REVIEW

General Characteristics of *Pinus* spp. Seed Fatty Acid Compositions, and Importance of Δ5-Olefinic Acids in the Taxonomy and Phylogeny of the Genus

Robert L. Wolff[a,]*, Frédérique Pédrono[a], Elodie Pasquier[a], and Anne M. Marpeau[b]

[a]ISTAB and [b]LCSV, Institut du Pin, Université Bordeaux 1, Talence, France

ABSTRACT: The Δ5-unsaturated polymethylene-interrupted fatty acid (Δ5-UPIFA) contents and profiles of gymnosperm seeds are useful chemometric data for the taxonomy and phylogeny of that division, and these acids may also have some biomedical or nutritional applications. We recapitulate here all data available on pine (*Pinus*; the largest genus in the family Pinaceae) seed fatty acid (SFA) compositions, including 28 unpublished compositions. This overview encompasses 76 species, subspecies, and varieties, which is approximately one-half of all extant pines officially recognized at these taxon levels. Qualitatively, the SFA from all pine species analyzed so far are identical. The genus *Pinus* is coherently united—but this qualitative feature can be extended to the whole family Pinaceae—by the presence of Δ5-UPIFA with C_{18} [taxoleic (5,9-18:2) and pinolenic (5,9,12-18:3) acids] and C_{20} chains [5,11-20:2, and sciadonic (5,11,14-20:3) acids]. Not a single pine species was found so far with any of these acids missing. Linoleic acid is almost always, except in a few cases, the prominent SFA, in the range 40–60% of total fatty acids. The second habitual SFA is oleic acid, from 12 to 30%. Exceptions, however, occur, particularly in the *Cembroides* subsection, where oleic acid reaches *ca.* 45%, a value higher than that of linoleic acid. α-Linolenic acid, on the other hand, is a minor constituent of pine SFA, almost always less than 1%, but that would reach 2.7% in one species (*P. merkusii*). The sum of saturated acids [16:0 (major) and 18:0 (minor) acids principally] is most often less than 10% of total SFA, and *anteiso*-17:0 acid is present in all species in amounts up to 0.3%. Regarding C_{18} Δ5-UPIFA, taxoleic acid reaches a maximum of 4.5% of total SFA, whereas pinolenic acid varies from 0.1 to 25.3%. The very minor coniferonic (5,9,12,15-18:4) acid is less than 0.2% in all species. The C_{20} elongation product of pinolenic acid, bishomo-pinolenic (7,11,14-20:3) acid, is a frequent though minor SFA constituent (maximum, 0.7%). When considering C_{20} Δ5-UPIFA, a difference is noted between the subgenera *Strobus* and *Pinus*. In the former subgenus, 5,11-20:2 and sciadonic acids are ≤0.3 and ≤1.9%, respectively, whereas in the latter subgenus, they are most often ≥0.3 and ≥2.0%, respectively. The highest values for 5,11-20:2 and sciadonic acids are 0.5% (many species) and 7.0% (*P. pinaster*). The 5,11,14,17-20:4 (juniperonic) acid is present occasionally in trace amounts. The highest level of total Δ5-UPIFA is 30–31% (*P. sylvestris*), and the lowest level is 0.6% (*P. monophylla*). Uniting as well as discriminating features that may complement the knowledge about the taxonomy and phylogeny of pines are emphasized.

Paper no. L8356 in *Lipids 35,* 1–22 (January 2000).

The Coniferophytinae (the conifers, in the broadest sense) is the largest and most diverse subdivision of living gymnosperms. They include two classes, Ginkgoatae and Pinatae. The first class is limited to a single extant family, Ginkgoaceae, with only one living representative, *Ginkgo biloba*. The second class encompasses 8–9 families, Taxaceae and Cephalotaxaceae (the limits between these two families are uncertain), Phyllocladaceae, Podocarpaceae, Araucariaceae, Sciadopityaceae, Cupressaceae, Taxodiaceae (distinction of these families appears artificial and only the family Cupressaceae, including Taxodiaceae, should be recognized), and Pinaceae (1). The latter family is the most important group of conifers in the Northern Hemisphere when considering its phytogeographical distribution, its biomass, its number of species, and its economical importance.

The family Pinaceae contains a total of 11 accepted genera: *Abies*, *Cathaya*, *Cedrus*, *Keteleeria*, *Larix*, *Nothotsuga*, *Picea*, *Pinus*, *Pseudolarix*, *Pseudotsuga*, and *Tsuga*. A twelfth genus, *Hesperopeuce*, has been suggested recently (2). Among these genera, *Pinus* is the largest and most heteromorphic genus, almost exclusively distributed in the Northern Hemisphere (one exception, *P. merkusii*, is known to cross the equator in northern Sumatra). This genus is ecologically versatile, "ranging from the tundra line in Eurasia to tropical coastal savannas in Nicaragua and from the salt spray zone of the Pacific coast to the alpine tree line in Europe and western U.S.A." (2). Some species are also broadly distributed in semiarid regions (e.g., southwestern United States and Mexico).

Morphologists, anatomists, physiologists, embryologists, paleobotanists, biochemists, and more recently, molecular biologists, have tried for almost one century and still continue to try to understand the phylogenetic interrelationships in conifers, because they are the most prominent components of

Abbreviations: *anteiso*-17:0, 14-methylhexadecanoic; FAME, fatty acid methyl ester; GLC, gas–liquid chromatography; SFA seed fatty acid; UPIFA, unsaturated polymethylene-interrupted fatty acid.

the extant flora, with a very long history and particularly rich fossil record, beginning in pre-Permian time (3). Most of the essential features of the modern *Pinus* cone had evolved by the Early Cretaceous period (130 million yr), with a significant history of the family Pinaceae prior to the Late Triassic period (180 million yr) (4). As we were involved in the systematic study of conifer and, more generally, gymnosperm seed fatty acid (SFA) compositions, essentially for nutritional applications, we noted that these data could be of some use as new, original, and supplementary chemometric markers for the taxonomy of this plant division (5–7).

Conifer SFA contain a series of constituents that were considered until recently as "unusual" (8), or as presenting an unusual structure, the Δ5-unsaturated polymethylene-interrupted fatty acids (Δ5-UPIFA), that have been shown in the meantime not only to be common constituents of seed oils from all Coniferophyte families but also to be characteristic of some Cycadophyte families (9), and likely of great antiquity on a geological time scale [estimated 300 million yr (9)]. In gymnosperms (Coniferophytes and Cycadophytes), Δ5-UPIFA have the following structures: 5,9-18:2 (taxoleic); 5,11-18:2 (ephedrenic); 5,9,12-18:3 (pinolenic); 5,9,12,15-18:4 (coniferonic); 5,11-20:1; 5,11,14-20:3 (sciadonic); and 5,11,14,17-20:4 (juniperonic) acids, all ethylenic bonds being in the *cis* configuration. In addition to seeds, these fatty acids also occur in the leaf and wood lipids of Coniferophytes and likely of some Cycadophytes (10). Considering the importance of gymnosperms, and particularly of conifers in the land plant biomass, it was recently observed that one or two of these Δ5-UPIFA, i.e., sciadonic and juniperonic acids, are probably the most abundant C_{20} polyunsaturated acids in land plants (10).

The chemical structures of Δ5-UPIFA have been repeatedly established since the 1960s through more or less complicated analytical procedures, and recently by gas–liquid chromatography (GLC) coupled with mass spectrometry of the easily prepared picolinyl ester and 4,4-dimethyloxazoline derivatives (9,11–14). Also, ^{13}C nuclear magnetic resonance spectroscopy allowed confirmation of GLC data regarding the total Δ5-UPIFA content of many gymnosperm seed oils (9,13,15,16).

The positions of ethylenic bonds along the hydrocarbon chains and the number of carbon atoms in Δ5-UPIFA have allowed construction of possible biosynthetic pathways of these acids (9,14,17,18). Briefly, individual Δ5-UPIFA fall inside the classical n-9, n-6, and n-3 series [except for the rare 5,11-18:2 (ephedrenic) acid (9,12), likely derived from palmitoleic acid *via cis*-vaccenic acid and thus belonging to the n-7 series], being possibly synthesized by Δ5-desaturation of oleic, linoleic, or α-linolenic acids, or by Δ5-desaturation of their elongation products (11-20:1, 11,14-20:2, or 11,14,17-20:3 acids, respectively). Only one elongation product of Δ5-UPIFA has been characterized so far, the 7,11,14-20:3 (bishomopinolenic) acid, which is apparently restricted to species of the Pinaceae family (19).

In this study, a compilation of data available on pine SFA is made, including 28 unpublished pine SFA compositions corresponding mainly to *Pinus* species that were not screened earlier for their seed Δ5-UPIFA content, or for which only partial data were available. This allows conclusions to be drawn on general features of the quantitative distribution of Δ5-UPIFA and other constituent SFA in this genus. The purpose of the present overview is not to propose another classification that would only add to the sufficiently confusing literature on this topic. We merely wish, when possible, to emphasize some features that unite a given group or that significantly distinguish a species or a group of species from others.

Another purpose of this study is to help find sources of individual Δ5-UPIFA, some of which are considered to have potential biomedical or nutritional applications or to be efficient tools to study lipid metabolism in animal experiments (20–31).

EXPERIMENTAL PROCEDURES

Seeds, oil extraction, and fatty acid methyl ester (FAME) preparation. Most pine seeds were purchased from Lawyer Nursery, Inc. (Plains, MT), F.W. Schuhmacher Co., Inc. (Sandwich, MA), and Sandeman Seeds (Pulborough, Great Britain). *Pinus sylvestris* seeds from different French orchards and indigenous stands were kindly donated by Vilmorin S.A. (La Ménitré, France). *Pinus pinaster* seeds were taken from three important lots of seeds collected in the Landes (southwest of France) for reforestation purposes and kindly donated by D'a Noste S.A.R.L. (Vendays-Montalivet, France). Seeds were kept at 4°C until used. Lipid extraction, always performed starting with 10-g samples taken from 20 ± 5 g of powdered seeds, and FAME preparation were performed as described in detail elsewhere for other gymnosperm seeds (5–7). All FAME preparations were done in duplicate, and each preparation was analyzed at least once by GLC. Generally, FAME were prepared within 24 h after lipid extraction and immediately analyzed, thus alleviating the use of antioxidants that may give rise to artifacts during methylation.

Analytical GLC. FAME were analyzed in a Carlo Erba 4130 chromatograph (Carlo Erba, Milano, Italy) equipped with a DB-Wax column (30 m × 0.32 mm i.d., 0.5 µm film; J&W Scientific, Folsom, CA). The oven temperature was 190°C, and the inlet pressure of the carrier gas (helium) was 140 kPa (*ca.* 30 m/min at the outlet). Occasionally, to confirm some identifications, a CP-Sil 88 column (50 m × 0.25 mm i.d., 0.2 µm film; Chrompack, Middelburg, The Netherlands) was operated with temperature programming in a Carlo Erba HRGC chromatograph from 150 to 185°C at 4°C/min with H_2 at 100 kPa. The injector (split mode) and flame-ionization detector were maintained at 250°C for both columns. Quantitative data were calculated by an SP 4290 integrator (Spectra Physics, San Jose, CA).

Identification of FAME peaks. The seed lipids from selected conifer species (11) were used as a source of Δ5-olefinic acid methyl esters with known structures to identify

fatty acids from pine seed lipids by GLC, either by coinjection, comparison of the equivalent chain lengths (DB-Wax column), or retention times (CP-Sil 88 column).

RESULTS AND DISCUSSION

Comments on the GLC analysis of Δ5-UPIFA and other fatty acids. The structures, as well as the formulas and trivial names of Δ5-UPIFA, are given in Figure 1. To date, no Δ5-monoenoic acids, such as those found in some rare angiosperms (32), have been detected in Pinaceae seeds, at least under routine analytical conditions. On columns coated with a polyethylene-glycol stationary phase (e.g., DB-Wax), as well as on more polar columns (e.g., CP-Sil 88, or Silar 5), these monoenes elute earlier than the corresponding Δ9-isomers, with a good resolution (32,33; Wolff, R.L., unpublished data). Among gymnosperms, however, a 5-18:1 isomer was tentatively identified in *Ephedra sinica* dried stalks (33), but this could not be confirmed in *Ephedra* spp. seed lipids (9). On the other hand, ephedrenic acid is a rather abundant fatty acid only in *G. biloba* (12) and *Ephedra* spp. (9) seeds, apparently associated with high levels of *cis*-vaccenic (11-18:1) acid. In most studies reported here, this dienoic acid may have been masked by taxoleic acid, from which it is poorly resolved on polyethylene glycol-coated columns (9,12). However, taxoleic and ephedrenic acids are fully separated on the CP-Sil 88 and Silar 5 capillary columns. Because no authors reported on this acid in Pinaceae and because the *cis*-vaccenic acid percentage is always low in this family, it is inferred that if present in *Pinus* seeds, ephedrenic acid can only reach trace levels. Otherwise, as illustrated in Figure 2, all fatty acids reported here, including Δ5-UPIFA, are base-line resolved. A minor exception is *cis*-vaccenic acid, not completely resolved from the isomeric oleic acid.

Juniperonic acid does not seem to occur in any significant amounts in *Pinus* SFA when total, neutral, or polar (33) lipids are analyzed. Minor amounts (<0.1%) of this fatty acid would however occur in some instances. Finally, no arachidonic or eicosapentaenoic acids, recently characterized in the seeds of a few species of the Araucariaceae family (14), were observed in pine seed lipids. It should however be noted that arachidonic acid was reported [cited in Ref. 34 (original paper in Russian)] to be present in the cambium zone of *L. sibirica* (Siberian larch) that belongs to another genus of the Pinaceae family.

The minor 14:0 and 15:0 acids, visible in Figure 2, are not reported individually in the present study and are included in the category "others" in the tables. On the other hand, the *anteiso*-17:0 (14-methylhexadecanoic) and 17:1 acids (likely the Δ9 isomer) are included in this study. These acids may correspond respectively to the 16:2n-6 and 16:3n-3 acids tentatively identified by Takagi and Itabashi (33) in several gymnosperm seeds. In conifer leaves, *anteiso*-17:0, 17:1, 16:2n-6, and 16:3n-3 acids occur together, along with the additional *trans*-3 16:1 acid (35; Pasquier, E., Destaillats, F., and Wolff, R.L., unpublished observations). Although *anteiso*-17:0 acid was unambiguously characterized by mass spectrometry in pine seed lipids (36), it cannot be excluded that trace amounts of 16:2n-6 and 16:3n-3 acids may coelute with *anteiso*-17:0

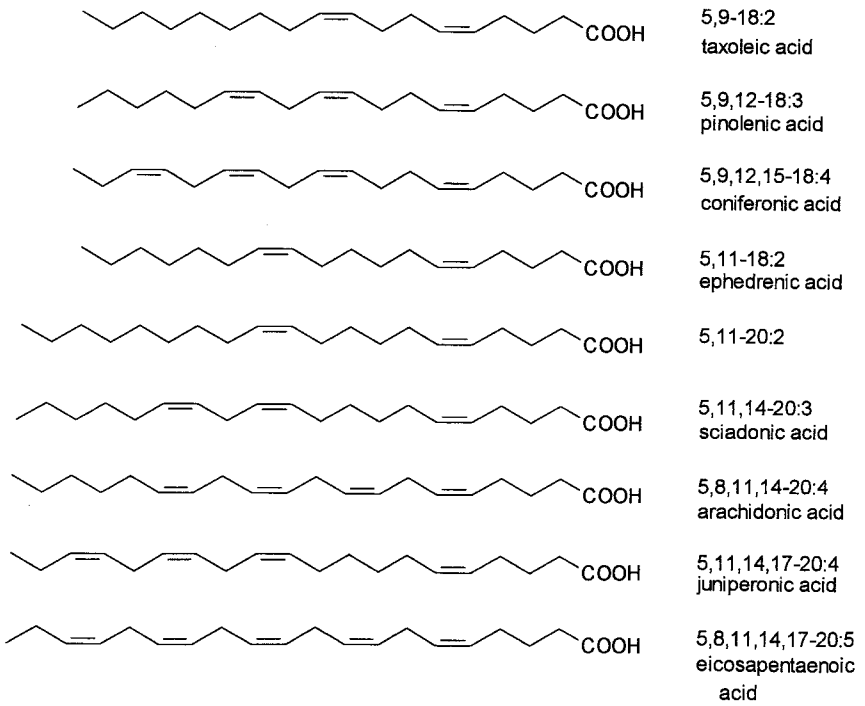

FIG. 1. Δ5-Unsaturated polymethylene- and methylene-interrupted fatty acids that may occur in the seed lipids from gymnosperms, and their trivial names. Generally, not all fatty acids occur together in a given species.

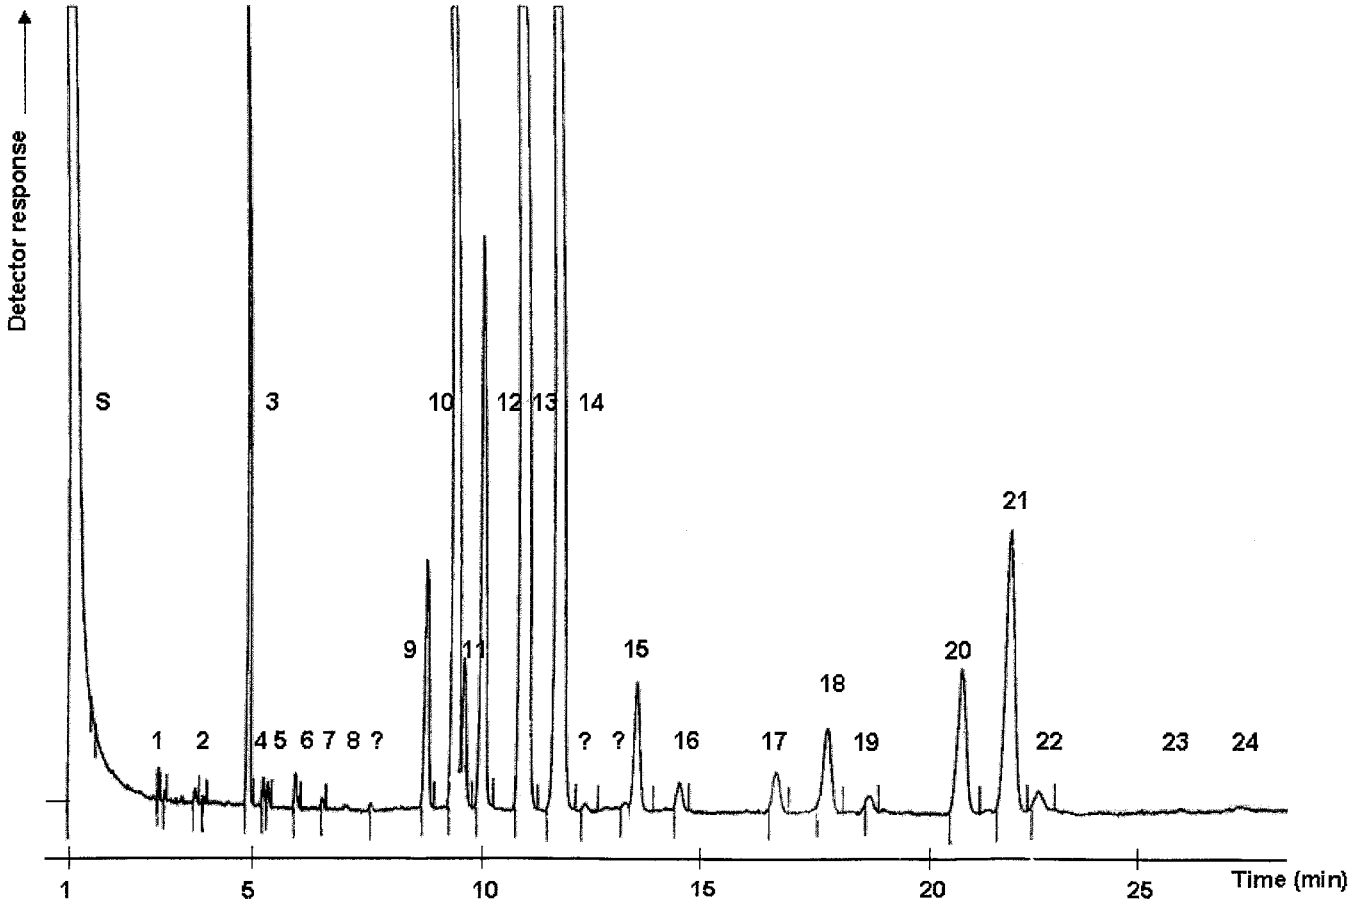

FIG. 2. Typical gas–liquid chromatogram of fatty acid methyl esters prepared from the seed lipids of *Pinus resinosa* and analyzed on a polyethylene glycol-coated capillary column (30 m) at 190°C (carrier gas, He, at 140 kPa). Identification of peaks: S, solvent (hexane); **1**, 14:0; **2**, 15:0; **3**, 16:0; **4**, 7-16:1; **5**, 9-16:1; **6**, *anteiso*-17:0; **7**, 17:0; **8**, 17:1; **9**, 18:0; **10**, 9-18:1; **11**, 11-18:1; **12**, 5,9-18:2; **13**, 9,12-18:2; **14**, 5,9,12-18:3; **15**, 9,12,15-18:3; **16**, 5,9,12,15-18:4; **17**, 20:0; **18**, 11-20:1; **19**, 5,11-20:2; **20**, 11,14-20:2; **21**, 5,11,14-20:3; **22**, 7,11,14-20:3; **23**, 11,14,17-20:3; **24**, 5,11,14,17-20:4 acids. Peaks with a question mark are unidentified; 22:0 acid, not shown, starts eluting at 30.7 min.

and 17:1 acids, respectively, owing to their similar GLC behavior. Some minor unidentified peaks with constant retention times, in amounts apparently species-dependent, occasionally appear on chromatograms between pinolenic and α-linolenic acid methyl esters (Fig. 2). No polyunsaturated C_{22} acids have been reported in pine seed lipids.

Remarks on Pinus *classification*. Only the basic division of pines at the subgenera level, *Strobus* (*Haploxylon*, or soft or white pines) and *Pinus* (*Diploxylon*, or hard pines), is widely accepted. Subdivisions of these subgenera into sections and subsections, and taxonomic ranking at the species, subspecies, or variety levels, as employed here (Table 1), may not appear satisfactory, as they are rather controversial and still disputed (37–43). DNA- and RNA-based investigations (44–46), though themselves having limitations, will certainly help in clarifying this situation. Regarding the nomenclature of the species employed here, it is important to quote A. Farjon's estimate (2) for the ratio of accepted names/synonyms/uncertain names at the species rank and below in the genus *Pinus*: 157/1071/27. For the sole species *P. sylvestris*, the most widespread pine species in Eurasia and possibly in the world, almost 150 variants have been described (47), of which only three are "officially" recognized as varieties (2). Within the polymorphic *P. mugo* complex (48), alternately known as *P. montana* (39), of more limited geographical distribution than *P. sylvestris*, the situation is equally complicated, with sometimes as many as four infraspecific taxa recognized, not to mention hybrids with *P. sylvestris* and nothotaxa (48). However, a study of the seed oil from *P. sylvestris* from 10 distinct locations in France (Marpeau, A.M., and Wolff, R.L., unpublished data), compared to similar data for Finland (49), showed that variations in the fatty acid percentages most often affect figures at the first decimal place, with little or no statistical significance. This observation would indicate that visible morphological differences will hardly affect the SFA composition within variants of a given species. With few exceptions, data in Table 1 (6,7,18,33,49–58) do not refer to infraspecific taxa because of obvious difficulties in getting information from tree-seed sellers, or correctly identifying infraspecific taxa.

SFA compositions in the Strobus *subgenus*. This subgenus encompasses two sections, *Strobus* and *Parrya* (Tables 2–4).

[a]The classification adopted here is essentially that suggested by Little and Critchfield (37). For both subgenera *Strobus* (soft pines) and *Pinus* (hard pines), other classifications have been proposed [*cf.* Debazac (38), Mirov (39), Critchfield (40), Klaus (41), or Farjon and Styles (42)]. However, molecular phylogeny of the *Pinus* genus will likely still modify these classifications (43–45). Subspecies (ssp.) or varieties (var.) (spontaneous, horticultural, geographical) are not systematically reported here. On the other hand, some species reported as such may be hybrids (hyb.), and ill-defined species may as well be described under two different names. However, synonyms were tentatively excluded, or grouped under a single accepted name where possible according to Farjon's *World Checklist and Bibliography of Conifers* (2). A few exceptions are for different spellings or names still most often used. Some uncertainties, however, still remain, owing to the lack of author references in the seed-sellers' price lists.

[b]The bulk of species mentioned in the table are from a compilation of descriptions in References 2, 37, 38, and 39 (156, *ca*. 110, 94, and 92 species described, respectively, including nothospecies, subspecies, etc.).

[c]Trivial names are mainly those given by Little and Critchfield (37), Mirov (39), and secondarily by Debazac (38), and those used by U.S. tree-seed sellers (in particular, Lawyer Nursery, Inc., Plains, MT, and F.W. Schuhmacher Co., Inc., Sandwich, MA).

[d]Reference 57 is a review on *P. koraiensis* seed oil fatty acids, including references not cited here.

[e]Seed fatty acid compositions not yet described and not available from the tree-seed sellers known by the authors.

[f]Seeds available from tree-seed sellers, for which the fatty acid composition has not been established in detail, or not at all (L, Lawyer Nursery, Inc.; S, Sandeman Seeds, Pulborough, United Kingdom).

[g]This part of the table lists some species mentioned in the literature, or available from tree-seed sellers, that the authors could not classify correctly (see text however).

Within the *Strobus* section, only the *Flexiles* subsection appears as quite distinct from the two other subsections, *Strobi* and *Cembrae*. *Pinus flexilis* (unknown variety) has a significantly higher level of oleic acid (34.9%) than any other species of the same section (≤27.3%), counterbalanced by the lowest taxoleic (0.3% vs. ≥1.5%) and pinolenic (1.6% vs. ≥7.7%) acid percentages. We will not discuss here the significance of that observation, because the status of species retained here in the *Flexiles* subsection (Table 1) is variously treated to relate to *P. strobiformis*, *P. armandii*, and *P. albicaulis*. Though the latter species has not yet been analyzed for its SFA, data for the former two species show completely different Δ5-UPIFA profiles (Table 2), and indeed, the completely original status of *P. flexilis* could justify maintaining the *Flexiles* subsection as distinct from both subsections *Strobi* and *Cembrae*. The single component that allows distinction of all species of a given subsection as compared to the other subsection is the level of sciadonic acid, being ≤1.1% in the *Cembrae* subsection and ≥1.3% in the *Strobi* subsection, except possibly in a variety of *P. parviflora*, reported as *P. pentaphylla*, and in *P. lambertiana*, 1.1%. However, *P. lambertiana* appears atypical regarding its level of total Δ5-UPIFA: 10.9%, instead of 17.5–29.7% as in other species of subsections *Strobi* and *Cembrae*. Incidentally, one should note the remarkable similitude of results for *P. parviflora* and *P. pentaphylla* (a variety, or synonym of *P. parviflora*) (Table 2), despite the fact that they were established with seeds from different origins, and by different authors using different analytical procedures, at about 15 years' interval. The same holds true for *P. armandii* SFA compositions, which indicate that each pine species has a constant SFA omposition, a prerequisite for its use as chemometric markers.

Within the *Cembrae* section, it should be pointed out that *P. cembra* and *P. sibirica* are two closely related species in spite of their geographical separation (Alps and Carpathians, and Siberia, respectively). Indeed, these two species can hardly be distinguished, or not at all, if one considers their SFA compositions, which are nearly identical (Table 3). However, their turpentine chemical compositions would considerably differ (39). *Pinus pumila* is a dwarf species diversely regarded as related to either *P. sibirica* (38,39) or *P. parviflora*

[d]Sum of Δ5-olefinic acids, including the 7,11,14-20:3 acid.
[e]Minor and unidentified components.
[f]Not detected or not reported.
[g]Trace amounts.
[h]Isomers not given separately.

(59). Its geographical distribution is indeed intermediate between those of the latter two species (roughly, from eastern Siberia to Japan). In many respects, the SFA of *P. pumila* resembles those of both *P. sibirica* (Table 3) and *P. parviflora* (Table 2), as well as *P. cembra* (Table 3). This does not indicate any particular relationships with one or more species, or conversely, may be indicative of close relationships between the four species.

Pinus lambertiana, an "archetypal white pine" (40), does not successfully cross with other species of the same subsection *Strobi*, with the exception of *P. armandii* (of uncertain taxonomic position), whereas it hybridizes with *P. koraiensis*, an Asian species of subsection *Cembrae* (40). *Pinus flexilis* also crosses with species of subsection *Strobi* (40). Clearly, relationships between subsections within section *Strobus* are not well understood. Except for *P. lambertiana*, this section however appears united by many features of their SFA composition, e.g., by their 9,12-18:2 acid content, in the narrow range 44–51%, that contrasts with that in pines of section *Parrya*, with higher or lower linoleic acid contents (see below).

Subsections *Cembroides*, *Balfourianae*, and *Gerardianae* of section *Parrya* (Table 4) display species with SFA profiles, in a general manner, quite distinct from those of the *Strobus* and *Cembrae* subsections (Tables 2 and 3). However, section *Parrya* and even some of its subsections, e.g., the highly complex *Cembroides* subsection, are not considered "natural" groups (43). From our SFA analyses of a single representative of the *Balfourianae* subsection, *P. aristata*, and of *P. bungeana* from the *Gerardianae* subsection, it would appear that these species are closer to species of section *Strobi* than to species of the *Cembroides* subsection. Among the *Cembroides* species analyzed so far, three are very similar (*P. edulis*, *P. monophylla*, and *P. nelsonii*), whereas the fourth one (*P. maximartinezii*) shows some significantly distinctive features. The four species are united in having the lowest total Δ5-UPIFA inside the subgenus *Strobus* (0.6–1.0%). They differ, however, in their prominent fatty acid, oleic acid in the *P. edulis-monophylla-nelsonii* group (44.8 to 46.8%) and linoleic acid in *P. maximartinezii* (52.5%). Apparently, all of these species show considerably low Δ5-desaturase activities, but the *P. edulis-monophylla-nelsonii* group would additionally present a somewhat reduced Δ12-desaturase activity, leading to an unusual accumulation of oleic acid in the seeds from this group. Specialists of the single-needle pinyons (60) regard *P. cembroides* as a species complex including among others, *P. monophylla* and its several subspecies. Seed fatty acid compositions for these subspecies have been published [(59); not included in Table 4], and despite some inconsistencies with our own data (50), very low Δ5-UPIFA (the C_{18} Δ5-UPIFA are likely those fatty acids reported as linolelaidic and β-eleostearic acids), and exceptionally high oleic acid levels (>42%) were established. Another report (61) on the fatty acid composition of "nuts from three seed coat phenotypes" of *P. cembroides* also indicates high oleic acid levels (range, 37–47%), and as no Δ5-UPIFA are reported, probably low amounts of such acids (data not reported in Table 4). As *P. monophylla* hybridizes with *P. edulis* (two-needle pinyon), not surprisingly SFA compositions for both species are almost indistinguishable (Table 4).

The two species constitutive of the *Gerardianae* subsection (Table 4) are quite distinct from one another, with relatively low (*P. bungeana*) or very low (*P. gerardiana*) levels of total Δ5-UPIFA (12.2 and 1.6%, respectively). Regarding its main SFA, *P. maximartinezii* is closer to *P. gerardiana* (*Gerardianae*) than to other members of subsection *Cembroides*, which is in line with a common rooting of these species as suggested by Malusa (43). However, *P. nelsonii*, also grouped with *P. maximartinezii* by Malusa (43), is hardly distinguishable from *P. edulis* and *P. monophylla* (grouped apart as "true pinyons") when considering their SFA compositions. The suggestion to segregate subsection *Cembroides* into three "groups" (62), *Pinceanae* (*P. maximartinezii* and *P. pinceana*, the latter species not yet analyzed), *Nelsoniae* (*P. nelsonii*), and *Cembroidae* (the remaining species of subsection *Cembroides*, including *P. edulis* and *P. monophylla*, analyzed for their SFA), is not incompatible with SFA compositions reported here.

SFA compositions in the Pinus *subgenus*. Within this subgenus, species from subsection *Sylvestres* are particularly well-documented (Tables 5–7), and deserve some comments. They are mostly Eurasian or Asian, with only *P. resinosa* (analyzed) and *P. tropicalis* (not analyzed) being native to North America. The first remark relates to the small variability inside the species *P. sylvestris*, despite its numerous variants or varieties. To support this observation, we established the fatty acid compositions from seeds collected in 10 different French stands (two lots in each case, two preparations of FAME per lot, totalling 40 GLC analyses), in Ukraine and in Mongolia, and compared them with a similar analysis of seeds collected in 10 different locations in Finland (49). As can be noted from Table 5, small variations occur, some of which are statistically significant, e.g., a decrease eastward of C_{20} fatty acids, particularly of sciadonic acid: from *ca*. 5.0% in France-Finland to 3.6% in Mongolia. Part of these variations, however, may be attributable to analytical causes or sampling as well. At least for the 10 French stands, no statistically significant differences could be established (results not shown). Moreover, an obvious limitation in SFA analysis is the history of the seeds (mainly authentification, perhaps storage conditions, e.g., duration and temperature), which is generally not known, though seeds were purchased from national (France) or reputable major (France, United States, and the United Kingdom) tree-seed sellers, and thus supposed to be viable and suited for plantation. The same limited variability can be observed in the *P. nigra* complex (Table 5).

All *Sylvestres* species have seed oils in which the major fatty acid is linoleic acid, with a mean in the narrow range 43.5 to 48.3% (52.0%, however, in *P. merkusii*), with the exception of data for *P. pinaster*, along with the circum-Mediterranean species alternately grouped in a *Halepenses* subsection (38,41), *P. halepensis*, *P. brutia*, and *P. eldarica*. For

[l]16:1 isomers plus *aiso*-17:0.

these species, linoleic acid is definitely higher than in species of the remainder of the *Sylvestres* subsection (means, 45.8 ± 1.2%), from 52.2% in *P. pinaster* (n = 60) to 55.5–60.5% in the other three pine species. Data from Reference 9 are excluded from the present calculations and discussion because they do not correspond to data from other authors when available for the corresponding species (e.g., *P. densiflora*, *P. thunbergii*, *P. massoniana*; Table 6). Oleic acid also shows rather small variations within the *Sylvestres* subsection, in the range 14.4–20.9%, except for *P. merkusii* and *P. halepensis*, which present slightly lower (12.3%) or higher values (23.7%), respectively.

The content and distribution profile of Δ5-UPIFA in the seed lipids from pines of the *Sylvestres* subsection also appear homogenous, here too after exclusion of *P. pinaster*, *P. merkusii*, and the *Halepenses* pines. The total Δ5-UPIFA percentage varies from a low of 25.4% to a high of *ca*. 30%, essentially distributed between taxoleic (2.2–4.5%), pinolenic (17.2–22.8%), and sciadonic (2.9–5.5%) acids. The specific case of *P. pinaster* has been discussed elsewhere (7), and we will comment here only on the distinctive features of the *Halepenses* pines, and of *P. merkusii* (Table 7). However, concerning the present data for *P. pinaster*, regardless of numerous analyses (duplicate analyses from 30 extracts of seeds from the Landes region in France), no significant statistical differences in SFA compositions could be established between the different lots analyzed (data not presented).

In addition to the above mentioned points, the *Halepenses* pines differ from other *Sylvestres* species by their higher level of 18:0 acid (≥3.3% instead of ≤2.0%, respectively), but the most conspicuous feature lies in individual C_{18} Δ5-UPIFA, taxoleic and pinolenic acids being less than 1.0 and 4.4%, respectively. This results in rather low total Δ5-UPIFA, between 9.1 and 11.1%. Two additional salient points that characterize *P. merkusii* SFA are their extreme 16:0 and 18:3n-3 acid levels, 8.4 and 2.6%, respectively, and as noted previously, their low oleic acid content, the lowest among all pine seeds analyzed so far. Finally, it should be pointed out that no obvious characteristics in its SFA profile can distinguish the North American *Sylvestres* species *P. resinosa* from its Eurasian and Asian relatives. In European *Sylvestres* pines, average total Δ5-UPIFA accounts for 30.1% of total SFA, slightly less in *P. nigra* and in the complex *P. uncinata-mughus-pumilio*, 26.7%, whereas corresponding values for Asian *Sylvestres* pines are in the range 25.7–28.4%, and 28.3% in the North American *P. resinosa*. Data for *Sylvestres* species indicate that only slight variations occurred in SFA compositions during the relatively recent differentiation of this subsection.

The four following subsections (Tables 8–10), *Ponderosae*, *Contortae*, *Australes*, and *Oocarpae*, taken as a whole, are hardly distinguishable one from another at first glance, except for *P. jeffreyii* (*Ponderosae* subsection; Table 8), which will be discussed separately. These subsections were grouped in Debazac's (38) description of pines in a *Ponderosa-Banksiana* section, also including *P. pinaster*, that we studied recently (7), and where most of the following observations were made. The major SFA is linoleic acid, from 43.3 to 49.5%, which is a somewhat broader range than that observed in the *Sylvestres* subsection. The second common fatty acid is oleic acid, in the range 15.4–21.8%, which compares well with the corresponding values established for the *Sylvestres* subsection. Concerning Δ5-UPIFA, the range of their total, 22.8–29.2%, is very similar to that presented by most species of subsection *Sylvestres*, a situation also observable at the level of individual C_{18} Δ5-UPIFA: taxoleic acid, 1.6–3.2%; pinolenic acid, 17.5–22.9%; and C_{20} Δ5-UPIFA: sciadonic acid, 1.6–4.4%. Older data for *P. taeda* (63) and *P. elliottii* (64) (not presented in Table 9) have also been reported, and at least for major components, are in the ranges reported here.

Pinus jeffreyi does not fit the general pattern of the *Sylvestres-Ponderosae-Contortae-Australes-Oocarpae* group. In particular, it shows a SFA composition with a higher level of oleic and taxoleic acids and a lower content of pinolenic and sciadonic acids. This might be indicative of a tendency in that species to a reduced Δ12-desaturase activity accompanied by a lower Δ5-desaturase activity of linoleic acid as compared to other species. Interestingly, Mirov (39), basing his conclusions on the chemistry of *P. jeffreyi* turpentine (presence of *n*-heptane), and on its natural and fertile hybridization with *P. coulteri*, suggested its inclusion in a "*Macrocarpae* group," here the *Sabinianae* subsection augmented with *P. oaxana*. However, *P. jeffreyi* would also be related to a variety of *P. ponderosa* (not analyzed) through the same crossability and turpentine composition criteria. Indeed, the total Δ5-UPIFA in *P. jeffreyi* (17.0%) is intermediary between that in *P. coulteri* (14.5%) and the bulk of species from the *Banksiana-Ponderosa* section (corresponding here to section *Pinus* without subsections *Sabinianae* and *Leiophyllae*; Tables 8–10) (23.0–29.2%).

The two species from the *Sabinianae* subsection analyzed so far (Table 10; *P. torreyana* does not seem to have been analyzed so far) reveal an apparent heterogeneity in this subsection. As mentioned above, *P. coulteri* is closer to *P. jeffreyi* than to any other species of the preceding subsections, whereas *P. sabiniana* displays a unique and quite distinct SFA profile. Regarding *P. coulteri*, the similitude with *P. jeffreyi* is unlikely to be coincidental, especially when considering the chemical point of view of Mirov (39). On the other hand, the SFA composition of *P. sabiniana* resembles that of many *Cembroides* species that belong to the *Strobus* subgenus, and not to species of the *Pinus* subgenus.

The *Canarienses* subsection (Table 11) embraces only two species, one native to the Canary Islands (*P. canariensis*) and the other to the Himalayas (*P. roxburghii*). Despite this geographical remoteness, the SFA compositions of both species are remarkably similar, with only minor differences. Among these is the content of α-linolenic acid, exceptionally high in *P. canariensis* (1.9%). Otherwise, both species have low C_{18} Δ5-UPIFA contents, relatively high levels of sciadonic acid, and general SFA profiles not very different from that of *P. halenpensis*.

[d]Sum of Δ5-olefinic acids, including the 7,11,14-20:3 acid.
[e]Minor and unidentified components.
[f]Not detected or not reported.
[g]Reported as *P. michoacana*.
[h]Trace amounts.

The *Pineae* subsection (Table 11) is monospecific, with the single *P. pinea* of circum-Mediterranean distribution. Its SFA composition closely resembles that of *P. gerardiana* (subgenus *Strobus*, Table 4), with, however, a sciadonic acid percentage typical of subgenus *Pinus*. Data on the SFA composition of *P. pinea* (not included in Table 11) showing similar levels of oleic and linoleic acids have been reported (65), but apparently no Δ5-UPIFA were detected, likely indicating their scarcity in *P. pinea* seeds.

Pinus krempfii (Table 11), a rare Vietnamese species, is the unique species of the third subgenus *Ducampopinus*, possibly artificial. For example, some observations indicate that *P. krempfii* would fit equally well in the subgenus *Strobus* (66), section *Parrya* (42,44), being even qualified a "*Geradianae*-like species" (44). Indeed, the level of sciadonic acid in the SFA from *P. krempfii* (1.3%) is in the range observed for pines of the *Strobus* subgenus (0.2–1.9%), and the whole SFA composition of *P. krempfii* shares many points in common with that of *P. bungeana*, of the *Parrya* section (subsection *Gerardianae*, Table 4), in particular the total Δ5-UPIFA content (*ca*. 12.2% in both cases).

The unclassified species, *P. shenkanensis* and *P. szemaoensis* (Table 11), may be Asian species or varieties of pines of the *Sylvestres* subsection, as deduced from their SFA compositions (related, e.g., to *P. tabuliformis* or *P. thunbergii*), or even hybrids. *Pinus szemaoensis* would thus present the highest sciadonic acid content (6.0%) after *P. pinaster* in subsection *Sylvestres*, provided its *Sylvestres* nature is confirmed.

General characteristics of Pinus *SFA compositions*. The pine species analyzed so far for their SFA composition (including species from this study) encompass 76 species (and some subspecies or varieties), which is approximately one-half the total number of extant species (Table 1). Regarding the fatty acid compositions of species analyzed in the present study, no other components than those previously described for other pine species were found. This does not exclude the possibility of characterizing in the future traces of fatty acids not observable under routine analytical conditions. A discussion of results on pine SFA compositions in general terms is made.

The major unsaturated fatty acids also common to most seed plants are linoleic acid, from 39.4% (*P. coulteri*) to 60.5% (*P. brutia*), and oleic acid [in the range 13.8 (*P. strobus*)–46.8% (*P. edulis*)], always accompanied by small amounts of *cis*-vaccenic acid (most often <1%, but that can reach 2.0% in *P. pinea*). Generally, linoleic acid predominates over oleic acid, except for some species principally from the *Cembroides* subsection. Though no clear relationships could be established between the two preceding fatty acids and C_{18} Δ5-UPIFA, it would however appear that oleic acid predominates over linoleic acid in those species with the lowest levels of Δ5-UPIFA, particularly, but not exclusively, in species of the *Cembroides* subsection. In no species could we observe α-linolenic acid at levels higher than 1.9% [in *P. canariensis*; otherwise, always less than 1.0%; data for *P. merkusii* are contradictory (Table 7)], and at least under routine analytical

[a]Same numbering of species as in Table 1.
[b]Two isomers, 7- and 9-16:1 acids.
[c]14-Methylhexadecanoic, or *anteiso*-17:0 acid.
[d]Sum of Δ5-olefinic acids, including the 7,11,14-20:3 acid.
[e]Minor and unidentified components.
[f]Trace amounts.
[g]Not detected or not reported.
[h]Reported as 20:3n-6.

conditions, its elongation product (11,14,17-20:3 acid) was not observed. Its presence at subtrace levels cannot be excluded, as juniperonic acid occasionally occurs in trace amounts (e.g., in *P. pentaphylla*). Among other detectable monoenes are 11-20:1 (up to 1.4% in *P. pumilio*), 7-16:1 plus 9-16:1, and 9-17:1 acids, totaling a maximum of 0.3% each. The intermediate metabolite between linoleic and sciadonic acids, 11,14-20:2 acid, is present in all species and can reach 1.6% in *P. resinosa*.

The principal saturated acids are 16:0 (3.1 to 9.2%, in *P. pumilio* and *P. maximartinezii*, respectively) and 18:0 acids (1.4%, in a few *Sylvestres* pines, to 4.5% in *P. roxburghii*). Eicosanoic acid is less than 0.6%, and minor even and odd linear saturated acids including 14:0, 15:0 (not reported here), and 17:0 acids are less than 0.1% each. The *anteiso*-17:0 acid, always observable, may reach 0.3%, and the 22:0 acid is always less than 0.25%. Thus, pine seed lipids have total SFA most often less than 10%, and slightly more in a few cases only (e.g., *P. merkusii* and species of subsection *Cembroides*).

Apart from the fatty acids described above, pine seed lipids contain taxoleic and pinolenic acids as main C_{18} Δ5-UPIFA (minor, 5,9,12,15-18:4 acid), and sciadonic acid as a main C_{20} Δ5-UPIFA [minor, 5,11-20:2 acid, and the Δ5-related 7,11,14-20:3 (bishomopinolenic) acid]. A compilation of data available (Tables 2–11) indicates that the highest percentage of pinolenic acid (25.3%) is found in *P. strobus*, whereas this acid represents only 0.13% in *P. monophylla*. Taxoleic acid apparently is always less than 4.5% (*P. coulteri*, *P. massoniana*) and sometimes present in trace amounts only (<0.05%; *P. roxburghii*, *P. monophylla*). The upper limits of coniferonic acid, and of the elongation product of pinolenic acid, bishomopinolenic acid, would be 0.2% (*P. attenuata, P. resinosa*) and 0.7% (*P. contorta*, *P. sylvestris*), respectively. Regarding C_{20} Δ5-UPIFA, the maximum level of sciadonic acid that can be reached is observed in *P. pinaster* (7%). The 5,11-20:2 acid is seldom higher than 0.5%. However, this acid allows distinction between species of the *Strobus* and *Pinus* subgenera, being less than 0.2% in the former (with however a slightly higher value in *P. aristata*) and presenting a generally higher value in the latter subgenus. A similar limit for sciadonic acid allows separation of the two subgenera at *ca*. 1.9%, lower values occurring mostly in the *Strobus* subgenus. Except for *P. ponderosa*, *P. jeffreyi*, and the two *Sabinianae* species, sciadonic acid levels in species from subgenus *Pinus* are equal to or higher than 2.0%. Total Δ5-UPIFA are in the range 0.6 (*P. monophylla*) to 30–31% (*P. sylvestris*).

The primeval status in pine seeds: low, or high Δ5-desaturase activities? Cladistic and phylogenetic studies based on restriction fragment analyses of either total genomic or chloroplastic DNA (45,46) have shown that the soft pines in section *Parrya* represented by species of subsections *Cembroides* (*P. edulis*, *P. monophylla*), *Balfourianae* (*P. aristata*, *P. longaeva*), and *Gerardiana* (*P. gerardiana, P. bungeana*) constitute the group closest to the hypothesized root of the genus *Pinus*. Except for *P. longaeva*, SFA compositions are fortunately available for the other species and show that most of these species are "united" by low to very low levels of total Δ5-UPIFA, i.e., *P. edulis*, *P. monophylla*, and *P. gerardiana*, less than 1.6% of total fatty acids. This also occurs in other *Cembroides* species, but *P. aristata* and *P. bungeana* have higher total Δ5-UPIFA percentages (up to 16%). On the other hand, all other species examined by DNA-fragment analyses appeared rather homogenous, suggesting a more recent radiation (44,45). Coincidentally, these species have higher total Δ5-UPIFA contents, from 17.0 to 29.7%.

Within diploxyl species (subgenus *Pinus*), *P. pinea* and *P. canariensis* would also form a clade, possibly along with *P. sabiniana*, near the base of the subgenus (44). Here too, *P. pinea* and *P. sabiniana* have SFA containing no more than 3.1% of total Δ5-UPIFA, whereas the corresponding value for the two *Canarienses* species is less than 6%. It is worth mentioning at this point the relationships suggested by Klaus (41) among "coast and island Mediterranean pines," based on morphological characters. This author has emphasized possible links between haploxyl ancestors of the *Parrya* section through the subsection *Canarienses*, to more advanced diploxyl species of the *Pineae* and *Halepenses* subsections, and also in some manner to *P. pinaster*. Data presented here would support this point of view in that all species from this "Mediterranean group" display total Δ5-UPIFA in their SFA that are the lowest, or among the lowest, in all sections. A low Δ5-desaturation activity might thus have been the primeval status in the genus *Pinus.*

Contradicting this possibility is the fact that a high Δ5-UPIFA content in SFA (largely contributed to by pinolenic acid) is also the rule in some other Pinaceae genera, i.e., *Picea*, *Larix*, *Tsuga*, and *Pseudotsuga* (5,18). Though relationships between these genera are diversely interpreted, depending on the characters considered (67–71), a common rooting is largely admitted (46). This view is supported by the striking resemblance of the overall SFA composition of the latter genera with "high Δ5-UPIFA" pine species (5,18). In a multiple-component analysis of their SFA compositions (5), *Picea* spp. were indistinguishable from *Larix* spp., whereas *Tsuga* spp. and *Pseudotsuga menziesii* were slightly outlying within the bulky *Pinus* spp. group. *Abies* spp., *Cedrus* spp. (5,18), and *Keteleeria davidiana* (unpublished data by the authors), though presenting the same individual Δ5-UPIFA and other common fatty acids in their seed lipids as all other Pinaceae genera, have however distinct quantitative distributions of these fatty acids that allow their distinction as individual groups upon multiple component analysis (5,18). However, they also can be considered as "high Δ5-UPIFA" species as their total Δ5-UPIFA content is generally higher than 20% (except for *K. davidiana*). It would thus be reasonable to consider that "low Δ5-UPIFA" species coexisted with "high Δ5-UPIFA" species in the early history of pines, perhaps to accommodate for different edaphic or climatic conditions, before other Pinaceae genera differentiated. Alternately, extant "low Δ5-UPIFA" pine species might be the descendants of extinct "high Δ5-UPIFA" species, and in this case too, a "high Δ5-UPIFA" content could have been the primeval status.

Though no precise physiological roles have been attributed to Δ5-UPIFA in gymnosperms, their possible evolutionary origin however has been discussed (14). The C_{20} Δ5-UPIFA sciadonic and juniperonic acids might be relict fatty acids resulting from modifications of the metabolic pathways that lead, in vegetables of lower phyletic rank, e.g., ferns and fern allies (Pteridophytes), to arachidonic and eicosapentaenoic acids. In the same way, it was suggested that pinolenic acid might be the equivalent of γ-linolenic acid, an intermediate in the biosynthesis of arachidonic acid, following a change of a C_{18} Δ6- (in pteridophytes) to a C_{18} Δ5-desaturase activity (in gymnosperms). Also, some arguments, mostly based on the stereospecific acylation of Δ5-UPIFA to triacylglycerols, were given (9) regarding a different biochemical origin for Δ5-UPIFA occurring in most gymnosperms [all Coniferophyte families, and several Cycadophyte families (10)] on the one hand, and in some rare angiosperms [especially in the archaic family Ranunculaceae (72)] on the other hand.

Some practical considerations. Regarding potential biomedical and nutritional applications of Δ5-UPIFA (20–31, 73), our systematic study of gymnosperm seed oils indicates that numerous pine species may be a source of Δ5-UPIFA. However, the Δ5-UPIFA percentage in the oil may considerably vary from one species to another species, and inside this particular class of fatty acids, the percentage of individual Δ5-UPIFA also is variable. Among pines, the best sources of sciadonic acid are to be found in the subgenus *Pinus*, mostly in species from the *Sylvestres* (generally in the range 2.9–5.5%, but *ca*. 7% in the particular case of *P. pinaster*), *Halepenses* (3.6–5.4%), and *Canarienses* (*ca*. 4.0%) subsections (all species but two of Eurasian location). In contrast, only few North and Central American hard pines have sciadonic acid contents equal to or higher than 3.5%: *P. devoniana*, *P. contorta* (subsections *Ponderosae* and *Contortae*, respectively), *P. taeda* (subsection *Australes*), *P. patula*, and *P. oocarpa* (both from subsection *Oocarpae*). On the other hand, species from the *Strobus* subgenus may not be as interesting, for the maximum level that is reached is at most 1.9% (in *P. strobus*). Good sources of pinolenic are easier to select, as most common pine species from both subgenera contain levels of pinolenic acid equal to or higher than 15% of total fatty acids, being limited to an apparent maximum of 25%. In this regard, however, a Russian report (74) indicates that *P. sibirica* seed oil would contain up to 30% of pinolenic acid, which appears exceptional.

In conclusion, the most common and widespread pine species have been described regarding their SFA compositions. The problem now is to get seeds from less common species, subspecies, or varieties not easily available from tree-seed sellers, nurseries, or botanical gardens. Obviously, SFA compositions alone, as is generally the case for other individual characters, cannot solve the problem of pine phylogeny, as extant species represent at most a small proportion of all species that have existed. Even when the remainder of species not yet studied are described regarding their SFA compositions, the problem may not be solved. However, our original approach has shown that Δ5-UPIFA in pine seeds are highly conservative biochemical characters, in most instances tightly associated with taxonomic groups otherwise recognized as such on the basis of different botanical criteria. As uniting or separative characters, pine SFA compositions, that are technically relatively easy to establish provided the seeds are available, should be considered a complement to be associated with studies on pine taxonomy and phylogeny.

ACKNOWLEDGMENTS

Authors R.L. Wolff and A.M. Marpeau would be most grateful to receive authenticated seeds from any Pinaceae species not already analyzed, more usefully rare ones, for further studies. Prof. Mike Powell, Sul Ross State University, Alpine, Texas, provided some trivial names. This is contribution No. 50 by R.L. Wolff to AOCS Press.

ARTICLE

The Biosynthesis of Oxylipins of Linoleic and Arachidonic Acids by the Sewage Fungus *Leptomitus lacteus*, Including the Identification of 8*R*-Hydroxy-9*Z*,12*Z*-octadecadienoic Acid

Simon R. Fox*, Arzu Akpinar[1], Asmita A. Prabhune[2], John Friend, and Colin Ratledge

University of Hull, Department of Biological Sciences, Hull HU6 7RX, United Kingdom

ABSTRACT: When the sewage fungus *Leptomitus lacteus* was grown in liquid culture aerobically and then transferred to medium containing long-chain fatty acids, it produced a number of oxygenated fatty acids. From linoleic acid (18:2n-6), the major metabolite produced was *R*-8-hydroxy-9*Z*,12*Z*-octadecadienoic acid (8*R*-HODE), with additional quantities of 8,11-di-HODE, 11,16-di-HODE, and 11,17-di-HODE. Other fatty acid derivatives identified included 7-HODE, 10-HODE, and 13-hydroxy-octadecamonoenoic acid. Arachidonic acid (20:4n-6) was metabolized primarily to 18- and 19-hydroxy-eicosatetraenoic acids (18- and 19-HETE) also as *R* enantiomers, along with smaller quantities of 17-HETE, 9-HETE, 14,15-dihydroxy-eicosatrienoic acid and 11,12,19-trihydroxy-eicosatrienoic acid. The oxygenated products of long-chain fatty acids, in particular the biosynthesis of 8*R*-HODE, a compound classified as a precocious sporulation inducer, were similar to those produced by an unrelated fungal species in the Ascomycota, the take-all fungus *Gaeumannomyces graminis.* As in *G. graminis*, the biotransformation of linoleate to 8*R*-HODE was not significantly inhibited by exposure of the organism to CO. This indicated that the enzyme responsible for 8*R*-HODE biosynthesis in *Leptomitus* could be similar to that of *G. graminis*; yet we did not detect 7,8-di-HODE as a product of 18:2n-6 metabolism as in *G. graminis*. CO did inhibit the biosynthesis of 14,15-di-HETE, 18-HETE, and 19-HETE in *L. lacteus*, which suggested the involvement of a cytochrome P_{450}-type monooxygenase. The biosynthesis of 8*R*-HODE from 18:2n-6 was found to occur in certain cell lysates, specifically in low speed (15,000 × *g*) supernatant, following cell disruption.

Paper no. L8339 in *Lipids 35*, 23–30 (January 2000).

Oxygenated long-chain fatty acids, known as oxylipins, are increasingly being identified as products of fungal fatty acid metabolism, and some evidence suggests that their biosynthesis may be associated with important features of the fungal life cycle such as changes from asexual to sexual reproduction (1). Some unusual oxylipins have been isolated from *Gaeumannomyces graminis*, a pathogen of agricultural crops, and these compounds have been implicated in the pathogenicity of this fungus (2). One of these fatty acids is 8-hydroxy-octadecadienoic acid (8*R*-HODE); this compound has some potent effects and is one of several sporulation factors in the ascomycete *Aspergillus nidulans* (3; 8*R*-HODE is categorized as a psi, otherwise known as a precocious sporulation inducer). The compound is secreted by the basidiomycete fungus *Laetisaria arvalis* and is fungicidal to some plant pathogenic strains of *Pythium ultimum* (4). This effect was later shown not to be affected by the enantiomeric composition of the 8-HODE.

Oomycetes are mostly aquatic fungi and characteristically contain eicosanoids. The oxygenated derivatives of C_{20} fatty acids have been extensively studied in mammalian tissues where they participate in a multitude of physiological processes (5). Among the Oomycetes, species such as *Saprolegnia parasitica* and *S. diclina* possess a 15-lipoxygenase, and in both fungi this results in the biosynthesis of significant quantities of oxygenated fatty acids during vegetative growth (6; Akpinar, A., Fox, S.R., Friend, J., and Ratledge, C., unpublished results).

Achlya ambisexualis, also in the same family, accumulates cyclooxygenase-type products in both vegetative and sexual stages of development (7); but despite the capacity for oxylipin biosynthesis by fungi, little is known about the potential physiological roles that such compounds might play in fungal life cycles. *Leptomitus lacteus*, classified as another Oomycete, is a member of a small order, the Leptomitales, and is found in large rivers and lakes, especially those with a high acid content where there tends to be sewage contamination (8,9). As part of a survey of secondary fatty acid metabolism in the Oomycetes, we have carried out an investigation into the capacity of *L. lacteus* to biotransform long-chain fatty acids.

MATERIALS AND METHODS

Growth conditions. *Leptomitus lacteus* (IMI 308.102) was obtained from The International Mycological Institute, (Surrey, United Kingdom). The organism was purified from bacterial contamination and maintained on Rose Bengal agar at 10°C. Stock cultures were kept on potato/dextrose/agar slants and subcultured every 2–3 mon. Inocula were taken from mycelial mats and grown for 48 h to the late stationary phase in 250-mL conical flasks. Each flask contained 50 mL of growth medium comprising: (g/L) glucose, 10; KH_2PO_4, 7; Na_2HPO_4, 2; defatted yeast extract, 1.5; diammonium tartrate, 2; $CaCl_2{\cdot}H_2O$, 0.5; $FeSO_4{\cdot}7H_2O$, 0.1; $ZnSO_4{\cdot}7H_2O$, 0.01; $MnSO_4{\cdot}2H_2O$, 0.001; $CuSO_4{\cdot}5H_2O$, 0.0005; pH 6. A starter culture was used to inoculate (at 2% vol/vol) conical flasks (1 L) containing 500 mL growth medium (as described) or an identical medium containing safflower oil (10 g/L) instead of glucose. In all experiments, *L. lacteus* cultures were routinely maintained under aerobic conditions at 10°C and 160 rev/min.

Addition of fatty acids. After 48 h growth in liquid culture, cells were separated from the growth medium by filtration and washed with 100–200 mL sterile water. The resulting mycelial mat (5 g wet wt) was reinoculated into 50 mL Tris/HCl buffer (50 mM), pH 7.5. Cultures received 10 mg linoleic acid (18:2n-6, Na salt) or 10 mg arachidonic acid (5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid, Na salt) in 200 µL ethanol. The cultures were then incubated for 1 h before extraction of oxygenated fatty acids.

Addition of inhibitors. In the first series of experiments, aimed at inhibiting potential enzymes of oxylipin biosynthesis, aspirin, indomethacin, aesculetin and nordihydroguaiaretic acid (NDGA) were individually included at 1 mM with either 10 mg 18:2n-6 (containing 3.7 kBq [1-^{14}C]18:2n-6, sp. act. 2.04 GBq/mmol), (all isotopes were obtained from Amersham International, Buckinghamshire, United Kingdom), or 10 mg arachidonic acid (20:4n-6) (containing 3.7 kBq [1-^{14}C]20:4n-6, sp. act. 2.04 GBq/mmol) and incubated for 1 h before extraction of fatty acid derivatives (see below). Control experiments were carried out using hyphae which had been boiled in 50 mM Tris/HCl, pH 7.5 for 10 min prior to incubation with [1-^{14}C]18:2n-6 or [1-^{14}C]20:4n-6. In a second series of inhibitor experiments, after the addition of 10 mg [1-^{14}C]18:2n-6 (as above) or similarly 10 mg [1-^{14}C]20:4n-6, carbon monoxide (CO) was bubbled through the cultures (at 1 mL min^{-1}) for either 1 or 10 min. Cultures were then removed from the CO chamber and incubated as before for 30 min before extraction of labeled fatty acid derivatives.

Extraction of fatty acids. Cells were separated from the buffer and fatty acid by filtration through Whatman No. 1 paper and weighed (wet weight). They were then resuspended in ethanol (8 parts ethanol/1 part cells, vol/vol) and homogenized in an Atomix blender (MSE; Fisher Scientific, Loughborough, United Kingdom) for 3 min. The slurry was stirred at 4°C for 24 h after which the mixture was filtered, and the resulting ethanolic solution was concentrated to dryness. The residue was saponified by resuspension in 10 mL 4 M NaOH and left at room temperature overnight (10). The hydrolyzed solution was subsequently adjusted to pH 1 with 6 M HCl and the fatty acids were extracted into 40 mL chloroform. The chloroform phase was concentrated to form the cell extract.

The Tris/HCl buffer in which *L. lacteus* had been incubated with fatty acids (from which cells had been removed by filtration) was adjusted to pH 3.0 with 0.14 M formic acid, and the fatty acids were extracted into an equal volume of chloroform. The chloroform phase was evaporated and the residue saponified (as described above), forming the medium extract.

The chloroform-extracted material from both the cell and culture medium extracts was methylated with diazomethane and also derivatized to methyl silyl ethers (11). Qualitative analysis of fatty acids was carried out using a Finnegan series 1020 automated gas chromatograph–mass spectrometer (GC–MS) operating in the electron impact (EI) mode. The GC parameters were: HP-1 30 m fused-silica capillary column (Hewlett-Packard, Palo Alto, CA), 0.25 mm i.d., 0.25 µm coating; helium carrier gas at 5.06×10^5 Pa head pressure; 10:1 split; injector temperature, 240°C; initial temperature, 220°C; initial time, 5 min; ramp rate, 5°C min^{-1}; final temperature, 280°C; final time, 10 min; injection volume, 1 µL. MS parameters were: source temperature, 240°C; manifold temperature, 100°C; ionization current, 0.30 A.

Chiral analysis. The cell and medium extracts containing fatty acids in chloroform were purified on amino-propyl Sep-Pak cartridges (500 mg) (Millipore Corp., Milford, MA). The cartridges were equilibrated with 5 mL hexane, and the cell or culture medium fatty acid extracts were applied in 200 µL chloroform. After an initial wash with 10 mL chloroform/propan-2-ol (2:1, vol/vol), monohydroxylated and unsubstituted fatty acids were eluted with 10 mL diethyl ether (containing 2% acetic acid by volume). Di- and trihydroxylated fatty acids were eluted with 10 mL methanol. The ethereal phases from the Sep-Pak cartridges were concentrated to dryness before resuspension of the residues in 50% aqueous acetonitrile. Monohydroxylated fatty acids were purified by high-performance liquid chromatography (HPLC) on a semipreparative LiChroprep 25-40 RP C18 column (250 × 10 mm; Chrompack International, Middelburg, The Netherlands). HPLC conditions comprised an isocratic gradient of 0.017 M H_3PO_4/acetonitrile (1:1, vol/vol) at a flow rate of 2 mL min^{-1}; hydroxylated fatty acids were monitored at 192 nm and fractions collected.

The chirality of 8-HODE was determined by Dr. M. Ham-

berg at the Karolinska Institute, Stockholm, Sweden. In short, the methyl ester of 8-HODE was derivatized to its (−)-menthoxycarbonyl analog, subjected to oxidative ozonolysis, and methylated (12,13). The corresponding racemic standard was then separated into *R* and *S* enantiomers by GC and compared with derivatized 8-HODE from *L. lacteus*.

Chiral analysis of certain monohydroxylated derivatives of 20:4n-6 was carried out by derivatization to naphthyl ester methyl esters (14). The enantiomers were separated by HPLC on an Apex Chiral AU 50 column (4.6 × 250 mm; Jones Chromatography, Glamorgan, United Kingdom). HPLC conditions comprised an isocratic gradient of 1% propan-2-ol in *n*-hexane with a flow rate of 1.0 mL/min and detection of peaks at 192 nm. In this system, the *R* enantiomers elute before *S* enantiomers (14). This was confirmed in the current study by using a standard naphthyl ester methyl ester of 3-hydroxyeicosatetraenoic acid (3-HETE), where chirality was previously established as an enantiomeric ratio of 95:5 (*R*/*S*) (Hamberg, M., personal communication); 3-HETE was purified from cultures of the yeast *Dipodascopsis uninucleata* metabolizing 20:4n-6 (15).

Quantitative analysis of oxylipins. In experiments in which [1-^{14}C]18:2n-6 or [1-^{14}C]20:4n-6 was used, fatty acids from the diethyl ether and methanol fractions of amino-propyl Sep-Pak cartridges were separated by thin-layer chromatography (TLC). Quantitative determinations of ^{14}C-labeled oxylipins were made using a Bioscan Autochanger 4000 (Bioscan Inc., Washington, DC). ^{14}C-monohydroxylated fatty acids were detected by running the diethyl ether fractions on silica gel plates (Autofolien, Kieselgel 60; Merck, Darmstadt, Germany) developed with petroleum ether (60–80°C)/diethyl ether/acetic acid (50:50:1, by vol). [1-^{14}C]Di- and trihydroxy fatty acids were detected by running the methanol fractions on silica gel TLC plates developed with the organic phase of ethyl acetate/2,2,4; trimethylpentane/acetic acid/water (110:50:20:100, by vol).

Preparation of cell lysates and microsomes. The fungus was separated from the medium of safflower oil-grown cultures and rinsed with Tris/HCl buffer (50 mM, pH 7.5). The cells were weighed and resuspended in two parts of the buffer (wet wt/vol). Cell rupture was achieved by two passages through a precooled French pressure cell. The homogenate was centrifuged at 15,000 × *g* for 30 min to precipitate whole cells, cell debris, and unwanted organelles. The low-speed supernatant (the cytosolic fraction) was centrifuged at 100,000 × *g* for 60 min to obtain microsomes and a high-speed supernatant (solubilized membrane components); the microsomes were dissolved in 2 mL 50 mM Tris/HCl pH 7.5. The cytosolic fraction, the microsomes, and the high-speed supernatant were each incubated with 0.1 mg 18:2n-6 or 0.1 mg 20:4n-6 (all in a final volume of 2 mL) in the presence and absence of 1 mM NADPH for 20 min. Reactions were terminated by adding ethanol (4 vol) and fatty acids extracted as before. The fatty acid derivatives were identified by GC–MS.

RESULTS AND DISCUSSION

Growth of Leptomitus. *Leptomitus lacteus* produced only vegetative structures on both the glucose and the safflower media. We did not observe oogonium formation in any culture, even when we monitored growth over longer periods of time of up to 4–5 wk. The formation of sexual structures, as far as we are aware, is unknown in this fungus. The hyphae appeared septate but they were, in fact, pseudoseptate; cellulin plugs cause the constrictions, which is a characteristic feature of this organism (16). The fungus grew more vigorously on safflower oil (5–10 g cells/L) than on glucose-based medium (<1 g cells/L). This led us to use *L. lacteus* cultured on safflower oil for experiments investigating oxylipin biosynthesis from exogenously added fatty acids. In a previous report (8), sugars were found to be unable to support growth of *L. lacteus*. Our findings were to the contrary, but we have no explanation for this other than the composition of the nutrient medium we used may have been different or perhaps different strains of *L. lacteus* exist.

Biotransformation of fatty acids. The following oxygenated fatty acids were all extracted from the medium extracts and qualitative determination made by GC–MS. The ion fragments of fatty acids are listed with our interpretation of likely structures.

Oxylipins of 18:2n-6. (i) 8-HODE. Scan no. 650 (scan nos. for 18:2n-6 refer to Fig. 1). The most abundant peak of the total ion chromatogram, the mass spectrum of the compound (Fig. 2) produced ions at *m*/*z* 382 [M^+], 367 [$M^+ - 15$; loss of a methyl group on the silyl derivative], 351 [$M^+ - 31$], 335 [possibly $(M^+ + 1) - 48$; loss of OCH–CH_2–CH_3], 311 [$M^+ - 71$; loss of $(CH_2)_4$–CH_3], 292 [$M^+ - 90$; loss of silyl group], 284 [possibly $(M^+ - 1) - 97$; loss of CH=CH–$(CH_2)_4$–CH_3], 271 [possibly a split at C_{10} representing CH=CH–$(CH_3)_3SiO^+$ =CH–$(CH_2)_6$–$COOCH_3$], 261 [possibly $M^+ - (31 + 90)$], 245 [split between C_8 and C_9; $(CH_3)_3SiO^+$=CH–$(CH_2)_6$–$COOCH_3$], 239 [fragmentation between C_7 and C_8 with the loss of CH–[OSi-$(CH_3)_3$]CH=CH–CH_2–CH=CH–$(CH_2)_4$–CH_3; indicative of a hydroxyl group at C_8], and 149 (possibly 239 − 90). The base ion, as in all mass spectra reported, was 73. The mass spectrum and abundance of ions were similar to that for 8*R*-HODE (8-hydroxy-9*Z*,12*Z*-octadecadienoic acid) from *G. graminis* (2). The conversion of exogenously supplied 18:2n-6 to 8-HODE was in the region of 10% as judged from the total ion chromatogram (result not shown).

(ii) 10-HODE. Scan no. 673. *m*/*z* 382 [M^+], 367 [$M^+ -15$], 311 [$M^+ -71$], 271 [the major fragment, representing cleavage from C_{10} to C_1 with hydroxyl group at C_{10} and the double bond shifting to C_8], 261 [$M^+ - (31 + 90)$], 239 [$M^+ - 143$; representing CH=CH–CH(OSi$(CH_3)_3$–CH_2–CH=CH–$(CH_2)_4$–CH_3], 181 [271 − 90], 149 [239 − 90], 129 [possibly $(CH_3)_3SiO^+$= CH–CH=CH_2], and 111 [$M^+ - 271$].

(iii) 7-HODE. Scan no. 697. *m*/*z* 382 [M^+], 367 [$M^+ - 15$], 334 [$M^+ - 48$], 311 [$M^+ - 71$], 292 [$M^+ - 90$], 284 [possibly $(M^+ - 1) - 97$], 261 [$M^+ - (31 + 90)$, 253 [split between C_6 and C_7 representing $(CH_3)_3SiO^+$=CH–CH_2–CH=CH–CH_2–CH= CH–$(CH_2)_4$–CH_3], 231 [split between C_7 and C_8; $(CH_3)_3SiO^+$= CH–$(CH_2)_5COOCH_3$; indicates hydroxyl group at C_7], and 151 [$M^+ - 231$]. The mass spectrum contained several ions we were not able to assign, notably *m*/*z* 225.

(iv) 13-Hydroxy-9Z-octadecamonoenoic acid (13-HOME).

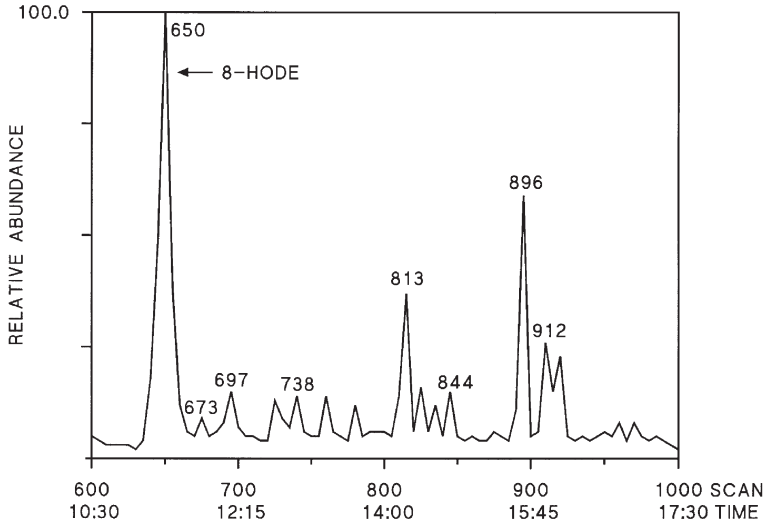

FIG. 1. Partial total ion current chromatogram (with scan numbers) of methyl and silyl derivatives of 18:2n-6 extracted from cultures of *Leptomitus lacteus*. 8-HODE, 8-hydroxy-9*Z*,12*Z*-octadecadienoic acid.

Scan no. 724. *m/z* 384 [M^+], 369 [$M^+ - 15$], 294 [$M^+ - 90$], 313, [$(CH_3)_3SiO^+$=CH–$(CH)_2$–CH=CH–$(CH_2)_7$–$COOCH_3$; cleavage from C_1 to C_{13} indicating a hydroxyl group at C_{13}], 294 [$M^+ - 90$], 223 [$M^+ - (90 + 71)$, 211 [split between C_{12} and C_{13} with loss of $(CH_2)_2$–CH=CH–$(CH_2)_7COOCH_3$], 187 [possibly 173 + CH_2], and 173 [the major ion fragment with cleavage from C_{13} to C_{18} representing $(CH_3)_3SiO^+$=CH–$(CH_2)_4$–CH_3].

(v) 16-HODE. FIG. 3. Partial total ion current chromatogram of methyl ester silyl ethers of mono-, di-, and trihydroxylated derivatives of 20:4n-6 extracted from cultures of *Leptomitus lacteus.*

(ix) 11,16-di-HODE. Scan no. 896. *m/z* 470 [M^+], 455 [$M^+ - 15$], 441 [$M^+ - 29$], 439 [$M^+ - 31$], 380 [$M^+ - 90$], 287 [cleavage at C_{11} to C_{18}], 285 [possible cleavage at C_{11} to C_1; $(CH_3)_3SiO^+$=CH–CH=CH–$(CH_2)_7$–$COOCH_3$; a prominent fragment for a hydroxyl group at C_{11}], 183 [$M^+ - 287$], and 131 (cleavage from C_{16} to C_{18}; $(CH_3)_3SiO^+$=CH–CH_2–CH_3].

(x) 11,17-di-HODE. Scan no. 912. *m/z* 470 [M^+], 455 [$M^+ - 15$], 365 [possibly $M^+ - (15 + 90)$], 287 [possible cleavage between C_{10} and C_{11} with the loss of $(CH_3)_3SiO^+$=CH–CH=CH–$(CH_2)_3$–CH[OSi–$(CH_3)_3$]–CH_3], 285 [cleavage from C_{11} to C_1], 183 [$M^+ - 287$] and 117 [loss of fragment C_{17} to C_{18} with hydroxyl group at C_{17}; $(CH_3)_3SiO^+$=CH-CH_3].

Oxylipins of 20:4n-6. (i) 18-HETE. The main compound (Fig. 2, scan no. 893) produced ions at *m/z* 407 [$M^+ + 1$], 391 [$M^+ - 15$], 377 [$M^+ - 29$], 375 [$M^+ - 31$], 348 [$M^+ - 58$, possible loss of OCH-CH_2-CH_3 with migration of $(CH_3)_3SiO^+$ to the carboxyl group], 316 [$M^+ - 90$], 285 [375 – 90] and 131 [hydroxyl group at C_{18} with loss of $(CH_3)_3SiO^+$=CH–CH_2–CH_3].

(ii) 19-HETE. Scan no. 909. *m/z* 406 [M^+], 391 [$M^+ - 15$], 375 [$M^+ - 31$], 316 [$M^+ - 90$], 289 [$M^+ - 117$; cleavage between C_{18} and C_{19}], 285 [375 – 90], 254 [285 – 31], 220 [289 – 69, loss of CH_2–CH=CH–CH_2–CH_3], and 117 [hydroxyl group at C_{19} with loss of $(CH_3)_3SiO^+$=CH–CH_3]. The percentage conversion of 20:4n-6 to 18- and 19-HETE was in the region of 5%, as judged from the total ion chromatogram (Fig. 2).

(iii) 17-HETE. Scan no. 878. *m/z* 406 [M^+], 391 [$M^+ - 15$], 375 [$M^+ - 31$], 316 [$M^+ - 90$], 285 [375 – 90], 275 [$M^+ - 131$; cleavage at C_{17} to C_{18}], and 145 [$(CH_3)_3SiO^+$=CH–$(CH_2)_2$–CH_3; indicating a hydroxyl group at C_{17}].

(iv) 9-HETE. Scan no. 804. *m/z* 406 [M^+], 391 [$M^+ - 15$], 375 [$M^+ - 31$], 316 [$M^+ - 90$], 255 [a major fragment, cleavage from C_9 to C_{10} with the double bond shifting to C_7, representing $(CH_3)_3SiO^+$=CH–CH=CH–CH=CH–$(CH_2)_3$–$COOCH_3$], 183 [possibly 255 – 72] and 143 [possibly 255 – (90 + 43)].

(v) 14,15-Dihydroxy-5Z,8Z,11Z-eicosatrienoic acid (14,15-di-HETriE). Scan no. 987. *m/z* 496 [M^+], 481 [$M^+ - 15$], 424 [cleavage at C_{15} to C_{16} representing $(CH_3)_3SiO^+$=CH–$(OSi(CH_3)_3)$–CH_2–CH=CH–CH_2–CH=CH–CH_2–CH=CH–$(CH_2)_3COOCH_3$], 396 [$M^+ - 100$], 275 [cleavage from C_{14} to C_{20} with loss of $(CH_3)_3SiO^+$=CH–CH$(OSi(CH_3)_3)$–$(CH_2)_4$–CH_3], and 173 [cleavage from C_{15} to C_{20}].

(vi) 11,12,19-Trihydroxy-5Z,8Z,14Z-eicosatrienoic acid (11,12,19-tri-HETriE). Scan no. 1149. *m/z* 585 [$M^+ + 1$], 569 [$M^+ - 15$], 403 [$M^+ - 181$; cleavage between C_{10} and C_{11} with the loss of $(CH_2$–CH=CH$)_2$–$(CH_2)_3$–$COOCH_3$], 385 [cleavage between C_{12} and C_{13} with the loss of $(CH_3)_3SiO^+$=CH–CH$(OSi(CH_3)_3)$–$(CH_2$–CH=CH$)_2$–$(CH_2)_3$–$COOCH_3$], 313 [385 – 72 (possibly $(CH_3)_3Si - 1$)]; 295 [385 – 90]; 283 [cleavage at C_{11} to C_{12} with loss of $(CH_3)_3SiO^+$=CH–$(CH_2$–CH=CH$)_2$–$(CH_2)_3$–$COOCH_3$]; 223 [295 – 72]; 191 [295– (72 + 32)], and 117 [$(CH_3)_3SiO^+$=CH–CH_3].

The controls did not produce oxygenated derivatives of either 18:2n-6 or 20:4n-6. During the growth of *L. lacteus* on safflower oil, the major oxygenated fatty acid recoverable from the medium was 8-HODE, as expected. The same appeared to be the case with glucose-grown cells, until it became apparent that the 8-HODE was the product of the oxygenation of fatty acids present in the yeast extract added to the growth medium. To overcome any ambiguities this may have caused when determining the origin of fungal oxylipins, we then switched to using yeast extract which had been defatted by repeated washing with chloroform prior to its addition to the growth medium.

After the addition of exogenous fatty acids, only trace amounts of the oxylipins of 18:2n-6 or 20:4n-6 were recovered in the cell extracts. One of two explanations may account for this: either the oxylipins were exported from the cells during the metabolism of 18:2n-6 and 20:4n-6 or the enzyme responsible for 8-HODE biosynthesis and derivatives of 20:4n-6 were secreted by the cells into the growth medium. The secretion in large quantities of an enzyme of this nature, a manganese-con-

taining lipoxygenase that results in the biosynthesis of oxylipins of linoleic acid, has been reported from the take-all fungus, *G. graminis* (17).

Unusually for an organism classified as an Oomycete and for an aquatic species, eicosanoids amounted to only a small proportion of the total cellular lipids in *L. lacteus*; 20:4n-6 accounted for 0.3% of the total cellular fatty acid. The major fatty acids were 18:2n-6, constituting 40% of cellular fatty acid; 18:1n-6, constituting 35%; and 16:0, constituting 30%.

Chiral analysis. The enantiomeric composition of 8-HODE was 98% *R* and 2% *S* (Hamberg, M., personal communication). The compound thus has the same chirality as 8*R*-HODE produced by *G. graminis* (18).

The most abundant oxylipins of 20:4n-6 were 18-HETE and 19-HETE which, when converted to their naphthyl ester methyl ester derivatives, displayed two peaks by HPLC; the first to be eluted was the *R* enantiomer (e.g., 18-HETE, Fig. 4). The enantiomeric distribution was 86% *R*/14% *S* for 18-HETE and 90% *R*/10% *S* for 19-HETE. The monohydroxylated oxylipins produced by *Leptomitus* are therefore formed stereospecifically.

Inhibition of oxylipin biosynthesis. Aspirin, an inhibitor of cyclooxygenase enzymes (19), indomethacin and aesculetin, inhibitors of lipoxygenases (20), all brought about a small decrease of 12–18% in the biotransformation of 18:2n-6 to 8*R*-HODE (Table 1); this was calculated in comparison to controls in which no inhibitors were added. 8*R*-HODE, for these experiments, was detected radiochemically by TLC and ran to an R_f of 0.40. The relatively small inhibition recorded with these compounds did not seem to represent firm evidence that 8*R*-HODE was produced by a cyclooxygenase or lipoxygenase-type enzyme. The extent of the inhibition of 8*R*-HODE biosynthesis with NDGA (30%) was significantly higher and may indicate that 8*R*-HODE was synthesized by a lipoxygenase-type enzyme. NDGA, however, possesses general antioxidative properties, and so caution is necessary in interpreting this result; NDGA has been shown to inhibit certain reactions catalyzed by cytochrome P_{450} monooxygenases in rat tissues (21). These experiments were carried out using whole cells, and it may be that some of the inhibitors could have become inactivated during the incubation.

Exposure of *L. lacteus* to CO, for either 1 or 10 min, had little effect on the ability of the organism to oxygenate 18:2n-6 to 8*R*-HODE. This appeared to rule out the involvement of a cytochrome P_{450}-type enzyme in the biosynthesis of this molecule, as it is well established that enzymes of this kind are inactivated by irreversible binding of CO to the catalytic site of the enzyme. The relative insensitivity of the enzyme responsible for 8*R*-HODE biosynthesis to CO is a feature shared by the enzyme isolated from *G. graminis* and characterized as linoleate diol synthase (LDS) (22). However, the similarities between the two enzymes may end there because LDS in *G. graminis* produces 7,8-di-HODE as a major metabolite of linoleic acid, a compound that was not detected in this study. The small amount of 8*R*-HODE which was synthesized by *G. graminis* appeared to be the result of the presence of heme in the LDS, which caused the reduction of some of the 8-hydroperoxylinoleic acid to 8*R*-HODE (22), while the remainder was metabolized to 7,8-di-HODE. Clearly, more detailed experiments are required, involving purification of the enzyme, before it can be established that a dioxygenase is responsible for the biosynthesis of 8*R*-HODE in *L. lacteus*. For example, we have yet to prove that a hydroperoxide is formed as a precursor to 8*R*-HODE biosynthesis.

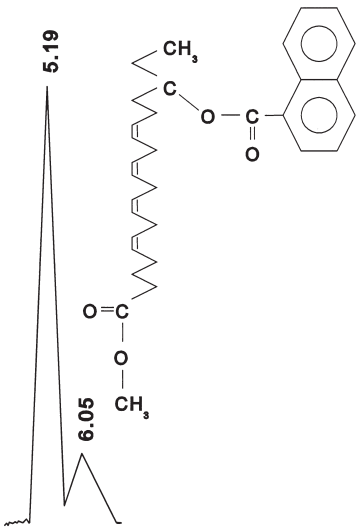

FIG. 4. Partial HPLC chromatogram (with retention times) showing the separation of the *R* (first peak) and *S* enantiomers of the naphthyl ester methyl ester derivatives of 18-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid from *Leptomitus lacteus.*

Exposure of *L. lacteus* to CO for 1 min decreased the oxygenation of [1-^{14}C]20:4n-6 to 18-HETE, 19-HETE, and 14,15-di-HETE by 37% (Table 1). This value rose to 62% when the exposure of the organism to CO was increased to 10 min. Neither aspirin nor indomethacin inhibited the oxygenation of 20:4n-6 to these mono- and di-HETE to any significant extent and the inhibition with aesculetin, at 14%, was also not significant. In contrast, NDGA decreased biosynthesis of mono- and di-HETE by 82%, but as with the biotransformation of 18:2n-6 to 8*R*-HODE, this may represent a general antioxidative effect of the drug.

TABLE 1
Inhibition of the Biosynthesis of 8-HODE from 18:2n-6 and Mono- and Di-HETE of 20:4n-6 in *Leptomitus lacteus*

	Inhibition in the biosynthesis of oxylipins of 18:2n-6 and 20:4n-6[a] (%)	
Inhibitor added	8-HODE	Mono/di-HETE
Aspirin (1 mM)	12	2
Indomethacin (1 mM)	18	2
Aesculetin (1 mM)	12	14
NDGA (1 mM)	30	82
CO (1 min)	2	37
CO (10 min)	2	62

[a]Calculated in comparison to controls where no inhibitors were added. 8-HODE, 8-hydroxy-9*Z*,12*Z*-octadecadienoic acid; mono-/di-HETE, 18-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid (HETE) + 19-HETE + 14,15-di-HETE; NDGA, nordihydroguaiaretic acid.

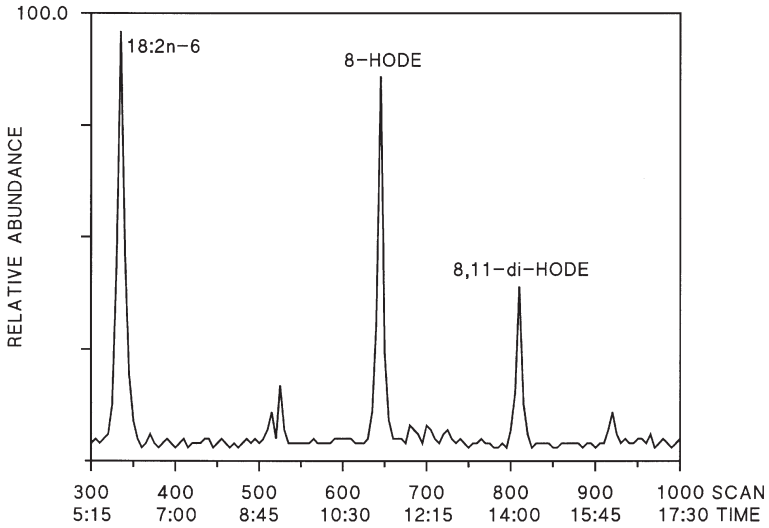

FIG. 5. Partial total ion current chromatogram of methyl and silyl derivatives of fatty acids extracted from a cell lysate low-speed supernatant (15,000 × *g*) of *Leptomitus lacteus* incubated with 18:2n-6. For abbreviation see Figure 1.

The susceptibility of the organism to CO with respect to the formation of 18-HETE, 19-HETE, and 14,15-di-HETE, as opposed to the biosynthesis of 8*R*-HODE, suggested that these reactions were catalyzed by a cytochrome P_{450} oxygenase.

Cell-free incubations. The 8*R*-HODE biosynthesis was found to occur in the supernatant from the initial centrifugation step (i.e., the cytosolic fraction; Fig. 5). The total yield of 8*R*-HODE under our incubation conditions was variable, but could be as high as 40–50%; the synthesis of 8*R*-HODE was unaffected by addition of NADPH. Other derivatives of 18:2n-6 were also produced, notably 8,11-di-HODE, as well as some uncharacterized derivatives. It therefore appeared that the enzyme synthesizing 8*R*-HODE in *L. lacteus* was probably soluble.

Our initial attempts at demonstrating cell-free 8*R*-HODE biosynthesis were unsuccessful; this may in part have been due to the presence of the widely used protease inhibitor PMSF (phenylmethanesulfonyl fluoride) in our extraction buffer (which we later eliminated). Some protease inhibitors have been reported to inhibit the biosynthesis of 7,8-di-HODE in *G. graminis* (23). 8*R*-HODE biosynthesis was not detected in either microsomes or a high-speed supernatant. We are at present unclear as to why enzyme activity for 8*R*-HODE biosynthesis was lost in our high-speed supernatant. The fact that 8*R*-HODE biosynthesis was achieved in soluble enzyme extracts may allow further characterization of this enzyme.

The fatty acid derivatives of 20:4n-6 we found were 18- and 19-HETE and uncharacterized di-HETE (results not shown). In this case, the compounds were only detected when the cytosolic fraction was incubated with NADPH, but the total yields of 18- and 19-HETE were less than 0.5%. This implied that the cytochrome P_{450} enzymes involved in the biotransformation of 20:4n-6 were, like that for 8*R*-HODE biosynthesis, probably cytosolic.

In conclusion, *L. lacteus* possesses several enzymes capable of oxygenating long-chain fatty acids; it remains to be discovered what role these enzymes play in the life cycle and biochemistry of the organism.

Fatty Acid Transport Across Lipid Bilayer Planar Membranes

L.G. Romano-Fontes, R. Curi, C.M. Peres, A. Nishiyama-Naruke, K. Brunaldi, F. Abdulkader, and J. Procopio*

Departamento de Fisiologia e Biofísica, Instituto de Ciencias Biomédicas, Universidade de São Paulo, Brazil

ABSTRACT: The transport of palmitic acid (PA) across planar lipid bilayer membranes was measured using a high specific activity [^{14}C]palmitate as tracer for PA. An all-glass *trans* chamber was employed in order to minimize adsorbance of PA onto the surface. Electrically neutral (diphytanoyl phosphatidylcholine) and charged (Azolectin) planar bilayers were maintained at open electric circuit. We found a permeability to PA of (8.8 ± 1.9) × 10^{-6} cm s^{-1} (n = 15) in neutral and of (10.3 ± 2.2) × 10^{-6} cm s^{-1} (n = 5) in charged bilayers. These values fall within the order of magnitude of those calculated from desorption constants of PA in different vesicular systems. Differences between data obtained from planar and vesicular systems are discussed in terms of the role of solvent, radius of curvature, and pH changes.

Paper no. L8056 in *Lipids 35,* 31–34 (January 2000).

Nonesterified fatty acids (FA) have a central role in cellular processes, such as cell signaling (1), K^+ channel activation (2), Na^+/Ca^{2+} exchange (3), uptake modulation of plasmatic lipoproteins (4), and uncoupling of oxidative phosphorylation (5), among others. Furthermore, recent studies suggest that FA may function as proton carriers across the cell membrane (6).

A crucial question in the physiology of FA refers to their mechanism of entry into and export from cells.

Studies of intravesicular acidification of unilamellar vesicles (UV) (6,7) have shown a very fast FA flip-flop rate in bilayers following pulses of FA on the bath. On the other hand, more recent studies (8) suggest the flip-flop is the limiting process in FA transfer across UV.

Furthermore, studies of FA transport across planar bilayer membranes (PBM) are scant and have provided mainly indirect evidence (9) of FA flip-flop.

The availability of [^{14}C]palmitic acid (PA) at a very high specific activity prompted us to investigate directly the transfer of this FA across planar bilayers and provided direct evidence that its translocation across the membrane occurs at a reasonably fast rate, comparable to that described for vesicular systems.

Abbreviations: cpm, counts per minute; DPPC, diphytanoyl phosphatidylcholine; FA, fatty acid; GUV, giant unilamellar vesicle; LUV, large unilamellar vesicle; PA, palmitic acid; PBM, planar bilayer membranes; SUV, small unilamellar vesicle; Trizma, tris(hydroxymethyl)aminomethane; UV, unilamellar vesicles.

MATERIALS AND METHODS

PA transfer across PBM was measured by tracer flow using ^{14}C-labeled ([U-^{14}C]palmitic acid, with a specific activity of 850 Ci mol^{-1}; DuPont, Boston, MA). Quantities of the tracer in the *cis* (hot) side ranged from 200,000–1,000,000 counts per minute cm^{-3}, giving a maximal PA concentration of 0.5 μmol L^{-1}.

Experiments were carried out under conditions of open electric circuit, with no attached electronics. Owing to the known adsorbance of FA to plastics (10), we employed an all-glass chamber as *trans* compartment. Also, samples from the *trans* (cold) side had no contact with plastics. To check for FA escape from the bilayer material, samples of aqueous solutions bathing the bilayers were run on high-performance liquid chromatography. Levels of FA contaminants were undetectable.

Electrically neutral PBM were formed from diphytanoyl phosphatidylcholine (DPPC) from Avanti Polar Lipids (Alabaster, AL), and negatively charged membranes were formed from soybean lecithin (Azolectin; Sigma Chemical Co., St. Louis, MO), which contains about 10% of charged phospholipids, mainly phosphatidylglycerol (11). The phospholipids were dissolved in *n*-decane (2.5 mg lipid/100 μl *n*-decane). Surface potentials of charged membranes in 5 mM KCl–5 mM Trizma [tris(hydroxymethyl)aminomethane] were determined, according to a modification of the method described by McLaughlin *et al.* (12), by measuring the ratio of the valinomycin-doped membrane conductances before and after addition of Ba^{2+} to the bath.

Bilayers were formed, using the technique of Mueller *et al.* (13), across a hole (1- to 2-mm diameter) in the lateral wall of a cylindrical glass vial. The hole was made using the procedure described by Procopio *et al.* (14). Both *trans* and *cis* sides were adequately stirred. Solutions had the same composition and had volumes between 2 and 3 mL. In experiments using neutral bilayers, solutions were 150 mM NaCl + Trizma base 20 mM, titrated to pH 7.4. Solutions used for charged membranes were KCl 5 mM + Trizma 5 mM, pH 7.2, in order to maintain low ionic strength and enhance the negative surface potential. Surface pH is lower than bulk pH in this condition; this difference increases FA partitioning into the membrane phase (see Ref. 15 for example and discussion).

Samples of 200 μL were drawn from the *trans* (cold) side at 15 and at 30 or 45 min after introduction of labeled palmi-

tate into the *cis* side. The use of these time intervals was dictated by the geometry of the system and bilayer permeability: 15 min was the minimum for obtaining statistically significant cpm on the trans (cold) side, and 45 min was the maximal membrane lifetime on average. A single 50-µL sample was obtained from the *cis* (hot) side. Samples were diluted in Universol™ from ICN Biomedicals (Costa Mesa, CA) and counted in a Beckman counter for β^- emission, from 20 kEV upwards.

Since the sampling procedure removes a significant number of cpm from the cold side, a correction was done for cpm withdrawal during multiple samplings, according to the procedure described in Figure 1. We also checked, using ink, that the mixing time in the solutions was below 1 min.

RESULTS

Figure 1 depicts a typical time evolution of the isotopic activity on the cold side, in a three-samples experiment. Thanks to the enormous $t_{1/2}$ (see Eq. A-12 in the Appendix) of the process during the first few hours after the tracer addition to the *cis* side, the following assumptions can safely be made: (i) The *cis* (hot) side isotopic activity is constant, and (ii) the increase in isotopic activity in the *trans* (cold) side is linear with time.

Indeed, in preliminary experiments, we did not identify any tendency of the cold-side activity vs. time plots to deviate from linearity.

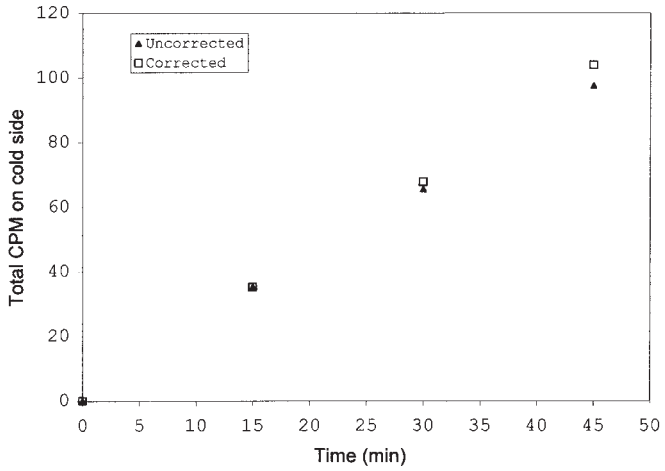

FIG. 1. Plot of total counts per minute (cpm) on the cold side as function of time for a typical 3-sample experiment. The point at time zero corresponds to a blank and has zero cpm by definition. Correction for cpm withdrawal during samplings was done according to the equation exemplifying the correction for Sample #3:

$$\text{total cpm}_3 = (\text{cpm}_3 - \text{cpm}_{\text{blank}})\ \frac{\text{CSV}}{\text{CSAV}} + (\text{cpm}_2 - \text{cpm}_{\text{blank}}) + (\text{cpm}_1 - \text{cpm}_{\text{blank}})$$

where total cpm_3 = total corrected cpm on cold side in sampling #3, at 45 min; $\text{cpm}_{\text{blank}}$ = average cpm of two blanks; cpm_1, cpm_2, and cpm_3 = counted cpm in samples #1, #2, and #3 respectively, at 15, 30, and 45 min; CSV = volume of cold side (variable); and CSAV = volume of aliquot taken from cold side (200 µL).

Table 1 shows the bilayer permeability to PA obtained in our study, compared with those calculated from the literature, in unilamellar vesicles. Permeability coefficients for [^{14}C]palmitic acid across PBM were calculated as follows:

$$\text{permeability to [}^{14}\text{C]palmitic acid} = \frac{\text{flow of cpm}}{[\text{cpm}]_{cis}} \quad [1]$$

where the flow of cpm is expressed as cpm s^{-1} cm^{-2} and $[\text{cpm}]_{cis}$ is cpm cm^{-3},

$$\text{flow of cpm} = \frac{\text{average difference in total cpm betwen 2 successive } \textit{trans} \text{ samples}}{\text{time difference} \times \text{membrane area}} \quad [2]$$

$[\text{cpm}]_{cis}$ counts for samples taken from the *cis* (hot) side,

$$\text{total cpm} = (\text{cpm in } \textit{trans} \text{ sample}) \times \frac{\textit{trans} \text{ volume}}{\text{sample volume}} + \Sigma \text{ cpm in previous } \textit{trans} \text{ samples} \quad [3]$$

Permeabilities to palmitic acid of UV membranes, used for comparison, were estimated from literature values (8,16) of the desorption rate contants (k_{off}), using Equation 4 (derived in the Appendix as Eq. A-12),

$$\text{permeability} = k\ \frac{\text{vesicular radius}}{3} \quad [4]$$

DISCUSSION

Our results indicate a permeability of planar bilayers to PA of about the same order of magnitude as those calculated for large unilamellar vesicles (LUV) and giant unilamellar vesicles (Table 1). The present comparison needs careful interpretation because of the present controversy as to the rate-limiting step for FA transfer across bilayers and the extremely

TABLE 1
Comparison Between PBM and UV Data on Palmitic Acid Permeability[a]

Planar bilayers (this paper) (T = 22–24°C) (mean ± SEM)	SUV (diam. ≈ 25 nm) (Ref. 16) (T = 24 ± 1°C) (k_{off} = 8.22 s^{-1})	GUV (diam. ≈ 200 nm) (Ref. 8) (T = 20°C) (k_{off} ≈ 0.5 s^{-1})
DPPC (neutral) (8.8 ± 1.9) × 10^{-6} (n = 15)	2.7 × 10^{-6}	1.7 × 10^{-6}
Soybean lecithin (charged) (10.3 ± 2.2) × 10^{-6} (n = 5)		

[a]Permeabilities (cm s^{-1}) of small unilamellar vesicles (SUV) and giant unilamellar vesicles (GUV) were calculated from Equation 2 (see Results section), based on reported rate constants for palmitic acid, k_{off}. DPPC, diphytanoyl phosphatidylcholine.

diverse geometry of these membrane systems. Our experiments measure a "lumped" transfer parameter which includes the three essential steps in FA translocation, i.e., adsorption, flip-flop, and desorption. It is generally assumed that the adsorption step is very fast compared either to flip-flop or desorption, but controversy still remains (8) regarding the difference between flip-flop and desorption rates. Table 1 compares the permeability of PBM to PA and permeability coefficients estimated from the reported desorption rates of PA from vesicles, assuming the limiting step is desorption. In Table 1, permeability values calculated from such diverse systems as PBM and UV fall within one order of magnitude of each other.

In the group of charged membranes, we determined the surface potential in KCl 5 mM + Trizma 5 mM as Ψ_o = –112.4 ± 11 mV (SEM) (n = 4) (see Materials and Methods section), which corresponds to an increase of surface apparent pK (17) given by:

$$\Delta pK_a = \frac{F}{2.3RT}\Psi_o = 2 \text{ units} \qquad [5]$$

thus favoring the protonated form of PA in the membrane vicinity. This effect supposedly increases the FA partitioning into the bilayer matrix. The finding of only a small increase in permeability in going from neutral to charged membranes favors the idea that the limiting step for FA passage is indeed desorption.

Differences between the PA permeability in UV and PBM might occur by the presence of solvent in the planar membranes (and absence in UV) and the small radius of curvature of UV. The extremely small radius of curvature of small unilamellar vesicles (SUV) and LUV may create mismatch between the areas of the inner and outer vesicular bilayer leaflets, increasing the probability of defects and leading to facilitation of FA flip-flop (8). This latter effect, however, may be rendered unnoticeable by the slower transfer imposed by desorption.

By having both compartments at a fixed pH (in our case, 7.4 and 7.2), we avoided the inherent pH decrease of the *trans* side observed in UV studies, due to FA entry. This decrease in pH was associated with the build-up of diffusion potentials (16) that could counteract proton passage.

APPENDIX

Derivation of kinetic parameters of FA transfer relating data on planar bilayers and vesicles. We analyzed the washout [uptake gives a similar result] of FA from a spherical compartment with volume V (*cis* side) across an area A and to an infinite external reservoir (*trans* side), with a rate constant k:

$$\text{FA } (cis) \xrightarrow{k \text{ (membrane)}} \text{FA } (trans) \qquad [A\text{-}1]$$

From the definition of the rate k, we have

$$-\frac{d[\text{FA}]_{cis}}{dt} = k[\text{FA}]_{cis} \qquad [A\text{-}2]$$

Rearranging and integrating Equation A-2, we obtain

$$\int \frac{d[\text{FA}]_{cis}}{[\text{FA}]_{cis}} = -kt \qquad [A\text{-}3]$$

giving, finally, the FA concentration (in the *cis* side) as a function of time as:

$$[\text{FA}]^t_{cis} = [\text{FA}]^0_{cis} e^{-kt} \qquad [A\text{-}4]$$

where $[\text{FA}]^0$ and $[\text{FA}]^t$ are the concentrations of FA at time zero and at time t in the *cis* compartment.

Multiplying both sides of Equation A-2 by the volume V and dividing by the area A, we obtain the flow of FA molecules (in mol s^{-1} cm^{-2}) from the internal (*cis*) compartment to the infinite external reservoir,

$$\text{flow of FA} = -\frac{d[\text{FA}]_{cis}}{dt}\left(\frac{V}{A}\right) = k\left(\frac{V}{A}\right)[\text{FA}]_{cis} \qquad [A\text{-}5]$$

But, since the relation between flow and concentration difference of a substance S across a membrane is the membrane permeability coefficient (P) to S we can write, from Equation A-5,

$$\text{flow of FA} = k\left(\frac{V}{A}\right)[\text{FA}]_{cis} = P[\text{FA}]_{cis} \qquad [A\text{-}6]$$

from which we obtain that:

$$P = k\frac{V}{A} \qquad [A\text{-}7]$$

Since k and $t_{1/2}$ are related by

$$t_{1/2} = \frac{0.693}{k} \qquad [A\text{-}8]$$

we obtain:

$$t_{1/2} = 0.693\,\frac{V}{P\,A} \qquad [A\text{-}9]$$

which is valid for any geometry.

For the particular case of a spherical vesicle we have:

$$\text{volume} = (4/3)\pi R^3 \qquad [A\text{-}10]$$

$$\text{area} = 4\pi R^2 \qquad [A\text{-}11]$$

from which we obtain the relation between the rate constant and permeability for a vesicular structure as

$$\text{permeability} = k\,\frac{\text{vesicular radius}}{3} \qquad \text{[A-12]}$$

Applying Equation A-9 to the case of a planar bilayer with area = 3×10^{-2} cm^2 separating an outer reservoir with large volume from an inner reservoir with 2-mL volume, we obtain (using our tracer-measured permeability for FA = 8.8×10^{-6} cm s^{-1})

$$t_{1/2} = 0.693\,\frac{V}{P\,A} = 0.693\,\frac{2}{(8.8 \times 10^{-6})(3 \times 10^{-2})} = 5.25 \times 10^{6}\ \text{s} = 60\ \text{d} \qquad \text{[A-13]}$$

which, of course, precludes the use of this system for determination of kinetic studies based on half-time determination for FA and justifies the use of tracer flow protocols.

Coordinate Packaging of Newly Synthesized Phosphatidylcholine and Phosphatidylglycerol in Lamellar Bodies in Alveolar Type II Cells

Avinash Chander*, Namita Sen, Sandra Wadsworth, and Alan R. Spitzer

Division of Neonatology, Department of Pediatrics, Jefferson Medical College, Thomas Jefferson University, Philadelphia, Pennsylvania

ABSTRACT: Methylamine, a weak base, inhibits packaging of newly synthesized phosphatidylcholine (PC) in lamellar bodies in 20–22 h cultured alveolar type II cells, suggesting a role for acidic pH of lamellar bodies. In this study, we tested if (i) the packaging of PC is similarly regulated in freshly isolated type II cells and (ii) methylamine also inhibits the packaging of other surfactant phospholipids, particularly, phosphatidylglycerol (PG). The latter would suggest coordinated packaging so as to maintain the phospholipid composition of lung surfactant. During the short-term metabolic labeling experiments in freshly isolated type II cells, methylamine treatment decreased the incorporation of radioactive precursors into PC, disaturated PC (DSPC), and PG of lamellar bodies but not of the microsomes, when compared with controls. The calculated packaging (the percentage of microsomal lipid packaged in lamellar bodies) of each phospholipid was similarly decreased (~50%) in methylamine-treated cells, suggesting coordinated packaging of surfactant phospholipids in lamellar bodies. Equilibrium-labeling studies with freshly isolated type II cells (as is routinely done for studies on surfactant secretion) ± methylamine showed that in methylamine-treated cells, the secretion of PC and PG was decreased (possibly due to decreased packaging), but the phospholipid composition of released surfactant (measured by radioactivity distribution) was unchanged; and the PC content (measured by mass or radioactivity) of lamellar bodies was lower, but the PC composition (as percentage of total phospholipids) was unchanged when compared with control cells. We speculate that the newly synthesized surfactant phospholipids, PC, DSPC, and PG, are coordinately transported into lamellar bodies by a mechanism requiring the acidic pH, presumably, of lamellar bodies.

Paper no. L8341 in *Lipids 35*, 35–43 (January 2000).

Pulmonary surfactant is a lipoprotein-like substance that lines the alveolar epithelium. It maintains alveolar stability during end-expiration by lowering the surface tension at the air–liquid interface (reviewed in 1,2). Various lipid and protein components of lung surfactant are synthesized and secreted by lung epithelial type II cells (reviewed in 2,3). The major phospholipids of lung surfactant, phosphatidylcholine (PC), disaturated PC (DSPC), and phosphatidylglycerol (PG) are stored in the lamellar bodies and secreted by exocytosis of lamellar body contents into alveolar lumen. Various agents can increase the secretion and clearance of lung surfactant to maintain its alveolar pool size (reviewed in 3,4). Although not investigated, any alteration in the packaging of one or more surfactant phospholipids has the potential to affect the quantity and quality of alveolar surfactant pool.

Various models have been suggested for phospholipids trafficking from their site of synthesis to target membranes (5,6). One of these involves molecular transfer of phospholipids through phospholipid transfer proteins (5), which also are present in type II cells, where they are suggested to mediate transfer of PC, DSPC, and PG to lamellar bodies (reviewed in Ref. 7). Another mechanism for transfer of phospholipids (and proteins) may involve vesicle trafficking from the site of synthesis to the targeted membrane (8–10). The phospholipid composition of lung surfactant is maintained within a narrow range, suggesting coordinated packaging of surfactant phospholipids in lamellar bodies. Such coordination can be exerted by controlling the activities of different phospholipid transfer proteins toward each of the surfactant phospholipids or by transport of surfactant phospholipids through vesicles, which may fuse with small or growing lamellar bodies.

The lamellar bodies are unique organelles in type II cells that are rich in phospholipids and hydrophobic proteins (11), contain lysosomal enzymes (12–14), and maintain an internal acidic pH by a vacuolar type H^+-ATPase (15–17). The intralamellar body pH can be increased with membrane-permeable weak bases (12,15). The function of the acidic pH is unclear, but may be necessary for the packaging of *de novo* synthesized surfactant PC (16), processing of surfactant protein B (18) or C (19), or the function of surfactant protein A (20).

For this study, we used methylamine treatment as a tool to investigate the mechanism of surfactant phospholipid trafficking from endoplasmic reticulum to lamellar bodies. Our previous study in 20–22 h cultured type II cells showed that methylamine inhibited the packaging of PC and DSPC in lamellar

Abbreviations: ANOVA, Analysis of variance; CL, cardiolipin; DPPC, dipalmitoyl phosphatidylcholine; DSPC, disaturated phosphatidylcholine; MEM, minimum essential medium; PMA, phorbol 12-myristate 13-acetate; PC, phosphatidylcholine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; PL, phospholipid; Sph, sphingomyelin; TLC, thin-layer chromatography.

bodies (16). Since lung epithelial type II cells show altered morphologic and metabolic characteristics during cell culture (21,22), we conducted metabolic studies in freshly isolated type II cells to test the following hypotheses: (i) Methylamine inhibits the packaging of PC in lamellar bodies in freshly isolated type II cells, which will suggest that the pH regulation of PC packaging is intrinsic to type II cells and is not an artifact of cell culture, and (ii) the acidic pH also regulates the packaging of PG, the third major surfactant phospholipid after DSPC and unsaturated PC. Such regulation of PG, DSPC, and unsaturated PC would suggest that the phospholipids of lung surfactant are transported in a coordinated manner so as to maintain the phospholipid composition of lung surfactant. We tested these hypotheses by conducting metabolic labeling studies in freshly isolated type II cells and found that freshly isolated type II cells packaged a higher percentage of microsomal PC in lamellar bodies when compared with 20–22 h cultured cells (16). Methylamine treatment inhibited PC and DSPC packaging in lamellar bodies in freshly isolated type II cells. Furthermore, methylamine also inhibited the packaging of PG in lamellar bodies but did not alter the phospholipid composition of secreted surfactant, supporting the concept of coordinated packaging of lung surfactant phospholipids in lamellar bodies. As in the previous study (16), the packaging of a phospholipid in lamellar bodies is defined as the ratio of incorporation into a lamellar body lipid to that in the microsomal lipid.

MATERIALS AND METHODS

Materials. [^{3}H-methyl]Choline, [9,10-^{3}H]palmitic acid, and [^{14}C]dipalmitoyl PC (DPPC) were obtained from Amersham Corp. (Arlington Heights, IL). Tissue culture plastic dishes were obtained from Corning (Corning, NY). Bacteriological plates were purchased from Becton Dickinson (Franklin Lakes, NJ). All other tissue culture supplies were obtained from Gibco/BRL (Grand Island, NY). Porcine elastase was obtained from Worthington Biochemicals (Freehold, NJ). Terbutaline, methylamine, phorbol 12-myristate 13-acetate (PMA), vanadate-free adenosine triphosphate (ATP), and all other chemicals were purchased from Sigma Chemical Co. (St. Louis, MO). All phospholipids were obtained from Avanti Polar Lipids, Inc. (Alabaster, AL). All chemicals were added at the indicated final concentrations.

Isolation of type II cells. Sprague-Dawley rats (180–200 g body weight) were used for isolation of alveolar type II cells according to Dobbs *et al.* (23), as described previously (24). Briefly, lungs of anesthetized and exsanguinated rats were visibly cleared of blood, and intratracheally treated (×3) with porcine elastase (3 units/mL). The lung tissue was then minced on a tissue chopper, and free cells were sequentially filtered through nylon filters of various sizes. The free cells were incubated for 1 h on rat IgG-coated bacteriological plates. Thereafter, the free cells were collected by "panning." Staining with phosphine showed that >85% of these cells were type II cells and >90% of cells excluded vital dye, erythrosin B. These cells were termed as freshly isolated type II cells.

Short-term labeling of freshly isolated cells: About 4×10^7 cells were taken up in 3.0 mL of fresh minimum essential medium (MEM) and incubated for 15 min in air containing 5% CO_2 at 37°C in a shaking water bath at 75 cycles/min. The radioactive substrate of interest, [^{3}H-methyl]choline or [9,10-^{3}H]palmitic acid, was added at a final concentration of 0.1 mM. In these experiments, [^{3}H]palmitic acid was complexed with fatty acid-poor bovine serum albumin (fatty acid to bovine serum albumin ratio 6:1; mol/mol) before addition to the cells. The incubations were continued for another 60 min after addition of 5 mM methylamine to experimental tubes. The labeling was terminated by addition of 10 mL of ice-cold MEM and the cells separated by centrifugation for 10 min at $300 \times g$. The cells were washed with fresh MEM and then processed for isolation of subcellular fractions as described below.

Long-term labeling of type II cells: In these studies, cells were incubated for 20–22 h in the presence of indicated radioactive substrate (as is routinely done for surfactant secretion studies) and ± methylamine. Preliminary studies indicated that >2.5 mM methylamine interfered with attachment of cells to tissue culture plastic dishes during 20–22 h incubation, although cells already attached to plastic were unaffected by up to 10 mM methylamine (16). Therefore, all long-term labeling studies employed 2.5 mM or lower concentrations of methylamine. Freshly isolated cells were plated in MEM containing 10% fetal bovine serum (1.5×10^6 cells/35 mm plate or 10^7 cells/100 mm plate at 10^6 cells per mL) for 20–22 h in tissue culture plastic dishes and in the presence of 0.25 μCi/mL of [^{3}H-methyl]choline (36 Ci/mol) or 2.5 μCi/mL of [9,10-^{3}H]palmitic acid (54 Ci/mmol). The latter was added from a stock solution in ethanol. The final concentration of ethanol was 0.25%. Where indicated, methylamine or NH_4Cl was added at the start of this incubation period. At the end of this culture period, cells attached to plastic dishes were routinely found to be >93% type II cells, as evaluated by fluorescence staining with phosphine, and >95% of these cells excluded vital dye, erythrosin B. These cells were then processed for isolation of subcellular fractions, surfactant secretion studies, or for distribution of [9,10-^{3}H]palmitic acid radioactivity into various phospholipid classes in the cells and the medium.

Secretion of PC and PG. To evaluate if decreased packaging of surfactant components is reflected in decreased secretion, we measured PC and PG secretion in type II cells that were labeled in the absence or presence of methylamine. Isolated type II cells were labeled for 20–22 h (the cells also attach to plastic dishes during this period) with either [^{3}H-methyl]choline or [9,10-^{3}H]palmitic acid and in the absence or presence of 2.5 mM methylamine. These cells were evaluated for surfactant secretion in the absence of methylamine. The protocol for measuring surfactant secretion has been described previously (24). Briefly, after the labeling period of 20–22 h, the cells were washed (5×) with MEM. Fresh MEM was plated, and the cells were equilibrated for 30 min in 5% CO_2 in air. At the end of this incubation period, secretagogues were added from appropriate stock solution in <1% volume, and the incubation continued for another 2 h. ATP and terbutaline were pre-

pared fresh in water at 100-fold higher concentrations. Stock solution of PMA was prepared in ethanol and diluted 100-fold before addition to the incubation medium so that the final concentration of ethanol was 0.01%. At the end of 2 h of incubation, the medium from each plate was collected, and centrifuged for 10 min at 300 × *g* to sediment any free cells that may have come off during the incubation. The cells on the plate were pooled with those recovered after centrifugation of the medium. Aliquots of cells and medium from each sample were processed for lipid extraction (25) after addition of 0.4 mg of egg PC and [^{14}C]DPPC as a tracer to assess the recovery of PC. In some experiments, lipid mixture containing major surfactant lipids was added as carrier lipids so as to facilitate recovery and separation of surfactant phospholipids. For this purpose, rat lung surfactant was purified (26) and extracted for lipids (25). All results on radioactivity measurement for secretion were corrected for recovery of [^{14}C]DPPC. Secretion of PC in the medium was expressed as a percentage of that in the medium plus cells.

Isolation of lamellar bodies and microsomes. Freshly isolated cells, or 20–22 h-cultured type II cells, harvested by gentle scraping of petri dishes, were suspended in 1 M sucrose solution and disrupted by sonication (3 × 15 s) with a probe sonicator set at 10% of maximum output (Cell Disrupter, Model 50; Fisher Scientific Co., Philadelphia, PA). The lamellar body and microsomal fractions were isolated as described previously (16).

Isolation of membranes and "residual" fractions from lamellar bodies. The isolated lamellar bodies were resuspended in 0.05 M sucrose solution containing 5 μg/mL each of aprotinin, leupeptin, and pepstatin. The suspension was mixed well with a pasteur pipette, layered on 0.5 M sucrose, and centrifuged for 1 h at 80,000 × *g* to recover membrane fraction in the pellet (27). At the end of this centrifugation, a band present at the interface of 0.05/0.5 M sucrose was also collected and was termed the "residual" fraction.

Analytical. Proteins were measured by reaction with the protein-binding dye-reagent (Bio-Rad Laboratories, Richmond, VA) using bovine-γ-globulin as standard (28). DSPC was separated after oxidation of lipid extract with OsO_4 followed by chromatography on neutral alumina column (29). PC in lipid extracts was separated by thin-layer chromatography (TLC) on boric acid-impregnated plates (30). In experiments aiming to measure distribution of [9,10-^{3}H]palmitic acid radioactivity, the phospholipids were separated by two-dimensional TLC on boric acid-impregnated silica gel G plates (31). This method, however, could not be used for experiments that required determinations of mass and radioactivity in PC and PG because of problems with Pi measurements in eluates from scrapings of boric acid-impregnated silica gel plates. Therefore, in experiments aiming to measure both the mass and radioactivity in PG, we first chromatographed lipid extracts on prepackaged silica gel-bonded aminopropyl columns (LC-NH_2, Supelco; St. Louis, MO) and separated phospholipids into neutral polar lipids (PC, phosphatidylethanolamine, and sphingomyelin) and acidic polar lipids (phosphatidylglycerol, phosphatidylinositol, and phosphatidylserine), according to Alvarez and Touchstone (32). Individual phospholipids in these two fractions were separated by one-dimensional TLC on silica gel G plates (33). The phospholipids on TLC plates were visualized by exposure to I_2 vapors and identified by co-migration of authentic phospholipid. The phospholipid spots were scraped and processed for measurement of phospholipid phosphorus and/or radioactivity. Phospholipid phosphorus was measured by reaction with 1,2,4-amino naphthol sulfonic acid (34) as described previously (35). Radioactive samples were counted in a scintillation counter, and the counts were corrected for quenching using computer-generated quench curves.

All secretion experiments were carried out in duplicate and the results averaged to yield single data points. Results were evaluated for statistical significance by Students' *t*-test for experiments unpaired or paired with respect to the cell preparation. Comparison between multiple groups was carried out by analysis of variance (ANOVA) followed by Tukey's post-hoc test. Differences were considered significant at $P < 0.05$.

RESULTS

Short-term labeling in freshly isolated cells. The effects of 5 mM methylamine on labeling of PC in cell homogenate, and the microsomal and lamellar body fractions are shown in Table 1. In control cells, the labeling of cellular and microsomal PC from [^{3}H-methyl]choline was similar to that previously reported in 20–22 h cultured cells (16). As demonstrated before, as well as in this study, the methylamine treatment did not affect choline incorporation into PC or DSPC in the cell homogenate or in the microsomal fraction. Methylamine, however, decreased the labeling of lamellar body PC and DSPC by almost 60% when compared with controls.

Next, we evaluated the incorporation of [9,10-^{3}H]palmitic acid into PC and PG in the absence or presence of 5 mM methylamine (Table 2). Compared to controls, methylamine decreased the incorporation of [9,10-^{3}H]palmitic acid into lamellar body PG, but not into PG of cell homogenate or microsomal fraction. As observed with the choline incorporation

[a]Alveolar epithelial type II cells in suspension were incubated for 60 min with 0.1 mM [^{3}H]palmitic acid ± 5 mM MA. Results are means ± SE of four separate experiments. *$P < 0.05$ when compared with corresponding control. See Table 1 for abbreviations.

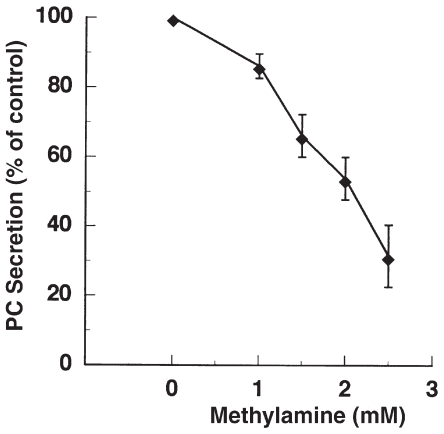

FIG. 2. Concentration-dependence of methylamine effect on packaging and secretion of surfactant PC. Isolated type II cells were labeled for 20–22 h with [^{3}H-methyl]choline in the absence or presence of indicated concentrations of methylamine. Thereafter, cells were washed and evaluated for PMA-stimulated secretion of PC. Results are means ± SE of experiments with four cell preparations and are expressed as percentage of phorbol 12-myristate 13-acetate (PMA)-stimulated secretion of PC (6.8 ± 0.8%) in untreated cells. See Figure 1 for other abbreviation.

(Table 1), methylamine also decreased the incorporation of [9,10-^{3}H]palmitic acid into PC of lamellar bodies but not of cell homogenate or the microsomal fraction. Using the incorporation results in Tables 1 and 2, we calculated the packaging of each phospholipid (PC, DSPC, and PG) into lamellar bodies. We specifically did not calculate the percentage incorporation of cellular lipid label into the lamellar bodies because of possible variations in the recovery of lamellar bodies, which would affect such calculations and, which cannot be corrected for recoveries because of lack of a specific lamellar body marker. As shown in Figure 1, the calculated percentage packaging (100 × labeling of lamellar body lipid per unit mass/labeling of microsomal lipid per unit mass) in control cells was higher for PG when compared with that of PC (49% PG and 23% PC). This difference in percentage packaging is possibly due to different PC pools in the endoplasmic reticulum, which is the site of synthesis of PC targeted for different subcellular compartment. Phosphatidylcholine is a major phospholipid class of most subcellular membranes while the microsomal PG pool may be intended mostly for the lamellar bodies. Compared to control cells, methylamine treatment decreased the packaging of all three phospholipids, DSPC, PC and PG, in the lamellar body fraction. The packaging of each phospholipid was decreased to the same extent (~50%) when compared with the corresponding controls. These results indicate that all three phospholipids are processed through a methylamine (or acidic pH)-sensitive step, suggesting coordinated packaging of surfactant phospholipids in lamellar bodies.

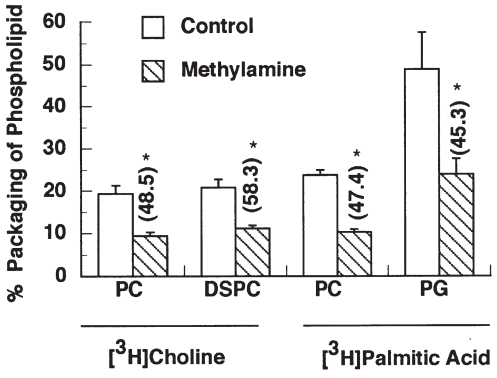

FIG. 1. Calculated percentage packaging of phosphatidylcholine (PC), disaturated phosphatidylcholine (DSPC), and phosphatidylglycerol (PG) in lamellar bodies of freshly isolated type II cells labeled with [^{3}H]choline or [^{3}H]palmitate in the absence (control) or presence of 5 mM methylamine. Percentage packaging was calculated from results given in Tables 1 and 2. *$P < 0.05$ when compared with corresponding controls. The numbers in parentheses indicate percentage inhibition of packaging of each phospholipid in methylamine-treated cells when compared with that in control cells.

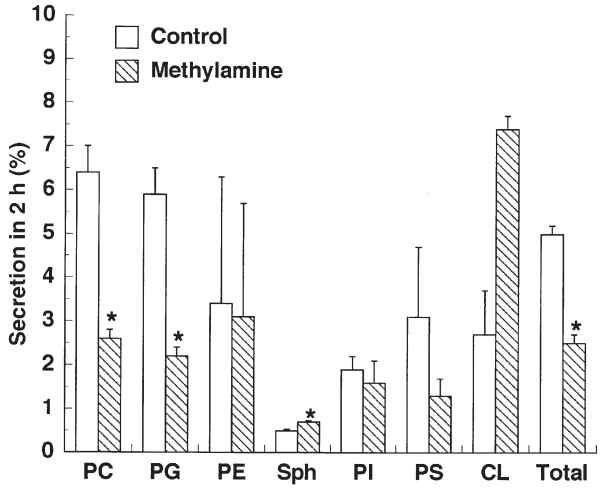

FIG. 3. PMA-stimulated secretion in cells labeled for 20–22 h with [^{3}H]palmitic acid and ± 2.5 mM methylamine. Results are means ± SE of three separate experiments except in case of PI and CL. *$P < 0.05$ when compared with control cells. CL, cardiolipin; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; Sph, sphingomyelin. See Figures 1 and 2 for other abbreviations.

[a]Cells were labeled for 20–22 h with [^{3}H-methyl]choline in the absence (control) or presence of 2.5 mM MA. Results are means ± SE of experiments with four cell preparations. *$P < 0.05$ compared to corresponding controls. **$P < 0.05$ compared to corresponding control by *t*-test for experiments paired with respect to cell preparation. See Table 1 for abbreviations.

The effects of methylamine are unlikely due to cellular toxicity of this drug. We have previously shown that 10 mM methylamine did not increase the uptake of a vital dye, erythrosin B, or the lactate dehydrogenase release in type II cells (16). In this study also, the cell viability, as judged by exclusion of erythrosin B, was not different in cells incubated in the absence or presence of 5 mM methylamine (not shown). The results on the incorporation of [^{3}H]choline or [^{3}H]palmitic acid into the cellular or microsomal phospholipids would also suggest that the methylamine treatment is not toxic to type II cells.

Long-term labeling studies. Since the lamellar body contents are released by exocytosis during surfactant secretion, the decreased packaging of surfactant components in lamellar bodies would likely reflect decreased PC secretion in methylamine-treated cells. However, such inhibition of packaging would not alter the phospholipid composition of the released surfactant if these phospholipids were coordinately transported to the lamellar bodies. During standard protocol for surfactant secretion, type II cells are labeled for 20–22 h with a radioactive precursor. In these experiments, we also added 2.5 mM or lower concentrations of methylamine during this labeling period. Results from such experiments are shown in Tables 3–7 and Figures 2 and 3. In control cells, the incorporations into PC (specific activity, dpm/μg PC phosphorus) in the cell homogenate and the lamellar body and microsomal fractions were similar (Table 3), suggesting equilibrium labeling of PC in different subcellular compartments. In comparison, the specific activity of PC was decreased by 18% in the cell homogenate and by 25% in the lamellar body fraction in methylamine-treated cells. The decrease in the specific activity of cell PC was likely due to decreased labeling of lamellar body PC since it comprised a significant part of cell PC. In control cells, we recovered almost 27% of the cell PC pool in the lamellar bodies. Such recovery agrees well with the 15 times higher phospholipid-to-protein ratio of the lamellar body fraction when compared with the cell homogenate (Table 4). In methylamine-treated cells, we recovered only 16% of cell PC pool in lamellar bodies from methylamine-treated cells, a decrease of 39% when compared with the control group. As a result of decreased mass and specific activity of PC in lamellar bodies, the percentage recovery of total cell PC radioactivity (mass × specific activity) in the lamellar bodies was lower. The recovery of radioactive PC in the microsomal fraction accounted for only a small percentage of cellular PC, but was higher (44%) in methylamine-treated cells when compared with the control group (Table 3).

TABLE 4
Effect of MA on PC of Subcellular Fractions in Type II Cells[a]

	Cells	Microsomes	Lamellar bodies
	PL/protein (mg/mg)		
Control	0.39 ± 0.08	0.24 ± 0.01	6.00 ± 0.38
MA	0.33 ± 0.05	0.22 ± 0.01	4.60 ± 0.75
	PC percentage (% of total PL)		
Control	57.3 ± 2.1	31.5 ± 2.9	66.7 ± 5.5
MA	58.3 ± 2.5	33.9 ± 3.3	65.0 ± 5.5

[a]Cells were incubated for 20–22 h in the absence (control) or presence of 2.5 mM MA. Results are means ± SE of experiments in four cell preparations. PL, phospholipids. See Table 1 for other abbreviations.

The lamellar body fraction was enriched in phospholipids, and the PC accounted for a significant proportion of total phospholipids (Table 4). In methylamine-treated cells, the phospholipid-to-protein ratio was unchanged in cell homogenate or in either subcellular fraction, although it had a tendency to be lower in the lamellar body fraction when compared with the control group ($P = 0.14$). Surprisingly, although the PC mass in lamellar bodies was decreased by almost 40% (Table 3), the PC composition of lamellar bodies was unchanged in methylamine-treated cells (Table 4), suggesting a parallel decrease in packaging of other surfactant phospholipids in lamellar bodies of methylamine-treated cells.

In the experiments described above, we also isolated the lamellar body membrane fraction, which was previously characterized extensively (27), and another fraction, which is lighter in density and was termed the "residual" fraction. We are yet to characterize the latter extensively but suspect it to be more like the alveolar surfactant with respect to the phospholipid composition. Some of its characteristics are described here. The "residual" fraction showed a high phospholipid-to-protein ratio (control, 8.4 ± 1.8; methylamine 8.1 ± 2.1, $n = 4$, $P > 0.05$), and the recovery of phospholipids in this fraction was seven times higher than in the membrane fraction (not shown). The PC (percentage of total phospholipid) in "residual" fraction was also higher when compared with the membrane fraction (Table 5). On the basis of phospholipid-to-protein ratio, recovery of PC, and the PC composition, we assume that the "residual" fraction represents the lamellar body contents. In methylamine-treated cells, the recovery of PC mass, radioactivity, and the specific activity of PC in the "residual" fraction were lower when compared with those in the "residual" fraction in control cells (Table 5). However, the percentage PC was unchanged, similar to that observed in the lamellar bodies.

Next, we evaluated PC secretion in type II cells that were labeled with [^{3}H-methyl]choline for 20–22 h in the absence or presence of 2.5 mM methylamine. The secretion was measured

TABLE 5
Effect of MA on PC Composition and Labeling in Sublamellar Body Fractions During Labeling with [^{3}H]Choline[a]

	Membranes		"Residual" fraction	
	Control	MA	Control	MA
PC (% of total PL)	40.1 ± 4.8	44.1 ± 6.4	72.1 ± 1.8	70.0 ± 3.0
Specific activity ($\times 10^5$ dpm/μg Pi)	3.5 ± 0.4	2.7 ± 0.7	3.3 ± 0.2	2.2 ± 0.1*
Recovery (% of cell PC)				
PC mass	1.4 ± 0.4	1.3 ± 0.1	20.2 ± 2.2	11.3 ± 0.8*
PC radioactivity	1.4 ± 0.4	1.2 ± 0.3	20.1 ± 1.5	9.7 ± 0.4*

[a]Lamellar bodies were isolated from type II cells labeled for 20–22 h with 0.1 mM [^{3}H-methyl]choline ± 2.5 mM MA, disrupted in hypotonic sucrose solution, and the membranes and the "residual" fractions were isolated. *$P < 0.05$ compared to corresponding controls. See Tables 1 and 4 for abbreviations.

in the absence of methylamine. As demonstrated previously (24), in control cells, the secretion of PC was higher with each of the agonists when compared with the basal secretion (Table 6). The secretagogue-stimulated secretion of PC was 414% (with ATP), 257% (with terbutaline), and 371% (with PMA) of basal secretion. In comparison, in cells labeled in the presence of methylamine, the absolute secretion was lower (40–50%) under basal and stimulated conditions (Table 6). However, the stimulation of PC secretion with each agonist was similar to that observed in control cells (ATP, 340%, terbutaline, 200%, and PMA, 360%). We also evaluated the dose-dependence of methylamine (added during the 20–22 h labeling period) effect on PMA-stimulated PC secretion. The absolute decrease in PMA-stimulated secretion was dependent on the methylamine concentration employed during the labeling period. The decrease was ~15% at the lowest (1 mM), and was ~70% at the highest (2.5 mM) concentration used in this study (Fig. 2).

In another set of experiments, we evaluated the effects of another weak base, NH_4Cl, on PMA-stimulated secretion. In these experiments, the PMA-stimulated PC secretion during the 2-h period was lower in cells labeled in the presence of 2.5 mM NH_4Cl or 2.5 mM methylamine (control, 5.85 ± 0.37%, $n = 7$; methylamine, 2.75 ± 0.32, $n = 6$; NH_4Cl, 2.07 ± 0.19, $n = 5$; $P < 0.05$ by ANOVA when control cells were compared with methylamine- or NH_4Cl-treated cells). In control cells, the addition of methylamine or NH_4Cl during the 2-h incubation period for measuring surfactant secretion did not affect the PMA-stimulated secretion (not shown). Since methylamine and NH_4Cl dissipate pH gradients across membranes of acidic compartments including lamellar bodies (16,17), the results of the secretion studies suggest that these two weak bases exert their effect on surfactant phospholipid packaging by raising the pH of acidic compartments, most likely, the lamellar bodies.

Similar effects on secretion of PC and PG in cells labeled for 20–22 h with [9,10-^{3}H]palmitic acid and ± 2.5 mM methylamine provide further support for coordinated packaging of surfactant phospholipids in lamellar bodies. In this study, we evaluated only PMA-stimulated secretion (Fig. 3). In control cells, the PMA-dependent secretions of PC and PG were approximately similar. In methylamine-treated cells, the PMA-dependent secretions for both PC and PG were decreased to about the same extent, suggesting that methylamine similarly affected the packaging of these two (and possibly other) surfactant phospholipids.

The surfactant released after PMA-stimulation of cells that were labeled with [9,10-^{3}H]palmitic acid and ± methylamine was evaluated for distribution of palmitate radioactivity in different phospholipid classes. In surfactant released from control cells, most of the palmitate radioactivity was present in PC and PG fractions (Table 7). In surfactant from methylamine-treated

TABLE 6
Surfactant Secretion in Type II Cells Labeled for 20–22 h in the Presence of MA[a]

		[^{3}H]PC Secretion in 2 h (%)	
		Control	MA*
Basal	(5)	1.4 ± 0.3	0.5 ± 0.1
ATP (1 mM)	(4)	5.8 ± 0.5	1.7 ± 0.4
Terbutaline (0.1 mM)	(3)	3.6 ± 0.8	1.0 ± 0.1
PMA (80 nM)	(3)	5.2 ± 0.5	1.8 ± 0.2

[a]Isolated type II cells were labeled for 20–22 h with [^{3}H-methyl]choline ± 2.5 mM MA. Secretion of PC ± indicated secretagogues was followed for 2 h according to standard protocol in the absence of MA. Results are means ± SE of experiments indicated in parentheses. *Labeling in the presence of MA significantly decreased the secretion of PC under each condition. PMA, phorbol 12-myristate 13-acetate.

TABLE 7
Distribution of [^{3}H]Palmitic Acid-Labeled PL in Surfactant Released by Type II Cells Labeled in the Presence of MA[a]

	[^{3}H]-Palmitic acid-labeled PL (%)	
PL	Control	MA
PC	94.4 ± 0.2	93.4 ± 0.1
Phosphatidylglycerol	4.09 ± 0.48	3.53 ± 0.34
Phosphatidylethanolamine	0.39 ± 0.14	0.89 ± 0.28
Sphingomyelin	0.22 ± 0.03	0.75 ± 0.03*
Phosphatidylserine	0.15 ± 0.06	0.20 ± 0.05
Phosphatidylinositol	0.30 ± 0.15	0.20 ± 0.07
Cardiolipin	0.32 ± 0.24	1.35 ± 0.32

[a]Freshly isolated type II cells were labeled for 20–22 h with [^{3}H]-palmitic acid ± 2.5 mM MA. Cells were then stimulated for 2 h with 80 nM PMA and the media analyzed for palmitic acid label in indicated PL. Results are means ± SE of three experiments in each case except for phosphatidylinositol and cardiolipin, which are means ± range of two experiments. * $P < 0.05$ when compared with corresponding control. See Tables 1, 4, and 6 for abbreviations.

cells also, most of the palmitate radioactivity was present in PC and PG. Thus, methylamine treatment did not affect the distribution of palmitate radioactivity in different phospholipid classes, suggesting that various phospholipids of lung surfactant follow a common pathway during packaging in the lamellar bodies.

DISCUSSION

Although lamellar bodies have long been recognized as surfactant storage organelles, there has been relatively little progress in understanding the mechanisms that regulate packaging of lung surfactant phospholipids and proteins in lamellar bodies. Using 20–22 h cultured type II cells, we have previously suggested that the acidic pH, presumably in lamellar bodies, might regulate the packaging of newly synthesized PC and DSPC in lamellar bodies (16). In the current study, our goal was to show that the acidic pH is also important in regulating the packaging of PC and DSPC in lamellar bodies in freshly isolated type II cells and that our previous observations on PC packaging were not an artifact of culture of these cells. However, the 20–22 h cultured cells demonstrate lower packaging (14), when compared with the freshly isolated cells (current study). Thus, it may be more useful to utilize freshly isolated cells for acute metabolic studies investigating surfactant phospholipid packaging.

The second major goal of this study was to understand the mechanism of surfactant phospholipid transport to the lamellar bodies. Specifically, we wished to determine if methylamine also inhibited the packaging of PG in lamellar bodies. Such inhibition would suggest that type II cells exercise some degree of coordination during the transport of different surfactant phospholipids to the lamellar bodies. Our short- and long-term metabolic labeling studies in freshly isolated type II cells show that methylamine also inhibited the packaging of PG in lamellar bodies. Thus, the acidic pH is important for packaging of all three phospholipids (PC, DSPC, and PG) and possibly other minor components of lung surfactant in lamellar bodies. It is unlikely that methylamine affects a specific metabolic pathway (e.g., remodeling) in type II cells, because (i) it similarly inhibited the labeling of the unsaturated PC and DSPC in lamellar bodies (16) and (ii) its effect on the labeling of lamellar body PC with choline or palmitic acid was similar (Tables 1 and 2, Fig. 1). An inhibition of PC remodeling should inhibit the palmitic acid, but not the choline, incorporation in lamellar body PC. Also, it should not affect the palmitic acid incorporation into lamellar body PG. Thus, the effects of methylamine appear to be on the packaging of PC, DSPC, and PG. Because the inhibition of packaging is of similar magnitude for each phospholipid, the phospholipid composition of the released surfactant remains unaltered. These findings suggest that type II cells exercise some degree of coordination in the transfer and packaging of surfactant phospholipids.

The mechanisms for phospholipid trafficking from the site of synthesis (endoplasmic reticulum) to the lamellar bodies are not known. However, several mechanisms for intermembrane transfer of lipids have been postulated in other cell types. One mechanism for intracellular transport of phospholipids involves the phospholipid transfer proteins, which, under specialized conditions, facilitate molecular transfer or exchange of individual phospholipids between the donor and acceptor organelles (5). These proteins are possibly present in soluble form although their association with membranes or specific organelles cannot be excluded. In type II cells also, several proteins have been postulated to mediate transfer of surfactant phospholipids, PC, DSPC, and PG, to lamellar bodies (7,36). Because methylamine decreased the packaging of all three phospholipids to a similar extent (Fig. 1), the transfer and packaging of all three surfactant phospholipids would proceed at rates comparable with their relative distribution. If several transfer proteins mediate the transfer of different surfactant phospholipids, then all these proteins may be similarly sensitive to methylamine to cause similarly decreased packaging of individual phospholipids. Alternately, a single protein with above-described characteristics may facilitate the transfer of PC, DSPC, and PG (and possibly other surfactant phospholipids) type II cells. A phospholipid transfer protein with these characteristics is yet to be described in type II cells or in any other system.

Bulk transfer of lipids can be one mechanism for the coordinated trafficking of several phospholipids to a target site. In other cell types, various investigators have suggested that bulk transfer of phospholipids and proteins involves vesicle budding, translocation, and fusion with the target membrane (9). Several systems have been described for the study of PC, cholesterol, or PS trafficking to intracellular membranes (8–10). In the liver (37), the transfer of PC from the endoplasmic reticulum to the Golgi apparatus is suggested to occur by transitional vesicles (~60 nm in diameter), which bud and pinch off from the transitional elements of endoplasmic reticulum (part rough and part smooth). PC comprises ~70% of total phospholipids in these vesicles (38). Previous ultrastructural and radioautographic studies in mouse lungs have reported the presence of small vesicles in close vicinity of lamellar bodies (39). It is likely that these vesicles contain surfactant lipids. By analogy with other systems, the transfer of lipids from these vesicles could occur after their fusion with the small or growing lamellar bodies, which would deliver the contents to the lamellar body interior (the "residual" fraction). These vesicles (possibly containing all phospholipids of lung surfactant) could also mediate some degree of coordination since any change in the transfer efficiency would similarly influence packaging of all surfactant phospholipids. If methylamine inhibits such transfer then it would not affect the percentage PC in lamellar bodies (or "residual" fraction) or the phospholipid composition of released surfactant (Tables 3–5, 7).

The acidic pH, possibly of lamellar bodies, which is increased with methylamine or other weak bases (15–17), appears to regulate the phospholipid packaging. One possibility is that the acidic pH facilitates the fusion of hypothesized vesicles with the lamellar bodies. *In vitro* studies on vesicle fusion have demonstrated that the internal pH of vesicles can affect the phospholipid distribution in the bilayer and the fusion of vesicles (40,41). Various studies have suggested that annexins

(42,43) or surfactant protein B (44) can facilitate vesicle fusion under appropriate conditions. However, the nature of surfactant-carrying vesicles and the proteins that mediate fusion of these vesicles with growing lamellar bodies are not known at present.

The inhibition of surfactant secretion under basal or stimulated conditions also appears to be due to decreased packaging of surfactant in the lamellar bodies. The secretion, in response to various secretagogues (Table 6), which act through different receptors or protein kinases, was similarly decreased in methylamine-pretreated cells. It is unlikely that all of these pathways are similarly affected in methylamine-treated cells. Nevertheless, our studies cannot exclude the possibility that methylamine treatment influences the signal-transduction pathway in type II cells.

In summary, we have shown that weak bases (methylamine and NH_4Cl) inhibit packaging of *de novo* synthesized PG, DSPC, or PC (and possibly other phospholipids) in lamellar bodies in freshly isolated type II cells, suggesting the significance of acidic pH in subcellular compartments (presumably lamellar bodies). Our results showing similar decrease in the packaging of three surfactant phospholipids and the unaltered composition of released surfactant lead us to suggest that the type II cells excercise coordination in the trafficking of different surfactant phospholipids to the lamellar bodies. We speculate that the coordinated tranport occurs through surfactant-phospholipid-containing vesicles. These surfactant-containing transport vesicles are yet to be described in type II cells although vesicles containing high PC content (~70%) have been described in the liver. However, we cannot exclude an alternate mechanism(s) involving novel phospholipid transfer protein(s), which is (are) yet to be described in any system.

ABSTRACT: On the basis of the results obtained with pilot studies conducted *in vitro* on human low density lipoprotein (LDL) and on cell cultures (Caco-2), which had indicated the ability of certain molecules present in olive oil to inhibit prooxidative processes, an *in vivo* study was made of laboratory rabbits fed special diets. Three different diets were prepared: a standard diet for rabbits (diet A), a standard diet for rabbits modified by the addition of 10% (w/w) extra virgin olive oil (diet B), a modified standard diet for rabbits (diet C) differing from diet B only in the addition of 7 mg kg^{-1} of oleuropein. A series of biochemical parameters was therefore identified, both in the rabbit plasma and the related isolated LDL, before and after Cu-induced oxidation. The following, in particular, were selected: (i) biophenols, vitamins E and C, uric acid, and total, free, and ester cholesterol in the plasma; (ii) proteins, triglycerides, phospholipids, and total, free, and ester cholesterol in the native LDL (for the latter, the dimensions were also measured); (iii) lipid hydroperoxides, aldehydes, conjugated dienes, and relative electrophoretic mobility (REM) in the oxidized LDL (ox-LDL). In an attempt to summarize the results obtained, it can be said that this investigation has not only verified the antioxidant efficacy of extra virgin olive oil biophenols and, in particular, of oleuropein, but has also revealed a series of thus far unknown effects of the latter on the plasmatic lipid situation. In fact, the addition of oleuropein in diet C increased the ability of LDL to resist oxidation (less conjugated diene formation) and, at the same time, reduced the plasmatic levels of total, free, and ester cholesterol (–15, –12, and –17%, respectively), giving rise to a redistribution of the lipidic components of LDL (greater phospholipid and cholesterol amounts) with an indirect effect on their dimensions (bigger by about 12%).

Paper no. L8329 in *Lipids 35*, 45–54 (January 2000).

In recent years, considerable evidence has accumulated that shows free radicals play a key role in the etiopathogenesis of atherosclerosis (1). It has, in fact, been demonstrated that the main cause of changes in the conformation of both low density lipoproteins (LDL) and high density lipoproteins (HDL) is lipid peroxidation, and that these oxidized lipoproteins (ox-LDL, ox-HDL) are among the main causes of the formation of atherosclerotic lesions. This theory is amply supported by data derived from biochemical studies, experiments on animal models, and epidemiological and clinical investigations (1–7). Much of the recent attention given to the pathogenic role of ox-LDL in the onset of atherosclerosis is a result of the increasing indications that ox-LDL are capable of causing both the migration of monocytes in the intima of the artery and their subsequent conversion into foam cells (8,9).

It is also important to remember that both ox-LDL and -HDL contain high concentrations of highly cytotoxic lipoperoxides in their hydrophobic region (2). Once ox-LDL and -HDL have been deposited on artery walls, they can release these endothelial toxins, which promote a state of irritation among the cells of the arterial wall, causing a series of side effects that certainly contribute to the further development of degenerative lesions. For example, it is known that oxidized lipoproteins inhibit the relaxation of smooth muscle cells induced by the endothelial release factor (EDRF), now identified as nitrogen monoxide (NO) freed from arginine by NO synthetase. This inhibition is able to induce a state of hypertension that can in turn contribute to increasing the gravity of the lesion.

Furthermore, ox-LDL are capable of promoting other proatherogenic lesions by setting off an immune-type inflammatory reaction and stimulating the endothelial cells into releasing a whole series of biologically active substances that promote the endothelial adhesion of leukocytes and stimulate the growth of monocytes (2,6,9).

Lastly, oxidized lipoproteins can modulate transcription factors such as API and NFkβ and modify the homeostasis of prostanoids (thromboxanes and leukotrienes), favoring platelet aggregation. The vast spectrum of direct and indirect actions of ox-LDL is thus extremely complex (2).

The above being said, it should be recalled that humans have efficient endogenous systems of protection against radi-

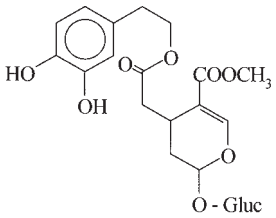
Abbreviations: EDRF, endothelial release factor; 4-HNE, 4-hydroxy-2(*E*)-nonenal; HPLC, high-performance liquid chromatography; LDL, low density lipoprotein; MDA, malondialdehyde; ox-LDL, oxidized LDL; PBS, phosphate-buffered saline; PGGE, polyacrylamide gradient gel electrophoresis, REM, relative electrophoretic mobility.

cal oxidative reactions able to reduce the reactivity and/or concentration of prooxidant species. Also exogenous compounds of dietary origin (i.e., free radical scavengers), can play an important role (10). Some studies have shown that inhibitors of lipid oxidation, such as vitamins E and C, carotene, and flavonoids, reduce the oxidation of LDL and diminish their catabolism by means of macrophages (11–15). The diet can therefore influence the oxidative processes that take place in the human body by regulating the supply of exogenous prooxidants and antioxidants or modulating the synthesis of endogenous antioxidants. In this context, the antioxidant potential of some biophenols contained, for example, in green tea and red wine has been recognized. These compounds have been evaluated, in both *in vitro* and *in vivo* models, as free radical scavengers and, consequently, as regulators of lipid metabolism or as protective factors against the induction of certain tumors, particularly cutaneous ones (16–18). The results obtained have been particularly encouraging and have suggested the extension of the studies in order to evaluate whether other components of the diet can, thanks to their biophenol content, contribute to biological defenses against cell aging and carcinogenesis.

In recent years, researchers have been focusing their attention on a typical item of the Mediterranean diet—olive oil. However, most experiments carried out so far on the biophenols of olive oil have been aimed at checking and, where possible, quantifying their antioxidant power only in relation to the stabilizing activity exercised on the oil itself (19–22). Not many studies have been made that evaluate the protective role of the biophenols contained in olive oil in biological systems, and very few have been done on animal models (23–26). The reason for this lack of information is due to the fact that planning studies on *in vivo* experimental models is very complicated and expensive. On the other hand, this type of study recognizes the real mechanisms of biophenols action and consequently makes a clearer indication of its antioxidant activity.

On the basis of data obtained from pilot studies conducted *in vitro* on human LDL and on cell cultures (Caco-2) (26,27) that had indicated the ability of certain molecules present in olive oil to inhibit prooxidative processes even at extremely low concentrations, an *in vivo* study was undertaken on laboratory rabbits fed special diets. Oleuropein was chosen for this study because of its peculiar presence in olives, its antibacterial, antifungal, and antioxidant effects, and because, to the best of our knowledge, its protective role in biological systems has not yet been tested on animal models. The chemical structure of oleuropein is shown in Scheme 1.

Particular attention was paid to the selection of indices, related both to rabbit plasma and isolated LDL, which could better define the influence of biophenols on peroxidative processes. The following biochemical parameters were selected: (i) biophenols, vitamins E and C, uric acid, and total, free, and ester cholesterol in the plasma; (ii) proteins, triglycerides, phospholipids, and total, free, and ester cholesterol in native LDL (for the latter, the dimensions, lipid hydroperoxides, and aldehydes were also measured); and (iii) conjugated dienes, lipid hydroperoxides, aldehydes, and relative electrophoretic mobility (REM) in ox-LDL.



OLEUROPEIN

SCHEME 1

EXPERIMENTAL PROCEDURES

Animals and diets. Twenty-four female New Zealand White rabbits, 8–10 wk old (Charles River S.p.A., Como, Italy), were used for the investigation. Upon their arrival, the animals were transferred into single cages put in a room where the environmental requirements (ventilation, temperature, humidity, illumination, and noise) complied with those required by Italian legislative decree 116 of 1992 (28). Food and water were available *ad libitum* during the whole study, and the health state of animals was verified every day.

Three different diets were prepared by Mucedola S.r.l. (Settimo Milanese, Italy): a standard diet (2RB 15) for rabbits (diet A); a standard diet for rabbits modified by the addition of 10% (w/w) extra virgin olive oil (diet B); and a modified standard diet for rabbits (diet C) differing from diet B only in the addition of 7 mg kg^{-1} of oleuropein (Extrasynthese S.A., Genay, France). This dose [corresponding to about 0.4 mg kg^{-1} rabbit body weight (b.w.) day^{-1}] was selected because it is comparable to the average daily biophenol intake per kilogram of human b.w. from olive oil in a Mediterranean diet.

The olive oil addition was carried out by replacing part of specific ingredients (i.e., dehydrated alfalfa and grass meal) in a standard diet so as not to change the content of some nutrients, such as water, elements and vitamins, that could be involved in oxidative processes occurring both in the feedstuffs and in rabbits. Since the replacement of dehydrated alfalfa and grass meal with extra virgin olive oil resulted in a vitamin E increase in diets B and C, a greater amount of vitamin E was supplemented in diet A. The nutritional composition of the three diets, experimentally assessed, is shown in Table 1, while in Table 2, the vitamin E and biophenol content of the extra virgin olive oil added to diets B and C is reported. The data shown in this latter table also provide information about the biophenol content of the diet supplemented with extra virgin olive oil. In fact, it is easy to estimate the biopherol contribution of the oil to diets B and C, considering its addition at 10%.

The group of rabbits fed standard diet A was included in the experimental protocol to verify in which manner the plasmatic lipid composition was influenced by the six-times-higher lipid content of diets B and C.

TABLE 1
Nutritional Composition of the Three Diets (% w/w on wet weight)[a]

Component	Diet A	Diet B	Diet C
Experimental data[b]			
Water	12.08 ± 0.34	11.97 ± 0.41	12.07 ± 0.28
Carbohydrates[c]	41.76	36.16	36.29
Protein	13.51 ± 0.78	12.21 ± 0.69	12.18 ± 0.87

[a]Diet A, standard rabbit food; diet B, standard food modified by the addition of 10% (w/w) extra virgin olive oil; diet C, same as diet B but with 7 mg kg^{-1} oleuropein.
[b]Values are expressed as mean ± SD (n = 5).
[c]Calculated for difference.
[d]Expressed as % α-tocopherol; calculated using activity coefficients for individual tocopherols (51).
[e]The value related to diet A is greater because it provides for higher vitamin E supplementation.

Before starting the experiment, the animals were acclimatized for a period of 15 d during which they all received the same food (standard diet A). Subsequently, the rabbits were randomly divided into three groups of eight animals each. One group continued to be fed standard diet A, while the other two groups were gradually adapted to diets B and C, respectively. This period of adaptation has been believed necessary considering the high lipid content of these last two diets compared with that of a standard diet for rabbits. The entire feeding design is reported in Table 3. Food consumption was checked daily and the animals were weighed every week.

Preparation of plasma and isolation of LDL. After 6 wk on the special diets, 30 mL of blood from rabbits that had been fasted for 12 h was taken by intracardiac injection and collected in test tubes containing 30 mg of EDTA. The plasma was immediately separated by centrifugation at 500 × g for 15 min at ambient temperature and divided into two aliquots. The first was immediately tested to determine biophenol, vitamins E and C, uric acid, and total, free, and ester cholesterol contents, while the second was used to isolate LDL.

LDL were isolated by sequential ultracentrifugation (UL-70 ultracentrifuge Beckman fitted with a 60 Ti rotor; Fullerton, CA) in the density range 1.015–1.063 mg mL^{-1}, at 140,000 × g for 22 h (two times) at a temperature of 15°C according to the method proposed by Havel *et al.* (29). After measuring the protein in the LDL, using the method of Lowry *et al.* (30), the LDL fraction was diluted with a phosphate-buffered saline (PBS) solution (150 mM sodium phosphate, 150 mM NaCl, pH 7.2) until a final concentration of 0.2 mg LDL protein/mL was obtained. This fraction was then dialyzed against NaCl (0.9%, wt/vol) in a proportion of 1:500.

Analysis of plasma and native LDL. The methodology used for analyzing the biophenol concentration in the plasma was based on the extraction of these compounds from the matrix, then purification and extraction by high-performance liquid chromatography (HPLC). The procedure is similar to that described by Papadopoulus and Tsimidou (31) except for some changes in the extraction procedure and the chromatographic conditions. These changes were ascribed to the fact that the above mentioned method refers solely to olive oil matrix, whereas in the present study it was also applied to plasma matrix. Briefly, SPE (Spe-ed SPE C_{18} 500 mg-6 mL, Applied Separations, Allentown, PA) cartridges, previously conditioned by passing 2 mL of an *n*-hexane/ethyl ether solution (98:2, vol/vol), were used for the extraction and purification of the biophenols. One milliliter of sample was then deposited on the top of the cartridge, which was subsequently washed

TABLE 2
Biophenol and Vitamin E Contents of the Extra Virgin Olive Oil Added to Diets[a] B and C

Component	mg L^{-1}[b]
Vitamin E[c]	11.9 ± 0.9
Total biophenols[d]	238 ± 54
Oleuropein	2.04 ± 0.78
Oleuropein aglycone	18.64 ± 3.36
3,4-Dihydroxyphenylethanol	1.62 ± 0.25
p-Hydroxyphenylethanol (tyrosol)	4.68 ± 0.77
Gallic acid	0.82 ± 0.18
Protocatechuic acid	1.83 ± 0.56
Vanillic acid	1.15 ± 0.39
Caffeic acid	0.04 ± 0.02
p-Cumaric acid	0.32 ± 0.09
o-Cumaric acid	0.07 ± 0.03
Ferulic acid	0.34 ± 0.10

[a]See Table 1 for information regarding diets.
[b]Values are expressed as mean ± SD (n = 5).
[c]Expressed as mg α-tocopherol calculated using activity coefficients for individual tocopherols (51).
[d]Expressed as tyrosol concentration.

Feeding Protocol for the Three Rabbit Groups

Time	Feedstuffs[a] Group 1 (*n* = 8)	Group 2 (*n* = 8)	Group 3 (*n* = 8)
1st wk	100% Diet A	75% Diet A + 25% Diet B	75% Diet A + 25% Diet C
2nd wk	100% Diet A	50% Diet A + 50% Diet B	50% Diet A + 50% Diet C
3rd wk	100% Diet A	25% Diet A + 75% Diet B	25% Diet A + 75% Diet C
4th–9th wk	100% Diet A	100% Diet B	100% Diet C

[a]See Table 1 for information regarding diets.

with 10 mL of the conditioning solution. The biophenol fraction was then eluted with 8 mL of methanol, filtered through disposable Teflon filters, and evaporated in a Rotavapor at 35°C. The dry residue was then dissolved in 0.5 mL of methanol and 10 μL of this solution was injected into a high-performance liquid chromatograph (Waters, Milford, MA) fitted with a Lichrosorb (Merck, Darmstadt, Germany) column (RP18 250 × 4.6 mm, 5 μm) and an ultraviolet/visible light (UV-Vis) detector set at 280 nm. The eluants were: (A) acetonitrile/methanol (50:50 vol/vol) and (B) phosphoric acid/water (1:99 vol/vol). The gradient was: t = 0 min, 4% A; t = 20 min, 20% A; t = 40 min, 50% A; t = 50 min, 60% A; t = 60 min, 100% A. For the sake of completeness, mention should be made of the fact that during HPLC–UV-Vis method validation, mass spectrometry was used for phenol identification.

The plasmatic content of vitamin E (α-, β-, δ-, and γ-tocopherols) was determined by extracting the analyte from the matrix and then separating it in a high-performance liquid chromatograph as reported by Cavina *et al.* (32).

An analytical methodology based on the use of an HPLC, as described by Ross (33), also was used for determining vitamin C and uric acid in the plasma.

Enzymatic spectrophotometric methods, involving the use of kits such as Chol MPR 1 (CHOD-PAP method), F-Chol MPR 1 (CHOD-PAP method), TG (GPO-PAP method), and PL MPR 2, all supplied by Boehringer Mannheim (Mannheim, Germany), were employed for determining, the total and free cholesterol in the plasma and native LDL and the triglycerides and phospholipids in the native LDL, respectively. The cholesteryl esters were calculated by the difference between total and free cholesterol multiplied by a factor of 1.68.

Lastly, polyacrylamide gradient gel electrophoresis (PGGE) (Pharmacia LKB Biotechnology, Uppsala, Sweden) was used to measure the dimensions of the native LDL (34). The diameter of the dominant LDL fraction was computed by interpolation from a plot of the logarithm of the diameter of three standards (i.e., apoferritin, thyroglobulin, and latex beads) vs. the migration length of the same standards, as reported by Coresh *et al.* (35).

Studies on ox-LDL. As far as ox-LDL are concerned, their susceptibility to Cu-induced oxidation was preliminarily evaluated by a test of the conjugated dienes (36,37). For this purpose, 250 μL of dialyzed LDL (0.2 mg of LDL protein mL^{-1}) was pipetted into 1-cm quartz cuvettes and brought to a volume of 1 mL with PBS, and then 10 μL of 1 mM $CuSO_4$ was added so that the final concentration of Cu^{2+} was 10 μM. Shortly after, measurements of absorbance at 234 nm were taken, at 10-min intervals for 8 h. A Beckman Instruments DU-640 UV-Vis spectrophotometer, equipped with an automatic cell exchanger and a thermostat set at 30°C, was used. The instrument was connected to a computer for automatic acquisition of the data. The oxidation kinetics of every LDL sample was graphically represented as absolute absorbance against time, and the lag phase was measured as indicated by Puhl *et al.* (37).

[b]Values are expressed as mean ± SD (n = 8 per group). Total biophenols are expressed as tyrosol concentration.
[c]$P < 0.05$ vs. diet A, as found by analysis of variance (ANOVA).
[d]$P < 0.05$ vs. diet B, as found by ANOVA.

In order to assess the resistance of LDL to Cu-induced oxidation by means of other tests, i.e., determination of lipid hydroperoxides, malondialdehyde (MDA), and 4-hydroxy-2(*E*)-nonenal (4-HNE), and the measurement of relative electrophoretic mobility, preliminary *in vitro* oxidation of the LDL of rabbits fed the three different diets was necessary. For this purpose, the dialyzed LDL solutions (0.2 mg of LDL protein mL^{-1}) were oxidized by incubating for 3 h with 20 μM $CuSO_4$ at 37°C.

The concentration of lipid hydroperoxides was calculated iodometrically according to the method proposed by El-Saadani *et al.* (38), with the reaction time changed from 30 to 60 min.

MDA and 4-HNE determination was done by an enzymatic spectrophotometric method, using a Bioxytech LPO-586 kit (Oxis International Inc., Portland, OR).

Electrophoresis of ox-LDL was done as described by Morel *et al.* (39), using a Beckman Paragon LIPO electrophoretic kit (Beckman Instruments Inc., Fullerton, CA).

Statistical analyses. The results obtained from each group of rabbits were subjected to both parametrical and nonparametrical statistical analysis. Furthermore, in order to evaluate the significance of the differences noted between the biochemical parameters of the groups fed different diets, multifactor analysis of variance (ANOVA) was applied. Statgraphics software (V. 7 for DOS, Manugistic, Rockville, MD) was used for processing.

RESULTS AND DISCUSSION

No statistically significant differences were noted in terms of increased body weight and consumption of food between the rabbits fed the three different diets (data not shown).

The results related to the determination of the parameters for plasma and native LDL are set out in Tables 5 and 6, while those related to the study of the parameters for ox-LDL are set out in Table 7.

Plasmatic parameters. The data clearly show that biophenols, derived from the diets, are present as such in the plasma and are therefore capable of exerting their functional activity on plasmatic components such as LDL. Previous studies have proven that very low concentrations of some phenolic compounds also have this antioxidant activity (24,40).

It appears equally evident that the inclusion of extra virgin olive oil in diets B and C had a clear influence on the total biophenol content. As expected, the addition of oleuropein in diet C further increased that content. It is also interesting to point out that a very small quantity of oleuropein was present in the plasma of rabbits fed diet B, whereas the plasma of rabbits fed diet C, to which the molecule had been added, showed a decidedly higher concentration. This confirms what has, in any case, already been amply proved (41): while the olives are ripening, and during processing for oil production, the oleuropein, in part, undergoes enzymatic hydrolysis, forming 3,4-dihydroxy-phenylethanol and enolic acid of 3,4-dihydroxy-phenylethanol, which are, in their turn, efficacious antioxidants. Obviously, the considerations above refer only to the most significant olive oil biophenols, as analytical determination in plasma was limited to these last. In reality, the rabbit diets supplied many other biophenols, but the investigation was focused on those of olive oil and, in particular, on their capacity to enter the blood stream as such. The differences found in plasma samples between the total phenol content and the sum of the analyzed individual phenols (see Table 4) corroborate the fact that other components of the rabbit diet contribute to the total phenol intake.

The average concentration of vitamin E measured in the plasma of the rabbits fed diet C was not much higher than that found in rabbits fed diet B (4%). However, as can be seen in Table 5, diets B and C, had a vitamin E content nearly doubled that of diet A (increases of 76 and 83%, respectively). In this connection it should be pointed out that diets B and C, in spite of the addition of extra virgin olive oil, had the same vitamin E content as diet A (Table 1). This is because, as mentioned before, it had expressly been requested that the manufacturer add more vitamin E to diet A. Therefore, the higher concentration found in the plasma of the rabbits fed diets B

Size (nm)	22.3 ± 0.6	23.3 ± 0.4	26.1 ± 0.5[c,d]

[a]See Table 1 for information regarding diets.
[b]Values are expressed as mean ± SD (n = 8 per group). MDA, malondialdehyde; 4-HNE, 4-hydroxy-2(*E*)-nonenal.
[c]Average percentage of the compound in lipidic fraction of native low-density lipoprotein (LDL) is reported in parentheses. Measured in mg mg^{-1} of LDL protein.
[d]$P < 0.05$ vs. diet A, as found by ANOVA.
[e]$P < 0.05$ vs. diet B as found by ANOVA. See Table 4 for abbreviation.

and C does not correlate to a greater vitamin intake. Presumably, as reported by some authors (42), an increase of polyunsaturated fatty acids (PUFA) in the plasma induced by a diet rich in such acids gives rise to a subsequent increase in vitamin E. This phenomenon is probably caused by a redistribution of the vitamin from the reserves, which would compensate for the increased oxidizability of the PUFA-rich lipoproteins that are more easily open to attack by radicals. Furthermore, it can be reasonably supposed that, by an exchange action, the contemporaneous presence of the olive oil biophenols in the plasma prevents vitamin E oxidation by increasing its plasmatic levels. This hypothesis was confirmed for other biophenols in earlier studies (10).

Both diets B and C caused a reduction in the levels of vitamin C and uric acid in the plasma of rabbits, evaluated at around 30–40% for vitamin C and 20% for uric acid. In this case, it is presumed that the increased presence of other water-soluble antioxidants with the same function, like the olive oil biophenols, depress the metabolic synthesis of vitamin C and modulate the excretion of uric acid (23).

The most noticeable differences deducible from the analysis of the plasma of rabbits fed diet C compared to those fed diet B concern cholesterol content (Table 5). Administration of diet C led to a 15% reduction in total cholesterol, which affected fairly uniformly both free and ester cholesterol (reductions of 12 and 17%, respectively). This fact appears ex-

TABLE 7
Results Related to the Determination of the ox-LDL Parameters[a]

ox-LDL parameter[b]	Diet A standard	Diet B modified	Diet C modified

[d]$P < 0.05$ vs. diet B as found by ANOVA. See Table 4 for abbreviations.
[e]Given as nmoles mg^{-1} of LDL protein.

tremely significant seeing that the composition of diets B and C was the same both from a quantitative and qualitative point of view (see Table 1). Therefore, the addition of oleuropein in diet C had a markedly different effect on the cholesterolemic situation of the plasma. As far as the comparison with diet A is concerned, there was a percentage increase of about 19% of total cholesterol in the plasma of rabbits fed diet B, but, no statistically significant variation in total cholesterol was found in the plasma of rabbits fed diet C. It is also interesting to note that free cholesterol content was lower in the plasma of rabbits fed diets B and C (Table 5). The percentage decreases were 9 and 20%, respectively, compared to the value found in the plasma of the control rabbits (diet A). Consequently there was an increase in cholesteryl esters in the plasma of rabbits fed diets B and C. In particular, the increase assessed was 45% in the first case and 20% in the second.

Parameters on native LDL. As was expected, given the higher number of calories supplied by the lipids in diets B and C as compared to diet A, there was an increase in the concentration of triglycerides both in the case of rabbits fed diet B and those fed diet C. The increase was about 33 and 29%, respectively. When diet C was compared with diet B, the variation in the triglyceride content of the respective LDL was not statistically significant.

The behavior of phospholipids was different; there was a significant increase (73%) in the LDL of rabbits fed diet C compared to those fed diet B. With regard to diet A, the data collected showed a moderate increase of about 10% in the concentration of phospholipids in the LDL of rabbits fed diet B, while there was a marked increase in rabbits fed diet C (90%). This confirms the remarks already made about the influence of the addition of oleuropein (diet C) on the plasmatic lipidic components.

Further confirmation of this influence comes from an analysis of the data related to the total cholesterol content, which increased sharply (40%) in the LDL of rabbits fed diet C compared to those fed diet B. This increase is to a large extent attributable to the increase in cholesteryl esters (45%) and, to a lesser extent, free cholesterol (29%). A comparison with diet A shows that, in the LDL of rabbits fed diet B, there was an increase in total cholesterol (about 15%), which had a marked influence on the levels of cholesteryl esters (increase of 20%) and, to a much lesser extent, on free cholesterol (percentage increase of 5%). The situation for the LDL of rabbits fed diet C was qualitatively similar, but quantitatively more marked. In the latter case, the levels of total, free, and ester cholesterol increased by 61, 35, and 73%, respectively. Considering that the data obtained for the plasma showed a different pattern, particularly for the plasma of rabbits fed diet C—where there was a statistically insignificant increase in total cholesterol, an increase in cholesteryl esters, and a decrease in free cholesterol—the influence of the oleuropein added to diet C on the lipidic component of plasma is confirmed once again. The significant increase in free cholesterol found in the LDL of rabbits fed diet C is of particular interest considering that some authors (43) have shown how this lipid can contribute, although the action mechanisms are not quite clear, to the resistance of LDL to oxidation. In particular, it has been suggested that free cholesterol limits propagation of the peroxidative processes outside the core of the LDL because the molecule present on the surface of the LDL interacts with the radicals and causes the formation of oxycholesterol, which participates less reactively in the propagation reactions than the lipidic hydroperoxides (44).

It may be supposed that the biophenols induce a redistribution of the various plasmatic components, with an indirect effect on the size and composition of the LDL. To better clarify the events observed, Table 6 shows the average values of the diameter of the native LDL found in the three groups of rabbits. Going from diet B to diet C, there was an increase of 12%. Compared to diet A, the increase was 5% for diet B, and 17% for C.

At the same time, Table 6 shows the average chemical compositions, relative to lipidic component, characterizing the LDL of the rabbits fed the three different diets. The observed variations are extremely significant from the metabolic point of view for two reasons. The first relates to the fact that, as suggested by some authors (43,45–47), larger LDL have greater resistance to peroxidative processes and the fluidity of the lipoproteins is increased. The second, concerns the chemical composition of the LDL. In this connection, it has been known for some time that phospholipids act as blockers of the free cholesterol and this effect is easy to understand from the chemical point of view, since the two compounds are capable of forming a molecular association with a ratio of 1:1. Considering this ratio, the state of saturation between the two compounds is given by a value exactly equal to 1. In addition to the characteristic of forming molecular associations with cholesterol, phospholipids are also agents with a strong emulsifying action capable of solubilizing lipophilic molecules (including cholesterol) by forming micelles. It is therefore clear that in any system—LDL, for example—when the molar ratio between phospholipids and free cholesterol is greater than 1, the affinity of the system for free cholesterol is stronger as the ratio increases (48). Taking into account the fact that, even though still under discussion, many authors believe levels of plasmatic cholesterol are closely linked to the onset of atherosclerosis (6,49), it seems clear how important it is for the phospholipids/free cholesterol ratio in LDL to be as high as possible. This is exactly what happens with the LDL of the rabbits fed diet C, where the increase in phospholipids is higher than that found for free cholesterol and is therefore a considerable increase in that ratio, from 2.5 (rabbits fed diet A) to 3.5.

Parameters on ox-LDL. It can be seen from the oxidation kinetics that the lag phase, which represents a significant index of the summation of all the antioxidants contained in the LDL, which should obviously become exhausted before the peroxidative processes can proceed in a quantitatively relevant manner (3,36), was markedly different for the LDL of the three groups of rabbits. Figure 1 shows the average curves

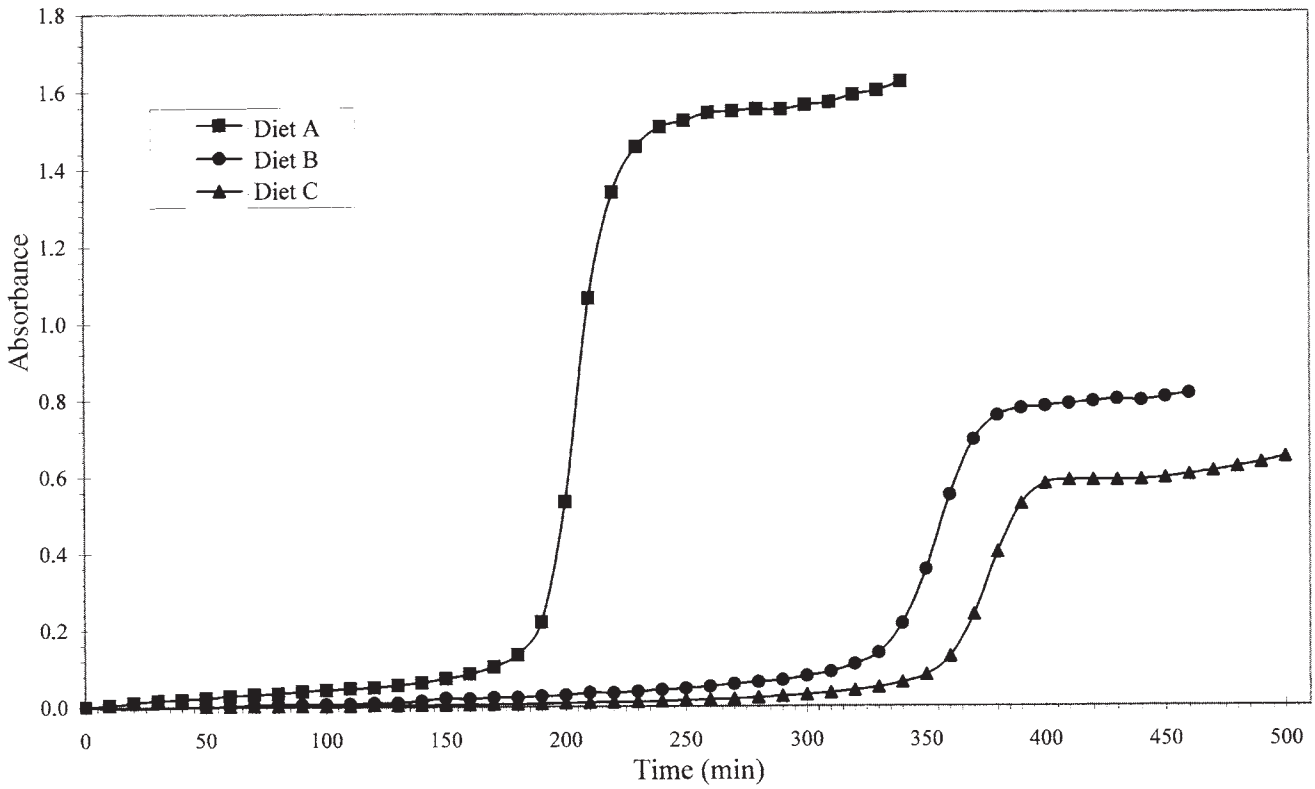

FIG. 1. Effect of the three different diets (A, standard; B, modified with 10% extra virgin olive oil; C, same as B, but with 7 mg kg^{-1} oleuropein) on Cu^{2+}-stimulated low density lipoprotein (LDL) conjugated diene formation *in vitro*. Each point represents the average value (n = 8 per group).

related to the kinetics of oxidation measured for the LDL of the rabbits. In particular, it was found that the lag phases associated with the LDL of rabbits fed diets B and C were noticeably longer than those for the LDL of the group fed diet A (345 and 350 min, respectively, as compared with 150 min). Furthermore, the maximal rate of the propagation reactions, easily calculable from the slopes of the tangents to the sigmoid or by means of the differential $\Delta A/\Delta t \times 33.8$ (where ΔA is the difference of absorbance measured at the end and beginning of the propagation reaction and Δt is the reaction time) also differed in a statistically significant way (see Table 7). Since the concentration of the LDL solutions was always equal to 0.1 μM on the spectrophotometer, it was also possible to calculate the number of molecules of dienes that formed every minute in each LDL at the maximal rate of propagation reaction (37). The count for the LDL of rabbits fed diets A, B, and C gave values of 15.5, 5.2, and 4.7 molecules min^{-1}, respectively. Lastly, a final remark concerns the absorbance measured at the end of the oxidation process which, in the case of the LDL of the group of rabbits fed diet A, was decidedly higher, showing a greater presence of conjugated dienes and therefore of lipidic radicals (see Table 7). Still, with regard to the total number of diene molecules formed for each LDL, it can be said that in the case of diet A, the number at the end of the reaction was 510, 258 for diet B, and 198 for diet C.

In the ox-LDL of rabbits fed diets B and C, the concentration of lipidic hydroperoxides was found to be less by about one order of magnitude to that measured for the ox-LDL of the rabbits treated with diet A (control).

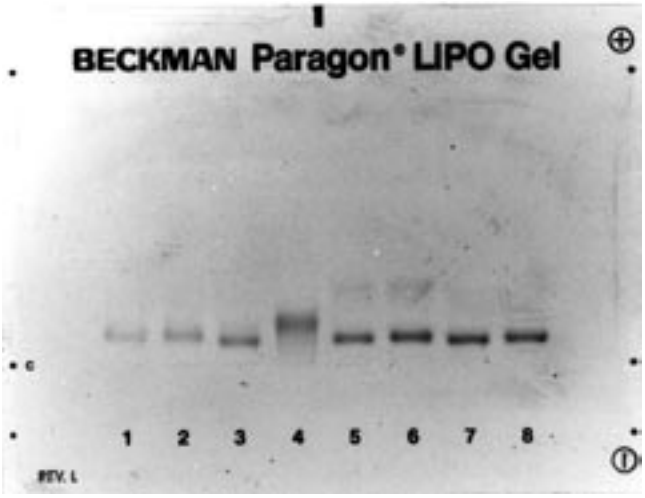

FIG. 2. Effect of the three different diets on relative electrophoretic mobility of Cu^{2+} oxidized LDL (ox-LDL). Number sequence: (1), native LDL (diet B); (2), ox-LDL (diet B); (3), native LDL (diet A); (4), ox-LDL (diet A); (5), native LDL (diet B); (6), ox-LDL (diet B); (7), native LDL (diet C); (8), ox-LDL (diet C). See Figure 1 for abbreviation and information on diets.

Similar results were obtained for the concentration of the two oxidation products MDA and 4-HNE. This last fact, combined with the results obtained from the test on the dienes (see the A_{max} values in Table 7), suggests that the action of the olive oil biophenols on peroxidative processes does not merely consist of slowing down the oxidation kinetics, but also increasing the resistance of the native LDL to oxidation.

A further confirmation of the diminished oxidizability of the LDL of rabbits fed diets B and C comes from the results of the electrophoretic test that are shown in Figure 2. The LDL of the rabbits in the group fed diet A, after Cu-induced stress, showed a much higher migration speed than that shown by the LDL of the other two groups.

Furthermore, the electrophoretic migration of the ox-LDL related to diet A causes the formation of more dispersed bands, probably because there has been fragmentation of the apolipoprotein B and/or aggregation of the LDL (50).

In an attempt to sum up the results obtained, it can be said that the investigation has not only verified the antioxidant efficacy of the biophenols contained in olive oil but also revealed a series of so far unknown effects of a specific biophenol on the plasmatic lipid situation. In fact, the addition of oleuropein in diet C not only increased the ability of LDL to resist oxidation but also reduced the plasmatic levels of total, free, and ester cholesterol and caused a redistribution of the lipidic components of the LDL with an indirect effect on their dimensions (greater).

The results of this investigation indicate that there is a need to plan *in vitro* and *in vivo* metabolic studies to verify the mechanisms of action by which the biophenols of olive oil exert their effect on the plasmatic lipid distribution.

The confirmation of certain theories would certainly have implications for the dietetics and pharmacological fields and might justify the recovery of olive oil processing residues, which are costly to eliminate.

ABSTRACT: The uptake of lipids and formation of foam cells are key events in atherosclerosis and in eruptive xanthomata formation in primary hyperchylomicronemia. Here we have compared the influence of low density lipoprotein (LDL), oxidized LDL (oxLDL), high density lipoprotein (HDL), and delipidated HDL (apoHDL) on the uptake by macrophages of zymosan (an insoluble fraction of yeast cell walls) and of triglyceride-rich emulsion (EM) particles that resemble chylomicrons, but, like zymosan, are equally devoid of protein components. Zymosan internalization is known to occur through unspecific phagocytosis, whereas natural chylomicrons are taken up by several specific lipoprotein receptors. We found that phagocytosis is not promoted as much by oxLDL as by normal LDL. HDL-coated zymosan was found to be inert and apoHDL slightly enhanced phagocytosis. LDL and apoHDL promoted the uptake of EM while oxLDL and HDL significantly inhibited the uptake. Therefore, the data support that HDL, and not apoHDL, particles inhibit EM uptake. We concluded that by using lipoprotein-coated zymosan particles, we could demonstrate different biological effects of LDL, oxLDL, HDL, and apoHDL on macrophage phagocytosis and that this method could be useful to delineate components of the various lipoproteins important for the propagation or inhibition of the formation of foam cells.

Paper no. L8302 in *Lipids 35,* 55–59 (January 2000).

The phagocytic process in monocyte macrophages represents a fundamental biological mechanism whereby lipoprotein molecules are rapidly taken up (1,2). In most cases, this is beneficial for the organism, but in some cases it may contribute and constitute a fundamental component of the pathogenic mechanism of a disease. A key event in atherosclerosis and in the formation of eruptive xanthomata in familial hyperchylomicronemia is the formation of lipid-laden foam cells resulting from the uptake of lipoproteins by skin and arterial intima resident macrophages (1).

Elevated plasma concentration of low density lipoprotein (LDL) is considered a major risk factor for atherosclerosis. This is true for LDL subjected to chemical modification, including acetylation, methylation, glycation, and oxidation (3–5). Besides oxidized LDL (oxLDL), epidemiological surveys strongly suggest that triacylglycerol (TG)-rich lipoproteins like very low density lipoprotein (VLDL) (6,7), as well as intestinally derived chylomicrons, contribute to atherogenesis, and their remnants drawn from patients with severe familial hyperchylomicronemia are also atherogenic (8,9). By contrast, several studies suggest that high density lipoprotein (HDL) is antiatherogenic as it removes cell cholesterol (10,11).

Although the function of various lipoprotein fractions in atherogenesis is under investigation (12,13), the interaction between these components in phagocytosis is less well studied (14).

To study the mechanisms of mouse peritoneal macrophage uptake, we used an assay whereby LDL, oxLDL, HDL, and delipidated HDL (apoHDL), which are known to interact with specific cell receptors, either were utilized to coat inert zymosan (an insoluble fraction of yeast cell walls) particles or were coincubated with TG-rich emulsions (EM) that resemble natural chylomicrons (15).

EXPERIMENTAL PROCEDURES

Lipoprotein isolation, delipidation of HDL, and oxidation of LDL. LDL (d = 1.006–1.063 g/mL) and HDL (d = 1.063–1.21 g/mL) from the plasma of healthy volunteer blood donors was isolated by sequential preparative ultracentrifugation (16) utilizing a 50 Ti rotor in an L-8 Beckman ultracentrifuge (Beckman Instruments, Palo Alto, CA). HDL was 96% delipidated by extraction with precooled (–20°C) diethyl ether/ethanol (3:2, vol/vol) (17), and the precipitated apolipoproteins were washed twice with ice-cold ether and then partially dried

Abbreviations: apoHDL, delipidated high density lipoprotein; DMEM, Dulbecco's modified Eagle's medium; EM, chylomicron-like triglyceride-rich emulsions; FCS, fetal calf serum; HDL, high density lipoprotein; IgG, immunoglobulin G; LDL, low density lipoprotein; oxLDL, oxidized LDL; PBS, phosphate-buffered saline; TG, triacylglycerol; VLDL, very low density lipoprotein; [^{3}H]-COE, [1α,2α,(N)-^{3}H]-cholesteryl oleoyl ether.

under a stream of N_2. LDL was oxidized with 1 µM $CuSO_4$ according to the method of Heinecke *et al.* (18). Total cholesterol and TG concentrations of the LDL and HDL preparations were measured by commercially available enzymatic kits, and the total protein concentration was by the method of Lowry *et al.* (19).

Mouse peritoneal macrophages. This experiment was approved by the Ethics Committee of the Hospital of the University of São Paulo Medical School. Resident peritoneal exudate cells were harvested from mice in phosphate-buffered saline (PBS), pH 7.4, washed twice in PBS, and had the final concentration of cells adjusted as indicated in RPMI 1640 medium (Sigma Chemical Co., St. Louis, MO) containing 10% (vol/vol) fetal calf serum (FCS), penicillin (100 IU/mL), streptomycin (100 IU/mL), and fungizone (2.5 µg/mL) (5).

Phagocytosis assay. Phagocytosis assay was done according to the method described by Miller (20). Briefly, 10^6 cells in 1 mL RPMI 1640 medium were cultured in Leighton tubes on micro-coverslips and maintained at 37°C for 30 min in a humid, 5% CO_2 atmosphere. The micro-coverslips were then washed in RPMI 1640 medium. Meanwhile, 10^7 zymosan particles [average diameter about 3 µm (21)] in 1 mL RPMI 1640 medium were incubated at 37°C for 30 min with either 10 mg protein/mL of HDL or apoHDL, or 0.25 mg protein/mL of LDL or oxLDL. Lipoprotein-coated zymosan suspension was added to each tube with micro-coverslips with adhered cells and incubated at 37°C for an additional 30 min in a humid, 5% CO_2 atmosphere. Then the micro-coverslips were washed in RPMI 1640 medium and stained with Leishman solution. The criterion for phagocytosis was that cells took up three or more coated or control uncoated zymosan particles. The results were expressed as a phagocytic index and calculated as [(number of macrophages with phagocytosis of coated zymosan particles/number of macrophages with phagocytosis of control uncoated zymosan particles) – 1]. At least 100 cells were counted on each coverslip.

Determination of zymosan-bound proteins. Particles (10^8) of zymosan in 1 mL RPMI 1640 medium were incubated with either 10 mg protein/mL of HDL or apoHDL, or 0.25 mg protein/mL of native or oxLDL at 37°C for 30 min, washed twice, and the pellets resuspended in 0.5 mL of RPMI 1640 medium for protein determination by the method of Lowry *et al.* (19). Proper blank controls containing zymosan were introduced in the method. The results were expressed as g protein bound/10^8 zymosan particles.

TG-rich EM. Cholesterol, cholesteryl oleate, triolein (Nu-Chek-Prep, Elysian, MN), and phosphatidylcholine (egg lecithin; Lipid Products, Surrey, United Kingdom) were dissolved in chloroform/methanol solution (2:1, vol/vol) and mixed in the following proportions, respectively, 2, 6, 69, and 23% (% by weight), together with 30 µCi of [1α,2α,(N)-^{3}H]-cholesteryl oleoyl ether ([^{3}H]-COE), specific activity 75 mCi/mg (Amersham Life Science, Buckinghamshire, United Kingdom). The solvent was evaporated under a nitrogen stream and the lipids were maintained at 4°C for 12 h in a vacuum chamber to eliminate the residual solvent. The lipid mixture was sonicated in a NaCl solution (d = 1.101 g/mL, pH 7.3) utilizing a Branson Cell Disruptor (model 450, Branson Sonifier, Danbury, CT), with a 1-cm probe, at 70–80 W for 30 min under nitrogen flow. TG-rich EM were purified after discontinuous gradient ultracentrifugation as previously described (15,22), and their particle size was about 0.1 µm.

Uptake of [^{3}H]-COE-EM by peritoneal macrophages. Peritoneal exudate cells (5×10^6) in 4 mL RPMI 1640 medium containing 10% FCS were cultured in Petri dishes in a humid 5% CO_2 atmosphere at 37°C for 12 h. Thereafter, each plate was washed twice with RPMI 1640 medium to remove nonadherent cells (5). Adherent cells were incubated in Dulbecco's modified Eagle's medium (DMEM, Sigma Chemical Co.) with [^{3}H]-COE-EM either alone (as control) or with HDL, apoHDL, LDL, or oxLDL (0.6 µg of protein/µg TG of EM) for 4 h at 37°C in a humid 5% CO_2 atmosphere. The cells were then washed in PBS and solubilized in 0.2 N NaOH for the measurement of the cell-associated radioactivity in a beta counter Beckman LS-6000 TA (Beckman Instruments, Palo Alto, CA). Cell protein content was measured by the method of Lowry *et al.* (19). Cellular EM uptake was defined as the percentage of radioactivity taken up by the cells from the medium. These values were subtracted from blank values found in Petri dishes incubated with radiolabeled emulsions without cells. Results of cellular EM uptake were expressed as an index: [(percentage of [^{3}H]-COE × mg of cell protein^{-1} in the presence of lipoprotein/percentage of [^{3}H]-COE × mg of cell protein^{-1} in the absence of lipoprotein as the experimental control) – 1].

Statistical analysis. The amount of protein bound to the zymosan particles was compared by Student's *t*-test. The Mann-Whitney test was used for statistical comparison of the phagocytic index of zymosan particles and of the uptake index of [^{3}H]-COE-EM by macrophages; a level of confidence of 0.05 was considered significant.

RESULTS

Initially, we analyzed the difference in the uptake by mouse peritoneal macrophages of zymosan particles coated with LDL or with the copper-oxidized form of the same preparation. The data in Table 1, presented as relative increase, demonstrate that LDL greatly enhances the ability of the zymosan to be recognized and phagocytized by macrophages. If the same LDL preparation were subjected to oxidative modification, it would lead to an approximately sixfold reduction in the number of cells able to ingest these particles. The data also show that this reduction was not due to an inability of the zymosan particle to be coated with oxLDL since the zymosan particles showed an equal degree of protein binding with both LDL and oxLDL. Table 1 also compares the phagocytosis of zymosan particles coated with either HDL or apoHDL. Most interestingly, while HDL was unable to modify the ability of the zymosan particle to be phagocytized, the removal of the lipid part of HDL, i.e., using apoHDL, significantly enhanced phagocytosis of the particle. Part of this effect could be due

TABLE 1
Phagocytic Index of Mouse Peritoneal Macrophage Exposed to Zymosan Particles Coated with LDL, oxLDL, HDL, or apoHDL

Coated with lipoproteins[a]	Phagocytic index[b]	Protein binding (μg/10^8 particles)[e]
LDL	6.1 (5.1–7.3)	23.7 ± 1.1
oxLDL	1.1 (0.9–1.7)[c]	26.4 ± 1.7
HDL	0.0 (–0.2–0.2)	10.1 ± 2.2
apoHDL	0.7 (0.7–0.8)[d]	18.7 ± 3.6[f]

[a]Zymosan particles were coated with indicated lipoprotein mixture and incubated with mouse peritoneal macrophages as described in the Materials and Methods section. LDL, low density lipoprotein; oxLDL, oxidized LDL; HDL, high density lipoprotein; apoHDL, delipidated HDL.
[b]Calculated as [(number of macrophages that took up three or more zymosan particles coated with lipoprotein mixture/number of macrophages that took up three or more uncoated zymosan particles) – 1]. Values are expressed as median (range) for each experimental group, which included five experiments each. Studies on LDL and oxLDL and those with HDL and apoHDL were carried out at different occasions.
[c]LDL × oxLDL: $P < 0.01$ by the Mann-Whitney test.
[d]HDL × apoHDL: $P < 0.05$ by the Mann-Whitney test.
[e]The mean amounts of LDL, oxLDL, HDL, and apoHDL protein that coated zymosan particles were obtained by the method of Lowry *et al.* (19) as presented in the Materials and Methods section. Values are expressed as mean ± SD for each experimental group, which included five experiments each.
[f]HDL × apoHDL: $P < 0.05$ by the *t*-test.

to the slight increase in the protein content of the apoHDL particle.

Finally, we analyzed to what extent LDL, oxLDL, HDL, and apoHDL could affect the uptake of chylomicron-like TG-rich EM labeled with [^{3}H]-COE. The results clearly demonstrate that the cellular uptake of the [^{3}H]-COE-EM was greatly stimulated by LDL if compared to oxLDL, and by apoHDL if compared to HDL (Fig. 1).

DISCUSSION

Two general mechanisms are involved in the macrophage uptake of large amounts of lipids: receptor-mediated endocytosis of plasma lipoproteins either in solution or forming complexes with other tissue constituents (3); or phagocytosis of whole cells, fragments of membranes containing cholesterol, or as aggregated LDL (2). These mechanisms may be involved in the lipid accumulation in the atherosclerotic lesions and in the formation of eruptive xanthomata of the primary hyperchylomicronemia (8,9). In other words, to study the influence of several lipoproteins in the receptor-mediated endocytosis, we have utilized EM, whereas zymosan was utilized to investigate the influence of these lipoproteins in phagocytosis.

The formation of lipid-laden foam cells *via* internalization of lipoproteins represents a key event in the formation of atherosclerotic lesions (1) and of the eruptive xanthomata of primary hyperchylomicronemia, but the mechanisms of cell uptake of these large particles are poorly understood (23). In the present study, we have analyzed whether LDL, oxLDL, HDL, or apoHDL can modify the uptake by macrophages of inert zymosan particles as compared to a known atherogenic lipoprotein, the intact chylomicron-like large EM. The uptake of zymosan particles (yeast cell walls) by macrophages is classified as unspecific phagocytosis, and this fact had previously been used to study the receptor-mediated uptake of ligands such as immunoglobulin G (IgG) or its complement (24). The interaction of coated zymosan particles with cells also promotes a number of important biological functions, such as superoxide generation, release of a variety of enzymes, and phagocytosis (25).

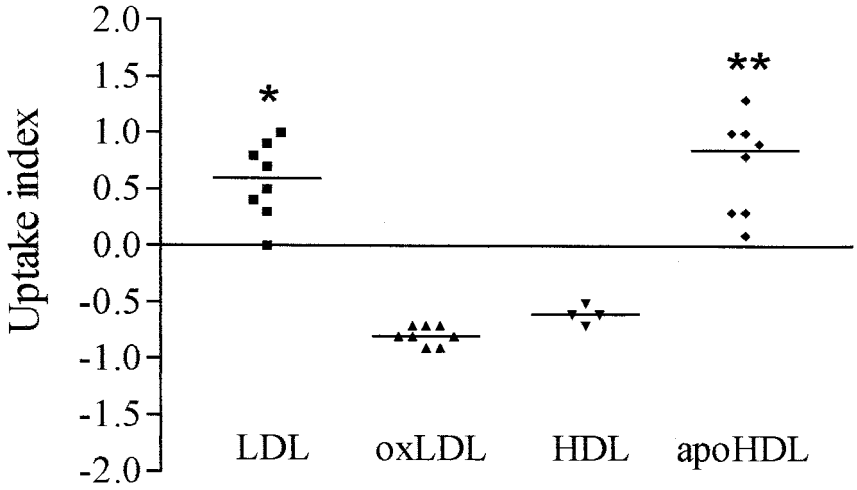

FIG. 1. Uptake index of [1α,2α(N)-^{3}H]-cholesteryl oleoyl ether from chylomicron-like triglyceride (TG)-rich emulsions (EM) by mouse peritoneal macrophages in the absence or presence of low density lipoprotein (LDL), oxidized LDL (oxLDL), as well as of high density lipoprotein (HDL) and delipidated HDL (apoHDL) (0.6 μg of protein/μg of TG of EM) during 4-h incubation periods. Studies on LDL and oxLDL and those with HDL and apoHDL were carried out on different occasions. Values are expressed as median (range) for each experimental group. Mann-Whitney test, $P < 0.001$: *LDL ($n = 8$ experiments) vs. oxidized LDL ($n = 8$ experiments), $P < 0.01$: **apoHDL ($n = 8$ experiments) vs. HDL ($n = 4$ experiments).

We showed that zymosan particles coated with LDL were efficiently and rapidly taken up by mouse peritoneal macrophages. This enhanced uptake could have occurred *via* specific receptors, such as through the LDL receptor, or by induction of phagocytosis. According to Bigler *et al.* (26), LDL promotes the expression of the Fc receptor, a known mediator of phagocytosis, and thus could explain the high macrophage phagocytic index of the LDL-coated zymosan. This process could also be influenced by several other factors, such as modification of surface charge, unspecific interactions of lipid or of protein components.

The oxidation of the LDL particle led, on the other hand, to a substantial loss of the ability of zymosan to be phagocytized, possibly because of competition toward the scavenger receptor. On the other hand, we noticed that, as opposed to the normal LDL, oxLDL facilitated the adherence to the macrophage surface of zymosan but not necessarily its internalization, a fact that had also been observed in regard to erythrocytes coated by oxLDL (27). Therefore, zymosan cell binding does not by itself define the process of phagocytosis, which in fact was severalfold lower when compared to phagocytosis elicited by coating of zymosan with nonoxidized LDL. In this regard, Sambrano *et al.* (28) had shown that oxLDL competed with oxidized erythrocytes for binding to macrophages. This suggests that the receptors described for oxLDL, including the scavenger receptor and the CD36 molecules (5,13,29), are involved in the attachment of zymosan to the cell, without, nonetheless, promoting internalization. Seemingly, the latter depends on other cell surface receptors, such as the Fc receptor.

Coating with HDL did not interfere with zymosan phagocytosis. However, coating with apoHDL, obtained through delipidation of HDL, resulted in a slightly increased ability of zymosan to be phagocytized. Even though the coating with apoHDL resulted in particles with slightly increased protein content, the data suggest that the lipid part of the HDL is not important for the phagocytosis of zymosan. According to previous reports, HDL_3, a fraction relatively richer in apolipoprotein than bulk HDL, although less efficiently than LDL, also mediates the expression of the phagocytic Fc receptor (26). Therefore, the enhanced phagocytosis elicited by apoHDL could be attributed to the protein component of HDL.

In the second part of this study, we analyzed the effect of the same lipoprotein fractions on the uptake of EM. EM are considered to closely resemble the metabolism of chylomicrons (15). Similarly to what occurred in regard to the zymosan particles, LDL increased while oxLDL inhibited the uptake of EM (Fig. 1). Since the uptake of EM particles also was considerably stimulated by LDL, phagocytosis seems to have taken part in the uptake of EM as suggested by others (9,30). This may have occurred because LDL particles are known to aggregate *in vitro* and *in vivo* (31) and thus could have adhered to the EM forming larger complexes or else LDL could have promoted the expression of the Fc receptor (26). Thus, the LDL-EM interaction brings on the formation of foam cells (32) due to production of much larger particles that facilitate EM phagocytosis, similar to what occurs with zymosan.

On the other hand, because oxLDL is atherogenic, the decrease of uptake by oxLDL that occurred with both zymosan and EM seems paradoxical in regard to atherogenesis. Accordingly, oxLDL would contribute to make the large triglyceride-rich particles that are abundant in hyperchylomicronemia less atherogenic (23). However, oxLDL itself remains highly atherogenic since it could compete with the other particles for the scavenger receptor.

A significant reduction of the uptake of EM by macrophages occurred in the presence of HDL. This was further confirmed by the fact that the HDL-zymosan particle was not phagocytized. On the other hand, apoHDL derived from the delipidation of HDL resulted in an increased uptake of EM, similarly to what occurred in regard to the zymosan particles. Thus, HDL facilitates, whereas apoHDL inhibits the metabolism of the large EM by macrophages. ApoHDL is the most abundant lipoprotein-derived component in the interstice and thus may contribute to formation of eruptive xanthomata and to the atherogenic role of chylomicrons in familial primary hyperchylomicronemia (23).

We thus conclude that by using coated zymosan particles and TG-rich EM we demonstrate different biological effects of LDL, oxLDL, HDL, and apoHDL on phagocytosis by macrophage and that this method could be used to identify the various lipoproteins, including other forms of hyperlipidemia, important for the propagation or inhibition of the formation of foam cells and the mechanisms involved.

ACKNOWLEDGMENTS

The authors would like to thank Santa Poppe, Lila Mina Harada, and Isac Castro for excellent and invaluable assistence and Hiro Goto for helpful suggestions. Zymosan was a gift from Allergy and Immunopathology Laboratory, São Paulo Medical School, Brazil. This work was supported in part by FAPESP (MG 99/00 158-4).

ABSTRACT: This study was designed to examine the immunomodulatory effects of dietary docosahexaenoic acid (DHA) in the absence of eicosapentaenoic acid (EPA). We investigated the effects of feeding dietary DHA ethyl ester (DHA-Et) (97% pure) at levels of 4.8 wt% of the total diet and of feeding EPA ethyl ester (EPA-Et) (99% pure) at 4.8 wt% on the inflammatory response in the challenge phase of the contact hypersensitivity reaction (CHR) in the ears of mice sensitized with 2,4-dinitro-1-fluorobenzene (DNFB). The effect of DHA-Et on T lymphocytes at the CHR site was examined using anti-CD4 antibodies. Furthermore, we examined the cytokines formed at the CHR site on the mRNA level. It was found that 24 h after the challenge, DHA-Et but not EPA-Et reduced the ear swelling. Infiltration of inflammatory cells, in particular, CD4-positive T lymphocytes, into the ears in the challenge phase of CHR was observed. DHA-Et reduced the infiltration of CD4-positive T lymphocytes into the ears. DHA-Et also decreased the expression of interferon-γ, interleukin (IL)-6, IL-1β , and IL-2 mRNA in ears. These observations suggest that DHA, but not EPA, may exert an antiinflammatory and immunosuppressive effect. The immunosuppressive effectiveness of fish oil may be attributed mainly to DHA.

Paper no. L8225 in *Lipids 35,* 61–69 (January 2000).

Many researchers have reported that intake of polyunsaturated fatty acids (PUFA), especially n-3 PUFA, have a beneficial role in the prevention of cardiovascular diseases (1,2), at least in part because of reduced arteriosclerosis (3). Eicosapentaenoic acid (EPA) in particular has been demonstrated to prevent hypertriglyceridemia (4) and osteoporosis (5). In the last decade, there has been great interest in the effects of different types of dietary PUFA upon the immune system (6). The reason for the interest in the immunomodulatory effects of fatty acids is that epidemiological studies have shown that people such as the Inuit, who consume large quantities of fish oil rich in n-3 PUFA EPA (20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3), have a very low incidence of inflammatory and autoimmune diseases (6).

Further, many clinical studies have reported that fish oil supplementation of the human diet has several beneficial effects in acute and chronic inflammatory conditions (7–13). Feeding laboratory animals diets rich in n-3 PUFA (canola, linseed, fish oils), particularly diets rich in fish oil, has resulted in immunosuppression (14–18). Arm *et al.* (19) reported fish oil supplementation ameliorated the condition of asthmatic subjects. However, the consumption of diets that contained n-3 PUFA aided immunosuppression, whereas those rich in n-6 PUFA were less suppressive (14–18).

Most of the studies cited investigated the effects of large amounts of n-3 or n-6 PUFA. The amounts used in many cases could not be achieved in the human diet. There is little information on how much n-3 PUFA needs to be present to bring about the beneficial effects of fish oil. Fish oil contains variable amounts of EPA and DHA, along with many other fatty acids, cholesterol, heavy metals, and chlorinated hydrocarbons. It is not known if the decline in immune response caused by fish oils is due to EPA or DHA, to both, or to some other factor. Purified esters of EPA lowered several aspects of the immune response in humans (20–22). *In vitro* studies conducted with human (23) and rat lymphocytes (24) and *in vivo* studies in rats (25) showed that DHA esters/salts also inhibit immune cell functions.

Kelley *et al.* (26) reported that when total fat intake was low and held constant, DHA consumption did not inhibit many of the lymphocyte functions that have been reported to be inhibited by fish oil consumption in young healthy men.

Bjørneboe *et al.* (27) reported improvement in the condition of atopic dermatitis patients with the treatment of Max-Epa (18% EPA and 12% DHA). In atopic dermatitis, the mechanism underlying skin lesion formation has remained unclear

Abbreviations: AA, arachidonic acid; CHR, contact hypersensitivity reaction; DHA, docosahexaenoic acid; DHA-Et, DHA ethyl ester; DNFB, 2,4-dinitro-1-fluorobenzene; EPA, eicosapentaenoic acid; EPA-Et, EPA ethyl ester; G3PDH, glyceraldehyde 3-phosphate dehydrogenase; ICAM-1, intercellular adhesion molecule-1; IFN, interferon; Ig, immunoglobulin; IL, interleukin; LT, leukotrienes; MAb, monoclonal antibody; PAF, platelet-activating factor; PBS, phosphate-buffered saline; PCR, polymerase chain reaction; PG, prostaglandin; PUFA, polyunsaturated fatty acid; RT, room temperature; Th cells, T-helper cells; TNF, tumor necrosis factor; VCAM-1, endothelial leucocyte adhesion molecule.

except for instances of delayed hypersensitivity reaction against environmental substances (28–30) or immunoglobulin E (IgE)-mediated immediate hypersensitivity reaction against food or inhalant allergens (31–33). Eczematous skin lesions in atopic dermatitis patients contain cytokine-producing CD4-positive T cells (34,35). CD4-positive T cells or T-helper cells (Th cells) have been divided into two subclasses depending on their cytokine secretion pattern: The Th1-like subtype, which is characterized by predominant production of interferon (IFN)-γ and interleukin (IL)-2, and the Th2-like subtype, which typically synthesizes IL-4 (36). In previous studies, 85% of skin samples obtained from chronic eczematous lesions of atopic dermatitis patients were found to contain increased levels of IFN-γ mRNA, whereas increased IL-4 mRNA expression could be observed in only 25 to 30% (33). In addition, in those atopic dermatitis patients whose skin disease responded to treatment, increased IFN-γ mRNA but not increased IL-4 mRNA levels were down-regulated. These studies indicate that the Th1-like cytokine IFN-γ plays a major role in the maintenance of chronic eczematous lesions in atopic dermatitis patients. It has already been reported that the expression of IFN-γ among several Th1 types of cytokine is especially important for the formation of contact hypersensitivity reaction (CHR) (37). Although there are limitations in the use of mouse CHR as a model for chronic atopic dermatitis, it is one approach for studying the late phase of this disease.

In our study, we investigated the immunomodulatory effects of dietary DHA ethyl ester (DHA-Et) fed at a level of 4.8 wt% of total diet and of EPA ethyl ester (EPA-Et) also fed at 4.8 wt% on the inflammatory response in the challenge phase of CHR in the ears of mice sensitized with 2,4-dinitro-1-fluorobenzene (DNFB). We used a 4.8 wt% corn oil diet as control. We show here that DHA-Et reduced the ear swelling and the expression of Th1 type cytokines and decreased the infiltration of inflammatory cells into the ears in the challenge phase of CHR.

MATERIALS AND METHODS

Diet. The low-fat (basal) diet was obtained from Clea Japan Inc. (Yokohama, Japan). Its composition, in weight percentages, was as follows: milk casein, 26.1; corn starch, 48.4; crystallized cellulose, 10.6; cellulose powder, 3.2; sugar, 2.1; potato α-starch, 1.1; vitamine mixture, 1.1; mineral mixture, 7.4. Each diet contained 94.0 wt% of basal diet and 1.2 wt% of safflower oil, to supply the essential fatty acid linoleic acid. The rest of the diet constituted the experimental lipid. The EPA-Et, DHA-Et, and control diets contained 4.8 wt% of EPA-Et (99% purity; NOF Corp., Tokyo, Japan), DHA-Et (97% purity; NOF Corp.), and corn oil, respectively. All lipids contained 0.2 wt% of α-tocopherol as an antioxidant. The fatty acid composition of experimental lipids that were added in the basal diet were shown in Table 1. Saibokuto (1.0 wt%; Tsumura Inc., Tokyo, Japan) was added in a control diet as a positive control diet (Saibokuto diet). Saibokuto is an antiinflammatory Chinese medicine that suppresses the production of leukotriene (LT) C_4 and platelet-activated factor (PAF). The diets were divided into small packages and stored at 4°C. To minimize lipid peroxidation, fresh diets were provided to the mice every day.

Feed design and induction of CHR. The use of animals in all of our experiments was in accordance with guidelines of the Tsukuba Research Laboratory, NOF Corporation. Four-week-old female ddy mice (this strain came to Japan from Germany in the early 1900s and has been kept in a closed colony since) were obtained from Charles River Japan Inc. (Tokyo, Japan). After a 1-wk accommodation period, the mice were divided into four groups (n = 12). Their body weights were measured twice a week. After 23 d of feeding the described diets, the fur on the backs of the mice was shaved off. The next day, to induce the inflammatory reaction, the mice were treated with 0.1 mL of 0.5% DNFB diluted with an acetone/olive oil mixture (4:1 vol/vol) on their backs (induction). Five days after induction, 20 μL of the same DNFB mixture as in the induction treatment was applied to both ears of the sensitized mice (challenge). Before the challenge and at 6 and 24 h afterward, the thicknesses of the mice ears were measured using a thickness gauge (Ozaki Mfg. Co. Ltd., Tokyo, Japan).

Increase in thickness is defined as ear swelling. DNFB solution was painted on both ears. The average for both ears of each animal was taken as the individual mouse ear swelling.

Histopathological analysis. Twenty-four hours after the challenge, the mice were sacrificed. Their ears were then removed, embedded in Tissue-Tek OCT (Miles, Elkhart, IN), and frozen with dry ice/acetone. Serial 6-μm sections were cut on a cryostat and placed on poly-L-lysine-coated slides (two sections per slide). The slides of the frozen sections were defrosted and dried at room temperature (RT) for an hour. After fixation in 5% paraformaldehyde, the sections were stained with hematoxylin-eosin solution.

Infiltration of inflammatory cells into the epidermis and the severity of edema were observed and the degree ranked in five levels. Rank 1 indicated very slight; rank 2, slight; rank 3, middle; rank 4, severe; rank 5, most severe.

Immunohistochemistry. Serial 8-μm sections were cut on a cryostat and placed on poly-L-lysine-coated slides (two sections per slide). Slides with frozen sections were defrosted and dried at RT for an hour. After fixation in cold acetone (10 min), they were allowed to dry at RT (10 min). After washing in phosphate-buffered saline (PBS) (5 min × 3), nonspecific

binding sites were blocked with block ace (Dainippon Seiyaku, Osaka, Japan). Excess solution was removed; the sections were then circled with a waterproof pen (Dako; Glosstrup, Denmark), and incubated with the primary monoclonal antibody (MAb), anti-mouse CD4 (L3/T4)(Cedarlane Laboratory Ltd., Canada) or anti-mouse CD8α (KT 15) (Serotec Ltd., Oxford, England) at 37°C for an hour. All MAb against mouse antigens were rat immunoglobulin G (IgG). Diluent was 10% block ace. Negative control slides were incubated in the diluent alone. After washing in PBS, the slides were incubated with biotinylated rabbit antirat IgG preadsorbed with mouse liver powder, followed by avidin-biotinylated horseradish peroxidase complex and diaminobenzidine according to the Vectastain protocol (Vector, Burlingame, CA). For individual slides, the nuclei were counterstained with methyl green (Vector).

Expression of cytokines. Cytokine mRNA expression was measured by reverse transcription-polymerase chain reaction (PCR). The ears were taken from mice 24 h after the challenge. The specimens were homogenized with 1.0 mL of 4 M guanidium isothiocyanate buffer. After this, the total RNA was extracted and reverse transcribed to cDNA using Moloney Murine Leukemia Virus (M-MuLV) Reverse Transcriptase and a random primer [pd $(N)_6$] (Amersham Pharmacia Biotech, Uppsala, Sweden). Identical amounts of cDNA were subjected to 35 PCR cycles with primers of cytokines (Clontec Inc., Palo Alto, CA). The products were subjected to electrophoresis on a 1.0% agarose gel and visualized by ethidium bromide staining. For the estimation of similar amounts of cDNA used for PCR, the samples were screened for the expression of glyceraldehyde 3-phosphate dehydrogenase (G3PDH) as the housekeeping gene. The relative amounts of cDNA of each sample to be inserted into PCR were calculated to yield similar amounts of G3PDH PCR products by using the computer software Bioimage Version 0.81 (Bioimage Japan Inc., Tokyo, Japan).

Data analysis. The data were expressed as the mean ± SD of four mice fed each diet. The data were analyzed by analysis of variance and Bonferroni's test. A P value of less than 0.05 was considered to be statistically significant.

RESULTS

Mouse growth. The final body weights, and therefore the total growth, were not found to differ among the mice fed on the different diets (data not shown). No side effects were observed among mice fed on the diets described in the Materials and Methods section.

Ear swelling. Ear swelling of mice fed the control diet was measurable 6 h after the challenge. The differences in ear thickness (mean ± SD) before the challenge and 6 and 24 h afterward (ear swelling) are shown in Figure 1. In the early and late phases (6 and 24 h after the challenge, respectively), the ear swelling of the mice fed the DHA-Et diet was significantly suppressed compared to that of those fed the control diet and the EPA-Et diet ($P < 0.01$). The ear swelling of the mice fed

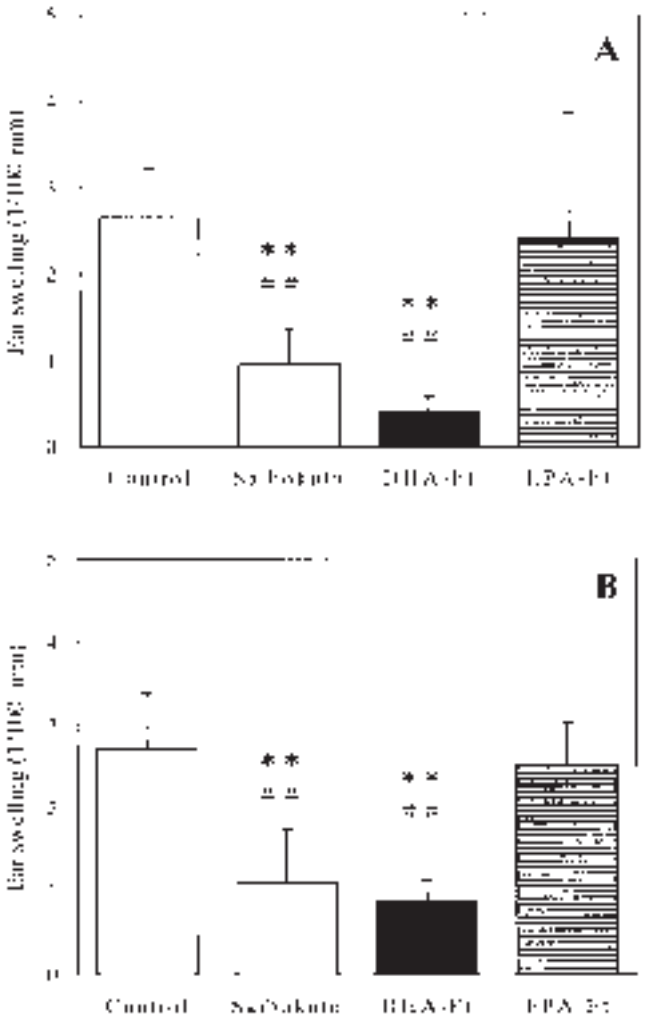

FIG. 1. Ear swelling of mice fed several kinds of diets (A) 6 h and (B) 24 h after the challenge. Control,Control diet; DHA-Et, docosahexaenoic acid ethyl ester diet; EPA-Et, eicosapentaenoic acid ethyl ester diet; Saibokuto, control diet to which was added 1.0 wt% Saibokuto. Six and 24 h after the challenge, ear swelling of mice fed on the DHA-Et diet was significantly suppressed compared with those fed on control diet ($P < 0.01$). Ear swelling of mice fed EPA-Et diet was not different from that of mice fed control diet. Six hours after the challenge, ear swelling of mice fed Saibokuto diet was also suppressed compared with that of mice fed control diet from. $^{**}P < 0.01$, significantly different from the control diet group. $\#\#P < 0.01$, significantly different from the EPA-Et diet group (one-way analysis of variance followed by Bonferroni's test). The data are expressed as the mean ± SD.

EPA-Et diet was found not to be different from that of the mice fed the control diet. The ear swelling of mice fed the saibokuto diet was also significantly suppressed compared to that of those fed the control diet and the EPA-Et diet ($P < 0.01$).

Histopathological analysis. On histological examination 24 h after the challenge, spongiosis (paracytic edema of the epidermis and corium) and mononuclear cell infiltration into the epidermis were observed in the ear tissues from the mice fed the control diet. Significant filtration of the lymphocytes (mostly monocytes) was also observed at the stratum reticular. Typical photomicrographs are shown in Figures 2A and

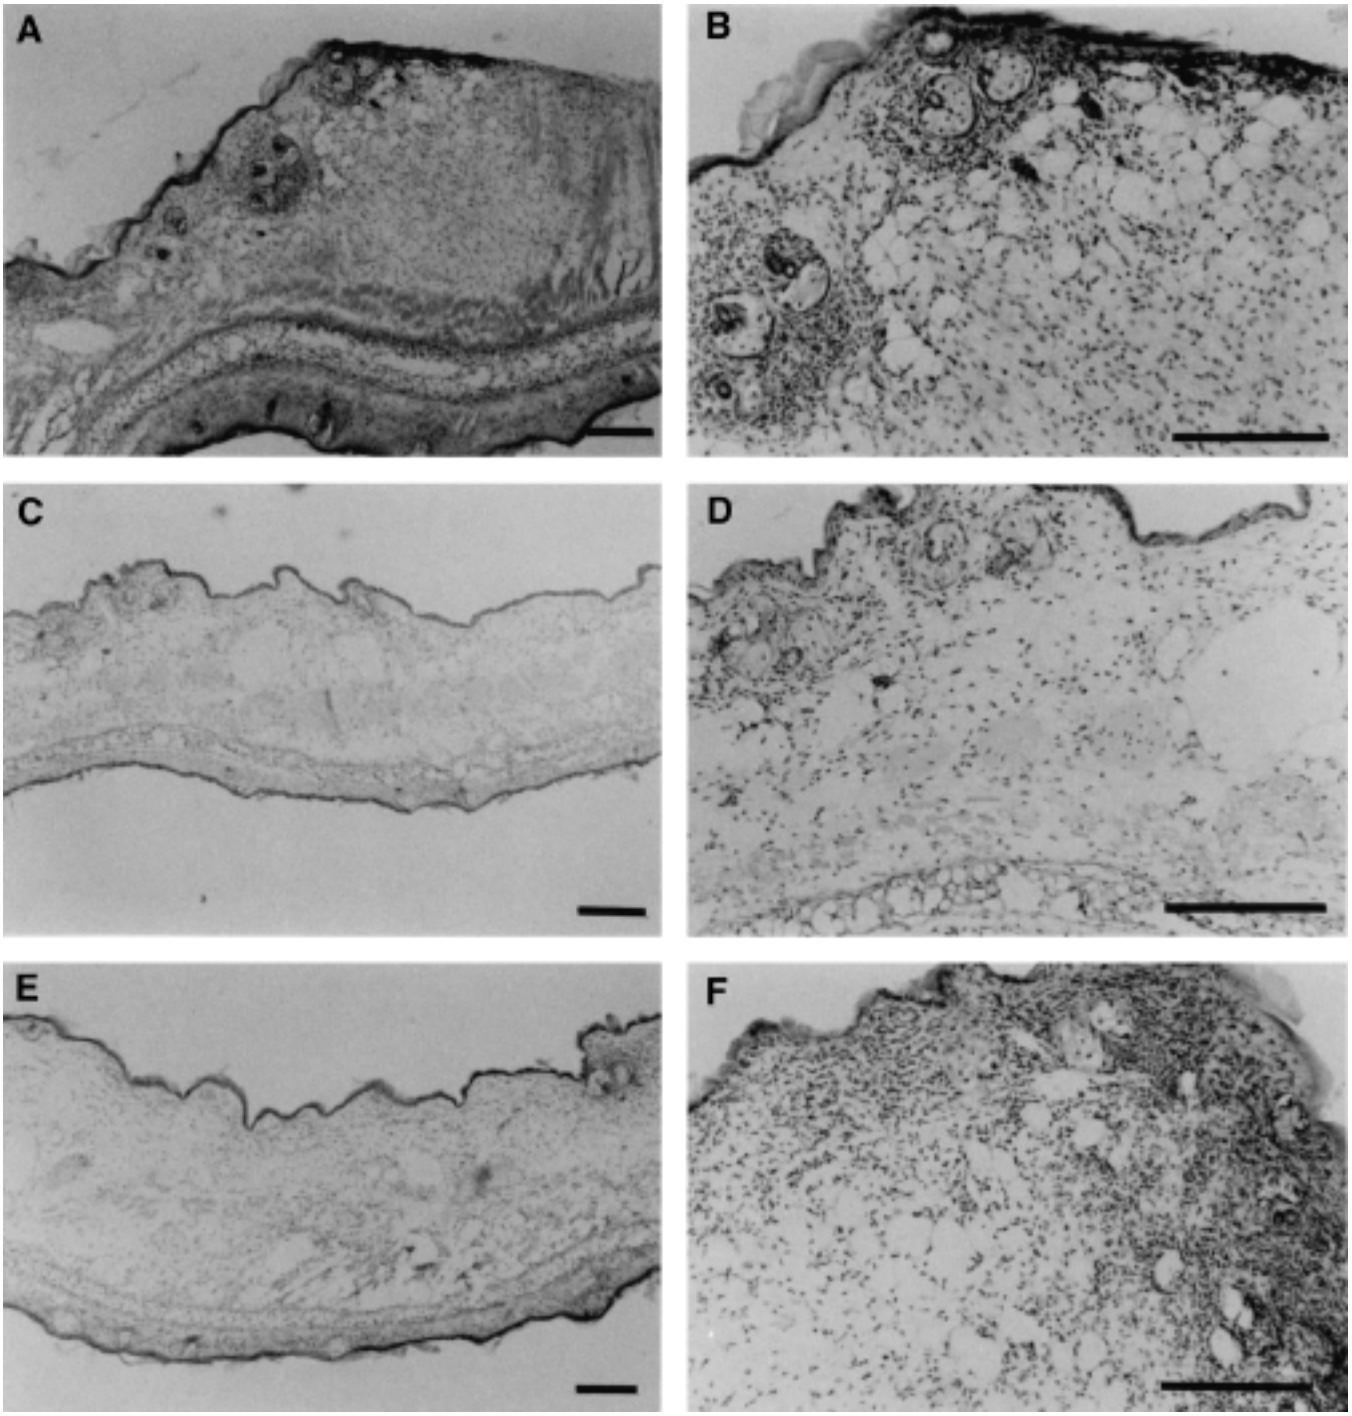

FIG. 2. Photomicrographs of mouse ear stained with hematoxyline and eosin. (A,B) Ear of a mouse fed the control diet, 24 h after challenge. Note spongiosis (paracytic edema of epidermis and corium) and mononuclear cell infiltration into the epidermis. (C,D) DHA-Et decreased the number of infiltrated inflammatory cells in the epidermis in comparison with control. (E,F) EPA-Et did not ameliorate the severity of spongiosis and did not decrease the number of filtrated inflammatory cells into the epidermis. Photomicrographs of B, D, and F are magnifications (10×) of A, C, and E, respectively. Each bar represents 200 μm. For abbreviations see Figure 1.

2B. The number of infiltrated inflammatory cells in the ear tissues from the mice fed the DHA-Et diet was reduced (Figs. 2C and 2D), while in the tissues from the mice fed the EPA-Et diet, the severity of spongiosis and the infiltration of inflammatory cells into the epidermis were almost the same as in the control diet (Figs. 2E and 2F).

The severity of the ear tissue damage in the mice fed each diet is shown in Table 2. Less edema was observed in ear tissues from mice fed the DHA-Et diet than in tissues from mice fed the EPA-Et and the control diet ($P < 0.01$). Focal granulation tissue formation in the dermis was not observed in the ear tissues from the mice 24 h after the challenge.

TABLE 2
Histopathological Findings

	Inflammatory cell infiltration	Edema
Nontreated	—	—
Control	4.0 ± 0.0	4.0 ± 0.0
Saibokuto	3.0 ± 0.0	3.8 ± 0.5
DHA-Et	*2.8 ± 0.5	* **2.5 ± 0.6
EPA-Et	3.0 ± 0.0	4.0 ± 0.0

[a]Scoring: —, no change; 1, very slight; 2, slight; 3, middle; 4, severe; 5, most severe. Data represent the mean of four specimens. *$P < 0.01$, significantly different from the control diet group. **$P < 0.01$, significantly different from the EPA-Et diet group. For abbreviations see Table 1.

Immunohistological study. Twenty-four hours after the challenge, infiltration of CD4-positive cells into the corium was observed in the ear tissues from the mice fed the control diet (Figs. 3A and 3B). The number of CD4-positive cells in the tissues from the mice fed DHA-Et was less than those from the control diet mice (Figs. 3C and 3D). CD4-positive cells in the tissues from the mice fed EPA-Et were not different from those in the mice fed the control diet (Figs. 3E and 3F).

Twenty-four hours after the challenge, infiltration of CD8-positive cells into the corium was also observed in the ear tissues from the mice fed the control diet, although the number of CD8-positive cells was less than that of CD4-positive cells. The number of CD8-positive cells in the tissues from the mice fed DHA-Et was not significantly less than that in the control diet (data not shown).

Expression of cytokines in the ear tissues from mice in the challenge phase of CHR. We examined the cytokine mRNA expressed at the CHR sites. At 24 h after the challenge, IL-1β, IL-2, IL-6, and IFN-γ mRNA were expressed in the ear tissues from the mice fed the control diet, but IL-4, IL-3, and TNF-α mRNA were not. The expression of IL-2, IL-6, and IFN-γ mRNA was decreased significantly in the tissues from the mice fed the DHA-Et diet compared with that from the mice fed the control diet (Fig. 4). The expression of IL-1β was decreased, but not significantly. In contrast, no decrease of the expression of IL-1β, IL-6, IFN-γ, and IL-2 mRNA in the tissues from the mice fed the EPA-Et diet was observed (Fig. 4).

Under these conditions, G3PDH mRNA was not seen to change.

DISCUSSION

In this study we compared DHA-Et with EPA-Et for their antiinflammatory and immunosuppressive effects in a rodent CHR model. Generally, inflammatory mediators are thought to convert from PUFA through an arachidonate cascade and play important roles in the development of the inflammatory process. Arachidonic acid (AA) is converted to 2-series prostaglandins (PG) and 4-series leukotrienes (LT), all of which are mediators of inflammation. In particular 4-series LT intensify neutrophil chemotactic responsiveness in the development of the inflammatory process. On the other hand, EPA displaces AA from macrophage phospholipids and effectively competes with AA for cyclooxygenase and lipoxygenase binding sites to foster formation of eicosanoids with relatively lower inflammatory properties (38), e.g., thromboxane A_3, LT B_5 and PGE_1, than those generated from AA (e.g., thromboxane A_2 and LT B_4). Palombo *et al.* (39) reported that short-time (i.e., 3 d) continuous enteral feeding of diets containing EPA and γ-linolenic acid to endotoxemic rats reduces the levels of AA and linoleic acid in alveolar macrophage and liver Kupffer and endothelial cell phospholipids with attendant decreases in PG formation by these cells *in vitro*. The suppression of inflammatory responses by EPA might be due to some adverse effect on the arachidonate cascade whereas DHA is thought not to be a substrate of the enzymes in the arachidonate cascade nor to be converted to eicosanoid products. Krokan *et al.* (40) reported that, since substituting DHA for AA in the phospholipids of the cell membrane was more difficult than substituting EPA for AA, the suppressive effect of DHA on the arachidonate cascade was less than for EPA. In contrast, Corey *et al.* (41) reported that DHA inhibited AA conversion to PGE_2 in an *in vitro* experiment. Nakamura *et al.* (42) reported that the inflammatory effects of DHA and EPA in carrageenan-induced edema in rats were essentially same. DHA suppressed the production of the PAF after stimulation of cultured Eol-1 cell by calcium ionophore A23187 (43). Matsumoto *et al.* (44) reported 1-oleic-2-docosahexaenoic phosphatidylcholine inhibited 5-lipoxygenase activity. These results lead to the conclusion that DHA may also suppress the inflammatory response through the modulation of the arachidonate cascade in a similar way to EPA.

Danno *et al.* (45) reported that (i) EPA did not suppress DNFB-induced ear edema (they did not examine DHA treatment), and (ii) EPA, but not DHA, suppresses AA-induced acute inflammation reaction in mice. They concluded that only EPA was able to inhibit AA conversion to 4-series LT and 2-series PG; DHA was not able to inhibit LT biosynthesis

Our results showed that ear swelling in CHR mice fed DHA-Et but not EPA-Et was significantly suppressed compared with that in the control diet in the early and late phases of CHR. We suggested in our report the inhibition of the arachidonate cascade by DHA is unlikely to be the mechanism through which DHA suppresses CHR. Although arachidonate casacade inhibition may be one of several antiinflammatory effects of DHA in CHR, DHA may be acting through the AA-independent mechanism.

In atopic dermatitis, the mechanism underlying skin lesion formation has remained unclear except for the possibility of a delayed hypersensitivity reaction against environmental pollutants (28,29,46) or an IgE-mediated immediate hypersensitivity reaction against food or inhalant allergens (30–32). Atopic eczema is thought to be caused by skin-infiltrating CD4 T cells of Th1- and/or Th2-like subtype, resulting in chronic inflammation of the skin. A dysregulated, cytokine-mediated response for the immune system to environmental, in particular inhalant, allergens is thought to be an important pathogenic factor (47). It has been reported that IFN-γ (Th1-like cytokine) mRNA expression is linked to the clinical

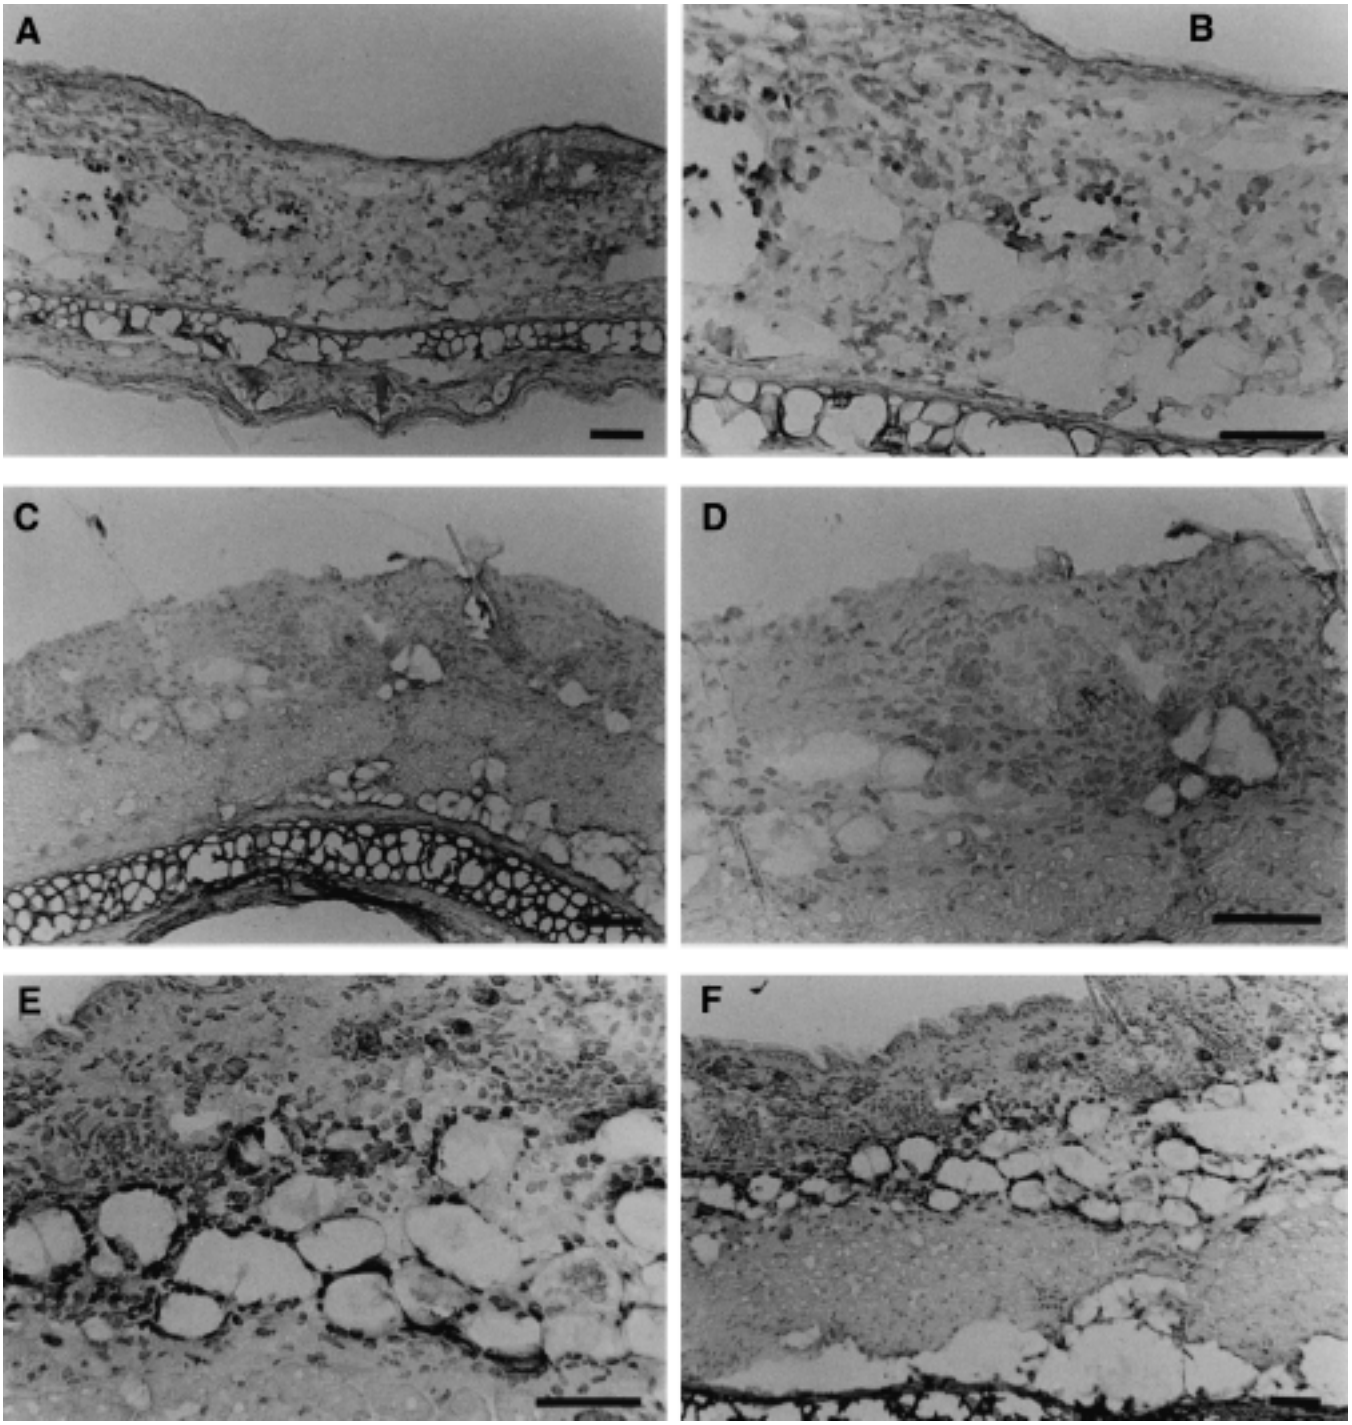

FIG. 3. Immunohistochemical analysis. (A,B) CD4-positive cells in ear from mouse fed control diet, 24 h after challenge. Determined using avidin-biotinylated horseradish peroxidase complex method. Note infiltration of CD4-positive cells into corium. (C,D) DHA-Et decreased the number of the infiltrated CD4-positive cells in inflammatory sites in comparison with control. (E,F) The level of CD4-positive cells in ear from mouse fed EPA-Et was not different from those of the control diet. Photomicrographs of B, D and F were are magnifications (10×) of A, C and E, respectively. Each bar represents 100 μm. For abbreviations see Figure 1.

course of atopic eczema since it was down-regulated after successful therapy but was unaltered in nonresponders (33). Lesional atopic skin clinically and histologically resembles allergic contact dermatitis, which may be mediated by a predominant expression of the Th1-like cytokine IFN-γ (48), and a potential role for IFN-γ in atopic dermatitis is further supported by the observation that the intercellular adhesion molecule-1 (ICAM-1), which is strongly inducible by IFN-γ, is expressed on keratinocytes in lesional atopic skin (49). To clarify the immunosuppressive effect of DHA, we used the

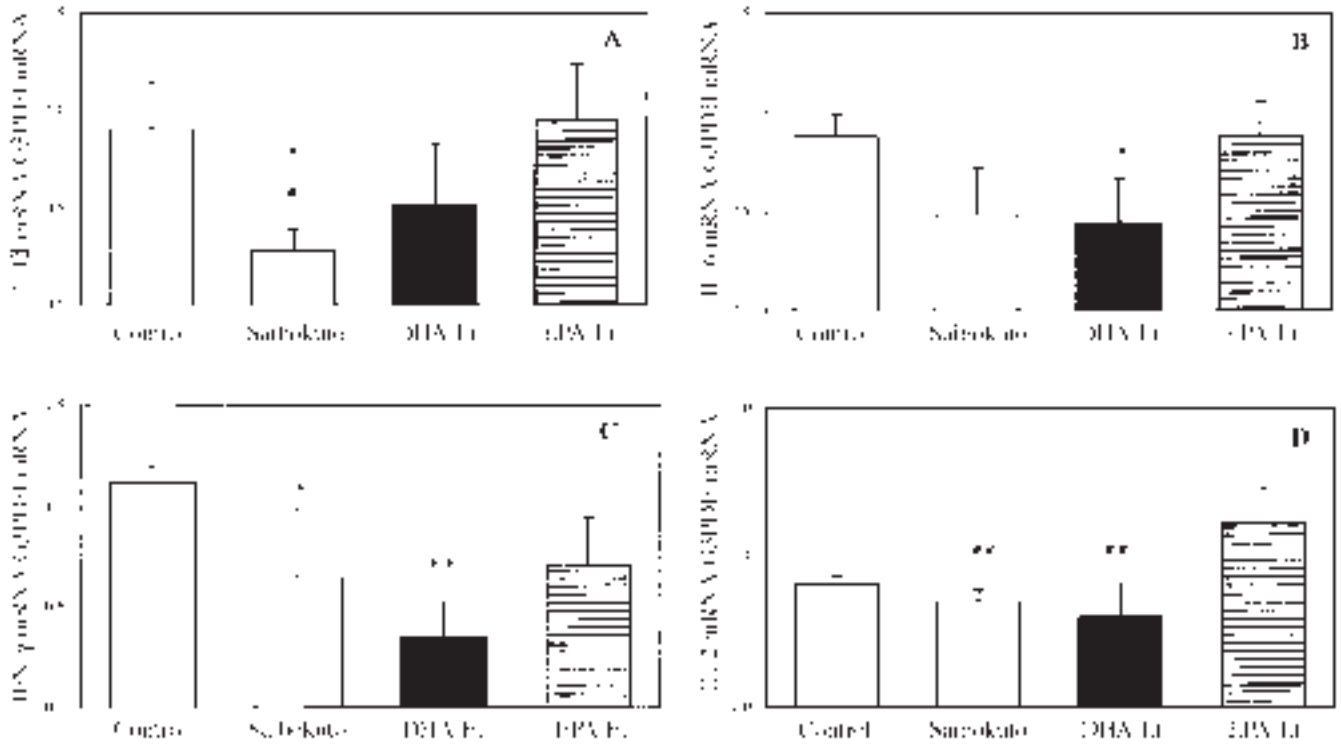

FIG. 4. Expression of cytokine mRNA in the ear of a mouse fed several diets 24 h after challenge. (A) Expression of IL-1β mRNA. (B) Expression of IL-6 mRNA. (C) Expression of IFN-γ mRNA. (D) Expression of IL-2 mRNA. The total RNA (2 μg) from each sample was used and subjected to reverse transcription-polymerase chain reaction (PCR) analysis. For the estimation of similar amounts of cDNA used for the PCR, samples were screened for the expression of glyceraldehyde 3-phosphate dehydrogenase (G3PDH) as the housekeeping gene. The relative amounts of cDNA of each sample to be inserted into the PCR were calculated to yield similar amounts of GAPDH PCR products by using the computer software Bioimage Version 0.81 (Bioimage Japan Inc., Tokyo, Japan). $^{*}P < 0.05$, $^{**}P < 0.01$, significantly different from the control diet group. $\#P < 0.05$, $\#\#P < 0.01$, significantly different from the EPA-Et diet group (one-way anaylsis of variance followed by Bonferroni's test). The data are expressed as the mean ± SD. For abbreviation see Figure 1.

mouse CHR model induced with DNBF. It was reported that ear swelling became worse after about 24 h and was ameliorated 48 h after the challenge, so this reaction in a mouse is based on a chronic delayed-type hypersensitivity (type IV hypersensitivity) (37). It was reported that 24 h after the challenge, IFN-γ, IL-6, and IL-1β mRNA were expressed in the ear tissues in the mice and 48 h after the challenge, IL-2, IL-4, and TNF-α mRNA were expressed in addition to these cytokines (37). Moreover, Yamazaki *et al.* (37) suggested that the expression of IFN-γ among several Th1 types of cytokine is especially important for the formation of CHR by analysis of IFN-γ knock-out mice and using anti-IFN-γ antibody (37). As in the previous study, 24 h after the challenge we found that ear swelling, the number of infiltrated CD4-positive cells into lesion sites, and the expression of IL-1β, IL-6, IFN-γ, and IL-2 mRNA were decreased in the ear lesion sites in mice fed DHA-Et not but EPA-Et compared with those in mice fed the control diet. It was suggested that decreased expression of these cytokines, in particular IFN-γ, might suppress the progression of ear swelling.

Inflammatory reaction was induced by the adhesion of circulating leukocytes into the endothelium and their subsequent transendothelial migration. This process depends on the endothelial expression of the endothelial leukocyte adhesion molecules (50,51). De Caterina *et al.* (52) reported DHA inhibited cytokine-stimulated expression of the endothelial leukocyte adhesion molecule VCAM-1 and two other cytokine-induced secretable products, IL-6 and IL-8, from human endothelial cells in culture. They found that the adhesion of cytokine-stimulated monocyte-like cells to activated endothelial cells was decreased with DHA not but EPA treatment. Their study suggested that dietary DHA might decrease the level of VCAM-1 mRNA, consistent with the protein expression; therefore, the infiltration and chemotaxis of T cells, monocytes, and neutrophiles into endothelial cells might be also decreased. It is unclear why DHA but not EPA reduced cytokine-induced leukocyte adhesion molecule expression in endothelial cells. An effect of DHA on cytokine-induced nuclear translocation of specific transcription factors (e.g., nuclear factor-κB) is a likely possibility (53). Several recent reports have described properties of DHA not shared by EPA (43,54–57).

Grewe *et al.* (33) showed the levels of ICAM-1 mRNA on keratinocytes in lesional atopic skin were also up-regulated to more than that in normal skin. The expression of IFN-γ could be linked to clinical treatment of a lesion of atopic skin

because it was down-regulated after successful therapy. Decreased *in-situ* expression of IFN-γ in the responders was paralleled by a reduced expression of ICAM-1 inducible by IFN-γ on keratinocytes, which suggests a functional relevance. In a chronic dermatitis phase, Th1-type cytokines, such as IFN-γ, predominate, which may be critical for the induction of keratinocyte ICAM-1 expression and subsequent accumulation of inflammatory cells in lesional skin (37).

Th1-like cytokine IFN-γ has been reported to play a major role in the maintenance of chronic eczematous lesions in atopic dermatitis patients (37). In this study, the level of IFN-γ mRNA was decreased in the ear tissues in the mice treated with DHA-Et. Because this effect is important for amelioration of the inflammatory response in lesional skin, it was expected that the DHA-Et treatment might improve on the severity in chronic atopic dermatitis. Jenski *et al.* (58) reported that concanavalin A-stimulated proliferation of T lymphocytes and the development of an immunologic memory, as modeled by the secondary mixed lymphocyte reaction, were severely decreased by DHA. They suggested that DHA might be used to modulate immune responses selectively, e.g., to suppress undesired autoimmunity while maintaining protective immunity. In our study, the results from immunohistochemical observation also showed that the infiltration of the inflammatory cells (especially CD4-positive cells) into lesional sites in mice fed DHA-Et diet 24 h after the challenge (late phase of the reaction) was suppressed compared with those in the control diet.

In this report the authors have shown DHA-Et, but not EPA-Et, suppresses ear swelling 24 h after the challenge with DNBF, the expression of Th1-type cytokines such as IFN-γ, and infiltration of inflammatory cells, in particular CD4-positive cells, into the lesion sites. Overall, our data suggest that DHA may ameliorate the inflammation and immune response in the late phase of atopic dermatitis.

ACKNOWLEDGMENT

We thank Dr. Terada (Kitasato University, Sagamihara Japan), who passed away in the winter of 1997, for his many useful suggestions. We pray for the repose of his soul.

[a]Institute of Environmental Science for Human Life, Ochanomizu University, Tokyo 112-8610, Japan, and [b]Institute for Fundamental Research, Suntory Limited, Osaka 618-8503, Japan

ABSTRACT: In this study, a new marine oil that contains 45% docosahexaenoic acid (DHA, 22:6n-3) and 13% docosapentaenoic acid (DPA, 22:5n-6) was administered to rats. The metabolism and distribution of DPA in rats was investigated. In experiment 1, the effects of DHA and n-6 fatty acids (linoleic acid, LA; arachidonic acid, AA; and DPA) on AA contents were investigated *in vivo*. LA group: LA 25%, DHA 30%; LA-DPA group: LA 15%, DPA 10%, DHA 35%; LA-AA-DPA group: LA 10%, AA 5%, DPA 10%, DHA 35% were administered to rats for 4 wk. In the liver, the AA content in the LA-DPA and LA-AA-DPA groups was significantly higher than in the LA group. The decreased AA contents in the LA group might be caused by DHA administration. Although DHA also was administered in the LA-DPA and LA-AA-DPA groups, the AA contents in these two groups did not decrease. These results suggested that DPA retroconverted to AA, blunting the decrease in AA content caused by DHA administration. To conduct a detailed investigation on DPA metabolism and its relation with AA and DHA, rat hepatocytes were cultured with purified DPA and DHA for 24 h. We discovered the retroconversion of DPA to AA occurred only when AA content was decreased by a high DHA administration; it did not occur when AA content was maintained at a normal level.

Paper no. L8212 in *Lipids 35*, 71–75 (January 2000).

Recently, a marine microbe was isolated by a screening test for polyunsaturated fatty acids (PUFA) and was found to accumulate lipids that contain docosahexaenoic acid (DHA, 22:6n-3) and docosapentaenoic acid (DPA,22:5n-6) (1). A new marine oil, DPA-DHA oil, containing 45% DHA and 13% DPA, is therefore available for study. Among n-3 PUFA, DHA has specific functions in the brain and retina (2–5). A recent trend in DHA research focuses on the relation between DHA and the immune system (6). Regarding DPA, its content in most organisms is low, and the n-3 isomer of DPA in most fish oils is at higher levels than is the n-6 isomer (7). It is also known that n-6 DPA is β-oxidized to arachidonic acid (AA, 20:4n-6) (8–11), and that the deficiency of n-3 essential fatty acids (EFA) in animals causes a compensatory rise in the n-6 DPA level in the brain/retina (12,13), but the physiological function of n-6 DPA itself has not yet been clarified.

AA is important in cell membrane phospholipids and serves as the precursor of eicosanoids. AA is maintained at a constant level under normal conditions *in vivo*. It was recently shown that breast milk contains AA that contributes to infant development (14). Moreover, Carlson *et al.* (15) reported that a condition of AA deficiency in preterm infants may lead to impaired growth over the first year of life. In the studies of DHA supplementation, however, high dietary intake of DHA resulted not only in an increase of DHA content but also in a decrease in AA content (16,17). The decrease in AA has been proposed to relate to the inhibition of Δ6 desaturases, reducing synthesis of AA from linoleic acid (LA, 18:2n-6). Both DHA and AA are essential components of the infant central nervous system, and a lack in either may lead to impaired growth. Therefore, an AA decline because of DHA supplementation is a problem that still must be addressed.

In this study, DPA-DHA oil was administered to rats, and its metabolism and distribution were investigated. In experiment 1, the effects of DPA-DHA oil on EFA metabolism was examined with a focus on the interaction and change in the composition of n-6 and n-3 fatty acids *in vivo*. In the second part of this study, primary cultured rat hepatocytes were used to conduct a more detailed investigation of the metabolism of n-6 DPA and its relations with other PUFA, especially DHA and AA.

MATERIALS AND METHODS

Materials. The DPA-DHA oil prepared from a single-cell marine microbe was donated by Suntory Ltd. (Osaka, Japan). DPA ethyl esters (purity >99%), DHA ethyl esters (purity >99%), and AA ethyl esters (purity <95%) also were donated by Suntory Ltd. (Osaka, Japan). Soybean oils, safflower oils, and rapeseed oils were provided by Ajinomoto Co., Inc. (Tokyo, Japan). The standard basal diet was purchased from Eisai Co., Ltd. (Tokyo, Japan). Collagenase (Lot. LEL7202) and L-glutamine were purchased from Wako Pure Chemical Industries, Ltd. (Tokyo, Japan). Trypsin inhibitor (from soybean, Lot. 40H8200)

*To whom correspondence should be addressed at Institute of Environmental Science for Human Life, Ochanomizu University, 2-2-1, Otsuka, Bunkyo-ku, Tokyo 112-8610, Japan. E-mail: sawada@cc.ocha.ac.jp

Abbreviations: AA, arachidonic acid; BSA, bovine serum albumin; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EFA, essential fatty acid; EPA, eicosapentaenoic acid; GLC, gas–liquid chromatography; LA, linoleic acid; PUFA, polyunsaturated fatty acid.

and bovine serum albumin (BSA, essentially fatty acid-free, Lot. 122H9318) were purchased from Sigma Chemical Co. (St. Louis, MO). Dulbecco's modified Eagle medium (DME) and phosphate-buffered saline (PBS) were purchased from Sankoh Pure Chemical Co. (Tokyo, Japan); 8.4% $NaHCO_3$ was purchased from Ohtsuka Pharmaceutical Co. (Tokyo, Japan).

Animals and diets. All experiments were approved by the Animal Experiment Ethics Committee of Ochanomizu University. Four-week-old male Wistar rats were initially fed a commercial diet (CE-2; Nippon Clea Co., Tokyo, Japan) for 1 wk. The animals were then divided into four groups of 5–6 animals each and fed experimental diets for 4 wk. These diets were prepared by mixing 5% (w/w) experimental oil mixtures with the basal diet. The basal diet, prepared according to the standards given by the American Institute of Nutrition (AIN) (18), was provided by Eisai Co. and contained the following percentage of ingredients according to weight: casein 20; glucose 25; sucrose 25; cornstarch 15; filter paper 5; AIN mineral mixture 3.5; AIN vitamin mixture; 1; choline bitartrate 0.2; and DL-methionine 0.3. In experiment 1, the oil mixtures were prepared as follows: (i) LA group: (rapeseed oil/soybean oil, 1:1)/DHA ethyl esters, 65:35; (ii) LA-DPA group: DPA-DHA oil/safflower oil, 4:1; (iii) LA-AA-DPA group: safflower oil AA ethyl esters/ DPA-DHA oil, 15:5:80. The fatty acid compositions of dietary oils are shown in Table 1.

Preparation of rat hepatocytes. Rat hepatocytes were prepared and cultured by the methods described previously (19). Hepatocytes were used for experiments after 17 h of incubation. DPA and DHA ethyl esters were dissolved in 10% BSA solution and added to the culture medium at a final concentration of 0.5 and 0.25 mM, respectively. Hepatocytes were incubated with fatty acids (DPA and/or DHA) for 24 h.

Lipids analyses. Lipids were extracted from the livers, testis, and brains of the rats in experiment 1 and the rat hepatocytes of the rats in experiment 2 by the method used by Folch *et al.* (20). Margaric acid (17:0) was added to the lipid extracts as an internal standard. The lipid extract was then methylated by using HCl/methanol to measure the content of fatty acids. The fatty acid methyl esters were measured by gas–liquid chromatography (GLC) (PerkinElmer Auto system GLC, Palo Alto, CA) on a Rascot Siller 5CP capillary column (0.25 mm × 50 m; Nihon Chromato Works Ltd., Tokyo, Japan), with conditions as described in detail previously (19). Protein was measured by the method of Lowry *et al.* (21).

Statistical analyses. All results are shown as means ± SD. The significance of differences in mean values was evaluated by analysis of variance (ANOVA). After ANOVA, a Bonferroni-Dunn *post-hoc* test was used. Analyses were performed by using a StatView (System 4.02) computer package (Abacus Concepts, Inc., Berkeley, CA).

RESULTS AND DISCUSSIONS

Experiment 1. DHA content in dietary oils was adjusted to 30 to 35% in all groups. The content of total n-6 fatty acids, LA, AA, and DPA was adjusted to about 25%. The concentration of main fatty acids in the different groups was: LA 25% and DHA 30% in the LA group; LA 15, DPA 10, and DHA 35% in the LA-DPA group; and LA 10, AA 5, DPA 10, and DHA 35% in the LA-AA-DPA group. The fatty acid composition of the diet is shown in Table 1.

Results from experiment 1 are shown in Tables 2, 3, and 4. The total fatty acid composition in liver is shown in Table 2. The AA content in the LA-DPA and LA-AA-DPA groups was significantly higher than in the LA group despite the similar total amount of n-6 fatty acids in the diet. The decrease in AA content in the LA group may be due to the high intake of DHA owing to the inhibition of Δ6 desaturation enzymatic reaction from LA to AA. However, a similar amount of DHA administered in the LA-DPA and LA-AA-DPA groups resulted in a much higher AA content. These results suggest that DPA retroconverted to AA to cover the decreased AA content caused by high DHA intake. On the other hand, the AA content in the LA-AA-DPA group was significantly higher than in the LA-DPA group and shows the direct effect of AA administration in the diet.

DPA (n-6) was observed in the LA-DPA and LA-AA-DPA groups, but no significant amount was detected in the LA group. Low DPA (n-3) and 22:4n-6 content was observed in all groups, but no significant difference was observed.

Eicosapentaenoic acid (EPA, 20:5n-3) contents in the LA-DPA and LA-AA-DPA groups were significantly lower than in the LA group. No significant difference was found between the EPA content of the LA-DPA and LA-AA-DPA groups. EPA, which may result from the retroconversion of DHA, was observed in low amounts in the two groups fed DPA and DHA, but not in the group that was fed only DHA. It may imply the occurrence of the retroconversion of DPA to AA (n-6) inhibits the similar retroconversion of DHA to EPA (n-3) in the LA-DPA and LA-AA-DPA groups. A similar fatty acid profile was found in liver phospholipids (phosphatidylcholine and phosphatidylethanolamine) (data not shown).

Table 1
Fatty Acid Composition of Dietary Oils[a]

	16:0	18:0	18:1n-9	18:2n-6	18:3n-3	AA 20:4n-6	EPA 20:5n-3	DPA 22:5n-6	DHA 22:6n-3
LA	5.5	2.4	29.0	26.4	6.0	0.0	0.0	0.0	30.7

The fatty acid content in the testis is shown in Table 3. DPA content in all groups was high compared with that in the liver or brain (Tables 2 and 4). We may assume that DPA accumulates the most in testis, although the physiological function of DPA in the testis still needs to be clarified.

Table 4 shows the total fatty acid composition in the brain. DHA, which is essential in the brain, has a high content in all groups.

The fatty acid profiles in the lung, heart, and kidneys of the different dietary groups were similar to the liver (data not shown).

Experiment 2. Highly purified DPA (>99%) and DHA (>95%) ethyl esters were used to conduct a more detailed investigation on the metabolism of DPA. The retroconversion of DPA to blunt the decreased AA content caused by DHA supplementation was also examined *in vitro*. The total fatty acid content of cultured rat hepatocytes is shown in Table 5.

22:5n-6	ND	6.97 ± 2.69[a]	ND	2.51 ± 0.51[b]
22:5n-3	0.06 ± 0.01	0.06 ± 0.01	0.06 ± 0.01	0.06 ± 0.01
22:6n-3	7.74 ± 7.88	12.3 ± 1.21	18.8 ± 8.14	19.4 ± 2.09

[a]Hepatocytes were cultured in the presence of 0.5 mM DPA in the DPA group or 0.25 mM DHA in the DHA group, or of both in the DPA-DHA group. Control means no addition of any fatty acid in medium. Results are expressed as nmol/mg protein and means ± SD (n = 3–4). The significance of differences between dietary treatments was analyzed by ANOVA. Values not sharing a common roman letter are significantly different. See Tables 1 and 2 for abbreviations.

The AA contents in the control and the DPA groups were similar. This shows that DPA supplementations did not lead to increased AA content. Thus, the retroconversion of DPA to AA is not active when the AA content is maintained at a normal level. On the other hand, the AA content in the DHA group was significantly lower than the control and DPA groups, suggesting that the decline of AA was caused by the presence of DHA. No significant difference was found between the AA content of the control and DPA-DHA group. These results indicate that the decreased AA content associated with DHA supplementation was blocked by DPA through its retroconverison to AA.

The 22:4n-6 content in the DHA group was significantly lower than in the other three groups. The AA content in the DHA group was lowered by DHA, and 22:4n-6, thought to be the elongation product of AA, was thus also decreased. The 22:4n-6 content in the DPA-DHA group, however, did not decrease despite the addition of DHA. This result suggests that retroconversion of DPA to AA was also associated with increased accumulation of 22:4n-6.

The DPA content in the DPA-DHA group was significantly lower than in the DPA group, and this difference in DPA content between the DPA and DPA-DHA groups suggests that DPA is converted to AA by retroconversion in the DPA-DHA group. From the results of experiment 2, we can conclude that the retroconversion of DPA to AA is active when the AA content is rapidly decreased by DHA and is not active when the AA content is maintained at a normal level.

From the results in this study, the following conclusions could be made: DPA (22:5n-6) is found to be extraordinarily high in testis. The most important finding in this study is the retroconversion of DPA to AA both *in vivo* and *in vitro*. The *in vitro* investigation also showed that the retroconversion of DPA occurred only when the AA content was decreased by high DHA administration, but it did not occur when AA content was maintained at a normal level. At present, there are some reports on the retroconversion of DPA to AA (8–11). However, a study on the condition for the occurrence of DPA to AA retroconversion has not been reported. This study may be the first report to suggest that the retroconversion of DPA to AA occurs only when AA content is decreased. Therefore, it is possible to increase DHA content without causing a rapid decrease in AA by administering DHA with DPA. This finding may suggest a solution to the problem of high DHA administration decreasing AA content. Moreover, DPA-DHA oil may be an appropriate oil for administing DHA *in vivo* without decreasing AA content.

ABSTRACT: Muscle membrane fatty acid (FA) composition is linked to insulin action. The aims of this study were to compare the FA composition of muscle and erythrocyte membrane phospholipid in young children; to investigate the effect of diet on these lipid compositions; and to investigate differential incorporation of FA into muscle, erythrocyte and adipose tissue membrane phospholipid, and adipose tissue triglyceride. Skeletal muscle biopsies and fasting blood samples were taken from 61 normally nourished children (45 males and 16 females), less than 2 yr old (means ± SE, 0.80 ± 0.06 yr), undergoing elective surgery. Adipose tissue samples were taken from 15 children. There were significant positive correlations between muscle and erythrocyte docosahexaenoic acid (DHA) ($r = 0.44$, $P < 0.0001$), total n-3 polyunsaturated fatty acids (PUFA) ($r = 0.39$, $P = 0.002$), and the n-6/n-3 PUFA ratio ($r = 0.39$, $P = 0.002$). Adipose tissue triglyceride had lower levels of long-chain PUFA, especially DHA, than muscle and erythrocytes (0.46 ± 0.18% vs. 2.44 ± 0.26% and 3.17 ± 0.27%). Breast-fed infants had higher levels of DHA than an age-matched group of formula-fed infants in both muscle (3.91 ± 0.21% vs. 1.94 ± 0.18%) and erythrocytes (3.81 ± 0.40% vs. 2.65 ± 0.23%). The results of this study show that (i) erythrocyte FA composition is a reasonable index of muscle DHA, total n-3 PUFA, and the n-6/n-3 PUFA ratio; (ii) breast feeding has a potent effect on the FA composition of all these tissues; and (iii) there is a wide range in long-chain PUFA levels in muscle, erythrocytes, and adipose tissue.

Paper no. L8284 in *Lipids 35,* 77–82 (January 2000).

Lipids have many important functions in the body: as a major metabolic fuel, as essential components of all cell membranes, as gene regulators, and as precursors of locally acting metabolites. Knowledge of the fatty acid (FA) composition of lipid in various tissues in the body can give an indication of the level of function of the tissue and also the degree of risk for development of certain diseases.

Abbreviations: DHA, docosahexaenoic acid; FA, fatty acid; LCPUFA, long-chain polyunsaturated fatty acids; PUFA, polyunsaturated fatty acid.

Work in rodents and humans has shown that dietary FA profiles strongly influence the FA composition of muscle phospholipid (the major structural lipid in membranes) (1). In turn, a higher proportion of long-chain (20 and 22 carbon) polyunsaturated fatty acids (LCPUFA) and a low n-6/n-3 PUFA ratio in muscle membrane are associated with enhanced insulin action (2,3). Since muscle is the major site of insulin-stimulated glucose uptake in the body, this translates to improved whole-body insulin action (4). Insulin resistance (the relative failure of insulin action) is strongly linked to a cluster of prevalent diseases including noninsulin-dependent diabetes mellitus, coronary heart disease, various dyslipidemias, hypertension, and central obesity (5–7).

Currently, the most direct measure of muscle FA composition is a muscle biopsy. However it would be highly advantageous to be able to obtain an index of the FA composition of lipid in muscle without the need to use an invasive method. To our knowledge, no studies have compared the FA composition of erythrocytes and muscle from the same human subjects. The aim of this study was to compare the FA composition of these tissues in young children and to investigate the effect of diet in infancy. In addition, little is known about the incorporation of FA into membrane structural lipid of different tissues. In the current study, we compared the FA composition of erythrocyte and muscle membrane and adipose tissue membrane and triglyceride to investigate whether there was evidence of differential incorporation of FA in these tissues.

METHODS

Participants. Sixty-one children (45 males and 16 females), less than 2 yr old, who were undergoing elective surgery at The Royal Alexandra Hospital for Children (Sydney, Australia) were recruited into the study. These children had no history of poor weight gain, significant systemic disease, major congenital malformations, or previous surgery. The types of elective surgery were correction of congenital talipes and several forms of cardiovascular, urological, or abdominal surgery. The muscle groups obtained were abductor hallucis

(n = 29), rectus abdominis (n = 14), latissimus dorsi (n = 4), and external oblique (n = 14). The study protocol was approved by the Ethics Committee of The Royal Alexandra Hospital for Children.

Protocol. Part of the protocol for this study has been described elsewhere (8). Briefly, patients were admitted to the hospital in the afternoon prior to the day of elective surgery. At this time, written, informed consent was obtained from their parents. The children were weighed, their length was measured, and a detailed diet history was obtained, focusing on duration of breast and/or formula feeding and time of introduction of solid foods.

A fasting blood sample (1.5–2.0 mL) was obtained at the time of insertion of an intravenous line directly after halothane induction of anesthesia. Blood was collected in tubes containing lithium heparin. After removal of plasma, erythrocytes were washed three times with cold isotonic saline containing 0.01% butylated hydroxytoluene and stored at −70°C.

Biopsies of muscle (40–200 mg; n = 61) and subcutaneous fat (40–300 mg; n = 15) were obtained in the operating theater at the time of surgery and immediately freeze-clamped in liquid nitrogen. The samples were stored at −70°C for later analysis of phospholipid and triglyceride (for adipose tissue only) FA composition.

Analytical methods. The extraction and derivatization of the FA components of muscle, erythrocyte, and adipose tissue phospholipids and triglycerides have been described elsewhere (9). Phospholipid is almost exclusively associated with membrane, but our analysis does not differentiate between cellular membranes, e.g., sarcoplasmic reticulum, plasma, and mitochondrial. In brief, tissue was homogenized in 2:1 (vol/vol) chloroform/methanol and total lipid extracts prepared according to Folch *et al.* (10). Phospholipids and triglycerides were separated by solid-phase extraction on Sep-pak silica cartridges (Waters, Milford, MA). Briefly, triglycerides were eluted with 30 mL of dichloromethane followed by 30 mL of ethyl acetate. Phospholipids were then eluted with 30 mL methanol. This procedure gave 100% separation and >95% recovery of [^{14}C]triolein and [^{14}C]phosphatidylcholine added to the $CHCl_3$–methanol fraction. Triglyceride and phospholipid fractions were transmethylated with 140 g/L boron trifluoride (Sigma, St. Louis, MO) at 85°C for 1 h. Methyl esters were extracted into hexane and passed through Sep-pak florisil cartridges (Waters) to remove cholesterol esters and polar contaminants. The methyl FA were separated, identified, and quantitated by gas chromatography. The content of individual FA in the phospholipids and triglyceride was expressed as a percentage of the total FA. Identified minor FA peaks (<0.5 percentage of the total) were excluded from the calculation.

Data analysis. The content of individual FA in phospholipids and triglyceride was expressed as a percentage of the total FA identified. Results for the different muscle groups were pooled because there were no major differences between them. Several FA indices were derived from the primary data: the total percentage of 20–22 LCPUFA (the sum of the individual LCPUFA 20:2n-6, 20:3n-9, 20:3n-6, 20:3n-3, 20:4n-6, 20:5n-3, 22:2n-6, 22:4n-6, 22:5n-6, 22:5n-3, and 22:6n-3) and the average degree of FA unsaturation (the unsaturation index), which was calculated as the average number of double bonds per FA residue multiplied by 100.

Length and weight measurements of the children were compared with the National Center for Health Statistics reference population (11). These measurements were normalized by being expressed as SD scores (12).

Diet histories were analyzed using Australian food composition tables (13) extended to specifically index LCPUFA intake.

In investigating the effect of infant feeding on FA composition, comparisons were made using results from infants who were either currently breast-fed or formula-fed (i.e., breast-fed for less than 4 wk). Note that breast milk contains significant quantities of LCPUFA, especially docosahexaenoic acid (DHA), whereas at the time of this study, commercially available infant formulas contained negligible quantities of LCPUFA (14,15).

Statistical analysis. All data are expressed as means ± SE. Statistical analyses were performed using SPSS/PC version 8.0 (SPSS Inc., Chicago, IL). The level of significance was set at $P < 0.05$. Multiple analysis of variance was used to examine differences between the FA composition of (i) muscle and erythrocyte membrane; (ii) muscle and erythrocyte membrane of breast-fed and formula-fed infants; (iii) muscle and erythrocyte membrane and adipose tissue triglyceride; and (iv) adipose tissue membrane and adipose tissue triglyceride. Simple correlation was used to investigate relationships between the FA composition of (i) erythrocyte and muscle membrane; (ii) adipose tissue triglyceride and muscle membrane; (iii) adipose tissue triglyceride and erythrocyte membrane; and (iv) adipose tissue membrane and adipose tissue triglyceride. Two-factor multiple analysis of variance was used to examine whether there was an interaction between tissue type (muscle and erythrocyte) and type of infant feeding. A nonparametric test (Kruskal-Wallis) was used to investigate differences in adipose triglyceride FA composition between breast-fed and formula-fed children because of the small numbers and inequality of variance in the groups.

RESULTS

Characteristics of children. The mean age ± SE of the 61 children (45 males/16 females) in the study was 0.80 ± 0.06 yr, range 0.20–1.93 yr. The mean SD scores for both weight (0.39 ± 0.11) and length (0.43 ± 0.12) were significantly different from zero, indicating that the children were slightly heavier (P = 0.001) and longer (P = 0.001) than the reference population.

The duration of breast-feeding for the 61 children ranged from 0–21 mon (means ± SE, 4.8 ± 0.6 mon). In this study, breast-feeding duration was calculated as the actual duration of breast feeding, whether sole (no food given other than breast milk) or partial (some solid foods and/or complementary formula feeds offered concurrently with breast feeding). None of the infant formulas consumed by children in this study contained added LCPUFA. Further dietary analysis

showed that major food sources of LCPUFA (e.g., fish, egg yolk, lamb brains, and liver) were consumed in negligible amounts in the diets of children of this study.

The length of time since breast feeding ceased ranged from 0 mon (still being breast-fed at the time of surgery) to 19 mon (mean ± SE, 4.8 ± 0.7).

Comparison of the FA composition of muscle and erythrocytes. Table 1 shows the FA composition of muscle and erythrocyte membrane. The pattern of FA composition suggests that erythrocytes have a higher percentage of total saturates (but similar 14:0% and 18:0%) and a higher percentage of monounsaturates than muscle. However erythrocytes have a lower percentage of total n-6 PUFA, in particular a lower percentage of 18:2n-6 than muscle. The pattern of n-3 PUFA in erythrocytes reflects that of muscle and the percentages of 20–22 PUFA are not significantly different in these two tissues.

Relationships between the FA composition of erythrocytes and muscle. Simple correlations between FA and FA indices of structural lipid in erythrocytes and muscle are also shown in Table 1. There was a significant positive correlation between muscle and erythrocyte DHA (22:6n-3, $r = 0.44$, $P < 0.0001$), sum of the n-3 PUFA ($r = 0.39$, $P = 0.002$), and the n-6/n-3 PUFA ratio ($r = 0.39$, $P = 0.002$), but a significant inverse correlation between these two tissues for 22:4n-6.

TABLE 1
Fatty Acid Composition[a] of Muscle and Erythrocytes of 61 Young Children (means ± SE)

[a]Individual fatty acids (FA) are expressed as the percentage of total FA identified.
[b]Comparison of FA composition of muscle and erythrocytes: means of corresponding FA in muscle and erythrocytes not significantly different by multivariate analysis of variance.
[c–e]Significant correlations between corresponding FA in muscle and erythrocytes: [c]$P < 0.02$, [d]$P = 0.002$, [e]$P < 0.0001$.
[f]Calculated as the sum of the percentage of the polyunsaturated fatty acids (PUFA) 20:2n-6, 20:3n-9, 20:3n-6, 20:3n-3, 20:4n-6, 20:5n-3, 22:2n-6, 22:4n-6, 22:5n-6, 22:5n-3, and 22:6n-3. Minor FA (i.e., <0.5% of total FA) not shown in table.
[g]Calculated as the mean number of double bonds per FA residue multiplied by 100.

Relationship between the type of feeding and membrane FA composition in erythrocytes and muscle. We investigated the relationship between the type of infant feeding and membrane FA composition. Only infants less than 1 yr old were included, to allow age-matching. The formula-fed group ($n = 17$) consisted of children who were breast-fed for less than 4 wk (mean time since breast feeding ceased was 5.3 ± 0.5 mon), and the breast-fed group ($n = 19$) consisted of children who were still being breast fed at the time of surgery. There was no significant difference in age, weight SD score, or length SD score between the two groups.

Table 2 shows the results of mulitvariate analysis of variance on the FA composition of erythrocytes and muscle of infants fed either breast milk or formula milk as a primary energy source. In erythrocytes, the breast-fed infants had significantly greater proportions of DHA and n-3 PUFA, but lower proportions of 16:1 and the n-6/n-3 PUFA ratio, in comparison to the formula-fed infants. In muscle, breast-fed infants had greater proportions of 16:1, 20:4n-6, 22:5n-3, DHA, n-3 PUFA, 20–22 PUFA and the unsaturation index, but lower proportions of 18:2n-6 and 22:4n-6.

Two-factor multivariate analysis of variance was used to investigate whether there was an interaction between type of feeding and tissue type. There was a significant effect [$F = 2.45$, df (1,68), $P = 0.023$] when the major indicators of n-6 and n-3 PUFA (i.e., sum n-3 PUFA, sum n-6 PUFA, n-6/n-3 PUFA ratio, unsaturation index, 20–22 PUFA) were used as the dependent variables. Examination of the means indicated that the n-6/n-3 PUFA ratio was the most important variable and univariate ANOVA showed that it was significant at the 0.008 level [$F = 7.42$, df (1,68)]. Figure 1 shows graphically that, for the n-6/n-3 PUFA ratio, the effect of type of infant feeding is greater in muscle than in erythrocytes.

Comparison with adipose tissue triglyceride FA. We were only able to analyze adipose tissue triglyceride FA composition from 15 children (Table 3). In comparison with muscle and erythrocyte membrane FA composition, adipose tissue triglyceride had significantly greater proportions of monounsaturates (especially 18:1), but lower proportions of n-6 PUFA (especially 20:4n-6), 20–22 PUFA, the unsaturation index, and n-3 PUFA (particularly DHA). Multivariate analysis of variance showed that there was a significant difference between means of adipose triglyceride and both muscle and erythrocytes for all variables with the exception of the sum of the saturates, 20:5n-3 and the n-6/n-3 ratio for muscle membrane and adipose triglycerides. The only significant intercorrelations were for 18:0 (with muscle; $r = –0.58$, $P = 0.02$) and 18:2n-6 (with erythrocytes; $r = 0.56$, $P = 0.03$).

Comparison of adipose tissue triglyceride FA composition between currently breast-fed ($n = 6$) and formula-fed ($n = 4$) children using a nonparametric test (Kruskal-Wallis) showed significantly higher levels of DHA (0.64 ± 0.38% vs. 0.12 ± 0.03%, $P = 0.05$) and lower levels of n-6 PUFA (12.44 ± 0.34% vs. 16.08 ± 1.24%, $P = 0.023$) with breast feeding. There was a nonsignificant trend toward higher n-3 PUFA in

[b]Results of multivariate analysis of variance: significant differences between FA composition of breast-fed and formula-fed infants in muscle ([a]$P < 0.008$, [b]$P < 0.05$, [c]$P < 0.0001$) and erythrocytes ([d]$P < 0.03$). See Table 1 for abbreviations.

breast-fed children compared with those who were formula-fed (1.41 ± 0.44% vs. 1.07 ± 0.15%).

We also compared the FA composition of adipose tissue membrane phospholipid with that of adipose tissue triglyceride in these 15 children by multivariate analysis of variance (Table 3). There was a significant difference between all means except for 16:0, 14:1, 18:3n-3, and the n-6/n-3 PUFA ratio. Interestingly, the only significant intercorrelations between FA were with 16:0, 18:2n-6, 20:3n-6, and the n-6/n-3 PUFA ratio.

DISCUSSION

This study shows that there are significant differences in the FA composition of muscle and erythrocyte phospholipid and adipose tissue triglyceride and phospholipid of young children. In particular, erythrocyte phospholipid has lower levels of n-6 PUFA (especially 18:2n-6) than muscle and a correspondingly lower n-6/n-3 PUFA ratio. Adipose tissue triglyceride has lower levels of n-6 and n-3 PUFA but higher total monounsaturated FA (especially 18:1) than both erythrocytes and muscle. However, despite these differences in FA composition between tissues, there are significant positive correlations between erythrocyte and muscle n-3 PUFA, in particular DHA, and the n-6/n-3 PUFA ratio.

A significant environmental factor in our study that influenced availability of FA for incorporation into different tissues was the type of infant feeding. Our results are in keeping with the known differences in FA composition between infant formulas and breast milk (14,15). Infant formulas contain the precursor FA linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3), but lack important LCPUFA such as DHA (22:6n-3) (15). Likewise, infant-weaning foods supply a negligible amount of LCPUFA, especially DHA (16). However breast milk contains a range of LCPUFA (14). In the current study, as a reflection of diet, breast-fed infants had more DHA and a lower n-6/n-3 PUFA ratio than formula-fed infants in both muscle and erythrocytes; in adipose tissue triglyceride, breast-fed children had a higher level of DHA and lower level of n-6 PUFA than formula-fed children. In addition, the influence of type of feeding on the n-6/n-3 PUFA ratio was significantly greater in muscle than in erythrocyte membrane phospholipid. This latter result suggests that dietary availability of particular FA is not the only factor influencing incorporation of FA into muscle and erythrocyte membranes.

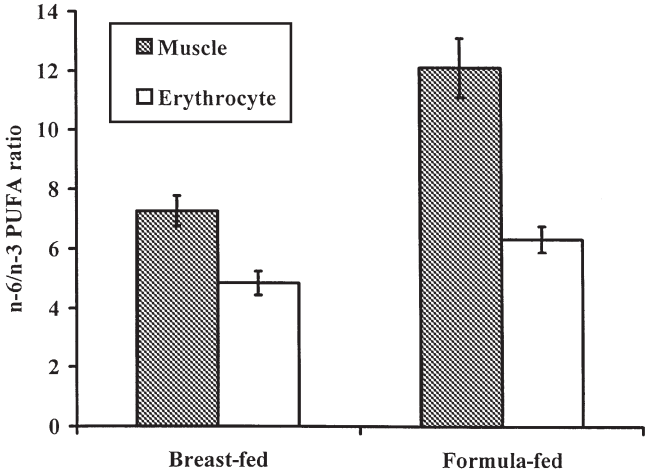

FIG. 1. The effect of type of feeding on the n-6/n-3 polyunsaturated fatty acid (PUFA) ratio in two different tissues: a significantly greater effect in muscle than in erythrocytes.

[a]Individual FA are expressed as the percentage of the total FA identified.
[b]Significant correlations ($P < 0.05$) between: [a]adipose phospholipid and adipose triglyceride, [b]muscle and adipose triglyceride, [c]erythrocytes and adipose triglyceride. See Table 1 for abbreviation.

A closer examination of the FA composition of muscle and erythrocyte membranes showed that there were no significant differences between the two feeding groups in levels of total saturates, monounsaturated FA, or n-6 PUFA. The major effects of feeding were on levels of n-3 PUFA (especially DHA) and the n-6/n-3 PUFA ratio and were more marked in muscle than in erythrocytes. In a subset of 15 infants from whom stored triglyceride was obtained, there was a much lower proportion of DHA stored in adipose tissue compared to both muscle and erythrocytes. Interestingly, an effect of type of feeding was again noticed in that there was a fivefold difference in adipose tissue DHA between breast-fed and formula-fed infants. Farquharson *et al.* (17) found that levels of DHA in adipose tissue of formula-fed infants were lower than those of breast-fed infants and decreased rapidly from birth. The current study suggests that DHA stored in the adipose tissue of breast-fed infants may provide a reasonable reserve of this FA that is so critical for nervous system development (18). If we calculate the DHA content of adipose tissue triglyceride for a child of mean age 0.8 yr in our study group, using available reference data (19) for total body fat in infants, then the breast-fed infants have 14 g of DHA while the formula-fed infants have 3 g. The lower reserves of adipose tissue DHA in formula-fed infants may represent a potential endogenous supply problem.

There are two possible explanations for the wide variation in DHA and n-3 LCPUFA in different tissue types. Firstly, in muscle and erythrocyte membranes and in adipose tissue stores, there may be a tight regulation of the relative levels of saturates, monounsaturates, and n-6 PUFA, whereas the proportion of n-3 LCPUFA appears to vary and may be highly influenced by availability in the diet. Alternatively, there may be such an avidity for n-3 LCPUFA in membranes that even with very low availability in the diet (e.g., formula feeding), the endogenous cellular mechanisms of desaturation and elongation are upregulated to increase the production of n-3 LCPUFA which are then retained assiduously. The low levels of DHA stored in adipose tissue reserves add more weight to the view that n-3 LCPUFA are avidly incorporated into muscle and erythrocyte membranes of formula-fed infants against very low availability in triglyceride stores or in the diet. This may be a function of alteration in facilitated transport of PUFA across membranes (20).

Studies have shown that lower proportions of the LCPUFA, especially n-3 PUFA, in muscle membrane phospholipid are associated with insulin resistance and obesity (3,4,21). Insulin resistance is a key etiological factor in the development of a cluster of prevalent diseases including non-insulin dependent diabetes mellitus, obesity, the dyslipidemias, hypertension, and coronary heart disease (5–7). Thus, the level of muscle membrane n-3 LCPUFA may be a key indicator of metabolic health. There is increasing interest in using circulating levels of n-3 PUFA and LCPUFA as potential markers of insulin resistance and risk of coronary heart disease (22,23). For example, in a population-based case-control study in the United States, Siscovick *et al.* (23) found that a red blood cell n-3 PUFA level of 5.0% of total FA was associated with a 70% reduction in the

risk of primary cardiac arrest compared with a red blood cell n-3 PUFA level of 3.3% (22). Such markers could be of use at both a clinical level and in population studies.

The results of the current study show that it is valid to use erythrocyte FA composition to give an index of the level of DHA, total n-3 PUFA, and the n-6/n-3 PUFA ratio in muscle, at least on a population basis. A test requiring 1.0–2.0 mL of blood is much less invasive and has fewer ethical problems than the procedure for biopsy of muscle tissue. The study also shows the potent effects of breast feeding on the n-3 LCPUFA composition of muscle and erythrocytes. These findings are important for those who are designing studies aimed at estimating risk for future development of diseases associated with metabolic syndrome and also for testing new therapeutic approaches to the prevention of these prevalent diseases. Further studies are required to extend these observations to older children and adults. However, current medical opinion emphasizes the need to determine level of risk of these costly lifestyle diseases at a young age in order to institute early intervention before significant morbidity occurs.

ACKNOWLEDGMENTS

Supported by The Children's Hospital Fund, Hoechst Diabetes Research and Development, the Diabetes Australia Research Trust, the National Health and Medical Research Council (Australia), and a Lilly Diabetes Fellowship (Dr. Baur). Dr. Pan is a Lilly Fellow of the Life Sciences Research Foundation. We are very grateful for the assistance of the anesthetists and surgeons of The Royal Alexandra Hospital for Children for supplying blood samples and muscle and adipose tissue biopsies. Their enthusiasm and cooperation have been greatly appreciated. We also wish to thank the theater staff and surgical nursing staff for their help in this study. Finally our thanks to Dr. Jenny Peat for her advice on statistical analysis for this study.

Effects of Different Medium-Chain Fatty Acids on Intestinal Absorption of Structured Triacylglycerols[1]

Huiling Mu* and Carl-Erik Høy

Department of Biochemistry & Nutrition, Center for Advanced Food Study, Technical University of Denmark, DK-2800 Lyngby, Denmark

ABSTRACT: To study the effect of the chain length of medium-chain fatty acids on the intestinal absorption of long-chain fatty acids, we examined the lymphatic transport of fat following administration of five purified structured triacylglycerols (STAG) containing different medium-chain fatty acids in the *sn*-1,3 positions and long-chain fatty acids in the *sn*-2 position in a rat model. Significant amounts of medium-chain fatty acids were found in lymph samples after intragastric administration of 1,3-dioctanoyl-2-linoleyl-*sn*-glycerol (8:0/18:2/8:0), 1,3-didecanoyl-2-linoleyl-*sn*-glycerol, and 1,3-didodecanoyl-2-linoleyl-*sn*-glycerol. The accumulated lymphatic transport of medium-chain fatty acids increased with increasing carbon chain length. The recoveries of caprylic acid (8:0), capric acid (10:0), and lauric acid (12:0) were 7.3 ± 0.9, 26.3 ± 2.4, and 81.7 ± 6.9%, respectively. No significant differences were observed for the maximal intestinal absorption of linoleic acid (18:2n-6) when the chain length of medium-chain fatty acids at the primary positions was varied, and the absorption of 18:2 and oleic acid (18:1) from 8:0/18:2/8:0 and 1,3-dioctanoyl-2-oleyl-*sn*-glycerol was similar. We conclude that the chain length of the medium-chain fatty acids in the primary positions of STAG does not affect the maximal intestinal absorption of long-chain fatty acids in the *sn*-2 position in the applied rat model, whereas the distribution of fatty acids between the lymphatics and the portal vein reflects the chain length of the fatty acids.

Paper no. L8321 in *Lipids 35,* 83–89 (January 2000).

In the intestine, normal long-chain triacylglycerols (LCT), such as those from vegetable oils, animal fats or fish oils, are hydrolyzed by several enzymes into monoacylglycerols and free fatty acids and incorporated into mixed micelles with bile acid and absorbed (1–3). Medium-chain triacylglycerols (MCT) have been suggested to undergo nearly complete hydrolysis to be absorbed predominantly as free fatty acids due to low activation to CoA esters and transported *via* the portal vein to the liver where they undergo preferentially oxidation by a carnitine-independent pathway (4,5). In the absence or deficiency of pancreatic lipase, previous studies have indicated that a large fraction of MCT can be absorbed as triacylglycerols, whereas LCT are not absorbed (4). Therefore, MCT have been used for certain groups of patients or infants based on their rapid digestion and fast energy supplement (4,6–8). However, an obvious problem with the use of MCT is the lack of the essential fatty acids (9,10), and a high dose of MCT also has caused certain toxic effects in the animal experiments (11). Therefore, alternative triacylglycerols have been used in absorption studies, such as physical blends of MCT and LCT, interesterified lipids with random triacylglycerol structure or specific triacylglycerol structure (12–18).

A physical blend of MCT and LCT does not improve the absorption of long-chain fatty acids since each of the individual triacylglycerols maintains its original absorption rate; the long-chain fatty acids in the primary positions of randomized triacylglycerols also have a slower rate of hydrolysis. However, structured triacylglycerols (STAG) containing long-chain fatty acids in the *sn*-2 position and medium-chain fatty acids in the primary positions have improved metabolic benefits in comparison with randomized triacylglycerols (12,13) and physical blends (13). Therefore, MLM (M, medium-chain fatty acid; L, long-chain fatty acid)-type STAG have potential advantages for providing polyunsaturated fatty acids.

Even though several studies have shown the metabolic benefits of STAG (12–14,19), still no systematic data are available comparing the intestinal absorption of different MLM-type STAG *in vivo*. In the present study, we studied the lymphatic transport of fatty acids from specific STAG containing different medium-chain fatty acids varying from caprylic acid (8:0) to lauric acid (12:0) in the *sn*-1,3 positions and long-chain fatty acids in the *sn*-2 position to investigate the effect of chain length of medium-chain fatty acids on the absorption of long-chain fatty acids and the distributions of medium-chain fatty acids between the portal vein and lymphatics in rats with normal fat absorption.

EXPERIMENTAL PROCEDURES

Preparation of the STAG. The STAG were produced by lipase-catalyzed interesterification of safflower oil (Róco, Copenhagen, Denmark) or high-oleic sunflower oil (Århus Olie A/S

(Århus, Denmark) and medium-chain fatty acids (caprylic, capric, and lauric acids from Sigma Chemical Co., St. Louis, MO) in a packed-bed reactor (20). The interesterification parameters and the yield of the STAG are listed in Table 1 (21). The interesterified products are mixtures of triacylglycerols, diacylglycerols, and free fatty acids; therefore, the required STAG were isolated from interesterified products with preparative high-performance liquid chromatography (HPLC). A Waters Delta Prep 3000 HPLC (Millipore Corporation, Milford, MA) was equipped with a Delta-Pak C18 column (47 × 300 mm, 15 μm particle size, and 100Å pore size; Waters Corporation, Milford, MA). Lambda-Max model 481 LC spectrophotometer (Waters Corporation) was used as the detector at 210 nm. The column was maintained at ambient temperature with a flow rate of 60 mL/min. A binary solvent system was applied; solvent A was acetonitrile and solvent B was isopropanol/hexane (2:1, vol/vol). All solvents were of HPLC grade (BDH Laboratory Supplies, Poole, England). The gradient of solvent was changed according to the composition of interesterified products. Two milliliters of the product solution at a concentration of 0.5 g/mL was injected, and the required STAG were collected.

The composition of the purified STAG was determined by gas–liquid chromatography (GLC) after methylation with 2 M KOH in methanol (Table 2). The fatty acid in the *sn*-2 position of the STAG was determined by Grignard degradation (22). In short, 30 mg of the STAG was dissolved in 10 mL diethylether. The reaction started after adding 0.3 mL allylmagnesium bromide (1 M in diethyl ether) and lasted for 1 min. It was then stopped by adding acid buffer (0.27 M HCl in 0.4 M boric acid). The organic phase was washed twice with 0.4 M boric acid and dried with anhydrous sodium sulfate and evaporated under nitrogen. The lipid residua were separated on a TLC plate that was precoated with boric acid, and the 2-monoacylglycerol fraction was scraped off and extracted with diethylether. After methylation with 2M KOH in methanol, the fatty acid methyl esters were analyzed by GLC.

Animal experiments. Male albino Wistar rats were obtained from Møllegård Breeding Center (Ll. Skensved, Denmark) and caged in groups of four. The light was regulated to a 12/12 h light-dark cycle, at 21°C, and 50% humidity. The animals were fed standard rat chow diet (Chr. Petersen A/S, Ringsted, Denmark) until surgery.

The animals weighed 250–300 g at the time of surgery and were anesthetized i.m. with 0.06 mL Zoletilmixture (The Royal Veterinary and Agricultural University, Frederiksburg, Denmark) per 100 g body weight. The mesenteric lymph duct was cannulated with a clear vinyl tubing (0.8 mm o.d., 0.5 mm i.d.; Critchley Electrical Products Pty. Ltd., NSW, Australia). A silicon tube (3.0 mm o.d., 1.0 mm i.d.; Polystan, Værløse, Denmark) was inserted into the stomach and secured in the stomach *via* a purse-string suture. Following surgery, the rats were placed in individual restraining cages in a room with 24-h light. They had free access to tap water and were kept hydrated by infusion of physiological saline (0.9% NaCl, 2 mL/h) through a gastrostomy feeding tube.

The lymph collection was initiated the next day 1 h prior to the administration of lipids to obtain a baseline level of intestinal absorption of fat. It was performed at room temperature. A fat emulsion containing 300 μL of STAG or safflower oil and 300 μL 20 mM sodium taurocholate (98%, Sigma Chemical Co.) and 10 mg/mL choline (99%, Sigma Chemical Co.) was prepared in an ice-water bath. A fat emulsion was administered through the feeding tube followed by 0.5 mL of physiological saline, and the infusion of saline was continued at a rate of 2 mL/min. The lymph was collected in 1-h fractions for the first 8 h, one fraction from 8–24 h postinjection. The collection tubes contained 100 μL of 10% EDTA (Titriplex III GR, Merck, Darmstadt, Germany) in 1-h fractions and 700 μL

[a]The fatty acids were analyzed and quantified by gas–liquid chromatography using internal standard. The fatty acids with lower concentration (<0.1%) are not listed in the table. TAG, triacylglycerol; see Table 1 for other abbreviation.

of EDTA (10%) in the final fraction. The lymph fractions were frozen at −20°C until further processing.

Experimental design. Six groups of rats (six rats in each group) were administered with five different STAG: 1,3-dioctanoyl-2-linoleyl-*sn*-glycerol (8:0/18:2/8:0); 1,3-didecanoyl-2-linoleyl-*sn*-glycerol (10:0/18:2/10:0); 1,2(2,3)-dilinoleyl-(1)3-decanoyl-*sn*-glycerol (10:0/18:2/18:2); 1,3-didodecanoyl-2-linoleyl-*sn*-glycerol (12:0/18:2/12:0); and 1,3-dioctanoyl-2-oleyl-*sn*-glycerol (8:0/18:1/8:0); and a control group was given safflower oil (75.5% 18:2n-6).

Analytical procedure. The total lipids from lymph samples were extracted with chloroform and methanol (12). The fatty acids in the purified STAG and the lipids from lymph samples were methylated to fatty acid methyl esters with 2 M KOH solution (in methanol). This procedure would not methylate free fatty acids. The fatty acid methyl esters were determined with an HP 6890 series gas–liquid chromatograph (Hewlett-Packard, Waldbronn, Germany) equipped with a fused-silica capillary column (SP-2380, 60 m × 0.25 mm i.d.; Supelco Inc., Bellefonte, PA). Oven temperature was programmed from 70 to 160°C at a rate of 15°C /min, followed by an increase to 180°C at a rate of 1°C/min, then to 185°C at a rate of 0.5°C/min, and finally to 200°C at a rate of 20°C/min and held for 10 min. A flame-ionization detector was used at 280°C, and the injector temperature was 250°C. The injector was used in split mode with a ratio 1:16. Carrier gas was helium with a column flow of 2 mL/min. The fatty acid methyl esters were identified by comparing their retention times with authentic standards (Sigma Chemical Co.), and the resulting compositions were calculated using the actual response factors for each fatty acid.

Calculation. The amount of fatty acids in lymph samples (FA_{lym}) was calculated using Equation 1,

$$FA_{lym} = \frac{FA_R \times FA_{RF}}{IS_R \times IS_{RF}} \times \frac{IS_W \times F_{lym}}{FA_{MW} \times W_{lym}} \quad [1]$$

where FA_R, FA_{RF}, and FA_{MW} are the GLC response, response factor, and molecular weight of the fatty acid, respectively; IS_R, IS_{RF}, and IS_W are the GLC response, response factor, and the amount of the internal standard, respectively; and F_{lym} and W_{lym} are the lymph flow and the amount of lymph used in the extraction, respectively.

The amount of intestinal absorbed fatty acids (FA_{abs}) was expressed as mole percentage. It was calculated from the amount of fatty acids found in lymph by reference to the amount of the FA in the intragastric administrated STAG (FA_{adm}):

$$FA_{abs} = \frac{FA_{lym}}{FA_{adm}} \times 100 \quad [2]$$

Statistical methods. The statistical program InStat (GraphPad Software Inc., San Diego, CA) was used in the calculation. A two-way repeated analysis of variance (ANOVA) was applied in the analysis of differences among groups for each hour of lymph collection and among different lymph fractions within each group. Paired *t* tests were used to evaluate the statistical significance.

RESULTS

Lymph flow. There were significant differences in lymph flow as a function of time for all 36 rats (Fig.1). The baseline lymph flow rate was 1.6 ± 0.1 g/h (all rats pooled). Two hours after the administration of STAG or safflower oil, it increased to 2.7 ± 0.1 g/h, and after 24 h, it was close to the baseline again (1.7 ± 0.1 g/h). There were no significant differences between different groups for each fraction, except that the baseline fraction of the 10:0/18:2/10:0 was significantly lower than other groups because of clotting of the lymph.

Lymphatic transport of medium-chain fatty acids. A portion of the medium-chain fatty acids was transported through the mesenteric lymph duct, and in studying lipid fractions of

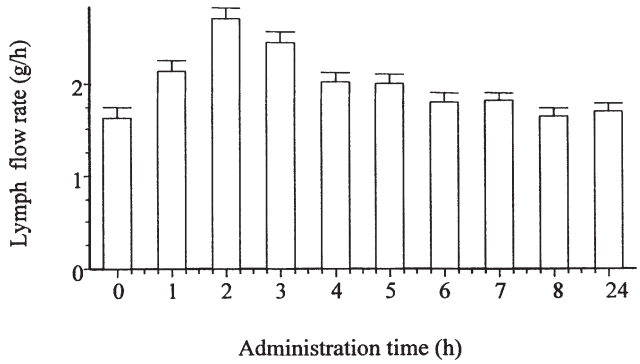

FIG. 1. The lymph flow of different fractions of all 36 animals (6 rats in each group and 6 groups), expressed as mean and standard error.

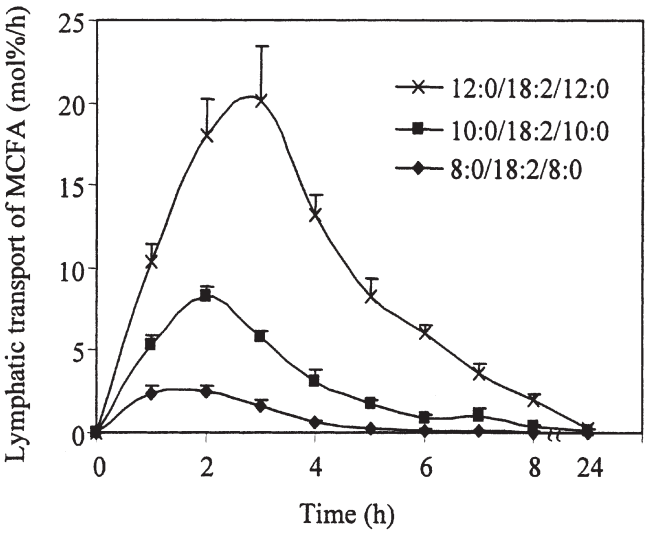

FIG. 2. The lymphatic transport of medium-chain fatty acids (MCFA) after intragastric administration of structured triacylglycerol (STAG) 1,3-dioctanoyl-2-linoleyl-*sn*-glycerol (8:0/18:2/8:0), 1,3-didecanoyl-2-linoleyl-*sn*-glycerol (10:0/18:2/10:0), and 1,3-dodecanoyl-2-linoleyl-*sn*-glycerol (12:0/18:2/12:0), expressed as molar percentage of the administered MCFA (mean ± SEM of 6 rats).

two samples, capric acid was detected only in the triacylglycerol fraction. A maximal lymphatic transport of medium-chain fatty acids was obtained after 2 or 3 h (Fig. 2), and there was a significant difference ($P = 0.0005$) between the maximal transport levels of the medium-chain fatty acids. From Figure 2, we also observe that the time needed to reach the maximal absorption of medium-chain fatty acids increased with increasing chain length, i.e., 8:0 reached maximal absorption sooner than 10:0, and 10:0 reached the maximal absorption sooner than 12:0.

The accumulated lymphatic transport level of medium-chain fatty acids increased significantly with increasing carbon chain length (Fig. 3). For lauric acid, 81.7 ± 6.9% was recovered in the lymph after administration of 12:0/18:2/12:0, whereas only 7.3 ± 0.9% of caprylic acid was recovered after administration of 8:0/18:2/8:0.

Lymphatic transport of linoleic acid. Maximal lymphatic transport of linoleic acid (25.6 ± 1.5%) was observed 2 or 3 h after administration of the lipids (Fig. 4). There was no significant difference for the maximal lymphatic transport of linoleic acid between the STAG and the safflower oil or between the individual STAG, even though they contained different medium-chain fatty acids.

Apparent higher accumulated lymphatic transport of linoleic acid was observed for 10:0/18:2/10:0, 10:0/18:2/18:2, and 12:0/18:2/12:0 in comparison with safflower oil, whereas lower value was observed for the 8:0/18:2/8:0 (Fig. 5). However, the differences between the accumulated lymphatic transport of linoleic acid were not significant, except the 10:0/18:2/10:0 had a significant higher value than safflower oil ($P = 0.034$).

Comparison of lymphatic transport of different long-chain fatty acids. The lymphatic transport of oleic acid and linoleic acid was compared by intragastric administration of STAG 8:0/18:1/8:0 and 8:0/18:2/8:0. Maximal transport of long-chain fatty acids was observed after 2 h of administration of lipids for both STAG; they were 20.5 ± 1.5 and 18.2 ± 3.1% for linoleic acid and oleic acid, respectively. The difference between the maximal transport level was not significant ($P = 0.49$).

The accumulated lymphatic transport of linoleic acid and oleic acid was 97.3 ± 5.0% and 91.0 ± 8.3%, respectively. There was no significant ($P = 0.46$) difference between the accumulated lymphatic transport of oleic acid and linoleic acid either.

The recovery of caprylic acid was 5.7 ± 0.6% in the lymph after intragastric administration of the 8:0/18:1/8:0. In the comparison of intestinal absorption of caprylic acid from 8:0/18:1/8:0 and 8:0/18:2/8:0, no significant difference was found between the maximal intestinal absorption of caprylic acid ($P = 0.56$), or between the accumulated lymphatic transport ($P = 0.22$).

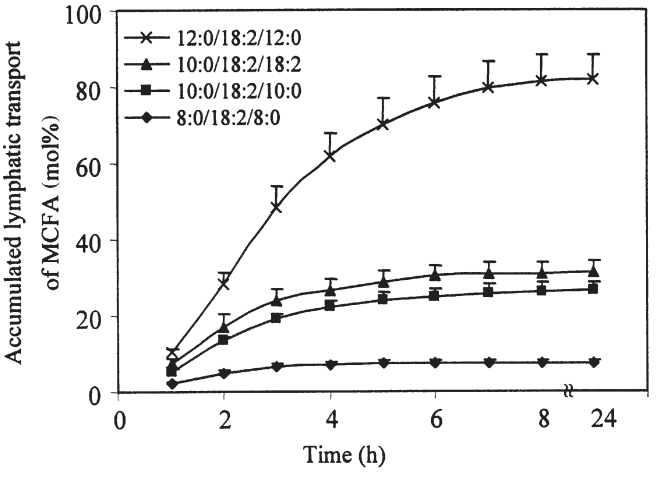

FIG. 3. Accumulated lymphatic transport of MCFA after intragastric administration of STAG 8:0/18:2/8:0, 10:0/18:2/10:0, 1,2(2,3)-dilinoleyl-(1)3-decanoyl-*sn*-glycerol (10:0/18:2/18:2), and 12:0/18:2/12:0, expressed as molar percentage of the administered MCFA (mean ± SEM of 6 rats). See Figure 2 for abbreviations.

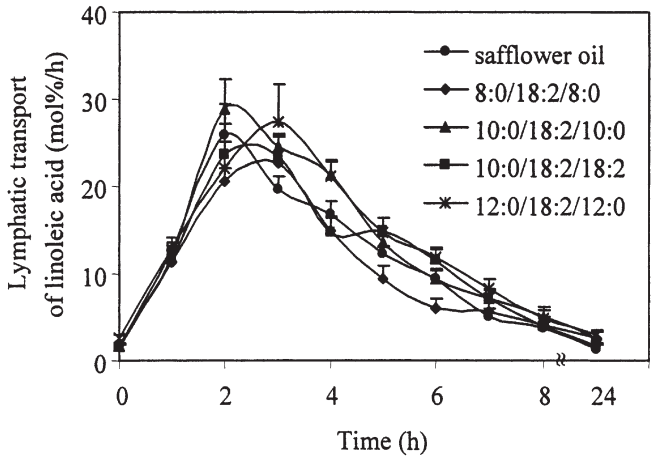

FIG. 4. The lymphatic transport of linoleic acid after intragastric administration of STAG 8:0/18:2/8:0, 10:0/18:2/10:0, 10:0/18:2/18:2, 12:0/18:2/12:0, and safflower oil, expressed as molar percentage of the administered linoleic acid (mean ± SEM of 6 rats). See Figures 2 and 3 for abbreviations.

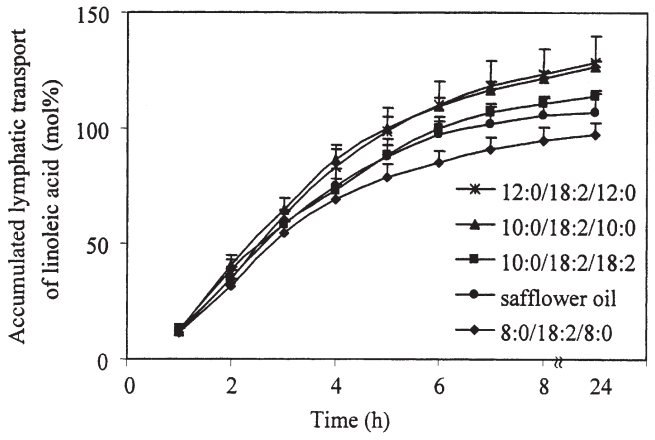

FIG. 5. Accumulated lymphatic transport of linoleic acid after intragastric administration of STAG 8:0/18:2/8:0, 10:0/18:2/10:0, 10:0/18:2/18:2, 12:0/18:2/12:0, and safflower oil, expressed as molar percentage of the administered linoleic acid (mean ± SEM of 6 rats).

DISCUSSION

Pancreatic lipase catalyzes the intestinal hydrolysis of the emulsified triacylglycerols in the presence of colipase, resulting in *sn*-2-monoacylglycerols and free fatty acids (released from the primary positions), which form the mixed micelles and diffuse through both the stagnant water layer and the brush border membrane into the enterocytes (23). The fatty acids located in the *sn*-2 positions in the dietary fat are thus conserved during absorption (24). Long-chain fatty acids are activated to their CoA derivatives through the action of fatty acyl-CoA ligase in the endoplasmic reticulum and resynthesized to triacylglycerols together with monoacylglycerol by acyltransferase, whereas medium-chain fatty acids are predominantly transported through the portal vein, since the ligase has low activity toward medium-chain fatty acids (25). The fatty acyl synthetase responsible for triacylglycerol reesterification is most effective with fatty acids of 14 or more carbons (5). In previous studies of absorption of STAG, medium-chain fatty acids have been found in lymph samples, and the medium-chain fatty acids esterified in the *sn*-2 position of a triacylglycerol are transported to a larger extent by the lymphatics than these medium-chain fatty acids esterified in the primary positions (12,14,24). However, the variation of the extent of the intestinal absorption of medium-chain fatty acids with chain length has not been systematically investigated yet. Therefore, we compared the intestinal absorption of different medium-chain fatty acids in the MLM-type STAG. We estimated the intestinal absorption of five STAG containing one long-chain fatty acid in the *sn*-2 position and one medium-chain fatty acid and one long-chain fatty acid or two medium-chain fatty acids in the primary positions.

LCT (18:2/18:2/18:2) has been used as the reference compound in previous studies, and Ikeda *et al.* (14) found higher lymphatic transport of linoleic acid from 10:0/18:2/10:0 than from 18:2/18:2/18:2. In the present study, safflower oil, which has been used in the production of the STAG, was selected as the reference oil.

Similar to the results of Tso *et al.* (16), we found that the intestinal lymph flow responded to a lipid meal. The lymph flow increased significantly as a result of intragastric administration of lipids in all groups, and maximal intestinal absorption was reached 2 or 3 h after administration. Although the lymph flow varied between different animals, there was no significant difference between different groups for each fraction (except the baseline fraction of 10:0/18:2/10:0). Therefore, the lymphatic transport of different STAG and the oil can be compared.

We found high recovery of medium-chain fatty acids in the rats' lymphatic ducts after intragastric administration of fat emulsions containing STAG, and the maximal intestinal absorption level increased significantly with increasing carbon chain length (Fig. 2). Most of the caprylic acid in 8:0/18:2/8:0 and 8:0/18:1/8:0 was probably transported through the portal vein after hydrolysis by pancreatic lipase, since only 6–7% of caprylic acid was transported *via* lymphatics. In lymph 26 and 31% of capric acid were recovered after administration of 10:0/18:2/10:0 and 10:0/18:2/18:2, respectively, whereas up to 82% of lauric acid was transported through lymphatics after administration of 12:0/18:2/12:0, and only a minor part of lauric acid was therefore transported through the portal vein. The large variation between the accumulated lymphatic transport of medium-chain fatty acids in different STAG suggests that the absorption pathway of medium-chain fatty acids differs significantly. The distribution of fatty acids between the lymphatics and the portal vein reflected the chain length of the fatty acids. Similar results for free fatty acids have been reported by McDonald *et al.* (26,27) and Bloom *et al.* (28), who studied the route of transport of free fatty acids from the rat intestine and found that the lymphatic recovery of infused fatty acids increased with the increase of carbon chain length for saturated fatty acids. Comparing our results with the results reported by the others, we find a similar tendency for the effects of carbon chain length on the intestinal absorption of triacylglycerols and free fatty acids, the absorption level increases with the increase of chain length of fatty acids (in both free acid form or as an acyl group in the STAG).

Comparing the level of lymphatic transport of lauric acid in our study with the studies reported by the others, it is rather clear that more medium-chain fatty acids can be transported *via* lymphatics from MLM-type STAG than from free fatty acid. McDonald *et al.* (26) reported that 72% of lauric acid bypassed the lymphatic pathway when it was infused intraduodenally in the form of free fatty acids; Bloom *et al.* (28) also found that only 15–55% of absorbed lauric acid was transported in the chyle when it was fed in the form of free fatty acid, whereas we found up to 82% of lauric acid in lymph. Since the level of lauric acid is very low in adipose tissue, we may exclude that the high recovery of lauric acid reflects mobilization of endogenous fatty acids. Comparing the concentration of medium-chain fatty acids in the *sn*-2 position of the STAG (Table 2) with the recovery of medium-chain fatty acids in the lymph (Fig. 3), the concentration of positional isomers of the STAG was much lower than the lymphatic transport of medium-chain fatty acids. Therefore, the large part of the medium-chain fatty acids was not transported through lymphatics in the form of monoacylglycerols after hydrolysis and resynthesized to triacylglycerols in the intestinal mucosa, although it cannot be excluded that some isomerization may have occurred during hydrolysis and absorption. Since the recovery of medium-chain fatty acids in the lymphatics was much higher in the form of MLM-type STAG than in the form of free fatty acids (26,28), it is most likely that the enterocytes have the ability to activate and reacylate medium-chain fatty acids into triacylglycerols, especially for lauric acid. However, the metabolic pathways of medium-chain fatty acids in the enterocytes are not clear at present.

In a study of *in vitro* lipase digestion, Jandacek *et al.* (19) reported that the triacylglycerols with medium-chain fatty acids in the 1- and 3-positions and a long-chain fatty acid in the 2-position could be hydrolyzed faster than the triacylglyc-

erols constituting all long-chain fatty acids. In our present study, we found an apparent delay for lauric acid to reach maximal absorption compared to capric acid and caprylic acid, which may indicate the differences of the hydrolysis rate between medium-chain fatty acids in the MLM-type STAG. The delay was correlated with the chain length, so the hydrolysis rate of medium-chain fatty acids might decrease with the increase of chain length. However, these data show a poor correlation with the maximal lymphatic transport of linoleic acid, i.e., there were no significant differences in the absorption of linoleic acid (located in the *sn*-2 position) between different STAG. This may reflect that the hydrolysis of medium-chain fatty acids was not the rate-limiting step for the absorption of linoleic acid, but rather the diffusion and the following activation of fatty acids before triacylglycerol synthesis. If the diffusion rate of the monoacylglycerol-containing linoleic acid is slower than the hydrolysis rate of medium-chain fatty acids in the STAG, the absorption of linoleic acid from different MLM-type STAG will be similar.

There was no significant difference between the recovery of capric acid in lymph from 10:0/18:2/10:0 and 10:0/18:2/18:2, although the absorbed capric acid (mmol) from 10:0/18:2/10:0 was two times of that from 10:0/18:2/18:2. Therefore, the different hydrolysis rate of medium-chain fatty acids and long-chain fatty acids does not affect the intestinal absorption of medium-chain fatty acids in MLM- or MLL-type STAG in rats with normal level of pancreatic enzymes.

Ikeda *et al.* (14) have declared that MLM-type STAG can be used both as a fast energy source and as a source of essential fatty acids. Our results have certain practical implications for the design of the MLM-type STAG. Since the chain length of medium-chain fatty acids does not affect the maximal intestinal absorption of the long-chain fatty acids at the *sn*-2 position, the selection of medium-chain fatty acids in MLM-type STAG can be based on the clinical and nutritional requirements. When STAG is used as fast energy source, the MLM-type STAG containing lauric acid can provide more energy than caprylic acid. If lauric acid is incorporated into chylomicrons, it can be used for oxidation in the muscle or it may be deposited in the adipose tissue. On the other hand, caprylic acid and capric acid will be directed preferentially toward the hepatic tissue for immediate oxidation and therefore have a protein-sparing effect. However, the effect of saturated fatty acids on cholesterol-raising properties in low density lipoproteins (LDL) and cardiovascular risk has been subject to much debate. Lauric acid has been reported as a hypercholesterolemic saturated fatty acid (29–31). Diverse results have been reported for the effects of caprylic and capric acid (30,32–34). In the latest review on dietary saturated fats and their effect on LDL concentrations and metabolism, Nicolosi (34) stated that caprylic and capric acid are neutral with respect to their LDL-cholesterol-raising properties and their ability to modulate LDL metabolism. Therefore, caprylic acid and capric acid may be the preferred choice in the production of MLM-type STAG.

We also studied the effect of medium-chain fatty acids on the lymphatic transport of different long-chain fatty acids by intragastric administration of 8:0/18:1/8:0 and 8:0/18:2/8:0. Similar intestinal absorption of oleic acid and linoleic acid was observed, indicating no significant difference between the intestinal absorption of long-chain fatty acids in MLM-type STAG. This result suggests that we may use similar type STAG to provide different long-chain fatty acids according to the clinical demand.

Our present study shows that the chain length of medium-chain fatty acids located in the primary positions does not affect the lymphatic transport of long-chain fatty acids in the *sn*-2 position. Similar intestinal absorption of different long-chain fatty acids can be expected in the MLM-type STAG. It is therefore possible by manufacturing STAG with different medium-chain fatty acids to direct the fatty acids from the *sn*-1,3 positions toward the liver through the portal vein or toward the muscle or adipose tissues through formation of chylomicrons without affecting the transport of the long-chain fatty acid in the *sn*-2 position.

ACKNOWLEDGMENTS

We thank Tina Dahl and Karen Jensen for their technical assistance, Xuebing Xu for producing some of the structured triacylglycerols, Ellen Marie Straarup and Trine Porsgaard for their help and valuable discussions on the animal experiments. ABSTRACT: Male weanling Wistar rats (n = 15), weighing 200–220 g, were allocated for 6 wk to diets containing 1% (by weight) of conjugated linoleic acid (CLA), either as the 9*c*,11*t*-isomer, the 10*t*,12*c*-isomer, or as a mixture containing 45% of each of these isomers. The five rats of the control group received 1% of oleic acid instead. Selected enzyme activities were determined in different tissues after cellular subfractionation. None of the CLA-diet induced a hepatic peroxisome-proliferation response, as evidenced by a lack of change in the activity of some characteristic enzymes [i.e., acyl-CoA oxidase, CYP4A1, but also carnitine palmitoyltransferase-I (CPT-I)] or enzyme affected by peroxisome-proliferators (glutathione *S*-transferase). In addition to the liver, the activity of the rate-limiting β-oxidation enzyme in mitochondria, CPT-I, did not change either in skeletal muscle or in heart. Conversely, its activity increased more than 30% in the control value in epididymal adipose tissue of the animals fed the CLA-diets containing the 10*t*,12*c*-isomer. Conversely, the activity of phosphatidate phosphohydrolase, a rate-limiting enzyme in glycerolipid neosynthesis, remained unchanged in adipose tissue. Kinetic studies conducted on hepatic CPT-I and peroxisomal acyl-CoA oxidase with CoA derivatives predicted a different channeling of CLA isomers through the mitochondrial or the peroxisomal oxidation pathways. In conclusion, the 10*t*,12*c*-CLA isomer seems to be more efficiently utilized by the cells than its 9*c*,11*t* homolog, though the Wistar rat species appeared to be poorly responsive to CLA diets for the effects measured.

Paper no. L8294 in *Lipids 35*, 91–98 (January 2000).

The collective term conjugated linoleic acids (CLA), describing positional and geometrical isomers of linoleic acid, has been receiving more attention in the last decade because of CLA pleiotropic biological activities. For instance, these fatty acids are effective anticarcinogens, antiatherosclerotic agents, fat reducers, and potent modulators of the immune function (see reviews 1–7). However, little is known about their mechanisms of action. Regarding the effects associated with fat utilization, CLA can, some authors found, induce a peroxisome-proliferation response in mice (8), although the issue seems to be less clear in the rat (9). Also, associated with their fat reduction properties, CLA increase the *in vitro* 3T3 adipose cells lipolysis and decrease the heparin-releasable lipoprotein lipase activity in mice (10,11). In addition, they potentially enhance the channeling of the fatty acids into the mitochondrial β-oxidation pathway in mice through an increase of the carnitine palmitoyltransferase (CPT) activity, both in the adipose tissue of the fed animal and in the skeletal muscle of the fasted mice (10). These effects may have collectively contributed to the observed reduction in the fat body mass of animals consuming CLA (10,12,13). However, most of these experimental results were obtained by using different brands of CLA mixtures obtained after alkali-isomerization of linoleic acid, which may greatly differ in their CLA isomer distribution and complexity (14–16). Therefore, it is generally not possible to date to determine whether one isomer is more potent than the others for any of the biological activities depicted. Nonetheless, one study demonstrated a significant effect of the 10*t*,12*c*-isomer on some biochemical mechanisms associated with fat reduction in mice (11).

Another important issue is how the different CLA isomers may be metabolized once absorbed, and especially how they are channeled toward the esterification or the oxidation pathways. This is of great importance since these pathways determine the availability of CLA to elicit their biological effects. In that instance, the determination of the kinetic parameters of CPT-I with selected acyl-CoA derivatives *in vitro* (17) generally gives a good prediction of their oxidative breakdown *in vivo* (18).

This study reports the relative impact of diets supplemented with different CLA isomers toward selected enzymes involved in lipid metabolism. In addition, the apparent kinetic parameters of two rate-limiting enzymes of fatty acid oxidation, i.e., CPT-I and acyl-CoA oxidase (ACO), were determined using CLA as their CoA derivatives.

EXPERIMENTAL PROCEDURES

Chemicals. The solvents were provided by SDS (Peypin, France) and were distilled before use (except diethylether). [1-^{14}C]Lauric acid (52 μCi/mmol) was purchased from Amersham (Amersham, Les Ulis, France). All the other chemicals

E-mail: jean-charles.martin@ibaic.u-psud.fr.

Abbreviations: ACO, acyl-CoA oxidase; CLA, conjugated linoleic acid; CPT, carnitine palmitoyl transferase; CYP, cytochrome P450; OD, optical density; PAP, phosphatidate phosphohydrolase.

were provided by Sigma-Aldrich (Sigma-Aldrich Co., L'Isle d'Abeau-Chêne, France).

Animals and diet. Male Wistar rats, weighing 200–220 g, were provided by the Centre d'élevage DEPRE (Saint Doulchard, France). They were housed individually and at a constant humidity and temperature with a 12-h light/dark cycle throughout the experiment. They had free access to water and received the same amount of the semisynthetic diet daily and were starved 12 h before killing. Rats used for the determination of the enzyme kinetic constants were fed with a commercial chow diet.

The CLA-diet composition is featured in Table 1. Rats were divided into four groups of five animals each and were fed for 6 wk with a 6% fat diet (by weight), containing 5% of fat as a mixture of high-oleic sunflower oil and linseed oil (98:2, w/w) and 1% of either 9*c*,11*t*-octadecadienoate (87% pure), 10*t*,12*c*-octadecadienoate (92% pure), or a mixture of both isomers (CLA 90) (43% of 9*c*,11*t*-isomer, 44.5% of 10*t*,12*c*-isomer), all of them being in the form of free acids. The control group received the same oil-mixture-based diet, except the CLA were replaced by oleic acid (89.4% pure).

The CLA 90 mixture was kindly provided by Natural Lipids (Hovdebygda, Norway). Its CLA isomer composition was determined by gas chromatography/mass spectrometry after conversion into dimethyloxazoline derivatives (19) as well as 4-methyl-1,2,4-triazoline-3,5-dione derivatives (20). Oleic acid was purchased from Sigma (Sigma-Aldrich Co.). The 9*c*,11*t*-octadecadienoic acid isomer was synthesized from castor oil (21), and the 10*t*,12*c*-octadecadienoic acid isomer was obtained by low-temperature crystallization from a mixture of CLA isomers obtained by alkali isomerization of linoleic acid (22). These fatty acids were then incorporated into the experimental diets.

TABLE 1
Composition of the Experimental Diets (in g per kg)

Casein	180
Sucrose	220
Corn starch	420
Cellulose	20
Mineral mixture[a]	50
Vitamin mixture[b]	10
Oil[c]	5
Free fatty acids[d]	1

[a]Contained $CaCO_3$ (12 g), K_2HPO_4 (10.75 g), $CaHPO_4$ (10.75 g), MgSO4·7H_2O (5 g), NaCl (3 g), MgO (2 g), $FeSO_4·7H_2O$ (400 mg), $ZnSO_4·7H_2O$ (350 mg), $MnSO_4·H_2O$ (100 mg), $CuSO_4·5H_2O$ (50 mg), $Na_2SiO_7·3H_2O$ (25 mg), $AlK(SO_4)_2·12H_2O$ (10 mg), K_2CrO_4 (7.5 mg), NaF (5 mg), $NiSO_4·6H_2O$ (5 mg), H_3BO_3 (5 mg), $CoSO_4·7H_2O$ (2.5 mg), KIO_3 (2 mg), $(NH_4)_6Mo_7O_{24}·4H_2O$ (1 mg), LiCl (0.75 mg), Na_2SeO_3 (0.75 mg), NH_4VO_3 (0.5 mg).

[b]Contained retinol acetate (5000 IU), cholecalciferol (1250 IU), DL-α tocopherol acetate (100 IU), phylloquinone (1 mg), thiamine chlorhydrate (10 mg), riboflavin (10 mg), nicotinic acid (50 mg), Ca-pantothenate (25 mg), pyridoxin chlorhydrate (10 mg), D-biotin (0.2 mg), folic acid (2 mg), cyanocobalamin (25 μg), choline chlorhydrate (1 g), DL-methionine (2 g), *p*-aminobenzoic acid (50 mg), inositol (100 mg).

[c]Contained 98% high-oleic sunflower oil and 2% linseed oil.

[d]Contained either 1% of oleic acid (89.4% pure), 9*c*,11*t*-octadecadienoate (87% pure), 10*t*,12*c*-octadecadienoate (92% pure), or a mixture of both isomers (CLA 90) (43% of 9*c*,11*t*-isomer, 44.5% of 10*t*,12*c*-isomer).

Tissue fractionation. After the end of the experimental diets, the starved animals were anesthetized with diethylether between 9 and 10.00 A.M. They were killed by exsanguination, and their blood was withdrawn at the abdominal artery. The organs, the epididymal adipose tissue, and the gastrocnemian muscle were removed, weighed and rinsed with cold saline prior to further analyses. Half of the liver, 0.9–1.2 g of the gastrocnemian muscle, 2.2–5.0 g of the epididymal adipose tissue, and 0.18–0.20 g of the heart (apex) were subsequently used for the cellular subfractionation which was carried out at 0°C. The tissues were first homogenized in a Tris buffer (10 mM, pH 7.4, 1 mM EDTA) containing 25 mM sucrose (muscle and adipose tissues) or 75 mM sucrose and 0.225 mM mannitol (heart), or a 0.25 M sucrose and 50 mM phosphate buffer (liver tissues). The homogenized tissues were then centrifuged at $1,000 \times g$ for 10 min to remove the cell debris. The gauze-filtered supernatants were subsequently spun at $12,000 \times g$ for 15 min. The peroxisome/mitochondrial pellet was then recovered and diluted with 3–5 mL of a 2 mM HEPES buffer for the heart, muscle, and adipose tissue fractions (pH 7.4, 70 mM sucrose, 220 mM mannitol, 1 mM EDTA), or 3–5 mL of a 50 mM phosphate buffer (pH 7.4, 250 mM sucrose) for the liver. The supernatants obtained from the $12,000 \times g$ centrifugation were further ultracentrifuged (two times 1 h at $105,000 \times g$) to yield the microsomal pellet and the cytosolic fraction. All the liver fractions were then stored at −80°C prior to analysis.

Enzymatic activities. The peroxisomal acyl-CoA oxidase and mitochondrial CPT activities were both assessed in the peroxisomal/mitochondrion fractions. The ACO activity, determined according to Lazarow (23), was assessed only in the liver. The peroxisomal fraction (≤0.3 mg protein) was mixed to the incubation medium (pH 8.3) containing CoA (0.075 mM), NAD (0.555 mM), nicotinamide (0.141 mM), dithiothreitol (4.4 mM), KCN (3 mM), and BSA (0.225 mg/mL) in Tris (60 mM), along with 20–100 μL of Triton X-100 (1% in Tris 60 mM), 20 μL of FAD (18 mM in Tris 60 mM) (final volume 3 mL). After incubation for 4 min at 37°C, 20 μL of palmitoyl-CoA (7.5 mM in Tris 60 mM) was added, and the reaction was monitored at 340 nm against the same medium without palmitoyl-CoA (ε for NADH = 6.22 mM^{-1} cm^{-1}) (Uvikon spectrophotometer, Basel, Switzerland).The activity of the liver peroxisomal acyl-CoA oxidase toward the different CLA preparation was determined by replacing palmitoyl-CoA with the respective conjugated linoleoyl-CoA (CLA-CoA) at different concentrations (5, 10, 20, 50 μM), as well as linoleoyl-CoA as a second reference. These acyl-CoA were chemically prepared by condensing the free fatty acids to the free CoASH, as described by Kawaguchi *et al*. (24).

CPT activity was determined in the liver, adipose tissue, heart, and gastrocnemian muscle according to the method of Bieber *et al*. (25). The incubation medium (pH 8.0, room temperature) contained (in mM), Tris (116), Na_2EDTA (1.1), palmitoyl-CoA, (0.035), 5-thio-2-nitrobenzoate (0.12), L(−)-carnitine (1.1) (experimental) or D(−)-carnitine (11) (blank). The reaction was initiated by adding 10–50 μL of the mitochondrion fraction (2 mg) and the change in optical density (OD) was monitored at

412 nm for 2–4 min (ε for 5-thio-2-nitrobenzoate = 13.6 $mM^{-1}cm^{-1}$). The kinetic parameters for the liver CPT-I were examined similarly, but using different kinds of acyl-CoA (16:0-, 18:2-, octadeca-9*c*11*t*-dienoyl-, octadeca-10*t*,12*c*-dienoyl-, and a mixture of CLA-CoA isomers) at several concentrations each (5, 10, 20, 40 μM).

The n- and (n-1)-laurate hydroxylation were determined as a marker of the cytochrome P4504A1 and cytochrome P4502E1 activities, respectively (26,27). Measurements were determined in the microsomal fraction according to Orton and Parker (28) and modified by Laignelet *et al.* (29). The microsomal protein concentration was adjusted at 1 mg/mL with a Tris buffer (pH 7.4, 66 mM, final volume 500 μL/assay). This medium was then incubated for 3 min at 37°C, with 1.5 mL in the same buffer containing [1-^{14}C]lauric acid (52 mCi/mmol, 1.1 μCi per assay). The reaction was initiated by adding 100 μL of NADPH (34 mM in Tris 66 mM, pH 7.4) and stopped with 0.1 mL HCl (1 N) after 15 min at 37°C. The reaction products were extracted with diethylether, separated by reversed-phase high-performance liquid chromatography, and quantified with a radiochromatographic detector Flo-one β (series A-100; Radiomatic Instruments, Tampa, FL) by peak integration high-performance liquid chromatography conditions: ODS column 25 cm length × 4.6 mm i.d., scintillation solution of Floscint II, 2:1, vol/vol). The mobile phase was made up of ammonium acetate (A, 27%), acetonitrile (B, 32%), and H_2O (C, 41%) and the samples were eluted with this mixture for 4 min. The mobile phase was then switched in 2 min to A (10%) and B (90%) and held for a further 4.5 min.

The phosphatidate phosphohydrolase (PAP) total activity (i.e., Mg^{2+}-dependent and Mg^{2+}-independent) was assessed in the microsomal fraction of the epididymal adipose tissue, essentially as described by Walton and Possmayer (30) and modified by Surette *et al.* (31). The reaction mixture contained 0.05 M Tris (pH 7.0), 1 mM phosphatidic acid, and 1 mM phosphatidylcholine prepared by sonication in 0.9% NaCl (at maximal frequency with a microprobe for 10 min with a model VC-500 sonicator; Sonics & Materials, Danbury, CT), Na_2-EDTA (1.25 mM), 50 to 100 μg microsomal or cytosolic protein, and 3.25 mM $MgCl_2$ (final volume of 0.2 mL). The mixtures were incubated at 37°C for 15 min, and the reaction was terminated by adding 0.8 mL of a solution containing 0.13% sodium dodecyl sulfate, 1.25% ascorbic acid, 0.32% $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$ and 0.375 M H_2SO_4. The phosphomolybdate color was developed at 45°C for 20 min, and the OD was determined at 820 nm (Uvikon spectrophotometer).

The glutathione *S*-transferase activity was determined in the cytosolic fraction of the hepatocytes according to Habig *et al.* (32). Glutathione (1 mM) was incubated at 30°C in a phosphate buffer (pH 6.5) with cytosolic protein (0.01 to 0.02 mg/mL), and the OD was followed at 340 nm for 3 min in presence of 1 mM of 1-chloro-2,4-dinitrobenzene (ε for the 1-chloro-2,4-dinitrobenzene/glutathione complex = 10 $mM^{-1}{\cdot}cm^{-1}$).

Statistics. The results were computed with Excel (Microsoft®). Comparison was made using the one-way analysis of variance (ANOVA) or the ANOVA on ranks (Jandel Scientific, San Rafael, CA) when the normality test failed. Student-Newman-Keuls test was used as soon as heterogeneity between groups was demonstrated. The level of significance was set at $P \leq 0.05$. Kinetic constants were derived by nonlinear regression of initial velocity data fitting a Michaelis-Menten plot as described by Sagnella (33), thereby allowing calculation of an apparent V_{max} ($V_{app\ max}$) and K_m ($K_{app\ m}$) (17).

RESULTS

Dietary treatment and enzymatic activities. The weight of the rats and the food efficiency did not differ between the animals throughout the experiment (Table 2). In addition, no liver enlargement was noticed in any of the dietary groups (Table 2). Independently of diet treatment, the activity of CPT-I differed among the mitochondrion fraction isolated from the four different tissues (hepatic, heart, skeletal muscle, and epididymal fat pad) (Table 3). Overall, this activity was the highest in mitochondrion of the heart tissue, then in decreasing order, in the fat pads, in the skeletal muscle and in the liver. No diet effect was detected, except in the adipose tissue where the activity was 25.5 to 31.6% higher in the CLA groups than in the oleic acid control group. However, the difference reached the statistical significance only in the 10*t*,12*c*- isomer group and the CLA 90 group ($P < 0.05$).

In the liver, the dietary treatment did not influence the acyl-CoA oxidase activity of the peroxisome either (Table 3), and the activity ranged from 12.5 to 14.3 nmol/min/mg of protein ($P > 0.05$). Also, the microsomal CYP4A1 activity, which is usually associated with the ACO activity, did not change with the type

of diet. In addition, the (n-1)-laurate hydroxylase activity, another phase-I detoxifying enzyme which reflects the CYP2E1 activity, did not differ with respect to the diet and was as high as the CYP4A1 activity (a range of 6.0 to 7.0 nmol/min/mg protein). The activity of the glutathione *S*-transferase was also determined in the cytosolic fraction of the hepatocytes. This activity ranged from 1.055 to 1.167 µmol/min/mg protein and did not significantly differ between the four experimental groups, as depicted in Table 3. Finally, the activity of the PAP, one of the rate-limiting enzymes involved in the *de novo* synthesis of triacylglycerols in the adipocytes, did not change with one diet or the other (Table 3).

CPT and ACO activities using hexadecanoic- and octadecadienoic-CoA as substrates. The mean activities of the mitochondrial CPT-I toward the different substrates and the kinetic constants derived from these activities are presented in Figure 1A and Table 4. The $V_{app\ max}$ differed ($P < 0.05$) between the substrates tested and was in decreasing order: 18:2-CoA, 16:0-CoA, 9*c*,11*t*-CoA, 10*t*,12*c*-CoA = CLA90-CoA. Conversely, no significant differences were observed between the corresponding $K_{app\ m}$ values. Comparison of the acyl-CoA substrates' efficiency for the enzyme based on the $V_{app\ max}/K_{app\ max}$ ratio showed lower values with the CLA mixture (Table 4, $P < 0.05$). This indicated that the conjugated linoleate CoA derivatives were not as good substrates for CPT-I as the linoleate homolog when given as a mixture (CLA 90).

The peroxisomal ACO activity toward the different acyl-CoA is displayed in Figure 1B and Table 4. No statistical differences were observed for $V_{app\ max}$ or $K_{app\ m}$ using either of the acyl-CoA substrates. In contrast, comparison of the $V_{app\ max}/K_{app\ m}$ indicated that the 10*t*,12*c*-CoA derivative was by far the best substrate for the enzyme (2.7 to 3.7 times more efficient) (Table 4). The $V_{app\ max}$ were significantly lower than the corresponding values found for CPT-I ($P < 0.05$), except for CLA90- and 10*t*,12*c*-CoA. The $K_{app\ m}$ were also consistently lower. As a result, in contrast to all the other acyl-CoA derivatives, both the CLA90- and 10*t*,12*c*-CoA were better substrates for ACO than for CPT-I, as indicated by their significantly higher $V_{app\ max}/K_{app\ m}$ for ACO than for CPT-I ($P < 0.05$, Table 4).

[a]Kinetic constants are calculated from nonlinear regression (coefficients for the nonlinear regression fit range from 0.81 to 0.91 for CPT-I, and from 0.79 to 0.95 for ACO; $P < 0.0001$ for all r; $n = 15$ to 25 data points).
[b,c]Numbers in the same column not sharing a common superscript are significantly different ($P < 0.05$; one-way ANOVA) (expressed as means ± SEM, $n = 4$ to 5 animals).
[d]Indicates a significant difference ($P < 0.05$; one-way ANOVA) between the ACO value and its CPT-I counterpart in the same row. See Table 2 for other abbreviation.

DISCUSSION

The present study examined the influence of two isomers of CLA (individually or in combination) in the diet upon selected enzymes associated with lipid metabolism. In addition, as the biological activity of CLA is obviously dependent on their cellular metabolism, the other goal of that experiment was to predict to which extent these conjugated fatty acids can be channeled and eventually degraded through β-oxidation. For that purpose, we measured the activity of two important rate-limiting enzymes toward CLA, namely, the mitochondrial CPT-I and the peroxisomal ACO, which govern the flux of the fatty acids through the β-oxidation pathway. The depicted CPT activities mainly reflect the activity of the mitochondrion enzyme (34).

Effects of on lipid-related metabolizing enzymes. Belury *et al.* (8) found a peroxisome-proliferator response in the liver of female SENCAR mice fed a commercial mixture of CLA. This conclusion was supported by examining the mRNA levels encoding for different proteins accompanying the peroxisome proliferation, such as CYP4A1, fatty acid-binding protein and ACO, as well as the ACO protein expression—an important issue since peroxisome proliferation is usually accompanied by a pleiotropic cellular response associated with gene regulation (35–38), whether potentially beneficial (hypolipemia) or pathological (hepatotoxicity). However, at the time the present manuscript was written, the same authors published another report in which they contradicted this observation, but female and male Sprague-Dawley rats were used instead of female SENCAR mice (9). Consistent with this latter report, our results also confirm the lack of a peroxisome proliferation effect in our male rats (strain Wistar), though using another method. We thus measured the enzyme activity and not the mRNA induction of target enzymes which are generally increased during peroxisome proliferation (36,37). For instance, the peroxisomal ACO activity and the microsomal CYP4A1 activity remained unchanged (Table 3). Additionally, in peroxisome proliferation, the mitochondrion CPT-I activity is also often increased (35,39), and the cytosolic glutathione *S*-transferase activity is decreased (40–42). These activities were not modified after dietary intake of any of the CLA isomers (Table 3). Therefore, by using a complementary approach (phenotypic), our findings extend and confirm the former rat study (genotypic) (9) and point out that great care should be exercised in interpreting data of CLA experiments obtained in different species. The question should thus be raised: Which animal model, i.e., rats or mice (or others), would best mimic the human situation for that aspect (and other aspects) of fat metabolism during CLA feeding? Interesting to note and as formulated above, the activity of the cytosolic glutathione *S*-transferase is not impaired along with CLA intake (Table 3). This phase-II detoxifying enzyme has a critical role in cellular protection, and its activity might be induced during a chemical stress or by chemoprotective agents (43), or declined with peroxisome proliferator molecules (40–42). Therefore, in addition to the two phase-I enzymes presently studied (CYP4A1 and CYP2E1), the CLA diets caused no impairment of this glutathione-dependent detoxication activity either (phase II enzyme). This can be seen as a lack of a detrimental effect and would additionally argue for the absence of toxicity of CLA in this species, as it also has been documented by others but while examining histopathological and hematological parameters (44).

Mixtures of CLA are potent in reducing the fat body mass in different species (10,12,13,45) including rats. Among the identified causes, a greater channeling of fatty acids toward β-oxidation (higher CPT-I activity) (10), a lower adipose fatty acid uptake (10,11), a greater adipose tissue lipolysis (10,11), and an overall increased metabolic rate (13) are responsible for body fat reduction in mice. A possible impairment of triacylglycerol synthesis in the adipocyte can not be ruled out as well. However, our results did not suggest that a reduced lipid synthesis in the adipose tissue occurs in male Wistar rats, as the activity of PAP, a rate-limiting enzyme in the glycerolipid synthesis, remained unchanged in the epididymal adipose tissue (Table 3). Nonetheless, consistent with others (10), our data suggest that part of the body fat reduction induced by CLA can be ascribed to a greater β-oxidation rate of fatty acids in the adipose tissue, as evidenced by a higher CPT-I activity in the adipocyte (Table 3). Our findings also indicate that the two diets containing the

10*t*,12*c*-isomer elicited a larger effect when compared to the control group, a result consistent with the identified role of that isomer in body composition changes (11). In contrast to fasted mice (10), no changes of the β-oxidative capabilities (CPT-I activities) were detected in skeletal muscle of our fasted rats with one or the other CLA isomers (Table 3). This observation additionally underlines the differences between these two rodent species in response to CLA feeding.

Kinetic parameters of CPT and ACO using CLA as their CoA derivatives. Individual CLA-CoA isomers have comparable CPT-I $V_{app\ m}$ and $K_{app\ m}$ as palmitoyl-CoA, but a lower $V_{app\ m}$ value than linoleoyl-CoA (Table 4, Fig. 1A). Hence, besides the double-bond geometry (46), CPT-I is also able to discriminate between a methylene-interrupted (linoleate) and a conjugated double-bond system, especially when located in the Δ10,12 position. On the other hand, both the 9*c*,11*t*- and 10*t*,12*c*-isomers have comparable kinetic constants and identical $V_{app\ m}/K_{app\ m}$ ratios, suggesting that the enzyme cannot differentiate positional isomers of conjugated linoleates. This would also suggest that both isomers, as their CoA derivatives, are equally degraded through β-oxidation within the mitochondria. Thus, the preferential accumulation of the 9*c*,11*t*-CLA isomer over the 10*t*,12*c*- that is usually observed in tissue lipids (1,47) cannot be explained based on a better substrate specificity for the liver mitochondrial CPT-I. Indeed, based on the geometrical and positional arrangements of the conjugated double-bond system and on the enzymatic sequence involved in the β-oxidation spiral, one would expect that the 10*t*,12*c*-isomer would be more efficiently oxidized in the mitochondrion matrix than the 9*c*,11*t*-homolog: the 10*t*,12*c*-isomer would escape four enzymatic steps that may be potentially rate-limiting (i.e., enoyl-CoA isomerase, 2-*trans*-enoyl-CoA hydratase, β-hydroxyacyl-CoA dehydrogenase, and acyl-CoA dehydrogenase), while the 9*c*,11*t*-isomer would bypass only two (acyl-CoA dehydrogenase and 2,4-dienoyl-CoA reductase). Such a potentially facilitating metabolism could preferentially drive the 10*t*,12*c*-isomer through the β-oxidation pathway compared to the 9*c*,11*t*-homolog, and give some rationale to the lower amount in the 10*t*,12*c*-isomer found in the tissue lipids. Oxidation studies carried out with mitochondrial preparations using CoA derivatives and oxygen electrodes such as described elsewhere (48–50) would give a more precise feature as to the relative importance of the β-oxidation pathway toward each of the individual CLA isomers. Differences in the activation of the CLA isomers into their respective CoA by the acyl-CoA synthase, whether in the mitochondria or in the endoplasmic reticulum, would also offer an explanation as to the differences in their content in tissue lipids, as observed with long-chain n-3 fatty acids (51). Interestingly, we found a lower $V_{app\ m}$ and a lower $V_{app\ m}/K_{app\ m}$ ratio with the mixture of CLA-CoA (made up of equal amounts of both the 9*c*,11*t*- and 10*t*,12*c*-isomers) compared to the individual isomers situation (Table 4). If it is possible to extend this observation to the *in vivo* situation, it would mean that to give CLA as a mixture of isomers would spare them from β-oxidation to a greater extent than to give them separately. They would be therefore potentially more available for other metabolic purposes.

In a normal situation, the overall peroxisomal β-oxidation is quantitatively less compared to the mitochondrial β-oxidation. However, it may efficiently contribute to channeling certain fatty acids into the β-oxidative pathways (52–54). Especially, the availability for the peroxisome β-oxidation seems to be greater for the 10*t*,12*c*-isomer than for the 9*c*,11*t*-isomer since the former had higher $V_{app\ m}/K_{app\ m}$ ratio for ACO than the latter (Table 4). In addition, since peroxisomal β-oxidation is not complete in contrast to mitochondrial β-oxidation (55), it is therefore not surprising that a 16-carbon conjugated retroconverted product arising from the 10*t*,12*c*-CLA isomer and not from the 9*c*,11*t*-isomer was detected in the glycerolipids of rats fed with CLA (either as a mixture or as separate isomers) (56). This better channeling into the peroxisome oxidative pathway would also explain why the 10*t*,12*c*-isomer is generally found at a lower level than the 9*c*,11*t*-isomer in most tissue lipids (1,47).

In conclusion, the present study confirms and extends the observation made by others (9) as to a lack of a peroxisome-proliferator response elicited by either the 9*c*,11*t*- or 10*t*,12*c*-CLA isomer in the liver of rats. Our results also indicate that the *β*-oxidation activity in highly oxidative tissues, i.e., skeletal and cardiac muscles, was not modified with any of the CLA diet used. This was not the case in the epididymal adipose tissue where the CLA diets and especially the 10*t*,12*c*-isomer diet brought about a 30% increase of the mitochondrial CPT-I activity. Kinetic data obtained with CPT-I and ACO using a pure preparation of CLA isomers as their CoA derivatives suggested a greater availability of the 10*t*,12*c*-isomer for the peroxisomal β-oxidation pathways, which in turn would potentially lower its bioavailability and further its biological efficiency. Comparison of our rat results with mice studies, especially with those related to peroxisome proliferation and CPT-I, underlines species differences in response to CLA feeding and raises the question of which animal species would be preferred to mimic the human model.

Apolipoprotein E Polymorphism: Automated Determination of Apolipoprotein E2, E3, and E4 Isoforms

Claudia Wiebe, Guido Holzem, Klaus Wielckens, and Karl Rolf Klingler*

Institut für Klinische Chemie, Universität zu Köln, Cologne, Germany

ABSTRACT: Apolipoprotein E (apo E) plays an essential role in lipoprotein metabolism, where it is involved in the clearance of chylomicrons and very low density lipoproteins. Apart from some rare variants, apo E exists in three common isoforms (E2, E3, and E4). The different isoforms have not only been associated with different plasma lipid levels but have also been correlated with certain pathological conditions, such as lipid disorders (dysbetalipoproteinemia, hypercholesterolemia), cardiovascular diseases, and Alzheimer's disease. Here we describe a rapid, automated test for the determination of the most frequent polymorphisms (E2, E3, and E4). This polymerase chain reaction-based test allows the reliable discrimination of all six genotypes. The assay has been developed especially for the nonspecialized routine clinical laboratory by employing an analyzer and chemistry often present in this type of laboratory. Because of its low costs and easy handling, the assay can be performed on a daily basis.

Paper no. L8369 in *Lipids 35,* 99–104 (January 2000).

Apolipoprotein E (apo E) plays a central role in the receptor-mediated uptake of chylomicrons and very low density lipoprotein remnants by the liver. Apo E is one of the major proteins of these particles and acts as the ligand to the low density lipoprotein (LDL) receptor and to other receptors of this receptor family (reviewed in 1). Apo E is polymorphic; it exists in three common isoforms (E2, E3, E4) (2,3) and in some rare variants (4,5). The major isoforms differ from each other only by single amino acid substitutions at two sites. The isoforms are associated with certain diseases: apo E2 homozygosity plays an important role in the development of type III hyperlipoproteinemia (6–8) and atherosclerosis (9), because apo E2 is defective in its ability to bind to lipoprotein receptors (10,11); apo E4, apart from being associated with elevated LDL concentrations, increases—in a dose-dependent manner—the likelihood of developing Alzheimer's disease (12,13).

Several methods have been employed for the determination of apo E isoforms. Basically, these methods can be divided into two groups: methods of the first group focus on the separation of the lipoprotein isoforms by isoelectric focusing with subsequent immunoblotting using an anti-apo E antibody (14,15) or by direct immunofixation (16). A second group of methods is based on the polymerase chain reaction (PCR) technique and therefore determines the patient's genetic status directly. Most of these methods employ restriction endonucleases followed by the analysis of the restriction fragment length polymorphism, which can be detected by separating the fragments on agarose or polyacrylamide gels (17–19), or even by employing microplate array diagonal gel electrophoresis (20). Others employ single-strand conformation polymorphism (21) or oligonucleotide binding (22).

Although all of these methods are certainly capable of determining a patient's apo E isoform status, most of them were developed in, and for, research laboratories and are, as such, time-consuming and laborious. It is therefore necessary to establish methods that especially meet the needs of a routine laboratory, i.e., are easy to perform, allow for a high throughput, require less hands-on time, are reliable, fast, and cost effective.

Here we describe a rapid, automated PCR-based method for the determination of the apo E isoforms that uses electrochemiluminescence (ECL) as detection technology, employs off-the-shelf chemistry, and uses the automated detection process of an immunoassay analyzer that is present in many clinical laboratories, thus avoiding an additional investment for more specialized equipment.

MATERIAL AND METHODS

DNA isolation. Genomic DNA was isolated from 10 μL of anticoagulated whole blood (EDTA, citrate, or Li-heparin), which we obtained for routine analysis from our hospital, using the Dynabeads DNA DIRECT™ kit from DYNAL (Oslo, Norway). DNA was dissolved in 30 μL of Tris-EDTA buffer and stored at –20°C until use.

All primers were designed according to the sequence published by Hixson and Vernier (17). The currently available version of the apo E sequence from GenBank (accession number M10065) shows a few differences that are marked by underlining the respective bases.

PCR. Two fragments, separated only by 22 bp, within exon 3 of the apo E gene were amplified (Fig. 1). Each fragment covers a single, diagnostic restriction site for the enzyme *Hin 6 I.* Fragment A (89 bp, GenBank: position 3914–4002), was

Abbreviations: apo, apolipoprotein; dNTP, deoxynucleotide triphosphates; ECL, electrochemiluminescence; LDL, low density lipoprotein; PCR, polymerase chain reaction.

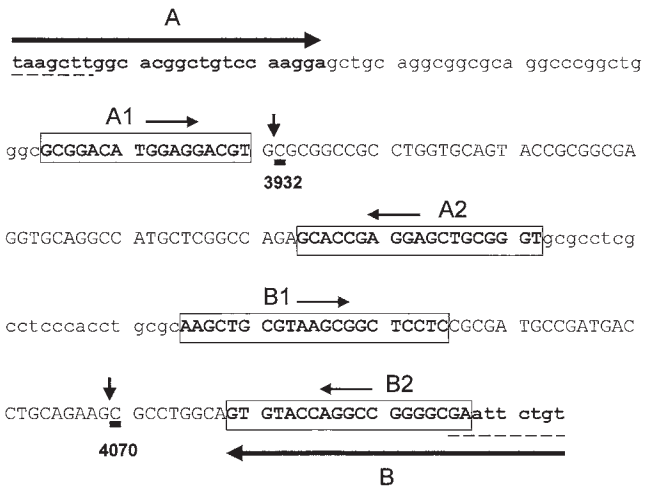

FIG. 1. Apolipoprotein E (apo E) polymerase chain reaction. Sequence of the 244-bp-long amplified fragment within exon 3 of the human apo E gene (GenBank accession number M10065, position 3861–4104), which was amplified with primer A and B. Dotted line: mismatch between GenBank sequence and primer sequences published by Hixson and Vernier (17). Primers A1 and A2 were used to generate fragment A, which includes the recognition sequence for *Hin 6 I* at position 3931–3934. Apo E isoforms E2 and E3 display "T" instead of "C" at position 3932 and by this destroy the recognition sequence of *Hin 6 I*. Primers B1 and B2 were used to generate fragment B, which includes the recognition sequence for *Hin 6 I* at position 4069–4072. Apo E isoform E2 carries "T" instead of "C" at position 4070 and by this destroys the recognition sequence for *Hin 6 I*. Down arrows indicate *Hin 6 I* cleavage sites in fragments A and B.

amplified using primer A1: 5′-ruthenium-GCG GAC ATG GAG GAC GT-3′ and primer A2: 5′-biotin-ACC CGC AGC TCC TCG GTG C-3′ (synthesized by MWG-Biotech-AG, Ebersberg, Germany). DNA (5 µL) was added to 45 µL of PCR mastermix containing 300 nM of each primer and 250 µM of each deoxynucleotide triphosphates (dNTP) (Promega, Madison, WI), 2% (vol/vol) dimethylsulfoxide (Sigma, St. Louis, MO), 10 mM Tris HCl (pH 8.3), 50 mM KCl, 1.5 mM $MgCl_2$, 1 unit Taq-polymerase (Sigma), 7% (vol/vol) glycerol (Merck, Darmstadt, Germany), and 27 µL of sterile water. The samples were then subjected to the following cycling conditions: 96°C for 2 min; cycles 1–4: 96°C for 1 min, 61°C for 50 s, and 72°C for 1 min; cycles 5–32: 91°C for 1 min, 61°C for 50 s, and 72°C for 1 min.

Fragment B (73 bp, GenBank: position 4025–4097) was amplified using primer B1: 5′-ruthenium-AAG CTG CGT AAG CGG CTC CTC-3′ and primer B2: 5′-Biotin-TCG CCC CGG CCT GGT ACA C-3′ (synthesized by MWG-Biotech-AG). DNA (5 µL) was added to 45 µL of PCR mastermix containing 250 µM of each dNTP, 2% (vol/vol) formamide (Merck), 10 mM Tris HCl (pH 8.3), 50 mM KCl, 1.5 mM $MgCl_2$, 1 unit Taq-polymerase (Sigma) 10% (vol/vol) glycerol (Merck) containing 300 nM of each primer. The samples were then subjected to the following cycling conditions: 96°C for 1 min, then cycles 1–5: 96°C for 1 min, 53°C for 50 s, and 72°C for 1 min; cycles 6–34: 90°C for 1 min, 53°C for 50 s, and 72°C for 1 min.

Hin 6 I *digestion.* Both PCR products were digested independently. Fifteen microliters from each PCR product was added to 5 µL of a digestion mastermix, containing 20 units *Hin 6 I* (FERMENTAS, Vilnius, Lithuania) and 3 µL of buffer "Y-Tango," supplied with the enzyme. The samples were digested for 40 min at 37°C.

DNA sequencing. A 244 bp (GenBank: position 3861–4104) within exon 3 of the apo E gene (Fig. 1), spanning fragments A and B, was amplified using primer A: 5′-TAA GCT TGG CAC GGC TGT CCA AGG A- 3′ and primer B: 5′-ACA GAA TTC GCC CCG GCC TGG TAC AC-3′ (MWG-Biotech-AG).The amplified DNA was sequenced with the Big-Dye™ DNA sequencing kit of PE-Applied Biosystems (Warrington, United Kingdom) on a 377 DNA Sequencer (PE-Applied Biosystems, Weiterstadt, Germany).

Detection. We used a modified Elecsys system 1010 ("Molecsys"), especially suited for molecular biology tests (not commercially available, Roche Diagnostics, Mannheim, Germany) in conjunction with the reagents (buffers, microbeads) supplied with the normal test kits by Roche Diagnostics. The system is a fully automated random access analyzer; its underlying principles have been described in great detail elsewhere (23). In principle, the system employs ECL for detection, which utilizes $Ru^{2+}(bipy)_3$-chelates as a label in combination with universal streptavidin-coated paramagnetic micro particles.

RESULTS

The basic principle of the assay is outlined in Figures 2 and 3. Briefly, two DNA fragments, spanning either of the diagnostic restriction sites, are amplified independently, using a pair of a biotin-labeled 3′ primer and a ruthenium-labeled 5′ primer for each fragment. After amplification, each of the two samples is split into two aliquots. One aliquot is incubated with the restriction enzyme *Hin 6 I*. If the restriction site is present, the ruthenium-labeled 5′ part of the fragment is removed from the biotinylated 3′ part. The other aliquot remains unaltered. Biotinylated DNA binds *via* streptavidin to paramagnetic beads, which keep the biotinylated DNA in the detection chamber of the analyzer while all other components are washed away. The amount of ruthenium bound to the biotinylated DNA is determined for both samples by measuring the ECL signal generated by the ruthenium complex in the detection chamber. The genotype is determined by calculating the ratio between the signals from the digested and the undigested aliquot for both fragments.

DNA preparation. We decided to use the Dynabeads DNA DIRECT™ kit, which allows the preparation of 10 samples within 15 min from blood samples anticoagulated with heparin, citrate, or EDTA. In almost all cases, blood samples reach the laboratory without being cooled or frozen during transport; thus DNA may degrade quite rapidly during transportation. Using the Dynabeads DNA DIRECT™ kit, we were able to obtain DNA from samples that had been stored up to 4 d at room temperature.

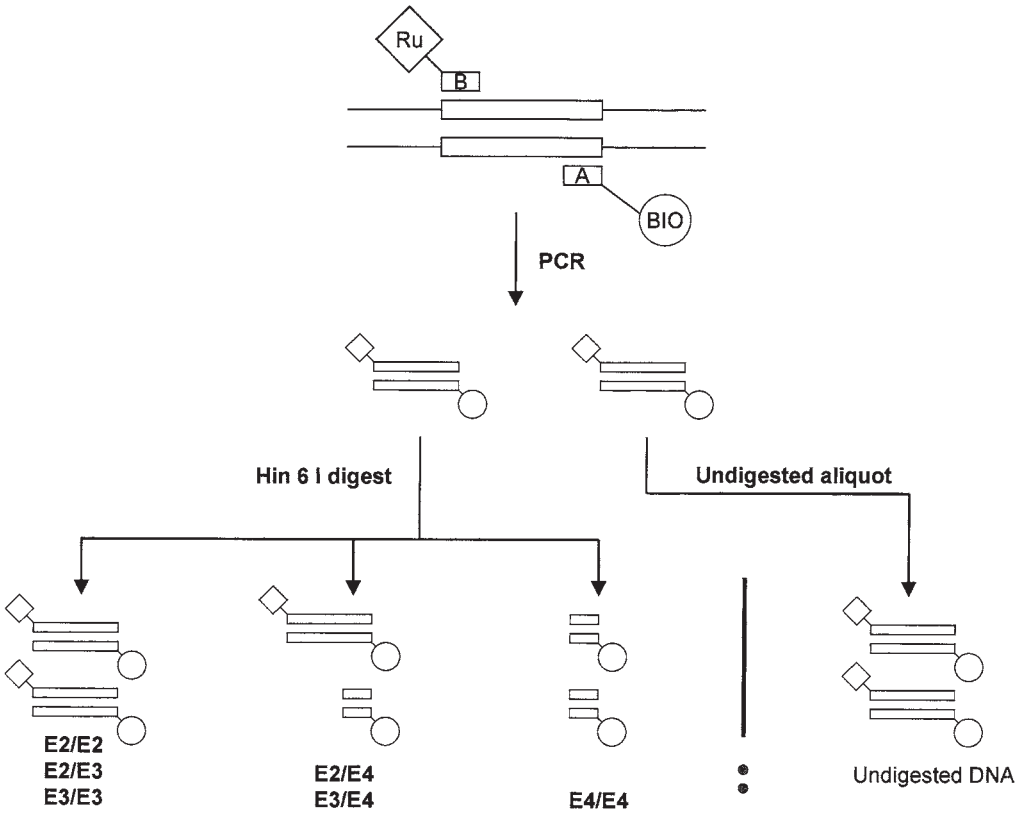

FIG. 2. The Apo E assay. After amplification, each sample is split into two aliquots. One of the two aliquots is incubated with the restriction enzyme *Hin 6 I*. If the restriction site is present, the ruthenium-labeled 5' part of the fragment is separated from the biotinylated 3' part. The other aliquot remains unaltered. Biotinylated DNA binds *via* streptavidin to paramagnetic beads, which keep the biotinylated DNA in the detection chamber of the analyzer while all other components are washed away. The amount of ruthenium bound to the biotinylated DNA is determined for both aliquots by measuring the electrochemiluminescence signal, which is generated by the ruthenium complex in the detection chamber. The apo E isoform is determined by calculating the ratios between the signals from the digested and the undigested aliquots for fragments A and B. Figure 2 represents the situation for fragment A. For abbreviation see Figure 1.

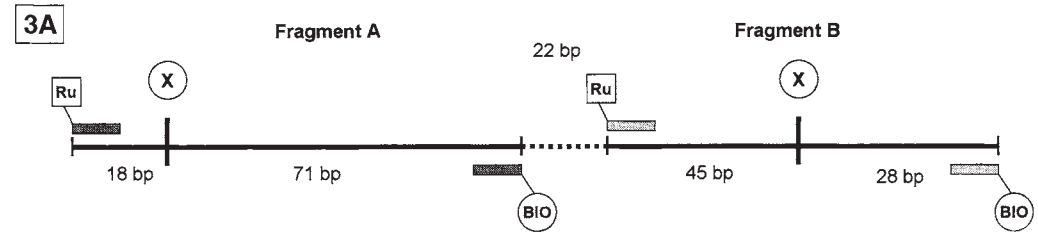
Validity of the new method. The assay is based on the presence of a single diagnostic *Hin 6 I* restriction site in each of the two short (89 and 73 bp) fragments (Fig. 3A) that were amplified by PCR. Depending on the genotype, the site is present in all, none, or one of the two fragments leading to a unique pattern of two distinctive ratios for each isoform (Fig. 3B; Table 1).

To demonstrate the validity of our method, we analyzed samples that had already been sequenced. For each of the six possible genotypes, we analyzed 10 samples (with the exception of E2/2: nine samples). The results are listed in Table 1, demonstrating total agreement of our method with the independently obtained results. Combination of the two ratios for fragments A and B allows for an unambiguous determination of the genotype; each analyzed sample falls into one of six nonoverlapping groups (Fig. 4).

The mean ratio of the heterozygous samples is significantly higher than theoretically expected (0.63–0.67 vs. 0.5). This is due to the formation of heteroduplex DNA during PCR amplification: a single strand of wild-type DNA and a single strand of mutated DNA form double-stranded DNA (heteroduplex DNA). This DNA cannot be cut by the restriction enzyme, thus leading to a ratio >0.5. Nevertheless, this does not hamper the ability of the test to distinguish clearly among all six genotypes.

Intra-assay and interassay imprecision. Following the procedure described here, we independently determined, for each of the two fragments, intra-assay and interassay imprecision. For each genotype, DNA from a single sample was split into 10 aliquots that were subsequently amplified by PCR and analyzed by the standard procedure: each sample was split into two secondary aliquots, and one of these secondary aliquots was incubated with the respective restriction enzyme. All 20 secondary aliquots were measured on the analyzer in the same run and the ratios were calculated. From these data, intra-assay imprecision was calculated. Further, DNA from a single sample was split into 10 aliquots that were subsequently amplified by PCR and stored at –20°C. For 10 d within a 14-d period, a



3A

	Fragment A	Ratio	Fragment B	Ratio
E2/E2	E2 / E2	1	E2 / E2	1
E2/E3	E2 / E3	1	E2 / E3	0.5
E2/E4	E2 / E4	0.5	E2 / E4	0.5
E3/E3	E3 / E3	1	E3 / E3	0
E3/E4	E3 / E4	0.5	E3 / E4	0
E4/E4	E4 / E4	0	E4 / E4	0

FIG. 3. Apo E isoforms and *Hin 6 I* restriction pattern. Restriction endonuclease *Hin 6 I* generates unique restriction patterns of fragments A and B which, together, allow the unambiguous identification of the respective apo E isoform. (A) In the case of E4, each fragment carries a single "diagnostic" restriction site (**X**) for *Hin 6 I*. In the case of the E2 and E3 isoforms, the recognition sequence in one or both fragments is destroyed, and *Hin 6 I* will not cut the DNA. (B) The pattern of DNA fragments generated by *Hin 6* and the corresponding results with the new assay as a ratio between the signals from the digested and the undigested aliquots is shown for each isoform combination.

single aliquot was thawed and two secondary aliquots were generated and analyzed ± digestion with the *Hin 6 I* restriction enzyme. These data were used to calculate interassay imprecision. The results are summarized in Table 2.

Costs. Since our intention was to design an assay for the average clinical laboratory, we not only focused on handling and reliability but also looked at cost effectiveness as well. Apart from a thermal cycler, no special equipment is needed. The costs of the consumables (enzymes, reagents, and plasticware) for one blood sample (both mutations) are less than $5 (U.S.).

DISCUSSION

A large variety of assays for the detection of point mutations in general and for the determination of apo E isoforms already exists. Our intention was to focus strictly on the development of an assay that is truly suited for use under the conditions and restraints present in the setting of an average clinical laboratory.

To reach this goal, chemicals and equipment usually available in such laboratories have to be integrated into the analytical procedure, and manual work has to be avoided whenever

TABLE 1
Comparison of Expected Ratios (based on DNA sequencing) and the Ratios That Were Obtained with the New Method

Genotype	E2/E2	E2/E3	E2/E4	E3/E3	E3/E4	E4/E4

Obtained ratio, mean	1.02	0.66	0.67	0.02	0.01	0.02
Range	0.94–1.1	0.56 -0.75	0.52–0.73	0.01–0.04	0.01–0.03	0.01–0.06

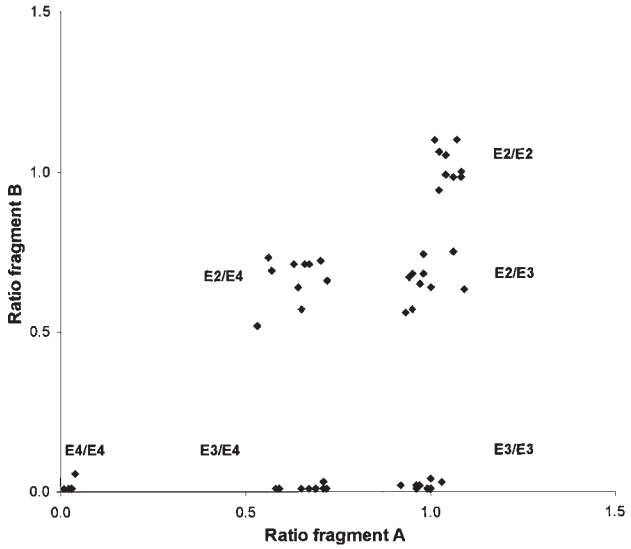

FIG. 4. Ratio distribution. Combination of the two ratios for fragments A and B allows for an unambiguous determination of the genotype: 10 samples for each of the six possible genotypes (E2/E2: nine samples) were analyzed by this method. Each analyzed sample falls into one of six nonoverlapping groups.

possible. Therefore, DNA sequencing or procedures requiring high-purity DNA were not options since these methods require the use of toxic chemicals and extensive manual labor, thereby increasing the costs.

Consequently we decided to use a DNA preparation method that yields DNA of only average purity but that is very quick and allows the handling of several samples simultaneously. For the same reason any quantification of DNA or cells was omitted. Instead, we decided to split every sample and carry the undigested sample through the whole assay, allowing on one hand control of all assay steps and on the other hand avoiding any quantification steps after DNA preparation and after PCR amplification. In addition, the undigested sample is the 100% base for the calculation of the ratio of each sample, thus avoiding extra handling steps and additional reagents or the necessity of comparing the result with an external 100% standard. These procedures do not compromise quality and reliability.

For the detection of the PCR product itself, we used an Elecsys system from Roche Diagnostics, because this type of instrument is widely distributed, thereby taking advantage of the possibility of using shelf reagents. Moreover, this analytical system allows the determination of the genotype with high reliability and low costs. The system employs ECL for detection, which is very sensitive and, since detection is linear over almost five orders of magnitude, allows the simultaneous processing of samples with varying amounts of amplified DNA.

The reliable identification of patients who are heterozygous for a mutation is often a problem and therefore was of primary importance for the assay design. The results prove that the "heterozygous" genotypes (leading to a ratio of ~0.65) can be reliably distinguished from the homozygous genotypes. In addition, the assay is fast enough to allow same-day reporting.

Nowadays, almost all clinical laboratories feel increasingly the impact of a tight budget. The fact that this assay, apart from the PCR step, does not require any specialized equipment, since the instrumentation is available in many laboratories, keeps the costs to less than $5 (U.S.) and avoids any major upfront investment in hardware.

The recently described fluorescence-based PCR method (LightCycler™) (24) is faster than the method described here, but it requires an analyzer exclusively dedicated to PCR-based testing, which represents an additional investment of $40,000 to $50,000 (U.S.). In a large percentage of clinical laboratories, this investment cannot be justified owing to low sample numbers. The only option left to most of these laboratories is to use equipment already present in conjunction with tests such as the one described here.

Assays, comparable to this test, may help genetic analyses in the future to become an affordable part of the daily workload of an average clinical laboratory.

ACKNOWLEDGMENTS

We thank Dr. Juergen Geisel, University Hospital, Homburg/Saar, for providing DNA samples. We gratefully acknowledge the support of Roche Diagnostics, Mannheim, Germany, which supplied the modified Elecsys 1010 system.

COMMENTARY

Breast-Fed Infants Achieve a Higher Rate of Brain and Whole Body Docosahexaenoate Accumulation Than Formula-Fed Infants Not Consuming Dietary Docosahexaenoate

ABSTRACT: Docosahexaenoate (DHA) has been increasingly recognized as an important fatty acid for neural and visual development during the first 6 mon of life. One important point of controversy that remains is the degree to which adequate levels of DHA can be acquired from endogenous synthesis in infants vs. what should be provided as dietary DHA. We have approached this problem by a retrospective analysis of published body composition data to estimate the actual accumulation of DHA in the human infant brain, liver, adipose tissue, remaining lean tissue, and whole body. Estimating whether infants can synthesize sufficient DHA required comparison to and extrapolation from animal data. Over the first 6 mon of life, DHA accumulates at about 10 mg/d in the whole body of breast-fed infants, with 48% of that amount appearing in the brain. To achieve that rate of accumulation, breast-fed infants need to consume a minimum of 20 mg DHA/d. Virtually all breast milk provides a DHA intake of at least 60 mg/d. Despite a store of about 1,050 mg of DHA in body fat at term birth and an intake of about 390 mg/d α-linolenate (α-LnA), the brain of formula-fed infants not consuming DHA accumulates half the DHA of the brain of breast-fed infants while the rest of the body actually loses DHA over the first 6 mon of life. No experimental data indicate that formula-fed infants not consuming DHA are able to convert the necessary 5.2% of α-LnA intake to DHA to match the DHA accumulation of breast-fed infants. We conclude that dietary DHA should likely be provided during at least the first 6 mon of life.

Paper no. L8211 in *Lipids 35,* 105–111 (January 2000).

Whether there is a need for dietary docosahexaenoate (DHA, 22:6n-3) to achieve optimal postnatal visual and cognitive development in human infants is controversial. Reasons for adding DHA to milk formulas include (i) the presence of DHA in human milk irrespective of maternal DHA intake (1); (ii) the lower brain DHA levels in human infants when preformed DHA is not provided (2,3); and (iii) the improvement in vision and/or neurodevelopment when DHA is provided in the milk formula (4–8). Reasons for not adding DHA to milk formula include (i) a lack of improvement in cognitive or motor development over the first 18 mon of life in a large study of term infants given a formula containing DHA and arachidonate (9), (ii) a similar level of visual and neural development in formula-fed term infants not receiving supplemental DHA as in breast-fed infants (10,11), and (iii) potentially impaired development when supplemental DHA is given without added arachidonate (12). One of the problems in achieving consensus on this issue relates to having a large enough sample size studied for long enough (13). This problem has been addressed recently (9) but other potential confounders remain, including the relatively low DHA intake of breast-fed infants in some studies.

Among a number of investigators, measurement of percentage DHA in fatty acid profiles has developed into a surrogate for functional indicators of DHA adequacy. Such data rely predominantly on percentage DHA in plasma total or phospholipid fatty acids which certainly reflects differences in intake of n-3 polyunsaturates but for which no "desirable" normal range has been established for infants. A higher percentage DHA in plasma fatty acids is usually encouraged because it suggests that more DHA is available for the brain. However, even detailed animal data do not clearly establish a relation between plasma or erythrocyte DHA and brain DHA (14). Indeed, one could argue that there should be no relation between blood and brain DHA because the brain presumably has a more rigid DHA requirement whereas the plasma is a transport medium that reflects a balance between intake and utilization of DHA but has no DHA requirement *per se*.

Thus, the limits may have been reached of what can be inferred from fatty acid profiles as a measure of DHA status. Practical and ethical restrictions may make it difficult to design and complete unambiguous clinical studies assessing DHA effects on neurodevelopment. Nevertheless, published data on DHA intake and its levels in organs of human infants are available that are relevant to this issue but have not been applied toward estimating whole-body DHA accumulation by the human infant. In an effort to contribute to the dialogue on the possible need for dietary DHA in human infants, the published literature on growth and fatty acid profiles of various organs was reviewed with an emphasis on determining the net accumulation of DHA in the term infant, particularly in the brain. DHA accumulation was compared to an estimate of ca-

Abbreviations: DHA, docosahexaenoate; α-LnA, α-linolenate.

pacity to provide DHA from breast milk, body fat stores, or synthesis from α-LnA.

The premise for this analysis was that if the combination of DHA synthesis and body stores of preformed DHA appears adequate to meet the rate of DHA accumulation in breast-fed infants for at least 6 mon, then it would not be necessary to provide DHA in milk formulas. Conversely, if DHA stores and synthesis are inadequate to match brain DHA accumulation of breast-fed infants over 6 mon then we would propose that there is a need for dietary DHA. The period from birth to 6 mon was chosen because few data on infant body composition and organ fatty acid profiles exist beyond this period and because exclusive breast or formula feeding is uncommon beyond this age.

COMPONENTS OF GROWTH AND DHA ACCUMULATION

All the data presented here are from literature values that have been previously reported elsewhere but have not been compiled to determine fatty acid accumulation. Changes in organ weights were assumed to be the same for breast- and formula-fed infants because most studies do not distinguish or else combine the data. Data on DHA concentration in the brain, liver, and body fat are in the literature; DHA in the remaining lean tissue of the body was estimated from animal data referenced against liver values (15). Brain and whole-body DHA accumulation data were then compared to DHA intake and bioavailability from breast milk. In essence, this is an analysis of whole-body docosahexaenoate balance comparing the breast- and formula-fed infant. No data on the DHA content of tissues are available for infants given formulas containing DHA, so a comparison cannot be made here.

Data from two papers reporting brain fatty acid profiles in infants (2,3) are central to the present analysis, so a brief description of those two studies is relevant. Farquharson *et al.* (2) reported phospholipid fatty acid profiles for parietal cortex samples from 20 infants who died of sudden infant death syndrome at 1–43 wk. Five infants were exclusively breast-fed and the remaining 15 received milk formulas providing a linoleate/α-LnA ratio of 10:1 ($n = 5$) or 40:1 ($n = 10$). Makrides *et al.* (3) reported fatty acid profiles for frontal cortex total lipids from 15 infants breast-fed for an average of 16 wk, and from 20 formula-fed infants. Most of the deaths in this study were also attributed to sudden infant death syndrome. The formula-fed infants consumed a linoleate/α-LnA ratio of about 10:1.

Over the first 6 mon of life, body weight increases by an average of 4,350 g (Table 1). Brain weight increases by 250 g, liver by 80 g, body fat by 1,440 g, and remaining lean tissue by 2,580 g. The concentration of DHA in the whole brain of a breast-fed infant increases by 39% (1.8 to 2.5 mg/g) from term to 6 mon (16). By extrapolating from the combined average of data reported by Farquharson *et al.* (2) and Makrides *et al*. (3), brain DHA concentration does not increase from birth over the first 6 mon in formula-fed infants not consuming DHA. Thus, the gain in whole brain DHA over the first 6 mon is about 905 mg in breast-fed infants, but is 450 mg in the formula-fed infant receiving no dietary DHA (Table 1).

In the liver, total DHA increases slightly in the breast-fed infant with a gain of 24 mg over 6 mon, but decreases by 136 mg in the formula-fed infant (Table 1). DHA is present in body fat at a higher concentration at term (0.4 wt% of total fatty acids) than after 6 mon of breast-feeding (0.1 wt%), but was not detectable in body fat of formula-fed infants (17). Hence, in absolute terms, body fat as a whole in breast-fed infants accumulates a small amount of DHA over 6 mon (147 mg), but appears to lose all its DHA if the infant is given a formula without DHA. These data assume that total body fat does not differ between breast- and formula-fed infants. They also take into account the lower amount of triglyceride (actual fat) in adipose tissue at birth (47% of total fat weight; 18), a value that we assumed rose to 60% by 6 mon of age, on its way to a mean of 82% in adults (19). DHA in lean tissues of the remaining body was estimated by extrapolation from animal data showing that DHA in skeletal muscle and viscera is about 25% of that in the liver (15). On that basis, and assuming that the DHA concentration of the remaining lean tissue changes in parallel to the DHA in the liver, the remaining lean tissue of breast-fed infants accumulates about 806 mg of DHA over the first 6 mon of life compared to a loss of about 194 mg of DHA if the infant consumes a formula without DHA (Table1).

Summing the DHA in each of these compartments gives a net whole-body content of DHA at term birth of about 3,800 mg. There is a gain of 1,882 mg or 10.3 mg/d of DHA in the whole body over 6 mon for the breast-fed infant. On the other hand, the whole body of the formula-fed infant loses 993 mg DHA over 6 mon or 5.1 mg/d (Table 1). In the breast-fed infant, 48% (5.0 mg/d) of the gain in whole-body DHA is in the brain and 43% (4.4 mg/d) is in lean tissue excluding the liver. In the breast-fed infant, the liver and body fat seem to be largely DHA "neutral" over the first 6 mon of life (jointly gaining <1 mg/d DHA as a whole). By contrast, only the brain gains DHA in the formula-fed infant (at 2.5 mg/d or half the rate in breast-fed infants), while the rest of the body undergoes a net loss of 7.6 mg/d (Table 1).

MEETING THE ESTIMATED RATE OF DHA ACCUMULATION

To achieve the rate of DHA accumulation calculated for breast-fed infants (about 10 mg/d), a higher DHA intake is needed, thereby allowing for obligate losses before and after absorption. Absorption of DHA from the gut of formula-fed term infants is above 95% (20); we are unaware of similar data for breast-fed infants, but it is likely to be the same. Oxidation is the main postabsorptive route of DHA catabolism. The amount of DHA that is catabolized in humans is unknown but can be estimated from a mixture of primate and rat data. In the liver, brain, and eye of the infant baboon, about 30% of a single dose of preformed isotopically labeled DHA is lost *via* carbon recycling into saturated and monounsaturated fatty acids synthesized *de novo* (21). Losses of DHA due to carbon recycling into cholesterol or

TABLE 1
Accumulation of Docosahexaenoate (DHA) in Breast-Fed or Formula-Fed Term Infants from Birth to 6 mon[a]

by oxidation to CO_2 were not reported in that study. However, in rat studies examining metabolism of other polyunsaturates, oxidation to CO_2 is equivalent in magnitude to the carbon recycling to *de novo* fatty acid synthesis (22,23). Thus, oxidation to CO_2 and carbon recycling into *de novo* lipogenesis would at least double the 30% loss of DHA to fatty acid synthesis alone. Hence, obligatory losses of dietary DHA in infants appear to be on the order of at least 50–60% of that consumed so, to achieve a whole-body DHA accumulation rate of 10 mg/d, at least double (20 mg/d) would have to be provided. This may be a conservative estimate of the amount of DHA needed to achieve the observed accumulation rates but no published data were found that support adjusting this estimate to a higher value.

We believe that it is important to be able to estimate the actual whole-body accumulation of DHA and the amount of dietary DHA or DHA precursors that is necessary to achieve the estimated DHA accumulation rate. However, we do not intend that the estimated accumulation rate for DHA in infants should be viewed as a DHA requirement *per se* because we have no proof that 20 mg/d achieves a desirable functional outcome, only that it approximates the amount of DHA needed to achieve the estimated rate of DHA accumulation in breast-fed infants. Furthermore, the source of the DHA (dietary or synthesized endogenously) to meet this accumulation estimate is also undefined. Once a measurable functional outcome dependent on DHA intake is defined, it will be possible to estimate DHA requirement.

DHA IN MILK RELATIVE TO ITS ACCUMULATION IN THE BREAST-FED INFANT

Over the first 6 mon of life, breast milk intake averages 750 mL/d (24,25). It contains about 4 g/dL fat and DHA at about 0.2 wt% of total fatty acids. This would provide about 60 mg/d of DHA to the breast-fed infant. A value of 0.2 wt% DHA in breast milk fatty acids seems to be more typical of North American and some European milk than of the rest of the world where it tends to be higher (1). Hence, breast milk typically provides about three times more DHA than appears to be needed by the whole infant between term birth and 6 mon of age.

The brain accounts for 48% of the whole body DHA accumulation during the first 6 mon of life (Table 1). By taking into account an obligatory loss of 50% of dietary DHA, the infant brain's accumulation of DHA is equivalent to about 16% of the average DHA intake from breast milk (5 of 30 mg/d available DHA). These calculations ignore both DHA stores (17) and the known capability of the neonate to synthesize DHA (26–28), which suggest that, normally, <16% of the available DHA is used by the developing brain of a breast-fed infant. Furthermore, if DHA intake is higher than 0.2% of milk fatty acids, the proportion of consumed DHA being used by the brain will decrease further. Hence, in using a conservative estimate of DHA in breast milk and disregarding DHA stores and synthesis, the average breast-fed term infant appears to have access to a surplus of preformed DHA.

DHA SYNTHESIS IN THE FORMULA-FED INFANT

The formula-fed infant consuming no dietary DHA must acquire its DHA from body stores or from endogenous synthesis, the latter primarily from α-LnA. α-LnA in milk formulas varies but, on average, is currently present at 1.5% of total fatty acids (6,11). Most formulas contain about 3.5 g/dL fat, so assuming a similar average fluid intake over 6 mon as in the breast-fed infant (750 mL/d; 24,25), this provides about 390 mg/d of α-LnA to the healthy term infant. To meet the brain's DHA accumulation rate alone, the conversion of α-LnA to DHA in human infants needs to be about 2.6% (10 out of 390 mg/d). For the whole body, the conversion of α-LnA needed to make 20 mg/d of DHA would have to be 5.2%. This conversion estimate takes into account the calculated obligate losses of DHA.

How feasible is it for human infants to convert 5.2% of α-LnA intake to DHA? There are several reports on desaturation and chain elongation of α-LnA to DHA by human infants (26–28). In each case, labeled α-LnA was given by mouth and the appearance of labeled metabolites such as DHA in plasma was compared to the amount of tracer given. However, this does not represent actual conversion of α-LnA to DHA because tracer accumulation by the tissues remains unknown in these studies. Hence, to date, we are aware of no study that has reported the actual quantitative capacity to convert α-LnA to DHA in infant or adult humans. This can probably only be achieved by whole-body fatty acid balance methods (15), which are inevitably restricted to animal studies.

Without being able to make direct measurements in humans, the remaining option is to extrapolate from tracer and/or fatty acid balance studies in animals as to whether is it likely that human infants can convert 5.2% of α-LnA intake to whole body DHA or 2.6% of α-LnA intake to brain DHA. Only one directly relevant study in an animal model similar to human infants appears to have been published. By using a stable isotope approach, formula-fed neonatal baboons not consuming DHA have been reported to convert 0.23% of an oral tracer dose of ^{13}C-α-LnA to brain DHA; whole-body conversion of α-LnA to DHA was not reported in that study (29). A commercially available human infant formula containing a linoleate to α-LnA ratio of about 10:1 was used in that study. Hence, baboon infants consuming a similar formula to those used for human infants achieved a rate of conversion of α-LnA to DHA that was 9% of that needed by human infants.

Whole-body fatty acid balance analysis of α-LnA conversion to DHA in growing rats not consuming DHA shows that the overall desaturation/chain elongation of α-LnA to DHA is about 1.4% (15) or 27% of that needed by human infants. The seemingly low conversion rate in rats and baboon infants is supported by the fact that some α-LnA is stored but 70–80% of α-LnA intake is completely β-oxidized. In addition, in the suckling rat, tracer studies show that recycling of α-LnA carbon into newly synthesized brain lipids consumes 30–50 times more ^{13}C-α-LnA than is converted into brain ^{13}C-DHA (22). Thus, carbon recycling consumes a significant additional amount of carbon from α-LnA beyond that which is oxidized to CO_2.

The rat is considered to have a relatively high capacity to desaturate and chain elongate α-LnA, while the baboon is an omnivorous primate that is close in many respects to the development of human infants. In both the primate and rodent models, the available conversion estimates are still well short of the apparent minimum value of 2.6% for the human brain, let alone the overall 5.2% conversion needed for the whole body. At present, no experimental or theoretical data support a capacity to achieve 5.2% conversion of α-LnA to DHA in human infants. Even if α-LnA intake was above 2 wt% of the fatty acids in a formula, as has been recommended (10), i.e., 2.5 wt% would provide 656 mg/d α-LnA, the brain alone would require 1.5% conversion efficiency (10 mg/d of the 656 mg/d consumed). This is still 6.5 times more than the reported capacity in baboon infants (29). Hence, in the absence of dietary DHA, it doesn't seem plausible that sufficient DHA synthesis from dietary α-LnA occurs in the human infant to achieve brain DHA accumulation equivalent to that of the breast-fed term infant.

DHA AND α-LNA IN BODY FAT STORES

Compared to adult humans, there is a relatively high proportion of DHA in adipose tissue at term birth. Regardless of breast or formula feeding, the proportion of DHA in adipose tissue DHA decreases postnatally but more so if the infant consumes a milk formula without DHA, in which case it decreases to an undetectable level during the first 6 mon of life (Table 1; 17). This decrease in percentage DHA in adipose tissue occurred regardless of α-LnA intake which varied between 0.4 and 1.5% of fatty acids in the three formulas used in that study. There is about 1,050 mg DHA in body fat at term, which, if exclusively available to the brain of the formula-fed infant not receiving DHA, would eliminate the need to synthesize DHA destined for the brain for about 3 mon (Table 1). This would reduce the necessary conversion of α-LnA for the brain alone from 10 mg/d to about 5 mg/d or to about 1.2% of the consumed α-LnA over the first 6 mon of

life. Such a value is still five times the 0.23% conversion of α-LnA to DHA achieved by baboon infants (29).

There are two crucial points indicating that, in a net sense, DHA in adipose tissue is probably inaccessible to the developing brain: (i) despite the decreasing percentage DHA in adipose tissue, the actual amount of DHA increases slightly in breast-fed infants (+147 mg over 6 mon; Table 1), and (ii) brain DHA accumulation in formula-fed infants is still significantly lower compared to equivalent breast-fed infants (2,3). Thus, the store of DHA in body fat does not prevent significantly lower accumulation of DHA in the brain when there is no dietary DHA. Indeed, it is possible that brain DHA of formula fed infants not getting dietary DHA might be even lower if DHA was not present in body fat stores at birth. This is clearly speculative but the point is that, if substantiated, these reports (2,3) clearly expose the fundamental problem that brain DHA accumulation is reduced when dietary DHA is not provided and they highlight an apparent need for a dietary source of DHA in human neonates. Furthermore, in low birth weight or premature infants, who are at higher risk of impaired neurodevelopment (4), total body fat is greatly reduced so the amount of DHA stored in body fat, whether available to the brain or not, would be substantially less than in healthy term infants.

The total amount of α-LnA present in body fat at term (0.1 wt% of fatty acids or about 260 mg in total; 17) is less than the amount of α-LnA consumed daily by the formula-fed infant so it would not have a significant impact on these estimates. We are unaware of data for n-3 polyunsaturated fatty acid intermediates between α-LnA and DHA that are presumably present in body fat stores and liver and which would somewhat reduce the necessary conversion of dietary α-LnA to DHA. However, their levels in fat are likely to be lower than those of α-LnA.

THE NEED FOR SURPLUS DHA

The apparent surplus of DHA intake in the healthy, breast-fed term infant is needed because the requirement for all nutrients, especially those that can be β-oxidized, must provide for potentially increased losses during disease, infection, surgery, undernutrition, or other conditions adversely affecting metabolism. These adverse conditions often involve voluntary or involuntary food restriction which, in addition to increasing fatty acid β-oxidation, impairs synthesis of DHA and arachidonate by inhibiting the desaturation chain elongation pathway (30). Hence, the apparent dietary surplus of DHA with breast-feeding could provide insurance against depletion in disease states or undernutrition.

Long-chain polyunsaturated fatty acids, especially DHA, are traditionally viewed as fatty acids with a "structural" role in membranes. However, they are not exempt from β-oxidation. In fact, the body content of long-chain polyunsaturates is more rapidly depleted by fasting or semistarvation than by dietary deficiency alone and was frequently used to accelerate linoleate deficiency (31). A substantial amount of β-oxidation and carbon recycling to *de novo* lipid synthesis seems to be a prominent pathway for polyunsaturates including DHA (21,22) and normally consumes the overwhelming majority of linoleate (18:2n-6) and α-LnA intake (15). Even an intentionally deficient linoleate intake does not prevent significant losses of linoleate to β-oxidation and carbon recycling, demonstrating that this is an obligatory pathway (23) that, with undernutrition, can readily consume the entire dietary intake and reduce body stores of linoleate and α-LnA (32).

Thus, a combination of increased β-oxidation and impaired desaturation–chain elongation during adverse nutritional or metabolic conditions (30,32) is an important reason for providing an apparent surplus of pre-formed DHA because α-LnA cannot be relied upon to be available for DHA synthesis when fatty acid oxidation increases. This diversion of α-LnA toward oxidation and impairment of desaturation-chain elongation (30) may contribute to the DHA deficit in the brain when dietary DHA is not provided. Hence, dietary DHA is not effectively replaced by DHA from endogenous stores or synthesis, both of which appear inadequate to meet the DHA needs of the formula-fed infant not receiving dietary DHA.

LIMITATIONS OF THIS ANALYSIS

The present analysis is subject to the constraints imposed by collecting and combining data from multiple sources published over several decades. In several instances, extrapolation from animal data also was necessary, though this was kept to a minimum and relevant primate data were used where available. The DHA data for body fat and liver were derived from single reports while the DHA values for the remaining lean tissue were estimated from animal data referenced to the liver. Nevertheless, most of the organ weight and fatty acid data are directly or indirectly substantiated by other reports. Similar to the present data but using less complete information, Farquharson *et al.* (17) estimated a DHA requirement in infants of about 30 mg/d. Clandinin *et al.* (33) reported that total n-3 polyunsaturates accumulated at about 3 mg/d in the fetal brain during the third trimester which is close to, but predictably lower than, the 5 mg/d calculated here for the early postnatal period. Hence, the present estimates fit with the limited literature in this area.

The estimated need to convert 5.2% of α-LnA intake to obtain sufficient DHA for the whole human infant has no clear comparison in the literature because fatty acid balance data for the rat (15) did not address a period when brain growth was rapid while the tracer data in baboon infants (29) were for the brain only. Microsomal desaturase activity is generally more rapid in rats than in other species but the baboon infant data should, in principle, be in a similar range to human rates of α-LnA conversion to DHA. In either case, the estimated accumulation of DHA by the human infant brain alone relative to its accumulation after conversion from α-LnA is about 10 times greater than the reported capacity in primates (2.6 vs. 0.23%; 29); the whole-body conversion needed is 3.7 times higher than that achieved by rats (5.2 vs.

1.4%; 15). Furthermore, and most importantly, human brain DHA levels are significantly lower without dietary DHA (2,3). Thus, to some extent, whether estimates of DHA synthesis from α-LnA or lean tissue DHA accumulation are correct is of secondary importance to the biological implications of the brain composition data.

CONCLUSION

From the current data, DHA stores and synthesis alone appear inadequate to meet the rate of DHA accumulation of breast-fed term infants. Therefore, a need for dietary DHA in infant formula seems to exist if the rate of DHA accumulation in breast-fed infants is to be achieved. Formulas containing both arachidonate and DHA are commercially available in some countries and it seems likely that DHA accumulation in infants given such formulas would more closely approximate that of breast-fed infants. The present analysis focuses on DHA, but current evidence suggests that arachidonate should be concurrently supplemented in formulas containing DHA (7). Further studies involving autopsy material are also needed to determine whether provision of a formula containing at least 0.2% DHA (providing 60 mg/d DHA) permits equivalent brain DHA accumulation to that of breast-fed infants.

ACKNOWLEDGMENTS

NSERC supported this study financially. Dr. Norman Salem provided a helpful critique and Dr. Robert Jensen provided information on breast milk fatty acids.

REVIEW

Lipids and Retroviruses

Jeanine Raulin*

Université Denis Diderot (Paris 7), 75251 Paris 05, France

ABSTRACT: The role that lipids may play in enveloped viruses is reviewed. Small lipid molecules can influence retrovirus binding to cell receptors, plasma membrane fusion, and transcription. Palmitoylation following myristoylation of viral glycoproteins is required at the transmembrane level for signal transduction as well as for virion budding and maturation. Cholesterol, ether lipids, phospholipids, platelet-activating factor, phosphatidic acids, diacylglycerols, and several analogs and derivatives influence human immunodeficiency virus (HIV) activity; when conjugated with inhibitors of the viral reverse transcriptase (RT) or aspartyl protease these compounds increase drug effectiveness. On the other hand, L-carnitine, in association with the mitochondrial cardiolipins, inhibits myopathy due to continued prescription of drugs [AZT (zidovudine), ddI (didanoside), or ddC (zalcitabine)], and the redox couple of α-lipoic-dihydrolipoic acid prevents production of the reactive oxygen species that trigger apoptosis of infected cells, with sphingomyelin breakdown to ceramides. Retroviral infection induces a shift from phospholipid to neutral fat synthesis in host cells, and a long antiviral, i.e., antiprotease, treatment may lead to lipodystrophy. Multitherapy involving lipids and their analogs in association with anti-RT and antiproteases might enhance the inhibition of growth and proliferation of retroviruses.

Paper no. L8336 in *Lipids 35,* 123–130 (February 2000).

Initial studies indicated that, like other retroviruses, human immunodeficiency virus (HIV) is enclosed in an envelope that is similar in composition to host cell plasma membranes and similar to those of other enveloped viruses. Like other biological membranes, the retroviral envelope is built of a phospholipid bilayer enclosed between two leaflets of proteins and glycoproteins. Further observations showed that the HIV envelope has a lower lipid-to-protein molar ratio than host cells and, in virtually every case, the cholesterol-to-phospholipid molar ratio (C/P) of the viral envelope is higher than in plasma membranes isolated from the host cells. C/P in infected cells is low compared with uninfected cells. Moreover, purified host cell membranes and retrovirus envelopes showed differences in their phospholipid bilayers. In comparison with lipids of plasma membranes, phosphatidylcholine (PC) and phosphatidylinositol (PI) are diminished by 50 and 80%, respectively, sphingomyelin (SM) is enriched threefold, and phosphatidylserine is elevated by 40% in HIV-1 and HIV-2 (1–3).

The above results imply that retrovirions select those regions of the host cell membranes through which they emerge during budding and maturation, i.e., the phospholipid and cholesterol domains through which virions evaginate. Such domains are presumed to be passive (pre-existing) or dynamic when induced by insertion of viral peptides into the inner monolayer of the plasma membrane. Lipid composition of the virus envelope plays a critical role in the course of virus infection and fusion between infected and uninfected cells. The capacity of cholesterol to modulate virus binding to cell receptors and cell fusion may reflect the requirement for a certain degree of membrane viscosity for successful infection (4,5).

In contrast to the huge number of studies on the genome and glycoproteins, retroviral lipids have rarely been investigated. The absence of genes for lipid-metabolizing enzymes in animal retroviruses implies their inaptitude for autonomous lipid synthesis and may explain this lack of interest. However, the clear differences between viral and host cell lipids obviously result from an influence of viral glycoproteins on cellular metabolism. Retroviruses either have to select preformed cellular lipids, or initiate the formation of new lipids or both, although appropriate pathways have yet to be described.

SIGNAL TRANSDUCTION, INFECTION, AND RETROVIRUS MATURATION

CD4, a transmembrane glycoprotein present in T-helper cells, serves as a receptor for major histocompatibility complex antigens and also for the HIV-1 viral coat protein gp120. The cytoplasmic tail of CD4 is coupled to the protein-tyrosine kinase p56 (PTK), an interaction necessary for an optimal response of T-cells to antigen. This process generates intracellular signals and other interactions with various downstream molecules. One such target is the PI 3-kinase (PI 3-K), which phosphorylates the third position of the inositol ring of PI, PI 4-phosphate, and PI 4,5 bisphosphate. CD4-p56 also associates with another lipid kinase, the PI 4-kinase (PI 4-K). The binding of PI 3- and PI 4-K to the CD4-

p56 complex contributes to activation of T-cells and has important implications to the pathogenesis of HIV-1 infection (6).

N-Palmitoylation of PTK by N-palmitoylacyl transferase (PAT), which palmitoylates proteins of the PTK family containing the N-terminal sequence "myrGlyCys," occurs on cysteine residues. This reversible modification, along with amino-terminal myristoylation of glycine, is critical for PTK association with GPI (glycan phosphatidylinositol)-anchored proteins. GPI-anchored protein subdomains are enriched in lipids, and PTK palmitoylation together with myristoylation are needed for PTK localization in the same membrane subdomains (7–10).

This cell activation cascade involves the production of lipid messengers, i.e., (i) platelet-activating factor (PAF), which plays an important role in HIV pathogenesis and can be inactivated by PAF-acetyl hydrolase, the specific hydrolase of the phospholipase A2 subfamily (11); (ii) phosphatidic acids (PA), generated from GPI hydrolyzed by a specific phospholipase D. PA production can be suppressed *in vitro* with CT-2576 [1-(11-octylamino-10-hydroxyundecyl)-3,7-dimethylxanthine] (12); and (iii) ceramides (CER): SM are hydrolyzed into CER by a specific sphingomyelinase, a process that stimulates a CER-activated protein kinase (13).

Initiation of HIV genome transcription, after integration of HIV proviruses into the host cell DNA, is determined by transcription factors interacting with long terminal repeats. For this event to occur and HIV transcription to be initiated, transcription factor (NF-κB) must be activated and translocated from the cytoplasm to the nucleus. In human monocytes and T-lymphocytes, PC hydrolysis into diacylglycerol (DAG), the potent second messenger, by a specific phospholipase C (PLC) is the major activation pathway leading to the induction of HIV enhancers (14).

Structural nucleocapsid proteins of most mammalian retroviruses including HIV-1 are specifically cleaved from a myristoylated polyprotein precursor. HIV-1 encodes the Pr*55gag*, normally processed by viral protease to the structural proteins found in mature virus particles. Pr*55gag* is myristoylated as well as p17 matrix protein, produced by proteolytic cleavage from the N-terminal end of Pr*55gag*. Myristoylation is required for virus assembly and production of infectious particles, whereas without the myristoyl moiety Pr*55gag* accumulates in infected cells and processing into mature virion structures is prevented. Myristoylation by N-myristoylCoA transferase (NMT) is an irreversible process specific to the N-terminal amino acid glycine of the proteins, part of a chain of events that drives proteins to their functional site (8–10,15–17) (see Fig. 1).

LIPID ANALOGS AND PRODRUGS ACT ON RETROVIRUS INFECTION

Cytotoxic T-lymphocyte (CTL) response. Possible mechanisms whereby HIV causes CD4+ T-cell depletion, as well as the influence of host cell factors on the disease process have been extensively debated (18), although the role of lipids is rarely documented. However, the ability of SUgp120 (virus surface glycoprotein) to transduce an activation signal directly in monocytes, resulting in the production of polyunsaturated acid metabolites, may affect the immune system. Prostaglandin E2 (PGE2), an arachidonic acid metabolite, is a suppressor of immune function, as demonstrated *in vitro* by its ability to inhibit the lymphokine production and the natural killer CTL proliferation (19). Conjugated linoleic acid-supplemented mice have higher splenocyte interleukin-2 production than those fed a control diet (20).

Subunits of purified SUgp120 peptides are inducers of antibody response but are less immunogenic unless associated with lipids. Generation of a long CTL response in mice is obtained by injecting lipopeptides of different amino acid sequences in association with 2-amino-hexadecanoic acid. CTL response of long duration can also be obtained from SUgp120 peptides injected in association with DAG derivatives, suggesting that DAG derivatives enhance the production of peptide-specific antibodies (21–23).

Stimulation of anti-HIV activity.

(i) Inhibition of the viral reverse transcriptase (RT). Zidovudine (AZT), didanosine (ddI), zalcitabine (ddC), and several other nucleosides are reference RT inhibition therapies. Certain lipid molecules strengthen their activity.

Ether lipids (EL) inhibitors of CD4 receptor phosphorylation. EL are membrane-targeted therapeutic agents that inhibit the production of infectious viruses. The lipophilic nature of EL-AZT conjugates permits large amounts of anti-RT to penetrate cells and be active, while the EL portion hinders phosphorylation of CD4 receptors by inhibiting protein kinase C (PKC). This results from a fall in DAG, the PKC activators, by inhibition of the PI-PLC. The replacement of long alkyl chains with aromatic groups in oxyalkyl ether phospholipid-AZT conjugates leads to even more potent compounds, less toxic than AZT for human T-lymphocytes (CEM) in culture. INK 14, a lipid-AZT conjugate in which AZT replaces choline in INK-3, a PC with two medium-chain fatty acids (12 and 8 carbon atoms), gives the highest selective index of activity against HIV-1 replication in CEM cells and also in a clinical isolate of peripheral blood leukocytes (24–26).

Phospholipid analogs as inhibitors of syncytium formation. CP-51 (1-octadecanamido-2-ethoxypropyl-*rac*-3-phosphocholine), one of the membrane interactive phospholipids, inhibits SUgp120 binding to CD4 receptors, bringing about an alteration of surface membranes. CP-92, the CP-51 covalent conjugate to AZT (1-octadecanamido-2-ethoxypropyl-*rac*-3-phospho-3′-azido-3′-deoxythymidine), combines the effects of AZT and the phospholipid analog and has greater potency than the free drug on inhibition of syncytium formation in infected cells (27).

Lipids and vitamins that increase anti-RT activity of the Cordycepin trimer. The 3′-deoxyadenosine (cordycepin) is extracted from *Cordyceps militaris,* and its d3 trimer core (A2′p5′A2′p5′A) provokes RT inhibition. The 2′-O- and 5′-O-cholesterol conjugates of (2′-5′)d3(A-A-A) display a highly increased (× 1000) anti-HIV-1 activity. Covalent conjugation of vitamin A, D_2, or E and palmitoyl or hexadecyl lipids to the 2′- or 5′-OH group of the trimer core supplies

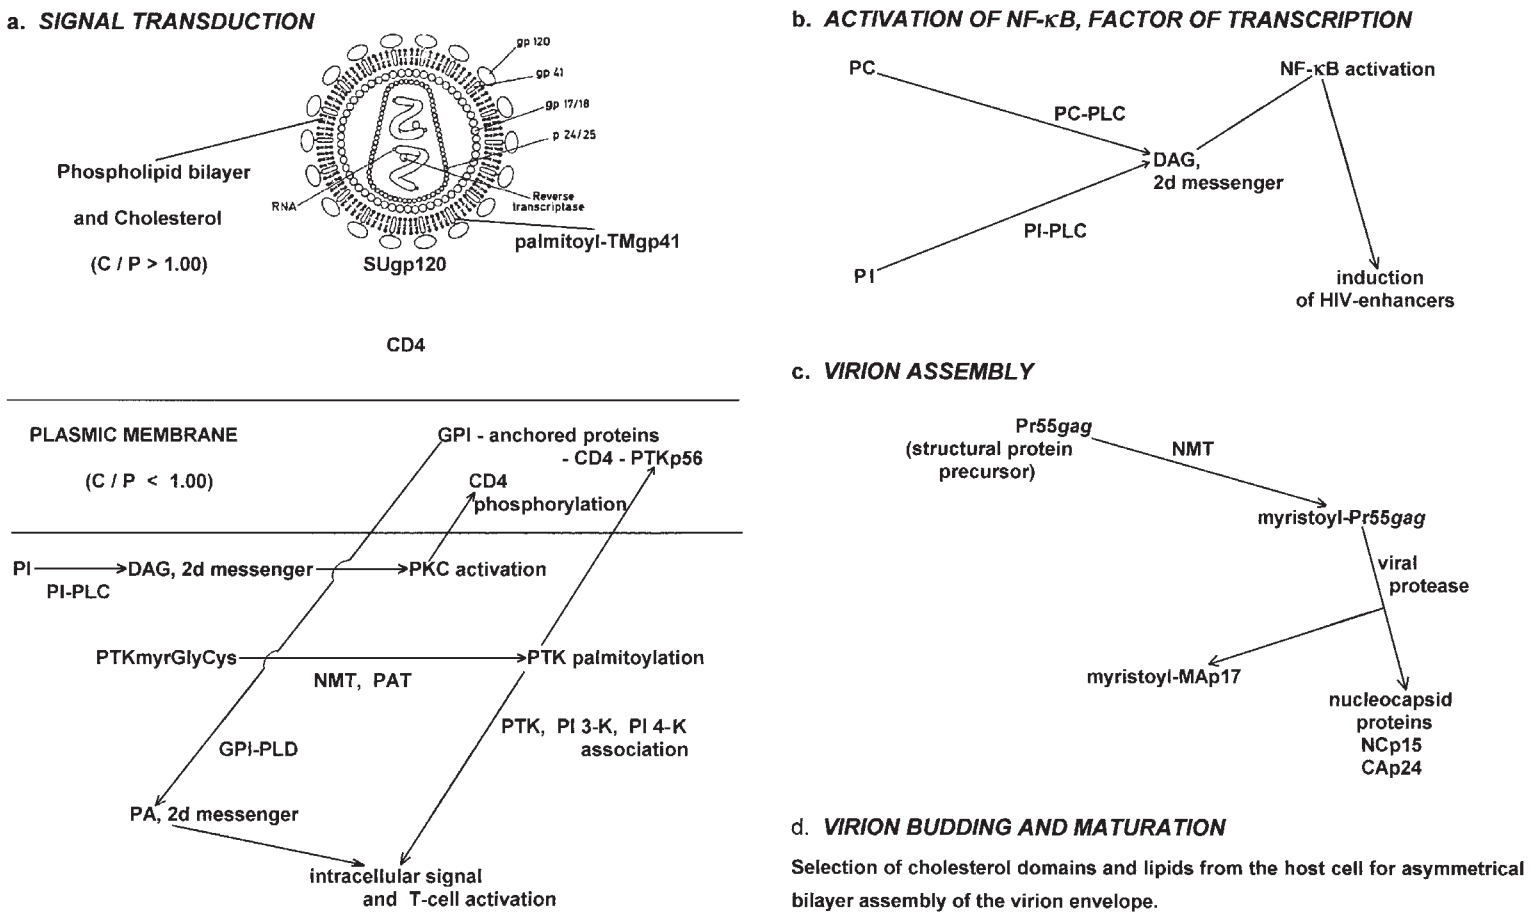

FIG. 1. Retroviruses and host cell lipid metabolism. The schematic representation of an enveloped virus particle and the accompanying legend were published by Hoestra, D., and de Lima, M.C.P. (1992) in *Membrane Interactions of HIV* (Aloia, R.C., and Curtain, C.C., eds.). Reprinted by permission of Wiley-Liss, Inc., a subsidiary or John Wiley & Sons, Inc. The structure of an HIV particle is shown in cross section. In general, the viral envelope consists of a lipid bilayer, commonly containing very few virus-specific membrane glycoproteins. These proteins can be distinguished by the electron microscope as "spikes." For HIV, this spike consists of protein gp160, which is composed of two subunits, gp120 (the knob of the spike) and gp41, the transmembrane part that anchors the protein to the membrane. Abbreviations: (a) C/P, cholesterol/phospholipid molar ratio; CD4, transmembrane glycoprotein, present in T-helper cells; DAG, diacylglycerol, second messenger; GPI, glycan phosphatidylinositol; PA, phosphatidic acid, second messenger; PC, phosphatidylcholine; PI, phosphatidylinositol; SUgp120, virus surface glycoprotein. (b) GPI-PLD, glycosyl phosphatidylinositol-phospholipase D—production of PA from GPI; HIV, human immunodeficiency virus; NF-κB, transcription factor: after activation and translocation from cytoplasm to nucleus, interacts with long terminal repeats and determines initiation of provirus transcription into the host cell DNA; NMT, N-myristoylCoA transferase: irreversible process specific to N-terminal amino-acid glycine of proteins, critical for PTK association with GPI-anchored proteins; PAT, N-palmitoylacyl transferase: reversible modification along with amino-terminal of glycine; PC-PLC, phosphatidylcholine phospholipase C: production of DAG from PC; PI 3-K, phosphatidylinositol 3-kinase; PI 4-K, phosphatidylinositol 4-kinase; PI-PLC, phosphatidylinositol phospholipase C; PKC, protein kinase C—phosphorylation of CD4 receptors; PTKp56, protein tyrosine kinase C; PTKmyr GlyCys, palmitoylation of PTKp56 on N-terminal cysteine residues after myristoylation on N-terminal glycine residues.

new series of inhibitors, active both on syncytium virus-induced formation and HIV-1 replication (28).

(ii) Inhibition of the viral polymerase. Phosphonoformate (PFA), a viral polymerase inhibitor, displays much greater anti-HIV-1 activity when coupled to *sn*-3-hydroxyl of the 1-*O*-octadecyl-*sn*-glycerol (ODG). Twenty-four hours after the addition of ODG-PFA, drug uptake by cells in culture is greater than after the addition of free PFA, while the antiviral effect is much increased. The marked increase in antiviral activity (43- to 93-fold) was observed on a large panel of viruses and retroviruses. Further studies are required to establish whether the lipid prodrug can significantly reduce PFA toxicity (29–31).

(iii) Inhibition of the viral aspartyl protease. Aspartyl protease of HIV is an important target for chemotherapeutic intervention, given its key role in cleaving the surface polyprotein during retrovirion assembly and budding. Antiprotease drugs are efficiently used in multitherapy.

Phospholipids—pentapeptide antiprotease prodrugs. C-terminal or N-terminal derivatization of the antiprotease Nr. *7194* pentapeptide, with a phosphatidylethanolamine to make the Nr. *7196* prodrug, does not interfere with pentapeptide activity *in vitro* (32). Cellular phospholipases A and/or C and phosphodiesterases catalyze the breakdown of the lipid portion, freeing the peptide to interact with the viral protease. Its slow removal from circulation suggests that phospholipid derivatives provide high levels of available material and may provide advantageous distribution *in vivo* (32).

Substituted myristic acid and 12-methoxydodecanoic acid (12MO)-AZT. Heteroatom analogs of myristic acid, containing oxygen or sulfur substituted for an alkyl methylene group,

have been reported to exhibit potent activity against HIV replication in infected cells. The compound 12MO is easily incorporated into host cell and retroviral proteins, bringing about inhibition of HIV polyprotein proteolysis. The potent anti-HIV activity of such myristic acid analogs can last for several days. L-AC2, a PC containing two 12MO, is synergistic with AZT, owing to the combined effects on the proteolytic processing and RT activity. On the other hand, the half-life of D-AC2 is higher than the half-life of its L-AC2 isomer, while yielding the same antiviral activity. Moreover, since phospholipase A2 cannot be active on D-isomers, D-AC2 does not undergo rapid degradation *in vivo*, and oral prescription of such conjugates might be considered (33–35) (Table 1).

CARDIOLIPIN–CARNITINE ASSOCIATION PRESERVES MITOCHONDRIA FROM MYOPATHY DUE TO LONG-TERM ANTIVIRAL THERAPY

Patients with acquired immune deficiency syndrome (AIDS) under long-term antiviral therapy incur the risk of mitochondrial myopathy. Mitochondria are structurally abnormal and functionally impaired, uncoupled and with lesser mtDNA and cytochromes. Human muscle cells exposed *in vitro* to AZT, ddI, or ddC show decreased proliferation and differentiation, lipid droplet and lysosome accumulation, increased lactate production, and decreased cytochrome c oxidase and succinate dehydrogenase. Added L-carnitine interacts with cardiolipins and preserves mitochondria (36–40). Besides the improvement of long-chain fatty acylCoA transport, protein synthesis is reinduced in cells, while lipid droplets disappear. Moreover, the number of lysosomes is reduced and the muscle cell proliferation and functions are restored *in vitro* (36–40).

TRANSPORT OF INHIBITORS

Liposomes are taken up by macrophages, the reservoirs for dissemination of HIV in the immune system, and they function as a carrier matrix in which HIV inhibitors are targeted to infected cells. Therefore, encapsulation in liposomes can improve anti-HIV drug delivery within cells that play a central role in HIV pathogenesis. Liposomal ddC, containing dipalmitoyl-PC/dicetylphosphate/cholesterol in a molar ratio of 4:1:5, is rapidly taken up by macrophages, whereas free ddC accumulates more slowly. HIV-1-induced cell fusion is critically dependent on liposome composition (41). The highest rate and extent are obtained with pure cardiolipin liposomes; pretreatment with cardiolipin liposomes much reduces HIV-1 infectivity. Liposomes appear to be an effective means of delivering an HIV inhibitor such as L-689,502 (42), since HIV protease acts at the membrane level during the last stages of the virion formation (43).

ALTERATION OF CELLULAR LIPIDS DUE TO THE RETROVIRUS INFECTION

Enhanced synthesis of neutral lipids is the primary effect of HIV infection and a consequence of diminished cell viability. Changes in cellular lipid composition have been characterized by a shift from phospholipid synthesis to neutral lipid synthesis. Prior to virus progeny production, during the eclipse period, host cell lipid synthesis is unaltered but is significantly changed when new viral proteins are detectable. In stages II and III of infection, all the metabolic routes are abnormal, and the metabolic indicators can be correlated with changes in the production of cytokines and steroid hormones. The resulting hypertriglyceridemia is one of the causes of cachexia and dementia, also facilitated by changes in cholesterol metabolism (44–46).

Phospholipids are especially susceptible to peroxidation in HIV-infected human T-cells. PGE2 and leukotriene B4 are products of eicosanoid metabolism, either through the cyclooxygenase or lipoxygenase pathway. Cyclooxygenase products of arachidonic acid are produced in excess by HIV-infected cells, and increased amounts of PGE2 are released by monocytes from HIV-1 infected patients, which lends support to the relevance of this lipid mediator in HIV infection (19,47–49). Moreover, there is a correlation between retroviral gene expression and the decreased level of antioxidants

TABLE 1
Alteration by Lipid Compounds of Cellular and Retroviral Enzyme Pathways. Stimulation of Drug Effectiveness[a]

Lipid compounds	Target	Impact	Inhibition of cellular enzyme activity
Ether lipids with alkyl or aryl group	PI-PLC	DAG generation	PKC activation, CD4 phosphorylation
Substituted myristic acid	GPI-PLD	PA generation	Signaling
	NMT, and PAT	PTK palmitoylation	CD4-PTK-GPI anchored protein complex
	NMT	Pr55*gag* myristoylation	Cleavage and maturation of structural proteins
			Enhancement of antiviral enzyme inhibition
Phospholipid analogs, ether lipids, cholesterol, fatty acyl-, vitamine A,E,D			Anti-RT nucleosides (AZT, ddC, ddI, Cordycepin)
sn-3-OH of 1-*O*-octadecyl-*sn*-glycerol			Anti-polymerase phosphonoformate
Phosphatidylethanolamine			Antiprotease
12MO (substituted myristic acid) incorporation into phosphatidylcholine			Antiprotease and synergism with anti-RT (AZT)

[a]Abbreviations: PI-PLC, phosphatidylinositol-phospholipase C; DAG, diacylglycerol; PKC, protein kinase C; CD4, a transmembrane glycoprotein present in T-helper cells; GPI-PLD, glycan phosphatidylinositol-phospholipase D; PA, phosphatidic acid; NMT, N-myristoylCoA transferase; PAT, N-palmitoylacyl transferase; PTK, protein-tyrosine kinase; RT, reverse transcriptase; AZT, zidovudine; ddC, zalcitabine; ddI,didanosine; Cordycepin, 3′-deoxyadenosine; 12MO, 12-methoxydodecanoic acid.

thioredoxin, superoxide dismutase, and catalase. In response to extracellular stimuli, reactive oxygen species (ROS) accumulate in cells. T-cells localized in, or passing through infected lymphoid tissues, are exposed to ROS released by activated phagocytic and inflammatory cells. The formation of lipid peroxides may trigger "activation-induced death" of HIV-infected, antioxidant-deficient T-cells (50,51). One of the primary signals for both the inflammatory response and T-cell susceptibility to apoptosis is the rapid breakdown of SM to CER (52–54).

On the other hand, one of the unsaturated fatty acid derivatives, the redox couple α-lipoic-dihydrolipoic acids (55,56), prevents activation of the NF-κB transcription factor and HIV replication, which are regulated by oxidative stress, in infected cells (57). In a pilot study conducted on HIV-positive men receiving oral doses of α-lipoate, plasmatic factors were improved and the number of T-helper cells was increased (57).

DISCUSSION

Control of genetic expression by exogenous lipids has been described for a long time in animals (58,59). Although nothing identical has been described for retroviruses, lipid compounds, analogs, and derivatives affect the retrovirus life cycle and infectivity. Given their structural and dynamic roles, lipids exert control on syncytium formation between infected and uninfected cells (27). Lipid control is observed at various levels: cytokine production by host cells (20,60), inhibition of viral RT (24–26), polymerase (29–31), and protease (32). Interestingly, the HIV-RT inhibitory effect is obtained from the diether sulfated glycolipid KN-208, the major component of the archaebacterium cell membrane (61).

The cell activation cascade during infection involves lipid messengers (11–13) including PAF, PA, CER, DAG, and small lipid derivatives, such as the redox couple α-lipoic-dihydrolipoic acid (55,56) that prevents oxidative stress due to virus infection and then, inhibits activation of NF-κB transcription factor (57). On the other hand, subunits of SUgp120 peptides, inducers of antibody response, bring about longer CTL response in mice when injected along with lipopeptides prepared from DAG derivatives (21–23).

In their huge role in the tissues, including brain (62), lipid kinases and transferases actually participate in retrovirus infectivity (6–10). Palmitoylation of amino-terminal cysteine residues by PAT, together with myristoylation of amino-terminal glycine residues by NMT, enables the association of PTK with GPI-anchored proteins. Viral Pr55*gag* is myristoylated, as is p17 matrix protein that has been proteolytically cleaved from N-terminal end of Pr55*gag*. Myristoylation is required for virion assembly and production of infectious particles. Without the myristoyl moiety, processing into mature virion structures is prevented. Given the importance of acylating steps in retrovirus replication, the development of specific inhibitors of protein acylation appears desirable. Fortunately, myristic acid analogs, well incorporated both in the virion and cell membranes, have already been prepared (33–35).

Apart from the improved transport when an antiviral drug is enclosed in liposomes, and especially in cardiolipin liposomes conjugated with anti-RT or antiprotease (41–43), a number of lipid molecules enhance antiviral effectiveness. This was shown with phospholipids and analogs (27,32), ether lipids (24–26), oxysterols (63), fatty acyl-CoA, vitamins (28), lipid prodrugs of phosphonoacids (29–31), and substituted or heteroatom analogs of myristic acid (33–35). However, a long-term antiviral treatment can induce mitochondrial myopathy. *In vitro*, the addition of L-carnitine to cultures of human myotubes reduces, and even prevents this side effect. The cardiolipin–carnitine association preserves mitochondrial functions and acts in protein synthesis and myotube proliferation (36–40).

As enhanced retrovirus replication is associated with an increased level in CER, therapeutic strategies aimed at down-modulating intracellular CER may slow the progression of HIV infection (64). On the other hand, a glycolipid (GalAAG) related but not identical to galactosylCER has been described at the surface membrane of human spermatozoa, despite plasmatic suppression of HIV-1 RNA. This glycolipid, able to bind gp120, could function as an alternative receptor for HIV and might be an additional target for multitherapy (65–67).

There is a need for new inhibitors of retrovirus infectivity with less toxicity and without such side effects as lipodystrophy, as recently described (68–71). Therefore, further studies should help to elucidate mechanisms of the lipid and cholesterol incorporation into the retroviral envelopes and their control.

ACKNOWLEDGMENTS

The author wishes to express warm thanks to Dr. Joyce L. Beare-Rogers, Department of Health and Welfare, Ottawa, Ontario, Canada, for her comments and for the scrupulous reviewing of the manuscript.

APPENDIX (SEE ALSO REF. 77)

Retroviruses, a single-stranded RNA virus subfamily: Lentiviruses (including HIV), oncoviruses, and spumaviruses.

Organization: 62% proteins (p) and glycoproteins (gp), 3% nucleic acids (dimer RNA), and 35% lipids (mostly phospholipid bilayer and cholesterol in the retrovirus envelope).

Protein and glycoprotein nomenclature: SUgp120 (surface), TMgp41 (transmembrane), MAp17 (matrix), NCp15 (nucleocapsid), CAp24 (capsid), and enzymes: RTp66 (reverse transcriptase), PRp12 (protease), INp32 (integrase).

RT activities: Reverse transcriptase, RNA and DNA matrix recognition, tRNA Lys3 primer recognition, DNA- and RNA-dependent DNA polymerase, endo- and exo-RNaseH, and double-helix denaturation.

Virion budding and maturation: After SUgp120 binding to T-lymphocyte CD4 receptors and fusion of membranes, the viral core is delivered into cell cytoplasm. Retroviral DNA is synthesized (RT and polymerase activity) using viral RNA as a matrix, and hydrolyzed afterward (RNase activity). Provirion (retroviral DNA) is then integrated into a host cell's chromo-

some (IN activity) and retranscripted to genomic RNA and mRNA, thus generating new viral proteins. Virion leaves the host cell by budding, after maturation of various structural proteins (protease), assemblage at the plasma membrane, and wrapped in its envelope (see also Ref. 77).

ABSTRACT: This paper deals with the reanalysis of serum lipids from previous studies in which deuterated fatty acids were administered to a single person. Samples were reanalyzed to determine if the deuterated fatty acids were converted to deuterium-labeled conjugated linoleic acid (CLA, 9*c*,11*t*-18:2) or other CLA isomers. We found 11-*trans*-octadecenoate (fed as the triglyceride) was converted (Δ9 desaturase) to CLA, at a CLA enrichment of *ca.* 30%. The 11-*cis*-octadecenoate isomer was also converted to 9*c*,11*c*-18:2, but at <10% the concentration of the 11*t*-18:1 isomer. No evidence (within our limits of detection) for conversion of 10-*cis*- or 10-*trans*-octadecenoate to the 10,12-CLA isomers (Δ12 desaturase) was found. No evidence for the conversion of 9-*cis*,12-*cis*-octadecadienoate to CLA (*via* isomerase enzyme) was found. Although these data come from four single human subject studies, data from some 30 similar human studies have convinced us that the existence of a metabolic pathway in one subject may be extrapolated to the normal adult population.

Paper no. L8342 in *Lipids 35,* 131–135 (February 2000).

Conjugated linoleic acid (CLA; 9-*cis*,11-*trans*-octadecadienoic acid; 9*c*,11*t*-18:2) has been associated with the reduction of chemically induced cancers in mice and rats and the suppression of atherosclerosis in rats (1–3). Whereas commercially available samples of CLA usually contain a mixture of conjugated fatty acid (FA) isomers (4,5), the 9-*cis*,11-*trans*-octadecadienoic acid isomer is considered to be the active constituent (6). Rats fed 11*t*-18:1 were shown to have increased levels of CLA in their tissues (7), and the presence of a similar metabolic pathway (11*t*-18:1 → 9*c*,11*t*-18:2 *via* Δ9 desaturase enzyme) has been suggested to occur in humans (8–11). Furthermore, Chin *et al.* (12) demonstrated that both the 9*c*,11*t*- and 10*t*,12*c*-18:2 FA isomers are produced in conventional, but not germ-free, rats fed linoleic acid and described the conversion of 9*c*,12*c*-18:2 to 9*c*,11*t*-18:2. (See Reference 13 for an extensive review of CLA biosynthesis.)

This study was undertaken to determine if, as postulated, detectable amounts [defined as present at >2 ng fatty acid methyl esters (FAME)/mL plasma] of the previously mentioned FA are actually converted to CLA or CLA isomers (i.e., 10*t*,12*c*-18:2) in humans. Samples from human metabolism studies in which deuterium-labeled fats were fed as triglycerides (TG) were reanalyzed for evidence of the following conversions: (i) 11*c*-18:1 to 9*c*,11*c*-18:2, (ii) 11*t*-18:1 to 9*c*,11*t*-18:2, (iii) 10*c*-18:1 to 10*c*,12*c*-18:2, (iv) 10*t*-18:1 to 10*t*,12*c*-18:2, and (v) 9*c*,12*c*-18:2 to 9*c*,11*t*-18:2. [The deuterium label is nonradioactive; thus deuterium-labeled fats can be safely fed to human volunteers (14–16).] Since conjugated 18:2 FAME isomers tend to elute by gas chromatography (GC) later than their methylene-interrupted analogs, the time windows set for selective ion monitoring in the original GC/mass spectrometry (MS) studies (Table 1) were not set to detect the CLA ions. By reanalysis of relevant samples, we were able to demonstrate the existence or absence of these biosynthetic pathways in humans. It must again be emphasized that each study is limited to a single human subject.

EXPERIMENTAL PROCEDURES

Materials. All reagents used were analytical grade or better.

Procedures/equipment. (i) Protocol of original studies. Complete details may be found in References 17–21. In these studies (designated I, II, III, and IV in Table 1), subjects were fed milkshakes containing a mixture of 8–10 g (studies I, II, III) or 2.5 g (study IV) each of 3–5 deuterium-labeled FA. The labeled fats were fed as homogeneous TG. (See Table 1 for spe-

E-mail: adlofro@mail.ncaur.usda.gov

cific fats fed.) Blood samples were collected by venipuncture at specified intervals (i.e., 0, 2, 4, 8, 12, 15, 24, 48 h), and the red blood cells were removed by centrifugation. One portion of the blood plasma was extracted with $CHCl_3$/methanol to obtain total plasma lipids, from which the neutral and phospholipid (PL) classes were separated by preparative thin-layer chromatography (TLC). An internal standard (17:0) was added to each fraction. The lipids in each fraction were converted to FAME with HCl/methanol (22), and each fraction was analyzed by GC to obtain total lipid composition and by GC/MS [chemical ionization conditions with isobutane as the reagent gas and selective ion monitoring (23,24)] to determine the deuterium-labeled FA composition. The blood lipid FAME samples were stored in isooctane under nitrogen gas in 1-dram vials (aluminum foil-lined caps) at 0°C (in the dark).

(ii) Sample selection. To maximize GC/MS sensitivity, samples were taken from studies in which the fats of interest fed were labeled with four or more deuterium atoms. The carbon-13 isotope contribution to the MS data for FA labeled with two deuterium atoms must be calculated, resulting in some loss of sensitivity. Given the low (0.1–0.3%) levels of CLA isomers present, the authors felt the highest sensitivity/accuracy would be obtained by analyzing for fats labeled with four or more deuterium atoms. A representative grouping of 4–6 blood lipid samples (plasma TG/PL or chylomicron TG/PL) from each of four different human metabolism studies were retrieved. The date of the study, the FA fed and pertinent publications resulting from these studies are listed in Table 1.

(iii) Sample preparation. Each sample was eluted through a Sep- Pak cartridge (Waters, Inc., Milford, MA) with 10 mL 10% ethyl ether (EE) in petroleum ether (PE; vol/vol) as solvent. The eluant was concentrated to 0.5 mL under a stream of inert gas and analyzed by TLC (Silica gel 60A, Whatman, Inc., Clifton, NJ), using 15% EE/85% PE as solvent and with I_2 visualization. The remaining solvents were removed by a stream of inert gas, and the residue was transferred to a sample vial with a minimal volume of isooctane for analysis by GC.

(iv) Blood lipid fraction analysis by GC. Samples (as FAME) were initially analyzed on a Varian 3400 GC (Varian Instruments, Palo Alto, CA) to obtain a total lipid profile. The GC was equipped with a 100 m × 0.32 mm SP2380 (Supelco, Inc., Bellefonte, PA) capillary column and flame-ionization detector (FID). Helium was utilized as carrier gas. Unknown peaks were identified by comparison with standard FAME mixtures of known composition. The extent of sample oxidation was estimated by comparing saturated and polyunsaturated FA compositions from our GC results with the original published data.

(v) GC/MS analysis of blood lipid fractions. GC/MS was utilized to determine the presence (or absence) of deuterium-labeled CLA and other deuterium-labeled metabolites. Analyses were made on a Hewlett-Packard model 5890/5988a GC/MS (quadrapole; positive chemical ionization mode; isobutane as ionizing gas; Palo Alto, CA) equipped with a 30 m × 0.25 mm Omegawax 10 fused-silica capillary column (Supelco, Inc.), Data collection and processing have been described previously (23). The isomerization of conjugated FA during their conversion to FAME by acidic catalysts such as HCl or BF_3 in methanol has been well documented (5,25). Since 5% HCl in methanol (at 50°C) had initially been used to convert the blood lipids to FAME (22), the 9*c*,11*t*- and 9*t*,11*t*-18:2-d_4 and -d_0 peak areas were combined to calculate total concentrations of labeled and unlabeled CLA, respectively. If deuterium-labeled CLA was detected, additional samples from that study were retrieved and prepared for analysis by GC and GC/MS as described previously.

RESULTS

Only in study I (in which 11*c*-18:1-d_6 and 11*t*-18:1-d_4 were fed) were deuterium-labeled CLA isomers detected in measurable (>2 ng FAME/mL plasma) quantities. Four samples (0-, 4-, 8-, and 15-h) of blood plasma TG (as FAME) were retrieved and reanalyzed by GC and GC/MS to provide the data presented in this study. A portion of a gas chromatogram (100 m SP2380 capillary column) containing the CLA isomers is shown in Figure 1. Peaks have been identified by coinjection with known standards or marked as "unknown."

The percentage of 9*t*,11*t*-18:2 formed during conversion (HCl/methanol) of the blood TG fractions to FAME varied significantly (from 10 to *ca.* 50% of total CLA concentration) from sample to sample. This amount of isomerization is typical when HCl/methanol or BF_3/methanol and 50°C are used to convert CLA-containing TG, PL, or free FA to FAME. The two peak areas were combined to calculate total % CLA. A representative GC/MS chromatogram, with the peaks of interest labeled, of the CLA region for the 4-h plasma TG sample is presented in Figure 2. As we demonstrate in Figure 2, the presence of deuterium-labeled CLA and CLA isomers may readily be detected by our methodology. The 9*c*,11*c*-18:2 isomer is also present, but at <0.01%. We also characterized the separation

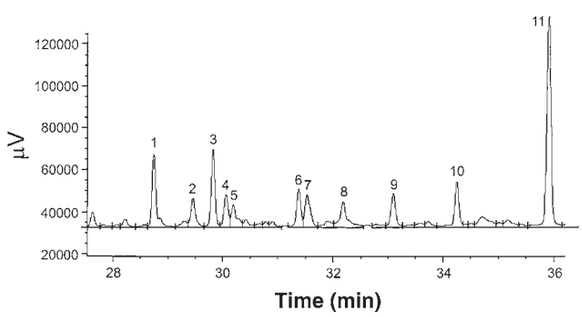

FIG. 1. Portion of gas chromatography trace (100 m SP2380 capillary column; Supelco Inc., Bellefonte, PA) with conjugated linoleic acid (CLA) and other minor (<1% each by weight total lipids) fatty acid methyl esters marked. (See Experimental Procedures section for details.) Designations: peak no. 1 = 6*c*,9*c*,12*c*-18:3; peak no. 2 = 11*c*-20:1, peak no. 3 = 9*c*,12*c*,15*c*-18:3; peak no. 4 = 9*c*,11*t*-18:2; peak no. 5 = 21:0; peak no. 6 = 9*t*,11*t*-18:2; peak no. 7 = unknown (8*c*,11*c*-20:2?); peak no. 8 = 11*c*,14*c*-20:2; peak no. 9 = 22:0; peak no. 10 = 8*c*,11*c*,14*c*-20:3; peak no. 11 = 5*c*,8*c*,11*c*,14*c*-20:4.

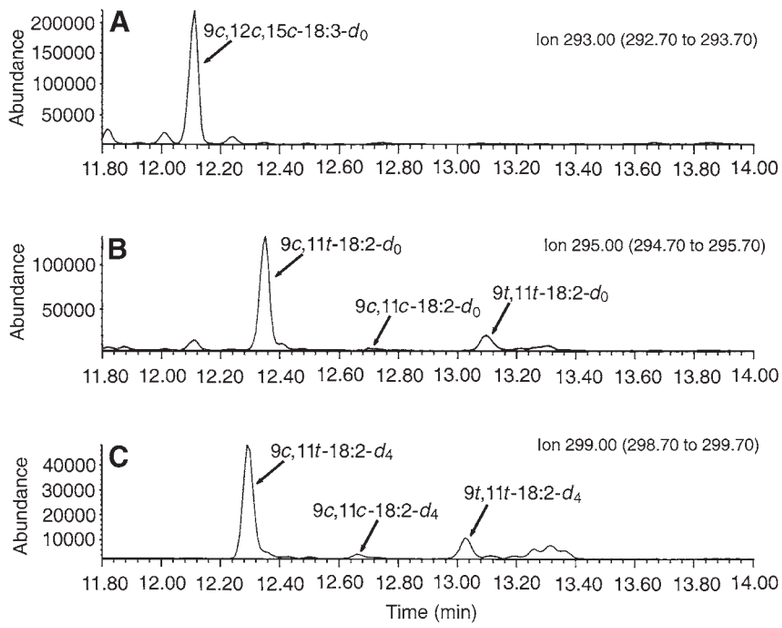

FIG. 2. Portion of gas chromatography/mass spectrometry chromatogram illustrating selective ion monitoring at molecular weights 292, 294, and 298 (molecular ions of 293, 295, and 299), corresponding to 18:3n-3-d_0, 9*c*,11*t*-18:2-d_0, and 9*c*,11*t*-18:2-d_4, respectively. (See Experimental Procedures section for details.)

capabilities of the Omegawax GC column by injecting a mixture of 9,11- and 10,12-18:2 FAME isomers. Under the GC conditions employed (see the Experimental Procedures section), we found the Omegawax column capable of achieving baseline separation of 9*c*,11*t*-18:2 and 10*t*,12*c*-18:2, the 9*c*-isomer eluting before the 10*t*-isomer. The 9*c*,11*c*-18:2 and 10*c*,12*c*-18:2 were only slightly resolved, with the 9*c*-isomer eluting first. The 9*t*,11*t*-18:2 and 10*t*,12*t*-18:2 isomer pair was not resolved.

The incorporation of 11*t*-18:1-d_4 and its conversion to CLA-d_4 and 9*t*-16:1-d_4 (formed by β-oxidation of 11*t*-18:1-d_4) are plotted (as enrichment data) in Figure 3. A small amount of 9*c*,11*c*-18:2-d_6 (from 11*c*-18:1-d_6 *via* Δ9 desaturase) was also detected at *ca.* 10% of the CLA-d_4 concentration. The total weight percentages of the isomers (labeled and unlabeled) plotted in Figure 3 are presented in Table 2.

DISCUSSION

After 10–20 yr in storage, some oxidation of the lipid samples was expected. Although some loss (2–5%) of polyunsaturated FA was noted, the overall lipid compositions were found to compare favorably with the original lipid data obtained by packed column GC (data not shown). A more limited selection of samples from studies II, III and IV was also analyzed for extent of oxidation. Since the oxidative stability of CLA has been reported to lie between arachidonic and docosahexaenoic acids (26), the 20:4 FA concentration was chosen as another marker for oxidation. The low concentration of this FA (0.8–2.2%), however, limited this approach. The formation of methoxy artifacts during the FAME preparation or the presence of plasticizers was also studied. By use of internal standards, we found methoxy artifacts to be formed at a total concentration of <0.5% during our HCl/methanol procedure. Plasticizers were also detected during our GC analyses, but at a total concentration of <0.01%. Any possible interference(s) due to methoxy artifacts or plasticizers were eliminated by use of selective ion monitoring (Fig. 2).

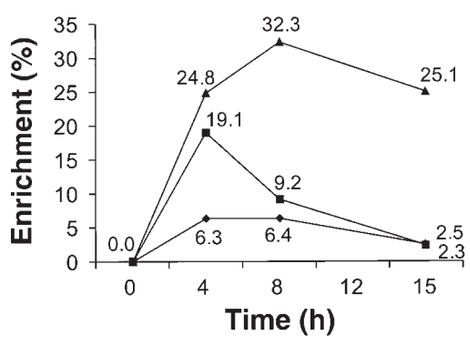

FIG. 3. Uptake and disappearance in plasma triglycerides of 11*t*-18:1-d_4 (■) related to formation and disappearance of 9*c*,11*t*-18:2-d_4 (▲) and 9*t*-16:1-d_4 (◆). Data plotted as percent isotopic enrichment within each individual fatty acid methyl ester.

[a]Total (deuterium-labeled and unlabeled) percentage of fatty acids. CLA, conjugated linoleic acid.

The only readily identifiable metabolic pathway for the biosynthesis of CLA in humans utilizes the Δ11-18:1 FA as precursors and, presumably, the Δ9 desaturase enzyme (10). As we demonstrated in study I (17), both the 9*c*-18:1 and the Δ11-18:1 isomers are equally well-absorbed in humans. The total percentage of CLA in blood plasma lipids 8 h after ingestion of more than 8 g of 11*t*-18:1 (fed as a homogeneous TG) was found to be only 0.3% by weight of total blood lipids. This number (0.3%) falls within the percentage composition ranges listed for CLA in blood lipids by Ackman (27) and Jiang *et al.* (28). At 33% enrichment, the CLA-d_4 was present at a maximum of only 0.1% (by weight) of total lipids. The presence of 9*c*,11*c*-18:2-14,14,15,15,17,18-d_6 at *ca.* 0.01% by weight suggests the existence of a similar, but less utilized, biosynthetic pathway for conversion of the 11*c*-18:1 isomer. No CLA-d_4 metabolites (6*c*,9*c*,11*t*-18:3-d_4 or 5*c*,8*c*,11*c*,13*t*-20:4-d_4) were detected. [In the original study (17), no metabolites of the Δ11-18:1 isomers were found (0.001% listed then as limit of detectability)].

It should again be stressed that a single human male was used in each of the feeding studies listed in Table I; the data thus cannot be statistically evaluated as representative of the normal population. The amounts of CLA formed from the 11*t*-18:1 isomer are expected to vary between individuals, but data from some 30 human studies have convinced us (17) that the existence of a metabolic pathway in one subject may be safely extrapolated to the normal adult population. Our results also agree with previous findings which show 9*c*,11*t*-18:1 to be "practically the only one of the CLA isomers found in humans" (10). Other postulated pathways for the biosynthesis of CLA isomers in humans (10*t*,12*c*-18:2 from 10*t*-18:1 or 10*c*,12*c*-18:2 from 10*c*-18:1, both by Δ12 desaturase) are still feasible but, if these isomers were formed, they were formed below the detection limits (again defined as <2 ng FAME/mL plasma) of our methodologies.

The conversion of 9*c*,12*c*-18:2 to CLA *via* an isomerase enzyme generated by bacteria in the human intestinal tract [as noted by Chin *et al.* in mice (12)] also remains a possibility, but any deuterium-labeled CLA formed in the human colon would be expected to be as poorly absorbed in the lower intestine of animals as are methylene-interrupted polyunsaturated FA (8). Previous studies in humans (19,29) have shown ingested 9*c*,12*c*-18:2 (as TG) to be >96% absorbed. Only a very small percentage of the labeled 9*c*,12*c*-18:2 fed would thus be available to bacteria in the intestine. Any metabolites formed *via* isomerization of 9*c*,12*c*-18:2 and absorbed in the lower intestine would again be present at levels below our limits of detection.

All other sources/pathways to explain the presence of deuterium-labeled CLA isomers (impurities in the fed materials, oxidation, etc.) in study I samples have been examined and eliminated. Utilizing isotopically labeled FA, we thus demonstrate the existence, in human(s), of a metabolic pathway for the biosynthesis of CLA. Since some oxidation may have occurred during storage, the concentrations of CLA presented in this manuscript should be considered at the low end of possible CLA levels in human plasma. The relatively large (>8 g) quantity of 11*t*-18:1 ingested also resulted in a relatively small increase in plasma CLA concentration (from 0.1 to 0.3% total lipids). Whether the amount of CLA formed from increased levels of 11*t*-18:1 in the diet will result in "positive health benefits" and a situation where "*trans* FA in dairy products represent a complete opposite situation to the possible adverse health effects of *trans* FA isomers from partially hydrogenated plant oils" (30) remains to be seen.

Effects of Dietary α-Linolenic Acid on the Conversion and Oxidation of ^{13}C-α-Linolenic Acid

Susanne H.F. Vermunt, Ronald P. Mensink*, Marianne M.G. Simonis, and Gerard Hornstra

Department of Human Biology, Maastricht University, 6200 MD, Maastricht, The Netherlands

ABSTRACT: The effects of a diet rich in α-linolenic acid vs. one rich in oleic acid on the oxidation of uniformly labeled ^{13}C-α-linolenic acid and its conversion into longer-chain polyunsaturates (LCP) were investigated *in vivo* in healthy human subjects. Volunteers received a diet rich in oleic acid (n = 5) or a diet rich in α-linolenic acid (n = 7; 8.3 g/d) for 6 wk before and during the study. After 6 wk, subjects were given 45 mg of ^{13}C-α-linolenic acid dissolved in olive oil. Blood samples were collected at t = 0, 5, 11, 24, 96, and 336 h. Breath was sampled and CO_2 production was measured each hour for the first 12 h. The mean (± SEM) maximal absolute amount of ^{13}C-eicosapentaenoic acid (EPA) in plasma total lipids was 0.04 ± 0.01 mg in the α-linolenic acid group, which was significantly lower (P = 0.01) than the amount of 0.12 ± 0.03 mg ^{13}C-EPA in the oleic acid group. Amounts of ^{13}C-docosapentaenoic acid (DPA) and ^{13}C-docosahexaenoic acid (DHA) tended to be lower as well. The mean proportion of labeled α-linolenic acid (ALA) recovered as $^{13}CO_2$ in breath after 12 h was 20.4% in the ALA and 15.7% in the oleic acid group, which was not significantly different (P = 0.12). The cumulative recovery of ^{13}C from ^{13}C-ALA in breath during the first 12 h was negatively correlated with the maximal amounts of plasma ^{13}C-EPA (r = –0.58, P = 0.047) and ^{13}C-DPA (r = –0.63, P = 0.027), but not of ^{13}C-DHA (r = –0.49, P = 0.108). In conclusion, conversion of ^{13}C-ALA into its LCP may be decreased on diets rich in ALA, while oxidation of ^{13}C-ALA is negatively correlated with its conversion into LCP. In a few pilot samples, low ^{13}C enrichments of n-3 LCP were observed in a diet rich in EPA/DHA as compared to oleic acid.

Paper no. L8240 in *Lipids 35*, 137–142 (February 2000).

Eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3) are important structural membrane components and play a major role in many physiological processes (1). These longer-chain polyunsaturated fatty acids (LCP) are not only provided by the diet, but can also be formed by alternate desaturation and elongation of α-linolenic acid (ALA; 18:3n-3), the parent essential fatty acid from the n-3 family. However, it is largely unknown to what extent this happens in humans.

From *in vitro* and rat studies with radioactive isotopes, it has been suggested that the conversion of ALA is positively related to the amount of substrate (ALA), but negatively to that of their LCP (EPA and DHA) (2,3). These results, however, have not been confirmed by others (4,5).

In humans, EPA and docosapentaenoic acid (DPA) concentrations increase after ALA consumption (6,7), while DHA concentrations are hardly affected (8). Fatty acid compositions of tissues, however, give no information about the origin of the fatty acids or their availability for conversion reactions. The introduction of stable isotopes has now created better opportunities to examine the *in vivo* metabolism of essential fatty acids in humans. So far, a few studies with deuterated ALA in adults (9–11) and infants (12), and some studies with ^{13}C labeled ALA in infants (13–15) have been carried out. These studies, however, only focused on the chain elongation and desaturation of ALA, although it is also possible to measure oxidation at the same time ^{13}C labeled fatty acids are used.

In the present study, we have therefore investigated the *in vivo* conversion of uniformly labeled ^{13}C-ALA into its LCP and its oxidation in healthy adults. In particular, the effects of a diet rich in ALA vs. a diet rich in oleic acid on ^{13}C-ALA metabolism have been examined. Finally, the relationship between the oxidation of ^{13}C-ALA and the conversion into LCP was studied. The effects of dietary EPA plus DHA on ^{13}C-ALA metabolism were examined in a pilot study.

EXPERIMENTAL PROCEDURES

Subjects. Fifteen subjects, both men and women (ages between 21 and 66 yr), who participated in an intervention trial on the effects of ALA and EPA/DHA on various cardiovascular risk markers (16), were asked to participate in this study. All subjects were healthy as indicated by a medical questionnaire and had fasting serum total cholesterol concentrations below 7.5 mmol/L and serum triacylglycerols below 3.0 mmol/L. None of the volunteers used medication or a diet known to affect fatty acid metabolism. Five of the participants smoked. Three younger women used oral contraceptives, while the elderly women were postmenopausal. The protocol had been approved by the local ethical committee and informed written consent was obtained from each volunteer.

Diets and experimental design. After a run-in period of 3 wk, in which all subjects consumed an oleic acid-rich diet,

Abbreviations: ALA, α-linolenic acid; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; FAME, fatty acid methyl esters; GC–C–IRMS, gas chromatography–combustion-isotope ratio mass spectrometer; GC–FID, gas chromatography–flame-ionization detector; LCP, long-chain polyunsaturated fatty acids.

the subjects were randomly allocated to three groups. The first group received for the following 7 wk the same diet they were given during the run-in period (n = 5); the second group received a diet rich in ALA (n = 7), while the third group received a diet rich in EPA plus DHA (n = 3). ALA and EPA/DHA replaced oleic acid. Fatty acids were provided as margarine from which pies, cakes, and chocolate paste were prepared. Subjects had to consume 30 g of the experimental fat daily. In order not to change energy intakes, the volunteers were required to replace their usual margarine, pastries, and sandwich spread with the experimental products provided in this study. Subjects in the oleic acid and ALA groups were not allowed to consume fatty fish during the whole study. Furthermore, subjects were urged not to change their background diets. The fatty acid compositions of the experimental margarines, which were prepared by Unilever Research (Vlaardingen, The Netherlands), have been presented elsewhere (16).

During the run-in and the experimental period, subjects recorded their food intake during the whole day for three consecutive days, one weekend, and two weekdays. After the food diary had been checked by a dietitian, foods were coded, and energy and nutrient intakes were calculated using the Dutch food composition table (17).

At wk 9, subjects came to the department at 8.00 A.M. after a fasting period of 12 h. First, a 10-mL blood sample was taken, whereafter 45 mg of uniformly labeled ^{13}C-ALA (isotopic purity >95% ^{13}C18:3n-3) was given as a methylester (Martek Biosciences Corp., Columbia, MD) dissolved in 8 g olive oil. Subjects were then given a breakfast, which consisted of 2 slices of white bread with jam. Two hours after ^{13}C-ALA intake, a second blood sample was taken, after which the subjects were allowed to eat and drink according to their respective dietary regimes. During the day, subjects stayed at the department and food was provided for the whole day. Other nonfasting blood samples were collected 2, 4, 6, 8, 10 and 12 h after the intake of labeled ALA, while fasting samples were taken after 24, 48, 72, 96, and 168 h. Subjects then returned to their usual diets and 1 wk later, a final fasting blood sample was taken at t = 336 h. At the same time points of blood sampling (except at t = 336 h and during the first day at t = 3, 5, 7, 9 and 11 h), a breath sample was taken. For this, subjects breathed for 5 min into a SensorMedics analyzer (SensorMedics 2900 analyzer, Anaheim, CA) in order to stabilize their breathing. For the next 5 min, CO_2 production was registered, after which a breath sample was taken. Breath samples were stored in vacutainers (Becton & Dickinson, Meylan, France).

Blood sampling and analysis. Until 12 h after ^{13}C-ALA administration, blood (10 mL) was sampled in an EDTA tube through a Teflon catheter (Baxter Quick Cath, Dupont, Ireland) or a vacuum tube using a 1.2-mm needle (Strauss Kanule; Luer, Wächtersbach, Germany) with the volunteer in a recumbent position. The catheter was flushed every hour with 1 mL heparin solution (0.5 IU heparin-sodium; Leo Pharmaceutical Products BV, Weesp, The Netherlands). The next fasting blood samples were taken with a vacuum tube. Plasma for ^{13}C enrichment analyses and analyses of fatty acid composition of total plasma lipids were obtained by centrifugation at 2,000 × g for 15 min at 4°C, within 1 h of venipuncture. Plasma samples were snap-frozen and stored at –80°C.

Lipids from plasma were extracted (18), using triheptadecanoate (17:0) as an internal standard. Thereafter, lipid extracts were hydrolyzed and the resulting fatty acids methylated (19). The absolute fatty acid composition in plasma total lipids was analyzed using a gas chromatograph with a flame-ionization detector (GC–FID) (PerkinElmer Autosystem, Norwalk, CT). Fatty acid methyl esters (FAME) were separated using a 50-m column (CP-SIL88, 0.25 mm, 0.20-μm film thickness; Chrompack, Middelburg, The Netherlands) with an injection temperature of 300°C. Helium gas was used as a carrier (injector inlet pressure 130 kPa). The oven was programmed from 160°C to 230°C in three temperature steps (160°C for 10 min, rise of 3.2°C min^{-1}, 190°C for 15 min, rise of 5°C min^{-1}, 230°C for 37 min).

^{13}C enrichments of individual FAME in total lipids from plasma and of CO_2 in breath were analyzed with a GC (Varian 3400) coupled to an isotope ratio mass spectrometer (IRMS; Finnigan MAT 252, Bremen, Germany) *via* a combustion interface. Samples were injected on a 50-m column (BPX70, 0.33 mm, 0.25-μm film thickness; SGE, Austin, TX) at a temperature of 250°C. Helium gas was used as a carrier (injector inlet pressure 124 kPa). For complete separation of the peaks, enrichments of the FAME were determined in two separate runs, as shown in the chromatograms in Figure 1. For 18:3n-3, 20:5n-3, and 22:6n-3, the oven was programmed from 185°C for 35 min (rise of 30°C min^{-1}) to 260°C for 33 min (Fig. 1A), and for 22:5n-3 from 205°C for 20 min (rise of 30°C min^{-1}) to 260°C for 25 min (Fig. 1B). The ^{13}C/^{12}C ratios were deter-

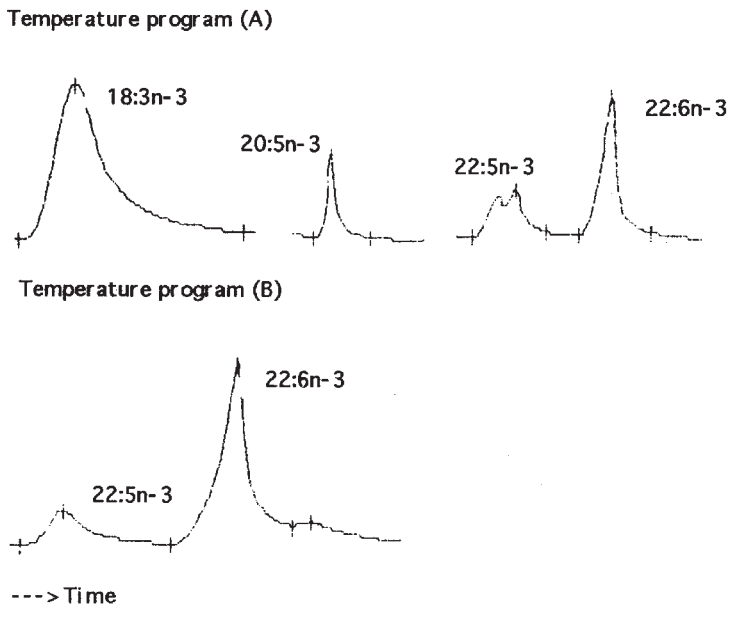

FIG. 1. Chromatograms showing the complete separation of the 18:3n-3, 20:5n-3, 22:5n-3, and 22:6n-3 peaks using gas chromatography–combustion-isotope ratio mass spectrometer. Temperature program (A): from 185°C for 35 min (rise of 30°C min^{-1}) to 260°C for 33 min for separation of 18:3n-3, 20:5n-3, and 22:6n-3; temperature program (B): from 205°C for 20 min (rise of 30°C min^{-1}) to 260°C for 25 min for separation of 22:5n-3.

mined with a precision of δ_{PDB}<1‰, while the reproducibility of the standard was δ_{PDB}<1‰.

Calculations. The difference between the $^{13}C/^{12}C$ ratio of the samples and a known reference standard was expressed as the delta ($\delta^{13}C$). The true ratio of the sample was then calculated by normalizing the isotopic enrichment ($\delta^{13}C$), against the international standard Pee Dee Belemate limestone (PDB), which has a $^{13}C/^{12}C$ ratio of 0.0112372. The concentration of a ^{13}C labeled fatty acid was calculated by correction for the plasma concentration of this particular fatty acid. It was assumed that during fatty acid elongation the two carbon-atom fragments added after elongation were not enriched above background. Absolute amounts of fatty acids were calculated based on a plasma volume of 4.5% of body weight (20).

Oxidation of ^{13}C-ALA was calculated from the $^{13}C/^{12}C$ ratio in breath and the absolute CO_2 production. From the second day after intake of ^{13}C-ALA onward, the CO_2 production was estimated only once a day. Since the determination of total $^{13}CO_2$ production during the day requires regular measurements of both ^{13}C enrichment and CO_2 production throughout the day, $^{13}CO_2$ production was calculated for the first 12 h only.

Statistical analyses. Results for the EPA/DHA group were not statistically analyzed as plasma ^{13}C-enrichments in n-3 fatty acids of only two subjects could be measured. Values of subjects within the other groups were averaged, and presented as means ± standard errors. For each subject, changes were calculated by subtracting baseline values ($t = 0$). Differences between the oleic acid group and the ALA group were tested with the Mann Whitney *U*-test. Spearman correlation coefficients were calculated to examine the relationship between the cumulative recovery of $^{13}CO_2$ in breath, derived from ^{13}C-ALA, and the maximal amount of plasma ^{13}C-labeled n-3 fatty acids. *P*-values are two-tailed, and differences were considered statistically significant when $P < 0.05$.

RESULTS

The mean daily energy and nutrient intakes are shown in Table 1. The mean supplemented daily ALA intake was significantly higher in the ALA (8.3 ± 1.3 g; 3.1 ± 0.4 energy%) as compared to the oleic acid group. Furthermore, the intake of protein and total polyunsaturated fatty acids differed between the groups.

First, plasma ^{13}C enrichments of all 13 plasma samples of four randomly chosen subjects, one or two from each intervention group, were analyzed. Results of one subject from the ALA group and one of the oleic acid group are shown in Figure 2. For ALA, results are presented for the first 24 h only, because values had nearly returned to baseline within 1 d. Results of EPA, DPA, and DHA are presented for 336 h. Based on these results, it was decided to analyze only samples from $t = 0$, 24, 96, and 336 h for the other 11 subjects so as to reduce the number of analyses to a more manageable quantity. In addition, samples from $t = 4$ and $t = 6$, and from $t = 10$ and $t = 12$ were pooled and analyzed. These samples are denoted as $t = 5$ and $t = 11$. In order to compare the results of the first four subjects with the others, the data from $t = 4$ and $t = 6$, and from $t = 10$ and $t = 12$ were averaged.

TABLE 1
Energy and Nutrient Intake at Baseline on Diets Rich in Oleic Acid or α-Linolenic Acid[a]

	Oleic acid group ($n = 5$)	ALA group ($n = 7$)
Energy (MJ/d)	9.5 ± 1.1	9.9 ± 0.6
Protein (En%)	15.0 ± 0.5	12.4 ± 0.8[b]
Fat (En%)	36.0 ± 2.7	38.3 ± 0.8
SAFA	12.1 ± 1.2	12.1 ± 0.5
MUFA	15.5 ± 1.6	14.5 ± 0.7
PUFA	6.0 ± 0.7	8.8 ± 0.7[b]
Linoleic acid	4.1 ± 0.7	4.5 ± 0.9
Carbohydrates (En%)	43.1 ± 3.1	46.9 ± 1.6
Alcohol (En%)	6.1 ± 1.5	2.5 ± 0.7
Cholesterol (mg/MJ)	16.1 ± 2.1	16.8 ± 3.1
Dietary fiber (g/MJ)	2.6 ± 0.5	1.8 ± 0.2

[a]Values are presented as mean ± SEM. Abbreviations: ALA, α-linolenic acid; SAFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.
[b]Denotes a significant difference between groups: $P < 0.05$.

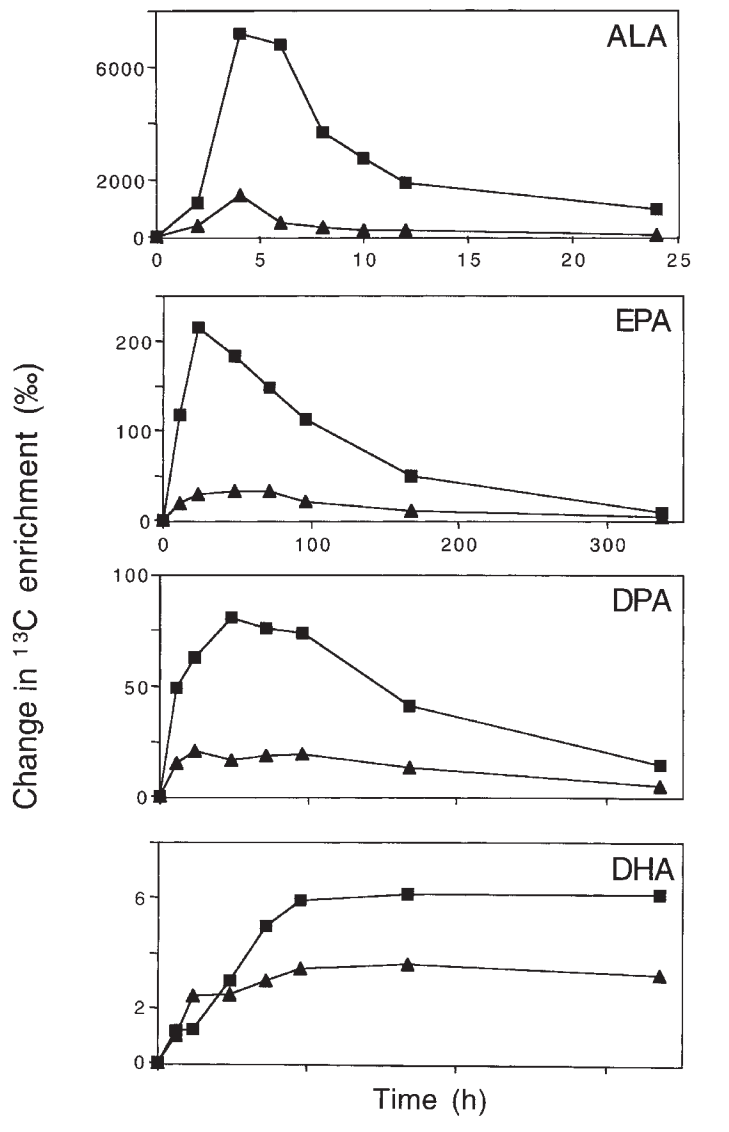

FIG. 2. Changes in plasma ^{13}C enrichments of ALA, EPA, DPA, and DHA after intake of a single dose of ^{13}C-ALA on diets rich in oleic acid (■) or ALA (▲) of two randomly chosen volunteers. Abbreviations: ALA, α-linolenic acid; EPA, eicosapentaenoic acid; DPA, docosapentaenoic acid; DHA, docosahexaenoic acid.

Enrichments. The changes in ^{13}C enrichments of ALA, EPA, DPA, and DHA are shown in Figure 3. Maximum changes in ^{13}C enrichment of ALA were reached after 5 h, followed by a rapid decrease. After 24 h, changes in ^{13}C enrichment were still about 15% of the maximal changes. Values had returned to baseline after 336 h (data not shown). The mean maximum ^{13}C enrichment of ALA relative to baseline in the ALA group was only 37% of that in the oleic acid diet. The ^{13}C enrichment peaks of EPA relative to baseline were much lower and were reached 19 h later than those of ALA. In the ALA group, maximal changes in ^{13}C enrichments of EPA were 43% of those in the oleic acid group. The ^{13}C enrichments of DPA hardly changed between 24 and 96 h in the ALA group. As compared to the oleic acid group, maximal changes in ^{13}C enrichment were 40% in the ALA group. After 336 h, ^{13}C enrichments of EPA and DPA had nearly returned to baseline values in both groups. Ninety-one hours after the ^{13}C enrichment peak of ALA, ^{13}C enrichment of DHA plateaued in both groups until after 336 h. The order of appearance of ^{13}C-labeled ALA, EPA, DPA, and DHA in plasma was thus in accordance with the conversion of ^{13}C ALA into its LCP.

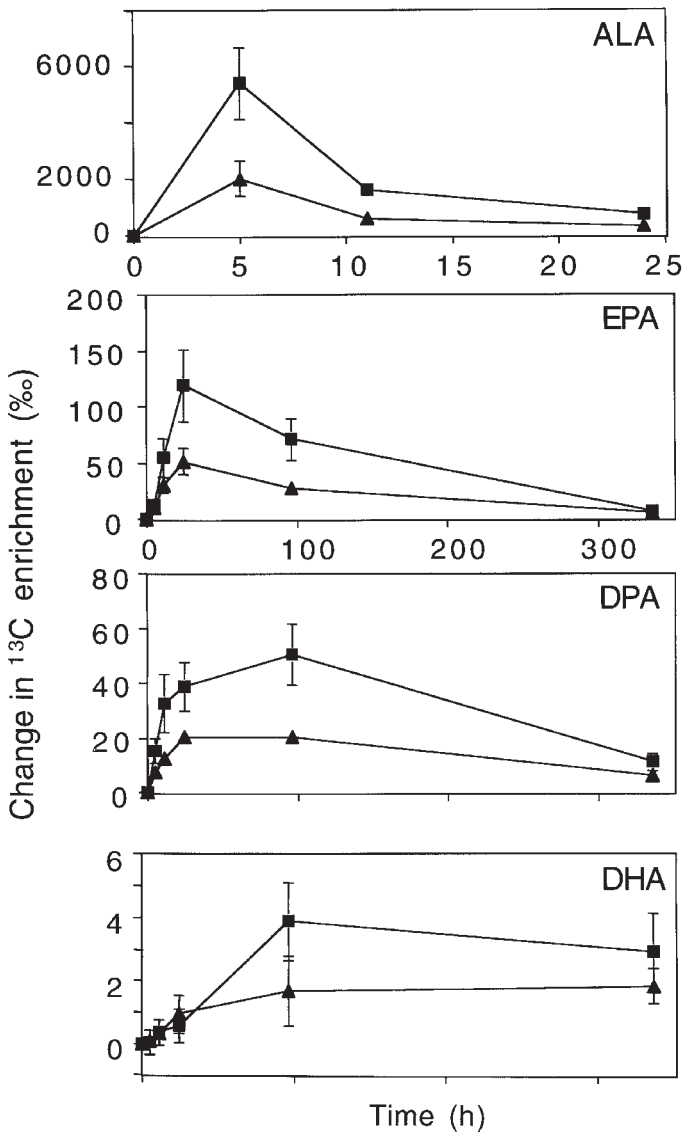

FIG. 3. Mean (± SEM) changes in plasma ^{13}C enrichments of ALA, EPA, DPA, and DHA after intake of a single dose of ^{13}C-ALA in diets rich in oleic acid (■) or ALA (▲). For abbreviations see Figure 2.

Plasma total fatty acid concentrations. Proportions of total ALA in plasma total lipids at baseline were 0.91 ± 0.35% of total fatty acids in the oleic acid group and 1.12 ± 0.17% of total fatty acids in the ALA group. Plasma total EPA, DPA, and DHA concentrations were 0.77 ± 0.12, 0.55 ± 0.06, and 1.61 ± 0.12% of total fatty acids for the oleic acid group and 0.63 ± 0.11, 0.48 ± 0.07, and 1.37 ± 0.13% of total fatty acids for the ALA group, respectively.

Absolute amounts of plasma-labeled fatty acids. Figure 4 shows the individual maximal absolute amounts of plasma ^{13}C n-3 fatty acids. The mean maximal amounts of plasma ^{13}C-ALA were 4.4 ± 0.7 mg (9.8% of the given dose) on the oleic acid diet and 2.8 ± 0.6 mg (6.2%) on the ALA diet ($P = 0.22$). Mean maximal amounts of ^{13}C-EPA were significantly lower in the ALA group (0.04 ± 0.01 mg) as compared to the oleic acid group (0.12 ± 0.03 mg) ($P = 0.01$). Values of ^{13}C-DPA and ^{13}C-DHA were very low, and were somewhat lower on the ALA-rich diet compared to the oleic acid-rich diet ($P = 0.17$ and $P = 0.17$, respectively).

Oxidation. During the first 12 h, maximum ^{13}C enrichments in breath were 11.2 ± 2.5‰ in the oleic acid group and 12.6 ± 1.7‰ in the ALA group, and were reached after about 5 h. Thereafter, ^{13}C enrichment decreased, until 3.8 ± 0.5‰ and 4.7 ± 0.9‰, respectively after 12 h (data not shown). The cumulative recovery of ^{13}C in breath derived from ^{13}C-ALA during the first 12 h after intake is presented in Figure 5. After 12 h, the mean recovery of ^{13}C was not significantly different on the ALA-rich diet (20.4 ± 0.8%) as compared to the oleic acid-rich diet (15.7 ± 2.3%) ($P = 0.12$).

Correlations. Spearman correlation coefficients were calculated between the cumulative recovery of ^{13}C in breath derived from ^{13}C-ALA during the first 12 h after tracer intake and the maximal amount of plasma ^{13}C-labeled n-3 fatty acids for all subjects. The cumulative recovery of $^{13}CO_2$ in breath was neg-

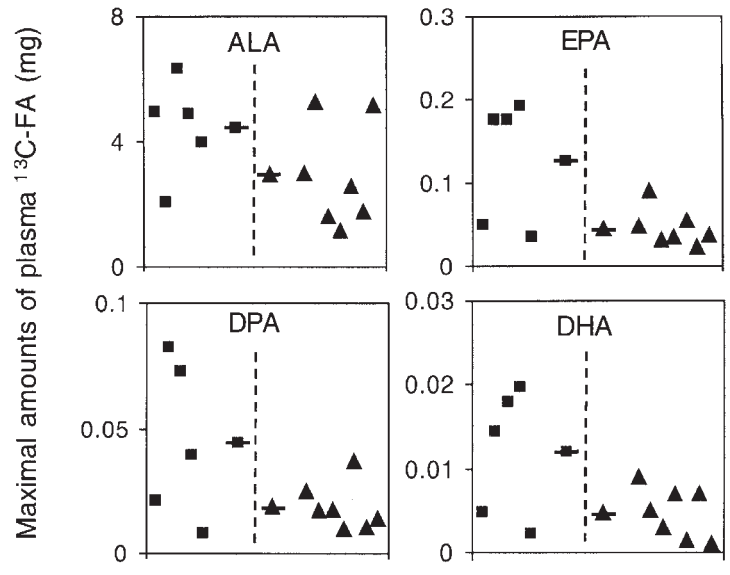

FIG. 4. Individual absolute amounts of plasma ^{13}C-labeled ALA, EPA, DPA, and DHA after intake of a single dose of ^{13}C-ALA in diets rich in oleic acid (■; mean ▬) or ALA (▲; mean ▲). For abbreviations see Figure 2.

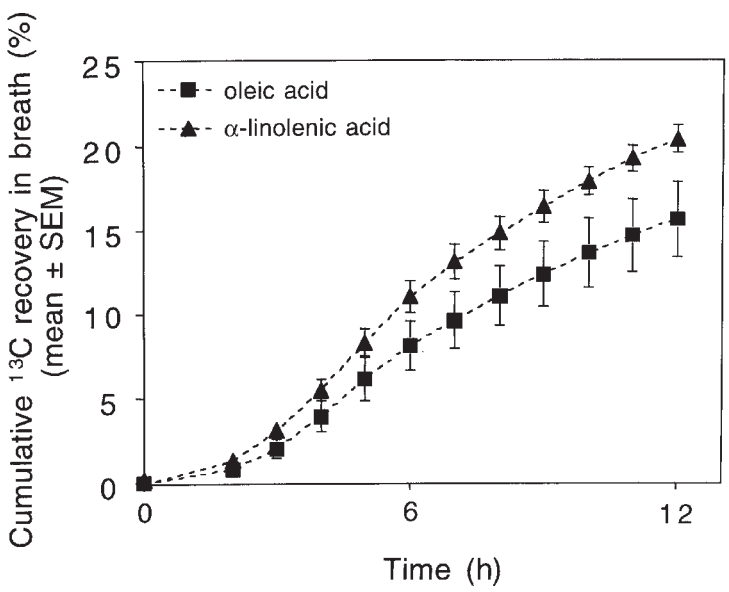

FIG. 5. Cumulative recovery of $^{13}CO_2$ in breath derived from ALA (mean ± SEM) after intake of a single dose of ^{13}C-ALA on diets rich in oleic acid (n = 5) or ALA (n = 7). For abbreviations see Figure 2.

atively correlated with plasma ^{13}C-EPA (r = –0.58, P = 0.047) and ^{13}C-DPA (r = –0.63, P = 0.027), but not with ^{13}C-ALA (r = 0.05, P = 0.888) and ^{13}C-DHA (r = –0.49, P = 0.108). The maximal amounts of plasma ^{13}C-ALA, ^{13}C-EPA, ^{13}C-DPA, and ^{13}C-DHA did not correlate with each other.

EPA/DHA group. The daily supplemented intake in the EPA/DHA group was 0.9 g (0.5 energy %) for EPA and 0.5 g (0.3 energy %) for DHA.

Conversion of ^{13}C-ALA could not be measured in one woman of the EPA/DHA group due to problems during preparation of FAME. Maximal changes in ^{13}C enrichment of ALA (2427‰) and EPA (5.1‰) were reached at the same time as in the ALA and oleic acid group, while changes were lower for EPA. Values had returned to baseline after 336 h. Changes in ^{13}C enrichments of DPA were very low (2.8‰), and that of DHA were zero.

The proportions of total ALA, EPA, DPA, and DHA in plasma total lipids at baseline were 0.56, 3.09, 0.71, and 2.40%, respectively. Maximal amounts of ^{13}C-ALA, ^{13}C-EPA, and ^{13}C-DPA were 2.1 mg, $3.4 \cdot 10^{-2}$ mg, and $5.1 \cdot 10^{-3}$ mg, respectively. The cumulative recovery of ^{13}C-ALA in breath during the first 12 h after intake was 24.8%.

DISCUSSION

In this study with healthy adults, maximal absolute amounts of labeled EPA in plasma were significantly lower in the ALA group as compared to the oleic acid group, after intake of a single oral dose of uniformly labeled ^{13}C-ALA. Although maximal absolute amounts of labeled DPA and DHA were not lowered on the ALA rich diet, our conversion data may suggest that the metabolism of dietary ALA depends on its intake.

Effects of ALA on the conversion of ALA *in vivo* have never been reported in humans before. Dietary linoleic acid, however, inhibits the conversion of deuterated linoleic acid (9), while a diet rich in arachidonic acid has no significant effect on the conversion of deuterated linoleic acid into arachidonic acid (21). This suggests that the reduced conversion of deuterated linoleic acid is caused by linoleic acid from the diet.

ALA is converted into 18:4n-3 by Δ6 desaturation, subsequently elongated into 20:4n-3, from which EPA can be formed by Δ5 desaturation. EPA is converted into DHA *via* two elongation steps, followed by another Δ6 desaturation step and one cycle of β-oxidation (22). The Δ6 desaturation has been suggested to be the rate limiting step in the conversion of ALA. We are unable to decide whether or not ALA affects the Δ6 or Δ5 desaturase activity, because plasma concentrations of 18:4n-3 and 20:4n-3 were too low to detect ^{13}C enrichments.

Our experimental design did not allow to quantify the conversion of ALA. One commonly used method is to calculate area under the curves (21). We think, however, that this method is not applicable in our study, since after administration of a single dose of ^{13}C-labeled ALA, the distribution of ^{13}C-n-3 fatty acids over the various tissue lipids did not reach a steady state. In addition, the slow appearance and disappearance rates of the tracer in plasma may indicate that these processes are not sequential, but overlap. Therefore, the area under the curve does not reflect the amount of ^{13}C-labeled fatty acids converted (23).

From rat studies, it is known that the activity of enzymes involved in the mitochondrial and peroxisomal fatty acid oxidation are increased by dietary EPA (24). The effects of dietary ALA on ALA oxidation in humans are, however, not known. In the present study, the mean proportion of labeled ALA recovered as $^{13}CO_2$ in breath after 12 h was slightly, although not significantly, higher in the ALA group compared to the oleic acid group, suggesting that the oxidation of ALA may not be inhibited by dietary ALA.

We hardly found any ^{13}C enrichment of n-3 LCP in a diet rich in EPA/DHA. However, the plasma total EPA and DHA concentrations were increased in an EPA/DHA-rich diet as compared to values on an oleic acid- or ALA rich diet. This suggests that plasma EPA and DHA were mainly derived from dietary sources. Absolute amounts of ^{13}C-LCP were very low, suggesting that conversion of ^{13}C-ALA may be lowered on dietary EPA/DHA. As suggested before (25), the conversion of ^{13}C-ALA may be inhibited by dietary EPA plus DHA. However, because of the small number of subjects in this group, results should be interpreted with caution. Recently, our suggestion was confirmed by Emken *et al.*, who found decreased accumulation of deuterated n-3 LCP in a diet enriched in DHA (11).

We observed negative correlations between the recovery in breath of $^{13}CO_2$ derived from ^{13}C-ALA after 12 h and the maximal amounts of plasma ^{13}C-EPA and ^{13}C-DPA in plasma total lipids. The correlation between the $^{13}CO_2$ recovery and ^{13}C-DHA amounts failed to reach statistical significance. If results of the EPA/DHA group are, however, also incorporated into the analysis, the negative correlations between the oxidation and conversion of ^{13}C-ALA become stronger. Even ^{13}C-DHA is now significantly correlated with the $^{13}CO_2$ recovery (r = –0.63; P = 0.008). The lack of significantly lower amounts of ^{13}C-DPA and ^{13}C-DHA on the ALA group as com-

pared to the oleic acid group, could also be due to the limited number of subjects.

Except for ALA, differences in energy and nutrient intakes between the treatment groups were small. We, therefore, suggest that conversion of ^{13}C-ALA into LCP may be lowered by dietary ALA, while oxidation of ^{13}C-ALA is negatively correlated with its conversion into LCP. The preliminary results of an EPA/DHA-rich diet showed very low amounts of ^{13}C-LCP, suggesting that conversion of ^{13}C-ALA may also be lowered on dietary EPA/DHA. Therefore, it seems it would be very interesting to examine this issue in more detail in further studies.

ABSTRACT: Endothelial dysfunction is associated with atherogenesis and oxidative stress in humans. In rat and rabbit blood vessels, wine polyphenol antioxidants induce vascular relaxation *in vitro* through the NO-cGMP pathway. To assess the effect of a regular high-fat diet (HFD) and moderate red wine consumption on endothelial function (EF), a study was performed in healthy male volunteers. EF was measured as flow-mediated dilatation of the brachial artery, employing high-resolution ultrasound after an overnight fast. Other clinical and biochemical parameters related to EF were also measured. Six volunteers received a control diet, rich in fruits and vegetables (27% calories as fat) and five volunteers received an HFD (39.5% calories as fat). Measurements were done twice on each volunteer: after a period of 30 d with diet plus 240 mL of red wine/d, and after a period of 30 d with diet, without wine. In the absence of wine, there is a reduction of EF with HFD when compared to the control diet ($P = 0.014$). This loss of EF is not seen when both diets are supplemented with wine for 30 d ($P = 0.001$). Plasma levels of *n*-3 fatty acids ($R^2 = 0.232$, $P = 0.023$) and lycopene ($R^2 = 0.223$, $P = 0.020$) show a positive correlation with individual EF measurements, but they do not account for the significant differences observed among dietary groups or after wine supplementation. These results help elucidate the deleterious effect of a high-fat diet and the protective role of wine, n-3 fatty acids and dietary antioxidants in cardiovascular disease.

Paper no. L8349 in *Lipids 35*, 143–148 (February 2000).

Normal endothelium-dependent vasomotor function or endothelial function (EF) is a physiological response, mediated by nitric oxide (NO), that appears to play a key role in the prevention or reduction of the risk of atherosclerosis (1,2). Endothelial dysfunction is associated with risk factors for coronary heart disease such as hypercholesterolemia, hypertension, cigarette smoking, hyperhomocysteinemia and diabetes mellitus and is detectable before anatomical vascular signs of atherosclerosis appear, supporting a pathogenic role of endothelial dysfunction in atherogenesis (3–5). Young healthy subjects with a family history of premature coronary disease and no other apparent risk factor also show impaired EF (6).

Hypercholesterolemia (7), genetic hyperlipidemias (8), or a single high-fat meal (9) decrease EF, suggesting that a regular high-fat diet (HFD) might lead to endothelial dysfunction. Ingestion of the antioxidant vitamins C and E (1,5,8,10,11) partially blocks the decrease in EF *in vivo*, a phenomenon attributed to protection of NO from inactivation by free radicals.

Vegetables and moderate wine consumption have been associated with a decreased risk of coronary disease (12,13), an effect related, at least in part, to their high content in flavonoids and other polyphenol antioxidants (14,15). Also, it has been shown that wine polyphenols exert vasorelaxing activity in rat and rabbit aortic rings and human coronary arteries rings (16–19). Plant polyphenols from other sources show a similar activity (20). Moderate wine consumption and a high intake of fruits and vegetables characterize Mediterranean diets (21,22). Therefore, plant polyphenol antioxidants could account, at least in part, for the cardiovascular health benefits associated with Mediterranean diets and moderate wine consumption.

The present study evaluates EF employing a noninvasive ultrasound detection method (23) in human volunteers on either an HFD or a control diet (CD) rich in fruits and vegetables, with and without moderate red wine consumption.

EXPERIMENTAL PROCEDURES

Study design. The experimental protocol employed was approved by the Ethics Committee of the Faculty of Medicine, Catholic University of Chile. Subjects were randomly selected from a larger group of volunteers participating in a diet and wine intervention study. For 90 d they received either an HFD ($n = 5$) or a CD ($n = 6$). From day 31 to 60 the diet was isocalorically supplemented with 240 mL/d of red wine (cabernet sauvignon). No other alcoholic beverage was allowed during the 3 mon of the study. EF, as well as the other measurements reported here, were performed at days 60 and 90.

Abbreviations: ANOVA, analysis of variance; CD, control diet; cGMP, guanosine 3′:5′-cyclic monophosphate; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EDRF, endothelium-derived vascular relaxing factor; EF, endothelial function; γ-GT, γ-glutamyl transferase; HFD, high-fat diet; HPLC, high-performance liquid chromatography; NO, nitric oxide; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; VLCn-3, very long-chain n-3-fatty acids.

Subjects. Subjects were healthy males, aged 20–28 yr, undergraduate or graduate students from the Faculty of Medicine, who signed an informed consent form and were well informed about the project procedures and objectives. They were randomly selected from a larger group of 42 subjects. The smaller size of the groups for EF measurement was determined both by the chronogram of biological sampling defined for the larger study, and limitations in the access to the ultrasound imaging equipment, since the volunteers were required to fast overnight. Criteria for inclusion were absence of clinical disease, body mass index 20–25 kg/m^2, and normal values for serum lipids, blood pressure, and blood glucose. They were normally active, nonsmokers, and were not taking any medication or vitamin supplementation. Clinical interview, physical examination, and laboratory evaluation were done every 30 d. Blood pressure values correspond to the mean of two measurements, separated 5 min, with the subject in a sitting position.

Diets. HFD and CD were prepared by a catering company, with daily supervision by a nutritionist and a food microbiologist working for the project. Diets were delivered at the work place, or at home at night and weekends, in isolated personalized boxes. The average daily caloric supply was 2,565 kcal. Proteins supplied 17.6% of calories for both diets. Fats, as detailed in Table 1 supplied 27.3 or 39.9% of calories for CD and HFD, respectively. Diet composition was calculated employing Food Processor II (Esha Research, Salem, OR). Fruits and vegetables consumption was an average of 675 g/d for CD and 246 g/d for HFD. HFD used preferentially red meats and was low in fish; CD used predominantly fish and white meat. On the whole, HFD resembled a regular Western or U.S. diet from the last decades (24,25) and CD a Mediterranean-style diet (21,22).

Biochemical analysis. Plasma glucose, serum enzymes, total cholesterol, low density lipoprotein cholesterol, and triglycerides were measured following routine clinical laboratory procedures. Fatty acids were measured by gas chromatography as follows: plasma lipids were extracted according to Bligh and Dyer (26) using chloroform/methanol (2:1, vol:vol) containing butylated hydroxytoluene (0.01%). Total fatty acids were transesterified with methanolic-HCl (1 N) overnight at room temperature; after extraction with *n*-hexane, the methyl esters were quantified by gas–liquid chromatography employing a capillary column (50 m × 0.25 mm, SGE BPX-70) with hydrogen as carrier gas and a temperature program of 5°/min from 110 to 230°C. Vitamin E (as α-tocopherol), β-carotene, and lycopene were determined by high-performance liquid chromatography (HPLC) with electrochemical detection (LC-4C, Bioanalytical Systems Inc., W. Lafayette, IN) (27). Serum vitamin C was detected by a procedure based on the reduction of ferric chloride (28); the accuracy of these measurements was checked by HPLC. Folate and vitamin B_{12} in serum were determined by ion capture and microparticle immunoassay, respectively (IMX® Folate and AxSYM B_{12}; Abbott Labs, Abbott Park, IL). Plasma homocysteine was measured by HPLC with fluorometric detection, employing a commercial kit (Chromsystems, München, Germany).

TABLE 1
Daily Intake of Fats and Fatty Acids[a]

	High fat diet (g/d)	Control diet (g/day)
Total fat	112.7 ± 12.9	77.0 ± 2.6
SFA	35.8 ± 9.6	22.7 ± 2.3
MUFA	35.3 ± 4.2	37.9 ± 2.5
PUFA	32.0 ± 4.5	9.6 ± 1.4
VLCn-3	0.12 ± 0.04	0.38 ± 0.13
Cholesterol	0.61 ± 0.12	0.29 ± 0.09

[a]Mean values ± SD. Abbreviations: SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; VLCn-3, very long-chain n-3 fatty acids = eicosapentaenoic acid + docosapentaenoic acid + docosahexaenoic acid.

EF. EF was assessed twice for each volunteer: on day 60, at the end of the 30-d wine supplementation period; and at day 90, after a period of 30 d without wine, only with diet. Measurement were made at 8–9 A.M., with an overnight fast. The noninvasive procedure employs 7.5 MHz ultrasound imaging (GAIA 8800, Medison, Seoul, Korea) and has been validated by Celermajer *et al.* (23). The measurements were performed essentially as described by Plotnick *et al.* (10). The brachial artery was longitudinally imaged approximately 5 cm proximal to the antecubital crease, twice at baseline and then 1, 3, and 5 min after release of 5 min arterial occlusion with a blood pressure cuff, 12.5-cm wide, placed on the forearm, kept at 200 mm Hg. Results are expressed as percent dilation at minute 1 after flow reestablishment. Two independent investigators, unaware of subject identity and dietary status, performed the measurements of end-diastolic brachial artery diameter in the video recordings obtained. Following flow-mediated reactivity measurement, after 15 min rest, volunteers received 300 μg nitroglycerin sublingually to control the dilatation response 3 min after nitroglycerin administration.

Statistical procedures Data are expressed as mean ± SD. The measurements within the same dietary group, at different times, were compared by analysis of variance (ANOVA) for repeated measures and paired *t* test with Bonferroni adjustment. To determine if wine supplementation to both dietary groups modifies the variables in the same direction, ANOVA for repeated measures with interaction between diet and wine was applied. For comparisons among the two dietary groups, the Student *t* test for independent samples was employed. Bivariant correlation analysis was performed according to Pearson. *P* values <0.05 were considered statistically significant.

RESULTS

The relative increase in brachial artery diameter that follows the reestablishment of circulation constitutes the basis of the noninvasive procedure to quantitate EF. The kinetics of the relative change in mean arterial diameter values for the two experimental conditions are shown in Figure 1. In the HFD maximal response occurs after 1 min of flow reestablishment, whereas for CD the vasodilation response apparently is slower. The difference observed with wine was maximal after 1 min for both dietary groups. In fact, this time interval is routinely em-

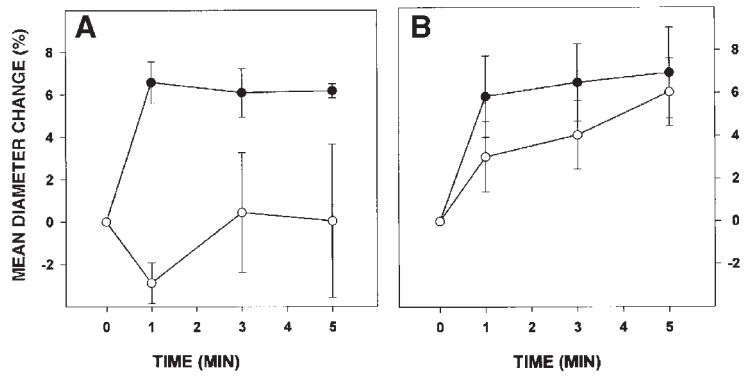

FIG. 1. Effect of diet and wine on endothelium-dependent brachial artery vasoactivity. Flow-mediated brachial artery vasoactivity, expressed as percent change in arterial diameter, was measured with high-resolution ultrasound, before and at various times after releasing the circulatory arrest imposed by an inflated cuff in the forearm. The measurements were made after 12 h without food and wine, and correspond to the mean values ± standard error, from (A) 5 subjects under a high-fat diet or (B) 6 subjects under a control diet rich in fruits and vegetables, with (●) or without (○) supplementation with red wine (240 mL/d). The change in diameter is expressed relative to the diameter before circulatory arrest.

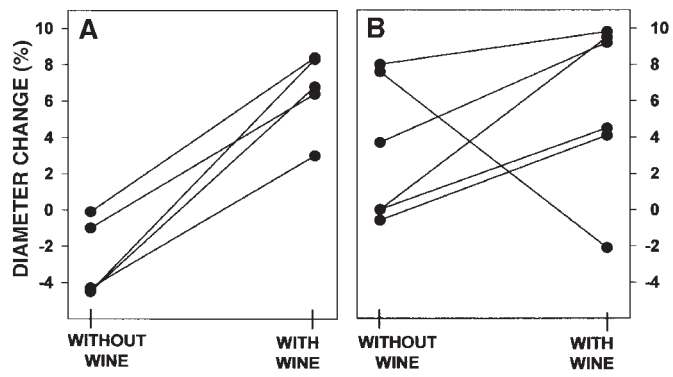

FIG. 2. Effect of wine supplementation on endothelium-dependent flow-mediated brachial artery vasoactivity, expressed as percent change in arterial diameter for each experimental subject consuming a high-fat (A) or a control (B) diet. Values represented correspond to individual measurements, 1 min after releasing the arterial flow, obtained during the observations summarized in Figure 1.

ployed in the standard procedure to evaluate EF. The individual EF values with and without wine, for the five HFD and the six CD volunteers, are shown in Figure 2. A striking result is the consistent increase of EF in the HFD subjects when wine is present in the diet. The average percent diameter change varies from –2.9 ± 2.1 without wine to 6.6 ± 2.2 with wine ($P = 0.001$ for paired data analysis). It can also be seen that in the absence of wine, HFD values are significantly lower than those for CD, average 3.1 ± 3.9 ($P = 0.014$). The effect of wine, clearly seen for HFD, is not evident with CD; 3.1 ± 3.9 is the average percent diameter change without wine supplementation and 5.8 ± 4.6 with wine supplementation ($P = 0.358$ for paired samples), yet ANOVA for repeated measurements with interaction among diet and wine shows a parallel behavior for HFD and CD, i.e., both groups change with wine in the same direction. Unexpectedly, one CD volunteer showed decreased EF in the wine supplementation period, a result for which we do not have a more precise explanation than biological variability.

Nitroglycerin-induced percent dilation values for HFD were 19.1 ± 10.3 and 26.5 ± 2.9 without and with wine supplementation; and for CD 21.4 ± 5.3 and 20.9 ± 3.5, without and with wine supplementation. These values suggest an increase in the nitroglycerin-induced dilatation for the HFD group after wine supplementation, but the difference is not statistically significant for the HFD group ($P = 0.262$ for paired samples).

The diets employed had either 39.5 (HFD) or 27% (CD) of total calories as fat. As shown in Table 1, both provided almost the same amount of monounsaturated fatty acids; in contrast, HFD supplied three times more polyunsaturated fatty acids (PUFA) and 1.6 times the saturated fatty acids (SFA) of CD. For CD, SFA amount to 8.7% of total energy consumption. For fruits and vegetables the supply was almost three times higher in CD.

The average values for some plasma biochemical parameters in both dietary groups, with and without wine, are shown in Table 2. The plasma fatty acid profiles apparently reflect the dietary pattern; nevertheless, statistically significant differences among diets are seen only in PUFA and very long chain n-3 fatty acids (VLCn-3) values after wine supplementation. Total and low density lipoprotein cholesterol values as well as triglycerides apparently reflect the diet composition, but the changes are not statistically significant, most probably as a consequence of the relatively small number of subjects evaluated. Other biochemical parameters known to influence EF do not show variations that could account for the changes in EF observed with diet and wine: homocysteine and vitamin B_{12} remain constant, and folic acid increases with the diet rich in fruits and vegetables, but without correlation with homocysteine levels. A consistent change observed with both diets is a statistically significant 14% decrease in plasma vitamin E (α-tocopherol) at the end of the wine supplementation period. Lycopene mean values do not show statistically significant variations within or among diets, yet there is a positive correlation among all individual lycopene values and EF values expressed as percent dilation of the brachial artery ($R^2 = 0.223$, $P = 0.020$). A similar correlation is seen among VLCn-3 mass plasma levels and EF ($R^2 = 0.232$, $P = 0.023$). This positive and statistically significant correlation of EF with n-3 fatty acids is mainly due to docosapentaenoic acid (DPA) ($R^2 = 0.504$, $P = 0.017$) and docosahexaenoic acid (DHA) ($R^2 = 0.437$, $P = 0.042$). A significant increase in VLCn-3 plasma concentration, in the presence of wine supplementation, is seen only in CD; in contrast, the most striking change in EF is seen with the HFD, when wine is added. In HFD, VLCn-3 plasma levels do not change with wine, in contrast to the striking effect of wine on EF. This probably means that lycopene and VLCn-3 plasma levels influence the absolute value for each EF measurement, while the relative changes observed with wine apparently are independent of lycopene or VLCn-3 concentration changes.

As part of the biochemical monitoring procedure, (γ-glutamyl transferase), serum glutamic-oxalacetic transaminase, and alkaline phosphatase levels in serum were measured (Table 3). The main change observed, a 40% increase in γ-GT in HFD

TABLE 2
Biochemical Measurements in Plasma[a]

Plasma variable	High-fat diet		Control diet	
	Without wine	With wine	Without wine	With wine
Glucose (mg/dL)	82.0 ± 3.3	83.0 ± 5.5	81.2 ± 5.5	87.3 ± 6.4
Total cholesterol (mg/dL)	177 ± 33	185 ± 33	155 ± 24	150 ± 19
LDL (mg/dL)	102 ± 24	111 ± 28	89 ± 21	88 ± 18
Triglycerides (mg/dL)	137 ± 128	127 ± 89	88 ± 41	68 ± 31
SFA (μg/mL)	622 ± 136	737 ± 180	559 ± 60	525 ± 14
MUFA (μg/mL)	404 ± 182	537 ± 214[a]	377 ± 81	421 ± 83
PUFA (μg/mL)	896 ± 116	1,166 ± 252[a]	776 ± 176	756 ± 90[b]
VLCn-3 (μg/mL)	80.2 ± 36.2	91.0 ± 16.0	80.8 ± 25.7	137 ± 18.9[a,b]
Vitamin E (μmol/L)	27.4 ± 10.5	23.6 ± 9.5[a]	19.9 ± 4.7	17.0 ± 3.9[a]
Vitamin C (μmol/L)	32.5 ± 23.4	25.8 ± 6.8	54.1 ± 7.2	58.3 ± 11.7[b]
Lycopene (nmol/L)	156 ± 63	318 ± 130	167 ± 62	245 ± 105
Folic acid (ng/mL)	3.96 ± 1.29	3.88 ± 0.62	5.82 ± 2.03	6.35 ± 2.19[b]
Vitamin B_{12} (pg/mL)	376 ± 177	334 ± 164	423 ± 173	381 ± 142
Homocysteine (μmol/L)	16.5 ± 6.1	15.3 ± 4.9	14.7 ± 2.4	11.8 ± 2.2

[a]Mean values ± SD. [a]Significant difference, within the same diet, with wine supplementation; Student *t* test for paired samples. [b]Significant difference among different diets; Student *t* test for independent samples. LDL, low density lipoprotein; for other abbreviations, see Table 1.

when compared to CD, was apparently due to the diet and not to wine supplementation. Wine supplementation induced only a slight, statistically significant, reduction in alkaline phosphatase in the CD group.

DISCUSSION

The results presented indicate that normal subjects experience a marked decrease or impairment of EF, under a usual western-style diet rich in fats. Strikingly, after moderate wine consumption vascular reactivity or EF is preserved. The EF measurements were done after an overnight fast, 12 h without food and wine; therefore, the changes induced by wine and diet do not correspond to a transient or acute postprandial response but rather to a stable change associated with the specific dietary condition.

The noninvasive procedure employed to measure EF has been validated (29–31). It has been applied to detect the consequences of an acute overload with fat (8) and the effect of antioxidant vitamins (1,5,8,10,11). The mechanism through which fats interfere with EF is apparently linked to free radical generation, since antioxidant vitamins prevent the effect. In the presence of free radicals NO is inactivated (32) and the reaction with superoxide leads to the formation of peroxynitrite. Therefore, as much as fats can lead to increased levels of free radicals and reactive oxygen species, it is not surprising that NO-mediated processes will be slowed, unless an adequate antioxidant defense is present. The initial *in vitro* observations with wine polyphenols (16) and the present work in humans suggest that wine polyphenols constitute an adequate source of antioxidants, readily available *in vivo*, capable of protecting NO function.

The finding that VLCn-3 plasma levels correlate with the degree of flow-mediated vasodilation is in agreement with previous findings. Dietary supplementation with fish oil, not necessarily with purified n-3 fatty acids, has been shown to augment endothelium-dependent vasodilation in human peripheral and coronary arteries, in a process apparently mediated by increased NO production (33,34). This effect of n-3 fatty acids is an example of the difficulties experienced when attributing to fats or fatty acids in general a specific biological effect: elevated lipid levels will favor free radical generation and oxidative stress, yet n-3 fatty acids protect EF and are antiatherogenic (35,36) in spite of their high degree of unsaturation, which makes them most susceptible to oxidation. The reduced EF observed with HFD might correlate with the three fold increase in PUFA, mostly 18:2n-6, when compared with CD. In fact, a diet rich in linoleic acid is expected to cause oxidative stress, and the mass or amount of linoleic acid supplied by the HFD is 100-fold or more higher than the amount of VLCn-3.

The present results most likely are the consequence of the

antioxidant properties of wine and the prooxidant effect of a HFD (37). We found no evidence in favor of other mechanisms. It has been observed that homocysteine plasma levels inversely correlate with EF values, and that the administration of antioxidants counteracts the homocysteine-induced inhibition of EF (5); however, in the present observations homocysteine levels did not correlate with EF changes. The supply of arginine in the diet (data not shown) was also unrelated to the changes observed in EF.

In our observations, among established plasma antioxidants, only lycopene levels correlate with vascular reactivity. This probably means that lycopene is particularly effective at this level, or that it is a marker for other antioxidants present in tomatoes (38), or that wine polyphenols from the diet exert a sparing or protective effect on plasma lycopene.

ACKNOWLEDGMENTS

We thank Dr. Diego Mezzano for constructive criticism of this work and Mr. Eduardo Aranda for the homocysteine measurements, at the Department of Hematology-Oncology, School of Medicine, Pontificia Universidad Católica de Chile. Effect of DHA Supplementation on DHA Status and Sperm Motility in Asthenozoospermic Males

Julie A. Conquer[a,]*, James B. Martin[b], Ian Tummon[b], Lynn Watson[b], and Francis Tekpetey[b]

[a]Human Nutraceutical Research Unit and Department of Human Biology and Nutritional Sciences, University of Guelph, Guelph, Ontario, Canada N1G 2W1, and [b]London Health Sciences Centre and Department of Obstetrics and Gynecology, University of Western Ontario, London, Ontario, Canada N6A 5A5

ABSTRACT: The effects of supplementation with docosahexaenoic acid (DHA) on DHA levels in serum, seminal plasma, and sperm of asthenozoospermic men as well as on sperm motility were examined in a randomized, double-blind, placebo-controlled manner. Asthenozoospermic men (n = 28; ≤50% motility) were supplemented with 0, 400, or 800 mg DHA/d for 3 mon. Sperm motility and the fatty acid composition of serum, seminal plasma, and sperm phospholipid were determined before and after supplementation. In serum, DHA supplementation resulted in decreases in 22:4n-6 (–30% in the 800-mg DHA group only) and total n-6 (–6 and –12% in the 400- and 800-mg DHA groups, respectively) fatty acids. Increases were noted in DHA (71 and 131% in the 400- and 800-mg DHA groups, respectively), total n-3 fatty acids (42 and 67% in the 400- and 800-mg DHA groups, respectively), and the n-3/n-6 ratio (50 and 93% in the 400- and 800-mg DHA groups, respectively). In seminal plasma, DHA supplementation resulted in a decrease in 22:4n-6 (–31% in the 800-mg DHA group only) and an increase in the ratio of n-3 to n-6 (35 and 33% in the 400- and 800-mg DHA groups, respectively). There were insignificant increases in DHA and total n-3 fatty acids. In sperm, decreases were noted in 22:4n-6 (–37 and –31% in the 400- and 800-mg DHA groups, respectively). There were no other changes. There was no effect of DHA supplementation on sperm motility. The results show that dietary DHA supplementation results in increased serum—and possibly seminal plasma—phospholipid DHA levels, without affecting the incorporation of DHA into the spermatozoa phospholipid in asthenozoospermic men. This inability of DHA to be incorporated into sperm phospholipid is most likely responsible for the observed lack of effect of DHA supplementation on sperm motility.

Paper no. L8322 in *Lipids 35,* 149–154 (February 2000).

The motility patterns of spermatozoa correlate closely with the rate of natural pregnancy (1) as well as pregnancy induced by *in vitro* fertilization (2). It is not clear which compounds in seminal plasma or spermatozoa may be involved in the regulation of sperm motility. Various compounds found naturally in the spermatozoa or seminal plasma, for example, levels and/or types of antioxidant enzymes (e.g., glutathione peroxidase, superoxide dismutase), oxidants (e.g., nitric oxide, hydrogen peroxide, singlet oxygen), and lipids (e.g., cholesterol, phospholipids, individual fatty acids), may all play a role (3–10). All of the factors controlling sperm motility in humans are as yet unknown.

Previous studies suggested that the level of docosahexaenoic acid (DHA; 22:6n-3) in human ejaculate and sperm is correlated with sperm motility (11,12). Furthermore, DHA levels have been shown to be lower in the total ejaculate (11,12), sperm (13,14), and seminal plasma (14) of asthenozoospermic men (men with ≤50% sperm motility) vs. normozoospermic men. It is unclear how DHA may be involved in regulating sperm motility in humans: it may be involved in the regulation of free fatty acid utilization by sperm (15,16) or it can be metabolized to other lipid-like compounds (19,20-dihydroxy-4,7,10,13,16-docosapentaenoic acid), as has been reported in monkey seminal vesicles (17). It is most likely that the biophysical properties of DHA contribute to the membrane fluidity and flexibility demanded by the motility of the tail (18).

Despite recent advances in treatments for female infertility, the ability to provide simple, effective treatment for male-factor infertility patients remains poor. The effect of dietary supplementation with various compounds on sperm motility has been investigated. In 1996, Suleiman *et al.* (19) determined that treatment of asthenozoospermic patients with oral vitamin E (100 mg; 6 mon), significantly decreased the malondialdehyde (MDA) concentration in spermatozoa, improved sperm motility, and increased the patient's chances of impregnating his spouse. In 1990, Knapp (20) fed 50 mL of menhaden oil [containing DHA + eicosapentaenoic acid (EPA, 20:5n-3)] per day to 10 normal male subjects for 4 wk. There was no effect on sperm motility, but semen phospholipids were enhanced in EPA. DHA also was increased in both the phosphatidylcholine (PC) and phosphatidylethanolamine (PE) fractions. In 1997, in two separate studies, male birds were supplemented with fish oil (rich in EPA and DHA; 21) or linseed oil [rich in α-linolenic acid (α-LNA); 22]. After 30 wk of supplementation with fish oil, sperm DHA levels increased in total phospholipid as well as in PC and PE fractions. α-LNA supplementation resulted in a decrease in sperm 22:4n-6 and an increase in docosapentaenoic acid (DPA; 22:5n-3) but had little effect on the concentration of DHA. The small increase

Abbreviations: DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; GLM, general linear model; α-LNA, α-linolenic acid; MDA, malondialdehyde; PC, phosphatidylcholine; PE, phosphatidylethanolamine.

in n-3 (as DPA) resulted in enhanced semen fertility. In a third study in broiler breeder roosters, fish oil supplementation increased DHA and total n-3 fatty acid levels in the sperm (23). In 1995, Paulenz *et al.* (24) reported that supplementation of fertile boars with 75 mL of cod liver oil (rich in EPA + DHA) every day for 9 wk resulted in increases in sperm phospholipid levels of DHA. EPA (nondetectable) and DPA levels did not change. In humans, there is evidence to suggest that the synthesis of DHA is reduced in infertile men (25) and that the intake of preformed DHA in the diet, in the presence of EPA, is associated with poorer sperm parameters. The effect of supplementation with an EPA-free DHA source on sperm function and DHA status has not been investigated.

In the present study, the responsiveness of blood serum phospholipid-, seminal plasma phospholipid- and sperm phospholipid-DHA status to supplementation with dietary DHA (EPA-free) was investigated in a group of asthenozoospermic men. The effect of DHA supplementation on sperm motility was studied as well.

MATERIALS AND METHODS

Subjects and experimental design. The subjects were 28 healthy asthenozoospermic individuals who were patients of the Reproductive Endocrinology and Infertility Program at the London Health Sciences Centre (London, Ontario, Canada). Approval for this study was granted by the Human Ethics Committee of the London Health Sciences Centre and the University of Western Ontario, and written informed consent was obtained from each subject. Subjects were determined to be asthenozoospermic after analysis of sperm motility for each individual. The sperm motility criteria applied to the asthenozoospermic individuals was ≤50% (of total sperm), based on the recommendation of Mortimer (26). The 28 subjects were randomly assigned to two DHA supplementation groups (400 or 800 mg/d) or to a placebo group. The DHA-enriched encapsulated triglyceride oil, Neuromins™, and the encapsulated placebo (corn oil/soy oil), were kindly provided by Martek Biosciences Corporation (Columbia, MD). Fatty acid analysis of Neuromins™ and placebo are as published by Conquer and Holub (27). Each group consumed the capsules for a period of 3 mon. Semen and blood samples were collected prior to and after the 3-mon supplementation.

Semen analysis. Semen samples (before and after supplementation) were produced on site by masturbation into a sterile container and allowed to liquefy for 30 min before analysis. Measurements of ejaculate volume, sperm motility, and sperm concentration using hemacytometer count were performed by an experienced technician, in accordance with the recommendations of the World Health Organization (28). Following the assessment, 0.5 or 1.0 mL aliquots of each sample were placed into an Eppendorf tube (1.5 mL capacity) and centrifuged at high speed (15,000 rpm) for 15 min to pellet the sperm. The supernatant seminal plasma was then carefully removed and transferred to a separate container. Both sperm and seminal plasma fractions were stored at –70°C until fatty acid analysis of total phospholipid.

Blood collection. Blood was collected from each subject (before and after supplementation) by antecubital venipuncture into siliconized tubes and centrifuged at 1200 × *g* for 10 min to obtain serum. Serum was stored at –70°C until analysis of the fatty acid composition of total serum phospholipid.

Fatty acid analysis of phospholipid of serum, seminal plasma, and sperm. The fatty acid composition of total phospholipid from serum, seminal plasma, and sperm was determined following lipid extraction, thin-layer chromatography, transmethylation, and gas–liquid chromatography as previously described (14). Gas–liquid chromatography of the fatty acid methyl esters was performed using a Varian 4000 gas chromatograph (Palo Alto, CA) with a 30-m DB-23 capillary column (0.32-mm internal diameter).

Statistical analysis. All data are reported as mean (SEM). Data were analyzed by the general linear model (GLM) procedure on least squared means (for between-group subject characteristics), or repeated measures GLM on least squared means (for fatty acid analyses and sperm characteristics), using the SAS system (SAS Institute, Cary, NC). Specific differences between groups, as well as before and after supplementation, were examined and reported only if $P < 0.05$.

RESULTS

Table 1 shows the subject characteristics for each group. There were no significant differences in height, weight, or body mass index between the groups ($P > 0.05$). Age was significantly higher in the group supplemented with 400 vs. 800 mg DHA/d. This was not considered to interfere with the outcome of this study.

The fatty acid compositions of the serum total phospholipid of asthenozoospermic individuals supplemented with placebo or DHA are given in Table 2 (SEM wt%). The fatty acid profiles of total serum phospholipid at entry were similar among the three groups. The levels of total saturated, monounsaturated, and polyunsaturated fatty acids, as well as total phospholipid, n-6 levels, and the ratio of n-3/n-6 fatty acids, were also similar among the three groups at entry. Supplementation of asthenozoospermic individuals with placebo did not result in the modification of fatty acid composition of serum. Supplementation with 400 and 800 mg DHA/d resulted in an increased DHA content (by 71 and 131% above pre-entry levels, respectively). This was coupled with a rise

[a]See Tables 1 and 2 for abbreviations. Values are reported as means (SEM) for a total of 28 individuals. [a,b,c,d]Values not sharing a superscript within the same row are significantly different ($P < 0.05$).

Table 3 shows the levels of fatty acids in the total phospholipid of human seminal plasma. The fatty acid profiles of total seminal plasma phospholipid at entry were similar among the three groups except for differences in 22:0 (lower in the group that was to receive 400 mg DHA/d). The levels of total saturated, monounsaturated, and polyunsaturated fatty acids, as well as total phospholipid, n-3, and n-6 levels and the ratio of n-3/n-6 fatty acids also were similar among the three groups at entry. DHA supplementation resulted in a significant decrease in 22:4n-6 (–31%) in the 800 mg group only, and a significant increase in the ratio of n-3 to n-6 fatty acids in the 400 and 800 mg supplemented groups (34.9 and 33.3%, respectively). DHA (37 and 40% in the 400 and 800 mg DHA groups, respectively) and total n-3 fatty acids (33 and 30% in the 400 and 800 mg DHA groups, respectively) tended to be slightly increased or unchanged compared to levels found prior to supplementation. There was no change in DPA.

The fatty acid composition of sperm total phospholipid is given in Table 4. Other than a difference in the initial concentration of 22:4n-6, there were no differences in concentrations of the various fatty acids among the three groups at entry; nor were there differences in total polyunsaturated, monounsaturated, or saturated fatty acids, total n-3 fatty acids, total n-6 fatty acids, the n-3/n-6 fatty acid ratio, or total phospholipid levels. DHA supplementation (400 or 800 mg per day) was associated with decreases in the 22:4n-6 content of the sperm phospholipid (–36.8 and –30.8% in the 400 and 800 mg DHA per day groups, respectively), but did not result in any other sperm phospholipid fatty acid composition modification. Slight decreases in 20:2n-6 and total n-6 fatty acids and an insignificant increase in the n-3/n-6 fatty acid ratio were noted.

Table 5 shows the effect of DHA supplementation on sperm motility and sperm concentration in the asthenozoospermic men. DHA supplementation had no effect on sperm motility or concentration (as measured by repeated GLM). Removing subjects with the highest (50%) or lowest (<10%) sperm motility values had no effect on this outcome.

DISCUSSION

This is the first study to examine the effect of supplementation with dietary DHA on DHA status and sperm motility in asthenozoospermic men. Serum n-3 fatty acid status, including DHA status, represents n-3 dietary intake (29–31). The effect of DHA supplementation on serum DHA status was used as a control. Previous studies in our laboratory have shown that dietary supplementation with DHA (from 800 to 1,620 mg per day) for 6 wk resulted in an increase in DHA content from 167 to 247%, depending on the amount of supplemented DHA (27,32,33). In the present study, the increase in serum DHA in the 800 mg

[a]See Table 4 for abbreviations. Values are reported as means (SEM) for a total of 28 individuals. There were no significant differences as measured.

DHA/d group (2.6 to 6.0% DHA) was consistent with that observed in an earlier study in our laboratory (2.4 to 6.4% DHA). DHA supplementation of asthenozoospermic men resulted in serum levels of this fatty acid that were much higher than the baseline levels observed in normozoospermic men (14).

The amount of DHA consumed in this study (400 to 800 mg/d) was not sufficient to cause a decrease in DPA levels or an increase in EPA levels, which are often reported in DHA supplementation studies (27,32,33). Insignificant increases in EPA and decreases in DPA, however, were noted in this study. The decreases observed in n-6 fatty acids in this study were also not as great as those observed in earlier studies. Again, this may have resulted from the smaller amount of supplemented DHA consumed by the subjects in this study (27,32,33). Interestingly, DHA appeared to decrease the elongation of 20:4n-6 to 22:4n-6, as indicated by the decrease in 22:4n-6 with DHA supplementation.

Previous work in our laboratory suggests that seminal plasma phospholipid DHA levels are lower in asthenozoospermic men than normozoospermic men (14). Supplementation with DHA in asthenozoospermic individuals resulted in decreases in 22:4n-6 but had no significant effect on other individual n-6 or n-3 fatty acids. As in serum, DHA incorporation may inhibit the elongation of 20:4n-6 to 22:4n-6 and/or inhibit the incorporation of 22:4n-6 into seminal plasma phospholipid. Although the increase in DHA and total n-3 fatty acids in the DHA-supplemented groups was not marked, only one subject in the 800 mg DHA/d supplemented group did not exhibit a rise in DHA levels. Interestingly, this subject did exhibit a marked rise in serum DHA, with DHA supplementation. Furthermore, all subjects exhibited a marked rise in the ratio of n-3 to n-6 fatty acids. This suggests that DHA supplementation will enhance levels of this fatty acid in the seminal plasma of most asthenozoospermic subjects. It is possible that high oxidant levels and/or low antioxidant levels (34–37) may be responsible for the lack of DHA accumulation in some subjects. It is also clear that DHA supplementation increases levels of this fatty acid in seminal plasma (4.2%) to levels comparable with those reported previously in normozoospermic men (3.7%) (14).

The levels of DHA in the sperm of asthenozoospermic men (average baseline 8.5%) were much lower than those of normozoospermic men (average 13.8%), as previously shown (14). Although DHA supplementation did modify levels of this fatty acid in serum and seminal plasma, supplementation had no effect on DHA levels in the spermatozoa. Although it is possible that higher concentrations of supplemented DHA may have resulted in increased DHA levels of spermatozoa, it is more likely that this was related to an inability of the sperm to take up preformed DHA. Indeed, one study in normozoospermic humans (20) suggests that DHA levels rise with supplementation by fish oil (a source of EPA + DHA). Christophe *et al.* (25) suggest that α-LNA intake may be more important in terms of sperm function and DHA status. The effect of DHA supplementation in the absence of EPA on DHA levels in the sperm of normozoospermic or asthenozoospermic men has never been published. Thus, it is difficult to know if the low DHA uptake by sperm from the men in our study could be attributed to limited supplies of the n-3 fatty acids and/or their protective antioxidants, or to fundamental structural/functional changes in the asthenozoospermic men (34–37). It would be interesting to know whether DHA supplementation would increase DHA levels in the sperm of normozoospermic patients, as well as in retinitis pigmentosa patients, who have decreased levels of DHA in their serum and sperm as well as decreased sperm motility (38).

DHA supplementation had no effect on sperm motility in the asthenozoospermic men. It is possible that the increased DHA levels in seminal plasma and concomitant decrease in 22:4n-6 in the seminal plasma and sperm, as observed with DHA supplementation, was not sufficient to increase sperm motility. These results, along with the correlation of sperm phospholipid DHA levels and sperm motility (14), further support the hypothesis that it is DHA itself, and not other fatty acids such as 22:4n-6, in the sperm phospholipid that may be involved in the regulation of sperm motility.

In conclusion, this study suggests that DHA supplementation in asthenozoospermic men increases DHA levels in serum, and possibly seminal plasma. However, DHA supplementation had little effect on DHA levels in sperm and had no effect on sperm motility. It would be interesting to determine the effect of supplementation with DHA precursors (for example α-LNA) and/or antioxidants on DHA levels in sperm as well as on sperm motility.

ACKNOWLEDGMENTS

We would like to thank Martek Biosciences Corporation for funding this investigation. In addition, special thanks go to Dr. Bruce Holub for his input in all aspects of this investigation and to Dr. Diana Philbrick for reading the manuscript.

Effects of Dietary Conjugated Linoleic Acids on Hepatic and Muscle Lipids in Hybrid Striped Bass

Ronald G. Twibell[a], Bruce A. Watkins[b], Laura Rogers[b], and Paul B. Brown[a,*]

Purdue University, [a]Department of Forestry and Natural Resources, and [b]Department of Food Science, Lipid Chemistry and Molecular Biology Laboratory, West Lafayette, Indiana 47907-1159

ABSTRACT: Conjugated linoleic acids (CLA) are the focus of numerous studies, yet the effects of these isomers of octadecadienoic acids have not been evaluated in many species of fish. In this study, graded amounts of CLA—0, 0.5, 0.75, or 1.0% of the diet—were fed to juvenile hybrid striped bass for 8 wk. Dietary treatments were fed to apparent satiation twice daily to triplicate groups of fish initially weighing 13.4 g/fish. Feed intake and weight gain of fish fed 1.0% CLA were significantly reduced compared to fish fed no CLA. Fish fed 0.5 and 0.75% CLA exhibited reduced feed intake similar to fish fed 1.0% CLA, but had growth rates that were not significantly different from those of fish fed no CLA. Feed efficiency improved significantly in fish as dietary CLA concentrations increased. Total liver lipid concentrations were significantly reduced in fish fed the diets containing CLA compared to those of fish fed the control diet, and intraperitoneal fat ratio was significantly lower in fish fed 1.0% CLA compared to fish fed no CLA. Fish fed dietary CLA exhibited significant increases in hepatosomatic index and moisture content of muscle and carcass. The CLA isomers were detected in liver and muscle of fish fed the diets containing CLA, while a low concentration of one isomer was detected in liver and muscle of fish fed the control diet. Dietary CLA resulted in a significant increase in 18:2(*c*-9,*c*-12) concentration in liver and muscle, but a significant reduction in 18:1n-7 in these tissues. Furthermore, feeding CLA resulted in a significant increase in the concentration of 20:5n-3 and 22:6n-3 in liver, but a reduction of these fatty acids in muscle. This study showed that feeding CLA elevated tissue concentrations of these fatty acid isomers, reduced tissue lipid contents, improved feed efficiency, and altered fatty acid concentrations in liver and muscle of fish.

Paper no. L8309 in *Lipids 35*, 155–161 (February 2000).

Conjugated linoleic acids (CLA) are an isomeric mixture of octadecadienoic fatty acids lacking a methylene group between double bonds. Research with CLA indicates that these fatty acids have anticarcinogenic, antiatherosclerotic, antioxidative, immunomodulative, and antibacterial properties (1–7). The CLA occur naturally in a wide variety of food products, including meat, poultry, seafood, cheese, butter, milk, and vegetable oils (8). Fats and meats from ruminant species are the richest natural sources of CLA.

Abbreviations: CLA, conjugated linoleic acids; E/P, energy/protein; FAME, fatty acid methyl ester; HSI, hepatosomatic index; IPF, intraperitoneal fat.

Dietary CLA improved feed efficiency and reduced body fat in growing pigs, rats, mice, rabbits, and chickens (1,2,3,9–12), but not in fish (13). Nutritional studies with CLA have shown that the isomeric fatty acids were incorporated into different animal organs and tissues, and enriched both neutral and polar lipid fractions (3,11,14–16). Moreover, CLA may affect the fatty acid composition of animal tissues and cultured cells (11).

Several hybrids of fish are being evaluated as new aquaculture species in the United States. Most of the interest in aquaculture arose from restrictions on harvest of wild fishes and increased consumption of seafoods (17). Fish are important sources of food protein and beneficial fatty acids and serve as an important link between n-3 fatty acid intake and reduced incidence of atherosclerosis (18,19).

One of the lingering concerns with hybrid striped bass (*Morone saxatilis* × *M. chrysops*) has been the macro- and microvesicular degeneration seen in hepatic samples of fish fed any commercial or experimental diet (20), resulting from accumulation of glycogen and lipid in hepatocytes. Regardless of the laboratory or diet, hepatic samples from hybrid striped bass consistently demonstrate these lesions and some pathologists consider this the normal liver. Hybrid striped bass also accumulate relatively high levels of fat in the visceral cavity, which increases production costs and reduces market value. The purpose of the present investigation was to examine the effects of feeding graded levels of CLA on growth, liver lipids, and fatty acid composition of hybrid striped bass.

MATERIALS AND METHODS

Fish and diets. Juvenile hybrid striped bass (male *Morone saxatilis* × female *M. chrysops*) were obtained from a commercial producer (Keo Fish Farms, Keo, AR) and transported to the Purdue University Aquaculture Research Facility. All fish were acclimated to laboratory conditions for 5 wk prior to initiation of the experiment. Procedures used during transport, quarantine, and experimental period were approved by the Purdue Animal Care and Use Committee (PACUC No. 89-060-98, "Nutritional Studies with Aquatic Animals," Principal Investigator Qualification No. BRO-249).

The closed recirculating system contained 24 individual 38-L aquaria and was equipped with two submerged filtration tanks for solid material removal and denitrification of the water.

Water was pumped through a sand filter to each aquarium at a rate of ~1 L/min and was maintained at 28 ± 1°C throughout the experiment. The diurnal light/dark cycle of the aquaculture facility remained at 16 h light/8 h dark throughout the study.

Groups of 20 randomly chosen fish were stocked into each of 12 aquaria. Fish were acclimated to the experimental system and their respective diets for 3 wk prior to the experiment. Following the acclimation period, the number of fish in each tank was reduced to 12 so that the total weight of fish in each tank was 160.0 ± 5.0 g. Dietary treatments were randomly assigned to triplicate aquaria. Upon initiation of the experiment, fish were fed to apparent satiation twice daily for 8 wk. Water quality was monitored daily and was within acceptable limits throughout the study. Dissolved oxygen concentrations were not below 5.0 mg/L at any time. Ammonia-N and nitrite-N concentrations did not exceed 0.25 and 0.20 mg/L, respectively.

The basal diet was formulated to provide 34.6% crude protein (Table 1). Casein and gelatin provided a total of 10.1% crude protein, while the remaining 24.5% crude protein was supplied by an L-amino acid mixture (Table 1). The L-amino acid mixture was formulated so that the diets contained 1.55% arginine (21), 1.40% lysine (22), and 0.73% total sulfur amino acids (23), thus meeting the dietary requirement of hybrid striped bass for these amino acids. The remaining dietary essential amino acid concentrations met or exceeded the highest known requirements for fish (24). All diets contained 500 mg choline/kg diet, provided as choline chloride (25). The basal diet contained 6.0% lipid (menhaden oil) and 25.0% carbohydrate (dextrin). The energy/protein (E/P) ratio of the basal diet was calculated as 8.5 kcal/g crude protein using physiological fuel values of 4.0, 4.0, and 9.0 kcal/g for protein, carbohydrate, and lipid, respectively. An E/P ratio of 8 kcal/g protein is nearly optimal for growth of hybrid striped bass (26).

TABLE 1
Composition of Basal Diet Fed to Juvenile Hybrid Striped Bass

Ingredient	Amount (g/kg dry mixture)
Casein	90.0
Gelatin	18.0
Amino acid mixture[a]	249.0
Dextrin	250.0
Mineral premix[b]	80.0
Vitamin premix[c]	3.3
STAY-C 25[d]	2.0
Choline chloride	0.7
Carboxymethylcellulose	20.0
Cellulose	227.1
Menhaden oil	60.0

[a]Amino acid mixture was formulated so that diets contained (g L-amino acid/kg dry diet): arginine, 15.5; histidine, 9.5; isoleucine, 19.3; leucine, 31.9; lysine, 14.0; methionine, 4.7; cyst(e)ine, 2.6; phenylalanine, 21.0; tyrosine, 20.0; threonine, 18.2; tryptophan, 4.9; valine, 23.5; aspartic acid, 21.9; proline, 21.9; glutamic acid, 21.8; serine, 21.8; glycine, 21.6.

[b]Mineral premix consisted of (g/kg of premix): Na_2SeO_3, 0.4; $CaCO_3$, 350; $NaH_2PO_4 \cdot H_2O$, 200; KH_2PO_4, 200; $MgSO_4 \cdot 7H_2O$, 10; $MnSO_4 \cdot H_2O$, 2; $CuCl_2 \cdot 2H_2O$, 1; $ZnSO_4 \cdot 7H_2O$, 2; $FeSO_4 \cdot 7H_2O$, 2; NaCl, 12; KI, 0.1; $CoCl_2 \cdot 6H_2O$, 0.1; $Na_2MoO_4 \cdot 2H_2O$, 0.5; $AlCl_3 \cdot 6H_2O$, 1; and KF, 1.

[c]Vitamin premix supplied the diets with (mg/kg dry diet): retinyl acetate, 40; cholecalciferol, 0.1; DL-α-tocopheryl acetate, 80; menadione, 15; niacin, 168; riboflavin, 22; pyridoxine HCl, 40; thiamine mononitrate, 45; D-Ca pantothenate, 102, biotin, 0.4; folic acid, 10; vitamin B-12, 0.04; and inositol, 450.

[d]Contained 25% ascorbic acid equivalents, as L-ascorbyl 2-polyphosphate.

Vitamins (with the exception of ascorbic acid and choline chloride) and minerals were added to the diets as nutritionally complete premixes (Table 1). Menhaden oil and reagent-grade minerals were obtained from commercial suppliers (Omega Protein, Reedville,VA, and Sigma Chemical Co., St. Louis, MO, respectively). Vitamins (with the exception of ascorbic acid), casein, gelatin, dextrin, carboxymethylcellulose, crystalline L-amino acids, and cellulose were acquired from U.S. Biochemical (Cleveland, OH). Ascorbic acid, as L-ascorbyl 2-polyphosphate, was obtained from Roche Inc. (Nutley, NJ). CLA were provided by Saskatchewan Wheat Pool (Saskatoon, Canada). Analysis of the supplement revealed that the total CLA isomers were 66.9% of the fatty acids [24.9% 18:2(*c*-9,*t*-11), 35.2% 18:2(*t*-10,*c*-12), 4.6% 18:2(*c*-9,*c*-11), and 2.2% 18:2(*t*-10,*t*-12)].

The dietary treatments were formulated to contain CLA at concentrations of 0, 0.5, 0.75, or 1.0% of the dry diet. Based on analyzed content, the diets supplemented with CLA at 0.75 and 1.0% contained 0.49 and 0.64% total isomers, respectively. The CLA supplement was added to the diets at the expense of menhaden oil to maintain a constant energy level among all dietary treatments.

Dry ingredients were thoroughly mixed in a twin-shell V-mixer (Patterson-Kelly, East Stroudsburg, PA). Diets were then transferred to a Hobart mixer (Hobart Corp., Troy, OH). Water, lipid, and CLA were then added to the dry ingredients and mixed. Diets were adjusted to pH 7.0 ± 0.2 with saturated NaOH (27) and pelleted. The diets were air-dried for 48 h, then stored under air-tight conditions at –20°C until needed.

Sample collection and analysis. All fish were anesthetized (tricaine methanesulfonate, Argent Chemical, Redmond, WA) and weighed 24 h after the final feeding. Three randomly chosen fish were collected from each dietary replicate group and frozen at –20°C for subsequent carcass proximate analysis. Fillets were obtained from an additional group of three randomly chosen fish and were also frozen at –20°C for subsequent proximate analysis. Both whole fish and fillet samples were pooled into one sample per replicate. Moisture concentration was determined by drying whole fish or muscle for 24 h in a forced-air oven maintained at 100°C. Crude protein was estimated from whole-body and muscle nitrogen values, which were determined in an elemental nitrogen analyzer (LECO Corp., St. Joseph, MI). Ash content was determined by incinerating samples at 600°C for 24 h in a muffle furnace. Lipid concentration of carcass and muscle was determined as described by Folch *et al.* (28).

Livers from three randomly chosen fish in each dietary replicate group were removed and weighed for calculation of hepatosomatic index (HSI) (liver weight × 100/body weight). The livers were then pooled and frozen at –20°C for subsequent determination of total lipids. Visceral fat was also removed from these same fish for calculation of intraperitoneal fat (IPF) ratio (IPF × 100/body weight).

Analysis of fatty acids. Liver and muscle samples were obtained from one randomly chosen fish in each dietary replicate group for determination of fatty acid composition. Individual samples were extracted with chloroform/methanol (2:1, vol/vol) and fatty acid methyl esters (FAME) prepared using 0.5 M sodium methoxide in anhydrous methanol following procedures described by Li and Watkins (11). Samples of diet also were subjected to lipid extraction, and FAME were produced (11). The FAME were quantified using a gas chromatograph (HP 5890 series II, autosampler 7673, HP 3365 ChemStation; Hewlett-Packard Co., Avondale, PA) equipped with a DB23 column (30 m, 0.53 mm i.d., 0.5 μm film thickness; J&W Scientific Co., Folsom, CA) and operated at 140°C for 2 min, temperature programmed 1.5°C/min to 198°C and held for 7 min (11). The injector and flame-ionization detector temperatures were held at 225 and 250°C, respectively. FAME were identified by comparison of retention times with authentic standards [GLC-422, CLA (UC-59-A and UC-59-M), Nu-Chek-Prep, Elysian, MN; CLA (Cat# 1245, *c*-9, *t*-11 and Cat# 1181, *t*-9, *t*-11), Matreya Inc., Pleasant Gap, PA] and with FAME prepared from menhaden oil (Matreya Inc.).

Statistical analyses. Weight gain, feed intake, feed efficiency, HSI, total liver lipid concentrations, IPF ratio, whole body and muscle proximate composition, and liver and muscle fatty acid concentrations were analyzed as a completely randomized design using each aquarium as an experimental unit. The data were subjected to one-way analysis of variance (ANOVA) using the Statistical Analysis System (SAS Users' Guide: Statistics, SAS Institute Inc., Cary, NC). Analyses were conducted with dietary treatment as the independent variable. Student-Neuman-Keuls test separated mean values when significant differences were detected by ANOVA. Accepted level of significance was 0.05.

RESULTS

There were no significant differences in weight gain between groups of fish fed 0, 0.5, or 0.75% CLA; however, growth rates of fish fed 1.0% CLA were significantly lower than those of fish fed the control diet (Table 2). Feed intake was significantly reduced in fish fed CLA compared to fish fed the control diet (0% CLA). Feed efficiencies improved significantly as dietary CLA concentrations increased. HSI increased and total liver lipid concentration decreased significantly with increasing dietary CLA concentrations (Table 2). Fish fed 1.0% CLA exhibited a 2.5-fold reduction in liver lipid concentration compared to fish fed the control diet.

IPF ratio was significantly reduced in fish fed 1.0% CLA compared to fish fed no CLA (Table 3). Moisture content of carcass and muscle increased significantly in fish fed increasing concentrations of CLA (Table 3). There were no significant differences in crude protein, fat, or ash concentrations in carcass or muscle of fish fed any of the dietary treatments.

Only one CLA isomer, 18:2(*c*-9,*t*-11) was detected in liver of fish fed the control diet (Table 4). Based on the retention time of the 18:2(*c*-9,*t*-11) standard, this peak immediately followed 18:4n-3 and was resolved at baseline. Four CLA isomers, 18:2(*c*-9,*t*-11/*c*-9,*c*-11) and 18:2(*t*-10,*c*-12/*t*-10,*t*-12), were detected in liver of fish fed 0.5, 0.75, and 1.0% dietary CLA. The highest concentrations were observed in fish fed 1.0% CLA. Total liver CLA concentrations in fish fed 0.5, 0.75, and 1.0% CLA were 2.8, 2.5, and 5.8% of fatty acids, respectively.

Significant differences were detected in fatty acid composition of liver between fish fed the control diet and those fed the diets containing CLA (Table 4). Fish fed 0.5% CLA and higher levels exhibited significantly greater concentrations of 14:0, 18:0, and 18:2(*c*-9,*c*-12), but significantly lower concentrations of 18:1n-7, 18:2(*t*-9,*t*-12) and 20:1n-9 in liver compared to fish fed the control diet. Furthermore, fish fed 1.0% CLA exhibited significantly higher liver concentrations of 20:4n-6, 20:5n-3, 22:5n-3, and 22:6n-3, but significantly lower concentrations of 18:1n-9 compared to fish fed 0, 0.5, or 0.75% CLA.

Similar to the liver fatty acid composition, 18:2(*c*-9,*t*-11) was the only CLA isomer detected in muscle of fish fed the control diet (Table 5). Three CLA isomers, 18:2(*c*-9,*t*-11) and 18:2(*t*-10,*c*-12/*t*-10,*t*-12), were detected in muscle of fish fed 0.5, 0.75, and 1.0% dietary CLA, while the 18:2(*c*-9,*c*-11) isomer was detected only in muscle of fish fed 0.75 and 1.0% CLA. Total muscle CLA concentrations in fatty acids of fish fed 0.5, 0.75, and 1.0% CLA were 3.4, 4.4, and 8.1%, respectively.

[c]Intraperitoneal fat (IPF) ratio was calculated as (IPF × 100/body weight).
[d]Probability (Pr > F) of treatment differences as determined by ANOVA. For other abbreviations see Table 2.

Significant differences in muscle fatty acid composition were detected between fish fed the control diet and those fed the diets containing CLA (Table 5). For example, fish fed 0.5% CLA and higher levels exhibited significant reductions in muscle 18:2(*t*-9,*t*-12) concentrations compared to fish fed the control diet. Fish fed 1.0% dietary CLA exhibited significantly higher concentrations of 18:2(*c*-9,*c*-12) in muscle compared to fish fed the control diet. Muscle concentrations of 20:5n-3 and 22:6n-3 were significantly decreased in fish fed 1.0% CLA compared to fish fed 0, 0.5, or 0.75% dietary CLA.

DISCUSSION

Research with terrestrial animals has demonstrated that dietary CLA elicit several positive responses, including reduced tumorigenesis (29), reduced atherosclerosis (6), enhanced immune response (5), increased feed efficiency (1,11), and reduced body fat (12,30). The implications of these findings for improved human health are obvious. Perhaps less obvious are the possible beneficial effects of dietary CLA on the production of food animals. Enhanced immune response and feed ef-

ficiency and reduced tissue lipids are desirable traits for food animals, including fish. However, CLA concentrations ≥1.0% of the diet have been shown to reduce growth rates in some experiments (5,13,14,30).

In the present study, hybrid striped bass fed 1.0% dietary CLA exhibited reduced feed intake and weight gain compared to control animals. Reduced growth rates have also been reported for mice fed dietary CLA at 1.0–1.5% of the dry diet (5,13,30), for tilapia and rockfish fed greater than 1.0% CLA, and for carp fed 10.0% CLA (13). Among the fishes examined to date, only the hybrid striped bass exhibited significantly lower weight gain when fed 1.0% dietary CLA.

Dietary CLA concentrations of less than 1.0% appear to have no significant effect on growth rates when compared to control animals. For example, growth rates of mice and rats fed 0.5% dietary CLA were not significantly different from those of animals fed no CLA (12,14,31), and hybrid striped bass fed 0.5 and 0.75% dietary CLA exhibited weight gains that were not significantly different from fish fed no CLA. Fish fed all dietary CLA concentrations evaluated exhibited significantly improved feed efficiencies compared to control animals. These results are consistent with studies conducted with rats (11). However, mice fed dietary CLA concentrations of 0.5, 1.0, and 1.5% exhibited reduced feed efficiencies compared to mice fed no CLA (14). Carp fed 5.0 or 10.0% dietary CLA exhibited reduced feed efficiencies compared to control animals, tilapia feed efficiency values were lower when fed 2.5% dietary CLA and higher concentrations, and feed efficiency values for rockfish were lower when fed 1.0% dietary CLA and higher concentrations (13).

Significant reductions in total liver lipid concentration and intraperitoneal fat ratio were observed in hybrid striped bass fed dietary CLA. Liver lipid concentration of fish fed 1.0% CLA was 2.5-fold lower than that observed in control fish. Dietary CLA have also been shown to modify body composition of rodents. Mice fed 0.5% CLA exhibited a significant reduction in body fat and a significant increase in body protein (12). In that experiment, carnitine palmitoyltransferase activity was significantly increased in fat pad and skeletal muscle of mice fed CLA, which indicates an increase in β-oxidation of fatty acids in response to dietary CLA. Furthermore, CLA caused a significant reduction in triglyceride concentration and lipoprotein lipase activity (consistent with reduced uptake of free fatty acids) in cultured 3T3-L1 adipocytes (12). In contrast to the significant reduction in lipid concentration of extrahepatic tissues, Belury and Kempa-Steczko (14) observed a two fold increase in liver lipid concentrations of mice fed 1.0 or 1.5% CLA. Similarly, rats fed 1.5% CLA exhibited a significant in-

crease in liver lipid concentration (32). Such differences in liver lipid accumulation between rodents and fish indicate that the effects of dietary CLA on lipid metabolism are likely to vary across species.

Four isomers of CLA were identified in both liver and muscle of hybrid striped bass fed dietary CLA, while only one isomer was identified in fish fed no CLA (Tables 4 and 5). In fish fed 0 CLA, mean values of 18:2(*c*-9,*t*-11) were 0.1 and 0.5% in liver and muscle, respectively, and both standard deviations were the same as the mean values. It seems unlikely the CLA was supplied in the experimental diets used in these studies, as the 9,11 isomers constituted only 29.5% of the supplement and only one isomer was identified. It is more probable that the CLA identified in control fish fed CLA in our studies was provided by previous diets fed to the experimental fish prior to acquisition. Those diets are proprietary, but it is common practice to include whey as an ingredient in diets of this type when price warrants inclusion.

Muscle CLA concentrations were as high as 7.97% of fatty acids in fish fed the highest dietary concentration (1.0% CLA) and 3.35% in fish fed the lowest concentration of CLA (0.5%). Regardless of the dietary level of CLA, the sum of the 10,12 isomers was slightly higher than the sum of the 9,11 isomers. Further, both sets of isomers constituted a relatively stable percentage of the total CLA across all treatments and in both tissues. The percentage of 10,12 isomers ranged from 53–57% of total CLA, and the 9,11 isomers were 43–46% of the total. These values are similar to the percentages of isomers in the diets (55.9% of 10,12 and 44.1% of 9,11). Thus, it appears CLA isomers are retained in tissues in similar proportions found in diets fed to fish. However, both 18:2(*c*-9,*t*-11) and 18:2(*t*-10,*c*-12) were retained in higher percentages than either all-*cis* or all-*trans* CLA. Further evaluation of these differences might be beneficial.

Muscle CLA concentrations in carp, tilapia, and rockfish fed 1.0% dietary CLA were 13.0, 4.1, and 5.1% of fatty acids, respectively (13). Those results indicate the ability of fish to accumulate CLA in muscle varies among species. Levels of CLA in those animals that naturally produce the fatty acid and its isomers are 0.27–0.56 g of CLA per 100 g of fatty acid (1). Cheese and milk fat contain 0.3–0.6 g of CLA per g of fatty acid (8). Thus, of the animals evaluated, fish appear to possess the ability to accumulate higher concentrations of CLA than other vertebrates. Additionally, there appears to be an interaction between CLA and long-chain n-3 fatty acids considered essential in this fish (20:5n-3 and 22:6n-3) (33) and beneficial for human health.

As dietary concentration of CLA increased, the concentration of 18:3n-3 was not significantly different in either liver or muscle, but the longer-chain n-3 fatty acids were significantly different across dietary treatments. In liver, 20:5n-3, 22:5n-3, and 22:6n-3 were significantly higher in fish fed 1.0% CLA, but were not significantly different in fish fed other levels of CLA or those in fish fed no CLA. Muscle concentrations of 20:5n-3 and 22:6n-3 were significantly lower in muscle of fish accumulating increasing levels of CLA and 18:2(*c*-9,*c*-12). Thus, as dietary concentrations and intake of CLA increased in hybrid striped bass, long-chain n-3 fatty acids appeared to be sequestered in liver resulting in decreasing concentrations in muscle, while 22:5n-3 concentrations were not significantly affected. At the same time, liver lipid concentrations dramatically decreased, and there were no clear distinctions regarding which fatty acids led to the decreased liver lipid concentrations. Since total liver lipid decreased and individual fatty acids remain somewhat constant as a percentage of the total, dietary CLA clearly affected hepatic lipid metabolism in hybrid striped bass.

Fish remain an important route of ingestion of beneficial fatty acids, and CLA is an important new component of fatty acid metabolism in humans. In this study, we demonstrated that the hybrid striped bass is capable of absorbing and retaining dietary CLA in liver and muscle and that the concentrations in muscle are higher than recorded for other vertebrates. Thus, fish appear to be a potential route of increased ingestion of CLA in humans.

Effects of Various Tocopherol-Containing Diets on Tocopherol Secretion into Bile

Kanae Yamashita*, Noriko Takeda, and Saiko Ikeda

Department of Food and Nutrition, School of Life Studies, Sugiyama Jogakuen University, Nagoya, 464-8662 Japan

ABSTRACT: γ-Tocopherol is abundant in common vegetable oil, but its concentration in plasma and liver is much lower than that of α-tocopherol. Discrimination between different forms of tocopherol is thought to take place *via* the hepatic α-tocopherol transfer protein (α-TTP). γ-Tocopherol, with a low binding capacity to α-TTP, is thought to be excreted *via* the bile. Our previous studies showed that γ-tocopherol administered with sesame seed exhibits significantly higher concentrations in the plasma and liver of rats than γ-tocopherol alone. Thus, we attempted to confirm whether a much higher amount of γ-tocopherol rather than α-tocopherol would be secreted in the bile, and whether sesame seed would suppress the secretion of γ-tocopherol. In one experiment, we examined the concentrations of α- or γ-tocopherol in the plasma, liver, and bile of rats fed diets containing 300 mg/kg of α-tocopherol, 300 mg/kg of γ-tocopherol, or 300 mg/kg each of α-tocopherol + γ-tocopherol, and in the other experiment, we compared the γ-tocopherol concentrations of rats fed a diet of γ-tocopherol alone to those of rats fed a γ-tocopherol + sesame seed diet (each diet contained 300 mg/kg γ-tocopherol). The bile collection was done over 6 h. The γ-tocopherol concentration in the bile was markedly lower than that of α-tocopherol, paralleling the concentrations in the plasma and liver. Intake of α-tocopherol and γ-tocopherol together further lowered the concentration of γ-tocopherol in the bile as well as in the plasma and liver, compared to the intake of γ-tocopherol alone. The γ-tocopherol concentration in the bile, as well as in the plasma and liver, was markedly higher in the sesame seed-fed group than in the γ–tocopherol alone group. We found that the concentrations of α- or γ-tocopherol in the bile showed a good correlation with the concentrations of α- or γ-tocopherol in the liver, though the concentrations in the bile were substantially lower than those in the liver. These findings suggest that secretion into the bile is not a major metabolic route of α- or γ-tocopherol.

Paper no. L8099 in *Lipids 35*, 163–170 (January 2000).

Among the eight structural forms of vitamin E, α-tocopherol is found in the highest concentrations in human plasma and tissue and shows the highest physiological activity. γ-Tocopherol is abundant in common vegetable oil, but its biological activity is estimated to be only 6 to 16% that of α-tocopherol (1,2). According to recent studies using various forms of vitamin E, no discrimination exists between α-tocopherol and γ-tocopherol during absorption (3,4), but following uptake by the liver, only *RRR*-α-tocopherol is preferentially bound to the α-tocopherol transfer protein (α-TTP) and secreted in nascent very low density lipoprotein (VLDL) (5–9). Thus, it is thought that discrimination between forms of tocopherol may occur in hepatic α-TTP. Tocopherols such as γ-tocopherol, which possess a low binding capacity to α-TTP, are thought to be excreted *via* the bile (6,9). Our previous studies have examined the antiaging effect of sesame seed. Sesame seed has long been used as a health food with purported antiaging effects, but contains only γ-tocopherol and negligible amount of α-tocopherol, which suggests low physiological vitamin E activity. Our experiments compared the *in vivo* concentrations of α- and γ-tocopherol in rats fed α-tocopherol, γ-tocopherol, or sesame seed-containing diets (50 mg/kg concentrations in all diets) (10,11). Sesame seed-fed rats showed almost the same concentration of γ-tocopherol in the plasma and tissue as α-tocopherol in rats fed the α-tocopherol-containing diet, but the γ-tocopherol concentration in rats fed a diet containing γ-tocopherol alone was very low in the plasma and tissue. In other words, γ-tocopherol administered with sesame seed exhibits significantly higher concentrations in the plasma and liver of rats than γ-tocopherol alone. One possibility we considered was that the biliary secretion of γ-tocopherol in rats fed sesame seed might be suppressed. Under this assumption, our preliminary investigation examined γ-tocopherol secretion in the bile of rats fed diets containing γ-tocopherol or sesame seed as the source of vitamin E. We found a higher γ-tocopherol concentration in the bile of rats fed the sesame seed-containing diet, though these rats showed higher γ-tocopherol concentrations in the plasma and liver than those of rats fed γ-tocopherol alone. Accordingly, we suspected that α-tocopherol, with concentrations higher than γ-tocopherol in the plasma and liver, might also be higher in the bile. Thus, we determined the investigation of biliary secretion of α- or γ-tocopherol in rats fed diets containing α- or γ-tocopherol as the vitamin E source. An additional consideration was that, when α-tocopherol and γ-tocopherol are administered together, the *in vivo* concentration of γ-tocopherol is substantially lower with administration of α-tocopherol

(12–16). This indicates that α-tocopherol promotes γ-tocopherol elimination. It was necessary to determine whether the biliary concentration of γ-tocopherol would be high or low in this case. Therefore, in the first of the present experiments, we examined the secretion of tocopherol into the bile in rats fed diets containing α-tocopherol, γ-tocopherol, or α- + γ-tocopherol. In the second experiment, we examined in more detail γ-tocopherol secretion into the bile in rats fed diets containing γ-tocopherol or γ-tocopherol with sesame seed as the source of vitamin E.

MATERIALS AND METHODS

Materials. α-Tocopherol, γ-tocopherol, and vitamin E homologs used for biochemical analysis were gifts of Eisai Co. (Tokyo, Japan). Vitamin E-stripped corn oil was purchased from Funahasi Nougyou Co. (Chiba, Japan). A vitamin E-free vitamin and mineral mixtures were both made according to AIN-76 formulation (17) by Nihon Hosan Kogyo (Yokohama, Japan). The white roasted sesame seed (donated by the Shinsei Co., Aichi, Japan) was ground finely in a mixer. The seed from the same batch was used throughout this investigation. Solvents used for chromatography were high-performance liquid chromatography (HPLC) grade from Katayama Chemicals Co., Ltd. (Osaka, Japan).

Animals and diets. Male Wistar rats, each weighing about 250 g (Japan SLC Inc., Shizuoka, Japan), were housed individually in stainless-steel wire-mesh cages at 24.5°C and 55% humidity, with a 12-h light/dark cycle. Rats were maintained in accordance with the Guidelines for Animal Experimentation of Nagoya University. They were allowed free access to a vitamin E-free diet (Table 1) for 7 d to standardize the *in vivo* conditions, and then given the experiment diets *ad libitum* for 1, 3, and 7 d. The experimental diets were in accordance with AIN-76 formulation (17) and consisted of 20% protein, 10% fat, vitamins excluding vitamin E, and minerals, as shown in Table 1. Tocopherol content in the diets was 300 mg/kg because we expected the high dose of tocopherols to produce a higher concentration of tocopherols in the body. In Experiment 1, a vitamin E-free diet, α-tocopherol alone diet, γ-tocopherol alone diet, and α- + γ-tocopherol combined diet were used. The amount of tocopherol was 300 mg/kg in the α-tocopherol and γ-tocopherol diets, and the amounts of α-tocopherol and γ-tocopherol were each 300 mg/kg in the α + γ diet. In Experiment 2, a vitamin E-free diet, γ-tocopherol diet, and sesame seed diet containing 20% ground white sesame seed (all diets contained a negligible amount of α-tocopherol) were used. The amount of γ-tocopherol in the γ-tocopherol diet was 300 mg/kg, and in the sesame seed diet (which already contained ~ 50 mg/kg of γ-tocopherol), it was adjusted to 300 mg/kg by the addition of γ-tocopherol. The concentration of tocopherol in the diets was confirmed by assay immediately after formulation. Diets were stored at –20°C until use. After the end of the experimental feeding, at 9:00 A.M. the next morning, rats were anesthetized with Nembutal (pentobarbital Na), and a laparotomy was performed to collect the bile, which was done for 6 h. Then rats were anesthetized again (at about 3:30 P.M.), blood was collected from the heart, and the liver was excised after perfusion with physiological saline. The concentrations of tocopherol in the plasma, liver, and bile were measured by HPLC according to the method developed by Ueda and Igarashi (18). The

γ-Tocopherol[b]		0.3	0.25

[a]In tocopherol- and sesame seed-containing diets, stripped corn oil was reduced, depending on the concentrations of tocopherol and sesame seed oil, which were calculated to be 50 g/100 g in the seed.
[b]Tocopherols were added dissolved in stripped corn oil. In sesame seed-containing diet, sesame seeds contained 23.5 mg/100 g of γ-tocopherol and negligible amounts of α-tocopherol.

plasma (0.15 mL) and the bile (0.5 mL) were pipetted into 10-mL centrifuge tubes with caps, and ethanol (1 mL), distilled water (0.5 mL), *n*-hexane (5 mL), and an hexanolic solution of 2,2,5,7,8-pentamethyl-6-chromanol (PMC) as an internal standard (0.2 mL) were added. The whole media were mixed vigorously for 1 min, and tocopherols were extracted in hexane. After centrifuging for 5 min at 1,000 rpm, the hexane layer was moved into the test tubes for the evaporation. Extraction with 5 mL *n*-hexane was repeated once more. The combined hexane layer was evaporated by the centrifugal vaporizer, redissolved in *n*-hexane (200 μL), and injected into the HPLC system. The liver (0.5 g) was homogenized with distilled water (1 mL). The homogenate (1 mL) was pipetted into a 25-mL test tube with a cap and 6% ethanolic pyrogallol (1 mL) and ethanolic solution of PMC (1 mL) were added. A 60% KOH solution (0.2 mL) was added and saponified at 70ºC for 30 min. After adding 2% NaCl solution (4.5 mL), the whole media were extracted with 10% ethylacetate in *n*-hexane (3 mL). After centrifuging, a portion of the hexane layer was evaporated, redissolved in *n*-hexane (200 μL), and injected into the HPLC system. Instrumentation used for HPLC was a Shimadzu Model LC-9A (Shimadzu, Kyoto, Japan) with a Shimadzu RF-535 fluorescence detector (Ex: 298 nm, Em: 325 nm). The analytical column used was a Nucleosil 5 NH_2 (4.6 Φ × 150 mm; Shinwa Chemical Industries, Ltd., Kyoto, Japan). The mobile phase was *n*-hexane/isopropylalcohol (99:1, vol/vol) at a flow rate of 1 mL/min.

Statistical analysis. Data are expressed as means ± SEM. Statistical analysis was performed using one-way analysis of variance (ANOVA) in SPSS Base 9.0 (Chicago, IL). When one-way ANOVA revealed $P < 0.05$, the data were further analyzed using Duncan's multiple comparison test (19). Differences were considered statistically significant at $P < 0.05$.

RESULTS AND DISCUSSION

(i) Concentrations of α-tocopherol and γ-tocopherol in plasma, liver, and bile (Experiment 1). In Experiment 1, rats were divided into four experimental groups: vitamin E-free, α-tocopherol (300 mg), γ-tocopherol (300 mg), and α- + γ-tocopherol (300 mg α-tocopherol + 300 mg γ-tocopherol). The results of body weight, liver weight, food intake, and amount of bile are shown in Table 2. The amount of bile collected during the 6-h period from 9:30 A.M. ranged from 1.8 to 4.9 mL, but was mostly in the range 3.0–3.5 mL. The concentrations of tocopherol in the plasma, liver, and bile of rats fed the experimental

[a]Values are presented as means ± SEM of six rats. Statistical analysis was performed combining all groups and times (12 in Experiment 1, and 9 in Experiment 2). Values not bearing the same superscript letter are significantly different at $P < 0.05$.
[b]The bile collection was performed for 6 h from 9:30 A.M.

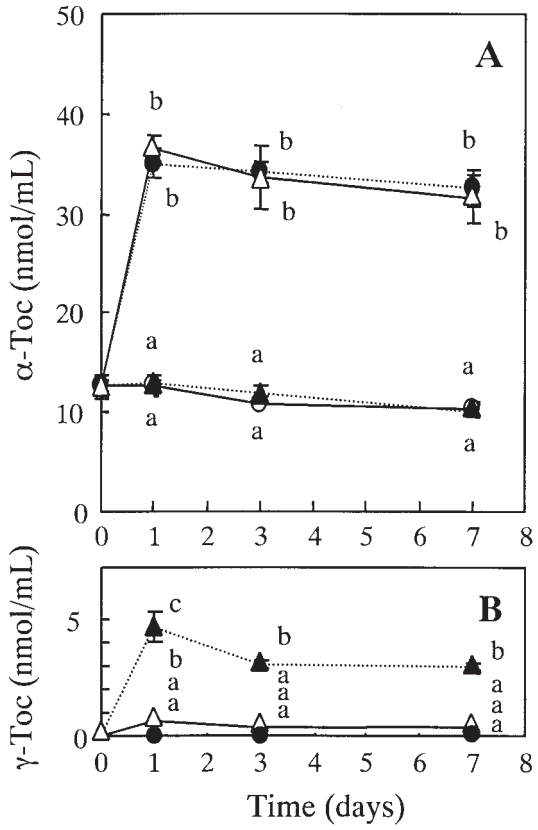

FIG. 1. α-Tocopherol (α-Toc) (A) and γ-tocopherol (γ-Toc) (B) concentrations in the plasma of rats fed a α-tocopherol diet, γ-tocopherol diet, and α- + γ-tocopherol diet in Experiment 1. After being fed a vitamin E-free diet for 7 d, rats were fed vitamin E-free diet, α-tocopherol diet (300 mg/kg), γ-tocopherol diet (300 mg/kg), or α- + γ-tocopherol diet (containing 300 mg/kg α-tocopherol and 300 mg/kg γ–tocopherol) for 1, 3, or 7 d. Each point represents the mean ± SE of six rats. Values not bearing the same superscript letter are significantly different at $P < 0.05$. ⅄ control (–E); ⅂ α-tocopherol; ⅁, γ-tocopherol; ⅋, α- + γ-tocopherol.

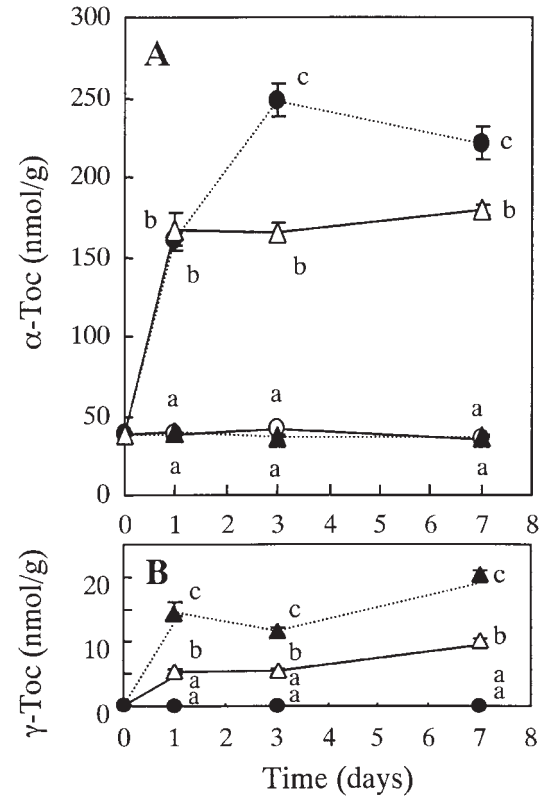

FIG. 2. α-Toc (A) and γ-Toc (B) concentrations in the liver of rats fed α-tocopherol diet, γ-tocopherol diet, and α- + γ-tocopherol diet in Experiment 1. See Figure 1 for abbreviations and point and symbol details.

diet for 1, 3, and 7 d are shown in Figures 1, 2, and 3. As shown in the figures, the concentrations of α-tocopherol and γ-tocopherol in the plasma, liver, and bile reached a plateau with only 1 d repletion of α- or γ-tocopherol after 1 wk of feeding with the vitamin E-free diet, with the exception of the liver in the α-tocopherol alone group which reached a plateau with 3 d repletion. Clement *et al.* (12) reported that α- or γ-tocopherol concentrations in the serum and liver reached a plateau after 8 d of repletion with *RRR*-α- or γ-tocopherol. Their experimental conditions differed in the acclimation period of the vitamin E-deficient diet (8 wk as opposed to our 1 wk) and in the quantity of repletion with tocopherol (they used a 30 mg/kg diet as opposed to our 300 mg/kg diet). Traber *et al.* (20) estimated that the binding capacity of α-TTP to α-tocopherol would be so large that it could bind an amount of α-tocopherol a few times larger than the apparent amount in the liver. Thus, the larger amount of feeding (300 mg/kg diet) caused the plateau to come sooner. We anticipated that a large amount of feeding would cause a large amount to be retained in the body, with a large amount secreted into the bile, thus providing us with clear-cut results. Our previous experiment showed that a large amount (250 mg/kg) of feeding produced 92.4 ± 3.5 μmol/g of α-tocopherol in the liver in comparison to 50 mg/kg feeding

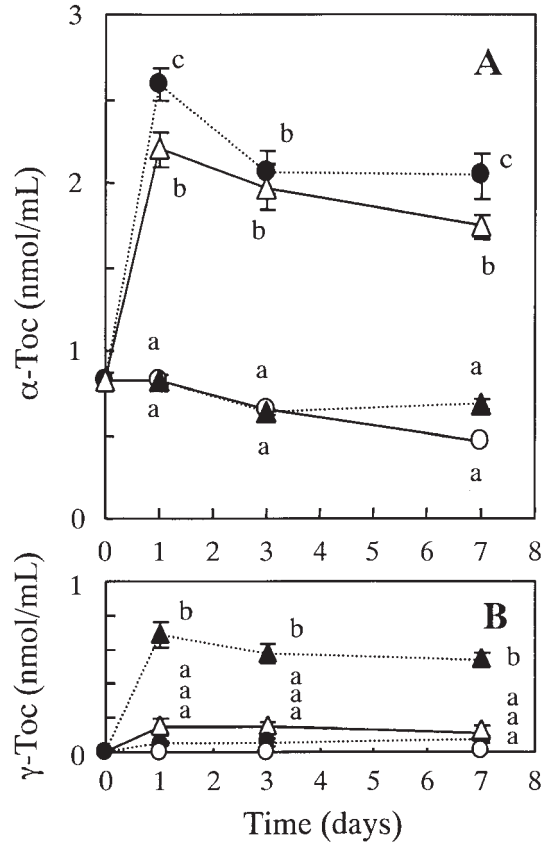

FIG. 3. α-Toc (A) and γ-Toc (B) concentrations in the bile of rats fed α-tocopherol diet, γ-tocopherol diet, and α- + γ-tocopherol diet in Experiment 1. Bile was collected for 6 h at the end of experimental feeding, starting at 9:30 the following morning. See Figure 1 for abbreviations and point and symbol details.

with 36.0 ± 1.4 μmol/g (11). Further, Traber *et al.* (20) showed with rats with cannulated thoracic lymph ducts that a large dose of α-tocopherol caused a lower percentage of tocopherol to be absorbed but the amount of tocopherol absorbed was large (4).

The α-tocopherol concentration in all rats was higher than γ-tocopherol not only in the plasma and liver but also in the bile. α-Tocopherol concentrations were high in the α-tocopherol and α + γ groups that took α-tocopherol. The concentrations of α-tocopherol in the plasma were similar in the α-tocopherol and α + γ groups, but those in the liver were slightly lower than in the α-tocopherol group on days 3 and 7. The large (300 mg) intake of γ-tocopherol apparently acts to lower the concentration of α-tocopherol in the liver. Behrens and Madere (15) reported on α- and γ-tocopherol concentrations in plasma and tissue in rats dosed of a large amount of *RRR*-α- and/or *d*-γ-tocopherol. They claimed that α-tocopherol levels in the plasma and tissue showed no significant difference between the α-tocopherol alone group and the α-tocopherol with γ-tocopherol group, but the data showed a tendency toward a slightly lower concentration of α-tocopherol in the α- + γ-tocopherol group than in the α-tocopherol alone group. Thus, the α-tocopherol concentration in the liver might become low due to the large accompanying dose of γ-tocopherol. It is not clear that a large dose of γ-tocopherol suppresses α-tocopheol absorption or promotes elimination of α-tocopherol from the liver. We initially thought that a large, simultaneously ingested amount of γ-tocopherol would promote secretion of α-tocopherol into the bile, with the concentration of α-tocopherol in the liver becoming subsequently low. However, the opposite result was achieved. The concentration of α-tocopherol in the bile was lower in α + γ combined group than in α-tocopherol alone group. On the other hand, we observed fairly large amounts of α-tocopherol in the vitamin E-free and γ-tocopherol groups, which consumed no α-tocopherol. The depletion of α-tocopherol from plasma and tissue takes over 8 wk. As the period of acclimation with the α-tocopherol-free diet was only 1 wk in the present experiment, we detected a rather large amount of α-tocopherol in the plasma, liver, and bile of the vitamin E-free and γ-tocopherol groups. Of course, the concentrations of α-tocopherol in the vitamin E-free control and γ-tocopherol groups were low in the bile as well as in the plasma and liver as compared with the α-tocopherol-fed groups. Thus, it was shown that the groups with a high concentration α-tocopherol in the liver were also high in the bile.

On the other hand, γ-tocopherol was detected in the plasma and liver only in the γ-tocopherol and α + γ combined groups that had been given γ-tocopherol. Furthermore, the γ-tocopherol was detected at extremely low concentrations in spite of the large nonphysiological dose (300 mg /kg), and the γ-tocopherol concentration in the plasma and liver of the α + γ combined group was lower than that in the γ-tocopherol group, which is in agreement with previous reports (12–15). Further, in the α-tocopherol and vitamin E-free groups, no γ-tocopherol was detected in the plasma and liver. The fact that γ-tocopherol is low in the plasma and tissue is caused by the low affinity of γ-tocopherol to α-TTP, though it is said that α- and γ-tocopherol are absorbed at the same rate (3,4). γ-Tocopherol, which does not bind to α-TTP, should have been secreted into the bile at the time we started this experiment (6,9,21). Thus, we anticipated that the large dose of γ-tocopherol would cause a larger amount of γ-tocopherol than α-tocopherol to be secreted into bile, and further that α-tocopherol in the α + γ combined group would also cause a larger amount of γ-tocopherol to be secreted into the bile. We expected the largest amount of γ-tocopherol in the α + γ combined group and next largest in the γ-tocopherol group. However, we obtained quite the opposite results. The concentration of γ-tocopherol in the bile was lower than that of α-tocopherol, and the concentration of γ-tocopherol in the γ-tocopherol group was lower than that of α-tocopherol in the α-tocopherol group and higher than that of γ-tocopherol in the α + γ combined group. These results suggest that γ-tocopherol is not simply excreted into the bile but instead that the elimination of γ-tocopherol from the animal body is effected by a different mechanism. Recently, metabolites of α- and γ-tocopherol have been found in the urine of humans and rats (22–26) and we discuss these factors below.

(ii) Effect of sesame seed on γ-tocopherol concentration in plasma, liver, and bile (Experiment 2). Sesame seed contains about 25 mg/100 g γ-tocopherol and negligible amounts of α-tocopherol. Thus, none of the three diets used in this experiment (vitamin E-free, γ-tocopherol, and sesame seed) contained α-tocopherol. As shown in Table 2, there were no significant differences among the three dietary groups in rat body weight and the amount of bile collected during the 6 h. The α- and γ-tocopherol concentrations in the plasma, liver, and bile in the rats fed the vitamin E-free, γ-tocopherol, and sesame diets for 1, 3, and 7 d are shown in Figures 4, 5, and 6. None of the rats in the vitamin E-free, γ-tocopherol, or sesame groups consumed α-tocopherol, but fairly large amounts of α-tocopherol were detected in all groups. The reason is described above. With the extension of the diet-feeding period, α-tocopherol in the plasma decreased slightly, but that in the liver and bile scarcely changed. Although statistically significant differences in the plasma and liver α-tocopherol concentrations were observed among the dietary groups, the result did not show a fixed tendency. Therefore, the amount of α-tocopherol stored should be similar in all three groups as a whole. The amount of α-tocopherol secreted into the bile tended to be low in the vitamin E-free group on days 1, 3, and 7, but generally, the intake of γ-tocopherol or sesame seed seemed to have a little effect on the amount of α-tocopherol secreted into the bile.

On the other hand, the concentration of γ-tocopherol in the plasma, liver, and bile greatly differed from group to group. In the vitamin E-free group, γ-tocopherol was not detected in the plasma, liver, or bile (as in Experiment 1). γ-Tocopherol and sesame groups consumed almost the same amount of γ-tocopherol, but showed a great difference in the concentration of γ-tocopherol in the plasma, liver and bile, the value in the sesame group being very high. For example, γ-tocopherol concentrations in the plasma on 1-d feeding of γ-tocopherol or sesame seed were 5.96 ± 1.27 μmol/mL and 37.28 ± 3.07 μmol/mL, respectively. Previously, we reported that the plasma and liver concentrations of γ-tocopherol increased with the administra-

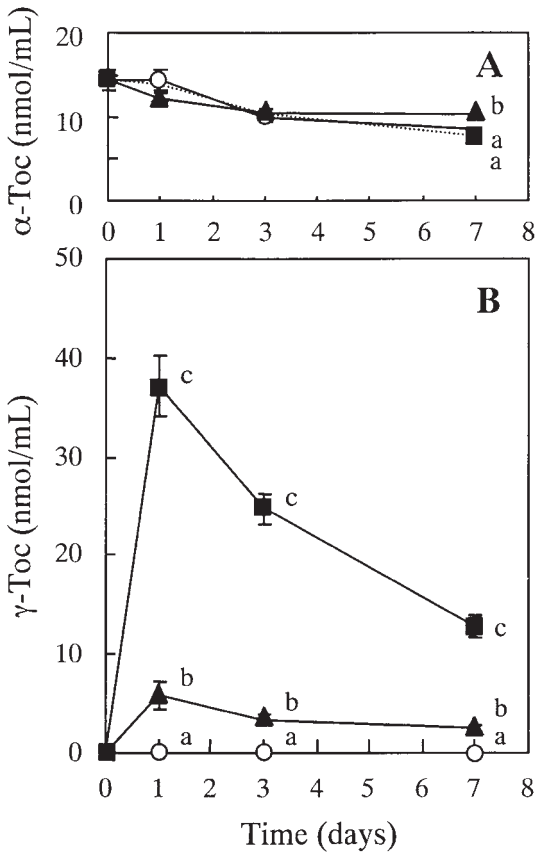

FIG. 4. The effect of sesame seed on α-Toc (A) and γ-Toc (B) concentrations in the plasma of rats in Experiment 2. After being fed a vitamin E-free diet for 7 d, the rats were fed vitamin E-free diet, γ–tocopherol (containing 300 mg/kg γ–tocopherol), or sesame seed diet (containing 300 mg/kg γ–tocopherol including γ–tocopherol in 20% sesame seed) for 1, 3, or 7 d. See Figure 1 for abbreviations and point and symbol details.

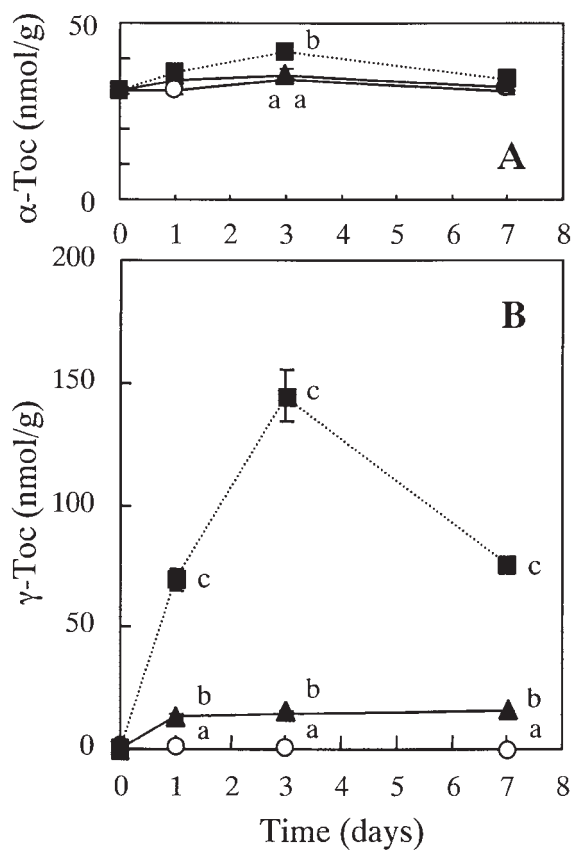

FIG. 5. Effect of sesame seed on α-Toc (A) and γ-Toc (B) concentrations in the liver of rats in Experiment 2. See Figure 1 for abbreviations and point and symbol details.

tion of sesame seed (10,11,16). The present experiment showed that the intake of sesame seed even for 1 d is greatly effective. The purpose of this experiment at the beginning was to clarify why sesame seed causes high concentrations of γ-tocopherol. Thus, this experiment was conducted under the assumption that a high concentration of γ-tocopherol is maintained in rats fed sesame seed due to the suppression of γ-tocopherol elimination into the bile. However, the concentration of γ-tocopherol in the bile was higher in the sesame seed group than in the γ-tocopherol group, contrary to our expectations. The increase of the plasma and liver concentrations of γ-tocopherol by sesame seed intake cannot be explained by the suppression of secretion into the bile. The explanation that γ-tocopherol, with a weak binding affinity to α-TTP, secretes into the bile quickly was too simple. The original data by Traber and Kaden (6), who proposed this idea, showed that a larger amount of γ-tocopherol than α-tocopherol was secreted into bile for the first 8 h after ingestion of a single dose (300 mg each), but that secretion into the bile from 12 to 24 h was higher in α-tocopherol than γ-tocopherol. The pattern of change in concentration in the bile was similar to that in the liver. Thus, plotting the α- and γ-tocopherol concentrations in the bile against those of the liver in all the rats combining the results in Experiments 1 and 2 showed that changes of α- and γ-tocopherol in the bile were linearly correlated with their liver

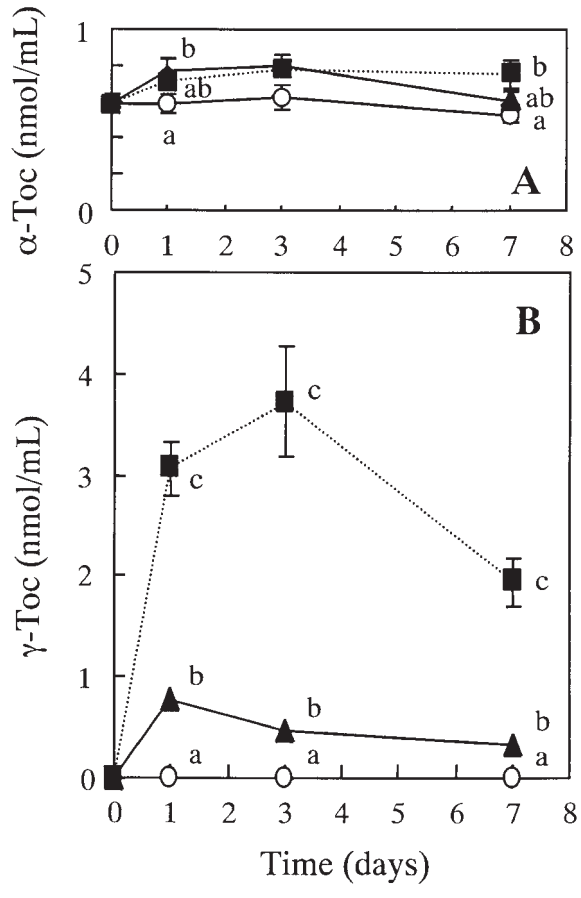

FIG. 6. Effect of sesame seed on α-Toc (A) and γ-Toc (B) concentrations in the bile of rats in Experiment 2. Bile was collected at the end of experimental feeding for 6 h, starting at 9:30 the following morning. See Figure 1 for abbreviations and point and symbol details.

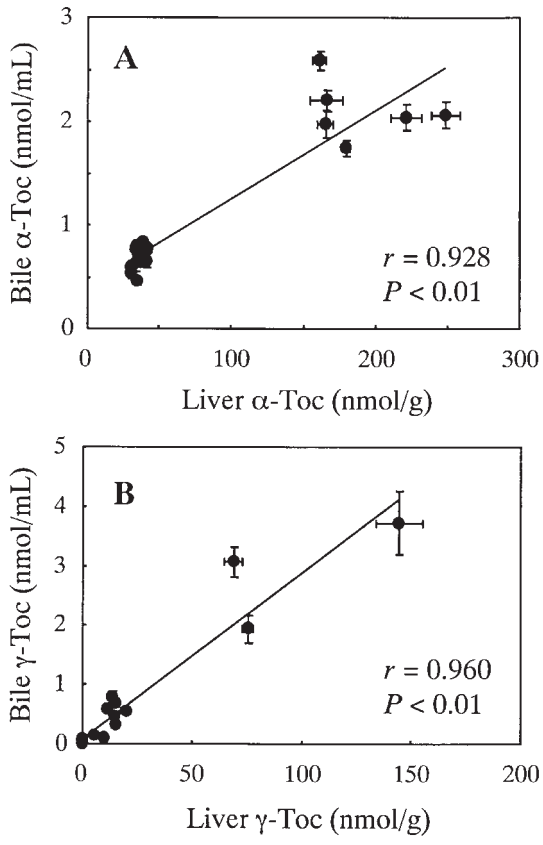

FIG. 7. Correlations between biliary concentrations of α-Toc (A) and γ-Toc (B) and those in the liver. See Figure 1 for abbreviations.

counterparts (Fig. 7). The strong correlation between the liver and the bile suggests that α- or γ-tocopherol in the liver leaked into the bile in proportion to the concentration in the liver. In addition, the amounts of α- or γ-tocopherol in the bile were very slight. We roughly calculated how much tocopherol in the liver was secreted into the bile over 6 h. The percentages of secreted tocopherol in the bile to α- and γ-tocopherol concentration in the liver were 0.3–0.7% of α-tocopherol and 0.3–1.7% of γ-tocopherol. An example of the calculation as shown in the rats fed α-tocopherol diet for 1 d is as follows. As the liver weight was 9.95 g and the concentration of α-tocopherol was 161 μmol/g, the total tocopherol in the liver became 1,604 μmol. The bile volume was 2.9 mL and its concentration of α-tocopherol was 2.56 μmol/mL; then the α-tocopherol in bile became 7.44 μmol/6 h. Thus, the percentage of α-tocopherol in bile to α-tocopherol in liver for 6 h came to 0.4%. Further, Bjorneboe *et al.* (27) determined the appearance of radioactivity in the bile duct after injection of α-[^{3}H]tocopherol. They recovered 14.2% of the given dose of radioactivity by draining the bile duct for 24 h. Only 13.5% of the radioactivity in the bile emerged with α-tocopherol. That means only 2% of the dose of α-tocopherol has recovered as α-tocopherol in the bile over 24 h. Our results as well as those of Bjorneboe *et al.* show that very slight quantities of α- and γ-tocopherol are secreted into the bile.

Recently, a urinary metabolite of α-tocopherol, α-CEHC [2,5,7,8-tetramethyl-2(2′-carboxyethyl)-6-hydroxychroman], was shown to be the major metabolite of α-tocopherol, which conjugates with glucuronic acid or sulfilic acid and is eliminated into urine. Schultz *et al.* (22) reported that urinary α-CEHC was an indicator of an adequate α-tocopherol supply. Traber *et al.* (24) reported that there was more α-CEHC from all-rac-α-tocopherol, which has lower biologic activity, than from *RRR*-α-tocopherol, which has higher biologic activity, and that γ-CEHC, a major metabolite of γ-tocopherol, was more prevalent than α-CEHC in human urine. Further, Swanson *et al.* (25) described that given an estimated mean intake of γ-tocopherol of 20 mg/d, the catabolism of γ-tocopherol to γ-CEHC, followed by glucuronide conjugation and urinary excretion, is a major pathway for elimination of γ-tocopherol in humans. Initially, γ-CEHC was reported by Wechter *et al.* (23) to be a new endogenous natriuretic factor, LLU-α. If γ-CEHC is a major metabolite for γ-tocopherol, its concentration would fluctuate greatly depending on the γ-tocopherol intake, that is, by dietary habit. However, Swanson *et al.* (25) observed in their paper that most γ-CEHC was eliminated as glucuronide conjugate and the quantity of free γ -CEHC, which might act as a similar hormone, would be slight. These results were shown using human subjects. However, CEHC derivative was first described as δ-CEHC, a δ-tocopherol metabolite in urine, by Chiku *et al.* (26) using rats. In our study, one of the reasons γ-tocopherol is high in rats fed sesame seed is that sesame lignans, characteristic compounds of sesame seed, might inhibit the enzymes that convert γ-tocopherol to γ-CEHC. It is necessary to further investigate this possibility.

Biliary secretion of small quantities of α- or γ-tocopherol does take place correlating with the concentrations in the liver, but these tocopherols in the bile might be recirculated from the small intestine to the liver as Lee-Kim *et al.* (28) have shown. However, the present findings suggest that secretion into bile is not a major metabolic route of α- or γ-tocopherols.

ABSTRACT: Studies were conducted to determine the comparative effects of tocopherols and tocotrienols on normal mammary epithelial cell growth and viability. Cells isolated from midpregnant BALB/c mice were grown within collagen gels and maintained on serum-free media. Treatment with 0–120 μM α- and γ-tocopherol had no effect, whereas 12.5–100m μM tocotrienol-rich fraction of palm oil (TRF), 100–120 μM δ-tocopherol, 50–60 μM α-tocotrienol, and 8–14 μM γ- or δ-tocotrienol significantly inhibited cell growth in a dose-responsive manner. In acute studies, 24-h exposure to 0–250 μM α-, γ-, and δ-tocopherol had no effect, whereas similar treatment with 100–250 μM TRF, 140–250 μM α-, 25–100 μM γ- or δ-tocotrienol significantly reduced cell viability. Growth-inhibitory doses of TRF, δ-tocopherol, and a-, γ-, and δ-tocotrienol were shown to induce apoptosis in these cells, as indicated by DNA fragmentation. Results also showed that mammary epithelial cells more easily or preferentially took up tocotrienols as compared to tocopherols, suggesting that at least part of the reason tocotrienols display greater biopotency than tocopherols is because of greater cellular accumulation. In summary, these findings suggest that the highly biopotent γ- and δ-tocotrienol isoforms may play a physiological role in modulating normal mammary gland growth, function, and remodeling.

Paper no. L8332 in *Lipids 35,* 171–180 (February 2000).

During the past decade a large volume of literature has accumulated indicating that dietary supplementation of the vitamin E isoform α-tocopherol (α-T) may have significant health benefits in preventing a variety of diseases (1–3). It is well established that α-T is an important antioxidant that regulates peroxidation reactions and free-radical production (1). Uncontrolled or excessive free-radical production can ultimately lead to cellular damage, dysfunction, or death (1). However, α-T and other vitamin E isoforms also have been shown to play an important role in modulating several intracellular signaling pathways involved with mitogenesis (4–7) and apoptosis (8–12).

Vitamin E is a generic term that represents a family of chemically related compounds that is subdivided into two subgroups called tocopherols and tocotrienols. Tocopherols are commonly found in high concentrations in a wide variety of foods, whereas tocotrienols are relatively rare and found in appreciable levels in only a few specific vegetable fats, such as palm oil (13,14). Previous studies have demonstrated that high dietary intake of crude palm oil, in contrast to other high-fat diets, suppressed carcinogen-induced mammary tumorigenesis in experimental animals (14–17). Furthermore, if tocotrienols are removed from palm oil, the protective effects of high palm oil diets are no longer observed (17). Similarly, tocotrienol treatment has been associated with beneficial effects in a variety of *in vivo* and *in vitro* experimental models, and the majority of these studies showed that specific tocotrienol isoforms are significantly more potent than corresponding tocopherol isoforms (18–23).

The exact reason why tocotrienols display greater bioactivity than tocopherols is still under investigation. Tocopherols and tocotrienols have the same basic chemical structure characterized by a long phytyl chain attached at the 1-position of a chromane ring (Scheme 1). However, tocopherols have a saturated, whereas tocotrienols have an unsaturated phytyl chain (Scheme 1). Individual isoforms of tocopherols and tocotrienols differ from each other based on the number of methyl groups bound to their chromane ring. Tocopherol and tocotrienol α-isoforms contain methyl groups on the 5-, 7-, and 8-positions, while their γ-isoforms lack the methyl group at the 5-position, and their δ-isomers lack methyl groups on the 5- and 7-positions on the chromane ring (Scheme 1). It is possible that the level of phytyl chain saturation and/or chromane ring methylation may be critical in determining the antiproliferative and apoptotic activity of individual tocopherol and tocotrienol isoforms.

At present, little information is available regarding the effects of specific vitamin E isoforms on the growth and viabil-

ity of normal cells. Therefore, the following studies were conducted to characterize the antiproliferative and apoptotic effects of specific tocopherol and tocotrienol isoforms on normal mouse mammary epithelial cells grown in primary culture and maintained in serum-free media. Additional studies were conducted to determine the relationship between biopotency and the magnitude of cellular accumulation for the various tocopherol and tocotrienol isoforms.

EXPERIMENTAL PROCEDURES

Isolation and culture of mammary epithelial cells. All procedures involving animals were approved by the institutional animal use and care committees at the University of Louisiana at Monroe and Washington State University. Mammary epithelial cells were isolated and prepared for culture, as previously described (24–27). All materials were purchased from Sigma Chemical Co. (St. Louis, MO), unless otherwise stated. Briefly, mammary glands from midpregnant BALB/c mice were removed, minced, and subjected to collagenase followed by pronase E (Type XIV bacterial from *Streptomyces griseus*) digestion. Mammary epithelial cells isolated from midpregnant mice were selected for experimentation because these cells are highly responsive to EGF-induced mitogenesis (28). Mammary epithelial cell organoids were isolated by a series of filtrations through sterile 250- and 48-μm nitex filters (Tetko Inc., Briarcliff Manor, NY), plated within rat tail collagen gels at a density of 2.2×10^7 cells/8 mL of collagen in 100 mm plastic plates, and fed 10 mL of growth media [Dulbecco's modified Eagle's medium (DMEM)/Ham's F-12 medium, 1:1, insulin 10 μg/mL, penicillin 100 U/mL, streptomycin 100 μg/mL, 10% bovine calf serum (Hyclone, Logan, UT)]. Plates were then placed in a humidified incubator at 37°C in an environment of 95% air and 5% CO_2. After a 2-d incubation period, mammary epithelial cell organoids were again isolated by collagenase digestion and filtration. This double isolation procedure provides isolated mammary epithelial cell organoids ready for experimentation that are devoid of fibroblast and adipocyte contaminants (29). Mammary epithelial cells were then plated within collagen gels at a density of 2×10^5 cells/0.5 mL collagen in 24-well tissue culture plates (growth studies) or 1×10^7 cells/8 mL collagen in 100-mm culture plates (DNA isolation studies). Cells were divided into different treatment groups and fed serum-free control or treatment media every other day, consisting of DMEM/F12 containing 5 mg/mL bovine serum albumin (BSA), 10 μg/mL transferrin, 100 U/mL soybean trypsin inhibitor, 100 U/mL penicillin, 0.1 mg/mL streptomycin, 10 ng/mL EGF, and 10 μg/mL insulin.

Medium vitamin E supplementation and experimental treatments. Tocopherol and tocotrienol isoforms were conjugated to BSA as previously described (24). Briefly, an appropriate amount of α-T, γ- and δ-tocopherol (γ-T and δ-T), α-, γ-, δ-tocotrienol (α-T^3, γ-T^3, and δ-T^3) or tocotrienol-rich fraction of palm oil (TRF) was placed into a 1.5-mL screw top glass vial and dissolved in 100 μL of 100% ethanol. Once dissolved, this ethanol solution was added to a small volume of sterile 10% BSA in water and incubated overnight at 37°C. The resulting sterile stock solutions of TRF, and individual tocopherol and tocotrienol isoforms conjugated to BSA, was then used to prepare various concentrations (0–250 μM) of tocopherol-, tocotrienol-, or TRF-supplemented treatment media. Ethanol was added to all treatment media so that the final ethanol concentration was the same in all treatment groups within a given experiment and was always less than 0.1%.

Measurement of viable cell number. Mammary epithelial cell number was determined in 24-well culture plates (6 wells/group) by the 3-(4,5-dimethylthiazol-2yl)-2,5-diphenyl

tetrazolium bromide (MTT) colorimetric assay as described previously (24–27). On the day of assay, treatment medium was replaced with fresh growth medium containing 0.83 mg/mL MTT, and cells were returned to the incubator for 4 h. Afterward, gels were removed from the culture plates, placed in 12 × 75 mm test tubes, and dissolved in 0.5 mL of 25% acetic acid. MTT crystals were pelleted by centrifugation, and the MTT crystals dissolved in 1 mL of 2-propanol. Optical density of each sample was read on a microplate reader (model 7520 Cambridge Technology, Inc., Watertown, MA) at 570 nm against a blank prepared from cell-free collagen gels. The number of cells/well was calculated against a standard curve prepared by plating various concentrations of cells, as determined by hemacytometer, at the start of each experiment (24–27). In separate control studies, various doses (0–250 μM) of TRF or specific tocopherol or tocotrienol subtypes were not found to affect the specific activity of the MTT colorimetric assay.

Apoptosis as determined by DNA fragmentation and nuclear condensation assays. Cells in each treatment group were grown in 100-mm plates (2–3 plates/group) and treated with various doses of specific tocopherols, tocotrienols, or TRF for 0–48 h. To determine treatment-induced programmed cell death, as indicated by DNA fragmentation, cells were isolated from collagen gels by collagenase digestion, rinsed three times, and pooled; DNA was then isolated from cells within each treatment group by phenol/chloroform extractions (30). Isolated DNA was then fractionated on a 1.2% Tris/acetic acid/EDTA agarose gel and visualized with an ultraviolet transluminator. Treatment-induced apoptosis was also determined *in situ* by visualization of treatment effects on nuclear condensation in mammary epithelial cells grown in primary culture. In these studies, cells were cultured within collagen gels for 5 d and then exposed for 24 h to 25 or 110 μM TRF. Ethidium bromide (10 μg/mL) was then added directly to the culture media and 30 min later, bright-field and epifluorescence photomicrographs of the same field were taken of mammary epithelial cell cultures in each treatment group. Cells undergoing apoptosis were characterized by enhanced nuclear epifluorescence intensity, an indication of increased nuclear accumulation of ethidium bromide (31).

Cellular accumulation of tocopherols and tocotrienols. Mammary epithelial cells were cultured in control media for 5 d and then treated with various doses of tocopherols, tocotrienols, or TRF for 0, 15 min, 6 h, 12 h, or 24 h. Cells within each treatment group were isolated from collagen gels by collagenase digestion, rinsed three times, and then extracted for assay of tocopherol and tocotrienol content as determined by reversed-phase high-performance liquid chromatography (HPLC) with fluorometric detection using a modification of the methods previously described (32,33). Briefly, aliquots of internal standard (1.6 nmol of α-T for determination of δ-T levels or 1.6 nmol of δ-T for quantification of all other tocopherol and tocotrienol isoforms) was added to the appropriate treatment group of isolated mammary epithelial cells. The same amount of the corresponding internal standard (1.6 nmol) was also added to the appropriate tocopherol and tocotrienol isoform standards. Cells in each treatment group were then resuspended by sonication in 0.3 mL of 1% asorbate in 0.1 M sodium dodecyl sulfate and 0.45 mL 100% ethanol. Hexane (0.8 mL) was next added to each sample, and then each sample/hexane mixture was vortexed for 30 s; the resulting hexane extracts were dried under nitrogen. The dried extracts were then resuspended in 1 mL methanol containing 2.5% ascorbate. Extracted and nonextracted standards of each tocopherol and tocotrienol isoform (0.05 to 5 nmol/sample) were run with each assay, and results were expressed as nmol/mg. Samples were injected on a Hewlett-Packard 1050 HPLC equipped with an autosampler, Chem Station software, McPherson 749 fluorescence detector, and Spherisorb ODS II column (250 × 4.6 mm i.d., 5 μm; Alltech, Avondale, PA). The mobile phase was 96% methanol, which was run isocratically at a flow rate of 1.8 mL/min. Excitation and emission wavelengths of 210 and 300 nm, respectively, were used for all tocopherol and tocotrienol isoform determinations. Samples and standards were assayed by HPLC on the same day of extraction. Cellular concentrations was expressed as the average of four replicates in each treatment group. TRF was assayed by HPLC prior to use in experimentation and determined to be composed of 20.2% α-T, 16.8% α-T[3], 44.9% γ-T[3], 14.8% δ-T[3], and 3.2% of a nonvitamin E lipid soluble contaminant. Treatment doses of TRF were then calculated based on the percent composition and molecular weights of individual vitamin isoforms within TRF.

Statistical analysis. Differences among the various treatment groups were determined by analysis of variance, followed by Duncan's multiple range test. A difference of $P < 0.05$ was considered to be significant, as compared to controls or as defined in the figure legends. Linear regression analysis of treatment effects on viable cell number in growth and cytotoxicity studies was used to determine the 50% growth inhibition concentration (IC_{50}) and 50% lethal dose (LD_{50}) for individual treatments.

RESULTS

The effects of various doses of TRF on normal mammary epithelial cell growth in primary culture are shown in Figure 1. Cells grown in serum-free control media displayed more than a twofold increase in viable cell number over the 5-d culture period (Fig. 1). Supplementation of culture medium with 12.5–50 μM TRF significantly inhibited EGF-induced cell proliferation in a dose-responsive manner as compared to controls (Fig. 1). The highest dose of TRF (100 μM) appeared to be cytotoxic since viable cell number after 5 d of culture was less than that initially plated at the start of experimentation (Fig. 1).

Since TRF contains a number of vitamin E isoforms, it was not possible to determine if one or all of these isoforms were responsible for mediating the growth inhibitory effects of TRF described in Figure 1. Additional studies were conducted to determine the antiproliferative effects of specific tocopherol and tocotrienol isoforms on EGF-induced mammary epithelial cell proliferation in primary culture (Fig. 2). After

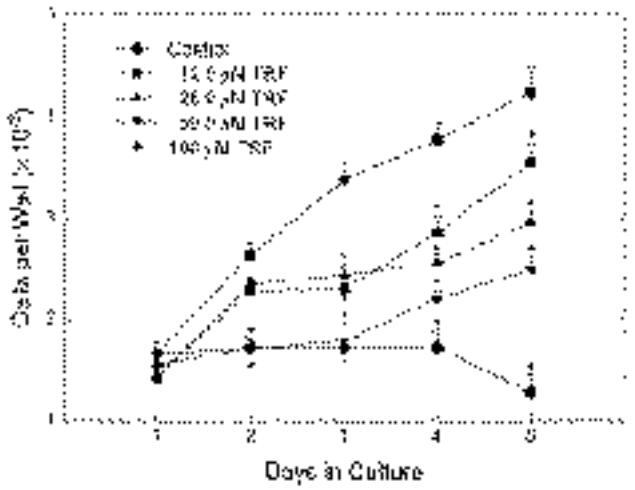

FIG. 1. Effects of various doses of tocotrienol-rich fraction (TRF) on normal mammary epithelial cell proliferation in primary culture. Data points indicate the mean cell count/well ± SEM for six replicates in each treatment group during the 5-d culture period. $^*P < 0.05$, as compared to controls.

5 d of culture, treatment with 0–120 μM α-T or γ-T had no effect (Fig. 2A and B), whereas treatment with 100–120 μM δ-T significantly inhibited mammary epithelial cell growth as compared to controls (Fig. 2C). Treatment with 50–60 μM α-T^3 (Fig. 2D), 8–14 μM γ-T^3 (Fig. 2E) or δ-T^3 (Fig. 2F) was also found to significantly inhibit mammary epithelial cell growth as compared to controls.

TABLE 1
Effects of Various Vitamin E Compounds on Mammary Epithelial Cell Growth (IC_{50}) and Viability (LD_{50})[a]

Vitamin E	IC_{50} (μM)	LD_{50} (μM)
TRF	25	110
α-Tocopherol	>120	>250
γ-Tocopherol	>120	>250
δ-Tocopherol	94	>250
α-Tocotrienol	45	238
γ-Tocotrienol	8	46
δ-Tocotrienol	7	36

[a]IC_{50}, treatment dose that induces 50% growth inhibition; LD_{50}, treatment dose that induces 50% cell death; TRF, tocotrienol-rich fraction.

The effects of a 24 h treatment exposure to various concentrations of tocopherols, tocotrienols, or TRF on viable cell number are shown in Figure 3. Acute treatment with 0–250 μM of α-T, γ-T, or δ-T had no significant affect on mammary epithelial cell viability (Fig. 3). In contrast, 24-h exposure to 100–250 μM TRF, 140–250 μM α-T^3, 25–100 μM γ-T^3, or 25–100 μM δ-T^3 caused a significant dose-responsive decrease in viable cell number, with 100 μM γ-T^3 and 60–100 μM δ-T^3 reducing viable cell number to undetectable levels (Fig. 3).

Table 1 summarizes the relative potencies of TRF and specific tocopherol and tocotrienol isoforms on normal mammary epithelial cell growth and viability. TRF was found to have an IC_{50} of 25 μM and LD_{50} of 110 μM (Table 1). Over

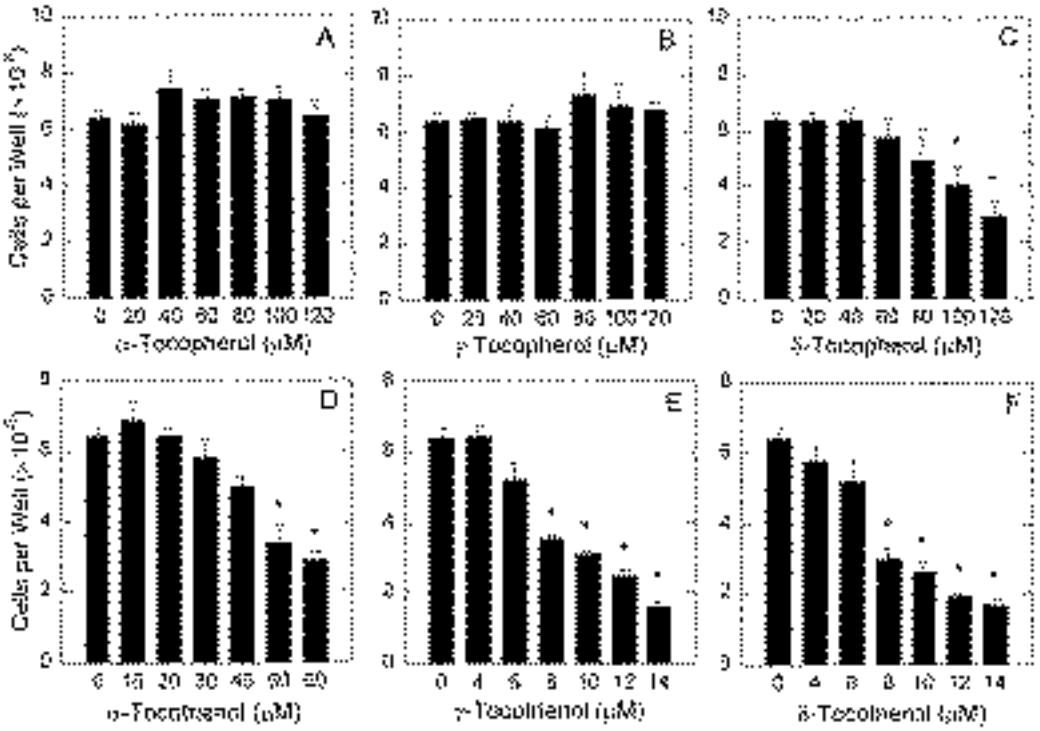

FIG. 2. Effects of various doses of individual tocopherol and tocotrienol isoforms on normal mammary epithelial cell proliferation in primary culture. Vertical bars represent mean cell count/well ± SEM for six replicates in each treatment group after 5 d in culture. $^*P < 0.05$, as compared to controls.

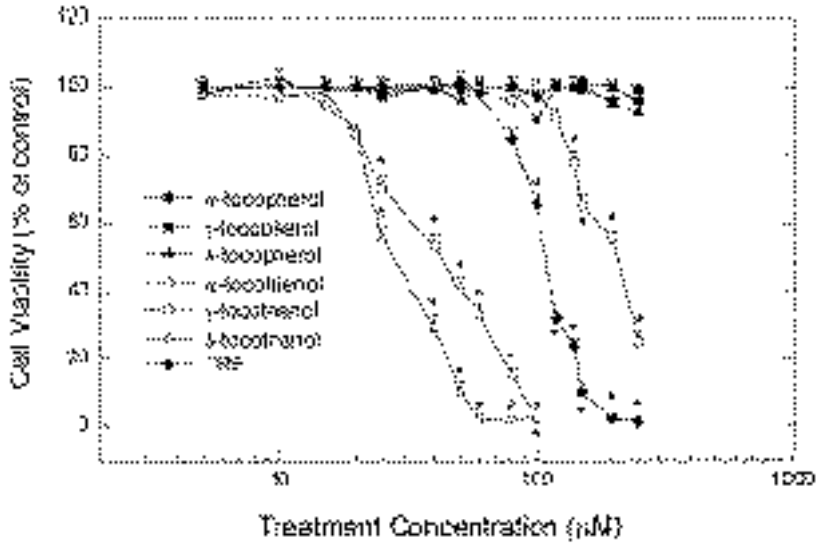

FIG. 3. Mammary epithelial cell viability after a 24-h exposure period to various doses of TRF or individual tocopherol and tocotrienol isoforms. Cells in each treatment group were grown in primary culture and maintained on control media for 5 d prior to exposure to their respective treatments. Data points indicate the percentage of viable cells/well ± SEM for six replicates in each treatment group, as compared to controls. $^*P < 0.05$, as compared to controls. For abbreviation see Figure 1.

the 0–250 μM dose range tested, α-T and γ-T were not found to alter cell growth or viability. Therefore, IC_{50} and LD_{50} doses were not determined for these compounds (Table 1). The IC_{50} for δ-T was calculated to be 94 μM, but the LD_{50} could not be determined over the dose range tested for this compound (Table 1). In contrast, α-T^3, γ-T^3, or δ-T^3 displayed IC_{50} doses of 45, 8, and 7 μM, and LD_{50} doses of 235, 46, and 36 μM, respectively (Table 1).

DNA isolated from untreated mammary epithelial cells grown in primary culture for 5 d did not show appreciable levels of fragmentation (Fig. 4). Following exposure to 25 μM TRF (IC_{50}) mammary epithelial cells displayed detectable levels of DNA fragmentation 48 h after the start of treatment (Fig. 4). In contrast, exposure to 110 μM TRF (LD_{50}) resulted in a rapid and intense DNA laddering response within 12 h and continuing for 48 h after the start of treatment (Fig. 4).

The effects of a 24-h exposure to IC_{50} or maximal doses previously tested for individual tocopherols and tocotrienols on DNA fragmentation in mammary epithelial cells grown in primary culture for 5 d are shown in Figure 5. DNA isolated from untreated controls showed little fragmentation or laddering (Fig. 5, lane C), and treatment for 24 h with 120 μM α-T or γ-T had little effect on DNA fragmentation in these cells (Fig. 5, lanes α-T and γ-T, respectively). Similar treatments with 94 μM δ-T, 45 μM α-T^3, 8 μM γ-T^3, or 7 μM δ-T^3 induced intense DNA fragmentation in mammary epithelial cells (Fig. 5, lanes δ-T, α-T^3, γ-T^3, and δ-T^3, respectively).

The effects of 24-h treatment with 0 (controls), 25 (IC_{50}), or 110 μM (LD_{50}) TRF on *in situ* nuclear condensation, as determined by ethidium bromide epifluorescence staining, in mammary epithelial cells are shown in Figure 6. Brightfield photomicrographs of untreated control mammary epithelial cell organoids were characterized by duct-like branching that extended throughout the collagen gel (Fig. 6A). Epifluorescence photomicrographs of the same field showed a small amount of epifluorescence staining (Fig. 6B). Cells grown in primary culture have a finite life span, and it is expected that some portions of these cells are undergoing apoptosis. Treat-

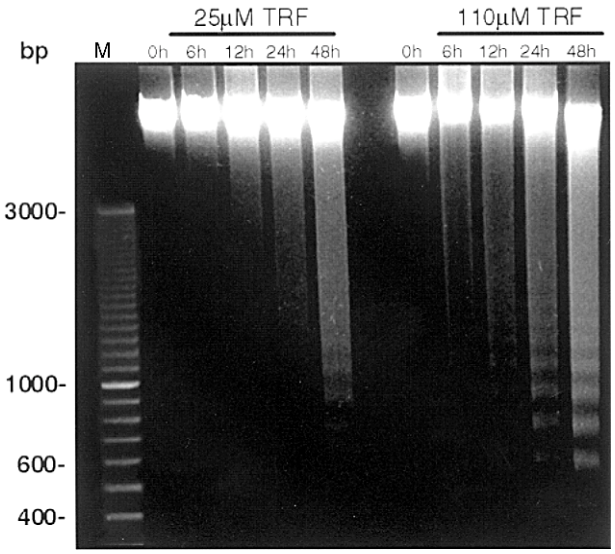

FIG. 4. Mammary epithelial cell internucleosomal DNA fragmentation during a 48-h period following exposure to either 25 [IC_{50} (treatment doese that induces 50% growth inhibition)] or 110 μM [LD_{50} (treatment dose that induces 50% cell death)] TRF. Cells were cultured in control media for 5 d and then exposed to their respective treatments. Lane M contains DNA laddering markers. For other abbreviation see Figure 1.

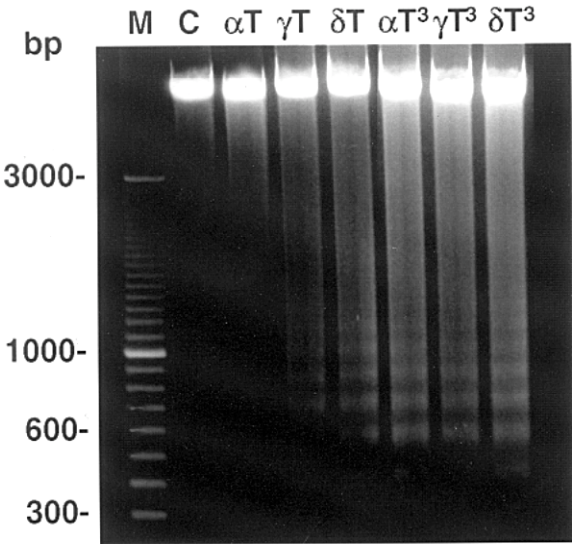

FIG. 5. Mammary epithelial cell internucleosomal DNA fragmentation following a 24-h exposure period to control media (lane C), 120 μM α-tocopherol (lane αT), 120 μM γ-tocopherol (lane γT), 94 μM δ-tocopherol (lane δT), 45 μM α-tocotrienol (lane αT^3), 8 μM γ-tocotrienol (lane γT^3), or 7 μM δ-tocotrienol (lane δT^3). Lane M contains DNA laddering markers.

ment for 24 h with 25 μM TRF (IC_{50}) resulted in a noticeable change in mammary epithelial cell organoid morphology that was characterized by a slight fragmentation in ductal branching in brightfield photomicrographs (Fig. 6C), and an increase in epifluorescence intensity (Fig. 6D). Brightfield photomicrographs of mammary epithelial cell organoids treated for 24 h with 110 μM TRF (LD_{50}) were characterized by severe fragmentation in ductal morphology (Fig. 6E) and a corresponding large increase in epifluorescence intensity (Fig. 6F).

Figure 7 shows cellular accumulation of specific tocopherol and tocotrienol isoforms in mammary epithelial cells treated for 24 h with 25 (IC_{50}) or 110 μM (LD_{50}) TRF. Cellular levels of α-T and α-T^3, γ-T^3, and δ-T^3 were undetectable 15 min after exposure to 25 or 110 μM TRF (Fig. 7). However, a dose- and time-responsive increase in cellular levels of these compounds was observed over the 24-h treatment period (Fig. 7). The relative magnitude of cellular accumulation of tocotrienol isoforms was greater than α-T, even though the concentration of α-T present in the TRF treatment media was higher than the concentrations of α-T^3 and δ-T^3 (Fig. 7).

Cellular accumulation of specific tocopherol and tocotrienol isoforms throughout the 24-h treatment period is

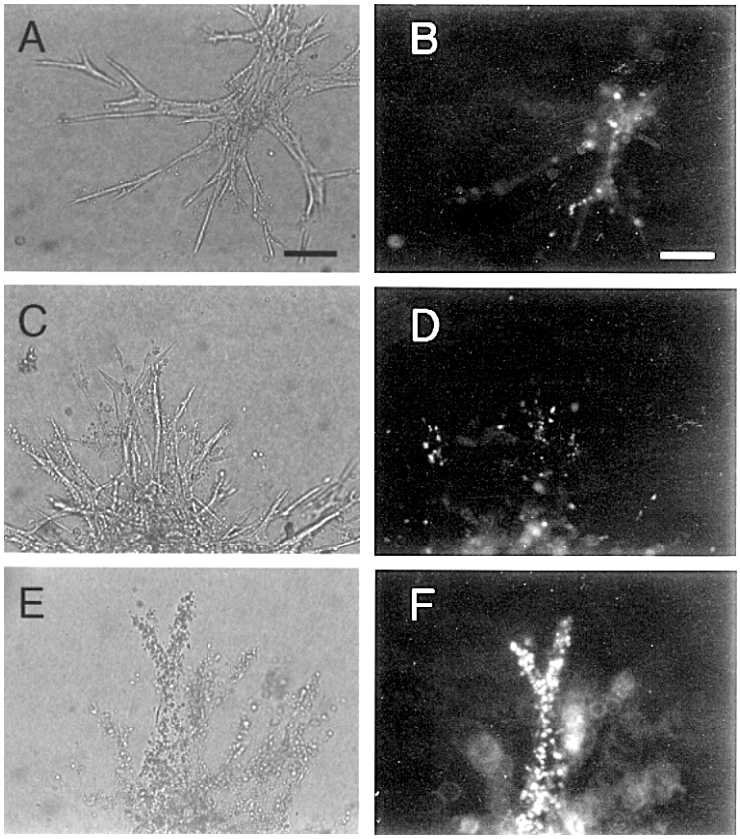

FIG. 6. Effects of TRF organoid morphology and DNA condensation in normal mammary epithelial cells grown in primary culture. Cells were cultured for 5 d in control media and then exposed to either 0 (Control), 25 (IC_{50}), or 110 μM (LD_{50}) TRF. Phase contrast and epifluorescence micrographs of the same field 24 h after treatment exposure are shown for Control (A and B), 25 μM TRF (C and D), and 110 μM TRF (E and F), respectively. Magnification for each photograph is 100× and the bar in A and B represents 10 μm in length. For abbreviations see Figures 1 and 4.

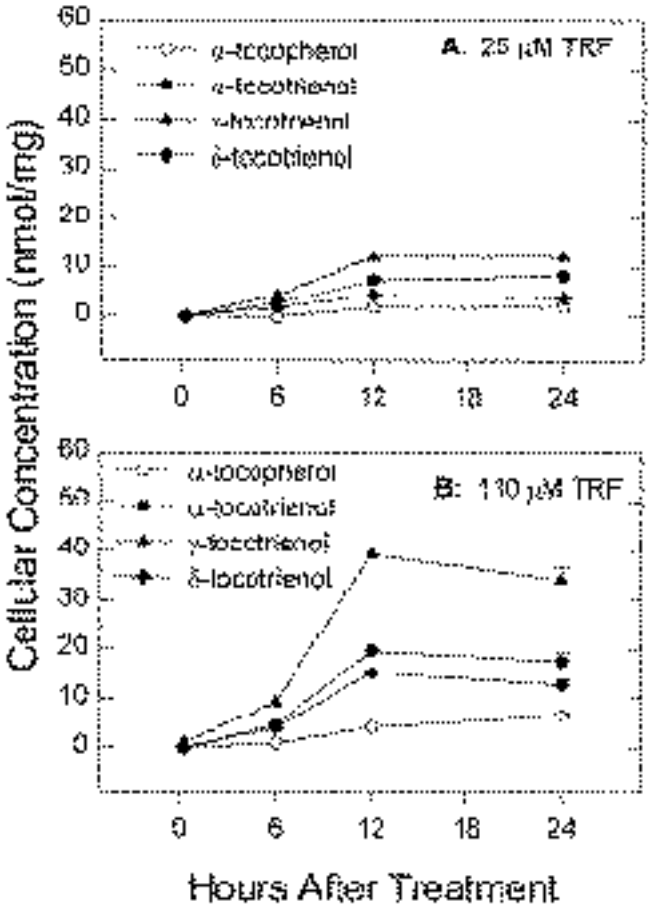

FIG. 7. Cellular accumulation of individual tocopherol and tocotrienol isoforms in normal mammary epithelial cells grown in primary culture during a 24-h exposure to either 25 (A) or 110 μM (B) TRF. Data points indicate mean cellular concentration ± SEM for four replicates in each treatment group containing 1×10^7 cells per each time point. For abbreviation see Figure 1.

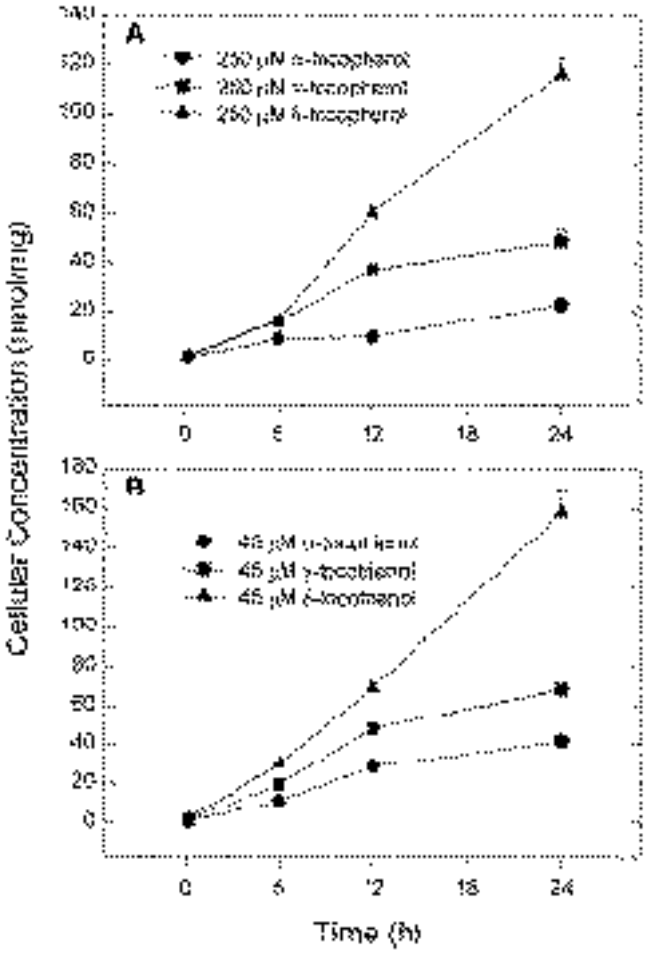

FIG. 8. Cellular accumulation of individual tocopherol and tocotrienol isoforms in normal mammary epithelial cells grown in primary culture during a 24-h exposure to either (A) 250 μM α-, γ-, or δ-tocopherol or 45 μM α-, γ-, or δ-tocotrienol. Data points indicate mean cellular concentration ± SEM for four replicates in each treatment group containing 1×10^7 cells per each time point.

shown in Figure 8. Treatment with 250 μM α-T, γ-T, or δ-T resulted in a time- and dose-dependent increase in cellular levels during the 24 h exposure period (Fig. 8A). However, cellular accumulation of individual tocopherol isoforms was not equal and characterized as δ > γ > α (Fig. 8A). Similarly, exposure to 45 μM α-T^3, γ-T^3, and δ-T^3 also showed a time- and dose-dependent increase in cellular accumulation, and a greater cellular accumulation of individual tocotrienol isoforms characterized as δ > γ > α (Fig. 8B).

DISCUSSION

These results demonstrate that individual tocopherols and tocotrienols display differential potencies in regard to their antiproliferative and apoptotic activity in normal mammary epithelial cells grown in primary culture. Direct comparisons between the two vitamin E subclasses show that tocotrienols are significantly more potent than tocopherols. Furthermore, the biopotency of specific isoforms displayed a consistent relationship corresponding to δ-T^3 ≥ γ-T^3 > α-T^3 > δ-T ≥ γ-T and α-T. Although the exact intracellular mechanism mediating the antiproliferative effects of tocotrienols is currently unknown, tocotrienol-induced reductions in cellular viability result from the induction of apoptosis, as indicated by DNA fragmentation. It was also shown that the biopotency of individual tocotrienol and tocopherol isoforms is directly related to the ease and/or preference with which these compounds accumulate within mammary epithelial cells.

Previous investigations have shown that very high treatment doses of α-T (millimolar) can induce antiproliferative and apoptotic effects in various cell types (11,34), but the physiological significance of these findings is unclear. Therefore, the exact IC_{50} and LD_{50} dose for individual tocopherols was not determined because the primary objective of the present study was to contrast the very high relative biopotency of tocotrienols vs. tocopherols. Although chronic treatment with 120 μM or acute treatment with 250 μM α-T and γ-T was not found to have significant effects on cell growth or viability, respectively, it should not be concluded that these compounds are devoid of bioactivity in normal mammary ep-

ithelial cells. Experimental results show that treatment with 120 μM of α-T or γ-T induced a small amount of DNA fragmentation as compared to untreated controls (Fig. 5), even though these effects were not of great enough magnitude to cause a corresponding reduction in mammary epithelial cell proliferation or viability. These findings indicate that both tocopherols and tocotrienols induce antiproliferative and apoptotic effects in normal mammary epithelial cells, but specific tocotrienol isoforms are significantly more potent than corresponding tocopherol isoforms.

EGF-dependent mitogenesis in normal mammary epithelial cells grown in primary culture is associated with the activation of phospholipid-dependent protein kinase C and cyclic AMP-dependent proteins (24,28,35–38). It has been established that treatments that enhance protein kinase C and cyclic AMP activation stimulate, whereas treatments that inhibit protein kinase C and cyclic AMP activation inhibit, EGF-induced mammary epithelial cell proliferation (24,28,35–38). Tocopherols and tocotrienols have also been shown to inhibit protein kinase C (4,5,7), adenylate cyclase and cyclic AMP-dependent protein activation (39,40). Therefore, it is possible that the antiproliferative effects of tocopherols and tocotrienols in mammary epithelial cells may result from an inhibition of these mitogenic-signaling pathways.

Various signaling pathways also have been suggested for mediating vitamin E-dependent apoptosis (8–12). Nevertheless, it remains unclear whether the antiproliferative and apoptotic effects of tocopherol and tocotrienol isoforms are mediated through similar or independent intracellular mechanisms. Dose-response studies showed that IC_{50} doses of individual tocotrienol isoforms were 5–6 times lower than their corresponding LD_{50} doses. These data might indicate that the antiproliferative and apoptotic effects of tocotrienols are mediated through different mechanisms. However, subsequent studies showed that IC_{50} doses for TRF, δ-T, and α-T^3, γ-T^3, and δ-T^3 induced substantially large amounts of DNA fragmentation within 24 h after exposure. Similar results were also observed *in situ*. Primary culture of normal mammary epithelial cells in collagen gels is characterized as multicellular organoids with duct-like branching similar in appearance to that of the intact mammary gland (25). Controls displayed a modest amount of epifluorescence staining, an indication of DNA condensation and programmed cell death occurring in some of these cells (31). Since mammary epithelial cells grown in primary culture have a limited life span (25), it is not surprising that portions of these cells are undergoing apoptosis. However, 24-h exposure to 25 (IC_{50}) and 110 μM (LD_{50}) TRF resulted in a dose-dependent increase in the deterioration of organoid morphology and epifluorescence intensity in these cells. These findings raise the possibility that the growth-inhibitory effects of vitamin E isoforms could result from an increase in the total number of cells undergoing programmed cell death. Additional studies are required to clarify if the growth-inhibitory effects of vitamin E result simply from a greater proportion of cells undergoing apoptosis or if they also involve a reduction in EGF-dependent mitogenic responsiveness in these cells.

Previous investigations have shown that vitamin E-dependent apoptosis is mediated through different intracellular mechanisms in different cell types (8–12). Furthermore, apoptosis in normal mammary epithelial cells can be initiated through more than one pathway (41–44). It has been established that mitogen-starved mammary epithelial cells will undergo apoptosis approximately 15 h after mitogen has been removed from the culture medium (43). Various mitogens such as EGF or transforming growth factor α (TGFα) have been shown to induce high cytosolic levels of Bcl-x_L, a protein that inhibits apoptosis (43). In the absence of mitogens, Bcl-x_L levels become significantly reduced, ultimately leading to the induction of apoptosis in these cells (43). Alternatively, activation of specific membrane-bound receptors by their ligands, such as TGFβ or Fas, can also induce apoptosis in mammary epithelial cells even in the presence of high levels of mitogens (43). Studies have also shown that TGFβ- and Fas-receptor signaling pathways appear to play a role in mediating vitamin E-induced apoptosis in some cell types (12,43). Therefore, it is possible that vitamin E-induced programmed cell death in normal mammary epithelial cells might involve the activation of more than one apoptotic signaling pathway. Studies are currently underway to investigate this possibility.

Another factor that may be important in determining tocopherol and tocotrienol isoform biopotency is the ease or preference with which these compounds are taken up by mammary epithelial cells. Prior to treatment, tocopherol and tocotrienol isoform levels were undetectable in mammary epithelial cells. The lack of detectable levels of tocopherols and tocotrienols prior to treatment is not unexpected since these cells were grown for 7 d (2 d preculture plus 5 d experimental culture) in vitamin E-free control media and tissue vitamin E turnover is very rapid (1). Exposure to tocopherol and tocotrienol treatment resulted in a time- and dose-responsive increase in cellular levels of these compounds. However, cellular accumulation of tocotrienols was much greater than that of tocopherols. It is possible that specific structural characteristics are responsible for a less restricted passage of tocotrienols through the mammary epithelial cell membrane. Tocotrienols differ from tocopherols in that they contain an unsaturated phytyl chain. The presence of double bonds in the tocotrienol phytyl chain would create a less planar molecular conformation that could allow for enhanced interaction and uptake at the surface of the cell membrane. Nevertheless, since mammary epithelial cells take up tocotrienols preferentially over tocopherols, higher levels of these compounds are present at their intracellular sites of action and are thereby able to induce a greater biological response.

In addition to enhanced cellular uptake, experimental evidence also indicates that tocotrienols are inherently more potent than tocopherols in regard to their antiproliferative and apoptotic activity. Results showed that similar cellular levels of corresponding tocopherol and tocotrienol isoforms could

be obtained in mammary epithelial cells with 250 μM α-T, γ-T, and δ-T and 45 μM of α-T^3, γ-T^3, and δ-T^3. However, treatment doses that produced similar intracellular levels of tocopherols and tocotrienols did not cause the same antiproliferative and apoptotic response in these cells. These findings indicate that tocotrienol isoforms are more potent than their corresponding tocopherol isoforms in activating the intracellular mechanisms responsible for inhibiting growth and inducing apoptosis in normal mammary epithelial cells.

It was also observed that different isoforms within each tocopherol and tocotrienol subgroup displayed differences in cellular accumulation and biopotency. Specifically, α-isoforms of tocopherols and tocotrienols are more highly methylated than their corresponding γ- or δ-isoforms, and cellular accumulation and biopotency of α-T and α-T^3 were less than their respective γ- and δ-isoforms. Since a decrease in the level of chromane ring methylation results in a corresponding decease in the partition coefficient of these compounds, cellular accumulation and biopotency displayed an inverse relationship with tocopherol and tocotrienol lipophilicity. The suggestion that less lipophilic tocopherol and tocotrienol isoforms are more easily taken up by mammary epithelial cells is supported by the findings that α-tocopheryl succinate or hemisuccinate, less lipophilic derivatives of α-T, display significantly greater cellular accumulation and bioactivity than α-T (33,45). It has not yet been determined if succinate or other less lipophilic derivatives of tocotrienol isoforms also display significantly greater cellular accumulation and biopotency than their parent compounds. In addition, these data suggest that cellular uptake of tocopherols and tocotrienols is most likely determined by nonspecific factors such as molecular conformation and lipid solubility rather than selective uptake mechanisms involving specific transporter or carrier proteins.

In conclusion, tocotrienols display greater biopotency than tocopherols, at least in part because of their greater cellular uptake and enhanced ability to activate the antiproliferative and/or apoptotic signaling pathways. Nevertheless, it is well established that the plasma concentration of individual tocopherol and tocotrienol isoforms is limited by the specificity and saturability of specific transfer proteins and transport mechanisms within the body that display significant preference for α-T (46). Although it remains to be determined whether the high biopotency displayed by individual tocotrienol isoforms *in vitro* is also evident in the intact mammary gland, the present findings provide evidence to suggest that the highly biopotent γ-T^3 and δ-T^3 isoforms may play a physiological role in modulating normal mammary gland growth, function, and remodeling.

ACKNOWLEDGMENTS

The authors thank the Palm Oil Research Institute of Malaysia (PORIM) for generously providing TRF, α-T^3, γ-T^3, and δ-T^3 for use in these experiments, and Dr. Michael Crider for his helpful discussion during the preparation of this manuscript. This work was supported by AICR Grant 96B053.

The Departments of [a]Pathology and Laboratory Medicine, [b]Biophysics, and [c]Microbiology, Boston University School of Medicine, Boston, Massachusetts 02118

ABSTRACT: Previous studies in our laboratory have shown that marine oils, with high levels of eicosapentaenoic (EPA, 20:5n-3) and docosahexaenoic acids (DHA, 22:6n-3), inhibit the growth of CT-26, a murine colon carcinoma cell line, when implanted into the colons of male BALB/c mice. An *in vitro* model was developed to study the incorporation of polyunsaturated fatty acids (PUFA) into CT-26 cells in culture. PUFA-induced changes in the phospholipid fatty acid composition and the affinity with which different fatty acids enter the various phospholipid species and subspecies were examined. We found that supplementation of cultured CT-26 cells with either 50 μM linoleic acid (LIN, 18:2n-6), arachidonic acid (AA, 20:4n-6), EPA, or DHA significantly alters the fatty acid composition of CT-26 cells. Incorporation of these fatty acids resulted in decreased levels of monounsaturated fatty acids, while EPA and DHA also resulted in lower levels of AA. While significant elongation of both AA and EPA occurred, LIN remained relatively unmodified. Incorporation of radiolabeled fatty acids into different phospholipid species varied significantly. LIN was incorporated predominantly into phosphatidylcholine and had a much lower affinity for the ethanolamine phospholipids. DHA had a higher affinity for plasmenylethanolamine (1-*O*-alk-1′-enyl-2-acyl-*sn*-glycero-3-phosphoethanolamine) than the other fatty acids, while EPA had the highest affinity for phosphatidylethanol-amine (1,2-diacyl-*sn*-glycero-3-phosphoethanolamine). These results demonstrate that, *in vitro*, significant differences are seen between the various PUFA in CT-26 cells with respect to metabolism and distribution, and these may help to explain differences observed with respect to their effects on tumor growth and metastasis in the transplantable model.

Paper no. L8155 in *Lipids 35*, 181–186 (February 2000).

The n-3 polyunsaturated fatty acids (PUFA) have been found to inhibit chemical-induced colon cancer in a number of animal models (1–3), and higher dietary n-3 PUFA intake has been associated with lower risk of colon and breast cancer in humans (4). Studies by Cannizzo and Broitman (5) have shown that marine oil diets containing eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), compared to safflower oil diets [predominantly linoleic acid (LIN; 18:2n-6)], inhibit the growth of CT-26, a BALB/c mouse colonic adenocarcinoma, implanted into the descending colon of syngeneic mice. Tumors in marine oil-fed mice were significantly smaller 21 d after implantation (5). Studies by Iigo *et al.* (6) have recently demonstrated that DHA alters the membrane characteristics and reduces the ability of CT-26 to metastasize.

Although n-3 fatty acids affect tumor development and growth (7–9), the mechanism by which this occurs is uncertain. Fish oil fatty acids may exert their effect on tumor growth once they are released by phospholipases and converted to oxygenated derivatives (10). Different types and proportions of such derivatives are produced from different PUFA. A number of phospholipase A_2 activities have been shown to cleave fatty acids from phospholipids bearing specific headgroups, fatty acids, or vinyl-ether linkages at the *sn*-1 position (11).

Incorporation of PUFA into CT-26 *in vitro* has not been examined even though PUFA have been shown to influence the rate of growth and metastatic potential of these cells *in vivo* (5,6). We have therefore studied the effects of supplementation of LIN, arachidonic acid (AA), EPA, and DHA on the phospholipid fatty acid composition of cultured CT-26 cells over a 24-h period. We also have studied the incorporation of radiolabeled fatty acids and determined into which phospholipid species and subspecies they are incorporated. These studies characterizing the behavior of PUFA in CT-26 cells further our understanding of potential anticancer effects and provide important background data for future studies examining the effects of n-3 fatty acids on colon tumor cell growth in this transplantable tumor system.

MATERIALS AND METHODS

Tissue culture. CT-26 cells were maintained in 75- or 150-mm^2 flasks (Falcon, Lincoln Park, NJ; or Corning, Corning, NY) in RPMI 1640 with 1% penicillin/streptomycin, 1% glutamine, and 2.5% fetal bovine serum (FBS; Sigma, St. Louis, MO). Cells were maintained at 37°C in a humidified atmosphere of 5% CO_2/95% air.

Abbreviations: AA, arachidonic acid; BSA, bovine serum albumin; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FAME, fatty acid methyl ester; FBS, fetal bovine serum; LIN, linoleic acid; PUFA, polyunsaturated fatty acid; TLC, thin-layer chromatography.

Fatty acid analysis of supplemented cells. LIN, AA, EPA, and DHA sodium salts (Sigma) were conjugated to fatty acid-free bovine serum albumin (BSA; Sigma) at a 3:1 molar ratio prior to addition to cultured cells. The growth rate of cultured CT-26 cells was not affected over a 24-h time period when n-6 or n-3 fatty acids (LIN, AA, EPA) were added to the medium in this way at concentrations as high as 100 μM (Broitman, S.A., and Kosakolsky-Singer, C., unpublished data). Cells (2×10^6) were plated into 100-mm dishes (Falcon). The next day, medium was removed, and growth medium containing the fatty acid/BSA mixtures was added to cells (this was considered time zero). At designated times, medium was removed and the dishes were washed twice with ice-cold phosphate-buffered saline (PBS); cells were harvested by scraping, and were then resuspended in 2 mL PBS. Cell suspensions were transferred to glass culture tubes and a phospholipid standard (diheptadecanoyl L-α-phosphatidylcholine; Sigma) was added to each sample. The lipids were extracted by the method of Folch *et al.* (12). Samples were dried under a stream of nitrogen and spotted on silica gel G thin-layer chromatography (TLC) plates (Analtech, Newark, DE). TLC plates were developed using hexane/diethylether/acetic acid (70:30:1, by vol), and were visualized with diphenyl-hexatriene (Sigma) under long-wave ultraviolet light. The origins, containing the phospholipids, were scraped into glass culture tubes, and fatty acid methyl esters (FAME) were generated by transesterification using boron trifluoride–methanol (1 mL of a 14% solution in methanol) for 1 h at 80°C. The reaction was stopped by addition of 1 mL of distilled H_2O. FAME were extracted twice, using 4 mL of hexane. Solvent was evaporated using a stream of nitrogen gas and resuspended in chloroform. Samples were injected into a Shimadzu 14A gas chromatograph (Kyoto, Japan) with a flame-ionization detector (FID) connected to a Shimadzu Chromatopac CR-501 data-processing system. The gas chromatograph was equipped with an SP-2330 fused-silica capillary column, 30 m × 25 mm i.d., 0.20-mm film (Supelco, Bellefonte, PA). Hydrogen was used for the FID mixed with compressed breathing air, zero grade (<10 ppm hydrocarbons). Helium, ultra-high purity, was used as the carrier gas as well as the makeup gas. Injector and detector temperatures were 240°C. The column initial temperature was 150°C, where it remained for 2 min and then increased at the rate of 5.0°C/min until 240°C. The column then remained at 240°C for 4 min. Chromatograms were analyzed by comparison of peak retention times to that of a standard (Matreya, Pleasant Gap, PA) containing FAME of interest.

Phospholipid composition. The phospholipid composition of CT-26 cells was determined using long-term ^{32}P labeling. This technique has been shown to provide similar results to phosphorus determination when performed side by side (13). Cells were plated to sterile glass scintillation vials (10^5 cells), to which they adhered and radioactive inorganic phosphate ($^{32}P_i$) was added, (5 μCi/mL). After 48 h of incubation at 37°C, the medium was aspirated and fresh medium containing [$^{32}P_i$] (5 μCi/mL) was added to the cells. The cells were incubated for an additional 24 h, washed twice with ice-cold PBS, and the lipids extracted by the method of Bligh and Dyer (14). Samples were dried under a stream of nitrogen gas and spotted onto silica gel 60 (20 × 20 cm, 250-μm thick) TLC plates. Phospholipids were separated by two-dimensional TLC (15). Samples were developed using chloroform/methanol/acetic acid/water (25:15:3:1.5, by vol) in the first dimension and chloroform/methanol/formic acid (65:25:10, by vol) in the second dimension. Between dimensions, plates were sprayed with 10 mM mercuric chloride in acetic acid to cleave vinyl ethers associated with plasmalogens and then dried. In this way, the resulting *sn*-1-lysophospholipid generated from the plasmalogen could be separated from the diacyl and 1-alkyl species in the second dimension. The phospholipid species were localized using autoradiography, and the different lipids were scraped into scintillation vials containing 1 mL of methanol. Scintillation cocktail (8 mL; National Diagnostics, Atlanta, GA) was added and the radioactivity quantitated by liquid scintillation spectroscopy.

Labeling cells with radioactive fatty acids. Cells (2.5×10^5) were plated to sterile glass scintillation vials in 1 mL of medium containing 2 μCi [4,5-^{3}H]DHA [58 Ci/mmol; New England Nuclear (NEN), Boston, MA], 2 μCi [5,6,8,9,11,12,14,15-^{3}H]AA (100 Ci/mmol; NEN), 2 μCi, [5,6,8,9,11,12,14,15,17,18-^{3}H] EPA (100 Ci/mmol; American Radiolabeled Chemicals, St. Louis, MO), or 1 μCi [1-^{14}C]LIN (50 mCi/mmol; NEN). Final concentration of all fatty acids in the labeling media was 50 μM. Fatty acids were added as fatty acid/BSA (3:1) complexes. Cells were incubated for 24 h at 37°C, after which the cells were washed twice with 3 mL of ice-cold RPMI medium containing 2.5% FBS. The lipids were extracted by the method of Bligh and Dyer and two-dimensional TLC performed as described above. TLC plates were sprayed with EN^{3}HANCE (NEN) and exposed to X-ray film (GBX-2; Eastman Kodak, Rochester, NY) at –80°C. Labeled phospholipid species were scraped and the radioactivity quantitated by liquid scintillation spectroscopy as described above.

Statistics. Data were analyzed by analysis of variance (ANOVA) and Tukey's *post-hoc* comparison using NCSS 6.0 statistics software program (Kaysville, UT).

RESULTS

Fatty acid analysis. All four PUFA studied were readily incorporated into cellular phospholipids, significantly altering the membrane fatty acid composition over a 24-h period (Table 1). Vehicle alone (medium and 16 μM BSA) had no effect on the fatty acid profile of CT-26 phospholipids (data not shown). Incorporation of 50 μM PUFA (LIN, AA, EPA, or DHA) for 24 h resulted in a reduction of the monounsaturated fatty acids (16:1 and 18:1) from approximately 40 to 20% of total phospholipid fatty acid. Addition of the n-3 PUFA, EPA and DHA, also resulted in significant decreases of AA levels from 10.9 to 4.3 and 3.1%, respectively.

The 20-carbon fatty acids, AA and EPA, were substantially elongated, although to different extents. Supplementation

[a]Values represent the mean ± standard deviation of three samples. Control groups were exposed to bovine serum albumin (16.6 μM) in medium. ND, not detectable. Asterisk indicates value is significantly different from control group ($P < 0.05$). LIN, linoleic acid; AA, arachidonic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

with 50 μM AA for 24 h resulted in an increase in AA from about 7% of total phospholipid to more than 26% and a greater than 10-fold increase in docosatetraenoic acid (22:4n-6) from 0.7 to 10.0%. There were no changes in LIN levels, suggesting that there was no significant retroconversion of AA to this fatty acid. Addition of EPA (50 μM) led to increases in both EPA, from 0.3 to 15.2%, and its elongation product, docosapentaenoic acid (22:5n-3), from 2.0 to 15.1%, although there was no accumulation of DHA.

Addition of LIN resulted in increased levels of LIN from 2.2% of the phospholipid fatty acids to 27.8% of total phospholipid fatty acid within 24 h. Surprisingly, there was relatively little desaturation or elongation of LIN with no significant changes in the levels of AA.

Addition of 50 μM DHA resulted in increased levels of DHA from 2.7 to 22.6%. There were no changes in the other long-chain n-3 fatty acids, suggesting that there is no significant retroconversion of DHA to 22:5n-3 or 20:5n-3. There was an increase in the levels of the saturated fatty acid palmitate (16:0) in cells supplemented with DHA.

Phospholipid composition. To better define the membrane phospholipid composition of CT-26 cells, we performed long-term labeling with $^{32}P_i$ to determine the phospholipid composition of CT-26 (Table 2, right-hand column). The predominant phospholipid head group class was choline (53.1% of total) while approximately 18% of the phospholipids contained the ethanolamine headgroup. More than 40% of ethanolamine phospholipids were plasmalogens (plas-

[a]Values represent the mean ± standard deviation of three samples. Other fatty acids include cardiolipin, phosphatidic acid, phosphatidylglycerol, and neutral lipids (in labeled fatty acids only). Superscript letters indicate values are significantly different (at $P < 0.01$) than the fatty acid indicated: l, linoleic acid, a, arachidonic acid, e, eicosapentaenoic acid d, docosahexaenoic acid, and *two values are significantly different at $P < 0.05$. See Table 1 for other abbreviations.

menylethanolamine, 1-*O*-alk-1′-enyl-2-acyl-*sn*-3-glycerophosphoethanolamine) while less than 4% of choline phospholipids were plasmalogens (plasmenylcholine, 1-*O*-alk-1′-enyl-2-acyl-*sn*-3-glycero-phosphocholine). Phosphatidylinositol constituted roughly 10% of the phospholipids, while phosphatidylserine, sphingomyelin, the lysophospholipid species, and other (cardiolipin, phosphatidic acid, phosphatidylglycerol), accounted for the remaining phospholipids in CT-26.

Incorporation of labeled fatty acids into phospholipids. Cells were labeled with the radioactive fatty acids to determine their distribution after 24 h among the different phospholipid species. Linoleate's pattern of labeling, for the most part, reflected the relative amounts of each phospholipid species (Table 2) with the majority of the label found associated with the most abundant phospholipid, phosphatidylcholine. There was, however, a reduced affinity for labeling of the plasmalogen, plasmenylethanolamine, when using LIN. The other fatty acids (AA, EPA, and DHA) displayed a preference for incorporation into inositol and ethanolamine phospholipids. This was most apparent in the cases of EPA and DHA; approximately one-third of the label was found in the ethanolamine phospholipids, while this head group class accounts for only 18.3% of the total phospholipid. The distribution of the label between plasmenylethanolamine and phosphatidylethanolamine favored the latter species when using either AA or EPA, but DHA showed a minor preference for the plasmenyl species. This preference was determined by dividing the percentage of fatty acid incorporated into a phospholipid species (percentage of total label recovered in phospholipids) by the percentage that the species contribute to the total phospholipid mass (see "phospholipid composition" in Table 2), such that a value greater than 1.0 indicates specificity. The greatest affinities observed are for DHA incorporation into plasmenylethanolamine (1.9) and EPA incorporation into phosphatidylethanolamine (2.2). A greater portion of the DHA label was also recovered in the fraction containing cardiolipin and phosphatidic acid (other phospholipids). As expected, there was little or no labeling of sphingomyelin or the lysophospholipids.

A significantly greater percentage of the n-6 fatty acids, LIN and AA, were recovered in phosphatidylcholine as compared to the n-3 fatty acids, EPA and DHA. This was the only phospholipid class that displayed this preference for n-6 PUFA.

DISCUSSION

A number of studies have found that, unlike the n-6 PUFA (16,17), EPA and DHA can inhibit the growth or metastasis of tumor cells within the host (4–9,18), as well as in culture (19,20); however, the mechanism behind these effects is still unclear. The physical properties of cell membranes can be altered by dietary PUFA (21,22), and these changes may affect the growth and/or the metastatic potential of tumor cells. Other evidence points toward a role for the n-3 PUFA in altering eicosanoid production in tumor cells (19,20,23); highly metastatic tumor cells contained higher levels of prostag-landins than similar less metastatic cells (23), and cyclooxygenase inhibitors have been shown to suppress the stimulatory effects seen with n-6 fatty acid supplementation in some cells (19,20). The n-3 fatty acids may exert their tumor-inhibiting effects by decreasing the synthesis of eicosanoids derived from n-6 fatty acids or by increasing the production of n-3 eicosanoid analogs, which counteract the n-6 eicosanoid's effects.

Our laboratory has previously demonstrated that CT-26 cells are nutritionally responsive to PUFA when implanted into the colons of male BALBc mice (5), growing more slowly in mice fed diets containing n-3 lipids than those fed n-6 lipids. The purpose of the present study was to develop an *in vitro* model to determine the effects of both n-6 and n-3 PUFA on phospholipid fatty acid composition. To this end, we have begun to determine the ability of these cells to assimilate both n-6 and n-3 PUFA into the phospholipid pool and to characterize the effects this has on the fatty acid composition of the membrane lipids.

There is a wide variation in the ability of different culture cells to incorporate and convert of fatty acids *via* desaturation and elongation (24). The present study demonstrated that *in vitro* all of the PUFA were incorporated readily into the phospholipids of CT-26 cells. Addition of LIN, AA, and EPA resulted in comparable incorporation of these fatty acids. Over a 24-h treatment period, these exogenous PUFA represented 26–28% of total phospholipid fatty. The increase of PUFA attributable to exogenous DHA, however, was less (20%). Several possibilities exist for this difference: DHA might be metabolized at a higher rate than the other fatty acids, resulting in its breakdown and loss from the phospholipids, or it may be shunted into nonphospholipid pools at a greater rate than the other fatty acids examined.

In all cases, incorporation of PUFA led to a corresponding decrease in the proportion of monounsaturated fatty acids. The monounsaturates 16:1 and 18:1, which originally constituted about 40% of phospholipid fatty acids, were reduced to about 20% after 24 h of supplementation with any of the fatty acids. This is consistent with studies by Tebbey and Butke (25), who observed that as AA levels increased in cultured murine lymphocytes, there was a 30% decrease in the amount of oleic acid. They further showed that AA regulates stearoyl-CoA desaturase gene expression by inhibiting transcription. Addition of LIN, AA, and EPA did not alter the levels of the saturated fatty acids in any consistent manner. However, addition of DHA did raise the level of palmitate slightly. It is possible that the addition of such a highly unsaturated fatty acid as DHA requires an increase in saturated fatty acids to maintain the membrane fluidity within a critical range.

Studies using an implanted tumor cell line, derived from CT-26 cells, resulted in similar trends as those observed in this study (6). When mice bearing these cells were fed PUFA, there was a marked increase in the PUFA levels in the phospholipids as well as elongation of AA and EPA. However, the changes were not as rapid and not of the same magnitude as observed when using cells in culture. This was probably due to the fact that, in culture, the cells are exposed directly to free

fatty acid, while in the host animal, the dietary fatty acids reach the tumor cells esterified to complex lipids and found within lipoprotein complexes. The free fatty acids are more readily taken up and activated for acylation. Also, in the *in vivo* studies (6), increased PUFA levels did not result in a reduction in the monounsaturated fatty acids.

Several studies have suggested that the effects observed with n-3 fatty acids occur because they displace AA from phospholipids (8). Our studies confirm that addition of EPA or DHA leads to a reduction of phospholipid AA levels; EPA and DHA reduced AA levels by approximately 40 and 60%, respectively. Two of the fatty acids, AA (20:4n-6) and EPA (20:5n-3), were significantly modified by elongation, to 22:4 n-6 and 22:5n-3, respectively. The process of elongation is thought to occur in all mammalian cells (24); however, the extent to which a cell elongates long-chain PUFA varies. These studies allowed us to observe the changes in mass of the elongation products of AA and EPA in CT-26. EPA was elongated more extensively than AA after 24 h; approximately 30% of the AA present had been elongated to 22:4n-6, while around 50% of EPA was elongated. Even at earlier time periods after addition of the fatty acid (1–3 h), EPA is elongated while AA appears to be elongated only after significant levels accumulate (data not shown). It was unclear whether this was due to a decreased elongation of AA or the reluctance of the phospholipids to incorporate the elongation product 22:4n-6. It seems likely that the former is true: umbilical vein endothelial cells, rat liver cells, and human skin fibroblasts have been shown to elongate EPA more readily than AA (24). Banerjee and Rosenthal (26) reported that AA was only elongated when there was a relative excess of this crucial fatty acid, however, EPA was elongated even when present at low concentrations, and was elongated to a greater extent. It has been suggested that this increased elongation of EPA functions as a mechanism to reduce the amount of EPA that can compete with AA for entry into cyclooxygenase or lipoxygenase pathways (24).

We could find no evidence that LIN was modified in these cells. LIN (18:2n-6) is converted by many cells to AA (20:4n-6) through a sequence of desaturation and elongation steps. We found no accumulation of AA or any of the intermediates of this process. These data are consistent, however, with the observations that certain tumors or tumor cell lines are deficient in the Δ6-desaturase activity, the first step in this process (24). Reduced Δ6-desaturase activity could also explain the inability of the cells to convert EPA to DHA. Conversion of EPA to DHA is presently believed to occur *via* two successive elongations (to 24:5n-3), insertion of a double bond *via* Δ6 desaturase (forming 24:6n-3), followed by one round of peroxisomal β-oxidation forming 22:6n-3. Isotopic conversion studies would be required to confirm this.

The present study demonstrated significant differences in the affinity of labeled fatty acids for the different phospholipid species. Studies by Hatala *et al.* (27) examining the incorporation of LIN and EPA into breast cancer cells found that 65% of [^{14}C]LIN was recovered in phosphatidylcholine after 24 h. This is very similar to the 60% we observed with [^{3}H]LIN in CT-26 cells after the same period of time. Their studies were different with respect to incorporation of [^{14}C]EPA: they found 58% in phosphatidylethanolamine, whereas we see considerably less EPA recovered in the ethanolamine phospholipids. It has been speculated that plasmalogen phospholipids serve as a sink for PUFA (28–30). Some studies have demonstrated increased selectivity of n-3 fatty acids for plasmalogens (31–33), while others have found incorporation to be dependent on chain length and degree of unsaturation (34). Our studies demonstrate that, in CT-26 cells in culture, chain length influences incorporation into plasmalogens, since DHA incorporation into plasmenylethanolamine is greater than AA and EPA, which in turn are greater than LIN. However, incorporation of AA into plasmalogen species was greater than EPA. This is in contrast to some studies, which showed increased incorporation with increasing unsaturation (34).

Prostaglandins, which are derived from membrane phospholipids, affect the rate of growth as well as the ability of tumors to metastasize (35,36). It is believed that ethanolamine plasmalogens are involved in the release of PUFA to form oxidized fatty acid derivatives such as leukotrienes and prostaglandins (37). Our data indicate that, in CT-26, DHA has a higher affinity for plasmenylethanolamine than the other PUFA studied. Other studies also have demonstrated that plasmalogens contain high levels of DHA (29,38). Certain tumors, including colon tumors, contain altered levels of plasmalogens (39). It is possible that n-3 fatty acids compete with arachidonic acid for incorporation into plasmalogens and, once incorporated, these cells produce fewer or different prostaglandins resulting in a reduced rate of cell growth and metastasis.

Accumulation of Docosahexaenoic Acid in Phosphatidylserine Is Selectively Inhibited by Chronic Ethanol Exposure in C-6 Glioma Cells

Hee-Yong Kim* and Jillonne Hamilton

Section of Mass Spectrometry, Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, Maryland 20852

ABSTRACT: Neuronal membranes are highly enriched with docosahexaenoic acid (22:6n-3), and its content can be altered by ethanol consumption. We have previously reported that the 22:6n-3 status in membrane affects the biosynthesis of phosphatidylserine (PS), a phospholipid class which contains an exceptionally high proportion of 22:6n-3. The aim of the present study is to investigate the effect of chronic ethanol exposure on PS accumulation in relation to the 22:6n-3 status. C-6 glioma cells were enriched with 25 μM 22:6n-3 for 48 h and the PS accumulation was first evaluated in comparison to nonenriched cells as well as cells enriched with arachidonic acid (20:4n-6). Electrospray liquid chromatography–mass spectrometry analysis revealed that cells treated with 22:6n-3 showed significantly higher accumulation of PS in comparison to nonenriched or 20:4n-6-enriched cells, primarily due to an increase of 1-stearoyl-2-docosahexaenoyl-glycerophosphoserine (18:0,22:6-PS). Chronic ethanol exposure selectively affected the accumulation of PS in 22:6n-3-enriched cells. After cells were exposed to 20 or 50 mM ethanol for 4 wk, accumulation of 18:0,22:6-PS upon 22:6n-3 supplementation was significantly lower, resulting in a drastic reduction of total PS. Concomitantly, ethanol-treated cells showed lower incorporation of serine in comparison to control cells. From these data, it was concluded that supplementation of cells with 22:6n-3 promotes the accumulation of PS and chronic ethanol treatment diminishes this effect at least in part through impaired serine incorporation processes. Attenuated accumulation of 22:6n-3 in PS and the reduction of PS thus may have significant implications in pathophysiological effects of ethanol, especially in tissues with abundant 22:6n-3.

Docosahexaenoic acid (22:6n-3) is highly concentrated in neuronal membranes (1,2). Normal brain development, visual acuity, and retinal function have been suggested to correlate with the enrichment of 22:6n-3 in neuronal tissues (1–5). This fatty acid represents a particularly high proportion in phosphatidylserine (PS) (1,2). In mammalian cells, PS is synthesized from phosphatidylethanolamine (PE) or phosphatidylcholine (PC) by base exchange reaction (6). Conversely, PS can be metabolized to PE or PC by base exchange reaction or to PE by PS decarboxylation (7). Recently, we have shown that the status of membrane 22:6n-3 affects PS biosynthesis in brain microsomes and C-6 glioma cells, implying 22:6n-3 is a modulator of PS accumulation (8). Involvement of PS in the activation of protein kinases (9,10) suggests that alteration in PS accumulation in cell membranes may have significant implication in cell signaling.

High levels of 22:6n-3 appear to be well maintained in neuronal cells. Maintenance of the membrane lipid profile is thought to be achieved through dynamic but tightly regulated biosynthetic and remodeling processes, including acylation, deacylation, and base exchange reactions. Ethanol is believed to exert its effect through the perturbation of structure and function of cell membranes. The results regarding the effect of ethanol on the membrane polyunsaturate content have been inconsistent (11), primarily due to differences in animal models and experimental conditions employed. Nevertheless, it has been reported that ethanol can alter the lipid composition in neuronal membranes with possible detrimental consequences in neuronal function. The decrease of polyunsaturates, especially 22:6n-3, has been demonstrated in the rodent brain (12) as well as its subcellular fractions including microsomes (13), synaptosomes (14,15), synaptic plasma membranes (16,17), and mitochondria (18). It has been also reported that *in utero* ethanol exposure decreased PS biosynthesis in rat pup cerebellum (19). While it is often difficult to find any significant effect of ethanol on the total lipid content, it may be possible to observe the effect of ethanol associated with particular phospholipid molecular species. The demonstration that PS biosynthetic activity is influenced both by the 22:6n-3 status (8) and by ethanol (19) and that ethanol can

deplete 22:6n-3 from neuronal membranes presents a possibility that the effect of ethanol may be indicated more prominently in PS molecular species.

In this study, we investigated the effect of chronic ethanol exposure in relation to the 22:6n-3 status using C-6 cells as a model system. Since cells under the normal culture conditions are deficient in 22:6n-3 fatty acids, cells were enriched with 22:6n-3 and the effect of enrichment on the phospholipid profile was first examined using reversed-phase liquid chromatography/electrospray mass spectrometry. The effect of ethanol on the accumulation of individual molecular species was subsequently evaluated. We report here that the accumulation of PS is considerably enhanced by 22:6n-3 in comparison to nonenriched or arachidonic acid (20:4n-6)-enriched cells and that long-term exposure to ethanol diminishes the effect of 22:6n-3 on PS accumulation. Ethanol treatment concomitantly decreased serine incorporation, providing it as a mechanism for the observed PS reduction.

EXPERIMENTAL PROCEDURES

Materials. Deuterium-labeled or nonlabeled phospholipid standards were either purchased from or custom-synthesized by Avanti Polar Lipids (Alabaster, AL). [^{3}H]Serine (100 Ci/mmol) was obtained from New England Nuclear (Wilmington, DE). Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), and other tissue culture reagents were purchased from Gibco Life Technologies Laboratories (Grand Island, NY). Silica gel 60 plates were obtained from Analtech (Newark, DE). All the solvents were high-performance liquid chromatography (HPLC) grade purchased from EM Scientific (Gibbstown, NJ). The phospholipid standards were calibrated by phosphorus assay (20) or gas chromatography (GC) analysis as described earlier (21).

Cell culture conditions. The rat C-6 glioma cell line was obtained from the American Type Cell Culture (ATCC CCL-107; Rockville, MD) and maintained in a culture medium consisting of DMEM supplemented with 10% FBS. Cells were grown in 20 mL of this culture medium in 75-cm^2 Corning culture flasks in a humidified environment of 5% CO_2, 95% air at 37°C. To investigate the effect of long-term exposure to ethanol, the medium was replaced daily with fresh medium containing ethanol at 20 or 50 mM concentrations for 4 wk as described earlier (22). During this period, cells were subcultured every 3–4 d upon confluency. Control cells received the same treatment with ethanol-free medium.

Incubation with polyunsaturated fatty acids. C-6 glioma cells were cultured in DMEM containing 10% FBS and 0, 20, or 50 mM ethanol by changing the medium daily. After 4 wk of ethanol treatment, 4×10^5 cells/well were subcultured in six-well plates for 24 h and then incubated with DMEM containing 10% FBS and 25 μM (final concentration) 22:6n-3 or 20:4n-6 for 48 h in the presence of 40 μM vitamin E as an antioxidant. The media with 10% FBS alone contained 9 μM 20:4n-6 and 4 μM 22:6n-3. At the end of the incubation period, unincorporated fatty acids were washed off with DMEM containing 2% bovine serum albumin and the cells were scraped on ice to minimize the free fatty acid release by mechanical disturbance (23). Aliquots were taken from the cell suspension for protein assay using bicinchoninic acid method (24) and for counting cell numbers using a hemacytometer. Lipids were extracted according to Bligh and Dyer (25) in the presence of tricosanoic acid (23:0) for GC analysis or deuterium-labeled phospholipid standards for phospholipid analysis by electrospray mass spectrometry. Separately, cells were incubated with 0.5 μCi of [^{3}H]20:4n-6 or [1-^{14}C]22:6n-3 (at the final concentration adjusted to 25 μM) under the same condition described above. At 5, 11, 24, and 48 h, cells were harvested and cell lipids were extracted. Aliquots were taken for measurement of radioactivity. Lipid extracts were subjected to thin-layer chromatography (TLC) using a solvent system containing hexane/diethylether/formic acid (90:60:4, by vol). Separated lipids were identified by comparison with standards visualized by exposure to iodine. Radioactivity for each lipid class was determined by liquid scintillation after scraping off the individual TLC spots.

Phospholipid molecular species analysis. Phospholipid molecular species were separated and determined using reversed-phase HPLC/electrospray mass spectrometry using similar conditions described previously (8,26). A C-18 column (Phenomenex, Torrance, CA; 5 μ, 2.0 mm i.d. × 15 cm) was used with mobile phase containing water/0.5% ammonium hydroxide in methanol/hexane changing from 12:88:0 to 0:88:12 in 17 min after holding at the initial composition for 3 min at a flow rate of 0.4 mL/min (27). A Hewlett-Packard (Palo Alto, CA) HPLC–MS series 1100 MSD instrument was employed to detect the separated phospholipid molecular species. For electrospray ionization, the capillary temperature was set at 350°C while the capillary exit voltage was set at 200 V. The drying gas flow rate and the nebulizing gas pressure were set at 13 L/min and 32 psi, respectively. Quantitation was performed in the presence of d_{35}-1-stearoyl-2-arachidonyl-glycerophosphocholine (18:0,20:4-PC), PE, and d_{35}-1-stearoyl-2-docosahexaenoyl-glycerophosphoserine (18:0,22:6-PS) as internal standards. The amount of phospholipid species was obtained based on the area ratio calculated against the standard of the same class.

Fatty acid analysis. Lipid extract was transmethylated according to Morrison and Smith (28) and analyzed using a Hewlett-Packard gas chromatograph and a J&W (Folsom, CA) DB-FFAP capillary column (30 m × 0.25 mm i.d., with a 0.25 μm film thickness) with hydrogen gas as the carrier gas (55 cm/s), as described earlier (21). The oven temperature was programmed from 130 to 175°C at 4°C/min and then raised to 240°C at 30°C/min. The injector and detector temperatures were set at 240°C. The mixture of transmethylation reagent (BF_3-methanol) and lipid extract was purged with argon prior to heating. Under this condition, BF_3-transmethylation did not affect the 22:6n-3 recovery (99 ± 0.3%) determined by re-transmethylating 22:6n-3 methylester in the presence of 23:0. Under the nitrogen atomosphere, the recovery of 22:6n-3 was 96 ± 0.5%.

Serine incorporation. Control and ethanol-treated C-6 glioma cells (4×10^5 cells/well) were incubated with [^{3}H]serine (0.5 μCi) in DMEM with 10% FBS for 48 h in the presence or absence of 25 μM 22:6n-3. At the end of incubation, the medium was discarded and cells were washed with DMEM containing 2% bovine serum albumin. The cells were scraped in 1 mL of BHT/methanol and the incorporated radioactivity was determined after the extraction of total cell lipids. Cell lipids were separated using a slightly modified two-step TLC method by Smith and Waite (29). The plates were chromatographed halfway up in a phospholipid system containing chloroform/(methanol with 50 μg/mL BHT)/glacial acetic acid/water (100:75:7:4, by vol), taken out and dried briefly under a stream of nitrogen. The plates were then developed again completely in a solvent system containing hexane/diethylether/formic acid (90:60:4, by vol). Radioactivity for each lipid class was determined by liquid scintillation after scraping off the individual TLC spots.

RESULTS

Incorporation of 22:6n-3 and 20:4n-6. C-6 glioma cells quickly incorporated both 22:6n-3 and 20:4n-6 fatty acids at 25 μM with no apparent toxic effect on cell survival as evaluated by trypan blue staining. The total incorporation of radioactive fatty acids steadily increased during 24 h of incubation and leveled off thereafter (data not shown) as has been reported previously (30). Both fatty acids were initially incorporated into neutral lipids, but gradually remodeled into the phospholipid fraction so that after 24 h over 90% of the total incorporated polyunsaturated fatty acids was found in phospholipids. After 48 h of incubation, 92.7 ± 0.8 or 92.3 ± 0.4% of total cellular radioactivity from 20:4n-6 or 22:6n-3 was found in phospholipid fraction, respectively. Incubation of cells with 22:6n-3 for 48 h increased the composition of 22:6n-3 in total lipids from 1.4 ± 0.1 to 10.9 ± 0.2% while 20:4n-6 increased from 4.0 ± 0.1 to 12.4 ± 0.2% after supplementation with 20:4n-6 (Table 1). Under the conditions employed, a significant proportion of 20:4n-6 was found to be chain-elongated to adrenic acid (22:4n-6), and the total content of 22:4n-6 reached 6.3 ± 0.2%. Concomitant decreases of 18:1n-9 compensated the increase of polyunsaturated fatty acids in cells treated with polyunsaturated fatty acids. Except for slight increases in 22:5n-3 and 20:5n-3 in 22:6n-3-treated cells, the composition of other fatty acids was not affected significantly.

Phospholipid molecular species analysis. Phospholipid molecular species analysis was performed using electrospray mass spectrometry as described earlier (8,26). It was found that 22:6n-3 was mostly incorporated into 18:0,22:6-PS followed by 18:0,22:6-PE plasmalogen, 1-palmitoyl-2-docosahexanoyl-glycerophosphocholine (16:0,22:6-PC), 18:0,22:6-PE and 16:0,22:6-PE plasmalogen and PE, in descending order (Fig. 1A). In contrast, 20:4n-6 was particularly enriched in 1-palmitoyl-2-arachidonyl-glycerophosphocholine (16:0,20:4-PC) followed by 18:0,20:4-PE, PC and PS, 16:0,20:4-PE and 18:1,20:4-PE species (Fig. 1B). In comparison to control cells, higher plasmalogen contents also were observed after enrichment with 20:4n-6. The content of 16:0,20:4- and 18:0,20:4-PE plasmalogen was raised from 1.2 ± 0.01 and 1.8 ± 0.2 pmol/μg protein to 2.2 ± 0.2 and 2.2 ± 0.2 pmol/μg protein, respectively. In addition, 22:4n-6, an elongation product of 20:4n-6, appeared in PE plasmalogen as 18:0,22:4 species (from the nondetectable level to 2.4 ± 0.7 pmol/μg protein).

Enrichment of cells with polyunsaturated fatty acids affected the distribution of glycerophospholipid classes although the absolute levels of total glycerophospholipids did not alter significantly (Fig. 2). The absolute level (Fig. 2A) as well as the mole percentage (Fig. 2B) of PS was higher after the supplementation with 20:4n-6 or 22:6n-3. In the cells enriched with 22:6n-3 in particular, the total PS content was more than twice as high in comparison to nonenriched cells (Table 2). The elevated level of total PS with 22:6n-3 enrichment was primarily due to the marked accumulation of 18:0,22:6-PS as this species changed from 0.67 to 8.00 pmol/μg protein. The observed higher PS content appeared to be compensated by slightly but significantly reduced total PC contents (Fig. 2), mainly due to lower accumulation of the PC

[a]Phosphatidylserine molecular species observed after the enrichment of C-6 glioma cells with 25 μM 20:4n-6 or 22:6n-3 for 48 h. The figures represent pmol/μg protein (mean ± SD). Statistical analysis was performed in comparison to values from nonenriched control cells using Student's *t*-test: *$P < 0.05$; **$P < 0.01$; ***$P < 0.001$.

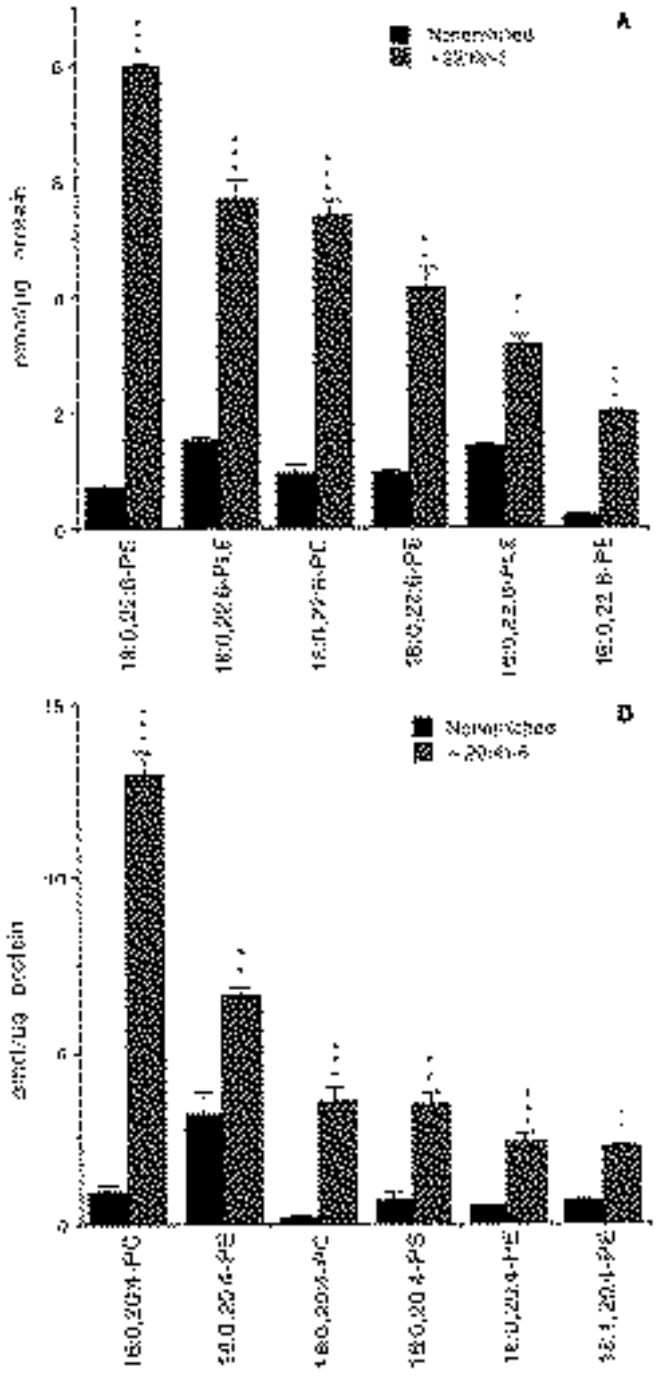

FIG. 1. The major molecular species observed after supplementation of cells with 25 μM (A) 22:6n-3 or (B) 20:4n-6 for 48 h. The phospholipid molecular species were determined by reversed phase high-performance liquid chromatography (HPLC)/electrospray mass spectrometry. The results are the mean ± SD of triplicates. Statistical analysis was performed in comparison to values from nonenriched control cells using Student's *t*-test: $^{**}P < 0.01$; $^{***}P < 0.001$. PS, phosphatidylserine; PE, phosphatidylethanolamine; PC, phosphatidylcholine; PLE, plasmalogen.

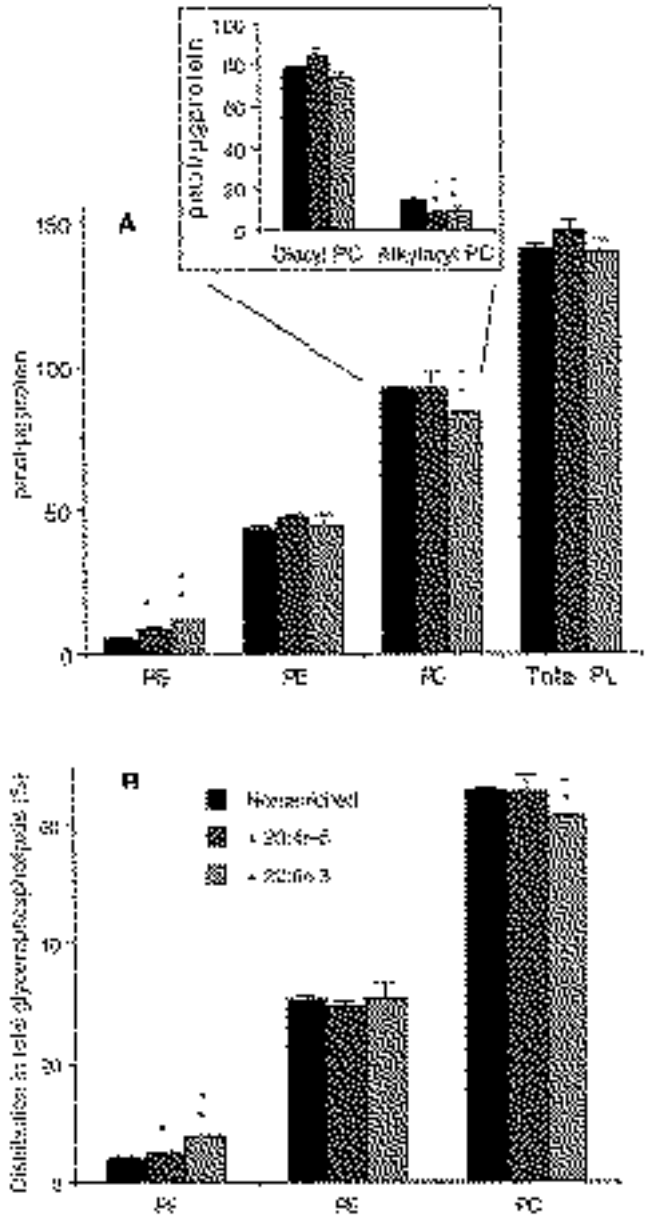

FIG. 2. Effect of supplementation on the phospholipid class distribution. C-6 cells were enriched with 25 μM 20:4n-6 or 22:6n-3 for 48 h and the phospholipid (PL) molecular species were determined by reversed-phase HPLC/electrospray mass spectrometry. The results are the mean ± SD of triplicates and presented as (A) pmol/μg protein and (B) percentage of total glycerophospholipids. Statistical analysis was performed in comparison to values from nonenriched control cells using Student's *t*-test: $^{*}P < 0.05$; $^{**}P < 0.01$. The effect of fatty acid supplementation on phosphatidylcholine subclasses is shown in the inset. See Figure 1 for abbreviation.

species containing 18:1n-9. In cells enriched with 20:4n-6, elevation of 18:0,20:4 and 18:0,22:4 species was the major cause for the slight increase of total PS. Supplementation of cells with 20:4n-6 or 22:6n-3 decreased 18:0,18:1-PC from 32 ± 2 to 17 ± 2 or 18 ± 2 pmol/μg protein and 16:0,18:1-alkylacyl PC from 14 ± 1 to 7 ± 1 or 8 ± 1 pmol/μg protein, respectively. Since incorporation of 22:6n-3 into PC was considerably less than that of 20:4n-6, the total PC content was significantly lower with 22:6n-3 enrichment but did not change significantly in 20:4n-6-treated cells. The content of

total alkylacyl-PC species, where 18:1n-9 is the major component, was also significantly lower after the enrichment with 20:4n-6 or 22:6n-3 (Fig. 2A inset).

Effect of ethanol on the accumulation of polyunsaturated species. The treatment of cells with ethanol at 20 or 50 mM for 4 wk showed lower long-chain polyunsaturate contents in 20:4n-6- or 22:6n-3-enriched cells in comparison to non-ethanol-treated cells while much less change was observed in nonenriched cells (Fig. 3). The 18:1n-9 content was raised concomitantly in ethanol-treated cells, as has been observed frequently after chronic ethanol exposure (18).

The observed higher levels of 18:1n-9 after ethanol exposure were reflected by a slight elevation of PC, especially due to the higher levels of 18:0,18:1- and 18:1,18:1-PC and 16:0,18:1-alkylacyl PC (data not shown). The decreased content of 22:6n-3 by ethanol was associated with specific phospholipid molecular species in 22:6n-3-enriched cells. Conversely, in 20:4n-6-treated cells, 20:4n-6-containing species either were decreased or remained unchanged by ethanol. Since the majority of phospholipid species containing either 22:6n-3 or 20:4n-6 were coupled to either 18:0 or 16:0 fatty acid at the *sn*-1 position, only these species are presented in

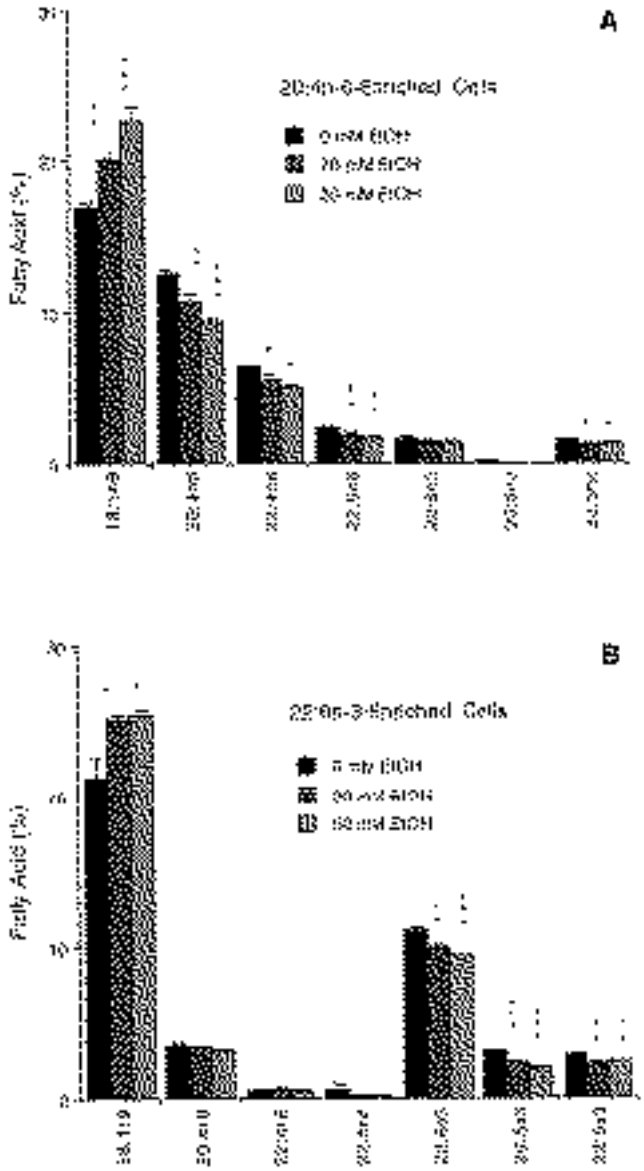

FIG. 3. Effect of long-term ethanol exposure on the incorporation of (A) 22:6n-3 and (B) 20:4n-6 into C-6 glioma cells. Cells were exposed to 0, 20, or 50 mM ethanol for 4 wk, and the incorporation of 25 μM (A) 20:4n-6 or (B) 22:6n-3 was monitored for 48 h as described in the Experimental Procedures section. The fatty acid distribution in total lipids are presented as the mean ± SD of triplicates. Statistical analysis was performed in comparison to values from control cells (0 mM ethanol) using Student's *t*-test: $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$.

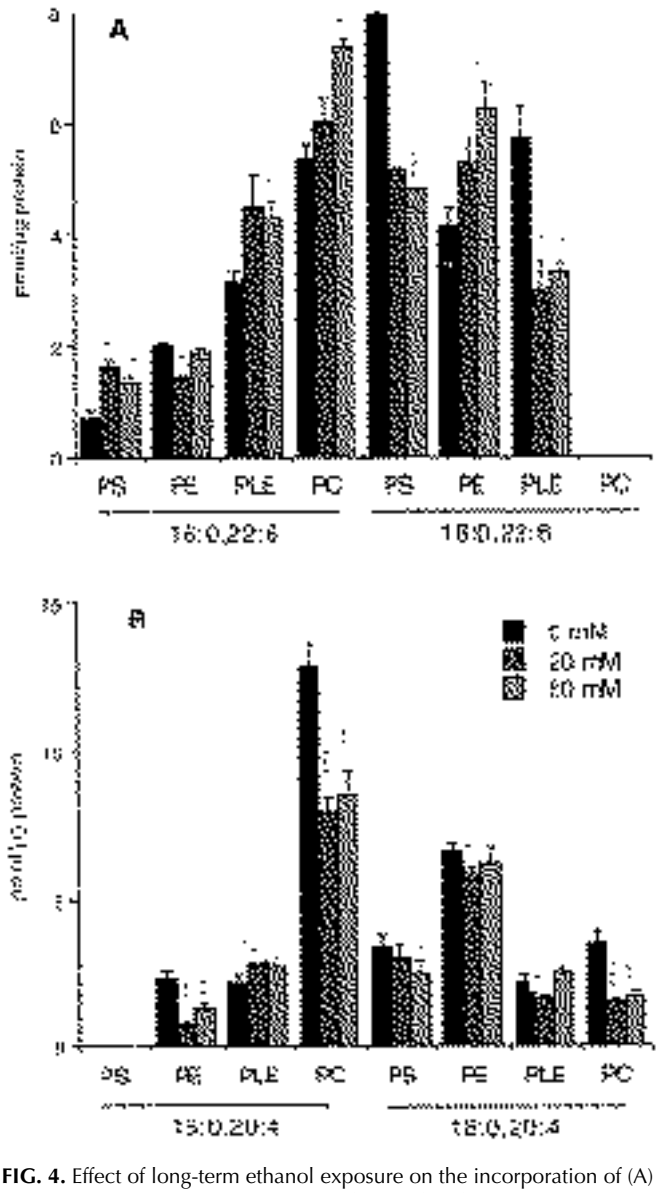

FIG. 4. Effect of long-term ethanol exposure on the incorporation of (A) 22:6n-3 or (B) 20:4n-6 into major phospholipid molecular species. Cells were exposed to 0, 20, or 50 mM ethanol for 4 wk and further incubated with 25 μM (A) 22:6n-3 or (B) 20:4n-6 for 48 h. Phospholipid molecular species were determined by reversed-phase HPLC/electrospray mass spectrometry. The results are the mean ± SD of triplicates. Statistical analysis was performed in comparison to values from control cells (0 mM ethanol) using Student's *t*-test: $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$. See Figure 1 for abbreviations.

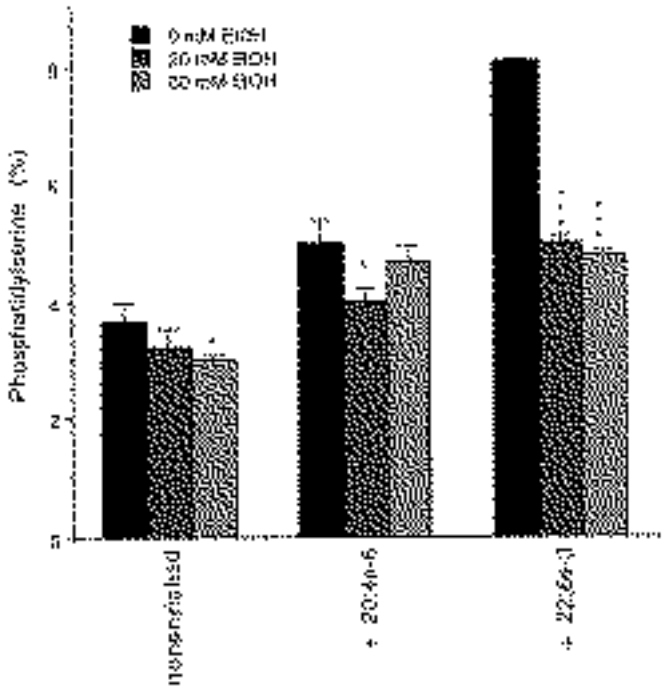

FIG. 5. Effect of long-term ethanol exposure on phosphatidylserine accumulation. Cells were exposed to 0, 20, or 50 mM ethanol for 4 wk and further incubated with 25 μM 20:4n-6 or 25 μM 22:6n-3 for 48 h. Phospholipid molecular species were determined by reversed-phase HPLC/electrospray mass spectrometry. The results are the mean ± SD of triplicates. Statistical analysis was performed in comparison to values from control cells (0 mM ethanol) using Student's *t*-test: $*P < 0.05$; $***P < 0.001$. See Figure 1 for abbreviation.

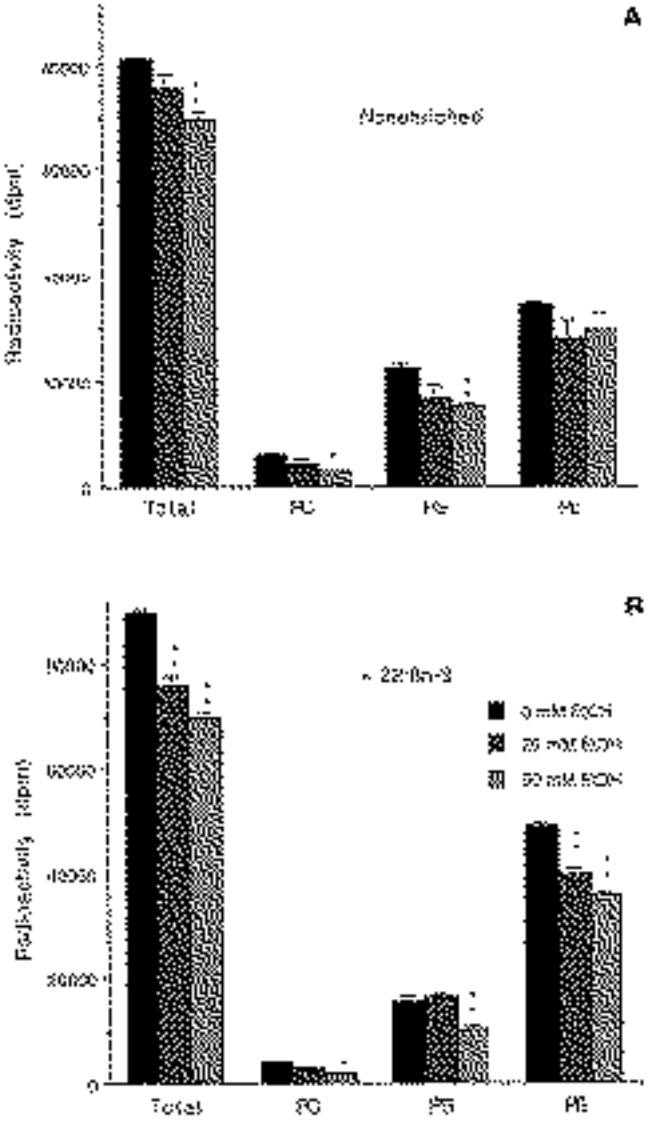

FIG. 6. Effect of long-term ethanol exposure on serine incorporation. Cells were exposed to 0, 20, or 50 mM ethanol for 4 wk. Control (0 mM ethanol) and ethanol-treated C-6 glioma cells were incubated with [^{3}H]serine (0.5 μCi) for 48 h in the (A) absence or (B) presence of 25 μM 22:6n-3. The total incorporated radioactivity was counted after extraction of the cell lipids. The radioactivity associated with individual phospholipid classes was counted after further separation of total cell lipids by thin-layer chromatography. The results are the mean ± SD of triplicates. Statistical analysis was performed in comparison to values from control cells using Student's *t*-test: $*P < 0.05$; $**P < 0.01$. See Figure 1 for abbreviations.

Figure 4. The most drastic effect of ethanol was the decreased accumulation of 18:0,22:6-PS and 18:0,22:6-PE plasmalogen in 22:6n-3 treated cells, as these species were reduced by approximately 40% (Fig. 4A). In contrast, ethanol increased 18:0,22:6-PE and 16:0,22:6-PC. In 20:4n-6-treated cells, 16:0,20:4- and 18:0,20:4-PC decreased most extensively (Fig. 4B). Although 18:0,20:4-PS also showed a decreasing trend after ethanol exposure, the reduction was not as significant as 18:0,22:6-PS in 22:6n-3-treated cells.

Altered accumulation of specific PS molecular species after ethanol exposure was reflected in the total PS content. As shown in Figure 5, there was a trend of decreasing PS by ethanol although the effect of ethanol on PS accumulation in nonenriched or 20:4n-6-enriched cells was not consistently significant. The effect of ethanol was most prominent for 22:6n-3-treated cells as the mole fraction of PS decreased by more than 40% from 8.3% to 5.0 or 4.8% after the exposure of cells to 20 or 50 mM ethanol, respectively. This decrease was primarily due to the dramatic reduction of 18:0,22:6-PS (Fig. 4A), indicating that preferential accumulation of PS caused by 22:6n-3 (Fig. 2) was prevented by ethanol exposure.

Effect of ethanol on the serine base exchange reaction. As indicated above, the negative effect of ethanol on polyunsaturated fatty acid incorporation was prominently shown for PS. In the mammalian system, PS is biosynthesized by serine base exchange reaction (6). In order to test whether PS biosynthetic activity was modified after the ethanol exposure, the cells treated with 0, 20, or 50 mM ethanol for 4 wk were incubated with ^{3}H-serine for 48 h. The total incorporation of serine into C-6 glioma cells pretreated with ethanol was much less than that observed with control cells, especially in the presence of 22:6n-3. The effect of ethanol on serine incorporation appeared to be ethanol-concentration dependent

(Fig. 6). A similar ethanol effect was also observed in the absence of 22:6n-3, although at a lesser extent. Further analysis of phospholipid classes by TLC showed that most radioactivity of the incorporated serine appeared in PE, then in PS and to a lesser extent in PC, indicating that remodeling of phospholipids, especially decarboxylation of PS to PE, actively occurs in C-6 glioma cells. The incorporation of the radioactivity derived from serine into all phospholipid classes showed a decreasing trend with ethanol exposure. The extent of conversion from PS to PE or PC in ethanol-treated cells was not significantly different from that in control cells, suggesting that decarboxylation of PS to PE and then methylation to PC may not be affected significantly by ethanol in this system. These data suggest that the reduced accumulation of polyunsaturates in PS by chronic ethanol exposure may be at least partly due to impaired PS biosynthetic activity. Since 22:6n-3 prefers the accumulation in PS, attenuated PS biosynthetic activity after the ethanol exposure may affect the accumulation of PS with a greater extent in 22:6n-3-treated cells in comparison to nonenriched cells.

DISCUSSION

Many investigators have demonstrated that chronic ethanol exposure can alter the content of polyunsaturates (6,11–18). Both polyunsaturate status (8) and ethanol (19) have been shown to modulate PS biosynthetic activity. These findings suggest that ethanol may specifically affect the accumulation of PS in cell membranes. In the present study, we examined the effect of ethanol on the accumulation of PS under different polyunsaturate status, using C-6 glioma cells as the model system. By using reversed-phase chromatography coupled to electrospray mass spectrometry, separation and detection of individual phospholipid molecular species from C-6 glioma cell extracts were achieved. The presence of deuterium-labeled internal standards facilitated reliable quantitation of targeted molecular species in cell lipids.

Enrichment of cells with polyunsaturated fatty acids increased PS accumulation without altering the total phospholipid content significantly (Fig. 2). Supplementation with 22:6n-3, in particular, resulted in the most significant increase of PS, as has been suggested with PS biosynthetic activity in our previous report (8). While the absolute changes observed seem small, PS accumulation was doubled in these cells (Table 2). This observation is consistent with the fact that neuronal cells, which are enriched with 22:6n-3, carry a higher PS proportion in comparison to cells of nonneuronal origin (31,32).

As cells in culture are generally deficient in polyunsaturates, especially n-3 fatty acids, supplementation with 22:6n-3 was necessary to accomplish the enrichment of this fatty acid to the level that is normally found in brain cells. Although exposing cells to 25 μM free fatty acid may not be physiological, we have observed that 22:6n-3 is incorporated in a concentration-dependent manner up to 40 μM without affecting cell viability (8).

The most prominent accumulations of molecular species found after incubation with either 20:4n-6 or 22:6n-3 were different. Whereas 20:4n-6 was mainly incorporated into PC, 22:6n-3 was incorporated mostly into PS and PE. As a single molecular species, 18:0,22:6-PS was the most abundant 22:6n-3-containing species observed after enrichment with 22:6n-3. The level of 18:0,22:6-PS was approximately 10 times higher than that of 16:0,22:6-PS, suggesting that PS synthesis may be preferred for species containing 18:0 at the *sn*-1 position as has been reported earlier (33). Enrichment of 22:6n-3 into 18:0-containing PS species is consistent with the fatty acyl composition observed in neuronal tissues (34). Our present finding that 16:0,20:4-PC was the most enriched species after 20:4n-6 enrichment is not consistent with the previous report by Sun *et al.* (35) where the greatest incorporation of [^{14}C]20:4n-6 was indicated in plasmalogen PE. The discrepancy may be due to the fact that radioactivity distribution may not reflect the resulting lipid profile as radioactivity enrichment depends on the turnover rates as well as the specific activities of lipid molecules involved in the turnover process. Alternatively, the different fatty acid concentration used (0.37 μM vs. 25 μM) may have contributed to the apparent discrepancy.

A few reports indicated that ethanol affects serine incorporation (19,36–38). Acute ethanol exposure of hepatocytes *in vitro* has been reported to increase the incorporation of radioactive serine (36). Hepatocytes isolated from rats treated with ethanol chronically also showed enhanced incorporation of radioactive serine (37). It has also been reported that NG108-15 cells showed higher serine incorporation after treatment with 100 mM ethanol for 2 d (38). Conversely, it has been reported that *in utero* exposure to ethanol decreased PS biosynthesis in rat pup cerebra (19), where it is known to have a high 22:6n-3 content. Our present findings indicated that long-term (4 wk) exposure of C-6 glioma cells to ethanol at 20 mM, which is below the legal intoxication concentration of ethanol (22.5 mM), the serine incorporation is considerably inhibited, particularly in cells where 22:6n-3 is highly enriched. This finding was corroborated by the marked reduction in the accumulation of 18:0,22:6-PS and total PS in 22:6n-3-treated cells by ethanol (Figs. 4 and 5). The significant decrease of 18:0,22:6-PS by ethanol observed in this study is consistent with previous reports that 22:6n-3 was depleted from PS of rat brain mitochondria (18) or mouse brain synaptic plasma membranes (16) after chronic ethanol exposure.

The inhibited incorporation of [^{3}H]serine into the lipid fraction observed in ethanol-treated cells may not directly represent the reduced serine base exchange reaction. Impaired [^{3}H]serine uptake into the endogenous pool by long-term ethanol exposure or changes in the serine pool size may also cause the decreased radioactive label in total lipids as well as in PS. It has been reported, however, that long-term ethanol exposure did not change the serine levels in human blood (39) and mouse brain (40) while several amino acid levels were affected significantly, suggesting that the serine pool size may

not be sensitive to ethanol exposure. Besides, attenuated total serine incorporation by ethanol was accompanied by the decrease in the PS content, suggesting that PS biosynthetic activity, whether it is serine uptake or the serine base exchange reaction itself, may have been compromised in ethanol-treated cells. Alternatively, the attenuated PS accumulation observed in ethanol-treated cells may have resulted from altered PS degradation by base exchange reaction or PS decarboxylation, although the distribution of the radiolabel from [^{3}H]serine into major phospholipid classes was not significantly affected by the ethanol exposure (Fig. 6).

The decrease of 18:0,22:6 or 18:0,20:4-PS by ethanol was not quantitatively compensated by the increase of the corresponding PC or PE species (Fig. 4). In addition, the effect of ethanol on the incorporation of serine radioactivity into PS (Fig. 6) did not simply correlate with that of the PS accumulation (Fig. 5). These results suggest that the decreased polyunsaturated PS is not the mere consequence of inhibited base exchange reaction. Rapid redistribution of radioactivity from serine into PE suggests that decarboxylation of PS may influence significantly the accumulation of polyunsaturated PS and PE in C-6 glioma. In a recent report, it has been suggested that chronic ethanol exposure can alter PE levels, depending on the biosynthetic pathway from which PE was originally derived (41). It has also been shown that ethanol exhibited a differential effect at higher concentrations (200–750 mM), inhibiting acylation of oleic acid in PE and PC, but stimulating acylation in PA and DG (42). Obviously, it is not easy to discern various overlapping metabolic pathways involved in the accumulation of certain molecular species in living cells. Nevertheless, our data does suggest that inhibited PS biosynthesis is involved, although it is not the only mechanism that is accountable for the reduction of polyunsaturated PS species.

In this report, we demonstrate that the 22:6n-3 status positively affects the accumulation of PS and that chronic ethanol exposure can inhibit PS accumulation. The preferential accumulation of PS in the presence of 22:6n-3 is consistent with the fact that tissues containing abundant 22:6n-3 show high proportions of PS as is observed in neuronal membranes (1,31,32). We found that chronic ethanol exposure at or near physiologically relevant concentrations (20–50 mM) inhibited the accumulation of PS promoted by 22:6n-3 in as little as 4 wk. Since the brain is particularly enriched with 22:6n-3, our findings imply that ethanol may exert greater influence on PS accumulation in brain cells. Considering the involvement of PS in various signal transduction events, such as the recruitment of protein kinase (9) or Raf-1 kinase to cell membranes (10), the effect of ethanol on the accumulation of PS may have a significant implication in pathophysiological effects of ethanol, especially in the brain.

Inhibition of Cholesterol Biosynthesis by Organosulfur Compounds Derived from Garlic

Lijuan Liu and Yu-Yan Yeh*

Graduate Program in Nutrition, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT: The study was undertaken to test the inhibitory potential on cholesterogenesis of organosulfur compounds derived from garlic. The primary rat hepatocytes maintained in Dulbecco's modified Eagle's medium were treated with [2-^{14}C]-acetate as substrate for cholesterol synthesis in the presence or absence of test compounds at 0.05 to 4.0 mmol/L. Eleven water-soluble and six lipid-soluble compounds of garlic were tested. Among water-soluble compounds, *S*-allyl cysteine (SAC), *S*-ethyl cysteine (SEC), and *S*-propyl cysteine (SPC) inhibited [2-^{14}C]acetate incorporation into cholesterol in a concentration-dependent manner, achieving 42 to 55% maximal inhibition. γ-Glutamyl-*S*-allyl cysteine, γ-glutamyl-*S*-methyl cysteine, and γ-glutamyl-*S*-propyl cysteine were less potent, exerting only 16 to 29% maximal inhibitions. Alliin, *S*-allyl-*N*-acetyl cysteine, *S*-allylsulfonyl alanine, and *S*-methyl cysteine had no effect on cholesterol synthesis. Of the lipid-soluble compounds, diallyl disulfide (DADS), diallyl trisulfide (DATS), and dipropyl disulfide (DPDS) depressed cholesterol synthesis by 10 to 25% at low concentrations (0. 5 mmol/L), and abolished the synthesis at high concentrations (1. 0 mmol/L). Diallyl sulfide, dipropyl sulfide, and methyl allyl sulfide slightly inhibited [2-^{14}C]acetate incorporation into cholesterol only at high concentrations. The complete depression of cholesterol synthesis by DADS, DATS, and DPDS was associated with cytotoxicity as indicated by marked increase in cellular LDH release. There was no apparent increase in LDH secretion by water-soluble compounds except *S*-allyl mercaptocysteine, which also abolished cholesterol synthesis. Judging from maximal inhibition and IC_{50} (concentration required for 50% of maximal inhibition), SAC, SEC, and SPC are equally potent in inhibiting cholesterol synthesis.

Paper no. L8348 in *Lipids 35,* 197–203 (February 2000).

Garlic has been recognized for its medicinal potentials since ancient times, but only recently has evidence emerged that garlic may decrease hypercholesterolemia (1,2) and reduce cancer risk (3). Extensive studies have been conducted to test anticarcinogenic and antitumorigenic properties of garlic and garlic components (4–9). It has been shown that *S*-allyl cysteine (SAC) and *S*-propyl cysteine (SPC) effectively blocked *N*-nitrosomorpholine (NMOR, a liver carcinogen) formation, and SAC and diallyl disulfide (DADS) reduced NMOR mutagenicity (10). Diallyl sulfides, such as diallyl sulfide (DAS), DADS, and diallyl trisulfide (DATS), also have been found to prevent benzo(a)pyrene-induced cancer in mice (11). However, less is known about garlic ingredients responsible for reducing plasma level of cholesterol.

Studies have shown that garlic can decrease plasma lipids, especially total cholesterol and low density lipoprotein cholesterol in humans and animals (1,2,12–17). The hypocholesterolemic effects were confirmed by meta-analyses showing a reduction of plasma cholesterol concentration between 9 and 12% in subjects treated with garlic as compared to a placebo group (18,19). A recent clinical study reported that garlic supplementation significantly reduced total serum cholesterol and triglycerides and increased high density lipoprotein-cholesterol in patients with coronary artery disease (20). However, the most recent studies of Berthold *et al*. (21), Isaacsohn *et al*. (22) and Simons *et al*. (23) failed to confirm such a beneficial effect of garlic. Despite the discrepancy in these studies, garlic has been shown to decrease hepatic cholesterol synthesis (24–27), which may explain in part the hypocholesterolemic effect of garlic in humans and animals (1,14,16,20). We recently have shown that water extract of garlic and a water-soluble component of garlic, SAC, depressed cholesterol synthesis in rat hepatocyte culture (27). Similarly, lipid-soluble sulfur compounds of garlic, such as DADS, allicin, and its derivative (ajoene), have been found to be potent inhibitors of cholesterol synthesis (26,28). However, since a wide variety of organosulfur compounds has been identified and isolated from different garlic preparations (29,30), it is essential to characterize the active ingredient(s) responsible for the cholesterol-lowering effect of garlic (30).

The present study was undertaken to identify the active compounds and their inhibitory potency of cholesterol

biosynthesis in cultured rat hepatocytes. Additionally, the cytotoxicity of these compounds was determined and correlated to the cholesterol-lowering effect of the compounds.

MATERIALS AND METHOD

Chemicals. [2-^{14}C]Acetate was purchased from Amersham Corp. (Arlington Heights, IL). Collagenase D was obtained from Boehringer Mannheim Corp. (Indianapolis, IN). Culture media, fetal bovine serum (FBS), penicillin, and streptomycin were from Gibco (Gaithersburg, MD). Organosulfur compounds tested in this study included 11 water-soluble compounds, SAC, SEC, *S*-methyl cysteine (SMC), SPC, γ-glutamyl-*S*-allyl cysteine (GSAC), γ-glutamyl-*S*-methyl cysteine (GSMC), γ-glutamyl-*S*-propyl cysteine (GSPC), *S*-allyl cysteine sulfoxide (i.e., alliin), *S*-allyl-*N*-acetyl cysteine (SANC), *S*-allyl-mercaptocysteine (SAMC), and *S*-allylsulfonyl alanine (SASA), and six lipid-soluble compounds: DAS, DADS, DATS, dipropyl sulfide (DPS), dipropyl disulfide (DPDS), and methyl allyl sulfide (MAS). All the water-soluble compounds were provided by Wakunaga of America Co., Ltd. (Mission Viejo, CA). Of the six lipid-soluble compounds tested, DAS, DADS, DPS, and DPDS were purchased from Fluka Chemika (Ronkonkoma, NY). MAS was obtained from Aldrich Chemical Co. (Milwaukee, WI). DATS was a generous gift from Dr. John Milner's lab (The Pennsylvania State University, University Park, PA). All other chemicals of reagent grade were purchased from Sigma Chemical Co. (St. Louis, MO).

Animals. Male Sprague-Dawley rats (200–300 g) were obtained from Harlan Sprague-Dawley Co. (Indianapolis, IN) and fed a nonpurified diet (Purina Rat Chow, Ralston Purina, St. Louis, MO). The animals were housed individually in stainless-steel cages at approximately 24°C and 50% relative humidity on a 12-h light/dark cycle (0600–1800). The animal protocol was approved by The Pennsylvania State University Institutional Animal Care and Use Committee.

Hepatocyte culture. Liver cells were isolated from rats according to the method of Berry and Friend (31), as modified by Seglen (32). Briefly, rats were anesthetized with Nembutal (5 mg/100 g body weight), and the hepatic portal vein was cannulated for perfusion with buffer (NaCl, 142 mmol/L; KCl, 6.7 mmol/L; HEPES, 10 mmol/L; NaOH, 5.5mmol/L; pH 7.4) for 15 min. Immediately after perfusion *in situ*, the liver was carefully excised and perfused with collagenase buffer (NaCl, 67 mmol/L; KCl, 6.7 mmol/L; HEPES, 100 mmol/L; $CaCl_2 \cdot H_2O$, 5.4 mmol/L; NaOH, 66 mmol/L; pH 7.6; 50 mg collagenase D/100 mL) for 10–15 min. The enzyme-treated liver was then subjected sequentially to mincing, incubation, filtration, and centrifugation for cell isolation and purification. From each liver, 100–250 × 10^6 cells were obtained with a viability of 92–94%, as judged by trypan blue exclusion. The cells were resuspended in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% FBS and antibiotics (100 units penicillin/mL, and 100 μg streptomycin/mL) to obtain 0.5–0.8 × 10^6 cells/mL of suspension. Two-milliliter aliquots of the suspension were plated per well in a six-well culture plate (Becton Dickinson Labware, Lincoln, NJ) and incubated at 37°C under an atmosphere of 95% air and 5% CO_2. After 4 h of incubation, nonadhering cells were removed and discarded. Hepatocytes that adhered to the culture plate were refed with DMEM and incubated for 16 h.

Metabolic studies. At the end of 20 h of incubation, cells were washed three times with 2 mL of FBS-free DMEM, followed by incubation with 2 mL of the same medium containing sodium salt of [2-^{14}C]acetate (specific activity, 37 MBq/mmol) and 0.5 mmol/L nonlabeled sodium acetate in the presence or absence of organosulfur compounds. The lipid-soluble organosulfur compounds were dissolved in dimethyl sulfoxide (DMSO) and then in DMEM. The final concentrations of DMSO did not exceed 2%, and appropriate controls containing DMSO were run. A preliminary study has established a linear rate of [2-^{14}C]acetate incorporation into cholesterol between 4- and 12-h incubation of hepatocytes. Thus, throughout the study, cells were incubated for 4 h. After the incubation, the medium was collected and cells were harvested with 1.3 mL of ice-cold water by scraping with a cell scraper.

Lipid analysis. The harvested cells were mixed with 20 mL of chloroform/methanol (2:1, vol/vol) to extract lipids according to the method of Folch *et al.* (33). For measurement of [2-^{14}C]acetate incorporation into cholesterol, the lipid extract was saponified in 6 mL of 3.75% methanolic KOH at 90°C for 4 h. Nonsaponifiable lipids were extracted with petroleum ether (b.p. 35–60°C), and cholesterol was precipitated with digitonin (34). Briefly, nonsaponifiable lipid fraction was evaporated to dryness under nitrogen stream and dissolved in acetone/ethanol (1:1, vol/vol). After the addition of 1% digitonin solution (in 50% ethanol and 1% acetic acid), the sample was allowed to stand overnight for digitonide formation. For further purification, digitonide was washed with acetone/ethyl ether (1:1, vol/vol), followed by a final wash with ethyl ether alone. The radioactivity of ^{14}C-labeled sterol digitonide was taken as a measure of cholesterol derived from [2-^{14}C]acetate. The radioactivity was determined by liquid scintillation counting (Beckman model LS 3801; Beckman Instruments, Fullerton, CA). The specific activity of cholesterol synthesis was expressed as pmol acetate incorporated into cholesterol/mg cellular protein. Cellular protein was determined by the procedure of Lowry *et al.* (35). The relative rate of cholesterol synthesis by cells treated with organosulfur compounds was expressed as percentage of control calculated by specific activity of treatment group/specific activity of control nontreatment group × 100. IC_{50} (concentration required for 50% of maximal inhibition) was calculated by regression and correlation analysis between substrate concentration and inhibition percentage.

Determination of cytotoxicity. Cytotoxicity of hepatocytes was determined by measuring release of cellular lactate dehydrogenase (LDH) into the culture medium. The percentage of LDH released was estimated by dividing the activity in the medium by the sum of LDH activity in cells and medium × 100. Hepatocytes were lysed with 0.2% Triton X-100. LDH

activity was measured according to the method of Chao *et al.* (36) with modification as follows: the reaction mixture contained 2.55 mL of potassium phosphate buffer (0.1 M, pH 7.4) and 0.1mL of NADH (4.5 mM). The cell lysate (0.05 mL) was added and mixed. At time zero, the reaction was initiated by adding 0.1 mL of 20 mM sodium pyruvate solution. The rate of decreasing absorbance at 340 nm was monitored at 25°C with a Beckman DU®-50 LS 5801 spectrophotometer (Beckman Instruments). The specific activity of the enzyme measured in hepatocytes of untreated group ranged from 1 to 2 μmol of substrate used /min/well.

Statistics. Data are presented as means ± SEM. The comparisons of the test compounds were analyzed by analysis of variance (ANOVA). When statistical significance was indicated by ANOVA, Fisher's multiple test was applied to identify the significant difference between the groups at $P < 0.05$.

RESULTS

Incorporation of [2-^{14}C]acetate into cholesterol was measured in hepatocytes treated with or without organosulfur compounds at various concentrations (0.05–4.0 mmol/L) throughout the study. As shown in Figure 1, the rate of [2-^{14}C]acetate incorporation into cholesterol in the untreated group was arbitrarily defined as 100%. The rates of incorporation expressed as pmol acetate/mg cellular protein/4 h for the control varied from one experiment to another, but ranged from 868 to 1,396 pmol acetate/mg cellular protein. Among *S*-alk(en)yl cysteines, SAC, SEC and SPC but not SMC inhibited [2-^{14}C]acetate incorporation into cholesterol in a concentration-dependent manner with a maximal inhibition of 42–55%. The inhibition was apparent at a concentration as low as 0.05 mmol/L for SEC and SPC, and 0.1 mmol/L for SAC. All γ-glutamyl *S*-alk(en)yl cysteines (i.e., GSAC, GSMC, and GSPC) inhibited the rate of cholesterol synthesis to a maximum of 16–30% (Fig. 2). The inhibition was not seen at concentrations lower than 2.0 mmol/L for GSAC and GSPC, while a significant inhibition was noted at 0.5 mmol/L for GSMC. SAMC, a disulfur containing *S*-allyl cysteine derivative, inhibited the [2-^{14}C]acetate incorporation into cholesterol by 7–17% at 0.05 and 0.5 mmol/L and diminished the incorporation into cholesterol at 2.0 and 4.0 mmol/L (Fig. 3).

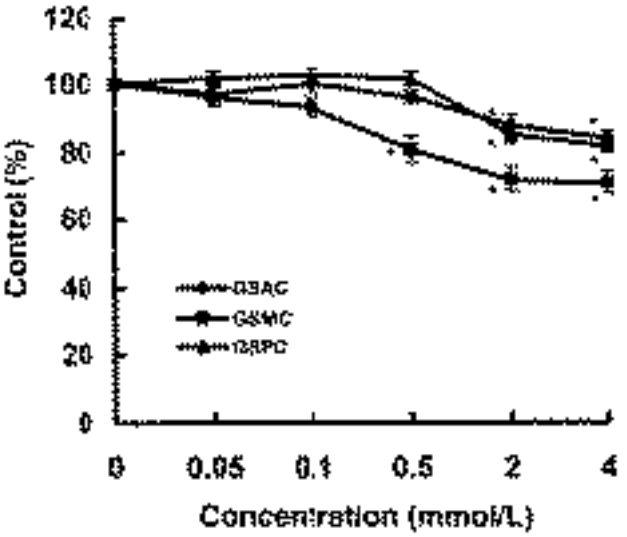

FIG. 2. Inhibition of [2-^{14}C]acetate incorporation into cholesterol by γ-glutamyl-*S*-allyl cysteine (GSAC), γ-glutamyl-*S*-methyl cysteine (GSMC), and γ-glutamyl-*S*-propyl cysteine (GSPC) in primary hepatocyte culture. Data are expressed as percentage of the control and represent means ± SEM of eight samples. *Statistically different from controls, $P < 0.05$.

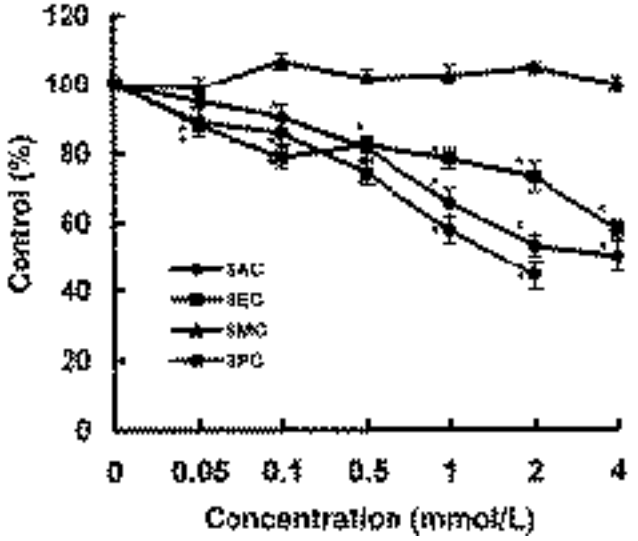

FIG. 1. Inhibition of [2-^{14}C]acetate incorporation into cholesterol by *S*-allyl cysteine (SAC), *S*-ethyl cysteine (SEC), *S*-methyl cysteine (SMC), and *S*-propyl cysteine (SPC) in primary hepatocyte culture. Data are expressed as percentage of the control and represent means ± SEM of eight samples. *Statistically different from controls, $P < 0.05$.

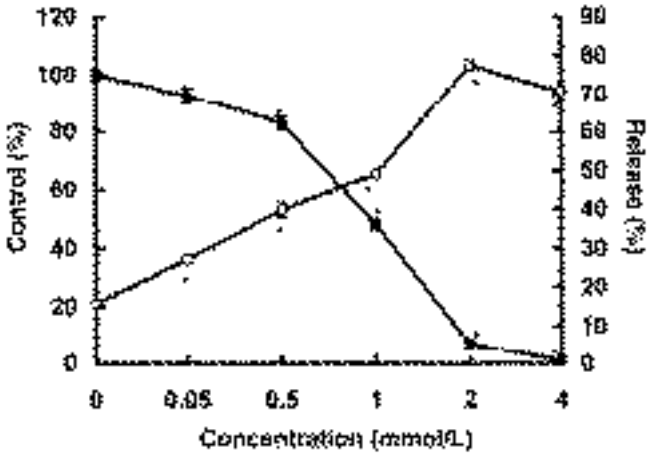

FIG. 3. Inhibition of [2-^{14}C]acetate incorporation into cholesterol and lactate dehydrogenase (LDH) release into the medium by *S*-allyl mercaptocysteine (SAMC) in primary hepatocyte culture. Data are expressed as a percentage of the control for [2-^{14}C]acetate incorporation into cholesterol (●) and a percentage of LDH activity in medium relative to total activity in cells and medium (○). The data represent means ± SEM of eight samples. *Statistically different from controls, $P < 0.05$.

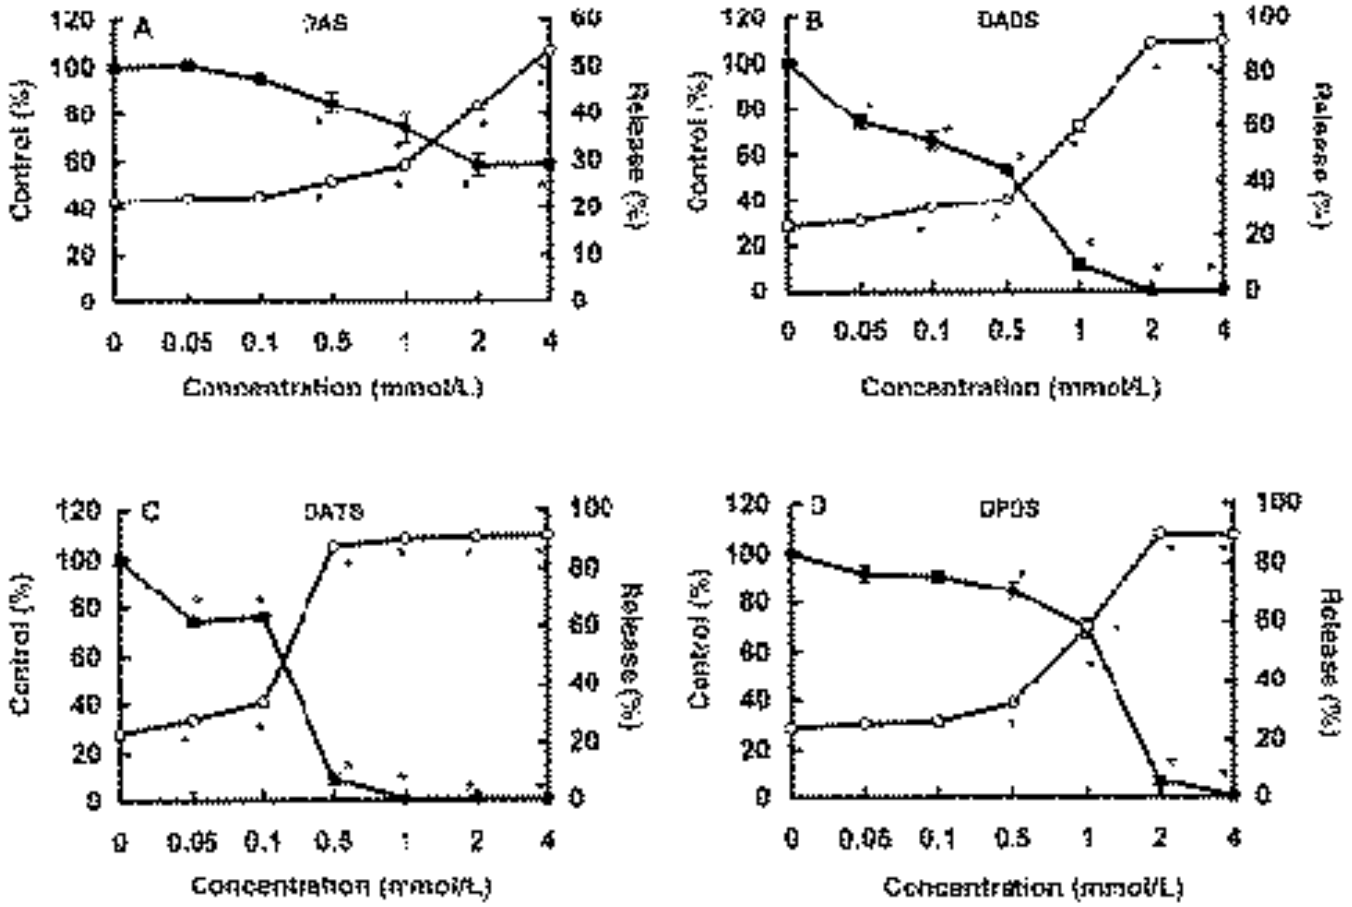

FIG. 4. Inhibition of [2-^{14}C]acetate incorporation into cholesterol and LDH release into the medium by diallyl sulfide (DAS), diallyl disulfide (DADS), diallyl trisulfide (DATS), and dipropyl disulfide (DPDS) in primary hepatocyte culture. Data are expressed as percentage control of [2-^{14}C]acetate incorporation into cholesterol (●) and percentage of LDH activity in medium relative to total activity in cells and medium (○), and represent means ± SEM of eight samples. *Statistically different from controls, $P < 0.05$. See Figure 3 for other abbreviation.

Other water-soluble compounds (i.e., alliin, SANC, and SASA) at concentrations from 0.05 to 4.0 mmol/L did not alter the rate of [2-^{14}C]acetate incorporation into cholesterol (data not shown).

The inhibition of cholesterol synthesis by lipid-soluble compounds was determined in subsequent experiments. Of three sulfur-containing diallyl compounds, DAS (monosulfide) exhibited the least effect with a maximal inhibition of 40% observed at 4.0 mmol/L concentration (Fig. 4A). The rate of cholesterol synthesis was decreased by 25% by both DADS and DATS (polysulfides) at 0.05 mmol/L (Fig. 4B and C). The synthesis was completely diminished by DATS and DADS at 1.0 and 2.0 mmol/L, respectively. The inhibition pattern by sulfur-containing dipropyl compounds resembled that of DAS and DADS. A maximum of 17% inhibition was achieved by DPS at 4.0 mmol/L (data not shown), while the synthesis was abolished by DPDS at the same concentration (Fig. 4D). An inhibition (by 15%) was apparent beginning at 0.5 mmol/L for DPDS. The synthesis was inhibited 15% maximally by MAS, a sulfide containing two different alk(en)yl groups, i.e., methyl and allyl moieties (data not shown).

In order to determine whether the inhibitory effect of sulfur compounds on cholesterogenesis could also be attributed to cytotoxicity, cellular release of LDH into the medium was measured. Increased release of lactate dehydrogenase (LDH) by hepatocytes into culture medium is widely used as an index of cytotoxicity (36,37). For hepatocytes treated without water-soluble compounds, the amount of LDH activity recovered in the medium accounted for 13–16% of total cellular LDH activity (Table 1). The treatment of cells with *S*-alk(en)yl cysteines and γ-glutamyl *S*-alk(en)yl cysteines except GSPC did not increase LDH release at 4.0 mmol/L (Table 1). However, GSPC did not alter the percentage of LDH release at 2.0 mmol/L (data not shown). Unlike these findings, SAMC increased LDH release in a concentration-dependent fashion and reached 70–78% at higher concentrations (2.0 and 4.0 mmol/L) (Fig. 3).

Since lipid-soluble compounds were dissolved in DMSO to a final concentration of less than 2%, cells in the control group were incubated in the presence of DMSO at the same concentration. LDH release into the medium of the control ranging from 21–24% was higher than that observed in the cells not treated with DMSO (Fig. 4 and Table 1). Incubation of cells with DAS and DPDS significantly increased percent-

Maximal Inhibition and Calculated IC_{50} of Water-Soluble Compounds on Cholesterol Synthesis[a]

Compounds	IC_{50} (mmol/L)	Maximal inhibition (%)
SAC	0.61	50
SEC	0.58	42
SPC	0.72	55
GSAC	1.66	16
GSMC	1.12	29
GSPC	1.92	18

[a]IC_{50}, concentration required for 50% of maximal inhibition. See Table 1 for other abbreviations.

age release of LDH at 0.5 mmol/L (Fig. 4A and D). The increase was noted for DATS at 0.05 mmol/L and for DADS at 0.1 mmol/L (Fig. 4B and C). Increasing the concentration to 1.0 mmol/L of DATS, 2.0 mmol/L of DADS, and 2.0 mmol/L of DPDS further increased LDH release to approximately 90%. At 4.0 mmol/L, DADS, DATS and DPDS did not further increase LDH release. DAS also elevated LDH release, but only up to 50%. DPS, another monosulfur compound, increased LDH release to 33% only at 4.0 mmol/L, whereas MAS had no effect on the release (data not shown).

Table 2 shows maximal inhibition and IC_{50} for water-soluble compounds that exhibited concentration-dependent inhibition on cholesterol synthesis. The maximal inhibition was the highest for SPC followed in increasing order by SAC > SEC > GSMC > GSPC > GSAC, while the calculated IC_{50} was the lowest for SEC followed in decreasing order by SAC < SPC < GSMC < GSAC < GSPC.

DISCUSSION

Previous studies from our laboratory (27) and that of Gebhardt *et al.* (26,28) have reported inhibitory effects of some garlic constituents on cholesterol biosynthesis *in vitro*. The present study not only confirmed the earlier findings but also expanded to test 11 water-soluble and 6 lipid-soluble compounds derived from garlic. When incubated with hepatocytes in culture, most water-soluble compounds were effective in decreasing [2-^{14}C]acetate incorporation into cholesterol. All *S*-alk(en)yl cysteines except SMC inhibited cholesterol synthesis to various degrees. The differences among the *S*-alk(en)yl cysteines are the numbers of carbon and/or the number of double bonds. The potency of inhibition on cholesterol synthesis increased with increasing carbon number. SMC containing only one carbon (CH_3–) in the alk(en)yl group was ineffective, while SEC containing two carbons (CH_3CH_2–) inhibited the rate of [2-^{14}C]acetate incorporation into cholesterol. A greater inhibition was noted by SAC and SPC, both containing three carbons, but with a double bond (CH_2=$CHCH_2$–) in SAC and none (CH_3CH_2 CH_2–) in SPC. Glutamylated products of *S*-alk(en)yl cysteines, i.e., GSAC, GSMC, and GSPC, were less potent than SAC, SEC, and SPC in inhibiting cholesterogenesis. However, unlike SMC, GSMC reduced [2-^{14}C]acetate incorporation into cholesterol and was more effective than GSAC and GSPC. Interestingly, SAMC, which contains one more sulfur atom than SAC, was more potent than the latter in inhibiting [2-^{14}C]acetate incorporation into cholesterol.

All six lipid-soluble compounds except MAS appeared to exert greater inhibition on [2-^{14}C]acetate incorporation into cholesterol than water-soluble compounds. The degree of inhibition was associated with the number of sulfur atoms in the molecules. At concentrations of 1.0 mmol/L or higher, the percentage of inhibition was in order of DATS > DADS > DAS. This is consistent with inhibition on the growth of canine mammary tumor cells in culture (8). Similarly, DPDS, a polysulfide compound, exerted a greater inhibition than a single sulfur-containing DPS. However, it should be stressed that the marked decrease of [2-^{14}C]acetate incorporation into cholesterol by the lipid-soluble compounds was closely associated with the extensive cytotoxicity as indicated by markedly increased release of cellular LDH into the medium.

For determination of cytotoxicity, LDH released into culture medium was measured in cells treated with the test compounds. In the presence of water-soluble compounds, percentage release of LDH remained unchanged from that seen in control group (i.e., 13–16%). It should be noted that the control values were consistent with the range observed by other investigators (37–40), although values as low as 10% and as high as 30% have been reported (41). DMSO added to the incubation medium alone at a final concentration of 2% or less augmented LDH release to 21–24%. Nonetheless, in the presence of DMSO, most lipid-soluble compounds further increased LDH release in a concentration-dependent manner, especially for those containing at least two sulfur atoms, e.g., DADS, DATS, and DPDS. Overall, the degree of LDH release was the greatest with DATS, followed in order by DADS, DPDS, and DAS. The results therefore revealed that the more sulfur atoms in the molecule, the higher the cytotoxicity of the compounds. Consistent with this notion, SAMC, the only water-soluble compound with two sulfur atoms in the molecule, was also highly cytotoxic.

It should be pointed out that an earlier study by Gebhardt

and Beck (28) showed that treatment of hepatocytes with DADS even at 10 mmol/L did not increase LDH release. The reason for the discrepancy observed between the studies is not known. However, it is worth noting that in the latter study (28), the cells were pretreated with the compound for 2 h in the culture medium. The medium was then replaced by new medium containing labeled acetate and incubated again for measurements of cholesterol synthesis and LDH release (28). In the present study, sulfur compounds were added directly to the culture medium and LDH release measured 4 h after incubation (27). Whether these different experimental conditions account for the observed difference warrants further investigation. At this juncture, it is interesting to note that the study of Abdul-Hussain and Mehendale (41) demonstrated that the degree of LDH leakage through the hepatocyte membrane was dependent on the duration of cell incubation in the medium (41).

The inverse relationship between cholesterol synthesis and LDH release led us to conclude the inhibition on cholesterogenesis by lipid-soluble compounds at concentrations higher than 0.5 mmol/L was likely due to cytotoxicity rather than impairment in the metabolic pathway of cholesterol synthesis. Similarly, the marked inhibition by SAMC was associated with cytotoxic effect. The unaltered percentage of LDH release associated with most water-soluble compounds therefore strongly suggests that inhibition of cholesterol synthesis by these compounds likely results from impairment of specific enzyme(s) of cholesterogenic pathway.

A comparison of cytotoxicity and cholesterol inhibition potency of various compounds suggests that water-soluble compounds of garlic may be of more potential than lipid-soluble compounds in lowering plasma concentration of cholesterol. In fact, in a recent clinical trial (21), garlic oil rich in polysulfides (42) given to patients with moderate hypercholesterolemia was ineffective in lowering serum cholesterol. On the other hand, aged garlic extract consisting mostly of water-soluble sulfur compounds supplemented to the diet of hypercholesterolemic patients decreased by plasma concentrations of total cholesterol and LDL-cholesterol 6–9% (1,2). It is apparent from the present study that three *S*-alk(en)yl cysteines (i.e., SAC, SPC, and SEC) effectively depressed hepatic cholesterogenesis at a low concentration and without a sign of cytotoxicity. However, SAC may be the most important contributor to the hypocholesterolic effect of aged garlic extract (1,2) because SAC is a major sulfur-containing amino acid derivative in garlic, especially in aged garlic extract (43). Aged garlic extract is known to contain 456 μg/g of SAC/g of dry powder (44).

The mechanisms underlying the inhibitory action of garlic compounds on cholesterol synthesis have not been fully elucidated. However, animal studies have suggested that garlic-supplemented diets decreased the cholesterogenic enzyme, 3-hydroxy-3-methyl-glutaryl-CoA reductase (16,45). Sulfur compounds of garlic such as allicin have been shown to inhibit the activity of acetyl-CoA synthetase (46). Since [2-^{14}C]acetate was used as a substrate in the present study, the activation of acetate to acetyl-CoA by the synthetase must also play a role in its incorporation into cholesterol.

In conclusion, although lipid-soluble compounds appeared to abolish cholesterol synthesis, the inhibition may be due to cytotoxicity. Water-soluble components of garlic, especially SAC, appears to be most responsible for the reduction of cholesterol synthesis. Furthermore, the results suggest that the hypocholesterolemic effect of garlic results in part from impaired cholesterol synthesis.

ABSTRACT: The interaction of lipid peroxides with cellular proteins has been postulated to contribute to cellular aging. A potential target for such effects is tubulin, the building block of microtubules. We examined the concentration-dependent effects of phosphatidylcholine hydroperoxides on the ability of tubulin to polymerize into microtubules. The results demonstrated that even very low concentrations of peroxides were sufficient to interfere with the tubulin and, therefore, the microtubule function. Decreased tubulin activity (as measured by tubulin GTPase activity) showed correlation with the modification of methionine and cysteine in tubulin and a change in the tubulin conformational state as indicated by fluorescence and ultraviolet spectroscopic measurements. As no effect on electric conductivity was observed, indicating that modulation of ionic binding was not involved, the interaction mechanism may be a hydrophobic one.

Paper no. L8235 in *Lipids 35,* 205–211 (February 2000).

Lipid hydroperoxides, which display deleterious effects upon protein structure and function and consequently the cellular function of lipid hydroperoxides, may contribute to cellular aging (1–5). What remains to be clarified is the molecular mechanism at the level of individual cellular proteins. Dietary lipid peroxidation products have been shown to be toxic to cells (6). Similarly, oxygen-free radicals can trigger human disease by causing functional and morphologic disturbances in cells (7). These effects are thought to be due to the accumulation of cellular lipid peroxidation products resulting in interference of normal cellular functions (8,9). The primary site of action of oxygen-free radicals is the plasma membrane, as lipids are easily oxidized into phospholipid hydroperoxides. A potential target for some of the observed effects of lipid peroxides on cellular function is microtubules, which are intrinsic to a variety of cellular functions including maintenance of cell form, motility, movement, and division (10–12).

The aging phenomenon is postulated to be affected by microtubule-related activities because the rate of microtubule formation has been found to be slow in old rats compared with young animals (13) and hydroperoxides produced in the cells eventually cause their death (14).

We have previously demonstrated with an *in vitro* system of microtubule assembly that lipid hydroperoxides interfere with microtubule formation. This system utilized an assay of tubulin GTPase activity, with tubulin being the protein building block of microtubules (15,16).

In the present study, we examined the mechanism at the structural level of tubulin by lipid peroxidation to further the understanding of this process. We also tried to determine the sensitivity of tubulin to lipid peroxidation in order to gauge whether long-term exposure to low concentrations of hydroperoxides could interfere with tubulin function. Previous studies have utilized strong oxidizing conditions (15–18), and this is the first work using weak oxidizing conditions, which more accurately simulate the *in vivo* state.

MATERIALS AND METHODS

Tubulin. Tubulin was prepared from bovine brain by the modified procedure of Lee *et al.* described previously (19,20). Bovine brain, obtained from a freshly slaughtered animal, was kept on ice and used within 30 min of slaughter. All steps were performed at 4°C as rapidly as possible. After purification, protein aliquots were stored at –80°C in 10 mM phosphate buffer, pH 7.0, containing 1 M sucrose, 0.1 mM GTP, and 0.5 mM $MgCl_2$. Prior to each experiment, the bulk of the sucrose was removed from the tubulin solution by a Sephadex (Pharmacia Biotech, Uppsala, Sweden) G-25 batch procedure (21). The resulting protein solution was cleared of aggregates by centrifugation at 20,000 × *g* for 30 min at 4°C. The final equilibration of the protein solution with the desired buffer was done by gel chromatography on a Sephadex G-25 column (10 × 10 cm; Pharmacia Biotech). Protein concentration was determined in 6M guanidine hydrochloride with an absorptivity value of 1.09 $mL \cdot mg^{-1} \cdot cm^{-1}$ at 275 nm (22).

Phosphatidylcholine hydroperoxides (PCOOH). Because the cell membrane is primarily composed of phospholipids, soybean phosphatidylcholine (PC) was used as the starting material for the generation of PCOOH. The PC was lipoid S-100 of soybean origin, obtained from Nisshin Oil Mills Ltd. (Tokyo, Japan). Lipoid S-100 is essentially pure PC. Photo-

sensitized oxidation was carried out in methanol, with methylene blue being added to the PC-methanol solution as a sensitizer. The final concentrations of methylene blue and PC were 0.004% and 10 mg/mL, respectively. PC was photooxidized by irradiation with a 30-W tungsten projection lamp, which was positioned 40 cm above the reaction mixture for 20 h at 4°C. Upon completion of the reaction, methylene blue was removed using a Disposil SL gel column (Nacalai Tesque, Kyoto, Japan), and methanol was removed by evaporation. Aliquots (50 μL) of the generated lipid peroxides were added to the protein solution to a final concentration of 0.1 mg/mL. For the control samples, no sensitizer was added and no irradiation was performed.

Other reagents. GTP was purchased from Sigma Chemical Co. (St. Louis, MO). Tetrabutyl ammonium dihydrogenphosphate (TBAP) was obtained from Nacalai Tesque Inc. All other chemicals were of reagent grade.

Characterization of the generated PCOOH. PC oxidation products were diluted with methanol, prior to measurement of ultraviolet (UV) absorption spectra in the wavelength range from 200 to 300 nm. This was to confirm the induction of conjugated diene formation by hydroperoxides which have characteristic absorption at 233 nm (23). Native lecithin was similarly diluted with methanol and the UV absorption spectrum was measured. The production of PCOOH was verified by reversed-phase high-performance liquid chromatography (HPLC) in a Tosoh (Tokyo, Japan) system composed of a CCPS pump, a UV-8020 UV absorption detector and a Chromatocorder 21 integrator, attached to an Irika Σ985 electrochemical detector (ECD) (Kyoto, Japan), and another Chromatocorder 21 integrator. The column was a packed octadecyl silica gel (ODS) column (4.6 i.d. × 150 mm) from YMC (Kyoto, Japan). The mobile phase solution was a mixture of methanol/water (95:5, vol/vol) containing 30 mM lithium acetate. The flow rate of the mobile phase was 1.0 mL/min. To detect PCOOH, the eluent was monitored at 210 nm with the UV detector and at –300 mV vs. Ag/AgCl with the ECD (24). The relationship between absorbance at 233 nm and the ratio of PCOOH to total native PC was also determined.

Assay of tubulin GTPase activity. Tubulin GTPase activity was measured as the indicator of tubulin function, with the tubulin GTPase activity being diagnostic of the microtubule assembly (15,16).

Measurement of enzyme activity was carried out as described previously by Seckler *et al.* (25). The total volume of the assay system was 250 μL in a microtube. Assays were performed in 10 mM phosphate buffer, pH 7.0, containing 0.1 mM GTP, 3.4 M glycerol, and 10 mM $MgCl_2$ with native PC or PCOOH at a final concentration of 0.1 mg/mL. The assay solution was constituted by successive addition of $MgCl_2$, the basic buffer (10 mM phosphate buffer, pH 7.0, containing 0.1 mM GTP, 3.4 M glycerol, and 0.5 mM $MgCl_2$), PCOOH, and tubulin (16). The lipid used in this interaction study with tubulin was a mixture of native and hydroperoxides of PC because the purification was too complicated and difficult to do. The reaction was terminated after 30 min (26) as this incubation time has been shown to be sufficient to measure steady-state tubulin GTPase activity. This activity was measured on the basis of GDP formation, with the GDP concentration being determined by reversed-phase HPLC using a Tosoh HPLC system which consisted of a CCPS pump and a UV-8020 UV absorption detector and a Chromatocorder 21 integrator. A packed ODS column (4.6 × 250 mm) obtained from Nacalai Tesque was used for all assays, with the flow rate set at 1.0 mL/min and the detection wavelength at 253 nm.

The GTPase activity was calculated from the amount of GDP obtained by comparing the area obtained with a Chromatocoder 21 integrator with that of a standard GTP solution. An extinction coefficient at 253 nm of 13,700 $M^{-1}\cdot cm^{-1}$ was used for both GTP and GDP (27).

Fluorescence spectroscopy. The effect of PCOOH on tubulin structure was monitored by fluorescence spectroscopy. A concentration of 0.1 mg/mL was utilized for PCOOH and tubulin in all cases. PCOOH was added to the basic buffer (10 mM phosphate buffer (pH 7.0) containing 3.4 M glycerol, 0.1 mM GTP and 0.5 mM $MgCl_2$) prior to ultrasonication. Tubulin and PCOOH were mixed in the fluorescence cuvette for 15 min prior to measurement of the fluorescence spectra. Excitation spectra were obtained at the emission wavelength of 330 nm, with the excitation being measured between 200 and 300 nm. For emission spectra, an excitation wavelength at 278 nm was utilized, and the emission was measured between 290 and 450 nm. The temperature was 20°C for all assays. A Shimadzu PF-540 spectrofluorophotometer (Kyoto, Japan), with an attached Shimadzu DR-3 data recorder was used for all fluorescence measurements.

UV difference spectra. In order to detect small changes in the conformation of tubulin induced by reaction with PCOOH, UV difference spectroscopy was utilized. The temperature of the reaction mixture was increased from 0 to 37°C, and the difference spectrum measured after 20 min. As tubulin polymerizes in the presence of a high concentration of glycerol (28), a buffer (10 mM phosphate buffer, pH 7.0, containing 0.1 mM GTP, and 0.5 mM $MgCl_2$) without glycerol was used. Because lipid hydroperoxides have an absorption maximum at 233 nm and GTP has one at 253 nm, the total absorption of the reaction mixture is potentially very high. Therefore, in order to minimize experimental and instrumental problems due to high absorbance, the PCOOH concentration was kept to a minimum. Difference spectra were obtained with a cell having a 1-mm partition in the reference cuvette. PCOOH (0.1 mg/mL) was added to one compartment and tubulin (1.0 mg/mL) to another of the reference cuvette.

Tubulin and PCOOH were mixed in the sample cell at concentrations equivalent to those in to the sample cells taking into account the thickness of the cell partition. The concentrations of PCOOH and tubulin in the sample cell were 0.045 and 0.45 mg/mL, respectively. A Shimadzu UV-2000 spectrophotometer, with an attached Neslab RTE-110 incubator (Portsmouth, NH) was used in all cases.

Measurement of electric conductivity. In order to monitor the binding state of tubulin with PCOOH, electric conductivity measurements were performed. The assay buffer (0.1 mM GTP and 0.5 mM $MgCl_2$ in 10 mM phosphate buffer, pH 7.0) did not contain glycerol. The concentration of tubulin was 0.1 mg/mL. This is lower than in other experiments due to the large volume of solution required in conductivity experiments and the known difficulty of purifying large amounts of tubulin from bovine brain. Glycerol was not included in the assay mixture as it has no electric charge and a high viscosity, which can result in an unstable conductivity signal. The concentration of PC or PCOOH was 0.1 mg/mL and the volume of the assay solution was 10 mL in all cases. Conductivity measurements were performed as follows. After each sample had been placed in a test tube, it was stirred using a test tube mixer (Koike Precision Instruments, Hyogo, Japan) for 10 s. The reaction mixture was then ultrasonicated for 30 s, the reaction temperature was brought to 25°C by being placed in an incubator and the reaction was allowed to take place for 20 min. The electric conductivity was then measured 30 s after the cells had been dipped into the sample. The electric conductivity meter was a model CM-15 meter from Kyoto Electronics Manufacturing Corp. (Kyoto, Japan).

Amino acid analysis. The effect of PCOOH on individual amino acids in tubulin was monitored using amino acid analysis. To prepare samples, mixtures of tubulin with PC or PCOOH in 10 mM phosphate buffer, pH 7.0, containing 0.1 mM GTP and 10 mM $MgCl_2$ in the presence or absence of 3.4 M glycerol were incubated at 37°C for 30 min or 5 h. The concentrations of tubulin and PC or PCOOH were 1.0 mg/mL and 0.1 mg/mL, respectively. Excess PC or PCOOH was removed by batch gel filtration (1.0 × 7 cm column) with Sephadex G-25 (m). Samples were hydrolyzed in 6 M HCl at 110°C for 24 h after removing oxygen by flushing with nitrogen gas. Cysteine was oxidized in 0.01 M NaOH for 5 h after hydrolysis. The instrument was a Hitachi 835 amino acid analyzer (Tokyo, Japan).

RESULTS AND DISCUSSION

Production of PCOOH. The formation of PCOOH was confirmed using ultraviolet absorption spectroscopy. Photooxidation of Lipoid S-100 resulted in an increase in absorbance at 233 nm attributable to the formation of hydroperoxides. Four main peaks, observed on analysis of the Lipoid S-100 by HPLC (Fig. 1), presumably are due to distinct molecular species. After photooxidation, four new peaks detectable by both UV absorption and ECD were observed (Fig. 1). ECD detects hydroperoxides and hydroxides (24). Monohydroperoxide was detected by mass spectrometry of photooxidized PC in our preliminary experiment (data not shown). The mass spectrum indicated two important peaks of MW = 782 due to dilinoleoyl-PC and of MW = 814 due to its monohydroperoxide. Linoleic acid (64.8%) is the most common fatty acid in soybean PC. Also, dilinoleoyl-PC accounts for the largest portion (31.1%) of the principal molecular species of soybean PC (29). These results indicate that the molecular species cor-

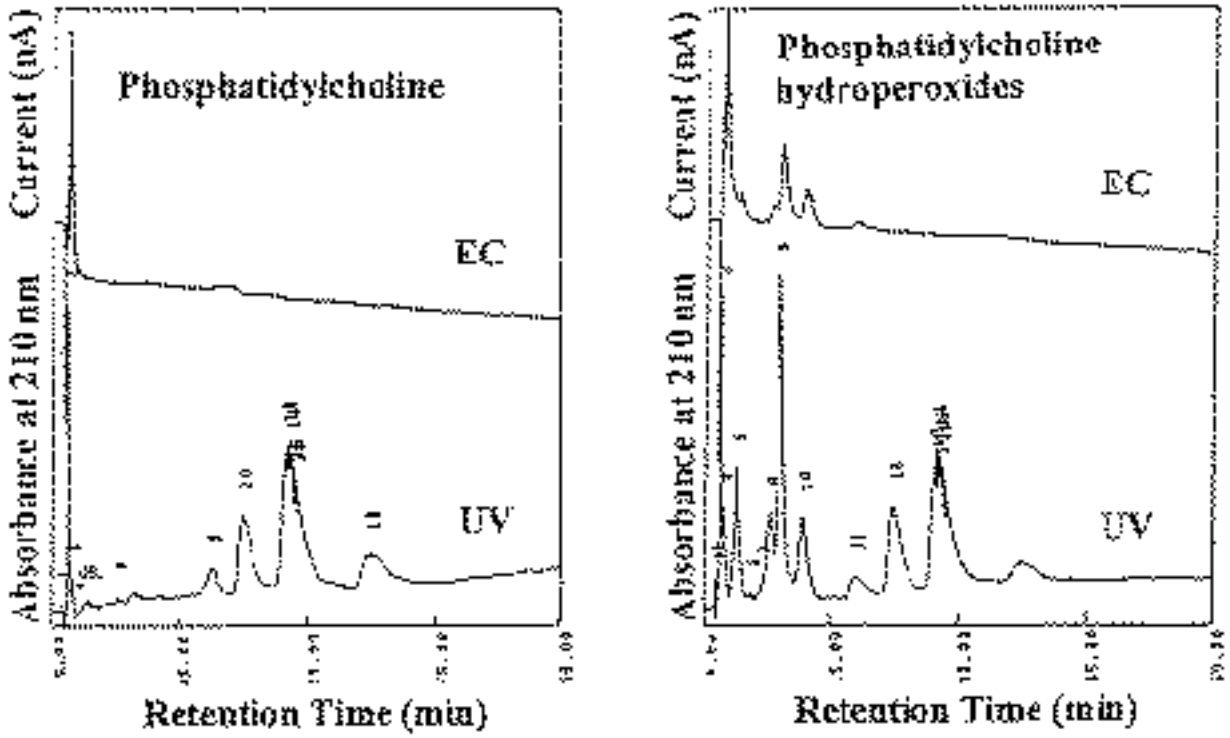

FIG. 1. High-performance liquid chromatography analyses of phosphatidylcholine (PC) and phosphatidylcholine hydroperoxides (PCOOH). PC, 25 µL (1.0 mg/mL); PCOOH, 25 µL (1.0 mg/mL). UV, ultraviolet; EC, electrochemical.

responding to the new peaks are hydroperoxides produced by photooxidation of PC. We can detect almost all compounds by the absorbance at 210 nm in HPLC. On the other hand, the increase of absorbance at 233 nm is due to conjugated hydroperoxides. Therefore, examining the relationship with the area of absorbance at 233 nm can provide information on the generation of secondary products.

Figure 2 shows the relationship between the observed absorbance at 233 nm and the integrated area of the peaks assigned to hydroperoxides in HPLC. The correlation coefficient was 0.945, indicating that the photooxidation in this experiment produced monohydroperoxides of PC but no secondary products. As 50% each of the conjugated and nonconjugated hydroperoxides are produced by photooxidation (30,31), twice the amount of hydroperoxides was used in this study compared the amount calculated from the UV absorbance at 233 nm.

We should be able to obtain the same results even if conjugated and nonconjugated dienes are used independently because the interaction between tubulin and lipid peroxides was due to a hydrophobic interaction as described below on the bases of photospectroscopy and electric conductivity measurements.

Tubulin GTPase activity. PCOOH clearly lowered tubulin GTPase activity, as shown in Figure 3. It is confirmed in the preliminary experiment that PC had no effect on tubulin GTPase activity. We reported previously that PCOOH acted directly on tubulin and that its ability to polymerize into microtubules was reduced (14,15).

Figure 4 shows the relationship between tubulin GTPase activity and the concentration of added PCOOH. There is a direct linear correlation between the reduction in tubulin GTPase activity (and therefore polymerization ability) and the concentration of conjugated PCOOH, the correlation efficient being –0.959. The concentration of conjugated PCOOH was calculated from the absorbance at 233 nm (23). The concentration of hydroperoxides can double when conjugated and nonconjugated hydroperoxides exist at equal concentration. These results emphasize that prolonged exposure of even low concentrations of lipid hydroperoxides to tubulin in a living cell will adversely affect the tubulin and therefore the microtubule function.

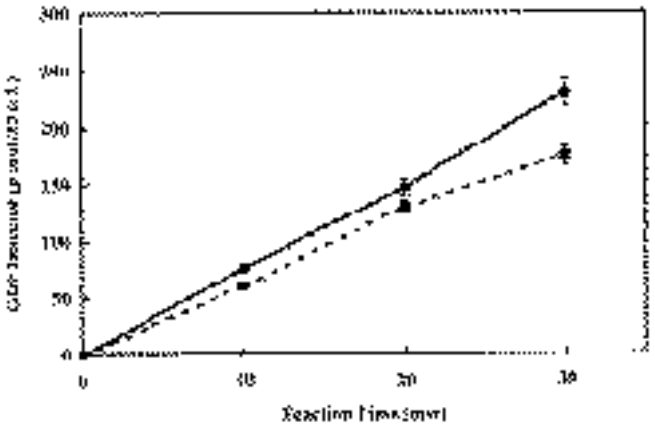

FIG. 3. Effect of PCOOH on tubulin GTPase activity. (●) Control (tubulin: 1.0 mg/mL); (■) PCOOH (84.3 μM) added. See Figure 1 for abbreviation.

Measurement of the fluorescence spectrum of tubulin. Figure 5 shows a typical fluorescence emission spectrum of tubulin in the absence and presence of PCOOH. PC had no effect on a fluorescence spectrum of tubulin in our preliminary experiment. When excited at 278 nm, the emission maxima of tubulin in the absence and presence of PCOOH were 326.4 and 330 nm, respectively. In addition, the emission intensity increased by about 15%. The fluorescence spectrum of tryptophan residue in protein shifts to the red region on contact with water (32). The red shift in the emission maximum indicates that the fluorescent aromatic amino acids become easier to dissolve on reaction with PCOOH. These results indicate a significant conformational change upon reaction with PCOOH.

Ultraviolet difference spectrum measurement. Figure 6 shows the UV difference spectrum of tubulin in the absence and presence of PCOOH. The UV spectra of protein in the re-

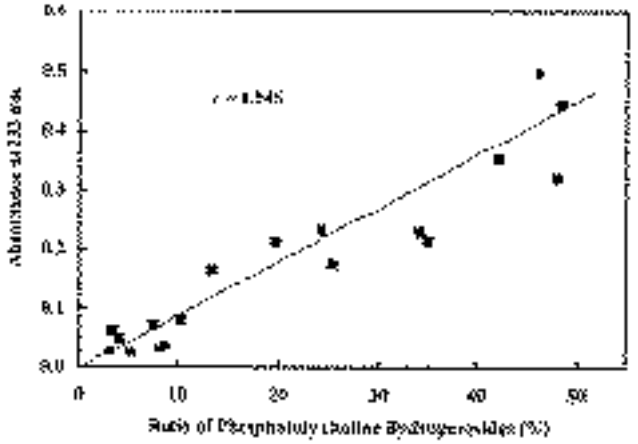

FIG. 2. Relationship between absorbance at 233 nm and ratio of PCOOH to total PC. See Figure 1 for abbreviations.

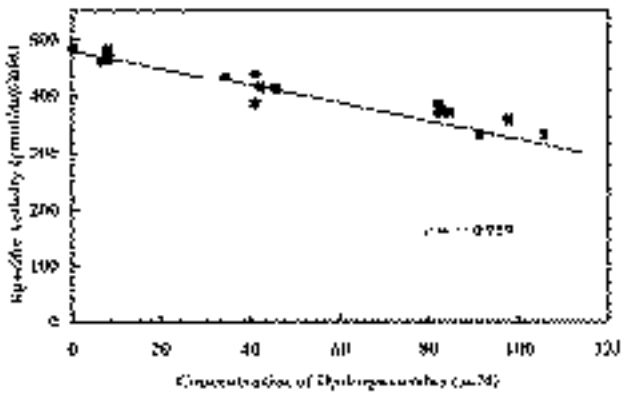

FIG. 4. Relationship between tubulin GTPase activity and PCOOH concentration. See Figure 1 for abbreviation.

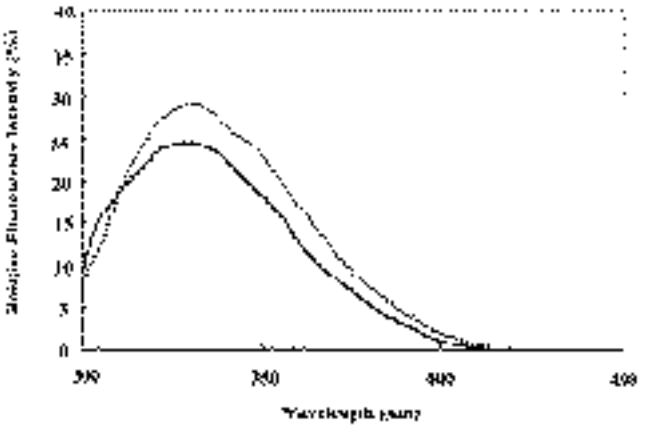

FIG. 5. Fluorescence spectra of tubulin in the presence and absence of PCOOH. ——, tubulin in the absence of PC; ·····, tubulin and PCOOH. See Figure 1 for abbreviations.

gion of 280 nm are dominated by the aromatic amino acids. Close scrutiny of the spectra in this region shows a reproducible decrease in the absorbance upon reaction with PCOOH. The differences are, however, much less obvious than the fluorescence measurement which presumably reflects the greater sensitivity of tryptophan fluorescence relative to its absorbance characteristics on the conformational state of the protein.

Electric conductivity measurement. Table 1 shows the electric conductivity of tubulin solution in the absence and presence of PCOOH. The electric conductivities of the tubulin and buffer solutions were 1.407 and 1.386 mS/cm, respectively.

The difference is due to the presence of charged tubulin. No difference was observed between the electric conductivities for the buffer and PC solution, indicating the PC has no charge under these experimental conditions. The electric conductivity increased from 1.386 to 1.395 mS/cm upon addition of PCOOH, reflecting a slight ionic dissociation of PCOOH in solution.

The electric conductivities measured for tubulin in the presence or absence of PC were almost identical. The conductivity measured for tubulin in the presence of PCOOH (1.417 mS/cm) is very close (1.416 mS/cm) to the calculated value obtained by adding the conductivity of tubulin solution (1.407 mS/cm) and the difference (0.009 mS/cm) between that of PCOOH solution (1.395 mS/cm) and buffer (1.386 mS/cm). These results indicate no change in the charge states of either tubulin or PCOOH. This supports the interpretation that the interaction is of a hydrophobic nature and does not involve a change in the net charge of the individual amino acids.

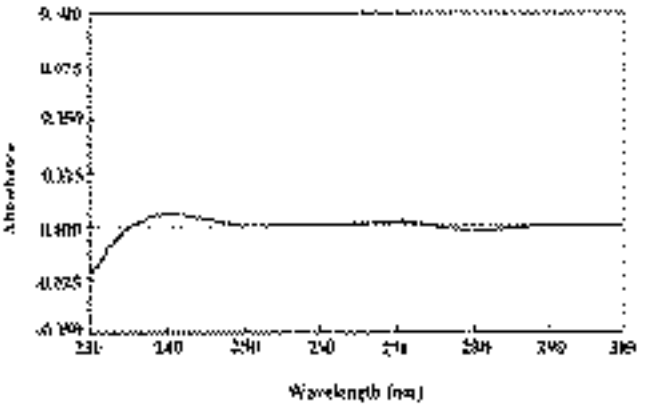

FIG. 6. Difference spectrum of tubulin in the presence and absence of PC or PCOOH. See Figure 1 for abbreviations.

TABLE 1
Electric Conductivities of Tubulin Solution in the Presence and Absence of Phosphatidylcholine or Phosphatidylcholine Hydroperoxides

Sample	(mS/cm)[a]
Tubulin	1.407 ± 0.0079
PC	1.386 ± 0.0087
PCOOH	1.395 ± 0.0111
Tubulin + PC	1.403 ± 0.0075
Tubulin + PCOOH	1.417 ± 0.0124
Buffer	1.386 ± 0.0078

[a]Values are expressed as means ± SE of seven independent determinations. PC, phosphatidylcholine; PCOOH, phosphatidylcholine hydroperoxide.

Amino acid analysis. The potential covalent modification of individual amino acids by lipid peroxides was examined using amino acid compositional analysis. Table 2 summarizes the results of amino acid analysis of tubulin when treated with PC or PCOOH in the presence or absence of glycerol. The presence of PC had no effect on the amino acid composition of tubulin either in the absence or presence of glycerol. However, a small reproducible effect of PCOOH on the observed methionine and cysteine contents was detected in the presence of glycerol. This decrease was clearly time dependent (Table 2). Many amino acids (Met, Cys, Tyr, His, Arg, and Trp) are susceptible to lipid peroxides in papers described below.

Soluble tubulin has been reported to interact with PC vesicles (33,34). However, these interactions were presumably noncovalent. The nature of the interaction of tubulin with phospholipid oxidation products has not been characterized, although it is known that membrane lipid is peroxidized (35), and that PCOOH is present in human plasma (36).

The nature of the modification of particular amino acids by lipid peroxides has yielded seemingly contradictory results. Crawford *et al.* (37) reported the interaction of glycine with malonaldehyde, which is one of the secondary products of lipid peroxidation. Chio and Tappel (38) reported that malonaldehyde formed a Schiff base with various amino acids and that the final product displayed fluorescence with an emission maximum at 450 nm excited at 370 nm. However, Kikugawa and Ido (39) examined in detail the formation of dihydropyridine from malonaldehyde and primary amines under mild conditions. Shimasaki *et al.* (40) have also reported the interaction of lipid with glycine in the presence of ascorbic acid. A decrease of methionine and lysine residues

has been observed during the autooxidation process between linoleic acid and casein (5).

As described above, the interaction of lipid peroxides with protein is very complicated at the mechanistic level and not easily interpretable. In this experiment, we observed that the molar concentration of methionine in tubulin decreases with the time of reaction with hydroperoxides.

As tubulin GTPase activity decreases in a similar time-dependent manner, it can be postulated that chemical modific ation of methionine leads to a decrease in the specific activity of the modified tubulin. Whether this effect is due to direct steric hindrance of the tubulin–tubulin contacts in the microtubule or to conformationally induced changes is unclear. Fluorescence spectra indicated clear conformational changes on lipid peroxidation, which probably were not due to global unfolding as they only involved a small red shift in the fluorescence spectra. Reinforcing this interpretation is the observation that there was only a very small change in UV spectra observed on peroxidation of tubulin. We previously examined the effect of strongly oxidized lipid on tubulin GTPase activity to examine the effect of one of the lipid peroxides on the cytoskeleton protein, tubulin. We observed a strong interaction between them, with the activity being inhibited during the assay, when strongly oxidized lipid was used (16–18). However, lipid may not be strongly oxidized in living cells which are known to contain hydroperoxides. We therefore decided that there was a need to study the effect of mildly oxidized lipid to clarify the interaction with protein. Although the conformational damage of protein *in vivo* may be small, the effect on cell functions can be expected to be large. In this paper, we have tried to clarify the effect of a small amount of lipid peroxides by examining the concentration dependence of mildly oxidized lipids and the change of protein structure, although the change was small. Our findings suggest that the binding style between lipid hydroperoxides and protein may be a hydrophobic one.

ABSTRACT: We examined changes in membrane properties upon acidification of dioleoylphosphatidylethanolamine/cholesterylhemisuccinate liposomes and evaluated their potential to deliver entrapped tracers in cultured macrophages. Membrane permeability was determined by the release of entrapped calcein or hydroxypyrene-1,3,6-trisulfonic acid (HPTS)-*p*-xylene-bis-pyridinium bromide (DPX); membrane fusion, by measuring the change in size of the liposomes and the dequenching of octadecylrhodamine-B fluorescence; and change in lipid organization, by ^{31}P nuclear magnetic resonance spectroscopy. Measurement of cell-associated fluorescence and confocal microscopy examination were made on cells incubated with liposomes loaded with HPTS or HPTS-DPX. The biophysical studies showed (i) a lipid reorganization from bilayer to hexagonal phase progressing from pH 8.0 to 5.0, (ii) a membrane permeabilization for pH <6.5, (iii) an increase in the mean diameter of liposomes for pH <6.0, and (iv) a mixing of liposome membranes for pH <5.7. The cellular studies showed (i) an uptake of the liposomes that were brought from pH 7.5–7.0 to 6.5–6.0 and (ii) a release of ~15% of the endocytosed marker associated with its partial release from the vesicles (diffuse localization). We conclude that the permeabilization and fusion of pH-sensitive liposomes occur as a consequence of a progressive lipid reorganization upon acidification. These changes may develop intracellularly after phagocytosis and allow for the release of the liposome content in endosomes associated with a redistribution in the cytosol.

Paper no. L8278 in *Lipids 35,* 213–223 (February 2000).

Delivery of macromolecules and other nonpermeant constituents into the cytosol of target cells is essential for the development of many new therapeutic approaches. Conventional liposomes are often ineffective in this context since they tend to bring their load to lysosomes (1). pH-sensitive liposomes (2) may represent a significant improvement for intracellular drug unloading thanks to their progressive, acid-driven destabilization along the endocytic pathway (3). These liposomes, indeed, not only are susceptible to releasing their content in acid vacuoles, such as late endosomes and lysosomes, but also are capable of promoting the transfer of encapsulated tracers to the cytosol (4). Accordingly, they have been assessed in a series of studies for potential therapeutic applications, including antitumor and antibacterial chemotherapy (5–6), and for the delivery of proteins, oligonucleotides, or even DNA (7–9).

In the present study, we examined a typical type of pH-sensitive liposomes made of dioleoylphosphatidylethanolamine and an anionic component, cholesterylhemisuccinate (DOPE/CHEMS). The small cross-sectional area of the headgroup of phosphatidylethanolamine, relative to that of the acyl chains, confers to this molecule a propensity to spontaneously form an inverted hexagonal phase H_{II} structure, a particular organization involved in membrane destabilization and fusion (10). At alkaline or neutral pH, however, the negatively charged CHEMS will reduce the intermolecular repulsions of phosphatidylethanolamine head groups and stabilize the structure in a bilayer organization. Yet, upon acidification, CHEMS will become less charged and will no longer hinder the reorganization of phosphatidylethanolamine in an H_{II} structure, ensuring the destabilization of the membrane structure (3). This mechanism has been documented concerning the increase in membrane permeability (11–16) and fusogenicity (2,12,14,17) of liposomes, and to a lesser extent, the cellular delivery of the vesicles' contents (1,4,18,19). Yet the changes in polymorphic organization of the lipids (20) remain largely undefined in this context. Moreover, most of these studies have used different types and compositions of liposomes, which make their conclusions difficult to generalize because lipid composition critically determines the pH sensitivity of acid-labile liposomes (4,11). In the present study, we have therefore undertaken to characterize, in a more systematic fashion, the biophysical phenomena (including changes in polymorphic organization) leading to an effective *in vitro* release of membrane-impermeant probes from one type of li-

MATERIALS AND METHODS

Liposome preparation. Large unilamellar vesicles (LUV) were used throughout all experiments, but large multilamellar vesicles (MLV) were also included for ^{31}P nuclear magnetic resonance (NMR) studies. Both DOPE/CHEMS and DOPC/CHEMS liposomes were made at a phospholipid/CHEMS molar ratio of 7:3. Depending on the experiments and on the sensitivity of the method used, the volume of buffer varied between 1 and 5 mL, and the concentration of lipids, between 1 and 50 mg/mL. MLV were obtained by hydration of the dry lipid films for 1 h under nitrogen at 37°C in a 40 mM glycine-NaOH solution adjusted to pH 11 and containing the fluorescent probes (see below). They were thereafter submitted to five successive cycles of freezing (at –80°C) and thawing (at 37°C). LUV were obtained by extruding the resulting suspension 10 times through two superposed polycarbonate filters (pore size, 100 nm; Nucleopore Costar Corporation, Badhoevedorp, The Netherlands) under a nitrogen pressure of 17 bars, in a 10-mL Thermobarrel Extruder (Lipex Biomembranes, Vancouver, Canada) (21,22). The actual phospholipid concentration of each preparation was determined by phosphorus assay, as decribed previously (22), and adjusted to the desired value by dilution in the appropriate buffer just prior to each experiment. (All concentrations of liposomes are expressed by reference to their total lipid concentration, based on phospholipid determination and on a molar ratio of phospholipid/CHEMS of 7:3. In preliminary experiments, we checked that the phospholipid/cholesterol molar ratio was effectively very close to 7:3 after the hydration and extrusion procedures.) Liposomes were stored under nitrogen at 4°C until the beginning of the experiment, to minimize the risk of extensive lipid hydrolysis and oxidation (23), and were used within 24 h. The lack of chemical hydrolysis of phosphatidylethanolamine in our experimental conditions was checked by preparing DOPE/CHEMS liposomes with a trace amount of phosphatidylethanolamine 1-palmitoyl-2-(1-^{14}C)-linoleoyl (100 μCi/mmol of DOPE), and letting them age at 4°C for 24 h. Samples were then analyzed by thin-layer chromatography using $CHCl_3/CH_3OH/NH_3$ (25%)/H_2O 24:16:2:1 (by vol) as mobile phase. The radioactivity associated with free fatty acid and lysophosphatidylethanolamine was then measured and found to be less than 2% of the total amount of radioactivity recovered, whereas approximately 94% co-migrated with phosphatidylethanolamine.

Studies on liposomes. (i) Permeability studies. The release of calcein [entrapped at a self-quenching concentration (18,22,24)] and of HPTS [hydroxypyrene-1,3,6-trisulfonic acid (25)] coentrapped with and quenched by DPX (*p*-xylene-bis-pyridinium bromide (11)] from the liposomes was fol-

vanced Instruments, Needham Heights, MA). HPTS and DPX were dissolved in a 40 mM glycine-NaOH mixture adjusted to pH 11 (393 mOsm/kg) at a concentration of 31.8 and 35 mM, respectively (4,11). In preliminary experiments, we checked that DPX effectively quenched the fluorescence of HPTS for this concentration ratio. These solutions were then used for hydration of the lipid films as described above. After liposome preparation at a lipid concentration of 30 mM, the unencapsulated dye was removed by minicolumn centrifugation (22). Before each experiment, liposomes were adjusted to a total lipid concentration of 7.14 μM and 2.16 μM for calcein- and HPTS-release studies, respectively, using isoosmotic phosphate buffers of pH ranging from 8.0 to 5.0. Calcein fluorescence was measured at room temperature on a PerkinElmer 2000 Fluorescence Spectrophotometer [PerkinElmer, Beaconsfield, United Kingdom; λ_{exc}, 490 nm; λ_{em}, 516 nm (22)]; the inner effect was checked and found to be negligible. The fluorescence of free calcein in solution was found to be time- and pH-dependent, and our measurements were therefore systematically corrected for by appropriate factors. These factors were calculated by measuring the fluorescence of calcein solutions at all the pH values investigated as a function of the time and by comparing these values to that a calcein solution incubated for the same period of time and at pH 7.5. Fluorescence of HPTS was recorded at room temperature, using a λ_{em} of 520 nm and λ_{exc} of 390 and 450 nm (25), using a LS-30 Fluorescence Spectrophotometer (PerkinElmer). The percentage of dye release at any given time was defined as the ratio between the fluorescence measured at that time and that observed at the same time after disruption of the liposomes by exposure to 0.1% Triton X-100 in the same buffer. For each pH- and time-condition tested, the fluorescence values recorded were corrected for the influence of Triton X-100 by comparing the fluorescence value measured for a calcein solution in the absence of Triton to that measured in the presence of the detergent. A leakage efficiency factor, defined as the ratio between the percentage of marker released at a given pH to that measured at pH 7.5, was then used to assess the lability of the liposomes upon pH change.

(ii) Mixing of the liposome membranes: studies with octadecylrhodamine B (R18). Mixing of the liposome membranes was followed by measuring the fluorescence increase of R18, a lipid-soluble probe, upon dilution in the membrane occurring by fusion between labeled and unlabeled liposomes (26,27). Labeled liposomes were obtained by incorporating R18 in the dry lipid film at a concentration of 5.7% of the total lipids. Labeled and unlabeled liposomes, prepared at 2 mM, were mixed at a ratio of 1:4 and diluted to a final concentration of 5 μM by addition of appropriate buffers at the time of

posomes labeled by 1.16% of R18 (i.e., an identical total amount of marker diluted five times in membranes).

(iii) Size studies. The apparent size of the liposomes diluted to 50 μM in 40 mM cacodylate buffers of pH ranging from 8.0 to 5.0 was measured by quasi-elastic light scattering spectroscopy (28) using a Coulter Nano-sizer N4 MD particle Analyzer (Coulter Electronics Inc., Luton, England) at an angle of 90°, using both unimodal and size distribution analysis modes to determine the mean diameter and the full size distribution profile of each preparation, respectively.

(iv) Polymorphic behavior of the lipids as determined by ^{31}P NMR. The phase behavior of liposomes was determined as a function of pH and temperature. Classically, three types of phases can be distinguished on the basis of their ^{31}P NMR signals. The so-called bilayer signal is characterized by a high-field maximum and a low-field shoulder; the inverted hexagonal phase, by an inverse symmetry and a twofold reduced width; and the isotropic signal, by a sharp symmetric signal. In practice, MLV give a bilayer signal due to their organization in concentric bilayers, where rapid motion of phospholipid molecules along their long axis results in axial symmetry and partially averages the chemical shift anistropy (29). LUV give an isotropic signal, because the ^{31}P atoms are submitted to rapid isotropic motion owing to the rapid tumbling of the vesicles (30). As stated in the introduction, phosphatidylethanolamine has a propensity to organize itself in hexagonal phase (especially upon warming), in which the molecules project radially from the center of a cylinder of very small radius. The rapid rotation of the cylinders causes further averaging of chemical shift anistropy, explaining the reversed shape and the reduced width of the spectrum by comparison with the bilayer spectrum (29). To compare the appearance of this hexagonal phase starting from an isotropic or a bilayer phase, we performed NMR studies on both LUV and MLV. Liposome suspensions prepared at an initial lipid concentration of 75 mM were diluted in the appropriate buffers (Na carbonate from pH 10.0 to 9.2; Tris-HCl from pH 9.0 to 7.0; citric acid-NaOH from pH 6.2 to 5.2; and Na citrate-HCl from pH 5.0–3.0) and mixed with 0.2 mL D_2O (for locking on the deuterium signal) in 10 mm RMN tubes (final lipid concentration, 12.5 mM). The actual pH value of each suspension was measured with a minielectrode and a 691 Metrohm pH meter (Herisau, Switzerland), at both 30 and 70°C. All spectra were obtained at 101.3 MHz with a WM 250 Bruker instrument. Typical Fourier transform conditions were as follows: spectral width 20 kHz; 8 K data acquisition points; flip angle 60° (17 μs); 1 s repetition time. Five thousand free induction decays (FID) were accumulated with broad-band proton powergated decoupling. A line broadening of 50 Hz was applied to the FID before

with liposomes. J774 macrophages, a continuous reticulosarcoma cell line of murine origin (32), were grown as monolayers in 5% CO_2/95% air, at 37°C in an RPMI (Rosewell Park Memorial Institute) 1640 medium supplemented with 10% (vol/vol) fetal calf serum, 1.45% (wt/vol) $NaHCO_3$, and antibiotics (streptomycin 50 μg/mL, penicillin 50 IU/mL). Confluent cells were suspended by incubation with trypsin (0.5%)/EDTA (0.2%) in phosphate-buffered saline (PBS; 8 g/L NaCl, 0.2 g/L KCl, 1.15 g/L Na_2HPO_4, 0.2 g/L KH_2PO_4; pH 7.4), centrifuged, and plated in six-well plates for 3 d in RPMI medium supplemented with fetal calf serum, $NaHCO_3$, and antibiotics, as decribed above. At the time of the experiment, the cells were washed three times with PBS and reincubated during 15 min with 2 mL PBS containing liposomes (90 μM total lipid concentration) loaded with HPTS or HPTS-DPX. In preliminary experiments, the total fluorescence of the liposome preparations was determined after disruption by exposure to Triton X-100 (0.1%) and corrected for Triton X-100 influence as described above. These studies showed that the amount of HPTS or HPTS/DPX entrapped in DOPC/CHEMS was slightly larger than that entrapped in DOPE/CHEMS liposomes (30% in excess). After 15 min of uptake at 37°C, the cells were washed 10 times with ice-cold PBS and returned in growth medium at 37°C for different chase times.

(ii) Fluorescence assay. The cells were detached by trypsinization, pelleted by centrifugation, washed twice with ice-cold PBS, and gently resuspended in PBS. Viability and membrane integrity were checked by measuring the release of the cytosolic enzyme lactate dehydrogenase. HPTS fluorescence was recorded at a λ_{em} of 520 nm upon excitation at 363, 390, 450, or 488 nm and the signal expressed by reference to the protein cell content (33). The wavelengths of 390 and 450 nm correspond to the maximum in the excitation spectrum of HPTS at acidic and neutral pH, respectively (25), whereas those at 363 and 488 nm were the λ_{exc} used for confocal microscopy studies (see below). The 450/390 fluorescence ratio of HPTS was then used to evaluate the pH at which the probe was exposed in cells, based on calibration curves constructed by preparing the probe in phosphate buffers of known pH (between 5 and 8).

(iii) Confocal microscopy. Cells were treated as described above, except that they were cultivated in Lab-Tek Permanox culture chambers (Nunc, Roskilde, Denmark) allowing for the observation of living cells at high magnification under an inverted microscope. Images were recorded during incubation at 37°C using a Bio-Rad MRC 1024-UV laser scanning confocal microscope (Hemel Hempstead, United Kingdom) operated under control of the Lasersharp 2.10 software. Conditions of imaging were: filters E2 and UBHS, 63× oil-immersion ob-

screen and micrographs. Although the excitation wavelengths, which were imposed by the equipment, are not optimal, they nevertheless allowed for a clear-cut analysis of the pH differences in HPTS environment. The pH at which the fluorescence signals recorded upon excitation at 363 and 488 nm are equal was determined to be ~7.15, setting therefore the value for shifting the appearance of the tracer from green to red.

Materials. DOPE and DOPC were obtained from Avanti Polar Lipids, Inc. (Alabaster, AL), and radiolabeled phosphatidylethanolamine (specific radioactivity = 54 mCi/mmol), from Amersham International plc (Amersham, United Kingdom). Calcein and CHEMS were purchased from Sigma Chemical Co (St. Louis, MO). HPTS, DPX, and R18 came from Molecular Probes Inc. (Eugene, OR). Cell culture media and fetal calf serum were obtained from Gibco-Biocult (Peisley, Scotland). Other products were of analytical grade and obtained from E. Merck (Darmstadt, Germany).

RESULTS

Studies with liposomes. (i) Permeability studies. Figure 1A shows the release of calcein from LUV as a function of the time of incubation in buffers of different pH. DOPE/CHEMS liposomes released a large proportion (~ 60%) of calcein almost instantaneously when exposed to pH 5.0, with no further release after this first burst. The effect was highly dependent on pH since less than 10% release was observed at pH 7.5. DOPE/CHEMS liposomes exposed to pH 5.5 showed an intermediate behavior. In contrast, DOPC/CHEMS liposomes released a much lower proportion of calcein at pH 5.0, and this release proceeded slowly over the first 10 min of observation (Fig. 1B). Figure 1C shows the comparative release of calcein at 5 min over pH values from 8.0 to 5.0. The data confirm that acidity exerts a marked influence on calcein-release from DOPE/CHEMS liposomes, with a significant effect already observed at pH 6.0 ($P < 0.05$ by *t*-test). In contrast, DOPC/CHEMS liposomes appear considerably less sensitive to the decrease of pH. In parallel experiments, we measured the release of another marker (HPTS/DPX) from DOPE/CHEMS liposomes (Fig. 1C) with essentially similar results. HPTS/DPX did not significantly leak out from DOPC/CHEMS liposomes under the same conditions (data not shown).

(ii) Liposome membranes mixing studies. Figure 2A shows the fluorescence of R18 upon mixing of labeled and unlabeled LUV made of DOPE/CHEMS at different pH values. Liposomes exposed to pH 5.0 quickly (<5 min) showed a marked signal increase which amounted to approximately 10 times that recorded for the same liposomes exposed to pH 7.4. Liposomes exposed to pH 5.4 showed an intermediate behavior. (More time seems to be needed to reach a plateau value at pH

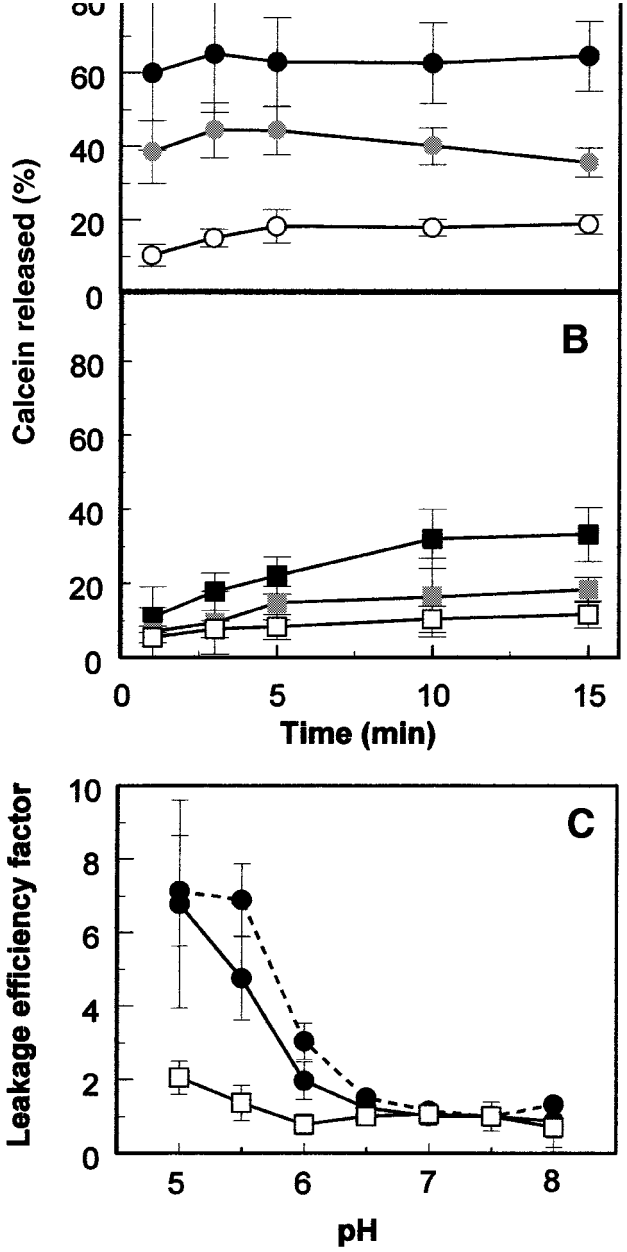

FIG. 1. Release of fluorescent tracers from large unilammelar vesicles (LUV) upon acidification. (A) Percentage of calcein released from dioleoyl phosphatidylethanolamine/cholesterylhemisuccinate (DOPE/CHEMS) or (B) dioleoylphosphatidylcholine/CHEMS (DOPC/CHEMS) liposomes after dilution and incubation at 37°C in isoosmotic phosphate buffers (closed symbols, pH 5.0; grey symbols, pH 5.5; open symbols, pH 7.5). Data shown are the mean values of three independent measurements in single liposome preparations. FIG. 2. Octadecylrhodamine B fluorescence dequenching in mixtures of labeled and unlabeled LUV upon acidification. (A) fluorescence recorded for DOPE/CHEMS liposomes after dilution and incubation of the mixed liposome population in 40 mM buffers (closed circles, pH 5.0; grey circles, pH 5.4; open circles, pH 7.4). Each curve is the mean of three independent determinations in single liposome preparations. (B) fluorescence recorded 5 min after dilution in 40 mM buffers for DOPE/CHEMS liposomes (closed circles) and DOPC/CHEMS liposomes (open squares). The right ordinate shows the percentage of fusion. Results are the mean ± SD of three independent measures on a single preparation of liposomes. For abbreviations see Figure 1.

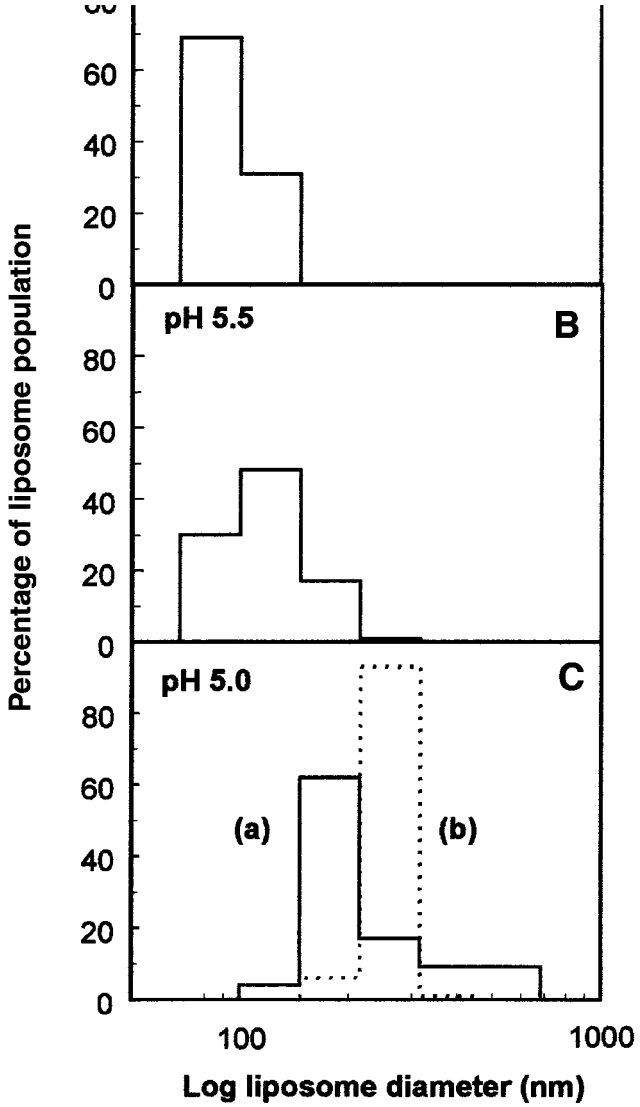

FIG. 3. Size distribution analysis of DOPE/CHEMS LUV determined by light-scattering spectroscopy 5 min after dilution and incubation at 37°C in buffers of different pH. For samples exposed to (C) pH 5.0, one reading was made after acidification [diagram in solid line (a)] and one additional reading was made after titration back to pH 7.5 [diagram in dotted line (b)]. For abbreviations see Figure 1.

slowly thereafter; thus time-dependence of the increase can only be assessed at pH 5.0.) These experiments were then repeated over a whole range of pH values, and DOPE/CHEMS liposomes were compared to DOPC/CHEMS liposomes. Figure 2B shows that the increase of the signal became significant at pH ≤ 5.4. DOPC/CHEMS liposomes did not show significant fluorescence increase throughout the whole range of pH values. The data of Figure 2 were also used to calculate the percentage of liposome fusion and this is shown on the right ordinate. Finally, similar experiments were also run in phosphate buffers (as used in permeability studies) to rule out any influence of the buffer system used. No difference were found when comparing data at the same pH with the phosphate and cacodylate buffer systems.

whereas the mean diameter of DOPC/CHEMS liposomes remained nearly constant at 100 nm in the same range of pH. The size distribution analysis of the DOPE/CHEMS liposomes illustrated in Figure 3 showed a narrowly distributed population at pH 7.5, but a progressive and marked shift toward large-diameter vesicles at acid pH. Titration back to pH 7.5 of liposomes exposed to pH 5.0 did not reverse this effect, and

obtained at other pH values is shown in the right panel of Figure 4. In alkaline medium and at 30°C, the spectrum was symmetric, with a half-height width of 3 ppm, and it can be considered as that of an isotropic-like phase. A decrease of pH caused the appearance of a spectrum characteristic of a hexagonal phase, showing a low-field peak and a high-field shoulder with a chemical shift anisotropy ($\Delta\sigma$) reduced by a factor of two compared to the $\Delta\sigma$ of a "bilayer" spectrum (10,29). Warming of the liposomes to 70°C caused a narrowing of the isotropic signal in alkaline medium and increased the proportion of hexagonal phase at intermediate pH values, but had no significant effect on the spectrum shapes of hexagonal phase at low pH values. By using the spectra obtained at 30°C for pH 3.7 and 9.3 as references for hexagonal and isotropic phases, respectively, the quantitative analysis showed that the

and 9.3 were taken as references for hexagonal and isotropic phases. The curves were very similar but slightly (approximately 0.4 pH units) displaced to less acidic values.

Similar studies were performed on MLV to better evidence the phase transitions. As shown in Figure 5 (left panel), these liposomes displayed a typical bilayer spectrum at 30°C and alkaline pH, with a high-field peak and a low-field shoulder. In contrast, the mixture was clearly organized in hexagonal phase at acidic pH. The phase transformation upon acidification was progressive and accompanied by the appearance of a low proportion of isotropic-type phase detected by a small peak at 0 ppm at pH 7.8. After warming to 70°C, the isotropic signal became detectable at pH 8.7 and was predominant at pH 7.8. After recooling to 30°C, the spectrum observed at pH

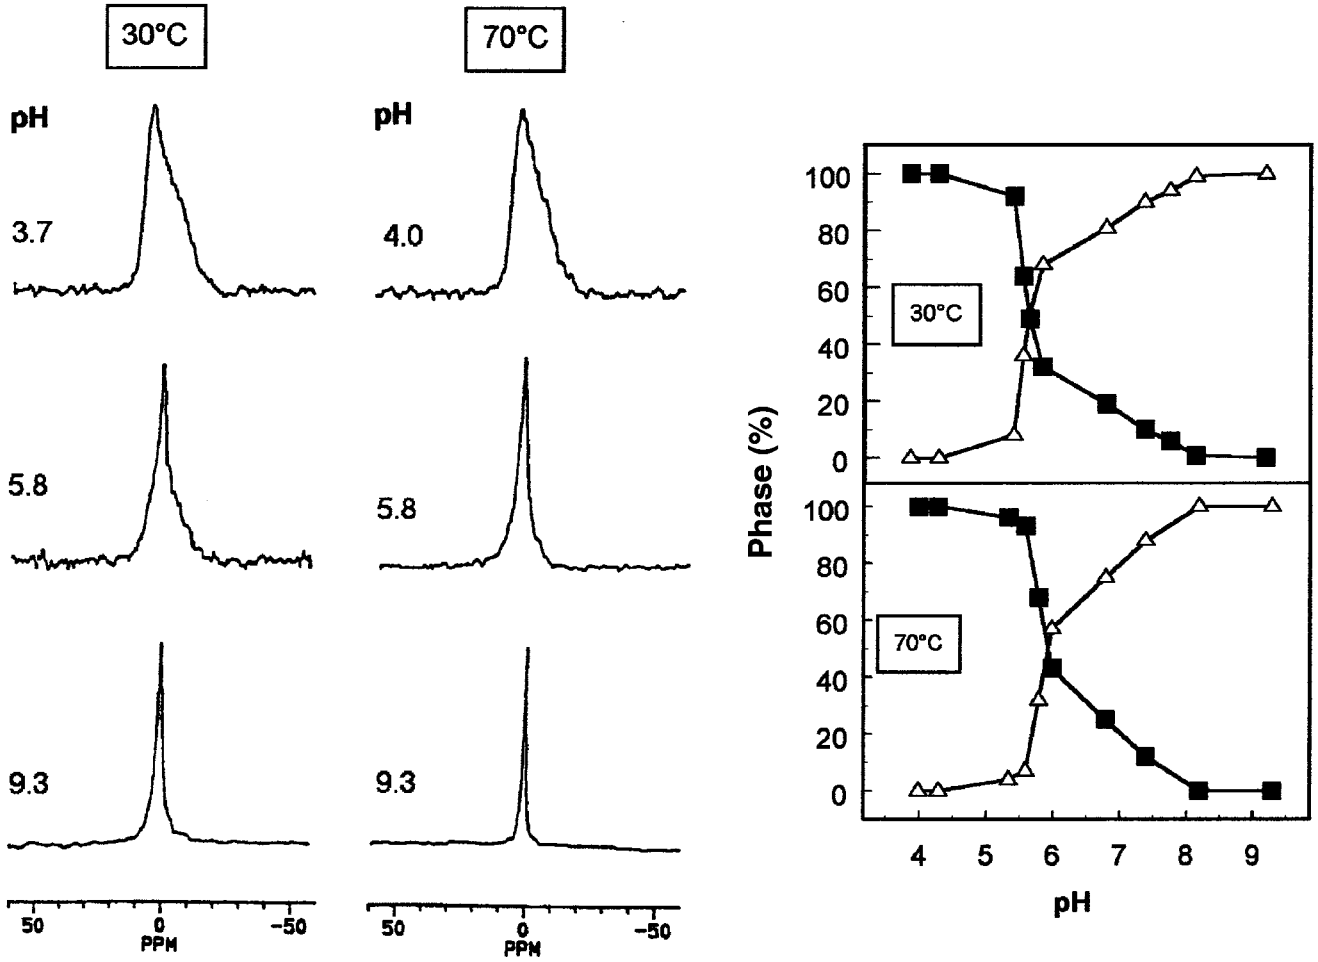

FIG. 4. ^{31}P nuclear magnetic resonance (NMR) spectroscopy of DOPE/CHEMS LUV. Left panel: typical spectra obtained at three different pH values at two temperatures. Right panel: phase behavior of the vesicles over the whole range of pH values investigated at both temperatures. Quanti-

reference to a bilayer phase, an isotropic phase, and an hexagonal phase, respectively. The results, presented in Figure 5 (right panel) show that 50% of the phospholipids adopt a hexagonal phase organization at a pH close to neutrality. This transformation from bilayer to hexagonal phase involved a passage through isotropic structures, the proportion of which drastically increased after one cycle of heating and cooling.

Studies with cultured cells. (i) Fate of entrapped HPTS. Figure 6 (upper panel) shows the accumulation and cellular fate of HPTS encapsulated in DOPE/CHEMS and DOPC/CHEMS LUV, in J774 macrophages during a first exposure to the vesicles for a 15-min period (uptake) followed

nal obtained by excitation at 450 nm declined while that obtained by excitation at 390 nm remained stable with a trend toward an increase. HPTS encapsulated in DOPC/CHEMS liposomes was accumulated to a considerably lesser extent, but its fate during the chase was qualitatively similar to that of HPTS encapsulated in DOPE/CHEMS liposomes. To get more insight on the intracellular fate of HPTS, we present in the panel B the ratio of the signals recorded upon excitation at 450 and 390 nm. This shows that a steady and significant shift of pH occurs in the environment of the probe, both with DOPE/CHEMS and DOPC/CHEMS liposomes from early uptake (pH 7.0–7.5) to late chase phase (pH 6.0–6.5); some

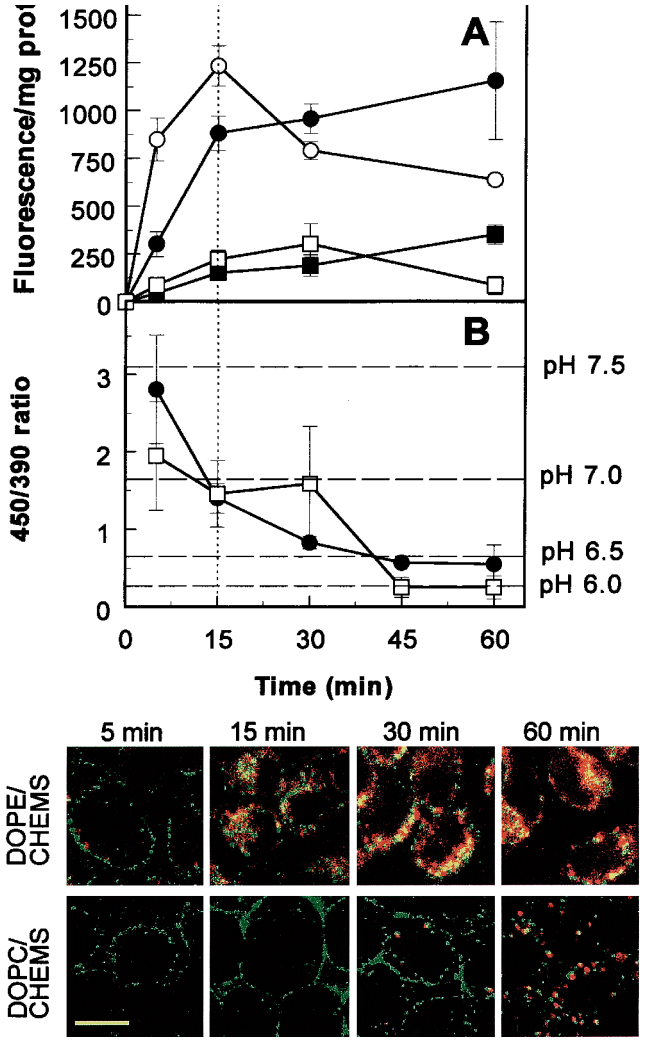

FIG. 6. Accumulation and distribution of fluorescence in J774 macrophages during incubation in the presence of HPTS-containing LUV (uptake) and subsequent transfer to liposome-free medium (chase). Circles, DOPE/CHEMS vesicles; squares, DOPC/CHEMS vesicles. (A) Readings obtained with suspensions of living cells upon excitation at 450 nm (open symbols) or 390 nm (closed symbols); (B), ratio of the recordings made upon excitation at these two wavelengths. Results are the mean of three independent experiments (±SD) (these ratios were used to calculate the mean pH to which HPTS is exposed, and the corresponding values are shown on the right ordinate). Bottom panel: confocal microscopy of cells treated as indicated in the upper panels. Cells were illuminated at 488 nm (green look-up table) and 363 nm (red look-up table). The yellow color results from the colocalization of green and red signals. Bar = 10 μm. For abbreviations see Figure 1.

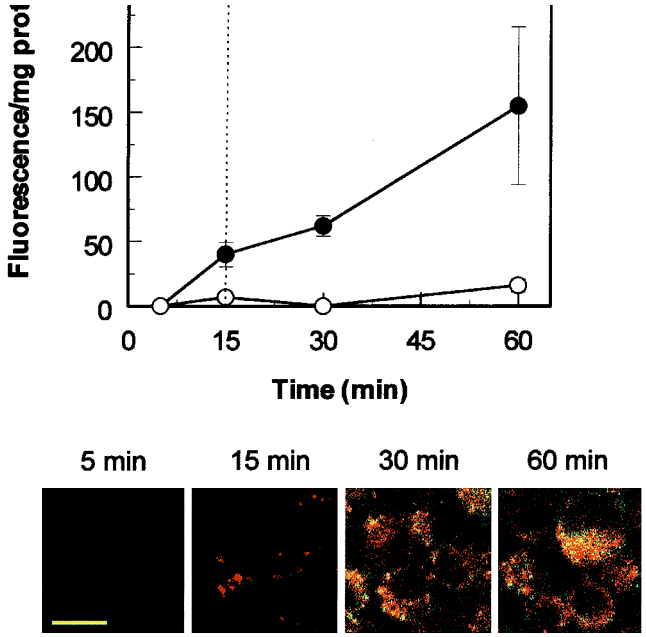

FIG 7. Accumulation and distribution of fluorescence in J774 macrophages incubated in the presence of DOPE/CHEMS LUV containing HPTS together with DPX. The protocol and the experimental conditions were similar to those of Figure 6. Upper panel: readings obtained with cell suspensions (open symbols, λ_{exc} 450 nm; closed symbols, λ_{exc} 390 nm). Lower panel: confocal microscopy observations. Bar = 10 μm. For abbreviations see Figure 1.

delay, however, was noted for DOPC/CHEMS liposomes (to make the link with the confocal microscopy studies, all measurements were also made at 488 and 363 nm, with essentially similar results). The confocal microscopic studies analysis (il-

entrapped in DOPC/CHEMS vesicles. With both types of liposomes, the tracer initially appeared as tiny dots located at the periphery of the cell (set to a green color). With DOPE/CHEMS liposomes, these structures became progressively enlarged and more centrally located in a perinuclear fashion, while also gradually emitting a larger proportion of the signal in the red channel, the yellow color resulting from the colocalization of green and red signals. Some of these structures were already visible at 5 min. After 45 min chase, most of the tracer was detected as large red/yellow patches, often with a diffuse appearance. With DOPC/CHEMS liposomes, the tracer still displayed a peripheral appearance after 30 min of incubation. It eventually, but slowly, became associated with larger structures, some of which appeared as red/yellow dots. Yet it was never present in a diffuse fashion.

(ii) Release of HPTS. Figure 7 (upper panel) shows that suspensions of cells incubated with DOPE/CHEMS LUV loaded with HPTS and DPX display almost no signal when excited at 450 nm. At the end of the uptake period, however, they showed a minor signal when excited at 390 nm, the value of which increased throughout the chase period. In confocal microscopy (lower panel), only a few red structures were seen

DISCUSSION

pH-sensitive liposomes have been developed for the purpose of enhancing the cytosolic delivery of drugs and other entrapped solutes through destabilization in the acid milieu of the endosomal/phagosomal apparatus (2–4). We selected DOPE/CHEMS liposomes since vesicles of this composition show a greater stability than liposomes made of DOPE and oleic acid (34), and also because CHEMS induces destabilization through transition to inverted hexagonal (H_{II}) phase (20) in a physiological pH range [7 to 5 (35)]. DOPC/CHEMS liposomes were used as controls since these vesicles cannot undergo reorganization to H_{II} phase, which is considered essential for membrane destabilization and fusion (10). As structural modifications could be the initiating factor of the destabilization of pH-sensitive liposomes upon acidification, we have focused our attention on the changes in lipid organization as well as their relation with membrane permeabilization and fusion.

A first observation in this respect is that change in polymorphic organization of the lipids occurs over a wide pH range and that the hexagonal-phase proportion increases from pH 8.0 down to ~6.0. At this pH value, it affects a large proportion of the lipids and probably reaches a critical threshold to cause alterations of other membrane properties. This threshold cannot, however, be more quantitatively defined in LUV. The broad component seen in the ^{31}P NMR spectra at acid pH, which is typical of a hexagonal phase (10), may indeed include a symmetrical broader component associated with fused liposomes of a still sufficiently small size (see below) to undergo motional averaging of $\Delta\sigma$ (30). The role of structures giving rise to an isotropic signal in the process of phase transition is further substantiated by the ^{31}P NMR studies made on MLV. The highly mobile structures responsible for the isotropic signal may also be involved in membrane fusion (36). However, a quantitative relationship between the proportion of these structures in the membrane and the fusion process cannot be established since MLV are too heterogeneous in size to be used in fusion assays. In addition, LUV, which were therefore used for fusion studies, reorganize in hexagonal phase at a lower pH than MLV. The endothermic character of the transition clearly appears for LUV, since it occurs at a higher pH at 70 than at 30°C. This effect of temperature is particularly dramatic for MLV, since a rise from 30 to 70°C increases the percentage of isotropic-type structures from ~10 to ~40%, and cooling down to 30°C causes a complete transformation of the spectrum in a narrow symmetrical signal. It therefore appears that heating and cooling induce the formation of isotropic-type structures in an irreversible manner. The nature of this structural change is difficritical membrane properties such as permeability and fusion capacity.

A second observation in this study is that DOPE/CHEMS liposomes require more membrane structure reorganization for fusion than for permeabilization, since there is a difference of approximately 0.5 pH units between the onset of each phenomenon (see data on calcein release on the one side and light-scattering spectroscopy and R18 dequenching on the other side). Our data therefore support and extend those obtained by Collins *et al.* (17), who also reported that leakage occurs at a less acidic pH than membrane fusion. Quite surprisingly, we found that a 100% leakage or fusion could not be achieved, at least in the range of pH investigated, suggesting that a part of the liposome population is resistant to acidification or that membrane perturbations are not sufficient to cause the complete release of the entrapped probe or the fusion of all the vesicles. Incomplete release of a tracer entrapped in DOPE/CHEMS liposomes containing higher proportions of CHEMS was also noted by other investigators (11). In the present study, the kinetic data unambiguously show that a plateau has been reached. It has been proposed (11) that destabilization of pH-sensitive liposomes is primarily mediated by bilayer contact. The degree of permeabilization may therefore be directly related to the lipid concentration. However, in these studies, the authors (11) did not specifically consider whether the aggregation process is followed by fusion of the liposomes. The mixing of lipid components we detected is actually highly suggestive of a true fusion process rather than a simple aggregation, since the increase in LUV size was moderate (only 2–3 times the diameter of control liposomes) and irreversible, and since R18 fluorescence increased very rapidly upon liposome mixing. The present data are therefore very similar to those we reported earlier for negatively charged liposomes incubated with typical fusogenic agents like melittin or (β-diethylaminoethylether)hexestrol (these agents cause a two to five times increase in liposome diameter and an immediate dequenching of R18 fluorescence). They are also in sharp contrast with what we found for aggregating agents like spermine and gentamicin, which induce an at least 10-fold increase in liposome diameter associated with a slow increase of R18 fluorescence (26,37). Altogether, the biophysical studies discussed so far strongly suggest that DOPE/CHEMS liposomes of the composition we selected may become destabilized and release their contents when pH falls from >7 to approximately 6. This range corresponds to that encountered along the endocytic pathway (38). The results of the cellular studies with HPTS-entrapped liposomes (in which the tracer is used to quantify the liposome uptake and to estimate the pH at which

represent an average value for a material that, as evidenced by confocal microscopy (Fig. 6, lower panel), is spread among vacuoles whose pH values range from neutrality to a low value. Our studies also show that cells handle DOPE/CHEMS and DOPC/CHEMS liposomes very differently. First, the fluorescence signal recorded in cells was markedly lower for DOPC/CHEMS liposomes than for DOPE/CHEMS liposomes. This cannot be attributed to a difference in the amount of probe entrapped (see Materials and Methods section) and must therefore be ascribed to a low endocytic rate of DOPC/CHEMS liposomes, as already observed in P388D1 macrophages (4). This clearly points to the importance of liposome composition for uptake, beyond a simple variation in charge (39). Second, the confocal microscopy studies show that HPTS entrapped in DOPC/CHEMS liposomes remains for about 30 min in the periphery of the cell and at neutral pH before being transferred to vesicles of lower pH. Because our calibration studies indicate that the shift from the green to the red signal should occur around pH 7.15, the data therefore suggest that DOPC/CHEMS liposomes remain associated with the cell surface, or with invaginations of the plasma membrane, for quite a time before being transferred to early endosomes and other acidic vacuoles. In contrast, HPTS entrapped in DOPE/CHEMS liposomes appears to move more quickly into the cell where it progressively shows a diffuse appearance in parallel with a marked shift from green to yellow and red. Again, taking into account the pH at which this shift is observed (~7.15), we interpret these images as indicating a rapid internalization into early endosomes followed by a partial release of the tracer in the cytosol, the pH of which appears to be precisely around this value in J774 macrophages (40). An effective release of the content of DOPE/CHEMS liposomes into the cytosol also is largely evidenced by the results of the experiments using vesicles containing both HPTS and its quenching agent DPX. Comparing the values of the fluorescence signal obtained with these liposomes (Fig. 7) to that obtained with vesicles without the quenching agent (Fig. 6), we suggest that approximately 15% of the HPTS has been made free within 45 min after endocytosis, a figure close to that found by Chu *et al.* (4) for DOPE/CHEMS (3:2) liposomes. This value may, however, be underestimated, since a significant increase in HPTS fluorescence will be only observed upon high dilution of the dye/quencher mixture (41).

In conclusion, our data confirm the potential usefulness of DOPE/CHEMS liposomes as pH-sensitive vehicles for the intracytosolic delivery of an entrapped tracer. This delivery seems to occur without grossly affecting cell viability, suggesting interesting applications for therapeutics. Our biologi-

Qualitative and Quantitative Analysis of Lipoxygenase Products in Bovine Corneal Epithelium by Liquid Chromatography–Mass Spectrometry with an Ion Trap

Maria Liminga* and Ernst Oliw

Division of Biochemical Pharmacology, Department of Pharmaceutical Biosciences, Uppsala University, Uppsala Biomedical Center, SE-751 24 Uppsala, Sweden

ABSTRACT: Electrospray ionization ion trap mass spectra of 5-, 12-, and 15-hydroperoxyeicosatetraenoic (HPETE), hydroxyeicosatetraenoic (HETE), and ketoeicosatetraenoic (KETE) acids were recorded. The HPETE were partly dehydrated to the corresponding KETE in the heated capillary of the mass spectrometer. 12-HPETE and 15-HPETE were also converted to KETE by collision-induced dissociation (CID) in the ion trap, whereas CID of 5-HPETE yielded little formation of 5-KETE. Subcellular fractions of bovine corneal epithelium were incubated with arachidonic acid (AA) and the metabolites were analyzed. 15-HETE and 12-HETE were consistently formed, whereas significant accumulation of HPETE and KETE was not detected. Biosynthesis of 12- and 15-HETE was quantified with octadeuterated 12-HETE and 15-HETE as internal standards. The average biosynthesis of 15-HETE and 12-HETE from 30 μM AA by the cytosol was 38 ± 8 and below 3 ng/mg protein/30 min, respectively, which increased to 78 ± 21 and 10 ± 4 ng/mg protein/30 min in the presence of 1 mM free Ca^{2+}. The microsomal biosynthesis was unaffected by Ca^{2+}. The microsomes metabolized AA to 15-HETE as the main metabolite at a low protein concentration (0.3 mg/mL), whereas 12-HETE and 15-HETE were formed in a 2:1 ratio at a combined rate of 0.7 ± 0.2 μg/mg protein/30 min at a high protein concentration (1.8 mg/mL). The level of 12-HETE in corneal epithelial cells was 50 ± 13 pg/mg tissue, whereas the endogenous amount of 15-HETE was low or undetectable (<3 pg/mg tissue). Incubation of corneas for 20 min at 37°C before processing selectively increased the amounts of 12-HETE in the epithelium fourfold to ~0.2 ng/mg tissue. We conclude that 12-HETE is the main endogenously formed lipoxygenase product of bovine corneal epithelium.

Paper no. L8409 in *Lipids 35*, 225–232 (February 2000).

Lipoxygenases (LOX) are widely distributed in mammalian and plant tissues (1–5). They catalyze dioxygenation of polyunsaturated fatty acids and formation of 1-hydroperoxy-2*E*,4*Z*-pentadiene structures. LOX metabolites can often be analyzed and quantified with chromatography with ultraviolet (UV) detection. Alternatively, deuterated internal standards may be used to quantify LOX metabolites by gas chromatography–mass spectrometry (GC–MS) or by liquid chromatography–mass spectrometry (LC–MS) .

Quantification by GC–MS methods has superior sensitivity and selectivity, but has nevertheless many drawbacks. It requires derivatization, and it is not suitable for analysis of labile compounds like hydroperoxy fatty acids. LC–MS with electrospray ionization is a robust technique without many of these disadvantages (8). LC–MS has proved to be valuable for analysis of LOX metabolites of arachidonic acid (AA) and linoleic acid in many tissues and experimental systems, e.g., hydroxyeicosatetraenoic acids (HETE), hydroperoxyeicosatetraenoic acids (HPETE), hydroxyoctadecadienoic acids, and hydroperoxyoctadecadienoic acids (6,7,9–13).

The corneal epithelia of many species contain prominent 12- and 15-LOX activities (14–18). The bovine corneal epithelial tissue expresses at least three LOX, 12(*S*)-lipoxygenase (12-LOX) of the leukocyte (tracheal) type, 12-LOX of the platelet type, and 15-LOX type 2 (19). 15-LOX activity is mainly present in the cytosol, whereas both 15- and 12-LOX activities are found in the microsomal fraction (17,18). In addition, 5-LOX is present along with inflammatory cells following corneal lesions in the rabbit *in vivo* (20). Reverse transcription-polymerase chain reaction (RT-PCR) and Northern blot analysis suggest that mRNA of 5-LOX is present in bovine corneal epithelium (Liminga, M., and Oliw, E., unpublished observation). In addition to these LOX, cytochrome P450 occur in the corneal epithelium (21) and are reported by Schwartzman and colleagues to synthesize 12(*R*)-HETE (22,23).

The main objective of the present investigation was to use LC–MS for analysis of LOX products in bovine corneal epithelium and to study the fragmentation mechanism of HPETE. With an ion trap mass spectrometer, we first recorded the LC–MS mass spectra of 5-, 12-, and 15-HPETE, the corresponding HETE and KETE, and some octadeuterated HPETE and HETE. In the second part, we analyzed subcellular fractions of corneal epithelial cells for biosynthesis of LOX products. We quantified the rate of biosynthesis of 15-HETE and

12-HETE *in vitro* and the endogenous amounts of 15-HETE and 12-HETE in the epithelium.

MATERIALS AND METHODS

Materials. AA (99%) was from Sigma Chemical Co. (St. Louis, MO) and [5,6,8,9,11,12,14,15-$^2H_8$]-AA (d_8-AA) was a gift from Unilever Research Laboratory (Vlaardingen, The Netherlands). 5(*R,S*)-HETE, d_8-12(*S*)-HETE, 12(*S*)-HPETE, 12-KETE, and 8(*R,S*)-HETE were purchased from Cayman Chemical Co. (Ann Arbor, MI). 15(*S*)-HETE, 15(*S*)-HPETE, d_8-15(*S*)-HETE, and d_8-15(*S*)-HPETE were prepared by biosynthesis from AA and d_8-AA with soybean LOX (lipoxidase IV, Sigma), essentially as described elsewhere; (24) 5(*S*)-HETE, 5(*S*)-HPETE, d_8-5(*S*)-HETE, and d_8-5(*S*)-HPETE were prepared with partially purified potato tuber 5-LOX as described by Reddanna *et al*. (25). HPETE were reduced to HETE with $SnCl_2$ or $NaBH_4$ (24). 15-KETE and 5-KETE were prepared from 15-HETE and 5-HETE by dehydrogenation as described elsewhere (26). All synthetic products were purified by reversed-phase high-performance liquid chromatography (RP-HPLC) and characterized by UV analysis and by MS. A-23187 was from Calbiochem (La Jolla, CA). Solvents for RP-HPLC and other chemicals were from Merck (Darmstadt, Germany). Bovine eyes were put on ice at a local slaughterhouse and brought to the laboratory within 2 h.

Preparation of subcellular fractions of corneal epithelial cells. Subcellular fractions were prepared at +4°C, essentially as described by Liminga *et al*. (17). Bovine eyes were thoroughly washed with phosphate buffered saline (PBS; pH 7.4). The epithelial cells were scraped off the cornea and put into homogenization buffer (0.05 M Tris-HCl/1 mM EDTA/1 mM EGTA/ 0.5 mM dithiothreitol/0.1 mM phenylmethane-sulfonylfluoride; pH 7.4). The tissue was carefully homogenized with a glass–glass homogenizer. The homogenate was sonicated and usually centrifuged at 10,000 × *g* for 15 min. The low-speed supernatant was either stored at –80°C or centrifuged at 100,000 × *g* for 90 min. The high-speed pellet was designated the microsomal fraction and the high-speed supernatant was designated the cytosolic fraction. Protein concentration was estimated by the Bradford method (27).

Biosynthesis of LOX products in vitro. Low-speed supernatant (4 mg protein) and cytosolic (4–6 mg protein) and microsomal fractions (0.3, 0.6, or 1.8 mg protein) were incubated with 30 μM AA in 1 mL of the buffer above for 30 min at 37°C with constant shaking. In some experiments, 1 mM ATP and/or 1 mM Ca^{2+} were added to PBS, which is sufficient to stimulate 5-LOX activity (*cf.* Ref. 28). The incubations were terminated with 4 vol of ethanol, and 90 ng d_8-15-HETE and 100 ng d_8-12-HETE were added.

Endogenous 12- and 15-HETE. Epithelial cells from four corneas (~200 mg) were analyzed in five different experiments. The cells were put into 1.5 mL ethanol containing d_8-15-HETE (45 ng) and d_8-12-HETE (50 ng), weighed, and immediately homogenized as described above. The metabolites were extracted on SepPak/C_{18} as described (17), and analyzed by LC–MS. In additional experiments, multiples of four corneas were placed in PBS (pH 7.4) with (n = 4) or without (n = 4) 1 mM added calcium and incubated for 20 min at 37°C. In three experiments, the calcium ionophore A-23187 (10 μM) was also added. After incubation, the corneas were chilled and immediately processed for endogenous LOX products as above.

LC–MS analysis. LC–MS analysis was performed with equipment as described by Bylund *et al.* and Oliw *et al.* (12,13). The pump for HPLC was from ThermoQuest (P2000). The column contained octadecasilane silica (5 μm, 250 × 2 mm; Phenomenex, Torrance, CA) and was eluted with methanol/water/acetic acid, 80:20:0.01 (by vol), at 0.2 mL/min. The effluent was first analyzed by UV detection at 235 nm and then by electrospray ionization MS with an ion trap mass analyzer (LCQ; ThermoQuest, San Jose, CA). Negative ions were monitored and prostaglandin $F_{1\alpha}$ was infused (100 ng/min) for tuning. The targets for automatic gain control were set at 5×10^7 for full MS and at 1×10^7 for MS^n. The capillary temperature was 230°C, but reduced to 170°C for analysis of HPETE. The source voltage was 4.25 kV and source current 0.1 mA. The sheath and auxillary flow of N_2 were 80 and 20 units, respectively, and He was used as collision gas. Off-line nanoelectrospray was performed with 2–3 μL samples (~10 ng/μL) in disposable gold-coated capillary probes (Protana A/S, Odense, Denmark) with a spray voltage of 0.8 kV. The samples were dissolved in methanol/water, 1:1. The collision energy (in arbitrary units) was adjusted 25–30% for MS^2 analysis so that >90% of the parent ion fragmented. The mass range was usually set from 80 to 400. Standard curves were constructed from analysis of different amounts 12-HETE and 15-HETE with fixed amounts of d_8-15-HETE and d_8-12-HETE by selective ion monitoring at *m/z* 319 (carboxylate anion of HETE) and *m/z* 327 (carboxylate anion of d_8-HETE). The ratio of the peak areas of 12-HETE and d_8-12-HETE and the ratio of the peak areas of 15-HETE and d_8-15-HETE yielded linear standard curves. The slopes of the standard curves for 12-HETE/d_8-12-HETE and for 15-HETE/d_8-15-HETE were 0.59 and 0.67, respectively. The d_8-HETE contained less than 0.5% HETE.

RESULTS

LC–MS analysis of HPETE and KETE. LC–MS analysis of 5-, 12-, and 15-HPETE yielded two strong signals, *m/z* 335 and *m/z* 317 (Fig. 1). They corresponded to the carboxylate anion of the hydroperoxide ($[M - H]^-$) and the anion of its dehydration product ($[M - H - H_2O]^-$), respectively. The intensity of the latter was relatively low (about 5%) at heated capillary temperatures of 170°C and increased with temperature to ~30% at 230°C. The temperature effect was more pronounced during nanoelectrospray ionization. 5-, 12-, and 15-KETE separated from 5-, 12-, and 15-HPETE, respectively, on RP-HPLC. These KETE were therefore likely formed by dehydration of 5-, 12-, and 15-HPETE in the heated capillary. As discussed below, collision-induced dissociation (CID) in the ion trap of 15-HPETE and 12-HPETE yielded 15-KETE and 12-KETE as

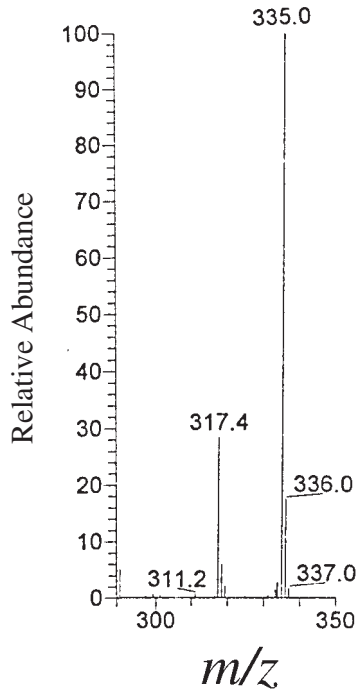

FIG. 1. A partial mass spectrum of 5-hydroperoxyeicosatetraenoic (HPETE) acid. The intensity of other ions than the carboxylate anion (*m/z* 335) and its dehydration product (*m/z* 317) was only a few percent.

major products, but 5-HPETE was not converted to 5-KETE in appreciable amounts.

5-HPETE and 5-KETE. LC–MS analysis of 5-HPETE showed that this compound eluted after 30 min (Fig. 2A, top panel). The mass spectrum yielded two strong signals at *m/z* 335 and 317 as discussed above. MS^2 analysis of the carboxylate anion of 5-HPETE (MS^2 335 → full scan) yielded virtually no daughter ions (Fig. 2A, middle panel), whereas analysis of the dehydration product (MS^2 317 → full scan) yielded many daughter ions (Fig. 2A, bottom panel).

Analysis of the facile dehydration product of 5-HPETE (MS^2 317 → full scan; *cf.* Fig. 2A, bottom trace) yielded an informative mass spectrum with many strong signals as shown in Figure 2B. Signals were noted at *m/z* 299 (317 – 18), 273 (317 – 44), and 255 (317 – 44 – 18). Other ions were noted at *m/z* 245, 239, 207, 203 (α-cleavage between C5 and C6), 181, 167, 153, 149 (167 – 18), 129, 123 (167 – 44), and 113. MS analysis of d_8-5-HPETE yielded signals corresponding to the carboxylate ions ($[M - H]^-$) at *m/z* 343 (100%, d_8-5-HPETE) and 342 (38%, d_7-5-HPETE) and the carboxylate ions of the dehydration product ($[M - H - H_2O]^-$) at *m/z* 325 (17%) and 324 (17%) (data not shown). The MS^2 analysis of the dehydration

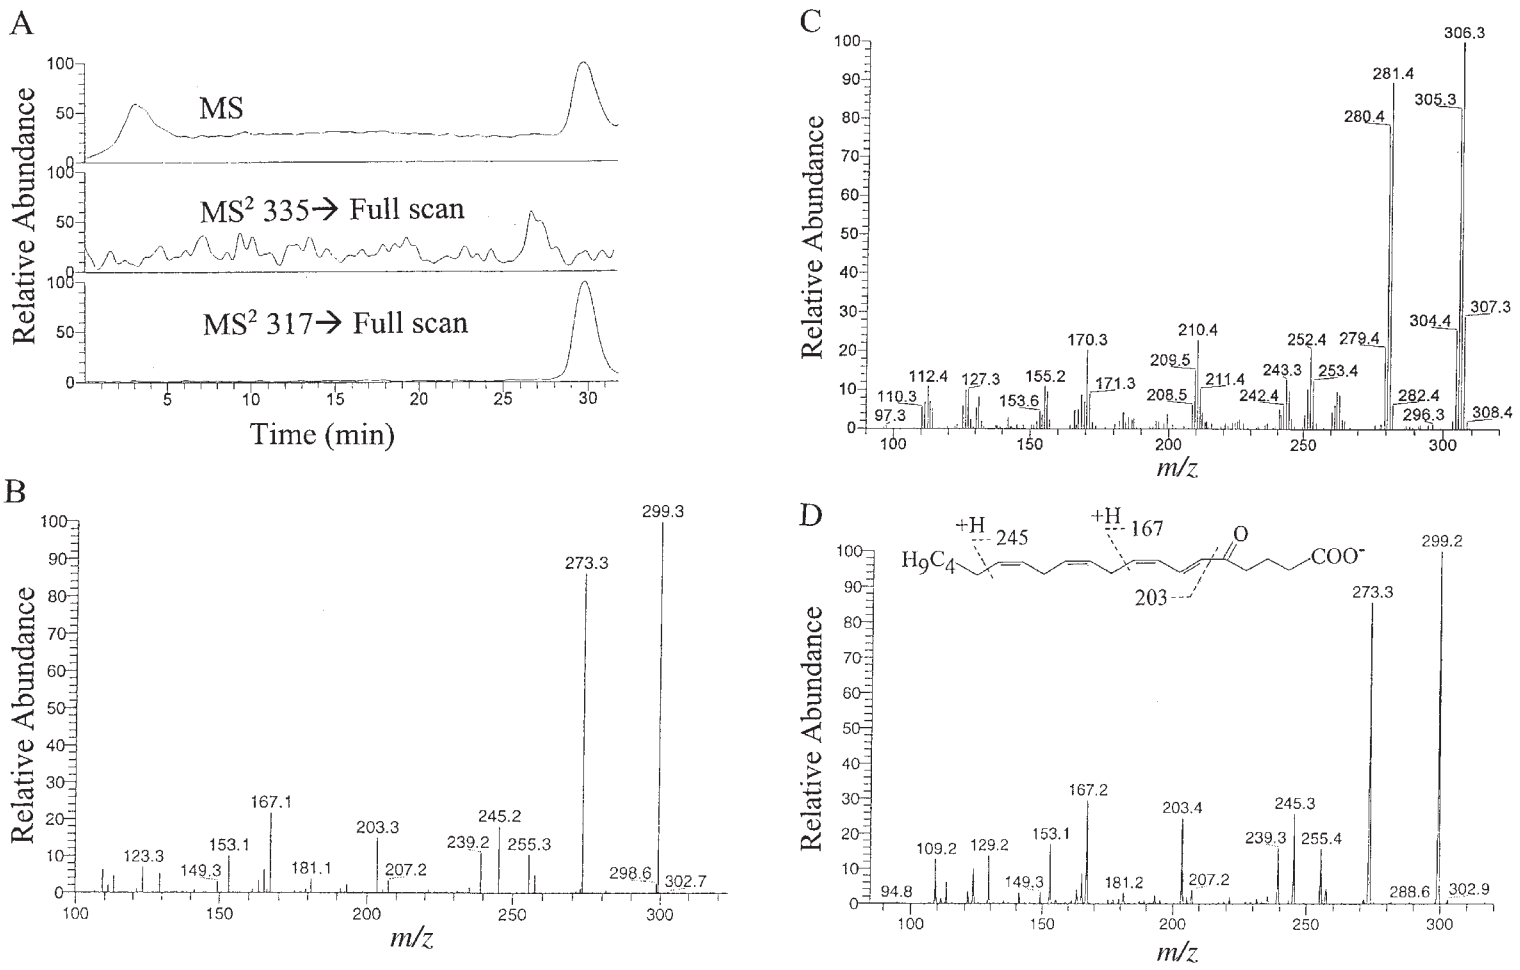

FIG. 2. Liquid chromatography–mass spectrometry (LC–MS) analysis of the carboxylate ions of 5-HPETE, its dehydration product, and 5-keto-eicosatetraenoic (KETE) acid. (A) Selected ion chromatograms from LC–MS analysis of 5-HPETE. Top trace, total ion intensity during full MS analysis; middle trace, total ion intensity of MS^2 analysis of *m/z* 335 (MS^2 335 → full scan); bottom trace, total ion intensity of MS^2 analysis of *m/z* 317 (MS^2 317 → full scan). (B) MS^2 analysis of the dehydration product of 5-HPETE formed in the heated capillary (MS^2 317 → full scan). The inset shows 12-KETE and its CID in the ion trap, as MS^2 analysis of 12-KETE (MS^2 317→ full scan) yielded an identical mass spectrum [and so did MS^3 analysis of 12-HPETE (MS^3 335→ 317→ full scan)]. (B) MS analysis of 15-HPETE (MS^3 335→ 317→ full scan). MS^2 analysis of 15-KETE (MS^2 317→ full scan) yielded an identical mass spectrum. The inset shows 15-KETE and its fragmentation in the ion trap. See Figures 1 and 2 for abbreviations.

product of d_8-5-HPETE was helpful for interpretation of the fragmentation. A comparison between this mass spectrum (Fig. 2C) and that of 5-HPETE (Fig. 2B) indicated that the signals at *m/z* 306 and 305 in Figure 2C corresponded to *m/z* 299 in Figure 2B; *m/z* 281 and 280 corresponded to *m/z* 273; *m/z* 253, 252, and 251 corresponded to *m/z* 245*; m/z* 210 and 209 corresponded to *m/z* 203; and *m/z* 171 and 170 corresponded to *m/z* 167. MS analysis of 5-KETE (MS^2 317 → full scan; Fig. 2D) and MS analysis of the heated capillary dehydration product of 5-HPETE (MS^2 317 → full scan; Fig. 2B) yielded virtually identical mass spectra. Based on the mass spectra discussed above, the CID of 5-KETE was deduced as shown by the inset in Figure 2D. We conclude that 5-HPETE is partially dehydrated to 5-KETE in the heated capillary.

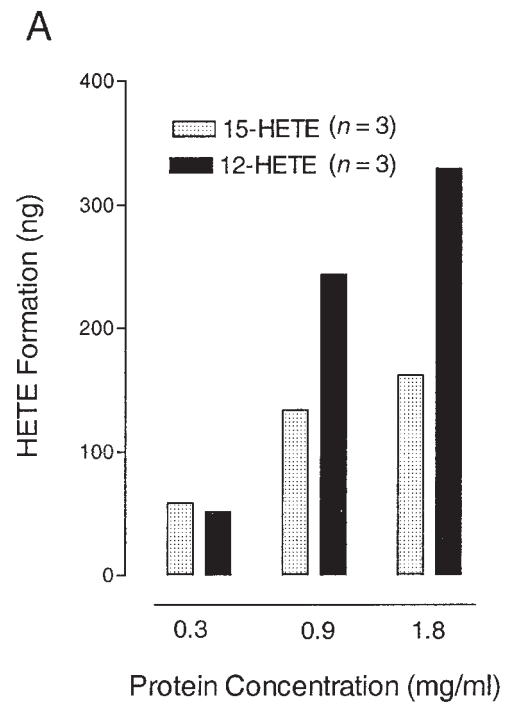
12-HPETE and 12-KETE. The carboxylate ion (*m/z* 335) and the facile dehydrated molecular ion (*m/z* 317) of 12-HPETE were subject to MS^2 analysis. MS^2 335 → full scan yielded mainly a prominent signal at *m/z* 317, whereas MS^2 317 → full scan gave rise to characteristic mass spectra with many informative fragments (Fig. 3A), which appeared to be almost identical to the MS^3 spectrum of 12-HPETE (MS^3 335 → 317 → full scan; data not shown) and the MS^2 spectrum of 12-KETE (MS^2 317 → full scan; data not shown). Signals were noted at *m/z* 299, 281, 273, 255, and 219, 205 (possibly α-cleavage between C11 and C12), 187 (205 – 18; weak), 179 (possibly α-cleavage between C12 and C13), 163, 161 (205 – 44) and 153. The major fragments could be formed as indicated by the inset in Figure 3A.

15-HPETE and 15-KETE. The MS^3 analysis of 15-HPETE [MS^3 335 → 317 → full scan (Fig. 3B)] showed signals at *m/z* 299 (317 – 18), 281 (299 – 18), 273 (317 – 44), 255 (317 – 44 – 18), 245 (317 – 72), 219 (317 – 98, possibly loss of $C_6H_{11}O$ with gain of a hydrogen), 203, 201 (245 – 44), 173, 139, and 113. The MS^2 analysis of the dehydration product (MS^2 317 → full scan) showed a similar mass spectrum, which also was identical to that of 15-KETE. The MS analysis of d_8-15-HPETE yielded signals at *m/z* 343 (335 + 8) and 342, and at *m/z* 325 (317 + 8) and 324. MS^2 analysis of *m/z* 325 (range *m/z* 327 – 323) showed strong signals at *m/z* 305 – 307, 279 – 281, and weaker signals at *m/z* 225 and 226, 207 and 208, 181, 152, 141 and 114. The MS^2 spectrum of 15-KETE (MS^2 317 → full scan) appeared to be virtually identical with the MS^2 and MS^3 spectra of 15-HPETE discussed above. The deduced fragmentation of 15-KETE is shown by the inset in Figure 3B.

We conclude that 5-HPETE, 12-HPETE, and 15-HPETE can be partially dehydrated to 5-KETE, 12-KETE, and 15-KETE, respectively, in the heated capillary of the mass spectrometer. 12-KETE and 15-KETE also can be formed by CID of the corresponding hydroperoxide anions in the ion trap. CID of 5-HPETE, however, indicated that 5-HPETE was mainly transformed to products outside the mass range of the ion trap with little formation of 5-KETE.

LC–MS analysis of HETE and d_8*-HETE.* MS^2 analysis of the carboxylate ions (*m/z* 319) of 15-HETE, 12-HETE, and 5-HETE yielded ion trap mass spectra which were similar to those previously reported with other MS/MS instruments (7,9,10). In addition to loss of 18 (water), 44 (CO_2), and 62 (water plus CO_2), MS^2 analysis of 15-HETE yielded signals at *m/z* 219 (α-cleavage between C14 and C15 with gain of H), 175, and 113, whereas12-HETE yielded characteristic signals at *m/z* 208 (α-cleavage C12-C13), 179 (α-cleavage C11-C12 with gain of H), and 163. 8-HETE showed a strong signal at *m/z* 155 (α-cleavage C8-C9 with loss of H), and weaker signals at 163 (α-cleavage, 319 – 156) and 127 (α-cleavage between C7-C8 with gain of H). 5-HETE showed a strong signal at *m/z* 115 (α-cleavage between C5-C6 with gain H), but the other fragment formed by α-cleavage (*m/z* 203) was very weak. d_8-15-HETE, d_8-12-HETE, and d_8-5-HETE fragmented as expected.

LOX activity of cell homogenates and subcellular fractions. Cell homogenates and low-speed supernatant of bovine corneal epithelium converted 30-μM AA to 15-HETE and 12-HETE, about 70% 15-HETE and 30% 12-HETE as judged from



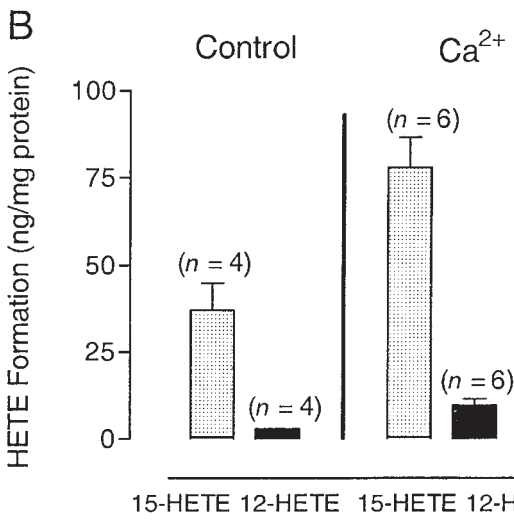


FIG. 4. Biosynthesis of 12-hydroxyeicosatetraenoic acid (HETE) and 15-HETE by subcellular fractions of bovine corneal epithelial cells. (A) Lipoxygenase activity at three different concentrations of microsomal protein. (B) Effect of 1 mM free Ca^{2+} on the biosynthesis of 12- and 15-HETE in the cytosolic fraction of bovine corneal epithelium. Left, control without calcium and, right, with calcium. Mean ± SD.

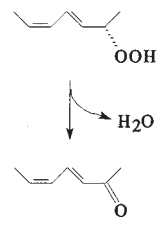
LC–MS analysis. The relative amounts of 15- and 12-HETE were unchanged with 3–100 μM AA. The microsomal fraction also metabolized AA to 15-HETE and 12-HETE as major products. The microsomal biosynthesis of 12-HETE increased with the amount of protein but the biosynthesis of 15-HETE did not increase to the same extent. The relative amounts of 12-HETE and 15-HETE thus changed. As shown in Figure 4A, 15-HETE was the main metabolite at low protein concentration (0.3 mg/mL), whereas 12-HETE was the most prominent metabolite at higher protein concentration (≥0.9 mg/mL). The total rate of biosynthesis of LOX products by the microsomes was high, ~0.7 ± 0.2 μg/mg protein/30 min (n = 6), equivalent to 0.07 ± 0.02 nmol/mg protein/min. 12-HPETE, 12-KETE, 15-HPETE, and 15-KETE could not be detected.

The high-speed supernatant formed 15-HETE as the main metabolite, but only small amounts of 12-HETE. The rate of biosynthesis of 15-HETE and 12-HETE was 38 ± 8 and below 3 ng/mg protein/30 min, respectively. As mRNA of 5-LOX is present in bovine corneal epithelium and biosynthesis of 5-HETE has been detected occasionally (Liminga, M., and Oliw, E., unpublished data), we investigated the effect of ~1 mM free Ca^{2+} and 1 mM ATP. There was no consistent 5-LOX activity, but the biosynthesis of 15-HETE and 12-HETE appeared to increase in the presence of added Ca^{2+} to 78 ± 21 and 10 ± 4 ng/mg protein/30 min (Fig. 4B), respectively. Addition of calcium had no apparent effect on microsomal LOX activity.

Endogenous 12-HETE and 15-HETE in corneal epithelial cells. The main endogenous LOX metabolite in bovine corneal epithelium was 12-HETE, whereas 15-HETE was found in much lower amounts (Fig. 5A). The amounts of 12- and 15-HETE were 50 ± 13 and 9 ± 6 pg/mg tissue, respectively (n = 5). In another set of experiments, the corneas were transferred from +4 to 37°C for 20 min [in PBS with (n = 4) and without 1 mM calcium (n = 4) and 10 μM A-23187 (n = 3)], and then processed. This procedure resulted in a fourfold increase in the biosynthesis of 12-HETE from endogenous AA to about 0.2 ng/mg tissue, while 15-HETE was undetectable in these experiments (Figs. 5B and 5C).

DISCUSSION

In the first part of this study, we looked at the mass spectra of 5-, 12-, and 15-HPETE, the corresponding HETE and KETE in an ion trap instrument. The carboxylate ions of 12-HPETE and 15-HPETE (m/z 335) were isolated in the trap and dehydrated to the corresponding KETE (m/z 317) by CID as indicated by the scheme below. 5-, 12-, and 15-KETE could also be formed from 5-, 12-, and 15-HPETE, respectively, by temperature-dependent dehydration in the heated capillary.



The present work demonstrates that the ion trap MS^2 spectra of these three dehydration products were indeed identical to the MS^2 spectra of the corresponding KETE compounds. Facile dehydration of fatty acid hydroperoxides to keto fatty acids by CID or the high temperature of the heated capillary is therefore a convenient way to analyze these compounds (6,7). 8- and 11-Hydroperoxylinoleic acids also appear to be dehydrated to 8- and 11-keto compounds by the same mechanisms (13).

By analogy, it seems likely that 5-HPETE also was dehydrated to 5-KETE by CID in the ion trap, but this daughter ion could hardly be detected. This finding was unexpected. MacMillan and Murphy (6) reported that tandem MS of the 5-HPETE (m/z 335) and 5-KETE (m/z 317) anions in a triple quadrupole mass spectrometer with argon as the collision gas

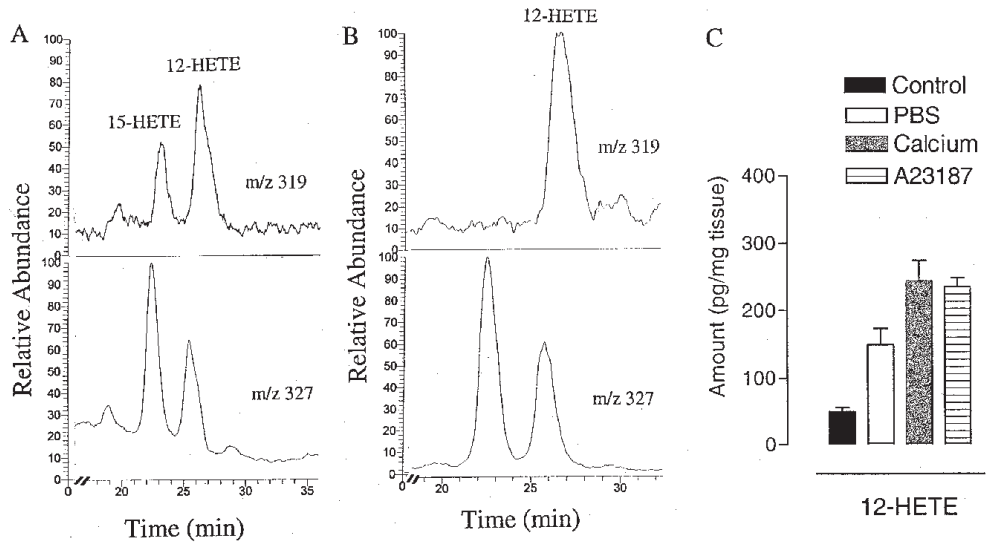


FIG. 5. LC–MS analysis of endogenous levels of 15-HETE and 12-HETE in bovine corneal epithelium. (A) The top trace shows the chromatogram of single ion monitoring of the carboxylate ions (*m/z* 319) of HETE in epithelial tissue from four corneas, whereas the bottom trace shows single ion monitoring of the carboxylate ions (*m/z* 327) of the internal standards, d_8-15-HETE and d_8-12-HETE. The deuterated standards elute ~1 min before the endogenous metabolites. (B) Analysis of HETE in epithelial cells from four bovine corneas, which were incubated in phosphate-buffered saline (PBS) for 20 min at 37°C before single ion monitoring as in A. (C) Amounts of 15-HETE and 12-HETE in epithelial cells from four corneas, which were placed in PBS for 20 min at 37°C in absence (n = 4) or presence of ~1 mM Ca^{2+} (n = 4) and 10 μM A-23187 (n = 3). Single ion monitoring as in (A). Data are presented as mean ± SD. See Figure 4 for abbreviations.

both yielded mass spectra with strong signals at *m/z* 317. The base peak of the 5-HPETE mass spectrum was *m/z* 59 ($H_2C{=}C(OH)O^-$, likely formed through a six-membered transition state from the dehydration product of 5-HPETE by cleavage between C-2 and C-3), whereas *m/z* 59 was much weaker in the 5-KETE mass spectrum (6). Although similar, the mass spectra of 5-HPETE and 5-KETE thus differed in a triple quadrupole instrument. A plausible explanation to the low intensity of the daughter ion at *m/z* 317 of 5-HPETE in the ion trap might be formation the daughter ion at *m/z* 59, which was below the mass range of the ion trap and could therefore not be detected.

In the second part, we measured and quantified the formation of LOX metabolites from exogenous AA in subcellular fractions of bovine corneal epithelial cells. 12-HPETE and 15-HPETE were not detected and were apparently efficiently reduced to 12-HETE and 15-HETE. Alternatively, 15-HPETE might be converted to 14,15-leukotrienes or related products (29). The biosynthesis of 12-HETE and 15-HETE by subcellular fractions appeared to be influenced by the calcium concentration in the cytosolic fraction and by the amount of protein in the microsomal assay. 15-HETE was the main product in the cytosol, and only small amounts of 12-HETE were formed. Addition of ~1 mM free Ca^{2+} augmented the biosynthesis of 15-HETE twofold. Effect of Ca^{2+} on LOX activity also has been reported in other broken cells (30–32). The microsomal fractions formed both 12-HETE and 15-HETE. 12-HETE was the main product at a high protein concentration, whereas 15-HETE was favored at low concentrations. These observations show that the experimental conditions must be standardized in order to assess pathological or physiological changes of LOX activity of broken cells. We used a fixed and relatively long incubation time. 15-LOX type 2 and 12-LOX of platelet type could be expected to be maintain a near linear rate for 30 min, whereas the rate 5-LOX and 12-LOX of the leukocyte type might decrease after a few minutes (33–35). There is also a marked intra-individual variation in LOX activity of bovine corneal epithelium (data not shown).

The endogenous levels of HETE were also determined in the epithelium. The rate-limiting step in LOX catalysis is likely release of AA from phospholipids (36). Phospholipases might be activated *post mortem* and the tissue levels we measured might not reflect the cellular levels of HETE under normal conditions. 12-HETE was the main LOX metabolite of endogenous AA. 15-HETE was undetectable or present in low amounts. This parallels findings in human leukocytes, where 15-LOX activity only could be detected following incubation with exogenous AA (37). 12-HETE increased 3–5 times after incubation of the cornea at 37°C, whereas 15-HETE now was undetectable. These findings were unexpected as 15-HETE was the main product from exogenous 3–100 μM AA by low-speed supernatant or cell homogenates. This suggests that incubation at 37°C makes AA available for 12-LOX. The concentration of endogenously released AA might be less than 3 μM. It is therefore conceivable that low concentrations of AA might be more efficiently oxidized by 12- rather than by 15-LOX. Indeed, 12-LOX of platelet type has a K_m of ~ 8 μM for AA (34), whereas the K_m of 15-LOX type 2 for AA is ~25 μM

(31). It will be of interest to determine whether the accumulation of 12-HETE can be explained by different kinetic properties of the bovine corneal LOX.

In summary, we have shown that the fragmentation of 5-HPETE differs from other HPETE during CID in the ion trap. 12-HETE is the main endogenous LOX product in bovine corneal epithelial cells, whereas 15-HETE is the main product from exogenous AA of crude cells homogenates. Our findings emphasize that corneal LOX of subcellular fractions should be studied under standardized conditions.

ABSTRACT: We applied a gas chromatography–mass spectrometry (GC–MS) method using dimethyl disulfide (DMDS) adducts and were able to determine the double-bond positions in monounsaturated 2-hydroxy fatty acids (2-HFA). 2-HFA methyl esters, prepared from the hydrolysate of *Arabidopsis thaliana* leaf glucosylceramides, were acetylated and methylthiolated. GC–MS analysis of the resulting DMDS adducts showed simple mass spectra with recognizable molecular ions and a series of key fragment ions indicating the original double-bond positions in the aliphatic chain. Based on this GC–MS elucidation, we confirmed that *Arabidopsis* leaf glucosylceramides have C_{22}, C_{23}, C_{24}, C_{25}, and C_{26} chain length 2-HFA with monounsaturation, and all their double bonds are placed at the n-9 position. This procedure is simple, time efficient, and highly sensitive.

Paper no. L8338 in *Lipids 35,* 233–236 (February 2000).

Locating the double-bond positions in monounsaturated 2-hydroxy fatty acids (2-HFA) of plant glucosylceramides (1,2) has been accomplished by using methods that employ ozonolysis (1) or OsO_4 oxidation (2). These methods, however, are complex, time consuming, and tedious, which might explain why in-depth studies on the structure of double-bond positions in these acids have been scarce, and the metabolic sequence for the biosynthesis of these monoenoic 2-HFA still remains unknown. Our simple gas chromatography–mass spectrometry (GC–MS) method with dimethyl disulfide (DMDS) adducts makes it possible to easily verify the double-bond positions in monounsaturated 2-HFA and will facilitate further research in this field.

MATERIALS AND METHODS

Plant materials. Seeds of *Arabidopsis thaliana* (L.) Heynh. ecotype Columbia were germinated in a soil mixture (Soil for Saintpaulia, Tosho Co., Yaizu, Japan) and grown for 8 wk under a 8/16 h light/dark cycle of at 23°C. Rosette leaves were harvested.

Lipid extraction. Fifty grams of the rosette leaves were steamed with boiling water for 3 min and homogenized with 150 mL of chloroform/methanol (1:2, vol/vol) in a homogenizer (Physcotron NS-50; Niti-on Irikaki, Funabashi, Japan) and filtered by suction through a sheet of filter paper. The resultant residue on the filter paper was homogenized again with 50 mL of chloroform and filtered again, as above. The filtrates were combined, and 50 mL of 0.9% (wt/vol) KCl in water was added. Total lipids were recovered in the lower phase, dried under reduced pressure, and dissolved in 1 mL of chloroform/methanol (2:1, vol/vol).

Purifying the glucosylceramides. The total lipids were subjected to mild alkaline hydrolysis, which removed the glycerolipids. After incubating for 1 h at 37°C with 4 mL of 0.4 M KOH in methanol, an alkaline preparation was neutralized with 150 μL of HCl and mixed with 80 mL of chloroform, 76 mL of methanol, and 40 mL of water. The alkaline-stable lipid fraction, including glucosylceramides, was then recovered in the lower phase. The lower phase was evaporated to dryness, dissolved in 0.5 mL of chloroform/methanol (2:1, vol/vol), and subjected to thin-layer chromatography (TLC) on precoated silica gel plates (Wakogel B-10; Wako Pure Chemical Industries, Osaka, Japan) using chloroform/methanol/water (65:16:2, by vol) as a solvent system. Spots of glucosylceramides contaminated with a small amount of steryl glycoside were scraped off the plate and acetylated with acetic anhydride in pyridine at room temperature overnight (3). These acetylated lipids were then separated by silica gel TLC using chloroform/benzene/acetone (8:2:1, by vol) as a developing system, and the acetyl esters of the glucosylceramides were scraped off the plates. The glucosylceramides reached satisfactory purity as determined by silica gel TLC.

Analyzing the 2-HFA. The glucosylceramides were methanolyzed with 3% (wt/vol) HCl (gaseous) in dry methanol at 100°C for 3 h. After adding water, the resultant total fatty acid methyl esters were extracted with *n*-hexane, dried under nitrogen, and separated into the 2-hydroxy and the non-HFA

Abbreviations: DMDS, dimethyl disulfide; GC–MS, gas chromatography–mass spectrometry; 2-HFA, 2-hydroxy fatty acid (Xh:Y, 2-hydroxy fatty acid containing X carbons with Y double bonds); TLC, thin-layer chromatography.

fractions by silica gel TLC using *n*-hexane/diethyl ether (17:3, vol/vol) as a mobile phase.

2-HFA methyl esters of the glucosylceramides were identified by GC–MS equipped with a mass data system (GCQ, Finnigan MAT Instruments, Austin, TX). The capillary column used was coated with dimethyl polysiloxane of 0.25 μm thickness (0.25 mm i.d. × 30 m; SPB-5, Supelco, Bellefonte, PA). The column temperature was programmed from 100°C (2 min hold) to 280°C at 10°C/min and maintained at 280°C for an additional 45 min. The mass spectra were measured under the following conditions: ion source temperature, 200°C; ionizing voltage, 70 eV; ionizing current, 250 μA; scanning rate, 1 s/cycle from 50 to 600 amu.

Preparing and analyzing DMDS adducts. An aliquot of the 2-HFA methyl esters of glucosylceramides was converted to *O*-acetyl derivatives as described by Renkonen (3). The *O*-acetylated methyl esters were subjected to I_2-catalyzed methylthiolation at 37°C for 30 min (4). After adding 1 mL of *n*-hexane/diethyl ether (1:1, vol/vol) with stirring, 10% (wt/vol) $Na_2S_2O_3$ of water solution was added with vigorous shaking until the color of I_2 disappeared. The mixture was allowed to stand for a few minutes, and the upper phase containing the resulting DMDS adducts was withdrawn, concentrated, and analyzed by GC–MS under the same conditions as mentioned in the preceding paragraph.

RESULTS AND DISCUSSION

Imai (5) had previously observed 13 kinds of 2-HFA in glucosylceramides from the leaves of *A. thaliana*. The 2-HFA profile is complex and clearly different from those of glucosylceramides from the leaves of Solanaceae (eggplant, tomato, etc.) and Leguminoseae (pea, white clover, etc.), which consist mostly of saturated 2-HFA (2). In that study (5), *Arabidopsis* 2-HFA had been identified using capillary GC, based on the coincidence of their retention times with those of the 2-HFA mixtures, which had been prepared from wheat leaf glucosylceramides (2), but we wanted more evidence to confirm the structure of *Arabidopsis* 2-HFA.

We once again prepared *Arabidopsis* 2-HFA methyl esters, and then, for this study, we analyzed them by GC–MS to ascertain the position of the hydroxyl group. Mass spectra taken at the mass chromatographic responses revealed characteristic fragment ions [$M^+ - 59$] resulting from the 1,2-cleavage and the loss of the methoxycarbonyl group (6). A typical mass spectrum of 2-HFA methyl ester from *Arabidopsis* leaf glucosylceramides is shown in Figure 1. The spectrum exhibits a molecular ion at *m/z* 368 and a characteristic peak at *m/z* 309 corresponding to the $M^+ - 59$ fragment. This indicates that the compound is a 2-hydroxy docosenoic acid methyl ester. By using a combination of capillary GC and GC–MS analysis, the other 12 kinds of the methyl esters were identified as saturated or monounsaturated 2-HFA.

To determine the double-bond positions in monounsaturated 2-HFA of *Arabidopsis* leaf glucosylceramides, a mixture of the 2-HFA methyl esters was *O*-acetylated and then methylthiolated. The resulting DMDS adducts were analyzed by GC–MS. Figure 2 shows the mass chromatogram in which five compounds (peaks 1 to 5) eluted.

Figure 3 shows the mass spectrum of the compound corresponding to peak 3 in Figure 2. A molecular ion at *m/z* 532 can be easily detected, identifying the adducts as methyl 2-*O*-acetyl bis(methylthio)tetracosanoate. Sets of fragment ions at *m/z* 173, 359, and 327 were produced from the cleavage be-

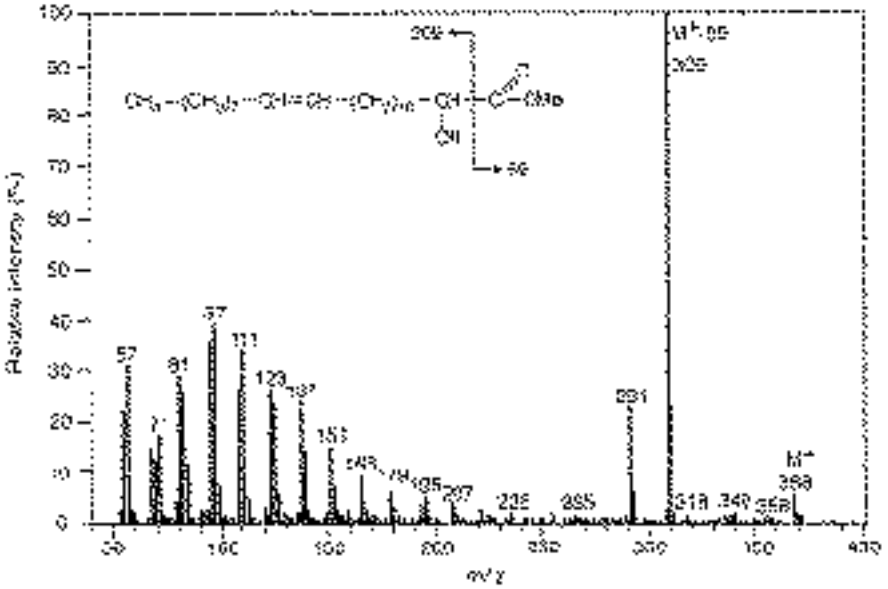

FIG. 1. Mass spectrum of one of 2-hydroxy fatty acid (2-HFA) methyl esters from *Arabidopsis* leaf glucosylceramides. The spectrum indicates the 2-hydroxy docosenoic acid (22h:1) methyl ester.

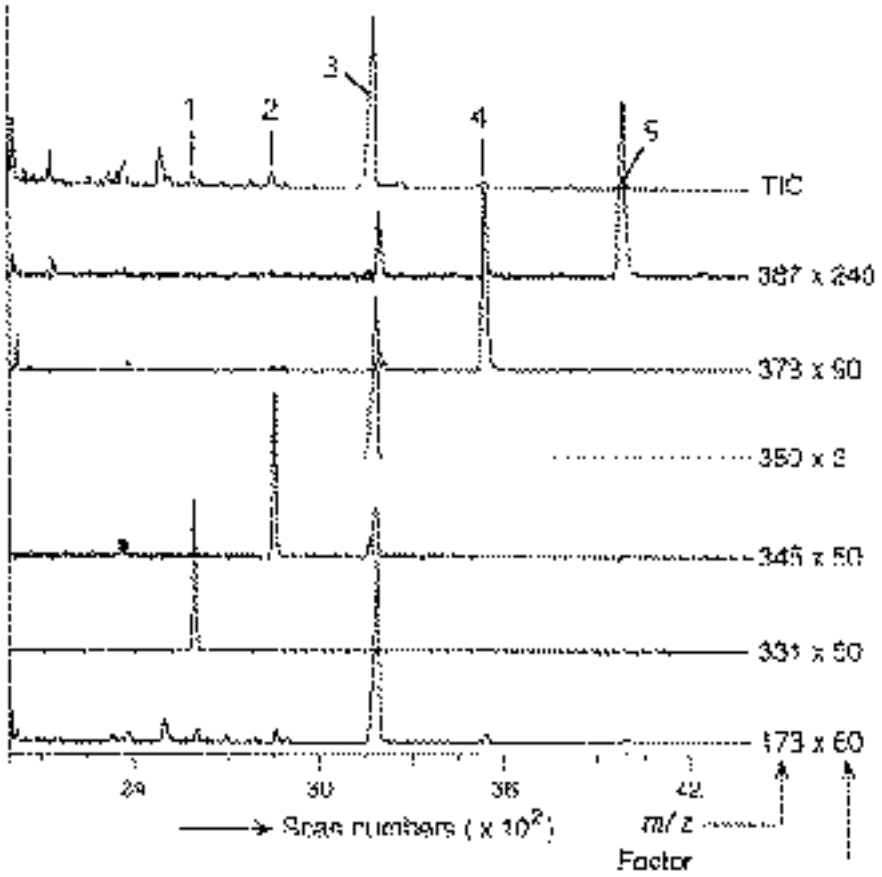

FIG. 2. Mass chromatogram of dimethyl disulfide adducts of 2-HFA *O*-acetyl methyl ester from *Arabidopsis* leaf glucosylceramides. (1) 22h:1; (2) 23h:1; (3) 24h:1; (4) 25h:1; (5) 26h:1. Gas chromatography–mass spectrometry conditions: ion source temperature, 200°C; ionizing voltage, 70 eV; ionizing current, 250 μA; scanning rate, 1 s/cycle from 50 to 600 amu. The other peaks not numbered in this figure are probably by-products from dimethyl disulfide adducts preparation. See Figure 1 for other abbreviation.

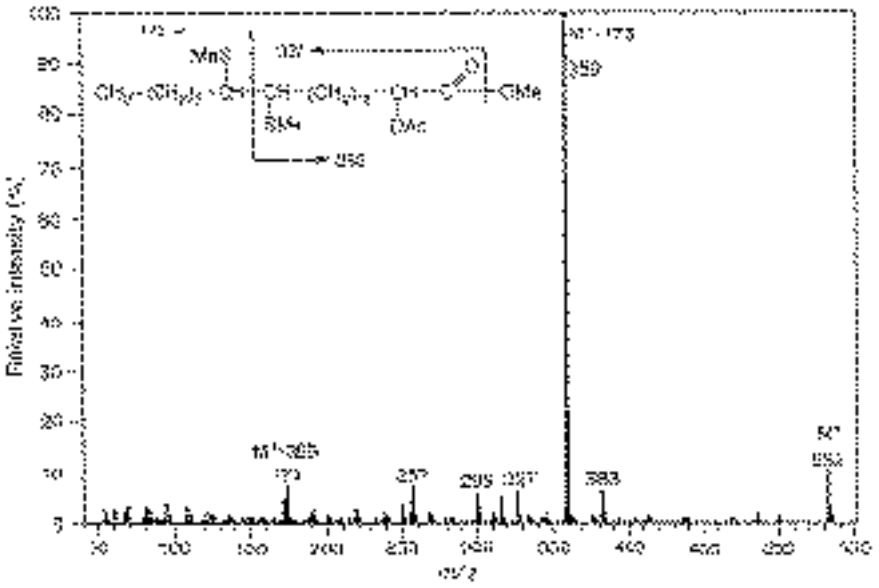

FIG. 3. Mass spectrum of dimethyl disulfide adducts of 2-HFA *O*-acetyl methyl ester from *Arabidopsis* leaf glucosylceramides. The spectrum is taken at peak 3 in Figure 2. The original acid is identified as 2-hydroxy-15-tetracosenoic acid (24h:1). See Figure 1 for abbreviation.

tween the methylthio-substituted carbons at C-15 and C-16. From these observations, the original acid was identified as 2-hydroxy-15-tetracosenoic acid.

The smaller peaks, 1, 2, 4, and 5 in Figure 2, also gave the key fragment ion at *m/z* 173 and the characteristic fragment ions [$M^+ - 173$] as the base peaks at *m/z* 331, 345, 373, and 387, respectively, indicating the presence of an n-9 series of monoenoates having C_{22}, C_{23}, C_{25}, and C_{26} chain lengths.

Based on this GC–MS elucidation, we confirmed that *Arabidopsis* leaf glucosylceramides have C_{22}, C_{23}, C_{24}, C_{25}, and C_{26} chain-length 2-HFA with monounsaturation, and all their double bonds are placed at the n-9 position.

We can easily prepare DMDS adducts of 2-HFA methyl esters. The yield of their adducts (over 90% of the original ester) is almost the same as that of the adducts of monoenoates without any hydroxyl groups (7). As a preliminary experiment, we analyzed the reaction products with DMDS and *O*-acetyl methyl ester of ricinoleic acid (12-hydroxy-9-octadecenoic acid), a major component in castor oil. The sets of ions resulting from the cleavage between the methylthio-substituted carbons, however, could not be identified. This may be due to steric hindrance; the distance between the double-bond position and the hydroxyl base may be important for the formation of the DMDS adducts of *O*-acetyl esters. Blocking the hydroxyl base (*O*-acetylated, in this study) is, however, necessary in electron impact ionization analysis of DMDS adducts.

Biosynthetic pathways for monounsaturated 2-HFA of plant glucosylceramides have not yet been verified. We speculate that the monounsaturated 2-HFA in glucosylceramides are formed either by elongation from an oleate moiety or by the action of an n-9 desaturase inserting a double bond relative to the methyl end of the acyl chain, because all the double bonds in monoenoic 2-HFA of *Arabidopsis* leaf glucosylceramides are at the n-9 position. Using a technique that combines three processes (stable isotopically labeled precursor preparation, DMDS adduct preparation, and GC–MS analysis), as Yamamoto *et al.* (4) discussed, will help in confirming the biosynthetic pathways for n-9 monounsaturated 2-HFA of plant glucosylceramides. Preliminary experiments are underway in our laboratories.

ACKNOWLEDGMENTS

We wish to thank Professor Masao Ohnishi (Obihiro University of Agriculture and Veterinary Medicine) for his helpful discussions. This work was supported, in part, by the Grant for Basic Science Research Project (970659) from The Sumitomo Foundation.

Chemistry, Biochemistry, and Function of Sterols

Presented at the 90th AOCS Annual Meeting & Expo in Orlando, Florida, May 1999

John D. Weete[a], Edward J. Parish[b], and W. David Nes[c]

Departments of [a]Biology, West Virginia University, Morgantown, West Virginia 28506, [b]Chemistry, Auburn University, Auburn, Alabama 36849, and [c]Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409

The first sterol symposium was held at the 1970 American Oil Chemists' Society Annual Meeting in New Orleans and was organized by Henry Kircher. Since that time, sterol symposia focusing on sterol structure, biosynthesis, chemistry, regulation, function, and other steroids and isoprenoids have been held regularly at AOCS annual meetings.

The 1999 Sterol Symposium, "Chemistry, Biochemistry, and Function of Sterols," held at the AOCS Annual Meeting in Orlando, Florida, was fittingly dedicated to Dr. George J. Schroepfer Jr. of Rice University in Houston, Texas. He was scheduled to be the keynote speaker, but unfortunately, Dr. Schroepfer passed away on December 11, 1998. Although this was to be his first sterol symposium, his contributions to the field of steroid chemistry and biochemistry have influenced many of the symposium participants as well as steroid researchers worldwide.

We would like to thank our corporate partners who gave generous financial support to help make the symposium a success: Steraloids, Inc., Pharmacia & Upjohn, and DuPont Pharmaceutical Co.

This symposium was sponsored by the biotechnology division of the AOCS. Speakers in the 1999 Sterol Symposium represented an international mix of senior and junior scientists, and students from six countries. We would like to express our appreciation to them for their cooperation during the planning process, and for their participation in the symposium. By all accounts, the symposium was a success, and we are looking forward to the next one.

In Remembrance

George J. Schroepfer Jr.

June 15, 1932–December 11, 1998

George J. Schroepfer Jr. was to have been the keynote speaker at the Steroid Symposium held at the 90th Annual Meeting of the AOCS in Orlando. His unexpected death represents a great loss to the community of scientists working in the field of sterols and sphingolipids.

The son of a distinguished professor of civil engineering, George was born in the midst of the Great Depression. The economic uncertainties and the influence of his family instilled in him a healthy dose of conservatism and skepticism that pervaded his life and his approach to science. Growing up in Minneapolis, Minnesota, George received an excellent education, due in no small part to the constant encouragement of his family. His parents suffered through his adolescent preoccupation with sports—basketball, tennis, football, speed skating, and hockey—and were relieved when George confronted the bitter reality that his athletic talents were not sought at the University of Minnesota.

Accepted into medical school after his junior year at Minnesota, George greatly enjoyed his medical studies. He showed a special gift for biomedical research and was encouraged to pursue advanced studies with Ivan D. Frantz after finishing an internship in internal medicine. George met many eminent scientists through Dr. Frantz, a profound experience for a young physician. After completing a Ph.D. in biochemistry with a minor in organic chemistry, George worked as a postdoctoral fellow with Sir John Cornforth and the late George Popjak to carry out a series of ingenious deuterium- and tritium-labeling studies that elucidated the stereospecificity of hydrogen transfer in the biosynthesis of squalene. During a subsequent postdoctoral year with Konrad Bloch, Schroepfer applied similar methods to delineate the stereospecific conversion of stearic acid to oleic acid and on to 10-hydroxystearic acid.

George returned to the University of Minnesota as an assistant professor, but was immediately recruited by the University of Illinois. By 1968, he had become director of the School of Basic Medical Sciences, an august title for a 36-year-old scientist. In 1972, George accepted an invitation from Rice University to establish a new department of biochemistry. His 13-year reign as a strong and dynamic chairman resulted in a flourishing department with a vigorous research program. In later years, he turned his attention from administrative responsibilities to concentrate on his expanding research program.

Much of George's research dealt with the biosynthesis of cholesterol, including 14α-demethylation, olefin migration from Δ^{14} to Δ^{5}, and alternative pathways of this migration. Another focus of his research was the role of oxysterols in the regulation of cholesterol metabolism and related processes, the subject of a monumental review completed just prior to his death. George developed painstakingly thorough methods for measuring oxysterol levels in blood and tissues and was often baffled by the slipshod methodology and implausible claims of many groups working in this area. He also oversaw the chemical synthesis of well over 100 oxysterols for use as standards and for study of their effects on the regulation of cholesterol homeostasis.

Perhaps the most important of these oxysterols was 3β-hydroxy-5α-cholest-8(14)-en-15-one. This 15-ketosterol and its various analogs were subjected to intensive investigations of their metabolism and biological activities. The 15-ketosterol markedly lowered serum cholesterol levels in nonhuman primates and simultaneously raised high-density lipoprotein cholesterol, effects that are generally considered desirable for the treatment and prevention of atherosclerosis. Although pharmaceutical development of the 15-ketosterol was terminated after phase I clinical trials, George continued to study the many intriguing properties of 15-ketosterols and their analogs until his death.

His laboratory always maintained strong synthetic capabilities, which ultimately led to a vast and diverse collection of sterols and sphingolipids. George routinely insisted on thorough characterization of virtually every sample, and this requirement contributed to the development of uncommon chromatographic and spectroscopic expertise in his laboratory. The combination of synthetic and analytical strengths led to definitive manuscripts on the analysis of oxysterols and unsaturated C_{27} sterols by gas chromatography, high-performance liquid chromatography (HPLC), mass spectrometry, and nuclear magnetic resonance. George also pioneered the application of silver ion HPLC to sterols and isoprenoids, with spectacular results for many separations that would otherwise be extremely difficult.

George was an enthusiastic and inspiring mentor, with a sharp mind and personal charm. He was a hard worker and expected the same of others, but his laboratory bore the mark of his infectious enthusiasm. Scores of postdoctoral scientists and graduate students matured scientifically under his tutelage. The experience of working with George left an indelible mark on each person, and most inherited his high scientific standards, learning to design and implement definitive experiments and to describe the protocols in precise detail. George's untimely death has left us with a large body of sound scientific knowledge in the field of sterols and sphingolipids. But more profoundly, he has given us an ideal to strive toward.

William K. Wilson

Biochemical Modifications and Transcriptional Alterations Attendant to Sterol Feeding in *Phytophthora parasitica*

W. David Dotson, Shirley R. Tove, and Leo W. Parks*

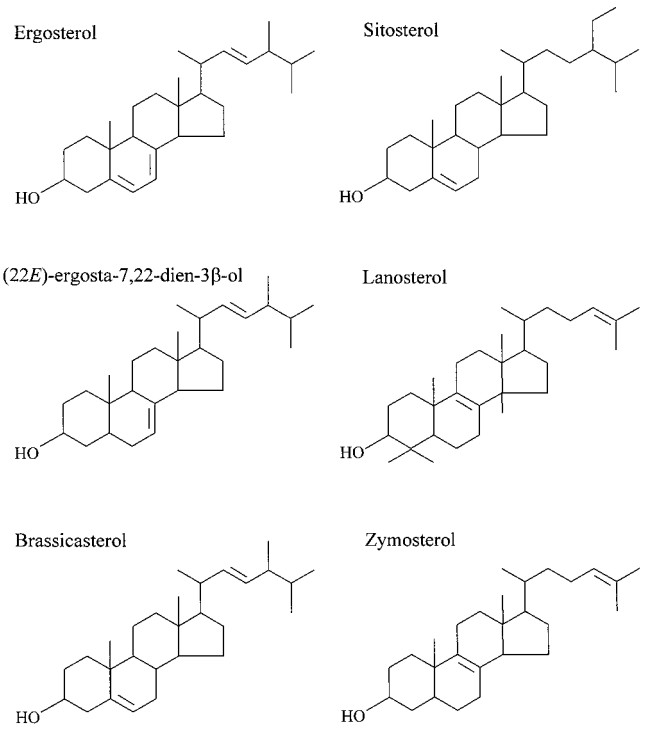
Department of Microbiology, North Carolina State University, Raleigh, North Carolina 27695-7615

ABSTRACT: *Phytophthora* species are eukaryotic sterol auxotrophs that possess the ability to grow, albeit poorly, in the complete absence of sterols. Growth of *Phytophthora* is often improved substantially when an exogenous source of sterol is provided. Additionally, sterols may be required for sexual and asexual sporulation in *Phytophthora*. Our research has been focused on identifying and characterizing the immediate physiological effects following sterol addition to cultures of *P. parasitica*. Through gas chromatographic analysis of extracts from *P. parasitica* cultures that were fed various sterols, we have obtained evidence for sterol C5 desaturase and Δ^7 reductase activities in this organism. Zoo blots were probed with DNA sequences encoding these enzymes, from *Saccharomyces cerevisiae* and *Arabidopsis thaliana*. Hybridization of a *S. cerevisiae ERG3* probe to *P. parasitica* DNA was observed, implicating sequence similarity between the sterol C5 desaturase encoding genes. Differential display experiments, using RNA from *P. parasitica,* have demonstrated a pattern of altered gene expression between cultures grown in the presence and absence of sitosterol. Characterization of sterol-related metabolic effects and sterol functions in *Phytophthora* should lead to improved measures for control of this important group of plant pathogens.

Paper no. L8273 in *Lipids 35,* 243–247 (March 2000).

Phytophthora species are eukaryotic pseudofungi, well known for their aggressive nature as plant pathogens. The type species, *P. infestans*, has been studied intensively since the Irish potato famine of the 19th century. Nevertheless, understanding the genetics and physiology of this genus has progressed slowly. Although many eukaryotes exist in nature as sterol auxotrophs, most require an exogenous sterol source in order to survive. *Phytophthora* species are sterol auxotrophs, however, they have the rare capacity to survive and even grow in the complete absence of sterols (1). When sterols are available, from a culture medium or a plant host, growth of *Phytophthora* is often greatly improved. It has been widely held that sterols are required for both sexual and asexual sporulation, although one recent study has indicated otherwise (2). Nevertheless, sterol metabolism may be a critical determinant of the success of *Phytophthora* as a pathogen. A protein secreted by *P. cryptogea,* which triggers a plant defense response, has recently been characterized as a sterol carrier protein (3). Differential expression of genes encoding 3-hydroxy-3-methylglutaryl coenzyme A, which may result in reduced levels of available sterol, has been demonstrated in plants inoculated with incompatible races of *P. infestans* (4). Clearly sterols must have broad and complex roles in the metabolism as well as in the pathogenicity of *Phytophthora*.

Sterols relevant to this study are illustrated in Scheme 1. Sitosterol (stigmast-5-en-3β-ol) is the predominant sterol form found in plants; ergosterol (22*E*-ergosta-5,7,22-trien-3β-ol) is the predominant sterol among higher fungi. Lanosterol (lanosta-8,24-dien-3β-ol) and zymosterol (5α-cholesta-8,24-dien-3β-ol) are relatively early intermediates in ergos-



SCHEME 1

Abbreviations: Brassicasterol, (22*E*)-ergosta-5,22-dien-3β-ol; DDRT-PCR, differential display reverse transcriptase polymerase chain reaction; ergosterol, (22*E*)-ergosta-5,7,22-trien-3β-ol; GC, gas chromatography; $HT_{11}VN$, modified oligo-dT anchored primers; lanosterol, lanosta-8,24-dien-3β-ol; PB, *Phytophthora* basal medium; RRT, relative retention time; sitosterol, stigmast-5-en-3β-ol; TLC, thin-layer chromatography; zymosterol, 5α-cholesta-8,24-dien-3β-ol.

terol biosynthesis, while (22*E*)-ergosta-7,22-dien-3β-ol is a later intermediate of the same pathway. Brassicasterol [(22*E*)-ergosta-5,22-dien-3β-ol] was recovered from *Phytophthora parasitica* cultures that were fed either ergosterol or (22*E*)-ergosta-7,22-dien-3β-ol.

In this study, we have used feeding experiments to investigate sterol metabolism in *P. parasitica*. Where enzymatic activities were found, DNA sequence similarities were sought in *Saccharomyces cerevisiae* and *Arabidopsis thaliana*. These model organisms are biochemically and genetically well characterized, and *S. cerevisiae* offers the further advantages of rapid growth and a completed genome sequence (5). Zoo blots, which are Southern blots done at reduced stringency to facilitate cross-species hybridization, were used as an indicator of possible sterol metabolic gene homologs. Finally, differential display reverse transcriptase polymerase chain reaction (DDRT-PCR) was used to investigate alterations in gene expression resulting from the addition of sterol to a culture. This technique employs sets of degenerate and arbitrary oligonucleotide primers, which allow amplification of sequence-specific subsets of an mRNA population (6,7). The gene expression profiles generated were compared for cultures that were treated identically except for the addition of sterol.

MATERIALS AND METHODS

Strains, media, and culture conditions. *Phytophthora parasitica* strain 5-3A was obtained as a gift from J.B. Ristaino (North Carolina State University, Raleigh, NC). Genotypes for the *S. cerevisiae* strains used were as follows: SY12A (**a** *erg3::LEU2 leu2 ura3-52 his4*) (8) and SY114 + pSN301 (**a** *LEU2 ura3-52 his3 trp1Δ1*; with p*ERG3-lacZ* fusion, integrated plasmid) (9). *Phytophthora* basal medium (PB) consisted of 1% sucrose and 0.67% yeast nitrogen base without amino acids, with 0.1% potassium phthalate (10) as a buffer (wt/vol). Sterols used in this study were obtained commercially (Sigma, St. Louis, MO). Exceptions were zymosterol and (22*E*)-5α-ergosta-7,22-dien-3β-ol, which were extracted from *S. cerevisiae* strains bearing *erg6* and *erg3* insertional inactivations, respectively, as indicated below. Sterols were dissolved in a solubilizing solution of Tergitol NP-40/ethanol (1:1, vol/vol) to give stock concentrations of 2.5 mg/mL. For supplemented cultures, the stock solutions were added to give a final sterol concentration of 10 mg/L. An equivalent volume of sterol-free solubilizing solution was added to nonsupplemented cultures, which were used as controls. Yeast strains were grown in YPD medium, which consisted of 2% D-glucose, 1% peptone, and 0.5% yeast extract (wt/vol). Both *P. parasitica* and *S. cerevisiae* were cultured in broth medium, with rotary shaking at 200 rpm. Incubation was at 24°C for *P. parasitica*, and at 30°C for *S. cerevisiae* cultures.

Sterol extraction and separation. Preparative and analytical sterol extractions were done by alkaline saponification (11). A Hewlett-Packard (Palo Alto, CA) model 5890 gas chromatograph was used for isothermal analysis of sterol extracts. The gas chromatograph was equipped with a 30 m × 0.32 mm i.d., 0.25 µm film thickness fused-silica capillary column (SPB-1; Supelco, Bellefonte, PA). Oven temperature was set at 235°C, injector and flame-ionization detector were at 280°C. Samples were dissolved in chloroform preceding injection, and cholesterol was added as an internal control. Identity and purity of preparative sterol extracts were further analyzed by thin-layer chromatography (TLC) on 20 × 20 cm silica gel plates ($60F_{254}$; EM Separation Labs, Gibbstown, NJ) in cyclohexane/ethyl acetate (85:15, vol/vol). Ultraviolet quenching of the fractions was ascertained before developing the chromatograms in a spray of 3% phosphomolybdic acid in ethanol (wt/vol) followed by heating.

Nucleic acid blotting and hybridization. Phenol/choroform (1:1, vol/vol) extraction followed by ethanol precipitation was used to prepare genomic DNA from *P. parasitica* (12) and *S. cerevisiae* cultures (13). Restriction enzymes, used in all DNA manipulations, were obtained commercially (New England Biolabs, Beverly, MA), and all digests were carried out under the conditions recommended by the manufacturer. Electrophoresis and immobilization of DNA onto nylon membranes (Genescreen; NEN, Boston, MA) were done according to accepted protocols (14). A radiolabeled DNA probe corresponding to the yeast *ERG3* gene was prepared by random priming (High Prime; Roche Molecular Biochemicals, Mannheim, Germany) a 2.2-kb *Hin*dIII fragment of pSN318 (8) with α^{32}P-dCTP (NEN). Another probe, corresponding to the yeast *ERG5* gene, was prepared as above except a 2-kb *Kpn*I-*Bam*HI fragment from pFLY105 (15) served as the template. A probe, corresponding to the *A. thaliana ST7R* (16) coding region, was obtained by standard PCR amplification (PE 2400 thermocycler; PerkinElmer, Norwalk, CT) of this sequence from a cDNA library (13). The ST7R product was subcloned into a pGEM-T vector (Promega, Madison, WI) and sequenced (DNA Sequencing Facility, Iowa State University, Ames, IA) to ensure PCR fidelity. A 0.8-kb *Pvu*I-*Spe*I fragment from the ST7R-pGEM-T construct was radiolabeled as described above. Membrane hybridizations were done under standard Southern blotting conditions (14), except the temperature was decreased incrementally within a 65–30°C range for different blots. Following hybridization, all blots were washed twice in a solution of 300 mM NaCl, 30 mM trisodium citrate (pH 7.0), and 0.1% (wt/vol) sodium dodecyl sulfate. Each wash was done for 30 min, at 25°C to reduce hybrid stringency. Autoradiograms were developed following 24-h exposure to X-ray film with no intensifying screens.

DDRT-PCR. *Phytophthora parasitica* cultures were grown in PB with no sterol supplementation. Each culture was subsequently divided equally by volume into two separate flasks, with sitosterol added to one flask and an equal volume of sterol-free solubilizing solution added to the other flask. After 2.5 h of further incubation, the cultures were harvested by vacuum filtration. Mycelia were then frozen under liquid nitrogen and ground thoroughly in sterilized mortars. Total RNA was extracted from each homogenate using hot acidic phenol (9). RNA quality and yield were assessed spectrophotometrically using ratios of A_{260}/A_{280}, and by agarose gel

electrophoresis. DDRT-PCR was done using enzymes and primers obtained commercially as a kit (RNAimage; GenHunter, Nashville, TN). Reverse transcription and PCR followed the protocol of the manufacturer. Briefly, first strand cDNA was synthesized from equal amounts of RNA using Maloney murine leukemia virus reverse transcriptase and modified oligo-dT anchored primers (designated $HT_{11}VN$ by the manufacturer). $HT_{11}VN$ primers consisted of 11 central dT residues, flanked by a 5′ terminal *Hin*dIII recognition sequence and two degenerate nucleotides at the 3′ terminus. Equal amounts of cDNA were used as template for PCR amplification and radiolabeling with α^{35}S-dATP. Arbitrary 16-mer primers (designated HAP by the manufacturer), which also included the 5′ terminal *Hin*dIII recognition sequence, were used along with the original $HT_{11}VN$ primer for PCR. Ten reactions were done, with different combinations of the arbitrary and $HT_{11}VN$ primers. Equal volumes of the PCR products were electrophoresed on a 6% polyacrylamide sequencing gel. After drying, the gel was placed on X-ray film for 48 h and an autoradiogram developed.

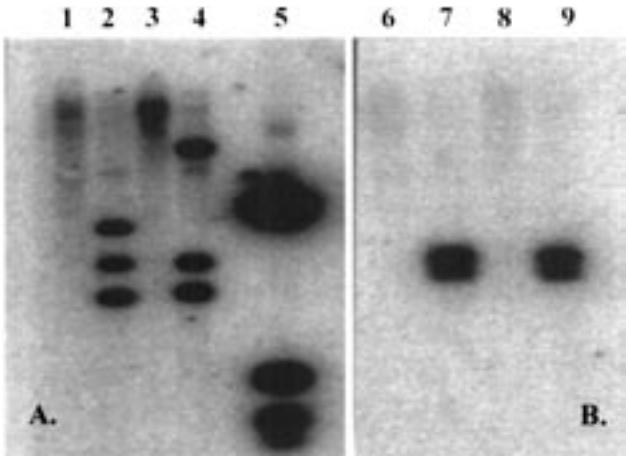

FIG. 1. Autoradiogram of Zoo blots hybridized at 45°C. (A) *ERG3* probe and (B) *ERG5* probe are shown. Lanes: (1) *Phytophthora parasitica* (*Eco*RI, *Bam*HI, *Hin*dIII), (2) *Saccharomyces cerevisiae* (*Eco*RI, *Bam*HI, *Hin*dIII), (3) *P. parasitica* (*Eco*RI, *Hin*dIII), (4) *S. cerevisiae* (*Eco*RI, *Hin*dIII), (5) Kb DNA ladder, (6) *P. parasitica* (*Eco*RI, *Bam*HI, *Hin*dIII), (7) *S. cerevisiae* (*Eco*RI, *Bam*HI, *Hin*dIII), (8) *P. parasitica* (*Eco*RI, *Hin*dIII), (9) *S. cerevisiae* (*Eco*RI, *Hin*dIII).

RESULTS AND DISCUSSION

In this study, we have sought to determine the immediate effects of sterol on the metabolism of *P. parasitica*. A field isolate of *P. parasitica* was used in this work. This strain was chosen based on the impressive magnitude of growth difference between cultures incubated in the presence and absence of sterols. Based on qualitative observations of the growth of this strain in PB medium, we estimate a two- to tenfold increase in mycelial mass following 1 wk of sterol supplementation. Feeding experiments involved the addition of individual sterols to cultures of *P. parasitica*. The cultures were then incubated for 8 d, harvested, and sterols were extracted. Extracts from each culture were analyzed by gas chromatography (GC). Transformation of the proffered sterol was determined based on retention time relative (RRT) to an internal cholesterol standard (Table 1). In extracts from cultures fed zymosterol, lanosterol, or sitosterol, the major GC peaks were observed at the same RRT as found for the respective pure sterols. The major peaks observed from cultures fed ergosterol and (22*E*)-5α-ergosta-7,22-dien-3β-ol occurred at an RRT of 1.11, which corresponded to neither of the pure sterols that were fed. Based on expected RRT values (17,18), we presume this compound to be brassicasterol. In order for these transformations to occur, *P. parasitica* must possess enzymes with sterol C5 desaturase and Δ^7 reductase activities. These results are consistent with activities demonstrated previously in *P. cactorum* (19).

We have sought to extend our biochemical evidence for these activities by investigating possible similarities between C5 desaturases in *S. cerevisiae* and *P. parasitica* at the DNA level. Following autoradiography of Zoo blots, bands were observed in *P. parasitica* genomic DNA lanes that had been probed with *ERG3* (Fig. 1). This binding of the *ERG3* probe was observed following separate hybridizations at 37 and 45°C, but not at 55 or 65°C (Table 2). The bands were present in similar positions for hybridizations at 37 and 45°C (data not shown).

Since no side-chain alterations were observed for any of the sterols fed to *P. parasitica*, we have used the yeast gene encoding a C22 desaturase (*ERG5*) as a control for stringency. No hybridization of the *ERG5* probe to *P. parasitica* DNA was observed over the same temperature range as used for *ERG3* above. Hybridization of the *ERG3* and *ERG5* probes to *S. cerevisiae* genomic DNA was observed at all temperatures tested.

TABLE 2
Zoo Blot Results

		Hybridization temperature (°C)[a]			
Probe	DNA tested	65	55	45	37
ERG3	*Saccharomyces cerevisiae*	+	+	+	+
ERG3	*Phytophthora parasitica*	–	–	+	+
ERG5	*S. cerevisiae*	+	+	+	+
ERG5	*P. parasitica*	–	–	–	–

[a]+ indicates band observed following hybridization at the specified temperature; – indicates no band observed following hybridization at the specified temperature.

Repeated hybridizations of the *ERG3* probe to *P. parasitica* DNA under conditions where *ERG5* failed to hybridize indicated that the stringency levels used were sufficient for this experiment. When considered along with the feeding experiments, these data suggest that the gene encoding the *P. parasitica* C5 desaturase may have considerable sequence similarity with the *ERG3* gene of *S. cerevisiae*. Attempts to alter the gel mobility of the *P. parasitica* DNA fragment that bound the *ERG3* probe by varying the restriction enzymes used were not successful. However, this may simply be due to the lack of a *Bam*HI recognition sequence in the *Phytophthora* DNA fragment.

Since *S. cerevisiae* does not exhibit Δ^7 reductase activity, the *A. thaliana* gene encoding this enzyme was employed as a probe. The predicted protein sequence encoded by *ST7R* displays a high degree of similarity with lamin B receptors and sterol reductases found in other organisms, including the *ERG24* gene product of *S. cerevisiae* (14). Surprisingly, the *ST7R* cDNA probe showed no significant hybridization with either *P. parasitica* or *S. cerevisiae* genomic DNA (at 30, 37, and 45°C; data not shown). One possible explanation is that the *P. parasitica* gene encoding a Δ^7 reductase may be dissimilar to any of those characterized to date in other organisms. This would not be unprecedented, since even a gene as generally conserved as that encoding actin has been shown to be divergent in certain species of *Phytophthora* (15,16). The results of this study have allowed us to predict low similarity between the *P. parasitica* Δ^7 reductase gene and *A. thaliana ST7R*.

DDRT-PCR results indicate a number of genes are differentially regulated following addition of sitosterol to *P. parasitica* cultures. Ten experiments were performed using different combinations of the arbitrary and anchored primers. The results from two of these experiments are shown (Fig. 2). Electrophoresis was done with DDRT-PCR products from *P. parasitica* cultures with and without added sitosterol in adjacent gel lanes, to facilitate comparison. The majority of bands corresponding to cDNA species that co-migrated were found to be of similar intensities. However, for every primer pair tested, some co-migrating bands of different intensity were observed between the two culture conditions. Because the culture conditions were otherwise identical, it is reasonable to conclude that differential expression of these genes resulted from the brief period of sterol supplementation. Examples of enhanced, as well as reduced, gene expression were observed to result from sitosterol feeding. While differential accumulation of the displayed transcripts has not yet been confirmed by other methods, the expression profile generated will provide targets for selective characterization of genes involved in sterol related functions. The sterol mediated differential gene expression implied by these experiments supports predictions of broad ranging physiological roles for sterols in *Phytophthora*.

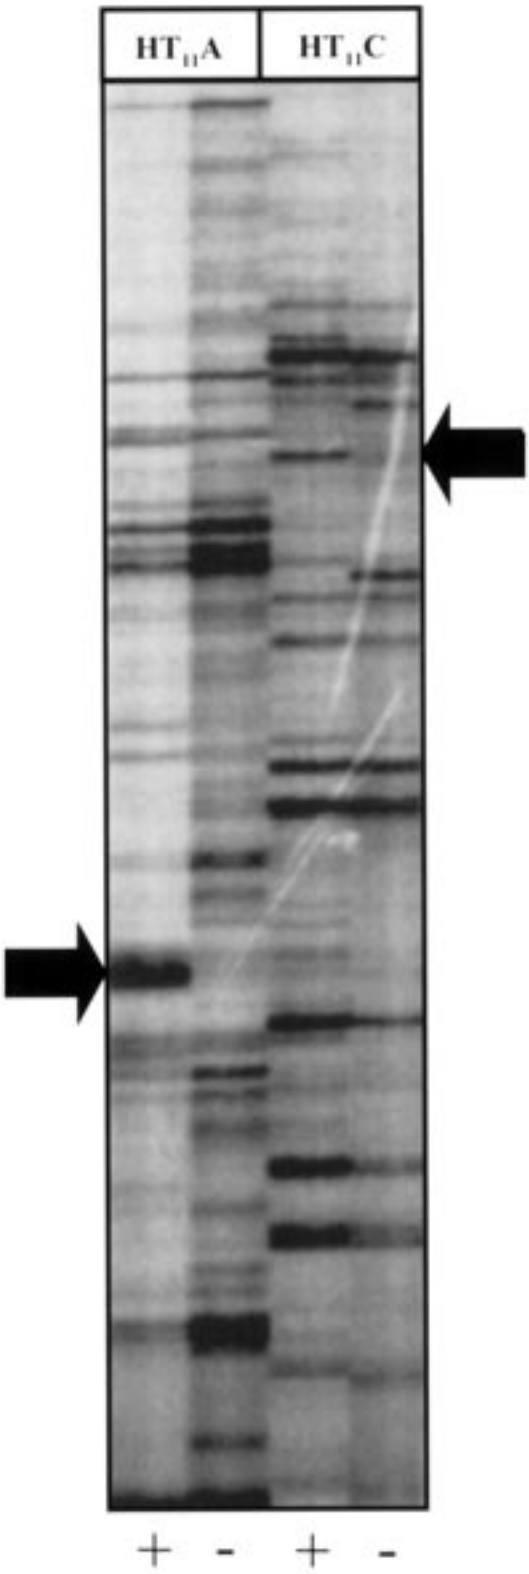

FIG. 2. Autoradiogram of a differential display reverse transcriptase polymerase chain reaction gel. Primers used for reverse transcription are shown above the lanes. Cultures supplemented with sitosterol (+) and nonsupplemented cultures (–) are indicated below the lanes. Arrows indicate bands where increased expression following sterol addition was observed.

ABSTRACT: Cycloartenol synthase converts oxidosqualene to cycloartenol, the first carbocyclic intermediate en route to sterols in plants and many protists. Presented here is the first cycloartenol synthase gene identified from a protist, the cellular slime mold *Dictyostelium discoideum*. The cDNA encodes an 81-kDa predicted protein 50–52% identical to known higher plant cycloartenol synthases and 40–49% identical to known lanosterol synthases from fungi and mammals. The encoded protein expressed in transgenic *Saccharomyces cerevisiae* converted synthetic oxidosqualene to cycloartenol *in vitro*. This product was characterized by ^{1}H and ^{13}C nuclear magnetic resonance and gas chromatography–mass spectrometry. The predicted protein sequence diverges sufficiently from the known cycloartenol synthase sequences to dramatically reduce the number of residues that are candidates for the catalytic difference between cycloartenol and lanosterol formation.

Paper no. L8307 in *Lipids 35*, 249–255 (March 2000).

The oxidosqualene cyclases are a family of enzymes that convert 2,3-(*S*)-oxidosqualene to more than 80 different cyclic triterpenes (1–3). The best-studied oxidosqualene cyclases are lanosterol synthase (4), which forms the first carbocyclic sterol precursor in animals and fungi, and cycloartenol synthase (5), which forms an isomeric sterol precursor in plants and many protists (6). Both of these enzymes cyclize oxidosqualene to the protosteryl cation and then to the lanosteryl cation (Fig. 1). These enzymes differ by abstracting alternative protons from the common intermediate to make distinct products.

We are studying how oxidosqualene cyclases catalyze these cyclization, rearrangement, and deprotonation reactions. Of particular interest is determining how two different oxidosqualene cyclases direct the formation of distinct products. Mutating conserved residues is now a classical method for identifying catalytic motifs, and residues that are apparently important in protonating oxidosqualene have been identified by mutating residues conserved in all oxidosqualene cyclases (7). A similar approach could uncover residues that promote specific deprotonation, but residues conserved in all oxidosqualene cyclases would not be good candidates. Residues that function in deprotonation to lanosterol should be conserved in all lanosterol synthases, but not in cycloartenol synthases, and vice versa. The best candidate positions for mutagenesis are those where lanosterol synthases conserve one residue, but cycloartenol synthases conserve a different one. The known lanosterol synthases (8–16) represent a sufficiently diverse array from both the animal and fungal kingdoms that relatively few positions (187/721 or 26%) are conserved. The known cycloartenol synthases (17–20) are all from dicots and are closely related (544/756 residues or 72% are conserved). The similarity of the known cycloartenol synthases makes the positions that are differently conserved in lanosterol synthases and cycloartenol synthases too numerous to be efficiently investigated by site-directed mutagenesis. Obtaining one or more cycloartenol synthases from organisms far diverged from plants should significantly reduce the number of differently conserved residues, possibly to a number that would be reasonably addressed by site-directed mutagenesis.

We report the cloning of a cycloartenol synthase complementary DNA (cDNA) from the slime mold *Dictyostelium discoideum*. The encoded protein cyclized oxidosqualene to cycloartenol following heterologous expression and is only ~50% identical to the previously reported cycloartenol synthases from plants.

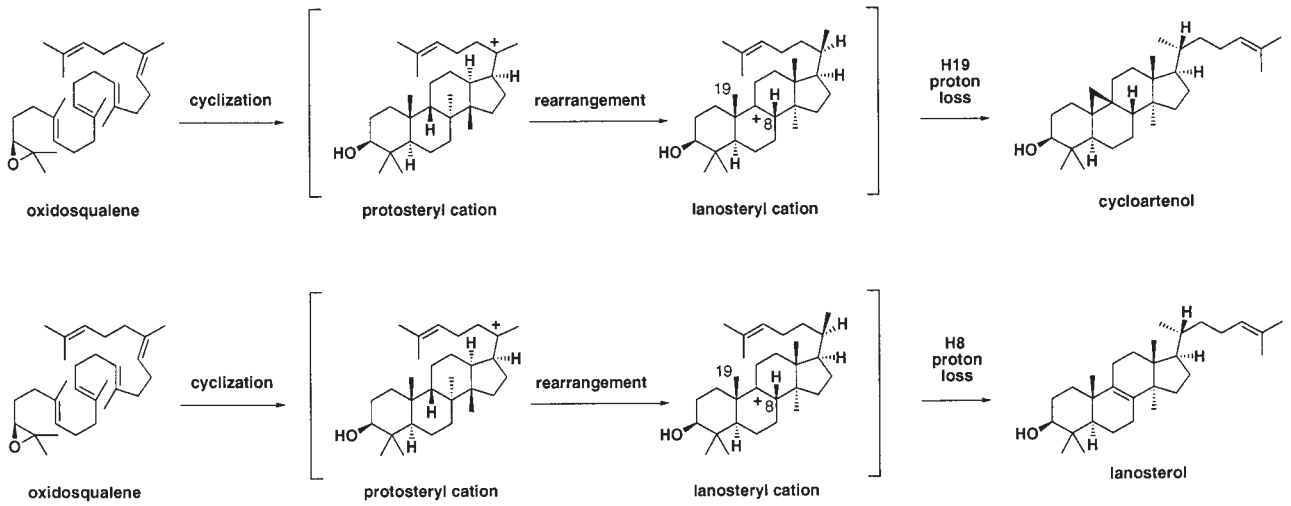

FIG. 1. Mechanism of cycloartenol synthase and lanosterol synthase. Cycloartenol synthase protonates oxidosqualene, cyclizes to the chair-boat-chair protosteryl cation, rearranges to the lanosteryl cation, and abstracts a proton from C19 to form cycloartenol. Lanosterol synthase catalyzes the same protonation, cyclization, and rearrangement, but abstracts a proton from C8 to form lanosterol.

EXPERIMENTAL PROCEDURES

Strains, media, molecular biological methods. Escherichia coli strain DH5α was the host for DNA manipulation, and transformants were maintained on Luria broth + 100 μg/mL ampicillin (21). The *D. discoideum* cycloartenol synthase was expressed in the *Saccharomyces cerevisiae* lanosterol synthase mutant SMY8 (*MAT***a** *erg7::HIS3 hem1::TRP1 ura3-52 trp1-Δ63 leu2-3,112 his3-Δ200 ade2* Gal^+) (16). Nontransformed yeast was grown in YPDHET (1% yeast extract, 2% peptone, 2% glucose, 13 mg/L heme, 20 mg/L ergosterol, and 0.5% Tween 80) (16), and yeast transformants were selected and grown in synthetic complete medium (21) lacking uracil and supplemented with 13 mg/L heme, 20 mg/L ergosterol, and 0.5% Tween 80 with 2% glucose for nonexpressing growth (SC-UHET + glu) or 2% galactose for expression (SC-UHET + gal). Restriction enzymes were purchased from New England Biolabs (Beverly, MA). Molecular biological manipulation followed established techniques (21).

Cloning a D. discoideum *oxidosqualene cyclase cDNA fragment.* A partial cDNA homologous to oxidosqualene cyclases was cloned serendipitously while screening for sequences encoding a cytoskeletal protein. The lambda Zap II cDNA library used (generously provided by Dr. Richard Firtel) was made from cells isolated between 8 and 12 h of development. The library was screened by hybridizing a radiolabeled probe at 65°C in phosphate buffer (250 mM NaH_2PO_4, 250 mM NaCl, 10% wt/vol polyethylene glycol (PEG) 8000, 1 mM EDTA, pH 7.2) as described (22). *In vivo* subcloning of the cDNA insert was performed according to the vector manufacturer's instructions (Stratagene). The plasmid was used to transform DH5α and sequenced using the Applied Biosystems International Automated Sequencer and the dye primer method. An alignment with other oxidosqualene cyclase sequences indicated that the cDNA encoded a nearly complete fragment of an oxidosqualene cyclase that was missing <100 bp from the 5′ end.

Obtaining the 5′ end of the D. discoideum *oxidosqualene cyclase cDNA.* A reverse primer (GGTACCTAAATCACATCCTTCTGGAC) complementary to the internal sequenced portion of the gene was designed. A polymerase chain reaction (PCR; 40 cycles of 30 s at 95°C, 30 s at 56°C, and 3 min at 72°C) using this primer and forward primer lac (from the library vector) amplified an appropriately sized DNA fragment. The nested reverse primer AATGTGTTCCTGGTTCTTTT (5′ of the original gene-specific primer) was designed and used with the lac forward primer to reamplify the DNA from the previous PCR reaction. The PCR product was polished (Perfectly Blunt Cloning Kit, Novagen), ligated to pBluescript II KS(+) linearized with *Eco*R V, and used to transform *E. coli.* The construct was sequenced and confirmed to contain the 5′ missing portion of the cDNA. This sequence was used to PCR-amplify the 5′ end with appropriate sites to reconstruct the full-length cDNA. Two gene-specific primers (TTCTCGAGAGCTCAATTTCACACAGGAAACAGG and GGGGATCCAATGTCTTCCTGGTTCTTTT) were used to PCR-amplify library DNA (using the same conditions as before) with the high-fidelity enzyme *Pfu*. The PCR product was subcloned as above to make pML3.9, which was sequenced with the original amplification primers. The amplified DNA had two base mutations, but neither altered the encoded amino acid sequence.

Reconstructing the D. discoideum *oxidosqualene cyclase cDNA.* The full-length *D. discoideum* oxidosqualene cyclase cDNA (GenBank accession number AF159949) was reconstructed using *Sca* I as follows. The *Kpn* I/*Sac* I fragment of the original cDNA was subcloned into pBluescript KS(+) cut with the same enzymes to give pML3.7. Both pML3.7 and pML3.9 contain *Sca* I sites in their oxidosqualene cyclase cDNA and

their β-lactamase gene, so both plasmids were bisected upon *Sca* I digestion. The 3.3 kilobase pair (kbp) band from the pML3.7 digest (containing the 2.2 kbp 3′ end of the cDNA and 1.1 kbp of the plasmid) and the 2 kbp band from the pML3.9 digest (containing the 200 bp 5′ end of the cDNA and 1.8 kbp of the plasmid) were ligated to one another and transformed into *E. coli*. Ampicillin-resistant transformants contained plasmids that assembled to reconstruct both the oxidosqualene cyclase cDNA and the β-lactamase gene in the plasmid. The resultant plasmid encodes the reconstructed *D. discoideum* oxidosqualene cyclase fused to the N-terminal peptide MNSSRFTR initiated by an ATG in the vector. A *Xho* I site 5 bp 3′ of the vector ATG was conveniently used to excise the false initiation site and allow translation initiation at an ATG within the *D. discoideum* sequence by subcloning a *Xho* I fragment into the *Sal* I site of the high-copy yeast expression plasmid pRS426GAL.

Yeast transformation, enzyme expression, and product characterization. A yeast expression subclone was created by ligating a 2.5 kbp *Sac* I/*Sal* I fragment containing the reconstructed fusion protein to pRS426GAL cut with the same two enzymes. The *erg7 hem1 S. cerevisiae* strain SMY8 (16) was transformed with plasmid DNA at 25°C overnight with 10 μg purified plasmid DNA, 500 μg single-stranded salmon sperm DNA, pelleted cells from a 5-mL SMY8 culture grown to saturation in sterile YPDHET, and 2 mL yeast transformation buffer (40% PEG 3350, 0.1 M lithium acetate, 10 mM Tris pH 7.5, 1 mM EDTA, 0.1 M dithiothreitol). Cells were allowed to recover at 25°C for 24 h in 2 mL YPDHET, and transformants were selected on (SC-UHET+glu) plates.

A 1-L culture grown to saturation in SC-UHET+glu was used to inoculate 5 L (SC-UHET+gal). After shaking for 48 h at 30°C, cells were pelleted, suspended as a 40% slurry in 0.1 M potassium phosphate buffer at pH 6.4, and lysed using a French press at 20,000 psi. After diluting the homogenate with 1 vol of the same buffer, racemic oxidosqualene was added to 0.2 mg/mL from a 20 mg/mL stock in 20% Triton X-100. The reaction continued for 24 h at 25°C, when thin-layer chromatography (TLC) with methylene chloride indicated that the cyclization had gone nearly to completion.

The reaction was quenched with 4 vol of ethanol and centrifuged to remove precipitated proteins. The supernatant was dried by rotary evaporation, and the resulting oil was dissolved in ethyl acetate. The solution was vacuum-filtered through a Celite-covered frit, dried with magnesium sulfate, and rotary evaporated. Ethyl ether and 230–400 mesh silica were added to the resulting oil. The slurry was passed through a dry silica plug, triterpenes were eluted with ethyl ether, and the combined extracts were rotary evaporated.

The triterpene alcohol (which comigrated with cycloartenol on TLC using methylene chloride) was purified by two silica columns. The first eluted with a gradient from 3 to 15% ethyl ether in hexane, and the second was run isocratically using 15% ether in hexane. The purified product was acetylated with excess triethylamine and acetic anhydride and catalytic dimethylaminopyridine, and the triterpene acetates were purified by two silica columns, the first using methylene chloride and the second 3% ether in hexane. The purified triterpenes were fully characterized by gas chromatography/mass spectrometry (GC/MS) and nuclear magnetic resonance (NMR; 500 MHz spectrometer; 25 mM solution in $CDCl_3$; 25°C). The clone lacking the fusion peptide was transformed and expressed similarly, and provided triterpenes that were examined by GC and GC/MS as the acetates.

RESULTS AND DISCUSSION

A search for cycloartenol synthases distantly related to dicot cycloartenol synthases should focus on the protists. Protists diverged early in the course of eukaryotic evolution, and many protists share with higher plants a cycloartenol-based sterol biosynthetic pathway. Protists that make sterol from cycloartenol include *Ochromonas malhamensis* (23), *Euglena gracilis* (24,25), *Acanthamoeba polyphaga* (26), *Naegleria lovaniensis* (27), *N. gruberi* (27), and *D. discoideum* (28). Finding cycloartenol biosynthesis in *N. lovaniensis*, *N. gruberi*, and *D. discoideum* was particularly interesting because it suggested that these amoebas are more closely related to plants than to fungi or animals.

It seemed advisable to pursue the gene from *D. discoideum* because it is a widely studied model organism, and both genetic information and libraries are available. While efforts were underway to clone the *D. discoideum* cycloartenol synthase by sequence homology, we serendipitously discovered a 3′ fragment of the corresponding cDNA during a search for an unrelated gene. The 5′ end was obtained by anchored PCR, and an appropriately sized cDNA fused to a short vector-derived sequence was reconstructed from the two fragments. This fusion was used for large-scale expression and NMR characterization. The derivative lacking the fusion peptide was later expressed, and was shown by GC and GC/MS to have equivalent catalytic properties. The *D. discoideum* sequence encoded a 81 kDa predicted protein 50–52% identical to known higher plant cycloartenol synthases and 40–49% identical to known lanosterol synthases from fungi and mammals (Fig. 2).

The reconstructed cDNA was subcloned into the yeast expression vector pRS426GAL (see Experimental Procedures section) and used to transform the yeast lanosterol synthase mutant SMY8 (16), which lacks oxidosqualene cyclase activity to complicate the analysis. A homogenate of SMY8 expressing the *D. discoideum* cDNA cyclized oxidosqualene to a compound that comigrated with cycloartenol on TLC. This triterpene alcohol was acetylated and was analyzed by GC–flame-ionization detection and GC/MS. Only two components have the appropriate mass for a triterpenyl acetate. The major component (99%) coeluted with cycloartenyl acetate at 36 min and displayed fragmentation patterns consistent with that compound. A minor component (1%) coeluted with parkeyl acetate at 35 min and has the appropriate mass for a triterpenyl acetate. Insufficient minor compound was available to separate and characterize as a pure sample. ^{1}H NMR of the acetylated product indicated a major (~90%) component with

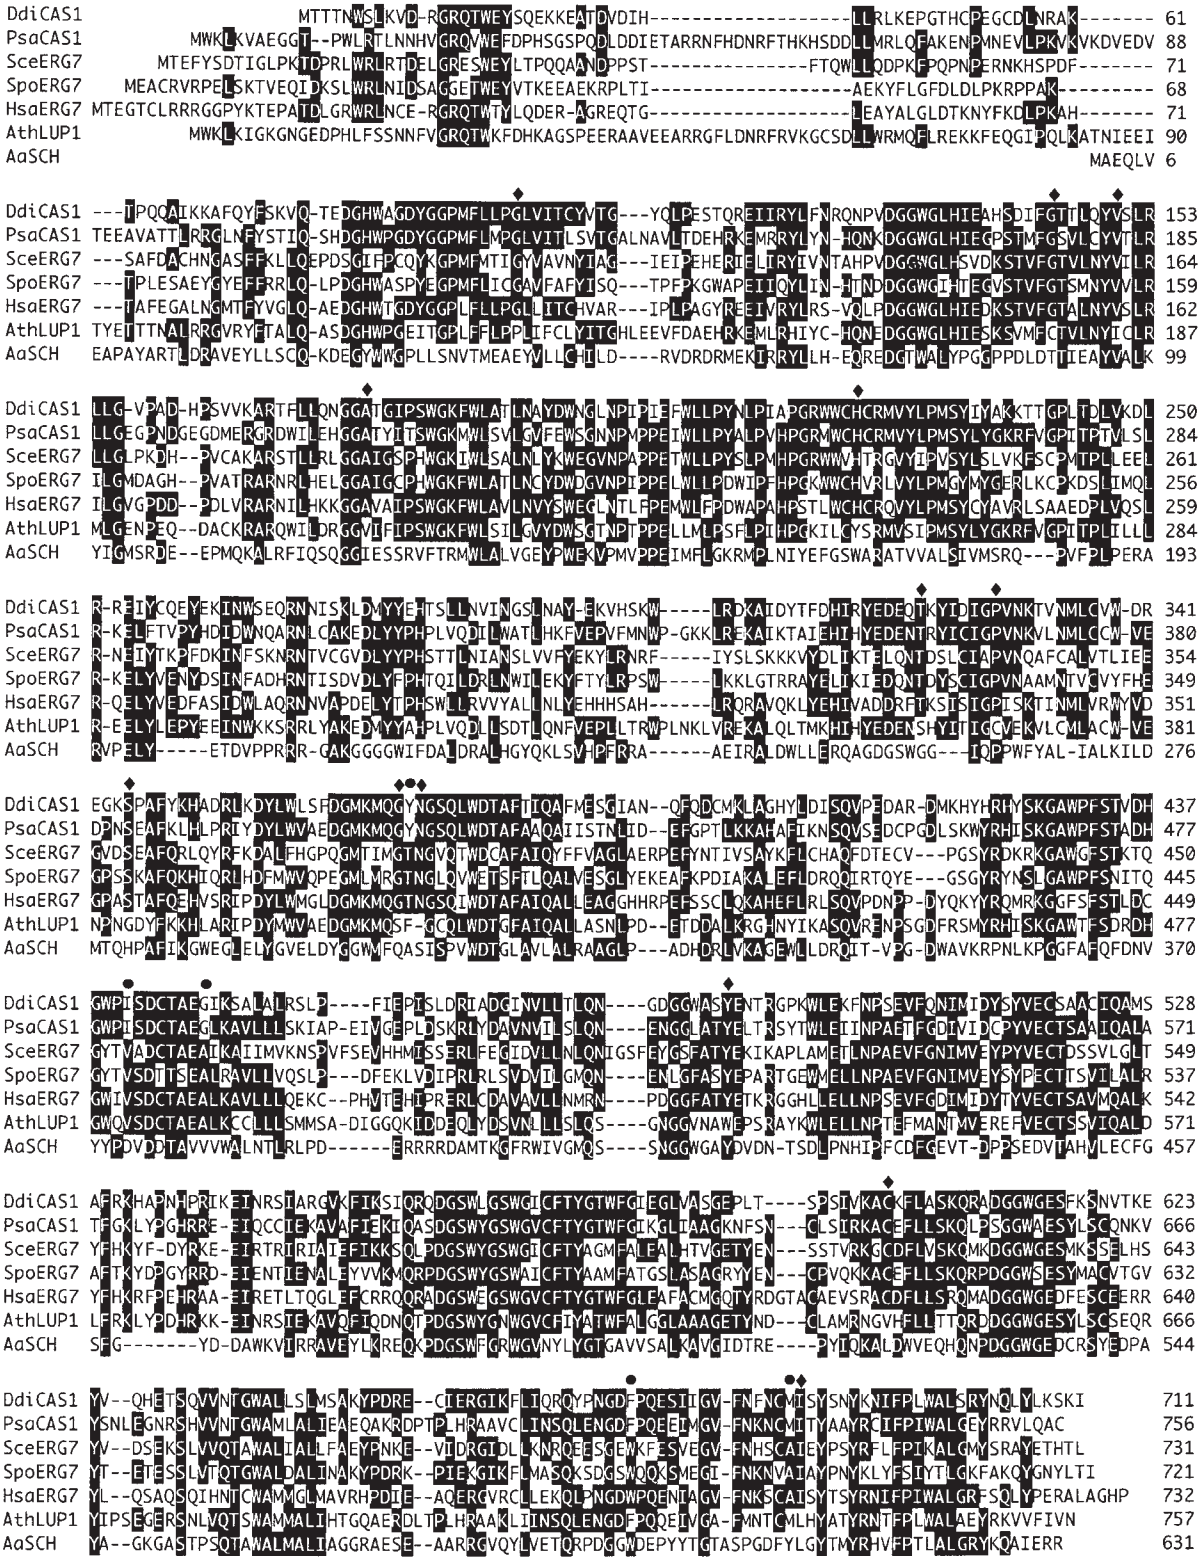

FIG. 2. Alignment of selected oxidosqualene cyclases with squalene-hopene cyclase. The *Dictyostelium discoideum* (DdiCAS1) and *Pisum sativum* (PsaCAS1) cycloartenol synthases (18), *Saccharomyces cerevisiae* (SceERG7), *Schizosaccharomyces pombe* (SpoERG7), and *Homo sapiens* (HsERG7) lanosterol synthases (10,11,14–16), *Arabidopsis thaliana* lupeol synthase (AthLUP1) (35), and *Alicyclobacillus acidocaldarius* squalene-hopene cyclase (AaSHC) (36) are aligned. Dashes indicate gaps introduced to maximize the alignment. Even using this restricted data set, only five residues (marked with a circle) are conserved as one residue in lanosterol synthases, but as a different residue in cycloartenol synthases. The 13 residues marked with a diamond are conserved as one residue in all enzymes with protosteryl intermediates (lanosterol synthase and cycloartenol synthase), and as a different residue in enzymes with dammarenyl intermediates (lupeol synthase and β-amyrin synthase).

signals essentially identical to those obtained from an authentic sample of cycloartenyl acetate: cyclopropyl δ_H 0.340 (*d*, 4.2 Hz), 0.576 (*d*, 4.2 Hz) and methyl δ_H 0.847 (*s*), 0.883 (*s*), 0.889 (*d*, 6 Hz), 0.894 (*s*), 0.960 (*s*), 1.606 (*dq*, 1.4, 0.6 Hz), 1.685 (*q*, 1.3 Hz). These signals agreed with literature values for the free alcohol (29). The ^{13}C NMR chemical shifts (δ_C 15.13, 17.63, 17.96, 18.22, 19.26, 20.12, 20.91, 21.33, 24.93, 25.41, 25.72, 25.80, 25.94, 26.48, 26.79, 28.12, 29.76, 31.59, 32.83, 35.52, 35.87, 36.33, 39.43, 45.26, 47.16, 47.81, 48.79, 52.24, 80.68, 125.24, 130.89, 171.00) were within 0.2 ppm of those reported for cycloartenyl acetate (30). ^1H NMR and heteronuclear single quantum coherence spectra of the acetylated product also revealed various minor 4α-methyl and $\Delta^{24(28)}$ sterols and a 1% component with resolved signals matching NMR data (±0.001 ppm for ^1H, ±0.1 ppm for ^{13}C) for a parkeyl acetate standard (31): δ_H 5.228 (*dt*, 6, 2 Hz, H-11), 4.484 (*dd*, 11.7, 4.2 Hz, H-3α), 1.068 (*s*, H-19; correlated to δ_C 22.3), 0.736 (*s*, 14α-Me; correlated to δ_C 18.5), 0.644 (*s*, H-18; correlated to δ_C 33.6). Despite the difficulty of identifying a trace component definitively, the GC and NMR data strongly suggest that this 1% component is parkeyl acetate. The 4α-methyl and $\Delta^{24(28)}$ sterols are structurally inconsistent with being direct oxidosqualene cyclization products and are probably metabolites of cycloartenol produced *in vivo.*

The origin of the parkeol is uncertain, but is probably not nonenzymatic degradation of cycloartenol during the reaction or workup. Cycloartenol can be isomerized to parkeol using acid (32), but the reaction requires extreme conditions (10% H_2SO_4 in isopropanol, 80°C, 24 h) and produces the by-products lanosterol and cucurbitadienol, neither of which appears in the enzymatic reaction. Yeast has been reported to metabolize cycloartenol to $\Delta^{9(11)}$ sterols (33), and some or all of the parkeol may result from the native yeast enzymes metabolizing the cycloartenol biosynthesized *in vitro*. Some may be a cycloartenol synthase by-product produced by inaccurate deprotonation. The contribution from each process will be most rigorously determined by purifying the enzyme to remove isomerase activity and for assaying parkeol synthase activity.

Comparing the *D. discoideum* cycloartenol synthase sequence with other oxidosqualene cyclases is informative. Analysis of oxidosqualene cyclase sequences has revealed shared features, including conserved aspartate and histidine residues shown to be catalytically essential (7), multiple QW motifs that may absorb thermal energy released upon cyclization (34,35), and an abundance of aromatic amino acids (8). Many of these amino acids are presumably conserved by chance, but some are probably catalytically essential. The conserved amino acid pool should include both the catalytic elements of the active site and components that maintain the correct structure of the active enzyme. Comparing oxidosqualene cyclases that are highly diverged from one another restricts the number of amino acids that are conserved due to chance.

Amino acids that are conserved among all oxidosqualene cyclases may perform a function common to these enzymes (maintaining the structure of the enzyme, protonating the epoxide, or forming the A-ring). When the *D. discoideum* cycloartenol synthase is aligned (Clustal W) with the known oxidosqualene cyclases (8–20,36), the number of conserved residues decreases to 95 (amino acid positions described here use the *S. cerevisiae* numbering system). These are G27, W31, Q88, G93, G101, P102, F104, E127, D140, G141, G142, W143, G144, H146, S151, F154, Y160, R164, L166, G167, G186, W194, G195, K196, W198, L199, L202, W207, G209, N211, E216, P221, P225, P228, R236, P241, Y244, R262, E264, Y288, H291, I338, F361, R367, D370, G378, M379, G386, Q388, W390, F394, Q397, Q425, R436, G441, F445, S446, G451, D456, E460, E511, E520, N523, P524, E526, E539, C540, F551, Q577, D580, G581, S582, W583, G585, W587, C590, Y593, F597, G606, F621, L622, G630, G631, W632, E634, Y644, W657, A658, L662, Q684, G688, G697, F699, Y707, and L719.

The likelihood that these residues are catalytic can be probed further by estimating their position within the protein. Some of them align with active-site residues in the 21–26% identical *Alicyclobacillus acidocaldarius* squalene-hopene cyclase (AaSHC) (37), which has been structurally characterized by X-ray diffraction (38,39). *Saccharomyces cerevisiae* lanosterol synthase (ScERG7) residues W194, W390, D456, W587, and Y593 clearly align with AaSHC residues F129, W312, D376, W489, and Y495, respectively. These SHC active-site residues are within 8 Å (measured using the Rasmol program) of the ligand in the 2 Å resolution *A. acidocaldarius* crystal structure. Mutagenic studies have already shown that ScERG7 residue D456 (7) and AaSHC residues W312 (40), D376 (41), and W489 (42) are catalytically important. A comprehensive list of conserved residues that map to the active site could not be compiled because the enzyme sequences did not align reliably.

The *D. discoideum* oxidosqualene cyclase sequence is particularly useful for identifying positions that contribute to the catalytic distinction between oxidosqualene cyclase classes. The early divergence of *D. discoideum* from plants makes its cycloartenol synthase only distantly related to the plant cycloartenol synthases. The plant cycloartenol synthases have 544 conserved residues, but including the *D. discoideum* sequence decreases the number to 312. The number of amino acid residues that have conservation patterns consistent with performing catalytic functions that differ between cycloartenol synthase and lanosterol synthase is reduced correspondingly. Positions where the identity of the residue correlates with product structure (such as where one residue is conserved in all cycloartenol synthases, but a different residue is conserved in all lanosterol synthases) may be active site components that control product structure. Twenty-three residues show this conservation pattern in the previously known cycloartenol and lanosterol synthases, but as shown in Figure 2, only five residues are similarly conserved when the *D. discoideum* cycloartenol synthase sequence is included (T384, V454, A461, W690, and A704 in the *S. cerevisiae* numbering system).

The first two residues are apparently closest to the active site and are consequently excellent candidates for the catalytic residues that cause the difference between cycloartenol synthase and lanosterol synthase. T384 aligns with either AaSHC

A306 or AaSHC S307, and V454 aligns with AaSHC D374. These SHC residues are within 5 Å (measured using the Rasmol program) of the ligand. A704 aligns with either AaSHC F605 or Y606, and both residues are <8 Å from the ligand. A461 aligns with AaSHC V381 (11 Å from the ligand), and W690 aligns with AaSHC W591 (20 Å from the ligand). These lanosterol synthase residues have conservation patterns consistent with a deprotonation-specific role, and several seem sufficiently near the ligand to participate in catalysis. It should be noted that residue conservation might result from coincidence rather than shared function. Furthermore, if either of two similar residues (e.g., aspartate or glutamate) can perform the same role, conservation may not be strict. Finally, this analysis will not reveal positions that have a catalytic role in one enzyme class but not in another.

Candidate residues for forming the intermediate protosteryl or dammarenyl cations can be identified similarly. Cycloartenol synthase and lanosterol synthase cyclize initially to the protosteryl cation, whereas lupeol synthase and β-amyrin cyclize to the dammarenyl cation (Fig. 3). The *D. discoideum* cycloartenol synthase is so far diverged from the plant cycloartenol synthases that the *A. thaliana* and *D. discoideum* cycloartenol synthases share fewer conserved residues (50%) than do the *A. thaliana* cycloartenol synthase and lupeol synthase (59%). This sequence divergence greatly decreases the pool of residues that are likely candidates for forming the protosteryl and dammarenyl cations. The 13 residues marked with a diamond in Figure 2 are conserved as one residue in both lanosterol synthase and cycloartenol synthase (which cyclize initially to the protosteryl cation), but are conserved as a different residue in β-amyrin synthase and lupeol synthase (which produce pentacyclic triterpenes *via* the dammarenyl cation). This conservation pattern is consistent with a role in forming the protosteryl or dammarenyl cations.

ScERG7 residues H234, T333, Y510, and I705 align with AaSHC residues W169, G259, Y420, and L607. ScERG7 G383 aligns with either AaSHC Q305 or A306, and ScERG7 N385 aligns with either residue AaSHC S307 or I308. All of these SHC residues map to within 8 Å of the ligand, making the corresponding oxidosqualene cyclase residues attractive candidates for directing dammarenyl or protosteryl cation formation. Mutating either ScERG7 H234 (7) or AaSHC Y420 (41) to alanine alters catalysis. Two differentially conserved ScERG7 residues seem too distant from the active site to participate directly in catalysis. ScERG7 residue V161 aligns unambiguously with AaSHC V96 (26 Å from the ligand), and A188 aligns with AaSHC I123 (18 Å from the ligand). Residues G108, G155, P340, S358, and C619 did not align reliably. Site-directed mutagenesis experiments are underway to determine whether the residues at these positions perform important functions in enzymatic oxidosqualene cyclization.

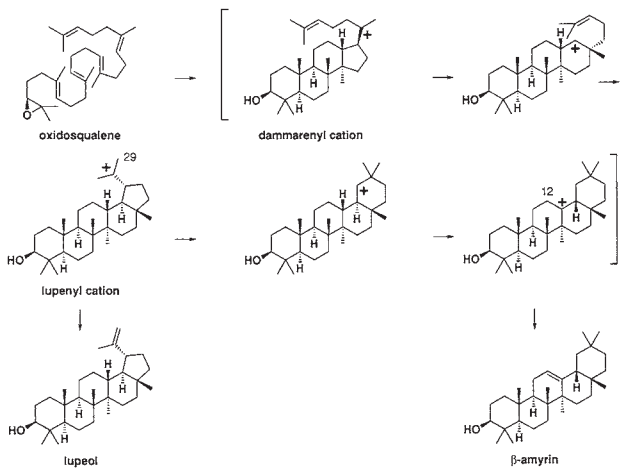

FIG. 3. Mechanisms of lupeol synthase and β-amyrin synthase. Lupeol synthase cyclizes oxidosqualene to the chair-chair-chair dammarenyl cation, catalyzes ring expansion and cyclization to the lupenyl cation, and deprotonates primarily at C29 to form lupeol. Substantial amounts of isomeric triterpenes (including β-amyrin) are also produced. β-Amyrin synthase promotes the same lupenyl cation formation, but terminates the reaction by ring expansion followed by deprotonation at C12.

ABSTRACT: The *ERG25* gene encoding the *Candida albicans* C-4 sterol methyl oxidase was cloned and sequenced by complementing a *Saccharomyces cerevisiae erg25* mutant with a *C. albicans* genomic library. The Erg25p is comprised of 308 amino acids and shows 65 and 38% homology to the enzymes from *S. cerevisiae* and *Homo sapiens*, respectively. The protein contains three histidine clusters common to nonheme iron-binding enzymes and an endoplasmic reticulum retrieval signal as do the proteins from *S. cerevisiae* and humans. A temperature-sensitive (ts) conditional lethal mutation of the *C. albicans ERG25* was isolated and expressed in *S. cerevisiae*. Sequence analysis of the ts mutant indicated an amino acid substitution within the region of the protein encompassed by the histidine clusters involved in iron binding. Results indicate that plasmid-borne conditional lethal mutants of target genes have potential use in the rescue of *Candida* mutations in genes that are essential for viability.

Paper no. L8270 in *Lipids 35,* 257–262 (March 2000).

The ergosterol biosynthetic pathway in fungi remains the target of the major classes of antifungal compounds currently employed to treat human infections. The recent, dramatic increase in reports of resistance (1) to these compounds has mandated a continued search for new antifungal target sites against which novel compounds can be developed and employed. Of particular concern is the rapidly emerging resistance to the azole antifungals, which are now the most widely employed antifungals in systemic, life-threatening infections. Most of the basic research in defining the ergosterol biosynthetic pathway and in determining the types of sterol molecules that support fungal growth has been conducted in *Saccharomyces cerevisiae* (2,3). This organism is readily amenable to genetic analysis, and the availability of haploid strains has made the isolation and characterization of ergosterol biosynthetic genes possible. At this time, all the genes encoding sterol biosynthetic enzymes in this organism have been cloned and disrupted with the exception of one of the genes involved in the complex series of reactions responsible for removing the two methyl groups from the C-4 position of the sterol molecule. All genes prior to the sterol methyl transferase (*ERG6*) gene are essential for viability and thus represent possible new targets for the discovery of novel antifungal compounds.

The use of S. *cerevisiae* as a model system for gene isolation and the determination of essential pathway steps is a useful tool in making similar determinations in pathogenic fungi such as *Candida albicans*, where haploid strains and sexual reproduction are not found. The complementation of *S. cerevisiae* sterol mutants with a *C. albicans* genomic library to isolate sterol genes in *C. albicans* is a first step in verifying gene essentiality in this organism and the suitability of that step for seeking inhibitors that might serve as antifungal agents. This approach has recently been used to clone and disrupt the *ERG6* gene of *C. albicans* (4). Although the *ERG6* gene is not essential in *S. cerevisiae*, its disruption results in a cell that is severely compromised in several functions associated with membrane permeability (5,6). The disruption of both copies of the *ERG6* gene in *C. albicans* likewise does not render the cell inviable but does make it hypersusceptible to a number of antifungal compounds and cellular inhibitors (4).

The final step in fungal sterol biosynthesis to be explored at the molecular level in *S. cerevisiae* is the multicomponent reaction which sequentially removes the two methyl groups from the C-4 position. Three enzymes are required, and the genes of two of these, the C-4 methyl oxidase gene (*ERG25*) and the C-3 sterol dehydrogenase (C-4 decarboxylase) gene (*ERG26*), have been isolated and characterized (7,8). Disruptions of *ERG25* and *ERG26* have been found to be lethal (7,8). Here we report the cloning and sequencing of the C-4 sterol methyl oxidase gene from *C. albicans* achieved by the complementation of an *S. cerevisiae erg25* mutant with a *C. albicans* library. Disruption of both copies of an essential sterol gene in *C. albicans*, however, is problematic since this organism will not take up exogenous sterol to allow viability

Abbreviations: *ERG25,* C-4 methyl oxidase gene; *ERG26,* C-3 sterol dehydrogenase; GC, gas chromatography; plasmid pCERG25, the original complementing clone of 4kb in the *Candida albicans* shuttle vector YPB1; SD, synthetic dropout; ts, temperature-sensitive.

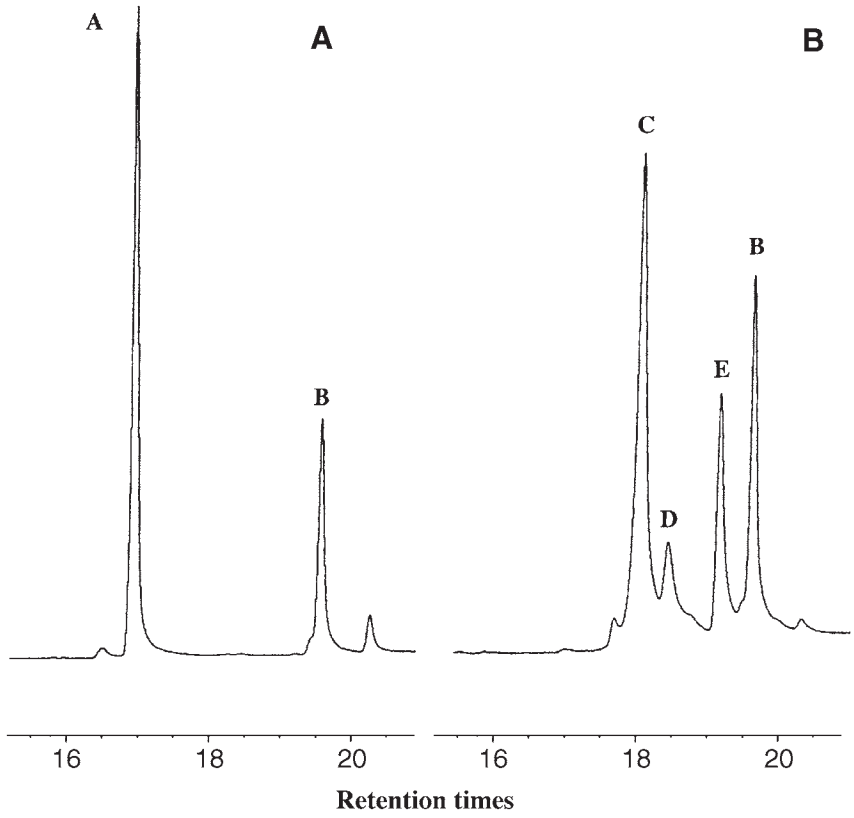

FIG. 1. Sterol profiles of *Saccharomyces cerevisiae* strain *erg25-25C* (A) and the same strain containing the *Candida albicans ERG25* on plasmid pIU873 (*erg25*/pCERG25) (B). Sterol extraction was carried out as described previously (Ref. 5). Peak A: cholesterol; peak B: 4,4-dimethyl zymosterol; peak C: ergosterol; peak D: fecosterol; peak E: 4-methyl fecosterol.

in order to verify that the double disruption has taken place. As a possible means to circumvent this situation, the *C. albicans ERG25* gene has been used to create a conditional lethal *ERG25* mutation which can be expressed on autonomous plasmids in *S. cerevisiae* to rescue *erg25* mutations under permissive conditions but not under nonpermissive conditions.

MATERIALS AND METHODS

Strains and plasmids. The *S. cerevisiae erg25* strain used in this study has been previously described (7). The *C. albicans* strain CAI8 (*ade2::hisG/ade2::hisG,* Δ*ura3::imm434/*Δ*ura3::imm434*) was a gift from William Fonzi, Georgetown University, and has been previously described (9). Plasmid pCERG25, the original complementing clone of 4 kb in the *C. albicans* shuttle vector YPB1, was isolated from a *C. albicans* genomic library obtained from Stew Scherer, University of Minnesota. The pIU870 contains the 2.5 kb *BglII-BamHI C. albicans ERG25* gene subcloned from pCERG25 into pRS316 at the *BamHI* site. The pIU908 is identical to pIU870 but with a temperature-sensitive (ts) conditional lethal mutation in *ERG25*. The pIU873 contains the 3.7 kb *XbaI-SalI C. albicans ERG25* gene subcloned from pCERG25 into pRS316 at the *XbaI-SalI* sites. *Escherichia coli* strain DH5α was used to manipulate and maintain all the plasmids used in this study.

Growth conditions. Sterol auxotrophs were grown anaerobically on complete medium supplemented with 1% ergosterol at 30°C. *Candida* strains were grown in complete or SD (synthetic dropout) media supplemented with 100 μg/mL uridine. Temperature shift growth conditions were as follows: duplicate cultures were grown to early log phase (OD_{660} = 0.4) at the permissive temperature in complete or SD media at which time one set of the cells was shifted to the nonpermissive temperature (38.5°C) and the second set remained at 30°C. Both sets were incubated for 24 h prior to sterol analysis.

Transformation. Saccharomyces cerevisiae transformations were carried out with the high-efficiency lithium acetate procedure previously described (10). *Escherichia coli* transformations were carried out by standard methods.

Mutagenesis. Conditional lethal mutations were isolated following mutagenesis of plasmid pIU870 carrying the *ERG25* gene. The pIU870 was transformed into *E. coli* strain XL1-Red (11), a strain that is deficient in three genes employed in DNA repair and has a mutation rate about 5,000 times higher than that in wild-type strains. Following 8 h of growth in XL1-Red, the plasmid DNA was isolated and transformed into *S. cerevisiae erg25*-25C. Transformants were plated at 30°C followed by replica plating on the same medium but incubated at 38.5°C. Colonies not growing at 38.5°C were screened to make certain that the ts mutation was

FIG. 2. The base and amino acid sequences of the *ERG25* gene from *Candida albicans*.

in the *ERG25* gene and not in the selectable *URA3* gene. The mutant strain carrying the plasmid with the ts *ERG25* (pIU908) was designated *erg25*-25C/pIU908 or ts. A control strain carrying a plasmid with the wild-type *ERG25* gene (pIU870) was designated *erg25*-25C/pIU870 or wild-type.

Sequencing. Sequencing was performed with the Sequenase 2.0 dideoxy-sequencing kit and [^{35}S-dATP] purchased from Amersham (Arlington Heights, IL).

Sterol analysis. Sterol extraction and preliminary gas chromatography (GC) sterol analyses were carried out as described previously (7). GC separation and mass spectral (MS) analyses were done with a 5890 Hewlett-Packard GC (Palo Alto, CA) coupled to a Hewlett-Packard 5972 mass selective detector. All data analyses were performed with the Hewlett-Packard Chemstation software. GC separations of sterols were obtained on a J&W Scientific DB-5MS column (20 m × 0.18 mm) (Folsom, CA) with a film thickness of 0.18 µm. Injections were programmed in the splitless mode with an inlet temperature of 280°C. Helium was used as the carrier gas with a linear velocity of 30 cm/s. The oven was programmed to hold the initial temperature of 100°C for 1 min and then increased to 300°C at 10°C per min. The oven temperature was held at 300°C for an additional 15 min. The interface temperature of 280°C resulted in a detector temperature of 180°C. Mass spectra were generated in the electron impact mode at an electron energy of 70 eV. The instrument was programmed to scan from 40 to 700 amu at 1-s intervals.

RESULTS AND DISCUSSION

The *ERG25* gene from *S. cerevisiae* has been cloned and characterized in our lab (7). The Erg25p is an essential enzyme that

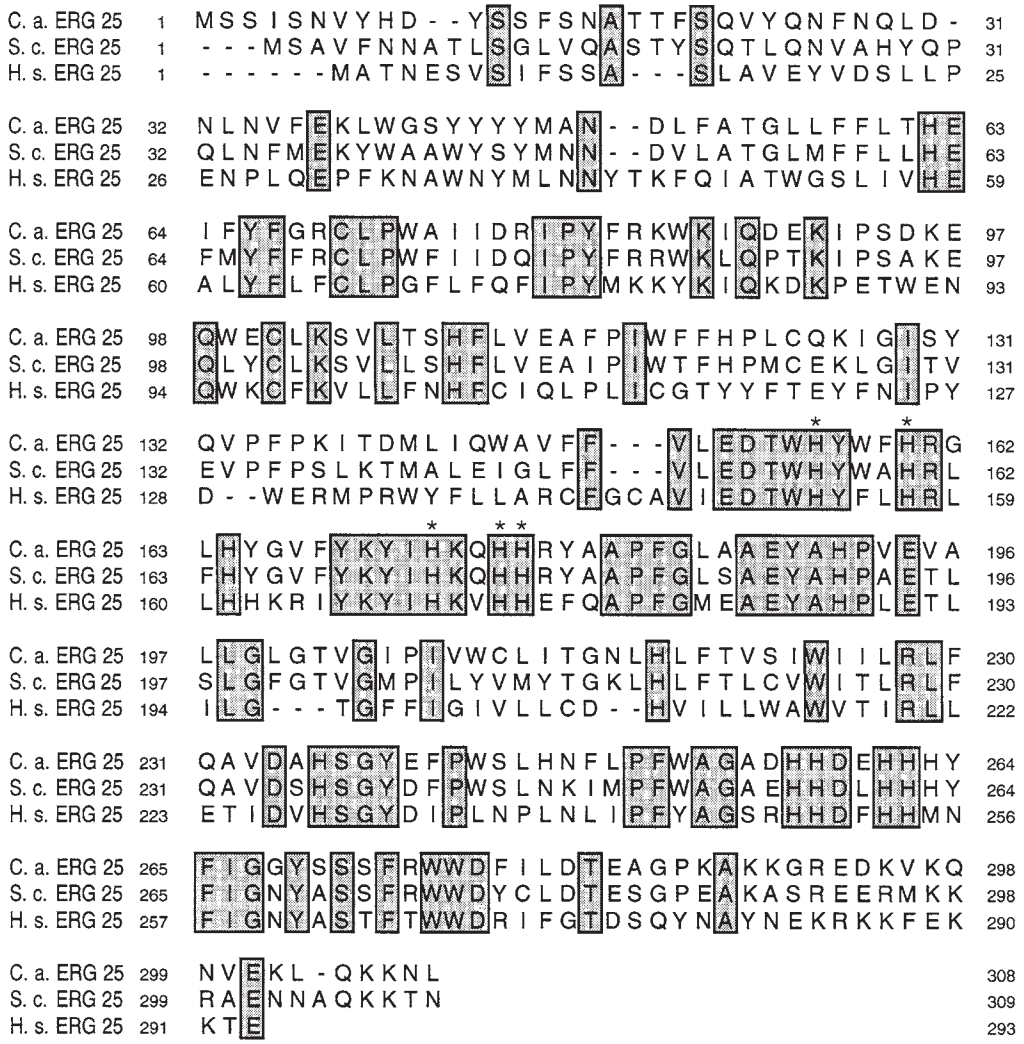

FIG. 3. The multiple sequence alignment for the *ERG25* genes from *Candida albicans* (C. a.), *Saccharomyces cerevisiae* (S. c.), and *Homo sapiens* (H. s.). Shaded boxes indicate regions of amino acid homology among all three species. Histidines in the three histidine clusters are designated by an asterisk at each position.

is responsible for the first of three reactions which sequentially remove the two methyl groups from the C-4 position of the sterol intermediate, 4,4-dimethylzymosterol. In this study *S. cerevisiae* strain *erg25*-25C was transformed with a *C. albicans* genomic library (12), and two clones (pCERG25) capable of growing without ergosterol supplementation were isolated. From these two clones, several subclones containing the *ERG25* gene were created. The two smallest complementing subclones, pIU870 (2.5 kb insert) and pIU873 (3.7 kb insert), were employed in this study. Restoration of ergosterol biosynthesis was used to confirm the cloning of the *ERG25* gene. Figure 1 shows the sterol profiles, as determined by GC, of the *S. cerevisiae erg25* mutant, grown on cholesterol to maintain viability, and a *C. albicans ERG25*-complemented transformant (*erg25*/pCERG25). The *erg25* strain accumulated 4,4-dimethylzymosterol and no ergosterol. The complemented strain accumulated both ergosterol and 4,4-dimethylzymosterol, indicating only partial complementation by the *C. albicans* gene.

DNA from several *ERG25* subclones was used to sequence the *C. albicans ERG25* gene. The nucleotide base and amino acid sequences (GenBank Accession Number AF051914) of the *C. albicans ERG25* are shown in Figure 2. The *ERG25* open-reading frame is comprised of 927 bases which encode a 308 amino acid protein. Figure 3 shows the multiple sequence alignment of the *ERG25* genes from *C. albicans*, *S. cerevisiae*, and *H. sapiens*. The shaded regions indicate where the sequences are identical among all three organisms. The CTG leucine codon at amino acid position 15 is translated as a serine in *C. albicans* (13). The *C. albicans* gene is 65% homologous at the amino acid level to the *S. cerevisiae* gene (7) and 38% homologous to the human gene (14). As in the case of the *S. cerevisiae* and human Erg25p, the *C. albicans* Erg25p contains three histidine-rich clusters comprising the eight histidine motif $HX_{3-4}H$, $HX_{2-3}HH$, and $HX_{2-3}HH$ starting at amino acid positions 156, 173, and 258, respectively. This motif is common to over 60 iron-binding, nonheme inte-

gral membrane desaturases, hydroxylases, and oxidases (15), including the *S. cerevisiae* C-5 sterol desaturase (16). The *C. albicans ERG25* gene also contained a C-terminal endoplasmic reticulum retrieval signal that is also present in the *S. cerevisiae* (7) and human (14) versions of the gene.

In the process of selecting new target sites in the ergosterol pathway for the identification of new antifungals, it would be advantageous to identify reactions that are essential for viability. This has been done extensively in *S. cerevisiae,* and several genes (7,8,17,18) have been identified by disruption techniques as providing sterol structural characteristics that are essential for cell viability. Repeating these determinations in *C. albicans* is more problematic due to its diploid nature, which requires two separate disruption events, and because of the inability of the organism to take-up exogenous sterol (19). Thus, the successful disruption of an essential gene would create an inviable cell with no obvious mechanism for rescue.

The isolation of conditional lethal mutations of the gene in question would provide a potential solution to this problem. The conditional lethal could be introduced into the cell on a complementing plasmid before the second allele is disrupted, and the absence of the wild-type gene product would occur only under nonpermissive conditions. This allows for the survival of the double disruptant and the opportunity for molecular confirmation of the disruption.

A ts conditional lethal of the *C. albicans ERG25* was isolated following mutagenesis in *E. coli* XL1-Red (11). Table 1 shows the sterol compositions of *S. cerevisiae* strains *erg25*-25C/pIU870 (wild-type *ERG25* allele) and *erg25*-25C/pIU908 (ts *ERG25* allele) grown under permissive (30°C) and nonpermissive (38.5°C) growth conditions on SD medium. Cells containing the wild-type allele show nearly identical sterol profiles at both temperatures. On the other hand, cells containing the ts allele produce significantly elevated levels of 4,4-dimethylzymosterol at the nonpermissive growth temperature. Growth of this strain at the permissive temperature results in some elevation of C-4 methyl sterol content, indicating that the ts mutation results in diminished enzyme efficiency even

at 30°C. Identical results were obtained with cells grown on complete medium. The 38.5°C grown cells were pregrown at 30°C and shifted to 38.5°C for 24 h prior to sterol extraction. Thus, the ergosterol detected was produced during pregrowth at 30°C. The cells grew for 1–1.5 generations after the shift to 38.5°C. Cessation of growth is likely due to the increased ratio of C-4 methyl sterol to ergosterol that results from the absence of a functional *ERG25* allele.

In order to conclusively demonstrate that the ts phenotype of *erg25*-25C/pIU908 is due to a mutation in the *ERG25* gene and not defects in the plasmid created by passage through XL1-Red, the *ERG25* insert was removed from the plasmid and reinserted into an identical, but nonmutagenized, plasmid backbone. The reconstructed plasmid was then transformed into the *S. cerevisiae erg25*-25c and analyzed for sterol composition following growth at 30 and 38.5°C. The profiles that emerged were identical to those shown for *erg25*-25C/pIU908 shown in Table 1, indicating that a mutation in the *ERG25* gene is responsible for the ts phenotype of *erg25*-25C/pIU908.

Further evidence for the nature of the ts mutation was derived from sequencing of the open-reading frame of the ts allele. Figure 4 shows the *C. albicans* wild type *ERG25* allele and the ts *ERG25* allele from base positions 837 to 857. The base at position 846 in the wild-type allele has been changed from an A to a G, resulting in a change from asparagine to aspartic acid at amino acid position 247. The location of the change is between histidine clusters 2 and 3 (Fig. 3) and could involve the inability of the altered gene product to bind iron.

The data presented report that the cloning and sequencing of the *C. albicans ERG25* gene encoding the C-4 sterol methyl oxidase, a nonheme, iron-binding enzyme, are similar in sequence and other characteristics to the enzymes found in *S. cerevisiae* and humans. A ts conditional lethal mutation of the *C. albicans ERG25* can be expressed in *S. cerevisiae,* indicating that plasmid-borne *ERG25* conditional lethals can be employed to rescue double disruptions of essential genes in *C. albicans.*

Plant Sterol-C24-Methyl Transferases: Different Profiles of Tobacco Transformed with *SMT1* or *SMT2*[1]

Aurélie Schaeffer, Pierrette Bouvier-Navé, Pierre Benveniste, and Hubert Schaller*

Institut de Biologie Moléculaire des Plantes, Département Biosynthèse et Fonctions des Isoprenoïdes, Institut de Botanique, 67083 Strasbourg, France

ABSTRACT: Higher plant cells contain a mixture of 24-desmethyl, 24-methyl(ene), and 24-ethyl(idene) sterols in given proportions according to species but also to cell type. As a first step to investigate the function of such sterol compositions in the physiology of a plant, we have illustrated in the present work the coexistence of two distinct (*S*)-adenosyl-L-methionine sterol-C24-methyltransferases (SMT) in transgenic *Nicotiana tabacum* L. Indeed, modulation of the expression of the tobacco gene *SMT1-1*, which encodes a cycloartenol-C24-methyltransferase, results in variations of the proportion of cycloartenol and a concomitant effect on the proportion of 24-ethyl sterols. Overexpression in tobacco of the *Arabidopsis thaliana* (L.) Heynh. gene *SMT2-1* which encodes a 24-methylene lophenol-C24[1]-methyltransferase, results in a dramatic modification of the ratio of 24-methyl cholesterol to sitosterol associated with a reduced growth, a topic discussed in the present work.

Paper no. L8306 in *Lipids 35*, 263–269 (March 2000).

Molecular cloning of (*S*)-adenosyl-L-methionine sterol-C24-methyltransferases (SMT) was recently achieved in a number of higher plant species including *Glycine max* (1), *Arabidopsis thaliana* (2), *Nicotiana tabacum*, *Oryza sativa*, and *Ricinus communis* (3,4), and *Zea mays* (5). Comparison of the amino acid sequences deduced from all of these cDNA indicated that SMT are distributed into two gene families, *SMT1* and *SMT2* (3) (Fig. 1). Furthermore, functional characterization of the SMT using a yeast *erg6* expression system demonstrated unambiguously that an *SMT1* sequence encodes a cycloartenol-C24-methyltransferase (SMT1) and a *SMT2* sequence encodes a 24-methylene lophenol-C24[1]-methyltransferase (SMT2) in a given plant species (3,4). This demonstration fully validates previous conclusions supporting the fact that exocyclic C24 carbon atoms are added during the course of plant sterol biosynthesis *via* discrete enzymatic steps (6–12).

Percent identity between two given clones was obtained from the alignment of *SMT* cDNA performed with the PILEUP program of the UGCG package run with the default parameters (3,4). *At*, *Arabidopsis thaliana*; *Nt*, *Nicotiana tabacum*; *Os*, *Oryza sativa*; *Rc*, *Ricinus communis*.

SMT in higher plant cells are responsible for their capability to produce a mixture of 24-methyl(ene) sterols and 24-ethyl(idene) sterols. The proportion of each of these sterols must be genetically defined since it is invariant with respect to species and, even more, organ. To understand the physiological significance of a given 24-alkylsterol composition in a plant material and the modality of its regulation throughout ontogeny, we have modified such a sterol composition in transgenic plants as a first step of this study.

Transgenic plants are a powerful tool to modulate the expression of a gene. In this article we report on transformation experiments of *N. tabacum* with *SMT1* (*Nt SMT1*) and comment on additional results to previous work on transformation of tobacco with *SMT2* (13) in order to demonstrate further the *in planta* coexisting SMT1 and SMT2 functions.

MATERIALS AND METHODS

Plasmid constructs. The cDNA *Nt SMT1-1* was isolated from a tobacco callus library as reported (3). A 1.4 kb BamHI-KpnI fragment comprising the open reading frame (ORF) of *SMT1-1* was excised from the pBluescript SK cloning vector (Strata-

Heynh.; AdoMet, (*S*)-adenosyl-L-methionine; cDNA, complementary DNA; GC–MS, gas chromatography–mass spectrometry; kb, kilobase; lophenol, 3β,4α,5α-isomer of 4-methyl-cholest-7-en-3-ol; MS, Murashige and Skoog culture medium; *Nt*, *Nicotiana tabacum* L.; ORF, open reading frame; PCR, polymerase chain reaction; SMT, AdoMet-sterol-C24-methyltransferase; SMT1, AdoMet-cycloartenol-C24-methyltransferase; SMT2, AdoMet-24-methylene-lophenol-C24[1]-methyltransferase; T-DNA, transfer DNA; TLC, thin-layer chromatography.

gene, La Jolla, CA) and subcloned in the same sites of the plant expression vector pBD515.3 to generate a sense expression cassette of *Nt SMT1-1*. A 0.6 kb SacI-KpnI fragment of the cDNA *Nt SMT1-1* was excised from the pSK vector and subcloned into the KpnI-SacI sites of pBD515.3 to generate an antisense expression cassette of *Nt SMT1-1*. The plant promoter of pBD515.3 is the CaMV 35S promoter sequence with a duplicated enhancer region (14); therefore, the sense expression cassette is referred to as pD35S-*Nt SMT1-1* and the antisense expression cassette as pD35S-a-*Nt SMT1-1*. Standard cloning procedures are described in Reference 15. Recombinant pD35S derivatives and the corresponding void plasmid pD35S referred to as control were introduced into the *Agrobacterium tumefaciens* strain LBA4404 by triparental mating using pRK 2013 in *Escherichia coli* HB101 as a helper plasmid (16).

Plant material, transformation, culture conditions, and genetic analysis. Nicotiana tabacum L. var. *xanthi* was transformed with pD35S, pD35S-*Nt SMT1-1*, and pD35S-a-*Nt SMT1-1 via A. tumefaciens* using the leaf-disk co-cultivation method originally reported (17). Shoots were regenerated on Murashige and Skoog (MS) medium with supplements as described in Reference 13 and 100 mg/L kanamycin as the transgenic plant-selective agent. Primary transformants (generation T1) and their progenies obtained by selfing (generation T2) were grown *in vitro* on MS medium under a 16-h light period at 24°C and an 8-h dark period at 20°C. Eight-week-old *in vitro* plants were transferred to the greenhouse to set seeds. Integration of the transgene(s) into the plant genome was checked by polymerization chain reaction (PCR) on chromosomal DNA according to the method described in (18); detection of pD35S-*Nt SMT1-1* was achieved with primer AS1 (sense, 5′ CATTTGGAGAGAACACGG 3′) complementary to the pD35S sequence and with primer AS2 (antisense, 5′ GCCGGGTACCTTACTGAGAGTCTGAAATGGGC 3′) complementary to *Nt SMT1-1*; detection of pD35S-a-*Nt SMT1-1* was achieved with AS1 and AS3 (antisense, 5′ GGCCTCCCTGAGGTTAGATTG 3′) complementary to *Nt SMT1-1*. The number of transgenic loci per plant line was determined according to the Mendelian segregation of the kanamycin-resistant phenotype in T2 generations: seed samples were germinated on MS medium supplemented with 300 mg/L kanamycin.

Transgenic *N. tabacum* L. var. *xanthi* expressing an *A. thaliana* cDNA encoding a 24-methylene-lophenol-C24^1-methyltransferase (*At SMT2-1*) is described in Reference 13. Greenhouse-grown plants from the T3 generation were used in the present work.

DNA and RNA gel blot analysis. Genomic DNA was prepared according to Dellaporta *et al.* (19). DNA (20 μg) was restricted with EcoRI, HindIII, or SacI; restriction fragments were separated electrophoretically on a 0.7% agarose gel and blotted onto Hybond N^+ (Amersham, Buckinghamshire, United Kingdom) membranes. Hybridizations with ^{32}P-radiolabeled DNA probes obtained by random priming were carried out at high stringency according to the manufacturer's recommendations.

Total RNA from leaf material were extracted according to Goodall *et al.* (20). Northern analysis was done by separating 10 to 20 μg RNA samples on formaldehyde gels as described (15) and blotting them onto Hybond N^+. Hybridizations were done as for DNA blots. Pictures were prepared by scanning the autoradiographs with Adobe Photoshop 5.0 (San Jose, CA).

SMT enzymatic assay. Isolation of membranes from *in vitro*- grown tobacco was carried out as follows: 6 g of leaf tissue was ground in a 0.2 M KH_2PO_4 buffer (pH 7.5) containing 0.35 M sorbitol, 10 mM $Na_2EDTA{\cdot}2H_2O$, 5 mM $MgCl_2{\cdot}6H_2O$, 40 g/L polyvinylpyrrolidone, and 10 mM dithioerythritol. The supernatant fraction resulting from a 15-min centrifugation at 10,000 × *g* was centrifuged for 1 h at 100,000 × *g*. The membrane fraction was then resuspended in a 0.1 M Tris-HCl buffer (pH 7.5) containing 1 mM β-mercaptoethanol and 20% (vol/vol) glycerol. Microsomal proteins were quantified by the Bio-Rad (Richmond, CA) protein assay using bovine serum albumin as a standard. A radiochemical assay for SMT activities was carried out based on that reported (7). The standard assay consisted of 0.1 M Tris-HCl at pH 7.5, 1 mM β-mercaptoethanol, 20% glycerol (vol/vol), 0.1% Tween 80 (wt/vol), 30 μM 24-methylene lophenol or 100 μM cycloartenol, 100 μM [methyl-^{3}H]-AdoMet (475,000 cpm) and 0.8 mg/mL microsomal proteins. The mixture was incubated at 30°C for 45 min and the reaction was then stopped by adding 100 μL of 12% (wt/vol) ethanolic KOH. Sterol carriers were added before neutral lipids were extracted with *n*-hexane. Sterols were purified by thin-layer chromatography (TLC) (two runs of dichloromethane), and bands of interest (4,4-dimethylsterols or 4α-methylsterols) were scraped off and collected into scintillation vials together with 10 mL of Beckman's Ready Organic cocktail (Fullerton, CA). Radioactivity was determined in a liquid scintillation counter (Packard Instruments, Downers Grove, IL).

Sterol analysis. Lipids from 5 to 10 mg (small-scale qualitative analysis) or 100 to 500 mg (quantitative analysis) of ground dry material were extracted at 70°C in dichloromethane/methanol (2:1, vol/vol). The dried residue was saponified with 6% (wt/vol) KOH in methanol at 90°C for 1 h to release the sterol moiety of steryl esters. Sterols were then extracted with 3 vol of *n*-hexane, and an acetylation reaction was performed on the dried residue for 1 h at 60°C in toluene with a mixture of pyridine/acetic anhydride (1:1, vol/vol). Steryl acetates were resolved by TLC (Merck 60F254 precoated silica plates; Darmstadt, Germany) with one run of dichloromethane as a single band at R_f = 0.5. Purified steryl acetates were separated, identified, and quantified by gas chromatography (GC) using a Varian 8300 gas chromatograph with a flame-ionization detector, a glass capillary column (Wall-Coated Open Tubular, 30-m long, 0.25 mm i.d., coated with DB1; J&W Scientific, Folsom, CA), and H_2 as a carrier gas (2 mL/min). The temperature program included a fast increase from 60 to 220°C (30°C/min) and a slow increase from 220 to 280°C (2°C/min). Data from the detector were monitored with the Varian Star computer program. Sterol structures were confirmed by GC–mass spectrometry (MS) [Fison MD800 equipped with a glass capillary column (WCOT coated with DB5; J&W Scientific, Folsom, CA] according to Rahier and Benveniste (21).

RESULTS AND DISCUSSION

Expression of A. thaliana *SMT2-1 in* N. tabacum. We have generated transgenic tobacco overexpressing *At SMT2-1* cDNA under control of a strong constitutive promoter, namely, the CaMV 35S promoter, and have shown that the accumulation of *At SMT2-1* transcripts led to an increase of 24-methylene lophenol-C24[1]-methyltransferase activity in microsomes from leaf tissue (13). Consequently, the sterol biosynthetic flux was boosted toward the 24-ethyl sterol branch of the pathway (Fig. 2) and therefore a dramatic drop in the amount of 24-methyl cholesterol and a concomitant increase in that of sitosterol was observed. Indeed, the ratio of 24-methyl cholesterol to sitosterol, which was ~1 in wild-type leaf tissue, decreased to 0.03 in leaf tissue from the engineered plants. In succeeding generations, a low ratio of 24-methyl cholesterol to sitosterol was associated with reduced growth. Because the size of cells was almost unchanged in small transgenic tobacco when compared to the wild-type, we suggested that cell division rather than cell elongation was affected by such a novel sterol profile (13).

Cells that undergo divisions are located at the shoot or root apex. The sterol composition of such material is reported in Table 1. These data indicate that the ratio of 24-methyl cholesterol to sitosterol is equal to ~0.5 in shoot meristematic tissue from wild-type tobacco; this value is half the one calculated for leaf tissue taken from the same plants (13) as just reported above. This observation underlines the fact that to a given cell type at a given stage of development corresponds a given 24-alkyl sterols status as already illustrated, for instance, in the case of maize (22). In transgenic shoot meristematic tissues expressing *At SMT2-1*, the ratio of 24-methyl cholesterol to sitosterol dropped to 0.1 (Table 1). This further verifies that a consistent variation in the 24-alkylsterol status is associated with plant growth reduction. The mechanisms through which a decrease of 24-methyl cholesterol and/or an increase of sitosterol may be responsible for modifications in cell division and (or) cell elongation have now to be clarified. Although we have shown that overexpressing an *SMT2* sequence results in a unique and selective change in a sterol profile, namely, a variation of the ratio of 24-methyl cholesterol to sitosterol (13), it is interesting to note a reduction of the proportion of cholesterol in the sterol composition of *At SMT2-1* shoot meristematic tissues when compared to the wild-type. At this point of our

study, a possible role for cholesterol in the reported plant growth modifications cannot be excluded.

Ectopic expression of N. tabacum SMT1-1. Tobacco *SMT1* cDNA have been isolated from a callus library. One of these cDNA, called *Nt SMT1-1*, has been expressed in the yeast mutant *erg6*, which is deficient in zymosterol-C24-methyltransferase (23–25). Whereas *erg6* is devoid of 24-alkyl sterols, *erg6 Nt SMT1-1* contained a majority of 24-methylene sterols; furthermore, delipidated microsomes from *erg6 Nt SMT1-1* were shown to efficiently convert cycloartenol into 24-methylene cycloartanol but not 24-methylene lophenol into 24-ethylidene lophenol in the presence of S-AdoMet (3). Therefore, *Nt SMT1-1* and sequences highly similar to it encode a cycloartenol C24-methyltransferase. Two full-length cDNA encoding a SMT1 have been isolated so far from the tobacco callus library; the deduced amino acid sequences share 91% identity (Fig. 1) indicating that they are encoded by two distinct genes. The existence of at least two transcribed genes at the callus stage is consistent with the number of genes evaluated from the genomic DNA gel blot analysis (Fig. 3A). Indeed, hybridization carried out at high stringency revealed more than two bands in the case of Hind III or EcoR I restriction patterns using the cDNA *Nt SMT1-1* as a probe. Therefore, *SMT1* gene family in tobacco contains at least two members. Likewise, it is shown in the same hybridization experiment using the cDNA *Nt SMT2-1* (4) as a probe that *SMT2* gene family in tobacco also contains at least two members (Fig. 3B). Although genetic redundancy is known to occur in higher plants, it is not excluded that a given function may be encoded by different genes from the same family, each of the genes presenting a unique spatio-temporal expression pattern.

SMT1 is the first step of the enzymatic conversion of cycloartenol into Δ^5-sterols (Fig. 2). This step has been studied as a putative key regulatory point in the pathway (22). In order to challenge such a regulatory aspect of this enzyme and its influence on the sterol composition of the plant cell, we have transformed tobacco *via Agrobacterium* using a transfer DNA (T-DNA) vector carrying an *Nt SMT1-1* ORF driven by a double CaMV 35S promoter for sense transformation or a truncated 3′ end of the same ORF cloned in antisense orientation behind the duplicated p35S promoter in order to promote lowered expression of the endogenous gene. Twenty primary transformants were subjected to PCR analysis with a T-DNA specific primer and a gene specific primer; amplification of a single product in the case of both sense and antisense plantlets demonstrated the integration of the T-DNA into the target genome (data not shown). The analysis of the transgenic lines was carried out as follows: a qualitative sterol profile was determined on leaf material from *in vitro*-grown primary transformants; after selfing of these plants and germination of the second generation (T2), the expression of the transgene, the enzyme activities for SMT, and the total sterol content were determined for a representative set of *SMT1-1* lines, all containing a single transgenic locus (data not shown).

Most strikingly, a significant variation in the proportion of cycloartenol was found among the transgenic lines when compared to the control. Cycloartenol accounted for 12% of the total sterols in the control (Table 2). Sense transformants A, B, and C had a reduced content in cycloartenol indicating an in-

[a]SMT1-1, cDNA which encodes a cycloartenol-C24-methyltransferase.

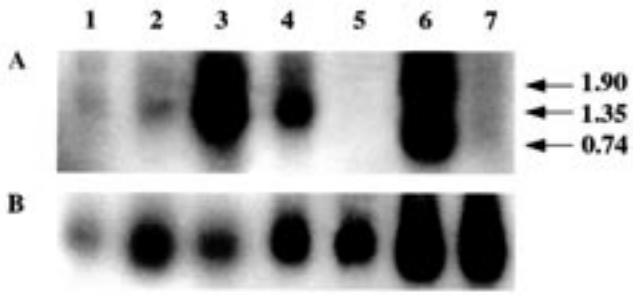

FIG. 4. Total leaf RNA gel blot analysis of transgenic *SMT1-1* tobacco. Lane 1, wild-type; lane 2, transgenic control; lanes 3 to 5, pD35S-*SMT1-1* plant lines A, B, and F, respectively; lanes 6 and 7, pD35S-a-*SMT1-1* plant lines G and I. (A) The blot was hybridized with a ^{32}P-labeled *Nt SMT1-1* cDNA probe. Sizes of bands are indicated in kb according to the standard RNA molecular markers. (B) The blot used in A was washed in 0.1% SDS at 80°C for 3 h and hybridized with a ^{32}P-random labeled 4.6 kb 18S rRNA probe as an internal standard.

creased metabolism of the latter *via* SMT1. Sense transformants D, E, and F and antisense transformants G, H, and I displayed an up to threefold increase in their cycloartenol content indicating a reduced rate of SMT1-mediated conversion of cycloartenol into 24-methylene cycloartanol. In the case of transformants D, E, and F the reduction of SMT1-mediated transformation of cycloartenol most probably results from cosuppression of *Nt SMT1-1* expression; in the case of transformants G, H, and I, the reduction in SMT1-mediated transformation of cycloartenol most probably results from antisense-mediated decrease of *Nt SMT1-1* messenger RNA (for literature on cosuppression and antisense gene expression see Ref. 26, 27).

In fact, these conclusions are fully validated by the pattern of *Nt SMT1-1* expression which was established for T2 *in vitro*-grown plants and is shown in Figure 4. The blot of leaf RNA was probed with *Nt SMT1-1* radiolabeled DNA fragments. A weak signal at ~1.35 kb was detected in the case of the wild-type and the transgenic control. A stronger signal of the same size was detected in the case of the sense transformants A and B; no signal was detected in the case of the sense transformant F. Such results demonstrating overexpression (lines A and B) and cosuppression (line F) of *Nt SMT1-1* are in agreement with an increase (lines A and B) and a decrease (line F) of SMT1-mediated metabolism of cycloartenol leading to a reduction and an increase, respectively, of the total percentage of 24-desmethyl sterols (Table 3). In the case of the antisense line G, the blot shows two distinct signals: the 1.9 kb signal might correspond to the unspliced transcript of *Nt SMT1-1* but this is at present still unclear; the 0.74 kb signal may indicate a significant expression of the antisense transgene. Interestingly, the key common point in the expression pattern of the antisense lines G and I and of the cosuppressed line F is the absence of a detectable signal at 1.35 kb corresponding to the *Nt SMT1-1* messenger RNA (Fig. 4). Consequently, antisense expression and cosuppression of *Nt SMT1-1* lead to the accumulation of 24-desmethyl sterols (Table 3) among which cycloartenol is predominant.

From the results in Table 2 one sees that the product of the SMT1 reaction, namely, 24-methylene cycloartanol, does not vary significantly. More generally, this is the case for all of the sterol intermediates leading to the end products of the pathway to 24-alkyl-Δ^5-sterols. This shows that a modified *SMT1-1* expression level and consequently an increase or a decrease in the proportion of cycloartenol does not have any apparent effect on enzymes beyond cycloartenol in the pathway. In addition, challenging the *SMT1-1* expression level in tobacco has a moderate effect on the total amount of sterols in the case of only some of the lines (Table 3).

Finally, a modification in the proportion of 24-methylsterols and of 24-ethylsterols is concomitant to the change in cycloartenol content (Tables 2 and 3). Essentially, an increase of sitosterol corresponds to a decrease of cycloartenol, and an increase of cycloartenol to a decrease of sitosterol (Table 2). Additionally, the proportion of stigmasterol [which results from the desaturation at C22 of sitosterol (6,28)] varies in the same sense as that of sitosterol does. This is intriguing because in the case of the overexpression of *At SMT2-1* in tobacco, a twofold increase in the amount of sitosterol is followed by only very moderate effects on the proportion of stigmasterol (Table 1; Ref. 13).

In order to explain the variations in the proportions of 24-ethylsterols (pathway end products) in transgenic *SMT1-1* to-

bacco compared to the control, two hypotheses may be proposed; (i) SMT1 has a minor SMT2 activity *in planta*; this might be deduced from the SMT activities measured in microsomes from transgenic tobacco leaves (Table 3). However, variations of SMT2 activity do not follow the variations of SMT1 activity in the case of transgenic *Nt SMT1-1* lines B and F (Table 3). Moreover, variations of SMT2 never exceed 13% when compared to the control, whereas SMT1 activity increases up to 62% or decreases up to 80% of the control value among transgenic *Nt SMT1-1* lines (Table 3), confirming the substrate specificity of the *Nt SMT1-1* gene product as it was determined in the yeast mutant *erg6* (3). In contrast, leaf microsomes from tobacco transformed with the *A. thaliana SMT2-1* displayed similar increases of SMT2 and SMT1 activities as compared with the wild-type activities (Table 4) in agreement with the lower substrate specificity of SMT2 as it was determined in the yeast mutant *erg6* (4). Finally, if SMT1 or SMT2 ever display a SMT nonspecific *in planta* activity, this definitely has a limited impact on the sterol composition of the plant material based on the radically different sterol composition of transgenic tobacco transformed either with *SMT1* or with *SMT2*: in the first case, the proportion of cycloartenol varies with a concomitant effect on 24-ethylsterols (Table 2), whereas in the second case, the ratio of 24-methyl cholesterol to sitosterol is specifically modified (Table 1). Hence, SMT1 and SMT2 are indeed two different enzymatic proteins *in planta*. (ii) *SMT1* and *SMT2* gene expression may be co-regulated, and changing the transcription level of one of the genes therefore would affect the transcription of the other. Further experiments are required on the expression pattern of *SMT* in wild-type and transgenic plants to clarify this point.

CONCLUDING REMARKS

Sterol-C24-methyltransferases in higher plants are distributed into two gene families, *SMT1* and *SMT2*, according to sequence comparison and to heterologous functional expression of *SMT1* or *SMT2* cDNA originating from the same plant species (3). In the present work we further demonstrate the *in planta* coexistence of two enzymatic proteins, SMT1 and SMT2, owing to the distinct sterol composition of transgenic tobacco expressing ectopically an *SMT1-1* cDNA or an *A. thaliana SMT2-1* cDNA. It is clearly shown indeed that in the first case a modulation of the expression of *SMT1* (and consequently a modulation of the cycloartenol-C24-methyltransferase activity) results in a significant variation of the proportion of cycloartenol with additional effects on the proportion of 24-ethylsterols; in the second case, an increase of the expression of *SMT2* (and consequently an increase of the 24-methylene lophenol-C24[1]-methyltransferase) results in a dramatic drop of the ratio of 24-methyl cholesterol to sitosterol (13). In the case of both sets of transformation experiments reported here, it is worth noting that the total amount of sterols does not vary significantly, indicating that *SMT1* and *SMT2* expression levels have no major effects on the biosynthetic flux, at least within the limits of the sterol profile modifications reported here. This is in agreement with previous results showing that tobacco lines overaccumulating sterols by means of an enhanced 3-hydroxy-3-methylglutaryl-coenzyme A reductase gene expression level/enzyme activity also accumulate cycloartenol, because SMT1-mediated conversion of cycloartenol into 24-methylene cycloartanol is a slow step in plant sterol biosynthesis (29,30).

The presence of both 24-methyl sterols and 24-ethyl sterols in higher plant cell membranes raised the exciting question of the significance of their relative proportions with respect to plant physiology and growth. We have been able to show that a modulation of SMT2 in tobacco has a remarkable impact on the 24-alkyl sterol status and consequently on plant growth (13). On the contrary, we have not detected either in *in vitro* or in greenhouse-grown transgenic *SMT1-1* tobacco any clear-cut biological effect putatively linked to a modified cycloartenol or 24-alkyl sterol profile. Further experiments that challenge the expression level of *SMT1* in a given plant species are required to further assess the influence of *SMT1* on plant cell biochemistry and physiology.

Design and Synthesis of New Steroidal Inhibitors of Estrogen Synthase (aromatase)

Edward J. Parish*, Shengrong Li, and Zhigang Rao

Department of Chemistry, Auburn University, Alabama 36849-5312

ABSTRACT: The estrogen synthase (aromatase) enzyme system is responsible for the biosynthesis of estrogen hormones in human females. Estrogens are vital for normal growth and development, but will promote the growth of certain breast cancers. Approximately 30–50% of breast cancers are considered to be hormone-dependent. Consequently regulation of estrogen biosynthesis has advanced as a potential therapeutic strategy. This has led to the development of active-site inhibitors, which may have potential for the control of breast cancer. We have recently prepared a number of new steroidal inhibitors that have been evaluated as aromatase inhibitors. These include steroidal A/B-ring isoxazoles and a series of A/B-ring pyrazoles with alkyl- and aryl-substituted nitrogen. In addition, we have developed new chemical procedures for the synthesis of 6β-hydroxy steroids, which could be key intermediates in the preparation of C-19 inhibitors of aromatase activity.

Paper no. L8317 in *Lipids 35,* 271–277 (March 2000).

Aromatase is the enzyme responsible for catalyzing the conversion of androgens to estrogens in the last step of estrogen biosynthesis and is important in estrogen metabolic and reproductive processes. The inhibition of aromatase is an important and specific route for control of estrogen levels and estrogen-dependent diseases (1,2). The estrogen synthase (aromatase) enzyme system is responsible for the biosynthesis of estrogen hormones in women. Estrogens are vital for normal growth and development, but will promote the growth of certain breast cancers. Approximately 30–50% of breast cancers are considered to be hormone-dependent. Consequently, regulation of estrogen biosynthesis has advanced as a potential therapeutic strategy (3,4). This has led to the development of active-site inhibitors that may have potential for the control of breast cancer (5).

The estrogen elements of the biochemical pathway, which utilize aromatase in the biosynthesis of estrogens from androgens, is shown in Scheme 1. Aromatase was first isolated by Ryan in 1959 (6) from the microsomal fraction of fresh human placental tissue. Aromatase is a cytochrome P-450 enzyme. The region of greatest homology among all steroidogenic P-450 enzymes is the heme-binding region (7). The term "aromatase" usually refers either to Thompson's crude, insoluble preparation (8) or to Vickery's solubilized preparation (9) rather than to the unstable, purified enzymes (10). Aromatase is 55 kDa protein of 503 amino acids. An X-ray structure of cytochrome P-450 aromatase is not available due to the difficulty of purification and crystallization of this membrane-bound enzyme. However, modeling studies using a variety of computational programs to predict the three-dimensional structure of aromatase have given us insights into the enzyme structure and its action (11).

Because of the importance of estrogen in mammalian metabolism and reproductive processes, considerable progress has been made in understanding the structure, biochemical mechanism, and inhibition of aromatase. The inhibition of aromatase is a potentially important and specific route to control estrogen levels. Inhibitors of aromatase have found application in such estrogen-related processes as contraception, maintenance of pregnancy, and treating gynecomatsia, endometriosis, and estrogen-dependent breast cancer (12–15).

The biochemical mechanism of aromatase has been studied extensively, and considerable progress has been made in understanding the important reactions (Scheme 1) catalyzed by this enzyme. Aromatase converts androgens to estrogens by oxidizing the C-19 methyl group and aromatizing the steroid A-ring. It has been shown that three molecular oxygens and six reducing equivalents from NADH are consumed during estrogen formation. The mechanisms involved in this enzymatic process have recently been extensively reviewed (4,5).

AROMATASE INHIBITION

Steroidal aromatase inhibitors have been studied extensively. A variety of substrate analogs with other functional groups on C-19, C-1, C-2, C-4 and C-6 has been synthesized and shown to be good inhibitors of aromatase (16). Mechanistically, steroidal inhibitors can be classified as competitive and noncompetitive. Almost all of the noncompetitive inhibitors are mechanism-based inhibitors. Modification of the A-ring of the androstenedione molecule initially focused on substituents at C4. The steroids 4-hydroxy-4-androstene-3,17-dione (4-OHA) and 4-acetoxy-4-androstene-3,17-dione are

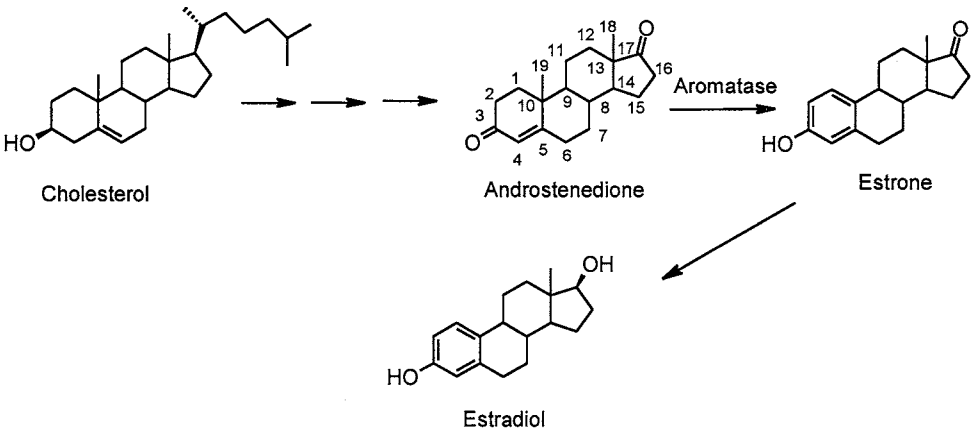


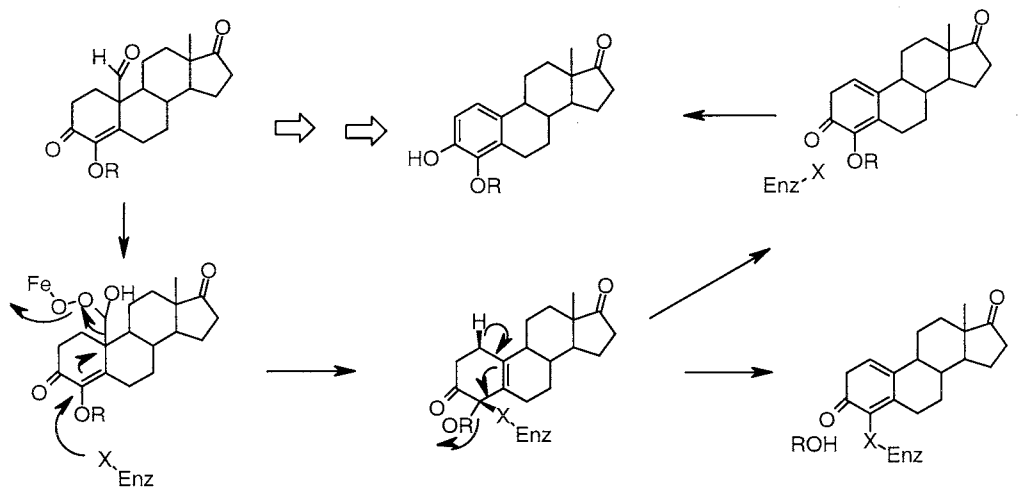
SCHEME 1

effective inhibitors *in vitro* with reported K_i values of 2 and 10 μM, respectively, and they produce enzyme-mediated inactivation (17,18). The mechanism possibly involves catalytic substrate conversion to a reactive intermediate, which then causes active-site inactivation. Covey and Hood (19) invoked enzyme-assisted addition–elimination at C-4 to explain the irreversible inhibition caused by 4-OHA and other 4-substituted androstenediones (Scheme 2). Lombardi (20) and collaborators have synthesized 4-aminoandrogens that are also mechanism-based irreversible inhibitors. Further modifications with extended conjugation through $\Delta^{1,4}$ or $\Delta^{4,6}$ double bonds enhance the inhibitory activity. In general, the spatial requirements of the A-ring for binding of the steroidal inhibitors to aromatase are rather restrictive and permit few structural modifications to be made. Incorporation of the polar hydroxy group at C-4 enhances inhibitory activity.

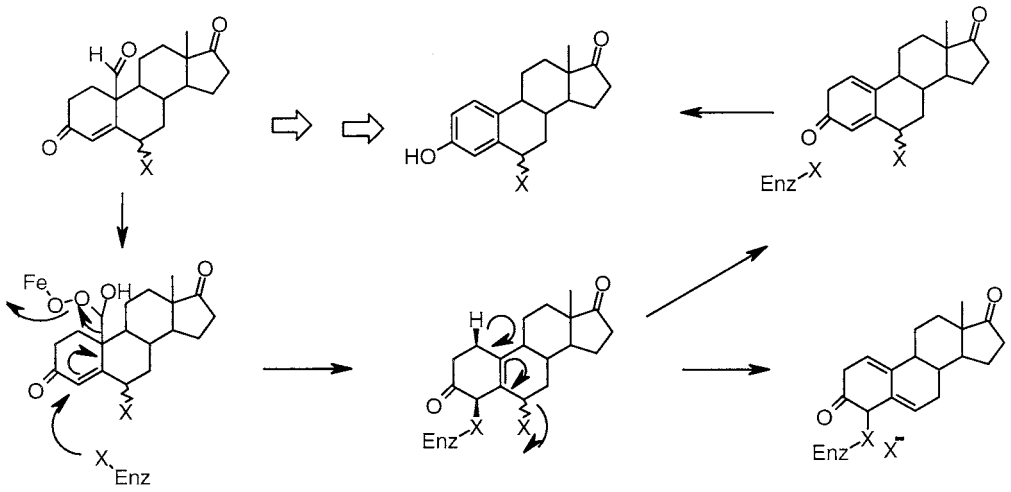
Effective aromatase inhibitors derived from B-ring modification are mainly C-6- and C-7α-substituted derivatives of 4-androstenedione. The 6-ketoxime derivatives of 4-androstenediones are potent aromatase inhibitors (21). Although the 6-keto derivative is one of the most common clinical inhibitors in use, it exhibits relatively poor affinity (19). Proposed mechanisms of inhibition have invoked delocalization of the charge toward the C-6 instead of the C-4 position. The nucleophile addition–elimination mechanism would explain the inhibition by androgens that bear leaving groups on C-6 (Scheme 3). Derivatives with 6-fluoro, chloro, hydroxy, or acetoxy groups showed good activity in the inhibition of human placental aromatase *in vitro* (22,23). In these proposed mechanisms, the nucleophile (Enz-X) shown in Schemes 2 and 3 is from the sulfhydryl group on the amino acid cysteine found in the active site of the enzyme (5,24,25).

Substituents at the C-7α position of the B-ring have provided a number of potent aromatase inhibitors (26,27). Brueggemeir has prepared a wide variety of these and has discovered the presence of a hydrophobic pocket at C-7α that is able to bond covalently to selective steroidal derivatives that are able to correctly extend into this lipophilic region of aromatase.

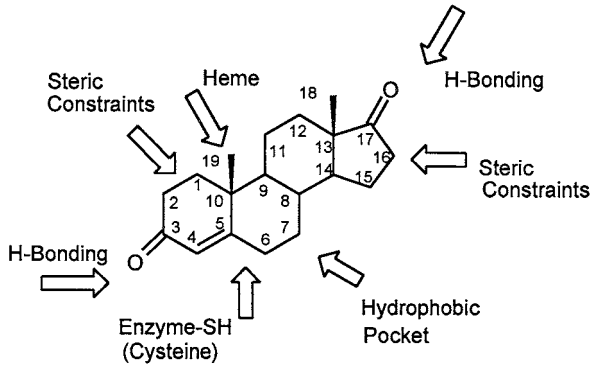
Combined with the results of site-directed mutagenesis studies and the structures of substrates and inhibitors, a number of attempts have been made to predict the structure of this



SCHEME 2



SCHEME 3

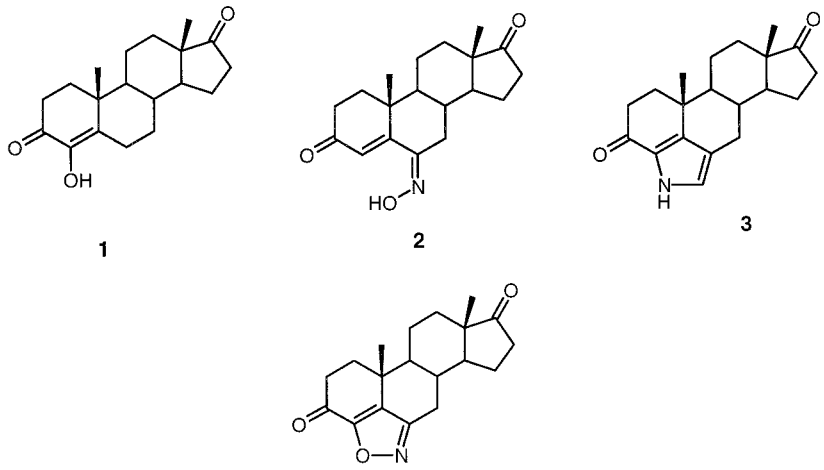


SCHEME 4

enzyme by a variety of computational programs (5). These predictions fit quite well with the required elements of the active-site structure of aromatase as deduced from the experimental data on substrates and inhibitors (Scheme 4).

NEW STEROIDAL INHIBITORS

Since the discovery that 4-OHA (**1**) is an effective aromatase inhibitor (17), many 4-substituted 4-OHA analogs have been synthesized and tested as aromatase inhibitors (18,20,28,29) (Scheme 5). Very recently, Di Salle *et al*. (30) reported that androst-3,17-dione-4-eno[4,5,6,*b*,*c*]pyrole (**3**) was effective as an aromatase inhibitor. The prevailing explanation for the inhibitory activity of these types of compounds is that the nearby nucleophile attacks at the C-4 position, and the following elimination of a C-4 leaving group results in permanent binding of the inhibitor to the enzyme (26). This hypothesis is based on the assumption that these inhibitors take the same orientation as the substrate in the active site of the enzyme. In addition, 6-hydroxyiminoandrost-4-en-3,17-dione (**2**) has shown a high affinity for human placental aromatase and functions as a competitive inhibitor of the enzyme (31). To take advantage of these structural features (Scheme 5), we



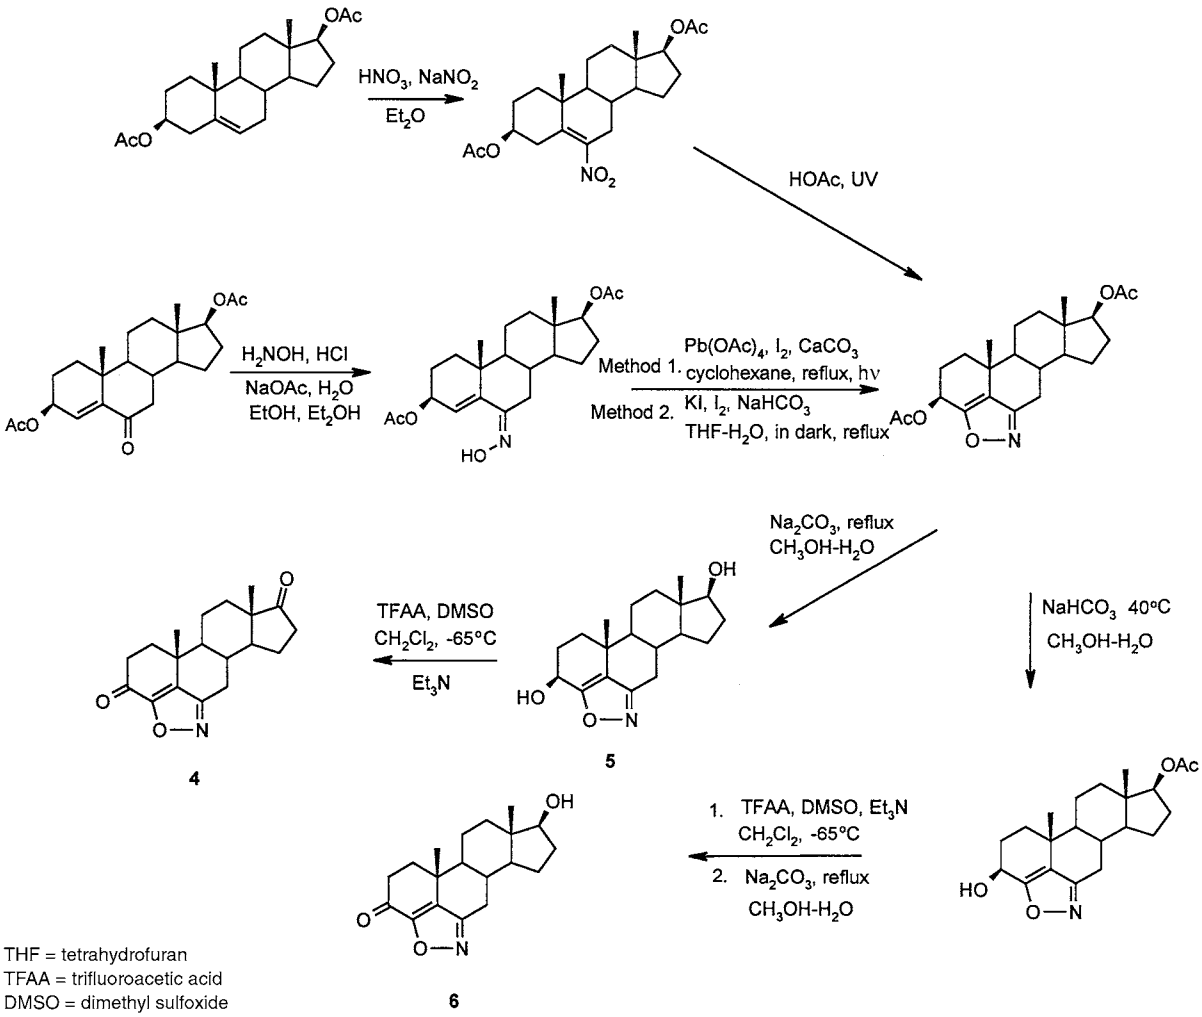
1 **2** **3** **4**

SCHEME 5

have recently prepared androst-3,17-dione-4-eno[6,5,4-*c,d*] isoxazole (**4**) and found it to be an effective inhibitor against aromatase (32).

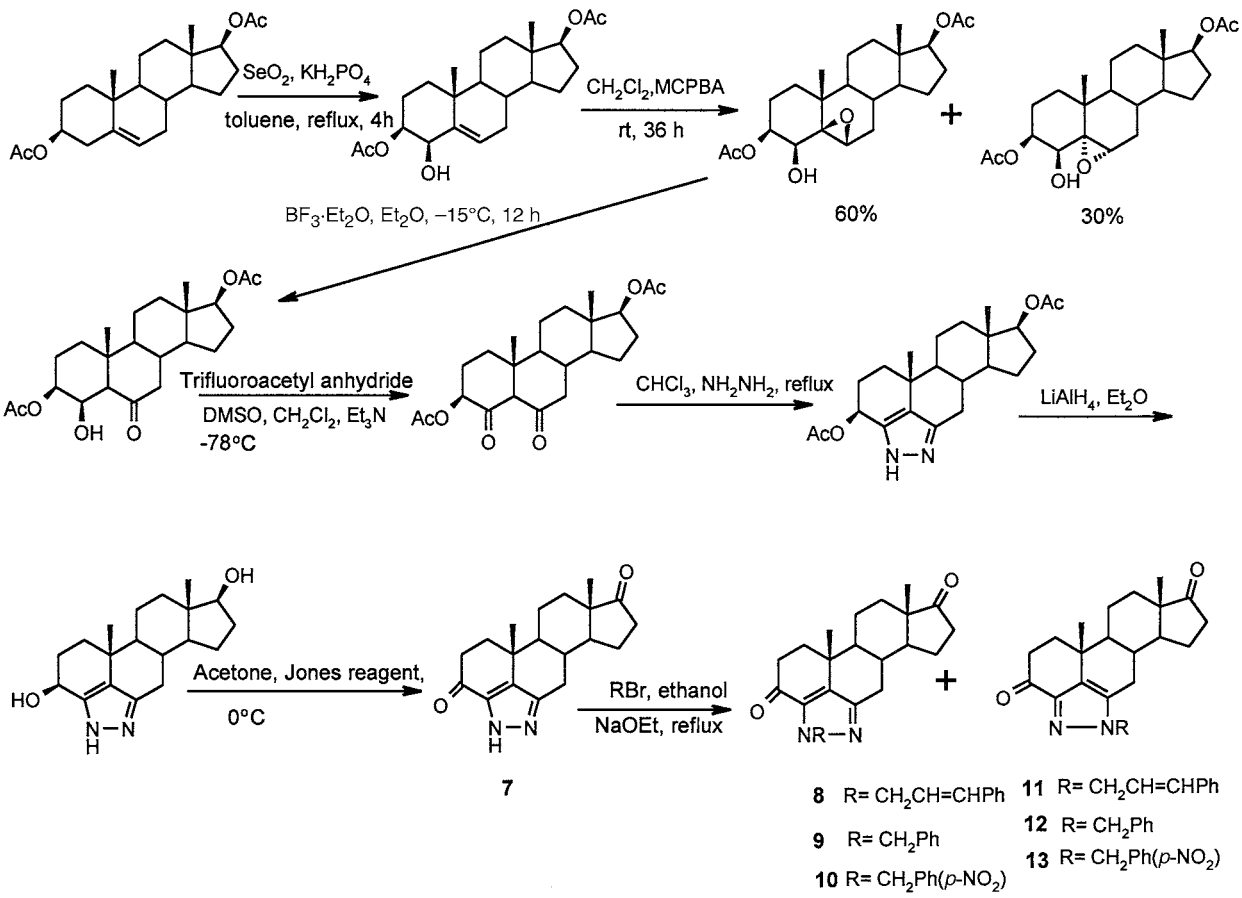
The chemical synthesis of **4** and its companion A/B-ring isoxazoles **5** and **6** is outlined in Scheme 6. We have prepared these products using two independent approaches utilizing 3β,17β-diacetoxyandrost-4-en-6-one as a starting material (32). Aromatase assays were performed using established procedures (32) and the following concentrations producing 50% inhibition (IC_{50}) were obtained: **4**, 1.889 μM; **5**, 120.5 μM; **6**,18.57 μM. The structural requirements of C-19 steroids needed for a favorable interaction with the enzymatic site of aromatase have been determined (29). These include ketone functionality at C-3 and a 17-keto or 17β-hydroxyl substituent. Also, steroids with a linear configuration (e.g., 4-en-3-one) in the A and B ring are known to be effective inhibitors. The isoxazoles **7** and **9** exhibited the most potent inhibition and possessed structural features that were most consistent with those described for previous effective inhibitors. The model steroids **1** and **2** (Scheme 5) have been shown to possess greater inhibitory activity than the described isoxazoles **4** and **6**. However, this is the first report describing the inhibition of aromatase activity by steroidal A/B-ring isoxazoles.

In related studies, we have completed the chemical synthesis of a series of H-aryl androsterone pyrazoles (Scheme 7) (33). Using the steroidal pyrole **3** (Scheme 5) and the isoxazoles **4,5**, and **6** (Scheme 6) as structural models, we have completed the chemical synthesis of the androsterone pyrazole **7** and its N-substituted derivatives **8–13** (Scheme 7; MCPBA, *m*-chloroperoxy-benzoic acid). If these inhibitors take the same orientation as the substrate in the enzymatic site, the aryl groups on the C-6 nitrogen could project to the 7α-hydrophobic pocket and increase the affinity according to the molecular modeling observations (27). The comparison of the low-energy conformers, generated using the SPARTAN molecular modeling program using the MM2 (molecular mechanics 2) force field, of *N*-benzylandrost-3,17-dion-5-eno[4,5,6-*c,d*]1H-pyrazole **12** and 7α-(phenylthio)androst-4-ene-3,17-dione (a well-known inhibitor) indicated the phenyl groups on these two molecules could be partially overlapped (33). However, the increased inhibitory activity was not observed for these N-substituted compounds in comparison with



THF = tetrahydrofuran
TFAA = trifluoroacetic acid
DMSO = dimethyl sulfoxide

SCHEME 6



SCHEME 7

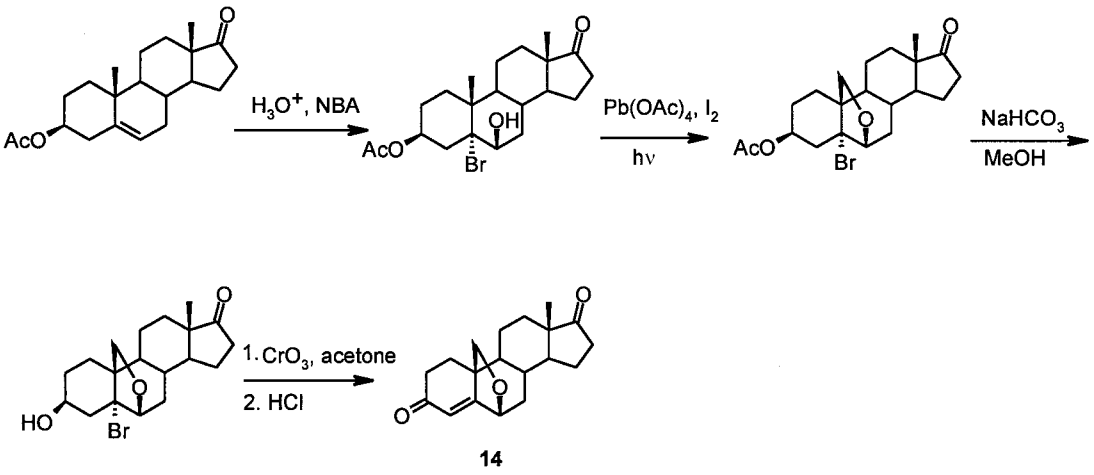
the unsubstituted parent compound androst-3,17-dione-5-eno[4,5,6-*c*,*d*]1H-pyrazole **7**. The results imply these inhibitors may not take the same orientation as the substrate in the enzyme active site. The C-4 heteroatom could orient toward the heme in the enzyme active site, which could result from the molecular rotation around an axis from C-3 to C-17, and therefore act as heme binders (Scheme 4).

The following are inhibitory results (IC_{50}, μM) obtained using human placental aromatase for compounds **7–13**: **7**, 0.236; **8**, 0.900; **9**, 0.342; **10**, 0.658; **11**, 0.950; **12**, 0.245; **13**, 0.490. The clinically used drug 4-OHA was tested in the same system for comparison. Androst-3,17-dione-4-eno[6,5,4-*c*,*d*]1H-pyrazole (**7**) and its *N*-benzyl derivatives (**9** and **12**) display relatively good inhibitory activity and appear to be about equiactive as 4-OHA. Interestingly, substitution of a 4′-nitro group in these compounds as in **10** and **13** appears to double the IC_{50} values (or decrease inhibitory activity by about 50%), suggesting that this substitution is detrimental toward activity. Replacing the *N*-benzyl substituents with a 3-phenylallyl moiety as in **8** and **11** appears to result in a further decrease in inhibitory activity.

In companion studies, we have made significant progress toward the synthesis of aromatase inhibitors at C-19 (the angular methyl group attached to C-10). Derivatives with heteroatoms at C-19 are obvious substrate analogs of aromatase, and many of them compete for the enzyme active site (Scheme 4). The heteroatom at C-19 could coordinate to the heme iron as the sixth ligand and compete with oxygen binding. Several of these types of inhibitors are modified as mechanism-based inhibitors, presumably undergoing enzyme-mediated oxidation at the C-19 carbon to form the alkylating group and in the process become potent enzyme-activated inhibitors of aromatase (4,5).

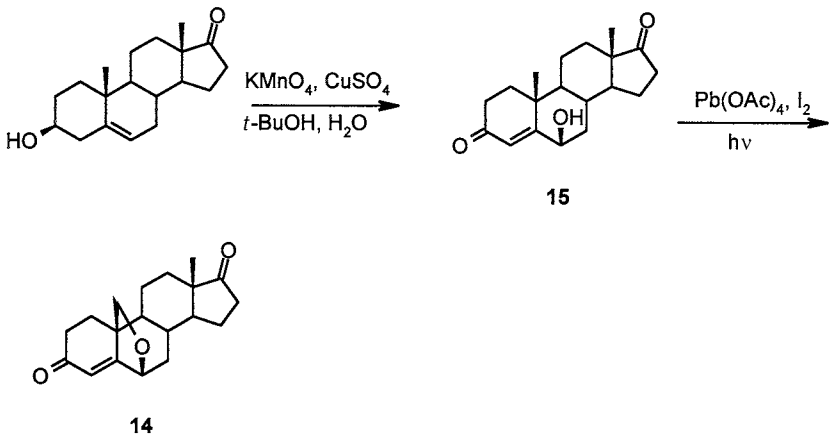
6β-Hydroxy steroids are key intermediates for the functionalization of the C-19 methyl group (34). Functionalization and subsequent modification at C-19 have previously yielded a large number and variety of potent inhibitors of aromatase (35,36). With these facts in mind, we have worked to develop a new and streamlined chemical synthesis of 6β-hydroxy steroids that could be easily converted to a C-19 functionalized derivative containing keto groups at C-3 and C-17. This type of intermediate can be prepared by "classical" synthesis using well-established chemical techniques (37,38). Unfortunately, this method requires a number of synthetic steps and is time-consuming (Scheme 8). The synthesis of the key intermediate **14** may be shortened by the use of our novel procedure to prepare the 6β-hydroxy intermediate **15** (Scheme 9) (38).

The intermediate **15** (Scheme 9; NBA, *N*-bromoacetamide) was prepared from a Δ^5-3β-hydroxy sterol using a mix-



14

SCHEME 8



15

14

SCHEME 9

ture of $KMnO_4$, $CuSO_4$, *t*-butanol, and water in methylene chloride, an oxidizing system previously used to prepare steroidal β-epoxides in high yields (39,40). This oxidizing reagent system serves as a phase-transfer catalyst and is believed to function in the omega phase, which is formed by water and *tert*-butyl alcohol over the surface of the inorganic salt, in the epoxidation with $KMnO_4$–$CuSO_4$ in methylene chloride and in the presence of water and *tert*-butyl alcohol (39,40). In contrast to these results, more hydrophilic substrates produced α-diketones as a predominant product (38). To further explore this permanganate reagent system, we studied its reaction with Δ^5-3β-hydroxy sterol substrates and found that sterols with hydrophobic side chains (e.g., cholesterol) gave 5β,6β-epoxy sterols in high yields. Identical sterols containing polar or hydrophilic side chains gave 3-keto-Δ^4-6β-hydroxy products (38).

These results may suggest that the face selectivity of this oxidizing reagent system results from the initial copper ion (or other metal ions) coordination on the less hindered α-face of the double bond forming a π-complex between the double bond and copper ion or other metal ions. The following permanganate attack on the β-face results in the β-epoxide. The formation of a π-complex also weakens the double bond and makes the permanganate attack possible. Apparently, the main group metal ions and metal ions with coordinate anions cannot form a π-complex with the double bond, so the reaction will not proceed. Mechanistically, further rearrangement may occur *via* the concomitant β-epoxidation of the Δ^5 double bond and oxidation of the 3-hydroxy group, followed by epoxide ring opening and proton elimination at C-4 to yield the Δ^4-unsaturated ketone (38).

In conclusion, we feel the results presented herein provide useful information on the structure–activity relationships of steroidal substrates and their orientation into the active site of aromatase. In addition, we have explored new chemical techniques that we believe will be useful to other investigators studying steroidal inhibitors of aromatase and will be of general interest to scientists in the steroid field.

ABSTRACT: Hairy roots of *Ajuga reptans* var. *atropurpurea* produce clerosterol, 22-dehydroclerosterol, and cholesterol as sterol constituents, and 20-hydroxyecdysone, cyasterone, isocyasterone, and 29-norcyasterone as ecdysteroid constituents. To better understand the biosynthesis of these steroidal compounds, we carried out feeding studies of variously ^{2}H- and ^{13}C-labeled sterol substrates with *Ajuga* hairy roots. In this article, we review our studies in this field. Feeding of labeled desmosterols, 24-methylenecholesterol, and $^{13}C_2$-acetate established the mechanism of the biosynthesis of the two C_{29}-sterols and a newly accumulated codisterol, including the metabolic correlation of C-26 and C-27 methyl groups. In *Ajuga* hairy roots, 3α-, 4α-, and 4β-hydrogens of cholesterol were all retained at their original positions after conversion into 20-hydroxyecdysone, in contrast to the observations in a fern and an insect. Furthermore, the origin of 5β-H of 20-hydroxyecdysone was found to be C-6 hydrogen of cholesterol exclusively, which is inconsistent with the results in the fern and the insect. These data strongly support the intermediacy of 7-dehydrocholesterol 5α,6α-epoxide. Moreover, 7-dehydrocholesterol, 3β-hydroxy-5β-cholest-7-en-6-one (5β-ketol), and 3β,14α-dihydroxy-5β-cholest-7-en-6-one (5β-ketodiol) were converted into 20-hydroxyecdysone. Thus, the pathway cholesterol → 7-dehydrocholesterol → 7-dehydrocholesterol 5α,6α-epoxide → 5β-ketol → 5β-ketodiol is proposed for the early stages of 20-hydroxyecdysone biosynthesis. 3β-Hydroxy-5β-cholestan-6-one was also incorporated into 20-hydroxyecdysone, suggesting that the introduction of a 7-ene function is not necessarily next to cholesterol. C-25 Hydroxylation during 20-hydroxyecdysone biosynthesis was found to proceed with *ca*. 70% retention and 30% inversion. Finally, clerosterol was shown to be a precursor of cyasterone and isocyasterone.

Paper no. L8274 in *Lipids 35,* 279–288 (March 2000).

20-Hydroxyecdysone is a molting hormone of most arthropods. The structure of the steroidal hormone is characterized by polyhydroxyl groups, a 7-en-6-one conjugated system, and a *cis*-A/B-ring junction. It is well documented that cholesterol serves as a biosynthetic precursor of the hormone in insects. Studies on the biosynthetic pathway of 20-hydroxyecdysone from cholesterol, exclusively carried out in insect species, are summarized in Scheme 1. 7-Dehydrocholesterol and 3β,14α-dihydroxy-5β-cholest-7-en-6-one (5β-ketodiol) are generally accepted intermediates. However, the mechanism of the early stages in 20-hydroxyecdysone biosynthesis (i.e., the mechanism of the formation of the 5β-H-7-en-6-one structure) remains uncertain (1–3).

20-Hydroxyecdysone and related steroids also are distributed in the plant kingdom (4,5), and they are designated as phytoecdysteroids. Cholesterol also is converted to 20-hydroxyecdysone in plants (6–10), but biosynthetic studies focusing on the chemical structures of intermediates have been limited in plants (11,12).

Ajuga (Labiatae) is a plant genus well known for its ecdysteroids. More than 150 varieties and subspecies of *Ajuga* plants are distributed over the world (13). These are especially abundant in China, Korea, and Japan and also are widespread in Europe. They have been used in folk medicine in various cultures; in China some *Ajuga* plants have been used to treat inflammation (14). Ecdysteroid constituents of a dozen of *Ajuga* plants are summarized in a review (15), and 20-hydroxyecdysone and cyasterone are phytoecdysteroids typical of these species. It is reported that *A. reptans* var. *atropurpurea* contains 20-hydroxyecdysone, cyasterone, 29-norcyasterone, and isocyasterone (16) (Scheme 2).

A decade ago, researchers of Daicel Chemical Industry Co. Ltd. developed clones of *A. reptans* var. *atropurpurea* hairy roots by infecting *Agrobacterium rhizogenes*, and this transformant reportedly contains ecdysteroids at levels several times higher than the original roots (16). We anticipated that the hairy roots would be appropriate for biosynthetic studies of ecdysteroids. In fact, our preliminary feeding studies of [1-^{13}C]acetate and [26,27 $^{13}C_2$]cholesterol resulted in successful incorporation; feeding of the ^{13}C-cholesterol (100 mg) to a liquid medium (1,000 mL distributed in four flasks, each containing cultures arising from *ca*. 1 g of fresh hairy roots) yielded *ca*. 5 mg of 20-hydroxyecdysone after a 2-wk incubation (following the 2-wk preincubation prior to the addition of substrate) with *ca*. 0.5% incorporation (17).

Ajuga plants are also unique in their sterol compositions, i.e., Δ^{25}-24β-alkylsterols (18). Analysis of the sterol fraction

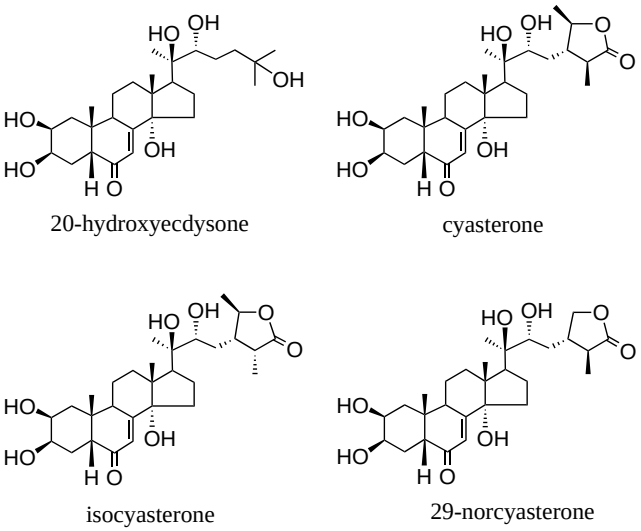


SCHEME 2

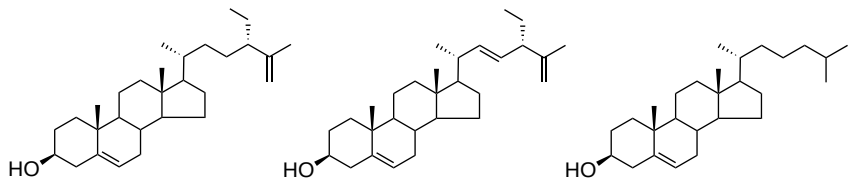
from the hairy roots of *A. reptans* var. *atropurpurea* revealed that clerosterol [(24*S*)-stigmasta-5,25-dien-3β-ol] and 22-dehydroclerosterol [(24*S*)-stigmasta-5,22,25-trien-3β-ol] were the two major sterol constituents, accompanied by a lesser amount of cholesterol (19) (Scheme 3). The two C_{29}-sterols are also identified in *A. nipponensis* (Fujimoto, Y., and Nomura, K., unpublished data).

We have undertaken studies of the mechanism of sterol and ecdysteroid biosynthesis with *Ajuga* hairy roots. Information on sterol biosynthesis is a prerequisite for better understanding of ecdysteroid biosynthesis. In this article, we review our work in this area.

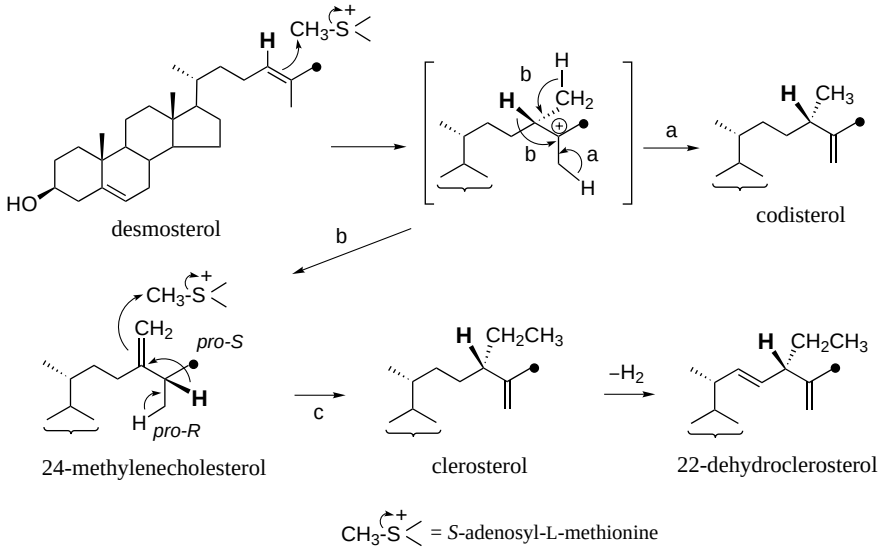
STEROL BIOSYNTHESIS

The Δ^{24}-double bond of a steroid side chain, such as cycloartenol, is alkylated to give 24-alkylsterols or reduced to afford cholesterol after a concomitant transformation of steroid nucleus structure. To obtain a general picture on the capacity of alkylative and/or reductive modification of Δ^{24}-double bond in *Ajuga* hairy roots, we first carried out a feeding experiment with [26,27-$^{13}C_2$]desmosterol. ^{13}C nuclear magnetic resonance (NMR) analysis of the biosynthesized sterols, isolated by a reversed-phase high-performance liquid chromatgraphy (HPLC), revealed that desmosterol is efficiently converted into clerosterol. Interestingly, a small amount of ^{13}C-enriched codisterol [(24*S*)-ergosta-5,25-dien-3β-ol], which has not been found in the original hairy roots but can be postulated as a precursor of 29-norcyasterone, was identified. ^{13}C-Desmosterol was also incorporated into cholesterol, but less efficiently than clerosterol and codisterol. Conversion into 22-dehydroclerosterol was negligible (19).

We then fed [28-^{13}C]-24-methylenecholesterol, which was found to be converted into clerosterol and 22-dehydroclerosterol. In addition, a small amount of ^{13}C-labeled campesterol, not present in the original hairy roots, was identified. Moreover, feeding of [24-^{2}H]-desmosterol revealed that the resulting codisterol and clerosterol had deuterium atoms at their C-24 positions, as indicated by ^{2}H NMR spectroscopy (19).



SCHEME 3

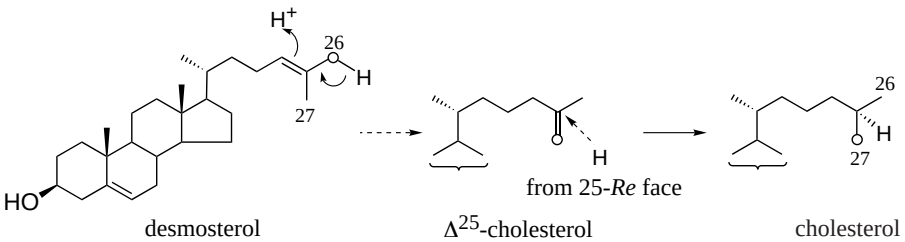


SCHEME 4

Metabolic correlation of C-26 and C-27 groups (Scheme 4; dots refer to a carbon correlated to C-2 of mevalonate) during these transformations was made possible by feeding desmosterol that was specifically ^{13}C-labeled at the isopropylidene (*E*)-methyl group. The resulting codisterol and clerosterol were ^{13}C-labeled at the methyl group, but not methylene, of the isopropenyl terminal (19). The relationships of C-26 and C-27 in these sterols was confirmed by experiments involving feeding [$^{13}C_2$]acetate. An intact ^{13}C-^{13}C bond connectivity was observed clearly between C-25 and exomethylene carbon of clerosterol and dehydroclerosterol, as evidenced by satellite doublet signals in ^{13}C NMR (Fujimoto, Y., and Nakagawa, T., unpublished data). Codisterol was not produced in this feeding condition.

On the basis of the data just described, the mechanism of Δ^{25}-24-alkyl sterol biosynthesis in *Ajuga* hairy roots is proposed as shown in Scheme 4 (19).The C-24 methylated cationic intermediate (in brackets in Scheme 4) generated by transfer of the methyl group of SAM from C-24 *Si*-face would be deprotonated by two pathways. Pathway "a" directly affords codisterol by deprotonation from the methyl group arising from (*Z*)-methyl group of desmosterol, i.e., C-6 of mevalonate. Pathway "b" leads to 24-methylenecholesterol *via* the migration of hydrogen at C-24 to C-25, followed by deprotonation from C-28. The second methylation from SAM at C-28 of $\Delta^{24(28)}$ double bond would produce the C-24 cationic intermediate, which affords clerosterol *via* the migration of hydrogen at C-25 to C-24, followed by deprotonation again from the methyl group arising from C-6 of mevalonate (Pathway "c").

Concerning the biosynthesis of cholesterol, puzzling data were obtained. Cholesterol obtained by feeding $^{13}C_2$-acetate showed satellite doublet signals for C-25 and C-27, whereas the C-26 signal appeared as a singlet, thus indicating that reduction of a Δ^{24}-sterol took place stereospecifically from the 25-*Si* face (20), in accordance with the observations with rats (21,22) and insects (23). In contrast, cholesterol derived from [(*E*)-methyl-^{13}C]desmosterol was enriched with ^{13}C both at *pro-R* (C-26) and *pro-S* (C-27) methyl groups, with the former being predominant. This partial scrambling of ^{13}C was further confirmed by complementary experiments using [(*Z*)-methyl-^{13}C]desmosterol (24). It appears that sterol Δ^{24}-reductase in the hairy roots works less efficiently than methyl transferase on desmosterol, since the conversion of desmosterol into cholesterol is rather poor. Feeding of the [exomethylene carbon-(C-27)-^{13}C]-Δ^{25}-cholesterol afforded cholesterol having ^{13}C label only at the *pro-S*-methyl group, thus establishing that hydrogen at C-25 was introduced stereospecifically from the 25-*Re* face (24). A similar stereospecific reduction of Δ^{25}-cholesterol was also observed with *Oryza sativa* cell cultures (24). On the basis of these findings, a double-bond isomerization pathway depicted in Scheme 5 [the carbons correlated to the (*E*)-methyl of desmosterol are indicated by



SCHEME 5

○], in addition to a straightforward reduction of desmosterol to cholesterol, would be proposed as an alternative route leading to cholesterol. A possible biological significance of Δ^{25}-cholesterol and a possible occurrence of sterol Δ^{25}-reductase distinct from Δ^{24}-reductase are open questions.

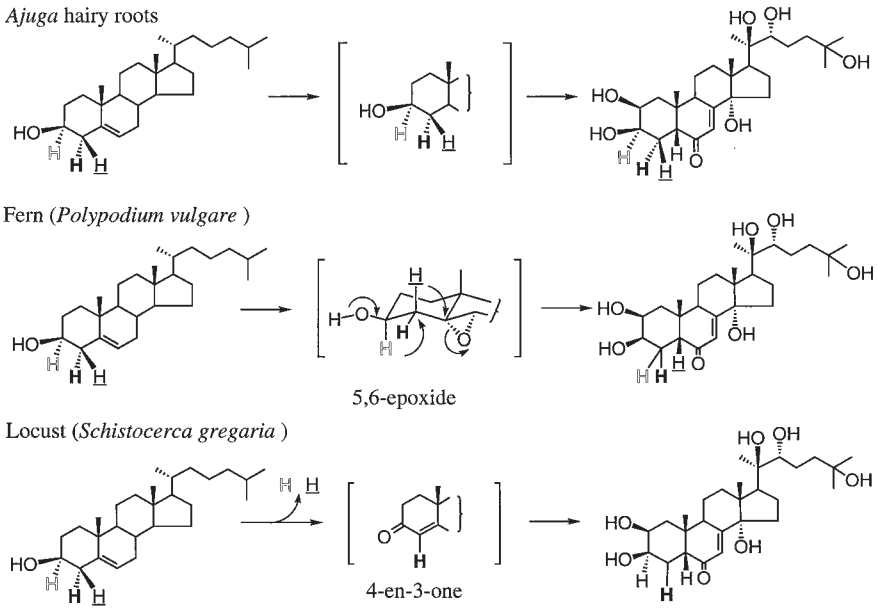
In an attempt to accumulate desmosterol or any 24,25-tetrasubstituted olefinic sterol, effects of addition of triparanol to the culture medium were examined. Triparanol is a well-known Δ^{24}-sterol reductase inhibitor in mammals (25), and various steps of sterol synthesis in yeast and/or algae also were reported to be inhibited by triparanol (26,27). However, its effects on sterol synthesis in higher plants have not fully been understood. Feeding of triparanol to *Ajuga* hairy roots did not lead to an accumulation of desmosterol, although the yields of cholesterol, clerosterol, and 22-dehydroclerosterol were decreased in a dose-dependent manner. Instead, two new sterols, (24ξ)-stigmasta-8,25-dien-3β-ol and (24ξ)-stigmasta-8,22,25-trien-3β-ol, appeared. Their structures were determined by spectral analysis of the isolated materials (Morisaki, M., and Takahashi, K., unpublished work). It seems that triparanol inhibited the isomerization of Δ^{8}- into Δ^{7}-olefin at some stage(s) of clerosterol and 22-dehydroclerosterol biosynthesis.

Effects of 25-azacholesterol, an inhibitor of sterol Δ^{24}-reductase and sterol Δ^{24}-methyl transferase (28), were also investigated. For example, addition (3 ppm) of 25-azacholesterol to the medium caused a reduction in growth of about one-half of the hairy roots; and accumulation of desmosterol (8% of total sterol), 24-methylenecholesterol (6%), and 24-methylcholesterol (2%) was observed (Fujimoto, Y., Nakagawa, T., and Ohyama, K., unpublished data). ^{13}C NMR analysis of desmosterol biosynthsized from [2-^{13}C]mevalonate in the presence of 25-azacholesterol revealed ^{13}C-label at the expected positions including the isopropylidene (*E*)-methyl group (Fujimoto, Y., and Ohyama, K., unpublished data). It appears that 25-azacholesterol is more potent in inhibiting Δ^{24}-sterol methyl transferase than triparanol in our hairy roots.

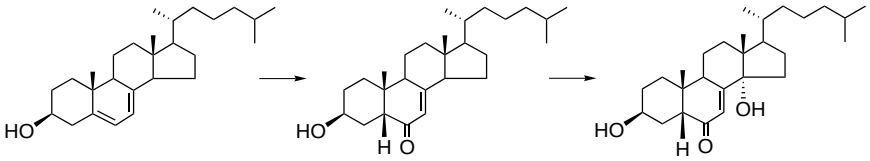
20-HYDROXYECDYSONE BIOSYNTHESIS

Once we knew that cholesterol was successfully converted into 20-hydroxyecdysone (17), we then investigated the fate of A-ring hydrogens during the conversion into 20-hydroxyecdysone. Our results obtained by feeding 3α-, 4α-, or 4β-^{2}H-labeled cholesterol followed by ^{2}H NMR analysis of the biosynthesized 20-hydroxyecdysone are summarized in Scheme 6 (29). Earlier data obtained by Goodwin's group using radioisotopes (^{3}H/^{14}C) in the fern *Polypodium vulgare* (30) and the insect *Schistocerca gregaria* (31) also are included in this scheme In *S. gregaria*, approximately 20% of 3α-hydrogen is reportedly retained at positions other than the C-3 of 20-hydroxyecdysone. In *Ajuga* hairy roots all three hydrogens remained at their original positions after conversion into 20-hydroxyecdysone (29). Very interestingly, comparison of the fates of A-ring hydrogens suggests that at least three distinct mechanisms are operating for the *cis*-A/B-ring formation. It was reported that in *Taxus baccatta* the 3α-hydrogen of cholesterol remains during the conversion into 20-hydroxyecdysone (32).

First, 7-dehydrocholesterol (in the form of 4-^{13}C) and 5β-ketodiol (in the form of 22,23,24,25-$^{3}H_4$) were fed to the hairy roots to compare the pathway established in insects. The two substrates were found to be incorporated into 20-hydroxyecdysone (Fujimoto, Y., Kushiro, T., Makka, T., and Sonobe, H., unpublished data). The results, combined with the observation that A-ring modification is not involved in *Ajuga* hairy roots, suggested that the Δ^{5}-double bond of 7-de-



SCHEME 6



7-dehydrocholesterol 5β-ketol 5β-ketodiol

SCHEME 7

hydrocholesterol is transformed to 5β-H-6-one system *via* a rather simple, but as yet unidentified mechanism. This prompted us to examine a possible intermediary role of 3β-hydroxy-5β-cholest-7-en-6-one (5β-ketol), which is not regarded as an intermediate in insects (33–35). [3α-^{2}H]- and [5-^{2}H]-5β-Ketols were converted into 20-hydroxyecdysone when fed to the hairy roots (29). The corresponding [3α-^{2}H]-5α-ketol was not converted into 20-hydroxyecdysone at all. It is therefore reasonable to place 5β-ketol as an intermediate between 7-dehydrocholesterol and 5β-ketodiol (Scheme 7).

We then focused on the origin of 5β-hydrogen of 20-hydroxyecdysone. In theory, it can be derived from C-4 or C-6 hydrogen of the substrate sterol, water, or a reducing cofactor such as NADPH. In the fern *P. vulgare*, the 4β-H of cholesterol reportedly is the origin (30), whereas in *S. gregaria*, 4β-H is lost during the transformation (30) (Scheme 6). In *Locusta migratoria*, we reported that most (90%) of 6-H of cholesterol is lost during the conversion into 20-hydroxyecdysone (36). In *Ajuga* hairy roots, feeding of [6-^{2}H]cholesterol followed by ^{2}H NMR analysis of the biosynthesized 20-hydroxyecdysone led to a deuterium signal at δ 2.95 corresponding to 5β-hydrogen, indicating 1,2-hydrogen migration from C-6 to C-5. Feeding a mixture of [6-^{2}H]- and [4β-^{2}H]-cholesterol as well as of a mixture of [6-^{2}H]- and [4α-^{2}H]cholesterol confirmed the 1,2-migration. However, the signal intensity of 5β-deuterium appeared to be somewhat smaller than expected (37). To eliminate a possible deuterium isotope effect and to estimate the precise magnitude of the 1,2-hydrogen migration, [3α,6-$^2H_2$]cholesterol was synthesized and fed to the hairy roots. The ^{2}H NMR spectrum of the resulting 20-hydroxyecdysone is illustrated in Figure 1, which clearly indicates that 70% of the 5β-hydrogen of 20-hydroxyecdysone comes from 6-H of cholesterol and the remaining 30% from other source (37).

Grebenok and Adler (9) have demonstrated that lathosterol is incorporated into 20-hydroxyecdysone in spinach leaves, but without discussing the intermediary role of 7-dehydrocholesterol. We synthesized [3α,6β-$^2H_2$]- and [3α,6α-$^2H_2$]-lathosterols, and they were separately fed to *Ajuga* hairy roots. ^{2}H NMR analysis of the resulting 20-hydroxyecdysone unambigously established that 6β-^{2}H migrated to the C-5 position of 20-hydroxyecdysone, whereas 6α-^{2}H was lost during the conversion, probably due to the well-known *cis*-elimination in the formation of Δ^5-sterol from Δ^7-sterol in plants (38–40). Again, the behavior of 6β-^{2}H of lathosterol was nonstoichiometric (*ca*. 70% migration) (41). The observed 1,2-migration of 6β-hydrogen of lathosterol supports the obligatory intermediary role of

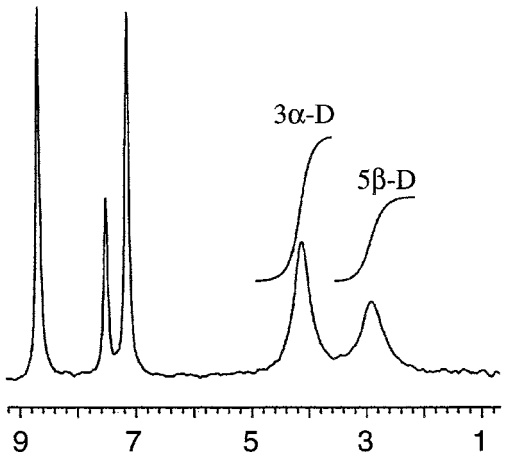


FIG. 1. ^{2}H Nuclear magnetic resonance (NMR) spectrum (pyridine, 77 MHz) of 20-hydroxyecdysone derived from [3α,6-$^2H_2$]cholesterol. The spectrum indicates that *ca*. 70% of the 6-hydrogen (compared to the 100% retention of the 3α-hydrogen) of cholesterol migrates to the C-5 position of 20-hydroxyecdysone.

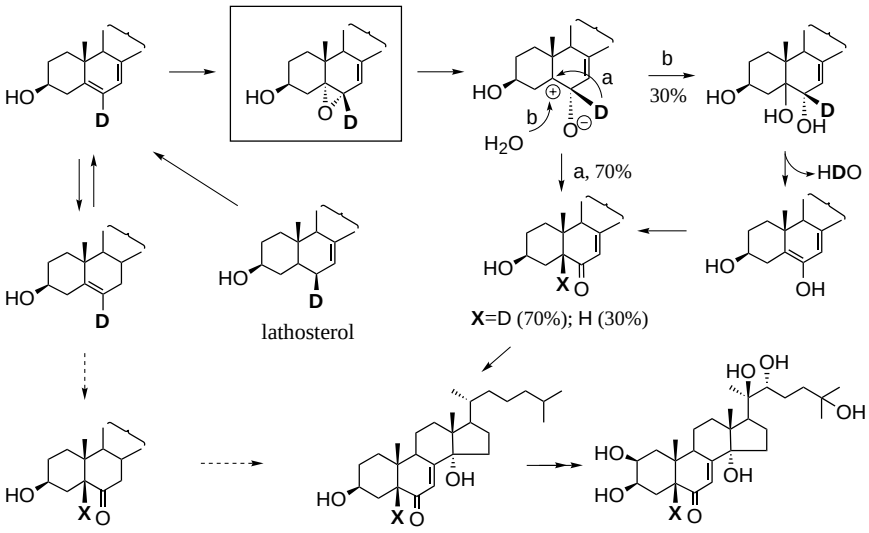
7-dehydrocholesterol, ruling out a pathway involving a direct C-6 oxidation of lathosterol in *Ajuga* hairy roots.

The ^{2}H NMR spectrum of cholesterol, isolated from hairy roots upon feeding [3α,6β-$^2H_2$]lathosterol, showed two deuterium signals at δ 3.51 and 5.35 corresponding to 3α-H and 6-H, respectively, in an equal intensity. As expected, cholesterol derived from [3α,6α-$^2H_2$]lathosterol showed a single signal at δ 3.51. These data further supported the highly stereospecific elimination of 6α-hydrogen and, more importantly, evidenced no loss of 6β-hydrogen during the conversion of lathosterol into cholesterol *via* 7-dehydrocholesterol (41). Furthermore, we recently found that the C-5 hydrogen of 5β-ketol is retained completely during the subsequent conversion into 20-hydroxyecdysone (41). Thus, it is in the step of *cis*-A/B-ring formation, i.e., the conversion of a key oxidized intermediate into 5β-ketol, that *ca*. 30% of C-5 hydrogen of 20-hydroxyecdysone not derived from 6-H of cholesterol is introduced.

We (42) and others (30,43–45) postulated a possible involvement of 7-dehydrocholesterol 5α,6α-epoxide in ecdysteroid biosynthesis. Chemical stability of this epoxide and its 5β,6β-isomer has also been reported (46). Our present demonstration of 1,2-hydrogen migration from C-6 to C-5 position strongly suggests that the 5α,6α-epoxide would produce 5β-ketol *via* epoxy-carbonyl rearrangement as shown in path "a" of Scheme 8. Partial (30%) solvolytic hydrolysis of the same epoxide (path "b" in Scheme 8) yielding the 5,6-gly-



SCHEME 8

col, which is reminiscent of the structure of bombycosterol isolated from ovaries of the silkworm, *Bombyx mori* (42), and the subsequent dehydration would account for the formation of the nonlabeled 5β-ketol.

Quite recently we found that [3-^{2}H]-3β-hydroxy-5β-cholestan-6-one is incorporated into 20-hydroxyecdysone, whereas the corresponding 5α-congener is not incorporated at all (47). Further, the isolation and characterization of 7,8-dihydroecdysteroids are reported (48,49). These data may suggest that a Δ^7-double bond (or its absence) is not essential for the enzymatic formation of 5β-H-6-one structure. In other words, Δ^7-double bond can be introduced at a later stage. Our preliminary study of feeding of [3-^{2}H]cholesterol 5α,6α-epoxide resulted in negligible conversion into 20-hydroxyecdysone (47). Neither 5α,6α- nor 5β,6β-epoxides, possible intermediates in this pathway, are reportedly converted into 20-hydroxyecdysone in a plant (50).

STEREOCHEMICAL COURSE OF 25-HYDROXYLATION

The transformation in the later stages of 20-hydroxyecdysone involves a hydroxylation at the C-2, C-20, C-22, and C-25 positions. It was reported that C-20, C-22, and C-25 hydroxylations are catalyzed by P_{450} monooxygenase enzymes (51–54), whereas a different type monooxygenase (not inhibited by CO) is responsible for C-2 hydroxylation (55,56). Further, C-2 hydroxylation in *S. gregaria* (57) and *Ajuga* hairy roots (58) and C-22 hydroxylation in *S. gregaria* (59) were reported to proceed with retention of stereochemistry.

As described above, C-26 and C-27 of cholesterol are stereospecifically derived from C-2 and C-6 of mevalonate, respectively. Inspection of the ^{13}C NMR spectrum of 20-hydroxyecdysone derived from [$^{13}C_2$]acetate revealed that the signal of C-25 (δ 71.3) has a flanking doublet. In accord with this pattern, one of the methyl signals on C-25 (δ 29.7) was accompanied by a flanking doublet. The other methyl signal (δ 28.9) on C-25 is also accompanied by satellite peaks with a weak, but significant intensity. The incorporation of an acetate unit into both C-25–C-26 and C-25–C-27 of 20-hydroxyecdysone, combined with the above finding on cholesterol (no scrambling), suggested a possibility that C-25 hydroxylation during the formation of 20-hydroxyecdysone is not stereospecific.

To know metabolic relationships of the isopropyl *pro-R* and *pro-S* methyl groups of cholesterol and 20-hydroxyecdysone, one must be able to discriminate the two methyl groups on C-25 prochiral center. A ^{13}C labeling technique can be conveniently employed to trace the metabolic fates of the diastereotopic methyl groups, provided that the ^{13}C chemical shifts for the isopropyl *pro-R* and *pro-S* methyl groups of the substrate and product are unequivocally assigned. Thus, the ^{13}C chemical shifts of *pro-S* (C-27) (δ 28.9) and *pro-R* (C-26) (δ 29.7) of 20-hydroxyecdysone were first assigned by chemical synthesis of stereochemically defined model compounds having the same 20*R*,22*R*,25-trihydroxy side-chain structure as in 20-hydroxyecdysone, [26-^{2}H]-(20*R*,22*R*,25)-trihydroxycholesterol 3-methyl ether (one of the hydrogen atoms of the *pro-R*-methyl group is substituted by deuterium) and its [27-^{2}H]epimer (20).

Stereospecifically synthesized [*pro-R*-methyl-^{13}C]- and [*pro-S*-methyl-^{13}C]cholesterols were separately fed to *Ajuga* hairy roots. As shown in the ^{13}C NMR spectrum (Fig. 2), 20-hydroxyecdysone derived from the former isomer revealed that ^{13}C label was found in *pro-S*- (*ca.* 75%) and *pro-R*- (*ca.* 25%) methyl groups. Feeding of [*pro-S*-methyl-^{13}C]cholesterol afforded complementary results (20). Subsequently, six hydrogens at the C-26 and C-27 methyl groups were shown to be completely retained during this conversion (Fujimoto, Y., and Tatara, A., unpublished data). It is therefore concluded that C-25 hydroxylation in the biosynthesis of 20-hydroxyecdysone

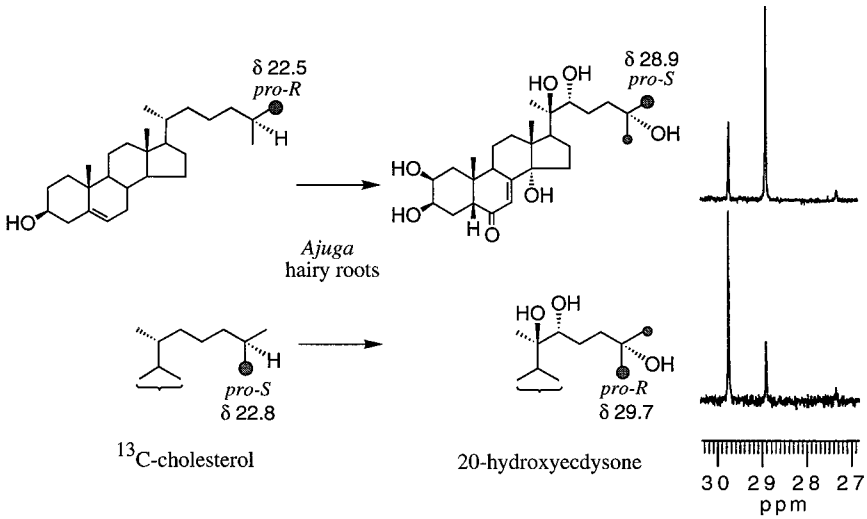


FIG. 2. Nonstereospecific C-25 hydroxylation (*ca*. 3:1 ratio retention/inversion) in 20-hydroxyecdysone biosynthesis in *Ajuga* hairy roots. The ^{13}C NMR spectra (in CD_3OD, 75 MHz) are those of 20-hydroxyecdysones derived from each ^{13}C-labeled cholesterol (>98% specifically labeled with ^{13}C at either C-26 or C-27). For abbreviation see Figure 1.

from cholesterol in *Ajuga* hairy roots is not stereospecific, but proceeds with a ratio of *ca*. 3:1 retention/inversion.

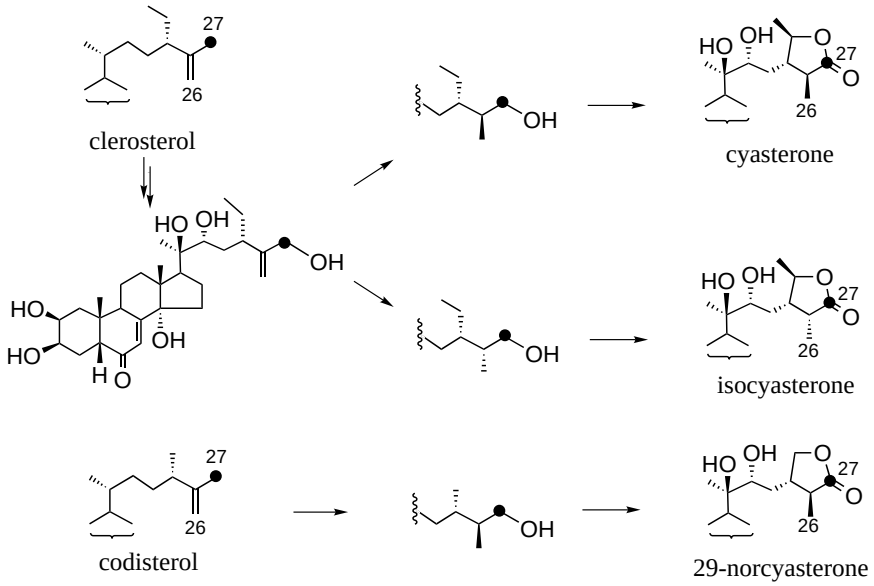
Another example of steroidal C-25 hydroxylation of vitamin D_3, mediated by the microorganism *Sphingomonas* sp. HD-1 (60), was revealed to be stereospecific with retention of configuration (Fujimoto, Y., and Tatara, A., unpublished data); C-25 hydroxylation in 20-hydroxyecdsone biosynthesis seems to be unique and studies in enzyme level are eagerly awaited. cDNA cloning of mouse and human cholesterol 25-hydroxylases has been reported recently (61).

BIOSYNTHESIS OF CYASTERONE AND ITS CONGENERS

In the feeding experiment with [26,27-$^{13}C_2$]cholesterol, which was converted into 20-hydroxyecdysone, neither cyasterone, isocyasterone, nor 29-norcyasterone was labeled with ^{13}C. On [1-^{13}C]- or $^{13}C_2$-acetate feeding, the C-24 substituents of these phytoecdysteroids were not labeled (17). These data imply that the biosynthetic route leading to these C_{29}- and C_{28}-ecdysteroids is branched at a stage before cholesterol. In fact, [26,27-$^{13}C_2$]cycloartenol was converted into cyasterone, isocyasterone, and 29-norcyasterone as well as 20-hydroxyecdysone (Morisaki, M., and Yamada, J., unpublished data). Cyasterone was first isolated from *Cyathula capitata* (62), whose major sterols appear to be [24α]-alkylsterols such as sitosterol and stigmasterol (63,64). Subsequently, a biosynthetic study was performed in this plant, resulting in negligible conversion of sitosterol and fucosterol into cyasterone (63,64). In contrast, Δ^{25}-24-ethylsterols and phytoecdysteroids of *Ajuga* hairy roots have the same 24β configuration. Thus, it is reasonable to assume that these sterols could serve as the precursors of C_{29}-phytoecdysteroids.

We previously found that a mixture of [26,27-$^{13}C_2$]clerosterol and its C-24 epimer was incorporated into cyasterone. More recently, several C_{29}-sterols including [27-^{13}C]clerosterol, its [27-^{13}C]-C-24-epimer, [26-^{13}C]-(25*RS*)-sitosterol, and [26-^{13}C]-(25*RS*)-clionasterol were fed to hairy roots, and only clerosterol was found to be incorporated into cyasterone and isocyasterone (Fujimoto, Y., Nomura, K., Takahashi, K., and Morisaki, M., unpublished data). This provides the first clear evidence for the structure of sterol precursor of the C_{29}-phytoecdysteroids. Similarly, codisterol is likely to be a precursor of 29-norcyasterone, although we only have the results obtained by feeding a mixture of ^{13}C-labeled codisterol and its C-24-epimer. It should be noted that the ^{13}C-label was found in lactone carbonyl both of cyasterone and isocyasterone biosynthesized from [27-^{13}C]clerosterol. Feeding experiments with $^{13}C_2$-acetate showed an intact ^{13}C-^{13}C connectivity between C-25 and methyl (C-26) group of cyasterone and isocyasterone as well as 29-norcyasterone. From these data it can be concluded that lactone carbonyl carbon of the three phytoecdysteroids is derived from C-2 of mevalonate while C-27 comes from C-6 of mevalonate (Scheme 9; dots refer to a carbon correlated to C-2 of mevalonate).

It was reported that co-occurrence of cyasterone and isocyasterone was caused by nonstereospecific hydroxylation of both methyl groups of the isopropyl terminal of side chain (65). Our observation above ruled out this possibility. Rather, the co-occurrence is due to a nonstereospecific hydrogenation at a certain stage in which exomethylene group is converted into methyl group. A biosynthetic pathway leading to cyasterone and isocyasterone is depicted as in Scheme 9, in which an intermediate structure with fully oxidized nuclei is adopted from several oxygenated steroids isolated from *C. capitata*, which also contains cyasterone (66).



SCHEME 9

CONCLUSION

In *Ajuga* hairy roots, feeding studies of synthetic ^{13}C- or ^{2}H-labeled sterols and/or $^{13}C_2$-acetate have provided several lines of evidence that shed light on the biosynthesis of Δ^{25}-24-alkylsterols (clerosterol, 22-dehydroclerosterol, and codisterol) as well as 20-hydroxyecdysone, cyasterone, isocyasterone, and 29-norcyasterone. The origin of C-26 and C-27 of these steroidal compounds was correlated with each other, and further with C-2 and C-6 of mevalonate. As demonstrated with *Ajuga* hairy roots and *O. sativa* cell cultures, plants appear to have a capacity to reduce Δ^{25}-cholesterol, although its physiological importance is unclear at present.

As for the biosynthesis of 20-hydroxyecdysone, crucial evidence supporting the intermediacy of 7-dehydrocholesterol 5α,6α-epoxide has been obtained for the first time; the C-6 hydrogen of cholesterol mostly migrates to the C-5 position of 20-hydroxyecdysone. An epoxy-carbonyl rearrangement of this epoxide would afford 5β-ketol which also characterized as an intermediate in *Ajuga* hairy roots. It should be noted that the metabolic fate of A-ring hydrogens as well as the C-6 hydrogen of cholesterol is different between *Locusta*, *Polypodium*, and *Ajuga* hairy roots. This suggests three distinct mechanisms are operating in construction of a 5β-H-7-en-6-one structure of 20-hydroxyecdysone, depending on the species. It is important to examine the fate of C-6 hydrogen of cholesterol in insects and other plants.

Based on our recent finding that 3β-hydroxy-5β-choletan-6-one is converted into 20-hydroxyecdysone in *Ajuga* hairy roots, an alternate pathway, cholesterol → cholesterol 5α,6α-epoxide → 3β-hydroxy-5β-cholestan-6-one → 5β-ketol should be also considered, in addition to the previously proposed route: cholesterol → 7-dehydrocholesterol → 7-dehydrocholesterol 5α,6α-epoxide → 5β-ketol.

ACKNOWLEDGMENTS

We wish to express our thanks to Professor Emeritus Nobuo Ikekawa of Tokyo Intitute of Technology for his continued encouragement. We are grateful to Mitsuhiro Nagakari, Takayoshi Nakagawa, Akinori Tatara, Kinya Nakamura, Tomoko Yazaki-Yagi, and Dr. Tetsuo Kushiro for their partial contribution in the work. Part of this research was supported by a Grant-in-Aid for Scientific Research (No. 02640422) and a Grant-in-Aid for Scientific Research on Priority Areas (08276207) to Y.F. from the Ministry of Education, Science, Sports and Culture of Japan. Thanks are also due to Drs. Takeshi Matsumoto and Nobukazu Tanaka, Bioassay Laboratory, Research Center, Daicel Chemical Industries Ltd., for providing *Ajuga* hairy root cultures, and Dr. Akio Ozaki, Tokyo Research Laboratories, Kyowa Hakko Kogyo Co. Ltd., for providing the strain of *Sphingomonas* sp.

ABSTRACT: Treatment of neonatal rats with U18666A, an inhibitor of desmosterol Δ^{24}-reductase, results in accumulation of desmosterol ($\Delta^{5,24}$) and depletion of cholesterol (Δ^{5}) in various bodily tissues and also causes cataracts. We evaluated the effects of U18666A on the sterol composition, *de novo* sterol synthesis, and histological structure of the retina. Neonatal Sprague-Dawley rats were injected subcutaneously with U18666A (15 mg/kg, in olive oil) every other day from birth through 3 wk of age; in parallel, control rats received olive oil alone. At 21 d, treated and control groups each were subdivided into two groups: one group of each was injected intravitreally with [^{3}H]acetate; retinas were removed 20 h later and nonsaponifiable lipids (NSL) were analyzed by radio-high-performance liquid chromatography. The other group was injected intravitreally with [^{3}H]leucine; 4 d later, one eye of each animal was evaluated by light and electron microscopy and light microscopic autoradiography, while contralateral retinas and rod outer segment (ROS) membranes prepared therefrom were analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis/fluorography. In the treated group, the $\Delta^5/\Delta^{5,24}$ mole ratio of retinas was *ca.* 1.0, and >88% of the NSL radioactivity was in $\Delta^{5,24}$; in contrast, control retinas had $\Delta^5/\Delta^{5,24}$ >170, with >80% of the NSL radioactivity in Δ^5. Retinal histology, ultrastructure, ROS renewal rates, and rhodopsin synthesis and intracellular trafficking were comparable in both treated and control animals. These results suggest that desmosterol can either substitute functionally for cholesterol in the retina or it can complement subthreshold levels of cholesterol by sterol synergism.

Paper no. L8271 in *Lipids 35*, 289–296 (March 2000).

One focus of our research over the past two decades has been the elucidation of the biological roles of sterols (e.g., cholesterol) and other isoprenoids in the vertebrate retina, with emphasis on their involvement in the biogenesis and renewal of retinal rod outer segment (ROS) membranes (reviewed in Ref. 1). To address this problem, we took two different general approaches. In the first, we attempted to deplete the retina of its endogenous cholesterol by intravitreal administration of lovastatin (mevinolin; Mevacor®, Merck & Co., Rahway, NJ), a global inhibitor of *de novo* isoprenoid biosynthesis (2), and then we examined the effects of this treatment on retinal lipid metabolism, histology, and ultrastructure. While this strategy proved effective in blocking *de novo* cholesterol synthesis in adult rat retinas (3,4) and caused a profound and irreversible retinal degeneration (4,5), we were unable to reduce appreciably the steady-state cholesterol content of the retina by this method. This latter finding likely is due to a combination of two factors: (i) lovastatin treatment does not prevent delivery and uptake of blood-borne cholesterol to the retina (e.g., *via* the low density lipoprotein pathway), and (ii) the endogenous cholesterol in the retina has a very slow turnover rate and also apparently is "recycled" within the retina (for a detailed discussion, see Ref. 1). The degenerative effects of intravitreal lovastatin are thought to be a consequence of the inhibition of protein prenylation, rather than due to effects on *de novo* sterol biosynthesis (4). Hence, we sought to use a different approach, this time attempting to replace the endogenous cholesterol in the retina with other, biogenically related sterols, using selective, late-stage inhibitors of the sterol pathway that cause reduction of endogenous cholesterol and concomitant accumulation of cholesterol precursors. One such late-stage inhibitor is 3-β(2-diethylaminoethoxy)androst-5-en-17-one hydrochloride (U18666A), which blocks desmosterol Δ^{24}-reductase and also (at much higher concentrations) can inhibit oxidosqualene cyclase (6,7) (Fig. 1). Previously, it was shown that systemic treatment of neonatal rats with U18666A leads to cataract formation (8). In the present study, we evaluated the effects of U18666A treatment on retinal sterol composition and metabolism, as well as its effects on retinal histology, ultrastructure, and ROS membrane assembly in neonatal rats.

Abbreviations: EM, electron microscopy; HPLC, high-performance liquid chromatography; LM, light microscopy; LMARG, light microscopic autoradiography; NSL, nonsaponifiable lipids; RIS, rod inner segment; ROS, rod outer segment; SDS, sodium dodecyl sulfate; SDS-PAGE, SDS-polyacrylamide gel electrophoresis; SLO, Smith-Lemli-Opitz syndrome; U18666A, 3-β(2-diethylaminoethoxy) androst-5-en-17-one hydrochloride; Δ^5, cholesterol (cholest-5-en-3β-ol); $\Delta^{5,24}$, desmosterol (cholesta-5,24-dien-3β-ol).

EXPERIMENTAL PROCEDURES

Materials. Unless otherwise stated, all reagents and lipid standards were of analytical reagent grade or higher and were used as purchased from Sigma Chemical Co. (St. Louis, MO).

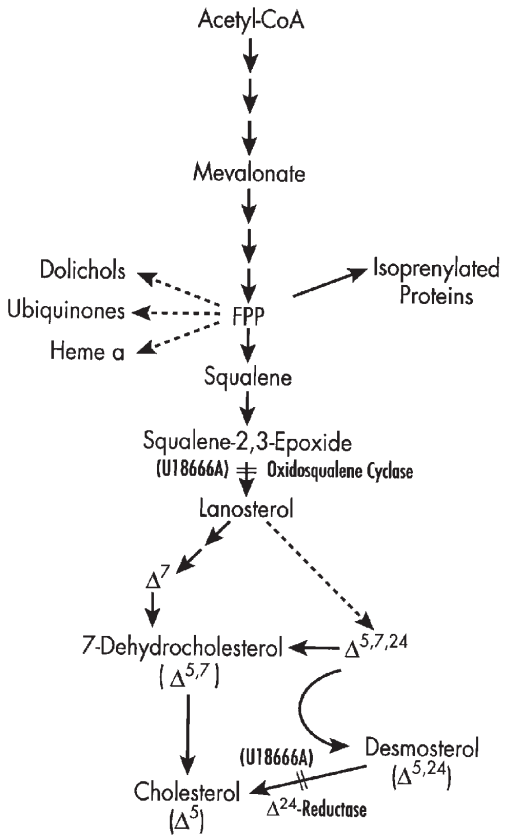

FIG. 1. Schematic diagram of the isoprenoid pathway, illustrating inhibition of the pathway by 3-β(2-diethylaminoethoxy)androst-5-en-17-one hydrochloride (U18666A). The primary site of enzymatic inhibition is at the level of desmosterol reductase (Δ^{24}-reductase); a secondary site of inhibition (at high concentrations of U18666A) is at the level of oxidosqualene cyclase. FPP, farnesyl pyrophosphate.

U18666A was a generous gift from Upjohn Co. (Kalamazoo, MI). [^{3}H]Acetate (Na salt; 15 Ci/mmol) and L-[3,4,5-^{3}H]leucine (120 Ci/mmol) were used as purchased from American Radiolabeled Chemicals (St. Louis, MO). All organic solvents were high-performance liquid chromatography (HPLC) grade (Burdick & Jackson, McGraw Park, IL). Microscopy supplies were obtained from Electron Microscopy Sciences (Fort Washington, PA) and from Polysciences, Inc. (Warrington, PA). Gel electrophoresis reagents and supplies and protein molecular weight markers were from Bio-Rad Laboratories (Richmond, CA).

Animals. All procedures performed on animals were in compliance with the *NIH Guide for the Care and Use of Laboratory Animals* and with the *ARVO Resolution on the Use of Animals in Research*. Female Sprague-Dawley rats (200–250 g; Hilltop Lab Animals, Scottdale, PA, or Harlan Sprague-Dawley, Inc., Indianapolis, IN) and their litters (8–11 pups each) were maintained under cyclic lighting (12 h light, 12 h dark; standard fluorescent room illumination) at 70–75°C ambient temperature, with *ad libitum* access to water and standard rodent chow (LM-485; Tek Lad, Indianapolis, IN). Animals were euthanized by exposure to carbon dioxide vapors.

U18666A treatment protocol. Using the protocol essentially as described by Cenedella and Bierkamper (8), litters of rat pups were injected every other day with U18666A (15 mg/kg, in U.S.P. olive oil suspension. *s.c.*), starting on postnatal day 1 (P1) and continuing through 3 wk (P21). Control pups received olive oil vehicle injections alone. In this series, at least 80% of the treated animals developed cataracts by P21, whereas cataracts were not observed in any of the control animals.

Lipid analysis. Retinas and lenses from P21 animals were harvested in pairs, pooling the tissues from both eyes of a given animal. Intracardiac blood was drawn and allowed to clot, and serum was obtained by centrifugation. Livers were removed, rinsed briefly with phosphate-buffered saline, blotted dry, and weighed prior to saponification. Conditions for saponification, extraction of nonsaponifiable lipids, and analysis of the nonsaponifiable lipids by HPLC and radio-HPLC were as described previously (9). For these analyses, we employed a Brownlee Spheri-5 C18 reversed-phase column (100 × 4.6 mm; PerkinElmer, Norwalk, CT) with a NewGuard® RP-18 guard column (PerkinElmer), using MeOH as the mobile phase (flow rate, 1 mL/min), with detection at 205 nm. Using this system, desmosterol (cholesta-5,24-dien-3β-ol) ($\Delta^{5,24}$) had a relative retention time of 0.82 [relative to that of cholesterol (cholest-5-en-3β-ol) (Δ^5), 1.00] and a relative molar response factor of 2.53 (relative to cholesterol, 1.00). Squalene had a relative retention time of 1.43 and a relative molar response factor of 12.89. By comparison, squalene-2,3-epoxide (a gift from Dr. Thomas Spencer, Department of Chemistry, Dartmouth College) had a relative retention time of 0.74. HPLC peak assignments were made in comparison with these reference standards, and each sterol was quantified by integrated peak area analysis in comparison with the empirically determined response factor (integration units per nmol) for the given standard compound.

Assessing de novo *lipid synthesis.* To evaluate the effect of U18666A on *de novo* synthesis of retinal sterols, 3-wk-old rat pups (four treated, four control) were injected in each eye with [^{3}H]acetate (0.43 mCi/eye), by methods described in detail previously (3). After allowing 20 h for metabolism of the radiolabeled precursor, the animals were euthanized, and retinas were harvested in pairs and subjected to subcellular fractionation to obtain purified ROS membranes and a "residual retina" membrane fraction (see below). Those tissue fractions were then saponified, extracted, and the nonsaponifiable lipids were analyzed by radio-HPLC.

Subcellular fractionation. Purified ROS membranes and a "residual retina" membrane fraction (ROS-depleted retinal membranes) were prepared from pairs of pooled rat retinas by discontinuous sucrose gradient ultracentrifugation, using a minor modification of a procedure originally designed for frog retina, as described in detail elsewhere (10). In this case, density gradient solutions of 36, 32, and 26% sucrose (by weight) were employed, and ROS membranes were harvested from the 26%/32% sucrose solution interface.

Microscopy and autoradiography. In order to evaluate the effect of U18666A on the rate of ROS membrane assembly, as

well as to assess the effects on retinal histology and ultrastructure, another group of 3-wk-old rat pups (four treated, four control) was injected in each eye with [^{3}H]leucine (0.164 mCi/eye). Four days later (P25), the animals were euthanized; one eye from each animal was subjected to fixation in mixed aldehydes, processed for embedment in plastic resin, and subsequently analyzed by light and electron microscopy (LM, EM), as well as by light microscopic autoradiography (LMARG), as previously described (4,11). LM and LMARG sections were viewed and photographed with an Olympus BH-2 photomicroscope, using a 20× DPlanApo lens. The displacement of "bands" of silver grains from the base of ROS in LMARG autoradiograms from treated and control retinas was measured using an ocular micrometer reticule and a 63× oil immersion lens, making five independent measurements from three retinal sections per animal and three animals per group (treated vs. controls). EM sections were viewed and photographed with a JEOL 1200EX electron microscope (Tokyo, Japan).

Gel electrophoresis of retinal proteins. Companion retinas from contalateral eyes of animals injected intravitreally with [^{3}H]leucine were harvested, and ROS and residual retina membranes were prepared therefrom (see above). The tissue fractions were solubilized in sodium dodecyl sulfate (SDS) "sample buffer" (12), subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE) on 10% polyacrylamide gels and then processed for fluorography as previously described (10,11) to visualize the radiolabeled retinal proteins. Total retinal protein (~50 μg) and ROS protein (5 μg) were loaded per lane from treated and control animal specimens. Apparent molecular weights of proteins were determined in comparison with authentic protein molecular weight standards.

RESULTS

The reversed-phase HPLC profiles for nonsaponifiable lipids obtained from the serum and livers of U18666A-treated and control rats at P21 are shown in Figure 2. In control tissues (Figs. 2C and 2D), cholesterol (Δ^5) was virtually the only sterol detected in appreciable amounts. However, in the corresponding tissues from U18666A-treated rats (Figs. 2A and 2B), the major identifiable sterol was desmosterol ($\Delta^{5,24}$), while cholesterol represented a comparatively minor component. Appreciable squalene mass also was observed in livers, but not serum, of both control and treated animals. Since the molar absorbance for desmosterol at 205 nm is 2.53 times that of cholesterol (due to the additional double bond), one cannot compare the peak heights directly by visual inspection to ascertain the relative proportion of each sterol. The corresponding quantitative data, taking the molar absorbance values for each sterol into account, for serum and liver sterols are given in Table 1. Total serum sterol levels were reduced by about one-third in treated animals, relative to controls. While serum cholesterol levels in treated rats were only about 17% of control values, desmosterol levels were nearly 280 times higher than in controls. Consequently, whereas the cholesterol/desmosterol molar ratio in control serum was ~480, this ratio was only 0.33 in the serum

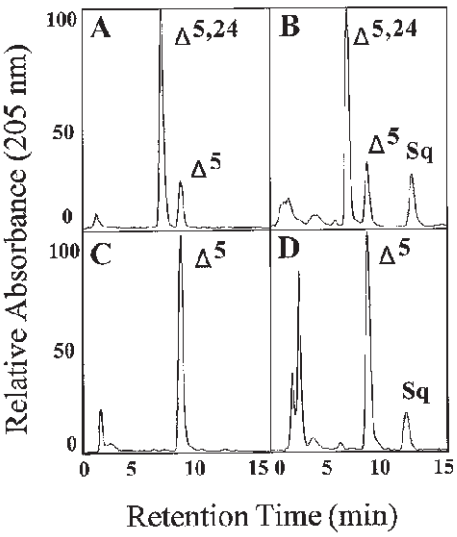

FIG. 2. Reversed-phase high-performance liquid chromatography (HPLC) chromatograms of nonsaponfiable lipids from serum (A,C) and liver (B,D) obtained from U18666A-treated (upper panels) and control (lower panels) rats. The elution positions corresponding to cholesterol (cholest-5-en-3β-ol) (Δ^5), desmosterol (cholesta-5,24-dien-3β-ol) ($\Delta^{5,24}$), and squalene (Sq) are indicated. Detector response (absorbance at 205 nm) is normalized to full-scale response for the predominant component. See Figure 1 for other abbreviation.

of treated animals (i.e., 0.07% of the control ratio). Similarly, total sterol levels in livers from treated animals were only about 84% of control levels, and cholesterol levels were only about 36% of control levels. However, desmosterol values from livers of treated animals were about 350 times the control levels; hence, the cholesterol/desmosterol molar ratio in livers of treated animals was only about 0.1% that of control livers.

A similar trend was found in the pattern of sterols obtained from "residual retina" and purified ROS membranes, as determined by HPLC (Fig. 3). Again, in control tissue fractions (Figs. 3C and 3D), cholesterol was the predominant sterol; a small peak corresponding to desmosterol also was observed. However, in retinas and ROS membranes from U18666A-treated animals (Figs. 3A and 3B), desmosterol was the major sterol, while cholesterol represented only a minor component. [The material eluting as broad, unresolved peaks prior to 5 min by reverse-phase HPLC represents variable, unidentified, polar components.] In good agreement with prior studies (3,9), rat retinas did not contain appreciable amounts of squalene. Quantitative sterol data for ROS membranes and residual retina are presented in Table 1. In control P21 rats, cholesterol accounted for >99 mol% of the total sterol mass in residual retina and ROS membranes, and the cholesterol/desmosterol molar ratios were ~171 and 149, respectively. In contrast, cholesterol represented only about one-half the total sterol mass in residual retina and ROS membranes (49.0 and 52.6%, respectively) of U18666A-treated P21 rats, so the cholesterol/desmosterol molar ratio in each was about one (0.98 and 1.11, respectively).

These data demonstrate that systemic treatment of neonatal rats with U18666A, using the given treatment protocol, re-

TABLE 1
Sterol Composition of Tissues from P21 Control and U18666A-Treated Rats[a]

	Total sterol	Cholesterol	Desmosterol	$\Delta^5/\Delta^{5,24}$ Molar ratio

sulted in abnormal and marked accumulation of desmosterol and substantial reduction of cholesterol in serum, liver, retina, and ROS membranes, with desmosterol accounting for the predominant sterol in all tissues examined. In addition, the lack of reduction in total sterols plus the absence of a component exhibiting the chromatographic properties of squalene-2,3-epoxide (which would have eluted just prior to desmosterol on the HPLC system employed) in the residual retina and ROS membrane fractions suggests that, under these conditions, the enzymatic inhibition was restricted to desmosterol reductase and did not compromise oxidosqualene cyclase (*cf.* Ref. 7 and Fig. 1). Although squalene-2,3-epoxide was not detected in the liver or serum of U18666A-treated rats, the apparent reduction of total sterols in these fractions (Table 1) suggests that inhibition occurred at an earlier enzymatic site in the cholesterol pathway, in addition to desmosterol reductase.

The data presented above represent the steady-state composition of the tissues examined. In the case of retina and ROS membranes, the marked increase in desmosterol could arise by two different mechanisms: either desmosterol synthesized in the liver and transported *via* the blood was taken up by the retina or the systemically administered U18666A was able to cross the blood-retina barrier and affect "local" (endogenous) retinal sterol metabolism. To distinguish between these two possibilities, control and U18666A-treated rats were injected intravitreally with [^{3}H]acetate, and the resulting radiolabeled nonsaponifiable lipid products from the retinas were analyzed by reversed-phase, radio-HPLC. The chromatographic profiles are shown in Figure 4. As before, cholesterol represented virtually all of the sterol mass in the control profile (Fig. 4A, upper panel), ~80% of the total recovered radioactivity was coincident with the cholesterol mass peak by radio-HPLC (Fig. 4A, lower panel). About 15% of the total radioactivity exhibited the chromatographic properties of desmosterol. In contrast, almost the reverse pattern of incorporation was observed in retinas from U18666A-treated animals (Fig. 4B). Of the total recovered nonsaponifiable radioactivity, ~88% was coincident with the major mass peak, which corresponded to desmosterol; only about 11% of the radioactivity exhibited the chromatographic properties of cholesterol, coincident with the minor sterol mass peak. These data demonstrate that U18666A, administered subcutaneously, was able to enter the retina (i.e., by crossing the blood-retina barrier) and alter endogenous retinal sterol metabolism, such that *de novo* cholesterol biosynthesis was effectively blocked and desmosterol levels were increased.

Having documented that treatment of neonatal rats for 3 wk with U18666A caused a dramatic change in the sterol composition and metabolism of the retina, we then examined the his-

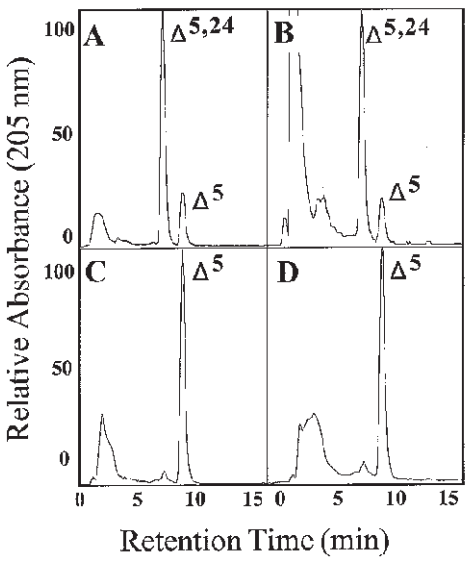

FIG. 3. Reversed-phase HPLC chromatograms of nonsaponfiable lipids from "residual retina" (A,C) and rod outer segment (ROS) layer membranes (B,D) obtained from U18666A-treated (upper panels) and control (lower panels) rats. FIG. 4. Reversed-phase, radio-HPLC chromatograms of nonsaponifiable lipids obtained from control (left panels) and U18666A-treated rat retinas (right panels), 20 h after intravitreal injection with [3H]acetate. The elution positions for Δ^5 and $\Delta^{5,24}$ are indicated. Upper panels, absorbance at 205 nm, normalized to full-scale response for predominant component; lower panels, radioactivity, normalized to full-scale response for predominant component. See Figures 1 and 2 for abbreviations.

tological and ultrastructural consequences of these alterations. Initially, we evaluated retinas of control and U18666A-treated rats by light microscopy. As shown in Figure 5, there were no apparent alterations in retinal histology of the treated animals (Fig. 5B), compared with controls (Fig. 5A). Retinas exhibited normal histological organization, without evidence of dysplasia, unusual incidence of cell death, or other cytopathological features. Cell layer thickness and nuclear counts (e.g., vertical rows of nuclei in the outer nuclear layer) were qualitatively comparable between control and treated specimens, and the photoreceptors exhibited normal outer segment length and appearance. At the EM level (Fig. 6), the ultrastructural features of U18666A-treated retinas (Figs. 6B and 6D) also were comparable to those of control retinas (Figs. 6A and 6C). Cells of the retinal pigment epithelium exhibited the normal, polarized distribution of intracellular organelles: mitochondria were localized in close apposition to the basal infoldings of the plasma membrane, the cytoplasm did not contain unusual or excessive inclusions, the apical microvilli were extended normally, and the cells did not exhibit hypertrophy, pyknosis, or other evidence of cytopathology. ROS exhibited comparable ultrastructure in treated and control specimens, although the membranes in both were somewhat disorganized, most likely as a consequence of the immersion fixation employed. Rod inner segments (RIS), which contain the cell's metabolic machinery (endoplasmic reticulum, Golgi apparatus, mitochondria, lysosomes, etc.), appeared normal, and there were no obvious defects in the connecting cilium or other cytological elements. Hence, despite the marked alteration of sterol composition and metabolism in the retina caused by U18666A treatment, there were no obvious concomitant histological or ultrastructural changes in the retina.

In order to evaluate the possibility that ROS membrane as-

Abbreviations (from top to bottom): Chor, choroid; PE, retinal pigment epithelium; RIS, rod inner segment layer; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. See Figures 1 and 3 for other abbreviations. Scale bar (both panels), 50 μm.

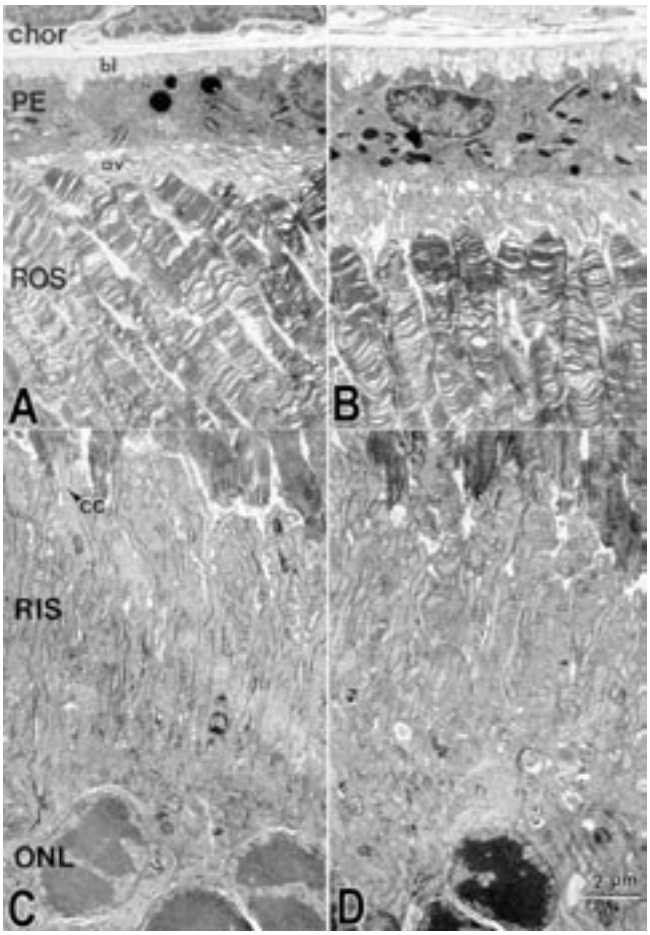

FIG. 6. Electron micrographs of the outer retinal layer from a control (A,C) and a U18666A-treated rat (B,D). Upper panels: PE and ROS; lower panels: RIS and ONL. Scale bar (all panels), 2 μm. See Figures 1,3, and 5 for abbreviations.

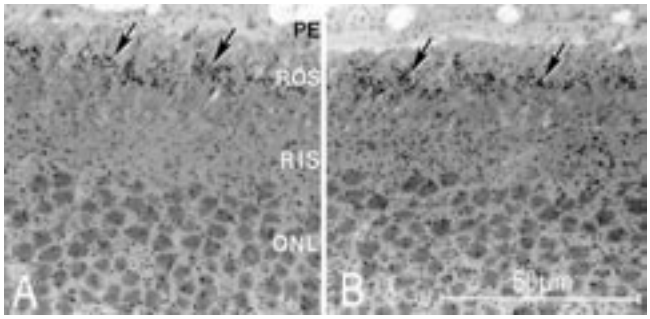

FIG. 7. Light microscopic autoradiograms of retinas from a control (A) and a U18666A-treated rat (B), 4 d after intravitreal injection with [^{3}H]leucine. "Bands" of silver grains (arrows), denoting the presence of newly synthesized proteins, are seen approximately half-way up the length of the ROS, while the other retinal layers exhibit a lighter, diffuse distribution of silver grains. See Figures 1, 3, and 5 for abbreviations. Scale bar (both panels), 50 μm.

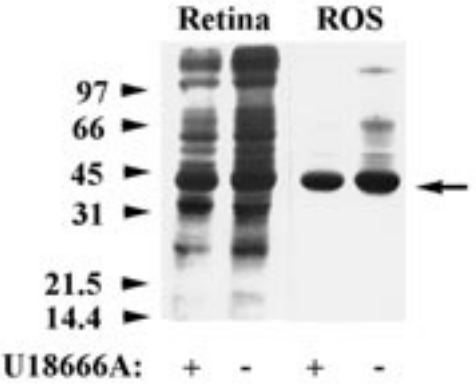

FIG. 8. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis fluorogram of proteins obtained from control (–) and U18666A-treated (+) rat retinas and ROS membranes, 4 d after intravitreal injection of [^{3}H]leucine. Arrow denotes the migration position of opsin, the visual pigment apoprotein. Migration position of authentic protein molecular weight markers is indicated (values in kilodaltons). See Figures 1 and 3 for abbreviations.

sembly and turnover rates might be affected by the changes in retinal sterol composition and metabolism, we examined the retinas of control and U18666A-treated animals 4 d after intravitreal injection of [^{3}H]leucine, using LMARG. The autoradiograms obtained are shown in Figure 7. While the majority of the retinal tissue exhibited a diffuse "peppering" with silver grains (indicative of active protein synthesis in all cell types), the ROS exhibited a distinct, focal concentration of silver grains (so-called "bands"; arrows, Fig. 5), corresponding to the assembly of newly synthesized proteins into ROS disc membranes and their subsequent displacement from the base of the ROS toward the distal tip of the cell, due to membrane renewal (13,14). ROS length at P25 in the region of the retina chosen for analysis (superior, midperipheral retina, along the vertical meridian) was ~23.0 ± 2.1 μm , in good agreement with previous authors (15). Since the ROS renewal rate in rats is about 3 μm/d (16), a 4-d renewal period should yield a linear displacement of the band of silver grains ~12 μm from the base of the ROS, or about half-way up the length of the ROS, in good agreement with our experimental results (12.5 ± 2.5 m). No differences in band displacement between treated and control rats were observed; hence, there was no detectable difference in ROS membrane renewal rates as a function of U18666A treatment, despite the marked difference in retinal sterol composition and metabolism. These results also are consistent with the finding that ROS lengths were comparable in treated and control animals.

We also evaluated the effect of U18666A treatment on the *de novo* synthesis of total retinal proteins as well as the biosynthesis and incorporation of opsin (the "bleached," apoprotein form of rhodopsin) into ROS membranes, analyzing companion retinas and ROS membranes prepared therefrom by SDS-PAGE and fluorography from animals that had been injected intravitreally with [^{3}H]leucine and used for LMARG analysis (see above). The fluorograms are shown in Figure 8. The lanes containing proteins from whole retinas exhibited numerous radiolabeled protein bands, with the band corresponding to opsin (Fig. 8, arrow; $M_r \approx 38$ kDa), representing a dominant radiolabeled component. Qualitatively, while the overall intensity of the lane corresponding to proteins from the control retinas was slightly greater than that corresponding to proteins from the U18666A-treated retinas [likely due to variations in the intravitreal isotope injection efficiency (17)], there was a one-to-one correspondence between radiolabeled protein bands between the two lanes. This indicates that overall retinal protein synthesis was not adversely affected by U18666A treatment. In addition, both lanes corresponding to ROS proteins exhibited an intensely labeled band of approximately equal intensity, corresponding to opsin, which accounted for the overwhelming majority of the label on each lane by qualitative inspection. Hence, these results demonstrate that U18666A treatment did not perturb either opsin synthesis or its intracellular trafficking and subsequent incorporation into ROS membranes.

DISCUSSION

Previously, it was shown that systemic treatment of neonatal rats over a 3-wk period with U18666A results in cataract formation, which represents a significant change compared to normal lens structure and optical properties (8). In striking contrast, the present study demonstrates that, despite profound alterations in retinal sterol composition and metabolism under similar treatment conditions, there are no apparent histological or ultrastructural consequences to the retina. Furthermore, ROS membrane assembly and the biosynthesis, intracellular trafficking, and integration of rhodopsin into ROS membranes are not compromised by U18666A treatment.

One interpretation of these findings is that desmosterol, which accumulates in the retina and other tissues of U18666A-treated animals with concomitant reduction in the normal levels of cholesterol in those tissues, can effectively replace cholesterol functionally in the retina. If true, this is surprising, in view of previous studies that have examined the structural requirements for various sterols to support membrane enzymatic or other functions and structural integrity in defined lipid-pro-

tein systems and in living cells (reviewed in Refs. 18–20). In general, those studies have shown that sterols other than cholesterol (including desmosterol) typically do not support these biological activities or functions as well as does cholesterol. For example, in one study comparing the effects of various sterols on the activity of muscle membrane ion transporters in reconstituted proteoliposomes (21), it was found that desmosterol and 7-dehydrocholesterol were only 16.5 and 27% as effective, respectively, as cholesterol in supporting Na^+/Ca^{2+} exchanger activity, whereas those same sterols were 11.6 and 83.2% as effective, respectively, as cholesterol in supporting Na^+/K^+-ATPase activity. However, it is important to realize that in most studies of this kind, cholesterol was replaced quantitatively with an alternate sterol. The *in vivo* treatment protocol employed in the present study was only effective in replacing about half of the cholesterol in the retina or ROS membranes with desmosterol. Hence, it may be that there was still sufficient amounts of endogenous cholesterol remaining to support its biological functions in the retina.

Another possible explanation for the findings in this study may be "sterol synergism"—the ability of a nonphysiological sterol to supplement or act in concert with subthreshold levels of the endogenous sterol normally present in a cell or tissue, thereby supporting normal biological structure and function. Sterol synergism has been demonstrated with broad phylogenetic diversity (22–26). In the present study, possibly the unusually high levels of desmosterol (the "nonphysiological" sterol) that form and accumulate in the retina in response to U18666A treatment can somehow compensate for the diminished levels of cholesterol (the endogenous, physiological sterol), and the two act together to fulfill the sterol requirements of retinal cells. In the vertebrate retina, cholesterol accounts for only about 10 mol% of the total lipid in the retina and ROS membranes (27), which is considerably lower than the level of cholesterol in most other vertebrate tissues and plasma membranes (18–20). Hence, this level of cholesterol may be close to the threshold level necessary to support sterol-dependent biological functions in retinal cells.

Very little is known about the exact functions of cholesterol in the retina. In a series of elegant studies, Albert and coworkers (28–30) have provided evidence for a specific requirement for cholesterol in modulating rod photoreceptor signal transduction, *via* rhodopsin–cholesterol interactions, stabilization of rhodopsin and early photopigment "bleaching" intermediates, and possible membrane structure stabilization. It remains to be demonstrated whether or not sterols such as desmosterol can mimic or replace cholesterol in these functions.

It should be noted that a lethal, human, autosomal recessive disease has been described recently (31), for which the biochemical hallmarks are diminished cholesterol levels and profoundly elevated desmosterol levels in all tissues examined. This disease has been termed "desmosterolosis," and the findings are consistent with a genetic defect in 3β-hydroxysterol-Δ^{24}-reductase. Multiple congenital malformations are associated with this disease, including macrocephaly, ambiguous genitalia, osteosclerosis, craniofacial abnormalities, and short limbs. In the single case report of this disease, there was no description of the gross ocular anatomy or histology; hence, it is not known whether there are any ocular abnormalities (e.g., cataracts, retinal dystrophy, etc.) associated with this disease. This general presentation is reminiscent, in some respects, of the first multiple congenital anomalies syndrome described in the literature, namely Smith-Lemli-Opitz syndrome (SLO) (32), an autosomal recessive, frequently lethal disease that involves a defect in 3β-hydroxysterol-Δ^7-reductase, another late-stage enzyme in the cholesterol pathway (reviewed in Refs. 33,34). In that syndrome, patients accumulate massively abnormal levels of 7-dehydrocholesterol ($\Delta^{5,7}$) in their tissues and exhibit moderately to severely diminished cholesterol levels. Interestingly, the one documented report of retinal histopathology in an SLO patient (35) described relatively normal retinal morphogenesis, including normal stratification of retinal cell layers and differentiated morphology of the rod and cone photoreceptors. Hence, there is the possibility that sterols other than cholesterol can be accommodated in the normal development and maturation of the visual system, particularly the retina. In support of this, we have shown recently (36) that rats treated with AY9944, a selective inhibitor of 3β-hydroxysterol-Δ^7-reductase, exhibit normal ocular development, without cataracts or retinal dysplasia, as well as normal retinal electrophysiology, despite the fact that their retinas, ROS membranes, and all other tissues examined contain markedly elevated 7-dehydrocholesterol levels and profoundly diminished levels of cholesterol. Currently, we are performing similar studies to develop an animal model of desmosterolosis, using U18666A in place of AY9944, in order to further examine the effects of desmosterol accumulation and cholesterol synthesis inhibition on ocular development, with particular regard to the histological and ultrastructural maturation and electrophysiological function of the retina.

ACKNOWLEDGMENTS

The authors dedicate this article to the memory of Prof. George J. Schroepfer Jr. (d. Dec. 11, 1998), whose rigorous professional standards and numerous contributions have significantly advanced the field of sterol biochemistry and have influenced the careers of many scientists worldwide. These studies were supported by U.S.P.H.S. grants EY07361 (S.J.F.) and EY02568 (R.J.C.).

ABSTRACT: The inhibition of squalene-hopene cyclase (SHC) (E.C. 5.4.99.-), an enzyme of bacterial membranes catalyzing the formation of pentacyclic sterol-like triterpenes, was studied by using different classes of compounds originally developed as inhibitors of oxidosqualene cyclase (OSC) (E.C. 5.4.99.7), the enzyme of eukaryotes responsible for the formation of tetracyclic precursors of sterols. The mechanism of cyclization of squalene by SHC, beginning with a protonation of the 2,3 double bond by an acidic residue of the enzyme, followed by a series of electrophilic additions of the carbocationic intermediates to the double bonds, is similar to the mechanism of cyclization of 2,3-oxidosqualene by OSC. The inhibitors studied included: (i) analogs of the carbocationic intermediates formed during cyclization, such as aza-analogs of squalene and 2,3-oxidosqualene; (ii) affinity-labeling inhibitors bearing a methylidene reactive group; and (iii) vinyldioxidosqualenes and vinylsulfide derivatives of the substrates. Comparison of the results obtained with the two enzymes, SHC and OSC, showed that many of the most effective inhibitors of OSC were also able to inhibit SHC, while some derivatives acted as specific inhibitors. Differences could be easily explained on the basis of the different substrate specificity of the two enzymes.

Paper no. L8276 in *Lipids 35,* 297–303 (March 2000).

Squalene-hopene cyclase (SHC) (E.C. 5.4.99.-) catalyzes a crucial step in the formation of hopene and hopanoids, a class of pentacyclic, sterol-like triterpenes present in many bacterial membranes. These molecules seem to be able to modulate membrane fluidity, similarly to the sterols in the membranes of eukaryotes (1). Squalene is cyclized by SHC with a mechanism sharing many important mechanistic similarities with the cyclization of 2,3-oxidosqualene by 2,3-oxidosqualene cyclase (OSC) (Scheme 1). During the complex cyclization reaction, the substrate squalene or 2,3-oxidosqualene, bound to the enzyme, is prefolded in a definite conformation, then protonated by a suitable aminoacidic residue of the active site, giving a series of carbocationic intermediates, which are stabilized by negative points of charge in the active site of the enzyme. The reaction is terminated by a final deprotonation which, in the case of OSC, follows a sequence of 1-2 hydride and methyl shifts (2).

Squalene-hopene cyclase from *Alicyclobacillus acidocaldarius* has been recently overexpressed in *Escherichia coli*, purified and crystallized (3,4). In comparing the sequence of SHC with sequences of eukaryotic OSC cloned from different animals, plants, and yeasts (5), a 17–27% identity between the two enzymes was found. Both enzymes have a molecular weight of 70–85 KDa and contain several repeats of a highly conserved motif rich in aromatic amino acids, the QW motif (6). Site-directed mutagenesis studies have shown that the two aspartate residues 376 and 377 in SHC and the corresponding aspartate residue 456 in yeast OSC are essential for enzymatic activity (7,8). These essential aspartic acid residues are located in a DCTAEA sequence, completely conserved in eukaryotic OSC, and in the corresponding sequence DDTA of SHC, similar to the known consensus DDXXD sequence of other terpene cyclases (9). Furthermore, the crystallization of SHC in the presence of the competitive inhibitor *N,N*-dimethyldodecylamine *N*-oxide has shown that the active site of the enzyme is a central cavity lined with aromatic amino acids, supporting a cyclization mechanism that starts with the protonation of the 2,3 double bond of squalene by the aspartate residue 376, situated on the top of the cavity and assisted by a near histidine residue (4).

Since no OSC have yet been crystallized, all information available about oxidosqualene cyclization mechanism is inferred from mutagenesis experiments and inhibition studies. The DCTAEA sequence has been shown to play a part in the active site of mammalian OSC by the irreversible inactivation and affinity labeling of the enzyme by the inhibitor 29-MOS, a methylidene derivative of the substrate (10) and a mechanistic hypothesis has been formulated by Corey *et al.* (11) on the basis of the results obtained with different sub-

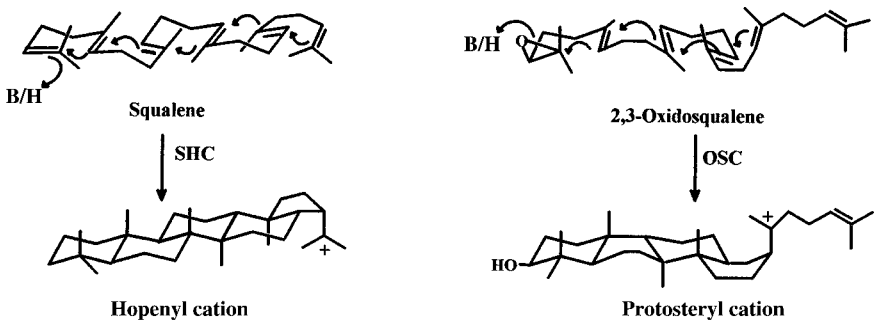


SCHEME 1

strate-modified inhibitors. So far, inhibition studies are the most important way to obtain insight into the mechanism of cyclization by OSC and have also given results consistent with crystallographic data on the active site structure of SHC.

Several inhibitors of OSC are known, but only few have also been studied as SHC inhibitors (12). Here we describe the effects on SHC of different classes of compounds previously studied by us only as OSC inhibitors. Our aim is to gather new information about similarities and differences in the mechanism of cyclization of the two enzymes, which could integrate the structural studies on SHC.

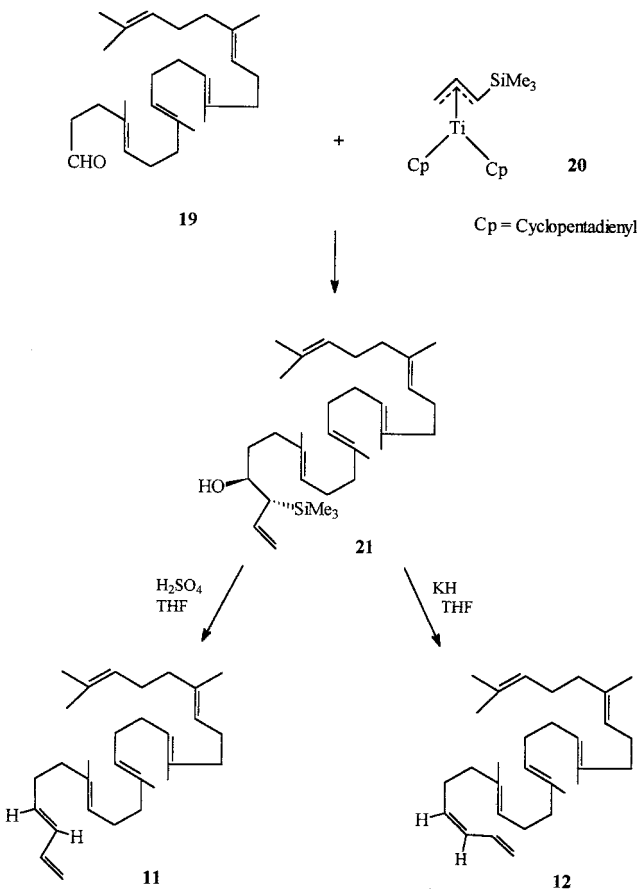
Basically three types of inhibitors were studied: (i) analogs of the carbocationic intermediates formed during cyclization, such as aza-analogs of squalene and 2,3-oxidosqualene (compounds **1–6**) (13), (ii) oxidosqualene derivatives bearing a conjugated methylidene group, designed as affinity-labeling inhibitors (compounds **7–13**) (14), and (iii) diepoxymethylidene and β-hydroxysulfide derivatives of the substrate, bearing the reactive groups at positions 15 or 19 (compounds **14–18**) (15,16).

MATERIALS AND METHODS

Chemicals. The ^{1}H nuclear magnetic resonance (NMR) spectra were recorded either on a JEOL EX 400 (JEOL, Inc., Peabody, MA) or a Bruker AC 200 instrument (Karlsruhe, Germany) in $CDCl_3$ solution at room temperature, with $SiMe_4$ as internal standard. Mass spectra were obtained on a Finnigan MAT TSQ 700 spectrometer (San Jose, CA). Infrared (IR) spectra were recorded on a PE 781 spectrophotometer (PerkinElmer, Palo Alto, CA). Microanalyses were performed on an elemental analyzer 1106 (Carlo Erba Strumentazione, Milano, Italy). The reactions were monitored by thin-layer chromatography (TLC) on F_{254} silica gel precoated sheets; after development, the sheets were exposed to iodine vapor. Flash-column chromatography was performed on 230–400 mesh silica gel. Tetrahydrofuran (THF) was dried over sodium benzophenone ketyl. All solvents were distilled prior to flash chromatography.

Nonradiolabeled and [3-^{3}H] squalene epoxide and [3-^{3}H] squalene were synthesized as previously described (17). Squalene, lanosterol, Triton X-100, and Na taurodeoxycholate were obtained from Sigma Chemical Co. (St. Louis, MO).

C_{27} squalene aldehyde **19** (Scheme 2) was obtained as previously reported (18). 2–Aza-2,3-dihydrosqualene **1** and its *N*-oxide **2** were synthesized and purified as previously reported (18). (6*E*)- **3** and (6*Z*)-10-azasqualene-2,3-epoxide **4** were obtained as described (19). 19-Azasqualene **5** and 19-azasqualene-2,3-epoxide **6**, respectively, were obtained as reported (13,20). The syntheses of (18*Z*)- **7**, (18*E*)-29-methylidene-2,3-oxidosqualene **8**, (18*E*)- **9,** and (18*Z*)-29-methylidene-2,3-oxidohexanorsqualene **10** were as reported (14). Vinyloxidosqualenes **13–15** and β-hydroxysulfide derivatives **16–18** were obtained as reported (21).



SCHEME 2

*(3*R**,4*S**,7*E*,11*E*,15*E*,19*E*)-7,11,16,20,24-Pentamethyl-3-(trimethylsilyl)-1,7,11,15,19,23-pentacosahexaen-4-ol (21, Scheme 2). (i) Reaction 1.* The allyl trimethylsilane (1.20 equiv., 174 mg, 1.52 mmol) was dissolved in anhydrous THF (5 mL) in a two-necked flask equipped with a perforable cap and stirred under a flux of dry argon. The reaction mixture was cooled to –60°C, and only a faint light was allowed in the laboratory. *n*-Butyllithium (1.6 M solution in hexane, 1.30 equiv., 1 mL, 1.65 mmol) was then added; during this time, the solution remained colorless. Hexamethylphosphoramide (0.4 mL) was added after 10 min, and the color turned orange. The mixture was then stirred for 1 h at –60°C.

(ii) Reaction 2. In another two-necked flask equipped with a perforable cap, dicyclopentadienyltitanium(II) dichloride $[(\eta^5C_5H_5)_2TiCl_2]$ (1.30 equiv., 411 mg, 1.65 mmol) was rapidly added, dissolved in anhydrous THF (5 mL), and stirred at room temperature under a flux of dry argon. Isobutylmagnesium chloride (2.0 M solution in diethyl ether, 1.30 equiv., 0.83 mL, 1.65 mmol) was added to the orange suspension. During the addition, effervescence occurred and the color turned to dark olive green. The flask was stirred in an oil bath at +40°C for 30 min.

(iii) Reaction 3. Both the flasks containing reaction 1 and reaction 2 were cooled to –90°C, and reaction 1 was transferred into reaction 2 using a cold glass syringe. The color turned immediately to dark purple, indicating the formation of the intermediate allyltrimethylsilyl dicyclopentadienyl titanium **20**; if the color turns brown, a sufficient amount of this intermediate has not formed. The reaction mixture was stirred for 30 min at –90°C.

(iv) Reaction 4. The C_{27} squalene aldehyde **19** (1 equiv., 488 mg, 1.27 mmol) dissolved in anhydrous THF (1 mL) was slowly added, with vigorous stirring at –90°C, slowly allowed to reach room temperature within 2 h in the acetone bath, and maintained for 30 min at room temperature. During this time the color turned to dark brown.

(v) Reaction 5. The 4 N HCl (5 mL) was slowly added at 0°C, while the reaction mixture turned orange, and was left for 30 min at this temperature, forming stereospecifically (3*R**,4*S**) trimethylsilyl alcohol **21**.

(vi) Reaction 6. The reaction mixture was transferred into an Erlenmeyer flask; water (50 mL) and diethyl ether (50 mL) were added, followed by oxidation with bubbling compressed air for 15 min. The mixture was extracted with diethyl ether (2 × 50 mL) after addition of brine (50 mL). The combined extracts were washed with brine (1 × 50 mL), dried with anhydrous sodium sulfate, and evaporated *in vacuo*. The crude orange oil was purified by flash chromatography with petroleum ether/diethyl ether, 99:1, to give 507 mg (80% yield from **19**) of (±)-(*R**,*S**) isomer **21** as a colorless oil. ^{1}H NMR ($CDCl_3$) δ 0.06 [*s*, 9 H, Si(C*H*$_3$)$_3$], 1.53–1.70 (*m*, 20 H, allylic CH_3 and C*H*$_2$CHOH), 1.98–2.20 (*m*, 19 H, allylic CH_2 and C*H*Si), 3.80 (*m*, 1 H, C*H*OH), 4.87–5.06 (*m*, 2 H, C*H*$_2$=CH), 5.00–5.25 (*m*, 5 H, vinylic CH), 5.82 (*m*, 1 H, CH_2=C*H*); IR (liquid film) 3620–3560, 2960, 2930, 2860, 1535, 1450 cm^{-1}; electron ion mass spectrometry (EIMS) *m/z* 498 (0.1), 481 (0.2), 411 (0.1), 365 (0.1), 343 (0.2), 310 (0.3), 203 (5), 134 (20), 93 (35), 81 (70), 73 (100); chemical ion mass spectrometry (CIMS) (isobutane) *m/z* 499 (0.5), 482 (40), 466 (33), 410 (100); high resolution mass spectrometry (HRMS) *m/z* 498.4261 (calc. for $C_{33}H_{58}OSi$ 498.4257). Anal. ($C_{33}H_{58}OSi$) C, H, O, Si.

(2E)-1-Methylidenenorsqualene: (3E,7E,11E,15E,19E)-7,11,16,20,24-pentamethyl-1,3,7,11,15,19,23-pentacosaheptaene (11, Scheme 2). Silyl alcohol **21** (150 mg, 0.30 mmol) was dissolved in THF (10 mL) and stirred under dry nitrogen. Two drops of concentrated H_2SO_4 were added, and it was allowed to react at room temperature for 24 h with stirring. The reaction mixture was poured in a separation funnel containing 10% nonradiolabeled $NaHCO_3$/diethyl ether, 1:1 (20 mL) and extracted with diethyl ether (3 × 30 mL). The combined extracts were washed with saturated brine (2 × 30 mL), dried with anhydrous sodium sulfate, and evaporated *in vacuo*. The resulting oil was purified by flash chromatography with petroleum ether to give 86 mg (70% yield from **21**) of compound **11** as a colorless oil. ^{1}H NMR ($CDCl_3$) δ 1.53–1.68 (*m*, 18 H, allylic CH_3), 2.00–2.20 (*m*, 20 H, allylic CH_2), 4.92–5.10 (*m*, 2 H, C*H*$_2$CH), 5.05–5.20 (*m*, 5 H, trisubstituted double-bond vinylic CH), 5.67 (*m*, 1 H, CH_2C*H*=CH), 6.03 (*m*, 1 H, CH_2CH=C*H*), 6.30 (*m*, 1 H, CH_2=C*H*); IR (liquid film) 2970, 2930, 2860, 1440, 1380 cm^{-1}; EIMS *m/z* 408 (1), 365 (0.5), 339 (1), 271 (2), 229 (4), 203 (5), 161 (8), 147 (12), 134 (40), 69 (100); CIMS (isobutane) *m/z* 409; HRMS *m/z* 408.3755 (calc. for $C_{30}H_{48}$ 408.3756). Anal. ($C_{30}H_{48}$) C, H.

(2Z)-1-Methylidenenorsqualene: (3Z,7E,11E,15E,19E)-7,11,16,20,24-pentamethyl-1,3,7,11,15,19,23-pentacosaheptaene (12, Scheme 2). KH (35% suspension in oil) was washed with pentane and rapidly dried. Pure KH (3 equiv., 36 mg, 0.90 mmol) was added in a two-necked flask, anhydrous THF (5 mL) was added, and the reaction mixture was stirred under dry nitrogen. Silyl alcohol **21** (150 mg, 0.30 mmol) was added at +10°C and allowed to react for 15 min. The mixture was then poured into nonradiolabeled 10% NH_4Cl/diethyl ether (1:1, 50 mL) and extracted with diethyl ether (3 × 30 mL). The combined extracts were washed with saturated brine (1 × 30 mL), dried with anhydrous sodium sulfate, and evaporated *in vacuo*. The resulting oil was purified by flash chromatography with petroleum ether, to give 105 mg (86% yield from **21**) of compound **12**, as a colorless oil. ^{1}H NMR ($CDCl_3$) δ 1.55–1.70 (*m*, 18 H, allylic CH_3), 1.98–2.20 (*m*, 18 H, allylic CH_2), 2.30 (*q*, 2 H, C*H*$_2$CH=CH), 5.02–5.24 (*m*, 7 H, trisubstituted double-bond vinylic CH and C*H*$_2$=CH), 5.45 (*m*, 1 H, CH_2C*H*=CH), 6.00 (*m*, 1 H, CH_2CH=C*H*), 6.63 (*m*, 1 H, CH_2=C*H*); IR (liquid film) 2970, 2930, 2860, 1440, 1380 cm^{-1}; EIMS *m/z* 408 (1), 365 (0.5), 339 (1), 271 (2), 229 (4), 203 (5), 161 (8), 147 (12), 134 (40), 69 (100); CIMS (isobutane) *m/z* 409; HRMS *m/z* 408.3759 (calc. for $C_{30}H_{48}$ 408.3756). Anal. ($C_{30}H_{48}$) C, H.

Enzymatic assays. Solubilized and partially purified pig liver and yeast oxidosqualene cyclase were obtained and the enzymatic activity determined as previously described (13,14). Recombinant squalene hopene cyclase was obtained as previously described (22).

For enzymatic activity determination, 10 μM squalene and 15,000 cpm of [3-^{3}H]squalene were dissolved in ethanol in the presence of Triton X-100 (final concentration 0.05%) in test tubes. Solvent was evaporated under nitrogen, and the enzyme (3 μg) in 1 mL of citrate buffer, 0.1 M, pH 6.0, containing 0.2% Na-taurodeoxycholate, was added to test tubes and incubated for 15 min at 60°C. The reaction was stopped by cooling the tubes in ice. After extracting with 2 mL of a mixture of *n*-hexane–isopropanol 3:2 (vol/vol), the solvent was evaporated. The extracts were redissolved in a small amount of CH_2Cl_2 and spotted on TLC plates developed twice, first 5 cm in CH_2Cl_2, then 15 cm in *n*-hexane. The conversion of squalene to labeled hopene and diplopterol was analyzed by radio-TLC scanner (Packard System 2000 Imaging Scanner; Hewlett-Packard, Palo Alto, CA), and percentage of transformation was calculated by integration. Alternatively, bands corresponding to squalene and hopene were scraped off and counted with a liquid scintillator (Beckman LS500 TD; Beckman Instruments, Fullerton, CA).

IC_{50} values (the concentration of inhibitor that reduced by 50% the enzymatic conversion) were determined by adding the inhibitors, as ethanolic solution, to the mixture of nonradiolabeled and labeled substrates and by incubating with SHC, as described.

The assay of cyclization of inhibitors **11** and **12** was carried out as follows: inhibitor (100 μM) was dissolved in ethanol in the presence of Triton X-100 (final concentration 0.05%) in test tubes. Ethanol was removed under nitrogen, and the enzyme (3 μg) in 1 mL of citrate buffer, 0.1 M, pH 6.0, containing 0.2% Na-taurodeoxycholate, was added to test tubes and incubated 1 h at 60°C. Reaction was stopped by cooling, and the mixture was worked up as described for substrate transformation except for the treatment of developed TLC plates, which were visualized by exposure to iodine or sulfuric acid.

RESULTS AND DISCUSSION

Several aza-derivatives of squalene and 2,3-oxidosqualene have already been studied as inhibitors of OSC. The most effective inhibitors were compounds such as 2–aza-2,3-dihydrosqualene **1** and its *N*-oxide **2** or 10- and 19-azasqualene-2,3-epoxide **3** and **6**. All of these compounds are supposed to be active because of their similarity to the carbocations formed in positions C-2, C-8, and C-20 during the cyclization of 2,3-oxidosqualene.

In Table 1, the IC_{50} inhibition values of SHC with these aza derivatives are compared with those found in pig liver and yeast OSC (13). It is evident that the aza derivatives **1** and **2** are inhibitors of SHC; our IC_{50} values are about the same as those obtained previously by Flesch and Rohmer (23). These compounds are analogs of the carbocation formed after the initial step of cyclization, i.e., the protonation of the 2,3 double bond in squalene cyclization, or the protonation of the 2,3-epoxide in the oxidosqualene cyclization.

The 6*E*-10-azasqualene-2,3-epoxide **3** was a very effective inhibitor, much more effective than the 6*Z*-10-aza-derivative **4**: a correct configuration of the analog, corresponding to the configuration of the substrate, is able to improve the inhibition of SHC as previously seen with OSC, indicating that the formation of the C-8 carbocation is an important step during the enzymatic cyclization of squalene and oxidosqualene.

The 19-azasqualene **5** and 19-azasqualene-2,3-epoxide **6**, differing only in the presence of the epoxidic function, were both active inhibitors of SHC: this result is not surprising,

since SHC is able to cyclize very efficiently, *in vitro*, not only squalene, the natural substrate, but 2,3-oxidosqualene, as well (16). The OSC, that cyclizes only (3*S*)-2,3-oxidosqualene, was differently inhibited by compounds **5** and **6**, the latter bearing the epoxidic function and being the only active inhibitor. The 19-azasqualene-2,3-epoxide **6** was a time-dependent, irreversible inhibitor of mammalian OSC (13). The SHC by contrast was not labeled after 1 h of incubation with [^{3}H]-19-azasqualene-2,3-epoxide: fluorography of the enzyme after the incubation in the presence of the labeled inhibitor showed no spots after 1 wk of exposure. Different inhibitory properties of **6** toward SHC (reversibly inhibited) and OSC (irreversibly inhibited) probably result from the different prefolding of inhibitor within the active site of the two enzymes and the different interaction between the nitrogen atom of the inhibitor and critical amino acidic residues in the active site.

The inhibitors listed in Table 2 are derivatives of different length, bearing a vinylic function at position C-19 or C-2. The (18*Z*)-29-MOS **7** (10,14) and the (18*E*)-hexanor-29-MOS **9** (14), were effective time-dependent inhibitors of pig liver and yeast OSC. Abe and Prestwich (9), using [^{3}H]-(18*Z*)-29-MOS **7**, have been able to label rat OSC, and Corey *et al*. (11), using a mixture of the two *E* and *Z* isomers **9** and **10** succeeded in labeling yeast OSC. Compound **7** has been found by Abe *et al.* (24) to label SHC 10 times less efficiently than OSC. A polycyclic C-31 dammarene derivative was obtained as cyclization product (24). Our results showed that SHC is inhibited at the same extent by the *Z* **7** and *E* **8** isomers of 29-MOS. Mammalian OSC by contrast was 10 times less sensitive to *E*-29-MOS **8,** which was also a poor time-dependent inhibitor (14).

SHC showed the same insensitivity for steric configuration, also with respect to *E* and *Z* isomers of hexanor derivatives **9** and **10**, which were both 5–15 times more efficient than *Z*-29-MOS **7** as inhibitors of SHC. The selective response to the configuration of the inhibitors bearing a vinyl function at C-19 seems to be a peculiar characteristic of OSC. This could be a consequence of mechanistic differences between the eukaryotic oxidosqualene and the bacterial squalene cyclases, which require a less elaborate system of directing the cyclization reaction, since the folding of the squalene in the active site of SHC is all prechair, a conformation less stressed than the prechair-preboat-prechair-preboat conformation of oxidosqualene in the active site of OSC. The rather free fitting of squalene-like molecules in the active site cavity of SHC is also demonstrated by the ability of SHC to cyclize not only (3*S*)-oxidosqualene but also the (3*R*)-isomer (2). The introduction of a vinylic group at C-19 in the oxidosqualene or hexanoroxidosqualene skeleton, such as in compounds **7**, **8**, **9**, **10**, made these compounds inhibitors of both OSC and SHC: conversely the introduction of the vinylic function at the C-2 of squalene, such as in compounds **11** and **12**, did not give any inhibitory properties either on OSC or SHC. Since a C-2 vinyl-derivative of oxidosqualene is both a poor inhibitor and a good substrate of OSC (25), compounds **11** and **12** could be expected to be cyclized by SHC: no metabolites or cyclization products, even in trace amounts, were instead detected after 1 h of incubation with SHC under conditions commonly adopted to obtain an effective transformation of the substrate to hopene. Surprisingly, *trans*-2-vinyl-2,3-oxido-1,1′-bisnorsqualene **13**, was selectively recognized by SHC and OSC, being a highly effective inhibitor of the prokaryotic enzyme and almost ineffective on the eukaryotic

cyclase. This result is difficult to explain, but we could tentatively hypothesize that this compound can be recognized by the enzymatic active site of SHC in both orientations: with the vinylepoxide in position 2,3 or in 22,23. In the second orientation it could interact with the cyclization of the fifth ring, only catalyzed by SHC. Experiments are in progress to check the time-dependent inhibition of **9** and **10** on SHC.

In Table 3, the inhibition values of some vinyldioxidosqualenes and β-hydroxysulfide derivatives are shown. The vinyldioxidosqualenes **14** and **15** were also inhibitors of SHC but with a lower extent than compounds **9** and **10**. The vinyl-β-hydroxysulfide derivatives **16**, **17,** and **18** are characterized by the presence of a sulfur atom at, or adjacent to, the critical positions of carbocationic intermediates formed by both OSC and SHC during the cyclization of substrate. All the compounds showed a good inhibition of SHC, while only **16** was very effective on pig liver OSC.

Work is in progress to crystallize SHC in the presence of some of the more active inhibitors.

ABSTRACT: Three oxidized analogs of cholesterol have been characterized for their ability to cause apoptotic cell death in CEM-C7-14 human leukemic cells. In addition to testing 15-ketocholestenol (K15), 15-ketocholestenol hydroxyethyl ether (CK15), and 7-ketocholesterol hydroxyethyl ether (CK7), an oxysterol of known apoptotic response, 25-hydroxycholesterol (25OHC), served as a standard for comparison. Growth studies based on dye exclusion by viable cells while using a sublethal concentration of oxysterols ranked their potency for cell kill as 25OHC > K15 > CK15 > CK7. Both the TUNEL assay (terminal deoxynucleotidyl transferase-mediated dUTP-X nick end labeling), which quantifies the amount of DNA nicks caused by a toxic agent, and the MTT assay, which measures cell metabolism and thus reflects cell viability, substantiated the same rank order. An ELISA assay for evaluating release of DNA fragments into the cytosol after treatment gave a similar potency order. The oncogene c-*myc* mRNA was suppressed by all three oxysterols, with 25OHC and K15 being the most potent suppressors. Hoechst and Annexin V staining documented that these oxysterols kill cells by an apoptotic pathway as evidenced by condensation of nuclear chromatin and plasma membrane inversion, respectively. From these *in vitro* studies, we believe that 25OHC, K15, and possibly CK15 have the potential to be chemotherapeutic agents.

Paper no. L8259 in *Lipids 35,* 305–315 (March 2000).

Both glucocorticoids and oxysterols can cause apoptosis of certain cells. For this action, glucocorticoids require a specific cytosolic protein, the glucocorticoid receptor (GR). No oxysterol receptor has been unequivocally identified, although two cellular proteins do specifically bind oxysterols: the oxysterol binding protein (OBP) and LXR, a member of the nuclear receptor family of proteins. As yet it is not certain that either protein is required for oxysterols' apoptotic actions. In our test system, the human leukemic cell line CEM, analysis of the events following addition of either class of steroid shows similarities at several points. These include a delay of about 1 d before the activation of caspases and nucleases, which occurs around the time of overt apoptosis. During this initial phase of cell death when the steroidal effects can be reversed, both types of steroids cause profound suppression of the oncogene product, cMyc (1,2). Because of their apoptotic action, glucocorticoids are used widely as antileukemic drugs. The similarity of effects of oxysterols suggests that they also might have therapeutic usefulness, alone, or in conjunction with glucocorticoids.

Oxysterols are able to elicit changes in cholesterol synthesis, cell growth, and membrane composition, and can cause immunosuppression (3–8). These activities have led to many studies of oxysterols, usually as toxins in the environment and foods (9,10), or as implicated in atherosclerosis (11–14). The relatively greater sensitivity of certain malignant, as opposed to normal, cells offers an opportunity to use oxysterols as chemotherapeutic drugs. A few investigators have recognized their potential as therapeutic agents (15–18).

Two oxysterols that are known to cause apoptosis have been well studied: one with high potency, 3β-hydroxycholest-5-en-25-diol (25-hydroxycholesterol, 25OHC) and the weaker 3β-hydroxycholest-5-en-7-one (7-ketocholesterol, K7) (19–23). Here we present tests of three oxysterols: 3β-hydroxy-5α-cholest-8(14)-en-15-one (15-ketocholestenol, K15), 3β-hydroxy-5α-cholest-8(14)-en-15-one 3β-2′-hydroxyethyl ether (15-ketocholestenol hydroxyethyl ether, CK15), and 3β-hydroxycholest-5-en-7-one 3β-2′-hydroxyethyl ether (7-ketocholesterol hydroxyethyl ether, CK7), comparing their apoptotoic effects and potencies to those caused by the known compound, 25OHC. The structures of these five oxysterols, as well as their parent compound, cholesterol, are shown in Scheme 1.

Two of the oxysterols under investigation were synthesized with bulky substitutions in the 3 position with the original intent of studying the importance of that position for binding to OBP. The third experimental oxysterol tests the effect of a keto substitution at position 15. C15 oxysterols have been evaluated for their synthetic paths, metabolism, occurrence, and effects on 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase; they are quite potent inhibitors of

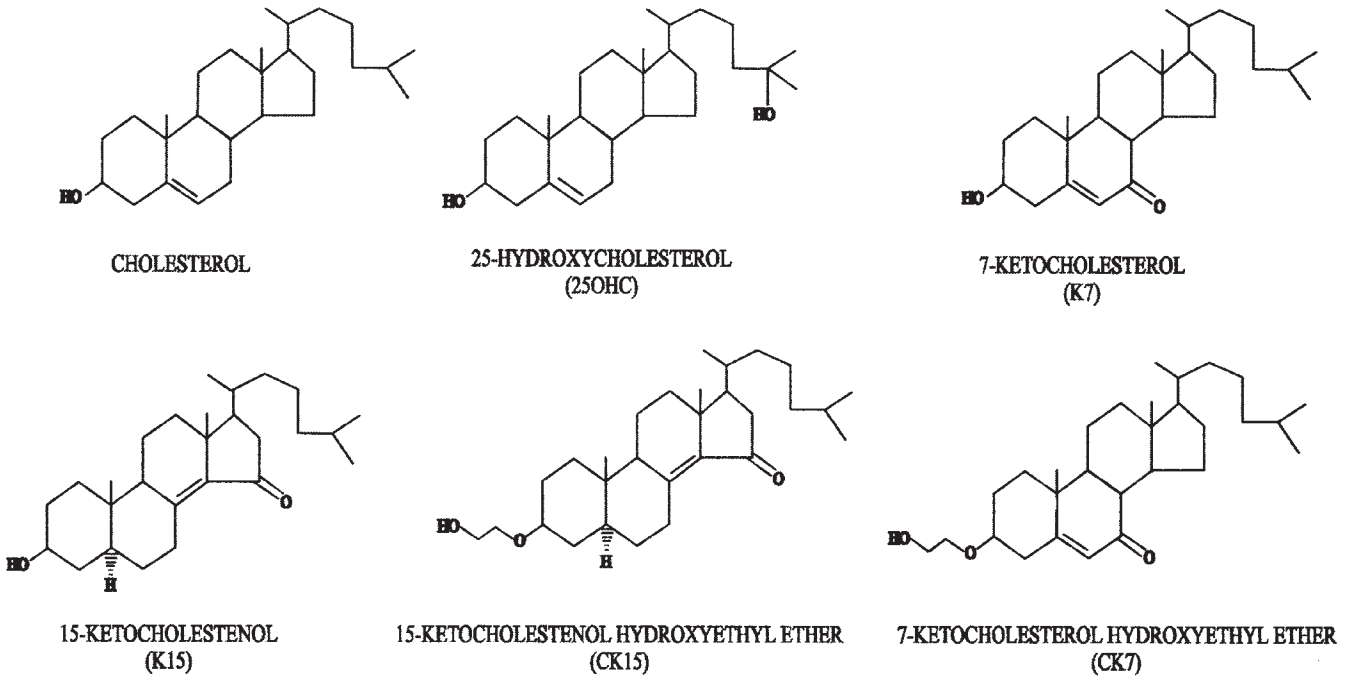

SCHEME 1

HMGCoA receptor expression and bind well to OBP (15). However, they have not been tested for their antileukemic effects. Clearly, it is important to determine the structural basis for other oxysterols' potency as apoptotic agents.

These agents were examined in the well-characterized human $CD4^+$ acute lymphoblastic leukemic clone CEM-C7, which was cloned without selective pressure from the original CEM line (24). CEM-C7 and cells of a recently obtained subclone CEM-C7-14 are both sensitive to glucocorticoids and oxysterols, but through independent pathways (20).

MATERIALS AND METHODS

Materials. K15, CK7, and CK15 were synthesized in the Cardiology Research Center (Moscow, Russia). 25OHC and K7 were purchased from Steraloids (Wilton, NH). All oxysterols were dissolved in ethanol and stored at a concentration of 10^{-2} M at –20°C in glass, protected from light. Prior to use each oxysterol was assayed by high-performance liquid chromatography (HPLC) to ascertain purity. RPMI 1640 medium was obtained from Fisher Scientific (Houston, TX), fetal bovine serum (FBS) from Atlanta Biologicals (Norcross, GA), and trypan blue dye from Gibco/BRL (Grand Island, NY). Delipidated FBS (DFBS), Dulbecco's phosphate-buffered saline (PBS), pH 7.4, propidium iodide, Hoechst 3342 stain, bovine serum albumin (BSA), growth supplements (insulin, transferrin, selenium), and the tetrazolium salt 3-[4,5-dimethyl(thiazol-2-yl)-3,5-diphenyl] tetrazolium bromide (MTT) were obtained from Sigma Chemical Co. (St. Louis, MO). All the reagents used for RNA extraction were molecular biology grade. Formamide and TRIzol reagent were purchased from Gibco/BRL, formaldehyde from J.T. Baker Chemical (Phillipsburg, NJ), and electrophoresis-grade agarose from FMS Products (Rockland, ME). The blotting membrane was from Schleicher & Schuell (Keene, NH). Radionuclides were purchased from ICN Radiochemicals (Cleveland, OH). The human c-*myc* exon 3 cDNA was obtained from Oncor (Gaithersburg, MD). The TUNEL and Cell Death Detection ELISA^{Plus} kits were purchased from Boehringer Mannheim (Mannheim, Germany). Ribonuclease A was obtained from Worthington Biochemical (Freehold, NJ). The Annexin V/FITC kit was from PharMingen (San Diego, CA).

Cell culture/growth inhibition. CEM-C7-14 cells were cultured in RPMI 1640 medium with 5% heat-inactivated whole FBS at 37°C, maintaining logarithmic growth in a humidified atmosphere of 95% air and 5% CO_2. To avoid any effects from the sterols in whole serum prior to oxysterol addition, cells were acutely transferred to 3% DFBS with 1% growth supplements in medium and incubated overnight. Oxysterols were then added as an ethanolic solution in 1% BSA in PBS; controls received ethanol only plus BSA; ethanol never exceeded 1% of culture volume. The number of viable cells at every time point was determined by using a hemacytometer and the trypan blue vital dye exclusion method (25). Control cells were fully viable for at least 4 d in medium containing delipidated serum and supplements.

MTT. An *in vitro* MTT assay for sensitivity to oxysterols was performed with the following modifications (26). For each concentration of oxysterol, triplicate 80 µL samples containing 2×10^5 cells/mL were plated in a 96-well tissue culture plate. Each well then received 20 µL oxysterol from stock solutions or dilutions thereof; final concentrations were 0.3, 0.5, 0.7, and 1 µM. Controls consisted of CEM-C7-14 cells in medium without oxysterol and medium without cells. After incubation at 37°C in 5% CO_2 for 48 h, 25 µL of MTT stock

solution was added. Following a 4 h incubation, 150 µL lysis buffer (20% sodium dodecyl sulfate, 20% dimethylformaldehyde, 2.5% 1 N HCl, 2.5% 80% acetic acid) was added to each well. After overnight incubation at 37°C, the samples were analyzed colorimetrically on a Biotek plate reader at 600 nm which was zeroed by assay blanks containing no cells.

DNA fragmentation. DNA fragmentation was followed by two methods. The first was a photometric enzyme immunoassay using the Cell Death Detection ELISA^{Plus} according to the protocol of the supplier (Boehringer Mannheim). CEM-C7-14 cells adapted to culture in supplemented medium with delipidated serum were treated with 1 µM oxysterol for 48 h. Triplicate samples (5×10^4 cells) were centrifuged 200 × *g* for 10 min at room temperature, and the supernatant was carefully removed. Two positive controls (DNA-histone complex) and two background samples (incubation buffer) were included. Color intensity was evaluated on a Packard microplate reader at 405 nm against the substrate solution as a blank.

The second DNA fragmentation method employed the terminal deoxynucleotidyl transferase-mediated dUTP-X nick end labeling (TUNEL) assay performed according to the protocol provided by the manufacturer (Boehringer Mannheim) with some modifications. Before fixation, 3×10^6 cells were washed twice with PBS containing 1% BSA. Cells were then fixed with freshly prepared 4% paraformaldehyde in PBS and incubated at room temperature for 30–60 min. Each assay contained one negative control (no transferase enzyme) and one positive control (cells treated with DNase I + transferase enzyme). After washing, all samples were stained with propidium iodide according to a method described by Van Houten and Budd (27) and incubated overnight in the dark. Samples (2×10^4 cells) were analyzed for DNA content and DNA breaks by flow cytometry using a FACScan (Fluorescence Activated Cell Sorter; Becton Dickinson, Bedford, MA) with Cell Quest 3.1 software (Becton Dickinson). Analysis was done with an argon-ion laser with excitation at 488 nm. Doublets and cells aggregates were excluded, and only the singlet cell population was analyzed. Red (propidium iodide) and green (fluorescein-dUTP) fluorescences were detected using 530- and 548-nm filters, respectively.

Northern blots. Total RNA was isolated using the TRIzol reagent according to the method provided by the manufacturer, Gibco/BRL. Total RNA was subjected to electrophoresis under denaturing conditions using a 1% agarose/6% formaldehyde gel and electroblotted on Nytran Plus nylon membranes. Hybridization was carried out for 18 h at 60°C with a ^{32}P-labeled random-primed c-*myc* cDNA fragment with specific activities of 1 to 8×10^9 dpm/µg of DNA. Normalization was accomplished by using the ethidium bromide stained ribosomal RNA that was transferred to the filter. The membranes were exposed for 24 h in a PhosphorImager cassette and analyzed using a PhosphorImager 425 (Molecular Dynamics, Sunnyvale, CA). The densities of the mRNA bands obtained from the PhosphorImager screen were quantified using the MD ImageQuant software (version 3.3) from Molecular Dynamics. The relative amounts of c-*myc* mRNA on the filters were compared by normalizing the quantified values to 18S ribosomal RNA bands on the same filters. At the exposure time selected for quantification, RNA signals were linear.

Flow cytometry. The staining for the flow cytometric evaluation of apoptotic changes was performed with the AnnexinV-FITC-7-AAD kit from Boehringer Mannheim. After CEM-C7-14 cells had been treated with 1 µM oxysterol for 4, 6, 24, 30, or 52 h, 2×10^5 cells were treated with Annexin V and 7-amino-actinomycin D (7-AAD) according to the supplier's protocol. CEM-C7-14 cells treated with 1 µM dexamethasone for 48 h were used as a positive control. Cells (2×10^4) were analyzed for Annexin V- and 7-AAD-positive cells by flow cytometry using a 488-nm excitation and a 515-nm bandpass filter for fluorescein detection and a filter >600 nm for 7-AAD detection on a FACScan (Becton-Dickinson). For photographs of stained cells, 3×10^5 CEM-C7-14 cells ± 1

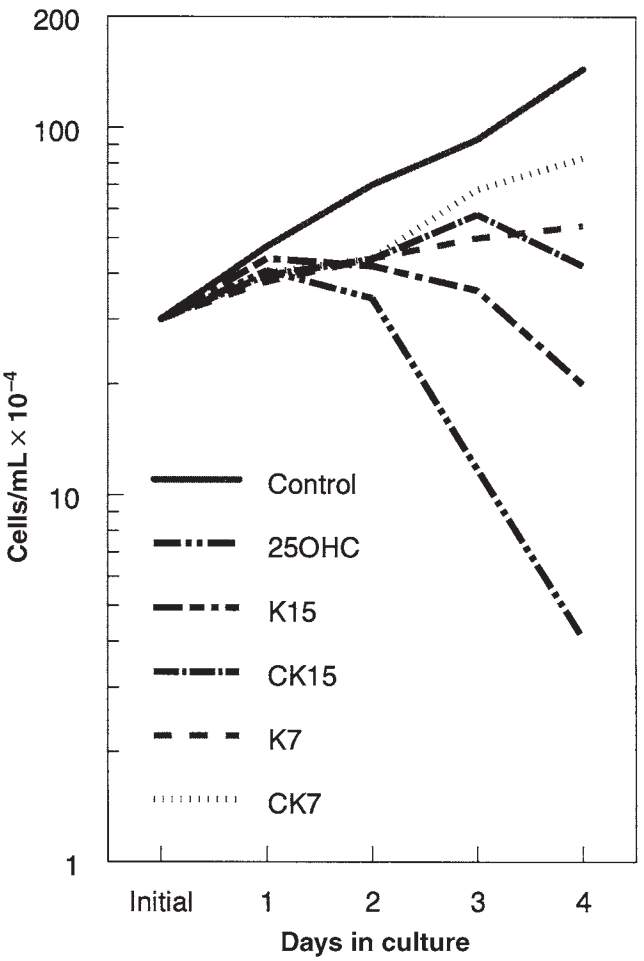

FIG. 1. Effect of 300 nM oxysterols on the growth and viability of CEM-C7-14 cells. Cells in logarithmic growth were exposed to 300 nM of each oxysterol, as described in the Materials and Methods section. Viable cells were counted daily for 4 d. The legend identifying each oxysterol is located to the left of the graph. Each time point represents the mean of 3–5 independent experiments; error bars were omitted for clarity of presentation, but the SD of each data point was less than or equal to 5%. 25OHC, 25-hydroxycholesterol; K15, 15-ketocholestenol; CK15, 15-ketocholestenol hydroxyethyl ether; K7, 7-ketocholesterol; CK7, 7-ketocholestenol hydroxyethyl ether.

μM oxysterols were treated with Annexin V/7-AAD as above and fixed with 4% fresh paraformaldehyde solution in PBS. Cells pellets were washed twice in cold PBS/BSA and resuspended in 100 μL permeabilization buffer (0.1% Triton-X 100 in 0.1% sodium citrate), washed twice in cold PBS/BSA, and resuspended in 800 μL PBS/BSA. Microscope slides that had been precoated with poly-L-lysine solution and dried were loaded with 2×10^4 cells and cytospun at 600 rpm for 5 min. The slides were stained for 10 min Hoechst 3342 stain (0.1 mg/mL water). Slides were mounted with Crystal Mount (Biomeda, Foster City, CA) and stored in the dark at 4°C. Photographs of the cytospun, stained cells were taken on a Nikon Eclipse E600 microscope (Melville, NY) with a Nikon FDX-35 camera at 100× magnification with illumination by white polarized light, 360/500-nm filter for the Hoechst stain and 488/515-nm for the Annexin V/7AAD stain.

RESULTS

Potency of oxysterol as judged by growth inhibition. The growth responses of cells from the freshly isolated CEM-C7-14 clone to the three experimental oxysterols were compared to those caused by the reaction of these cells to the standards 25OHC and K7. Sublethal concentrations of each oxysterol (300 nM) were added to cultures growing logarithmically in supplemented, delipidated RPMI 1640 medium. Total viable cells were counted initially and every 24 h for 4 d. Figure 1 shows the results of such a study with little to no cell death occurring in any oxysterol treatment during the first 24 h, though all slowed cell growth. Even by 48 h, there was little difference in the effect caused by these agents. However, beyond 72 h, 25OHC exhibited the greatest cell kill, followed by K15, K7 and CK15 continued to retard growth, and CK7 had the least effect. All of the treated cultures did contain trypan blue-positive cells, indicating that some cell death had occurred.

Extent of apoptosis as judged by MTT, cytosolic DNA fragmentation, and TUNEL assays. Although there are numerous assays available to evaluate cell death, we selected three diverse methods to quantify an apoptotic process: the MTT, cytosolic DNA fragmentation, and TUNEL assays. The MTT assay evaluates mitochondrial reduction of the yellow MTT tetrazolium salt dye to a highly colored blue formazan prod-

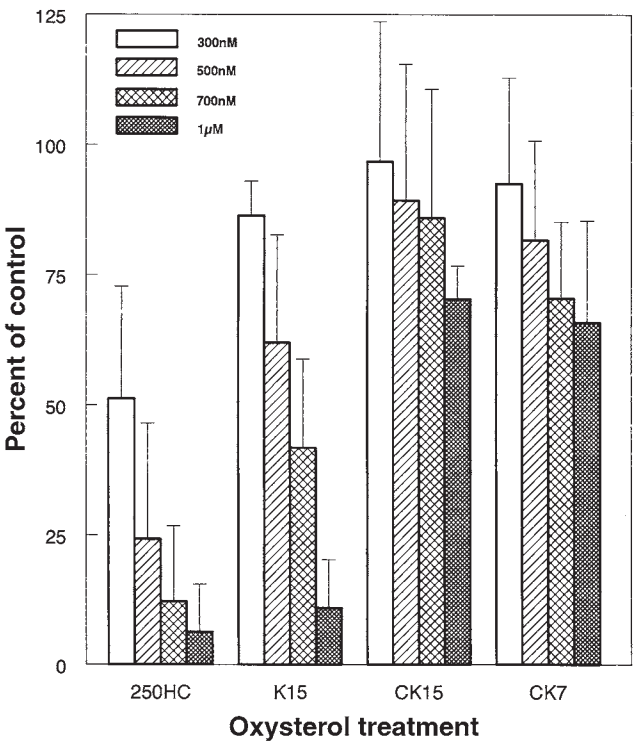

FIG. 2. Effects of varying concentrations (300 nM, 500 nM, 700 nM, and 1 μM) of oxysterols on the mitochrondrial reductive capacities of CEM-C7-14 cells. Growth conditions and delivery of oxysterols were the same as in Figure 1. After 48 h of incubation, the dimethyl tetrazolium salt MTT reagent was added, and cells were cultured for an additional 4 h before being lysed and then analyzed on a Biotek plate reader at 600 nm. The results were an average percentage of absorbance values by oxysterol-treated wells vs. the average of control wells and expressed as percentage of control. Each bar represents the mean from five independent experiments; error bars = 1 SD. See Figure 1 for abbreviations.

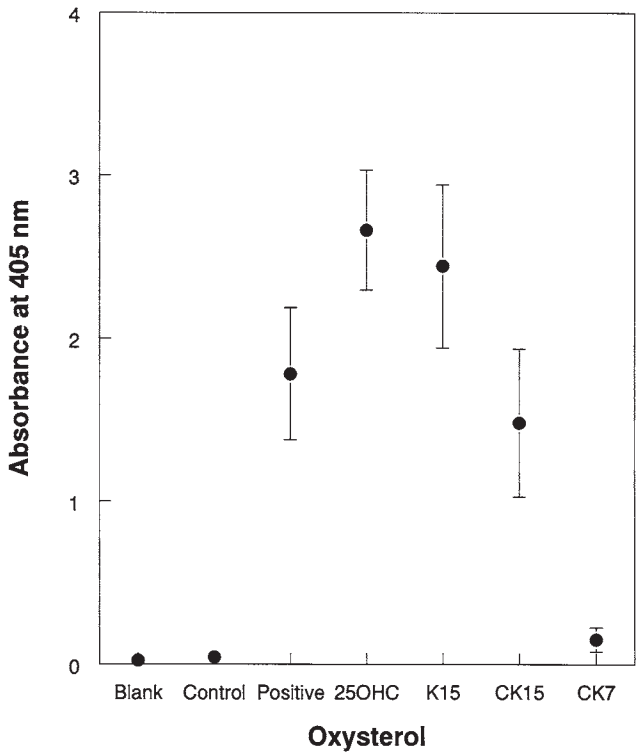

FIG. 3. Effect of 1 μM oxysterols treatment on internucleosomal DNA fragmentation in CEM-C7-14 cells. Growth conditions and delivery of oxysterols were the same as in Figure 1. After 48 h of treatment with each oxysterol, cells were collected, lysed, and the cytosolic fraction was prepared. Of this, triplicate samples were complexed with biotin-labeled antihistone and peroxidase-conjugated anti-DNA antibodies. The absorbance was read on a microplate reader at 405 nm against the substrate solution as blank. The blank averaged 25 mU, CEM-C7-14 control 44 mU, and the positive control (DNA histone complex) 1759 mU. Each dot with its error bar represents the mean ± 1 SD from three independent experiments. See Figure 1 for abbreviations.

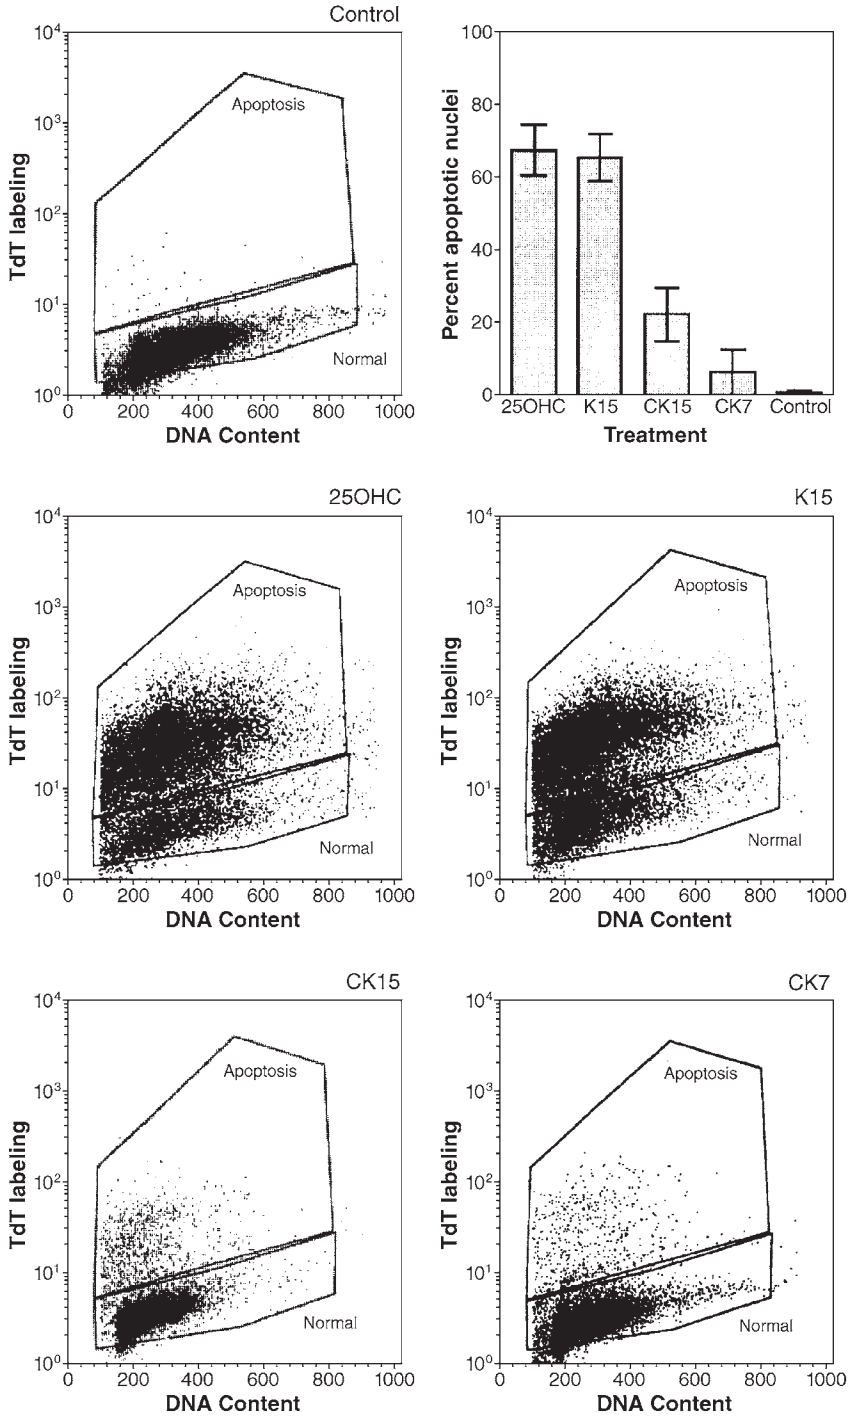

FIG. 4. Terminal deoxynucleotidyl transferase (TdT)-mediated dUTP nick end labeling (TUNEL) evaluation of single-stranded nicks and double-stranded breaks in DNA caused by the treatment of CEM-C7-14 cells with 1 μM oxysterols for 48 h. Growth conditions and delivery of oxysterols were the same as in Figure 1. Vehicle-treated control cells were used to establish the gates for normal and apoptotic cells. Twenty thousand cells were counted for controls and each oxysterol treatment, and the data were expressed as "percent apoptotic nuclei," i.e., percentage TUNEL-positive nuclei. The upper right-hand graph shows the mean values from four separate experiments with standard deviations. The remaining five panels are typical data obtained by FACS (Fluorescence Activated Cell Sorter; Becton Dickinson, Bedford, MA) analyses. See Figure 1 for abbreviations.

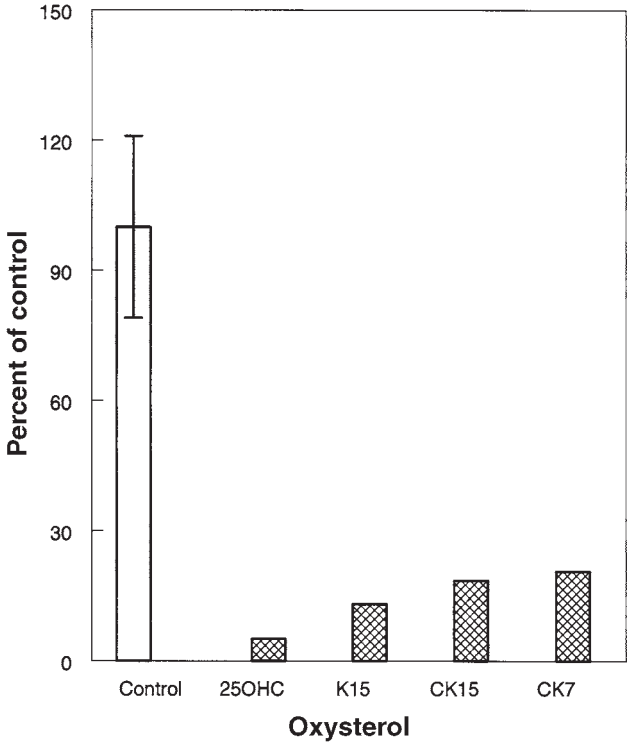

FIG. 5. Effect of 1 µM oxysterols on the level of c-myc mRNA in CEM-C7-14. Growth conditions and delivery of oxysterols were the same as in Figure 1. After 48 h in oxysterol, total RNA was extracted from the cells and 20 µg was electrophoresed, transferred to Nytran Plus® nylon membrane, and hybridized with a human c-myc exon 3 cDNA. Ethidium bromide-stained 18S ribosomal RNA was transferred to the same membrane to estimate the efficiency of RNA loading and transfer. Each oxysterol treatment included an individual control of vehicle-treated CEM-C7-14 cells. The error bar indicates the mean ± SD for the four control samples of constitutive c-myc mRNA levels. See Figure 1 for abbreviations.

uct. This assay has shown a high correlation with cell viability (28). Figure 2 demonstrates that at each of four sterol concentrations K15 was slightly less potent than 25OHC. At 1 µM, the two were not statistically different. Both CK15 and CK7 were much less able to suppress cell reductive capacity.

The "cytosolic" DNA fragmentation assay evaluates internucleosomal DNA cleavage, assayed by measuring the accumulation of mono- and oligonucleosomes in the cytoplasm of apoptotic cells, which occurs before plasma membrane breakdown. In Figure 3, a pattern of potency similar to that seen in Figures 1 and 2 for the four oxysterols is observed: 25OHC and K15 were the most potent apoptotic agents with almost the same ability to cause extensive appearance of DNA/histones in the cytoplasm. In this assay, CK15 clearly caused some DNA cleavage in CEM-C7-14 cells and CK7 showed little effect.

A flow cytometric TUNEL assay combined with a secondary stain for total DNA was used to detect both single-stranded nicks and double-stranded breaks in DNA. In Figure 4 (upper right-hand panel) the percentage of TUNEL-positive "apoptotic nuclei" in CEM-C7-14 cells after 48 h of treatment with 1 µM oxysterol showed the potency pattern: 25OHC ≥ K15 > CK15 > CK7 ≥ control cells. The remaining panels in Figure 4 present the data as directly obtained by FACS analyses. In each panel, the lower gated area reflects the normally cycling cells, while the upper gated area shows the TUNEL-positive cells.

Suppression of c-myc *mRNA by oxysterols.* In 1993, the suppression of the c-*myc* protooncogene, which plays an important role in the control of normal cell growth and differentiation, was shown to be a critical step in the glucocorticoid-induced lysis of CEM-C7 cells (1). More recently, Ayala-Torres *et al.* found that c-*myc* also is suppressed by 25OHC in apoptotic CEM-C7 cells (2). Figure 5 documents that in CEM-C7-14 cells treated with 1 µM 25OHC or K15 for 48 h, c-*myc* mRNA levels were also suppressed to 5 and 13%, respectively, of constitutive levels. The 1 µM concentrations of the CK15 and CK7 also depressed c-*myc* mRNA significantly (19% of control for CK15 and 21% for CK7). Thus, the rank order of potency for c-*myc* suppression is 25OHC > K15 > CK15 > CK7, although all oxysterols depressed c-*myc* significantly.

Documentation of apoptosis by phosphatidylserine (PS) and DNA staining. One of the earliest features of cells undergoing apopotsis is the translocation of the phospholipid PS from the inner to the outer side of the plasma membrane. This externalization of PS precedes the nuclear changes associated with apoptosis. The phospholipid-binding protein Annexin V, when conjugated to a fluorochrome, such as fluorescein isothiocyanate (FITC), can be used to identify cells that have translocated their PS to the outer plasma membrane. The nucleic acid dye 7-AAD enters and binds to DNA in dead cells. We followed its entry with FITC-labeled monoclonal antibodies. Two-color analysis, with minimal spectral overlap between the 7-AAD and FITC fluorescence emissions, allowed simultaneous assay of the two reactions. Chromatin condensation, another hallmark of apoptosis, was followed by staining the same cells with Hoechst 33342 dye.

Figure 6 presents the density plots from a two-color FACS analysis of CEM-C7-14 cells treated for 52 h and stained with Annexin V and 7-ADD. The upper panel shows the reactivity of control cells and defines the areas containing cells with specific fluorochrome reactions. The lower panels illustrate the effects of treatment with the various oxysterols. Note the dense numbers of dead cells after 25OHC and K15 treatment (quadrant 3). Virtually no cells reacted with 7-AAD unless they were also positive for Annexin V binding, but some cells were Annexin V positive without being 7-ADD positive (quadrant 2). Table 1 provides the percentages of cells for these five conditions over the time course of 4, 6, 24, 30, and 52 h. The increase in apoptotic cells in the 1 µM 25OHC is seen by 24 h, in K15 by 6 h, in CK15 by 52 h, and little increase is seen in CK7 treated cells at any time of treatment. By 52 h, both 1 µM 25OHC and K15 had killed >90% of the CEM-C7-14 cells.

The upper photographs in Figure 7 were taken at 30 h for control CEM-C7-14 cells and 1 µM 25OHC- and K15-treated cells, while the lower two sets of photographs were taken at 52 h for 1 µM CK15- and CK7-treated cells. The photographs using polarized white light clearly identify the field of cells. Hoechst dye staining of the same cells reveals the onset of nu-

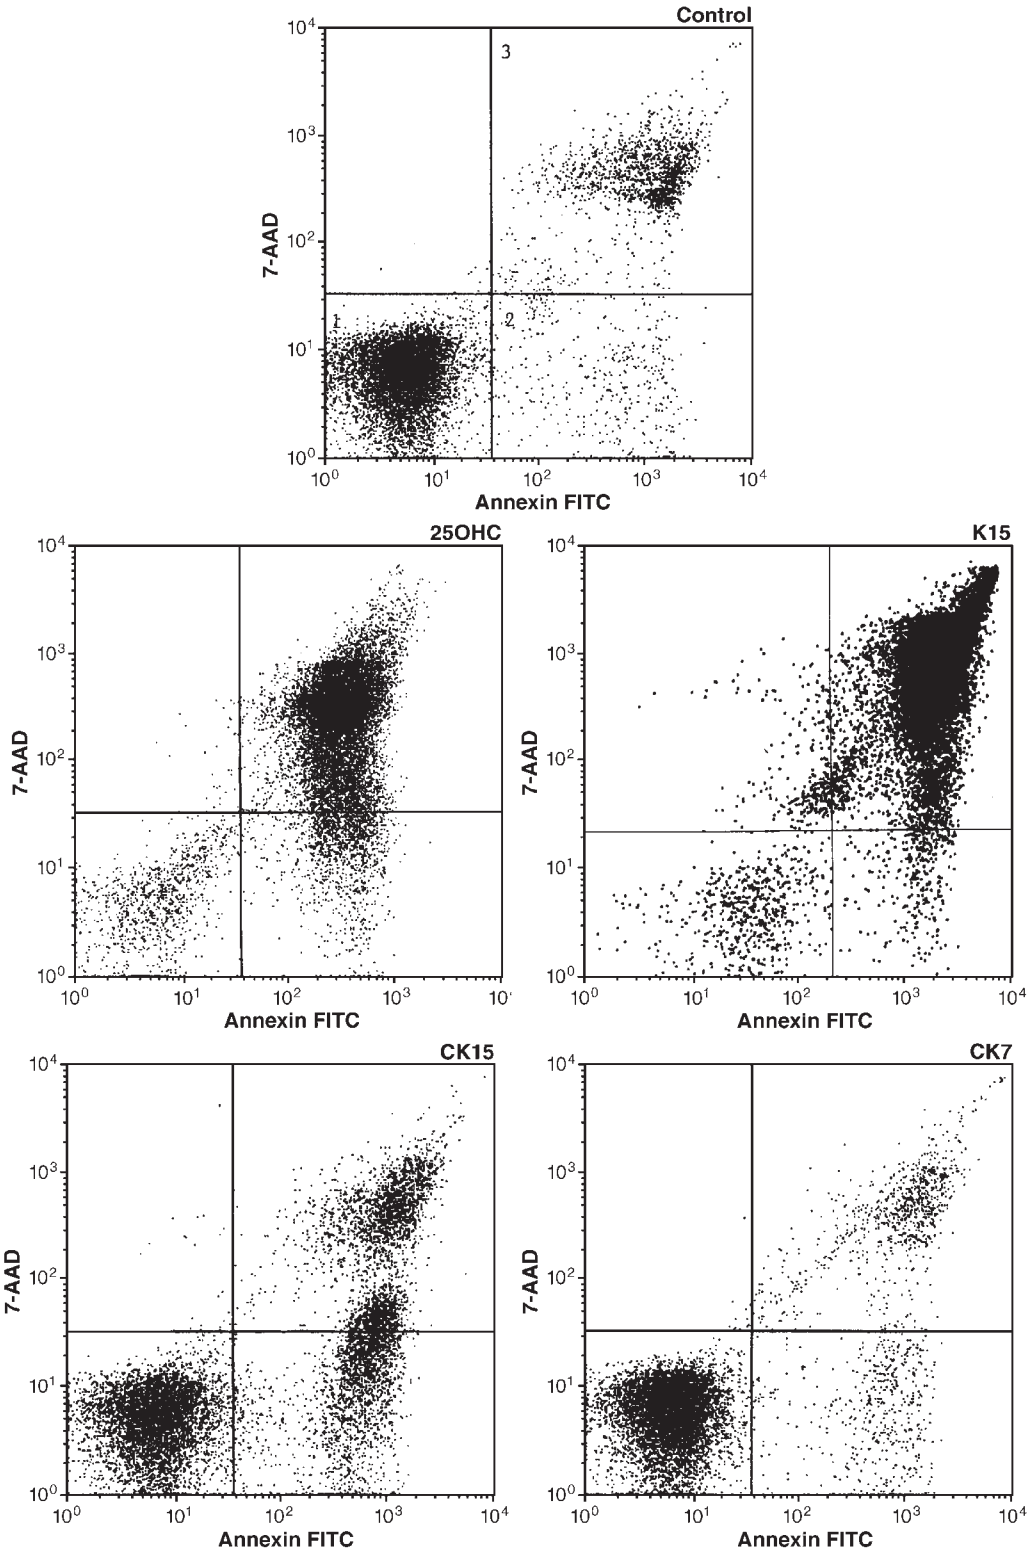

FIG. 6. Two-color FACS analysis of cells reacted with Annexin V for evidence of externalized membrane phosphatidylserine (PS) and 7-amino-actinomycin D (7-AAD) for DNA staining due to loss of membrane integrity. CEM-C7-14 cells were treated with 1 μM of each oxysterol for 52 h. Growth conditions and delivery of oxysterols were the same as in Figure 1. The five panels represent FACS analyses of CEM-C7-14 cells treated with oxysterol or vehicle. Upper panel: vehicle-treated control cells were used to establish the gates for unstained, viable cells in the lower left quadrant [1]; Annexin V positive/7-AAD negative, apoptotic cells in the lower right quadrant [2]; and Annexin V/7-AAD positive, dead cells in the upper right quadrant [3]. Other panels: cells that had been exposed to the indicated sterol. FITC, fluorescein isothiocyanate; for other abbreviations see Figure 1.

TABLE 1
Apoptotic Response of CEM-C7-14 Cells (control and 1 μM oxysterol-treated)

	Time (h)				
Treatment	4	6	24	30	52
Control					
Annexin V positive (%)	5.6	5.6	4.4	5.6	5.8[b]
+ 7-AAD positive (%)	10.0	7.1	11.1	13.6	8.1[c]
25OHC					
Annexin V positive (%)	4.7	5.9	5.4	26.5	7.9
+ 7-AAD positive (%)	10.6	8.7	9.0	48.8	86.5
K15					
Annexin V positive (%)	6.1	6.7	12.9	15.0	1.7
+ 7-AAD positive (%)	10.8	11.9	18.8	17.6	93.2
CK15					
Annexin V positive (%)	5.2	5.6	4.1	6.1	19.3
+ 7-AAD positive (%)	8.1	11.6	9.5	4.5	24.6
CK7					
Annexin V positive (%)	5.1	5.9	5.3	7.0	7.1
+ 7-AAD positive (%)	7.9	5.9	7.9	11.4	8.5

[a]25OHC, 25-hydroxycholesterol; K15, 15-ketocholestenol; CK15, 15-ketocholestenol hydroxyethyl ether; CK7, 7-ketocholesterol hydroxyethyl ether; 7-AAD, 7-amino-actinomycin D.
[b]Mean for controls = 5.4 ± 0.6.
[c]Mean for controls = 10.0 ± 2.5.

clear condensation and fragmentation as seen in the second panel. The intensity of the fluorescent dyes is sometimes faint, making it difficult to identify every cell in the second and third panels. In viewing the same field, the third panel shows the progressive stages of apoptosis as monitored by Annexin V/7-AAD. Those cells in the early stage of apoptosis contain only the green stain of Annexin V-FITC. The strong yellow to orange signal is due to the movement of 7-AAD across the plasma membrane, which becomes increasingly permeable during the later stages of apoptosis. In order to demonstrate apoptosing cells in the CK15 and CK7 cultures, it was necessary to photograph increased times (52 h), whereas late-stage apoptotic cells could be seen in 30-h cultures of 25OHC- and K15-treated cells.

DISCUSSION

The focus of this study has been threefold: (i) to examine three oxysterols for their ability to kill human leukemic cells; (ii) to determine if the pathway of death was an apoptotic one; and (iii) to assess their relative cell-kill potency. We designed and implemented a battery of tests that were useful in the evaluation of such agents for their apoptotic potential, which could lead to future drug discovery and development. In each of the assays utilized, 25OHC served as a standard for comparison of cell-kill potency because there have been several studies of oxysterol-dependent apoptosis that have used this agent.

To avoid the confounding effects of sterols in whole serum, we carried out this study on cells cultured in medium supplemented with DFBS. We also added BSA as an oxysterol carrier to prevent the loss of drug because of adhesion to the culture flask wall. The *in vivo* environment may be quite different. Human cells express cell-surface receptors for low density lipoprotein (LDL) (29). Since LDL is the major cholesterol-carrying lipoprotein in human plasma, oxysterols may enter cells through this mechanism as well as directly. Previous *in vitro* studies have shown that LDL receptor activity can be enhanced by incubating cells in a lipoprotein-deficient medium (30). However, for this systematic evaluation of the effects of oxysterols on these leukemic cells, a defined culture medium was deemed desirable.

The compounds studied here examined the effects of a keto group on C15 and the addition of a 3β-2′-hydroxyethyl ether on C15 or C7. The initial growth studies demonstrated that all three test oxysterols did inhibit cell growth in treated cultures as compared to control cells under conditions in which the untreated cells maintained logarithmic growth. The most potent agent of the experimental oxysterols to diminish proliferating cells was K15, which was nearly as potent as 25OHC. Adding the 3β-2′-hydroxyethyl ether group reduced the potency of both K15 and K7; in fact, the already weak K7 was rendered nearly nonapoptotic.

Having established that all three test oxysterols could decrease the number of leukemic cells in culture relative to controls, the remainder of our study evaluated the nature of this reduction. Were the cells killed or merely slowed in growth? By examining the reductive metabolism of the treated cells' mitochrondria in the MTT assay, it was demonstrated that these three oxysterols did diminish CEM-C7-14 cells' ability to reduce the MTT dye, with K15 again being the most potent. CK15 and CK7, at the highest concentration tested, only reduced this mitochrondrial function by ~25%.

The Hoechst chromatin staining, TUNEL, and cytosolic DNA fragmentation assays all indicated that the test sterols did cause apoptotic cell death, as determined by DNA condensation, nicks, and fragmentation. Again, K15 created far more DNA damage than CK15 or CK7. Finally, this apoptotic cell death was associated with the classic alterations of the cellular plasma membrane as well as the suppression of an important growth controlling gene, c-*myc*. Fluorescence staining using Annexin V and 7-AAD demonstrated that in K15-treated CEM-C7-14 cells, the plasma membrane's integrity was compromised earlier than with CK15 or CK7.

Northern blot analyses showed a decrease in the level of c-*myc* mRNA for all four oxysterols tested. CK15 and CK7 were much more effective in reducing c-*myc* mRNA than they were in causing apoptosis. This may account for their ability to slow cell growth (Fig. 1) since progression through the cell cycle demands an adequate level of cMyc. Our studies so far have only examined c-*myc* mRNA levels after treatment with the test sterols. Since cMyc protein can be regulated independently from its mRNA, it will be necessary to determine the levels of the protein before drawing further conclusions.

In sum, oxysterols continue to show potential as chemotherapeutic agents. Some reports have even suggested that oxysterols could increase the sensitivity of tumor cells to other cancer drugs (31,32). The ability of oxysterols to kill cells could result from the simple regulation of sterol *de novo* synthesis or from the inhibition of the many biologically impor-

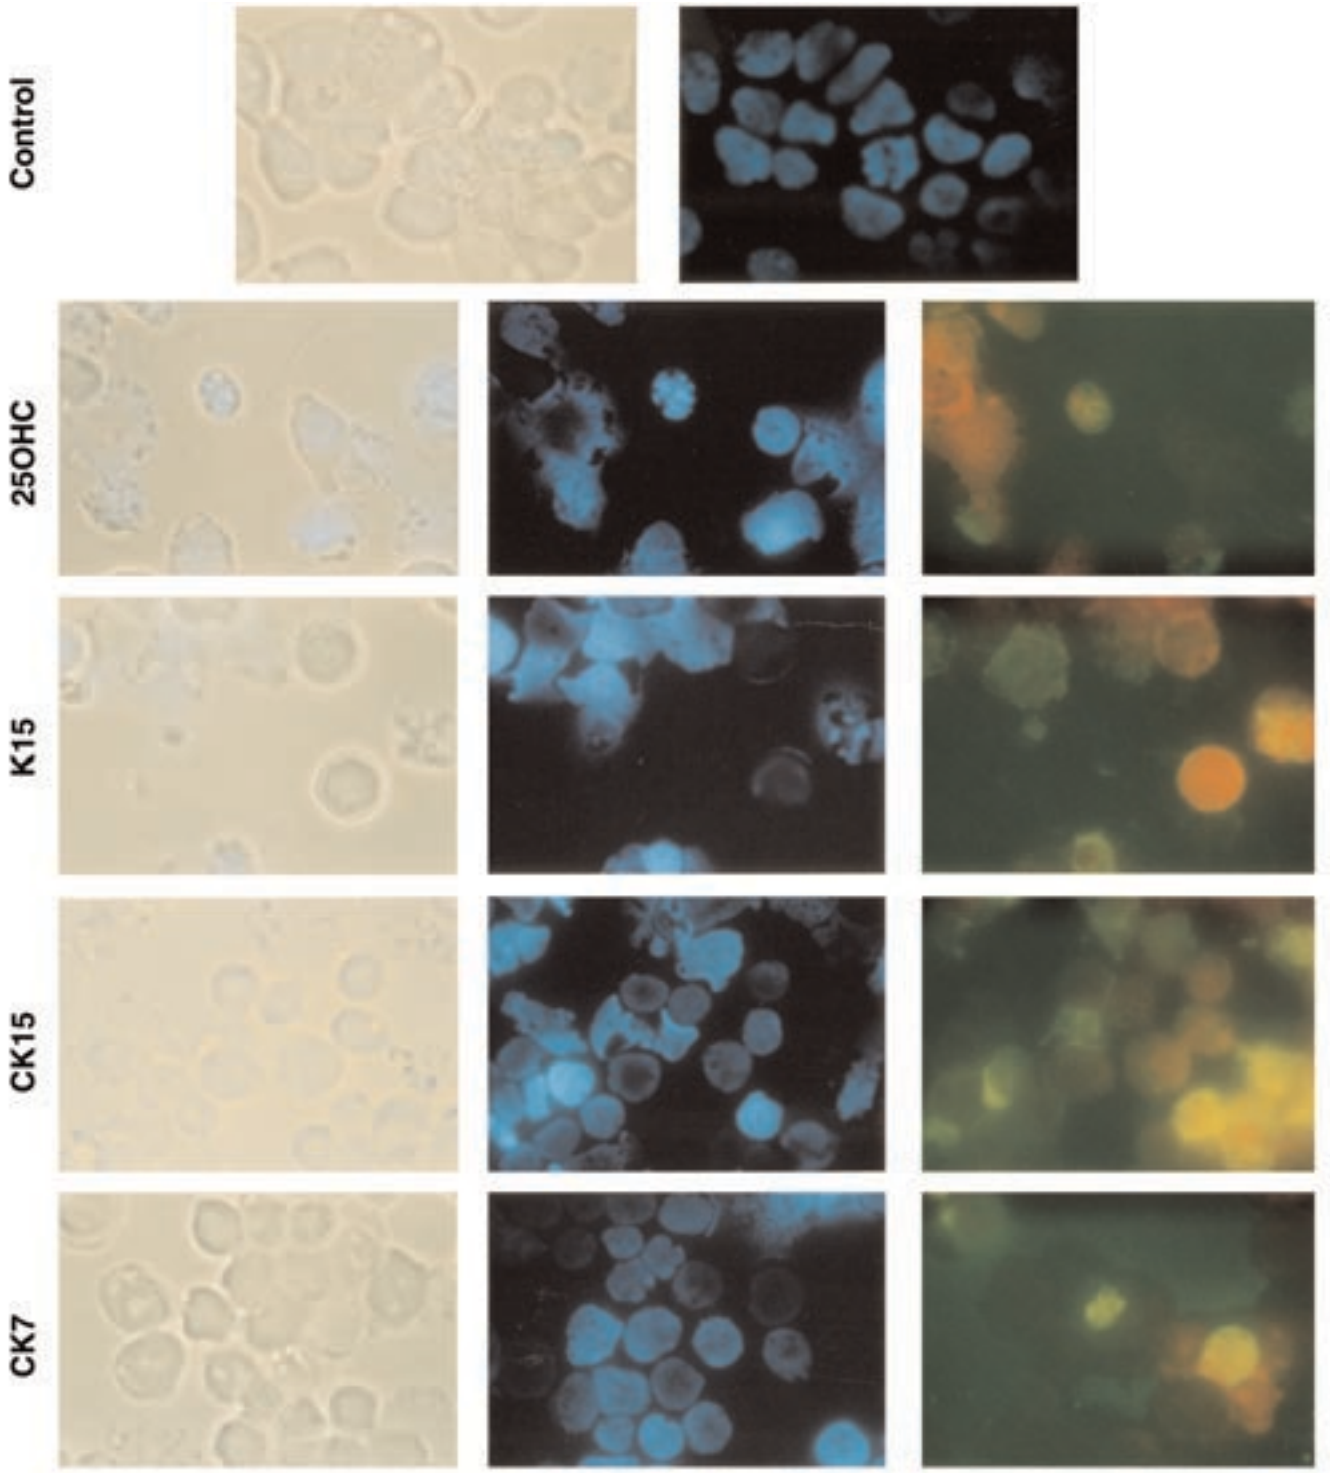

FIG. 7. Fluorescent microscopy of apoptotic events in CEM-C7-14 cells treated ± 1 μM oxysterol. Growth conditions and delivery of oxysterols were the same as in Figure 1. CEM-C7-14 cells were stained with Hoechst 33342, Annexin V, and 7-AAD at the various time points, 30 h for 25OHC and K15; 52 h for CK15 and CK7. Photographs of stained cells were taken on a Nikon Eclipse E600 microscope with a Nikon FDX-35 camera at 100× magnification: first, viewed with polarized light to demonstrate all the cells in the field, second viewed at 488 and at 515 nm to detect the initial loss of membrane integrity (Annexin V, green/yellow) followed by the death of the cell (7-AAD, red); and third, at 355 and at 460 nm to reveal condensed chromatin found in apoptotic cells. See Figures 1 and 6 for abbreviations.

tant mevalonate-derived products such as dolichol, ubiquinones, or isopentyl/farnesyl moieties or some other unidentified pathway. Some years ago it was shown that the relative binding affinity of many oxysterols to OBP correlated with their ability to suppress the rate-limiting step in *de novo* cholesterol synthesis, which is essential for cell homeostasis and

proliferation (33). Taylor and Kandutsch (34) reported that the 3β-hydroxy position of an oxysterol was essential for high OBP binding affinity and that substitution of a hydroxyl or keto function at positions C15, 20, 25, or 26 of the parent cholesterol molecule also produced high OBP affinity ligands. In 1993, our laboratory reported that oxysterol-induced cell death correlated with OBP occupancy with 25OHC demonstrating ~30 nM and K7 ~450 nM OBP-binding affinity in serum-free medium (20). Of the test oxysterols, K15 was the strongest ligand for OBP and in one competition assay was a slightly better competitor than 25OHC for OBP; 50% competition of 25OHC by 8.8 pM for K15, whereas unlabeled 25OHC required 12.5 pM. CK15 required 40 pM for 50% competition and CK7 competed only 10% at 40 pM (Alexander S. Krylov, unpublished data). While there have been studies evaluating the effects of different oxysterols on cholesterol biosynthesis (35), Sinensky *et al*. have challenged the correlation between the regulation of HMG-CoA reductase and the effectiveness of those agents as anticancer drugs (36).

The effectiveness of oxysterols *in vivo* might be diminished by the availability of cholesterol from LDL. For cells in the circulation, this could be protective. In tissues or malignant cells outside the vascular compartment, LDL-cholesterol is not as available. Certainly, higher concentrations of 25OHC are required to kill CEM cells when serum is present. Even so, the protection is not absolute, and no amount of added cholesterol can protect if sufficient 25OHC is present (20). Therefore, the question will be whether *in vivo* oxysterols can be administered to levels sufficient to overcome whatever protection LDL-cholesterol gives.

As to structure–function relations, Zhang *et al*. have reported that 7α-hydroxylation and 3-dehydrogenation abolish the ability of 25OHC and 27-hydroxycholesterol to induce apoptosis in thymocytes (37). For the present study we find that the sterols tested can cause apoptosis. We conclude that a keto group at position 15 produces an oxysterol with high apoptotic potency. The 3β-2′-hydroethyl ethers greatly reduce potency. Our data show the usefulness of applying a battery of tests for cell changes correlated with apoptosis, and they add to the body of relevant structure–function knowledge.

ACKNOWLEDGMENTS

The authors wish to acknowledge the work of summer student Jacquelyn Payne, as well as the technical assistance in the MTT assays of David Chilton and the use of the fluorescence microscope in the laboratory of Dr. Tensheng Chan in the Microbiology Department of the University of Texas Medical Branch. The evaluation of the purity of the oxysterols was performed by Drs. Jon Teng and Stefan Serabyn of the HPLC Core facility of the Sealy Center for Molecular Science at this institution. The authors also would like to express their appreciation for the privilege to preview the late Dr. George J. Schroepfer Jr.'s review in *Physiological Reviews* titled "Oxysterols: Modulators of Cholesterol Metabolism and Other Processes." Dr. Leland L. Smith, professor emeritus in this department, provided invaluable advice in the preparation of this manuscript. This work was supported in part by National Institutes of Cancer grant CA 41407 and The Walls Medical Research Foundation.

C_{27} to C_{32} Sterols Found in *Pneumocystis*, an Opportunistic Pathogen of Immunocompromised Mammals

Edna S. Kaneshiro* and Michael A. Wyder

Department of Biological Sciences, University of Cincinnati, Cincinnati, Ohio 45221-0006

ABSTRACT: *Pneumocystis carinii* is the paradigm of opportunistic infections in immunocompromised mammals. Prior to the acquired immunodeficiency syndrome (AIDS) pandemic and the use of immunosuppressive therapy in organ transplant and cancer patients, *P. carinii* was regarded as a curiosity, rarely observed clinically. Interest in this organism exploded when it was identified as the agent of *P. carinii* pneumonia (PcP), the direct cause of death among many AIDS patients. Aggressive prophylaxis has decreased the number of acute PcP cases, but it remains among the most prevalent opportunistic infections found within this patient population. The taxonomic assignment of *P. carinii* has long been argued; molecular genetics data now demonstrate that it is a fungus. Several antimycotic drugs are targeted against ergosterol or its biosynthesis, but these are not as effective against PcP as they are against other fungal infections. This can now be explained in part by the identification of the sterols of *P. carinii*. The organism lacks ergosterol but contains distinct C_{28} and C_{29} Δ^7 24-alkylsterols. Also, 24-methylenelanost-8-en-3β-ol (C_{31}) and pneumocysterol, (24*Z*)-ethylidenelanost-8-en-3β-ol (C_{32}) were recently identified in organisms infecting humans. Together, the Δ^7 24-alkylsterols and pneumocysterol are regarded as signature lipids of the pathogen that can be useful for the diagnosis of PcP, since no other lung pathogen is known to contain them. Cholesterol (C_{27}), the dominant sterol component in *P. carinii*, is probably totally scavenged from the host. *De novo* synthesis of sterols has been demonstrated by the presence of lovastatin-sensitive 3-hydroxy-3-methylglutaryl-CoA reductase activity, the incorporation of radiolabeled mevalonate and squalene into *P. carinii* sterols, and the reduction in cellular ATP in cells treated with inhibitors of enzymes in sterol biosynthesis.

Paper no. L8325 in *Lipids 35,* 317–324 (March 2000).

Pneumocystis carinii pneumonia (PcP) remains among the most prevalent opportunistic infections in acquired immunodeficiency syndrome (AIDS) patients (1,2). It is now evident that the high incidence of PcP is not limited to AIDS patients in the United States of America and Europe, but is true globally. The combination of trimethoprim and sulfamethoxazole (TMP/SMX) and other agents (e.g., atovaquone) used for prophylaxis and for clearing *P. carinii* infection has successfully reduced the number of deaths directly attributed to PcP (1,2). However, about 80% of AIDS patients still develop PcP at least once, and many patients experience recurrent episodes due to their long-term immunodeficient status. Also, some individuals cannot tolerate certain drugs and some develop undesirable side effects, and the development of drug-resistant pathogen populations is of serious concern. Thus, there is a need to develop a larger armamentarium of diverse drugs to handle these problems. The most effective and widely prescribed antimycotics are targeted against ergosterol in the pathogen's membranes (e.g., amphotericin B), or against its synthesis (e.g., azoles, morpholines, thiocarbamates, allylamines) (3,4). Antiergosterol agents have proved to be particularly useful for deeply invasive or systemic mycosis, but at clinical doses, amphotericin B does not clear PcP. Unlike other fungal pathogens of humans, *P. carinii* does not contain ergosterol (6,7). In this article, we describe what is currently known about the sterols in this unique and unusual organism.

THE *PNEUMOCYSTIS* COMPLEX

Since its discovery almost a century ago, the taxonomic status of *Pneumocystis* has been actively debated (8–11). Investigators have given particularly good arguments for placing it among the protozoa or fungi. Within the last two decades, molecular genetic analyses have provided strong evidence for placing it within the fungi, but there is yet insufficient evidence for solidly placing it among the ascomycetes, basidiomycetes, or on a branch independent of the major fungal groups (1).

It is widely accepted that *P. carinii* is host species-specific; experimental introduction of *P. carinii* isolated from one host species into another host species does not result in fulminant infections (12,13), but transient colonization probably occurs (14–20). Although subtle phenotypic differences have been reported between isolates from different host species (21–26), nucleotide sequences of a number of regions of DNA indicate that *P. carinii* populations isolated from different hosts have highly divergent genetic backgrounds: sequences can vary from 15–50% at selected gene loci (2,9,10,27–29). Genetic populations exhibiting different chromosomal patterns (kary-

otypes) have also been detected in organisms within a single host species (2,9,10,29–34). The distinct populations in rats have been designated "prototype" (*P. carinii carinii*) and "variant" (*P. carinii ratti)* (31,32,34). Investigators working on *Pneumocystis* have yet to agree on designating separate species, but use an interim trinomial nomenclature indicating the mammalian host species; e.g., *P. carinii hominis* for organisms proliferating in humans (2,9,10).

PNEUMOCYSTIS ORGANISM PREPARATIONS FOR LIPID ANALYSIS

One of the most serious hindrances to advancing *P. carinii* research has been the lack of continuous cultivation procedures for this organism (35). Until now, most *in vitro* studies have been performed on short-term primary cultures of *P. carinii* freshly isolated from infected animal lungs, and on monoxenous cultures with freshly isolated organisms placed in tissue cultures with mammalian cell lines. These primary cultures begin to die out after about 2 wk.

Recently, Merali *et al.* (36) have succeeded in making a major breakthrough by achieving continuous axenic cultivation of rat-derived *P. carinii* and *P. carinii hominis* placed in transwell plates. The present culture conditions allow for only very slow organism proliferation and have not yet been modified to produce mass amounts of organisms to perform most types of direct biochemical analyses.

Analysis of organisms in continuous axenic cultures may identify compounds synthesized by the organism. On the other hand, microbes can take up nutrients such as lipids from the culture medium similar to that by which parasites scavenge nutrients from their hosts. Analysis of infectious agents freshly isolated from their host provides insight into the biochemical nature of the organisms as they are actually growing in the host. Metabolic processes in parasites grown in culture very likely differ from those proliferating in the host.

To study *P. carinii* isolated from mammalian lungs, it was imperative that the purity of the organisms prepared from a given protocol be rigorously characterized, thus enabling credible interpretion of data obtained from such preparations. The alveolar lining in which *P. carinii* proliferates is bathed in lung surfactant, 88% of which is lipid with smaller amounts of protein and carbohydrate (37). Lung surfactant lipids are characterized by the predominance (75%) of phosphatidylcholine (PC), especially dipalmitoyl PC. Cholesterol constitutes approximately 3–10% of surfactant total lipids. Lung surfactant lipids and proteins bind avidly to the surfaces of *P. carinii* and are not completely removed by washing with ordinary buffered salt solutions. Treatment with reagents, such as the divalent cation chelator EDTA, is required to remove surfactant components (e.g., surfactant protein A, SP-A) (38).

During the initial phase of our studies on *P. carinii*, we developed a protocol for the isolation and purification of organisms from the lungs of corticosteroid-immunosuppressed rats (39). Included in the protocol is the mucolytic agent glutathione, which detaches organisms from each other and from type I pneumocytes of the lung epithelium, presumably by breaking disulfide linkages. Hence, alveolar type I cells to which *P. carinii* are adherent (40–43) and the elaborate tubular extensions of the surface membrane of trophic forms (44) remain intact.

The critical aspect of developing a contaminant-free preparation is the documentation that it is free of host cell fragments and molecules. Thus, the purity of our preparations was demonstrated by multiple criteria, including light and electron microscopy, biochemical, and immunochemical (SP-A) analyses. The lowest (not average) values obtained by at least four separate criteria were >95–100% purity of the organism preparations (39). The final pure preparations contain mixed life-cycle stages (trophic and cystic forms plus intermediate stages and other forms whose placement within the pulmonary life cycle is not yet understood) (44).

Using (i) a dual fluorescence staining live/dead assay (44), (ii) quantitation of cellular ATP (46), and (iii) the incorporation of radiolabeled precursors into *P. carinii*-specific compounds (47–50) also shows that these preparations contain metabolically active organisms.

STEROLS IN *PNEUMOCYSTIS* ISOLATED FROM RAT AND HUMAN PcP LUNGS

In considering the difficulties faced in studying *P. carinii* by direct analytical biochemistry, significant advances have been made with respect to its lipids within the last decade (47–60). Over 20 sterol components have been detected in rat-derived *P. carinii carinii* (5–7,53,58) and human-derived *P. carinii hominis* (6–8,60) (Table 1). The structural identities of most major sterols have been determined by relative retention times and cochromatography with authentic standards using gas–liquid chromatography (GLC) and high-resolution mass spectrometry (MS). In a few cases, nuclear magnetic resonance spectroscopy has been performed on isolated and purified sterol components, providing unequivocal structural identifications (60). The structural assignments for some minor sterol components and those with several double bonds are considered tentative.

Campesterol and β-sitosterol were identified in both rat and human-derived organisms (5–9), but these were also found in the sterols of their respective lung controls without *P. carinii* infection. Thus, it is very likely that these plant sterols are scavenged by *P. carinii* from the host, and the presence of these components in the host lung lipids results from plant material in the hosts' diets.

It is interesting that Δ^7 24-alkylsterols are the dominant sterols present in representatives of the rust fungi (61,62). It is unclear whether this observation has any phylogenetic or environmental implications (e.g., lateral gene transfer) for the apparent commonality between the sterols of *P. carinii* and the rust fungi (basidiomycetes).

Distinct C_{31} and C_{32} Δ^8 sterols were also found in *P. carinii hominis* samples. Pneumocysterol [(24*Z*)-ethylidenelanost-8-en-3β-ol] was found in some, but not all *P. carinii hominis* preparations. The only other reported occurrence of pneumocysterol is in the plant *Neolitsea sericea* (63). This sterol is not

[a]ND, not detected.

found in any organism known to infect mammalian lungs and hence is another distinct signature sterol of *P. carinii*. The proportions of pneumocysterol can vary widely from sample to sample, from only undetectable or trace amounts up to 50% of the *P. carinii*-specific sterols (i.e., excluding cholesterol) (8,60,67; Amit, Z., Baughman, R.P. and Kaneshiro, E.S., unpublished results) (Fig. 1). The occurrence and accumulation of pneumocysterol is not correlated with coinfection with human immunodeficiency virus (HIV).

Among several possible explanations for the wide range of pneumocysterol concentrations in human-derived *P. carinii hominis* is the highly divergent nature of organisms within the *Pneumocystis* complex (2,9,10,29). It is now well accepted that an individual host can harbor single or mixed populations of *P. carinii* with highly divergent genetic backgrounds equivalent to distances separating at least species of fungi and metazoa. If organisms within the *P. carinii* complex are that different, the synthesis and accumulation of different compounds such as sterols would not be extraordinary. Thus, the population of organisms used for sterol analyses may represent single or mixed populations of *P. carinii hominis*. If one species/strain synthesizes pneumocysterol and another does not, the full range of pneumocysterol proportions actually observed could result from single populations represented by these two species/strains with intermediate values representing different percentages of the two species/strain (which differ in their sterol composition) in a simultaneous infection. More samples from humans as well as from mammalian species other than humans and rats need to be examined for a better understanding of sterol profile diversity in the *P. carinii* complex.

Because pneumocysterol and 24-methylenelanost-8-en-3β-ol (found in substantial amounts in samples with high pneumocysterol; Giner, J., Parish, E.J., Jayasimhulu, K., and Kaneshiro, E.S., unpublished data) are 24-alkylated lanosterol molecules, this indicates that *P. carinii S*-adenosylmethionine:sterol methyltransferase (SAM:SMT) can readily use lanosterol as a substrate and suggests that sterol C-24 alkylation activity in this organism is high. Consistent with this suggestion is that the gene for SAM:SMT was among the first identified in an expressed sequence tag analysis in an ongoing *P. carinii* genome project (Cushion, M.T., personal communication). The message for this gene could have been detected as a random event, or because it is there in several copies. Nonetheless, it appears that the gene encoding SAM:SMT is expressed in *P. carinii*.

PNEUMOCYSTIS SIGNATURE STEROLS IN NON-PcP HUMAN SUBJECTS

The Δ^7 24-alkylsterols found in *P. carinii* are not common among fungi (61,62), and are not found in any other pathogen known to infect mammalian lungs. These are distinct signatures of *P. carinii carinii* and *P. carinii hominis* and are therefore useful marker compounds of the pathogen.

The identification and detection of signature lipids is a powerful approach employed by microbial ecologists. The assem-

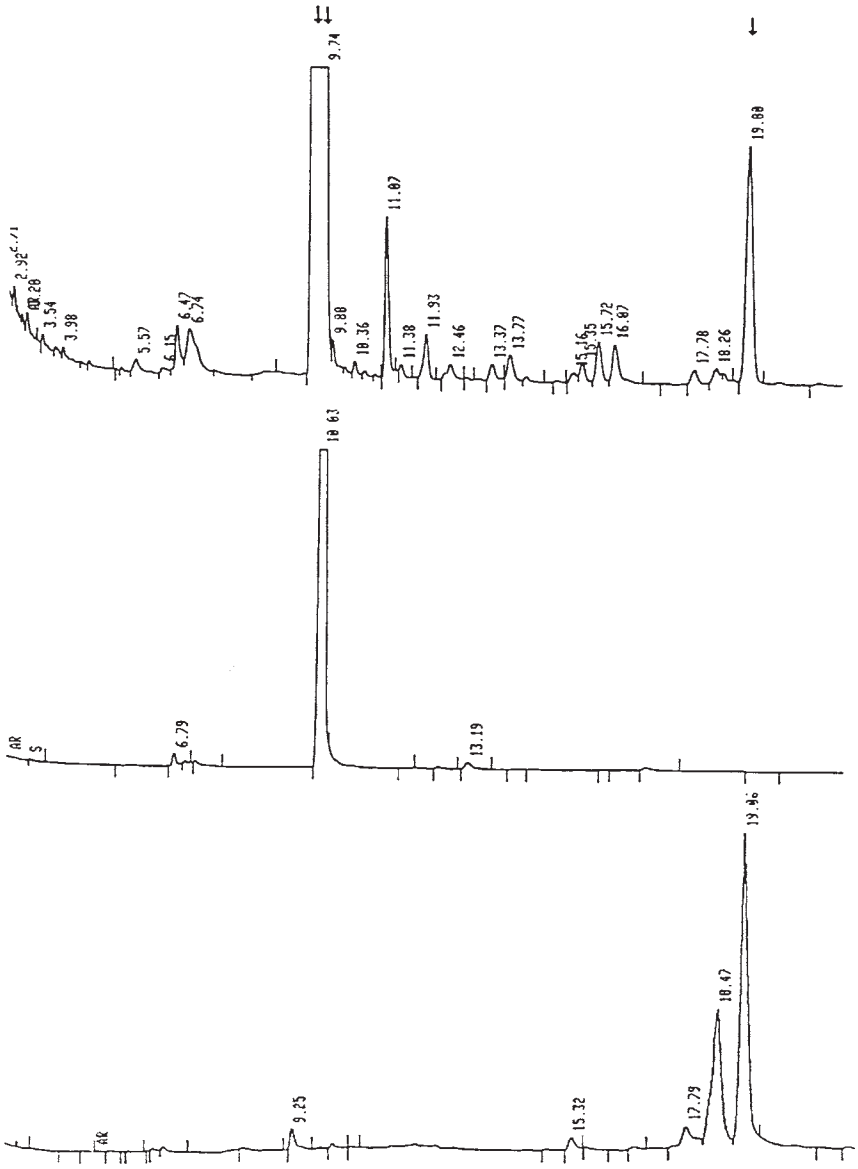

FIG. 1. Gas–liquid chromatography (GLC) tracing of the sterols of a human lung infected with *Pneumocystis carinii hominis*. This sample was prepared from a formalin-fixed lung taken from a patient who died from *Pneumocystis carinii* pneumonia with no known history of treatment for the infection. Thin-layer chromatographically purified free sterols were analyzed using a DB-5 or SPB-5 capillary column (Supelco, Bellefonte, PA) in a Hewlett-Packard gas–liquid chromatograph (Palo Alto, CA) with He as the carrier gas (1 mL/min; split ratio was 50:1). Isothermal (280°C) analysis was performed with injection and flame-ionization detector temperatures set at 300 and 290°C, respectively. Top tracing, sterols from lungs of *P. carinii*-infected patient. Cholesterol (double arrow; retention time, 9.74 min) from the host lung and scavenged by the organism was the dominant component. Pneumocysterol (single arrow; retention time, 19.00 min) was the major *P. carinii*-specific sterol in this sample. Middle tracing, authentic standard of cholesterol (retention time, 10.03 min). Bottom tracing, authentic (24*Z*)-ethylidenelanost-8-en-3β-ol (chemically synthesized by E.J. Parish; retention time, 19.06 min). The smaller peak eluting at 18.47 min is the 24*E* isomer. GLC tracings were kindly provided by D.H. Beach.

blages of different soil, aquatic, and other microbiota are characterized by detecting markers for specific bacterial species, and their signature lipids are among the most utilized for that purpose (64–66). In a similar fashion, the relatively rare, distinct *P. carinii* signature sterols could be used to detect the organism in human samples and may prove useful for diagnosis of infection or transient colonization by the pathogen.

In a recent study of bronchoalveolar lavage fluid (BALF) from HIV patients with PcP, the *P. carinii* signature sterols were detected by GLC analysis in samples containing suffi-

cient levels of sterols (67). It was also found that the BALF of PcP patients had dramatically reduced levels of total sterols, only about 20% of normal. A reduction in total lipids and phospholipids in BALF obtained from PcP patients was previously reported (68). Thus, for this patient group, a 1-mL BALF sample did not contain sufficient levels of total and *P. carinii* signature sterols for identification by routine GLC procedures (67).

The analyses of sterols in human BALF from normal, healthy volunteers and from different groups of patients, including those with pulmonary disease other than PcP (Amit, Z., Baughman, R.P., and Kaneshiro, E.S., unpublished observations) provided some additional interesting and potentially important observations with respect to *P. carinii* epidemiology. In every patient group examined, as well as in at least one normal healthy individual, the *P. carinii* signature sterols were present even though the organism was not detected by light microscopic analysis of the samples. One patient group consisted of sarcoidosis patients (pulmonary disorder of unknown cause characterized by granulomatous tubercles of the skin, lymph nodes, lungs, eyes, and other tissues and organs). The *P. carinii* signature sterols were detected in about 78% of the samples from these patients, suggesting that BALF sterol analysis may be a good alternative method complementing light microscopy for the detection of this pathogen. Furthermore, the detection of *P. carinii* signature sterols in some samples from HIV-positive patients cleared of PcP suggests that even though the patients' lungs had been cleared of live organisms, these signature lipids persist in the host lung, i.e., *P. carinii* sterols are retained in the host lung after the organisms are no longer identifiable by light microscopy or DNA amplification by polymerase chain reaction (PCR). The sterols may be recycled in the lung surfactant and alveolar type II epithelial cells that synthesize and secrete lung surfactant. Alveolar type II epithelial cells have been shown to take up lung surfactant components as well as secrete them (69).

The detection of *P. carinii* signature sterols in normal, healthy individuals is consistent with reports that asymptomatic animals, including those trapped from the wild, have *P. carinii* (15–19). These organisms have been detected by employing DNA amplification techniques; light microscopic examinations usually do not provide sufficient sensitivity. Hence, signature sterols by routine GLC techniques may be a sensitive procedure for detecting low-level infections. The detection of the signature sterols in healthy individuals is also consistent with the proposal that, although *P. carinii* organisms are host species-specific, they could transiently colonize and persist for some time in other closely related species (14,70). Thus, colonization in those with intact immune systems and by organisms that can cause fulminant infections in other host species may be detectable by the sterol profiles of BALF.

DE NOVO BIOSYNTHESIS OF STEROLS

De novo sterol biosynthesis in *P. carinii carinii* was initially demonstrated by the incorporation *in vitro* of radiolabeled mevalonate and squalene into the organism's sterols as determined by radioactivity in the sterol TLC fraction (47,49). The individual sterol components that became radioactive have yet to be identified.

Preliminary results demonstrate 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase activity in *P. carinii* organisms incubated with radiolabeled mevalonate and a detergent to permeabilize the cells (47). In the absence of detergent, no activity was observed. Under normal conditions, the gene for this enzyme is not expressed in mammalian lungs. In the *P. carinii* studies, only low HMG-CoA reductase activity was detected in the lungs of normal and corticosteroid-treated uninfected rats, which verified that the activity detected was in the organism. Under these experimental conditions, the activity in the purified *P. carinii* preparations was approximately 100 pmol/mg protein/min at 37°C. Lovastatin inhibited the activity at an IC_{50} concentration of 4 nM (49).

Lanosterol, but not cycloartenol, was detected by GLC/MS among the *P. carinii* sterols (Jayasimhulu, K., and Kaneshiro, E.S., unpublished results). Thus, lanosterol is the key intermediate leading to the synthesis of a variety of sterols found in this organism.

Responses to inhibitors targeted against sterol biosynthesis further demonstrate that *P. carinii* synthesizes some of the sterols found in the organism. In earlier studies (71), antisterol drugs appeared to have no effect on this pathogen. For example, six imidazole drugs, presumably targeted against lanosterol demethylation (3,72,73) were tested against PcP in rats; none was effective in clearing the infection (71). Five of the six had no effect on isolated organism proliferation *in vitro* at the highest concentration tested (10 μg/mL), and miconazole had only a slight effect. On the other hand, terbinafine, an inhibitor of squalene epoxidase, reduced the cellular ATP content of *P. carinii* primary axenic cultures (74), suppressed *P. carinii* proliferation *in vitro* (75), and cleared experimental PcP in immunosuppressed rats (75). Recently, several inhibitors of squalene synthase, squalene epoxide:lanosterol cyclase, lanosterol demethylase, and Δ^8-to-Δ^7 isomerase were tested for their effects on *P. carinii* viability. All were found effective in reducing ATP when organisms were treated *in vitro* with 100 μg/mL of these drugs; several were effective at lower concentrations at shorter incubation times (74). Together, these observations demonstrate that *P. carinii de novo* synthesizes sterols, particularly those that are unique to the organism and that are not found in mammalian lungs or in other infectious agents.

Organisms with parasitic life styles commonly scavenge host sterols to synthesize new membranes and to participate in other cellular functions. An organism must maintain the precise three-dimensional conformation of its specific membrane components involved in vital functions (e.g., pumps). Thus, if the array of available host sterols does not include molecules that fulfill the precise stereochemical requirements for proper functioning of the parasite's membrane components, the organism must synthesize those distinct sterols to survive and proliferate. These parasite-synthesized sterols,

distinct from those available from the host and which are essential for the organism, have been described as "metabolic" sterols (76). The *P. carinii* Δ^7 24-alkylsterols appear to be required for viability and proliferation of the pathogen; blocking their syntheses inhibited cell proliferation (58). Since mammals lack SAM:SMT, the reactions involved in sterol C-24 alkylation in *P. carinii* represent attractive targets for the development of chemotherapeutic approaches against this opportunistic pathogen. Drugs that inhibit the formation of 24-alkylsterols are likely to have less toxicity in humans than drugs that inhibit the synthesis of compounds made by both humans and pathogens.

SUMMARY

Pneumocystis, the agent that can cause a life-threatening pneumonia in AIDS and other immunocompromised or immunodeficient patients, actually includes organisms of broad genetic backgrounds. Different genetic populations most likely represent different species. The sterols of this exotic fungus have been analyzed by direct biochemical analysis on organism preparations isolated from the lungs of rats and humans. The sterol profiles of these preparations include sterols scavenged from its environment in the lungs of mammalian hosts, dominated by cholesterol (C_{27}). Several C_{28} and C_{29} Δ^7 24-alkylsterols are also present, which are either synthesized *de novo* by *P. carinii* or formed by metabolism of sterols scavenged from the host. In some, but not all, organism preparations obtained from humans, C_{31} and C_{32} Δ^8 24-alkyllanosterol compounds have been identified. The distinct *P. carinii*-specific sterols, which include some very rare compounds, appear useful as signatures or markers of the organism, since no other organisms known to infect mammalian lungs have been reported to synthesize these sterols. Thus, these signature sterols may be useful for detecting the organism in samples obtained from patients suspected of having the infection. Since mammals lack SAM:SMT activity, the reactions in the pathogen involved in sterol C-24 alkylation are an excellent target for the development of drugs designed to clear PcP.

The Effects of Dehydroepiandrosterone on Carcinogenesis, Obesity, the Immune System, and Aging

John R. Williams*

Department of Chemistry, Temple University, Philadelphia, Pennsylvania 19122

ABSTRACT: With the passage of the U.S. Dietary Supplement Health and Education Act of 1994, dehydroepiandrosterone (DHEA , 5-androsten-3β-ol-17-one) has become widely available, and a large and growing market has developed for this "fountain of youth." DHEA has been shown to have significant beneficial effects in animals, which may lead to clinical uses in man. Historically, the U.S. Food and Drug Administration removed DHEA from the over-the-counter market in 1985 because there was no support for the health claims that were made for this product. Almost all of the biological data was on animals and there was a lack of demonstrated efficacy in humans. Recently there have been a number of small clinical trials in humans but the results have not been as positive as in the animal tests. This review will be restricted to the effects of DHEA on carcinogenesis, obesity, the immune system, and aging. Four hypotheses have been proposed to explain the underlying biochemical mechanism(s) by which DHEA exerts its beneficial properties. The first is based on the inhibitory effect of DHEA on mammalian glucose-6-phosphate dehydrogenase. This mechanism can explain the antiinitiation and antipromotion steps in some cases of carcinogenesis. The second biochemical mechanism involves the induction of peroxisomes and peroxisome-associated enzymes. The third explanation is that DHEA works in a similar fashion to the known anticarcinogenic action of food restriction. An antiglucocorticoid mechanism has also been suggested. A hypothesis for the increase followed by the decrease in the levels of DHEA with age is proposed. A number of new synthetic DHEA analogs have been synthesized and tested. They offer the best hope for the development of a clinically useful drug based on the properties of DHEA.

Paper no. L8319 in *Lipids 35*, 325–331 (March 2000).

There is increasing evidence that dehydroepiandrosterone (DHEA, 5-androsten-3β-ol-17-one) **1a** may have a number of significant clinical uses (1–3). With the passage of the U.S. Dietary Supplement Health and Education Act of 1994, DHEA has become widely available, and a large and growing market has developed for this "fountain of youth." DHEA has become a topic for talk shows and reports in the print and broadcast media. It has been claimed to be a "super hormone" that can help with obesity; build muscle mass; prevent cancer, heart disease, and noninsulin dependent diabetes; slow aging, prevent or slow the progression of Alzheimer's and Parkinson's diseases; boost libido; strengthen the immune system; and help in the treatment of systemic lupus erythematosis. Unfortunately most of the work done so far has been on animals, and there is still no large randomized clinical trial on the long-term effects of DHEA in humans.

Historically, the U.S. Food and Drug Administration removed DHEA from the over-the-counter market in 1985 because there was no support for the health claims that were made for this product. Almost all of the biological data was on animals, and there was a lack of demonstrated efficacy in humans. One major problem in much of the extrapolation of data obtained from the administration of DHEA to subprimate species is that primates synthesize adrenal androgens to a greater degree than do many other mammals, and the metabolism and effects of these compounds are known to be different in, for instance, rodents and primates. Thus, many of the metabolic and immune effects that this compound might have in laboratory animals have not been found in humans. Since so many people are now taking DHEA, what are the risks and what are the benefits to them? Owing to the large number of beneficial effects attributed to DHEA, I have chosen to restrict this review to carcinogenesis, obesity, immune system, and aging. Other topics are covered in a number of excellent reviews (1–3).

DHEA **1a** is formed from DHEA sulfate (DHEAS) **1b** by sulfatases in peripheral tissue (4,5). DHEAS is the major circulating steroid in blood plasma and arises primarily by secretion from the adrenal cortex (5). The ratio of DHEAS to DHEA in plasma is approximately 200:1 (5). The levels of DHEAS rise through puberty, reaching maxima at age 20–24 yr in men and 15–19 yr in women (6). Levels then decline steadily with age with males having approximately 40% more DHEAS than women of the same age (5).

Metabolism of cholesterol **2** proceeds *via* pregnenolone **3** to yield DHEA **1** as outlined in Scheme 1. Further metabolism of DHEA by oxidation at C-3 yields the androstendione **4**, which is isomerized to the conjugated androstendione **5** ("andro," the steroid taken by Mark McGwire, the 1998 baseball star), testosterone **6**, androsterone **7a**, etiocholanolone **7b**, and estradiol **8**, many of which are biologically active (7).

Carcinogenesis. In 1971 Bulbrook *et al.* (8) presented re-

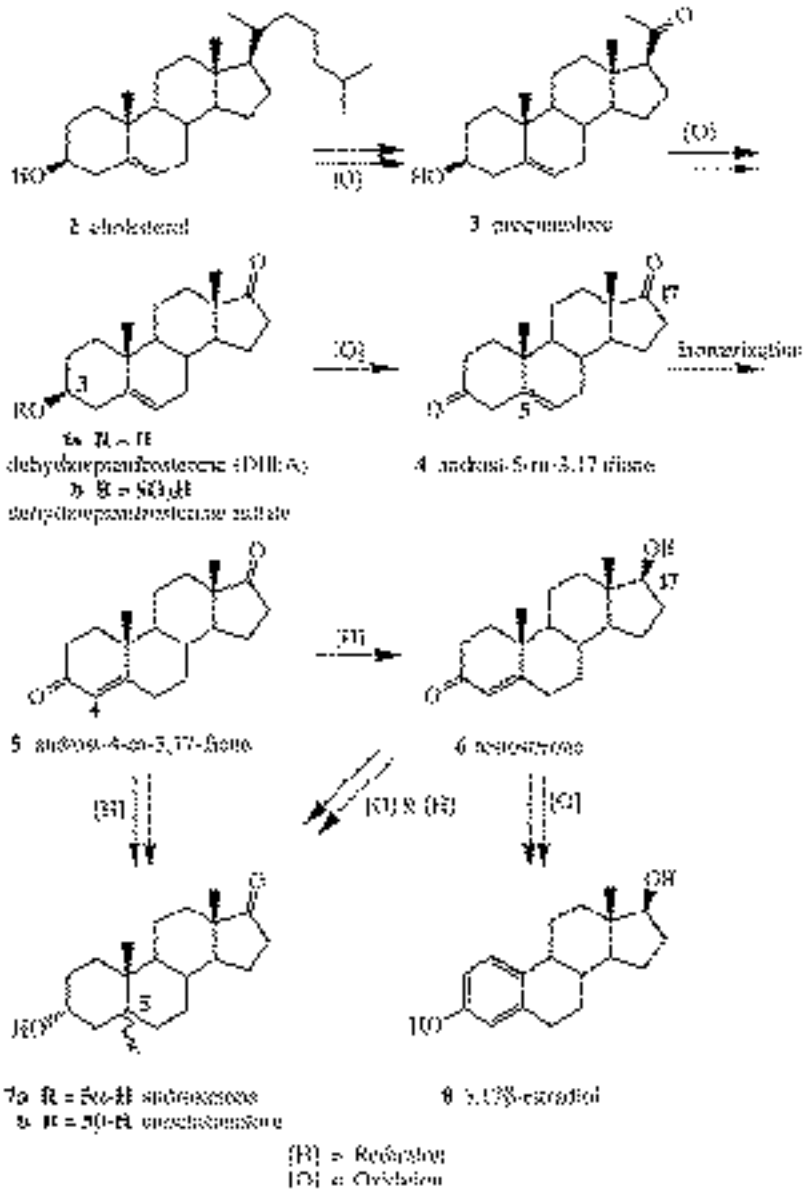


SCHEME 1

sults regarding 5,000 premenopausal women who had been studied for up to 9 yr and reported that the excretion of the DHEA metabolites androsterone **7a** and etiocholanolone **7b** was subnormal in 27 women who subsequently developed breast cancer. This result assumes there is a correlation between the endogenous level of a steroid and the level of a metabolite when it is excreted. To avoid diurnal fluctuation in steroid levels, Zumoff *et al.* (9) measured the 24-h mean plasma concentrations of DHEA and DHEAS on pooled blood samples obtained every 20-min from 11 women with primary operable breast cancer. When matched with 37 normal women those premenopausal women with breast cancer were found to have subnormal levels of DHEA and DHEAS (9). Similarly, in a study of 20,300 women, the 15 who developed premenopausal breast cancer were compared to 29 matched controls. The mean serum level of DHEA among cases was 10% lower than among controls. No correlation between DHEAS level and premenopausal breast cancer was observed (10). It is uncertain whether the lower levels of DHEA precede or are a consequence of breast cancer.

Since the 1970s Schwartz *et al.* (11) and others have been studying the metabolic effects of DHEA on mice and rats. DHEA shows an amazingly wide range of beneficial and therapeutic effects in rodents, including prevention of cancer, use in antiautoimmune diseases, antiatherogenic effects as well as antiobesity and antidiabetic activities (11). However, the effect of DHEA on any of these diseases is only now being studied in humans.

In 1975 Schwartz and Perantoni (12) demonstrated that DHEA protected rat liver epithelial-like cells and hamster em-

bryonic fibroblasts against aflatoxin B_1 and 7,12-dimethylbenz[a]anthracene (DMBA)-induced cytotoxicity and transformation. The rate of metabolism of [^{3}H]DMBA to water-soluble products by cultured fibroblasts was also inhibited by DHEA. Schwartz and coworkers also showed that long-term administration of DHEA inhibited the development of spontaneous breast cancer in C3H-*A^{vy}/A* (obese) (13) and C3H-*A/A* mice (14) and of DMBA- and urethane-induced lung tumors in A/J mice (15).

Topical DHEA treatment inhibits papilloma formation when applied 1 h before 12-*O*-tetradecanoylphorbol-13-acetate (TPA) treatment, a result indicating that the steroid also blocks tumor promotion. A single intraperitoneal injection of DHEA into CD-1 mice immediately before TPA application also abolishes the TPA stimulation in epidermal [^{3}H]thymidine incorporation (16,17). Tumor promoters such as TPA produce diverse effects on mammalian cells, and the mechanism by which they enhance skin papilloma formation is not fully understood.

Some evidence exists that justifies concern about the safety of DHEA supplements. Large doses of DHEA can be converted to potent androgens such as testosterone, which can masculinize women, resulting in increased hair growth on the face and body. Furthermore in a nested, case control prospective study of serum samples from 20,000 women, a higher risk of ovarian cancer was associated with increased levels of DHEA and DHEAS (18). However, these results are contradicted by other workers who found the circulating levels of DHEAS are lower in those women who have ovarian cancer (19). In another study a woman was given a 150-mg dose of DHEA and developed transient jaundice and hepatic dysfunction 1 wk later (20).

A number of hypotheses have been proposed to explain the underlying biochemical mechanism(s) by which DHEA exerts its beneficial properties. The first hypothesis is based on the inhibitory effect of DHEA on mammalian glucose-6-phosphate dehydrogenase (G6PDH).

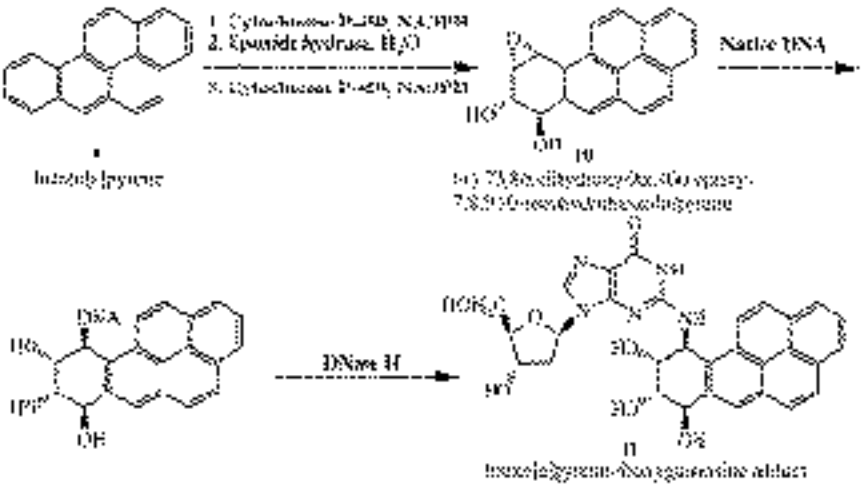
G6PDH DEHYDROGENASE INHIBITION

Although DHEAS is the main precursor of placental estrogen and may be converted into DHEA and then into biologically active androgens, there is no obvious role for DHEAS or DHEA in the normal individual. DHEA is a potent uncompetitive inhibitor of mammalian G6PDH (21-23). G6PDH is the rate-controlling enzyme in the pentose-phosphate cycle, a pathway that is a major source of ribose-5-phosphate and extramitochondrial NADPH. Two moles of NADPH are generated in the conversion of glucose-6-phosphate into ribose-5-phosphate (Eq. 1). Thus, as one ages and the level of DHEA decreases, the availability of ribose-5-phosphate and extramitochondrial NADPH should increase.

$$\begin{matrix}\text{Glucose 6 - phosphate} + \\ 2\,\text{NADP}^+ + \text{H}_2\text{O}\end{matrix} \xrightarrow{\text{G6PDH}} \begin{matrix}\text{ribose 5 – phosphate} + \\ 2\,\text{NADPH} + 2\,\text{H}^+ + \text{CO}_2\end{matrix} \quad [1]$$

Agents that damage DNA or interfere with its replication or repair cause most cancers. Three processes that contribute to tumor development are the following: (i) tumor initiation by covalent binding of an active species (usually a hard electrophile) to DNA. The active species can be generated by metabolic activation of a carcinogen through the action of cytochrome P-450 (24); (ii) tumor promotion by cell stimulation to produce activated forms of oxygen, including superoxide anion radicals (0_2^-) and peroxides, agents that are free radicals or generators of free radicals (25); and (iii) tumor promoter stimulation of cell proliferation *via* agents such as TPA (26).

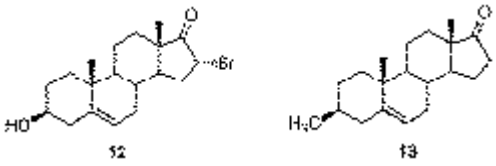
In the first process, cytochrome P-450 oxidizes polyaromatic hydrocarbons such as benz[a]pyrene **9** twice to yield a highly electrophilic and highly carcinogenic polyaromatic epoxy diol, **10** (Scheme 2). This epoxy diol **10** has been shown to bind covalently with native DNA to yield an adduct, from which a polyaromatic-deoxyguanosine adduct **11** has been obtained (24). Since cytochrome P-450 is an NADPH-dependent enzyme, lowering the amount of NADPH should decrease the



SCHEME 2

amount of metabolic activation resulting in a decrease in the initiation of cancer. In the second process, tumor promoters stimulate the generation of activated forms of oxygen by mixed function oxidases (25). Here again the generation of activated forms of oxygen by mixed function oxidases is also an NADPH-dependent process. Lowering the amount of NADPH should decrease the amount of metabolic activation resulting in a decrease in the initiation of cancer.

In the third process, there is a good correlation between a steroid's ability to inhibit G6PDH and its inhibition of cell proliferation by the tumor promoter TPA (26). Treatment of CD-1 mice with DHEA immediately before the application of TPA stops the TPA stimulation in epidermal [H]thymidine incorporation (27). 16α-Bromoepiandrosterone **12** (Scheme 3) is 30 to 50 times more potent as an inhibitor of mammalian G6PDH and is similarly much more active as an inhibitor of TPA stimulation (27). Conversely, various sex steroids that do not inhibit G6PDH also failed to inhibit TPA stimulation.



12 13

SCHEME 3

Furthermore cancer cells undergo excessive proliferation when compared to normal cells, thereby increasing the demand for cellular components. By inhibiting the pentose-phosphate pathway, DHEA inhibits the formation of ribose-5-phosphate, an important component in cancer cell growth.

A second biochemical mechanism that may explain the effect of DHEA on the livers of mice and rats is the induction of peroxisomes and peroxisome-associated enzymes, which would lead to an increase in fatty acid β-oxidation (28). Whether the beneficial and therapeutic effects that result from the administration of DHEA are associated with changes in the liver remains to be established (29).

A third explanation is that DHEA works in a similar fashion to the known anticarcinogenic action of food restriction (30). Dietary restriction also significantly extends the life of rodents *via* an anti-aging mechanism (31). The anti-aging effect is now felt to be due to the lowering of the body temperature during sleep, and there is evidence suggesting that this temperature fall enhances the DNA reparative action *via* DNA polmerases (31) and decreases the expression of protooncogenes (32). Do DHEA or its metabolites effect the efficiency of DNA repair to mutagenesis or radiation? DHEA has been shown to stimulate mutagenic repair mechanisms *via* promotion of sister chromosomal exchange (33). Furthermore, Sonka *et al.* reported that, depending on timing of DHEA administration to whole body radiation, it has radiation-protective and/or -enhancing action (34).

In other experiments, DHEA has been shown to oppose the anti-inflammatory action of glucocorticoids by an unknown mechanism (35).

In conclusion, there does not appear to be a unifying biochemical mechanism to the anticarcinogenic action of DHEA. There may be no single answer as to its anticarcinogenic effects.

OBESITY

Administration of DHEA to metabolically obese mice bearing the A^{vy}/a mutation, significantly inhibited their weight gain (36). Measurements of food consumption showed that treated and untreated mice consumed equivalent amounts of food but that the DHEA-treated mice weighed less. Thus, DHEA is exerting its antiobesity effect by altering the metabolism of the mice in decreasing the efficiency of their food utilization rather than as a result of appetite suppression (37). DHEA inhibits G6PDH thereby decreasing the formation of NADPH, which is an essential cofactor with one mole needed for every methylene unit in the biosynthesis of a fatty acid. Thus, this anabolic pathway may be reduced under conditions of reduced NADPH availability. The stoichiometry of the synthesis of hexadecanoic acid (palmitic) is:

$$8\ \text{Acetyl CoA} + 7\ \text{ATP} + 14\ \text{NADPH} \rightarrow \text{CH}_3(\text{CH}_2)_{14}\text{COOH} + 14\ \text{NADP}^+ + 8\ \text{CoA} + 6\ \text{H}_2\text{O} + 7\ \text{ADP} + 7\ \text{Pi} \quad [2]$$

It appears unlikely that the antiobesity action of DHEA is completely due to G6PDH inhibition. 16α-Bromoepiandrosterone **12** failed to produce an antiweight effect or lower blood sugar in genetically diabetic (*db/db)* C57BL/KsJ mice when fed in the diet at 0.4%, even though the bromosteroid **12** is a much more potent inhibitor of G6PDH than DHEA (38). In contrast, DHEA had a dramatic effect on the control of diabetes in genetically diabetic (*db/db)* C57BL/KsJ mice and in regulating weight in similar mutant strains.

In a study of weight gain in lean and obese mice it was found that obese mice ate less food but this resulted in a decrease in body weight which was greatest for those DHEA-fed obese mice (39). These changes in body weight were also accompanied by less body fat and lower fat cell size and number in the DHEA- treated rats. Fat-free mass and organ growth was preserved in DHEA-treated rats. This is a different response from that found in food-restricted obese rats which preserve body fat at the expense of lean tissue. Recently Cleary (39,40) showed that when obese rats were food-restricted to the degree necessary to weight-match them to DHEA-treated obese rats, fat pad weights of the weight-matched rats were substantially greater than those of the DHEA-treated rats. The fat pad weights of the weight-matched rats were similar to those of *ad libitum* fed rats. Thus, the results of both pair-feeding and weight-matching studies indicate that DHEA treatment is mediated through a different mechanism than that for caloric intake (40).

DHEA has been shown to increase liver weight in rats as well as other effects including enhanced ATP synthesis (41). The activity of the enzyme, long-chain fatty acyl-coenzyme A hydrolase, was found to be elevated, resulting in an increase in

a futile cycle of deacylation/reacylation. These mechanisms could explain DHEA's antiobesity effects (42).

In humans there is conflicting data. Some studies indicate there is a relationship between body mass index (BMI) and DHEA and/or DHEAS (43–46). Other studies conclude there is no relationship between DHEA and BMI (47–50). The administration of DHEA to volunteers in controlled trials to assess whether DHEA can affect body fat has been studied by a number of groups (51–53). The results of these studies show that exogenous DHEA does not have any significant effect on human obesity or fat-store distribution. The most obvious reason for this lack of activity is that the dosage is too low. Animal studies require at least 60–75 mg/kg/d, but such levels in humans would be intolerable owing to androgenic side effects.

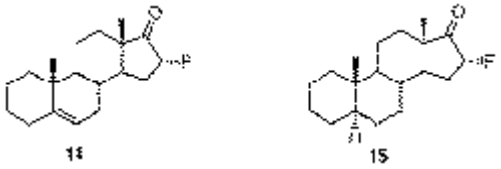
IMMUNE FUNCTION

There is also conflicting clinical data concerning the immunoaugmentory effects of DHEA replacement in the elderly. A dose of 50/mg/d of DHEAS, given twice a day at the time as a vaccination, was found to increase influenza (but not tetanus) titer response over that seen with a placebo (54). On the other hand in a different study in which elderly volunteers were given 50 mg of DHEA for four consecutive days starting 2 d before immunization, DHEA treatment did not enhance established immunity (55). A significant decrease in attainment of protective antibody titer against A/Texas in subjects with nonprotective baseline antibody titer was recorded following DHEA treatment compared to placebo (52 vs. 84%, $P < 0.05$) (55).

NEW SYNTHETIC DHEA ANALOGS

The studies reported in this review have demonstrated that oral treatment of mice and rats with DHEA protects against the development of a broad range of tumors and has antiobesity activity. Although long-term treatment of mice and rats is without apparent side effect, DHEA is convertible into testosterone and estrone. DHEA is uterotrophic at therapeutic doses in the sexually immature rat, and conversion into sex steroids should limit the usefulness of DHEA as a cancer chemopreventive drug. The synthetic steroid 3β-methylandrost-5-en-17-one **13**, (Scheme 3) in which the 3β-hydroxyl group of DHEA is replaced by a 3β-methyl group, was specifically designed to prevent metabolism of **1** into androstenedione, **4**, an intermediate on the pathway to testosterone **6** and estradiol **8** (16,17). 3β-Methylandrost-5-en-17-one **10** was without activity in the rat uterotrophic test at doses at which DHEA was highly active. On oral administration the steroid **10** is about three times as active as DHEA as an antiobesity and antidiabetic agent in the mouse.

Two other synthetic steroids, 16α-fluoroandrost-5-en-17-one, **14**, and 16α-fluoro-5-androstan-17-one, **15**, which also lack the uterotrophic and seminal vesicle-enlarging effects of DHEA, have shown 15 times greater potency than DHEA when given orally in blocking both [^{3}H]DMBA binding to skin DNA and TPA stimulation in epidermal [^{3}H]thymidine incorporation (56). The lack of estrogenic and androgenic activity of **14** and **15** along with their greater potency suggests that these analogs may find application as cancer chemopreventive drugs in humans.



SCHEME 4

AGING

The aging process is accompanied by the development of obesity and glucose intolerance. Hyperinsulinemia has been shown to lead to low levels of DHEAS and DHEA. The mechanism whereby insulin decreases DHEAS production without affecting adrenal production of glucocorticoids or mineralocorticoids is unknown. DHEA administration had no effect on tissue sensitivity to insulin, unlike androgen therapy, which results in decreased tissue sensitivity to insulin (57).

Why should DHEA levels vary with age? A possible explanation of why mankind has evolved with varying levels of DHEA upon aging is because it aided in our survival as a species. The rise in DHEAS and DHEA levels that maximize in the late teens and early twenties corresponds with mankind's optimal time for reproduction. The increased levels of sex hormones should result in the increased physical strength, increased libido, and procreation. Then why should DHEA decrease with aging? Lower levels of DHEA result in higher levels of NADPH, leading to more fat formation, i.e., more efficient metabolism. It has only been in recent centuries that mankind has not been constantly faced with starvation. People survived who could get by on less, i.e. those with the most efficient metabolisms. As we get older we need less food to maintain the same weight.

Conversely, many of today's problems associated with aging may be the result of lower levels of DHEA resulting in a higher NADPH cellular pool. The ready availability of food in unlimited quantities has resulted in the increase in cancer, obesity, and heart disease. It is well known that reducing the weight gain of laboratory mice and rats through food restriction is a very effective method for cancer prevention (30). Spontaneous, chemically induced, and radiation-induced tumors in many different organs are all reduced in frequency in food-restricted rodents. Not only does underfeeding inhibit tumor development but also it retards the rate of appearance of autoimmune disease processes as well as many age-related pathological changes, and it is believed to slow the rate of aging (58). The biochemical mechanism by which underfeeding protects against cancer and autoimmune disease is obscure. As we grow older we get "the middle aged spread." The decrease in DHEA and androgenic metabolites could explain the resulting decrease in muscle mass as we age and our increase in flabby tis-

sue. In males, higher levels of NADPH may lead to more dihydrotestosterone resulting in increased hair loss, benign prostate hyperthropy, and increased prostate cancer.

In conclusion, the new synthetic analogs of DHEA should be more active and have fewer side effects than DHEA. It is hoped that one of these new molecules will be approved clinically for some or all of the beneficial properties attributed to DHEA.

ABSTRACT: The plasma levels of free oxysterols (7-ketocholesterol; 7α-hydroxy-,7β-hydroxy-, 25-hydroxy-, and 27-hydroxycholesterol; and 5α,6α-epoxycholestanol) in patients with diabetes mellitus and hypercholesterolemia were determined using gas chromatography–mass spectrometry with selective ion monitoring. We studied 39 patients with diabetes mellitus, 20 nondiabetic patients with hypercholesterolemia, and 37 normal controls. Plasma cholesterol levels in diabetic and hypercholesterolemic patients showed no statistical difference. Plasma 7-ketocholesterol was significantly higher in patients with diabetes (31.6 ± 2.8 ng/mL) or hypercholesterolemia (52.3 ± 5.9) than in the control group (22.4 ± 1.2). The increased plasma cholesterol can be regarded as an oxidation substrate for the oxidant stress and the higher absolute levels of oxysterols in hypercholesterolemic plasma compared with the control plasma. This difference disappeared when 7-ketocholesterol was expressed in proportion to total cholesterol. The oxidizability of plasma cholesterol was evaluated by comparing the increased ratio of 7-ketocholesterol after $CuSO_4$ oxidation to the ratio before. We demonstrated that the patients with diabetes showed increased oxidizability (77.5%) compared with the control (36.6%) or hyperlipemic group (45.3%), which is likely due to the lower amounts of α-tocopherol in the diabetics. Measurement of oxysterols may serve as a marker for *in vivo* oxidized lipoproteins in diabetes and hyperlipemia.

Paper no. L8081 in *Lipids 35*, 333–338 (March 2000).

Oxidation of lipoproteins is believed to play an important role in atherosclerosis in patients with diabetes mellitus (DM) and hypercholesterolemia (HL) (1). When low density lipoprotein (LDL) undergoes oxidation *in vitro*, various changes in lipid composition occur, including a substantial loss of free and esterified cholesterol and the concomitant generation of oxidation products of cholesterol (oxysterols) (2,3). In fact, oxidatively modified lipoproteins in the circulating plasma are reported to contain an oxysterol-enriched subfraction (4,5), and oxysterols are considered to be the important lipid component in oxidized lipoproteins. Oxysterols have potent biological effects, some of which suggest a role in the initiation and/or progression of atherosclerosis (1,6). Further support for an atherogenic role for oxysterols comes from an epidemiological study of Indian migrants who were exposed to oxysterols in their diet: they had higher than expected morbidity and mortality from atherosclerosis but did not show the usual risk factors for this disorder (7).

In this study, we measured plasma free oxysterols in patients with DM, using gas chromatography–mass spectrometry (GC–MS) with selective ion monitoring (SIM). We also compared the oxidizability of plasma cholesterol among the patients on the basis of increased 7-ketocholesterol in response to *in vitro* incubation with $CuSO_4$ (8,9).

MATERIALS AND METHODS

Subjects. Subjects included 39 patients with DM, 20 non-diabetic patients with HL, and 37 normal controls. We defined HL as a total cholesterol level more than 220 mg/dL. Blood was collected in blood collection tubes containing heparin after overnight fasting. One microgram of butylated hydroxytoluene was added per milliliter of plasma, and samples were stored at –20°C until analysis.

Table 1 summarizes the clinical characteristics, including age, sex, body mass index, plasma lipid levels, and glycosylated hemoglobin (HbA1c), for each group of subjects. In the DM group, 18 patients were treated by dietary management, 11 with oral hypoglycemic agents (glibenclamide 1.25–7.5 mg/d), and 10 with insulin. Diabetic complications included nephropathy in 28 patients (microalbuminuria in 18 patients and macroalbuminuria in 10 patients), neuropathy in 10 patients, and retinopathy in 25 patients. The frequencies of diabetic complications were not affected by the presence or absence of hypercholesterolemia. None of the subjects was taking supplementary antioxidants such as probucol or α-tocopherol.

Measurement of plasma free oxysterols. Cholestane-3β,6α-diol dissolved in ethanol (22 ng/5 mL) was added to 2 mL of plasma as an internal standard. Plasma lipids were extracted with 20 vol of chloroform/methanol (2:1,vol/vol), and the separation of oxysterols from cholesterol was carried out in an early step in the procedure because it is important to prevent cholesterol autoxidation during sampling. The dried material was dissolved in 4 mL of hexane/dichloromethane(4:1, vol/vol) solution and applied to a packed silica column (800 mg; 0.8 cm i.d., Gasukuro Kogyo Inc., Tokyo, Japan). The column was washed out with 8 mL of hexane/dichloromethane (4:1, vol/vol) solution and 10 mL of dichloromethane, and the free oxysterols were then eluted with 8 mL of ethyl acetate. This fraction was dried and dissolved in 10 mL of chloroform and passed through another silica column (400 mg, 0.8 cm i.d.) to remove cholesterol completely. Then the oxysterols were eluted with 6 mL of ethyl acetate.

The average recovery rate of 7α- and 7β-hydroxycholesterol, 7-ketocholesterol, cholestane-3β,6α-diol, and 25- and 27-hydroxycholesterol were 87.5 ± 2.8, 97.3 ± 8.7, 85.3 ± 9.3, 82.7 ± 9.3, 68.3 ± 8.9, and 82.7 ± 6.3%, respectively.

Analysis by GC–MS. Extracted oxysterols were derivatized to their trimethyl (TMS) ether derivatives by treatment with 350 mL pyridine/hexamethyldisilazane/trimethyl-chlorosilane (3:2:1, by vol) at 60°C for 30 min. After evaporation of the solvent under a nitrogen stream, the residue was dissolved in 10 mL hexane and analyzed by GC–MS, using a Shimadzu gas chromatograph (model GC-17A; Kyoto, Japan) equipped with a high-resolution capillary column, DB-1 (30 m × 0.25 mm i.d., J&W Scientific, CA), and a QP-5000 mass spectrometer with a Shimadzu Chemical Laboratory Analysis System & Software CLASS-5000. The oven temperature program was as follows: 150°C for 2 min, 20°C/min to 280°C, and then 5°C/min to 300°C and held for 10.0 min. Helium was used as the carrier gas at a flow rate of 0.8 mL He/min. The injector was operated in the splitless mode and was kept at 270°C, while the detector transfer line was heated at 280°C. The separator and ion source temperatures were 300°C, and the ionization energy was 70 eV.

7-Ketocholesterol and 7β-hydroxycholesterol were purchased from Sigma Chemical Co. (St. Louis, MO), and 7α-hydroxycholesterol, 5α,6α-epoxycholestanol, 25-hydroxy- and 27-hydroxycholesterol, and cholestane-3β,6α-diol were obtained from Steraloids Inc. (Wilton, NH).

The selected ions used for analysis (*m/z*) and the retention times (min) of the compounds were as follows: 7α-hydroxycholesterol, 456 (M – 90), 14.78; 7β-hydroxycholesterol, 456 (M – 90), 16.19; 5α,6α-epoxycholestanol, 384, 16.64; cholesterol-3β,6α-diol, 458, 16.78; 7-ketocholesterol, 472 (M), 18.74; 25-hydroxycholesterol 131, 18.85; and 27-hydroxycholesterol, 456 (M – 90), 19.82.

Figure 1 presents the total ion chromatogram and mass chromatogram for each of the authentic compounds. Each of the oxysterols and the internal standard (cholestane-3β,6α-diol) were separated and quantified with adequate sensitivity. The detection limit for every oxysterol was under 0.02 ng/mL. In triplicate experiments, the within-day variation (coefficient of variation, CV) for 7α-hydroxy, 7β-hydroxy-, and 7-ketocholesterol was 16.2%, and the day-to-day variation (CV%) within one week was 11.9%.

In a preliminary study, we monitored the formation of oxysterols by $CuSO_4$-catalyzed oxidation of plasma. $CuSO_4$ was added to 2 mL of plasma at a final concentration of either 0.5 or 1.0 mM. Incubation was carried out for 24 h at 37°C. The oxidized plasma samples were subjected to polyacrylamide gel electrophoresis (LipoPhor kit, Jyoko, Tokyo, Japan), and the oxysterols were extracted and measured as described above. As shown in Figure 2, the LDL fraction was dispersed and then it migrated depending on the negative charge. Figure 3 presents the gas chromatograms of oxysterols in the same plasma. The C-7 position of the cholesterol ring was predominantly oxidized, and 7-keto-, 7α-hydroxy-, and 7β-hydroxycholesterol increased as a result of $CuSO_4$ induced oxidation in a dose-dependent fashion. Other oxysterols also increased, however, those increases were not so large as those for the C-7 oxidized products. This finding demonstrated that increases in electrophoretic mobility and in yields of oxysterol products are equally useful as indicators of oxidative modification of lipoproteins.

Next, the oxidizability of the plasma cholesterol was evaluated in response to incubation with $CuSO_4$. Plasma samples were selected randomly from each group (DM, $n = 16$; HL, $n = 8$; control, $n = 10$). After incubation of plasma samples with 100 μM $CuSO_4$ for 24 h at 37°C, oxysterols were measured as described above. The oxidizability of plasma cholesterol was expressed in terms of the ratio (%) of the amount of 7-ketocholesterol after the oxidation to the level before.

Statistical analysis. The values in the text and tables are given as means ± SE. Statistical analysis was performed using analysis of variance and the least significant difference to compare differences among three groups. $P < 0.05$ was considered to represent statistical significance.

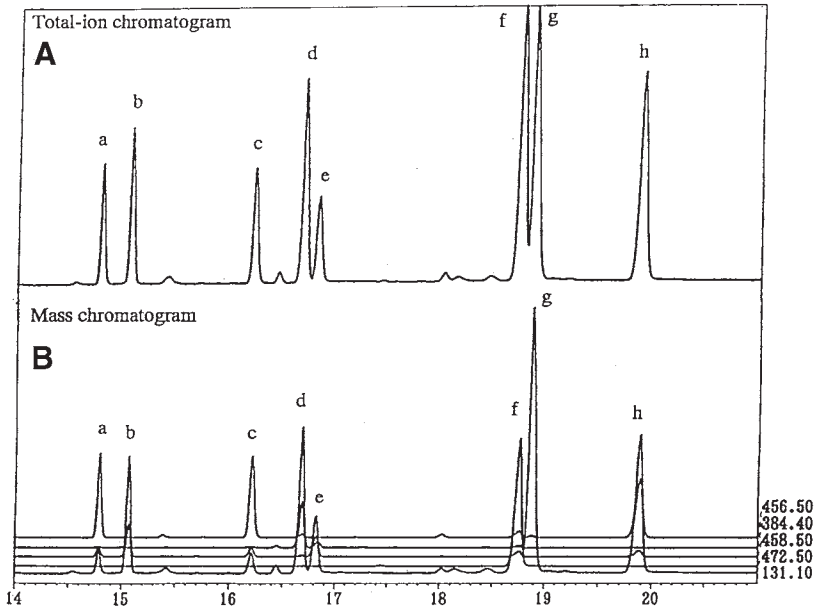

FIG. 1. Gas chromatography–mass spectrometry chromatograms of each oxysterol. Total-ion chromatogram (A) and mass chromatogram (B) are illustrated. The selective ion (*m/z*) of each oxysterol was as follows: 131, 25-hydroxycholesterol (g); 384, 5α,6α-epoxycholesterol (d); 456, 7α-hydroxycholesterol (a), 7β-hydroxycholesterol (c) and 27-hydroxycholesterol (h); 458, cholestane-3β,6α-diol (internal standard) (e); 472, 7-ketocholesterol (f); (b), cholesterol.

RESULTS

Table 2 presents the data on the oxysterol concentrations in each group. Total cholesterol (TC) levels in patients in the DM group showed no difference from those in the HL group (Table 3). There was no difference in oxysterol levels among the subgroups with age or body weight (data not shown). In the DM group, significantly higher absolute levels of 7-keto-, 25-hydroxy- and 27-hydroxycholesterol were observed compared with the control group. In the HL group, all oxysterols except 7α-hydroxycholesterol were significantly increased. 7-Ketocholesterol, the major autoxidation product of cholesterol, was highest in the HL group, and lowest in the control group. However, this difference disappeared when oxysterols were expressed in proportion to TC (Table 3). In the DM group, there was no significant correlation between the oxysterol levels and glycemic control. However, patients with long duration of diabetes showed a tendency to have high plasma oxysterol.

We compared the susceptibility of the plasma cholesterol of each group to oxidation by $CuSO_4$. Based on the results of the preliminary study, as described in Materials and Methods section, we focused on 7-ketocholesterol as the marker of cholesterol autoxidation. 7-Ketocholesterol level before and after the $CuSO_4$-oxidation in each group is indicated in Table 4. The mean increased rate of 7-ketocholesterol from before to after $CuSO_4$ oxidation was 77.5% (23.42 to 41.56 ng/mL) in DM, 45.3% (42.57 to 61.86 ng/mL) in HL, and 36.0% (23.31 to 31.70 ng/mL in the control group. α-Tocopherol levels relative to plasma triglyceride (TG) were also compared, and the value was lowest in the diabetic group as shown in Table 4.

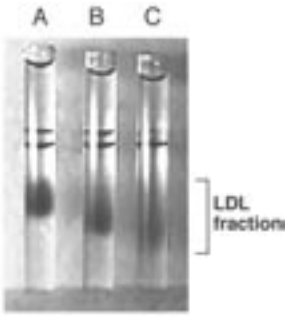

FIG. 2. $CuSO_4$ oxidation of plasma lipoproteins. $CuSO_4$ was added to plasma to a final concentration to 0 (A), 0.5 (B), or 1.0 (C) mM. Incubation was carried out for 24 h at 37°C. Then the oxidized plasma was analyzed by polyacrylamide gel electrophoresis.

DISCUSSION

Oxidation of cholesterol gives rise to a large number of oxidation products (oxysterols) (10). Oxysterols such as 7α-hydroxycholesterol (11) and 27-hydroxycholesterol largely are formed enzymatically and may be involved in elimination of cholesterol from macrophages and endothelial cells (12). On the other hand, a free radical-mediated process (autoxidation) can lead to the formation of a variety of oxysterols, e.g., epoxy, keto-, and hydroxy-derivatives of cholesterol (10). These oxys-

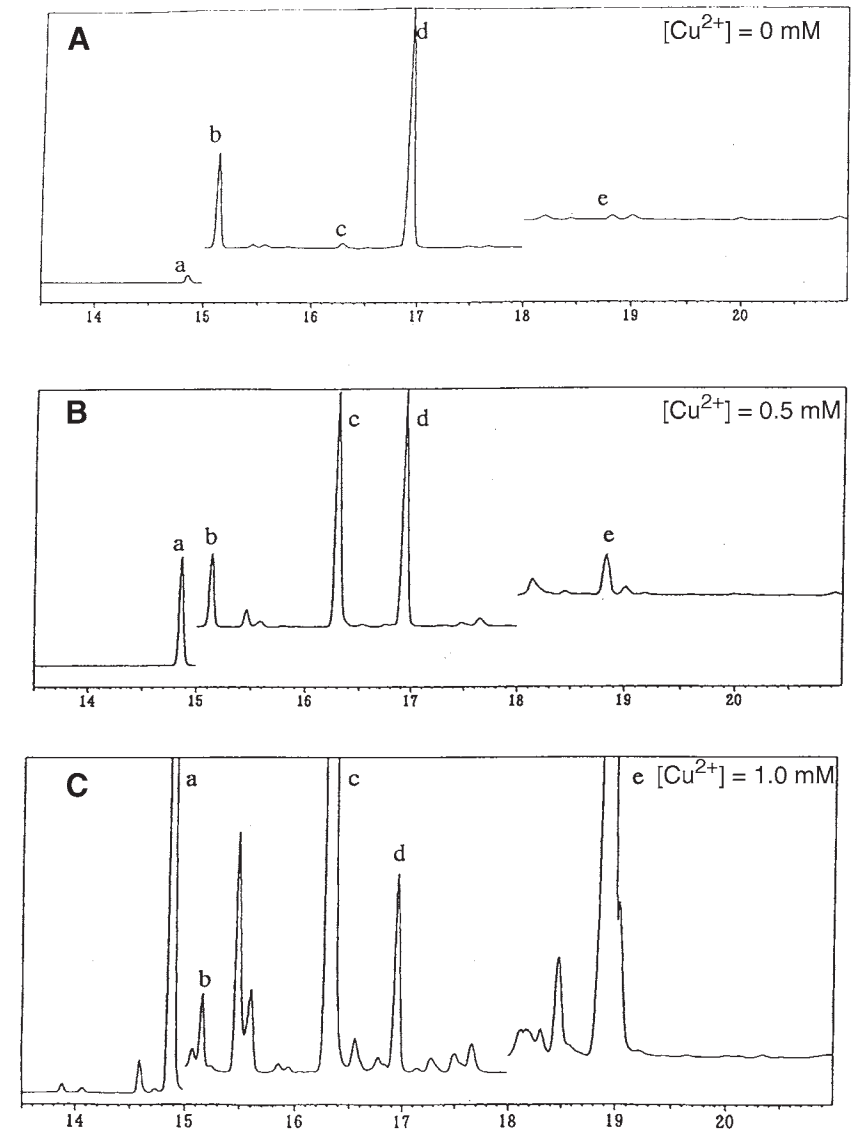

FIG. 3. $CuSO_4$ oxidation of plasma cholesterol. Total-ion chromatograms of plasma oxysterols before and after oxidation with 0, 0.5, or 1.0 mM $CuSO_4$. (a) 7α-Hydroxycholesterol; (b) cholesterol; (c) 7β-hydroxycholesterol; (d) cholestane-3β,6α-diol (internal standard); (e) 7-ketocholesterol.

terols have various biological activities (13), including cytotoxicity (8,10), inhibition of DNA synthesis (14), inhibition of cholesterol synthesis (15), and effects on cell membrane structure and function (16).

Analysis of oxysterols in biological materials is not easy because of the presence of various compounds having structures closely related to cholesterol and because of great differences between their concentrations and the concentration of cholesterol. At present, most analytical methods for oxysterols are based on GC–MS with SIM (17). A substantial portion of the oxysterols in plasma is present as fatty acyl esters like cholesterol (10). Most oxysterols with an established enzymatic origin are esterified to a great extent, whereas other oxysterols are less esterified (17). In order to determine the total or esterified oxysterols by GC, a hydrolysis step is necessary (18). However, the reaction conditions have to be chosen carefully, otherwise, cholesterol autoxidation products induced artifactually could completely mask the endogenous oxysterol levels (19). In our method, plasma free oxysterols were separated from free and esterified cholesterol, and the analytical procedures were practical and highly reliable. Each molecular species was analyzed using a GC-quadrupole mass spectrometer with SIM, and sufficient sensitivity for plasma oxysterols was demonstrated.

The oxidation of LDL may possibly take place during its circulation in the blood. Actually, the lipoprotein particles enriched in oxidatively modified lipids and proteins are proposed

[a]Results are expressed as means ± SE. [a]$P < 0.05$ vs. control; [b]$P < 0.05$ vs. DM. Abbreviations: 7KC, 7-ketocholesterol; T.OXY, total oxysterol (which includes 7α-, 7β-, 25-, 27-hydroxy-, 5α,6α-epoxy-, and 7keto-cholesterol); αToc, α-tocopherol. For other abbreviations see Table 1.

to exist in the plasma on the basis of measurements of small amounts of plasma cholesterol oxides (4), fragmented apolipoprotein B (20), and thiobarbituric acid-reactive substances (21). Hodis *et al.* (4) reported that circulating oxidatively modified lipoproteins in the monkey contain an oxysterol-enriched subfraction (53% of cholesterol as oxysterols), and oxysterols are important lipid components of oxidized LDL (22,23).

We evaluated the extent of cholesterol oxidation by assessing the plasma free oxysterol levels. In our study, the plasma free 7-ketocholesterol levels in patients with DM and HL were significantly higher than those in normal subjects. However, there was no difference between the groups when expressed in proportion to total cholesterol level (Table 3). The increased plasma levels of cholesterol can be regarded as an oxidation substrate to oxidation stress, by endothelial cells and activated monocytes (24). This may explain the higher absolute levels of oxysterols in hypercholesterolemic plasma compared with the control plasma.

DM has been proposed to be a state of increased free radical activity and high oxidant stress (25,26). This may include increased nonenzymatic glycosylation, which can also be associated with generation of oxygen free radicals (27,28). Although the factors determining the susceptibility of LDL to oxidation are not thoroughly understood (29), $CuSO_4$ oxidation of lipoproteins has been widely used to examine LDL oxidation (8,11). As demonstrated in the present study, free oxysterols, particularly C-7 oxidized oxysterols, are major products of $CuSO_4$ oxidation of plasma lipids. In this study, we compared plasma levels of 7-ketocholesterol and 7-ketocholesterol/TC after $CuSO_4$ oxidation (100 μM) with the basal level (Table 4). We found that the rate of 7-ketocholesterol/TC in the DM group was higher than that in other groups, likely owing to the lowest amounts of α-tocopherol in expression per plasma TG (Table 4). The small number of data from these groups did not allow statistical difference to be identified, however, our results may indicate one reason for the susceptibility of plasma cholesterol to $CuSO_4$ oxidation in diabetics in our study. However, reports on the levels of antioxidants as defense mechanisms (i.e., superoxide dismutase, vitamin E, or C, etc.) in diabetic patients are still contradictory: both increases and decreases of antioxidant activity are reported (30). Oxidizability has also been postulated to increase in small, dense LDL, which is commonly found in diabetic patients with hypertriglyceridemia (29). The patient's age, sex, type of treatment, and diabetic complications had no correlation with plasma oxysterol levels (data not shown).

In conclusion, plasma free oxysterol levels were measured using a GC–MS SIM method. Plasma oxysterol levels were high in patients with DM and HL. Our study suggests the possibility that oxysterols may serve as a marker for *in vivo* lipoprotein oxidative modification (31).

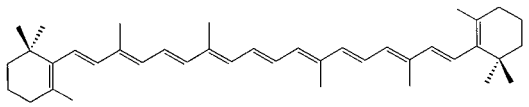
ABSTRACT: Increased intake of lutein from vegetables promotes increased density of the macular pigment and therefore may protect against age-related macular degeneration. Our objective was to use a ^{13}C tracer and high-precision gas chromatography–combustion interfaced–isotope ratio mass spectrometry (GC–C–IRMS) to investigate metabolism of a lutein dose equivalent to that absorbed from vegetables. Biosynthetic per-labeled (>99% ^{13}C) lutein was purified from a commercially available extract of algal biomass. Subjects (n = 4) ingested 3 mg of [^{13}C]lutein with a standardized low-carotenoid breakfast. Blood samples were collected at baseline and then hourly for 12 h; additional blood samples were drawn at 16, 24, 48, 72, 96, 192, 360, and 528 h. To produce perhydro-β-carotene suitable for analysis by GC–C–IRMS, the plasma lutein fraction was hydrogenated on palladium-on-carbon catalyst with acid-catalyzed hydrogenolysis. The stable carbon isotope ($^{13}C/^{12}C$) ratio measured by GC–C–IRMS was used to calculate the plasma concentration of [^{13}C]lutein. There was a rapid increase in [^{13}C]lutein in plasma until peak enrichment at 16 h followed by a decline to the next measurement at 24 h. At 528 h, small changes in ^{13}C enrichment from baseline could still be measured in plasma lutein. High-precision GC–C–IRMS enables complete definition of the appearance and disappearance of [^{13}C]lutein in plasma after ingestion of a dose similar to that absorbed from foods.

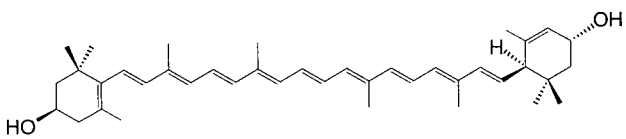
Paper no. L8328 in *Lipids 35,* 339–348 (March 2000).

Gas chromatography–combustion interfaced–isotope ratio mass spectrometry (GC–C–IRMS) combines the resolving capacity of gas–liquid chromatography and the high precision of IRMS. To be separated by a gas–liquid chromatograph, carotenoids such as β-carotene and lutein (β,ε-carotene-3,3′-diol) (Fig. 1) must be converted to derivatives that are thermally stable, chemically inert, and volatile at temperatures below *ca.* 300°C (1). Due to the thermal instability of the conjugated polyene chain of β-carotene, stable carbon isotope ratio analysis using GC–C–IRMS requires hydrogenation to the perhydro analog (2,3). We showed that stable carbon isotope ratio analysis of the dihydroxy carotenoid lutein using GC–C–IRMS requires alcohol hydrogenolysis and hydrogenation to enhance volatility and provide thermal stability (4). The major derivatization product of both β-carotene and lutein was identified by using GC–MS as perhydro-β-carotene which is suitable for GC–C–IRMS analysis (4,5).

GC–C–IRMS and a biosynthetically labeled [^{13}C]β-carotene tracer have been successfully applied to investigate metabolism of β-carotene in humans (2,3,6). A major advantage is the ability to use small tracer doses that model those typically derived from the major dietary sources, fruits and vegetables (7). Knowledge of the metabolism of such small doses is important for preventive medicine. People who ingest the highest dietary amounts of carotenoids such as β-carotene and lutein have reduced risks of epithelial cancers (8,9) and of coronary heart disease (10,11). High dietary intakes of lutein and an isomeric dihydroxy carotenoid zeaxanthin (β,β-carotene-3,3′-diol) may protect against age-related macular degeneration (12), the leading cause of new cases of legal blindness in the United States (13). Of the individual



β-Carotene



Lutein

FIG. 1. Lutein is a nonprovitamin A dihydroxy structural analog of β-carotene.

Abbreviations: AMD, age-related macular degeneration; APE, atom percent excess; AUC, area under the concentration vs. time curve; C_{max}, maximum plasma concentration; EA–IRMS, elemental analyzer–isotope ratio mass spectrometry; GC–C–IRMS, gas chromatography–combustion interfaced–isotope ratio mass spectrometry; GC–MS, gas chromatography–mass spectrometry; HPLC, high-performance liquid chromatography; IRMS, isotope ratio mass spectrometry; LDL, low density lipoproteins; MTBE, methyl *tert*-butyl ether; PDB, Pee Dee Belemnite; t_{max}, time to maximum plasma concentration; VLDL, very low density lipoproteins.

carotenoids circulating in the blood, lutein and zeaxanthin are selectively deposited in the retina and accumulate to form an area of dense pigmentation known as the macular pigment (14). The macular pigment is thought to protect the light-sensitive portions of the photoreceptor cells from damage mediated by blue visible light (15). Increased consumption of lutein and zeaxanthin in the form of corn and spinach increases the density of the macular pigment (16), which in turn is thought to provide greater protection against photooxidative damage to the retina and retinal pigment epithelium. Estimated mean intakes of lutein among adults in the United States stratified by gender and by race are 1.65–3.64 mg/d (17). Because of the potential public health importance, there is a need to investigate the metabolism of lutein in amounts that simulate such dietary exposures.

Our objective was to modify the ^{13}C tracer approach using GC–C–IRMS developed by Parker *et al.* (2,3) for human metabolic studies of β-carotene to enable similar studies of the plasma appearance and metabolism of lutein. Due to the scarcity of carotenoids labeled with stable isotopes, no tracer studies in humans using labeled carotenoids other than β-carotene appear in the literature.

EXPERIMENTAL PROCEDURES

Subjects. Healthy women (n = 4), aged 25–38 yr, were selected based on interview, physical examination, and complete blood count and blood biochemistry profile. Criteria for exclusion were current or recent cigarette smoking, chronic disease, lipid malabsorption or gastrointestinal disorder, lactose intolerance, vegetarianism, hyperlipidemia confirmed by blood lipid profile, history of anemia or excessive bleeding, pregnancy, use of oral contraceptive agents or contraceptive implants, use of medications that may affect lipid absorption or transport (including antibiotics), use of vitamin or mineral supplements, and frequent consumption of alcoholic beverages (>1 drink per day). Informed consent was obtained from all subjects, and the study protocol was approved by the Human Subjects Review Committee of Iowa State University.

Diets. Subjects were provided a list of foods to exclude and were instructed to avoid consumption of carotenoid-rich fruits and vegetables for 4 d before the beginning of the study period. During the study period, subjects consumed a controlled low-carotenoid diet of conventional foods for 2 d before and 4 d after dosing. A single daily menu of weighed food portions was provided. The meals were prepared and consumed in the Human Nutrition Metabolic Unit of the Center for Designing Foods to Improve Nutrition at Iowa State University, except for the carry-out lunches and evening snacks on weekdays. Adherence to the experimental diet was monitored by written self-report and by analysis of fasting plasma carotenoid concentrations using high-performance liquid chromatography (HPLC). Duplicate aliquots of 24-h diet composites from each of the two study periods were analyzed for carotenoid content. The extraction of the carotenoids followed the protocol described previously (18). On average, across two study periods, the daily diet provided (means ± SD): 123.3 ± 5.2 μg lutein, 46.0 ± 0.7 μg β-carotene, 7.4 ± 0.7 μg zeaxanthin, and no detectable α-carotene, β-cryptoxanthin, or lycopene. The macronutrient composition of the diet was estimated using Nutritionist V software (N-Squared Computing Inc., Salem, OR). The daily diet of 8.8 MJ was distributed as 14% of total energy from protein, 59% of total energy from carbohydrate, and 27% of total energy from fat.

Preparation of a biosynthetic ^{13}C-labeled tracer. Autotrophic algae grown with $^{13}CO_2$ as sole carbon source were previously used to economically produce per-labeled (>98% ^{13}C) β-carotene for use as a stable tracer (2,3). In the current study, we applied the same biotechnology and a different algal strain to produce tracer doses of per-labeled [^{13}C]lutein. Solvent partitioning was used to purify per-labeled [^{13}C]-lutein from the nonsaponifiable fraction of a crude lipid extract of *Chlorella* sp. generously donated by Martek, Inc. (Columbia, MD). The nonsaponifiable fraction (50 mg) was mixed with 5 mL of HPLC-grade water and extracted repeatedly with 15 mL of a mixture of hexane and ethyl ether (2:1, vol/vol) until the residue was almost colorless. The combined hexane/ethyl ether layers were evaporated to dryness *in vacuo.* Hexane (2 mL) was added to the residue to dissolve β-carotene and other hydrocarbon carotenes but to sparingly dissolve lutein (19), which was then isolated by filtration. Lutein was further purified from the yellow residue by crystallization. The yellow residue was dissolved in 4 mL of warm (40°C) methanol/water (90:10, vol/vol) solution and stored under argon overnight at –20°C to allow crystallization of lutein. The lutein crystals in methanol/water solution were then filtered and washed with hexane (50 mL). The purity of the lutein was estimated to be 93% on the basis of peak area using HPLC analysis with photodiode array detection; the contaminants were 2% β-carotene and 5% zeaxanthin. The ^{13}C enrichment was >99% as determined by using serial dilution with unlabeled lutein (Kemin Industries, Des Moines, IA) and stable carbon isotope-ratio analysis by GC–C–IRMS. A confirmatory mass spectrum of the purified [^{13}C]lutein was obtained using a Finnigan (currently Thermoquest, San Jose, CA) TSQ 700 triple quadrupole mass spectrometer in electron ionization mode (70 eV). The sample was introduced into the ion source by direct insertion probe at 200°C. Mass spectra were acquired over the range m/z 100–800 in 0.75 s.

A tracer dose of 3 mg (5.3 μmol) of [^{13}C]lutein was ingested with 28.0 g of high-oleic acid safflower oil (Neobee 18; Stepan Co, Maywood, NJ), 30 g of banana, and 120 mL of nonvitamin-fortified nonfat milk (generously donated by Anderson Erickson Dairy Co., Des Moines, IA). Specifically, the lutein was solubilized in 18.7 g of high-oleic acid safflower oil and emulsified using a hand-held mixer with a puree of 30 g of banana and 70 mL of nonvitamin-fortified nonfat milk (3). An additional 9.3 g of safflower oil was used to rinse the original vial that contained the tracer dose and the rinse was added to the emulsion while blending. The original vial and the hand-held mixer were then rinsed with 30 mL of

nonvitamin-fortified nonfat milk, which was added to the emulsion. After drinking the emulsion, the subjects were instructed to rinse the container with 20 mL of nonvitamin-fortified nonfat milk and to consume the rinse.

Study protocol. On the morning of the third day on the low-carotenoid diet, subjects arrived at the metabolic unit after an overnight (12-h) fast, and a baseline blood sample (14 mL) was drawn *via* a catheter placed in a forearm vein by a registered nurse. After ingestion of the [^{13}C]lutein, blood samples (14 mL) were drawn at hourly intervals for 12 h *via* the intravenous catheter into a syringe and transferred to tubes containing heparin as anticoagulant. The patency of the catheter was maintained by flushing with sterile physiological saline, as described previously (20). During the period of hourly blood collection, subjects continued the low-carotenoid experimental diet, including a breakfast ingested with the [^{13}C]lutein tracer dose, a lunch ingested immediately after the 5-h blood draw, and an evening meal ingested immediately after the 10-h blood draw. Additional blood samples were drawn from the antecubital vein *via* venipuncture at 16 h and after an overnight fast at 24, 48, 72, 96, 192, 360, and 528 h. Blood samples were immediately placed on ice and protected from light. Plasma was separated by centrifugation (1380 × *g*, 4°C, 20 min) and stored at –80°C in the dark until analyzed.

Purification of the plasma lutein fraction. Lutein was purified from individual plasma samples in amounts needed to produce sufficient perhydro-β-carotene (major derivatization product of alcohol hydrogenolysis and hydrogenation of lutein) to enable stable carbon isotope ratio measurement by using GC–C–IRMS. Plasma samples (4.0 mL) were divided into four 1.0-mL aliquots to ensure efficient extraction of lutein, deproteinized with 1 vol of ethanol, and extracted twice with 8 vol of hexane containing 0.1 g/L of butylated hydroxytoluene. The combined hexane layers were evaporated to dryness under vacuum. A saponification step was needed to remove lipid that would otherwise interfere with the gas–liquid chromatographic separation of the major product of lutein derivatization, perhydro-β-carotene, before elution into the combustion interface of the GC–C–IRMS. The dried hexane extract was dissolved in 0.5 mL of ethanol containing 0.1 g/L of butylated hydroxytoluene in a 3-mL screw-capped vial. Another 0.5 mL of ethanol containing 5.5 mM pyrogallol was added to the vial followed by 1.0 mL of 5.3 M aqueous potassium hydroxide. The contents of the vial were mixed and saponified at 65°C for 60 min in the dark under an atmosphere of argon. After cooling, the contents were transferred to a glass culture tube (16 × 100 mm) and extracted twice with 8.0 mL of hexane containing 0.1 g/L of butylated hydroxytoluene. The combined hexane extracts were washed twice with 5.0 mL of water and dried under vacuum in preparation for isolation of the lutein fraction by HPLC.

The dried residue was dissolved in 50 μL of ethyl ether and 150 μL of methanol, and 195 μL was injected into the HPLC system. The components of the HPLC system were manufactured by Waters Chromatography (Milford, MA) and consisted of the 717Plus autosampler with temperature control set at 5°C, two 510 solvent delivery systems, and the 996 photodiode array detector. The system operated with Millennium 2010 Chromatography Manager software. Solvents were HPLC grade; methanol, methyl *tert*-butyl ether (MTBE), and ammonium acetate were purchased from Fisher Scientific (Chicago, IL). The mobile phase was filtered (nylon-66 filter, 0.2 μm; Rainin Instruments Co., Woburn, MA) and degassed before use. A 5-μm C_{30} carotenoid column (YMC, Inc., Wilmington, NC) (4.6 × 250 mm) protected by a precolumn packed with the same stationary phase was used to achieve baseline resolution of lutein and the constitutional isomer, zeaxanthin. Carotenoids were eluted by using a linear mobile phase gradient from 100% methanol (1g/L ammonium acetate) to 100% MTBE over 35 min, as modified from Sander *et al.* (21). The flow rate was 1.0 mL/min. Elution of plasma carotenoids was monitored at 453 nm. The lutein fraction was collected, dried under vacuum, and repurified by using the same reversed-phase HPLC conditions in order to reduce residual sample matrix and prevent contamination by the close-eluting constitutional isomer, zeaxanthin. The lutein fraction was again collected, dried under vacuum, and redissolved in 50 μL of ethyl ether and 150 μL of isooctane/ethanol (95:5, vol/vol).

The lutein fraction was then subjected to further purification to remove contaminating lipids by using normal-phase HPLC (3). A 195-μL aliquot was injected into a Betasil Cyano analytical column (Keystone Scientific, Bellefonte, PA) (4.6 × 150 mm) and eluted by using an isocratic mobile phase of isooctane/ethanol (95:5, vol/vol). The flow rate was 1.0 mL/min. The lutein fraction was collected and dried under vacuum in preparation for derivatization for stable carbon isotope ratio analysis using GC–C–IRMS. Procedures were performed under yellow light.

Derivatization of lutein for GC–C–IRMS analysis. The conjugated polyene system of carotenoids is thermally labile so that alcohol hydrogenolysis and hydrogenation of lutein to produce a thermally stable analog, perhydro-β-carotene, was necessary prior to stable carbon isotope analysis by using GC–C–IRMS. We compared catalytic activities on platinum and palladium catalysts for hydrogenation of β-carotene and for alcohol hydrogenolysis and hydrogenation of lutein to produce perhydro-β-carotene. Lutein (Reagent grade, 95% purity; Kemin Industries, Des Moines, IA) and β-carotene (>97% purity; Fluka Chemical, Milwaukee, WI) were used as the reactants. The platinum oxide catalyst and the platinum and palladium catalysts supported on carbon (5 wt%) were supplied by Alfa Aesar (Ward Hill, MA). The catalyst (1 mg of platinum oxide or 10 mg of platinum-on-carbon or 10 mg of palladium-on-carbon) was suspended in 0.5 mL of HPLC-grade cyclohexane and 0.5 mL of glacial acetic acid containing 0.02 M *p*-toluenesulfonic acid monohydrate (Aldrich, Milwaukee, WI), and reduced by hydrogen gas prior to addition of 1.0 μg of β-carotene or lutein in 250 μL of cyclohexane; the reaction proceeded at 60°C and 10 psi hydrogen

pressure for 16 h. The reaction products were washed with 2 mL of HPLC-grade water and extracted twice with 3 mL of hexane. The combined hexane layers were washed twice with 2 mL of HPLC-grade water, dried under vacuum, and stored at –20°C until analyzed by using GC–C–IRMS. The yield of the perhydro-β-carotene product was quantified by using gas–liquid chromatography after addition of squalane (Aldrich) as an internal standard. Calibration curves were generated from the ratio of the peak height of the perhydro-β-carotene standard to that of the squalane internal standard plotted against the injected amount of perhydro-β-carotene standard. The perhydro-β-carotene standard was prepared by two sequential hydrogenations of β-carotene using platinum oxide as catalyst, and the purity was determined to be 100% by using gas–liquid chromatography. Because catalytic hydrogenation on palladium-on-carbon was determined to result in the highest yield of perhydro-β-carotene and the lowest production of side reaction products, this catalyst was used for derivatization of the plasma lutein fraction for analysis by using GC–C–IRMS.

A confirmatory mass spectrum of the perhydro-β-carotene reaction product was obtained using a Fisons (currently Thermoquest, San Jose, CA) GC 8000 gas chromatograph interfaced to a Fisons Trio 1000 quadrupole mass spectrometer in electron ionization mode (70 eV). A 15 m × 0.25 mm i.d. (0.25-μm film thickness) DB™-1 (J&W Scientific, Folsom, CA) fused-silica capillary column with on-column injector was used with ultrapure helium as carrier gas at a flow rate of 40 cm/s. The temperature program proceeded from 50°C followed by a gradient of 30°C/min to 150°C followed by a gradient of 15°C/min to 310°C, and a 10-min hold at 310°C. The interface temperature was 310°C, and the ion source temperature was 150°C. Mass spectra were acquired over the range *m/z* 50–600 in 0.90 s.

To determine whether derivatization resulted in isotopic alteration of the sample (isotopic fractionation), the isotopic composition of commercial lutein standard (reagent grade, 95% purity; Kemin Industries) was determined before derivatization and compared with that of the major derivatization product, perhydro-β-carotene. The $^{13}C/^{12}C$ ratio of lutein was analyzed without hydrogenation by using a NA1500 elemental analyzer (EA) (CE Elantech, Lakewood, NJ) interfaced to the Optima isotope ratio mass spectrometer. Lutein was quantitatively combusted to CO_2 and H_2O; H_2O vapor was removed by a chemical trap, and the CO_2 was further purified by GC on a Poropak QS column (2 m × 4 mm i.d.) and admitted into the Fisons/VG Isotech Optima IRMS (currently Micromass UK, Manchester, United Kingdom). The stable carbon isotope ratio (expressed as $\delta^{13}C$ vs. the international standard, Pee Dee Belemnite, in per mil units, denoted ‰) of lutein measured without derivatization by using EA–IRMS was compared with that of the perhydro-β-carotene product of lutein derivatization measured by using GC–C–IRMS.

GC–C–IRMS analysis. The stable carbon isotope ratio of the perhydro-β-carotene product of lutein derivatization was determined using a 5890A Hewlett-Packard (Wilmington, DE) GC fitted with a Fisons/VG Isotech Isochrom GC-combustion interface to the Fisons/VG Isotech Optima IRMS. A 10 m × 0.25 mm i.d. (0.25 μm film thickness) DB-1 (J&W Scientific) fused-silica capillary column with on-column injector was used with ultrapure helium as carrier gas at a flow rate of 40 cm/s. The temperature program proceeded from 50°C followed by a gradient of 30°C/min to 150°C followed by a gradient of 15°C/min to 325°C and a 20-min hold at 325°C. The computer-generated stable carbon isotope ratio measurements, expressed in delta (δ), per mil (part per thousand, ‰) units, were used to calculate the atom percent ^{13}C in each plasma lutein sample according to the following formula:

$$\text{atom\% } ^{13}\text{C} = \frac{(100 \times R_{PDB}) \times \left(\delta^{13}\text{C}/1000 + 1\right)}{1 + (R_{PDB}) \times \left(\delta^{13}\text{C}/1000 + 1\right)} \quad [1]$$

in which R_{PDB} represents the $^{13}C/^{12}C$ ratio for the international standard for carbon, Pee Dee Belemnite (PDB), with an accepted value $R_{PDB} = 0.0112372$ (7). For each subject, the atom percent excess (APE) ^{13}C in plasma lutein at each time point was calculated by subtraction of the atom percent ^{13}C in plasma lutein at baseline from that in plasma lutein after ingestion of the [^{13}C]lutein tracer. The APE reflects the percentage of plasma lutein that is present as the ^{13}C-enriched isotopomer after ingestion of the tracer and controls for natural abundance ^{13}C (3).

Calculation of [^{13}C]lutein in plasma. The plasma concentration of [^{13}C]lutein was calculated from the total (labeled plus unlabeled) plasma lutein concentration determined by using HPLC and the APE ^{13}C in the plasma lutein fraction determined by using GC–C–IRMS. In order to measure the total plasma lutein concentration, duplicate 200-μL aliquots of plasma were denatured by addition of an equal volume of absolute ethanol containing 0.1g/L butylated hydroxytoluene and echinenone (generously donated by Roche Vitamins, Parsippany, NJ) as internal standard. Samples were then extracted twice with 2 mL hexane containing 0.1 g/L butylated hydroxytoluene, and the combined hexane layers were evaporated to dryness under vacuum. The residues were reconstituted with ethyl ether and methanol (1:3, vol/vol), and 50-μL aliquots were injected into the HPLC system. The HPLC conditions were as previously described for purification of the plasma lutein fraction by reversed-phase HPLC. Calibration curves were generated from the ratio of the peak area of the lutein standard (reagent-grade lutein, 95% purity; Kemin Industries) to that of the echinenone internal standard plotted against the injected amount of the lutein standard. Analyses were performed under yellow light. The plasma concentration of [^{13}C]lutein was calculated as the product of the total plasma lutein concentration determined by using HPLC and the atom fraction excess ^{13}C (F), where F = APE/100. The areas under the plasma [^{13}C]lutein concentration vs. time curves (AUC) were calculated by using trapezoidal approximation (22).

RESULTS

The retention time and ultraviolet/visible absorbance spectrum of the biosynthetic [^{13}C]lutein tracer (Fig. 2) measured by using HPLC with photodiode array detection were identical to those of a commercial lutein standard (reagent-grade lutein, 95% purity, Kemin Industries). The electron ionization (70 eV) mass spectrum showed fragmentation of perlabeled [^{13}C]lutein to form a molecular ion of *m/z* 608.4 (Fig. 3). The molecular mass of unlabeled lutein, a C_{40} carotenoid, is 568.4. The tracer was therefore identified as lutein in which all carbon atoms were uniformly labeled with ^{13}C.

Hydrogenation of the hydrocarbon β-carotene with platinum as catalyst is complete and produces a single product, perhydro-β-carotene (3). Catalytic hydrogenation of the dihydroxycarotenoid, lutein, produces perhydro-β-carotene and secondary products, which likely result from the favored acid-catalyzed dehydration of the allylic hydroxyl group (4). In order to optimize the yield of the perhydro-β-carotene product, we compared catalytic activities on platinum and palladium catalysts for hydrogenation of β-carotene and for alcohol hydrogenolysis and hydrogenation of lutein (Fig. 4). Perhydro-β-carotene was quantified by using GC. For the respective catalysts, respective recoveries of perhydro-β-carotene (mol% ± SD; $n = 3$) from β-carotene and lutein were: platinum oxide, 102.8 ± 0.5 and 21.7 ± 3.9; platinum-on-carbon, 101.9 ± 3.0 and trace; palladium-on-carbon, 45.9 ± 1.0 and 55.3 ± 4.8. The identity of the major product of lutein derivatization was determined to be perhydro-β-carotene based on comparison of retention time during GC analysis with that of perhydro-β-carotene produced by hydrogenation of synthetic β-carotene (>97% purity; Fluka), and was further confirmed by using GC–MS (Fig. 5). Catalytic activity for hydrogenation of β-carotene was optimal on platinum, whereas catalytic activity for alcohol hydrogenolysis and hydrogenation of lutein was optimal on palladium; palladium is known to be the best catalyst for most hydrogenolysis reactions (23). There was good-to-excellent yield of the perhydro-β-carotene product which enabled reliable GC–C–IRMS analysis of nanomolar quantities of derivatized lutein. Thus our approach was sufficiently sensitive to measure the stable carbon isotope ratio of perhydro-β-carotene produced from lutein isolated from small volumes of human plasma; such sensitivity is a requisite for stable isotope tracer methods.

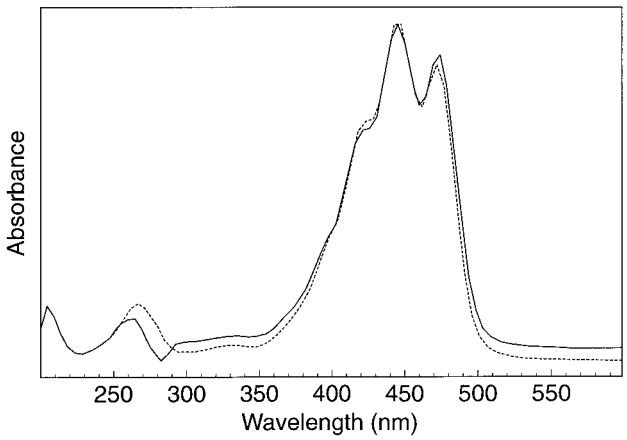

FIG. 2. Near identical ultraviolet/visible absorbance spectra of commercial lutein standard (reagent-grade lutein, 95% purity; Kemin Industries, Des Moines, IA) (----) and of biosynthetic [^{13}C]lutein (—) isolated from a commercially available extract of algal biomass (Martek Bioscience, Columbia, MD).

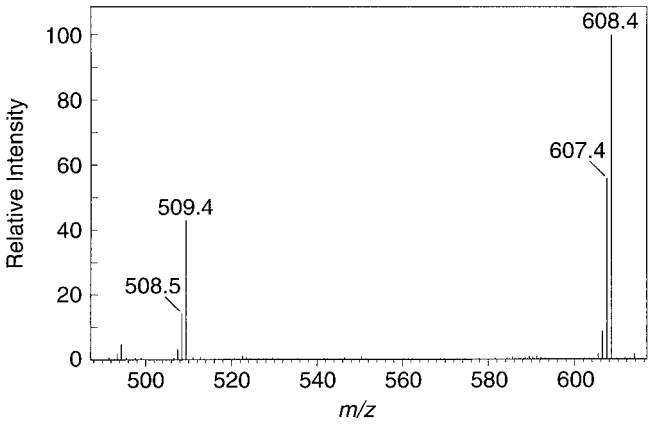

FIG. 3. Electron ionization (70 eV) mass spectrum showing fragmentation of per-labeled [^{13}C]lutein to form a molecular ion of *m/z* 608.4. The molecular mass of unlabeled lutein, a C_{40} carotenoid, is 568.4. This confirms the identity of the biosynthetically-labeled [^{13}C]lutein tracer.

The incomplete yield of the perhydro-β-carotene product of lutein derivatization indicates a potential for isotopic fractionation during derivatization of the plasma lutein fraction for GC–C–IRMS analysis. The stable carbon isotope ratio (expressed as δ^{13}C vs. the international standard, PDB, in per mil units, denoted ‰) of lutein measured without derivatization by using EA–IRMS was determined to be −30.82 ± 0.10‰ (mean ± SD; $n = 4$); the stable carbon isotope ratio of the perhydro-β-carotene product of lutein hydrogenation on palladium measured by using GC–C–IRMS was determined to be −30.97 ± 0.27‰ (means ± SD; $n = 7$). Thus our protocol for derivatization of lutein did not result in carbon isotopic fractionation; such isotopic alteration would preclude accurate determination of ^{13}C enrichment in lutein isolated from human plasma.

A representative GC–C–IRMS chromatogram of derivatized plasma lutein with the *m/z* 44 ($^{12}CO_2$) signal trace and corresponding upper 45 ($^{13}CO_2$ + $^{12}C^{17}O^{16}O$)/44 isotope ratio signal trace is shown in Figure 6. The chromatogram at *m/z* 44 is almost identical to that from a flame-ionization detector, since both arise from the detection of carbon (24). The 45/44 isotope ratio trace is indicative of the shift of isotope ratio from background to that of enriched plasma lutein. The derivatization products and coeluting components or contaminants are simultaneously combusted to CO_2 and detected in the mass spectrometer. Therefore, accurate and precise measurement of the stable carbon isotope ratio requires high-resolution GC separation of the analyte, perhydro-β-carotene. Despite extensive purification of the plasma lutein fraction,

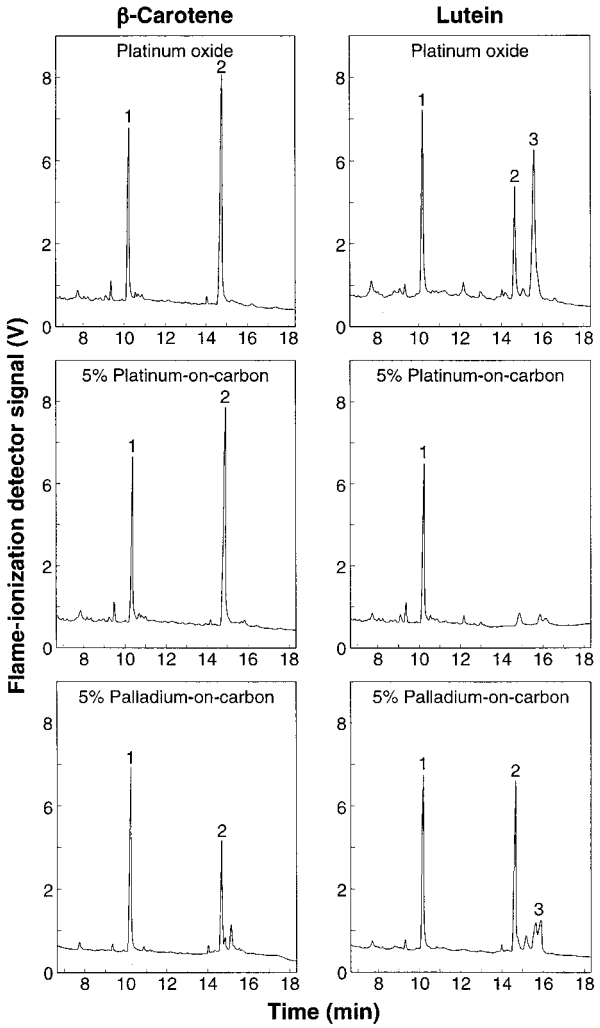

FIG. 4. Gas chromatograms of hydrogenated commercial standards of β-carotene (>97% purity; Fluka Chemical, Milwaukee, WI) and lutein (reagent-grade lutein, 95% purity; Kemin Industries, Des Moines, IA). Catalytic activities for hydrogenation of β-carotene and for alcohol hydrogenolysis and hydrogenation of lutein were compared on palladium and platinum catalysts. Peak identity: 1, squalane internal standard (Aldrich Chemical, Milwaukee, WI); 2, perhydro-β-carotene; 3, unidentified side reaction product(s).

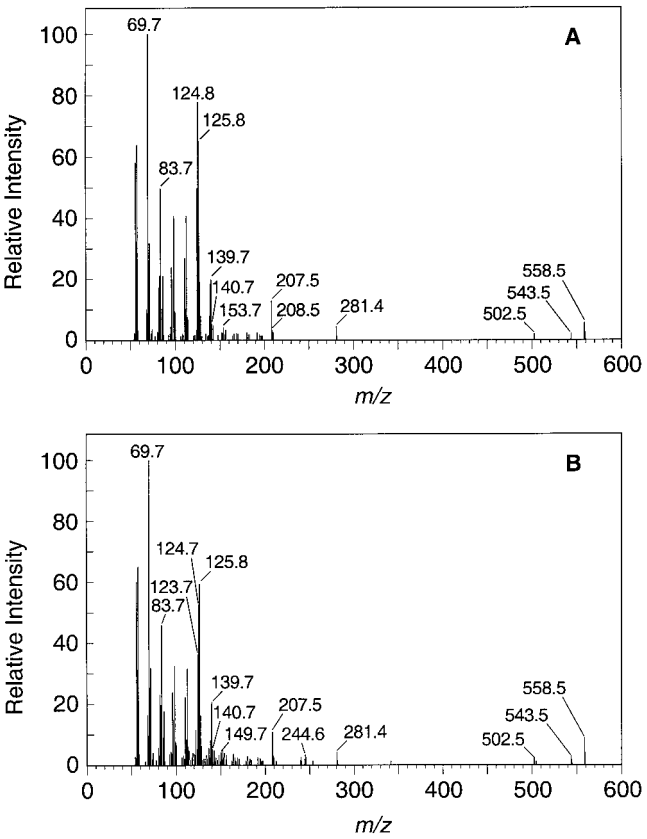

FIG. 5. Electron ionization (70 eV) mass spectra showing similar fragmentation of the product of β-carotene hydrogenation (A) and of the major product of alcohol hydrogenolysis and hydrogenation of lutein (B). Both produced the perhydro-β-carotene molecular ion at *m/z* 558.5.

the presence of sample matrix is apparent in the baseline of the GC–C–IRMS chromatogram. The 45/44 isotope ratio measurement was corrected by automated data processing for this contribution to background. However, sensitivity would be enhanced by elimination of sample matrix which would reduce ^{12}C dilution of measured ^{13}C enrichment. Our approach was still sufficiently sensitive to enable measurement of the stable carbon isotope ratio of lutein isolated from small volumes of plasma after ingestion of only 3 mg of [^{13}C]lutein.

The plasma concentration vs. time curve for [^{13}C]lutein after subjects ingested a 3-mg (5.3-μmol) dose of per-labeled [^{13}C]lutein is shown in Figure 7. The relatively rapid increase to a peak at 11–16 h was followed by a moderate and then slow decline to the final measurement at 528 h. At 528 h, ^{13}C enrichment was still detected in the plasma lutein pool. Thus,

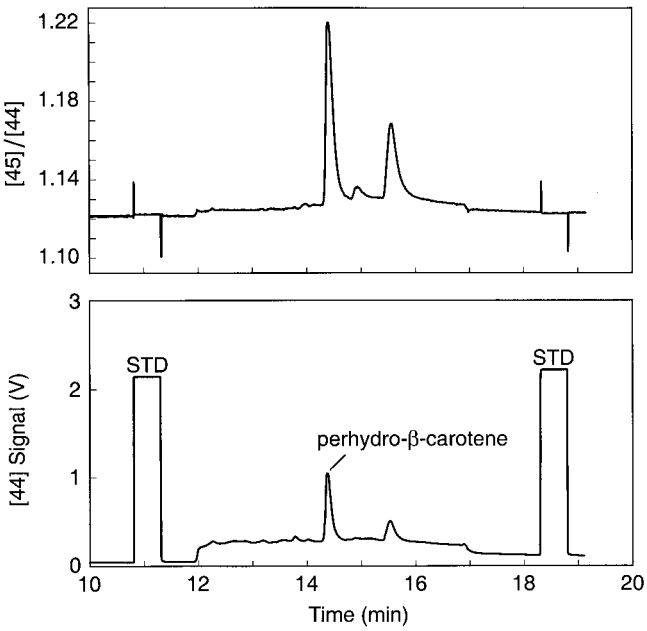

FIG. 6. Gas chromatography–combustion interfaced–isotope ratio mass spectrometry plot of the hydrogenated lutein fraction isolated from the plasma of a subject who ingested 3.0 mg of per-labeled [^{13}C]lutein. Shown are the *m/z* 44 ($^{12}CO_2$) signal trace and corresponding upper 45 ($^{13}CO_2$ + $^{12}C^{17}O^{16}O$)/44 isotope ratio signal trace.

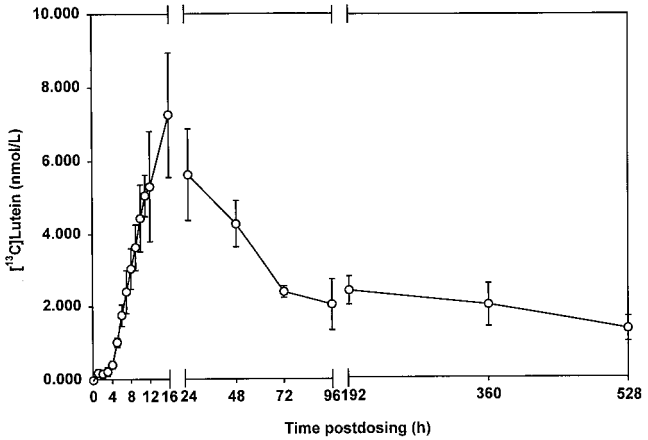

FIG. 7. The appearance and disappearance of [^{13}C]lutein in the plasma of subjects who each ingested a 3-mg oral dose of per-labeled [^{13}C]lutein. $\bar{x}$ ± SEM; n = 4.

the ^{13}C tracer approach using GC–C–IRMS is able to measure small changes in stable carbon isotope ratio in lutein over a prolonged period of time. Such sensitivity and precision are needed in order to characterize the kinetics of elimination of carotenoids which are transported in lipoproteins with slow turnover rates, such as low density lipoprotein (LDL) and high density lipoprotein (7). The maximal plasma concentrations (C_{max}), corresponding times (t_{max}), and areas under the concentration vs. time curve (AUC) for the four subjects are shown in Table 1. The peak plasma concentration of [^{13}C]lutein for individual subjects ranged from 5.22–11.82 nmol/L. For three of four subjects, the highest measured plasma concentration of [^{13}C]lutein occurred at 16 h; for the remaining subject, the highest concentration occurred at 11 h after ingestion of the dose. Bioavailability is proportional to the AUC (22). The AUC data in Table 1 indicate that there was a threefold variation among subjects in the bioavailability of the [^{13}C]lutein tracer dose.

DISCUSSION

We successfully adapted the ^{13}C tracer approach developed by Parker *et al.* (2,3) and previously used in human studies of the metabolism of β-carotene (6) for use in study of the metabolism of another prominent dietary carotenoid, lutein. Of the 14 major dietary carotenoids absorbed in the small intestine and incorporated into plasma (25), lutein and zeaxanthin are selectively deposited in the macular pigment of the human retina (26). The macular pigment is thought to function to attenuate transmission of blue visible light and resultant photoxidative damage to photoreceptor cells (15). The amount of macular pigment was recently shown to be modifiable by the amount of lutein ingested in vegetables (16). Consumption of lutein-rich vegetables is negatively correlated with deterioration of the retina in the form of age-related macular degeneration (AMD) (12). Thus there is a need for experimental approaches to identify factors that modulate the intestinal absorption and plasma appearance of lutein when ingested in physiologically relevant amounts by humans. The advantage of a tracer approach using GC–C–IRMS is the sensitivity and selectivity to quantify the appearance of ^{13}C in the plasma lutein pool after ingestion of 3 mg or less of [^{13}C]lutein.

The basis for the current application is a metabolic tracer technique using highly enriched substrates uniformly labeled with ^{13}C and analysis by high-precision GC–C–IRMS (27). Isotope-ratio monitoring differs from conventional GC–MS in that organic samples are combusted on line in order to quantitatively produce analytes (CO_2, N_2, and potentially other fixed gases) amenable to high-precision isotope ratio analysis (28). In our application, the carbon atoms of the major derivatization product of lutein, perhydro-β-carotene, are combusted to CO_2, which is admitted to the mass spectrometer. Ion currents at *m/z* 44 ($^{12}C^{16}O_2$), 45 ($^{13}C^{16}O_2$ + $^{12}C^{17}O^{16}O$), and 46 ($^{12}C^{18}O^{16}O$) are continuously monitored using three Faraday cup detectors. To control for instrumental effects, the isotope ratio of CO_2 derived from the analyte is compared with that of a CO_2 standard admitted to the ion source. The CO_2 standard is isotopically calibrated relative to PDB, the accepted primary standard for carbon isotopic abundances. Results are expressed in δ notation defined as

$$\delta(‰) = \left(\frac{R_{sample} - R_{standard}}{R_{standard}} \right) \times 10^3 \quad [2]$$

where R is the $^{13}C/^{12}C$ isotope ratio. The computer-generated δ value is used to calculate the atom percent ^{13}C in the analyte, as previously described (see the Experimental Procedures section).

A major advantage of this approach for metabolic tracer studies is the low detection limits and high-precision isotope-ratio monitoring that enable use of physiological amounts of tracer. GC–MS in selected ion-monitoring mode is widely used to measure stable isotope abundance in nanomole samples, but is limited by relatively poor precision (0.1–0.5 mol%) (29). Conventional IRMS offers high precision (<0.0001 mol%) but requires micromoles of sample. Isotope-ratio monitoring using GC–C–IRMS combines the small sample amount of GC–MS and the high precision of conventional

IRMS. We have adapted this approach for use with a highly enriched [^{13}C]lutein tracer that is readily purified from a commercially available extract of algal biomass.

Most studies of the intestinal absorption of carotenoids have focused on β-carotene. However, the majority of carotenoids are oxycarotenoids, also referred to as xanthophylls, that are distinguished from the hydrocarbon carotenes by one or more oxygen functions (30). Lutein is the predominant oxycarotenoid in human plasma, which reflects its wide dietary distribution in green vegetables, in corn, and, to a lesser extent, in fruits such as mango and papaya. Although internationally lutein is more consistently detected than β-carotene in human plasma (31), the metabolism of β-carotene has been comparatively well studied. The comparative interest in β-carotene reflects its role as the major dietary source of provitamin A, whereas lutein lacks provitamin A activity. Of the components of green and yellow vegetables and fruits, carotenoids are most strongly correlated with decreased risk of cancer (32). Investigations of the phytoprotective component(s) in these foods focused initially on β-carotene because of its established nutritional importance as a provitamin A carotenoid and the known importance of retinoids in cancer prevention (33). After the disappointing results of the β-carotene supplementation trials (34–36), interest has shifted to other major dietary carotenoids such as lutein and to physiological ingestion of carotenoids in the form of fruits and vegetables rather than pharmacological ingestion in the form of supplements.

In the current study, the high precision of GC–C–IRMS was used to quantify the plasma appearance and disappearance of a physiological 3-mg dose of [^{13}C]lutein in healthy women. The bioavailability of lutein in spinach products was recently shown to be 45–55% relative to that of crystalline lutein suspended in vegetable oil when ingested by humans (37). Thus the bioavailability of 3 mg of [^{13}C]lutein tracer would be roughly equivalent to that of 6 mg of lutein ingested in the form of spinach, which, in turn, would equate to *ca.* 0.50 cup (90 g) of cooked or 1.0 cup (56 g) of raw spinach (38). By using a per-labeled [^{13}C] tracer and the high-precision of GC–C–IRMS, we were able to completely define the plasma appearance and disappearance of lutein after a dose equivalent to that absorbed from a single vegetable serving.

The mean plasma concentration of [^{13}C]lutein showed a single peak at 16 h, which is consistent with the plasma appearance observed in healthy adults who ingested a single pharmacological dose (0.5 μmol/kg body weight) of unlabeled lutein (39). The data provide additional evidence of the metabolic heterogeneity of dietary carotenoids (40). The monophasic plasma appearance of [^{13}C]lutein is distinct from the biphasic plasma appearance of a physiological (1-mg) dose of [^{13}C]β-carotene (6). The plasma concentration vs. time curve for [^{13}C]β-carotene is characterized by a peak enrichment at 5 h and a second broader peak between 24 and 48 h. These two peaks reflect the dynamics of incorporation of [^{13}C]β-carotene into plasma lipoproteins involved in the transport and disposition of β-carotene (7). Our previous studies (20,41) and those of others (42,43) using large, unlabeled doses of β-carotene showed that the initial plasma peak coincides with appearance of β-carotene in postprandial triacylglycerol-rich lipoproteins [chylomicrons and large very low density lipoproteins (VLDL)] and the second peak with delayed appearance of β-carotene in LDL. The interval that separates the two peaks is presumed to reflect uptake of β-carotene in chylomicron remnants by the liver, incorporation of β-carotene into nascent VLDL secreted by the liver, and subsequent metabolism of VLDL to LDL.

Like that of [^{13}C]β-carotene, the plasma appearance of [^{13}C]lutein would be expected to reflect movement into and out of plasma lipoproteins involved in absorption and distribution. The plasma appearance of [^{13}C]lutein resembles that of another oxycarotenoid, canthaxanthin (β,β-carotene-4,4′-dione) (18). Previously, we showed that the monophasic plasma appearance of canthaxanthin is the result of coincident increments in triacylglycerol-rich lipoproteins and in LDL (20). In contrast, the accumulation of β-carotene in LDL is delayed. In the present study, we showed that the plasma appearance, and most likely the plasma lipoprotein transport, of lutein is distinct from that of β-carotene, which was studied previously (2,6). Because of the physiological tracer doses used, our findings are extrapolatable to the metabolism of lutein and β-carotene absorbed from dietary fruits and vegetables.

ABSTRACT: [1-^{14}C]Linoleic acid was incubated with a whole homogenate preparation from potato stolons. The reaction product contained four major labeled compounds, i.e., the α-ketol 9-hydroxy-10-oxo-12(*Z*)-octadecenoic acid (59%), the epoxy alcohol 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoic acid (19%), the divinyl ether colneleic acid (3%), and a new cyclopentenone (13%). The structure of the last-mentioned compound was determined by chemical and spectral methods to be 2-oxo-5-pentyl-3-cyclopentene-1-octanoic acid (trivial name, 10-oxo-11-phytoenoic acid). Steric analysis demonstrated that the relative configuration of the two side chains attached to the five-membered ring was *cis,* and that the compound was a racemate comprising equal parts of the 9(*R*),13(*R*) and 9(*S*),13(*S*) enantiomers. Experiments in which specific trapping products of the two intermediates 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid and 9(*S*),10-epoxy-10,12(*Z*)-octadecadienoic acid were isolated and characterized demonstrated the presence of 9-lipoxygenase and allene oxide synthase activities in the tissue preparation used. The allene oxide generated from linoleic acid by action of these enzymes was further converted into the cyclopentenone and α-ketol products by cyclization and hydrolysis, respectively. Incubation of [1-^{14}C]linolenic acid with the preparation of potato stolons afforded 2-oxo-5-[2′(*Z*)-pentenyl]-3-cyclopentene-1-octanoic acid (trivial name, 10-oxo-11,15(*Z*)-phytodienoic acid), i.e., an isomer of the jasmonate precursor 12-oxo-10,15(*Z*)-phytodienoic acid. Quantitative determination of 10-oxo-11-phytoenoic acid in linoleic acid-supplied homogenates of different parts of the potato plant showed high levels in roots and stolons, lower levels in developing tubers, and no detectable levels in leaves.

Paper no. L8431 in *Lipids 35,* 353–363 (April 2000).

Abbreviations and trivial names: 9-H(P)OD, 9-hydro(pero)xy-10(*E*),12(*Z*)-octadecadienoic acid; 9-H(P)OT, 9-hydro(pero)xy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid; 12-oxo-PDA, 12-oxo-10,15(*Z*)-phytodienoic acid {4-oxo-5-[2′(*Z*)-pentenyl]-2-cyclopentene-1-octanoic acid}; 12-oxo-PEA, 12-oxo-10-phytoenoic acid [4-oxo-5-pentyl-2-cyclopentene-1-octanoic acid]; 13-H(P)OD, 13-hydro(pero)xy-9(*Z*),11(*E*)-octadecadienoic acid; 13-H(P)OT, 13-hydro(pero)xy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid; AOS, allene oxide synthase; colneleic acid, 9-[1′(*E*),3′(*Z*)-nonadienyloxy]-8(*E*)-nonenoic acid; colnelenic acid, 9-[1′(*E*),3′(*Z*),6′(*Z*)-nonatrienyloxy]-8(*E*)-nonenoic acid; CP-HPLC, chiral-phase high-performance liquid chromatography; FTIR, Fourier transform infrared; GC–MS, gas chromatography–mass spectrometry; GLC, gas–liquid chromatography; GSH, reduced glutathione; GSH-px, glutathione peroxidase; MC, (–)-menthoxycarbonyl; NMR, nuclear magnetic resonance; RP-HPLC, reversed-phase high-performance liquid chromatography; SP-HPLC, straight-phase high-performance liquid chromatography; UV, ultraviolet.

Jasmonates constitute a group of biologically important compounds in plants. Members of the jasmonate family have been implicated in defense reactions against insects and other pathogens, in mechanical responses such as tendril coiling, and in pollen development (1). Jasmonic acid is biosynthesized from the cyclopentenone 12-oxo-10,15(*Z*)-phytodienoic acid (12-oxo-PDA) by action of reductase and β-oxidation enzymes (2). 12-Oxo-PDA is formed by a pathway involving 13-lipoxygenase, allene oxide synthase, and allene oxide cyclase (3,4). The last-mentioned enzyme is specific for allene oxides in which the epoxide group is located in the n-6,7 position and in which there is also a double bond in the n-3 position (5). In agreement with these structural requirements, cyclopentenone fatty acids hitherto isolated from higher plants originate in linolenic acid (1,4) or 7(*Z*),10(*Z*),13(*Z*)-hexadecatrienoic acid (6). The present paper is concerned with the oxidative metabolism of linoleic and linolenic acids in preparations of stolons of potato. An alternative route to cyclopentenone fatty acids initiated by a 9-lipoxygenase is described.

EXPERIMENTAL PROCEDURES

Plant materials. Tubers of potato (*Solanum tuberosum* L., var. Bintje) were stored in the dark at 18°C. Stolons of 0.5–5 cm length were used for the incubations.

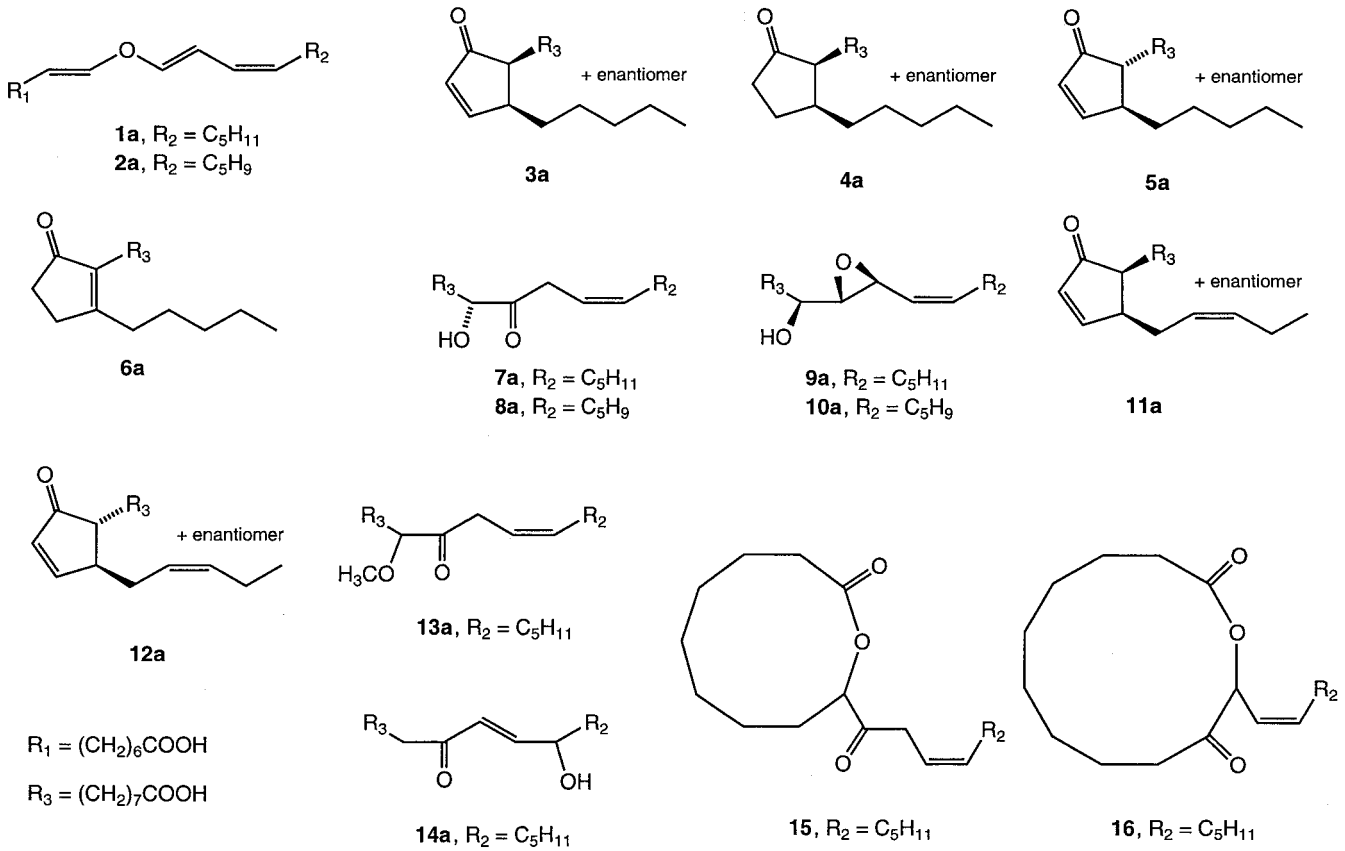
Fatty acids. Linoleic and linolenic acids were purchased from Nu-Chek-Prep (Elysian, MN). [1-^{14}C]Linoleic and [1-^{14}C]linolenic acids (DuPont NEN, Boston, MA) were mixed with the corresponding unlabeled acids and purified by SiO_2 chromatography to afford specimens having specific radioactivities of 5.4 and 9.1 kBq/μmol, respectively. [1-^{14}C]9(*S*)-Hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid [9(*S*)-HPOD] and [1-^{14}C]9(*S*)-hydroperoxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid [9(*S*)-HPOT] were prepared in 30–50% yield by incubation of labeled linoleic acid and linolenic acid, respectively, with tomato lipoxygenase (7) under an atmosphere of oxygen gas. The α-ketol 9-hydroxy-10-oxo-12(*Z*)-octadecenoic acid and the γ-ketol 13-hydroxy-10-oxo-11(*E*)-octadecenoic acid were prepared by incubation of 9(*S*)-HPOD with allene oxide synthase (AOS) from corn seeds (8,9) followed by isolation by reversed-phase high-performance liquid chromatography (RP-HPLC). 9-Methoxy-10-oxo-12(*Z*)-octadecenoic acid was prepared from 9(*S*)-HPOD in brief incu-

bations with corn seed AOS interrupted by addition of 20 vol of methanol (8,9). The macrolactones 10-oxo-12(*Z*)-octadecen-9-olide and 10-oxo-12(*Z*)-octadecen-11-olide were obtained in a similar way in incubations interrupted by addition of 20 vol of acetonitrile (9,10). Incubation of 13(*S*)-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid [13(*S*)-HPOT] with corn seed AOS in the presence of corn allene oxide cyclase afforded natural 9(*S*),13(*S*)-12-oxo-10,15(*Z*)-phytodienoic acid [9(*S*),13(*S*)-12-oxo-PDA] (11), whereas 12-oxo-10-phytoenoic acid [12-oxo-PEA (side-chain *trans* form)] was obtained by brief incubation of 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid [13(*S*)-HPOD] with corn seed AOS followed by addition of bovine serum albumin (12). The methyl ester of the epoxy alcohol 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoic acid was obtained by incubation of 9(*S*)-HPOD with a homogenate of potato leaves (13), whereas the divinyl ethers colneleic acid and colnelenic acid were prepared by incubation of 9(*S*)-HPOD and 9(*S*)-HPOT, respectively, with a preparation from potato tubers (14).

Enzyme preparations. Stolons of potato were minced and homogenized at 0°C in 0.1 M potassium phosphate buffer pH 7.4 (1:10, wt/vol) with an Ultra-Turrax. The homogenate was filtered through gauze, and the filtrate (protein, 1.3 mg/mL) was used as enzyme source in preparative incubations carried out to generate products for structural analysis. Centrifugation at 9300 × *g* for 15 min afforded a low-speed sediment and a supernatant. Further centrifugation of the latter at 105,000 × *g* for 60 min provided a high-speed particle fraction and a particle-free supernatant (protein, 0.9 mg/mL). The former was resuspended in buffer to give a suspension (protein, 0.8 mg/mL), which was used as enzyme source in experiments carried out to study conditions affecting formation of cyclopentenones. A particle fraction containing AOS from corn seeds was prepared as described (15). Glutathione peroxidase (GSH-px) and reduced glutathione (GSH) were purchased from Sigma Chemical Co. (St. Louis, MO).

Incubations and treatments. Incubations of [1-^{14}C]linoleic acid, [1-^{14}C]linolenic acid, 9(*S*)-HPOD and 9(*S*)-HPOT (63–245 μM as indicated) were carried out by stirring the substrate at 23°C for times indicated with the whole homogenate preparation of potato stolons. The mixtures were extracted with 2 vol of diethyl ether at pH 5, and the products were methyl-esterified and subjected to straight-phase high-performance liquid chromatography (SP-HPLC) [solvent system, 2-propanol/hexane (1:99, vol/vol)]. Cyclopentenone formation under various conditions was studied by stirring [1-^{14}C]9(*S*)-HPOD at 23°C with a suspension of the 105,000 × *g* particle fraction of potato stolons (2 mL, pre-warmed at 23°C for 5 min). This incubation was modified as indicated with respect to temperature, pH, and substrate concentration.

*Preparation of **3a***. For large-scale preparation of cyclopentenone **3a** (see Scheme 1 for numbered key to all struc-



SCHEME 1

tures; free carboxylic acids are designated by **a** and methyl esters by **b**), batches of 13 g of potato stolons were minced and homogenized in 130 mL of 0.1 M potassium phosphate buffer pH 7.4 at 0°C. The homogenate was filtered through gauze, and 110 mL of the filtrate was diluted with 400 mL of potassium phosphate buffer and warmed at 26°C for 5 min. Linoleic acid (245 μM) was added, and the mixture was stirred at 26°C for 30 min. The material obtained by extraction with diethyl ether was subjected to RP-HPLC using a column of Nucleosil C_{18} 100-7 (250 × 10 mm) purchased from Macherey-Nagel (Düren, Germany) and a solvent system consisting of acetonitrile/water/2 M hydrochloric acid (55:45:0.013, by vol; 4 mL/min). The material collected was subjected to SP-HPLC using a column of Nucleosil 50-7 (250 × 10 mm) and a solvent system of 2-propanol/hexane/acetic acid (1.5:98.5:0.01, by vol; 4 mL/min). This procedure afforded **3a** as a colorless oil in 2–4% overall yield.

*Quantitative determination of **3a** in potato plant homogenates supplied with linoleic acid*. Different tissue types (2 g) from the potato plant were placed in ice-cold potassium phosphate buffer pH 7.4 (20 mL) and homogenized with an Ultra-Turrax. The homogenate was filtered through gauze, and an aliquot of the filtrate (5 mL) was prewarmed at 23°C for 5 min. Linoleic acid or 9(*S*)-HPOD (both 200 μM) was added, and the mixture was stirred for 10 min at 23°C. Ethanol (15 mL) containing 12-oxostearic acid (51.5 μg) was added, and the mixture was extracted with diethyl ether. Aliquots of the methyl-esterified material were directly subjected to gas chromatography–mass spectrometry (GC–MS) operated in the selected ion monitoring mode. The ions *m/z* 95 and 152 (typical for **3b**) and *m/z* 242 and 281 (typical for methyl 12-oxostearate) were used. The amounts of **3a** were calculated from the ratio of intensities of ions (*m/z* 95 + 152)/(*m/z* 242 + 281) and a standard curve constructed by analyzing mixtures of **3a** and 12-oxostearic acid in known proportions.

Chemical methods. Catalytic hydrogenation, oxidation with potassium permanganate, oxidative ozonolysis, and derivative preparation for GC–MS were performed as described earlier (13,16). Preparation of diastereomeric derivatives of cyclopentenones and steric analysis of these by gas–liquid chromatography (GLC) were carried out using a published procedure (15). Methyl-esterification was performed by brief (*ca.* 10 s) treatment with ethereal diazomethane.

Chromatographic and instrumental methods. The equipment and conditions used for RP-HPLC, SP-HPLC, GLC, GC–MS, ultraviolet (UV), and Fourier transform infrared (FTIR) spectrometry have been described in detail (13,16). Chiral phase HPLC (CP-HPLC) was carried out with a Chiralcel OB-H column (250 × 4.6 mm) purchased from Daicel Chemical Industries (Osaka, Japan) using mixtures of 2-propanol/hexane as the solvent and a flow rate of 0.5 mL/min. Nuclear magnetic resonance (NMR) spectra were recorded with a JEOL JNM-EX270 instrument. Deuteriochloroform containing 0.03% tetramethylsilane was used as the solvent.

RESULTS

Isolation and structure determination of oxidation products. (i) Incubation of linoleic acid. [1-^{14}C]Linoleic acid (200 μM) was stirred at 23°C for 10 min with whole homogenate of potato stolons, and the methyl-esterified product was subjected to SP-radio-HPLC. As seen in Figure 1A, four major radioactive compounds appeared, i.e., **1b** (3% of the recovered radioactivity; effluent volume, 2.5 mL), **3b** (13%; 6.3 mL), **7b** (59%; 7.5 mL), and **9b** (19%; 9.7 mL).

*(ii) Identification of compound **1b***. The UV spectrum of **1b** showed an absorption band with λ_{max} = 250 nm, suggesting a fatty acid divinyl ether derivative (14,16). The C-value (*cf.* Ref. 13), i.e., 19.41, and the mass spectrum were identical to those of methyl colneleate, a lipoxygenase product formed in tubers of potato (14). Results of catalytic hydrogenation and oxidative ozonolysis performed on compound **1b** (*cf.* Refs. 14,16) conclusively established its identity to methyl colneleate.

*(iii) Identification of compound **7b***. The UV spectrum of **7b** was featureless, whereas the FTIR spectrum showed strong absorption bands at 3480 (OH), 1739 (ester C=O), and 1716 cm^{-1} (ketone C=O). No significant absorption band was observed in the region 900–1000 cm^{-1}, thus excluding the presence of a *trans* double bond. The Me_3Si derivative of **7b** gave a C-value of 20.93 on GLC analysis, and the mass spectrum showed prominent ions at *m/z* 383 (3%; $M^+ - 15$; loss of $\cdot CH_3$), 259 [100; $Me_3SiO^+{=}CH{-}(CH_2)_7{-}COOCH_3$], 155 [37; $OHC{-}(CH_2)_7{-}C{\equiv}O^+$], 129 (9; $Me_3SiO^+{=}CH{-}CH{=}CH_2$), 109 (19), and 73 (47; Me_3Si^+). Identical results were obtained upon analysis of the methyl ester/Me_3Si derivative of 9-hydroxy-10-oxo-12(*Z*)-octadecenoic acid, an α-ketol fatty acid which is formed as the major product upon incubation of 9(*S*)-HPOD with corn seed AOS (9). An aliquot of **7b** (0.5 mg) was treated with sodium borohydride in methanol and subsequently subjected to catalytic hydrogenation. The product was identified by GLC and GC–MS as methyl 9,10-dihydroxystearate (mixture of *erythro*- and *threo*-isomers; authentic reference compounds were prepared by *cis*- and *trans*-hydroxylation, respectively, of methyl oleate). In another experiment, compound **7b** (1 mg) was derivatized with (−)-menthoxycarbonyl (MC) chloride, and the resulting MC derivative was subjected to $KMnO_4$ oxidation. The methyl-esterified product consisted of a main chiral fragment, i.e., the MC derivative of dimethyl 2-hydroxy-1,10-decanedioate. Steric analysis by GLC revealed that 92% of the sample was due to the 2(*R*)-hydroxy derivative and 8% 2(*S*)-hydroxy derivative. Steric analysis of compound **7b** also could be effected by resolution by CP-HPLC [solvent system, 2-propanol/hexane (6:94, vol/vol)]. Peaks due to the *R* (effluent volume, 10.0 mL) and *S* (9.0 mL) enantiomers in a 92:8 ratio were observed. Accordingly, **7b** was a mixture containing 92% methyl 9(*R*)-hydroxy-10-oxo-12(*Z*)-octadecenoate and 8% methyl 9(*S*)-hydroxy-10-oxo-12(*Z*)-octadecenoate.

*(iv) Identification of compound **9b***. Analysis of the Me_3Si derivative of **9b** by GC–MS showed a C-value (20.86) and a mass spectrum identical to those of the corresponding deriva-

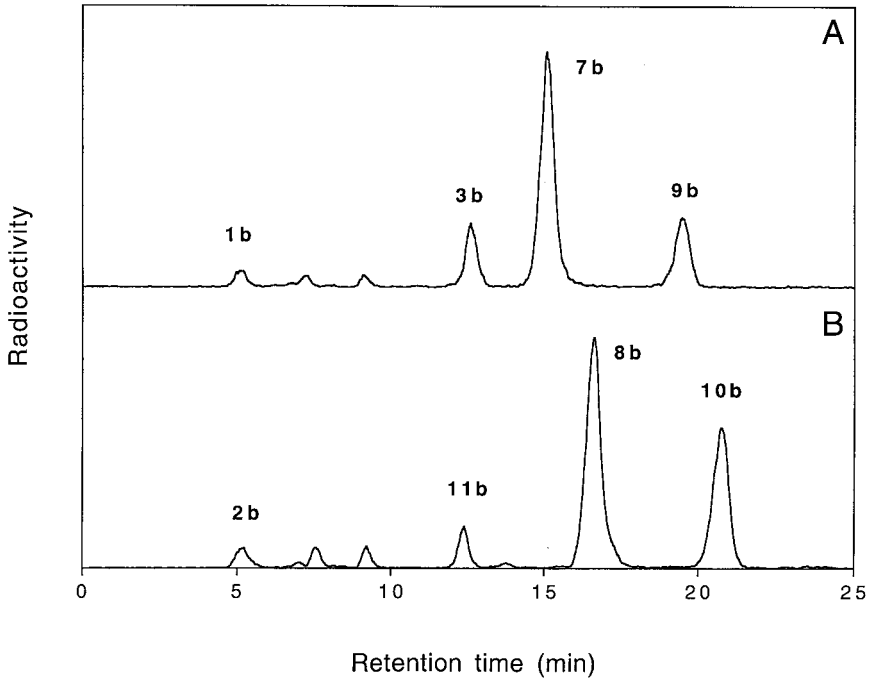


FIG. 1. Analysis by straight-phase radio high-performance liquid chromatography of methyl-esterified reaction products obtained following incubations of [1-^{14}C]linoleic acid (200 μM; panel A) and [1-^{14}C]linolenic acid (200 μM; panel B) at 23°C for 10 min with whole homogenate of stolons of potato. The column was eluted at a flow rate of 0.5 mL/min with 2-propanol/hexane (1:99, vol/vol). The structures of the compounds indicated are given in Scheme 1.

tive of methyl 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoate, an epoxy alcohol recently isolated following incubation of linoleic acid with a preparation of potato leaves (13). Further support for the identity of **9b** with this epoxy alcohol was provided by catalytic hydrogenation, which afforded methyl *erythro*-9,10-dihydroxystearate, and by results of mild acid-catalyzed hydrolysis, which afforded methyl 9(*S*),10(*R*),13(*R*)-trihydroxy-11(*E*)-octadecenoate and methyl 9(*S*),10(*R*),13(*S*)-trihydroxy-11(*E*)-octadecenoate as the main products (13).

*(v) Structure of compound **3b***. The UV spectrum of **3b** showed a strong absorption band with λ_{max} = 220 nm (solvent, ethanol) (Table 1), and the FTIR spectrum showed carbonyl absorption bands at 1739 (ester C=O) and 1709 cm^{-1} (ring ketone C=O) (Fig. 2). The mass spectrum showed ions at *m/z* 308 (3%; M^+), 277 (9; $M^+ - 31$; loss of $\cdot OCH_3$), 237 [2; M^+ - 71; loss of $\cdot(CH_2)_4CH_3$], 233 (3), 192 (5), 152 [93; $M^+ - 156$; cleavage β to ring carbonyl and elimination of CH_2=CH–$(CH_2)_5COOCH_3$], 123 (11), 109 (20), 95 [100; C_6H_7O; tentatively ascribed to loss of $\cdot(CH_2)_3CH_3$ from *m/z* 152], and 82 [34; C_5H_6O; loss of CH_2=CH–$(CH_2)_2CH_3$ from *m/z* 152]. These spectral data suggested that **3b** was built up by a cyclopentenone ring carrying two side chains, i.e., C_5H_{11} and C_7H_{14}–$COOCH_3$. Signals observed in the NMR spectrum of **3b** are given in Table 2. Protons belonging to a pentyl side chain (H14 to H18; 11 protons) and to a carboxylic ester side chain (H2 to H8; 14 protons) were readily discerned. Olefinic protons that were part of a cyclopentenone structure (H11 and H12; 2 protons) appeared at 6.15 and 7.71 ppm, whereas the protons at the side chain bearing carbons (H9 and H13; 2 protons) gave rise to signals at 2.32 and 2.96 ppm. The chemical shifts of the two last-mentioned signals were similar to those previously recorded for the H13 and H9 protons, respectively, of the methyl ester of natural 12-oxo-PDA (17), thus indicating a *cis* relationship between the two side chains in **3b**. Conclusive evidence for the *cis* relative configuration was provided by the alkali-promoted conversion of **3b** into the side-

TABLE 1

chain *trans* isomer **5b**, and the NMR spectrum of this compound (see below).

Independent support for the structure of **3b** was provided by an experiment in which a sample (0.5 mg) was subjected to oxidative ozonolysis. The methyl-esterified product was analyzed by GC–MS and found to be due to a major fragment identified as trimethyl tetradecane-1,8,9-tricarboxylate by its mass spectrum, i.e., *m/z* 341 (63%; $M^+ - 31$; loss of $\cdot OCH_3$), 308 (12; $M^+ - 2 \times 32$), 270 [26; $M^+ - (70 + 32)$; loss of $CH_2{=}CH{-}(CH_2)_2CH_3$ plus CH_3OH], 216 [22; $M^+ - 156$; loss of $CH_2{=}CH{-}(CH_2)_5COOCH_3$], 184 (37; *m/z* 216 – 32), 152 (46; *m/z* 216

[a]Proton nuclear magnetic resonance spectra were recorded at 270 MHz in $CDCl_3$ with tetramethylsilane as internal chemical shift reference.
[b]The absorptions due to H-8 and H-14 were hidden in other absorption bands and could not be adequately resolved. For abbreviations see Table 1.

– 2 × 32), and 55 (100). Formation of this product involved cleavage of the double bond of the five-membered ring followed by oxidative decarboxylation of the resulting 2-oxoacid.

The absolute stereochemistry of **3b** was studied in two ways. In one set of experiments, previously developed methodology for steric analysis of 12-oxo-PDA (11,15) and 12-oxo-PEA (12) involving reduction into epimeric cyclopentanols and derivatization of these with MC chloride was applied to a sample of **3b**. Analysis of the diastereomeric MC derivatives showed two peaks in a ratio of 50:50 corresponding to the 9(*R*),13(*R*) and 9(*S*),13(*S*) enantiomers of **3b**. In another experiment, **3b** was subjected to CP-HPLC using a solvent system of 2-propanol/hexane (1:9, vol/vol). Two peaks (8.6 and 10.6 mL effluent) appeared in a ratio of 50:50 (49:51 – 51:49 in different runs). On the basis of these results, compound **3a** was assigned the structure (±)-2-oxo-5-pentyl-3-cyclopentene-1-octanoic acid. The trivial name of **3a** will be 10-oxo-11-phytoenoic acid using the phytonoic acid (18) stem.

*(vi) Preparation and analysis of **5b***. Compound **3b** (4 mg) was treated with 0.1 M NaOH in 90% aqueous methanol at 23°C for 30 min. The reesterified product was purified by SP-HPLC to yield compound **5b**. Analysis of this material by UV spectroscopy showed an absorption band with λ_{max} (EtOH) = 221 nm. The FTIR spectrum showed carbonyl absorption bands at 1739 (ester C=O) and 1708 cm^{-1} (ring ketone C=O), and the mass spectrum was similar to that of **3b**. As seen in Table 1, the C-value of **5b** (19.77) was significantly lower than that of **3b** (20.17), suggesting that **5b** was a side-chain *trans* isomer (*cf.* Refs. 12,19). Conclusive evidence for the notion that alkali-treatment of **3b** resulted in reversible enolization at C-9 and formation of the thermodynamically more stable *trans* isomer **5b** was provided by the NMR spectrum of **5b** (Table 2). As seen, the protons attached to C-9 and C-13 gave rise to signals (1.94 and 2.58 ppm, respectively) that were shifted upfield compared to the corresponding signals of **3b** (2.32 and 2.96 ppm, respectively). Such an upfield shift is expected for a vicinal dialkylcyclopentane derivative in which the carbon chains are oriented *syn* with respect to the vicinal ring juncture proton (20), and therefore demonstrated that in the pair **3b** and **5b** the latter is the *trans* and the former is the *cis* side-chain stereoisomer. The NMR spectra of **3b** and **5b** were analogous to those earlier recorded on the *cis*- and *trans*-forms, respectively, of the methyl ester of 12-oxo-PDA (17).

*(vii) Preparation and analysis of **6b***. Compound **3b** (1 mg) was treated with 0.5 M NaOH in 50% aqueous methanol at 70°C for 1 h. The product was methyl-esterified and purified by SP-HPLC to afford **6b**. The UV spectrum of this compound showed a strong absorption band with λ_{max} (EtOH) = 237 nm, and the FTIR spectrum showed carbonyl absorption bands at 1739 (ester C=O) and 1699 cm^{-1} (ring ketone C=O) as well as an olefinic absorption band at 1640 cm^{-1} (C=C stretching of tetrasubstituted double bond conjugated to ring ketone). Analysis by GC–MS revealed a C-value of 20.37 and a mass spectrum showing prominent ions at *m/z* 308 (50%; M^+), 276 (37; M^+ – 32; loss of CH_3OH), 237 [59; M^+ – 71; loss of $\cdot(CH_2)_4CH_3$], 233 [100; M^+ – (43 + 32); loss of $\cdot(CH_2)_2CH_3$ plus CH_3OH], 205 (38; *m/z* 237 – 32), 123 (79), and 110 (93).

Oxidative ozonolysis performed on cyclopentenone **6b** followed by methyl-esterification afforded comparable amounts of dimethyl 1,9-nonanedioate and methyl 4-oxononanoate. The latter compound was identified by its mass spectrum, which showed prominent ions at *m/z* 155 (20%; M^+ – 31; loss of $\cdot OCH_3$), 130 (59; M^+ – 56; β-cleavage with loss of CH_2=CH–CH_2CH_3), 115 [67; M^+ – 71; α-cleavage with loss of $\cdot(CH_2)_4CH_3$], 98 (100; *m/z* 130 – 32), 71 (57), and 55 (75). The ozonolysis fragments were likely formed from **6b** by initial cleavage of the tetrasubstituted double bond followed by oxidative cleavage of the resulting α-dioxo structure.

*(viii) Preparation and analysis of **4b***. Compound **3b** (0.5 mg) was hydrogenated using platinum catalyst to provide dihydro derivative **4b** (C-value, 19.87) as well as a smaller amount of the corresponding side-chain *trans* derivative (C-value, 19.60). The mass spectra recorded on these compounds were similar and showed a molecular ion at *m/z* 310 (1%), as well as prominent ions at *m/z* 154 [18; M^+ – 156; β-cleavage with loss of CH_2=CH–$(CH_2)_5COOCH_3$], and 83 [100; C_5H_7O; loss of $\cdot(CH_2)_4CH_3$ from *m/z* 154].

(ix) Incubation of 9(S)-HPOD. Stirring 9(*S*)-HPOD (200 μM) at 23°C for 10 min with the whole homogenate preparation from potato stolons afforded compounds **1a**, **3a**, **7a**, and **9a** in a proportion closely similar to that observed following incubation of linoleic acid. The enzymes catalyzing hydroperoxide metabolism were mainly located in the particle fraction sedimenting at 105,000 × *g* as shown by experiments in which 9(*S*)-HPOD incubated with this fraction was converted into a mixture of **1a**, **3a**, **7a**, and **9a**. It seemed likely that an AOS was involved in the conversion of 9(*S*)-HPOD into α-ketol **7a** and cyclopentenone **3a**, and it was therefore of interest to study the metabolism of 9(*S*)-HPOD by another AOS. To this end, a suspension of the 105,000 × *g* particle fraction of corn seed homogenate was stirred with 9(*S*)-HPOD, and the methyl-esterified reaction product was analyzed by HPLC. As seen in Figure 3, the preparation of corn seed AOS produced a high yield of **7a** (analyzed as its methyl ester **7b**) but only a very small amount of cyclopentenone **3a** (analyzed as **3b**; ratio **3a**/**7a**, 0.005). The corresponding ratio observed with the AOS from potato stolons was 0.11 (Fig. 3).

(x) Incubation of linolenic acid and 9(S)-HPOT. As seen in Figure 1, linolenic acid (200 μM) was converted by the whole homogenate preparation of potato stolons in a way analogous to that of linoleic acid. In the methyl-esterified product, divinyl ether **2b** (4% of the product) and α-ketol **8b** (50%) were identified using the authentic reference compounds, whereas the structure of epoxy alcohol **10b** (31%) was tentatively assigned as methyl 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*),15(*Z*)-octadecadienoate on the basis of analysis by GC–MS and on experiments in which isomeric trihydroxyesters (13) were isolated and characterized following mild acid-catalyzed conversion of **10b**. Compound **11b** (6%)

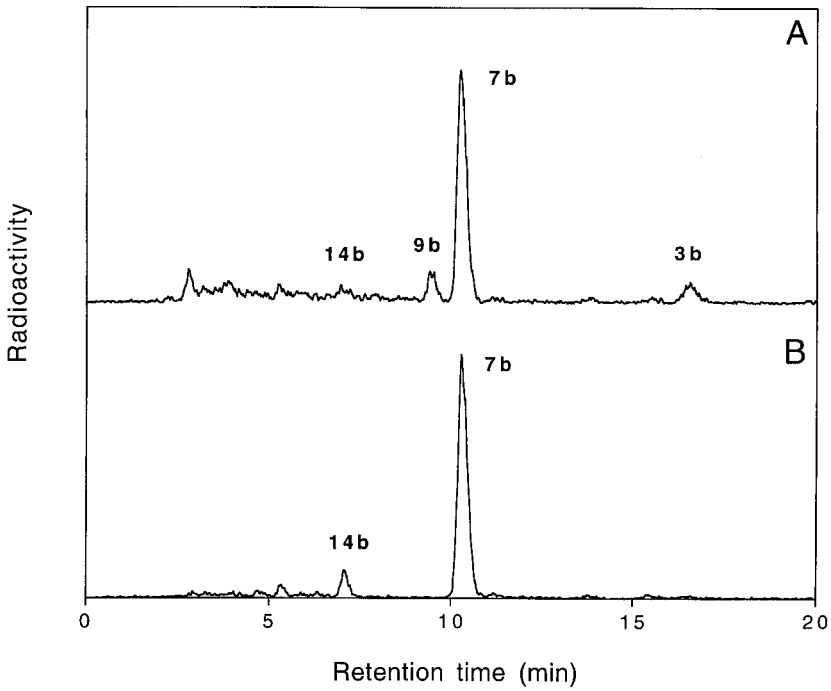

FIG. 3. Analysis by reversed-phase radio high-performance liquid chromatography of methyl-esterified reaction products obtained following incubations of [1-^{14}C]9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid (100 μM) at 23°C for 2 min with the 105,000 × *g* particle fraction of homogenate of potato stolons (panel A) or with the corresponding fraction of homogenate of corn seed (panel B). The column was eluted at a flow rate of 1.5 mL/min with acetonitrile/water (65:35, vol/vol). The structures of the compounds indicated are given in Scheme 1. Compound **1b** was not eluted from the column during the time period used, and under the conditions used, compound **9b** suffered partial hydrolysis into more polar trihydroxy derivatives.

was a new cyclopentenone and was characterized as described below. A similar pattern of products was observed following incubation of 9(*S*)-HPOT.

*(xi) Structure of compound **11b***. The UV spectrum of **11b** showed a λ_{max} (EtOH) = 217 nm due to the cyclopentenone chromophore. Analysis by GC–MS showed a C-value of 20.11 and a mass spectrum exhibiting prominent ions at *m/z* 306 (1%; M^+), 275 (3; $M^+ - 31$; loss of $\cdot OCH_3$), 238 (4; $M^+ - 68$; loss of C_5H_8), 150 [9; $M^+ - 156$; β-cleavage with loss of $CH_2{=}CH{-}(CH_2)_5COOCH_3$], 121 (15), and 82 (100; C_5H_6O; loss of C_5H_8 from *m/z* 150). Treatment of **11b** with 0.1 M sodium hydroxide resulted in epimerization at C-9 and, following reesterification, to the formation of the side-chain *trans* derivative **12b**. As would be expected (12,19), the mass spectrum of **12b** was very similar to that of **11b**, but the C-value was lower (Table 1). Catalytic hydrogenation of **11b** afforded a tetrahydro derivative that was identical in all respects to **4b** prepared by hydrogenation of **3b**. The double bond in the pentenyl side chain of **11b** was localized by oxidative ozonolysis, which afforded tetramethyl decane-1,8,9,10-tetracarboxylate as the predominant product. Prominent ions in the mass spectrum of this compound were observed at *m/z* 343 (100%; $M^+ - 31$; loss of $\cdot OCH_3$), 310 (48; $M^+ - 2 \times 32$); 229 [32; $M^+ - 145$; cleavage at C-8/C-9 and elimination of $\cdot CH(COOCH_3){-}CH_2COOCH_3$], 218 [38; $M^+ - 156$; β-cleavage with loss of $CH_2{=}CH{-}(CH_2)_5COOCH_3$], 186 (70; *m/z* 218 – 32), 146 {39; cleavage at C-8/C-9 and charge retention in the fragment $[CH_3OOC{-}CH_2{-}CH{=}COH(OCH_3)]^+$}, 114 (43; *m/z* 146 – 32), and 55 (64).

Analysis of **11b** by CP-HPLC [solvent system, 2-propanol/hexane (2:8, vol/vol)] showed two peaks in a 1:1 ratio (7.5 and 10.0 mL), thus demonstrating that **11b** was a racemate due to equal parts of the 9(*R*),13(*R*) and 9(*S*),13(*S*) enantiomers. Based on the results mentioned, **11a** was assigned the structure (±)-2-oxo-5-[2′(*Z*)-pentenyl]-3-cyclopentene-1-octanoic acid.

Trapping experiments. (i) Incubations in the presence of GSH-px. Linoleic acid (200 μM) was stirred with a suspension of the 105,000 × *g* particle fraction of homogenate of potato stolons in the presence of GSH-px (2 U/mL) and GSH (2 mM). Analysis of the methyl-esterified product by SP-HPLC showed a major peak accounting for 90% of the total radioactivity. This material cochromatographed with the methyl ester of 9-HOD and was conclusively identified as this compound by analysis of the Me_3Si derivative by GC–MS. Only trace amounts (<1%) of the regioisomeric 13-HOD methyl ester could be detected. Analysis of the 9-HOD methyl ester by CP-HPLC revealed it to be the natural *S* enantiomer.

(ii) Trapping of an allene oxide with methanol. 9(*S*)-HPOD (63 μM) was stirred at 0°C for 30 s with 2 mL of a suspen-

sion of the 105,000 × *g* particle fraction of homogenate of potato stolons. Methanol (40 mL) was added, and the mixture was kept at 23°C for 1 h. Analysis of the reaction product by SP-HPLC [solvent system, 2-propanol/hexane/acetic acid (1:99:0.01, by vol)] revealed the presence of compound **13a** (16% of the total radioactivity; 9.2 mL effluent)) in addition to α-ketol **7a** (51%; 24.8 mL) and other minor compounds. Formation of **13a** successively decreased when longer times of incubations were used and was not noticeable at 5 min of incubation. Its identity with 9-methoxy-10-oxo-12(*Z*)-octadecenoic acid was ascertained using GC–MS analysis of the methyl ester with the authentic compound as reference. The mass spectrum of **13b** showed prominent ions at *m/z* 340 (2%; M^+), 309 (5; $M^+ - 31$; loss of $\cdot OCH_3$), 201 [100; $CH_3O^+{=}CH{-}(CH_2)_7COOCH_3$], 169 (24; *m/z* 201 – 32), 137 (44; *m/z* 201-2 × 32), and 71 (35). Analysis of **13b** by CP-HPLC [solvent system, 2-propanol/hexane (4:96, vol/vol)] showed separation into two enantiomers, tentatively assigned as methyl 9(*R*)-methoxy-10-oxo-12(*Z*)-octadecenoate (76%; 7.5 mL effluent) and methyl 9(*S*)-methoxy-10-oxo-12(*Z*)-octadecenoate (24%; 6.5 mL). Steric analysis of **13b** obtained as a trapping product in the corn seed AOS-catalyzed reaction gave a similar enantiomeric composition, i.e., 73:27.

As shown in previous work, α-methoxy ketones are formed as trapping products of unstable allene oxides (8,9), and the transient appearance of **13a** indicated the formation of 9(*S*),10-epoxy-10,12(*Z*)-octadecadienoic acid from 9(*S*)-HPOD catalyzed by potato stolon AOS. The half-life of the allene oxide estimated from the rate of disappearance of **13a** was 44 s (0°C; pH 7.4). The half-life of the corresponding allene oxide generated in the corn seed AOS system was 33 s, a value almost identical to that (34 s) previously published (9).

(iii) Intramolecular trapping of an allene oxide—formation of macrolactones. 9(*S*)-HPOD (100 μM) was stirred at 0°C for 30 s with 11 mL of a suspension of the 105,000 × *g* particle fraction of homogenate of potato stolons. Ice-cold acetonitrile (220 mL) was added, and the mixture was kept at 0°C for 1 h. The mixture was extracted with hexane (no acidification), and the product was subjected to SP-HPLC using a solvent system of 2-propanol/hexane (0.2:99.8, vol/vol). Two peaks of nonpolar radioactive materials appeared, i.e., **16** (3.9 mL effluent; 25%) and **15** (6.2 mL; 75%). The mass spectrum of **16** showed prominent ions at *m/z* 294 (13%; M^+), 223 [4; $M^+ - 71$; loss of $\cdot(CH_2)_4CH_3$], 169 (13), 98 (100), and 55 (63), whereas the mass spectrum of **15** exhibited ions at *m/z* 294 (2%; M^+), 183 [10; $M^+ - 111$; loss of $\cdot CH_2{-}CH{=}CH{-}(CH_2)_4CH_3$], 155 [100; $M^+ - 139$; loss of $\cdot CO{-}CH_2{-}CH{=}CH{-}(CH_2)_4CH_3$], 109 (38), and 55 (39). Authentic macrolactones **15** and **16**, which were prepared by short-time incubation of 9(*S*)-HPOD with corn seed AOS (9), gave identical analytical results. Interestingly, a significant difference between the proportions of **15**/**16** was noted, i.e., 75:25 using the potato stolon AOS and 89:11 using the corn seed AOS.

*Formation of **3a** and **14a** under various conditions*. *(i) Effect of pH, temperature, and substrate concentration*. In a series of incubations, 9(*S*)-HPOD was stirred with the 105,000 × *g* particle fraction from homogenate of potato stolons or with the corresponding fraction from corn seed homogenate. The compositions of the reaction products were determined by SP-radio-HPLC. As seen in Table 3, formation of **3a** (relative to **7a**) was temperature- and pH-dependent. On the other hand, diluting the enzyme preparation 10-fold, or changing the substrate concentration in the range 30–300 μM, did not alter the ratio **3a**/**7a**.

γ-Ketols are significant products in incubations with corn seed AOS (8,15). Although the γ-ketol **14a** accounted for only 2% of the recovered radioactivity in the potato stolon incubations, it appeared to be of interest to include this AOS product in the analyses and to study the pH-dependency of its formation. γ-Ketols can give a by-product when methyl-esterified by diazomethane (21), and the radio-HPLC analysis was accordingly carried out on the nonesterified incubation products. As seen in Table 3, formation of **14a** showed a pH-dependency in agreement with its postulated formation from the protonated allene oxide (22). The reason for the lower ratio

Abbreviations: **3a**, 2-oxo-5-pentyl-3-cyclopentene-1-octanoic acid (1,5-*cis* isomer); **7a**, 9-hydroxy-10-oxo-12(*Z*)-octadecenoic acid; **14a**, 13-hydroxy-10-oxo-11(*E*)-octadecenoic acid .

TABLE 4
Formation of Compound 3a in Homogenates of Tissues from the Potato Plant[a]

Tissue	Compound **3a** (nmol/g)	
	Linoleic acid incubation	9(*S*)-HPOD incubation
Stolons	79.4 ± 9.5	84.3 ± 6.4
Tubers, 5–10 mm diam.	20.7 ± 7.1	24.7 ± 4.3
Tubers, 30–40 mm diam.	7.4 ± 2.8	7.7 ± 2.8
Leaves	<1.5	<1.5
Roots	159.0 ± 21.8	172.8 ± 15.5

[a]For determination of **3a**, 2 g of tissue was minced and homogenized in 20 mL of 0.1 M potassium phosphate buffer pH 7.4. Five milliliters of the filtrate were prewarmed at 23°C and subsequently stirred with 200 μM linoleic acid or 200 μM 9(*S*)-HPOD for 10 min. The amounts of **3a** were determined by gas chromatography–mass spectrometry using 12-oxostearic acid as internal standard. For abbreviation see Table 3.

14a/**7a** in the potato stolon incubation compared to the corn seed incubation is unknown.

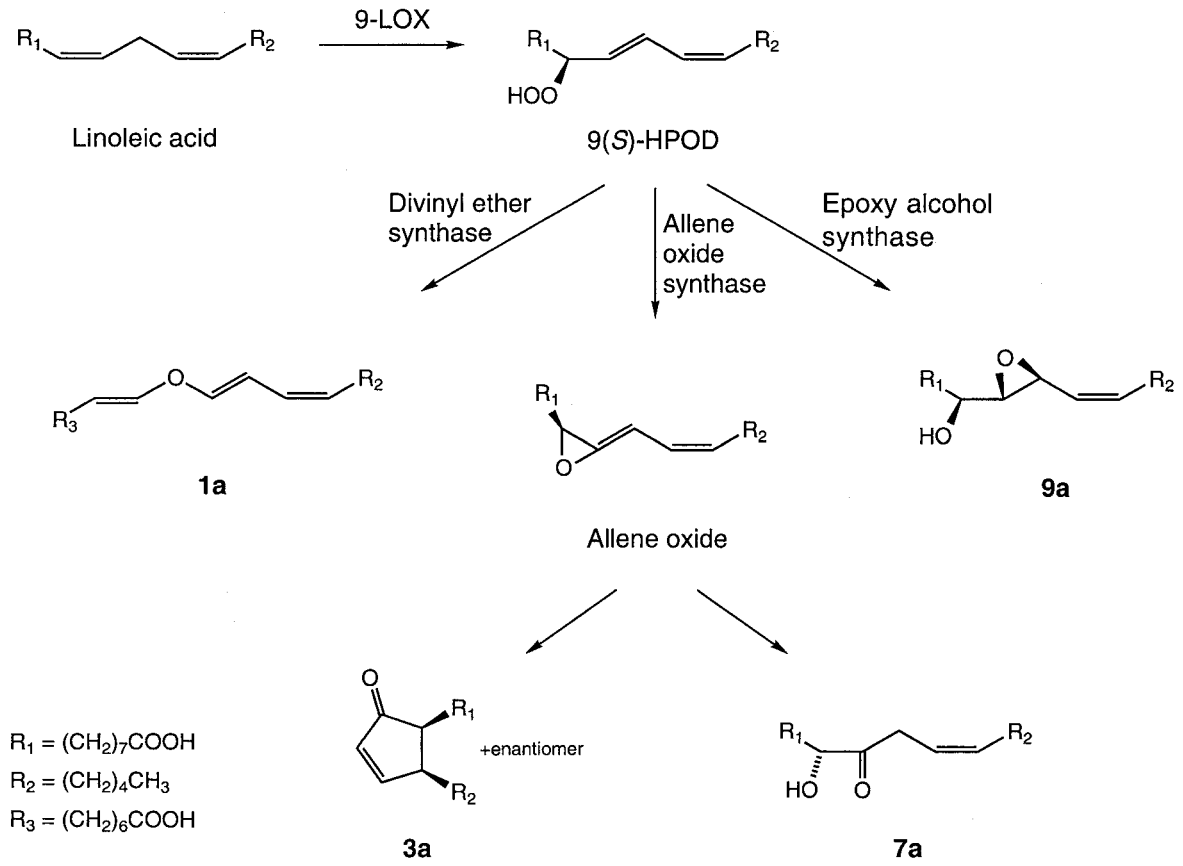
(*ii) Stereochemical compositions of **3a** and **7a***. Compounds **3b** and **7b** obtained from the various incubations shown in Table 3 were subjected to steric analysis using CP-HPLC. As seen in Table 3, cyclopentenone **3a** was consistently formed as a racemate, whereas the α-ketol **7a** was enriched with respect to the *R* enantiomer. The latter result was in agreement with its mode of formation from the allene oxide partly by S_N2 type of hydrolysis at C-9 (8,9,22,23). Interestingly, **7a** generated in the potato stolon system had an enantiomeric purity that was significantly higher than that of **7a** produced in the corn seed system (Table 3).

*(iii) Formation of **3a** in different parts of the potato plant*. Whole homogenate preparations (1:10, wt/vol; 5 mL) of different parts of the potato plant were stirred with linoleic acid or 9(*S*)-HPOD (200 μM), and the amounts of **3a** were determined by GC–MS. As seen in Table 4, the highest levels were obtained with homogenates of roots and stolons. Homogenate of potato tubers gave smaller amounts, and leaves produced no detectable levels of **3a**. The fact that multiple enzymes metabolizing 9(*S*)-HPOD were present in the homogenates used meant that the amounts of **3a** did not necessarily reflect the capacity of formation of **3a**. Rather, the values indicated the partitioning of 9(*S*)-HPOD between different hydroperoxide-degrading enzymes present in the tissue preparations.

DISCUSSION

The present study is mainly concerned with the metabolism of linoleic acid by an enzyme preparation from potato stolons. The initial reaction was catalyzed by a 9-lipoxygenase (9-LOX) and resulted in the formation of 9(*S*)-HPOD. Three enzymes, i.e., divinyl ether synthase, epoxy alcohol synthase and AOS, catalyzed the further metabolism of 9(*S*)-HPOD to afford colneleic acid (**1a**), the epoxy alcohol 10(*S*),11(*S*)-epoxy-9(*S*)-hydroxy-12(*Z*)-octadecenoic acid (**9a**), and the allene oxide 9(*S*),10-epoxy-10,12(*Z*)-octadecadienoic acid, respectively (Scheme 2). Of these compounds, colneleic acid was originally obtained following incubation of linoleic acid with a preparation of potato tubers (14), and the epoxy alcohol was recently isolated as one of the major products of linoleic acid metabolism in homogenate of potato leaves (13). The allene oxide, like allene oxides derived from the 13-hydroperoxides of linoleic and linolenic acids (8,23), was highly unstable and had an estimated half-life at 0°C of 44 s. No attempts at its isolation were made; however, its presence was proved by trapping experiments with methanol, which afforded 9-methoxy-10-oxo-12(*Z*)-octadecenoic acid. Furthermore, when brief incubations of 9(*S*)-HPOD were carried out at 0°C and interrupted by the addition of 20 vol of the nonhydroxylic solvent acetonitrile, the two macrolactones **15** and **16** were formed. These compounds had been encountered in an earlier study as products formed by intramolecular trapping of the allene oxide structure (9). Under normal conditions for incubation, further conversion of the allene oxide resulted in the formation of compounds **7a** and **3a** (Scheme 2). α-Ketol **7a** was originally isolated and characterized in a study of linoleic acid metabolism in corn seed homogenate (24) and was later shown to be a product formed by hydrolysis of an allene oxide generated by corn seed AOS (9). Cyclopentenone **3a**, a new oxylipin, was fully characterized by chemical and spectral methods. Steric analysis by NMR spectroscopy, CP-HPLC, and GLC demonstrated that the two appendages of the five-membered ring had the *cis* relative configuration and that the compound was a racemate consisting of equal parts of the 9(*R*),13(*R*) and 9(*S*),13(*S*) enantiomers. Compounds related to **3a** had been encountered previously in studies of the formation of cyclopentenones employing the hydroperoxides 9(*S*)-hydroperoxy-6(*Z*),10(*E*),12(*Z*)-octadecatrienoic acid (5,25) and 9(*R*,*S*)-hydroperoxy-10(*E*),12(*E*)-octadecadienoic acid (26), i.e., two hydroperoxides which are not typical constituents of plant tissue. In the present study, natural linoleic acid 9-hydroperoxide served as the precursor of cyclopentenone, and this result was extended to linolenic acid and its 9-hydroperoxide, which were metabolized to cyclopentenone **11a**. This compound [10-oxo-11,15(*Z*)-phytodienoic acid] was a regioisomer of the jasmonate precursor 12-oxo-10,15(*Z*)-phytodienoic acid, differing from this compound with respect to the positions of the keto group and the double bond in the five-membered ring.

Studies of the mode of formation of cyclopentenone **3a** and α-ketol **7a** were carried out by performing incubations of 9(*S*)-HPOD with the 105,000 × *g* particle fraction of homogenate of potato stolons. As seen in Table 3, formation of **3a**, as monitored by the ratio **3a**/**7a**, was temperature- and pH-dependent. Interestingly, when different concentrations of 9(*S*)-HPOD (30–300 μM) were used, thus providing varying concentrations of the corresponding allene oxide, the ratio **3a**/**7a** remained unchanged. Likewise, diluting the enzyme preparation 10-fold did not affect the ratio. These results, and the fact that **3a** was isolated as a racemate, suggested that **3a** (and **11a**) were formed from their allene oxide precursors by way of nonenzymatic cyclization. This conclusion was unexpected in view of the fact that earlier reported cases of nonen-



SCHEME 2

zymatic cyclization of fatty acid allene oxides had been restricted to allene oxides possessing a double bond in the β,γ-position relative to the epoxide group (5,15,23,27). In agreement with this notion, it was confirmed in the present study that the allene oxide generated from 9(*S*)-HPOD using the previously studied AOS from corn seeds (8,9,15) was a very poor precursor of cyclopentenone (Table 3, Fig. 3). Interestingly, the potato stolon and corn seed AOS-catalyzed reactions differed also in another way, i.e., with respect to the enantiomeric composition of the α-ketol product (Table 3). The large proportion of the *R* enantiomer in **7a** produced by the potato stolon AOS indicated that this α-ketol was formed from its allene oxide precursor largely by an S_N2-type of hydrolysis (*cf.* Refs. 8,23). A third difference between the potato stolon and corn seed AOS preparations was the different extent of formation of the γ-ketol **14a** (Table 3). Further studies are needed in order to explain these results. It can only be speculated that a configurational or conformational property in the allene oxide generated by the potato stolon AOS exists, or is induced, which has consequences for the further conversion of the allene oxide.

It seems likely that the cyclopentenones **3a** and **11a** can be further converted in plant tissue in the same way as 12-oxo-PDA, i.e., by reduction of the ring double bond and β-oxidation. Such transformations as well as the biological properties of the new cyclopentenones are being studied (Kod, Y., and Hambeg, M., unpublished data).

ACKNOWLEDGMENTS

Gunvor Hamberg is thanked for expert technical assistance. The author is indebted to Prof. Per-Erik Jansson and Reine Eserstam (Clinical Research Center, Huddinge University Hospital, Stockholm) for their help with the NMR analyses and to Dr. A.N. Grechkin (Institute of Biochemistry and Biophysics, Russian Academy of Sciences, Kazan, Russia) and Prof. B.A. Hess (Department of Chemistry, Vanderbilt University, Nashville, TN) for discussion of possible mechanisms of allene oxide cyclization into cyclopentenones. This work was supported by the Swedish Medical Research Council (Proj. No. 03X-5170) and by Vesical Co. (Stockholm).

ABSTRACT: Fatty acid α-hydroxylase from *Sphingomonas paucimobilis* is an unusual cytochrome P450 enzyme that hydroxylates the α-carbon of fatty acids in the presence of H_2O_2. Herein, we describe our investigation concerning the utilization of various substrates and the optical configuration of the α-hydroxyl product using a recombinant form of this enzyme. This enzyme can metabolize saturated fatty acids with carbon chain lengths of more than 10. The K_m value for pentadecanoic acid (C_{15}) was the smallest among the saturated fatty acids tested (C_{10}–C_{18}) and that for myristic acid (C_{14}) showed similar enzyme kinetics to those seen for C_{15}. As shorter or longer carbon chain lengths were used, K_m values increased. The turnover numbers for fatty acids with carbon chain lengths of more than 11 were of the same order of magnitude (10^3 min^{-1}), but the turnover number for undecanoic acid (C_{11}) was less. Dicarboxylic fatty acids and methyl myristate were not metabolized, but monomethyl hexadecanedioate and ω-hydroxypalmitic acid were metabolized, though with lower turnover values. Arachidonic acid was a good substrate, comparable to C_{14} or C_{15}. The metabolite of arachidonic acid was only α-hydroxyarachidonic acid. Alkanes, fatty alcohols, and fatty aldehydes were not utilized as substrates. Analysis of the optical configurations of the α-hydroxylated products demonstrated that the products were *S*-enantiomers (more than 98% enantiomerically pure). These results suggested that this P450 enzyme is strictly responsible for fatty acids and catalyzes highly stereo- and regioselective hydroxylation, where structure of ω-carbon and carboxyl carbon as well as carbon chain length of fatty acids are important for substrate–enzyme interaction.

Paper no. L8370 in *Lipids 35*, 365–371 (April 2000).

α-Hydroxy fatty acids are found in the sphingolipids of a wide variety of organisms. *Sphingomonas paucimobilis* is a bacterium having a large amount of sphingolipids, most of which contain α-hydroxymyristic acid as an acyl moiety (1). To clarify biosynthesis of α-hydroxy fatty acids, we have used *S. paucimobilis* as a source of fatty acid α-hydroxylase and identified this enzyme and its gene (2). Sequence analysis of the fatty acid α-hydroxylase gene and spectral analysis of the recombinant enzyme revealed that this enzyme is a member of cytochrome P450 (P450) superfamily. Interestingly, this P450 enzyme [designated $P450_{SP\alpha}$ here; tentatively given systematic name of CYP 152B1 by Dr. David Nelson, University of Tennessee Medical Center (personal communication)] oxidizes fatty acids with high turnover rates in the presence of H_2O_2, where an oxygen atom from H_2O_2 is introduced into the α-carbon of fatty acids to form the corresponding α-hydroxy fatty acids (3). Moreover, we demonstrated that $P450_{SP\alpha}$ specifically required H_2O_2, but not other hydroperoxides such as cumene hydroperoxide (4).

Many P450 enzymes have been isolated from various organisms, including both prokaryotes and eukaryotes, and then characterized. P450 enzymes constitute a superfamily, members of which catalyze hydroxylation of a variety of endogenous substances (e.g., fatty acids) and xenobiotics (e.g., drugs and other hydrocarbon derivatives in the environment). In terms of the hydroxylation of fatty acids by P450 enzymes, ω-hydroxylation has been well studied. From these studies, researchers have determined that some fatty acid-hydroxylating P450 can, to some extent, metabolize hydrocarbon substrates other than fatty acids, i.e., the substrate specificity may not be specifically limited. In fact, some members of the CYP 4 and CYP 52 families are able to ω-hydroxylate alkanes, fatty alcohols, and fatty aldehydes, as well as fatty acids. CYP 4A1, which ω-hydroxylates fatty acids such as lauric acid, is also able to metabolize lauroyl alcohol but not dodecane (5). CYP 4B1, which is most commonly recognized as a xenobiotics-metabolizing P450 enzyme, hydroxylates *n*-alkanes as well as fatty acids (6). CYP 52A3, isolated from an alkane-assimilating yeast, is able to metabolize hexadecane, 1-hexadecanol, hexadecanal, hexadecanoic acid, and 16-hydroxyhexadecanoic acid (7).

Regioselectivity of the hydroxylated carbon of fatty acids appears to be loosely restricted. For example, CYP102A, which is a bacterial P450 enzyme metabolizing fatty acids, attacks not only the n-1, n-2, or n-3 carbon of fatty acids to produce hydroxy fatty acids but also double bonds of polyunsaturated fatty acids to produce epoxy fatty acids (8). In contrast to

Abbreviations: *ADAM*, 9-anthryldiazomethane; GC–MS, gas chromatography–mass spectrometry; HPLC, high-performance liquid chromatography; P450, cytochrome P450; $P450_{SP\alpha}$, fatty acid α-hydroxylating P450 enzyme from *Sphingomonas paucimobilis*; TMS, trimethylsilyl.

regioselectivity, ω-hydroxylation of fatty acid by P450 is enantiomerically restricted. In the case of CYP102A, highly stereoselective oxidation of polyunsaturated fatty acids such as arachidonic acid has been reported (8).

In a previous study (4), we observed that $P450_{SP\alpha}$ metabolizes several saturated and monounsaturated fatty acids. However, it remained to be elucidated whether $P450_{SP\alpha}$ was able to metabolize other hydrocarbon derivatives such as long-chain alkanes, fatty alcohols, fatty aldehydes, and xenobiotics, and whether stereospecific hydroxylation occurred. In this study, we investigated whether various hydrocarbon derivatives were utilized as substrates of $P450_{SP\alpha}$. Additionally, we performed kinetic studies to elucidate the affinity of the substrate for the enzyme and, moreover, investigated the optical configurations of the α-hydroxyl products by the reaction of $P450_{SP\alpha}$. Based on the results obtained, we discuss what $P450_{SP\alpha}$ requires structurally of its substrates.

MATERIALS AND METHODS

Materials. 1,14-Tetradecanedioic acid, 1,16-hexadecanedioic acid, monomethyl hexadecanedioate, and 9-anthryldiazomethane (ADAM) were purchased from Funakoshi Co., Ltd. (Tokyo, Japan). Other fatty acids, 7-ethoxycoumarin, and 7-ethoxyresorufin were purchased from Sigma-Aldrich Japan (Tokyo, Japan). Diazomethane was synthesized from *N*-nitroso-*N*-methylurea (Sigma-Aldrich Japan). *n*-Tetradecane and cholic acid were purchased from Nacarai Tesque (Kyoto, Japan). Benzphetamine was provided as a gift from Upjohn (Kalamazoo, MI). [1-^{14}C]Myristic acid was obtained from Daiichi Pure Chemicals Co. Ltd. (Tokyo, Japan). Other reagents were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan).

Preparation of the recombinant $P450_{SP\alpha}$ and enzyme assay. Expression and purification of the recombinant $P450_{SP\alpha}$ was described previously (9). The recombinant enzyme was almost pure, as manifested by sodium dodecyl sulfate-polyacrylamide gel electrophoresis. The purified enzyme was then dissolved in 0.1 M sodium phosphate buffer (pH 7.0), 30% ethylene glycol, 0.4% cholate, and 1mM dithiothreitol. The standard reaction mixture contained 0.1 M Tris-HCl (pH 8.0), 0.2 mM H_2O_2, 80 μM substrate, and 1 pmol of $P450_{SP\alpha}$ in a total volume of 0.2 mL. All of the substrates were added to the reaction mixture as an ethanol solution. When fatty acids were used as the substrates, α-hydroxylation activity was determined as described previously (4). Briefly, the reaction was carried out at 37°C for 2 min and then stopped by the addition of HCl. The fatty acid substrate and the product were extracted with ethyl acetate. After washing the extract with distilled water, the organic layer was collected. The extract was evaporated and then the residue was treated with ADAM. ADAM-derivatized fatty acids were analyzed by high-performance liquid chromatography (HPLC) according to a minor modification of the method described by Sawamura *et al.* (10). Kinetic studies for fatty acid substrates were carried out within the substrate concentration of 0 to 120 μM.

For determination of the metabolites by the reaction of $P450_{SP\alpha}$ by gas chromatography–mass spectrometry (GC–MS), the product and the substrate were extracted by ethyl acetate, and the extract was washed with distilled water and evaporated. The residue was treated with diazomethane and then with *N*,*O*-bis(trimethylsilyl)trifluoroacetamide. The methyl, trimethylsilyl (TMS) product and substrate were dissolved in hexane and subjected to GC–MS analysis described previously (9).

When methyl myristate, *n*-tetradecane, 1-tetradecanol, or tetradecanal was used as the substrate, the hydrocarbon derivatives were extracted by chloroform/methanol (2:1, vol/vol) after the reaction of $P450_{SP\alpha}$ and α-hydroxylation activity was determined by analysis of gas chromatography (9). In turn, H_2O_2 consumption in this reaction was determined by using the method of Bos *et al*. (11) to confirm whether $P450_{SP\alpha}$ utilized these compounds as the substrates. Competition experiments of myristic acid α-hydroxylation by these hydrocarbon derivatives were performed by the assay method using [1-^{14}C]myristic acid and thin-layer chromatography as described previously (3). Briefly, the assay condition was the same as described above except the reaction mixture contained 80 μM [1-^{14}C]myristic acid (231 Bq/nmol) as a substrate and 800 μM myristic acid analog as a competitor. After the reaction, nonradiolabeled myristic acid and α-hydroxymyristic acid were added as carriers into the reaction mixture, the reaction mixture was extracted with ethyl acetate, and the extract was evaporated. The residue was dissolved in a small amount of ethanol, applied to a thin-layer plate of silica gel G (Analtech Inc., Newark, DE), and developed with hexane/diethylether/acetic acid (70:30:3, vol/vol/vol). The lipid spots corresponding to myristic acid and α-hydroxymyristic acid were detected by spraying distilled water; they were scraped from the plate, and the radioactivities were determined by liquid scintillation counting.

N-Demethylation activities for benzphetamine were determined by measuring formaldehyde production (12). O-Deethylation activities for 7-ethoxycoumarin and 7-ethoxyresorufin were determined by the method of Greenlee and Poland (13) and the method of McDanell and McLean (14), respectively.

Analysis of optical configuration of α-hydroxy fatty acids. The optical configuration of the α-hydroxyl products was determined by HPLC with an OA-3100 column (Sumika, Osaka, Japan) according to the method of Nakagawa *et al*. (15). For the analysis of optical configuration, the enzyme preparation was dialyzed against 0.1 M Tris-HCl (pH 7.5), 30% ethylene glycol, and 1 mM dithiothreitol in order to remove cholate. After the reaction by $P450_{SP\alpha}$ the α-hydroxyl fatty acids were treated with 3,5-dinitrophenyl isocyanate (SUMIKA, Osaka, Japan) in the presence of a small amount of dry pyridine at room temperature overnight. Solvents used for analysis of the products included methanol containing 50mM ammonium acetate and 10% distilled water. The flow rate was 0.5 mL/min.

RESULTS

Substrate specificity. We investigated the utilization of various substrates by $P450_{SP\alpha}$. $P450_{SP\alpha}$ was able to metabolize saturated fatty acids with carbon chain lengths of 11 to 18 (Table

TABLE 1
Substrate Specificity of $P450_{SP\alpha}$

Tetradecanal[c]		

[a]Kinetic study was performed within the substrate concentration range of 0 to 120 μM. The highest activity is shown.
[b]The activity was determined by high-performance liquid chromatographic analysis (see Material and Methods section).
[c]The activity was determined by gas chromatography and H_2O_2 consumption (see Material and Methods section). —, Catalytic activity not detected.

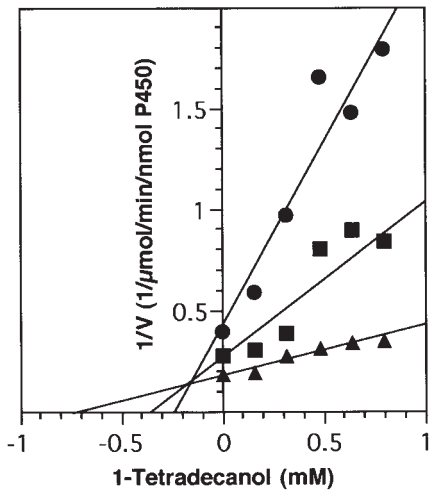

FIG. 1. Inhibition of myristic acid α-hydroxylation by 1-tetradecanol. Dixon plot of α-hydroxylation activity in the presence of 30 μM (●), 60 μM (■), and 120 μM (▲) of myristic acid. The K_i value was 145 μM.

1). No activity was detected when capric acid was used as a substrate. 1,14-Tetradecanedioic acid and 1,16-hexadecanedioic acid were not metabolized by $P450_{SP\alpha}$, whereas 16-hydroxypalmitic acid and monomethyl hexadecanedionate were α-hydroxylated. Methyl myristate was not metabolized. Interestingly, though, $P450_{SP\alpha}$ can metabolize arachidonic acid with a high turnover rate. Among fatty acid analogs, no hydroxylated products of *n*-tetradecane, 1-tetradecanol, and tetradecanal were detected by gas chromatography. Moreover, when 1,14-tetradecanedioic acid, methyl myristate, *n*-tetradecane, 1-tetradecanol, or tetradecanal were used as substrates, no H_2O_2 consumption was detected in the same assay conditions where myristic acid substrate was completely α-hydroxylated (data not shown). To further confirm that these hydrocarbon derivatives were not metabolized by $P450_{SP\alpha}$, the inhibition of myristic acid α-hydroxylation by these same hydrocarbon derivatives was investigated. In the absence of competitor, the reactive rate was 2.3 ± 0.2 μmol product formed/min/nmol of $P450_{SP\alpha}$, where values are means ± SD, calculated from triplicate experiment. In the presence of the following competitors [added at a concentration 10-fold that of myristic acid (80 μM)], the reaction rates are given as μmol product formed/min/nmol of $P450_{SP\alpha}$: methyl myristate, 27 ± 0.3; 1,14-tetradecanedioic acid, 2.2 ± 0.1; *n*-tetradecane, 3.3 ± 0.1; 1-tetradecanol, 1.2 ± 0.03; tetradecanal, 2.3 ± 0.1. That is, no inhibition was observed when 1,14-tetradecanedioic acid, methyl myristate, tetradecanal, or *n*-tetradecane were added as competitors, while the α-hydroxylation activity was, to some extent, increased by the addition of *n*-tetradecane. These results suggested that at least 1,14-tetradecanedioic acid, methyl myristate, tetradecanal, or *n*-tetradecane did not bind to the catalytic pocket of $P450_{SP\alpha}$. Unexpectedly, the addition of 1-tetradecanol significantly inhibited myristic acid α-hydroxylation. This inhibition seemed to be competitive in nature toward myristic acid (Fig. 1). N-Demethylation of benzphetamine and O-deethylation of 7-ethoxycoumarin or 7-ethoxyresorufin were not detected even when excess amounts of $P450_{SP\alpha}$ were used (data not shown).

Determination of metabolite by GC–MS. In order to determine the metabolite of arachidonic acid following the reaction with $P450_{SP\alpha}$, we analyzed a methyl, trimethyl (TMS) derivative of the product by GC–MS. The total ion chromatogram showed that only one product was found at the retention time of 22.1 min (Fig. 2A). The fragmentation pattern of this product corresponded to that of the methyl, TMS derivative of α-hydroxyarachidonic acid (Fig. 2B). The ion of *m/z* 391 (M – 15) is formed by cleavage between CH_3 and Si of the TMS moiety. The ion of *m/z* 347 (M – 59) is the characteristic fragment ion of a 2-hydroxy fatty acid that has lost the carboxylmethyl group of *m/z* 406 (M). Cleavage of the C_2–C_3 bond and the McLafferty rearrangement yield *m/z* 162. No peaks derived from auto-oxidation products were detected. Therefore, we concluded that the metabolite of arachidonic acid was only α-hydroxyarachidonic acid. Furthermore, we determined the metabolites of 16-hydroxypalmitic acid and monomethyl hexadecanedioate by GC–MS. In the mass spectra of methyl, TMS-derivatives of the metabolites that we obtained, peaks of (M – 15) ion and (M – 59) ion were found (data not shown). Thus, these metabolites were α-hydroxyl derivatives of 16-hydroxypalmitic acid and monomethyl hexadecanedioate, respectively.

Kinetic study for various fatty acid substrates. We attempted to determine the affinity of substrate for $P450_{SP\alpha}$ by spectral analysis, but failed because $P450_{SP\alpha}$ did not show significant substrate-binding spectra. Thus, we performed kinetic studies for various fatty acid substrates in order to estimate the affinity

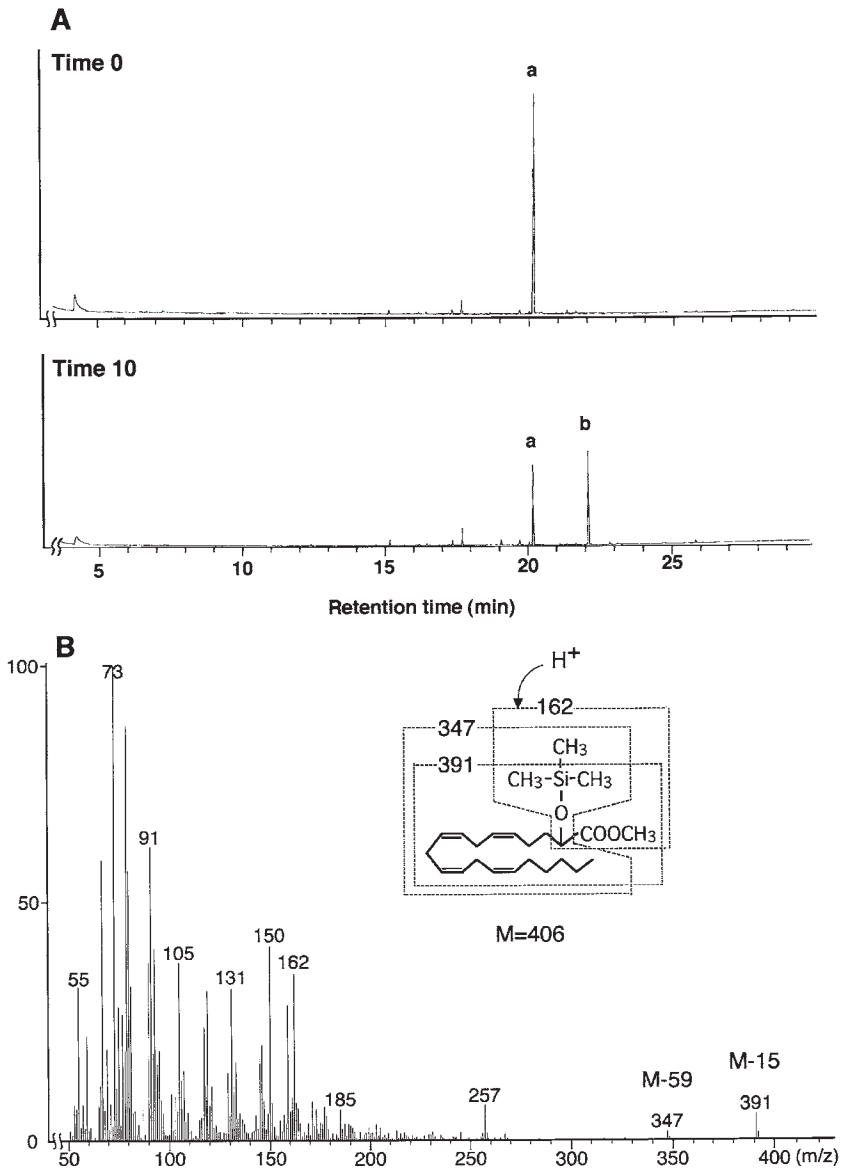

FIG. 2. Gas chromatography–mass spectrometric analysis of arachidonic acid metabolite from the reaction with $P450_{SP\alpha}$. (A) Total ion chromatograms at time 0 and after a 10 min incubation of $P450_{SP\alpha}$. Peaks of arachidonic acid and its metabolite are indicated as **a** and **b**, respectively. (B) Mass spectrum of the methyl, trimethylsilyl metabolite of arachidonic acid from the reaction with $P450_{SP\alpha}$.

of substrate for the enzyme by their apparent K_m values. When saturated fatty acids were used as the substrates, pentadecanoic acid showed the smallest K_m value (Table 1). The K_m value for myristic acid was comparable to that of pentadecanoic acid. As shorter or longer carbon chain lengths were tested for the fatty acids, the K_m values increased. The turnover rates for the fatty acids with carbon chain lengths of more than 11 were similar, but that for undecanoic acid was about eightfold smaller than that for myristic acid. The K_m value and turnover rate for ω-hydroxypalmitic acid were approximately twofold greater and sevenfold smaller than those of palmitic acid, respectively. The K_m value for monomethyl hexadecanedioate was threefold greater than that for ω-hydroxypalmitic acid. The K_m value and the turnover rate for arachidonic acid were comparable to those for myristic acid or pentadecanoic acid.

Configuration of α-hydroxyl products. We investigated the optical configuration of the α-hydroxyl product when myristic acid was used as a substrate. By HPLC analysis of the 3,5-dinitrophenyl isocyanate derivative of hydroxymyristic acid, a peak and a second very small peak, newly produced after the α-hydroxylation reaction, were detected at the retention times of 23.5 and 18.9 min, respectively (Fig. 3A). The retention times of these peaks corresponded to those of *S*-α-hydroxymyristic acid and *R*-α-hydroxymyristic acid, respectively. α-

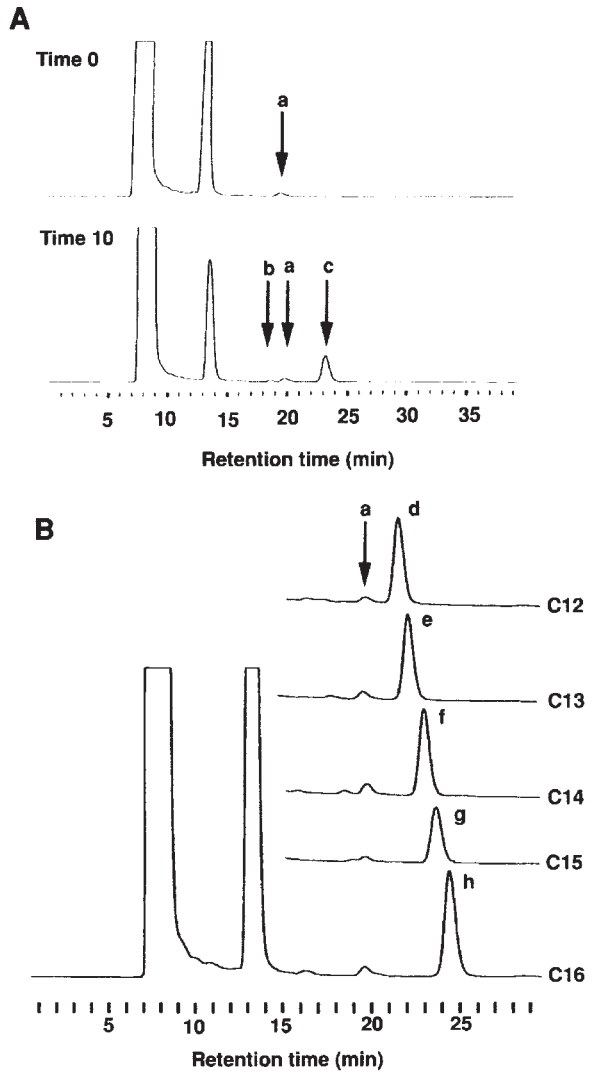

FIG. 3. Stereospecific α-hydroxylation of fatty acids by $P450_{SP\alpha}$. (A) High-performance liquid chromatographic (HPLC) analysis of optical configuration of the myristic acid metabolite at time 0 and after a 10 min incubation with $P450_{SP\alpha}$. Arrows show the retention times of authentic *R*-enantiomer (**b**, 18.9 min), *S*-enantiomer (**c**, 23.5 min), and cholic acid (**a**, 20.1 min). (B) HPLC analysis of optical configuration of the products when lauric acid (C_{12}), tridecanoic acid (C_{13}), myristic acid (C_{14}), pentadecanoic acid (C_{15}), and palmitic acid (C_{16}) were used as the substrates. The retention times of major peaks (**d**–**h**) correspond to those of *R*-α-hydroxy fatty acids.

Hydroxy fatty acids produced during reactions with $P450_{SP\alpha}$ were nearly enantiomerically pure (more than 98%). Next, we investigated the effect of carbon chain length of fatty acids for enantiomerically restricted hydroxylations. As shown in Figure 3B, any dominant products obtained from these reactions were *S*-enantiomers (L-form) when fatty acids with carbon chain lengths of 12 to 16 were used as the substrates. The amounts of derived *R*-α-hydroxy fatty acids were, if any, very small.

DISCUSSION

$P450_{SP\alpha}$ was strictly responsible for fatty acids and did not act upon any of the additional substrates known to exist for the other fatty acid-hydroxylating P450. This specificity of the enzyme was different from other members of fatty acid-hydroxylating P450 family such as CYP 4 and CYP 52. The observation that $P450_{SP\alpha}$ utilized fatty acids but not long-chain alkanes, fatty alcohols, and fatty aldehydes suggests that the negative charge of the carboxyl moiety of fatty acid substrates is crucial for appropriate substrate–enzyme interaction. In fact, methylation of the carboxyl moiety of myristic acid appeared to prevent substrate binding, as judged from competition analysis. Alterman *et al.* (5) proposed a model of the CYP 4A1 active site and described its key feature as a recognition site for a carboxyl or polar end group located approximately the length of an extended 12-carbon chain from the heme iron. Presumably owing to the relatively loose selectivity of this recognition site, CYP 4A1 utilized lauryl alcohol, methyl laurate, and lauric acid as substrates. In the case of $P450_{SP\alpha}$, selectivity of such recognition sites, if it does exist as the data suggest, appears to be more strict. This selective recognition site may be located near the heme iron, given that $P450_{SP\alpha}$ attacks α-carbon of fatty acids. Fatty alcohol appears to bind to the catalytic pocket of $P450_{SP\alpha}$ with low affinity, but is not metabolized by $P450_{SP\alpha}$. Although this reason remains unclear, fatty alcohol may not be able to bind in the catalytic pocket in an appropriate position to permit its metabolism.

The structures of the ω-end of fatty acid substrates also affect utilization of substrate by $P450_{SP\alpha}$. ω-Hydroxy fatty acid was metabolized with a higher K_m value and a lower turnover rate than the corresponding nonhydroxy fatty acid. The hydroxyl group of the ω-carbon of a fatty acid appeared to prevent substrate affinity and metabolism by $P450_{SPa}$. Moreover, dicarboxylic fatty acids with carbon chain lengths of 14 and 16 were not metabolized, whereas monomethyl derivatives of 1,16-hexadecanedioic acid were metabolized, although with higher K_m values and lower turnover rates. Because the fatty acid methylated on one hand of two carboxyl moieties was able to bind $P450_{SP\alpha}$ and was metabolized, the negative charge of the carboxyl moiety of dicarboxylic fatty acid appear to prevent substrate binding to the catalytic pocket of $P450_{SP\alpha}$. Interestingly, such substrate specificity has been observed on *Pisum sativum* α-oxidase which does not metabolize dicarboxylic acid but is able to metabolize monomethyl ester of the dicarboxylic acid, albeit at a significant diminished reaction rate (16).

Fatty acid substrates with carbon chain lengths of more than 11 were metabolized with high turnover rates. However, the turnover rate was dramatically decreased when undecanoic acid was used as a substrate, and capric acid was not metabolized at all by $P450_{SP\alpha}$. These results indicated that a carbon chain length of at least 12 was required for effective metabolism by $P450_{SP\alpha}$. As described in the Results Section, we were not able to determine the binding affinities of substrates for this

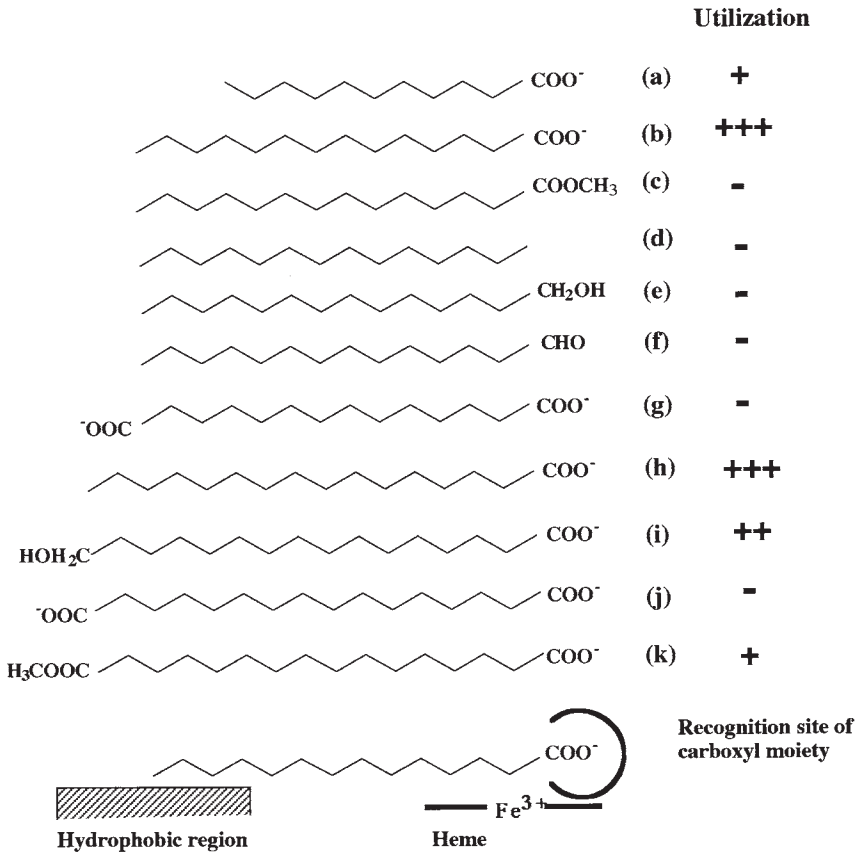

FIG. 4. Utilization of substrates by $P450_{SP\alpha}$ and schematic representation of a presumed model of catalytic pocket of $P450_{SP\alpha}$. Degree of efficiency of each substrate utilization by $P450_{SP\alpha}$ was represented with 3+ (highly utilized), 2+ (moderately utilized), 1+ (slightly utilized), or minus (–, not utilized). (a) Undecanoic acid; (b) myristic acid; (c) methyl myristate; (d) -tetradecane; (e) 1-tetradecanol; (f) tetradecanal; (g) 1,14-tetradecanedioic acid; (h) palmitic acid; (i) 16-hydroxypalmitic acid; (j) 1,16-hexadecanedioic acid; (k) monomethyl hexadecanedioic acid.

enzyme by spectral analysis. Instead, we estimated the binding affinity of a given substrate from its apparent K_m value obtained by kinetic study. Among those for the saturated fatty acids tested, the K_m values for myristic acid or pentadecanoic acid were smallest, suggesting that fatty acids with 14 or 15 carbon atoms can bind to the enzyme most efficiently. In known ω-hydroxylating P450, a hydrophobic region interacting with the methylene unit of the substrate was theorized (6). In $P450_{SP\alpha}$, such a hydrophobic interaction between the enzyme and the fatty acid substrate could restrict substrate specificity.

Analysis of the optical configuration of a-hydroxy fatty acids produced by $P450_{SP\alpha}$ demonstrated that the product was nearly enantiomerically pure *S*-isomer. This result can be considered informative with respect to the biosynthesis of α-hydroxy fatty acid. For instance, Nakagawa *et al.* (15) clearly demonstrated that α-hydroxymyristic acid in sphingolipid of *S. paucimobilis* is the *S*-enantiomer (L-form). This observation was consistent with our result obtained from the optical configuration analysis of the α-hydroxyl product from $P450_{SP\alpha}$ supporting the idea that the α-hydroxymyristic acid in this bacterium is produced by $P450_{SP\alpha}$.

Capdevila *et al.* (8) demonstrated that arachidonic acid is a good substrate for CYP102A. Specifically, CYP102A metabolizes arachidonic acid to produce 18(*R*)-hydroxyeicosatetraenoic acid and 14(*S*),15(*R*)-epoxyeicosatrienoic acid in a highly stereoselective manner, and moreover, metabolizes eicosatrienoic acid to produce 17-, 18-, and 19-hydroxyeicosatrienoic acid. In the case of $P450_{SP\alpha}$, not only the stereoselectivity but also the regioselectivity of this enzyme were very strict. That is, $P450_{SP\alpha}$ strictly attacks the α-carbon of polyunsaturated fatty acids such as arachidonic acid as well as saturated fatty acids with different carbon chain lengths. Unlike CYP 102A, $P450_{SP\alpha}$ did not attack the double bond of arachidonic acid to produce epoxy fatty acid. Thus, it is possible that the α-carbons of fatty acids are "fixed", presumably near the heme group within the catalytic pocket of this enzyme.

In this study, we investigated the relationship between the structure of substrates and their utilization by $P450_{SP\alpha}$. The appropriate substrate for $P450_{SP\alpha}$ has a carboxyl moiety, a methyl

group in the ω-end, and a carbon chain length of more than 11. Here, we propose a presumed model of the catalytic pocket of $P450_{SP\alpha}$ (Fig. 4). In this model, the carboxyl moiety of the substrate is "recognized" by the site located near the heme group and the α-carbon of the substrate located at the position where the carbon most closely interacts with the heme iron. At the opposite site, the methylene group of the ω-terminus of the substrate loosely binds to the hydrophobic region in the catalytic pocket. The substrate is, thus, "fixed" by the recognition site and the hydrophobic region. To confirm whether this model is correct, analysis of crystal structure of $P450_{SP\alpha}$ is now required. Regardless, it is encouraging that progress is being made in characterizing this important enzyme. A molecule which is classified within the P450 group should provide important information about sphingolipid metabolism not only in this bacterium but also in other organisms, and the mechanism of P450 reactions in general.

ABSTRACT: The compositions of ester- and amide-linked fatty acids from ceramides of human vernix caseosa were described with emphasis on the distribution of the branched-chain fatty acid (BCFA). Two novel ceramides were isolated from vernix caseosa in the course of this study: the acylated type of esterified α-OH-hydroxyacid/sphingosine ceramide (Cer[EAS]) and nonacylated type of non-OH fatty acid/hydroxysphingosine ceramide (Cer[NH]). Their chemical structures were identified by nuclear magnetic resonance and chemical procedure. The Cer[EAS] was an acylceramide and consisted of the highest concentrations of ester- and amide-linked BCFA (62 and 67%, respectively). The iso- or anteiso-branching structures of the aliphatic chains were confirmed by the mass spectra of their picolinyl or pyrrolidide derivatives. As a whole, amide-linked fatty acids of ceramides 1-7 and Cer[NH] were normal types of straight-chain fatty acids with or without α- or ω-hydroxylation. The BCFA concentrations of amide-linked fatty acids in these ceramides (ceramides 1–7 and Cer[NH]) were low and less than 10%. The BCFA thus occurred exclusively in a novel acylceramide of Cer[EAS] in the vernix caseosa.

Paper no. L8401 in *Lipids 35,* 373–381 (April 2000).

Vernix caseosa is a mixture of lipids covering the skin surface of a fetus, and is believed to be a protective substance against undesirable influences from the environment (1). A number of studies therefore have been devoted to understanding the chemical nature of vernix caseosa (2–5). These studies, however, mainly focused on the chemical structures of the neutral lipids, and few studies were conducted to characterize the polar lipid of vernix caseosa. Our preliminary (Tokitsu, Y., unpublished data) and subsequent studies (6) have suggested that the polar lipid constituted a significant proportion of vernix caseosa, and the ceramides are the largest component of the polar lipids from human vernix caseosa.

The present study thus describes the amide- or ester-linked fatty acid compositions of ceramides from human vernix caseosa. Since our interest has been on the biosynthesis of the branched-chain fatty acids (BCFA) in mammalian skin tissues, a special emphasis was placed on the distribution of the BCFA among the ceramide subclasses. As a result, the present study is the first to demonstrate the presence of BCFA with or without α-hydroxy groups in the ceramides of human vernix caseosa, and also reveals a higher concentration of BCFA in acylceramides compared with the case for nonacylated-type of ceramides.

Abbreviations: BCFA, branched-chain fatty acid; Cer[EAS], esterified α-OH-hydroxyacid/sphingosine ceramide; Cer[NH], non-OH fatty acid/hydroxysphingosine ceramide; GC–MS, gas chromatography–mass spectrometry; HPTLC, high-performance thin-layer chromatography; NMR, nuclear magnetic resonance; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Vernix caseosa. Samples of vernix caseosa were collected from 22 male and 24 female newborn babies immediately after birth at the hospital of St. Marianna University School of Medicine. The vernix caseosa collected with a gauze was dissolved and stored in chloroform/methanol (2:1, vol/vol).

Purification of ceramides. The ceramides of human vernix caseosa were purified by a combination of column and thin-layer chromatography (TLC). Figure 1 shows the purification protocol of ceramides from human vernix caseosa. Vernix caseosa (4.1 g) was dissolved in a minimal volume of chloroform/methanol (39:1, vol/vol) and loaded to 450 g of Iatrobeads (6RS-8060, Iatron Laboratory, Tokyo, Japan) packed in a glass column (50 mm i.d. × 500 mm length). The column was then washed with 700 mL of chloroform/methanol (39:1, vol/vol) and eluted with the mixture of chloroform/methanol as shown in Figure 1. The eluant fractions in a volume of 200–300 mL were concentrated to dryness by flushing with a N_2 stream. The lipid concentrations of 11 successive fractions are shown in Figure 1. The ceramides in these Iatrobeads column fractions were further resolved by two developments of TLC (20 × 20 cm, 2-mm thickness; Merck, Tokyo, Japan). Development solvents used were chloroform/methanol (49:1, 39:1, or 29:1, vol/vol) for ceramides Cer[EAS], 1 and 2; chloroform/methanol (19:1, vol/vol) for ceramides 3, 4, 5, and Cer[NH]; and chloroform/methanol (15:1 or 9:1, vol/vol) for ceramides 6 and 7. (See the Results section for discussion of ceramide nomenclature.) The chromatogram was visualized by spraying 0.01% primuline, and the ceramide bands localized were extracted with chloroform/methanol (2:1, vol/vol). The identical ceramides were combined and further purified by TLC for homogeneity. Reso-

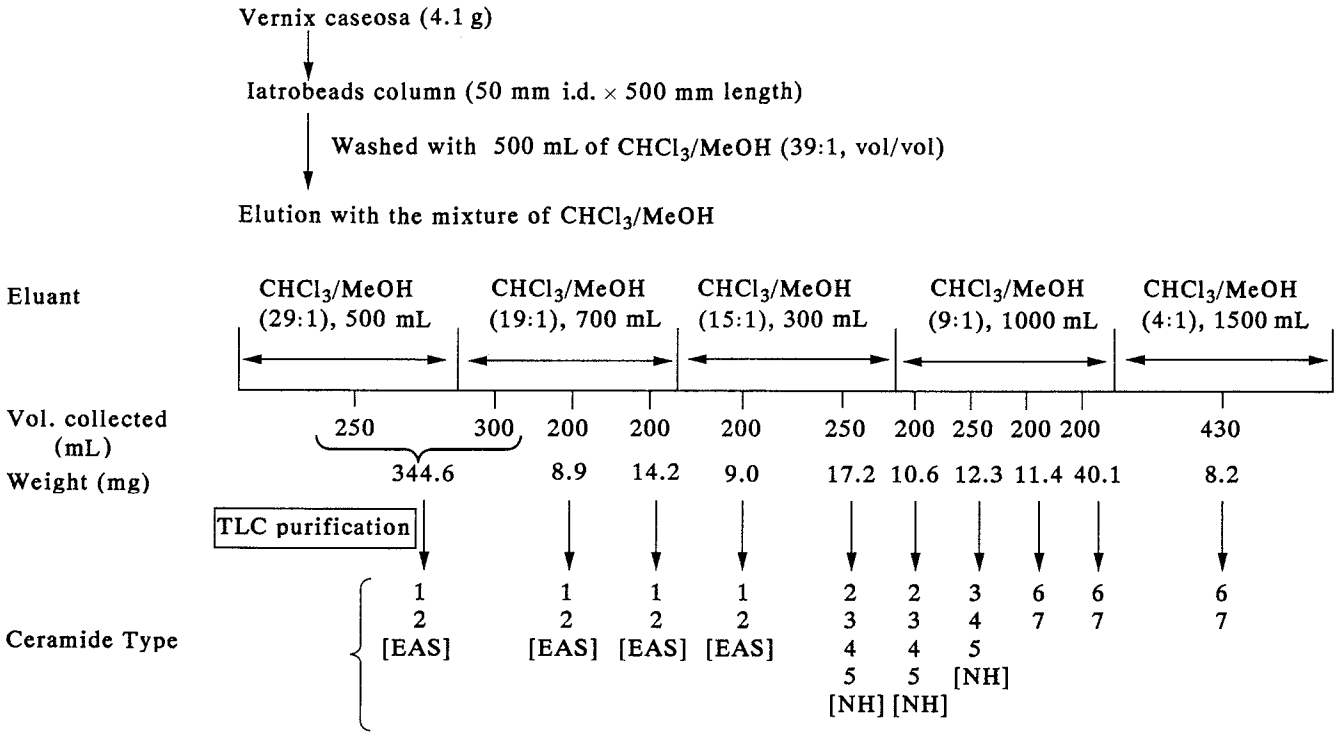

FIG. 1. Purification protocol of human vernix caseosa ceramides.

lution by TLC was repeated at least three times to give a single band on TLC analysis. The purified ceramides dissolved in chloroform/methanol (9:1, vol/vol) were passed through an Iatrobeads column packed in a cotton-plugged Pasteur pipette and concentrated to dryness for later analysis by high-performance thin-layer chromatography (HPTLC).

Chemical structure of ceramides. The chemical structure of ceramides was determined by proton nuclear magnetic resonance (NMR) spectra and by chemical procedure. Ceramides dissolved in $CDCl_3/CD_3OD$ (4:1, vol/vol) were used to obtain proton NMR spectra in a 400-MHz spectrometer (JMN-LA400; JEOL, Tokyo, Japan).

Fatty acid composition. The ester-linked fatty acids were liberated by alkaline hydrolysis and converted into methyl ester as follows. The acylceramide (1 mg) was reacted with 1 mL of 1 N NaOH in 95% methanol at 45°C for 60 min. The reactions were acidified to pH 2–3 with 2 N HCl, and mixed with 1.9 mL of chloroform and 0.72 mL of H_2O. The fatty acids extracted into chloroform were then redissolved in chloroform/methanol (19:1, vol/vol) and purified by passing through an Iatrobeads column packed in a Pasteur pipette.

The amide-linked fatty acids were directly transmethylated with methanolic hydrogen chloride. Briefly, ceramides (1 mg) dissolved in 1 N methanolic hydrogen chloride were heated at 75°C for 18 h in glass-stoppered tubes. Prepared fatty acid methyl esters were extracted into hexane and concentrated on a rotary evaporator. This transmethylation procedure also was applied for the preparation of the methyl esters from ester-linked fatty acids isolated as described above. In the case of amide-linked fatty acids, the methyl esters were further trimethylsilylated by heating them with (trimethylsilyl)trifluoroacetamide at 60°C for 10 min (7).

The fatty acid derivatives (3 μg) were analyzed by a gas chromatograph (GC 14A; Shimadzu, Kyoto, Japan) equipped with a flame-ionization detector. A fused-silica capillary column (CBP1-M50-025, 0.2 mm i.d. × 50 m length; Shimadzu) was used with nitrogen as the carrier gas at a flow rate of 0.35 mL/min. The column temperature was programmed from 50°C for 1 min, to 100°C at a rate of 10°C/min, and then raised to the final temperature of 300°C at a rate of 5°C/min. The final temperature for analysis of trimethylsilyl derivatives of α- or ω-hydroxy fatty acids was 320°C.

Chain structure of fatty acid. The identification of the chemical structure of fatty acids was made by interpretation of the mass spectrum. The amide- or ester-linked ceramide fatty acids were converted into picolinyl esters or pyrrolidides as described previously (7,8). The authors first attempted to prepare the picolinyl derivatives from both ester- and amide-linked fatty acids. Preparation of picolinyl esters from amide-linked fatty acids was, however, unsuccessful for unknown reasons. We therefore prepared pyrrolidides of amide-linked fatty acids, and analyzed them by gas chromatography–mass spectrometry (GC–MS). The mass spectrometer used was a Shimadzu GC/MS-QP1000EX. The column used was the same as described above, and operated with helium as the carrier gas at a flow rate of 0.38 mL/min. The column temperature was programmed from 50°C for 1 min to 100°C at a rate of 10°C/min, and then raised to the final temperature of 320°C at a rate of 5°C/min. Ionization of samples was by electron impact at 70 eV.

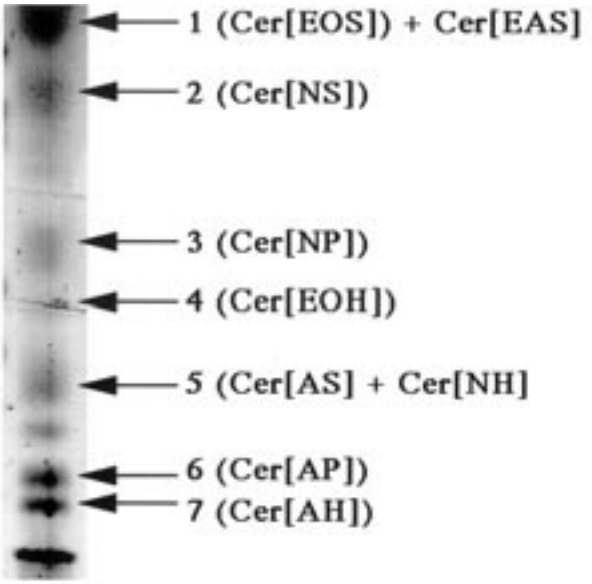

FIG. 2. High-performance thin-layer chromatogram of human vernix caseosa ceramides. Human vernix caseosa (100 μg) was spotted onto high-performance thin-layer chromatography plates, and developed first with benzene, followed by two developments with chloroform/methanol/acetic anhydride (180:10:1, by vol). The chromatogram was sprayed with 10% copper sulfate in 8% phosphoric acid, and charred at 180°C for 10 min. The authors adopted the nomenclature system of Motta *et al*. (9) for the new ceramides of Cer[EAS] and Cer[NH].

RESULTS

Figure 2 shows the HPTLC chromatogram of human vernix caseosa ceramides. The authors adopted the nomenclature system of Motta *et al*. (9) for the new ceramides based on grouping ceramides carrying structural similarities under common codes. The combination of Iatrobead column chromatography and TLC isolated two new types of ceramides, Cer[EAS] and Cer[NH], from human vernix caseosa besides the free types of ceramide 1–7. [While this paper was in preparation, Stewart and Downing (10) reported the presence of a new 6-hydroxy-4-sphingenine-containing ceramide identical to our Cer[NH] in human skin.] The identification of the chemical structure of new ceramides was mainly by interpretation of proton NMR spectra, and will be described in detail in a forthcoming paper. A densitometric analysis of the chromatogram revealed that the vernix caseosa had a higher concentration of ceramide 6 and a lower concentration of ceramide 5 compared with the data for adult epidermal lipid (11) (data not shown). In addition to new free ceramides, two unidentified ceramides also were seen between ceramides 2 and 3, and between ceramides 5 and 6 (see Fig. 2). The chemical structure for these novel ceramides should be determined in a coming study.

Cer[EAS] was resolved from ceramide 1 by TLC by two developments with chloroform/methanol (49:1, vol/vol), and migrated slightly faster than ceramide 1. The proton NMR spectrum showed that Cer[EAS] was an acylceramide, and the sphingoid base for this ceramide was dihydrosphingosine (sphinganine).

Figure 3 shows the gas chromatogram of the methyl ester of ester-linked fatty acids from Cer[EAS]. Inspection of the mass spectrum of fatty acid methyl ester found that the ester-linked fatty acids from Cer[EAS] consisted largely of saturated fatty acid. Furthermore, a major proportion of fatty acids was eluted slightly faster than the corresponding straight-chain fatty acid counterpart on gas chromatography, suggesting the presence of methyl branching in the aliphatic carbon chain of these fatty acids. The mass spectrum of the methyl esters gives little information on aliphatic chain structures. The fragmentation pattern of picolinyl ester, however, had been shown to be useful for the structural identification of the fatty acid carbon chain. The authors therefore prepared the picolinyl derivative from ester-linked fatty acids of Cer[EAS]. The gas chromatogram of picolinyl ester was similar to that of methyl ester with increased elution temperature.

Figures 4 and 5 depict the mass spectra for iso-24:0 and

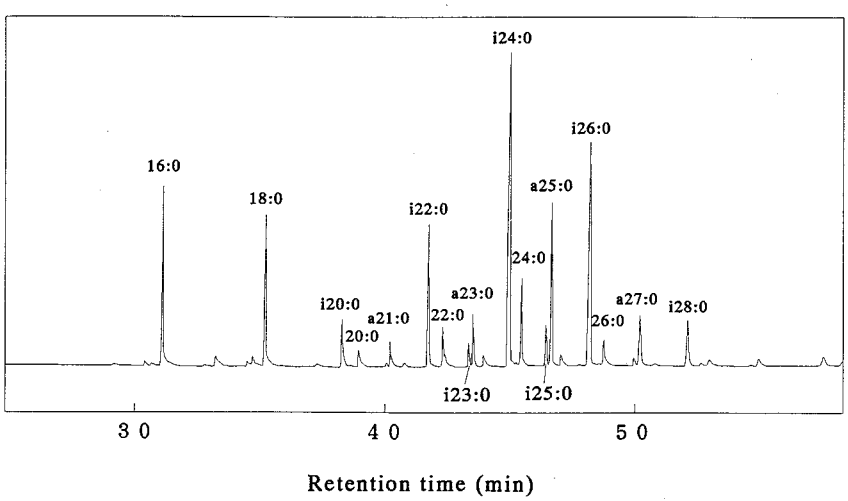

FIG. 3. Gas chromatogram of methyl ester of Cer[EAS] ester-linked fatty acid. The identifications for major fatty acid components are given. Abbreviations: i, iso; a, anteiso.

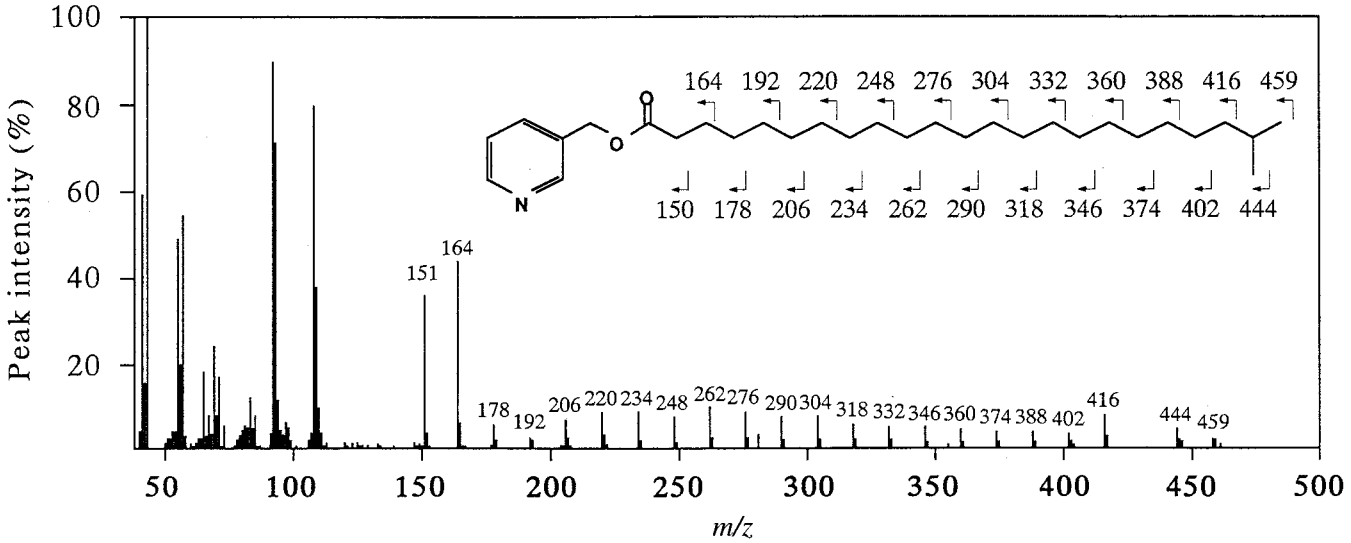

FIG. 4. Mass spectrum of picolinyl ester of iso-tetracosanoic acid (iso-24:0) from Cer[EAS] ester-linked fatty acids. The figure inset shows the formation of fragments.

anteiso-25:0 fatty acids esterified to Cer[EAS], respectively. As has already been demonstrated, the fragmentation pattern of the picolinyl ester was sensitive to the structure of the fatty acid aliphatic chain. The presence of a methyl substitution on one of the aliphatic carbons caused a 28-mass-unit gap in the series of fragments separated by 14 mass units. This series of ions can clearly be seen in the spectra of the picolinyl ester of the iso-24:0 and anteiso-25:0 fatty acids isolated from Cer[EAS]. The mass spectra for iso- and anteiso-fatty acids therefore lack M – 29 and M – 43 ions, respectively (see Figs. 4 and 5). Thus, we herein first demonstrate the presence of the BCFA in ceramides of human vernix caseosa. Inspection of the mass spectra found no evidence of the presence of other types of methyl-substituted fatty acids in this new ceramide.

Table 1 lists the composition of ester-linked fatty acids of Cer[EAS] from human vernix caseosa. The ester-linked fatty acids consisted of a large spectrum of fatty acids C_{16} to C_{28}. The largest component consisted of iso-24:0 fatty acids. The sum of the BCFA, iso- and anteiso-series, amounted to 62.6%, while the sum of the straight-chain fatty acids was 33.8%.

Figure 6 is the gas chromatogram of amide-linked fatty acids from Cer[EAS]. With respect to amide-linked fatty acids of Cer[EAS], there were a limited number of fatty acid components compared with ester-linked fatty acids. The mass spectrum of methyl ester showed that large parts of amide-linked fatty acids had the characteristic fragmentation profile of α-hydroxy fatty acids: the intense molecular ion, *m/z*

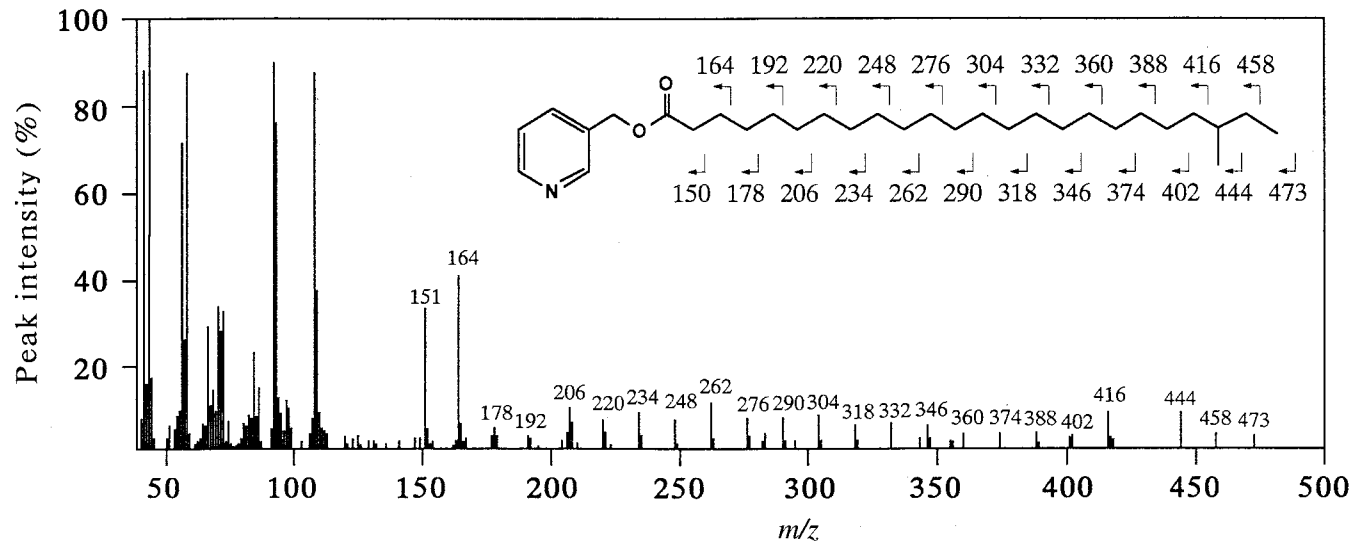

FIG. 5. Mass spectrum of picolinyl ester of anteiso-pentacosanoic acid (anteiso-25:0) from Cer[EAS] ester-linked fatty acids. The figure inset shows the formation of fragments.

M – 59 generated by loss of $COOCH_3$, M – 32, 90, 57, and 55 fragments (data not shown). The elution volumes in gas chromatography also were slightly earlier than those expected for straight-chain α-hydroxy fatty acids, suggesting the presence of branched-aliphatic chain structure in these fatty acids. As stated in the Materials and Methods section, the authors first tried to prepare the picolinyl derivatives of these fatty acids to elucidate their chain structure. However, the preparation of picolinyl esters from the amide-linked fatty acids was unsuccessful for unknown reasons. We therefore prepared the pyrrolidides of these fatty acids for the structural identification of aliphatic chain.

In the case of pyrrolidides, the intensities of the diagnostic ions at high mass range appeared to be less abundant than in the case of picolinyl ester. These derivatives were, however, useful for the identification of the aliphatic chain structure. Fragmentation of pyrrolidides involves the same type of radical-induced cleavage as observed with the picolinyl ester (data not shown). A series of ions of carbon atoms separated by 14 mass units were demonstrated with α-hydroxy hexadecanoic acids as shown in Figure 7. The rationale for the generation of these ions was also shown in the inset of Figure 7.

Figure 8 thus shows the mass spectrum for pyrrolidides of amide-linked α-hydroxy iso-24:0 fatty acid in Cer[EAS]. The fragment of *m/z* 408 for the straight-chain structure was missing, and the 28-mass-unit gap occurred between *m/z* 394 and 422 ions, showing clearly the iso-branching chain structure at methyl terminus. This elucidation of the chain structure herein first allows us to demonstrate the presence of α-hydroxy BCFA in the amide-linked fatty acids of Cer[EAS].

Table 2 lists the fatty acid composition of amide-linked fatty acids from Cer[EAS]. As was the case for ester-linked fatty acid composition, BCFA constituted the major proportion of amide-linked fatty acid, accounting for 67.8% of total fatty acid.

Tables 3 and 4, respectively, show the fatty acid compositions for ester- and amide-linked fatty acids of ceramide 1. In both cases, BCFA with or without α-hydroxy group were present. The sum of BCFA was 21.4% for the ester-linked and

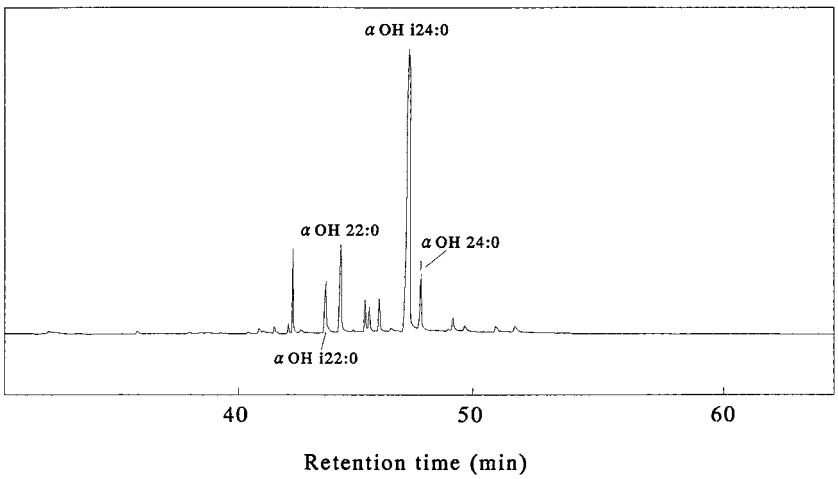

FIG. 6. Gas chromatogram of methyl ester of Cer[EAS] amide-linked fatty acid. The identifications for major fatty acid components are given. Abbreviations: α-OH, α-hydroxy; i, iso.

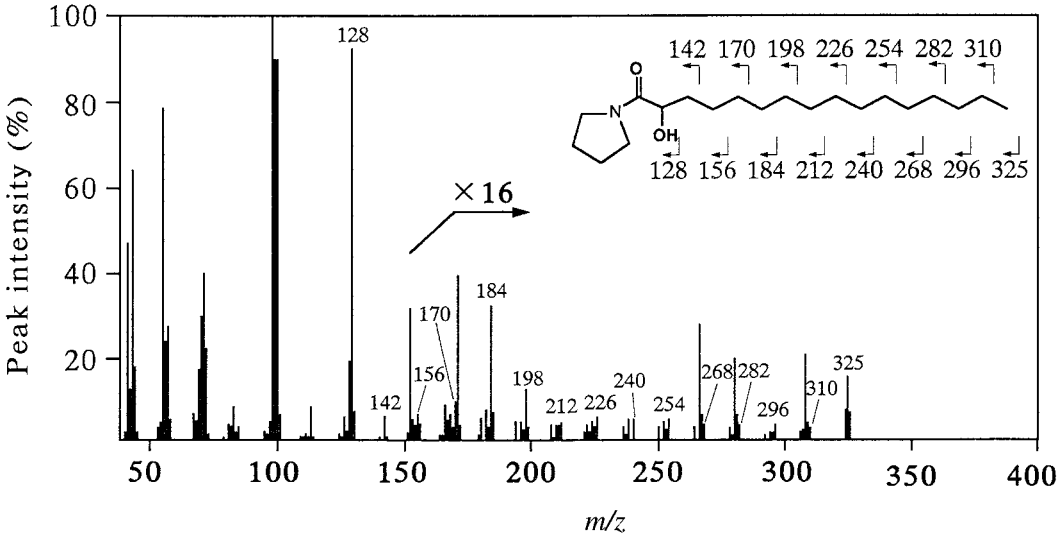

FIG. 7. Mass spectrum of pyrrolidide derivatives of authentic α-hydroxy hexadecanoic acid. The fragments of *m/z* greater than 150 were magnified 16 times (note the arrow). The figure inset shows the formation of fragments.

10.9% for the amide-linked fatty acids. The BCFA concentrations of both ester- and amide-linked fatty acids for ceramide 1 were lower than those for Cer[EAS]. The largest fatty acid constituent was predictably linoleic acid (18:2), and the predominant fatty acid for ceramide 1 was therefore a straight-chain fatty acid.

Table 5 shows the composition of amide-linked fatty acids from ceramide 2. The length of the aliphatic chain of the fatty acids ranged from C16 to C30 with the largest being C24. The lower concentration (13.6%) of the BCFA compared to Cer[EAS] was noted with this ceramide as well as for ceramide 1. Table 6 lists the fatty acid composition of ceramide 3. The profile was largely similar to that of ceramide 2 with a much lower concentration (8.1%) of BCFA.

Table 7 shows the fatty acid composition of ceramide 5. In this case, α-hydroxy straight-chain fatty acids were the major amide-linked fatty acids, which accounted for 49.8% of total fatty acids. The sum of BCFA was 7.5%.

Table 8 shows the fatty acid composition of Cer[NH]. An analysis of the proton NMR spectrum revealed that the sphingoid base of this ceramide was 6-hydroxy-4-sphingenine, and was identical with that of ceramide 7. The chemical structure of this ceramide was as follows: the amide-linked α-hydroxy fatty acid of ceramide 7 was substituted by normal-type fatty acids. Thus, this ceramide was less polar than ceramide 7 and co-migrated with ceramide 5 on development of the thin-layer chromatogram with chloroform/methanol/acetic anhydride (180:10:1, by vol) as shown in Figure 2. The Cer[NH] was, however, resolved from ceramide 5 by a thin-layer chromatogram developed with chloroform/methanol/acetic anhydride

(250:10:2, by vol). Table 8 shows that the predominant amide-linked fatty acids were straight-chain fatty acids, and supported the identification described above. The sum of the BCFA was 4.3% in this ceramide. The largest amide-linked fatty acid constituent of Cer[NH] was hexacosanoic acid (26:0), and this appeared to be a characteristic of this ceramide because the largest one for ceramides 2, 3, 5, 6, and 7 was tetracosanoic acid (24:0).

Tables 9 and 10 show the amide-linked fatty acid composition of ceramides 6 and 7, respectively. In both cases, α-hydroxy fatty acids were predictably the major amide-linked fatty acid component. The concentration of BCFA was 3.3% for ceramide 6 and 5.3% for ceramide 7.

DISCUSSION

The present study describes the fatty acid composition of human vernix caseosa ceramides for the first time. Two new free ceramides, Cer[EAS] and Cer[NH], were isolated by a combination of column chromatography and TLC. Cer[EAS] is an acylceramide and consists of ester- and amide-linked fatty acids and the sphingoid base of dihydrosphingosine. The amide-linked fatty acid of Cer[EAS] was found to be an α-hydroxy branched-chain fatty acid in this study. There were

therefore three hydroxy groups for the esterification: two on dihydrosphingosine base and one on α-hydroxy acyl moiety. The site for the ester linkage is under investigation, and will be described in a forthcoming paper.

Even though there was some uncertainty as to the chemical structure of Cer[EAS], analysis of amide-linked fatty acids in this study gave additional evidence for the structural identification of Cer[EAS]. Cer[EAS] was thus apparently different from ceramide 1 in that the amide-linked fatty acid for this ceramide was an α-hydroxy fatty acid, while that for ceramide 1 was an ω-hydroxy fatty acid.

In this study, the authors employed GC–MS of the picolinyl ester for the elucidation of the fatty acid chain structure. The

equivalent chain length on isothermal analysis is a good index, but not decisive for the identification of the chain structure of fatty acid. As mentioned in the Results section, the mass spectrum of picolinyl ester was sensitive to the location of methyl substitution in the aliphatic chain. In the case of straight-chain fatty acid, the radical-induced fission of every carbon–carbon bond gives a series of fragments separated by 14 mass units. The presence of methyl substitution in the aliphatic chain, however, interrupts the generation of this series of ions, and gives a 28-mass-unit gap at the site of methyl branching. Thus the mass spectra of iso- and anteiso-fatty acids, respectively, lack M – 29 and M – 43 fragments, as shown in Figures 4 and 5, and this feature enables us to distinguish easily the iso- and anteiso-branching structure. The radical-induced cleavage of pyrrolidides has essentially the same mass spectrometric characteristics as picolinyl derivatives.

A single class of ceramide cannot have two types of amide-linked fatty acid. Analysis in the current study, however, found two types of amide-linked fatty acids in a single ceramide subclass. This may largely be due to insufficient purification of the ceramides. Even though the ceramide subclasses gave a single band on the HPTLC chromatogram, this

may not necessarily guarantee the purity of the specimen. The removal of any impurities may be essential for the detection of the single type of amide-linked fatty acid for the single ceramide subclass.

The uniqueness of Cer[EAS] manifested itself in that the greater proportion of ester- or amide-linked fatty acids of this ceramide consisted of the BCFA of the iso or anteiso series. The physiological significance of BCFA in skin surface lipids is still an open question. A postulate for the physiological role is that the BCFA resist bacterial flora, and consequently prevent the possible outgrowth of bacteria on the skin surface. This explanation appears to be true in the case of triacylglycerols of BCFA (12,13). The lower digestibility of BCFA therefore may contribute to some extent to minimize the undesirable growth of bacteria on the skin surface of a newborn baby.

Another point to note is that the melting point of BCFA is much lower than that of its straight-chain counterpart (14). This property also may be beneficial to keep the skin surface moist at the relatively low temperature of the skin surface. The BCFA concentration of vernix caseosa has been shown to be much higher than that for the skin surface lipid of adults (15,16). The pseudo skin surface lipid of a newborn baby showed a higher water-holding and -retaining capacity than that of an adult and superior aqueous vapor permeability (17).

The skin surface lipid of an adult is a mixture of cutaneous and sebaceous contributions, and the sebum production appears to be a determinant of the BCFA concentration of the skin surface lipid (18,19). An exclusively high concentration of BCFA in Cer[EAS] thus could be related to the contribution of this lipid by the sebaceous gland. The sebaceous gland of a fetus has been shown to be active after 110 gestational days (6).

Utilization of Docosahexaenoic Acid from Intravenous Egg Yolk Phospholipid

Scott Morris, Karen Simmer, and Robert Gibson*

Faculty of Health Sciences, Flinders University of South Australia, and the Department of Pediatrics and Child Health, Flinders Medical Centre, Bedford Park, South Australia, 5042, Australia

ABSTRACT: Docosahexaenoic acid (DHA, 22:6n-3) is provided directly to human premature infants during parenteral nutrition from the egg yolk fraction of an intravenous fat emulsion. This study aimed to determine whether the high egg yolk phospholipid content of Intralipid 10% (IL 10%, Pharmacia, Uppsala, Sweden) relative to the standard emulsion Intralipid 20% (IL 20%, Pharmacia) could be a strategy to increase the delivery of DHA to the developing brain. Male, Large White piglets were randomly selected from sows 3 d after birth. Piglets were assigned to receive a 9-d continuous intravenous infusion commencing 5 d after birth of either Intralipid (IL) 10%, IL 20%, or Lipofundin S 20% (LFS; B. Braun, Melsungen, Germany). There were four piglets in each treatment group. IL 10% provides twice as much DHA as IL 20%, while LFS provides no DHA. Protein and other nutrients were provided enterally using a low-fat milk formula. After 9 d, animals were killed, and the fatty acid compositions of blood, liver, and cerebral cortex were analyzed. IL 10% infusion approximately doubled the amount of plasma phospholipid DHA (μg/mL of plasma) in comparison to IL 20%. However, red blood cells, liver, and cerebral cortex phospholipid DHA levels were indistinguishable between these two groups. LFS was associated with reduced levels of DHA in plasma, red blood cell and liver phospholipids in comparison to IL 20%. We conclude that infusion of additional phospholipid is an ineffective strategy for increasing DHA delivery to piglet tissues. This may be due to the formation of inert phospholipid particles in plasma. The data do not support the concept of using IL 10% as a means of providing additional DHA to premature human infants.

Paper no. L8224 in *Lipids 35*, 383–388 (April 2000).

A dietary source of docosahexaenoic acid (DHA, 22:6n-3) is potentially important for normal functional development of the human premature infant's brain (1,2). This hypothesis raises concerns regarding DHA provision to very immature infants, in whom significant quantities of milk feeds are often precluded and for whom a reliance is placed on parenteral nutrition (3). The only external source of DHA and precursor fatty acids during parenteral nutrition is an intravenous fat emulsion. The standard fat emulsion utilized in most neonatal units worldwide is Intralipid 20% (IL 20%, Pharmacia, Uppsala, Sweden), which is composed of soybean triglyceride emulsified with egg yolk phospholipid. DHA is contained within the egg yolk phospholipid fraction.

The quantity of DHA provided by the maximal infusion rate of IL 20% recommended by the American Academy of Pediatrics (3g/kg/d of triglyceride) is approximately 13 mg/d for a 1,500-g preterm infant (based on our laboratory measurement of 2.94 mg DHA/g of triglyceride) (4). This quantity of DHA is approximately 40% of that provided by 200 mL/kg/d of breast milk, assuming a fat content of 3.5 g/100 mL with DHA constituting 0.3% of total fatty acid. Limited data also indicate that DHA levels in liver of preterm infants that received parenteral nutrition with IL 20% are reduced in comparison to infants nourished *in utero* (5). These observations suggest that even maximal recommended quantities of IL 20% may be inadequate to support normal fetal accretion of DHA during parenteral nutrition. Infants receiving less than recommended quantities of IL 20% would be expected to be at greater risk of abnormally low tissue DHA levels.

Our aim was to determine whether the infusion of a commercially available intravenous fat emulsion with a high egg yolk phospholipid content (and therefore a relatively high DHA content) could increase the level of DHA in cerebral cortex above that induced by IL 20%. A newborn piglet model of the human infant was utilized because the perinatal timing of the brain growth spurt in the piglet provides an opportunity to study the effect of intravenous fat infusion on the immature brain (6).

EXPERIMENTAL PROCEDURES

All study methods were approved by the Animal Ethics Committee at Flinders Medical Centre.

Treatment groups. Male, pure-bred Large White piglets were randomly selected from litters after 72 h of suckling and assigned to receive one of three intravenous fat emulsions: IL 20% (Pharmacia, Sweden), IL 10% (Pharmacia), or Lipofundin S 20% (LFS; B. Braun, Melsungen, Germany). The fatty acid composition of these three emulsions is shown in Table 1. Soybean triglyceride is the predominant fat in all three emulsions, and the fatty acid composition of this fraction was similar in each case. The rationale was to maintain a constant triglyceride fatty acid intake, and therefore a constant supply of essential

[a]All values are the mean ± SD of three analyses, expressed as percentages of total fatty acid. Where no value is entered, the fatty acid constituted <0.05% of the total. The amount of phospholipid provided per gram of triglyceride is 60 mg for IL 20%, 120 mg for IL 10%, and 75 mg for LFS. Intravenous fat emulsions: IL 20% (Pharmacia, Uppsala, Sweden), IL 10% (Pharmacia), and LFS (Lipofundin S 20%; B. Braun, Melsungen, Germany). Abbreviations: Total sat., total saturated fatty acids; total mono; total monounsaturated fatty acids.

precursor fatty acids for long-chain polyunsaturated fatty acid synthesis. The isolated effect of infused phospholipid on tissue fatty acid composition could then be assessed. DHA is contained in the egg yolk phospholipid fraction of both IL 20% and IL 10%. IL 10% provides double the amount of phospholipid and hence DHA for a given quantity of triglyceride in comparison to IL 20%. LFS contains soybean phospholipid and is therefore devoid of DHA.

Calculations of sample size were based on cerebral cortex fatty acid data derived from milk-fed piglets (7). To detect a difference in cortex DHA of 0.6% (percentage of total phospholipid fatty acid) with a study power of 80%, four piglets per group were required (7). All piglets within each treatment group were from separate litters.

Nutrition. A model was established whereby fat was delivered intravenously, while other nutrients were provided *via* the enteral route using a low-fat milk formula. The details of the development of this model have been published previously, and information regarding milk composition and macronutrient and energy intake in the experimental piglets is referenced (8). Briefly, piglets were first trained over a 36-h period to accept a low-fat milk formula devoid of DHA (Wombaroo Foods, Glen Osmond, Australia). The milk contained 0.4 g fat, 6.1 g protein, 4.8 g carbohydrate, and 198 kJ total energy per 100 mL of milk. The fatty acid composition of the milk fat (percentage of total fatty acid expressed as the mean ± SD of three analyses) was 61.7 ± 0.1% saturates, 31.8 ± 0.1% monounsaturates, 2.8 ± 0.2% 18:2n-6, 0.2 ± 0.0% 20:3n-6, 0.3 ± 0.0% 20:4n-6, 1.3 ± 0.0% 18:3n-3, 0.3 ± 0.0% 20:5n-3, and 0.5 ± 0.1% 22:5n-3. The milk was made daily by reconstituting dry milk powder with water. Piglets were required to suck the milk *via* a straw from a graduated container positioned below the teat, to minimize milk losses. Piglets were housed individually in clean pens with a plastic grill floor, to avoid the animals eating feces, urine, or bedding. A constant thermoneutral environment (30°C) was maintained.

On experimental day 1 (day 5 of life), a central venous catheter was inserted, and a continuous intravenous infusion of fat emulsion commenced at 3.0 g/kg/d of the triglyceride component within 2–3 h of surgery. The infusion rate was increased to 6.0 g/kg/d on experimental day 2 and to 10 g/kg/d from experimental d 3 to 9. At the peak rate of triglyceride infusion, IL 20% and IL 10% provide 29 and 61 mg/kg/d of DHA from egg yolk phospholipid, respectively, while LFS provides no DHA. A limit of 10 g/kg/d of fat infusion had been determined from pilot studies, as higher infusion rates had been associated with lung injury (8).

Piglets were weighed daily, and nutrient intake (dose of intravenous fat and mass of dry milk powder) was determined for the subsequent 24 h based on a predicted daily weight gain of 150 g. If the daily lipid dose was not delivered due to line occlusion or pump failure, then the deficit was given over the following 24 h. As the rate of lipid infusion (and therefore intravenous fluid) increased, the milk concentration was increased (enteral fluid intake reduced) to ensure piglets consumed a constant mass of protein and other nutrients each day before satiation.

By using this method, approximately 90% of total fat was delivered intravenously, with the quantity of enteral fat consumed kept constant between the groups (8). During the period of maximal intravenous lipid infusion (10 g/kg/d), the total energy provided *via* the combined intravenous and enteral routes was approximately 978 kJ/kg/d, with intravenous fat providing approximately 38% of total energy. Enteral fat intake was approximately 1.1 g/kg/d (4.3% of total energy), protein 18.8 g/kg/d (32% of total energy), and carbohydrate 14.7 g/kg/d (25% total energy).

The rationale for a 9-d period of lipid infusion was based on validation studies showing that the newborn piglet model could be reliably maintained for this period, but not beyond (8). Large changes in DHA levels in cerebral cortex and other tissues are also inducible by diet over a 14-d time period (7). Hence a 9-d period was considered likely to be adequate to detect an effect of differing parenteral DHA intakes.

Collection of tissue samples. On experimental day 10 (9 full days after surgery), the lipid infusion was turned off and the central venous catheter clamped. The piglets were then immediately anesthetized by intravenous injection of pentobarbitone sodium (30 mg/kg) *via* the catheter, and 1 mL of blood was collected by cardiac puncture into lithium heparin tubes. Piglets were then killed with intracardiac pentobarbitone sodium (110 mg/kg). Body weight was then recorded, and the liver and brain were removed and weighed. Blood and tissue samples were transported to the laboratory on ice and unfrozen. Fatty acids were extracted from red blood cells within 2 h of collection. Plasma and tissue samples were frozen within the same time period.

Fatty acid analysis of red blood cells. A 400-μL aliquot of blood was centrifuged at 13,000 rpm for 2 min, and the plasma removed and frozen at –20°C for batch analysis. Red blood cells were washed three times with isotonic saline and transferred to a glass tube for immediate analysis.

Total lipids from red blood cells were extracted according to the method of Broekhuyse (9). The volume of packed red blood cells after centrifugation was made up to 1.5 mL with isotonic saline, and isopropanol and chloroform (2 mL/4 mL) added. Following centrifugation (3,000 rpm for 10 min), the bottom layer was transferred to an evaporation flask and the solvents were evaporated under nitrogen. The evaporation flasks were rinsed twice with 9:1 chloroform/methanol to transfer the lipid extract to glass vials.

The solvent–lipid extract was then evaporated to dryness under nitrogen, 150 μL of chloroform/methanol 9:1 added, the solution spotted onto a silica gel-coated thin-layer chromatography plate (Merck Silica Gel spread on 10 × 20 or 20 × 20 cm glass plates, 0.30-mm thick, activated at 100°C for 30 min), and the plate run in a solvent solution of petroleum spirit/acetone 3:1. The phospholipid band was scraped into glass vials containing 1% sulfuric acid in methanol, and heated for 3 h at 70°C. After cooling, 0.25 mL of distilled water and 0.5 mL of heptane were added to each vial, the solution was mixed, and the top layer transferred into gas chromatography vials containing anhydrous sodium sulfate.

Gas chromatographic analysis of fatty acid methyl esters was performed with a Hewlett-Packard 5880 gas chromatograph. Separation utilized a 50-m capillary column, 0.33 mm i.d. coated with 0.25 μm BPX-70 (SGE Pty. Ltd., Victoria, Australia). The injector temperature was set at 250°C, and the initial oven temperature was 140°C and programmed to rise to 220°C at 5°C/min. Helium was used as the carrier gas at a velocity of 35 cm/s. The flame-ionization detector temperature was set at 300°C. Fatty acid methyl esters were identified based on the retention time of authentic lipid standards (Nu-Chek-Prep Inc., Elysian, MN). Fatty acid peaks were integrated using Hewlett-Packard Chemstation software and expressed as a percentage of total phospholipid fatty acid.

Fatty acid analysis of plasma. Plasma samples were defrosted by standing, and allowed to come to room temperature (22°C). Lipid extraction from plasma followed the method of Bligh and Dyer (10), with the exception of the addition of diheptodecanoyl glycero-3-phosphocholine and triheptadecanoic acid internal standards (10). The volume of each plasma sample was determined by weighing into a tared glass tube to an accuracy of five decimal places. Isotonic saline was added to make the volume to 1.5 mL, followed by 2 mL of methanol. The internal standards were added at this step, and chloroform (4 mL) was then added. Data validating this method of fatty acid quantitation have been presented elsewhere by the authors (11).

The subsequent treatment of plasma lipids was identical to that described for red blood cells with the exception of separation of plasma phospholipids and triglycerides by thin-layer chromatography using petroleum spirit/diethylether/glacial acetic acid 90:15:1. Individual fatty acids were expressed both as a percentage of total phospholipid or triglyceride fatty acid and as μg/mL of plasma. Microgram per milliliter values were utilized to reflect the quantity of infused fatty acids, whereas percentages of total fatty acid were considered more reflective of plasma composition.

Fatty acid analysis of cerebral cortex and liver. The whole left cerebral hemisphere and a constant portion of the left lobe of the liver from each piglet were frozen at –20°C for later batch analysis. Each cerebral hemisphere was defrosted by standing at room temperature. The frontal area of the hemisphere was sliced in a coronal plane, and the gray and white matter were separated by manual dissection without magnification. A sample of gray matter approximately 50 μg in weight was extracted with 2.45 mL of saline, 3 mL of methanol, and 6 mL of chloroform and subsequently analyzed as for red blood cell phospholipid fatty acids. Fatty acids were expressed as a percentage of total phospholipid fatty acid. Validation of this methodology in our laboratory has shown the coefficient of variance for fatty acids in the frontal cortex contributing >5% of the total to range between 0.4–7.2%, and for fatty acids contributing 0.5–5.0% of the total to range between 0.3 and 14.5%. The lipid extraction and fatty acid analysis of liver samples followed the same method as cerebral cortex.

Statistical methods. Data were analyzed by one-way analysis of variance, with *post-hoc* analysis using the Tukey Honestly Significant Difference test, and using SPPS for Windows 6.1.3 (SPSS Inc., Berkeley, CA, 1995).

RESULTS

Nutrient intake and growth. Nutrient intake and growth of piglets was detailed in a previous methodological paper (8). There were no detectable differences in the measured amounts of intravenous triglyceride, enteral carbohydrate, protein, or fat received over the experimental period between the treatment groups.

There were no detectable differences in the initial and final body weights, and final brain weights between the groups. The final body weight (mean ± SD) of the 12 experimental piglets was 2,950 ± 241 g. Final body weight was less than that observed in age-matched sow-fed piglets (95% confidence intervals of four sow-fed piglets, 3,570–3,958 g). The final brain

[a]Data are presented as μg/mL of plasma on the first line of each row, with percentages of total fatty acid in parentheses on the second line. All data are means ± SD. Unlike superscripted letters indicate statistical difference, $P < 0.05$. For abbreviations and manufacturers see Table 1.

weight of the experimental piglets was 30.1 ± 2.2 g, comparable to that of sow-fed piglets (95% confidence intervals of four sow-fed piglets 30.7–31.5). The energy intake of the experimental piglets was limited to 978 ± 23 kJ/kg/d, in comparison to estimates of 1,410 kJ/kg/d in sow-fed piglets, due to limitations in the quantity of intravenous fat able to be safely infused (8).

Plasma triglyceride fatty acids. Plasma triglyceride fatty acid data are shown Table 2. Plasma triglyceride composition and total fatty acid levels showed only minor differences between the treatment groups, reflecting the constancy of intravenous triglyceride input between the groups.

Plasma phospholipid fatty acids. Plasma phospholipid data are presented in Table 3. When expressed as μg/mL amounts, plasma phospholipid DHA levels were higher during IL 10% in comparison to IL 20% infusion. A similar pattern was seen with other plasma phospholipid fatty acids. When expressed as a percentage of total phospholipid fatty acid, phospholipid fatty acids during IL 10% infusion were similar to or reduced in comparison to IL 20% infusion. LFS infusion resulted in trends to lower DHA levels expressed as μg/mL, and to lower DHA levels as a percentage of total phospholipid fatty acids. The enrichment of the soybean phospholipid of LFS with 18:2n-6 and 18:3n-3 was reflected in the higher levels of these fatty acids in comparison to IL 20%.

Red blood cell phospholipid fatty acids. Red blood cell phospholipid fatty acids were indistinguishable in piglets receiving IL 20% or IL 10% (Table 4). Trends to higher levels of linoleic acid (LA) and a statistically significant reduction in red blood cell DHA were induced by LFS in comparison to IL 20%.

Liver and cerebral cortex phospholipids. In liver and cerebral cortex phospholipids, IL 20% and IL 10% had a similar effect on fatty acid composition (Table 5). LFS induced statistically significant elevations in LA in comparison to the other emulsions in both tissues, although this increase was quantitatively minor in the brain. LFS also induced a statistically significant reduction in DHA and a trend to lower arachidonic acid levels in liver in comparison to the other emulsions, but these changes were not apparent in the brain.

DISCUSSION

Increasing the intravenous delivery of phospholipid DHA is one potential strategy to provide additional DHA to developing tissues during parenteral nutrition. This strategy was tested by comparing the effect of IL 10% (high phospholipid content) with IL 20% (low phospholipid content) on tissue DHA composition. IL 10% induced high μg/mL amounts of plasma phospholipid DHA relative to IL 20%, indicating a greater influx of phospholipid DHA from the emulsion. However, there was no detectable difference in the DHA composition of red blood

cells, liver, and cerebral cortex of piglets receiving either IL 10% or IL 20%.

One explanation for this result is the accumulation of DHA in an inert plasma phospholipid pool. The majority of phospholipid in IL 10% is not associated with the surface of triglyceride particles, but rather exists as liposomal phospholipid (12–14). The quantity of liposomal material infused with IL 10% is approximately fourfold in comparison to IL 20% (14). High rates of liposome infusion exceed the capacity for clearance and lead to the formation of circulating phospholipid particles, termed lipoprotein X (LP-X), which are enriched in free cholesterol (13). LP-X particles have a half-life of up to 6 d in human studies (14). This indicates stability in plasma and poor interaction of the particle phospholipid with cell membranes and other circulating lipoprotein particles (14). Observations in parenterally fed rats suggest that egg yolk phospholipid infused with IL 10% accumulates in plasma, partially replacing endogenous phospholipids (15). Data derived from the rat model also show a discordance in plasma and tissue fatty acid composition, consistent with poor bioavailability of the infused phospholipid (15).

Alternative explanations for the inability of the additional phospholipid DHA from IL 10% to increase tissue DHA levels may be a confounding influence of early sow milk feeding, or an inadequate study length. It is unlikely that the early intake of sow milk would influence later treatment effects, because the duration of sow milk feeding was short (3 d) and sow milk from our experimental herd contains very low (0.06% of total fatty acid) DHA levels. While it is possible that the study duration of 9 d was too short to see a change in cerebral cortex, an adequate time frame for change in red blood cells and liver is confirmed by reduced DHA in these tissues in the LFS group compared to the IL 20% group. This is consistent with other observations of a rapid response in newborn piglet tissue fatty acid composition following enteral DHA supplementation, where an increase in DHA content to saturation levels has been achieved in liver and cerebral cortex after 14 d (7).

Other possible explanations for our results are that the additional amount of DHA was too small to induce a detectable change in tissues, or that membranes have reached saturation with DHA. The additional quantity of DHA provided by IL 10% (IL 20% provides 29 mg/kg/d of DHA, and IL 10% provides 61 mg/kg/d when 10 g/kg/d of triglyceride is infused) would be expected to induce a detectable change in liver and cerebral cortex based on the liver and synaptic membrane DHA response to incremental increases in enteral DHA provision over a similar dose range in newborn piglets fed milk for 15 d (16). Membrane saturation is unlikely as the DHA levels in liver and frontal cortex observed in this study are well below the saturation levels of corresponding piglet tissues achieved after 2 wk of enteral DHA supplementation (approximately 19 and 15–16% of total phospholipid fatty acid in liver and frontal cortex, respectively) (7). Furthermore, the plasma–tissue disparity is also apparent with fatty acids other than DHA.

Although the μg/mL quantity of DHA was higher in plasma during IL 10% infusion in comparison to IL 20%, when expressed as a percentage of total phospholipid fatty acid, DHA was lower during IL 10% compared to IL 20%. It is possible that tissue DHA levels could remain unchanged by IL 10%

[a]Data are presented as percentages of total phospholipid fatty acid. All data are means ± SD. Unlike superscripts indicate statistical difference, $P < 0.05$. Where no value is entered, the fatty acid constituted <0.05% of the total. For abbreviations see Table 1.

owing to an increase in the total amount of phospholipid, were the phospholipid composition to reflect that of the plasma. We did not measure total phospholipid in tissues, although the total phospholipid content of rat liver (mg/g wet weight) has been shown to remain stable during IL 10% infusion, suggesting this to be an unlikely explanation (15). However, an increase in red blood cell phospholipid (mg/g protein) has been noted under the same conditions in the rat (17).

The effect of IL 10% infusion on levels of plasma lipoproteins, and the distribution of DHA between lipoprotein subfractions, were not investigated in this experiment. Therefore, the ultimate fate of the infused liposomal DHA cannot be determined. Liposomal phospholipid is cleared from the circulation by facilitated transfer and direct fusion with plasma lipoproteins, in particular high density lipoprotein, and with cell membranes (14). LP-X particles are predominantly cleared by reticuloendothelial and hepatic phagocytosis (14). It may be speculated that DHA in LP-X particles becomes sequestered in a reticuloendothelial pool. The subsequent availability of DHA to developing tissues is unknown and requires further study.

One limitation of the piglet as a model of the human premature infant is the large quantity of intravenous fat required to maintain adequate health and growth, in comparison to the human infant where maximal rates of 3 g/kg/d of triglyceride are recommended (4,8). However, an accumulation of liposomal phospholipid has also been shown in human premature infants receiving IL 10% at standard infusion rates of the triglyceride fraction (2 g/kg/d), indicating that this phenomenon is not restricted to the piglet nor purely related to the high rate of fat infusion used in our experiment (18,19). The accumulation of LP-X during the infusion of IL 10% in human infants is associated with impaired triglyceride clearance, due to inhibition of lipoprotein lipase and the hepatic clearance of remnant triglyceride particles, placing an important clinical limitation on the use of this emulsion (14,18,19).

We conclude that the use of IL 10% for the specific purpose of providing additional DHA cannot be justified in human premature infants based on this data, as the capacity of tissues to assimilate the phospholipid from this emulsion appears limited. If the hypothesis of an inadequate supply of DHA to the human preterm infant during parenteral nutrition is accepted, then alternative strategies to provide DHA are required.

High Dietary 18:3n-3 Increases the 18:3n-3 but Not the 22:6n-3 Content in the Whole Body, Brain, Skin, Epididymal Fat Pads, and Muscles of Suckling Rat Pups

Raffick A.R. Bowen[a] and Michael T. Clandinin[a,b,*]

ABSTRACT: The objective of this study was to test the hypothesis that increasing maternal dietary 18:3n-3 by decreasing the 18:2n-6/18:3n-3 ratio will increase the 18:3n-3 and 22:6n-3 content of the whole body, liver, skin (epidermis, dermis, and subcutaneous tissue), epididymal fat pads, and muscles (arms and legs) of 2-wk-old rat pups. Sprague-Dawley dams at parturition were fed semipurified diets containing either a low (18:2n-6 to 18:3n-3 ratio of 24.7:1) or a high (18:2n-6 to18:3n-3 ratio of 1.0:1) 18:3n-3 fatty acid content. During the first 2 wk of life, rat pups received only their dams' milk. Fatty acid composition of the pups' stomach contents (dams' milk), whole body, brain, liver, skin, epididymal fat pads, and muscles was determined. The stomach fatty acid composition of 18:3n-3 reflected the dams' diet. The content of 18:3n-3 in whole body, brain, liver, skin, epididymal fat pads, and muscles was significantly ($P < 0.05$) greater in rat pups fed the high compared with the low 18:3n-3 fatty acid diet. The 22:6n-3 content of the whole body, brain, skin, epididymal fat pads, and muscles was not quantitatively different in rat pups fed either the low or high 18:3n-3 fatty acid diet. The 20:5n-3 and 22:5n-3 content of the whole body, skin, and epididymal fat pads was significantly increased in rat pups fed the high compared with the low 18:3n-3 fatty acid diet. High content of 18:3n-3 was found in the skin of rat pups fed either a low or high 18:3n-3 fatty acid diet. These findings demonstrate that high maternal dietary 18:3n-3 significantly increases the 18:3n-3 but not the 22:6n-3 content of the whole body, brain, skin, epididymal fat pads, and muscles with approximately 39 and 41% of the whole body 18:3n-3 content being deposited in the skin of suckling rat pups fed either the low or high 18:3n-3 diet, respectively.

Paper no. L8298 in *Lipids 35*, 389–394 (April 2000).

Research in infant nutrition has demonstrated that during the last trimester of gestation the fetal brain accrues fatty acids of the n-6 and n-3 types (1). These fatty acids may be derived from the placenta *in utero* (1–3). The hepatic and adipose reserves cannot meet whole body needs for essential fatty acids and total fat if fetal development is interrupted by premature birth early in the third trimester (3). Mothers' milk provides 20:4n-6 and 22:6n-3, approximating the predicted requirements at day 16 of life at oral intake (3). Long-chain essential fatty acids are synthesized from 18:2n-6 or 18:3n-3; however, the amounts produced *in vivo* may be inadequate to support the accretion rates attained in breast-fed infants (4–8). Deficiencies of dietary 22:6n-3 during perinatal development results in poor 22:6n-3 accretion in brain and retina, subsequently leading to altered neurological and visual function in animals (9,10). Thus, it seems prudent to feed the preterm infant human milk or formulas with a fatty acid balance similar to human milk containing long-chain polyenoic homologs of 18:2n-6 and 18:3n-3 (11).

Current infant formulas in North America contain 18:2n-6 and 18:3n-3 but are devoid of 20:4n-6 and 22:6n-3 (12,13). Infants fed these formulas must rely on *in vivo* elongation and desaturation of 18:2n-6 and 18:3n-3 to support a similar rate of accretion of 20:4n-6 and 22:6n-3 to that attained in breast-fed infants. Addition of 20:4n-6 and 22:6n-3 to preterm infant formulas to optimize brain development has been recommended (3,11,14–17). Infant formulas supplemented with 20:4n-6 and 22:6n-3 produce a clear dose response in the content of 20:4n-6 and 22:6n-3 in erythrocyte total plasma membrane phospholipids with 0.6% 20:4n-6 and 0.4% 22:6n-3 in the formula fat providing sufficient amounts of these fatty acids to achieve a fatty acid composition of 20:4n-6 and 22:6n-3 similar to that of infants fed human milk (18). Thus, in the United Kingdom, Europe, South America, Australia, and the Middle East, 20:4n-6 and 22:6n-3 have been added to infant formulas.

The question of whether preformed 22:6n-3 is needed or if providing more 18:3n-3 can enable synthesis of 22:6n-3 persists. In human adults, it is more effective to supply a dietary source of preformed 22:6n-3 from fish oil to increase the 22:6n-3 content in plasma phospholipids than 18:3n-3 from flaxseed oil (19). Increasing maternal dietary 18:3n-3 by decreasing the diet 18:2n-6/18:3n-3 from 7.3:1 to 4:1 was not as effective as preformed 22:6n-3 at raising the 22:6n-3 content of neuronal cell phospholipids of weanling rats (20,21). Increasing maternal dietary 18:3n-3 content does not significantly increase the 22:6n-3 content in phosphatidylcholine, phosphatidylethanolamine, or

phosphatidylserine of neuronal cell phospholipids of rat pups at 2 wk of age (22). These observations beg the question: If 18:3n-3 does not give rise to significant quantities of 22:6n-3, then what is the metabolic fate of high intakes of 18:3n-3?

The purpose of this study was to determine if the dietary 18:3n-3 consumed could increase the 18:3n-3 and 22:6n-3 content of other whole body tissue lipids. It is hypothesized that increasing maternal dietary 18:3n-3 by decreasing the 18:2n-6/18:3n-3 ratio will increase the 18:3n-3 and 22:6n-3 content in the whole body, liver, skin (epidermis, dermis, and subcutaneous tissue), epididymal fat pads, and muscles (arms and legs) in 2-wk-old rat pups.

EXPERIMENTAL PROCEDURES

Animals and diets. The University of Alberta Animal Ethics Committee approved all animal procedures. Sprague-Dawley rats were obtained from the University of Alberta vivarium. During breeding, three females and one male were housed together for a 2-wk mating period. Females were then moved to individual cages in a room maintained at 21°C with a 12-h light/dark cycle. Water and food were supplied *ad libitum*. Laboratory rodent diet, 5001 (PMI Feeds, Inc., St. Louis, MO) was fed to the rats when not receiving experimental diets. Rats were switched to experimental diets on the day of parturition. All litters were culled to 12 pups within 24 h of parturition. Pups received only maternal milk. Pups were sacrificed at 2 wk of age.

One entire litter of rat pups fed the same experimental diet was sexed and weighed prior to decapitation. Rat pups randomly chosen for whole body lipid analysis were frozen in liquid nitrogen. The brains, livers, skin (epidermis, dermis, and subcutaneous tissue), epididymal fat pads, and muscles (arms and legs) were quickly removed and rinsed with ice-cold physiological saline, blotted dry, weighed, and frozen in liquid nitrogen. Stomach contents of three rats from each litter were also removed and analyzed for fatty acid composition to reflect the composition of maternal milk. All tissue samples were stored under nitrogen and kept in a –80°C freezer until analysis. Analysis of whole organs was performed on at least three individual rat pups from each of three different litters per diet treatment. Three litters per diet treatment were used.

The basal diet fed to the dams contained 20% (w/w) fat varying in 18:2n-6 and 18:3n-3 fat composition. Two experimental diets were formulated by addition of various triglycerides from vegetable oils to alter the fatty acid 18:2n-6/18:3n-3 ratio (Table 1). An 18:2n-6 to 18:3n-3 fatty acid ratio of 24.7 to 1 (low 18:3n-3) was obtained by addition of corn oil to the diet fat blend. The 18:2n-6 to 18:3n-3 fatty acid ratio of 1 to 1 (high 18:3n-3) was obtained by the addition of flaxseed oil. The low and high 18:3n-3 fatty acid diet was nutritionally adequate, providing for all known essential nutrient requirements as described earlier (23). To minimize any changes in sample composition due to fatty acid oxidation, the diets were sealed under nitrogen and stored in a freezer at –30°C in darkness. Every day, the required amount of diet was taken out, mixed, and placed in individual feed cups.

Lipid extraction and fatty acid analysis. Total lipids were extracted from aliquots of tissue homogenate (24). The extracted lipids were evaporated under nitrogen and weighed to determine the total fat content of the tissues. The tissue lipids were saponified by a 0.5 N KOH in 95% methanol solution and heated at 100°C for 1 h. Fatty acid methyl esters were prepared using BF_3/methanol reagent (25).

Fatty acid methyl esters were separated by automated gas–liquid chromatography (Varian model 6000 GLC equipped with a Vista 654 data system and a Vista 8000 autosampler; Varian Instruments, Georgetown, Ontario, Canada) using a bonded fused-silica BP20 capillary column (25 × 0.25 mm i.d.)

TABLE 1
Fatty Acid Composition of Experimental Diets Fed to Lactating Dams and Stomach Contents of Rat Pups of 2 wk of Age[a]

	Diet[b]		Stomach contents[b]	
Fatty acid (wt%)	Low 18:3n-3	High 18:3n-3	Low 18:3n-3	High 18:3n-3

[b]Values represent mean ± SEM for $n = 9$ rat pups for each experimental diet. Values without a common roman letter superscript are significantly different at $P < 0.05$.

and quantitated using a flame-ionization detector as described earlier (20,21). These conditions are capable of separating methyl esters of saturated, *cis*-monounsaturated, and polyunsaturated fatty acids from 12 to 24 carbons in chain length. Quantitation and identification of peaks were based on relative retention times compared with known standards [polyunsaturated fatty acids (PUFA) 1 and 2, bacterial methyl ester mix-14; Supelco Canada, Mississauga, Ontario, Canada] (26).

Statistical analysis. The effects of diet treatment and sex of rat pups on the lipid content and fatty acid composition of whole body and tissues lipids were assessed by one-way analysis of variance (ANOVA) procedures using the SAS package, version 6.11 (27). Significant differences between diet treatments and sex were determined by a Duncan's multiple range test at a significance level of $P < 0.05$ after a significant ANOVA (28). Values are expressed as mean ± SEM for $n = 9$.

RESULTS

Fatty acid composition of stomach contents. The stomach content of rat pups was analyzed for the fatty acid composition. These analyses reflected dams' milk composition (20,21,29–32). The increase in dietary 18:3n-3 fed to the dams increased the 18:3n-3 in the stomach contents of the rat pups (Table 1) indicating that the range of dietary fat composition fed in the present experiment produced similar changes in the fat composition of the dams' milk.

Whole body and tissue weights and lipid content. Whole body and tissue weights, lipid content, and fatty acid composition of the tissues were not significantly different for male ($n = 5$) and female ($n = 4$) rat pups (data not shown), hence in statistical analyses to test subsequent effects of diet, treatments were combined for both sexes. The whole body and tissue weights were not significantly different between the two experimental diet treatments (Table 2), indicating that the body and tissue growth in the 2-wk-old rat pups is not different between low and high 18:3n-3 fatty acid diets. The lipid content of whole body and tissues was not significantly different in rat pups fed either the low or high 18:3n-3 fatty acid diet (Table 2).

Brain. The brain of 2-wk-old rat pups contained small amounts of 18:3n-3 and 18:2n-6. The 18:3n-3 content of brain was significantly increased in rat pups fed the high compared with the low 18:3n-3 fatty acid diets. The 18:2n-6 content of brain was significantly increased in animals fed the low compared with a high 18:3n-3 fatty acid diet. The predominant n-3 and n-6 fatty acids in brain of rat pups fed low or high 18:3n-3 fatty acid diet were 22:6n-3 and 20:4n-6, respectively. The 22:6n-3 content of brain was not significantly different in the animals fed the high compared with the low 18:3n-3 fatty acid diets. The 20:5n-3 content of brain was not significantly different between rat pups fed low vs. high 18:3n-3 fatty acid diet. However, the 22:5n-3 content of brain was significantly different between rat pups fed low vs. high 18:3n-3 fatty acid diet. The 20:4n-6 content of brain was significantly increased in rat pups fed the low vs. high 18:3n-3 fatty acid diet.

Liver. The partial fatty acid composition of liver from 2-wk-old rat pups is shown (Table 3). The 18:3n-3 and 22:6n-3 content of liver was considerably lower than the 18:2n-6 and 20:4n-6 content for animals fed either the low or high 18:3n-3 diets. High content of 18:2n-6 and 20:4n-6 was observed in the liver of rat pups fed either a low or high 18:3n-3 fatty acid diet. The content of 18:3n-3 in liver was approximately 3% in animals fed the high 18:3n-3 fatty acid diet and was significantly different when compared with animals fed the low 18:3n-3 fatty acid diet. Significant differences were observed in the 18:2n-6 content of liver between rat pups fed low vs. high 18:3n-3 fatty acid diet. The 22:6n-3 content of liver was significantly increased in animals fed high vs. low 18:3n-3 fatty acid diets (Table 3). The 20:5n-3 and 22:5n-3 content of liver was significantly different between rat pups fed low vs. high 18:3n-3 fatty acid diet. The 20:4n-6 content of liver did not differ between rat pups fed low vs. high 18:3n-3 fatty acid diet.

Skin (epidermis, dermis, and subcutaneous tissue). The fatty acid composition of skin (epidermis, dermis, and subcutaneous tissue; Table 3) shows that 18:3n-3 content of skin was significantly increased by high maternal dietary 18:3n-3 content. The 22:6n-3 content of skin, however, was not statistically different in animals fed either the low or high 18:3n-3 diet. The 20:5n-3 and 22:5n-3 content of skin was significantly different between rat pups fed low vs. high 18:3n-3 fatty acid diet. The 18:2n-6 plus 20:4n-6 were major fatty acids of skin constituting approximately 23 and 17% for animals fed the low and high 18:3n-3 fatty acid diet, respectively. The 18:2n-6 content in skin was significantly higher in rat pups fed a low compared with a high 18:3n-3 fatty acid diet. However, there was no significant difference in 20:4n-6 content of skin between the two diet groups.

TABLE 2
Whole Body and Tissue Weights and Lipid Content of Rat Pups at 2 wk of Age[a]

	Weight (g)		Lipid (%)	
	Low 18:3n-3	High 18:3n-3	Low 18:3n-3	High 18:3n-3
Whole body	31.8 ± 1.0[a]	32.0 ± 1.2[a]	13.6 ± 1.0[a]	13.4 ± 0.8[a]
Brain	1.15 ± 0.0[a]	1.12 ± 0.1[a]	4.40 ± 0.4[a]	4.20 ± 0.3[a]
Liver	0.66 ± 0.1[a]	0.67 ± 0.1[a]	6.90 ± 0.7[a]	6.90 ± 0.8[a]
Skin	9.00 ± 1.0[a]	8.95 ± 1.0[a]	24.0 ± 1.3[a]	25.0 ± 1.1[a]
Epididymal fat pads	0.05 ± 0.0[a]	0.05 ± 0.0[a]	ND	ND
Muscles	1.00 ± 0.0[a]	0.91 ± 0.1[a]	1.70 ± 0.0[a]	1.60 ± 0.0[a]

[a]Values represent mean ± SEM for $n = 9$ rat pups for each experimental diet. Values without a common roman superscript are significantly different at $P < 0.05$.

TABLE 3
Effect of Low and High 18:3n-3 Diet on the Essential Fatty Acid Composition of Whole Body and Tissue Lipids[a]

Diet 18:3n-3 content	Whole body		Brain		Liver		Skin		Epididymal fat pad		Muscles	
	Low	High	Low	High	Low	High	Low	High	Low	High	Low	High

[a]Values represent mean ± SEM for $n = 9$ rat pups for each experimental diet. Values without a common roman superscript for each fatty acid are significantly different at $P < 0.05$.

Epididymal fat pads. The 18:3n-3 content of this tissue was significantly increased by the dietary 18:3n-3 content (Table 3). The content of 18:3n-3 in epididymal fat pads was approximately 1.8 and 13.3% for animals fed either low or high 18:3n-3 fatty acid diet, respectively. The 18:2n-6 content of epididymal fat pads from rat pups was high, approximately 19–20% of the total fatty acids. The 18:2n-6 content in epididymal fat pads was not significantly affected by the two dietary fat treatments. However, unlike 18:2n-6, 22:6n-3 and 20:4n-6 content in epididymal fat pads was not significantly different between animals fed the two diet groups. The 20:5n-3 and 22:5n-3 content of epididymal fat pads was significantly different between rat pups fed low vs. high 18:3n-3 fatty acid diet.

Muscle (arms and legs). The fatty acid composition of muscle (arms and legs) from 2-wk-old rat pups is shown (Table 3). The 18:3n-3 content of muscles was significantly different between rat pups fed low vs. high 18:3n-3 fatty acid diet (1.6 vs. 10.7%, respectively). The 18:2n-6 content in muscles was significantly different between rat pups fed low vs. high 18:3n-3 fatty acid diet. The 18:2n-6 content in muscles of rat pups fed low or high 18:3n-3 fatty acid diet was approximately 21 and 16%, respectively. No significant differences were observed in the 22:6n-3 content of muscles in the two diet groups. The 20:5n-3 but not the 22:5n-3 content of muscles was significantly different between rat pups fed low vs. high 18:3n-3 fatty acid diet. The 20:4n-6 content in muscles of rat pups was significantly higher in the low compared with the high 18:3n-3 fatty acid diet (1.7 vs. 0.9%, respectively).

Tissue 18:3n-3 content (i) Whole body. Raising the 18:3n-3 content from a low to a high 18:3n-3 fatty acid diet significantly increased the 18:3n-3 content of whole body lipids (Table 3). Feeding a low 18:3n-3 fatty acid diet to the dams significantly increased the 18:2n-6 content of whole body lipids of the rat pups compared with the high 18:3n-3 fatty acid diet. The 22:6n-3 content of whole body lipids was not significantly different between rat pups fed the low vs. high 18:3n-3 fatty acid diet. The 20:5n-3 and 22:5n-3 content of whole body was significantly different between rat pups fed low vs. high 18:3n-3 fatty acid diet. However, the 20:4n-6 content of whole body lipids was significantly different. Based on the lipid content and 18:3n-3, 20:5n-3, 22:5n-3, and 22:6n-3 content, as well as the weight of the tissues examined in the present study, the 18:3n-3, 20:5n-3, 22:5n-3, and 22:6n-3 content in whole body of rat pups fed either low or high 18:3n-3 fatty acid diet was calculated to be approximately 39 and 630 mg, 0 and 30 mg, 4.3 and 30 mg, and 12.9 and 21.4 mg, respectively (data not shown). The other tissues examined in this study including brain, liver, epididymal fat pads, and muscles (arms and legs) from 2-wk-old rat pups fed either low or high 18:3n-3 fatty acid diet contained small amounts of 18:3n-3, 20:5n-3, and 22:5n-3 (data not shown). Interestingly, the skin (epidermis, dermis, and subcutaneous tissue) of rat pups fed either low or high 18:3n-3 fatty acid diet contained a significant amount of 18:3n-3. The total 18:3n-3 content in skin for the low and high 18:3n-3 fatty acid diet was approximately 15 and 260 mg, respectively (data not shown).

DISCUSSION

The results from the present study demonstrate that increasing maternal dietary 18:3n-3 significantly increases the 18:3n-3 but not the 22:6n-3 content of the whole body, brain, skin (epidermis, dermis, and subcutaneous tissue), epididymal fat pads, and muscles (arms and legs) in 2-wk-old rat pups. The 2-wk-old rat pups in the present study were used because at this age very active brain growth occurs with rapid accretion of PUFA, especially 22:6n-3, for brain membrane synthesis (33,34). Therefore, the demand for 22:6n-3 in 2-wk-old rat pups for postnatal brain growth and development is high and must be provided by the maternal diet.

It is well known that the fatty acid composition of tissues can be readily modified by dietary fat [reviewed by Clandinin *et al.* (35,36)]. The significant differences observed in whole body and tissue 18:2n-6 and 18:3n-3 content between rat pups fed low vs. high 18:3n-3 fatty acid diet were largely a reflection of the dietary fatty acid composition (37–39).

The content of 22:6n-3 was not significantly increased in whole body, brain, skin (epidermis, dermis, and subcutaneous tissue), epididymal fat pads, and muscles (arms and legs) when rat pups were fed the high 18:3n-3 diet. This could be due to the fact that desaturase activity is age-related and that at 2 wk of age desaturase activity may be limited. In this regard, Bourre *et al.* (40) demonstrated in rats that Δ-6 desaturase activity, a rate-limiting step in 20:4n-6 and 22:6n-3 synthesis, varies during the first 21 d following gestation. Therefore, if Δ-6 desaturase activity is low at 2 wk of age, the amount of 18:3n-3 added in the diet would not have any significant effect on increasing the 22:6n-3 content of these tissues. The significant increase in 20:5n-3 (except for brain) and 22:5n-3 (except for muscles) but not 22:6n-3 content of tissues examined in this study when rat pups were fed the high compared with low 18:3n-3 diet shows that 18:3n-3 is metabolized to long-chain n-3 metabolites but that there is a limit on the conversion of 20:5n-3 and 22:5n-3 to 22:6n-3.

The milk (stomach contents) provided to the rat pups by the dam during the 2-wk feeding period provides some preformed 22:6n-3 (Table 1). It is possible that the preformed 22:6n-3 (0.1%) present in the milk of dams fed the high 18:3n-3 fatty acid diet (Table 1) is sufficient to significantly increase the content of 22:6n-3 observed in liver of rat pups fed the high 18:3n-3 fatty acid diet (Table 3) without the need for additional synthesis of 22:6n-3 from dietary 18:3n-3. With the exception of the brain, increasing dietary 18:3n-3 by reducing the 18:2n-6/18:3n-3 ratio from 24.7:1 to 1.0:1 did not show any competitive effect of reduced 20:4n-6 and increased 22:6n-3 incorporation into whole body or tissue lipids. This would suggest that either desaturase activity is low or that a lower 18:2n-6/18:3n-3 ratio than that used in the present study may be required to reduce the 20:4n-6 and increase the 22:6n-3 content in the tissues examined (20).

Quantitative analysis of the 18:3n-3 content in rat pup tissues examined in the present study showed that a significant amount of 18:3n-3 was incorporated into whole body lipids. The 18:3n-3 content of rat pup whole body lipids was significantly greater in rat pups fed the high compared with the low 18:3n-3 diet (approximately 630 vs. 39 mg, respectively). The skin of rat pups fed low or high 18:3n-3 fatty acid diet contained significant quantities of 18:3n-3 (approximately 39 and 41% of the total 18:3n-3 content in whole body, respectively). The high amounts of 18:3n-3 found in the skin were stored as part of the fatty acid component of triglycerides in the subcutaneous fat (data not shown).

Thus, it appears that the skin, including epidermis, dermis and subcutaneous tissue, is a major deposition site for 18:3n-3 in 2-wk-old rat pups.

The saturated fatty acid content in whole body, skin, and epididymal fat pads was significantly decreased ($P < 0.05$) when the pups were fed maternal milk from the dams fed the high 18:3n-3 diet (data not shown). This decrease in the saturated fatty acid content of tissues was due to the substantial increase in the content of 18:3n-3 in these tissues by the high 18:3n-3 diet.

In conclusion, the results from the present study demonstrate that increasing maternal dietary 18:3n-3 content from 1.1 to 20.1% of the total dietary fatty acids significantly increases the 18:3n-3 but not the 22:6n-3 content in most tissues. If the present findings from this study are extrapolated to neonates, it appears that increasing the dietary 18:3n-3 content of the neonate's feed will significantly increase the 18:3n-3 but not the 22:6n-3 content of neonatal tissues.

Increased α-Linolenic Acid Intake Increases Tissue α-Linolenic Acid Content and Apparent Oxidation with Little Effect on Tissue Docosahexaenoic Acid in the Guinea Pig

Zhong Fu and Andrew J. Sinclair*

Department of Food Science, RMIT University, Melbourne, Victoria, 3001, Australia

ABSTRACT: The essential fatty acids do not have identical roles in nutrition. Linoleic acid (LA) accumulates throughout the body of most mammals, whereas α-linolenic acid (ALA) is rarely found in tissue lipids to the same extent as LA. It has been argued that this is the result of metabolism of ALA to docosahexaenoic acid (DHA) or that ALA is rapidly β-oxidized to acetyl CoA and CO_2. In this study, we consider the effect of high and low ALA levels on the tissue distribution of ALA and other n-3 polyunsaturated fatty acids (PUFA) in all tissues. Guinea pigs were fed one of two defined diets for 3 wk from weaning with both diets containing 1.8% (by weight) of LA and either 1.7% ALA or 0.03% ALA. The high ALA diet was associated with significantly increased ALA levels in all tissues except the brain and significantly increased levels of long-chain n-3 PUFA in all tissues except intestines, brain, carcass, and skin. The long-chain n-3 PUFA content of the whole body was less than 5% of that of the ALA content in both diet groups, and the major long-chain n-3 PUFA (>66% of total) in the body was 22:5n-3. The brain was the only tissue where the DHA content exceeded that of 22:5n-3. On the low ALA diet, there appeared to be conservation of ALA based on a comparison of the ratio of LA to ALA in the tissues compared with that in the diet. On the high ALA diet there was a loss of ALA relative to LA in the tissues compared with the diet. These studies suggest that the low levels of tissue ALA in the guinea pig are likely the result of β-oxidation or excretion *via* the skin and fur rather than metabolism to DHA.

Paper no. L8412 in *Lipids 35,* 395–400 (April 2000).

Since the discovery of the essential fatty acids (EFA), linoleic (LA) and α-linolenic acid (ALA) in 1930 (1), there has been much emphasis on the importance of LA in nutrition in different species such as man and domestic animals (2). It is acknowledged that LA is the more important EFA in reversing the classical symptoms of EFA deficiency such as scaly skin, dry hair, and membrane dysfunction, although recent studies have raised important questions about the role of LA in EFA deficiency (3). It is recognized that LA prevents water loss through the skin (4), while arachidonic acid (AA) is the precursor of all the main eicosanoids and related compounds. In the last 20 yr the importance of the ALA family has been recognized in different terrestrial species (5,6), with eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) being effective in reducing plasma triacylglycerol levels (7) while DHA plays an important role in membrane structure and function in excitable tissues such as the brain, retina, and heart (8–11).

For many years, scientists have remarked on apparent differences in deposition of LA and ALA in the tissues of different species. This is exemplified by the extent to which LA accumulates in tissue lipids in a wide variety of species compared with ALA (5,11), which does not appear in high concentrations even in circumstances where equal amounts of LA and ALA are fed (12,13). Often the only evidence of the presence of the ALA family is in tissues like retina and brain where its metabolite, DHA, is found in relative abundance and there is almost no ALA. There are several explanations offered for this, including (i) that ALA is rapidly converted to EPA, docosapentaenoic acid (DPA), and DHA (14), (ii) that ALA is even more rapidly metabolized to saturated and monounsaturated fatty acids and cholesterol in neural tissue (14,15), and (iii) that ALA is rapidly β-oxidized by comparison with LA, a suggestion which has support from direct measurements of LA and ALA β-oxidation in the rat *in vivo* and *in vitro* (16–18). It is interesting that the extent of ALA β-oxidation may depend on the LA intake, based on data in the rat showing increased ALA β-oxidation with increasing levels of LA in the diet (18). Humans also show differences in LA and ALA accumulation. For example, in a recent study in vegetarian males, Li *et al.* (13) showed that equal amounts of LA and ALA fed for 4 wk raised the levels of ALA in platelets and plasma lipids, but the amount of ALA in these fractions was substantially less than that of LA. In that study there were only minor increases in long-chain n-3 polyunsaturated fatty acids (PUFA) in plasma and platelets.

Many studies on tissue distributions of ALA in animals and man have investigated only a few tissue compartments, such as liver, muscle and brain, which may limit the ability to interpret the events in the whole body. The aim of this study was to examine the distribution of ALA throughout the body

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EFA, essential fatty acids; EPA, eicosapentaenoic acid; LA, linoleic acid; PUFA, polyunsaturated fatty acid; TLC, thin-layer chromatography.

in young guinea pigs raised on diets with either a high or low ALA intake in an attempt to determine why ALA does not accumulate in tissue lipids.

MATERIALS AND METHODS

Eight 4-wk-old male pigmented guinea pigs were purchased from Monash University (Melbourne, Australia). After having been fed on a guinea pig chow diet for 10 d, they were randomly divided into two groups, fed with one of two semisynthetic diets (Glen Forrest Stockfeeders, Glen Forrest, Western Australia) mixed with normal chow for 1 wk, and then fed with the semisynthetic diet only for the next 3 wk. The major ingredients including the vitamin and mineral composition have been reported previously in similar studies by our group using guinea pigs (19). The fat (vegetable oils), protein (casein), and carbohydrate (sucrose, glucose and starch) contents of the diets were 10, 30, and 47%, respectively. The fatty acid compositions of these two different diets are shown in Table 1; the 18:2n-6 content of each diet was 18% of the total fatty acids, while 18:3n-3 was 17.3% in the high ALA diet and 0.3% in the low ALA diet. The oils used in the diets consisted of mixtures of coconut, linseed, palm stearin, safflower, sunola, and canola oils in order to provide a constant LA and variable ALA contents. At the conclusion of the study, the guinea pigs were asphyxiated in CO_2 gas, the head was severed from the body, and then the skin and fur removed from the skull and carcass of the body, respectively. The other tissues were collected, washed free from blood in ice-cold normal saline, and dried with blotting paper; the total weight of the organs was recorded and then the tissues were stored at –20°C. The stomach and intestines were opened and washed free of digesta/feces and stored as above. Prior to lipid extraction, all tissues were finely cut up using a scalpel and were thoroughly mixed, except in the case of the carcass (muscle plus bone) which was minced using an industrial mincer prior to being diced as above. Lipids were extracted from approximately 2 g of each tissue (2 × 2 g for the carcass) using chloroform/methanol as described by Nelson (20); a precise amount of internal standard fatty acid (23:0; Nu-Chek-Prep, Elysian, MN) was added to each tissue at the start of the lipid extraction. One aliquot of each tissue lipid was converted to fatty acid methyl esters for determination of the tissue fatty acid content by capillary GLC using on a BPX-70 column (SGE, Melbourne, Australia) (21). The fatty acids were identified by comparison with standard mixtures of fatty acid methyl esters, and the results were calculated using response factors derived from chromatographing standards of known composition which contained 23:0.

TABLE 1
Fatty Acid Composition of the Two Diets

	Fatty acid composition (%)	
Fatty acid	High ALA diet[a]	Low ALA diet[a]
12:0 + 14:0	10.9	11.4
16:0	13.7	31.7
18:0	4.3	4.1
18:1	35.3	34.5
18:2n-6	18.2	17.5
18:3n-3	17.3	0.3
18:2/18:3	1.05	58

[a]Twenty- and 22-carbon polyunsaturated fatty acids were below the level of 0.01% of total fatty acids. ALA, α-linoleic acid.

RESULTS

The weights of the animals at the conclusion of the feeding study were 587 ± 55 and 570 ± 55 g in the high- and low-ALA diet groups, respectively. The animals in each group appeared healthy.

The distribution of PUFA in the different tissues is shown in Table 2. LA was the major PUFA in the whole body (>20 g), followed by ALA (2–9 g), AA (≈1 g), and relatively small amounts of long-chain n-3 PUFA (0.3 g). The adipose tissue, skin, and carcass (muscle plus bone) were the main sites of LA, ALA, AA, and EPA deposition. The main sites for DHA deposition were carcass and brain. This table also shows that the high ALA diet resulted in a significant accumulation of ALA in every tissue except the brain, with the greatest difference between the two diets being in the adipose tissue, and the highest proportional rise in liver and digestive tract. The high ALA diet significantly increased the EPA, DPA, and DHA levels in most tissues although the increases were not large by comparison with the increases in the ALA in different tissues. Although the intake of LA was constant in the two diet groups, the LA content was significantly increased in most of the tissues in the high ALA diet group, except for liver, kidney, and brain. AA was significantly increased in heart, stomach, and intestines, and significantly decreased in adipose, carcass, and skin in the high ALA group. The whole body content of ALA and EPA showed significant increases in animals with high ALA diet.

The complete tissue fatty acid compositions are presented in Table 3. With high ALA intake, the ALA proportion was increased in all tissues except brain. The EPA, 22:5n-3, and DHA proportions were significantly increased in all tissues except skin. The high ALA diet was associated with some significant changes in saturated fatty acids in most tissues. In all tissues except brain, there were significant decreases in the proportions of palmitic acid on the high ALA diet which had less than half the palmitic acid content of the low ALA diet. On the high ALA diet, the proportion of stearic acid rose in heart, lung, and spleen. On the high ALA diet, the proportion of LA increased significantly in heart, lung and spleen, skin, and carcass.

DISCUSSION

The aim of this study was to examine the distribution of ALA throughout the body in young guinea pigs on diets with either a high or low ALA intake in an attempt to determine why ALA does not accumulate in tissue lipids.

TABLE 2
Tissue n-6 and n-3 Fatty Acid Contents in Guinea Pigs Fed a Diet High or Low in ALA[a] (mg/tissue)

[a]Means ± SD. n = 4 animals in each group. With each tissue, for each fatty acid, means followed by the superscript roman letter "a" are significantly different between diets, $P < 0.05$. For abbreviations see Tables 1 and 2.

Where did ALA accumulate in the body? The major sites for ALA accumulation were adipose, carcass, and skin, these tissues accounting for approximately 90% of the whole body distribution of ALA. In this study, skin would include epidermis, dermis, and perhaps some subcutaneous fat. Skin has not been reported as a major site of ALA deposition previously, in this species. LA was also mainly found in the same tissues (adipose, carcass, and skin). The carcass, as sampled in this study, includes muscle and bone; however, it is assumed that the majority of the lipids originated from muscle. Few other studies have examined all tissues as sites for deposition of PUFA. Becker *et al*. (22) showed that in the rat, the major sites in the body for the deposition of radiolabeled ALA were liver, brown fat, and adrenal cortex. It is presumed that the skin was removed prior to autoradiography in that particular study. Cunnane and Anderson (23) examined all major tissues in young rats fed equal amounts of LA and ALA and found that adipose, carcass, and skin were the main sites for both LA and ALA accumulation. In the present study, the major sites of EPA and DPA deposition were adipose, skin, and carcass, while DHA deposition occurred in the carcass, brain, skin, and adipose tissue. Since the carcass contained 47–62% of the whole body DHA, it is possible that this tissue could act as a reservoir of long-chain n-3 PUFA such as DHA for vital times such as pregnancy and lactation, even on diets low in ALA.

Did the high ALA diet result in more DHA in the whole body and other tissues? This is an important issue since there is evidence that in the brain ALA is rapidly metabolized to DHA (14,15), while in the infant formula area there has been much discussion recently about the effectiveness of ALA as a DHA precursor (24–27). Increasing the ALA content of the diet substantially increased the tissue stores of ALA; however, there were only modest increases in the long-chain n-3 PUFA; these increases occurred in all tissues except skin and carcass in the guinea pig. While the whole body ALA content increased 3.8× on the high-ALA diet, the EPA content increased 6×, the DPA content did not change, and the DHA content increased only 1.1×. On a mass basis, the high ALA diet led to a 5.5 g increase in the whole body ALA level, compared with an increase of 0.06 g of long-chain n-3 PUFA. In this species therefore, conversion of ALA to DHA does not appear to be a major metabolic route for ALA metabolism unless there is a very high turnover of DHA. Several groups have reported that in the brain β-oxidation of ALA and carbon recycling into saturated and monounsaturated fatty acids and cholesterol are quantitatively more important than conversion of ALA to DHA (15,28).

If ALA is not being converted to DHA, what happens to it? The proportion of LA in all tissues, except brain, lung and spleen, was high, where it ranged from 18–32% of the total

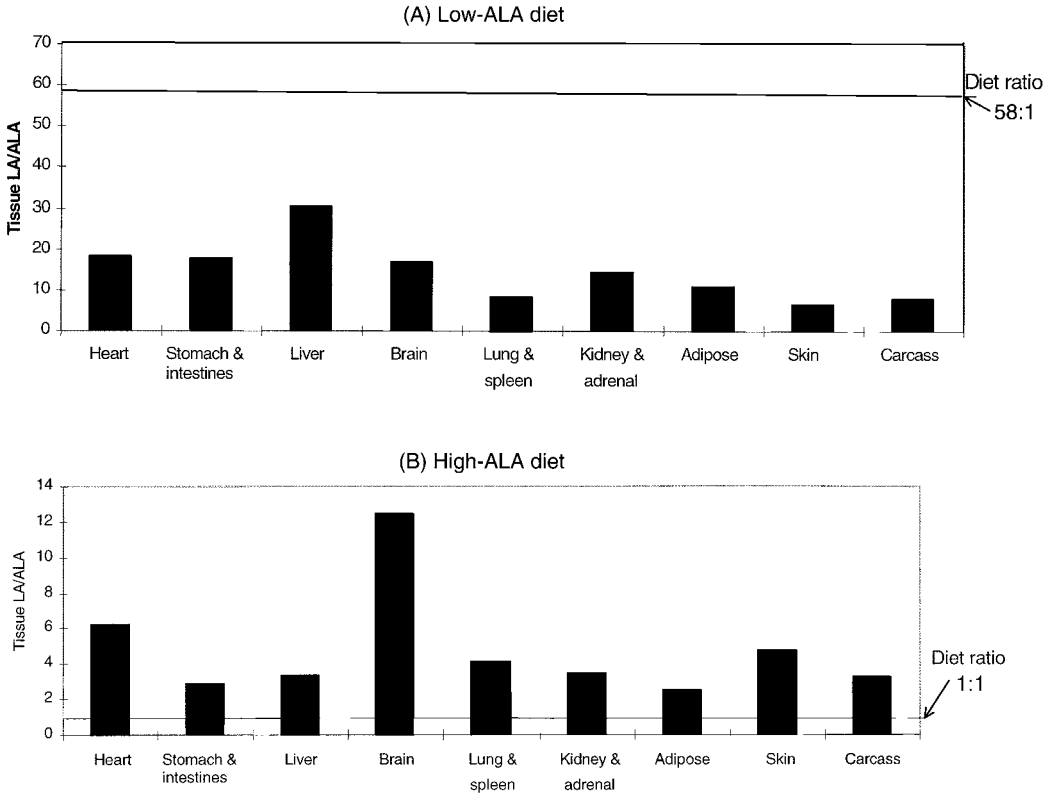

FIG. 1. The effect of high- and low-α-linolenic acid (ALA) diets on the proportions of ALA in body tissues in guinea pigs. The data are shown as the ratio of linoleic acid (LA) to ALA in each tissue compared with the LA to ALA ratio in the diet. (A) On the low-ALA diet, all tissue LA/ALA ratios were less than that in the diet, indicating conservation of ALA relative to LA; (B) on the high-ALA diet, all tissue LA/ALA ratios were higher than that in the diet indicating a relative loss of ALA compared with LA.

tissue fatty acids. In comparison, the ALA levels in these tissues varied from 4–9% on the high ALA diet and 1–2% on the low ALA diet. Cunnane and colleagues (29) have used a modification of a balance method to determine the apparent oxidation of fatty acids in the rat based on the disappearance of fatty acids (intake – [accumulation + losses from excretion]). We did not determine food intake or excretion of fatty acids; however, since the LA and ALA are essential, it is possible to arrive at an expression of fatty acid losses based on a comparison of the ratios of LA to ALA in the tissues compared with the same ratio in the diet. On the diet low in ALA, the LA/ALA value in all tissues was substantially less than that of the diet. For example in the diet the LA/ALA was 58:1, while in the whole body it was 9:1 and in the individual tissues it ranged from 2:1 to 18:1 (Fig. 1A). This suggests that there was a conservation of ALA in the body relative to LA on the diet with the very low ALA intake (0.03 g/100 g diet). This is consistent with data in rats from Becker *et al.* (30,31) who showed that less LA was β-oxidized in rats on a low-EFA diet compared with a high-EFA diet. In contrast, on the high-ALA diet, there appeared to be a loss of ALA relative to LA. That is, on the high-ALA diet with a LA/ALA value of 1.05:1 the whole body ratio was 3:1, and in individual tissues it ranged from 3 to 10:1 (Fig. 1B). These data suggest that in the circumstances of a high-ALA intake there is increased loss of this fatty acid. Others have reported that ALA is preferentially β-oxidized *in vivo* and *in vitro* (16–18), while the long-chain n-3 PUFA induce a marked stimulation of brown adipose tissue thermogenic activity (32). The effect of these two dietary regimes on ALA can be summarized as follows: first, the low-ALA diet was associated with a conservation of tissue ALA while on the diet rich in ALA there was a preferential loss of ALA, possibly through β-oxidation or other routes of excretion such as that *via* the skin and fur as reported recently in the guinea pig (33). On the high-ALA diet, there was a 30% increase in tissue LA content. This observation is hard to explain, however, since those tissues which showed increased proportions of LA also showed decreases in the proportions of palmitic acid; it may be related to the lower palmitic acid level of this high ALA diet. An alternative explanation could be that there was a relative conservation of LA due to the apparent increase in β-oxidation of ALA.

In conclusion, these data show that (i) high intakes of dietary ALA (1.7% ALA in diet) in the guinea pig led to very little increase in the whole body content of long-chain n-3 PUFA compared with a diet with a low ALA level (0.03% ALA in diet), (ii) the high-ALA diet resulted in an increased tissue ALA level and decreased palmitic acid level in all tissues except the brain, (iii) no one tissue mirrors the whole body distribution of n-3 or n-6 PUFA, (iv) ALA retention in the body varied according to intake, with low ALA intakes being associated with a higher retention of ALA in the body than on diets rich in ALA. These data suggest the low tissue levels of tissue ALA in the guinea pig are likely to be the result of β-oxidation of ALA to CO_2 or excretion *via* skin and fur, rather than metabolism to DHA.

ABSTRACT: The present study was undertaken in order to re-examine the effect of n-3 polyunsaturated fatty acid (PUFA)-rich diet supplementation on lipid peroxidation and vitamin E status of rat organs. Male Wistar rats were fed a diet containing safflower or fish oil at 50 g/kg diet and an equal amount of vitamin E at 59 mg/kg diet (1.18 g/kg oil; and 1.5 g/kg PUFA in safflower oil diet, and 4.3 g/kg PUFA in fish oil diet) for 6 wk. Fatty acid composition of total lipids of brain, liver, heart, and lung of rats fed fish oil was rich in n-3 PUFA, whereas that of each organ of rats fed safflower oil was rich in n-6 PUFA. The vitamin E levels in liver, stomach, and testis of the fish oil diet group were slightly lower than those of the safflower oil diet group, but the levels in brain, heart, lung, kidney, and spleen were not different between the two diet groups. The levels of phospholipid hydroperoxides were determined by the high-performance liquid chromatography–chemiluminescence method and the levels of thiobarbituric acid-reactive substances (TBARS) were determined at pH 3.5 in the presence of butylated hydroxytoluene with or without EDTA. Levels of phospholipid hydroperoxides and TBARS in the brain, liver, heart, lung, kidney, spleen, stomach and testis of the fish oil diet group were similar to those of the safflower oil diet group. The results indicate that high fish oil intake does not induce increased levels of phospholipid hydroperoxides and TBARS in rat organs.

Paper no. L8346 in *Lipids 35*, 401–407 (April 2000).

Epidemiological studies have shown apparent beneficial effects of fish oil containing high n-3 polyunsaturated fatty acids (PUFA), eicosapentaenoate (20:5n-3) and docosahexaenoate (22:6n-3), on mortality from heart disease and cancer (1,2). On the other hand, undesirable effects of high fish oil intake have been a concern because n-3 PUFA whose unsaturation index (UI) and peroxidizability index (PI) are higher than those of n-6 PUFA and n-9 monounsaturated fatty acids are more readily oxidized under aerobic conditions (3). Lipid peroxidation occurring in the human body has been considered to cause various disorders including atherosclerosis, diabetes, burn injury, and retinopathy (4).

Many earlier studies suggested that intake of a diet high in fish oil results in high n-3 PUFA content in membrane lipids and enhances lipid peroxidation in organs, blood and urine of experimental animals and humans (5–16). Low doses of fish oils do not significantly affect lipid peroxidation *in vivo* (17–22). Decreased tissue levels of vitamin E following an increase in the intake of fish oil have been demonstrated (7,9,23–31). Most of these studies, however, have employed traditional thiobarbituric acid (TBA) assay without incorporation of an antioxidant for estimation of lipid peroxidation of the samples. Artificial TBA-reactive substances (TBARS) generated during the assay in the absence of an antioxidant may have been measured.

The present study was undertaken to reexamine the effect of supplementation of safflower or fish oil on vitamin E status and lipid peroxidation of rat organs. Two different classes of lipid peroxidation products, phospholipid hydroperoxides (32,33) and TBARS in the presence of butylated hydroxytoluene (BHT) as an antioxidant (34–38), were measured.

MATERIALS AND METHODS

Materials. Phosphatidylcholine (egg yolk) (PC) and phosphatidylethanolamine (egg yolk) (PE) were obtained from Nippon Fats and Oil Liposome Company (Tokyo, Japan). PC hydroperoxide (PCOOH) and PE hydroperoxide (PEOOH) were prepared just before use according to a method described elsewhere (32). Briefly, PC and PE were photooxidized at 10°C for 10 h in the presence of methylene blue, and methylene blue was removed by passing through a column of florisil. Peroxide values of PCOOH and PEOOH were estimated to be 1380–1680 and 770–840 neq/mg, respectively. Cytochrome c and luminol were purchased from Sigma Chemical Co. (St. Louis, MO) and Wako Pure Chemical Industries (Osaka, Japan), respectively. TBA was obtained from Merck (Darmstadt, Germany).

Animals and diets. The protocol of animal preparations for the present experiment was approved by the Ethics Committee of our institute. Twenty-four 4-wk-old male Wistar rats weighing 50–70 g were supplied by Japan Laboratory Animals Corp. (Tokyo, Japan). Rats were divided into two groups of six animals each, and each group was fed a diet with safflower or fish oil at 50 g/kg diet for 6 wk as described previously (39). Saf-

Abbreviations: BHT, butylated hydroxytoluene; HPLC, high-performance liquid chromatography; PC, phosphatidylcholine; PCOOH, PC hydroperoxide; PE, phosphatidylethanolamine; PEOOH, PE hydroperoxide; PI, peroxidizability index; PUFA, polyunsaturated fatty acids; TBA, thiobarbituric acid; TBARS, TBA-reactive substances; UI, unsaturation index.

flower oil was rich in n-6 fatty acids (n-6 total: 78.0%, and n-3 total: 0.3%), and fish oil was rich in n-3 fatty acids (n-6 total: 1.3%, and n-3 total: 26.5%) (39). While UI, as expressed by the sum of percentages of individual fatty acids × number of double bonds, of fish oil [168] was equal to that of safflower oil, PI, as expressed by the sum of percentages of individual fatty acids × number of active methylene groups (40), of fish oil [114] was higher than that of safflower oil [78], indicating that fish oil can be more readily peroxidized under aerobic conditions. Peroxide and acid values of safflower oil were 1.1 and 0.2, respectively, and those of fish oil were 1.2 and 0.2, respectively. The overall content of vitamin E in both the diets was equal at 59 mg/kg dried solid diet (1.18 g/kg oil; and 1.5 g/kg PUFA in safflower oil diet, and 4.3 g/kg PUFA in fish oil diet).

Rat organ sampling. At the end of the feeding period, six rats of each diet group were sacrified by bleeding. Brain, liver, heart, lung, kidney, spleen, stomach, and testis were quickly isolated and washed with physiological saline. Each organ was homogenized in about tenfold amount of 10 mM potassium phosphate buffer containing 30 mM KCl (pH 7.8) (wt/vol) with a ice-cooled Potter-type Teflon homogenizer. The homogenate was stored at –80°C under nitrogen atmosphere before use. The amount of protein in the homogenate was determined by the Lowry *et al.* method (41) using bovine serum albumin as a reference standard.

Fatty acid composition of total lipids of rat organs. Total lipids of rat brain, liver, heart, and lung were extracted according to the method of Bligh and Dyer (42). Thus, 1–10 mL of each homogenate containing 0.3–10 g wet isolated organ was mixed with sixfold volumes of $CHCl_3$/MeOH (2:4, vol/vol), and the mixture was centrifuged at 800 × *g* at 4°C for 30 min. Supernatant and pellet were separated. The pellet was mixed with threefold volumes of the organic solvent mixture and 0.8-fold volume of water, and the mixture was centrifuged to obtain supernatant. The supernatants were combined and mixed with threefold volumes of $CHCl_3$ and threefold volumes of water, and the mixture was centrifuged. The lower organic phase was dried by purging with nitrogen gas, and redissolved into 2 mL of $CHCl_3$. The solution was stored at –20°C before analysis. Fatty acid composition was determined by gas chromatography after methylation with HCl/methanol by Special Reference Laboratory Inc. (Tokyo, Japan).

Determination of vitamin E levels in the homogenates of rat organs. Vitamin E levels of rat organs were determined according to the method previously described (43). To 0.1–1.0 mL of the organ homogenate, 1.0 mL of 6% pyrogallol solution in ethanol and 1.0 mL of ethanol were added. After heating the mixture at 70°C for 2 min, 0.2 mL of 60% KOH solution was added, and the mixture was heated at 70°C for 30 min. Vitamin E was extracted by addition of 2.5 mL of water and 5.0 mL of *n*-hexane, and subsequent centrifugation at 1,500 × *g* for 5 min. The upper phase (4.0 mL) was collected and evaporated to dryness to be redissolved into 0.2 mL of methanol. High-performance liquid chromatography (HPLC) was carried out by using an Hitachi 655 liquid chromatograph (Tokyo, Japan) equipped with an Inertsil ODS-2 column (4.6 mm i.d. × 250 mm; GL Sciences Incorporated, Tokyo, Japan) by injection of 10 μL of the sample solution in methanol, and the column was eluted with a mobile phase composed of methanol/water (98:2, vol/vol) at a flow rate of 1.4 mL/min. A fluorescent peak was detected at 292/335 nm with a Shimadzu RF-535 fluorescence spectromonitor (Osaka, Japan). The peak due to vitamin E appeared at a retention time of 17–19 min. The amount of vitamin E in the sample was estimated by comparing the peak area with those of the calibration curve of the standard DL-α-tocopherol. Vitamin E level in each organ was expressed per milligram protein.

HPLC–chemiluminescence determination of PEOOH and PCOOH in total lipids of rat organs. Levels of PCOOH and PEOOH in the total lipid fractions of rat organ homogenates were determined by HPLC–chemiluminescence method (32,33). The lipid fraction was obtained from 0.5–3 mL of each organ homogenate containing 0.1–0.7 g wet organ according to the method of Bligh and Dyer (42), as described. The lower organic phase was dried by purging nitrogen gas, and redissolved into 2.5 mL of a mixture of $CHCl_3$/MeOH (2:1, vol/vol) and 0.5 mL of 0.05 M KCl. The mixture was centrifuged to obtain 1.6 mL of lower phase, which was evaporated to dryness and redissoved into 100 μL of $CHCl_3$. A 10-μL portion of this extract was subjected to HPLC using a column of YMC A-012 S-5 120 A SIL (4.6 mm i.d. × 250 mm) (Yamamura Chemical Laboratories, Kyoto, Japan) and a mobile phase composed of chloroform/methanol (1:9, vol/vol) at a flow rate of 1.0 mL/min. A solution composed of 10 μg/mL cytochrome c and 1 μg/mL luminol in 50 mM borate buffer (pH 9.3) was mixed with the eluate at a flow rate of 0.9 mL/min and chemiluminescence generated was detected using a JASCO 825-CL Intelligent CL detector (Tokyo, Japan). The chemiluminescent peaks due to PEOOH and PCOOH exhibited retention times of 4 and 8 min, respectively. The amounts (neq) of PCOOH and PEOOH were determined by comparing their peak areas with a calibration curve of the peak areas of the standard solutions of PCOOH and PEOOH (0–100 neq).

TBARS in the homogenates of rat organs. TBARS in the homogenates of rat organs were determined according to the method previously described (34–38). The homogenate of each rat organ (200 μL); 650 μL of a mixture consisting of 0.20 mL of 5.2% sodium dodecyl sulfate in water, 50 μL of 0.8% BHT solution in glacial acetic acid, 1.50 mL of 0.8% TBA solution in water, and 1.70 mL of water with or without EDTA at a final concentration of 2 mM; and 150 μL of 20% acetate buffer (pH 3.5) were placed in this order (total volume: 1.0 mL). The mixture was kept at 5°C for 60 min and then heated at 100°C for 60 min. The mixture was extracted with 1.0 mL of a mixture of 1-butanol/pyridine (15:1, vol/vol). Absorbance at 532 nm of the extract was measured. The amount of red pigment reflecting TBARS was calculated using a molecular extinction coefficient of pigment:156,000 M^{-1} cm^{-1}.

Statistical analysis. Data were analyzed by Student's *t*-test.

RESULTS

Two groups of male Wistar rats (n = 6) were fed a diet containing safflower oil or fish oil with an equal amount of vitamin E.

[a]Expressed as percentages (w/w) of total fatty acids present. Values are means ± SD for three rats. *Significantly different from S as measured by Student's *t*-test at $P < 0.05$.
[b]UI: Unsaturation index (sum of percentages of individual fatty acids × number of double bond).
[c]PI: Peroxidizability index (sum of percentages of individual fatty acids × number of active methylenes).

Fatty acid compositions of total lipids of brain, liver, heart, and lung of three rats of each rat group were determined (Table 1). Each organ of the rats fed fish oil showed significantly higher n-3 PUFA content than the organs from rats fed safflower oil. Likewise, each organ of the rats fed safflower oil showed significantly higher n-6 PUFA content than those fed fish oil. In total lipids of these organs, the amounts of linoleate (18:2n-6) and arachidonate (20:4n-6) were decreased, and the amounts of eicosapentaenoate (20:5n-3) and docosahexaenoate (22:6n-3) were increased in the fish oil diet group. UI and PI of the total lipids of these organs from the fish oil diet group were slightly higher than or similar to those of the corresponding organs from the safflower oil diet group.

Vitamin E levels in brain, liver, heart, lung, kidney, spleen, stomach, and testis from six rats were compared between two diet groups (Table 2). The levels in liver and testis of the fish oil diet group were slightly lower than those of the safflower oil diet group, but the levels in other organs were not different between two diet groups.

Levels of phospholipid hydroperoxides, PCOOH and PEOOH, in rat organs of two diet groups were determined by HPLC–chemiluminescence method (32,33). A representative HPLC chromatogram from rat brain is shown in Figure 1. PEOOH levels were always higher than PCOOH levels in each organ. The mean values of the levels of these phospholipid hydroperoxides of six rats were compared between two diet groups (Table 3). There were large variations in the levels of the hydroperoxides in some organs, which may be due to the instability of the hydroperoxides converting into more stable TBARS. The PCOOH and the PEOOH levels of organs of both the diet groups were lower than 3 nmol/mg protein, and there were no differences in the levels between two diet groups.

TBARS levels in rat organs of two diet groups were determined. TBA assay of the Ohkawa's procedure at pH 3.5 was employed by incorporating BHT into the assay medium (36–38). Representative absorption spectra of the TBA assay mixtures with and without EDTA of rat brain are shown in Figure 2. Absorption spectra of the assay mixtures of brain, heart, and kidney were very similar to the spectrum of the pure red pigment with a maximal absorption at 532 nm, but the spectra of other organs indicated contamination with yellow or orange pigments with maximal absorptions at the lower wavelengths. When the mean values of TBARS of organs of six rats of two diet groups as assessed by the assay with and without EDTA were compared (Table 4), no significant differences between the two diet groups were observed. While TBARS level of each organ obtained in the presence of EDTA was slightly lower than that obtained in the absence of EDTA, TBARS of each organ may be derived mainly from malonaldehyde derivatives. TBARS levels of brain of both the diet groups were the highest among those of eight organs, and estimated to be 6 nmol/mg protein in the absence of EDTA and 4 nmol/mg protein in the presence of EDTA.

DISCUSSION

Many earlier data have suggested undesirable effects of dietary fish oil or n-3 PUFA intake on the lipid peroxidation of organs, blood, and urine in animal and human subjects (5–31). In the studies of rats, the TBARS levels of plasma and liver of the rats

fed fish oil with the higher vitamin E content were lower than those of rats fed fish oil with the low vitamin E content (9). The TBARS levels of liver microsomal fraction of the rats fed fish oil were decreased by increased vitamin E levels (23). Fish oil intake reduces vitamin E content in rat liver (25). Vitamin E levels in the heart of rats fed n-3 PUFA were lowered (26). Urinary TBARS were higher in the rats fed n-3 PUFA compared with those in rats fed n-6 PUFA (27). In human subjects, higher doses of fish oil have been shown to increase plasma (10,11), low density lipoprotein (14), and urinary TBARS levels (12,13), although some authors (12) have suggested that the increase in urine is caused by the lipid peroxidation products formed in food before its consumption.

Most of these studies employed the traditional TBA assay for estimation of degree of lipid peroxidation. It is now known that the TBA assay should be conducted in the presence of an antioxidant, such as BHT, in order to avoid artificial lipid peroxidation during the assay (35). In the heated acidic medium of the TBA assay under aerobic conditions, biological samples with higher n-3 PUFA would be more susceptible to artificial oxidation. Recent studies by Kubo *et al.* (44) have shown that isolated organs of the rats fed high dietary n-3 PUFA do not contain TBARS to the levels expected from PI of the total organ lipids by the TBA assay with an antioxidant (BHT) indicating that incorporation of BHT in the TBA assay system is important to avoid artificial lipid peroxidation during the assay.

It is claimed that TBARS obtained at pH 3.5 in the presence of EDTA reflect exclusively malonaldehyde derivatives that liberate malonaldehyde under the assay conditions, and TBARS obtained at pH 3.5 in the absence of EDTA reflects not only malonaldehyde but alkadienals/alkenal derivatives that liberate malonaldehyde and alkadienals/alkenals, respectively, under the assay conditions (36–38). Moreover, plasma and urine may not be good samples for TBARS. Hackett *et al.* (45) have strongly argued that the TBA asssay of plasma is not reliable, and the present authors (46) have shown that TBARS in serum or plasma are usually very low and cannot be identified. Human urinary TBARS levels vary from time to time and from day to day (47).

Another important reason for the estimation of lipid peroxidation of biological samples is to employ more than two assay methods based on different principles. The present authors employed two assay methods for *in vivo* lipid peroxidation studies of the organs of rats fed fish oil: HPLC–chemiluminescence assay for phospholipid hydroperoxides developed by Miyazawa *et al*. (32,33) and the TBA assay at pH 3.5, originally developed by Ohkawa *et al.*, in the presence of BHT with and without EDTA (36–38).

In the present study, the oil content in the rat diet was 50 g/kg diet, which was lower than those (100–300 g/kg diet) in the earlier studies (9,23,25–27). However, the oil content in the present study was enough to affect the fatty acid composition of rat organs. Vitamin E content in the diet was regulated at 59 mg/kg diet and 1.2 g/kg oil, which was in the ranges used in the earlier studies (45–210 mg/kg diet and 0.03–2.1 g/kg oil) (9,23,25–27). Vitamin E contents against PUFA were 1.5 g/kg PUFA (for safflower oil diet) and 4.3 g/kg PUFA (for fish oil diet), whereas those were between 0.7 and 5 g/kg PUFA in the earlier studies (9,23,26). The vitamin E content against PUFA in the fish oil diet was threefold higher than those in the safflower oil diet.

We have previously demonstrated the effect of the fish oil feeding on lipid peroxidation of rat erythrocyte membranes (39). Phospholipids of erythrocyte membranes of the safflower oil diet group are rich in n-6 PUFA and those of the fish oil diet group are rich in n-3 PUFA. UI and PI of the membrane phospholipids of the fish oil diet group are higher than those of the safflower oil diet group, and the vitamin E level of the membranes of the fish oil diet group is slightly lower than that of the membranes of the safflower oil diet group. Both the phospholipid hydroperoxide levels and the TBARS levels estimated in the presence of BHT with and without EDTA are not different between the two diet groups.

In the present study, we showed the effect of feeding fish oil on lipid peroxidation of total lipids of rat brain, liver, heart, lung, kidney, spleen, stomach, and testis. n-3 PUFA contents of brain, liver, heart, and lung of the fish oil diet group were higher than those of the safflower oil diet group. UI and PI of total lipids of the organs of the fish oil diet group were higher than or similar to those of the corresponding organs of the safflower oil diet group. The vitamin E levels in liver and testis of the fish oil diet group were slightly lower than those of the safflower oil diet group, but the levels in other organs were not different between the diet groups. Both the phospholipid hydroperoxide and TBARS levels in each organ of the fish oil diet group were similar to those of the safflower oil diet group. The present results indicate that high fish oil intake does not induce increased levels of phospholipid hydroperoxides and TBARS in rat organs.

The discrepancy between the observations in the earlier *in vivo* rat studies (9,23,25–27) and those in our present and previous (39) studies may be due to the difference of the assay methods for TBARS. In the earlier studies, the TBARS levels obtained in the assay without an antioxidant may have reflected the susceptibility of the samples to *in vitro* lipid peroxidation during the assay. In our present and previous (39) studies, the phospholipid hydroperoxide and TBARS levels may little reflect the *in vitro* susceptibility of the samples to the oxidation. In the previous study (39), we showed that both the phospholipid hydroperoxide and TBARS levels of the erythrocyte membranes of the rats of the fish oil diet group become remarkably higher than those of the membranes of the safflower oil diet group when the *in vitro* oxidation is induced. Although the susceptibility of the isolated organs of the rats of the fish oil diet group to the *in vitro* oxidation may be increased when compared to that of the safflower oil diet group, the levels of lipid peroxidation products *in vivo* may not be different.

In conclusion, n-3 PUFA supplementation did not increase lipid peroxidation in rat organs *in vivo* as well as erythrocyte membranes. It is likely that when a sufficient amount of vitamin E is supplied, n-3 PUFA supplementation does not induce undesirable effects in relation to lipid peroxidation.

ABSTRACT: In recent studies, the life span of stroke-prone spontaneously hypertensive (SHRSP) rats was altered by a variety of dietary fats. It was relatively shorter in rats fed canola oil as the sole source of fat. The present study was performed to find out whether the fatty acid profile and the high content of sulfur compounds in canola oil could modulate the life span of SHRSP rats. SHRSP rats (47 d old, n = 23/group) were matched by body weight and systolic blood pressure and fed semipurified diets containing 10% canola oil, high-palmitic canola oil, low-sulfur canola oil, soybean oil, high-oleic safflower oil, a fat blend that mimicked the fatty acid composition of canola oil, or a fat blend high in saturated fatty acids. A 1% sodium chloride solution was used as drinking water to induce hypertension. After consuming the diets for 37 d, five rats from each dietary group were killed for collection of blood and tissue samples for biochemical analysis. The 18 remaining animals from each group were used for determining their life span. The mean survival time of SHRSP rats fed canola oil (87.4 ± 4.0 d) was not significantly different (P > 0.05) from those fed low-sulfur canola oil (89.7 ± 8.5 d), suggesting that content of sulfur in canola oil has no effect on the life span of SHRSP rats. The SHRSP rats fed the noncanola oil-based diets lived longer (mean survival time difference was 6–13 d, P < 0.05) than those fed canola and low-sulfur canola oils. No marked differences in the survival times were observed among the noncanola oil-based groups. The fatty acid composition of the dietary oils and of red blood cells and liver of SHRSP rats killed after 37 d of treatment showed no relationship with the survival times. These results suggest that the fatty acid profile of vegetable oils plays no important role on the life span of SHRSP rat. However, phytosterols in the dietary oils and in liver and brain were inversely correlated with the mean survival times,indicating that the differential effects of vegetable oils might be ascribed, at least partly, to their different phytosterol contents.

Paper no. L8311 in *Lipids 35,* 409–420 (April 2000).

Canola oil (CO) is generally considered to provide positive cardiovascular benefits (1,2) because of its favorable fatty acid profile. It has a low content of saturated fatty acids (SFA) (6–7%) and high content of oleic acid (55–60%). In addition it is a good source of α-linolenic acid (7–10%) and provides a low ratio of linoleic to linolenic acids (2:1). Nevertheless, a series of recent studies reported that CO was one of the oils that had a life-shortening effect on stroke-prone spontaneously hypertensive (SHRSP) rats (3–6). CO shortened the survival time by about 15–50% under 1% NaCl loading compared to soybean oil (SBO) and perilla oil. The life-shortening activity, however, is not specific to CO. A few other common vegetable oils, including high-oleic sunflower, olive and evening primrose oils, also shortened the life span compared to SBO. Although many experiments were performed using various fat blends and subfractions prepared from CO, the life-shortening factor and the mechanism by which CO and other vegetable oils shorten the life span of SHRSP rats are yet to be resolved (5,6).

This study was therefore undertaken to determine whether the fatty acid profile *per se* in CO might account for the shortening of life span of SHRSP rats associated with CO treatment. In order to exclude an effect of the high sulfur content in CO, a special canola variety low in sulfur compounds was used, in addition to regular CO. CO contains slightly higher levels of sulfur compounds than other common edible vegetable oils (7), and historically nothing is known about the health effects of sulfur compounds in CO.

In this report, survival data are presented for SHRSP rats fed diets containing CO, high-palmitic CO (HPCO), low-sulfur CO (LSCO), SBO, high-oleic safflower oil (HOSFO), a fat blend that mimicked the fatty acid composition of CO (MIMIC), another fat blend that provided a large proportion of SFA (HSFAB), and laboratory rat chow (CHOW). The systolic blood pressure (SBP), hematological indices, serum cho-

Abbreviations: AAS, flame atomic absorption spectroscopy, AES, atomic emission spectroscopy; BUN, blood urea nitrogen; CO, canola oil; CHOW, rat chow; CNO, coconut oil; FO, flaxseed oil; HDL, high density lipoprotein; HOSFO, high-oleic safflower oil; HPCO, high-palmitic canola oil; HSFAB, a fat blend high in saturated fat; LC-PUFA, long-chain (C20 + C22) polyunsaturated fatty acids; LSCO, low-sulfur canola oil; MIMIC, a fat blend which mimicked the fatty acid composition of canola oil; MUFA, monounsaturated fatty acids; PO, palm oil; PUFA, polyunsaturated fatty acids; RBC, red blood cells; SBO, soybean oil; SBP, systolic blood pressure; SD, pooled standard deviation; SFA, saturated fatty acids; SHRSP, stroke-prone spontaneously hypertensive rats, TBARS, thiobarbituric acid-reacting substances.

lesterol, fatty acid profiles, sterols, vitamin E and trace elements of some selected tissues are compared in order to assess whether these parameters are correlated with the mean survival time of SHRSP rats.

EXPERIMENTAL PROCEDURES

Dietary oils. The oils used in these studies, alone or in blends, included CO (Loblaws, Ottawa, Canada), SBO (Loblaws), coconut oil (CNO) (CanAmera Foods Inc., Toronto, Canada), palm oil (PO) (CanAmera Foods Inc.), HPCO (CanAmera Foods Inc.), LSCO (TR4 turnip rapeseed oil, extracted and refined by POS Pilot Plant Corp., Saskatoon, Canada), HOSFO (Damingo Inc., Mississauga, Canada), and flaxseed oil (FO) (Canola Industries Canada Inc., Nisku, Canada). It may be noted here that HPCO and LSCO are oils derived from new varieties of canola, and their physical and chemical characteristics are different from those of CO. Two fat blends were prepared. MIMIC (major fatty acids only) was prepared by mixing HOSFO (75 parts), FO (15 parts), and SBO (10 parts). The second blend, HSFAB, was prepared by mixing HOSFO (55 parts), PO (31 parts), CNO (10 parts), and FO (4 parts).

Experimental diets. Seven semipurified diets were prepared using CO, SBO, HOSFO, MIMIC, HSFAB, HPCO, and LSCO as test oils. The diets contained 20.0% casein, 49.95% cornstarch, 10% granulated sugar, 5% alphacel, 3.5% AIN-93G mineral mix, 1% AIN-93VX vitamin mixture (8), 0.3% L-cysteine, 0.25% choline bitartarate, 10% test oil, and 0.0014% *tertiary*-butylhydroquinone as antioxidant. The diets were prepared weekly and stored at –4°C. Laboratory Rodent Diet 5001 (rat chow) (PMI Feeds, Inc., St. Louis, MO) was used as the control diet. According to the specifications provided by the supplier, this commercial diet contained 23% protein, 4.5% fat, not more than 6% fiber, not more than 8% ash, and not more than 2.5% added minerals. Table 1 shows the relative proportions of the fatty acids in the eight diets. The sulfur content of CO and LSCO oils (analyzed by POS Pilot Plant Corporation, Saskatoon, Canada, using inductively coupled plasma) is also shown in Table 1.

Animals and feeding phase. One hundred eighty four SHRSP rats obtained from Seac Yoshitomi Ltd. (Yoshitomi-Cho, Chikujyo-gun, Fukuoka-ken, Japan) at 28 d of age were acclimatized to the environment for 19 d. During this period they were fed the control diet (rat chow) and normal drinking water. After the acclimation period, animals were placed in 8 dietary groups of 23 rats per group in a randomized block according to body weight and SBP. The rats were housed individually in metal cages in a climate-controlled room maintained at 22 ± 1°C and 60% relative humidity with 12-h day/12-h night cycle. Drinking water contained 1% NaCl to induce earlier hypertension. The rats had free access to one of the eight diets and the 1% NaCl solution. SBP was measured once every 2 wk by trained technicians by the tail cuff method (Rat Tail Blood Pressure Systems, Harvard Instruments).

[a]In addition to the fatty acids listed, rat chow contained 0.2% 20:4n-6, 1.4% 20:5n-3, 0.3% 22:5n-3, 0.9% 22:6n-3, and 0.4% other minor n-6 and n-3 long-chain (>C20) polyunsaturated fatty acids (LC-PUFA).

[b]The sums for SFA (total saturated fatty acids), MUFA (total monounsaturated fatty acids), and PUFA (total polyunsaturated fatty acids) may include some minor fatty acids not listed in the table. Dietary oil abbreviations: CO, canola oil; SBO, soybean oil; HOSFO, high-oleic safflower oil; MIMIC, canola oil mimic; HSFAB, a fat blend high in saturated fatty acids; HPCO, high-palmitic canola oil; LSCO, low-sulfur canola oil; CHOW, rat chow. S (ppm), total sulfur content in parts per million; ND, not determined.

At 37 d on the diet, five animals from each group were randomly selected and placed in metabolic cages; fasting urine samples were collected overnight. Immediately after the urine collection, these rats were euthanized by complete exsanguinations under isofluorene anesthesia, and blood from aorta and tissues was collected for biochemical analyzes. The tissue samples intended for lipid analyzes were immediately frozen in liquid nitrogen and stored at –80°C.

The 18 remaining animals from each group were used for the life span study. When an animal was found to suffer from severe stroke, paralysis, to be in pain, or was judged to be unable to survive overnight, euthanasia was performed. The study protocol was approved by the Animal Care Committee of Health Canada.

Blood lipid and clinical measurements. About 3 mL of fasting blood was centrifuged in a vacutainer serum separation tube at 1300 × *g* for 20 min and serum separated. Triglyceride and total cholesterol were determined using an Abbott-VP Bichromatic Analyzer, with the A-Gent Triglyceride test and A-Gent Cholesterol test enzymatic kits (Abbott Laboratories, Mississauga, Canada). High density lipoprotein (HDL) cholesterol was isolated by selectively precipitating the non-HDL cholesterol with A-Gent HDL Reagent (Abbott Laboratories).

Urine and serum creatinine, and serum urea nitrogen (BUN) were determined on an Abbott-VP autoanalyzer using A-Gent reagents, kits and standards (Abbott Laboratories).

Hematological measurements. For hematological analysis 0.5 mL of blood was taken into a tube containing EDTA as anticoagulant. Complete blood cell count was measured using a Coulter Counter S-PLUS IV system (Coulter Electronic Inc., Hialeah, FL).

Fatty acid analysis. For analysis of fatty acids in diets, lipids were extracted using 25 vol of chloroform/methanol (1:2, vol/vol). For analysis of fatty acids in red blood cells (RBC), about 3 mL of blood was placed in tubes containing silicone and centrifuged at 2500 × *g* for 20 min. Serum was drawn and RBC were collected. After tissue homogenization (Polytron, Brinkmann, Rexdale, Canada) total lipids in RBC, liver and brain were extracted using chloroform/methanol/water as outlined by Brooks *et al*. (9). The extracted lipids were converted to methyl esters using 14% BF_3/methanol and analyzed by gas–liquid chromatography using an SP-2560 flexible fused-silica capillary column (100 m × 0.25 mm i.d.; Supelco Inc., Bellefonte, PA).

Analysis of sterols in diets and tissues. Tissues (200–400 mg) and fat (20 mg) extracted from the diets were mixed with 25 mg betulinol (internal standard), and the mixture was saponified (0.5 g KOH, 0.4 mL water, 5 mL ethanol). The nonsaponifiable matter was recovered by extraction with hexane/methylene chloride (85:15) and purified by successive washing with water and water/ethanol (80:20, vol/vol). After drying with anhydrous sodium sulfate, the nonsaponifiable matter was treated with 100 μL of 1-methyl imidazole/*N*-methyl-*N*-(trimethylsilyl)-heptafluorobutyramide (1:20, vol/vol) for converting the sterols to trimethylsilyl ethers. The content and composition of the silylated sterols were determined in relation to the internal standard by gas–liquid chromatography using a DB-1 flexible fused-silica capillary column (30 m × 0.25 mm i.d.; J&W Scientific, Folsom, CA).

Analysis of vitamin E. α- and γ-Tocopherols in tissues were determined by the high-performance liquid chromatography method of Thompson and Hatina (10).

Analysis of minerals and thiobarbituric acid-reacting substances (TBARS). Drinking water and urine samples were acidified with 1% nitric acid and sodium was determined by flame atomic emission spectroscopy (AES). Liver samples were dry-ashed, dissolved in 1 N HCl, and minerals (Fe, Cu, Zn) were determined by flame atomic absorption spectroscopy (AAS). Na and K were determined by flame AES and Ca and Mg determined by AAS in the presence of 0.5% lanthanum in 1 N HCl. Urinary TBARS were determined as described previously (11).

Statistics. Survival data were analyzed using Wilcoxon's nonparametric test for comparing survival curves to provide tests for the effects of diet (12). The effects of diet on mean survival time and various biochemical parameters were examined by analysis of variance using the STATISCA system for personal computers (Release 5, 1997 Edition, Statsoft, Inc., Tulsa, OK). *Post-hoc* comparisons of means were performed using Tukey Honest Significant Difference Test. Differences were considered significant when $P < 0.05$. All data in tables are reported as means and pooled standard deviations (SD). Correlations between mean survival times and the various variables of the diets (fatty acid, vitamin E, and sterol contents) or the tissue biochemical parameters (fatty acid, vitamin E, mineral, and sterol contents) were examined by linear regression analysis using mean values for each dietary group.

RESULTS

The fatty acid composition of the eight diets is shown in Table 1. The total content of SFA varied between 6.1 and 32.5% in all diets. CO, LSCO, HOSFO, and MIMIC diets containing very low levels of SFA (<8.5%), while the high-SFA diet and rat chow contained the highest levels of SFA. CO, LSCO, and MIMIC contained almost similar amounts of total SFA, total monounsaturated fatty acids (MUFA), linoleic acid, and α-linolenic acid. The HPCO displayed a slightly different fatty acid profile from the other two CO; in particular, HPCO contained higher levels of 16:0, 16:1, 18:1n-7, 18:3n-3, and lower levels of 18:1n-9, 20:1n-9 than the other two CO. The fat derived from rat chow contained minor amounts of arachidonic (20:4n-6), eicosapentaenoic (20:5n-3), docosahexaenoic (22:6n-3), and other C20 and C22 n-6 and n-3 fatty acids, which may indicate the use of fish meal and some animal products in the preparation of the commercial rat chow used in this study.

The survival curves of the rats in the life span study are shown in Figures 1 and 2. One rat in the CHOW group died

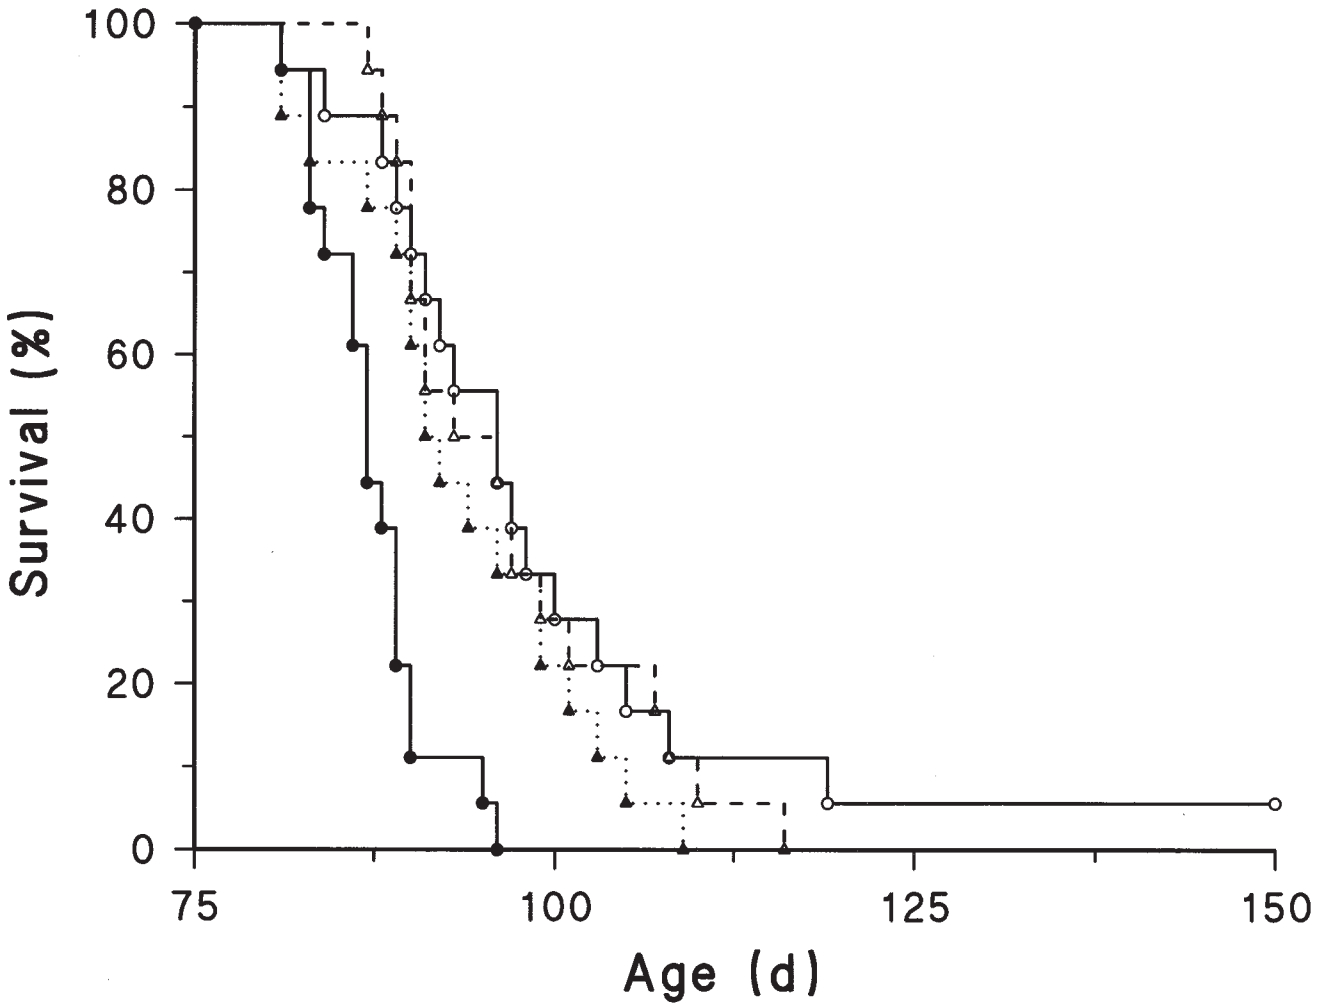

FIG. 1. Survival curves of stroke-prone spontaneously hypertensive rats (SHRSP) fed diets containing canola oil (CO, ●), soybean oil (SBO, ○), high-oleic safflower oil (HOSFO, ▲), and canola oil mimic (MIMIC, △). n = 18 per group. Survival rate for CO group significantly different from that of all the other dietary groups (Wilcoxon test $P < 0.0001$). No significant differences were found in the survival rates between SBO, HOSFO, and MIMIC groups (Wilcoxon test $P > 0.05$).

early, 8 d on diet, of dehydration (kidney failure) and was not included in the analysis of the survival data. One animal in the SBO group had an unusually longer life span (207 d) than all the other animals in this study and therefore, this animal was also not included in the analysis of the survival data. There was a highly significant effect ($P \leq 0.0001$) of diet on the survival rates. This was largely due to lower survival rates for CO and LSCO groups. There was no evidence ($P = 0.58$) that the survival rates for these two groups were different from each other. The HPCO group exhibited a lower survival than the non-CO diets after 95 d, but there was no evidence ($P = 0.17$) of a diet effect among these groups.

Analysis of the mean survival times also showed significant ($P < 0.05$) life-shortening activity associated with CO and LSCO groups compared to non-CO groups (Table 2). The mean survival time of the HPCO group was slightly higher than the other two CO groups and slightly lower than non-CO groups, but the differences were not significant ($P > 0.05$). There were no significant differences in the mean survival times among the non-CO groups ($P > 0.05$).

During the course of the study, SBP was measured five times, at 2-wk intervals. The SBP readings (160–210 mm Hg) were highly variable but confirmed the hypertensive-prone

TABLE 2
Mean Survival Times of SHRSP Rats Fed Various Dietary Oils[a]

Dietary oil	Mean survival time ± SD (d)
CO	87.4 ± 4.0[a]
SBO[b]	95.9 ± 9.3[b]
HOSFO	93.4 ± 8.0[b]
MIMIC	96.7 ± 8.6[b]
HSFAB	100.2 ± 9.2[b]
HPCO	92.2 ± 6.5[a,b]
LSCO	89.7 ± 8.5[a]
CHOW[b]	98.6 ± 11.6[b]

[a]For abbreviations see Table 1. SD, standard deviation.
[b]n = 17 in SBO and CHOW; n = 18 in all other groups. Mean survival times with different superscripts are significantly different ($P < 0.05$).

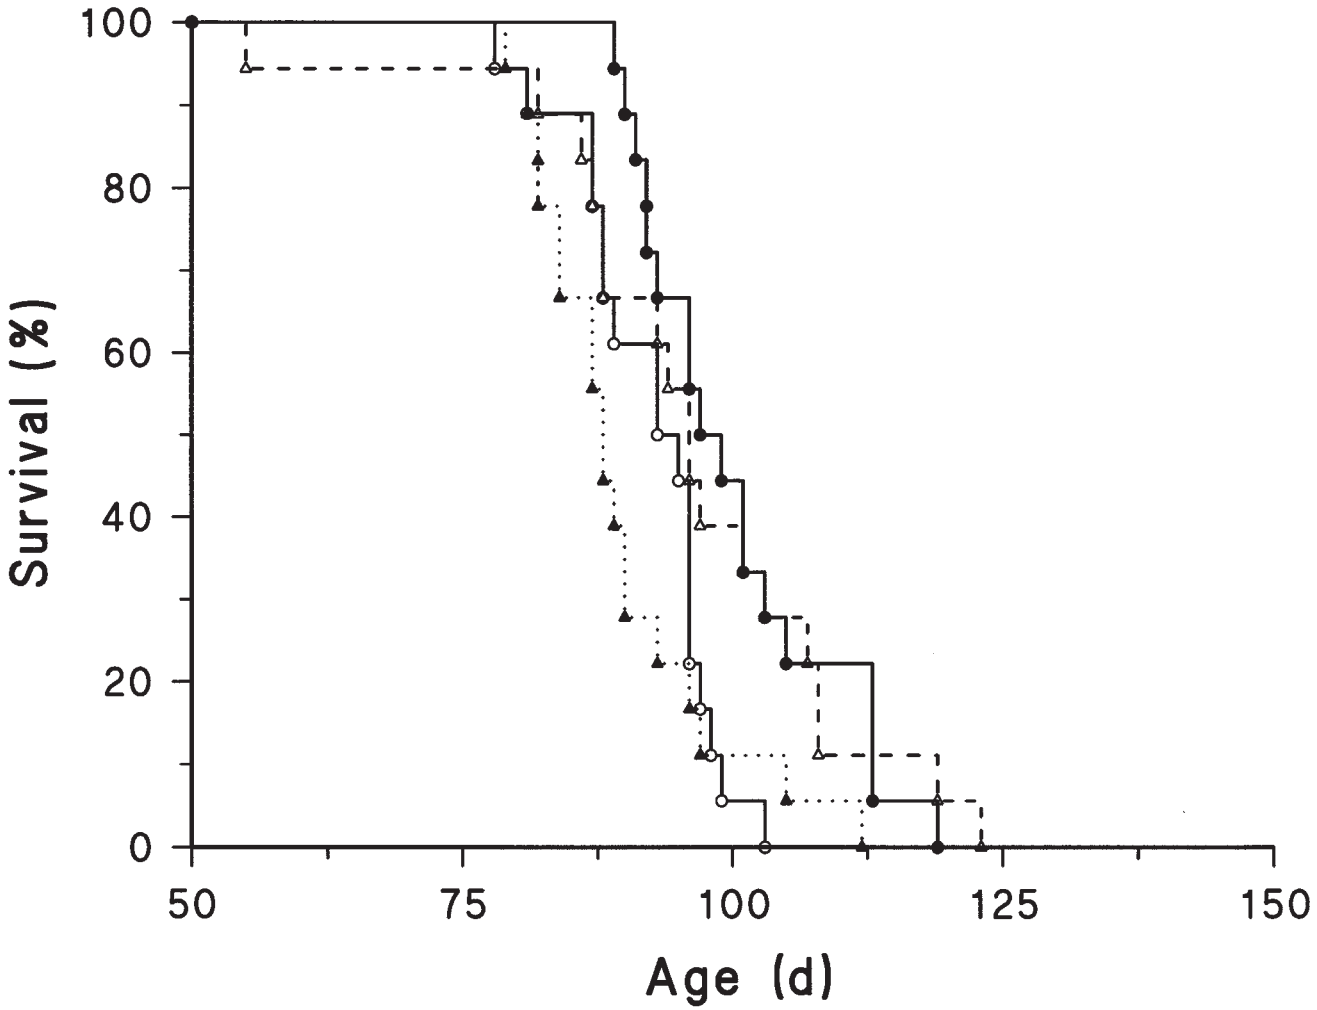

FIG. 2. Survival curves of SHRSP fed diets containing a fat blend high in saturated fatty acids (HSFAB, ●), high-palmitic canola oil (HPCO, ○), low-sulfur canola oil (LSCO, ▲), and rat chow (CHOW, △). n = 18 per group. Survival rate for LSCO significantly different from that for HSFAB and CHOW groups (Wilcoxon test $P < 0.0001$). Survival rate for HPCO not significantly different from that of LSCO, HSFAB, and CHOW (Wilcoxon test $P > 0.05$). There was no significant difference between HSFAB and CHOW (Wilcoxon test $P > 0.05$).

nature of the SHRSP rats. No significant differences were noted in the SBP among the dietary groups (data not shown). The hematological indices (mean platelet volume, platelet count, white blood cell, RBC, hemoglobin, mean corpuscular volume, mean corpuscular hemoglobin, and red cell distribution width) of the animals killed at 37 d on diet were not significantly influenced by the type of dietary oil (data not shown). Similarly, no significant changes related to the diet were observed in the levels of serum total cholesterol (68–82 mg/dL), HDL cholesterol (30–41 mg/dL), and triglycerides (58–106 mg/dL) of the animals killed at 37 d on diet (data for each group are not shown).

The content of α-tocopherol in the semipurified diets was substantially higher than that in CHOW (Table 3). This is to be expected because the semipurified diets were supplemented with a 1% vitamin mixture containing vitamin E and in addition, the test oils themselves contributed important amounts of α-tocopherol and other vitamin E congeners to the diet. The dietary vitamin E levels in various tissues reflected the levels in the corresponding diets (γ-tocopherol values are not shown). The tissues from the CHOW group contained significantly lower levels of α-tocopherol compared to all the other groups, whereas tissues of rats fed HOSFO, MIMIC, and HSFAB displayed higher levels. The α-tocopherol level of animals fed CO was almost identical to that of animals fed SBO-diet. The γ-tocopherol content in the all the diets was low (0–17 μg/g diet), except in SBO-diet (39 μg/g diet) and consequently, all the tissues (heart 0–0.2, kidney 0–0.7, liver 0–0.6, and plasma 0–0.6 μg/g) , except adipose tissue (1.0–5.4 μg/g) had only trace levels of this vitamin E congener. There was no correlation between tissue mean levels of α- and γ-tocopherol of the animals killed after 37 d with the mean survival times of the animals in the life span study (Table 4; correlation data for γ-tocopherol are not shown).

Fatty acid composition of RBC, liver, and brain were analyzed and used for diet comparisons. The different diets virtually had no influence on the fatty acid profile of the brain (data not shown). Generally, the fatty acid profiles of RBC

TABLE 3
α-Tocopherol Content in Diets and Tissues of Animals Killed After 37 d on Different Dietary Oils

Dietary oil[a]	Diet (μg/g)	Tissue (μg/g wet weight)

CHOW	38.8	17.5 ± 2.0[a]	11.0 ± 2.1[a]	11.9 ± 1.2[a]	24.3 ± 2.4[a]	4.0 ± 3.4[a]

[a]For abbreviations see Table 1. $n = 5$ in all dietary groups. Means in a column with different roman superscript letters are significantly different ($P < 0.05$).

(Table 5) and liver lipids (Table 6) of animals fed CO, SBO, MIMIC, HPCO, LSCO, and HSFAB were not different from each other. The most notable changes in the fatty acid profiles of RBC and liver were generally associated with the animals fed HOSFO and CHOW. The HOSFO diet contained the highest amount of oleic acid and the lowest amount of α-linolenic acid (Table 1). Consequently, the RBC and liver of the animals of this group contained the highest proportion of oleic acid and the lowest proportion of the n-3 long chain (C20 + C22) polyunsaturated fatty acid (LC-PUFA) metabolites (mainly 22:6n-3) of α-linolenic acid. The animals fed CHOW, which received appreciable amounts of pre-formed 20:5n-3, 22:5n-3, and 22:6n-3 from CHOW diet, showed higher abundance of these n-3 LC-PUFA in the liver and RBC. However, none of the fatty acids in brain, liver, and RBC showed a correlation with the mean survival time of SHRSP rats in the life span study (Table 7). The dietary total SFA content was significantly correlated ($R = 0.78$, $P = 0.0219$) with the mean survival time. However, RBC or liver total SFA content was not significantly correlated with mean survival time ($P > 0.24$).

The diets prepared with CO, HPCO, and LSCO contained higher contents of campesterol, β-sitosterol, and brassicasterol (Table 8). The CO and HPCO diets contained more brassicasterol than the LSCO diet. Among the non-CO diets, CHOW contained the largest content of phytosterols. In addition, this diet contained a considerable amount of cholesterol, whereas all the other diets contained very little cholesterol. The amount of phytosterols in liver (Table 9) and brain (Table 10), of the animals killed after 37 d on diet, reflected the levels in the corresponding diets. Animals fed the CO-based diets (CO, HPCO, and LPCO) showed significantly higher amounts of campesterol, β-sitosterol and total phytosterols compared to those animals fed non-CO-based diets. In all the dietary groups, campesterol was the major phytosterol followed by β-sitosterol (Tables 9 and 10). In addition to the common phytosterols, trace levels (<1 mg/100 g tissue) of brassicasterol were detected in tissues of rats fed the three CO-based diets. These data on the relative amounts of phytosterols in brain and liver are consistent with the previous studies on the absorption rates for phytosterols in animal studies, where higher intestinal absorption rates are reported for campesterol than for sitosterol and stigmasterol is absorbed minimally (13). The content of cholesterol in liver and brain was not significantly different among the dietary groups (Tables 9 and 10).

The campesterol, sitosterol, and total phytosterol contents in the diets as well as those of liver and brain of the SHRSP rats killed after 37 d on the diets displayed significant and strong inverse correlations ($R > 0.69$) with the mean survival times of the SHRSP rats in the life span study group (Table 11). Regression analysis to examine whether brassicasterol, which is the characteristic sterol of CO, is associated with the mean survival time was not performed, because only two diets (CO and HPCO) had reasonable levels of this sterol. Furthermore, as mentioned previously, even with CO and HPCO dietary groups, only very little brassicasterol was found in liver or brain.

The urinary creatinine levels were highest in the CO and LSCO groups and lowest in the CHOW and MIMIC groups; levels in the other dietary groups were in between (Table 12). These levels showed an inverse correlation with mean survival times of the rats in the life span study group ($R = –0.70$, $P = 0.0517$) (Table 13). Urinary sodium levels were higher only in the CHOW fed group as were BUN levels (Table 12). These parameters showed no significant relationship with mean survival times (Table 13). No significant differences

were seen in liver mineral levels (Table 12); although liver iron levels were different between the different groups, the differences were not related to the mean survival time of the different groups (Table 13).

DISCUSSION

The present study confirms the recent observation of Okuyama's research group (3–6) of the life-shortening activity of several vegetable oils, including CO compared to SBO in salt-loaded SHRSP rats. Although the rats fed CO died earlier than those fed SBO, the difference in the mean survival time was only 8.5 d (or 8.9%). In contrast, differences ranging from 53 to 121 d were reported in the earlier reports of Okuyama's research group (2,3). Also, all the animals in their study, including those fed CO lived longer (mean survival time ranged from 122 to 146 d vs. 87 d in the present study) than those in the present study. The source of animals in our study was different from that of Okuyama's earlier studies, and this might be the reason for the large difference in the

[a]Correlation coefficients obtained from linear regression analysis of mean survival time vs. total SFA, MUFA , n-6 and n-3 PUFA (mean values for tissues). n = 17 or 18 per dietary group in life span study and n = 5 per group in rats killed after 37 d. For abbreviations see Tables 1 and 2.

mean survival time between the two laboratories. Consistent with this suggestion, the difference between CO and SBO was shown to be much smaller (16–24 d) in the subsequent experiments of Okuyama (3–6) performed using animals purchased from the same source as in our experiments.

In the present study we observed a positive association between dietary SFA content and the mean survival times. However, when all the dietary and tissue fatty acid data are taken into consideration, it would appear that the lower SFA content or the fatty acid profile might not be the life-shortening factor associated with CO. This is primarily because the CO mimic of this study, which closely resembled the fatty acid profile of CO, and HOSFO, which also contained a lower level of SFA (8%), prolonged the life span of SHRSP rats by 9.6 and 6.4%, respectively, compared to those fed CO. Furthermore, although the HSFAB of this study, which mimicked the ideal fatty composition for the optimal growth of normal rats in studies by Hopkins *et al.* (14), displayed the best survival results, the mean survival time (100 ± 9 d) was not significantly different from the dietary groups fed other non-CO. These data further suggest that the life span of SHRSP rats is not modulated by the dietary fatty acid composition. Similarly Huang *et al.* (4) postulated that high oleic acid content in CO, high-oleic sunflower oil, HOSFO, and olive oil could not be the life-shortening factor associated with these oils, because feeding lard and a microbial oil containing approximately 35% oleic acid prolonged the life span of SHRSP rats whereas evening primrose oil, containing only 13% oleic acid, shortened the life span in a manner similar to that found with CO.

Fish oils, however, could be exceptional dietary fats. Previous studies have shown that fish oils, relative to olive oil, CO and safflower oil, are more effective in controlling blood pressure and stroke (15,16), and in prolonging the life span of SHRSP rats (3). Fish oil also prevents the development of proteinurea, which is a marker of renal damage in SHRSP rats (16). The efficacy of fish oil has been attributed to increased incorporation of 20:5n-3 and 22:6n-3 in the kidney. In the present study the different diets contained variable levels of α-linolenic acid (ranging from 0 to 11% of total fatty acids), with CO, SBO, MIMIC, and HPCO diets providing the highest levels. In addition, the rat chow contained about 2% preformed n-3 LC-PUFA metabolites of α-linolenic acid. These different amounts and types of n-3 LC-PUFA in the diets, however, showed no association with the life span of SHRSP rats. The tissue (RBC and liver) levels of 22:6n-3 and other n-3 LC-PUFA metabolites of α-linolenic acid also showed no relationship with the life span. The SBP and BUN content also were not correlated with the life span. These results therefore suggest that α-linolenic acid in vegetable oils and the minor amounts of dietary n-3 LC-PUFA cannot alter the life span, SBP or development of proteinuria in SHRSP rats. A similar suggestion was made by Hobbs *et al.* (16) regarding CO and they concluded that, although CO is a rich source of α-linolenic acid, it may not be possible to derive sufficient 22:6n-3 from consumption of vegetable oils to alter blood pressure and renal function significantly. This suggestion could be equally applicable to SBO, which also contains the same proportion of α-linolenic acid as does CO. Perilla oil on the other hand is an exceptional vegetable oil. In experiments performed by Huang *et al.* (3,4), this oil consistently prolonged the life span of SHRSP rats to a very great extent

TABLE 8
Cholesterol and Phytosterol Contents of Different Diets[a] (mg per 100 g diet)

[a]For abbreviations see Tables 1 and 2. SD, pooled standard deviation. Minor phytosterols (<0.1 mg/100 g liver) are not shown in the table but are included in the total phytosterols. Means across a row with different roman superscript letters are significantly different ($P < 0.05$) and those rows without a superscript are not significantly different ($P > 0.05$). $n = 5$ per group.

compared to CO and SBO. Perilla oil is a rich source of α-linolenic acid (55 vs. 7–8% in CO or SBO) and therefore may support the view of Hobbs *et al*. (16) regarding the beneficial effects of n-3 fatty acids. But unfortunately, Huang *et al*. (3,4) did not report the levels of n-3 LC-PUFA in tissues of SHRSP rats, and therefore whether the life-prolonging activity of perilla oil is due to its high α-linolenic acid content or some other component in the oil is unknown.

The present study also indicated that the amount of sulfur in CO has no influence on the life span of the SHRSP rat, because the mean survival time of rats fed LSCO, despite its lower sulfur content (0.5 vs. 7.5 ppm in CO), was not significantly different from that of CO.

This study also showed that the high sodium load, although known to accelerate the development of hypertension in this animal model (17), is not reflected in abnormalities in tissue levels of sodium or other minerals. The high urinary excretion of Na in the chow-fed group likely reflects the very high Na content of this diet (4,000 ppm, manufacturer's specification). In addition, there is no biochemical evidence of impairment of kidney function, which can be related to the differences in survival between the different groups, nor of increased lipid peroxidation and SBP. Thus, it might be suggested that the mechanism by which vegetable oils alter the life span of SHRSP rats is not related to any of the above biochemical parameters. The significant correlation seen in the present study between urinary creatinine and mean survival is not surprising, because very sick animals, such as the SHRSP rat, would be expected to excrete high amounts of creatinine, indicative of increased muscle wasting (18).

Recently it was reported that there is significantly higher vitamin E requirement when neonatal pigs are fed milk replacers containing CO as the sole fat source (19). In contrast, piglets fed SBO showed no evidence of vitamin E deficiency. The factor present in CO which increases vitamin E requirements of newborn piglets has not been identified yet. In the present study, however, canola-fed SHRSP rats, compared to other test oils, showed no signs of vitamin E deficiency, which indicates that a factor other than vitamin E antagonistic factor may be responsible for the shorter life span of SHRSP rats fed CO.

In contrast with the other parameters examined in this study, inverse associations were observed between life span and levels of phytosterols, specifically campesterol and β-sitosterol, of rat tissues and diets. This was mainly due to the high content of phytosterols in the three CO varieties. Certainly, further studies are required to determine whether the life-shortening activity of CO could be attributed to their high

TABLE 10

Total phytosterols	–0.84	0.0091

[a]Correlation coefficients obtained from linear regression analysis of mean survival time and sterol concentrations (mean values for tissues). n = 17 or 18 per dietary group in life span study and n = 5 per group in rats killed after 37 d.

content of phytosterols, and these are currently ongoing in our laboratory. Meanwhile, it is interesting to note that phytosterols have been shown to replace the cholesterol complement in cell membranes and consequently increase the osmotic fragility of human erythrocytes in *in vitro* experiments (20) and rigidity of liver microsomes in Wistar rats fed a diet supplemented with 3% β-sitosterol + 2% campesterol (21). Such changes in cell membrane characteristics might exert adverse physiological consequences for SHRSP rats, because these animals have defective and abnormal cell membranes (17). The abnormalities include high membrane rigidity and low fluidity, and they are considered to be the key factors related to pathogenesis of hypertension and hemorrhagic stroke (22–25). Moreover, the abnormalities of cell membrane in essential hypertension appear to be related to its low content of cholesterol (26–28). Studies have shown that dietary cholesterol is beneficial in delaying the onset of hemorrhagic stroke and prolonging the life span of SHRSP rats (29). Considering these reports, it is reasonable to propose that replacement of cholesterol in tissues by phytosterols from the diet may further weaken the functionality of cell membranes, which could be detrimental to SHRSP rats.

On the basis of the phytosterol hypothesis, HPCO with the largest phytosterol content of the three canola oils tested would be expected to produce the most adverse effects on SHRSP rats. However, the survival rates of SHRSP rats fed this oil were not different from those of the other two CO varieties. This might be explained by the high content of palmitoleic acid (16:1n-7, 2.4% of total fatty acids) in HPCO. A significant reduction in the incidence of stroke and marked increase in the life span (mean survival time increased by 64 d) of SHRSP rats were observed following supplementation of basal diet with 1% palmitoleic acid, whereas supplementation with 1% palmitic, oleic, linoleic, or linolenic acids produced no changes in the life span (30). The preventive mechanism of palmitoleic acid was ascribed to its rapid incorporation into the vascular wall and efficient utilization in improving the impaired metabolism of vascular muscle cells exposed to hypertension (31). Thus it might be suggested that in HPCO, the adverse effect of phytosterols would have been counteracted by palmitoleic acid. In the other two CO varieties such a counteraction was not possible because they contained very little palmitoleic acid (0.1–0.3%).

TABLE 12
Urinary Creatinine, TBARS, and Sodium; Blood Urea Nitrogen; and Liver Mineral Levels of SHRSP Rats Fed Different Dietary Oils for 37 d

	CO	SBO	HOSFO	MIMIC	HSFAB	HPCO	LSCO	CHOW	SD
Urinary creatinine (mg/100 mL urine)	12.3[b]	8.4[a,b]	6.2[a,b]	5.8[a]	8.4[a,b]	11.4[a,b]	9.5[a,b]	5.2[a]	4.7

[a]Correlation coefficients obtained from linear regression analysis of mean survival time vs. urinary, blood, and tissue parameters (mean values). $n = 17$ or 18 per dietary group in life span study and $n = 5$ per group in rats killed after 37 d. For abbreviations see Tables 2 and 12.

Data reported in other SHRSP rat studies may not appear to be consistent with the proposed life-shortening effect of phytosterols. In efforts to identify the life-shortening factor in CO, Huang *et al*. (4) prepared several fractions from CO using different techniques and then mixed these fractions with SBO, fed them to SHRSP rats, and determined survival times. The various canola fractions, however, did not exhibit any life-shortening activity. The fractions tested included CO nonsaponifable matter prepared by a conventional procedure, components soluble in polar organic solvents (acetone, ethanol, and methanol), and a hexane/diethyl ether soluble fraction isolated after treating a hexane solution of CO with silicic acid. Unfortunately, the report provided no information on the purity, composition, and levels of phytosterols of the CO fractions. Therefore, the results of the Huang *et al*. (4) study are difficult to interpret, particularly with regard to antinutrient effects of phytosterols. Information on phytosterols was also lacking in another SHRSP rat study that examined the effects of lipase-treated CO and other vegetable oils (6).

It has been noted that olive oil, high-oleic sunflower oil, HOSFO, and evening primrose oil have life-shortening activities comparable to that seen with CO (4). The life-shortening activity of these oils may not be solely attributable to their phytosterol contents, because these oils contain much lower levels of phytosterols than do CO. In addition to phytosterols, these oils may contain some other component(s) that significantly affect the life span of SHRSP rats. Results from the present study and other studies (4–6) suggest that this unknown component might not be associated with fatty acids. More research would be required to fully elucidate the different factors in various common vegetable oils that would affect the life span of SHRSP rat.

In conclusion, we have demonstrated that neither the high level of sulfur nor the fatty acid profile of canola are the factors responsible for the observed life-shortening effects of CO on SHRSP rats. Our results appear to indicate that a high content of phytosterols may be a possible antinutritional factor in CO for SHRSP rats. This hypothesis is being currently examined in our laboratory.

ACKNOWLEDGMENTS

Partial funding was provided by the Canola Council of Canada. We are grateful to the members of the Scientific Subcommittee of the Canola Council of Canada for their oversight and helpful input: Bruce McDonald (University of Manitoba, Winnipeg), Sheila Innis (University of British Columbia, Vancouver), and Peter Fischer (Health Canada, Ottawa). The staff of the Animal Resources Division, Health Canada is acknowledged for care of the animals. Stephen Hayward is thanked for statistical analysis of the survival data and Keith Trick, René Madère, and Judy Edgar for technical assistance.

Dietary Fat-Induced Suppression of Lipogenic Enzymes in B/B Rats During the Development of Diabetes

S.K. Cheema[a] and M. Thomas Clandinin[a,b,*]

Departments of [a]Agricultural, Food and Nutritional Science and [b]Medicine, University of Alberta, Nutrition and Metabolism Research Group, Edmonton, Alberta, T6G 2P5, Canada

ABSTRACT: This study was designed to determine the level of inhibition of gene transcription by the reduction in insulin levels upon the onset of diabetes in spontaneously diabetic B/B rats and if reducing the level of polyunsaturated fatty acids (PUFA) in the diet will increase lipogenic enzyme activity. Control (eight animals per group) and spontaneously diabetic B/B male weanling rats (25 animals per group) were fed semipurified diets containing 20% (w/w) fat of either low (0.25) or high (1.0) polyunsaturated to saturated (P/S) fatty acid ratio. Rats were killed at the onset of diabetes [blood glucose level of ≅100 mg/dL (5.55 mM)] and as they became highly diabetic [blood glucose level of ≅400 mg/dL (22.22 mM)]. Total RNA was extracted from liver, and the relative amount of mRNA coding for fatty acid synthase (FAS), acetyl-CoA carboxylase, malic enzyme, pyruvate kinase, and phosphoenolpyruvate carboxykinase was determined. Liver enzyme activities were also measured. The mRNA levels for FAS, acetyl-CoA carboxylase, and malic enzyme decreased compared to control animals. The mRNA level for pyruvate kinase decreased at the onset of diabetes as compared to control animals. Feeding animals the low P/S diet treatment elevated the level of mRNA and lipogenic enzyme activity compared to animals fed the high P/S diet treatment, suggesting that the effect of PUFA on lipogenic enzymes is through a direct effect on gene expression.

Paper no. L8389 in *Lipids 35,* 421–425 (April 2000).

Lipogenic enzymes are affected by dietary nutrients and hormones (1–4). Fatty acids are known to potentiate glucose-induced insulin release *in vitro*, whereas *in vivo* fatty acids increase plasma insulin levels in various species, including humans (5). The mechanism by which fatty acids may modulate β-cell function has not been characterized. The composition of dietary fat is a key determinant of membrane fatty acid composition, membrane-bound enzyme activity, glucose transport, insulin binding, and signal transduction mechanisms (6–8). Essential fatty acids govern the transcription of specific genes (9–12). Polyunsaturated fatty acids (PUFA) inhibit transcription of genes coding for lipogenic enzymes and enzymes for glucose metabolism (13).

The spontaneously diabetic B/B rat is a unique model exhibiting human type I diabetes mellitus (14). Diabetes in B/B rats results from an autoimmune disease where insulin-producing β-cells of the pancreas are destroyed (15). Once B/B rats become diabetic, immunoreactive insulin declines to almost zero. Thus, gene transcription should be suppressed in spontaneously diabetic B/B rats for genes normally stimulated by insulin. The objective of this study was to assess the amount of effect of dietary fatty type on expression of lipogenic genes as insulin becomes limiting *in vivo*.

MATERIALS AND METHODS

Animals and diets. B/B rats were obtained from BioBreeding Laboratories of Canada Ltd. (Ottawa, Canada). The incidence of diabetes in these B/B rats in our facility is 40–70%. The onset of diabetes occurs 60–120 d of age. Control (eight animals per group) and spontaneously diabetic B/B male weanling rats (25 animals per group) were randomly assigned a semipurified diet containing 20% (w/w) fat of either low (0.25) or high (1.0) polyunsaturated to saturated (P/S) fatty acid ratio (Table 1; 8). The dietary fat treatments were similar in fatty acid composition to the range of fat intakes typical of that consumed by much of the North American population. Animals were housed in individual wire-bottom cages in a well-ventilated room maintained at 22 ± 2°C on a 12:12 h

TABLE 1
Fatty Acid Composition of Diet Fats[a]

Fatty acid	P/S = 1.0	P/S = 0.25
14:0	1.3	3.7
16:0	16.1	23.0
16:1	0.2	0.3
18:0	27.5	47.11
18:2n-6	44.0	17.6
18:3n-3	0.9	0.9
∑ Polyunsaturated	44.9	19.1
∑ Saturated	44.9	71.8
∑ Monounsaturated	8.2	4.5
P/S ratio	1.0	0.25

[a]P/S, polyunsaturated to saturated fatty acid ratio.

Abbreviations: ACC, acetyl-CoA carboxylase; FAS, fatty acid synthase; ME, malic enzyme; PEPCK, phosphoenolpyruvate carboxykinase; PUFA, polyunsaturated fatty acid; P/S, ratio of polyunsaturated to saturated fatty acid; SSC, a solution containing 0.3 M NaCl + 0.03 M sodium citrate at pH 7.0; SDS, sodium dodecyl sulfate.

light/dark cycle. Animals were fed *ad libitum* and weighed twice weekly. Blood glucose level was checked daily, and diabetes was diagnosed on the basis of a plasma glucose level in excess of 250 mg/dL (13.89 mM), polyuria, and failure to gain weight. Animals with a blood glucose level of 350–500 mg/dL (19–28 mM) were characterized as highly diabetic. Serum insulin level was determined by radioimmune assay (Insulin RIA 100 kit; Pharmacia Co., Uppsala, Sweden) against a rat insulin standard. Rats were killed at the onset of diabetes [blood glucose level of ~100 mg/dL (5.55 mM)] and when they became highly diabetic [blood glucose level of ~400 mg/dL (22.22 mM)]. Livers were collected immediately and frozen at –70°C.

Quantitation of mRNA. Total RNA was extracted from liver samples using a guanidinium-isothiocyanate method (16). RNA concentrations were measured spectrophotometrically. A known amount of total RNA was applied to nitrocellulose paper, and the relative amount of mRNA coding for fatty acid synthase (EC 2.3.1.85), acetyl-CoA carboxylase (EC 6.4.1.2), malic enzyme (ME) (EC 1.1.1.40), pyruvate kinase (EC 2.7.1.40), and phosphoenolpyruvate carboxykinase (PEPCK) (EC 4.1.1.32) was determined by slot-blot hybridization with specific ^{32}P-labeled cDNA probes. The probes, generously donated by Dr. D.W. Back of Queen's University, Kingston, Ontario, Canada, were labeled by the random primer method (Prime-A-Gene Labeling System; Promega, Madison, WI). Hybridization was carried out in a shaking water bath for 36 h at 42°C. After hybridization, the membranes were washed in 2 × SSC (a solution containing 0.3 M NaCl and 0.03 M sodium citrate, pH 7.0), 0.1% SDS (sodium dodecyl sulfate); 1 × SSC, 0.1% SDS at room temperature; and 0.1 × SSC, 0.1% SDS at 50°C for 30 min. Membranes were air-dried and slots were cut out and counted in a scintillation counter, or membranes were used for autoradiophy. Nonspecific binding was evaluated using pBR322.

Enzyme assays. Fatty acid synthase (FAS) activity was measured. A unit of enzyme activity represents the synthesis of 1 nmol of palmitic acid/min/mg of protein (17). ME was using the rate of NADPH (18). For determination of acetyl-CoA carboxylase (ACC) (19) and pyruvate kinase (20), one unit of enzyme was defined as the amount catalyzing the formation of 1 µmol of product/min/mg of protein. PEPCK was measured as nmol of NADH oxidized/min/mg protein (21).

Statistical analysis. The effect of diet and diabetes on enzyme activities and mRNA levels was determined by analysis of variance procedures. Values are group means ± SE, n = 8. Treatments without a common superscript are significantly different ($P > 0.05$).

RESULTS

Spontaneously diabetic rats weighed less and exhibited a lower serum insulin level compared to control animals (Table 2). The serum insulin level decreased further in spontaneously diabetic rats with the increase in blood glucose level. Dietary fat did not alter the insulin or glucose level in control or spontaneously diabetic rats (Table 2) or the time of onset of diabetes.

Effect of diet fat and diabetes on lipogenic enzymes. FAS is a multifunctional polypeptide which, using acetyl-CoA as a primer, catalyzes formation of long-chain saturated fatty acids from malonyl-CoA and NADPH. ACC is an important rate-controlling enzyme both in the synthesis of fatty acids and in generating intracellular malonyl-CoA, whereas ME catalyzes the oxidative decarboxylation of malate to pyruvate and CO_2, simultaneously generating NADPH from NADP. The effect of diet and diabetes on activity and mRNA level of these lipogenic enzymes revealed that enzyme activity of FAS, ACC, and ME decreased at the onset of diabetes compared to control animals (Fig. 1). As the animals became highly diabetic, the enzyme activity decreased further compared to animals at the onset of diabetes (Fig. 1). The mRNA levels for FAS, ACC, and ME also decreased compared to control animals (Fig. 1). As the animals became highly diabetic, the mRNA level decreased below that observed for animals at the onset of diabetes. Feeding the higher polyunsaturated fat diet reduced the level of lipogenic enzymes in both control and diabetic animals.

TABLE 2
Effect of Diet and Diabetes on the Body Weight, Liver Weight, and Serum Insulin of Control and Spontaneously Diabetic B/B Rats[a]

Group	Diet	Blood glucose (mg/dL)	Final body weight (g)	Final liver weight (g)	Serum insulin (mU/L)
Control	P/S = 1.0	84	404 ± 12.0[a]	14.2 ± 0.7[a]	82.0 ± 8.0[a]
	P/S = 0.25	84	384 ± 11.0[a]	14.0 ± 1.2[a]	75.0 ± 6.0[a]
Spontaneously diabetic	P/S = 1.0	100	303 ± 7.3[b]	11.1 ± 0.2[b]	76.0 ± 9.4[a]
	P/S = 0.25	100	311 ± 12.0[b]	11.0 ± 0.6[b]	68.0 ± 8.5[a]
Spontaneously diabetic	P/S = 1.0	400	311 ± 14.0[b]	9.1 ± 0.4[b]	26.0 ± 6.5[b]
	P/S = 0.25	400	300 ± 12.0[b]	10.5 ± 1.4[b]	30.0 ± 3.4[b]

[a]Weanling rats were fed a semipurified diet either high or low in polyunsaturated fatty acids as explained in the Materials and Methods section. At 50 d postpartum, blood glucose level was checked on alternate days. Values are group means ± SE, n = 10. Treatments without a common superscript are significantly different ($P < 0.05$). See Table 1 for abbreviation.

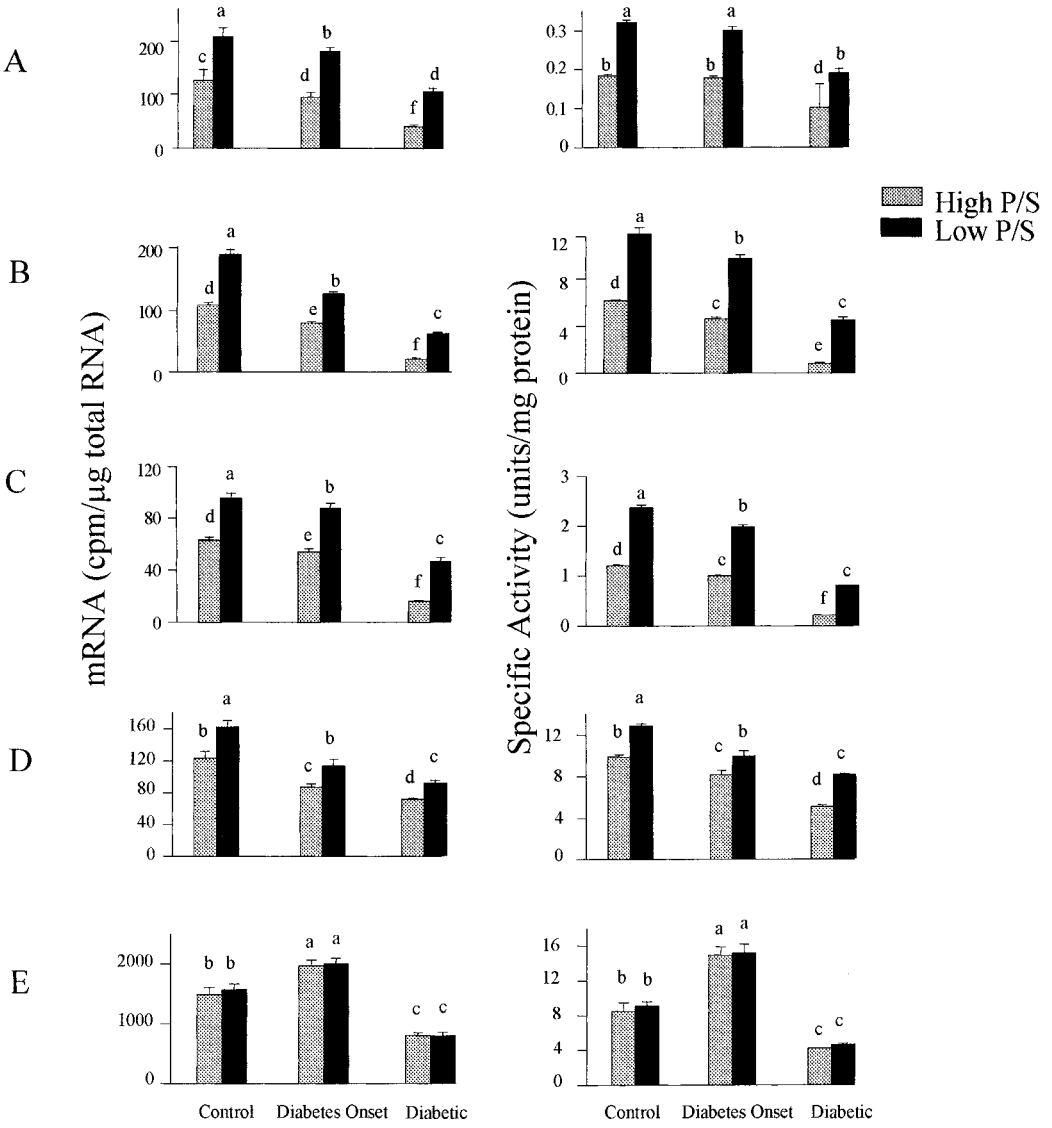

FIG. 1. Effect of diet and diabetes in B/B rats on the mRNA level and specific activity of: (A) acetyl-CoA carboxylase; (B) fatty acid synthase; (C) malic enzyme; (D) pyruvate kinase; (E) phosphoenolpyruvate carboxykinase. P/S, polyunsaturated to saturated ratio. Treatments without a common superscript are significantly different ($P > 0.05$).

Effect of diet and diabetes on enzymes of glucose metabolism. L-type pyruvate kinase catalyzes conversion of phosphoenolpyruvate to pyruvate, whereas PEPCK is part of a potentially futile cycle involved in interconversion of pyruvate and phosphoenolpyruvate, playing a central role in the regulation of glucose synthesis. The mRNA level for pyruvate kinase decreased at the onset of diabetes compared to control animals. A further decrease in specific activity occurred as animals became highly diabetic compared to animals at the onset of diabetes (Fig. 1). PEPCK mRNA level and enzyme specific activity also decreased as the animals became highly diabetic compared to control animals (Fig. 1). However, the mRNA level and specific activity were significantly higher at the onset of diabetes compared to control animals. Feeding the high polyunsaturated fat diet reduced the level of pyruvate kinase but not phosphoenol carboxykinase in both control and diabetic animals.

DISCUSSION

Diverse physiological conditions that modify rates of FAS are accompanied by corresponding changes in other lipogenic enzymes. In uncontrolled, treated diabetes, fatty acids reach extremely high levels and may play a role in causing an insulin-resistant state. Our results with B/B rats agree with previous observations, suggesting that lack of insulin reduces ACC, FAS, and ME mRNA and activity (2,4). Witters and Kemp (22) proposed an insulin-modulated cascade of action initiated through inhibition of 5′-AMP activated protein kinase, leading to activation of ACC. For FAS, insulin primarily stimulates transcription of the FAS gene as the effect of insulin on mRNA level is abolished by treatment with cycloheximide (2). For pyruvate kinase activity, mRNA level decreased with onset of diabetes, suggesting that change in con-

centration of L-type pyruvate kinase protein is due to changes in the rate of mRNA synthesis.

The increase in rate of transcription caused by insulin is by a mechanism requiring ongoing protein synthesis. Noguchi *et al.* (23) showed that 5′-flanking region up to 3 kb of the L-type pyruvate kinase gene contained all *cis*-acting elements necessary for tissue-specific expression of L-type pyruvate kinase and its stimulation by diet and insulin. These elements alone were not sufficient for dietary and hormonal regulation of L-type pyruvate kinase (24).

In the present investigation, PEPCK activity and mRNA level increased significantly at the onset of diabetes, and then decreased as the animals became highly diabetic. The reason for this observation is not apparent.

Feeding a diet containing a higher PUFA content suppressed gene expression of the lipogenic enzymes studied. Dietary polyunsaturated fats are known to be potent inhibitors of hepatic fatty acid and triglyceride synthesis. For protein S14, which behaves like FAS, Jump *et al.* (12) showed that feeding a menhaden oil diet to rats rapidly attenuates hepatic S14 gene transcription. Deletion analysis of transfected S14 CAT fusion gene indicates that *cis*-linked PUFA response elements were localized to a region within the S14 proximal promoter (at –80 to –220 Lp). Blake and Clarke (9) also showed that ingestion of a diet containing fats rich in n-6 and n-3 fatty acids results in a very low level of FAS mRNA; however, the inhibitory action of dietary PUFA did not extend to PEPCK genes as observed in the present investigation. Inability of dietary PUFA to influence PEPCK expression is not consistent with the notion that dietary PUFA may enhance gluconeogenesis. The PEPCK gene contains a cAMP response element that is very sensitive to changes in intracellular cAMP concentrations (24). The failure of PUFA to influence PEPCK gene expression perhaps suggests that suppression of FAS, ME, ACC, and PK gene transcription is not mediated by cAMP. Specific nuclear proteins involved in regulating genes coding for lipogenic enzymes may bind PUFA or their metabolites, and such lipid-binding may directly govern the rate of gene transcription (11). Recently we showed that physiological levels of insulin at the nucleus causes phosphorylation of a nuclear protein to enhance its binding to the promoter region of the ME to simulate gene expression (25). The interaction of this binding with PUFA remains to be determined.

Dietary fatty acids also may be rapidly incorporated into nuclear fatty acid pools and thus may be involved in nuclear regulation of induction of the lipogenic enzyme. In the present study, we observed suppression of enzymes for lipogenesis and glucose metabolism by PUFA, suggesting that the effect of PUFA is through a direct effect at the level of gene expression. The notion that a more saturated dietary fat will tend to normalize the changes in lipogenic capacity that occurs with the development of diabetes is clearly worthy of further research.

Effects of Dietary Phenolic Compounds on Tocopherol, Cholesterol, and Fatty Acids in Rats

Afaf Kamal-Eldin[a,*], Jan Frank[a], Alexander Razdan[a], Siv Tengblad[b], Samar Basu[b], and Bengt Vessby[b]

[a]Department of Food Science, Swedish University of Agricultural Sciences, S-750 07 Uppsala, Sweden, and [b]Department of Public Health and Caring Sciences/Geriatrics, University of Uppsala, 751 25 Uppsala, Sweden

ABSTRACT: The effects of the phenolic compounds butylated hydroxytoluene (BHT), sesamin (S), curcumin (CU), and ferulic acid (FA) on plasma, liver, and lung concentrations of α- and γ-tocopherols (T), on plasma and liver cholesterol, and on the fatty acid composition of liver lipids were studied in male Sprague-Dawley rats. Test compounds were given to rats *ad libitum* for 4 wk at 4 g/kg diet, in a diet low but adequate in vitamin E (36 mg/kg of γ-T and 25 mg/kg of α-T) and containing 2 g/kg of cholesterol. BHT significantly reduced feed intake ($P < 0.05$) and body weight and increased feed conversion ratio; S and BHT caused a significant enlargement of the liver ($P < 0.001$), whereas CU and FA did not affect any of these parameters. The amount of liver lipids was significantly lowered by BHT ($P < 0.01$) while the other substances reduced liver lipid concentrations but not significantly. Regarding effects on tocopherol levels, (i) feeding of BHT resulted in a significant elevation ($P < 0.001$) of α-T in plasma, liver, and lung, while γ-T values remained unchanged; (ii) rats provided with the S diet had substantially higher γ-T levels ($P < 0.001$) in plasma, liver, and lung, whereas α-T levels were not affected; (iii) administration of CU raised the concentration of α-T in the lung ($P < 0.01$) but did not affect the plasma or liver values of any of the tocopherols; and (iv) FA had no effect on the levels of either homolog in the plasma, liver, or lung. The level of an unknown substance in the liver was significantly reduced by dietary BHT ($P < 0.001$). BHT was the only compound that tended to increase total cholesterol (TC) in plasma, due to an elevation of cholesterol in the very low density lipoprotein + low density lipoprotein (VLDL + LDL) fraction. S and FA tended to lower plasma total and VLDL + LDL cholesterol concentrations, but the effect for CU was statistically significant ($P < 0.05$). FA increased plasma high density lipoprotein cholesterol while the other compounds reduced it numerically, but not significantly. BHT, CU, and S reduced cholesterol levels in the liver TC ($P < 0.001$) and percentages of TC in liver lipids ($P < 0.05$). With regard to the fatty acid composition of liver lipids, S increased the n-6/n-3 and the 18:3/20:5 polyunsaturated fatty acids (PUFA) ratios, and BHT lowered total monounsaturated fatty acids and increased total PUFA (n-6 + n-3). The effects of CU and FA on fatty acids were not highly significant. These results suggest some *in vivo* interactions between these phenolic compounds and tocopherols that may increase the bioavailability of vitamin E and decrease cholesterol in rats.

Paper no. L8310 in *Lipids 35*, 427–435 (April 2000).

Currently, much research interest is focused on the beneficial effects of bioactive phytochemicals present at a micro level in our daily diet, especially the heterogeneous group of phenolic antioxidants. Phenolic compounds are common constituents of our diet and are abundant in grains, vegetables, fruits, seeds, nuts, and processed foods thereof (1,2). As early as the 1930s, the Nobel Laureate Szent-Györgyi and co-workers reported that a number of bioactive compounds from fruits and vegetables could heal scorbutic pigs and gave a vitamin P (for permeability) status for flavonoids (3,4). Phenolic compounds in red wine were suggested as one factor responsible for the "French paradox," the phenomenon of a lower incidence of cardiovascular diseases in France compared to matching European populations with similar exposure to risk factors (5,6). Besides cardiovascular diseases (7,8), phenolic compounds are believed to contribute positively to prevention of other degenerative malfunctions such as aging (9) and cancer (1,10,11). The mechanisms behind the different beneficial effects of dietary phenolic compounds are not fully elucidated, but these compounds are known to act as antioxidants (12,13), hypocholesterolemic (14,15) and enzyme-modulating agents (16–18) as well as phytohormones (19).

Research strongly indicates that protection against degenerative diseases cannot be attributed to a single dietary factor, such as vitamin E (e.g., 20,21), but that a wide range of environmental, dietary, and life-style factors determine our resistance or vulnerability to such diseases. On the dietary level, protection seems to require the right balance of a multitude of phytoprotectants including essential n-6 and n-3 fatty acids, vitamins, antioxidants, folates, and dietary fiber components (e.g., 22–24). Studies on interactive mechanisms of protection are therefore highly warranted. For example, synergistic

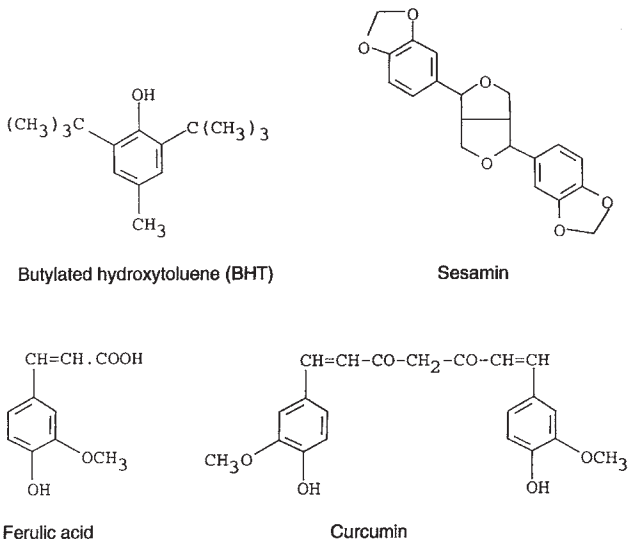

SCHEME 1

TABLE 1
Composition of the Basal Diet[a]

Ingredient	g/kg
Maize starch	528
Casein (vitamin-free)	200
Rapeseed oil[b]	100
Sucrose	80
Cellulose powder	40
Mineral and trace element premix[c]	40
Vitamin premix (vitamin E-free)[c]	10
Cholesterol[d]	2

[a]Antioxidants were added to the experimental diets at a concentration of 4 g/kg.
[b]All vitamin E in the diet originated from the rapeseed oil. Tocopherol and tocotrienol concentrations were determined according to IUPAC 2.432 and were as follows: α-tocopherol 252 ppm, γ-tocopherol 361 ppm, δ-tocopherol 9 ppm; α-, γ-, and δ-tocotrienol were present at concentrations less than 5 ppm. The fatty acid composition of the rapeseed oil, determined according to IUPAC 2.302, was 16:0 (4.3%), 16:1 (0.1%), 17:1 (0.2%), 18:0 (1.6%), 18:1 (60.2%), 18:2 (20.1%), 18:3 (10.2%), 20:0 (0.6%), 20:1 (1.5%), 20:2 (0.1%), 22:0 (0.4%), 22:1 (0.5%), 24:0 (0.1%), and 24:1 (0.2%).
[c]The mineral and trace element premix and the vitamin premix were formulated to meet the nutritional requirements of laboratory rats with the exception of vitamin E and were purchased from Lactam (Lidköpingh, Sweden).
[d]The cholesterol was dissolved in ethanol and sprayed onto the diet.

interactions between tocopherols (T) and dietary phenolic antioxidants, such as sesamin (S) and caffeic acid, have been shown to lead to an increase in the biological activity of T and whole-body resistance to oxidation (25–28).

Within the concept of interactive antioxidant mechanisms, this work aimed to test the effect of selected phenolic compounds , *viz.*, butylated hydroxytoluene (BHT), S, curcumin (CU) and ferulic acid (FA) (Scheme 1), on T and cholesterol levels in rat plasma and tissues. The effects of these compounds on the fatty acid composition of the liver lipids were also studied.

MATERIALS AND METHODS

Experimental animals and diets. The animals used in this study were 50 male, 21-d old Sprague-Dawley rats with a mean body weight of 57 g purchased from B&K Universal AB (Sollentuna, Sweden). They were housed individually in Macrolon IV cages with mesh bottoms (Ehret GmbH & Co., Emmendingen, Germany) in a conditioned room at 25°C and 60% relative humidity with a cycle of 12 h light (0700 to 1900) and 12 h darkness. Each cage was equipped with a water bottle with metal lid, a cup for feed administration attached to a stainless steel plate to avoid overthrowing and spillage, a black plastic tube which the rats used for resting and hiding in, and a table-tennis ball to play with. This experiment was carried out according to the guidelines of and approved by the Ethical Committee for Animal Experiments in the Uppsala region.

The composition of the basal diet is shown in Table 1. Rapeseed oil was provided by Karlshamns AB (Karlshamn, Sweden), and cholesterol was purchased from Sigma Chemical Co. (St. Louis, MO). The phenolics, added to the basal diet at concentrations of 4 g/kg, were obtained from the following sources: S (a mixture of equal amounts of sesamin and episesamin, <0.1 μg/g γ-tocopherol by high-performance liquid chromatography (HPLC) was a gift from Takemoto Oil & Fat Co. Ltd. (Gamagori Aichi, Japan), BHT and FA were purchased from Sigma Chemical Co. while curcumin (CU) was purchased from E. Merck (Darmstadt, Germany). The rats had free access to water and feed throughout the whole experiment.

Study design and sample collection. The 50 animals were divided into five groups of 10 rats of about the same average body weight and fed the experimental diets *ad libitum* for 4 wk. Feed intakes were monitored every day during feeding, and body weights were determined weekly. After the feeding period, the animals were fasted for 12 h before intraperitoneal injection of an overdose of sodium pentobarbital and killed by exsanguination. Blood samples were taken from the *vena cava* and collected in test tubes containing EDTA. After centrifugation (3000 rpm, 10 min), blood plasma was transferred to a test tube with screw cap and stored at –20°C until analyzed. Liver and lung tissues were excised, weighed, and stored in isopropanol at –80°C.

Extraction of tissue lipids. For the extraction of plasma T, blood plasma (500 μL) was mixed with ethanol containing 0.005% BHT (500 μL) and extracted with hexane (2 mL) after manually shaking for 3 min. Liver and lung lipids were extracted according to the method developed by Hara and Radin (29). The tissues, which were collected in isopropanol, were homogenized in 100 mL hexane/isopropanol after adjusting the ratio of these solvents to 3:2 (vol/vol) employing a Diax 600 homogenizer (Heidolph Elektro GmbH & Co. Kelheim, Germany), centrifuged (5000 rpm, 10 min, 0°C), and the lipid extract was collected. The extraction was repeated twice and the extracts were pooled and mixed with 150 mL aqueous sodium sulfate. After 30 min the lower layer was discarded, and the upper layer was filtered after drying with anhydrous sodium sulfate. The solvent was evaporated on a ro-

tary vacuum evaporator at 30°C and the lipids were dissolved in 10 mL chloroform and stored at –20°C until analyzed.

Tocopherol analyses. Plasma T were analyzed by HPLC using a Merck-Hitachi system (pump L-6000, autosampler AS-4000, detector D-2500). The separation of plasma T was performed on a LiChrospher 100 NH_2 column (250 × 4 mm, E. Merck) using isooctane/methyl *tert*-butylether/methanol (75:25:0.035, by vol) as the mobile phase. Because the chromatograms of liver T analyzed by this method contained an unknown substance that interfered with the determination of γ-T, liver and lung T were analyzed on a LiChrosorb Diol 5 μm column (250 × 4 mm, E. Merck) using hexane/1,4-dioxane (96:4, vol/vol) as mobile phase, in an HPLC system consisting of an LKB 2157 autosampler, LKB 2248 pump (Pharmacia LKB Biotechnology AB, Bromma, Sweden) and a Fluor LC 304 fluorescence detector (Linear Instruments, Reno, NV). In both cases the detectors were set to excitation wavelengths of 294 nm and emission wavelengths of 326 nm. Peaks were recorded and integrated using the chromatography software JCL 6000 (Jones Chromatography, Mid-Glamorgan, United Kingdom). The concentrations of α- and γ-T were quantified using authentic T as external standards (T standards, Art. No. 15496 from E. Merck).

Cholesterol analyses. Cholesterol was quantified in the plasma and in the isolated lipoprotein fractions according to the IL test cholesterol Trinder's method 181618-80 and IL test enzymatic-colorimetric method 181709-00 employing a Monarch apparatus (Instrumentation Laboratories, Lexington, MA). Serum high density lipoproteins (HDL) were separated and quantified as reported by Seigler and Wu (30) using sodium phosphotungstate and magnesium chloride with the modification of leaving the sample to precipitate at 4°C for 20 min. Very low density lipoprotein (VLDL) + low density lipoprotein (LDL) cholesterol levels were calculated by subtraction of HDL-cholesterol values from those for total cholesterol (TC).

For cholesterol analyses in the liver and lung tissues, cholestane (Sigma) was added as an internal standard to a part of the lipid extracts in a glass-stoppered test tube, and solvents were removed under nitrogen gas. KOH in ethanol (1 mL, 2 M) was added for saponification in a boiling waterbath with intermittent shaking for 10 min. After cooling to room temperature, water (1 mL) and hexane (2 mL) were added and the test tubes were shaken and allowed to stand until the two layers separated. The hexane layer was transferred to another glass tube and dried under a stream of nitrogen. Trimethylsilyl (TMS) ether derivatives of cholesterol were prepared by incubation at 60°C for 45 min with Tri-Sil reagent (Reagent No. 48999 from Pierce Chemical Co., Rockford, IL). Thereafter, the solvent was evaporated under nitrogen, and the TMS ether derivatives were dissolved in hexane, shaken and centrifuged at 3000 rpm for 3 min. TMS ether derivatives of cholesterol were analyzed on a Varian 3700 gas chromatograph (Varian, Walnut Creek, CA) equipped with a nonpolar fused-silica BP5 column (25 m × 0.33 mm i.d., 0.25 μm film, SGE Scientific Pty. Ltd., Ringwood, Victoria, Australia). Helium was used as carrier gas at an inlet pressure of 16 psi and a flow rate of 25 mL/min. The injector temperature was set to 250°C, the oven temperature to 280°C, and the detector temperature to 300°C.

Fatty acid analyses. The fatty acid composition of the liver lipids was determined by gas chromatography after methylation with acidic methanol (85°C, 2 h). The relative percentages of fatty acid methyl esters from 14:0 to 22:6 were determined after separation on a 25-m NB-351 capillary column (0.32 mm i.d., 0.2 μm film thickness, Nordion, Ltd., Helsinki, Finland) by using flame ionization for detection and quantification.

Statistical analyses. Statistical analysis of the registered variables was performed by an analysis of variance procedure, the general linear model (GLM) supported by the Statistical Analysis System (31). Least significant differences from the *t*-test function of the SAS GLM procedure were used to make statistical comparisons.

RESULTS

Table shows parameters related to animal performance during the experimental time and the body and liver weights at sacrifice. Feed intake and body weights were similar in all groups except for the BHT group where both parameters were significantly reduced ($P < 0.05$). The conversion of feed into body weight, expressed as feed conversion ratio (feed intake/weight gain), was not affected by S, CU, or FA intake but was significantly impaired in rats fed BHT ($P < 0.001$). Total liver weight

TABLE 2
Animal Performance and Body and Liver Weights[a]

Diet	Control (n = 10)	Sesamin (n = 10)	BHT (n = 10)	Curcumin (n = 10)	Ferulic acid (n = 10)	P less than
Feed intake (g/4 wk)	337 ± 3.4[a]	335 ± 5.8[a]	325 ± 1.8[b]	342 ± 1.7[a]	340 ± 2.1[a]	0.05
Feed conversion ratio[b]	1.8 ± 0.04[a]	1.8 ± 0.03[a]	2.0 ± 0.01[b]	1.8 ± 0.03[a]	1.8 ± 0.02[a]	0.001
Body weight (g)	248.5 ± 3.68[a]	246.0 ± 5.88[a]	220.0 ± 1.34[b]	252.7 ± 3.49[a]	251.4 ± 2.44[a]	0.001
Liver weight (g)	12.4 ± 0.40[a,b]	15.3 ± 0.54[c]	13.5 ± 0.29[b]	12.2 ± 0.37[a,*]	12.4 ± 0.26[a,b]	0.05

[a]*n* = number of observations; values represent means ± SEM. Values within each row not sharing a common superscript roman letter are statistically different at *P*.
[b]The level of this unknown substance (US) was calculated as relative peak area to that of α-tocopherol (α-T), i.e., using the same response factor as α-T, γ-tocopherol; for other abbreviation see Table 2.

was increased significantly only by S ($P < 0.001$). When corrected for body weight, BHT-feeding also resulted in a significant enlargement of the liver ($P < 0.001$). The liver lipid content was significantly lower in rats receiving the BHT diet ($P < 0.01$) and slightly lower in all other groups.

Table 3 shows the effects of the four phenolic compounds on the absolute and relative levels of α-T and γ-T in rat plasma, liver and lung. Results showed that S-feeding did not alter the α-T level but caused more than a 10-fold increase in γ-T levels in plasma, liver, and lungs ($P < 0.001$). The γ-T/α-T-ratio, normally about 0.1, ranged from 1.6 in the plasma to 3.3 in the lung of the S-fed rats. Feeding of BHT to rats led to more than a twofold increase in α-T concentrations in plasma, liver, and lung ($P < 0.001$) but changed neither the level of γ-T nor the γ-T/α-T ratio. CU feeding affected neither plasma and liver α-T nor γ-T, but significantly elevated α-T ($P < 0.01$) levels in the lung. No effects on α-T and γ-T levels or on γ-T/α-T ratios were observed in plasma, liver, and lung of rats fed FA.

During the determination of T in the liver lipids, an unknown substance (US; not present in plasma and lung) eluted immediately before γ-T (Fig. 2). This US was not fully separated from γ-T on the amino column used for the analysis of plasma T and, therefore, a diol column was employed for the analysis of T in liver and lung (see Materials and Methods section). The level of this unknown substance expressed as a relative value of the peak area of α-T (Table 3) in the liver

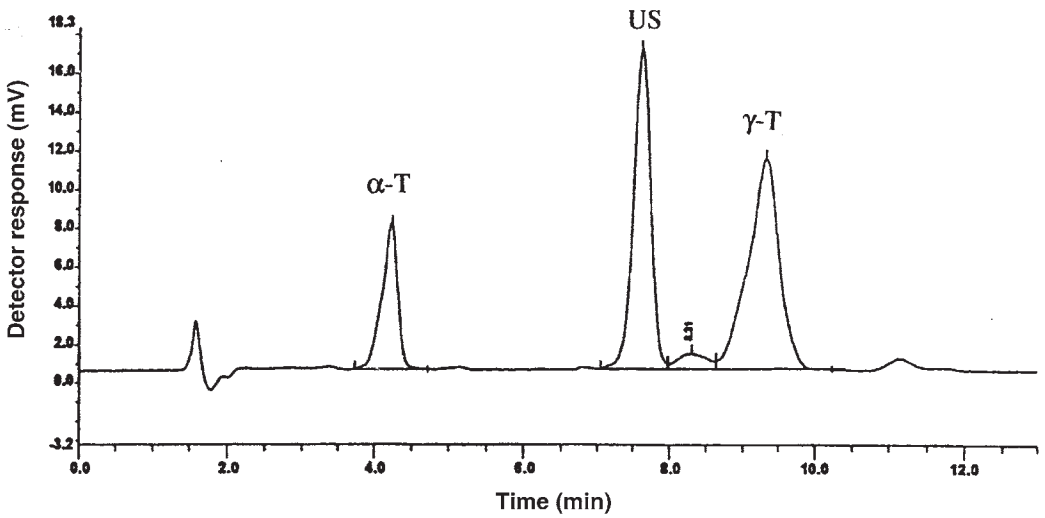

FIG. 1. Chromatogram from high-performance liquid chromatographic-analyses of a liver lipid extract, employing a diol silica column to separate the unknown substance (US) from γ-tocopherol (γ-T) and α-tocopherol (α-T).

TABLE 4
Effect of Phenolic Compounds on Plasma Cholesterol (mg/dL) and Liver Cholesterol and Total Lipids (mg/g fresh weight)[a]

HDL/TC	0.59 ± 0.05^{a,b,c}	0.55 ± 0.03^{a,b}	0.52 ± 0.03^{a}	0.63 ± 0.03^{b,c}	0.67 ± 0.03^{c}	0.05
Liver concentrations of cholesterol and lipids (mg/g fresh weight)						
	n = 8	*n* = 8	*n* = 9	*n* = 6	*n* = 9	
TC	42.20 ± 4.42^{a}	25.76 ± 4.09^{b}	16.25 ± 2.02^{b}	26.75 ± 1.83^{b}	40.86 ± 4.20^{a}	0.001
Liver lipids	119.6 ± 8.03^{a}	108.9 ± 9.34^{a}	77.1 ± 4.53^{b}	114.9 ± 8.11^{a}	109.1 ± 6.74^{a}	0.01
%TC in liver lipids	36.9 ± 5.72^{a}	24.6 ± 4.22^{b}	21.1 ± 2.50^{b}	24.2 ± 2.83^{b}	38.3 ± 4.04^{a}	0.05

[a]Values within each row not sharing a common roman superscript letter are statistically different at indicated *P*-values. Abbreviations: HDL, high density lipoprotein; VLDL, very low density lipoprotein; LDL, low density lipoprotein; for other abbreviation see Table 2.

was not affected by S, FA, or CU but was significantly reduced by BHT ($P < 0.001$).

The results on the effect of phenolic compounds on the cholesterol levels in the plasma and liver are shown in Table 4. BHT numerically elevated plasma TC and VLDL + LDL cholesterols and lowered HDL but significantly lowered liver TC ($P < 0.001$), liver lipids ($P < 0.01$), and the percentage of TC in liver lipids ($P < 0.05$). S did not induce significant effects on plasma cholesterols but significantly lowered liver TC ($P < 0.01$) and percent TC in liver lipids ($P < 0.05$). CU significantly lowered plasma TC ($P < 0.05$) and hepatic TC ($P < 0.001$) and percent TC in liver lipids ($P < 0.05$) while only slightly lowering the values for HDL and VLDL + LDL cholesterol. FA did not cause significant effects on cholesterol levels in the blood or in the liver although it slightly lowered liver lipids, plasma TC, and VLDL + LDL concentrations and slightly elevated HDL cholesterol.

Table 5 shows results on the fatty acid composition of liver lipids. Generally CU and FA did not show significant effects but S and BHT did. S significantly increased the percentages of 18:3n-6, 20:3n-6, 20:4n-6 ($P < 0.001$). BHT, on the other hand, significantly decreased the percentage of 16:0 and the monounsaturated fatty acids ($P = 0.001$) and increased the percentages of 18:0 ($P < 0.001$) and of the polyunsaturated

fatty acids (PUFA) 18:2, 18:3n-6, 20:3n-6, 20:4n-6 ($P < 0.001$) and 18:3n-3, 20:5n-3, and 22:5n-3 ($P < 0.005$). In addition to its effect on the fatty acid percentages, S also significantly increased the ratios of n-6/n-3 ($P < 0.005$) and 18:3n-3/20:5n-3 ($P < 0.05$).

DISCUSSION

This experiment was designed to investigate the effects of BHT, CU, FA, and S on T and cholesterol levels in rat plasma and tissues and on the fatty acid composition of the liver lipids. In order to attribute these effects to the different test compounds, the compounds were added at supra-physiological levels as compared to their expected daily intake. For example, Srinivasan and Satyanarayana (32) estimated an average daily intake of CU for Indian citizens in the range of 0.4–1.5 mg/kg body weight. For the synthetic phenolic antioxidant BHT, the average human daily consumption in Canada and the United States of America was estimated to be approximately 0.1–0.4 mg/kg body weight (33). Throughout this experiment, the average daily intake of these compounds was from 480–850 mg/kg body weight. To be able to compare their effects, we established the phenolic compounds as the only variables in the experimental diets.

Effect of phenolic compounds on rat performance and body and liver weights. Results from the study of the effect of the phenolic compounds on animal performance (Table 2) showed that only BHT led to a decrease in body weight. Both BHT and S induced a significant increase in liver weight relative to body weight in agreement with previous studies carried out with rats (15,27,33–39). Our results are, however, in contrast with Simán and Eriksson (39) who reported an accumulation of lipids in livers of rats fed a BHT diet. Liver enlargement in BHT-fed rats was previously attributed to an induction of detoxifying enzymes (33,34), an effect thought to play an important role in the anticarcinogenic action of phenolic antioxidants (33). Liver enlargement in rats fed S was previously reported but was not attributed to hypertrophy and was found not to disturb the "normal" function of the liver (15,35,36). In the present study, the liver lipid content was significantly lower in rats receiving the BHT diet ($P < 0.01$), in general agreement with previously published data (15,32,34,37,38,40,41).

Effect of phenolic compounds on α-T and γ-T levels. Results from this study showed that S-feeding caused a 10-fold increase in γ-T levels while BHT-feeding caused a two-fold increase in α-T levels in plasma, liver, and lungs (Table 3). The increase in γ-T levels in plasma, liver, and lungs of rats fed Sesamin is in general agreement with our previous results (26) and with those of Yamashita *et al.* (25,27) while the results with BHT are in contradiction with those of Simán and Eriksson (39) who found BHT to lower α-T levels in rat liver but to increase it in the adipose tissue of rats. Despite the fact that γ-T is the major T in the human diet (42,43), α-T is the predominant form of vitamin E in animal plasma and tissues, and its biological activity was estimated to be 10 times that of γ-T (44–46). A Tocopherol transfer protein (TTP) in the hepatocytic cytosol with a specific affinity for α-T (47–49) is considered responsible for the discrimination between the different E-homologs by a selective incorporation of α-T into nascent VLDL (50). γ-T and other forms of vitamin E which are discriminated during this process as well as excess α-T are metabolized and excreted *via* the bile (46,51) and urine (52–55). At the time a transfer-mechanism was saturated, excess α-T was found in the bile to the same extent as the other vitamers (46,50). The fact that the total T levels in plasma were increased by some phenolic compounds, represented by BHT and S, suggests that discrimination by the TTP may not be the only reason for the elimination of T and that other mechanisms might also be involved in vitamin E metabolism and retention.

Although a hypothesis implying that S-feeding in a diet low in α-T might improve the binding capacity of γ-T to the TTP was proposed (27), other possibilities cannot be excluded. Possible mechanisms may involve: (i) stimulatory or inhibitory effects on enzymes involved in the production of free radicals that consume T in the body, (ii) antioxidant interactions of dietary phenols and/or their metabolites with these free radicals, and/or (iii) stimulatory or inhibitory effects on the TTP.

Simán and Eriksson (39) attributed the α-T-decreasing effect to a cytochrome P_{450}-catalyzed formation of prooxidative compounds from BHT that lead to oxidative depletion of hepatic α-T stores. Lignans possessing the methylenedioxyphenyl function, such as S, are known to inhibit mixed function oxidases (56), suggesting that S might spare T by protecting them from radicals produced by the metabolism of lipids and other xenobiotics. Piperonyl butoxide, a synthetic methylenedioxy-phenyl compound, was shown to decrease the hepatic level and to increase the biliary output of α-T in the rat (57). These results, dissimilar to our findings with S, were attributed to increased integrity of the biliary microtubule system, which is disrupted by chemicals such as colchine and vinblastine (58). The reasons for variation in effects of S (this study), BHT (39), and piperonyl butoxide (57,58) on Tocopherol cannot be explained and require more knowledge about coupled metabolism of T and these phenolics. These anomalous effects coupled with the facts that CU did not affect plasma or liver concentrations of α-T or γ-T but significantly elevated α-T levels in the lungs, and that FA lacked effect on α-T and γ-T levels in plasma, liver, and lung show that different phenolic compounds behave differently as regards their effects on body T. It is also worth mentioning that caffeic acid was found to elevate α-T concentrations in plasma and plasma lipoproteins and to improve the antioxidant defense system in the rat (28). Further studies involving a multivariate design based on dose-dependent interactions between these phenolics and T are necessary for further insights into the mechanism of interaction.

Effect of phenolic compounds on cholesterol levels. In the present study (Table 4), BHT had no effect on plasma cholesterol but significantly lowered TC ($P < 0.001$), total lipids (*P*

< 0.01), and percentage of TC in lipids ($P < 0.05$) in the liver. Different results were reported by previous workers who had used very high doses of cholesterol; e.g. Yamamoto *et al.* (38) reported reduced plasma TC and elevated HDL but no changes in liver TC after feeding BHT to rats at a concentration of 0.2% for 4 wk and Takahashi and Hiraga (34) reported that BHT increased liver weight and liver TC and lowered the amount of liver lipids when fed to rats for 1 wk at a 1.2% level. The amount of BHT used in the latter experiment was approximately 150% of the oral LD_{50} reported for rats (59). Our results are comparable to those obtained using the rabbit as a model animal, which showed an increase in plasma TC, triacylglycerols, LDL, and VLDL as well as lower levels of cholesterol oxidation products and a reduced area of atherosclerotic lesions after BHT intake (60). A similar study using butylated hydroxyanisole also revealed an increase in serum TC accompanied by a decrease in liver cholesterol (61). BHT was also shown to lower the activity of lecithin-cholesterol-acyltransferase (62), the enzyme located in HDL that catalyzes the conversion of cholesterol to cholesterol esters, and which is essential for the formation of HDL. An impaired incorporation of cholesterol esters into nascent HDL and thus a lower rate of HDL formation may explain the reduced plasma HDL and elevated TC and VLDL + LDL concentrations observed in the present work. A decrease in the activity of acyl-CoA cholesterol acyltransferase in liver microsomes coupled with impaired reverse cholesterol transport from the peripheral tissues may explain the decrease in liver TC content (61). The elevation of VLDL + LDL and the reduction of HDL concentrations in blood plasma, caused by the oral intake of BHT, may not be true for the concentrations in which BHT is actually taken up by humans; the daily intake of BHT per kg body weight in humans appears to be about 1:1000 to 1:2500 of the concentrations administered to the rats throughout this experiment.

In this study, S lowered plasma values of TC and HDL and liver TC and percent cholesterol in liver lipids but did not affect VLDL + LDL, in agreement with previous results (15,35–37,63). Hirose *et al.* (15) showed that S feeding reduces both cholesterol absorption and synthesis due to a reduced activity of hydroxy methylglutaryl-CoA reductase in liver microsomes. In addition, the total activity of cholesterol 7α-hydroxylase was higher in S-fed rats, suggesting an enhanced cholesterol catabolism and, thereby, reduced liver cholesterol concentrations (15,36). Nakabayashi *et al.* (37) also showed that increasing α-T concentrations enhanced these hypocholesterolemic effects of S. Hirata *et al.* (63) showed that S reduces plasma concentrations of TC and LDL cholesterol in humans although less significantly.

CU significantly lowered both plasma and hepatic TC in conformity with previous publications (40,64). Furthermore, these studies showed an increase in fecal excretion of bile acids and free cholesterol when CU was included in the diet, suggesting that an enhanced requirement of cholesterol for synthesis of biliary juices and a reduced uptake of cholesterol from the intestines, due to a lower concentration of bile acids, causes the reduction in blood and tissue cholesterol levels.

FA feeding did not induce significant effects on cholesterol levels in the blood or in the liver. Feeding of rats with 75 mg% of FA in a 1% cholesterol diet for 7 wk was reported to cause a significant decrease in serum TC and VLDL + LDL and an increase in HDL cholesterol, but no effect on liver TC (65). These results show that phenolic compounds have different effects on cholesterol levels in the rat and that these effects vary with the type and the concentration of the phenolic compound in question.

Effect of phenolic compounds on fatty acid composition of liver lipids. Apart from their effects on T and cholesterol levels (*vide supra*), BHT and S also significantly influenced the fatty acid composition of the total liver lipids. In agreement with previous results (66), S increased the n-6/n-3 PUFA ratio by significantly elevating the percentages of the n-6 acids without affecting the n-3 acids. On the other hand, BHT did not affect the n-6/n-3 PUFA ratio since it increased the percentages of both n-6 and n-3 at the expense of the monounsaturated acids. S elevated the 20:3/20:4n-6 ratio slightly and the 18:3/20:5n-3 ratio significantly, supporting the previous findings on its specific inhibition of Δ^5-desaturase (67). The effect of S on the fatty acid composition of different tissues was found to differ slightly depending on the type of dietary fatty acids.

With increased interest in dietary phenolic compounds in cereals, fruits, and vegetables as protective agents against coronary heart disease and cancer (23,68–70), results obtained in the present investigation show that different phenolic compounds may employ various mechanisms to induce variable effects on different lipid parameters. In this study, S, BHT, and CU increased T bioavailability and lowered cholesterol in plasma and/or tissues (liver and lungs). Further studies aiming to screen various phenolic compounds for their effects on rat lipids and to elucidate their mechanisms of action are underway in our laboratories.

ACKNOWLEDGMENTS

Our research on the antioxidant and cholesterol-lowering properties of dietary phenolic compounds is financed by the Swedish Council for Forestry and Agricultural Research (SJFR, grant No. 50.0496/98) and partially by Kalsec Inc. (Kalamazoo, MI). We thank Karlshamns AB (Sweden) for supplying rapeseed oil, and Takemoto Oil & Fat Co. Ltd. (Gamagori Aichi, Japan) for the kind gift of sesamin/episesamin and Charlotta Wall, from this Department, for kind help with rat sacrifice.

Cholesterol-Lowering Effects of Guar Gum: Changes in Bile Acid Pools and Intestinal Reabsorption

Stéphanie Moriceau, Catherine Besson, Marie-Anne Levrat, Corinne Moundras, Christian Rémésy, Christine Morand, and Christian Demigné*

Unité Maladies Métaboliques & Micronutriments, INRA de Theix, 63122 St-Genès-Champanelle, France

ABSTRACT: Soluble fibers such as guar gum (GG) may exert cholesterol-lowering effects. It is generally accepted that bile acid (BA) reabsorption in portal blood is reduced, thus limiting the capacity of BA to down-regulate liver cholesterol 7α-hydroxylase, the rate-limiting enzyme of BA synthesis. In the present work, rats were adapted to fiber-free (FF) or 5% GG diets (supplemented or not with 0.25% cholesterol), to investigate various aspects of enterohepatic BA cycling. GG in the diet at a level of 5% elicited a significant lowering of plasma cholesterol during the absorptive period, in cholesterol-free (–13%) or 0.25% cholesterol (–20%) diet conditions. In rats adapted to the GG diets, the small intestinal and cecal BA pools and the ileal vein-artery difference for BA were markedly enhanced; reabsorption in the cecal vein was also enhanced in these rats. [^{14}C]Taurocholate absorption, determined in perfused ileal segments, was not significantly different in rats adapted to the FF or GG diet, suggesting that a greater flux of BA in the ileum might support a greater ileal BA reabsorption in rats adapted to the GG diet. In contrast, capacities for [^{14}C]cholate absorption from the cecum at pH 6.5 were higher in rats adapted to the GG diet than to the FF diet. Acidification of the bulk medium in isolated cecum (from pH 7.1 down to pH 6.5 or 5.8) or addition of 100 mM volatile fatty acids was also found to stimulate cecal [^{14}C]cholate absorption. These factors could contribute to accelerated cecal BA absorption in rats fed the GG diet. The effects of GG on steroid fecal excretion thus appear to accompany a greater intestinal BA absorption and portal flux to the liver. These results suggest that some mechanisms invoked to explain cholesterol-lowering effect of fibers should be reconsidered.

Paper no. L8087 in *Lipids 35,* 437–444 (April 2000).

A large part of the adult population in Western countries have elevated cholesterol values (>5 mmol/L) and may be in need of treatment. Pharmacological treatment should be reserved to cases of hypercholesterolemia not responding satisfactorily to dietary changes, because of cost and persistent doubts on the long-term safety of cholesterol-lowering drugs. A treatment program for hypercholesterolemia usually consists of dietary changes toward low-fat/low-cholesterol diets that should also be rich in complex carbohydrates, especially fiber. Evidence for a cholesterol-lowering effect of fiber in animals models and man has accumulated in recent years, especially with viscous fibers such as guar gum (1–5). The effect varies depending on the amount and properties of the gums and the cholesterol level of the diet.

The mechanism by which guar gum (GG) lowers serum cholesterol is still unclear on some points. The enterohepatic cycling of steroids, especially bile acids (BA), is a process susceptible to the interfering effects of BA sequestrants or of high-viscosity compounds such as GG (6): a reduced BA reabsorption is likely to reduce the body's pool of cholesterol. Furthermore, cholesterol absorption itself could also be depressed by soluble fibers, compared to fiber-free conditions (2,7,8), resulting in a greater excretion of neutral sterols (chiefly bacterial metabolites of cholesterol). The prevailing concepts of the effect of fibers on BA cycling in the splanchnic area have probably been influenced by studies carried out with cholestyramine or other types of sequestrants such as β-cyclodextrin, which are potent inhibitors of BA reabsorption in the small intestine (6). It is generally accepted that unconjugated BA, which constitute a small fraction of the luminal BA, are reabsorbed by passive diffusion along the entire small intestine. Active transport systems in the distal ileum account for the bulk of conjugated BA reabsorption, especially when BA are conjugated with taurine (9). Finally, BA escaping absorption in the terminal ileum are deconjugated and partially 7α-dehydroxylated by colonic bacteria; these luminal BA may be reabsorbed by passive diffusion across colonic mucosa (9). The first step of active transport of BA from the distal intestinal lumen is performed by the apical sodium-dependent bile acid transporter (ASBT). This brush border membrane glycoprotein, which co-transports Na^+ and BA into ileocytes, has been cloned and characterized (10,11). After internalization, BA bind to specific cytosolic proteins and subsequently exit the ileocyte by an anion exchanger located in the basolateral membrane. It is conceivable that viscous fibers exert effects on the physical characteristics of the ileal bulk phase (enhanced viscosity, accumulation of endogenous materials) that may alter BA access to the transporter units and thus impair their reabsorption. Little is known of a possi-

Abbreviations : ANOVA, analysis of variance; ASBT, active sodium-dependent bile acid transporter; BA, bile acid; C, cholate; FF, fiber-free; GG, guar gum; Iv-A, arteriovenous difference; PBS, phosphate-buffered saline; SCFA, short-chain fatty acid; TC, taurocholate. Convention: steroid = sterols + bile acids (in digestive or fecal samples).

ble effect of fiber on the BA-transporting capacity of the ileum; however, investigations in rats fed resistant starch showed a doubling of [^{14}C]taurocholate (TC) transport (12). Up-regulation of ASBT has been reported in rodents when there is a spillover of the BA pool (13) or, alternatively, in cholic-acid fed rats (14). Attempts to quantify the reabsorption flux in the portal vein have not provided data that clearly show an impaired recycling of BA to the liver when the diet contains sequestrants (15) or GG (4,16). This point is particularly important because a lowering of portal BA is likely to be (i) the result of intestinal BA spillover and (ii) a stimulatory factor for hepatic BA synthesis, *via* cholesterol 7α-hydroxylase induction (17,18).

Thus, to further investigate the mechanisms of cholesterol-lowering effects of GG in rats, experiments were carried out to measure the effects of this gum on plasma cholesterol and on the digestive BA pools, as well as on ileal BA and cecal reabsorption (*in vivo* or on perfused segments).

MATERIALS AND METHODS

Animals and diets. Male Wistar rats (IFFA-CREDO, l'Arbresle, France) weighting approximately 150 g, were fed semi-purified diets distributed as a moistened powder for 21 d. The experimental diets were: fiber-free (FF) control, 5% GG, 0.25% cholesterol, or 5% GG/0.25% cholesterol (Table 1). GG or cholesterol was included at the expense of wheat starch.

Animals were housed two per cage and maintained in temperature-controlled rooms (22°C), with the dark period from 2000 to 0800. Rats were maintained and handled according to the recommandations of the Institutional Ethics Committee (Clermont-Ferrand University). The body weights of rats were recorded every 48 h during the experimental period; food intake and fecal excretion were recorded over two 3-d periods during the last 10 d.

[a]Louis François, Paris, France.
[b]Sigma, St. Quentin, France.
[c]Minerals supplied, per kg of diet: $CaHPO_4$, 15 g; KCl, 6 g; NaCl, 6 g; $MgCl_2{\cdot}6H_2O$, 6.8 g; Fe_2O_3, 2.5 mg; $MnSO_4$, 125 mg; $CuSO_4{\cdot}7H_2O$, 0.2 mg; $ZnSO_4{\cdot}7H_2O$, 100 mg; KI, 0.4 mg. Vitamins supplied, per kg of diet: thiamin, 20 mg; riboflavin, 15 mg; pyridoxin, 10 mg; nicotinamide, 100 mg; calcium pantothenate, 70 mg; folic acid, 5 mg; biotin, 0.3 mg; cyanocobalamin, 0.05 mg; retinyl palmitate, 1.5 mg; DL-α-tocopheryl acetate, 125 mg; cholecalciferol, 0.15 mg; menadione, 1.5 mg; ascorbic acid, 50 mg; *myo*-inositol, 100 mg; choline, 1.36 g. Both mixes were purchased from UAR (Villemoisson, Epinay-sur-Orge, France).

Sampling procedures. Rats were killed at the end of dark period, namely, at a time when cecal fermentations are still very active. They were anesthetized with sodium pentobarbital (40 mg/kg) and maintained at 37°C. An abdominal incision was made and blood was withdrawn from the ileal branch of the mesenteric artery (after clamping a lower afferent branch that drains the cecum and the proximal colon) and from the abdominal aorta (two 1-mL samples taken). The blood of each animal was placed in a plastic tube containing heparin and centrifuged at 10,000 × *g* for 5 min. After centrifugation, plasma was removed and kept at +4°C for lipid and BA analysis.

After blood sampling, the cecum with contents was removed and weighed, and two aliquot samples of cecal content were transferred into microfuge tubes and immediately frozen at –20°C. The small intestine was clamped at the pylorus and the ileal-cecal junction, removed, stripped of mesentery and fat, and weighed. After injection of 5 mL saline, the contents were drained into a tube by gentle finger stripping, then frozen at –20°C (total small intestine pool). In a separate experiment on two groups of rats (adapted to the FF/control diet or to the GG diet), jejunal and ileal segments were treated separately: after collection of the contents as described above, the intestine segments were opened longitudinally and fixed on a support with pins; then the mucosa was recovered by scraping and frozen at –20°C.

In situ *absorption studies*. In separate series of anesthetized rats, the appearance of radiolabeled BA in bile was used to monitor absorption from intestinal segments (ileum or cecum). A mid-line laparotomy was performed and the bile duct exposed and ligated distally. The bile duct was then catheterized with a PE10 polyethylene catheter (Biotrol, Paris, France), and bile was allowed to drain into preweighed vials cooled on ice.

(i) Ileum. Ileal segments (extending proximally from the ileocecal junction, measured with a 15-cm length of string) were isolated, care being taken to protect the mesenteric vasculature. An opening was made at the distal end of the segment and this last was gently flushed with 20 mL of phosphate-buffered saline (PBS; pH 7) at 37°C. Then, a cannula (external diameter 4 mm, internal diameter 2.5 mm) was inserted at each extremity of the segment and secured. Determination of [^{14}C]TC absorption was performed by two procedures: (i) kinetic determination of [^{14}C]TC absorption from segments filled with 2 mL of a medium containing 1 mM [^{14}C]TC and either 0, 0.5, or 1% GG (this procedure is suitable to study a viscous medium), or (ii) determination of transport by continuous infusion (1 mL/min) of a medium containing 1 mM [^{14}C]TC (to minimize influence of unstirred layer and to achieve steady-state conditions). The composition of the medium was: NaCl 75 mM, KCl 50 mM, $NaHCO_3$ 5 mM, $MgCl_2$ 2 mM, $CaCl_2$ 2 mM, glucose 10 mM, mannitol 40 mM, and potassium phosphate buffer (pH 7.0) 10 mM. Bile was collected sequentially either every 2 or 3 min (procedure 1) or every 5 min (procedure 2) for 30–40 min.

(ii) Cecum. A cannula was introduced in the cecum *via* the ileocecal valve and secured, then an opening was effected at

the appendix extremity and the cecum was flushed by 20 mL of PBS by gentle finger stripping, drained, and this extremity was tied. The cecum was then filled with 2 mL (FF-adapted rats) or 3 mL (fiber-fed rats) of a solution containing 100 mM major anions [sodium salts of short-chain fatty acids (SCFA) or sodium isothionate], 20 mM KCl, 2 mM $MgCl_2$, 2 mM $CaCl_2$, 25 mM potassium phosphate buffer, and 1 mM [^{14}C]-cholate (C) (the pH was adjusted to the required value, namely, 7.1, 6.5, or 5.8). Bile was collected every 5 min during 30 min; because of the relatively low rate of BA absorption and the size of the BA cecal pool, steady-state conditions were maintained over more than 15 min (generally from 5 to 25 min).

Analytical procedures. BA were quantified using the reaction catalyzed by the 3α-hydroxysteroid dehydrogenase (EC 1.1.1.50; Sigma). The enzymatic determination was effected either directly on undiluted plasma, or on digestive samples (small intestine or cecal contents, intestinal mucosa) extracted by a two-step procedure. For this purpose, 1 vol sample was first dispersed in 10 vol ethanolic KOH (0.5 M) using a Polytron disintegrator (Lucerne, Switzerland) and extracted at 70°C for 2 h, then 1 vol of this suspension (typically 2.5 mL) was redispersed in 4 vol of ethanolic KOH and re-extracted at 70°C for 2 h. Triglycerides and total cholesterol were determined in plasma by enzymatic procedures (Biotrol, Paris, France, and Biomerieux, Charbonnières-les-bains, France, respectively).

Calculations and data analysis. Values are given as the means ± SEM. Statistics were examined using a statistical software package (Statview/SuperANOVA; Abacus, Berkeley, CA) on an Apple Macintosh. Data were analyzed either by two-way analysis of variance (ANOVA) to examine the main effect of GG, cholesterol, and their interaction, or one-way ANOVA for other experiments. Least significance difference was used for mean comparison when significant treatment differences existed. Some experiments were analyzed using by Student's *t*-test. Significant differences among means were determined at $P < 0.05$.

RESULTS

As shown in Table 2, the plasma cholesterol concentration was markedly enhanced by 0.25% cholesterol in the diet in rats adapted to FF diet. In rats fed cholesterol-free diets, GG had a slight but significant cholesterol-lowering effect (–13%); this effect was more potent (–20%) in rats fed diets enriched in cholesterol. Plasma triglycerides were not significantly affected by dietary GG or cholesterol in the present experiment.

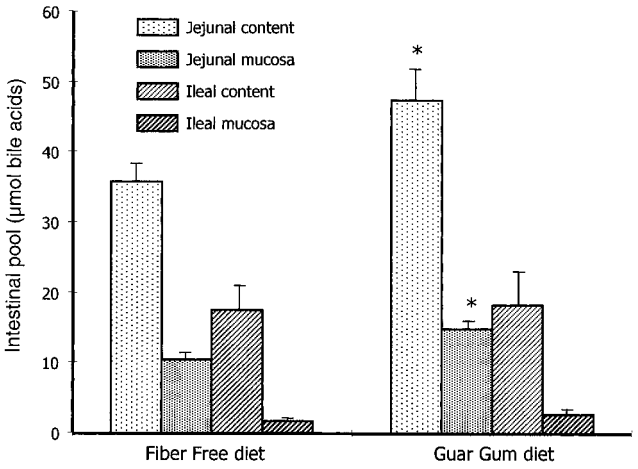

FIG. 1. Comparison of the bile acid pools in the small intestine of rats adapted to a fiber-free or a 5% guar gum diet. Values are means ± SEM (n = 8/group); *$P < 0.05$ vs. fiber-free by Student's *t*-test.

Effects of GG and cholesterol on the BA digestive pools and reabsorption. In rats fed FF diets, the BA pool in the small intestine was about 45 µmol, and the presence of GG in the diet caused a marked enlargement of this pool (Table 3). Cholesterol feeding was also very effective in raising the small intestinal pool, and the maximal value (up to 73 µmol) was found in rats fed the GG/cholesterol diet. The cecal BA pool (about 10 µmol in rats fed an FF diet) was much lower than the small intestine pool. It was enhanced by either dietary GG or cholesterol, and there was a synergistic effect between these two factors. In a separate experiment on rats adapted to FF or GG diets, the intestinal luminal and mucosal bile acids were measured (Fig. 1). It appeared that the rise of the intestinal pool observed in rats fed GG was chiefly due to an enlargement of the jejunal pool. In this segment, a noticeable mucosal pool was measured, corresponding to about 30–35% of the luminal pool. In contrast, the ileal mucosal pool was relatively low, representing about 10% of the luminal pool.

In Figure 2 are presented concentrations of BA in the arterial and ileal venous (mesenteric branch draining the ileum)

TABLE 2
Effect of the Diets on Plasma Cholesterol and Triglyceride Concentrations[a]

	Dietary groups			
	Fiber-free	Guar gum	Fiber-free/cholesterol	Guar gum/cholesterol
Plasma cholesterol (mmol/L)	1.59 ± 0.05[c]	1.37 ± 0.04[b]	2.09 ± 0.07[d]	1.68 ± 0.0[c]

TABLE 3
Effect of the Diets on the Intestinal Pools and Reabsorption of Bile Acids[a]

	Dietary groups			
	Fiber-free	Guar gum	Fiber-free/cholesterol	Guar gum/cholesterol
Small intestinal pool (μmol/organ)	45.1 ± 3.1[b]	59.2 ± 5.4[c]	64.5 ± 3.4[c]	73.8 ± 5.2[d]
Cecal pool (μmol/organ)	9.7 ± 1.4[b]	15.8 ± 1.2[c]	19.7 ± 3.0[b]	38.6 ± 9.6[d]
Portal vein flux (μmol/min)	37.0 ± 8.0[b]	60.2 ± 7.3[c]	45.6 ± 5.6[b]	68.0 ± 9.7[c]
Cecal vein flux (μmol/min)	7.3 ± 0.8[b]	9.0 ± 1.8[b,c]	11.2 ± 2.0[c]	19.4 ± 2.5[d]

[a]Values are means ± SEM (n = 8/group); means not sharing a common superscript are significantly different at $P < 0.05$ by two-way ANOVA and LSD comparison. For abbreviations see Table 2.

plasma. No significant differences in the arterial BA concentrations were observed (ranging from 0.05 to 0.08 mmol/L). In all diet conditions, much higher concentrations were found in the ileal vein, some exceeding 0.30 mmol/L in rats adapted to the GG/cholesterol diet. When the diet contained GG or was supplemented with cholesterol, the ileal vein concentrations were significantly higher than in FF controls. The calculated arteriovenous difference (Iv-A) was +0.12 mmol/L in FF controls, and this difference was not substantially enhanced in rats fed the FF/cholesterol diet (+0.15 mmol/L). In contrast, a striking rise in the Iv-A arteriovenous difference (practically doubled) was found in rats adapted to GG diets, and the highest arteriovenous difference was observed in the GG/cholesterol diet group.

Effect of GG on [^{14}C]TC absorption rate in ileal segments. The time course recording of [^{14}C]TC appearance in bile indicates a very rapid absorption from the ileal loop; the maximal level of ^{14}C BA was achieved within 5–8 min after introduction of the experimental TC solution in the loop (Fig. 3). The plot of the cumulative [^{14}C]TC as a function of time offers a possibility to estimate the kinetic characteristic of TC absorption. In control conditions, the maximal slope corresponded to a rate of 2.8 nmol/min/cm. When GG was present in the experimental medium, the lowest concentration (0.5%) was apparently ineffective in modifying the rate of TC absorption whereas the 1% concentration exerted a marked inhibition on TC absorption (–52%).

By using the procedure of isolated ileal loop perfusion, steady-state conditions of [^{14}C]TC appearance in bile were found to be attained readily, within about 5 min. Sequential collection of bile was effected over 20 min. In this model, the rate of [^{14}C]TC absorption from the ileum (in nmol/min/cm

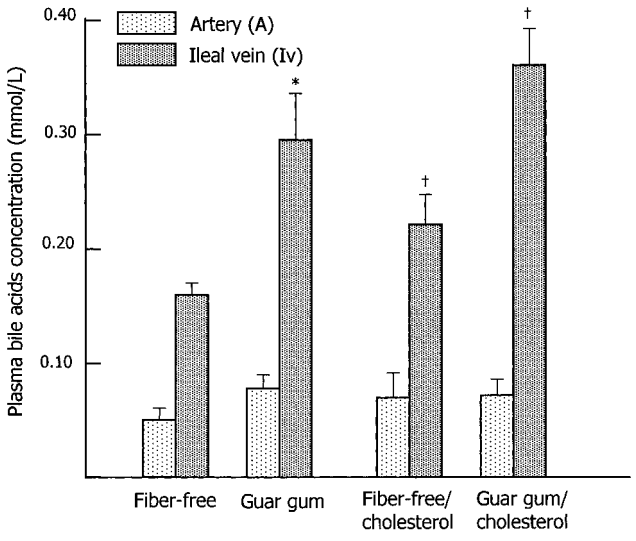

FIG. 2. Ileal vein and artery concentrations of bile acids in rats adapted to dietary guar gum; the experimental diets were either cholesterol-free or contained 0.2% cholesterol. Values are means ± SEM (n = 8/group); means not sharing a common superscript are significantly different at $P < 0.05$ by two-way analysis of variance and least squares difference comparison.

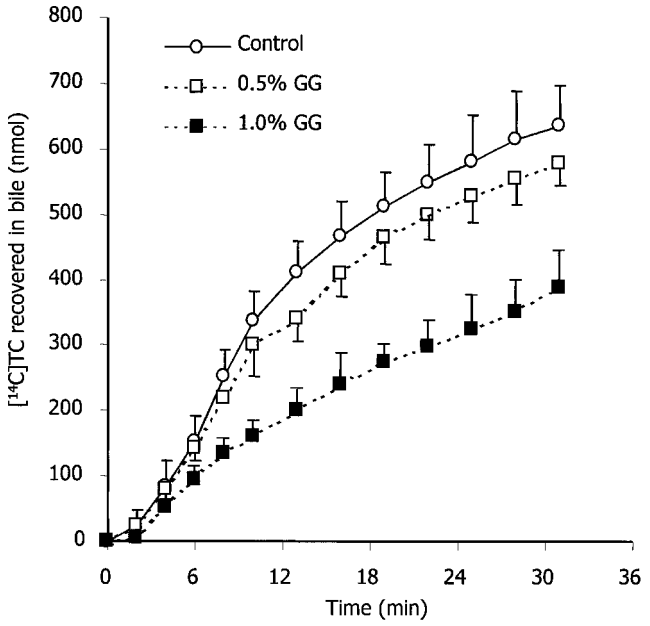

FIG. 3. Taurocholate absorption from ileal segments filled with 1 mmol/L [^{14}C]taurocholate medium, and 0, 0.5, or 1.0% guar gum. Appearance in bile of radiolabeled bile acids was used to monitor absorption from the ileum. Values are means ± SEM (n = 6/group).

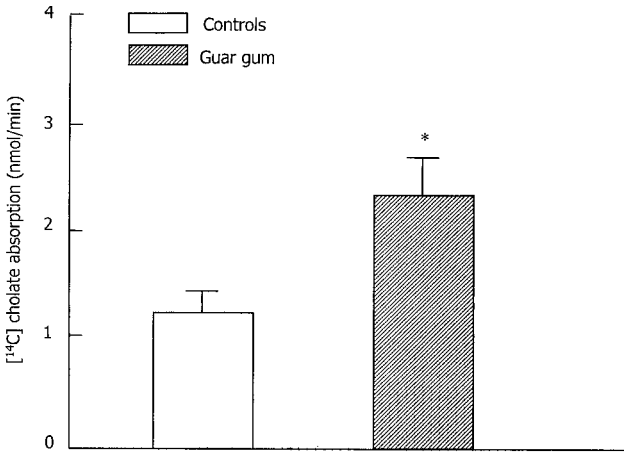

FIG. 4. Effect of adaptation to a fiber-free control or a 5% guar gum diet on cholate absorption from the cecum. The cecum was flushed with saline, then the experimental solutions containing 1 mmol/L [^{14}C]-cholate were injected. Appearance of radiolabeled bile acids was used to monitor absorption from the cecum. The medium contained 100 mM short-chain fatty acid salts pH 6.5. Values are means ± SEM (n = 6/group). *P < 0.05 vs. control by Student's t-test.

intestine) of rats adapted to a 5% GG diet (6.37 ± 0.69) was not significantly modified, compared to FF controls (5.05 ± 0.69).

Effects of pH, short-chain fatty acids (SCFA), and adaptation to a GG diet on the capacity for [^{14}C]cholate (C) absorption in the cecum. The rate of [^{14}C]C absorption from the cecum was affected by the bulk pH and the major anions present in the experimental solution. Substitution of 100 mmol/L SCFA Na salts (a realistic concentration in the caecum), as 60 mmol acetate + 25 mmol propionate + 15 mmol butyrate, by equimolar Na isothionate elicited a 31% lower absorption of [^{14}C]C (1.64 ± 0.23 vs. 2.41 ± 0.30 nmol [^{14}C]cholate absorbed/min/cecum; n = 6; P < 0.05).

In another experiment the luminal pH was modified in the presence of 100 mmol/L SCFA, within a physiological range, namely from 7.5 to 5.8 with an intermediate value at 6.5. The results indicated that the cecal [^{14}C]C absorption was slightly accelerated in acidic pH conditions, but the highest absorption rate was found at pH 6.5 [at pH 7.1, 1.56 ± 0.24 nmol [^{14}C]cholate absorbed vs. 2.32 ± 0.26 at pH 5.8, n = 7, P < 0.05; absorption at pH 6.5 was 2.61 ± 0.31, n = 7; absorption at pH 7.1 was significantly different from pH 6.5 (P < 0.5), but absorption at pH 6.5 and 5.8 were not significantly different].

The cecum was enlarged and its wall heavier in rats fed GG than in controls (0.97 vs. 0.59 g, respectively). As shown in Figure 4, the rate of [^{14}C]C absorption from the cecum was significantly greater in the cecum of rats adapted to the GG diet than in controls (+87%). Taking into account the differences in volume of test solution between the two groups, it appears that cecal [^{14}C]C absorption was only 26% greater in rats fed the GG diet than in those fed the control FF diet.

DISCUSSION

The present work confirms, in agreement with other investigations (4,19,20), that GG is liable to lower plasma cholesterol, this effect being more potent when the diet contains a significant percentage (0.25%) of cholesterol. Effects of GG, which should be related to modifications of luminal viscosity, have been ascribed to disturbances of micelle formation, slowing of cholesterol transfer across the unstirred layer, and inhibition of bile acid reabsorption (1,6,19). This last mechanism has been frequently invoked for steroid sequestrants, such as resins or cyclodextrins, or gel-forming compounds, such as pectin, psyllium or gums (6,21). The present experiments indicate that GG, in the isolated ileal loop model, may be very effective in inhibiting TC reabsorption in the distal part of the small intestine. Nevertheless, the fact that the 0.5% concentration was ineffective, whereas the 1% concentration was markedly inhibitory, suggests that there is a threshold effect in the inhibition of TC absorption by GG. This could be connected to differences in medium viscosity, which could impair TC diffusion to the ileal brush border membrane, as suggested by examining the kinetics of ^{14}C appearance in the bile.

Previous work showed that fecal excretion of bile acids is raised by GG (4) but, with moderate levels of dietary GG (5% or less) this rise is rather limited. In fact, enhanced fecal steroid excretion is represented chiefly by neutral sterols rather than bile acids (22). In parallel, biliary BA secretion may be accelerated by GG, as shown also for other fibers (23,24). In the rat, the BA pool is almost entirely found in the digestive tract, especially in the small intestine. The present work, in keeping with previous data (4,25), indicates that the small intestine pool is markedly enhanced by GG and to a lesser extent by cholesterol,and both factors are apparently cumulative. A more detailed study of the small intestinal pools in rats adapted to the FF or GG diet indicated that most of BA were present in the duodenal/jejunal part, and this pool was the most affected by GG. The ileal pool was found to be smaller than the jejunal pool and was not markedly enlarged by GG. A substantial mucosal BA pool (about 30% of the luminal pool) was found in the jejunum but it represented less than 10% in the ileum, as previously reported (26). The significance of a large capacity for BA accumulation in the jejunal mucosa is still unclear, but it tended to increase in rats adapted to a GG diet. This could represent a storage compartment for a portion of the BA in rats since this species is devoid of a gall bladder, or it could be involved in BA absorption since the proximal small bowel may take a significant part in this process (27). Capacities for passive BA reabsorption have been identified in both the upper and lower part of the small intestine, as well as in the large intestine (9). In the small intestine, this passive process should essentially transfer glyco-conjugates whereas, in the large intestine, it represents the unique possibility of unconjugated BA reabsorption. Besides the passive component, ASBT exhibiting a high affinity for tauro-conjugated BA is located in the ileum. Neg-

ative feedback regulation by conjugated BA has been reported in rats and guinea pigs, together with an upregulation of ileal transport by cholestyramine (13). Enhanced capacities of ileal BA reabsorption have been reported by Riottot and Sacquet (12) in rats adapted to a resistant starch diet. Upregulation of ileal ASBT has been described in the presence of excess cholic acid or after glucocorticoid treatment (14,28). However, Arrese *et al*. (29) have recently questioned the view that a reduction in presentation of bile salts to the apical surface of the ileum would modulate the expression of the genes involved in their transport. In the present case, no significant change in TC absorption capacity could be found in rats adapted to the GG diet, at least under conditions in which an unstirred layer plays practically no role. The IvA differences across the ileum were markedly elevated in rats adapted to a GG diet. Because local blood flow is not available, these IvA differences cannot be interpreted in terms of fluxes. Nevertheless, blood flow in the ileum of rats fed GG diets was probably as great as in controls (or even somewhat greater) since (i) GG elicits trophic effects on the ileal intestinal wall (30) and (ii) digesta in the ileum are bulkier than in FF controls. Gel-forming fibers are effective in slowing digestive transit in the upper part of the digestive tract (31) but, owing to the bulking effect of GG (31,32), the flux of materials (hence of BA) might be higher in rats fed GG than in controls. The dietary load of cholesterol may cause an inhibition of BA absorption in the ileum (33), but this is not particularly clear in the present experiment with a relatively limited cholesterol supplementation.

Soluble fiber has been reported to alter BA conjugation by increasing the percentage of glyco-conjugated at the expense of tauro-conjugated BA(34). It is still unclear whether ileal reabsorption of glyco-conjugated BA is really different from that of the tauro-conjugates, especially *in vivo* in the presence of complex mixtures of both glyco- and tauro-conjugates. As reported recently (11), ileal ASBT mediates the uptake of TC as well as that of unconjugated C, or of glycine conjugates of deoxycholate, chenodeoxycholate, or ursodeoxycholate (with a low K_m for these last). A shift of BA conjugation from tauro- to glyco-conjugation could thus improve BA reabsorption because glyco-conjugated compounds are subjected to active transport by ASBT as well as to passive diffusion in the jejunum and the ileum. In this last segment, diffusion could be higher through a less fluid membrane (high cholesterol/phospholipid ratio) than in the jejunum (35). It must be noted that dietary factors, including cholesterol, are likely to affect ileal transport through membrane lipid compositional changes (36), a domain still poorly known.

Possibilities of passive BA diffusion across the large intestine wall are reflected by the presence of secondary BA in the body's pool (9,37) and by absorption measurements (4). This reabsorption was found to be greater in rats adapted to GG than in controls, and it was also greater when cholesterol was present in the diet, in parallel to an enlargement of the BA cecal pool. The solubility of bile acids in the large intestine lumen is governed by complex factors: luminal pH, CaPi concentration, bacterial proliferation (38,39). Expression of ASBT in the cecal wall is uncertain (10,11), but in rats fed GG diets the larger surface area of exchange and local blood flow are likely to accelerate the diffusion flux. Furthermore, parameters related to the presence of active fermentations in the cecal lumen may promote BA reabsorption, that is, moderately acidic pH conditions and the presence of high SCFA concentrations. The mechanisms are still unclear, and they could be related to the general effects of SCFA on mineral and water fluxes. *In vivo*, the cecal BA flux may represent less than 10% of the portal flux (FF diet) but nearly 25% under favorable conditions (GG/cholesterol diet) (16). The contribution of the cecum is probably enhanced when the small intestine pool is enlarged and when ileal absorption fails to match a very large flux of BA.

The existence of a higher portal BA concentration in rats adapted to GG or GG/cholesterol diets, compared to FF controls (16), probably resulted in a larger hepatic uptake since the systemic BA concentration was not substantially enhanced by the various diet treatments. Furthermore, the overall BA synthesis might be increased by GG, in keeping with previous observations showing a larger fecal BA excretion and an induction of cholesterol 7α-hydroxylase with GG diets (2,22) compared to FF conditions. Classical concepts on the lipid-lowering effects of soluble fiber postulate that portal BA should be depressed which, in turn, up-regulates the hepatic cholesterol 7α-hydroxylase. In fact, some experimental reports do not verify this view: Cronholm and Sjövall (40), for example, and Fukushima *et al*. (15) did not find any significant decrease of portal BA in rats fed a sequestrant. Pandak *et al*. (41) have proposed that the effects of BA on cholesterol 7α-hydroxylase may be indirect and involve intestinal factors secreted (or absorbed) under the influence of BA in the intestine lumen. Negative control of cholesterol 7α-hydroxylase expression by BA has been extensively investigated, and secondary (hydrophobic) BA are considered as the most effective (42). This action may involve the protein kinase C (PKC) signaling pathway; it has be shown that the α isoform of Ca-dependent PKC is translocated to the plasma membrane in response to application of physiological concentrations of BA (43). At a molecular scale, regulation of cholesterol 7α-hydroxylase expression is particularly complex: several elements have been identified that confer to the gene responsiveness to BA (BA response elements) and to stimuli such as insulin, cAMP, and phorbol esters (44). This point suggests that the metabolic and endocrine status is liable to modulate the activity of cholesterol 7α-hydroxylase (18). In this view, a high-fiber diet may blunt postprandial hyperinsulinemia and alter the profile of the nutrients absorbed in the portal vein, especially the glucose/SCFA ratio (45,46). Furthermore, it must be kept in mind that part of BA synthesis is dependent on a sterol 27 hydroxylase pathway, the nutritional regulation of which is still poorly known, although it is generally considered less inducible than cholesterol 7α-hydroxylase (18,47).

In conclusion, GG elicits marked changes in the intestinal pools of BA and, since secretion and fecal excretion fluxes

may be raised in such diet conditions (4,16), it seems conceivable that enterohepatic cycling of BA is accelerated by GG. Nevertheless, cholesterol oxidation could remain relatively active in the presence of high concentrations of BA in hepatic afferent blood, supporting the view that the control of cholesterol 7α-hydroxylase activity is particularly complex. Compositional changes of portal BA or other metabolic factors (subtrates, hormones) could play a critical role in this control.
