glands of *Agabus affinis*, *cf.* Fig. 2).

mammals are well known; the effects depend on dose and structure of the steroid (26–29). An anesthetic effect of dytiscid steroids on fish was demonstrated, causing reversible loss of balance and mobility at lower doses, but being irreversible and lethal at high doses (30–33). In contrast to the anesthetic and toxic effects against predators observed with percutaneous administration, a deterring effect of steroids was found by feeding to the sunfish *Lepomis macrochirus* agar pellets that contained dytiscid defensive steroids leading to a significant decrease of pellet acceptance rates (10). These results have been confirmed recently in a bioassay with the European minnow *P. phoxinus* (34).

An intriguing question exists about the possible synergistic effect of the prothoracic defensive steroid of *A. affinis*, 15α-hydroxypregna-4,6-dien-3,20-dione, and the polyunsaturated monoglycerides. Unfortunately, this effect could not

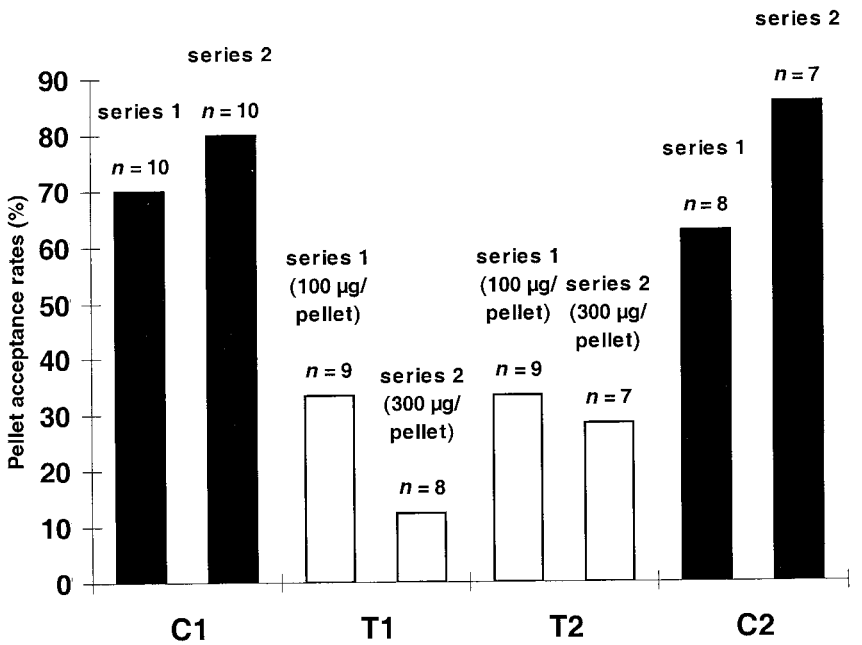

FIG. 6. Results of feeding assays with six minnows (*Phoxinus phoxinus*); 100 µg 2-arachidonoylglycerol + 100 µg 2-(*cis*-5,8,11,14,17-eicosapentaenoyl)glycerol per pellet or 300 µg 2-ara-gl + 300 µg 2-epa-gl per pellet as active agents; C1 = C2 = control pellet 1 and 2, T1 = T2 = test pellet 1 and 2; *n* = number of pellets that were noticed by the minnows, total number of test repetitions = 10; statistical evaluation, see text. Open bars (□), test pellets; solids bars (■), control pellets.

be examined because sufficient amounts of the authentic steroid were not available for testing. Additionally, it would be highly desirable to test the activity of the natural secretion, which also has not been possible so far owing to the small-sized prothoracic defensive glands and the low abundance of *A. affinis* (which cannot yet be kept under laboratory conditions) in its natural habitats.

ACKNOWLEDGMENTS

The authors express their thanks to Dr. Werner Boidol and Schering AG, Berlin, for supplying reference steroids and personal support, to Prof. Raphael Mechoulam and Dr. Shimon Ben-Shabat (Hebrew University Jerusalem), Dr. Thomas Paululat (Hans-Knöll-Institut für Naturstoff-Forschung, Jena), and Prof. Karlheinz Seifert (Universität Bayreuth) for help and assistance in identifying 2-ara-gl and 2-epa-gl, and to BASF AG, Ludwigshafen, and the Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie (BMBF; reference no. 0310722) for financial support.

Lipids of Gelatinous Antarctic Zooplankton: Cnidaria and Ctenophora

Matthew M. Nelson[a,b,*], Charles F. Phleger[a], Ben D. Mooney[c], and Peter D. Nichols[c,d]

[a]Department of Biology, San Diego State University, San Diego, California 92182 and [b]Department of Zoology, University of Tasmania, Hobart, Tasmania 7001, Australia, [c]CSIRO Marine Research, Hobart, Tasmania 7001, Australia, and [d]Antarctic CRC, Hobart, Tasmania 7001, Australia

ABSTRACT: Antarctic gelatinous zooplankton, including Cnidaria (*Calycopsis borchgrevinki, Diphyes antarctica, Stygiomedusa gigantea, Atolla wyvillei, Dimophyes arctica*) and Ctenophora (*Beroe cucumis, B. forskalii, Pleurobrachia pileus, Bolinopsis infundibulum*) were collected near Elephant Island, South Shetland Islands, during January and February 1997 and 1998. Total lipid was low in all zooplankton (0.1–5 mg g^{-1} wet mass) and included primarily polar lipids (59–96% of total lipid). Triacylglycerols were 0–26% of total lipids, and wax esters were 0–11% in all species. Cholesterol was the major sterol in all Cnidaria (50–63% of total sterols) whereas in most ctenophores it was lower at 26–45%. These cholesterol levels are consistent with a combined carnivorous and phytoplanktivorous diet in the ctenophores, with the carnivorous diet more dominant in the Cnidaria. Other sterols included primarily *trans*-dehydrocholesterol, desmosterol, 24-methylcholest-5,22*E*-dien-3β-ol, 24-nordehydrocholesterol, and 24-methylenecholesterol. Total stanols were 0–6% in all zooplankton. Eicosapentaenoic acid and docosahexaenoic acid were the major polyunsaturated fatty acids (PUFA) in all samples (7–25% of total fatty acids) except for *A. wyvillei* in which docosapentaenoic acid was 10% of total fatty acids. The PUFA 18:5n-3 was not detected in 1997 samples, but constituted 0.2–0.8% in most 1998 samples. Monounsaturated fatty acids included primarily 18:1n-9*c*, 16:1n-7*c*, and 18:1n-7*c*. The principal saturated fatty acids in all samples were 16:0, 18:0, and 14:0. These data are the first for many of these zooplankton species and the first sterol data for most species. The use of the signature lipid approach has enabled examination of aspects of trophodynamics not obtainable by conventional techniques.

Paper no. L8387 in *Lipids 35*, 551–559 (May 2000).

The Southern Ocean has a complex food web including planktivorous herbivores (krill, salps, copepods) fed upon by birds, fish, squid, seals, and baleen whales (1). Gelatinous organism, such as salps, ctenophores, and medusae are often neglected in studies of energy flow through marine pelagic ecosystems. Their importance has only recently been recognized (2,3). They are major zooplankton constituents in the ocean and are important regulators of biogeochemical flux (4).

Lipid class, fatty acid, and sterol compositional profiles can be used to understand and identify food web interactions (5,6). There are limited lipid studies of Antarctic gelatinous zooplankton in the literature. Low lipid values are characteristic of most species, such as *Calycopsis borchgrevinki* and *Diphyes antarctica* (7), with an average lipid content of approximately 3% for Antarctic gelatinous zooplankton (8). Polar lipid (PL) is typically the major lipid class, as in *C. borchgrevinki* and *D. antarctica* (7,9). High cholesterol was reported in *Bolinopsis infundibulum* from a Scottish sea loch (10). Fatty acid composition of the scyphomedusan *Atolla wyvillei* was provided by Reinhardt and Van Vleet (1) who first noted high docosapentaenoic acid (DPA, 22:5n-3) in this species. High DPA was also reported in another Antarctic scyphomedusan, *Periphylla periphylla*, and sterol and fatty acid compositions were given for the Antarctic cnidarian *C. borchgrevinki* and *Arctopodema ampla* (11). Lipids of gelatinous salps (*Salpa thompsoni*) have been observed to be reflected in their commensal hyperiid amphipods (12). Lipid and fatty acid compositions of a number of non-Antarctic Cnidaria have been reviewed by Joseph (13).

The purpose of this study, conducted with animals collected in Elephant Island waters, is to examine lipid classes, specific sterols, and fatty acid biomarkers of the Antarctic Cnidaria *C. borchgrevinki, D. antarctica*, *Stygiomedusa gigantea*, *A. wyvillei*, and *Dimophyes arctica*, and the Ctenophora *Beroe cucumis, B. forskalii*, *Pleurobrachia pileus*, and *Bolinopsis infundibulum*. The data, to our knowledge, are the first reports for some of these species. The use of signature lipids in food chain studies offers potential to gain additional information not available with conventional procedures. The lipid profiles obtained will help to clarify trophodynamics of the oceanographic region near Elephant Island. This area, intensively surveyed for zooplankton by the United States Antarctic Marine Living Resources (U.S. AMLR) Program, is noted for high biological productivity and rich krill populations (14).

MATERIALS AND METHODS

Sample description. Cnidarians and ctenophores were collected from the R/V *Yuzhmorgeologiya* by Isaacs-Kidd midwater trawl fitted with a 505-μm mesh plankton net during January and February, 1997 and 1998. The samples were obtained as part of the AMLR Field Study conducted annually in the Elephant Island region of the Antarctic Peninsula (14–16). The AMLR study area is located between 60–62.5°S and 53–59°W. The net was obliquely towed to 170 m depth for 30 min at a speed of 2 knots, or to 10 m above the bottom in shallower waters. Samples were identified with the assistance of V. Loeb and V. Siegel. Samples were frozen in liquid nitrogen directly after identification and sorting on board ship. Samples were then transported frozen (dry ice) by air to CSIRO Marine Research, in Hobart, Tasmania, where they were maintained at –70°C prior to analysis. Fresh masses of zooplankton extracted for lipid analysis were as follows: *A. wyvillei*, 2.4–5.6 g; *D. antarctica*, 3.5 g (which included 18 pooled individuals for 1997; for 1998 2 or 3 individuals were pooled for each sample, 0.2–0.5 g); *C. borchgrevinki*, 0.6 g; *S. gigantea*, 2.1 g (oral arm tissue only); *Dimophyes arctica*, 0.1 g (3 pooled individuals); *B. forskalii*, 0.9–8.8 g; *B. cucumis*, 2.9 g; *Pleurobrachia pileus*, 0.1 g; and *Bolinopsis infundibulum*, 0.7–1.2 g.

Lipid extraction. Samples were quantitatively extracted using a modified Bligh and Dyer (17) one-phase methanol/chloroform/water extraction (2:1:0.8, by vol); the sample was extracted overnight and the phases were separated the following day by the addition of chloroform and water (final solvent ratio, 1:1:0.9, by vol, methanol/chloroform/water). The total solvent extract was concentrated (i.e., solvents removed *in vacuo*) using rotary evaporation at 30°C. Lipid class analyses were conducted immediately; samples were stored for no more than 3 d in a known volume of chloroform.

Lipids. An aliquot of the total solvent extract was analyzed using an Iatroscan MK V TH10 thin-layer chromatography–flame-ionization detector (TLC–FID) anlyzer (Tokyo, Japan) to determine the abundance of individual lipid classes (18). Samples were applied in duplicate or triplicate to silica gel SIII chromarods (5 μm particle size) using 1 μL disposable micropipettes. Chromarods were developed in a glass tank lined with pre-extracted filter paper. The solvent system used for the lipid separation was hexane/diethyl ether/acetic acid (60:17:0.2, by vol), a mobile phase that resolves nonpolar compounds such as wax esters (WE), triacylglycerols (TAG), free fatty acids (FFA) and sterols (ST). A second nonpolar solvent system of hexane/diethyl ether (96:4, vol/vol) was also used to separate hydrocarbons from WE and TAG. After development, the chromarods were oven-dried and analyzed immediately to minimize adsorption of atmospheric contaminants. The FID was calibrated for each compound class (phosphatidylcholine, cholesterol, cholesteryl ester, oleic acid, squalene, triolein, and diacylglyceryl ether purified from shark liver oil; 0.1–10 μg range). A laboratory standard of WE (derived from orange roughy oil) was used for peak identification, and steryl ester was used for quantification of WE. WE and steryl esters coelute in the systems used. Based on the TLC–FID analyses and subsequent analysis of component fatty acids and alcohols by gas chromatography (GC), steryl esters were either absent or present only as trace components. Peaks were quantified on an IBM-compatible computer using DAPA software (Kalamunda, Western Australia). Iatroscan results are generally reproducible to ±5% (Nichols, P., unpublished data).

Fatty acids. Samples of the solvent extract were treated with potassium hydroxide/methanol (5% wt/vol) under N_2 for 3 h at 80°C. Nonsaponifiable neutral lipids (e.g., 1-*O*-alkyl glycerols, fatty alcohols, and hydrocarbons) were then extracted into hexane/chloroform (4:1, vol/vol, 3 × 1.5 mL) and transferred to sample vials. Following acidification of the remaining aqueous layer using hydrochloric acid (pH = 2), fatty acids were extracted and methylated to produce their corresponding fatty acid methyl esters using methanol/hydrochloric acid/chloroform (10:1:1, by vol; 80°C, 2 h). Products were then extracted into hexane/chloroform (4:1, vol/vol, 3 × 1.5 ml) and stored at –20°C. The nonsaponifiable neutral lipid fractions were treated with *N*,*O*-bis-(trimethylsilyl)-trifluoroacetamide (BSTFA, 50 μL, 60°C, 1 h) to convert alcohols and ST to their corresponding TMSi (trimethylsilyl) ethers.

GC analyses of ST-containing nonsaponifiable neutral lipids and methyl esters of fatty acids were performed with a Hewlett-Packard 5890A gas chromatograph (Avondale, PA) equipped with an HP-1 cross-linked methyl silicone fused-silica capillary column (50 m × 0.32 mm, i.d.), an FID, a split/splitless injector, and an HP 7673A auto sampler. H_2 was the carrier gas. Following addition of methyl tricosanoate internal standard, samples were injected in splitless mode at an oven temperature of 50°C. After 1 min, the oven temperature was raised to 150°C at 30°C min^{-1} then to 250°C at 2°C min^{-1}, and finally to 300°C at 5°C min^{-1}. Peaks were quantified with either DAPA Scientific or Waters Millenium software. Individual components were identified using mass spectral data and by comparing retention time data with those obtained for authentic and laboratory standards. GC results are subject to an error of ±5% of individual component abundance.

GC–mass spectrometry (GC–MS) analyses were performed on a Fisons MD 800 GC–mass spectrometer (Manchester, United Kingdom) fitted with an on-column injector. The gas chromatograph was fitted with a capillary column similar to that described above.

Determination of double-bond configuration in fatty acids. Dimethyl disulfide (DMDS) adducts of monounsaturated fatty acids (MUFA) were formed for selected samples by treating the total fatty acid methyl esters with DMDS (19,20). Adducts were then extracted using hexane/chloroform (4:1, vol/vol) and treated with BSTFA to form TMSi derivatives prior to GC–MS analysis.

RESULTS

Lipid content and class composition. Lipid content was low in all gelatinous zooplankton from both years (0.1–5 mg g^{-1}

[d]Calculated assuming 95% water data presented as mean ± SD; trace (<0.5%).

wet mass). PL were the major lipid class in all Antarctic gelatinous zooplankton (59–96%, Table 1). TAG were the second-most abundant lipid class in *C. borchgrevinki*, *D. antarctica*, *S. gigantea*, and *Dimophyes arctica* (6–26% of total lipids). WE constituted 11% of the total lipid in *C. borchgrevinki*, 7% in *A. wyvellei*, and 0.1% in *D. antarctica*; only trace amounts were detected in *S. gigantea* (Table 1). FFA were 1–5% of total lipid in all samples and ST 4–16% in all samples. ST were the second-most abundant lipid class in ctenophore species (8–16% of total lipids).

Sterols. Cholesterol was the major ST in all Cnidaria, and constituted 50–63% of total ST (Table 2). In most ctenophores, cholesterol was less than half of the total ST (26–43%). The ctenophore *B. forskalii* (1998) was an exception; cholesterol constituted 82% of total ST (Table 2). A number of other ST were present in all gelatinous zooplankton. *trans*-Dehydrocholesterol was 14–26% of total ST in zooplankton, except for lower levels in *A. wyvillei* (8%), *S. gigantea* (4%), and *B. forskalii* (2%). There were low levels of all ST (0.0–3%) in *B. forskalii*, except for cholesterol. Levels of desmosterol in Cnidaria were 0–8% and Ctenophora 3–21% (Table 2). Desmosterol was not detected in *A. wyvillei* and *D. arctica*. 24-Methylcholest-5,22*E*-dien-3β-ol was 0–15% of total ST in all zooplankton; it was not detected in *D. antarctica*, and levels were highest in the ctenophore *Bolinopsis infundibulum* (15%). 24-Nordehydrocholesterol was 3–12% in all zooplankton; it was not detected in *B. forskalii*. Levels of 24-methylenecholesterol were 2–9% of total ST in all zooplankton, except for lower levels in *A. wyvillei* (1%), *Bolinopsis infundibulum* (1%), and *B. forskalii* (0.1%) (Table 2). Total stanols were 0–6% in all zooplankton, with 6% stanols in *A. wyvillei*. Low levels of 24-nordehydrocholestanol were present in seven of the zooplankton species (<1%, Table 2). Cholestanol was detected in all but one species (1998; *D. antarctica*) at 0.3–3.5%. Dehydrocholestanol was also present at low levels (0–1%) in most organisms.

Fatty acids. Eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) were the two major polyunsaturated fatty acids (PUFA) in all samples (7–23% and 4–25% of total fatty acids, respectively), except 1998 *A. wyvillei* (Table 3). In 1998 *A. wyvillei*, DPA (22:5n-3) was 10% of total fatty acids vs. 4% for DHA. In 1997 DPA in *A. wyvillei*, *C. borchgrevinki*, and *S. gigantea* constituted 2% of total fatty acids, whereas in all other organisms DPA was 0–0.4% (not detected in *Bolinopsis infundibulum*). The PUFA 18:5n-3, included as "other" in Table 3, was not detected in 1997 samples. However, 18:5n-3 made up 0.2–0.8% of total fatty acids in all 1998 samples of Cnidaria and *B. forskalii*; 18:5n-3 was not detected in *Bolinopsis infundibulum*. The PUFA 18:4n-3 comprised 0.1–5% in all samples, except *P. pileus* and *B. infundibulum*, where none was detected. Total PUFA ranged from 31–52% in all samples except *C. borchgrevinki* (24% PUFA), *Pleurobrachia pileus* (21% PUFA), and *Dimophyes arctica* (20% PUFA) (Table 3).

Total MUFA ranged from 21–47% in all samples, with highest total MUFA in *C. borchgrevinki* (47%), *S. gigantea* (41%), and *Dimophyes arctica* (41%) (Table 3). The MUFA included primarily 18:1n-9*c* (5–26%), 16:1n-7*c* (1–15%), and 18:1n-7*c* (2–11%). Total saturated fatty acids (SFA) ranged from 21–39% in all samples except *Pleurobrachia pileus* where SFA made up 53% of total fatty acids. The principal SFA in all samples were 16:0 (12–26%), 18:0 (2–20%), and 14:0 (2–8%) (Table 3).

DISCUSSION

Lipid content and class composition. Lipid values for most gelatinous zooplankton in this study ranged from 0.1–5 mg g^{-1} wet mass. To facilitate comparison, lipid as percentage dry mass was calculated (assuming 95% water) (21) with a range from 0.3–6.8%. *Stygiomedusa gigantea* had 10.2 mg lipid g^{-1} dry mass. *Stygiomedusa gigantea* has oral arms up to 10 m long and a medusa up to 50 cm in diameter (22). These massive oral arms capture and digest prey, which may cause the high observed lipid values. According to Larson and Harbison (8) the average lipid content of Antarctic gelatinous zooplankton is approximately 3% (0.4–6% range), whereas Arctic gelatinous zooplankton have on average 8% lipid as a percent dry mass (1.5–22% range). Lower lipid levels in Antarctic gelatinous predators probably reflect lower lipid in their prey, such as the pteropod *Limacina helicina* (23).

Visible stored lipid in the lumen of the gastrovascular system was less abundant in Antarctic than in Arctic Cnidaria and Ctenophora (8). *Beroe cucumis* from Bute Inlet, Canada, had 13% lipid as percent dry mass (24), which was greater than calculated values for *B. cucumis and B. forskalii* (2.9 and 2.2–6.8% lipid, as percent dry mass) in this study. Another ctenophore, *Bathocyroe fosteri*, from the Cape Hatteras, NC, area, had very low lipid (0.01%, as percent wet mass) (4). The ctenophores *Bolinopsis infundibulum* and *B. cucumis* from the Arctic had 4.7 and 0.6 mg lipid per g fresh mass (25). These latter values are similar to those in this study (Table 1). Lipid values for *C. borchgrevinki* and *D. antarctica* from Southern Ocean waters were 2.7 and 2.3% dry mass, respectively (7), similar to our lipid values for those species (3.1 and 1.2–1.3% lipid, as percent dry mass, respectively).

PL, the major lipid class in both 1997 and 1998 Antarctic gelatinous zooplankton (Table 1), is primarily a structural membrane component. *Beroe* sp., *D. antarctica*, and *Sibogita* (*Calycopsis*) *borchgrevinki*, from the Southern Ocean around South Georgia Island, were also characterized by high values for structural lipid classes (PL and ST) (9). PL are also important in nematocysts, which are stinging organelles on tentacles of Cnidaria. PL were constituted primarily of phosphatidylcholine and phosphatidylethanolamine in the scyphomedusan *Pelagia noctiluca* (26). Nemotocyst toxin in another scyphomedusan *Physalia physalis* was high in lipid, according to Stillway (27), who proposed that nematocyst lipids have important roles in stability and pharmacology of the toxin. PL or proteins could also possibly be used as an energy reserve during starvation. *Bolinopsis infundibulum*, from a sea loch in Scotland, shrank to less than two thirds of its length after 4 wk of starvation (10). Low FFA (0–5%, Table 1) and no detectable diacylglycerols are evidence for almost no sample degradation during frozen storage and analysis. The levels of WE present in *C. borchgrevinki* (11%, as percent of total lipids) and *A. wyvillei* (7%) may reflect feeding on WE-rich copepods or their larvae. The low level of WE, and the absence of it in other 1998 samples, suggest that this dietary contribution is only minor.

Cholesterol and phytosterols. The cholesterol level in all

[a]18 pooled samples.

[b]3 pooled samples; Trace = below integration; data presented as mean ± SD; other includes all fatty acids present at <1% of total fatty acids: i.e., 10:0, 17:0, 20:0, i14:0, i15:0, a15:0, i16:0, i17:0, a17:0, i19:0, 4,8,12-trimethyltridecanoic acid, 14:1n-7*c*, 14:1n-5, 15:1, 16:1n-9*c*, 16:1n-7*t*, 16:1n-5*c*, 17:1, 18:1, 18:1n-7*t*, 20:1n-11/13, C_{16} PUFA, 18:5n-3, C_{19} PUFA, 20:3n-6, 20:4n-3, 22:2, C_{24} PUFA; EPA, eicosapentaenoic acid (20:5n-6); DHA, docosahexaenoic acid (22:6n-3).

these scyphozoan Cnidaria (50–63%, as percent of total ST, Table 2) is consistent with a largely carnivorous diet. It is uncertain if Cnidaria can synthesize cholesterol; it may be a slow process inhibited by dietary ST (28). Attempts to demonstrate [1-^{14}C]acetate incorporation into ST failed in the jellyfish *Rhizostoma* (29). The hydrozoan jellyfish species *Spirocodon saltatrix*, *Aurelia aurita*, and *Stomolophus* sp. were characterized by even higher cholesterol levels (72–89%) (30).

The ST profiles of the 1997 Ctenophora and 1998 *Bolinopsis infudibulum* were characterized by less cholesterol (26–43%, as percent of total ST, Table 2). The 1998 *B. forskalii* specimens, in contrast, contained higher levels of cholesterol. Higher levels of the phytoplankton-derived ST were present in animals with lower cholesterol, although several ST, such as *trans*-dehydrocholesterol and 24-nordehydrocholesterol, may also be either intermediates in cholesterol biosynthesis or from animal sources, respectively. *trans*-Dehydrocholesterol was the major ST in the Antarctic ice diatom *Nitzschia cylindrus* (31), and interestingly the structurally similar 27-nor-24-methylcholest-5,22*E*-dien-3β-ol has also been recently found as a major ST in an Antarctic dinoflagellate (Thompson, P., unpublished data). Care is needed, through examination of other signature lipids or other procedures, before the precise algal source of this ST can be determined. Further research is also needed examining the lipid composition of Southern Ocean dinoflagellates and other phytoplankton. The ST of these Ctenophora (except *B. forskalii*) were relatively enhanced in *trans*-dehydrocholesterol (14–22%) and desmosterol (15–21%; except *Bolinopsis infundibulum* with 15% 24-methylcholest-5,22*E*-dien-3β-ol and 3% desmosterol). With the exception of the 1998 *B. forskalii*, the ST composition of the ctenophores is less consistent with a carnivorous diet than the Cnidaria. This may reflect the fact that their foods (such as *Limacina helicina*) are herbivorous. Cholesterol is generally not a major phytoplankton ST, although it was present in 6 of 14 diatoms species analyzed by Barrett *et al*. (32) and in the Antarctic sea-ice diatom *N. cylindrus* (31).

The ST composition of Cnidaria and Ctenophora is usually quite diverse. *Bolinopsis infundibulum*, from a sea loch in Scotland, had a complex range of C_{26}–C_{29} ST (including 67% cholesterol) that was deemed to reflect a diet of surface calanoid copepods (10). *trans*-Dehydrocholesterol, the second-most common ST in most species (Table 2), is, as noted above, an intermediate in cholesterol synthesis. Similar levels of *trans*-dehydrocholesterol were reported in the Cnidaria *C. borchgrevinki*, *Arctopodema ampla*, and *P. periphylla* from Antarctic waters as well as the Antarctic ctenophore *B. cucumis* (23).

The greater amount of desmosterol in 1997 gelatinous zooplankton than in 1998 may reflect a different phytoplankton diet in their prey. Desmosterol is produced as an intermediate from phytosterol dealkylation and is also found in marine microalgae *N. closterium* (100% demosterol) and *Rhizoselenia setigeria* (94% desmosterol) (32). 24-Methylcholest-5,22*E*-dien-3β-ol (2–15% of total ST, Table 2) may have originated from dietary prymnesiophytes such as *Phaeocystis* and diatoms, where brassicasterol is a major ST (33,34). Levels of 24-nordehydrocholesterol observed in these gelatinous zooplankton are similar to levels reported for 1996 Cnidaria from the same study area (23). 24-Methylenecholesterol is the main ST in the diatom *Chaetoceros* (34). Levels of 24-methylenecholesterol, which were higher in 1997 jellies (1.6–8.5% of total ST, Table 2) than in 1998 (0.1–5.3%) may reflect differences in herbivore diatom diet between these years.

Stanols, which reflect diet, were generally low in all gelatinous zooplankton (Table 2). Cholestanol was 24% of total ST in the marine dinoflagellate *Scrippsiella* sp. (35), and a *Gymnodinium* species from Australian waters had 24% dinosterol (6). Dinosterol, a biomarker for dinoflagellates, was not detected in the gelatinous zooplankton analyzed in this study, nor was dinosterol detected in salps and their hyperiid amphipods from the same study area during the same years (11). This suggests that either dinoflagellates are absent from the diet, or, if members of this algal group are present, they are species that lack dinosterol.

Fatty acids: trophic relationships. All Cnidaria and Ctenophora were characterized by moderate to high levels of PUFA (20–47%, Table 3) with the exception of *Pleurobrachia pileus*. An inverse relationship between n-3 PUFA and MUFA was apparent (Fig. 1). A similar relationship has been noted for fish (36). MUFA content of fish has been observed to increase with increasing lipid content (37), however, MUFA content of the gelatinous Antarctic zooplankton was not related to lipid content. MUFA levels were in the range 20–25% for most species analyzed, with three species containing 40–47% MUFA (*S. gigantea*, 1998 *D. arctica*, *C. borchgrevinki*, Table 3). EPA and DHA levels observed in this study are in agreement with values for *B. cucumis*, *C. borchgrevinki*, and *Arctopodema ampla* collected from the same AMLR study area in 1996 (23). Somewhat lower values for *B. cucumis* from Bute Inlet, British Columbia (3–16% 22:6 and 20:5), were observed by Lee (24). High EPA and DHA were also observed in the pink jellyfish *Cyanea capillata* (38) and the Portuguese man-of-war *Physalia physalis* from tropical waters (39).

The ratio EPA/DHA was higher (≥3) in *A. wyvellei* (both years) and *S. gigantea*, but in all other animals the ratio was between 0.7–1.4 (Table 3). The differences observed may be due to variations in metabolic rates of the two PUFA. However, it may also reflect differences in the diatom vs. dinoflagellate diet; EPA is typically found in higher proportions in diatoms whereas dinoflagellates contain higher DHA relative to EPA. Of the two species showing a high EPA/DHA ratio, only *S. gigantea* also exhibited a high 16:1/16:0 ratio (Table 3). The latter is a characteristic feature of diatom fatty acid profiles, particularly in combination with elevated proportions of EPA.

The level of DPA (22:5n-3) in 1998 *A. wyvillei* (10% of total fatty acids, Table 3) is higher than DHA (4%), and higher than DPA levels in 1997 *A. wyvillei* (2.4%) and all other species of gelatinous zooplankton in this study (Table 3). High DPA was also observed in *A. wyvillei* (18.4%) collected in the Croker Passage off the Antarctic Peninsula in 1983 (5). Levels of 12–19% DPA were reported in another

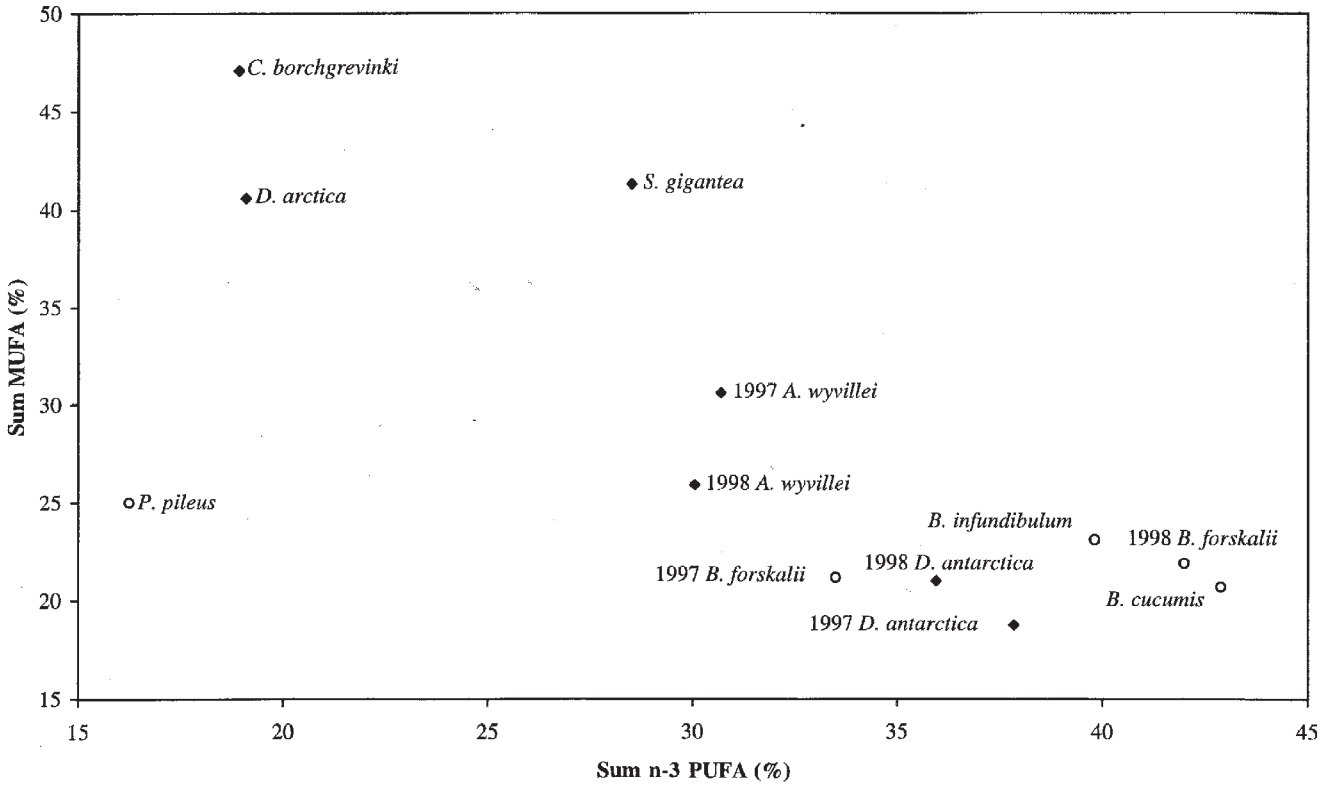

FIG. 1. Sum of monounsaturated fatty acids (MUFA) vs. sum n-3 polyunsaturated fatty acids (PUFA) in 1997 and 1998 gelatinous Antarctic zooplankton. ◆ = Cnidaria; ○ = Ctenophora. Species: *Calycopsis borchgrevinki, Atolla wyvillei, Diphyes antarctica, Dimophyes arctica, Stygiomedusa gigantea, Beroe cucumis, Beroe forskalii, Pleurobrachia pileus, Bolinopsis infundibulum.*

large Antarctic scyphomedusan, *P. periphylla*, collected in the AMLR study area in 1996 (23). There are few animals that contain appreciable levels of DPA. Of the lower members of the food chain, a high level of DPA has recently been reported in the California green abalone, *Haliotis fulgens* (up to 12% in the foot muscle) (40). DPA levels of 11–15% were found in the foot muscle of the Australian abalone *H. laevigata* and *H. rubra* (41). DPA levels in *H. laevigata* and *H. rubra* were associated with the occurrence of C_{22} PUFA in their diet. However, in *H. fulgens*, DPA was suggested to be a desaturation product of DHA (22:6n-3), since there was no correlation with the levels of C_{22} PUFA in their macroalgal diet (40). Presently, we have no explanation for the high DPA in *A. wyvillei* observed in this study, since its diet is unknown.

The unusual octapentadecaenoic acid (18:5n-3) is synthesized by certain species of dinoflagellates from 20:5n-3 (42). It is found as a major fatty acid in dinoflagellates (6) and coccolithophorids (43), and was first reported in marine zooplankton (chaetognaths and copepods) by Mayzaud *et al.* (44), who recognized its usefulness as a biomarker. We did not detect 18:5n-3 in zooplankton samples from 1997 (Table 3) nor 1996 (23). We detected 18:5n-3 in the 1998 samples reported here (up to 0.8%, Table 3) and in 1998 pteropods (*Spongiobranchaea australis*) and amphipods (*Hyperiella dilatata*) (11). Its presence in these 1998 samples, albeit at low relative abundance, points to a greater contribution from dinoflagellates and possibly other algal groups, such as coccolithophorids, in the AMLR study area during 1998. Very long chain PUFA (C_{24}, C_{26}, and C_{28} VLC-PUFA) were detected in the samples analyzed in this study. Novel VLC-PUFA were detected in 1998 salps and their commensal amphipods from the same AMLR study area (12). VLC-PUFA have been reported from dinoflagellates (35), and VLC-MUFA were present in sea ice diatoms (31). The lack of VLC-PUFA in the gelatinous zooplankton analyzed in this study indicates different dietary sources compared to salps and their commensal amphipods.

Oleic acid varied from 4.9–26.4% (Table 3). In a range of Antarctic zooplankton, higher levels of oleic acid have been proposed as consistent with a carnivorous diet (23). With a phytoplankton diet, 16:1n-7*c* is converted to 18:1n-7*c*. These observations have been exploited with the use of the ratio 18:1n-7*c*/18:1n-9 (Table 3) In animals with a carnivorous diet, the ratio is less than 0.5, and it is greater than 0.5 in animals with a phytoplankton diet. The long-chain MUFA (20:1 and 22:1, several isomers of each) were present in all animals (2.5–13%; Table 3). The long-chain MUFA are present in large amounts in calanoid copepods and are reported as the major site for their formation in the marine food web (45). Their presence in the Cnidaria and Ctenophora is further supporting evidence for the carnivorous/omnivorous nature of the diet of these animals.

A range of Antarctic gelatinous zooplankton have shown

broadly similar lipid profiles. These profiles are consistent with a largely carnivorous diet for most animals. Specific differences observed are due to dietary and other influences. Only single samples were available for some species analyzed here; these, however, are the first data for many species and the first ST data for most species. While comparisons are made, we recognize the need for further detailed sampling and analysis. The use of the signature lipid approach has enabled examination of aspects of trophodynamics not obtainable by conventional techniques.

ACKNOWLEDGMENTS

This work was supported in part by FRDC. We thank Jane Martin, Valerie Loeb, Roger Hewitt, and Rennie Holt for the AMLR Expeditions to the Elephant Island study area. Volker Siegel, Valerie Loeb, Dawn Outram, Wesley Armstrong, Ellie Linen, Rachel Johnson, Jackie Popp, David Demer, and Michael Force gave invaluable help in collection and identification of samples. Danny Holdsworth managed the CSIRO GC–MS and Kendrea Snyder assisted in preparation of the manuscript. Our appreciation is extended to the captain and crew of the R/V *Yuzhmorgeologiya*. Charles F. Phleger was a recipient of a 1997–98 CSU award for Research, Scholarship, and Creative Activity.

ABSTRACT: This study reports the fatty acid composition of subcutaneous adipose tissue in French women with special emphasis on the content of *trans* fatty acids originating from two main dietary sources, ruminant fats and partially hydrogenated vegetable oils (PHVO). Adipose tissue *trans* fatty acid levels from 71 women, recruited between 1997 and 1998, were determined using a combination of capillary gas chromatography and silver nitrate thin-layer chromatography. Results indicate that on average *cis* monounsaturates accounted for 47.9% of total fatty acids, saturates for 32.2%, and linoleic acid for 14.4%. *Cis* n-3 polyunsaturates represented only 0.7%. Total content of *trans* fatty acids was 2.32 ± 0.50%, consisting of *trans* 18:1 (1.97 ± 0.49%), *trans* 18:2 (0.28 ± 0.08%), and *trans* 16:1 (0.06 ± 0.03%). *Trans* 18:3 isomers were not detectable. The level of *trans* fatty acids found in adipose tissue of French women was lower than those reported for Canada, the United States, and Northern European countries but higher than that determined in Spain. Therefore, *trans* fatty acid consumption in France appears to be intermediate between that of the United States or North Europe and that of Spain. Based on the equation of Enig *et al.*, we estimated the mean daily *trans* 18:1 acid intake of French women at 1.9 g per person. The major *trans* 18:1 isomer in adipose tissue was Δ11*trans*, as in ruminant fats. Estimates of relative contribution of *trans* fatty acid intake were 55% from ruminant fats and 45% from PHVO. This pattern contrasts sharply with those established for Canada and the United States where PHVO is reported to be the major dietary source of *trans* fatty acids.

Paper no. L8376 in *Lipids 35,* 561–566 (May 2000).

At the beginning of the 1990s, epidemiological and clinical studies (1–8) suggested that dietary *trans* fatty acids might represent a risk for coronary heart disease. Clinical studies showed that *trans* fatty acids cause, in a dose-dependent manner (2), an increase of plasma low density lipoprotein cholesterol, and in some cases a decrease of plasma high density lipoprotein cholesterol (1–5,7). Occurrence of *trans* fatty acids in human tissues depends on their availability in the diet, because humans do not synthesize these fatty acid isomers. It is now well known that *trans* fatty acids are provided by three different dietary sources: the ruminant fats (milk and dairy products, beef, mutton, tallow) (9), the partially hydrogenated vegetable oils (PHVO) (some margarines, shortenings, baked goods, and chips) (10), and to a lesser extent, the refined vegetable oils (11). In France, the *trans* fatty acid content of most table margarines, both soft and hard, and low-fat spreads has decreased since 1995. At present, most of these products contain less than 1% total *trans* fatty acids (12) except for a few products which may contain up to 15% total *trans* fatty acids. In addition, products such as biscuits, crackers and French-fried potatoes that are marketed in France still contain 10–20% total *trans* fatty acids.

Estimates of *trans* fatty acids intake in France are 2.8 g/d capita from fat disappearance data (9) or 2.3 g from food consumption survey data (13). There are limitations in determining the *trans* fatty acids intake from nutrient databases, and therefore another approach should be considered. The *trans* fatty acid composition of adipose tissue is a reliable biochemical indicator of the consumption of "exogenous" fatty acids (14,15). The turnover rate of fatty acids in adipose tissue was shown to be approximately 3 yr (16), and therefore, its fatty acid composition would reflect dietary fats over that period.

The main objectives of this study were to determine the level of the different *trans* isomers (16:1*t*, 18:1*t*, 18:2*t*, and 18:3*t*) in adipose tissue of French adults, to assess their availability in the diet, and to determine their dietary origin (animal or processing) using the distribution of selected positional *trans* 18:1 isomers present in adipose tissue. In addition, the total fatty acid composition of adipose tissue of these French adults is reported, since such data are not available to date.

EXPERIMENTAL PROCEDURES

Subjects and sample collection. The study protocol was approved by the local ethical review committee, and informed consent was obtained from 71 participating women (age, 37 ± 10 yr; body mass index, 22 ± 3). They were recruited be-

tween 1997 and 1998. The selected participants were free of cancer and diabetes, and their lifestyles had not changed in the past 5 yr. Those who reported making major changes in their diet in the previous 5 yr were excluded. About 0.5–1 g abdominal subcutaneous adipose tissue was removed during abdominal surgery (hysterectomy, ovary cyst removal, etc.). The adipose tissue samples were immediately rinsed with an isotonic saline solution (0.9% NaCl) and then frozen and stored at –20°C until analyzed.

Sampling of foods containing PHVO. Fifteen brands of margarines and bakery products (biscuits, brioches, puff pastry, etc.) were purchased in local supermarkets in 1996 and 1997.

Lipid extraction. Thawed adipose tissue and food samples were ground in a mixture of chloroform/methanol (2:1, vol/vol). Total lipids were then extracted according to the method of Folch *et al.* (17). Solvents were evaporated to dryness under a stream of nitrogen. Lipids were taken up in an appropriate volume of chloroform/methanol (2:1, vol/vol) and stored in glass tubes at –20°C under nitrogen.

Fatty acid analysis. Fatty acid methyl esters (FAME) of total lipids were prepared using 14% boron trifluoride in methanol according to Morrison and Smith (18) and stored in hexane at –20°C under nitrogen. Analyses of total FAME were carried out on a gas chromatograph (Carlo Erba 5160, Milano, Italy) equipped with a flame-ionization detector and a split injector. A fused-silica capillary column (BPX 70, 60 m × 0.25 mm i.d., 0.25 μm film; SGE, France) was used with H_2 as a carrier gas (inlet pressure: 90 kPa). The split ratio was 1:70. The column temperature was programmed from 150 to 200°C at 1.5°C/min, then to 230°C at 2.5°C/min and held at 230°C until completion of the analysis (30 min). The injection port and the detector were maintained at 250°C. The gas chromatography (GC) peaks were integrated using an SP 4400 integrator (Spectra Physics, San Jose, CA). The different *trans* isomers of 18:2 and 18:3 were identified by comparing the GC retention times with authentic standards (Sigma, Saint Quentin Fallavier, France) or with well-characterized FAME mixtures prepared in our laboratory (11,19). In using these chromatographic conditions, all positional *trans* 18:1 isomers (6*t*-18:1 to 16*t*-18:1) could not be measured because of the overlap of five isomers (12*t*-18:1 to 16*t*-18:1) with *cis* 18:1 isomers. To measure the levels of all these isomers, the total *trans* 18:1 isomers were separated from *cis* 18:1 isomers by an additional step using $AgNO_3$ thin-layer chromatography (TLC) according to Wolff (19), with one minor modification. The developing solvent used for FAME separation was a mixture of hexane/diethylether (90:10, vol/vol). Analysis of the *trans* fraction was performed using a fused-silica capillary column (CP Sil 88, 100 m × 0.25 mm i.d., 0.20 μm film; Chrompack, Middelburg, The Netherlands) operated isothermally at 160°C, and using H_2 as the carrier gas (inlet pressure: 130 kPa) (19). Individual positional isomers of *trans* 18:1 were identified by comparison with synthetic isomers purchased from Sigma and with literature values (20). The total *trans* 18:1 content was calculated according to Ratnayake and Pelletier (21) by comparing the *trans* monoene fraction with the total FAME prior to $AgNO_3$ TLC fractionation. The *trans* 18:1 isomers, 6*t*-18:1 to 11*t*-18:1, well-separated on the total FAME chromatogram were therefore used as internal standard.

All the results are expressed as weight percentages of fatty acids using the factor (F'_t) described by Wolff *et al.* (22). This factor is linked to the theoretical response factor (F_t) by: $F'_t = F_t \times$ (fatty acid molecular weight/FAME molecular weight).

RESULTS

Fatty acid composition of abdominal adipose tissue. The detailed fatty acid compositions of women's adipose tissue (mean, standard deviation, and range) are presented in Table 1. *Cis* monounsaturated fatty acids accounted for about half (47.9% of total fatty acids), the major being oleic acid (9*c*-18:1) with 39.7%. The mean content of saturated fatty acids was 32.2%; palmitic acid (16:0) was the most prevalent with 22.2%. *Cis* n-6 polyunsaturated fatty acids (PUFA) ranged from 9.0 to 22.9% of total fatty acids (mean 15.3%), the main component being linoleic acid (9*c*,12*c*-18:2). *Cis* n-3 PUFA were present at very low levels (0.7% of total fatty acids).

The mean content of all *trans* fatty acids combined in adipose tissue in the 71 women examined was 2.32 ± 0.50% of total fatty acids, with a range of 1.41 to 3.96%. The *trans* fatty acids comprised isomers of 16:1, 18:1, and 18:2 acids (Table 2). The most prevalent *trans* isomers in adipose tissue were *trans* 18:1 acids, which were also the most abundant in foods. They represented 85% of the *trans* content and 1.97 ± 0.49% of adipose total fatty acids. There were several *trans*-18:1 isomers that ranged from Δ6 to Δ16. Accurate determination of the positional *trans* 18:1 isomers was obtained by a combination of $AgNO_3$-TLC and GC methods described above. The 18:1 isomers of the *trans* monounsaturated fatty acid band isolated from adipose tissue total FAME by $AgNO_3$-TLC were separated by GC into six individual FAME and two groups of FAME. The first group comprised 6*t*-, 7*t*-, and 8*t*-18:1, and the second the 13*t*- and 14*t*-18:1. Individual *trans* 18:1 isomers were 9*t*-, 10*t*-, 11*t*-, 12*t*-, 15*t*-, and 16*t*-18:1. Mean and range of their respective levels in all samples are shown in Table 2. The 11*t*-18:1 isomer was the most prevalent (0.65 ± 0.19%) in adipose total fatty acids. The only *trans* 16:1 fatty acid found in adipose tissue was 9*t*-16:1 which was well-separated from the iso and anteiso branched chain 17:0 fatty acids present in adipose tissue. The average content of 9*t*-16:1 was 0.06% of adipose tissue total fatty acids.

Total *trans* 18:2 isomer content was 0.28% of total fatty acids. The main 18:2 *trans* isomer was 9*c*,12*t*-18:2 at 0.13%, followed by 9*t*,12*c*-18:2 (0.06%). It is worth noticing that in our GC conditions, we could not exclude the possibility that the peak identified as the 9*t*,12*c*-18:2 also contained the 11*t*,15*c* isomer which has been found in bovine milk fat (23). The 9*t*,12*t*-18:2 was partially separated from 9*c*,13*t*-18:2. This isomer was identified in hydrogenated oils (21) and in bovine milk fat (23). Based on the partial overlap of these two

[a]9*t*,12*c*-18:2; this peak might correspond to the sum of 9*t*,12*c* + 11*t*,15*c*. See Table 1 for abbreviations.

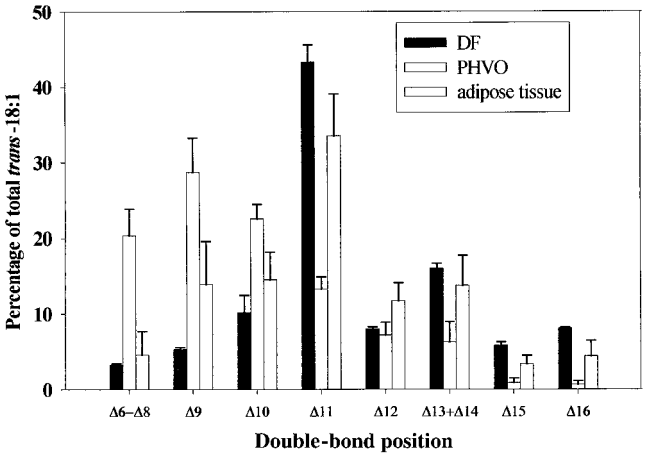

FIG. 1. Comparison of *trans* 18:1 positional isomer profiles in women's adipose tissue (n = 71), in dairy fat (DF; n = 10), and in partially hydrogenated vegetable oils (PHVO; n = 15). Positional isomers were analyzed using a combination of gas chromatography and silver nitrate thin-layer chromatography of fatty acid methyl esters. Values for each positional isomer are expressed as percentage of total positional isomers. Error bars represent standard deviation.

18:2 isomers, we estimated that 9*t*,12*t*-18:2, on average, represented about 20% of the complex peak (9*t*,12*t* plus 9*c*,13*t*), or 1% of the *trans* content and 0.02% of total fatty acids in adipose tissue. Therefore, 9*t*,12*t*-18:2 was the least common isomer of *trans*-18:2 found.

Profile of positional trans*-18:1 isomers in abdominal adipose tissue.* Figure 1 illustrates the mean distribution of positional *trans*-18:1 isomers in abdominal adipose tissue found in the 71 participating women; values were compared to those found in ruminant fats (average of 10 dairy products) and in PHVO (average of 15 selected *trans*-containing food products in France). The average distribution of *trans*-18:1 isomers in adipose tissue showed a greater similarity to ruminant fats than to PHVO *trans* fatty acids (Fig. 1). Vaccenic acid (11*t*-18:1) was the most prevalent both in adipose tissue fat (33% of total *trans* 18:1 acids) and in ruminant fats (43%).

DISCUSSION

Adipose tissue is regarded as a good reflection of long-term intake of fatty acids, some of which cannot be synthesized by humans, like linoleic, α-linolenic, and *trans* fatty acids

(15,24). Consequently, adipose tissue measurements may provide independent information on dietary habits. There are few data on the fatty acid composition of adipose tissue in European adults, and to our knowledge, none in France. Therefore, besides *trans* fatty acids, we report here the whole fatty acid composition of adipose tissue for 71 French women in 1997–1998. The content of *cis* PUFA (16%), consisting mainly of linoleic acid, was similar to that observed in 1985 in 59 Dutch women (17%) (24) or in 1986 in 76 U.S. males (16%) (25). However, it was lower than that reported in 1986 in 115 post-menopausal U.S. women (19.7%) (15) or in 1986 in 140 U.S. women (20.8%) (26). The contents of saturated (32.2%) and *cis* monounsaturated (47.9%) fatty acids found in this study were similar only to those reported in U.S. males (25). Because saturated and monounsaturated fatty acids are endogenously synthesized, their adipose content may not reflect their dietary intake.

Conversely, some studies have observed a correlation of *trans* fatty acid content between adipose tissue and the diet (14,15,27). The *trans* content in our French adipose tissue samples was 2.32% of total fatty acids, present as 16:1, 18:1, and 18:2 in all samples. On the other hand, *trans* fatty acids with 14 and 20–22 carbon atoms, and *trans* 18:3 isomers were below detection limits (0.01%) by GC. We noted that the 9*t*-16:1 level (0.06%), without contamination by branched-chain 17:0 fatty acids, was often lower than previously reported (15,25,27–29). The origin of this isomer is ruminant fats (30) and partially hydrogenated fish oils (31). Because *trans* 16:1 isomers sometimes have been associated with an increased risk of coronary artery disease (32), accurate chromatographic analysis is mandatory to avoid the overestimation due to closely coeluting branched-chain 17:0 fatty acids that are present. *Trans* polyunsaturates in adipose tissue of these French women contained less *trans* 18:2 acids (0.28%) than those observed in the American studies (0.9–1.3%). Data reported for Germany and the United Kingdom were similar to ours (0.34–0.59%) (29,33). These *trans* isomers were provided by PHVO (<2%) and by ruminant fats (about 1%). Differences of *trans* polyunsaturate adipose content between American and European populations reflect differences of their dietary fats. The *trans*-18:2 acids in decreasing order were: 9*c*,12*t* (0.13%) > 9*c*,13*t* (0.07%) > 9*t*,12*c* (0.06%) > 9*t*,12*t* (0.02%). *Trans* isomers of long-chain n-6 PUFA could be endogenously synthesized from mono-*trans*-18:2, and they are potential precursors of *trans* eicosanoid isomers (34). However, no *trans* isomers of long-chain n-6 PUFA were detected in adipose tissue. The di-*trans* isomer (9*t*,12*t*-18:2), which is known to alter the activity of Δ6-desaturase toward linoleic acid (9*c*,12*c*-18:2) (35), was found at <0.09%.

The bulk of *trans* fatty acids present in adipose tissue was *trans*-18:1 isomers. Their content ranged from 1.06 to 3.50% of total fatty acids of adipose tissue, with a mean value of 1.97%. These results are directly comparable to those determined in Canada (28), since the same combination $AgNO_3$-TLC and GC was used. *Trans*-18:1 content of adipose tissue from French women was lower than that of Canadians (4.8%), while the U.S. study (2.7 to 3.9%) was probably underestimated by omitting the 12*t*-18:1 to 16*t*-18:1 isomers (15,24–26). This suggests that *trans* fatty acid intake of these French women was lower than that of the Canadian and U.S. adults. The European data on *trans*-18:1 content of adipose tissue show that it varied from 0.43 to 2.43% among the eight countries participating in the Euramic Study (36). These values did not take into account the 12*t*-18:1 to 16*t*-18:1 isomers. As shown in Figure 1, these isomers constituted an average of 33% of total *trans*-18:1 isomers present in adipose tissue of the French women. Based on this estimate, we recalculated the published European data for comparison and observed that the *trans* content of French adipose tissue (1.97 ± 0.49%) was lower than those of North Europe countries (3.2–3.6%), but higher than that of Spain (0.6%). That would suggest that *trans*-18:1 acid intake in France was intermediate between countries of North and South Europe, which is in agreement with fat consumption data (9,37). Furthermore, our results on adipose tissue *trans*-18:1 acid content were similar to those obtained in France on *trans*-18:1 acid level in human milk (30,38), a biochemical indicator of *trans* fatty acid consumption of the previous day (39). Values of 1.8 ± 0.9% and 2.0 ± 0.6% (relative to total fatty acids) were found in milk of French women in 1995 by Combe *et al.* (38) in the Bordeaux region, and by Chardigny *et al.* (40) in the Dijon region, respectively.

The percentage value of *trans*-18:1 in adipose tissue of the 71 French women was applied to the equation of Enig *et al.* (14):

$$y = 0.97 + 0.44\,x \qquad [1]$$

which describes the relationship of *trans*-18:1 percentages between adipose tissue (y) and dietary fat (x). The estimated average of *trans*-18:1 in dietary fat was 2.27%, using this equation (Table 3). The mean total fat intake of our French women was 85 g/d/person, or 42% of energy based on dietary records (Boué, C., and Combe, N., unpublished data). We calculated that the consumption per capita of *trans*-18:1 acid might vary from 0.12 to 4.10 g/d, with an average value of 1.9 g/d (Table 3).

If we assume that there are no metabolic differences in turnover between the several positional *trans*-18:1 isomers in adipose tissue, then the respective proportions of these isomers in adipose tissue would depend on the availability in the diet. As shown in Figure 1, the pattern of *trans*-18:1 acids in adipose tissue was the result of contributions from both ruminant fats and PHVO. These results contrast widely with those reported by Chen *et al.* (28) for Canada and Ohlrogge *et al.* (41) for the United States. In these countries, the distributions of *trans*-18:1 isomers in adipose tissue were similar to those of dietary PHVO, indicating that they were the major dietary sources of *trans*-18:1 acids.

We assessed the relative contribution of both dietary origins to adipose storage of *trans*-18:1 isomers, using an equation proposed by Wolff (30) for human milk, which is based on the absence of 16*t*-18:1 in PHVO and its presence in ruminant fats. In Equations 2 and 3,

TABLE 3
Estimates of Human Consumption of Dietary *trans* Fatty Acids Based on Percentage of *trans* 18:1 in Adipose Tissue of 71 Women

		Range	
	Means	Min	Max
% *Trans* 18:1 in adipose tissue = *y* (wt% total fatty acids)	1.97	1.06	3.50
Equation of Enig *et al.* (Ref. 14)		$y = 0.97 + 0.44\,x$	
Estimate % *trans* 18:1 in women dietary fat = *x* (wt% total fatty acids)	2.27	0.33	5.34
Daily per capita total fat intake (g/d/person)	84.70	31.10	136.00
Estimate daily per capita intake of *trans* 18:1 (g/d/person)	1.93	0.12	4.10

$$8.1X + 0.5Y = Z \quad [2]$$

$$X + Y = 1 \quad [3]$$

X represents the intake of milk fat and *Y* the intake of margarines. *Z* is the percentage of 16*t*-18:1 relative to total *trans*-18:1 isomers in human milk. The author considered cow milk as the primary dominant source of ruminant fats for lactating French women and therefore used the value 8.1 as the mean proportion of the 16*t*-18:1 isomer in cow milk fat (30). However, this value was found to be 4.9% of the total *trans*-18:1 isomers in ruminant meat (30). Based on our dietary questionnaire, we found that ruminant fats were derived from 85% dairy products and 15% ruminant meat (Boué, C., and Combe, N., unpublished data). By using these values, the average percentage of 16*t*-18:1 in ruminant fats was 7.6%, which was applied to the above equations: $7.6X + 0.5Y = 4.4$ and $X + Y = 1$. *Z*, the mean 16*t*-18:1 proportion in adipose tissue, was 4.4% (Table 2). The relative contributions to *trans* fatty acid in the diet were estimated at 55% from ruminant fats and 45% from PHVO. These values were very similar to those deduced (58 and 42%, respectively) from the 16*t*-18:1 proportion in French human milk (30). These results suggest that lactating women consume little more dairy products than nonlactating women.

Ascherio *et al.* (42) recently reported clinical studies utilizing diets containing 3.3–10% of energy from *trans* fatty acids (elaidic acid: 9*t*-18:1). They showed that an increase of 2% in the intake of *trans* fatty acids raised the ratio of low density lipoprotein cholesterol to high density lipoprotein cholesterol by 0.1 unit when compared to a diet with isocaloric amounts of oleic acid. For the diet of the French women of our study, the percentage of energy from *trans*-18:1 acid was about 1%, with extreme values of 0.1 and 2.2% of total energy. These data were determined from the percentage of *trans*-18:1 acid in dietary fats (2.3%; range: 0.3–5.3%) and from total energy as fats (42%) in the diet of these subjects. The cholesterol levels of serum lipoproteins in these French women in relation to their total *trans* fatty acid intake and from either dietary source will be the subject of a further report.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the expert technical assistance of Laurence Fonseca and Pascale Nonatel. The work was supported by grants from CSM (Chambre Syndicale de la Margarinerie), ONIDOL (Organisation Nationale Interprofessionnelle des Oléagineux), SIDO (Société Interprofessionnelle des Oléagineux), and SGFHTF (Syndicat Général des Fabricants d'Huile et de Tourteaux de France). Carole Boué received a joint grant from the Ministère de la Recherche et de la Technologie and the Société Astra-Calvé (CIFRE, n°: 538/96).

Blood Fatty Acid Composition of Pregnant and Nonpregnant Korean Women: Red Cells May Act as a Reservoir of Arachidonic Acid and Docosahexaenoic Acid for Utilization by the Developing Fetus

K. Ghebremeskel[a,]*, Y. Min[a], M.A. Crawford[a], Joo-Hyun Nam[b], Ahm Kim[b], Ja-Nam Koo[b], and Hiramitsu Suzuki[c]

[a]Institute of Brain Chemistry and Human Nutrition, The University of North London, London N7 8DB, United Kingdom, [b]Asan Medical Centre, Department of Obstetrics and Gynaecology, College of Medicine, University of Ulsan, Seoul, South Korea, and [c]National Food Research Institute, Konnondai, Tsukuba, Ibaraki 305-8642, Japan

ABSTRACT: Relative fatty acid composition of plasma and red blood cell (RBC) choline phosphoglycerides (CPG), and RBC ethanolamine phosphoglycerides (EPG) of pregnant (n = 40) and nonpregnant, nonlactating (n = 40), healthy Korean women was compared. The two groups were of the same ethnic origin and comparable in age and parity. Levels of arachidonic (AA) and docosahexaenoic (DHA) acids were lower ($P < 0.05$) and palmitic and oleic acids higher ($P < 0.0001$) in plasma CPG of the pregnant women. Similarly, the RBC CPG and EPG of the pregnant women had lower AA and DHA ($P < 0.05$) and higher palmitic and oleic acids ($P < 0.01$). The reduction in DHA and total n-3 fatty acids in plasma CPG of the pregnant women was paralleled by an increase in docosatetraenoic (DTA) and docosapentaenoic (DPA) acids of the n-6 series and in DPA/DTA ratio. In the RBC phospholipids (CPG and EPG) of the pregnant women, DTA and DPA acids of the n-6 series and DPA/DTA ratio did not increase with the decrease of the n-3 metabolites (eicosapentaenoic acid, DPA, and DHA) and total n-3. Since pregnancy was the main identifiable variable between the two groups, the lower levels of AA and DHA in RBC CPG and EPG of the pregnant women suggest that the mothers were mobilizing membrane AA and DHA to meet the high fetal requirement for these nutrients. It may also suggest that RBC play a role as a potential store of AA and DHA and as a vehicle for the transport of these fatty acids from maternal circulation to the placenta to be utilized by the developing fetus.

Paper no. L8318 in *Lipids 35*, 567–574 (May 2000).

The fetus and neonate require arachidonic acid (AA) and docosahexaenoic acid (DHA) for the development of all vital cellular and subcellular membranes (1). The demand for these essential nutrients is at its highest in the later part of pregnancy and in early infancy, when priority is given to brain growth. In the human cerebrum and cerebellum, over a threefold increase in AA and DHA occurs, during the third trimester and another threefold increase between birth and postnatal week 12 (2–4). AA and DHA are selectively transferred to the fetus by the placenta from maternal circulation *in utero* and supplied in maternal milk postnatally (5).

In longitudinal studies, a decrease in the relative amounts of plasma AA and DHA has been reported in plasma total phospholipids of British, Dutch, Hungarian, and Ecuadorian (6) and Dutch (7) pregnant women. Differences in plasma phospholipid DHA levels between lactating and nonlactating mothers and a decline in plasma DHA with lactation have been observed (8). Al *et al.* (9) have found that the DHA content of maternal plasma phospholipids is significantly lower in multigravidae and neonates compared with primagravidae and their babies. Similarly, Prentice *et al.* (10) have reported a marked reduction in the proportions of endogenous fatty acids in breast milk of Gambian mothers of very high parity. These studies indicate that pregnancy, parity, and lactation deplete maternal AA and DHA stores.

There are no comprehensive data that compare the essential fatty acid status of pregnant and nonpregnant, nonlactating women. Hence, the extent of metabolic adjustment and the consequential changes in blood AA and DHA levels that may occur during the transition from nonpregnancy to pregnancy are not apparent. We have studied plasma and red blood cell (RBC) fatty acid composition of pregnant, and nonpregnant, nonlactating women from Seoul, South Korea. The aims of the study were to (i) establish if there is a difference in blood fatty acid composition between pregnant and nonpregnant women who are ethnically homogenous and (ii) explore whether the fatty acid composition of plasma and RBC phospholipids, and RBC phospholipid classes are differentially influenced by pregnancy.

MATERIALS AND METHODS

Subjects and sample collection. Healthy women with a singleton pregnancy were recruited during the third trimester from the Asan Medical Centre, Seoul, South Korea. Their age range was 23–38 yr and parity 0–2. All the mothers delivered at term and had no health complication during delivery. Nonpregnant, nonlactating healthy women aged 23 to 39 and par-

ity 0–3 were also enrolled from the Medical Centre. Demographic data of the population groups are given in Table 1.

Blood samples were collected in EDTA from the pregnant women between pregnancy week 36 and 42, and from the nonpregnant women at recruitment. Plasma and RBC were separated by cold centrifugation at 1000 × *g* for 15 min. After washing the RBC twice with an equal volume of saline (0.85% NaCl), both blood fractions were flushed with nitrogen and stored at –70°C and subsequently transported in dry ice to London for analysis. Ethical approval for the protocol was granted by the Ethics Committee of the Asan Medical Centre, and informed consent was obtained from the participating women. The samples were processed within 2 mon of collection.

Fatty acid analysis. Total plasma and RBC lipid was extracted by the method of Folch *et al.* (11) by homogenizing the samples in chloroform and methanol (2:1 vol/vol) containing 0.01% butylated hydroxytoluene (BHT) as an antioxidant under N_2. Phosphoglyceride classes were separated by thin-layer chromatography on silica gel plates by the use of the developing solvents: chloroform/methanol/water (60:30:4, by vol) containing 0.01% BHT. Bands were detected by spraying with a methanolic solution of 2,7-dichlorofluorescein (0.01% wt/vol) and identified by the use of standards.

Fatty acid methyl esters (FAME) were prepared by heating the lipid fractions with 4 mL of 15% acetyl chloride in methanol in a sealed vial at 70°C for 3 h under N_2. FAME were separated using a gas–liquid chromatograph (HRGC MEGA 2 Series; Fisons Instruments, Milan, Italy) fitted with a BP20 capillary column (25 m × 0.32 mm i.d., 0.25 μm film). Hydrogen was used as a carrier gas; and the injector, oven, and detector temperatures were 250, 200, and 280°C, respectively. The FAME were identified by comparison of retention times with authentic standards and calculation of equivalent chain-length values. Peak areas were quantified by a computer chromatography data system (EZChrom Chromatography Data System; Scientific Software, Inc., San Ramon, CA).

Data analyses. Data are expressed as means ± SD. Unpaired *t*-test was use to compare the difference in plasma and RBC fatty acid composition between the pregnant and nonpregnant women. A statistical package, SPSS for Windows (Release 7; SPSS (UK) Ltd., Woking, Surrey, United Kingdom) was used to analyze the data.

RESULTS

Plasma and RBC choline phosphoglycerides (CPG) and RBC ethanolamine phosphoglycerides (EPG) were analyzed from 40 pregnant and an equal number of nonpregnant, nonlactating women. CPG is the major phospholipid in plasma. CPG and EPG are major phospholipid fractions in RBC membranes, representing the outer and inner leaflet, respectively.

Plasma CPG fatty acid composition. Percentage fatty acid data of plasma CPG are shown in Table 2. Palmitic, palmitoleic, oleic acids, Σsaturates, and Σmonoenes were higher ($P < 0.0001$), and stearate was lower ($P < 0.0001$) in the pregnant compared with the nonpregnant women. Of the n-6 fatty acids, AA was lower ($P = 0.005$), and eicosadienoic (20:2n-6), dihomo-γ-linolenic (DHGLA; 20:3n-6), docosatetraenoic (DTA; 22:4n-6) and docosapentaenoic (DPA; 22:5n-6) acids were higher in the pregnant women ($P < 0.0001$). There was no difference in the mean proportion of linoleic acid (LA) between the two groups ($P > 0.05$). Eicosapentaenoic (EPA; 20:5n-3), DPA (22:5n-3), docosahexaenoic (DHA; 22:6n-3) acids and Σn-3 were lower ($P < 0.0001$), and α-linolenic acid (ALA) was higher ($P = 0.002$) in the pregnant as compared to the nonpregnant women. The level of Mead acid (20:3n-9) was significantly elevated in the pregnant women ($P = 0.004$).

RBC CPG fatty acid composition. Mean fatty acid composition of RBC CPG is given in Table 3. Similar to the plasma CPG, the percentage levels of palmitic, palmitoleic, oleic acids, and Σ monoenes were higher, and stearic acid was

lower ($P < 0.01$) in the RBC CPG of the pregnant women compared with that of the nonpregnant group. The proportions of eicosadienoic acid (20:2n-6) and DHGLA were higher ($P < 0.0001$), AA ($P < 0.05$), and DPA (22:5n-6) lower ($P < 0.0001$) in the RBC CPG of the pregnant women. In contrast to the plasma CPG, there was no difference in the level of DTA (22:4n-6) in RBC CPG of the two groups. Total n-3 fatty acids, EPA, DPA (22:5n-3), and DHA were reduced ($P < 0.01$) and ALA increased ($P < 0.0001$) in the RBC CPG of the pregnant women compared with the nonpregnant group. There was no difference in the level of Mead acid between the two groups ($P > 0.05$).

RBC EPG fatty acid composition. Consistent with the pattern in the plasma and RBC CPG, the RBC EPG of the pregnant women had elevated levels of palmitic and palmitoleic acids, total saturates and monoenes ($P < 0.0001$) in comparison with the RBC EPG of the nonpregnant, nonlactating women. In contrast to saturates and monoenes, the proportions of AA, DTA (22:4n-6), DPA (22:5n-6), total n-6 fatty acids, EPA, DPA (22:5n-3), DHA and total n-3 fatty acids were higher ($P < 0.05$) in the nonpregnant group. The parent n-6 and n-3 fatty acids, LA ($P = 0.002$) and ALA ($P = 0.001$) were higher in the pregnant women. Compared to the pregnant women, the nonpregnant group had higher levels of Mead acid ($P < 0.0001$). Data of the fatty acid composition of RBC EPG are shown in Table 4.

DISCUSSION

The present plasma and RBC fatty acid data of pregnant and nonpregnant women of the same ethnic origin and comparable age and parity provided comprehensive information on the changes in fatty acid metabolism which may occur as a consequence of pregnancy.

The results demonstrate a striking difference in the relative composition of blood fatty acids between the pregnant and the nonpregnant, nonlactating women. The pregnant women did not report a change in dietary habits as a result of their pregnancy. Their response was consistent with the classical longitudinal study covering 20 yr (12) which demonstrated that women change diets very little on becoming pregnant. Hence, the observed difference in fatty acid status, as assessed by a relative percentage, between the two groups of women appears to be primarily a reflection of a shift in metabolism in response to the demands of pregnancy.

There were contrasting levels of saturated, monounsaturated, n-6 and n-3 fatty acids in the phospholipid classes in the pregnant and nonpregnant women. Palmitic, palmitoleic, stearic, oleic acids, total saturates and monoenes followed a similar trend in the plasma and RBC CPG during the transition from nonpregnancy to pregnancy. The RBC EPG differed from plasma and red cell RBC in that the level of stearic acid was lower in the pregnant compared with the nonpregnant

women (Fig. 1). In contrast, pregnancy was characterized by a decrease in the relative amounts of the major n-3 fatty acids with the exception of ALA in plasma CPG, and RBC CPG and EPG (Fig. 2). The pregnant women had lower levels of AA in plasma CPG and RBC CPG and EPG, and total n-6 in RBC EPG; however, they had higher DHGLA in plasma and RBC CPG and LA in RBC EPG (Fig. 3). A decline in the n-3 fatty acids in plasma CPG of the pregnant women was marked by a

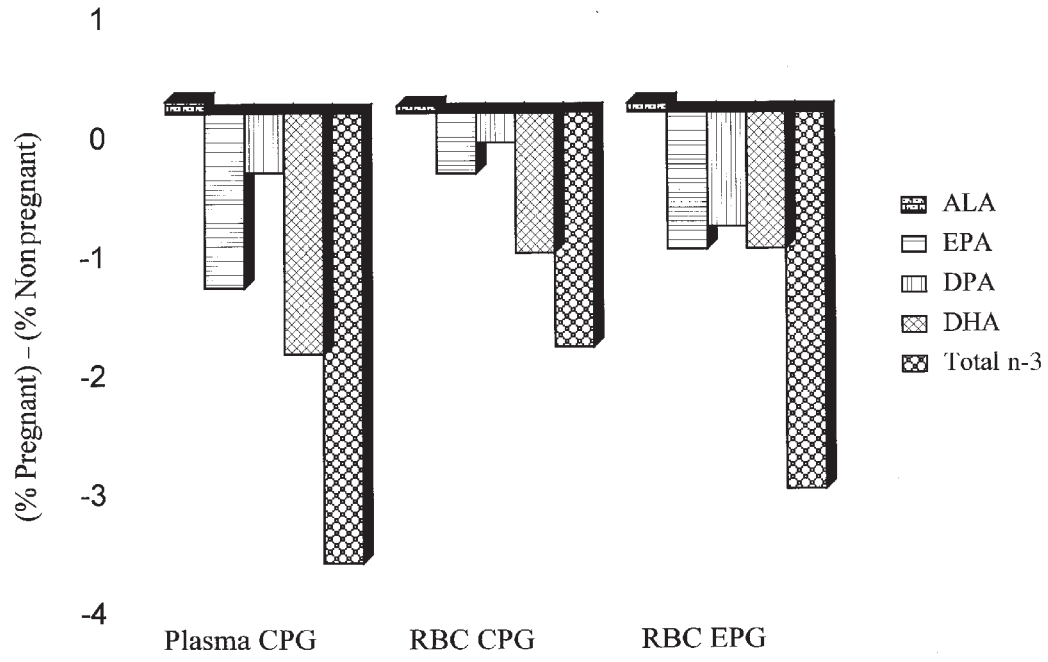

FIG. 2. Percentage difference in α-linolenic (ALA), eicosapentaenoic (EPA), docosapentaenoic (DPA), docosahexaenoic (DHA), and total n-3 fatty acids of pregnant compared to nonpregnant women. For other abbreviations see Figure 1.

corresponding increase in the incorporation of DTA and DPA of the n-6 series. DPA/DTA ratio, a biochemical indicator of DHA deficiency (13), was also significantly higher in plasma CPG of the pregnant women (2.4 vs. 0.82, $P < 0.0001$). Surprisingly, in spite of the significant reduction in total n-3 fatty acids, DHA, DPA (22:5n-3), and EPA in RBC of the pregnant women, there was no concomitant increase in the incorporation of DPA of the n-6 series or DPA/DTA ratio. Indeed, the DPA/DTA ratio was higher in RBC CPG (1.5 vs. 0.62, $P < 0.0001$) and EPG (0.41 vs. 0.19, $P < 0.0001$) of the nonpregnant women. This may have been due to the transfer of maternal RBC DPA (22:5n-6) to the fetus to meet the enhanced fetal requirement for DHA. There is some indication to support this conceivable explanation. In the small number (six cases) of cord blood collected from the group, the level of DPA was three times higher in the RBC of the neonates compared to the mothers.

Predictably, in response to the lower levels of AA, DHA, and total n-3 fatty acids, there was a higher proportion of Mead acid in plasma CPG of the pregnant women (Table 2). A similar pattern was not apparent in RBC CPG and EPG (Tables 3 and 4). This incongruity suggests the two blood components (plasma and RBC) respond differently to an "insufficiency" of AA and DHA during pregnancy. As is the case with AA and DHA, there may be a decline in the proportion of Mead acid in RBC of pregnant women. This could be due to reduced incorporation or to mobilization and transfer to the fetus. Indeed, the presence of an appreciable proportion of Mead acid in cord blood (Ghebremeskel, K., and Crawford, M.A., unpublished data) indicates that it may be transferred from the mother to the fetus to compensate for the shortage of n-6 and n-3 long-chain polyunsaturated fatty acids (PUFA). In contrast to our results, Holman *et al.* (14) did not find an increase in Mead acid in plasma total phospholipids during pregnancy. The authors suggested that deficiency of n-6 and n-3 PUFA in pregnancy is distinct from a simple nutritional deficiency of essential fatty acids and may not lead to an increase in the level of Mead acid.

Al *et al.* (7) have shown an initial increase and subsequent decline in plasma phospholipid DHA during pregnancy. Similarly, Otto *et al.* (6) have reported a decline in relative amounts of plasma phospholipid AA and DHA in pregnancy. Sanjurjo *et al.* (15) have found notable difference in the levels of some fatty acids in plasma total lipids of pregnant and nonpregnant women. Our plasma CPG data are consistent with the above findings. Significantly, the results also show that RBC of the pregnant women have reduced levels of these two vital nutrients. Since AA and DHA are not oxidized in preference to either palmitic acid, LA, α-ALA, or monounsaturates (16), it is not clear why the percentage levels of AA and DHA in RBC CPG and EPG were lower in the pregnant women. There is a suggestion that RBC may be involved in the transfer of glucose (17) and amino acids (18). Moreover, it has been postulated (19) that fetal erythrocytes play an important role in the transport of essential fatty acids to the developing tissue. If this is the case, maternal erythrocyte may play a role as a potential store of the long-chain PUFA, AA and DHA and as a vehicle for the transport of these nutrients to the placenta.

To our knowledge, there are no published studies that have investigated the role of maternal RBC as a source of PUFA to

the fetus. RBC have particular advantages as a potential store and delivery vehicle for AA and DHA. Primarily, they are relatively rich in AA and DHA and can enrich themselves through dynamic interaction with the plasma environment. Secondarily, RBC will be able to transport PUFA to the placenta without the involvement of mediators. In contrast, plasma fatty acid transport is a complex process of modeling and remodeling, which involves transport proteins and several enzymes.

Is the lower relative amount of AA and DHA in plasma CPG and RBC CPG and EPG of the pregnant women a physiological response to pregnancy or a reflection of the depletion of maternal AA and DHA stores due to the demand for these nutrients by the developing fetus? If it is the latter, it should be possible to forestall the depletion by raising maternal status before or during pregnancy. Indeed, studies demonstrate that maternal and neonatal DHA status can be enhanced by administration of fish oil (20) and sardines and fish oil (21) sources of DHA, during pregnancy.

It has been claimed that a low level of AA in cord plasma and umbilical artery is associated with low birth weight (22–24); and cord plasma levels of both AA and DHA are positively correlated with head circumference (24,25). Biochemical signs of essential fatty acid deficiency have been reported in the endothelium and umbilical arteries of low birthweight babies with reduced synthesis of prostacyclin by the umbilical endothelium (26). These studies suggest that an imbalance between maternal supply and fetal demand for AA and DHA during the prenatal period may impair development.

Healthy women may have some restricted ability of mobilizing AA and DHA in order to meet the high demand of pregnancy for these fatty acids. However, regardless of this ability of mobilization, the requirement for AA and DHA is unlikely to be met if the mothers had low status prior to their pregnancy, and/or impairment of PUFA metabolism. Women from some developing countries where the first pregnancy occurs at a very young age followed by successive pregnancies at short intervals also may not be able to provide AA and DHA required for optimal fetal development.

Simultaneous Derivatization of Acyl and *S*-Alkyl Moieties of Acyl Thioesters by Using Trimethylsulfonium Hydroxide for Gas Chromatographic Analysis

Erika Klein and Nikolaus Weber*

Institut für Biochemie und Technologie der Fette, Bundesanstalt für Getreide-, Kartoffel- und Fettforschung, 48147 Münster, Germany

ABSTRACT: The reaction of long-chain acyl thioesters, *viz.* lauric acid dodecyl thioester, 1,8-di-*S*-palmitoyl octanedithiol, and tristearoyl α-monothioglycerol, with trimethylsulfonium hydroxide in the presence of methanol leads to simultaneous derivatization of acyl moieties and *S*-alkyl moieties of acyl thioesters to the corresponding fatty acid methyl esters and methyl alkylsulfides, respectively. These derivatized products were analyzed by gas chromatographic technique.

Paper no. L8374 in *Lipids 35*, 575–577 (May 2000).

The preparation of methylthio derivatives by the treatment of thiol groups of compounds with trimethylsulfonium hydroxide (TMSH) in the presence of methanol is well known (1). Very recently we demonstrated that TMSH is also useful for derivatization of thiol compounds to the corresponding methyl alkylsulfides for gas chromatography (GC) analysis (2).

Base-catalyzed transesterification of *O*-acyl lipids with methanol in the presence of TMSH is a convenient method for the preparation of fatty acid methyl esters for GC analyses (3–5). So far, this method has not been applied to the transesterification of *S*-acyl lipids (lipid thioesters), which are common constituents of microorganisms, plants, and animals (6).

In this paper, we describe the analysis of acyl and *S*-alkyl moieties of long-chain acyl thioesters by GC after derivatization with TMSH reagent. This method allowed simultaneous derivatization of both acyl and *S*-alkyl moieties of acyl thioesters. In contrast, acid- and alkali-catalyzed transmethylations, which are commonly used for the derivatization of acyl thioesters (6), yield fatty acid methyl esters and alkane thiols. The latter easily form thiyl radicals which are able to attack >C=C< double bonds, finally leading to *cis/trans*-isomerization of, e.g., unsaturated fatty acids (7,8).

EXPERIMENTAL PROCEDURES

Chemicals. 1-Dodecanethiol, 1,8-octanedithiol, and α-monothioglycerol (3-mercapto-1,2-propanediol) as well as lauric acid were purchased from Sigma-Aldrich-Fluka (Deisenhofen, Germany). Palmitoyl and stearoyl chlorides were purchased from Nu-Chek-Prep (Elysian, MN). TMSH reagent (0.2 M TMSH in methanol) was a product of Macherey-Nagel (Düren, Germany).

Preparation of standards. Methyl sulfide derivatives were prepared by the reaction of thiol compounds with TMSH (1,2) or diazomethane (2). Lauric acid was thioesterified with 1-dodecanethiol in the presence of immobilized lipase Novozym 435® (Novo Nordisk, Bagsvaerd, Denmark); the lauric acid dodecyl thioester was separated from the reaction mixture as described recently (9,10). 1,8-Di-*S*-palmitoyl octanedithiol was synthesized by the reaction of palmitoyl chloride with 1,8-octadecanedithiol in pyridine (11). Similarly, tristearoyl α-monothioglycerol was prepared by reacting α-monothioglycerol with stearoyl chloride. After stirring for 24 h at room temperature, water was added to the reaction mixture and thioester compounds were extracted with isohexane. The extract was washed with water, dried, and concentrated. Lauric acid dodecyl thioester was finally purified by preparative thin-layer chromatography (TLC) on 0.5-mm layers of Silica Gel H (E. Merck, Darmstadt, Germany) using isohexane/diethyl ether (99:1, vol/vol) as the developing solvent. In the case of 1,8-di-*S*-palmitoyl octanedithiol and tristearoyl α-monothioglycerol isohexane/diethyl ether (80:20, vol/vol) was used as the solvent system. Bands were located by slight iodine staining, scraped off the plates; and acyl thioesters were eluted from the adsorbent with water-saturated diethyl ether. Purity of the isolated compounds was checked by GC (9,10) and/or TLC.

Derivatization for GC. Under standard conditions, 20 μL TMSH reagent was added to 1 μmol thioester compound (molar ratio TMSH/thioester equivalent = around 4:1) in 40 μL methyl *t*-butyl ether. The derivatization mixtures were concentrated in a stream of nitrogen at 40°C to 20–40 μL and then reacted in closed screw-capped Teflon-lined 1-mL autosampler vials at 120°C in a heating block for 3 min. The reaction mixtures were cooled to room temperature, and dimethylsulfide was removed under a stream of nitrogen. The samples were dissolved in 20 μL methyl *t*-butyl ether and 1–2 μL of these solutions were injected into the gas chromatograph.

GC. These derivatized products of long-chain acyl thioesters, i.e., fatty acid methyl esters as well as methyl dodecylsulfide or 1,8-di-*S*-methyl octanedithiol or 1-*S*-methyl α-monothioglycerol were analyzed by GC on a Hewlett-Packard (Böblingen, Germany) HP-5890 Series II instrument equipped with a flame-ionization detector. Separations were carried out on a 0.2-μm DB-23 fused-silica capillary column (J&W Scientific, Folsom, CA), 40 m × 0.18 mm i.d., using hydrogen as the carrier gas (column pressure 140 kPa; linear velocity 31 cm · s^{-1}) initially at 160°C for 2 min, followed by linear programming from 160 to 180°C at 2°C · min^{-1}. The final temperature was kept constant for 10 min. The split ratio was 1:10, the injector as well as flame-ionization detector temperature was 250°C. Peaks in gas chromatograms were identified by comparison of their retention times with those of authentic standards (2,9). Peak areas and percentages were calculated using Hewlett-Packard GC ChemStation software.

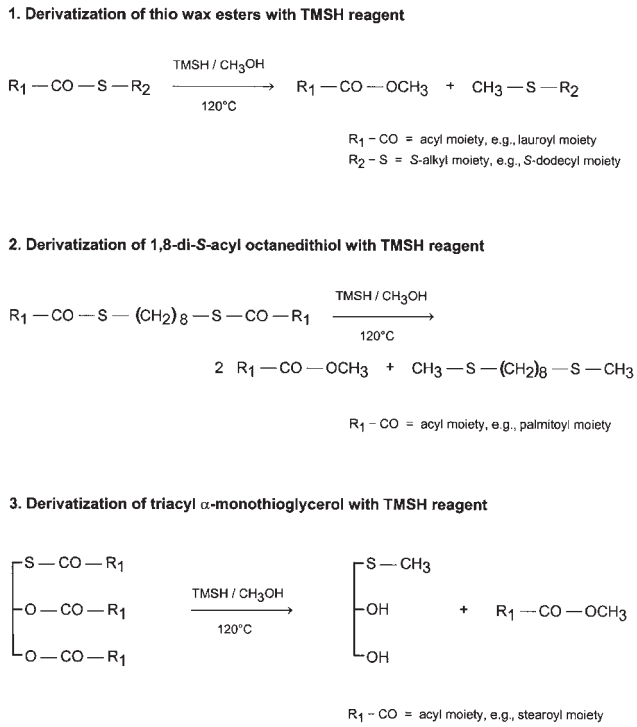
RESULTS AND DISCUSSION

Base-catalyzed transesterification of *O*-acyl lipids using TMSH in the presence of methanol is a convenient method for the preparation of fatty acid methyl esters for GC analyses (3–5). *S*-Acyl lipids such as long-chain acyl thioesters are generally derivatized by acid- or alkali-catalyzed transmethylation leading to fatty acid methyl esters and alkanethiols (6). We have studied the reaction of a 0.2 M TMSH solution in methanol (TMSH reagent) for its use as derivatization reagent for very different long-chain acyl thioester compounds.

Figure 1 shows the gas chromatogram of lauric acid dodecyl thioester after derivatization with TMSH reagent. The peaks in Figure 1 match the retention times of known standards, showing that this thioester compound was converted to methyl laurate and methyl dodecylsulfide according to Scheme 1.

Figure 2 shows the GC separation of the products of the reaction of 1,8-di-*S*-palmitoyl-octanedithiol with TMSH reagent (Scheme 1). As expected the derivatization products, i.e., methyl palmitate and 1,8-di-*S*-methyl octanedithiol, were in a ratio of about 2:1.

GC separation of the derivatization products of tristearoyl



SCHEME 1

α-monothioglycerol with TMSH reagent is shown in Figure 3. The reaction products were identified as methyl stearate and *S*-methyl α-monothioglycerol (Scheme 1).

Triradyl sulfonium compounds such as TMSH are involved in very different types of chemical reactions (1,3,12–14). The first is base-catalyzed transesterification of acyl lipids using methanolic TMSH solutions, which transmethylate acyl lipids to the corresponding fatty acid methyl esters (3–5). The second type is a nucleophilic substitution reaction of TMSH leading to the methylation of nucleophiles including thiol compounds (1,2,14). In addition, pyrolytic methylation reactions of TMSH or similar thermally assisted methylation reactions, which have been described for tetramethylammonium hydroxide, may also be involved in *S*-methylation of thiol compounds (12,15). Both transesterifica-

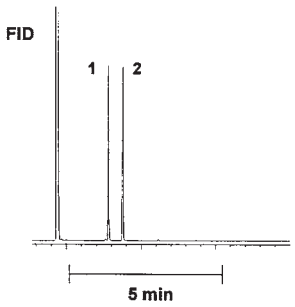


FIG. 1. Gas chromatographic separation of the products of the reaction of lauric acid dodecyl thioester with trimethylsulfonium hydroxide reagent (1, methyl dodecylsulfide; 2, methyl laurate).

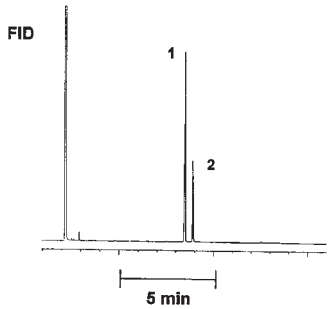

FIG. 2. Gas chromatographic separation of the products of the reaction of 1,8-di-*S*-palmitoyl octanedithiol with trimethylsulfonium hydroxide reagent (1, methyl palmitate; 2, 1,8-di-*S*-methyl octanedithiol).

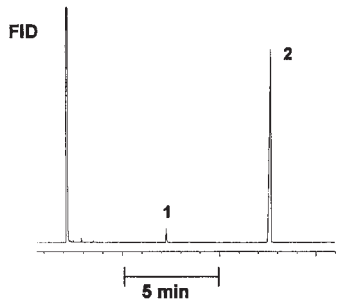

FIG. 3. Gas chromatographic separation of the products of the reaction of tristearoyl α-monothioglycerol with trimethylsulfonium hydroxide reagent (1, S-methyl α-monothioglycerol; 2, methyl stearate).

tion and nucleophilic substitution reactions may be involved in the derivatization of acyl thioesters by TMSH reagent leading to simultaneous derivatization of both acyl moieties and *S*-alkyl (alkylthio) moieties of long-chain acyl thioesters to the corresponding fatty acid methyl esters and methyl alkyl-sulfides, respectively. Thus, derivatization of acyl thioesters using TMSH reagent is advantageous over the usual acid- or alkali-catalyzed transmethylation of acyl thioesters for the analysis by GC.

COMMUNICATION

Reinvestigation of Positional Distribution of Fatty Acids in Docosahexaenoic Acid-Rich Fish Oil Triacyl-*sn*-glycerols

Yasuhiro Ando*, Motoi Satake, and Youichi Takahashi

Department of Marine Bioresources Chemistry, Faculty of Fisheries, Hokkaido University, Hakodate 041-8611, Japan

ABSTRACT: Positional distribution of fatty acids in triacyl-*sn*-glycerols of docosahexaenoic acid (DHA)-rich tuna orbital and bonito head oils has been reanalyzed by a method based on chromatographic separation of isomeric and enantiomeric monoacyl-*sn*-glycerol (MAG) derivatives. When boric acid thin-layer chromatography (TLC) was used for separation of 1(3)- and 2-MAG analytical intermediates, the stereospecific analysis showed the preferential association of DHA to the *sn*-2 position followed by the *sn*-3 position. This distribution pattern differed from that obtained by silicic acid TLC of their bis-3,5-dinitrophenylurethane (DNPU) derivatives. Reversed-phase high-performance liquid chromatography elution profiles of 1(3)- and 2-MAG intermediates revealed that 1(3)- and 2-MAG made up of both short- and long-chain lengths cannot be clearly resolved by TLC after preparation of the DNPU derivatives. The 1(3)- and 2-MAG must be resolved by boric acid TLC prior to derivatization.

Paper no. L8390 in *Lipids 35,* 579–582 (May 2000).

A method for stereospecific analysis of triacyl-*sn*-glycerols (TAG) involves chiral high-performance liquid chromatography (HPLC) of 1(3)-monoacyl-*sn*-glycerol (MAG) derivatives formed from TAG (1,2). For preliminary separation of isomeric 1(3)- and 2-MAG analytical intermediates, two procedures of thin-layer chromatography (TLC) were used, i.e., boric acid TLC of free form MAG prior to preparation of bis-3,5-dinitrophenylurethane (DNPU) derivatives (1) and silicic acid TLC after preparation of the derivatives (2). When the latter procedure was used in the analysis of docosahexaenoic acid (DHA)-rich tuna orbital and bonito head oil TAG, a high proportion of DHA was observed in the *sn*-3 position followed by the *sn*-1 position (3). However, many data obtained by other methodologies, such as chiral HPLC of diacyl-*sn*-glycerol derivatives (4), lipase hydrolysis (5,6), and ^{13}C nuclear magnetic resonance spectroscopy (7), showed preferential association of this acid to the *sn*-2 position. The present paper reports that the difference in distribution pattern is attributable to unsuitable TLC separation in the stereospecific analysis. Positional distribution of fatty acids in the same fish oil TAG was reanalyzed by the boric acid TLC procedure. Reversed-phase HPLC profiles of 1(3)- and 2-MAG intermediates were compared between the boric acid and silicic acid TLC separations to clarify which is applicable to analysis of DHA-rich fish oil TAG.

Abbreviations: DHA, docosahexaenoic acid; DNPU, dinitrophenylurethane; GLC, gas–liquid chromatography; HPLC, high-performance liquid chromatography; MAG, monoacyl-*sn*-glycerols; TAG, triacyl-*sn*-glycerols; TLC, thin-layer chromatography.

EXPERIMENTAL PROCEDURES

Materials. Tuna orbital and bonito head oils had been kept frozen at –30°C for 4 yr under nitrogen atmosphere. TAG were isolated from the other lipids by column chromatography on Silica gel 60 (Merck, Darmstadt, Germany) with *n*-hexane/diethyl ether for elution.

Stereospecific analysis of TAG. The method for stereospecific analysis of fish TAG (1,8) was used without essential modifications as follows. TAG (100 mg), mixed with trinonadecanoylglycerol (5 mg), were dissolved in 3 mL of dry diethyl ether, and ethyl magnesium bromide in dry diethyl ether (0.33 mL of 3 M solution) was added. The mixture was shaken for 1 min, and then 0.1 mL of glacial acetic acid followed by water (3 mL) was added to stop the reaction. The products were extracted with diethyl ether. The ether extract was washed six to seven times with 2% aqueous sodium bicarbonate, then washed with water, and dried over anhydrous sodium sulfate. After removal of the solvent at ambient temperature, resulting 1(3)- and 2-MAG were isolated by preparative TLC on a boric acid-impregnated silica gel plate (20 cm × 20 cm, 0.5 mm thickness, boric acid 10 wt% to Silica gel 60G) developed in chloroform/methanol (98:2, vol/vol) containing 0.002% of butylhydroxytoluene.

About a half of the 1(3)-MAG obtained was dissolved in dry toluene (0.5 mL) and reacted overnight at room temperature with 3,5-dinitrophenylisocyanate (15 mg) in the presence of dry pyridine (50 µL). Resulting bis-3,5-DNPU derivatives of 1(3)-MAG were purified by preparative TLC on a Silica gel 60G plate (0.5 mm thickness) with chloroform/acetone (96:4, vol/vol) for development. The 1(3)-MAG derivatives were resolved into *sn*-1- and *sn*-3-MAG fractions by HPLC with a Hitachi L-6200 pump (Hitachi Co., Tokyo, Japan), a Hitachi L-4200 ultraviolet spectrophotometric detector, and a Shimadzu C-R6A integrator (Shimadzu Co., Kyoto, Japan). Two columns of Sumichiral OA-4100 (25 cm × 4 mm i.d., 5 µm particles; Sumitomo Chemical Co., Osaka, Japan) in se-

ries were used with *n*-hexane/1,2-dichloroethane/ethanol (40:12:3, by vol) as mobile phase at a flow rate of 0.5 mL/min at –10°C. Detection was 254 nm.

Fatty acid methyl esters were prepared by reacting intact TAG, 1(3)-, 2-, *sn*-1-, and *sn*-3-MAG in a mixture of 1,2-dichloroethane (0.6 mL), methyl acetate (25 µL), and 1 M sodium methoxide–methanol solution (25 µL) at room temperature overnight. After adding acetic acid (6 µL) and removing the solvents, the products were taken up in *n*-hexane. Gas–liquid chromatography (GLC) of the methyl esters was performed on a Shimadzu GC-14A gas chromatograph equipped with a flame-ionization detector and an open-tubular column, Omegawax 320 (30 m × 0.32 mm i.d., 0.25 µm film thickness; Supelco Inc., Bellefonte, PA). The column temperature was 200°C, and injector and detector temperatures were 250 and 260°C, respectively. Helium was the carrier gas. Peak area percentages were measured with a Shimadzu C-R6A integrator. Assignments of each fatty acid to the *sn*-1-, *sn*-2-, and *sn*-3-positions of TAG were obtained from the peak area ratio of each fatty acid to 19:0 formed from the trinonadecanoylglycerol internal standard, and the fatty acid composition of each position was calculated on the basis of the assignments.

Reversed-phase HPLC of MAG derivatives. Chromatographic behaviors of the MAG intermediates on boric acid and silicic acid TLC plates were compared by reversed-phase HPLC of their bis-3,5-DNPU derivatives. HPLC was done by the same pump and detection systems described above. A column of Capcellpak C18 UG120-5 (25 cm × 4.6 mm i.d.; Shiseido Co., Tokyo, Japan) was used with acetonitrile and water as mobile phase at a flow rate of 1.0 mL/min. A linear gradient of 70% acetonitrile/30% water (held at this for 5 min) to 100% acetonitrile was generated over 185 min. Column oven temperatures were held at 10°C for 80 min and then immediately changed to 30°C. Samples were injected in 3 µL of 2-propanol.

RESULTS AND DISCUSSION

Table 1 shows the positional distribution of fatty acids in the DHA-rich fish oil TAG examined. In all of the fish oils, DHA was preferentially esterified in the *sn*-2 position, followed by the *sn*-3 position. DHA was low in the *sn*-1 position. When proportional distributions were calculated from the data, 50–52 and 42–43% of DHA were located in the *sn*-2 and *sn*-3 positions, respectively, whereas less than 8% of this acid was

esterified in the *sn*-1 position. This distribution pattern resembles that observed for tuna oil TAG in the report of Myher *et al.* (4). In contrast, our previous paper (3) reported 24–39, 8–26, and 50–59% of DHA were located in the *sn*-1, *sn*-2, and *sn*-3 positions, respectively. An opposite distribution pattern was obtained in the present study.

The analytical method used in our studies is based on chromatographic separation of isomeric and enantiomeric MAG formed from TAG (1,2). The method involves partial hydrolysis of TAG to MAG, isolation of 1(3)- and 2-MAG from the hydrolysis products, preparation of bis-3,5-DNPU derivatives of 1(3)-MAG, resolution of them by chiral HPLC, and GLC analysis of their fatty acids. In our previous study (3), the hydrolysis mixture of TAG was converted directly to the bis-3,5-DNPU derivatives, and then 1(3)- and 2-MAG derivatives were isolated by TLC on silicic acid with chloroform/acetone (96:4, vol/vol) as developing solvent. Presently, 1(3)- and 2-MAG generated by Grignard hydrolysis of TAG were resolved by boric acid TLC prior to the derivatization.

Figure 1 shows the reversed-phase HPLC elution profiles of the 1(3)- and 2-MAG intermediates formed from bonito head oil TAG. Under the HPLC conditions, peaks of 1(3)- and 2-docosahexaenoyl glycerols, prepared by Grignard hydrolysis of tridocosahexaenoyl glycerol, were partially separated from each other as their bis-3,5-DNPU derivatives. Figures 1A and 1B show the chromatograms of 1(3)- and 2-MAG isolated by boric acid TLC and then converted to the bis-3,5-DNPU derivatives, respectively. Essentially no cross-contamination of isomeric 1(3)-docosahexaenoylglycerol (peak I) and 2-docosahexaenoylglycerol (peak II) was observed in the chromatograms. A mixture of the bis-3,5-DNPU derivatives of 1(3)- and 2-MAG were subjected to preparative silicic acid TLC under the conditions previously used (see above). Figures 1C and 1D show 1(3)- and 2-MAG fractions resolved by silicic acid TLC as their bis-3,5-DNPU derivatives, respectively. The 1(3)-MAG fraction showed an apparent peak of 2-docosahexaenoylglycerol (Fig. 1C, peak II). In the 2-MAG fraction (Fig. 1D), this peak was much smaller than that observed in Figure 1B. Under the silicic acid TLC conditions used, 1(3)-MAG species migrate ahead of corresponding isomeric 2-MAG species. Although bis-3,5-DNPU derivatives of MAG formed from the fish oil TAG were split up into two bands, tentatively named as 1(3)- and 2-MAG bands, reversed-phase HPLC profiles of them (Figs. 1C and 1D) indicate that 2-docosahexaenoylglycerol species overlapped with the 1(3)-MAG band. Therefore, silicic acid TLC of bis-3,5-DNPU derivatives is unsuitable for separation of 1(3)- and 2-MAG prepared from DHA-rich fish oil TAG, and cannot be used in the stereospecific analysis without any modifications. In contrast, 1(3)- and 2-MAG could be clearly resolved into lower and upper bands on the boric acid-impregnated silicic acid plate, respectively.

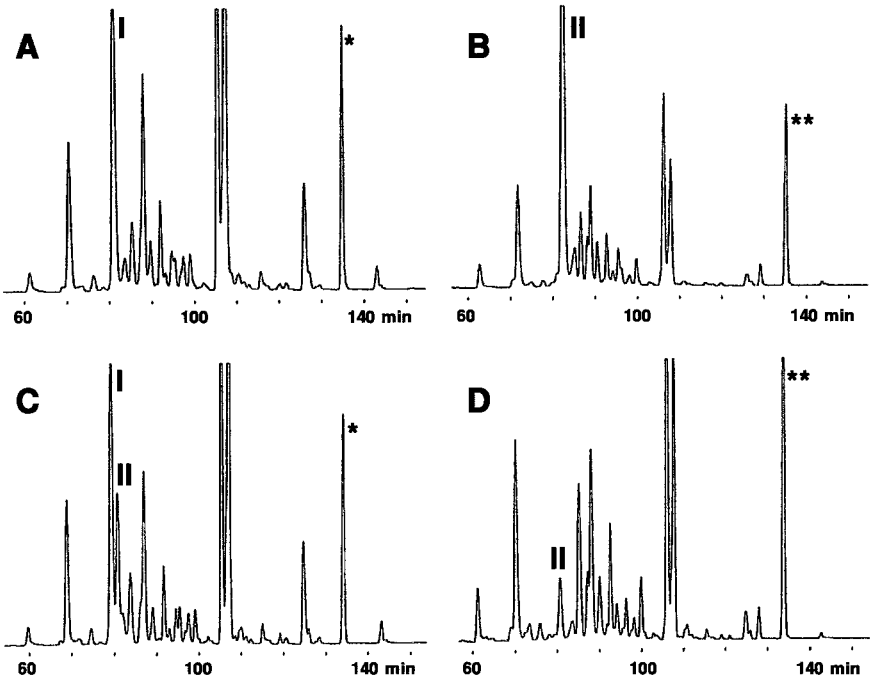

FIG. 1. Reversed-phase high-performance liquid chromatography (HPLC) profiles of bis-3,5-dinitrophenylurethanes (DNPU) of 1(3)- and 2-monoacyl-*sn*-glycerols (MAG) derived from bonito head oil triacyl-*sn*-glycerols. (A) and (B), 1(3)- and 2-MAG fractions separated by boric acid-impregnated silicic acid thin-layer chromatography (TLC) as free form of MAG, respectively; (C) and (D), 1(3)- and 2-MAG fractions separated by silicic acid TLC as bis-3,5-DNPU derivatives of MAG, respectively. I and II, 1(3)- and 2-docosahexaenoyl-*sn*-glycerols, respectively. *1(3)- and **2-Nonadecanoyl-*sn*-glycerols derived from trinonadecanoylglycerol internal standard. HPLC conditions are as given in the text.

The high content of DHA in the *sn*-1 and *sn*-3 positions observed in our previous analysis (3) is found to result from unsuitable TLC separation of 1(3)- and 2-MAG intermediates. Positional distributions obtained in the present study were similar in high content of DHA in the *sn*-2 position to those obtained by other stereospecific (4) or regiospecific (5–7) analyses. In conclusion, the 1(3)- and 2-MAG made up of both short- and long-chain lengths cannot be clearly resolved by TLC after preparation of the bis-3,5-DNPU derivatives. The 1(3)- and 2-MAG must be resolved by boric acid TLC prior to derivatization.

Alterations in 3-Hydroxy-3-methylglutaryl-CoA Reductase mRNA Concentration in Cultured Chick Aortic Smooth Muscle Cells

Angel Carazo, Mª José Alejandre, Mª Dolores Suarez, and Ana Linares*

Department of Biochemistry and Molecular Biology, Faculty of Sciences, University of Granada, 18071 Granada, Spain

ABSTRACT: We observed and compared alterations in 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase at the transcriptional level in unsynchronized, three-passage cultures of smooth-muscle cells from the aorta of chicks fed on a control diet (C-SMC) and those of chicks fed on a similar diet plus cholesterol (Ch-SMC). Alterations in reductase mRNA concentrations in senescent cultures were much lower. We used a modification of the competitive (c) reverse transcription polymerase chain reaction method, using a *Thermus thermophilus* DNA polymerase (Tth pol) to quantify the very scarce species of HMG-CoA reductase mRNA in samples of cytoplasmic SMC mRNA. We cloned and sequenced a 199 bp cDNA fragment of chicken HMG-CoA reductase, which encoded a region of 66 amino acids belonging to the catalytic domain of the enzyme. HMG-CoA reductase mRNA concentrations from young C-SMC cultures rose 3.89-fold 4 h after the change of medium and returned to base levels between 8 to 12 h afterward. Concentrations in Ch-SMC cultures increased less (2.36-fold) 8 h after the change to fresh medium. Increases in reductase mRNA in senescent cultures of Ch-SMC and C-SMC measured under similar conditions were only 1.28- and 1.39-fold, respectively.

Paper no. L8379 in *Lipids 35,* 587–593 (June 2000).

3-Hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase (EC 1.1.1.34) is an endoplasmic-reticulum-membrane enzyme that catalyzes the conversion of HMG-CoA to mevalonate, the rate-limiting step in cholesterol and polyisoprenoid biosynthesis (1). Several different mechanisms have been reported for regulating reductase activity in animal cells, including: (i) long-term control by changes in HMG-CoA reductase concentration through transcriptional, posttranscriptional, and posttranslational control levels as well as by enzyme degradation (2–4); (ii) the modulation of reductase activity or degradation by altering the lipid composition of the endoplasmic reticulum (5–7); and (iii) regulation by a bicyclic cascade system involving reversible phosphorylation of both HMG-CoA reductase and reductase kinase (8,9). The multivalent feedback regulation of HMG-CoA reductase involves cholesterol and one or more of the other products synthesized from mevalonate (10,11). In cell cultures, the addition of exogenous sources of cholesterol or mevalonate at the time of the change of medium blocks the rise found in reductase activity associated with feeding the cells (12).

Furthermore, HMG-CoA reductase activity is involved in cell division, showing a marked rise just before the S phase of the cell cycle (13,14). Parallel changes in HMG-CoA reductase activity are, however, observed to vary widely in both synchronized and unsynchronized cells under normal culture conditions [with fresh medium supplemented with fetal bovine serum (FBS)]. This variation is associated with feeding the cells (12), and thus other factors besides the cell cycle alone also may play a role. We report here on the variations in HMG-CoA reductase mRNA in cultures of aortic smooth-muscle cells isolated in our laboratory from cholesterol-fed chicks (Ch-SMC) and from control-fed chicks (C-SMC). The main characteristics of these two culture lines are: (i) The proliferation rate of Ch-SMC under identical culture conditions is superior compared to C-SMC; thus, DNA synthesis in Ch-SMC during the S phase (at 8 h) is fourfold higher, and (ii) with identical maintenance, the intracellular cholesterol content is the same in both cell lines for the first 14 d of culture but subsequently increases in Ch-SMC, rising to more than double the C-SMC value (15). To quantify the very scarce species of HMG-CoA reductase mRNA in samples of cytoplasmic SMC RNA, we used a modification of competitive reverse transcription-polymerase chain reaction [(c) RT-PCR], involving same-tube co-amplification of the gene and a synthetic internal standard fragment (16). Because the chick HMG-CoA reductase gene sequence is unknown, we designed and synthesized a fragment of reductase cDNA. We observed alterations in HMG-CoA reductase mRNA concentration in unsynchronized, three-passage C-SMC and Ch-SMC cultures associated with the feeding of the cells. These alterations are much lower in senescent cultures.

MATERIALS AND METHODS

Chicks. Newly hatched, male, White Leghorn chicks (*Gallus domesticus*) were bought from a commercial hatchery and fed

Abbreviations: (c) RT-PCR, competitive reverse transcription-polymerase chain reaction; DMEM, Dulbecco's modification of Eagle's medium; dNTP, deoxy nucleotide 5′-triphosphate; FBS, fetal bovine serum; HMG-CoA, 3-hydroxy-3-methylglutaryl-CoA; PBS, phosphate-buffered saline; SMC, smooth muscle cell; UV, ultraviolet.

ad libitum in a chamber with a light cycle from 0900 to 2100 and a controlled temperature of 29–31°C.

Two groups of 10-d-old chicks were used; a control group was kept on a standard diet (Sanders A-00) while a treated group was fed on the same diet supplemented with 5% w/w powdered cholesterol mixed homogeneously (Panreac Reagent Barcelona, pure grade; Montplet & Esteban S.A., Barcelona, Spain). The diets were begun at hatching and continued until the chicks were killed 10 d afterward. Water was constantly available. None of the chicks died a natural death nor developed any illness during the treatment.

SMC cultures. SMC were isolated from the aortic arch of the chicks as described elsewhere (17,18) with slight modifications (15) and cultured in Dulbecco's modification of Eagle's medium (DMEM) supplemented with D-glucose (4.5 g/L), L-glutamate (0.584 g/mL) (Flow), an antibiotic cocktail composed of penicillin (100 µg/mL) and amphotericin (0.25 µg/mL) (Sigma, St. Louis, MO) and 10% (vol/vol) FBS. The medium was buffered with bicarbonate, and the cultures were kept at 37°C in a humidified atmosphere of 95% air and 5% CO_2. The medium was renewed three times a week. Secondary cultures were initiated after either low or high passages using 0.05%/0.02% trypsin-EDTA solution (Flow Laboratories Ltd., Irvine Ayrshire, Scotland).

All experiments were conducted using 3 or 13 passages. The cells were seeded at approximately 2×10^4 cells per dish (60 mm) containing 4 mL fresh medium. They were determined to be vascular smooth-muscle by their hill-and-valley configuration at confluence (18) and positive fluorescence staining for smooth-muscle actin and myosin (19). Trypan blue (Sigma) was added to the cells with the help of a hemacytometer, and the flasks were examined with an inverted light microscope (Olympus Opticals Co. Ltd., Tokyo, Japan) to count live and dead cells. Cell viability in our cultures was 90%.

Flow cytometry. Cell fixation was carried out as described elsewhere (20). They were harvested and washed with phosphate-buffered saline (PBS) containing 10% FBS. Cell pellets were resuspended in 250 µL PBS, followed by 250 µL PBS containing 2% paraformaldehyde. After incubation for 15 min at 4°C, the cells were washed, resuspended in 5 mL of ice-cold 70% ethanol, and incubated overnight at –20°C. They were then processed for DNA content and the cell-cycle distribution of SMC populations. Fixed cells were resuspended in PBS containing 200 µg/mL ribonuclease and 5 µg/mL propidium iodide and incubated for 30 min at room temperature. They were analyzed for red fluorescence (propidium iodide, allowing DNA quantification) using a FACS Vantage dual laser for flow cytometry (Becton Dickinson Immunocytometry System, San Jose, CA) with a Coherent Enterprise laser [160 mW, 488 nm; and 60 mW, ultraviolet (UV)]. The laser was set at 488 nm and 15 mW with the sample in the FL_2 detector regulated to 495 nm (linear), with a 585/42 BP filter; 5000 cells were analyzed (300 cells/s), and the data were processed on a CellFiT (v 2.01.2 Becton Dickinson).

Bacterial strain, growth conditions, plasmid, and primers. Cloning was carried out in *Escherichia coli* strain JM101 (F *tra*D36 *pro*A+ *pro*B+ *lac*I *lac*ZΔM15/*sup*E *thi* Δ(lac-*pro*AB) using the pGEM-T vector system I (Promega). *Escherichia coli* was cultured in Luria-Bertani broth containing the appropriate antibiotic (ampicillin, 50 µg/mL).

Oligonucleotide primers were synthesized with Gibco BRL (Barcelona, Spain) custom primers.

Isolation of total cytoplasmic RNA. Total cytoplasmic RNA from both the C-SMC and Ch-SMC lines was isolated by the acid guanidinium isothiocyanate method as described elsewhere (21) with the slight modifications described below.

The adherent cultured cells were harvested with a cell scraper, transferred to an autoclaved 1.5-mL microcentrifuge tube (10^6–10^8), and washed once with cold PBS. They were then centrifuged at room temperature at 12,000 rpm for 5 s (N.B. To avoid cell death, they should never be centrifuged for longer than 20 s.) The supernatant was removed and the cell pellet kept on ice; 100 µL ice-cold lysis buffer A [10 mM Tris-Cl pH 7, 0.15 M NaCl, 0.65% Nonidet P-40 (NP-40)] was added. The cells were then vortexed and incubated on ice for 5 min and subsequently centrifuged for 5 min to pellet the nuclei. The RNA contained in the supernatant was extracted by adding 400 µL guanidinium thiocyanate solution (4 M guanidinium thiocyanate, 25 mM sodium citrate, pH 7, 0.5% *N*-lauroylsarcosine, 0.1 M 2-mercaptoethanol) and precipitated as described elsewhere (22). The final RNA concentration was determined by absorbance using a spectrophotometer. This method yields about 30 µg of cytoplasmic RNA per 25 cm^3 plaques at 60% confluency.

Construction and sequencing of a chick HMG-CoA reductase c-DNA fragment. We designed two pairs of heterologous primers corresponding to *Xenopus laevis* HMG-CoA reductase using the primer sense 5′-AGCCAGCTGCTATTAACTGGAT-3′ (anneals with the 2023–2044 region of *X. laevis* cDNA) and antisense: 5′-ACCTGTTGTGGACCATGTGACT-3′ (annealing to the 2692–2713 region of *X. laevis* cDNA), giving a single band of 243 pb of cDNA of chicken HMG-CoA reductase detected by RT-PCR. The 243 pb fragment obtained was cloned into a pGEM-T plasmid, the result being referred to as pRC-243 (3246 pb). This gave a fragment without primers (22 pb) of 199 pb, which was gel-purified and both strands sequenced by the chain-termination DNA sequencing method of Sanger *et al.* (23) using AmpliTaq® FS and deoxy nucleotide 5′-triphosphates (dNTP) (ABI PRISM™ fluorescence labeled) in a Dye Terminator Cycle Sequencing Ready Reaction (Perkin-Elmer/Applied Biosystems Division, Foster City, CA). Nucleotide sequences were analyzed with the Clustad X, Macaw, and TreeView program (National Center for Biotechnology Information, Bethesda, MD).

Competitive RT-PCR. RT-PCR was carried out in a single reaction tube using Tth polymerase (Gene Craft, Münster, Germany), a thermostable DNA polymerase that shows RT activity, by using Mn^{2+} (24,25). All RT and PCR reactions took place in a DNA Thermal Cycler 480 (Techne, Cambridge, United Kingdom). The RT reaction was set up in 20 µL containing the appropriate amount of total cytoplasmic RNA, 10× RT buffer [670 mM Tris-HCl, pH 8.8, 166 mM

$(NH_4)_2SO_4$, 0.1% Tween-20], 1 mM $MnCl_2$, 0.25 mM dNTP, 1.25 pmol/μL downstream primer, and 0.12 units/μL of Tth polymerase, and incubated at 72°C for 30 min. Competitor DNA, as indicated above, was added before amplification. For the amplification reaction, 30 μL of a mix containing 5× PCR buffer [33.5 mM Tris-HCl, pH 8.8, 83 mM $(NH_4)_2SO_4$, 3.75 mM EGTA, 25% glycerol, 0.196 Tween-20], 1.5 mM $MgCl_2$, 0.2 mM dNTP, 0.5 pmol/μL of both primers (upstream and downstream) and 0.05 units/μL Tth polymerase were added per reaction. Routinely performed were 30 cycles with 1 min denaturation at 95°C, 1 min annealing at 52ºC, and 1 min per cycle of PCR at 72ºC.

Separation and quantification of PCR products. PCR products were loaded directly onto a 2% agarose gel and electrophoresed at 5 V/cm for 1.5 or 2 h. DNA was visualized and photographed under UV light (320 nm) after ethidium bromide staining (25). The picture was digitalized and analyzed using the Quantyscan Program (Biosoft, Ferguson, MO). This DNA quantitation system is very sensitive and is able to detect nanogram amounts of DNA. Reactions containing the different mass of DNA were performed in triplicate. All the ethidium bromide colorimetric data included fall into the range where the DNA quantity ratio was linear. A plot of the log of the ratio of target to competitor product against the log of the competitor concentration should give a straight line with a slope of −1 (26). The amount of competitor used at which the ratio of target to competitor PCR products is equal to unity (log ratio = 0; the equivalence point) can be used to calculate the initial number of molecules of the target sequence.

RESULTS

To establish the experimental design, we prepared unsynchronized C-SMC cultures of different numbers of passages; early-passage, or young cultures (3 passages) and late-passage, or senescent cultures (13 passages). Flow cytometry was used to analyze the cell cycles by cell DNA content. Figure 1A shows the cell cycle of young cultures with 30.4% of the cells in the S phase and Figure 1B the cell cycle of senescent cultures with 15.5% of the cells in the S phase. We chose

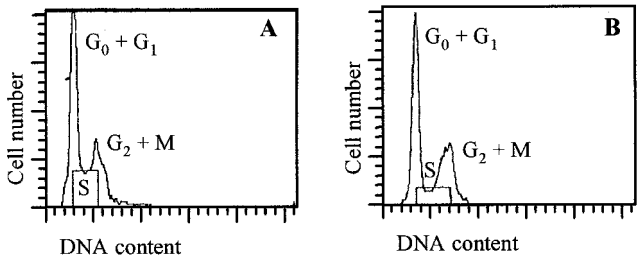

FIG. 1. DNA content histogram of chick smooth muscle cells. Cells were fixed in ethanol and stained with propidium iodide prior to analysis by flow cytometry, as described in the Materials and Methods section. (A) Third passage cultures, the percentages of cells in G_0/G_1, S, and G_2/M phases, respectively, are: 46.6, 30.4, and 23%. (B) Thirteenth passage cultures, the percentages of cells in G_0/G_1, S, and G_2/M phases, respectively, are: 56, 15.5, and 28.5%.

2 to 12 h after the change of medium to measure the HMG-CoA reductase mRNA concentration because the S phase occurs in chick Ch-SMC and C-SMC cultures at about 8 h.

HMG-CoA mRNA in chick aorta SMC was quantified after the change of medium. Unsynchronized Ch-SMC and C-SMC of 3 and 13 passage cultures were used to carry out competitive RT of mRNA from the cytoplasm of these cells, followed by PCR. Because the chick HMG-CoA reductase sequence is unknown, the design and construction of a cDNA were our first necessity. We sequenced a 199 bp fragment of chick HMG-CoA reductase cDNA from the pRC-243 plasmid and obtained a sense sequence of: 5′-AGAGGGAA-GAGGGAAGTCTGTTGTCTGTGAAGCAGTCATTC-CAGCCAAGGTTGTTAAAGAAGTACTGAAGACAAC-TACGGAAGATATAGTTGAAGTGAATATAAACAAAAA-TCTGGTGGGTTCTGCTATGGCTGGTAGCATAGGTG-GCTACAACGCGCATGCTGCAAACATTGTTACAGC-TATCTACATTGCCTGTGGT-3′. This sequence was analyzed using the Clustad X program to check that it did in fact correspond to a fragment of HMG-CoA reductase gene. By aligning the 199 nucleotides of *Gallus domesticus* reductase with other species, it could be seen that the reading frame started on the second nucleotide, and we deduced a sequence of 66 amino acids belonging to the soluble carboxy terminal. The similarity index found with the published sequences from other species is shown in Figure 2.

As the quantification of mRNA by (c) RT-PCR includes a standard RNA molecule to coamplify with the mRNA problem, we synthesized homologous primers. From the 199 pb cDNA fragment of chick HMG-CoA reductase, we designed the primers referred to as Sen-G sense: 5′-GAAGTCTGT-TGTCTGTGAAGCA-3′ (13–34 position of 199 pb fragment) and Ant-G antisense: 5′-CACAGGCAATGTAGATAGCT-GT-3′ (176–197 position of 199 pb fragment). Using the Sen-G and Ant-G primers, RT-PCR with cytoplasmic RNA from chick SMC cultures showed the amplification of only one molecule (185 bp).

To construct a chick HMG-CoA reductase mRNA standard (competitive template), we designed composite primers. Figure 3 is a scheme for the construction of a competitive template and PCR quantification.

One primer contained the upstream primer Sen G, resulting in the composite primer sense, referred to as Sen-L: 5′-GAAGTCTGTTGTCTGTGAAGCACCATAGTTGCCT-GACTCC-3′ (the Sen-G sequence is 40 nucleotides: upstream of 22 nucleotides and the rest is the upstream position 1378–1395 of pGEM).

The other composite primer contained the downstream primer Ant G, resulting in the antisense, referred to as Ant-L: 5′-CACAGGCAATGTAGATAGCTGTATGCCAA-CAACGTTGCGC-3′ (the Ant-G sequence is represented by 40 nucleotides: downstream of 22 nucleotides and the rest to the downstream position 1616–1633 of pGEM-T). Using the composite primers Sen-L and Ant-L and the plasmid pGEM, we synthesized a DNA 300 pb by PCR (annealing to the primers SenG and AntG). The 300 bp PCR product was

FIG. 2. Comparison of the deduced amino acid sequence from 199 bp cDNA fragment of chick 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase and homology with other species.

constructed by cloning into pGEM-T, and the result was a recombinant plasmid, referred to as pST-300 (3.303 pb). This plasmid linearized with EcoRI was used as a standard in c-RT-PCR.

This RNA fragment was subsequently purified, quantified, and used in cRT-PCR to measure HMG-CoA reductase mRNA. The concentration of mRNA was determined by UV absorption spectrometry. Four experiments were made with the amount of standard ranging between 10,000 and 740,000 copies.

Competitive RT-PCR analysis involves titrating the standard with a constant amount of sample SMC cytoplasmic RNA per reaction tube (25 ng from young cells and 50 ng from senescent cells). The amount of competitor used at which the ratio of target to competitor PCR products is equal to unity (log ratio = 0; the equivalence point) can be employed to calculate the initial number of molecules in the target sequence. A plot of the log of the ratio of the densitometric values for reductase products against the log of the number of copies of reductase RNA added was linear, with a slope of 1 (Fig. 4).

The quantification of HMG-CoA reductase mRNA in young SMC cultures is shown in Figure 5A; the number of molecules from C-SMC cultures shows a rise of 3.89-fold 4 h after changing the medium and thence returns to base values between 8 and 12 h. Figure 5A also shows the rise in the number of HMG-CoA reductase mRNA molecules in Ch-SMC, albeit with a lower increase (2.36-fold) in reductase mRNA 8 h after changing the medium in Ch-SMC. Figure 5B shows a comparison between the increase in reductase mRNA in both C-SMC and Ch-SMC senescent cultures (1.39 and 1.28, respectively), which represents the smallest changes and the smallest numbers of mRNA molecules.

DISCUSSION

Quantitative measurements of gene expression at transcriptional level are hampered by generally low quantities of HMG-CoA reductase mRNA. To combat this, we used the competitive (c) RT-PCR method to quantify the very scarce species of HMG-CoA reductase mRNA in cytoplasmic SMC mRNA.

We report the development and validation of a simple, nonradioactive, and highly reproducible technique (RT-PCR) to determine the relative HMG-CoA reductase gene expression in different SMC cultures. This technique exploits the tremendous sensitivity of competitive RT-PCR (17,19) and the advantages of RT at elevated temperature using Tth DNA

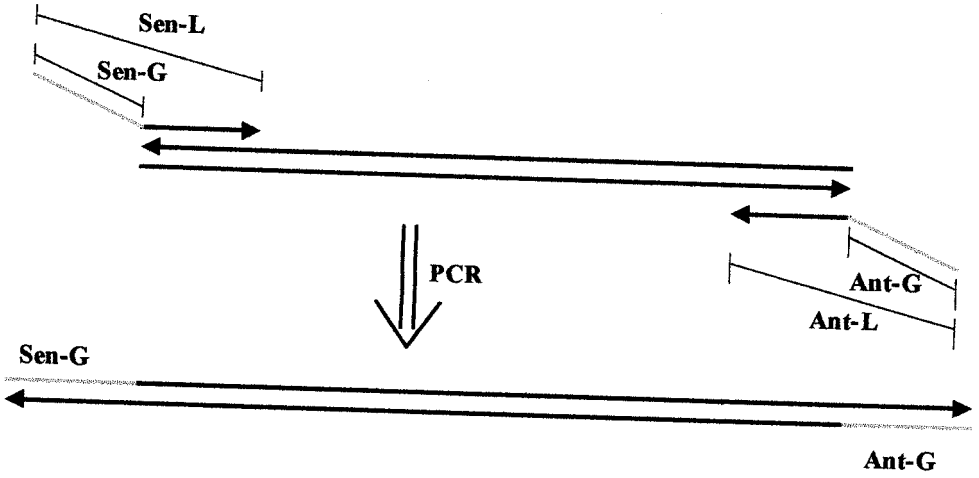

FIG. 3. A scheme for the construction of a competitive template and polymerase chain reaction (PC) quantification.

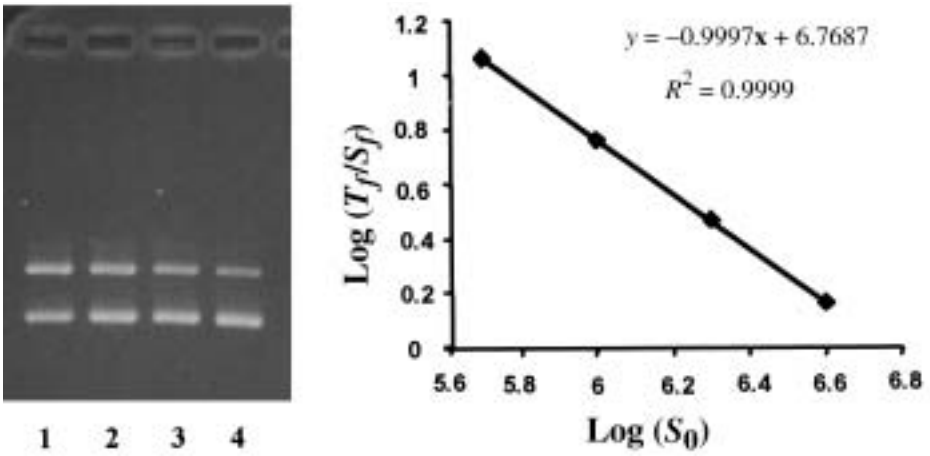

FIG. 4. Competitive reverse transcriptase-polymerase chain reaction (RT-PCR). In the left-hand panel, the four RT-PCT products were run in gel electrophoresis and stained with ethidium bromide. The DNA product was 243 bp (final target) and 300 bp (final standard) in length. In the right-hand panel, the densitometric results were plotted. T_f final target amount, S_f, final standard amount and S_0, initial standard amount. Each sample was assayed in triplicate. The ± SEM do not exceed 5%.

polymerase (a thermostable enzyme that also has RT activity) (16,18). The DNA quantitation system used by ethidium bromide staining is really sensitive; we performed the assay in the linear range of total DNA added per reaction. Only the assays made in the linear range of DNA gave an $R^2 > 0.98$.

As this method includes an mRNA standard and the chick HMG-CoA reductase gene sequence is unknown, we sequenced and cloned a 199 bp cDNA fragment, which encodes a region of 66 amino acids (Fig. 2) belonging to the soluble (catalytic) domain of the enzyme (28,29). From the alignment of this sequence, we made a cladogram (not shown), where the sequence of *G. domesticus* is located between amphibians and mammals. The 199 bp cDNA fragment and the composite primers designed to construct a chick HMG-CoA reductase mRNA standard (competitive template) will be essentials to quantify the mRNA and study in the future the regulation of this enzyme in chick aorta SMC at transcriptional levels.

In this paper we present an application to validate this method by measure of the fluctuations of HMG-CoA reductase mRNA concentration after media change in SMC cultures. It is well-established that marked changes in HMG-CoA reductase activity occur under normal cell-culture conditions; early experiments by Brown *et al.* (27), for example, demonstrated a small increase in HMG-CoA reductase activity in cultured fibroblasts 19 h after changing the medium to a fresh one supplemented with FBS, and a large increase (fivefold) with lipoprotein-deficient serum. The increase in activity has been put down to an induction of reductase after a change in the medium. Other previous studies into reductase activity, using

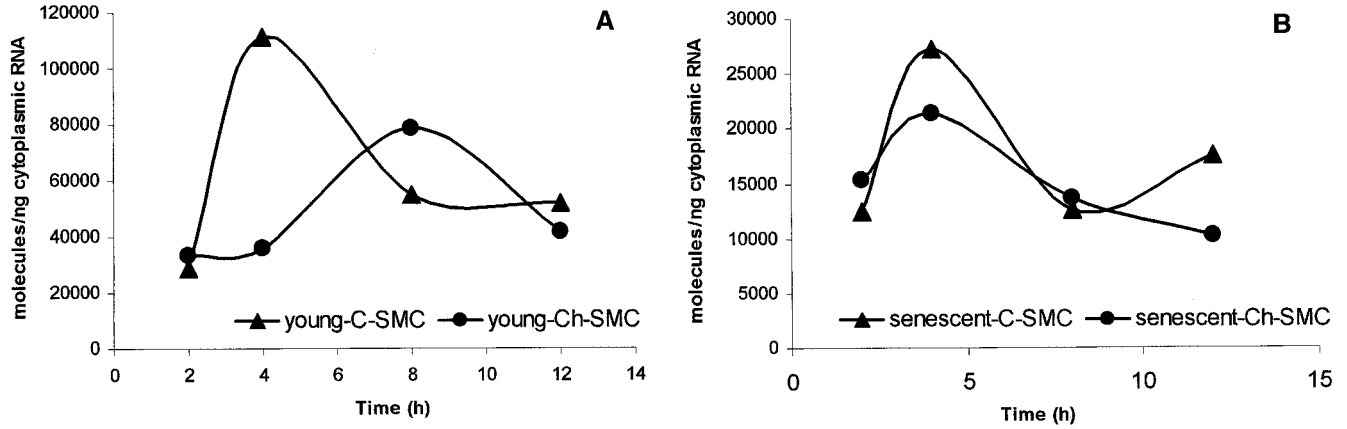

FIG. 5. Alterations to HMG-CoA reductase mRNA in smooth muscle cell (SMC) cultures after changing the medium. At $T = 0$, monolayer third-passage cultures (A) and 13-passage cultures (B) that presented a 60–70% confluency were washed with phosphate buffered saline and then fed a fresh medium. Cells were harvested at each point of time and the HMG-CoA reductase mRNA was quantified by (c)RT-PCR as described in the Materials and Methods section. Aortic SMC cultures were obtained from both control chick (SMC-C) and hypercholesterolemic chick (SMC-Ch). Each sample was assayed in triplicate. The ± SEM do not exceed 10%. See Figures 2 and 4 for abbreviations.

the murine macrophage as cell line J774 (12), suggested that HMG-CoA reductase activity varies widely under normal culture conditions with FBS and that these variations are associated with feeding the cells. Nevertheless, few reports have been published concerning changes in reductase mRNA concentrations after changing the medium.

Our results indicate that after a change of medium alterations in HMG-CoA reductase mRNA occur at transcriptional level both in C-SMC and Ch-SMC cultures (Fig. 5A,B). The exposure of cultured C-SMC to a fresh medium containing FBS caused a rapid increase in HMG-CoA reductase mRNA molecules as soon as 4 h after feeding the cells. Although some of the media supplements contained lipoprotein cholesterol sources (FBS), the amounts added to the media were insufficient to block the increase seen in HMG-CoA reductase mRNA. The intracellular cholesterol level in C-SMC and Ch-SMC remained the same during the first 12 h of culture, although subsequently it increased in Ch-SMC to double the levels found in C-SMC (15). In identical medium and culture conditions, the increase in reductase mRNA concentration in CH-SMC was almost 50% lower after feeding the cells for 8 h, although both C-SMC and Ch-SMC reductase mRNA returned to base values by 12 h. Senescent cultures of both C-SMC and CH-SMC had low concentrations of reductase mRNA and showed small changes after changing the medium, which agrees with Figure 1, where it can be seen that senescent cultures contain only half as many cells in the S phase (i.e., less rapidly dividing cells) as do the young cultures. We obtained similar results with HMG-CoA reductase activity, with a greater increase in young C-SMC cultures compared to Ch-SMC cultures and very low activity in senescent cultures (data not shown). It is known that HMG-CoA reductase activity is high in rapidly dividing cells and decreases as they reach confluency (30–32). The C-SMC and Ch-SMC cultures used in our work were unsynchronized (Fig. 1A,B), and the sustained increase in reductase mRNA concentration did not depend upon the cell cycle, although both lines did contain rapidly dividing cells (60–70% confluency), which might explain the increase in reductase mRNA. Nevertheless, further studies will be necessary to explain the differences between the increases in mRNA reductase in the two lines of SMC culture.

Membrane Physical Properties Do Not Explain Increased Cyclic AMP Production in Hepatocytes from Rats Fed Menhaden Oil

Michael E. Bizeau* and Jeffrey R. Hazel

Department of Biology, Arizona State University, Tempe, Arizona 85287

ABSTRACT: To study the effect of altering plasma membrane fatty acid composition on the glucagon signal transduction pathway, cAMP accumulation was measured in hepatocytes from rats fed diets containing either menhaden oil (MO) or coconut oil (CO). Hepatocytes from MO-fed animals produced significantly more cAMP in response to glucagon and forskolin compared to CO-fed animals. Glucagon receptor number and affinity were similar in MO- and CO-fed rats. Liver plasma membranes from MO-fed animals were enriched in long-chain n-3 fatty acids and contained significantly lower amounts of saturated C_{10}–C_{16} and 18:1n-9 than CO-fed animals. Membrane physical properties were examined using both Fourier transform infrared spectroscopy (FTIR) and the fluorescent probe 1,6-diphenyl-1,3,5-hexatriene (DPH). FTIR analysis revealed that below 34°C, CO membranes were more ordered than MO membranes. However, as assay temperature approached 37°C, MO and CO membranes became similarly ordered. DPH polarization values indicated no differences in membrane order at 37°C, whereas membrane order was decreased in CO-fed animals at 25°C. These data indicate the importance of assay temperature in assessing the influence of membrane physical properties on the activity of signal transduction pathways. Whereas increased signal transduction activity has been correlated to reduced membrane order in MO-fed animals, these data indicate that at physiological temperatures membrane order did not vary between groups. Enhanced cAMP accumulation in response to forskolin indicates that adenylate cyclase activity or content may be elevated in MO- vs. CO-fed rats. Enhanced adenylate cyclase activity may result, in part, from changes in specific fatty acids in hepatocyte plasma membranes without demonstrable changes in membrane physical properties.

Paper no. L8297 in *Lipids 35,* 595–600 (June 2000).

Signal transduction is a membrane-dependent process and is regulated, in part, by the fatty acid composition of the plasma membrane (1). In the liver, the glucagon-signaling pathway (GSP) is a principal regulator of hepatic glucose output (2). The GSP pathway comprises three distinct components that are all either embedded in or associated with the plasma membrane (3). These are the glucagon receptor, the G-protein complex, and the enzyme adenylate cyclase. Alterations in plasma membrane lipid composition can alter signal transduction at any of these steps in the cascade by altering the physical or chemical properties of the membrane (1).

In mammals, a primary determinant of membrane fatty acid composition is the fatty acid composition of the diet (4). In general, changes in plasma membrane fatty acid composition mimic changes in dietary fatty acid composition. An increase in the percentage of polyunsaturated fatty acids in plasma membranes increases the binding of insulin to the insulin receptor in adipose tissue, skeletal muscle and liver (5–7), increases cAMP production in liver and heart (8,9), and increases catecholamine binding in heart and adipose tissue (9–11).

Although dietary fatty acids have the potential to alter the transcription of components involved in signal transduction pathways (12), the activation of adenylate cyclase is remarkably sensitive to alterations in plasma membrane lipid composition (1,8,9,13–15). Changes in membrane fatty acid composition most likely alter adenylate cyclase activation by altering the bulk physical properties of the membrane or the specific chemical environment surrounding the signal transduction components. Studies relating signal transduction activity to membrane physical properties have produced contradictory results: in some cases lipid-induced changes in adenylate cyclase activity have been attributed to changes in membrane physical properties (16,17), whereas other studies suggest that changes in membrane fatty acid composition do not elicit significant changes in membrane physical properties (9,18). This disparity may, in part, reflect the condition and methods used to assess membrane physical state. While some studies have determined membrane order at 37°C (18), others have assessed order at 25°C (11) or assumed that changes in fatty acid composition must result in altered membrane physical properties (16,17).

In an attempt to resolve these disparities, we characterized membrane order over a broad temperature range using Fourier transform infrared (FTIR) spectroscopy in plasma membranes in which membrane fatty acid composition was altered by feeding diets enriched in menhaden oil (MO) or coconut oil (CO). Infrared spectroscopy has the advantage of permitting the estimation of membrane physical properties

from stretching vibrations of native membrane constituents without the introduction of potentially perturbing membrane probes (19). Additionally, we have assessed the efficacy of glucagon signaling in functionally intact hepatocytes and have related these measurements to FTIR measurements of membrane order.

METHODS

Animals and feeding. Male Sprague-Dawley rats were obtained from an institutional breeding stock at 35–40 d of age, weighed, and divided into two groups. Each group received a nutritionally complete semipurified diet containing, in g/kg: casein (239), corn starch (179), sucrose (247), cellulose (60), AIN-76 vitamin mix (12), AIN-76 mineral mix (41), DL-α-tocopherol (4), DL-methionine (4), choline bitartrate (2), corn oil (12), treatment oil (205). Fatty acid composition of the diets was determined by gas chromatography (Table 1). Diets were prepared fresh weekly, gassed with nitrogen, and stored at –20°C until used. Animals had free access to food and water and were housed in wire-bottomed cages in a room that was maintained at 25°C on a 12 h light/dark cycle. Animals consumed the experimental diet for 4 wk. Food consumption was monitored daily, and animal weight was recorded weekly. All procedures for animal use were approved by the Institutional Animal Care and Use Committee at Arizona State University.

Hepatocyte isolation. Hepatocytes were obtained by collagenase perfusion of the liver as described by Berry and Friend (20) and modified by Blackmore and Exton (21). Cells were suspended at 100 mg/mL wet weight and kept on ice until used in experiments. The initial quality of the cell preparation was assessed by trypan blue exclusion (0.2% final concentration) and measurement of cellular ATP content (22).

Measurement of cyclic AMP. Before being used to assess rates of cAMP production, hepatocytes were gassed with 95% O_2/5% CO_2 for 20 min at 37°C. Cells (50 mg/mL) were then incubated for 10 min in Krebs-Ringer's bicarbonate buffer (pH 7.4) containing either no addition (basal), glucagon (1 nM), forskolin (1 μM), or a combination of glucagon and insulin (1 nM glucagon + 10 nM insulin). After 10 min, incubations were stopped using ice-cold ethanol (final concentration 66% vol/vol) and cAMP was assayed using a radioimunoassy (Amersham, Arlington Heights, IL).

Liver plasma membrane isolation. Liver plasma membranes were isolated using a combination of differential and density gradient centrifugation according to a modification of the methods of Armstrong and Newman (23). Membrane preparations were enriched in the plasma membrane markers Na^+/K^+ ATPase and 5′-nucleotidase activity (~9- and ~8-fold, respectively) and essentially devoid of cytochrome-C-reductase (<0.2-fold), acid phosphatase (<0.5-fold), and NADPH cytochrome-C-reductase (<0.9-fold) activity.

Glucagon receptor assay. Glucagon receptor binding characteristics were assayed using the method of Rojas and Birnbaumer (24). Briefly, liver plasma membranes were incubated (in duplicate) at a final protein concentration in the assay of ~0.025 mg/mL in a final volume of 100 μL of reaction medium containing 20 mM HEPES, 0.1% bovine serum albumin (BSA), 1.0 mM EDTA, and various concentrations of ^{125}I-glucagon (cat.# NEX-207; New England Nuclear, Boston MA) pH 7.6. Nonspecific binding was determined in the presence of 1 μM (final concentration) unlabeled glucagon. Samples were incubated at 32.5°C for 20 min. Incubations were terminated by adding 4 mL of wash buffer (20 mM HEPES, 0.2% BSA pH 7.6) and vacuum-filtered onto presoaked (10% BSA overnight) cellulose acetate filters. The tubes were rinsed and vacuum-filtered twice with an additional 4 mL of rinse buffer. Radioactivity of the filters was quantified using a gamma counter, and the amount of specifically bound ^{125}I-glucagon was calculated as the difference in the mean (duplicate determinations) of total and nonspecific binding. Binding data were analyzed with Graph Pad Prism software (GraphPad Software, San Diego, CA) using nonlinear regression with a single binding site model. Binding affinity and receptor number are expressed as the K_D (nM) and the B_{max} (pmol/mg protein), respectively.

FTIR measurements. Plasma membrane samples were placed between two CaF_2 windows separated by a 50.8 μm Teflon spacer. Sample temperature was controlled to within 0.1°C by a combination of circulating coolant and microprocessor-controlled heating elements in a custom-designed (CIC Photonics) cell. Data were collected under continuous nitrogen gas purge with a PerkinElmer Spectrum 2000 FTIR spectrophotometer. Seventy-five spectra were averaged at each temperature and Fourier-transformed employing a strong apodization function to yield data every 1 cm^{-1}. Peak frequencies were determined, without baseline correction, from second-derivative spectra following subtraction of a background scan (collected under nitrogen purge) using spectrum 2000 software. From the FTIR data, the midpont temperature (point of inflection) of the gel–fluid transition was determined by first-derivative analysis of the temperature de-

TABLE 1
Fatty Acid Composition of the Diets[a]

Fatty acid	MO	CO
8:0	ND	2.12
10:0	ND	6.0
12:0	ND	45.09
14:0	7.41	19.23
16:0	19.09	10.72
16:1n-7	9.21	ND
18:0	3.97	10.82
18:1n-9	12.9	ND

pendence of the methylene asymmetric stretching frequencies employing the TableCurve-2D software package (SPSS Inc., Chicago, IL).

1,6-Diphenyl-1,3,5-hexatriene (DPH) polarization. Plasma membrane was suspended in a 20 mM potassium phosphate buffer (pH 7.4) to give a final protein concentration of 200 μg/mL. The fluorescent probe DPH (4 mM) in tetrahydrofuran was added to the membrane suspension in a ratio of 3 μL of probe solution to 5 mL of membrane suspension and incubated for 1 h at 25°C. Steady-state polarization measurements were performed using a PerkinElmer (Norwalk, CT) LS 50B luminescence spectrophotometer fitted with a constant-temperature cuvette holder. Excitation and emission monochromators were set at 358 and 430 nm, respectively. Polarization was calculated from the fluorescence intensities according to Equation 1:

$$P = (IV_V - GIV_H)/(IV_V + GIV_H) \quad [1]$$

where P = polarization, IV_V = emission intensity of vertically polarized light parallel to the plane of excitation, IV_H = emission intensity of horizontally polarized light perpendicular to the plane of excitation, and G is a configuration-specific correction factor. Measurements were performed at 25 and 37°C.

Membrane lipid extraction and analysis. Membrane lipid was extracted by the method of Bligh and Dyer (25). Neutral lipids were separated from phospholipids by thin-layer chromatography (TLC) using a solvent mixture composed of hexane/ether/acetic acid (90:10:1, by vol). Lipid spots were visualized in iodine vapors. The phospholipid and neutral lipid spots were scraped from the TLC plate and lipids extracted by washing with chloroform/methanol (2:1, vol/vol) three times, dried under a stream of nitrogen, and stored at –20°C until used for fatty acid analysis.

Fatty acid analysis. Phospholipids were prepared for fatty acid analysis by acid-catalyzed transesterification to their respective methyl esters (26). Fatty acid analysis was performed on a Hewlett-Packard 2850A gas chromatograph at 190°C equipped with an Omegawax™ 320 capillary column, 30 m × 0.32 mm × 0.25 μm film thickness (Supelco, Bellefonte, PA). Identification of fatty acids was accomplished by running multiple sets of standards (Matreya, Inc., Pleasant Gap, PA) and matching their retention times to those of the samples.

Statistical analysis. A two-way analysis of variance was used to examine differences between groups. If the overall F test was significant, comparisons between means were made using a student Newman-Kuels test. Statistical significance was set at $P < 0.5$ for all comparisons

RESULTS

Animal and cell characteristics. After 4 wk on the experimental diets there were no differences in body or liver weights between diet groups (Table 2). Food consumption averaged 15.5 ± 1.5 g/d and 15.2 ± 1.5 g/d for MO- and CO-fed groups, respectively, over the entire dietary treatment period with no differences between diet groups. Isolated hepatocytes from both groups displayed >90% trypan blue exclusion and normal cellular ATP content (Table 2), indicating a high quality cell preparation.

TABLE 2
Animal and Cell Characteristics[a]

	MO	CO
Animal weight (g)	297 ± 5.4	301 ± 3.4
Liver weight (g)	18.8 ± 1.2	19.7 ± 1.4
Dye exclusion (g)	94.5 ± 0.5	93.7 ± 0.4
Cell ATP (nmol/mg)	2.75 ± 0.05	2.68 ± 0.04

[a]Data are mean ± SE for $n = 6$ per diet group. Dye exclusion is the percentage of cells excluding trypan blue immediately prior to the start of incubations. For abbreviations see Table 1.

cAMP accumulation in isolated hepatocytes. Rates of cAMP accumulation (pmol/10 min) were measured in the absence (basal) and presence of several hormone and agonist combinations (Fig. 1). Basal cAMP accumulation was not different between the MO- and CO-fed groups. When glucagon (1 nM) was added to the incubation, hepatocytes from MO-fed rats accumulated significantly greater (~2-fold) amounts of cAMP than those from CO-fed animals. To examine if there had been a direct effect of MO feeding on adenylate cyclase, we employed forskolin (1 μM). Forskolin directly stimulates adenylate cyclase (27), bypassing the glucagon receptor and G-protein coupling steps in the GSP. In the presence of forskolin, significantly greater (~1.25-fold) cAMP accumulation occurred in hepatocytes from MO- vs. CO-fed rats. Insulin (10 nM), which stimulates cAMP degradation, was also added in combination with 1 nM glucagon to assess the

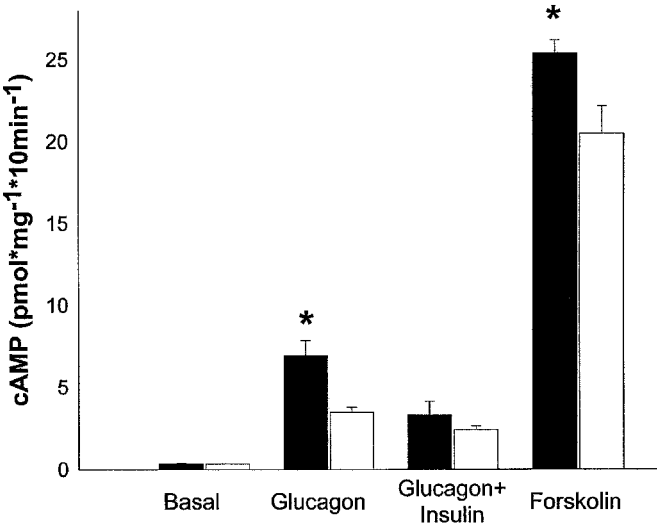

FIG.1. cAMP accumulation measured in hepatocytes from menhaden oil (MO; ■)- and coconut oil (CO; □)-fed animals. Cells were incubated in assay buffer containing no hormone (basal), 1 nM glucagon, 1 nM glucagon + 10 nM insulin, and 1 μM forskolin for 10 min and cAMP was measured. Data are the average ± SE for hepatocytes prepared for 6 animals from each diet group. *Significantly different ($P < .05$) from the other diet group for a given incubation condition.

ability of insulin to suppress cAMP production. cAMP accumulation in the presence of insulin did not differ between MO- and CO-fed groups although the relative magnitude of the reduction, compared to maximal glucagon stimulation, was greater ($P < .05$) in the MO-fed (45 ± 2.4 vs. 30 ± 3.2%) compared to the CO diet group.

Glucagon receptor binding characteristics. There were no differences in glucagon receptor B_{max} or K_D between the MO and CO groups. B_{max} for the MO-fed group was 5.02 ± 0.29 pmol/mg protein, and for the CO group it was 4.72 ± 0.43 pmol/mg protein. K_D values were 1.54 ± 0.45 nM and 1.71 ± 0.73 nM for MO- and CO-fed animals, respectively.

Membrane lipid composition. Plasma membrane fatty acid composition, in general, reflected the composition of the respective dietary fatty acids provided (Table 3). Plasma membranes from CO-fed animals were enriched in 14:0, 16:0, and 18:1n-9 and essentially depleted of 18:2n-6 and the long-chain n-3 fatty acids 20:5 and 22:6 compared to MO-fed animals.

FTIR and DPH. Measurements of membrane physical properties at different temperatures were performed using the fluorescent membrane probe DPH and by FTIR spectroscopy. DPH measurements indicated that at 37°C membranes from CO- and MO-fed animals exhibit similar degrees of acyl chain order, whereas at 25°C membranes from CO-fed animals are significantly more ordered compared to MO-fed membranes (Table 4). Higher frequencies of CH_2 stretching vibration in the FTIR spectra are associated with a less-ordered membrane. At temperatures below 34°C, membranes from CO-fed animals were more ordered than those from MO fed animals (Fig. 2). The gel–fluid transition midpoint temperature was significantly reduced in MO vs. CO, being 11.3 vs. 19.8°C in MO and CO, respectively. However, as assay temperature is increased to the animal's body temperature, MO and CO fed membranes exhibit similar CH_2 vibrational motion, indicating similar degrees of order in the acyl chain region.

TABLE 3
Fatty Acid Composition[a] of Liver Plasma Membranes Isolated from Animals Fed MO or CO for 4 wk

Fatty acid	MO	CO

DPH Polarization Values[a] of Plasma Membranes Isolated from MO- and CO-Fed Animals Measured at 37 and 25°C

	Diet group	
Temperature (°C)	MO	CO
25	0.248 ± 0.011	0.278 ± 0.012*
37	0.246 ± 0.011	0.245 ± 0.013

[a]Values presented are the mean ± SE for measurements obtained from four separate membrane preparations per diet group. *Significantly different ($P < .05$) from all other groups. DPH, 1,6-diphenyl-1,3,5-hexatriene; for other abbreviations see Table 1.

DISCUSSION

Dietary-induced alterations in GSP function may result from changes in binding properties of the glucagon receptor, the number of glucagon receptors, altered functioning of the G-protein complex, or increases in the activity or amount of the terminal component in the pathway, adenylate cyclase. Additionally, changes in membrane fatty acid composition may result in altered coupling efficiency (29) between these components, which may, in turn, alter cAMP production. It has been

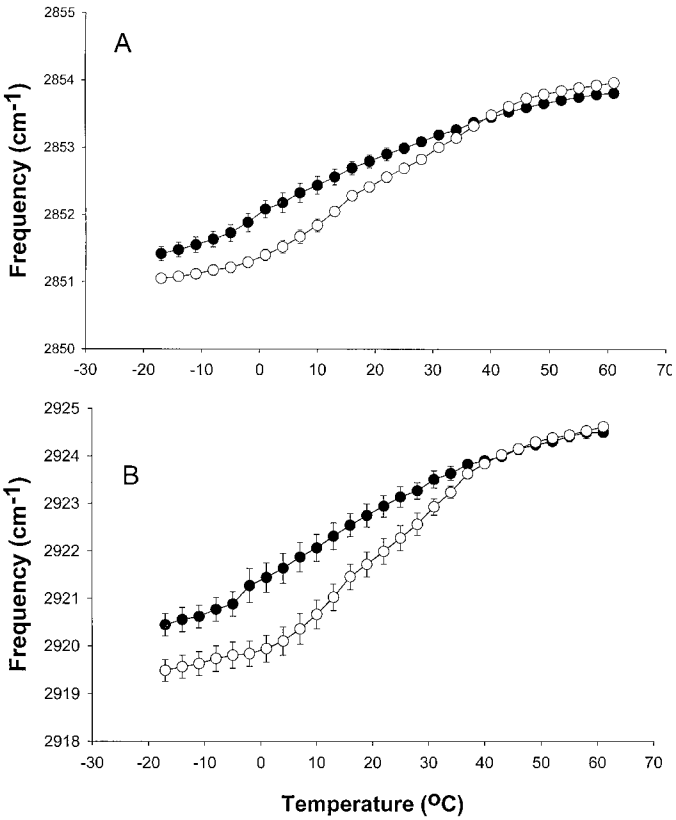

FIG. 2. Temperature dependence of CH_2 symmetric (panel A) and asymmetric (panel B) stretching vibrations in plasma membranes obtained from animals fed either MO (●) or CO (○). Data are average ± SE for plasma membranes obtained from 4 separate membrane preparations per diet group. Values are significantly different ($P < .05$) from the other diet group at all temperatures below 34°C. Above 34°C values are not significantly different. For abbreviations see Figure 1.

shown previously that the capacity to produce cAMP is higher in plasma membranes isolated from animals fed a MO diet vs. diets containing either butter or corn oil as the fat source (8). By using functionally intact hepatocytes, the results of the present study confirm that feeding MO increases glucagon-stimulated cAMP accumulation in whole cells. In order to determine the locus of the altered glucagon signaling, cAMP production was stimulated with forskolin. Forskolin stimulates cAMP production by directly and maximally stimulating adenylate cyclase at the catalytic subunit (28). Forskolin-stimulated cAMP production was 1.25-fold greater in hepatocytes fed a MO compared to a CO diet. This result suggests that a proportion of the increased glucagon-stimulated cAMP production may be due to changes in activity of adenylate cyclase, which may be attributed to the observed changes in membrane lipid composition. Although it cannot be ruled out that diet influenced the amount of enzyme in the membrane by regulating transcription, there were no differences in glucagon receptor numbers or binding characteristics between the two groups, a result similar to previous studies (8). These results suggest that the additional contributions to the twofold rise in glucagon-stimulated cAMP production may be attributed to alterations in membrane fatty acid composition, which could alter the coupling between components in this signal transduction pathway.

Altered functioning of signal transduction pathways in response to feeding different dietary fats has been most frequently explained by alterations in membrane "fluidity." In these studies we used FTIR to measure the CH_2 vibrational frequency in the acyl chains of isolated plasma membrane from animals fed MO or CO diets. Additionally, these measurements were conducted over a wide temperature range (–20 to 58°C) which enabled us to examine the possible involvement of the gel-to-liquid crystalline phase transition temperature in altered GSP functioning. FTIR measurements of CH_2 symmetric and asymmetric stretching vibrations indicate that when assayed at body temperature the vibrational motion of methylene stretching (i.e., membrane order) is similar between the two diet groups. When assay temperature is reduced, membranes from CO-fed animals have lower CH_2 vibrational motion and are more ordered than MO-fed animals. Previous reports have been equivocal as to whether dietary fat alters hepatocyte membrane "fluidity" (8,16). The results of the FTIR measurements conducted in this study clearly demonstrate that although membrane order is decreased at temperatures below the physiological range in CO-fed membranes, a compensatory mechanism exists to preserve membrane order at body temperature. This mechanism is most likely the inclusion of greater amounts of the monounsaturated fatty acid 18:1n-9 in the membranes of CO-fed animals. The addition of 18:1n-9 has been demonstrated to be highly effective at reducing membrane order (29). One important result revealed by the FTIR measurements is the importance of assay temperature in interpreting the results of studies in which membrane lipid composition is thought to influence signal transduction pathways. It is clear from both the symmetric and asymmetric stretching vibrations of the CH_2 moieties that motion in the CO-fed membranes is restricted relative to MO-fed membranes below 34°C. If measurements of cAMP production, receptor binding, or other hormonally stimulated events that are dependent on membrane physical properties are to be meaningful, they must all be conducted at the same, and ideally, the physiological temperature. This is exemplified by examining FTIR measurements of CH_2 vibrational stretching at 32 vs. 37°C. Many measurements of hormone binding are conducted at temperatures from 32 down to 25°C. The FTIR spectra demonstrate that membrane order is indeed increased in the CO-fed animals at these temperatures. Given this observation, hormone binding to receptors could therefore be influenced at lower assay temperatures by membrane physical properties. Whereas if the receptor-binding measurements are made at 37°C, where membrane physical properties are similar, differences in hormone binding may not exist. Additionally, if the results of assays conducted at temperatures below 37°C are correlated to those made below 37°C, this may lead to false interpretation of the role the membrane is playing in regulation signal transduction pathways.

Alterations in plasma membrane fatty acid composition have been associated with the development of many disease processes. In diabetes, glucagon-stimulated cAMP production is decreased along with insulin inhibition of cAMP production (30–32). The relative lack of cAMP production in response to glucagon in CO-fed animals resembles the alteration in glucagon signaling that is present in diabetes. Thus, diets high in CO may lead to alteration in glucagon signal transduction that can directly affect the regulation of hepatic glucose metabolism *via* multiple mechanisms. First, the capacity to produce glucose from glycogen may be compromised. Since a major regulator of hepatic glycogenolysis is cAMP, the decreased accumulation of cAMP in CO-fed rats suggests this process could be impaired. Second, and of major importance, decreased levels of cAMP may lead to changes in the expression of the enzymes that regulate the flow/production of glucose into and out of the liver. This lack of glucagon signaling may contribute to the enzymatic profile that is present in non-insulin dependent diabetes mellitus. Thus, modifications in dietary fatty acid composition could be directly involved in the etiology /prevention of diabetes by altering glucagon signaling in the liver.

In summary, the results of these experiments demonstrate that in intact hepatocytes, cAMP accumulation with either glucagon or forskolin stimulation is markedly elevated in animals where plasma membrane fatty acid composition was enriched in n-3 fatty acids *via* MO feeding compared to a diet high in saturated fats. This effect is not the result of changes in membrane physical properties induced by dietary fat, although dietary fat type did significantly influence membrane fatty acid composition. The results of this study, when taken together with those of Lee and Hamm (8), strongly suggest that the specific fatty acids present in MO such as 20:5n-3 or 22:6n-3 may directly modulate adenylate cyclase activity in the liver. The

exact mechanism by which MO increases adenylate cyclase activity in liver is unknown. It is quite possible that MO feeding results in the formation of specific lipid microdomains in the membrane which directly influence adenylate cyclase activity and is an area which has yet to examined in detail.

Dietary Cod Liver Oil Decreases Arachidonic Acid in Rat Gastric Mucosa and Increases Stress-Induced Gastric Erosions

Sigurdur Oli Olafsson[a], Jonas Hallgrimsson[b], and Sigmundur Gudbjarnason[a,*]

[a]Science Institute and [b]Department of Pathology, University of Iceland, IS-107 Reykjavík, Iceland

ABSTRACT: The purpose of this study was to examine the influence of long-term feeding of dietary fat rich in either n-3 or n-6 fatty acids on the availability of arachidonic acid (20:4n-6) in major phospholipids of gastric mucosa in rats. Three groups of male Wistar rats were fed either a standard diet, a cod liver oil-enriched diet (10% by weight), or a corn oil-enriched diet (10% by weight) for 8 mon. Dietary cod liver oil significantly reduced the level of 20:4n-6 in phosphatidylcholine (PC) and in phosphatidylethanolamine (PE) of gastric mucosa. The loss of 20:4n-6 was compensated for by eicosapentaenoic acid (20:5n-3) in PC, whereas the decrease in 20:4n-6 in PE corresponded to the increase in three n-3 fatty acids: 20:5n-3, docosapentaenoic acid (22:5n-3), and docosahexaenoic acid (22:6n-3). The level of 20:5n-3 was higher than the level of 22:6n-3 both in PC and PE of mucosa in rats fed cod liver oil. Diets supplemented with corn oil increased the level of 18:2n-6 but decreased the monoene fatty acids 16:1 and 18:1n-7 in PC but not in PE of gastric mucosa. The 20:4n-6 levels of both PC and PE were markedly reduced by dietary cod liver oil, to about one-third of control levels. Similar changes were also observed in the stomach wall. Gastric erosions were observed in all rats exposed to restriction stress, but this form of stress induced twice the number of erosions in rats fed fish oil compared to control rats or rats fed corn oil. We conclude that a diet rich in fish oil altered the balance between n-6 and n-3 fatty acids in major gastric mucosal phospholipids, markedly reduced the availability of 20:4n-6, and increased the incidence of gastric erosions induced by restriction or emotional stress.

Paper no. L8358 in *Lipids 35*, 601–605 (June 2000).

The fatty acid composition of membrane phospholipids plays an important role in the stomach. On the luminal surface of the stomach is a layer of surface-active phospholipids that render the mucosal surface hydrophobic and resistant to damage induced by luminal acid (1,2). Ulcerogenic substances cause a dissipation of this layer, leading to back-diffusion of acid and mucosal necrosis (3).

Infection with *Helicobacter pylori* has been shown to be associated with peptic ulcer disease (1). *Helicobacter pylori* release phospholipases and ammonia, which have the capacity to reduce the phospholipid-dependent hydrophobic lining of the stomach and reduce mucosal defenses. The majority of people infected with this bacterium do not, however, develop ulcers, suggesting that individual differences in mucosal response to infection determine whether an ulcer develops (4).

The availability of arachidonic acid in gastric phospholipids plays an important role in the stomach because the ability of gastric mucosa to resist injury induced by luminal irritants is influenced by eicosanoids derived from arachidonic acid. The influence of specific n-6 fatty acids, such as linoleic acid (18:2n-6) and arachidonic acid (20:4n-6), on gastric mucosal resistance to injury in rats has been studied extensively (5–8). Dietary deficiency of linoleic acid was shown to predispose rats to increased gastric mucosal injury, whereas chronic dietary supplementation with linoleic acid increased the concentration of prostaglandin E_2 (PGE-$_2$) in the gastric lumen and decreased cold restraint injury. Reduced availability of arachidonic acid and impaired conversion of arachidonic acid to gastric prostaglandins diminish the ability of gastric mucosa to resist injury (8).

Diets enriched in fish oils protect duodenal (9) and gastric mucosae (10) against ethanol injury. The polyunsaturated fatty acids present in fish oils are eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), and EPA has reportedly been converted to a family of trienoic eicosanoids with reduced inflammatory potential (11). The n-3 fatty acids are readily incorporated into gastric phospholipids, displacing arachidonic acid and potentially affecting both the cyclooxygenase and lipoxygenase pathway. The result is a likely decrease of prostaglandin PGE_2 and thromboxane A_2 synthesis and an increase in that of PGE_3 and leukotriene B_5 which may be less biologically active in inflammation. Furthermore, in some *in vitro* studies, dietary fish oil reduces leukotriene B_4, free radicals, and platelet-activating factor, all of which are considered significant mediators of mucosa damage.

The type and degree of stomach pathology depend on age and the nature of stress (12). The fatty acid composition of dietary fat also has significant effects on development of stomach pathology, either decreasing or increasing the susceptibility to mucosal damage depending on the nature of the injury. Dietary fish oil has thus been shown to protect the mucosa against ethanol-induced damage of gastric or duodenal mucosa in rats and humans (9,10,13). The damaging effects

Abbreviations: DHA, docosahexaenoic acid (22:6n-3); EPA, eicosapentaenoic acid (20:5n-3); PC, phosphatidylcholine; PE, phosphatidylethanolamine; PGE_2, prostaglandin E_2.

of aspirin on the gastric mucosa, however, are not influenced by dietary fish oil (14).

The purpose of this study was to examine the long-term influence of dietary cod liver oil and corn oil upon the balance between the n-3 and n-6 fatty acids in major phospholipids of gastric mucosa in middle-aged rats and upon the resistance to mucosal erosions induced by restriction or emotional stress. The results indicate that consumption of dietary cod liver oil can enhance the development of gastric erosions during emotional stress.

MATERIALS AND METHODS

Animals. Male Wistar rats at the age of 2 mon were randomly assigned to three groups. One group was fed a diet enriched with 10% cod liver oil containing 14.2% 18:2n-6, 15.8% 18:1n-9, 7.2% 20:5n-3, 6.7% 22:6n-3, and 11.2% of 20:1 + 22:1, for 8 mon. Another group was fed a diet enriched with 10% corn oil containing 50.9% 18:2n-6 and 28.2% 18:1n-9 for the same length of time. The diet enriched with fat was prepared once a week by mixing 90 g of regular diet (rat and mouse maintenance diet no. 1, Special Diets Services Ltd., Essex, United Kingdom) with 10 g of the dietary oil, followed by storage in the dark at 4°C. The antioxidant nutrient status of the diets is comparable: the corn oil contained 71.4 μg vitamin E/g oil, whereas the cod liver oil contained 65 μg vitamin E, 302 μg vitamin A and 130 IU vitamin D/g. The total sterol content of the cod liver oil was 0.6%.

A third group was fed a standard diet containing 18.1% 16:0, 13.9% 18:n-9, 56.5% 18:2n-6, and 6.5% 18:3n-3, with a fat content of 2% in the diet. The rats were housed in cages, three or four rats per cage, and maintained on 12 h/12 h light/dark cycle with free access to water and food. At the age of 10 mon the rats from each of these three groups were separated into a treatment group and a control group, with 15 rats in each group. Those in the treatment groups were placed in a narrow plastic cage where the rats were unable to move about or turn around (restriction stress) (15). All rats were fasted during the 18 h period of restraint and at the end they were anesthetized with CO_2 and killed by decapitation. The control rats were unrestrained and fasted for 18 h but had free access to water before decapitation. The stomachs were removed, opened along the greater curvature, and thoroughly washed with saline and inspected for gastric erosions following pinning on a board. The number of erosions was recorded by macroscopical examination. For further confirmation of the nature of the lesions eight stomachs were examined histologically (16).

Lipid extraction and analyses. Gastric mucosa from three stomachs were pooled for each experiment to reduce the effect of individual variations within each group. The lower glandular part was gently scraped, and the mucosal scrapings were immediately suspended in a mixture of chloroform/methanol (2:1, vol/vol). Each mucosal fraction was extracted in chloroform/methanol (2:1, vol/vol) for 8 h at room temperature as described previously (17).

Parts from mucosally denuded stomachs were used for each analysis. The upper part of the stomach, the forestomach, was cut from the glandular part along the limiting ridge and each part was analyzed separately, cut into small pieces in 76 mL of methanol/chloroform/water [2:1:0.8, by vol (15)] and homogenized in a Polytron model PTA. After filtration a biphasic system was produced by dilution with 1 vol of chloroform and 0.73% NaCl solution. The lower layer was withdrawn and evaporated in a rotary evaporator.

The lipid extracts from mucosa and the two mucosally denuded stomach parts were dissolved in a small volume of chloroform and separated on silicic acid columns. The phospholipids were separated by thin-layer chromatography as described previously (17).

The statistical tests used in the analyses of data were one-way analyses of variance. Data are expressed as mean ± SE for five preparations where mucosa from three rat stomachs were pooled per preparation.

RESULTS

There were some differences in the weight gain of rats fed the fat-supplemented diets during the 8-mon feeding period, final body weights being: standard diet, 450 ± 11 g; corn oil, 462 ± 8 g; and cod liver oil, 488 ± 14 g. The weight gain of rats fed cod liver oil was 8.4% greater than observed for rats fed the standard diet ($P < 0.01$) whereas the weight gain of rats fed the corn oil was not significantly different from the rats fed the standard diet.

Effect of dietary fat upon the fatty acid composition of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) in the mucosa. The effects of dietary fat upon the fatty acid composition of PC and PE in the gastric mucosa are shown in Tables 1 and 2. In rats fed cod liver oil there was a significant decrease in 20:4n-6 in PC, to one-third of control

levels (Table 1). The loss of 20:4n-6 was compensated in part by a marked increase in EPA (20:5n-3), whereas DHA (22:6n-3) did not increase significantly. In rats fed corn oil there was an increase in 18:2n-6 and a corresponding decrease in 16:1 and 18:1n-7 in PC. The n-6/n-3 ratio of PC was 116 for rats fed the control diet, 5.3 for rats fed the cod liver oil, and 665 for rats fed corn oil.

In mucosal PE dietary cod liver oil also induced a marked decrease in 20:4n-6, to about one-third of control levels (Table 2). The decrease in 20:4n-6 was met by a corresponding increase in 20:5n-3, EPA, and DHA, with the greatest increase in 20:5n-3. Diets supplemented with corn oil did not influence the fatty acid composition of PE, compared to rats fed the standard diet. The n-6/n-3 ratio of PE was 25 for rats fed the control diet, 1.4 for rats fed cod liver oil, and 54 for rats fed corn oil.

Effect of dietary fat upon PC and PE in the denuded glandular parts and forestomach. The effects of dietary fat upon the fatty acid composition of PC and PE in the glandular parts and forestomach are shown in Tables 3 and 4. Dietary cod liver oil decreased the level of 20:4n-6 in PC by two-thirds in the glandular parts, the same as in mucosa, whereas the decrease in the forestomach was about 50%, compared to rats fed the regular diet. The loss of 20:4n-6 in PC was compensated for by an increase in several fatty acids, primarily 18:2n-6, EPA, and DHA. Dietary corn oil induced a small increase in 18:2n-6 and 20:4n-6 and a corresponding decrease in 16:1 and 18:1n-7 (Table 3).

Dietary cod liver oil reduced the level of 20:4n-6 in PE by about 50% in the glandular parts and by 36% in the forestomach. This decrease in 20:4n-6 was largely compensated for by the n-3 fatty acids, 20:5n-3, 22:5n-3 and DHA (Table 4). Dietary corn oil had only a minor influence on the fatty acid profile of PE in the stomach wall.

Restriction stress and pathological changes in gastric mucosa. Restriction stress caused gastric erosions that appeared as hemorrhagic spots measuring 1–2 mm in diameter in the glandular acid-bearing portion of the stomach. To confirm the nature of these lesions eight stomachs were examined microscopically. The lesions were acute and consisted of necrotic areas confined to the mucosa, i.e., in the category of erosions. The squamous epithelium of the forestomach was erosion-free in all rats.

The results are summarized as follows: Of the 15 rats in each group, two control rats fed standard diet and one control rat fed corn oil had erosions, whereas six control rats fed cod liver oil-enriched diet had gastric erosions. Erosions were observed in all rats exposed to restriction stress. The number of stress erosions was significantly greater in rats fed cod liver oil, with 17.14 ± 0.89 erosions per rat stomach, than in rats fed the

standard diet, with 9.50 ± 0.64 erosions per stomach ($P < 0.01$), or corn oil-enriched diet, with 7.69 ± 0.60 erosions per stomach. The difference in number of gastric erosions between corn oil-fed rats and rats fed the standard diet was not significant.

DISCUSSION

In a previous study we showed that the functionally most active part of the stomach, the gastric mucosa, has the lowest level of 20:4n-6 in PC (17), reflecting the high turnover and utilization of 20:4n-6 in mucosa. The dietary modification of fatty acid composition of gastric phospholipids observed in this study was primarily seen in rats fed a cod liver oil-enriched diet. The most noticeable effect was a 63–67% decrease in 20:4n-6 in PE and PC, respectively. The loss of 20:4n-6 was mostly compensated for by the n-3 fatty acids derived from the fish oil. The cod liver oil-induced decrease in gastric arachidonic acid levels extended also to the stomach wall, with the greater loss in PC of the glandular part, underlying the mucosa (65% decrease) and somewhat less in the forestomach (50% decrease).

The corn oil-enriched diet had only a minor effect on the fatty acid composition of PC and no significant effect on PE. This is not surprising since the fatty acid profiles of the standard diet and the corn oil-enriched diet were similar. The fat content of the diet did not seem to influence the fatty acid profile of PC and PE since the fat content of the corn oil-enriched diet was much greater than in the standard diet.

Reduced availability of arachidonic acid and impaired conversion of arachidonic acid to gastric prostaglandins have been shown to diminish the ability of gastric mucosa to resist injury caused by aspirin (8). It is curious, however, that dietary fish oil had little effect on aspirin-induced gastric erosions in human volunteers (14). The ability of gastric mucosa to resist injury induced by luminal irritants is influenced by prostaglandins. Prostaglandin and nitric oxide influence the various components of mucosal defenses: they inhibit acid secretion, stimulate mucus and bicarbonate secretion, elevate mucosal blood flow, and accelerate the healing of ulcers (18). Among the eicosanoids are also lipid mediators of inflammation, such as leukotrienes and thromboxane, which may contribute to the pathogenesis of gastric ulcers.

The n-3 fatty acid EPA present in fish oils has been demonstrated to be metabolized to trienoic eicosanoids, and in some models these have exhibited less inflammatory potential than the arachidonate-derived analogs. The n-3 fatty acids are readily incorporated into gastric phospholipids, displacing arachidonic acid as described above and potentially affecting both the cyclooxygenase and lipoxygenase pathways. It has been shown that gastric prostaglandin synthesis can be adversely affected by ingestion of fish oil (13).

In this study we have shown that long-term and large intakes of fish oil leads to a very marked reduction of 20:4n-6 in mucosa. The results show furthermore that dietary fish oil, accompanied by restriction stress, enhanced the development of gastric erosions in rats. Dietary fish oil influences the susceptibility of gastric mucosa to injury differently, depending on the nature of the injury. Fish oil reduces ethanol-induced mucosal injury (9), whereas it increased the development of gastric erosions induced by emotional stress, as shown in this study. The injury may be caused by elevated levels of stress hormones (19) and persistent stimulation of the adrenergic system accompanied by increased activity of phospholipases. Rats fed the cod liver oil-supplemented diet developed twice the number of gastric erosions, induced by restriction stress, compared to control rats or rats fed the corn oil-supplemented diet. Our data support the view that arachidonic acid and prostaglandins play an important role in protection of gastric mucosa during emotional stress.

Low Erucic Acid Canola Oil Does Not Induce Heart Triglyceride Accumulation in Neonatal Pigs Fed Formula

Timothy J. Green and Sheila M. Innis*

Department of Paediatrics, University of British Columbia, Vancouver, British Columbia, Canada V5Z 4H4

ABSTRACT: Canola oil is not approved for use in infant formula largely because of concerns over possible accumulation of triglyceride in heart as a result of the small amounts of erucic acid (22:1n-9) in the oil. Therefore, the concentration and composition of heart triglyceride were determined in piglets fed from birth for 10 (n = 4–6) or 18 (n = 6) d with formula containing about 50% energy fat as 100% canola oil (0.5% 22:1n-9) or 100% soybean oil, or 26% canola oil or soy oil (blend) with palm, high-oleic sunflower and coconut oil, providing amounts of 16:0 and 18:1 closer to milk, or a mix of soy, high-oleic sunflower and flaxseed oils with C_{16} and C_{18} fatty acids similar to canola oil but without 22:1. Biochemical analysis found no differences in heart triglyceride concentrations among the groups at 10 or 18 d. Assessment of heart triglycerides using Oil Red O staining in select treatments confirmed no differences between 10-d-old piglets fed formula with 100% canola oil (n = 4), 100% soy oil (n = 4), or the soy oil blend (n = 2). Levels of 22:1n-9 in heart triglyceride and phospholipid, however, were higher (P<0.01) in piglets fed 100% canola oil or the canola oil blend, with higher levels found in triglycerides compared with phospholipids. The modest accumulation of 22:1n-9 associated with feeding canola oil was not associated with biochemical evidence of heart triglyceride accumulation at 10 and 18 d.

Paper no. L8232 in *Lipids 35*, 607–612 (June 2000).

Diets containing rapeseed oils with greater than 10% erucic acid (22:1n-9) result in accumulation of 22:1n-9 in tissue lipids, reduced growth and rates of fatty acid oxidation, and myocardial lipidosis and necrosis in rats. The maximal safe intake of 22:1n-9 that does not lead to lipidosis in rat heart has been estimated to be 2 to 10% dietary fatty acids (1–8). The U.S. Food and Drug Administration currently permits dietary oils containing no more than 2% fatty acids as 22:1n-9 in foods for adults and children, but does not permit use of canola oils in infant formulas (9). Canola, a low 22:1n-9 hybrid derived from rapeseed, is widely used to prepare cooking and salad oils, table spreads, and in the preparation of bakery and fast foods in many countries. Canola oils are generally considered favorable dietary oils because of the relatively high proportion of 18:1 (about 50–60% fatty acids) and α-linolenic acid (18:3n-3), modest levels of linoleic acid (18:2n-6), and low levels of saturated fatty acids (10–15).

The restriction relating to the use of canola oil in infant formula is based, in part, on concerns that infants fed formula may consume higher amounts of 22:1n-9 than would be consumed through usual diets that contain a variety of foods, and the absence of experimental evidence demonstrating the safety of feeding formulas with canola oils to infants. In contrast to usual diets, infant formulas provide about 40–50% energy from fat, and formulas represent the major source of dietary fat for bottle-fed infants for the first 6 mon. Transient lipidosis has been noted in 5-d-old piglets fed sow's milk or a milk replacer with canola oil (0.8% 22:1n-9) (16). Definite lipidosis was observed in the heart of piglets fed oils containing between 7 and 42.9% 22:1n-9, values that generally paralleled the percentage of 22:1n-9 in heart triglyceride (16). Infant formulas usually provide a mixture of oils to provide levels of saturated and unsaturated fatty acids resembling human milk. Although some studies have reported that replacing a portion of the rapeseed oil with a saturated fat resulted in a lower incidence and/or severity of myocardial necrosis (17–19), a more recent study found that addition of saturated fat to the diet along with rapeseed oil (with 2.5 or 9% 22:1n-9) did not alter myocardial lipidosis, heart triglyceride, or 22:1n-9 in rats (20).

The present study was undertaken to determine whether the small amount of 22:1n-9 in canola oil resulted in increased heart triglyceride or 22:1 accumulation in formula-fed piglets, when canola oil was used as the sole source of fat or was blended with saturated fat to resemble more closely the fatty acid composition of pig and human milk and of infant formula. To address the possibility that the small amount of 22:1 or some other unusual feature of canola oil, such as the sterol components or triglyceride fatty acid distribution, is responsible for the adverse effects on heart lipids we designed an oil mix to mimic the levels of C_{16} and C_{18} carbon chain fatty acids of canola oil without 22:1 or the sterols components. Piglets were used for these studies because the proportion and composition of fat in pig milk resembles human milk, and lipid metabolism in pigs is similar to humans (21).

Abbreviations: ANOVA, analysis of variance; Canola blend, 26% canola, 42% palm, 4% high-oleic sunflower, 16% sunflower, 12% coconut oil; Canola mimic, 29% soybean, 59% high-oleic sunflower, 12% flax oil; OCT, tissue embedding compound; Soy blend, 26% soybean, 48% palm, 14% high-oleic sunflower, 12% coconut oil.

METHODS

Animals and formulas. The formulas were prepared as liquid ready-to-feed formulas using procedures identical to those used in the manufacture of infant formula by Ross Laboratories, (Columbus, OH). The formulas contained identical amounts of carbohydrate, protein, fat, vitamins, and minerals and differed only in the source and composition of the fat (Table 1). Five fat blends, each providing about 50% of the dietary energy, were prepared: 100% canola oil (Canola); 100% soybean oil (Soy); 26% canola, 42% palm, 4% high- oleic sunflower, 16% sunflower, and 12% coconut oil (Canola blend); 26% soybean, 48% palm, 14% high-oleic sunflower, and 12% coconut oil (Soy blend); or 29% soybean, 59% high-oleic sunflower, and 12% flax oil (Canola mimic) (Table 1). The Canola mimic was designed to give as similar a composition of 16:0, 18:1, 18:2n-6, and 18:3n-3 to that in canola oil as practically possible, without the inclusion of 20:1n-9, 22:1n-9, or the sterol components of canola oil. The formulas with 26% canola or soybean oil (Canola blend and Soy blend, respectively) were designed to resemble formula for feeding healthy term gestation infants that include 16:0 and 18:1 at levels similar to those in human milk.

Male piglets of birth weight >1 kg were obtained from Kintail Meats (Langley, British Columbia, Canada). The piglets were randomly assigned to one of the five formulas, 10–12 piglets each, and bottle-fed from the first day of life until day 10 (n = 4–6/group) or 18 (n = 6/group) after birth (22). The piglets were housed in groups of three in a temperature-, humidity-, and light-controlled animal unit. The formula-fed piglets were bottle-fed the formula by hand every 1 1/2 to 2 h for the first 5 d, then every 3 h from 0600 to 2400 h. Passive immunity was provided to the formula-fed piglets by inclusion of colostrum-derived immunoglobulins (La Belle Assoc. Inc. Bellingham, WA) in the formula, 15 g/L for the first 72 h after birth, then 7.5 g/L for the next 72 h, and 2.5 g/L for the following 72 h. A group of piglets fed sow's milk (n = 10) by their natural mothers was studied for reference at a similar age and time after the last feed. All of the formula-fed and sow milk-fed piglets were given iron dextran, 10% (MTC Pharmaceutical, Cambridge, Ontario, Canada) on day 5 after birth. The Animal Care Committee of the University of British Columbia approved all procedures.

Pathology. The piglets were killed at 10 or 18 d of age, 3–4 h after the last feed by intracardiac injection of sodium pentabarbitol (1 mL) and decapitated. The heart was immediately excised and five sections, each 5-mm thick, were cut laterally from the heart starting at the apex (sections A, B, C, D, E). The fifth section (E) was cut just below the atria and was composed of tissue from both ventricle and the intraventricular septum. Sections F and G (5-mm in thickness) were cut from the left and right atria and an additional section of atria (H) was removed. Sections A, C, E, F, and G were cut into four small (5-mm) sections and used for histology. Sections B, D, and H were used for biochemical analysis and were frozen in liquid N_2 and stored at –80°C until analyzed. Two of the four sections from samples A, C, E, F, and G were placed into OCT compound (Tissue-Tek, Sakura Finetek, U.S.A. Inc., Torrance, CA), frozen in liquid N_2, and stored at –80°C.

TABLE 1
Fat Blend and Fatty Acid Composition of Formulas[a]

	Formula oil

22:1n-9	0.5	0.0	0.0	0.1	0.0

[a]The formulas were made to contain (per liter) 58 g total fat, 60 g protein from nonfat milk, 62 g carbohydrate with 240 μg vitamin A as retinyl palmitate, 4.4 μg cholecalciferol, 6.4 μg d-α-tocopherol equivalents, 60 μg phylloquinone, 150 mg vitamin C, 1.2 mg thiamin, 225 μg folic acid, 2.0 mg riboflavin, 13 mg niacin, 0.75 mg pyridoxine, 8.0 μg vitamin B_{12}, 7 mg pantothenic acid, 300 mg choline, 50 μg biotin, 56 mg inositol, 85 mg taurine, 2.3 g calcium, 1.76 g phosphorus, 175 mg magnesium, 800 mg sodium, 1.75 g potassium, 900 mg chloride, 25 mg iron, 25 mg zinc, 1.5 mg copper, 0.42 mg iodine, 0.8 mg manganese, 34 μg selenium.

Biochemistry. A portion (0.5–1.0 g) of each heart section (B, D, H) was homogenized, total lipids were extracted (23), and the concentrations of triglycerides and total cholesterol were analyzed using enzymatic methods (22,24). Phospholipid phosphorus was assayed after digestion with 70% perchloric acid according to Chen *et al.* (25). Triglycerides and phospholipids were separated from the total lipids by thin-layer chromatography (22), the fatty acid components converted to their respective methyl esters, and separated and quantitated by gas–liquid chromatography (26). The fatty acid composition of the formulas was determined following direct methylation of fatty acids (27), as in previous studies (26).

Histology. Heart histology was performed on 10-d-old piglets from select treatments only to confirm and extend the biochemical analysis of triglyceride concentrations. The hearts of piglets fed 100% Canola or 100% Soy oil (n = 4 each) were compared because these formulas contained 100% oil as either canola or soy, thus any effect of canola oil on cardiac lipid accumulation should be apparent by comparison of these treatments. The hearts of piglets fed the Soy blend (n = 2) were also analyzed because this formula is similar to some current commercial infant formulas. Sections (A, C, E, F, G), 8–10 μm thick, were cut from the tissues in OCT longitudinally on a cryostat at –16°C, stained with Oil Red O, and examined at a 400-fold magnification for the presence of myocardial lipid. Forty consecutive fields were examined and the number of cells that showed lipid accumulation counted. Because most of the myocardial lipid was extracellular, the number of individual streaks of lipid within each field was also determined. The pathologist was blinded with respect to formula and oils fed.

Statistical analysis. The results concerning growth, formula intake, heart lipid concentrations and fatty acids were analyzed by one-way analysis of variance (ANOVA) for piglets fed the Canola, Soy, Canola blend, or Soy blend formula for 10 or 18 d. The results for piglets fed the formula with Canola or the Canola mimic were also analyzed using ANOVA (secondary hypothesis). The natural log was used to obtain homogeneity of variance (Levene's Statistic) across treatment groups where appropriate. Two-way ANOVA found no significant differences ($P > 0.05$) in the concentration or composition of lipids in different regions of the heart within piglets. Therefore, values for different regions were averaged for each piglet for subsequent analysis of treatment effects. Results were compared between the groups of formula-fed piglets using one-way ANOVA and Fisher's Exact Test.

Preplanned comparisons (contrasts) were used to determine how the effect of feeding the formula with canola oil (Canola) compared with feeding soy oil (Soy) and how the effect of feeding 100% canola or soy oil compared with feeding a blend containing 26% canola (Canola blend) or soy oil (Soy blend) with other oils, respectively. The latter analysis considered the effect of replacing a portion of canola or soy oil with saturated fat. Finally, the effect of feeding 100% canola oil (Canola) compared to the effect of an oil blend with a similar fatty acid profile but with no 22:1n-9 or 20:1n-9 (Canola mimic) was considered. All calculations were performed with SPSS, release 7.5.1, for Windows 95. Results for a group fed sow's milk are included with the tables for reference but were not considered in the statistical analysis because of the many differences, in addition to lipids, between milk and formula, and in the housing and feeding environment of sow-fed and bottle-fed piglets.

RESULTS

There were no significant differences in formula intake, body weight, weight gain, liver weight or kidney weight among the groups at either 10 or 18 d of age (data not shown). The mean heart weight of piglets fed the Canola formula was higher than for those fed the Canola mimic, but was not different from that of piglets fed the other formulas at 18 d of age (mean ± SEM, 37.9 ± 1.5, 35.8 ± 2.5, 33.4 ± 0.9, 34.1 ± 1.1, 33.7 ± 1.2 g) for piglets fed the Canola, Soy, Canola blend, Soy blend and Canola mimic formula, respectively). There were no differences in heart weight at 10d, or in the heart per kg body weight, among the groups at 10 or 18 d.

The analysis of the heart triglyceride, phospholipid, and cholesterol concentrations found no significant difference among the groups at 10 or 18 d of age (Table 2). Histological evaluations using Oil Red O found trace to moderate amounts

Sow reference	3.90 ± 0.51	3.58 ± 0.22

[a]Data reported as mean ± SEM, n = 4–6/group at 10 d, and n = 6/group at 18 d. There were no statistically significant differences between the groups at 10 or 18 d for piglets fed formula with Canola compared to Soy oil, the Canola blend compared to Soy blend, Canola compared to the Canola Blend, or Canola compared to the Canola mimic. Definitions: Canola, 100% canola oil; Soy, 100% soybean oil; Canola blend, 26% canola, 42% palm, 4% high-oleic sunflower, 16% sunflower, and 12% coconut oil; Soy blend, 26% soybean, 48% palm, 18% high-oleic sunflower, and 12% coconut oil; Canola mimic, 29% soybean, 59% high-oleic sunflower, 12% flax oil.

TABLE 3
Cardiac Triglyceride Accumulation[a] in 10-d-old Pigs for Select Treatments[b]

	Formula oil		
	Canola	Soy	Soy blend
Intracellular lipid[c]	0.66 ± 0.23	0.69 ± 0.08	0.66 ± 0.16
Extracellular lipid[d]	9.33 ± 2.42	9.13 ± 1.73	6.39 ± 3.06
Total	10.00 ± 2.61	9.83 ± 1.65	7.06 ± 2.94

[a]Sections were stained with Oil Red O and were examined at a 400-fold magnification. Forty consecutive fields were counted
[b]Data are presented as means ± SEM for each of Canola and Soy and for Soy blend (n = 4).
[c]Number of cells that showed lipid accumulation was counted.
[d]Number of individual streaks of lipid located extracellularly. For formula compositions see Table 2.

of lipid in the hearts of almost all the 10-d-old piglets, irrespective of whether the formula contained canola oil, soy oil, or the blended oils (Table 3). Consistent with the biochemical analysis, there were no significant differences in the number of cells containing intercellular lipid, that is, 0.66 ± 0.23, 0.69 ± 0.08, 0.66 ± 0.16 cells with lipid for piglets fed the 100% Canola, 100% Soy, or the Soy oil blend, respectively. Similarly, there was no statistically significant difference among the groups in the number of extracellular lipid streaks at 10 d of age (9.33 ± 2.42, 9.13 ± 1.73, 6.39 ± 3.06, respectively).

The fatty acid composition of the heart triglycerides is shown in Table 4. The differences in the fatty acid composition of the heart triglycerides among the groups reflected the differences in fatty acid composition of the formulas fed. The results concerning the levels of 22:1, the fatty acid of concern in canola oil, are discussed in detail. The results for the n-3 fatty acids, particularly docosahexaenoic acid (22:6n-3) are also discussed because canola oil is high in 18:3n-3, while providing modest amounts of linoleic acid (18:2n-6). The statistical analysis to show treatment effects on other major fatty acids are shown in Table 4. At 18 d of age the heart triglyceride 20:1n-9 and 22:1n-9 of piglets fed the Canola formula were significantly higher than of piglets fed the Soy or the Canola mimic formulas. There were no significant differences in the heart triglyceride 22:1n-9 between piglets fed the Canola and Canola blend formulas, despite the difference in 22:1n-9 in the formulas (0.5 and 0.1%, respectively, Table 1). The heart triglyceride 20:1n-9, however, was significantly higher in piglets fed the Canola than Canola blend formula at 18 d. The concentrations of 24:1n-9 were not increased in the heart triglycerides of piglets fed either Canola or the Canola blend when compared to Soy or the Soy blend, or the Canola mimic. The concentrations of 20:1n-9 and 22:1n-9 in the heart phospholipid were much lower than in the triglycerides and did not exceed 0.5 and 0.2% fatty acids, respectively (data not

[g]There is a statistically significant higher 22:1 in heart triglyceride at 18 d compared to 10 d of age in analysis of variance considering the effect of age for all animals.

shown). The concentrations of 20:1n-9, 22:1n-9, and 24:1n-9, however, were significantly higher in the heart phospholipids of piglets fed the Canola oil formula at 10 d (0.3 ± 0.1, 0.2 ± 0.1, 0.4 ± 0.1%, respectively) and 18 d (0.5 ± 0.0, 0.2 ± 0.0, 0.4 ± 0.0, respectively) than in piglets fed the Soy oil formula at 10 d (0.1 ± 0.0, 0.1 ± 0.0, 0.2 ± 0.0, respectively) or 18 d (0.1 ± 0.0, 0.1 ± 0.0, 0.1 ± 0.0, respectively). The levels of 22:1n-9 and 24:1n-9 at 10 d, and 20:1n-9, 22:1, and 24:1n-9 at 18 d were also significantly higher in piglets fed the Canola blend compared to Soy blend formula, although again the levels were very low and did not exceed 0.4% fatty acids. The physiological significance, if any, of these differences is not known.

Canola oil, like soy oil, has relatively high amounts of 18:3n-3, which can be desaturated and elongated to 22:6n-3. There were no significant differences in the concentration of 20:5n-3 or 22:6n-3 in the heart triglycerides at either 10 or 18 d. The concentrations of 18:3n-3 were higher in the heart triglyceride at 18 d in piglets fed Canola compared with Soy, or the Canola blend, but not the Canola mimic formula. The heart phospholipid concentrations of 18:3n-3 and 20:5n-3 were also higher in piglets fed the Canola compared with Soy or the Canola blend formula at both 10 and 18 d of age (data not shown). There were, however, no significant differences in 22:6n-3, with the exception of higher 22:6n-3 in the heart phospholipid of the 10-d-old piglets fed the Canola compared with Soy formula.

DISCUSSION

The studies described here show that the fat composition of formulas fed to rapidly growing young piglets had no significant effect on body weight, weight gain, or organ weight with the exception of a higher heart weight (by about 12%), but not heart/body weight in 18-d-old piglets fed the formula with 100% Canola oil compared with the Canola mimic. The heart weight, however, was not different between piglets fed the Canola and Soy formulas, or the Canola and Canola blend formulas, suggesting that the differences between piglets fed Canola and the Canola mimic are best explained as a lower heart weight in piglets fed the canola oil mimic.

The biochemical and histological analyses found no evidence of increased heart lipid in piglets fed formula with canola oil, containing 0.5% of fatty acids as 22:1n-9 and representing about 0.25% dietary energy, when compared to piglets fed formula with soy oil. Newborn piglets show a transient myocardial lipidosis that resolves by 7 d (16), possibly reflecting the rapid increase in capacity for fatty acid oxidation in the first week of life (28). Thus, histological analysis was done at 10 d, and biochemical analysis was done at 10 and 18 d of age to assess potential lipid accumulation due to feeding Canola oil. Our studies confirm the work of Kramer *et al.* (16), who showed no increased incidence of myocardial lipidosis either in piglets fed a sow milk replacer with canola oil (0.8% 22:1n-9) when compared to sow-fed animals, or in 10-d-old piglets fed a milk replacer with rapeseed oil (4.7% 22:1n-9) when compared to soybean oil. Definite myocardial lipidosis that correlated with dietary 22:1n-9, however, was found in piglets fed a milk replacer with 7 to 43% 22:1n-9 (16). Most of the 10-d-old piglet hearts that we examined showed the presence of lipid droplets. These droplets were unevenly distributed, with the majority located extracellularly and subjacent to the epicardium.

These findings were not unexpected because several studies have noted trace to moderate lipidosis in rats and piglets fed oils without 22:1n-9 (1,7,8,16,20), and the neonate is known to have an immature capacity for fatty acid oxidation (28). The biochemical analysis did not find lower heart triglyceride concentrations in piglets fed the Canola mimic (which provided similar amounts of C_{16} and C_{18} fatty acids without 22:1n-9 or the sterols of canola oil) or the formula with soybean oil than in piglets fed the formulas with canola oil. The weight of evidence therefore suggests that formula with canola oil providing ≤0.5% 22:1n-9 in total fatty acids has no adverse effect on neonatal heart lipid accumulation. The reason for the lower heart triglyceride at 10 ($P = 0.37$) and 18 d ($P = 0.22$) in piglets fed the canola oil blend (0.57 ± 0.08 and 0.51 ± nmol/g protein, respectively) than in piglets fed 100% canola oil (0.91 ± 0.28 and 0.81 ± 0.22, respectively) is not known, and may warrant further investigation.

Our studies show higher 22:1n-9 levels in heart triglyceride and phospholipid of piglets fed formulas with canola oil, either as the single oil or when blended with other oils. The amounts of 22:1n-9 in heart triglyceride and phospholipid of the piglets fed canola oil were less than 2.0 and 0.25% total fatty acids, respectively. Despite the much lower amount of 22:1n-9 in the Canola blend, piglets fed the Canola blend with 26% canola oil did not have lower 22:1n-9 in heart lipids than those fed the Canola formula with 100% canola oil. Whether this is explained by the relatively low levels of 22:1n-9 in all the treatment groups or by selective oxidation of fatty acids other than 22:1n-9 resulting in 22:1n-9 accumulation is not known. The small amounts of 22:1n-9 in the heart triglycerides and phospholipids of piglets fed the soy and canola mimic formulas and in the reference group of sow milk-fed piglets probably reflects exposure to 22:1n-9 from canola oil in the maternal diet. Canola oil is used as a fat source in pig feeds in British Columbia.

In conclusion, these studies show that formulas with canola oils providing 0.5% fatty acids as 22:1n-9, representing about 0.25% total dietary energy, have no adverse effects on growth, feed intake, or organ weight. The modest accumulation of 22:1n-9, predominantly in triglycerides, associated with feeding canola oil was not associated with biochemical evidence of heart triglyceride accumulation at 10 and 18 d, or histological evidence of heart lipid accumulation at 10 d of life.

Dehydroepiandrosterone Alters Lipid Profiles in Zucker Rats

Jude M. Abadie[a,*], Gray T. Malcom[a], Johnny R. Porter[b], and Frank Svec[c]

Departments of [a]Pathology, [b]Physiology, and [c]Medicine, Louisiana State University Medical Center, New Orleans, Louisiana 70112

ABSTRACT: High free fatty acid (FFA) levels are common in obesity and in diseases such as diabetes that are associated with the obese state. Dehydroepiandrosterone (DHEA) decreases dietary fat consumption, body fat content, and insulin levels in the obese Zucker rat (ZR), a genetic model of human youth-onset obesity and type 2 diabetes mellitus. This study was conducted to investigate the effects of DHEA on lean and obese ZR serum, adipose, and hepatic tissue fatty acid (FA) profiles and serum FFA levels. Because DHEA is known to decrease fat consumption and body fat, we postulate that DHEA may also alter FA profiles and FFA levels of the obese ZR such that they more closely resemble the profiles and levels of their lean siblings. In this study there was a DHEA and a pair-fed (PF) group ($n = 6$) for 12 lean and 12 obese ZR. The diet of the treatment groups was supplemented with 0.6% DHEA, and PF groups were given the same average calories consumed by their corresponding DHEA group for 30 d. Fasted animals were sacrificed, and FA profiles and FFA levels were measured. Serum FFA levels were higher in obese (~1 mmol/L) compared to lean rats (~0.6 mmol/L). After 30 d of DHEA treatment, FFA levels were lower ($P < 0.05$) in both lean and obese groups. Although several significant differences in FA profile of serum, hepatic, and adipose lipid components were observed between lean and obese ZR, DHEA-related changes were only observed in the serum phospholipid (PL) and liver PL and triglyceride fractions. The slight but significant decrease in serum FFA levels may be reflected by changes in serum PL FA profiles. Specific hepatic FA profile alterations may be related to DHEA's known effects in inducing hepatic peroxisomes. We speculate that such FA changes may give insight into a mechanism for the action of DHEA.

Paper no. L8340 in *Lipids 35,* 613–620 (June 2000).

The fa/fa obese Zucker rat (ZR) is a genetic model of human youth-onset obesity and diseases associated with the obese state. Specifically, compared to their lean siblings, obese ZR demonstrate higher serum free fatty acid (FFA) levels, hyperphagia, hyperinsulinemia, hypertriglyceridemia, hypercorticosteronemia, hyperleptinemia, increased lipogenesis, adipoctye hypertrophy, and hyperplasia (1–6), and they become hyperglycemic with advancing age (7).

Excess adipose tissue, a fatty liver, and increased hepatic lipid synthesis alter fatty acid (FA) flux (8). It is often suggested that this "lipotoxicity" may be responsible for the increased serum FFA levels associated with obesity-related diseases (9–11). Although the liver is the first site for insulin resistance (IR) development in obese ZR, adipose is the most insulin sensitive tissue (8). Many investigators implicate FA as a major mediator of IR development in hepatic and adipose tissue (12–20), and specific FA in serum highly correlate with the development of IR and diabetes in humans (21). Mechanisms by which FA alterations may lead to IR are poorly understood.

Altered adipose FA flux may be an important metabolic alteration central to the pathophysiology of the obese ZR (9,10). However, control mechanisms governing FA flux have not been determined. Moreover, such mechanisms may be quite difficult to establish. After all, FA are critical energy substrates, building blocks for cell membrane components, precursors of cell mediators such as prostaglandins, and important intracellular mediators of gene expression (22). Such diverse roles suggest complex and specific regulatory factors governing FA flux.

This study investigates possible lipid-altering effects of dehydroepiandrosterone (DHEA), the most abundantly produced human adrenal steroid. In the past we and others have shown that DHEA treatment in the obese ZR acts as an anti-obesity agent in that it decreases body weight, fat intake (2–4), size of specific adipose depots and their cellularity, and liver adiposity (2–4,24). Additionally, we have shown that DHEA alters the total lipid (TL) FA compositions of skeletal and cardiac muscle in the obese ZR such that they resemble more closely the profile of their lean siblings (Abadie, J.M., Malcom, G.T., Porter, J.R., and Svec, F., unpublished data).

Because of the specific anti-obesity effects of DHEA on adipose mass, fat intake, and liver fat content, as well as alterations in muscle TL FA profiles and serum FFA levels, we hypothesize that these DHEA alterations may correlate with changes in FA profiles in serum, adipose, and hepatic tissue.

This study was conducted to determine the effect of DHEA on (i) adipose tissue TL FA profiles (mammary, retroperi-

toneal, and subcutaneous depots), (ii) liver phospholipid (PL), FFA, and TG FA lipid profiles, and (iii) serum FFA levels and PL, FFA, triglyceride (TG), and cholesteryl ester (CE) FA lipid profiles.

EXPERIMENTAL PROCEDURES

Animals. Twenty-four female ZR 12 to 16 wk of age were obtained from our colony in the Department of Physiology at the Louisiana State University Medical Center in New Orleans, LA; the study was approved by the IRB and IACUC boards from the Louisiana State University Medical Center in New Orleans. Twelve lean (Fa/fa) and 12 obese ZR (fa/fa) were used for the experiment. Animals were maintained on a 12-h light-dark cycle (lights on at 0600) in a room whose temperature was maintained at 22 ± 1°C. Prior to the experiment, all animals were maintained on Purina Rodent Laboratory Chow #5001 whose physiologic fuel value, as reported by the manufacturer, is 3.30 kcal/g. The proportions of energy as carbohydrate, protein, and fat are 63.7, 30.4, and 5.9%, respectively. Both food and water were available *ad libitum*. Animals were housed individually in wire mesh cages.

Specialized diet. A specialized macronutrient diet as previously described (24) was combined so that the proportions of energy as carbohydrate, protein, and fat were 30, 20, and 50%, respectively. This "high fat" single-bowl diet was given to each animal for the duration of the experiment. The energy density of the diet was 5.256 kcal/g. The diet of the group designated DHEA was supplemented with 0.6% DHEA.

Study design. On day 1, 24 female ZR 9 to 12 wk old were weight/age matched and divided into four groups ($n = 6$). For both lean and obese rats there was a DHEA and a pair-fed (PF) group. For days 1 through 7, each animal had *ad libitum* access to their dish containing the DHEA-free diet. For the subsequent 30 d (days 8 through 37), the diet of the two DHEA groups (lean and obese) was supplemented with 0.6% DHEA. The PF groups were pair-fed to the intakes of their corresponding DHEA-treated group. Because DHEA decreases caloric intake, each animal in each PF group was given the average number of calories consumed by their corresponding DHEA group during the previous day. On the first day of pair-feeding, PF groups were given half the amount that they had consumed during the previous day (day 7). After 30 d of DHEA treatment or pair-feeding, animals were fasted for 14 h and sacrificed by rapid decapitation. Serum, livers, mammary adipose tissue (MAT), retroperitoneal adipose tissue (RPAT), and a 500-mg piece of subcutaneous adipose tissue (SQAT) were frozen in liquid nitrogen and stored at –80°C until lipid analysis.

All FA profiles were determined by gas–liquid chromatography. Adipose depots and livers were homogenized in a chloroform/methanol solution (2:1, vol/vol), and TL was extracted, evaporated to dryness, and redissolved in 10 mL of chloroform as described earlier (25).

The 10 mL of chloroform containing the TL extracts was dried down under a nitrogen stream, and 150 μL of petroleum ether (BP 35–50°C) was added to the TL extract, spotted on glass plates coated with Silica Gel-G (E. Merck, Darmstadt, Germany), and separated into PL, FFA, TG, and CE (for serum) fractions. The thin-layer chromatography solvent mobile phase used was petroleum ether/ethyl ether/glacial acetic acid (90:10:1, by vol).

A standard mixture of lipids was spotted adjacent to the samples to ensure correct class identification at the end of a migration period of approximately 45 min. Plates containing the partitioned lipid classes were visualized under ultraviolet light after spraying with 2,7-dichlorofluorescein in methanol. The band of silica gel containing each lipid class was scraped off of the glass plate, and transmethylation was performed with 2 mL of 6% (vo/vol) sulfuric acid in anhydrous methanol in Teflon-lined screw-cap tubes at 75°C for 15 h. The mixture containing FA methyl esters was washed with water and extracted with hexane. The hexane was stored under nitrogen prior to injection directly onto the column of a gas chromatograph as previously described (25).

A standard mixture of FA methyl esters (Applied Science Labs, College Station, PA) was run daily for standardization and proper identification of each FA. The proportions of individual FA were calculated and expressed as a weight percentage of the TL FA present in the sample.

Statistical analysis. Variations in experimental measurements were examined by one-way analysis of variance (ANOVA) on a Power Macintosh 7600/120 Superanova program (®Abacus Concepts from Macintosh). Significance for $P < 0.05$ was measured using Fisher's Projected least squares difference, giving the exact P-value for each comparison.

RESULTS

For all tables, values are presented as means ± SEM. Rows not sharing the same letter are significantly different ($P \leq 0.05$). Significant differences occurring when comparing measurements from PF control vs. the corresponding DHEA group are presented in **bold** type. Values in columns are not statistically compared. The abbreviations for the groups are: obese pair-fed (OPF), obese DHEA (ODHEA), lean pair-fed (LPF), and lean DHEA (LDHEA).

Body weights (BW) in grams on days 7, 14, 21, and 36 and caloric intakes (CI) in kcal on days 5, 6, 8, 14, 21, 28, and 36 are recorded in Table 1. On day 7, BW were not different within phenotype groups; however, on days 14, 21, and 36, both lean and obese DHEA groups weighed significantly less than their PF controls. CI decreased by the first day of DHEA treatment (day 8) for both lean and obese rats. This decrease remained lowered in the obese; however, by day 14, the CI of the LDHEA group returned to their pretreatment consumption.

The TL liver content, weights of right MAT and RPAT, and liver weights are recorded in Table 2. For each of these measurements, values for obese controls (OPF) are significantly higher than lean controls (LPF). The liver weights of both DHEA groups were significantly greater compared to their corresponding control group. For every other measurement in

CI day 28		65.0 ± 3.5 a		70.2 ± 2.9 b
CI day 36		64.6 ± 4.1 a		62.8 ± 2.6 a

[a]BW (g) and CI (kcal) are recorded on the indicated study days as mean ± SEM for each group (n = 6): obese pair-fed (OPF), obese dehydroepiandrosterone (ODHEA), lean pair-fed (LPF), and lean DHEA (LDHEA). Values in rows that do not share the same letter are significantly different ($P \leq 0.05$).

Table 2, the values of both DHEA groups were significantly less compared to their corresponding PF control group.

Figure 1 represents the serum FFA levels for each group. The FFA levels of the OPF group were almost twice as high compared to the LPF group ($P \leq 0.0001$). The FFA levels of both DHEA groups were significantly lower ($P \leq 0.05$) compared to their corresponding control group.

Serum PL FA profiles are recorded in Table 3. The proportions of linoleic acid (18:2n-6) and adrenic acid (22:4n-6) are significantly greater in lean compared to obese control rats. After 30 d of DHEA treatment, there were greater proportions of palmitic acid (16:0) in both lean and obese DHEA groups. Serum PL FA proportions of stearic acid (18:0) and docosahexaenoic acid (DHA) (22:6n-6) are significantly lower in both lean and obese DHEA groups.

Serum FFA profiles are recorded in Table 4. The proportions of palmitic acid, palmitoleic acid (16:1), DHA, and saturated fatty acids (SFA) are significantly lower in lean compared to obese control rats, and proportions of linoleic acid and polyunsaturated (PU) FA are significantly greater in lean compared to obese control rats. There are no DHEA treatment effects observed in serum FFA profiles.

Serum TG FA profiles are recorded in Table 5. The proportions of palmitic acid, palmitoleic acid, DHA, SFA, and

[a]Values are recorded as mean ± SEM for each group (n = 6). Values in rows that do not share the same letter are significantly different ($P \leq 0.05$). For abbreviations see Tables 1 and 3.

monounsaturated (MU) FA are significantly lower in lean compared to obese control rats. Proportions of linoleic acid, lignoceric acid, and PU FA are significantly greater in lean compared to obese controls. There are no DHEA treatment effects observed in serum TG FA profiles.

Serum CE FA profiles are recorded in Table 6. The proportions of palmitic acid, palmitoleic acid, stearic acid, and oleic acid (18:1) are significantly lower in lean compared to obese control rats. Proportions of adrenic acid, nervonic acid (24:1) and eicosapentaenoic acid (22:5n-3) are significantly greater in lean compared to obese controls. There are no DHEA treatment effects observed in serum CE FA profiles.

Liver PL FA profiles are recorded in Table 7. The proportions of stearic acid are significantly greater in lean compared to obese controls. After 30 d of DHEA treatment, there were greater proportions of palmitic acid in both lean and obese DHEA groups. Serum CE FA proportions of DHA are significantly lower in both lean and obese DHEA groups.

Liver FFA profiles are not reported in this study. First, for many of these samples, FFA yield was not great enough to generate readable peaks from our gas chromatography. Second, readable chromatograms containing strong peaks were highly variable from sample to sample due to the highly variable flux of this lipid component.

Liver TG FA profiles are recorded in Table 8. This is the only FA profile measured in this study where phenotypic differences were not observed; however, it is the fraction where the greatest DHEA-related alterations were observed. After 30 d of DHEA

treatment, there are greater proportions of stearic acid, oleic acid, DHA, SFA, and MU FA in both lean and obese DHEA groups. Liver PL FA proportions of acid and PU FA are significantly lower in both lean and obese DHEA groups.

In each instance where DHEA-related alterations in FA profiles were observed in this study, the same changes were observed for both phenotypes.

The TL FA profiles for MAT, RPAT, and SQAT are recorded in Tables 9, 10, and 11, respectively. For each of these adipose tissue depots, the proportions of palmitic acid and palmitoleic acid are significantly lower in lean compared to obese control rats, and proportions of linoleic acid are significantly greater in lean compared to obese controls. For FA totals, MU FA are proportionally lower and PU FA are proportionally greater in the lean compared to obese rats for both MAT and SQAT. For RPAT, the proportions of SFA are lower and proportions of PU FA were greater in the lean compared to obese rats. After 30 d of DHEA treatment, there were no FA profile alterations in any of these three adipose depots.

DISCUSSION

Perhaps the lipid profile differences between lean and obese ZR observed in this study better distinguish these two phenotypes than do the combined differences in FFA levels, liver lipid content, and degree of adiposity. ZR treated with DHEA have altered tissue FA profiles such that the obese become more like the lean with respect to FA composition.

This study investigates DHEA's lipid-altering effects on liver, specific fat depots, and serum. Defining these areas in terms of lipid and FA profiles seemed to be the next logical step in our investigation of DHEA's effects on lipid profiles. Elevated serum FFA levels are common in obesity (7,21) and IR (26). Several studies show that high FFA levels decrease hepatocyte insulin sensitivity (27–31). This study shows a significant decrease in FFA levels in both lean and obese ZR after 30 d of DHEA treatment. This decrease is slight; however, it may reflect the specific alterations that we observed in serum PL FA profiles.

DHEA-related alterations in serum PL FA profiles may be a reflection of specific tissue changes. This study shows significant phenotypic FA profile differences in each of the four serum lipid fractions measured. Some of the DHEA-induced changes may be reflected as accumulation of elongation end products. For example, adrenic acid is an end product of arachidonic acid. Subsequently, when serum proportions of arachidonic acid increase, there is a proportional increase in adrenic acid.

As mentioned earlier, FA profiles and levels can be related to diseases associated with the obese state. For example, several investigators have shown that palmitic acid potentiates glucose-induced insulin release (32–34). Our study shows that palmitic acid is proportionally greater in the serum FFA, TG FA, and CE FA lipid fractions of obese compared to lean ZR. Other studies suggest that increased CE oleic acid strongly correlates with high FFA levels and possibly IR development (21,35). CE was the only serum lipid fraction whose proportion of oleic acid was significantly greater in obese compared to lean ZR.

Although the significance of these FA alterations in the development of IR is not known, corresponding FA alterations in insulin-sensitive tissue may reflect a mechanism by which IR is decreased with DHEA treatment. This study does not measure IR. Therefore, any discussion of a DHEA effect on IR is only speculative.

In our study, liver TL content is much greater in obese compared to lean ZR. Table 2 shows that TL liver content significantly decreases after 30 d of DHEA treatment in both lean and obese rats. Moreover, several DHEA-related changes are noted in the liver PL and TG FA fractions. These changes may be related to DHEA-induced changes in hepatic stearoyl-CoA desaturase reported by Imani *et al*. (36). This would explain the selective proportional elevation that we observed in liver TG oleic acid (18:1).

DHEA is a known peroxisome proliferator in hepatic tissue (37). Hepatic peroxisomal proliferation is accompanied by hepatomegaly, resulting from hyperplasia and hypertrophy (38). This may explain the increased liver weights observed in lean and obese rats after 30 d of DHEA treatment (Table 2). Because FA, specifically arachidonic acid (20:4), also have been shown to induce peroxisome proliferation (38), perhaps the DHEA-induced FA alterations observed in this study favor increased peroxisomal proliferation.

Our study suggests that adipose tissue FA profiles are phenotype specific and, within each phenotype, are nearly identi-

cal for MAT, RPAT, and SQAT. If the speculation is true that DHEA alters peroxisomal activation indirectly by increasing proportions of 20:4, then the same speculation for adipose tissue is not likely. First, adipose tissue contains very few FA greater than 18 carbons long. Second, because DHEA did not proportionately alter any adipose tissue FA, a corresponding mechanism utilizing different FA to activate adipose peroxisomes is not likely. Furthermore, the rate of adipose FA turnover is not as rapid as in other tissue. Therefore, 30 d of DHEA treatment may not be long enough to demonstrate FA profile alterations in adipose tissue. Such changes occurring within 30 d of DHEA treatment seem to be better observed in serum and in hepatic tissue than in adipose tissue.

The results of this study show that there are marked FA profile differences between lean and obese ZR and that DHEA has multiple effects on FA profiles of several tissues. These FA profile alterations are changed consistently in both phenotypes. If FA profiles are phenotypically specific between lean and obese ZR, then DHEA's ability to alter FA profiles needs further investigation. Further studies may provide a better understanding and elucidate a mechanism to link DHEA-induced FA profile alterations to metabolic differences between lean and obese ZR.

ABSTRACT: Earlier work has shown that increasing concentration of palmitic acid at the *sn*-2 position of a fat enhances the atherogenic properties of that fat. This effect has been observed with lard, tallow, cottonseed oil, and palm oil. In the experiment reported here, we have studied the atherogenic effects of four synthetic fats fed to rabbits as 58% (w/w) of the total fat (15%) (w/w) of a semipurified diet containing 0.05% cholesterol. The fats being tested were: 1,3-stearoyl-2-oleoylglycerol (SOS); 1,2-stearoyl-3-oleoylglycerol (SSO); 1,3-palmitoyl-2-oleoylglycerol (POP); and 1,2-palmitoyl-3-oleoylglycerol (PPO). After 20 wk on diet there were no differences among the groups in weight gain, liver weight, serum, or liver lipids. These data are consistent with our previous findings. There were significant differences in atherosclerosis. The most severe atherosclerosis was observed in group PPO and the least in groups SSO and POP. Severity of atherosclerosis was graded visually on a 0–4 scale. The average atherosclerosis [(aortic arch and thoracic aorta) ÷ 2] was: SOS—1.35; SSO—0.97; POP—0.83; and PPO—1.80. Fecal fat excretion (an indicator of fat absorption) was higher in the two groups fed the stearic acid-rich fats and lower in groups fed the palmitic acid-rich fats. There were no differences in low density lipoprotein particle size. The results confirm previous findings concerning the increased atherogenicity of fats bearing palmitic acid at the *sn*-2 position. The mechanism underlying these observations is moot but may, in part, reflect greater absorption of the atherogenic fat.

Paper no. L8422 in *Lipids 35,* 621–625 (June 2000).

We have observed in the course of studies of atherogenesis in rabbits that the atherogenicity of fats appears to be, in part, a function of the level of palmitic acid (16:0) present at the *sn*-2 position. Thus, lard, which contains 21.4% 16:0 of which 98% is at *sn*-2, is 51% more atherogenic than randomized lard, which contains 21.4% 16:0 only 7.6% of which is at *sn*-2 (1); tallow, which contains 24.8% 16:0 of which 3.8% is at *sn*-2, is 9% less atherogenic than randomized tallow, which contains 24.8% 16:0 of which 8.5% is at *sn*-2 (1); cottonseed oil, which contains 25% 16:0 of which 1.7% is at *sn*-2, is 66% less atherogenic than randomized cottonseed oil (9.9% at *sn*-2) (2); and palm oil, which contains 41.2% 16:0 of which 2.6% is at *sn*-2, is 24% less atherogenic than randomized palm oil (13.6% 16:0 at *sn*-2) (3). The atherogenic, semipurified diets used in the studies cited here contained between 0.1 and 0.4% cholesterol.

The present study involves the use of synthetic triglycerides, namely, 1,3-stearoyl-2-oleoylglycerol (SOS), 1,2-distearoyl-3-oleoylglycerol (SSO), 1,3-dipalmitoyl-2-oleoylglycerol (POP), and 1,2-dipalmitoyl-3-oleoylglycerol (PPO). Comparison of the atherogenic effects of these four fats when fed as part of an atherogenic, semisynthetic diet is the subject of this report.

MATERIALS AND METHODS

Male New Zealand White rabbits were used. The rabbits were housed individually in stainless steel cages in an air-conditioned, humidified room maintained on a 12-h on–off light schedule. Rabbits were allowed free access to water and food. The rabbits were obtained as weanlings and placed on an adaptation diet (Tables 1 and 2). The purpose of the adaptation diet was to ensure that the starting serum cholesterol lev-

els of all the rabbits would be in the same range. The diet was intended to cull out hyper- or hyporesponders. After 2 wk the rabbits were randomized into four groups of 10 animals each. Each group had the same average serum cholesterol level. The rabbits were then placed on semipurified diets (Table 3) containing 0.05% cholesterol and 15% fat of which 58% was one of the special test fats, 24% was sunflower oil, and 18% was oleic acid-rich safflower oil. SOS was fractionated from the stearate fraction of shea nut oil. SSO was obtained by enzymatic rearrangement (interesterification) of fully hydrogenated sunflower seed oil with high-oleic sunflower seed oil fatty acids. POP was obtained from regular palm oil midfraction, and PPO was obtained by fractionation of the product obtained after enzymic rearrangement of a palm oil stearate fraction with high-oleic sunflower seed oil fatty acids. The fatty acid composition of the test diets is given in Table 4. Diets were prepared to our specifications and pelletted by Dyets, Inc. (Bethlehem, PA). The rabbits were maintained on the special diets for 20 wk and were weighed and their serum cholesterols were determined every 5 wk. After 20 wk, rabbits were bled under light barbiturate anesthesia and killed by exsanguination. Serum total cholesterol, high density lipoprotein (HDL) cholesterol, and triglycerides were determined using appropriate kits (Sigma, St. Louis, MO).

Livers were weighed, washed and aliquots were extracted with chloroform/methanol 2:1 (4). The lipid extract was analyzed for free and total cholesterol (5) and triglycerides (6). Aortas were cleaned of adhering tissue, opened longitudinally, and severity of atherosclerosis was graded visually on a 0–4 scale (7). The molecular diameters of the low density lipoproteins (LDL) were carried out using the method of Krauss and Burke (8). Briefly, nondenaturing polyacrylamide gradient gel electrophoresis of whole plasma was performed at 10°C by using 2–16% polyacrylamide gradient gels for 24 h at 125 V in Tris (0.09 M)/boric acid (0.08 M)/Na_2EDTA (0.003 M) buffer (pH 8.3). Gels were fixed and stained for lipids in a solution containing oil red 0 in 60% ethanol at 55°C. Gels were scanned at 530 nm with a transidyne densitometer. Migration distance for each absorbance peak was determined, and the molecular diameter corresponding to each

[a]SOS = 1,3-distearoyl-2-oleoylglycerol; SSO = 1,2-distearoyl-3-oleoylglycerol; POP = 1,3-dipalmitoyl-2-oleoylglycerol; PPO = 1,2-dipalmitoyl-3-oleoylglycerol. Boxed values represent predominant fatty acids in the particular fats.

peak was calculated from a calibration curve generated from the migration distance of protein standards of known diameter, which included carboxylated latex beads (Duke Scientific, Palo Alto, CA), thyroglobulin, and apoferritin (HMW Std; Pharmacia, Piscataway, NJ) with molecular diameters of 380, 170, and 122 Å, respectively, and lipoprotein calibrators of previously determined particle size. The precise methodology, including staining for proteins, has been described by Nichols *et al*. (9). For extraction of fecal fat, feces were collected for 3 d after the rabbits had been on the diets for 10 wk. The feces were dried in an oven at 100°C and pulverized. Aliquots (1 g) of the dry fecal powder were slurried with 10 mL water containing 1 mL of concentrated HCl. Each slurry was extracted with 20 mL of chloroform/methanol 1:1 by vigorous stirring on a magnetic stirrer for 6 h. The chloroform layer was separated, washed with saline, dried over anhydrous Na_2SO_4, and an aliquot was taken to dryness under N_2 and weighed.

All experimental procedures were approved by the Wistar Institutional Animal Care and Use Committee.

RESULTS

Forty weanling male New Zealand White rabbits were fed an adaptation diet containing 0.05% cholesterol for 2 wk (Table 1). At 2 wk the average weight (±SE) of all the rabbits was 842 ± 65 g. The average serum cholesterol level was 4.93 ± 0.01 mmol/L, and the average triglyceride level was 1.24 ± 0.08 mmol/L. The rabbits were randomized to four groups of 10 each of approximately similar weight and serum cholesterol. They were then placed on the four test diets (Table 2) containing 15% fat. The test fats represented 58% of the total fat or 8.7% of the diet. The rabbits were weighed and bled under light anesthesia every 5 wk (weeks 5, 10, 15 in Table 5). All four groups gained weight—1.42 kg for group SOS, 1.30 kg for group SSO, 1.23 kg for group POP, and 1.14 kg for group PPO. Serum cholesterol levels rose significantly in all four groups in the first 5 wk; at 10 wk serum cholesterol levels had plateaued and they fell at week 15, but not significantly. The drop in serum cholesterol levels between weeks 10 and 15 was 30% in group SOS, 21% in group SSO, 22% in group POP, and 32% in group PPO. Between week 0 and 15, triglyceride levels fell in group SOS (by 32%), were unchanged in group SSO, and rose by 32 and 61%, respectively, in groups POP and PPO; none of the changes was statistically significant. After 20 wk on the diet the rabbits were weighed, bled, and exsanguinated under heavy anesthesia. The results are summarized in Table 6. At week 20 there were no differences in weight gain or in actual or relative liver weight. All the rabbits had lost weight in the last 5 wk of the experiment. Serum cholesterol levels had risen between weeks 15 and 20, and while none of the changes were significant, the percentage increase was 44.5% in group SOS, 21.6% in group SSO, 3.2% in group POP, and 32.0% in group PPO. There were no significant differences between the serum cholesterol levels in the four groups. The percentage of HDL cholesterol was also similar for all groups. Serum triglyceride levels were all lower than they had been at week 15, but there were no differences among the groups. Liver total cholesterol, percentage esterified cholesterol, and triglycerides were virtually identical among the groups. Average total liver cholesterol was 3.03 ± 0.01 mmol/100 g, esterified cholesterol was 63.8 ± 0.8%, and liver triglyceride was 0.86 ± 0.01 mmol/100 g.

LDL particle size (angstroms) was the same in all four groups, namely: SOS, 283.3 ± 3.23; SSO, 285.2 ± 3.37; POP, 283.4 ± 2.89; and PPO, 279.8 ± 1.88. Fecal fat, determined after 10 wk of feeding, was: SOS, 47 ± 4 mg/g feces; SSO, 38 ± 3 mg/g feces; POP, 28 ± 3 mg/g feces; and PPO, 23 ± 2 mg/g feces.

Severity of atherosclerosis was not significantly different

between the two groups fed the stearic acid-rich triglycerides. In the rabbits fed the palmitic acid-rich triglycerides, the severity of atherosclerosis in the group fed PPO was significantly greater in both the aortic arch and thoracic aorta [both $P < 0.05$ by analysis of variance (ANOVA)]. Of all four groups, severity of atherosclerosis was greatest in the PPO group. Comparison by ANOVA of aortic atherosclerosis in group PPO vs. the other groups showed it to be significantly higher ($P < 0.017$). The same test for the thoracic aorta was not significant.

DISCUSSION

In this study we tested the atherogenic effects of specific fatty acids present at the *sn*-2 position of a dietary triglyceride. Comparison of SOS and SSO showed no significant difference in atherogenicity. Comparison of the palmitic acid-containing fats showed PPO to be significantly more atherogenic than POP ($P < 0.05$). This comparison confirms results obtained with lard and tallow (1), cottonseed oil (2), and palm oil (3) and shows that increasing the proportion of palmitic acid present at *sn*-2 of a triglyceride enhances the atherogenicity of that triglyceride. The mechanism underlying these observations remains moot, but there are several possibilities. Serum cholesterol levels are unaffected in rabbits fed native or randomized fats. Studies in rats have shown that serum lipids are unaffected when the animals are fed native or randomized peanut oil (10), fish oil (10), or palm oil (11). In human subjects Zock *et al*. (12) also found no difference in cholesterol levels between probands fed native or randomized fat. Nelson and Innis (13) compared cholesterol levels in human infants fed a standard formula containing 27.2% palmitic acid (5.0% at *sn*-2), a formula containing a synthetic triglyceride (24.8% palmitic acid, 29.1% at *sn*-2), or breast milk (23.1% palmitic acid, 56.4% at *sn*-2). Breast milk-fed infants had significantly higher cholesterol levels after 30 or 120 d, but cholesterol levels in the groups fed either standard or special formulas were the same. In our study of native and randomized cottonseed oil (2), we hypothesized that the LDL derived from the two fats might be of different sizes; this was found not to be the case. In this present study LDL particle size was also the same in all four dietary groups.

Studies in human infants (14–16) and rats (17,18) have indicated that fats containing palmitic acid at the *sn*-2 position are absorbed more completely than other fats. Increased absorption was indicated by decreased fecal excretion of fat. After the rabbits in this study had been on the various diets for 10 wk, we determined the level of fat excretion by group. Fat excretion was higher in the two groups fed the stearic acid-rich fats than in those fed the palmitic acid-rich fats. The rabbits fed the 2-oleoyl glycerides excreted more fat than their counterparts whose diets contained 16:0 or 18:0 in that position.

Redgrave *et al*. (19) reported that the structure of a triglyceride affected its removal from the circulation of rats, that rate being slower when saturated fatty acids were present at the *sn*-2 position. However, a more recent study (20) showed no clear pattern of lipolysis as a function of triglyceride structure. Generally, the authors concluded that a saturated fatty acid at *sn*-2 does not affect lipolysis, but rather the specific arrangement of acyl chains is important. Still, in their hands SOS was lipolyzed more rapidly than SSO, whereas the reverse was true with POP and PPO. A mechanism to explain the consistent observations relating to the atherogenic effects of 2-palmitoyltriglycerides cannot be based on either plasma or liver lipids or on LDL size since they do not differ. Martins *et al*. (21) have studied the effects of particle size and number on plasma clearance of chylomicrons and lipoprotein remnants and conclude that particle number is more important than particle size. Clearance was significantly decreased

when there were increased numbers of particles. The more efficient absorption of triglycerides bearing palmitic acid at *sn*-2 may reduce clearance time, thus increasing contact between lipid-bearing lipoproteins and the vessel wall. The increased absorption of the triglycerides in question suggests a mass effect, i.e., the tissues are exposed to greater concentrations of the fat over a given time. Differences in catabolic rate or tissue uptake may also have an effect, but there are no data relating to such effects in rabbits.

The study described above confirms again the increased atherogenicity of fats bearing palmitic acid at the *sn*-2 position.

ACKNOWLEDGMENTS

ABSTRACT: L-Carnitine plays an important role in the mitochondrial uptake of long-chain fatty acids in mammals. It has recently been shown that this compound has a marked hypo-cholesterolemic effect when used in conjunction with lipid-rich diets. The aim of this study was to investigate the effects of L-carnitine on the fatty acid composition of plasma lipoproteins in rabbits fed with different diets. Four different groups were investigated: group I (standard diet), group II (standard diet supplemented with L-carnitine at 80 mg/kg), group III (standard diet supplemented with 0.5% cholesterol), and group IV (standard diet supplemented with 0.5% cholesterol plus L-carnitine at 80 mg/kg). The feeding period was 126 d. Total plasma cholesterol was indistinguishable in groups I and II, but increased nearly 40-fold in group III. This increment was reduced by 50% in group IV. Correspondingly, total cholesterol content in lipoprotein fractions [very low density lipoprotein (VLDL), low density lipoprotein (LDL), high density lipoprotein (HDL) separated by agarose gel chromatography was the same for groups I and II, while for animals fed a cholesterol-rich diet (III) total cholesterol in VLDL + LDL increased nearly 100-fold when compared with groups I and II but, again, the increment was reduced by 50% in group IV. In contrast, total cholesterol in HDL increased only fivefold for both groups III and IV when compared with groups I and II, indicating no effects of L-carnitine on this parameter. The reduction of total cholesterol in VLDL + LDL particles in animals fed a cholesterol-rich diet plus L-carnitine was associated with a marked decrease in the ratio of cholesteryl ester to free cholesterol and a dramatic increase in their phospholipid content; opposite effects were observed for HDL. L-Carnitine induced a marked decrease in the saturated to unsaturated $C_{16} + C_{18}$ fatty acid ratio in cholesteryl esters associated with VLDL and LDL from animals fed with both normal and cholesterol-rich diets. The opposite effect (a large increase in the saturated to unsaturated fatty acid ratio) was observed for both cholesteryl esters and phospholipids associated with HDL in animals fed with both diets. The results suggested that the hypocholesterolemic effects of L-carnitine could be associated with increased systemic breakdown of cholesteryl esters, a probable increase in reverse cholesterol transport, and the stabilization of a phospholipid-based structure of VLDL + LDL particles.

Paper no. L8292 in *Lipids 35*, 627–632 (June 2000).

L-Carnitine (β-hydroxy-γ-trimethylamino butyrate) is a conditionally essential nutrient for humans (1) and animals (2). Among other cellular functions, this compound has been associated with the uptake of long-chain fatty acids by mitochondria, where they are utilized in energy-yielding processes, and with the removal of short- and medium-chain fatty acids that accumulate as a result of normal and abnormal metabolism (3–5). Additionally, L-carnitine has been reported as a hypolipidemic drug, capable of reducing the circulating levels of cholesterol, triglycerides, free fatty acids, phospholipids, and very low density lipoproteins (VLDL) and increasing the levels of high, intermediate, and low density lipoproteins (HDL, IDL, LDL, respectively; refs. 6–9). However, other reports indicated that this compound was unable to modify plasmatic levels of total cholesterol and LDL and that the levels of HDL were only reduced after cessation of therapy (6,10,11). Mondola *et al.* (12) reported that L-carnitine was able to restore normal plasma levels of cholesterol and patterns of lipoproteins in rats nourished with a high cholesterol diet. Further, Bell *et al.* (13) reported that administration of L-carnitine modified the chemical composition of lipoproteins, both *in vitro* and *in vivo*, and also modulated hepatic lipogenesis from oleate and mevalonate.

On the other hand, it has been found that nutritional or pharmacological intervention with L-carnitine or its esters may be beneficial for infants and children with various clinical conditions associated with low circulating L-carnitine levels and in some chronic diseases associated with aging such as cardiovascular disease and Alzheimer's disease.

The plasma lipid-lowering effects of L-carnitine have been associated with several possible processes, including increase in whole body cholesterol turnover due to increased biliary excretion, increased conversion of cholesterol to bile acids, or repartitioning of whole body cholesterol (13); however, very little is known on the molecular basis of such processes. The purpose of the present study was to examine the compo-

sitional changes induced by L-carnitine treatment in plasma lipoproteins of rabbits subject to both normal and cholesterol-rich diets.

MATERIALS AND METHODS

Male New Zealand rabbits (2.5–3 kg) were used in all experiments. Animals were fed with 100 g of basic rabbit chow per day (Alimentos Protinal, Valencia, Venezuela) and water *ad libitum*. The cholesterol-rich diet consisted of the basal diet supplemented with 0.5% (wt/wt) cholesterol (Sigma-Aldrich Chemical Company, St. Louis, MO; >95% purity) dissolved at 5% (wt/vol) in corn oil, which contained 15% saturated fatty acids and 85% unsaturated acids (Mazeite, Refinadora de Maiz Venezolana, Aragua, Venezuela). L-Carnitine (Laboratorios Elmor, S.A., Caracas, Venezuela, >95%) was given by gavage, using a stainless steel cannula. The experimental protocols used in the present study conformed to accepted standards, defined by the Bioethics Commission of the Institute Venezolano de Investigaciones Científicas.

After an initial adaptation period, rabbits were randomized and separated into four groups: group I (normal diet), 6 animals; group II (normal diet supplemented with L-carnitine at 80 mg/kg), 6 animals; group III (cholesterol-rich diet), 6 animals; and group IV (cholesterol-rich diet supplemented with L-carnitine at 80 mg/kg). Feeding was carried out for 126 d.

Blood samples were taken at day 0 from marginal ear veins and at day 126 by cardiac puncture; EDTA was used as anticoagulant, at a final concentration of 4 mM. Blood cells were removed by centrifugation at 2000 × *g* for 20 min and plasma from the six rabbits of each group was pooled for subsequent analysis. Lipoprotein fractions were isolated sequentially by centrifugation through KBr gradients as described by Camejo *et al.* (14); solid KBr was used to obtain the desired densities. The isolated fractions were dialyzed exhaustively against phosphate buffer (0.2 M monobasic sodium phosphate, 0.2 M dibasic sodium phosphate, 0.16 M sodium chloride, pH 7.4) and stored at 2ºC until further use. Final purification was achieved by agarose gel electrophoresis (14).

Analysis of lipid components of lipoprotein fractions was carried out using the following methods: Bowman and Wolf (15) for the determination of cholesterol and its esters, after separation by thin-layer chromatography (TLC); Biggs *et al.* (16) for the determination of tryglycerides; Beveridge and Johnson (17) for phospholipids; and Schacterle and Pollack (18) for proteins.

For gas–liquid chromatographic (CLC) analysis of fatty acids esterified to different components, methyl ester derivatives were first prepared by transesterification as described (19), after separation of phospholipids and cholesteryl esters by TLC (20). Methyl esters were separated in a 180-cm fused-silica column (2 mm i.d.), packed with 10% Silar 10C, coated with 30–200 mesh Diatoport S. The analyses were carried out in a Varian 3700 gas chromatograph, equipped with a flame-ionization detector and a digital PerkinElmer integrator. Helium was used as carrier gas (1.9 mL/min) and nitrogen as makeup gas. The temperature was programmed from 145 to 245ºC at 4ºC/min. External fatty acid standards (Sigma-Aldrich Chemical Company) were used to identify components.

All data are expressed as means ± standard deviations; when applicable Wilcoxon or Mann-Whitney tests were used to determine statistical significance.

RESULTS AND DICUSSION

Figure 1 shows the effect of L-carnitine administration (80 mg/kg) on total plasma levels of cholesterol in normal and cholesterol-fed rabbits (126 d of feeding). L-Carnitine had no significant effects on plasma cholesterol levels of animals that received normal diet (groups I and II). Animals fed with the atherogenic diet alone (group III) responded with marked (>40-fold) increase in plasma cholesterol levels, but this increment was reduced by 50% in group IV ($P = 0.0065$). The total cholesterol levels in lipoprotein fractions, separated by agarose gel electrophoresis, for the different experimental groups are presented in Table 1. In agreement with the results from total serum cholesterol, the cholesterol load in VLDL, LDL, and HDL from animals fed with normal diets was not altered by L-carnitine supplementation. In cholesterol-fed animals (group III), VLDL and LDL appeared as a single fraction, as reported before (14), and there was a great (>100-fold) increase in their cholesterol content after 126 d of feeding, when compared with groups I and II. For group IV (cholesterol-fed supplemented with L-carnitine) the increase in cholesterol levels was about 50% of that observed in group III ($P = 0.0065$). In contrast, the cholesterol load in HDL increased only five fold in both groups III and IV, when compared with I and II, indicating no effect of L-carnitine supplementation in this parameter. The dose of L-carnitine used in the present study (80 mg/kg·d) has been employed previously

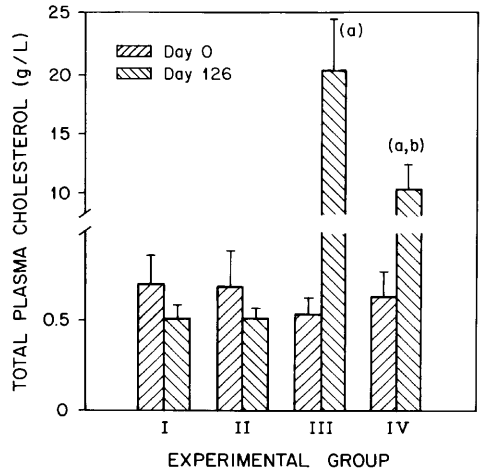

FIG. 1. Effects of L-carnitine on total plasma cholesterol levels in rabbits fed with normal and high cholesterol diets. in humans, without adverse effects, for the treatment of different primary or secondary disturbances of the levels of this important metabolic component (21). Additionally, L-carnitine at the same level has been reported as a cholesterol- and triglyceride-lowering agent in both humans and experimental animals (11,12,22,23), although its mechanism of action was not established. On the other hand, dietary supplementation with L-carnitine at 40 mg/kg led to rapid elevation of plasma and hepatic carnitine levels, without effects on total serum cholesterol levels (13). In our studies we confirmed that L-carnitine at the high dose level (80 mg/kg) leads to a marked and statistically significant reduction in total plasma cholesterol and the cholesterol load of all serum lipoproteins in hypercholesterolemic animals but has no significant effects on total plasma cholesterol in animals that receive normal diets and have normal cholesterol levels.

Detailed chemical analyses of isolated lipoprotein fractions from the different experimental groups were carried out from a pool of sera for each group and are presented as absolute concentration and percent composition in Tables 2 and 3. Only minor differences in the percent composition were observed as a result of L-carnitine supplementation in animals fed with a normal diet (Table 2), except for a probably significant (*ca.* threefold) reduction of the level of triglycerides associated with HDL, with a concomitant increase in phospholipids. In hypercholesterolemic animals (group III, Table 3) both the absolute and percent cholesterol content increased markedly in VLDL + LDL particles when compared with groups I and II (see Table 2), but there was a marked reduction of this parameter as consequence of L-carnitine supplementation (group IV, Table III). These differences are most probably significant, as they correspond to the statistically significant effects observed in total serum cholesterol level and lipoprotein cholesterol load (Fig. 1 and Table 1). The reduction in cholesterol content of VLDL + LDL as a consequence of L-carnitine supplementation was also associated with a three fold reduction in the percentage of esterified cholesterol and a concomitant increase in free cholesterol (FC; see Table 3). Although the relative content of triglycerides in VLDL + LDL particles of cholesterol-fed animals decreased, its absolute value increased *ca.* threefold (probably associated with the corn oil carrier), but this increment was again reduced by half as consequence of L-carnitine supplementation (Table 3). There was also a remarkable (>50-fold) increase in the relative phospholipid content of VLDL + LDL particles associated with L-carnitine supplementation, which suggested important structural modifications in these lipoproteic particles. Finally, the relative cholesterol content of HDL

particles also increased in cholesterol-fed animals, and L-carnitine supplementation led to a reduction of this parameter, mostly associated with a drop in both the absolute and relative content of FC.

These concerted compositional changes could be explained by an increased peripheral and hepatic breakdown of cholesterol esters (CE) from VLDL + LDL as a consequence of L-carnitine-induced catabolism of fatty acids (3,21), combined with transfer of CE from VLDL + LDL to HDL, probably mediated by cholesteryl ester transfer protein (see Refs. 24,25), leading to increased cholesterol reverse transport and excretion (26,27). The compositional changes of HDL in hypercholesterolemic animals treated with L-carnitine could also suggest activation of lecithin-cholesterol acyl transferase (LCAT). An increase in the activity of hepatic acyl-CoA cholesterol acyl transferase (ACAT) has been observed in rabbits given a hyperlipidemic diet along with L-carnitine (9). It has been postulated that ACAT must first be stimulated by exogenous cholesterol before a stimulatory effect by L-carnitine can take place (13,28); a similar effect on LCAT could explain the differential effects of L-carnitine supplementation on HDL composition of normo- and hypercholesterolemic animals (Tables 2 and 3).

The $C_{16} + C_{18}$ fatty acid composition of cholesteryl esters associated with lipoproteins in different experimental groups is presented in Tables 4–6. These fatty acids constituted >70% of total fatty acids, the rest being a variable mixture of long-chain polyunsaturated acids. In both normal and cholesterol-fed animals L-carnitine supplementation led to a large increase in the saturated ($C_{16} + C_{18}$) to unsaturated ($C_{18:1} + C_{18:2}$) fatty acid ratio in association with cholesteryl esters (Table 4) and, to a lesser extent, with phospholipids (Table 5) associated with HDL. In contrast, L-carnitine supplementation was associated with a marked reduction in the ratio of saturated to unsaturated fatty acids of cholesteryl esters pres-

ent in VLDL and LDL in both normal and cholesterol-fed animals (Table 6). These fatty acid compositional changes could be associated with a preferential stimulation by L-carnitine of saturated fatty acid breakdown in peripheral tissues due to the specificity of the transesterifying enzymes of mitochondrial outer membranes (3). Although these effects were seen in both normo- and hypercholesterolemic rabbits they could be significant in terms of the reduction of the atherogenic potential of VLDL + LDL particles due to their increased unsaturated fatty acid and phospholipid content (29).

ABSTRACT: The protective effect of phenolic compounds from an olive oil extract, and of olive oils with (extra-virgin) and without (refined) phenolic components, on low density lipoprotein (LDL) oxidation was investigated. When added to isolated LDL, phenolics [0.025–0.3 mg/L caffeic acid equivalents (CAE)] increased the lag time of conjugated diene formation after copper-mediated LDL oxidation in a concentration-dependent manner. Concentrations of phenolics greater than 20 mg/L inhibited formation of thiobarbituric-acid reactive substances after AAPH-initiated LDL oxidation. LDL isolated from plasma after preincubation with phenolics (25–160 mg/L CAE) showed a concentration-dependent increase in the lag time of conjugated diene formation after copper-mediated LDL oxidation. Refined olive oil (0 mg/L CAE) and extra-virgin olive oil (0.1 and 0.3 mg/L CAE) added to isolated LDL caused an increase in the lag time of conjugated diene formation after copper-mediated LDL oxidation that was related to olive oil phenolic content. Multiple regression analysis showed that phenolics were significantly associated with the increase in lag time after adjustment for effects of other antioxidants; α-tocopherol also achieved a statistically significant effect. These results indicate that olive oil phenolic compounds protect LDL against peroxyl radical-dependent and metal-induced oxidation *in vitro* and could associate with LDL after their incubation with plasma. Both types of olive oil protect LDL from oxidation. Olive oil containing phenolics, however, shows more antioxidant effect on LDL oxidation than refined olive oil.

Paper no. L8314 in *Lipids 35,* 633–638 (June 2000).

Coronary heart disease (CHD) is the main cause of mortality in industrialized countries, with the Mediterranean area having the lowest CHD mortality rate (1). A Mediterranean diet has been shown to be effective in secondary prevention of CHD endpoints such as death and reinfarction (2). The lower incidence of CHD in Mediterranean countries has been attributed to a diet rich in fruits, vegetables, legumes, and grains, the major fat component of which is olive oil. These foods contain natural antioxidants that can prevent low density lipoprotein (LDL) oxidation (3).

There is evidence that oxidation of LDL by free radicals plays a significant role in the development of atherosclerosis (4). In some human and animal dietary studies, oleic acid-rich diets have been shown to reduce LDL susceptibility to oxidation (5–7). Studies on olive oil as a protective factor against atherosclerosis have focused mainly on the role of oleic acid. However, the nonsaponifiable fraction of extra-virgin olive oil, which is obtained from the first pressing of the olive fruit, is rich in phenolic compounds that have strong antioxidant properties (8,9). Phenolic compounds isolated from olive oil such as phenolic acids (10), resveratrol (11), and hydroxytyrosol (12) have antioxidant properties *in vitro*. Some flavonoids (13,14) and catechins (15) also have antioxidant properties *in vivo*. Olive oil contains other antioxidant compounds such as α-tocopherol and, in small amounts, β-carotene.

Phenolic compounds are removed in the olive oil refining processes. However, unlike other oils, extra-virgin olive oil of high quality is consumed directly without further refining. In this study we examined antioxidant activity of different olive oils against *in vitro* LDL oxidation to determine whether a protective effect correlates with their phenolic content. Our study also investigated whether phenolic compounds extracted from olive oil could be incorporated into lipophilic LDL particles after their incubation with plasma.

MATERIALS AND METHODS

Materials and chemicals. The fatty acid compositions of refined and extra-virgin olive oils were determined by gas chromatography, and α-tocopherol and β-carotene contents in olive oils were determined by high-performance liquid chromatography (HPLC) as previously described (16–18). Total phenolic content of olive oils was measured by the Folin-Ciocalteau method (19). Measurement of phenolic compounds of

Abbreviations: AAPH, 2,2′-azobis(2-amidinopropane) dihydrochloride; ANOVA, analysis of variance; CAE, caffeic acid equivalents; CHD, coronary heart disease; HPLC, high-performance liquid chromatography; IC, inhibitory concentration; LDL, low density lipoprotein; MDA, malondialdehyde; MUFA, monounsaturated fatty acids; PBS, phosphate-buffered saline; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; TBARS, thiobarbituric acid-reactive substances.

extra-virgin olive oil was also performed by HPLC as previously described (20). Phenolics were extracted from extra-virgin olive oil by liquid–liquid extraction with 80% ethanol (21). Cupric sulfate, 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH), and 2-thiobarbituric acid were purchased from Sigma Chemical Co. (St. Louis, MO). All chemicals and organic solvents were of analytical grade.

LDL preparation and isolation. Blood from healthy volunteers was collected after an overnight fast in tubes containing 1 g/L EDTA. Plasma was separated by centrifugation at 1000 × *g* at 4ºC for 15 min. LDL isolation was performed by sequential flotation ultracentrifugation (22). Native LDL was dialyzed by molecular size exclusion chromatography in a G-25 Sephadex column (Pharmacia, Uppsala, Sweden), with 2.7 mL phosphate-buffered saline (PBS), 0.01 M, pH 7.4, under gravity feed at 4ºC. Protein content was determined by the red pyrogallol method (Sigma).

Copper-mediated LDL oxidation. To initiate oxidation, dialyzed LDL (0.05 g protein/L) was incubated with cupric sulfate (5 μM) in PBS at a final volume of 1 mL. Absorbance at 234 nm was continually monitored at 2-min intervals for 5 h at 35ºC (23) by using a spectrophotometer (Hewlett-Packard, Palo Alto, CA) fitted with a heater and equipped with a 7-position automatic sample changer.

AAPH-initiated LDL oxidation. To initiate oxidation, dialyzed LDL (0.10 g protein/L) was incubated with 10 mM AAPH in PBS plus 1 mM EDTA at 35ºC for 8 h at a final volume of 1 mL. Oxidation of LDL, quantified as the generation of malondialdehyde (MDA) equivalents, was measured by the thiobarbituric acid-reactive substances (TBARS) method as previously described for isolated LDL (24). TBARS formation was measured at intervals of 2 h.

Assays for antioxidant activity of phenolic compounds on LDL oxidation. Copper-mediated LDL oxidation was performed as just described in two separate experiments: (i) after addition to the isolated LDL of phenolic extracts containing from 0.025 to 0.3 mg/L (final concentration) caffeic acid equivalents (CAE). (ii) After plasma incubation with phenolic extracts containing from 25 to 160 mg CAE/L (0.09 to 0.58 mg CAE/mg LDL protein) (final concentration) for 3 h at 35ºC, followed by LDL isolation. The incubation of plasma with phenolics was performed with rotatory incubation in the dark to avoid antioxidant photodegradation.

AAPH-initiated oxidation was performed as described above with addition of phenolic extracts containing from 5 to 25 mg CAE/L (final concentration) to isolated LDL.

Assay for antioxidant activity of olive oils on LDL oxidation. Extra-virgin olive oil was diluted (1:10) with refined olive oil. Carefully weighed aliquots of refined (40 mg) and diluted extra-virgin olive oil (11 and 40 mg) were added to isolated LDL to produce phenolic concentrations of 0 mg CAE/L (refined) and 0.1 and 0.3 mg CAE/L (extra-virgin). LDL oxidation was performed as decribed above.

Statistical analysis. Linear and quadratic regression analyses were used to assess the relationship between continuous variables. One-way analysis of variance (ANOVA) followed by Dunnett's *t*-test was used for simultaneous, multiple comparisons between groups. Spearman's correlation test was employed to assess the association between two continuous variables. Multiple linear regression analysis was performed, with data of six experiments, to estimate the increase of lag time of conjugated diene formation associated with a 0.1 mg CAE/L concentration increase in olive oil. An adjustment by the concentrations of other antioxidants added to isolated LDL with the olive oils was performed. A criterion of $P < 0.1$ in simple associations was used to include variables in the model. $P < 0.05$ was considered statistically significant. These statistical analyses were performed using the SPSS statistical package (SPSS Inc. Co., Chicago, IL).

RESULTS

Olive oil analysis. The percentages of monounsaturated (MUFA), polyunsaturated (PUFA), and saturated fatty acids (SFA) were 73, 10, and 17% for extra-virgin and 74, 11, and 15% for refined olive oil, respectively. α-Tocopherol and β-carotene concentrations of each oil were 214 and 5.05 mg/kg for extra-virgin and 174 and <0.01 mg/kg for refined olive oil, respectively. The concentrations of phenolic compounds were 139 and 0 mg CAE/kg for extra-virgin and refined olive oil, respectively. Figure 1 is a chromatogram of the phenolic compounds present in the extra-virgin oil used in the assay. The percentages of phenolic compounds were as follows: Peak 1 (hydroxytyrosol), 1.7; Peak 2 (protocatechuic acid), 2.8; Peak 3 (tyrosol), 1.5; Peak 4 (vanillic acid), 0.5; Peaks 5, 6, and 7 (unidentified), 0.8, 2.6, and 0.8, respectively; Peak 8 (*m*-coumaric acid), 6.7; Peak 9 (oleuropeine), 0.7; Peak 10 (oleuropeine aglycone), 41.6; Peaks 11, 12, and 13 (unidentified), 14.7, 4.0, and 16.4 , respectively.

Effects of olive oil phenolic compounds on LDL oxidation. (i) Addition of phenolic extracts to isolated LDL. In copper-mediated LDL oxidation the addition of olive oil phenolics at concentrations ranging from 0.025 to 0.3 mg CAE/L increased ($P < 0.001$) the lag time before the formation of conjugated dienes in a concentration-dependent manner ($r^2 = 0.994$, $P < 0.0001$, linear regression) (Fig. 2). From extrapolation of the dose–response plot of percentage increase in lag phase, the concentrations of phenolic compounds required to cause 50 (IC_{50}) and 100% (IC_{100}) inhibition of the lag phase were established at 0.115 and 0.235 mg CAE/L, respectively. The generation of TBARS during AAPH-initiated LDL oxidation is shown in Figure 3. In control LDL, a significant increase in MDA equivalents ($P < 0.001$) was observed from 0 to 8 h. The same occurred with concentrations of 5 ($P < 0.01$) and 10 mg CAE/L ($P < 0.01$). The increase was maximal following 8 h of oxidation. When 15 mg CAE/L phenolic extract was added to isolated LDL, the increase in TBARS formation was significant ($P < 0.01$) only after more than 6 h of incubation. Concentrations of phenolics greater than or equal to 20 mg CAE/L inhibited TBARS formation in AAPH-initiated LDL oxidation ($P < 0.01$).

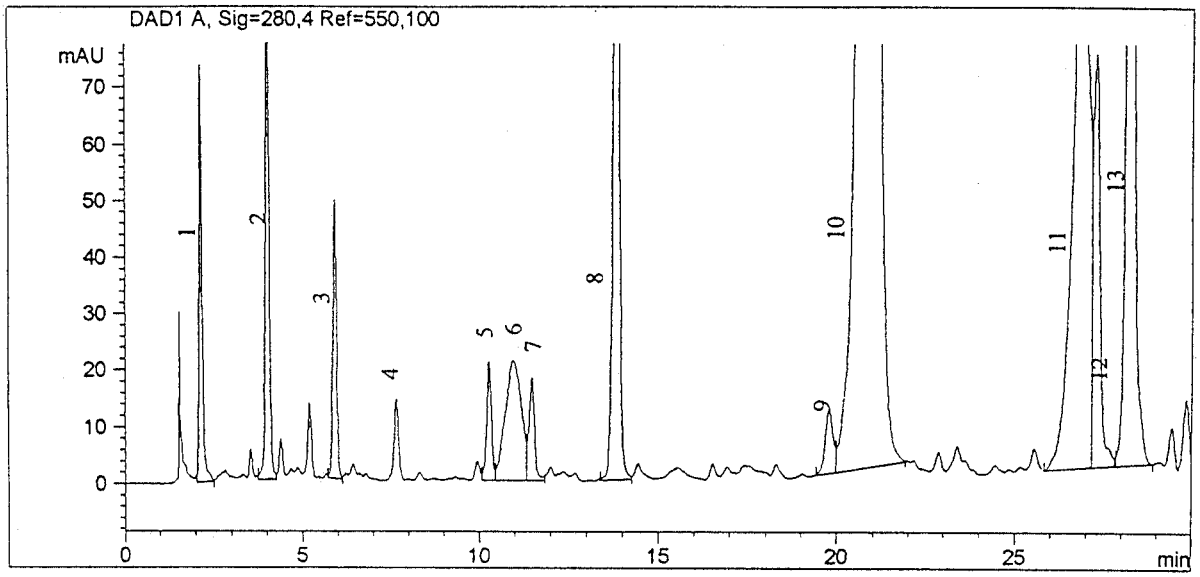

FIG. 1. High-performance liquid chromatogram showing the phenolic profile of extra-virgin olive oil. Peak numbers: (1) hydroxytyrosol; (2) protocatechuic acid; (3) tyrosol; (4) vanillic acid; (8) *m*-coumaric acid; (9) oleuropeine; (10) oleuropeine aglycone; (5–7) and (10–13) unidentified phenols.

(ii) Preincubation of phenolic extracts with plasma and subsequent LDL isolation. When copper-mediated oxidation of LDL that had been isolated from plasma following preincubation with olive oil phenolics (25 to 160 mg CAE/L; 0.09 to 0.58 mg CAE/mg LDL protein) was carried out, the lag time before conjugated diene formation increased ($P < 0.001$, ANOVA) in a phenol concentration-dependent manner ($r^2 = 0.995$, $P < 0.0001$, quadratic regression) (Fig. 2). From extrapolation of the dose–response plot of percentage increase in lag phase, IC_{50} and IC_{100} were established at 98.5 and 148 mg CAE/L, respectively.

Effect of olive oil on LDL oxidation. As shown in Figure 4 all olive oils increased the lag time of diene formation in comparison with the control in a phenol concentration-dependent manner ($P < 0.001$, ANOVA). When simple associations were performed, a positive correlation was obtained between lag time of conjugated diene formation and the concentrations of phenolics ($P = 0.001$), α-tocopherol ($P = 0.05$), and β-carotene ($P = 0.01$) added to isolated LDL. No associations between lag time and MUFA, PUFA, or SFA added to LDL were found. Results of multiple linear regression analysis (Table 1) showed that phenolics concentration was significantly ($P < 0.001$) associated with the increase in lag time of conjugated diene formation. The effects of α-tocopherol concentrations were of borderline significance ($P = 0.064$). The increase in lag time associated with an increase of 0.1 mg/L in phenolics concentration, adjusted for α-tocopherol and β-carotene, was 108 min (88–129 min, 95% confidence interval).

TABLE 1
Multiple Linear Regression Analysis of the Increase in the Lag Time of LDL Oxidation and of Antioxidant Compounds in Olive Oil[a]

Antioxidant	B (SE)	*P*
Phenolics	108 (9.8)	<0.001
α-Tocopherol	6.54 (3.0)	0.064
β-Carotene	—	—

DISCUSSION

Growing epidemiological evidence indicates that a Mediterranean diet has beneficial effects on diseases associated with oxidative damage such as CHD and cancer, and on aging (2,3,25). Olive oil (and its constituent antioxidant compounds) is one of the main components of the Mediterranean diet. Olive oil consumption has been associated with a lower coronary risk profile (26) and with a reduced breast-cancer risk (27). Besides antioxidant olive oil components, dietary MUFA are associated with lower risk of CHD (28). Also, the results of some large prospective studies have indicated that a high vitamin E intake is associated with lower CHD risk (29). Intake of flavonoids has been associated with a reduction in cardiovascular mortality in some epidemiological prospective studies (30). The effects of olive oil and its antioxidant compounds warrant evaluation since their presence in food may explain at least part of the benefits of the Mediterranean diet. Our experiments were designed to examine the effect of olive oils, with and without phenolic compounds, as well as the antioxidant activity of the entire phenolic content of an extra-virgin olive oil. The present study has confirmed *in vitro* the antioxidant activity of extra-virgin olive oil phenolic compounds in inhibiting LDL oxidation by copper- and AAPH-initiated systems.

The copper-catalyzed oxidation of LDL, isolated from plasma preincubated with olive oil phenolics, was also significantly inhibited. In this situation, only phenols that are on the surface of or within LDL particles can be responsible for

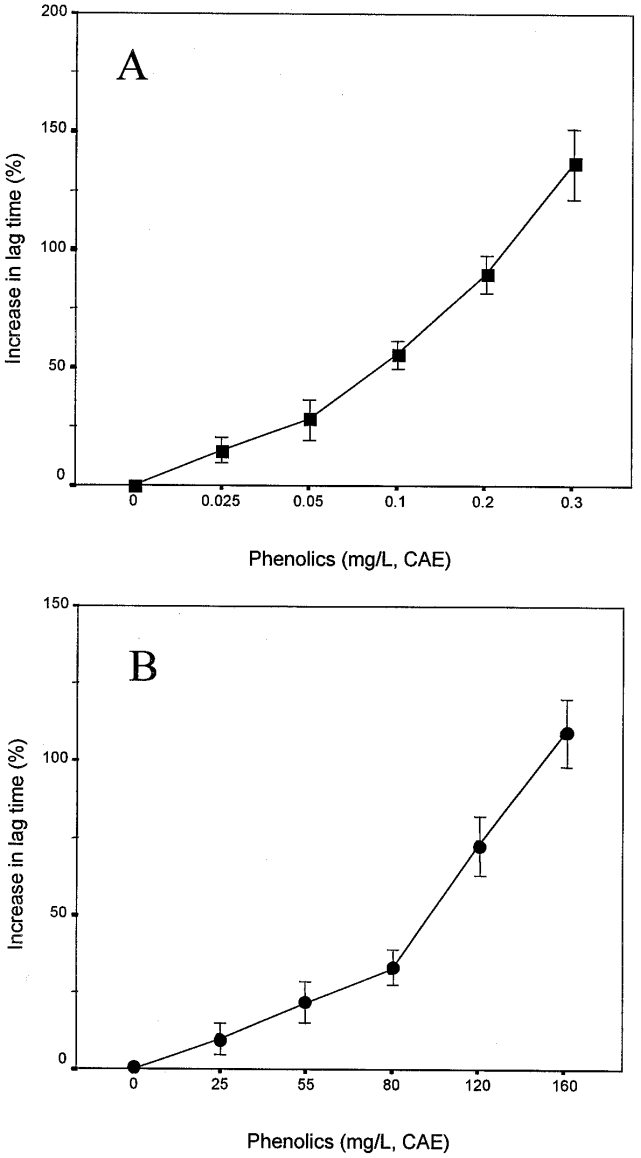

FIG. 2. Effect of the extra-virgin olive oil phenolics on the lag time of copper-mediated low density lipoprotein (LDL) oxidation. (A) Isolated LDL (0.05 g protein/L) was oxidized with 5 μM copper in the presence of indicated amounts of phenolic compounds (CAE, caffeic acid equivalents). (B) Plasma was incubated at 35°C for 3 h with indicated amounts of phenolic compounds; LDL was isolated from plasma and oxidation was performed. Each point represents the mean ± standard deviation of three experiments. For both experiments there was a significant ($P < 0.001$) relationship between the amount of phenolics added and the lag time of conjugated diene formation.

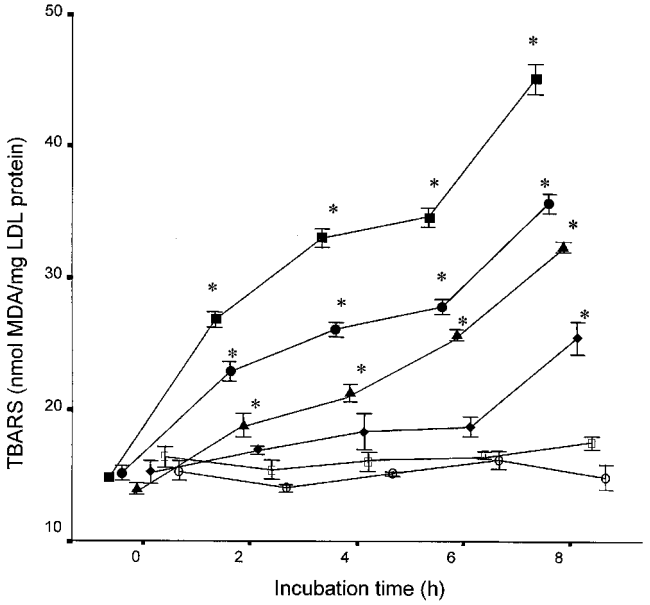

FIG. 3. Effect of extra-virgin olive oil phenolics on thiobarbituric acid-reactive substances (TBARS) generation following AAPH-initiated LDL oxidation. LD (0.10 g protein/L) was incubated with azo-compound (10 mM) at 35°C for up to 8 h in the presence of the indicated amounts of phenolic compounds expressed as CAE: (■) 0 mg/L (control); (●) 5 mg/L; (▲) 10 mg/L; (◆) 15 mg/L; (□) 20 mg/L; (○) 25 mg/L. TBARS formation was measured at intervals of 2 h. Each point represents the mean ± standard deviation of three experiments. *$P < 0.01$ compared with 0 h. MDA, malondialdehyde; for other abbreviations see Figure 2.

the inhibition of LDL oxidation. Preincubation of plasma with different doses of phenolic extract led to antioxidant activity against LDL oxidation that exhibited an exponential relationship to phenol concentration. This type of effect could relate to direct suppression by the phenolic compounds of the autocatalytic chain reaction of fatty acid peroxidation or to preservation of other chain-breaking antioxidants such as α-tocopherol (12).

The concentration of olive oil phenolics required to inhibit copper-mediated LDL oxidation when added directly to LDL *in vitro* (IC_{50} = 0.115 mg CAE/L; IC_{100}= 0.235 mg CAE/L) or following their preincubation with plasma (IC_{50} = 98.5 mg CAE/L; IC_{100}= 148 mg CAE/L) differs considerably. We es-

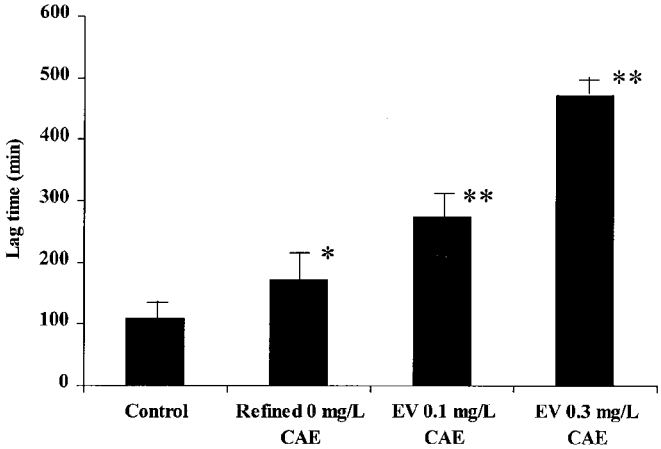

FIG. 4. Effect of olive oil on the lag time of copper-mediated LDL oxidation *in vitro.* LDL (0.05 g protein/L) was oxidized with 5 μM copper in the presence of refined olive oil and extra-virgin (EV) olive oil with indicated amounts of phenolic compounds, expressed as CAE. Bars represent the mean ± standard deviation of six experiments. There was a significant ($P < 0.001$) relationship between the amount of phenolics added and the lag time of conjugated diene formation. Asterisks indicate significant differences from control. *$P < 0.05$; **$P < 0.001$. For abbreviations see Figure 2.

timate in this last case that an 850- and a 650-fold greater concentration of olive oil phenols is required to cause a 50 and a 100% inhibition, respectively, in the lag time of conjugated diene formation. These results suggest that only a small fraction of the phenolic compounds in extra-virgin olive oil binds to LDL *in vitro*, as has been reported for other phenolic compounds. Ishikawa *et al*. (15) and Kerry and Abbey (31) recently published the results of experiments involving the preincubation of tea flavonoids (15) or red wine (31) with plasma. Concentrations of 93 mg/L of epigallocatechin gallate and 70 mg/L of red wine were required to achieve an inhibition of 50 and 60 % in conjugated diene formation, respectively.

The results from the preincubation of plasma with olive oil phenolic compounds indicated they could be incorporated into the LDL particles. The addition of olive oil phenolics to isolated LDL could be representative of the situation in plasma where phenolic compounds inhibit oxidation both in the aqueous medium and from within the lipoprotein. Plasma preincubation with olive oil phenolics after LDL isolation may be more like the situation in arterial intima, where lipoprotein oxidation appears to occur predominantly in microdomains sequestered from antioxidants present in plasma (4). Thus, olive oil phenols, in accordance with their amphipathic nature, may act both within the LDL particle and in the extraparticle environment of LDL.

Beside phenolic compounds, olive oil contains other compounds with antioxidant capacity. We examined the antioxidant capacity of olive oils with and without phenolic content. Although both olive oils protected LDL from oxidation, an increase in the antioxidant activity was observed with increasing concentration of phenolics. Refined olive oil, without detectable phenols, delayed the lag phase of diene formation by 52%. Thus, this delay in LDL oxidation could be attributed to the presence other, nonphenolic compounds with antioxidant capacity. When refined olived oil was added to isolated LDL the final concentration of α-tocopherol was 4.38 mg/L. At similar α-tocopherol concentrations Frankel *et al*. (11) reported delays up to 42% in the lag phase of conjugated diene formation on copper-induced LDL oxidation. We found that lag-time delay with refined olive oil was lower than that obtained when extra-virgin olive oil was added to the incubation. Thus, olive oil phenolics showed more antioxidant activity against LDL oxidation in the present experiment than did α-tocopherol. These results agree with those obtained by others (11,15), in which antioxidant activity of other phenolic compounds such as resveratrol, epicatechin, or quercetin was higher than the α-tocopherol antioxidant activity as studied by *in vitro* LDL oxidation.

The concentrations of phenolics, α-tocopherol and β-carotene, added to LDL with the olive oils, correlated with the lag time of LDL oxidation. Thus, to estimate the effect on LDL oxidation that was attributable to each antioxidant component, a multiple regression analysis was performed with these variables. Only the phenolic content, present in extra-virgin olive oil, was significantly correlated; the α-tocopherol content showed a weak association as well. On the other hand, the concentrations of β-carotene present in the incubation mixture were smaller than those commonly tested for their ability to inhibit conjugated diene formation (32). These results indicate that, although all antioxidant components of olive oil could be involved in protection against LDL oxidation, phenols showed the greatest antioxidant activity. These results support the hypothesis that consumption of olive oil and particularly of extra-virgin olive oil with high phenolic content, may have a protective effect on atherosclerotic processes.

In summary, phenolic compounds of extra-virgin olive oil protected LDL from peroxyl radical-dependent and copper-induced oxidation *in vitro*. Extra-virgin olive oil phenols could be incorporated into LDL particles following their incubation with plasma and exert their antioxidant activity. The amounts of extra-virgin olive oil phenols required to achieve this effect are comparatively high, and further studies investigating the bioavailability and the subsequent antioxidant activity of olive oils phenols *in vivo* need to be undertaken. Although olive oils both with and without phenolic content protected LDL from oxidation, an increase in antioxidant activity that was dependent on the concentration of phenolics in the olive oil was observed.

ABSTRACT: Germfree (GF) mice were orally inoculated with human fecal suspension or various components of human fecal microbiota. Three weeks after the inoculation, cecal bile acid composition of these mice was examined. More than 80% of total bile acids was deconjugated in the cecal contents of ex-GF mice associated with human fecal dilutions of 10^{-2} or 10^{-6}, or anaerobic growth from a dilution of 10^{-6}. In these ex-GF mice, deoxycholic acid accounted for about 20% of total bile acids. In the cecal contents of ex-GF mice associated only with clostridia, unconjugated bile acids made up less than 40% of total bile acids, about half of those in other ex-GF groups. However, the percentage of deoxycholic acid in these mice was the same as that in the other groups. These results indicate that dominant anaerobic bacterial combination is efficient for deconjugation of primary bile acids, and that clostridia in the human feces may play an important role in 7α-dehydroxylation of unconjugated primary bile acids in the intestine.

Paper no. L8347 in *Lipids 35,* 639–644 (June 2000).

In humans and animals, intestinal flora are indispensable for bile acid transformation. Many experimental reports imply the correlation between colorectal cancer and secondary bile acids, deoxycholic acid and lithocholic acid, which are the 7 α-dehydroxylated forms of cholic acid and chenodeoxycholic acid, respectively (1–3). Deconjugating activity of conjugated bile acids is widely observed in many kinds of intestinal bacteria (4–7), and 7 α-dehydroxylating activity has also been reported in certain groups of intestinal bacteria (8). However, for some of the species, the results of investigators are contradictory (9–16), and only certain strains belonging to *Eubacterium* and *Clostridium* have been reported specifically (17–21). Many reports indicated that the difficulties of isolating 7 α-dehydroxylating intestinal bacteria arise from the small populations of these bacteria in the intestine (15,22). However, most of the primary bile acids in the intestine are deconjugated and transformed into secondary bile acids, and the precise mechanism of transformation of bile acids by intestinal bacteria in the intestine is still unknown.

Previously, we inoculated human intestinal bacteria that had the ability to transform bile acids *in vitro* into germfree (GF) mice; however, only a little amount of secondary bile acids was found in their cecal contents, indicating that bacterial transforming ability of bile acids *in vitro* is not necessarily reflected *in vivo* (23,24). In this study, we produced various groups of ex-GF mice associated with human fecal dilution, or with anaerobic growth from a dilution of 10^{-6}, or with only human fecal clostridia. The aim of this study is to clarify which bacterial groups harbored in the human intestine are responsible for bile acid transformation in the intestine.

MATERIALS AND METHODS

Animals. GF ICR female mice (15 wks old) were purchased from Japan SLC Co. (Hamamatsu, Japan). Each group of five female GF mice was kept in an autoclavable stainless steel isolator (25) and given pelleted commercial diet (CMF; Oriental Yeast Co., Tokyo, Japan) sterilized with γ-irradiation at 50 kGy and autoclaved water *ad libitum*. Specific pathogen-free (SPF) ICR mice of the same age were also purchased from Japan SLC Co. The study was approved by the Laboratory Animal Use and Care Committee of Faculty of Agriculture, the University of Tokyo.

Production of ex-GF and gnotobiotic (GB) mice. Human fecal samples were obtained from a 47-yr-old healthy male donor. Of the bile acids in the fecal sample 99.6% were deconjugated, and 96% of the unconjugated bile acids were transformed to secondary bile acids. Preparation of the fecal dilution and bacterial suspension is summarized in Scheme 1.

(i) Groups A to E. One gram of fresh feces was immediately placed in 9 mL of an anaerobic diluent (26) under oxygen-free CO_2 gas. A portion was transferred into an anaerobic chamber and serially diluted with anaerobic Trypticase soy (TS) broth supplemented with 0.084% Na_2CO_3, 0.05% agar, and 0.05% cysteine hydrochloride monohydrate. The 10^{-2} and 10^{-6} diluted fecal suspensions were prepared for inoculation into GF mice to produce ex-GF mice of group A

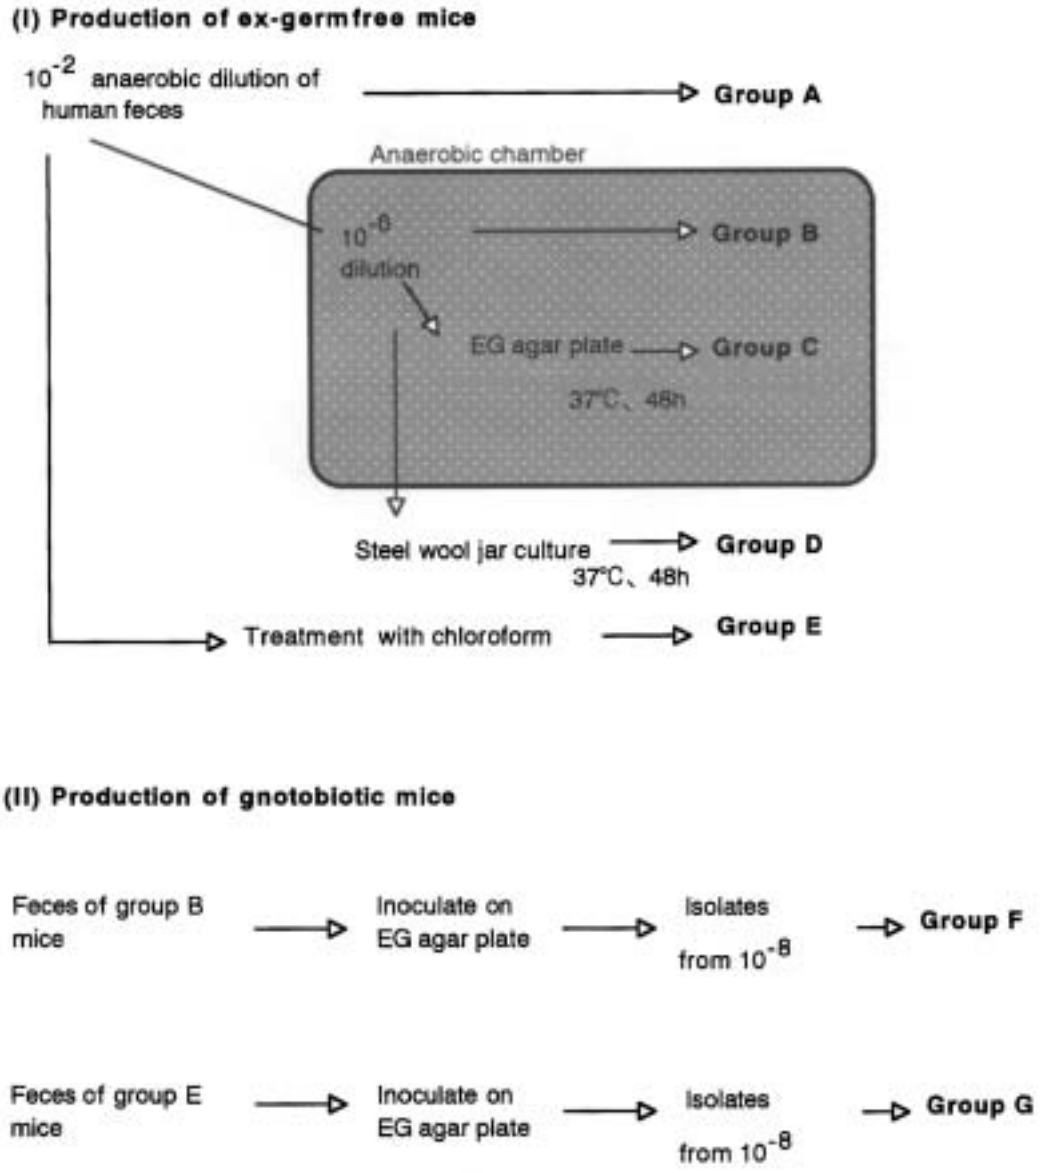

SCHEME 1

and group B, respectively. Another 0.1 mL of 10^{-6} diluted solution was inoculated on Eggerth Gagnon (EG) agar plates (26) in an anaerobic chamber with 5% CO_2, 10% H_2 and 85% N_2, and incubated at 37°C for 48 h. Another 0.1 mL of 10^{-6} solution was inoculated on modified EG agar (Nissui Pharmaceutical Co. Ltd., Tokyo, Japan) plates and incubated in an anaerobic steel wool jar filled with 100% CO_2 at 37°C for 48 h. From all colonies which developed on each plate, cells were scratched and suspended in anaerobic TS broth for group C and group D, respectively. The remaining portion of the 10^{-1} dilution of human feces was further diluted to 10^{-2} and treated with chloroform as described below for group E.

(ii) Groups F and G. Two weeks after the inoculation, fecal bile acid composition in ex-GF mice of groups A to E was examined. From the feces of ex-GF mice of groups B and E in which deoxycholic acid was detected, we prepared two groups of bacterial combinations. Feces of group B mice was diluted to 10^{-8} in anaerobic TS broth, inoculated on EG agar plates, and incubated in an anaerobic chamber at 37°C for 48 h. Each of the developed colonies was isolated from the agar plates, purified, and subcultured. Each bacterial growth was then suspended in an anaerobic TS broth, and this predominant bacterial suspension was inoculated into GF mice for group F. From the feces of ex-GF mice of group E, we also obtained the predominant bacterial suspension for group G. Both groups F and G were gnotobiotic (GB) mice.

Each fecal dilution and bacterial suspension (0.5 mL) was orally inoculated into the stomach of GF mice with a stainless steel catheter.

Treatment of feces with chloroform. Chloroform-treated

feces of humans and mice were prepared according to the method of Itoh and Mitsuoka (27). A fecal suspension was added for a final concentration of 3% chloroform, was shaken vigorously for about 30 s, and was subsequently incubated for 1 h at 37°C. After the incubation chloroform was eliminated from the suspensions by percolating with O_2-free N_2 gas. Only bacterial spores survived this treatment.

Cecal bile acid determination. Three weeks after the inoculation, cecal contents from each mouse were collected, freeze-dried, and pulverized. A portion of 50 mg dry cecal contents was extracted three times with 10 mL of absolute ethanol at 90°C for 1 h and filtered. The extracts were mixed, dried, and purified through a Bond Elute LRC cartridge (Varian, Palo Alto, CA). A purified solution in 90% ethanol was subjected to piperidinohydroxypropyl Sephadex-LH-20 (PHP-LH-20) column chromatography (Shimadzu Co., Kyoto, Japan) to obtain free, glycine-conjugated, and taurine-conjugated fractions (28).

Bile acids were analyzed using the LC module-1 high-performance liquid chromatography system (Waters, MA) with a Symmetry C18 separation column (150 × 4.6 mm i.d. Waters). Bile acids were then detected by the post-column fluorescent method with a 3 α-hydroxysteroid dehydrogenase (HSD) immobilized column (E-3 α-HSD, 20 × 4.0 mm i.d., Sekisui Chemical Co. Ltd., Osaka, Japan), and β-NAD solution by an A-60-S pump (Eldex Laboratories Inc., Napa, CA) and a 474 scanning fluorescence detector (Waters) at an excitation wavelength of 340 nm and an emission wavelength of 460 nm (28,29). Each bile acid was identified by its relative retention time compared with that of standard bile acids, and peak heights were calculated automatically on a Waters 805 data station.

Analysis of intestinal flora. Cultivation of fecal bacteria was carried out according to the methods of Mitsuoka *et al.* (26,30) and Itoh and Mitsuoka (27), except that an anaerobic chamber was employed instead of the "plate-in-bottle" method. Three weeks after inoculation, feces from two mice of each group were collected, immediately weighed, and transferred into an anaerobic chamber. They were homogenized with a 50-fold volume (vol/wt) of anaerobic TS broth, serially diluted, and plated on 5 nonselective and 11 selective agar media (26,27,30). Isolated bacteria were identified on the basis of Gram staining, colony morphology, cell morphology, and aerobic growth. The bacterial numbers were expressed as $\log_{10}$ counts of viable bacteria per gram wet weight of feces.

Statistical analysis. A statistical analysis was performed by analysis of variance followed by Bonferroni's *t*-test, and a *P* value less than 0.05 was considered to be significant.

RESULTS

Table 1 shows the bacterial counts in feces of ex-GF and GB mice 3 wk after the inoculation of fecal suspensions. Among the ex-GF mice in groups A, B, C, and D, bacteroidaceae were detected at the highest levels, and eubacteria and clostridia were also detected in high numbers. Among aerobic bacteria, enterobacteriaceae and streptococci were detected in the feces of the four ex-GF groups, but staphylococci were detected only in the feces of group A mice. Bacilli, yeasts, bifidobacteria, veillonellaceae, and lactobacilli, which were detected in the original human donor feces, were lower than the minimum detectable level of 10^3 CFU per g in feces of inoculated mice. In feces of group E mice, which were inoculated with chloroform-treated fecal suspension, only clostridia were observed. In group F mice inoculated with 15 strains of predominant bacteria isolated from feces of a group B mouse, 10 strains colonized at a level of 10^9 CFU per g feces. In group G mice associated with 15 strains of predominant clostridia isolated from feces of a group E mouse, the total fecal bacterial count was 6.0×10^{10} CFU per g feces, and 10 out of 15 strains showed more than 10^9 CFU per g feces.

[a]Mean ± SD nmol/g wet cecal contents.
[b]Significantly higher than SPF, C, D, E, and G ($P < 0.05$).
[c]% of total bile acids.
[d]Un, unconjugated; Tc, taurine conjugated.
[e]ND, not detected.
[f]Trace, amounts less than 0.5%. SPF, specific pathogen free; for other abbreviations see Table 1.

Table 2 shows the bile acid composition in the cecal contents of ex-GF and GB mice 3 wk after inoculation. All conjugated bile acids in ex-GF mice were taurine-conjugated, and no glycine-conjugates were detected. ω-Muricholic acid was detected in the cecal contents of SPF mice as a major bile acid, but was not detected in any of the ex-GF mice associated with human intestinal bacteria. Deoxycholic acid, a secondary bile acid transformed from cholic acid, was observed in the cecal contents of ex-GF mice in groups of A–E. The percentage of deoxycholic acid in total bile acids was about 20%, and no significant difference was detected among the five groups. However, deoxycholic acid was not formed in the cecal contents of GB mice in groups F and G.

Figure 1 shows the percentage of unconjugated bile acids in the cecal contents of ex-GF mice. In groups A to D, the deconjugating ratio was 80–90% of total bile acids. However, in group E, in which intestinal bacteria consisted of only clostridia, the percentage of unconjugated bile acids was significantly lower than those in groups A to D ($P < 0.05$). In group F, about 30% of total bile acids were unconjugated, but the percentage of unconjugated bile acids in groups G was remarkably low.

Figure 2 shows the conversion ratio from unconjugated primary bile acids to secondary bile acids. In the cecal contents of SPF mice, 44.1% of muricholic acid was transformed into ω-muricholic acid, but transformation to ω-muricholic acid did not occur in the cecal contents of any group of ex-GF or GB mice associated with human fecal bacteria. The conversion ratio from cholic acid to deoxycholic acid and from chenodeoxycholic acid to lithocholic acid was significantly higher in SPF mice than that in ex-GF mice. Although the difference was not statistically significant, the cecal contents of ex-GF mice in group E showed a tendency toward a slightly higher conversion ratio from cholic acid to deoxycholic acid than those in groups in A, B, C, and D.

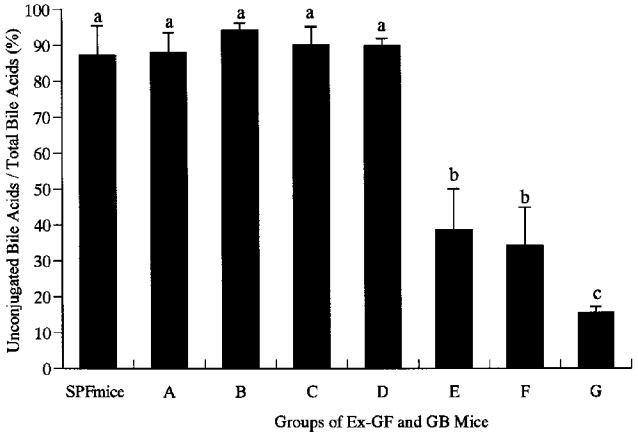

FIG. 1. Deconjugation ratio of total bile acids in the cecal contents of ex-germfree (GF) and gnotobiotic (GB) mice. Bars marked with different letters are significantly different ($P < 0.05$). SPF, specific pathogen free.

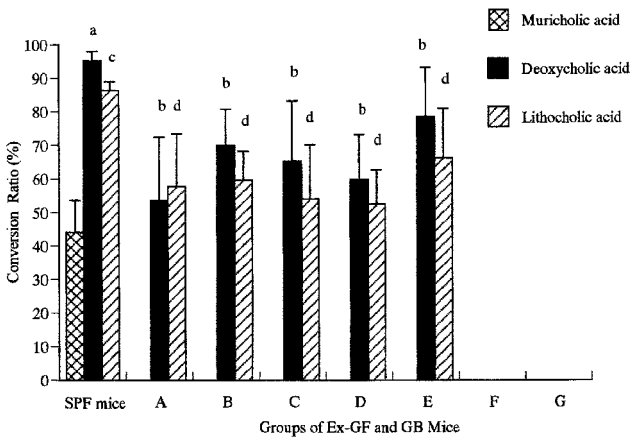

FIG. 2. Conversion ratio (primary to secondary) of unconjugated bile acids in the cecal contents of ex-GF and GB mice. Values in the same coded bars with different letters are significantly different ($P < 0.05$). For abbreviations see Figure 1.

DISCUSSION

The present data show that a 10^{-6} fecal dilution of human feces can transform bile acids to the secondary form in the intestines of mice. In the human intestine, the bacterial count reaches the order of 10^{11} CFU per gram. According to our results, it was suggested that the count of 7 α-dehydroxylating bacteria in the human feces of this sample may be at least 10^6 CFU per g feces. This number is a little higher than those in previous reports (19,31). Takamine and Imamura reported (22) that 7 α-dehydroxylation was detected in dilutions of human feces below 10^{-5}.

Total bile acid concentration in GB mice group F was significantly higher than that in SPF, C, D, E, and G mice. However, we have no speculation or data to explain this difference.

In the ex-GF A, B, C, and D groups, with fecal bacteria consisting mainly anaerobic bacteria, including bacteroidaceae, eubacteria and clostridia, about 90% of the cecal bile acids were deconjugated. In contrast, in the cecal contents of ex-GF mice of group E, only 40% of total bile acids was deconjugated. These results indicate that deconjugation of cecal bile acid mainly depends on bacteria belonging to bacteroidaceae or eubacteria, as reported in *in vitro* experiments (4,5,32,33). It was also suggested that bile acid-transforming bacteria are culturable on EG agar plates and do not require extreme anaerobic conditions, since there was no significant difference in the cecal bile acid composition between ex-GF groups C (including extremely oxygen sensitive bacteria) and D (not including strict anaerobic bacteria).

ω-Muricholic acid was not detected in any group of ex-GF mice. This result is consistent with that of Sacquet *et al.* (34), indicating that human intestinal bacteria have no activity to transform α- or β-muricholic acid to ω-muricholic acid. It is suggested that human intestinal bacteria react differently, especially to chenodeoxycholic acid group, from murine intestinal bacteria.

In mice and rats, clostridia (fusiform-shaped bacteria) are one of the key groups for the normalization of GF animals (35,36). Recently, Uchida *et al.* (37) reported that clostridia isolated from rat cecum play an important role in the formation of secondary bile acids in rats. Although it is not yet clear what intestinal bacterial groups in humans correspond to fusiform-shaped bacteria in mice and rats, it is suspected from the results of this study that clostridia also exert an effect on the formation of secondary bile acids in human intestines. In the cecal contents of ex-GF mice associated with chloroform-treated human fecal suspension, deoxycholic acid was detected at a level equivalent to that of SPF mice, even though the deconjugating ratio was significantly lower than those in other ex-GF mice. It is assumed that clostridia transformed almost all unconjugated cholic acid to the secondary form.

No deoxycholic acid was detected in the cecal contents of GB mice in group F or G. They were inoculated with predominant bacteria isolated from ex-GF mice in group B or E, respectively, in which a considerable amount of deoxycholic acid was detected in the cecal contents. There may be some reasons for the absence of deoxycholic acid in group F or G. One possibility is that 7 α-dehydroxylating bacteria are not present in large numbers in the intestine of group B or E, and bacterial combinations isolated from a 10^{-8} fecal dilution of a group B or E mouse may not have 7 α-dehydroxylating activity. Another reason for the absence of deoxycholic acid in the cecal contents of these mice may be the lower percentage of deconjugated bile acids in group F or G. Batta *et al.* (38) reported that previous deconjugation of bile acids is required for further bacterial 7 α-dehydroxylation *in vitro*. Bacteroidaceae harbored in group F might be able to deconjugate muricholates, not cholic acid.

Lipid and Fatty Acid Composition and Energy Partitioning During Embryo Development in the Shrimp *Macrobrachium borellii*

Horacio Heras*, M.R. Gonzalez-Baró, and Ricardo J. Pollero

Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), CONICET-UNLP, (1900) La Plata, Argentina

ABSTRACT: Energy partitioning, composition of lipids and fatty acids, and their utilization by embryos were determined in the lecithotrophic shrimp *Macrobrachium borellii* during seven development stages. The biochemical composition at stage I is represented by lipids, proteins, and carbohydrates, with 29.3, 28.7, and 0.2% dry weight, respectively. The former two were identified as the major energy-providing components, contributing 131 and 60 cal/100 mg egg, dry weight, respectively. The overall conversion efficiency (CE) was 45.0% (calculated as percentage of vitelline energy transformed into embryonic tissues). Lipids were the most important energy reserve (CE 39.3%), followed by proteins (CE 57.1%), both being simultaneously utilized during development while carbohydrates were synthesized *de novo* (CE 587.5%). Variation in the lipid class composition of embryos and vitellus showed an accumulation of triacylglycerols (TAG) and phospholipids (PL) up to stage IV, a more active accumulation and selective utilization phase (stages V and VI), and a consumption and *de novo* synthesis period until hatching. Structural lipids (PL and cholesterol) and pigment astaxanthin were selectively conserved in embryos, but TAG, hydrocarbons, and esterified sterols were preferentially depleted. Monounsaturated fatty acids (FA) were the major group in TAG, whereas polyunsaturated FA (PUFA) were the major group in PL after organogenesis. Certain PUFA such as 22:6n-3 and 20:5n-3 were selectively accumulated in PL.

Paper no. L8410 in *Lipids 35,* 645–651 (June 2000).

Physiological energetics encompasses the study of gains and losses of energy and the efficiency of its transformation from the standpoint of the whole organism. Studies on the energetics during embryogenesis in invertebrates are difficult to compare because of the different methodologies employed and also because of the varied life histories of invertebrate species (1–5).

Conversion efficiency (CE) gives a rough estimate of the amount of each constituent used for growth and formation of energy reserves in the embryo and of the amount used for metabolism. In most cases CE is significantly higher for proteins than for lipids, a fact that is consistent with the assumption that during development amino acids are conserved to build up the structure of embryos, while lipids would serve as fuel for active cell division and differentiation (2).

In many aquatic invertebrates such as crustaceans, bivalves, cephalopods, and sea urchins, the amount of proteins and lipids in the egg is higher than carbohydrate, clearly showing that carbohydrate is not the major energy reserve for egg development (2,6–8).

Crustacean oviposited eggs have two compartments, the ooplasm and the vitellus or yolk, which are enclosed by an egg membrane, the chorion. The ooplasm contains mitochondria, cortical granules (glycoproteins), and lipid globules. The yolk is surounded by the vitelline sac which contains water, lipids, proteins, and also minor amounts of carotenoid pigments, carbohydrates, and free amino acids (9,10). Most crustacean eggs store some of the nutrients in the yolk in the form of a complex lipoprotein called lipovitelin or as lipid droplets scattered throughout the cytoplasm. Most studies made on crustacean eggs refer to whole egg composition and show that lipid is the major energy reserve, although there is no mention of species such as *Macrobrachium borellii, in* which the egg has an abbreviated development and hatches into a postlarval stage. There are also no available data on the transfer of yolk into decapod embryos from the biochemical point of view. For our study we selected the decapod *M. borellii,* which is an endemic South American lecithotrophic freshwater shrimp in Argentina, Paraguay, and Uruguay (approximately from 22 to 37°S and 53 to 60°W) (11). Females brood large, yolky eggs during late spring and summer in turbid, temperature water streams (November to February). The small clutches (50–60 eggs) are kept by females attached to the pleopods. Eggs take about 50 d to hatch at 25°C (11). Hatchlings are 5–6 mm long, translucent postlarvae of benthic habits and are omnivorous scavengers.

In the present work, we studied the energy partitioning and the lipid and fatty acid (FA) composition in *M. borellii* eggs from fertilization until hatching in order to identify the nutrient sources of eggs, and how they are utilized by embryos during development.

Abbreviations: BSA, bovine serum albumin; CE, conversion efficiency; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FA, fatty acid; HP-TLC, high-performance thin-layer chromatography; PL, polar lipid; PUFA, polyunsaturated fatty acid; SM, sphingomyelin; TAG, triacylglycerol; TLC, thin-layer chromatography.

EXPERIMENTAL PROCEDURES

Sample collection. Eggs from *M. borellii* were sampled from ovigerous females collected during spring and summer (October to February) in the Zapata Stream (20 km southwest of La Plata, Argentina), which has turbid waters with temperatures ranging from 22 to 26°C. The females were taken to the laboratory and kept in dechlorinated tap water at room temperature until the eggs were removed for the experiments. Embryo size and development stages were checked in each egg brood using a stereoscopic microscope (Nikon SMZ-10, Tokyo, Japan). Seven developmental stages were therefore identified using major development events.

Stage I constitutes embryos from four-cell morula to gastrula with a highly viscous vitellus that takes up about 90% of the egg; in Stage II (10–18 d) vitellus fills up to 80% of the egg volume; in Stage III (18–26 d), embryos have incipient eyes visible and the vitellus fills up to 70%. At stage IV (26–35 d) the vitellus mass is divided into four lobules; in Stage V (36–40 d) the cuticle pigmentation becomes evident and embryo is under active organogenesis. At stage VI (40–46 d) blue from hemocyanin becomes visible and the vitellus has almost internalized into the embryo and represents about 20% of the egg volume; organisms in Stage VII (46–50 d) are 4–5 mm long with all the characteristics of postlarvae ready to hatch. In general, vitellus decreases its viscosity along with development.

Wet weight and moisture were obtained from egg masses of each developing stage and analyzed following a method from the International Association of Fish Meal Manufacturers (12). Samples were analyzed in triplicate and each replicate was composed of pools including eggs from 3 or 4 clutches.

Isolation of embryos and vitellus. Eggs were weighed; then egg shells, vitellus, and embryos were separated from each other. Embryos from stage I were virtually impossible to isolate free from vitellus due to its high viscosity and the size of the morula. Therefore, at this stage we studied the whole egg homogenate without the egg shells, which were separated by gentle centrifugation.

Stages II to IV: Embryos were first manually isolated from vitellus by breaking the vitelline sac under a stereoscopic microscope followed by the separation of embryo, egg shell, and vitellus using a Percoll® discontinuous density gradient (Pharmacia LKB, Uppsala, Sweden) with solutions of 100, 50, and 25% Percoll diluted with 75 mM NaCl. Samples were loaded onto the gradient and then centrifuged at 400 × *g* for 10 min (13). Thus, a shell-containing pellet was formed while the embryos were located in the interphase of the two Percoll solutions, and the yolk floated on top of the gradient.

Stage V and VI: Embryos were manually isolated from vitellus under a stereoscopic microscope and washed repeatedly with a solution of 75 mM NaCl. Stage VII embryos have already internalized the vitelline sac and therefore were analyzed as a whole egg homogenate.

Embryos were homogenized in a Potter-type homogenizer (Thomas Scientific, Swedesboro, NJ) using 0.02 M, pH 7.5 Tris-HCl buffer containing 2 mg/mL aprotinin (Trasylol, Mobay Chemical Co., New York). The ratio buffer/sample was kept at 3:1, vol/vol. All samples obtained were frozen at –70°C until analysis.

Protein, lipid, and carbohydrate determination. Proteins were determined by the method of Markwell *et al*. (14) using bovine serum albumin (BSA) as a standard. Samples and BSA were first digested with 1 N NaOH, 5:1 vol/vol, vortexed, and incubated overnight at 37°C.

Lipids were extracted with a chloroform/methanol mixture following the method of Bligh and Dyer (15), and total lipid concentrations were determined gravimetrically. Carbohydrates were determined following the spectrophotometric procedure of van Handel (16).

Lipid analysis. Eighty percent of each sample was employed for lipid analysis. Lipid class analysis was performed by thin-layer chromatography (TLC) on silica gel Chromarods (type S-III) with quantitation by flame-ionization detection using an Iatroscan TH-10, Mark III (Iatron Laboratories Inc., Tokyo, Japan) as described by Parrish and Ackman (17). The separation was conducted with a sequence of three different solvent systems according to Ackman and Heras (18). The first development was carried out for 45 min in hexane/ethyl acetate/diethyl ether/formic acid (91:6:3:1, by vol). Chromarods were dried, partially scanned to determine neutral lipids, and then developed in acetone for 15 min to quantify the carotenoid (astaxanthin) peak. Finally, the Chromarods were developed in chloroform/methanol/formic acid/water (50:30:4:2, by vol) for 60 min and completely scanned to reveal the different phospholipids. Tetracosanol was used as an internal standard, and quantitation was performed with calibration curves of authentic standards run under the same conditions. Lipids were also identified on HP-TLC plates (Merck, Darmstadt, Germany) developed with hexane/diethyl ether/acetic acid (80:20:1.5, by vol) for neutral lipids and chloroform/methanol/acetic acid/water (65:25:4:4, by vol) for polar lipids (PL). Esterified sterols and hydrocarbons coeluted using the first developing solvent system, although a qualitative separation performed on HP-TLC showed that esterified sterols were the major component of the unresolved peak. Standard lipids, iodine vapor, and specific reagents were used to identify lipid classes. Preparative HP-TLC of neutral lipids, as described above, was used to isolate PL and neutral lipids for fatty acid analysis and to isolate an egg carotenoid pigment, which was then employed as a standard for Chromarod calibration.

FA analysis. FA methyl esters from total lipids, triacylglycerols (TAG), and PL, were prepared with BF_3/MeOH according to the method of Morrison and Smith (19). The analyses were performed by gas chromatography using a Shimadzu 9A gas chromatograph (Tokyo, Japan) fitted with an Omegawax 250 fused-silica column, 30 m × 0.25 mm, with 0.25 µm phase (Supelco, Bellefonte, PA). Peaks were identified by comparing the retention times with those from a mixture of standard methyl esters.

Energy conversion factors. We employed the energy conversion factors described by Beningher (3) calculated for aquatic invertebrates: carbohydrates, 4.1 kcal/g or 17.2 kJ/g; proteins, 4.3 kcal/g or 17.9 kJ/g; and lipids, 7.9 kcal/g or 33.0 kJ/g.

Statistical analyses. Data collected from all experiments were analyzed by analysis of variance using Instat v.2.0 (GraphPad Software, San Diego, CA). Whenever significant differences among samples were found, a *post-hoc* Tukey's test was performed to identify the differing means. Results were considered significant at the 5% level.

RESULTS

Dry weight variations. The optimized methodology, employing Percoll gradients, allowed us to separate the vitellus from embryos and egg shells of *M. borellii*. Dry weight of whole eggs showed a steady decrease during development from 0.98 ± 0.05 mg/egg to 0.81 ± 0.08 mg/egg ($P < 0.05$). Morphological changes under the stereoscopic microscope were also evident in the 1.7–2.0 mm eggs, the vitellus being more condensed and reduced in size as the embryo developed, finally occupying about 20% of the egg volume at the last stage.

Energetic changes during development. Analysis of the composition of just-layed-egg vitellus showed that the major nutrients were lipids (29.3% dry weight) followed by proteins (28.7% dry weight) and carbohydrates (0.2% dry weight) (Fig. 1). From the biochemical composition of the developing eggs it was possible to calculate the equivalent calories depicted in Figure 2. The overall CE calculated as the percentage of vitellus total energy transformed into embryonic tissue energy was 45.5%. All reserves displayed significant changes from stages IV to V (Fig. 1), evidencing a net fall in the vitellus and an increase in the embryo content. The CE for lipids was 39.3, 57.1 for proteins, and 587.5% for carbohydrates.

Changes in lipid and FA composition along development. In order to determine the role of lipids during development, each lipid class was studied separately in embryos and in yolk. PL and TAG were the most important lipids in vitelline fluid, representing more than 89% w/w at stage I (Table 1). TAG evidenced significant changes between stages IV and V ($P < 0.01$), decreasing to 33% of the whole lipids, a reduction of more than 30% compared to the percentage in the original vitellus total lipid (Table 1). On the other hand, sphingomyelin (SM) increased in the embryos ready to hatch. Phosphatidylcholine was the second-most important lipid during the whole development, changing its relative amount from 14 to 25% by weight but without any defined pattern. Phosphatidylethanolamine also showed significant changes in vitellus between stages IV and V. Therefore, at the end of development, the composition of the vitellus remaining in the hatched postlarvae is particularly enriched in esterified sterols, astaxanthin pigments, and SM at the expense of TAG. The changes observed at stage V yolk were accompanied by an increase of PL in embryos, followed by a significant increase in embryo cholesterol at stage VI (Table 2). The astaxanthin pigment was also taken up by embryos at stages VI and VII, mainly at the end of embryogenesis, accounting for 11% of the total lipids in embryos ready to hatch as postlarvae. Free FA were always found in small amounts in the vitellus as well as in embryos, except in the yolk at stage V where it was 3.3% w/w. Esterified sterols, which cochromatographed with hydrocarbons, did not show any changes in embryos, although they were selectively conserved in vitellus, particularly at the end of development ($P < 0.01$). Nevertheless, they were always minor components.

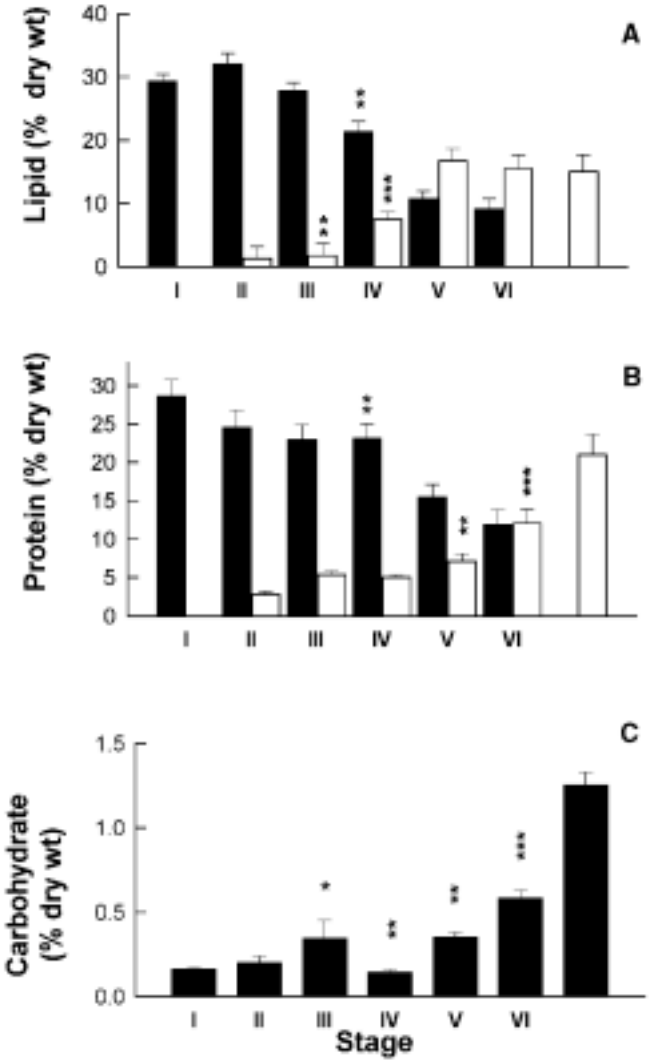

FIG. 1. Changes in (A) lipid, (B) protein, and (C) carbohydrate content in embryos (□) and vitellus (■) during development. Values are expressed as % dry weight of whole egg. Bars with different characters on top are significantly different from the next bar. $*P < 0.05$; $**P < 0.01$; $***P < 0.001$.

Regardless of variations according to lipid class or development stage analyzed, the major FA were 16:0, 18:0, 16:1n-7 18:1n-9, 18:1n-7, 18:2n-6 18:3n-3, 20:4n-6, and 20:5n-3 (Table 3). Monounsaturated FA were the major group in the TAG fraction at all stages. Polyunsaturated fatty acids

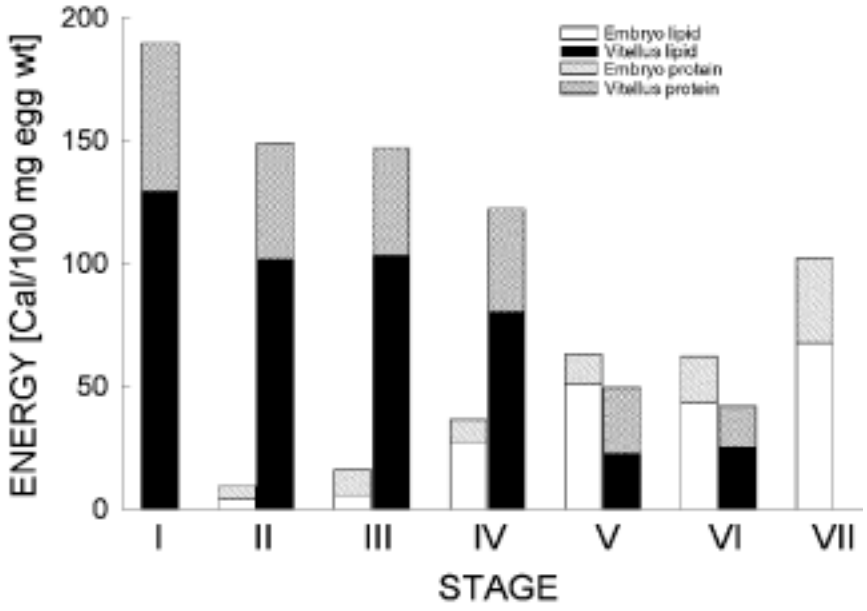

FIG. 2. Total caloric changes in embryos and vitellus during development. Values are expressed as total cal/100 mg egg (wet weight) for each stage, and they were calculated by adding protein and lipid calories. Carbohydrates represented less than 1.5% of the calories, and they were omitted for calculations.

(PUFA), on the other hand, were the main FA group in PL after embryos reached stage V; this increase was paralleled by a decrease in PL saturated and monounsaturated FA. The PUFA increment in PL fraction continued until hatching, reaching a value of 43.6% of total FA. Moreover, some PUFA such as 22:6n-3 (docosahexaenoic acid; DHA) and 20:5n-3 (eicosapentaenoic acid; EPA) were selectively accumulated in PL during development while 18:0 and 16:3 showed a clear association with PL throughout development.

Changes in protein and carbohydrate composition along development. Protein reserves in *M. borellii* yolk represent about 29% dry weight at stage I. Lipid and proteins were catabolized in equal proportion for energy until stage VII, where a much greater proportion of energy appears to have been derived from the catabolism of lipids and a greater proportion of the protein retained for converting into body components (Figs. 1 and 2). Therefore, yolk protein values fell, reaching a minimum of 14% at stage VII. The protein uptake by embryos was rather constant from stage II on, and did not increase until the end of embryogenesis. Embryo protein reached a maximum of 24% dry weight before hatching.

Compared to protein and lipid, the total carbohydrate content was low throughout development and increased strikingly at the end of embryogenesis, but it never exceeded 1.2% dry weight (Fig. 1).

DISCUSSION

Eggs in decapod carideans are surrounded by a chitin membrane that confers impermeability. However, it was interesting to note that *M. borellii* eggs increased their water content with development, probably due to a variation in inside os-

molarity that favored the exchange of water and some other compound responsible for keeping the embryos under optimal conditions. Nevertheless, *M. borellii* is a lecithotrophic shrimp, and therefore once fertilized, the yolk content of each egg wholly supports the development of the embryo and the first postlarval stage until the postlarva starts feeding. This strategy implies that maternal diet modifies the biochemical composition of eggs because there is, to a variable extent, a direct dietary input to oocyte lipid accumulation (20). Therefore, the composition of *M. borellii* eggs was always analyzed using wild gravid females. Yolk composition of just-layed eggs (stage I) showed that the major component was lipid (34.8% dry weight) followed by proteins (33.0%), but only a small amount of carbohydrates was detected (1.5%). High lipid levels are a common feature of other crustacean eggs. Holland (2) reviewed the biochemical composition of several invertebrate eggs, reporting that crustaceans showed a heterogeneous picture, with protein prevailing in some cases whereas lipids were the most important reserves in the majority of crustaceans, with carbohydrates always being a minor component. It is worth pointing out that comparisons among decapod eggs should be made taking into account the different life histories of the group. For example, the prawn *M. idella* has an egg composition in which proteins constitute more than 80% of dry weight (2) and a life cycle that includes very small eggs and feeding larvae. On the other hand, Sarojini *et al.* (21) reported the composition of eggs of *M. kistnensis,* showing that lipids were the most important reserve. Although the three species belong to the genus *Macrobrachium*, their life histories and type of eggs are different. Anger (22) reviewed the importance of lecithotrophy, as compared to feeding, on early larval development.

Regarding the use of the energy sources, we found that lipids, followed by proteins, are the major source of energy available in vitellus for embryogenesis. On the other hand, there was a net carbohydrate synthesis as the mass in the em-

bryos exceeds the mass incorporated from the vitellus. Approximately 78% of the vitellus lipid was absorbed by the embryos during development, particularly during organogenesis (stages IV and V), and about 22% was left in hatchlings, suggesting lipids were actively catabolized by embryos for their growth and maintenance. There was a delay in the utilization of vitellus lipids until stage V, which is coincident with observations in a related work where we found at this stage the highest activity of several enzymes involved in the lipid metabolism. In particular, we found higher β-oxidation and TAG-lipase and palmitoyl-CoA ligase activities at stage V (23).

Protein levels showed significant changes along development. Embryos took up 90% of vitellus proteins, which decreased sharply between stages IV and V, similarly to the case for lipids. Subramoniam (24) also found that proteins were used for the growth of *Emerita asiatica* during embryogenesis, and Claybrook (25) reported that during embryonic development of *Palaemon serratus*, yolk proteins were apparently oxidized for energy as well as reincorporated into tissues of the embryo, indicated by a 25% decrease in total protein content of the whole egg.

Interestingly, there was no net increase in embryo protein content until stage VII, just before hatching, suggesting that most proteins incorporated at stages IV and V must have been consumed as energy sources or were converted into other body components. The embryo protein level also showed a trend of increasing between stages III and IV. The major vitellus protein in decapods is vitellin, whose site of biosynthesis has aroused great controversy. A combination of autosynthesis as well as heterosynthesis occurring sequentially in ovaries along with vitellogenesis is the most probable picture (26–29). The ratio of energy supplied by lipids and proteins throughout development was quite constant at around 2, indicating a simultaneous utilization of both.

The calculated protein CE was 57%, comparable to CE values of 50 to 80% that have been observed in other crustaceans that use proteins as the major energy source (2). The protein at stage VII would be all newly synthesized protein and represents 57% of the total protein available in the egg provided from maternal sources.

Stage VII embryos increased their carbohydrate content fivefold compared with stage I. The energy CE was 587%, suggesting an active carbohydrate synthesis throughout development, probably associated with the active shell synthesis that takes place in the late stages of embryogenesis.

We could therefore suggest that absorption of nutrients from vitellus should be divided into two phases. The first one shows a mild uptake up to stage IV, followed by very active uptake and consumption phase from stage V until hatching where carbohydrates, lipids and proteins would be used for organogenesis. At the same time embryos would consume the previously accumulated nutrients, particularly after stage V, together with a *de novo* synthesis of molecules. This is merely a simplification of the real picture, because we are only considering interconversions from the different reserves, but as postlarvae hatch, they become an open system. On the whole, vitellus seems to provide the embryo with both an adequate environment throughout development and a nourishing medium, particularly for late embryogenesis. Proteins provide structural precursors during embryogenesis, and they also contribute to the embryo energetics, mainly supplied by lipids, especially TAG.

FA of PL and neutral lipids presented a similar pattern throughout development, regardless of variation either in lipid class or development stage. Some n-3 PUFA such as DHA and EPA were selectively accumulated in PL during development, while 18:0 and 16:3 showed a clear association with PL. Teshima *et al*. (30), using a double tracer experiment in *Penaeus japonicus,* reported that n-3 FA were partitioned primarily into PL whereas palmitic acid was partitioned into TAG. We have shown that in this direct-development species, PUFA are only preferentially conserved in PL at the end of development, whereas at the begining PUFA are equally distributed in TAG and PL. In the lobster *Homarus americanus*, Sasaki *et al.* (31) found that reserves of egg yolk, especially essential FA, may be depleted during embryogenesis and thus are insufficient to support larval development.

The amount of EPA and DHA is somewhat higher than that expected for a freshwater species and for other invertebrates living in the same area (32) where the n-3/n-6 ratio is below one. Nevertheless, values are similar to those observed in adult *M. borellii* (33). This composition may probably be linked to the fact that the genus *Macrobrachium* has recently colonized the freshwater environment and came from a marine environment where n-3 fatty acids prevail over the n-6 family.

Lipids have the highest energetic yield of all molecules and represent a compact and concentrated form of energy storage. Most aquatic invertebrates have taken advantage of this property, and a high lipid content is a common feature in many marine species (34). This is a common situation for females that need a compact energy store since egg volume imposes body space restrictions. Thus, the use of lipid catabolism as an energy source during embryogenesis may endow the species with some advantages in the unpredictable freshwater environment. Ongoing research in our laboratory has revealed a very active lipid metabolism in these shrimp embryos (23). This is also coincident with the general observation on the life history of marine species that conquered freshwater environments; they frequently present a series of adaptations to this environment, including a tendency to brood protection, low fecundity, large egg size, unusually high lipid content in eggs and larvae, abbreviated larval development, and lecithotrophy (35,36). All of these characteristics were found in *M. borellii* eggs compared to other members of the genus, making this species well-adapted to the nonmarine environment.

Lipid Metabolism and Tissue Composition in Atlantic Salmon (*Salmo salar* L.)—Effects of Capelin Oil, Palm Oil, and Oleic Acid-Enriched Sunflower Oil as Dietary Lipid Sources

Bente E. Torstensen*, Øyvind Lie, and Livar Frøyland

Institute of Nutrition, Directorate of Fisheries, N-5804 Bergen, Norway

ABSTRACT: Triplicate groups of Atlantic salmon *(Salmo salar* L.*)* were fed four diets containing different oils as the sole lipid source, i.e., capelin oil, oleic acid-enriched sunflower oil, a 1:1 (w/w) mixture of capelin oil and oleic acid-enriched sunflower oil, and palm oil (PO). The β-oxidation capacity, protein utilization, digestibility of dietary fatty acids and fatty acid composition of lipoproteins, plasma, liver, belly flap, red and white muscle were measured. Further, the lipid class and protein levels in the lipoproteins were analyzed. The different dietary fatty acid compositions did not significantly affect protein utilization or β-oxidation capacity in red muscle. The levels of total cholesterol, triacylglycerols, and protein in very low density lipoprotein (VLDL), low density lipoprotein (LDL), high density lipoprotein (HDL), and plasma were not significantly affected by the dietary fatty acids. VLDL, LDL, and HDL fatty acid compositions were decreasingly affected by dietary fatty acid composition. Dietary fatty acid composition significantly affected both the relative fatty acid composition and the amount of fatty acids (mg fatty acid per g tissue, wet weight) in belly flap, liver, red and white muscle. Apparent digestibility of the fatty acids, measured by adding yttrium oxide as inert marker, was significantly lower in fish fed the PO diet compared to the other three diets.

Paper no. L8415 in *Lipids 35,* 653–664 (June 2000).

Farmed Atlantic salmon (*Salmo salar* L.) are traditionally fed high-lipid diets with ingredients of marine origin containing high levels of n-3 fatty acids, resulting in a salmon fillet high in n-3 fatty acids. Lipids of marine origin are recommended in human health care as beneficial in protection against heart disease, autoimmune disease, and other disorders because of their high levels of n-3 fatty acids (1). However, the recent decreasing worldwide supplies of marine oils and fish meal have forced the industry to investigate alternative lipid sources for use in Atlantic salmon diets. Plant oils do not contain n-3 fatty acids with a chain length exceeding 18 carbon atoms and more than three double bonds. Instead, plant oils contain higher levels of saturated, monoene, and n-6 fatty acids, and their fatty acid compositions are different from marine oils. Little information is available on how these dietary fatty acids influence the uptake, transport, and utilization of fatty acids in Atlantic salmon.

Lipids are a major part of the Atlantic salmon diet, constituting more than 30% of the diet, and are an important source of energy. Atlantic salmon posses a high capacity to utilize fat as energy source (2–4). *In vitro* studies done on mitochondrial β-oxidation in fish suggest that substrate preferences exist for saturated and monounsaturated fatty acids over polyunsaturated fatty acids (PUFA). Especially 16:0, 16:1, 18:1n-9, and 18:2n-6 seem to be preferentially mobilized during starvation whereas 22:6n-3 is oxidized at low rates (5) [reviewed by Henderson (6)]. Further, 22:1n-11 and 16:0 serve equally well as substrates for mitochondrial β-oxidation in trout liver (7). However, in developing yolk-sac larvae of Atlantic halibut (*Hippoglossus hippoglossus* L.) 22:6n-3 is reported to be the quantitatively most important fatty acid in energy metabolism (8). Certain vegetable oils contain a great surplus of fatty acids such as 16:0 and 18:1n-9, which are possibly preferred for β-oxidation. This surplus might increase β-oxidation capacity and thus spare dietary protein for muscle growth. Results obtained after the onset of the current study indicate that, when measuring β-oxidation capacity, acyl-carnitines are β-oxidized at significantly higher rates compared to acyl-CoA by Atlantic salmon mitochondria in several tissues (4,9). Carnitine palmitoyl transferase-I (CPT-I) is considered to be the key enzyme for β-oxidation regulation, thus by using acyl-CoA as substrate in the assay for β-oxidation, measurement might be more physiologically relevant.

The transport of fatty acids and other lipid-soluble components to peripheral tissues is predominantly mediated by lipoproteins (10). Both the amount and fatty acid composition of dietary lipids are reported to affect plasma lipoprotein composition and metabolism in different species of rodents (11–14), in humans (15,16), and in Atlantic salmon (17; Torstensen, B.E., Lie, Ø., and Hamre, K., unpublished data).

The digestibility of monoene and saturated fatty acids by fish is generally lower compared to PUFA (18–20). The ab-

Abbreviations: AD, apparent digestibility; BW, body weight; CO, capelin oil; COSF, mix (1:1) of oleic acid-enriched sunflower oil and capelin oil; CPT-I, carnitine palmitoyl transferase-I; FCR, feed conversion ratio; HDL, high density lipoprotein; LDL, low density lipoprotein; NFE, nitrogen-free extract; PCA, principal component analysis; PL, phospholipid; PO, palm oil; PPV, productive protein value; PUFA, polyunsaturated fatty acid; SF, oleic acid-enriched sunflower oil; SGR, specific growth rate; TAG, triacylglycerol; VLDL, very low density lipoprotein.

sorption of fatty acids in fish is reported to decrease with increasing saturation of the acid and increasing chain length (19–21). This is probably due either to the melting point of the individual fatty acids or to the fact that fatty acids form insoluble soaps especially with long-chain saturated and monoene fatty acids with divalent cations in the intestine (19–21).

The aim of this study was (i) to investigate whether the dietary fatty acid composition, based on marine and different vegetable oil sources, influences the β-oxidation capacity of fatty acids in adult Atlantic salmon tissues, and (ii) to examine possible effects on plasma, lipoprotein, and tissue lipid composition and on the digestibility of fatty acids.

MATERIALS AND METHODS

Fish and diets. The feeding experiment was performed with four diets containing three lipid sources fed to four triplicate groups of Atlantic salmon. The following oils were used: capelin oil (CO) (Norsildmel, Norway), palm oil (PO) (Karlshamns Sweden AB, Karlshamn, Sweden), oleic acid-enriched sunflower oil (SF) (Loders Croklaan Inc., USA), and a 1:1 (w/w) mixture of SF and CO (COSF). The feeding experiment was carried out at NorAqua Innovation A/S Research Station, Dirdal, Norway, from March to August 1998 (total: 21 wk). Adult Atlantic salmon (*S. salar,* L.) (1.5 ± 0.6 kg) were stocked at 40 fish/tank in 12 indoor tanks of 2.8 m^3. Four different diets were produced by NorAqua Innovation A/S; Table 1 summarizes the fatty acid contents of the diets. The main components of the diets were 296 g kg^{-1} oil (CO, COSF, SF, or PO), 20 g kg^{-1} binder, 114.5 g kg^{-1} wheat flour, 549 g kg^{-1} low-temperature (LT) fish meal, and 20.5 g kg^{-1} vitamin and mineral mix. The four diets were formulated to contain 400 g kg^{-1} protein, 350 g kg^{-1} lipid, 63 g kg^{-1} water, 72 g kg^{-1} ash, and 92 g kg^{-1} nitrogen-free extract (predominantly carbohydrates). The diets were fed in excess by automatic feeders. Yttrium oxide was added to the experimental diets as inert marker (90 ± 5 mg kg^{-1}) for calculations of apparent digestibility of fatty acids. Feces were collected by stripping. Mortalities were recorded and dead fish removed daily. Biomass and average weight were determined by bulk weighing and counting of all fish in each tank at every sampling. The mean temperature, O_2 level, and salinity during the experimental period were 8.0 ± 0.4°C, 12.5 ± 0.6 mg/L, and 30.5 ± 1.0 g/L, respectively. The fish were exposed to continuous light. The protocol was approved by the Norwegian State Board of Biological Experiments with Living Animals.

[a]Data reported as weight % and mg fatty acid g^{-1} tissue (wet weight). Data are presented as mean (n = 3). Values <0.1 are represented by an em dash (—).

Sampling procedure. Samples were taken from all diets and stored at –20°C. Fish were sampled at the start, after 12 wk, and at the end of the feeding trial, i.e., after 21 wk. The fish were fasted for 24 h prior to sampling. Five randomly sampled fish from each tank were anesthetized with methomidate (7 g/L). Blood was collected from caudal vein using EDTA vacutainers, and the fish was killed by a blow to the head followed by dissection of liver, belly flap, red muscle, and white muscle. Plasma was separated from the blood samples by low-speed centrifugation, the five plasma samples from each tank were pooled, and the 12 plasma samples were stored on ice until lipoprotein fractionation. The liver, belly flap, red muscle, and white muscle samples from the same five fish from each tank were homogenized. These samples as well as an aliquot of the pooled plasma were immediately frozen on dry ice and stored at –80°C until further analyses.

Mitochondrial β-oxidation. Liver, red and white muscle were weighed and homogenized to 20% (wt/vol) in ice-cold sucrose solution containing 0.25 M sucrose in 10 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES) buffer and 1 mM EDTA, pH 7.4. The resulting total homogenates were then stored on ice during transport before being centrifuged (1,880 × *g* for 10 min at 2°C). The resulting postnuclear fractions were collected, and portions were used immediately to determine mitochondrial β-oxidation. The mitochondrial β-oxidation was determined in postnuclear fractions as acid-soluble products using radiolabeled [1-^{14}C]-palmitoyl-CoA as a substrate as described previously (22). [1-^{14}C]Palmitoyl-CoA was purchased from New England Nuclear (Boston, MA). Palmitoyl-CoA and other cofactors were purchased from Sigma Chemical Co. (St. Louis, MO).

Separation of lipoproteins. Very low density lipoprotein (VLDL), low density lipoprotein (LDL), and high density lipoprotein (HDL) in pooled plasma samples of five fish from each tank were obtained by sequential centrifugal flotation (23,24) as described by Lie *et al*. (25) using a Pegasus 65 ultracentrifuge equipped with a 70-Ti fixed-angle rotor. The centrifugation was done at 107,500 × *g* and 4°C. The density intervals were obtained by addition of solid KBr (26). Run times for separation of the lipoproteins were: VLDL, $d <$ 1.015 g mL^{-1} for 20 h; LDL, 1.015 < d < 1.085 g mL^{-1} for 20 h; HDL, 1.085 < d < 1.21 g mL^{-1} for 44 h. The fractions were stored at –80°C until further analyses.

Analytical procedures. Fatty acid composition was analyzed in the diets, feces, liver, white muscle, red muscle, belly flap, plasma, and lipoproteins. Lipids from the pooled samples were extracted by adding chloroform/methanol (2:1, vol/vol), and 19:0 was added as internal standard. The samples were filtered, saponified, and methylated using 12% BF_3 in methanol. Fatty acid composition of total lipids was analyzed using methods described by Lie and Lambertsen (27) where the methyl esters were separated using a Carlo Erba gas chromatograph ("cold on column" injection, 69°C for 20 s, increase at 25°C/min to 160°C, hold at 160°C for 28 min, increase at 25°C/min to 190°C, hold at 190°C for 17 min, increase at 25°C/min to 220°C, hold at 220°C for 9 min), equipped with a 50-m CP-Sil 88 (Chrompack, Middelburg, The Netherlands) fused-silica capillary column (i.d. 0.32 mm). The fatty acids were identified by retention time using standard mixtures of methyl esters (Nu-Chek-Prep, Elysian, MN), and the fatty acid composition (wt%) was calculated using an integrator (Turbochrom Navigator, Version 4.0, PerkinElmer Corp.), connected to the gas–liquid chromatograph. The amount of fatty acid per gram of tissue was calculated using 19:0 as internal standard. Total protein, triacylglycerol, and total cholesterol in lipoproteins and plasma were analyzed on a Technicon RA-1000 clinical analyzer system (Bayer) according to standard Technicon methods, also described by Sandnes *et al*. (28). Total lipid in feces was measured gravimetically after acidification to dissolve fatty acids bound to cations and extraction with ethyl acetate.

Statistics. The relative fatty acid composition data of the tissues and lipoproteins were analyzed using SIRIUS for Windows (Version 6.0) (Pattern Recognition Systems) (Fig. 1). Principal component analysis (PCA) (29) of the relative fatty acid compositions was performed in each data matrix. The purpose of PCA is to express the main information in the variables by a lower number of variables, the so-called principal components (PC1, PC2, …). A high positive or negative loading reveals a significant variable in the actual PCA model. Score plots from the PCA explore the main trends in the data, and their respective loadings reveal fatty acids with a significant loading. The samples with similar relative fatty acid composition are located in the same area in the score plot. These classes are indicated in Figures 1A and 1C by circles drawn on freehand. Since samples with the same relative fatty acid composition will be located on top of each other, to ease interpretation the samples the classes contain are written beside the circle.

Significant differences in amount of fatty acid (mg g^{-1}, wet weight) between the dietary treatments in the final sampling, lipid class and protein content in the lipoproteins and plasma, and β-oxidation in red muscle were analyzed by breakdown and one-way analysis of variance followed by Tukey's honest significant difference (HSD) test, using CSS:Statistica (version 4.5) (Statsoft Inc. 1993). The β-oxidation data and lipoprotein composition data were analyzed by using the same statistical methods. The following fatty acids were tested: 14:0, 16:0, 18:0, 16:1n-7, 18:1n-9, 22:1n-11, 18:2n-6, 20:4n-3, 20:5n-3, 22:5n-3, 22:6n-3, sum n-6, sum n-3, sum saturated, sum total fatty acids, and n-3/n-6. The significance level was set to $P \leq 0.05$, and data are presented as mean ± SEM. The apparent digestibility (AD) of dietary fatty acids (d.w.), related to yttrium oxide (Y_2O_3) (d.w.) as inert marker, was calculated as follows:

$$\text{AD (\%)} = 100 - [100 \cdot (\text{conc. of } Y_2O_3 \text{ in feed/conc. of } Y_2O_3 \text{ in feces}) \cdot (\text{conc. FA in feces/conc. of FA in feed})] \quad [1]$$

For calculation of the fatty acid AD percentage, the amount of fatty acids in feces was calculated based on the relative fatty acid composition and total lipid in feces.

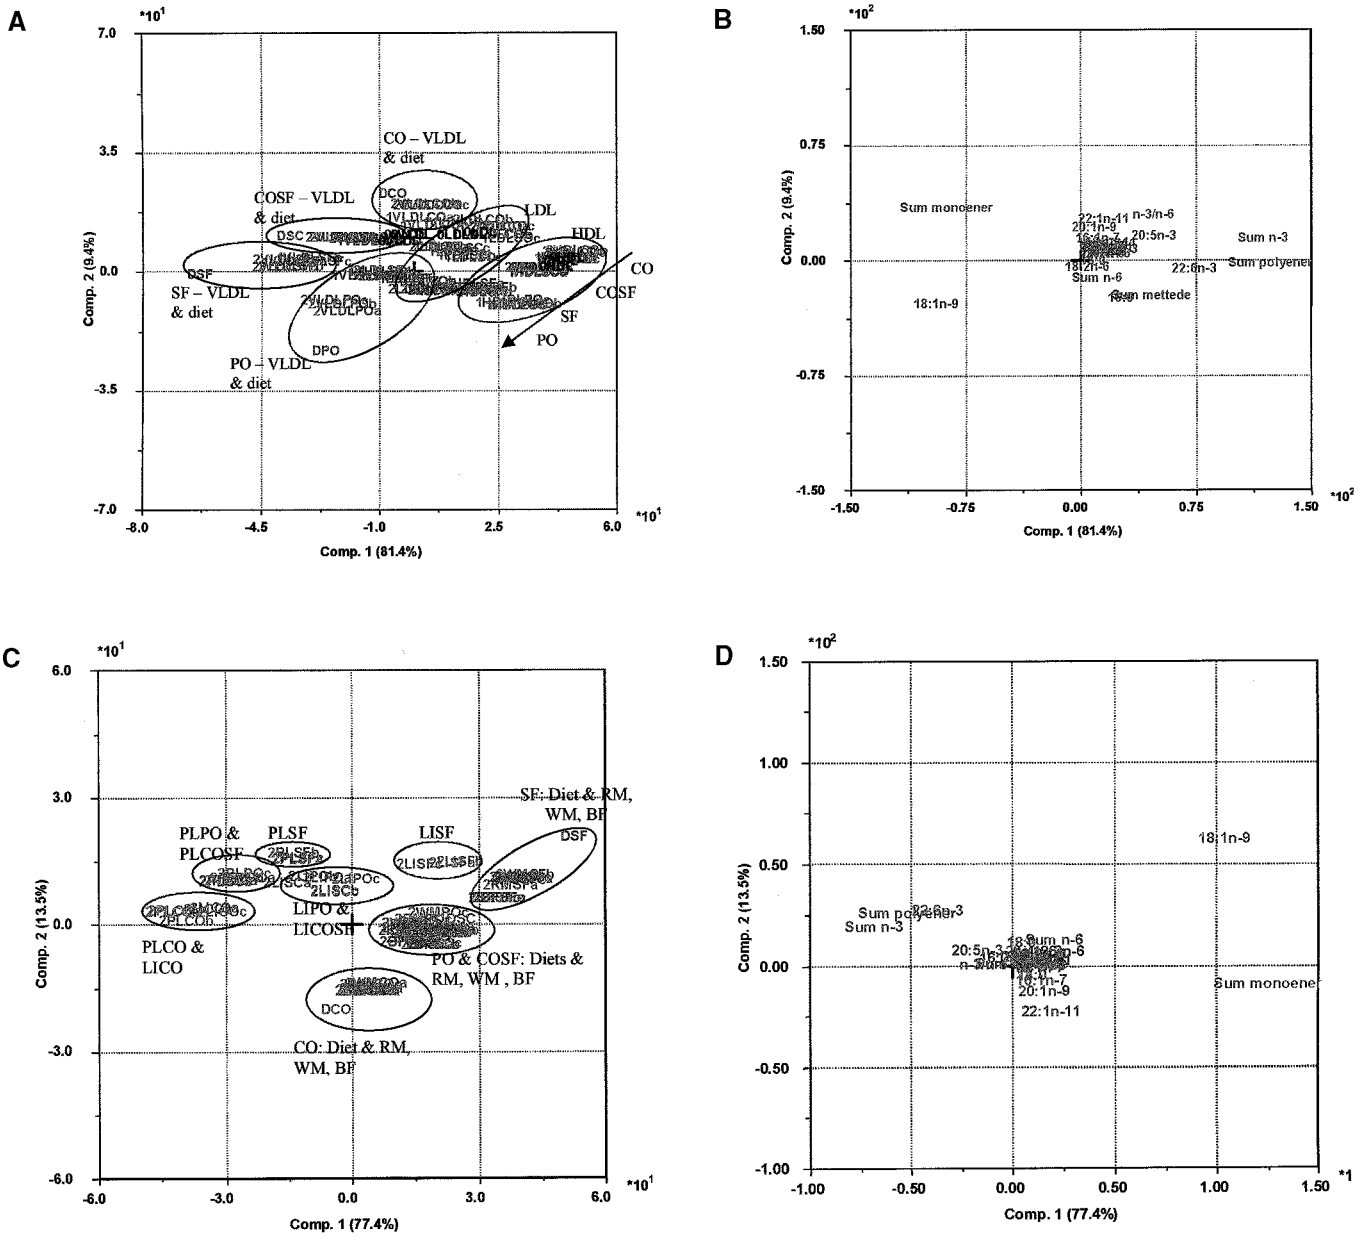

FIG. 1. Score plots (A and C) and load plots (B and D) revealed from principal component analysis of fatty acid composition data. (A and B) Score and load plots of the fatty acid composition data of very low density lipoprotein (VLDL), low density lipoprotein (LDL), and high density lipoprotein (HDL) from Atlantic salmon fed the experimental diets for 21 wk and dietary fatty acid composition data. (C and D) Score and load plots of the fatty acid composition data of plasma (PL), red muscle (RM), white muscle (WM), belly flap (BF), and liver (LI) from Atlantic salmon fed the experimental diets for 21 wk and dietary fatty acid composition data. The arrow in Figure 1A indicates the orientation of the different dietary groups within HDL and LDL. The diets are coded according to dietary oil source; CO, capelin oil; COSF, capelin oil and oleic acid-enriched sunflower oil; SF, oleic acid-enriched sunflower oil; and PO, palm oil.

RESULTS

Triplicate groups of Atlantic salmon were fed four diets containing different oils, i.e., CO, SF, PO, and COSF. The four diets had characteristic fatty acid compositions: CO, high levels of long-chain monoenes and n-3 PUFA; SF, high levels of 18:1n-9 and low levels of n-3 PUFA; COSF, intermediate levels of the characteristic fatty acids of CO and SF; and PO, high levels of 16:0 and 18:1n-9 and low levels of n-3 PUFA. Fish weights increased 2.4 times during the experimental period, and growth was not significantly affected by dietary lipid source. Although the PO group had the lowest [0.55 ± 0.08% body weight (BW) d^{-1}] and the SF group the highest (0.67 ± 0.01% BW d^{-1}) growth, the differences were not statistically significant. The fish weight (mean ± SD) at the end of the experiment was 3.6 ± 0.2 kg in the CO group, 3.7 ± 0.4 kg in the COSF group, 3.8 ± 0.2 kg in the SF group, and 3.2 ± 0.2 kg in the PO group. The feed conversion factor (feed/weight gain) was affected by dietary lipid source, however, not statistically significant. The PO group had a higher

feed conversion factor (1.04) compared to the other three dietary groups (0.91–0.95). Mortality was negligible throughout the experimental period with no more than two dead fish per dietary group. Calculated for the whole experimental period, the productive protein value (PPV) ranged from 0.43 ± 0.01 in the PO group to 0.47 ± 0.05 in the CO group, and there were no significant differences in PPV between the dietary groups. The lipid utilization [(biomass lipid final sampling) – (biomass lipid initial sampling)/(amount of lipid intake)], however, was significantly lower in the PO group (0.51 ± 0.03) compared to the other three dietary groups (CO: 0.78 ± 0.04, COSF: 0.78 ± 0.04; SF: 0.83 ± 0.04).

Total β-oxidation. The red muscle was the only tissue with significant β-oxidation of [1-^{14}C]palmitoyl-CoA in all samplings (Fig. 2). The β-oxidation capacity was not significantly affected by the dietary treatments in any of the samplings. However, there was a trend toward higher β-oxidation capacity in the SF group compared to the other dietary treatments in the intermediate sampling. The β-oxidation capacity in white muscle and liver was low at the initial sampling with 4.9 and 0.7 pmol/min/mg protein, respectively. At the two following samplings, no β-oxidation was detected in liver or white muscle using the [1-^{14}C]palmitoyl-CoA assay.

Plasma and lipoprotein lipid composition. Protein, total cholesterol, and triacylglycerol (TAG) were analyzed in total plasma, VLDL, LDL, and HDL at the intermediate and final sampling (Table 2). The levels of all the analyzed components increased significantly from the intermediate to the final sampling in plasma, VLDL, and LDL. HDL composition was, however, unchanged from intermediate to final sampling. There were no significant differences between the four dietary treatments regarding levels of protein, total cholesterol, or TAG in any of the lipoproteins or plasma. However, the SF group in the final sampling tended to have higher levels of protein, cholesterol, and TAG in the HDL fraction compared to the other three dietary groups. Further, the PO group had lower levels of protein and total cholesterol in the HDL fraction in both samplings. The recoveries of cholesterol and TAG ranged from 77 to 97% and from 80 to 98%, respectively.

Fatty acid composition of VLDL, LDL, and HDL was affected decreasingly by dietary fatty acid composition (Figs. 1A and 1B). The LDL and HDL fractions contained higher levels of polyenes and n-3 fatty acids compared to the diets and VLDL. HDL was the lipoprotein fraction with the highest relative levels of polyene and n-3 fatty acids. Sum monoene, 22:1n-11, n-3/n-6, and sum n-3 had high positive loadings along principal component 2 (PC2), whereas 16:0, sum n-6, and 18:1n-9 had high negative loadings along PC2 (Fig. 1B). Therefore, the samples from the dietary groups have gradually decreasing scores along PC2: CO > COSF > SF > PO (indicated by an arrow in Fig. 1A).

Tissue lipid composition. Relative fatty acid composition of white muscle, red muscle, and belly flap almost directly reflected the dietary fatty acid composition in the four dietary groups (Figs. 1C and 1D). Further, PCA of the relative fatty acid composition of plasma, liver, white and red muscle, and belly flap revealed that the plasma and liver fatty acid compositions were differently affected in the four dietary groups. Especially in the dietary SF group, plasma and liver had distinctly different relative fatty acid compositions. The variables 22:6n-3, sum n-3, and polyenes had high negative loadings, and monoenes and 18:1n-9 had high positive loadings along PC1 (Fig. 1D). Consequently, the plasma and liver samples containing higher levels of n-3, 22:6n-3, and polyene fatty acids had high scores along PC1 whereas the diets, white- and red muscle, and belly flap samples containing high levels of 18:1n-9 and monoenes had low scores along PC1

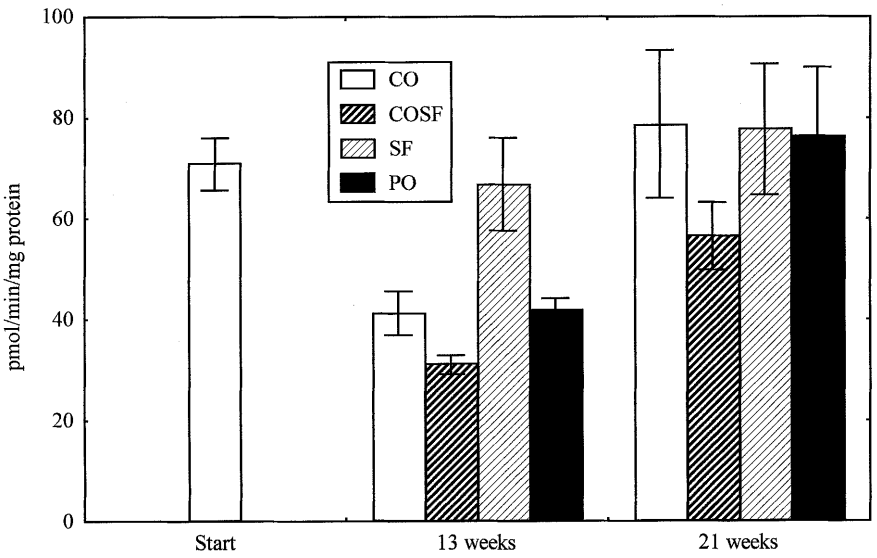

FIG. 2. Mitochondrial β-oxidation of [1-^{14}C]palmitoyl-CoA in red muscle from Atlantic salmon fed the experimental diets for 21 wk. Data are presented as mean ± SEM (n = 3). For abbreviations see Figure 1.

[a]Protein, g/L; Chol (cholesterol), mM; TAG (triacylglycerol), mM; VLDL, very low density lipoprotein; LDL, low density lipoprotein; HDL, high density lipoprotein. Lipoproteins and plasma were sampled from fish prior to feeding the experimental diets and from salmon fed the experimental diets for 12 wk and for 23 wk. Data are presented as mean ± SEM, $n = 3$. Values <0.1 are represented by an em dash (—).
[b]Superscript roman letters indicate significant differences ($P \leq 0.05$) between the intermediate and final sampling for each analyzed parameter. Where no letters are present, no significant differences were observed.

(Fig. 1C). The acid 18:1n-9 had a high positive loading whereas 22:1n-11 had a high negative loading along PC2 (Fig. 1D). This resulted in samples from the SF group having high positive scores and samples from the CO group having high negative scores along PC2 in the score plot (Fig. 1C).

The amount of fatty acids (mg g^{-1} tissue, wet weight) of belly flap, liver (Table 3), red and white muscle (Table 4) shows that the different dietary treatments produced significantly different fatty acid contents and composition in the tissues analyzed. The dietary PO and SF groups generally had the lowest and highest levels of total fatty acids, respectively, in the tissues analyzed. However, this was statistically significant only in red muscle and liver in the groups fed PO and SF, respectively. When comparing the levels of 16:0, 18:1n-9, 18:2n-6, and sum n-3 fatty acids of the dietary CO group with the other three dietary treatments, the large differences seen in the diets were rather modified in the various tissues. The SF diets, characterized by high 18:1n-9 levels, had significantly higher 18:1n-9 levels in all tissues analyzed. The PO diet contained 5.2 and 2.7 times more 16:0 than the SF and CO diet, respectively. When studying the tissue 16:0 levels, the PO groups contained significantly more 16:0 only in belly flap. The 16:0 levels in belly flap were 1.7 and 1.3 times higher in the PO groups compared to SF and CO groups, respectively. The SF and PO diets both contained 3.7 times more 18:2n-6 compared to the CO diet. In all tissues analyzed, the CO groups contained significantly less 18:2n-6 than the SF and PO groups. CO is characterized by high levels of 22:1n-11, thus in all tissues analyzed the dietary CO group contained the significantly highest tissue levels of 22:1n-11. The dietary COSF group contained intermediate tissue levels of 22:1n-11, whereas the dietary SF and PO groups had significantly the lowest tissue levels of 22:1n-11. The diets that supplied oils of plant origin typically contained low levels of long-chain n-3 fatty acids. This was reflected in belly flap, liver, plasma, red and white muscle where the CO groups contained the significantly highest levels of 20:5n-3, 22:6n-3, and sum n-3. The dietary groups fed a mixture of capelin and sunflower oil (1:1, w/w) (COSF) contained intermediate levels of n-3 fatty acids in the tissues analyzed, often

[a]Compositions given in mg fatty acid g^{-1} sample, wet weight. Data are shown as mean ± SEM. Values <0.1 are represented by an em dash (—).
[b]Superscript roman letters indicate significant differences ($P \leq 0.05$) between the dietary groups for individual fatty acids. Where no letters are present, no significant differences were observed. (Fatty acids tested for significant differences are listed in the Materials and Methods section).

not significantly different from the CO groups. Furthermore, in HDL the levels of n-3 fatty acids in the four dietary groups were not significantly different. The HDL 18:2n-6 levels, however, were six and seven times higher in PO and SF groups compared to the CO group. Thus, the n-3/n-6 ratios were significantly different between the dietary groups. The n-3/n-6 ratio in all tissues analyzed was significantly highest in the CO groups, followed by the COSF; and finally, the SF and PO groups had the lowest n-3/n-6 ratio. The 20:5n-3/22:6n-3 ratios were reversed in all tissues analyzed in all dietary groups, except the PO group, compared to the ratio in the diets.

AD of dietary fatty acids. The AD% was analyzed at the end of the experimental period (Table 5) using yttrium oxide as inert marker (0.01% inclusion level). The general trend was to decreasing AD% with increasing fatty acid chain length and to increasing AD% with increasing desaturation of the fatty acids. However, the dietary SF and PO groups had significantly lower AD% of monoene and n-3 fatty acids. The PO groups had significantly lower AD% of the saturated fatty acids, and especially 16:0 and 18:0 with, respectively, only 15.7 and 22.5 AD%. The dietary CO and COSF groups generally had the same AD% for all fatty acids, whereas the dietary groups with plant oils as dietary oil source, and especially the PO groups, had significantly lower AD% for a large number of fatty acids.

DISCUSSION

Total β-oxidation. The Atlantic salmon tissues were measured for total β-oxidation. However, in both Atlantic salmon (9) and mammals (30) peroxisomal β-oxidation is reported to account for less than 10% of the total β-oxidation. Thus, the β-oxidation measured is predominantly mitochondrial. Lipid catabolism has been shown to provide energy for sustained slow swimming, which is employed by the red muscle fibers. Red muscle was the only tissue in the adult Atlantic salmon with significant β-oxidation capacity, whereas liver and white muscle had negligible or undetectable β-oxidation capacities using the current assay with palmitoyl-CoA as substrate. Red muscle, liver, and heart, but not white muscle, are generally regarded as the most important tissues of fatty acid oxidation

in fish (31). However, when analyzing β-oxidation capacity using palmitoyl-L-carnitine and expressing it as activity per tissue, the white muscle is reported to contribute significantly to the overall β-oxidation of fatty acids in adult and post-smolt Atlantic salmon (4). Recent experiments by Frøyland *et al.* (4,9) on β-oxidation in various tissues in adult Atlantic salmon, done after starting the current fish experiment, demonstrated that the substrate used in the assay was significant to the obtained results. When β-oxidation capacities in Atlantic salmon tissues were measured using palmitoyl-L-carnitine as substrate, the results were approximately 2.5-fold higher in red muscle compared to experiments using palmitoyl-CoA as substrate. The measured β-oxidation capacities in liver and white muscle were 5- to 20-fold higher when measured using palmitoyl-L-carnitine compared to palmitoyl-CoA as substrate (4,9). Atlantic salmon post-smolt (weight approximately 400 g) are also reported to have higher β-oxidation capacities in red muscle (twofold), liver (twofold), and white muscle (10-fold) than adult Atlantic salmon (weight approximately 4 kg) (9). Consequently, the use of palmitoyl-CoA as substrate in the current experiment, as well as the high fish weights might explain the relatively low β-oxidation activity in red muscle and the lack of β-oxidation detectability in liver and white muscle. CPT-I in the outer mitochondria membrane converts acyl-CoA to acyl-carnitine (32). This step is essential since acyl-CoA cannot penetrate the inner mitochondrial membrane. By adding palmitoyl-L-carnitine as substrate in the β-oxidation assay, the CPT-I step is avoided, thus this substrate is more readily available for β-oxidation. Since palmitoyl-L-carnitine as substrate results in higher β-oxidation capacity compared to palmitoyl-CoA, this indicates that either the CPT-I activity or the availability of carnitine is rate-limiting for β-oxidation in Atlantic salmon tissues. It can therefore be argued that using palmitoyl-CoA as substrate when measuring mitochondrial β-oxidation gives a more physiologically accurate picture since the probable key point of regulation is included in contrast to using palmitoyl-carnitine as substrate.

Saturated and monoene fatty acids are reported to be preferred substrates, whereas PUFA are reported to be poor sub-

strates for mitochondrial β-oxidation in fish red muscle (5,6). The SF diet contained high levels of oleic acid (68.5%), and one could expect that this fatty acid would be selectively β-oxidized *in vivo* since 18:1n-9 are oxidized by mitochondria at relatively high rates *in vitro* (7 and 44% higher than, respectively, 16:0 and 22:6n-3) (6). The β-oxidation capacity in red muscle at the intermediate sampling was higher in the SF groups than in the other dietary treatments, however, not significantly. To increase the total β-oxidation capacity in a tissue, the number of mitochondria, peroxisomes, and enzymes, and/or the enzyme activity has to be increased (33). Certain fatty acids, such as 20:5n-3, have been found to act as a mitochondrial proliferator, thus increasing β-oxidation capacity, whereas prolonged feeding of 22:6n-3 increased peroxisomal β-oxidation capacity in rats (34). This effect of 20:5n-3 and 22:6n-3 was not detected in the groups fed the CO or COSF diets, which contained significantly higher dietary levels of these n-3 fatty acids. The fatty acid 16:0 is considered to be a good substrate for β-oxidation in mammals and fish. The PO group fed high levels of 16:0 (37.8%) and high levels of 18:1n-9 (35.9%) showed no tendency of induced mitochondrial β-oxidation in red muscle. However, when considering the low digestibility of 16:0 in the PO diet (15.7%), the actual amount of 16:0 absorbed by the fish was only 15.5 mg 16:0 per g feed, a lower 16:0 level than in both the CO and COSF diets. Studies done with acyl-carnitine as substrate suggest that 22:1n-11 is selectively utilized as an energy source by fish (7,35) and that 22:1 and 16:0 fatty acids serve equally well as substrates for β-oxidation (36). The CO and COSF diets contain, respectively, high and intermediate levels of 22:1n-11; thus, these diets are thought to contain fatty acids that are preferred substrates for β-oxidation. To detect possible significant differences in tissue β-oxidation capacities between dietary treatments, a diet containing fatty acids that are poor substrates for β-oxidation should be included. Further, high levels of dietary lipids increase fish growth, spare dietary protein, and increase feed efficiency. A dietary fatty acid composition that induces β-oxidation would further increase the protein utilization by selectively providing energy through lipid oxidation, sparing protein for muscle growth. The growth, feed efficiency, and protein utilization were not significantly affected by dietary fatty acid composition during the experimental period. The observed trends, however, indicate that the experimental diets, fed over longer time periods and in life stages with higher growth rates, would probably result in significant differences. Further, when already operating at dietary lipid levels exceeding 30%, the possible effects on β-oxidation capacity of adding dietary fatty acids preferred as substrates for β-oxidation might be masked by high dietary lipid levels. To fully study *in vivo* induction of β-oxidation by dietary fatty acids, factors such as digestibility, transport and absorption of fatty acids into cells have to be taken into account. To achieve conclusive results regarding which fatty acids possibly induce β-oxidation in fish, further *in vitro* experiments would be valuable.

Plasma and lipoprotein composition. It is well established

through studies on mammals that dietary fatty acid composition is important in determining plasma lipoprotein cholesterol concentrations. Saturated fatty acids especially are reported to increase plasma cholesterol levels (37). In this experiment the amount of dietary saturated fatty acids varied from 12.5% in the SF diet to 45.3% in the PO diet. These differences in dietary fatty acid composition did not affect plasma or lipoprotein cholesterol levels in the Atlantic salmon. However, when taking the digestibility of the fatty acids into account (Table 5), the actual amount of 16:0 absorbed from the PO diet is close to the SF dietary 16:0 level. Thus, unaffected salmon plasma cholesterol levels might be due to the low digestibility of the saturated fatty acids especially in the PO groups.

Generally the amounts of cholesterol, protein, and TAG in plasma, VLDL, and LDL increased (not always significantly) from the intermediate to the final sampling, whereas the HDL levels remained unchanged. The fish were unfed 24 h prior to sampling, which probably was too short a time for the fish to totally empty its intestine at the final sampling. Thus, the salmon were not in a postabsorptive phase in the final sampling, giving the higher levels of plasma VLDL and LDL. Plasma HDL levels, however, seem to be unaffected by the feeding status of the fish.

Although the fatty acid composition of the lipoproteins were affected by dietary fatty acid composition, it seems that HDL is especially high in n-3 fatty acids and that this level is independent of dietary fatty acid composition. This is in accordance with previously reported (17) and submitted (Torstensen, B.E., Lie, Ø., and Hamre, K., unpublished data). results on lipoprotein fatty acid composition in Atlantic salmon. These differences in dietary fatty acid response might be related to the different metabolism and site of synthesis of the different lipoproteins (17). HDL is the dominant lipoprotein in Atlantic salmon (17; Torstensen, B.E., Lie, Ø., and Hamre, K., unpublished data), and the plasma fatty acid composition mirrored the HDL fatty acid composition in all dietary groups.

Tissue lipid composition. It is well known that tissues of Atlantic salmon, as well as other fish species, are markedly influenced by dietary fatty acid composition (38–40). However, different Atlantic salmon tissues are affected by dietary fatty acid composition in varying degree (40). Especially belly flap, red and white muscle were affected by dietary fatty acid composition (Figs. 1C and 1D; Tables 3 and 4). Histological studies have shown that belly flaps, the subcutaneous fat layer, and myosepta are the main sites for adipocytes in Atlantic salmon, whereas lipid droplets are found in the endomysium around red muscle fibers (41). Adipocytes and lipid droplets contain considerable amounts of TAG, which have been shown to be more influenced by dietary fatty acid composition than phospholipids (PL) (42). This observation, in addition to some influence on PL fatty acid composition, might to some extent explain the great influence of dietary fatty acids on belly flap, red and white muscle fatty acid compositions. The Atlantic salmon liver was relatively low in lipids (approximately 4%), and the fatty acid composition was less affected by dietary fatty acid composition than muscle and belly flap. A significantly increased liver lipid level (6% lipid) was observed in the SF group (Table 3). A pale-lipid enriched liver in Atlantic salmon is an indication of essential fatty acid deficiency (43). Thus, the minor accumulation of liver lipids in the SF group might be an indication of lipid metabolism imbalance in this dietary group.

AD of fatty acids. To fully evaluate the effects of adding alternative oil sources to salmon feeds it is important also to investigate the effects of different dietary fatty acid compositions on the digestibility of lipids and other feed ingredients. AD% indicates fractional net absorption of the fatty acids from the experimental diets, and it does not account for any variation in dietary intake of lipids ($\mu g\ g^{-1}$ BW d^{-1}) (44). Yttrium oxide is increasingly used as an inert nonabsorbable marker as a preferred alternative over chromium oxide for evaluation of AD (44). AD% of the fatty acids in the groups fed CO, COSF, and SF diets was in the same range as previously reported fatty acid digestibility in Atlantic salmon (19), with CO and COSF groups having somewhat higher AD%. In the groups fed the experimental PO diets, however, the AD was significantly lower for all fatty acids investigated except the n-3 fatty acids. The saturated and n-6 fatty acids especially had low AD in the PO groups. Concomitantly, lipid utilization was significantly lower in the PO group compared to the other dietary groups, probably owing to the significantly lower digestibility of lipids in the PO group. This affected the specific growth rate (SGR) and feed conversion ratio (FCR), however not statistically significantly. This might be due to the short experimental time period and to the fact that the high dietary lipid level (above 30%) allows large variations in lipid digestibility before significant effects are seen in SGR and FCR. Saturated and long-chain monounsaturated fatty acids have lower digestibility in Atlantic salmon (19), cod *(Gadus morhua)* (18), and Arctic charr *(Salvelinus alpinus)* (20). The fatty acid compositions of the PO and SF diet were drastically different from fish oil-based diets. However, the Atlantic salmon managed to digest the SF lipids more efficiently than the high saturated fatty acid PO diet. Ringø (45) found that 18:2n-6 supplementation to formulated feed reduced growth and the lipid and proein digestibility by Arctic charr, possibly by affecting the intestinal bacterial flora (46). The dietary levels of 18:2n-6 were higher in both the SF (7%) and PO (8%) groups compared to the COSF (4%) and CO (2%) groups. However, since the digestibility of 16:0 was particularly low in the PO group, a high load of 16:0 may disturb the overall lipid digestibility in this group, in addition to a negative effect of 18:2n-6 on digestibility in both the SF and PO groups. To fully understand the mechanisms of the effects of dietary fatty acid composition on fatty acid AD in Atlantic salmon, further studies need to be performed.

In conclusion, the different dietary oil sources—CO, SF, COSF, and PO—resulted in diets with significantly different fatty acid compositions. The dietary fatty acid compositions were gradually less reflected by the belly flap, red muscle,

white muscle, VLDL, LDL, liver, plasma and HDL concomitantly with increased liver lipid level in the fish fed the SF diet. Mitochondrial β-oxidation capacity in red muscle was not significantly induced by any of the dietary fatty acid compositions. The fatty acids in the diet based on PO as dietary oil source were poorly digested. Further, the mixture of CO and COSF resulted in a salmon with n-3 white muscle levels similar to the CO group; no negative effects were observed using this oil mixture in the adult Atlantic salmon diet.

ABSTRACT: Five 1,2-cyclic acetal-type *sn*-glycero-3-phosphoethanolamines (CGPE) were isolated in a pure state from the sea anemone, *Actiniogeton* sp. (Coelenterata). Their structures, including the absolute configurations, have been determined on the basis of chemical and spectral data to be so-called Feulgen's acetalphosphatides, which have been regarded as artifacts derived from original plasmalogens. We examined whether these CGPE are intact constituents in the animal tissues and obtained reliable confirmation that CGPE are normally present in the sea anemone.

Paper no. L8395 in *Lipids 35,* 665–671 (June 2000).

In 1939, 1,2-cyclic acetal-type glycerophospholipids were first obtained from bovine muscle by Feulgen and Bersin (1). During the structural elucidation of naturally occurring plasmalogens, these compounds have usually been called Feulgen's acetalphosphatide, and they are generally believed to be artifacts derived from the native plasmalogens in the course of isolation procedures, which involves alkaline treatment of a tissue (2,3).

In 1958, Bergmann and Landowne obtained analogous compounds from the sea anemone, *Anthopleura elegantissima* (4) by the use of neutral solvents, and they suggested that at least two types of plasmalogens occur in nature. They did not prove, however, that the compound was naturally present in the sea anemone.

In our systematic survey of the lipid compositions of invertebrates (5–8), we examined a phospholipid fraction from the sea anemone, *Actiniogeton* sp., and isolated five glycerophospholipids in a homogeneous state. Unlike the known constituents of sea anemones, such as phospho-, phosphonosphingolipids (9–11) and cerebrosides (12,13), all five have 1,2-cyclic acetal structures corresponding to the so-called Feulgen's acetalphosphatide.

In this study, we determined the structures of five 1,2-cyclic acetal-type glycerophosphoethanolamines (CGPE), including the absolute configurations, using homogeneous samples. We have made detailed nuclear magnetic resonance (NMR) spectral analyses of the phospholipid fraction, together with a histochemical assay of the tissue (14), and concluded that the CGPE are not artifacts but are natural constituents of the sea anemone.

MATERIALS AND METHODS

Isolation of 1,2-cyclic acetal-type sn*-glycero-3-phosphoethanolamines,* ***1–5***. Whole bodies of the sea anemone, *Actiniogeton* sp. (50 kg), which were collected from the Ariake Sea (Japan) in 1997, were soaked in 10 L of ethanol, then 8 L of chloroform/methanol (1:1, vol/vol), each stage being 7 d at room temperature. The extracts were combined and concentrated *in vacuo* to give a crude extract (570 g). This was shaken with 900 mL of chloroform/methanol/water (1:1:1, by vol). The lower phase gave, on evaporation, a fraction (35 g), which was placed on a silica gel column (Kieselgel 60; Merck, Darmstadt, Germany) and eluted successively with the following solvent systems: chloroform/methanol (20:1 → 10:1 → 8:2, vol/vol) → chloroform/methanol/water (7:3:0.5 → 6:4:1 → 1:2:0.5, by vol) . The eluates were monitored by silica gel thin-layer chromatography (TLC) (Silica gel 60 F_{254}; Merck) using as mobile phase chloroform/methanol/water (6:4:1, by vol). Those eluates showing a positive tailing band on spraying with Dittmer-Lester's reagent (15) were combined and concentrated *in vacuo* to give two phospholipid fractions, fr-a (7 g) and fr-b (4 g). The former was passed through a Sephadex LH-20 column (Pharmacia, Uppsala, Sweden) using chloroform/methanol (3:7, vol/vol) to give three fractions, fr-1 (0.6 g), fr-2 (3.0 g), and fr-3 (3.2 g). Fraction 3 was treated with ether, and the ether layer was subjected to preparative high-performance liquid chromatography (HPLC) on a reversed-phase octadecylsilylated column (ODS; Chemicals Inspection and Testing Institute, Tokyo, Japan; size, 10 mm i.d. × 250 mm × 2 columns) using chloro-

form/methanol/water (1:9:0.5, by vol) to give a crude CGPE fraction (fr. I, 2.8 g), together with compound **1**. A part of fr. I (0.4 g) was separated by HPLC using chloroform/methanol/water (1:10:1.1, by vol). Fractions corresponding to peaks (I-a–I-d) were collected and were further subjected to HPLC in a recycling mode using chloroform/methanol/water (1:10:1.1, by vol) to furnish five compounds, **1–5**. **1** (80 mg, $[\alpha]_D$ +15.1° at a concentration *c* of 1.5 g/100 mL solvent in chloroform/methanol, 1:1 by vol. Negative ion fast atom bombardment mass spectrometry (FAB MS), *m/z* = 464 $[M - H]^-$). **2** (12 mg, $[\alpha]_D$ +14.2° at *c* of 0.8 g/100 mL in chloroform/methanol, 1:1 by vol. *m/z* = 450 $[M - H]^-$). **3** (20 mg, $[\alpha]_D$ +16.1° at *c* of 0.6 g/100 mL in chloroform/methanol, 1:1 by vol. *m/z* = 436 $[M - H]^-$). **4** (4 mg, $[\alpha]_D$ +2.7° at *c* of 0.1 g/100 mL in chloroform/methanol, 1:1 by vol. *m/z* = 462 $[M - H]^-$). **5** (2 mg, $[\alpha]_D$ +2.7° at *c* of 0.1 g/100 mL in chloroform/methanol, 1:1 by vol. *m/z* = 450 $[M - H]^-$).

A commercial plasmalogen (Sigma Chemical Co., St. Louis, MO) α-L-phosphatidylethanolamine-type plasmalogen) was placed on silica gel and treated with the same separation procedures described above.

NMR spectroscopy. The NMR spectra were recorded at 600 MHz (^{1}H) and 150 MHz (^{13}C) (Omega 600, Fremont, CA) and at 400 MHz (JMN GSX 400, JEOL Ltd., Tokyo, Japan) with tetramethylsilane (TMS) as the internal standard, at a probe temperature of 35°C. The two-dimensional nuclear Overhauser effect (NOESY) spectrum was obtained using a mixing time of 300 ms. The two-dimensional heteronuclear multiple bond connectivity (HMBC) spectrum was recorded at 600 MHz with 32 scans ($^{2,3}J_{CH}$ = 7.0 Hz).

Mass spectrometer. The mass spectra were taken on a JMS DX-300 spectrometer equipped with a JMA 3500 data system (JEOL Ltd.) [FAB MS: accelerating voltage, 3 kV; matrix, triethylene glycol and triethylamine; collision gas, Xe; electron impact mass spectrometry (EI MS): ionization voltage, 30 eV; accelerating voltage, 3 kV].

*Preparation of the dimethyl disulfide derivative of **4***. According to the method reported by Vincenti *et al*. (16), carbon disulfide (0.2 mL) and iodine (1 mg) were added to **4** (1 mg) in dimethyl disulfide (0.2 mL). The mixture was kept at 60°C for 60 h, quenched with a 5% aqueous solution of sodium thiosulfate, and then shaken with chloroform/methanol (1:1, vol/vol, 3 mL). The lower phase was evaporated under a nitrogen stream, and the residue was subjected to analysis by EI MS spectrometry.

*Syntheses of four stereoisomers, **6–9***. Stearyl aldehyde (3.5 g) was dissolved in benzene (100 mL). (*R*)-3-Chloro-1,2-propanediol acetonide (6 mL, Azmax Co. Ltd. Kisarazu, Japan) and *p*-toluenesulfonic acid (100 mg) were added to the solution and heated at 55°C for 2.5 h. The reaction mixture was poured into ice water and shaken. The benzene layer was collected and concentrated *in vacuo* to give a fraction that was subjected to column chromatography on silica gel to give a mixture of two stereoisomers (3.2 g). They were separated by preparative HPLC (ODS; GL Science Inc., Tokyo, Japan; 20 mm i.d. × 25 cm, methanol) to give two 2*R*-derivatives, **6** and **7**. (*S*)-3-Chloro-1,2-propanediol acetonide was treated in the same manner as described above to yield two 2*S*-derivatives, **8** and **9**. **6** (2*R*, 1′*R* form, m.p. 43.2–45.0°C. $[\alpha]_D$ +17.0° at a *c* of 2.0 g/100 mL in chloroform. EI MS *m/z* = 360 $[M]^{\cdot+}$). **7** (2*R*, 1′*S* form, m.p. 38.0–40.2°C. $[\alpha]_D$ +21.9° at a *c* of 2.0 g/100 mL in chloroform. *m/z* = 360 $[M]^{\cdot+}$). **8** (2*S*, 1′*R* form, m.p. 43.5–44.3°C. $[\alpha]_D$ −20.7° at a *c* of 2.0 g/100 mL in chloroform). **9** (2*S*, 1′*S* form, m.p. 46.2–46.5°C. $[\alpha]_D$ −19.9° at a *c* of 2.0 g/100 mL in chloroform).

*Preparation of **10***. Compound **6** was dissolved in 1% KOH in methanol/water (4:1, vol/vol, 10 mL) and refluxed for 10 h to give 3-OCH_3 derivative (**10**). **10** $[\alpha]_D$ +9.8° at a *c* of 0.8 g/100 mL in chloroform. *m/z* = 356 $[M]^{\cdot+}$.

*Preparation of **10** from **1***. Compound **1** (42 mg) was dissolved in 1.5% $Ba(OH)_2$ in *n*-hexane/methanol/water (1:1:1, by vol, 4.5 mL), and the mixture was refluxed for 3 h. After removal of the *n*-hexane layer, *n*-hexane (1.5 mL) was added to the remaining solution, and it was refluxed again for 3 h. The *n*-hexane layers were combined and the solvent evaporated under a nitrogen stream to give a dephosphorylated product (25.4 mg). This product was methylated by the Hakomori method (17), and the product was subjected to silica gel column chromatography with *n*-hexane/ethyl acetate (20:1, vol/vol) to give **10** (9.2 mg, $[\alpha]_D$ +10.2° at a *c* of 0.9 g/100 mL in chloroform).

Histochemical assay. Frozen sea anemone tissues were sectioned at 5–8 μm and were treated according to the modified Feulgen-Voit method reported by Hayes (18).

RESULTS AND DISCUSSION

Isolation of five 1,2-cyclic acetal-type sn*-glycero-3-phosphoethanolamines, **1–5***. The total sea anemone lipid fraction obtained by the method of Folch *et al*. (19) was subjected to a combination of Sephadex LH-20 and silica gel column chromatographies with various solvent systems to give a crude phospholipid fraction (Fig. 1). The final purification was achieved by mean of preparative HPLC under a recycling mode to give five CGPE **1–5** (Scheme 1). Each exhibited a single $[M - H]^-$ ion peak in its negative ion FAB MS spectra, and no other $[M - H]^-$ ion peak due to analogous compounds. These observations showed that all were homogeneous compounds.

^{1}H and ^{13}C NMR spectroscopy. The ^{1}H NMR spectrum of **1** showed signals due to a saturated carbon chain and a phosphoethanolamine group, together with signals, 1-H_2 (*dd*, δ 3.68 and 4.13) and 2-H (*m*, δ 3.92), of a glycerol moiety. In addition, a characteristic double doublet signal ascribable to an acetal proton was observed at δ 4.98. In the ^{13}C NMR spectrum, the signals of 1-C, 2-C, and 3-C due to the glycerol unit as well as two methylene carbon signals of the ethanolamine group appeared as doublets owing to coupling with ^{31}P (7). Furthermore, the signal of the acetal carbon was observed at δ 105.0. Its HMBC spectrum showed long-range correlation peaks between the acetal proton (1′-H) and two carbons (1-C and 2-C of the glycerol unit). From the information obtained above, compound **1** was defined as 1,2-cyclic

Column: L-column (10 × 250 mm) × 2; refractive index detector. (A) Solvent: $CHCl_3$/MeOH/H_2O, 1:9:0.5 by vol, 2.0 mL/min. (B) Solvent: $CHCl_3$/MeOH/H_2O, 1:10:1.1, by vol, 2.5 mL/min.

acetal glycero-3-phosphoethanolamine with a C_{18} straight carbon chain.

Determination of the absolute configuration. Compound **1** showed specific rotation, $[\alpha]_D$ + 15.1°. The NOESY spectrum of **1** exhibited a clear NOE correlation between 1′-H and 2-H, suggesting that the stereochemistry between 1′-H and 2-H is *cis*, namely, 2*R*,1′*R* or 2*S*,1′*S* configuration. From this finding, in conjunction with the fact that 2-C of the glycerol moiety of natural glycerophospholipid commonly has the *R* configuration, 1′-C was considered to be *R* configuration.

For confirmation of the above hypothesis, four stereoisomers, **6**–**9**, were synthesized using the starting materials, (*R*)- and (*S*)-3-chloro-1,2-propanediol acetonides (Scheme 2).

The ^{1}H NMR spectrum of **6** (2*R*,1′*R*) showed, when compared with that of **1**, quite similar chemical shifts and coupling patterns attributable to 1′-H and 2-H of **6** to those of **1** (Table 1). In the NOESY spectrum of **6**, a NOE correlation between 1′-H and 2-H similar to that of **1** was observed (Scheme 3). In contrast, compound **7** (2*R*,1′*S*) gave no correlation peak between 1′-H and 2-H in its NOESY spectrum. These facts exclude the possibilities of 2*R*,1′*S* or 2*S*,1′*R* structures, and therefore **1** was concluded to have 2*R*,1′*R* or 2*S*,1′*S* configuration. The final discrimination between 2*R*,1′*R* and 2*S*,1′*S* was achieved by comparing the specific rotation value.

Treatment of **6** with 1% KOH in methanol/water (4:1, vol/vol) for 10 h yielded **10** ($[\alpha]_D$ +9.8°). In addition, when **1** was refluxed with 1.5% $Ba(OH)_2$ in 50% methanol/*n*-hexane (2:1, vol/vol), and the lyso product formed methylated according to the Hakomori method to give a 3-OCH_3 derivative, it showed almost the same specific rotation ($[\alpha]_D$ +10.2°) as that of **10** (Scheme 2). On the basis of the results described above, the stereochemistry of **1** was concluded to be 2*R*,1′*R*.

*Structures of **2**–**5***. The structures of **2**–**5** were elucidated in the same manner as described for **1**, and their spectral data revealed that they have the same 1,2-cyclic acetal structures as **1**, and that they differ only in the long carbon-chain structure. Among these, compound **4** has a double bond in the carbon chain. The position of the double bond was determined according to the method of Vincenti *et al*. (16) with compound **4** converted into a dimethyl disulfide derivative. Its EI MS spectrum gave a diagnostically important fragment ion peak at *m/z* = 174 ($C_{10}H_{22}S$), which was regarded as due to the fragment ion peak produced by cleavage between the 9′-C and 10′-C sulfided carbons. The geometry of the double bond was assigned as *cis,* based on the coupling constants of 9′-H and 10′-H, together with the chemical shifts of the allylic carbons, 8′-C and 11′-C (δ 27.6, 27.8) (Table 2) (20). Taking account of the fact that the signals of 2-H and 1′-H showed almost the same chemical shifts and coupling patterns as those of **1**, and the same specific rotation signs, all were considered to have 2*R*,1′*R* configurations.

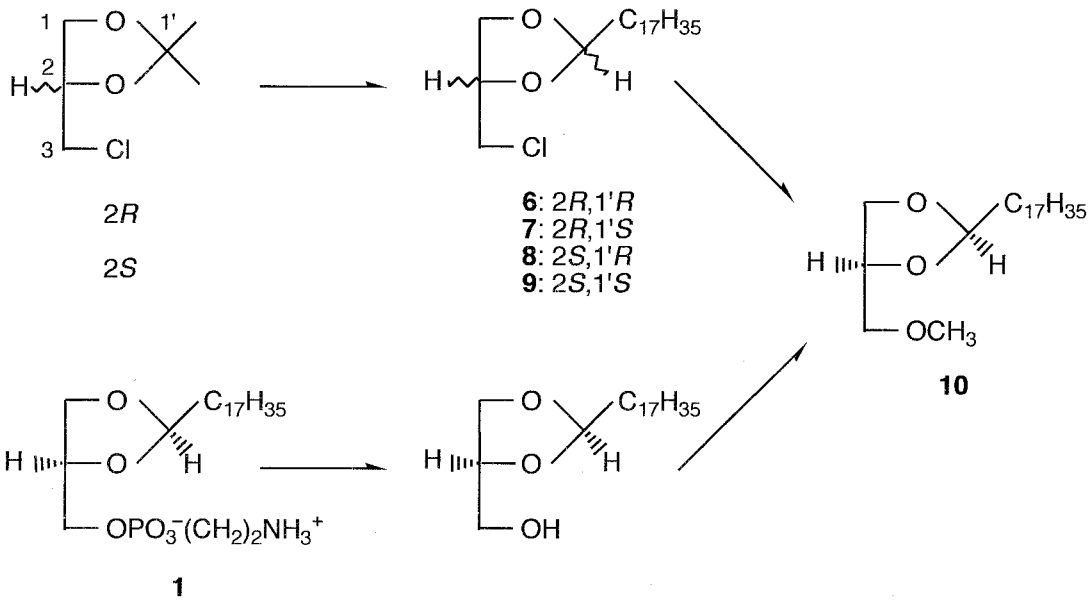

SCHEME 2

^{1}H NMR examination of the total lipid fraction obtained from fresh tissue. Live sea anemone materials were freeze-dried and then soaked in chloroform/methanol (1:1, vol/vol) at –5°C for 1 d. The solvent was added to water and shaken. A lower phase was collected and shaken with *n*-hexane. The lower phase was then concentrated to give a crude phospholipid fraction. This fraction showed no spot corresponding to that of the commercial plasmalogen on TLC. Moreover, its ^{1}H NMR spectrum showed the characteristic double doublet signal due to the acetal proton at δ 4.99, but no diagnostically important signal (*ca.* δ 5.9) ascribable to the vinyl proton of the native plasmalogen appeared (Fig. 2).

Formation of 1,2-cyclic acetal. The commercial plasmalogen was placed on silica gel and treated with the same isola-

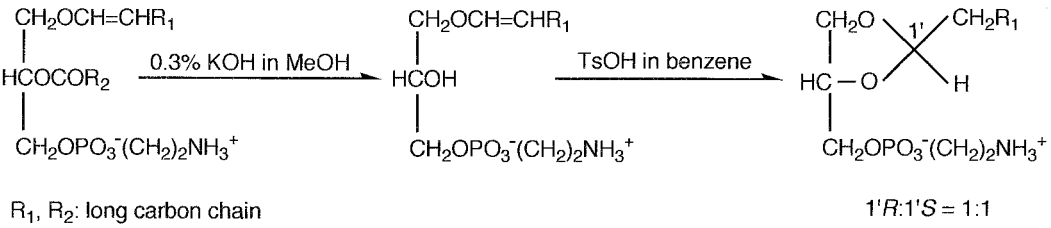
[a]δ in ppm from TMS. **1–5** were dissolved in $CDCl_3/CD_3OD$ (1:1, vol/vol) and **6–9** were dissolved in $CDCl_3$. For abbreviations see Table 1. For structures of **1–9** see Schemes 1 and 2.



SCHEME 4

tion procedures to give a product. The ^{1}H NMR spectrum of the product was identical with that of the starting material. Then, it was refluxed with 0.3% KOH in methanol for 3 h to afford a lyso product which was refluxed with benzene for 30 min in the presence of *p*-toluenesulfonic acid to give a product that showed two characteristic signals in the ^{1}H NMR spectrum attributable to the acetal protons at δ 4.8 and 5.0 (ratio of the peak intensity, *ca.* 1:1). Table 1 shows that the acetal proton signal of the 2*R*,1′*S* form appears at a higher field than that of 2*R*,1′*R* form. It was concluded that this product was the mixture of 2*R*,1′*S* and 2*R*,1′*R* forms in the ratio of 1:1 (Scheme 4). This finding demonstrated that a lyso plasmalogen having an *sn*-2 free hydroxyl group is required as an intermediate for conversion of a plasmalogen into a 1,2-cyclic acetal compound.

Histochemical assay with the plasmal reagent. Fresh tissues prepared from bovine brain could be stained with an appropriate histochemical reagent (18); in contrast, the sliced tissues of the sea anemone, as well as compound **1**, did not stain on treatment under the same conditions. This observation showed that **1** released no fatty aldehyde on treatment with mercuric chloride.

In conclusion, five CGPE were obtained from the sea anemone, *Actiniogeton* sp. The structures of all were assigned to the 2*R*,1′*R* cyclic acetal type *sn*-glycero-3-phosphoethanolamines based on the NMR spectral analyses and chemical synthesis.

Currently there is a general conception that 1,2-cyclic acetal-type glycerophospholipids are formed during the course of isolation procedures, and hence that they are artifacts derived from native ethanolamine or choline plasmalogens. Contrary to the above conception, we have concluded from our results that the CGPE are actually present in the live sea anemone.

ACKNOWLEDGMENTS

The authors thank Dr. Hiroomi Uchida of the Laboratory of Sabiura Marine Garden, Wakayama, for identification of the sea anemone. Thanks are also due to Dr. Masatoshi Nishi and Mr. Shoji Yamaguchi of this university for the measurements of NMR and MS spectra. We are indebted to Dr. Kiyokazu Ozaki and Dr. Toshiyuki Takagi of this university for their valuable discussion. This work was financially supported by a Grant-in-Aid for Scientific Research (No. 10672013) from the Ministry of Education, Science, Sports and Culture.

ABSTRACT: Two novel lipopeptides, which have the peptide ligands [α-melanocyte stimulating hormone (α-MSH)] sequence and repeated [Gly-Arg-Gly-Asp-Se (GRGDS) sequence], are designed, synthesized by the solid-phase method, and introduced into liposome membranes by the freeze–thaw method. These liposomes bearing the peptide ligands on their surface are expected to bind to cell membranes. We have confirmed that the lipopeptides are introduced into liposome membranes almost quantitatively, while such a high degree of incorporation has not been accomplished in conventional methods. In this respect, the present method is superior to prepare surface-modified liposomes that are applicable to drug carriers and so on. We have also confirmed by using immunoelectron microscopy that the peptide ligands are actually located in an aqueous phase. It has been shown by flow cytometry that the liposome bearing α-MSH peptide ligand binds to B16 cells and the liposome bearing the repeated GRGDS sequence binds to NIH3T3 cells.

Paper no. L8373 in *Lipids 35,* 673–679 (June 2000).

Though liposomes have been extensively studied as promising carriers of drugs (1), proteins (2), and DNA (3–5) for drug delivery systems (DDS), one of the major problems in using liposomes for DDS is their nonspecificity of delivery, which is the result of the entrapment of liposome by reticuloendothelial systems (6). Another type of drug carrier is a virus, which is used as a vector in the field of gene therapy (7). In spite of their prominent function as a drug carrier, problems endangering vital functions have not been fully solved yet, and therefore their clinical usage is restricted. In contrast to viruses, liposomes have superior points in safety and reproducibility if their specificity can be improved. Many studies have been undertaken to provide liposome with the binding specificity to cells. There are examples in which the liposome surface has been equipped with a glycolipid (8), transferrin (9), or an antibody (10,11) as a binding anchor to cells. Peptides seem to be the most suitable among various ligand candidates (12–14), because information about amino acid sequences of ligands and corresponding receptors can be easily obtained and synthetic methods have been well investigated (15). In usual methods like the "succinimide method" (10), peptides are reacted with lipids already incorporated into a liposome membrane. With these techniques, however, it is very difficult to modify the surface of liposomes at high density because the reaction is inhibited by steric repulsion between liposome surface and peptide parts. To solve this problem, we have developed a new method to modify the liposome surface efficiently and quantitatively using peptide ligands (16). Lipopeptide composed of peptide and lipid parts is chemically synthesized in advance and then is incorporated into liposome bilayer membrane at the same time that liposome is prepared. A notable feature of this method is the synthesis of lipopeptide by a solid-phase method. Namely, peptide ligands bound to resin are prepared first, then coupled with a lipid portion in the solid state; finally, the resultant lipopeptides are removed from the resin simultaneously with deprotecting reactions of the side chains. In the present study, two types of peptide sequences, α-melanocyte-stimulating hormone (α-MSH) (17) and cell adhesion sequence of fibronectin [*viz.*, [Gly-Arg-Gly-Asp-Se (GRGDS) sequence] (18), are used; their structures and properties are well known as ligands to receptors of cell membrane.

EXPERIMENTAL PROCEDURES

Chemicals. Fmoc (9-fluorenylmethyloxycarbonyl) amino acids and trifluoroacetic acid (TFA) were purchased from Watanabe Chemical Ind. (Hiroshima, Japan). TGR-resin for peptide synthesis was commercially available from Calbiochem Novabiochem Corp (La Jolla, CA). Egg phosphatidylcholine (EPC) was purchased from Avanti Polar Lipids (Birmingham, AL). All other reagents were of the highest grade commercially available.

Instruments. Proton nuclear magnetic resonance (NMR) spectra were recorded at 270 MHz on a JEOL JNM EX-270 FT spectrometer (Tokyo, Japan). Matrix assisted laser desorption/ionization time of flight mass spectra (MALDI-TOFMS) were acquired on a Kratos Analytical Kompact Maldi III spectrometer (Kyoto, Japan), and fast atom bombardment mass spectra were measured on a JEOL JMS-SX102A mass spectrometer. Peptides were prepared with a PerSeptive Pioneer peptide synthesizer (Foster, CA). Fluorescence emitted from cells was analyzed by a Coulter Epics Elite flow cytometer (Hialeah, FL). Morphology of the liposomes was observed under a Hitachi H-7000 electron microscope operated at 75 kV (Tokyo, Japan).

Syntheses. (i) W5GRGDS. The peptide on TGR-resin was synthesized by the Fmoc solid-phase method (19). To obtain free peptide W5GRGDS (Fig. 1), the peptide-resin (0.1 mmol) was treated with a mixture of TFA (5.0 mL), 1,2-ethanedithiol (EDT) (125 μL), thioanisole (125 μL), and water (250 μL). After the mixture had reacted at room temperature for 5 h, it was filtered and cold diethyl ether (volume of more than 50 times) was added to the filtrate to obtain white precipitates. After the precipitate was isolated by centrifugation (3000 rpm, 30 min) and dried *in vacuo*, it was purified by high-performance liquid chromatography (HPLC) and the isolated fraction was lyophilized. Yield: 90 mg (37.8%, 37.8 μmol). Retention time in HPLC [YMC-Pack ODS-AM (YMC Co., Ltd., Kyoto, Japan), ϕ: 4.6 × 250 mm, TFA (0.08% in water)/acetonitrile from 100:0 to 70:30 over 25 min, flow rate: 0.8 mL/min]: 18.3 min. ^{1}H NMR (D_2O) δ 7.62 (*d*, 2H, Trp, J = 7.9 Hz), 7.49 (*d*, 2H, Trp, J = 7.9 Hz), 7.19 (*s*, 1H, Trp), 7.23 (*m*, 1H, Trp), 7.14 (*m*, 1H, Trp), 4.78 (*m*, 6H, CH), 4.24–4.46 (*m*, 10H, CH), 3.80–4.06 (*m*, 30H, Ser-CH_2, Gly-CH_2), 3.21 (*m*, 10H, Arg-$CH_2CH_2CH_2N$), 2.74–3.02 (*m*, 10H, Asp-CH_2), 1.54–2.00 (*m*, 20H, Arg-$CH_2CH_2CH_2N$), MALDI-TOFMS Calc'd: 2565 (MH^+), found: 2566.

(ii) RGD-C4A2 (Fig. 1). Lipid C4 (Fig. 1) (100 mg, 114 μmol) and 1-hydroxybenzotriazole (HOBt) (34.8 mg, 227 μmol) were dissolved in 5.0 mL of chloroform at 50°C, which was then added to the peptide-resin (363.2 mg, 38 μmol) suspended in 10.0 mL of *N,N*-dimethylformamide (DMF). 4-Dimethylaminopyridine (DMAP) (27.8 mg, 227 μmol) and 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride (WSCD·HCl) (43.6 mg, 227 μmol) dissolved in chloroform (1.0 mL) were added to the above suspension and stirred for 12 h at 50°C. Following separation of the resultant lipopeptide-resin by filtration, it was washed with DMF, chloroform, and methanol (2.0 mL × 10 times each), and dried *in vacuo*. This lipopeptide-resin was then added to a solution of TFA (2.5 mL), thioanisole (62.5 μL), EDT (62.5 μL), triisopropylsilane (62.5 μL), and water (125 μL) at 0°C. The suspension was shaken for 5 h at room temperature, the resin was removed by filtration, and a large excess of cold ethyl ether (*ca.* 50 mL) was added to the filtrate. The resultant white precipitate was separated by centrifugation (3000 rpm, 30 min) and dried *in vacuo*. The product was purified by HPLC and lyophilized. Yield: 10.1 mg, (7.9%, 3 μmol). Retention time in HPLC [YMC-Pack ODS-AM, ϕ: 4.6 × 250 mm, eluant: TFA (0.08% in water)/acetonitrile from 100:0 to 50:50 over 30 min, flow rate: 0.8 mL/min]: 17.4 min. ^{1}H NMR (D_2O); δ 7.34–7.60 (*m*, 2H, Trp), 7.19 (*s*, 1H, Trp), 6.98–7.14 (*m*, 2H, Trp), 4.68–4.82 (*m*, 6H, CH), 4.28–4.50 (*m*, 10H, CH), 3.75–4.12 (*m*, 30H, Ser-CH_2, Gly-CH_2), 3.21 (*m*, 10H, Arg-$CH_2CH_2CH_2N$), 2.74–2.94 (*m*, 10H, Asp-CH_2), 2.04–2.34 (*m*, 4H, $COCH_2$), 1.54–1.98 (*m*, 20H, Arg-$CH_2CH_2CH_2N$), 1.36–1.54 (*m*, 4H, $NHCH_2CH_2$), 1.27 (*s br*, 52H, $2(CH_2)_{13}CH_3$), 0.88 (*t*, 6H, $2CH_2CH_3$, J = 6.6 Hz). MALDI-TOFMS Calc'd: 3369.8 (MH^+), found: 3370.

Incorporation of lipopeptides to liposome membranes. Lipopeptide-containing liposomes were prepared according to the following method. The lipopeptide was dissolved in 10 μL of 20% acetic acid, and 100 μL of EPC/chloroform solution (5.0 mmol dm^{-3}) was added. These two separated phases

became homogeneous by adding a few drops of methanol. After evaporating the solvent under reduced pressure, a thin lipid film was formed on the wall of a test tube. To thoroughly remove the solvent, the lipid film was left *in vacuo* for at least 12 h. After adding 1.0 mL of Hank's buffer solution (pH 7.2) to the thin lipid film, this was vortexed for 5 min at room temperature, and freezing (–196°C) and thawing (70°C) procedures were repeated seven times (20). The resultant mixture was then extruded five times through a polycarbonate membrane with 0.1 μm pore size.

To confirm incorporation of the lipopeptides into liposome membranes, the liposome solution was eluted through a Sephacryl S-500HR column (Pharmacia Biotech AB, Uppsala, Sweden) immediately after the final extrusion (21). The chromatogram was obtained by measuring the fluorescence at 340 nm (λ_{ex} = 280 nm) of the indole groups in the tryptophan residues. A chromatogram of the control liposome without the lipopeptide was also obtained by measuring the light scattering of liposome at 340 nm. To confirm the existence of the inner aqueous phase, liposomes containing 1.0 mmol dm^{-3} calcein in this phase were prepared and subjected to gel filtration. The chromatograms were measured by monitoring the fluorescence of calcein (λ_{ex} = 490 nm, λ_{em} = 520 nm). The amount of lipopeptide incorporated in the liposome membranes was estimated as follows. The liposome suspension was first filtered through a polycarbonate membrane, and the amount of the lipopeptide entrapped on the membranes was determined by measuring the fluorescence intensity (λ_{ex} = 280 nm, λ_{em} = 340 nm) after the entrapped lipopeptides were dissolved in 1.0 mL of 20% acetic acid. The amount of incorporated lipopeptide was thus calculated by subtracting the entrapped amount from the total amount.

Electron microscopy. That the peptide parts are located in the aqueous phase was actually confirmed by immunoelectron microscopy (22,23). For this purpose, an antibody against CW5GRGDS, in which one cysteine residue was added to the N terminal of W5GRGDS, was prepared by the following method. A female New Zealand white rabbit (3 kg) (Japan Clea) was immunized by subcutaneous injection (in the footpads or back) of 100 mg KLH (keyhole limpet, hemocyanin)-CW5GRGDS mixed with complete Freund's adjuvant (2.0 mL). The rabbit had earlier been anesthetized with ketamine (Sankyo Co., Tokyo, Japan) and selectin (2.1 mg/kg) (Bayer Japan Co., Tokyo, Japan). Five booster injections of the same amount of KLH-CW5GRGDS were given subcutaneously at intervals of 2 wk, and 5.0 mL of blood was obtained each time from the ears. The serum was purified by affinity chromatography prepared from CNBr-activated Sepharose 4B column (Pharmacia Biotech AB) and CW5GRGDS. Production of antibody (the heavy chain) was detected by sodium dodecylsulfate-polyacrylamide gel electrophoresis (24) and Western blotting using horseradish peroxidase (HRP) antirabbit IgG (Wako Pure Chem. Ind., Ltd., Osaka, Japan) as a 50 kDa band. Antibody specificity was confirmed by Western blotting of a fibronectin fragment digested by α-chymotrypsin using the serum fraction as the first antibody and HRP-antirabbit IgG as the second antibody. Five μL of lipopeptide-containing liposome was put on collodion-coated copper mesh grids for 10 min, and the remaining fluid was drained off with filter paper. For labeling with immunogold, the grids were floated on droplets containing the primary antibodies at room temperature, where rabbit anti-α-MSH IgG (Biogenesis Inc., Poole, England) and the rabbit anti-RGD IgG were diluted 100 times and two times by 1% bovine serum albumin (BSA) in phosphate-buffered saline (PBS)(–) (i.e., PBS without calcium and magnesium), respectively. The labeling times were 1.5 h for the anti-α-MSH IgG and overnight for the anti-RGD IgG. After the labeling by the primary antibodies, both of the grids were washed by 1% BSA in PBS(–) 10 times. The grids were then floated on the droplets of secondary antibody, goat antirabbit IgG (E-Y Laboratories Inc., San Mateo, CA), at room temperature, which was diluted (1:50) by 1% BSA in PBS(–). After the labeling by the secondary antibody for 1 h, both of the grids were washed by 1% BSA in PBS(–) 10 times. The samples on the grids were negatively stained with droplets of 1% uranyl acetate for 15 min, stabilized by perpendicular carbon evaporation, and observed under a transmission electron microscope.

Binding of lipopeptide-containing liposome to cell. Two kinds of liposomes containing the lipopeptides RGD-C4A2 and MSH-C4A2 were prepared, and their binding ability toward two kinds of cell lines, NIH3T3 (25) and B16 (26), was estimated. The fluorescence emitted from the cells was measured on a flow cytometer. Table 1 summarizes the conditions

TABLE 1

of the binding experiment between the liposomes and the cells. As cholesterol (Ch) (30 mol%) increases the stability of liposomes bearing MSH-C4A2 (27), we added Ch to the liposome membranes in the binding experiment. The liposomes were prepared as follows. Into the lipopeptide (0.1 μmol) dissolved in 20% acetic acid (10 μL) was added chloroform solution containing EPC (1.6 μmol), Ch (0.4 μmol), and *N*-(fluorescein-5-thiocarbamoyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine (FITC-PE) (0.02 μmol). A few drops of methanol were added to make the solution homogeneous. The lipopeptide-liposome was then prepared in a similar manner as described above. In the binding experiment between RGD liposome and the cells, the sample was incubated at 37°C for 30 min. The cells were washed by centrifugation (1000 rpm, 3 min) at 37°C, twice with Dulbecco's modified Eagle's medium (DMEM) and once with calcium magnesium free PBS (DMF-PBS). The cells were suspended in 1.0 mL of CMF-PBS containing BSA (0.1%) and sodium azide (0.1%), and the fluorescence emitted from the cells was measured on the flow cytometer. In the binding experiment between the MSH liposome and the cells, the sample was incubated at 0°C for 1 h; the cells were isolated by centrifugation (1000 rpm, 3 min), washed, and the fluorescence was measured in a similar manner as for RGD liposome.

RESULTS

Synthesis of lipopeptide. The following items are important in the design of the lipid portion: (i) it should contain two long alkyl chains; (ii) a polar group should be situated between a binding anchor (peptide ligand) and the two long alkyl chains to prevent the peptide part from migrating into the bilayer membrane; (iii) suitable distance is necessary between the peptide ligand and the lipid part situated in the bilayer membrane to lower the steric hindrance between cell receptors and liposome membrane; (iv) the lipid part should have a carboxyl group for binding to the peptides on the TGR-resin; and (v) the lipid part should be stable against TFA used to cut the lipopeptide from resin and to remove the protecting groups. In view of these necessary factors, the finally designed structure of the lipid is C4 in Figure 1, whose synthetic method has already been reported (27). It has two long alkyl chains (C16) and a terminal COOH group for binding to the terminal amino groups of the peptides. More hydrophobic lipids having the same skeleton as C4 were found to induce pH-controlled liposome fusion (28). For peptide sequences, we have chosen α-MSH and W5GRGDS as shown in Figure 1. Peptide α-MSH is a melanocyte-stimulating hormone of 13 amino acid residues (17), and the GRGDS sequence is observed on fibronectin and has the ability to recognize integrin (29). As repetition of RGD sequence can improve the binding ability to cells (30), GRGDS is repeated five times in W5GRGDS. Here, one tryptophan residue (W) is included at the N terminal of the peptide as a fluorescence probe for detecting the lipopeptide in gel chromatography. Figure 1 also shows the structures of lipopeptides MSH-C4A2 and RGD-C4A2; the synthetic method for MSH-C4A2 was reported earlier (27).

The peptide W5GRGDS was synthesized by the solid-phase Fmoc method. We used TGR-resin, since it has the advantage that the C terminal of a free peptide becomes an amide form under the deprotection condition with TFA. The observed ^{1}H NMR and MALDI-TOFMS were highly compatible with the structure of W5GRGDS, though the yield was not high (37.8%). The coupling between the peptide on the TGR-resin and W5GRGDS was performed using various reagent systems. The optimized system was HOBt/WSCD/DMAP, in which the coupling yield of RDG-C4A2 was 7.9%.

Incorporation of lipopeptide to liposome membrane. We first investigated which method was suitable for preparing liposomes. Both the ultrasonic method and the freeze-thaw method were tried, but the lipopeptides were efficiently incorporated into liposome membrane only by the latter method. Figures 2 and 3, respectively, show the elution patterns of the MSH liposome and the RGD liposome, which were monitored by fluorescence emitted at 340 nm. Liposomes composed of only EPC (control liposome) exhibited a small peak around 10 mL elution, which was attributed to the light scattering by liposomes. The MSH liposomes and the RGD liposomes gave peaks at almost the same elution volume with much higher fluorescence intensity emitted from the tryptophan residues, which unambiguously indicates that the lipopeptides exist in the liposome bilayer membranes. In Figures 2 and 3, some degree of trail-off was observed after the main peaks of the liposomes, probably due to the formation of small aggregates such as micelles.

To confirm that the peptide liposomes surely had the inner aqueous phase, calcein was introduced into the inner phase and the gel filtration pattern was observed at 340 and 520 nm, respectively, corresponding to tryptophan and calcein. If calcein exists in the inner phase, these two curves should give the peaks at the same elution volume. Figures 4 and 5 show the chromatograms of the MSH liposome and the RGD liposome, respectively, where two chromatograms measured at different wavelengths gave similar patterns. It is obvious therefore that both the MSH liposome and the RGD liposome have the inner aqueous phase and that they both hold the lipopeptides in the

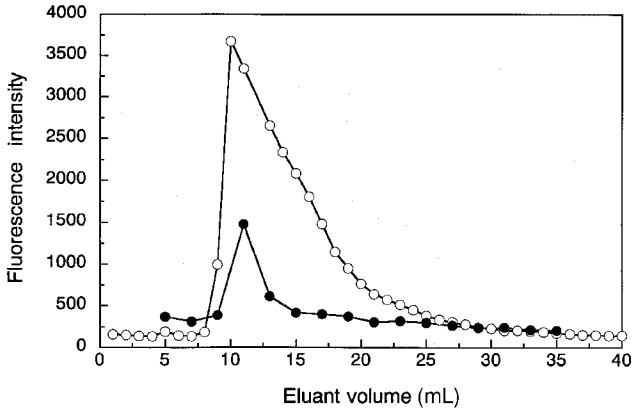

FIG. 2. Chromatograms of MSH liposome (○) and control liposome (●) See Figure 1 for abbreviation.

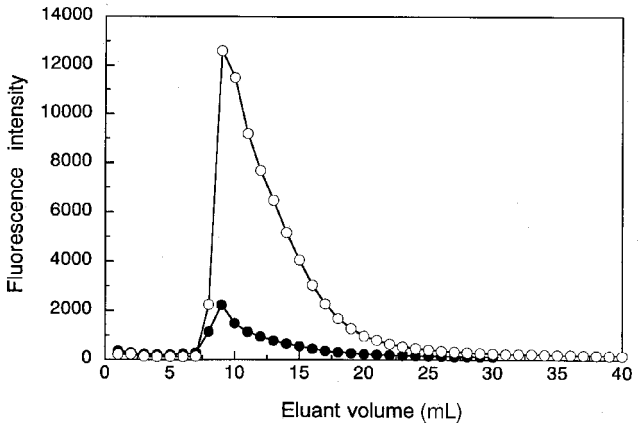

FIG. 3. Chromatograms of RGD liposome (○) and control liposome (●) See Figure 1 for abbreviation.

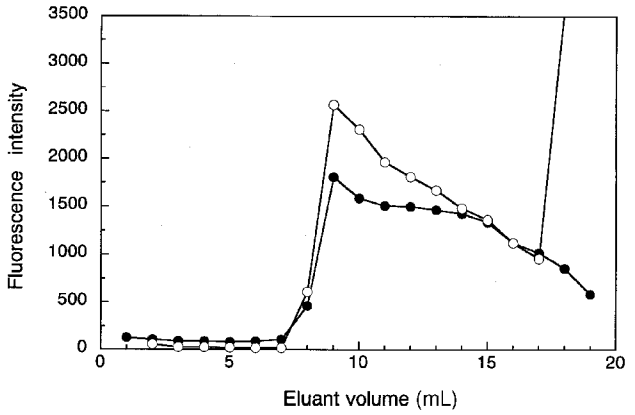

FIG. 5. Chromatograms of RGD liposome detected at 520 (○) and 340 nm (●). See Figure 1 for abbreviation.

bilayer membranes. It is also important to determine the amount of lipopeptides incorporated into liposome membranes. The results are summarized in Table 2, where the yields of incorporation are very high in both liposomes: 94–99% for RGD liposomes and 85–98% for MSH liposomes.

Electron microscopy. The peptide chain situated in the aqueous phase is believed to bind specifically to antipeptide antibody. Therefore the exposure of the peptide chains can be confirmed by detecting antipeptide antibody using a secondary antibody, which was labeled with colloidal gold. The gold colloidal particles attached on liposomes were detected by electron microscopy. The electron micrographs of the MSH liposomes and the RGD liposomes are shown in Figures 6 and 7, respectively, where we can clearly discriminate the liposomes with and without the lipopeptides. When the peptides were anchored to the liposomes, gold colloidal particles were observed (Figs. 6A and 7A), while the colloidal particles were hardly seen in the liposome without the peptides (Figs. 6B and 7B). These findings definitely show that the peptide ligands are located in the aqueous phase.

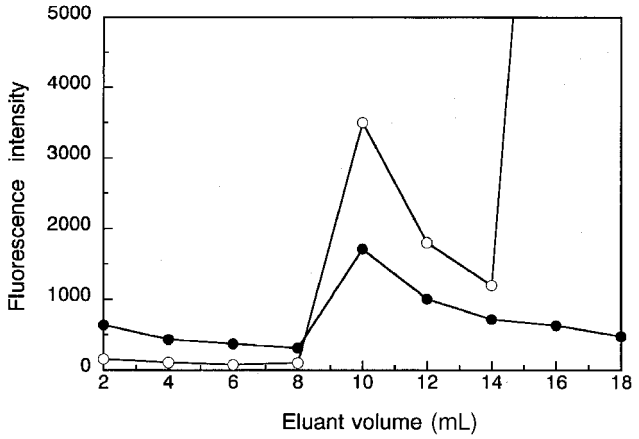

FIG. 4. Chromatograms of MSH liposome detected at 520 (○) and 340 nm (●). See Figure 1 for abbreviation.

Binding of liposome to cell. We applied the flow cytometry method to evaluate the binding ability of the liposomes to two cell lines, NIH3T3 and B16. Compositions of samples used are summarized in Table 1. NIH3T3 is established from mouse fibroblast, has normal cell-like properties, and is thought to have fibronectin receptors and to bind to the RGD liposomes. The result of flow cytometry is shown in Figure 8. It is worth noting that the RGD liposome/NIH3T3 (#2) gave higher fluorescence intensity than either the NIH3T3 alone (#0) or the EPC control-liposome/NIH3T3 (#1). We did an inhibition experiment to confirm that the peptide chain of the RGD liposome actually participates in the binding to the receptor of NIH3T3 cell. The fluorescence intensity was reduced by 34.8% by addition of the corresponding free RGD peptide (#3), which proves that the binding between the RGD liposome and NIH3T3 cells occurs through the RGD peptide ligand. The results of binding between the MSH liposomes and B16 cells are also shown in Figure 9. The fluorescence intensity was greatly increased on addition of the MSH liposomes to B16 cells, while the EPC liposomes did not enhance. This also demonstrates that the MSH liposomes bind to B16 cells through the MSH ligands.

DISCUSSION

The lipopeptide RGD-C4A2 was synthesized by the solid-phase method, but the final yields were not high owing to the low coupling yield between the lipid parts and the peptide ligands bound to the TGR-resin. It is thought that the solid-phase reaction between these large molecules is difficult owing to their steric repulsion and poor solubility of the lipid component. The coupling yields were actually 12.6% for MSH-C4A2 (27) and 7.9% for RDG-C4A2. We investigated various combinations of solvents, temperature, and coupling reagents to find the best reaction conditions. Lipid C4 was scarcely dissolved in DMF and *N*-methylpyrrolidone (NMP) up to about 60°C. As this condensation reaction was undertaken in a solid phase, it was essential that C4 should be completely dissolved

TABLE 2
Incorporation Efficiency of Lipopeptides to Liposome Membranes

Lipopeptide	Total amount (mol)[a]	Trapped amount (mol)[b]	Incorporation efficiency (%)[c]
RGD-C4A2 (5 mol%)[d]	2.5×10^{-8}	1.54×10^{-9}	93.8
RGD-C4A2 (10 mol%)	1.0×10^{-7}	2.95×10^{-9}	97.1
RGD-C4A2 (20 mol%)	2.5×10^{-7}	3.73×10^{-9}	98.5
MSH-C4A2 (2.5 mol%)	1.25×10^{-8}	1.87×10^{-9}	85.1
MSH-C4A2 (10 mol%)	5.0×10^{-8}	1.79×10^{-9}	96.4
MSH-C4A2 (20 mol%)	1.0×10^{-7}	1.92×10^{-9}	98.1

in a solvent. To increase the solubility, we tried various solvents (38% chloroform/DMF, NMP, hexamethylphosphoramide, DMF, 20% dimethylsulfoxide/DMF), but the yields were not significantly enhanced. Another important property of the solvent is the ability to swell the resin to allow the reagents to approach each other easily. The solvents finally selected were NMP for MSH-C4A2 (27) and 38% chloroform/DMF for RGD-C4A2. We then tried three coupling reagents of active-ester type [HOBt; 2-(1H-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate; *O*-(7-azobenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate], two coupling reagents of carbodiimide type [*N,N′*-diisopropylcarbodiimide (DIPCI), WSCD], and two bases (DMAP, *N,N′*-diisopropylethylamine). From these candidates, we chose DIPCI/HOBt in NMP for MSH-C4A2 (27) and WSCD/HOBt/DMAP in chloroform/DMF for RGD-C4A2. Since both DIPCI and WSCD were carbodiimide-type coupling reagents, HOBt was thought to increase the yields by depressing racemization and side reactions.

The GRGDS sequence is an integrin-recognition site on fibronectin, and the adhesion between cells takes place through this sequence (18). Polypeptides composed of repeated RGD sequences bind to the fibronectin receptor on B16 cell membrane and inhibit the adhesion between B16 and fibronectin-coated plates (30), where the high binding ability of these repeated RGD sequences might be induced by the conformational properties such as β-turn. It is also known that α-MSH is capable of binding to melanocyte (17). It was anticipated therefore that liposome could gain the ability to bind to cells by providing the liposome surface with these peptide ligands. Based on the above knowledge, we designed and synthesized the peptide with the repeated RGD sequences (RGD-C4A2) (16) and the peptide with α-MSH sequence (MSH-C4A2) (27). Actually it was confirmed by the increment of fluorescence using flow cytometry analysis that the liposomes bearing the lipopeptides bind to the cells while those without the lipopeptides do not. The RGD and the MSH liposomes are thought to bind to the NIH3T3 and B16 cells, respectively, through the peptide ligands on their surface. There is a possibility that side effects might be induced by the present liposomes, since the ligand peptides can bind to the membrane receptor and thus may act as agonists or antagonists affecting the signal response of the cells. This influence might be decreased, however, if the pinocytosis proceeds smoothly and thus the time of binding to the receptors is short.

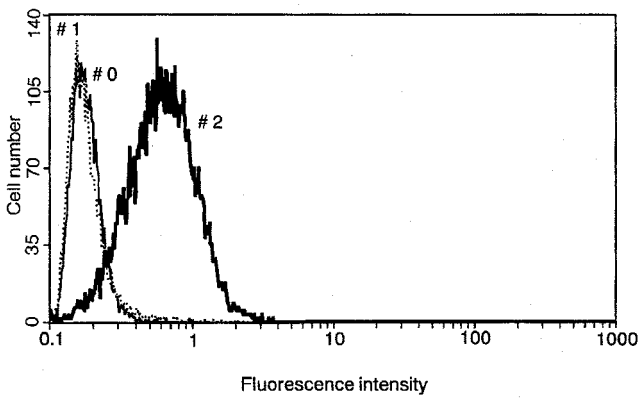

FIG. 9. Flow cytometry of MSH liposome/B16 cell; (#0) B16 only, (#1) B16 + control liposome, (#2) B16 + MSH liposome. See Figure 1 for abbreviation.

The liposomes which we have developed have the following three characteristics. The most notable feature is that the lipopeptide molecules (RGD-C4A2 and MSH-C4A2) can be incorporated into liposome membrane in a very high degree, *viz.*, more than 93% for the RGD liposome and more than 85% for the MSH liposome (Table 2); this is attributable to the adequate hydrophobicity of the two long alkyl chains in these lipopeptides. A conventional method using succinimide (10), in which ligands are added after preparing liposome, normally does not result in such a high degree of modification on the liposome surface. Another important property which the present liposomes should have is that the peptide ligands are located in an aqueous phase. This was actually confirmed by the immunogold labeling method with electron microscopy. The present method is consequently superior to the conventional ones and thus would be applicable for the preparation of various modified functional liposomes. The liposomes developed in the present study seem to be applicable to a DDS. Generally there are some characteristics in using liposomes as DDS. There is no need to modify drugs to accomplish targeting toward cells; namely, already-known drugs can be used, which makes the application to DDS easier. Instead, targeting becomes possible, for example, by modifying the surface of liposomes with ligands capable of binding to cell membrane receptors. There is a possibility that the present liposomes are incorporated into cells by pinocytosis. Though it is a preliminary experiment, it was actually observed by using a fluorescence microscope (data not shown) that FITC-PE (a fluorescence-probe lipid) included in the liposome membranes was introduced into both B16 and NIH3T3 under the conditions of the binding experiment. To confirm the pinocytosis, however, we should proceed with a further experiment carefully. A study along this line is now in progress.

In conclusion, we have succeeded in preparing new functional liposomes having α-MSH or repeated GRGDS sequence on the surface, which can bind to NIH3T3 or B16. These liposomes might be applied to DDS as specific drug carriers.

Quantitative Analysis of Long-Chain *trans*-Monoenes Originating from Hydrogenated Marine Oil

Robert Wilson[a,*], Karin Lyall[a], J. Anne Payne[a], and Rudolph A. Riemersma[a,b]

ABSTRACT: Gas chromatography (GC) is used for the analysis of *trans*-fatty acids in partially hydrogenated vegetable oils. Although *trans*-isomers of C_{18} carbon length predominate in partially hydrogenated vegetable oils, *trans*-isomers of C_{20} and C_{22} carbon length occur in partially hydrogenated fish oil. We report a simple silver ion chromatographic combined with capillary GC technique for quantitative analysis of *trans*-monoenes derived from partially hydrogenated fish oil. Silver nitrate thin-layer chromatographic (TLC) plates are developed in toluene/hexane (50:50, vol/vol). Fatty acid methyl esters are separated into saturates (R_f 0.79), *trans*-monoenes (R_f 0.49), *cis*-monoenes (R_f 0.27), dienes (R_f 0.10), and polyunsaturated fatty acids with three or more double bonds remaining at the origin. The isolated *trans*-monoenes are quantitatively analyzed by capillary GC. The technique of argentation TLC with GC analysis of isolated methyl esters is highly reproducible with 4.8% variation (i.e., coefficient of variation , CV%) in R_f values and 4.3 and 6.9% CV% in quantification within batch and between batch, respectively. Furthermore, the combined technique revealed that direct GC analysis underestimated the *trans*-content of margarines by at least 30%. In this study, C_{20} and C_{22} *trans*-monoenes were found in relatively large quantities; 13.9% (range 10.3–19.6%) and 7.5% (range 5.3–11.5%), respectively, in margarine purchased in 1995, but these C_{20} and C_{22} *trans*-monoenes were much reduced (0.1%) in a fresh selection of margarine purchased in 1998. Compositional data from labels underestimated the *trans*-content of margarines, especially those derived from hydrogenated marine oil. Low levels of C_{20} *trans*-monoenes (range 0.1–0.3%) and C_{22} *trans*-monoenes (range 0.0–0.1%) were identified in adipose tissue obtained from healthy volunteers in 1995, presumably indicating consumption of partially hydrogenated fish oil.

Paper no. L8388 in *Lipids 35*, 681–687 (June 2000).

Trans-fatty acids are produced by the process of microbial biohydrogenation in the intestinal tract of ruminants and consequently are present in the milk, butterfat, and the meat of these animals (1). The process of partial catalytic hydrogenation of vegetable or marine oil, used by the food industry to produce stable and semisolid edible fats, increases the *trans*-fatty acid content of these foods (2,3). Butter, margarine, and shortenings (cakes, biscuits, etc.) are therefore major dietary sources of *trans*-fatty acids (1–7).

Partially hydrogenated vegetable oil has a complex fatty acid profile with 18:1 *trans*-isomers predominating. Gas chromatography (GC) has been used for the quantitative analysis of *trans*-fatty acids derived from vegetable oils (4–12). However, even when using a specialized 100-m column, overlap between C_{18} *cis*- and *trans*-monoenes can still occur (8,9), leading to the underestimation of some of these *trans*-fatty acids. Partially hydrogenated fish oil is much more complex in fatty acid composition than are hydrogenated vegetable oils. This material also contains many *trans*-isomers derived from C_{20} and C_{22} polyunsaturated fatty acids (PUFA) including *trans*-monoenes, *trans*-dienes, and *trans*-trienes (4,13). Techniques have been developed to determine *trans*-fatty acids in partially hydrogenated fish oil or other marine oils or in margarines derived from these oils (4,8,13). However, many *trans*-isomers are present in small concentrations, and the lack of authentic reference standards often confounds the analysis of *trans*-fatty acids.

The interest in *trans*-fatty acids originates from their association with coronary heart disease. Dietary intake of 18:1 *trans* increases the low density lipoprotein/high density lipoprotein (LDL/HDL) cholesterol ratio (14) and is therefore expected to augment the risk of coronary heart disease (15,16). There appears to be a discrepancy between studies using semiquantitative food frequency questionnaires and those using fatty acid analysis of adipose tissue, in estimation of dietary intakes of *trans*-fatty acids (15). Consumption of hydrogenated fish oil may lead to coronary heart disease (17), but in that case-control study *trans*-fatty acids were analyzed using a 40-foot packed column (17), now considered inadequate for this task. Thus, the issue of whether hydrogenated fish oil leads to coronary heart disease in humans will remain a question, unless better analytical methods are available.

In this paper we report a simple and efficient silver-ion thin-layer chromatographic (TLC) technique that permits the isolation and subsequent quantitative analysis by GC of *trans*-monoenes derived from partially hydrogenated fish oil in adi-

Abbreviations: BHT, butylated hydroxytoluene; CV, coefficient of variation; FAME, fatty acid methyl ester; GC, gas chromatography; HDL, high density lipoprotein; LDL, low density lipoprotein; MS, mass spectrometry; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; R_f, distance migrated by compound divided by the distance of solvent mobility; SPE, solid phase extraction; TLC, thin-layer chromatography.

pose tissue samples. The method therefore has the potential to resolve the controversy about whether hydrogenated fish or other oils do or do not lead to coronary heart disease.

MATERIALS AND METHODS

Materials. Butylated hydroxytoluene (BHT) was obtained from Sigma Chemical Co. (Poole, Dorset, United Kingdom). *Trans*-monoenoic and *trans*-dienoic fatty acid methyl esters (FAME) were obtained from Sigma Chemical Co. and Nu-Chek-Prep (Blast of Copenhagen, Denmark). Silver nitrate was obtained from Johnson Matthey (Royston, United Kingdom). Silica gel 60 TLC plates (Merck 5721, 20 cm × 20 cm × 0.25 mm; Darmstadt, Germany) and platinum (IV) oxide were purchased from BDH (Poole, Dorset, United Kingdom) A CP-Sil 88 fused-silica capillary column (50 m × 0.25 mm i.d. and 0.2 μm film thickness) was obtained from Chrompack (Middelburg, the Netherlands). Aminopropyl solid phase extraction (SPE) columns (500 mg) were purchased from IST (Hengoed, United Kingdom). High-performance liquid chromatography-grade solvents were purchased from Rathburn Chemicals (Walkerburn, Peebleshire, United Kingdom).

Margarine. Margarines were selected at random from a list provided by the Margarine and Shortening Manufacturers Association and were purchased from local supermarkets during 1995 (n = 22) and 1998 (n = 5). They included branded and nonbranded margarines. There was limited compositional data for margarine purchased in 1995. All margarines listed total fat, and the majority listed the saturated fat content. Only three margarines from 1995 listed the *trans*-content (less than 1%). Typical compositional data of margarines from 1995 were: hard [77% fat, 37% saturates, 23% monounsaturated fatty acids (MUFA), 14% PUFA], soft (82% fat, 23% saturates, 40% MUFA, 16% PUFA), spreads (71% fat, 27% saturates, 23% MUFA, 20% PUFA), low-fat spreads (40% fat, 12% saturates, 4% MUFA, 14% PUFA), and unsaturated spreads (73% fat, 15% saturates, 24% MUFA, 31% PUFA). Soft margarines purchased in 1998 gave more compositional data and indicated that margarines were being produced using various hydrogenated/nonhydrogenated vegetable oils. There was on average 79 ± 3% fat, 22 ± 2% saturates, 32 ± 7% MUFA, 20 ± 6% PUFA with the *trans*-content given as 1% in one margarine and 9% in another.

Preparation of FAME. A 25-mg sample of margarine was added to a screw-cap tube. To the sample was added 3 mg 17:0 and 0.28 mg Δ10-*trans*-17:1 (both as the methyl ester) as internal standards (in toluene). Δ10-*trans*-19:1 (0.56 mg) was used as an internal standard for recovery experiments. The sample was treated with sodium hydroxide (1 M), and FAME were prepared from the recovered fatty acids using etheral diazomethane (18). FAME were purified using 500 mg aminopropyl SPE columns (19) and then redissolved in hexane. Adipose tissue (15–20 mg) was cut up and treated as above using one-third of the amount of internal standards described above.

Separation of trans*-monoenes by argentation TLC.* Silver nitrate plates were prepared by dipping silica gel 60 TLC plates in acetonitrile containing 10% silver nitrate (wt/vol). Plates were air-dried in subdued light, heated at 110°C for 30 min to activate, and used within 1 h (20). FAME were applied to the impregnated TLC plates over 2–3 cm at a loading of 1.0 mg/cm. A solution containing Δ9-*trans*-22:1 and Δ9-*cis*-22:1 was streaked over 0.3 cm and used to identify the upper and lower limit of migration of the *trans*-monoenes (Fig. 1). The plates were developed at room temperature with toluene/hexane (50:50, vol/vol) to 1 cm from the top in a standard TLC chamber. The plates were dried, then lightly sprayed with 0.1% dichlorofluorescein and bands visualized under ultraviolet light. The areas corresponding to *trans*-monoenes were located, scraped from the plates, and eluted from the silica using 20 mL chloroform/methanol (2:1, vol/vol) containing 0.005% butylated hydroxytoluene (BHT); 5 mL 0.88% aqueous KCl was added and the solutions mixed (20). After separation, the chloroform layer was removed and the solvent removed under argon. Samples were redissolved in hexane containing 0.005% BHT and washed with 20% NaCl to precipitate any remaining silver (20). The hexane layer was removed, and FAME were purified on 500 mg aminopropyl SPE columns (19). Appropriate dilutions were made and samples analyzed by GC as described below.

FAME analysis. FAME were analyzed using a Fisons GC8000 gas chromatograph equipped with flame-ionization

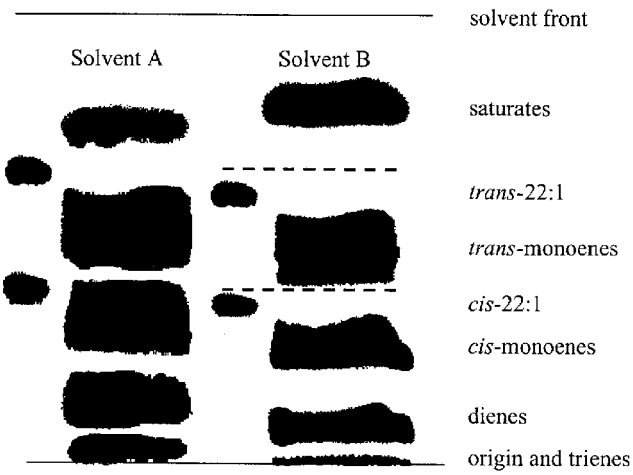

FIG. 1. Separation of *trans*-monoenes by silver-ion thin-layer chromatography (TLC). Methyl esters were separated by silver-ion TLC using hexane/ether (90:10, vol/vol); solvent A or toluene/hexane (50:50, vol/vol); solvent B. Bands were visualized by charring. The solvent system as described in the Materials and Methods section (solvent B) separated fatty acid methyl esters (FAME) into four distinct bands of saturates (R_f 0.79), *trans*-monoenes (R_f 0.49), *cis*-monoenes (R_f 0.27), dienes (R_f 0.10), and polyunsaturated fatty acids with three or more double bonds remaining at the origin. (R_f = distance migrated by compound divided by the distance migrated by solvent). The dotted lines show the upper and lower limits of the migration of *trans*-monoenes defined by the elution of *trans*-22:1 and *cis*-22:1. The area between the dotted lines is scraped from the plate and used for the analysis of *trans*-monoenes by capillary gas chromatography (GC). There is an improvement in resolution over that of solvent A; this method has been cited in the literature (18) as a method for separating *trans*-monoenes.

detector (FID) and autosampler (Fisons, Manchester, United Kingdom). For analysis 0.5 μL volumes were injected using an on-column injector. FAME were analyzed on a CP-Sil 88 capillary column (50 m × 0.25 mm i.d. and 0.2 μm film thickness) using an optimized temperature program: 1 min at 80°C, 25°C/min to 165°C, 12 min at 165°C, 2°C/min to 220°C, and 6 min at 220°C. Helium was carrier gas at a constant flow of 1.1 mL/ min, and the analysis time was 35 min. Under the chromatographic conditions just described there was optimal but not complete resolution between C_{18} *cis*- and *trans*-monoenes.

In the absence of authentic C_{20} and C_{22} *trans*-monoenes reference standards, the position of the carbon-carbon double bond was not identified. Hydrogenation to the corresponding saturated fatty acid confirmed that isolated *trans*-monoene fractions contained fatty acids of C_{16}, C_{18}, C_{20}, and C_{22} chain length. Analysis by GC/mass spectrometry (MS) and by GC of a few samples of margarine derived from fish oil confirmed that the isolated fraction contained only *trans*-monoenes. Notably, the position of the double bond can be assigned by GC/MS of dimethyloxazoline-derivatized monoenoic fatty acids (21). C_{18} *trans*-dienes were identified using authentic standards, whereas C_{18} *trans*-trienes were identified by reference to a *trans*-triene fraction isolated using silver nitrate TLC as described in the Materials and Methods section but using toluene as development solvent. Isolated *trans*-triene (or isolated *trans*-diene) fractions contained fatty acids of C_{20} and C_{22} chain length also.

Data were recorded and analyzed using Turbochrom software (PerkinElmer, Beaconsfield, United Kingdom). Δ10-*trans*-17:1 was used to quantify isolated *trans*-monoenes and to cross-reference between *trans*-analysis and total FAME analysis. Percentage composition was obtained after combining the weights of *trans*-fatty acids with the weights of other individual fatty acids from total FAME analysis.

Adipose tissue from healthy volunteers. Adipose tissue was obtained under local anesthetic from the abdominal wall from 16 men in 1995 and stored under liquid nitrogen until used. These apparently healthy volunteers (aged 25 to 55 yr) were selected at random from the Lothian Health Board Register, Edinburgh, United Kingdom. All men gave written informed consent.

RESULTS

Separation of *cis*- and *trans*-monoenes using a typical solvent system (Solvent A, hexane/ether, 90:10, vol/vol) as cited in the literature (18) is shown in Figure 1. We examined several other solvent systems for improved separation of *trans*-monoenes. Development of silver nitrate TLC plates in toluene (not shown) permitted separation of *trans*-dienes (R_f 0.38) and *trans*-trienes (R_f 0.10) from the corresponding *cis*-isomer, 18:2n-6 (R_f 0.25) and 18:3n-3 (R_f 0.03). However, there was overlap between C_{18}, C_{20}, and C_{22} *cis*-monoenes (R_f 0.53) with C_{18}, C_{20}, and C_{22} *trans*-monoenes (R_f 0.77) and that of saturates (R_f 0.91). Optimal separation of C_{18}, C_{20}, and C_{22} *cis*-monoenes from C_{18}, C_{20}, and C_{22} *trans*-monoenes was obtained using a mixture of toluene with hexane (50:50, vol/vol), and this solvent was used routinely when analyzing *trans*-monoenes (Solvent B; Fig. 1). FAME are resolved into four distinct bands of saturates (R_f 0.79), *trans*-monoenes (R_f 0.49), *cis*-monoenes (R_f 0.27), and dienes (R_f 0.10). PUFA containing more than three double bonds remain at the origin. The improved separation of *cis*- and *trans*-monoenes is illustrated.

TABLE 1
Comparison of Direct GC Analysis with Combined Argentation TLC Gas Chromatography Analysis for Measuring C18 *trans*-Isomers[a]

	C18 *trans*-isomers	
	Direct analysis	Combined analysis
Margarine 1	0.5 ± 0.1	0.7 ± 0.1
Margarine 2	1.7 ± 0.2	2.8 ± 0.2
Margarine 3	4.5 ± 0.1	6.9 ± 0.2
Margarine 4	10.2 ± 0.3	15.4 ± 0.7

[a]Values are gram fatty acid per 100 gram total fatty acid and represent means ± SD for triplicate analysis and have been rounded to one decimal place. The direct analysis as described in the Materials and Methods section underestimated C18 *trans*-monoenes by at least 30%.GC, gas chromatography; TLC, thin-layer chromatography.

The technique is highly reproducible with 4.8% variation (coefficient of variation %, CV%) in R_f values being recorded over repeated analysis (n = 6). For quantification of *trans*-monoenes, the within-batch CV% was 4.3% and between-batch CV% was 6.9% based on the recovery and quantification of Δ10-*trans*-17:1 using Δ10-*trans*-19:1 as the internal standard (n = 12). A comparison of the combined silver nitrate GC analysis with direct GC analysis is given in Table 1. Four margarines with increasing levels of *trans*-fatty acids were analyzed for C_{18} *trans*-isomers. Under optimal analysis conditions, as described in the Materials and Methods section, direct GC analysis underestimated C_{18} *trans*-isomers by 30% and failed to identify C_{20} and C_{22} *trans*-monoenes accurately.

We applied our method to the analysis of margarine (Table 2). There was on average 7.2% (range 4.2 to 18.1%) of C_{18} *trans*-monoenes in margarine purchased in 1995 (n = 17). However, many of the brands of margarine analyzed also contained *trans*-monoenes of 20- and 22-carbon chain length. The level of C20 and C22 *trans*-monoenes was of similar order of magnitude as that of *trans*-dienes and *trans*-trienes.

It was surprising that five brands of margarine purchased in 1995 contained on average 14 and 8% C20 and C22 *trans*-monoenes and 4.0% C18 *trans*-monoenes (Table 3). *Trans*-dienoic and *trans*-trienoic fatty acids of 20- and 22-carbon chain length were also present in some of these margarines but at a substantially reduced concentration (not shown). Analysis of a fresh selection of the same brand of margarine purchased in 1998 revealed substantially reduced amounts of C_{20} and C_{22} *trans*-monoenes (Table 3). The lowest level of C_{18} *trans*-monoenes (0.5%) was found in a recently purchased margarine, but relatively high levels of C_{18} *trans*-monoenes were found in recently purchased margarine (Table

TABLE 2
Fatty Acid Composition in a Random Selection of Margarine Determined by Combined Argentation TLC GC Analysis[a]

Fatty acid	Means (n = 17)	Range

[c]Including some 22:1 *trans*-monoene isomers)
[d]*trans*-18:2 included all identifiable isomers using authentic reference standards.
[e]*trans*-18:3 included all identifiable isomers using silver nitrate isolated *trans*-triene standards.
[f]Not analyzed in these samples. See Table 1 for abbreviations.

3). The fatty acid profile of margarine containing C_{20} and C_{22} *trans*-monoenes and the isolated *trans*-monoene fraction is shown in Figure 2.

Adipose tissue (n = 16) was analyzed for *trans*-monoenes. Direct GC analysis failed to quantify C_{20} and C_{22} *trans*-monoenes in adipose tissue and underestimated C_{18} *trans*-monoenes by 30% (1.6 vs. 2.6% of fatty acids) when compared to the combined silver nitrate GC method. It was also found that hydrogenation improved the quantification of C_{20} and C_{22} *trans*-monoenes because a single distinct peak corresponding to the saturated fatty acid was integrated, whereas normally numerous small amorphous unidentifiable peaks are integrated in the nonhydrogenated sample. The combined silver nitrate GC analysis revealed that C_{18} *trans*-monoenes were 2.6% of the total fatty acids, with C_{20} and C_{22} *trans*-monoenes accounting for 0.2 and 0.1% of total fatty acids, respectively (Table 4). The concentrations of C_{20} and C_{22} *trans*-monoenes are of a similar order of magnitude to that of most of the PUFA identified in adipose tissue.

DISCUSSION

Quantification of *trans*-fatty acids in edible fats has been performed using a number of different techniques, and these were recently and comprehensively reviewed (8). Traditionally, infrared spectroscopy has been used for quantification of *trans*-fatty acids, and the development of Fourier-transform infrared spectroscopy has greatly improved the accuracy of the technique especially for samples with *trans* content less than 5% (8). However, the technique can not give information about the chain length or the double-bond position of the *trans*-fatty acids present in the foods or tissues and has largely been used to analyze the *trans* content of partially hydrogenated vegetable oil (8).

GC, using highly polar capillary columns, has also been used routinely to analyze *trans*-fatty acids in partially hydrogenated vegetable oil (4–12), and overlap between C_{18} *cis*- and *trans*-monoenes still occurs when using a specialized 100-m column with optimized column temperature program (8,9). Also notably, highly polar columns as used in the analysis of *trans*-monoenes can degrade in efficiency, and resolution between C_{18} *cis*- and *trans*-monoenes can be further compromised. Several studies have isolated *trans*-fatty acids mainly of 18 carbon atoms together with saturated fatty acids using silver-ion chromatography prior to analysis by GC (4,6). These studies, as in this study, demonstrated that C_{18} *trans*-monoene content is underestimated using GC alone. It appears that current methods are unable to provide sufficient data on the complex composition of partially hydrogenated fish or marine oil. It was concluded in a recent review of available techniques that precise *trans*-fatty acid data and detailed isomer profiles could be obtained only by combining silver-ion chromatography with GC analysis (8).

It should be noted that there was limited compositional data on margarine purchased in 1995. Only three margarines purchased in 1995 gave the *trans* content as less than 1%,

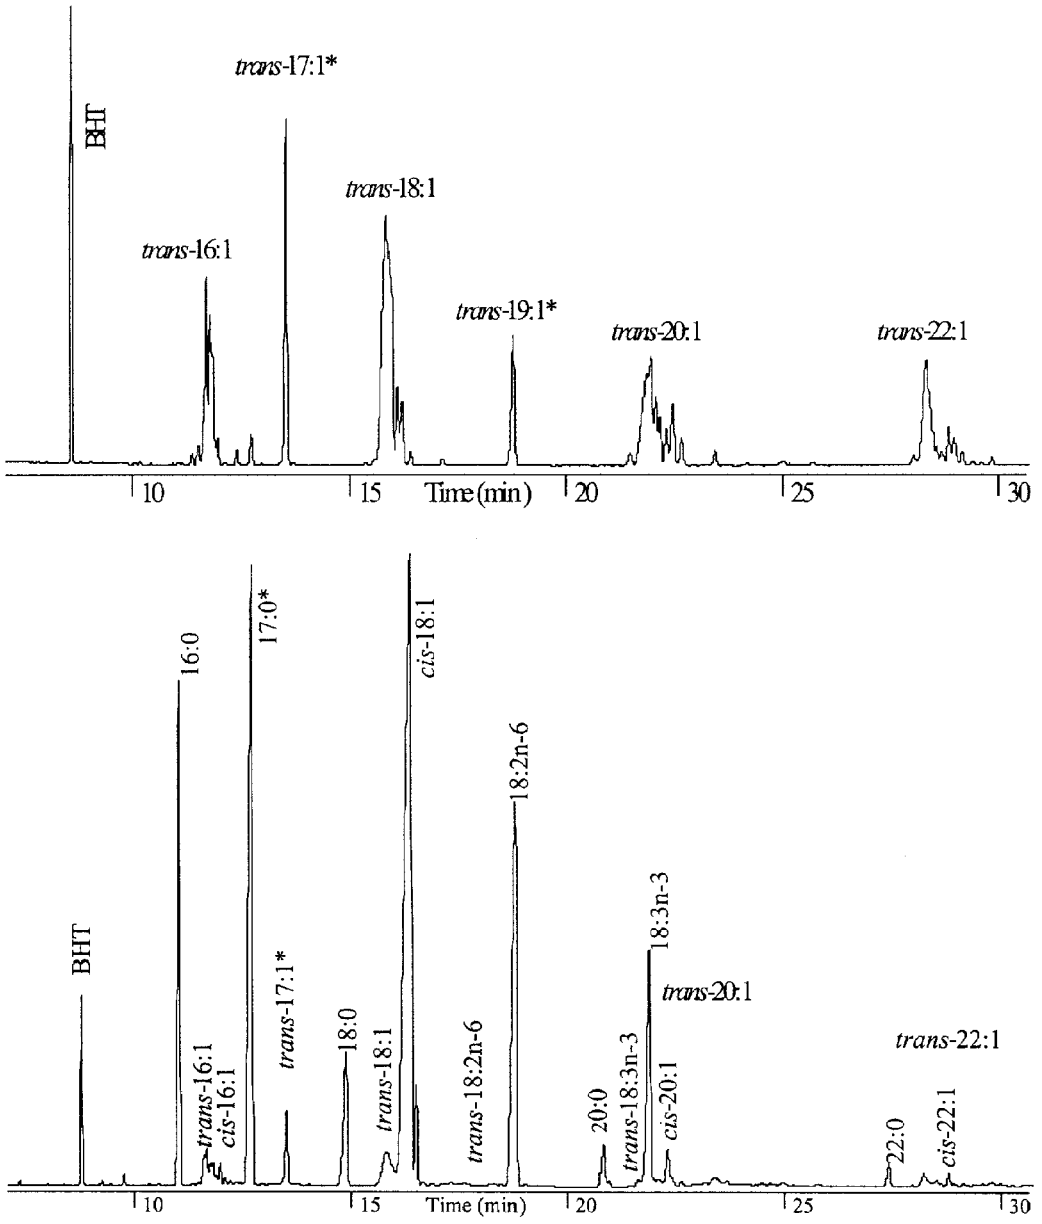

FIG. 2. Chromatogram showing C_{20} and C_{22} *trans*-monoenes in a margarine. Gas chromatogram of total FAME (lower trace) and isolated *trans*-isomers (upper trace) from a margarine made from hydrogenated fish oil. Sample preparation as described in the Materials and Methods section. The upper chromatogram of argentation TLC isolated *trans*-FAME demonstrates the complexity of the *trans*-isomer profile and shows the two internal standards, *trans*-17:1 and *trans*-19:1. The C_{18} *trans*-monoene content of this margine was 3.3% by direct GC analysis while the combined analysis gave 4.3% C_{18} *trans*-monoene, 3.8% C_{20} *trans*-monoene, and 2.9% C22 *trans*-monoene. *Trans*-18:2 was 0.1% of total fatty acids. BHT, butylated hydroxytoluene. See Figure 1 for other abbreviations. Asterisk indicates internal standards.

whereas in 1998 one brand of margarine gave the *trans* content as less than 1% and another gave the *trans* content as 9%. Our analysis revealed that the *trans* content of margarines was underestimated or not reported. Comparing margarine as a whole, then, there was a reduction in C_{18} *trans*-monoenes between 1995 and 1998. A reduction in C_{18} *trans*-monoenes has also been reported for German margarines over a similar period of time (5). Soft margarines purchased in 1995 contained relatively high levels of C_{20} and C_{22} *trans*-monoenes. However, recently purchased margarine had little C_{20} and C_{22} *trans*-monoenes, indicating that hydrogenated fish oil was no longer used in the production of these margarines. Nevertheless, hydrogenated fish or other oils are used in the production of margarine and shortenings in Northern Europe (1–4). Only brassica oils, such as rapeseed or low erucic acid rapeseed oil, are large-volume sources of 20:1 and 22:1 fatty acids.

Epidemiological and nutritional studies linking consumption of *trans*-fatty acids and coronary heart disease renewed

TABLE 4
Fatty Acid Composition of Adipose Tissue of 16 Healthy Men Determined by Combined Argentation TLC and GC Analysis[a]

Fatty acid	Mean	Range

trans-20:1	0.2	0.1–0.3
trans-22:1	0.1	0.0–0.1
trans-18:2[b]	0.5	0.0–0.7

[a]Values are percentage of total fatty acids and represent means and range. Data represent combined GC analysis of silver nitrate TLC-isolated *trans* monoenes and total FAME as described in the Materials and Methods section.
[b]*trans*-18:2 included all identifiable isomers using authentic reference standards. See Table 1 for abbreviations.

the interest in the possible detrimental health effects of *trans*-fatty acids (14–16). It should be noted that studies linking ischemic heart disease to the consumption of partially hydrogenated fish oil were founded on adipose tissue levels of C_{16} *trans*-monoenes (17), using inadequate analytical methodology. However, dietary *trans*-monoenoic fatty acids (22), including those from partially hydrogenated fish oil (23), raise serum LDL cholesterol or lower HDL lipoprotein cholesterol (22,23). The debate will therefore remain unless we have better methodology for the analysis of partially hydrogenated fish oil fatty acids in human tissues.

Fatty acids from the diet are incorporated into body tissues, and in humans adipose tissue fatty acid composition is used in many studies as a surrogate measure for long-term dietary intake of essential PUFA and 18:1 *trans*-fatty acids (24). The relative amount of C_{20} *trans*-monoenes in adipose tissue is related to the dietary intake of these *trans*-fatty acids in animals (25,26). In those studies (25,26) this relationship was not examined for C_{22} *trans*-monoenes because of overlapping peaks. It was interesting that for a given amount of *trans*-fatty acid in the diet, less C_{20} *trans*-monoenes than C_{18} *trans*-monoenes were deposited in adipose tissue (25,26). This could be attributed to increased oxidation of the longer-chain *trans*-monoenes or a conversion of C_{20} *trans*-monoenes to C_{18} *trans*-monoenes (27). Nevertheless, adipose tissue fatty acid composition is adequate to characterize a dietary intake of C_{18}, C_{20}, or C_{22} *trans*-monoenes in animals (25,26) and humans (24).

Our analysis of adipose tissue revealed that, on average, 2.6 and 0.5% of total fatty acids were C_{18} *trans*-monoenes and C_{18} *trans*-dienes. These levels are similar to those observed previously in British men (28). In that study it was not possible to quantify C_{20} and C_{22} *trans*-monoenes (28). C_{20} and C_{22} *trans*-monoenes were present in adipose tissue in apparently healthy Edinburgh men. Thus our analysis demonstrated that these Scottish subjects consumed C_{20} and C_{22} *trans*-monoenes. However, it is difficult from the small number of subjects analyzed at this time to estimate how much C_{20} and C_{22} *trans*-monoenes are consumed either in absolute terms or in relation to C_{18} *trans*-monoenes or total *trans*-monoenes.

In conclusion, we describe a simple and efficient silver-ion TLC technique for the isolation and subsequent quantitative analysis of the *trans*-isomer content of margarine and adipose tissue samples. The chromatographic separation of *cis*- and *trans*-monoenoic fatty acids and that of saturated fatty acids is improved when compared to existing techniques. The use of odd-chain *trans*-fatty acids as internal standards allows the quantitative analysis of the various *trans*-monoenoic fatty acids. The isolation of *trans*-monoenes without interference of saturated fatty acids permits hydrogenation of samples. Hydrogenation was only important in analyzing adipose tissue because of the limited sample size and the low concentrations of C_{20} and C_{22} *trans*-monoenes in adipose tissue. Hydrogenation improved the quantification of C_{20} and C_{22} *trans*-monoenes because a single distinct peak was quantified. The accurate measurement of C_{20} and C_{22} *trans*-monoenes in adipose tissue, which may be valuable as a biomarker of long-term consumption of hydrogenated fish oils, has implications in epidemiological and clinical studies. The method therefore has the potential to resolve the controversy as to whether hydrogenated fish or other oils lead to coronary heart disease.

ACKNOWLEDGMENTS

This study was supported by a LINK Agro Food Programme grant AFQ112. We wish to thank MAFF and the members of the Link management group (Nestlé UK Ltd., Roche Products Ltd., and Van den Bergh Foods Ltd.) for their support. We thank the nurses of the Cardiovascular Research Unit, University of Edinburgh, for collecting adipose fat biopsies and Jouni Niemelä of Räisio Margarinii, Räisio, Finland, for a sample of margarine prepared from hydrogenated fish oil.

ABSTRACT: A novel lipid analog with two long alkyl (C_{16}) chains, an aspartate skeleton, a connecting alkyl (C_8) chain, and 2-nitrophenol trigger group is synthesized by an efficient synthetic route, which can induce liposome fusion at physiological pH.

Paper no. L8428 in *Lipids 35*, 689–691 (2000).

For the last decade, liposomes have been exploited predominantly for potent carriers of various polar materials into cells (1–6). In the present study we design and synthesize a novel functional lipid analog which accelerates the fusion between liposomes under physiological pH conditions. The lipid analog **8** (Scheme 1) designed for this purpose is composed of four parts: (A) two long hydrophobic alkyl chains (C_{16}) bound to an aspartate residue, which can be anchored to lipid bilayer, (B) a polar moiety (an aspartate residue) containing a free carboxyl group in the middle part, (C) an alkyl chain (C_8) connecting the aspartate skeleton and a terminal trigger part, and (D) a terminal trigger (2-nitrophenol group). The polar moiety (B) is thought to be necessary for **8** to exist stably in the lipid bilayer of a liposome. The terminal trigger of **8** is expected to be anchored into the lipid bilayer of another liposome before initiating membrane fusion. Here the 2-nitrophenol group is used as the trigger to induce liposome fusion at the physiological pH, since it is relatively hydrophobic and its pK_a value is normally around 7. Although there have been several studies on liposome fusion using carboxyl groups as triggers, the starting point of the fusion is in the acidic region since the pK_a values of the carboxyl group are less than 5 (7–9).

EXPERIMENTAL PROCEDURES

Lipid analog **8** was synthesized according to Scheme 1 in a manner similar to that previously reported (10) (yield 87%). Anal. Calc. for $C_{56}H_{97}N_6O_{10}$: C, 66.33; H, 9.57; N, 8.29. Liposome (PC-**8** liposome) composed of PC (egg yolk phosphatidylcholine) and **8** was prepared by the method described elsewhere (9). The fusion efficiency (%) was determined from the decrease in the efficiency of fluorescence resonance energy transfer between NBD-PE [*N*-(7-nitro-benza-2-oxa-1,3-diazol-4-yl) phosphatidylethanolamine], λ_{ex} = 460 nm, λ_{em} = 534 nm and Rh-PE (lissamine rhodamine B-sulfonyl phosphatidylethanolamine, λ_{ex} = 550 nm, λ_{em} = 590 nm) (9).

RESULTS AND DISCUSSION

Figure 1 exhibits the pH dependence of the fusion efficiency (%) at various reaction times. The three lines denote different measurement times: 5, 10, and 15 min. Liposome fusion is facilitated when pH is lowered and the 2-nitrophenolate group is protonated to form the more hydrophobic neutral form, though the starting pH point is somewhat shifted toward basic region. In order to interpret this pH-dependency, we estimated pK_a values of compound **8** located in a lipid bilayer of liposome. It was found unexpectedly that the pK_a value of **8** was shifted to basic side (pK_a = *ca*. 9.5) compared to ordinary 2-nitrophenol derivatives such as **10** (Scheme 1), whose pK_a is

6.8 in aqueous solution. A similar shift of pK_a was observed for **9** (Scheme 1), whose pK_a is 8.7 in a lipid bilayer. These phenomena appear quite reasonable, if the 2-nitrophenol groups are assumed to be situated in hydrophobic environments such as the vicinity of liposome surface or inside the bilayer membrane, since the electrostatic interaction between the 2-nitrophenolate anion and a proton should be stronger in hydrophobic environments than in water. This is also supported by the absorption maxima (λ_{max}) of **8**, **9,** and **10** shown in Table 1, where λ_{max} in an aqueous solution is as a whole shorter than those in organic solvents such as chloroform and methanol. It is generally recognized that the blue shift in polar solvents is characteristic of n→π* transitions (11). In view of the pK_a values of **8** in liposome, it is concluded that the 2-nitrophenol group of **8** should be located in hydrophobic envi-

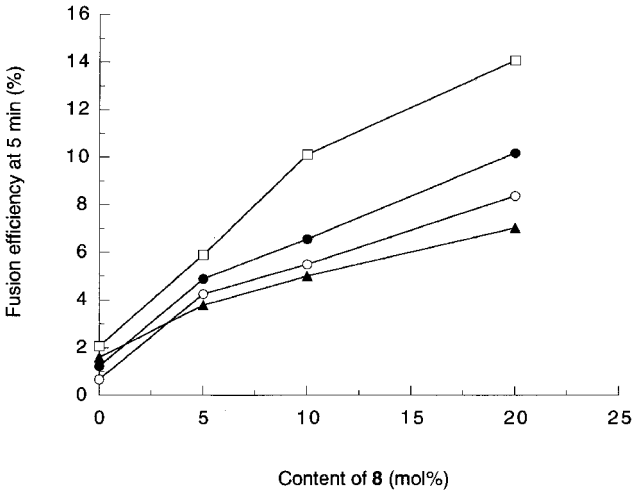

FIG. 2. Relation between fusion efficiency at 5 min (%) and content of **8** (mol%). pH: 5.1 (□), 5.8 (●), 6.4 (○), 6.8 (▲).

ronments. This is further suggested by the conformational analysis of **8** by molecular mechanics and dynamics calculation using MM3 parameters, from which two types of conformation with similar energies were obtained, *viz.*, stretched ones and folded ones. MM3 is the improved version of MM2 molecular mechanics method, which is used to determine molecular geometries using equations from classical Newtonian physics. In the folded conformations, the 2-nitrophenol group inevitably should be oriented toward the liposome surface. Figure 2 shows the relation between the fusion efficiency (%) and the content of **8** (mol%) included in the lipid bilayer of a liposome. The four lines denote different pH values of the solution: 5.1, 5.8, 6.4, and 6.8. The result, that the fusion efficiency increases monotonously with the amount of **8,** is compatible with our conclusion that lipid **8** is the key trigger compound to start the liposome fusion. Though the fusion occurred to a small extent in the absence of **8**, the fusion efficiency was considerably enhanced in the presence of **8**. In fact, it was increased about seven times when 20 mol% of **8** was included in the liposome membrane at pH 5.1. We are now preparing analogous lipids with 2-nitrophenol groups to explore in more detail the mechanism of liposome fusion.

ABSTRACT: Concentration and distribution of long-chain acylcarnitines in control microwaved and ischemic (decapitated) rat brain were measured by electrospray ionization tandem mass spectrometry. The total acylcarnitine concentration from control rat brains equaled 7–8 nmol/g wet weight brain, about one-fourth the total concentration of long-chain acyl-CoA, indicating a small role in buffering the total acyl-CoA pool concentration. Furthermore, acylcarnitine did not differ between ischemic and control rat brain with regard to total concentration or concentrations of molecular species of acylcarnitine. Therefore, the size of the acylcarnitine pool in brain is not affected by the dramatic increase in unesterified fatty acids (~4×) that occurs in ischemia.

Paper no. L8231 in *Lipids 35,* 693–696 (June 2000).

Acyl-CoA and acylcarnitine (acyl-Cn) are two fatty acid metabolic intermediates involved in the incorporation of fatty acids into phospholipids and neutral lipids (1) and in β-oxidation of fatty acids (2), respectively. Carnitine (Cn) palmitoyltransferase (CPT-1) (EC 2.3.1.21) catalyzes the reversible transfer of long-chain fatty acids from acyl-Cn to acyl-CoA (Eq. 1) (3):

$$\text{acyl-CoA} + \text{Cn} \xrightarrow{\text{CPT}} \text{acyl-Cn} + \text{CoA} \xrightarrow{\text{CPT}} \text{acyl-CoA} + \text{Cn} \quad [1]$$

Fatty acids entering the brain from plasma, or synthesized *de novo*, can be incorporated into lysolipids after being activated to acyl-CoA by acyl-CoA synthetase (EC 6.2.1.3) in the endoplasmic reticulum of the cell (1,4,5). Additionally, in the mitochondrial membrane cytosolic acyl-CoA can be converted by CPT-1 to acylcarnitine, which in turn is converted to acyl-CoA in the mitochondrial interior, which is further metabolized by β-oxidation (2,3).

Arduini *et al*. have proposed an additional role for acyl-Cn and CPT (6–8) based on their location in nonmitochondrial compartments [the endoplasmic reticulum, peroxisomes (9), and plasma membrane of red blood cells (6)] such that a cytosolic pool of acyl-Cn is maintained (9). Cytosolic, nonmitochondrial acyl-Cn is a potential reservoir of activated fatty acid for either mitochondrial or nonmitochondrial acyl-CoA and can buffer acyl-CoA and CoA concentrations at set levels (9).

In cerebral ischemia or trauma, there is a dramatic, well-documented increase (4–5 times) in the size of the brain unesterified fatty acid pool (10–12). However, in rat brain after decapitation (10), and in gerbil brain after ischemia (12), the total concentration of brain acyl-CoA is not altered, although there is a redistribution in the concentrations of individual molecular species of acyl-CoA (arachidonoyl-CoA increases at the expense of other molecular species). Cardiac ischemia also results in increased concentrations of unacylated fatty acids, but acyl-CoA (13) and acyl-Cn are both elevated (14).

We previously reported the concentrations of fatty acid and acyl-CoA molecular species in ischemic compared to control rat brain (10). In those studies, however, concentrations of acyl-Cn species were not measured, due to the lack of suitable analytical methodology. With recent advances in electrospray ionization tandem mass spectrometry (ESI/MS/MS) technology, quantifications of acyl-Cn in heart (ischemic and control) (14), and subsequently plasma have been reported (15–17).

In this study we measured the concentrations of long-chain acyl-Cn in ischemic (decapitation model) and microwaved (control) rat brain. Our aim was to determine baseline concentrations and monitor the effect of ischemia.

MATERIALS AND METHODS

Acyl-Cn standards were obtained from Deva Biotech (Hatboro, PA). *n*-Butanol and acetylchloride were purchased from Aldrich (Milwaukee, WI). Male rats, 200–250 g (Sprague-Dawley, Charles Rivers Laboratories, Wilmington, MA) were anesthetized with pentobarbital (50 mg/kg i.p.) and their heads subjected to microwave irradiation (Cober Electronics, Norwalk, CT), or they were decapitated (ischemic brain, 10 min). Brain (100–200 mg) was rapidly removed and then was mixed with methanol (2.0 mL), spiked with tetradecanoyl-d_3-Cn and heptadecanoyl-d_3-Cn (100 ng) as internal standards, and sonicated (Misonix, Farmingdale, NY) for 20 s. In the assay not all the molecular species have the same recovery. A

Abbreviations: acyl-Cn, acylcarnitine; Cn, carnitine; CPT-1, carnitine palmitoyltransferase; ESI/MS/MS, electrospray ionization tandem mass spectrometry.

recovery of 72–75% was obtained for heptadecanoyl-Cn and 95–98% for tetradecanoyl-Cn. To overcome this difference, we used two internal standards: trideuterated tetradecanoyl-Cn for estimation of dodecanoyl-Cn and tetradecanoyl-Cn and heptadecanoyl-d_3-Cn for hexadecanoyl-Cn and stearoyl-Cn. After centrifugation, the extract was concentrated under nitrogen to 0.5 mL and the supernatant filtered and dried. We found that both the reproducibility and recovery decrease significantly if the proteins from the methanolic extract are not completely removed by filtration.

The dry extract was treated with a freshly prepared solution (0.5 mL) of *n*-butanol/acetylchloride (9:1) at 0°C for derivatization. The mixture was allowed to stand at room temperature for 10 min, concentrated under nitrogen at 40°C to 0.1 mL, and heated to 80°C for 20 min. The product was dried and the residue redissolved in 150 µL 60% acetonitrile. Ten microliters of solution was injected into a mass spectrometer. ESI/MS/MS was performed with a VG QUATTRO II instrument (Micromass, Altrincham, United Kingdom).

RESULTS

Extracts from nondecapitated, control brains and decapitated brains were analyzed for acyl-Cn molecular species. A tentative molecular species hydrocarbon profile from 14–22 carbon atoms long was anticipated based on previous analysis of brain acyl-CoA (10). Qualitative profiles of the acyl-Cn *n*-butyl esters were obtained by monitoring precursor-ion scans of the common fragment at *m/z* 85 of *n*-butylcarnitine derivatives (Scheme 1).

Mass spectral patterns are illustrated in Figure 1 and include long-chain acyl-Cn 20:4, 18:0, 18:1, 16:0, 16:1, 14:0, 14:1, and 12:0 from control rat brains and brains after decapitation (Table 1).

Results for acyl-Cn molecular species (n = 3) and total acyl-Cn (n = 3) in control brains and ischemic brains are presented in Table 1 and were compared by a standard t-test. Significance was assumed if $P > 0.05$. Control brains had a total acyl-Cn concentration of 7.24 ± 0.60 nmol/g while the concentration of total acyl-Cn in ischemic brains was 9.14 ± 0.83 nmol/g (average ± SEM), and these values were not significantly different. Although the concentrations of individual molecular species in ischemic brains were all numerically higher than those in control brains the numerical difference in each case was not significant.

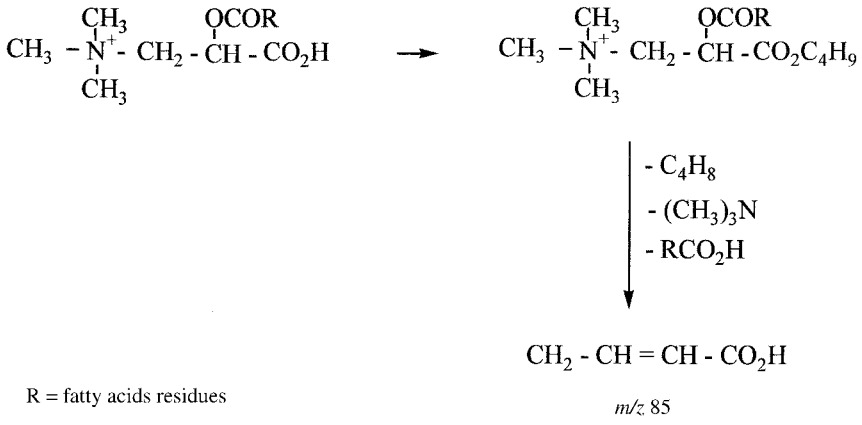
TABLE 1
Distribution of Molecular Species of Acylcarnitines in Ischemic and Microwaved (control) Rat Brain

Molecular species acylcarnitine	Ischemic	Microwaved
	Concentration (nmol/g brain)[a]	
12:0	0.41 ± 0.58	0.38 ± 0.08
14:1	0.38 ± 0.10	0.22 ± 0.01
14:0	0.81 ± 0.10	0.67 ± 0.01
16:1	0.98 ± 0.26	0.80 ± 0.11
16:0	2.84 ± 0.39	2.46 ± 0.54
18:1	1.99 ± 0.26	1.75 ± 0.21
18:0	0.97 ± 0.14	0.82 ± 0.02
20:4	0.43 ± 0.12	0.14 ± 0.01
Total	9.14 ± 0.83	7.24 ± 0.60

[a]Mean ± SEM (n = 3). No statistical difference was found between individual molecular species of acylcarnitine in control vs. ischemic brains ($P > 0.05$).

DISCUSSION

The average total acyl-Cn concentration in this study was 7 nmol/g brain, which is considerably lower and only 25% of the 30 nmol/g brain for acyl-CoA (10). In the ischemic decapitated brain, four- to fivefold elevations of total unesterified fatty acids have been reported for this decapitated rat brain model (10,11), and in other ischemic brain models (11,12). The increases in unesterified fatty acids following ischemia in rat brain are clearly established. Unesterified arachidonic acid increases up to 50 times, whereas relative increases in the concentration of other fatty acids are of lesser magnitude (10,11). However, the net brain concentration of acyl-CoA is not altered, but arachidonoyl-CoA is elevated



SCHEME 1

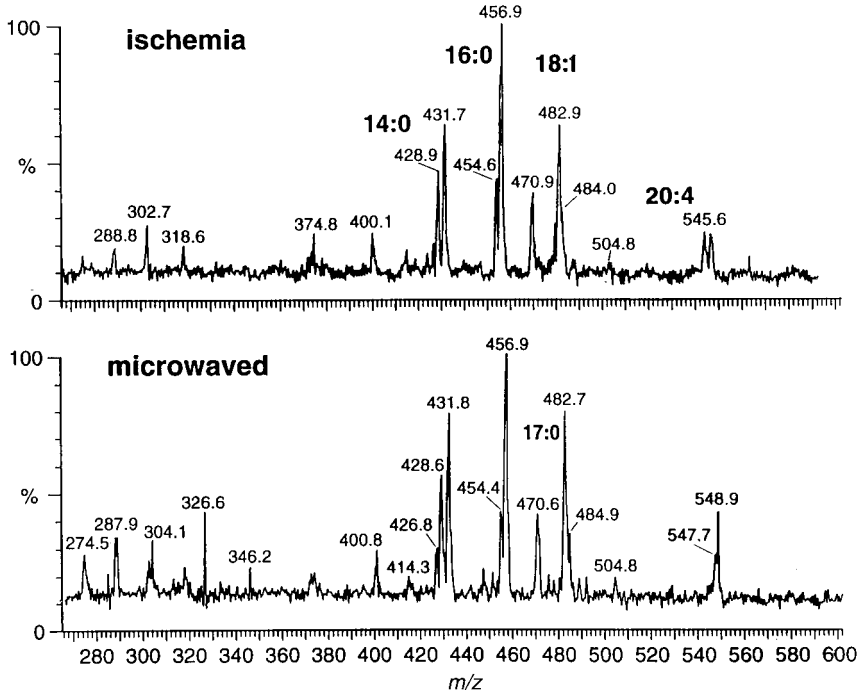


FIG. 1. Electrospray ionization tandem mass spectrometry of molecular species of acylcarnitines from rat brain spiked with tetradecanoyl-d_3-carnitine and heptadecanoyl-d_3-carnitine as internal standards (ischemia vs. microwaved).

fivefold, at the expense of changes in concentrations of palmitoyl-, stearoyl-, and docosahexaenoyl-CoA (10–12,18). In the present study, we found that the acyl-Cn pool also was not altered in the ischemic brain, and, furthermore, there was no redistribution involving arachidonoyl-Cn or other molecular species. Interestingly, we found an increase in the concentration of arachidonoyl-Cn in traumatized rat brain (15). In this work a trend toward an increase in arachidonoyl-Cn is evident ($P < 0.12$) compared to other molecular species, but no significant difference between ischemic and control brains was found.

In ischemic heart, there is evidence for an elevation of acyl-Cn in sarcolemmal membranes (13,14). In contrast, our work indicates that such elevations do not occur in ischemic brain, at least following the complete ischemia of decapitation. Therefore, membrane-destabilizing effects of increased levels of acyl-Cn on the membrane bilayer are not a concern in ischemic brain. This indicates a profound difference in the processing of fatty acids by brain and heart. It may be that the trend toward an increase in levels of acyl-Cn molecular species seen in our data (Table 1) may substantially increase with time during reperfusion *in vivo* such that significant differences would be observed. A thorough investigation of the time course of acyl-Cn concentration during reperfusion after different lengths of ischemia will investigate such metabolism.

The relatively low concentration of acyl-Cn compared to acyl-CoA (~7 nmol/g vs. ~30 nmol/g, respectively) in control brain could provide only a modest buffering capacity for maintaining the acyl-CoA/CoA ratio. The transit time of palmitic acid through the palmitoyl-CoA pool is approximately 6 s in rat brain (5). Obviously, an isolated pool of palmitoyl-Cn (2.4 nmol/g) could maintain a constant level of palmitoyl-CoA for only a few seconds. Similar considerations can be applied to other molecular species of these metabolic intermediates. However, we cannot deny a kinetic role for acyl-Cn in the incorporation of fatty acids into phospholipids or in helping to maintain the acyl-CoA/CoA ratio. Arduini *et al.* have demonstrated involvement of acyl-Cn in the acylation of lysophospholipids and diglyceride (6,9). There are 117 nmol Cn/g in control brain (18) which, with the 7 nmol/g acyl-Cn, indicates a considerable reserve of Cn for acylation and maintenance of acyl-Cn levels. Therefore, any decrease in acyl-CoA could be met by rapid transfer of fatty acid from acyl-Cn to acyl-CoA, and reacylation of carnitine could maintain acyl-Cn concentration. Of course, any increase in either acyl-CoA or acyl-Cn could be modulated through the reversible equilibration shown in Equation 1 and the equilibration between acyl-CoA and the unesterified fatty acid pool.

Studies of the entry of radiolabeled fatty acids into the acyl-Cn pool in brain could provide information on acyl-Cn turnover (5,11). During reperfusion in gerbil brain following 5 min of ischemia, we demonstrated accelerated reincorporation of arachidonic acid into brain phospholipids and a normal rate of incorporation of palmitic acid, in the face of very high concentrations of these fatty acids in brain (19). Maintenance of the total acyl-CoA and total acyl-Cn pools at control levels during reperfusion following ischemia may be crucial to the reacylation of lysolipids.

Diversity of Mouse Lipoxygenases: Identification of a Subfamily of Epidermal Isozymes Exhibiting a Differentiation-Dependent mRNA Expression Pattern

Markus Heidt, Gerhard Fürstenberger, Sonja Vogel, Friedrich Marks, and Peter Krieg*

Research Program on Tumor Cell Regulation, Deutsches Krebsforschungszentrum, 69120 Heidelberg, Germany

ABSTRACT: By using reverse transcription-polymerase chain reaction technology (RT-PCR) and Northern blot analysis, the tissue-specific mRNA expression patterns of seven mouse lipoxygenases (LOX)—including 5S-, 8S-, three isoforms of 12S-, 12R-LOX, and a LOX of an as-of-yet unknown specificity, epidermis-type LOX-3 (*e*-LOX-3)—were investigated in NMRI mice. Among the various tissues tested epidermis and forestomach were found to express the broadest spectrum of LOX. With the exception of 5S- and platelet-type 12S-LOX (*p*12S-LOX) the remaining LOX showed a preference to exclusive expression in stratifying epithelia of the mouse, in particular the integumental epidermis. The expression of the individual LOX in mouse epidermis was found to depend on the state of terminal differentiation of the keratinocytes. mRNA of epidermis-type 12S-LOX (*e*12S-LOX) was detected in all layers of neonatal and adult NMRI mouse skin, whereas expression of *p*12S-LOX, 12R-LOX, and *e*-LOX-3 was restricted to suprabasal epidermal layers of neonatal and adult mice. 8S-LOX mRNA showed a body-site-dependent expression in that it was detected in stratifying epithelia of footsole and forestomach but not in back skin epidermis. In the latter, 8S-LOX mRNA was strongly induced upon treatment with phorbol esters. With the exception of *e*12S-LOX and *p*12S-LOX, the isozymes that are preferentially expressed in stratifying epithelia are structurally related and may be grouped together into a distinct subgroup of epidermis-type LOX.

Paper no. L8451 in *Lipids 35,* 701–707 (June 2000).

Lipoxygenases (LOX) are a family of dioxygenases that catalyze the stereo- and regiospecific oxygenation of polyunsaturated fatty acids with 1-*cis*,4-*cis*-pentadiene moieties. Mammalian LOX metabolize arachidonic acid into a series of bioactive compounds, such as leukotrienes, lipoxins, hydroxyeicosatetraenoic acids and hepoxilins (1). LOX metabolites play important roles in inflammatory processes, blood clotting, leukocyte chemotaxis (2,3), in distinct inflammatory skin diseases like psoriasis (4,5), atherosclerosis (6,7), and cancer (8,9).

Mammalian LOX are categorized according to the positional specificity of oxygen insertion into arachidonic acid. Four positional LOX isoforms have been identified in mammalian tissues, including the 5-, 8-, 12-, and 15-LOX, which insert oxygen to yield as primary products the corresponding S-enantiomeric hydroperoxyeicosatetraenoic acids. A further increase of LOX diversity was found to be due to the existence of isozymes with identical positional specificity such as the leukocyte-type (*l*), platelet-type (*p*), and epidermis-type (*e*) 12S-LOX. An additional complexity is introduced by the identification of a new mammalian LOX generating products with *R*-chirality.

We and others have cloned seven different LOX isoenzymes from mouse tissues, six of which were isolated from normal, phorbol ester-treated, and neoplastic epidermis including *l*-, *p*-, and *e*12S-LOX (9–13), an inducible 8S-LOX (14,15), a 12R-LOX (16), and another LOX of an as-of-yet unknown enzymatic specificity termed *e*-LOX-3 (17). In addition, a mouse 5S-LOX cDNA was cloned from mouse peritoneal macrophages (18). In this paper we analyzed the mRNA expression pattern of these LOX in mouse tissues and, in particular, in stratifying epithelia. According to the predominant expression in epidermis and the structural relationship of the proteins, 8S-, 12R-LOX, and *e*-LOX-3 are grouped together in a distinct LOX subfamily, i.e., the epidermis-type LOX, whereas *p*- and *e*12S-LOX belong to a distant subfamily.

EXPERIMENTAL PROCEDURES

Animals; treatment with phorbol ester. All tissues were obtained from 7-wk-old female NMRI mice (BRL, Füllinsdorf, Switzerland). Three days before treatment the back skin of the mice was shaved with electrical clippers. For topical application, 10 nmol of 12-*O*-tetradecanoylphorbol-13-acetate (TPA) was dissolved in 0.1 mL of acetone and applied onto the shaved back skin. After various time points (0.5, 1, 2, 4, 6, 24, 48 h) the animals were killed by cervical dislocation. After dissection of the back skin total RNA was extracted from epidermis. The animal experiments have been per-

formed according to the guidelines and with permission of the German animal protection committee.

Fractionation of keratinocytes from neonatal and adult epidermis. After decapitation (neonatal mice, 2 d old)/or cervical dislocation (adult mice) the back skin of the mice was dissected as described in detail (19,20). Epidermal cells were obtained from skin by trypsinization. The keratinocyte suspension was then centrifuged on a discontinous Percoll density gradient, obtaining a separation into four fractions. Fraction I on top of the gradient consisted mainly of squamous and large granular cells. With increasing density of the gradient fraction II consisted of early granular and spinous cells, and fractions III and IV contained basal keratinocytes. The individual fractions have previously been characterized thoroughly by monitoring expression of differentiation-specific keratin and lectin markers (19).

Preparation of RNA. Cells were washed with phosphate-buffered saline and scraped directly in guanidinium thiocyanate solution (RNA-Clean, AGS, Heidelberg, Germany). Various tissues frozen at –80°C were first homogenized in a dismembrator and then in guanidinium thiocyanate solution (RNA-Clean, AGS). Total RNA was extracted according to the manufacturer's instructions. RNA concentration was quantified by ultraviolet absorption at 260 nm.

Reverse transcription-polymerase chain reaction (RT-PCR) analysis. RNA samples were treated with DNAse I, and first strand cDNA synthesis was carried out with 1 μg of total RNA in 20 μL reaction mixtures using the RT-PCR kit (PerkinElmer, Foster City, CA) with oligo(dT) primer according to the manufacturer's specifications. The reverse transcription mixture contained 1 mM of deoxynucleotide triphosphate mixture (dNTP), 2 μL 10 × PCR buffer (500 mM KCL, 100 mM Tris-HCl, pH 8.3), 4 μL $MgCl_2$ (25 mM), 1 μL oligo(dT) primer (50 μM), 1 μL RNase inhibitor (20 units/μL), and 1 μL MuLV (Murine Leukemia Virus) reverse transcriptase (50 units/μL). This mixture was incubated for 10 min at room temperature and 15 min at 42°C, and heated to 99°C for 5 min.

Isoenzyme-specific primers (primer set "a") were selected from 3′-untranslated regions using "Oligo" primer analysis software (National Biosciences, Plymouth, MA). Second primer sets (set "b") spanning conserved intron positions were designed to discriminate amplification products originating from contaminating genomic DNA. Sequences of the PCR primers and the length of the the PCR products are listed in Tables 1 and 2. Amplification of β-actin (429 bp) was also performed as an internal control using the forward primer 5′-AAACTGGAACGGTGAAGGC-3′ and the reverse primer 5′-GCTGCCTCAACACCTCAAC-3′. The PCR reactions were primed with 3 μL of 10^{-1} dilutions of the cDNA reactions using 20 pmol of primers in 10 mM Tris/HCl, pH 9.0, 50 mM KCl, 1.5 mM $MgCl_2$, 0.1% Triton X100, 0.2 mg/mL bovine serum albumin with 0.2 mM of each dNTP, and 2.5 units Taq polymerase (Appligene Oncor, Illkirch, France) in 50 μL reactions. The PCR was programmed in a PTC-200 DNA Engine (MJ Research, Watertown, CA) as follows: 94°C, 5 min for one cycle; 94°C for 90 s, 51.8–60°C (see Table 2) for 4 min, and 72°C for 2 min 30 s for 30 cycles; 72°C for 10 min for one cycle. Then, the block temperature was held at 4°C. Aliquots (10 μL) of the reaction products were analyzed by electrophoresis on 2% agarose gels. The identity of the PCR products was confirmed either by restriction enzyme analysis or sequence determination.

Cloning of PCR products and DNA sequencing. The PCR-amplified bands were cloned into the vector pCRII-TOPO (Invitrogen, San Diego, CA). Sequences of the inserts were determined using the ABI Big Dye Terminator Cycle Sequencing Ready Reaction kit (PerkinElmer/Applied Biosystems, Foster City, CA), and the products were resolved on an ABI prism 310 Genetic analyzer (PerkinElmer/Applied

Biosystems, Foster City, CA). The sequences were analyzed using the Heidelberg Unix Sequence Analysis Resources (HUSAR, Heidelberg, Germany) software programs.

Northern blot analysis. Northern gels loaded with 10 μg of RNA were electrophoresed, and RNA was transferred to Hybond-N^+ membranes (Amersham Pharmacia Biotec, Freiburg, Germany) by established procedures (9). Labeling was performed using the Random Primed DNA labeling kit (AGS) with electroeluted and purified cDNA fragments. The filters were washed with a final stringency of 0.1 × standard saline citrate and 0.5% sodium dodecyl sulfate (SDS) for 20 min and exposed using intensifying screens at −80°C. Rehybridization of the blots with a second 18S-rRNA-specific probe was performed by washing off the filters with 0.1% SDS, 20 mM Tris-HCl, pH 7.0 three times for 20 min each time at 60°C and hybridizing under the same conditions as described above.

RESULTS

LOX mRNA expression in mouse tissues. The mRNA expression of seven LOX was investigated in 15 different tissues of NMRI mice by RT-PCR and Northern blot analysis. Two primer sets were used for each sample and isozyme in order to ensure specificity. The PCR products were further characterized by restriction enzyme analysis or by sequence determination. Expression of 5S-LOX mRNA was evident in epidermis of back skin and footsole, forestomach epithelium, colon, and small intestine by PCR amplification of two specific amplicons of 239 and 307 bp. PCR reactions using primer set b for the amplification of 5S-LOX specific sequences were in general more efficient. By using this primer set, 5S-LOX-specific amplification products of 307 bp were also identified in brain, platelets, kidney, and testis (Fig. 1A). An 8S-LOX-specific product of 143 bp was found in footsole epidermis and less abundantly in forestomach epithelium, but not in epidermis of back skin. In addition, 8S-LOX-specific signals were observed in lung, colon, and brain (Fig. 1A). After epicutaneous administration of the phorbol ester TPA to mouse back skin, 8S-LOX expression was found to be induced, reaching a maximum 6 h after treatment (Fig. 1B).

*l*12S-LOX-specific PCR products could not be demonstrated in any of the tissues analyzed in this study. On the other hand, *p*12S-LOX-specific bands were found in every tissue tested, with the strongest signal intensities localized in back skin and footsole epidermis, tongue, forestomach, and above all in platelets (Fig. 2).

Specific signals for *e*12S-LOX (200 and 337 bp) were found exclusively in back skin and footsole epidermis and in platelets (Fig. 2). 12R-LOX-specific fragments (333 and 235 bp) were identified preferentially in epidermis, tongue, forestomach, and trachea, and with lower abundance in lung, liver, and kidney (Fig. 3). No 12R-LOX signal was found in

platelets. The most recent member of mouse LOX, *e*-LOX-3, showed a similar but not identical expression pattern as compared with that of 12R-LOX (Fig. 3). Strong specific signals of 313 bp were characteristic for epithelia, brain, and testis. Liver, colon, and kidney showed only weak signals, whereas no mRNA expression was found in platelets, reticulocytes, small intestine, and muscle (Fig. 3).

mRNA expression of LOX in keratinocyte layers of neonatal and adult mouse skin. As described above, preferential mRNA expression in stratifying epithelia was a consistent

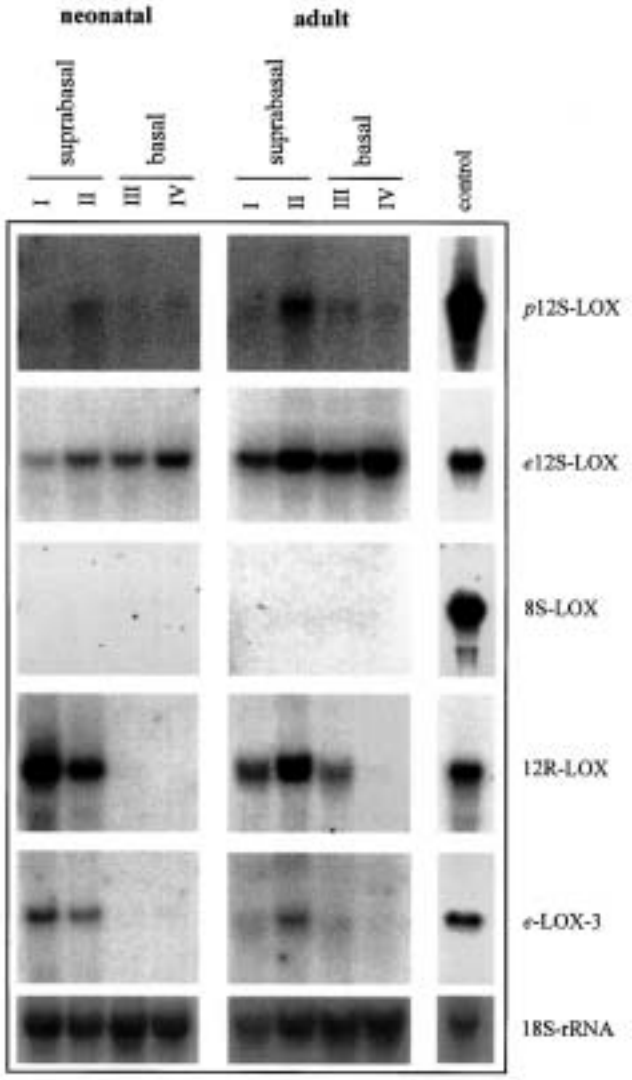

FIG. 4. Quantitation of mouse LOX mRNA in cellular subfractions of neonatal and adult mouse epidermis by Northern blot analysis. Single cell suspensions from neonatal and adult mouse epidermis were fractionated on Percoll gradients into basal (fractions III and IV) and differentiated cells (fractions I and II). Total RNA was isolated, separated on Northern gels , blotted and probed with ^{32}P-labeled isoenzyme-specific cDNA fragments as indicated on the left and then with a 18S rRNA-specific probe (lower panel). Control, RNA isolated from HEK 293 cells transiently transfected with the corresponding LOX-isoenzyme expression construct. For abbreviations see Figures 1 and 2.

feature for 8S-LOX (in particular upon induction by phorbol esters), *p*- and *e*12S- and 12R-LOX and *e*-LOX-3 as well. A more detailed Northern blot analysis of these LOX species indicated a differentiation-dependent expression pattern in skin epidermis. By centrifugation using a discontinuous Percoll density gradient, keratinocytes obtained from mouse epidermis can be subfractionated according to their stage of terminal differentiation (19,20). In using this approach, *e*12S-LOX mRNA was found to be associated with basal (fractions III and IV) and suprabasal (fractions I and II) cell layers of

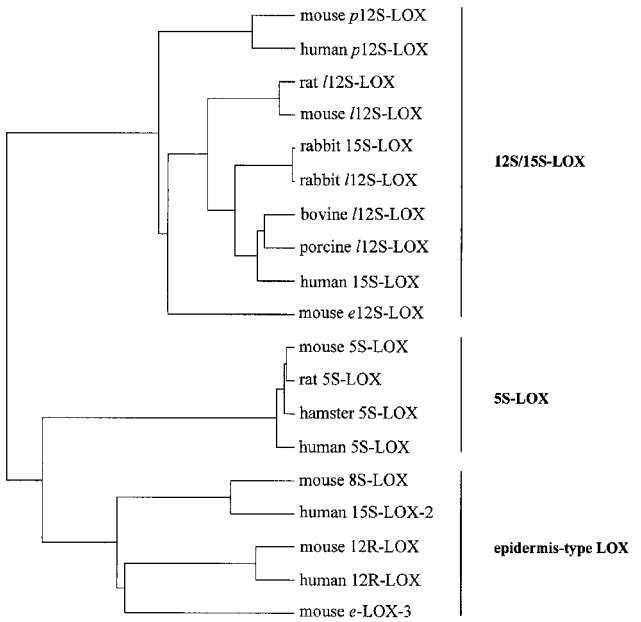

FIG. 5. Evolutionary tree of mammalian LOX. Multiple sequence alignments were performed using PileUp programs, and a phylogenetic tree was created from a distance matrix using the GrowTree program of the Heidelberg Unix Sequence Analysis Resources (HUSAR) software programs. Abbreviations and sources are as follows: *p*12S-LOX, platelet-type 12S-lipoxygenase (9,30); *l*12S-LOX, leukocyte-type 12S-lipoxygenase (9,31–34); 15S-LOX, 15S-lipoxygenase (35,36); *e*12S-LOX, epidermis-type 12S-lipoxygenase (12); 5S-LOX, 5S-lipoxygenase (18,37–39); 8S-LOX, 8S-lipoxygenase (15); 15S-LOX-2, 15S-lipoxygenase-2 (40); 12R-LOX, 12R-lipoxygenase (15,41); *e*-LOX-3, mouse epidermis-type lipoxygenase-3 (17).

neonatal epidermis, whereas12R-LOX and *e*-LOX-3 were predominantly expressed suprabasally with the strongest signals in fraction I (Fig. 4). *p*12S-LOX was predominantly expressed in fraction II consisting of spinous and early granular keratinocytes. A slightly different distribution of the mRNA for 12R-LOX and *e*-LOX-3 was found in adult epidermis in that the expression of the latter was restricted to fraction II whereas 12R-LOX mRNA could also be detected in basal keratinocytes of fraction III. All cell fractions obtained from untreated neonatal or adult mouse skin were negative for 8S-LOX (Fig. 4), 5S-LOX and *l*12S-LOX mRNA (data not shown).

Epidermis-type LOX. According to their preferential expression in epidermis and their phylogenetic relationship 8S-, 12R-LOX, and *e*-LOX-3 can be grouped together into a separate LOX subfamily. This subfamily of epidermis-type LOX also comprises the human ortholog of the mouse 12R-LOX as well as 15S-LOX-2, the human homolog of mouse 8S-LOX (Fig. 5). A remarkable feature of epidermis-type LOX isozymes is the diversity of the positional specificity and chirality of the LOX reaction of the individual members of this subfamily. *e*12S-LOX and *p*12S-LOX, being approximately equally expressed in epidermis and platelets, belong to a distant subfamily containing 12S- and 15S-LOX (Fig. 5).

DISCUSSION

The mRNA expression patterns of seven mouse LOX were analyzed in various tissues of NMRI mice. Stratifying epithelia such as back skin and footsole epidermis, forestomach, and tongue showed the most abundant mRNA content, both with respect to the spectrum of individual LOX isozymes and the relative strength of expression. The LOX species found in these stratifying epithelia included the more ubiquitously expressed *p*12S-LOX and the more specifically expressed 8S-, *e*12S-, 12R-LOX, and *e*-LOX-3, while expression of mouse *l*12S-LOX, representing the analog of the human and rabbit 15S-LOX (1), could not be detected in all tissues tested. A constitutive expression of *p*12S-LOX was previously demonstrated both in mouse and human epidermis (9,10). One might argue that the rather weak expression of *p*12S-LOX in all other tissues tested is attributable to platelet contamination. However, *e*12S-LOX, which also is strongly expressed in platelets, was not detected. Although not expressed in normal back skin epidermis (15,21) significant amounts of 8S-LOX mRNA were found in footsole epidermis and forestomach of NMRI mice. Lower amounts were also observed in lung and brain, confirming previously published data obtained using another mouse strain (14). Unique among all LOX is the strong inducibility of 8S-LOX upon TPA treatment of back skin, which leads to skin inflammation and a regenerative epidermal hyperproliferation (14,15,21,22). This response as well as the level of constitutive expression, has been shown to be strongly mouse strain-dependent (14). In general, 8S-LOX expression appears to be restricted to epithelial sites that are exposed either to permanent mechanical stress such as pressure (footsole) or stretching (forestomach) or to chemical irritation. *e*12S-LOX mRNA (11–13) showed the most selective expression in that it was found only in back skin and footsole epidermis as well as, unlike all other epidermis-type LOX, in platelets. A preferential expression in stratifying epithelia was also observed for 12R-LOX and *e*-LOX-3, which exhibited only weak signals in all other tissues. The strong constitutive mRNA expression of these LOX species suggests housekeeping functions in stratifying epithelia. Furthermore, the discrete expression on day 16.5 of fetal life indicates a critical function of 12R-LOX during embryonic development of skin (23).

5S-LOX mRNA was clearly detectable in back skin and footsole epidermis. Since a concomitant expression of the *l*12S-LOX was not detected, occurrence of 5S-LOX may not be attributed to contamination of the tissue with inflammatory cells. Furthermore, we were able to identify 5S-LOX mRNA in mouse skin-derived keratinocyte lines (data not shown), indicating that skin keratinocytes are a cellular source of this mRNA species. Accordingly, it was previously shown that human epidermis expressed 5S-LOX mRNA in both keratinocytes and Langerhans cells resident in epidermis (24,25).

The mRNA expression of LOX isozymes exhibited a complex differentiation-dependent pattern in mouse epidermis.

*e*12S-LOX was detected both in proliferating basal keratinocytes and—albeit less intensively—in terminally differentiating keratinocytes. Our observations differ from that of Funk *et al.* (11), which showed a strong expression of *e*12S-LOX restricted to newly differentiating keratinocytes by using *in situ* hybridization. Since they used C57BL/6x129 Sv mice, this difference may be explained by a strain-specific expression pattern.

For all other enzymes a characteristic compartmentalization was observed, indicating that mRNA for 12R-LOX and *e*-LOX-3 were predominantly to exclusively expressed in suprabasal keratinocytes of neonatal and adult mouse epidermis, i.e., these genes are expressed late in terminal differentiation. mRNA of *p*12S-LOX was predominantly found in spinous and granular keratinocytes. In contrast, the human enzyme has been identified in the basal cell compartment of epidermis by using immunohistochemistry (26).

Provided that the distinct expression pattern of mRNA for epidermal LOX reflects the distribution at the level of proteins and activity, it may be concluded that the constitutively expressed isozymes exhibit distinct functions for the structural and functional integrity of stratifying epithelia. Thus, the exclusive expression of 12R-LOX and *e*-LOX-3 in late granular and squamous keratinocytes points to a critical function of these isozymes in advanced stages of terminal differentiation such as the establishment of the epidermal lipid barrier. It has indeed been shown that suppression of LOX activity in skin leads to a disturbance of lipid barrier function (27). A recent report on changes of barrier function in *p*12S-LOX gene-knock-out mice is in line with this observation (28).

The strong expression of the *e*12S-LOX in basal keratinocytes indicates an association of this isozyme with cell proliferation. Accordingly, induction of cell proliferation in mouse epidermis was found to be accompanied by an induction *e*12S-LOX. In human skin a similar function may be attributed to the *p*12S-LOX, in that chronically proliferating psoriatic skin was shown to overexpress the human isozyme in the germinative compartment of epidermis (26). Interestingly, the human ortholog of the mouse *e*12S-LOX gene has been shown to be a functionally inactive pseudogene (29). As detailed above, the expression of 8S-LOX also seems to correlate with a distinct functional state of skin caused by chemical or mechanical stress. The delineation of the functional specificity of the epidermis-type LOX will require additional experimental efforts including the generation of transgenic mouse lines with a targeted expression or knock-out of the individual genes.

Most of these LOX isozymes expressed in stratifying epithelia are structurally related, as shown by sequence alignment. 12R-LOX, 8S-LOX, 15S-LOX-2, and *e*-LOX-3 share a higher overall amino acid similarity between each other than to all other mammalian LOX and thus can be grouped together into a novel subfamily within the LOX multigene family. Nevertheless, these enzymes exhibit a heterogeneous regio- and stereospecificity that is not easily explained on the basis of the available structural data. *p*- and *e*12S-LOX, which were found to be strongly expressed in epidermis and platelets, can be assigned with a distinct subgroup containing 12S- and 15S-LOX.

In summary, our findings demonstrate that among all tissues tested stratifying epithelia express the most diverse spectrum of LOX. In epidermis, the expression of individual LOX can be localized to different compartments, indicating that their expression and activity may be involved in processes of terminal differentiation. Our results may initiate further investigations into the functions of LOX in stratifying epithelia. Further efforts will critically depend on appropriate models as well as on further characterization of the enzymatic properties.

ABSTRACT: Guava fruit was identified as a particularly rich source of 13-hydroperoxide lyase activity. The enzyme proved stable to chromatographic procedures and was purified to homogeneity. Based on gel filtration and gel electrophoresis, the native enzyme appears to be a homotetramer with subunits of 55 kD. Starting with primers based on the peptide sequence, the enzyme was cloned by polymerase chain reaction with 3′ and 5′ rapid amplification of cDNA ends. The sequence shows approximately 60–70% identity to known 13-hydroperoxide lyases and is classified in cytochrome P450 74B subfamily as CYP74B5. The cDNA was expressed in *Escherichia coli* (BL21 cells), with optimal enzyme activity obtained in the absence of isopropyl-β-D-thiogalactopyranoside and δ-aminolevulinic acid. The expressed enzyme metabolized 13(*S*)-hydroperoxylinolenic acid over 10-fold faster than 13(*S*)-hydroperoxylinoleic acid and the 9-hydroperoxides of linoleic and linolenic acids. 13(*S*)-Hydroperoxylinolenic acid was converted to 12-oxododec-9(*Z*)-enoic acid and 3(*Z*)-hexenal, as identified by gas chromatography–mass spectrometry. The turnover number with this substrate, with enzyme concentration estimated from the Soret absorbance, was ≈2000/s, comparable to values reported for the related allene oxide synthases. Distinctive features of the guava 13-hydroperoxide lyase and related cytochrome P450 are discussed.

Abbreviations: δ-ALA, δ-Aminolevulinic acid; AOS, allene oxide synthase; GC–MS, gas chromatography–mass spectrometry; GPC, gel permeation chromatography; HIC, hydrophobic interaction chromatography; HPL, hydroperoxide lyase; HPLC, high-pressure liquid chromatography; IFC, isoelectric focusing chromatography; IPTG, isopropyl-β-D-thiogalactopyranoside; LOX, lipoxygenase; NTA, nitrilotriacetic acid; PAGE, polyacrylamide gel electrophoresis; PCR, polymerase chain reaction; RACE, rapid amplification of cDNA ends; RP–HPLC, reversed-phase–high pressure liquid chromatography; SDS, sodium dodecyl sulfate; TFA, trifluoroacetic acid; UV, ultraviolet.

The metabolism of fatty acid hydroperoxides [lipoxygenase (LOX) products] involves conversion to epoxides, aldehydes, alcohols, and other derivatives, and these reactions are often catalyzed by cytochrome P450 enzymes. In green plant tissue, the fatty acid hydroperoxide lyase (HPL), an enzyme in the LOX pathway, catalyzes the cleavage of 13- and 9-hydroperoxides of linoleic and linolenic acid into volatile C_6- or C_9-aldehydes and C_{12}- or C_9-oxoacids, respectively (1,2). The C_6 and C_9 volatile compounds have a commercial value in the production of "natural" flavor in the food industry, and are potentially important in plant defense against pathogens (3) and pests (4).

The green notes [hexanal, hexan-1-ol, 2(*E*)-hexenal, 3(*Z*)-hexenal, 2(*E*)-hexen-1-ol, and 3(*Z*)-hexen-1-ol (also known as pipol)] are used widely in flavors (particularly fruit) to impart a fresh green character. The synthesis of these compounds starts from free polyunsaturated fatty acids such as linoleic [9(*Z*),12(*Z*)-octadecadienoic] and linolenic acids [9(*Z*),12(*Z*),15(*Z*)-octadecatrienoic]. In nature, these acids are released from cell membranes by lipolytic enzymes after cell damage. Fatty acid 13-hydroperoxides are formed by the action of a specific lipoxygenase (13-LOX), and these are subsequently cleaved by a 13-hydroperoxide lyase (13-HPL) into a C_6-aldehyde and a C_{12}-ω-oxoacid moiety. The aldehydes can subsequently undergo thermal isomerization and/or be reduced by dehydrogenase enzymes to give the other C_6 products mentioned above (2,5).

13-HPL was demonstrated for the first time in banana fruits (6) and subsequently characterized in a number of different plant materials (7–10). The enzyme has been purified to apparent homogeneity from tea leaves (11) and more recently green bell pepper fruits (12) and sunflower (13).

Cloning of the pepper 13-HPL cDNA confirmed that the enzyme is a member of the cytochrome P450 family of hemoproteins (14). The P450 family is designated as CYP74B. Subsequently, the 13-HPL of *Arabidopsis* was cloned from published expressed sequence tag sequences and identified as a related cytochrome P450 (15).

We began the present work with a survey of HPL activities in various commercial fruits and vegetables, and on this basis selected guava fruit as the starting material for further characterization. The 13-HPL activity in guava is substantially higher than in several other well-characterized sources such as bean and pepper. Guava is available on an almost year-round basis, making it an attractive source for the commercial production of fatty acid aldehydes. In the present paper, we describe purification of the 13-HPL from guava fruit, molecular cloning of the cDNA, and expression of the active protein in *Escherichia coli*.

EXPERIMENTAL PROCEDURES

Materials. For protein purification, fruits of *Psidium guajava* from Thailand (bought at a local market in Zürich) were frozen and stored at −20°C. For the molecular cloning, immature guava (≈3 cm in diameter) were collected in Brazil, frozen on dry ice on the same day, and subsequently stored at −80°C.

Measurement of 13-HPL activity in fruits and vegetables. The lyase reactions were performed in a four-necked glass vessel equipped with a mechanical stirrer, a dropping funnel topped with a nitrogen bubbler, a thermometer, and a pH electrode. Guava fruit homogenate (20 g) prepared in a Waring blender was stirred vigorously under nitrogen at the selected temperature and pH. An aqueous solution of hydroperoxyoctadecadienoic acid or hydroperoxyoctadecatrienoic acid, 20 g, containing 35 g/kg hydroperoxide as determined by iodometric titration, was then added. This solution of hydroperoxides consisted of either saponified sunflower oil (serving predominantly as a source of linoleic acid) or saponified linseed oil (linolenic acid) that had been treated with soybean flour (LOX) to form the corresponding 13-hydroperoxides. The formation of hexanal or 3(*Z*)- and 2(*E*)-hexenal was monitored by gas chromatography (GC) every 5 min for the first 15 min, and subsequently every 30 min. The C_6-aldehydes were quantified by direct injection of the filtered crude reaction samples onto a 3-m column of Carbowax 10% on Chromosorb W HP 80/100 mesh (Supelco, Bellefonte, PA) operated isothermally at 100°C in a PerkinElmer 2900 gas chromatograph equipped with a flame-ionization detector. The concentrations of hexanal or 3(*Z*) and 2(*E*)-hexenal were determined by comparison with an external standard solution of 500 mg/L hexanal or 2(*E*)-hexenal in 0.5% EtOH/99.5% water solution.

Purification of the 13-HPL from guava fruit. (i) Preparation of the crude extract. Guava fruits were peeled and the pericarp tissues chopped into small pieces. Two volumes of extraction buffer (50 mM sodium phosphate, 0.1% Triton X-100R, 5 mM sodium ascorbate, pH 7.0) were added to 500 g of chopped pericarp and homogenized for 2 min in a Sorvall mixer at 4°C. All of the following steps were carried out at room temperature.

(ii) Enzyme solubilization. The crude extract containing the 13-HPL activity was solubilized with 1% (vol/vol) of Triton X-100R with stirring for 30 min. After centrifugation at 16,000 × *g* for 15 min, 0.02% Pectinex Ultra SP-L solution from Novo Nordisk Ferment (Bagsvaerd, Denmark) was added to degrade pectin.

(iii) Ammonium sulfate precipitation. Solid $(NH_4)_2SO_4$ was added in small portions to the crude extract under stirring until 30% saturation was achieved. After stirring for 30 min, the mixture was centrifuged at 20,000 × *g* for 15 min and the resulting pellet discarded. The supernatant was brought to 60% saturation with more solid $(NH_4)_2SO_4$ added in portions. After stirring for 30 min, the pellet was collected by centrifugation as above.

(iv) Gel permeation chromatography (GPC). The $(NH_4)_2SO_4$ pellet was dissolved in 45 mL of extraction buffer and chromatographed on a Superdex 200 HL 26/60 column (Pharmacia, Uppsala, Sweden) with 50 mM sodium phosphate, 0.1% Triton X-100R pH 7.0 as running buffer at a flow rate of 2 mL/min. After GPC, samples were run on anion exchange chromatography or hydrophobic interaction chromatography (HIC) columns.

(v) Anion exchange chromatography. The sample from GPC was applied to a Q-Sepharose column (Pharmacia) with a loading buffer of 20 mM Tris-HCl pH 8.5 containing 0.1% Triton X-100R. 13-HPL activity was eluted with a gradient of NaCl in eluting buffer (0–100% 1 M NaCl in 133 min at a flow rate of 3 mL/min).

(vi) HIC. The fractions containing the 13-HPL activity from the GPC were brought to 30% $(NH_4)_2SO_4$ saturation before loading onto a Phenyl-Sepharose HR 26/10 column (Pharmacia) with loading buffer [50 mM sodium phosphate, 1 M $(NH_4)_2SO_4$, pH 7.0]. The proteins were eluted with a decreasing salt gradient (100–0% 1 M ammonium sulfate over 70 min) in 50 mM sodium phosphate pH 7.0 containing 1% Triton X-100R at a flow rate of 8 mL/min. Fractions containing the 13-HPL activity were concentrated by dialysis against polyethylene glycol 20,000 and desalted on a PD-10 column (Pharmacia) against the loading buffer for hydroxylapatite chromatography (10 mM sodium phosphate, 0.1% Triton X-100R, pH 6.8).

(vii) Hydroxylapatite chromatography. After HIC, the sample was applied to an Econo-Pac HTP column (BioRad, Cambridge, MA) in 10 mM sodium phosphate, 0.1% Triton X-100R, pH 6.8. The proteins were eluted with a gradient to 200 mM sodium phosphate buffer pH 6.8, containing 0.1% Triton X-100R over 30 min using a flow rate of 1 mL/min. Fractions with 13-HPL activity were concentrated by dialysis against polyethylene glycol 20,000 and desalted against the isoelectric focusing chromatography (IFC) loading buffer (75 mM Tris-acetic acid, pH 9.3).

(viii) IFC. The prepared sample from hydroxylapatite chromatography was applied to a Mono P HR 5/20 column (Phar-

macia). The proteins were eluted with 10% Polybuffer 96 (Pharmacia)/acetic acid, pH 6.0, at a flow rate of 0.5 mL/min.

Tryptic digest and amino acid sequence determination. Fractions of purified 13-HPL were concentrated and separated on a 6.5% sodium dodecyl sulfate-polyacrylamide gel (SDS-PAGE). The proteins were electrotransferred (0.8 mA cm^{-2} for 75 min) to an Immobilon CD membrane (Millipore, Bedford, MA) using 10 mM 3-[cyclohexylamino]-1-propanesulfonic acid containing 10% (vol/vol) methanol pH 11.0 as transfer buffer. Proteins were detected by staining using Quick-Stain (Zoion Research Inc., Newton, MA).

Direct sequencing of the purified 13-HPL by Edman degradation was not possible as the N-terminus was blocked. The 13-HPL purified protein was therefore cut out separately and incubated in 10 µL of 0.1 M Tris pH 8.2 containing 1 M NaCl, 10% (vol/vol) acetonitrile, 2 mM $CaCl_2$, and 0.1 µg trypsin at 37°C for 15 h. After acidification with 1 µL of 10% trifluoroacetic acid (TFA), the solution was injected directly into the high-pressure liquid chromatography (HPLC) system equipped with a Brownlee Aquapore RP-300 C8 column (PE Applied Biosystems, Foster City, CA). Chromatography solvents were 0.05% TFA and 2% acetonitrile in water (solvent A) and 0.045% TFA and 80% acetonitrile in water (solvent B). The gradient and flow rates used were as follows: 0–5 min, 80 µL/min at 2% solvent B; 5–65 min 50 µL/min at 2–65% solvent B; and 65–70 min 50 µL/min at 65–100% B. Absorbance at 214 nm was measured in a 200 nL flow cell with a path length of 2 mm. Peptides resolved by HPLC were collected manually for sequence analysis and applied to precycled polyprene-treated glass fiber discs. Automated sequencing used a model 477A pulsed-liquid phase sequencer (Applied Biosystems) equipped with a model 120A analyzer.

RNA isolation. Total RNA was extracted using the method of Wan and Wilkins (16). Immature guava fruit (1 g) was crushed to a fine powder in liquid nitrogen in a precooled pestle and mortar. The powder was added to 5 mL at 80°C of lysis buffer [200 mM borax, 30 mM EGTA, 10 mM dithiothreitol, 1% wt/vol SDS, 1% wt/vol sodium deoxycholate, 2% PVP 40,000 (Sigma Chemical Co., St. Louis, MO), 0.5% vol/vol NP-40 (Sigma)] and the mixture homogenized. Proteinase K (2.5 mg, Sigma) was added, and this mixture was incubated at 42°C for 90 min with shaking sufficient for mixing without excessive foaming. One milliliter of 1 M KCl was added. After mixing, the tubes were incubated on ice for 1 h and then centrifuged at 10,000 × *g* for 10 min. Three milliliters of 4 M LiCl was added, and the tubes were incubated at 4°C overnight. After 10 min of centrifugation at 10,000 × *g*, the supernatant was discarded, and the pellet washed with 2 M LiCl and centrifuged as before. The supernatant was discarded and the pellet resuspended in Tris/EDTA buffer (10 mM Tris, pH 8, 1 mM EDTA) or in H_2O.

For the purification of mRNA from total RNA, the mRNA purification kit from Pharmacia was used. This kit is based on the use of spun columns for the affinity purification of polyadenylated RNA on oligo(dT)-cellulose. The RNA was quantified by ultraviolet (UV) spectrophotometry. The yield was approximately 1 mg of total RNA and 20 µg of mRNA.

Cloning. (i) cDNA synthesis. Total RNA (20 µg) or 1 µg of mRNA was used in 50-µL reactions for the first strand cDNA synthesis using an oligo(dT)-adaptor primer (17). Aliquots of 1 µL cDNA were used directly in polymerase chain reactions (PCR).

(ii) PCR cloning. The PCR were primed with 1 µL cDNA (from a 50-µL cDNA synthesis using 20 µg total RNA), and using 10 mM Tris, pH 8.3, 50 mM KCl, 3 mM $MgCl_2$ with 0.2 mM each of dNTPs and 0.25 µL (1.25 units) of AmpliTaq DNA polymerase (PerkinElmer) in a PerkinElmer 480 thermocycler. After the addition of the cDNA at 80°C (hot start), the PCR reactions conditions were: 94°C, 2 min for 1 cycle; 50–55°C for 1 min, 72°C for 1 min, and 94°C for 1 min for 30 cycles; 72°C for 10 min for 1 cycle; and the block temperature was held at 4°C.

3′-Rapid amplification of cDNA ends (RACE) and 5′-RACE: The 3′-sequence was obtained using gene-specific upstream primers: $^{5'}$CCT CAA CAC GCT CAG GTG AAG$^{3'}$, $^{5'}$CTC CAA AAG TTC CTC TTC AAC TTC$^{3'}$, or $^{5'}$CCA GCT CCT CCC CAC CAT CAA$^{3'}$ against a downstream primer based on the adaptor-linked oligo(dT) primer used for cDNA synthesis (17). The 5′RACE was accomplished using a kit from GibcoBRL (Grand Island, NY), according to the manufacturer's instructions. The gene-specific downstream primers were: $^{5'}$GTC AGC GCC GAA GAT GGA CTT$^{3'}$ or $^{5'}$GTG TTG AGG CTC GGA AGT GTC$^{3'}$.

Full-length clones obtained by PCR. Four gene-specific primers were synthesized corresponding to the putative start sites of the coding sequence (at the four different methionines) and one primer corresponding to the stop codon. *Bam*HI and *Eco*RI restrictions sites were incorporated at the 5′ and 3′ ends, respectively, to facilitate subcloning. The four upstream primers were: $^{5'}$TAG GAT CCG ATC ATG GCG AGG GTC GTG$^{3'}$, $^{5'}$GCG GAT CCG GCC ATG AGC AAC ATG TCG$^{3'}$, $^{5'}$GCG GAT CCG GCC ATG TCG CCG GCC AT$^{3'}$, and $^{5'}$GCG GAT CCG GCC ATG TCG TCC ACC TAC$^{3'}$; and the downstream primer was: $^{5'}$GCG AAT TCT CAG TTG GCC TTT TCA ACG GCT GT$^{3'}$. These primers were purified by HPLC as the dimethoxytrityl derivative (17). After deprotection, they were used in PCR reactions (at 20 pmol/50 µL final concentration) with a proof-reading mixture of *Taq/Pwo* DNA polymerase (Expand High Fidelity, Boehringer-Mannheim, Indianapolis, IN) according to the manufacturer's instructions. The reactions conditions were 94°C, 2 min for 1 cycle; 60°C for 1 min, 72°C for 1 min, and 94°C for 1 min for 30 cycles; 72°C for 10 min for 1 cycle; and the block temperature was held at 4°C.

DNA sequencing. cDNA were sequenced using the Thermo Sequenase radiolabeled terminator cycle sequencing kit (Amersham Life Science, Inc., Arlington Heights, IL).

Bacterial expression. (i) Preparation of constructs. The four cDNAs encoding the 13-HPL-Met 1, 6, 9, and 13 in pCR2.1 were cut with *Bam*HI and *Eco*RI and subcloned into the expression vector plasmid pET30b (Novagen) digested

also with *Bam*HI and *Eco*RI. The 13-HPL-Met 1, 6, 9, and 13 constructs were transformed into *E. coli* strain XLI-Blue. The plasmid DNA was then used for transformation of *E. coli* strain BL21(DE3) to express the 13-HPL.

(ii) Preparation of bacterial cultures. The four different constructs described above were expressed in BL21(DE3) (Novagen, Madison, WI) cells using a modified expression methodology (18). A typical preparation of 50-mL culture was carried out as follows: A single bacterial colony from a complex agar plate containing 30 μg/mL of kanamycin was grown in 1 mL of LB medium containing 50 μg/mL of kanamycin at 37°C and 250 rpm for 3 h. An aliquot (200 μL) of this culture was used to inoculate 10 mL of TB medium containing 50 μg/mL of kanamycin and the culture was again grown at 37°C. After 3 h, this culture was diluted with 40 mL of TB containing 30 μg/mL of kanamycin and grown at 28°C, 250 rpm for 24 h. The bacterial cells were centrifuged at 4°C for 15 min at 5,000 rpm (3,500 × *g*) in a Jouan CR422 centrifuge, washed by resuspension in 10 mL of Tris-HCl buffer 50 mM pH 7.9, and centrifuged as before. The resulting pellet of cells was resuspended in 10 mL of Tris-acetate buffer 100 mM pH 7.6 containing 500 mM of sucrose, 0.5 mM of EDTA, and 1 mg/mL of lysozyme. After 30 min on ice, the cells were centrifuged as before to obtain a pellet of spheroplasts which were resuspended in 10 mL of potassium phosphate buffer (100 mM, pH 7.6). After at least 10 min at –80°C, a protease inhibitor (phenylmethylsulfonyl fluoride, 1 mM) was added, the cells were allowed to thaw for 10 min, and then they were sonicated twice for 30 s using a Virsonic 100 at a setting of 5. The resulting membranes were spun down at 100,000 × *g* for 90 min at 4°C. The 13-HPL activity was recovered in the 100,000 × *g* pellet. After solubilization using 1% Emulphogen BC-700™ (polyoxyethylene 10 tridecyl ether, Sigma) at 4°C overnight and centrifugation as before, the 13-HPL activity was recovered in the supernatant.

Purification of His-tagged proteins. The histidine-tagged 13-HPL was purified following the protocol described by Imai *et al*. (19). After solubilization, the 100,000 × *g* supernatant was loaded on a Ni-nitrilotriacetic acid (NTA) column (0.5 mL bed volume, Qiagen, Valencia, CA) equilibrated with potassium phosphate buffer 50 mM pH 7.6 containing 100 mM NaCl and 0.1% Emulphogene BC-720 detergent (buffer A) at 0.5 mL/min. The column was washed with the buffer A containing 50 mM glycine. The His-13-HPL was then eluted with the buffer A containing 40 mM L-histidine. Fractions of 1 mL were collected and assayed for the 13-HPL activity. Fractions containing the 13-HPL activity were dialyzed overnight against potassium phosphate 100 mM, pH 7.6 using a microdialyzer (Pierce, Rockford, IL).

Enzyme assays. (i) UV assay. 13-Hydroperoxides from linolenic and linoleic acids were produced with soybean lipoxygenase L1 (type V, Sigma) according to the methods of Vick (20) or Brash and Song (21). 13-HPL activity was measured by following the decrease in absorbance at 234 nm, representing disruption of the conjugated diene system in the fatty acid hydroperoxide substrate. The assay contained 5–10 μg of fatty acid 13-hydroperoxide in 0.5 mL of 100 mM potassium phosphate buffer at pH 7.

For the HPLC assay, 50 or 100 μM of a mixture of unlabeled and [1-^{14}C]-13(*S*)-hydroperoxylinole(n)ic acid (200,000 cpm) was used in 100 mM potassium phosphate buffer at pH 7. The reactions were stopped with 100 μL potassium dihydrogen phosphate (1 M) and the products extracted twice with 0.5 mL ethyl acetate. The combined organic phases were washed with water and dried under a stream of nitrogen. The extracts were dissolved in 50 μL methanol and stored at –20°C under argon prior to analysis. The compounds were analyzed using a Beckman Ultrasphere ODS column (5 μm, 25 × 0.46 cm) using MeOH/H_2O/glacial acetic acid (77.5:22.5:0.01, by vol) as solvent at a flow rate of 1.1 mL/min. Products were detected online using a Hewlett-Packard 1040A diode array detector and a Packard Flo-One radioactive monitor. The main ^{14}C-labeled enzymatic product from [1-^{14}C]13(*S*)-hydroperoxylinolenic acid on reversed-phase (RP)-HPLC (12-oxo-dodecenoic acid) was resolved into the main 9*Z* isomer and the 10*E* isomer formed during sample workup by normal-phase HPLC on a Beckman 5 μm silica column (25 × 0.46 cm) with a solvent of hexane/isopropanol/glacial acetic acid (100:1:0.01, by vol). The 9*Z* isomer chromatographed as a broad symmetrical peak (retention volume 17–22 mL), and the 10*E* isomer as a typically shaped peak at 24 mL. The two compounds were converted to the methoxime derivative (which eliminated further isomerization of the 9*Z* double bond) and methyl ester derivative and analyzed by GC–mass spectrometry (MS).

GC–MS. GC–MS analyses were carried out in the electron impact mode (70 eV) using a Finnigan Incos 50 mass spectrometer (for 3*Z*-hexenal analysis) or a Hewlett-Packard 5889A mass spectrometer (for 12-oxo-dodecenoate analysis), each coupled to a Hewlett-Packard 5890 gas chromatograph equipped with a SPB-1 fused-silica capillary column (15 or 30 m × 0.25 mm internal diameter). Samples were injected at 60°C, and the temperature was subsequently programmed to 300°C at 10 or 20°/min.

RESULTS

13-HPL in fruits and vegetables. The fruits of a number of commonly available plants were screened for the ability to convert 13-hydroperoxylinoleic acid (Table 1) and 13-hydroperoxylinolenic acid (Table 1) to the corresponding C_6 HPL products. On the basis of these results, initially bean was selected as a readily available and relatively inexpensive material for the purification of the enzyme. However, in pilot experiments the bean lyase proved to be unstable to freeze–thawing, and this compromised our ability to purify the enzyme. Accordingly, guava was chosen as an even more promising candidate on the basis of activity. It was soon established that this enzyme survived freezing and that its robust properties permitted its purification through multiple chromatographic steps.

Purification of the guava 13-HPL. Preliminary work confirmed literature reports that 13-HPL is a membrane-bound

[a]g/kg reaction.
[b]With guava, optimized yields using higher substrate concentrations (80 g/kg hydroperoxide) were 5.07 g/kg hexanal and 1.43 g/kg hexenals. Abbreviations: HPOD, hydroperoxyoctadecadienoic acid; HPOT, hydroperoxyoctadecatrienoic acid.

enzyme and that detergents are necessary to solubilize the enzyme (11). The guava tissue was homogenized with a sodium phosphate buffer pH 7.0 containing 5 mM sodium ascorbate to prevent oxidation and 0.1% Triton X-100R. When the concentration of Triton X-100R was increased to 1% (vol/vol) and the homogenate was stirred for 30 min, the yield of soluble and active 13-HPL was doubled (data not shown).

A typical purification of 13-HPL from guava fruit is shown in Table 2. The crude extract was concentrated by $(NH_4)_2SO_4$ precipitation followed by a subsequent GPC step on a Superdex 200 column (Pharmacia). The fractions containing 13-HPL activity were pooled and chromatographed on an HIC column. After concentration and desalting, the pooled active fractions were chromatographed on a hydroxylapatite column. The eluted 13-HPL activity was again concentrated, desalted, and loaded onto an IFC column. Each purification step resulted in a considerable loss of 13-HPL activity, which was probably not due to proteolysis, and only 0.2% of the initial 13-HPL activity was recovered (Table 2). Analysis of the preparation by SDS-PAGE showed that the purified sample contained only one, apparently homogenous band with an apparent molecular weight of 48 kD. Because of the high losses of 13-HPL activity, an

[a]HPL, hydroperoxide lyase; GPC, gel permeation chromatography; HIC, hydrophobic interaction chromatography; IFC, isoelectric focusing chromatography.

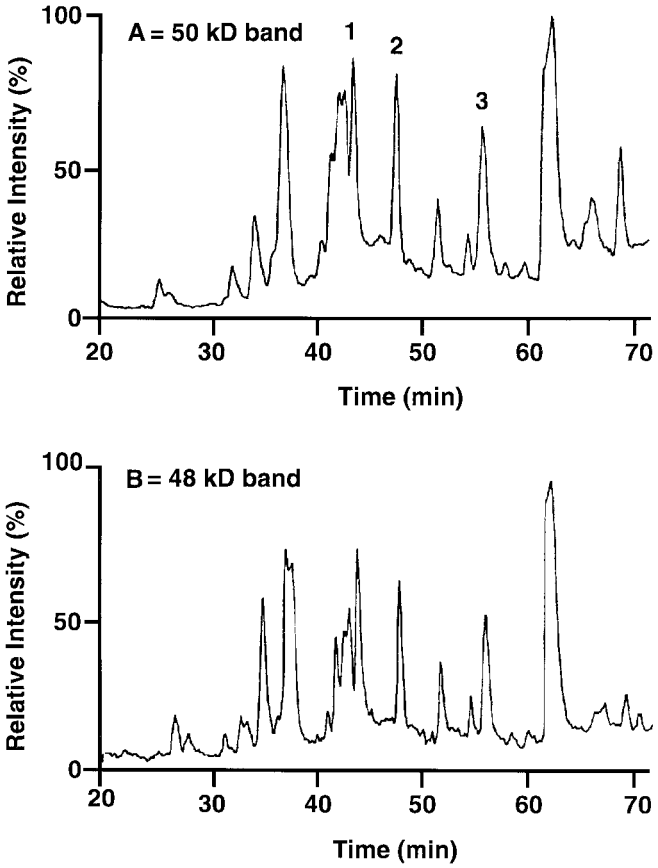

FIG. 1. High-pressure liquid chromatography (HPLC) analysis of purified guava 13-hydroperoxide lyase (13-HPL) digested with trypsin: comparison of the peptide maps of the 50 and 48 kD protein bands.

anion exchange chromatography step was used in place of HIC. In this case, analysis of the purified enzyme by SDS-PAGE showed two bands of 48 and 50 kD. The 13-HPL purified from guava fruit tissue had maximal activity around pH 6.0 and a pI of 6.8 determined by chromatofocusing.

The HPLC peptide maps of the trypsin cleavage products from the two protein bands are very similar (Fig. 1), indicating that there are only minor differences in amino acid composition and/or posttranslational modification. Three peptides of the 50 kD band were sequenced (Table 3).

A computer-aided search of the Swissprot and genEMBL databases found that five amino acids of peptide 3 (Phe Asn Phe Leu Ser, Table 3) are identical to amino acids 236 to 240 of flaxseed allene oxide synthase (AOS) (22). At this stage there was no obvious homology between the peptide sequences and the 13-HPL from green bell pepper fruit (14).

Cloning. Sense and antisense degenerate oligonucleotides (Table 4) deduced from the peptides sequences (Table 3) were synthesized. PCR reactions were performed using the different pairs of oligonucleotides with or without cDNA as template. One main product of 160 bp was subcloned and sequenced, and this was found to contain the three peptides, which were thus from the same peptide chain (see later). Moreover, a multiple alignment of this sequence with the AOS from flax (22), the AOS from guayule (23), the 13-HPL from green pepper (14), and the 13-HPL from *Arabidopsis* (15) showed the highest homology with the 13-HPL enzymes.

The remainder of the cDNA from guava fruit was cloned using 3′- and 5′-RACE (see Experimental Procedures section). cDNA corresponding to the open reading frame was prepared by PCR using a proof-reading mixture of *Taq/Pwo* as DNA polymerase. An amplification product was obtained, subcloned, and sequenced. The complete cDNA (1467 bp) and deduced amino acid sequence are shown in Figure 2. The open reading frame encodes a total of 489 amino acids corresponding to a protein with a molecular weight of 54,817 Daltons. The isoelectric point of the protein is estimated to be 7.29. Previously, the molecular weight of the native protein was estimated by SDS-PAGE as 50 kD, and we found a pI of 6.8 using chromatofocusing. The derived amino acid sequence has an identity of 65% with the pepper 13-HPL (14). The guava cDNA encodes four possible start sites within the first 13 amino acids (methionines 1, 6, 9, and 13) whereas the pepper gene has only two methionines, corresponding to guava-Met9 and guava-Met13.

Expression. Four different cDNA clones of the 13-HPL (13-HPL-Met1, -Met6, -Met9, -Met13) were inserted into the *E. coli* expression plasmids pET30b (see Experimental Procedures section) and transformed into *E. coli* strain BL21(DE3). The expression level was examined at different induction temperatures, with or without addition of isopropyl-β-D-thiogalactopyranoside (IPTG) and the heme precursor, δ-aminolevulinic acid (δ-ALA). The best activities were obtained at 28°C with both δ-ALA and IPTG omitted. Thus, in the system used here, with the pET30 plasmid, its T7 RNA

FIG. 2. Nucleotide and deduced amino acid sequence of the guava 13-HPL. The four N-terminal methionines are boxed. The location of three peptides of known amino acid sequence are shown in bold. The enzyme is classified as CYP74B5, and the GenBank accession number is AF239670. For abbreviation see Figure 1.

polymerase promoter, and with the cells grown in a rich medium (TB), addition of heme precursor or IPTG inducer did not help with expression of active lyase.

Proteins from the transformed and induced cells were analyzed by SDS-PAGE (Fig. 3). High levels of protein with the expected molecular weight were expressed under all culture conditions (Fig. 3; lanes 2, 3, and 4). These levels appear to account for about half of the cellular protein. We obtained

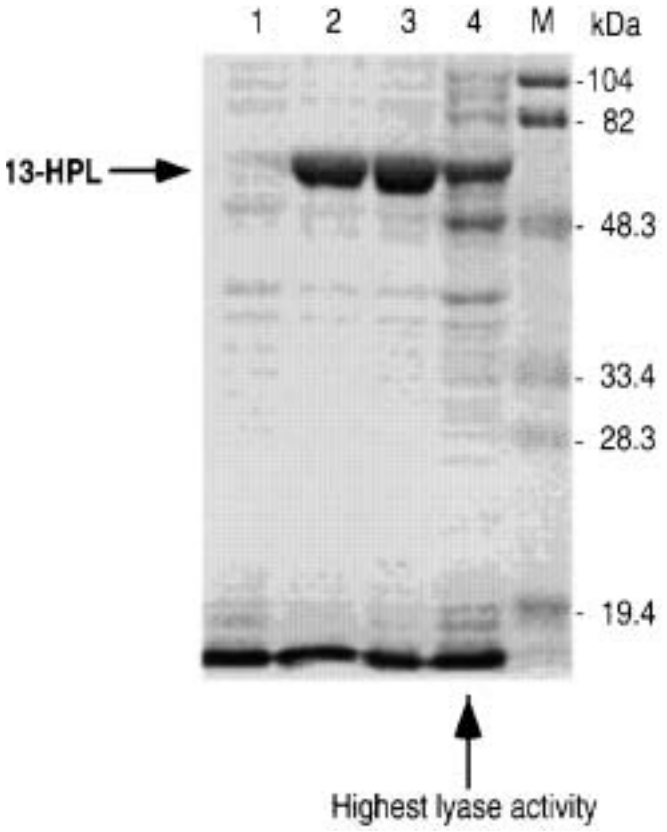

FIG. 3. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis analysis of guava 13-HPL expressed in *Escherichia coli* (BL21 cells). Lane 1: cells were transformed with pET30 vector alone. In the other lanes, cells were transformed with pET30:13-HPL (containing all four N-terminal methionines) cultured with δ-ALA and IPTG (lane 2), with IPTG only (lane 3), and without δ-ALA and IPTG (lane 4). Molecular weight markers (M) are in the right-hand lane. δ-ALA, δ-aminolevulinic acid; IPTG, isopropyl-β-D-thiogalactopyranoside; for other abbreviation, see Figure 1.

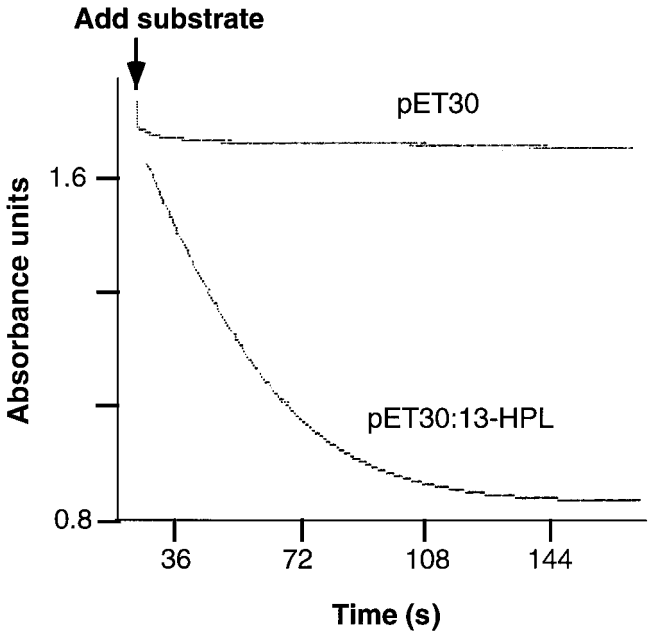

FIG. 4. Spectrophotometric assay of the guava 13-HPL expressed in *E. coli*. Absorbance changes were monitored at 235 nm in potassium phosphate buffer, pH 7.6. Comparison of activity of 1 µL aliquots of bacterial lysates transformed with pET30 vector alone and with pET30:13-HPL. For abbreviations, see Figures 1 and 3.

lower levels of protein but the highest lyase activity when the cells were grown in the absence of δ-ALA and IPTG (Fig. 3, lane 4). By using Emulphogen or cholate detergents, most of the expressed 13-HPL protein failed to solubilize, and the insoluble material was catalytically inactive. This likely reflects the fact that there is a very high basal induction in this system, and the cells are barely capable of handling the expressed protein. Examination of the cells under the microscope revealed many inclusion bodies, with the highest number in cells grown with IPTG. This supports the concept that the bacteria cannot handle the level of expressed protein and the main part of the translated lyase is deposited in inclusion bodies. Using IPTG as a further stimulus results in even lower recovery of correctly folded protein with catalytic activity.

Lyase activity. The four different guava 13-HPL constructs (-Met1, -Met6, -Met9, and -Met13) did not differ markedly in their catalytic activities in the UV assay. Figure 4 illustrates an example with pET30Met1, and also shows the lack of significant activity in the negative control in comparison to the reaction with 13-hydroperoxylinolenic acid. Approximately 10-fold lower rates of reaction were obtained with 13(*S*)-hydroperoxylinoleic acid, 9(*S*)-hydroperoxylinoleic acid, and 15(*S*)-hydroperoxyeicosatetraenoic acid.

For HPLC analysis of the nonvolatile products, an aliquot of the sonicated protein preparation containing the 13-HPL was incubated with [1-^{14}C]13(*S*)-hydroperoxylinolenic acid for 1 min as described in the Experimental Procedures section. Essentially all the substrate was metabolized in the 1 min of incubation, and the 1-^{14}C label was recovered in a major polar product (Fig. 5) with a retention time expected of the

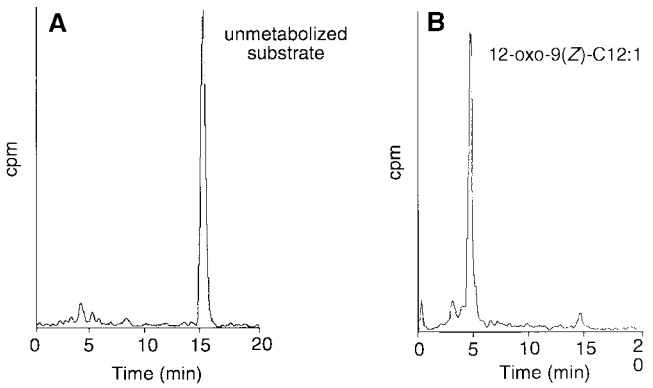

FIG. 5. HPLC analysis of catalytic activity of guava 13-HPL expressed in *E. coli*. Extracts were incubated with [1-^{14}C]13(*S*)-hydroperoxylinolenic acid, extracted, and aliquots injected on a Beckman Ultrasphere ODS column (25 × 0.46 cm) and eluted with a solvent system of methanol/water/glacial acetic acid (77.5:22.5:0.01, by vol) at a flow rate of 1.1 mL/min. (A) Incubation of extracts of BL21 cells expressing vector pET30 only. (B) Incubation of extracts of BL21 cells expressing pET30:13-HPL. Radioactivity was detected on-line using a Packard Flo-One scintillation detector. For abbreviations, see Figures 1 and 3.

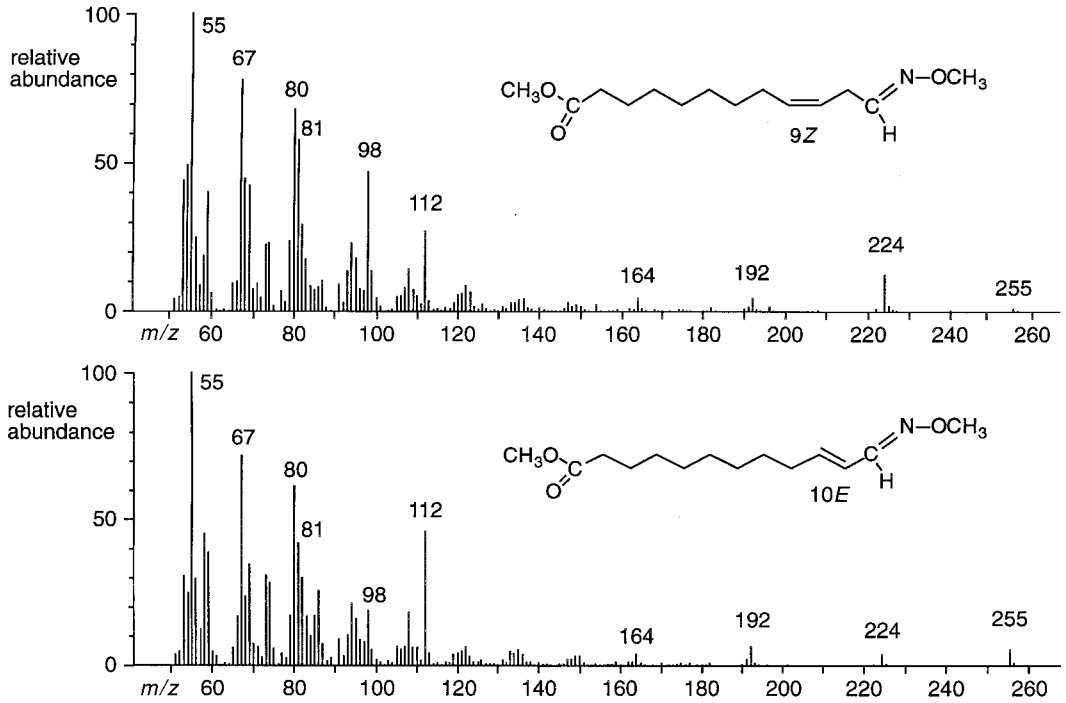

FIG. 6. Electron impact mass spectra of (9*Z*)-12-oxo-dodecenoic acid formed by reaction of the guava lyase with 13(*S*)-hydroperoxylinolenic acid and its 10*E* isomer. The two isomers were resolved by normal-phase HPLC and analyzed as the methyl ester methoxime derivative (top spectrum, 9*Z*; bottom, 10*E*). For abbreviation, see Figure 1.

13-HPL-derived aldehyde, 12-oxo-9(*Z*)-dodecenoic acid. This product, which partly isomerized to the 10*E* isomer during sample workup, was resolved into the 9*Z* and 10*E* isomers by normal-phase HPLC (as described in the Experimental Procedures section). The two isomers were converted to the methoxime methyl ester derivatives and identified by GC–MS analysis (Fig. 6). The methyl (9*Z*)-12-oxo-dodecenoate methoxime eluted from the GC as a single peak at the retention time approximately of a saturated C_{16} fatty acid methyl ester; the 10*E* analog eluted 0.6 min later as a double peak of *syn* and *anti* methoxime isomers. The 9*Z* isomer (assigned based on its featureless UV spectrum, recorded before and after methoxime formation) gave a mass spectrum that was particularly close in appearance to the first reported spectrum of methyl 12-oxo-dodecenoate methoxime (24). The similarity in the mass spectra was noticeable particularly in terms of the pattern of abundances of the higher mass ions [M^+ 255 (1% abundance), M – 31 at *m/z* 224 (14%), and *m/z* 192 (4%)], and the relative abundance of certain prominent lower mass ions such as *m/z* 98 (47%) and *m/z* 81 (54%). In retrospect, the original spectrum may have been predominantly the 9*Z* isomer. We assigned the 10*E* isomer as such on the basis of the characteristics of its UV spectrum: it displayed the expected enone chromophore with λ_{max} 225 nm in MeOH/H_2O (75:25, vol/vol) and extended conjugation after methoxime formation, producing a broad chromophore with λ_{max} 239 nm in MeOH. The mass spectrum of the 10*E* derivative contained the same ions as in the 9*Z*, but there were different patterns of ion abundances (Fig. 6). For example, M^+ (5% relative abundance) was slightly more prominent than *m/z* 224 (3%), whereas *m/z* 98 (20%) and *m/z* 81 (39%) were less prominent than in the 9*Z* isomer. This mass spectrum was a good match with another reported spectrum of the 10*E* isomer (25).

To detect the more volatile aldehyde product, we utilized direct GC–MS analysis of diethyl ether extracts of the reaction of 13-hydroperoxylinolenic acid with the expressed guava enzyme. The GC profile and mass spectrum identified the volatile product formed as 3(*Z*)-hexenal (Fig. 7).

DISCUSSION

An initial screening of the levels of 13-HPL in fruits and vegetables pointed to guava as a rich source of this activity. From the subsequent isolation of the protein we found that approximately a 70-fold purification was sufficient to give a homogeneous preparation of the enzyme. Seventyfold enrichment implies a level of about 1–2% of the protein in the original extract, consistent with guava as an abundant source of 13-HPL. The two bands isolated in the purification process are almost certainly an indication of partial proteolysis or deglycosylation of the higher molecular weight protein. The difference in molecular weight (2 kD) between the two forms could be explained if the heavier form is glycosylated by as few as the equivalent of 10 glucose residues. The purification of the 13-HPL from tea leaves (11) showed that the enzyme was separated with hydroxylapatite chromatography into two fractions, HPLI and HPLII with molecular weights of 53 and 55 kD. For the 13-HPL from green bell pepper fruits, Shibata *et al.* (12)

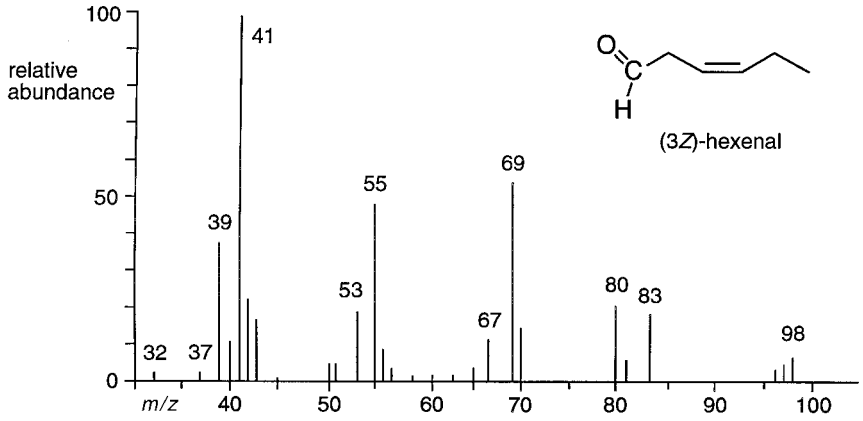

FIG. 7. Electron impact mass spectrum of the volatile C_6 product formed by reaction of the guava lyase with 13(*S*)-hydroperoxylinolenic acid. The spectrum matches a reference of (3*Z*)-hexenal (Chemical Abstract Service No. 006789-80-6) in the NIST (National Institute of Science and Technology) 75K database on a Hewlett-Packard 5989A mass spectrometer/DOS Chemstation software, entry number 1285 (1992).

showed also that 13-HPL could be resolved into two isoforms by hydroxylapatite chromatography; in this case, both isoforms had molecular masses of 55 kD (12). Similar to the lyases of sunflower (13), the apparent molecular weight of the guava 13-HPL as determined by gel filtration is in the order of 200,000 kD, implying a tetrameric structure for the native enzyme. This is in agreement with Olias *et al.* (10) who reported that 13-HPL from soybean seedlings had a native molecular mass of 240–260 kD and a subunit size of 62 kD. However, Shibata *et al.* (12) proposed that the 13-HPL from green bell pepper fruits is a trimer based on their measurements of the native molecular mass (170 kD) and subunit size (55 kD).

The 13-HPL of guava has a substrate specificity similar to several other reported 13-HPL enzymes. The preferred substrate is 13*S*-hydroperoxylinolenic acid. The corresponding linoleic acid 13*S*-hydroperoxide shows about one-tenth the rate of reaction, and the 9-hydroperoxides also are poor substrates. These results apparently contrast with the original data of lyase activity in guava fruit which indicated excellent recovery of the C_6-aldehydes of linoleic and linolenic acids (Table 1). However, a number of factors could account for this difference that relate more to differences in assay conditions. The activity values in fruit comprise recovered products whereas rates of reaction were measured with the expressed enzyme. As the hexenals derived from linolenate are considerably less stable than the saturated product of linoleate, this gives a bias favoring recovery of hexanal. Similarly, changes in enzyme activity due to the different substrate and product concentrations and the different reaction times (<1 min, vs. 1 h) in the two assays could further influence the results. It is also possible that other isoforms of hydroperoxide lyase might exist in guava. Of the two hydroperoxide lyases purified by Itoh and Vick (13) from sunflower hypocotyl, one resembled the guava and pepper enzymes and a second showed equal reactivity with the C18:2 analog, 13-hydroperoxylinoleic acid.

The guava cDNA sequence has about 60% amino acid identity to the 13-HPL of bell pepper and *Arabidopsis,* placing it in the same subfamily of cytochrome P450, CYP74B. The enzymes share about 35–40% identity with the plant AOS, which comprise the CYP74A subfamily. Within the majority of cytochrome P450 families there is a conserved sequence next to the cysteine that forms the proximal ligand to the heme (e.g., Ref. 26). In the CYP74 family, there are some unusual and distinctive sequences around this cysteine (Fig. 8). All reported 13-HPL and AOS enzymes have the sequence Asn-Lys-Gln (NKQ) immediately before the cysteine.

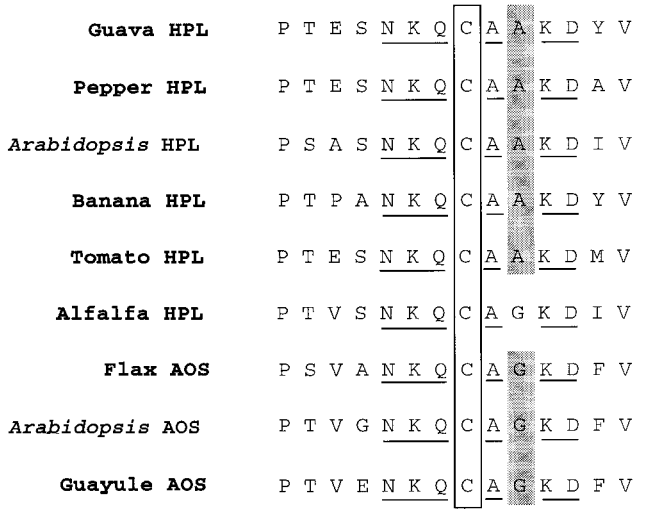

FIG. 8. Alignment of amino acid sequences around the proximal heme ligand. The cysteinyl heme ligand is boxed. The absolutely conserved sequence NKQCA is underlined. The shaded position is usually Ala in 13-HPL, whereas in AOS enzymes the residue is the more typical P450 consensus Gly. The GenBank accession numbers of the sequences, given in parentheses, are for guava HPL (AF239670), bell pepper HPL (U51674), *Arabidopsis* HPL (AF087932), banana HPL (A65873, the subject of U.S. patent 6,008,034, and patent EP0801133 assigned to Givaudan-Roure International S.A.), alfalfa HPL (AJ249247), flax AOS (U00428), *Arabidopsis* AOS (AF172727), and guayule AOS (X78166). AOS, allene oxide synthase; for other abbreviation, see Figure 1.

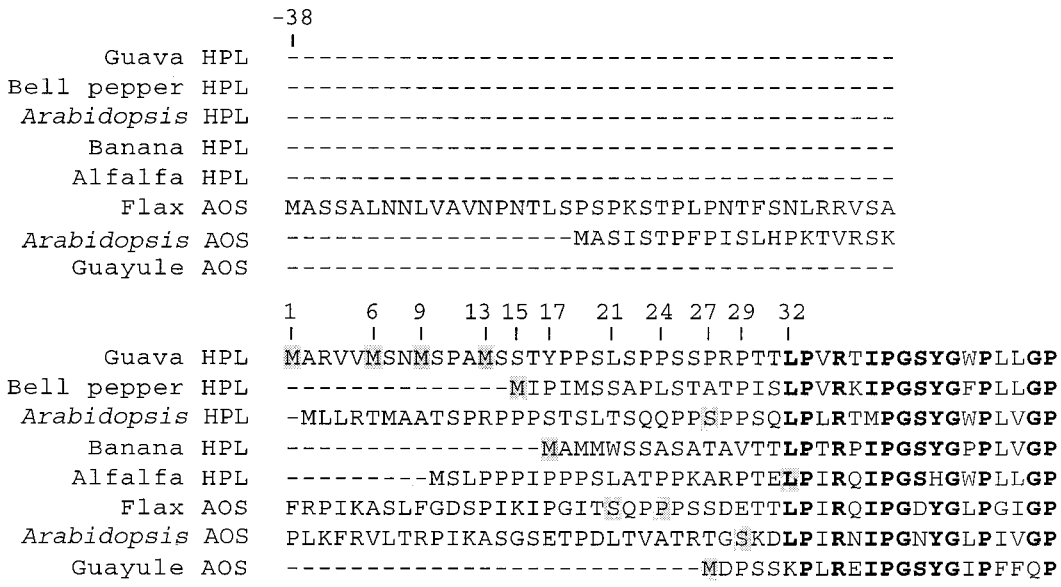

FIG. 9. N-terminal sequence comparison of 13-HPL and AOS enzymes. Comparison of the guava 13-HPL with other CYP74 members. The different enzyme sequences are presented with the conserved residues aligned and shown in bold. The shaded residues indicate the N-terminal start site for the four guava constructs described here and the reported constructs of other enzymes that expressed with catalytic activity (14,15,22,23,27, 31). GenBank accession numbers are given in the legend to Figure 8. For abbreviations, see Figures 1 and 8.

Following the cysteine, the AOS (CYP74A) enzymes have the commonly occurring sequence Ala-Gly (Gly in this position is the P450 consensus sequence), giving the overall sequence NKQCAG. On the other hand, the lyases are distinguished by having the sequence Ala-Ala after the Cys. The second alanine, conserved in the lyases, occurs among less than 5% of all reported cytochromes P450. It is possible that the CAA sequence gives a structurally significant tilt to the supporting polypeptide under the heme group. Mutation of this second alanine residue would be of interest for future experiments. Figure 8 also illustrates the absolutely conserved Val in the last position of this alignment. This is a very unusual residue in this position, which is normally represented by Gly or Ala in over 95% of all families of cytochrome P450.

There are remarkable differences in the sequences of the CYP74 family at the N-termini of the proteins (Fig. 9). Certain of the AOS, exemplified in Figure 9 by the flax and *Arabidopsis* enzymes, have a long presequence that includes a chloroplast transit peptide. In the flaxseed AOS, as deduced by Laudert *et al.* (27), this includes 21 amino acids that are cleaved to give the mature protein. By contrast, the AOS of guayule has a short N-terminus, more similar to the 13-HPL enzymes. The N-terminal sequence of the guava 13-HPL has some unusual features compared to the HPL of bell pepper and *Arabidopsis*. There are four methionines in the first 13 amino acids. We tested the effect of deleting these sequences (albeit with an additional N-terminal sequence from the pET vector still present in each of the expressed proteins). Active lyase was obtained when either the full-length cDNA was expressed, or in the shortened cDNAs with one, two, or three methionines removed. The *Arabidopsis* 13-HPL could be expressed as catalytically active enzyme after deletion of the first 28 amino acids. The shaded residues in Figure 9 indicate the most N-terminal amino acid in constructs that have been successfully expressed with catalytically active enzyme. For the guayule AOS, the CYP74 family member with the shortest known N-terminus, the clear homology to the other enzymes (bold characters in Fig. 9) begins only six amino acids after the initiating methionine. For the CYP74 family, it has yet to be determined what is the shortest possible N-terminus that remains compatible with expression of catalytically active enzyme.

One of the outstanding properties of the AOS enzymes is their very high initial rate of reaction, in the order of 1000 turnovers per second. This contrasts with turnover numbers as low as 1/min for sluggish P450 reactions (28,29), and ≈3200/min for the fastest P450-hydroxylations as catalyzed, for example, by the heme domain of $P450_{BM3}$ (30). The turnover number for HPL has not been reported. We were able to determine a value for the guava 13-HPL following its expression in *E. coli*. After partial purification of the His-tagged enzyme on a nickel affinity column, we obtained a weak UV-visible spectrum that permitted only an approximate quantitation of the enzyme based on the main Soret band at ≈400 nm. Nonetheless, the value obtained was sufficient to permit calculation of the turnover number. The initial reaction rates indicate a turnover number for the 13-HPL of approximately 2000/s, a value comparable to the AOS counterparts in the subfamily CYP74A.

ACKNOWLEDGMENTS

This work was supported by Firmenich S.A., Geneva, Switzerland, and the Kanton of Zürich (KWF Projekt Nr. 2544.1). We thank Dr.

Fredi Bruhlmann for helpful comments. Use of guava fruit in the commercial production of aliphatic aldehydes and alcohols from natural fatty acid precursors is covered by U.S. Patent number 5,464,761 assigned to Firmenich S.A.

Gastroprotection of DNA with a Synthetic Cholic Acid Analog

Edmund J. Niedzinski[a], Michael J. Bennett[b], David C. Olson[b], and Michael H. Nantz[a,*]

[a]Department of Chemistry, University of California-Davis, Davis, California 95616, and [b]Genteric, Inc., Alameda, California 94501

ABSTRACT: The oral delivery of functional DNA to the gastrointestinal system would constitute a desirable, noninvasive method for potentially treating a variety of diseases. The digestive process, however, remains a formidable barrier. This dilemma may be addressed by using targeted liposomes both to protect the polynucleotide and to deliver the therapeutic DNA with high tissue specificity. The present study represents the initial steps toward developing a novel gene delivery system designed to interact with the enterohepatic receptors of the small intestine. Two cholic acid esters were synthetically modified at position C(3) to incorporate a DNA-binding domain. These novel compounds were evaluated for their ability to protect DNA from the nucleases found in gastrointestinal segments. Additionally, the compounds were screened as a component of a gene delivery vector. Formulations containing the new bile salt derivatives protected DNA from degradation for more than 2 h and were capable of transfecting cultured NIH 3T3 cells.

Paper no. L8456 in *Lipids 35,* 721–727 (July 2000).

Delivery of polynucleotides to the gastrointestinal system *via* oral administration potentially would provide an opportunity to treat a variety of disorders in a noninvasive manner (1). Even though challenging, the oral administration of a gene pharmaceutical also would constitute a more convenient route of administration than current methods. Although gene therapy clinical trials have proceeded using intranasal (2,3), intramuscular (4), or intravenous administration (5), gastrointestinal (GI) gene therapy remains to be clinically developed. To develop this route of administration, we have begun to address the barriers of GI gene delivery. Previous attempts to deliver DNA to the GI tract have utilized both viral and nonviral delivery vectors (6–9). While results from these studies are promising, we anticipate that thorough evaluation of the physical and biochemical obstacles in combination with the development of tissue specific vectors will lead to more effective GI transfection. We report herein the synthesis of novel cholic acid derivatives that have been designed to protect DNA from gastric digestion and to effectively promote DNA uptake by the enterohepatic receptors in the ileum. Using a series of stability studies and transfection assays, we present our analysis of these compounds as a potential GI delivery system.

Oral gene delivery must overcome a number of barriers to effectively present a polynucleotide to the intestinal lumen. These barriers include low gastric pH, high concentrations of digestive enzymes, detergents, and the mucosa that limits access to the gut epithelium. Since the selection of delivery vector ultimately will dictate how these obstacles are addressed, careful consideration must be given to the choice between viral or lipid-based delivery systems. Viral vectors have shown much promise in gene delivery; however, their use in clinical studies continues to be problematic (10). Low titer production, immunogenicity, and limitations on plasmid DNA size plague the use of viral vectors. Cationic lipid vectors do not suffer from these specific limitations. There have been many improvements in the use of cationic lipids as transfection agents since the prototype agent *N*-[2,3-(dioleyloxy)propyl]-*N,N,N*-trimethylammonium chloride (11) was reported (12,13). Furthermore, lipids may be chemically modified to interact with specific molecular receptors. This targeting aspect makes the use of cationic lipids an attractive choice for GI gene therapy.

To increase the interaction of a lipid-DNA complex (lipoplex) (14) with the terminal ileum, we prepared novel transfection lipids from cholic acid (Scheme 1) where the conditions for "a" include $(imid)_2CO$ (1.5 eq.), Et_3N, CH_2Cl_2, 0°C–room temperature; the conditions for "b" include $(CH_3)_2NCH_2$-CH_2NH_2 (1.5 eq), Et_3N, CH_2Cl_2, room temperature. We envisioned that these compounds would localize lipoplexes to the epithelium of the terminal ileum by taking advantage of the bile acid specificity for enterohepatic receptors. The enterohepatic receptors in the ileum are responsible for circulating between 12–30 g of bile salts in a day, and the

bile salts are reabsorbed in the terminal ileum with recovery efficiencies of up to 95% (15). C(3)-functionalized cholic acid derivatives have shown the ability to interact with molecular receptors in the ileum, aiding the delivery of molecules through the intestinal wall (16,17). Thus, we reasoned that a cholic acid derivative fitted with a DNA-binding domain might condense DNA and promote the intracellular delivery of DNA in a similar manner. Walker *et al.* (18) reported a series of cholic acid derivatives that were speculated to act as facial amphiphiles and were successfully used to facilitate DNA transfection. This work provides good precedent for the use of cholic acid derivatives in transfection experiments. We prepared novel cholate derivatives by straightforward chemical modifications of positions C(3) and C(24). Previous investigations showed that these positions may be functionalized for conjugation without compromising recognition by the bile acid transport system (19). The new cholate amphiphiles were evaluated for the ability to complex and protect DNA in the gastric environment. We also screened the novel lipids as lipoplex components to determine their compatibility with transfection agents. Results of these studies are presented herein.

MATERIALS AND METHODS

General. All chemical reactions were carried out under an atmosphere of nitrogen. CH_2Cl_2 was distilled from calcium hydride immediately prior to use. Methanol was distilled from magnesium and stored over 4 Å molecular sieves. All amine reagents were distilled from CaH_2. Dioleoylphosphatidylethanolamine (DOPE) was purchased from Avanti Polar Lipids, Inc. (Alabaster, AL), and *N*-[2,3-(dioleyloxy)propyl]-*N,N,N*-trimethylammonium chloride (DOTAP) was prepared using a literature procedure (20). Column chromatography was carried out using 230–400 mesh silica gel, slurry packed in glass columns, eluting with the solvents indicated. Thin-layer chromatography (TLC) was performed on Kieselgel 60 F_{254} plates, staining with a 3% w/w phosphomolybdic acid/ethanol solution. ^{1}H nuclear magnetic resonance (NMR) (300 MHz) and ^{13}C NMR (75 MHz) were recorded in $CDCl_3$. ^{13}C NMR assignments noted by an asterisk (*) are interchangeable for the carbons indicated. High-resolution mass spectrometry (HRMS) was performed by Mass Spectrometry Service Labs of the University of California, Riverside, and the University of Minnesota. Infrared (IR) data were obtained on Matteson Galaxy FTIR 3000 infrared spectrometer (Madison, WI), and melting point determination was obtained using a Thomas-Hoover (Swedesboro, NJ) capillary melting point apparatus and are uncorrected.

*Tetradecyl 3α,7α,12α-trihydroxy-5β-cholanate **(2)**.* Potassium carbonate (0.92 g, 6.0 mmol) was added to a suspension of cholic acid (2.72 g, 6.6 mmol) in hexamethylphosphoric triamide (HMPA) (10 mL). To the suspension was added tetradecyl iodide (1.8 g, 5.5 mmol), and the resultant mixture was heated to 130°C for 48 h. The reaction was cooled and diluted by addition of Et_2O and water. The layers were separated, and the organic layer was washed with water (5×) and dried with Na_2SO_4. The solvent was removed by rotary evaporation to afford the crude product. Purification by column chromatography, eluting with a gradient of MeOH in $CHCl_3$ (0 to 4%), yielded 1.32 g (39%) of **2** as a white foam; m.p., 69.4–70.0°C, R_f = 0.47 (MeOH/CH_2Cl_2 1:9); IR (neat) 3393, 2922, 2853, 1738 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 4.02 [*t*, *J* = 6.9 Hz, 2H, –C(O)CH_2–], 3.93 (*m*, 1H, C3-H), 3.81 (*m*, 1H, C7-H), 3.41 (*m*, 1H, C12-H), 2.19–0.70 (*m*, 59H), 0.64 (*s*, 3H); ^{13}C NMR ($CDCl_3$) δ 174.4 (C24), 73.0 (C3), 71.9 (C7/C12*), 68.4 (C7/C12*), 64.4 [–C(O)O$\underline{C}H_2$–], 47.1, 46.4, 41.6, 41.5, 39.5, 35.2, 34.8, 34.7, 31.9, 31.4, 30.9, 30.4, 29.6 (2), 29.5, 29.3, 29.2, 28.7, 28.2, 27.5, 26.4, 25.9, 23.2, 22.6, 22.4, 17.3, 14.1, 12.4; HRMS, $C_{38}H_{68}O_5$ calc'd 604.5067, found 622.5386 (M + NH_4^+).

*Methyl 3α-(*N*-imidazolecarbamoyl)-7α,12α-dihydroxy-5β-cholanate **(3)**.* Triethylamine (35 μL, 0.55 mmol) was added to a solution of **1** (150 mg, 0.37 mmol) in CH_2Cl_2 (10 mL). The solution was cooled to 0°C, and carbonyldiimidazole (90 mg, 0.55 mmol) was added. The reaction was allowed to warm to room temperature, and after 18 h the reaction was diluted with CH_2Cl_2. The organic layer was washed with a saturated solution of $NaHCO_3$, followed by brine, and finally water. The organic layer was separated and dried with Na_2SO_4. Purification by column chromatography eluting with a gradient of MeOH in CH_2Cl_2 (0 to 5%), yielded pure **3** (190 mg, 77%) as a white solid; m.p., 173.6–174°C; TLC, R_f = 0.64 (MeOH/CH_2Cl_2 1:19); IR (neat) 3416, 2964, 2870, 1759, 1739 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 8.06 (*s*, 1H), 7.35 (*d*, *J* = 1.2 Hz, 1H), 7.00 (*d*, *J* = 1.2 Hz, 1H), 4.73 (*m*, 1H, C3-H), 3.96 (*m*, 1H, C7-H), 3.82 (*m*, 1H, C12-H), 3.62 (*s*, 3H, –OCH_3), 2.31–0.87 (*m*, 34H), 0.66 (*s*, 3H); ^{13}C NMR ($CDCl_3$) δ 174.1 (C24), 147.7, 136.6, 129.8, 116.6, 78.9 (C3), 72.4 (C7/C12*), 67.6 (C7/C12*), 50.9 [–C(O)O$\underline{C}H_3$], 46.8, 45.9, 40.9, 40.2, 39.1, 34.4, 34.2, 30.6, 28.0, 26.9, 26.1, 22.7, 21.9, 16.9, 12.1; HRMS, $C_{29}H_{44}N_2O_6$ calc'd 516.3199, found 516.3199.

*Tetradecyl 3α-(*N*-imidazolecarbamoyl)-7α,12α-dihydroxy-5β-cholanate **(4)**.* Triethylamine (40 μL, 0.24 mmol) was added to a solution of **2** (93 mg, 0.16 mmol) in CH_2Cl_2 (3 mL). The solution was cooled to 0°C, and carbonyldiimidazole (40

mg, 0.24 mmol) was added. The reaction was warmed to room temperature and stirred for 18 h, after which the reaction was diluted with CH_2Cl_2. The organic layer was washed sequentially with saturated aqueous $NaHCO_3$, brine, and water. The organic layer was separated and dried (Na_2SO_4). Evaporation of the solvents afforded **4** (84 mg, 78%), and this material was used without further purification; TLC, R_f = 0.22 (MeOH/ CH_2Cl_2 1:19); ^{1}H NMR ($CDCl_3$) δ 8.10 (*s*, 1H), 7.38 (*d*, *J* = 1.5 Hz, 1H), 7.03 (*d*, *J* = 1.5 Hz, 1H), 4.77 (*m*, 1H, C3-H), 4.03 [*t*, *J* = 6.9 Hz, 2H, –C(O)CH_2–], 4.00 (*m*, 1H, C7-H), 3.86 (*m*, 1H, C12-H), 2.58–0.80 (*m*, 59H), 0.69 (*s*, 3H); ^{13}C NMR ($CDCl_3$) δ 174.3 (C24), 148.2, 137.0, 130.3, 117.1, 79.3 (C3), 72.9 (C7/C12*), 68.1 (C7/C12*), 64.4 [–C(O)-O$\underline{C}H_2$–], 47.3, 46.5, 42.0, 41.2, 39.5, 35.1, 34.8, 34.6, 34.3, 31.9, 31.3, 30.8, 29.6, 29.2, 28.6, 27.4, 26.7, 26.5, 25.9, 23.1, 22.6, 22.3, 17.3, 14.1, 12.5; HRMS, $C_{42}H_{70}N_2O_6$ calc'd 698.5234, found 699.5310 (M + H^+).

Methyl 3α [N-(N,N-*dimethylaminoethane)-carbamoyl*]-*7α,12α-dihydroxy-5β-cholanate* ***(5)***. To a solution of **3** (21 mg, 0.04 mmol) in CH_2Cl_2 (1 mL) at room temperature was added *N,N*-dimethylethylenediamine (10 μL, 0.06 mmol). After 16 h, the reaction was diluted with CH_2Cl_2 and washed sequentially with saturated aqueous $NaHCO_3$, brine, and water. The organic layer was separated and dried (Na_2SO_4). Purification by column chromatography, eluting with a gradient of MeOH in CH_2Cl_2 (0 to 15%), yielded 20.4 mg (95%) of **5** as a white solid; m.p., 116.6–120.7°C; TLC, R_f = 0.17 (MeOH/ $CHCl_3$ 1:7); IR (neat) 3425, 2939, 2870 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 5.53 (*m*, 1H, NH), 4.41 (*m*, 1H, C3-H), 3.93 (*m*, 1H, C7-H), 3.80 (*m*, 1H, C12-H), 3.63 (*s*, 3H, –OCH_3), 3.22 [*m*, 2H, –OC(O)NHC$\underline{H}_2$–], 2.41 [*t,* *J* = 5.1 Hz, 2H, $(CH_3)_2NC\underline{H}_2$–], 2.45–0.76 (*m*, 38H), 0.65 (*s*, 3H); ^{13}C NMR ($CDCl_3$) δ 174.7 (C24), 156.5 [–NH$\underline{C}$(O)O–], 74.5 (C3), 72.8 (C7/C12*), 68.1 (C7/C12*), 58.3 [–$\underline{C}H_2$NHC(O)O–], 51.4 [–C(O)O$\underline{C}H_3$], 47.0, 46.4, 45.0, 41.8, 41.2, 39.4, 38.0, 35.6, 35.1, 34.9, 34.6, 34.4, 31.0, 30.82, 28.29, 27.4, 26.9, 26.5, 23.1, 22.4, 22.2, 17.2, 12.4; HRMS, $C_{30}H_{52}N_2O_6$ calc'd 536.3825, found 537.3901 (M + H^+).

Tetradecyl-3α [N-(N,N-*dimethylaminoethane)-carbamoyl*]-*7α,12α-dihydroxy-5β-cholanate* ***(6)***. To a solution of **4** (84 mg, 0.12 mmol) in CH_2Cl_2 (2.5 mL) at room temperature was added *N,N*-dimethylethylenediamine (30 μL, 0.28 mmol). After 16 h, the reaction was diluted with CH_2Cl_2 and washed sequentially with saturated aqueous $NaHCO_3$, brine, and water. The organic layer was separated and dried (Na_2SO_4). Purification by column chromatography, eluting with a gradient of MeOH in CH_2Cl_2 (4 to 20%), yielded 46 mg (53%) of **6** as a white solid; m.p., 77.7–78.9°C; TLC, R_f = 0.40 (MeOH/ $CHCl_3$ 1:7); IR (neat) 3428, 2925, 2855, 1721, 1692, cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 5.36 (*m*, 1H, NH), 4.43 (*m*, 1H, C7-H), 4.02 [*t,* *J* = 6.9 Hz, 2H, –C(O)OCH_2–], 3.95 (*m*, 1H, C7-H), 3.81 (*m*, 1H, C12-H), 3.21 [*m*, 2H, –C$\underline{H}_2$NHC(O)O–], 2.42–0.76 (*m*, 64H), 0.66 (*s*, 3H); ^{13}C NMR ($CDCl_3$) δ 174.5 (C24), 156.6 [–NH$\underline{C}$(O)O–], 74.6 (C3), 72.8 (C7/C12*), 68.2 (C7/C12*), 64.5 [–C(O)O$\underline{C}H_2$–], 58.2 [–$\underline{C}H_2$NHC(O)O–], 47.1, 46.5, 45.1, 41.9, 41.0, 39.4, 38.2, 35.5, 35.0, 34.6, 31.9 (2), 31.3, 29.6 (2), 29.5 (2), 29.2, 28.6, 25.9, 23.0, 22.6, 22.5, 17.3, 14.1, 12.36; HRMS, $C_{43}H_{78}N_2O_6$ calc'd 718.5860, found 719.5904 (M + H^+).

Formulations. All lipids were dissolved in chloroform to give 10 mg/mL solutions and then aliquoted into vials to give the desired amounts. The solvent was removed either by rotary evaporation or by passing a stream of nitrogen over the vial. Trace solvent was removed by placing the sample vial under vacuum for 30 min prior to use. Lipid films were hydrated in water, followed by vortex mixing and sonication to obtain homogeneous opaque solutions.

Plasmid DNA. Vector pFGH.cytomegalovirus (CMV) contains the genomic human growth hormone DNA sequence under transcriptional control of the immediate early promoter of human CMV (21). This vector yields high level expression in rodent cells. A similar plasmid, pCMV.FOX.Luc-2, yields high level expression of firefly luciferase (generously provided by Genteric, Inc., Alameda, CA). All vectors were prepared as endotoxin-reduced, supercoiled plasmids using anion exchange resins (Qiagen, Santa Clarita, CA).

Intestinal extracts. Fasted (24 h) female Balb-C mice (15–18 g) from Simonsen laboratories were sacrificed using CO_2 asphyxiation. One-inch sections were taken from the stomach and ileum. A syringe was fixed to the proximal end of each segment, and 1 mL of deionized water was flushed through each intestinal segment. The extracts were collected and stored at –20°C. The samples were thawed, vortexed and centrifuged at 4,000 rpm for 1 min prior to use. All studies involving animals were conducted at Genteric, Inc. in accordance with protocols approved by the Institutional Animal Care and Use Committee.

Intestinal stability. Hydrated lipid suspensions were diluted with water to obtain the desired concentration, vortex mixed, and an appropriate quantity of DNA was then added to form the lipoplex (typically 3 μg DNA/15 μL). For the control experiments, DNA was diluted with either an EDTA solution (10 mmol) or water. The lipoplex and control solutions were then incubated with 7.5 μL of the intestinal washes. The reactions were quenched at the appropriate time by adding 7.5 μL of a 10 mmol EDTA/20% sodium dodecyl sulfate solution. A 10 μL aliquot of quenched reaction (*ca.* 1 μg of DNA) was loaded onto a 0.7% agarose gel in tris/acetic acid/EDTA (TAE) buffer that was treated with ethidium bromide. The agarose gels were electrophoresed at 120 V and visualized under ultraviolet light.

Cell culture. NIH 3T3 cells were obtained from the American Type Culture Collection (Rockville, MD) and grown in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal calf serum in a humidified 10% CO_2 atmosphere at 37°C. The cells were plated on 24-well tissue culture plates 72 h before transfection. Cells were used at 80–90% confluency. Hydrated lipid solutions were diluted with DMEM-serum free media to obtain the desired concentration, vortexed, and mixed with an appropriate volume of DNA. The growth medium was aspirated, and the cells were washed with 0.5 mL of phosphate-buffered saline (PBS). After re-

moval of the PBS, the lipid/DNA solution was added to the cells (200 μL, 1 μg DNA). After 4 h of exposure, the transfection solution was removed and replaced with growth medium (500 μL). Cells were lysed 48 h after lipid/ DNA administration by adding lysis buffer from the Enhanced Luciferase Assay Kit (Pharmingen, San Diego, CA).

Luciferase assays. Luciferase activity was assayed using the Enhanced Luciferase Assay Kit and a Moonlight 2010 luminometer. Luciferase activity was measured from 25-μL aliquots of the cell lysate over a 10-s period. The activity was expressed as relative light units, which is a function of assay conditions, luciferase concentration, instrument sensitivity, and background.

RESULTS AND DISCUSSION

The methyl ester of cholic acid was prepared using a literature procedure (22). Preparation of the tetradecyl ester **2** was achieved by reaction of potassium cholate with tetradecyliodide in HMPA. Cholate esters **1** and **2** were selectively functionalized at C(3) by reaction with carbonyl diimidazole to obtain the *N*-acyl-imidazole derivatives **3** and **4** in 77 and 78% yield, respectively. We were gratified with the regioselectivity of these reactions in that previous attempts to selectively functionalize the C(3)-hydroxyl group employed laborious protection-deprotection schemes (23,24). At this stage, attachment of a DNA-binding domain was accomplished by reaction of the C(3) activated carbamate with excess *N,N*-dimethylethylenediamine to obtain amphiphiles **5** and **6**. These compounds incorporate the DNA-binding domain of the transfection agent DC-cholesterol (Fig. 1) (25). This choice was motivated by the successful application of DC-cholesterol in many transfection studies (26). The robust nature of the C(3)-*N*-acyl imidazole should make this synthetic strategy adaptable to the synthesis of a variety of C(3) bile acid conjugates.

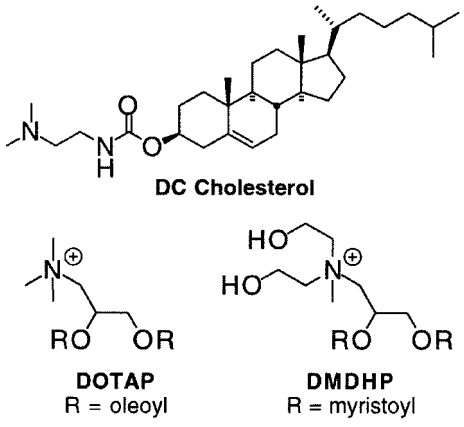

FIG. 1. Common transfection lipids. DC cholesterol, 3-β-[*N*-(*N′,N′*-dimethylaminoethane)carbamoyl]cholesterol; DOTAP, *N*-[2,3-(dioleoyloxy)propyl]-*N,N,N*-trimethylammonium chloride; DMDHP, *N,N*-bis(2-hydroxyethyl)-*N*-[2,3-(dimyristoyloxy)propyl]-*N*-methylammonium chloride.

The stability of lipoplex preparations containing amphiphiles **5** and **6** was examined by incubation with extracts obtained from the stomach and ileum of Balb-C mice. Solutions from the stomach and ileum were obtained by flushing water through freshly dissected segments. The integrity of DNA (pFGH.CMV) (27) was measured using electrophoresis (0.7% agarose in TAE buffer) after exposure of the plasmid to the GI extracts (Fig. 2). Uncomplexed DNA was incubated with extracts from the stomach and ileum (lanes 1 and 2). Comparison to the control experiment (lane 5) revealed that these extracts severely degraded the plasmid. An equivalent volume of an EDTA solution was added to the intestinal extracts to neutralize enzymatic activity (28). Subsequent incubation of DNA with the EDTA-intestinal extracts (lanes 3 and 4) revealed that the level of plasmid digestion was significantly reduced. This result supports a view that DNA digestion in the stomach and ileum is due to nuclease activity.

Next, we investigated the stability of DNA in the GI extracts by prior complexation of the plasmid with a cationic lipid. Gershon *et al.* (29) have shown that DNA within a lipoplex is resistant to nuclease activity. However, the GI tract contains other factors that might contribute to degradation of a lipoplex and its DNA. To establish lipid-based gastroprotective parameters, preliminary experiments were conducted using the transfection lipid DOTAP (30) (Fig. 1). Lipoplexes were prepared using a 1:1 formulation of DOTAP and DOPE as previously reported (31). Our preliminary work suggested that the cationic lipid/DNA phosphate molar ratio should be at least 2.5:1 to achieve plasmid protection. Thus, lipoplexes were formulated at a 3:1 charge ratio. After incubating the complexed DNA with the intestinal extracts for varying times (Table 1), the extent of degradation was analyzed by agarose

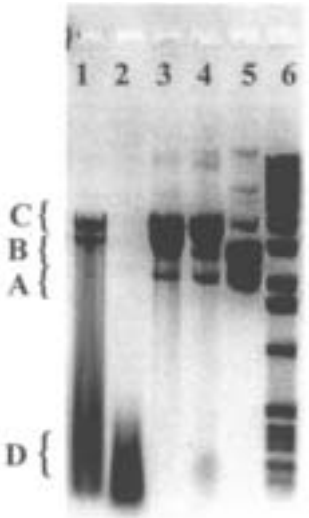

FIG. 2. Effect of gastrointestinal (GI) extracts on DNA. 0.7% Agarose in Tris/acetic acid/ethylenediaminetetraacetic acid (EDTA) buffer; lanes 1, 2: DNA after incubation (10 min at 37°C) with GI washes taken from the stomach and ileum, respectively; lanes 3, 4: DNA after incubation with EDTA-treated GI washes taken from the stomach and ileum, respectively; lane 5: DNA (control); lane 6: 1 kb ladder. Forms of DNA: A, supercoiled; B, linear; C, nicked circular; and D, digested.

TABLE 1
Incubation Conditions Using Extracts from Mouse Stomach and Ileum

Lane	Experiment (extract, DNA form)	Time (min)	Lane	Condition (extract, DNA form)	Time (min)
3	Stomach, free DNA	10	11	Stomach, free DNA	60
4	Ileum, free DNA	10	12	Ileum, free DNA	60
5	Stomach, lipoplex	10	13	Stomach, lipoplex	60
6	Ileum, lipoplex	10	14	Ileum, lipoplex	60
7	Stomach, free DNA	30	15	Stomach, free DNA	120
8	Ileum, free DNA	30	16	Ileum, free DNA	120
9	Stomach, lipoplex	30	17	Stomach, lipoplex	120
10	Ileum, lipoplex	30	18	Ileum, lipoplex	120

gel electrophoresis (Fig. 3). To dissociate the DNA from the cationic lipids and facilitate analysis by electrophoresis, the lipoplexes were treated with 10% SDS solution immediately following incubation (32). The results clearly show that DNA was protected from the GI extracts for up to 2 h only when complexed to the cationic lipid (lanes 17 and 18). Uncomplexed DNA was completely digested within 1 h (lanes 11 and 12). Based on the typical transit time in the GI (33), 2 h of gastroprotection may be a suitable time frame for achieving *in vivo* GI transfection.

Having noted that a lipoplex preparation survives the GI extracts, we examined whether addition of the cholate amphiphiles **5** and **6** would interfere with the gastroprotection. Cholates **5** and **6** were evaluated by formulation with DNA in varying ratios with DOTAP and DOPE (Table 2), incubated with the ileum extract, and then analyzed by agarose gel electrophoresis (Fig. 4). Once again, uncomplexed "free" DNA was degraded by the ileum extract without the protection afforded by lipid complexation (lane 3). However, DNA encapsulated as a lipoplex containing a cholate amphiphile (lanes 4–9) survived the incubation period. Thus, addition of the cholate lipids does not appear to compromise the gastroprotection afforded by lipoplex formulation of DNA.

Cholates **5** and **6** were formulated with DOPE and *N,N*-bis(2-hydroxyethyl)-*N*-[2,3-(dimyristoyloxy)propyl]-*N*-methyl-ammonium chloride (DMDHP) (31) and screened in NIH 3T3 cells using the luciferase assay. DMDHP was selected for the transfection experiments based on the superior transfection activity exhibited by DMDHP (34). Additionally, this provides the opportunity to determine whether adding a cholic acid amphiphile to a commercially available transfection system would impart a beneficial or detrimental effect on overall transfection activity. Cholate **5** was more active than cholate **6** as a transfection additive in the lipid formulations examined (Fig. 5). The inverse relationship between the molar ratio of **6** and the level of luciferase expression suggests that cholate **6** inhibits the activity of DMDHP as a transfection agent. In contrast, the formulations containing 20 and 30% of cholate **5** exhibited a two- to threefold increase in transfection activity relative to the 1:1 DMDHP/DOPE formulation. This result indicates that cholate **5** may be suitable for addition to a therapeutic lipoplex preparation without compro-

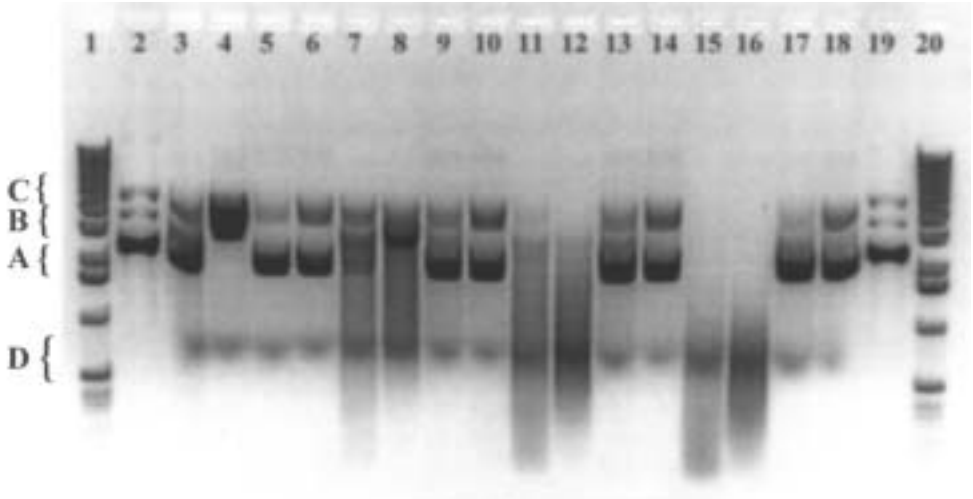

FIG. 3. Effect of GI extracts on lipoplexes and uncomplexed "free" DNA. Lanes 1 and 20, 1 kb standard; lanes 2 and 19, DNA (control); lanes 3–18, free or complexed DNA after incubation with stomach or ileum extracts as described in Table 1. All lipoplex preparations were formed using 1:1 *N*-[2,3-(dioleoyloxy)propyl]-*N,N,N*-trimethylammonium chloride/1,2-dioleoyl-*sn*-3-phosphoethanolamine (DOTAP/DOPE) at a 3:1 cationic lipid/DNA phosphate charge ratio. Forms of DNA: A, supercoiled; B, linear; C, nicked circular; and D, digested.

TABLE 2
Lipoplex Formulations for the Incubation Studies of Figure 4[a]

Lane	Ratio DOTAP/cholate/DOPE	Cholate no.

5	2:1:3	5
6	0:1:1	5
7	1:2:3	6
8	2:1:3	6
9	0:1:1	6

[a]DOTMA, *N*-[2,3-(dioleyloxy)propyl]-*N,N,N*-trimethylammonium chloride; DOPE, 1,2-dioleoyl-*sn*-3-phosphoethanolamine.

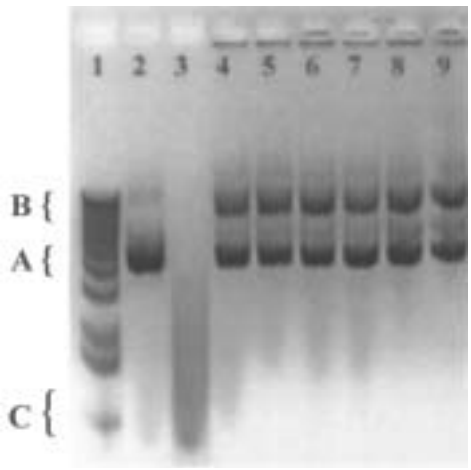

FIG. 4. Effect of ileum extracts on cholate-based lipoplexes. Lane 1, 1 kb standard; lane 2, DNA (control); lane 3, DNA after incubation with the ileum extract; lanes 4–9, lipoplex DNA after incubation with the ileum extract. Lipid/DNA complexes were formed at a 3:1 cationic lipid/DNA phosphate charge ratio using varying combinations of DOTAP, cholate amphiphile, and DOPE (see Table 2). All ileum extract incubations were performed for 30 min at 37°C. Forms of DNA: A, supercoiled; B, linear; C, digested. See Figure 3 for abbreviations.

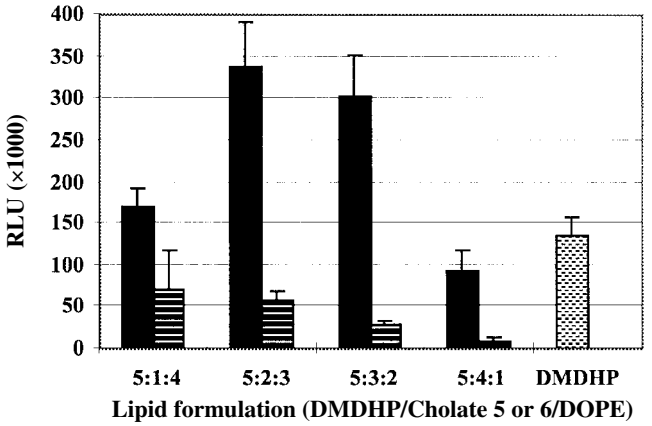

FIG. 5. DNA transfection of NIH 3T3 cells using cholate lipids 5 and 6. Solid bars represent formulations incorporating cholate **5** and dashed bars represent formulations incorporating cholate **6**. *N,N*-bis(2-hydroxyethyl)-*N*-[2,3-(dimyristoyloxy)propyl]-*N*-methylammonium chloride (DMDHP) was formulated as a 1:1 mixture with DOPE. All lipoplex preparations were formulated at a 4:1 molar ratio of DMDHP/DNA phosphate. Results are summarized as the means ($n = 4$) and standard deviation of total luciferase relative light units (RLU) obtained from cells lysed after administration of 1 μg DNA. See Figure 3 for other abbreviation.

mising the transfection activity of the principal transfection agent.

We have disclosed a convenient and readily adaptable synthesis of new C(3)-functionalized cholic acid analogs. Co-formulation of these lipids did not compromise the gastroprotection of DNA imparted by a lipoplex preparation. These modified lipoplexes were also shown to be active in a transfection experiment. The present study demonstrates that cationic lipid-complexation of DNA serves to protect the polynucleotide from GI degradation and represents the first step toward development of orally administered gene medicines.

ACKNOWLEDGMENTS

We are grateful to the Cystic Fibrosis Foundation and Genteric for support of this work. EJN is thankful for a fellowship from Genteric. We thank Kathleen Galligan for DNA preparation and Dr. Stephen Rothman and Dr. Hsein Tseng for helpful discussions.

ABSTRACT: Although fatty acid-binding proteins (FABP) differentially affect fatty acid uptake, nothing is known regarding their role(s) in determining cellular phospholipid levels and phospholipid fatty acid composition. The effects of liver (L)- and intestinal (I)-FABP expression on these parameters were determined using stably transfected L-cells. Expression of L- and I-FABP increased cellular total phospholipid mass (nmol/mg protein) 1.7- and 1.3-fold relative to controls, respectively. L-FABP expression increased the masses of choline glycerophospholipids (ChoGpl) 1.5-fold, phosphatidylserine (PtdSer) 5.6-fold, ethanolamine glycerophospholipids 1.4-fold, sphingomyelin 1.7-fold, and phosphatidylinositol 2.6-fold. In contrast, I-FABP expression only increased the masses of ChoGpl and PtdSer, 1.2- and 3.1-fold, respectively. Surprisingly, both L- and I-FABP expression increased ethanolamine plasmalogen mass 1.6- and 1.1-fold, respectively, while choline plasmalogen mass was increased 2.3- and 1.7-fold, respectively. The increase in phospholipid levels resulted in dramatic 48 and 33% decreases in the cholesterol-to-phospholipid ratio in L- and I-FABP expressing cells, respectively. L-FABP expression generally increased polyunsaturated fatty acids, primarily by increasing 20:4n-6 and 22:6n-3, while decreasing 18:1n-9 and 16:1n-7. I-FABP expression generally increased only 20:4n-6 proportions. Hence, expression of both I- and L-FABP differentially affected phospholipid mass, class composition, and acyl chain composition. Although both proteins enhanced phospholipid synthesis, the effect of L-FABP was much greater, consistent with previous work suggesting that these two FABP differentially affect lipid metabolism.

Paper no. L8406 in *Lipids 35*, 729–738 (July 2000).

The cytosolic fatty acid-binding protein (FABP) superfamily is comprised of immunologically distinct proteins that share similar structures, overlapping ligand specificity, and considerable sequence homology. Why some tissues and cell types contain multiple FABP is not known. For example, intestinal-FABP (I-FABP), a 15.1 kDa cytosolic protein, is found in the columnar epithelial cells of the small intestine, where it constitutes 2–4% of the total cytosolic protein (1). I-FABP expression also varies depending upon developmental stage, diet, and position of the cells along the longitudinal axis of the intestinal tract (2). Liver-FABP (L-FABP), a 14.2 kDa protein, is also found in intestinal enterocytes, where it accounts for 2% of the total cytosolic protein, as well as in the liver, where it accounts for 3–5% of the total cytosolic protein (2–4). The N-terminus of both proteins is blocked by acetylation consistent with the intracellular localization (5). I- and L-FABP have a similar affinity for fatty acids (3,6,7), although some studies suggest that L-FABP has a greater affinity for polyunsaturated fatty acids (PUFA), such as arachidonic acid, than I-FABP (8). This is consistent with our finding that endogenous L-FABP isolated from rat liver contains a substantial quantity of PUFA (9). Furthermore, I- and L-FABP not only bind fatty acids but also are thought to bind long-chain fatty acyl CoA with a high affinity (10–12). In addition, L-FABP binds a number of lipophilic ligands including prostaglandins (13), hydroperoxy- and hydroxyeicosatetraenoic acids (14), heme (15), and warfarin (16). Although suggestive of function, ligand binding alone has not allowed discrimination of the respective physiological role(s) for the different FABP in altering cellular lipid metabolism.

To better assess the physiological function of these FABP in cells, L-FABP (17,18) and I-FABP (19) were stably expressed in L-cell fibroblasts. In these cells, L-FABP (18,20) but not I-FABP expression (19–21) increased fatty acid uptake, whereas both proteins increased the apparent fatty acid cytoplasmic diffusion coefficient (20). A recent study in murine stem cells suggests that the cellular differentiation state affects I-FABP-induced fatty acid uptake, with I-FABP expression enhancing fatty acid uptake only in undifferentiated cells (22). Furthermore, expression of L-FABP or I-FABP dif-

Abbreviations: CerPCho, sphingomyelin; ChoGpl, choline glycerophospholipid; ER, endoplasmic reticulum; EtnGpl, ethanolamine glycerophospholipid; FABP, fatty acid binding protein; FAME, fatty acid methyl ester; GLC, gas–liquid chromatography; HPLC, high-performance liquid chromatography; I-FABP, intestinal-FABP; L-FABP, liver-FABP; MUFA, monounsaturated fatty acid; PlsCho, choline plasmalogen; PlsEtn, ethanolamine plasmalogen; PtdEtn, phosphatidylethanolamine; PtdIns, phosphatidylinositol; PtdOH, phosphatidic acid; PtdSer, phosphatidylserine; PUFA, polyunsaturated fatty acid; TLC, thin-layer chromatography.

ferentially affected targeting of exogenous fatty acids for esterification into specific lipid pools (18,19,21). This enhancement of fatty acid targeting is supported by studies showing that both L-FABP (10,23,24) and I-FABP (24) stimulate phosphatidic acid (PtdOH) synthesis *in vitro*, although L-FABP has a more robust effect on synthesis than I-FABP (24). In other studies, expression of adipocyte-FABP in Chinese hamster ovary cells enhanced fatty acid uptake and esterification into cellular lipids 1.5- and 2.0-fold, respectively, compared to nontransfected cells (25). Expression of heart-FABP in a human breast cancer cell line increased fatty acid uptake nearly 1.7-fold compared to control cells but did not increase the targeting of fatty acids to either neutral lipids or phospholipids (26). Thus, studies using transfected cell lines suggest that FABP differentially affect fatty acid uptake, cytoplasmic diffusion, and targeting (18–22).

Despite these findings, whether L-FABP and I-FABP expression differentially affects phospholipid mass, class composition, or phospholipid fatty acid composition is not known. We report that L-FABP, and to a lesser extent I-FABP, expression differentially increased L-cell phospholipid mass, including plasmalogen mass, resulting in a dramatic decrease in the cholesterol-to-phospholipid ratio. Likewise, L-FABP, and to a lesser extent I-FABP, expression altered phospholipid fatty acid composition, suggesting that these proteins not only enhance phospholipid synthesis but also can modulate fatty acyl chain composition.

MATERIALS AND METHODS

Cells. Murine L-cell fibroblasts (L arpt⁻tk⁻) were stably transfected with the cDNA encoding for either I-FABP (19) or L-FABP (17,18). The transfected cells express these proteins at similar levels as determined by quantitative Western blotting (17–19). Control and transfected cells were grown to confluency in Higuchi medium containing 10% fetal bovine serum (Hyclone, Logan, UT) (27).

Lipid extraction. Lipids were extracted from confluent control and transfected cells using *n*-hexane/2-propanol (3:2 vol/vol) (28,29). Before extraction, the cell culture medium was removed and the cells were washed twice with ice-cold phosphate-buffered saline. Following removal of the last wash, the cell plate was floated on liquid N_2 to minimize acylhydrolase activity during cell removal (30). The cell plate was removed from the liquid N_2, 2 mL of 2-propanol was added, and the cells were removed from the plate by scraping. The 2-propanol containing the cells was transferred to a tube containing 6 mL of *n*-hexane. The cell plate was washed with another 2-mL aliquot of 2-propanol, which was transferred to the tube containing the *n*-hexane, resulting in *n*-hexane/2-propanol (3:2 vol/vol).

Cell extracts were centrifuged at 2,500 rpm to pellet the denatured protein and other cellular debris. The lipid-containing organic phase was decanted and stored under a $N_{2(g)}$ atmosphere at –80°C until analysis. These storage conditions limit oxidation of lipids, including PUFA, as demonstrated previously (29,31–33). The residual protein pellet was dried overnight at room temperature.

Phospholipid separation. Before separating the phospholipid classes by high-performance liquid chromatography (HPLC), the sample volume was reduced under a stream of $N_{2(g)}$ and the samples were filtered through a Nylon 66 0.2-μm filter (Ranin, Emeryville, CA). The filtered sample was then dried to completeness and redissolved in a known volume of HPLC-grade *n*-hexane/2-propanol (3:2 vol/vol).

The HPLC system consisted of a Beckman 125 pump module, a Beckman 166 UV/Vis detector (Fullerton, CA), and a column heater (Jones Chromatography, Littleton, CO) containing a Phenomenex Selectosil column (5 μm, 4.6 × 250 mm, Torrance, CA) maintained at 34°C. The eluant absorbance was monitored at 205 nm.

The phospholipids were separated using a binary gradient of (A) *n*-hexane/2-propanol (3:2 vol/vol) and (B) *n*-hexane/2-propanol/water(56.7:37.8:5.5 by vol). Initial solvent conditions were 65% A/35% B with a step gradient to 100% B over 75 min. This method separates all of the major phospholipids including phosphatidylserine (PtdSer) and phosphatidylinositol (PtdIns) (34). The ethanolamine glycerophospholipid (EtnGpl) and choline glycerophospholipid (ChoGpl) fractions were quantitatively divided into two equal parts, one of which was used to quantify phospholipid mass by assaying lipid phosphorus (35). The other half was dried under $N_{2(g)}$ and exposed to HCl vapor for 15 min to cleave the vinyl ether linkage of the plasmalogen subclasses (36). The latter fractions were re-separated by HPLC and the glycerophospholipid and lysophospholipid fractions collected and quantified by assaying for lipid phosphorus (35). All other phospholipid fractions were also quantified by analysis of lipid phosphorus (35).

The neutral lipid fraction from the phospholipid separation was saved and separated using a binary solvent system consisting of *n*-hexane/2-propanol/acetic acid (98.7:1.2:0.1) and *n*-hexane (18,37). The column used was a Selectosil column (5 μm, 4.6 × 250 mm) maintained at 55°C. Data were collected using the Dionex UI-120 (Sunnyvale, CA) analog-to-digital interface. The unesterified cholesterol mass was calculated by converting absorbance at 205 nm from peak area to mass using a standard curve.

Thin-layer chromatography (TLC). Phospholipid fatty acid composition was analyzed in individual phospholipids separated by TLC. Silica gel G plates (Analtech, Newark, DE) were heat-activated at 110°C for 1 h and samples streaked onto the plates. The developing solvent was chloroform/methanol/water (65:25:4 by vol). This solvent system separates the PtdIns from the PtdSer as well as the ChoGpl from the sphingomyelin (CerPCho) (38). Bands were visualized using 1 mM 6-*p*-toluidino-2-naphthalene sulfonic acid dissolved in 50 mM Tris (pH 7.4) (39). Bands corresponding to authentic lipid standards were scraped into screw-top test tubes and subjected to base-catalyzed transesterification.

Transesterification. Methanol was added to the individual phospholipid fractions, which were subjected to base-catalyzed transesterification, converting the phospholipid acyl chains to fatty acid methyl esters (FAME) (40). This method

of transesterification avoids formation of dimethylacetals and oxidative side reactions common with acid-catalyzed methods. FAME were extracted from the methanol by using 2 mL of *n*-hexane, and the *n*-hexane phase containing the FAME was removed. The lower phase was re-extracted two more times with 2-mL aliquots of *n*-hexane, and these washes were combined with the original aliquot.

Gas–liquid chromatography (GLC). FAME were separated by GLC and quantified using flame-ionization detection. Individual fatty acids were identified using FAME standards (Nu-Chek-Prep, Elysian, MN). Relative correction factors for fatty acids were established using standards and based upon a set concentration of 17:0 added prior to analysis. Detector response was linear within the sample concentration range for all of the fatty acids.

The GLC system consisted of a GLC-14A (Shimadzu, Kyoto, Japan) equipped with an SP-2330 capillary column (0.32 mm i.d. × 30 m length, Supelco, Bellefonte, PA). Column temperature was maintained at 185°C, with the injector and detector temperature set at 220°C. The split ratio was 40:1. Peak area data were collected using a Dionex UI-120 analytical-to-digital interface and converted to peak area using Dionex PeakNet software.

Protein assay. Proteins were measured using a modified dye-binding assay (41). The dried protein residue from the extracts was digested overnight in 0.2 M KOH at 65°C. Following digestion, aliquots were used to measure the protein concentration by converting absorbances to concentrations using a bovine serum albumin standard curve.

Statistics. All groups were compared by a one-way analysis of variance and Tukey-Kramer multiple comparisons posttest using Instat II (GraphPad, San Diego, CA). All values are expressed as means ± SD. Statistical significance was defined as $P < 0.05$. The *n* is defined as the number of cultures used to determine each data point.

RESULTS

Total phospholipid mass. The effect of L- and I-FABP expression on total cellular phospholipid mass (nmol/mg protein) was determined in L-cells expressing L-FABP and I-FABP at similar levels. Total phospholipid mass was increased from 266 ± 53 in control cells to 452 ± 26 and 343 ± 23 for L-FABP- and I-FABP-expressing cells, respectively. Values represent means ± SD, $n = 4$. I-FABP expression increased total cellular phospholipid mass 1.3-fold compared to control cells, but this increase was significantly less than the 1.7-fold increase observed with L-FABP expression. Thus, FABP expression differentially affected phospholipid mass in L-cells.

Endoplasmic reticulum (ER)-synthesized individual phospholipid class mass. Changes in total cellular phospholipid mass are not indicative of changes in the mass of individual phospholipid classes. To assess the effects of I- and L-FABP expression on the mass of individual phospholipids formed in the ER, phospholipids were resolved using HPLC and their individual masses calculated. In the I-FABP-expressing cells, the masses of PtdSer and ChoGpl were elevated 3.1- and 1.2-fold, respectively, compared to the control (Table 1). In contrast to I-FABP-expressing cells, L-FABP expression increased the mass of every major phospholipid class relative to control cells, but the magnitudes of these changes were greater than those for I-FABP-expression. In L-FABP-expressing cells, EtnGpl mass was increased 1.4-fold, ChoGpl mass was elevated 1.5-fold compared to control, whereas PtdIns and PtdSer masses were increased 2.6- and 5.6-fold, respectively, compared to the control. Relative to I-FABP-expressing cells, PtdIns and PtdSer masses were increased 3.3- and 1.8-fold in L-FABP-expressing cells, respectively. Lastly, in L-FABP expressing cells, CerPCho mass was increased 1.7- and 1.5-fold relative to control and I-FABP-expressing cells, respectively. Thus, L-FABP expression increased phospholipid mass in L-cells to a much greater extent than I-FABP expression, indicating that these two FABP had differential effects on phospholipid metabolism.

Peroxisomal and ER-synthesized plasmalogen mass. The effects of L- and I-FABP expression on plasmalogen levels were determined. [Plasmalogens are phospholipids containing a vinyl ether linkage in the *sn*-1 position that are synthesized by steps involving both peroxisomes and ER; they have a role in lipid-mediated signal transduction (42–45)]. In I-FABP-expressing cells, ethanolamine plasmalogen (PlsEtn)

CerPCho	31.0 ± 2.5	35.7 ± 7.9	53.8 ± 8.8*,**	11.1 ± 1.5	10.4 ± 2.2	11.9 ± 1.9
LysoPtdCho	4.6 ± 1.9	5.0 ± 2.9	6.2 ± 1.4	1.6 ± 0.6	1.5 ± 0.9	1.4 ± 0.3

[a]Values are expressed as means ± SD, $n = 4$. A single asterisk (*) indicates significantly different from the control; a double asterisk (**) indicates significantly different from I-FABP-expressing cells, $P < 0.05$. Abbreviations: I-FABP, intestinal fatty acid-binding protein; L-FABP, liver fatty acid-binding protein; EtnGpl, ethanolamine glycerophospholipid; lysoPtdEtn, lysophosphatidylethanolamine; PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine; ChoGpl, choline glycerophospholipid CerPCho, sphingomyelin; lysoPtdCho, lysophosphatidylcholine.

mass was increased 1.1-fold in these cells (Table 2). In contrast, PlsEtn mass was increased in L-FABP-expressing cells 1.6- and 1.4-fold compared to the control and I-FABP-expressing cells, respectively. Similarly, the choline plasmalogen (PlsCho) levels were also differentially affected by I-FABP and L-FABP expression. In I-FABP-expressing cells, the acid-labile ChoGpl, PlsCho, was increased 1.7-fold relative to the control. However, L-FABP expression increased PlsCho mass 2.3- and 1.3-fold compared to the control and I-FABP-expressing cells, respectively. These data also indicate that L-FABP, and to a lesser extent I-FABP, expression increased both the EtnGpl and ChoGpl acid-stable fractions, which contain mainly the diacyl phosphatidyl fraction. Thus, both I- and L-FABP expression increased PlsEtn and PlsCho levels, although only L-FABP expression appeared specifically to affect PlsEtn formation.

Phospholipid class composition. Although both L- and I-FABP expression dramatically increased total phospholipid mass and differentially affected the masses of individual phospholipid classes, these data do not provide information regarding the relative distribution of the individual phospholipids. Therefore, the effect of L- and I-FABP expression on L-cell phospholipid composition was determined from the phospholipid mass data in Table 1. Expression of I-FABP had no effect on the phospholipid percentage composition compared to control cells (Table 1). In contrast, L-FABP expression produced marked changes in phospholipid percentage composition relative to both control and I-FABP-expressing cells (Table 1). PtdSer and PtdIns proportions were increased 3.4- and 1.7-fold, respectively, compared to the control. Both PtdIns and ChoGpl proportions were altered with respect to I-FABP-expressing cells, with the ChoGpl proportion decreased in L-FABP-expressing cells by 10% and the PtdIns increased 2.5-fold. ChoGpl proportions were decreased 6% in L-FABP expressing cells relative to control.

L- and I-FABP expression also differentially affected ChoGpl and EtnGpl subclass composition (Table 2). L-FABP expression increased the proportion of acid-labile EtnGpl, PlsEtn, relative to the acid-stable fraction consisting primarily of phosphatidylethanolamine (PtdEtn) (Table 2). As such, the proportion of the acid-stable fraction was also significantly reduced compared to either control or I-FABP-expressing cells. In contrast, I-FABP and L-FABP expression increased the proportion of acid-labile ChoGpl, PlsCho, compared to the control. Hence, L-FABP expression differentially affected phospholipid composition in L-cells relative to I-FABP and control cells, suggesting a specific increase in PtdSer and PtdIns relative to the other phospholipids.

Free cholesterol to phospholipid ratio. Earlier studies from this laboratory demonstrated a change in the biophysical membrane dynamics in L-FABP-expressing cells (17,20,46), although such data are limited for I-FABP expressing cells (20). Because of the large changes in phospholipid mass in these FABP-expressing cells, the cholesterol-to-phospholipid ratio was determined. Unesterified (free) cholesterol values (nmol/mg protein) were 73 ± 5, 69 ± 11, and 65 ± 6 for control, L-FABP-, and I-FABP-expressing cells, respectively. The cholesterol- to-phospholipid ratio was 0.28 ± 0.02, 0.15 ± 0.02, and 0.19 ± 0.02 for the control, L-FABP-, and I-FABP-expressing cells, respectively. In I-FABP-expressing cells, the cholesterol-to-phospholipid ratio was significantly decreased, 32% compared to the control, whereas in L-FABP-expressing cells this significant reduction was nearly 50%. Furthermore, similar to the effects on phospholipid metabolism, the extent of the decrease in the cholesterol-to-phospholipid ratio was significantly greater in L-FABP-expressing cells than I-FABP-expressing cells. Because there was little change in the free cholesterol levels, the change in the cholesterol-to-phospholipid ratio was primarily the result of increased phospholipid mass. Nonetheless, these results indicate that this ratio, which is a major determinant of membrane structure, was decreased in L- and I-FABP-expressing cells. These results are consistent with previous reports of increased membrane fluidity in L-FABP-expressing cells (17,20,46).

Phospholipid fatty acid composition. In addition to the cholesterol-to-phospholipid ratio and phospholipid composition, the other major determinant of membrane structure is the phospholipid fatty acid composition. The effect of L- and I-FABP expression on the phospholipid fatty acid composition was determined for the EtnGpl, ChoGpl, PtdIns, and PtdSer (Tables 3–6) in L-FABP-expressing, I-FABP-expressing, and control L-cells.

For EtnGpl, expression of either protein increased the mole percentage of 18:0 and 20:3n-6 1.3- and 1.9-fold, respectively, whereas only L-FABP expression increased the mole percentage of 22:6n-3 (Table 3). Because of the limited increase in PUFA, there was no significant change in the PUFA/saturated fatty acid index, and there was a decrease in the unsaturated/saturated fatty acid index in both L- and I-FABP-expressing cells. Hence, the net result of either L- or I-

TABLE 2
Effect of I- and L-FABP Expression on Plasmalogen Composition and Mass in L-Cells[a]

FABP expression on the EtnGpl fatty acid composition was an increase in saturated fatty acids despite a small, but significant increase in specific PUFA.

Changes observed in ChoGpl were similar to those observed in EtnGpl (Table 4). Of the PUFA, 20:4n-6 and 22:6n-3 mole percentages were increased 2.4- and 2.5-fold in L-FABP- expressing cells, but only the 20:4n-6 mole percentage was elevated in I-FABP-expressing cells. Both proteins significantly elevated the proportion of the n-6 fatty acids relative to the control. Although the percentages of these PUFA were changed in I-FABP-expressing cells, only L-FABP expression significantly elevated PUFA levels and led to an increase in the PUFA/saturated fatty acid index. Because both proteins decreased the mole percentage of 18:1n-9 and 16:1n-7, there was a net decrease in monounsaturated fatty acids (MUFA), resulting in an overall decrease in the unsaturated/saturated fatty acid index. Thus, L- and I-FABP expression altered ChoGpl fatty acid composition, although L-FABP expression appeared to elicit a larger effect.

For PtdSer, expression of either protein had dramatic effects on the fatty acid composition (Table 5). In L-FABP-expressing cells, several PUFA were increased including 2.7-and 1.4-fold increases in 20:3n-6 and 20:4n-6, respectively, relative to the control. These changes, including an increase in 22:6n-3 above the level of detection in L-FABP-expressing cells, resulted in a 2.3-fold increase in PUFA and a 2.4-fold increase in the PUFA/saturated fatty acid index. Even though there is a large decrease in the proportions of 18:1n-9, 16:1n-7, and 18:0 in L-FABP-expressing cells, and to a lesser extent in I-FABP-expressing cells, the 16:0 proportion increased twofold in L-FABP-expressing cells, leaving the overall proportion of saturated fatty acids unchanged in L-FABP-expressing cells relative to control and I-FABP-expressing cells. Thus, in the PtdSer fraction, L-FABP-increased the amount of PUFA, thereby increasing the PUFA/saturated fatty acid index; however, the marked decrease in MUFA left the unsaturated/saturated fatty acid index unchanged. I-FABP expression, on the other hand, had limited effects on PtdSer fatty acid composition, although there was a significant decrease in MUFA/saturated fatty acid index.

L- or I-FABP expression had limited effects on PtdIns fatty acid composition (Table 6). L- and I-FABP expression increased 16:0 proportions nearly 1.8-fold compared to the control. L-FABP-expressing cells had a decreased mole percentage of 18:1n-9; whereas I-FABP-expressing cells had an increase in 18:2n-6 mole percentage. Although the effects by either protein were limited, in both, the overall amount of saturated fatty acids increased, causing a significant decrease in the unsaturated/saturated fatty acid index relative to control.

[a]Values are mole percentages and represent means ± standard deviation, $n \geq 3$. A single asterisk (*) indicates significantly different from the control; double asterisk (**) indicates significantly different from I-FABP-expressing cells, $P < 0.05$. For abbreviations see Table 1 and 3.

The decrease in the mole percentage of 18:1n-9 in L-FABP-expressing cells resulted in a net decrease in MUFA, leading to a decrease in the MUFA/saturated fatty acid index and an increase in the PUFA/MUFA index, illustrating that even though there were no significant changes in individual PUFA, there was nonetheless a net increase in PUFA.

In summary, both L-FABP and I-FABP expression altered phospholipid acyl chain composition, although L-FABP expression appeared to have a greater effect than I-FABP expression. In general, L-FABP expression increased PUFA, predominantly through a 1.5- to 2.5-fold increase in 22:6n-3 and a 1.4- to 2.4-fold increase in 20:4n-6 proportions relative to the control. MUFA was decreased, resulting in a decrease in the unsaturated/saturated fatty acid index but an increase in the PUFA/saturated fatty acid index. In I-FABP-expressing cells, there was a 6–15% decrease in MUFA along with limited changes in PUFA, resulting in a decrease in the unsaturated/saturated fatty acid index. Hence, L-FABP and I-FABP expression differentially affected L-cell phospholipid fatty acid composition.

DISCUSSION

The physiological role(s) proposed for FABP include fatty acid uptake, intracellular metabolism, cellular growth, and differentiation (2,12). Previously, we showed that I- and L-FABP expression in L-cells differentially affects fatty acid uptake (21) and targets exogenous fatty acids for esterification into distinct lipid pools (18,19,21). However, both I- and L-FABP increase the apparent fatty acid intracellular diffusion coefficient (20), indicating both proteins are involved in intracellular fatty acid trafficking, consistent with results showing that FABP stimulate fatty acid transfer between membranes *in vitro* (47,48). Because both I- and L-FABP differentially stimulate an increase in PtdOH synthesis (24), this suggests that both I- and L-FABP expression in L-cells may affect not only phospholipid mass but also the phospholipid acyl chain composition. To determine if I- and L-FABP expression differentially affects these properties, cells expressing either L-FABP or I-FABP and control cells were grown under the same conditions, and the phospholipid acyl chain composition, phospholipid, and cholesterol mass were analyzed.

Phospholipid levels. Prior studies suggested that L-FABP expression, but not I-FABP expression, increased phospholipid mass in L-cells (18,19). In contrast, we show here that L-FABP, and to a lesser extent I-FABP, expression increased total cellular phospholipid mass compared with the control. These data with transfected cells are supported by results showing that L-FABP had a significantly greater effect on PtdOH biosynthesis *in vitro* than I-FABP (24). When the individual phospholipid classes were separated, the effect of I-FABP was limited to increased ChoGpl and PtdSer mass

(Table 1). On the other hand, L-FABP expression increased the mass of all the major phospholipids between 1.4- and 5.6-fold, depending upon the phospholipid class (Table 1). Previous results suggested only CerPCho, ChoGpl, and EtnGpl mass was increased in L-cells expressing L-FABP (18); however, results presented here clearly indicate a robust effect on both PtdIns and PtdSer mass. Thus, L-FABP markedly increased phospholipid mass of all the phospholipid classes, whereas I-FABP expression had a limited effect on total phospholipid mass; and these changes were limited to two phospholipid classes.

Both I- and L-FABP-expressing cells had altered plasmalogen mass and proportions relative to control cells (Table 2). L-FABP expression significantly increased the mass of PlsCho and PlsEtn to a much greater extent than I-FABP expression. Similarly, both proteins differentially increased the mass of the acid-stable fraction. Thus, by analyzing the ChoGpl and EtnGpl subclasses, it became evident that these proteins elevated both the acid-stable and acid-labile fractions relative to the control, indicating I- and L-FABP facilitated not only plasmalogen biosynthesis but also PtdEtn and PtdCho synthesis. Because plasmalogens have a role in lipid-mediated signal transduction (42–44), FABP may support not only the synthesis of PtdIns but also of other phospholipids involved in cell signaling.

Phospholipid composition. In L-cells, expression of L-FABP but not I-FABP significantly altered the phospholipid percentage composition. In L-FABP-expressing cells, total cellular phospholipid composition was dramatically changed, with proportions (mol%) of both PtdIns and PtdSer increased and ChoGpl proportions decreased (Table 1). These results are consistent with data showing plasma membrane phospholipid composition is altered in L-FABP-expressing L-cells (46). We also report an alteration in the composition of ChoGpl and EtnGpl subclasses (Table 2). In L-FABP-expressing cells, PlsEtn proportions, expressed as mole percentage of EtnGpl, were increased. In contrast, I-FABP expression had no effect on the composition of the EtnGpl subclasses. These results indicate that PlsEtn synthesis was increased at the expense of the predominantly diacyl subclass, PtdEtn. In contrast, both I- and L-FABP expression increased PlsCho proportions, once again with a decrease mainly in the PtdCho subclass. Clearly, there was a profound effect on plasmalogen biosynthesis, with the increase in PlsCho proportions suggesting an increase in the utilization of PlsEtn to form the PlsCho (49,50). This increase in PlsCho proportions is important as PlsCho is the active plasmalogen pool involved in signal transduction (42–44,50,51).

Possible mechanisms for enhanced phospholipid synthesis. Several mechanisms may account for the observed increases in phospholipid levels. The general increase in phospholipid mass in the L-FABP-expressing cells may be the result of elevated PtdOH biosynthesis, since L-FABP stimulates PtdOH synthesis *in vitro* (10,23,24). This appears plausible as PtdOH is the central and key intermediate for the Kennedy pathway (52,53). The reported difference in the magnitude of stimulation by L-FABP and I-FABP *in vitro* (24) may account, in part, for the reduced effect of I-FABP expression on L-cell phospholipid mass. In addition, L-FABP, and not I-FABP, has been reported to be localized in the ER as well as the cytosol (12). It is also quite possible that L-FABP affected other enzymes in the Kennedy pathway, in particular, the portion of the pathway involved in PtdIns and PtdSer biosynthesis. These two phospholipids were selectively elevated, suggesting L-FABP expression enhanced more than just PtdOH synthesis and may have stimulated activity of key enzymes in the Kennedy pathway.

Both I- and L-FABP expression increased plasmalogen mass in L-cells. Plasmalogen synthesis requires both peroxisomal (54,55) and microsomal (56–58) steps. Formation of the 1-*0*-alkyl linkage occurs in the peroxisome (54,55), whereas the desaturation of the 1-*0*-alkyl moiety occurs in the microsome (56–58). Because L-FABP has been detected in the ER but not in peroxisomes (12), FABP expression more likely stimulates the microsomal as compared to peroxisomal pathways. However, because L-FABP increased 22:6n-3 proportions to a greater extent than I-FABP and because 22:6n-3 formation is peroxisome-dependent (59), increased plasmalogen mass may merely be the result of an overall increase in peroxisomal function, stimulated to a greater degree by L-FABP expression than I-FABP expression. This postulated increase in peroxisomal function may be correlated with increased fatty acid uptake in L-FABP-expressing cells and the enhancement of peroxisome proliferator-activated receptor activity by L-FABP (60).

Alternatively, because the final steps for plasmalogen biosynthesis are microsomal (56–58), I- and L-FABP expression may also increase desaturase activity. Such a mechanism is consistent with the known (10,23,24) and proposed effects on Kennedy pathway enzymes. Furthermore, expression of either protein dramatically increased levels of PlsCho, which is made using PlsEtn as the direct precursor (49,50). Regardless of whether I- and L-FABP expression enhanced either the peroxisomal steps or the microsomal steps of plasmalogen synthesis or both, expression of either protein increased plasmalogen levels. This elevation in plasmalogens may be very important as plasmalogens are active components of several cascades involved in lipid-mediated signal transduction (42–44, 50,51,61).

Free cholesterol to phospholipid ratio. We also report a large decrease in the cholesterol to phospholipid ratio. Similar to all of the other effects of I- and L-FABP expression on lipid metabolism, L-FABP decreased the cholesterol-to-phospholipid ratio to a greater extent than I-FABP. The decrease in this ratio is consistent with another study indicating L-FABP expression decreased this ratio (17). Furthermore, the lateral membrane mobility in L-FABP expressing cells is reduced (20), consistent with a decrease in the cholesterol-to-phospholipid ratio. The reduction in this parameter may account for the observed decrease in acyl chain order in these cells (17,46).

Phospholipid acyl chain composition. Lastly, expression of either L- or I-FABP caused significant changes in the phospholipid fatty acid composition (Tables 3–6). In general, the effect of FABP expression on phospholipid fatty acids was a decrease in MUFA and an increase in PUFA. For L-FABP, this included a 1.5- to 2.5-fold increase in 22:6n-3 and a 1.4- to 2.4-fold increase in 20:4n-6 proportions (mol%) relative to control. In contrast, I-FABP expression produced limited increases in 20:4n-6 proportions along with a 6–15% decrease in the MUFA. These changes are consistent with binding affinity data showing a preferential binding of PUFA to L-FABP compared to I-FABP (8). Because I- and L-FABP bind both fatty acids and fatty acyl-CoA with a high affinity, these proteins may facilitate interactions of fatty acids and fatty acyl-CoA with CoA-dependent and CoA-independent acyltransferases (62). Within the cellular milieu, L-FABP may exhibit preferential binding for PUFA over MUFA, similar to that observed *in vitro* (8), accounting for the differential effects on PUFA composition in I- and L-FABP-expressing cells. Taken in context with the increased levels of particular phospholipids involved in lipid-mediated signal transduction, an increase in the amount of 20:4n-6 in the phospholipids would increase the amount of 20:4n-6 potentially liberated during signal transduction. This increase in the potential availability of 20:4n-6 could profoundly affect cellular function.

In summary, both L- and I-FABP expression increased total cellular phospholipids; however, the extent of this increase was significantly different between L- and I-FABP-expressing cells. L- and I-FABP expression also differentially affected individual phospholipid levels and phospholipid composition. We speculate that both L- and I-FABP stimulated an increase in phospholipid biosynthesis *via* the Kennedy pathway by affecting not only PtdOH biosynthesis, but also specific enzymes in the pathway, thereby accounting for the increased PtdSer and PtdIns mass. Furthermore, L- and I-FABP increased plasmalogen mass, perhaps indicating an increase in peroxisomal function or ER function or both, especially in the L-FABP-expressing cells. The increased phospholipid levels, in the absence of elevated cholesterol mass, resulted in a substantial decrease in the cholesterol to phospholipid ratio. Lastly, both proteins altered the phospholipid fatty acid composition by increasing the mole percentage of PUFA at the expense of MUFA. In conclusion, L- and I-FABP expression in L-cells differentially enhanced phospholipid synthesis and altered phospholipid fatty acid composition. These findings extend the previously reported differential effect of L- and I-FABP expression on fatty acid uptake (18–21) and targeting (18,19,21). However, the dramatic effects on phospholipid pools involved in cell signaling as well as an increase in 20:4n-6 proportions suggest that FABP may have an important role in maintaining lipid pools used in lipid-mediated signal transduction. Our results suggest L-FABP has a greater role in this process than I-FABP.

Do Glycerolipids Display Lateral Heterogeneity in the Thylakoid Membrane?

Sylvie Duchêne and Paul-André Siegenthaler*

Laboratoire de Physiologie Végétale, Université de Neuchâtel, CH-2007 Neuchâtel, Switzerland

ABSTRACT: The lateral heterogeneity of lipids in the thylakoid membrane has been questioned for over 20 yrs. It is generally believed that glycerolipids are asymmetrically distributed within the plane of the membrane. In the present investigation, we isolated several thylakoid membrane domains by using sonication followed by separation in an aqueous dextran–polyethylene glycol two-phase system. This technique, which avoids detergent treatments, allowed us to obtain stroma and grana lamellae vesicles as well as grana central core and grana margin vesicles from thylakoids. The relative distribution of the four lipid classes, i.e., monogalactosyldiacylglycerol, digalactosyldiacylglycerol, sulfoquinovosyldiacylglycerol, and phosphatidylglycerol, was found to be statistically identical in all four thylakoid fractions and in whole thylakoids. Similarly, the relative amount of fatty acids in each individual lipid and the eight main phosphatidylglycerol molecular species was identical in all thylakoid membrane fractions tested as well as in the intact thylakoid membrane. Based on presently available procedures for obtaining thylakoid subfractions that are unable to discriminate microdomains within the membrane, it is concluded that glycerolipids are evenly distributed within the plane of the thylakoid membrane. These data are discussed in terms of "bulk" and "specific" lipids.

Paper no. L8426 in *Lipids 35,* 739–744 (July 2000).

Glycerolipids are major components of the thylakoid membrane. They consist of four classes: monogalactosyldiacylglycerol (MGDG), digalactosyldiacylglycerol (DGDG), sulfoquinovosyldiacylglycerol (SQDG), and phosphatidylglycerol (PG). These lipids are characteristic of photosynthetic membranes. Galactolipids (MGDG and DGDG) represent about 80 mol% of total lipids and are therefore considered to be the most abundant membrane lipids in the world. In addition, they are characterized by an exceptionally high content of trienoic acids, mainly, α-linolenic acid; additionally, in the so-called 16:3-plants, hexadecatrienoic acid is found in MGDG. SQDG is enriched in palmitic acid (35 mol%), whereas PG contains a unique fatty acid, *trans*-Δ^3-hexadecenoic acid (e.g., 1,2). The fatty acid composition of these glycerolipids is unique and gives rise to a great number of molecular species (3,4). It is surprising that, up to now, none or only a few of these lipid molecular species have been assigned to a specific location in the membrane or to a specific role in the photosynthetic function.

During the past years, several attempts have been made to determine whether, in a manner similar to proteins, acyl lipids are also asymmetrically distributed in the plane of the thylakoid membrane (TM). Among them, the following approaches have been used: (i) mild solvent extraction of freeze-dried membranes (e.g., 5); (ii) fractionation of subchloroplast particles enriched in photosystem I (PSI) or photosystem II (PSII) activities (e.g., 6); (iii) separation of appressed (granal) and nonappressed (stromal) regions of thylakoids (e.g., 7–10); (iv) purification of the membrane protein complexes (e.g., 11–19); (v) detection of glycerolipids by using antibodies directed to individual lipids bound to the surface of the TM, to subchloroplast particles, or to individual proteins (e.g., 20–22, and references therein); (vi) reconstitution of photosynthetic structures and activities with lipids (for a review, see Ref. 23). The general conclusions of these studies are that glycerolipids are asymmetrically distributed within the plane of the TM, although the lateral heterogeneity of thylakoid proteins is much more pronounced than that of lipids (for a review, see Ref. 1).

Several studies argue for this conclusion. For instance, one molecule of MGDG (and possibly one molecule of PG) was found to bind one PSII reaction center complex (18). Furthermore, the fatty acids of these two lipids are much more saturated (50% of the total fatty acids) than those in the bulk lipids of thylakoid and PSII membranes (10% of the total fatty acids). The removal of DGDG from isolated light-harvesting chlorophyll *a/b* protein complex (LHCII) renders the complex unable to form two- or three-dimensional crystals. The ability to crystallize is completely restored by the addition of DGDG at a ratio of about four molecules of DGDG per polypeptide for three-dimensional crystallization, suggesting the existence of several binding sites at the periphery of the trimeric complexes (24). The sulfolipid SQDG was found to be associated with the coupling factor complex (CF_0–CF_1) of spinach (16). This suggests that this acidic glycolipid is

Abbreviations: B3, grana lamellae vesicles; B3-420S, grana central core vesicles (or central core of the appressed region); Chl, chlorophyll; DGDG, digalactosyldiacylglycerol; F695, fluorescence at 695 nm; F740, fluorescence at 740 nm; LHCII, light harvesting chlorophyll *a/b* protein complex; MGDG, monogalactosyldiacylglycerol; PG, phosphatidylglycerol; 420S, grana margin vesicles; SQDG, sulfoquinovosyldiacylglycerol; TM, thylakoid membranes; T3, stroma lamellae vesicles.

firmly bound to the ATP-synthetase complex and may play a special role in the mechanism of energy coupling. Several examples show the involvement of PG molecular species in the maintenance of the structure and function of the TM. In lipid-depleted LHCII, only PG containing 16:1 (3t), but not PG containing 16:0 fatty acids, induced reoligomerization from monomer forms of LHCII (25). In addition, PG is involved in the stacking of thylakoids (23).

Because most of the above methods, especially those for obtaining subchloroplast particles, involved the use of detergents, which are known to partially extract and/or displace lipids (8), in the present investigation we isolated the TM in several domains by using sonication followed by separation in an aqueous dextran–polyethylene glycol two-phase system (26). When comparing the content and the characteristics of lipids in TM, stroma lamellae vesicles (T3) and grana lamellae vesicles (B3), grana central core vesicles (B3-420S) and grana margin vesicles (420S), our results indicate that, considering the domains tested in this investigation, no lateral heterogeneity occurred in the TM.

EXPERIMENTAL PROCEDURES

Preparation of thylakoid vesicles. Spinach plants (*Spinacia oleracea* L.) were grown in a growth chamber at 20°C with a light period of 12 h and incident light intensity of 400 μE/m^2/s. Thylakoids were prepared from leaves according to Andreasson *et al.* (27). After the final centrifugation, the thylakoid preparation was suspended for 45 min in 10 mM sodium phosphate buffer (pH 7.4), 5 mM NaCl, and 100 mM sucrose supplemented with 1 mM $MgCl_2$ to allow a complete stacking of the membranes before fragmentation, then adjusted to 4 mg chlorophyll (Chl)/mL. T3, B3, B3-420S, and 420S were obtained by essentially following the procedure described by Wollenberger *et al.*, (28): (i) thylakoids were mixed with two polymers (5.6 dextran and 5.6% polyethylene glycol), then sonicated on ice (6 × 30 s, with 1-min resting intervals); the mixture was submitted to a series of three partition steps in the same aqueous dextran–polyethylene glycol two-phase system allowing the separation of T3 and B3; (ii) polymers were added to the B3 fraction, and the mixture was sonicated (14 × 30 s, with 1-min resting intervals); then a series of three partition steps in the same aqueous dextran–polyethylene glycol two-phase system allowed the separation of B3-420S and 420S. The four vesicle preparations were diluted 4 to 5 times with the initial suspension medium and centrifuged at 100,000 × *g* for 30 min to remove polymers. The pellets were resuspended in 10 mM sodium phosphate buffer (pH 7.4), 5 mM NaCl, 1 mM $MgCl_2$, and 100 mM sucrose, then adjusted to 1 mg Chl/mL.

Chemical analyses. Total lipids were extracted by adding 4 mL chloroform/methanol (53:37, vol/vol) and 2 mL 0.5 M KCl to the thylakoid suspension (150 μL). This resulted in a two-phase system. The lipids of the lower phase were separated by thin-layer chromatography on silica gel plates (precoated silica gel plates, no. 5626; Merck, Darmstadt, Germany) in two dimensions. Then, MGDG, DGDG, SQDG, and PG were methylated and the resulting fatty acid methyl esters separated and identified by gas–liquid chromatography (29). Molecular species of PG were identified in the TM fraction, T3, and B3-420S by high-performance liquid chromatography following the procedure described by Kito *et al.*, (30), modified by Xu and Siegenthaler, (4). Chl concentration was determined according to Bruinsma (31). The relative content of Chl *a* and *b* was estimated (32).

Photosynthetic activities. Fluorescence emission spectra at 77 K of thylakoid preparations were determined (33).

RESULTS

Characterization of thylakoid domains. Table 1 shows a few biochemical characteristics of the TM and the derived thylakoid domains, i.e., T3, B3, B3-420S, and 420S. When total glycerolipids, i.e., the sum of MGDG, DGDG, SQDG, and PG, were expressed in nmol/mg Chl, μg/mg Chl, or nmol/nmol Chl, the data did not display significant differences between TM and the different fractions. Though there are no statistical values available for expressing the content of total glycerolipids as a function of proteins (nmol/mg protein or μg/mg protein), Table 1 shows that the difference between the values characterizing the TM, grana, and stroma lamellae did not exceed 13.5%. On the basis of the standard deviations calculated for the level of total glycerolipids/Chl, this difference cannot be considered as significant.

As shown by other authors (28), the Chl *a/b* ratio was the highest in stroma lamellae and the lowest in the grana central core. The low-temperature emission of fluorescence at 695 and 740 nm reflects the relative amount of PSII and PSI in the different thylakoid fraction. In Table 1, we see that the thylakoid membrane was slightly enriched in PSII (F_{695}/F_{740} = 1.2, where F_{695} is the fluorescence at 695 nm and F_{740} is the fluorescence at 740 nm). When TM was fractionated in distinct domains, the two photosystems were not distributed uniformly. B3 and B3-420S, which are enriched in PSII, displayed the highest F_{695}/F_{740} ratio values, whereas T3 exhibited a very low value. The 420S had intermediate F_{695}/F_{740} ratio values. Altogether, these results confirmed that the foregoing thylakoid fractions, which originate from different TM domains, are distinct and well-defined, as described in the literature (34).

Composition of lipids, fatty acids, and PG molecular species. The composition in lipid classes (MGDG, DGDG, SQDG, and PG) of four TM domains compared to that of the whole membrane is shown in Table 2. The relative amount of each lipid, expressed as mole percentage, in TM was similar to the values published in the literature (1). The relative distribution of the four lipid classes in T3 and B3, as well as in B3-420S and 420S, was statistically identical. This shows that these domains displayed the same relative lipid distribution as that observed in the whole TM. In a similar fashion, the relative amount of fatty acids in each individual lipid was identical in the four TM domains as well as in the whole TM (Table 3).

TABLE 1
Biochemical Characteristics of Thylakoid Membrane Domains

Membrane characteristic	Thylakoid membrane domain[a]				
	TM	T3	B3	B3-420S	420S
Total glycerolipids					
nmol/mg Chl	1641 ± 162 (n = 7)	1788 ± 272 (n = 10)	1586 ± 40 (n = 4)	1601 ± 151 (n = 11)	1806 ± 116 (n = 4)
μg/mg Chl[b,c]	1319 ± 130	1437 ± 219	1275 ± 32	1287 ± 121	1452 ± 93
nmol/nmol Chl[c,d]	1.48 ± 0.15	1.61 ± 0.24	1.43 ± 0.04	1.45 ± 0.13	1.63 ± 0.10
nmol/mg protein	560	520	590	ND[e]	ND

Protein[f]					
μg/mg Chl	2900	3400	2700	ND	ND
Chl *a*/*b* (n = 12)	2.8 ± 0.1	4.0 ± 0.1	2.2 ± 0.1	2.1 ± 0.1	2.6 ± 0.2
F_{695}/F_{740} ratio	1.2 ± 0.2 (n = 12)	0.3 ± 0.1 (n = 12)	3.9 ± 0.3 (n = 7)	4.6 ± 1.5 (n = 10)	2.4 ± 0.9 (n = 4)

[a]TM, thylakoid membranes; T3, stroma lamellae vesicles; B3, grana lamellae vesicles; B3-420S, grana central core vesicles; 420S, grana margin vesicles; F695/F740, ratio of fluorescence at 695 nm compared to fluoresence at 740 nm; Chl, chlorophyll.
[b]Total glycerolipids expressed in μg/mg Chl were calculated by taking into consideration the molecular weight of each lipid class and the relative amount of each lipid class in the thylakoid membrane.
[c]The number of experiments (n) for the calculation of the standard deviation is the same as that indicated in the second line of this table.
[d]Total glycerolipids expressed in nmol/nmol Chl was calculated by taking into consideration the molecular weights of chlorophyll *a* and *b* and the Chl *a*/*b* ratio.
[e]ND, not determined.
[f]Protein content is from Albertsson *et al.* (26).

It is well established that in spinach plants, a chilling-resistant species, thylakoids contain 10 molecular species of PG, three of them, 18:3/16:1(3t), 18:3/16:0 and 16:0/16:1(3t), being prominent (3,4). PG molecular species were determined only in two thylakoid domains, i.e., T3 and B3-420S, because of the lack of material in the other fractions. Concerning the eight main PG molecular species, there were no differences between the two fractions and the TM (Table 4).

DISCUSSION

The four TM domains (T3, B3, B3-420S, and 420S) used in this study were obtained after a series of sonication and repeated partition steps in an aqueous dextran–polyethylene glycol two-phase system. Compared to other techniques using detergents to solubilize the membrane, the two-phase system technique offers real advantages, namely, in avoiding unverifiable displacement and selective extraction of lipids, which generally occurs in the presence of detergents and therefore may generate biased conclusions.

According to the pioneering work of Murphy and Woodrow, (9) and Gounaris *et al.*, (7), who used a similar experimental approach to isolate B3 and T3, TM was found to display considerable lateral heterogeneities in the distribution of all major membrane components, including lipids. On the contrary, the present results show quite clearly that the relative distribution of the four lipid classes (MGDG, DGDG, SQDG, and PG), as well as the relative amount of fatty acids in each individual lipid and the main PG molecular species, was statistically identical in all four thylakoid fractions and in intact thylakoids. This finding is quite important for understanding the molecular organization of lipids in the TM and argues in favor of the existence of two types of lipid molecules, i.e., the bulk lipids and the specific lipid molecules. This hypothesis was first proposed in 1980 (35) and subsequently refined (36,37).

TABLE 2
Composition in Lipid Classes of Four Thylakoid Membrane Domains[a]

Thylakoid fractions	Lipid class[b] (mol%)			
	MGDG	DGDG	SQDG	PG
TM (n = 7)	50 ± 1	28 ± 2	9 ± 1	13 ± 2
T3 (n = 10)	51 ± 1	28 ± 3	9 ± 1	12 ± 2
B3 (n = 4)	47 ± 4	27 ± 2	12 ± 3	14 ± 3
B3-420S (n = 11)	49 ± 6	29 ± 3	10 ± 3	12 ± 2
420S (n = 4)	52 ± 1	28 ± 2	10 ± 2	10 ± 1

[a]MGDG, monogalactosyldiacylglycerol; DGDG, digalactosyldiacylglycerol; SQDG, sulfoquinovosyldiacylglycerol; PG, phosphatidylglycerol; for other abbreviations see Table 1.
[b]The mol% values are calculated from the data shown in Table 1. For each thylakoid fraction, the 100% values corresponded to the sum of the four acyl lipids.

TABLE 3
Fatty Acid Composition of the Four Lipid Classes in Various Thylakoid Membrane Domains

Acyl lipid Thylakoid fraction	Fatty acid[a] (mol%)						
	16:0	16:1(3t)	16:3	18:0	18:1	18:2	18:3

[a]Tr, traces (less than 1 mol%). Results are expressed in mol% for each lipid class. For TM, 100% values corresponded in nmol/mg Chl to 825 ± 89 for MGDG, 450 ± 57 for DGDG, 140 ± 12 for SQDG, and 214 ± 45 for PG; for T3 fraction, to 924 ± 143, 501 ± 103, 158 ± 20, and 214 ± 43; for B3 fraction, to 745 ± 38, 428 ± 13, 190 ± 20, and 222 ± 64; for B3-420S, to 774 ± 101, 474 ± 77, 163 ± 62, and 190 ± 43; for 420S fraction, to 944 ± 53, 510 ± 47, 181 ± 26, and 171 ± 11. For other abbreviations see Tables 1 and 2.

The bulk lipids predominate in the TM and fill the spaces between the various proteins. They can be considered as having a structural role. For instance, they offer a hydrophobic matrix to the proteins and pigments and, owing to their high degree of unsaturation, confer an appropriate fluidity to the membrane. In addition, MGDG, which is the major lipid in the TM, can form, under certain conditions, nonbilayer configurations and therefore influence the structure and the photosynthetic function of the membrane (38). The analyses of lipids in the different domains of the membrane (Tables 2–4) concern the bulk lipids and reveal that the level of the four lipid classes (MGDG, DGDG, SQDG, and PG), the nature of their acyl chains, and the main molecular species of PG are identical in B3 and T3, as well as in B3-420S and 420S.

By contrast, the specific lipids are by nature less abundant than the bulk lipids, but especially much more saturated than the bulk lipids (15,18,19). These specific lipid molecules can be considered as functional or strategic lipids. They are involved in specific interactions with proteins, resulting in an appropriate maintenance of the conformation and/or orientation of protein molecules in the membrane and high photosynthetic performances. These lipids are encountered in the four lipid classes and display specific functions. For instance, MGDG sustains charge separation (18), DGDG induces three-dimensional crystallization of the LHCII (24), and SQDG is associated with the structure and function of the coupling factor complex (16). In addition, specific molecules of PG have been reported to be involved in oligomerization of LHCII (25), the stacking of thylakoids (23), and the support of the electron flow activity (39,40). The specific lipid molecules are, of course,

TABLE 4
Composition in PG Molecular Species of Four TM Domains[a]

Thylakoid fraction	Molecular species (mol%)							
	18:3/16:1(3t)	18:3/16:0	18:2/16:1(3t)	18:2/16:0	18:1/16:1(3t)	16:0/16:1(3t)	18:1/16:0	16:0/16:0
TM (n = 8)	61.8 ± 4.3	10.6 ± 1.8	5.2 ± 2.7	6.0 ± 1.6	2.8 ± 1.4	9.6 ± 1.1	1.2 ± 0.7	2.8 ± 1.9
T3 (n = 11)	63.2 ± 4.8	11.1 ± 1.3	4.5 ± 1.6	6.0 ± 1.7	2.4 ± 1.1	9.7 ± 2.1	1.6 ± 1.5	1.5 ± 1.4
B3-420S (n = 11)	64.2 ± 4.9	9.7 ± 1.1	5.3 ± 2.1	5.7 ± 1.7	2.8 ± 1.7	9.5 ± 1.3	1.4 ± 0.8	1.4 ± 1.5

[a]The 100% values correspond to 209 ± 35 nmol PG/mg Chl for TM, 208 ± 37 nmol PG/mg Chl for T3, and 185 ± 31 nmol PG/mg Chl for B3-420S; n = number of experiments. The 18:0/16:1(3t) and 18:0/16:0 PG molecular species were found only in trace amounts. For abbreviations see Tables 1 and 2.

concentrated at different locations in the membrane where they are associated with their interacting protein(s). But, owing to their scarcity, they do not change the global composition and the distribution of the four classes of lipids between the membrane domains considered in this study (Tables 1–4).

In conclusion, we propose that the current model of thylakoid membrane lipid composition is one that contains simultaneously bulk and specific lipids. Current experimental evidence (as described in this investigation) indicates that only the latter ones display lateral heterogeneity in the membrane.

ACKNOWLEDGMENTS

This research was supported in part by the Swiss National Science Foundation (grants number 31.336 93.92 and 31.432 97.95). The authors thank very much Per-Åke Albertsson and his collaborators for help and advice in preparing thylakoid vesicles. This work is part of a doctoral program that has been carried out by Sylvie Duchêne in the Laboratoire de Physiologie végétale, Université de Neuchâtel, Switzerland.

ABSTRACT: Larval Dover sole fed an *Artemia* diet supplemented with n-3 long-chain (C_{20} + C_{22}) polyunsaturated fatty acids (PUFA) are known to be more resistant to low-temperature injury. Here we explore the relationship between tissue fatty acid composition and tolerance of stressful environmental conditions over the larval and early juvenile periods. *Artemia* nauplii supplemented with n-3 long-chain PUFA-deficient and PUFA-enriched oil emulsions were fed to two groups of larvae. Whole body tissue samples from the resulting PUFA-deficient and -enriched juveniles possessed 12.1 and 21.9% n-3 long-chain PUFA, respectively. These differences were at the expense of C_{18} PUFA, while proportions of saturated fatty acids, monounsaturated fatty acids, and total PUFA were unaffected. Brain and eye tissues from the PUFA-deficient fish contained lower levels of 22:6n-3, known to be important for optimal nervous system function, incorporating instead a range of fatty acids of lower unsaturation. PUFA-deprived juveniles showed substantially greater mortality when exposed to a combination of low temperature and low salinity, as well as to high temperature and to hypoxia. After adaptation to the different diets, both dietary groups were fed a common formulated feed high in n-3 long-chain PUFA. Tissue PUFA in both groups progressively increased to the same high value, with a consequent loss of the differences in cold-susceptibility. These correlated changes support a link between dietary manipulation of n-3 long-chain PUFA and development of a stress-sensitive phenotype. PUFA deprivation had no detectable effect upon static hydrocarbon order of purified brain membranes (as assessed by fluorescence polarization) but was associated with an increase in the whole-body content of prostaglandins. We conclude that susceptibility to environmental stress is responsive to dietary n-3 long-chain PUFA manipulation, possibly due to altered tissue development or the overproduction of eicosanoids.

Abbreviations: AA, arachidonic acid (20:4n-6); ANOVA, analysis of variance; DHA, docosahexaenoic acid; DPH, 1,6-diphenyl-1,3,5-hexatriene (22:6n-3); EPA, eicosapentaenoic acid (20:5n-3); GLC, gas–liquid chromatography; ICES, International Council for Exploration of the Seas; MUFA, monounsaturated fatty acids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PGE, prostaglandin E; PUFA, polyunsaturated fatty acid; SFA, saturated fatty acid; TLC, thin-layer chromatography.

Resistance of fish to biotic and abiotic environmental stress is heavily dependent upon health and physical condition, and circumstances leading to a loss of condition may significantly affect survival. The control of whole organism environmental tolerance has practical significance in aquaculture of marine fish larvae where the emphasis has focused on maximizing larval numbers at the expense of larval condition. Consequently, it is common for artificially reared marine fish to display reduced resistance to environmental stress when compared with wild-caught individuals. It seems clear, for some commercially important species at least, that larval production techniques have not yet been properly optimized, nor have the factors that contribute to reduced larval quality been identified.

There is evidence that whole-animal resistance to thermal stress is linked to the biophysical structure and lipid composition of cellular membranes (1). The primary lesion of thermal damage has been identified as a disruption of the physical structure of cellular membranes. Secondary effects such as loss of barrier properties and subsequent increased permeability may be followed by tertiary effects caused by impairment of important homeostatic processes, notably respiration and neuromuscular coordination, leading ultimately to death (1). The brain is certainly critical in defining thermal limits in adult fish since direct manipulations of brain temperature can ameliorate or enhance the early symptoms of thermal damage without effects on other body functions (2). The principal evidence in support of the lipid theory of acquired thermotolerance comes from the correlated changes in thermotolerance during thermal acclimation of fish with changes in the lipid saturation and biophysical structure ("fluidity") of brain membranes (3,4).

Neuronal tissue is somewhat unusual in that its lipid requirements for successful development, differentiation, and function are quite specific. The cell membranes of these tissues are enriched in n-3 long-chain (C_{20} + C_{22}) polyunsaturated fatty acids (PUFA), particularly docosahexaenoic acid (DHA, 22:6n-3). In fish retina DHA can exceed 50% of the total fatty acids in membrane phospholipids (5). Studies on rats have shown this pool of specific membrane PUFA may be highly conserved during starvation or dietary manipulation (6), but restriction of these lipids during early life stages

may have serious consequences for nervous system development. A good example is the effect of DHA deficiency upon visual performance at low light intensities in juvenile herring (7). Deficiency during development resulted in decreased levels of 22:6n-3 in retinal phospholipid molecular species, which correlated with a reduced feeding ability at low light intensities. This depression in feeding efficiency of the juvenile would have effects upon growth rate and subsequent survival. In humans, functional impairment caused by a dietary insufficiency in early life stages may not be rectified by subsequent sufficiency (8), suggesting some interference with the ontogenetic progression of neuronal cells and tissue into an otherwise functional system.

Dietary lipid deficiency may also have additional adverse effects, including the overproduction of certain PUFA-derived eicosanoids. Eicosanoids are cellular mediators involved in a whole range of transient signaling events and are formed from both n-3 and n-6 long-chain PUFA (9,10). Enhanced levels of the bioactive 2-series eicosanoids (e.g., prostaglandin E_2, PGE_2) derived from arachidonic acid (AA, 20:4n-6) are implicated in a host of pathological conditions, including thrombosis, tumor growth, atherosclerosis, and immune inflammatory disorders (11,12). However, high levels of dietary eicosapentaenoic acid (EPA, 20:5n-3) and DHA are thought to ameliorate these effects by reducing the synthesis of AA-derived eicosanoids (13).

Successful rearing of marine fish larvae requires specific fatty acid supplementation of the diet (14). In contrast to terrestrial food webs, the marine food chain is rich in n-3 long-chain PUFA, particularly 20:5n-3 and 22:6n-3, produced by the basal unicellular phytoplanktonic algae (15). As a result marine fish have no endogenous capacity for essential long-chain PUFA production and are entirely dependent upon dietary provision. Recent work has demonstrated that the survival of juvenile Dover sole, *Solea solea,* to low temperatures (5°C) is improved by supplementation of their *Artemia* diet with n-3 long-chain PUFA-enriched emulsions. Thus, the larval and juvenile diet appears to define the thermotolerance of subsequent stages (16). This offers a very clear-cut model with which to explore the influences of larval nutrition upon environmental stress resistance (i.e., quality) of both larval and subsequent life history stages. We have thus fed larval and juvenile Dover sole *Artemia* diets enriched with high or low n-3 long-chain PUFA contents and assessed their tolerance to high and low lethal temperatures and to hypoxia.

MATERIALS AND METHODS

Larval rearing procedures. All fish-handling and experimental procedures were performed in accordance with and under the control of the Home Office 1986 Animal Procedures Act (U.K.), and reviewed by the Natural Environmental Research Council (U.K.). Sole larvae were hatched from the same batch of naturally spawned eggs from a captive broodstock maintained under the conditions described by Baynes *et al*. (17). The eggs were incubated at 12 ± 1°C. Two to three days after hatching the yolk-sac larvae were transferred to 60-cm diameter mat-black rearing tanks containing 60 L of seawater. Each tank was gently aerated through a single diffuser block and received a continuous supply of fresh seawater. Illumination was provided by fluorescent lights set to follow the ambient photoperiod. Similarly, temperature changes followed approximately the natural cycle and increased from 14 to 18°C during the rearing period.

Following eye pigmentation and opening of the mouth, larvae were fed newly-hatched *Artemia* nauplii for 5 d before the introduction of the variously enriched *Artemia*. Food was added twice daily in sufficient quantity to provide excess at all times. The *Artemia* cysts were hatched at 28°C for 24 h in 80 L cylindroconical tanks. The nauplii were enriched for 24 h in identical tanks stocked with 150 nauplii per mL. The lipid emulsion was added during the morning and evening at a rate of 150 mg emulsion/L/100,000 nauplii. *Artemia* harvested during the morning were stored at 4–5°C until used.

Larval and juvenile feeding regimes. Two 60-L rearing tanks were each stocked with about 3,000 yolk-sac larvae hatched from the same batch of eggs. After an initial 4–5 d period of feeding on newly hatched *Artemia* nauplii of San Francisco origin, larvae were subsequently fed Great Salt Lake *Artemia* which had been previously enriched for 24 h with different lipid emulsions. One diet was supplemented with a lipid emulsion containing high proportions of n-3 long-chain PUFA (high-PUFA) [30/4/C/5 (order code); International Council for Exploration of the Seas (ICES) standard emulsions, Laboratory of Aquaculture and *Artemia* Research Centre, Ghent, Belgium] and the other enriched with a low-PUFA (θ/-/C/3; ICES) emulsion of equal lipid content. Batches of sole were also reared on *Artemia* enriched with the low-PUFA emulsion to which had been added high proportions of EPA (EPA/25/C; ICES). These standard reference emulsions facilitate comparisons in marine aquaculture research, and the quantities used were based upon what is known of the dietary lipid requirements for marine fish.

Fifty-five days after hatching, when approximately 3 cm in length, all fish were transferred to weaning tanks of a similar design and weaned onto a common formulated feed (agglomerated weaning diet, 98042 size 0.8–1.4 mm; SSF, Bergen, Norway) which also contained high proportions of n-3 long-chain PUFA (18).

Stress tests. Juveniles were subjected to short-term stress tests at intervals pre- and postweaning. Each challenge involved abrupt transfer from the rearing tanks to experimental tanks with sea water of (i) low temperature and low salinity (3°C, 10‰), (ii) high temperature (32°C), and (iii) hypoxia (10% oxygen saturation). Tests were carried out using mesh-bottomed trays, divided into compartments (0.6 L), held in the experimental tank. Conditions in each of the tray compartments mirrored those of the whole tank. For each experiment, groups of fish from each dietary treatment were simultaneously transferred to the experimental tanks. At intervals of 2–3 h, groups of 20 fish were successively removed to a recovery tank of ambient temperature and salinity (16–17°C,

30 ± 2‰), where they were allowed to recover for 24 h before survival was assessed. For hypoxia experiments, the oxygen content of the experimental tank was reduced by bubbling with oxygen-free N_2 gas. Fine control of P_{O_2} was achieved with an oxygen meter in the tank and a flow meter on the N_2 gas supply. P_{O_2} was uniform throughout the experimental tank.

Lipid extraction and fatty acid analysis. Fatty acid compositional analysis was performed for lipid emulsions, enriched *Artemia* diets, and whole carcass of the larval and juvenile Dover sole throughout the rearing period. Sole were stunned by a blow to the head and killed by bisection of the spinal cord. Carcasses were chopped, blended, and homogenized in 1–5 mL of water, and total lipid was extracted following the method of Bligh and Dyer (19). Lipids were separated by silica gel thin-layer chromatography (TLC) using a neutral solvent of hexane/diethyl ether/acetic acid (80:20:2, by vol). The polar lipids at the origin (primarily phospholipids) were eluted by washing with 2:1 chloroform/methanol (vol/vol) containing 0.005% butylated hydrooxytoluene, dried under flowing N_2 gas, and methylated by heating at 100°C with 14% boron trifluoride–methanol complex (20). The fatty acid methyl esters were analyzed by gas–liquid chromatography (GLC; 610 Series F.I.D. gas chromatograph; ATI Unicam, Cambridge, United Kingdom) on a free fatty acid phase fused-silica capillary column, 30 m × 0.25 mm (J&W Scientific, PhaseSep, Clwyd, United Kingdom). The methyl esters were identified by comparing peak retention times with those of known standards whose identity had been confirmed by mass spectrometry (courtesy of Dr. D. Tocher, University of Stirling). The fatty acid composition of whole eye and brain phospholipids was also assessed. Phospholipids were separated by two-dimensional TLC (21) using solvent systems of chloroform/methanol/7 M ammonia (103:40:7, by vol) and chloroform/methanol/acetone/acetic acid/water (47:16:63:16:8, by vol) in the first and second directions, respectively. Phospholipids were revealed by spraying with Rhodamine 6G, and phosphatidylcholine (PC) and phosphatidylethanolamine (PE) fractions were collected and processed for GLC analysis.

Assessment of brain membrane order. Whole brain membrane samples were prepared by modification of established procedures (22,23). All procedures were carried out at 0–4°C. Three replicate groups of 20 sole (length 40–50 mm) from each dietary treatment were stunned by a blow to the head and their spinal cords severed. Brains were rapidly removed, placed in 15 mL of ice-cold isolation medium (280 mM sucrose, 2 mM EDTA, 20 mM imidazole, pH 7.4), cut, blended, and homogenized before centrifugation at 1000 × *g* for 10 min. The supernatant was centrifuged at 12,000 × *g* for 30 min, and the upper white portion of the pellet was gently resuspended and homogenized in 15 mL of lysing medium (1 mM EDTA, 10 mM imidazole pH 7.4) before centrifugation at 20,000 × *g* for 30 min. The resulting crude synaptosomal pellet was then resuspended by gentle homogenization in 2.5 mL 10 mM imidazole pH 7.4.

Membrane biophysical order was determined by steady-state fluorescence polarization on a PC1 spectrofluorometer (ISS Inc., Urbana, IL) using anisotropy measurements of the probe 1,6-diphenyl-1,3,5-hexatriene (DPH) (24). A small aliquot of the brain membrane preparation was added to 2.5 mL of 0.1 M potassium phosphate buffer (pH 7.1) in a 10-mm pathlength quartz cuvette to give an optical density of 0.10 at 500 nm. Two microliters of 2 mM DPH dissolved in tetrahydrofuran was added while mixing with a pipette. The probe was left to equilibrate with the membranes for 10 min at room temperature prior to the polarization assays. The temperature of the cuvette block was controlled to ±0.1°C by circulating water from a computer-controlled thermostated bath. Polarization scans were performed from 5 to 40°C at a rate of increase of 1°C/min. The measurement temperature within the cuvette was recorded to ±0.1°C by computer *via* a digital thermistor probe.

Extraction and enzyme immunoassay of prostaglandins. Gill tissue from six fish and whole carcass samples were taken for prostaglandin analysis after the feeding of the different *Artemia* diets. Gill tissue is a major source of prostaglandins, thought here to be involved in cellular osmoregulatory function (13). Samples were weighed and then homogenized in 3 mL Hanks balanced salt solution (without calcium) containing 0.45 mL absolute ethanol and 0.15 mL 2M formic acid. Homogenates were then frozen in liquid nitrogen and stored at −20°C. Eicosanoid extraction and measurement of total PGE content were as given in Bell *et al*. (13). Total PGE was determined using a commercial enzyme immunoassay kit for PGE_2 (SPI-Bio, Massy, France).

Statistical analysis. Fatty acid composition, fish length, and prostaglandin data were analyzed using one-way analysis of variance (ANOVA). For stress test data, the numbers surviving at each time period were modeled as a binomially distributed random variable within a generalized linear model (25) of time and dietary effects. This model was fitted with a probit link with time expressed on a log scale to base 2, with zero time given the value zero on the log scale. Hence:

$$\text{number of survivors at time } t = \text{number of fish} \times \Phi(a + b \log_2 t) \quad [1]$$

where Ø is the normal distribution function and the intercept *a* depends on the dietary treatment. Model terms were tested assuming a chi-square distribution for the decrease in the deviance following the introduction of a model term.

RESULTS

Dietary lipids and effects upon tissue fatty acid composition. Total lipid fatty acid compositions of the low-PUFA and high-PUFA emulsions are shown in Table 1. The high-PUFA emulsion possessed appreciable proportions of EPA and DHA, whereas the low-PUFA emulsion contained no n-3 long-chain PUFA. The effects of these emulsions on *Artemia* lipid composition are shown in Table 2. *Artemia* fed the PUFA-deficient diet contained small proportions of 20:5n-3 but negligible amounts of other long-chain PUFA. In contrast, the n-3 PUFA-enriched *Artemia* contained considerable amounts of

n-3 LC PUFA	6.6 (0.1)	18.9 (0.8)	31.3 (2.0)	26.3 (0.9)
n-3/n-6	2.9 (0.1)	4.5 (0.3)	7.2 (0.5)	2.4 (0.2)

[a]Values are means for three different samples and are given as weight % (±SD) of total composition. Only fatty acids present at >2% are shown.
[b]Low + EPA refers to *Artemia* enriched with the low-PUFA emulsion to which had been added high proportions of eicosapentaenoic acid (EPA, 20:5n-3).
[c]Formulated feed weaning diet was fed to all fish 55 d after hatching. For abbreviations, see Table 1.

Whole carcass phospholipid fatty acid compositions of each treatment group were determined over the full larval stage (days 9–55 after hatching) and up to 70 d after weaning. Dietary lipid composition had a major influence on membrane phospholipid content; during the *Artemia* feeding stage, fish fed the PUFA-enriched diet possessed 21.9% n-3 long-chain PUFA compared to 12.1% for the deficient sole, with correspondingly greater proportions of the C_{18} PUFA 18:2n-6 and 18:3n-3 in the latter (Table 3). By contrast, the proportions of saturated fatty acids (SFA), monounsaturated fatty acids (MUFA), and total PUFA were very similar. Also shown for comparison are data for wild-caught sole of similar size. These fish contained 5% greater proportion of SFA and much smaller proportions of MUFA. Of particular significance is the greater proportion of n-3 long-chain PUFA, even compared to those reared in the laboratory with high-PUFA food; thus 22:6n-3 constituted over 30% of all fatty acids in the wild specimens, compared to only 10% for the PUFA-enriched reared fish. Wild fish also possessed negligible levels of C_{18} PUFA.

Figure 1 shows how the proportions of the different fatty acid classes for whole carcass polar lipids of the sole varied over the full rearing period. All fish were adapted to the same n-3 long-chain PUFA-rich agglomerated diet (Table 2) 55 d after hatching. For reference, metamorphosis occurred approximately 20 d posthatching. There was little difference between the two treatment groups during the entire rearing period, although the low-PUFA group possessed elevated proportions of PUFA and reduced proportions of MUFA during the early postweaning phase.

[a]Values are means for three different samples and are given as weight % (±SD) of total composition. Only fatty acids present at >2% are shown.
[b]Low + EPA refers to *Artemia* enriched with the low-PUFA emulsion to which had been added high proportions of EPA. For abbreviations, see Tables 1 and 2.
[c]The composition of wild-caught sole of comparable size is also given.

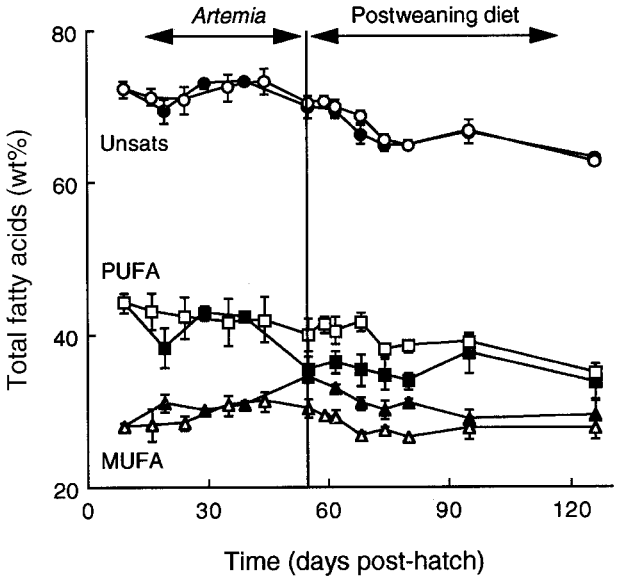

FIG. 1. Proportions of monounsaturated (MUFA; △, ▲), polyunsaturated (PUFA; □, ■), and total unsaturated (unsats) fatty acids (○, ●) in Dover sole whole carcass polar lipids during the *Artemia* and postweaning feeding periods. Fish were fed either low-PUFA (△, □, ○)- or high-PUFA (▲, ■, ●)-enriched *Artemia* diets. Data points represent means from three replicate samples and are given as weight % (±SD) of total fatty acid composition.

Figure 2 shows the proportion of n-3 long-chain PUFA during the rearing period. During the *Artemia* feeding stage, the high-PUFA juveniles possessed high proportions (20–25%) of these fatty acids, whereas the low-PUFA sole contained much lower proportions (11–14%). Upon weaning at day 55, when all fish were fed the same PUFA-rich diet, PUFA levels in the previously deficient sole progressively increased over 30 d, leading to a convergence in the n-3 long-chain PUFA contents.

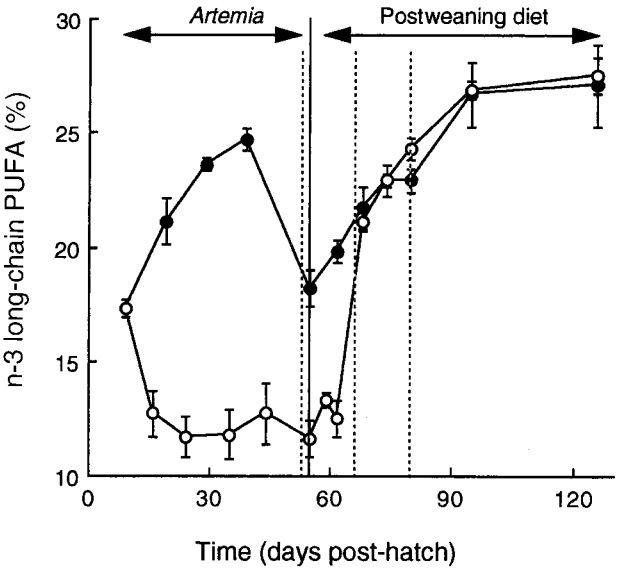

FIG. 2. n-3 Long-chain PUFA content of sole whole carcass polar lipids during the *Artemia* and postweaning feeding periods. Fish were fed either low-PUFA (○)- or high-PUFA (●)-enriched *Artemia* diets. Data points represent means from three replicate samples and are given as weight % (±SD) of total fatty acid composition. Solid line represents transfer from the different *Artemia* diets to the common weaning diet (day 55). Dashed lines indicate time points for the low-temperature and low-salinity stress tests shown in Figure 3. For abbreviation, see Figure 1.

Temperature and hypoxic stress tests. Results for combined low-temperature and low-salinity stress tests, performed at preweaning and 2 and 4 wk postweaning (indicated by vertical dashed lines in Fig. 2), are shown in Figure 3. Statistical analysis of the data (Table 4) showed that before weaning (Fig. 3A), the high-PUFA sole were significantly more resistant than the low-PUFA group. Here, 50% mortality was evident after 4.3 h in the low-PUFA group and 10.6 h in the high-PUFA group. After 2 wk of being fed the same postweaning diet (Fig. 3B), tolerance in the low-PUFA fish increased with a 50% mortality of 7.0 h compared to 9.8 h in the high-PUFA group, yet the difference was still significant (Table 4). However, at 4 wk postweaning (Fig. 3C), there was no significant difference (Table 4) between the two groups, i.e., 50% mortality at ~10.5 h. Thus, the low-PUFA group had increased resistance similar to that of the high-PUFA group. Similarly, results from a hypoxia stress test (Fig. 4) for preweaned sole showed that members of the high-PUFA group were significantly more resistant (Table 5); 50% mortality occurred at 14.1 h compared to 8.9 h in the low-PUFA group. Treatment groups were also tested at high lethal temperature (32°C, results not shown) with identical results, that is, the high-PUFA sole were more tolerant.

EPA supplementation. To ascertain whether other n-3 long-chain PUFA can substitute for 22:6n-3 in promoting stress resistance, batches of sole larvae were fed *Artemia* enriched with the low-PUFA emulsion to which had been added high proportions of EPA. This EPA-enriched diet contained high levels of EPA but no DHA (Table 2). Effects of this diet on Dover sole lipid composition are shown in Table 3 and Figure 5. First, proportions of n-3 long-chain PUFA in the high- and EPA-enriched sole were very similar, 21.9 and 23.1%, respectively (Table 3). Very high proportions of EPA were evident in the EPA-enriched fish (Fig. 5A). Proportions of DHA were low and more comparable to the low-PUFA fish (Fig. 5B). On feeding the DHA-rich postweaning diet, the proportion of EPA fell rapidly to be replaced by DHA.

Stress resistance of the EPA-enriched fish was compared to the zero- and high-PUFA sole for hypoxia (Fig. 4) and combined low temperature and low salinity (Fig. 6). The

TABLE 4
Statistical Analysis of Survival Data for Low-PUFA and High-PUFA Sole Subjected to Low Temperature/Salinity Stress Tests[a]

Stress test period	df	X^2	Probability[b]	Significance
Prewean	1	66.0	<0.001	S
2 wk Postwean	1	11.1	<0.001	S
4 wk Postwean	1	0.7	<0.5	NS

[a]Results shown in Figure 3.
[b]See the Materials and Methods section for details of statistical analysis. S, significant; NS, not significant; for other abbreviation, see Table 1.

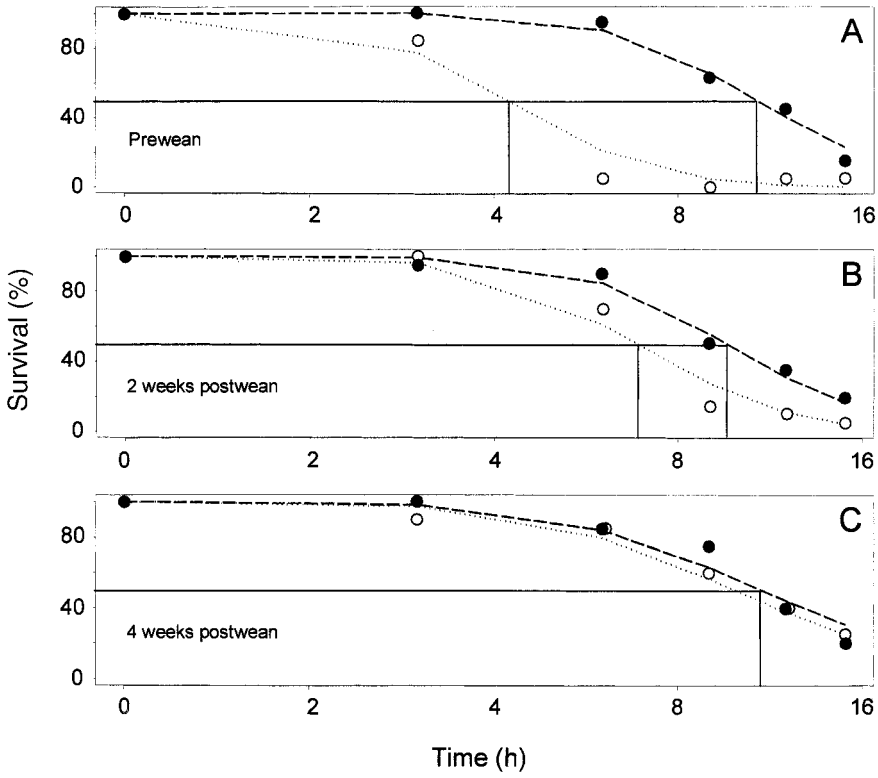

FIG. 3. Effect of dietary treatment on stress tolerance of Dover sole subjected to low temperature and low salinity (3°C, 10‰). Fish were fed either low-PUFA (○)- or high-PUFA (●)-enriched *Artemia* diets. Each data point is for 20 fish. Results are given for experiments performed before weaning (A) and 2 wk (B) and 4 wk (C) postweaning. For abbreviation, see Figure 1.

EPA-enriched fish possessed similar high resistance in each test, similar to that of the high-PUFA sole, indicating that a high dietary EPA content also confers the stress-resistant phenotype. Statistical analysis (Table 5) showed the significant differences between the low-PUFA and both n-3 PUFA-enriched groups accounted for nearly all of the dietary effects, implying no difference between the EPA and high-PUFA treatments.

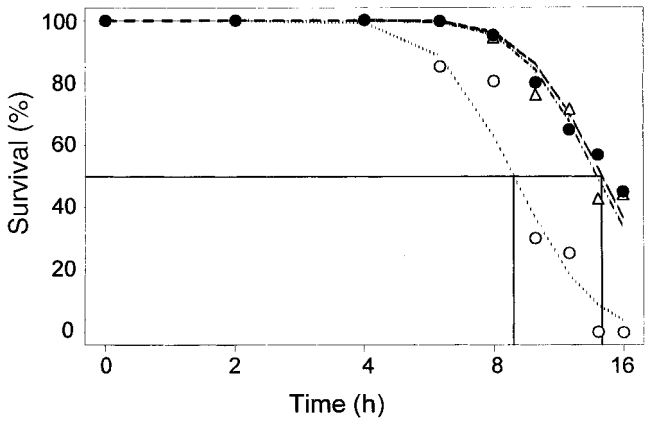

FIG. 4. Effect of dietary treatment on stress tolerance of Dover sole subjected to hypoxia (10% full aeration). Fish were fed either low-PUFA (○), high-PUFA (●), or low-PUFA + eicosapentaenoic acid (EPA; △)-enriched *Artemia* diets. Each data point is for 20 fish. For other abbreviation, see Figure 1.

Brain and eye lipids. The proportions of long-chain PUFA in brain and eye phospholipids from the different dietary groups are shown in Figure 7. The small size of the eye prevented the quantification of retinal fatty acid composition alone, but 70% of total eye phospholipids in marine fish are retinal (7). As with whole carcass composition, dietary restriction of DHA severely reduced its deposition in these tissues. For PE of the eye, 22:6n-3 accounted for 12% of the total fatty acids in the low-PUFA sole (L, Fig. 7A), compared to 35% in the high-PUFA supplemented fish (H). This is compensated for by incorporation of a range of other C_{20} and C_{22}

[c]Results shown in Figure 4.
[d]Results shown in Figure 6. For abbreviations, see Tables 1 and 2.

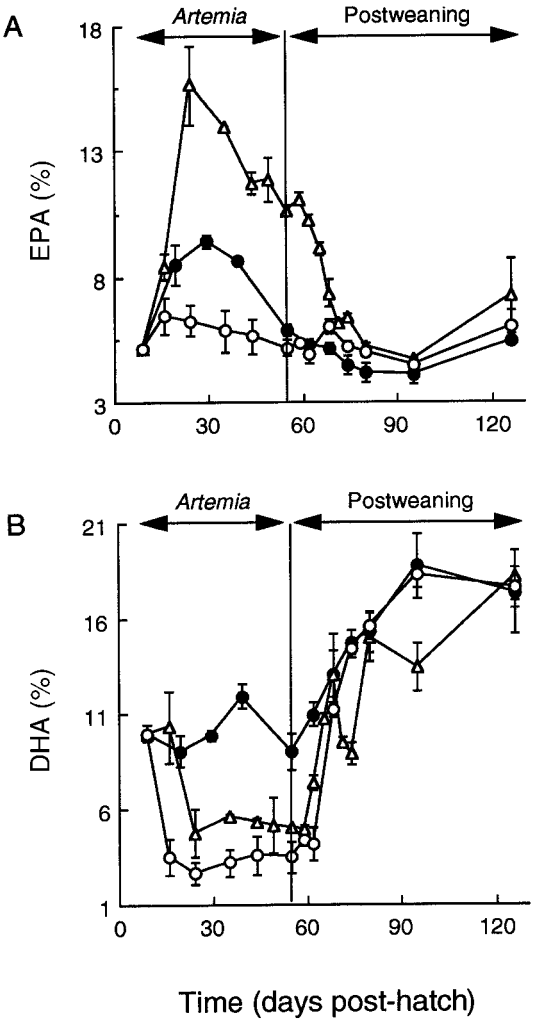

FIG. 5. EPA (A) and DHA (B) content of sole whole carcass polar lipids during the *Artemia* and postweaning feeding periods. Fish were fed either low-PUFA (○), high-PUFA (●), or low-PUFA + EPA (△) enriched *Artemia* diets. Data points represent means from three replicate samples and are given as weight % (±SD) of total fatty acid composition. For abbreviations, see Figures 1 and 4.

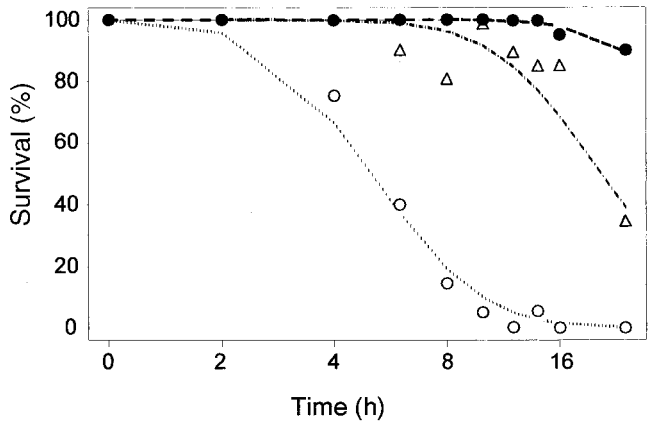

FIG. 6. Effect of dietary treatment on stress tolerance of Dover sole subjected to low temperature and low salinity (3°C, 10‰). Fish were fed either low-PUFA (○), high-PUFA (●), or low-PUFA + EPA (△)-enriched *Artemia* diets. Each data point is for 20 fish. For abbreviations, see Figures 1 and 4.

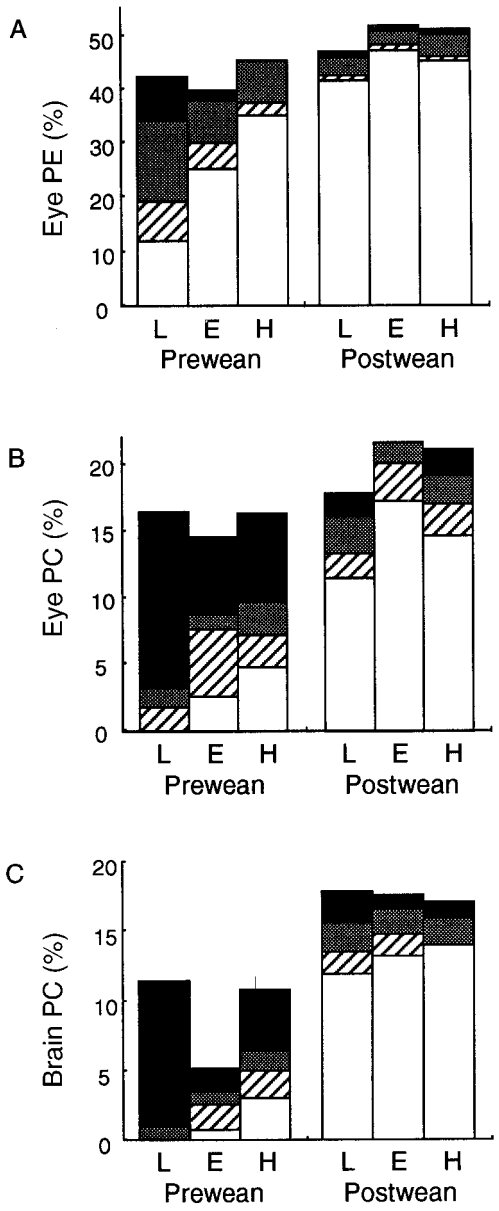

FIG. 7. Effect of dietary treatment on the PUFA content of eye and brain membrane phospholipids in Dover sole. The data show the proportions of 22:6n-3 (open bar), 20:5n-3 (lined bar), other C_{20} + C_{22} PUFA (stippled bar), and C_{18} PUFA (closed bar) within eye phosphatidylethanolamine, PE (A), and eye (B) and brain phosphatidylcholine, PC (C). Compositions are given both preweaning and postweaning for sole fed the low-PUFA (L), low-PUFA + EPA (E), and high-PUFA (H) *Artemia* diets. Values shown are percentages of total fatty acids in the sample, e.g., in 7A, H postwean, 22:6n-3 + 20:5n-3 + other C_{20} + C_{22} PUFA = 50% of total fatty acids. For abbreviations, see Figures 1 and 4.

PUFA, including 20:5n-3 (7.3%), 22:5n-3 (3.5%), 20:4n-6 (5.0%), and 20:3n-6 (5.2%). The low-PUFA fish also possessed elevated proportions of the C_{18} PUFA 18:2n-6 and 18:3n-3. Following weaning, however, levels of 22:6n-3 increased appreciably to over 40% for all groups, with other PUFA being present in only small amounts.

Similarly, 22:6n-3 was completely absent in PC from the eye of the low-PUFA sole (L, Fig. 7B), with 20:5n-3 (1.9%)

and 20:4n-6 (1.4%) being the only long-chain unsaturates present. This was compensated by greatly increased proportions of 18:2n-6 and 18:3n-3. The EPA (E) and high-PUFA (H) sole also contained significant amounts of C_{18} PUFA in PC, presumably as a result of the low levels of $C_{20} + C_{22}$ fatty acids found in these lipids preweaning. Following weaning, proportions of DHA for all treatment groups increased largely at the expense of C_{18} PUFA. The composition for brain membrane phospholipids reflected those of the eye, with similar changes after weaning (Fig. 7C).

Finally, preweaning sole reared on the low-PUFA + EPA (E) diet did not contain particularly enhanced proportions of 20:5n-3 in their neural membranes compared to the other groups (Fig. 7A–C). This may be surprising considering the amount of 20:5n-3 in the diet (Table 2) and that incorporated into whole carcass lipids (Fig. 5A). The low levels of 20:5n-3 indicated this PUFA could not functionally replace 22:6n-3 to any great extent in membranes of the nervous system. Rather, high dietary 20:5n-3 appeared to result in an increase in the proportions of 22:6n-3 in neural tissue membranes, particularly in PE lipids.

Comparison of membrane lipid order. The effects of dietary manipulation of tissue phospholipid composition upon membrane biophysical order, as measured by steady-state fluorescence anisotropy using DPH as probe, are shown in Figure 8. The profiles were approximately linear with no difference between treatments either in the values of anisotropy or the profile over the full range of measurement temperatures.

Gill and whole carcass PG production. The levels of PGE ($PGE_2 + PGE_3$) found in gill tissue homogenates and whole carcass homogenates are given in Table 6. No differences were found for gill tissue, but there was a significant difference in the carcass values, with the PUFA-deficient sole possessing more than double the levels of PGE found in the high-PUFA group. Immunoreactive prostaglandin values were low for the carcass, pg/g as compared to ng/g for the gills, as skeletal muscle is not particularly active in eicosanoid production. However, homogenization of the skin, kidney, brain, heart, and other organs will all yield eicosanoids of different types and ratios.

TABLE 6
Prostaglandin E Content of Gill and Whole Body Samples from Dover Sole Fed Low-PUFA and High-PUFA Enriched *Artemia*[a]

Tissue	Low-PUFA	High-PUFA	Probability[b]
Gill	17.0 (5.5)	22.1 (4.9)	0.301
Whole body	277.3 (50.5)	124.3 (29.7)	0.002

[a]Values given are means for three different gill samples, each comprising gills from six fish, and four different carcass samples, ±SD. Units are ng/g gill and pg/g carcass.
[b]Statistical analysis was performed by one-way analysis of variance. For abbreviation, see Table 1.

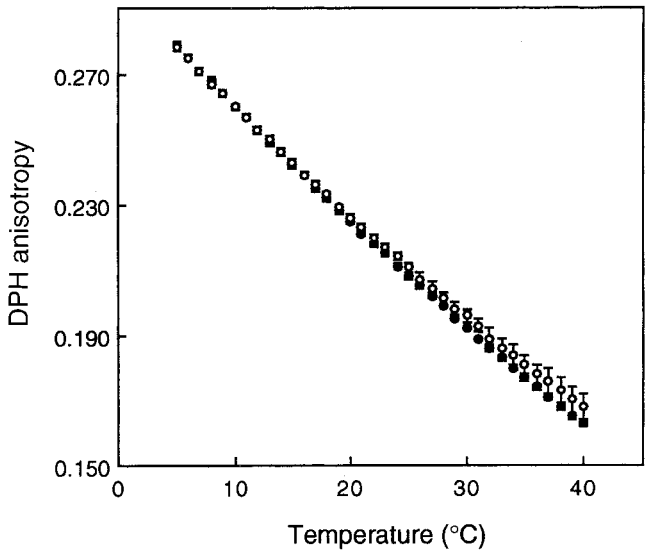

FIG. 8. Effects of dietary treatment upon physical order of brain membrane fractions. Results are shown for the preweaned sole fed the low-PUFA (○) and high-PUFA (●)-enriched *Artemia* diets. Membrane order was determined by steady-state fluorescence anisotropy using the probe 1,6-diphenyl-1,3,5-hexatriene. Data points represent means ± SD from three different membrane preparations. For abbreviation, see Figure 1.

DISCUSSION

Effects of dietary PUFA manipulation upon whole carcass fatty acid composition. The fatty acid composition of membrane phospholipids of Dover sole larvae and juveniles is substantially affected by dietary lipid composition. Larvae fed a diet low in n-3 long-chain PUFA possessed lower proportions of these fatty acids in their tissue phospholipids with correspondingly higher proportions of the C_{18} PUFA, 18:2n-6 and 18:3n-3. However, the overall proportions of SFA, MUFA, and total PUFA were largely unaffected by diet, as shown by other studies (26,27), and were constant throughout the larval and juvenile periods.

Correlating dietary treatment with stress resistance. Larvae and juveniles deprived of dietary n-3 long-chain PUFA in our study possessed reduced tolerance to combined low temperature and low salinity, high temperature, and hypoxia. The sensitivity to stress is general and not specific to cold. Furthermore, as n-3 long-chain PUFA content increased on restoration of these fatty acids in the postweaning diet, so does their capacity to withstand these stresses. Stress resistance is clearly not fixed in the very early stages of life but is subject to change according to the dietary experiences of the fish, the critical feature being the proportion of n-3 long-chain PUFA.

DHA, which is the most abundant long-chain PUFA found in the high-PUFA Dover sole (Table 3), is thought to be crucial in early development of neural tissues. However, dietary provision of 20:5n-3 as the principal n-3 long-chain PUFA confers the stress-resistant phenotype with equal potency to 22:6n-3. Although 20:5n-3 in the EPA-enriched fish is incorporated into whole body tissues in large amounts, there was no evidence of large-scale incorporation into the membranes of the nervous system. Thus, 20:5n-3 does not directly replace 22:6n-3 in these highly polyunsaturated membranes. Instead,

the capacity to synthesize 22:6n-3 from 20:5n-3, albeit limited, appears to be sufficient to bolster levels of 22:6n-3 within neural membrane lipids. Similarly, in the absence of high proportions of 22:6n-3 or 20:5n-3, a range of C_{18} and C_{20} fatty acids of lower unsaturation was incorporated into the neural tissues of the PUFA-deficient sole. However, given their stress susceptibility, it follows that these alternative fatty acids are unable to fulfill the functional role of the absent 22:6n-3. Thus, the stress resistance phenotype appears correlated with high proportions of 22:6n-3 alone in neural tissue, with stress susceptibility associated with low proportions of 22:6n-3, irrespective of other long-chain PUFA that may be present.

Despite the provision of an *Artemia* diet enriched with a PUFA-containing emulsion, the resulting sole juveniles still contained much lower proportions of n-3 long-chain PUFA (21.9%) than wild-caught fish (42.6%). The natural diet of wild sole (20–30 mm), predominantly copepods, is richer in long-chain PUFA, particularly DHA, than artificial feeds (27,28). Although we were unable to test the stress tolerance of wild-caught fish, we predict on the basis of our PUFA deprivation experiments that it would exceed that of reared sole fed the PUFA-enriched *Artemia*. It is therefore likely that commercial rearing diets for marine fish larvae based on enriched *Artemia* nauplii are suboptimal, both in the sense that they fail to achieve sufficiently high levels of PUFA supplementation and that the physiological condition of the resulting larvae is less than maximal.

A neural mechanism underlying long-chain PUFA-induced stress tolerance. It is unlikely that the observed differences in tolerance were due to a deficiency in energy provision as both the low- and high-PUFA emulsions used in this study contained similar lipid contents (29), and growth rates were not significantly different between groups (measurements of weight tested by one way ANOVA, data not shown). It is therefore more likely that the protective effects of dietary long-chain PUFA provision are linked to the specific functions of these molecules within biological systems.

The n-3 long-chain PUFA, particularly 22:6n-3, are found in high proportions in the neural tissue membranes of all vertebrates. This is especially true for marine fish species, where 22:6n-3 can constitute over 60% of total fatty acids in retinal PE lipids (5,30,31). These high levels are thought to be crucial for optimal nervous system function (32), but their exact role within these membranes and the reason for their essentiality are unclear. Such highly unsaturated, bulky components may lend themselves to the regulation of bilayer physical and barrier properties (33–35) while maintaining functionality of these excitable tissues (36,37).

Removal of these fatty acids from the diets of fully formed adults tends to have little effect either on neuronal lipid composition or performance because the nervous system tenaciously conserves its lipid complement (6). However, restriction of essential lipid supply during the early life stages may have much more serious effects. Growth, development, and differentiation of neuronal tissue require the provision of large quantities of essential nutrients, and restriction of supply would directly affect these processes and the functional properties of the resulting nervous system. This principle is clearly demonstrated by the effect of 22:6n-3 deprivation upon the feeding ability of herring juveniles at low light intensities (7). Similarly, aquaculture of marine flatfish larvae is associated with a high incidence of abnormal pigmentation. A proposed cause is an impaired nervous and/or visual system, whereby visual signals in the eye, brain, or other regions of the neural network are processed incorrectly, resulting in a discrepancy between the shade of the fish and that of its environment. This condition can be improved or resolved by increasing dietary 22:6n-3 provision (29,38,39).

Overproduction of eicosanoids. We show here an increase in total PGE (PGE_2 + PGE_3) production in homogenates of PUFA-deprived juvenile sole carcass. PGE_2 are derived from AA and PGE_3 from EPA. Despite the large excess of EPA over AA found in all fish cells, PGE_2 tends to be the predominant PGE homolog produced in fish tissues (9,10,40). Even when fish are fed high-EPA diets, little or no increase in PGE_3 production is observed (40,41). Furthermore, the PGE_2 antibody used for the detection of PGE in this study has a 100% reactivity with PGE_2 but only a 43% cross-reactivity with PGE_3. Thus it is likely that differences in prostaglandin synthetic capacity reported here are due predominantly to elevated PGE_2 in the low-PUFA group. The 2-series PG are the most bioactive eicosanoids, overproduction of which is implicated in many pathophysiological conditions (11).

In addition to acting as a precursor for PGE_3, EPA also competitively inhibits the production of PGE_2 from AA (42). Consequently, the ratio of AA/EPA (20:4n-6/20:5n-3) influences the rate and type of eicosanoids produced in some systems. An imbalance in the proportions of dietary n-3 and n-6 PUFA may possibly offset the balance of their respective eicosanoids, resulting in enhanced PGE_2 production and consequent physiological abnormalities *in vivo*. We show that the ratio of n-3/n-6 fatty acids was indeed significantly different, with values of 1.7 and 3.4 for the low- and high-PUFA sole, respectively. Feeding Atlantic salmon smolts a diet enriched with n-6 fatty acids resulted in a high n-6/n-3 acyl chain ratio in body tissues but a nonsignificant change in A23187-stimulated PGE_2 production *in vitro* (43). Associated with this diet were severe tissue lesions of the heart and increased mortality when animals were subjected to handling and transportation stress (44).

In summary, we have demonstrated that feeding a diet deficient in n-3 long-chain PUFA causes Dover sole larvae to lose resistance to common abiotic stressors such as high temperature, hypoxia, and combined low temperature and low salinity. This deficiency was reversible since adapting to a diet high in n-3 long-chain PUFA increased stress resistance compared to that observed in high-PUFA-fed control fish. These correlated changes support a link between dietary manipulation of n-3 long-chain PUFA and development of a stress-sensitive phenotype. The low levels of neural tissue n-3 PUFA and/or possibly enhanced production of 2-series PG

associated with n-3 long-chain PUFA deprivation are associated with this stress susceptibility during the critical larval and early juvenile periods.

The dietary effects reported here are not limited to artificial feeding conditions imposed during aquaculture but may also occur under natural conditions. Marine phytoplankton is frequently dominated by a limited number of species. Whereas the lipids of dinoflagellates contain high proportions of 22:6n-3, diatoms and green algae contain predominantly C_{16} fatty acids (14). Adequate dietary provision of 22:6n-3 in early larval stages of marine fish therefore depends critically upon the species composition of the algal community at the base of the food web, which can vary both spatially and temporally (28,45). Blooms of 22:6n-3-deficient diatoms during the larval period would result in low levels of these fatty acids within body tissues, leading to a reduced general fitness, increased susceptibility to natural environmental stresses, and consequent increased mortality rate. Thus, dietary input of essential long-chain PUFA may have important consequences for recruitment of juveniles into natural fisheries as well as being vital for the continued success of marine aquaculture.

Long-Term Feeding of Dietary Oils Alters Lipid Metabolism, Lipid Peroxidation, and Antioxidant Enzyme Activities in a Teleost (*Anabas testudineus* Bloch)

Sheelu Varghese and Oommen V. Oommen*

Endocrinology and Biochemistry Division, Department of Zoology, University of Kerala, Kariavattom-695 581, Kerala, India

ABSTRACT: *Anabas testudineus* (climbing perch), average body weight 21 ± 1 g, were maintained in culture tanks and fed a 35% protein feed plus an additional supplementation of three dietary oils (20% each of coconut oil, palm oil, or cod liver oil). Body weight gain was similar among all groups. However, several hepatic lipogenic enzymes such as malic enzyme (ME), NADP-isocitrate dehydrogenase (ICDH), glucose 6-phosphate dehydrogenase (G6PDH), 6-phosphogluconate dehydrogenase (6PGDH) and β-hydroxy-β-methyl glutaryl CoA reductase (HMG CoA reductase) were assayed, and they responded differently. Hepatic ME and G6PDH activities showed a significant decrease in the coconut oil and palm oil groups, but there was no significant change in ICDH activity. The 6PGDH activities were reduced, whereas HMG CoA reductase activity was increased in the palm oil-treated group. Cholesterol synthesis in the liver and muscle increased in the palm oil-treated group, but liver phospholipids did not show any significant change in fish supplemented with oils rich in saturated fatty acids. Triacylglycerol and free fatty acid concentrations were high in the coconut oil- and palm oil-supplemented groups. Lipid peroxidation products such as thiobarbituric acid-reactive substances and conjugated dienes decreased in the same two groups. Antioxidant potential was high in all groups as evidenced by increased activity of superoxide dismutase, glutathione peroxidase, and glutathione content. The results of this study indicate that in fish, dietary lipids depress hepatic lipogenic activity as well as lipid peroxidation products by maintaining high levels of antioxidant enzymes.

Paper no. L8293 in *Lipids 35,* 757–762 (July 2000).

Lipids in fish contain comparatively high levels of polyunsaturated fatty acids (PUFA) of the n-3 series that provide diets of high nutritional value. Lipid metabolism in fish is not simply a matter of availability of dietary fatty acids. Physiological processes such as growth, metabolism, behavior, and even more particularly the structural and functional integrity of the cellular membranes are dependent on these macromolecules (1,2). Experiments with dietary treatments have shown that a strong parallel exists between fatty acids of the diet and the enzymes of intermediary metabolism. Generally, commercial fish diets are rich in fat and low in carbohydrate and protein, and their influences on metabolic pathways have been frequently studied (3,4). However, alteration in body lipid content by dietary manipulation is least understood even though lipids serve as the principal depot of energy reserves for metabolic process (5).

Lipid at a level of 10–20% in fish diet gives an optimal growth rate, but an intraspecific variation exists in the ability of fish to utilize lipid as a source of energy (6). For many fish long-chain n-3 fatty acids must be supplied in the diet. Inclusion of fish oil rich in eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) in fish feed is now common as such oils are usually available. Moreover, fish oil rich in n-3 fatty acids in the diet can produce farmed fish with a greater content of these fatty acids in their lipids. Fish oil often gives better growth rates when compared to other oils in the diet (7). The productivity and cost effectiveness of a commercial culture farm is highly dependent on the availability of a cheaper diet. However, the commonly used ingredients such as fish meal and fish oil are expensive due to the world's limited resources (8).

Coconut oil, which is rich in saturated fatty acids (92%) and also contains 2% PUFA and 6% monounsaturated fatty acids (MUFA), is a main cooking oil in India. Of that 92%, lauric acid (12:0) constitutes 47%, myristic acid (14:0) 18%, and palmitic acid (16:0) 9%. Palm oil, a major edible oil used worldwide, contains 10% PUFA, 40% MUFA, and 50% saturated fatty acids. Among the saturated fatty acids are palmitic acid, 47%; lauric acid, 0.1–0.5%; and myristic acid, 0.09–0.15%. Cod liver oil, which is rich in PUFA of the n-3 series, should have a greater impact on *in vivo* lipid metabolism in farmed fish.

Oxidative metabolism in fish is regulated by diet (9,10) and free radicals are generated as a result of normal metabolism. They are controlled to a great extent by antioxidant enzymes, primarily by a glutathione-dependent system (11). Reports on ectotherms suggest the occurrence of a strong defense mecha-

nism against free radical attack (12,13). In this study of the teleost *Anabas testudineus* (climbing perch), our objective is to analyze the role of edible oils rich in either saturated fatty acids or unsaturated fatty acids on lipogenic enzymes, lipid turnover, lipid peroxidation, and antioxidant enzyme activities.

MATERIALS AND METHODS

Fish were collected from fresh water ecosystems. Female *A. testudineus* weighing 21 ± 1 g were selected and kept in large storage tanks, where they were acclimated in constantly flowing water at 25 ± 2°C for a month prior to experimentation. Fish were fed with a 35% protein feed prepared in the laboratory by mixing 57.2% fish meal, 43.5% groundnut oil cake, 6.7% rice bran, 2% tapioca powder, 0.02% vitamin mix, and antioxidant (50 mg α-tocopherol/kg diet); this mixture was ground and reconstituted into pellets (14), and fed once daily *ad libitum*. Prior to experimental feeding, fish were weighed individually and mean values were noted. Acclimated fish were divided into four groups of eight each (n = 8) and kept in aquarium tanks (24″ × 12″ × 12″). The tanks were subjected to the natural photoperiod. Group I fish, fed the standard 35% protein feed, served as control. Groups II, III, and IV fish were fed a pelletized diet prepared in the laboratory by mixing, respectively, 20% (wt/vol) of coconut oil, palm oil, or cod liver oil into the 35% protein feed. Fish feeds were then stored at –20°C to avoid oxidation. The fish were fed once daily *ad libitum* and maintained on the respective diets for a period of 60 d. They were deprived of feed 24 h before sampling. Fish were weighed individually, and mean values were noted to assess the differences in weight gain.

Sampling and fractionation. Fish were killed by severing the spinal column posterior to the brain. The liver, heart, and muscle were removed immediately. Perfused liver was taken for biochemical analysis. The gall bladder was removed carefully from the liver. The liver was perfused *via* the hepatic vein with Hanks balanced salt solution containing 10 mM HEPES and 1 mM EDTA with a 20-gauge needle fitted to a perfusion apparatus to remove blood from the tissue (15). Muscle samples were taken from a similar position above the lateral line and in front of the dorsal fin (nape region). All the samples were stored at –20°C until analyzed.

Biochemical analyses. The activities of major lipogenic enzymes were determined in the liver and heart. The activities of malic enzyme (ME) and isocitrate dehydrogenase (ICDH) were assayed by the method of Ochoa (16,17). Glucose-6-phosphate dehydrogenase (G6PDH) activity was determined by the method of Kornberg and Horecker (18) and 6-phosphogluconate dehydrogenase (6PGDH) activity by the method of Horecker and Smyrniotis (19). β-Hydroxy-β-methyl glutaryl CoA reductase (HMG CoA reductase) was determined by the method of Rao and Ramakrishnan (20) from the ratio between HMG CoA and mevalonate (H/M ratio). Extraction of total lipid from the liver and muscle was performed by the method of Folch *et al.* (21). From these extracts aliquots were used for the quantitative estimation of cholesterol by the method of Abell *et al.* (22); free fatty acids by the method of Falhot *et al.* (23); and triacylglycerols (TAG) and phospholipids by the methods of Weidman and Schonfeld (24).

The rate of lipid peroxidation in the liver was determined by quantitative estimation of thiobarbituric acid-reactive substances (TBARS) and conjugated dienes by the method of John and Steven (25) and hydroperoxides by that of Mair and Hall (26). The changes in the antioxidant defense system were determined by studying superoxide dismutase (SOD) by the method of Kakkar *et al.* (27), glutathione peroxidase (GPx) activity according to Lawrence and Burk (28), glutathione reductase (GR) by the procedure of David and Richard (29), and glutathione content by the method of Patterson and Lazarow (30). Total protein was estimated by the biuret method of Gornall *et al.* (31) with bovine serum albumin as reference standard. Absorbance was determined using an ultraviolet (UV)-visible spectrophotometer (UV-1601; Shimadzu, Kyoto, Japan).

Statistical analysis. An SPSS (Chicago, IL) setup was used for statistical analysis. Significance of difference among groups was determined by one-way analysis of variance (ANOVA) with Duncan's multiple range test at the level of $P < 0.05$ (32). In all of these cases comparison was made between control group and groups fed with different dietary oils.

RESULTS

The average body weight after supplementation of different oils in the diet did not show any significant difference among groups (Table 1). ME, a major lipogenic enzyme involved in fatty acid biosynthesis, decreased in the liver of coconut oil- and palm oil-treated animals. In heart, ME activity was unaffected by dietary manipulation. In liver, ICDH activity was not affected by diet; in heart there was increased activity associated with palm oil and cod liver oil diets but there was no

Effect of Different Dietary Oils on Lipogenic Enzymes of *Anabas testudineus* (climbing perch)[a]

Parameters analyzed	Group I	Group II	Group III	Group IV
Malic enzyme (L)	1.37 ± 0.27[a]	0.95 ± 0.13[b]	0.82 ± 0.35[b]	1.43 ± 0.49[a]
Malic enzyme (H)	1.7 ± 0.5[a]	1.89 ± 0.12[a]	2.16 ± 0.6[a]	1.92 ± 0.4[a]
Isocitrate dehydrogenase (L)	3.72 ± 0.8[a]	3.05 ± 0.54[a]	3.52 ± 0.76[a]	3.32 ± 0.4[a]
Isocitrate dehydrogenase (H)	6.0 ± 0.48[a]	6.58 ± 0.4[a,b]	7.61 ± 0.68[c]	6.78 ± 0.64[b]
G6PDH (L)	0.1 ± 0.01[a]	0.09 ± 0.01[b]	0.05 ± 0.009[c]	0.08 ± 0.02[b]
6PGDH (L)	0.12 ± 0.01[a]	0.1 ± 0.01[a,b]	0.08 ± 0.01[c]	0.12 ± 0.02[a]
H/M ratio	5.07 ± 0.33[a]	4.43 ± 0.98[a]	2.19 ± 0.66[b]	4.78 ± 0.36[a]

[a]Results expressed as mean ± SD (n = 8). Values are IU/mg protein except for HMG CoA/mevalonate ratio. For HMG CoA reductase activity high HMG CoA/mevalonate ratio shows low enzyme activity. The significant difference between the groups was analyzed by one-way ANOVA. Mean values of different superscript roman letters significantly different ($P < 0.05$) as determined by Duncan's multiple range test. Group I, control; Group II, 20% coconut oil; Group III, 20% palm oil; Group IV, 20% cod liver oil. L, liver; H, heart; G6PDH, glucose-6-phosphate dehydrogenase; 6PGDH, 6-phosphogluconate; H/M ratio, ratio between HMG CoA (β-hydroxy-β-methyl glutaryl CoA) and mevalonate. For other abbreviation see Table 1.

significant difference in coconut oil-fed fish. G6PDH activity in liver was reduced significantly in all oil-fed groups. In the liver, 6PGDH activity decreased only in the palm oil-treated group. In the palm oil-treated group HMG CoA reductase activity was increased compared to the control group, suggesting an increased cholesterol biosynthesis whereas in all other groups no significant changes were observed (Table 2).

Lipid profile analysis showed that total cholesterol in the liver and muscle increased in the palm oil-treated group, and no alteration was found in the coconut oil- and cod liver oil-treated groups. Phospholipids in the liver were unaffected by consumption of oil rich in saturated fat whereas an increased concentration was found in the cod liver oil-treated group. In muscle, dietary treatment did not cause any alteration in phospholipid concentration. Coconut oil and palm oil feeding increased TAG concentration in the liver whereas cod liver oil supplementation did not cause any change. On the other hand, all treatments with dietary oils increased TAG concentrations in muscle. Free fatty acid concentration in the liver increased in all groups compared to control whereas in muscle, dietary treatment of oils had no significant effect on the free fatty acid content (Table 3).

Lipid peroxidation products such as TBARS and conjugated dienes decreased significantly in liver of the coconut oil- and palm oil-treated animals. Hydroperoxides in the liver showed decreased concentrations only in palm oil-treated group.

The activity of SOD and GPx increased in all oil fed groups. The glutathione content in the liver also showed an increase in all oil-fed groups (Table 4).

DISCUSSION

The growth of fish and food conversion efficiency vary with physiological as well as environmental factors (33). In the present study the groups of fish fed diets supplemented with lipids had similar growth rates as in control fish fed with 35% protein feed. Many different experimental approaches using carbohydrate, protein, or lipid and their effects on PUFA in fish species have been reviewed (1,10,34). However, the action of dietary fat on lipogenic enzymes and on lipid peroxidation in fish is not understood. Supplementation of diet with carbohydrate, protein, or lipid invariably affects the synthesis and degradation of various lipid classes (9,35,36). In this study the major lipogenic enzymes responded differentially to the dietary fat content in various tissues. ME, which is involved in fatty acid biosynthesis in converting malate to pyruvate with subsequent generation of extramitochondrial

NADPH, was significantly reduced in liver with a diet rich in saturated fat, whereas in heart tissue there was no significant change. It is reported that when more fat is absorbed from the intestine the activities of major lipogenic enzymes are reduced (9). The cytosolic ICDH is suggested as an important source of reducing equivalents for fatty acid biosynthesis. In this experiment liver ICDH activity was unaltered irrespective of the nature of the fat present in the diet. The other two enzymes involved in the oxidative phase of pentose-phosphate pathway, G6PDH and 6PGDH, responded differentially to dietary fat content. The G6PDH activity is an excellent model system to analyze the regulation of intracellular metabolism by dietary fat since it participates in multiple metabolic pathways such as lipogenesis, cellular growth and reductive biosynthesis. It also has a direct influence on detoxification reactions (37). Supplementation with three different oils reduced the activity of this enzyme in the liver. This is in broad agreement with other observations in different fish species, as reviewed by Greene and Selivonchick (1). The 6PGDH activity in the liver was not affected by coconut oil and cod liver oil treatment, but a decreased activity was associated with dietary palm oil. HMG CoA reductase, the rate-limiting enzyme involved in the cholesterol biosynthesis pathway and responsible for the synthesis of isoprenoid precursor mevalonate, was unaltered by coconut oil and cod liver oil treatment. However, in the palm oil-supplemented group hepatic HMG CoA reductase activity increased, indicating increased cholesterol biosynthesis.

In this experiment most of the lipogenic enzymes decreased in the liver when more fat was absorbed. In heart muscle no such correlation could be found in lipogenic enzyme activity. It has been reported that absorbed fat is the most important factor in influencing the activity of lipogenic enzymes. Even though absorption and utilization of fat may vary with species, physiological status, food intake and absorbed fat are generally and negatively correlated with lipogenic enzyme activity (9,33).

In this study, only the livers of the 20% palm oil-treated group had higher cholesterol content compared to other groups. This may be due to increased cholesterol biosynthesis as evident from increased HMG CoA reductase activity.

In *A. testudineus,* supplementation of oil rich in saturated fat does not alter phospholipid concentration in the liver whereas cod liver oil treatment increases the concentration. In muscle, treatment with different dietary oils does not produce any change. The increase in the phospholipid content of the liver of cod liver oil-treated animals may be because of the incorporation of long-chain PUFA into phospholipids. The primary storage molecules in higher bony fish are TAG (36). In our study, the TAG content in the liver was high only in fish fed with a diet high in saturated fat, indicating the probable presence of saturated fat as circulating TAG, whereas in muscle all dietary oil treatments led to an increased TAG concentration.

In the liver, free fatty acids concentration increased in all treated groups. A corresponding increase was not observed in muscle. The increase in free fatty acids in the liver of the group fed 20% cod liver oil may have taken place postmortem, as enzyme activity could be emphasized by additional cellular phospholipids. In the two saturated fat-treated groups, the hydrolysis of stored TAG probably caused an increased concentration of free fatty acids (39).

The overall physiological functions in a cell are dependent on the integrity of membranes. Fluidity of membranes is directly correlated with membrane function and is maintained by the integrity of lipids combined with other macromolecules. Membrane lipids undergo autoxidation, leading to reactive oxygen and nitrogen radicals that affect the structural and functional integrity of plasma membranes. A strong defense mechanism that exists against free radical attack in mammals is SOD, which converts O_2 into H_2O_2 (40). Another vital defense against lipid peroxidation is glutathione-dependent enzymes that can metabolize the H_2O_2 involved in the initiation of lipid peroxidation. A paucity of information is available to elucidate the action of dietary fat on lipid peroxidation and antioxidant enzyme activity in fish. Among the lipid classes, the most susceptible substrates undergoing autoxidation are those rich in PUFA, and there may be greater chances of lipid peroxidation leading to the generation of reactive oxygen species. In the present study, lipid peroxidation products such as TBARS and conjugated dienes decreased significantly when more saturated fat was being absorbed. Meanwhile, in the PUFA-treated group, a high level of TBARS was observed since these fatty acids are the obvious

substrates for lipid peroxidation. However, a possible deleterious effect in cellular function can be ruled out because of the high levels of antioxidant enzymes in all of the experimental animals in this study. In addition, glutathione, a tripeptide and an intracellular reductant involved in the cellular defense system, also increased with increased fat absorption.

In summary, these results suggest that supplemented dietary fat is well utilized and has pronounced influences on the regulation of lipogenic enzymes assayed. The important observation from the present study is that supplemental fat in the diet reduces lipid peroxidation products by maintaining high levels of antioxidant enzymes such as SOD and GPx in *A. testudineus.*

ABSTRACT: Although essential to host defense, neutrophils are also involved in numerous inflammatory disorders including rheumatoid arthritis. Dietary supplementation with relatively large amounts of fish oil [containing >2.6 g eicosapentaenoic acid (EPA) plus 1.4 g docosahexaenoic acid (DHA) per day] can attenuate neutrophil functions such as chemotaxis and superoxide radical production. In this study, the effects of more moderate supplementation with fish oil on neutrophil lipid composition and function were investigated. The rationale for using lower supplementary doses of fish oil was to avoid adverse gastrointestinal problems, which have been observed at high supplementary concentrations of fish oil. Healthy male volunteers aged <40 yr were randomly assigned to consume one of six dietary supplements daily for 12 wk ($n = 8$ per treatment group). The dietary supplements included four different concentrations of fish oil (the most concentrated fish oil provided 0.58 g EPA plus 1.67 g DHA per day), linseed oil, and a placebo oil. The percentages of EPA and DHA increased (both $P < 0.05$) in neutrophil phospholipids in a dose-dependent manner after 4 wk of supplementation with the three most concentrated fish oil supplements. No further increases in EPA or DHA levels were observed after 4 wk. The percentage of arachidonic acid in neutrophil phospholipids decreased ($P < 0.05$) after 12 wk supplementation with the linseed oil supplement or the two most concentrated fish oil supplements. There were no significant changes in *N*-formyl-met-leu-phe-induced chemotaxis and superoxide radical production following the dietary supplementations. In conclusion, low-to-moderate amounts of dietary fish oil can be used to manipulate neutrophil fatty acid composition. However, this may not be accompanied by modulation of neutrophil functions such as chemotaxis and superoxide radical production.

Paper no. L8303 in *Lipids 35,* 763–768 (July 2000).

Polymorphonuclear granulocytes (neutrophils) are derived from stem cells and mature in the bone marrow. Upon activation, neutrophil responses include adherence to endothelial cells, migration into inflamed tissue (chemotaxis), and production of superoxide radicals (1–4). Toxic metabolites of superoxide such as hydrogen peroxide (H_2O_2), hypochlorous acid (HOCl), and hydroxyl radicals ($OH^{\bullet}$) play an important role in the ability of neutrophils to kill invading microorganisms. The neutrophil is also capable of releasing the toxic contents of granules, which include elastase, collagenase, myeloperoxidase and lysozyme, upon activation. The combination of superoxide radical metabolites and granule-derived toxins provides a potent defense against invading microorganisms.

Although essential to host defense, neutrophils have been implicated in the pathology of several inflammatory disorders (1,3,5). This appears to be due to the same set of metabolites and toxins which are involved in host defense. Supplementing the diet with fish oil has been shown to attenuate neutrophil functions such as superoxide radical production (6,7) and chemotaxis (8,9). Many authors have reported moderate improvement in several inflammatory disorders including psoriasis (10) and rheumatoid arthritis (11) after dietary supplementation with fish oil and suggest that this might be, in part, due to reduced neutrophil responsiveness. Interest in such effects of fish oil stemmed from the observation that populations that ingest relatively large amounts of oily fish and marine mammals in the diet (e.g., Eskimos) have a lower incidence of inflammatory disorders than populations which consume little or no oily fish (12). The beneficial effect of fish oil on neutrophil function has been attributed to the n-3 polyunsaturated fatty acids (PUFA), eicosapentaenoic acid (EPA; 20:5n-3), and docosahexaenoic acid (DHA; 22:6n-3), which are found in relatively high concentrations in fish oil. Arachidonic acid (ARA; 20:4n-6), a member of the alternative n-6 PUFA family, can be metabolized to a variety of pro-inflammatory mediators, and may itself be a pro-inflammatory second messenger (13). It is believed that EPA competes with ARA for use as substrate in several important pathways, resulting in reduced production of pro-inflammatory products of ARA (14–17). This competitive inhibition by EPA of ARA metabolism is due to the similarity in structure between the molecules, and may explain in part the anti-inflammatory effect of fish oil.

Numerous studies have used large amounts of fish oil (up to 9.4 g EPA plus 5 g DHA per day) to attenuate neutrophil function (6–9,18,19). However, the amounts of fish oil used

Abbreviations: ARA, arachidonic acid; DHA, docosahexaenoic acid; DMSO, dimethyl sulfoxide; EPA, eicosapentaenoic acid; fMLP, *N*-formyl-met-leu-phe; HBSS, Hank's balanced salt solution; LA, linoleic acid; LTB_4, leukotriene B_4; PBS, phosphate-buffered saline; PUFA, polyunsaturated fatty acids; SOD, superoxide dismutase.

are not practical or sustainable, and some volunteers experienced gastrointestinal symptoms such as diarrhea and mild steatorrhea (9). It would seem reasonable to assume that such an extreme dietary regime would not achieve widespread acceptance for long-term use. The aim of this study was to determine whether dietary supplementation with lower amounts of fish oil could be used to bring about both structural and functional changes to neutrophils.

MATERIALS AND METHODS

Materials. Diazomethane, Histopaque-1077, cytochrome c, cytochalasin B, catalase, Hank's balanced salt solution (HBSS) with calcium and magnesium, *N*-formyl-met-leu-phe (fMLP), superoxide dismutase, and phosphate-buffered saline (PBS) tablets were all purchased from Sigma Chemical Co. (Poole, Dorset, United Kingdom). All solvents were from Fuher Scientific Ltd. (Loughborough, Leicestershire, United Kingdom). Lysis buffer (autoclaved and filter-sterilized) was prepared by dissolving 37.2 mg EDTA, 8.29 g NH_4Cl, and 1.00 g $KHCO_3$ (all from Sigma) in 1 L of distilled water.

Subjects and study design. Healthy male volunteers, with a mean age of 23.8 ± 0.8 yr (range 18–39), were randomly assigned to receive one of six dietary supplements (n = 8 subjects per group, no difference in mean age between groups). Each volunteer consumed nine capsules of oil (1 capsule = 1 g) daily for 12 wk. The subjects were instructed not to change their diets or lifestyles during the course of the study. None of the volunteers reported any side effects during or after the supplementation period. Fasting blood samples (40 mL) were taken from the volunteers prior to the beginning of supplementation (baseline) and after 4, 8, and 12 wk of supplementation; a final blood sample was taken 8 wk after the end of supplementation.

Compositions of the dietary supplements. The dietary supplements contained the following oil mixtures: (i) Placebo oil: comprised of 80% palm oil and 20% soybean oil [The fatty acid composition of this oil mix mimics closely that of the average United Kingdom diet (20)]; (ii) tuna oil; (iii) a 50:50 mix of tuna oil and placebo oil; (iv) a 25:75 mix of tuna oil and placebo oil; (v) a 12.5:87.5 mix of tuna oil and placebo oil; and (vi) linseed oil. Table 1 shows the fatty acid composition of each of the dietary supplements.

Neutrophil isolation. Whole heparinized blood was carefully layered onto an equal volume of Histopaque-1077 and then centrifuged at 600 × g for 15 min. The plasma and mononuclear cell layers were aspirated off. Contaminating erythrocytes were removed by washing with lysis buffer (prepared as described above) twice (10 min each wash), and the purified neutrophils were then finally washed and resuspended in HBSS containing calcium and magnesium. Neutrophils were counted with a Coulter Counter (Coulter Electronics Ltd., Luton, Bedforshire, United Kingdom) and adjusted to the appropriate concentration.

Superoxide generation. The superoxide dismutase (SOD) inhibitable reduction of cytochrome c was used to measure production of superoxide radicals by neutrophils. Neutrophils (1×10^6) were incubated with cytochalasin B (final concentration 10.4 μM); dissolved in dimethyl sulfoxide (DMSO), catalase (final concentration 35 IU/mL), and cytochrome c (final concentration 1.5 mg/mL) for 5 min at 37°C. The cells were then stimulated with 100 nM fMLP, and the rate of superoxide generation was followed for 10 min by determining the change in absorbance of the reaction mixture at 550 nm using a kinetic microtiter plate reader; initial rates of superoxide production were obtained over the first 3 min only. The final reaction volume was 200 μL. SOD was included in the reaction mix in some determinations (at a concentration of 10 units/mL) to demonstrate that cytochrome c reduction was superoxide-dependent. Neutrophils incubated with HBSS, 35 IU/mL catalase, 10.4 μM cytochalasin B, and 1.5 mg/mL cytochrome c, ONLY, did not produce measurable amounts of superoxide.

Neutrophil chemotaxis. Neutrophil chemotaxis was assayed in a modified Boyden chamber. The wells of the 96-well plate contained a 100-nM solution of fMLP in HBSS.

TABLE 1
Fatty Acid Composition of Dietary Supplements[a]

	Supplement					
Fatty acid	PO	LO	100% TO	50% TO	25% TO	12.5% TO

[a]Values shown are percentage of fatty acids present and are means of three determinations; values in brackets are SEM. Abbreviations: PO, placebo oil; LO, linseed oil; TO, tuna oil.

Neutrophils (suspended in HBSS at a concentration of 3×10^6 cells per well) were separated from the fMLP by a 5-μm pore filter (purchased from Neuro Probe Inc., Gaithersburg, MD). The chamber was incubated for 1 h at 37°C. Chemotaxis was measured as the number of neutrophils migrating across the filter into the wells containing fMLP. Neutrophils were counted using a Coulter counter. The number of migrated cells in control wells was in the range of 2.8×10^4 to 5.0×10^4 cells per well. Mean values of migrated cells in control wells (i.e., no fMLP) did not change at any time point for any dietary supplement (data not shown).

Neutrophil fatty acid composition. Neutrophil lipids were extracted by addition of 5 vol of a 2:1 chloroform/methanol mixture to the neutrophil suspension (containing 15×10^6 cells per sample) in PBS. The tubes were sealed under nitrogen to prevent lipid oxidation, vortexed vigorously, and then centrifuged at 400 × *g* for 10 min. After collection of the solvent phase, any remaining lipids in the aqueous phase were extracted using 3 vol of pure chloroform. The solvent phases containing lipids were pooled and then washed twice with 0.88% KCl solution in order to remove traces of water. The lipid extract was dried down completely under nitrogen. The lipids were resuspended in 100 μL of methanol, and 1 mL of 0.5 M KOH was added. The lipids were sealed under nitrogen and saponified by incubation at 80–90°C for about 4 h. After this time, the mixture was allowed to cool to room temperature, and 50 μL of 5 M H_2SO_4 was added to bring the mixture to ~pH 7. The fatty acids were then extracted as in the initial lipid extraction phase and finally dissolved in ~10 μL methanol. Fatty acids were methylated by addition of 200 μL of diazomethane in ether. After 20 min, the samples were dried down completely under nitrogen. The fatty acid methyl esters were redissolved in hexane and separated by gas chromatography in a Hewlett-Packard 6890 gas chromatograph (Hewlett-Packard, Avondale, PA) fitted with a 30 m × 0.32 mm BPX70 capillary column, film thickness 0.25 μm. Helium at 2.0 mL/min was used as the carrier gas, and the split/splitless injector was used with a split/splitless ratio of 10:1. Injector and detector temperatures were 170 and 250°C, respectively. The column oven temperature was maintained at 170°C for 12 min after sample injection and was programmed to then increase from 170 to 200°C at 5°C/min before being maintained at 200°C for 15 min. The separation was recorded with HP GC Chem Station software (Hewlett-Packard). Fatty acid methyl esters were identified by comparison with standards run previously.

Statistical analysis. The effect of dietary supplementation was assessed by using analysis of variance and suitable post-hoc tests; a significance level of $P < 0.05$ was used.

RESULTS

Neutrophil fatty acid composition. Significant increases in the proportions of both EPA and DHA were observed after dietary supplementation with the 100, 50, and 25% tuna oils (Fig. 1A,B,C and Fig. 2A,B,C). The content of both n-3

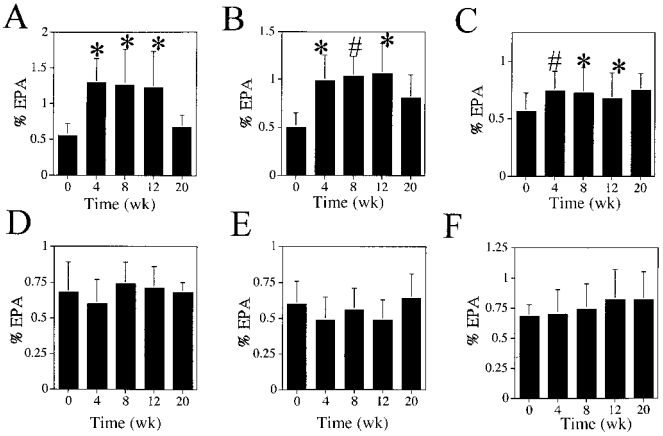

FIG. 1. The effect of 9 g/d of 100% tuna oil (A), 50% tuna oil (B), 25% tuna oil (C), 12.5% tuna oil (D), placebo oil (E), and linseed oil (F) on neutrophil eicosapentaenoic acid (EPA) content. In each case, neutrophil EPA content was determined prior to supplementation (0 wk), during supplementation (at 4, 8, and 12 wk), and after an 8-wk post-supplementation washout period (20 wk). Results are expressed as means percentage EPA found in neutrophil lipids ± SD ($n = 8$). $^*P < 0.05$, $^\#P < 0.01$ vs. value at 0 wk (one-way analysis of variance).

PUFA was maximal after 4 wk of dietary supplementation. The other supplements had no effect on neutrophil EPA or DHA content (Fig. 1D,E,F and Fig. 2D,E,F). There were significant linear correlations ($P < 0.0001$) between the amounts of EPA and DHA provided per day by the dietary supplements and the proportions of EPA and DHA, respectively, in neutrophil lipids (Fig. 3). A significant decrease in neutrophil ARA was observed after supplementation with the 100 and 50% tuna oils and the linseed oil (Fig. 4A,B,F). The decrease occurred after 8 wk supplementation in each case, and was maximal at 12 wk for the linseed oil supplement (Fig.

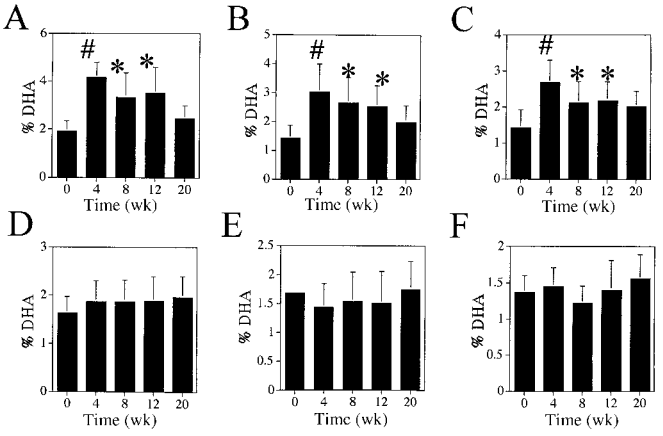

FIG. 2. The effect of 9 g/d of 100% tuna oil (A), 50% tuna oil (B), 25% tuna oil (C), 12.5% tuna oil (D), placebo oil (E), and linseed oil (F) on neutrophil docosahexaenoic acid (DHA) content. In each case, neutrophil DHA content was determined prior to supplementation (0 wk), during supplementation (at 4, 8 and 12 wk), and after an 8-wk post-supplementation washout period (20 wk). Results are expressed as means percentage DHA found in neutrophil lipids ± SD ($n = 8$). $^*P < 0.05$, $^\#P < 0.01$ vs. value at 0 wk (one-way analysis of variance).

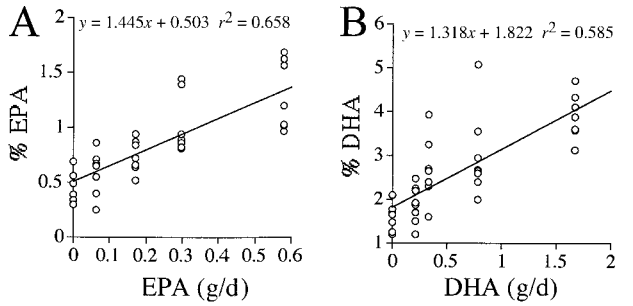

FIG. 3. The effect of EPA and DHA dose on EPA and DHA levels in neutrophil lipids after 4 wk supplementation. The relationship between the daily amounts of EPA and DHA provided by the dietary supplements and the proportions of those fatty acids in neutrophil lipids was determined by calculating Spearman's correlation coefficient (*r*). (A) EPA dose vs. phospholipid EPA; (B) DHA dose vs. phospholipid DHA. See Figures 1 and 2 for abbreviations.

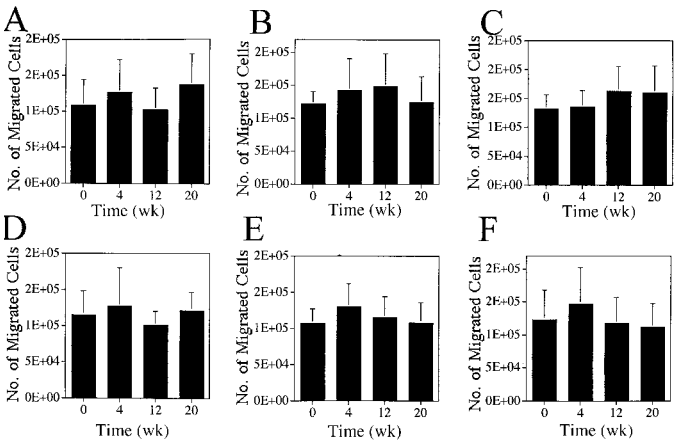

FIG. 5. The effect of 9 g/d of 100% tuna oil (A), 50% tuna oil (B), 25% tuna oil (C), 12.5% tuna oil (D), placebo oil (E), and linseed oil (F) on chemotaxis by neutrophils stimulated with 100 nM *N*-formyl-met-leu-phe (fMLP). Neutrophil chemotaxis was assessed prior to supplementation (0 wk), during supplementation (at 4, 8, and 12 wk), and after an 8-wk postsupplementation washout period (20 wk). Results are expressed as means number of neutrophil migrations occurring per hour ± SD ($n = 8$). Not significant vs. value at 0 wk (one-way analysis of variance).

4A,B,F). The other supplements had no effect on neutrophil ARA content (Fig, 4C,D,E).

Neutrophil superoxide generation and chemotaxis. The dietary supplements did not significantly affect neutrophil chemotaxis or superoxide radical generation (initial rate and total production) (Figs. 5–7).

DISCUSSION

Neutrophil fatty acid composition was found to change in a dose-dependent fashion. The changes observed after tuna oil supplementation in this study are in agreement with the findings of studies where larger amounts of fish oil were used to supplement the diets of healthy volunteers (14,20). For example, provision of 1.4–4.2 g EPA plus 0.9–1.4 g DHA per day resulted in an increase of EPA content in neutrophils from 1.2 ± 0.2 to 3.2 ± 0.7% ($P < 0.05$) after 2 wk and an increase in DHA content from 1.9 ± 0.8 to 2.7 ± 0.8% ($P < 0.05$) after 12 wk (20). In the present study, provision of up to 0.58 g EPA plus 1.7 g DHA per day resulted in an increase in the EPA content of neutrophils from 0.55 ± 0.17 to 1.29 ± 0.34% ($P < 0.05$) and an increase in the DHA content from 1.92 ± 0.41 to 4.16 ± 0.63% ($P < 0.05$) after 4 wk supplementation, and remained so without increasing for the ensuing 8 wk.

The linseed oil supplement was included in the study because it contains a high concentration of α-linolenic acid

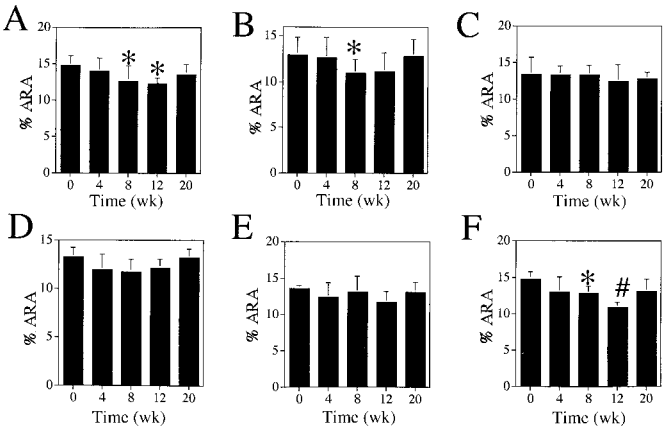

FIG. 4. The effect of 9 g/d of 100% tuna oil (A), 50% tuna oil (B), 25% tuna oil (C), 12.5% tuna oil (D), placebo oil (E), and linseed oil (F) on neutrophil arachidonic acid (ARA) content. Neutrophil ARA content was determined prior to supplementation (0 wk), during supplementation (at 4, 8, and 12 wk), and after an 8-wk postsupplementation washout period (20 wk). Results are expressed as means percentage ARA in neutrophil lipids ± SD ($n = 8$). $^{*}P < 0.05$, $^{\#}P < 0.01$ vs. value at 0 wk (one-way analysis of variance).

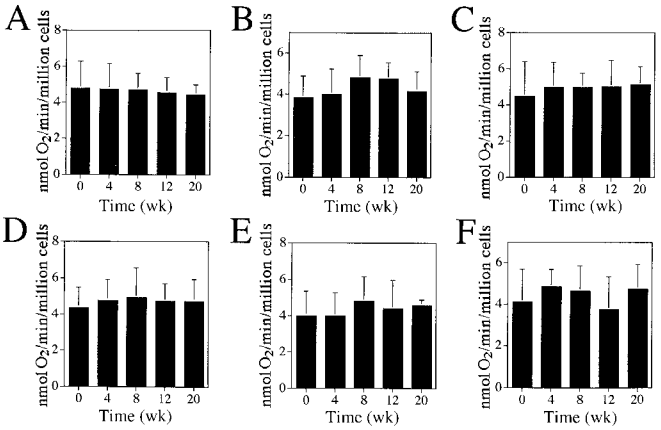

FIG. 6. The effect of 9 g/d of 100% tuna oil (A), 50% tuna oil (B), 25% tuna oil (C), 12.5% tuna oil (D), placebo oil (E), and linseed oil (F) on initial rate of superoxide generation by neutrophils stimulated with 100 nM fMLP. Initial rate of superoxide generation was determined prior to supplementation (0 wk), during supplementation (at 4, 8, and 12 wk) and after an 8-wk postsupplementation washout period (20 wk). Results are expressed as mean nanomoles superoxide produced per minute per million cells ± SD ($n = 8$). Not significant vs. value at 0 wk (one-way analysis of variance). See Figure 5 for abbreviation.

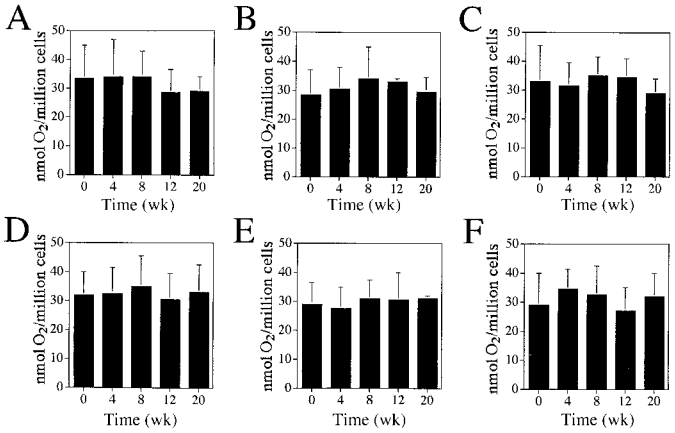

FIG. 7. The effect of 9 g/d of 100% tuna oil (A), 50% tuna oil (B), 25% tuna oil (C), 12.5% tuna oil (D), placebo oil (E), and linseed oil (F) on total superoxide generation by neutrophils stimulated with 100 nM fMLP. Superoxide generation was determined prior to supplementation (0 wk), during supplementation (at 4, 8, and 12 wk), and after an 8-wk postsupplementation washout period (20 wk). Results are expressed as means nmoles superoxide generated per million cells ± SD (n = 8). Not significant vs. value at 0 wk (one-way analysis of variance). See Figure 5 for abbreviation.

(α-LA; 18:3n-3), which is a precursor of both EPA and DHA *in vivo*. It was speculated that supplementation with the linseed oil would lead to increased biosynthesis of EPA and DHA *in vivo*, with a subsequent increased incorporation of EPA and DHA into neutrophil lipids. However, the results showed that provision of up to 4 g extra α-LA per day had no effect on neutrophil lipid EPA or DHA levels. The linseed oil significantly decreased the amount of ARA found in the neutrophil lipids. This may be due to an inhibitory effect of α-LA on ARA biosynthesis from linoleic acid.

Despite the changes in neutrophil composition observed after tuna oil supplementation, there were no concomitant changes in neutrophil superoxide radical formation or chemotaxis following exposure to an inflammatory stimulus (100 nM fMLP). This is in contrast to other studies where amounts of fish oil providing more than 2.6 g EPA plus 1.4 g DHA per day were ingested, resulting in significant changes in neutrophil functions (6,7,9,14,18,19,21,22). High doses of fish oil led to significantly decreased superoxide production in response to phorbol myristic acid (PMA) (6) or opsonized zymosan (7), and also significantly reduced the chemotactic response to stimulants including leukotriene B_4 (LTB_4) (21), autologous serum (18,19), and fMLP (18,19,22). Other neutrophil functions attenuated by fish oil supplementation include LTB_4 production (9,21) and ARA release (21) following stimulation by the calcium ionophore A23187. However, other studies using lower amounts of fish oil have reported no effect of fish oil on neutrophil superoxide production and adhesion following stimulation with fMLP, PMA, or opsonized zymosan (23,24).

Due to limited availability of neutrophils in the present study, only two functional parameters were studied in detail, namely superoxide production and chemotaxis in response to fMLP. It is possible that the level of fish oil supplementation in the present study did alter other parameters of function, but these were not assessed.

The results obtained here suggest that supplementation of the diet with low-to-moderate amounts of fish oil daily may be of little benefit in the treatment of inflammatory disorders. However, several points regarding this assessment need to be addressed. First, during this study the volunteers were instructed to maintain their normal diet and lifestyle. Therefore, the n-6 PUFA intake of the volunteers remained unchanged. It has been speculated that the high n-6 PUFA of the modern Western diet may not be optimal for the expression of the anti-inflammatory effects of the n-3 PUFA (25). Although the n-6/n-3 PUFA ratio of the neutrophils was significantly decreased by the fish oil supplementation, it may still be too high for any anti-inflammatory effect of the fish oil to be evident. Also it has been shown that LA inhibits the incorporation of dietary n-3 PUFA into human (26) and rat (25) immune cell lipids. Therefore, a moderate increase in n-3 PUFA intake combined with a decrease in n-6 PUFA intake may produce significant anti-inflammatory effects. This remains to be investigated. Second, in this study, the effect of low-to-moderate fish oil supplementation on neutrophil responses was examined in young males, whereas older subjects are more vulnerable to inflammatory diseases. The possibility that fish oil may behave differently among individuals of different ages cannot be excluded.

Moderate fish oil supplementation of the diet may have an important role to play in the therapy of inflammatory disorders when used as an adjunct to conventional pharmacological therapy. Several studies have shown drug-sparing effects of fish oil when used in conjunction with drugs in the treatment of rheumatoid arthritis (27,28). Use of multicomponent therapy for inflammatory disorders may be of greater benefit than drug use alone. This is especially important where existing drug-based treatments result in significant toxicity.

ABSTRACT: The aim of this study was to use whole-body magnetic resonance imaging (MRI) together with biochemical and anthropometric measurements to study the influence of regular moderate exercise with no dietary intervention on adipose tissue distribution in nonobese healthy women. We found significant decreases in both total (28.86 ± 2.24 vs. 27.00 ± 2.27 liters, $P < 0.05$) and regional fat depots (visceral fat: 1.68 ± 0.21 vs. 1.26 ± 0.18 liters, $P < 0.01$) using whole-body MRI despite no significant change in body weight, body mass index, or the waist-to-hip ratio. Interestingly, no changes in body fat content were found using anthropometry or impedance. There was a significant increase in high density lipoprotein cholesterol (1.58 ± 0.06 vs. 1.66 ± 0.08 mmol/L $P < 0.02$) following exercise although there were no changes in other blood lipids such as triglycerides. In summary, moderate aerobic exercise over a period of 6 mon resulted in a preferential loss in visceral fat in nonobese healthy women, and this may help to explain some of the health benefits associated with regular and moderate physical activity.

Paper no. L8300 in *Lipids 35*, 769–776 (July 2000).

The health benefits of regular exercise are well-established (1,2). However, results regarding the effect of exercise on adipose tissue are conflicting (3,4). Many studies have shown the effect of exercise and diet on the amount and distribution of adipose tissue (3), but the effect of exercise alone on different adipose tissue depots is less well-studied. Furthermore, many studies examining the effects of exercise on body morphology and composition have used overweight or obese subjects, given that they appear to be more likely to benefit from a change in physical activity. Less is known, however, regarding the effect of a moderate amount of aerobic exercise on body fat content in nonobese healthy women.

Abbreviations: BASES, British Association of Sports and Exercise Science; BMI, body mass index; CI, confidence interval; CT, computer-assisted tomography; CV, coefficient of variation; DHEAS, dehydroepiandrosterone sulfate; HDL-C, high density lipoprotein cholesterol; LDL-C, low density lipoprotein cholesterol; MRI, magnetic resonance imaging; NEFA, nonesterified fatty acid; SHBG, sex hormone-binding globulin; VeO_2, ventilatory oxygen equivalent; VO_2 max, maximal rate of oxygen consumption; WHR, waist-to-hip ratio.

A number of techniques have been applied to the study of body fat content following exercise. Underwater weighing and anthropometry are often used, although these indirect techniques can be used to measure total body fat, they cannot be used to assess regional fat depots such as visceral fat (5,6). Computer-assisted tomography (CT) allows the direct measurement of visceral fat, but owing to the radiation dose involved, only single slices tend to be acquired (6). Magnetic resonance imaging (MRI) provides an accurate measure of body fat content as well as a direct measure of visceral fat content. MRI has previously been applied to studies which have shown changes in regional and total body fat in obese women following a combination of energy restriction and exercise (7,8).

In this study we used whole-body MRI together with biochemical and anthropometric measurements to determine the influence of regular moderate exercise with no dietary intervention on adipose tissue distribution in nonobese sedentary healthy women.

SUBJECTS AND METHODS

Written informed consent was obtained from all volunteers. Permission for this study was obtained from the Ethics Committee of the Royal Postgraduate Medical School, Hammersmith Hospital, London (REC. 92/3995).

Thirty women were initially recruited; data from the 17 who completed all parts of the study are presented in this paper. Thirteen women did not complete the study, mainly because they were a young, mobile population, and many of whom moved out of the area and thus were unable to attend the gym used for their exercise to be monitored. Regular attendance at a specific gym was an essential prerequisite for participation in this study.

Seventeen nonobese, premenopausal healthy (previously nonexercising) female volunteers (mean age: 32.6 ± 1.8 yr; range: 25–45 yr) were studied before and after 6 mon of three times per week aerobic exercise. Volunteers were recruited for this study following advertisements placed in local newspapers. All women were interviewed by the senior investigator prior to inclusion in the study. The primary motivation given by the women joining the study was to improve their

fitness. Exclusion criteria included a history of obesity, dieting, or eating disorders, any form of medication including the contraceptive pill, smoking, or a previous history of regular exercise. Each woman served as her own control for the purpose of this study.

Regional and total body fat contents were measured by whole-body MRI. Body fat content was also measured by bioelectric impedance and skinfold anthropometry. Exercise records were regularly obtained from all the volunteers to ensure compliance with the exercise regime. Dietary intake was also measured at the beginning and at the end of the study to ensure that volunteers were not restricting their energy intake.

MRI and analysis. Subjects were imaged lying prone in a Picker 1.0T HPQ system (Marconi Medical Systems, Cleveland, OH) with a rapid T_1 weighted spin-echo sequence (TR 36 ms, TE 14 ms) (9). Subjects were scanned from their fingertips to their toes by acquiring 10-mm thick transverse images with a 30-mm gap between slices in the arms and legs and a 10-mm gap in the torso (10). Images were analyzed using an image segmentation software program that employs a threshold range and a contour-following algorithm with an interactive image-editing facility (11). The total internal fat content of each subject was subdivided into visceral and nonvisceral (i.e., intramuscular, pericardial, and fat from depots other than visceral fat) internal body fat. Visceral fat content was obtained by quantifying fat signals in the slices from the femoral heads to the slice containing the top of the liver or the base of the lungs (T10). Subcutaneous fat in these slices was labeled as abdominal subcutaneous fat. All other internal fat was labeled as nonvisceral internal fat. The coefficient of variation (CV) varies between different depots, but the data analysis method is generally highly reproducible, 3% internal fat, 5% visceral fat, and less than 1% for total, subcutaneous, subcutaneous abdominal, fat and bone marrow fat, respectively.

Exercise testing. All participants were assessed for their physical fitness at the National Sports Medicine Institute of the United Kingdom (Exercise Physiology Laboratory) before starting and at regular intervals throughout the study. Prior to testing, each subject completed a standard health questionnaire (Par-Q) to inform the physiologist of any health details that might influence the test results or her participation (12).

Physiological assessment. Following informed consent, all subjects were assessed for cardiorespiratory fitness at the beginning of the study. The measurements on each visit to the test facility included resting lung function and the maximal rate of oxygen consumption (VO_2 max).

Resting lung function. This was measured using a standard bellows Vitalograph (Vitalograph Ltd., Buckinghampshire, United Kingdom). Standard measures of forced vital capacity and forced expiratory volume in 1 s were made. Established tables of normative values (of age-, height-, and sex-matched individuals) were used for comparison (Vitalograph Ltd.).

VO_2 max. Each subject performed an incremental treadmill walking test at a constant 5 km/h, where the slope was increased by 2.5% every 2 min (Astrand protocol). All subjects were encouraged to continue the test to volitional exhaustion (or their measured peak capacity). Expired air was analyzed continuously for percentages of oxygen and carbon dioxide and minute ventilation (volume of air per minute) to measure oxygen consumption using an on-line metabolic cart [Jaeger Eos Sprint, Erich Jaeger (U.K.) Ltd.]. Subjects rated their perceived exertion using an unmodified Borg Scale in the last 30 s of each treadmill stage (13). The subject's heart rate was monitored continuously throughout the test (by using a Hewlett-Packard 43120A combined three-lead electrocardiogram monitor/defibrillator). The subject's resting (seated) heart rate was recorded before the test and her recovery (seated) heart rate 3 min immediately posttest. British Association of Sport and Exercise Science (BASES) guidelines were followed for all calibration and testing protocols (14). All measurements were carried out by the same accredited (BASES) exercise physiologist (JM). The CV of repeated VO_2 measurement in the laboratory is less than 2% (gas analyzer accuracy level = 0.1%). The CV for VO_2 measurements for any given individual on a day-to-day basis was approximately 3%.

Exercise. (i) Prescription. The results of the baseline cardiorespiratory test were used to ensure all subjects performed the same level of exercise. All participants were requested to perform three exercise sessions per week for a minimum of 30-min duration each time at an intensity corresponding to 60–70% of their individual VO_2max (derived from graphs of their VO_2 max vs. heart rate).

(ii) Progression. Because the individuals included in this study had not previously exercised and may therefore increase their VO_2 max quite quickly, it was necessary to retest everyone at 12 wk to ensure that their personalized "training zone" had not altered owing to improved fitness. All tests were scheduled to coincide with the individual's phase of their menstrual cycle and similar time of day from the baseline assessment. A new heart rate training zone was prescribed for those who had improved their fitness, to maintain the 60–70% of VO_2 max level of work in all their exercise classes for the duration of the study.

Exercise classes. Exercise classes consisted of pre-set aerobic routines including step-classes and aerobic exercise to music. All subjects were educated as to the correct use of heart rate monitors and how to exercise within their training zone. During the exercise period, all subjects were provided with ambulatory heart rate monitors (Polar/Cardiosport, Cardiosport Healthcare Technology Limited, Chichester, United Kingdom) and training diaries. The participants were asked to record their exercising heart rate at 10-min intervals during the organized classes. Each participant achieved and maintained her prescribed heart rate as instructed—maintenance was achieved by individual attenuation of the workload where necessary throughout the class. The attenuation was reinforced by visits from the researchers to the fitness establishment, during laboratory test sessions, and by periodic telephone contact. Activities outside the classes included danc-

ing (classes), swimming, jogging, and cycling for a small minority of participants and occurred mainly with subjects that were away for short periods of time, e.g., holidays. Guidelines were given in written format about forms of exercise and the required intensities.

Dietary analysis. Each volunteer completed a 7-d dietary diary at the beginning and at the end of the 6-mon exercise study, using methodology validated by Bingham *et al.* (15). Subjects were given a standard booklet containing written instruction on prospectively recording their food intake, which was also backed up by verbal advice. Portion sizes were estimated using handy household measures. The diaries were then returned and the volunteers contacted by telephone if clarification of intake was needed. Dietary analysis was carried out using a standard database (Dietplan 5, Forest Field Software, Horsham, West Sussex, United Kingdom) containing all data from current food tables (16).

Indirect calorimetry. Energy expenditure was measured using a Deltatrac II indirect calorimeter (S.W. Vickers Ltd., Kent, United Kingdom). The calorimeter was calibrated using standard gas before every subject, and alcohol burning was performed once a month. Weight was measured to the nearest 0.5 kg (Seka Scales, West Germany) and height to the nearest centimeter using a standometer. Measurements lasted 23 ± 2.3 min (means ± SEM) excluding a 5-min run-in period and were carried out in the morning after a 12-h overnight fast.

Skinfold anthropometry. Anthropometric assessment was obtained on each subject by a single trained observer (AB). Measurements of weight, height, waist and hip circumference, and skinfold thicknesses from the triceps, biceps, subscapular, and suprailiac regions were obtained. Percentage total body fat was calculated for each individual using standard methods (17).

Bioelectric impedance. Body fat content was measured by bioelectrical impedance analysis using the Bodystat 1500 Unit (Bodystat, Isle of Man Ltd., United Kingdom).

Biochemical analysis. Blood was obtained from each volunteer following a 12-h overnight fast. Serum was assayed for total cholesterol and triglycerides (enzymatic method, Technicon Dax system, Bayer Diagnostics, Leverkusen, Germany), high density lipoprotein cholesterol (HDL-C; direct measurement, RIAXT machine; Biostat Diagnostics, Cheshire, United Kingdom), and low density lipoprotein cholesterol (LDL-C) was calculated using the Friedwald formula. Serum was also assayed for insulin by immunoradiometric assay (guinea pig antiinsulin antibody; Scottish Antibody Production Unit, Carluke, Lanarkshire, Scotland). Plasma glucose was measured using an automated glucose analyzer (RA-1000; Technicon Instrument Co. Ltd., Basingstoke, United Kingdom).

Sex hormone-binding globulin (SHBG) was measured using an automated assay employing enzyme tracer and chemiluminescent endpoints [Immulite Diagnostic Products Corporation (DPC), Los Angeles, CA]. Testosterone and dehydroepiandrosterone sulfate (DHEAS) were measured using the St. Thomas's Extraction Assay (Chelsea Kits, London, United Kingdom). Free testosterone index was calculated by dividing testosterone (nmol/L) by SHBG (nmol/L) and multiplying by 100. C-peptide was measured using an enzyme immunometric assay (Immulite, DPC) is presented as the ratio of C-peptide to insulin, which is a good marker of insulin resistance. Cortisol levels were assessed using a TDX FPIA (fluorescence polarization immunoassay) (Abbott, IL). Serum nonesterified fatty acids (NEFA) were measured using a colorimetric assay (Wako, Osaka, Japan). Plasma leptin was measured using a double-antibody radioimmunoassay (Linco Research, St. Charles, MO). CV values for these assays were <10%. Samples were collected and stored till the end of the study, then analyzed in a single batch.

Statistical analysis. All data from the 17 women who completed the study are presented as means ± SEM. Possible differences before and after exercise were tested for using the Student's paired *t*-test. Significance was taken as $P < 0.05$; 95% confidence intervals (CI) are provided in parentheses. Because of the relatively small number of subjects and the possibility of a nonnormal distribution, these data were also analyzed using nonparametric statistics (Wilcoxon Signed Rank Test), with no difference in the results. Pearson product movement correlation coefficients (*r*) were used to assess the relationship between variables.

RESULTS

Results are presented from the 17 women who completed the study. There were no significant differences at baseline between the women who completed the study and those who dropped out (results not shown). The compliance rate of the subjects completing the study over the 6 mon was approximately 93% with occasional holiday and illness periods causing minor disruptions. On average, during a given 7-d period, each subject performed three classes of 40-min duration (heart rate within required training zone—i.e., excluding warm-up and cool-down periods). On a few occasions two subjects performed additional exercise sessions—but when averaged over the 6-mon period, 3 d-per-wk was standard.

Fitness. Following the 6-mon exercise training, there was an improvement in fitness, with significant increases in VO_2 max [36.35 ± 1.87 vs. 40.23 ± 1.33 mL/kg/min, $P < 0.05$ (95% CI −7.00– −0.75)] and maximal ventilation [87.12 ± 3.29 vs. 96.23 ± 4.21 L/min, $P < 0.01$ (95% CI −15.50– −2.73)]. There was also a significant decrease in heart rate recovery [113.8 ± 2.1 vs. 106.8 ± 2.4 beats/min, $P < 0.05$ (95% CI, 0.67–12.03)] (Table 1). There was no significant change in mean VeO_2 (ventilatory oxygen equivalent), which would have been expected to decrease with improving fitness.

Indirect calorimetry. There was no change in resting metabolic rate, measured by indirect calorimetry [1345 ± 56 vs. 1305 ± 78 kcal (95% CI, 162.11–204.37)] or in respiratory quotient [0.85 ± 0.02 vs. 0.84 ± 0.02 (95% CI, −0.04–0.08)] after 6 mon of aerobic exercise.

Dietary intake. No subjects were excluded because of dieting, as there was good agreement between recorded dietary

TABLE 1
Changes in Fitness Post-exercise[a]

	Pre-exercise (n = 17)	Post-exercise (n = 17)	Significance	95% CI
VO_2max (mL/kg/min)	36.35 ± 1.87	40.23 ± 1.33	$P < 0.05$	7.00––0.75
VeO_2	32.06 ± 1.04	30.65 ± 0.96	NS	–1.49–4.31
Maximal ventilation (L/min)	87.12 ± 3.29	96.23 ± 4.21	$P < 0.01$	–15.50––2.73
Heart rate recovery (beats/min)	113.2 ± 2.1	106.8 ± 2.4	$P < 0.05$	0.67–12.03

[a]Results presented as means ± SEM and 95% confidence interval (CI). NS, not significant. VD_2 max, maximal rate of oxygen consumption.

intake and resting metabolic rate (RMR) × 1.5 physical activity ratio (PAR) activity factor ($r = 0.78$, $P < 0.05$). There were no significant changes in daily calorific intake by 7-d food diaries [1920.0 ± 179.62 vs. 1971.0 ± 146.24 kcal/d (95% CI, –264.86–162.86)] following the 6-mon exercise protocol. Furthermore, levels of protein [14.39 ± 0.95 vs. 15.61 ± 1.48% (95% CI, –4.26–1.80)], carbohydrate [49.46 ± 2.36 vs. 51.43 ± 2.18% (95% CI, –7.18–3.23)] and fat [32.20 ± 2.36 vs. 29.47 ± 2.71% (95% CI, –3.98–9.44)] did not change significantly over the 6-mon period. The macronutrient content did not differ from the normal United Kingdom diet.

Body morphology. There was no significant change in body weight following 6 mon of exercise. Furthermore, body composition measurements by impedance and anthropometry did not significantly change following 6 mon of exercise (Table 2). Similarly, there were no significant changes in waist circumference, the waist-to-hip ratio (WHR), or the body mass index (BMI) after exercise.

Significant decreases in both total and some regional fat depots were observed with whole-body MRI (Table 3). There was a 6.4% decrease in the absolute amount of total body fat present [pre: 28.9 ± 2.2 vs. post: 27.0 ± 2.3 liters, $P < 0.05$ (95% CI, 0.49–3.21)]. There were also significant decreases (–4.6 and –16.8%) in the amount of subcutaneous [24.6 ± 1.9 vs. 23.4 ± 1.9 liters, $P < 0.05$ (95% CI, 0.10–2.15)] and internal fat [4.3 ± 0.4 vs. 3.6 ± 0.3 liters, $P < 0.01$ (95% CI, 0.33–1.12)], respectively. The biggest decrease was in the level of visceral fat (Fig. 1), which was reduced by 25% following exercise [1.7 ± 0.2 vs. 1.3 ± 0.2 liters, $P < 0.01$, (95% CI, 0.22–0.64)]. There was also a decrease of 11.5% in the level of non-visceral internal fat [2.6 ± 0.2 vs. 2.3 ± 0.2 liters, $P < 0.05$ (95% CI, 0.04–0.56)]. The change in the level of subcutaneous fat from the abdominal region was not significant [6.1 ± 0.6 vs. 5.7 ± 0.5 liters (95% CI, –0.08–0.90)].

Biochemistry. A significant increase in plasma HDL-C levels [1.58 ± 0.06 vs. 1.66 ± 0.08 mmol/L (60.11 ± 2.59 vs. 62.95 ± 3.12 mg/dL), $P < 0.02$ (95% CI, –0.18– –0.02)] was observed following exercise. However, there were no significant changes in total or LDL-C, plasma triglycerides, plasma glucose, or insulin (Table 4). Furthermore, there were no significant changes in NEFA, cortisol, testosterone (or free testosterone), C-peptide/insulin ratio, DHEAS, or SHBG following exercise (Table 4). There was no significant change in leptin levels following exercise.

Relationship between variables. There was a significant correlation between serum insulin and visceral fat both before ($r = 0.81$, $P < 0.01$) and after ($r = 0.54$, $P < 0.02$) exercise. There was also a significant correlation between abdominal subcutaneous fat and insulin before ($r = 0.71$, $P < 0.01$) but not after exercise. Interestingly, although there was no change in waist circumference with exercise, there was a significant correlation between waist circumference and visceral fat both pre- ($r = 0.78$, $P < 0.01$) and post-exercise ($r = 0.82$, $P < 0.01$). There were no significant correlations between visceral fat and the WHR either before or after exercise. There were no significant correlations between visceral fat and HDL-C, cortisol,

TABLE 2
Changes Post-exercise[a]

	Pre-exercise (n = 17)	Post-exercise (n = 17)	Significance	95% CI
Weight (kg)	68.2 ± 2.5	67.6 ± 2.7	NS	–1.16–1.39
BMI (kg/m^2)	24.5 ± 0.8	24.4 ± 0.8	NS	–0.39–0.52
Waist/hip	0.7 ± 0.01	0.7 ± 0.01	NS	–0.01–0.02
Body fat (%) (anthropometry)	30.3 ± 1.1	29.5 ± 1.2	NS	–1.18–2.19
Body fat (%) (impedance)	28.0 ± 1.5	28.9 ± 1.5	NS	–2.81–1.00
Body fat (%) (MRI[b])	29.9 ± 1.3	28.1 ± 1.4	$P < 0.01$	0.75–3.32

[a]Results presented as means ± SEM and 95% CI. BMI, body mass index. For other abbreviations see Table 1.
[b]Magnetic resonance imaging (MRI). For comparison with the anthropometry and impedance data, it is necessary to convert the absolute fat measurement in liters to a percentage. Therefore, MRI data in liters (Table 3) are converted to percentage body fat using the following equations (11): body fat in kg = [body fat in liters] × 0.9 [1]/% body fat = [(body fat in kg)/(body weight)] × 100 × 0.8 [2]. The factor 0.9 in Equation 1 is the widely accepted value for the density of adipose tissue in kg/L and is required to convert volume of fat in liters to mass of fat in kilograms. In Equation 2, the factor 0.8 accounts for the fat content of adipose tissue and is required to convert from fractional adipose tissue content to percentage fat in the body.

TABLE 3
Body Fat Content by Whole-Body MRI Expressed in Liters[a]

	Pre-exercise (n = 17)	Post-exercise (n = 17)	Mean % change	Significance	95% CI
Total fat	28.9 ± 2.2	27.0 ± 2.3	–6.4	$P < 0.05$	0.49—3.21
Subcut fat	24.6 ± 1.9	23.4 ± 1.9	– 4.6	$P < 0.05$	0.10—2.15
Abdo fat	6.1 ± 0.6	5.7 ± 0.5	–6.7	NS	–0.08—0.90
Internal fat	4.3 ± 0.4	3.6 ± 0.3	–16.8	$P < 0.001$	0.33—1.12
Visceral fat	1.7 ± 0.2	1.3 ± 0.2	–25.0	$P < 0.001$	0.22—0.64
Nonvisceral internal fat	2.6 ± 0.2	2.3 ± 0.2	–11.5	$P < 0.05$	0.04—0.56

[a]Results presented as means ± SEM and 95% CI. Subcut = subcutaneous; abdo = abdominal subcutaneous fat. For other abbreviations see Tables 1 and 2.

C-peptide/insulin, or NEFA before or after exercise. The correlations between visceral fat and DHEAS ($r = -0.41$, $P < 0.05$), and SHBG ($r = 0.72$, $P < 0.01$) and testosterone ($r = -0.46$, $P < 0.05$) were only significant following exercise.

DISCUSSION

In this study we showed that a moderate exercise program (only 3 h a week) had a significant effect on the body fat content of nonobese sedentary healthy women. Furthermore there was a preferential loss of fat from certain fat depots. These changes were observed even though there were no significant changes in body weight, BMI, waist circumference, or WHR.

The changes in body fat content reported in this cohort of subjects were only detected using whole-body MRI, probably because MRI is the only technique that can measure total and regional adipose tissue directly. Anthropometry and impedance only provide an indirect measure of body fat and are therefore unable to detect regional changes. Furthermore, the most significant changes detected in this study were from internal fat depots which overall correspond to <20% of total body fat. Therefore, even a significant decrease in fat from a small depot may be missed in the total body fat measurement.

Numerous studies have examined the effects of exercise on total body fat content. However, there is a paucity of information regarding the impact of exercise on specific body fat depots. This is partly because many research protocols include dietary restriction/modification in addition to the exercise regime. Also the technique(s) used to measure body fat may not allow separation of different body fat compartments. In our study we used a protocol which only included aerobic exercise, with no dietary restriction, with fat depots assessed directly by MRI. The results showed that a preferential loss of visceral fat followed a 6-mon regime of aerobic exercise.

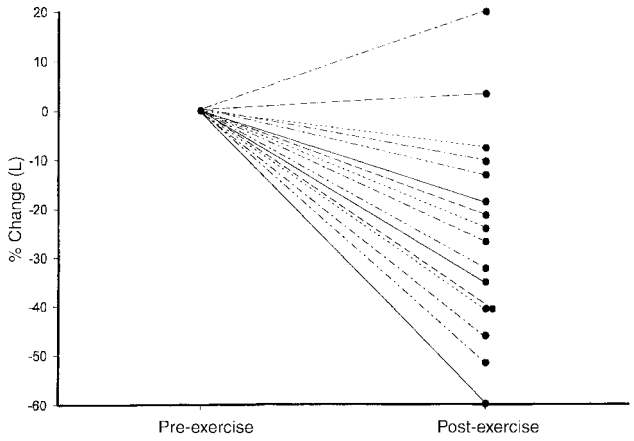

FIG. 1. Percentage change in visceral fat (in liters) for each volunteer following 6 mon aerobic exercise training.

Results from the present study are similar to those reported by Treuth *et al.* (6) with obese volunteers but differ from those of Despres *et al.* (18), who showed preferential loss of subcutaneous abdominal fat without changes in visceral fat following a set exercise regimen. Furthermore, in a separate study Schwartz *et al.* (19) showed exercise led to overall body fat loss, including visceral fat. These apparent differences regarding the effects of exercise on body fat depots may be due to a number of factors, including scanning methodology, exercise regime (aerobic or resistance), and choice of volunteers (lean or obese; pre- or postmenopausal).

To study regional changes in adipose tissue, it is essential to use direct imaging techniques such as CT or MRI. However, it is important that sufficient data be collected from the whole region of interest so that subtle changes are not missed or overinterpreted. A change or lack of change reported using single slice CT or MRI scans from a selected region of the abdomen might not reflect the effect of the intervention on the entire adipose tissue depot. Indeed, it has previously been shown that a single CT scan obtained at the level of the umbilicus contains a substantial amount of retroperitoneal fat, which is less metabolically active than other visceral fat depots (20). It has therefore been suggested that changes occurring in the entire visceral fat depot may be diluted out by the presence of the less-active retroperitoneal fat in the single slice (19). Factors like this can have a profound effect on the final results. Similarly, exercise protocols and choice of volunteers appear to be important and should be taken into account when comparing different published studies. Nevertheless, our results and those from other groups clearly suggest that different body fat depots are affected differently by environmental stresses such as exercise and diet.

The possible underlying mechanism(s) responsible for the

preferential loss of fat from certain fat depots are not fully understood. Fat depots differ metabolically and may be controlled differently by environmental and genetic factors. Indeed, visceral and subcutaneous fats are known to be differentially affected by glucocorticoids, sex hormones, insulin, and adrenergic hormones (21). Changes in a number of these hormones occur with exercise, including cortisol secretion and in the balance of sex hormones (22). However, we found no changes in cortisol or sex hormone levels following exercise in the present study, suggesting the influence of an alternative factor. It is possible that the decrease in fat cell size reported to occur following exercise is greater in visceral fat than subcutaneous fat (23). For example, norepinephrine stimulates lipolysis more actively in visceral fat than in subcutaneous adipose tissue, mainly due to differences in adrenoreceptor levels (24). It has been reported that a preferential mobilization of abdominal subcutaneous fat is related to the initial size of the depot (8,25). Clearly complex interactions between a number of factors result in differential fat metabolism, which requires further investigation.

An interesting finding arising from using whole-body MRI was the fact that there was a significant decrease in nonvisceral internal fat depot (internal fat from regions other than visceral fat) with exercise. A substantial part of this fat depot arises from adipose tissue between muscle fibers (extracellular skeletal muscle fat). These changes may be important, particularly in light of the potential influence of muscle triglycerides on insulin sensitivity (26). The extra-muscular fat depot is perhaps the least well-understood adipose depot in the body, in part because of the difficulty in measuring it accurately. Although the MRI technique used in the present study was not optimized for measuring this depot, we were still able to detect significant changes with exercise, suggesting that MRI techniques may play an important role in the study of this fat depot. Further work is required to determine if extracellular skeletal muscle fat is an independent factor in the modulation of insulin sensitivity.

There was a significant correlation between the level of visceral fat and waist circumference both before and after exercise. This would appear to confirm the suggestion that waist circumference as opposed to WHR is a more suitable surrogate measure of visceral fat (27). However, there was a significant reduction in visceral adipose tissue, there were no significant changes in either waist circumference or abdominal subcutaneous fat following exercise. This would suggest that the relationship between waist circumference and visceral fat content is not straightforward. Indeed in this study we found a stronger correlation between abdominal subcutaneous fat and waist circumference ($r = 0.90$, $P < 0.01$) than for visceral fat and waist circumference ($r = 0.78$, $P < 0.01$). In nonobese women, such as those included in this study, abdominal subcutaneous fat makes up a far greater proportion of the area described by the waist circumference than visceral fat. A significant change in the waist circumference will not likely be seen unless there is a significant reduction in abdominal subcutaneous fat. The findings of this and a previous study highlight the potential problem of using surrogate measures of visceral fat (21).

The significant loss of visceral fat (25%; Table 3) explains some of the positive effects of moderate exercise on health (e.g., the increase in plasma HDL-C levels). The beneficial effects of exercise on plasma lipid levels have been well-documented (28). Trained individuals generally have higher levels of plasma HDL-C and lower levels of triglycerides than control subjects. Furthermore, plasma HDL-C levels increase following exercise over a period of months, a finding we confirmed in the present study. However, there were no changes

in plasma triglycerides. In some ways it is not surprising that there were not more significant changes in the biochemical profile. The volunteers' plasma lipid levels and those of their other metabolites were all within the normal range, so they would not necessarily be expected to change significantly with exercise alone. We found no significant changes in leptin levels before and after exercise. The greatest percentage change in fat was visceral. Previous studies have shown that visceral fat produces considerably less leptin than subcutaneous fat (29).

In summary, in this study we demonstrated that a moderate amount of aerobic exercise, without dietary restriction, produces a significant preferential loss of MRI-measured visceral fat content. In the future, we hope to determine the effects of different types of exercise regimes on different fat depots and their relationship to health benefits.

ACKNOWLEDGMENTS

Financial support from the Medical Research Council and Marconi Medical Systems are gratefully acknowledged. We thank all of the volunteers who took part in this study and The Women's Gym (in particular Myriam Thompson and Thuvia Jones) for their cooperation. We also thank Dr. Basant Puri, Simon Taylor-Robinson, Gabby Jenkinson, and Po-Wah So from the MRI unit for their assistance. Finally we thank Biochemical Endocrinology, Hammersmith Hospital for performing the hormone assays and the Oxford Lipid Metabolism Group, Radcliffe Infirmary, Oxford for performing the NEFA assay. APG is a U.K. Medical Research Council Training Fellow.

Conjugated Linoleic Acid Supplementation in Humans: Effects on Body Composition and Energy Expenditure

Kirsten L. Zambell, Nancy L. Keim*, Marta D. Van Loan, Barbara Gale, Paloma Benito, Darshan S. Kelley, and Gary J. Nelson

U.S. Department of Agriculture/Western Human Nutrition Research Center, University of California, Davis, California 95616

ABSTRACT: Recent animal studies have demonstrated that dietary conjugated linoleic acid (CLA) reduces body fat and that this decrease may be due to a change in energy expenditure. The present study examined the effect of CLA supplementation on body composition and energy expenditure in healthy, adult women. Seventeen women were fed either a CLA capsule (3 g/d) or a sunflower oil placebo for 64 d following a baseline period of 30 d. The subjects were confined to a metabolic suite for the entire 94 d study where diet and activity were controlled and held constant. Change in fat-free mass, fat mass, and percentage body fat were unaffected by CLA supplementation (0.18 ± 0.43 vs. 0.09 ± 0.35 kg; 0.01 ± 0.64 vs. –0.19 ± 0.53 kg; 0.05 ± 0.62 vs. –0.67 ± 0.51%, placebo vs. CLA, respectively). Likewise, body weight was not significantly different in the placebo vs. the CLA group (0.48 ± 0.55 vs. –0.24 ± 0.46 kg change). Energy expenditure (kcal/min), fat oxidation, and respiratory exchange ratio were measured once during the baseline period and during weeks 4 and 8 of the intervention period. At all three times, measurements were taken while resting and walking. CLA had no significant effect on energy expenditure, fat oxidation, or respiratory exchange ratio at rest or during exercise. When dietary intake was controlled, 64 d of CLA supplementation at 3 g/d had no significant effect on body composition or energy expenditure in adult women, which contrasts with previous findings in animals.

Paper no. L8437 in *Lipids 35,* 777–782 (July 2000).

Conjugated linoleic acid (CLA) refers to a group of linoleic acid isomers in which the double bonds are conjugated. The double bonds, each of which may be in the *cis* or *trans* configuration, can be in any position on the carbon chain but are usually in the 9 and 11 or 10 and 12 positions, giving rise to at least eight theoretical isomers in mixed CLA preparations. CLA is found naturally in foods such as grilled ground beef (1) and some dairy products (2). The estimated consumption of CLA by adults in the United States is 1 g/person/d (2).

CLA has been reported to be protective against atherosclerosis in rabbits (3) and to suppress mammary carcinogenesis in rats (4–6) when the animals were fed diets supplemented with CLA. Recently, the addition of CLA to the diet of mice has reportedly caused a decrease in body fat (7–11). Studies with adipocytes exposed to exogenous CLA showed reduced lipoprotein lipase activity, reduced levels of triglyceride and glycerol inside the cells, and increased glycerol levels outside the cells (8,10). These data suggest that CLA may reduce body fat by affecting key enzymes involved in lipid mobilization and storage.

Although CLA caused a decrease in body fat in mice, overall body weight was either unchanged (8,9) or decreased (7,10,11). Supplementation studies in rats showed no effect of CLA on body weight (body fat was not measured) (4–6). The body weight decrease and the reduction in body fat may be countered by an increase in lean body mass and body water (8,9). Changes in body composition could also be due to changes in energy intake and/or expenditure. Energy intake was unaffected (7) or reduced (8,11) in mice on a CLA-supplemented diet. The effects of CLA on energy expenditure have not been fully studied.

Despite the previous results in animal models, the effect of CLA in humans has not been thoroughly studied. In the study reported here, we observed the effects of CLA supplementation (3 g/d/person) on body composition and energy expenditure in healthy women. The dosage of CLA used was threefold higher than the reported daily consumption for American adults (2). This amount is similar to that used in previous animal and human studies, and it is within the reasonable range for a healthy, non-vegan adult.

MATERIALS AND METHODS

Subjects. Seventeen women, 20–41 yr of age, completed the entire 94-d study. Subject selection criteria included being a healthy nonsmoker, premenopausal with normal menstrual cycles, and free of any abnormal physiological conditions or diseases. Prior to being selected for the study, all subjects completed medical and dietary histories, physical examination, urinary test for pregnancy, resting electrocardiogram, and a standard battery of blood tests. Participation was by informed consent. The study protocol was approved by the Human Subject Committees of the U.S. Department of Agriculture and the University of California, Davis.

Abbreviations: CLA, conjugated linoleic acid; DXA, dual x-ray absorptiometry; FFM, fat-free mass; RER, respiratory exchange ratio; TOBEC, total body electrical conductivity; VCO_2, carbon dioxide production; VO_2, oxygen consumption.

Subjects lived in the metabolic suite at the Western Human Nutrition Research Center, 24 h/d, 7 d/wk for 94 d of the study. Times for meals and routine daily activities were standardized to keep the activities similar throughout the study. Routine activities included a daily outdoor walk (2 mi/d) and other forms of outdoor exercise.

Experimental design. This randomized, blind, and placebo-controlled study was conducted with two cohorts (9 in the first cohort and 8 in the second) since the metabolic suite could not accommodate 17 subjects at once. The duration of each cohort was 94 d, consisting of a 30-d baseline period followed by a 64-d intervention period during which either CLA or placebo capsules were administered. During the baseline period, all subjects received a daily placebo containing sunflower oil to become accustomed to taking the capsules. On day 31, 10 subjects were randomly assigned to the group receiving supplemental CLA (approximately 1% of calories, ~3 g/d) for the remainder of the study. The seven remaining subjects served as controls and consumed placebo capsules for the entire study.

CLA capsules were obtained from Pharmanutrients, Inc. (Lake Bluff, IL). CLA constituted approximately 65% of the total fatty acids in the capsule with the remainder consisting primarily of oleic acid. Isomer composition of the CLA was determined by gas chromatography and found to be 22.6% *trans*-10,*cis*-12; 23.6% *cis*-11,*trans*-13; 17.6% *cis*-9,*trans*-11; 16.6% *trans*-8,*cis*-10; 7.7% *trans*-9,*trans*-11 and *trans*-10,*trans*-12; 11.9% other isomers. The placebo capsule contained 72.6% linoleic acid with the remainder consisting mainly of palmitic, stearic, and oleic acids and no detectable CLA isomers. The capsules used were identical in appearance and were packaged in the same manner.

Dietary intake. The subject's diets were equivalent to the American Heart Association's Step II Diet containing the reference daily intake for all known nutrients with 30% of calories from fat, 15% from protein and 55% from carbohydrate. The energy intake of each subject was estimated using the Harris-Benedict equation. During the baseline period, the energy intake was adjusted if body weight changed by ±3% over time. The ratio of saturated, monounsaturated, and polyunsaturated fat was 1:1:1 for both placebo and intervention groups with saturated fat, linoleic acid, and other n-6 polyunsaturated fat held constant among the two groups. The cholesterol content of the diets was between 250 and 300 mg/d.

Body weight and composition. Subjects were weighed daily by a member of the nursing staff in the morning, after urinating to empty their bladders and before ingesting breakfast. Subjects wore standard hospital gowns for all weight measurements.

Body composition was determined three times per week by total body electrical conductivity (TOBEC) measured by an HA-2 body composition analyzer (EM-SCAN, Springfield, IL). This method exploits the difference in the electrical conductivity of fat vs. fat-free tissue to estimate fat-free mass (FFM). Body fat mass was determined by subtracting FFM from body weight. This method has been validated in our laboratory and shown to produce values for FFM similar to that estimated by hydrostatic weighing in humans (12) and carcass analysis in pigs (13). All measurements were taken before breakfast.

Body composition was also determined by using dual x-ray absorptiometry (DXA) (DPX, software package 3.63, Lunar Corp., Madison, WI) at three times during the study—baseline and twice during the supplementation period. DXA directly measures fat mass and FFM by passing a small quantity of x-rays through the body. The change in fat mass and FFM was calculated by subtracting the baseline DXA measurement from the final measurement. Owing to the exposure of the subjects to x-rays, DXA could not be used on a more frequent basis throughout the study.

To avoid reporting spurious changes in body weight and composition that may be due to the menstrual cycle, we analyzed body weight and composition data by fitting a regression line to the plot of each variable vs. time for the baseline and intervention periods. The change in body weight or composition was determined by multiplying the slope of the regression line by the number of days in the baseline or intervention period.

Energy expenditure and utilization. Metabolic rate and respiratory exchange ratio (RER) were determined from measurements of oxygen consumption (VO_2) and carbon dioxide production (VCO_2). The gas exchange measurements were made with an automated respiratory gas exchange system (2900; SensorMedics, Anaheim, CA). The system was calibrated with standard gas mixtures and the calibration was verified at intervals throughout the collection periods. Subjects wore inflatable facemasks that were connected to the gas analyzers *via* a tubing assembly. Energy expenditure was calculated from VO_2 and VCO_2 using the equations of Weir (14). A correction factor for urinary nitrogen output was made by estimating a nitrogen excretion rate of 0.01 g/min. This estimate was based on dietary nitrogen intake, fecal nitrogen losses (~1 g/d) and insensible nitrogen losses (~1 g/d). Fat oxidation (g/min) was calculated using the equation of Frayn (15).

Energy expenditure was measured once during the baseline period and twice during the intervention period (weeks 4 and 8). Following an overnight fast, subjects rested quietly in a comfortable chair for 30 min, then respiratory gas exchange was measured for 20 min intervals: first, while resting in a seated position, then, during steady-state walking on a treadmill at 60% VO_2max (at time intervals of 5–25 and 30–50 min).

Statistical methods. Values are reported as means ± SEM. Data represent combined data for all subjects because statistical analysis showed no effect of cohort. To compare subject characteristics among placebo and CLA groups *t*-tests were used. Analysis of variance was used to determine the effect of CLA on changes in body weight and composition. The baseline rate of change was used as a covariate in the model. Analysis of variance was used to determine the effect of CLA, time, and the interaction of CLA and time on energy expenditure parameters. To adjust for differences in body size among

subjects, body FFM was used as a covariate in the analysis. The probability level for significance was set at $P < 0.05$. All statistical analyses were performed using the Statistical Analysis System (SAS Institute Inc., Cary, NC).

RESULTS

Subject characteristics at start of intervention. Physical and metabolic characteristics of the subjects at the end of the baseline period are listed in Table 1. Mean values for age, body weight, height, FFM, percentage body fat, resting metabolic rate, and RER were similar for the groups prior to the CLA supplementation.

Change in body weight and composition. Dietary energy intake was similar during baseline and supplementation periods for both the placebo and CLA groups (Table 2). Daily CLA supplementation did not cause a significant change in body weight after 64 d of intervention compared to the placebo group (Fig. 1; Table 3). In using the TOBEC method, there were no significant differences in body composition among the CLA and placebo groups (Table 3). Likewise, body composition results from the DXA method indicated that CLA had no effect on body fat mass (–0.19 ± 0.67 vs. –0.49 ± 0.44 kg change, placebo vs. CLA) or body FFM (0.17 ± 0.40 vs. 0.07 ± 0.24 kg change, placebo vs. CLA).

Energy expenditure and utilization. The energy expenditure and fat oxidation data were adjusted for differences in FFM by using FFM as a covariate. During the baseline period, energy expenditure (kcal/min) was similar between placebo and CLA groups while resting and exercising (Fig. 2). No significant effects of CLA were observed at 4 or 8 wk of intervention during rest or while walking. An expected increase in energy expenditure was observed with the onset of walking in both placebo and CLA groups at all timepoints.

As with energy expenditure, fat oxidation (g/min) was similar between the placebo and CLA groups at rest and while exercising during the baseline period (Fig. 2). CLA had no significant effect on fat oxidation during resting or walking at 4 or 8 wk of intervention. Because of the increase in energy expenditure associated with walking, fat oxidation was higher while walking as compared to rest at all three timepoints.

In both the CLA and placebo groups, the RER increased with the onset of walking (5–25 min) but gradually dropped as walking progressed (30–50 min; Fig. 3). When an average value for the 20-min rest and 50-min walk periods was calculated, there was no significant effect of CLA on the RER during resting or walking (data not shown).

DISCUSSION

Healthy, adult women, fed a CLA mixture daily for 64 d, showed no significant change in FFM, fat mass, or percentage body fat compared to the placebo group (Table 2). These findings contrast markedly with previously reported human and animal studies in which diets were supplemented with CLA. Medstat Research Ltd. (16) performed the only other known study in which CLA was fed to humans. The Medstat Research study reported a 20% decrease in body fat after 12 wk of CLA supplementation (~1.8 g/d) in free-living, healthy men and women. There are several differences between the present study and the Medstat study that might explain the discrepancy. First, in the present study, body composition was

Fat mass (kg)	0.01 ± 0.64	–0.19 ± 0.53	0.82
Body fat (%)	0.05 ± 0.62	–0.67 ± 0.51	0.39

[a]Body composition measurements were made using the TOBEC (total body electrical conductivity) method. For abbreviation see Table 1.

measured three times per week throughout the entire study using a whole-body measurement, TOBEC. In the Medstat study, body composition was measured once every 4 wk using infrared technology on the bicep of the better arm. Second, the Medstat study included males and females but did not break down the results by gender so the effect of CLA on body composition in women was not reported. Third, the present study was conducted in a metabolic suite so diet and activity could be controlled and held constant throughout, whereas the Medstat study was a free-living study with no documented evidence of activity or diet intake levels. Fourth, the isomer composition of the CLA supplement in the Medstat study was not reported and may be different from the present study. Therefore, it is difficult to interpret the body composition data from the Medstat study and compare them to the present data.

Previous work with mice (7–11), rats (17), and pigs (18) showed a decrease in body fat with consumption of a CLA mixture. Several studies have also shown an increase in FFM with a supplemental CLA mixture (7–9). All of these studies used weanling or adolescent animals that were still growing and changing in body composition. There are data to suggest that CLA may affect growing animals differently from adults by depressing body fat accumulation *via* a reduction in preadipocyte number when given during periods of growth (19). The subjects in the present study were weight-stable adults with steady body compositions prior to CLA supplementation (Table 1). Unfortunately, there are no studies currently available reporting the effect of dietary CLA on body weight and composition in an adult animal model.

Consumption of a CLA mixture also had no effect on body weight in adult women in the present study (Table 3; Fig. 1). Although the placebo group had a tendency to gain weight while the CLA group lost weight, the changes were very small and within the measurement variability. This finding is consistent with previous human and animal studies in which body weight remained stable, or the increase in body weight was similar between CLA and placebo groups. The Medstat study also showed no significant change in body weight after 12 wk of CLA supplementation in humans (16). In general, a dietary CLA mixture (0.05–1.5%, by weight, for 6–36 wk) had no effect on body weight or feed intake in rats (4,5,20,21)

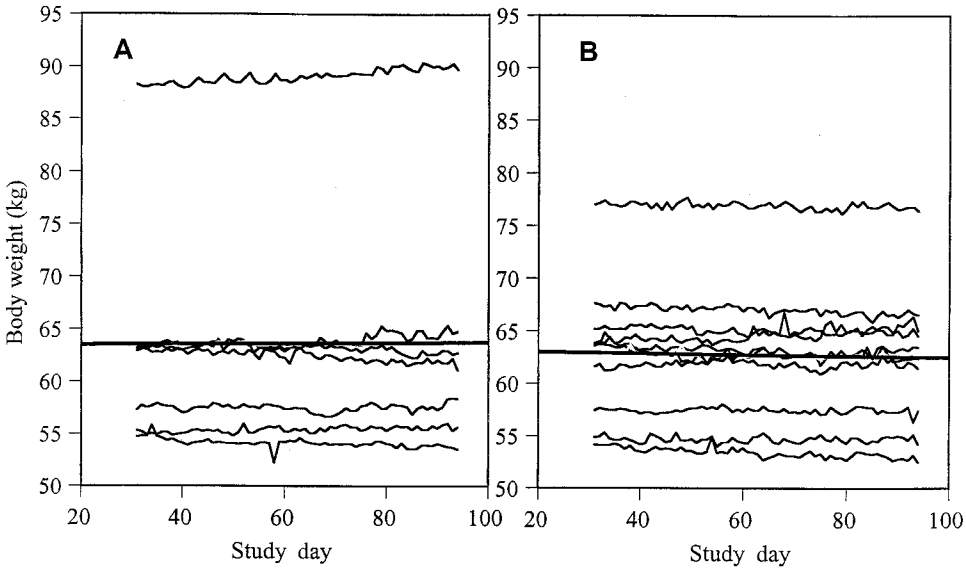

FIG. 1. Daily body weights (kg) during the conjugated linoleic acid (CLA) supplementation period (days 31–94) of the placebo (A; n = 7) and CLA (B; n = 10) groups. The bold line indicates the regression line for the average daily weight in each group.

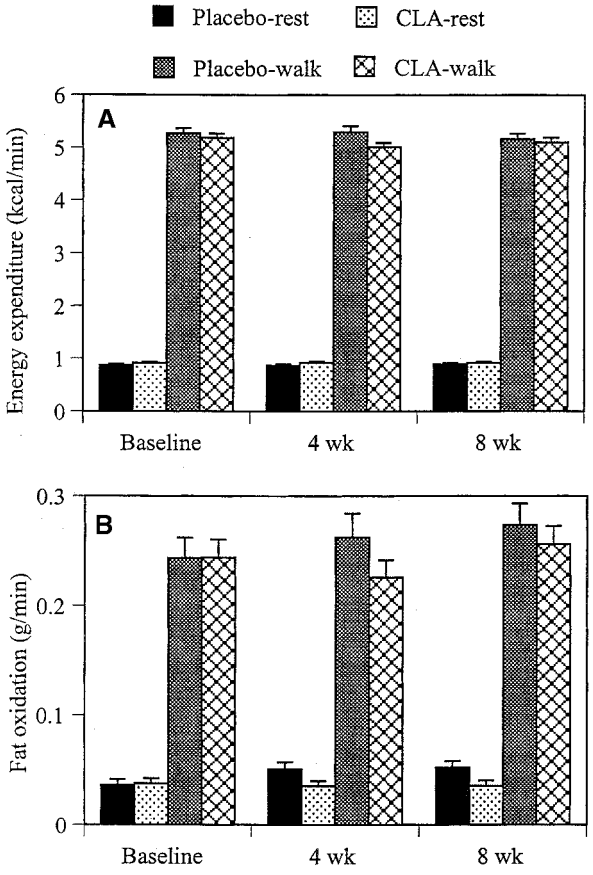

FIG. 2. The effect of CLA on energy expenditure (A) and fat oxidation (B) at baseline, 4 or 8 wk of intervention during resting and walking. Energy expenditure and fat oxidation were adjusted for fat-free mass. The bars represent means ± SEM for all subjects because statistical analysis showed no effect of cohort; $n = 7$ for placebo group, $n = 10$ for CLA group. No significant differences were found when placebo and CLA groups were compared during rest or during exercise. For abbreviation see Figure 1.

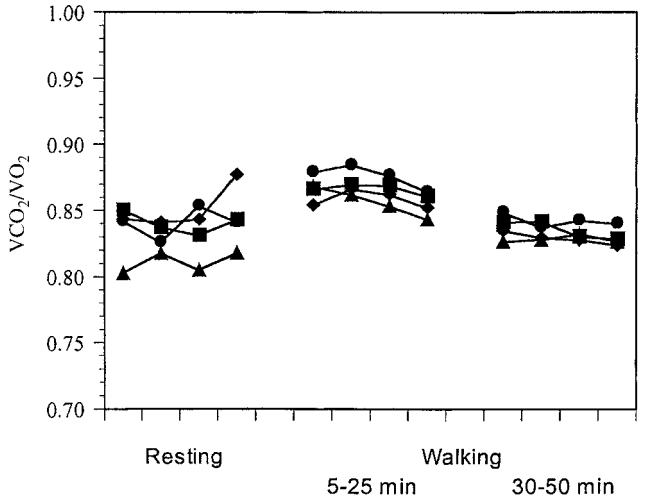

FIG. 3. The effect of CLA on the respiratory exchange ratio at baseline or 8 wk of intervention during resting and walking. Each point represents the average of five 1-min data collections. No significant differences were found when placebo and CLA groups were compared at baseline (● and ■, respectively) or 8 wk (▲ and ◆, respectively) during rest or exercise; $n = 7$ for placebo group and $n = 10$ for CLA group. For abbreviation see Figure 1.

or rabbits (3). Decreases in body weight due to consumption of a CLA mixture (0.25–1.2% for 4–6 wk) have been observed in mice, however, they were associated with a decrease in food intake (9,10). The short duration of the mice studies may have confounded the body weight results since a decrease in food intake has been observed during the first few weeks of CLA supplementation (11). The authors suggested that the addition of CLA may have caused an initial decrease in the palatability of the diet. Overall, the data are consistent with the idea that feeding a mixture of CLA isomers does not significantly affect body weight in humans or rodents when food intake is maintained.

Energy expenditure was unaffected by consumption of a CLA mixture in adult women as well (Fig. 2). A previous animal study suggested that CLA might decrease body fat by increasing overall energy expenditure (11). During the sixth week of CLA supplementation, energy expenditure (kcal/d) was significantly higher in the CLA-fed mice vs. the placebo group. However, the CLA-supplemented mice also exhibited a decrease in feed intake compared to controls. Therefore, it is difficult to determine if the observed changes in body composition were due to the decrease in food intake or the increase in energy expenditure.

There was no effect of consumption of a CLA mixture on fat oxidation during rest or while walking (Fig. 2). The effect of supplemental CLA on fat oxidation has not been measured previously. Based on earlier studies with adipocytes exposed to a CLA mixture, we expected to observe an increase in fat oxidation. Exposure to a mixture of CLA isomers reduces lipoprotein lipase activity and enhances lipolysis, causing a reduction in the intracellular triglyceride and glycerol concentrations (8,9). Muscle carnitine palmitoyltransferase activity was also stimulated in mice fed a CLA mixture (8) suggesting increased fatty acid oxidation in the muscle tissue. Although carnitine palmitoyltransferase activity was increased, fat oxidation was not directly measured. CLA has also been shown to increase hepatic lipid concentrations, suggesting that nonoxidized fatty acids are routed to the liver (22). Thus, CLA may increase triglyceride recycling (triglycerides broken down in the adipose tissue and reformed in the liver) without affecting fatty acid oxidation.

The onset of walking did lead to an increase in fat oxidation vs. the resting state in both the placebo and CLA groups (Fig. 2). This is to be expected since working muscles burn more fatty acids for energy during exercise than at rest. An expected transient increase in the RER with the onset of walking was also observed in both placebo and CLA groups (Fig. 3). Walking at 60% VO_2max increased the energy expenditure of the subjects by about fivefold (Fig. 2). However, the mean RER (over the 50-min walk) was not different from the RER at rest in both treatment groups.

It should be noted that the CLA supplement used in the present experiment was not pure and included a number of isomers along with the presumed biologically active form, *trans*-10,*cis* 12 (9). In the present study, the *trans*-10,*cis*-12 isomer was the most abundant isomer, along with the *cis*-11,*trans*-13 (~23% for each), in the CLA supplement. However, previous studies that observed changes in body composition in mice employed CLA supplements that consisted of 40–45% *trans*-10,*cis*-12 (7,9–11). Although feeding CLA containing 44 or 79% *trans*-10,*cis*-12 to mice resulted in similar reductions in percentage body fat (9), it is possible that 23% of the active isomer may be below the threshold level necessary to elicit body composition changes. Further studies using various levels of the pure isomers would be useful to understand fully the metabolic effect of dietary CLA.

In conclusion, consumption of a CLA mixture at 1% of calories had no significant effect on body composition or energy expenditure in healthy women after 64 d of intervention. These results are in marked contrast to previous animal studies which used adolescent, growing animals for supplementation studies.

Conjugated Linoleic Acid Supplementation in Humans: Effects on Circulating Leptin Concentrations and Appetite

ABSTRACT: Conjugated linoleic acid (CLA) has been demonstrated to reduce body fat in animals. However, the mechanism by which this reduction occurs is unknown. Leptin may mediate the effect of CLA to decrease body fat. We assessed the effects of 64 d of CLA supplementation (3 g/d) on circulating leptin, insulin, glucose, and lactate concentrations in healthy women. Appetite was assessed as a physiological correlate of changes in circulating leptin levels. Analysis of plasma leptin concentrations adjusted for adiposity by using fat mass as a covariate showed that CLA supplementation significantly decreased circulating leptin concentrations in the absence of any changes of fat mass. Mean leptin levels decreased over the first 7 wk and then returned to baseline levels over the last 2 wk of the study in the CLA-treated group. Appetite parameters measured at around the time when the greatest decreases in leptin levels were observed showed no significant differences between supplementation and baseline determinations in the CLA-supplemented group or between the CLA and placebo-supplemented groups. There was a nonsignificant trend for mean insulin levels to increase toward the end of the supplementation period in CLA-treated subjects. CLA did not affect plasma glucose and lactate over the treatment period. Thus, 64 d of CLA supplementation in women produced a transient decrease in leptin levels but did not alter appetite. CLA did not affect these parameters in a manner that promoted decreases of adiposity.

Paper no. L8438 in *Lipids 35,* 783–788 (July 2000).

Conjugated linoleic acid (CLA) is the generic name for a group of positional and geometric conjugated dienoic isomers of linoleic acid. CLA has received considerable attention for its anticarcinogenic (1) and antiatherogenic activities (2,3). More recently CLA has been demonstrated to reduce body fat in mice (4–6) and lower glucose and insulin levels in genetically obese Zucker fatty (fa/fa) rats (7). However, CLA has also been shown to increase plasma insulin levels in mice (4). Because CLA supplementation is being considered for the treatment and prevention of obesity and diabetes, it would be useful to determine the effects of CLA on plasma insulin and glucose levels in humans.

The mechanism by which CLA exerts its effects on body composition is unknown. *In vitro* studies suggest that CLA reduces body fat by acting directly on adipocytes to enhance lipolysis and decrease lipoprotein lipase activity (5). However, it is also possible that CLA mediates reductions of body fat through leptin, the *ob* gene product that regulates adiposity through decreases of food intake and increases in metabolic rate (8–11). Leptin has also been shown to directly stimulate lipolysis in adipose tissue explants (12) and cultured adipocytes (13,14). CLA has been shown to decrease food intake and increase metabolic rate to varying degrees in mice (5,6,15). Thus, increases of plasma leptin concentrations could indeed mediate the effect of CLA to reduce body fat.

In this study, we sought to assess the effects of 9 wk of CLA supplementation on circulating leptin levels in healthy women. Because a number of studies indicate that insulin (16) and insulin-mediated glucose metabolism (17) regulate leptin production by adipose tissue as well as changes of circulating leptin concentrations in response to energy intake (18–20) and energy restriction (21,22), plasma insulin and glucose concentrations were measured throughout the study. Appetite was assessed as physiological correlate of changes in leptin production.

MATERIALS AND METHODS

Subjects and study design. Twenty-four women were recruited for this study, and 17 women completed it. Potential subjects completed a medical and physical examination, standard blood test, diet history, assessment of eating behavior to rule out eating disorders, and a urine test for pregnancy. Subjects selected for inclusion were all healthy, nonsmoking women between the ages of 20 and 41 yr of age and with normal menstrual cycles. Subjects lived in the metabolic suite at the Western Human Nutrition Research Center, University of California (Davis, CA) 24 hr/d, 7 d/wk for the entire study, which consisted of a 30-d stabilization period followed by a 64-d intervention period. At the end of the baseline period,

Abbreviations: AUC, area under the curve; BMI, body mass index; CLA, conjugated linoleic acid; PPAR-γ, peroxisome proliferator activated receptor-γ.

10 subjects were randomly assigned to receive a CLA supplement and 7 were assigned to receive a sunflower oil placebo. The subjects and technical/support staff were blinded as to the treatment assignments.

At the beginning of the intervention period, 3 g/d (approximately 1% of daily energy intake) of CLA was given in the form of a treatment capsule from Pharmanutrients, Inc. (Lake Bluff, IL) until the study was completed. Of the fatty acids in the capsules 65% were CLA isomers, and gas chromatography showed that the isomer composition was 22.6% *trans*-10, *cis*-12; 23.6% *cis*-11,*trans*-13; 17.6% *cis*-9,*trans*-11; 16.6% *trans*-8,*cis*-10; 7.7% *trans*-9,*trans*-11 and *trans*-10,*trans*-12; and 11.9% other isomers. Placebo capsules made from sunflower oil contained 72.6% linoleic acid and no detectable CLA; they were taken during the baseline period by all subjects and during the intervention period by the control group. The CLA and placebo capsules were identical in appearance.

Both baseline and intervention diets met the Recommended Daily Allowance for all known nutrients and were matched with respect to energy as a percentage of calories from carbohydrate, protein, and fat (55, 15, and 30%, respectively). The caloric intake of each subject was estimated with the Harris-Benedict equation and intake adjusted during the baseline period to maintain body weight. The diet was provided as a rotating 5-d menu. Four meals were served daily. Meal times were set at 8:30–9:00 A.M. for breakfast, 12:00–12:30 P.M. for lunch, 5:00–5:30 P.M. for dinner, and 7:00–7:30 P.M. for evening snack. Subjects walked 2 mi twice daily; this and other activities were controlled carefully throughout the study. For all subjects, blood was collected between 7:00–8:00 A.M. by antecubital venipuncture after an overnight fast. Weight was assessed daily before breakfast. All subjects gave their informed consent. The study protocol was approved by the Human Subjects Committees of the U.S. Department of Agriculture and the University of California, Davis.

Appetite assessment. Appetite was assessed with the use of visual analog scales. Subjects marked their answers on a line displayed on the screen of a handheld computer (Palm Pilot©). Feelings of hunger, fullness, and prospective consumption (an assessment of the amount of food that could be eaten) were reported hourly from 7:00 A.M. to 10:00 P.M.; the area under the curve (AUC) was then calculated from the responses. Baseline appetite was assessed during the third week of the baseline period, and treatment effects were measured after 6 wk of intervention. Appetite measurements were performed every other day for three replicates. The same menu days of the baseline test were chosen as the measurement days for the treatment period.

Assays. Leptin concentrations in the plasma were determined with radioimmunoassay kits (Linco Research, St. Louis, MO) as previously described (23). For human leptin, the intra- and interassay coefficients were <8%. Plasma insulin concentrations were measured with a specific radioimmunoassay for human insulin (ICN Diagnostic Div., ICN, Costa Mesa, CA) according to the method of Yalow and Berson with minor modifications (24). Plasma glucose and lactate concentrations were measured with a YSI 2300 StatPlus Glucometer (Yellow Springs Instruments, Yellow Springs, OH).

Data analysis. A linear model with time taken as a repeated measure was used to determine the effects of CLA on appetite, plasma leptin, glucose, and lactate levels. The leptin data were also analyzed after adjustment for body fat mass by including body fat mass as a covariate in the model. The fat mass values utilized were obtained as previously described (25). These analyses were performed using the Statistical Analysis System (SAS Institute, Inc., Cary, NC). Owing to the wide variation in fasting insulin levels between subjects, the insulin data were analyzed as the percentage change in insulin from baseline levels for each subject. To determine the effect of CLA on plasma insulin levels, the AUC (trapezium rule) for the percentage change in insulin levels was calculated for each subject, and the mean AUC for the CLA and placebo-supplemented groups were compared by a two sample *t*-test. Data are expressed as the mean ± SEM. The probability level for significance was set at $P < 0.05$, and a Bonferroni adjustment applied to multiple comparisons where appropriate.

RESULTS

Effect of CLA on plasma leptin concentrations. Leptin levels initially decreased and then returned to baseline levels in CLA-treated subjects (Table 1, Fig. 1A). Analysis of plasma leptin concentrations adjusted for adiposity by using fat mass as a covariate showed that CLA supplementation significantly decreased leptin levels ($P = 0.05$). Adiposity-adjusted leptin levels tended to be low at 33 d and were decreased significantly after 49 d in the CLA-supplemented group compared to the placebo-supplemented group and baseline values ($P = 0.02$ and $P = 0.04$, respectively). From the low point at 49 d, leptin concentrations in the CLA-treated group increased until they returned to near-baseline levels by the end of the study. After 57 d of supplementation, mean leptin levels in the CLA-treated group, although lower, were not significantly different from leptin levels in the placebo-treated group or from baseline values ($P = 0.12$ and $P = 0.17$, respectively). Since plasma leptin levels were not assessed between 33 and 49 d, the maximal effect of CLA on plasma leptin levels could have occurred during this time period. Changes of absolute and plasma leptin concentrations normalized as the ratio of leptin to fat mass or percentage fat mass in the CLA-supplemented group (Table 1) were similar to changes of adiposity-adjusted leptin concentrations. For example, mean absolute leptin levels were at their lowest point after 49 d of CLA supplementation. Over the entire supplementation period, CLA tended to decrease absolute and normalized plasma concentrations of leptin ($P = 0.10$). All of the observed changes in leptin concentrations occurred in the absence of detectable changes of fat mass (25) and body mass index (BMI) (Table 1).

Effect of CLA on plasma insulin, glucose, and lactate concentrations. There was a nonsignificant trend for mean plasma insulin levels to increase in CLA-treated subjects

[a]Mean ± SEM; $n = 7$ for placebo and $n = 10$ for CLA. Treatment change (Δ) values represent mean change from baseline; BMI, body mass index; CLA, conjugated linoleic acid. [a]$P < 0.05$ vs. baseline. [b]$P < 0.05$ vs. placebo.

(Table 1 and Fig. 1B). The mean percentage change in insulin levels from baseline increased over the last 2 wk of the study in the CLA-supplemented group; this change coincided with the increase in leptin from the low point in leptin concentrations at 49 d (Figs. 1A and 1B). The mean AUC for the percentage change in insulin levels from baseline was 1039 ± 708 and −208 ± 895 for the CLA and placebo-supplemented groups, respectively. Although the difference in the mean AUC between the two groups was not significant ($P = 0.17$), it is possible that significance would have been attained with a larger sample size. CLA did not have any effect on plasma glucose ($P = 0.524$) and lactate concentrations ($P = 0.845$) (Table 1).

Effect of CLA on appetite. The AUC ratings during the baseline and supplementation periods for hunger, fullness, and prospective consumption showed that none of the three appetite measures was significantly affected by CLA treatment (Table 2). In addition, an approximately equal number of subjects had increased or decreased hunger, fullness, or prospective consumption in the CLA and placebo-supplemented groups (data not shown).

DISCUSSION

The present study is the first to examine the effects of CLA supplementation on circulating leptin levels in humans. CLA supplementation significantly decreased leptin concentrations without any detectable changes of body fat mass. After 7 wk of treatment, in the CLA-supplemented group, circulating leptin concentrations were at their lowest point. Thereafter, over the last 2 wk of intervention, leptin concentrations rose to pretreatment levels. These data are consistent with a recent study, which showed that plasma leptin concentrations tended to decrease in CLA-treated mice maintained on a high-fat diet (4). In mice fed a diet of 1% CLA by weight, plasma leptin levels were significantly decreased after 6 wk of treatment but did not differ from controls after 8 wk. However, since the 1% CLA diet decreased several different fat depots by greater

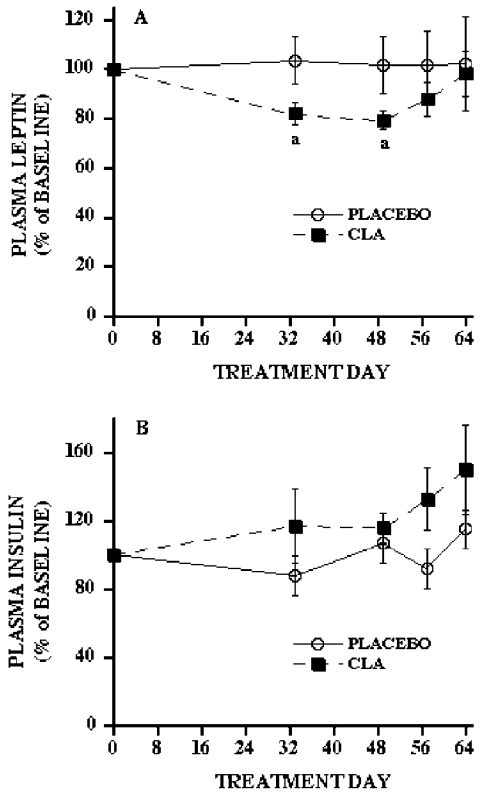

FIG. 1. Percentage change in leptin (A) and insulin (B) concentrations from baseline levels in conjugated linoleic acid (CLA) and placebo-supplemented subjects. Blood samples were collected after an overnight fast at baseline and at days 33, 49, 57, and 63 of intervention. Leptin and insulin concentrations were assessed by radioimmunoassay. Mean ± SEM; $n = 7$ for placebo and $n = 10$ for CLA. $^aP < 0.05$ vs. baseline.

than 50% after 6 wk of treatment, it is possible that the decreased leptin levels resulted from a reduction of body fat in the mice. However, by the end of that study, while overall fat mass decreased nearly 43%, leptin levels no longer differed from control levels. Thus, it is possible, like the present study, that CLA had effects on leptin levels that were independent of changes in fat mass.

To assess whether CLA-mediated changes in leptin levels were related to changes in appetite, self-ratings of hunger, fullness, and prospective consumption were determined. We have previously reported that in energy-restricted human females, subjects with lower leptin concentrations and greater percentage decreases in circulating leptin reported greater feelings of hunger, desire to eat, and prospective consumption than those with higher leptin concentrations and smaller decreases in leptin (26). In the present study, although appetite parameters were measured at around the time when the greatest decreases in leptin levels were observed, there were no significant differences between supplementation and baseline determinations in the CLA-supplemented group or between the CLA and placebo-supplemented groups. It is possible that there were undetected changes in appetite that were related to the decrease in leptin levels; the subjective assessment of appetite may be a gross measure that does not pick

TABLE 2
Mean Ratings of Hunger, Fullness, and Prospective Consumption[a]

	Baseline	After 6 wk of treatment
Hunger (AUC as mm·h)		
Placebo	486 ± 59	467 ± 50
CLA	508 ± 77	518 ± 64
Fullness (AUC as mm·h)		
Placebo	798 ± 75	
CLA	716 ± 56	727 ± 32
Prospective consumption (AUC as mm·h)		
Placebo	514 ± 97	500 ± 72
CLA	531 ± 83	568 ± 61

[a]Summarized mean of area under the curve (AUC) ± SEM for 16 hourly inquiries throughout the day; $n = 7$ for placebo and $n = 10$ for CLA.

up subtle changes in appetite. However, in the present study, in contrast to the previous one, the subjects were on a maintenance rather than an energy-restricted diet. Therefore, the decreases of circulating leptin levels were much more modest (~20%) in the present study than during energy restriction (~50–70%). It is also possible that other physiological changes, in addition to decreases in leptin concentration, are required to mediate changes of appetite. Although changes in leptin levels have been shown to modulate energy expenditure (8–11), it was also not affected in the present study by CLA treatment despite the changes in circulating leptin concentrations (25). Thus, the physiological significance of the changes that were observed in circulating leptin levels are not clear.

Plasma insulin levels tended to increase in CLA-treated subjects over the last 2 wk of the supplementation period. This change coincided with the increase in leptin concentrations from their low point at 49 d. A recent study showed that changes in plasma leptin correlate with changes of fasting plasma insulin independent of changes of BMI or percentage body fat (27). It was also demonstrated that insulin administration, at doses producing increments of insulin within the physiological range, increases circulating leptin concentrations in humans (28, 29). Thus, it is possible that the increase in insulin levels mediated the return of leptin concentrations to baseline levels. A trend for circulating insulin levels to increase with CLA supplementation was recently demonstrated in rodents by DeLany and colleagues (4). They reported that plasma insulin levels of CLA-fed mice tended to increase over the treatment period but did not reach significance until after 8 wk. Similar to the present study, this change in insulin levels occurred about 1 wk following the greatest difference in leptin levels between CLA-treated and control mice, and it also coincided with the increase in leptin to control levels. Thus, for both studies, it is possible that increases in insulin levels influenced circulating leptin concentrations.

The increase in insulin levels may have been part of a homeostatic response to counter the effect of CLA to decrease leptin. There are other possible explanations for the transient effect of CLA on circulating leptin concentrations. Initially, as suggested by a recent *in vitro* study (7), CLA could have acted as a ligand that activated peroxisome proliferator-acti-

vated receptor-γ (PPAR-γ). In turn, activation of PPAR-γ has been demonstrated to decrease leptin gene expression in rodents (30) and an adipocyte cell line (31). An event that could have occurred later during the intervention is demonstrated by a study in which rats fed a 1% CLA diet incorporated the *cis*-9,*trans*-11-isomer into membrane phospholipids of mammary epithelial cells (1). The investigators suggested that the incorporation of CLA into phospholipids could have various effects on signal transducing pathways. It is conceivable that altered signaling affected leptin production as CLA incorporation into adipocyte membranes increased.

In summary, 64 d of CLA supplementation in women produced a transient decrease in leptin levels but did not alter appetite or energy expenditure. These results are counter to what would be expected if CLA were able to reduce body fat in humans as it does in animals.

Determination of the Conjugated Linoleic Acid-Containing Triacylglycerols in New Zealand Bovine Milk Fat

Nicholas P. Robinson* and Alastair K.H. MacGibbon

New Zealand Dairy Research Institute, Palmerston North, New Zealand

ABSTRACT: Reversed-phase high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection at 233 nm was used to separate, quantify, and identify the triacylglycerols (TAG) of milk fat that contain conjugated linoleic acid (CLA). The absorbance at 233 nm was substantially due to CLA-TAG (chromatography of some representative TAG devoid of CLA, such as tripalmitin and triolein, showed poor responses at 233 nm, 1/800th that of CLA-TAG). A CLA molar extinction coefficient at 233 nm of 23,360 L mol^{-1} cm^{-1} and an HPLC UV response factor were obtained from a commercially available *cis*-9,*trans*-11-CLA standard. This molar extinction coefficient was only 86% of reported literature values. Summation of all chromatographic peaks absorbing at 233 nm using the corrected response factor gave good agreement with independent determinations of total CLA by gas chromatography and UV spectrophotometry. This agreement allowed quantification of individual CLA-TAG peaks in the HPLC separation of a typical New Zealand bovine milk fat. Three CLA-containing TAG, CLA-dipalmitin, CLA-oleoyl-palmitin and CLA-diolein, were prepared by interesterification of tripalmitin with the respective fatty acid methyl esters and used to assign individual peaks in the reversed-phase chromatography of total milk fat, of which CLA-oleoyl-palmitin was coincident with the largest UV peak. Band fractions from argentation thin-layer chromatography of total milk fat were similarly employed to identify five predominant CLA-TAG groups in total milk fat: CLA-disaturates, CLA-oleoyl-saturates, CLA-vaccenyl-saturates, CLA-vaccenyl-olein, and CLA-diolein.

Paper no. L8386 in *Lipids 35*, 789–796 (July 2000).

Ruminant fats are the most important natural source of conjugated linoleic acid (CLA). The high natural levels in ruminant depot fat originate partly from bacteria in the rumen (1), of which *Butyrivibrio fibrisolvens* is the most widely known. In milk fat, the level is further enhanced by the activity of 9-desaturase on *trans*-11-vaccenic acid (2), and humans apparently have a similar facility. CLA isomeric mixtures, synthesized by alkaline isomerization of linoleic acid, have been of recent import owing to their broad physiological impact in animal models: the evidence indicates protective effects against mammary cancer (3,4) and atherosclerosis (5), and a role in depot fat reduction while increasing lean body mass (6). These are the reasons for the intense interest in the distribution, synthesis, and concentration of CLA.

A knowledge of the triacylglycerols (TAG) containing CLA within milk fat is important in terms of both the mechanism of TAG synthesis and TAG digestibility. Milk fat is a complex natural substance. It contains TAG made from over 400 detectable fatty acids (7,8), of which CLA constitutes only about 1% by mass (8). To elucidate this complex array of TAG, there have been many detailed separations, often involving gas chromatography (GC) or reversed-phase (RP) high-performance liquid chromatography (HPLC) (10–13). An RP-HPLC separation of typical New Zealand milk fat has been reported previously by this group (14); when detected by evaporative light scattering, milk fat separated into 61 peaks, based on total acyl chain length (Carbon Number), number of double bonds, and, surprisingly, double bond configuration (*cis*- or *trans*-). A key finding (14) was the accuracy with which differences in HPLC retention time could be used to identify molecular groups. As most of the major TAG were discernible within a given Partition Number, and samples of separate molecular groups were available from argentation thin-layer chromatography (Ag-TLC), there was a sound basis on which to assign whole sets of chemically related TAG.

If TAG detection is on the basis of mass only (such as flame ionization or evaporative light scattering), it is unlikely to give any specific indication of the TAG that contain CLA—the concentrations are either too low or the peaks are likely to be overwhelmed by other, more dominant TAG with the same retention time. However, CLA has a particular advantage—conjugated dienoic fatty acids are highly absorptive of ultraviolet (UV) light around 233 nm (15–20), whereas the other fatty acids of milk fat have generally low absorptivities at this wavelength (21,22). Methods are already available in which this property of conjugated dienoic acids is exploited (21–24), and some of these have provided valuable information about the positional and geometric isomers of transmethylated CLA in a range of biological samples. However, little work has been conducted on intact CLA-TAG, and no study has to our

knowledge described the CLA-TAG of bovine milk fat.

At the CLA absorbance maximum of 233 nm (15,16), an opportunity was foreseen to specifically detect CLA-TAG in milk fat, without the complication of the many other TAG. In addition, we hypothesized that UV detection, with its proven linear dynamic range, would provide absolute concentrations of individual TAG containing CLA.

The aims of this study therefore were fourfold: to obtain a practical HPLC separation and detection of CLA-TAG in total milk fat using UV detection; to determine if all or most of the absorbance at 233 nm was due to CLA-TAG; to obtain accurate quantitative information from HPLC about the level of some specific CLA-TAG in milk fat; and to use HPLC and Ag-TLC to assign identities to those TAG containing CLA. We report here an existing reversed-phase HPLC method for which we have added UV detection at 233 nm to monitor the elution of CLA-containing TAG. As a precursor to quantification of individual HPLC peaks, the level of total CLA observed by HPLC was confirmed by static UV-visible spectrophotometry and fatty acid methyl ester–GC (FAME–GC). Finally, an HPLC analysis of bands from Ag-TLC of total milk fat is described, providing a means to identify the components of many of the peaks arising from detection at 233 nm.

EXPERIMENTAL PROCEDURES

Reagents and samples. All solvents (BDH, Poole, United Kingdom) were of HPLC grade and were used as received. Helium and nitrogen (Oxygen Free grade) gas were supplied by BOC Gases (Palmerston North, New Zealand). Tripalmitin (99% grade), 1,2-dipalmitin (racemic, 99%), and 2-linoleoyl-1,3-dipalmitin (PLP, 99% grade) were obtained from Sigma-Aldrich Pty. Limited (Castle Hill, Australia). Triolein (99%+) and methyl linoleate were obtained from Nu-Chek-Prep (Elysian, MN). CLA was available in various grades of isomeric purity: an isomeric mixture of *cis,trans-/trans,cis*-9,11- and *cis,trans-/trans,cis*-10,12-isomers was obtained from Sigma-Aldrich Pty. Limited; a 75–78% *cis*-9,*trans*-11 and a 97% *cis*-9,*trans*-11 grade were obtained from Matreya Inc. (Pleasant Gap, PA). Diazomethane was used to methylate both the Sigma-Aldrich CLA for interesterification and the Matreya CLA for absorbance measurements, by an established procedure (25). Oxalyl chloride was supplied by BDH. The TAG standard, 2-elaidoyl-1,3-distearin, was synthesized, and the ratio of stearic to elaidic acid confirmed by FAME analysis. Milk fat samples were obtained from the New Zealand Dairy Research Institute, Palmerston North, or were typical commercial samples.

Ag-TLC. Ag-TLC experiments were performed according to a previously reported procedure (26). TAG samples were typically 10 mg in size. Some modification to the published method was made for isolation of the TAG: silica from a recovered band was washed with *tert*-butylmethyl ether (TBME)/hexane (1:1, 2 × 2 mL), and the sample solution was put through a solid phase extraction (SPE) cartridge (SI type, BondElut, Varian, Harbor City, CA), before evaporating to dryness.

UV/visible absorbance measurements. UV/visible absorbance measurements were carried out on a Jasco V-560 Spectrophotometer, calibrated with the internal calibration function. Spectrometer settings were all controlled by the computer software. Absorbance measurements, performed in isooctane solution (1 cm quartz cell) were obtained from the mean of three individual readings. Molar extinction coefficients were calculated (27) from a plot of absorbance vs. concentration (for CLA, at four concentrations that ranged from 0.003 to 0.043 g/L), by multiplying the slope of the resulting plot by the molecular weight of CLA. Total CLA determination at 233 nm was performed according to the AOCS Official Method (23), also using the Jasco V-560 Spectrophotometer. β-Carotene absorbance measurements were performed on a 50 μg/L solution in isooctane.

CLA-TAG preparation. The basis of the following interesterification procedure was described by Marangoni and Rousseau (28). The procedure involves heating a TAG in the presence of a FAME and sodium metal, and the net effect is substitution of one or more of the TAG fatty acids by the methyl-esterified fatty acid. The reaction is not regioselective, and is sensitive to both water and the proportions of reagents, but it has the advantage of simplicity, cheap reagents, and minimal workup. Thus, a three-necked round bottom 250 mL flask, flushed with N_2 gas, was charged with isooctane (15 mL) and tripalmitin (0.483 g, 0.60 mmol). Dissolution of tripalmitin was incomplete at ambient temperature. Methyl conjugated linoleate (Sigma-Aldrich; mixture of *cis*- and *trans*-9,11- and 10,12-, 0.326 g, 1.11 mmol) was added by Pasteur pipette. Sodium metal (0.009 g, 0.39 mmol), prewashed with hexane, was added to the three-necked flask. The mixture was heated to gentle reflux and maintained there for 30 min, during which time it turned from colorless to yellow/gold. The boiling point of isooctane, 98–99°C at ambient pressure, assisted the progress of the reaction. Sodium is molten at this temperature and readily provided fresh metal surfaces to catalyze the reaction. The reaction mixture was allowed to cool. While taking care to leave the sodium metal in the reactor flask, the mixture was poured into a separatory funnel containing aqueous ammonium chloride (saturated solution, 50 mL). TBME (50 mL) was used to rinse the reactor flask, and the rinses were added to the separatory funnel. The organic layer was washed with aqueous sodium bicarbonate (1% solution, 50 mL) and saturated sodium chloride solution (50 mL), dried (solid sodium sulfate, anhydrous), and filtered. Solvent removal under reduced pressure gave a pale yellow oil (0.776 g). TLC indicated the presence of FAME, TAG, free fatty acids, and diacylglycerols. A TAG fraction was obtained by SPE, using aminopropyl cartridges to remove free fatty acids, and SI (silica) cartridges to remove FAME and diacylglycerols. Tripalmitin and the mono-CLA, di-CLA, and tri-CLA TAG were separated by Ag-TLC, using chloroform/toluene (1:1) as eluant (26). FAME analysis of the band at R_f 0.44 confirmed the presence of a group of mono-CLA-dipalmitic TAG (all regioisomers assumed), whereas

the di-CLA-monopalmitic TAG were identified in the band at R_f 0.22. Tripalmitin was detected at R_f 0.66. A mixture of regioisomeric TAG containing linoleic acid was also prepared by the same method. The synthesis of 3-CLA-1,2-dipalmitin was achieved by reacting CLA (Matreya, 75-78% 9*Z*,11*E* isomer; 92+% 9,11 isomers, 0.348g, 1.24 mmol) with oxalyl chloride (120 μL, 1.37 mmol) in dry dichloromethane to generate the acyl chloride of CLA. The solvent was removed under reduced pressure, and to the flask containing CLA acyl chloride were added pyridine (1 mL, 12.36 mmol), dichloromethane (5 mL) and 1,2-dipalmitin (0.700 g, 1.23 mmol). The P-P-CLA product was isolated by the same extraction procedure described above for interesterification. Silica column chromatography (25 g silica), using 5% step changes in eluant from 0–15% TBME in hexane, gave two fractions (combined mass 0.238 g) that contained P-P-CLA. The first of these fractions was adjudged purer than the second by silica TLC, and was thus used for RP-HPLC, where it gave a single peak that agreed well with the mono-CLA-dipalmitin obtained from interesterification. Further purification of the first silica column fraction by Ag-TLC gave a white solid residue that, after FAME-GC analysis, gave a molar ratio of two P groups to one CLA. FAME-GC also confirmed that neither set of preparative conditions, acyl chloride synthesis or interesterification, had altered the original ratios of 9,11-CLA or 10,12-CLA isomers.

GC. FAME were obtained by transmethylation of TAG samples, according to the procedure of MacGibbon (29). Separation of FAME and CLA isomers was carried out on a Shimadzu GC 17A (Shimadzu Corporation, Kyoto, Japan) equipped with a flame-ionization detector, operated at 250°C, with hydrogen supplied at 50 mL/min, and air at 500 mL/min. Hydrogen was used as carrier gas at a flow rate of 1.2 mL/min. The capillary column was a BPX70, 50 m × 0.22 mm i.d., film thickness 0.25 μm (SGE Incorporated, Austin, TX). The column was operated at 50°C for 1.5 min, then the temperature was increased at 3°C/min until the final temperature of 220°C was reached, where it was held for a further 10 min. Routinely, 0.2 μL of each sample solution was injected, constituting approximately 0.5 μg FAME. Response factors were calculated relative to P, using values from Ackman and Sipos (30) and Bannon *et al.* (31).

HPLC. RP-HPLC was performed on an LC Module 1 Plus (Waters Associates, Milford, MA), following a previously described method (14), with the addition of in-line detection at 233 nm. HPLC sample solutions were prepared by dissolving an aliquot (50 mg) of the melted fat sample in 1,2-dichloroethane/acetonitrile (2:1, 10 mL, final fat concentration 5 mg/mL). Filtration through a polytetrafluoroethylene syringe filter into an autosampler vial (1 mL size) gave a clear, pale yellow solution. The injection volume for a total milk fat sample was 20 μL (total fat injected 100 μg). Larger injections of total milk fat, of the order of 300 μg (as described in Fig. 1), can also be used and provide improved ratios of UV signal to noise, but we note that sample solutions more concentrated than 5 mg/mL require the addition of neat 1,2-dichloroethane to dissolve all TAG. When total milk fat TAG (12.8 mg) were separated by Ag-TLC, band extracts were reconstituted in 1,2-dichloroethane (0.2 mL), and the injection volume was 20 μL. The chromatography column was a Waters Nova-

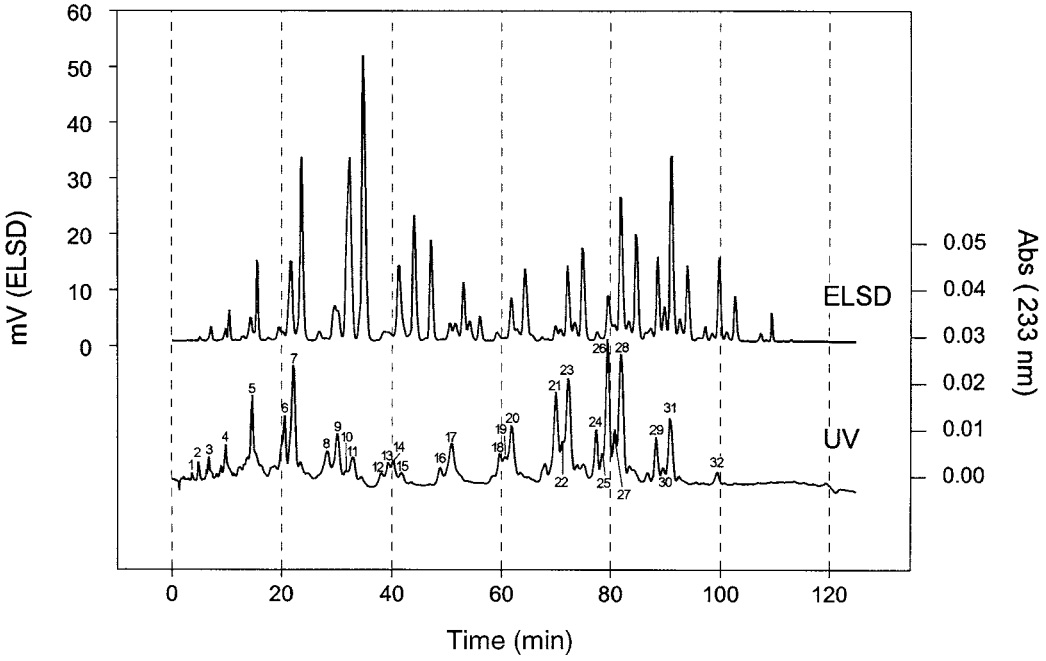

FIG. 1. High-performance liquid chromatography (HPLC) separation of total milk fat (317 μg injection) on a Waters Nova-Pak™ C18 reversed-phase column, 4 μm, 3.9 × 150 mm, with evaporative light-scattering detection (ELSD) and ultraviolet (UV) 233 nm detection. Peak numbers used in the UV trace pertain to those in Table 1.

Pak™ C18 (4 μm, 3.9 × 150 mm), with a pre-column module containing inserts of the same bonded phase. The column temperature was maintained at 20°C by water circulated from a bath to a column jacket. TAG were serially detected by UV at 233 nm (Waters 486 detector) and ELSD (Alltech 500; Alltech Associates Inc., Deerfield, IL). The time difference between UV and ELSD was of the order of 5 s. Nitrogen gas was supplied to the ELSD at a pressure of 80 psi, and the nitrogen flow at the nebulizer was maintained at 2.00 standard liters per minute, generating a nebulizer gas pressure of 32 psi. The solvent pressure at the nebulizer was typically less than 10 psi, and the ELSD drift tube temperature was set at 70°C. Peak data, collected at a sampling rate of 2 points/s, were acquired through a BUS/LACE interface and analyzed using Millennium^{32}™ software (Waters Associates, Milford, MA). The mobile phase gradient program was as previously described (14). During each cycle of the pump gradient program, the baseline absorbance at 233 nm increased with increasing dichloromethane content, generating a significant slope in the baseline. To remove this slope, a blank sample was injected and the blank data were subtracted from the sample data.

RESULTS AND DISCUSSION

A single injection of total milk fat TAG (317 μg), with serial detection at 233 nm and by ELSD, is shown in Figure 1. Three important features were evident from the overlaid traces: first, there was a wide variety of UV-absorbing species; second, the most dominant peaks by mass (ELSD) did not necessarily have any UV absorbance (for example, the biggest peak in the ELSD trace, at a retention time of 35 min, corresponds to only a small UV peak); and third, many of the clusters of UV peaks were very similar in shape and spacing to those of the ELSD data. The data indicated that the TAG detected by UV and ELSD had been separated in similar ways, and that if most of the UV absorbance was due to CLA, then it was widely distributed among the TAG of milk fat. It was suspected that both were true, but proof of the specificity of the 233 nm absorbance for CLA, and of whether the summed UV peaks accounted for all the CLA, was required before any individual peaks could be quantified.

Total CLA quantification. There were two aspects to the determination. The question of whether TAG without CLA accounted for any significant absorbance of a peak was addressed by HPLC analysis of some common TAG, representative of those found in milk fat, with detection at 233 nm. The resulting absorbances were small compared to CLA-TAG. Tripalmitin, triolein, 2-elaidoyl-1,3-distearin, and 2-linoleoyl-1,3-dipalmitin gave UV peak responses that were 1/500 that of the "standard" CLA-P-P/P-CLA-P (synthesized with CLA from Sigma-Aldrich) prepared by interesterification, although a purer CLA standard later showed that this factor should be closer to 1/800. 2-Linoleoyl-1,3-dipalmitin, with methylene-interrupted double bonds, gave a response that was only 20% higher than tripalmitin. In a similar observation, Brown and Snyder (24) reported that trilinolein does not absorb appreciably at 233 nm, and that its extinction coefficient is similar to that of tristearin. In a report by Angers *et al.* (32), total milk fat TAG were detected by UV at 220 nm; at this wavelength the TAG containing CLA may have represented the predominant signals, but the authors did not indicate that. Repeating the HPLC procedure of Angers *et al.* in our own laboratory gave a trace that was dominated by the same signals as had occurred at 233 nm.

To further indicate the low absorbance of non-CLA-TAG, and to estimate their combined absorbance in a total milk fat sample, a hydrogenated milk fat sample was analyzed by HPLC. Of 24 peaks detected by ELSD, only the two largest (identified as P-S-S/S-P-S and S-S-S) were detected at 233 nm, and their combined UV area was only 2% of the summed UV area commonly observed for total milk fat. It was therefore provisionally concluded that the total absorbance of peaks detected at 233 nm was greater than 95% CLA-TAG.

A second consideration was whether the HPLC peaks observed at 233 nm accounted for all the CLA-TAG. For quantification of individual peaks at 233 nm to be meaningful and accurate, the summed UV absorbance from a sample trace had to agree with independent measures of total CLA. This would address the possibility of some underlying baseline absorbance (due to CLA-TAG) being missed by integration and therefore not included in the quantification. Injections of 1,2-dichloroethane solvent blanks indicated no UV-absorbing signals after a breakthrough peak at 1.4 min. A set of 12 fat samples of known CLA content were independently analyzed by FAME-GC and the AOCS spectrophotometric method (23) and compared with the results from HPLC peak summation. To allow valid comparison, the HPLC UV detector response at 233 nm was determined using a CLA standard of stated purity, 97% 9*Z*,11*E* (Matreya), although methylation of the standard was required for chromatography. The molar extinction coefficient of this CLA free fatty acid standard as received was 24,400 L mol^{-1}cm^{-1} in isooctane, 10% lower than two previous reports of 26,600 L mol^{-1}cm^{-1} in carbon disulfide solution (15) and 27,000 L mol^{-1}cm^{-1} in isooctane solution (16), although in each report the methyl ester of CLA was described. For other commercial CLA samples ε_{233} was significantly lower; for the Nu-Chek-Prep methyl conjugated linoleate, ε_{233} was 15,300 L mol^{-1}cm^{-1}; for the Matreya 75–78% 9*Z*,11*E* CLA (free fatty acid), ε_{233} was 22,100 L mol^{-1}cm^{-1}. After methylation, we observed a slightly lower molar extinction coefficient of 23,360 L mol^{-1}cm^{-1}, and an HPLC UV peak area of 1.23×10^6 mAbs × s (units of peak area) per nanomole methyl-CLA. If the literature values are taken as more accurate, this HPLC peak response should be corrected to 1.42×10^6 mAbs × s per nanomole methyl-CLA.

On comparison with FAME-GC and AOCS measurements, the corrected UV detector response (1.42×10^6 mAbs × s per nanomole CLA, multiplied by the mass of CLA methyl ester to provide a mass percentage of CLA in the sample) gave better agreement. The correlation of each independent method with these samples is shown in Figure 2. The

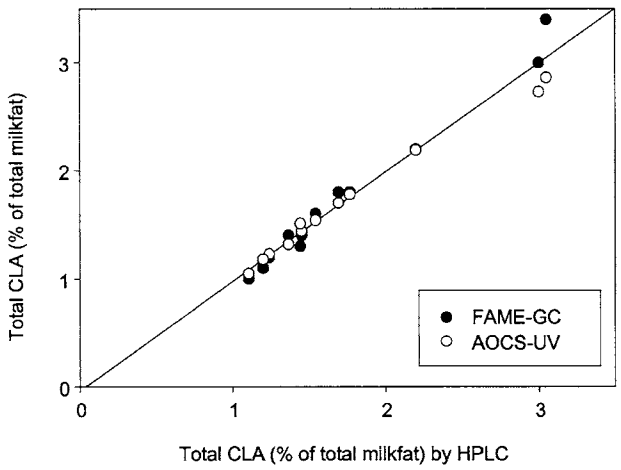

FIG. 2. Total conjugated linoleic acid (CLA) (% of total milk fat fatty acids) determined by HPLC, fatty acid methyl ester-gas chromatography (FAME-GC) and American Oil Chemists' Society (AOCS)-UV (23) methods. Total CLA by HPLC is calculated from a corrected response factor using the literature value for ε_{233} of 27,060 L $mol^{-1}cm^{-1}$. For abbreviations see Fig. 1.

AOCS method is potentially susceptible to absorbance from other non-CLA compounds, such as carotenoids, in milk fat. UV measurements of β-carotene solutions at 233 nm, at concentrations typically found in milk fat (approximately 10 mg/kg), indicated that β-carotene accounted for less than 1% of the total absorbance of a typical milk fat sample by the AOCS method. Literature reports indicated ε_{233} for β-carotene of 13,400 (33), similar in magnitude to ε_{233} for CLA, but the low concentrations of β-carotene in milk fat (1/1000th that of CLA) accounted for its small contribution to total absorbance.

The good agreement of summed UV 233 nm absorbance with total CLA and the finding of minimal interference from non-CLA-TAG at 233 nm provided some confidence for the quantification of individual CLA-TAG peaks in a typical commercial milk fat sample (described below and in Table 1). For comparison, FAME-GC data of the same milk fat sample are described in Table 2.

Peak identification. If the TAG of total milk fat were made up of randomly distributed fatty acids, CLA at the level of 1% would produce only minute quantities of di-CLA and tri-CLA TAG due to statistical probability. The positional selectivities of fatty acids in milk fat, such as short chains preferentially at the *sn*-3 position, further limit multiple esterification by a single fatty acid. These two premises simplified the framework for identification of CLA-TAG, for which it was assumed that practically all CLA-TAG were singly esterified with CLA. Thus, for the three groups of CLA-TAG reference compounds prepared by chemical synthetic means, we focused primarily on the mono-CLA compounds. The first of these "standards," mono-CLA-dipalmitin, was prepared by the two independent routes of interesterification of tripalmitin with the methyl ester of CLA followed by Ag-TLC separation, and reaction of the acyl chloride of CLA with 1,2-dipalmitin. An Ag-TLC plate depicting the TAG generated from the latter experiment is shown in Figure 3. HPLC analysis of the mono-CLA-dipalmitin from each experiment consistently gave a single peak that was in agreement with peak 28 in Figure 1.

[a]Calculated from 100 × (observed area/1.42×10^6) × (molecular weight of the CLA-TAG)/(total injection mass in ng).
[b]Indicates 0.01% or less.
[c]Fatty acid composition: no specific regioisomers are implied by the nomenclature, although it is well known that the short-chains 4:0 and 6:0 are almost exclusively at *sn*-position 3.
[d]18:1 is *cis*-9 oleic acid; vaccenic acid is indicated as 18:1*t*.
[e]An impure CLA-TAG peak. The concentration of the CLA-TAG listed is therefore overestimated when measured from a trace of the total milk fat. Argentation thin-layer chromatography indicated that there are unidentified CLA-TAG with coincident retention times underlying the CLA-TAG described.

A second interesterification, from which 10 TAG products (excluding regioisomers) were possible, was carried out by reacting tripalmitin with methyl conjugated linoleate and methyl oleate. The reaction produced detectable amounts of three CLA-TAG: CLA-P-P, CLA-P-O, and CLA-O-O (and their respective regioisomers). These were separated by Ag-TLC into three bands. Small amounts of P-CLA-CLA, O-CLA-CLA, and CLA-CLA-CLA and their respective regioisomers were also produced.

FAME analysis of the Ag-TLC bands confirmed the identities of bands at R_f = 0.02 as CLA-O-O and R_f = 0.14 as

[a]Measured as fatty acid methyl esters by gas chromatography (for conditions see Experimental Procedures section), but reported as fatty acid weight percentage of total fatty acids. The values do not add to 100%. Minor fatty acids—predominantly branched chains, saturated, and unsaturated isomers—have been omitted.
[b]Conjugated linoleic acid.

CLA-P-O. CLA-O-O coincided with the peak numbered 24 in Figure 1, and CLA-P-O coincided with peak 26. This "standard mixture" was also a useful indicator of the R_f values of these TAG in the Ag-TLC separation of total milk fat described below.

To enable a more comprehensive assignment of CLA-TAG, nine bands from Ag-TLC of total milk fat (depicted in Fig. 3) were recovered for analysis by RP-HPLC. Analysis of Ag-TLC band 6, equivalent at R_f 0.48 to the CLA-P-P standard, provided a strong indication that a series of mono-CLA-disaturated TAG had been isolated (Fig. 4), as the dominant peak was in good agreement with CLA-P-P, and the periodic spacing of other peaks was in agreement with that previously observed for two carbon spacings of other TAG in milk fat

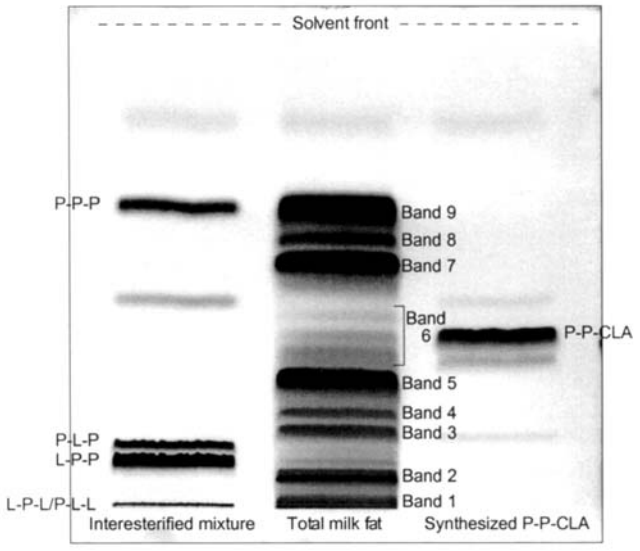

FIG. 3. Argentation thin-layer chromatography (Ag-TLC) plate of a L-P-P/P-L-P regioisomeric mixture obtained by interesterification (left lane), total milk fat triacylclycerols (TAG) (middle lane), and CLA-P-P obtained from the reaction of 1,2-dipalmitin with CLA (right lane) P, palmitic acid; L, linoleic acid; for other abbreviation see Figure 2.

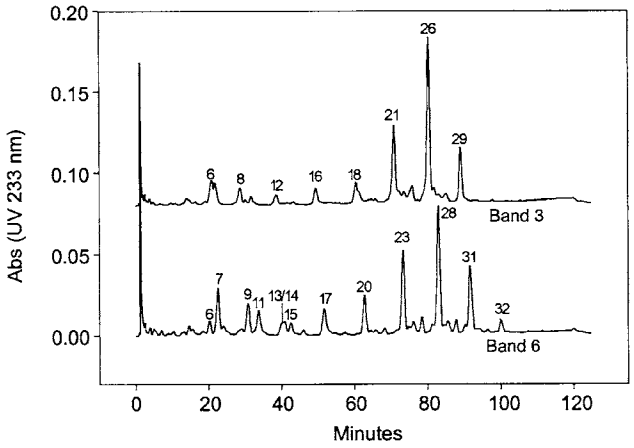

FIG. 4. Reversed-phase HPLC separation, with UV 233 nm detection, of the two major CLA-TAG groups in total milk fat, obtained from Ag-TLC of total milk fat. TAG of Band 6 are of the type mono-CLA-disaturate, and in Band 3 are of the type mono-CLA-oleoyl-saturate. Peak numbers correspond to those in Figure 1 and Table 1. For abbreviations see Figures 1–3.

(14). Complete recovery of all regioisomers of mono-CLA-disaturated TAG from band 6 was ensured by using the mono-CLA-dipalmitin regioisomeric mixture to indicate the R_f of these CLA-TAG on the plate. No UV absorbances were observed in Ag-TLC bands 7, 8, and 9.

The other major series of CLA-TAG occurred at R_f 0.09, between bands 2 and 3, which we propose was the series CLA-oleoyl-saturates (Fig. 4), and at R_f 0.02, band 1, which we propose was CLA-O-O. Some small UV peaks were observed in bands 2 and 5 that suggest the presence of CLA-V-O and CLA-V-saturate TAG respectively (where V = vaccenic acid), but these were not independently confirmed with proven CLA-TAG compounds. The chain-length-based separation of all TAG under Ag-TLC conditions, as described previously (26), was noted here also for CLA-TAG: mono-CLA-disaturated TAG, for example, were spread over a wide area of the plate from R_f 0.27 to R_f 0.48 and the HPLC results indicated that this separation pertained to fatty acid length. The observed R_f of mono-CLA-disaturated TAG, approximately midway between *cis*-monoenoic TAG (band 5) and *trans*-monoenoic TAG (band 7) was in accord with reported behavior of methyl esters of *cis*-monoenoic, *trans*-monoenoic, and conjugated *cis, trans*-dienoic fatty acids, in similar eluant mixtures (34).

Although di-CLA-monopalmitin was isolated by Ag-TLC after the interesterification of tripalmitin with methyl conjugated linoleate, and its elution during RP-HPLC noted at a retention time of 70 min, no HPLC signals detected by UV 233 nm pertaining to di-CLA-monosaturate TAG were observed in the corresponding bands from Ag-TLC of total milk fat.

In RP-HPLC the regioisomeric mixture of CLA-P-P/P-CLA-P was coincident with a commercial standard P-L-P, indicating that under RP conditions, conjugated double bonds behaved very similarly to methylene-interrupted double bonds, and that, as previously reported (14), regioisomeric

TAG were not resolved by this RP-HPLC method. This was confirmed after co-injection of a regioisomeric mixture of L-P-P and P-L-P. The regioisomeric mixture was obtained from interesterification and Ag-TLC, and the identities of bands at R_f = 0.13, 0.10, and 0.00 (Fig. 3, far-left lane) were established by FAME-GC, which indicated ratios of P/L = 2:1, 2:1, and 1:2, respectively. The observations were also confirmed by co-injection of a mixture of L-P-P and CLA-P-P, which gave only one signal by ELSD.

In summary, the absorbance of UV-detected peaks at 233 nm was shown to be substantially due to CLA-TAG. Two independent methods of total CLA quantification were employed to obtain good agreement with total CLA determination by HPLC, and this was a necessary step for quantification of particular CLA-TAG separated by HPLC. The highest-purity CLA standard available is adequate for determining an HPLC UV peak response at 233 nm, although we recommend that the CLA molar extinction coefficient at 233 nm be verified and a correction be made, if needed, before using it as the sole basis for quantification.

The range of TAG in total milk fat containing CLA was found to be wide. Although the broad groups of CLA-TAG isolated from Ag-TLC were less numerous than the other TAG, this is mostly by virtue of one fatty acid being fixed. Indeed, within each Ag-TLC band, the CLA-TAG displayed a similarly wide variety of total carbon chain lengths as the regular TAG. By using proposed identities deduced from the commercial standards, synthesized standards, and Ag-TLC bands, a summary of CLA-TAG in the major peaks of a UV trace is given in Table 1, along with an estimated concentration in a typical New Zealand bovine milk fat. The most prominent CLA-TAG were of the type mono-CLA-disaturated and CLA-oleoyl-saturated, as might be predicted from the known dominant concentrations of saturated and oleic fatty acids in milk fat.

These conclusions indicate a challenging task for those wishing to concentrate CLA in milk fat, without either first hydrolyzing it from the glycerol backbone or substantially boosting the natural level.

ABSTRACT: High-resolution selected-ion recording (SIR) of the exact molecular ion mass was used to confirm unambiguously the presence of conjugated linoleic acid (CLA) derivatives in biological matrices and standard mixtures and to differentiate non-CLA derivatives from CLA derivatives in the CLA region of the gas chromatogram. The success of this method was based on the selectivity of the SIR technique and its sensitivity, which was comparable to that of flame-ionization detection. A minor fatty acid methyl ester (FAME) was identified as methyl heneicosanoate (21:0), and six isomers of 20:2 FAME were found to elute in the CLA region. Isomerization of a standard CLA mixture resulted in a non-CLA flame-ionization response eluting in the CLA region of the gas chromatogram. It is therefore recommended that the identification of minor CLA isomers in natural products or biological matrices should include their direct confirmation by mass spectrometry

Paper no. L8385 in *Lipids 35*, 797–802 (July 2000).

Analysis of fatty acid methyl esters (FAME) by gas chromatography (GC) using long capillary columns and a flame-ionization detector (FID) has become the generally accepted method for the determination of the fatty acid composition of natural products and standard compounds (1). Identification of the FAME peaks often is performed solely by comparison of the retention times with those of known standards. However, independent direct confirmation of identity by alternative techniques is essential to establish definitive assignments, particularly of minor or co-eluting FAME peaks. Comparable sensitivity to GC–FID is generally a problem with alternative detectors, such as ultraviolet (UV) (1) or infrared (2,3). Although an electron impact mass spectrometry (EIMS) detector has adequate sensitivity, unsaturated FAME provide similar EI mass spectra that are of little use in distinguishing between isomers because the double bonds tend to migrate along the carbon chain under EI conditions (4). On the other hand, high-resolution selected-ion recording (SIR) mass spectrometry (MS) can provide unambiguous molecular weight confirmation for targeted analytes by GC–EIMS as demonstrated for drug residue analysis (5).

The direct GC–EIMS SIR confirmation of identity of unspecified minor conjugated linoleic acid (CLA) isomers in natural products is simple and unambiguous. In contrast, two recent reports on CLA isomers in cheese lipids included CLA-methyl ester (CLA-ME) GC peaks that were only tentatively assigned (6,7). Silver-ion high-performance liquid chromatography (HPLC) with UV detection at 234 nm was shown to be effective in separating and identifying individual CLA isomers (8–10), but this technique could not identify interfering FAME that do not absorb at 234 nm but that are found in the CLA region of the gas chromatogram. Furthermore, it is difficult to compare all the peaks observed in the CLA isomers in the GC–EIMS and Ag^+–HPLC chromatograms. A detailed positional analysis of the double bonds of fatty acids must be subsequently performed using one of several fatty acid derivatives other than FAME, such as dimethyloxazoline (DMOX) derivatives; see reviews (11–14).

In the present study high-resolution MS with the SIR technique is presented as a rapid and sensitive technique to confirm directly the presence of minor CLA-ME isomers in natural products and to distinguish them from interfering fatty acids or unknowns in the CLA region of the gas chromatogram without additional sample treatment.

MATERIALS AND METHODS

The ME of heneicosanoic acid (21:0), 99% purity, was purchased from Sigma (St. Louis, MO). A mixture of CLA as

Abbreviations: CLA, conjugated linoleic acid; DMOX, dimethyloxazoline; EIMS, electron impact mass spectrometry; FAME, fatty acid methyl esters; FID, flame-ionization detector; GC, gas chromatography; HPLC, high-performance liquid chromatography; ME, methyl ester; MS, mass spectrometry, SIR, selected-ion recording; UV, ultraviolet.

ME, 99% purity, was obtained from Nu-Chek-Prep, Inc. (Elysian, MN). A 10% solution of trimethylsilyldizomethane in hexane was obtained from TCI America (Portland, OR). Cheeses were purchased locally. All solvents were distilled-in-glass quality.

Extraction of lipids and preparation of fatty acid derivatives. Cheese was extracted with diethyl ether/petroleum ether (1:1) after homogenization with ethyl alcohol in the presence of potassium oxalate as described previously (6). Total cheese lipids were methylated using anhydrous $NaOCH_3$/methanol (6,15). DMOX derivatives were prepared as described (6).

GC–FID. The gas chromatograph (model 5890 Series II; Hewlett-Packard, Palo Alto, CA) was equipped with an FID, a fused-silica capillary column (100 m × 0.25 mm i.d. × 0.2 m film CP-Sil 88; Chrompack, Inc., Raritan, NJ), hydrogen as carrier gas at a head pressure of 26 psi, a split vent flow of 20 mL/min, and a septum purge of 2.4 mL/min. All injections were under data system control with an auto-injector and a glass split injector insert packed with silanized glass wool. The injection port temperature was 250°C. The oven temperature program was: 75°C for 2 min after injection, 5°C/min to 180°C, held at 180°C for 33 min, then 4°C/min to 225°C, and held at 225°C for 43.8 min.

GC–EIMS. Low- and high-resolution mass spectra were recorded with a double-focusing magnetic sector instrument (Autospec Q; Micromass, Wythenshawe, United Kingdom). The gas chromatograph (Hewlett-Packard 5890 Series II) used hydrogen carrier gas at 26 psi and a 100-m CP-Sil 88 fused-silica capillary column. Split vent flow was 100 mL/min, and septum purge flow was 3.0 mL/min. Injections were manual, split or splitless into a double-gooseneck glass injector insert at an injection port temperature of 220°C. The oven temperature program was: 75°C for 2 min after injection, 5°C/min to 170°C, held at 170°C for 40 min, 5°C/min to 220°C, and held at 220°C for 20 min. Transfer line temperature was 220°C, and the ion source temperature was 250°C. Filament trap current was 400 μA at 70 eV.

RESULTS AND DISCUSSION

In a recent study of CLA isomers in cheese (6), a partial FID profile was reported of the CLA-ME region from total cheese FAME using a 100-m polar fused-silica capillary column. The identity of the most intense of the minor ME peaks was not confirmed and was tentatively labeled 11*t*,13*c*-18:2? (6). The correct identity is reported next.

SIR of the molecular ions of CLA and of related FAME at a resolution of 10,000 provided accurate retention times of the CLA-ME isomers, with enhanced analyte sensitivity and selectivity (5). The SIR molecular ion profile of CLA-ME at *m/z* 294.2559 recorded for the same total cheese FAME is shown in Figure 1B. The CLA components of a commercial CLA-ME standard (Nu-Chek-Prep) are shown for comparison in Figure 1C. Most importantly, this comparison established the relative retention times of the four major positional *cis/trans*- and the previously identified *cis,cis*- and *trans,trans*- CLA-ME isomers (16).

A careful reexamination of the major non-CLA-ME peak (labeled A*) in the FID chromatogram of cheese FAME (Fig. 1A) revealed a spectrum with a weak molecular ion at *m/z* 340 and fragmentation consistent with methyl heneicosanoate (21:0) (Fig. 2A). The identity of this FAME (A*) in cheese lipids was subsequently confirmed as 21:0 by comparison of its retention time and mass spectrum (Fig. 2B) with that of a standard 21:0 ME analyzed under identical conditions.

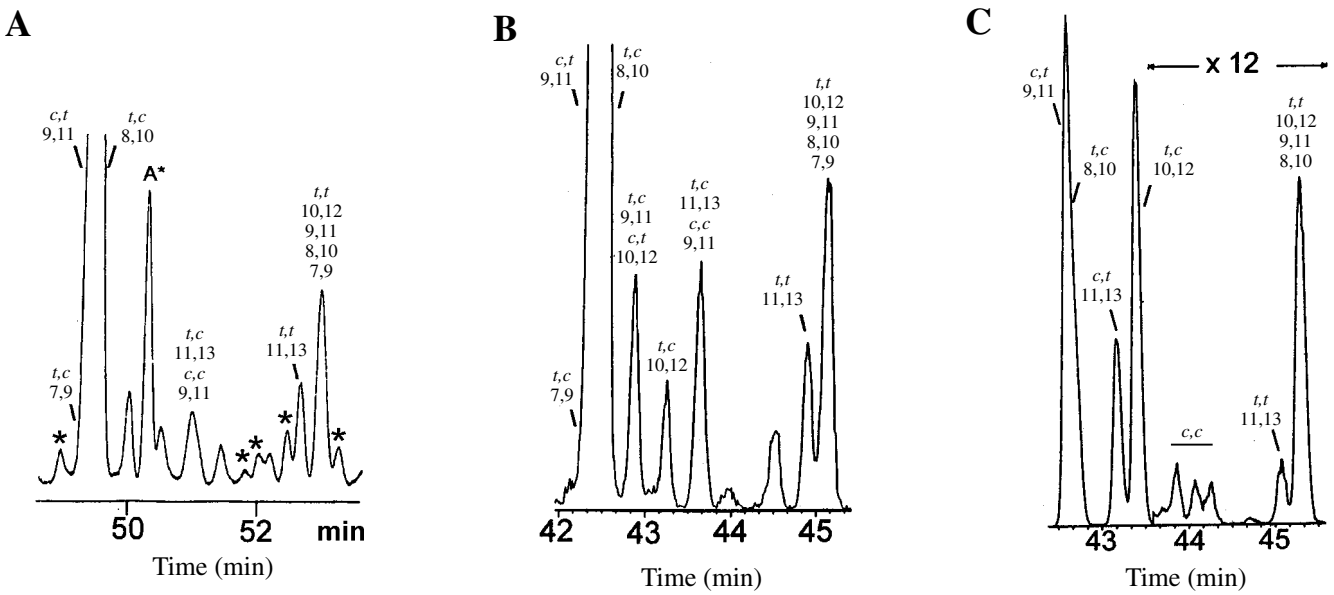

FIG. 1. Comparison of (A) a partial gas chromatography–flame-ionized detector (GC–FID) chromatogram of total cheese fatty acid methyl esters (FAME) with (B) the same conjugated linoleic acid-methyl ester (CLA-ME) region obtained by high-resolution selected-ion recording (SIR) at *m/z* 294.2559 for total cheese FAME and (C) a standard CLA-ME mixture obtained from Nu-Chek-Prep Inc. (Elysian, MN). Peaks not found in the SIR chromatogram of cheese FAME (B) are not isomers of CLA and are indicated by an asterisk (*) in Figure 1A. The most intense FID peak not found in the SIR data is indicated by A* in Figure 1A. The peaks adjacent to peak A* in Figure 1A are labeled in Figure 1B.

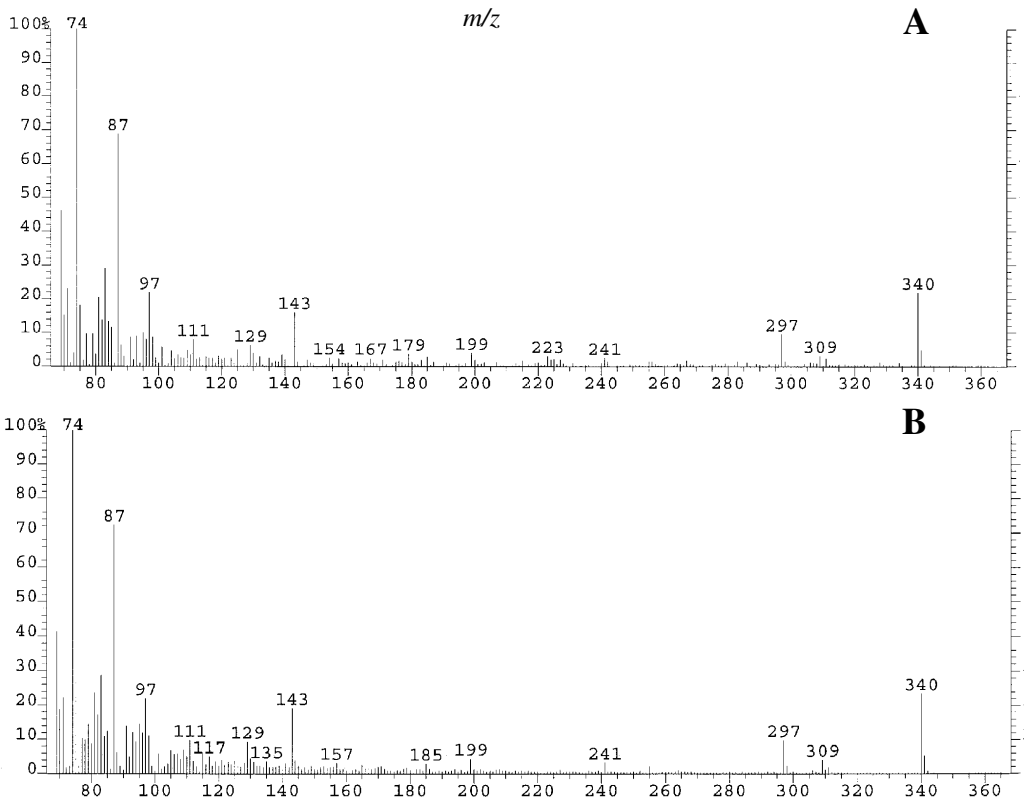

FIG. 2. Low-resolution GC–mass spectrum of (A) the peak labeled A* in Figure 1A, and (B) methyl heneicosanoate (21:0) standard recorded under identical GC–electron impact mass spectrometry conditions. For abbreviation see Figure 1.

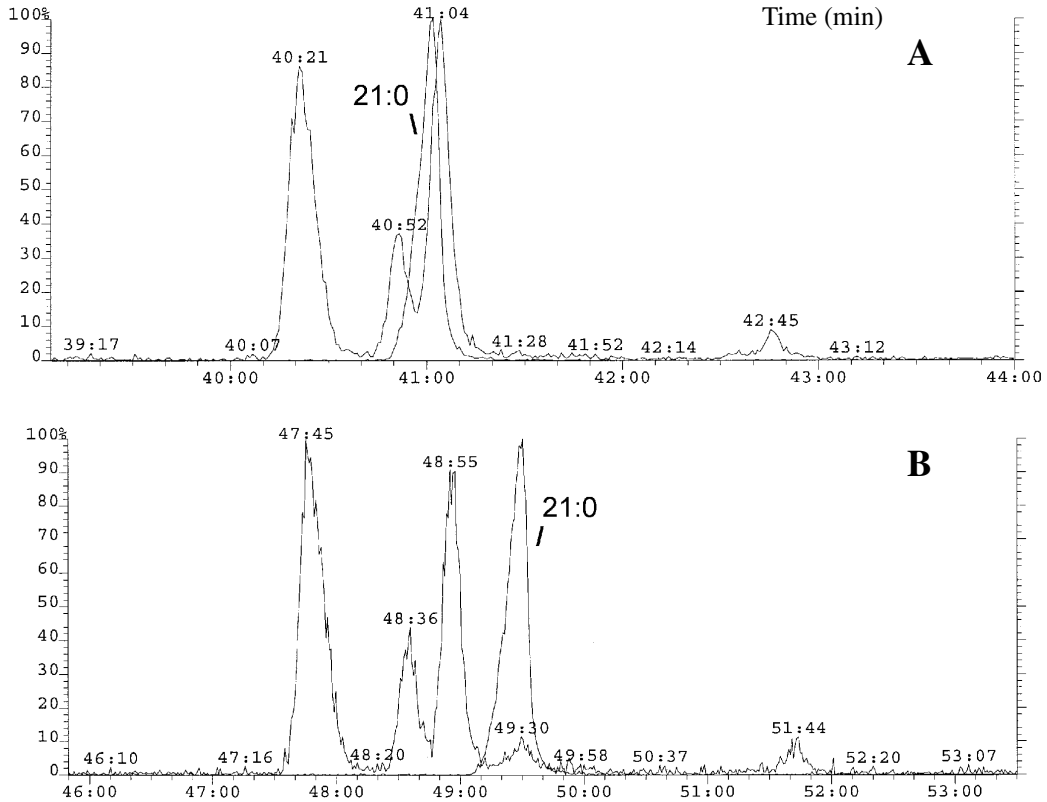

FIG. 3. Low-resolution reconstructed ion profiles of the molecular ions of a mixture of the methyl esters of the commercial CLA mixture (*m/z* 294) and 21:0 (*m/z* 340). The gas chromatograph was operated at 180°C (A) and 170°C (B). For abbreviation see Figure 1.

The

21:0 FAME was previously reported (16) as co-eluting with 8*cis*,10*cis*-18:2 in the gas chromatogram of sphingomyelins isolated from heart and liver lipids of pigs fed CLA. The assignment was made based on comparing the retention time of this GC peak with that of a known standard of 21:0, analyzed under identical GC conditions. However, no attempt was made to confirm its identity by MS in that study (16).

At first it appeared as though we were dealing with two different FAME in the sphingomyelin fractions and in cheese lipids, since a similar 100-m SP-Sil 88 column was used, but the relative retention times were different. We failed to appreciate the effect of differences in temperature programming on the relative retention times of different FAME. Figure 3 shows the differences in the relative retention times obtained between 21:0 and the standard CLA-ME mixture when co-injected and analyzed at 180 (Fig. 3A) and 170°C (Fig. 3B). Ion profiles for the respective molecular ions of methyl CLA, *m/z* 294, and 21:0, *m/z* 340, were extracted from low-resolution GC–EIMS full-scan data to prepare Figure 3. At 180°C, 21:0 eluted between 11*cis*,13*trans*-18:2 and 10*trans*,12*cis*-18:2 (Fig. 3A) as observed in the total cheese FAME (6), whereas at 170°C, 21:0 co-eluted with the *cis,cis* CLA isomers as reported in the analysis of the sphingomyelins (16).

High-resolution multiple ion screening for the molecular ions of other FAME that may possibly elute in the CLA retention time window detected signals only for the *m/z* 322.2872 ion, suggesting the presence of several 20:2 isomers in the CLA region (Fig. 4). These signals were two orders of magnitude less than the combined signal recorded for the 9*cis*,11*trans* and 8*trans*,10*cis* CLA-ME isomers in cheese. Screenings for the molecular ions of 18:1, 18:3, 18:4, 19:1, 19:2, 19:3, 20:0, 20:1, and 20:3 within the CLA-ME window were negative. The major 20:2 FAME in cheese was 11*cis*,14*cis*-20:2, which eluted after the CLA region (Fig. 4B). Although the apparent 20:2 FAME signals were significantly smaller than the signals for the principal isomers of CLA in cheese, they did have the potential to interfere with the determination of the minor isomers of CLA either as FAME or DMOX derivatives. No structural identification of the much weaker 20:2 isomers as DMOX derivatives was attempted. A prior separation of the 18:2 and 20:2 would be required, because of interference and low concentrations of the minor 18:2 and 20:2 isomers.

The SIR technique proved invaluable in unambiguously establishing the identity of CLA-DMOX derivatives in the GC–FID chromatogram and in revealing the presence of interferences in the GC–FID data. Careful adjustment of the column temperature resulted in a good agreement of the rela-

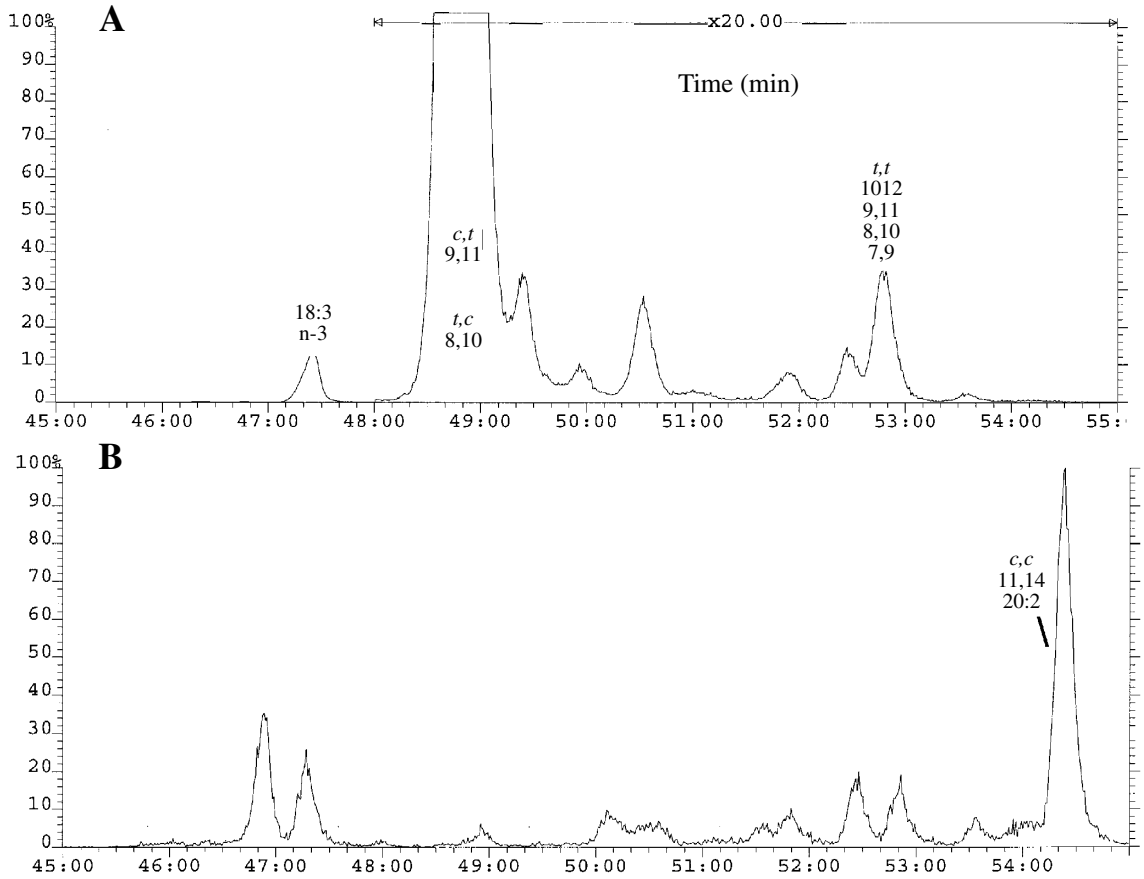

FIG. 4. High-resolution selected ion profiles of *m/z* 294.2559 (A) and *m/z* 322.2872 (B) recorded for total cheese FAME. The signals recorded for *m/z* 322 are on the order of 1% of the 294 signal recorded for the principal CLA peak and represent the co-elution of the 9*cis*,11*trans*- and

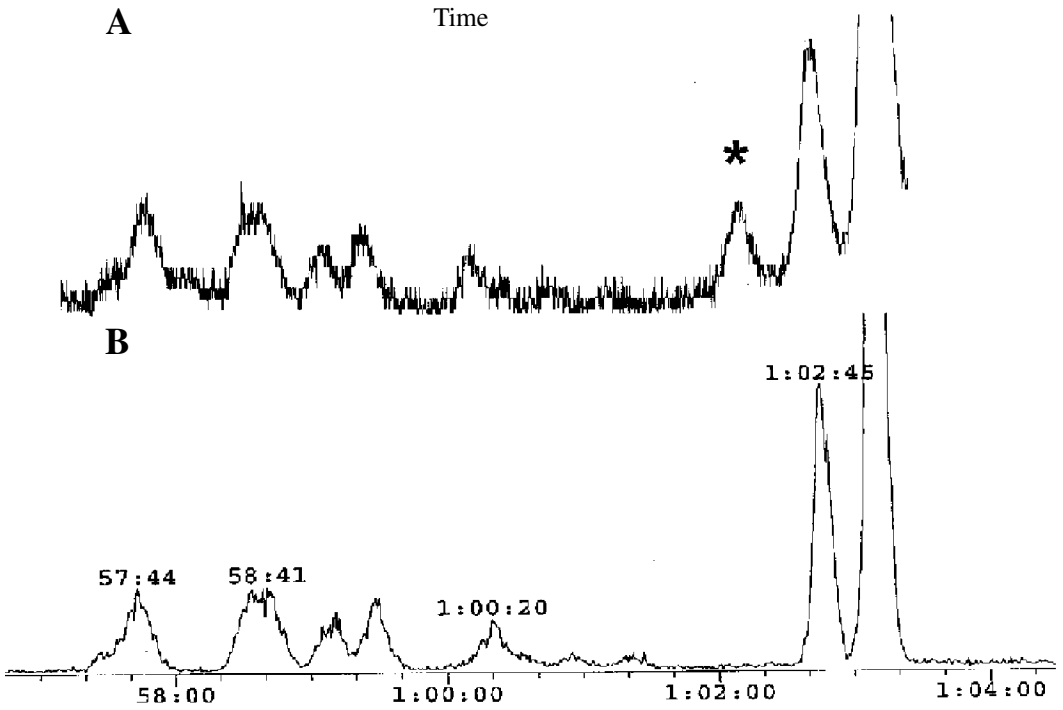

FIG. 5. (A) A partial GC–FID chromatogram of the dimethyloxazoline (DMOX) derivatives of an isomerized CLA mixture prepared as described previously (9), and (B) a high-resolution SIR chromatogram for the same isomerized CLA mixture at *m/z* 333.3032, the molecular ion for CLA-DMOX. The same test portion was injected at the same concentration under closely matched GC conditions. The peak labeled with an asterisk (*) in the FID (A) trace was not a CLA-DMOX. See Figure 1 for other abbreviations.

tive retention time data recorded by GC–FID and GC–EIMS for an isomerized standard CLA mixture described previously (9) (Fig. 5). The data shown in Figure 5A represent the GC–FID analysis of DMOX derivatives from the isomerized CLA mixture (9), whereas high-resolution SIR mass spectral data at *m/z* 333.3032 (molecular ion for 18:2 DMOX derivative) are shown in Figure 5B. The relative retention times of the different CLA-DMOX derivatives in the GC–FID and GC–EIMS chromatograms were in good agreement, except for an extraneous unknown FID peak, labeled by an asterisk (*) in Figure 5A, which is clearly absent in Figure 5B, and hence is not a DMOX derivative of CLA.

The results of this study clearly demonstrate the importance of routinely checking GC–FID data of FAME for correct molecular weight assignments by monitoring their molecular ions in the SIR mode. In the analysis of total cheese FAME, a minor peak in the CLA region of the GC–FID chromatogram was confirmed as 21:0 FAME. In addition, a presumed CLA–DMOX derivative in the FID analysis of an isomerized CLA mixture was likewise determined by SIR to be an extraneous FID response. It is highly recommended that future analyses of the minor CLA isomers from natural products of biological matrices include a demonstration of unequivocal identification of the CLA isomers by using high-resolution SIR MS.

COMMUNICATION

A Comparison of Lycopene and Astaxanthin Absorption from Corn Oil and Olive Oil Emulsions

Richard M. Clark*, Lili Yao, Li She, and Harold C. Furr

Department of Nutritional Sciences, U-17, University of Connecticut, Storrs, Connecticut 06269-4017

ABSTRACT: The effect of different oils on the absorption of carotenoids was investigated in mesenteric lymph duct cannulated rats. Sixteen treatment emulsions containing increasing concentrations of either lycopene (LYC) or astaxanthin (AST) (5, 10, 15, 20 μmol/L) were prepared with olive oil or corn oil and continuously infused into the duodenum of the rat. Absorption of carotenoids into the mesenteric lymph duct was determined. Absorption of LYC and AST from both oils increased with the amount infused into the duodenum. The average recovery of AST in the lymph from the olive oil emulsion was 20% but was decreased to 13% from emulsions containing corn oil. Lycopene was not as well absorbed as AST. The average recovery of LYC was 6% from olive oil emulsions but only 2.5% when infused with corn oil. The LYC used in this study was isolated from tomato paste and was primarily in the all-*trans* form. We did not observe any significant isomerization of all-*trans* LYC to 9-*cis* LYC during absorption. We conclude that the type of oil with which a carotenoid is consumed can influence its absorption.

Paper no. L8416 in *Lipids 35*, 803–806 (July 2000).

Compared to other dietary lipids, carotenoids are not well absorbed, and factors influencing carotenoid absorption are poorly understood (see recent reviews 1–4). Because carotenoids are lipid soluble, the amount and type of lipid with which they are consumed may influence their absorption. Several studies have shown that concurrent consumption of dietary lipid significantly increases carotenoid absorption (5–8). Although the presence of dietary lipid appears to be a key factor in carotenoid absorption, information on the effect of different types of lipid on absorption of carotenoids is relatively sparse.

Hollander and Ruble (9) measured the disappearance of β-carotene from micellar perfusates in rat intestinal loops. The disappearance rate from perfusates containing polyunsaturated fatty acids (PUFA) (linoleic acid and linolenic acid) was lower than when oleic acid was added to the perfusate (9). In assuming that disappearance rates are an index of absorption, these results suggest that the unsaturated fatty acid composition of a diet can influence carotenoid absorption. The purpose of this study was to further investigate the influence of dietary lipid on carotenoid absorption by comparing the absorption of lycopene (LYC) and astaxanthin (AST) from a polyunsaturated triacylglycerol emulsion containing corn oil to their absorption from a monounsaturated triacylglycerol emulsion made with olive oil.

Abbreviations: AST, astaxanthin; CRBP, cellular retinol-binding protein type II; HPLC, high-pressure liquid chromatography; LYC, lycopene; PUFA,

MATERIALS AND METHODS

Animals and surgical procedure. Male Holtzman albino rats obtained from Harlan Sprague Dawley (Indianapolis, IN) and weighing 300–350 g at the time of surgery were used. A feeding tube was placed into the duodenum and the major mesenteric lymph duct was cannulated. Surgery and animal care were conducted as previously described (10) and were approved by The University of Connecticut Institutional Animal Care and Use Committee.

Following surgery, the animals were placed in a warm, dark environment and allowed to recover for about 36 h. During recovery animals had access to water and received intraduodenally a glucose/electrolyte solution (Pedialyte; Ross Laboratories, Columbus, OH) at 2.0 mL/h. After recovery, treatment emulsions were infused into the duodenum for 12 h at a rate of 2.0 mL/h . The lymph was collected during the final 6 h of infusion for analysis. Lymph was stored at −70°C until analyzed.

Preparation of carotenoid stock solutions. Stock solutions of the two carotenoids were prepared and used within 48 h. Lycopene was purified from tomato paste on a 5% water-weakened alumina column eluted with hexane/ethyl acetate (95:5 vol/vol). Solvent was removed under reduced pressure and a stock solution of LYC prepared in dichloromethane. Astaxanthin was a gift from Dr. Harry Frank (University of Connecticut, Storrs, CT). A stock solution of AST also was prepared with dichloromethane. The concentration of carotenoid in each stock solution was determined by absorption spectroscopy. Astaxanthin concentration was estimated at 466 nm ($E^{1\%}_{1\ cm}$ = 2135) and LYC concentration was estimated at 472 nm ($E^{1\%}_{1\ cm}$ = 3450) (11).

Treatment emulsions. The basic treatment emulsion consisted of a buffer solution (115 mmol/L NaCl, 5.0 mmol/L KCl, 6.8 mmol/L Na_2HPO_4, and 16.5 mmol/L NaH_2PO_4), 10 mmol/L sodium taurocholate (Sigma Chemical, St. Louis, MO) and 3.0% (wt/vol) olive oil or tocopherol-stripped corn oil (ICN, Costa Mesa, CA) with different concentrations of AST or LYC.

Treatment emulsions were prepared by placing olive oil or corn oil in a round-bottomed flask and adding an appropriate amount of carotenoid stock solution to the oil. The carotenoid, either AST or LYC, and oil were mixed, and the solvent was removed with a stream of nitrogen. Sodium taurocholate and buffer were added to the lipid/carotenoid mixture. The contents of the flask then were emulsified using a probe sonicator producing approximately 40 watts output for 15 s, repeated four or five times until no lipid droplets were observed. An aliquot of the emulsion was extracted three times with hexane and the final concentration of carotenoid in the emulsion determined by high-pressure liquid chromatography (HPLC) as described below for lymph analysis.

Carotenoid analysis of lymph. Lymph samples were thawed to room temperature and an aliquot taken for analysis. To extract the carotenoids, dichloromethane/methanol (2:1, vol/vol) containing an internal standard, ethyl-β-apo-8′-carotenoate (Fluka, Ronkonkoma, NY), and lymph were placed in a separatory funnel at a solvent to lymph ratio of 9:1 (vol/vol) and stored in the dark at 4°C for 4–6 h. The bottom phase was removed and saved. Methanol at 1.5 times and dichloromethane at six times the original volume were added to the upper phase. The separatory funnel was again stored for several hours in the dark at 4°C. After phase separation the bottom phase was removed and combined with the original bottom phase. Preliminary studies showed that further extraction of the upper phase with a salt solution and solvents, as called for in the original extraction method of Folch *et al.* (12), did not improve the recovery of carotenoids from lymph.

Samples were prepared for injection into the HPLC by removing the solvent from the lipid extract under reduced pressure and redissolving the residue in dichloroethane/2-propanol (1:1 vol/vol). Carotenoids then were separated by HPLC using a Waters C18 Resolve column (15 cm × 3.9 mm; Millipore, Milford MA.) with an Upchurch C18 guard column (Upchurch Scientific, Oak Harbor, WA). An isocratic mobile phase consisting of acetonitrile/dichloromethane/methanol/*n*-butanol/ammonium acetate (90:15:10:0.1:0.1, by vol) was used for analysis of LYC and an isocratic mobile phase of methanol/water (98:2, vol/vol) was used for AST analysis. The carotenoids and ethyl-β-8′-carotenate were identified and quantified at a wavelength of 450 nm.

Fatty acid analysis of treatment emulsions and lymph. A 200-μL aliquot of treatment emulsion or lymph was used for fatty acid analysis. Fatty acids in the aliquot were prepared for analysis by direct transmethylation in methanol/hexane (4:1, vol/vol) in the presence of acetyl chloride (13). The fatty acid methyl esters were separated by gas–liquid chromatography on a Supelcowax 10 fused-silica capillary column (30 m, 0.53 mm i.d.: Supelco, Bellefonte, PA), and identification of individual fatty acids was based on comparison of retention times with known standards.

Statistical arrangement of treatments. This study was a completely randomized design with treatments in a $2 \times 2 \times 4$ factorial arrangement. The 16 treatment emulsions contained either olive oil or corn oil with one of four different concentrations of LYC or AST (5, 10, 15, 20 μmol/L). There were three rats per treatment. Data were analyzed as a three-way analysis of variance using the General Linear Model procedure in SAS (14).

RESULTS AND DISCUSSION

The carotenoids used in this study were chosen because they have very different physical properties. Astaxanthin, a 3,3′ dihydroxy-4,4′-diketo derivative of β-carotene, was selected because it is a polar xanthophyll. Astaxanthin is a major carotenoid in marine animals with strong quenching activity against singlet oxygen and is an active scavenger of reactive oxygen species (15). Although AST is important in aquaculture, very little is known about its absorption by mammals. Mice fed a diet containing AST have significant levels of AST in the plasma which suggests that AST is readily absorbed (16). The second carotenoid used in this study was LYC, a nonpolar open-chained isomer of β-carotene associated with numerous health benefits such as prevention of cardiovascular disease and cancers of the prostate or gastrointestinal tract (17).

The fatty acid composition of a representative test emulsion containing each of the oils and the lymph collected from the rats intraduodenally infused with each of these emulsions is shown in Table 1. The fatty acids in the lymph reflect the fatty acids of the treatment emulsions. However, the lymph contained a greater proportion of palmitic acid and arachidonic

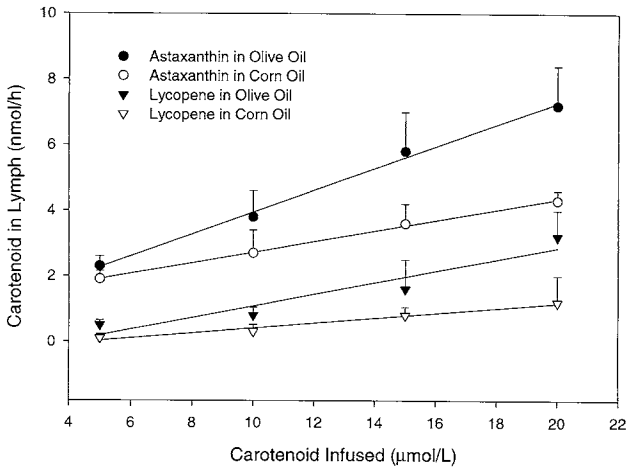

FIG. 1. Relationship between concentration of carotenoid continuously infused into the duodenum at the rate of 2.0 mL/h and concentration of carotenoid recovered per hour in the mesenteric lymph. The lymph samples were collected from 6 to 12 h after the initiation of infusion. These samples represent absorption under steady-state conditions. Each point is the mean ± SD from three individual rats. For both carotenoids, there was a significant ($P < 0.05$) linear relationship between the amount of carotenoid infused and the amount absorbed.

acid than the original emulsions. The additional fatty acids in the lymph may have originated from endogenous sources such as biliary phospholipids, or cells sloughed from the intestine. The major differences in the fatty acid composition of both the emulsions and lymph were the much greater amount of linoleic acid associated with the corn oil treatment and the greater amount of oleic acid associated with the olive oil treatment.

The results of the study are shown in Figure 1. There was a significant ($P < 0.05$) linear relationship between the amount of carotenoid infused into the duodenum and the amount recovered in the lymph. AST was more efficiently absorbed than LYC, and both carotenoids were significantly ($P < 0.05$) better absorbed from olive oil than from corn oil emulsions.

The calculated efficiencies of absorption are presented in Table 2. To calculate absorption efficiencies, conditions of steady-state absorption were assumed. Absorption efficiency was defined as the amount of carotenoid recovered in the lymph per hour divided by the amount infused into the duodenum per hour. In an earlier study with lymph duct cannulated rats, we observed that carotenoids reached a plateau or steady-state transport into the lymph by 6 h of continuous infusion of the carotenoid emulsions (18). Based on the results of this earlier study, lymph samples in the current study were collected from 6 to 12 h after the initiation of intraduodenal infusions and therefore represent steady-state absorption.

The efficiency of AST absorption from olive oil averaged 20% with individual samples having a range of 14 to 28%. In a similar study with rats the xanthophyll canthaxanthin was absorbed from olive oil emulsions with approximately the same efficiency as AST in this study (18). The efficiency of AST absorption from emulsions with corn oil was less than with olive oil and averaged only 13% with a range of values from individual samples of 9 to 25%.

LYC was not as well absorbed as AST. The absorption of LYC from olive oil emulsions averaged only 6% with a range of 3 to 11%. Absorption of LYC was further reduced to 2.5% with a range of 0.7 to 6.5% when infused with corn oil.

The less efficient absorption of AST and LYC from corn oil in the current study is consistent with the earlier observation that PUFA reduced the rate of disappearance of β-carotene from perfused rat intestinal loops. In the earlier study β-carotene disappearance was decreased by 15% from a linoleic acid or linolenic acid micellar perfusate when compared to oleic acid micellar perfusate (9). The mechanism for decreased carotenoid absorption when dispersed in PUFA is unknown.

There are several potential intraluminal and intracellular events where dietary oils could influence carotenoid absorption. Oils high in PUFA might promote carotenoid oxidation in the intestinal chyme resulting in less carotenoid available for absorption. Another explanation may be that the transfer of carotenoid from lipid emulsions containing large amounts of PUFA to mixed bile salt micelles is reduced. Incorporation into bile salt micelles appears to be a required step for carotenoid absorption (19). After carotenoids are transferred to mixed bile salt micelles, it has been suggested that micelles containing PUFA are larger in size than micelles containing saturated fatty acid and that the larger micelles diffuse more slowly through the unstirred water layer adjacent to the enterocyte, thereby decreasing the rate of carotenoid absorption (9). Another possibility is the two oils contain different amounts of stanols and phytosterols, which are known to interfere with the absorption of carotenoids (20).

Once carotenoids are absorbed into the enterocyte, intracellular processing of the carotenoid may be altered. Recently, β-carotene 15,15′-dioxygenase activity and cellular

TABLE 2
Recovery of Carotenoids in the Lymph[a]

	Amount of carotenoid intraduodenally infused							
	10 nmol/h		20 nmol/h		30 nmol/h		40 nmol/h	
Treatment	Amount	Percent	Amount	Percent	Amount	Percent	Amount	Percent
Astaxanthin (olive oil)	2.3 ± 0.3	23	3.8 ± 0.8	19	5.8 ± 1.2	19	7.2 ± 1.2	18
Astaxanthin (corn oil)	1.7 ± 0.2	17	2.7 ± 0.7	14	3.6 ± 0.6	12	4.3 ± 0.3	11
Lycopene (olive oil)	0.5 ± 0.2	5	0.8 ± 0.2	4	1.7 ± 0.9	6	3.2 ± 0.2	8
Lycopene (corn oil)	0.2 ± 0.1	2	0.3 ± 0.2	2	0.8 ± 0.3	3	1.2 ± 0.8	3

retinol-binding protein type II (CRBP II) level were observed to increase in response to dietary unsaturated triacylglycerol in the rat intestine (21). Altered dioxygenase activity and level of CRBP II would influence absorption of carotenoids that are cleaved to vitamin A. There may be other events influenced by dietary lipid that affect carotenoid uptake and transport through the enterocyte.

Finally, it should be noted that we did not observe isomerization of LYC during absorption by the rat. Significant amounts of *cis* LYC are present in human plasma even when dietary LYC is mostly in the all-*trans* form (17). The source of the *cis* isomers is unknown. Isomerization of all-*trans* β-carotene to the 9-*cis* form during absorption has been suggested (22) and might also explain the presence of *cis* LYC in human plasma. The HPLC chromatogram of the treatment emulsions showed that LYC was primarily in the all-*trans* form, and the chromatograms from the lymph were essentially identical. Because the HPLC method used in this study would not fully resolve geometric isomers of LYC, we are cautious in providing precise values for *cis* isomers of LYC. However, we estimate the *cis* isomers of LYC to be less than 10% of the total LYC in emulsions or lymph.

In conclusion, AST and LYC were absorbed in a dose-dependent manner with the xanthophyll (AST) more efficiently absorbed than the nonpolar hydrocarbon carotenoid (LYC). To our knowledge this is the first report that has directly measured absorption of AST by mammals. Both carotenoids were less efficiently absorbed from corn oil than from olive oil suggesting that the type of lipid with which a carotenoid is absorbed will influence its absorption. Additional research is needed to identify the mechanism responsible for the decreased absorption with corn oil.

ACKNOWLEDGMENTS

Follow-Up of the Δ4 to Δ16 *trans*-18:1 Isomer Profile and Content in French Processed Foods Containing Partially Hydrogenated Vegetable Oils During the Period 1995–1999. Analytical and Nutritional Implications

Robert L. Wolff[a,*], Nicole A. Combe[b], Frédéric Destaillats[a], Carole Boué[a,b], Dietz Precht[c], Joachim Molkentin[c], and Bernard Entressangles[a]

[a]ISTAB and [b]ITERG, Talence, France, and [c]Bundesanstalt für Milchforschung, Kiel, Germany

ABSTRACT: A survey of the total content of *trans*-18:1 acids and their detailed profile in French food lipids was conducted in 1995–1996, and 1999. For this purpose, 37 food items were chosen from their label indicating the presence of partially hydrogenated vegetable oils (PHVO) in their ingredients. The content as well as the detailed profile of these isomers was established by a combination of argentation thin-layer chromatography and gas–liquid chromatography (GLC) on long polar capillary columns. With regard to the mean *trans*-18:1 acid contents of extracted PHVO, a significant decrease was observed between the two periods, i.e., from 26.9 to 11.8% of total fatty acids. However, only minor differences were noted in the mean relative distribution profiles of individual *trans*-18:1 isomers with ethylenic bonds between positions Δ4 and Δ16 for the two periods. The predominant isomer was Δ9-18:1 (elaidic) acid, in the wide range 15.2–46.1% (mean, 27.9 ± 7.2%) of total *trans*-18:1 acids, with the Δ10 isomer ranked second, with a mean of 21.3% (range, 11.6 to 27.4%). The content of the unresolved Δ6 to Δ8 isomer group was higher than the Δ11 isomer (vaccenic acid), representing on average 17.5 and 13.3%, respectively. Other isomers Δ4, Δ5, Δ12, Δ13/Δ14, Δ15, and Δ16, were less than 10% each: 1.0, 1.6, 7.4, 7.1, 1.8, and 1.0%, respectively. However, considering individual food items, it was noted that none of the extracted PHVO were identical to one another, indicating a considerable diversity of such fats available to the food industry. A comparison of data for French foods with similar data recently established for Germany indicates that no gross differences occur in PHVO used by food industries in both countries. Estimates for the absolute mean consumption of individual isomers from ruminant fats and PHVO are made for the French population and compared to similarly reconstructed hypothetical profiles for Germany and North America. Differences occur in the total intake of *trans*-18:1 acids, but most important, in individual *trans*-18:1 isomer intake, with a particular increase of the Δ6–Δ8 to Δ10 isomers with increasing consumption of PHVO. It is inferred from the present and earlier data that direct GLC of fatty acids is a faulty procedure that results (i) in variable underestimates of total *trans*-18:1 acids, (ii) in a loss of information as regards the assessment of individual isomeric *trans*-18:1 acids, and (iii) in the impossibility of comparing data obtained from human tissues if the relative contribution of dietary PHVO and ruminant fats is not known.

Paper no. L8460 in *Lipids 35,* 815–825 (August 2000).

The industrial use of partially hydrogenated vegetable oils (PHVO) in food processing has been and is still a matter of debate among nutritionists (1–5), owing to the presence in more or less high amounts of unsaturated fatty acids with ethylenic bonds in the *trans* configuration. The conversion of *cis* ethylenic bonds to *trans* and positional isomers by catalytic hydrogenation is aimed at producing fats with superior physical properties and stability toward autoxidation (6). The *trans*-18:1 isomers are by far the major constituents of the so-called *trans* fatty acids that in fact embrace mono-, di-, and triunsaturated fatty acids with one *trans* double bond or more, at variable positions along the hydrocarbon chain, each with a particular metabolic fate (7,8). Regarding the *trans*-18:1 isomers, their presence in PHVO would not be particularly extraordinary, because "natural" foods derived from ruminant milk and meat, and these natural foods themselves, contain exactly the same individual *trans*-18:1 isomers, yet in different proportions, as PHVO (9). From time immemorial, humans have consumed such isomers, not to mention the widespread *trans*-3 16:1 isomer, a major constituent of the *sn*-2 position of chloroplastic diacylglycerophosphorylglycerol (10), and consequently present in all green vegetables, and also in ruminant milk fats (Destaillats, F., Wolff, R.L., Precht, D., and Molkentin, J., unpublished data).

Following the conclusions of some epidemiological and nutritional studies published in the early 1990s, manufacturers in many countries, e.g., France, Germany, Austria, Denmark, and Canada, have been producing margarines with lower contents of *trans* isomers (11–15). Except for the cheapest margarines we could find in France in 1999, imported from the Netherlands, some of which contained partially hydrogenated fish oils (not analyzed here), all popular French margarine brands exhibited no or rather low contents

Abbreviations: Ag-TLC, argentation thin-layer chromatography; FAME, fatty acid methyl ester; GLC, gas–liquid chromatography; PHVO, partially hydrogenated vegetable oils.

of *trans*-18:1 acids. This is probably because fully hydrogenated oils and/or tropical fats instead of PHVO are used in their manufacture (some are still labeled as containing hydrogenated vegetable oils). However, it was not known whether "hidden fats" (those used in food processing) had followed this trend, and the present study was aimed at determining the level as well as the detailed profile of individual *trans*-18:1 isomers in French processed foods labeled as containing PHVO. Recently, Ratnayake *et al*. (15) estimated that the major contribution to the *trans* fatty acid intake by Canadians was from hidden fats, not from margarines.

The analytical methods used here involve a combination of argentation thin-layer chromatography (Ag-TLC) and gas–liquid chromatography (GLC) on 100-m polar capillary columns operated under optimal temperature and carrier gas pressure conditions. This procedure, though time-consuming, allows resolution of practically all major individual *trans*-18:1 isomers with no interferences with any other overlapping fatty acids, as well as accurate quantitation. This contrasts with so-called "optimized" methods based on single GLC runs (16,17) that lead to elution of *trans*-18:1 isomers under an asymmetrical and uneven peak, more or less well separated from oleic acid, and that obviously do not allow any accurate insight into the distribution profile of individual isomers.

Although the analysis of 21 French food items purchased locally in supermarkets in 1999, and of 16 items purchased earlier (1995–1996), showed that the mean contents of *trans*-18:1 isomers in food lipids for the two periods were somewhat different, their mean relative profiles were rather similar, differing in detail only. This allows establishment of a mean profile for these PHVO and comparison with corresponding data for German margarines and shortenings. To our knowledge, no similar studies have been published on PHVO used as ingredients in food processing. Thus, data presented here appear of general use to accurately estimate the consumption of individual *trans*-18:1 isomers in European countries where food consumption or disappearance data are known.

EXPERIMENTAL PROCEDURES

Samples. Twenty-one food items with labels indicating the presence of PHVO were purchased locally in supermarkets near Bordeaux (France) in May 1999. They included, among others, 11 different dehydrated soups. Another set of 16 foods, also labeled as containing PHVO, was purchased earlier in the same region during 1995 and 1996.

Fat extraction. For dehydrated soups and other food items containing less than 10% water, a representative sample of foods, or the whole item, was homogenized with a household electric grinder. Forty grams of the resulting powder or homogenate was extracted for 4 h in an all-glass Soxhlet extractor using *ca*. 200 mL of petroleum ether (b.p. 40–60°C). For foods with a higher water content, a smaller portion of the homogenates (*ca*. 10 g) was extracted according to Folch *et al.* (18), with methanol being added first and the sample dispersed with a 20 M Ultraturrax homogenizer (Janke & Kunkel GmbH & Co. KG, Staufen, Germany) before adding chloroform and performing a second homogenization with the Ultraturrax. After removal of the solvent in a rotary evaporator at 45°C, fats were transferred with a small volume of hexane into 5-mL vials and stored at 4°C until use.

Fatty acid methyl esters (FAME) preparation. FAME were prepared by vigorously shaking for 1 min a mixture of 5 mL hexane containing approximately 500 mg of fat and 300 µL of a 0.5 N sodium methoxide solution with further incubation at 50°C for 10 min and frequent shaking. After completion of the reaction, 1 mL of a 5% (wt/vol) aqueous solution of NaCl was added, and the upper layer was withdrawn and stored in stoppered glass tubes at 4°C until use. Completeness of the reaction was regularly checked for each category of foods by TLC using hexane/diethyl ether (90:10, vol/vol) as the solvent.

Fractionation of FAME by Ag-TLC. FAME were fractionated according to the number and geometry of double bonds by TLC on silica-gel plates impregnated with $AgNO_3$. The plates were prepared by immersion in a 5% solution of $AgNO_3$ in acetonitrile as described by Wolff (19). The developing solvent was the mixture hexane/diethyl ether (90:10, vol/vol). At the end of the chromatographic runs, the plates were briefly air-dried, sprayed with a solution of 2′,7′-dichlorofluorescein, and viewed under ultraviolet light (234 nm). Generally, the *trans*-band was quite well separated from the *cis*-band, and no cross-contaminations occurred. The bands corresponding to the saturated and *trans*-monoenoic acids were scraped off into aluminum foil, and the gel from the two bands was transferred into the same test tube. To the gel were added successively 1.5 mL of methanol, 2 mL of hexane, and 1.5 mL of a 5% (wt/vol) aqueous solution of NaCI (19). Thorough mixing followed each addition. After standing for *ca*. 1 min, the hexane phase was withdrawn almost quantitatively and concentrated under a light stream of N_2. The residue was dissolved in a small volume of hexane for further GLC analysis. Palmitic and stearic acids, determined by total fatty acid analysis before performing Ag-TLC fractionation, were used as internal standards to calculate the content of *trans*-18:1 isomers (19).

Analysis of FAME by GLC. Analyses of total *trans*-18:1 acids by GLC were performed with a CP 9003 chromatograph (Chrompack, Middelburg, The Netherlands) equipped with a flame-ionization detector and a split injector that were maintained at 250°C. A 50 m × 0.25 mm i.d. CP-Sil 88 fused-silica capillary column (stationary phase: 100% cyanopropyl polysiloxane, 0.20 µm film thickness; Chrompack) was used and operated isothermally at 190˚C. Helium was the carrier gas with an inlet pressure of 100 kPa (split ratio, 1:50). The chromatograph was coupled with an SP 4290 integrator equipped with the memory module (Spectra Physics, San Jose, CA).

Analysis of individual *trans*-18:1 isomer fractions isolated by Ag-TLC was performed by using a gas chromatograph CP 9000 (Chrompack) with a split injector, a flame-ionization detector, and a fused-silica capillary column (100 m × 0.25 mm) coated with 0.20 µm CP-Sil 88 (Chrompack) under the following conditions: H_2 as the carrier gas; injector temperature

255°C; and detector temperature 280°C. Monoenoic TLC fractions were analyzed isothermally at 172°C with a column head pressure of 160 kPa (split ratio 1:50).

Identification of individual isomeric *trans* octadecenoates was achieved by comparison of retention times with FAME standards of the 18:1 isomers Δ6, Δ7, Δ9, Δ11, Δ12, Δ13, and Δ15 (Sigma, St. Louis, MO). *Trans*-18:1 acids isolated from butterfat were used as a secondary standard (20). Integration and quantitation were accomplished with an HP 3365 II ChemStation system (Hewlett-Packard, Palo Alto, CA). Calibration of GLC data included the conversion from FAME to free fatty acids. Thus, results expressing absolute concentrations are given as g/100 g of total fatty acids.

RESULTS AND DISCUSSION

Individual trans-*18:1 acids in PHVO prepared from French foods*. In the past, the only means to analyze individual *trans*-18:1 isomers in complex FAME mixtures (e.g., prepared from ruminant fats or PHVO) was to isolate these components, often by a combination of argentation chromatography and preparative GLC, and to submit them to an oxidative cleavage (21). The resulting fragments were further analyzed by GLC, allowing quantitation of individual isomers. A drawback of this procedure was that the shortest volatile fragments were prone to losses, and correction factors had to be applied to compensate for the unequal response of the flame-ionization detector *vis à vis* methylene and carboxylic groups. However, until recently, this analytical procedure was frequently applied to PHVO from several countries to gain insight into the *trans*- as well as the *cis*-18:1 isomer distributions (22–30).

Yet, very early after the advent of capillary columns, encouraging results (31) had demonstrated the potentiality of this material in the resolution of individual 18:1 isomers. Chromatograms published as early as 1966 (31) were of better quality than many chromatograms published nowadays. However, the use of long capillary columns (100 m) operated at rather low temperatures became a routine procedure only after 1995 (20,32,33). Despite the remarkable improvement that was achieved with this procedure, the isolation of the *trans*-monoenoic acid fraction by argentation chromatography (most often, Ag-TLC) is still a prerequisite, for many *trans*-18:1 isomers overlap *cis*-18:1 isomers (34,35). Without this fractionation, inaccurate data (always underestimates) are obtained (35), particularly when 50-m instead of 100-m columns are used, or when these columns are operated at too high a temperature. Unfortunately, there are no unique factors to correct published data obtained in such a way, as the correction factor varies with the *trans*-18:1 isomer profile in the range 1.2–1.8, depending on the fat analyzed (e.g., PHVO vs. ruminant fats) (35).

In the present study, FAME prepared from all food samples were processed through the Ag-TLC/GLC procedure to establish their *trans*-18:1 acid content and profile. Data for food items analyzed in 1995 and 1996 are given in Table 1, and those for foods analyzed in 1999 in Tables 2 and 3. From our experience with foods analyzed during the first period, we knew that the profiles of *trans*-18:1 acids were highly

variable. To understand whether there was a relationship between the nature of the foods and the PHVO used to manufacture them, we analyzed eleven samples of dehydrated soups in 1999, where PHVO have no obvious roles in the structure of the food, except that they are solid at ambient temperature and resistant to oxidation. Not one of the extracted fats was identical to another one (Table 3). Evidently, the extracted fats may not be exactly representative of the added PHVO, as some ingredients also naturally contain some fat. If this fat is derived from beef or mutton, or from milk, then a small part of the *trans*-18:1 isomers may come from these food constituents.

For the two periods considered, the mean *trans*-18:1 isomer contents are 26.9 (range, 13.0–61.0%) and 11.9% (range, 0.1–27.0%), respectively, of total fatty acids (Tables 1–3). This difference does not strongly indicate that hydrogenation habits have changed in the meantime. The categories of foods analyzed at the two periods were somewhat different, and for a given category, the brands differed too. However, PHVO with very high *trans*-18:1 acid levels (>30%) seem to have disappeared in 1999. Regarding the profile of these isomers, in 1999 as well as in 1995–1996, foods with identical *trans*-18:1 isomers are exceptional, which means either that food processors had and still have access to a very wide range of

such fats or that blending is a current practice. Also, this means that analysis of only a few food items in dietary survey studies is unlikely to be representative of a "mean PHVO." Sampling of foods thus must be wide enough to take into account the great variability of the *trans*-18:1 isomer profile in PHVO.

Comparison with German PHVO. In the present study, we observed that the mean relative profile established for dehydrated soups was nearly identical to that established for other food items in 1999 (Fig. 1 and Table 4). Moreover, combining results for dehydrated soups and other food items for the period 1999 gives a mean profile that only differs in details from that established for foods analyzed in 1995–1996 (Fig. 2). Averaging all *trans*-18:1 isomers profiles (n = 37) leads to a mean profile thought to accurately represent a "mean PHVO" present in foods consumed by French people. This profile is compared in Table 4 and Figure 3 to the mean profiles established for margarines on the one hand, and shortenings and frying fats on the other hand, commercialized in Germany (36–38). Differences are visible, e.g., between margarines and foods, which may be attributed to different hydrogenated oils being used in each category. The influence of the source of oil on the pattern of *trans*-18:1 isomers, which also depends on the conditions of processing, is well known. Also, it may be reasonably hypothesized that hidden PHVO in foods may be derived from cheaper raw materials than in margarines (e.g., rapeseed oil vs. sunflower oil).

When all French and German samples are considered, it appears on average that the Δ9 isomer (elaidic acid) is the predominant isomer in all categories of foods and that it may vary in the approximate range 9–46% (Table 4), averaging 22–30%. The Δ10 isomer is ranked second, at *ca.* 21% (range, 8.7–30.8%). In contrast to elaidic acid, and with few exceptions only, the proportion of the latter isomer is remarkably constant from one category of food to another. The unresolved Δ6 to Δ8 group represents *ca.* 16%, which is higher than the content of vaccenic acid that accounts for approximately 14%. Considering the Δ6 to Δ8 group, it is likely that the Δ8 is the predominant isomer (22–30). All other isomers are less than 10%, and appear rather variable quantitatively. Special attention, however, should be paid to the late-eluting Δ12, Δ13 + Δ14, Δ15, and Δ16 isomers. These isomers have often been neglected, although from Ag-TLC they are accessible without difficulties on 50-m capillary columns operated at moderately high temperatures, that is, allowing reasonable times of analysis. Finally, the minor Δ4 and Δ5 isomers, which are the earliest-eluting components of the *trans*-18:1 fractions, are not always easily quantitated (e.g., not reported for French foods analyzed in 1995–1996), as they may not be taken into account by integrators when the quantity of *trans*-18:1 FAME injected is not appropriate for their detection. This also holds for the Δ15 and Δ16 isomers.

In Figure 4, the relative *trans*-18:1 isomer profile of PHVO as established in the present study for French foods is compared with that of ruminat fats. For the latter profile, data from Wolff (19,39), Bayard and Wolff (40), and Wolff *et al*.

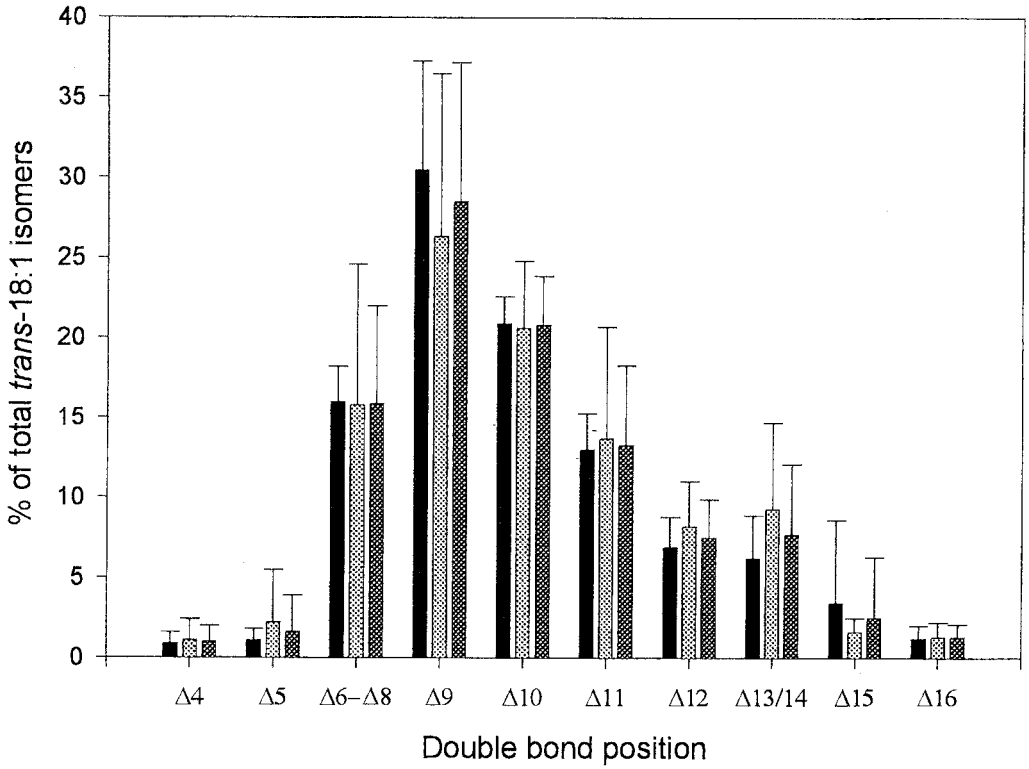

FIG. 1. Relative isomeric distribution (mean ± SD) of individual *trans*-18:1 isomers prepared from partially hydrogenated vegetable oils extracted from foods purchased in France in 1999. Black bars, dehydrated soups (n = 11); light grey bars, other food items (n = 10); dark grey bars, all samples (n = 21).

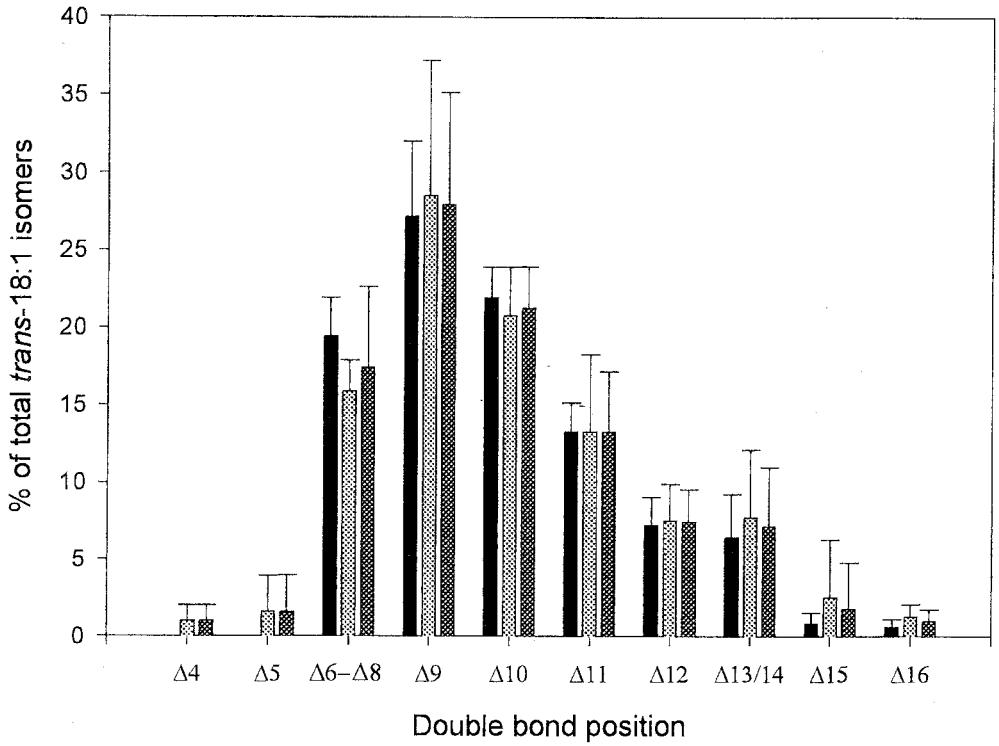

FIG. 2. Comparison of the relative isomeric distribution (mean ± SD) of individual *trans*-18:1 isomers prepared from partially hydrogenated vegetable oils extracted from foods purchased in France in 1995–1996 (black bars, n = 16) and in 1999 (light grey bars, n = 21); all samples for both periods (dark grey bars, n = 37).

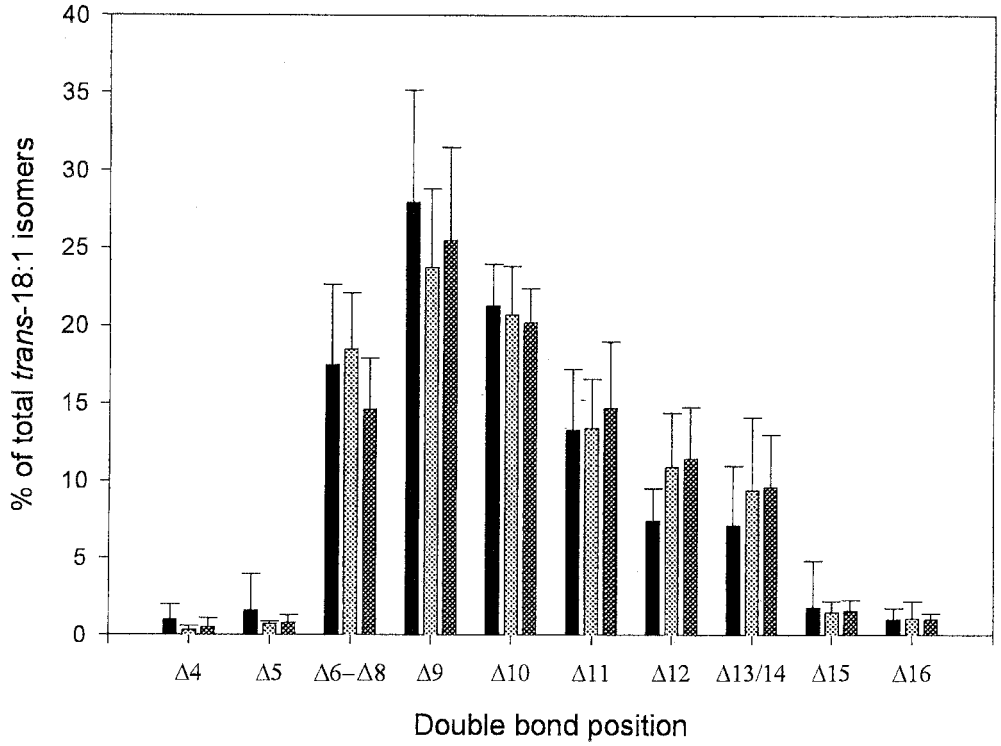

FIG. 3. Comparison of the relative isomeric distribution (mean ± SD) of individual *trans*-18:1 isomers prepared from partially hydrogenated vegetable oils extracted from foods purchased in France (black bars, $n = 37$) with corresponding data for German margarines (light grey bars, $n = 46$) and shortenings and cooking fats (dark grey bars, $n = 16$) purchased in 1994.

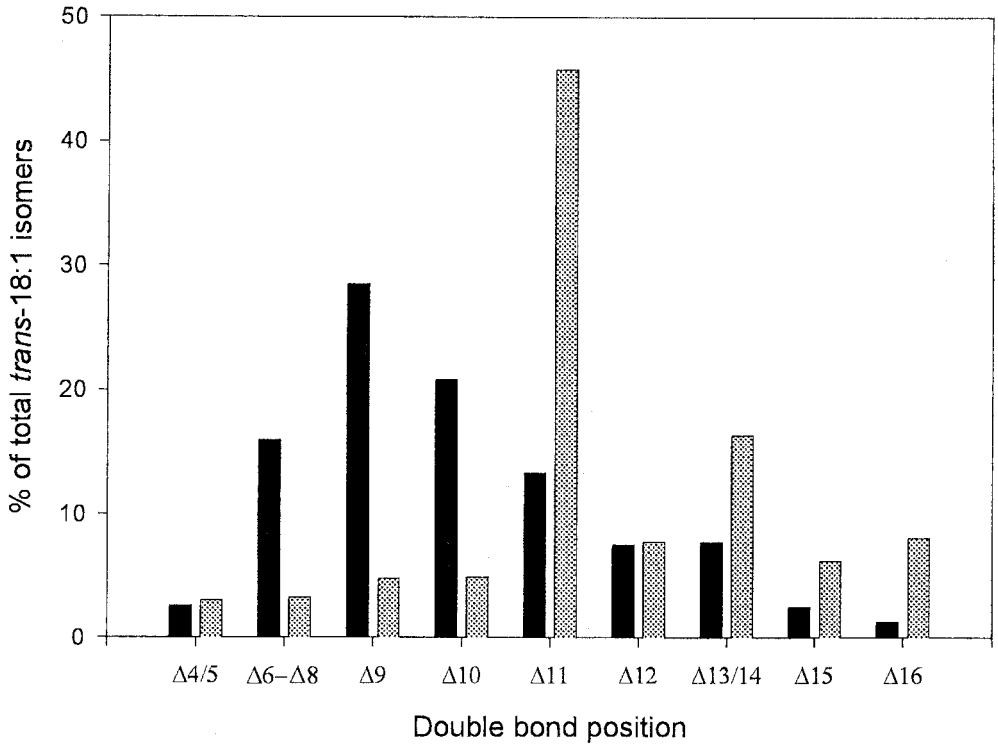

FIG. 4. Relative isomeric distribution of individual *trans*-18:1 isomers prepared from partially hydrogenated vegetable oils extracted from foods purchased in France (black bars, $n = 37$) and from ruminant fats (grey bars, essentially calculated from data in Refs. 39–41; see text, however).

(41) for France were used, with additional new data for individual isomers of French ruminant fats not available previously (Precht, D., Molkentin, J., Destaillats, F., and Wolff, R.L., unpublished data). In fact, totaling *trans*-18:1 isomers from all ruminant fats (taking into account their respective share in the French diet) leads to a profile almost undistinguishable from that of French or German bovine milk fat alone (results not shown; see Refs. 9 and 42, however). The differences between PHVO and ruminant fats are obvious, with a shift of the bulk of *trans*-18:1 acids toward low Δ positions of the ethylenic bond in PHVO as compared to ruminant fats. More than two-thirds of total *trans*-18:1 isomers have their ethylenic bond between the Δ4 and Δ10 positions in PHVO, whereas the great majority (>65%) of *trans*-18:1 isomers have their ethylenic bond at position Δ11 and farther in ruminant fats.

Nutritional and analytical implications. The dissimilarity in the distribution of *trans*-18:1 isomers from the two dietary sources becomes even more apparent when the absolute profile of the daily intake of *trans*-18:1 isomers is constructed (Fig. 5). The French profile is based on a mean daily intake of 1.5 g of *trans*-18:1 acids from ruminant fats (39), and 1 g from PHVO (43). Vaccenic acid represents approximately one-third (800 mg) of the total, originating mostly from ruminant fats. The contribution of PHVO to the intake of vaccenic acid is small and is far below that attributable solely to seasonal variations of the quantity of vaccenic acid in bovine milk fat. Depending on the feed, 100 g of milk fatty acids contains from *ca.* 1 (barn feeding) to almost 3 g (pasture feeding) of vaccenic acid (44). A similar influence of diet also affects the Δ12 to Δ16 isomers. On the other hand, the amounts of Δ6 to Δ10 isomers vary little with the feed of the cattle, and the contribution of PHVO to the intake of these isomers is crucial.

The model shown in Figure 5 can be extended to other countries. For Germany, where an estimated mean intake of 3.0 g/person/d appears reasonable (45), half of which coming from ruminant fats and the other half from PHVO, the diagram shown in the center of Figure 5 is obtained. The increase of the Δ6 to Δ10 part becomes more conspicuous, with little effect on the Δ11 to Δ16 part, even if the difference in *trans*-18:1 acid intake between German and French people is 0.5 g/person/d.

Extrapolation of our data to North America (Canada and the United States) is also interesting. *Trans*-fatty acid consumption by Canadian and U.S. people has been reviewed several times (46–49), and considerable discrepancies between estimates were noted. These show in particular the weakness of food frequency questionnaires to assess the *trans*-fatty acid consumption, resulting in *ca.* two to three times less than assessments based on disappearance and consumption data, or estimates based on the *trans*-18:1 acid content in human milk obtained by Ag-TLC coupled with GLC or related procedures (reviewed in Ref. 50). As a matter of comparison with France and Germany, we have chosen a value of 7.0 g/person/d, which should be realistic, of which

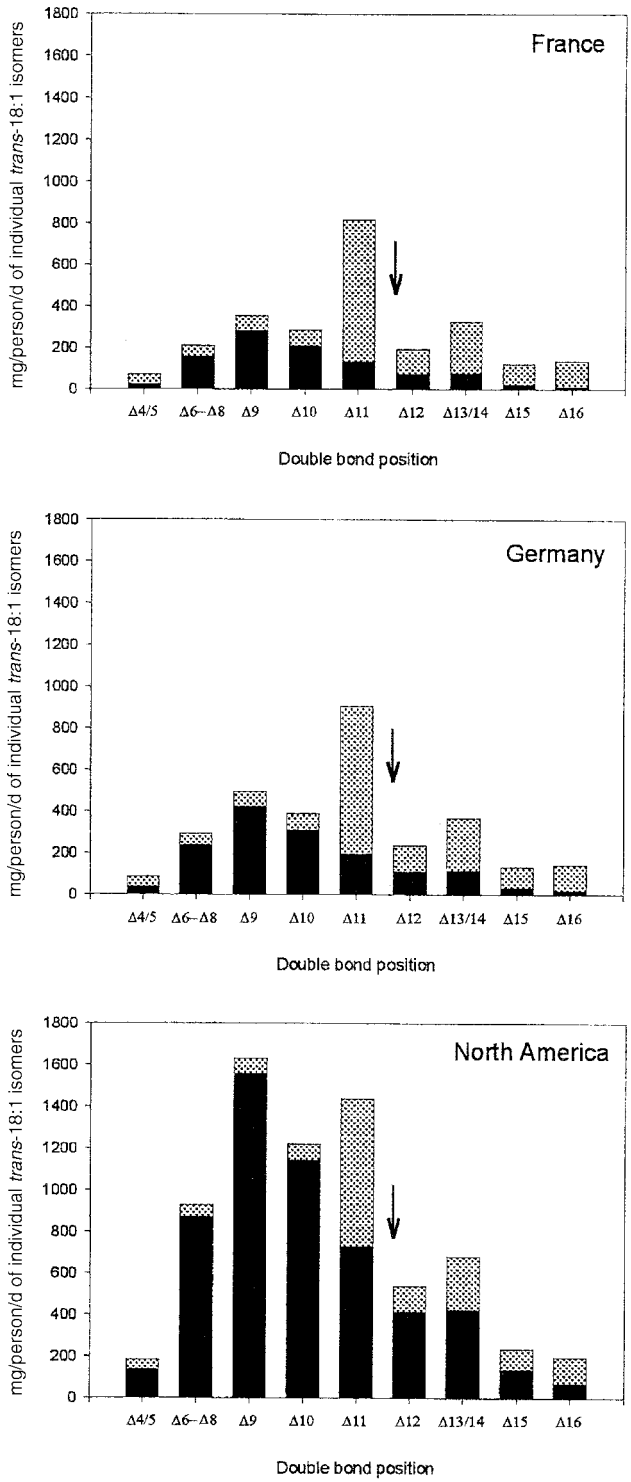

FIG. 5. Estimated absolute per capita daily intake of individual *trans*-18:1 acids in France (top), Germany (center), and North America (bottom). Black bars: contribution by partially hydrogenated vegetable oils; grey bars, contribution by ruminant fats. The arrows show the limit between visible (left side) and masked (right side) isomers that occurs during direct gas–liquid chromatography on 50-m columns.

1.5 g (approximately 20% of the total) would come from ruminant fats. These values allow construction of the diagram on the bottom of Figure 5. The preponderance of elaidic acid

among other *trans*-18:1 acids becomes obvious, and this contrasts with data for France or Germany (top and central diagrams in Fig. 5). There is a difference not only in the total intake of *trans*-18:1 isomers but also in the distribution of individual isomers. The latter diagram compares well with those published by Emken (51) for the United States, and by Ratnayake (28) for Canada. However, it is likely that in these two countries, the raw materials that are hydrogenated may not be the same as in European countries (e.g., soybean in the United States, canola in Canada). Thus, small differences between our predictive diagram and the true distribution in North American diets should probably occur.

We repeatedly pointed out (3,34,35,45,48) the faulty use of direct GLC to assess the *trans*-18:1 acid content in foods or biological samples. The diagrams in Figure 5 once again examplify how direct GLC leads to unavoidable underestimates, and hence, to erroneous data. On 50-m columns systematically, or on 100-m columns operated at too high a temperature, isomers with a Δ12 ethylenic bond (or at best, the Δ13 plus Δ14 critical pair) and all other isomers with ethylenic bonds still further along the chain elute under oleic and *cis*-vaccenic acids and even after them. Isomers lost in this way are those to the right of the arrows in Figure 5. These isomers are not taken into account because only the Δ6 to Δ11 (or Δ12, at least in part) are more or less well separated from oleic acid and integrated. The proportion of these isomers relative to total *trans*-18:1 acids varies with the proportions of PHVO and ruminant fats in the sample to be analyzed, with underestimates in the range 8–67% (35,36). Clearly, direct GLC determinations of *trans*-18:1 isomeric acids only allow gross estimates that are of little use, unreliable, and inaccurate.

An example will help to illustrate why case-control studies for ischemic heart diseases based on direct GLC are unable to lead to reliable conclusions. Let us imagine two groups, one consuming mostly ruminant fats with little PHVO (group A), and the other one, principally PHVO with little ruminant fats (group B). Admittedly, no differences are found in the content of *trans*-18:1 isomers determined by direct GLC in their adipose tissue, say 2.0% of total fatty acids in both groups. The conclusion, based on a wealth of statistical treatments, will lead to an absence of relationships between diets and effects. In fact, the true proportion of *trans*-18:1 isomers in group A would be 2.0 × 1.5 = 3.0%, whereas in group B, the corresponding value would be 2.0 × 1.3 = 2.6%, with 1.5 and 1.3 being the mean correction factors for consideration of the masked *trans*-18:1 isomers (35). Possibly, the difference would then be significant. Conversely, two different percentages of *trans*-18:1 isomers in the adipose tissue of group A (1.8%) and group B (2.1%), here too established by direct GLC and considered statistically different, may be identical: group A, 1.8 × 1.5 = 2.7%, and group B, 2.1 × 1.3 = 2.7%. This clearly demonstrates that an accurate knowledge of all individual *trans*-18:1 isomers is imperative before drawing any conclusions as to their effects in case-control studies based on data obtained by direct GLC. Because this has never been done, the problem of the potential harmfulness or harmlessness of these isomers must be considered unresolved and remains a fully open question.

Retrospectively, considering conclusions based on "mixed-up *trans*-fatty acids" determined in such a way, one should rather critically look at the methodology before accepting the findings. Moreover, it possibly is not the quantity of *trans*-18:1 isomers that should be questioned, but their intimate profile, only accessible by Ag-TLC/GLC with specifically optimized GLC operating conditions. Surprisingly, with rare exceptions employing the Ag-TLC/GLC procedure (52), in practically none of the case-control studies published so far was a chromatogram given showing the resolution of *trans*-18:1 isomers, and eventually other *trans*-fatty acids. Consequently, suspicion should be cast on their conclusions.

ABSTRACT: Apolipoprotein E allele 4 (apo ε_4) and smoking each have been associated with an unfavorable lipid profile. We used data collected on 1,472 subjects in the National Heart, Lung, and Blood Institute Family Heart Study to assess whether smoking interacts with apo ε_4 to influence the levels of plasma lipids. We dichotomized smoking and apo ε_4 and used analysis of covariance to estimate the means of lipids. Smokers had lower body mass index, were younger, and consumed less fruits and vegetables. Among individuals without apo ε_4, comparing nonsmokers with smokers, mean low density lipoprotein cholesterol (LDL) was 129.3 and 134.4 mg/dL, respectively, for women and 126.1 and 127.6 mg/dL, respectively, for men. Among subjects with an apo ε_4 allele, corresponding means were 132.0, and 152.9 mg/dL, respectively, for women and 131.3 and 137.3 mg/dL, respectively, for men (P for interaction <0.001 for women and 0.11 for men). A similar interaction was observed for total cholesterol among women ($P = 0.02$). This study shows a statistically significant effect modification of the relation of apo ε_4 to LDL and total cholesterol by smoking among women. Smoking may enhance genetic susceptibility to an unfavorable lipid profile among subjects with apo ε_4.

Paper no. L8482 in *Lipids 35*, 827–831 (August 2000).

Elevated low density lipoprotein cholesterol (LDL) and triglycerides and low levels of high density lipoprotein cholesterol (HDL) are established risk factors for coronary heart disease (CHD) (1–6). Plasma levels of LDL, HDL, and triglycerides are influenced by both genetic and environmental factors. Genetic polymorphism of apolipoprotein (apo) E, a protein found in very low density lipoprotein and HDL, is common. The major isoforms E2, E3, and E4 are coded by the alleles ε_2, ε_3, and ε_4, respectively. Apo ε_4 has been associated with increased risk of CHD (7–8), raised LDL (9–12) and triglycerides (11), and lower HDL (11). Contrary to apo ε_4, which is a nonmodifiable risk factor for cardiovascular disease, cigarette smoking is a modifiable risk factor which can be targeted for preventive interventions. Smoking is also associated with increased LDL (13–19) and triglycerides (20), and with decreased HDL (19). The effects of smoking on LDL may be mediated through decreased activity of lipoprotein lipase (21). In this study, we have used data collected in the National Heart, Lung, and Blood Institute (NHLBI) Family Heart Study to evaluate whether smoking and apo ε_4 interact to influence the levels of LDL, HDL, and triglycerides among women and men.

MATERIALS AND METHODS

Study population. The NHLBI Family Heart Study is a multicenter, population-based study designed to identify and evaluate genetic and nongenetic determinants of CHD, preclinical atherosclerosis, and cardiovascular risk factors. A detailed description of the methods and design has been reported (22). Subjects in this study are members of families from previously established population-based cohort studies: the Framingham Heart Study in Framingham, Massachusetts; the Atherosclerosis Risk in Communities (ARIC) cohorts in North Carolina and Minnesota; and the Utah Health Family Tree Study in Salt Lake City, Utah. In 1993–1995, groups of individuals participating in each of the four studies were selected at random and invited to furnish an updated family health history that contained information on their parents, children, and siblings. Of 4,679 individuals contacted, responses were obtained from 3,150 (67%); their other family members were then contacted, and self-reported health data were obtained from 22,908 other family members (86% of those contacted). Of the families furnishing data, 588 were chosen at random and 657 were chosen because of higher than expected CHD rates among family members. All members of these families were invited to come to one of the four study clinics for clinical evaluation. The evaluation included a detailed medical and lifestyle history, obtained through interview. All interviewers were trained centrally and required periodic certification; standardization of interviews was facilitated by periodic review of taped interviews, and by frequent circulation of the distributions of responses obtained by different interviewers and different centers, with prompt corrective actions taken when nonstandardized interviewing

Abbreviations: Apo ε_4, apolipoprotein E allele ε_4; ARIC, Atherosclerosis Risk in Communities; BMI, body mass index; CHD, coronary heart disease; HDL, high density lipoprotein cholesterol; LDL, low density lipoprotein cholesterol; Ln: natural logarithm; NHLBI, National Heart, Lung, and Blood Institute; PCR, polymerase chain reaction.

techniques were detected. The study protocol was reviewed and approved by the Institutional Review Boards of each of the participating institutions.

Blood collection and assays. All participants were asked to fast for 12 h before their arrival at the study center. Evacuated tubes without additives were used to collect samples for lipids; blood samples were then spun at 3,000 × *g* for 10 min at 4°C. Sera were stored at −70°C until shipment to a central laboratory at the Fairview-University Medical Center in Minneapolis, Minnesota, for processing. LDL was estimated using the method of Friedewald *et al.* (23) except for subjects with triglycerides above 400 mg/dL, whose LDL was measured by ultracentrifugation. Total cholesterol and triglycerides concentrations were measured by a Roche COBAS FARA high-speed centrifugal analyzer (Roche Diagnostic Systems, Montclair, NJ). HDL cholesterol was measured after precipitation of the other lipoprotein fractions by dextran sulfate (24).

Apo E genotyping was performed using polymerase chain reaction (PCR) to amplify a 267 base-pairs fragment from exon 4 of the apo E gene (25). The PCR product was digested with the HhaI restriction endonuclease (an isoschizomer of CfoI), which resulted in a specific banding pattern for the three isoforms of the apo E protein when they were separated by polyacrylamide gel electrophoresis and then silver-stained. Information on cigarette smoking was obtained by the question "Do you now smoke cigarettes?" Classification of smoking was based on the dichotomous answer to this question.

Other variables. Anthropometric data were collected with subjects wearing scrub suits. A balance scale was used to measure body weight, and height was measured using a wall-mounted vertical ruler. Information on alcohol intake (drinks per week) and physical activity (minutes per day of leisure activity) was obtained by interview. Calorie intake and fruit and vegetable consumption (servings per week) were assessed using a food frequency questionnaire (26,27) administered by a trained interviewer. The proportion of calories from fat was calculated by dividing the number of calories from total fat by total calories. Estrogen use by women was obtained by interview and by review of all medications being taken (brought to the clinic).

Statistical analysis. Apo E phenotype was determined among 1,744 subjects. Of these, 272 were excluded because of (i) $\varepsilon_2/\varepsilon_4$ genotype (41 subjects), (ii) current treatment for hyperlipidemia (41 subjects), or (iii) missing covariates (190 subjects). Because women have higher HDL levels and estrogen use is an important predictor of both LDL and HDL, we performed gender-specific analyses. Current cigarette smoking and apo ε_4 were dichotomized, and the following categories were generated: (i) absence of apo ε_4 and no smoking, (ii) absence of apo ε_4 and smoking, (iii) presence of apo ε_4 and no smoking, and (iv) presence of apo ε_4 and smoking. We used analysis of covariance to estimate the means of lipid values according to the above categories. Adjustment was made for age, age^2, calories from total fat, fruit and vegetable intake, body mass index (BMI), all on continuous scale, and estrogen use for women. For HDL cholesterol, further adjustment was made for alcohol intake and physical activity. Additional analyses using 5-yr age categories and quintiles of BMI and calories from fat yielded similar results. Because the distributions of triglycerides were markedly skewed, we used natural logarithmic-transformed values for the analyses. A product term (smoking × apo ε_4) was used in the multivariate model to assess the interaction. To assess the influence of menopause, we conducted additional analyses among women stratified by menopausal status. We used a bootstrap technique (300 replications) to adjust the variance for familial correlation. All analyses were performed using SAS (28).

RESULTS

Of the 1,472 subjects included in the analysis, 783 were women and 689 were men. The age range was 25 to 93 years for women [mean (SD): 56.4 (11.0) yr] and 25 to 91 years for men [mean (SD): 56.2 (11.1) yr]. The prevalence of current smoking was 13.7% for women and 14.4% for men. The frequency distributions of apolipoprotein $\varepsilon_2/\varepsilon_2$, $\varepsilon_2/\varepsilon_3$, $\varepsilon_3/\varepsilon_4$, $\varepsilon_4/\varepsilon_4$, and $\varepsilon_3/\varepsilon_3$ were 0.5, 11.1, 26.2, 2.9, and 59.3%, respectively. Table 1 presents gender-specific characteristics of the study population by apo ε_4 and smoking status. Among women without apo ε_4, smokers had lower BMI ($P = 0.08$), were younger ($P = 0.01$), had higher calories from fat ($P = 0.007$), and consumed fewer fruits and vegetables ($P = 0.08$). Among females with apo ε_4, smoking was associated with younger age ($P = 0.08$), lower BMI ($P = 0.03$), and lower consumption of fruits and vegetables ($P = 0.001$). [Female smokers were less likely to use estrogen compared with nonsmokers, but these results were not statistically significant ($P = 0.41$ for women without apo ε_4 and $P = 0.25$ for women with apo ε_4), Table 1.] For males, smoking was associated with younger age irrespective of apo ε_4 status ($P = 0.05$) and was related to lower BMI ($P = 0.01$), greater calories from fat ($P = 0.001$), and lower consumption of fruits and vegetables ($P = 0.003$) among subjects without apo ε_4.

Table 2 presents adjusted means of lipids according to the combination of apo ε_4 and smoking status. Compared with subjects who lacked apo ε_4 and who were not current smokers, current smoking and the presence of apo ε_4 were individually associated with a slight increase of LDL (4 and 2%, respectively, for women; 1 and 4%, respectively, for men), whereas the presence of both apo ε_4 and current smoking was associated with much larger increases of LDL (18 and 9% for women and men, respectively; P for interaction < 0.001 for women and 0.11 for men). The joint presence of smoking and apo ε_4 was associated with 7% increases of total cholesterol in both women and men (P for interaction = 0.02 for women and 0.14 for men). Among women, compared with the category of nonsmoking and absence of ε_4, smoking alone and apo ε_4 alone were associated with a 6 and 13% decrease in HDL, respectively, whereas the joint presence of smoking and apo ε_4 was associated with a 17% decrease in HDL. Corresponding values for men were 7, 6, and 11% decrease of HDL with smoking alone, apo ε_4 alone, and joint presence of smoking and apo ε_4, respectively (P for interaction = 0.99 for women and 0.22 for men). For the ratio of total cholesterol to HDL, the highest values were among women and

Calories from fat (%)	30.7 ± 7.7[b]	33.9 ± 7.4[b]	32.7 ± 7.9	32.0 ± 6.4

[a]+ and — indicate presence and absence, respectively, of the corresponding variable; apolipoprotein ε_4 is considered present if at least one allele of ε_4 is present. NHLBI, National Heart, Lung, and Blood Institute.
[b]$P < 0.05$ comparing smokers with nonsmokers within category of apolipoprotein ε_4.

men who had apo ε_4 and smoked. There were no major changes of mean triglycerides according to smoking and apo ε_4 in either gender (Table 2). Additional analysis restricted to postmenopausal women revealed a stronger interaction between smoking and apo ε_4 for LDL and total cholesterol (Table 3).

DISCUSSION

Studies have reported a positive association between apolipoprotein ε_4 and plasma LDL and triglycerides (9–12). In addition, smoking has been shown to be associated with an increase in plasma LDL and triglycerides, and a decrease in HDL (13–20,29,30). Physiologic mechanisms by which different isoforms of apo E influence plasma cholesterol have been described: triglyceride-rich particles containing apo ε_4 are removed faster by the liver; the faster clearance of apo ε_4-rich particles results in downregulation of LDL receptors and subsequent increased level of plasma cholesterol (31). On the other hand, inconsistent findings have been reported on the mechanisms by which smoking may influence LDL cholesterol. Some authors have suggested that the effect of smoking on LDL is mediated through a reduction of lipoprotein lipase (21,32), whereas others have reported no difference in lipoprotein lipase activity between smokers and nonsmokers (33,34). Plasma lipases are important regulators of plasma lipoprotein composition. Lipoprotein lipase is a catalyst for triglyceride-rich lipoprotein hydrolysis and enables blood clearance of triglycerides. Hepatic lipase has been shown to be activated

among smokers (33). This enzyme plays a role in converting very low density lipoprotein to LDL (35). An experimental study has shown that blood exposure to smoking leads to inhibition of lecithin:cholesterol acyl transferase (36). In addition, nicotine exerts hyperlipidemic effects by increasing the synthesis of triglyceride-rich lipoproteins (18).

In the present study, we demonstrated that cigarette smoking significantly modified the relation of apo ε_4 to LDL and total cholesterol among women. Although not statistically significant, the trend was suggestive of greater risk of higher LDL and total cholesterol among male smokers with apo ε_4. We are not aware of any previous study that assessed whether smoking interacts with apo ε_4 to influence plasma LDL, HDL, and triglycerides. Our results are consistent with previous reports indicating that both smoking and apo ε_4 are associated with increased LDL and total cholesterol (9–12,29,30).

In this study, subjects with apo ε_4 and current smoking status were on average younger than subjects in the other three groups. One possible explanation is that subjects with the apo ε_4 isoform who smoked may have died at a younger age from cardiovascular diseases than subjects without apo ε_4. If this hypothesis were true, our measure of effect would have been underestimated. The findings observed among women are not likely to be explained by estrogen use; the fact that women were not aware of their apolipoprotein genotype precludes differential estrogen use among women with ε_4 allele. The lack of statistically significant difference in the frequency distribution of estrogen use across smoking-ε_4 cross-classification in our data supports this hypothesis. Our results are unlikely to be influenced by recall bias, as subjects in this study were not aware of their apo E phenotype and thus were unlikely to show differential reporting of smoking habits. Furthermore, the use of standardized questionnaires and trained interviewers may have further minimized any information bias, which might have threatened the validity of this study.

In conclusion, this study shows that smoking modifies the relation of apo ε_4 to LDL among women; among men, there is a trend toward a similar relation. Subjects with apo ε_4 who smoke are at greater risk of CHD, elevated LDL, triglycerides, and lower HDL. Smoking cessation measures should be directed toward any smoker but should be enhanced among those with apo ε_4.

ABSTRACT: The response of the plasma cholesterol concentration to changes in dietary lipids varies widely in humans and animals. There are variations in the *in vivo* absorption of cholesterol between different strains of mice. This study was undertaken in three strains of inbred mice to test the hypotheses that: (i) there are strain differences in the *in vitro* uptake of fatty acids and cholesterol and (ii) the adaptability of the intestine to respond to variations in dietary lipids is genetically determined. An *in vitro* intestinal ring technique was used to assess the uptake of medium- and long-chain fatty acids and cholesterol into jejunum and ileum of adult DBA/2, C57BL6, and C57L/J mice. The jejunal uptake of cholesterol was similar in C57L/J, DBA/2, or C57BL6 fed *ad libitum* a low-fat (5.7% fat, no cholesterol) chow diet. This is in contrast to a previous demonstration that *in vivo* cholesterol absorption was lower in C57L/J than in the other murine strains. The jejunal uptake of several long-chain fatty acids was greater in DBA/2 fed for 4 wk the high-fat (15.8% fat and 1.25% cholesterol) as compared with the low-fat diet. Furthermore, on the high-fat diet, the uptake of many long-chain fatty acids was higher in DBA/2 than in C57BL6 or C57L/J. The differences in cholesterol and fatty acid uptake were not explained by variations in food uptake, body weight gain, or the weight of the intestine. In summary: (i) there are strain differences in the *in vitro* intestinal uptake of fatty acids but not of cholesterol; (ii) a high-fat diet enhances the uptake of long-chain fatty acids in only one of the three strains examined in this study; and (iii) the pattern of strain- and diet-associated alterations in the *in vivo* absorption of cholesterol differs from the pattern of changes observed *in vitro*. We speculate that genetic differences in cholesterol and fatty acid uptake are explained by variations in the expression of protein-mediated components of lipid uptake.

Paper no. L8234 in *Lipids 35*, 833–837 (August 2000)

The response of the plasma cholesterol concentration to changes in dietary lipids varies widely in humans and in animals (1–8). Alterations in the efficiency of cholesterol absorption can account for differences in serum cholesterol concentrations between hypo- and hyper-responding rabbits after feeding a cholesterol-rich diet (9). Using human intestinal biopsy samples, Safonova and co-workers (10) demonstrated that cholesterol uptake is clustered into low, medium, and high rates. The suggestion that cholesterol absorption might be regulated by specific gene(s) was strengthened by the recent study by Carter and co-workers using inbred strains of mice (11). They showed that cholesterol absorption measured with an *in vivo* fecal recovery technique varied between mouse strains under low dietary fat conditions. Furthermore, there were different changes between strains in cholesterol absorption observed in response to feeding a high-fat/cholesterol diet.

This study was undertaken to determine (i) if the initial uptake step in cholesterol absorption varied between three inbred mouse strains and in response to a high-fat diet and (ii) if the variability in cholesterol uptake also included the uptake of fatty acids. The results support the hypothesis that the specific gene(s) controlling cholesterol uptake are different from those which influence the uptake of long-chain fatty acids and that the adaptation of lipid uptake in response to alterations in dietary fats is also regulated by genetic factors. Furthermore, the reported genetically influenced differences in the *in vivo* absorption of cholesterol cannot be explained by variations in the uptake step demonstrated *in vitro*.

METHODS

Animals and diets. The C57BL6 and DBA/2 mice were purchased from Harlan Bioproducts (Indianapolis, IN), and C57L/J mice were obtained from The Jackson Laboratories (Bar Harbor, ME). Male chimeric mice derived from cholesterol esterase gene-targeted embryonic stem cells, with a 129/SvEv genetic background, were mated with female Black Swiss mice (12). Heterozygotes from different parents were mated with female Black Swiss mice. Black Swiss and 129/SvEv mice were obtained from Taconic Farms (Germantown, NY). Animals with the normal cholesterol esterase genotype were selected for the current study. The mice were housed in a temperature- and humidity-controlled room with a 12-h light/dark cycle for at least 7 d before experiments. Female mice between the ages of 10 and 12 wk were used for all ex-

Abbreviations: BBM, brush border membrane; FAT, fatty acid transporter; UWL, unstirred water layer.

periments. The mice were fed either the basal nonpurified low-fat chow diet (Teklad LM485; Madison, WI) containing 5.7% fat and no cholesterol or a high-fat/high-cholesterol nonpurified diet (Purina Mouse Chow 5015 supplemented with 7.5% cocoa butter and 1.25% cholesterol to yield final concentrations of 15.8% fat and 1.25% cholesterol). Mice were fed *ad libitum* the high-fat/high-cholesterol diet for at least 4 wk, and up until the morning that the transport studies were performed. All experimental protocols described in the text were reviewed and approved by the Institutional Animal Care and Use Committee of the University of Cincinnati and the Health Sciences Animal Welfare Committee of the University of Alberta, in compliance with Guide for Care and Use of Laboratory Animals and the Canadian Committee on Animal Care, respectively.

Probe and marker compounds. [^{3}H]-inulin was used as a nonabsorbable marker to correct for the adherent mucosal fluid volume. The [^{14}C]-labeled probes included lauric acid (12:0), palmitic acid (16:0), stearic acid (18:0), oleic acid (18:1), linoleic acid (18:2n-6), linolenic acid (18:3n-3), and cholesterol. D- and L-glucose uptake was assessed as a control for the anticipated changes in lipid uptake. Unlabeled and [^{14}C]-labeled probes were supplied by Sigma Co. (St. Louis, MO) and New England Nuclear (Boston, MA), respectively. Probes were shown by the manufacturer to be more than 99% pure by high-performance liquid chromatography.

Tissue preparation and determination of uptake rates. The *in vitro* uptake into everted intestinal rings was examined in mouse jejunum and ileum. Animals were weighed at the time of sacrifice. Animals were anesthetized by the intraperitoneal injection of Euthanyl® (pentobarbital, 35 mg/kg body weight; MTC Pharmaceuticals, Mississauga, Ontario, Canada). A midline incision was made into the peritoneal cavity. The ligament of Treitz, which marks the proximal end of the jejunum, was clamped and cut. The small intestine was pulled out until it reached the ileocecal junction, which marks the distal end of the ileum. The whole length of small intestine was removed rapidly. In these studies, the jejunum was represented by the proximal third and the ileum by the distal third of the removed intestine; the middle third of the intestine was discarded.

The intestine was everted and cut into small rings of approximately 3 mm each, which were immersed immediately in pre-incubation beakers containing oxygenated Krebs-bicarbonate buffer (pH 7.2) at 37°C (13). The rings were allowed to equilibrate for approximately 5 min prior to commencement of the uptake studies. Nutrient uptake was initiated by the timed transfer of everted tissue rings into a shaking water bath (37°C) containing 5-mL plastic vials with oxygenated Krebs buffer plus [^{3}H]-inulin and one of the following [^{14}C]-labeled substrates: 0.1 mM fatty acids (12:0, 16:0, 18:0, 18:1, 18:2, 18:3), 0.05 mM cholesterol. The long-chain fatty acids and cholesterol were solubilized in 20 mM taurocholic acid. The uptake of glucose was also assessed to establish whether strain differences in lipid uptake also influenced the active carrier-mediated uptake of a water-soluble nutrient: the concentrations of D-glucose were 4, 8, 16, 32, and 64 mM, and L-glucose 16 mM. After incubation for 5 min, the uptake of nutrient was terminated by pouring the vial contents onto filters on an Amicon vacuum filtration manifold (Millipore Canada Ltd., Nepean, Ontario, Canada) maintained under suction, followed by washing the jejunal or ileal rings with ice-cold saline. The tissue was dried overnight at 55°C to a constant weight. The dry weight of tissues was determined, and the tissues were saponified with 0.75 N NaOH. Scintillation fluid was added, and radioactivity was determined by means of an external standardization technique to correct for variable quenching of the two isotopes.

Expression of the results. The rates of uptake were expressed as nanomoles of substrate taken up per milligram dry weight of tissue per minute (nmol·mg tissue^{-1}·min^{-1}). The values obtained from the dietary groups are reported as the means ± SEM for results obtained from five to six animals in each group.

Glucose uptake kinetics were determined by fitting the observed data points to the Michaelis-Menten equation and by nonlinear regression analysis using the Sigma Plot (Jandel Scientific, San Rafael, CA) program for best fit curves. As variance increased with the size of the y-axis variable (rate of uptake of glucose), data points were weighted in proportion to the reciprocal of the within-concentration estimates of variance (14).

Analysis of variance was used to test for a difference between the five dietary groups. Individual differences were determined using a Student Neuman-Keuls multiple range test. A value of $P < 0.05$ was accepted as statistically significant.

RESULTS

There were no differences between the three strains of mice in the rates of jejunal or ileal uptake of cholesterol when the animals were fed either chow or the high-fat diet (Table 1). When fed chow, the jejunal uptake of 12:0 was highest and 18:3 was lowest in the C57L/J mice as compared with the other animals, whereas the ileal uptake of 18:0 was highest. When the animals were fed the high-fat diet, the jejunal uptake of 16:0, 18:2, and 18:3 was highest in DBA/2, and the ileal uptakes of 16:0 and 18:1 were also highest in this strain. In C57L/J fed chow or the high-fat diet, the jejunal uptake of 12:0 was greater than in DBA/2 or C57BL6.

The chow and high-fat/cholesterol diets were not isocaloric, but the animals were fed *ad libitum* and there were no differences in food intake (Table 2). The rate of body weight gain was lower in C57L/J fed either chow or the high-fat diet, as compared with DBA/2 or C57BL6. The variations in fatty acid uptake were not due to any differences in the animals' food intake, the weight of the intestine, or the weight of the mucosa (Table 2).

A curvilinear relationship was noted between glucose concentration and uptake (data not shown). In the jejunum the rate of uptake of L-glucose was unchanged by diet or by the strain of mouse. In the ileum, uptake of L-glucose was lower in C57L/J mice fed the basal diet. When the high-fat diet was fed, the uptake of L-glucose was higher in C57L/J than in the other two strains. After correcting for the minor differences in passive uptake, there were no differences in the maximal transport rate (V_{max}) or the apparent Michaelis affinity constant (K_m) for jejunal or ileal glucose uptake between DBA/2, C57BL6, or C57L/J (Table 3).

DISCUSSION

The topic of the intestinal absorption of lipids has been reviewed (15,16). Once cholesterol or long-chain fatty acids have been solubilized in bile salt micelles in the intestinal lumen, they diffuse across the intestinal unstirred water layer (UWL). The lipids then partition from the micelle, either directly into the lipophilic enterocyte brush border membrane (BBM) or into an aqueous phase, and then diffuse across the BBM. There also may be a carrier-mediated component to the uptake of fatty acids and cholesterol (7,8,10,17–20).

There was no difference in the initial step of cholesterol uptake observed between the three murine strains (Table 1). The greater *in vitro* uptake of 12:0 into the jejunum of C57L/J fed chow or the high-fat diet suggests but does not prove that the UWL resistance is lower in these animals than in the DBA/2 or C57BL6 mice (21). The measurement of the uptake of fatty acid 12:0 is not the ideal measure of UWL resistance, and the value of the diffusion coefficient for cholesterol under these conditions is unknown. Thus, the BBM permeability of cholesterol in C57L/J is either similar to or higher than in the two other strains of mice. This is in contrast to the lower *in vivo* absorption of cholesterol in the C57L/J mice when fed either the low-fat chow or the high-fat diet (11). Thus, the strain differences in the intestinal absorption of cholesterol observed *in vivo* (11) cannot be explained simply on the basis of variations in the uptake step when studied *in vitro.* Although these strain differences in the *in vivo* as compared with *in vitro* absorption of cholesterol may result from the presence of bile, an intact blood circulation, diet, or desquamated cells, the possibility exists that there may be genetic variations related to the process of digestion of the luminal lipids prior to absorption by the enterocytes, intracellular metabolism, or transport out of the enterocyte.

Genetic differences in the lipid uptake of long-chain fatty acids have not been reported. In this study the mice fed chow did not display major differences in jejunal or ileal uptake of long-chain fatty acids, but, when fed the high-fat diet, the uptake of most fatty acids was greater in DBA/2 than in C57BL6 or C57L/J mice (Table 1). DBA/2 mice also had a greater uptake of lipids when fed the high- as compared with the low-fat diet. This suggests that uptake of long-chain fatty acids is also genetically influenced and that the pattern is different from changes observed in the *in vivo* absorption of cholesterol (11). Of note, the uptake of only some fatty acids was affected by strain differences. This argues for the change in the uptake process not being the result of a general alteration in the lipophilic properties of the BBM, which would have been expected to have altered the uptake of all lipids. Instead, the finding of the change in the uptake of only some fatty acids argues in favor of there being BBM or cytosolic proteins mediating the uptake of only some lipids, or having a greater affinity for the transport of some lipids. Furthermore, the variability in lipid uptake between the three strains when fed chow was different when they were fed the high-fat diet. This suggests that there may be involvement of a protein-mediated component in lipid absorption, as has been proposed by others (7,19,21–23).

Feeding a sunflower oil-enriched diet upregulated fatty acid transporter (FAT) mRNA 2.6-fold over feeding a medium-chain triglyceride-enriched diet (21). The increases in linoleic acid and linolenic acid uptake in DBA/2 mice after fat and cholesterol feeding reported in the present study may be associated with the upregulation of FAT. The binding of several long-chain fatty acids (stearic acid, oleic acid, arachidonic acid) to FAT was not significantly different from each other (22), but studies were not done on linoleic acid, linolenic acid, docosahexaenoic acid, or short-chain fatty acids. Furthermore, the differences in lipid uptake between strains fed the low-fat vs. the high-fat diet raise the possibility that there may be several genes modifying cholesterol and long-chain fatty acid uptake.

The uptake of glucose is mediated by a sodium-dependent transporter in the BBM, SGLT1 (24). The activity of SGLT1 may be influenced by the lipophilic properties of the BBM (25). For this reason, we speculated that if the strain-associated alterations in cholesterol and long-chain fatty acid absorption were on the basis of changes in the lipophilic properties of the BBM, then glucose uptake also might have been influenced. However, there was no effect of strain differences on the values of the V_{max} or K_m for glucose uptake (Table 3). Therefore, this also suggests that the mechanism(s) responsible for the strain-associated change in the uptake of cholesterol and long-chain fatty acids is not a process caused by generalized alterations in the lipophilic properties of the BBM.

The lower rate of body weight gain in C57L/J as compared with DBA/2 or C57BL6 fed either chow or the high-fat diet occurred despite similar amounts of food being ingested (Table 2).The lower rate of uptake of some long-chain fatty acids in C57L/J fed the high-fat diet may have contributed in part to their lower body weight gain as compared with DBA/2, in which fatty acid uptake and weight gain were both higher. However, this would not explain the greater weight gain in C57BL6 than C57L/J, since there were similar rates of fatty acid uptake (Table 1). Presumably, the lower rate of weight gain in C57L/J was due to lower total lipid absorption, and not just to lower rates of lipid uptake. This speculation of the difference between murine strains and the *in vitro* fatty acid uptake vs. *in vivo* absorption is supported by the variations between the *in vivo* absorption and the *in vitro* uptake of cholesterol, in which absorption was lowest in C57L/J (11) but *in vitro* uptake was similar in the three strains (Table 1).

In this study we did not determine which protein-mediated component might be responsible for the strain-associated variations in fatty acid uptake observed when the mice were fed the low- or the high-fat diets. The failure of some strains to modify their lipid uptake when switched from a high- to a low-fat diet leads us to speculate that dietary lipid modification is likely to be a successful therapeutic strategy to modify the exogenous contribution of lipids to hyperlipidemia only in those strains which are genetically capable of modifying

their lipid absorption in response to dietary lipid changes. We speculate that these genetically determined differences in cholesterol and fatty acid uptake and absorption also may exist in humans and may be responsible for known variations in cholesterol absorption between individuals (i.e., hypo- and hyper-responsiveness), as well as their variable responses to a high-cholesterol/lipid diet (1–6,9,10,18). If a marker could be discovered in humans for high rates of lipid uptake and absorption, this would potentially lead the way to screening young persons before the development of hyperlipidemia. Such a marker also would be useful to determine which persons with hyperlipidemia would be most likely to respond to dietary treatment with a low-fat/cholesterol diet. Finally, finding the gene products responsible for the variations in cholesterol and fatty acid uptake and absorption would open the way to the development of targeted therapeutic agents which could reduce the absorption of lipids for the treatment of hyperlipidemia or obesity.

ABSTRACT: The Zucker diabetic fatty (ZDF) rat is a genetic model of type II diabetes mellitus in which males homozygous for nonfunctional leptin receptors (fa/fa) develop obesity, hyperlipidemia, and hyperglycemia, but rats homozygous for normal receptors (+/+) remain lean and normoglycemic. Insulin resistance develops in young fa/fa rats and is followed by evolution of an insulin secretory defect that triggers hyperglycemia. Because insulin secretion and insulin sensitivity are affected by membrane phospholipid fatty acid composition, we have determined whether metabolic abnormalities in fa/fa rats are associated with changes in tissue phospholipids. Electrospray ionization mass spectrometric analyses of glycerophosphocholine (GPC) and glycerophosphoethanolamine (GPE) molecular species from tissues of prediabetic (6 wk of age) and overtly diabetic (12 wk) fa/fa rats and from +/+ rats of the same ages indicate that arachidonate-containing species from heart, aorta, and liver of prediabetic fa/fa rats made a smaller contribution to GPC total ion current than was the case for +/+ rats. There was a correspondingly larger contribution from species with *sn*-2 oleate or linoleate substituents in fa/fa heart and aorta. The relative contributions of arachidonate-containing GPC species increased in these tissues as fa/fa rats aged and were equal to or greater than those for +/+ rats by 12 wk. For heart and aorta, relative contributions from GPE species with *sn*-2 arachidonate or docosahexaenoate substituents to the total ion current increased and those from species with *sn*-2 oleate or linoleate substituents fell as fa/fa rats aged, but these tissue lipid profiles changed little with age in +/+ rats. GPC and GPE profiles for brain, kidney, sciatic nerve, and red blood cells were similar among fa/fa and +/+ rats at 6 and 12 wk of age, and pancreatic islets from fa/fa and +/+ rats exhibited similar GPC and GPE profiles at 12 wk of age. Under-representation of arachidonate-containing GPC and GPE species in some fa/fa rat tissues at 6 wk could contribute to insulin resistance, but depletion of islet arachidonate-containing GPC and GPE species is unlikely to explain the evolution of the insulin secretory defect that is well-developed by 12 wk of age.

Paper no. L8469 in *Lipids 35*, 839–854 (August 2000).

Abbreviations: CAD, collisionally activated dissociation; ESI, electrospray ionization; GPC, glycerophosphocholine; GPE, glycerophosphoethanolamine; HPLC, high-performance liquid chromatography; IDDM, insulin-dependent diabetes mellitus; NIDDM, non-insulin-dependent diabetes mellitus; NP, normal phase; MS, mass spectrometry; PBS, phosphate-buffered saline; ZDF, Zucker diabetic fatty.

The Zucker diabetic fatty (ZDF) rat (1–22) is a genetic model of non-insulin-dependent diabetes mellitus (NIDDM), in which metabolic abnormalities arise from a mutation in the intracellular domain of the receptor for leptin (6,7), an adipocyte hormone that signals fat store content (23,24). Males homozygous for this mutation (fa/fa) become obese and diabetic, but males of the same genetic background with wild-type receptors (+/+) remain lean and normoglycemic. As in human NIDDM (25,26), insulin resistance develops in fa/fa rats, but normoglycemia is initially maintained by compensatory insulin hypersecretion (2–5,11). Progressive elevations in blood free fatty acid and triglyceride concentrations begin at 7–8 wk in male fa/fa rats, and, at 9–10 wk, an insulin secretory defect develops that triggers hyperglycemia (3,11).

Insulin secretory defects in fa/fa rats include increased basal secretion, blunted responses to glucose, abnormalities in secretory pulsations, and defective modulation of secretion by fatty acids (2–5,8). There is also a loss of β-cell mass *via* apoptosis as fa/fa rats age (15,18,19). Abnormal accumulation of lipids in fa/fa rat islets is implicated in these abnormalities. Modest accumulation of triglycerides in islets of young fa/fa rats contributes to insulin hypersecretion, and marked islet triglyceride accumulation as the rats age impairs secretion and increases β-cell sensitivity to injurious stimuli (3,5,8,9,11–14,16–20). Accumulation of the sphingolipid ceramide in islets of older fa/fa rats contributes to β-cell apoptosis (18,19).

Accumulation of complex lipids in fa/fa rat islets is driven by hyperlipidemia and increased expression of lipid biosynthetic enzymes, including glycerol-3-phosphate acyltransferase (9,17), which catalyzes an early step in *de novo* synthesis of triglycerides and other glycerolipids (27). ZDF fa/fa rat islets overexpress serine palmitoyltransferase (18,19), which catalyzes

the first step in *de novo* synthesis of ceramide. Islet glycerophospholipid composition may affect secretion (28–31), but these molecules have not been extensively studied in ZDF rats. Normal rat and human β-cells are enriched in arachidonate-containing glycerophosphocholine (GPC) and glycerophosphoethanolamine (GPE) species (32–34). Such molecules may serve as substrates for phospholipases in β-cell signaling (35–38), in which arachidonate hydrolysis from phospholipids may amplify secretagogue-induced rises in cytosolic [Ca^{2+}] and insulin release (39–43).

Arachidonate-containing phospholipids also may play structural roles in β-cells. The β-cell secretory granule and plasma membranes are enriched in GPE species with a *sn*-1 vinyl ether linkage and esterified arachidonate in the *sn*-2 position (34). Such polyunsaturated plasmenylethanolamines facilitate fusion of membrane bilayers (44,45) and of β-cell secretory granule and plasma membranes (34,46). Interference with biosynthesis of arachidonate-containing plasmenylethanolamines can induce apoptosis (47), and conditions that induce loss of arachidonate from islet GPE lipids (48) induce β-cell apoptosis (49). A decline in arachidonate-containing phospholipids might thus impair β-cell secretion or survival.

Insulinoma cells undergo loss of arachidonate-containing phospholipid species when cultured in arachidonate-poor medium, and this is associated with reduced insulin secretion (50,51). These effects are partially reversed by culture with arachidonic acid (51). This raises the possibility that islet β-cells might be affected by blood lipid content. The hyperlipidemia that develops in fa/fa rats might cause replacement of arachidonate in β-cell phospholipids with more saturated substituents, and this could impair β-cell survival or secretion. The phospholipid composition of tissues subject to diabetic complications might be similarly affected. A decline in tissue phospholipid arachidonate content occurs in a rat model of insulin-dependent diabetes mellitus (IDDM) induced by streptozotocin (52).

We have used electrospray ionization mass spectrometry (ESI/MS), a powerful tool for determining phospholipid structures (34,53–55), to examine GPC and GPE lipid species in tissues from prediabetic and diabetic ZDF fa/fa rats and from age-matched, nondiabetic +/+ rats.

EXPERIMENTAL PROCEDURES

Materials. Phospholipid standards were obtained from Avanti (Birmingham, AL); organic solvents from Burdick and Jackson (Muskegee, MI); LiOH and buffer salts from Sigma (St. Louis, MO); high-performance liquid chromatography (HPLC) columns from Alltech (Deerfield, IL); and collagenase from Boehringer Mannheim (Indianapolis, IN).

Experimental animals. Animal studies were approved by the Washington University Animal Studies committee and conformed to accepted standards. ZDF fa/fa and +/+ rats were obtained from Genetic Models (Indianapolis, IN). Rats were fed Purina Formulab 5008 high-fat chow *ad libitum*, which contains 23% crude protein, 6.5% crude fat, 4% crude fiber, 8% ash, and 2.5% added minerals. ZDF fa/fa rats consume about 15–30 g daily and +/+ rats about 12–15 g daily. The diet lipid composition is 280 ppm cholesterol, 1.37% linoleic acid, 0.09% linolenic acid, 0.01% arachidonic acid, 0.29% n-3 fatty acids, 2.51% saturated fatty acids, and 2.32% monounsaturated fatty acids.

Plasma measurements. Blood was collected at 9:00–10:00 A.M. by vascular puncture with a syringe containing 50 μL of 15% Na_2EDTA. Plasma and red blood cells were separated by centrifugation. Plasma glucose was measured by the glucose oxidase method, and plasma triacylglycerol was measured with a Sigma kit (GPO-Trinder procedure no. 337), as described (3).

Collection and processing of pancreatic islets and other tissues. Rats were anesthetized with intraperitoneal sodium pentobarbital and islets isolated after pancreatic excision, collagenase digestion, and centrifugation through a discontinuous Ficoll gradient (32–34,56). Islet phospholipids were extracted by the method of Bligh and Dyer (57). Heart, brain, liver, kidney, and sciatic nerve were excised and placed on ice in conical polypropylene tubes containing phosphate-buffered saline (PBS) without added Ca^{2+} or Mg^{2+}. Tissues were rinsed twice (ice-cold PBS), transferred to silanized glass beakers, and minced. Minced tissues were transferred to conical polypropylene tubes and rinsed (five times, ice-cold PBS) to remove blood. Minced tissues were drained, blotted, weighed, and transferred to conical glass tubes containing chloroform/methanol (1:1, vol/vol), homogenized, vortex-mixed, and incubated on ice (2 h) before completing lipid extraction by adding PBS (0.375 vol/vol) of chloroform/methanol (1:1), centrifugation (900 × *g*, 5 min) to separate phases, and collection of the chloroform-rich, lipid-containing lower phase.

Normal-phase HPLC isolation of GPE and GPC lipids from phospholipid extracts. GPE and GPC lipids were isolated from extracts by normal-phase HPLC (32–34) on a silicic acid HPLC column (LiChrospher Si-100, 10 μm particle size, 250 × 4.6 mm; Alltech) in a solvent system consisting of a gradient between solvent mixtures A and B, the compositions of which were hexane/isopropanol/water (100:100:3, by vol) and (100:100:7, by vol), respectively. Initial solvent composition (100% A/0% B) was maintained for 6 min (flow 2 mL/min) and followed by a linear gradient over 24 min to the final composition (50% A/50% B) to isolate GPE (8 min retention time) and GPC (55 min retention time).

Determination of acid-lability of phospholipids. Acid-lability was determined (32–34,58) after dividing samples into two aliquots and concentrating to dryness. One was treated with acid (1 N HCl in methanol/chloroform, 1:1, vol/vol, 1 mL, 45 min, room temperature) and the other sham-treated (chloroform/methanol, 1:1, vol/vol, 1 mL). Samples were neutralized (1 M Na_2CO_3, 0.5 mL), extracted (chloroform, 1 mL), concentrated, reconstituted (methanol/chloroform, 1:9, vol/vol, 0.1 mL), and analyzed by ESI/MS. Acid-stable diacyl- and alkylacyl-lipids appear in acid- and sham-treated sample spectra, but acid-labile plasmalogens do not appear in acid-treated sample spectra.

MS. ESI/MS was performed on a Finnigan (San Jose, CA) TSQ-7000 triple stage quadrupole mass spectrometer with

ESI source controlled by Finnigan ICIS software. Phospholipids were dissolved (1–5 pmol/μL) in methanol/chloroform (9:1, vol/vol) containing LiOH (2–5 pmol/μL). GPC lipids were analyzed in positive- and GPE lipids in negative-ion mode (34,55). Samples were infused (1 μL/min) into the ESI source with a Harvard syringe pump. Electrospray needle and skimmer were operated at ground potential. To acquire positive or negative ions, respectively, electrospray chamber and the glass capillary entrance were operated at positive or negative potentials; positive or negative potentials were applied to the glass capillary exit; and positive or negative potentials were placed on the tube lens. The heated capillary temperature was 250°C. For collisionally activated dissociation (CAD), precursor ions were selected in the first quadrupole and accelerated (32–36 eV) into a collision chamber containing argon (2.2–2.5 mtorr). Product ions were analyzed by *m/z* value in the final quadrupole. Spectra were acquired with a signal-averaging protocol in profile mode (one scan/3 s).

Statistical analyses. Student's *t*-test was used to compare two groups, and multiple groups were compared by one-way analysis of variance with *post-hoc* Newman-Keul's analyses.

RESULTS

Age-related changes in blood glucose and triglyceride concentrations in ZDF rats. Lean ZDF rats homozygous for functional leptin receptors (+/+) maintained normal blood glucose (Fig. 1A) and triacylglycerol (Fig. 1B) concentrations at 6 and 12 wk of age. In contrast, obese ZDF rats homozygous for nonfunctional leptin receptors (fa/fa) exhibited significant increases in both blood glucose and triacylglycerol concentrations between 6 and 12 wk, and the 12-wk rats were hyperglycemic and hypertriglyceridemic (Fig. 1), as reported by others (3,11). We determined whether age-related changes in blood lipid concentrations were associated with changes in tissue phospholipid species by ESI/MS analyses of GPC and GPE lipids.

GPC lipids from ZDF rat heart. Figure 2 illustrates ESI/MS spectra of Li^+ adducts of GPC lipids from hearts of +/+ rats at 6 (Fig. 2A) and 12 wk (Fig. 2C) of age and from fa/fa rats of the same ages (Fig. 2B and D). CAD and tandem MS (Fig. 3) were used to identify GPC species in these mixtures. In tandem spectra of Li^+ adducts of GPC lipids, the headgroup is identified by ions reflecting loss of phosphocholine with Li (loss of 189) or with H (loss of 183^+) (55), and ions reflecting these losses are present in each spectrum in Figure 3. Identities of fatty acid substituents are reflected by ions, reflecting loss of trimethylamine plus either the *sn*-1 or *sn*-2 substituent as a free fatty acid. The relative abundance of the former ion exceeds that of the latter (55).

In GPC ESI/MS spectra for extracts from hearts of +/+ rats and from 12-wk fa/fa rats, the most abundant $[M + Li]^+$ ion oc-

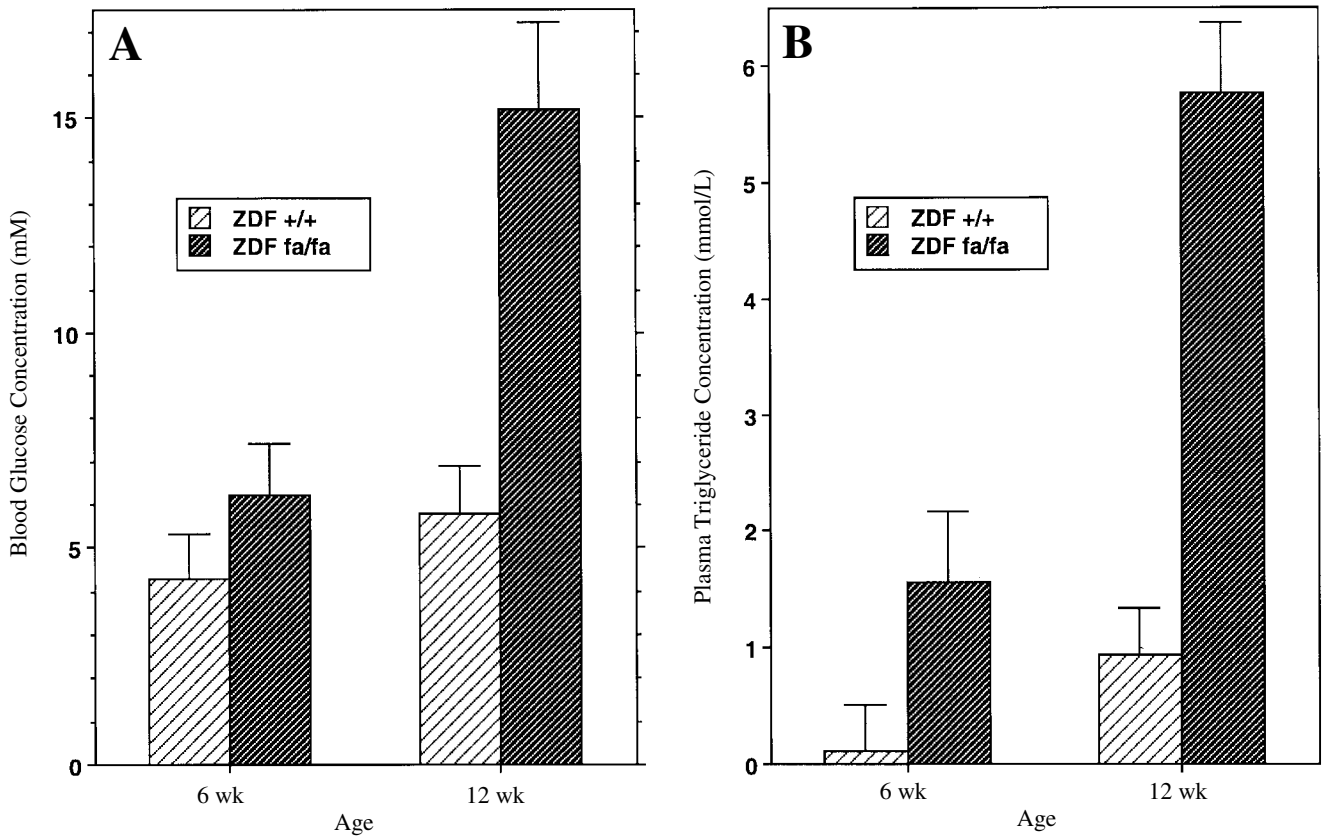

FIG. 1. Blood glucose and triglyceride concentrations in Zucker diabetic fatty (ZDF) rats of various ages. Blood glucose (A) or triglyceride (B) concentrations were determined in ZDF +/+ (light bars) or ZDF fa/fa (dark bars) rats at 6 (left set of bars in each panel) or 12 (right set of bars in each panel) wk of age. Means values ± SEM are displayed ($n = 6$).

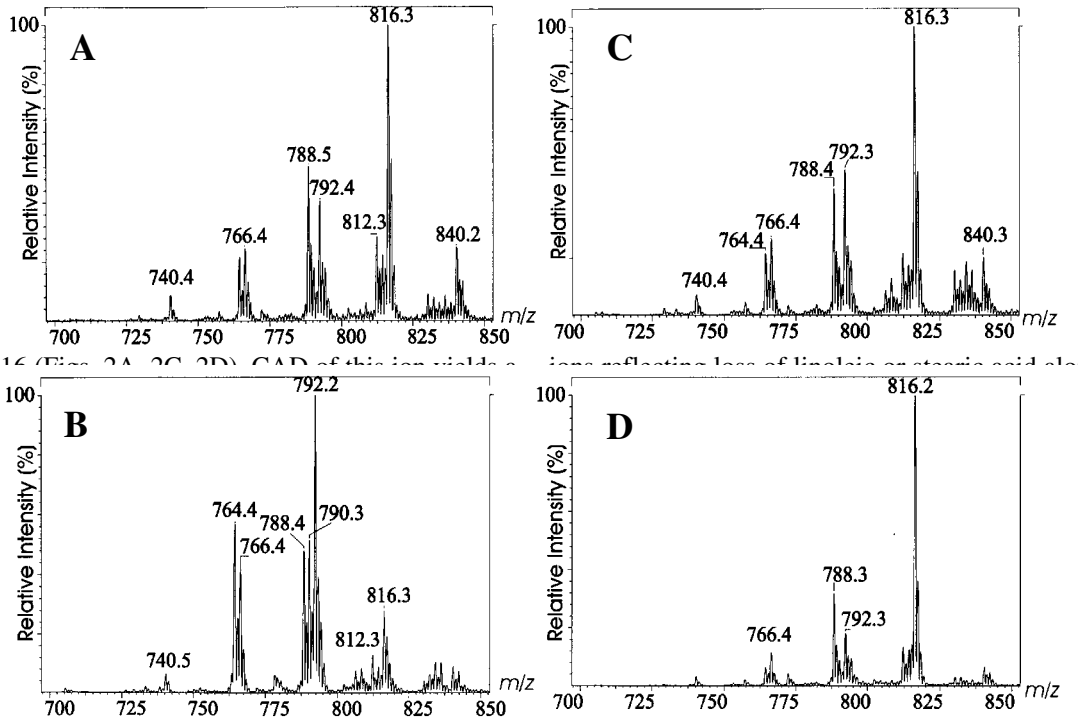

FIG. 2. Electrospray ionization (ESI) positive-ion mass spectrometric (MS) analysis of Li^+ adducts of glycerophosphocholine (GPC) lipids from hearts of ZDF rats. Phospholipids extracted from hearts of 6-wk-old (A and B) or 12-wk-old (C and D) ZDF +/+ (A and C) or ZDF fa/fa (panels B and D) rats were analyzed by normal-phase high-performance liquid chromatography (NP-HPLC) to isolate GPC lipids, which were then analyzed by ESI/MS as Li^+

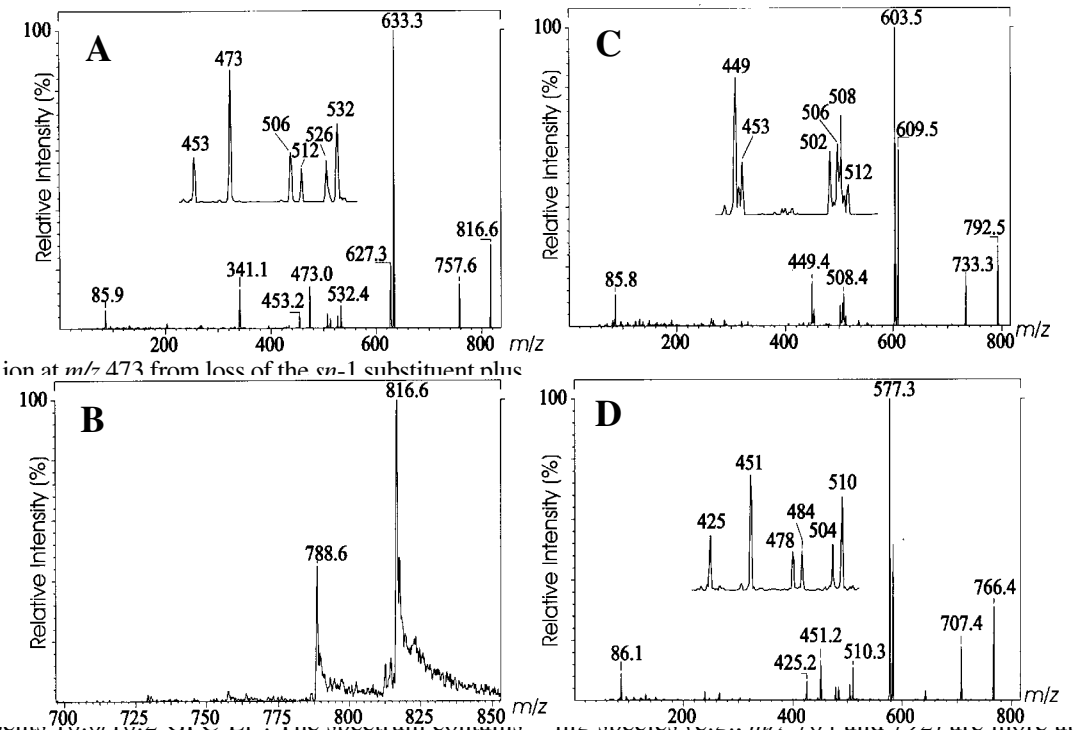

FIG. 3. Tandem mass spectra obtained from collisionally activated dissociation (CAD) of $[M + Li]^+$ ions of GPC lipids from hearts of ZDF rats. ESI/MS was performed as in Figure 2, and $[M + Li]^+$ ions at *m/z* 816 (A: 18:0/20:4-GPC), 792 (C: 18:0/18:2-GPC), or 766 (D: 16:0/18:1-GPC) were isolated in the first quadrupole and subjected to CAD. Product ions were then analyzed in the final quadrupole. B: (20:4) represents a tandem MS scanning experiment performed with the GPC-Li^+ mixture from hearts of 12-wk ZDF fa/fa rats in which parent ions were identified that yielded a product ion at *m/z* 473 upon CAD. See Figures 1 and 2 for other abbreviations.

those representing arachidonate-containing species (e.g., *m/z* 816) less abundant than for the 12-wk rats. The relative abundances of ions reflecting both oleate- (e.g., *m/z* 766) and linoleate-containing (e.g., *m/z* 764 and 792) species are lower in heart GPC mixtures from 12-wk fa/fa rats than in mixtures from +/+ rats, and the relative contribution of arachidonate-containing species to the GPC $[M + Li]^+$ ion current is correspondingly higher in 12-wk fa/fa rats.

GPE lipids from ZDF rat heart. Figure 4 illustrates ESI/MS analyses of $[M - H]^-$ ions of GPE lipids from hearts of +/+ rats at 6 (Fig. 4A) and 12 wk (Fig. 4C) of age and from fa/fa rats of the same ages (Fig. 4D). Ions representing plasmenylethanolamine species are designated with asterisks in Figure 4, based on acid-lability studies (32–34). Plasmalogens are acid-labile, and ions representing them are not observed upon ESI/MS analyses of acid-treated samples. Diacyl-GPE species are acid-stable. CAD and tandem MS (Fig. 5) were used to identify GPE species in the mixtures illustrated in Figure 4.

In GPE ESI/MS spectra for heart extracts from +/+ and 12-wk fa/fa rats, the most abundant $[M - H]^-$ ion occurs at *m/z* 790, and the species represented by this ion is acid-stable, indicating that it is not a plasmalogen. The tandem spectrum of this ion (Fig. 5A) contains ions at *m/z* 140 and 196, representing a dehydration product of the GPE moiety and phosphoethanolamine anion (34,54,58), respectively, and these ions identify the headgroup. The spectrum also contains stearate (*m/z* 283) and docosahexaenoate (*m/z* 327) anions and an ion (*m/z* 480) reflecting loss of docosahexaenoate as a ketene, thus identifying the parent as 18:0/22:6-GPE.

In GPE ESI/MS spectra for heart extracts from 6-wk fa/fa rats, the most abundant $[M - H]^-$ ion occurs at *m/z* 766, and the species represented by this ion is acid-stable, indicating that it is not a plasmalogen. The tandem spectrum of this ion (Fig. 5B) contains arachidonate (*m/z* 303) and stearate (*m/z* 283) anions and ions reflecting loss of arachidonate as a ketene (*m/z* 480) or as a free fatty acid (*m/z* 462). These features identify the parent as 18:0/20:4-GPE.

An $[M - H]^-$ ion at *m/z* 722 is observed in ESI/MS spectra of GPE mixtures from hearts of all four groups of animals (Fig. 4), and an $[M - H]^-$ ion at *m/z* 742 is prominent in the mixture from 6-wk fa/fa rats (Fig. 4B). The latter represents an acid-stable and the former an acid-labile species. CAD of the $[M - H]^-$ ion at *m/z* 742 yields a tandem spectrum (Fig. 5C) that identifies the parent as 18:0/18:2-GPE. The spectrum contains linoleate (*m/z* 279) and stearate (*m/z* 283) anions and ions reflecting loss of linoleate as a ketene (*m/z* 480) or as a free fatty acid (*m/z* 462).

TABLE 1
Glycerophosphocholine (GPC) Lipid Species Identified in ZDF Rat Heart by Positive Ion ESI/MS[a]

	ZDF rat heart GPC lipid species ($[M + Li]^+$)				Relative abundance in percentage			
m/z	Combined chain length	*sn*-1 linkage	Double bonds	Major species	6-wk +/+	12-wk +/+	6-wk fa/fa	12-wk fa/fa

Percentage of ion current represented by species with *sn*-2:								
				18:1	17.1 ± 4.5	12.9 ± 1.3	30.5 ± 6.2**	7.8 ± 0.5
				18:2	29.6 ± 3.5	28.9 ± 3.9	40.0 ± 6.1*	12.1 ± 3.9**
				20:4	39.2 ± 6.1	43.9 ± 1.9	10.5 ± 4.6**	61.9 ± 2.2*
				22:6	10.7 ± 3.1	11.2 ± 1.1	3.5 ± 1.1*	12.6 ± 3.3

[a]Zucker diabetic fatty (ZDF) rat heart lipid extracts were analyzed by normal-phase high-performance liquid chromatography (NP-HPLC) to isolate GPC lipids, which were analyzed by electrospray ionization/mass spectrometry (ESI/MS) as Li^+ adducts as in Figure 2. Relative abundances of $[M + Li]^+$ ions at tabulated *m/z* values were determined from total positive ion current profiles of 32 spectra from eight animals and are expressed as means values (±SEM). $[M + Li]^+$ ions were subjected to collisionally activated dissociations (CAD) and tandem MS to identify molecular species. The combined chain length and number of double bonds in fatty side chains are tabulated, as are chain length and double-bond number for each substituent of the major species at each *m/z* value. At some *m/z* values, more than one isomer was observed. The designation "e" denotes an *sn*-1 alkyl ether linkage and "a" an *sn*-1 acyl linkage. For each condition, contributions of species containing an *sn*-2 oleate (18:1), linoleate (18:2), arachidonate (20:4), or docosahexaenoate (22:6) fatty acid residue to the total tabulated ion current are indicated. For 18:1-containing species, only the value for 6-wk fa/fa rats differed significantly from the other three groups. For 18:2- and for 20:4-containing species, the values for 6-wk fa/fa rats differed significantly from those for the other three groups, and this was also true for the value for the 12-wk fa/fa rats. For 22:6-containing species, the value for the 6-wk fa/fa animals differed significantly from those for the other three groups. For the fa/fa rats, values denoted with an asterisk (*) differed from those of the +/+ rats with a *P* value of less than 0.05, and values denoted with a double asterisk (**) differed from those of the +/+ rats with a *P* value of less than 0.01.

CAD of the $[M - H]^-$ ion at *m/z* 722 yields a tandem spectrum (Fig. 5D) that, in conjunction with acid-lability studies, identifies the parent as 16:0p/20:4-GPE, where "p" denotes an *sn*-1 plasmenyl linkage. This spectrum contains arachidonate anion (*m/z* 303), an ion (*m/z* 259) reflecting loss of CO_2 from arachidonate anion, and ions reflecting loss of arachidonate as a ketene (*m/z* 435) or as a free fatty acid (*m/z* 418). Tandem spectra of other $[M - H]^-$ ions in the heart GPE mixtures illustrated in Figure 4 identified the components summarized in Table 2.

Figure 4 and Table 2 indicate that relative abundances of major GPE $[M - H]^-$ ions are similar in +/+ rat heart lipid extracts at 6 and 12 wk. In contrast, heart GPE $[M - H]^-$ profiles change with age in fa/fa rats. For 6-wk fa/fa rats, ions representing linoleate-containing species (e.g., *m/z* 714 and 742) are more abundant and those representing docosahexaenoate-containing species (e.g., *m/z* 790) less abundant than for 12-wk rats. As for GPC, there is thus a shift of heart GPE with age toward species with longer, more unsaturated substituents in fa/fa but not in +/+ rats.

GPC and GPE lipids from ZDF rat aorta and liver. ESI/MS analyses of GPC and GPE species from +/+ rat aorta exhibited little change with age (not shown). Age-related changes in distribution of both GPC and GPE species were observed in fa/fa rats (Fig. 6, Table 3). For GPC, the relative contribution of arachidonate-containing species (e.g., *m/z* 816) to total $[M + Li]^+$ ion current increased and that of species containing monounsaturated *sn*-2 substituents (e.g., *m/z* 738) declined with age in fa/fa rat aorta mixtures (Figs. 6A, 6B, and upper substituents (e.g., *m/z* 738 and 766) to $[M + Li]^+$ ion current decreased, and the contribution of arachidonate-containing species increased with age (Figs. 7A, 7B, upper part of Table 4). Age-related changes in distribution of GPE species were not observed in fa/fa rat liver, and GPE $[M - H]^-$ profiles were similar at 6 and 12 wk (Figs. 7C, 7D, lower part of Table 4).

GPC and GPE lipids from ZDF rat pancreatic islets, red blood cells, kidney, sciatic nerve, and brain. ESI/MS profiles of GPC $[M + Li]^+$ and GPE $[M - H]^-$ ions did not change appreciably with age in pancreatic islets isolated from +/+ rats, and, at 12 wk, islets from fa/fa rats exhibited profiles of GPC and GPE ions similar to those for +/+ islets (Fig. 8, Table 5). In red blood cells, kidney, sciatic nerve, and brain there was also little change with age in GPC or GPE lipid profiles and little difference between +/+ and fa/fa rats (not shown).

DISCUSSION

GPC and GPE lipid profiles in cardiovascular tissues of male fa/fa rats change as the rats age from 6 to 12 wk, a period during which hyperlipidemia and hyperglycemia develop. Cardiovascular GPC and GPE lipid profiles are relatively constant with age in +/+ rats. In GPC mixtures from heart and aorta of 6-wk fa/fa rats, arachidonate-containing species contribute a smaller fraction of $[M + Li]^+$ total ESI/MS ion current than is the case for 6-wk +/+ rats. Oleate- and linoleate-containing species contribute a correspondingly larger fraction of GPC $[M + Li]^+$ ion current for heart and aorta for 6-wk

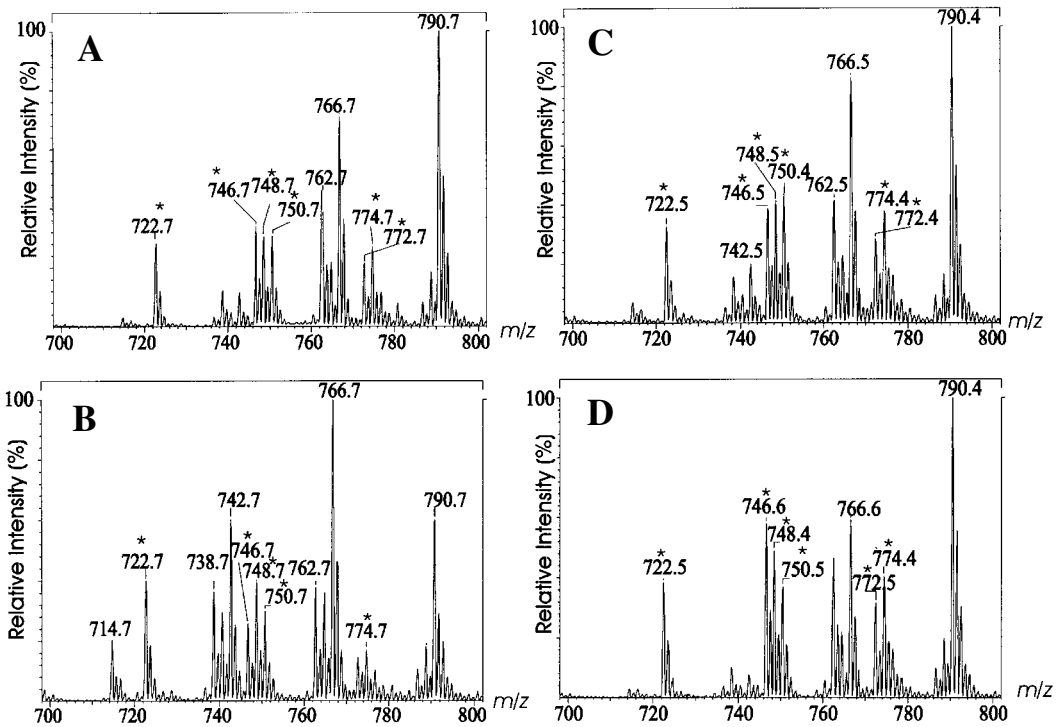

FIG. 4. ESI negative-ion MS analyses of GPE lipids from hearts of ZDF rats. Phospholipids extracted from hearts of 6-wk-old (A and B) or 12-wk-old (C and D) ZDF +/+ (A and C) or ZDF fa/fa (B and D) rats were analyzed by NP-HPLC to isolate GPE lipids, which were then analyzed by ESI/MS as $[M - H]^-$ ions. Peaks designated with asterisks were not observed when the GPE mixture was treated with acid before ESI/MS analysis. See Figures 1 and 2 for other abbreviations.

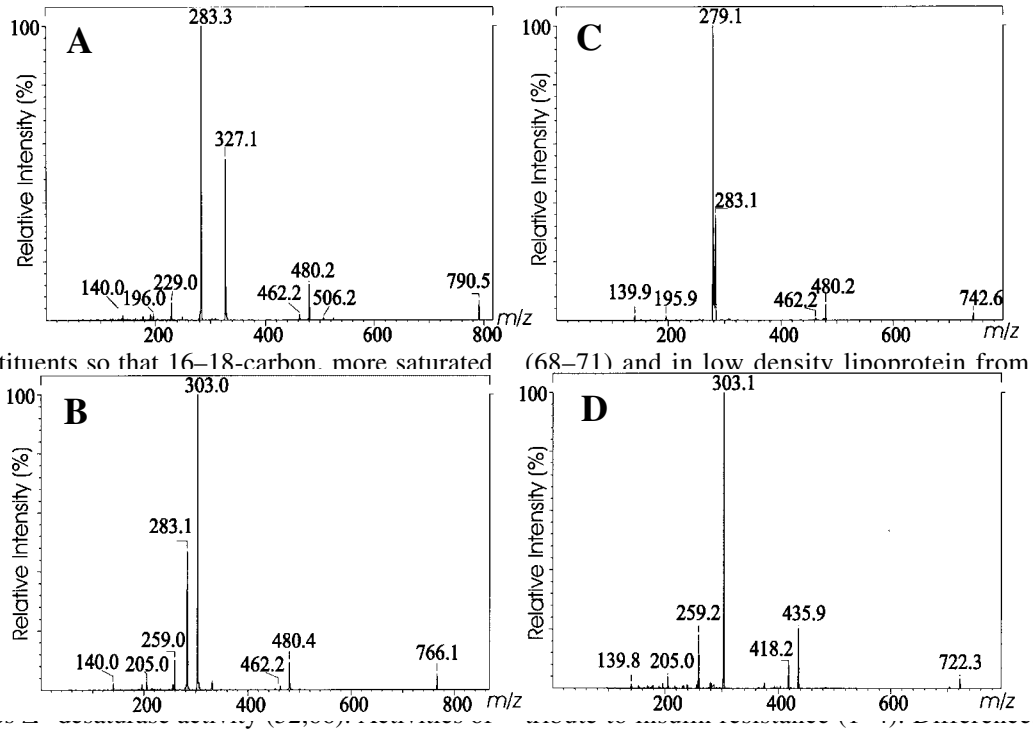

GPE *sn*-2 substituents so that 16–18-carbon, more saturated (68–71) and in low density lipoprotein from NIDDM and

FIG. 5. Tandem spectra obtained from CAD of $[M - H]^-$ ions of GPE lipids from hearts of ZDF rats. ESI/MS was performed as in Figure 4, and $[M - H]^-$ ions at *m/z* 790 (A: 18:0/22:6-GPE), 766 (B: 18:0/20:4-GPE), 742 (C: 18:0/18:2-GPE), or 722 (D: 16:0p/20:4-GPE) were isolated in the first quadrupole and subjected to CAD. Product ions were then analyzed in the final quadrupole. See Figures 1–3 for abreviations.

Δ^9- and Δ^6-desaturases are also reduced in experimental diabetes, and insulin corrects these defects (66). In streptozotocin-diabetes, the arachidonate content of heart GPC declines progressively (63), while in ZDF fa/fa rat hearts, the relative abundance of arachidonate-containing GPC species is diminished only at 6 wk. By 12 wk, the contribution of arachidonate-containing species to GPC $[M + Li]^+$ ion current for ZDF fa/fa rats rises to values equal to or exceeding those for +/+ rats.

Differences between the diabetic state induced by β-cell toxins and that in ZDF fa/fa rats include the fact that toxins induce IDDM from insulin deficiency. ZDF fa/fa rats develop NIDDM characterized by insulin resistance, hyperinsulinemia, and hyperlipidemia. ZDF fa/fa rats also lack functional leptin receptors, which influence lipogenic enzyme expression (3,9,12–14,16,17–20). In ZDF fa/fa rats, hepatic Δ^6- and Δ^5-desaturase activities rise between 6 and 12 wk, and hepatic Δ^5-desaturase capacity doubles, achieving levels exceeding those of lean littermates (67). While the arachidonate content of liver microsomal lipids for ZDF fa/fa rats is lower than that for lean littermates at 6 wk, it rises to levels exceeding that of lean littermates by 12 wk (67). These changes are similar in character to those in contribution of arachidonate-containing GPC species to $[M + Li]^+$ ion current that we observe in fa/fa rat heart, aorta, and liver.

In contrast to the reduced tissue phospholipid arachidonate content in rodent IDDM (52,59–64), increased arachidonate is observed in platelet phospholipids in human NIDDM GPE lipid profiles between ZDF fa/fa and +/+ rats are not observed in all tissues, and heterogeneity in fatty acid compositional abnormalities occurs in other diabetes models. Brain (63) and kidney (59) phospholipids do not undergo fatty acid compositional changes in rodent IDDM, but such changes do occur in heart (63) and aorta (62). We observe no differences in GPC or GPE profiles in pancreatic islets from 12-wk ZDF fa/fa rats compared to those from +/+ rats, suggesting that depletion of arachidonate-containing GPE and GPC species in islet cell membranes is not likely to explain the fa/fa rat insulin secretory defect.

[a]ZDF rat heart extracts were analyzed by NP-HPLC to isolate GPE lipids, which were analyzed as [M – H]⁻ ions by ESI/MS as in Figure 4. Relative abundances of [M – H]⁻ ions were determined from total negative ion current profiles of 32 spectra from eight animals and are expressed as mean values ± SEM. [M – H]⁻ ions were subjected to CAD and tandem MS to identify molecular species. The combined chain length and number of double bonds in fatty side chains are tabulated, as are chain length and double-bond number for each substituent of the major species at each *m/z* value. At some *m/z* values, more than one isomer was observed. The designation "p" denotes an *sn*-1 vinyl ether (plasmalogen) linkage. All other GPE lipid species had two acyl substituents. For each condition, contributions of species containing an *sn*-2 oleate (18:1), linoleate (18:2), arachidonate (20:4), or docosahexaenoate (22:6) fatty acid residue to the total tabulated ion current are indicated. For 18:1- and for 20:4-containing species, there were no significant differences among the four groups. For 18:2- and for 22:6-containing species, the values for 6-wk fa/fa rats differed significantly from those for the other three groups. See Table 1 for abbreviations.

[a]ZDF fa/fa rat liver lipid extracts were analyzed and the results tabulated as in Table 3. For each condition, contributions of GPC lipid species containing an *sn*-2 saturated or mononusaturated species (16:0, 16:1, or 18:1) or containing *sn*-2 linoleate (18:2), arachidonate (20:4), or docosahexaenoate (22:6) fatty acid residue to the total tabulated ion current are indicated. The values for 6- and 12-wk rats differed significantly for GPC species containing an *sn*-2 saturated or monounsaturated substituent and for species containing *sn*-2 arachidonate but not for species containing *sn*-2 linoleate or docosahexaenoate. For each condition, contributions of GPE lipid species containing an *sn*-2 oleate (18:1), linoleate (18:2), arachidonate (20:4), or docosahexaenoate (22:6) fatty acid residue to the total tabulated ion current are indicated. Values for 6- and 12-wk rats did not differ significantly for GPE species containing any of these substituents. See Tables 1 and 2 for abbreviations.

Response of Urinary Lipophilic Aldehydes and Related Carbonyl Compounds to Factors That Stimulate Lipid Peroxidation *in vivo*

A. Saari Csallany*, Song-Suk Kim, and Daniel D. Gallaher

Department of Food Science and Nutrition, University of Minnesota, St. Paul, Minnesota 55108

ABSTRACT: Peroxidation of lipids results in the formation of a number of aldehydic and other carbonyl-containing secondary degradation products. The effect of peroxidative stimuli mediated by vitamin E deficiency, a diet high in polyunsaturated fatty acids (containing cod liver oil), and carbon tetrachloride administration on urinary excretion of a number of lipophilic aldehydes and related carbonyl compounds was examined in rats. These secondary lipid peroxidation products were measured as 2,4-dinitrophenylhydrazine derivatives. All three treatments increased urinary excretion of secondary lipid peroxidation products, although the pattern of excretion of these products varied somewhat among the treatments. Significant increases were found in butanal, hexanal, octanal, butan-2-one, pentan-2-one, hex-2-enal, hepta-2,4-dienal, 4-hydroxyhex-2-enal, 4-hydroxyoct-2-enal, 4-hydroxynon-2-enal, and a number of unidentified carbonyl compounds. These results suggest that urinary excretion of these lipophilic secondary lipid peroxidation products is a useful and noninvasive marker of whole-body lipid peroxidation.

Paper no. L8350 in *Lipids 35*, 855–862 (August 2000).

All organisms have evolved antioxidant defense systems to tolerate mild oxidative stress, which can result from either depletion of antioxidants or from excess production of free radicals and reactive oxygen species such as superoxide, singlet oxygen, hydrogen peroxide, and hydroxy free radicals. However, severe oxidative stress can produce cell damage and tissue injury by reaction of free radicals and active oxygen species with essential cell constituents (1,2). It is well-known that frequent cellular targets of free radicals are membrane lipids, resulting in lipid peroxidation. This potentially deleterious reaction can be controlled in part by antioxidants that scavenge free radicals. Among the antioxidant defense systems, vitamin E (*RRR*-α-tocopherol) is the most effective endogenous lipid-soluble antioxidant for protecting cell membranes from peroxidative damage (3,4). The antioxidant activity of this vitamin is related to its scavenging action of peroxyl radicals by hydrogen donation. A number of *in vivo* and *in vitro* studies have shown that vitamin E deficiency results in lipid peroxidation and the formation of fatty acid peroxides and a number of secondary aldehydic degradation products (5–8).

It is also well-known that the n-3 and n-6 polyunsaturated fatty acids (PUFA) containing lipids are highly oxidizable. Furthermore, increasing the content of these fatty acids in tissues and cells by dietary manipulation can readily modify the extent of cellular oxidative damage, thereby increasing the amount of endogenous peroxidation of lipids (9,10). Dietary lipids have been shown to induce extensive modification in the fatty acid composition of cell membranes and various cellular functions (11,12). Recently diets rich in fish oils which contain n-3 PUFA (20:5, eicosapentaenoic acid and 22:6, docosahexaenoic acid) were recommended for the treatment and prevention of atherosclerosis and heart disease (13,14). However, increasing incorporation of n-3 PUFA into membrane fatty acids potentiates the susceptibility of cellular membranes to lipid peroxidation (15–17). Besides vitamin E deficiency and high-PUFA diets, certain chemical agents such as the hepatotoxic carbon tetrachloride (CCl_4) are known to induce lipid peroxidation *in vivo* (18).

The decomposition of lipid hydroperoxides in biological systems leads to formation of a variety of saturated and unsaturated aldehydes and other carbonyl compounds (19,20). The main mechanism for their formation is the so-called beta-cleavage reaction of lipid alkoxyl radicals (21). Evidence indicates that certain of these aldehydes, including malondialdehyde (MDA), hydroxyaldehydes, and other short-chain carbonyl compounds, contribute to peroxidative cell damage by inhibiting DNA, RNA, and protein synthesis, inhibiting respiration and depleting glutathione, among other effects (22). These aldehydes are sufficiently long-lived to damage target molecules distant from the site of their formation (23,24) and are capable of impairing protein function, inhibiting protein synthesis, causing cell lysis and affecting cellular reproductive integrity (25–27).

Abbreviations: CCl_4, carbon tetrachloride; CH_2Cl_2, dichloromethane; CLO, cod liver oil; CO, corn oil; DNPH, 2,4-dinitrophenylhydrazine; –E, vitamin E deficiency; HE, high vitamin E; HHE, 4-hydroxyhex-2-enal; HNE, hydroxynon-2-enal; HOE, 4-hydroxyoct-2-enal; HPLC, high-performance liquid chromatography; MDA, malondialdehyde; NE, normal vitamin E; NONPOL, nonpolar carbonyl compounds; POL, polar carbonyl compounds; PUFA, polyunsaturated fatty acids; TLC, thin-layer chromatography.

Previous experiments in this laboratory showed the existence of a number of lipophilic aldehydes and related carbonyl compounds in normal rat and human urine. These included butanal; butan-2-one; pentan-2-one; hex-2-enal; hexanal; hepta-2,4-dienal; hept-2-enal; octanal; non-2-enal; deca-2,4-dienal; 4-hydroxyhex-2-enal; and 4-hydroxynon-2-enal (28). In the present experiment, the effect of lipid peroxidative stress in the form of vitamin E deficiency, a high-PUFA diet, and CCl_4 administration on the urinary excretion of lipophilic aldehydes and related carbonyl compounds was determined in rats.

MATERIALS AND METHODS

Chemicals and supplies. 2,4-dinitrophenylhydrazine (DNPH), hexanal, and sodium tungstate were obtained from Sigma Chemical Company (St. Louis, MO); pentan-2-one (97%), hept-2-enal (97%), hepta-2,4-dienal (90%), decanal, and deca-2,4-dienal from Aldrich Chemical Co. (Milwaukee, WI); hydrochloric acid, high-performance liquid chromatography (HPLC)-grade acetone, methanol, dichloromethane, hexane, and water from EM Science (Gibbstown, NJ); sulfuric acid from Mallinckrodt Inc. (Paris, KY); and alkaline picrate reagent from Sigma Diagnostics (St. Louis, MO). DNPH derivatives of butanal, butanone, hexanal, octanal, non-2-enal, 4-hydroxyhex-2-enal, and 4-hydroxynon-2-enal were a gift from Dr. Esterbauer, University of Graz (Graz, Austria). Pentan-2-one, hept-2-enal, hepta-2,4-dienal, and deca-2,4-dienal DNPH derivatives were synthesized from pure standards and purified by repeated recrysta1ization from methanol (29). Silica gel thin layer chromatographic (TLC) plates (Silica gel 60, aluminum-backed 20 cm × 20 cm, 0.2 mm thickness) were purchased from Alltech Associates Inc. (Deerfield, IL). Amicon cell equipped with a YCO5 Diaflo Ultrafilter was obtained from Amicon Corp. (Beverly, MA).

Diet ingredients. Anhydrous d(+)-dextrose, vitamin-free casein, vacuum-distilled corn oil, and cod liver oil were obtained from United States Biochemical Corp. (Cleveland, OH). Salt mixture 4179, vitamin E free vitamin mixture (vitamin A acetate, 500,000 I.U./g, 1.80; vitamin D_2 calciferol, 850,000 I.U./g, 0.125; inositol, 5.0; choline chloride, 75.0; menadione, 2.250; biotin, 0.020; *p*-aminobenzoic acid, 5.0; ascorbic acid, 45.0; niacin, 4.250; riboflavin, 1.0; pyridoxine hydrochloride, 1.0; thiamin hydrochloride, 1.0; calcium pantothenate, 3.0; folic acid, 0.090; vitamin B_{12}, 0.00135; dextrose, 855.46365), and *RRR*-α-tocopheryl acetate were purchased from ICN Biochemicals Inc. (Aurora, OH).

Animals. Four groups of eight or nine Sprague-Dawley female weanling rats were fed one of the following diets: a diet containing 8% vacuum-distilled corn oil as the fat source that was adequate in all respects except for vitamin E (–E group) (30); the same diet supplemented with a normal amount of vitamin E (30 mg/kg *RRR*-α-tocopheryl acetate) (NE group); the diet supplemented with 300 mg/kg *RRR*-α-tocopheryl acetate (HE group); a diet containing 5% corn oil, 3% cod liver oil, and 30 mg/kg *RRR*-α-tocopheryl acetate (CLO group). After 19 wk, six rats from the NE and HE groups received 100 μL CCl_4/100 g body weight by gavage.

Urine collection. At the end of the experiment, the animals were individually held in stainless steel metabolic cages and fasted for 48 h with access to water *ad libitum.* Urine samples were collected during the second 24 h of fasting and stored at –70°C.

Instrumentation. The HPLC system consisted of an Altex Model 11OA solvent metering pump, an Altex Model 1lOA sample injector (Beckman Instruments, Berkeley, CA), a Spectra-Physics Model SPS4OO UV/VIS detector, and a Spectra-Physics Model SP4100 computing integrator (Spectra-Physics, Arlington, IL). The HPLC separations were performed on an Ultrasphere ODS C_{18} reverse-phase column (25 cm × 4.6 mm i.d., 5 μm particle size) (Altex) with a 2 cm × 2 mm i.d. guard column (Chrom Tech, Apple Valley, MN). Samples were filtered through a 0.2-μm polyvinylidene difluoride filter (Chrom Tech) prior to injection. A Spectronic 20 spectrophotometer (Bausch & Lomb, Rochester, NY) was used for urinary creatinine assay.

Measurement of urinary lipophilic aldehydes and carbonyl compounds. Urine analysis was carried out as previously described by Kim *et al.* (31). Briefly, the method includes ultrafiltration of urine to remove compounds with molecular masses larger than 500 dalton using Amicon cells, synthesis of 2,4-dinitrophenylhydrazone (DNP-hydrazone) derivatives of urinary aldehydes and carbonyl compounds, extraction of the DNPH-hydrazones with dichloromethane (CH_2Cl_2) and preliminary separation of nonpolar compounds (NONPOL) and polar carbonyl compounds (POL) on silica gel TLC plates developed with CH_2Cl_2. Separation and quantitation of the hydrazones were achieved by HPLC on a reverse-phase C_{18} column in two different solvent systems. NONPOL were eluted using methanol/water (75:25, vol/vol) and POL using methanol/water (50:50, vol/vol). Identification of DNPH hydrazones was accomplished by cochromatography with pure standards in three different solvent systems (31). The limit of detection was 1 ng.

Measurement of urinary creatinine. Creatinine concentration was determined in duplicate samples by the method of Sonnenwirth and Jarett (32).

Statistical analysis. Data were presented as means ± SEM. Significant differences between means were determined using analysis of variance coupled with Student-Newman-Keuls method. Student's *t*-test and paired *t*-tests were used to compare the values for other groups. A P-value <0.05 was considered significant for all analysis.

RESULTS AND DISCUSSION

Effect of dietary vitamin E. Typical HPLC chromatograms for NONPOL and POL excreted by vitamin E-deficient rats are shown in Figures 1 and 2, respectively. Fourteen NONPOL were separated by HPLC, and nine were identified: butanal, butan-2-one, pentan-2-one, hex-2-enal, hexanal, hepta-2,4-dienal, hept-2-enal, octanal, and oct-2-enal. There were five unidentified compounds. Thirteen POL were detected and

High performance liquid chromatography (HPLC) separation of 2,4-dinitrophenylhydrazine (DNPH) derivatives of urinary lipophilic nonpolar aldehydes and related carbonyl compounds from a vitamin E-deficient (–E) rat. A, butanal; B, butan-2-one; D, pentan-2-one; F, hex-2-enal; G, hexanal; H, hepta-2,4-dienal; I, hept-2-enal; K, octanal; X_3, oct-2-enal; C, E, J, X_1, X_2, unidentified. Separation conditions: Ultrasphere ODS column (4.6 mm × 25 cm, 5 μm), isocratic elution with methanol/water (75:25, vol/vol) for 10 mm, followed by a linear gradient from methanol/water (75:25, vol/vol) to methanol for 30 min, flow rate; 0.8 mL/min, detector wave length; 378 nm, injected volume, l00 μL.

two were identified: 4-hydroxyhex-2-enal (HHE) and 4-hydroxyoct-2-enal (HOE). 4-Hydroxynon-2-enal (HNE) was detected and identified only in animals treated with CCl_4. Figs. 3 and 4 show differences in the urinary excretion of

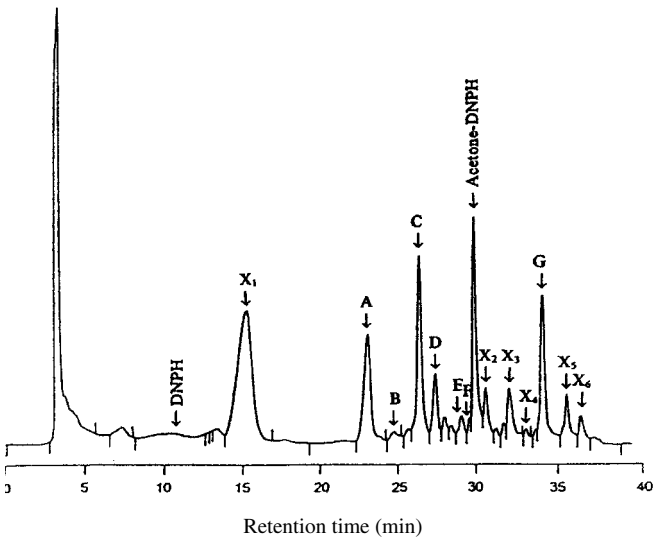

FIG. 2. HPLC separation of DNPH derivatives of urinary lipophilic polar aldehydes and related carbonyl compounds from a –E rat. E, 4-hydroxyhex-2-enal; X_4, 4-hydroxyoct-2-enal; A, B, C, D, F, G, X_1, X_2, X_3, X_5, and X_6, unidentified. Separation conditions: Ultrasphere ODS column (4.6 mm × 25 cm, 5 μm), isocratic elution with methanol/water (50:50, vol/vol) for 10 mm, followed by a linear gradient from methanol/water (50:50, vol/vol) to methanol for 30 min, flow rate; 1.0 mL/min, detector wave length; 378 nm, injected volume; l00 μL. See Figure 1 for abbreviations.

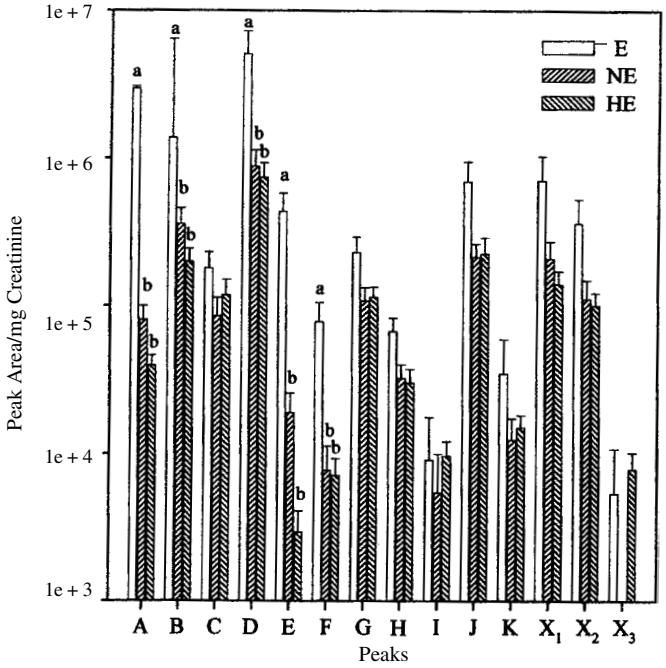

FIG. 3. Comparison of the DNPH derivatives of urinary nonpolar aldehydes and related carbonyl compounds from rats –E, normal vitamin E (NE), and high vitamin E (HE) diets. A, butanal; B, butane-2-one; D, pentane-2-one; F, hex-2-enal; G, hexanal; H, hepta-2,4-dienal; I, hept-2-enal; K, octanal; X_3, oct-2-enal; C, E, J, X_1, X_2, unidentified. Values represent means ± SEM of six to nine animals per dietary group and are expressed on a logarithmic scale. Different letters denote significant differences between groups by Student-Newman Keuls method ($P < 0.05$). See Figure 1 for abbreviations.

NONPOL and POL on the –E, NE, and HE diets. There was a general tendency for the excretion of NONPOL to be greater on the –E diet compared to the NE and HE diets; these differences were statistically significant for butanal, butan-2-one, pentan-2-one, hex-2-enal, and unidentified compound E (Fig. 3). There were no significant differences in excretion between the rats fed the NE and HE diets for any compound. The effect of vitamin E status on the excretion of POL is shown in Figure 4. All 14 POL showed increased concentrations in the urine due to vitamin E deficiency compared to animals given the NE and HE diets; however, significant increases were found only for HOE and unidentified compounds A, C, D, and X_2. Variations in urinary NONPOL and POL concentrations were much greater between individual animals in vitamin E deficiency than in animals fed the NE and HE diets. High variability in urinary excretion of lipid peroxidation products in vitamin E deficiency was found previously (33). This may be due to variations in depletion rate among individual animals (34). Urinary excretion of the sum of NONPOL and POL was significantly greater ($P < 0.05$) in the –E group than in the NE and HE groups (Tables 1 and 2).

Others have found increases in certain lipophilic aldehydes as a result of dietary lack of vitamin E. Yosino *et al.* (35) found hexanal and HNE in the plasma and liver of vitamin E-deficient rats. Elevated levels of HNE were found in the retina in vitamin E-deficient rats and dogs (8). *In vitro* oxidation of

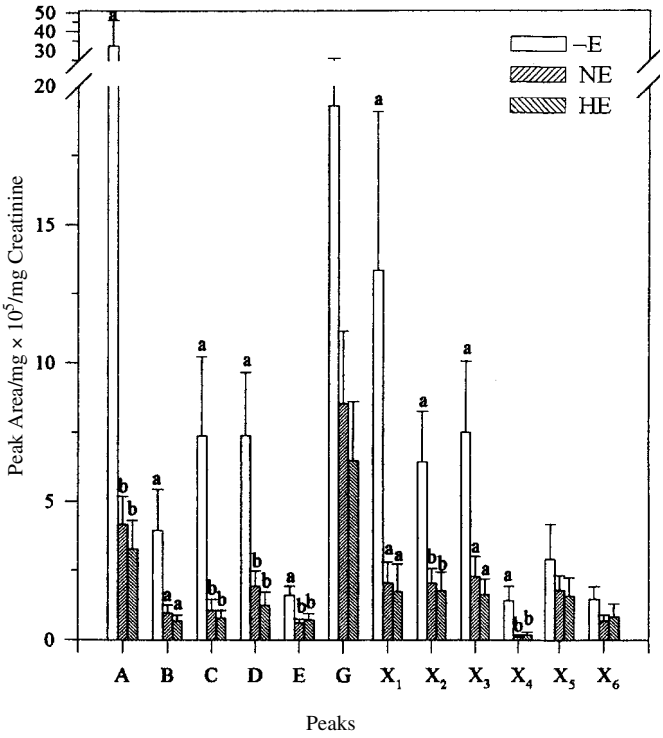

FIG. 4. Comparison of the DNPH derivatives of urinary polar aldehydes and related carbonyl compounds from rats fed –E, NE, and HE diets. E, 4-hydroxyhex-2-enal; X_4, 4-hydroxyoct-2-enal; A, B, C, D, G, X_1, X_2, X_3, X_5 and X_6, unidentified. Values represent means ± SEM of 6–9 animals per dietary group. Different letters denote significant differences between groups by Student-Newman Keul's method ($P < 0.05$).

vitamin E-depleted human low density lipoproteins yielded butanal, propanal, hexanal, 2,4-heptadienal, HHE, HNE, and HOE (36). In the present experiment, the increased oxidative stress caused by vitamin E deficiency resulted in increases in the urine in many of the same lipophilic secondary oxidation products. This demonstrates that oxidation products formed by *in vitro* lipoprotein oxidation are also formed *in vivo* under oxidizing conditions.

A quantitative estimation of urinary excretion of the NONPOL and POL compounds from animals fed NE, –E, and HE diets are shown in Tables 1 and 2. There was approximately twice the concentration of POL as NONPOL compounds. The compounds excreted in greatest amounts in the –E fed animals were the POL compounds A, C, D, G, X_1, X_2, and X_3 and the NONPOL compounds A (butanal), D (pentan-2-one), B (butan-2-one), E, J, and X_1. Although no HNE was detected in these animals, it was found in animals administered CCL_4 (see below).

Effect of dietary PUFA. Excretion of NONPOL and POL for CO- and CLO-fed rats is illustrated in Figures 5 and 6, respectively. All 13 NONPOL except butan-2-one (B) and all 10 POL except the two unidentified compounds B and X_1 were in greater concentration in the urine of the high n-3 CLO animals compared to the CO group. The increases in NONPOL were significant for hexanal (G), hepta-2, 4-dienal (H), oct-2-enal (X_3), and three unidentified compounds C, E, and

X_2. The significant increase of hepta-2, 4-dienal (H) reflects the decomposition of n-3 fatty acids. Among POL compounds, HHE (E), HOE (X_4), and two unidentified compounds G and X_6 were significantly increased compared to the control. Although total urinary NONPOL and POL were

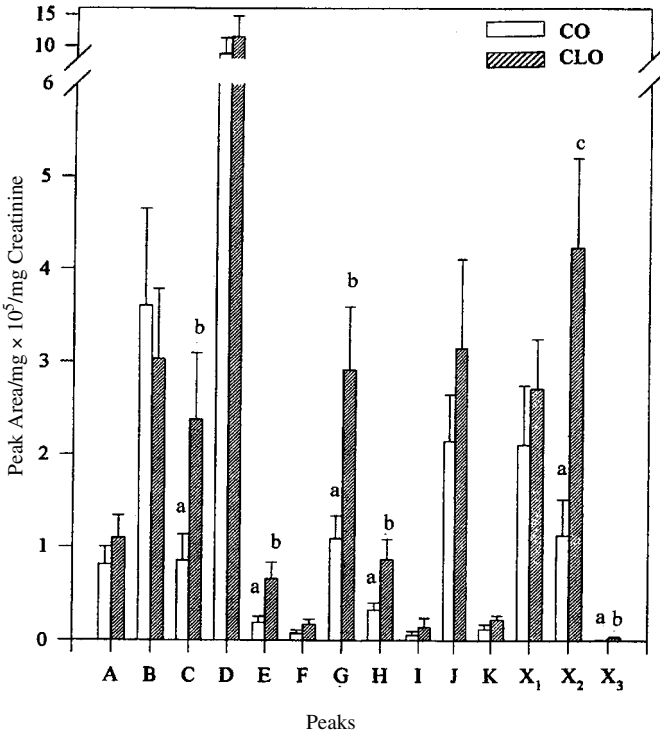

FIG. 5. Comparison of the DNPH derivatives of urinary nonpolar aldehydes and related carbonyl compounds from rats fed either a normal diet containing 8% corn oil (CO) or a polyunsaturated fatty acids (PUFA) diet containing 3% cod liver oil (CLO) and 5% CO. A, butanal; B, butan-2-one; D, pentan-2-one; F, hex-2-enal; G, hexanal; H, hepta-2,4-dienal; I, hept-2-enal; K, octanal, X_3, oct-2-enal; C, E, J, X_1, X_2, unidentified. Values represent means ± SEM of nine and six animals in CO and CLO groups, respectively. Statistical significant difference is determined by Student's *t*-test; a vs. b, $P < 0.05$ and a vs. c, $P < 0.01$. See Figure 1 for abbreviations.

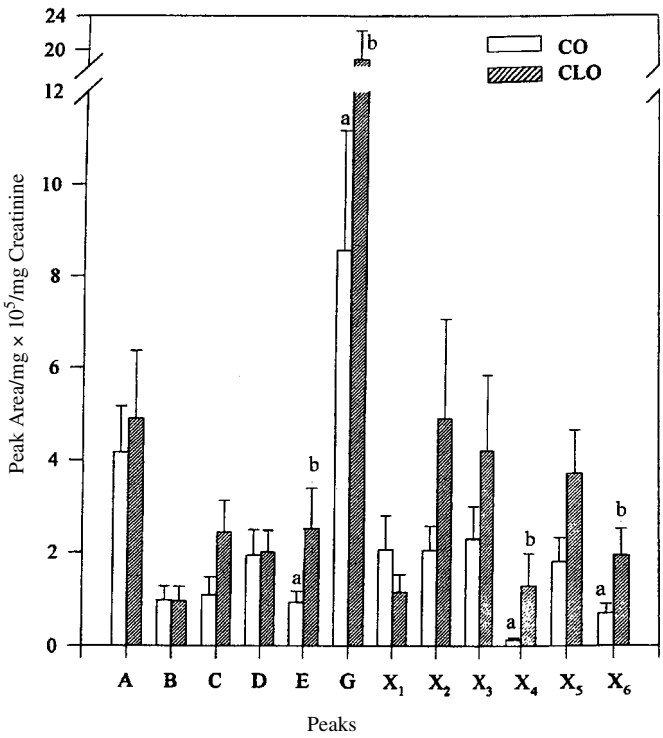

FIG. 6. Comparison of the DNPH derivatives of urinary polar aldehydes and related carbonyl compounds from rats fed either a normal diet containing 8% CO or a PUFA diet containing 3% CLO and 5% CO. E, 4-hydroxyhex-2-enal; X4, 4-hydroxyoct-2-enal; A, B, C, D, G, X_1, X_2, X_3, X_5, and X_6, unidentified. Values represent means ± SEM of nine and six animals in CO and CLO groups, respectively. Statistical significance of difference is determined by Student's *t*-test; a vs. b, $P < 0.05$. See Figures 1 and 5 for abbreviations.

increased in the CLO-fed rats compared to the CO control (NE) group, due to high variability within groups, these differences did not achieve statistical significance (Tables 1 and 2).

It is well-established that feeding diets containing cod liver oil or other fish oils increases incorporation of n-3 PUFA into plasma lipids and cell membranes (37–39). Studies *in vivo* and *in vitro* (40–42) demonstrated that cellular membranes and tissues containing relatively high amounts of n-3 PUFA-containing phospholipids become more vulnerable to peroxidative damage. Saito and Nakatsugawa (43) found that lipid peroxides increased in rat liver microsomal fatty acids after consumption of a fish oil diet. In addition, incorporation of n-3 PUFA into the lipids of cultured cells enhanced the cellular susceptibility to oxidants, especially H_2O_2 (44,45). Recent studies also showed that a fish oil-enriched diet induced vitamin E deficiency in animals and increased lipid peroxides in human plasma (46,47). Thus, the greater excretion of urinary lipophilic aldehydes and carbonyl compounds in rats fed cod liver oil diet found here is consistent with these observations by other investigators.

Effect of CCl_4 administration. CCl_4 administration induces liver damage due to peroxidation of hepatic lipids by CCl_3• and CCl_3O_2•, free radical metabolites of CCl_4 (48). DNPH-reactive carbonyl compounds have been detected in membrane phospholipids of hepatic endoplasmic reticulum in CCl_4-treated rats (49), and increased concentrations of HNE have been demonstrated in liver homogenates from CCl_4-treated mice and in liver microsomes peroxidized with CCl_4 (50). Further, numerous secondary lipid peroxidative products, including HHE, alkanals, alkenals, and ketones, were found both *in vivo* and *in vitro* in studies using mice liver extracts, isolated rat hepatocytes, or rat liver microsomes (51,52). CCl_4 administration in the present study yielded generally greater urinary excretion of lipophilic aldehydes and carbonyl compounds (Figs. 7 and 8), consistent with an enhanced lipid peroxidation *in vivo*. Following CCl_4 intubation, 11 of the 14 NONPOL and all 13 POL had a tendency to be in greater concentration in the urine. Hex-2-enal (F), hexanal (G), hepta-2,4-dienal (H), and unidentified compounds C and J were significantly greater in NONPOL and HHE (E), HNE (H), HOE (X_4), and unidentified compounds C, G, X_2, X_3, and X_5 were significantly greater in POL compared to controls (Figs. 7 and 8). Total urinary excretion of NONPOL and POL was increased in animals treated with CCl_4; however, due to high variability within groups, only the urinary excretion of POL was statistically different from the control (NE) group (Ta-

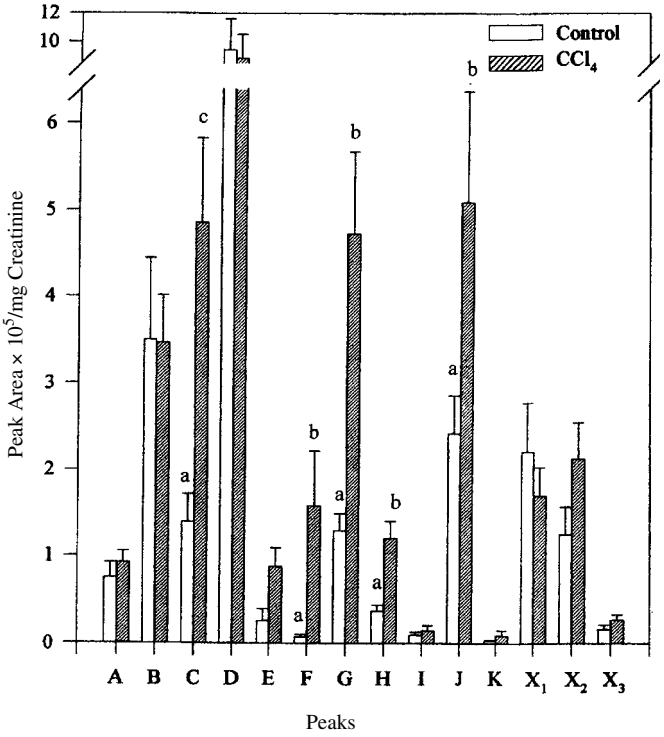

FIG. 7. Comparison of the DNPH derivatives of urinary nonpolar aldehydes and related carbonyl compounds from rats fed a normal control diet and the control diet group treated with carbon tetrachloride (CCl_4). A, butanal; B, butan-2-one; D, pentan-2-one; F, hex-2-enal; G, hexanal; H, hepta-2,4-dienal; I, hept-2-enal; K, octanal; X_3, oct-2-enal; C, E, J, X_1, X_2, unidentified. Values represent means ± SEM of 10 animals per group. Statistical significance of difference is determined by paired *t*-test; a vs. b, $P < 0.05$ and a vs. c, $P < 0.01$. See Figure 1 for abbreviations.

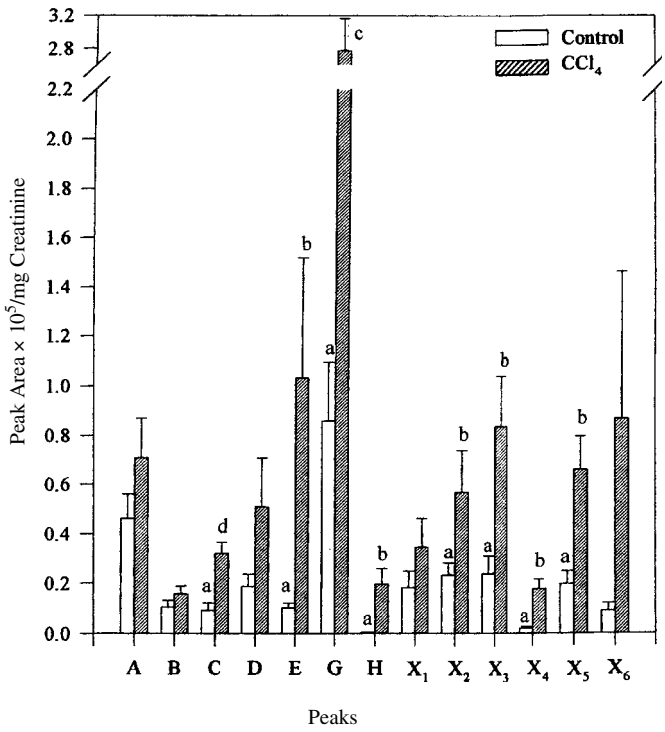

FIG. 8. Comparison of the DNPH derivatives of urinary polar aldehydes and related carbonyl compounds from rats fed a normal control diet and the control diet group treated with CCl_4. E, 4-hydroxyhex-2-enal; H, 4-hydroxynon-2-enal; X4, 4-hydroxyoct-2-enal; A, B, C, D, G, X_1, X_2, X_3, X_5, and X_6, unidentified. Values represent means ± SEM of 10 animals per group. Statistical significance of difference is determined by paired *t*-test; a vs. b, $P < 0.05$; a vs. c, $P < 0.01$; and a vs. d, $P < 0.001$. See Figures 1 and 7 for abbreviations.

bles 1 and 2). These results are consistent with those of Dhanakoti and Draper (53), who found increased urinary MDA excretion due to CCl_4 administration. The increased concentrations of some urinary lipophilic aldehydes and carbonyl compounds in CCl_4-intoxicated rats in this study indicate that these secondary lipid peroxidative products enter the bloodstream and ultimately are excreted into the urine.

The major forms of urinary HHE and HNE are as mercapturic acid conjugates (54,55), which are not detected using the present method. Thus, it appears that the peroxidizing action of CCl_4 increases production of HHE, HNE, and possibly HOE *in vivo* to levels that exceed the ability to form mercapturic acid conjugates. The result is excretion of these compounds in the urine in a form that is detectable by the present method (e.g., free form or as amino acid conjugates). Consequently, the total quantity of HHE and HNE excreted in the urine must exceed that which was measured here, perhaps substantially.

A collation of the results of the pro-oxidant effects of vitamin E deficiency, high dietary PUFA, and CCl_4 administration on the excretion of the urinary lipophilic nonpolar and polar aldehydes and related carbonyl compounds is presented in Tables 1 and 2. For each treatment, there was a greater excretion of urinary total POL than total NONPOL. The profile of excretion differed somewhat among the treatments. Overall, –E led to the greatest urinary excretion of both NONPOL and POL. However, with the exception of butan-2-one, excretion of every compound was increased in at least two of three of the treatments. The excretion of the vast majority of the compounds was increased in all three treatments. Thus, in each case, these secondary *in vivo* peroxidation products clearly accumulated in tissues and were excreted to some extent in the urine.

In summary, peroxidative stimuli mediated by vitamin E deficiency, high PUFA, and CCl_4 administration in rats induced lipid peroxidation *in vivo* and resulted in increased urinary excretion of a number of lipophilic aldehydes and related carbonyl compounds. These secondary lipid peroxidation products were measured as 2,4-dinitrophenylhydrazine derivatives by HPLC. Measurement of the urinary excretion of these compounds would appear to be a useful and noninvasive index of lipid peroxidation *in vivo*.

n-3 Fatty Acid Deficiency Decreases Phosphatidylserine Accumulation Selectively in Neuronal Tissues

Jillonne Hamilton, Rebecca Greiner, Norman Salem Jr., and Hee-Yong Kim*

Section of Mass Spectrometry, Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, Maryland 20852

ABSTRACT: We have previously shown that the docosahexaenoate (22:6n-3) status in membrane phospholipids influences the biosynthesis and accumulation of phosphatidylserine (PS) in brain microsomes and C6 glioma cells. In the present study, we investigated whether the observed effect of membrane docosahexaenoic acid status on PS accumulation is universal or occurs specifically in neuronal tissues. We observed that rat brain cortex, brain mitochondria, and olfactory bulb, where 22:6n-3 is highly concentrated, contain significantly higher levels of PS in comparison to liver and adrenal, where 22:6n-3 is a rather minor component. Phospholipid molecular species analysis revealed that in brain cortex, mitochondria, and olfactory bulb 18:0,22:6n-3 was the most abundant species representing 45–65% of total PS. In nonneuronal tissues such as liver and adrenal, 18:0,20:4n-6 was the major PS species. Dietary depletion of n-3 fatty acids during prenatal and postnatal developmental periods decreased the brain 22:6n-3 content by more than 80%, with a concomitant increase in 22:5n-6 in all tissues. Under these conditions, an approximately 30–35% reduction in total PS in rat brain cortex, brain mitochondria, and olfactory bulb was observed, while PS levels in liver and adrenal were unchanged. The observed reduction of PS content in neuronal membranes appears to be due to a dramatic reduction of 18:0,22:6n-3-PS without complete replacement by 18:0,22:5n-6-PS. These results establish that variations in membrane 22:6n-3 fatty acid composition have a profound influence on PS accumulation in neuronal tissues where 22:6n-3 is abundant. These data have implications in neuronal signaling events where PS is believed to play an important role.

Paper no. L8490 in *Lipids 35,* 863–869 (August 2000).

Docosahexaenoic acid (22:6n-3) is the major polyunsaturated fatty acid in neuronal membranes (1,2). This lipid profile appears to be rigorously maintained, and increasing evidence suggests that maintenance of high levels of 22:6n-3 is necessary for optimal neural development and function (3–5). Phosphatidylserine (PS), the major anionic phospholipid class in biomembranes, is particularly enriched with this fatty acid (1,2). PS is synthesized from pre-existing molecules of phosphatidylcholine (PC) or phosphatidylethanolamine (PE) *via* base-exchange of L-serine with either choline or ethanolamine (6–8). The reaction, which is catalyzed by base-exchange enzymes, is energy independent and stimulated by Ca^{2+}. In mammalian cells, at least two distinct enzymes located in the endoplasmic reticulum or mitochondria-associated membrane are responsible, phosphatidylserine synthase I (PSS I) and phosphatidylserine synthase II (PSS II) (9,10). PPS I utilizes primarily PC as the substrate for the base-exchange reaction, while PSS II utilizes only PE as the substrate (11). Once formed, PS can be exported into the mitochondria and become decarboxylated to PE by phosphatidylserine decarboxylase, which is found in the inner mitochondria membrane (12).

The importance of PS revolves around its functions in cellular events, such as translocation of protein kinases to the plasma membrane and apoptosis. For example, it is known that PS interacts selectively with the cystine-rich amino-terminal end of Raf-1 kinase (13,14) and facilitates translocation of Raf-1 to the plasma membrane. Translocation of Raf-1 to the plasma membrane is one of the first steps necessary to transduce growth factor signaling (15). PS also participates in the translocation of protein kinase C to the membrane for activation (16). Apoptosis, or programmed cell death, is a physiological phenomenon that occurs extensively in the developing central nervous system, but can also occur in many pathological conditions (17). During apoptosis, PS, which is normally found in the inner leaflet of the plasma membrane, appears in the outer leaflet (18). The outer leaflet PS may serve as a signal for noninflammatory engulfment of apoptotic cells (19). PS is also important in protein-lipid interactions, an example being the recently reported human serum deprivation response gene, that encodes for a specific PS-binding protein (20). In addition to the role of PS in cellular signaling events, it may also be useful in treating neurological disorders such as Alzheimer's disease (21) and amnesia (22). Thus, dietary signals, which can regulate the level of membrane PS, may also serve to regulate these PS functions.

We have previously reported that depletion of 22:6n-3 fatty acid leads to a decrease in PS biosynthesis and a reduc-

Abbreviations: 20:4n-6, arachidonic acid; 22:6n-3, docosahexaenoic acid; 22:5n-6, docosapentaenoic acid; 22:4n-6, docosatetraenoic acid; 18:3n-3, α-linolenic acid; ESI/MS, electrospray ionization/mass spectrometry; GC, gas chromatography; HPLC/MS, high-performance liquid chromatography/mass spectrometry; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; PSS, phosphatidylserine synthase.

tion of PS in brain microsomes (23). Furthermore, we have reported that enrichment of membrane phospholipids with 22:6n-3 significantly promotes incorporation of this fatty acid into PS and the synthesis of PS by serine base exchange, leading to increased PS levels (24). Others have shown that intraamniotic injection of ethyl-docosahexaenoate increases brain 22:6n-3 as well as PS content in rats (25). In this study, we determine whether modulation of PS accumulation, due to the 22:6n-3 status, is a general phenomenon or occurs specifically in tissues where 22:6n-3 concentration is particularly high. Phospholipid composition of various rat tissues and organelles including brain cortex, olfactory bulb, adrenal gland, liver, and brain mitochondrial fractions in both n-3-adequate and n-3-deficient rats were examined using electrospray high-performance liquid chromatography/mass spectrometry (HPLC/MS). The data establish that PS levels are considerably higher in neuronal tissues in comparison to non-neuronal tissues and that n-3-deficiency results in a dramatic reduction of PS only in neuronal cells.

MATERIALS AND METHODS

Materials. Deuterium-labeled or nonlabeled phospholipid standards and brain PS were purchased from or custom-synthesized by Avanti Polar Lipids (Alabaster, AL). All solvents were HPLC grade, and purchased from EM Scientific (Gibbstown, NJ), or Burdick & Jackson (Muskegon, MI). BF_3/methanol was obtained from Alltech (Deerfield, IL). Fiske and Subbarow reagent was purchased from Sigma (St. Louis, MO). Deuterated phospholipid standards used for quantitation were calibrated by phosphorus assay (26) and gas chromatography (GC) analysis.

Animals and tissue preparation. Procedures for the rearing of animals were previously described in detail (27). Briefly, 21-d-old Long-Evans rats (Charles River, Portage, MI) were randomized into two groups and began consuming one of two experimental diets. The two experimental diets were designed to contain only one primary fatty acid variable, α-linolenic acid (18:3n-3). Safflower oil contributed adequate and identical amounts of linoleic acid (18:2n-6) to both diets. A small amount of flaxseed oil was added to provide α-linolenate in the n-3-adequate diet. Thus, 18:3n-3 was 3.1% of total fatty acids in the n-3-adequate diet and 0.04% in the n-3-deficient diet. The male offspring of these rats, denoted as the F2 generation, were weaned to the diet of the dam and maintained on these diets throughout the study. At 8 wk of age, F2 generation rats consuming the n-3-deficient diet had an 82% decrease in 22:6n-3 compared to rats consuming the n-3-adequate diet. All animal procedures were approved by the National Institute on Alcohol Abuse and Alcoholism (LMBB OC09).

The brain mitochondrial fractions were prepared according to Cotman (28), with slight modifications. Homogenates of rat brain were prepared in a solution of 0.32 M sucrose with 10 mM tris HCl and 1 mM EDTA (pH 7.3) and centrifuged at 1,000 × *g* for 5 min to remove nuclei and unbroken cells. The resulting supernatant was transferred and centrifuged at 11,000 × *g* for 20 min to provide a supernatant and a pellet. The pellet was suspended in 30 mL of 0.32 M sucrose, and centrifuged at 11,000 × *g* for 20 min. To isolate the mitochondrial fraction, the resulting pellet was suspended in a 12% Ficoll solution, a 7.5% Ficoll solution was placed on top of the 12% layer, and 0.32 M sucrose buffer was placed on top of the 7.5% layer and centrifuged at 100,000 × *g* for 60 min. The mitochondrial fraction precipitated at the bottom and was collected, washed with phosphate-buffered saline, and stored at −70°C until further use. A protein assay was performed using the bicinchoninic acid reagent (29), and lipids were extracted according to the method of Bligh and Dyer (30). For phospholipid molecular species analysis, internal standards, d_{35}-18:0,20:4-PC and PE, and d_{35}-18:0,22:6-PS, were added prior to lipid extraction. Similarly, tissue samples of brain cortex, liver, adrenal gland, and olfactory bulb were homogenized and aliquots were removed for protein assay (29) and lipid extraction (30).

Fatty acid analysis. Lipids were extracted in the presence of tricosanoic acid (23:0) as the internal standard, and fatty acids were determined by GC analysis after transmethylation as previously described (31). The content of each individual fatty acid was expressed as a weight percentage of total fatty acids. Fatty acids were identified by the retention times of known fatty acid standards, and the content of each individual fatty acid was expressed as a weight perentage of total fatty acids.

PS molecular species analysis by HPLC/MS. Phospholipid molecular species were separated and determined using reversed-phase HPLC/electrospray ionization-mass spectrometry (ESI-MS) with a C18 column (150 × 20 mm, 5 µm; Phenomenex, Torrance, CA) as described previously (32). Separation was accomplished using a mobile phase containing water; 0.5% ammonium hydroxide in methanol; and hexane, changing from 12:88:0 to 0:88:12 in 17 min after holding the initial composition for 3 min at a flow rate of 0.4 mL/min (33). A Hewlett Packard HPLC-MS Series 1100 MSD instrument (Palo Alto, CA) was employed to detect the separated phospholipid molecular species. For electrospray ionization, the drying gas temperature was 350°C while the drying gas flow rate and nebulizing gas pressure were 13 L/min and 32 psi, respectively. The capillary voltage was set at 4000 V, and the exit voltage was set at 200 V. Quantification was based on the area ratio calculated against the internal standard of the same phospholipid class. Identification of molecular species was based on the mono- and diglyceride ion peaks as described previously (32). Quantification was based on the area ratio calculated against the internal standard of the same phospholipid class using diglyceride ions.

The HPLC-ESI/MS method employed for phospholipid molecular species analysis was validated by phosphorus assay with 16:0,18:1-PS and a commercial preparation of brain PS (Avanti Polar Lipids). The amounts of 16:0,18:1-PS in aliquots of a standard stock solution were determined by phosphorus assay (26) performed in triplicate. Separately, the

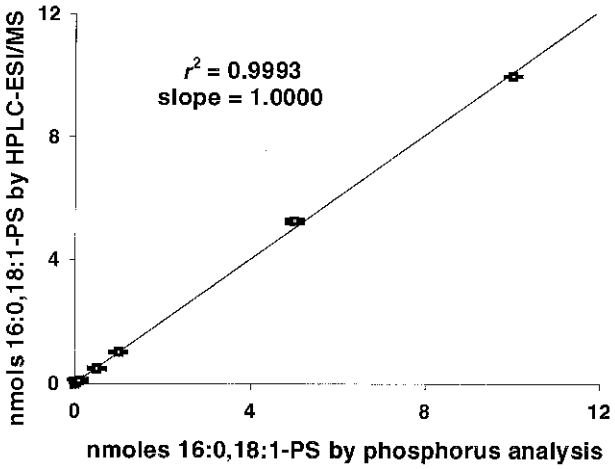

FIG. 1. Correlation between 16:0,18:1-PS content determined by phospholipid molecular species method using d_{35}-18:0,22:6-PS as an internal standard and by phosphorus analysis. Representative data from two experiments are shown. PS, phosphatidylserine.

16:0,18:1-PS amount was determined by phospholipid molecular species analysis using HPLC-ESI/MS after addition of d_{35}-18:0,22:6-PS as an internal standard. The results obtained by these two independent methods were in good agreement in the 50–10,000 pmol range (Fig. 1). To validate the HPLC-ESI/MS method for analysis of phospholipid mixtures, aliquots of a commercial brain PS mixture were analyzed by GC, HPLC-ESI/MS, and phosphorus assay. Total PS contents determined by HPLC-ESI/MS and phosphorus assay were comparable, as shown in Table 1. When fatty acid contents obtained by GC analysis were converted to mol% and compared with species data, consistent results were obtained (Table 1), indicating that the HPLC-ESI/MS method can be generally applied to the analysis of PS molecular species in biological mixtures.

Phospholipid class separation followed by phosphorus assay. Phospholipid classes were separated employing normal-phase chromatography with a silica column (100 × 2 mm i.d., 3 μm; Thompson, Springfield, VA). Separation was accomplished using a mobile phase containing isopropyl alcohol, water, and hexane, changing from 54.4:3.7:41.9 to 51.6:8.6:39.8, respectively, in 14 min after holding the initial composition for 8 min at a flow rate of 0.5 mL/min (34). Fractions were collected from the olfactory bulb and subjected to phosphorus analysis (26).

Statistical analysis. Statistical differences between n-3-adequate and n-3-deficient animals were assessed by the Student's *t*-test.

RESULTS

Effect of n-3 deficiency on the total lipid composition. As expected, fatty acid analysis indicated that in neuronal tissues of n-3-adequate animals, 22:6n-3 levels were high. Brain cortex, brain mitochondria, and the olfactory bulb contained ap-

proximately twice as much 22:6n-3 as liver and 12 times more than the adrenal gland (Table 2). The most abundant polyunsaturated fatty acid in liver and adrenal gland was arachidonic acid (20:4n-6), and the adrenal also contained a significant amount of docosatetraenoic acid (22:4n-6). An n-3 fatty acid deficiency resulted in a dramatic reduction in 22:6n-3 for all tissues with concomitant increases in docosapentaenoic acid (22:5n-6) (Table 2). The decrease in 22:6n-3, in all tissues except adrenal, was mostly compensated for by increases in 22:5n-6. In the case of the adrenal, total 22:5n-6 content of deficient rats exceeded the 22:6n-3 content of n-3-adequate rats. In brain cortex, 20:4n-6 was significantly higher in the n-3-deficient animals. For adrenal, liver, and brain mitochondria, 22:4n-6 was also increased with n-3 fatty acid deficiency. Total phospholipid content, as determined by phosphorus assay, was not significantly changed by n-3-deficiency in any of the tissues examined (Table 3). The phospholipid to protein ratio was highest in brain cortex, followed by brain mitochondria and olfactory bulb, and lowest in adrenal and liver (Table 3).

Effect of n-3 deficiency on the phospholipid molecular species profile. Molecular species analysis of PS indicated that neuronal tissues contain significantly higher levels of PS in comparison to nonneuronal cells (Table 4). In the n-3-adequate animals, brain cortex, brain mitochondria, and olfactory bulb contained approximately 24, 12, and 9 times more PS than adrenal gland or liver, respectively, when the data were expressed as nmol/mg protein (Table 4). In terms of molecular species, 18:0,22:6n-3-PS was the most abundant, constituting 45–65% of total PS in neuronal tissues. In adrenal and liver, however, 18:0,20:4n-6-PS was the most abundant species, making up approximately half of total PS (Table 4).

The effect of n-3 deficiency on total PS content expressed as an absolute value normalized to protein content is shown in Table 4 and Figure 2A. The PS content was greatest in brain cortex (129 ± 5.4 nmol/mg protein) followed by brain mitochondria and olfactory (72.2 ± 3.5 and 49.2 ± 2.5 nmol/mg protein) (Fig. 2A). Adrenal and liver PS amounts were 5.4 ± 0.3 and 5.5 ± 0.2 nmol/mg protein, respectively. Dietary depletion of n-3 fatty acids resulted in an approximately 30% reduction in total PS for neuronal tissues, but did not alter PS levels in adrenal or liver (Fig. 2A). Due to the low phospholipid/protein ratio in the olfactory bulb, the percentage of PS normalized to total phosphorus was higher than that of cortex or mitochondria (Table 3 and Fig. 2B). However, the decrease of PS was consistently observed in neuronal tissues of n-3-deficient animals. The largest decrease in PS (38%) occurred in brain cortex; the proportion of PS (expressed as % of total phospholipid) in brain cortex for control rats was 12.3 ± 0.4%, which is similar to a previously reported value of 10.2 ± 0.1% (35), and was reduced to 7.6 ± 0.4% in the n-3 deficient rats. In the olfactory bulb, PS was reduced from 16.8 ± 0.3 to 11.7 ± 0.3%, while in brain mitochondria, PS was reduced from 8.3 ± 0.4 to 6.5 ± 0.7%. The percentages of PS in adrenal and liver of n-3-adequate animals were 2.4 ± 0.1 and 3.0 ± 0.1%, respectively, which are similar to previously reported values (35,36). Unlike the neuronal tissues, there was no significant decrease in the PS percentage for the adrenal gland or liver.

In neuronal tissues, but not adrenal and liver, di-polyunsaturated species of PS were detected (Table 4). The brain cortex, brain mitochondria, and olfactory bulb of n-3-adequate animals contained 22:6,22:6n-3 and 22:4,22:6n-3-PS, and/or 22:5,22:5-PS species (Table 4). Also present in the brain cortex of n-3-adequate animals was 22:5,22:6-PS (Table 4). While significantly less, 22:4,22:6n-3 and/or 22:5,22:5-PS was present in n-3-deficient animals in all neu-

[e]The current HPLC-ESI/MS technique could not distinguish PS species containing 22:5n-6 from those with 22:5n-3.

ronal tissues, and di-22:6n-3 was detected only in brain cortex. In all neuronal tissues from n-3-deficient animals, the 22:5,22:6-PS species increased slightly but significantly, presumably due to the increased content of 22:5n-6 by dietary manipulation. The current HPLC-ESI/MS technique could not distinguish PS species containing 22:5n-6 from those with 22:5n-3.

DISCUSSION

The molecular species composition of membrane phospholipids is a determinant of the biochemical and biophysical properties of cell membranes with consequences for the function and activity of membrane-bound proteins (37,38). Dietary α-linolenate deficiency has been shown to induce dramatic modifications in membrane lipid composition, mainly by decreasing 22:6n-3 and increasing 22:5n-6 (1,2,39,40). This leads to a number of functional changes such as alterations in enzymatic activities (41,42), suboptimal retinal and brain development (4,43–45), and poorer performance in learning-related tasks (27,46). Low levels of 22:6n-3 have also been correlated with peroxisomal disorders associated with severe and progressive neurological deterioration (47).

The present study demonstrates that dietary n-3 fatty acids positively modulate PS accumulation in neuronal tissues. Previous work with rats fed a balanced or an n-3 polyunsaturated fatty acid-deficient diet showed that PS accumulation eventually decreases (–22%) at 24 mon in the hippocampus of rats fed the deficient diet (48). Also, intraamniotic injection with ethyl esters of 22:6n-3 has been shown to increase the PS content in rat pup brains (25). In a study of herring raised on either a 22:6n-3 supplemented diet (4.3%) or one lacking in 22:6n-3, it was found that total PS decreased in the retina of fish fed the 22:6n-3 deficient diet; the loss of 22:6n-3 was most pronounced in di-22:6n-3 species (49). Furthermore, the phospholipid composition of cerebral cortex in "sudden infant death syndrome" infants fed breast milk contained 39% more PS in comparison to formula-fed infants (50). The ranges of 18:3n-3 and 22:6n-3 in breast milk were 0.5–1.2 and 0.1–0.5%, respectively, whereas the formula contained 0.4% of 18:3n-3 and no 22:6n-3 (50). These reports and our earlier studies (23,24) corroborate with the present finding that 22:6n-3 is a potent modulator of neuronal PS accumulation.

Our current data show that the 18:0,22:6-PS molecular species contributes most to PS accumulation as well as to the reduction of PS in neuronal tissues, suggesting that the biosynthesis of PS may have a substrate specificity for 18:0,22:6 containing PC and/or PE. Alternatively, PS degradation pathways, such as PS decarboxylation, may favor other PS molecular species in comparison to 18:0,22:6-PS. In addition, acylation and/or reacylation reactions may also be in-

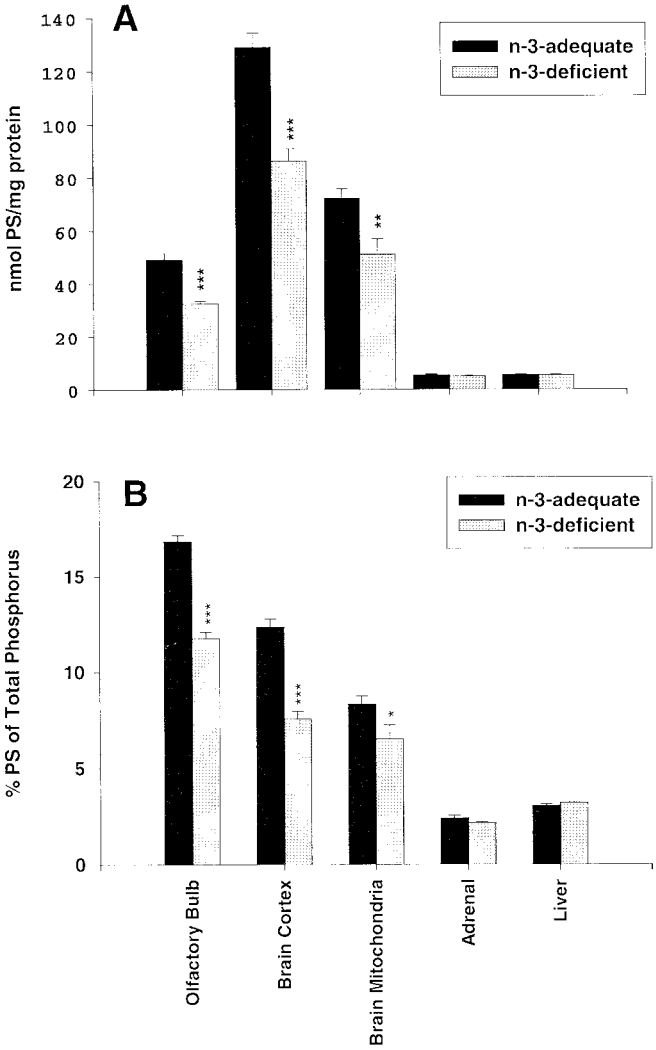

FIG. 2. (A) Absolute levels of PS in olfactory bulb, brain cortex, brain mitochondria, adrenal gland, and liver from n-3-adequate and n-3-deficient rats determined by high-pressure liquid chromatography-electrospray ionization-mass spectrometry phospholipid molecular species analysis and expressed as nmol/mg protein. Representative data from three experiments are shown. (B) Percentage PS normalized to total phosphorus content in olfactory bulb, brain cortex, brain mitochondria, adrenal and liver from n-3-adequate and n-3-deficient rats. $***P < 0.001$, $**P < 0.01$, $*P < 0.05$. Data shown represent the results from two experiments. See Figure 1 for other abbreviations.

volved in enrichment of 22:6n-3 in PS. Under n-3 fatty acid deficiency, the activity of these enzymes may be altered so that 18:0,22:6n-3-PS as well as total PS decrease. Further studies will be necessary to address these issues.

The present study establishes that membrane levels of 22:6n-3 affect PS accumulation selectively in cells where levels of 22:6n-3 are abundant. When 22:6n-3 levels are reduced in these cell membranes, either through prolonged dietary depletion (23) or ethanol treatment (24), PS accumulation decreases. This phenomenon occurs specifically in neuronal cells suggesting that n-3-deficiency may have a profound effect on PS-related signaling events in the nervous system.

ACKNOWLEDGMENTS

The assistance in tissue preparation by Karl Kevala and phospholipid quantitation by SonMi Lee are greatly appreciated.

The Questionable Role of a Microsomal Δ8 Acyl-CoA-Dependent Desaturase in the Biosynthesis of Polyunsaturated Fatty Acids

Qi Chen, Feng Qin Yin, and Howard Sprecher*

Department of Molecular and Cellular Biochemistry, The Ohio State University, Columbus, Ohio 43210, USA

ABSTRACT: Several experimental approaches were used to determine whether rat liver and testes express an acyl-CoA-dependent Δ8 desaturase. When [1-^{14}C]5,11,14-eicosatrienoic acid was injected *via* the tail vein, or directly into testes, it was incorporated into liver and testes phospholipids, but it was not metabolized to other labeled fatty acids. When [1-^{14}C]11,14-eicosadienoic acid was injected, *via* the tail vein or directly into testes, or incubated with microsomes from both tissues, it was only metabolized to 5,11,14-eicosatrienoic acid. When ethyl 5,5,11,11,14,14-d$_6$-5,11,14-eicosatrienoate was fed to rats maintained on a diet devoid of fat, it primarily replaced esterified 5,8,11-eicosatrienoic acid, but not arachidonic acid. No labeled linoleate or arachidonate were detected. Dietary ethyl linoleate and ethyl 19,19,20,20-d$_4$-1,2-^{13}C-11,14-eicosadienoate were about equally effective as precursors of esterified arachidonate. The doubly labeled 11,14-eicosadienoate was metabolized primarily by conversion to 17,17,18,18-d$_4$-9,12-ocatdecadienoic acid, followed by its conversion to yield esterified arachidonate, with a mass four units greater than endogenous arachidonate. In addition, the doubly labeled substrate gave rise to a small amount of arachidonate, six mass units greater than endogenous arachidonate. No evidence was obtained, with the radiolabeled substrates, for the presence of a Δ8 desaturase. However, the presence of an ion, six mass units greater than endogenous arachidonate when doubly labeled 11,14-eicosadienoate was fed, suggests that a small amount of the substrate may have been metabolized by the sequential use of Δ8 and Δ5 desaturases.

Paper no. L8471 in *Lipids 35*, 871–879 (August 2000).

It is generally accepted that 18:3n-3 and 18:2n-6 are metabolized, respectively, to 20:5n-3 and 20:4n-6 *via* pathways requiring the sequential use of position-specific Δ6 and Δ5 desaturases. Klenk and Mohrhauer (1) and Stoffel and his colleague (2,3) presented evidence that the following twenty carbon acids could also be synthesized *via* a pathway requiring a Δ8 desaturase 9,12,15-18:3→11,14,17-20:3→8,11,14,17-20:4→5,8,11,14,17-20:5 and 9,12-18:2→11,14-20:2→8,11,14-20:3→5,8,11,14-20:4. We subsequently reported that, in liver, these pathways were not operative since 11,14-20:2; 11,14,17-20:3; and several other polyunsaturated fatty acids, with their first double bond at position 11, were only desaturated at position 5 (4,5). Subsequent studies supported the concept that a variety of tissues and cells lack a Δ8 desaturase. When [1-^{14}C]18:2n-6 (6) was injected into rat brains, it was metabolized to radioactive 20:4n-6, but small amounts of labeled 20:2n-6 were detected. When [1-^{14}C]20:2n-6 was injected, only trace amounts of labeled 20:4n-6 were detected with 5,11,14-20:3 being the major metabolite. When [3-^{14}C]11,14,17-20:3 was injected into rat brains, a complex labeling pattern was obtained since retroconversion yielded labeled 18:3n-3, which was metabolized to longer chain n-3 fatty acids *via* the pathway independent of a Δ8 desaturase (7). In addition, the substrate was desaturated to 5,11,14,17-20:4. The authors of these two studies (6,7) concluded that a Δ8 desaturase is not used to synthesize n-6 and n-3 fatty acids. When [1-^{14}C]18:3n-3 was incubated with HTC cells (8) and hepatoma cells (9), it was converted to 20:5n-3 and chain elongated to 11,14,17-20:3, which was desaturated to 5,11,14,17-20:4. All of the labeled acids could be synthesized *via* the pathway that did not require a Δ8 desaturase. Maeda *et al.* (10) compared the pathways for the biosynthesis of polyunsaturated fatty acids in a number of cell lines. Again, no evidence was found for a Δ8 desaturase, but both 5,11,14-20:3 and 5,11,14,17-20:4 were detected. Naval *et al.* (11) reported that K562 cells had negligible Δ6 activity. These cells metabolized 18:2n-6 and 18:3n-3, respectively, to 5,11,14-20:3 and 5,11,14,17-20:4, which in turn were chain elongated. If cells lack a Δ6 desaturase the synthesis of labeled 20:4n-6 and 20:5 n-3 requires a Δ8 desaturase. These two 20-carbon acids were not detected.

Although the preponderance of studies present no conclusive evidence for a Δ8 desaturase, several other studies do not support this conclusion. Most notably, studies in Coniglio's laboratory (12,13) have shown that rat and human testes convert small amounts of 11,14-20:2 to 20:4n-6, although the major product is desaturation of the substrate to 5,11,14-20:3. When microsomes from a number of cancer cells were incubated with [1-^{14}C]11,14-20:2, small amounts of a radioactive metabolite were produced having a retention time identical to methyl arachidonate. The 20:3 that was produced had a retention time identical to methyl 5,11,14-20:3, but its structure was not established by degradative techniques (14). More re-

cently, Cook *et al.* (15) and Schenck *et al.* (16) reported that when a number of deuterium-labeled acids were incubated with C16 glial cells, or fed to mice, the labeling patterns were consistent with the presence of a Δ8 desaturase.

When 5,11,14-20:3 is produced, conflicting reports exist as to whether it is (17), or is not (18) desaturated to 20:4n-6. In the study reported here, several experimental approaches were used to determine whether liver and testes express a Δ8 desaturase and the metabolic fate of 5,11,14-20:3.

MATERIALS AND METHODS

Materials. Ethyl linoleate and ethyl 11,14-eicosadienoate were obtained from Nu-Chek Prep (Elysian, MN). Both 4,7,10-nonadecatrien-1-ol and 5,11,14-eicosatriynoic acid were synthesized as previously described (19). The 4,7,10-nonadecatrien-1-ol and 10,13-nonadecadien-1-ol, made by 1-carbon chain elongation of linoleic acid, were used as the starting materials to make [1-^{14}C]-labeled 5,11,14-20:3 and 11,14-20:2 (20). Reduction of 5,11,14-eicosatriynoic acid with deuterium, using Lindlars catalyst in ethyl acetate, in the presence of quinoline, gave 5,5,11,11,14,14-d_6-5,11,14-20:3. The chemical purity of the ethyl ester, when analyzed on a 30 m × 0.25 mm i.d. DB-223 capillary column at 185°C (J & W Scientific, Folsum, CA) was 88.4%. The ethyl ester, without further purification, was used for the feeding studies. An aliquot was purified by argentation thin-layer chromatography. Following saponification, the acid was derivatized by reacting it with equal volumes of acetonitrile and *N*-methyl-*N*-(*t*-butyldimethylsilyl)trifluoracetamide at 70°C for 1 h (21). Gas chromatography–mass spectrometry (GC–MS) was carried out with a Hewlett Packard 5890 gas chromatograph, containing a 30 m × 0.25 mm i.d. HP-5 MS column and a 5972 mass selective detector (Avondale, PA). The isotopic purity, as calculated by integration of appropriate M-57 ions, was 78.6% d_6, 19.1% d_5, and 2.5% d_4. The starting material to synthesize 17,17,18,18-d_4-octadecadiynoic acid, which was reduced with Lindlars catalyst was 4,4,5,5-d_4-1-pentanol, prepared as previously described (21). The acid was then converted to 19,19,20,20-d_4-1,2-^{13}C-11,14-20:2 using a sequence of reactions previously described (20). The Na^{13}CN was obtained from Cambridge Isotopes, Andover, MA. The doubly-labeled acid had a chemical purity of 96.8% and the isotopic purity was 94.6% for the M+6 isotopomer, 3.9% for the M+5 isotopomer, and 1.0% for the M+4 isotopomer.

Injection studies. Sodium salts of labeled fatty acids (55 Ci/mol) were dissolved in a 1% solution of bovine serum albumin in isotonic saline. Male weanling rats, maintained on a fat-free diet (Dyets, Bethlehem, PA) for three months, were anesthetized with diethyl ether, and 40 μCi of each fatty acid, in 500 μL, was injected into the tail vein. Each testes was injected with 2 μCi of labeled acid in a volume of 20 μL. After 6 h, the rats were sacrificed and testes and liver lipids were extracted (22). Neutral lipids were separated from phospholipids by the sequential elution of columns packed with Unisil (Clarkson Chemical Co., Williamsport, PA), $CHCl_3$, and MeOH. Phospholipids were transesterified by reaction with 5% anhydrous HCl in MeOH for 1 h at 80°C. Methyl esters were isolated and separated by high-performance liquid chromatography (HPLC) using a 25 cm × 4.6 mm Zorbax ODS column. The column was eluted with acetonitrile/water (85:15, vol/vol) at a flow rate of 1 mL/min. The effluent was mixed with ScintiVerse LC (Fisher, Cincinnati, OH) at 3 mL/min, and radioactivity was measured with a Beckman 171 radioisotope detector (Fullerton, CA). Methyl esters were identified by comparing their retention times with purchased standards (Nu-Chek Prep.) or with compounds made by total synthesis.

Microsomal Incubations. Liver and testes were homogenized in 10 mM KH_2PO_4-0.25 M sucrose buffer, pH 7.4 at 4°C. Microsomes, prepared by differential centrifugation (23), were suspended in the homogenization buffer at 25 mg/mL of protein using the BCA protein kit (Pierce Chemical, Rockford, IL) with bovine serum albumin as a standard. Incubations were carried out with 5 mg of protein in a total volume of 1 mL in 1.5 × 12.5 cm culture tubes at 37°C in a metabolic shaker. Incubations to measure desaturase activity contained 100 mM potassium phosphate buffer (pH 7.4), 10 mM ATP, 2 mM NADH, 0.4 mM CoASH, 10 mM $MgCl_2$ and 100 μM [1-^{14}C]9,12-18:2 with a specific activity of 5 μCi/μmol. Fatty acids were bound to bovine serum albumin at a molar ratio of fatty acid/albumin of 2:1 assuming a molecular weight of 68,000 for albumin. When combined desaturation-chain elongation reactions were assayed, the incubations also contained 2 mM NADPH and 0.4 mM malonyl-CoA. All co-factors were obtained from Sigma (St. Louis, MO). Reactions were terminated by the addition of 0.25 mL of 4 N NaOH and 2.5 mL of MeOH. After 1 h at 37°C, 0.25 mL of 6 N HCl and 5 mL of $CHCl_3$ were added. The tubes were centrifuged, and the solvent from the bottom layer was removed under a stream of N_2. The lipids were transesterified and the methyl esters were analyzed by HPLC as described above.

Feeding studies and fatty acid analysis. Rats, maintained on the fat-free diet for three months, were fed 70 mg/day of one of the three ethyl esters for a period of 14 days, i.e., ethyl linoleate, ethyl 5,5,11,11,14,14-d_6-11,14-20:2, or ethyl 19,19,20,20-d_4-1,2-^{13}C-11,14-20:2. Because of a limited supply of the later compound, rats were fed 70 mg of ethyl 11,14-20:2 on days 3, 7, and 10. After the 14-d feeding period, the rats were sacrificed, the lipids were extracted, and neutral lipids were separated from phospholipids by column chromatography. Phospholipids were separated by thin-layer chromatography using Whatman LK6 plates (Fisher, Cincinnati, OH), which were developed with $CHCl_3$/MeOH/40% methylamine (60:20:5,vol/vol/vol) (24). Phospholipids were detected by spraying the plates with 0.2% (wt/vol) 2′,7′-dichlorofluorescein in ethanol and identified by using phospholipid standards purchased from Avanti (Alabaster, AL). The individual phospholipids were recovered by transferring the silica gel to screw cap tubes, followed by extraction with $CHCl_3$/MeOH/H_2O (5:5:1,vol/vol/vol). The 10 mL of extract,

obtained from two extractions, was washed by addition of 4.5 mL of $CHCl_3$ and 2 mL of H_2O. The tubes were centrifuged, the solvent from the bottom layer was removed under N_2, and the lipids were transesterified. Methyl esters were separated using a Varian 3600 gas chromatograph containing a 30 m × 0.25 mm i.d. DB-223 capillary column. Injections were made in the split mode at 185°C. After 10 min, the oven was programmed to 215°C at 3°C/min to 215°C, where it was maintained until the methyl ester of 22:6n-3 had eluted. For GC–MS, the lipids were saponified, and fatty acids were derivatized by reacting them with equal volumes of acetonitrile and *N*-methyl-*N*-(*t*-butyldimethylsilyl)trifluoracetamide. The isotopic composition was determined by monitoring appropriate M-57 ions.

RESULTS

When [1-^{14}C]-labeled 8,11,14-20:3; 5,11,14-20:3; and 11,14-20:2 were injected *via* the tail vein in duplicate experiments, between 13–15% of the injected radioactivity was recovered in total liver lipids. When the two 20-carbon trienoic acids were injected into testes, between 23–26% of the injected radioactivity was recovered in the total lipid extracts. An average of 54% of the injected radioactivity was recovered in the lipid extracts from testes after injection of [1-^{14}C]11,14-20:2. With all three substrates, and with both tissues, between 76–96% of the radioactivity was phospholipid associated.

When the methyl esters, derived from phospholipids of rats injected with [1-^{14}C]5,11,14-20:3, were separated by HPLC, no radioactive metabolites were produced by either liver (Fig. 1A) or testes (Fig. 1C). Conversely, both liver (Fig. 1B) and testes (Fig. 1D) metabolized [1-^{14}C]8,11,14-20:3 to 5,8,11,14-20:4. Both liver (Fig. 2A) and testes (Fig. 2D) metabolized [1-^{14}C]11,14-20:2 into a single metabolite. Panels B and C of Figure 2 show the HPLC radiochromatograms when [1-^{14}C]-labeled 8,11,14-20:3 and 5,11,14-20:3 were added, respectively, to the phospholipid derived methyl esters from liver. Labeled 8,11,14-20:3 eluted immediately before the metabolite (Fig. 2B), while exogenous [1-^{14}C]5,11,14-20:3 co-eluted with the metabolite (Fig. 2C). Identical results, as shown in panels E and F of Figure 2, were obtained with testes. These results show that in liver and testes 11,14-20:2 is only desaturated to yield 5,11,14-20:3.

When liver microsomes (Fig. 3A) and testes microsomes (Fig. 3D) were incubated with [1-^{14}C]11,14-20:2, a single radioactive metabolite was produced. Again, by adding radioactive [1-^{14}C]-labeled 5,11,14-20:3 and 8,11,14-20:3, it was shown that the metabolite generated by liver microsomes co-eluted with 5,11,14-20:3 (Fig. 3B) and not with 8,11,14-20:3 (Fig. 3C). Using an identical protocol, it was shown that the metabolite generated by testes microsomes co-eluted with 5,11,14-20:3 (Fig. 3E) and not 8,11,14-20:3 (Fig. 3F). The results show that liver and testes microsomes desaturate 11,14-20:2 only to 5,11,14-20:3.

Additional studies with microsomes were carried out to determine whether 5,11,14-20:3 could be produced *via* a reaction sequence starting from linoleate. As shown in Figure 4A, when [1-^{14}C]9,12-18:2 was incubated with microsomes, it was desaturated to 6,9,12-18:3 with loss of enzyme activity after about 10 min. When malonyl-CoA and reduced nicotinamide adenine dinucleotide phosphate (NADPH) were included in the incubation, only small amounts of 6,9,12-18:3 accumulated (Fig. 4A), but the substrate was also chain elongated to 11,14-20:2. By using the internal standard protocol described above, it was shown that the 20:3 was only 8,11,14-20:3. The results suggest, but do not prove, that arachidonate was only synthesized *via* the pathway requiring the sequential use of Δ6 and Δ5 desaturases. When 11,14-20:2 was incubated with microsomes, it was desaturated to 5,11,14-20:3. However, when 11,14-20:2 was produced by chain elongation of 9,12-18:2, no 5,11,14-20:3 was detected. Possibly, when 8,11,14-20:3 is produced, it is a much better substrate for desaturation at position 5 than is 11,14-20:2.

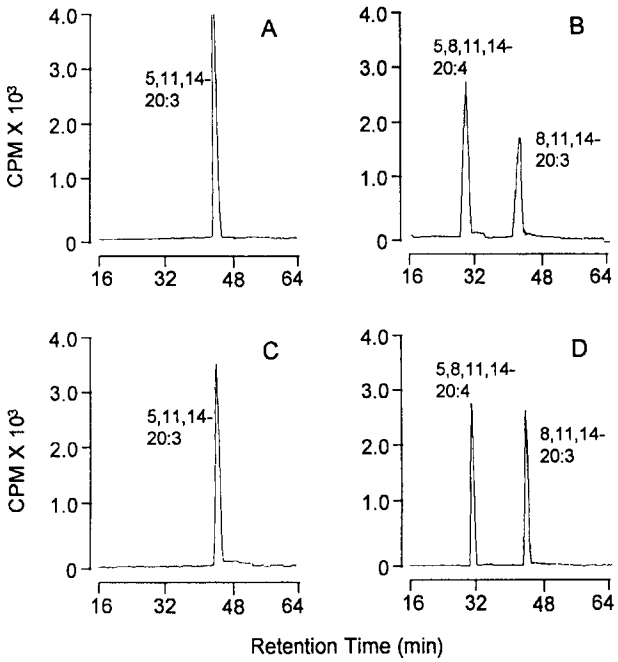

FIG. 1. High-performance liquid chromatography (HPLC) radiochromatograms of the methyl esters derived from liver phospholipids after the tail vein injections of (A) [1-^{14}C]5,11,14-20:3 and (B) [1-^{14}C]8,11,14-20:3. The bottom panels show the corresponding results from testes phospholipids obtained after the intratesticular injections, respectively, of (C) [1-^{14}C]5,11,14-20:3 and (D) [1^{14}C]8,11,14-20:3.

The data with radioactively labeled substrates presents no conclusive evidence for a Δ8 desaturase. To further define how 11,14-20:2 and 5,11,14-20:3 are metabolized, they were fed to rats. The results in Table 1 compare the fatty acid composition of liver phospholipids of rats maintained on the fat-free diet versus when they were fed one of the three experimental acids. Rats maintained on the fat-free diet had the expected high level of 20:3n-9. Two methyl esters eluted between 20:3n-9 and 20:4n-6. By using synthetic standards, it was found that 20:3n-7, a possible palmitoleate metabolite,

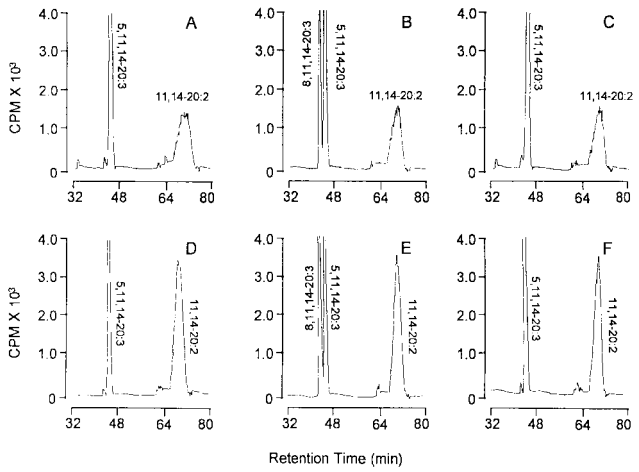

FIG. 2. HPLC radiochromatograms of the methyl esters derived from liver phospholipids after the injection of (A) [1-^{14}C]11,14-20:2 and when (B) [1-^{14}C]8,11,14-20:3 and (C) [1-^{14}C]5,11,14-20:3 were added as external standards. The bottom panels show the corresponding results of testes phospholipids after injection of (D) [1-^{14}C]11,14-20:2 and when (E) [1-^{14}C]8,11,14-20:3 and (F) [1-^{14}C]5,11,14-20:3 were added as external standards. See Figure 1 for abbreviation.

and 5,11,14-20:3 co-eluted. In a similar way, 20:3n-6 and 20:4n-7 co-eluted. These compounds, when detected, are labeled in Table 1 as possible mixtures. When 18:2n-6 was fed, the level of esterified 20:3n-9 decreased with an increase in the 20:4n-6 content.

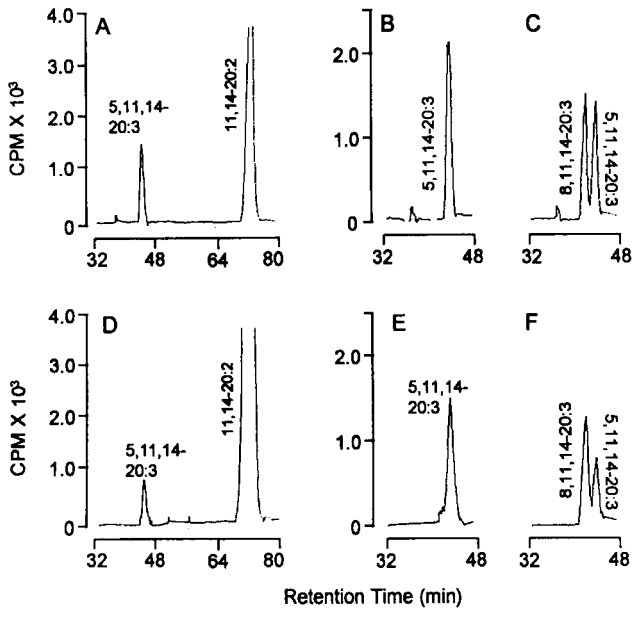

FIG. 3. HPLC radiochromatograms showing the metabolism of (A) [1-^{14}C]11,14-20:2 by liver microsomes as well as when [1-^{14}C]5,11,14-20:3 and (C) [1-^{14}C]8,11,14-20:3 were added as external standards. The bottom panels show, respectively, the metabolism of (D) [1-^{14}C]11,14-20:2 by testes microsomes as well as when exogenous (E) [1-^{14}C]5,11,14-20:3 and (F) [1-^{14}C]8,11,14-20:3 were added. See Figure 1 for abbreviation.

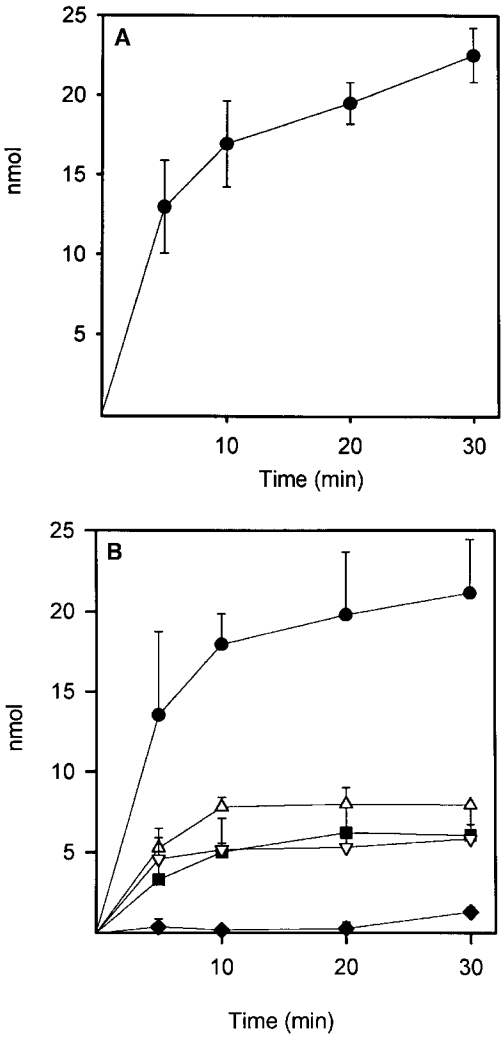

FIG. 4. (A) The metabolism of [1-^{14}C]9,12-18:2 when liver microsomes were incubated without malonyl-CoA and reduced nicotinamide adenine dinucleotide phosphate (NADPH). (B) The time-dependent metabolism of [1-^{14}C]9,12-18:2 when malonyl-CoA and NADPH were included; (●), total nmols of products; (△), 11,14-20:2; (■), 5,8,11,14-20:4; (▽), 8,11,14-20:3; and (◆), 6,9,12-18:3.

When 5,5,11,11,14,14-d$_6$-5,11,14-20:3 was fed, there was a marked decrease in the level of esterified 20:3n-9, but the level of 20:4n-6 was similar to that of the animals fed the fat-free diet. The metabolite labeled as a possible mixture of 20:3n-7:5,11,14-20:3 was isolated by HPLC and shown by GC–MS to be only the dietary acid. When 18:2n-6 and 20:4 n-6 were isolated by HPLC and analyzed by GC–MS, only the unlabeled isotopomers were detected. These *in vivo* studies agree with the radioactive data showing that, although 5,11,14-20:3 is readily incorporated into phospholipids, it is not metabolized to either 18:2n-6 or 20:4n-6. The primary role of 5,11,14-20:3 is to replace esterified 20:3n-9, but not 20:4n-6.

Small amounts of dietary 19,19,20,20-d$_4$-1,2-^{13}C-11,14-20:2 were incorporated into phospholipids, as defined both

by gas chromatography (Table 1) and isolation of this compound by HPLC and analysis by GC–MS. The levels of esterified arachidonate were similar to those when linoleate was fed. There are two possible pathways for the synthesis of 20:4n-6 from the dietary acid. First, partial β-oxidation of the substrate results in the loss of the two carbons labeled with C-13, giving rise to 17,17,18,18-d_4-9,12-18:2, which upon conversion to arachidonate, yields an isotopomer four mass units greater than unlabeled 20:4n-6. Second, sequential desaturation of the substrate, at positions 8 and 5, yields an isotopomer six mass units greater than endogenous 20:4n-6. When 18:2n-6 was isolated and analyzed by GC–MS, 76 ± 1% was unlabeled while 24.2 ± 2% contained four deuterium atoms (averages ± SEM of three rats), showing that the dietary acid was partially β-oxidized. The results in Figure 5 show select ion chromatograms of compounds formed by loss of 57 mass units from isotopomers of 20:4n-6. The top trace, at *m/z* = 361, corresponds to the loss of 57 mass units from unlabeled 20:4n-6. The second ion chromatogram at *m/z* = 362 is the M+1 isotopomer of unlabeled 20:4n-6. The third ion chromatogram at *m/z* = 365 is the ion expected for 20:4n-6 labeled with four deuterium and shows that the 17,17,18,18-d_4-9,12-18:2, formed by partial β-oxidation of the dietary acid, is converted to 20:4n-6. The ion trace at *m/z* = 366 is the M+1 isotopomer of 20:4n-6 labeled with four deuterium atoms. The ion chromatogram at *m/z* = 367, corresponds to the M+2 isotopomer of 20:4n-6 labeled with four deuterium atoms. An ion of this composition would also be produced if the substrate was directly converted to arachidonate, giving rise to an isotopomer six mass units greater than unlabeled 20:4n-6. The bottom ion chromatogram at *m/z* = 368 corresponds to the M+1 isotopomer which would be produced from arachidonate six mass units greater than unlabeled

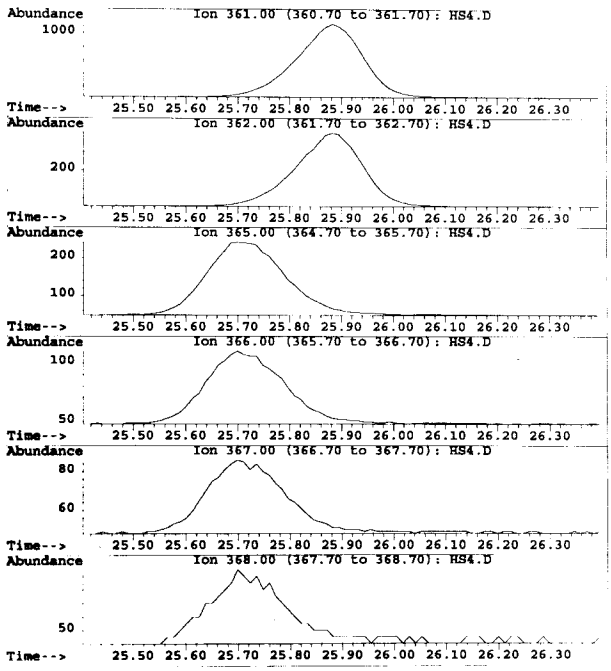

FIG. 5. Ion chromatograms obtained by loss of 57 mass units from arachidonic acid isotopomers when 19,19,20,20-1,2-^{13}C-11,14-20:2 was fed to rats. Ion traces from top to bottom are respectively; *m/z* = 361, endogenous 20:4n-6; *m/z* = 362, the M+1 isotopomer of endogenous arachidonate; *m/z* = 365, the M+4 isotopomer formed by metabolism of the substrate to d_4 linoleate and its conversion to arachidonate; *m/z* = 366 the M+1 isotopomer of d_4-labeled arachidonate; *m/z* = 367, an ion of this composition corresponds to the M+2 isotopomer from d_4-labeled arachidonic acid but it also would be the ion expected by conversion of the substrate directly to arachidonic acid; *m/z* = 368, the M+2 isotopomer expected from arachidonic acid six mass units greater than endogenous arachidonic acid.

[b]19,19,20,20,-d_4-1,2-^{13}C-11,14-20:2
[c]5,5,11,11,14,14-d_6-5,11,14-20:3.

20:4n-6. An ion of this composition would be expected if the substrate was sequentially desaturated at positions 8 and 5. The presence of the ion at *m/z* = 368, coupled with the observation that the ion at *m/z* = 367 was too intense for the M+2 isotopomer derived from d_4-20:4n-6, suggests that small amounts of 11,14-20:2 were metabolized directly to 20:4n-6. By correcting for isotopomer composition of the *m/z* = 367 ion, it was calculated that the isotopic composition of 20:4n-6 was d_0, 81.3 ± 2.7%; d_4 , 17.0 ± 2.4%; and d_6, 1.6 ± 0.3% (averages ± the SEM from three animals). These stable isotope studies suggest that a small amount of the substrate is metabolized to 20:4n-6 *via* a pathway not requiring its partial degradation 9,12-18:2.

The results in Table 2 compare the levels of 20:3n-9, 20:4n-6, and 5,11,14-20:3 in individual phospholipids versus those in total phospholipids (Table 1). There are four points to be made as it relates to this compositional data. First, in the fat-free controls, the 20:3n-9/20:4n-6 ratio differs among the four individual phospholipids. These ratios in the choline-, ethanolamine-, serine-, and inositol-containing phospholipids were, respectively, 2.1, 0.5, 0.4, and 3.3. Second, as expected, when linoleate was added to the diet there was an increase in the amount of 20:4n-6 esterified in all phospholipids, which was accompanied by a reduced level of 20:3n-9. The rank order of the 20:3n-9/20:4n-6 ratio remained the same as was found in the animals raised on the fat-free diet. Third, when 19,19,20,20-d_4-1,2-^{13}C-11,14-20:2 was added to the diet, the amount of 20:4n-6 esterified in individual phospholipids was approximately the same as when linoleate was fed. Based on the isotopic data obtained with the total phospholipids (Fig. 4), the majority of 20:4n-6 was formed by partial β-oxidation of the substrate to 19,19,20,20-d_4-18:2 n-6 followed by its metabolism to 20:4n-6. The 20:3n-9/20:4n-6 ratio in individual phospholipids was approximately the same when linoleate or labeled 20:2n-6 were fed. Indeed, as shown in Table 2, the summed amounts of 20:3n-9 plus 20:4n-6, in individual phospholipids, were approximately the same in animals raised on the fat-free diet vs. when 18:2n-6 or 20:2n-6 were fed. Finally, when 5,5,11,11,14,14-d_6-5,11,14-20:3 was fed, it was incorporated, in rather large amounts, into all four phospholipids. The primary metabolic fate of 5,11,14-20:3 was to replace esterified 20:3n-9 rather than arachidonate. As shown in Table 2, the level of esterified 20:4n-6 in the choline- and ethanolamine-containing phospholipids was about the same in the fat-free controls as when 5,11,14-20:3 was fed. Interestingly, when 5,11,14-20:3 was fed, there was a 40% decrease in the amount of 20:4n-6 esterified in the serine-containing phospholipids, which was accompanied by a 43% increase in the amount of 20:4n-6 esterified in the inositol-containing phospholipids. Since the injection experiments with [1-^{14}C]5,11,14-20:3 showed that it was not metabolized to 20:4n-6 the compositional data suggests that

there was some movement of 20:4n-6 among the phospholipids during the 14 d feeding period.

DISCUSSION

Over the years, several types of studies have contributed to the concept that position-specific desaturases are expressed. These include competitive substrate studies using microsomes (25), and feeding studies (26) using a variety of unsaturated fatty acids. Several types of cells were able to desaturate fatty acids at position 5, but not at position 6 (10,27). However, it was not until molecular techniques evolved that definitive proof was obtained to prove the presence of position specific Δ6 and Δ5 desaturases. Several groups of investigators have cloned and expressed Δ6 desaturases from animals (28–30). The gene product desaturated both linoleate and linolenate (28,29), but not 8,11,14-20:3 (29). Two groups of investigators (31,32) isolated a gene from *Caenorhabditis elegans,* and when it was expressed in yeast, it was shown that the gene product did not desaturate fatty acids at position 6, but it desaturated 8,11,14-20:3 as well as 11,14-20:2 and 11,14,17-20:3 at position 5 (32).

In the study reported here, we confirm the findings of Schlenk *et al*. (18), that 5,11,14-20:3 is not desaturated to 20:4n-6 in either liver or testes. We also confirmed our previous findings that [1-^{14}C]11,14-20:2 is only desaturated in liver to 5,11,14-20:3 (4,5). Our *in vivo* data with testes, as well as with microsomes, also show that the substrate is only desaturated at position 5. Thus, it seems likely, based on the work of Watts and Browse (32), that a single protein in rats desaturates both 8,11,14-20:3 and 11,14-20:2 at position 5.

Our findings with testes, however, are not in agreement with those reported by Albert and Coniglio (12) for rat testes or by Albert *et al.* (13) for human testes as to whether a Δ8 desaturase is expressed in rats. The reason for these discrepancies is not known. Our studies with rat testes differed only slightly from those used by Albert and Coniglio (12). They used rats maintained on a chow diet while our studies were carried out on rats raised on a diet devoid of fat. We selected the later dietary condition since it is well known that in these animals, there is considerable synthesis and esterification of 20:4n-6.

If a Δ8 desaturase is expressed, it is a matter of conjecture when it is used to make polyunsaturated fatty acids. The most conclusive evidence for the presence of this activity is observed when acids, with their first double bond at position 11, are used as substrates (12,13,15,16). In the study reported here, the labeling pattern of 20:4n-6, when 19,19,20,20-d_4-1,2-^{13}C-11,14-20:2 was fed, is consistent with the direct conversion of small amounts of the substrate directly to 20:4n-6. The rationale for using the doubly labeled substrate was that after one cycle of β-oxidation it would yield 17,17,18,18-d_4-9,12-18:2, which upon metabolism to 20:4n-6 would yield the M+4 isotopomer of 20:4n-6. This was the major pathway by which the substrate was metabolized. The possibility exists that when acetate, labeled with C-13 was produced, it was reutilized. If this labeled acetate was used to chain elongate 17,17,18,18-d_4-6,9,12-18:3 when it was produced from 17,17,18,18-d_4-9,12-18:2, a M+6 isotopomer of 20:4n-6 could be produced by the pathway independent of a Δ8 desaturase. Although we cannot rule out this possibility, it seems highly unlikely since M+2 isotopomers of other fatty acids were not detected.

It is very difficult to design experiments to conclusively demonstrate that a Δ8 desaturase is, or is not, used when the initial substrate is either linoleate or linolenate. When linoleate is used as a substrate, both 6,9,12-18:3 and 8,11,14-20:3 are obligatory intermediates in the synthesis of arachidonate, *via* the pathway that is independent of a Δ8 desaturase. When the Δ8 desaturase is required, 11,14-20:2 and 8,11,14-20:3 are obligatory intermediates. None of these intermediates accumulate in large amounts in tissue lipids. When [3-^{14}C]-labeled 11,14-20:2, 11,14,17-20:3, or stable isotopes of these two acids are used as substrates, their primary metabolic fate is one cycle of β-oxidation to yield linoleate and linolenate, which may then be metabolized *via* the Δ8 desaturase independent pathway (4,5,7,15,16). If 11,14-20:2 is synthesized *in vivo,* under normal physiological conditions, what is its metabolic fate, i.e., desaturation at position 8, or partial β-oxidation to yield linoleate? Interestingly, when Bridges and Coniglio (33) studied the metabolism of [1-^{14}C]9,12-18:2 to longer chain n-6 polyunsaturated fatty acids in testes, no labeled 11,14-20:2 was detected. Their studies (12), like ours, present no evidence for the presence of a hepatic Δ8 desaturase. Then, is there any condition when it might be advantageous for cells to express a Δ8 desaturase? If cells were devoid of Δ6 desaturase activity, the expression of a Δ8 desaturase would provide an optional way to synthesize 20:4n-6 and 20:5n-3. Naval *et al.* (11) reported that K562 leukemic cells lack a Δ6 desaturase, but they metabolized linoleate to 5,11,14-20:3 and linolenate to 5,11,14,17-20:4, a finding which would not be expected if the cells express a Δ8 desaturase. Recently, Wallis and Browse (34) reported the isolation of a Δ8 desaturase from *Euglena gracilis* with a high degree of homology with Δ6 and Δ5 desaturases isolated from *Caenhorabditis elegans*. A conclusive answer as to whether mammals do or do not express a Δ8 desaturase may well require the molecular techniques, which have just recently been used as they relate to defining the number and specificities of other acyl-CoA-dependent desaturases.

In these studies, the addition of linoleate to the diet resulted as expected, in a decrease in the level of esterified 20:3n-9 accompanied by an increased level of esterified 20:4n-6 in all phospholipids. Both the synthesis of 20:4n-6 from 18:2n-6, as well as its use as a substrate for phospholipid biosynthesis, are processes localized primarily in the endoplasmic reticulum (35,36). Although the 20:3n-9/20:4n-6 ratio varied among phospholipids, the addition of labeled 11,14-20:2 to the diet resulted in an increase in the level of esterified 20:4n-6 in all phospholipids, similar to what was observed when linoleate was fed. The primary pathway of 11,14-20:2 metabolism was partial β-oxidation to yield

linoleate. Based on studies with 22- and 24-carbon n-3 and n-6 polyunsaturated fatty acid, the degradation of 11,14-20:2 to linoleate takes place in peroxisomes (37,38). Since the levels of esterified 20:4n-6 were similar when 18:2n-6 and 11,14-20:2 were fed, the findings imply that when 18:2n-6 is produced from 11,14-20:2 in peroxisomes, it preferentially moves to the endoplasmic reticulum for use in fatty acid and phospholipid biosynthesis, rather than continued peroxisomal degradation.

Interestingly 5,11,14-20:3 was metabolized quite differently than was 11,14-20:2. The structures of 5,8,11-20:3; 5,8,11,14-20:4; and 5,11,14-20:3 are similar. The sole anabolic fate of dietary 5,11,14-20:3, when fed to animals raised on a fat-free diet, was direct esterification and in this regard it replaced 5,8,11-20:3 and not arachidonate. Labeled linoleate or arachidonate were not produced from the 5,5,11,11,14,14-d_6-5,11,14-20:3. Two pathways exist in both peroxisomes and mitochondria for degrading fatty acids with their first double bond at position 5 (39). With 5,11,14-20:3 as substrate, the pathway using only the enzymes of saturated fatty acid degradation, yields 3,9,12-18:3 after one cycle of degradation. The pathway using $\Delta^{3,5}$-$\Delta^{2,4}$-dienoyl-CoA isomerase and NADPH-dependent 2,4-dienoyl-CoA isomerase would convert 5,11,14-20:3 to 9,12-18:2 after one cycle of β-oxidation. Both of these enzymes have been purified from peroxisomes (40,41). Failure to detect labeled 18:2n-6 or 20:4n-6 suggests that the pathway using these two enzymes was of marginal significance. Conflicting reports exist in the literature as to the relative roles of these two pathways in the mitochondrial degradation of fatty acids with their first double bond at position 5 (42,43). Our results may be explained in two possible ways. First, if 5,11,14-20:3 is primarily degraded by mitochondria, *via* either pathway, it would probably be completely degraded without the accumulation of intermediates (39). Alternatively, if peroxisomes are the primary intracellular site for degradation, most likely the first cycle of β-oxidation used only the enzymes of saturated fatty acid degradation so that labeled 18:2n-6 was not produced.

ABSTRACT: A mutant of the red microalga *Porphyridium cruentum* was selected on the basis of impaired growth at suboptimal temperatures (15 vs. 25°C). Fatty acid and lipid analyses revealed diminished proportions of eicosapentaenoic acid (from 41 to 30%) and of the eukaryotic molecular species (from 38 to 28% of monogalactosyldiacylglycerol (MGDG) and elevated proportion (10 vs. 2%) of triacylglycerols (TAG) in the mutant, as compared with the wild type. Pulse labeling of the wild type cells with radioactive fatty acid precursors indicated an initial incorporation of the fatty acids into phosphatidylcholine (PC) and TAG. Following the pulse, the label of PC and TAG decreased with time (from 25 to 5% of the total dpm in TAG) while that of chloroplastic polar lipids, mainly MGDG, continued to increase. In the mutant, however, the labeling of TAG after the pulse was higher (30% of the total dpm) than that of the wild type and decreased only slightly to 20%. This may indicate that in *P. cruentum*, TAG can contribute to the biosynthesis of eukaryotic species of MGDG.

Paper no. L8444 in *Lipids 35*, 881–889 (August 2000).

The complex biosynthetic pathways leading to the formation of the polyunsaturated fatty acid (PUFA) 18:3n-3 in higher plants' leaf lipids were reviewed by Browse and Somerville (1). The model consists of a prokaryotic pathway and a eukaryotic pathway. In the former, the fatty acids, which are synthesized *de novo* in plastids, are used as building blocks for the production of chloroplastic lipids. These lipids are characterized by the presence of a C_{16} acyl group at the *sn*-2 position of the glycerol moiety of the lipid. In the eukaryotic pathway, acyl, groups, which are synthesized *de novo* in the chloroplast, are exported from the chloroplast to the cytoplasm and incorporated into phospholipids. After desaturation, most of the diacylglycerol (DAG) moieties of the phospholipids are transported back into the chloroplast to be galactosylated and further desaturated (1). These galactolipids typically contain a C_{18} acyl group at their *sn*-2 position. DAG can also be acylated in the cytoplasm at their *sn*-3 position by a diacylglycerolacyltransferase (DAGAT) to produce (TAG). It is generally accepted that this reaction is not reversible and that TAG are end products that do not participate in any known pathway of fatty acid or lipid metabolism (1).

Although PUFA of leaf lipids and many algae contain 16 or 18 carbon atoms, some algae are unique in producing PUFA with longer carbon chains, such as 20:4n-6 [arachidonic acid (AA)], 20:5n-3 [eicosapentaenoic acid, (EPA)], and 22:6n-3 [docosahexaenoic acid, (DHA)]. The biosynthetic pathways leading to the production of 18:3n-3 in algae are believed to be similar to those suggested for higher plants (2). However, the biosynthesis of C_{20} and C_{22} PUFA from C_{18} fatty acids in algae is still rather obscure (3,4). Following our study of EPA biosynthesis in *Porphyridium cruentum* (5), one of its promising sources (5,6), we recently proposed (7,8) several possible pathways leading to the biosynthesis of EPA in *P. cruentum*. In the major, n-6 pathway (Scheme 1), 18:2-bound phosphatidylcholine (PC) is converted to 20:4n-6-PC by a sequence of reactions that includes a Δ6 desaturation, an elongation step, and a Δ5 desaturation. In the minor n-3 pathway (not shown), first 18:2-PC is apparently desaturated to 18:3n-3-PC, which is further converted to 20:5n-3-PC, presumably by the same enzymes involved in the n-6 pathway. The products of both pathways are exported, as their DAG constituents, to the chloroplast to be galactosylated into the respective monogalactosyldiacylglycerol (MGDG) molecular species. Apparently, 20:4n-6 is also imported from an extrachloroplastic lipid and inserted into the *sn*-1 position to form 20:4/16:0 MGDG, which is structurally analogous to prokaryotic species of higher plants' galactolipids. The source of 20:4 for prokaryotic lipids and its mode of transfer from the cyto-

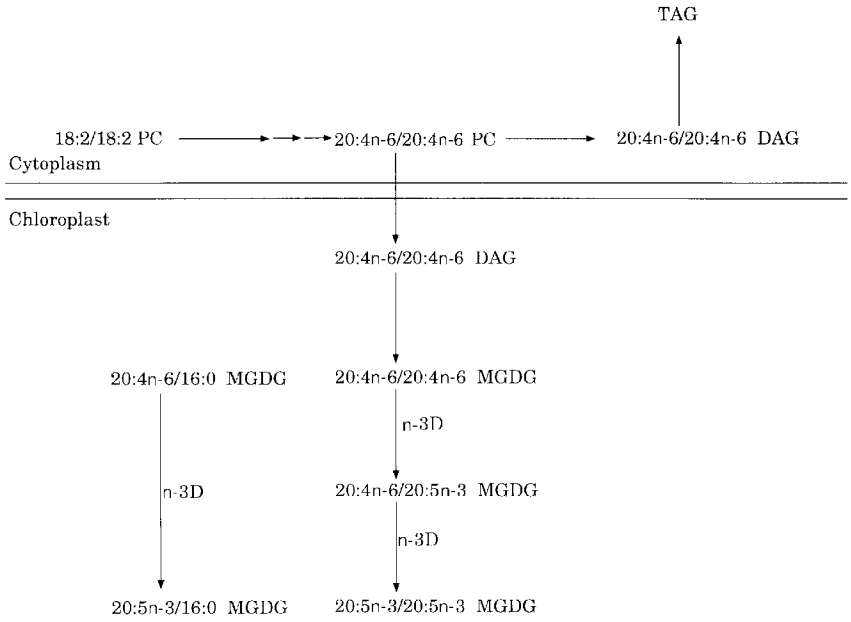
Abbreviations: AA, arachidonic acid; C_n fatty acid, fatty acid with *n* carbon atoms; DAG, diacylglycerol; DAGAT, diacylglycerol acyltransferase; DGDG, digalactosyldiacylglycerol; EPA, eicosapentaenoic acid (20:5n-3); MGDG, monogalactosyldiacylglycerol; PC, phosphatidylcholine; PUFA, polyunsaturated fatty acid; TAG, triacylglycerol; WT, wild type; X:Y, a fatty acyl group containing X carbon atoms and Y double bonds (*cis*). Pairs of numbers representing the fatty acids, when separated by a slash, designate the components in the *sn*-1 and *sn*-2 positions, respectively, of the molecular species.



SCHEME 1

plasm to the chloroplast still are not clear. The 20:4n-6 in both eukaryotic and prokaryotic molecular species of MGDG can be further desaturated to EPA by a chloroplastic n-3 desaturase (8).

Elucidation of the biosynthesis of PUFA in higher plants was made possible by the use of mutants of *Arabidopsis thaliana,* deficient in various steps of the biosynthesis (1). Similar mutants could be very valuable tools in the elucidation of biosynthetic pathways of long-chain PUFA in algae. Indeed, using a mutant deficient in EPA production, Schneider *et al.* (9) pointed to the existence of an extrachloroplastic Δ17 desaturase in *Nannochloropsis*. Wada *et al.* (10) showed that PUFA are necessary for growth and tolerance to photoinhibition in cyanobacteria at low temperatures. Based on the assumption that in *P. cruentum* EPA fulfills a role similar to that of 18:3n-3 in cyanobacteria and *Arabidopsis* (11), we employed the strategy utilized by Wada and Murata (12) to select for chill-sensitive mutants of *P. cruentum.* We anticipated that some mutants deficient in EPA biosynthesis could be found. Indeed, we describe here the successful selection of an EPA-deficient mutant of *P. cruentum* that is sensitive to low temperature and provides some biochemical characterization. Based on the data we have obtained, we suggest that TAG participate in the eukaryotic pathway of EPA biosynthesis in *P. cruentum*. Furthermore, HZ3 is the first described mutant of a higher or lower plant, that appears to be deficient in the ability to utilize TAG for lipid biosynthesis.

MATERIALS AND METHODS

Organism and Culture Conditions. Porphyridium cruentum strain 1380.1d was obtained from the Göttingen Algal Culture Collection (Göttingen, Germany) and was grown on Jones' medium (13) as previously described (11) in Erlenmeyer flasks under an air/CO_2 (99:1) atmosphere at 25°C, unless otherwise stated. The flasks were placed in an incubator shaker and illuminated from above at a light intensity of 115 μmol quanta m^{-2} s^{-1}. Cultures were grown exponentially (with proper dilution) for at least 4 d prior to the onset of the experiment.

Selection of mutants. Cultures of *P. cruentum* in the logarithmic phase of growth ($1.4 \cdot 10^7$ cells mL^{-1}) were treated with 1-methyl-3-nitro-1-nitroso guanidine at a final concentration of 25 μg mL^{-1}) for 30 min. This concentration of the mutagen caused less than 5% survival. The surviving cells were plated on solid medium at a density that resulted in about 200 colonies per 90 × 15 mm plate. Then they were incubated at 25°C for 15 d. The surviving colonies were then plated onto two plates using toothpicks and incubated at 25 and 15°C, respectively. Colonies that failed to show appreciable growth at 15°C as compared to wild type (WT) cells were scored and inoculated into a small volume of liquid medium in test tubes and incubated at 25°C. When the cultures of the putative chill-sensitive lines reached comparable density, as judged by observation, the low-temperature screening was repeated by streaking equal volumes of the scored cultures on sectors of two plates side by side with aliquots of WT cultures treated similarly. One of the plates was incubated at 25°C and the other at 15°C. Cell lines that were inhibited at 15°C as compared to the WT were scored again and the screening was repeated once more.

Pulse label experiments. Ammonium salts of (1-^{14}C)AA (5 μCi, specific activity 58 mCi/mmol) (Amersham, Little Chalfont, United Kingdom), (1-^{14}C)linoleic acid (25 μCi, specific activity 53 mCi/mmol), and (1-^{14}C) α-linolenic acid (25 μCi, specific activity 53 mCi/mmol) (NEN Research

Products, Mississauga, Ontario, Canada) were used in this work. Cultures were pulse-labeled for 30 min, centrifuged, washed twice with label-free medium, resuspended in one-half of the original volume, and cultivated as previously described (11). Aliquots were taken at various times after the end of the pulse. Experiments were repeated three times. The data in the figures depict the average of duplicate analyses in a representative experiment.

Nitrogen starvation. Cultures were resuspended in nitrate-free medium for 3 d. Ferric ammonium citrate was substituted with ferric citrate. After 2 d of nitrogen starvation, the cultures were labeled for 24 h with 5 μCi [1-^{14}C]AA and resuspended in label-free control medium. Labeling of lipids and their fatty acids was determined at various times.

Lipid extraction and analysis. Lipids were extracted using the procedure of Bligh and Dyer (14). Fatty acid methyl esters of total and individual lipids were obtained by transmethylation with 2% sulfuric acid in methanol. Fatty acid methyl esters were separated by reversed-phase high-performance liquid chromatography (HPLC) on an RP-18, 5 μm (250 mm, Lichrospher 100; Merck, Darmstadt, Germany) column using a solvent system of methanol/acetonitrile/water, 76:12:12 (by vol), detected at 205 nm, and identified using authentic standards. Radioactivity of individual peaks was determined by a Flo-One\Beta series A-100 detector (Radiomatic Instruments and Chemical Co., Inc., Tampa, FL). Distribution of radioactivity among individual lipids was assessed by thin-layer chromatography (TLC) on 10 × 10 cm plates (Silica Gel 60, 0.25 mm thickness, Macherey-Nagel, Duren, Germany). Two-dimensional separations of polar lipids were carried out using a solvent system of chloroform/methanol/water, 65:25:4 (by vol) for the first direction and chloroform/methanol/1-ethylpropylamine/concentrated ammonia, 65:35:0.5:5 (by vol) for the second direction. To estimate distribution of label in neutral lipids, aliquots of total lipid extracts were separated by TLC using a solvent system of petroleum ether/diethyl ether/acetic acid, 80:20:1 (by vol). Lipids were visualized by brief exposure to I_2 vapors. Radioactivity was detected by autoradiography with x-ray films (X-OMAT AR; Kodak, Rochester, NY) exposed to the TLC plates for 17 h. Lipid spots were scraped directly into scintillation vials containing 1 mL of methanol, a scintillation cocktail was added, and radioactivity was measured in a liquid scintillation counter (Rackbeta LKB, model 1217; Wallac Oy, Turku, Finland). MGDG and digalactosyldiacylglycerol (DGDG) extracted from the silica gel plates were separated to the constituent molecular species by reverse-phase HPLC (column as mentioned above) with a solvent mixture of methanol/water, 95:5 (vol/vol) (15) on a Waters (Millipore, Milford, MA) chromatograph, equipped with ultraviolet and radioactivity detectors.

RESULTS

Selection of mutants and growth characteristics. By comparing the growth of putative mutants of *P. cruentum* on agar plates at 15 and 25°C to that of the WT, we were able to select a series of mutants defective in growth at low temperatures. We chose the HZ3 mutant for further studies. The growth characteristics of the mutant and the WT at two temperatures are summarized in Figure 1. The growth of the mutant line at 15°C and at the optimal growth temperature of 25°C was severely inhibited. At 30°C however, inhibition of the mutant line could be observed only when cultures of low density biomass were compared, whereas at higher density, mutant cultures attained a final cell concentration similar to that of the WT cultures (data not shown).

Lipid and fatty acid composition. The proportion of TAG in the HZ3 mutant increased from 2 (in the WT) to 10% (of total fatty acids) with MGDG decreasing from 37 to 32% (Table 1). The proportion of EPA decreased from 41% (of total fatty acids) in the WT to 30% in the mutant, while the proportions of 16:0, 18:2, 18:3n-6 and 20:4n-6 increased (Table 1). The most affected lipids in the mutant were TAG, where the proportion of EPA decreased from 17 to 5%, and MGDG, with a decrease from 63 to 47%. In *P. cruentum*, the molecular species of DGDG and sulfoquinousyl diacylglycerol (SQDG) are almost entirely of prokaryotic structure, i.e., they contain C_{20} (or C_{18}) and C_{16} fatty acids in the *sn*-1 and *sn*-2 positions, respectively, while those of MGDG are partly eukaryotic and contain C_{20} fatty acids in both positions. Since MGDG was predominantly affected by the mutation, we suspected that only the synthesis of eukaryotic species was impaired. Therefore, separated MGDG and DGDG into their constituent molecular species. Indeed, the proportion of the major eukaryotic molecular species of MGDG, 20:5/20:5, decreased while that of the prokaryotic species 18:2/16:0, 20:4/16:0, and 20:5/16:0 increased (Table 2). The composition of DGDG, however, was not significantly changed. We have interpreted this as an indication that the mutation affected the eukaryotic pathway.

Incorporation of exogenously supplied radiolabeled fatty acids. Using exogenously supplied radiolabeled fatty acids, we

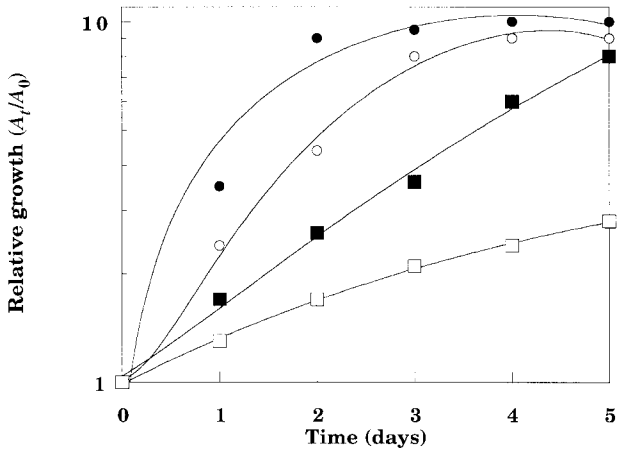


FIG. 1. Growth (expressed as chlorophyll concentration relative to day 0) of wild type (filled symbols) and HZ3 mutant (open symbols) of *Porphyridium cruentum* cultivated at 25 (circles) and 15°C (squares) and at a light intensity of 100 μmol quanta m^{-2} sec^{-1}.

[a]The data shown represent mean values with a range of less than 5% for major peaks (over 10% of fatty acids) and 15% for minor peaks, of three independent samples, each analyzed in duplicate.
[b]Sum of two isomers. In PG 16:1Δ3*t* constituted 36.5 and 35.5% of fatty acids in WT and HZ3, respectively. Abbreviations: WT, wild type; MGDG, monogalactosyldiacylglycerol; DGDG, dialactosyldiacylglycerol; SQDG, sulfoquinovosyldiacylglycerol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PA, phosphatidic acid; TAG, triacylglycerol.

recently showed (8) that 18:2 is converted to EPA through a major n-6 and a minor n-3 (not shown) pathway in *P. cruentum* (Scheme 1). Thus, to obtain more insight into the biosynthesis of EPA in the mutant, WT and mutant cells were pulse-labeled with [^{14}C]18:2n-6 or [^{14}C]20:4n-6 and the redistribution of label in the lipids and fatty acids was followed.

Incorporation of [1-^{14}C]linoleic acid. Immediately after the pulse of [^{14}C]18:2, most of the label in both the WT and the HZ3 mutant was in PC and TAG (Fig. 2A,B). Total counts did not change significantly in both cases. In the WT, the label in the lipids decreased with time in favor of chloroplastic lipids (Fig. 2C,D). While the label of PC in the mutant decreased in time in a similar pattern to that of the WT, the extent of label in TAG was relatively stable and decreased much more slowly over a period of 22 h (Fig. 2). In TAG of the WT, most of the radioactivity coming from 18:2 disappeared after 22 h, whereas in the mutant, the decrease was much milder (Fig. 3). Radiolabeled 20:4n-6, which appeared after 4 h, accumulated faster in the mutant than in the WT. In MGDG of the mutant, 18:2 was more highly labeled, whereas 20:4 and 20:5 were less than in the WT (Fig. 4).

In comparison to the WT the molecular species analysis of MGDG of the mutant revealed a delay in the accumulation of radioactivity and eventually a decrease in all eukaryotic species, (Fig. 5). The proportion of the labeled prokaryotic species 20:4n-6/16:0 and 20:5n-3/16:0 was similar to that of the WT while that of 18:2/16:0 increased.

We also labeled the WT and the mutant with [1-^{14}C]18:3n-3. The label pattern was rather similar to that obtained following the incorporation of radioactive 18:2 (data not shown).

Incorporation of [1-^{14}C]arachidonic acid (AA). At the end of the pulse, PC of the WT was the most highly labeled lipid,

TABLE 2
Molecular Species Composition of Galactolipids of Wild Type and HZ3 Mutant of *P. cruentum*[a]

		Molecular species composition (% of total)					
Culture	Lipid	20:5/20:5	20:4/20:5	20:4/20:4	20:5/16:0	20:4/16:0	18:2/16:0

HZ3	MGDG	22.6	2.2	tr	55.9	2.8	16.5
WT	DGDG	tr	—	—	94.2	0.7	5.1
HZ3	DGDG	tr	—	—	94.6	1.6	3.8

[a]Galactolipids were isolated by 2D thin-layer chromatography. Molecular species of galactolipids were separated by reversed phase high-performance liquid chromatography as detailed in the Materials and Methods section and are arranged in the order of their elution. The data shown represent mean values with a range of less than 10% for major peaks of three independent samples. See Table 1 for abbreviations.

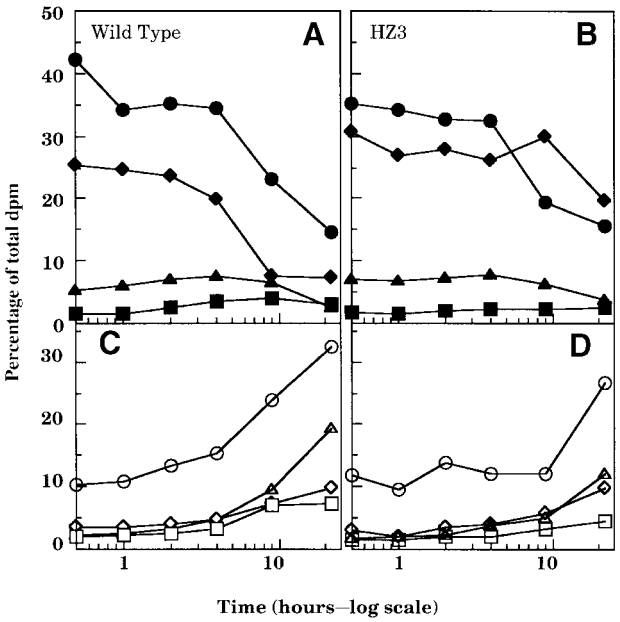

FIG. 2. Redistribution of radioactivity in lipids of wild type and HZ3 mutant of *P. cruentum* after labeling with 25 μCi of [1-^{14}C]linoleic acid. Lipids were separated by two-dimensional thin-layer chromatography, ●, phosphatidylcholine (PC); ◆, triacylglycerol (TAG); ■, phosphatidylethanolamine (PE); ▲, phosphatidylinositol (PI); ○, monogalactosyldiacylglycerol (MGDG); △, digalactosyldiacylglycerol (DGDG); ◇, sulfoquinovosyldiacylglycerol (SQDG); □, phosphatidylglycerol (PG).

accounting for 76% of total radioactivity, while TAG constituted only 9% (Fig. 7). Gradually, the label in these lipids decreased to 15 and 1%, respectively. In the mutant, the label of PC was slightly less at the end of the pulse, but much higher after 22 h (22 vs. 15%). The label of mutant TAG was higher than that of the WT throughout the time course and showed very little decrease. Chloroplastic lipids of the mutant were more highly labeled in the first 2 h, in comparison to the WT, but less labeled after 22 h. In the mutant, the fatty acid composition of total lipids and MGDG showed a decrease in the conversion of 20:4n-6 to 20:5 (data not shown).

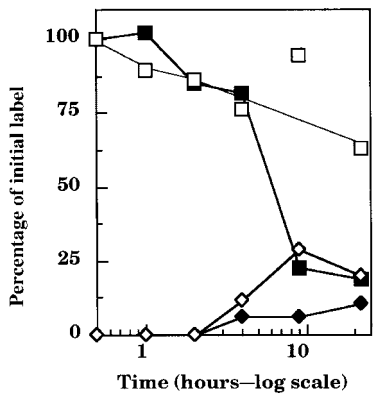

FIG. 3. Redistribution of radioactivity in fatty acids of TAG of wild type (filled symbols) and HZ3 mutant (open symbols) after labeling with [1-^{14}C]linoleic acid. Data presented as percentage of initial label. Fatty acids were determined by radio-high-performance liquid chromatography, ■, 18:2; ◆, 20:4n-6. For abbreviation see Figure 2.

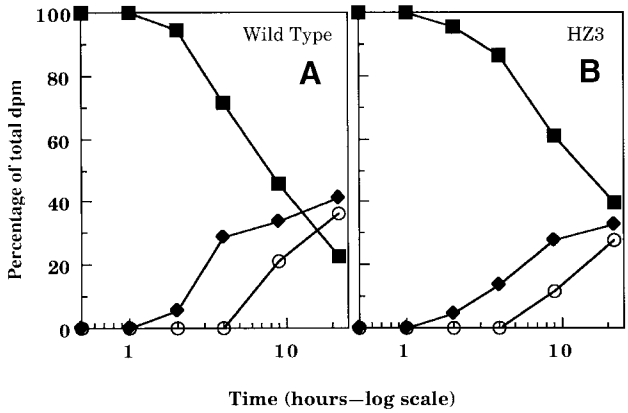

FIG. 4. Redistribution of radioactivity in fatty acids of MGDG of wild type and mutant after labeling with [1-^{14}C]linoleic acid. ■, 18:2; ◆, 20:4n-6, ○, 20:5n-3. For abbreviation, see Figure 2.

Recovery from nitrogen starvation. Under nitrogen starvation, cells of *P. cruentum* accumulate TAG (16). Thus, to evaluate the extent of the involvement of TAG in the biosynthesis of eukaryotic MGDG, we studied growth resumption following recovery from nitrogen starvation. When nitrogen is replenished, growth is resumed and chloroplastic lipids, especially eukaryotic MGDG, are actively produced (16,17). AA was used for labeling since it is one of the major fatty acids of TAG, especially under nitrogen starvation. Furthermore, the acyl moieties exported from the cytoplasm are predominantly C_{20} fatty acids, AA and EPA. We resuspended cultures of WT and HZ3 *P. cruentum* in nitrogen-free medium and kept them in this medium for 3 d. Two d after the medium change, the cultures were labeled with [1-^{14}C]AA for 24 h, as

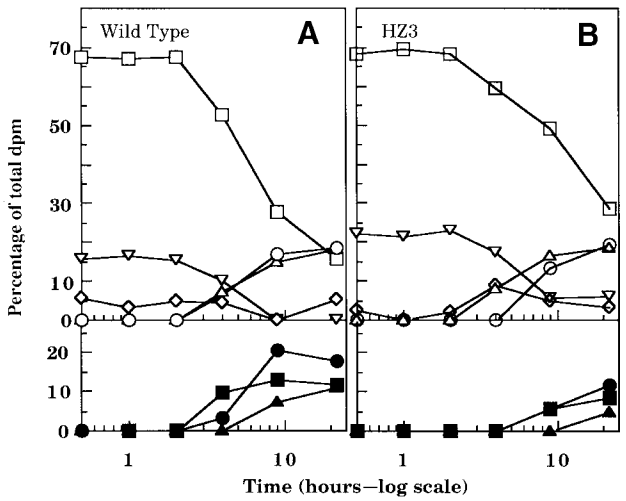

FIG. 5. Redistribution of radioactivity in molecular species of MGDG of wild type and HZ3 mutant after labeling with [1-^{14}C]linoleic acid. □, 18:2/16:0; ○, 20:4/16:0; ▽, 20:4/18:2; △, 20:5/16:0; ◇, 20:5/18:2; ■, 20:4/20:4; ●, 20:4/20:5; ▲, 20:5/20:5. See Figure 2 for abbreviation.

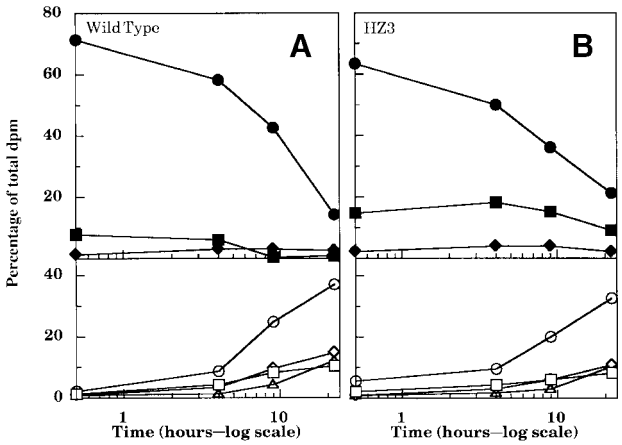

FIG. 6. Redistribution of radioactivity in lipids of wild type and HZ3 mutant *P. cruentum* after labeling with 10 μCi [1-^{14}C]20:4n-6. ●, PC; ◆, TAG; ■, PE; ○, MGDG; △, DGDG; ◇, SQDG; □, PG. See Figure 2 for abbreviations.

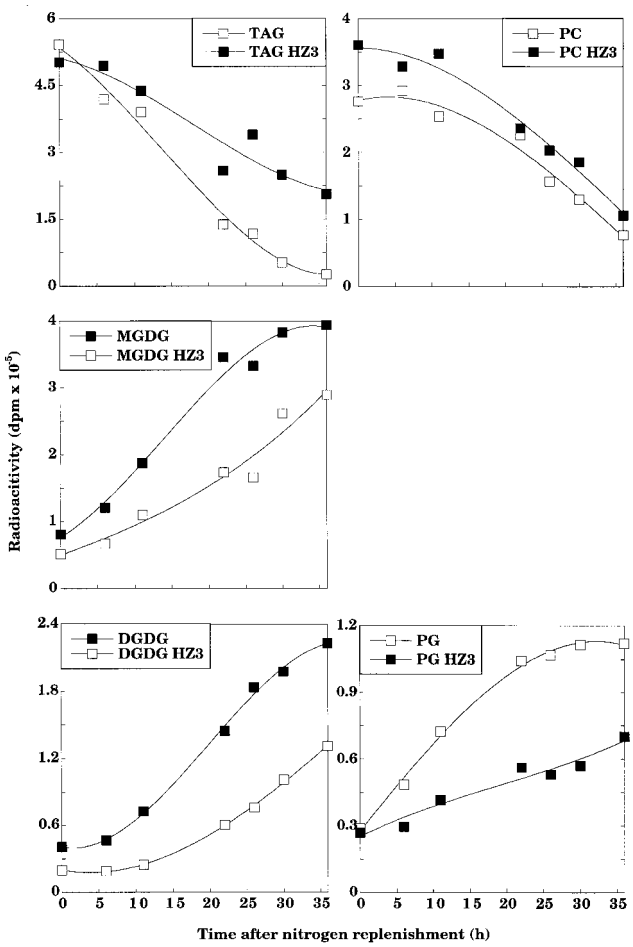

FIG. 7. Transfer of radioactivity from cytoplasmic (TAG and PC) to chloroplastic (MGDG, DGDG, and PG) lipids in wild type and HZ3 mutant *P. cruentum* following recovery from nitrogen starvation and labeling with 5 μCi [1-^{14}C]20:4n-6. See Figure 2 for abbreviations.

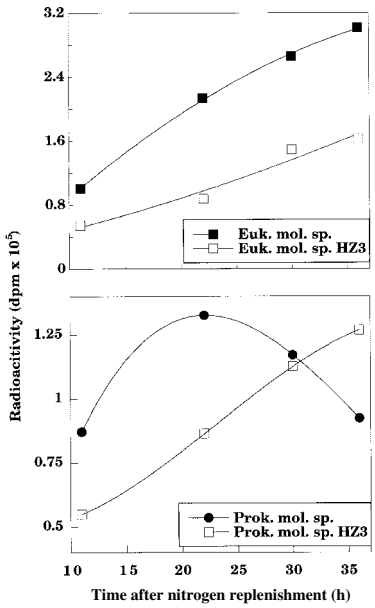

FIG. 8. Increase in label of prokaryotic (prok.) and eukaryotic (euk.) molecular species (mol. sp.) of MGDG in wild type and HZ3 mutant *P. cruentum* following recovery from nitrogen starvation and labeling with 5 μCi [1-^{14}C]20:4n-6. See Figure 2 for abbreviation.

preliminary studies have shown that after that period, TAG were already maximally labeled. Following the pulse, there were no significant differences between the level of radioactivity incorporated into the WT and the mutant, or in the distribution of the label between cytoplasmic and chloroplastic lipids (Figs. 7,8). However, with time, the label in the cytoplasmic lipids of the WT declined faster than that of the mutant, while that of the chloroplastic lipids increased to a greater extent in the WT compared to the mutant. After 36 h, WT cytoplasmic lipids retained only 15% of total counts in comparison to 40% in the mutant (data not shown). While PC of both cultures lost about 70% of their label, WT TAG lost 95% of its original label in comparison to only 59% in the mutant (Fig. 7). Molecular species analysis of MGDG showed that, whereas the prokaryotic species (20:4n-6/16:0 and 20:5n-3/16:0) were similarly labeled throughout the time course, there were large differences in the labeling of the eukaryotic species. Labeling of all the eukaryotic species (20:4n-6/20:4n-6, 20:4n-6/20:5n-3, 20:5n-3/18:2, and mostly 20:5n-3/20:5n-3) of the mutant was about half of the WT (Fig. 8).

DISCUSSION

C_{18} PUFA contribute to chill tolerance in higher plants (18) and cyanobacteria (19). In *P. cruentum*, the proportion of the main PUFA, EPA, increases in MGDG, its major depot, from 10% at 30°C to 51% at 20°C (17). This is reflected in an enhancement in the proportion of the ultimate eukaryotic molecular species, 20:5/20:5, from 6 to 40%. Furthermore, we have shown that the proportion of EPA at each temperature is

correlated with growth rate (11). We have thus hypothesized that the comparison of the growth rates at optimal and low temperatures would be a tool for the isolation of mutants of *P. cruentum* deficient in EPA content. Indeed, we were able to select such mutants. One of these mutants, HZ3, displayed the most severe growth impairment at reduced temperatures (Fig. 1) and was selected for further studies. The lipid and fatty acid analysis of the HZ3 mutant indicated a reduced level of eukaryotic molecular species of MGDG, which could be the consequence of a deficiency in the eukaryotic pathway. The reduced growth rate at 15°C (Fig. 1) of the HZ3 mutant and the low level of EPA, suggest that this fatty acid may have a role in the growth of microalgae at lower temperatures. However, further studies are required in order to exclude the possibility that the inhibition of growth and the impairment of lipid metabolism are not the result of a pleiotropic effect of a single mutation or the result of two or more independent mutations.

The labeling experiments with each of the different radioactive fatty acids revealed that mutant TAG accumulated a higher percentage of the initial label and were severely limited in turning over the label in comparison to the WT. One may argue that the higher TAG content of the HZ3 mutant represents a larger pool size, which is responsible for the delay in the turnover of the label. However, some decrease would have been expected in the first h after the pulse, but there was no decrease whatsoever in the label of mutant TAG for the first 10 h (Figs. 2,6). Under nitrogen starvation, the TAG content was similar in the WT and the mutant, and yet the same differences were observed (Fig. 7). That the disappearance of label from PC in the mutant was similar to that of the WT indicates that any contribution of DAG moieties of PC to the eukaryotic pathway is not impaired. We interpret our *in vivo* radiolabeling studies as showing that, in addition to PC, there is a notable contribution of TAG to the synthesis of chloroplastic lipids of *P. cruentum*. Possibly, the mutant is deficient in its ability to mobilize DAG (or acyl) moieties from TAG for the production of eukaryotic molecular species of MGDG. In oilseeds, which accumulate PUFA, TAG share a common DAG pool with phospholipids, primarily with PC. The conversion of DAG to TAG in oil-accumulating tissues is generally considered to be unidirectional (1) and TAGs are regarded metabolically as end-products that are used only as an energy store. However, Garces *et al.* (20) showed that when the growth temperature of developing sunflower seeds is reduced, the oleate acyl groups of TAG are superseded by linoleates. Recently, Stobart *et al.* (21) obtained evidence that supports a transacylation mechanism that can account for the TAG turnover in microsomal membranes of developing safflower seeds.

Nevertheless, we cannot exclude the possibility that the genetic lesion occurred in a different site that is responsible for the production of a component requiring high levels of eukaryotic MGDG. In the mutant, lower levels of this component would require lower levels of eukaryotic MGDG, resulting in a down regulation of the contribution of TAG to the production of these molecular species.

Under nitrogen starvation, much of the acyl flux of *P. cruentum* is diverted from the production of chloroplastic lipids, predominantly eukaryotic MGDG, to the accumulation of TAG (16). Replenishing the nitrogen to the algal cells results in a quick return to exponential growth. This, in turn, requires the synthesis of new chloroplastic membranes. The massive transfer of label from TAG to eukaryotic MGDG supports our hypothesis that C_{20} PUFA deposited in TAG of *P. cruentum* can be utilized as a reservoir for the swift production of eukaryotic MGDG when necessary.

Algal TAG are generally characterized by saturated and monounsaturated fatty acids, thought to serve as storage material (22). These characteristics seem to be common to most algal species studied for their potential to produce C_{20} PUFA. The TAG of the eustigmatophyte *Nannochloropsis*, an EPA producer, contains mainly 14:0, 16:0, and 16:1 (23). Similar findings were reported for other EPA-producing algae such as *Monodus subterraneus* (24) and *Phaeodactylum tricornutum* (25). Likewise, the TAGs of the DHA-rich cryptomonad *Chroomonas salina* (26) are almost entirely made of C_{18} fatty acids. However, certain algae are able to produce TAG rich in EPA and AA, e.g., *Ectocarpus fasciculatus* (27), *Pavlova lutheri* (28), *Nitzschia frigida,* and *Melosira antartica* (29). A high content of AA in TAG appears to be a feature of many, if not all, rhodophytes. Thus, the proportion of AA in TAG was reported to be 36% in *Chondrus crispus*, 49% in *Polysiphonia lanosa* (30), 40 to 64% in various *Gracilaria* sp. (31), and 33% in *P. cruentum* (as well as 17% EPA) (11). The ability of *P. cruentum* to utilize its TAG may explain the unique fatty acid composition of these lipids. However, it remains to be seen whether other microalgae having PUFA-rich TAG are able to utilize their TAG for similar purposes.

At present, we have no data to support any hypothesis concerning the mechanism by which the reutilization of TAG may take place. Nonetheless, several possibilities can be considered: i) a transacylation of monoacylglycerol by TAG to produce two molecules of DAG (21); (ii) a lipase activity that hydrolyzes TAG to DAG; and (iii) a DAGAT activity that is also capable of operating in the reverse direction. However, in the case of the latter, one would have expected a lower than normal level of TAG since this enzyme is likely to affect the incorporation of label into TAG, not just its turnover.

In higher plants, especially in *Arabidopsis*, mutants deficient in the production of either the prokaryotic or the eukaryotic molecular species of chloroplastic lipids demonstrated normal behavior at normal or low temperatures. Furthermore, it was shown that these mutants were able to ameliorate the damage to their membranes by adjusting the fatty acid flux leading to the prokaryotic and the eukaryotic pathways (32). In higher plants, the ultimate prokaryotic molecular species of MGDG, 18:3/16:3, differs from the eukaryotic species, 18:3/18:3, by only two carbon atoms. We speculate that for this reason, prokaryotic and eukaryotic molecular species of MGDG of higher plants are, to a certain extent, interchangeable. In *P. cruentum,* however, the eukaryotic molecular species, 20:5/20:5, contain four more carbon atoms and five more double bonds than the prokaryotic species, 20:5/16:0.

P. cruentum is found mainly in shallow marshes where temperature fluctuations are rapid and more pronounced than in deeper water bodies. The increase in the proportion of EPA in MGDG at low temperatures, and especially in that of the eukaryotic component of MGDG, 20:5/20:5, could possibly be attributed to the organism's attempt to cope with the stress inflicted by sudden drops in temperature. However, the *de novo* synthesis of EPA is apparently not fast enough to accommodate the increased demand for EPA. When *P. cruentum* was labeled with radioactive acetate, labeled EPA appeared only after 10 h (data not shown, see also Fig. 4). We hypothesize that TAG can be utilized as a buffering system for 20:4- and 20:5-containing DAG, which can be mobilized relatively rapidly for the production of eukaryotic molecular species of the major chloroplastic lipid MGDG. The role of these PUFA is not just maintenance of membrane fluidity. In various algae, enhanced n-3 desaturation was shown to be correlated with the activity of photosystem I (33). This hypothesis is supported by the work of Wanner and Kost (34) who found that rapid formation of cellular membranes from lipid bodies of different intracellular localization (cytoplasmic oil bodies and chloroplastic plastoglobules) has been observed during regeneration of starved cells of *P. cruentum*.
