ABSTRACT: The differential uptake and targeting of intravenously infused [1-^{14}C]palmitic ([1-^{14}C]16:0) and [1-^{14}C]arachidonic ([1-^{14}C]20:4n-6) acids into heart lipid pools were determined in awake adult male rats. The fatty acid tracers were infused (170 μCi/kg) through the femoral vein at a constant rate of 0.4 mL/min over 5 min. At 10 min postinfusion, the rats were killed using pentobarbital. The hearts were rapidly removed, washed free of exogenous blood, and frozen in dry ice. Arterial blood was withdrawn over the course of the experiment to determine plasma radiotracer levels. Lipids were extracted from heart tissue using a two-phase system, and total radioactivity was measured in the nonvolatile aqueous and organic fractions. Both fatty acid tracers had similar plasma curves, but were differentially distributed into heart lipid compartments. The extent of [1-^{14}C]20:4n-6 esterification into heart phospholipids, primarily choline glycerophospholipids, was elevated 3.5-fold compared to [1-^{14}C]16:0. The unilateral incorporation coefficient, *k**, which represents tissue radioactivity divided by the integrated plasma radioactivity for heart phospholipid, was sevenfold greater for [1-^{14}C]20:4n-6 than for [1-^{14}C]16:0. In contrast, [1-^{14}C]16:0 was esterified mainly into heart neutral lipids, primarily triacylglycerols (TG), and was also found in the nonvolatile aqueous compartment. Thus, in rat heart, [1-^{14}C]20:4n-6 was primarily targeted for esterification into phospholipids, while [1-^{14}C]16:0 was targeted for esterification into TG or metabolized into nonvolatile aqueous components.

Paper no. L8403 in *Lipids 35,* 891–898 (August 2000).

While it is well-established that phospholipid breakdown is accelerated during myocardial ischemia (1–3), until recently the roles of phospholipids and their constitutive fatty acids in lipid-mediated signal transduction and membrane turnover in the heart were poorly understood. A number of signal transduction mechanisms in the heart function through a phospholipase A_2-mediated release of arachidonic acid (20:4n-6). In rat ventricular myocytes, interleukin-1β (IL-1β) activates the plasmalogen selective phospholipase A_2 through a receptor-linked mechanism, resulting in increased 20:4n-6 levels (4). Tumor necrosis factor-α also increases phospholipase A_2 activity in rat ventricular myocytes, although the phospholipase A_2 which is activated is apparently different from that activated by IL-1β (5). Angiotensin II stimulates the release of both 20:4n-6 and inositol phosphates through activation of multiple receptor subtypes involving increased phospholipase A_2 and phospholipase C activity (6). The β_2-adrenergic receptor stimulation leads to 20:4n-6 release through activation of a cytosolic phospholipase A_2 (7). Furthermore, the heart has an active phosphoinositide pathway that responds to α-1-adrenergic and muscarinic receptor stimulation (8,9). This pathway is partially regulated by lysophosphatidylcholine levels, with its activity decreasing with increasing levels (10). This suggests that, lysophosphatidylcholine produced by phospholipase A_2-mediated hydrolysis of choline glycerophospholipids (ChoGpl) regulates another lipid-mediated signal transduction system in the heart. Despite the role of 20:4n-6 in heart lipid-mediated signal transduction, the uptake and targeting of this fatty acid in the heart are controversial.

The mammalian heart uses palmitic acid (16:0) as a primary source of metabolic energy *via* β-oxidation (11), but the heart also takes up polyunsaturated fatty acids such as 20:4n-6 (12). The uptake rate and ultimate deposition of fatty acids depend, in part, upon chain length (11). Palmitic acid, a saturated fatty acid, is targeted for esterification into triacylglycerol (TG) pools and used to meet energy demands (11, 13). Oleic acid, a monounsaturated fatty acid, is also taken up by heart and is targeted for esterification into TG (14). Uptake and targeting of these fatty acids toward β-oxidation are decreased with high glucose levels (15). However, when glucose levels are in the physiologic range, saturated and monounsaturated fatty acids are esterified into TG and used almost exclusively for β-oxidation (13–15).

In contrast, the ultimate fate of 20:4n-6 in heart is unclear. A number of studies in isolated hearts or isolated myocytes

Abbreviations: CE, cholesteryl esters; CerPCho, sphingomyelin; ChoGpl, choline glycerophospholipids; DG, diacylglycerols; EtnGpl, ethanolamine glycerophospholipids; FFA, free fatty acids; IL-1β, interleukin-1β; *k**, unilateral incorporation coefficient; PET, positron emission tomography; PlsCho, choline; PlsEtn, ethanolamine plasmalogen; PtdIns, phosphatidylinositol; PtdOH, phosphatidic acid; PtdSer, phosphatidylserine; TG, triacylglycerols; TLC, thin-layer chromatography.

suggest that esterification of 20:4n-6 into lipid pools is concentration-dependent (12,16). For instance, in a perfused isolated heart model, when the concentration of 20:4n-6 in the perfusate is high, it is preferentially esterified into myocyte TG (12,16), while when the concentration is low, it is preferentially esterified into phospholipids (12). Regardless, very little 20:4n-6 is used for β-oxidation, thereby conserving this fatty acid for other uses (12). This conservation is consistent with the utilization of 20:4n-6 in lipid-mediated signal transduction. Other studies in myocytes have shown that 20:4n-6 and other polyunsaturated fatty acids are esterified into the TG pool much more than into phospholipid pools (17). Under these experimental conditions, the heart did not elongate or desaturate the fatty acids, suggesting that it lacks the high levels of enzymic activity for these functions (17). Results also indicate that 20:4n-6 found in heart is not formed from linoleic acid but rather arises from direct uptake from the circulation (17). Thus, the targeting of 20:4n-6 in heart remains unclear. These conflicting results suggest that 20:4n-6 uptake and targeting need to be reexamined in the heart.

Others have used perfused heart models or isolated myocytes to study 20:4n-6 uptake and targeting, but these models may not represent the situation found *in vivo*. Therefore, we examined 20:4n-6 uptake and targeting, as compared to 16:0, by intravenously infusing awake adult male rats with either [1-^{14}C]20:4n-6 or [1-^{14}C]16:0 and quantifying the uptake and deposition of each tracer into different heart lipid pools. By using high specific activity tracers, unlabeled plasma fatty acid levels were unaltered (18). We found that [1-^{14}C]20:4n-6 was largely esterified into rat heart phospholipids, whereas [1-^{14}C]16:0 was preferentially esterified into heart TG and found in the nonvolatile aqueous fraction representing by-products of β-oxidation.

MATERIALS AND METHODS

Animals. Male Sprague-Dawley rats (200 g) were obtained from Charles River Laboratories (Wilmington, DE) and maintained *ad libitum* on standard laboratory rat chow and water prior to surgery. This study was conducted in accordance with the National Institutes of Health Guidelines for the Care and Use of Laboratory Animals (NIH publication 80-23), under a protocol approved by the National Institute of Child Health and Development's Institutional Animal Care and Use Committee.

Animal surgery. Unfasted rats were anesthetized with respired halothane (1–3%), and their femoral artery and vein were catherized with polyethylene tubing (PE-50). Following catheter insertion, the wound was closed using standard surgical staples and the area anesthetized with xylocaine (1%). The rats were wrapped in plaster body casts, taped to wooden blocks, and maintained postoperatively in a quiet temperature-controlled environment that kept body temperature at 37°C for 3 h prior to infusion. Seven out of eight rats survived (88%) the surgical procedure.

Awake rats were infused with 170 μCi/kg of either [1-^{14}C]20:4n-6 or [1-^{14}C]16:0 into the femoral vein over 5 min, using a constant rate infusion pump (Harvard Apparatus Co., South Natick, MA). Throughout the experimental period, arterial blood samples (200 μL) were taken to determine plasma radioactivity. Fifteen minutes from the start of infusion, the rats were killed using sodium pentobarbital (100 mg/kg, i.v.). The hearts were rapidly removed, bisected, and residual blood was removed by rinsing with ice-cold 0.9% KCl. After blotting, the hearts were frozen in dry ice.

Preparation of radiotracer. Radiotracers (Moravek Biochemical, Brea, CA) were prepared by taking an aliquot of either tracer in ethanol and evaporating the ethanol under a constant stream of N_2 at 50°C. Radiotracer purity was assessed by thin-layer chromatography (TLC) and found to be >97% pure for each tracer. The fatty acid tracers were individually solubilized in 5 mM HEPES (pH 7.4) buffer containing fatty acid free-bovine serum albumin (50 mg/mL; Sigma Chemical Co., St. Louis, MO). Solubilization was facilitated by sonication in a bath sonicator for 10 min. Radioactivity was determined using liquid scintillation counting and adjusted to 100 μCi/mL. The appropriate amount of radiotracer was prepared for each animal to administer 170 μCi/kg (18).

Plasma extraction. Arterial blood samples, taken at predetermined time points during the infusion period, were stored on ice for up to 10 min before separating the plasma by centrifugation using a Beckman microfuge (Fullerton, CA). Plasma lipids were extracted by transferring a 100-μL aliquot of plasma into a tube containing 3 mL of chloroform/methanol (2:1, vol/vol), then vortexing. The addition of 0.63 mL of 0.9% KCl to these tubes resulted in two phases, which were thoroughly mixed and allowed to separate overnight in a −20°C freezer. The upper phase was removed and the lipid-containing lower phase was rinsed with 0.63 mL of theoretical upper phase to remove any water-soluble contaminants (19). Phase separation was facilitated by centrifugation at 1500 rpm and 0°C in a refrigerated Sorvall RT 6000 B centrifuge (DuPont Instruments, Wilmington, DE). The upper phase was discarded, the lower phase was dried, and its radioactivity quantified using a Packard 2200 CA Tricarb liquid scintillation counter (Packard Instruments, Downers Grove, IL).

Heart extraction. Frozen heart tissue was weighed, minced, and extracted in a Tenbroeck tissue homogenizer using a two-phase system (19). Briefly, the tissue mass (g) was multiplied by a correction factor of 1.28 to convert it to an equivalent value expressed in mL (20). This value represented 1 vol. The minced tissue was placed in the homogenizer and 17 vol of chloroform/methanol (2:1, vol/vol) added. Tissue was homogenized to a fine particulate-like powder. The solvent was removed and the homogenizer rinsed with 2 vol of chloroform/methanol (2:1, vol/vol). The rinse was added to the original sample, and 4 vol of 0.9% KCl solution added to this combined lipid extract. After vigorous mixing, phase separation was facilitated by centrifugation as described above. The upper phase and proteinaceous interface were removed and saved in a 20-mL glass scintillation vial. The lower organic phase was washed twice with 2 mL of theoretical upper phase, with phase separation facilitated by cen-

trifugation between washes. The washes were removed and combined with the previously removed upper phase. The washed lower phase was dried under a stream of nitrogen and the lipids redissolved in 1 mL of *n*-hexane/2-propanol (3:2, vol/vol) containing 5.5% H_2O.

Aqueous fraction. The aqueous fraction was processed for liquid scintillation counting by first being dried at 80°C for 18 h to remove $^{14}CO_2$. The dried material was then solubilized in 2 mL of Soluable (Packard Instruments) in tightly capped scintillation vials heated at 80°C for 2 h. Radioactivity was determined after addition of 10 mL of Ready-Solv (Beckman Instruments) using a Packard 2200 CA Tricarb liquid scintillation counter.

TLC. Phospholipids and neutral lipids were separated by TLC. For each separation, 100 µL of sample was spotted onto a TLC plate. Phospholipids were separated on heat-activated Whatman silica gel-60 plates (20 × 20 cm, 250 µm) developed in chloroform/methanol/acetic acid/water (60:30:3:1, by vol). This solvent system resolves cardiolipin, phosphatidic acid (PtdOH), and ethanolamine glycerophospholipids (EtnGpl) but not phosphatidylinositol (PtdIns) and phosphatidylserine (PtdSer). Neutral lipids were separated using heat-activated silica G plates (Analtech, Newark, DE) developed in petroleum ether/diethyl ether/acetic acid (70:30:1.3, by vol) (21). This solvent system resolves cholesteryl esters (CE) and TG. Lipid fractions were determined using authentic standards (Doosan-Serday, Englewood Cliffs, NJ, and Nu-Chek-Prep, Elysian, MN).

Bands corresponding to PtdOH, EtnGpl, combined PtdIns/PtdSer, ChoGpl, and sphingomyelin (CerPCho) were scraped into 20-mL liquid scintillation vials, and 0.5 mL H_2O was added followed by 10 mL of Beckman Ready-Solv. After mixing, the samples were quantified by liquid scintillation counting at least 1 h after the addition of the Ready-Solv. Bands corresponding to TG, CE, diacylglycerol (DG), and free fatty acids (FFA) also were scraped into 20-mL scintillation vials and counted as described above.

Plasmalogens. Fatty acid esterification into choline and ethanolamine plasmalogen was also determined. ChoGpl and EtnGpl were separated by TLC, the phospholipids removed by scraping, and the phospholipids extracted from the silica using *n*-hexane/2-propanol (3:2, vol/vol) containing 5.5% H_2O. The extraction was 97–98% efficient based on the recovery of radioactivity. The ChoGpl and EtnGpl fractions were dried under a stream of nitrogen and exposed to HCl vapor for 15 min to hydrolyze the vinyl ether linkage (22). The samples were redissolved in solvent, and the acid-labile and -stable fractions were separated by high-performance liquid chromatography (22) and collected in 20-mL scintillation vials. The solvent was evaporated and the radioactivity determined as described above.

Unilateral incorporation coefficient of labeled fatty acid. Integrated areas for the plasma radioactivity curves were determined using the trapezoidal method (Sigma Plot; Jandel Scientific, San Rafael, CA). Total radioactivity for each individual heart fraction was normalized to the wet weight (g ww) and divided by the integrated area of plasma radioactivity. This calculation essentially normalizes the tissue radioactivity to the exposure of plasma tracer. The resulting coefficient is called the unilateral incorporation coefficient or k^*, with values expressed as s^{-1} (23). Hence, the k^* represents the radioactivity of each fraction normalized to the amount of presented radioactivity in the plasma. The following equation was used to calculate the k^*:

$$k^* = c^*_{\text{tissue}} \Big/ \int_0^T c^*_{\text{plasma}}\, dt \qquad [1]$$

where k^* = incorporation coefficient of tracer into a heart compartment, c^*_{tissue} = tracer radioactivity in the heart compartment, c^*_{plasma} = tracer radioactivity in the plasma, and T = time of tissue sampling.

Statistical analysis. Statistical analysis was done using a two-tailed Student's *t*-test or one-way analysis of variance coupled with Tukey-Kramer multiple comparisons test when appropriate. Statistical significance was defined at $P < 0.05$. For the [^{14}C]20:4n-6 group, $n = 4$, and for the [^{14}C]16:0 group, $n = 3$. Data are given as means ± standard deviation.

RESULTS

Plasma curves. Infusion of [1-^{14}C]20:4n-6 or [1-^{14}C]16:0 for 5 min produced a rapid increase in total organic plasma radioactivity, followed by a decline in radioactivity which was indistinguishable between the two tracers (Fig. 1). Tracer plasma half-lives were 81 ± 1 and 79 ± 1 s for [1-^{14}C]20:4n-6 and [1-^{14}C]16:0, respectively. The average areas under the curve were also equivalent, 1061 ± 223 and 1184 ± 59 nCi × mL plasma^{-1} × min^{-1} for [1-^{14}C]20:4n-6 and [1-^{14}C]16:0, respectively. The bulk of this radioactivity (>95%) was found in the plasma FFA fraction, with only minor amounts found esterified to plasma lipids (data not shown).

[1-^{14}C]16:0 and [1-^{14}C]20:4n-6 radioactivity. Total radioactivity of [1-^{14}C]20:4n-6 and [1-^{14}C]16:0 in heart tissue, 15 min after infusion began, was determined by measuring the radioactivity in the combined organic and dried aqueous phases (Table 1). Total radioactivity for [1-^{14}C]20:4n-6 was twofold greater than for [1-^{14}C]16:0. In the lipid-containing organic fraction, [1-^{14}C]20:4n-6 radioactivity was threefold higher relative to [1-^{14}C]16:0. There was no significant difference between radioactivities in the dried aqueous phase.

TABLE 1
Incorporated [1-^{14}C]16:0 and [1-^{14}C]20:4n-6 into Rat Heart[a]

	Radioactivity (µCi/g ww)		
	Total	Aqueous (nonvolatile)	Organic
[^{14}C]16:0 ($n = 3$)	0.34 ± 0.11	0.14 ± 0.06	0.20 ± 0.13
[^{14}C]20:4n-6 ($n = 4$)	0.68 ± 0.18*	0.06 ± 0.02	0.61 ± 0.19*

[a]Values represent means ± SD. *Statistical significance, $P < 0.05$, using a two-tailed Student's *t*-test. Abbreviation: ww, wet weight.

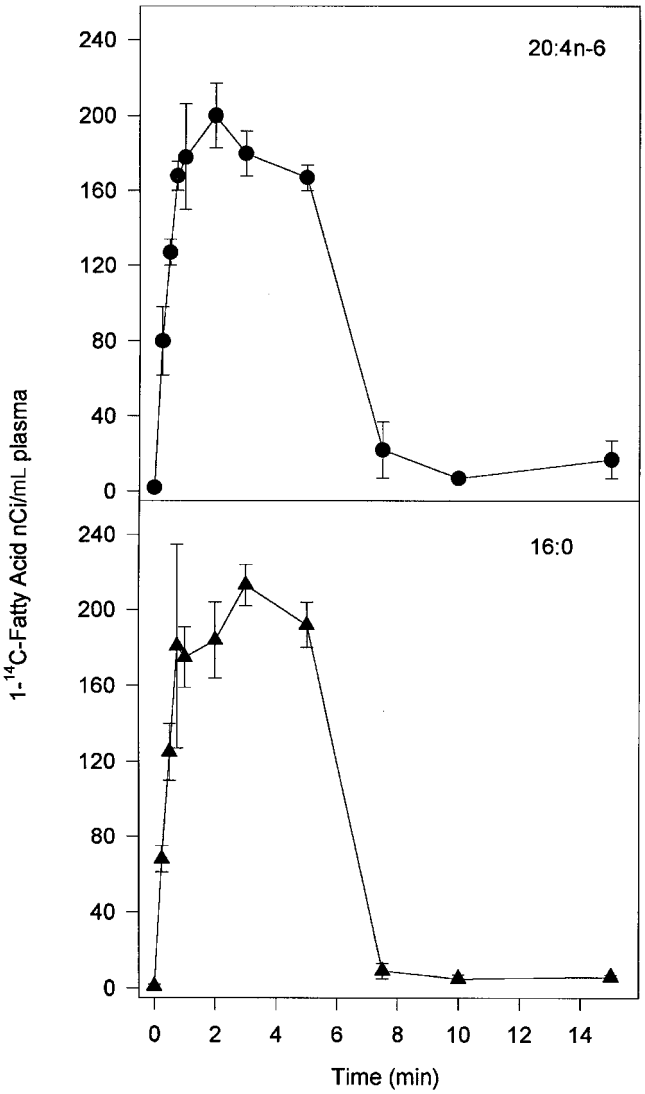

FIG. 1. Plasma curves for [1-^{14}C]20:4n-6 and [1-^{14}C]16:0. Values are expressed as nCi/mL plasma and represent means ± SD, $n = 3$.

Thus, [1-^{14}C]20:4n-6 was found primarily in the organic fraction, where 91% of the total tissue radioactivity was found. For [1-^{14}C]16:0, 60% of the total tissue radioactivity was found in the organic fraction. Furthermore, calculating the percentage extraction of each radiotracer by the heart from the total amount infused, the percentage oxidation was 0.37 ± 0.11 and 0.16 ± 0.06% ($P = 0.0292$) for 20:4n-6 and 16:0, respectively.

k*. The differences between [1-^{14}C]20:4n-6 and [1-^{14}C]-16:0 levels in heart may have arisen from preferential fatty acid extraction from plasma. To assess this possibility, radioactivity in different heart compartments was normalized to net exposure to plasma tracer, by calculating the unilateral incorporation coefficient for each tracer, *k** (Eq. 1). The *k** was calculated for total heart (combined organic and nonvolatile aqueous fractions), the lipid-containing organic fraction, and for the nonvolatile aqueous compartments (Table 2). The organic fraction was then fractionated into phospholipid, esterified neutral lipid, and FFA fractions, and *k** were calculated for these pools (Table 2). In the total heart, *k** was 2.2-fold greater for [1-^{14}C]20:4n-6 than for [1-^{14}C]16:0. There was no significant difference between the tracers in *k** in the aqueous compartment. For the organic fraction, *k** was 3.3-fold greater for [1-^{14}C]20:4n-6 than for [1-^{14}C]16:0. When the organic fraction was divided into its phospholipid and esterified neutral lipid compartments, differences were very apparent (Table 2). In the phospholipid fraction, *k** was 7.5-fold greater for [1-^{14}C]20:4n-6 than for [1-^{14}C]16:0. In the FFA compartment, *k** was over fivefold greater for [1-^{14}C]20:4n-6 than for [1-^{14}C]16:0. It was difficult to ascertain whether this increase in free [1-^{14}C]20:4n-6 represented fatty acid available for esterification or fatty acid that had been released by phospholipase A_2 during heart removal. There was no significant difference between the *k** for each tracer for the neutral lipid fraction. In any case, [1-^{14}C]20:4n-6 was more rapidly incorporated into the heart organic fraction than was [1-^{14}C]16:0, and this disparity was largely accounted for by a 7.5-fold greater *k** into heart phospholipids.

Incorporation coefficients were then calculated for different lipid classes (Table 3). In the phospholipids, *k** was larger for [1-^{14}C]20:4n-6 than for [1-^{14}C]16:0 in all fractions except PtdOH. Most notable was a 12.3-fold greater *k** for incorporation into the ChoGpl. Similar in magnitude was the ninefold greater *k** for [1-^{14}C]20:4n-6 relative to [1-^{14}C]16:0 in the combined PtdIns/PtdSer fraction. In esterified neutral lipids, the only difference was in the DG fraction, where *k** for [1-^{14}C]20:4n-6 was fivefold greater than that for [1-^{14}C]16:0. The values of *k** for the individual lipid classes confirm that [1-^{14}C]20:4n-6 was incorporated selectively into the phospholipid classes and that there was no difference between *k** for [1-^{14}C]20:4n-6 and [1-^{14}C]16:0 into neutral lipid fractions except for the DG fraction.

Distribution of [1-^{14}C]16:0 and [1-^{14}C]20:4n-6. The percentage distribution of radioactive fatty acids that were esterified into the neutral and phospholipid fractions was calculated by dividing an individual *k** by total *k** (Table 2). A significantly greater percentage of [1-^{14}C]20:4n-6 was esterified into the total phospholipid fraction compared to [1-^{14}C]16:0. In contrast, the percentage of [1-^{14}C]16:0 esterified into neutral lipids was threefold greater than that for [1-^{14}C]20:4n-6, despite a similar incorporation coefficient (Table 2). A greater percentage of [1-^{14}C]20:4n-6 was found as unesterified or free fatty acid compared to [1-^{14}C]16:0. These results confirm the selective targeting of [1-^{14}C]20:4n-6 for esterification into phospholipids, while [1-^{14}C]16:0 was targeted for esterification into neutral lipids.

To better understand these differences, the phospholipid and neutral lipid fractions were further separated into individual classes, and the percentage distribution of individual values of *k** relative to total *k** was determined (Table 3). For the neutral lipids, [1-^{14}C]16:0 was found primarily in TG. The percentage of [1-^{14}C]16:0 in the TG was increased 7.2-fold greater than for [1-^{14}C]20:4n-6. Distribution of radioactivity into CE was not significantly different between the radiola-

[a]Incorporation coefficients are expressed as s^{-1} and represent means ± SD. Percentage of total k^* was calculated by dividing individual k^* for each fraction by the total k^* and represents means ± SD. *Statistical significance, $P < 0.05$, using a two-tailed Student's *t*-test.
[b]Values under this heading represent distribution of radioactivity in all of the fractions.
[c]Values under this heading represent the major fraction found in the organic fraction under the heading "Fractions."

beled fatty acids, although there was a 2.5-fold increase in the percentage of [1-^{14}C]20:4n-6 in the DG fraction compared to [1-^{14}C]16:0. Whether this DG fraction represents an anabolic or catabolic intermediate is not clear.

Because [1-^{14}C]20:4n-6 was found mainly in phospholipids (Table 3), the distribution of radioactive fatty acids into individual phospholipid classes was evaluated. In the ChoGpl, the percentage of [1-^{14}C]20:4n-6 was 5.7-fold greater than for [1-^{14}C]16:0. Similarly, in the combined PtdIns/PtdSer fraction, [1-^{14}C]20:4n-6 percentages were increased 4.3-fold over the percentage of [1-^{14}C]16:0 in the same fraction. The smallest difference was seen in the CerPCho fraction, while the EtnGpl fractions were not different between groups. Thus, [1-^{14}C]20:4n-6 was preferentially targeted for esterification into phospholipids and found primarily in the ChoGpl fraction.

The vast proportion of heart arachidonic acid is found in choline and ethanolamine plasmalogens (24,25). To determine if [1-^{14}C]20:4n-6 and [1-^{14}C]16:0 were also targeted to the plasmalogens, the distributions of [1-^{14}C]20:4n-6 and of [1-^{14}C]16:0 in choline (PlsCho) and ethanolamine plasmalogens (PlsEtn) were measured. Only a small proportion of either fatty acid tracer was found in plasmalogen subclasses. For PlsEtn, 1.6 ± 0.1% and 1.9 ± 0.7% of total heart radioactivity was found in this subclass for [1-^{14}C]20:4n-6 and [1-^{14}C]16:0, respectively. In the PlsCho subclass, 2.4 ± 0.6 and 2.2 ± 1.7% of the total radioactivity were present for the [1-^{14}C]20:4n-6 and [1-^{14}C]-16:0 infused rats, respectively. These results indicate that within the 15-min time frame of this study, there was limited pulse labeling of plasmalogens by either fatty acid tracer.

[a]Incorporation coefficients are expressed as s^{-1} and represent means ± SD. Percentage of total k^* was determined by dividing individual compartment k^* by the total k^* and represents means ± SD. *Statistical significance, $P < 0.05$, using a two-tailed Student's *t*-test. Abbreviations: EtnGpl, ethanolamine glycerophospholipids; ChoGpl, choline glycerophospholipids; PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine; PtdOH, phosphatidic acid; CerPCho, sphingomyelin; TG, triacylglycerols; DG, diacylglycerols; CE, cholesteryl esters.

DISCUSSION

Because of the increasing recognition of the importance of phospholipids and their fatty acids in heart function and structure (4,5,8,10, 26,27), we quantified incorporation coefficients and targeting of [1-^{14}C]20:4n-6 and [1-^{14}C]16:0 in heart, using intravenous infusion of tracer in awake adult male rats. Previously, this method was used to quantify fatty acid incorporation and turnover rates for various fatty acids in the brains of awake adult rats (28,29). Because the quantity of radiotracer injected does not alter the plasma concentration of the infused fatty acid, this model avoids artifacts that may result from elevating plasma fatty acid levels above normal physiological levels (18,23,29). This avoids possible problems related to the observed concentration dependence for 20:4n-6 targeting in isolated hearts and myocytes (12,16,17).

In heart, saturated and monounsaturated fatty acids are utilized as the primary energy source, consistent with the fact that the heart has a tremendous capacity for fatty acid uptake and esterification (11,15). Palmitic acid is targeted for esterification into TG pools (12,13,16) or is used for β-oxidation directly (16). Oleic acid is also targeted to neutral lipids; nearly 80% of the oleic acid is localized in TG in both isolated perfused hearts and isolated myocytes (14). Our results confirm that 16:0 is preferentially esterified into the neutral lipid compartment, with the neutral lipids accounting for over 30% of the total radioactivity and into the nonvolatile aqueous pool accounting for 44% of the total radioactivity (Table 2). However, in contrast to other reports, we found nearly 18% of total [1-^{14}C]16:0 esterified into the heart phospholipid pools (Table 2). This value is similar to that reported in isolated myocytes, where 18% of the fatty acid is found in myocyte phospholipids, although this distribution in myocytes was not calculated from total radioactivity; thus the contribution of the aqueous radioactivity to the total radioactivity was not included (12). In isolated working rat heart, 9.5% of 16:0 in the lipid fraction is esterified into heart phospholipids (16). This value is not very different from ours, considering the difference in models. Thus, although [1-^{14}C]16:0 was esterified into heart phospholipids in awake rats, it was primarily targeted to the neutral lipid fraction where it was esterified into TG, or it was metabolized to products found in the nonvolatile aqueous phase.

In various isolated heart models and myocyte preparations, 20:4n-6 uptake and targeting appear to be linked to fatty acid availability (12,16,17). In isolated working rat heart, nearly all 20:4n-6 taken up from the perfusate (20:4n-6 concentration 1.2 mM) enters TG, with only 14% going into phospholipids (16). However, the 20:4n-6 concentration used in this study (16) is supraphysiologic, as the free 20:4n-6 concentration in rats *in vivo* is on the order of 16 μM (30). Consistent with these observations, much lower concentrations of 20:4n-6 (0.02–0.4 μM) are targeted almost exclusively in isolated rat myocytes to TG (82.3%), whereas only 12.3% is esterified into phospholipids (17). However, in isolated adult rat myocytes, 39% of the labeled 20:4n-6 in the lipid fraction is found in phospholipids when the medium 20:4n-6 concentration is 20 μM, but at a medium concentration of 5 nM; over 71% of the labeled 20:4n-6 is esterified into phospholipids (12). Clearly, targeting of 20:4n-6 is concentration-dependent in these models, suggesting a need to reevaluate 20:4n-6 uptake and targeting in an intact awake animal using physiologically relevant concentrations of each fatty acid.

In contrast to published results, we report that [1-^{14}C]-20:4n-6 was targeted selectively into heart phospholipids (60% of total radioactivity) in awake adult male rats (Table 2) and found primarily in ChoGpl (Table 3). Only 9% of the total radiotracer in heart at 15 min was found in the nonvolatile aqueous phase, compared with nearly 41% for [1-^{14}C]16:0. This suggests that [1-^{14}C]20:4n-6 was minimally metabolized to water-soluble nonvolatile compounds and was conserved relative to [1-^{14}C]16:0. Using the same fatty acid model, nearly 40% of the [1-^{14}C]16:0 found in the brain following infusion had been metabolized to slowly-disappearing nonvolatile aqueous phase compounds, mainly glutamate and aspartate (31). In rats infused with [20-^{18}F]20:4n-6 at radiotracer levels, 72.9% of the labeled 20:4n-6 in heart was found in the organic fraction and the majority of that radioactivity in the phospholipid fraction (32). In isolated heart models or myocytes, 20:4n-6 also appears to be conserved (12) and minimally metabolized by β-oxidation (12,17). Our data support these results. We also found that [1-^{14}C]20:4n-6 had a greater incorporation coefficient and was taken up to a greater extent by the heart than [1-^{14}C]16:0 (Tables 1 and 2), although our calculations did not take into account the complete conversion of 16:0 to CO_2. The published values for plasma fatty acid concentrations are 16.1 ± 0.9 and 161.3 ± 7.0 nmol × mL^{-1} for 20:4n-6 and 16:0, respectively (30), a 10-fold difference in the cold fatty acid concentrations. Using the unilateral incorporation coefficient determined in this study (Table 2), the incorporation of cold 20:4n-6 and 16:0 was 0.152 ± 0.002 and 0.758 ± 0.011 nmol × mL^{-1} × s^{-1} ($P <$ 0.0001), respectively. This is only a fivefold difference in uptake despite a 10-fold difference in availability, suggesting that there are selective processes for the uptake of 20:4n-6 from the plasma. These results indicate that in awake rats, relatively more cold 20:4n-6 appeared to have been extracted by the heart from the plasma than cold 16:0 and that this extracted 20:4n-6 was mainly esterified into phospholipids, despite a 10-fold greater availability of cold 16:0 in the plasma (30).

One mechanism that may explain the differential targeting of [1-^{14}C]20:4n-6 and [1-^{14}C]16:0 in heart could be the different affinities of CoA-dependent and -independent acyltransferase and transacylases for these two fatty acids (33). In rabbit heart, a cytosolic CoA-dependent acyltransferase exists which selectivity acylates 20:4n-6 onto ChoGpl (34). This might explain our observation that [^{14}C]20:4n-6 was preferentially esterified into ChoGpl (Table 3). Furthermore, this enzyme is highly selective for 20:4n-6 and is not found in the liver, suggesting it is localized solely in heart (34). In contrast, the CoA-independent acyltransferase does not exhibit

any substrate selectivity (34), suggesting that our observed differences in fatty acid targeting were accounted for by a heart-specific, 20:4n-6 selective, cytosolic CoA-dependent acyltransferase, which targets fatty acids primarily into ChoGpl.

The importance of the ethanolamine and choline plasmalogen subclasses in lipid-mediated signal transduction has become more apparent in heart since the isolation and characterization of a plasmalogen-selective phospholipase A_2 from heart (35–37). Further, because the plasmalogen subclass comprises a large proportion of ChoGpl and EtnGpl in mammalian heart (24,25,38,39) and because the *sn*-2 position contains a large proportion of heart 20:4n-6, we determined [1-^{14}C]20:4n-6 distribution into the PlsCho and PlsEtn. In awake rats, very little (<3%) [1-^{14}C]20:4n-6 was esterified into the PlsCho or PlsEtn. A plausible explanation for these results is that ether lipid biosynthesis *de novo* proceeds at a rate in heart that is much slower than the experimental time frame used. Indeed, heart plasmalogen biosynthesis *de novo* occurs on the order of hours, with no newly formed plasmalogen evident until up to 3 h after infusion of [1-^{3}H]-hexadecanol (40). This certainly may account for the minimal amount of [1-^{14}C]20:4n-6 found in the plasmalogens if the majority of the 20:4n-6 is esterified into plasmalogens during the synthetic process as opposed to esterification into lysoplasmenylcholine or to a direct transfer by a transacylase (33).

Lastly, because of the preferential targeting of [1-^{14}C]-20:4n-6 to phospholipid pools and the lack of appreciable alternative metabolism *via* other pathways, [^{11}C]20:4n-6 infusion coupled with positron emission tomography (PET) could be used to clinically study dynamic phospholipid turnover in heart. Past human heart studies using [^{11}C]palmitate with PET scanning have focused on the β-oxidation aspect of myocardial fatty acid metabolism (41,42); however, our findings suggest that these studies could be extended to examine lipid-mediated signal transduction in diseased human heart using [^{11}C]20:4n-6.

In summary, upon entering the heart, [1-^{14}C]20:4n-6 was predominantly esterified into ChoGpl, while [1-^{14}C]16:0 was targeted for esterification into TG or found in the nonvolatile aqueous fraction. The k^* for phospholipids was sevenfold greater for [1-^{14}C]20:4n-6 compared to [1-^{14}C]16:0, while there was no difference in values of k^* for esterified neutral lipids. Thus, in the awake adult rat, where the normal plasma fatty acid levels were maintained, there was a differential targeting of [1-^{14}C]20:4n-6 and [1-^{14}C]16:0 into distinct heart lipid pools. This suggests that fatty acid targeting in heart is based upon function. Further, this differential targeting suggests that 20:4n-6 and 16:0 have substantially different roles in heart metabolism and function.

ABSTRACT: Four sets of experiments were conducted to examine the influence of conjugated linoleic acid (CLA) isomers during proliferation and differentiation of cultures of 3T3-L1 preadipocytes using physiological culturing conditions. Cultures treated with either albumin [bovine serum albumin (BSA) vehicle] or linoleic acid (LA) served as controls. For the proliferation study (Expt.1), cells were cultured in media containing a crude mixture of CLA isomers or pure LA at 0, 10, 50, or 200 μM for 4 d. Preadipocyte proliferation (cell number, ^{3}H-thymidine incorporation into DNA) decreased as the level of CLA increased in the cultures. In contrast, LA had no impact on DNA synthesis. In Experiment 2a, postconfluent cultures were grown in media containing a crude mixture of CLA isomers or LA at 0, 10, 50, or 200 μM for the next 6 d. Postconfluent cultures supplemented with 50–200 μM CLA had less triglyceride (TG) and were smaller in size than cultures supplemented with similar amounts of LA. In Experiment 2b, postconfluent cultures supplemented with 200 μM of a crude mixture of CLA isomers or LA were harvested on days 1, 3, 6, or 9. Differences in TG content of cultures supplemented with 200 μM CLA compared to control and LA-supplemented cultures became apparent after 3 d of culture. Experiments 3a and 3b examined whether the fatty acid vehicle (BSA vs. ethanol) or the vitamin E status (±0.2 mM α-tocopherol) of the cultures altered CLA's impact on preadipocyte TG content. In Experiment 3a, ethanol-treated cultures had more TG than non-ethanol-treated cultures regardless of the fatty acid treatment. In Experiment 3b, cultures treated with 100 μM of either a crude mixture of CLA or the *trans*-10, *cis*-12 CLA isomer without supplemental vitamin E for 6 d had less TG than CLA-treated cultures containing vitamin E. In Experiment 4, postconfluent cultures were grown in media containing 100 μM LA or either a crude mixture of CLA isomers or the *trans*-10,*cis*-12 CLA isomer for 24–96 h to assess CLA's influence on the cell cycle and indices of apoptosis. Cultures treated with 100 μM CLA for 24–96 h had more apoptotic cells than BSA- or LA-treated cultures. Furthermore, cultures treated for 48 h with CLA had fewer cells in the S-phase than control cultures. The effects of the *trans*-10,*cis*-12 CLA isomer were more pronounced than those of the crude mixture of CLA isomers. These data suggest that CLA may exert its antiobesity effects by inhibiting proliferation, attenuating TG content, and/or inducing apoptosis in (pre)adipocytes.

Paper no. L8418 in *Lipids 35,* 899–910 (August 2000).

Conjugated linoleic acid (CLA) consists of a group of positional and geometric fatty acid isomers that are derived from linoleic acid (LA) (18:2n-6). CLA occurs naturally in ruminant meats, pasteurized cheeses, and dairy products and therefore is a dietary constituent of many Americans. However, health organizations continue to recommend we limit our intake of these animal products. Thus, as we decrease our consumption of animal fats, CLA consumption also decreases. Ironically, consumption of a crude mixture of CLA isomers by rodents has been shown to have a variety of health benefits, including anticarcinogenic (1), antiatherogenic (2,3), antidiabetic (4), and antiobesity actions (4–9). As an antiobesity agent, mice and pigs fed low levels of CLA (<1.5%, w/w) had less body fat and more lean body mass than controls (5–8,10–12). Furthermore, Park *et al*. (6) demonstrated that mature 3T3-L1 adipocytes treated with 20–200 μM CLA for 2 d had less triglyceride (TG) content and lipoprotein lipase (LPL) activity compared to control cultures. Moreover, Park *et al.* (7) recently found that the *trans*-10,*cis*-12 isomer of CLA is the bioactive isomer responsible for reducing adipocyte LPL activity and TG content. In contrast, Satory and Smith (13) showed that post-confluent cultures of differentiating 3T3-L1 preadipocytes treated with a crude mixture of CLA treatment had greater rates of lipogenesis [↑ lipogenesis; effective concentration that reduces activity by 50% (EC_{50}) ~ 18 μM] and more TG than nontreated cultures. However, CLA attenuated proliferation of preconfluent preadipocytes at concentrations as low as 1.7 μM. In contrast, Brodie *et al*. (14) demonstrated that 25–100 μM CLA inhibited both proliferation and differentiation (↓ glycerol-3-phosphate dehydrogenase activity; EC_{50} ~ 35 μM) of cultures of 3T3-L1 preadipocytes. Nevertheless, the culturing conditions used in these last two studies raise questions about the physiological relevance and interpretations of these data.

Abbreviations: AA, arachidonic acid; ANOVA, analysis of variance; BCA, bicinchoninic acid; BCS, bovine calf serum; BSA, bovine serum albumin; CLA, conjugated linoleic acid; DAG, diacylglycerol; DMEM, Dulbecco's modified Eagle's medium; DMSO, dimethyl sulfoxide; EC_{50}, effective concentration that reduces activity by 50%; FBS, fetal bovine serum; HBSS, Hank's balanced salt solution; HMDS, hexamethyldisilazane; LA, linoleic acid; LDH, lactate dehydrogenase; LPL, lipoprotein lipase; PBS, phosphate-buffered saline; PI, propidium iodide; PPAR-γ2, peroxisome proliferating activated receptor-γ2; SEM, scanning electron microscopy; TG, triglyceride.

These data suggest that the antiobesity actions of a crude mixture of CLA isomers may be due to the direct influence of CLA on preadipocyte growth and differentiation. However, the results of these preadipocyte studies are conflicting and may be due to differences in experimental conditions. Moreover, the physiological relevance of the studies by Satory and Smith (13) and Brodie *et al.* (14) are not clear since they used ethanol or dimethyl sulfoxide (DMSO) as the delivery vehicle for the fatty acids, whereas, *in vivo,* free fatty acids are transported by albumin. Furthermore, these authors did not include antioxidants in the media to prevent fatty acid peroxidation. Therefore, we investigated the influence of CLA on the growth and differentiation of cultures of 3T3-L1 preadipocytes using a physiological delivery method, e.g., using albumin as the fatty acid vehicle and supplementing the cultures with 0.2 mM α-tocopherol to protect CLA from peroxidation. Cultures treated with LA served as fatty acid controls to determine if CLA's effects are unique to its geometric structure or a generic effect of unsaturated fatty acids.

EXPERIMENTAL PROCEDURES

Cell model. Pre- (Expt. 1) and postconfluent (Expts. 2–4) monolayers of 3T3-L1 preadipocytes were used as the cellular model for these studies (see Fig. 1 for details). The 3T3-L1 preadipocytes are a nontransformed cell line, which is a continuous substrain of Swiss albino 3T3 murine cells developed through clonal expansion (15). These cells can be converted from a preadipose to adipose-like phenotype when appropriately stimulated. Furthermore, transplantation studies with this cell line demonstrate normal development of fat cells at the site of implantation. Lastly, these cells are capable of differentiating in culture in response to agents that induce adipose tissue differentiation *in vivo*.

Experimental designs and culture conditions (Fig. 1). As outlined in Figure 1, Experiment 1 was designed to examine the influence of continual supplementation of preconfluent, proliferating cultures with various doses of a crude mixture of CLA isomers and pure LA during the first 4 d of the preadipocyte proliferation program. The objective of Experiment 2a was to investigate the impact of continual supplementation of postconfluent, differentiating cultures with various doses of a crude mixture of CLA isomers and pure LA during the first 6 d of preadipocyte differentiation into mature adipocytes. The purpose of Experiment 2b was to assess the time course of supplementation with 200 μM of a crude mixture of CLA isomers and pure LA over the entire differentiation program (days 1–9). The objectives of Experiment 3 were to determine if the vehicle [bovine secum albumin (BSA) vs. ethanol] and the vitamin E status (±0.2 mM α-tocopherol) of the cultures influenced CLA's effects on adipogenesis based on conflicting data from several recent reports (13,14). Experiment 4 examined potential mechanisms by which a crude mixture of CLA or the *trans*-10, *cis*-12 CLA isomer may attenuate preadipocyte differentiation, including cell cycle arrest and apoptosis using flow cytometry and nuclear staining techniques.

CLA or LA was complexed to 7.5% fatty acid-free BSA (w/w; 4:1 molar ratio of fatty acid/BSA) and added to the cultures on day −6 to preconfluent, proliferating cultures and day 1 to postconfluent, differentiating cultures (Fig. 1) based on protocol used in Dr. Steven Clarke's lab (University of Texas, Austin, TX: personal communication). The mixture of crude isomers of CLA (major isomers includes 41% *cis*- or *trans*- 9, 11 isomers; 44% *trans*-10,*cis*-12 isomers; and 10% *cis*-10, *cis*-12 isomers according to the manufacturers), and the pure LA were obtained from Nu-Chek-Prep (Elysian, MN). The *trans*-10,*cis*-12 CLA isomer (98+% pure according to the manufacturers) was obtained from Matreya, Inc. (Pleasant Gap, PA). Since we did not analyze CLA and LA for their purity, we realize that other isomers could be present in each fatty acid. All treatments contain 0.2 mM α-tocopherol (Sigma Chemical

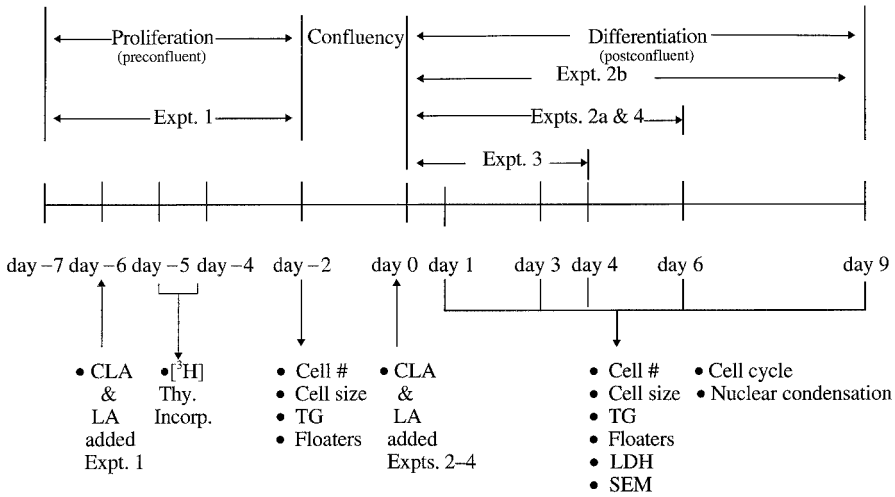

FIG. 1. Design of experiments. Abbreviations: CLA, conjugated linoleic acid; LA, linoleic acid; [^{3}H]-thy incorp, [^{3}H]-thymidine incorporation; TG, triglyceride; LDH, lactate dehydrogenase; floaters, nonadherent cells floating in media; SEM, scanning electron microscopy; Expt., experiment.

Co., St. Louis, MO) to prevent lipid peroxidation unless otherwise indicated (e.g., Expt. 3) based on protocol used in Dr. Steven Clarke's lab (personal communication). Media were changed at 2-d intervals and fresh fatty acids added to each medium change until the day of harvest. Each treatment combination per experiment was conducted in triplicate and repeated at least once (e.g., $n = 6$) unless otherwise indicated.

Cells were seeded at a density of $3.3 \times 10^3/cm^2$ in 12-well plates and cultured in Dulbecco's modified Eagle's medium (DMEM), 10% bovine calf serum (BCS), 0.2 mM α-tocopherol (only Expt. 1), and antibiotics until confluent. Two days postconfluence, the cells were stimulated to differentiate with DMEM containing 10% fetal bovine serum (FBS) (charcoal-stripped to remove endogenous fatty acids), 10 µg/mL insulin, 0.5 mM isobutylmethylxanthine, 0.1 µM dexamethasone, 0.2 mM α-tocopherol (except Expt. 3), and 1% antibiotics. On day 3 of differentiation, the above media were replaced with DMEM, 10% stripped FBS, 2.5 µg/mL insulin, 0.2 mM α-tocopherol, and 1% antibiotics. From day 5 onward, media containing DMEM, 10% stripped FBS, 0.2 mM α-tocopherol, and 1% antibiotics were used.

For DNA staining and cell cycle analysis, cells were seeded at 3.3×10^3 cells per cm^2 in six-well culture plates and grown to confluence. Forty-eight hours after reaching confluence, cultures were treated with differentiation media containing 100 µM of each fatty acid. Cells were harvested and/or stained at 24-, 48-, 72-, and 96-h intervals for DNA cell cycle analysis and Hoechst staining.

[^{3}H]-thymidine incorporation (Expt. 1). The 3T3-L1 preadipocytes were plated in 200 µL of proliferation media (DMEM, 10% BCS, 10 mM HEPES, and antibiotics) at a density of $3.3 \times 10^3/cm^2$ in 96-well plates (1.1×10^3 cells/well). Twenty-four hours later, the media were removed and proliferation media containing either 0, 10, 50, or 200 µM of a crude mixture of CLA isomers or pure LA were added to the cultures. When the control cultures had reached approximately 30% confluence (~56 h after seeding), 0.5 µCi of [^{3}H]-thymidine (methyl[^{3}H]-thymidine; specific activity 248 GBq/mmol; NEN, Boston, MA) was added to each well. After ~18 h of incubation, the cultures were frozen at −70°C for 1 h and then thawed at room temperature to promote cell lysis. The DNA from each well was then transferred to filters by a cell harvesting system (Flow Laboratories-Skatron A/S, Lier, Norway), placed in scintillation vials containing 3 mL scintillation fluid, and counted on a Beckman LS 6000 Coulter Counter (Beckman Instruments, Palo Alto, CA).

Cell number and size (Expts. 1–4). Adherent and floating cells were counted and sized using a Coulter Multisizer IIE (Coulter Corp., Miami, FL). Spent media containing floating cells were removed at each media change and on the day of harvest and centrifuged at 500 × *g*. The supernatant was removed and saved for lactate dehydrogenase (LDH) analysis in Experiment 2a. The remaining cell pellet was resuspended in phosphate-buffered saline (PBS) and the number of cells counted. Viability of floating cells was assessed by trypan blue exclusion using a hemacytometer. Adherent cells were harvested in a cell counting solution (25 mM glucose, 0.154 M NaCL, 0.01 M NaH_2PO_4 [monobasic], 5 mM EDTA, 2% albumin, pH 7.4) and counted and sized on the Coulter Multisizer.

TG content (Expts. 2 and 3). TG content was measured using a commercially available colorimetric kit (Sigma #339-10; Sigma Chemical Co.) and modified for cell culture as previously described (16). This procedure employs enzymatic hydrolysis of glycerol and fatty acids. The glycerol is then measured by enzyme coupled reduction of a dye that absorbs light at 500 nm and can be quantified spectrophotometrically.

Protein content (Expts. 1 and 2). Protein was measured using the bicinchoninic acid (BCA) assay (Pierce, Rockford, IL). This assay measures the reduction of Cu^{2+} to Cu^+ by protein in an alkaline medium, thereby forming a tetradentate-Cu^+ complex. The Cu^+ ions then chelate with two molecules of BCA which absorbs light at 562 nm and can be quantified spectrophotometrically.

LDH activity (Expt. 2). The presence of LDH in the spent media relative to its activity in adherent cells has been used as an index of cell necrosis and a late indicator of apoptotic cell death (17). However, it does not distinguish between the two processes involved in cell death. Spent media removed from cell monolayers at the time of each medium replenishment and the day of cell harvest were frozen at −20°C. Adherent cells were rinsed twice with Hank's balanced salt solution (HBSS), scraped into 0.5 mL ice-cold sucrose buffer (29 mM sucrose, 73 µM TRIS, 24 µM EDTA, 0.02% β-mercaptoethanol), and stored at −70°C. The resulting extract was sonicated with two 5-s bursts and centrifuged for 30 min at 1600 × *g* at 4°C and the supernatant assayed for LDH activity. LDH activity in cell extracts and spent media was determined spectrophotometrically at 25°C by measuring the oxidation of NADH at 340 nm in the presence of pyruvate (18). Data are presented as the cumulative LDH activity after 6 d of treatment with CLA, LA, or albumin (controls) per mg protein (1 mU/mg protein = nmol of NADH oxidized per min per mg protein).

Scanning electron microscopy (SEM) (Expt. 2). 3T3-L1 monolayers were grown and treated until day 6 of differentiation on inserts (Falcon) that fit into individual wells where the media and solutions for processing were applied. Cells on inserts were fixed with 2% glutaraldehyde in 0.1 M cacodylate in 0.1 M sucrose buffer for 1 h. Cells were rinsed with cacodylate-sucrose buffer prior to postfixation for 1 h in 1% osmium tetroxide. Cells were then rinsed with 0.1 M piperazine-*N*-*N*′-bis[2-ethane sulfonic acid] buffer and refrigerated until being processed for SEM. The inserts with attached cells were processed for SEM by chemically drying with hexamethyldisilazane (HMDS). They were dehydrated in a series of ethanol dilutions (70, 85, 95, and 100%) for 5 min each. Next, they were placed in HMDS and dried overnight under vacuum. After drying, the insert membranes with attached cells were placed on aluminum stubs and coated with gold in a SPI Module' Sputter coater. Samples were examined with a JSM-35CF scanning electron microscope. Images at 480× and 2000× magnification were recorded on Type 52 Polaroid film.

Propidium iodide (PI) staining (Expt. 4). Cultured cells were trypsinized at harvest and rinsed once in a washing solution containing Dulbecco's Ca^{2+}, Mg^{2+} free PBS (Sigma) and 1% FCS. The cell pellet was then fixed with 70% ice-cold absolute ethanol. Samples were stored at −20°C until all harvests were collected, then removed from storage, pelleted, and washed once with washing solution. Pellets were resuspended and stained for 30 min at room temperature with PI (Sigma) (50 µg/mL), RNase (Sigma; 0.2 µg/mL), and immediately analyzed by flow cytometry on a FACSCalibur flow cytometer (Becton Dickinson Immunocytometry Systems, San Jose, CA).

DNA cell cycle analysis (Expt. 4). Samples from adherent cultures were analyzed on a FACSCalibur flow cytometer equipped with a 15 mW air-cooled 488 nm argon-ion laser. PI fluorescence was collected using linear amplification, FL2 area (A) and width (W) to permit doublet discrimination. A minimum of 10,000 events was collected for each DNA histogram with a low flow rate (112 µL/min) for optimal peak resolution. Doublet contamination was minimal; therefore analysis was done on all histogram events without gating. A noise threshold of about 20% of the G_1 peak fluorescence intensity was established to reduce nonspecific signal. Measurements were made with CellQuest (BDIS) and ModFit LT Software (Verify Software House, Topsham, ME).

Hoechst staining (Expt. 4). All staining was performed in the cell culture dish and all fluid changes were performed gently in order to prevent loss of loosely attached cells. Media were removed, and the monolayer was fixed with Baker's formalin (37% formaldehyde, 10% $CaCl_2$) at 4°C for 5 min. Cells were rinsed with HBSS, stained with Hoechst 33258 (Sigma; 8 µg/mL in HBSS) for 10 min, and rinsed again with buffer. Cells were then treated with one drop of 50% glycerol and coverslipped.

Fluorescence microscopy and photography of nuclear condensation (Expt. 4). A preliminary study was conducted using the 24-h serum starvation technique described by Magun *et al.* (19) to induce nuclear condensation in cultures of differentiating 3T3-L1 preadipocytes. Three different researchers that were blinded to the treatments examined the cultures. In our preliminary study, cultures supplemented with either 0, 1, 5, or 10% FBS for the first 24 h of the differentiation program had 52.0, 36.1, 7.2, and 1.2% of their cells demonstrating chromatin condensation, respectively. An Olympus IX70 microscope (Olympus, Melville, NY) equipped with an inverted reflected light fluorescence observation attachment was used to view and photodocument nuclear condensation. Cell monolayers were subjected to ultraviolet excitation and observed with a 20× objective. A cooled CCD camera (Spot; Diagnostic Instruments Inc., Sterling Heights, MI) integrated with the microscope was used to capture digitized cell images. All image acquisitions were controlled by Adobe Photoshop 5.0 software (Adobe Systems, Inc., San Jose, CA) and printed on color paper for subsequent quantification of cell number and nuclear condensation.

Statistical analyses. Data were analyzed by the Least Squares ANOVA General Linear Models Procedures (PROC GLM) of SAS (SAS Institute, Cary, NC). For Experiments 1–3, a two-way analysis of variance (ANOVA) was conducted and their interactions (fatty acid × dose in Expts. 1 and 2; fatty acid × vehicle in Expt. 3a; fatty acid × vitamin E status in Expt. 3b) were compared for significance at the $P < 0.05$ level. For Experiment 4, a three-way ANOVA was conducted, and the fatty acid by dose interactions within each treatment period (e.g., 24, 48, 72, and 96 h) were compared for significance at the $P < 0.05$ level. The means ± SE of the treatment interactions and their statistical differences are presented in the figures and Table 1. (Means not sharing common letters are significantly different.)

TABLE 1
Effect of Treating Cultures of Differentiating 3T3-L1 Preadipocytes for 24, 48, 72, or 96 h with 100 µM LA, a Crude Mixture of Mixed CLA, or the 10,12 Isomer of CLA (10,12-CLA) on the Percentage of Cells in the G_1, S, and G_2M Phases of the Cell Cycle[a]

[a]Cultures were treated continuously and harvested after 24, 48, 72, or 96 h of treatment. Means (±SEM; $n = 6$) not sharing a common letter are significantly different ($P < 0.05$). BSA, bovine serum albumin; LA, linoleic acid; CLA, conjugated linoleic acid.

RESULTS

Experiment 1: Proliferation (days –6 to –2); dose response (Figs. 2 and 3). (i) Cell number and size. Proliferating cultures supplemented with 10 and 50 μM of a crude mixture of CLA isomers and pure LA had fewer cells than control cultures (Fig. 2). At the 200 μM level, cultures supplemented with CLA had fewer cells than those supplemented with LA. Neither cell size nor the number of floating cells in spent media (viable and dead cells) was influenced by either fatty acid (data not shown).

(ii) *DNA synthesis.* [^{3}H]thymidine incorporation into DNA decreased as the level of a crude mixture of CLA isomers in proliferating cultures increased (Fig. 3). In contrast, cultures treated with LA had similar amounts of [^{3}H]thymidine incorporation.

Experiment 2a: Differentiation (days 1–6); dose response (Figs. 4–8). (i) TG content. The TG content/10^6 cells of differentiating cultures of 3T3-L1 preadipocytes increased as the level of LA increased in the cultures (Fig. 4). In contrast, the TG content of CLA-treated cultures was similar to the BSA controls. Cultures treated with 50 and 200 μM of a crude mixture of CLA isomers had less TG than 50 and 200 μM LA-treated cultures.

(ii) *Cell size.* Adipocyte size decreased as the level of a crude mixture of CLA isomers in differentiating cultures increased (Fig. 5). In contrast, adipocyte size was not affected by LA treatment.

(iii) *Cell viability.* Cultures supplemented with 50–200 μM of a crude mixture of CLA isomers had slightly more floating cells than control and LA-supplemented cultures (Fig. 6). Furthermore, LDH activity in the spent media of CLA-treated cultures was greater than control and LA-treated cultures. This effect of CLA was most pronounced at the 200 μM level (Fig. 7).

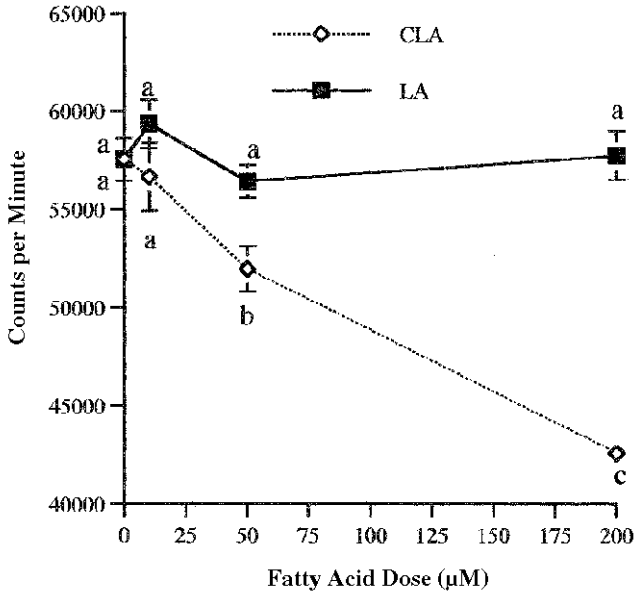

FIG. 3. The influence of a crude mixture of CLA isomers and LA on [^{3}H]-thymidine incorporation into DNA in cultures of proliferating 3T3-L1 preadipocytes. Cultures were treated with 0–200 μM CLA or LA continuously and harvested after 4 d of treatment. Means (±SEM; n = 6) not sharing a common letter are significantly different ($P < 0.05$). See Figure 1 for abbreviations.

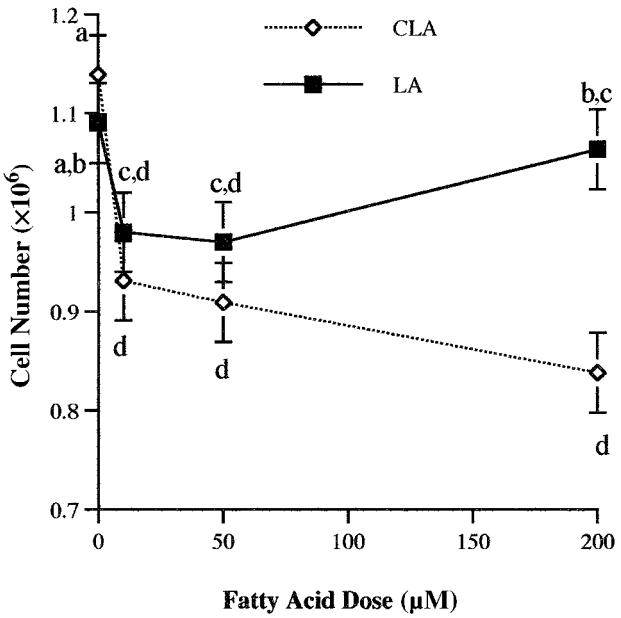

FIG. 2. The influence of a crude mixture of CLA isomers and LA on the number of cells in cultures of proliferating 3T3-L1 preadipocytes. Cultures were treated with 0–200 μM CLA or LA continuously and harvested after 4 d of treatment. Means (±SEM; n = 10–12/treatment) not sharing a common letter are significantly different ($P < 0.05$). See Figure 1 for abbreviations.

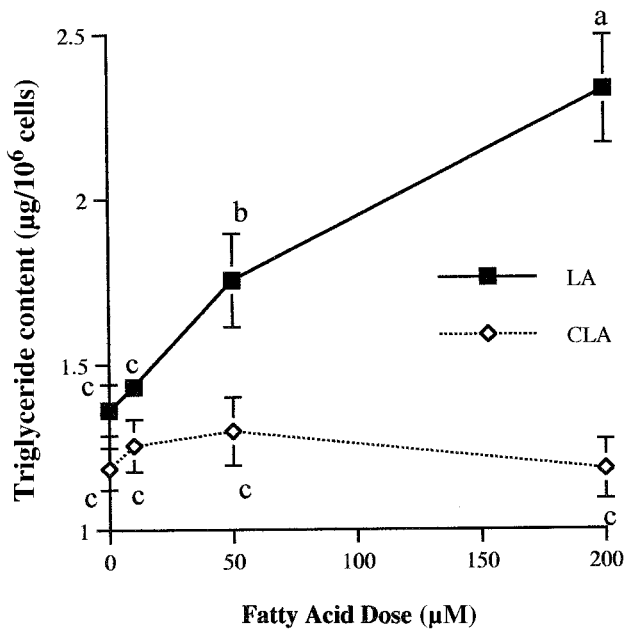

FIG. 4. The effect of increasing doses of a crude mixture of CLA isomers or LA on TG content on day 6 of postconfluent cultures of differentiating 3T3-L1 preadipocytes. Cultures were treated with 0–200 μM CLA or LA continuously and harvested after 6 d of treatment. Means (±SEM; n = 6) not sharing a common letter are significantly different ($P < 0.05$). See Figure 1 for abbreviations.

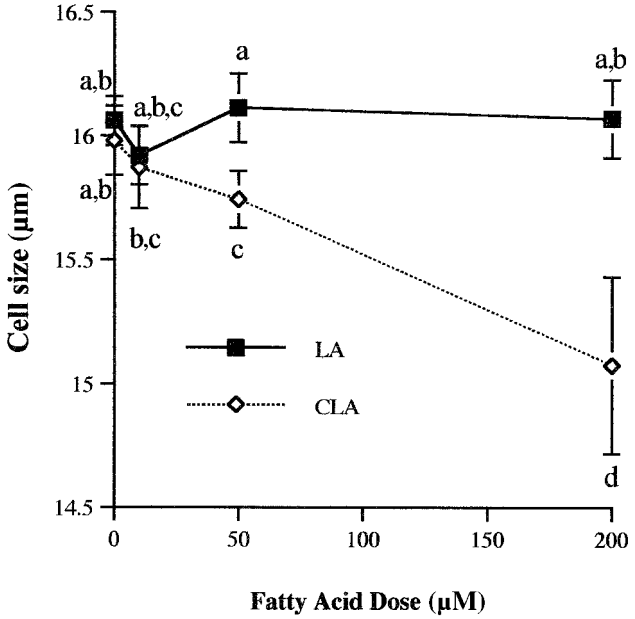

FIG. 5. The effect of increasing doses of a crude mixture of CLA isomers or LA on mean cell size on day 6 of postconfluent cultures of differentiating 3T3-L1 preadipocytes. Cultures were treated with 0–200 μM CLA or LA continuously and harvested after 6 d of treatment. Means (±SEM; $n = 6$) not sharing a common letter are significantly different ($P < 0.05$). See Figure 1 for abbreviations.

(iv) SEM micrographs (480×). SEM of the cultures revealed normal cell morphology for the control cultures (Fig. 8; 0 μM LA and CLA). Cells were fibroblastic in shape with numerous microvilli and sharp-pointed lamellipodia. At 50 μM LA, some cells still retained a flattened fibroblastic appearance. However, number and length of microvilli per cell appeared decreased. Also, the number of rounded-up cells had increased remarkably, indicative of mitosis or lipid accumulation. At 50 μM of a crude mixture of CLA isomers, there were still some flattened cells, but there were large numbers of small, rounded cells that appeared lumpy in appearance. Microvilli were also decreased. At 200 μM LA, cells retained some of the fibroblastic characteristics and some cells still had microvilli. The number of rounded-up cells increased in cultures supplemented with 200 μM LA. Several large, round, and smooth vesicles can be seen. We speculate that these are lysed lipid droplets that remained after washing and prior to cell fixation. At 200 μM CLA, no cells with typical characteristics were seen. Large numbers of cells were found that appeared to be blebbing, a characteristic of apoptotic cells. Images photographed at 2000× (data not shown) confirmed this membrane blebbing that appeared in cultures treated with both 50 and 200 μM CLA. As was observed in the 200 μM LA cultures, a number of small, round, and smooth vesicles presumed to be lysed lipid droplets can be seen in the 200 μM CLA cultures.

Experiment 2b: Differentiation (days 1–9); time course. Differences in TG and protein contents of cultures supplemented with 200 μM of a crude mixture of CLA isomers compared to control and LA-supplemented cultures became appar-

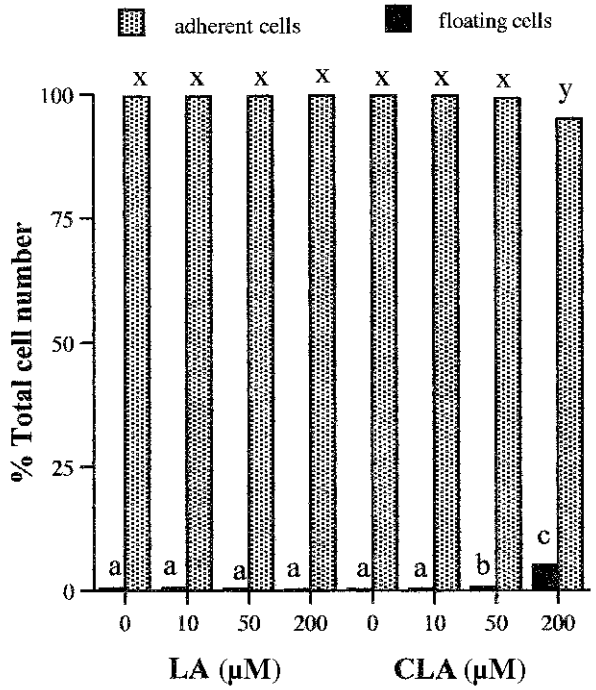

FIG. 6. The effect of increasing doses of a crude mixture of CLA isomers or LA on the number of floaters vs. adherent cells on day 6 of postconfluent cultures of differentiating 3T3-L1 preadipocytes. Cultures were treated with 0–200 μM CLA or LA continuously and harvested after 6 d of treatment. Means (±SEM; $n = 6$) not sharing a common letter are significantly different ($P < 0.05$). See Figure 1 for abbreviations.

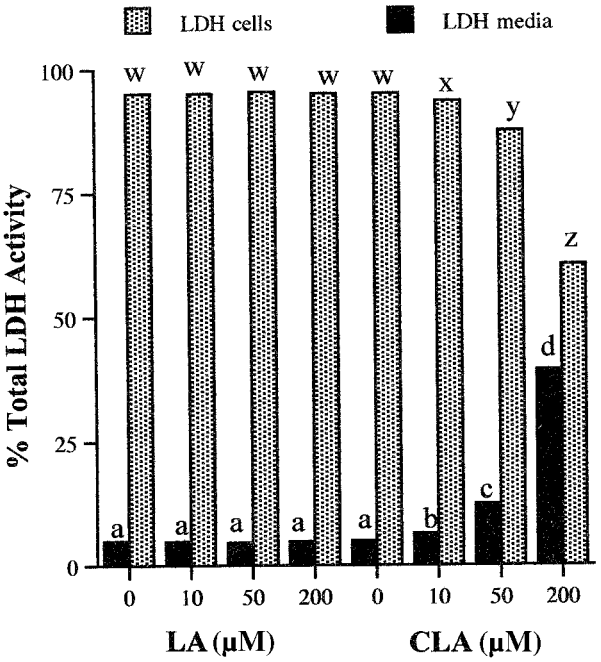

FIG. 7. The effect of increasing doses of a crude mixture of CLA isomers or LA on lactate dehydrogenase (LDH) activity in the media and in the adherent cells on day 6 of postconfluent cultures of differentiating 3T3-L1 preadipocytes. Cultures were treated with 0–200 μM CLA or LA continuously and harvested after 6 d of treatment. Media were collected at each medium change and LDH activity determined so that the cumulative LDH activity during the entire 6 d could be determined. Means (±SEM; $n = 6$) not sharing a common letter are significantly different ($P < 0.05$). See Figure 1 for other abbreviations.

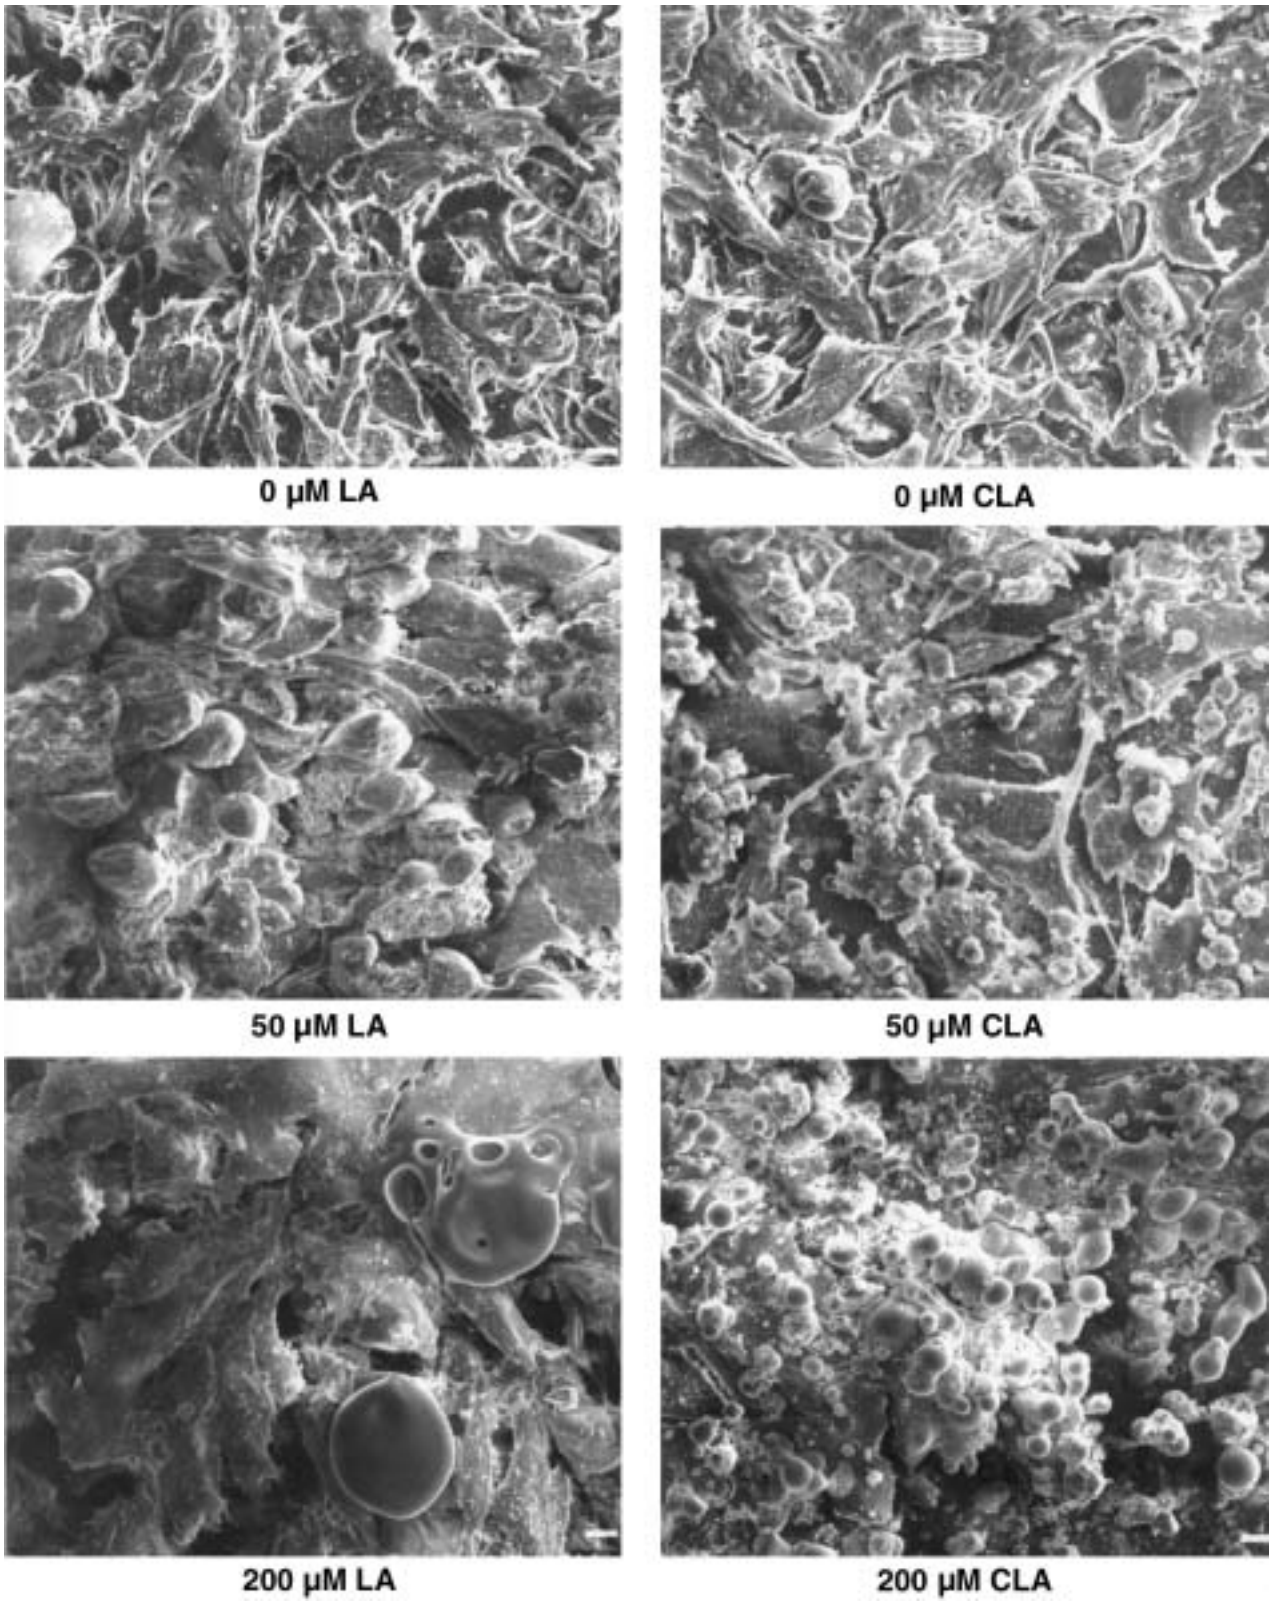

FIG. 8. Scanning electron micrographs of postconfluent cultures of differentiating 3T3-L1 preadipocytes treated with either a crude mixture of CLA isomers or LA for 6 d. Cultures were treated with 0–200 μM CLA or LA continuously and harvested on day 6. Magnification (480×) is the same in all photographs. Representative samples that were taken from at least two different cultures in each treatment group were similar in appearance. See Figure 1 for abbreviations.

ent after 3 d of culture (data not shown). For example, cultures supplemented with either 200 μM of a crude mixture of CLA isomers or pure LA had 0.6 ± 0.03 and 1.0 ± 0.05 μg TG/10^6 cells, respectively, after 3 d of treatment. By day 9, CLA-supplemented cultures had 36 and 32% less TG and protein content, respectively, than the LA-supplemented cultures.

Experiment 3a: Differentiation (days 1–6); ethanol vs. BSA as vehicle (Fig. 9). Cultures in which ethanol was used as the vehicle to deliver the fatty acids had more TG than treatment-matched cultures in which BSA was used as the vehicle (Fig. 9). No treatment by vehicle interactions was observed.

Experiment 3b: Differentiation (days 1–6); ± vitamin E supplementation (Fig. 10). Fatty acid-treated cultures supplemented with 0.2 mM α-tocopherol had more TG than non-supplemented cultures (Fig. 10). This was particularly evident for cultures treated with the crude mixture of CLA isomers. Within vitamin E treatments, cultures treated with the *trans*-10,*cis*-12 isomer of CLA had the lowest amount of TG/10^6 cells compared to the other cultures.

Experiment 4: Differentiation (days 1–4); nuclear condensation (Fig. 11) and cell cycle analyses (Fig. 12, Table 1). (i) Indices of apoptosis. The percentage of adherent cells exhibiting nuclear condensation was higher in the CLA-treated cultures for all treatment periods compared to the control and LA-treated cultures. This apoptotic effect of CLA was clearly evident after only 24 h of treatment (Fig. 11). The *trans*-10, *cis*-12 isomer of CLA was more effective than a crude mixture of CLA isomers in inducing nuclear condensation after 72 and 96 h of treatment. The percentage of adherent cells in

FIG. 9. FIG. 12. The effect of treating cultures for either 24, 48, 72, or 96 h with either 100 μM of LA, a crude mixture of mixed-CLA isomers, or the *trans*-10,*cis*-12 isomer of CLA (10,12-CLA) on the percentage of cells in the sub-G1 phase of the cell cycle (i.e., apoptotic) in postconfluent cultures of differentiating 3T3-L1 preadipocytes. Cultures were treated continuously and harvested after 24, 48, 72, or 96 h of treatment. Means (±SEM; $n = 6$) not sharing a common letter are significantly different ($P < 0.05$). See Figure 1 and 9 for abbreviations.

the sub-G_1 phase of the cell cycle, another measurement of apoptosis, was higher in the CLA-treated cultures for all treatment periods compared to the control and LA-treated cultures (Fig. 12). As with the nuclear condensation data, the *trans*-10,*cis*-12 isomer of CLA was more effective than the crude mixture of CLA isomers in increasing the percentage of cells in the sub-G_1 phase.

(ii) Cell cycle analyses. Data on the influence of BSA, LA, a crude mixture of CLA isomers, and the *trans*-10,*cis*-12 isomer of CLA on the G_1, S, and G_2M phase of the cell cycle are presented in Table 1. With the exception of the 48-h treatment period, cultures treated with the *trans*-10,*cis*-12 isomer of CLA had fewer cells in the G_1 phase of the cell cycle than the BSA or control cultures. Cultures treated with CLA for 48 h had fewer cells in the S phase than BSA or control cultures. In contrast, cultures treated with CLA for 96 h had more cells in the S phase than BSA or control cultures. Cultures treated for 72 h with *trans*-10,*cis*-12 CLA had more cells in the G_2M phase of the cell cycle than the other treatments.

DISCUSSION

The present study provides direct evidence that CLA attenuates preadipocyte proliferation and TG content in monolayer cultures of 3T3-L1 (pre)adipocytes. Moreover, these data demonstrate that the *trans*-10,*cis*-12 isomer is a major antiadipogenic isomer of CLA. To our knowledge, this is also the first time that the *trans*-10,*cis*-12 isomer of CLA has been shown to cause apoptosis, assessed by nuclear condensation and cells in the sub-G_1 peak of the cell cycle, in postconfluent cultures of 3T3-L1 preadipocytes. These data provide further support for the concept that the antiobesity effects of a crude mixture of CLA isomers observed in mice (5–8,10) and pigs (11,12) may indeed be due to the direct actions of the *trans*-10,*cis*-12 isomer of CLA on adipose tissue mass and cellularity. The crude mixture of CLA isomers used in this study contained 41% 9–11 (an unknown mixture of *cis-trans* and *trans-cis*) isomers, 44% *trans*-10,*cis*-12 isomers, and 10% *cis*-10,*cis*-12 isomers according to the analyses by the supplier, Nu-Chek-Prep. Therefore, in Experiments 1 and 2, it was not clear which of the isomers reduced preadipocyte growth and TG content compared to LA. Furthermore, other isomers of CLA may have also been present in these CLA preparations, since we did not confirm the fatty acid isomer profiles ourselves. However, when comparing the effects of the crude mixture of CLA isomers to that of the *trans*-10,*cis*-12 CLA isomer on TG content in Experiment 3 (Figs. 9 and 10), the *trans*-10,*cis*-12 CLA isomer was 36–50% more potent than the crude mixture of CLA isomers within respective treatments. This reduced potency of the crude mixture of CLA isomers corresponds to its lower content of the *trans*-10,*cis*-12 isomer (e.g., 44%). Furthermore, the *trans*-10,*cis*-12 isomer of CLA was generally more potent than the crude mixture of CLA isomers in inducing nuclear condensation (e.g., ~7 vs. 35% in Fig. 11) and the percentage of cells in the sub-G1 phase of the cell cycle (e.g., ~27 vs. 64% in Fig. 12). In support of our findings, a recent study by Park *et al.* (7) demonstrated that the *trans*-10,*cis*-12 isomer of CLA is the antiadipogenic isomer in mature 3T3-L1 adipocytes. They found that the *trans*-10,*cis*-12 isomer decreased LPL activity and increased lipolysis to a greater extent than the crude mixture of CLA isomers from Nu-Chek-Prep. In contrast, the *cis*-9,*trans*-11 isomer of CLA, which has anticarcinogenic actions (20), had no influence on mature adipocytes. In further support of these data, we have preliminary data demonstrating that the *cis*-9,*trans*-11 isomer of CLA actually increases TG content of differentiating cultures of 3T3-L1 (pre)adipocytes. When taken together, these data suggest that the *trans*-10,*cis*-12, not the *cis*-9,*trans*-11, isomer of CLA may attenuate adipocyte cellularity and mass by reducing preadipocyte differentiation, inducing apoptosis, and promoting adipocyte delipidiation.

These data also demonstrated that CLA supplementation attenuates the growth (e.g., decreased cell number and ^3H-thymidine incorporation into DNA) of preconfluent cultures of 3T3-L1 preadipocytes using a physiological method to deliver fatty acids (i.e., complexed to albumin) to monolayer cultures of preadipocytes. The inhibitory effect of a crude mixture of CLA isomers on preadipocyte growth during the proliferation program is in agreement with Brodie *et al.* (14)

and Satory and Smith (13), who used either DMSO or ethanol to deliver CLA to the cultures. However, they reported that LA also reduced preadipocyte proliferation, whereas we found no effect of LA on thymidine incorporation and only a small effect of LA on cell number. These differences in the effects of CLA on proliferation may be due to the organic solvent used to deliver fatty acids to cell cultures vs. using a more physiological carrier such as albumin. This difference in vehicles employed to deliver fatty acids may also explain why these researchers found that CLA and LA suppressed proliferation at much lower concentrations (i.e., 1.7 μM) than we did (i.e., 10–50 μM). Alternatively, the inclusion of vitamin E in our study may have reduced the peroxidation of LA and CLA in the cultures. Peroxidized lipids can undoubtedly influence cell growth. For this reason, many researchers using unsaturated fatty acids in cell culture supplement the media with an antioxidant such as α-tocopherol. In support of this concept, data in Figure 10 demonstrated that LA- and CLA-treated cultures without additional vitamin E during differentiation have significantly less TG/10^6 cells compared to vitamin E-supplemented cultures.

These CLA-mediated changes in preadipocyte TG content were accompanied by a dose-dependent increase in indices of growth arrest (e.g., decreased protein content and cell numbers) and cell death (e.g., floating cells and LDH activity in the media, morphological changes indicative of membrane blebbing, nuclear condensation, cells in the sub-G_1 peak of the cell cycle). It is unclear whether these effects of CLA are due to a direct influence on regulators of growth and/or differentiation or perhaps more general cytotoxic or apoptotic effects. Unfortunately, the LDH assay does not discriminate between apoptosis and cytotoxicity (17). However, it is possible that CLA treatment increases apoptosis or cell detachment, thereby increasing the number of floating cells or cell bodies that release their LDH into the media before, during, or after cell harvest.

Several studies with normal mammary cells (21) and transformed cells, including MFC-7 human breast cancer cell lines (22), indicate that CLA may inhibit growth by inducing cell cycle arrest (1). These data suggest that CLA may inhibit preadipocyte proliferation and/or differentiation by a similar mechanism. In agreement with this concept, we found cell number and DNA synthesis were lower in cultures treated with a crude mixture of CLA isomers compared to cultures treated with LA. Furthermore, differentiating cultures treated for 48 h with CLA had fewer cells in the S-phase of the cell cycle. However, cultures treated for 96 h actually had a greater percentage of cells in the S-phase than control cultures. Therefore, CLA appears to have its greatest impact on cell growth during the proliferative program and the clonal expansion phase of 3T3-L1 adipogenesis.

Alternatively, CLA could be influencing cell growth by inducing programmed cell death or apoptosis. Since post-confluent 3T3-L1 preadipocytes undergo several rounds of replication during the first 48 h of the differentiation program, induction of apoptosis may be a potential mechanism by which CLA attenuates adipogenesis. This hypothesized antiadipogenic mechanism of CLA could result in smaller and/or fewer adipocytes containing less lipid. The three indicators of apoptosis used in this study that suggest CLA induces apoptosis were: (i) nuclear condensation; (ii) cells in the sub-G_1 peak of the cell cycle; and (iii) floating cells and LDH activity in the media. Morphological changes observed using SEM were characteristic of membrane blebbing in cultures treated with CLA, also supporting an apoptotic mechanism of action of CLA. In support of this concept, Ip *et al*. (21) found that CLA, not LA, inhibited the growth of normal mammary epithelial cells by inducing apoptosis. Surprisingly, we found that a crude mixture of CLA isomers has no influence on the cell cycle nor the number of floating cells in the media of cultures of preconfluent, proliferating 3T3-L1 preadipocytes (data not shown). Therefore, CLA's apoptotic effects seem to be most pronounced in postconfluent, differentiating cultures of preadipocytes. Interestingly, we have preliminary data demonstrating that the *cis*-9,*trans*-11 isomer of CLA does not influence these indices of cell growth. This observation provides further support for the concept that the antiadipogenic effects of CLA are mediated by the *trans*-10,*cis*-12 isomer of CLA.

CLA also could be impacting cell growth and/or differentiation by altering cellular membrane phospholipid composition and phospholipid metabolism to intracellular signals. Indeed, feeding diets rich in CLA to cattle (23) or humans (9) alters the lipid content and the fatty acid composition of their milk. CLA is incorporated into mouse forestomach (24) and rat mammary (25) tumor phospholipids and neutral lipids. Furthermore, supplementing preadipocyte cultures with CLA influences the types and amounts of cellular fatty acids (13). For example, the percentage of arachidonic acid (AA), a precursor to prostaglandins that stimulate lipogenesis [e.g., prostaglandin I_2 is a ligand for peroxisome proliferating activated receptor-γ2 (PPAR-γ2)], was reduced by >50% in CLA-treated cultures of 3T3-L1 preadipocytes (13). Moreover, incorporation of fatty acids into phospholipid membranes is known to alter the activities of enzymes involved in signal transduction processes (26). Therefore, CLA could be displacing certain fatty acids associated with membrane phospholipids such as AA, thereby decreasing intracellular signals such as diacylglycerol (DAG), inositol triphosphate, and AA. These phospholipid-derived signals are know to influence numerous signaling cascades that alter cellular metabolism including intracellular calcium, protein kinase activity, and PPAR-γ2. Interestingly, Brodie *et al*. (14) found that CLA-treated cultures had lower levels of mRNA expression of PPAR-γ2 and fatty acid binding protein. Alternatively, CLA-derived phospholipids may generate CLA-specific eicosanoids that suppress adipogenesis and/or induce apoptosis.

Finally, CLA could be attenuating TG content by causing lipid peroxidation. This theory is based on our finding that supplementation of CLA-containing cultures with 0.2 mM α-tocopherol significantly reduced CLA's attenuation of TG content in postconfluent cultures. In support of this theory,

O'Shea *et al*. (27) demonstrated that treatment of cultures of human MCF-7 and SW480 cancer cells with a crude mixture of CLA isomers increases lipid peroxidation (thiobarbitiuric acid-reactive substance) and induced the activities of several antioxidant enzymes. Schonberg and Krokan (28) also found that treatment of cultures of lung adenocarcinoma and gliablastoma cells with up to 40 μM of mixed CLA isomers significantly increased lipid peroxidation. The formation of peroxides was abolished by the addition of 30 μM α-tocopherol to the media. However, cell growth was not completely restored by α-tocopherol, suggesting that lipid peroxidation was only partially responsible for CLA's suppression of cell growth. In contrast, several studies have found no effect of CLA on lipid peroxidation *in vivo* (25) or *in vitro* (29). Furthermore, both the *cis*-9,*trans*-11 and the *trans*-10,*cis*-12 isomers were found to be resistant to peroxidation catalyzed by hydoperoxide (30). Alternatively, it is conceivable that the *trans*-10,*cis*-12 isomer of CLA simply has a decreased capacity for esterification into TG.

In conclusion, these data demonstrate that CLA attenuates 3T3-L1 preadipocyte proliferation and TG content compared to LA-treated cultures. Potential mechanisms responsible for CLA's antiadipogenic actions to be examined in future studies include: (i) induction of apoptosis; (ii) alterations in phospholipid signals that impact cell growth and differentiation; (iii) influence on lipid peroxidation; and (iv) impaired esterification of the *trans*-10,*cis*-12 isomer of CLA.

ABSTRACT: To study the ability of long-chain *trans* fatty acids (FA) to be incorporated and metabolized into endothelial cells, bovine aortic endothelial cells were incubated with medium enriched eicosapentaenoic acid (EPA) bound to albumin (M2) or one of its geometrical isomers: 20:5 5*c*,8*c*,11*t*,14*c*,17*c* (M3), 20:5 5*c*,8*c*,11*c*,14*c*,17*t* (M4), or 20:5 5*c*,8*c*,11*t*,14*c*,17*t* (M5). After 48 h of incubation, supernatant and cells were harvested and their lipids were analyzed, including prostacyclin synthesis. EPA and 22:5n-3 of endothelial cells incubated with M2 were, respectively, three and two times higher than in control cells (incubated in M1, without any fatty acid added), whereas 22:6n-3 increased only in the supernatant, suggesting its release after biosynthesis. However, 18:2n-6 and 22:4n-6 decreased (about 30%). *Trans* 20:5 isomers represented 4.7, 3.9, and 5.2% of total phospholipid FA in endothelial cells incubated with M3, M4, and M5, respectively. They were elongated into *trans* 22:5 and *trans* 24:5, as revealed by gas chromatography–mass spectrometry and gas chromatography–Fourier transform infrared analysis. In cells incubated with M2, M3, M4, and M5, prostacyclin synthesis was inhibited by 49.0, 62.5, 60.5, and 72.0%, respectively. This effect may be due to less available arachidonic acid in the cells and to a competition between EPA isomers and AA at the level of cyclooxygenase pathway, as it was demonstrated that 20:5 Δ17*t* was metabolized by this enzyme.

Paper no. L8457 in *Lipids 35*, 911–918 (August 2000).

Trans isomers of n-3 polyunsaturated fatty acids (FA) are formed during heat treatment of vegetable oils including deodorization or deep-frying treatments (1–3). Geometrical isomers of linolenic acid are present in human food such as dietary oils, low-calorie spreads (4–6) or infant formulas (7–9). As a consequence, the major geometrical isomers of 18:3n-3, i.e., the 18:3 9*c*,12*c*,15*t* (18:3 Δ15*t*) and the 18:3 9*t*,12*c*,15*c* were found in several human tissues such as serum (10), milk (11), plasma, and platelets (12). Furthermore, *trans* 18:3 can be desaturated and elongated into *trans* 20:5 (13,14). Indeed, 20:5 5*c*,8*c*,11*c*,14*c*,17*t* (20:5 Δ17*t*) formed from the 18:3 Δ15*t,* was found in human platelets (12,15), plasma (12), and umbilical vein endothelial cells (Loï, C., and Chardigny, J.M., unpublished data).

In rat platelets, this *trans* 20:5 seems to be recognized as arachidonic acid (AA), its structural analog (16). Since endothelial cells play a crucial role by maintaining hemostasis (AA) (17) and protecting against thrombogenesis, we wondered (i) whether, in these cells, 20:5 Δ17*t* is recognized as AA, the major precursor of eicosanoid synthesis and (ii) whether 20:5 Δ17*t* has the same effects as its *cis* homolog, eicosapentaenoic acid (EPA).

Several studies reported that the incorporation of EPA into endothelial cell lipids leads to its conversion into 22:5n-3 (18–20) and induces (i) an increase in nitric oxide (NO) production and intracellular free calcium concentration (21), (ii) an increase of the release of endothelium-derived relaxing factors (22), and (iii) a decrease in AA content and in synthesis of eicosanoids such as prostacyclin (PGI_2) (18,23–25) or prostaglandin (PG) E_2 (26). Kanayasu *et al.* (27) also demonstrated that EPA may act as an endogenous inhibitor of angiogenesis under various pathological conditions. Thus, incorporation of EPA in endothelial cell lipids has been extensively studied, but no data are available so far on the incorporation of geometrical isomers of EPA, i.e., 20:5 5*c*,8*c*,11*t*,14*c*,17*c* (20:5 Δ11*t*), 20:5 5*c*,8*c*,11*t*,14*c*,17*t* (20:5 Δ11*t*,17*t*), and 20:5 Δ17*t*.

Thus, the aims of this study were (i) to explore the ability of *trans* 20:5 to be incorporated and metabolized by bovine aortic endothelial cells (BAEC), (ii) to evaluate if the position or the number of the *trans* double bonds influences the metabolic effects of these *trans* FA, (iii) to assess if the incorporation of these *trans* FA influences PGI_2 synthesis, and (iv) to compare the metabolism of 20:5 Δ17*t* with that of AA, its structural analog.

MATERIAL AND METHOD

EPA and AA were purchased from Sigma (L'Isle d'Abeau, France). The 20:5 Δ11*t*, the 20:5 Δ17*t*, and the 20:5 Δ11*t*,17*t*

Abbreviations: AA, arachidonic acid; BAEC, bovine aortic endothelial cells; DHA, docosahexaenoic acid; DMOX, dimethyloxazoline derivative; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; FA, fatty acids; FCS, fetal calf serum; FTIR, Fourier transform infrared; GC, gas chromatography; HPLC, high-performance liquid chromatography; NO, nitric oxide; PG, prostaglandin; PGI, prostacyclin; RV, retention volume; SFA, saturated fatty acid; 18:3 Δ15*t*, 18:3 9*c*,12*c*,15*t*; 20:5 Δ11*t*, 20:5 5*c*,8*c*,11*t*,14*c*,17*c*; 20:5 Δ17*t*, 20:5 5*c*,8*c*,11*c*,14*c*,17*t*; 20:5 Δ11*t*,17*t*, 20:5 5*c*,8*c*,11*t*,14*c*,17*t*.

were synthesized as methyl esters (28,29) and saponified (30) prior to being bound to a delipidated human serum albumin (Sigma).

[1-^{14}C]-Radiolabeled AA (specific activity 2.04 GBq/mmol) was purchased from NEN, Life Sciences (Les Ulis, France). [18-^{14}C]-Radiolabeled 20:5 Δ17*t* (specific activity 1.96 GBq/mmol) and [18-^{14}C]-radiolabeled EPA (specific activity 1.96 GBq/mmol) were obtained by total synthesis (31). These three FA were diluted with their respective unlabeled homologs to obtain specific activities required for our experiments.

Endothelial cell growing factor and trypsin were purchased from Sigma and Biochrom KG (Berlin, Germany), respectively. Medium M199, antibiotics, and fetal calf serum (FCS) were supplied by Polylabo (Strasbourg, France). The collagenase was obtained from Boehringer (Grenoble, France).

Cell cultures. Endothelial cells were isolated from bovine aortae (obtained from freshly slaughtered animals) by scraping the luminal surface with a razor blade, and were then dispersed by treatment with collagenase (0.02% in phosphate-buffered saline containing 0.011 M of glucose) for 15 min at 37°C, under gentle shaking. The cells were sedimented (200 × *g* for 5 min), plated in complete Medium 199 [with Earle's salt, 30 μM/mL of endothelial cell growing factor, 20% heat-inactivated FCS, penicillin (100 U/mL), and streptomycin (100 μg/mL)] on 25-cm^2 tissue culture dishes (Falcon, Primaria). They were incubated at 37°C under an atmosphere containing 5% CO_2 and 95% air. Subcultures were performed with trypsin and by scraping the dishes with a plastic spatula. As for primary cultures, cells were sedimented and plated in complete Medium 199 on 25-cm^2 dishes. The cells were identified as endothelial cells by morphology and by immunofluorescent staining for von Willebrand factor. They were used at confluence in the second passage.

Preparation of media enriched with different FA. Tenfold-concentrated FA solutions, as compared to the final FA concentration, were prepared by incubating delipidated bovine serum albumin with EPA (M2), 20:5 Δ11*t* (M3), 20:5 Δ17*t* (M4), 20:5 Δ11*t*,17*t* (M5), [1-^{14}C]AA (0.74 GBq/mmol, M6), [18-^{14}C]EPA (0.74 GBq/mmol, M7), [18-^{14}C]20:5 Δ17*t* (0.74 GBq/mmol, M8), and without any fatty acid (= control = M1) for 5 h at 37°C under N_2 and gently shaking. The final FA/albumin ratio was 2:1. Then, the solutions were diluted with Medium 199, 20% FCS; filtered; and added to the cells at confluence. Incubations were carried out for 48 h.

Lipid analysis. At the end of the incubation period, lipids of cell supernatant from pools of two dishes were extracted according to the method of Folch *et al.* (32). The free FA were separated from the other lipid classes by thin-layer chromatography, transmethylated (33), and analyzed by gas chromatography (GC) (BPX70, 50 × 0.33 i.d., film thickness 0.25 μm, SGE, Melbourne, Australia) using a Hewlet-Packard 5890 series II gas chromatograph (Avondale, PA), fitted with a splitless injector and a flame-ionization detector. Both were maintained at 250°C. The oven temperature was programmed from 60 to 185°C (20°C/min) for 35 min and then from 185 to 220°C (20°C/min).

Cells (pools from two dishes) were rinsed with phosphate-buffered saline solution and scraped off into methanol. Lipids were extracted according to Folch *et al.* (32). Phospholipids of half the samples were separated from neutral lipids by the method of Kaluzny *et al*. (34), and their FA were transmethylated (33) and analyzed by GC. The remaining methyl esters of these phospholipid FA were separated by high-performance liquid chromatography (HPLC) (column: Nucleosil C18, 5 μM, 250 × 4.6, mobile phase: acetonitrile at 1 mL/min) in order to obtain the 20:5 + 22:6 fraction [F1, retention volume (RV) of 6 mL], the 20:4 + 22:5 fraction (F2, RV of 7.2 mL), and the 22:4 + 24:5 fraction (F3, RV of 8.7 mL). F2 and F3 were then divided into two samples. One was analyzed by GC (HP5890 gas chromatograph, BPX70, 30 m × 0.25 mm i.d., film thickness 0.25 μm; SGE) coupled with Fourier-transform infrared (FTIR) spectrometry (FTS 60A; Biorad, Cambridge, MA) and fitted with a splitless injector maintained at 250°C. The oven temperature was programmed from 60 to 200°C (20°C/min). The second samples of F2 and F3 were reacted to form dimethyloxazoline derivatives (DMOX) (35). Briefly, the fractions were evaporated to dryness under nitrogen. Next, 100 μL of 2-amino-2 methyl-1-propanol was added before heating at 170°C for 8 h. DMOX derivatives were extracted twice using dichloromethane. After washing by distilled water, DMOX derivatives were injected onto an HP5 wall-coated capillary column (30 m × 0.25 mm i.d., film thickness 0.25 μm) interfaced with a MSD5970 quadrupole mass spectrometer (Hewlett-Packard). The oven temperature was programmed from 50 to 240°C at a rate of 20°C/min. The mass spectrometer was operated in electron impact mode at an ionization energy of 70 eV.

Phospholipids of the remaining half of the samples were separated from neutral lipids, the different phospholipid classes were separated by HPLC (column: Lichrosorb Si60, 5 μm, 250 mm × 4 mm) (36), and their FA were transmethylated and analyzed by GC as described above.

Prostaglandin synthesis analysis. Cells incubated for 48 h with M1, M2, M3, M4, and M5 were stimulated for 15 min at 37°C with [1-^{14}C]AA (20 μM, 0.55 GBq/mmol) to assess if incorporation of geometrical isomers of EPA has an influence on PGI synthesis from exogenous AA. Cells and supernatant were harvested. Radiolabeled AA metabolites were extracted using octadecyl-silica minicolumns (Amprep; Amersham, Courtaboeuf, France) (37) and analyzed with a reversed-phase-HPLC technique (38,39), slightly modified in our laboratory. Separation of PG from the other eicosanoids and unmetabolized AA was performed on a Nucleosil-C18 (5 μm, 4.6 × 250 mm) column (Interchim, France). Solvent A was acetonitrile and solvent B was water acidified to pH 3 with acetic acid. PG were eluted isocratically at a flow rate of 1 mL/min over 40 min with 31% solvent A/69% solvent B. Following elution of the PG, the concentration of acetonitrile was increased to 100% over 45 min and then maintained at 100% for 10 min. The column effluent was collected in 1-mL fractions and radioactivity determined by liquid scintillation spectrometry. Unlabeled 6-keto ($PGF_{1\alpha}$), (PGD_2), and AA were used as standards to identify the chromatogram peaks. They

were detected using an ultraviolet detector (Varian 9050, Palo Alto, CA). Absorbance was monitored at 207 nm for the first 50 min and then at 220 nm.

*[18-^{14}C]20:5 Δ17*t *metabolism.* BAEC at confluence (second generation) were stimulated for 15 min at 37°C with [18-^{14}C]20:5 Δ17*t* (20 μM, 0.55 GBq/mmol) to assess if these cells are able to metabolize this *trans* isomer of EPA in PG. Eicosanoid extraction and analysis were performed as described above.

Cyclooxygenase inhibition. BAEC at confluence (second generation) were incubated for 5 min at 37°C with indomethacin [5 μM diluted in ethanol (0.5% of total medium volume)], a specific inhibitor of the cyclooxygenase (40). Then they were incubated with [18-^{14}C]20:5 Δ17*t* (20 μM, 0.55 GBq/mmol) for 15 min at 37°C to assess PG synthesis. Analyses were performed as described above.

Statistical analysis. The results were analyzed using the NCSS package (Kaysville, UT). An analysis of variance with a Newman-Keuls test at one-factor term was performed to compare the different groups. Results are expressed as mean ± standard deviation.

RESULTS

FA profile of BAEC phospholipids. As shown in Table 1 and Figure 1, BAEC incorporated the different 20:5 fatty acids added in the culture medium. Unknown compounds named Y1 and W1 (M3), Y and W (M4), and Y2 and W2 (M5) were detected. Mass spectra of the DMOX derivatives of these molecules revealed that they are 22:5n-3 (Y, Y1, Y2, Fig. 2A) and 24:5 isomers (W, W1, W2, Fig. 2B), as it is shown in Figure 3B with the IR spectrum of Y revealing the presence of a *trans* double bond.

FA incorporation in the different phospholipid classes was also assessed, and there was no difference between 20:5 Δ17*t*, EPA, and AA incorporation into phosphatidylethanolamine and phosphatidylcholine.

Composition of cell supernatant free FA. Table 2 shows that the FA added to the initial medium and their 22:5 metabolites were found in all cell supernatants. Only the 24:5 isomer produced from the 20:5 Δ17*t* was detected.

There was an increase in AA ($P < 0.001$), 22:4n-6, and sum of n-6 FA ($P < 0.01$) in M2 and M4 media. Docosahexaenoic acid (DHA) content was increased in M2, M4, and M5 media compared to the control (M1).

PGI_2 synthesis. Figure 4 shows that incorporation of EPA, 20:5 Δ11*t*, 20:5 Δ17*t,* and 20:5 Δ11*t*,17*t* in BAEC inhibited PGI_2 synthesis from exogenous AA by 49.0, 62.5, 60.5, and 71.9%, respectively. The effect of the di-*trans* isomer was more potent than that of the other FA. The effects of the different mono-*trans* isomers were similar.

*20:5 Δ17*t *metabolism.* Figures 5B and C present chromatograms of the 20:5 Δ17*t* metabolites from BAEC stimulated with [18-^{14}C]20:5 Δ17*t* (20 μM, 0.55 GBq/mmol) in the presence (C) or absence (B) of indomethacin (5 μM).

BAEC were able to metabolize 20:5 Δ17*t* into compounds where synthesis was inhibited by indomethacin. Furthermore, the Δ17 *trans* isomer of EPA was metabolized into nonpolar

Part of gas–liquid chromatograms of phospholipid fatty acid methyl esters of cells incubated for 48 h with 12.5 μM of bovine delipidated albumin and 25 μM of eicosapentaenoic acid (B), 20:5 Δ11*t* (20:5 5*c*,8*c*,11*t*,14*c*,17*c*) (C), 20:5 Δ17*t* (20:5 5*c*,8*c*,11*c*,14*c*,17*t*) (D), 20:5 Δ11*t*,17*t* (20:5 5*c*,8*c*,11*t*,14*c*, 17*t*) (E), or only albumin (control, A).

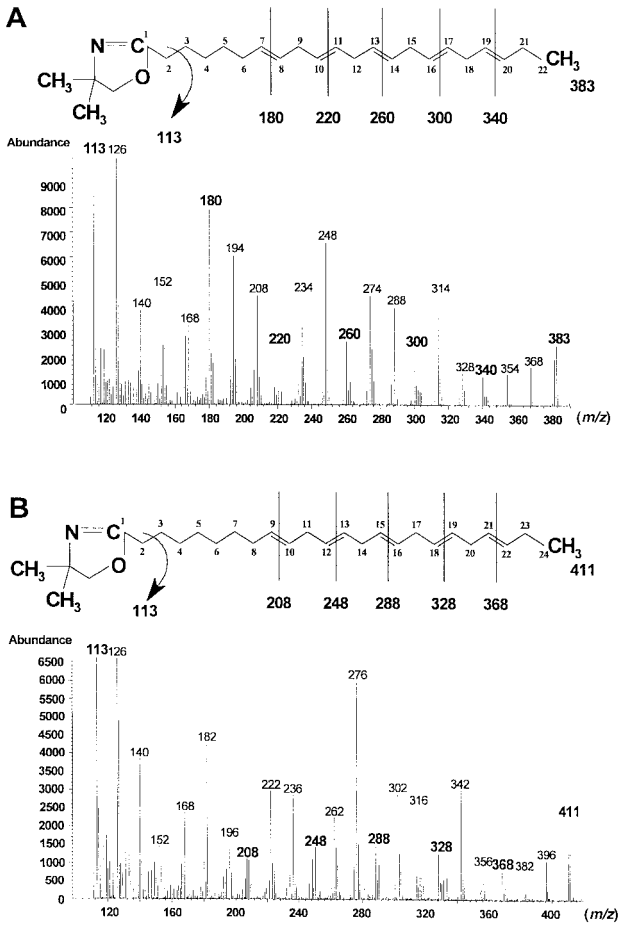

FIG. 2. Mass spectra of dimethyloxazoline derivatives of Y (22:5 7*c*,10*c*,13*c*,16*c*,19*c*) (A) and W (24:5 9*c*,12*c*,15*c*,18*c*,21*t*) (B). Mass spectra of Y1 and Y2 (22:5 7*c*,10*c*,13*t*,16*c*,19*c* and 22:5 7*c*,10*c*,13*t*,16*c*,19*t*, respectively) are identical to that of Y, those of W1 and W2 (24:5 9*c*,12*c*,15*t*,18*c*,21*c* and 24:5 9*c*,12*c*,15*t*,18*c*,21*t*, respectively) are similar to that of W.

metabolites, as illustrated by several peaks with a retention volume of 50 to 75 mL.

DISCUSSION

Effect of 20:5 incorporation on n-3 FA metabolism. As already shown with EPA (20–22), BAEC are able to incorporate *trans* 20:5 FA (Fig. 1). This incorporation induced a decrease in EPA content in cell phospholipids. Furthermore, BAEC were able to elongate these *trans* isomers of EPA into *trans* 22:5 (Table 1, Figs. 2A, 3A) named, Y_1 (from 20:5 Δ11*t*), Y (from 20:5 Δ17*t*) and Y_2 (from 20:5 Δ11*t*,17*t*) and into *trans* 24:5 (Figs. 2B, 3B). Y has already been detected in tissues of rats fed a diet enriched with heated oil (13,41), but it has never been identified. However, it has been suspected to be a FA that is intermediate between the 20:5 Δ17*t* and the 22:6 4*c*,7*c*,10*c*,13*c*,16*c*,19*t* in the desaturation and elongation cascade. On the other hand, the *trans* 24:5 are not desaturated into 24:6, and it seems that there is no retroconversion into *trans* 22:6 as it is not detected in the cell phospholipids or in cell supernatant. An elongation in such long-chain FA has already been demonstrated in human umbilical vein endothelial cells for the n-6 family of FA (42).

When analyzed on a BPX70 capillary column, the geometrical isomers of 22:5 (Fig. 1) and 24:5 (data not shown) are eluted in the same order as those of 20:5. This particularity has already been observed by Piconneaux (43). Results of GC analyses of radiolabeled (data not shown) or unlabeled FA of endothelial cell phospholipids, in GC–mass spectrometry and GC-FTIR plus the fact that BAEC were incubated with only one *trans* FA at a time, allow us to say that Y is the 22:5 7*c*,10*c*,13*c*,16*c*,19*t*; W is the 24:5 9*c*,12*c*,15*c*,18*c*,21*t*, Y1 is the 22:5 7*c*,10*c*,13*t*,16*c*,19*c*; W1 is the 24:5 9*c*,12*c*,15*t*,18*c*,21*c*; Y2 is the 22:5 7*c*,10*c*,13*t*,16*c*,19*t*; and W2 is the 24:5 9*c*,12*c*,15*t*,18*c*,21*t*.

In phospholipids from BAEC incubated with EPA, we observed a decrease of the content of DHA; therefore, we expected an increase of this metabolite, as it is a desaturation and elongation product of EPA, which was present in large quantities. In fact, most of the synthesized DHA should be released in the medium as its content was increased in the supernatant of the cells. These results are in agreement with those of Achard *et al.* (44).

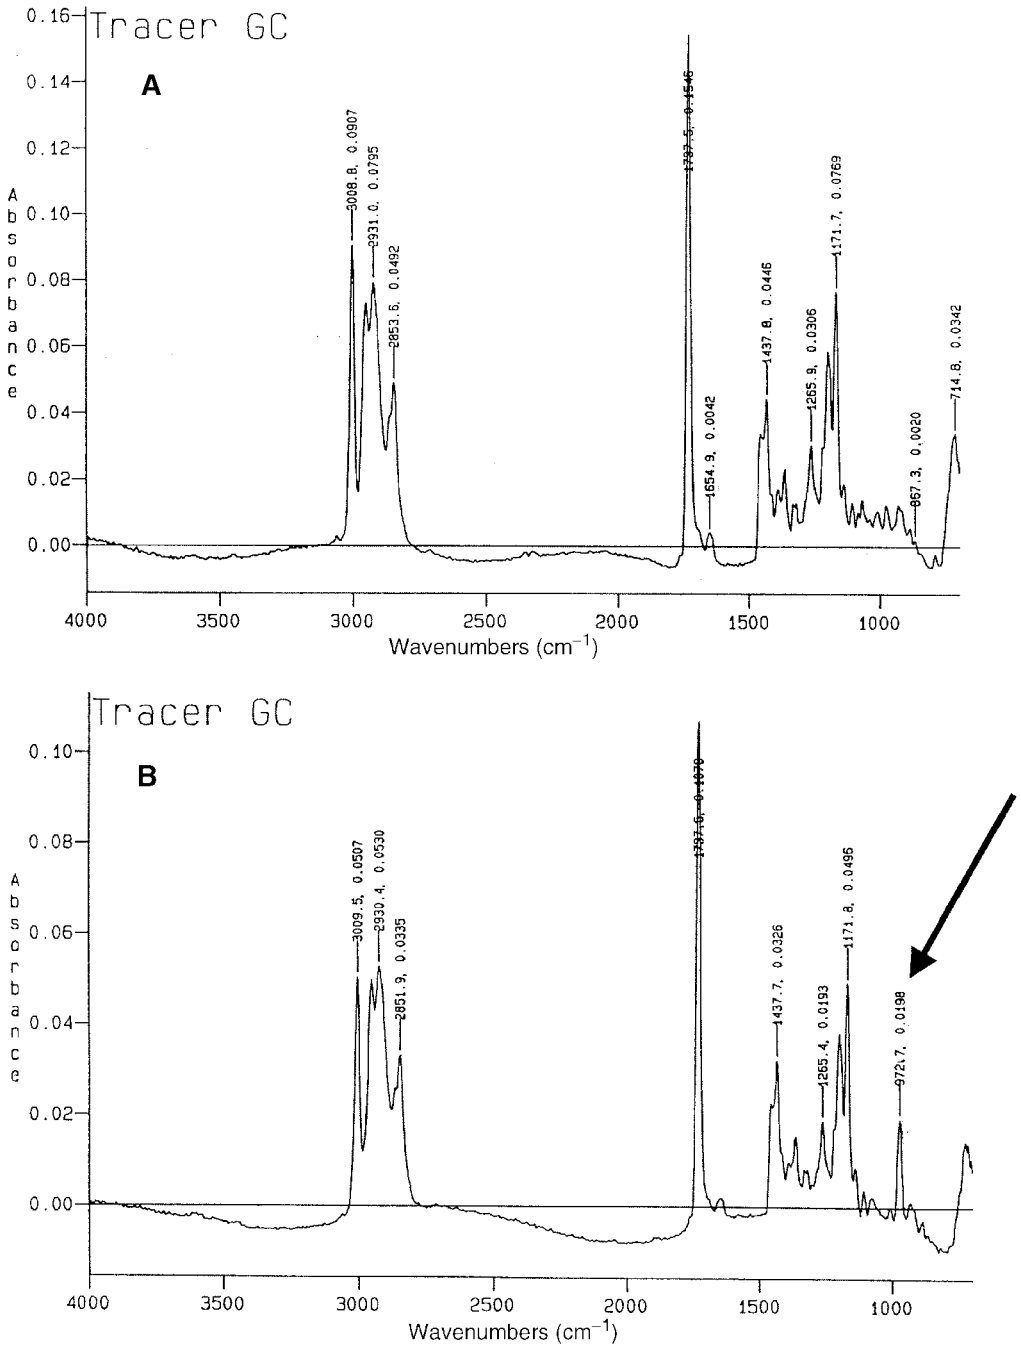

FIG. 3. Gas–liquid chromatography–Fourier transform infrared spectra of dimethyloxazoline derivatives of 22:5n-3 (A) and Y (B). (A) reveals the presence of a highly desaturated fatty acid (3008.8 cm^{-1} for δ = CH). (B) shows a highly desaturated fatty acid (3009.5 cm^{-1} for δ = CH) with a *trans* ethylenic bond (972.7 cm^{-1} for δ = CH).

Similarly, cells incubated with 20:5 Δ17*t* showed a decrease in their DHA content and an increase of DHA in their supernatant. This is one of the similarities found between the cells incubated with a medium enriched with EPA and those with 20:5 Δ17*t*. Another difference is that the 20:5 Δ17*t* was as much converted into Y as was EPA into 22:5n-3. Hence, it would be of interest to compare the effects of cells enriched with EPA on platelet regulation to cells enriched with 20:5 Δ17*t*.

Effect of 20:5 incorporation on n-6 FA metabolism. Influence on PGI_2 synthesis. The 20:5 incorporation induced a decrease in 18:2n-6 content in cell phospholipids. Its content in supernatants was unchanged. Furthermore, AA was also decreased in phospholipids of cells incubated with EPA, 20:5 Δ17*t,* and 20:5 Δ11*t*,17*t*. Such a decrease was already reported with EPA (18,24–26,45,46). This may be due to a competition between 20:5 and 20:4 for incorporation in phospholipids.

[a]Values in rows having different roman superscript letters are significantly different ($P < 0.01$). See Table 1 for abbreviations.
[b]Including *cis* and *trans* isomers.

Consequently, free AA may be released from the cells, and this explains the increase of its content in the supernatant of cells incubated with the 20:5. On the other hand, in phospholipids from cells which have incorporated 20:5 with a *trans* double bond at the Δ17 position, the elongation of AA into 22:4 was greater than for the other cell phospholipids. These changes in n-6 FA content in cell phospholipids correspond to a lesser availability of AA to be metabolized into PGI_2. Consequently, 20:5 incorporation could influence endothelial cell function.

These observations could partially explain the inhibitory effect of EPA and *trans* 20:5 incorporation in cells on PGI_2 synthesis, as exogenous AA enters in competition, at the level of the cyclooxygenase metabolism, with the other FA released from membrane phospholipids. However, it is of interest to know if 22:5 isomers or 20:5 FA are responsible for this inhibition. Indeed, Bénistant *et al.* (47) observed that inhibition of PGI_2 synthesis in endothelial cells treated with docosapentaenoic acid (DPA) might depend on EPA formed by retroconversion of DPA.

Metabolism of 20:5 Δ17t. Figure 5 shows that endothelial cells were able to metabolize 20:5 Δ17*t* into two unknown compounds with RV close to those of 6-keto $PGF_{1\alpha}$ and PGD_2. Using indomethacin as a specific inhibitor of the cyclooxygenase showed that these compounds were produced by this enzymatic pathway. Consequently, these metabolites may be *trans* isomers of Δ17-6-keto-$PGF_{1\alpha}$ (stable metabolite of PGI_2) and PGD_2, but only determination of their chemical structure would confirm this hypothesis. As it was already demonstrated in platelets (16), it seems that 20:5 Δ17*t* is recognized as AA, its structural analog, by the cyclooxygenase. A competition at the level of this enzyme could also explain the inhibitory effect of its incorporation on PGI_2 synthesis.

In contrast, the Δ17 *trans* isomer of EPA was more metabolized in nonpolar compounds than AA. Their RV were similar to those of hydroxyacids. It would be of interest to incubate endothelial cells with nordihydroguaiaretic acid and/or baicalein prior to stimulating them with 20:5 Δ17*t* in order to assess if these compounds are synthesized by 5-, 12- or 15-lipoxygenase.

In conclusion, the present study shows that *trans* 20:5 can be incorporated in endothelial cells and elongated into *trans* 22:5 and *trans* 24:5. The 20:5 Δ17*t*, which is the major 20:5 isomer found in human tissues, was as much converted in Y and W as was EPA into 22:5n-3 and 24:5. The differences observed between the *trans* 20:5 groups show that there is an in-

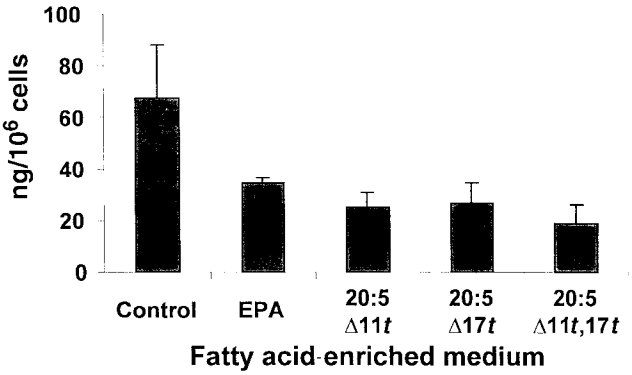

FIG. 4. Prostacyclin (PGI_2) synthesis inhibition in cells incubated for 48 h with medium enriched with different *trans* 20:5 (25 μM) or not (control). Cells were stimulated for 15 min at 37°C with radiolabeled arachidonic acid. PGI_2 was quantified by reversed phase-high-performance liquid chromatography (RP-HPLC) as described in the Material and Methods section.

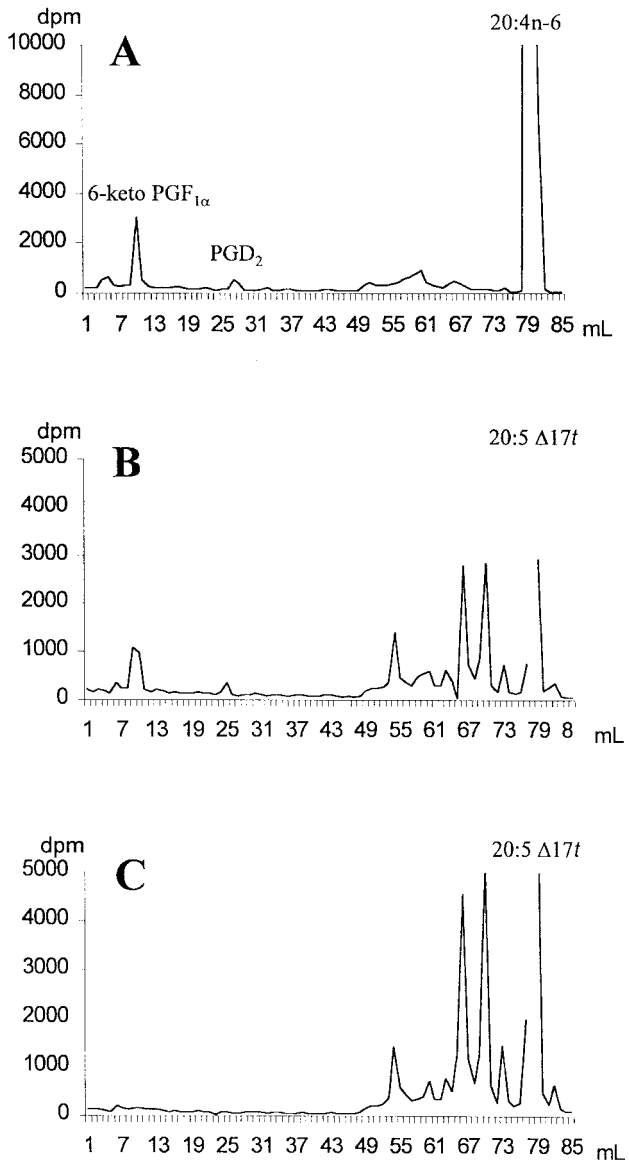

FIG. 5. HPLC profile of radio-labeled eicosanoids resolved using RP-HPLC. Cells were incubated for 15 minutes at 37°C with (A) [1-^{14}C]arachidonic acid (20 μM, 0.55 GBq/mmol) and (B) [18-^{14}C]20:5 Δ17*t* (20 μM, 0.55 GBq/mmol). (C) Cells were incubated for 5 min at 37°C with 5 μM of indomethacin prior to being stimulated for 15 min with [18-^{14}C]-20:5 Δ17*t* (20 μM, 0.55 GBq/mmol). See Figures 1 and 4 for other abbreviations.

fluence of the position of the *trans* double bond on the metabolism of these *trans* FA. An inhibitory effect on PGI_2 synthesis due to the 20:5 FA incorporation can be explained by (i) a decrease in 18:2n-6 and 20:4n-6 (except with M3) and an increase in 22:4n-6 (M4 and M5), which leads to less available AA for the cyclooxygenase pathway and (ii) the fact that the 20:5 Δ17*t* (and possibly the other *trans* 20:5) competes with the 20:4n-6 at the level of the cyclooxygenase step. Further studies are required to assess if there is a competitive inhibition between these two FA, to identify whether 20:5 Δ11*t* and 20:5 Δ11*t*17*t* are metabolized by the same enzymes, to determine the chemical structures of these metabolites, and to understand the mechanism of action of these *trans* 20:5.

[a]Laboratoire de Chimie Biologique Appliquée, Faculté des Sciences et Techniques, St-Jérôme, 13397 Marseille Cedex 20, France, [b]Université de Provençe, CTM-CNRS (UPR 7461) Faculté St-Charles, 13331 Marseille Cedex 3, France, and [c]Laboratoire de Biochimie, Faculté St-Charles, Université de Provence, 13331 Marseille Cedex 3, France

ABSTRACT: *Penicillium cyclopium* produces two lipases with different substrate specificities. Lipase I is predominantly active on triacylglycerols whereas lipase II hydrolyzes mono- and diacylglycerols but not triacylglycerols. In this study, we compared the kinetic properties of *P. cyclopium* lipases and human pancreatic lipase, a classical triacylglycerol lipase, by using vinyl esters as substrates. Results indicate that *P. cyclopium* lipases I and II and human pancreatic lipase hydrolyze solutions of vinyl propionate or vinyl butyrate at high relative rates compared with emulsions of the same esters, although, in all cases, maximal activity is reached in the presence of emulsified particles, at substrate concentrations above the solubility limit. It appears that partially water-soluble short-chain vinyl esters are suitable substrates for comparing the activity of lipolytic enzymes of different origin and specificity toward esters in solution and in emulsion.

Paper no. L8467 in *Lipids 35,* 919–925 (August 2000).

Penicillium cyclopium produces two extracellular lipases that have been isolated and characterized at the molecular and biochemical levels (1–4). Lipase I is produced mainly in stationary culture. It hydrolyzes short-, medium-, and long-chain triacylglycerols and has low activity on mono- and diacylglycerols. Its N-terminal amino acid sequence is similar to that of lipases of *P. expansum* (5) and *P. solitum* (6). Lipase II is predominantly produced in shaken culture (7). It hydrolyzes mono- and diacylglycerols but has almost no activity toward triacylglycerols. It is a glycosylated enzyme of the same size and substrate specificity as the partial acylglycerol lipase from *P. camembertii*. The N-terminal sequences of *P. cyclopium* lipase II and *P. camembertii* lipase are similar and differ from that of *P. cyclopium* lipase I (8). Because of their difference in substrate specificity, the kinetic properties of lipases I and II from *P. cyclopium* cannot be directly compared using the same acylglycerol substrate.

As shown earlier by Brockerhoff (9,10), vinyl esters, which contain a highly electrophilic alcohol moiety, are good substrates of porcine pancreatic triacylglycerol lipase. Recently, Yamaguchi and Mase (11) used vinyl laurate to measure the activity of *P. camembertii* lipase. Vinyl esters also have been widely used in recent studies of lipase-catalyzed transfer reactions (12–14). Unlike tributyrin and dioctanoin, which are used to specifically determine the activity of *P. cyclopium* lipases I and II, short-chain vinyl esters like vinyl propionate and vinyl butyrate are partially soluble in water and therefore can be used to study the interfacial activity of lipases by measuring the rates of enzymatic hydrolysis of the ester substrate in solution and in emulsion. In this communication, we report the results of comparative kinetic studies of *P. cyclopium* and human pancreatic lipases carried out with vinyl esters.

EXPERIMENTAL PROCEDURES

Solubility of vinyl esters. The solubilities of vinyl propionate and vinyl butyrate in aqueous solution were estimated by the turbidimetric method. Increasing amounts of vinyl propionate (0–600 μL) or vinyl butyrate (0–400 μL) were added to 30 mL of 2.5 mM Tris-HCl buffer (pH 7.0) in the absence or presence of 100 mM NaCl. (NaCl is generally added at the concentration of 100 or 150 mM to aqueous suspensions of tributyrin or tripropionin routinely used to assay triacylglycerol activity.) The vinyl ester was dispersed by mechanical stirring for 2 min under the same conditions as used in the potentiometric assay of lipase activity with the pH-stat (see below). The optically clear solution or turbid emulsion of vinyl ester was transferred into a 3-mL spectrophotometer cell (Uvicord II), and absorbance was read at 600 nm (Fig. 1). The absorbance increased as soon as insoluble particles were formed in oversaturated solutions of ester. The concentrations of saturated solutions of vinyl propionate and vinyl butyrate are 86 mM (8.6 g L^{-1}) and 22 mM (2.5 g L^{-1}), respectively. These concentrations correspond to the addition of 280 μL and 85 μL of ester, respectively, into 30 mL of Tris buffer used in the potentiometric assay. The solubility limits of the vinyl esters are the same in the absence and presence of 100 mM NaCl. The solubility limit of vinyl laurate, determined by the same method, is as low as 0.25 mM ($6 \cdot 10^{-2}$ g L^{-1}), which corresponds to the addition of 2 μL of ester into 30 mL

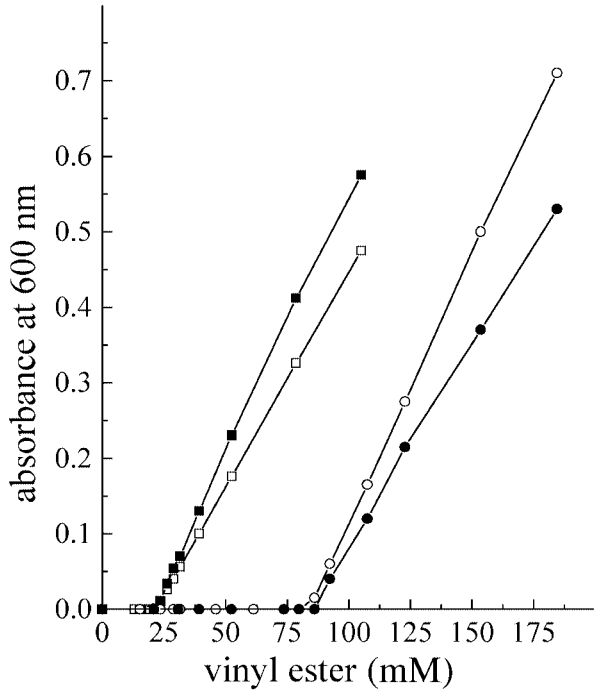

FIG. 1. Determination of the solubility limits of vinyl propionate and vinyl butyrate by the turbidimetric method. Vinyl propionate (○,●) and vinyl butyrate (□,■) were dispersed by mechanical stirring for 2 min at 25°C in 2.5 mM Tris-HCl buffer (pH 7.0) in the absence (○,□) and presence (●,■) of 100 mM NaCl. The absorbance of solutions and emulsions of the vinyl esters was read at 600 nm.

of Tris buffer. Finally, the solubility limit of tripropionin is 10 mM (2.4 g L^{-1} or 70 μL in 30 mL of Tris buffer) in the absence and presence of NaCl.

Enzymatic hydrolysis of vinyl esters. Hydrolysis of vinyl propionate and vinyl butyrate by *P. cyclopium* lipases and human pancreatic lipase was followed potentiometrically at 25°C for 5 min with a pH-stat (TTT 80 Radiometer, Copenhagen, Denmark). Released acid was titrated at pH 7.0 with 0.02 M NaOH. Kinetic studies were performed with increasing amounts of ester ranging from 0 to 500 μL (0–153 mM) of vinyl propionate and from 0 to 300 μL (0–78 mM) of vinyl butyrate in 30 ml of Tris buffer, pH 7.0, in the absence and presence of 100 mM NaCl. The concentration of the vinyl ester in the lipase assay system was expressed as millimoles per liter at concentrations below and above the solubility limit. Enzymatic hydrolysis of vinyl laurate or tripropionin was measured under the same conditions as above with amounts of ester ranging from 0 to 300 μL (0–37.5 mM) and from 0 to 180 μL (0–25 mM), respectively, in 30 mL of 2.5 mM Tris buffer, pH 7.0, in the presence of 100 mM NaCl. Correction was made for partial dissociation of lauric acid at pH 7.0, assuming an apparent pK_a of 7.4. Lipolytic activity on olive oil emulsified with gum arabic was assayed as described previously (7). In all cases, enzyme activity was expressed as lipase units. One unit corresponds to the release of one microequivalent of acid per minute. The amount of enzyme used to determine lipolytic activity potentiometrically was equivalent to 10 lipase units measured at a substrate concentration ensuring maximum enzyme activity (V_{max}). All assays were performed in duplicate with less than 5% deviation. Experiments were performed to check that *P. cyclopium* and human pancreatic lipases are resistant to acetaldehyde, the unavoidable by-product released in lipolysis reactions with vinyl esters. The rates of lipase-catalyzed hydrolysis of vinyl propionate was measured as described above, in the absence and presence of 100 mM NaCl, with an amount of acetaldehyde ranging from 0.5 to 30 mM added to the assay system prior to enzyme. Experiments were performed with saturated ester solutions and with emulsions at ester concentrations ensuring maximal lipolytic activity. In all cases, activity was not affected by acetaldehyde.

Enzymes. Penicillium cyclopium lipases I and II were prepared at the laboratory as reported previously (4,7). The specific activities of lipases I and II, measured at pH 7.0 and 25°C on emulsified tributyrin and dioctanoin, were 8,000 and 1,100 units mg^{-1}, respectively. Human pancreatic lipase, with a specific activity of 6,500 units mg^{-1} measured on emulsified tributyrin at pH 7.0 and 25°C, and human pancreatic colipase were gifts from Dr. F. Carrière (Marseille, France). Protein was estimated with the colorimetric method of Lowry *et al.* using bovine serum albumin as standard protein (15).

Chemicals. Vinyl propionate, vinyl butyrate, vinyl laurate, tripropionin, tributyrin, and acetaldehyde were from Sigma-Aldrich-Fluka (St-Quentin-Fallavier, France). Dioctanoin was prepared at the laboratory by chromatographic separation of a partial enzymatic hydrolysate of trioctanoin, as described previously (7). Olive oil was from local origin.

RESULTS AND DISCUSSION

Hydrolysis of vinyl laurate by P. cyclopium *lipases and human pancreatic lipase.* The emulsion of vinyl laurate was prepared in 30 mL of 2.5 mM Tris-HCl buffer pH 7.0 containing 100 mM NaCl with amounts of ester ranging from 0 to 300 μL (0–37.5 mM), and the rates of hydrolysis by lipases I and II were measured at pH 7.0 with the pH-stat. The specific activities of *P. cyclopium* lipases I and II were 2,100 and 3,200 units mg^{-1}, respectively. The specific activity of human pancreatic lipase, measured at pH 8.0, was 450 units mg^{-1} (Table 1). In all cases, half-maximal activity was obtained in the presence of 30 μL of vinyl laurate in the reaction system, which corresponds to 3.75 mM.

Hydrolysis of vinyl propionate by P. cyclopium *lipases.* The effect of increasing concentration of vinyl propionate on enzyme activity is presented in Figure 2. It can be observed from the curves of Figures 2A and 2B that the activity of lipases I and II is maximum (V_{max}) at substrate concentrations above the solubility limit, both in the absence and presence of 100 mM NaCl. The specific activities of lipases I and II are 950 and 1,250 units mg^{-1}, respectively (Table 1). The relative rates of hydrolysis of a saturated solution of vinyl propionate by lipases I and II amount to 0.45 V_{max} and 0.30 V_{max}, respectively, in the absence of NaCl, and to 0.90 V_{max} and 0.85 V_{max},

TABLE 1
Specific Activity of *Penicillium cyclopium* Lipases I and II and Human Pancreatic Lipase[a]

	P. cyclopium lipase I	*P. cyclopium* lipase II	Human pancreatic lipase
Vinyl propionate	950	1,200	960
Vinyl butyrate	3,000	2,000	750
Vinyl laurate	2,100	3,200	450
Tripropionin	1,250	0	4,000
Tributyrin	8,000	0	9,500
Trioctanoin	4,200	50	6,500
Olive oil	3,700	0	4,000
Dioctanoin	500	1,100	ND

[a]Activity is determined at 25°C against emulsions of vinyl propionate, vinyl butyrate, vinyl laurate, tripropionin, tributyrin, trioctanoin, olive oil, and dioctanoin at the optimal ester concentration and is expressed as lipase units. Specific activity is expressed as unit per mg of protein. Activities of *P. cyclopium* lipases I and II were measured at pH 7.0 and those of human pancreatic lipase at pH 8.0. ND, not determined.

respectively, in the presence of NaCl. Finally, from the curves of Figures 2A and B one sees that activity increases steadily with substrate concentration and that no abrupt increase occurs at at the point of saturation of the aqueous phase (86 mM). It appears that in this substrate system *P.cyclopium* lipases do not display interfacial activation.

Hydrolysis of vinyl butyrate by P. cyclopium *lipases.* The effect of increasing concentration of vinyl butyrate on the rate of hydrolysis of vinyl butyrate by *P. cyclopium* lipases I and II is shown in Figure 3. As previously found with vinyl propionate, the two lipases display maximal activity (V_{max}) on emulsified ester. The specific activities of the two lipases are 3,000 and 2,100 units mg^{-1}, respectively, both in the absence and presence of 100 mM NaCl. Lipases I and II are active on solutions of vinyl butyrate in the presence of sodium chloride. Activities against a saturated solution of vinyl butyrate amount to 0.90 V_{max} and 0.35 V_{max}, respectively. Surprisingly, lipase I hydrolyzes solutions of vinyl butyrate in the absence of sodium chloride whereas, under the same conditions, lipase II is almost inactive on the vinyl ester. The minimum concentration of sodium chloride allowing maximal activity on soluble vinyl butyrate is around 10 mM (data not shown).

Hydrolysis of vinyl propionate and vinyl butyrate by human pancreatic lipase. Kinetic studies were performed with human pancreatic lipase under the same conditions as above except that colipase was systematically added to the reaction system in 5 M excess to lipase. Results are shown in Figure 4. The specific activities of human pancreatic lipase calculated from the maximal activity (V_{max}), measured against emulsified vinyl propionate and vinyl butyrate, are 960 and 750 units mg^{-1}, respectively (Table 1). Human pancreatic lipase hydrolyzes solutions of vinyl propionate (Fig. 4A) and vinyl butyrate (Fig. 4B) in the presence of NaCl but at a lower relative rate than *P. cyclopium* lipases. The relative rates of hydrolysis of saturated solutions of vinyl propionate and vinyl butyrate amount to 0.60 V_{max} and 0.30 V_{max}, respectively. NaCl has little effect on the rate of hydrolysis of the solutions of the vinyl esters. As found with *P. cyclopium*

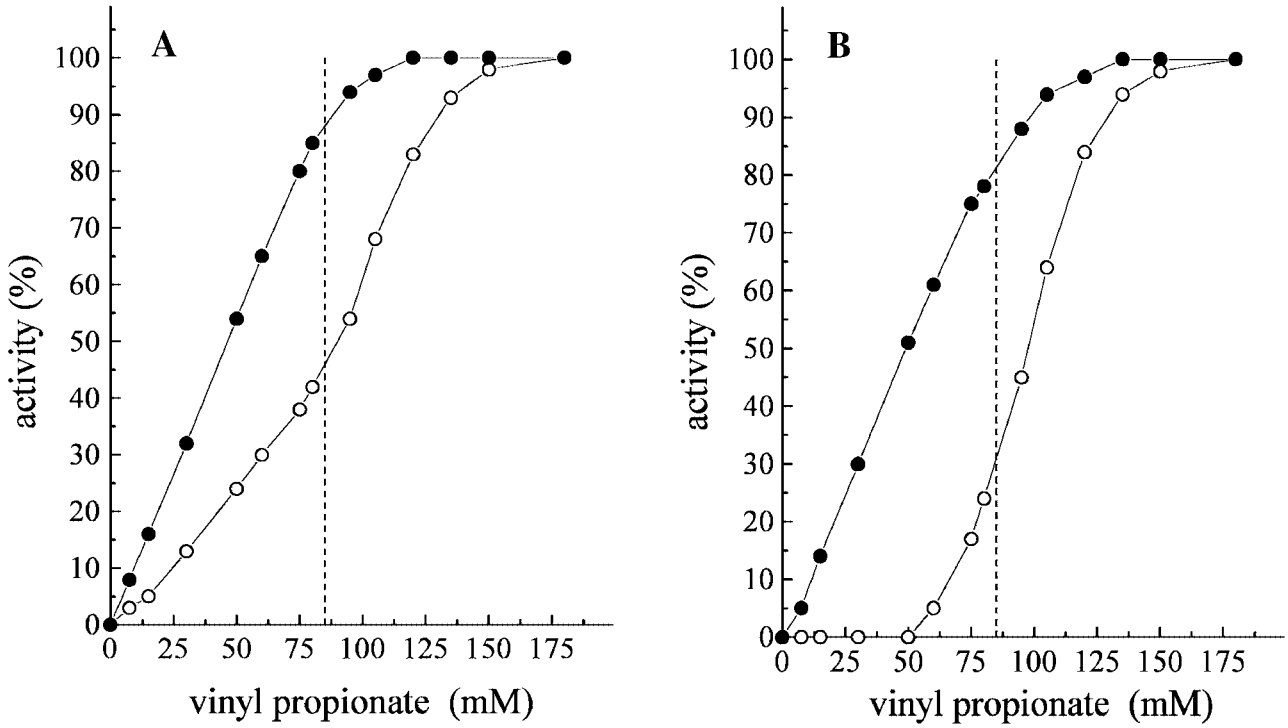

FIG. 2. Effect of substrate concentration on the rate of hydrolysis of vinyl propionate by *Penicillium cyclopium* lipase I (A) and II (B). Activity is expressed as percentage of maximal activity (V_{max}) measured at optimal ester concentration. The dotted line indicates the solubility of vinyl propionate (86 mM). Activity was determined at pH 7.0 and 25°C in 2.5 mM Tris-HCl buffer in the absence (○) and presence (●) of 100 mM NaCl.

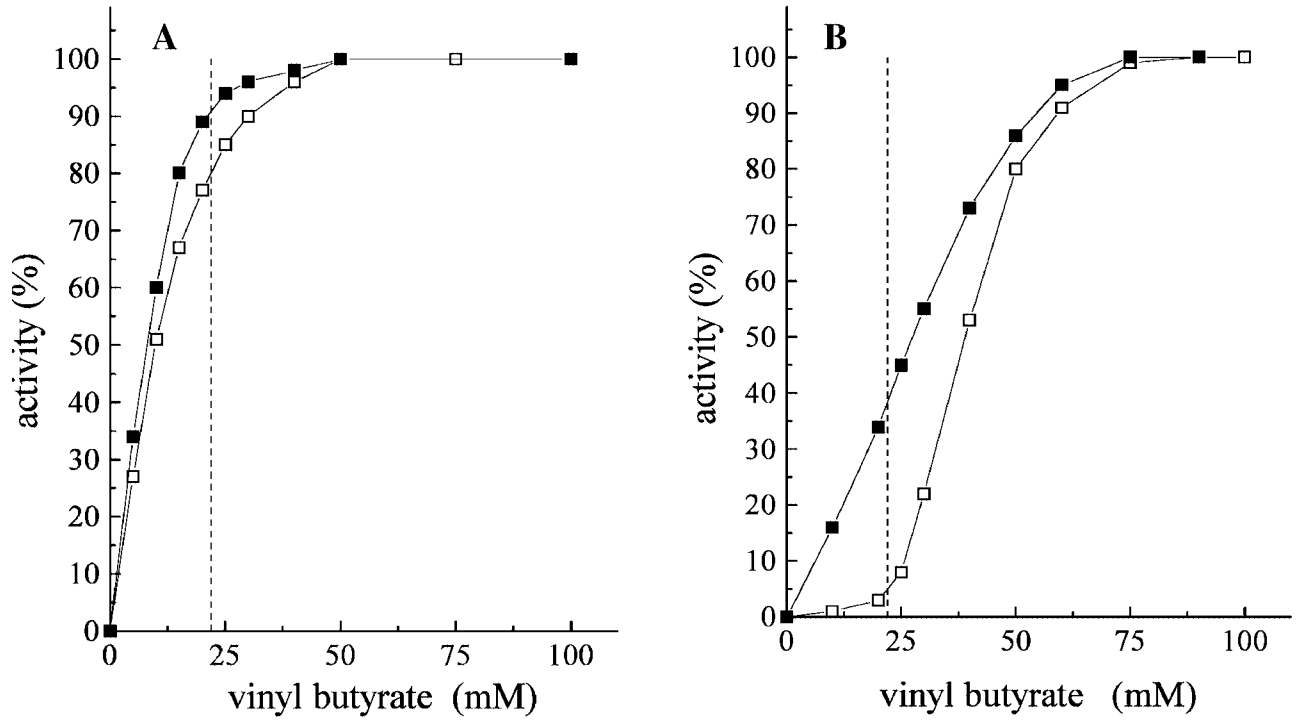

FIG. 3. Effect of substrate concentration on the rate of hydrolysis of vinyl butyrate by *Penicillium cyclopium* lipase I (A) and II (B). Assays were performed as described in Figure 2. The solubility of vinyl butyrate is indicated by the dotted line. Experiment performed in absence (□) and presence (■) of 100 mM NaCl.

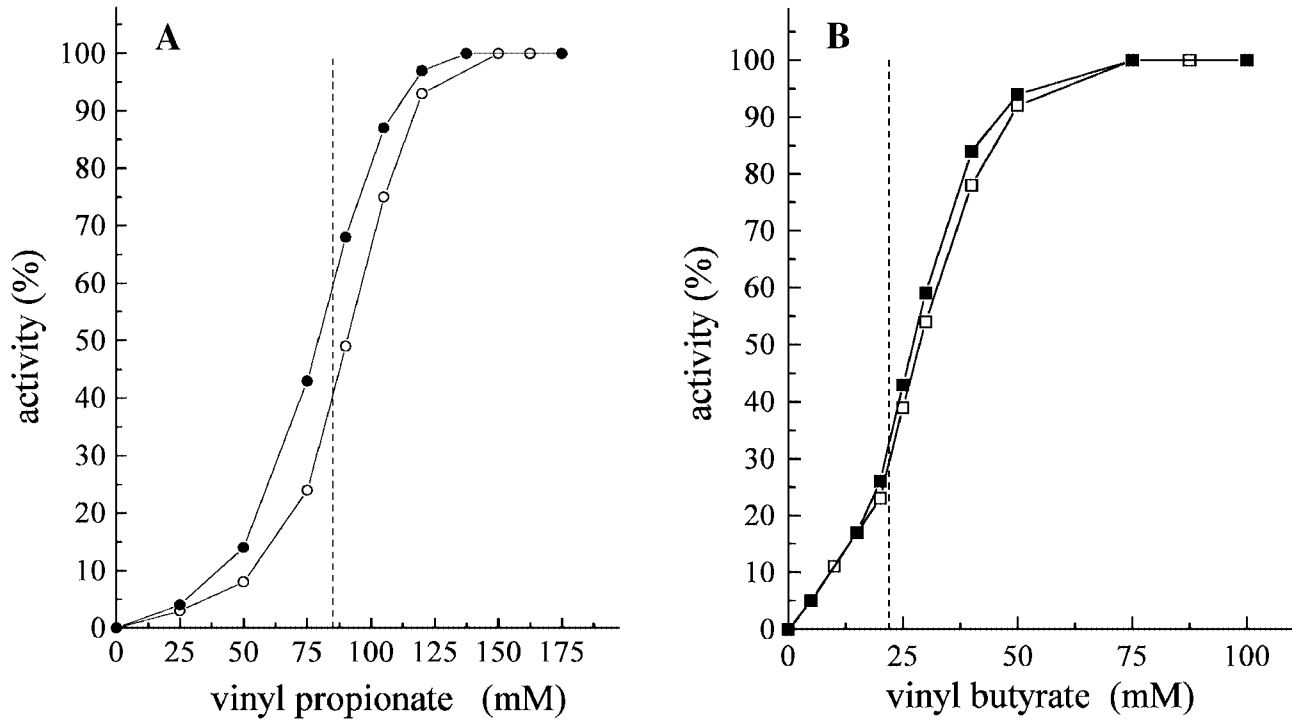

FIG. 4. Effect of substrate concentration on the rate of hydrolysis of (A) vinyl propionate and (B) vinyl butyrate by human pancreatic lipase. Assays were performed as described in Figure 2 except that enzymatic hydrolysis was measured at pH 8.0. Symbols are the same as in Figure 1, and dotted lines are as in Figures 2 and 3.

lipases I and II, the activity of pancreatic lipase increases with substrate concentration irrespective of the physical state of the vinyl ester, and in this assay system, the pancreatic lipase does not display interfacial activation.

Hydrolysis of tripropionin by P. cyclopium *lipase I and by human pancreatic lipase.* Results of comparative kinetic studies of the hydrolysis of tripropionin by triacylglycerol lipases from *P. cyclopium* (lipase I) and from human pancreas are shown in Figure 5. Curves of Figure 5A confirm the well-documented capacity of classical pancreatic triacylglycerol lipases from higher mammals to hydrolyze tripropionin in solution in the presence of NaCl (13,14). The relative rate of hydrolysis of a solution of tripropionin at saturating concentration is around 0.70 V_{max} compared with the maximal activity against an emulsion of the triacylglycerol (specific activity: 4,000 units mg^{-1}). In the absence of sodium chloride, the shape of the curve is unchanged although the curve is shifted toward higher concentrations of substrate. The same observations can be made from the curves representing the effect of substrate concentration on the rate of hydrolysis of tripropionin by *P. cyclopium* lipase I (Fig. 5B). The specific activity of lipase I calculated from the activity measured on emulsified tripropionin is 1,200 units mg^{-1} (Table 1).

It can be concluded from the results presented above that the triacylglycerol lipases from *P. cyclopium* (lipase I) and from human pancreas and the partial acylglycerol lipase from *P. cyclopium* (lipase II) hydrolyze short- and long-chain vinyl esters at high relative rates compared with their respective specific substrates (Table 1). Therefore, vinyl esters are suitable for comparing the hydrolytic activity of lipases of various origins and specificities. All lipases studied here display maximal activity against emulsions of vinyl esters. However, they hydrolyze solutions of slightly water-soluble short-chain vinyl esters, namely, vinyl propionate and vinyl butyrate, at variable relative rates compared with emulsions. Addition of NaCl to the reaction system enhances enzyme enzymatic lipolysis although it does not affect the solubility limit of the esters (Fig. 1).

The patterns of substrate concentration dependency of the rates of hydrolysis (*V/S* curves) of vinyl propionate, vinyl butyrate or tripropionin by *P. cyclopium* lipases or human pancreatic lipase (Figs. 2–5) do not show an abrupt increase in activity at the point of saturation of the solution, which corresponds to the transition from soluble to emulsified substrate. The lipases do not show the classical phenomenon of interfacial activation under the conditions used for assaying activity. In the kinetic studies reported in Figures 2–5, the *V/S* curves deviate from the shape of a rectangular hyperbola derived from the classical Michaelis-Menten model. For example, Figures 6A and B show double reciprocal plots (V^{-1}/S^{-1}) of the *V/S* curves shown in Figures 3A and 4A which are representative of the hydrolysis of vinyl butyrate by *P. cyclopium* lipase I and of vinyl propionate by human pancreatic lipase, respectively. It can be seen that the V^{-1}/S^{-1} curves are composed of two straight lines intersecting at the substrate concentration corresponding to the solubility limit of the substrate. Taken together, these observations are reminiscent of the results of studies of lipase-catalyzed hydrolysis of solu-

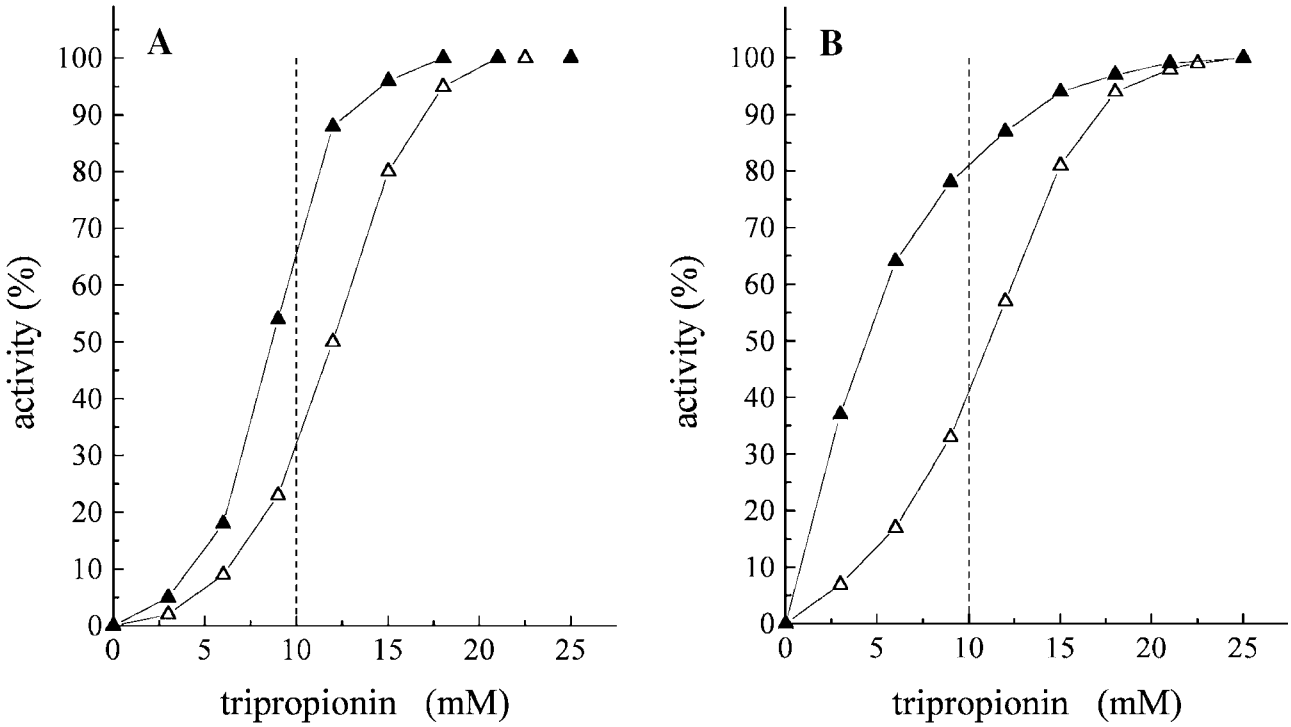

FIG. 5. Effect of substrate concentration on the rate of hydrolysis of tripropionin by (A) human pancreatic lipase and (B) *Penicillium cyclopium* lipase I. Assays were performed at 25°C and pH 7.0 (lipase I) or pH 8.0 (pancreatic lipase) in 2.5 mM Tris-HCl buffer in the absence (△) and presence (▲) of 100 mM NaCl. The solubility of tripropionin is indicated by the dotted line.

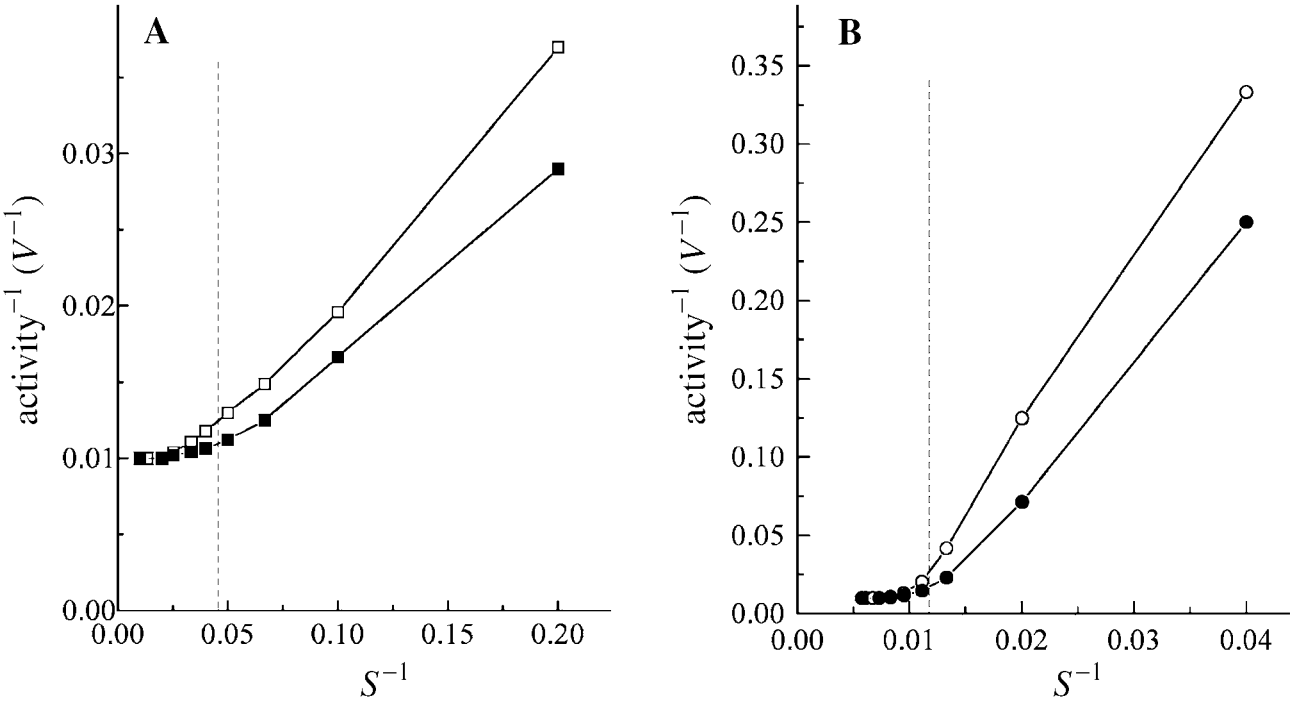

FIG. 6. Double reciprocal plots (V^{-1}/S^{-1}) for the hydrolysis of solution and emulsion (A) of vinyl butyrate by *Penicillium cyclopium* lipase I and (B) of vinyl propionate by human pancreatic lipase. Experimental data are taken from Figures 3A and 4A, respectively. Substrate concentration and relative activity are expressed as in Figures 2–5. Symbols are the same as in Figure 1.

tions of tributyrin or *p*-nitrophenyl butyrate. As reported recently, guinea pig pancreatic lipase, a type 2 pancreatic-related protein active on both triacylglycerols and phospholipids, shows high relative activity on solutions of tributyrin in the presence of NaCl and is not interfacially activated (18). Kinetic studies of *Candida antarctica* lipase B with solutions and emulsions of *p*-nitrophenyl butyrate have shown that the enzyme does not display interfacial activation, whereas lipase from *Thermomyces* (*Humicola*) *lanuginosa* shows unambiguous interfacial activation in the same assay system. The very low solubilities of tributyrin (0.4 mM) and *p*-nitrophenyl butyrate (1 mM) make it difficult to know whether the substrate molecules dispersed in the aqueous phase are in the monomeric or/and aggregated form; this information is needed to interpret the mode of action of the enzymes on soluble esters. It can be hypothesized that the irregularities of the *V/S* curves observed in the kinetic studies of lipase-catalyzed hydrolysis of solutions and emulsions of short-chain vinyl esters might reflect changes of the affinity constants and kinetic parameters due to phase transitions from monomers to micelles in optically clear solutions and from micelles to particles at ester concentrations beyond the solubility limit. The solubility limits of vinyl propionate (86 mM) and vinyl butyrate (22 mM), which are high compared with those of tributyrin and *p*-nitrophenyl butyrate, should allow further experimental determination of the physical state of the ester molecules in solution and provide valuable information on lipase-substrate interaction in view to interpret the lipase-catalyzed hydrolysis of soluble esters.

ABSTRACT: Insulin resistance and altered maternal metabolism in gestational diabetes mellitus (GDM) may impair fetal arachidonic acid (AA) and docosahexaenoic acid (DHA) status. The objectives were to test the hypothesis that fetal polyunsaturated fatty acids would be altered with GDM and identify factors related to fetal phospholipid (PL) AA and DHA. Maternal and cord vein erythrocyte PL fatty acids were determined in GDM (n = 13) and healthy pregnant women (controls, n = 12). Cord vein erythrocyte PL AA and DHA concentrations were significantly lower in GDM vs. controls. Maternal blood hemoglobin A_1C was inversely correlated to fetal erythrocyte PL DHA and AA in controls and GDM (n = 25). Pregravid body mass index was negatively associated with fetal PL DHA. The data support the hypothesis that there is impairment in fetal accretion of DHA and AA in GDM.

Paper no. L8366 in *Lipids 35,* 927–931 (August 2000).

Arachidonic acid (20:4n-6, AA) and docosahexaenoic acid (22:6n-3, DHA) play important roles in fetal growth and development (1,2). The ability of the fetus and neonate to synthesize long-chain polyunsaturated fatty acids (LC-PUFA) from precursor essential fatty acids (EFA) is relatively low (3,4). Thus, placental transfer of maternal AA and DHA is likely the major source for fetal accretion of these LC-PUFA *in utero* (4,5). Therefore, alterations in maternal polyunsaturated fatty acid (PUFA) metabolism and placental transfer during gestation would significantly impact fetal accretion of these essential PUFA.

EFA metabolism is altered in pathologies characterized by insulin resistance, such as insulin-dependent diabetes mellitus (6) and obesity (7). Further, impairment in placental transfer of AA *in vitro* in perfused placentas of women with insulin-dependent diabetes mellitus has been reported (8). Gestational diabetes mellitus (GDM) is a pathological condition in which glucose intolerance is recognized for the first time during pregnancy (9). Insulin resistance and alterations in maternal metabolism during the third trimester in pregnancy complicated with GDM (10,11) may alter placental transfer and fetal LC-PUFA accretion. To our knowledge, fetal PUFA status in pregnancy complicated with diet-treated GDM has not been studied. Therefore, the current study was undertaken with the following objectives: (i) to test the hypothesis that fetal phospholipid (PL) PUFA will be altered in pregnancy complicated with GDM and (ii) to determine maternal factors associated with fetal PL AA and DHA.

METHODS

Subjects and study design. Thirteen women diagnosed with GDM and 12 healthy pregnant women (controls) participated in this study. Criteria for subject recruitment and diagnosis of GDM have been previously reported (12,13). Women with GDM in this study were treated with diet which consisted of individualized diet plans following the recommendations for normal pregnancy (14).

Maternal erythrocyte PL fatty acids, fasting plasma insulin concentration, and blood hemoglobin A_1C (HbA_1C) were determined at term in women with GDM and controls. Cord vein erythrocyte PL fatty acids were determined at delivery in all subjects.

Data collection. Fasting maternal blood samples were collected at 36–39 wk gestation. Maternal blood (~10 mL) was sampled from the antecubital vein and collected in EDTA-containing tubes. Cord vein blood samples were collected into heparinized syringes using a double-clamp procedure. Maternal and cord vein erythrocytes were separated from plasma by centrifugation (1500 × g at 4°C for 10 min), portioned, and immediately stored at –80°C until analysis.

Abbreviations: AA, arachidonic acid; ANOVA, analysis of variance; BMI, body mass index; DHA, docosahexaenoic acid; EFA, essential fatty acid; GDM, gestational diabetes mellitus; HbA_1C, hemoglobin A_1C; LA, linoleic acid; LC-PUFA, long-chain polyunsaturated fatty acid; LNA, linolenic acid; PL, phospholipid; P/S, polyunsaturated to saturated fatty acid ratio; PUFA, polyunsaturated fatty acid; SFA, saturated fatty acid.

Maternal dietary PUFA intake during the third trimester was assessed using three 24-h recalls and analyzed using the University of Minnesota Nutrition Data System (NDS 2.91; Minneapolis, MN).

Sample analysis. Erythrocyte lipid was extracted by the Dodge and Phillips method (15). Methodologies for the separation of lipid classes, preparation of fatty acid methyl esters, and identification and quantification of individual fatty acids were previously published (12).

Statistical analysis. All statistical analyses were performed using the Statistical Analysis System software (16). The normal distribution assumption was checked for all the variables. Variables which were not normally distributed were log-transformed. One-way analysis of variance (ANOVA) was used to determine differences between the group means for the maternal descriptive data, age, parity, pregravid body mass index (BMI), length of gestation, fasting plasma insulin concentration (μU/mL), HbA_1C, neonatal data, and maternal dietary PUFA intake. Group differences in cord vein erythrocyte PL fatty acids were assessed using one-way ANOVA and analysis of covariance with maternal blood HbA_1C as the covariate. Paired *t*-tests were performed to compare cord vein with maternal vein PL linoleic acid (LA), linolenic acid (LNA), AA, and DHA (wt%). Pearson correlation and linear regression analyses were performed to study the associations of maternal plasma PL PUFA, HbA_1C, insulin concentration, pregravid body mass index (BMI), parity, and length of gestation to cord vein erythrocyte AA and DHA.

RESULTS

Maternal and neonatal characteristics of the study population are shown in Table 1. Women with GDM gained less weight during gestation compared with controls. GDM women had higher fasting plasma insulin concentration and blood HbA_1C than the controls at 36–39 wk gestation. Neonatal birth weight, birth length, ratio of birth weight to birth length, and head circumference adjusted for length of gestation and sex of the infant did not differ between the two groups.

Maternal mean estimated dietary intake of PUFA during the third trimester is shown in Table 2. Macronutrient and individual fatty acid intake of the controls and GDM have been reported (12). Women with GDM had significantly higher dietary intake of AA, eicosapentaenoic acid (20:5n-3, EPA), and DHA compared with controls.

Maternal and cord vein erythrocyte fatty acids are presented in Table 3. Cord vein erythrocyte PL (wt% and μg/mL) n-6 and n-3 LC-PUFA were different for GDM vs. controls. AA and DHA (wt% and μg/mL) were lower (by approximately 28%, $P = 0.02$ and 37%, $P = 0.005$ in wt%, respectively) in the cord vein erythrocyte of women with GDM than the controls. Further, cord vein erythrocyte PL (wt% and μg/mL), ∑n-6 PUFA, ∑n-3 PUFA, and DHA sufficiency index (ratio of 22:6n-3 to 22:5n-6 wt%) were lower in women with GDM compared with controls. In contrast, saturated fatty acids (SFA), 16:0, 18:0, and ∑SFA (wt%) were higher by approximately 12% ($P = 0.05$), 33% ($P = 0.02$), and 21%

(P = 0.02), respectively, in cord vein erythrocyte in GDM subjects relative to controls. Cord vein erythrocyte PL P/S (polyunsaturated to saturated fatty acid wt%) ratio was lower in women with GDM than controls.

Cord vein erythrocyte PL (wt%) LA and LNA were significantly lower compared with maternal PL LA and LNA, respectively, in controls and GDM (Table 3). On the other hand, their long-chain derivatives, AA and DHA (wt%) were higher in the cord vein erythrocyte PL than the maternal vein PL AA and DHA (wt%), respectively, in controls. In contrast, in women with GDM, PL DHA (wt%) was significantly lower in cord vein erythrocyte PL than the maternal PL DHA. A similar trend was observed in the fetal–maternal difference for erythrocyte PL AA (wt%) in women with GDM.

Maternal plasma PL AA (wt%) was positively associated with fetal erythrocyte PL AA wt% (r = 0.83, P = 0.003, n = 12) in controls. Similarly, maternal plasma PL DHA (wt%) showed significant positive correlation with fetal erythrocyte PL DHA wt% (r = 0.62, P = 0.04, n = 12) in controls. In contrast, in GDM women there was a trend for a negative association between maternal plasma PL DHA and fetal erythrocyte PL DHA wt% (r = –0.54, P = 0.08, n = 13). There was no correlation between maternal plasma and fetal erythrocyte PL AA wt% in women with GDM (r = –0.10, P = 0.77, n = 13).

Maternal glucose control, measured by blood HbA_1C at 36–39 wk gestation, showed a significant negative association with fetal erythrocyte PL DHA and AA wt% (r = –0.53, P = 0.02, and r = –0.51 and P = 0.03, respectively) in controls and GDM combined (n = 25). Additionally, maternal pregravid BMI (kg/m^2) was inversely related to fetal erythrocyte PL DHA wt% (r = –0.45, P = 0.05, n = 25).

DISCUSSION

The current study demonstrates decreased DHA and AA (wt% and μg/mL) in cord vein erythrocyte PL in GDM treated with diet compared with controls. The decrease in the LC-PUFA in fetal erythrocyte PL was accompanied by higher proportions of SFA in women with GDM. Fetal erythrocytes play a key role in the provision of maternal LC-PUFA, particularly DHA and n-3 LC-PUFA, to the fetus (17). Placental transfer of maternal LC-PUFA to the fetus may occur *via* exchange with fetal erythrocyte membranes and preferential enrichment of erythrocyte membrane PL with DHA and AA (17). Given the potential significance of this transport mechanism, lower DHA and AA in the cord vein erythrocyte PL provide evidence for impaired fetal accretion of these LC-PUFA in pregnancy complicated with GDM.

In controls, enrichment of AA and DHA in fetal erythrocyte PL relative to maternal PL AA and DHA (wt%), respectively, is consistent with the findings of previous studies (18,19). However, in women with GDM, lower fetal PL DHA compared with maternal PL DHA (wt%) and a lack of fetal–maternal difference for PL AA (wt%) suggest that placental transfer of maternal LC-PUFA during the third trimester may have been altered in GDM. Further, higher maternal dietary intake of DHA and AA and elevated maternal PL DHA in GDM women compared with controls, coupled with lack of correlation between maternal and fetal PL DHA and AA in GDM, support the above hypothesis.

In women with GDM, fetal erythrocyte total fatty acid concentration in PL was lower compared with controls (189.2 ± 28.5 vs. 251.3 ± 30.4 μg/mL, respectively), whereas maternal PL total fatty acids were elevated (573.7 ± 85.8 vs. 460.4 ± 103.2, respectively). Decrease in the absolute concentrations of PL per unit cholesterol in cord erythrocytes membranes and/or impairment in the assimilation of fatty acids into cord erythrocyte membrane PL in GDM subjects due to altered erythrocyte membrane function may underlie these changes. Whether these changes in fatty acid concentrations of cord erythrocyte membranes lead to alterations in oxygen-carrying capacity of fetal erythrocytes and other erythrocyte membrane-related functions in GDM needs to be investigated.

Maternal glycemic control in the third trimester and pregravid BMI were associated with fetal erythrocyte PL DHA in this study population. GDM subjects treated with diet in the present study had blood HbA_1C values within the accepted clinical range of 4–6% (9), indicating that glucose control was not severely compromised. However, maternal blood HbA_1C was significantly elevated in GDM women compared with controls, suggesting moderate impairment of glucose control in GDM. Further, there was little overlap for individual HbA_1C values between GDM and control subjects. These findings point to altered blood glucose control in women with GDM relative to controls as an important maternal factor associated with the lower fetal LC-PUFA status in GDM. Additionally, the present study suggests that pregravid obesity may be an independent maternal factor associated with impaired *in utero* DHA accretion in the fetus. This finding warrants further investigation.

In summary, fetal cord vein erythrocyte PL (wt% and μg/mL) AA, DHA, ∑n-6, and ∑n-3 PUFA were lower in women with diet-treated GDM than the controls. Maternal blood HbA_1C and pregravid BMI were inversely related to

TABLE 3
Maternal and Fetal Erythrocyte PL Fatty Acids in Controls (n = 12) and Women with GDM (n = 13)[a]

REVIEW

Current Methods for the Identification and Quantitation of Ceramides: An Overview

Aida E. Cremesti* and Anthony S. Fischl[1]

The University of Rhode Island, Department of Food Science and Nutrition, West Kingston, Rhode Island 02892

ABSTRACT: Ceramides are key compounds in the metabolism of sphingolipids and are emerging as important second messengers for various cellular processes including cell cycle arrest, differentiation, senescence, apoptosis, and others. Because of their important biological functions, exact analysis of their molecular species and concentrations is crucial for elucidating their function and metabolism. Toward this goal, several methods have been developed for the identification and quantitation of cellular ceramide levels. Methods have been developed utilizing thin-layer or high-performance liquid chromatography. Mass spectrometry also has become increasingly utilized. The *Escherichia coli* diacylglycerol kinase assay is one of the most frequently used techniques for ceramide quantitation. This review presents a current summary of methods used for the identification and quantitation of ceramides.

Paper no. L8419 in *Lipids 35*, 937–945 (September 2000).

The major role of phospholipids and sphingolipids was previously thought to be structural, whereby they establish a barrier for cell permeability and form a matrix for the association of membrane proteins (1,2). With the discovery that sphingosine acts as a potent inhibitor of protein kinase C (3), sphingolipids were thrust into a central role in signal transduction and cell regulation. Various experimental approaches have suggested that ceramide is a key signaling molecule generated in response to a variety of stresses that mediate growth arrest, differentiation, senescence, apoptosis, or an immune response (4–10). Recently, ceramides and sphingoid bases (SB) have been shown to be involved in the stress response of the yeast *Saccharomyces cerevisiae* to heat shock (11–13). Sphingolipids are involved in various aspects of the stress responses and metabolism in yeast (reviewed in Ref. 10). Ceramide has been proposed to be the intracellular mediator of some agents like γ-interferon, dexamethasone, tumor necrosis factor-α (TNF-α), interleukin-1β, and vitamin D_3 (6,7). These agents induce the hydrolysis of plasma membrane sphingomyelin (SM) by a sphingomyelinase, followed by the downstream activation of several cellular targets that mediate the cellular actions of ceramides.

Lipid-dependent cell signaling represents a rapidly expanding field. The growing interest in this field and its significance makes an accurate and quantitative determination of intracellular second messengers both necessary and desirable. It is difficult to isolate free ceramide quantitatively and in completely pure form since its content in biological materials is quite low, being less than 1% of the total extractable lipids (14). However, because ceramides are key compounds in the metabolism of sphingolipids and are thought to be important second messengers, exact analysis of their molecular species and concentrations would seem to be crucial for elucidating their function and metabolism. Toward this goal, several methods have been developed for the identification and quantitation of cellular ceramide levels utilizing a wide variety of analytical and enzymological techniques. And although every method has its advantages and inherent weaknesses, recent reports have raised serious questions about the validity of some of the most frequently used methods for ceramide quantitation (15–17). The following review presents a summary of the various methods and techniques used for the identification and quantification of ceramides in different types of tissues and cells.

The use of chromatography for ceramide quantitation. Structurally, ceramide consists of a long-chain amino alcohol, referred to as SB or long-chain base (LCB), covalently linked *via* an amide linkage to a fatty acyl chain (Fig. 1). The SB and fatty acid could vary in length, degree of unsaturation or hydroxylation, giving rise to a very complex and diverse group of molecules, the ceramides. These lipid molecules have proven to be very difficult to study due to their apolar nature, enormous diversity, and relatively low levels in biological samples.

The lack of a chromophore in the ceramide molecule makes it impossible to identify these molecules using ultraviolet (UV) detection. Various methods have been developed based on the derivatization of ceramides with fluorescent or

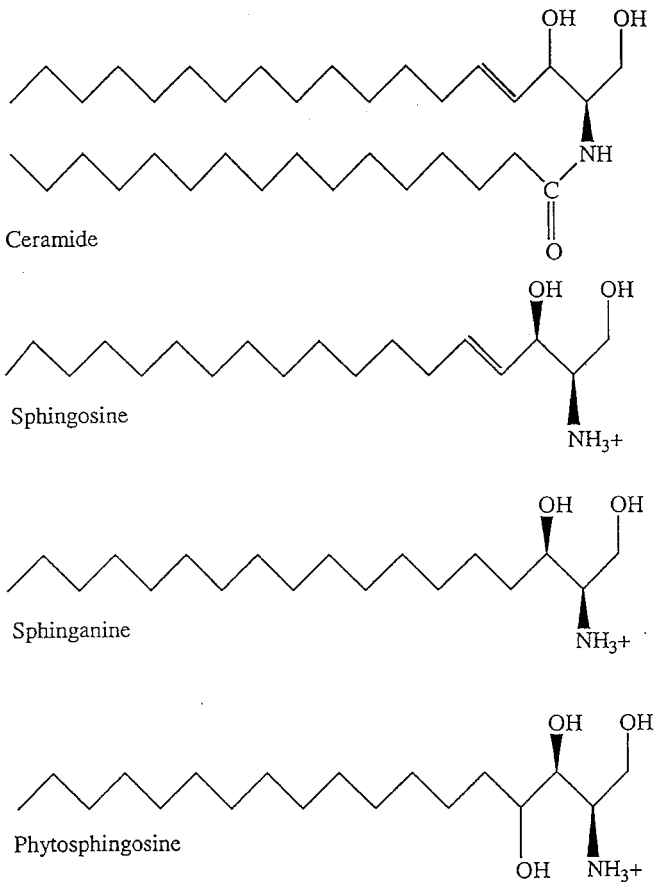

FIG. 1. Chemical structure of ceramide and sphingoid bases.

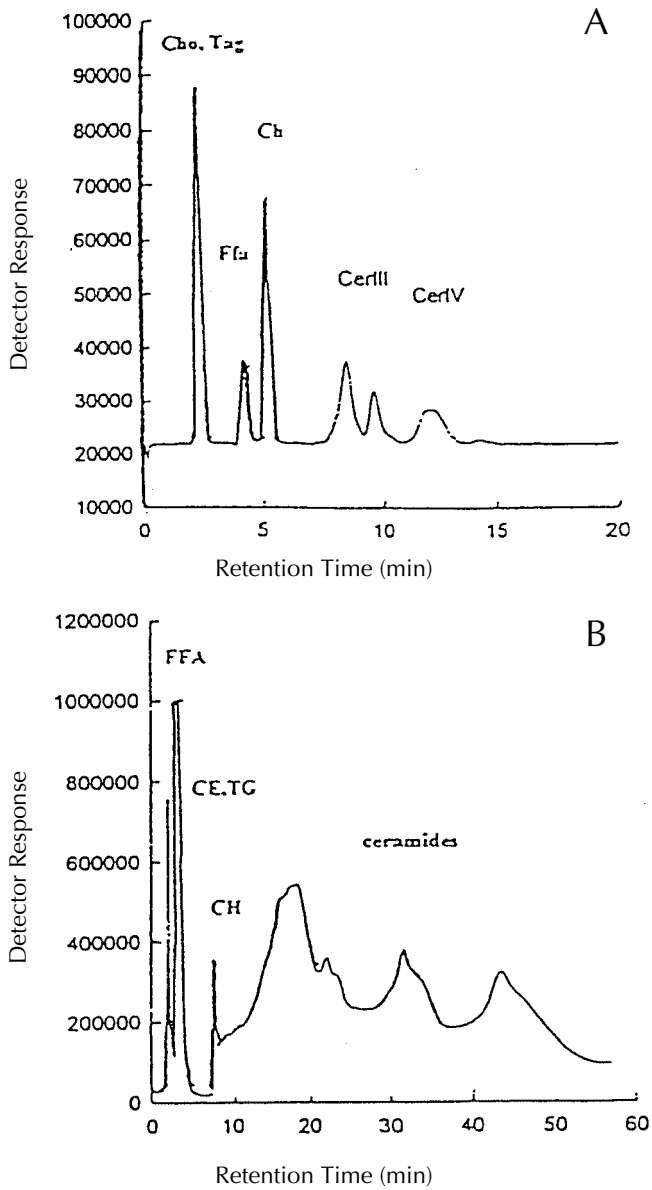
UV-absorbing compounds and the subsequent identification and quantitation of the derivatized ceramides. The use of high-performance liquid chromatography (HPLC) has been reported for the quantitation of ceramides; however, the full potential of this analytical tool for the separation and quantitation of ceramides has yet to be achieved. HPLC has been used owing to its rapidity, reproducibility, and sensitivity in addition to the high degree of resolution attained with the use of the proper stationary and mobile phases.

Iwamori *et al.* (14) were the first to develop a method for the derivatization of ceramides with benzoyl chloride or benzoyl anhydride, leading to the production of *N*-acyl derivatives which absorb UV light strongly in the 230–280 nm range, depending on the type of ceramide. Benzoylation was achieved by incubation with benzoyl chloride or benzoyl anhydride and pyridine for 3 h at 70°C. For ceramides containing nonhydroxy fatty acids (NHFA), benzoyl anhydride was preferred because the *N*-acyl benzoyl derivatives of ceramides overlapped with methyl benzoate, a by-product of the reaction with benzoyl chloride, on thin-layer chromatography (TLC) and HPLC. For hydroxy fatty acid (HFA)-containing ceramides, treatment with benzoyl chloride was necessary to achieve perbenzoylation, and prolonged reaction times of 4 h were necessary because the 2-hydroxy group of the fatty acid moiety would interfere in the formation of the *N,N*-acyl benzoyl derivative due to steric hindrance (14). Ceramides were separated by normal-phase (NP) HPLC with a silica gel column using hexane/ethyl acetate (94:6, vol/vol) or 0.05% methanol in pentane as mobile phase. Authors reported a recovery of 85–90% for various ceramides, and the response was linear within the 10–100 nanomole range (14). This method allowed for the quantitative determination of ceramide levels in various samples (14,18). Recently, a modified version of this method was used for quantifying ceramide levels in the yeast *S. cerevisiae* using hexane/dioxane (93:7, vol/vol) as mobile phase and a Lichrosorb silica column (Micro Pak, Varian Associates, Palo Alto, CA) as stationary phase (19). However, despite its good quantitative results, this procedure is cumbersome and time-consuming. The reaction is very sensitive to water, and even traces have to be removed to achieve complete benzoylation. The chemicals involved, benzoyl chloride and pyridine, have to be prepared fresh each time and stored and handled anhydrously. These chemicals are extremely toxic, and benzoyl chloride is carcinogenic. Also, radioactive ceramide has to be prepared and used as an internal standard in order to determine the recovery and percentage of benzoylation for quantitation purposes. For derivatization to be of optimal use, the reaction should yield only one derivative per analyte, and the derivative should be resistant to hydrolysis, solvolysis, and thermal decomposition (20). A major disadvantage of most derivatization procedures is the low stability of the derivatized products, which demands that samples not be stored for prolonged times and analysis be done shortly after derivatization (18).

The use of fluorescent tags to label and quantify ceramides has been reported as well. Previati *et al.* (21) developed a method for determining ceramide levels after coupling of the free oxydril group of ceramide to the carboxylic group of the fluorescent label 6-methoxy-α-methyl-2-naphthalene acetic acid. The reaction was achieved after prolonged incubation at –20°C under anhydrous conditions. The authors reported an 80% yield after 3 h of incubation. Separation of ceramides was achieved by using an Econosphere CN column (Phase Sep, a subsidiary of Waters, Inc., Milford, MA) as stationary phase with a gradient of isopropanol in hexane as mobile phase. Linearity was reported in the 5–100 ng range with fluorescent detection and 50–5000 ng with UV absorbance (21). However, inhibition of the reaction could arise from the oxydril group of phospholipids, which necessitates some extra purification steps before the initiation of the reaction to remove interfering lipids and optimize the reaction conditions (21). In addition, radioactive internal standards should be used in order to determine the percentage conversion and recovery of the reaction. Yano *et al.* (22) developed a method for the quantitative analysis of molecular species of ceramide and dihydroceramide by reversed-phase (RP) chromatography. Various *N*-acyl- chain-containing ceramides were synthesized as standards and derivatized with anthroyl-cyanide, a fluorescent reagent. The derivatization process was conducted in the presence of acetonitrile/dichloromethane containing quinuclidine at 4°C overnight. Anthroyl derivatives

of ceramide and dihydroceramide were analyzed with HPLC using a Lichrosorb PR-18 column with a fluorescence detector. Isocratic mode of elution was used with acetonitrile/methanol/ethyl acetate (12:1:7, by vol) as mobile phase and a flow rate of 1.2 mL/min. Successful separation of 17 different species of ceramide and dihydroceramide was achieved in a 40-min run. Species were separated according to fatty acid chain length and SB backbone, whereby retention times increased with increasing number of carbon atoms in the fatty acid chain. The linear range for quantification was reported to be from 1 to 18 picomoles of ceramide. This method could be useful for elucidating the functions of particular subspecies of ceramide since it can effectively separate them. However, long incubation times for successful derivatization pose a drawback. Santana *et al.* (23,24) used a modification of the method developed by Merrill *et al.* (25) for determining sphingosine levels and used it for the quantification of ceramide. The procedure is based on the fact that ceramide can be deacylated to generate free sphingosine, which in turn can be derivatized with *O*-phthaldehyde reagent to form a fluorescent compound. Lipids were separated on a Nova pack C-18 RP-HPLC column (Waters, Inc.) run isocratically with methanol/5 mM potassium phosphate (90:10, vol/vol) at 0.6 mL/min. A fluorescence detector at 340 nm excitation and 455 nm emission wavelength was used to identify ceramides.

The full potential of the resolving power of HPLC in the separation and analysis of simple and complex lipid classes from tissues was not achieved until the introduction of the evaporative light-scattering detector (ELSD), which is a mass detector. The use of ELSD for ceramide detection and quantitation could offer a unique approach which would enable direct analysis without any prior derivatizations (26). There are many advantages to the use of ELSD for the analysis of lipid classes. This type of detector is ideal for the analysis of solutes which do not have a UV chromophore, where the chromophore has a low extinction coefficient, or where the mobile phase contains a chromophore (27). The ELSD is designed to separate nonvolatile solute particles from a volatile eluant. By using this detector, the solvent emerging from the HPLC column is evaporated in a stream of nitrogen gas; the solute does not evaporate and passes in the form of minute droplets through a light beam which is reflected and refracted. The amount of scattered light is measured and bears a relationship to the mass of the sample (26). Quantitation with ELSD can be achieved since the response is a function of mass. However, the relationship is generally not linear (27). The use of this detector has greatly simplified the separation of lipid classes. This type of detector has been used with a ternary gradient pump system to separate all simple and complex lipids from tissues in a single chromatographic run (28). For this, ELSD has become the method used most often in the detection of lipids by HPLC. Several methods based on ELSD have been reported for the identification and quantitation of ceramides. Gildenast and Lasch (29) have used ELSD for the detection of ceramides from stratum corneum lipid extracts. They developed a NP-HPLC method using Lichrospher silica as stationary phase and ethanol/hexane (1:19, vol/vol) as mobile phase. Samples were concentrated with the use of a semipreparative HPLC column in order to make the ceramides detectable from those extracts (Fig. 2). This method was sensitive enough to separate ceramide type III, containing NHFA, from ceramide type IV, containing HFA, which is more polar. Wells *et al.* (13) developed a NP-HPLC method with ELSD using



Lichrosorb silica gel column as the stationary phase and a gra-

dient mobile phase consisting of various proportions of methanol in chloroform. This method is fast, does not require any preliminary purifications, and can be used to identify and quantitate ceramides in crude lipid extracts, provided the appropriate authentic standards are used. McNabb *et al.* (30) were the first to develop an NP-HPLC method to separate ceramides and SB simultaneously using an ELSD detector. Methods for the quantitation of SB have been mainly limited to derivatization techniques (25). Van Veldhoven *et al.* (31) also developed an enzymatic assay to quantitate sphingosine after converting it to ceramide by acylation and using the *E. coli* diacylglycerol (DAG) kinase assay. McNabb *et al.* (30) achieved separation of ceramides from SB in yeast lipid extracts on both silica gel and diol bonded phase columns with an isocratic flow of chloro-

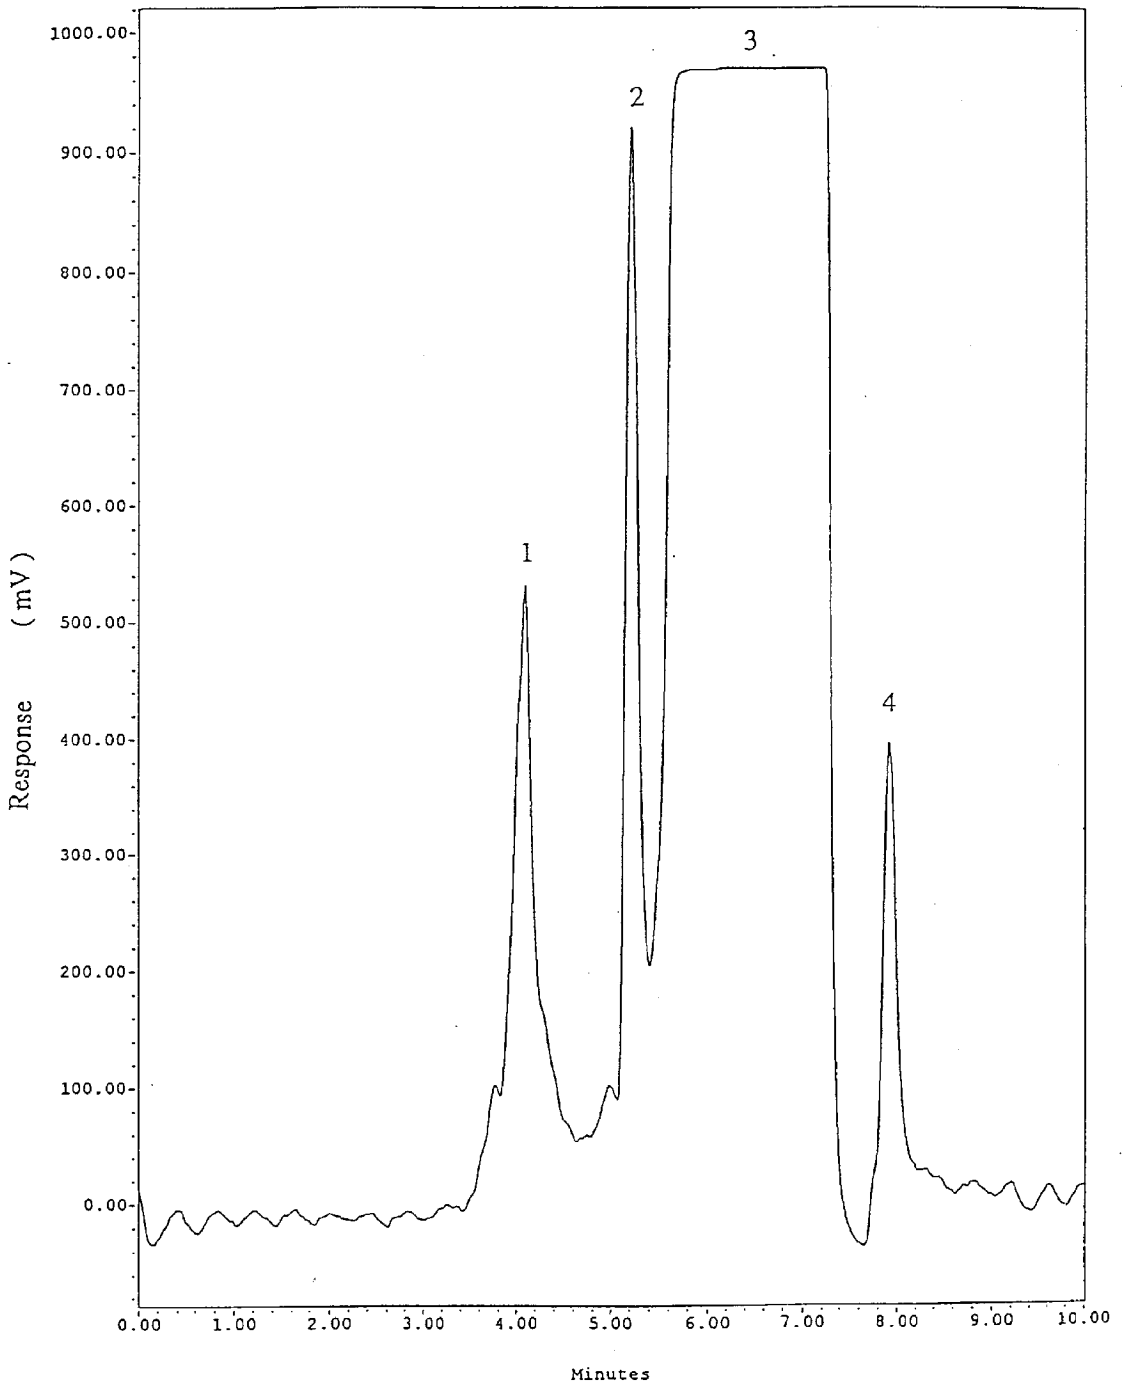

FIG. 3. Chromatograms of lipid extracts from yeast obtained by McNabb *et al.* (27). Lipids were separated on a silica gel column and a mobile phase of chloroform/ethanol/triethylamine/formic acid and detected using an ELSD detector. Peaks: 1, hydroxy fatty acid ceramide; 2, C-2 ceramide; 3, sphingolipid; 4, phytosphingosine. Peaks were identified by comparison of retention times to those of pure authentic standards. See Figure 2 for other abbreviations.

form/ethanol/triethylamine/formic acid (90:10:1:1, by vol) at a flow rate of 0.5 mL/min. Figure 3 shows a chromatogram of a typical complex yeast lipid extract obtained by McNabb *et al.* (30). The method was capable of separating ceramides containing HFA and NHFA and ceramides with fatty acids of varying chain lengths (30). The authors reported sensitivity in the nanomole to picomole range. This is the first method developed capable of separating several subspecies of ceramides and SB in a single run.

A major disadvantage for the quantification of lipids by ELSD is the lack of a simple rectilinear relationship between sample size and the response (28). The nature of the lipid sample and the mobile phase also will exert an effect. However, if calibration is performed with the appropriate standards, high precision and accuracy can be achieved (28). HPLC-based methods offer sensitivity, excellent resolution, reproducibility, and short analysis times. Resolution could be improved by the use of smaller-sized particles for the stationary phase and various modifiers for the mobile phase. Also, sensitive methods could be developed that would allow the separation of various subspecies of ceramides, varying in fatty acid chain length, or the nature, degree of unsaturation or degree of hydroxylation of the SB. RP-HPLC could be particularly useful for the separation of various types of LCB (25).

Much more common in the literature are methods for the separation and isolation of ceramides based on TLC techniques (32–36). Lipid extracts are usually subject to mild alkaline hydrolysis followed by TLC separation on silica gel plates with different proportions of chloroform/methanol/acetic acid. Identification of ceramides is usually done by staining with copper sulfate in orthophosphoric acid or 8-anilino-1-naphthalene sulfonic acid and quantitation is done by densitometry (34). Frequently, various radioactive precursors have been used for labeling cells and following their incorporation into radioactive ceramide (37–41). Motta *et al.* (34) optimized a method based on TLC separation of lipid extracts derived from human stratum corneum cells, followed by scanning densitometry for the identification and quantitation of various types of ceramides using TLC silica gel plates and chloroform/methanol/glacial acetic acid (190:9:1, by vol) as mobile phase (34). This method was sensitive enough to separate ceramides into five different fractions based on the presence or absence of hydroxyl groups in the fatty acid or long-chain base moieties. However, separation of the ceramide species could not be achieved by a single TLC run and required separation of the ceramide fraction first, concentration, and a second TLC run (34). Although this method is sensitive and quantitative significant problems are associated with it. Preparative TLC is sensitive to sample overload and is time-consuming and cumbersome. Also, the capacity of high-performance TLC is too low to separate substantial amounts of ceramides, a drawback for the use of this method for preparative operations. In this respect, HPLC is more efficient and provides a higher recovery.

Radiolabeling of sphingolipid metabolites by various radioactive precursors and subsequent extraction and separation by TLC has been widely used for ceramide identification and quantitation (19,37–40,42). However, care should be taken with the choice of radioactive precursor. The use of tritiated [^{3}H]palmitate would introduce a heavy bias toward the palmitate-containing sphingolipids. Also, radioactive palmitate might be metabolized through other pathways, such as β-oxidation, leading to the production of radioactive by-products, especially with the use of [^{14}C]palmitate. [^{3}H]dihydrosphingosine (DHS) has been shown to be taken up readily into the cells and utilized to make all known classes of complex sphingolipids (37). Uptake of [^{3}H]DHS is greatly enhanced by using detergents and by blocking the synthesis of endogenous DHS with inhibitors of serine palmitoyl transferase (SPT), the first enzyme in the *de novo* biosynthesis of sphingolipids. Labeling with [^{3}H]serine has also been used for separation of ceramides (23,24,42) since it is used by SPT for the synthesis of long-chain SB. Usually, growing cells are incubated with the radioactive precursor for varying lengths of time after which lipids are extracted and isolated on TLC plates. Quantitation is done by scanning the amount of radioactivity with phosphor imagers or incubation of the plates with X-ray film, identifying the spots, scraping them, and estimating the amount of radioactivity by liquid scintillation counting. Santana *et al.* (23,24) used this technique to quantitate ceramides and SM in HL-60 cells after labeling cells with [^{3}H]serine for 24–48 h, followed by alkaline hydrolysis to remove phosphatidylserine that might interfere with separation on TLC. These techniques allow for the identification of ceramides but are not an accurate depiction of the actual amount of ceramide present in the cells. Since not all the radioactive precursor is taken up into the cells and since the synthesis of nonradioactive endogenous precursors cannot be stopped, it becomes impossible to determine the exact amount of ceramide produced by the cells. These methods are more applicable to pulse-chase type of experiments, in studies on the relative amounts of ceramide produced in cells grown under different conditions, or in monitoring the transport and metabolism of lipids (42), rather than determining the exact amount of ceramides formed by the cell *per se*. Thus, even though ceramide labeling with tritiated precursors has been widely used, it does not provide real mass data, and care should be taken with the choice of radioactive precursor. If the precursor chosen is a fatty acid, it will co-extract with the labeling products and the separation of sphingolipids from glycerolipids cannot be achieved in a single TLC run, thus requiring either a glycerolipid hydrolysis step to remove the radioactive fatty acid in the aqueous phase, or several TLC steps to achieve the separation. Also, these studies often require very large amounts of starting material, extensive chromatographic separations, prolonged incubation times, and have very low yields of radiolabeled products, in addition to the low sensitivity and detection limits characteristic of TLC.

The use of mass spectrometry (MS) for ceramide quantification. MS is a powerful tool for determining the levels of endogenous physiologically active compounds because of its high level of sensitivity and selectivity. MS identifies a mole-

cule on the basis of its mass to charge ratio (*m/z*). Electrospray ionization MS (ESI/MS) and tandem MS (ESI–MS/MS collision-induced decomposition) have been successfully used for several years mainly for the analysis of proteins and peptides (17) and have more recently been extended to the analysis of other molecular species, such as carbohydrates and glycolipids (43,44). Rubino *et al.* (45) used fast atom bombardment, precursor and fragment ion analysis MS to characterize the fatty acid and LCB composition of a complex mixture of ceramides obtained from beef brain lipid extracts. Precursor ion analysis allowed recognition of ceramides with 14 different fatty acid chains. Kerwin *et al.* (44) have used positive and negative ion electrospray MS and MS/MS (tandem MS) to identify glycerophospholipid and ceramide headgroups and their alkyl, alkenyl, and acyl constituents. In ESI, molecules are injected onto the electrospray interface as dilute solutions to obtain positive ions. These ions are usually formed by protonation of covalent analytes or by dissociation of ionic compounds. Gu *et al.* (46) developed a method for the separation and quantification of ceramides based on ESI–MS/MS technique where collision-induced decomposition of ceramides produced ions of different spectra that were identified and compared to those of standards (46). The authors reported sufficient resolution and sensitivity with this technique to allow the detection of subpicomolar amounts from samples (15,46), requiring minimal amounts of starting biological material. This method is rapid and sensitive enough to determine the relative amounts of sphingosine and sphinganine subspecies of ceramide using C-2 ceramide as an internal standard. Authors separated and identified several species of ceramide differing in fatty acid chain length and degree of unsaturation of the SB backbone. However, this technique was used for determining ceramide levels in cells only after the crude lipid extracts were subject to silica gel chromatography to remove polar lipids that would interfere with the ESI–MS analysis and suppress the signal (15,46). Care should be taken in preparing the samples because overdilution of cellular lipids would result in a high degree of variation in the detected signal intensities. This necessitated that fractions be concentrated on silica gel columns, separated, and redissolved in the right amount of solvent before subjecting to ESI–MS (46). Watts *et al.* (15) used this method to determine ceramide levels in cells following the activation of the Fas receptor, and in cells following treatment with TNF (17), and were able to quantitate ceramides from as little as 2.5 $\times 10^7$ cells. Mano *et al.* (47) developed a liquid chromatography-ionspray tandem MS (LC/MS/MS) technique for ceramide quantification. Separation of lipid classes, which preceded MS/MS, was done on a C-18 silica gel RP column using HPLC with a gradient mobile phase of ammonium formate/methanol/tetrahydrofuran (47) (Fig. 4). However; the presence of a stream splitter was necessary before the ionspray interface because the sensitivity of ionspray MS is greatly reduced with high solute concentrations (47). This method allowed for the quantification of ceramides over a range of 0.1–100 ng/10^4 cells. Couch *et al.* (48) have even utilized an atmospheric pressure chemical ionization MS method for determining ceramide

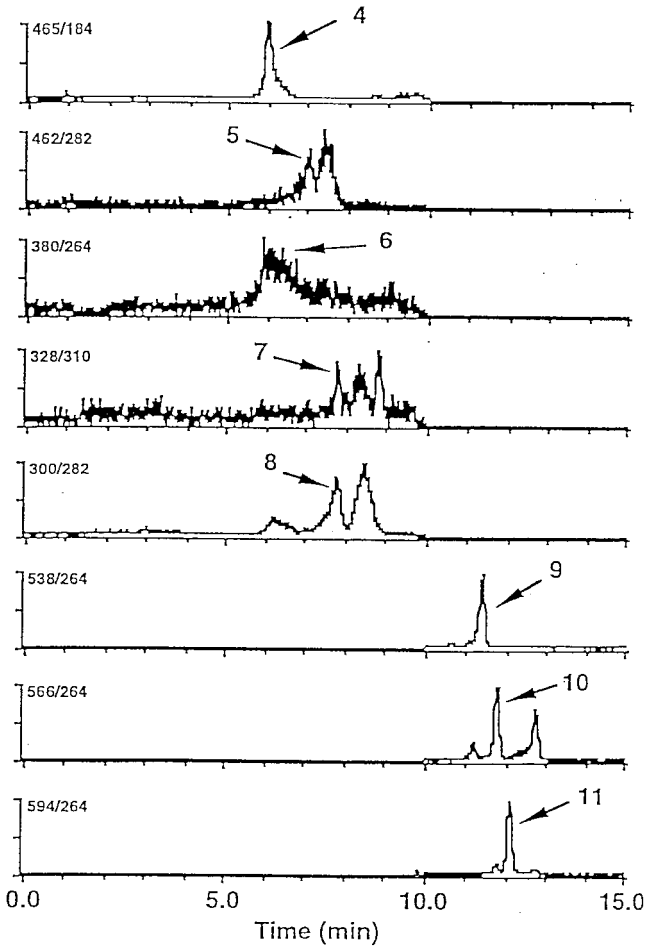

FIG. 4. Typical chromatograms of endogenous sphingolipid metabolites in HL-60 cells obtained by Mano *et al.* (47) using liquid chromatography–ion spray tandem mass spectrometry (MS/MS). Separation of lipid classes which preceded MS/MS was done on a C-18 silica gel reversed-phase column with a gradient mobile phase of formate/ methanol/tetrahydrofuran. (4) Sphingosyl phosphoryl choline; (5) psychosine; (6) sphingosine-1-phosphate; (7) dimethylsphingosine; (8) sphingosine; (9) C-16 ceramide; (10) C-18 ceramide; (11) C-20 ceramide. Numbers on the upper left indicate the *m/z* of precursor ion (first number) and product ion (second number). (1997) Simultaneous Quantitative Determination Method for Sphingolipid Metabolites by LC/Electrospray Ionization Tandem Mass Spectrometry, *Anal. Biochem. 244*, 291–300.

levels following RP-HPLC which gave significant structural information and differentiated ceramides on the basis of their fatty acid constituents (48). Kuksis *et al.* (43) developed an HPLC assay using chloride attachment negative chemical ionization MS for detection of glyceryl esters and ceramides in plasma samples. Carboxyl or hydroxyl groups of lipids were derivatized by trimethyl or *tert*-butyl dimethyl chlorosilane, after phospholipase C treatment of plasma. The lipids were separated on a RP column with 20–90% propionitrile in acetonitrile containing 1% dichloromethane. However, the mass spectra yielded only a single peak for ceramide, and the results were not quantitative in nature for ceramide. The au-

thors reported an overestimation of the more saturated short-chain ceramide and an underestimation of the long-chain ceramides (43).

Gaudin *et al.* (49) developed a method for the separation and structural identification of ceramides. The authors achieved separation of ceramides using nonaqueous RP chromatography on a Kromasil C18 column (Eka Nobel, Bohus, Sweden) with 5 μm particle size and a gradient mobile phase of 100% methanol to methanol/0.2% acetone and a flow rate of 0.4 mL/min. Furthermore, they used a gas chromatography (GC)/MS approach to confirm the structures deduced from their HPLC analysis. GC/MS analysis was done after cleavage of ceramides by acidic methanolysis and conversion of the products to volatile trimethylsilyl derivatives. Methanolysis was necessary to convert the fatty acid moiety in ceramide to fatty acid methyl esters and release the LCB (48). For the GC, a gradient of acetonitrile/tetrahydrofuran (95:5, vol/vol) to acetonitrile/tetrahydrofuran/ propanol (63:35:5, by vol) in 30 min was used having triethylamine and formic acid as modifiers. The method was capable of identifying three types of fatty acids: saturated, unsaturated, and hydroxy-saturated fatty acids. They were also capable of analyzing three types of LCB: sphingosine, dihydrosphingosine, and phytosphingosine (49). Gaudin *et al.* (49) used this technique to confirm and identify the composition and structures of commercially available ceramides and SB, but did not apply this technique to the analysis of ceramides in biological samples. Karlsson *et al.* (50) used atmospheric pressure chemical ionization MS with NP-chromatography to separate and identify species of SM. Their method was capable of determining SM molecular masses as well as their LCB and fatty acid (saturated and unsaturated) compositions.

MS is a very powerful analytical tool and provides important structural information. This would be essential in determining the particular molecular species of ceramides that are involved in cellular responses since evidence has shown that not all isomers of ceramides are biologically active (6). However, MS is generally nonquantitative in nature unless appropriate internal standards are utilized. Watts *et al.* (16) have discussed some of the shortcomings of MS analysis of lipids. They pointed out that the mass obtained for a molecule should not serve as the sole basis for its identification and that fragmentation analysis is needed when complex lipid mixtures from biological extracts are analyzed (16). Also, MS involves the use of very expensive equipment and requires the knowledge and expertise of skilled analysts to use and interpret results which have limited its use in many applications in sphingolipid research, even though it has become increasingly utilized.

The use of biochemical assays for ceramide quantification. One of the most frequently used assays for ceramide quantification is the *E. coli* DAG assay (4,11,41,51). This enzyme was first identified, partially purified and characterized by Schneider and Kennedy in 1970 (52), who were also the first to show that *E. coli* DAG kinase effectively utilized ceramides as well as DAG as substrate. Later, this enzyme was overexpressed in a plasmid-bearing *E. coli* strain which accounted for 10–15% of membrane proteins and subsequently used as a source of the enzyme for the quantification of DAG by converting it to [^{32}P]phosphatidic acid in the presence of [γ-^{32}P]ATP (53,54). It was observed that the enzyme was also capable of converting ceramide to [^{32}P]ceramide-phosphate (52–54) as well, and the assay was subsequently used for the quantification of ceramides after correction for conversion and recovery. DAG kinase catalyzes the transfer of the γ-phosphate group of ATP to the free 3′ hydroxyl group of diglyceride and the 1′ hydroxyl group of ceramide and requires the presence of a fatty acid linked through an acyl bond to an amino group. Lipids from tissue samples are usually extracted using the Bligh and Dyer (55) or Folch *et al.* (56) procedure, dried, and incubated with DAG kinase and [γ-^{32}P] ATP in the presence of the detergent β-octylglucoside in a mixed micelle assay (4,11,51). Products are reextracted, spotted on silica gel TLC plates, and developed with chloroform/methanol/acetic acid (65:15:5, by vol) and then subjected to autoradiography or phosphor imaging and quantified (4,11,31,53,54). Although this assay has been widely used, several drawbacks exist and could affect the enzymatic conversion and lower the reliability of the procedure (15,16,57). The enzyme source, either a crude membrane fraction (54,57) or a chromatographically purified enzyme (54,57) available commercially (4,11,51), could contain contaminating lipases that would contribute to increased background by carrying undesirable substrates into the product (21). Perry and Hannun (57) have emphasized the importance of the enzyme source in the validity of the assay. They argue that a lyophilized preparation of the enzyme available commercially can be activated by a ganglioside, leading to incorrect determination of ceramide levels. They also recommend the use of C6–C12 ceramide as an internal standard in order to determine percentage conversion for quantitative purposes. The use of C2 ceramide is not recommended since it is a poor substrate for the DAG kinase (57). Also, the source of [γ-^{32}P] ATP should be highly pure, since impurities in the ATP preparation could inhibit the enzyme (54), so this reagent must be prepared and monitored with care. Accurate determination of the specific activity of ATP is also crucial since this radionucleotide has a very short half-life, and samples should be prepared and used while fresh where the [γ-^{32}P] ATP has a very high specific activity. Another disadvantage of this assay is the use of the very high energy radionucleotide which mandates certain precautions. The assay becomes very cumbersome if a phosphor imager is not available because the radioactive spots have to be scraped and subjected to scintillation counting. Van Veldhoven *et al.* (58) evaluated the phosphorylation of ceramides by the *E. coli* DAG kinase enzyme in an octylglucoside/phosphatidylglycerol mixed micelle assay. They reported that ceramides containing NFH were phosphorylated quantitatively over a broad range from 25 to 2,000 picomoles, whereas the conversion of HFA ceramide was not quantitative.

Perry and Hannun (57) have elaborated on the kinetics of the enzyme, pointing out that proper use of the assay necessi-

tates the use of excess enzyme in order to avoid Michaelis-Menten kinetics and achieve a complete and quantitative conversion of the ceramide to ceramide-1-phosphate. Under Michaelis-Menten conditions, the enzyme becomes limiting and hence subject to factors that affect the velocity of the reaction and the affinity of the enzyme and alter its activity (57). Although this technique has been very widely used for ceramide quantification, recent reports have raised serious questions about the validity of this approach (15,16). Watts *et al.* (15) have used this assay in conjunction with an MS approach to determine ceramide levels in cells following the activation of the Fas receptor which has been associated with elevation in ceramide levels and apoptosis (6). The authors reported elevated ceramide levels when using the DAG kinase assay but could not detect elevations with MS. They concluded that increases in ceramide levels observed were due to fluctuations in DAG kinase activity rather than changes in the endogenous ceramide levels *per se*. Others have attributed these conflicting results to the use of a commercially available lyophilized preparation of the enzyme which appears to be activated by certain lipids (57).

Although discrepancies in the reported results using the DAG kinase assay in various cell systems exist, this method cannot be completely dismissed but should be used with caution. The need for new, reliable, and accurate methods for identification and quantitation of ceramides becomes evident in light of the increasing body of literature attributing important biological roles to ceramides. The choice of method for ceramide quantitation would depend on the purpose of the study, as well as the availability of resources and skilled personnel.

Autoxidation of Methyl Linoleate: Identification of the Bis-allylic 11-Hydroperoxide

Alan R. Brash*

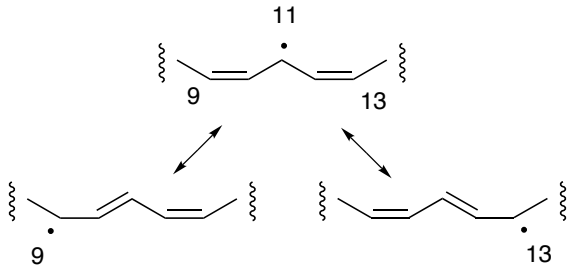
Department of Pharmacology, Vanderbilt University, Nashville, Tennessee 37232

ABSTRACT: Based on the understanding of lipid peroxidation as a free radical chain reaction, over 50 yr ago the three primary products of linoleic acid autoxidation were predicted to be the 9-, 11-, and 13-hydroperoxides. The 9- and 13-hydroperoxides were found at the time, but formation of 11-hydroperoxylinoleate or any other bis-allylic fatty acid hydroperoxide has not been reported heretofore as a product of lipid peroxidation reactions. In vitamin E-controlled autoxidation of methyl linoleate, the 11-hydroperoxy derivative was identified as the next most prominent primary peroxidation product after the 9- and 13-hydroperoxides. It was present in approximately 5–10% of the abundance of the 9- or 13-hydroperoxide. The structures of 11-hydroperoxylinoleate and its 11-hydroxy derivative were established by high-pressure liquid chromatography, ultraviolet spectroscopy, gas chromatography–mass spectroscopy, and ^{1}H nuclear magnetic resonance spectroscopy. The 11-hydroperoxide was not detectable in the absence of α-tocopherol, indicating that efficient trapping of the 11-peroxyl radical as the hydroperoxide is critical to permitting its accumulation.

Paper no. L8520 in *Lipids 35,* 947–952 (September 2000).

Following development of the concepts of lipid peroxidation as a free radical chain reaction in the 1940s (reviewed in Ref. 1), attempts were made to characterize the nature of the primary peroxidation products of the prototypical polyunsaturated lipid, linoleic acid. It follows from an understanding of tautomerism of the initial free radical that three positions are available for reaction with molecular oxygen, namely, C9, C11, and C13 (Scheme 1).

In studying the products from linoleic acid, Bergstrom and colleagues found the expected 9- and 13-hydroperoxides, whereas the 11-hydroperoxide was not detected (2,3). It was uncertain at the time whether the 11-hydroperoxide was formed in very low yield and/or was highly unstable and thus could not be isolated. In further studies over the years, the allylic nonconjugated 8- and 14-hydroperoxylinoleates were isolated as autoxidation products (4), but detection of the 11-hydroperoxide remained elusive (e.g., Refs. 4–6). The present report describes conditions for the isolation of the bis-allylic hydroperoxide from autoxidation of methyl linoleate.



SCHEME 1

EXPERIMENTAL PROCEDURES

Materials. Methyl linoleate was purchased from Nu-Chek-Prep Inc. (Elysian, MN). Autoxidation products with conjugated diene chromophores were quantified by ultraviolet (UV) spectroscopy (ε = 23,000 M^{-1} cm^{-1} at 235 nm). Vitamin E (α-tocopherol; Sigma Chemical Co., St. Louis, MO) was quantified by using a value of $E_{1\%}$ = 76 at 292 nm in ethanol, (i.e., 100 μg/mL gives an absorbance of 0.76 at 292 nm).

Autoxidation conditions. Reactions were run essentially as described by Peers and Coxon (7) using mixtures of methyl linoleate and 5% by weight of α-tocopherol. The mixture (0.25–0.6 g) was taken to dryness in a 1-L flask, flushed with oxygen, and kept for several days in an oven at 35–37°C. The sample was flushed again with oxygen, usually every day. After 3 d, the sample was examined daily by UV spectroscopy: the whole sample was dissolved in 10 mL dichloromethane, and the UV spectrum of a 5-μL aliquot was recorded in 2 mL of methanol using a Beckman DU-7 (Fullerton, CA) scanning spectrophotometer. Reaction was continued as a dry film under oxygen until ≈20% conversion to conjugated diene was evident from UV spectroscopy. After several days, the distinct 292 nm absorbance of α-tocopherol became less evident and the sample was replenished with an additional 5% α-tocopherol by weight.

High-pressure liquid chromatography (HPLC) analyses. Autoxidized methyl linoleate was analyzed by straight-phase (SP)-HPLC using a Beckman 5 μm silica column and a sol-

vent of hexane/isopropanol 100:1 or 100:0.5 (vol/vol). For analytical work, the products were monitored by on-line detection using a Hewlett-Packard 1040A diode array UV detector (Palo Alto, CA). For collection of products, samples of up to 4 mg total of hydroperoxide products (and including in the sample larger amounts of unchanged methyl linoleate) were injected on an Alltech (Deerfield, IL) 10 µm semipreparative silica column (25 × 1 cm) eluted with hexane/isopropanol (100:0.5, vol/vol) at a flow rate of 5 mL/min. For collection of products, the column effluent was monitored using a Spectrophysics (San Jose, CA) variable wavelength UV detector set at 210 nm. Reversed-phase (RP)-HPLC analysis and purification of 0.5-mg aliquots of the novel product were carried out using a Beckman Ultrasphere 5 µ ODS column (25 × 0.46 cm) with an Upchurch guard column and a solvent system of methanol/water, 85:15 (vol/vol). Final purification by SP-HPLC was carried out on aliquots of up to 0.5 mg per injection using the Beckman analytical silica column and the hexane/isopropanol 100:1 (vol/vol) solvent.

Derivatization. Hydrogenation of 5–10 µg of hydroxy fatty acid methyl ester was carried out by bubbling hydrogen through a suspension of platinum oxide (*ca.* 1 mg) in 100 µL ethanol for 2 min followed by addition of water and extraction with ethyl acetate. Trimethylsilyl (TMS) ether derivatives were prepared by treatment with bis(trimethylsilyl)trifluoracetamide (10 µL) and pyridine (5 µL) for 15 min at room temperature. Subsequently, the reagents were evaporated under a stream of nitrogen and the samples dissolved in hexane for gas chromatography–mass spectrometry (GC–MS) analysis.

GC–MS. Mass spectra were recorded in the electron impact mode using a Hewlett-Packard HP5980 engine mass spectrometer operated at 70 eV and coupled to a Hewlett-Packard 5890 gas chromatograph equipped with an SPB-1 fused-silica capillary column of 5 or 15 m × 0.25 mm inner diameter. Samples were injected on column at an oven temperature of 150°C, and after 1 min the temperature was programmed to 300°C at 10 or 20°C/min.

Nuclear magnetic resonance (NMR) analyses. Spectra were recorded in deuterated benzene using a Bruker 400 MHz instrument (Billerica, MA). Chemical shifts are reported in relation to tetramethylsilane (δ 0.0).

RESULTS

Isolation of a novel product. SP-HPLC analysis of vitamin E-controlled autoxidation reactions of methyl linoleate showed the formation of 13- and 9-hydroperoxy products and one distinct minor product that chromatographed between the two main peaks (Fig. 1). In contrast to the major 13- and 9-hydroperoxides, the minor product did not contain a conjugated diene chromophore and was detectable only at lower wavelengths in the UV. The unreduced product was collected from injections of the autoxidation mixture on a semipreparative SP-HPLC column. Following reduction of the hydroperoxides, the retention times of all the products on SP-HPLC increased, and the minor product shifted its chromatographic mobility and now eluted with the 9-hydroxylinoleate (Fig. 2A), or, on a silica column from a different manufacturer (Alltech), as a peak in the tail of the 9-hydroxylinoleate (not shown).

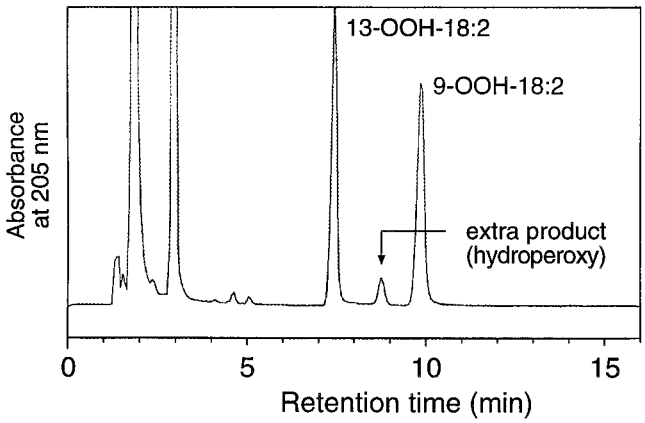

FIG. 1. Straight-phase high-pressure liquid chromatographic (SP-HPLC) analysis of autoxidized methyl linoleate. Vitamin E-controlled autoxidation of methyl linoleate was analyzed on an Alltech (Deerfield, IL) silica column (25 × 0.46 cm) using a solvent of hexane/isopropanol (100:0.5, vol/vol) eluted at 2 mL/min with ultraviolet detection at 205 nm. The large peak near the solvent front is methyl linoleate and the second large peak at 3 min is α-tocopherol. The novel product is marked as "extra product, (hydroperoxy)."

On the RP-HPLC system used for further purification (Fig. 2B), the novel product (as the hydroperoxide or the hydroxy derivative) eluted at ≈10 mL, substantially earlier than the combined peak of 9- and 13-hydro(per)oxides (retention volume ≈13 mL), allowing complete removal of these contaminants from the semipreparative SP-HPLC. The hydroperoxy and hydroxy derivatives of the new product were not resolved from each other on RP-HPLC; they formed shoulders of the same chromatographic peak. Prior to GC–MS and NMR analyses, the new product was finally re-purified as the hydroperoxide or hydroxy derivative by SP-HPLC. It was recovered in a yield of approximately 5–10% relative to one of two main products, or up to a 5% yield of the combined products. About 0.5–0.75 mg of 11-hydroperoxide was recovered pure from autoxidations that gave 7.5 mg each of purified 9- and 13-hydroperoxides.

Spectral analyses. When analyzed as the methyl ester TMS ether of the triphenylphosphine-reduced (hydroxy) derivative, the novel product had a similar mass spectrum to 9- and 13-hydroxylinoleates. The most prominent ions were present at *m/z* 382 (M^+, 35% relative abundance), *m/z* 311 ($M - C_5H_{11}$, 48%), *m/z* 225 (C9–C18, base peak), and *m/z* 130 (55% relative abundance). The differences from the spectra of the 9- and 13-hydroxylinoleates were in ion abundances, making it difficult to distinguish the different compounds with the double bonds still present. The position of the hydroxyl group in the new product was established unambiguously from the mass spectrum of the methyl ester TMS ether derivative of the hydrogenated product (Fig. 3). The

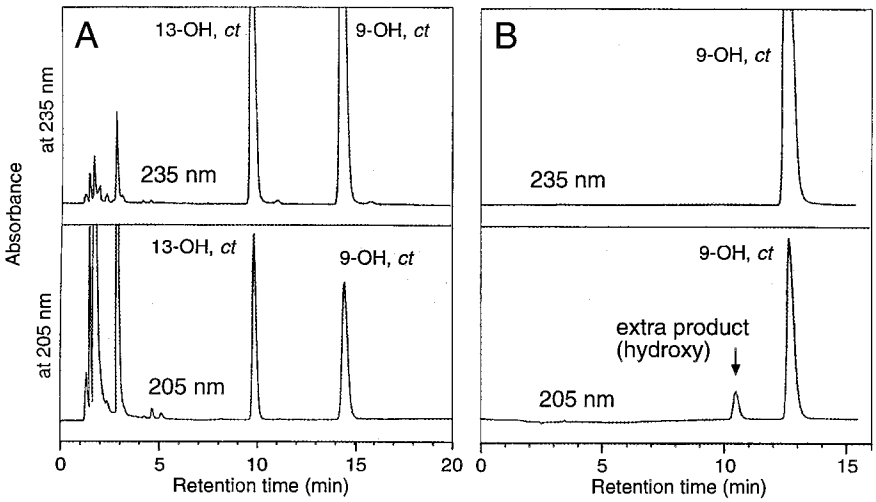

FIG. 2. SP-HPLC and reversed-phase (RP)-HPLC analyses of hydroxylinoleate methyl esters. (A) Following reduction with triphenylphosphine to the corresponding hydroxy products, the sample shown in Figure 1 was analyzed by SP-HPLC using the identical chromatographic conditions. The absorbance scales at 205 and 235 nm are set at identical values [0.35 absorbance units (AU) full scale]. (B) The peak of 9-hydroxylinoleate methyl ester collected from SP-HPLC was chromatographed on RP-HPLC using a Beckman 5 μm ODS Ultrasphere column (25 × 0.46 cm; Fullerton, CA) and a solvent of methanol/water (85:15, vol/vol) with a flow rate of 1 mL/min. The absorbance scales at 205 and 235 nm are set at identical values (0.5 AU full scale). For abbreviation see Figure 1.

base peak was recorded at *m/z* 73. The two most prominent ions above *m/z* 100 were the two α-cleavage ions at *m/z* 287 and 201 (26 and 62% relative abundance, respectively). This establishes the position of the hydroxyl group at C-11. Other structurally significant ions were recorded at *m/z* 371 (M – 15, <0.5% relative abundance), *m/z* 355 (M – 31, <0.5%), and *m/z* 339 (M – 47, 1%). Additional prominent ions above *m/z* 100 were *m/z* 258 [M – 128, 7%, an ion that

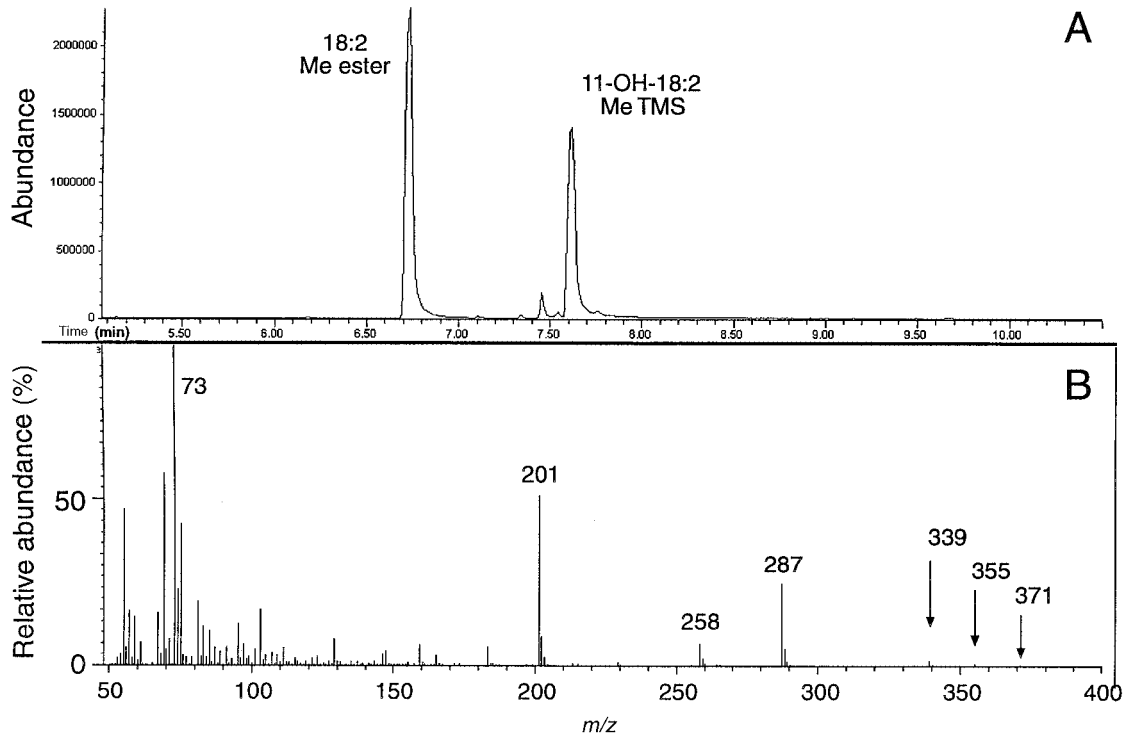

FIG. 3. Gas chromatography–mass spectrometry analysis of hydrogenated 11-hydroxylinoleate, methyl ester trimethylsilyl (TMS) ether derivative. Panel A shows the total ion chromatogram. The largest peak is methyl stearate (18:2 Me ester) formed by loss of the C-11 hydroxyl during hydrogenation. (B) The mass spectrum of the methyl ester TMS ether derivative of 11-hydroxy-stearate (11-OH-18:2 MeTMS) is shown.

had the same chromatographic profile as the major diagnostic ions in the GC peak; it may represent migration of the TMS group to the ester carbonyl followed by cleavage at C-10/C-11 and elimination of the fragment OHC–$(CH_2)_6$–CH_3], *m/z* 183 (6%), *m/z* 159 (7%), *m/z* 129 (8%), and *m/z* 103 (16%).

The ^{1}H NMR spectra of the 11-hydroperoxide and the 11-hydroxylinoleate are in accord with the spectral characteristics reported for the bis-allylic arachidonate products, 13-hydroxyeicosatetraenoic acid (13-HETE) (8) and 10-HETE (9). Most notably, the geminal hydro(pero)xy proton at C-11 has a chemical shift unusually far downfield and it appears among the olefinic protons (Fig. 4). In the hydroxy derivative (Fig. 4B), H11 occurs at 5.37 ppm as a double triplet. The triplet is accounted for by the equivalent coupling to H10 and H12 (J = 8.5 Hz), while a 3.5 Hz coupling that splits the triplet occurs between the geminal H11 proton and the proton on the hydroxyl group itself; the latter is a doublet (J = 3.5 Hz) at 1.00 ppm. The C-11 geminal proton reverted to a simple triplet upon exchange of the hydroxyl proton with D_2O, with concomitant elimination of the hydroxyl signal at 1.00 ppm. In the hydroperoxide, H11 appears as a clean triplet at 5.75 ppm (Fig. 4A) accounted for by the equal couplings to H10 and H12. An additional 3.5 Hz coupling can occur through the oxygen atom in the hydroxy derivative, but no significant long-range coupling is possible through both oxygens of the hydroperoxide.

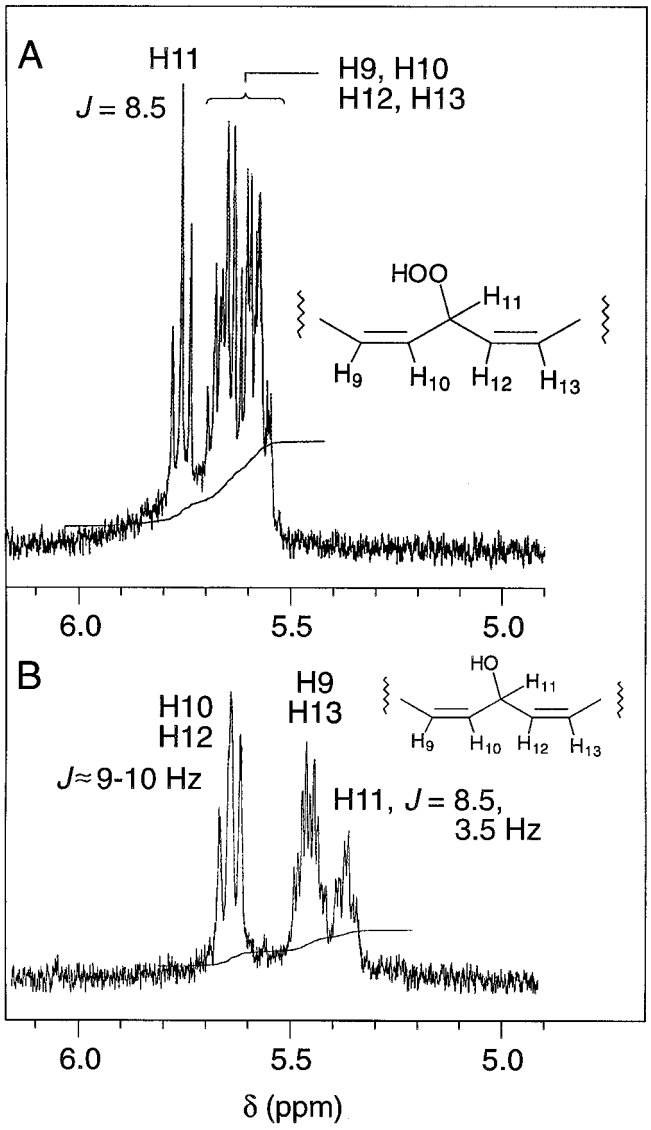

FIG. 4. Olefinic and H11 protons in the ^{1}H nuclear magnetic resonance spectra (400 MHz) of 11-hydroperoxy- and 11-hydroxylinoleate methyl esters in d_6-benzene. The two panels show the signals from H9, H10, H11, H12, and H13 of (A) 11-hydroperoxylinoleate, and (B) 11-hydroxylinoleate.

The spectrum of 11-hydroxylinoleate has the four olefinic protons resolved into two pairs, permitting assessment of the double-bond configurations. As the signals from H10 and H12 at 5.65 ppm are superimposed, the olefinic region centered on C11 must be symmetrical. The slightly broad triplet of H10/H12 (almost a doublet of doublets) is caused by the partially superimposed couplings of 8.5 Hz to the geminal proton H11 ($J_{10,11} = J_{11,12}$) and the ≈10 Hz coupling across the double bonds ($J_{9,10} = J_{12,13}$). The latter defines the two double bonds as *cis*.

^{1}H NMR (400 MHz, in deuterated benzene, using 7.24 ppm for the residual protons in the solvent) gave for 11-hydroperoxylinoleate methyl ester (ppm): δ 0.95 (*t*, 3 protons, H18), 1.2–1.5 (*m*, 14 protons, H4, H5, H6, H7, H15, H16, H17), 1.65 (*p*, 2 protons, H3), 2.2 (*m*, 6 protons, H2, H8, H14), 3.45 (*s*, 3 protons, C$\underline{H}_3$O), 5.55–5.7 (*m*, 4 protons, H9, H10, H12, H13), 5.75 (*t*, 1 proton, H11, $J_{9,10} = J_{11,12}$ = 8.5 Hz), 7.55 (*s*, 1 proton, –OO$\underline{H}$). For 11-hydroxylinoleate methyl ester (ppm): δ 0.95 (*t*, 3 protons, H18), 1.0 (*d*, 1 proton, <1 in area, –OH, $J_{11,-OH}$ = 3.5 Hz), 1.2–1.4 (*m*, 14 protons, H4, H5, H6, H7, H15, H16, H17), 1.6 (*p*, 2 protons, H3), 2.2 (*m*, 6 protons, H2, H8, H14), 3.45 (*s*, 3 protons, C$\underline{H}_3$O), 5.37 (*dt*, 1 proton, H11, $J_{10,11} = J_{11,12}$ = 8.5 Hz, $J_{11,-OH}$ = 3.5 Hz), 5.45 (*m*, 2 protons, H9, H13), 5.65 (*t/dd*, 2 protons, H10, H12, J ≈ 8.5–10 Hz).

The 11-hydroperoxy and 11-hydroxy products do not contain a conjugate diene chromophore yet their UV spectra can be distinguished from the spectrum of linoleate and from each other (Fig. 5). A similar extension to the end absorbance of the nonconjugated chromophore was reported for bis-allylic 7-, 10-, and 13-HETE (10).

Autoxidation in the absence of vitamin E. In autoxidation of a dry film of methyl linoleate in the absence of α-tocopherol (analyzed after ≈15% conversion to conjugated diene), the SP-HPLC profile showed prominent peaks for the 9- and 13-hydroperoxides with both *cis-trans* and *trans-trans* conjugated dienes (Fig. 6). The 11-hydroperoxide was not visible, even though, based on retention time, it should have appeared as a peak in the tail of the 13-hydroperoxy-9-*trans*,11-*trans*-linoleate. When the peak and tail of the *trans-trans* 13-hydroperoxide were collected from SP-HPLC and examined on RP-HPLC at 205 and 235 nm, there was no trace of a product with the chromatographic and spectral characteristics of 11-hydroperoxylinoleate methyl ester.

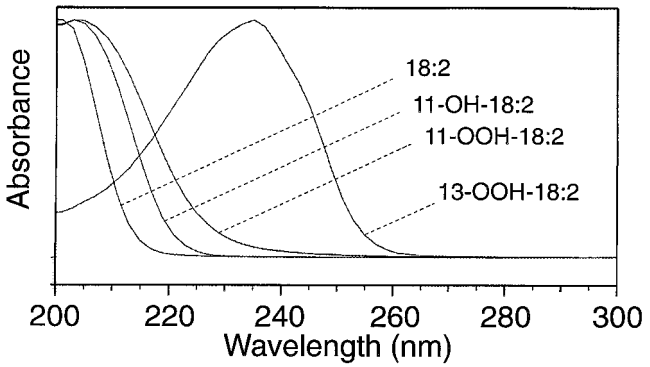

FIG. 5. Ultraviolet spectra of methyl linoleate and its 11-hydroperoxy and 11-hydroxy derivatives. Spectra were recorded using a Hewlett-Packard 1040A diode array detector (Palo Alto, CA) during an RP-HPLC run in methanol/water (85:15 vol/vol) solvent (or 100% methanol for methyl linoleate, 18:2). To avoid saturation of the signal at the low wavelengths, the maximal absorbance at 205 nm was kept below 0.5 AU; spectra at the apex and on the upslope of chromatographic peaks were indistinguishable, confirming that there was no significant saturation of the signal in these spectra. The spectrum of 13-hydroperoxylinoleate is included for comparison. The spectra are normalized to λ_{max} and do not convey relative molar extinction values. Previous studies suggest that at 205 nm the bis-allylic products and the nonconjugated fatty acid derivatives have similar molar absorptions (Ref. 10), estimated here as around 10,000 for the linoleic acid derivatives. For abbreviations see Figure 2.

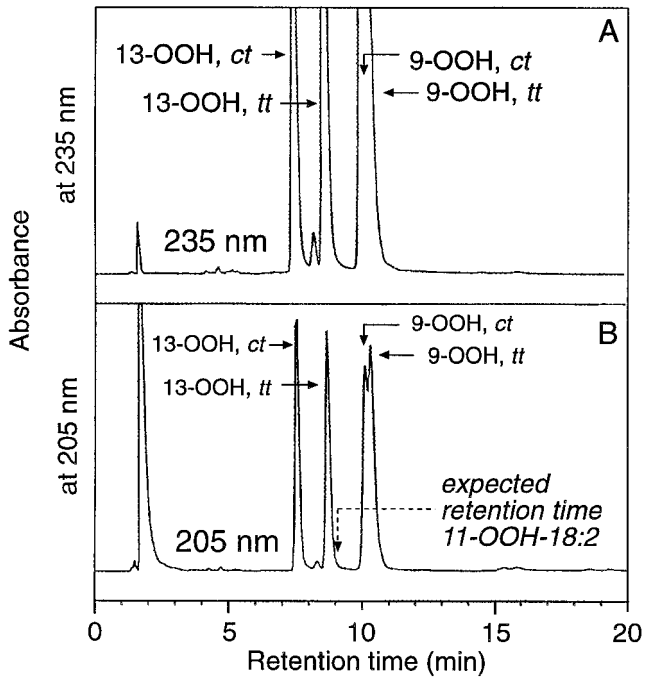

FIG. 6. SP-HPLC analysis of methyl linoleate autoxidized in the absence of vitamin E. Chromatographic conditions were identical to those given in the legend of Figure 1. The absorbance scales at 205 and 235 nm are set at identical values (0.35 AU full scale). See Figures 1 and 2 for abbreviations.

DISCUSSION

The presence of α-tocopherol in the autoxidation of methyl linoleate allowed detection of a previously unrecognized primary product of lipid peroxidation, the bis-allylic 11-hydroperoxide. Efficient trapping of peroxyl radicals by α-tocopherol and other hydrogen atom donors is known to suppress the isomerization of the *cis-trans* conjugated 9- and 13-hydroperoxyl radicals and thus reduce the formation of *trans-trans* isomers and other secondary products (cf. Figs. 1 and 6) (7,11). This activity also appears to be the basis of the trapping and preservation of the bis-allylic product. The critical competition is at the peroxyl radical stage. The relatively unstable bis-allylic peroxyl radical is formed as originally predicted (1,2,12). If vitamin E is present, the peroxyl radical is trapped; the bis-allylic hydroperoxide product is stable under the conditions of its formation, and it does not convert to the 9- and 13-hydroperoxides. If vitamin E is not present, the 11-peroxyl radical fragments and re-adds molecular oxygen to give the thermodynamically more stable conjugated diene peroxyls, which then go on to the 9- and 13-hydroperoxide products.

In the course of relatively recent experiments on the oxygenation of polyunsaturated fatty acids, bis-allylic hydroxy or hydroperoxy products have been found as enzymatic products. The first report was of the occurrence of the 13-hydroxyeicosapentaenoic acid in the marine red algae *Lithothamnion corallioides* and *L. calcareum* (8). As a product of linoleic acid metabolism in *L. corallioides* (13), 11*R*-hydroxylinoleate was subsequently found. Later in the 1990s, bis-allylic product(s) were detected as hydroxy derivatives in cytochrome P450 reactions (10,14,15) and in the myoglobin-catalyzed monooxygenation of linoleic acid (16), and as hydroperoxide products of the manganese-containing lipoxygenase of the fungus *Gäumannomyces graminis* (17) and of the 8*R*-lipoxygenase domain of the peroxidase-lipoxygenase fusion protein from the coral *Plexaura homomalla* (18).

The bis-allylic 11-hydroperoxylinoleate derivative is fairly stable to chromatographic and other analytical manipulations, provided the sample is not subjected to low pH (10,14). For methyl esters, as in the present study, there is no need to acidify during chromatography or HPLC. For long-chain free fatty acids the pK_a values are approximately pH 7–8 for the parent fatty acids (19,20) and probably in the region of pH 6–7 for the monohydro(pero)xy products, so it is not necessary to acidify to pH 3–4 to achieve an efficient extraction. The long-term stability of these products is similar to other fatty acid hydroperoxides. A sample of oxidized linoleate methyl ester kept in the −20°C freezer for 4 yr (in ethanol in the presence of α-tocopherol from the original autoxidation) contained a similar proportion of the 11-hydroperoxide as freshly autoxidized methyl linoleate.

Under the appropriate conditions, formation and accumulation of bis-allylic products can be expected for other polyunsaturated lipids. As evidence of this, several years ago we detected the 10,15-dihydro(pero)xyeicosatrienaoate among the primary oxygenation products in the vitamin E-controlled autoxidation of 15-hydroxyeicosa-8,11,13-trienoate methyl ester (Brash, A.R., and Boeglin, W.E., unpub-

lished observations). At the time there was some doubt as to the origin of this bis-allylic hydroperoxy derivative, but it is now evident that its formation as a primary oxygenation product is no longer in question.

ACKNOWLEDGMENTS

I thank Dr. Ned Porter for discussions on bis-allylic oxygenation, Dr. Thomas M. Harris for comments on the NMR spectra, Sam Saleh for acquiring the spectra, Betty Fox for help with the mass spectrometry, and the reviewers for helpful comments. This work was supported by NIH grant GM-53638.

Synthesis of 9,12-Dioxo-10(*Z*)-dodecenoic Acid, a New Fatty Acid Metabolite Derived from 9-Hydroperoxy-10,12-octadecadienoic Acid in Lentil Seed (*Lens culinaris* Medik.)

Bernd A.W. Gallasch and Gerhard Spiteller*

Organische Chemie I, Universität Bayreuth, 95440 Bayreuth, Germany

ABSTRACT: The previously unknown linoleic acid peroxidation product 9,12-dioxo-10(*Z*)-decenoic acid (***Z*5**) was detected in lentil seed flour (*Lens culinaris* Medik.) by electron impact mass spectrometry (EI-MS) after derivatization with pentafluorobenzyl-hydroxylamine-hydrochloride, methylation of acidic groups with diazomethane, and protection of hydroxylic groups with *N*-methyl-*N*-trimethylsilyl-trifluoroacetamide. The structure of the natural product was confirmed by synthesis of ***Z*5**, 9,12-dioxo-10(*E*)-decenoic acid, and derivatives. EI-MS, nuclear magnetic resonance and gas chromatographic data of these compounds and synthetic intermediates are discussed.

Paper no. L8479 in *Lipids 35*, 953–960 (September 2000).

Lipid peroxidation processes induced by lipoxygenase (LOX; EC 1.13.11.12) are reported to occur in plant systems; they were observed for instance in germinating cereals, in wheat flour suspensions (1–3), and in legumes (4). Linoleic acid is transformed by LOX to 9-hydroperoxy-10,12-octadecadienoic acid (9-HPODE) or 13-hydroperoxy-9,11-octadecadienoic acid (13-HPODE) depending on LOX type and conditions. Further oxidation and decay of HPODE generate aldehydes, e.g., 4-hydroxynonenal (4-HNE), 9-oxononanoic acid, and 2,4-decadienal, along with other products (5,6). Some of these compounds show biological activity (7–9). An excellent method for trapping aldehydic products is the reaction with pentafluorobenzylhydroxylaminehydrochloride (PFBHA·HCl) added to reaction or extraction mixtures (10,11). The pentafluorobenzyloximes are generated under very mild conditions [3 h at room temperature (RT)]. Their electron impact (EI) mass spectra often show a characteristic fragmentation pattern (12).

Abbreviations: CC, column chromatography; DMO, dimethyldioxirane; DMS, dimethylsulfide; EI-MS, electron impact mass spectrometry; GC–EI-MS, gas chromatography–electron impact mass spectrometry; HNE, 4-hydroxynonenal; HPODE, hydroperoxyoctadecadienoic acid; LOX, lipoxygenase; MCPBA, metachloroperbenzoic acid; MSTFA, *N*-methyl-*N*-trimethylsilyl trifluoroacetamide; NMR nuclear magnetic resonance; PCC, pyridinium chlorochromate; PFBHA·HCl, pentafluorobenzyloxime hydrochloride; PFBO, pentafluorobenzyloxime; RI, retention index; RT, room temperature; TEG, triethyleneglycol; TLC, thin-layer chromatography; TPP, tetraphenylporphine; UV, ultraviolet; XOD, xanthine oxidase.

Hamberg and Gotthammar (13) found that among other reactions 9-HPODE suffered transformation to 12,13-epoxy-9-hydroxy-10-octadecenoic acid, which was degraded by hydrolysis to 9,12,13-trihydroxy-10-octadecenoic acid (14). This compound was cleaved oxidatively to 9-hydroxy-12-oxo-10-dodecenoic acid (**4**) by reaction with $NaIO_4$ (15) or $Pb(OAc)_4$ (16). Recently, Gardner (17) and Noordermeer *et al.* (18) identified **4** to be an enzymic product after incubation experiments of 13*S*-HPODE with LOX-1 protein preperations from soybean and alfalfa. Loidl-Stahlhofen *et al.* (19) and Mlakar and Spiteller (20) detected **4** in traces after autoxidation of linoleic acid in the form of its 12-*O*-2,3,4,5,6-pentafluorobenzyloximino-9-trimethylsilyloxy-10(*E*)-dodecenoic acid methyl ester derivative ($M^{+\cdot}$ = 509). In this paper we describe the structure of the new metabolite 9,12-dioxo-10(*Z*)-decenoic acid and its *E* isomer.

EXPERIMENTAL PROCEDURES

Materials. If not otherwise marked, all reagents were purchased from Aldrich, Fluka, or Sigma (Deisenhofen, Germany). All solvents, except MeOH, were freshly distilled and dried with Alox B and $LiAlH_4$, if required. Dry MeOH was prepared by continuous distillation over Mg. *N*-Methyl-*N*-trimethylsilyl-trifluoroacetamide (MSTFA) was obtained from Machery-Nagel (Düren, Germany). An etheral solution of diazomethane was freshly prepared. A solution of 2,2-dimethyldioxirane in acetone was prepared according to Adam *et al.* (21). Photolysis was carried out with a 500 W Hg-lamp from LOT-Oriel (Darmstadt, Germany).

Chromatographic and instrumental methods. Gas chromatography (GC) was performed with a United Technologies Packard Model 438 gas chromatograph equipped with a methyl silicone capillary column DB-5 (30 m × 0.32 mm, film thickness 0.1 μm) from J&W Scientific (Mainz-Kastel, Germany), column head pressure 60 kPa. Hydrogen was used as carrier gas. Linear retention indices (RI) were calculated (22). GC–electron impact mass spectrometry (EI-MS) was carried out with a Finnigan MAT 95 mass spectrometer (Bremen, Germany) connected to a Hewlett-Packard 5890 series II gas chromatograph equipped with a methyl silicone capillary column DB-5ms (30 m × 0.32 mm, film thickness 0.32 μm) from

J&W Scientific. The nuclear magnetic resonance (NMR) spectra were acquired on an AM 300 Bruker NMR instrument (Rheinstetten, Germany) at 300 MHz for ^{1}H and 75 MHz for ^{13}C NMR, under standard conditions.

Indices of derivatives. Derivatization of the functional groups is indicated by addition of Latin letters to the compound number with respect to derivatization type. The first letter indicates derivatization of the acidic group at C-1 (**a**, methoxy; **a′**, ethoxy; **c**, trimethylsilyloxy). The second letter indicates derivatization of the functional group at the last carbon atom (**b**, pentafluorobenzyloximino, **c**, either MSTFA addition product to an aldehyde or trimethylsilyloxy product of a hydroxy function). The third letter indicates derivatization of the hydroxyl or oxo group in the chain (**b**, pentafluorobenzyloximino; **c**, trimethylsilyloxy).

Incubation experiments with lentil seed flour and structure elucidation by GC–MS. Freshly milled lentil seed flour (10 g) was stirred with 55.8 mg linoleic acid as substrate in 200 mL 0.067 M phosphorus buffer at pH 5.6 for 1 h at room temperature (RT). Twenty-five mL CH_2Cl_2, 50 mL MeOH, and 100 mg PFBHA·HCl were added to 20-mL aliquots to prepare a homogenous solution (23) and to transform carbonyl groups to their pentafluorobenzyloximes. After 3 h of incubation time and centrifugation the supernatant was separated. Two layers were obtained by addition of 25 mL H_2O and 25 mL CH_2Cl_2 to the supernatant. The solvent was removed from the organic layer *in vacuo*. The residue was subjected to saponification by treatment with 10 mL sodium methylate (1 M in MeOH) followed by neutralization with methanolic HCl (2 N in MeOH). After washing and removal of the solvent, acidic groups were protected by reaction with an etheral diazomethane solution, then hydroxy groups were trimethylsilylated with MSTFA (30 μL, 1 h, RT). The obtained samples were ready for GC and GC–EI-MS without removal of excess reagent.

Synthesis of the known starting compounds 12-hydroxy-10-dodecenoic acid or its methyl ester (**2** or **2a**) was carried out by formylation of undecenoic acid or its methyl ester (**1** or **1a**) according to Metzger and Biermann (24).

*Synthesis of 9,10-epoxy-12-hydroxydodecanoic acid (**3**).* Seven grams of 4-chloroperbenzoic acid [containing 70% metachloroperbenzoic acid (MCPBA), 20% water, and 10% metachlorobenzoic acid] was dissolved in 100 mL CH_2Cl_2 to separate the 4-chloroperbenzoic acid from water. After removing the solvent of the organic layer *in vacuo,* the residue was redissolved in 70 mL dry CH_2Cl_2. Fifty mL of the dried solution (Na_2SO_4) corresponding to 4 g (26 mmol) 4-chloroperbenzoic acid were added dropwise to 4.48 g (20.9 mmol) **2** in 50 mL dry CH_2Cl_2 at 0°C and stirred for 2 h at RT. A column head was prepared by addition of 25 g silica 60 (40–63 μm) and removal of the solvent. Fast column chromatography (CC) was carried out on 400 g silica 60 (40–63 μm) with 2.5 L cyclohexane/ethylacetate (1:2, vol/vol) resulting in 4.09 g (17.8 mmol) **3** (yield = 85%, by GC). After preparative thin-layer chromatography (TLC) of 400 mg of the epoxides on silica 60 with cyclohexane/ethylacetate (2:1 vol/vol) 200 mg (0.9 mmol) ***Z*3** (R_f = 0.39) and 50 mg (0.2 mmol) ***E*3** (R_f = 0.55) were obtained, corresponding to the *E*/*Z*-ratio of the primary product. ^{1}H NMR 300 MHz ($CDCl_3$) δ ppm ***Z*3**: 3.77 (2H, *dt, J* = 6.6*,* 1.4 Hz*,* on C12), 2.85 (1H, *m*, on C-10), 2.78 (1H, *td, J* = 5.5, 2.4 Hz, on C-9, *cis*), 2.33 (2H, *t, J* = 6.4 Hz), 1.95, 1.68 (2H, *m*, on C-11), 1.62 (2H, *m*, on C-8), 1.51 (2H, *m*, on C-7), 1.41 (2H, *m*, on C-3), 1.25–1.35 (6H, on C-4, C-5, C-6); ^{13}C NMR (75 MHz, $CDCl_3$) δ ppm ***Z*3**: 178.7 (C-1), 60.1 (C-12), 58.3 (C-9), 56.9 (C-10), 34.1 (C-11), 33.8 (C-2), 31.8 (C-8), 29.0, 28.8, C-4, C-5, C-6, 25.8 (C-7), 24.5 (C-3).

*Synthesis of methyl 9,10-epoxy-12-hydroxydodecanoate (**3a**).* Thirty-five mL (2.8 mmol) 2,2-dimethyldioxirane (DMO) in acetone (0.07 M) was added to 500 mg (2.2 mmol) **2a** and stirred at 0°C for 1 h. The solvent was removed *in vacuo* at RT. The residue (**3a**) was used without further purification (yield> 95% by GC). ^{1}H NMR 500 MHz ($CDCl_3$) δ ppm **3a**: 3.72 (2H, *brd*, on C-12), 3.61 (3H, *brt*, –O–CH_3), 2.80 (1H, *brdt*, on C-10), 2.72 (1H, *brdt*, on C-9), 2.24 (2H, *brt*, on C-2), 1.89, 1.65 (2H, *m*, on C-11), 1.56 (2H, *m*, on C-8), 1.47 (2H, *brt*, on C-7), 1.37 (2H, *brt*, on C-3), 1.22–1.35 (6H, *brt*, on C-4, C-5, C-6); ^{13}C NMR (125 MHz, $CDCl_3$) δ ppm **3a**: 59.8 (C-12), 58.2 (C-9), 56.8 (C10), 51.4 (–O–CH_3), 34.2 (C-11), 33.9 (C-2), 31.8 (C-8), 29.0, 28,8 C-4, C-5, C-6, 25.8 (C-7), 24.7 (C-3), C-1 not determined; retention index (RI) **3ac** (DB-5) = 2020. EI–MS data are given in Table 1.

*Synthesis of methyl 9-hydroxy-12-oxo-10(*E*)-dodecenoate (**E*4a*) and methyl 9,12-dioxo-10(*E*)-dodecenoate (**E*5a*).* Eighty mg (0.33 mmol) **3a** were added dropwise to 194 mg (0.9 mmol) pyridinium chlorochromate (PCC) dissolved in 5 mL dry CH_2Cl_2 and stirred for 1 h at RT. After addition of 30 mL dry Et_2O and 16 h stirring at RT, the black gum was extracted with dry ether. After derivatization of hydroxyl groups with MSTFA, the ratio of the main products ***E*4a**/***E*5a** was deduced by GC integrals to be ~ 1:1. Yield after preparative TLC on SiO_2 plates from Fluka with cyclohexane/ethylacetate (3:1, vol/vol) was 17 mg (0.07 mmol, yield = 21%) of ***E*4a** and 12 mg (0.05 mmol, yield = 15%) of ***E*5a**. ^{1}H NMR 300 MHz ($CDCl_3$) δ ppm ***E*4a**: 9.55 (1 H, *d, J = 7.85* Hz), 6.80 (1H, *dd, J = 15.87, 4.66* Hz, on C-10), 6.30 (1H, *dd, J* = 15.87, 7.85 Hz, on C-11), 4.40 (1H, *brtdd*, on C-9), 3.63 (3H, *s*, –O–CH_3), 2.28 (2H, *brt*, on C-2), 1.5–1.8 (8H, *m*, C-3, C-4, C-5, C-6); ^{13}C NMR 75 MHz ($CDCl_3$) δ ppm ***E*4a**: 193.5 (C-12), 170.6 (C-1), 158.9 (C-10), 130.6 (C-11), 71.0 (C-9), 53.4 (–O–CH_3), 36.4 (C-8), 34.0 (C-2), 29.0, 28.9 C-4, C-5, C-6, 25.0 (C-7), 24.7 (C-3); RI ***E*4abc** (DB-5) = 2521, 2561; EI-MS data are given in Table 1. EI-MS data of **4ac** were in agreement with those published by Gardner (17).

^{1}H NMR 300 MHz ($CDCl_3$) δ ppm ***E*5a**: 9.80 (1H, *d, J* = 6.98 Hz, on C12), 6.85 (1H, *d, J = 16.25* Hz, on C10), 6.55 (1H, *dd, J* = 16.26, 6.82 Hz, on C-11), 3.62 (3H, *s*, –O–CH_3), 2.67 (2H, *brt, J* = 7.29 Hz, on C-2), 1.5–1.7 (8H, *m*, on C-3, C-4, C-5, C-6); ^{13}C NMR 75 MHz ($CDCl_3$) δ ppm ***E*5a**: 193.5 (C-12), 144.8 (C-10), 137.3 (C-11), 51.4 (–O–CH_3), 41.1 (C-8), 33.9 (C-2), 28.9, 28.8 C-4, C-5, C-6, 24.7 (C-3), 23.5 (C-7); C-1 and C-9 not determined; RI ***E*5abc** (DB-5) = 2706; EI–MS data shown in Table 1.

*Synthesis of 9,12-dioxo-10(Z)-dodecenoic acid (**Z5**).* Four mg tetraphenylporphine (TPP) was added to 30 mg (0.14 mmol) 8-[2-furyl]-octadecanoic acid **(7)** in 20 mL CH_2Cl_2 at −78°C. The reaction mixture was photolyzed for 4 h under a mild stream of oxygen. Photolysis was terminated by addition of 100 μL dimethylsulfide (DMS) at −78°C for 10 min. Complete conversion of **7** to ***Z5*** was proven by ^1H and ^{13}C NMR after removal of the excess DMS *in vacuo* and redissolving the residue in $CDCl_3$.

^1H NMR 300 MHz ($CDCl_3$) δ ppm ***Z5***: 10.18 (1H, *d, J* = 7.13 Hz, on C-12), 6.90 (1H, *d, J* = 11.82 Hz, on C-10), 6.14 (1H, *dd*, on C-11), 2.59 (2H, *t, J* = 7.26 Hz, on C-2), 2.29 (2H, *brdt, J* = 7.40, 2.20 Hz, on C-8), 1.2–1.7 (8H, *m*); ^{13}C NMR 75 MHz ($CDCl_3$) ppm ***Z5***: 200.7 (C-9), 192.6 (C-12), 178.5 (C-1), 140.2 (C-10), 137.8 (C-11), 40.3 (C-8), 33.9 (C-2), 28.9, 28.7 C-4, C-5, C-6, 24.5 (C-3), 23.4 (C-7); RI ***Z5*abc** (DB-5) = 2664, 2679; to obtain pentafluorobenzyloxime derivatives an aliquot of the crude extract was treated with 0.1 M solution of PFBHA·HCl in MeOH/H_2O (1:1, vol/vol) for 3 h at RT. Monooximes (R_f = 0.48) and dioximes (R_f = 0.65) of **5** were separated by preparative TLC on SiO_2-TLC plates from Fluka with cyclohexane/ethylacetate (3:1, vol/vol). EI-MS data of derivatives are given in Table 1.

*Synthesis of ethyl 8-[2-furyl]-8-oxo-octanoate (**9a′**).* Thionyl chloride (0.3 mL) was added to a solution of 170 mg (0.84 mmol) monoethyl suberate from Lancaster (Eastgate, England) in 10 mL CH_2Cl_2 under N_2 at RT. Excess of $SOCl_2$ was removed in a mild stream of dry N_2. The resulting monoethyl suberate monochloride was used without further purification. Sixty-three mL dry furan (0.84 mmol), (0.84 mmol), was added to a suspension of 670 mg (0.14 mol) $AlCl_3$ and 212 mg (0.84 mmol) monoethyl suberate monochloride in 10 mL CH_2Cl_2 under dry N_2 and stirred overnight. The reaction mixture was poured onto 20 g ice. $Al(OH)_3$ was redissolved by addition of concentrated HCl. After distribution between H_2O and CH_2Cl_2 (2 × 20 mL), the CH_2Cl_2 solution was dried (Na_2SO_4) and CH_2Cl_2 removed *in vacuo*. IR spectrum **9a′**: 3017 cm^{-1} (aromatic C–H), 2937 cm^{-1} (aliphatic C–H), 1733 cm^{-1} (ester C=O), 1677 cm^{-1} (carbonyl C=O), and 1569 cm^{-1} (aromatic C=C vibrations). The product was used for Wolff-Kishner reduction without further purification (yield 90%, by GC). RI **9a′** (DB-5) = 1920; EI-MS data are given in Table 1.

Synthesis of 8-[2-furyl]-octanoic acid (**7**). Three hundred mg (76 mmol) **9a′**, 100 μL $N_2H_4 \cdot H_2O$ (85 %) from Merck (Hohenbrunn, Germany), 170 mg powdered KOH ,and 10 mL triethylene glycol (TEG) were boiled at 180°C for 2 h. After cooling to RT, 20 mL H_2O was added. The solution was acidified with HCl and distributed between H_2O and CH_2Cl_2 (2 × 20 mL). The washed CH_2Cl_2 solution was dried over Na_2SO_4. CH_2Cl_2 was evaporated *in vacuo*. After preparative TLC, 96 mg (0.58 mmol) 8-[2-furyl]-octanoic acid was obtained (yield = 69%). IR spectrum **7**: broad band at 2800 to 3500 cm^{-1} (acidic O–H), and bands at 2935 cm^{-1} (aliphatic C–H), 1704 cm^{-1} (broad, carbonyl C=O), 1490 and 1560 cm^{-1} (aromatic C=C vibrations). ^1H NMR 300 MHz ($CDCl_3$) δ ppm **7**: 7.28 (1H, *d, J* = Hz, on C-12), 6.26 (1H, *dd, J* = Hz, on C-11), 5.98 (1 H, *dd*, *J* = Hz, on C-10), 2.63 (2H, *brt, J* = Hz, on C-8), 2.36 (2H, *brt, J* = Hz, on C-2) 1.66 (4H, *brt*, on C-3, C-7), 1.35 (6H, *m*, on C-4, C-5, C-6); ^{13}C NMR 75 MHz ($CDCl_3$) δ ppm **7a**: 180.6 (C-1), 156.3 (C-9), 150.6 (C-12), 109.9 (C-11),

[a]Derivatization of the functional groups is indicated by addition of Latin letters to the compound number in respect of derivatization type. The first letter indicates derivatization of the acidic group at C-1 (**a**, methoxy; **a′**, ethoxy; **c**, trimethylsilyloxy). The second letter indicates derivatization of the functional group at the last carbon atom (**b**, pentafluorbenzyloximino; **c**, MSTFA adduct to aldehyde group or trimethylsilyloxy). The third letter indicates derivatization of the hydroxyl or oxo group in the chain (**b**, pentafluorbenzyloximino; **c**, trimethylsilyloxy). Compound structures are illustrated in Schemes 2 and 3. DB-5 column from J&W Scientific (Maiz-Kastel, Germany). Abbreviations: EI-MS, electron impact-mass spectrometry; MSTFA, *N*-methyl-*N*-trimethylsilyl-trifluoroacetamide; RI, retention index.

104.5 (C-10), 34.0 (C-2), 28.8, 27.9, 27.8 C-4, C-5, C-6, C-7, C-8, 24.5 (C-3); RI **7a** (DB-5) = 1619; EI-MS data are given in Table 1.

Mass spectra of derivatives. In order to identify free fatty acids as well as methyl esters derived by saponification, different derivatives of the natural and synthetic products [**4** and 9,12-dioxo-10-dodecenoic acid (**5**)] were prepared by reaction with PFBHA·HCl, MSTFA, and diazomethane according to literature data.

RESULTS AND DISCUSSION

In an investigation of lipid peroxidation in lentil seed flour (*Lens culinaris* Medik.), we trapped aldehydes by addition of PFBHA·HCl). Samples were withdrawn from the extract at 10-min intervals and investigated by GC. We detected, in the C_{24} to C_{28} RI region of gas chromatograms, with increasing incubation time, increasing amounts of four peaks representing pentafluorobenzyloximes (PFBO) (25). The reconstituted ion current of a GC run is reproduced in Figure 1.

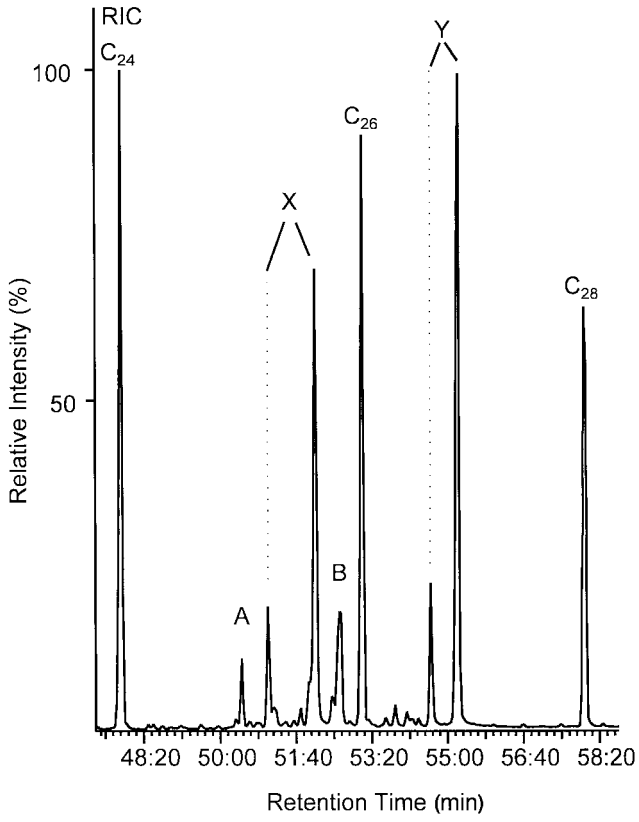

FIG. 1. Reconstituted ion current of the C_{24} to C_{28} region after extraction of lipids and derivatization with pentafluorobenzyloxime hydrochloride, saponification with 1 M NaDMe, and trimethylsilylation with *N*-methyl-*N*-trimethylsilyl trifluoroacetamide (C_{24}, C_{26}, C_{28} = linear hydrocarbons; A = di-(2-ethylhexyl)phthalate (solvent impurity); B = methyl 9,12,13-tris-(trimethylsilyloxy)-10-octadecenoate; X = methyl 12-*O*-2,3,4,5,6-pentafluorobenzyloximino-9-trimethylsilyloxy-10(*E*)-dodecenoate (***E*4abc**); Y = methyl 12-*O*-2,3,4,5,6-pentafluorobenzyloximino-9-trimethylsilyloxy-8,10(*Z*)-dodecadienoate (***Z*5abc**).

The peaks marked X were identified to correspond to *anti*- and *syn*-oxime derivatives of 9-hydroxy-12-oxo-10-dodecenoic acid according to their mass spectra (Fig. 2) and RI values (19). Both peaks marked Y showed nearly identical mass spectra (Fig. 3) and resembled those of X. The main difference in mass spectra of compounds X and Y is a shift of the molecular ions (509 to 507 *m/z*) and the fragment ions of 312 to 310 *m/z*. The presence of a pentafluorobenzyloxime in Y was confirmed by peaks at M – 181 (*m/z* 326) and M – 197 (*m/z* 310) as well as a peak at *m/z* 181, corresponding to the pentyfluorobenzyl ion itself.

The generation of the ion m/z 364 (Fig. 3) is explained by loss of a $–(CH_2)_6–COOCH_3$ side chain forming a 1,3-disubstituted pyridinium ion (Scheme 1), that of *m/z* 378 by benzylic cleavage. Presence of a trimethylsilyloxy group was recognized by the intense peaks at mass 73 and 75. Thus, it was assumed that compound Y might be a further oxidation product of 9-hydroxy-12-oxo-10-dodecenoic acid, obtained by transformation of the hydroxy group into an oxo function, which might have suffered enolization by reaction with MSTFA. Therefore, the original structure of compound Y (Fig. 3) **5** was tentatively deduced to be 9,12-dioxo-10-dodecenoic acid with unknown configuration of the double bond.

To prove the deduced structure of compound Y, **5** had to be synthesized. Since generation of **5** was visualized to be an oxidation product of **4**, synthesis of **5** was envisaged by oxidation from **4**, which is distinguished from 4-HNE only by exchange of the C_5H_{11} residue by $(CH_2)_6–COOH$. Thus, we followed, for synthesis of ***E*4** the route to 4-HNE published by Gardner *et al.* (26), except we started with 10-undecenoic acid **1** as precursor. In a second modification, we used PCC as an oxidant instead of periodine in order to carry out the reaction in nonaquous medium. We reacted **1** with formaldehyde to generate a mixture of *cis/trans* 12-hydroxy-9-dodecenoic acid **2** (24) (Scheme 2). This acid was transformed with DMO (21) or 4-chloroperbenzoic acid to **3**. Compound **3** was then oxidized to ***E*4** and 9,12-dioxo-10(*E*)-dodecenoic acid (***E*5**). Complete oxidation of **3** or ***E*4** to ***E*5** with PCC failed since most of ***E*4** was cyclized to **6** in the acidic medium, which spontaneously eliminated water to **7**, proven by ^{1}H NMR spectroscopy. When ***E*4** was dissolved in unstabilized $CDCl_3$ due to the presence of traces of HCl it was converted within a few hours to **7** as deduced by NMR measurements (data not shown).

Synthesis of ***Z*5** was achieved *via* the furan derivative **7**, which was synthesized by acylation of furan, followed by Wolff-Kishner reduction (Scheme 3). Compound **7** was subjected to a photolytic oxidation in analogy to a reaction described by Wasserman and Lipshitz (27) and Saito *et al.* (28) to the endoperoxide **8**, which suffered cleavage to *cis* 9,12-dioxo-10-dodecenoic acid ***Z*5** by treatment with DMS at –70°C. The latter isomerizes to its *trans* isomer by treatment with ultraviolet (UV)-light at RT. Reaction of **8** with DMS at RT generates the *trans* isomer directly.

The configuration of double bonds at C-10/C-11 was determined in the synthetic samples by NMR. Since the syn-

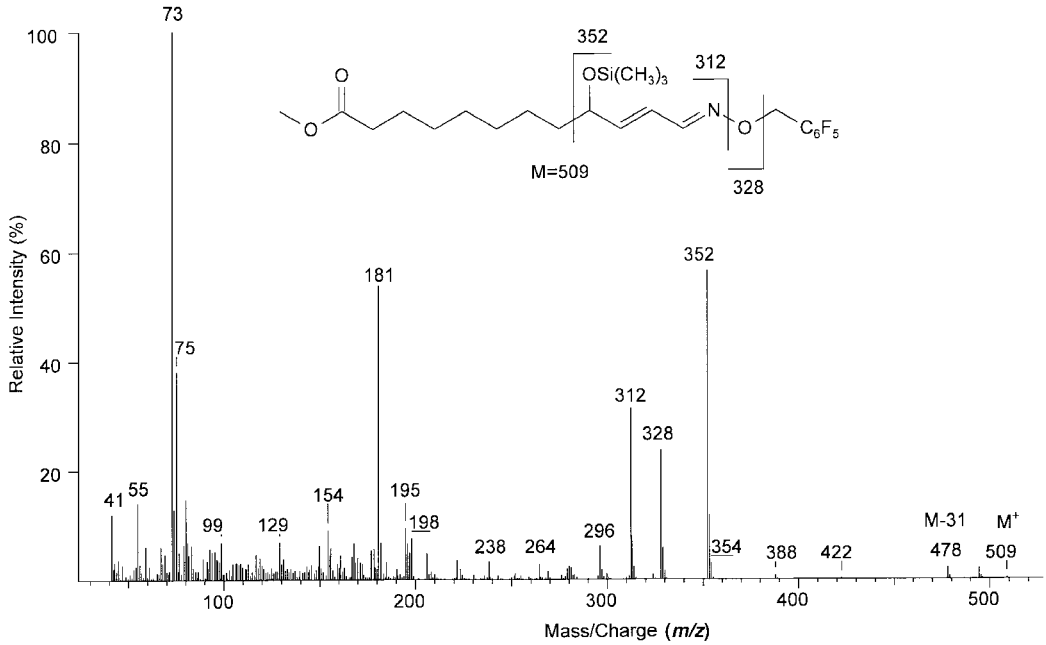

FIG. 2. Mass spectrum of (***E*4abc**). For abbreviation see Figure 1.

thetic isomers of ***E*5** and ***Z*5** show different RI values, it was possible to identify the natural isomers. The large RI difference observed for the two isomers of **4abc** and **5abc**, respectively, was found to be caused by the *E/Z* isomers of the C=N bond of the oximes (*syn/anti* isomers) and not by C=C isomerism. Compound **4** occurs in lentil seed flour incubations only in the form of its *E*-isomer, whereas **5** is generated only in the *Z*-isomeric form. This was unambigiously proven by synthesis and purification of three authentic *E* and *Z* aldehydes ***E*4**, ***E*5** and ***Z*5** and their derivatives.

Compound **5** is an oxidation product of compound **4**. **4** is the counterpart of 4-HNE [exchange of C_5H_{11} with $(CH_2)_6$-COOH]; 4-HNE was detected in enzyme suspensions of soybean (17) and alfalfa (18). Its genesis was derived from 9-HPODE (29–32). Following the deductions in these papers, the precursor of **4** is visualized to be 13-HPODE.

Compound ***E4*** is stable at room temperature, in solid form or in solutions, in the absence of protic reagents. In contrast, we have not been able to isolate ***Z4*** since it spontaneously cyclized to **7** during PCC oxidation. The oxidation of **7** to com-

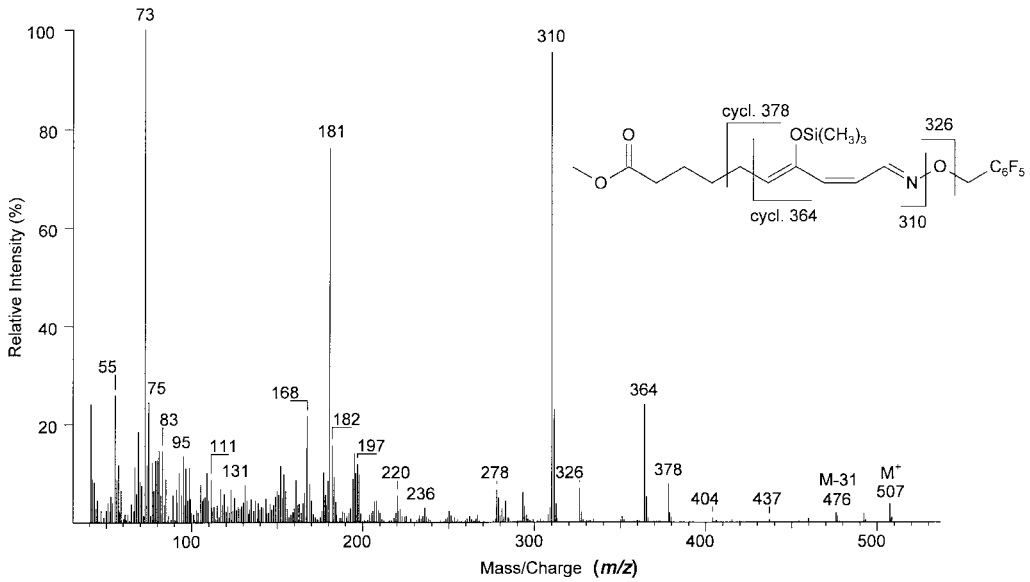

FIG. 3. Mass spectrum of (***Z*5abc**). For abbreviation see Figure 1.

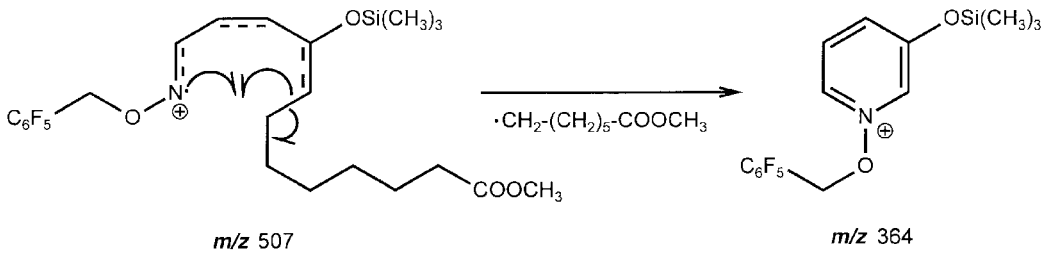
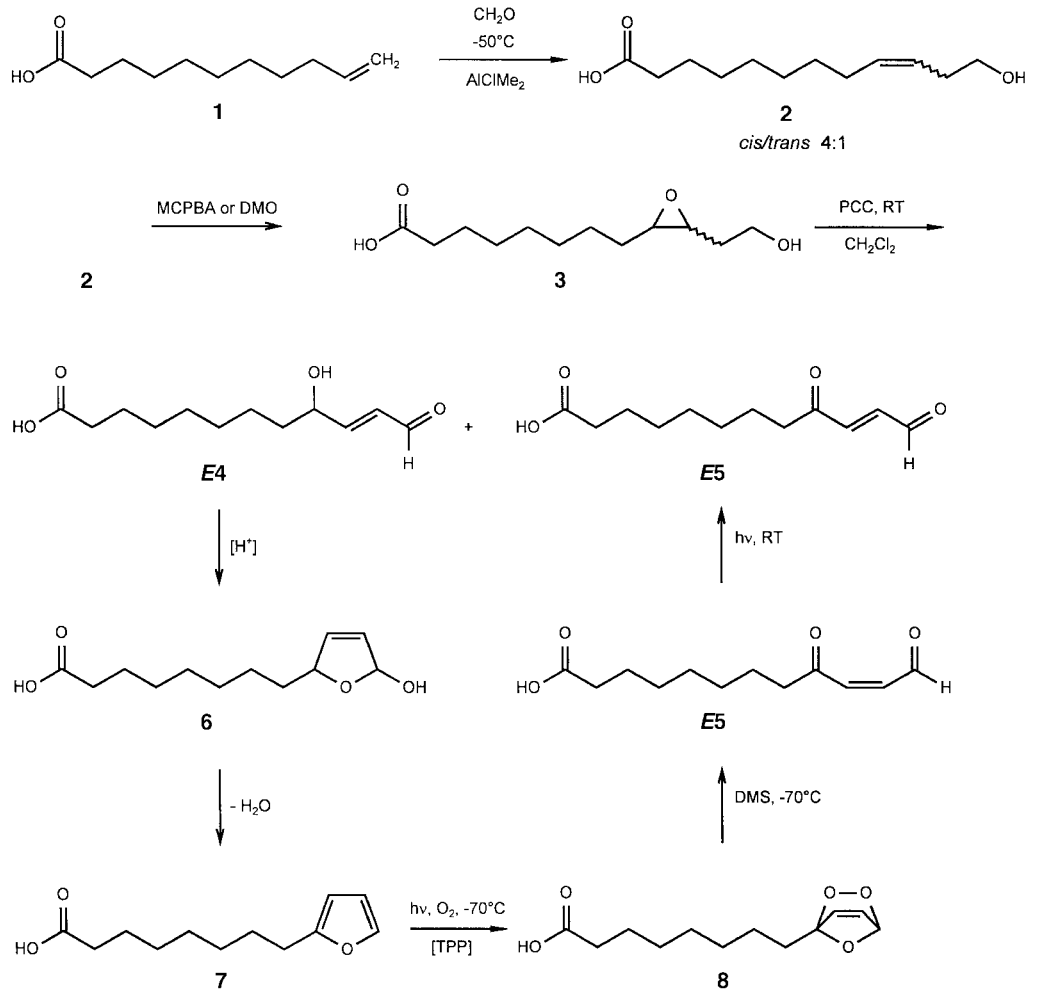


SCHEME 1

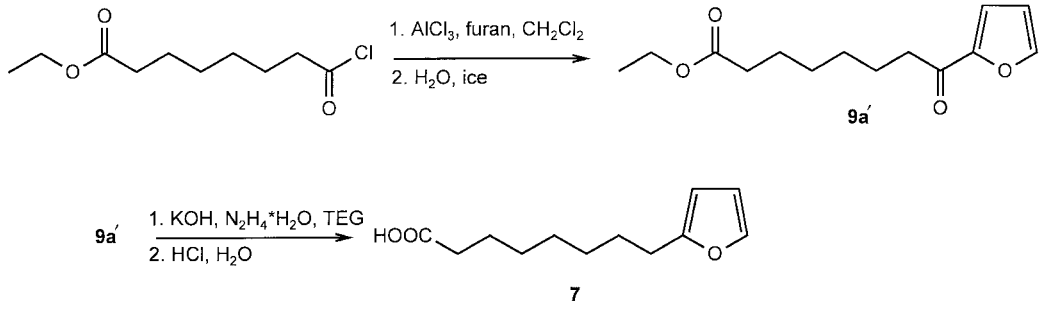


SCHEME 2

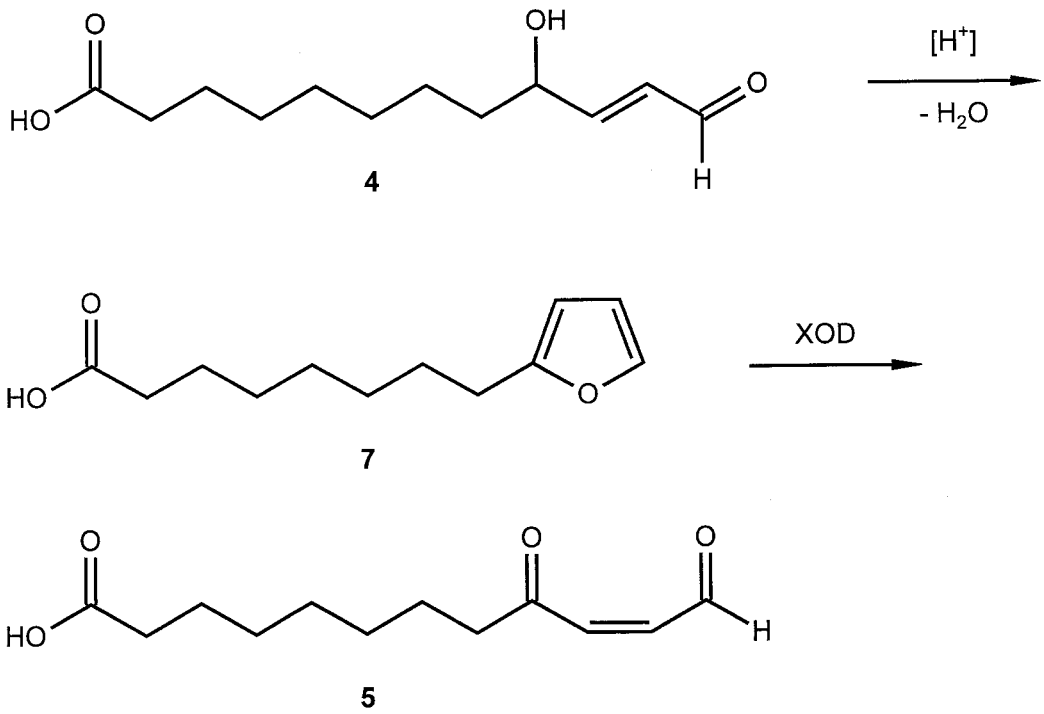
pound ***Z*5** (Scheme 2) by oxygen with UV-light in presence of a suitable sensitizer at –70°C resembles the opening of a furan ring by xanthine oxidase (XOD; EC 1.1.3.22) described by Kellog and Fridovich (33). The described synthesis of ***Z*5** mimics this pathway (Scheme 4). Therefore, it might be possible that **5** is generated in a similar way in lentils by XOD activity.

Treatment of **5** with diazomethane [even for only 10 s (34) and by cooling], still does not produce characterized side products if the aldehyde group is not protected. However, methylation of the free acid with diazomethane was achieved without side reactions after derivatization of the aldehyde group with PFBHA·HCl.

Yamaguchi *et al.* (35) described that **4** inhibits phospholipase A. Compound **5** is very sensitive to nucleophilic or electrophilic attack. Owing to the accumulation of functional



SCHEME 3



SCHEME 4

groups, this compound might show activity in biological material. The synthesis of **5** reported in this paper offers the possibility to elucidate its physiological effects in plant chemistry.

ACKNOWLEDGMENTS

We are obliged to Werner Kern for preparation of solvents and diazomethane, Markus Seitz for experimental assistance, Dr. Joseph Reiner and Marco Burkhard for NMR spectra, and Michael Glaeßner for MS spectra. Formation of 8-Oxo-2′-deoxyguanosine in the DNA of Human Diploid Fibroblasts by Treatment with Linoleic Acid Hydroperoxide and Ferric Ion

Takao Kaneko* and Shoichi Tahara

Tokyo Metropolitan Institute of Gerontology, Itabashi-ku, Tokyo 173-0015, Japan

ABSTRACT: Lipid peroxides are suggested to be related to the occurrence of a variety of diseases including cancer and atherosclerosis. We examined whether lipid peroxides cause oxidative damage to DNA in intact cells. Linoleic acid hydroperoxide (LOOH) and ferric chloride were used at concentrations at which separate treatment had no effect on the formation of 8-oxo-2′-deoxyguanosine (8-oxodG) in DNA or the survival rate of cultured human diploid fibroblasts, TIG-7. The amount of 8-oxodG in the cellular DNA increased significantly when TIG-7 cells were treated concurrently with LOOH and ferric chloride. In a LOOH concentration-dependent manner 8-oxodG was formed. However, no significant induction of the activities of superoxide dismutases, catalase, or glutathione peroxidase was observed under these conditions. The formation of 8-oxodG by lipid hydroperoxides seems to be due to the generation of reactive species other than superoxide radicals and hydrogen peroxide. These results indicate that some species formed during the reaction of lipid hydroperoxides with ferric ion can cause oxidative damage to DNA.

Paper no. L8491 in *Lipids 35,* 961–965 (September 2000).

Amounts of dietary lipids have been suggested to be related to mortality in the case of cancers of some organs, such as breast, colon, kidney, and pancreas (1,2); and lipid peroxides, oxidative products formed when lipids are subjected to oxidative stress, are often considered as a cause of these cancers. Furthermore, lipid peroxides have also been suggested to play roles in atherosclerosis and aging (3). Unsaturated fatty acids are readily oxidized to form their hydroperoxides by both atmospheric oxygen and singlet oxygen. Lipid peroxidation also takes place *in vivo* through the controlled oxidation of unsaturated lipids catalyzed by lipoxygenases. It is known that DNA is damaged during lipid peroxidation (4). Damage to DNA is strongly suggested to be involved in the etiology of a variety of diseases such as cancer and aging because it induces mutagenesis of DNA if it is not repaired. Unsaturated fatty acid hydroperoxides have been reported to cause the cleavage of DNA strands (5) and the formation of fluorescent products in the presence of metal ions (6). Further, it has been reported that autoxidation mixtures of unsaturated fatty acids cause oxidative damage to calf thymus DNA in homogeneous solutions to form 8-oxo-2′-deoxyguanosine (8-oxodG) (7,8). 8-OxodG is a major product of oxidative damage to DNA bases and is thought to be a typical marker of oxidative damage in organisms. The attack of hydroxyl radicals on the C-8 position of the guanine base forms 8-oxodG, which has also been found in DNA after the *in vivo* reaction of DNA with mutagens or carcinogens such as nitrosoamines (9). Thus, DNA damage, such as the formation of 8-oxodG or strand breaks, induced by lipid peroxides appears to be involved in mutagenesis and carcinogenesis. However, lipid peroxides should be present in cellular membranes, since lipid peroxides are lipophilic except for small molecular weight aliphatic aldehydes. It is unclear whether compounds produced during lipid peroxidation actually influence nuclear and/or mitochondrial DNA in cells. To clarify this point, we studied the effect of polyunsaturated fatty acid hydroperoxide, a primary product of lipid peroxidation, on the formation of 8-oxodG in the DNA of cultured human diploid fibroblasts, TIG-7.

MATERIALS AND METHODS

Materials. Nuclease P1 and alkaline phosphatase from *Escherichia coli* were purchased from Sigma Chemical Co. (St. Louis, MO). Ribonucleases T1 and A were obtained from Boehringer Mannheim (Indianapolis, IN) and proteinase K was from E. Merck (Darmstadt, Germany). Wako Pure Chemicals Industries (Osaka, Japan) provided 8-oxodG and polyethylene glycol (PEG; molecular weight: 7,300–9,000) was from Nacalai Tesque Inc. (Kyoto, Japan). Eagle's minimum essential medium (MEM) was purchased from Nissui Pharmaceutical Co. (Tokyo, Japan), and fetal bovine serum (FBS) was from Moregate (Melbourne, Australia). Linoleic acid hydroperoxide (LOOH) was prepared by oxidation of linoleic acid with soybean lipoxygenase-1, and 13-(*S*)-hydroperoxy-9*Z*,11*E*-octadecadienic acid, a main isomer, was purified by

Abbreviations: dG, 2′-deoxyguanosine; ECD, electrochemical detection; FBS, fetal bovine serum; GPx, glutathione peroxidase; HPLC, high-performance liquid chromatography; 8-oxodG, 8-oxo-2′-deoxyguanosine; LOOH, linoleic acid hydroperoxide; MEM, minimum essential medium; PEG, polyethylene glycol; SDS, sodium dodecyl sulfate; SOD, superoxide dismutase; UV, ultraviolet.

high-performance liquid chromatography (HPLC) before use (10). All other chemicals were of analytical grade and used without further purification. The water used in this study was treated with Chelex 100 to remove trace amounts of transient metal ions such as iron ion.

Cell culture. Human embryonic fibroblasts TIG-7 (11), established in the Tokyo Metropolitan Institute of Gerontology, were grown at 37°C in Eagle's MEM supplemented with 10% FBS in 10 cm plastic dishes under a humidified atmosphere of 5% CO_2 and 95% air. Cells at confluency were incubated in Earle solution, pH 7.2, containing LOOH (10–50 μM) solubilized in ethanol and/or 10 μM ferric chloride ($FeCl_3$) at 37°C for 3 h. The final ethanol concentration was less than 0.1% and had no effect on cells. Earle solution is a buffered solution whose only organic compound is glucose. The influence of components such as FBS in the growth medium is expected to be excluded in the system using Earle solution.

Isolation of DNA from TIG-7 cells. DNA was isolated by the sodium iodide and polyethylene glycol method. In brief, cells (*ca*. 5×10^6) incubated in Earle solution containing LOOH and/or $FeCl_3$ were harvested by trypsinization followed by centrifugation at 1,000 rpm for 5 min. Cell pellets were washed twice with phosphate-buffered saline (pH 7.2), resuspended in 50 μL of an aqueous solution of proteinase K (25 mg/mL) and 300 μL of 1% sodium dodecyl sulfate (SDS)/1 mM EDTA (pH 8.0), and incubated at 37°C for 1 h under an argon atmosphere. The resulting solution was mixed with 300 μL of 7 M NaI and 600 μL of isopropyl alcohol and kept at –20°C for 10 min. The mixture was then centrifuged at 14,000 rpm for 20 min. The pelleted DNA was rinsed twice with 70% ethanol and dissolved in 200 μL of 0.01 × SSC (saline-sodium citrate) buffer. Ribonucleases T1 (40 units) and A (80 μg) were added to the crude DNA solution, and the mixture was incubated at 37°C for 1 h under an argon atmosphere. Following incubation, 300 μL of chloroform/isoamyl alcohol (25:1, vol/vol) was added and mixed, and the mixture was centrifuged at 14,000 rpm for 10 min. The aqueous phase was transferred to another tube and mixed with 200 μL of 13% PEG solution containing 1.6 M NaCl, and the mixture was left overnight at 4°C. The mixture was then centrifuged at 14,000 for 20 min, and the DNA was rinsed twice with 70% ethanol and dissolved in 30–50 μL of water treated with Chelex 100. The concentration and purity of the DNA were determined by ultraviolet (UV) absorption as described previously (12).

Hydrolysis of DNA and quantitation of 8-oxodG. DNA, isolated as described above, was hydrolyzed to prepare nucleosides. Acetate buffer (pH 4.8, 20 mM, 25 μL) containing 25 μg DNA and 2 μg of nuclease P1 was incubated at 37°C for 30 min under an argon atmosphere. Then, 3 μL of 1 M Tris-HCl (pH 7.4) and 0.3 units of alkaline phosphatase were added and the mixture was incubated at 37°C for 20 min under an argon atmosphere. The mixture was filtered through an Ultrafree-MC filter (Millipore Co., Bedford, MA) and the filtrate was applied to HPLC equipped with a Symmetry C18 column (particle size, 3.5 μm; 4.6 × 75 mm; Waters Co., Milford, MA). The mobile phase was 12.5 mM citrate buffer (pH 5.1) containing 6% methanol, and the flow rate was 0.8 mL/min. 8-OxodG was detected by electrochemical detection (ECD; ESA Coulochem II 5200; Bedford, MA) using an analytical cell model 5011 (Detector I, 150 mV; Detector II, 350 mV). Oxidative damage to DNA is expressed as the molar ratio of 8-oxodG to 10^5 deoxyguanosine (dG). The amount of dG was calculated from the absorption at 260 nm in the same sample as measured with a UV detector.

Biochemical analysis. Superoxide dismutase (SOD) activity was assayed by the method of Oyanagi (13), catalase activity by the method of Aebi (14), and glutathione peroxidase (GPx) activity by the method of Flohé and Günzler (15). Protein content was measured by the method of Bradford (16).

Statistical analysis. Data are expressed as means ± SD. Scheffe *F*-test was used for the statistical analysis of the data. Differences were considered significant when the probability (*P*) values were less than 0.05.

RESULTS

Damage to TIG-7 cells by LOOH and ferric ion. The survival rate of TIG-7 cells incubated in Earle solution was not affected up to 4 h (survival rate: 99.9 ± 1.9%). Although the survival rates did not change when TIG-7 cells were incubated in Earle solution containing 50 μM LOOH for 3 h, treatment with 100 μM LOOH reduced the survival rate (Table 1). On the other hand, treatment with $FeCl_3$, even at 100 μM, had no effect on the cell survival rate. The rate was decreased by concurrent treatment with LOOH and $FeCl_3$ as shown in Table 1. The 8-oxodG content (0.342 ± 0.066 8-oxodG/10^5 dG) in cellular DNA was slightly increased by incubation with 50 μM LOOH, but the change was not significant (Table 2). On the other hand, incubation of the cells with 25 μM $FeCl_3$ produced a slight increase in 8-oxodG content in cellular DNA (0.386 ± 0.128 8-oxodG/10^5 dG). As shown in Figure 1, concurrent treatment with 10 μM LOOH and 10 μM ferric ion produced a significant elevation in the 8-oxodG content in the DNA of TIG-7 cells (0.587 ± 0.105 8-oxodG/10^5 dG). The content of 8-oxodG in the DNA of TIG-7 cells treated with 10 μM ferric ion and 50 μM LOOH rose further (0.764 ± 0.258 8-oxodG/10^5 dG). If ferric ions

100	63.3 ± 11.0*	94.4 ± 16.5	37.9 ± 9.4*

[a]Cells were incubated in Earle solution containing different concentrations of linoleic acid hydroperoxide (LOOH) and/or $FeCl_3$ at 37°C for 3 h. Results show the means ± SD of four separate experiments performed in duplicate. *Significantly different from the control (0 μM) value at $P < 0.01$.

TABLE 2
Increase in 8-OxodG in the DNA of TIG-7 Cells Treated with LOOH or Ferric Ion[a]

Concentration (μM)	8-OxodG/10^5 dG	
	LOOH	$FeCl_3$
0	0.317 ± 0.062	0.317 ± 0.062
10	0.316 ± 0.039	0.335 ± 0.035
25	0.307 ± 0.054	0.386 ± 0.128
50	0.342 ± 0.066	0.560 ± 0.185*

[a]Cells were incubated in Earle solution containing different concentrations of LOOH or $FeCl_3$ at 37°C for 3 h. The content of 8-oxo-2′-deoxyguanosine (8-oxodG) in the DNA was measured by a high-performance liquid chromatography–electrochemical detection system as described in the Materials and Methods section. Results show the means ± SD of four separate experiments performed in duplicate. *Significantly different from the control (0 μM) value at $P < 0.01$. See Table 1 for other abbreviation.

adhere to the surface of cellular membranes or pass through cellular membranes into the cytosol, they may catalyze the oxidation of DNA during the isolation of DNA from cells. To check this possibility, $FeCl_3$ was added to cell suspensions in an aqueous solution of proteinase K and SDS/EDTA, and then the DNA was isolated. However, the addition of $FeCl_3$ did not change the amount of 8-oxodG in the isolated DNA (0.314 ± 0.104 8-oxodG/10^5 dG).

Effect of LOOH and ferric ion on antioxidant enzyme activity in TIG-7 cells. To clarify whether reactive oxygen species are primarily involved in the formation of 8-oxodG in DNA of cells treated with LOOH and ferric ion, the induction of antioxidant enzyme activities was examined. All the enzyme activities measured showed a tendency to increase with concurrent treatment with LOOH and ferric ion, but the increases were not significant as shown in Table 3.

DISCUSSION

Artificial oxidation is always a serious problem during the isolation of oxidized products of biological molecules such as DNA, lipids, and proteins. In particular, the guanine bases in DNA are easily oxidized during the isolation of DNA from animal tissues or cultured cells and during the hydrolysis of DNA to produce nucleosides or bases (17–22). Phenol and atmospheric oxygen are proposed to be responsible for the formation of 8-oxodG during these procedures (23). In this study, incubation with enzymes during the isolation and hydrolysis of DNA was performed under an argon atmosphere. Furthermore, sodium iodide and isopropyl alcohol were used instead of phenol, sodium chloride, and ethanol for the extraction of crude DNA from samples treated with proteinase K and SDS. The water used in these experiments was treated with Chelex 100 resin to remove trace amounts of iron ions.

Chemical agents that enhance free radical reactions in membranes may accelerate oxidative damage not only to lipids but also to DNA. That is, some products formed during

[a]Cells were incubated in Earle solution containing 50 μM LOOH and 10 μM $FeCl_3$ at 37°C for 3 h. Values represent the means ± SD of four experiments. SOD, superoxide dismutase; GPx, glutathione peroxidase. See Table 1 for other abbreviation.

lipid peroxidation may cause oxidative stress to DNA, because lipid peroxides have been found to cause DNA damage such as strand breaks (24). Furthermore, it has been reported that calf thymus DNA exposed to autoxidized methyl linolenate in solution or in liposomes forms 8-oxodG (8). In this study, we found that unsaturated fatty acid hydroperoxides such as LOOH, primary products of lipid peroxidation, caused oxidative damage to cellular DNA in the presence of ferric ion. As shown in Figure 1, concurrent treatment of TIG-7 cells with LOOH (10 or 50 μM) and $FeCl_3$ (10 μM) induced 8-oxodG formation in a LOOH dose-dependent manner. Ferric ion was essential to the formation of 8-oxodG in the DNA of TIG-7 cells treated with LOOH because treatment with LOOH alone produced little change in the amount of 8-oxodG in the cellular DNA. If ferric ions are attached to the surface of cellular membranes, or if they pass through the cellular membrane into the cytosol, the DNA molecules may encounter ferric ions when the cells are homogenized and this may accelerate the formation of 8-oxodG. To examine this effect of ferric ions, we added $FeCl_3$ (final concentration: 10 μM) to cell suspensions containing proteinase K, SDS, and extracted cellular DNA. The amounts of 8-oxodG were not elevated by the addition of ferric ions. Furthermore, the possibility that the DNA in dead cells might be oxidized by ferric ions to produce 8-oxodG was excluded by the finding that the 8-oxodG contents in cellular DNA, treated concurrently with 10 μm LOOH and 10 μm $FeCl_3$, were elevated without a decrease in the cell survival rate. These results indicate that the concurrent existence of LOOH and ferric ion enhances the formation of 8-oxodG in cellular DNA. Lipid hydroperoxides have been reported to induce DNA strand breaks in cultured human lung fibroblasts (25) and human lymphocytes (26). From this study, it was found that lipid hydroperoxides not only cause DNA strand breaks but also the oxidation of DNA bases.

Lipid hydroperoxides are effectively reduced by GPx or glutathione S-transferase in cells to the corresponding alcohols (27). However, if these antioxidant enzyme activities are lowered or hydroperoxide contents overcome the defense ability, hydroperoxides will exert their harmful effects upon biological systems. Lipid hydroperoxides are readily decomposed in the presence of transient metal ions to form alkyl peroxyl radicals, alkoxyl radicals, and hydroxyl radicals. Since lipids are present in membranes in biological systems, endogenous lipid hydroperoxides should be located mostly within membranes. Lipid hydroperoxides added to the medium are thought to be present in membranes if they are incorporated into cells. Thus, species formed by the decomposition of lipid hydroperoxides must shift to the cytosol to cause damage to DNA. The fact that 8-oxodG was formed in cellular DNA in the concurrent presence of LOOH and ferric ion indicates that hydroxyl radicals are finally formed in this system. If superoxide radical and/or hydrogen peroxide is the primary product formed in this system, then the induction of antioxidant enzyme activities, such as SOD, catalase and GPx, might be observed. However, the activities of these enzymes are only slightly increased by concurrent treatment with LOOH and ferric ion, and these changes are not significant. Thus, superoxide or hydrogen peroxide may not be present as the primary cause of DNA oxidation.

The mechanism of oxidative DNA damage in cellular systems by unsaturated fatty acid hydroperoxides and ferric ion is unclear at present. However, the formation of 8-oxodG indicates the involvement of hydroxyl radicals in this system. The production of hydroxyl radicals is well known in the reaction of various hydroperoxides with transition metal ions (28). However, it is hardly considered that hydroxyl radicals have a direct influence on DNA in nuclei or mitochondria even if they are formed from the decomposition of LOOH. On the other hand, alkyl peroxyl radicals have been reported to be generated from the reaction of organic hydroperoxide and heme iron, to be a major cytotoxic species against gram-positive bacteria, and to be stably generated at steady concentrations for 30 min or longer (29). Furthermore, it has also been shown that the alkyl peroxyl radicals generated by the reaction of alkyl hydroperoxide with hemoglobin cause single-strand breaks (30). Alkyl peroxyl radicals may be generated in our reaction system. Further research is needed to clarify more precisely the reactive species in this reaction.

ABSTRACT: Oxidative stress is believed to play an important role in the pathophysiology of asthma. Recently discovered F2-isoprostanes, of which 8-iso-$PGF_{2\alpha}$ is the most well-known isomer, have emerged as the most reliable marker of *in vivo* oxidative stress. The aim of this study was to examine 8-iso-$PGF_{2\alpha}$ as a biomarker of oxidative stress in mild asthma in relation to endogenous and dietary antioxidant protection. Total (free and esterified) plasma 8-iso-$PGF_{2\alpha}$, plasma dietary antioxidants (vitamins E and C, β-carotene, Zn, and Se), and erythrocyte antioxidant enzyme activities (glutathione peroxidase and superoxide dismutase) were measured in 15 mild asthmatics and 15 age- and sex-matched controls. Total plasma 8-iso-$PGF_{2\alpha}$ levels [median (quartile 1 – quartile 3)] were significantly increased in the asthmatics [213 pg/mL (122–455) vs. 139 pg/mL (109–174), P = 0.042]. The 8-iso-$PGF_{2\alpha}$ levels were found to be associated with clinical asthma severity (P = 0.044) and inhaled corticosteroid use (P = 0.027) in asthmatics. No differences were observed in the plasma dietary antioxidant vitamins. The asthmatics had significantly lower plasma levels of Zn (P = 0.027) and Se (P = 0.006). Plasma Se correlated negatively with 8-iso-$PGF_{2\alpha}$ (r = –0.725, P = 0.002). No differences between the groups were observed for glutathione peroxidase or superoxide dismutase, however, superoxide dismutase activity was negatively associated with asthma severity (P = 0.042). In conclusion, oxidative stress is increased in mild asthmatics, as reflected by increased plasma levels of 8-iso-$PGF_{2\alpha}$ and a deficiency in plasma Zn and Se. The isoprostane 8-iso-$PGF_{2\alpha}$ may provide a useful tool in intervention studies aimed at improving clinical status in asthma.

Paper no. L8398 in *Lipids 35,* 967–974 (September 2000).

Oxidative stress is believed to play an important role in the pathophysiology of asthma (1,2), which is characterized by many factors such as bronchial hyperresponsiveness, increased vascular permeability with edema of airway walls, mucus hypersecretion with small airway plugging, and infiltration by inflammatory cells (1). Inflammatory cells that are sequested and activated in asthmatic airways include mast cells, macrophages, eosinophils, neutrophils, lymphocytes, and platelets (1). These cells release a variety of mediators that are involved in the inflammatory response, including a range of toxic reactive oxygen species (ROS), such as the superoxide, hydrogen peroxide, and hydroxyl radicals (1,2). These ROS can have many detrimental effects on airway function such as peroxidation of membrane lipids, leading to epithelial cell disruption and/or death; DNA damage; alteration in important biomolecules such as surface receptor proteins and enzymes; enhanced release of arachidonic acid from membranes causing smooth muscle contraction; impaired β-adrenergic responsiveness; increased airway reactivity and secretions; and increased vascular permeability (1). Many of these effects will contribute to the variable and reversible airway narrowing that is characteristic of asthma, suggesting that ROS may contribute to the pathophysiology of the disease by several different mechanisms.

Evidence for the occurrence of oxidative stress in asthma includes: increased exhaled hydrogen peroxide and nitric oxide (3,4), increased thiobarbituric acid-reactive substances (TBARS) (2), decreased Trolox equivalent antioxidant capacity (TEAC) (2), altered status of antioxidant enzymes [glutathione peroxidase (GSHPx), superoxide dismutase (SOD), and catalase] (4–8) and their cofactors (Se and Zn) (5,6,9), decreased vitamin E (4,10), decreased vitamin C (10), increased generation of ROS from inflammatory cells *in vitro* (11), and decreased levels of lipoperoxidation substrates (12). Although measurements such as the *in vitro* TBARS test, breath alkane levels, hydroperoxides, conjugated dienes, and others are satisfactory in many circumstances, they have met criticism by a number of investigators, particularly when examining oxidative stress *in vivo* (13,14). These tests have limited specificity and/or sensitivity for oxidative stress or

may be unreliable when applying the techniques to human subjects (14).

Isoprostanes, a recently discovered marker of oxidative stress, can be measured in plasma, urine, or other biological fluids (15–18), and overcome many of the methodological problems surrounding other markers. They are prostaglandin-like compounds produced *in vivo via* the cyclooxygenase-independent free radical-catalyzed oxidation of arachidonic acid (16). The most well-known isomer is 8-iso-$PGF_{2\alpha}$. Isoprostanes are now accepted to be the most accurate and reliable marker of oxidative stress, because they are structurally stable, are produced *in vivo*, and are present in relatively high concentrations (16). Indeed, as a marker of oxidative stress, the 8-iso-$PGF_{2\alpha}$ determination of carbon tetrachloride-induced lipid peroxidation is believed to be 20 times more sensitive than measurement of TBARS (17). Furthermore, isoprostane levels have been shown to increase in experimental models of injury, and can be suppressed using antioxidants (16).

The aim of this study was to examine oxidative stress in mild asthma using plasma 8-iso-$PGF_{2\alpha}$ as a biomarker and to examine antioxidant defenses in asthmatics, by studying both endogenous (erythrocyte GSHPx and SOD) and dietary (plasma vitamins E and C, β-carotene, Zn, and Se) antioxidant protection.

MATERIALS AND METHODS

Subject recruitment. Fifteen asthmatic subjects and 15 age- and gender-matched healthy controls were recruited for the study. All asthmatics studied had attended asthma clinics at the John Hunter Hospital and undergone pulmonary function testing in our laboratory. The diagnosis of asthma was made by a respiratory physician based upon a history of episodic respiratory symptoms, a doctor's prior diagnosis of asthma, the use of inhaled asthma therapy (β_2 agonists, corticosteroids, cromolyn, long-acting β_2 agonists), and all patients demonstrated a >12% improvement in their forced expiratory volume in 1 s (FEV1) in response to bronchodilator in our pulmonary function laboratory (19,20). All patients were clinically stable from an asthma viewpoint. Specifically, none had required oral corticosteroids for 3 mon prior to participation in this study. None had altered their preventive medications in the 4 wk prior to enrollment. The exclusion criteria were (i) age less than 5 yr (unable to perform reproducible spirometry), (ii) vitamin supplements taken in the last 4 wk, (iii) presence of other diseases known to be associated with elevated oxidative stress (cancer, diabetes, arthritis, or cystic fibrosis). Informed written consent was obtained from the subjects and/or their guardians. Ethics approval was obtained from the Hunter Area Health Service and the University of Newcastle Human Research Ethics Committees.

Subject characteristics. Each subject was assessed by a respiratory physician, who administered a questionnaire to assess current symptoms and treatment, past severity, and prior hospitalization. Subsequently, each subject's asthma severity was classfied as infrequent episodic, frequent episodic, or persistent, using standard criteria (19) (Table 1). All subjects were clinically stable when assessed. Routine pulmonary function tests were performed in all subjects using a spirometer (Medgraphics 1085D Breeze™ cardiorespiratory diagnostic software 1991, St. Paul, MN) with established normal values (21). FEV1 and forced vital capacity (FVC) were recorded and compared to predicted values. Height was measured with a Holtain, Crymych, Dyfed stadiometer. Weight was recorded using GEC/Avery digital scales (model number 824/890). Blood was collected in EDTA-coated tubes for full blood counts, performed using a Coulter Gen-S analyzer.

Vitamins and minerals. Blood samples were collected in EDTA-coated tubes and then centrifuged at 3,000 rpm at 4°C for 10 min. Plasma was collected and frozen at –70°C within half an hour of blood collection. Plasma levels of vitamins A and E and β-carotene were separated on a reversed-phase high-performance liquid chromatography (HPLC) column and measured using a variable wavelength ultraviolet (UV)-visible detector. Samples were thawed, mixed with ethanol to precipitate proteins, and vortexed; then hexane was added. After vortexing again, samples were centrifuged and the hexane phase removed and injected into an HPLC column [lab-packed Whatman ODS 3 (5 µm) 300 × 3.5 mm i.d.], with a flow rate of 1 mL/min, run time of 20 min, at ambient temperature. At 0.01 min, vitamin A was measured at 310 nm; at 5.5 min, vitamin E was measured at 280 nm; and at 9.0 min, β-carotene was measured at 450 nm. Plasma vitamin C was separated on a reversed-phase HPLC column and measured using an electrochemical detector. Samples were mixed with trichloracetic acid to precipitate proteins, vortexed, and centrifuged; and the supernatant was injected into an HPLC column [lab-packed Whatman ODS 3 (5 µm) 150 × 3.5 mm i.d.], with a flow rate of 1 mL/min, run time of 15 min, at ambient temperature. Measurements were made with an amperometric electrochemical detector with potential +0.6 V vs. Ag/AgCl reference electrode. Plasma levels of zinc, selenium, and copper were analyzed by inductively coupled plasma–mass spectrometry (ICP–MS). Samples were diluted in an ammonium EDTA-based diluent in a quantitative appli-

TABLE 1
Classification of Asthma

	Infrequent episodic	Frequent episodic	Persistent

Use of bronchodilators	Not needed between exacerbations	< 3 Times weekly	Most days
Interval preventative therapy	Not required	May be required	Always required

cation. Platinum and rhodium were used as internal standards in the diluent. Calibration was by additions calibration in a pooled plasma base.

Total (free and esterified) 8-iso-$PGF_{2\alpha}$ assays. Blood samples were collected in EDTA-coated tubes, containing reduced glutathione (Sigma Chemical Company, St. Louis, MO) as an antioxidant. The samples were centrifuged at 3,000 rpm at 4°C for 10 min. The plasma fraction was removed and stored at −70°C in tubes precoated with butylated hydroxytoluene (BHT) (Sigma) for 8-iso-$PGF_{2\alpha}$ analysis. To an aliquot of plasma, a known amount of tritium-labeled thromboxane B_2 (TxB_2) (Amersham, Arlington Heights, IL) was added, to allow determination of recovery rate after purification procedure. Ethanol was added, the sample was chilled at 4°C, then centrifuged at 1,500 × *g* for 10 min to remove the precipitated proteins. The supernatant was decanted, an equal volume of 15% KOH was added and the resultant solution incubated at 40°C for 1 h, to cleave any esterified isoprostane. The sample was diluted with H_2O, then the pH was lowered with HCl to below 4.0. The sample was passed through a Sep-Pak C-18 reversed-phase cartridge (Waters, Milford, MA) which had been activated by rinsing with methanol, then H_2O. After passing the sample through, the cartridge was rinsed again with H_2O, then hexane. Finally, the 8-iso-$PGF_{2\alpha}$ was eluted with ethyl acetate containing 1% methanol. This solvent was evaporated using N_2, and the sample reconstituted with assay buffer. Purified sample was added to aqueous biodegradable counting scintillant (Amersham), and counted using a liquid scintillation counter, to determine recovery rates. A quantity of the remaining portion was analyzed with an 8-isoprostane enzyme immunoassay kit (Cayman Chemical, Ann Arbor, MI). Absorbance values were measured by using a plate reader and a wavelength of 405 nm, and the raw data were corrected for recovery. The assay was validated by adding a series of known amounts of pure 8-iso-$PGF_{2\alpha}$ standard to equal volumes of purified plasma. The concentration of total 8-iso-$PGF_{2\alpha}$ in these samples was determined by using enzyme immunoassay (EIA). A high correlation (0.99) was obtained between the known amounts of pure 8-iso-$PGF_{2\alpha}$ added and the concentration determined by EIA. The antiserum used in this assay has a 100% cross-reactivity with 8-iso-$PGF_{2\alpha}$; 0.2% each with $PGF_{2\alpha}$, $PGF_{3\alpha}$, PGE_1, and PGE_2; and 0.1% with 6-keto-$PGF_{1\alpha}$. The detection limit of the assay is 4 pg/mL. This kit has been used to measure 8-iso-$PGF_{2\alpha}$ concentration in human plasma, bronchoalveolar lavage, and other fluids (15,18,22).

GSHPx enzyme assay. Whole blood was collected into EDTA-coated tubes and centrifuged at 8,500 × *g* at 4°C for 10 min. Plasma was discarded, and cells were washed with 10 vol of ice-cold buffer (50 mM Tris-HCl, pH 7.5, containing 5 mM EDTA and 1 mM dithiothreitol). Samples were centrifuged again at 8,500 × *g* at 4°C for 10 min, and supernatant was discarded. Cells were then lysed by adding exactly 4 vol of ice-cold deionized water. After centrifuging again at 8,500 × *g* at 4°C for 10 min, supernatant was collected and stored at −70°C for analysis. Erythrocyte GSHPx activities were measured using a GPx-340 spectrophotometric assay kit (Bioxytech; OXIS International, Portland, OR), to obtain values in units per mL. The hemoglobin (Hb) concentration of the samples was also measured using Sigma Kit No. 525 for Total Hemoglobin, to allow erythrocyte GSHPx activity to be expressed as units per g of Hb.

SOD enzyme assay. Whole blood was collected into EDTA-coated tubes, and centrifuged at 3,000 rpm at 4°C for 10 min. The erythrocyte pellet was separated and stored at −70°C before analysis. The erythrocyte pellet was thawed and resuspended in 4 vol of ice-cold water and vortexed thoroughly. Ice-cold extraction reagent (ethanol/chloroform, 62.5:37.5 vol/vol) was added to the erythrocyte suspension and vortexed for 30 s. Samples were centrifuged at 3,000 × *g* at 4°C for 10 min. The upper phase was collected and stored at −70°C for analysis. Erythrocyte Zn/Cu-SOD activities were measured using SOD-525 spectrophotometric assay kit (Bioxytech; OXIS International), to obtain values in units per mL. The Hb concentration of the samples was also measured using Sigma Kit No. 525 for Total Hemoglobin, to allow erythrocyte Zn/Cu-SOD activity to be expressed as units per mg of Hb.

Dietary intake. Dietary intake was assessed using the 24-h recall method (23). Analysis of food records was conducted using the Diet/1 Nutrient Calculation Software, which is based on the 1992 Australian food tables and the composition of Australian manufactured foods (24). The mean intakes of energy, protein, fat, carbohydrates, fiber, retinol, β-carotene, vitamin A equivalents, vitamin C, iron, and zinc for each subject group were determined from these.

Statistical analysis. Results were analyzed using a standard computer statistical package (Minitab Inc. Version 12 for Windows 1997, State College, PA). Data were tested for normality using the Anderson-Darling test. Statistical comparisons were performed using the paired Student *t*-test for normally distributed data and the Wilcoxon paired test for nonparametric data. Correlations between variables were studied by linear regression, with calculation of Pearson's correlation coefficient for normal data, and Spearman's rank correlation coefficient for nonparametric data. Subgroup analysis was done using the Kruskal-Wallis test for nonparametric variables and the analysis of variance test for normal variables (25). The mean ± standard error is reported for normal data; for nonparametric data the median (quartile 1 – quartile 3) is reported. Differences were considered significant when $P < 0.05$.

RESULTS

Demographic data are reported for 15 asthmatic subjects (median age 14.0 yr) and 15 age- and sex-matched healthy controls (median age 14.0 yr) (Table 2). There were no significant differences between the mean height or weight of the two groups. Pulmonary function testing revealed no difference in lung function between the groups as indicated by the percentage predicted FEV1, percentage predicted FVC, and

TABLE 2
Characteristics of Healthy Controls and Asthmatics

Variable	Controls (n = 15)	Asthmatics (n = 15)	P value
Sex (M/F)	8/7	8/7	
Age (yr)[a]	14.0 (11.0–29.0)	14.0 (11.0–29.0)	1.000
<18 yr	9	9	
≥ 18 yr	6	6	
Smoking status (Y/N)	0/15	0/15	
Height (cm)[b]	164.0 ± 3.8	165.7 ± 4.7	0.576
Weight (kg)[b]	60.8 ± 4.6	62.1 ± 6.4	0.754
%FEV1[b]	102.7 ± 2.7	99.5 ± 4.3	0.533
%FVC[b]	102.5 ± 3.0	103.6 ± 4.4	0.836

Neutrophil count (10^9/L)[b]	2.91 ± 0.23	3.21 ± 0.30	0.260
Eosinophil count (10^9/L)[a]	0.20 (0.10–0.23)	0.30 (0.20–0.40)	0.014

[a]Non-parametric data analyzed by using Wilcoxon paired test. Values reported are median (quartile 1 – quartile 3).
[b]Normal data analyzed using Student's paired *t*-test. Values reported are mean ± SEM.

FEV1/FVC (Table 2). Subjects were classified as infrequent episodic, frequent episodic, and persistent asthmatics (Table 3) (19).

As expected, the peripheral blood eosinophil count was significantly higher in the asthmatic group (P = 0.014) than in the controls, indicative of the disease often being atopic in nature (Table 2). Eosinophil count was associated with clinical asthma severity (P = 0.032) and inhaled corticosteroid use (P = 0.003).

Total (free and esterified) plasma 8-iso-$PGF_{2\alpha}$ levels were found to be elevated in the asthmatics compared to the controls (P = 0.042) (Fig. 1). The 8-iso-$PGF_{2\alpha}$ levels were associated with clinical asthma severity (P = 0.044) and inhaled corticosteroid use (P = 0.027) in asthmatics (Figs. 2A and 2B). All subjects had normal lung function (Table 2), and no correlation was observed between total 8-iso-$PGF_{2\alpha}$ levels and lung function. There was no relationship between lung function and disease severity.

Plasma levels of Zn and Se were both significantly lower in the asthmatics (P = 0.027 and 0.006, respectively) (Table 4), with Se levels correlating negatively with total plasma 8-iso-$PGF_{2\alpha}$ levels (r = –0.725, P = 0.002). Erythrocyte SOD activity was lower in the asthmatics, with this difference approaching significance (P = 0.076). SOD activity was negatively associated with clinical severity of asthma (P = 0.042), with the more severely asthmatic subjects having reduced SOD activity. There was, however, no significant difference in the erythrocyte activity levels of GSHPx and no association between GSHPx activity and clinical severity.

Plasma levels of the dietary antioxidants β-carotene and vitamins E and C were similar in the two groups. There was no correlation between total plasma 8-iso-$PGF_{2\alpha}$ and plasma dietary antioxidants. Dietary analysis indicates that there was no significant difference in the nutrient intake of the groups (Table 5).

DISCUSSION

This study demonstrated reduced levels of plasma Zn and Se, increased total plasma 8-iso-$PGF_{2\alpha}$ levels, and a negative cor-

relation between plasma 8-iso-$PGF_{2\alpha}$ and Se levels in mild asthmatics, providing further evidence that oxidative stress is elevated in asthma. Moreover, this study showed a positive association between asthma severity and the level of total plasma 8-iso-$PGF_{2\alpha}$ and a negative association between asthma severity and erythrocyte SOD enzyme activity. By implication, simple dietary antioxidant supplementation may provide adjunctive therapy for asthmatics, especially those more severely affected.

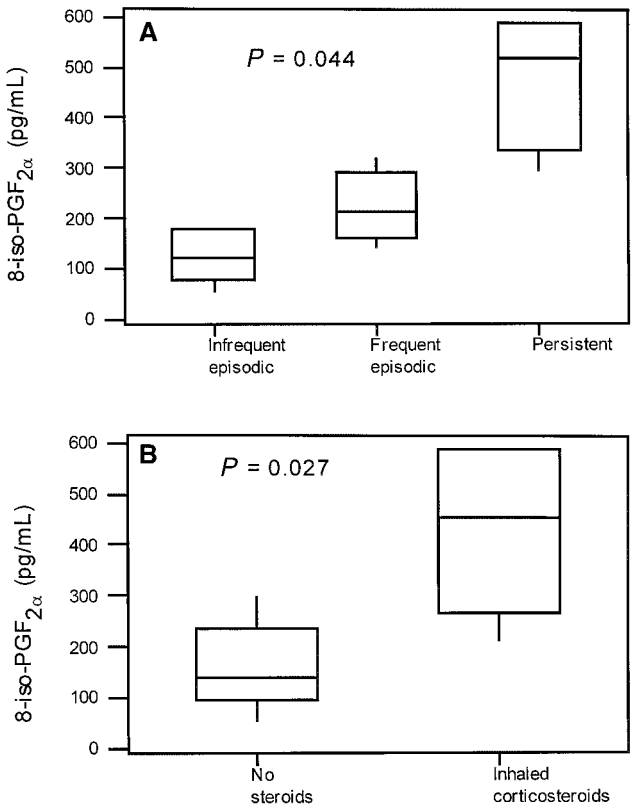

FIG. 2. (A) Total plasma 8-iso-$PGF_{2\alpha}$ levels in asthmatics with infrequent episodic (n = 7), frequent episodic (n = 4), and persistent (n = 4) asthma. An association between 8-iso-$PGF_{2\alpha}$ and asthma severity is observed (P = 0.044). (B) Total plasma 8-iso-$PGF_{2\alpha}$ levels in steroid-naïve asthmatics (n = 10) vs. asthmatics using inhaled corticosteroids (n = 5). An association between 8-iso-$PGF_{2\alpha}$ and steroid use is observed (P = 0.027). Plots show medians and interquartile ranges (quartile 1 – quartile 3).

Inflammation of the airways is believed to be a main contributor to oxidative stress in asthma (1). Inflammatory cells that may release ROS into asthmatic airways include mast cells, macrophages, neutrophils lymphocytes, platelets, and, in particular, eosinophils (1). In our study, the higher eosinophil count in the asthmatics and the association between eosinophil count and asthma severity demonstrate that severity of asthma is related to the degree of inflammation. Furthermore, the positive association demonstrated between eosinophil count and inhaled corticosteroid use indicates that inflammation persists despite steroid use in these patients.

As inflammation is persistent and increases with disease severity in the asthmatics, it is not surprising that we observed an elevation in oxidative stress, as measured by plasma 8-iso-$PGF_{2\alpha}$ levels, and a positive association between 8-iso-$PGF_{2\alpha}$ levels and asthma severity. A similar trend was recently reported by Montuschi *et al.* (18), who reported elevated 8-iso-$PGF_{2\alpha}$ levels in breath condensate of asthmatics, with 8-iso-$PGF_{2\alpha}$ levels increasing as asthma severity increased. The positive association we observed between 8-iso-$PGF_{2\alpha}$ levels and inhaled corticosteroid use also agrees with the work of Montuschi *et al.* (18), who reported higher 8-iso-$PGF_{2\alpha}$ in breath condensate of severe asthmatics using oral steroids, compared to mild asthmatics who were steroid-naive. In contrast, studies using other indices of oxidative stress have reported inhibition of oxidation in response to steroid use (3,26). In our study, it is likely that 8-iso-$PGF_{2\alpha}$ concentrations remained elevated in patients using inhaled corticosteroids because the treatment had not effectively controlled their asthma, resulting in residual inflammation and oxidative stress. Studies examining the relationship between steroid use, residual inflammation, and oxidative stress are warranted.

As isoprostanes have also been observed to be potent vasoconstrictory agents in rat lungs (27), one can speculate about their contribution to the airway narrowing that is characteristic of asthma. Although the situation in humans *in vivo* may be different, the full impact of elevated isoprostane levels on pulmonary function remains to be established, and isoprostanes may prove to have an important biological role as well as being an important *in vivo* marker of oxidative stress.

While there is evidence suggesting 8-iso-$PGF_{2\alpha}$ may also be produced enzymatically by cyclooxygenase activity in some cells and tissues (28), this does not appear to occur in humans *in vivo* (29). Thus, this marker is still believed to be an accurate indicator of oxidative stress (30). The EIA methodology used in this study to measure 8-iso-$PGF_{2\alpha}$ provides an inexpensive, accessible alternative to analysis by gas chromatography–mass spectrometry (GC–MS). The values of total 8-iso-$PGF_{2\alpha}$ we observed in normal plasma using the EIA method are similar to those obtained by Morrow *et al.* using GC–MS (31). As discussed by Morrow and Roberts (16), GC–MS assay is expensive and labor-intensive and uses technology that is not widely available. Thus, the use of spe-

TABLE 4
Biochemical Markers—Plasma Levels of 8-iso-$PGF_{2\alpha}$, Vitamin E, Vitamin C, β-Carotene, Vitamin A, Zn, Se, Cu, and Erythrocyte Levels of GSHPx and SOD Activity

Biochemical marker	Controls	Asthmatics	*P* value
8-Iso-$PGF_{2\alpha}$ (pg/mL)[a]	139 (109 – 174)	213 (122 – 455)	0.042
Vitamin E (μmol/L)[a]	17 (14 – 21)	17 (15 – 20)	0.900
Vitamin C (μmol/L)[b]	57.2 ± 7.4	54.2 ± 7.1	0.562
β-Carotene (μmol/L)[a]	0.4 (0.2 – 0.6)	0.3 (0.2 – 0.6)	0.701
Vitamin A (μmol/L)[a]	1.6 (1.4 – 1.9)	1.6 (1.3 – 1.9)	0.286
Zn (μmol/L)[b]	12.8 ± 0.4	11.5 ± 0.4	0.027
Se (μmol/L)[b]	1.35 ± 0.06	1.16 ± 0.08	0.006

cific immunoassays has expanded research in this area, with several studies using the EIA methodology recently being reported (15,18,22).

Our data showed a significant deficiency in plasma Zn levels in asthmatics, supporting results from other researchers (32). Zn plays an important role as an antioxidant, with the probable mechanisms being stabilization of sulfhydryl groups to prevent intramolecular disulfide formation, displacement of bound Cu and Fe to prevent electron transfer, and reduction of free radical production in neutrophils (33). Thus, the consequence of Zn deficiency in the asthmatics is reduced antioxidant protection.

Zn is also a cofactor for the antioxidant enzyme, Cu,Zn-SOD. Located primarily in the cytosol and mitochondria of cells, SOD catalyzes the dismutation of the superoxide anion into oxygen and hydroperoxide, which is then acted upon by GSHPx to form water. The activity and synthesis of this enzyme, however, are not decreased by dietary Zn deficiency (34), as Zn can be replaced at the structural site by other metals. Previous studies of SOD activity in asthmatics are inconsistent, with both decreased activity (7,26) and increased activity (8) being reported. These data are difficult to compare owing to variations in disease severity and differences in the cell types and blood components being measured. In our study, erythrocyte SOD activity was not significantly reduced in the asthmatics. There was, however, a negative association between SOD activity and asthma severity. This suggests that SOD levels are only diminished in the case of severe oxidative stress, when the oxidant burden exceeds the host's ability to upregulate antioxidant enzyme protection.

The asthmatic subjects in our study also had low plasma Se levels, supporting results of other researchers, who have reported decreased levels of Se in whole blood (5,9), plasma/serum (6,9), and erythrocytes (6). Se is an essential component of the GSHPx enzyme, necessary for both its synthesis and activity. Thus, many reports have linked Se deficiency to a decrease in GSHPx activity (5,6). Our data, however, which are also supported by other researchers (9,26), showed no deficiency in erythrocyte GSHPx activity despite low plasma Se levels. This suggests that Se has another func-

TABLE 5
Nutrient Intake of Healthy Controls and Asthmatics

Nutrient/kg body weight	Controls	Asthmatics	*P* value
Energy (kJ)[a]	171.3 ± 12.4	158.6 ± 10.7	0.360
Protein (g)[a]	1.7 ± 0.2	1.3 ± 0.1	0.116
%Protein[a]	16.9 ± 1.0	14.7 ± 0.9	0.119
Fat (g)[a]	1.5 ± 0.2	1.3 ± 0.2	0.415
%Fat[b]	32 (30 – 36)	31 (21 – 41)	0.496
Carbohydrate (g)[a]	5.1 ± 0.4	5.1 ± 0.3	0.948
%Carbohydrate[a]	49.7 ± 2.4	53.9 ± 3.1	0.269
Fiber (g)[a]	0.35 ± 0.03	0.34 ± 0.01	0.981
Vitamin A (μg)[a]	6.8 ± 1.1	7.0 ± 1.1	0.926
β-Carotene (μg)[b]	42.6 (18.1 – 90.6)	16.7 (11.0 – 36.1)	0.164
Vitamin C (mg)[b]	1.7 (1.1 – 3.4)	2.0 (1.3 – 3.3)	0.932
Iron (mg)[a]	0.22 ± 0.02	0.20 ± 0.02	0.442
Zinc (mg)[b]	0.20 (0.10 – 0.28)	0.11 (0.09 – 0.18)	0.201

[a]Normal data analyzed using Student's paired *t*-test. Values reported are mean ± SEM.
[b]Non-parametric data analyzed using Wilcoxon paired test. Values reported are median (quartile 1 – quartile 3).

tion, independent of its association with GSHPx. The negative correlation observed between Se and total plasma 8-iso-$PGF_{2\alpha}$ levels suggests that Se has a role as an antioxidant. In humans, only about 10% of total erythrocyte Se is bound to GSHPx (35). Much of the remaining Se is incorporated into several different selenoproteins, most of which have redox functions, suggesting that an antioxidant role is likely. Selenoprotein P is one such protein, which has been identified as having a protective effect against oxidation (36). In the case of Se deficiency, as observed in our asthmatics, it is possible that while the available Se is used to maintain GSHPx activity, the production and activity of other selenoproteins such as Selenoprotein P have been reduced, thereby reducing overall antioxidant protection. In future studies, measurement of these selenoproteins will be important if the role of Se in asthma is to be better understood.

Plasma concentrations of vitamins C and E and β-carotene in the asthmatics showed no deficiencies compared to the controls. Although some have found similar results (37), others have shown a decrease in plasma levels of vitamin C (38) and erythrocyte vitamin E (4). This inconsistency may be due to differences in the dietary intake and/or asthma severity of the subjects in each study. In our study, patients had relatively mild disease (no subjects required oral steroids). Also, the dietary analysis indicates that the nutrient intake of the asthmatics in our study was similar to the control group. Thus, while the presence of ROS was apparently elevated in the asthmatics, the utilization of these antioxidant vitamins was not increased. This suggests that the mechanisms described above, involving the minerals Se and Zn, may be the first line of antioxidant defense in asthma. Alternatively, another recent report (10) suggested that peripheral blood markers may be less sensitive than direct lung measurements. Thus, plasma antioxidant levels may be a poor reflection of local antioxidant defenses in the lung and while plasma antioxidant vitamin levels are normal, deficiencies may be occurring in the lung lining fluid. This highlights the importance of directly measuring the antioxidant defenses in the lung in future studies.

In conclusion, this study indicates that oxidative stress is elevated and contributes to the clinical severity of asthma, with a deficiency in plasma Se and Zn being usual. As these minerals have been shown to play an important role in antioxidant defense, it would be sensible to supplement asthmatic patients with these nutrients, in order to minimize the effects of oxidant stress. A previous report of Se supplementation improving antioxidant defenses and clinical symptoms in asthmatics (39) is encouraging and suggests that further investigation of oxidative stress during Se and Zn supplementation is warranted. The discovery of 8-iso-$PGF_{2\alpha}$ as the best indicator of oxidative stress *in vivo* allows examination of the effects of future antioxidant interventions in asthmatics.

ABSTRACT: We have utilized transgenic technology to develop a new source of γ-linolenic acid (GLA) using the canola plant as a host. The aim of the present study was to compare the growth and fatty acid metabolism in rats fed equal amounts of GLA obtained from the transgenic canola plant relative to GLA from the borage plant. Young male Sprague-Dawley rats (n = 10/group) were randomized and fed a purified AIN93G diet (10% lipid by weight) containing either a mixture of high GLA canola oil (HGCO) and corn oil or a control diet containing borage oil (BO) for 6 wk. GLA accounted for 23% of the triglyceride fatty acids in both diets. Growth and diet consumption were monitored every 2–3 d throughout the study. At study termination, the fatty acid composition of the liver and plasma phospholipids was analyzed by gas chromatography. The growth and diet consumption of the HGCO group were similar to the BO group. There were no adverse effects of either diet on the general health or appearance of the rats, or on the morphology of the major organs. There was no significant difference between the diet groups for total percentage of n-6 polyunsaturated fatty acids present in either the total or individual phospholipid fractions of liver or plasma. The relative percentage of GLA and its main metabolite, arachidonic acid, in each phospholipid fraction of liver or plasma were also similar between groups. The percentage of 18:2n-6 in liver phosphatidylethanolamine and phosphatidylinositol/serine was higher ($P < 0.05$) and 22:5n-6 was lower in the HGCO group than the BO group. This finding could be attributed to the higher 18:3n-3 content in the HGCO diet than the BO diet. Results from this long-term feeding study of rats show for the first time that a diet containing transgenically modified canola oil was well-tolerated, and had similar biological effects, i.e., growth characteristics and hepatic metabolism of n-6 fatty acids, as a diet containing borage oil.

Paper no. L8525 in *Lipids 35*, 975–981 (September 2000).

Conversion of the essential fatty acid, linoleic acid (18:2n-6), to γ-linolenic acid (GLA, 18:3n-6) and dihomo-γ-linolenic acid (DHGLA, 20:3n-6) is rate-limited by Δ6 desaturase activity. GLA may become essential under certain pathological conditions that depress Δ6 desaturase activity and reduce production of DHGLA and its anti-inflammatory metabolites, prostaglandin E_1 (PGE_1) and 15-hydroxy-eicosatrienoic acid (15-HETrE) (1–3). A chronic imbalance between the fatty acids DHGLA and arachidonic acid and their respective derivatives (PGE_1 and 15-HETrE, vs. the 2-series of prostaglandins) has been proposed to be one contributing factor in the etiology of some inflammatory and cardiovascular disorders (4). In this regard, dietary studies have shown that provision of GLA to bypass Δ6 desaturase alleviated pathologic conditions associated with low levels of PGE_1 and 15-HETrE (5,6). More recently, experimental (7,8) and clinical studies (9) have revealed that supplementation of nutritional formulas with a combination of eicosapentaenoic (20:5n-3) and GLA can favorably reduce an inflammatory response while promoting vasodilation and oxygen delivery following acute lung injury.

These beneficial effects have increased the demand for GLA-enriched oils. At the present time, the predominant sources of GLA are oils from plants such as borage, evening primrose, and black currant. Since all GLA-containing oils on the market are relatively expensive due to large fluctuations in availability, and production and purification costs, there is a need for more economical sources of GLA. For this purpose, we have utilized transgenic technology to develop a new source of GLA using the canola plant as a host. The production of GLA in the canola plant starts with oleic acid (18:1n-9) and requires two desaturation steps at the Δ12 and Δ6 positions. Recently, cDNA clones encoding Δ12 and Δ6 desaturases from *Mortierella alpina* have been identified (10). By recombinant expression of both desaturases, the yield of GLA from the modified canola plant can range from 22 to 45% of the total fatty acids.

The aim of the present study was to compare, for the first time, the growth and fatty acid metabolism in rats fed diets containing equal levels of GLA from high GLA canola oil (HGCO) or borage oil (BO) for 6 wk. We also determined the fatty acid composition of the principal phospholipid fractions

of liver and plasma and triglycerides in epididymal adipose at study termination to compare the dietary effects on the metabolism of the principal n-6 fatty acids in these tissues.

MATERIALS AND METHODS

The study design was approved by the Institute Animal Care and Use Committee. The care of the animals was in accordance with the guidelines set forth by the National Institute of Health's, *Guide for the Care and Use of Laboratory Animals*. Pathogen-free male (78–100 g) Sprague Dawley rats (Taconic Farms, Germantown, NY) were housed in plastic cages (two rats per cage) and maintained on a 12-h light-dark cycle in a temperature- and humidity-controlled room.

After a 2-d acclimatization period, the rats were weighed and randomly assigned to receive a semisynthetic diet supplemented with 10% by weight of HGCO or BO (n = 10/group). Each diet was prepared at Ross Products Division (Columbus, OH) using a fat-free purified powder diet (AIN93G; Harlan Teklad, Madison, WI) fortified with vitamins and minerals according to recently established guidelines (11). The fatty acid compositions of the original HGCO oil and the two diets (HGCO and BO) are presented in Table 1. The HGCO was blended with corn oil (54:46, w/w) to approximate the relative percentages of GLA (23%) and LA (36%) in the BO. The percentage of α-linolenic acid (18:3n-3) was 1.1 and 0.3% in the HGCO and BO diets, respectively. Both HGCO and BO were extracted and processed in similar methods by the same processor (POS Pilot Plant Corp., Saskatoon, Canada). The mean total nonsaponifiable fractions in HGCO and BO were 1.7 and 1.6 g/100 g oil, respectively, while the mean total tocopherols were 922 and 763 mg/kg oil, respectively.

Gas chromatographic analysis of diet samples taken before and after the 6-wk feeding period indicated that no significant changes in the relative percentages of the fatty acids had occurred during the study period. Aliquots of each diet were stored under N_2 in sealed, plastic bags at –20°C. Every second or third day fresh aliquots of diet were weighed into clean, stainless steel feeders that hung vertically within the cages. Using this system, diet spillage within the cage was minimal. The rats were allowed free access to the diets and water during the study. Body weights and diet consumption were measured every 2–3 d throughout the study period. The rats' appearance and behavior were observed daily for signs of diet intolerance or toxicity.

TABLE 1
Principal Triglyceride Fatty Acids of Original HGCO and Study Diets[a]

Fatty acid	HGCO	HGCO diet	BO diet
16:0	4.2	8.3	10.8
18:0	3.7	2.8	4
18:1n-9	21.6	20.4	15.5
18:1n-7	3.4	2.1	0.7
18:2n-6	26.0	38.7	36.4
18:3n-6	37.0	23.3	22.6
18:3n-3	1.3	1.1	0.3
22:1n-9		0.4	2.9

[a]Expressed as the mole percentage of total fatty acids identified. HGCO, high γ-linolenic acid-canola oil; BO, borage oil.

After 6 wk of feeding, food was withheld from the animals overnight prior to study termination. Under pentobarbital anesthesia (50 mg/kg intraperitoneally), the abdomen was opened and blood drawn from the vena cava into heparinized syringes. The whole blood was centrifuged at 2500 × g at 4°C for 10 min to isolate the plasma. All rats were subjected to gross necropsy. The liver, kidneys, spleen, heart, and epididymal fat were excised, examined and weighed. Samples of plasma, liver, and epididymal fat were stored under N_2 at –20°C for compositional analysis of phospholipid or triglyceride fatty acids.

Fatty acid analysis of triglyceride and individual phospholipid fractions (10). Total tissue lipids were extracted immediately after samples had been thawed. Liver, epididymal tissue, plasma, and diet powder were extracted with chloroform/methanol, 2:1 (vol/vol). The extraction solvent mixture of each sample was allowed to stand in the refrigerator overnight. Saline was added to separate the chloroform and aqueous phase. Samples were centrifuged and the chloroform layer was transferred into Teflon-lined screw cap tubes. The chloroform was then evaporated at 40°C under N_2 and the lipid residues were redissolved in chloroform. The total lipid extracts were separated by thin-layer chromatography (TLC) into their neutral and phospholipid classes using LHPK Silica Gel on 10 × 20 cm plates with a thickness of 200 μm (Whatman, Fairfield, NJ). Neutral lipids were developed for 12 min with hexane/ethyl ether/glacial acetic acid, 70:30:1 (by vol). The solvent system for the phospholipids was chloroform/ethanol/de-ionized water/triethylamine, 4:5:1:5 (by vol). After visualization by spraying with 2,7-dichlorofluorescin in 2% ethanol, the areas corresponding to triglycerides and total phospholipids were scraped off the neutral TLC plate, and phosphatidylethanolamine (PE), phosphatidylinositol/serine (PI/PS), and phosphatidylcholine (PC) were obtained from the phospholipid plate. All lipid fractions were derivatized by methylation with 12% boron trifluoride in methanol. For fatty acid quantitation, a known amount of triheptadecanoin (17:0) was added as the internal standard to each lipid fraction. The fatty acid methyl esters obtained from each lipid fraction were extracted in hexane and analyzed by gas–liquid chromatography (GLC).

A Hewlett-Packard 6890 series GLC (Palo Alto, CA) was set up with the following conditions: Omegawax 320™ capillary column (Supelco, Bellefonte, PA), 30 m × 0.32 mm i.d., 0.25 μm film; helium carrier gas; flame-ionization detector; pulsed splitless injection mode; injector 205°C; detector 235°C; column 120°C for 1 min, then raised 4°C/min to 205°C and held for 25 min. A sample volume of 2 μL was injected and analyzed with Hewlett-Packard ChemStation software version G2070AA. Peaks were identified based upon the relative responses of an external standard of pure fatty acid methyl esters.

Statistics. Descriptive and inferential statistics were computed on all continuous data for each parameter. The sample size was based primarily on the historical adequacy in similar studies using this model (12,13). Group differences were determined by *t* test and repeated measures of analysis of variance (ANOVA) across time points. Tukey's test was used for *post hoc* comparison of means of significant ANOVA. Estimates and 95% confidence intervals for group differences at each time point were also computed. Statistical significance was set at a P value less than 0.05.

RESULTS

The control (BO) and experimental (HGCO) diets were well tolerated throughout the study. There was no evidence of adverse effects of the diets with regard to the general appearance or behavior of the animals based on daily observations. The growth of the rats from each treatment group was similar. Initial and final body weights, mean body weight trends, and mean cumulative weight gain (288 vs. 286 g per rat for HGCO vs. BO groups, respectively) for each group were similar (Fig. 1). Diet consumption (Fig. 2) was also similar between treatment groups throughout the 6 wk study. The mean total consumption (±SD) of the HGCO and BO diets per two rats per cage over 6 wk was 2.13 (± 0.23) and 2.20 kg (± 0.14), respectively. Results from an earlier pilot study of Sprague-Dawley rats fed either the HGCO and BO diet for 3 wk revealed that the mean (±SD) outputs of fecal fat over three separate 48 h collections were similar for each diet group (0.07 ± 0.01 g/d for each group) (Palombo, J., unpublished observation).

Gross postmortem examination of the major organs did not reveal any adverse treatment effects. The mean liver weight (±SD) was not significantly different between diet groups (11.1 ± 1.1 vs. 11.5 ± 0.9 g for the HGCO and BO groups, respectively). In addition, mean weights (g) of heart (1.5 vs. 1.5), kidneys (2.7 vs. 2.7) or spleen (1.2 vs. 1.1) were similar for the HGCO vs. BO group, respectively.

Principal fatty acids in liver phospholipids. The effects of feeding either the HGCO or BO diets on the composition of n-6 fatty acids in the total and individual liver phospholipids are shown in Tables 2–5. There was no difference between diets for the total percentage of n-6 polyunsaturated fatty acids (PUFA) present in either the total (Table 2) or individual (Tables 3–5) phospholipid fractions. The relative percentages of 18:2n-6 and 18:3n-6 in the liver total phospholipids (Table 2) and PC fraction (Table 3) were also similar for both diets. The percentage of 18:2n-6 in liver PE (Table 4) and PI/PS (Table 5) was significantly higher ($P < 0.05$) in the HGCO diet group as compared with the BO group. The percentage of 20:3n-6 in the total phospholipids was slightly lower in the HGCO group than the BO group (Table 2); however, the percentages of 20:3n-6 in the individual phospholipid fractions (Tables 3–5) were similar between diets. There were no diet-induced differences in the percentages of 20:4n-6 and 22:4n-6 present in the total or individual phospholipids. The percentage of 22:5n-6, the end-product of the n-6 series of PUFA, in the HGCO group was significantly lower ($P < 0.05$) in the total phospholipids and each phospholipid fraction (Tables 2–5) in comparison with the BO group.

The percentage of total n-3 PUFA in each phospholipid fraction of liver was similar across the two diets. However, we observed small differences between the two diets for percentages of 22:5n-3 and 22:6n-3 within the phospholipid frac-

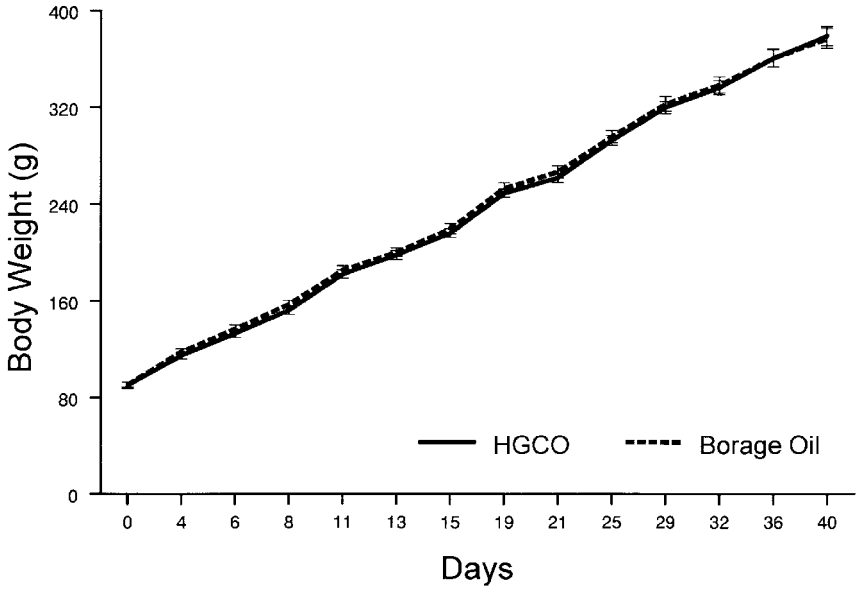

FIG. 1. Cumulative body weight gain (g) over 6 wk. Data points represent the mean ± SD for 10 male Sprague-Dawley rats fed an AIN93G diet containing 10% by weight high γ-linolenic acid (GLA) canola oil (HGCO) or borage oil for 6 wk.

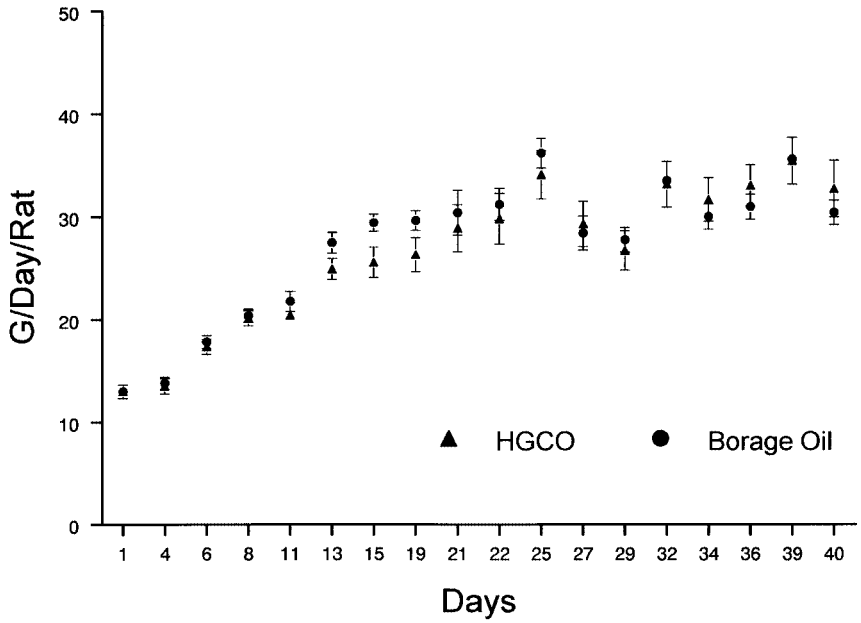

FIG. 2. Mean ± SD food consumption (g) per rat over 6 wk. Data points represent the calculated intake per rat of AIN93G diet containing 10% by weight HGCO or borage oil over a 2–3 d period (n = 10/group). See Figure 1 for abbreviations.

tions. Specifically, the relative percentage of 22:5n-3 was significantly higher, while the concurrent percentage of 22:6n-3 was lower in the total phospholipids (Table 2), and the PC (Table 3) and PE (Table 4) fractions from the HGCO group compared with the BO group. The mean percentage of 22:6n-3 in the PI/PS fraction of livers from the HGCO group was also lower as compared with the BO diet group (Table 5). Total monounsaturates (i.e., primarily the sum of 18:1n-9 and 18:1n-7) in the PC and PE fractions were higher in livers from rats fed the HGCO diet as compared with those from the BO diet group. The percentage of total saturates in each phospholipid fraction was similar between the treatment groups.

Principal fatty acids in plasma phospholipids. The effects of feeding either the HGCO or BO diets on the composition of n-6 fatty acids in the total and individual plasma phospholipids are shown in Tables 6–9. The total n-6 PUFA, n-3 PUFA, monounsaturates, and saturates in the total (Table 6) and individual (Tables 7–9) fractions of phospholipids were similar between diet groups. The relative percentages of individual n-6 PUFA, i.e., 18:2n-6, 18:3n-6, 20:3n-6, 20:4n-6,

[a]Mean relative mole percentage ± SD, $n = 10$/group. *$P < 0.05$ by t test vs. HGCO group. See Table 1 for abbreviations.

22:4n-6, and 22:5n-6, in the total phospholipids were similar between the HGCO and BO diet groups (Table 6). The percentage of 18:2n-6 in the PI/PS fraction of plasma was slightly higher for the HGCO group than the BO group (3.4 vs. 2.5%, respectively).

As observed in the liver, the percentages of 22:5n-3 in the total phospholipids (Table 6) and PC fraction (Table 7) of the plasma from the HGCO group were slightly higher ($P < 0.05$) than the corresponding levels of 22:5n-3 from the BO group. Unlike the liver, there was no significant difference in the relative percentage of 22:6n-3 in any phospholipid fraction between the groups.

Epididymal triglyceride fatty acids. The percentages of 18:2n-6, 20:3n-6, 20:4n-6, and 22:4n-6 in the epididymal triglycerides of the HGCO group were similar to the corresponding levels in the BO group (Table 10). The mean percentage of triglyceride 18:3n-6 was slightly higher (11.9 vs. 10.1%, $P < 0.05$) in the BO group than the HGCO group.

DISCUSSION

These data represent the first dietary studies undertaken to evaluate the biological effects of transgenic HGCO in mammals. The results revealed that, when feeding equal amounts of GLA from either HGCO or BO, no significant differences were observed in growth characteristics and diet consumption by the rats over 6 wk. In addition, there was no evidence of any adverse effect of feeding a diet containing HGCO on the rats' appearance, behavior, or organ morphology.

In both plasma and liver total phospholipids, we observed no significant changes in the levels of 18:3n-6, 20:4n-6, or 22:4n-6 in rats fed the HGCO diet as compared to those fed

the BO diet. Similar findings were reported by Raederstorff and Moser in a GLA feeding study comparing BO with primrose oil (14). They found no changes in liver GLA and DHGLA levels within groups given equal amounts of dietary GLA from either oil source, indicating that the relative percentages of GLA and DHGLA in tissue phospholipids are dependent upon the GLA content in the diet, but not on the oil source of GLA. The only exception in the present study was that we found that the percentage of 20:3n-6 in liver total phospholipids from the rats given the BO diet was slightly higher than that in rats fed the HGCO diet (1.4 vs 1.0, $P < 0.05$) (Table 2). However, there were no dietary differences in the relative percentage of 20:3n-6 present in the liver PC, PE, or PI/PS fractions (Tables 3–5), suggesting that this may have been a statistical anomaly.

When fatty acid profiles within individual liver phospholipids were examined more closely, we observed minor changes in the relative percentage of several fatty acids in rats fed diets containing HGCO as compared to BO. For example, the levels of 18:2n-6 in PE (Table 4) and PI/PS (Table 5) were increased in the HGCO group. The elevation of 18:2n-6 may indicate a decrease in the hepatic Δ6 desaturation of 18:2n-6 in rats fed the HGCO diet. This could be due to competition for binding of Δ6 desaturase by 18:3n-3, which was present in higher amounts in the HGCO diet as compared with the BO diet (1.1 vs. 0.3, Table 1). A greater ratio of n-3/n-6 is known to suppress the metabolism of n-6 fatty acids given that n-3 PUFA are the preferred substrates for the Δ6-desaturase binding (15,16) and acyltransferase (17). The above finding was not unexpected as our main objective was to maintain the ratio of comparable levels of n-6 PUFA (18:2n-6 and 18:3n-6) in both diets. As a consequence the n-3/n-6 fatty acids were not balanced. In addition to an increase in 18:2n-6, we have also observed a decrease in the levels of 22:5n-6 in rats fed the HGCO diet as compared with rats fed the BO diet (Tables 2–5). This finding, in the absence of differences in levels of 18:3n-6, 20:3n-6, 20:4n-6, and 22:4n-6, suggests that any inhibition on desaturation of 18:2n-6 after feeding the HGCO diet may exclusively affect the levels of its end metabolite, 22:5n-6. In this regard, Sprecher *et al.* (18) have proposed a revised pathway for the biosynthesis of 22:5n-6, which requires elongation of 22:4n-6 to 24:4n-6 followed by Δ6 desaturation to 24:5n-6, which in turn undergoes partial β-oxidation to 22:5n-6. Thus, preferential binding of n-3 vs. n-6 fatty acids at this later Δ6 desaturation step would result in decreased production of 22:5n-6 as observed in the liver phospholipids for the HGCO group. Similar changes in 22:5n-6 have been reported by others who also fed diets with equal amounts of GLA, but unbalanced n-3/n-6 fatty acids (14). It should be noted, however, that the level of 22:5n-6 represents only a minor fraction of the overall PUFA content in liver lipids.

[a]Mean relative mole percentage ± SD, n = 10/group. *$P < 0.05$ by t test vs. HGCO group. See Table 1 for abbreviations.

In summary, the growth and hepatic metabolism of the principal n-6 fatty acids was similar between rats fed diets containing the same amounts of fat (10%, by weight) and GLA (23% of total fats) whether the source of GLA was HGCO or BO. Additional bioequivalency studies are now warranted to determine the effects of long-term feeding (i.e., >12 wk) of diets containing HGCO on clinically relevant biochemical and hematologic parameters.

Calcium Deficiency Modifies Polyunsaturated Fatty Acid Metabolism in Growing Rats

Carlos A. Marra* and María J.T. de Alaniz

INIBIOLP (Instituto de Investigaciones Bioquímicas de La Plata), CONICET-UNLP, Facultad de Ciencias Médicas, Universidad Nacional de La Plata, La Plata, Argentina

ABSTRACT: Fatty acid desaturase activities were determined in liver microsomes from calcium-deficient rats and compared to calcium-sufficient ones. The calcium-deprived diet (0.5 g/kg) administered for 60 d caused a 30% inhibition in the Δ5 desaturase activity and a 45–55% decrease in Δ6 and Δ9, respectively, facts that cannot be attributed to a reduction in food intake. *In vitro* addition of calcium, ethyleneglycol-bis(β-aminoethyl ether)*N,N*-tetraacetic acid, and/or cytosol fractions from control or calcium-deficient rats to microsomes from both groups of animals indicates that the reduced desaturase capacities would be the consequence of an indirect effect of calcium deprivation. The present work shows that the reduced unsaturated fatty acid biosynthesis might be the result of modifications in the physicochemical properties of microsomal membranes. Such changes could also be derived from the inhibition of phospholipase A_2 activity induced by calcium deficiency.

Paper no. L8344 in *Lipids 35,* 983–990 (September 2000).

A series of experimental reports carried out either in animals (1–3) or in human populations (4–9) shows a clear correlation between serum concentrations of metal cations and cardiovascular diseases. The effect of dietary manipulations of mineral components on the development of atherosclerosis and related diseases suggests that the nonsaturated fatty acid metabolism is clearly influenced by its metabolic actions. Previous works have documented that metal cations play an important role in polyunsaturated fatty acid biosynthesis and degradation. The availability of zinc is essential for linoleic acid metabolism, probably at both desaturation and elongation steps (10–14). These early findings were then corroborated by other authors (15–17). Similarly, the effect of magnesium as an essential cofactor in the fatty acid oxidative desaturation reactions was previously reported (1,18). The Δ5 and Δ9 desaturation steps are also particularly influenced by the level of copper, which has an opposite effect to that of zinc (19–26). It was also demonstrated that sodium loading increases arachidonic acid metabolism by means of prostaglandins from series two. At the same time, a hypernatriuretic diet modifies arachidonic acid content in liver lipids through the increment in the Δ5 and Δ6 liver microsomal desaturase activities (27,28). Recently, a peroxidiferric intermediate was found to be required for the Δ9 desaturation reaction (29). The crucial role of iron in the desaturation process is now well-established (24–26,30). Selenium and cadmium are also involved in fatty acid desaturation in mammals (31–33).

Regarding the effect of calcium, Huang *et al.* (1) reported that the levels of 18:3n-6 fatty acid in calcium-deficient rats are elevated, whereas those of 20:4n-6 are diminished. These results were interpreted as an indication of a reduced elongation capacity. On the other hand, we demonstrated a close correlation between calcium levels and fatty acyl composition of lipids from hepatoma culture cells (34) or rat liver microsomes (35), suggesting that the desaturase activities would be under a calcium-dependent regulatory effect. Taking into account that there are previous studies dealing with the involvement of various metal ions in polyunsaturated fatty acid transformation, and considering the potential regulatory action of calcium in the metabolism of the nonsaturated fatty acids, it is surprising that the possible effect of calcium deficiency on fatty acid desaturase reactions still remains unexplored. For this reason, it was our aim to investigate the fatty acid desaturase capacity in liver microsomes from calcium-deficient (CD) rats compared to the calcium-sufficient (S) ones.

MATERIALS AND METHODS

Fatty acids and other chemicals. Unlabeled fatty acids were obtained from Nu-Chek-Prep, Inc. (Elysian, MN). ATP (disodium salt), NADH, *N*-acetylcysteine, CoA (lithium salt), snake venom (*Crotalus atrox*, western diamondback rattlesnake), and sodium deoxycholate (grade II) were purchased from Sigma Chemical Co. (St. Louis, MO). Phospholipids were obtained from Serdary Research Laboratories (London, Ontario, Canada). The following radioactive fatty acids were supplied by Amersham International (Buckinghamshire, United Kingdom) (specific activity as mCi/mmol and percent degree of radiochemical purity are, respectively, indicated in parentheses): [1-^{14}C]palmitic (58.0, 99), [1-^{14}C]stearic (56.5, 98), [1-^{14}C]linoleic (55.5, 99), [1-^{14}C]α-

Abbreviations: CD, calcium-deficient; GLC, gas–liquid chromatography; EGTA, ethyleneglycol-bis(β-aminoethyl ether)-*N,N*-tetraacetic acid; PC, phosphatidylcholine; S, sufficient (control); SEM, standard error of the mean; RP-HPLC, reversed-phase high-performance liquid chromatography; TLC, thin-layer chromatography.

linolenic (57.0, 99), and [1-^{14}C]eicosa-8,11,14-trienoic (58.5, 99). [1-^{14}C]Palmitoyl-CoA (57.0, 99) and [1-^{14}C]eicosa-8,11,14-trienoyl-CoA (52.2, 98) were purchased from New England Nuclear Research Products (Boston, MA). The concentration and degrees of purity of the fatty acids were routinely checked by liquid scintillation counting and gas–liquid chromatography (GLC) of their fatty acid methyl esters prepared in the presence of internal standard (eicosa-11-monoenoic acid). Fatty acids were appropriately diluted in absolute ethanol (Riedel-de Haen, Seelze, Germany) and stored in the dark at –20°C under an atmosphere of N_2 until used. Solvents for high-performance liquid chromatography (HPLC) were provided by Carlo Erba (Milano, Italy). Other chemicals used were supplied by commercial sources.

Animal treatment. Female Wistar rats from Comisión Nacional de Energía Atómica (Buenos Aires, Argentina) weighing 170 ± 10 g were bred and maintained on a control diet (Cargill type "C," Rosario, Argentina) throughout gestation and lactation. The dams were housed in plastic cages (one animal per cage) in a vivarium kept at 22 ± 1°C with a 12-h light/dark cycle and a relative humidity of 60 ± 10%. After weaning, 24 female pups (weighing 47 ± 4 g/animal) were randomly divided into two groups of 12 animals each, and fed *ad-libitum* either on a CD diet (group CD) or on a balanced diet (group S). The composition of the CD diet, prepared in our laboratory, was reported in detail in a previous paper (35). The Ca^{2+} content (0.5 g/kg), was determined by a Shimadzu Atomic Absorption Spectrophotometer AA-630-12 (Shimadzu Corp., Kyoto, Japan) following the mineralization procedure described elsewhere (36). Control animals were fed a standard balanced diet supplemented with 5.0 g/kg calcium in order to supply the mineral at a level equivalent to that recommended by the American Institute of Nutrition for the Formulation of the AIN-93 Purified Diets for Laboratory Rodents (37). The content of Ca^{++} in drinking water (given *ad-libitum*) was determined either by atomic absorption or by calcium-selective electrode Orion model 93-20 (Orion Research Inc., Cambridge, MA), and it was generally below 15 ppm. During the feeding period, body weight, water consumption, and food intake were determined every day. Samples of blood were collected in order to determine plasma calcium levels. Food intake and water consumption, relative to body weight, were not significantly different between the groups of animals at the time the rats were killed (after the 60-d feeding period). CD animals grew at a similar rate for the initial 20 d of feeding, then they grew at a reduced rate until day 59 when differences between groups became significant. In order to avoid individual differences among animals, as might result from an *ad-libitum* feeding, on day 59 all rats were fasted for 24 h, re-fed with the corresponding diet for 2 h, and then killed by decapitation without prior anesthesia 12 h after the refeeding period.

All diet components used were purchased from Carlo Erba or Mallinckrodt Chem. Works (NY). The casein was depleted of calcium by ethyleneglycol-bis(β-aminoethyl ether)*N*,*N*-tetraacetic acid (EGTA) treatment and then defatted with boiling acetone. The calcium content in the extracted casein was negligible. Animal maintenance and handling were in accordance with the National Institute for Health's Guide for the Care and Use of Laboratory Animals (38).

Microsomal suspensions. Livers from S and CD rats were rapidly excised and immediately placed in an ice-cold homogenizing medium (39). The homogenates were processed individually at 1°C, and the microsomal fractions were separated by differential centrifugation at 110,000 × *g* as previously described (39). Microsomal pellets were resuspended in a cold homogenizing solution to a final protein concentration of 30–40 mg/mL. Cytosol samples (110,000 × *g* supernatant fractions) from S and CD rats were also collected and stored at –80°C under N_2 atmosphere until further use.

Preparation of labeled phosphatidylcholine ([^{14}C]PC). The procedure to obtain labeled PC was developed in our laboratory after assaying different experimental conditions. Briefly, a suspension of liver microsomes from a female Wistar rat (150 ± 20 g body weight), obtained as described above, was incubated at 30°C in a metabolic shaker in the proportion of 5 mg microsomal protein/mL of incubation medium, which consisted of 0.1 M potassium phosphate buffer (pH: 7.40), 0.1 M $MgCl_2$, 10 mM Na_2ATP, 1 mM CoA (lithium salt), 5 mM *N*-acetylcysteine, 0.5 mM lysophosphatidylcholine, and 0.5 mM [1-^{14}C]eicosa-8,11,14-trienoic acid. The lysophospholipid was previously scattered, under carefully controlled temperature, in cold potassium buffer plus 0.1 mM sodium deoxycholate (grade II) by means of three 20-s sonication periods with a Heat System-Ultrasonic Sonicator model W-220F (Plainview, NY) equipped with a 1/8-inch diameter microtip at 50% output. The labeled fatty acid was prepared as follows: an aliquot of the acid was evaporated to dryness under N_2, neutralized with ammonium hydroxide, and diluted in pure propylenglycol. After vigorous vortexing at 30°C for 3 min, an aliquot from this preparation was directly transferred to the incubation medium. An hour later, under continuous agitation, the biosynthesis was stopped by the addition of 5 mL chloroform/methanol (2:1, vol/vol) according to Folch *et al.* (40). The total lipid extract was concentrated under vacuum at low temperature, and further fractionated by preparative HPLC according to the method of Patton *et al.* (41) with minor modifications. [^{14}C]PC was separated on a 150 × 4.0 mm Bio-Sil ODS 5S column (Bio-Rad, Richmond, CA) and eluted with 50 mM choline chloride in methanol/water/acetonitrile (90:5:5.8, by vol) at a flow rate of 1.5 mL/min, using a Merck-Hitachi L-6200 Intelligent Delivery System (Darmstadt, Germany). Detection was performed by absorption at 205 nm using an L-4200 Ultraviolet-Visible Detector (Merck-Hitachi). The PC fraction was identified on the basis of its retention time relative to authentic standards. Di-20:1n-9-PC was used for quantification. Once the phospholipid was identified, the corresponding eluate was carefully collected and concentrated under vacuum at low temperature. Samples were taken for phosphorus measurements (42) and liquid scintillation counting in a Wallac Rackbeta Liquid Scintillation Counter (Turku, Finland) with 92% efficiency for ^{14}C. The specific activity, ranging from 21 to 27

mCi/mmol, was routinely obtained by this procedure. Similar results were obtained by purification of the PC fraction in preparative thin-layer chromatography (TLC) on Silicagel G-60 plates (Riedel-de Haen) following the method described elsewhere (43,44).

Phospholipase A_2 activity assay. Phospholipase A_2 activity was determined with [^{14}C]PC (24.0 mCi/mmol, 99% pure) as substrate according to the method of Hirata *et al.* (45) with the modifications described as follows. The phospholipid was dispersed in the incubation medium by three 20-s sonication periods (small probe, 50% maximum intensity). The reaction mixture contained (0.5 mL total volume) 1.5 mM radioactive substrate, 50 mM Tris/glycylglycine buffer at pH 8.0, and 0.1 mM sodium deoxycholate (grade II). After preincubation at 37°C for 1 min, the assay was started by the addition of 20–40 μg of protein. Under these conditions, the reaction was completely linear up to 30 min. It was stopped after 10 min incubation by the addition of 3 mL isopropyl alcohol/heptane/1 N H_2SO_4 (40:10:1, by vol) followed by 2 mL distilled water, plus 2 mL of petroleum ether containing 5 μg/tube unlabeled eicosatrienoic acid, thorough mixing and incubation for 10 min at room temperature. Unlabeled eicosatrienoic acid was added to facilitate the extraction of [1-^{14}C]20:3n-6. Labeled fatty acids, released by the action of phospholipase, were recovered from the upper phase (at least 95% yield) and counted by liquid scintillation. Blanks consisting of boiled samples (10 min at 100°C) were routinely run in all incubations. Formation of unlabeled lysophosphatidylcholine was routinely checked by recovering the phospholipids from the aqueous phase and identifying of the lipid components by TLC as described previously (43,44).

Assay for in vitro *fatty acid desaturation.* Each fatty acid (16:0, 18:0, 18:2n-6, 18:3n-3, or 20:3n-3) was diluted to a specific activity of 0.20–0.25 μCi/mol with the respective pure unlabeled fatty acid. The assay procedure was as follows: 1.25 mg of microsomal protein was incubated in an open test tube with 100 nmol of diluted labeled substrate in a Dubnoff shaker at 37°C for 10 min. The total volume of the incubation medium was 0.8 mL; it consisted of 0.04 M potassium phosphate buffer (pH: 7.40), 0.15 M KCl, 0.25 M sucrose, 0.04 M NaF, 1.3 mM ATP, 0.06 mM CoA, 0.7 mM *N*-acetylcysteine, 0.87 mM NADH, and 5 mM $MgCl_2$. In some cases free fatty acids were replaced by the corresponding acyl-CoA esters (CoA was omitted in these incubations). The reaction was stopped with 1.0 mL of 10% potassium hydroxide in ethanol and the mixture was saponified at 80°C for 45 min under N_2 atmosphere. The unsaponifiable lipids were extracted twice with 2 mL hexane and discarded. The remaining lipids were acidified with 0.3 mL of concentrate HCl and extracted three times with 2 mL hexane. The organic solvent of each sample was pooled and evaporated to dryness at low temperature under vacuum. The fatty acids were then dissolved in the chromatographic mobile phase (methanol/water/acetic acid; 85:15:0.2, by vol), and separated by reversed-phase (RP)-HPLC in an apparatus equipped with a L-6200 Solvent Delivery System and a L-4200 UV/VIS Detector set at 205 nm from Merck-Hitachi as previously described (46). A 250 × 4.6 mm Econosil C-18 column (Alltech Associates, Deerfield, IL), coupled to a 10 × 4 mm guard column (packed similarly) was used at a flow rate of 0.9 mL/min. The peaks were identified on the basis of their retention times relative to appropriate fatty acid standards. Radioactivity was continuously detected by a Radiomatic Model Flo-One/Beta Radioactivity Flow Detector from Packard Instruments (Downers Grove, IL) using Ultima Flo-M liquid scintillation cocktail (Packard Instruments).

Other analytical determinations and statistical treatment of the data. Calcium content in liver microsomal suspensions was determined after mineralization (36) by atomic absorption as described above. The protein content was determined by the micromethod of Lowry *et al.* (47) with crystalline serum albumin as standard. All values represent the mean of three to six individual determinations (assayed in duplicate or triplicate) ± SEM. In order to test the statistical significance of numerical differences in results, data were analyzed by either the Student's *t*-test or by analysis of variance, with the aid of the GB-STAT Professional Statistics Program (version 4.0) from Dynamic Microsystems Inc. (Silver Springs, FL).

RESULTS

In previous papers we demonstrated that the CD diet here employed evokes a significant decrease in the calcium content of various rat tissues and subcellular fractions including microsomes (35,48). Table 1 shows that in these kinds of calcium-depleted microsomes, the fatty acid desaturase activities are strongly depressed compared to the ones found in microsomes from sufficient rats. The *in vitro* biosynthesis of arachidonic acid from labeled eicosa-8,11,14-trienoate was reduced 30%, whereas the Δ6 desaturation of both linoleic and α-linolenic acids was diminished 40 and 45%, respectively. The formation of monoenoates from either palmitic or stearic acids was significantly reduced (45–55%), indicating that Δ9 desaturation capacity was also decreased in CD microsomes.

In order to investigate the possible direct effect of calcium deficiency on the fatty acid desaturase system, an experiment was designed in which free calcium ions were added to CD microsomes in excess amount with respect to the content of the cation determined in the control microsomal suspensions. Atomic absorption measurements performed on S and CD microsomes demonstrated that the CD diet evoked a decrease in the total calcium content from 0.026 ± 0.001 μmol Ca/mg protein in control animals up to 0.015 ± 0.01 μmol in sufficient ones. Cytosolic fractions from CD rats were also significantly affected, showing a 40% decrease with respect to the values determined in S rats (0.008 μmol Ca/mg protein). Taking into account that the effect of calcium deprivation could be reverted by the cation itself or by the presence of another unknown soluble-factor (calcium-dependent), supernatants from 110,000 × *g* centrifuged liver homogenates were also added. EGTA addition was performed to investigate if the in-

[a]The substrates used to determine the enzyme activities were [1-^{14}C]palmitic, [1-^{14}C]linoleic, and [1-^{14}C]eicosa-8,11,14-trienoic acids for Δ9, Δ6 and Δ5 desaturases, respectively.
[b]Results are expressed as mean ± SEM of four independent determinations.
[c]0.5 mg of liver microsomal protein/tube.
[d]0.5 μM final concentration.
[e]1 μM final concentration.
*Significantly different ($P < 0.01$) respect to the corresponding control assay. Incubation details were described in Materials and Methods section. EGTA, ethyleneglycol-bis(β-aminoethylether)*N,N*-tetraacetic acid. See Table 1 for other abbreviations.

hibitory effect observed on the desaturase system could be augmented by *in vitro* sequestering of the total free calcium present in the microsomal suspension. As shown in Table 2, *in vitro* calcium restitution—in excess amount with respect to control levels—was unable to restore the diminished desaturase capacity in any of the cases. No significant changes were observed due to the addition of cytosolic fractions or to an excess of EGTA.

In our laboratory, it was demonstrated that the acyl-S-CoA synthetase activity was significantly increased in CD rats (35,48). It is also well known that the formation of acyl-S-CoA esters is an obligatory step in the desaturation process (49,50). In spite of the fact that the supply of activated substrates was guaranteed in CD animals, the possibility that a defined calcium level would be necessary in a step subsequent to the activation process should not be discarded. For that reason, an experiment designed to highlight this question was performed. Results shown in Table 3 indicate that the fatty acid desaturase activities in microsomal suspensions from CD rats remain significantly depressed even after replacing free fatty acids by their corresponding acyl-S-CoA esters with or without the addition of calcium ions.

Table 4 shows the results obtained of phospholipase A_2 activities in different fractions from livers of S or CD rats. In homogenates and microsomes, the calcium deprivation caused a significant loss of activity (~80%) in both fractions. In contrast, the activity of cytosol was not significantly modified. Calcium addition partially restored the phospholipase A_2 activity in homogenate from CD rats, whereas in microsomes the addition of calcium not only restored the enzyme activity but also produced a significant increment (25%) with respect to the basal level. Although the amount of EGTA added was enough to bind the free calcium present in the fractions studied completely, none of them showed a significant decrease in their phospholipase A_2 activity under this treatment. Moreover, the addition of an EGTA excess to the cytosol from both S or CD rats—prior to the enzyme assay—led to a slight increase in the phospholipase activity.

[a]Results are expressed as the mean ± SEM of six independent determinations. Incubation conditions were described in the Materials and Methods section.
[b]Calcium was added at a final concentration of 0.50 μM for cytosolic fraction, 3 mM for homogenates, and 1 μM for microsomes.
[c]EGTA was added at 3 mM final concentration in all assays. * Significantly different ($P < 0.001$) with respect to the corresponding control assay. See Tables 1 and 2 for abbreviations.

DISCUSSION

It is evident that calcium deprivation leads to a general inhibition of the fatty acid desaturase activities in rat liver microsomes (Table 1). Previous studies from our laboratory have extensively shown the effect of several hormones and nutritional conditions on polyunsaturated fatty acid metabolism in rats (49,51). Fasting and energy restriction profoundly modify desaturase activities and, as reported previously, the gain in body weight is directly involved in this regulatory effect (49,51–53). Taking into account these considerations, a decreased desaturase activity for CD rats compared with the S rats (paired-fed controls) can therefore be ascribed to calcium deprivation and not to a decreased food intake. This finding is consistent with Ca involvement in the liver microsomal desaturase reactions. However, results from Table 2 led us to discard, rather confidently, the direct effect of this cation on the desaturase enzyme itself or on other components involved in the transport of electrons to the terminal component. Currently, no experimental evidence has been presented related to the possible role of Ca as a desaturase cofactor and/or any other role of this cation as an essential part in the catalytic process. Results in this paper showed that *in vitro* addition of an excess of calcium to the microsomal suspension was unable to restore the inhibition evoked by CD diet. Moreover, no effect was observed even in the presence of cytosolic proteins; and no additional inhibitory effect was found after complexing the available calcium with excess EGTA. Previous experiments from our laboratory demonstrated that glucocorticoids can induce a soluble second messenger recovered as a low molecular weight peptide in the 110,000 × *g* supernatant fraction from liver cell homogenates. The addition of this factor modulates desaturase activities in *in vitro* enzyme assays (39,54,55). It was our aim to investigate if calcium deprivation could modify desaturase activity through a similar mechanism of action. Several investigations have described the dramatic influence exerted by Ca level modification on the calmodulin-mediated events, and it is well-known that a depletion of only 5–10% of the total cytosolic calcium is sufficient to substantially modify several cellular processes (56,57). The results presented here (Table 2) discard this mechanism of action since the addition of cytosol S to CD microsomes was un-

able to restore Δ9, Δ5, or Δ6 desaturase activities. On the other hand, calcium deficiency would not modify straightforwardly the desaturase activities through the inhibition of the coupled electron transport chain since the electron flux, produced from the NADH to the desaturase, is not a limiting factor for the reaction. It was demonstrated that the lowest step is located at the desaturase itself (58,59), where a variety of stimuli exert their regulatory effects.

The fact that the effect of calcium deprivation on the desaturase activity was also observed using acyl-S-CoA as substrate (Table 3) clearly demonstrates that acylation was not the rate-limiting reaction for this regulatory phenomenon, though considering that acyl CoA synthetase activity significantly increases under calcium deficiency (35).

It seems therefore that the effect of calcium deficiency on the desaturase activity may be produced by an indirect modification, which would involve another metabolic event. We also hypothesized that the inhibition of phospholipase A_2 would be able to diminish the substrate supply for desaturation in CD rats. However, if this consideration were valid in the whole animal, it would not be the same for *in vitro* determinations in which free fatty acids are used as substrates. Results in Table 4 led us to recognize that the alterations found in phospholipase A_2 activity under a CD diet modify the acylation/deacylation cycles, altering the physicochemical properties of the microsomal membranes. Experimental evidence would confirm this hypothesis. Storch and Schachter (60) demonstrated that calcium ions decrease the lipid fluidity of isolated rat hepatocyte plasma membranes by altering the hydrophobic interior of the bilayer. These authors also suggested that the change in the fluorescent anisotropy results from the activation of the Ca-dependent phospholipase A_2, located in the hepatocyte plasma membrane. The increase in this enzyme activity may result in the cleavage and loss of polyunsaturated fatty acids (mainly arachidonate) from membrane phospholipids and the subsequent reduction of the fluidity (60). On the other hand, we demonstrated in a recent study that calcium-deficiency evoked a significant increment in the fluidity of rat liver microsomal membrane as determined by the rotational mobility of the probe diphenylhexatriene (35). We also proved that the CD diet produced an important increase in saturated fatty acids (palmitic and stearic) in both neutral and polar lipid fractions of liver microsomes (35). An important increment of linoleic acid in both lipid fractions with a concomitant decrease in the polyunsaturated fatty acids of the n-3 and n-6 families also led to a significant decrease in the double-bond unsaturation index, suggesting a loss of the desaturation capacity in the liver microsomes from CD rats (35). Several interlipid and lipid/protein relationships were also affected by deprivation of this cation, including those parameters closely associated to the physical state of the membrane. In CD rats, the proportion of cholesterol, usually associated with a decreased membrane fluidity, was significantly reduced compared to S rats (35). This experimental evidence, together with the results shown in Table 4, supports the direct involvement of the altered calcium-dependent phospholipase A_2 in those changes observed on the physicochemical properties of microsomal membranes. So far, it is well known (49,51,58,61–63) that there exists a clear dependence between desaturase activities and membrane fluidity. Such dependence may result, as suggested by Brenner *et al.* (64), in a self-regulatory process by which an increased fluidity leads to a depletion in the nonsaturated fatty acid biosynthesis and *vice versa*.

These findings are supported by a recent report by Kan *et al.* (65) and Xing and Insel (66), who stated that calcium increase in cytosol gives rise to the release of arachidonic acid into the nucleus by means of phospholipase A_2 translocation to the nuclear envelope. Arachidonic acid increment would evoke the subsequent increase in prostacyclin synthesis (65,66). This fact may be related to the stimulated transcription of desaturase genes described by Landschulz *et al.* (67). Then, the decrease in calcium availability would imply a reduced transcription rate of fatty acid desaturase genes. Currently, we are working to gain insight into this mechanism.

In summary, we found that calcium deprivation in rats brings about a thorough alteration in the quality and/or quantity of the fatty acids acylated to neutral and polar lipid fractions from liver microsomal membranes. At least part of these modifications can be attributed to the inhibition of the calcium-dependent phospholipase A_2. The general inhibition observed in the desaturase activities would be the consequence of an adaptable phenomenon to the increased membrane fluidity, evoked by the calcium deficiency.

Literature dealing with the relationship between calcium deprivation and fatty acid metabolism in humans has been recently reviewed (68). Calcium loss in bones of elderly people is closely related to membrane transport alterations and several changes in lipid composition (69). Recently, mortality studies have demonstrated that these kinds of alterations may be far more dangerous than the calcium loss itself, since in women with osteoporosis most deaths are due to either vascular diseases or non-related bone abnormalities (68). We think that the interaction between fatty acid metabolism and calcium levels deserves more investigation since it offers novel approaches for the understanding of human illnesses, which in fact, involve both fields of study.

Response of Plasma Lipids to Dietary Cholesterol and Wine Polyphenols in Rats Fed Polyunsaturated Fat Diets

Lucie Frémont*, Marie T. Gozzelino, and Alain Linard

Laboratoire de Nutrition et Sécurité Alimentaire, INRA-CRJ, 78352 Jouy-en-Josas Cedex, France

ABSTRACT: This experiment was designed to evaluate the effects of dietary red wine phenolic compounds (WP) and cholesterol on lipid oxidation and transport in rats. For 5 wk, weanling rats were fed polyunsaturated fat diets (n-6/n-3 = 6.4) supplemented or not supplemented with either 3 g/kg diet of cholesterol, 5 g/kg diet of WP, or both. The concentrations of triacylglycerols (TAG, $P < 0.01$) and cholesterol ($P < 0.0002$) were reduced in fasting plasma of rats fed cholesterol despite the cholesterol enrichment of very low density lipoprotein + low density lipoprotein (VLDL + LDL). The response was due to the much lower plasma concentration of high density lipoprotein (HDL) (–35%, $P < 0.0001$). In contrast, TAG and cholesteryl ester (CE) accumulated in liver (+120 and +450%, respectively, $P < 0.0001$). However, the cholesterol content of liver microsomes was not affected. Dietary cholesterol altered the distribution of fatty acids mainly by reducing the ratio of arachidonic acid to linoleic acid ($P < 0.0001$) in plasma VLDL + LDL (–35%) and HDL (– 42%) and in liver TAG (–42%), CE (–78%), and phospholipids (–28%). Dietary WP had little or no effect on these variables. On the other hand, dietary cholesterol lowered the α-tocopherol concentration in VLDL + LDL (–40%, $P < 0.003$) and in microsomes (–60%, $P < 0.0001$). In contrast, dietary WP increased the concentration in microsomes (+21%, $P < 0.0001$), but had no effect on the concentration in VLDL + LDL. Cholesterol feeding decreased ($P < 0.006$) whereas WP feeding increased ($P < 0.0001$) the resistance of VLDL + LDL to copper-induced oxidation. The production of conjugated dienes after 25 h of oxidation ranged between 650 (WP without cholesterol) and 2,560 (cholesterol without WP) μmol/g VLDL + LDL protein. These findings show that dietary WP were absorbed at sufficient levels to contribute to the protection of polyunsaturated fatty acids in plasma and membranes. They could also reduce the consumption of α-tocopherol and endogenous antioxidants. The responses suggest that, in humans, these substances may be beneficial by reducing the deleterious effects of a dietary overload of cholesterol.

Abbreviations: ANOVA, analysis of variance; apo, apolipoprotein; CE, cholesteryl ester; CVD, cardiovascular diseases; HDL, high density lipoprotein; HDL-C, HDL cholesterol; LCAT, lecithin:cholesterol acyltransferase; LDL, low density lipoprotein; PL, phospholipid; PUFA, polyunsaturated fatty acids; TAG, triacylglycerol; VLDL, very low density lipoprotein; WP, wine phenolic compounds.

Moderate consumption of red wine is considered to decrease morbidity and mortality due to cardiovascular diseases (CVD) (reviewed in Ref. 1). The protection seems partly due to ethanol (reviewed in Ref. 2) through a hemostatic mechanism and an increase in plasma levels of high density lipoprotein (HDL) (3–5), but there is some evidence that the nonalcoholic fraction of wine plays an important role in cardioprotection (6). This fraction contains large amounts of phenolic compounds, mainly flavonoids, which favorably influence several biological mechanisms such as oxidation of polyunsaturated fatty acids (PUFA) and platelet aggregation involved in the development of CVD. These substances mainly act by scavenging free radicals and chelating metal ions (7,8). The beneficial effect of flavonoids on human health is supported by epidemiological studies showing an inverse relationship between dietary intake and coronary heart disease (9–11).

In 1993, Frankel *et al.* (12) showed that phenolic substances in Californian red wine protected human low density lipoprotein (LDL) from copper-catalyzed oxidation. The authors showed that the effect was due not only to flavonoids but also to resveratrol (3,4′,5-trihydroxystilbene) present at low amounts in some red wines (13). The biological properties of this compound were confirmed in further studies (14,15). By using total or alcohol-free red wine, *ex-vivo* experiments demonstrated the favorable effects of moderate consumption (16–22).

It may be advantageous to increase the dietary intake of PUFA since they are believed to reduce risk factors associated with CVD such as thrombosis and hyperlipemia (23). However, it should be taken into consideration that the enrichment of body fluids and membranes in highly oxidizable PUFA may increase the consumption of endogenous antioxidants. We recently found that the resistance of very low density lipoprotein (VLDL) + LDL to lipid peroxidation was much lower in rats fed PUFA than in rats fed monounsaturated fatty acids. The consumption of diets supplemented with two defined flavonoids, quercetin and catechin, which are found in red wine, protected PUFA and increased the α-tocopherol content of liver microsomes in rats fed PUFA (24).

The resistance of LDL to lipid peroxidation may also be linked to cholesterol status since this compound is involved

in the etiology of CVD. The intake of high amounts of dietary cholesterol may induce changes in concentrations and composition of plasma and liver lipids, which modify the properties of lipoproteins such as resistance to lipid peroxidation. In humans, plasma lipoproteins derived from hypercholesterolemic patients are more susceptible to lipid peroxidation than those from normal subjects (25). Hence, supplementation of diet with antioxidant compounds such as polyphenols is potentially beneficial. Moreover, these substances may lower the cholesterol content of plasma. Such an effect was found in rats fed tea catechins and their gallate esters, which inhibit intestinal absorption by reducing solubility in mixed micelles (26).

This study was undertaken to determine whether responses to dietary wine phenolic compounds (WP) were influenced by the presence of cholesterol in high-PUFA diets. For this purpose, we compared diet-induced changes in plasma and liver lipids in weanling rats. In particular, we investigated the effects of dietary supplementation on the susceptibility of VLDL + LDL to lipid peroxidation and on the concentration of α-tocopherol in plasma and liver.

MATERIALS AND METHODS

All the chemicals used were of analytical reagent grade and were purchased from Sigma-Aldrich (Saint Quentin Fallavier, France).

Animals and diets. Male Wistar rats (IFFA Credo, L'Arbresle, France) bred in our laboratory were maintained at 22 ± 1°C with a 12 h light/dark cycle, with free access to water and food. The nutrient composition of experimental diets has been previously reported (27). The fat source (100 g/kg diet) was a mixture of oils rich in PUFA (75% sunflower oil, 25% sardine oil). This mixture provided 52% n-6 PUFA including 51.9% linoleic acid (18:2n-6), and 0.1% arachidonic acid (20:4n-6). They also provided 8.1% n-3 PUFA including 3% eicosapentaenoic acid (20:5n-3) and 3.2% docosahexaenoic acid (22:6n-3). Rats were randomly distributed into four groups of 18 animals each, just after weaning (21 d old) in a 2 × 2 factorial design. Two groups of rats were fed the diets without cholesterol whereas the other two received the same diets containing 3 g/kg diet cholesterol (previously dissolved in the oil mixture). One diet with cholesterol and one diet without cholesterol were supplemented with 5 g/kg diet of a dry powder of red wine (Cabernet Sauvignon grape variety) from the Institut National de la Recherche Agronomique (Montpellier, France). One liter of red wine produced 2 g of dry powder (WP) containing 0.98 g/g of total polyphenols. The main components (per g of WP) were monomeric flavonols (catechin + epicatechin) 8.6 mg; free anthocyanins (including 52% malvidin-3 glucoside), 52.4 mg; phenolic acids (including 19.5% caftaric acid), 8.7 mg; and proanthocyanidols expressed as catechin, 480 mg. One gram of WP contained 235 mg *trans*-resveratrol (M_r = 228) as analyzed according to Jeandet *et al.* (28).

The French instructions 88-123 concerning ordinance 87-848 about animal experimentation rules were followed.

After 5 wk of dietary treatment, rats were food-deprived for a night before weighing and killing by decapitation between 0800 and 0900. Blood was collected on heparin sodium salt (100 mg/L), and a mixture of 2 mmol/L benzamidin and 200 mmol/L gentamycin was added as preservative. Plasma samples from each group, obtained after low-speed centrifugation, were randomly pooled three by three into six subgroups. After adding 2 g/L Chelex-100 (Biorad, Ivry sur Seine, France) to remove traces of contaminating transition metals and aprotinin (100 kallikrein inhibitory units/L), plasma samples were stored at –80°C until analysis. Liver was rapidly removed, rinsed with ice-cold 150 mmol/L NaCl, blotted and weighed. Individual aliquots were freeze-clamped and stored at –80°C.

Lipoprotein isolation. Lipoprotein classes were isolated by sequential ultracentrifugation at 145,000 × *g* according to Havel *et al.* (29) using saline solutions stored on Chelex-100 (3 g/L) to remove traces of contaminating transition metals. As both VLDL (precursor of LDL) and LDL undergo lipid peroxidation and as rats have relatively small amounts of LDL (30), the following two fractions were isolated: VLDL + LDL, d < 1.050 kg/L and HDL, d = 1.050–1.21 kg/L, after a 20- and a 36-h centrifugation, respectively.

Preparation of liver membranes. All operations were performed at 4°C. Liver tissue was rinsed with ice-cold EDTA/NaCl 6 mmol/L: 150 mmol/L), minced with scissors, and homogenized in 2 mL/g of buffer (10 mmol/L Tris-HCl, 250 mmol/L sucrose, and 1 mmol/L EDTA, pH 7.4) using a Polytron homogenizer (PT 1200 Kinematica, Bioblock, Strasbourg, France). An aliquot was filtered through a nylon gauze and centrifuged at 500 × *g* for 5 min. The supernatant was centrifuged at 15,000 × *g* for 15 min followed by centrifugation of the supernatant at 105,000 × *g* for 60 min. The pellet termed "microsomes" was suspended in the same buffer at a protein concentration of 2 g/L and stored at –80°C.

Chemical analysis. Liver lipids were extracted from homogenate according to Folch *et al.* (31) using 6 mL of chloroform/methanol (2:1, vol/vol) for 1.5 mL homogenate. After washing twice, the lower chloroform phase was dried under nitrogen and resolubilized in 0.25 mL of 2-propanol. Liver triacylglycerol (TAG) and cholesterol (total and free) were quantified by enzymatic colorimetric tests (240052 and 1442341 Boehringer Mannheim, Meylan, France). The phospholipid (PL) content was estimated from the phosphorus content (P × 25) determined by the method of Bartlett (32). Plasma and lipoprotein TAG and cholesterol concentrations were directly measured using the same tests. HDL cholesterol (HDL-C) was determined in the fraction (d 1.050–1.21 kg/L) isolated from a defined volume of plasma. VLDL + LDL cholesterol was estimated as the difference between total cholesterol and HDL-C. The protein concentration of liver, lipoproteins, and plasma samples was determined by the method of Bradford (33) using the Biorad Protein assay (Biorad, Richmond, CA) with bovine serum albumin (fraction V) as standard. The HDL composition was determined by measuring amounts of components: free cholesterol, cholesteryl esters (CE), TAG, PL, and protein in

isolated HDL. Amounts of CE were calculated as the difference between total HDL-C and HDL free cholesterol multiplied by 1.7. The plasma HDL concentration (g/L) was calculated by adding weights of components.

Fatty acid composition. Methyl esters were prepared and analyzed by gas–liquid chromatography using a bonded fused-silica capillary column (Carbowax 20M, 50 m × 0.3 mm i.d.) and a flame-ionization detector as previously described (27).

Tocopherol analysis. Lipids were extracted from total plasma and HDL according to Burton *et al.* (34) by mixing the sample (0.5 mL), water (0.5 mL), and absolute ethanol (1 mL) in a glass tube. After adding *n*-hexane (1 mL), the mixture was stirred using a vortex for 50 s, and the organic phase was separated by centrifugation. The aqueous phase was re-extracted, and the hexane extract was dried under N_2 and resolubilized in a defined volume of hexane. The sample was analyzed by high-performance liquid chromatography using a Microporasil column (300 × 3.9 mm, 10 μm i.d.) supplied by Waters (Milford, MA). The mobile phase was *n*-hexane/ethyl acetate (100:7.5, vol/vol) at a flow rate of 1 mL/min. Detection was performed with a Hitachi spectrofluorimeter (model F-2000; Tokyo, Japan) with excitation at 290 nm and fluorescence emission at 330 nm. Quantification was performed with external standards of dl-α-tocopherol. The VLDL + LDL α-tocopherol concentration was calculated as the difference between total plasma and HDL concentration. The same procedure was used for analysis in liver fractions, but 1 mL of sodium dodecylsulfate aqueous solution (100 mmol/L) was added to 0.5 mL of either homogenate (100 mg fresh tissue) or microsomes (1 mg protein). Then, ethanol (2 mL) and *n*-hexane (2 mL) were added to extract α-tocopherol.

Oxidation of lipoproteins. The kinetics of conjugated diene formation in the VLDL + LDL fraction were followed by continuous monitoring of the 234-nm absorption according to Esterbauer *et al.* (35). Just before use, the lipoprotein was filtered through a 0.2-mm Millipore filter (Saint-Quentin en Yvelines, France) to remove Chelex, and lipoprotein aliquots (25 mg protein/L) in oxygenated phosphate-buffered saline (10 mmol/L, pH 7.4) were incubated at 37°C with 5 μmol/L $CuSO_4$. The increase of absorbance was recorded every 15 min for 24 h in a Uvikon 930 spectrophotometer (Kontron, Montigny le Bretonneux, France). The maximum diene concentration was determined from the difference between the absorbance at the maximum slope of the absorbance curve and the absorbance at time zero using the extinction coefficient for conjugated dienes at 234 nm [ε = 29,500 L/(mol · cm)].

Statistical analysis. Values are presented as means and SEM with significance set at $P < 0.05$. One-way analysis of variance (ANOVA) was used to compare the four group means. Two-way ANOVA was used to test effects of supplementation with cholesterol and WP and their interaction on variables. The differences between means were tested using least significant differences when the *F*-value was significant. The statistical computer program was Super ANOVA (Abacus Concepts, Berkeley, CA).

RESULTS

There were no significant differences among dietary groups for final body weight (no supplementation, control group, 353.7 ± 8.7 g; group fed cholesterol, 346.7 ± 7.5 g; group fed WP, 346.1 ± 9.6 g; group fed cholesterol + WP, 351.8 ± 10.3 g). As shown in Table 1, the dietary intake of cholesterol significantly lowered plasma levels of TAG ($P < 0.01$), total cholesterol ($P < 0.0002$), and HDL-C ($P < 0.0001$) and HDL-C to total cholesterol ratios ($P < 0.0001$). However, it increased the cholesterol to protein ratio in the VLDL + LDL fraction (+60%, $P < 0.005$).

The dietary-induced changes in HDL were assessed by quantifying the components of the fraction isolated by centrifugation (Table 2). Dietary cholesterol, but not WP, significantly reduced the plasma HDL concentration from 235–258 mg/L to 160 mg/L ($P < 0.0001$). Hence, the amounts of cholesterol carried by plasma HDL were 40–55% lower than in rats fed diets without cholesterol. The distribution of fatty acids in HDL was influenced by dietary cholesterol (and WP for 20:4n-6). The decreasing effect of dietary cholesterol on the proportion of arachidonic acid (20:4n-6) was compensated by opposite changes in the proportion of the precursor. As a result, the ratios of 20:4n-6 to 18:2n-6, unaffected by dietary WP, were lowest in rats fed cholesterol (1.05 vs. 1.75, $P < 0.0001$).

The lipid content of liver (Table 1) was affected by dietary cholesterol, but not by WP. The response, as opposed to that of plasma, was reflected by the 20% higher liver weight in rats fed cholesterol (10.2 ± 0.20 vs. 8.6 ± 0.14 g; $P < 0.0001$). This was mainly due to the accumulation of TAG (+120%, $P < 0.0001$) and cholesterol (+450%, $P < 0.0001$). In contrast, the PL content of liver was slightly lower (–10%, $P < 0.0002$).

Cholesterol feeding lowered the α-tocopherol concentration of plasma by about 40% ($P < 0.0001$) whereas it did not influence that of total liver. Relative to protein, the cholesterol content of microsomes was unaffected by either dietary supplementation, but the α-tocopherol content was lower in rats fed cholesterol (–60%) and higher in rats fed WP (+21%), $P < 0.0001$ for both compared to unsupplemented counterparts.

The kinetics of conjugated diene formation during copper-catalyzed oxidation of VLDL + LDL showed striking differences among groups for resistance to lipid peroxidation (Fig. 1). The amounts produced at 25 h oxidation were highest in rats fed cholesterol without WP (2560 μmol/g VLDL + LDL protein) whereas they were 75% lower in rats fed WP without cholesterol (cholesterol effect, $P < 0.006$; WP effect, $P < 0.0001$) (Table 1). The distribution of fatty acids in VLDL + LDL was influenced by dietary cholesterol but not by WP (Table 3). The highest response to cholesterol concerned 20:4n-6, which was reduced by almost 30% ($P < 0.0001$). This was compensated by higher proportions of 18:1n-9 and 18:2n-6.

WP supplementation had little or no effect on the distribution of fatty acids in liver esterified lipids (Table 4). In contrast, the response to cholesterol supplementation was significant ($P < 0.0001$ for almost all fatty acids). TAG incorporated less saturated fatty acids (–23%) and 20:4n-6 (–40%), but

TABLE 1
Effects of Cholesterol and Wine Polyphenols (WP) Supplementation on Lipids and a-Tocopherol in Plasma and Liver of Rats Fed Diets Rich in Polyunsaturated Fatty Acids[a,b]

more n-3 PUFA (+29%). In CE, the 62% lower proportion of saturated fatty acids and 20:4n-6 was compensated by the higher proportion of 18:1n-9, 18:2n-6, and n-3 PUFA. The fatty acid composition of PL was moderately affected by dietary treatments. However, the proportion of 20:4n-6 was 20% lower in cholesterol-fed rats. In the three lipid classes, the response was reflected by the lower 20:4n-6 to 18:2n-6 ratio. Figure 2 represents the liver content of major fatty acyl chains incorporated in esterified lipids (as calculated from Tables 1 and 4). Supplementation with cholesterol dramatically enhanced the amounts of acyl chains present in CE (from 2 to 25 μmol/g liver, $P < 0.0001$) and in TAG (from 38 to 81 μmol/g liver, $P < 0.0001$). In contrast, WP supplementation did not alter these variables. PL amounts were not or were only slightly influenced by dietary treatments and the response contrasted with that of other esters (from 74 to 67 μmol/g liver, $P < 0.001$). This was mainly due to the decreasing effect of dietary cholesterol ($P < 0.0001$) on 20:4n-6 (–26%) and n-3 PUFA (–17%) and of dietary wine on 18:2n-6 (–12%).

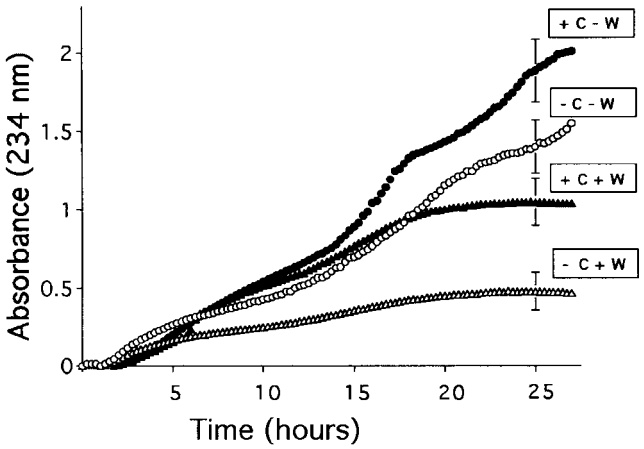

FIG. 1. Kinetics of copper-catalyzed oxidation of very low density lipoprotein + low density lipoprotein in rats fed diets not supplemented or supplemented with cholesterol (C) and red wine polyphenols (W). The changes in absorbance at 234 nm were continuously monitored and recorded every 15 min. The initial absorbance was subtracted from all data. Each value of each curve represents the mean of six pooled samples (3 rats per pool). With the exception of that at 25 h, the bars showing SEM have been omitted for clarity. At 25 h, there was a significant difference among groups for the effect of dietary C ($P < 0.006$) and W ($P < 0.0001$) without interaction. Amounts of dienes are given in Table 1.

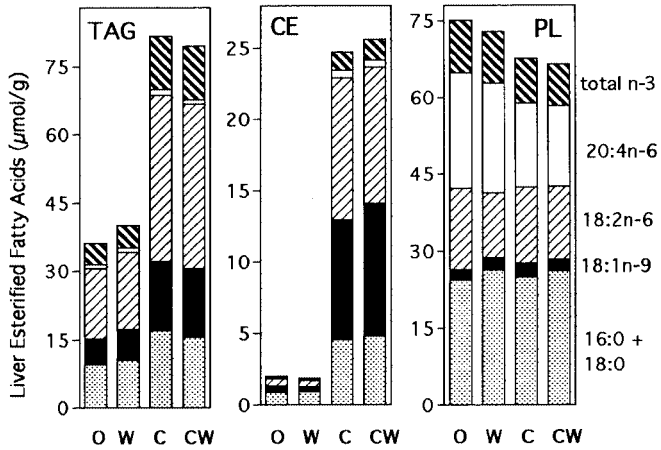

FIG. 2. Amounts of major fatty acids in liver-esterified lipids (μmol/g fresh tissue). Values were calculated using data from Tables 1 and 3 considering that triacylglycerol (TAG), cholesteryl ester (CE), and phospholipid (PL) contain 3, 1, and 2 mol fatty acid/mol ester, respectively. Esterified cholesterol is total cholesterol minus free cholesterol. Letters in abcissa represent dietary groups: not supplemented (O) or supplemented with wine polyphenols (W), cholesterol (C), cholesterol and wine polyphenols (CW). Values are mean ($n = 18$). Bars showing SEM have been omitted for clarity. There was a significant difference among groups for 1) the effect of dietary C on the acyl chain content of TAG and CE ($P < 0.0001$ except 20:4n-6 in TAG, $P < 0.0002$) and of PL ($P < 0.0001$ for 20:4n-6 and total n-3, $P < 0.03$ for 18:1n-9; 2) for the effect of dietary W on the 18:2n-6 content of PL ($P < 0.0003$).

DISCUSSION

The major findings of this study are the opposing responses of plasma and liver lipids to dietary cholesterol. Paradoxically, cholesterol feeding induced a reduction of total plasma cholesterol levels despite the cholesterol enrichment of the VLDL + LDL fraction. The overall hypocholesterolemic effect was due to the reduction of HDL which, in rats, are the main vehicles of plasma CE. They are mainly synthesized in plasma through the action of lecithin:cholesterol acyltransferase (LCAT) with large differences between species for the substrate specificity. Thus in rat, the LCAT reaction produces predominantly 20:4n-6 CE (36,37). The accumulation of CE in plasma HDL is believed to result from the deficiency of a lipid transfer protein that, in humans, transfers HDL CE to lipoproteins of lower density (38). Moreover, the plasma LDL levels are low because rats have an efficient mechanism for hepatic clearance of chylomicrons and VLDL remnants from the circulation (30).

The level and type of dietary fats largely influence the lipid content of plasma. In rats, dietary long-chain n-3 PUFA reduce both TAG and cholesterol plasma concentrations (39,40). Such effects were observed in rats fed 10% safflower oil diets (rich in 18:2n-6) when 50% of the lipid source was

replaced by fish oil. The addition of 1% cholesterol to diets did not impair the response to long-chain n-3 PUFA but increased the plasma cholesterol content and the liver weight (41). Our data are consistant with that obtained by Lu and Wu (42) in rats fed diets resembling that of this study (10% fat with 42% PUFA and a n-6 to n-3 ratio of about 5). The addition of 1% cholesterol to diets induced a reduction of plasma TAG, cholesterol, and HDL levels and an increase of liver TAG and CE levels. The authors suggested that most of the cholesterol transported into the blood stream from the gut was immediately removed from the circulation by the liver. Indeed, the activity of the hepatic acyl-CoA:cholesterol acyltransferase, which catalyzes the formation of cholesteryl esters, is high in rats fed fish oils (43), and cholesterol feeding increases the activity (44). This lead to an hepatic overload of CE. The hepatic accumulation of TAG reported in rats fed diets rich in n-6 PUFA without fish oil supplemented with cholesterol was ascribed to the reduction of fatty acid oxidation and to the stimulation of TAG synthesis (45). In this study, the intake of dietary fish oils, which reduce the hepatic synthesis of TAG (46), did not impair the hepatic accumulation. The concentration of fish oils in diet could be insufficient to neutralize the response to dietary cholesterol.

The present findings suggest that the lowering effect of dietary cholesterol on the HDL content of plasma was linked to the availability of 20:4n-6. Indeed, dietary cholesterol alters the metabolism of hepatic fatty acids by inhibiting the conversion of 18:2n-6 to 20:4n-6 (47). Moreover, dietary cholesterol accentuates the inhibitory effects of long-chain n-3 PUFA on the desaturation of 18:2n-6 (41). In this study, this was reflected by the lower 20:4n-6 to 18:2n-6 ratio in either class of liver lipids as well as in plasma lipids. The reduction of the hepatic pool of 20:4n-6 could be partly responsible for the lower PL content of liver. Despite a greater liver weight, the amounts of 20:4n-6 in the whole tissue were slighty lower than in unsupplemented counterparts (167 μmol vs. 192 μmol).

In plasma, the reduction of 20:4n-6 likely affected the PL class thereby decreasing the production of HDL CE through the LCAT reaction. In total HDL, the amounts of 20:4n-6 reached about 27 μmol/100 dL plasma with cholesterol-free diets whereas they were lowered to 10 μmol/100 dL plasma with cholesterol-supplemented diets. The reduction in the synthesis of HDL could also be due to dysfunctions in the liver metabolism in response to lipid accumulation. This could impair the synthesis of apolipoproteins (apo) and their association with lipid fractions.

The proportion of 18:2n-6, which is considered as the primary predictor of oxidative susceptibility of LDL (48), was only 5% higher in VLDL + LDL from rats fed cholesterol as compared to unsupplemented counterparts. Accordingly, the increasing effect of dietary cholesterol on the production of dienes could be linked in a minor way, to the 18:2n-6 content of particles. The cholesterol enrichment of particles likely enhanced their susceptibility to oxidation. Such an effect was reported in the case of rabbits fed diets containing 2% cholesterol (49). On the other hand, the oxidizability of lipoproteins is partly dependent on the concentration of substances having antioxidant properties. Quantitatively, the main lipophilic antioxidant associated with particles is α-tocopherol. Hence, the reducing effect of dietary cholesterol on the α-tocopherol content of VLDL + LDL could also contribute to the production of higher amounts of dienes.

Feeding WP resulted in a lower oxidizability of VLDL + LDL fatty acids. The highly significant response suggests that the assay mixture contained wine antioxidants. They could be either bound to particles or solubilized in their aqueous environment. As was the case previously (14), the VLDL + LDL fraction was not dialyzed after isolation so as to prevent the loss of soluble antioxidants. Actually, with diets similar to that of this study, we observed that the intake of dietary quercetin and catechin inhibited the formation of conjugated dienes in VLDL + LDL. In other studies, epicatechin administered orally to Wistar rats was found to decrease the oxidizability of plasma. The compound exhibited antioxidative activity even after intestinal absorption and metabolic conversion (50).

The intestine can also absorb the phenolic substances of red wine. In humans consuming red wine, Furhman *et al.* (17) found that LDL were enriched in phenolic compounds whereas their capacity to undergo peroxidation induced by copper ions was reduced. Further studies showed that the response was not due to alcohol intake. Thus, a significant increase in plasma antioxidant potential and polyphenol concentration was found in humans consuming alcohol-free red wine (21). The protective effects of WP against atherosclerosis were demonstrated in apo E-deficient mice in which LDL are highly susceptible to oxidation and aggregation. Indeed, dietary supplementation with red wine or its polyphenolic compounds, quercetin and catechin, lowered the susceptibility of their LDL to oxidation and inhibited the development of aortic lesions (51).

The wine powder used in this study contained anthocyanins. These flavonoid pigments, which are strong antioxidants (52), are partially absorbed (53). The major fraction of wine polyphenols consists of proanthocyanidols which are oligomers and polymers of flavonols. In wine, a fraction is present as condensed tannins containing three to five subunits, which are potent metal chelators (1). Moreover, they may reduce the intestinal absorption of cholesterol (54).

It is not known whether the oxidizability of VLDL + LDL is linked to the plasma HDL content. However, it should be taken into consideration that not only *in vitro* (55) but also *in vivo*, HDL have been found to protect LDL. The effect might be related to that of HDL-associated antioxidants such as α-tocopherol and paraoxonase, which can destroy oxidized lipids (56). Moreover, HDL are potent scavengers of free radicals (57). In rabbits, cholesterol-feeding reduced the plasma HDL concentration, suggesting that this effect could contribute to the formation of atherosclerotic lesions (49).

In liver microsomes, there were no major differences between groups for the cholesterol content and for the distribution of fatty acids (assuming that liver PL are representative

of membrane PL). The α-tocopherol enrichment of microsomes in rats supplemented with WP is consistent with previous findings using diets enriched with defined flavonoids (14). This suggests that the cholesterol-induced reduction of α-tocopherol in membranes could be partially prevented by dietary WP.

Even if the present findings cannot be extrapolated to the human situation, they provide useful informations about responses to the intake of dietary wine polyphenols. They prove that these compounds, which are potent antioxidants, are absorbed at sufficient levels to contribute to the protection of PUFA in plasma and membranes, thereby sparing α-tocopherol and endogenous antioxidants. In particular, they suggest that the intake of dietary wine polyphenols is beneficial more especially when feeding high cholesterol diets.

ACKNOWLEDGMENTS

The authors thank Dr. Michel Bourzeix and Dr. Véronique Cheynier (INRA, Montpellier) for the gift of wine powder and Dr. Philippe Jeandet (Laboratoire d'Oenologie, Reims) for measuring the resveratrol content.

ABSTRACT: The changes in guinea pig brain (cerebrum) glycerophospholipid molecular species resulting from a low α-linolenic acid (ALA) diet are described. Two groups of six guinea pigs were raised from birth to 16 wk of age on either an n-3 deficient diet containing 0.01 g ALA/100 g diet or n-3 sufficient diet containing 0.71 g ALA/100 g diet. Molecular species of diradyl glycerophosphoethanolamine (GroPEtn), glycerophosphocholine, glycerophosphoserine, and glycerophosphoinositol were analyzed by high-performance liquid chromatography with on-line electrospray ionization mass spectrometry (HPLC/ESI/MS). Alkenylacyl GroPEtn species were determined by comparing spectra before and after mild acid treatment while diacyl- and alkylacyl species were distinguished by HPLC/ESI/MS. The proportions of phospholipid classes and of the diradyl GroPEtn subclasses were not altered by diet changes. The main polyunsaturated molecular species of diradyl GroPEtn subclasses and of phosphatidylcholine and phosphatidylserine (PtdSer) contained 16:0, 18:0, or 18:1 in combination with docosahexaenoic acid (DHA, 22:6n-3), docosapentaenoic (DPA, 22:5n-6), or arachidonic acid (ARA, 20:4n-6). A significant proportion of DPA containing species were present in both diet groups, but in n-3 fatty acid deficiency, the proportion of DPA increased and DHA was primarily replaced by DPA. The combined value of main DHA and DPA containing species in the n-3 deficient group ranged from 91–111% when compared with the n-3 sufficient group, indicating a nearly quantitative replacement. The n-3 fatty acid deficiency did not lower the content of ARA containing molecular species of PtdSer of the guinea pig brain as reported previously for the rat brain. The molecular species of phosphatidylinositol were not altered by n-3 fatty acid deficiency. The present data show that the main consequence of a low ALA diet is the preferential replacement of DHA-containing molecular species by DPA-containing molecular species in alkenylacyl- and diacyl GroPEtn and PtdSer of guinea pig brain.

Paper no. L8448 in Lipids 35, 1001–1009 (September 2000).

Previous studies have shown (1–4) that a low n-3 polyunsaturated fatty acid (PUFA) content in an infant diet may lead to disorders in visual and cognitive development, but the biochemical basis for this observation has remained obscure. Decreasing α-linolenic acid (ALA) content in formula led to a reduced proportion of docosahexaenoic acid (DHA) in phospholipids, while the level of docosapentaenoic acid (DPA) was increased (5). These changes in infant brain or other tissues are not easily investigated. However, there are some post mortem studies that show a reduced DHA level in the brain of formula fed infants when compared with breast-fed infants (6–8). In animal studies (9,10), n-3 fatty acid deficiency strongly reduces the proportion of DHA and increases that of DPA in the nervous system. In the rat, n-3 deficiency has been reported (11) to reduce the total PUFA content of brain phosphatidylserine (PtdSer), and DHA has been suggested to be a modulator of brain PtdSer biosynthesis. A basic strategy for investigating the role of brain DHA in neurological functions has been to manipulate tissue levels of DHA and evaluate appropriate functional endpoints (12–14). It has been shown that an artificial rearing method with a low n-3 fat diet can produce rats with brain DHA reduced by 50% in the first generation and more than 90% in the second generation (15). Reductions of even more than this were achieved in three generations of guinea pigs reared normally (16). Most previous studies have been based on analyses of the total fatty acid content of different phospholipid classes, which may conceal specific effects upon individual molecular species that may be important in overall membrane function. Therefore, the present study describes the changes in glycerophospholipid molecular species of guinea pig brain (cerebrum) caused by low dietary ALA content.

MATERIALS AND METHODS

Materials. All solvents were high-peformance liquid chromatography (HPLC) or reagent grade and were purchased from

Abbreviations: a, alkylacyl; ACN, acyl carbon number; ALA, α-linolenic acid (18:3n-3); ARA, arachidonic acid (20:4n-6); CL, cardiolipin; DB, double bond; DHA, docosahexaenoic acid (22:6n-3); DPA, docosapentaenoic acid (22:5n-6); GroPCho, glycerophosphocholine; GroPEtn, glycerophosphoethanolamine; GroPIns, glycerophosphoinositol; GroPSer, glycerophosphoserine; HPLC, high-performance liquid chromatography; HPLC/ESI/MS, high-performance liquid chromatography/electrospray ionization/mass spectrometry; p, alkenylacyl; PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine; PUFA, polyunsaturated fatty acid; TLC, thin-layer chromatography.

Caledon Chemicals (Toronto, Canada). All reagents used were of reagent grade or better quality. Sep-Pak®-silica cartridges were purchased from Waters Corporation (Milford, MA). Lipid standards: bovine brain galactocerebrosides (type I and type II), bovine brain galactocerebroside sulfate, bovine heart cardiolipin, 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine, 1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine, 1,2-palmitoyl-*sn*-glycero-3-phosphocholine, 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine, 1,2-dipalmitoyl-*sn*-glycero-3-phosphoserine, bovine brain sphingomyelin, and bovine liver phosphatidyl inositol were purchased from Sigma Chemical Co. (St. Louis, MO).

Animals and diets. Two groups of six pigmented female guinea pigs (English short hair), raised from mothers maintained on two different diets for the last one-third of pregnancy, were fed from birth to 16 wk of age. The diets, fed to guinea pigs *ad libitum,* differed in fatty acid composition, providing an n-3 fatty acid sufficient diet group and n-3 deficient diet group (Table 1). The lipid content of both diets was 10% (w/w) and the triacylglycerols in the diets contained n-6 fatty acids and n-3 fatty acids, entirely in the form of linoleic acid (18:2n-6) and ALA (18:3n-3), respectively. The proportion of linoleic acid in both diets was 16% of the total fatty acids, while that of ALA was 7.1% in the sufficient diet and 0.1% in the deficient diet. DHA or arachidonic acid (ARA) were not present in either of the diets.

Sample preparation. At the end of the feeding period, animals were sacrificed using CO_2 asphyxiation. The brain was removed, washed in saline and the cerebrum was divided into halves along the midline. Lipids from one half of the homogenized cerebrum were extracted overnight in chloroform/methanol (2:1, vol/vol) containing 10 mg/mL butylated hydroxytoluene as an antioxidant using 50 mL of solvent per gram of brain. The extraction mixture was filtered and filtrate washed with saline (20% of filtrate volume). After phase separation, the organic phase was evaporated under vacuum. Oil residue was redissolved in chloroform and evaporation was repeated to remove any remaining water. The final residue was stored in chloroform solution.

TABLE 1
Fatty Acid Composition of n-3 Fatty Acid Sufficient Diet and n-3 Fatty Acid Deficient Diet Fed to Two Groups of Six Guinea Pigs[a]

Fatty acid	n-3 Sufficient diet	n-3 Deficient diet
8:0	1.9	6.1
10:0	1.6	5.0
12:0	11.5	36.4
14:0	4.6	14.0
16:0	6.1	8.9
16:1	0.2	0.1
18:0	4.6	8.9
18:1	42.7	3.1
18:2n-6	16.1	16.2
18:3n-3	7.1	0.1
18:2/18:3	2.3/1	161/1

[a]Results expressed as % of total fatty acids.

Separation of phospholipid classes. To avoid coelution of glycolipids with phospholipids, brain total lipid extracts were fractionated into neutral lipids, glycolipids, and phospholipids by normal phase silica gel column chromatography prior to phospholipid class separation by thin-layer chromatography (TLC). Approximately 15 mg of brain total lipid extract was loaded into a commercial Sep-Pak® cartridge and lipid classes were separated by step-wise elution. Neutral lipids were eluted with 10 mL $CHCl_3$ containing 1% acetic acid to facilitate the elution of free fatty acids. Glycolipids were then eluted by 20 mL acetone/methanol (14:1, vol/vol), followed by elution of phospholipids by 10 mL methanol. The elution system was developed by testing with lipid standards and the purity of brain lipid fractions obtained was checked by HPLC/electrospray ionization/mass spectrometry (HPLC/ESI/MS) method. Phospholipid classes were separated by TLC using boric acid impregnated silica gel G plates prepared in the laboratory. A slurry of silica gel (0.5 g/mL) was prepared in 2.4% (wt/vol) boric acid solution and a layer of 250 µm spread on 20 × 20 cm glass plates. Before use, the plates were air dried and activated at 120°C for 1 h. Plates were developed in a solvent system consisting of chloroform/ethanol/water/triethylamine (30:35:6:35, by vol) (17). Lipid bands were visualized by spraying with 0.1% 2′7′-dichlorofluorescein in ethanol and phospholipids were extracted with chloroform/methanol (2:1, vol/vol) followed by removal of staining reagent by 2% $KHCO_3$ (wt/vol).

Fatty acid analysis. Phospholipid fractions, obtained by TLC separation, were transmethylated using 6% sulfuric acid in methanol for 2 h at 80°C. Fatty acid methyl esters of each phospholipid class were analyzed by a HP 5880 (Hewlett-Packard, Palo Alto, CA) gas–liquid chromatograph equipped with SP-2380 column (15 m × 0.25 mm i.d., 0.20 µm film thickness) and a flame-ionization detector. Column oven temperature was set to rise after 0.5 min from 100 to 130°C (20°C/min) and from 130 to 240°C (5°C/min). Transmethylated fatty acids were identified by comparing retention times with known fatty acid methyl esters used as external standards.

HPLC/ESI/MS apparatus. The HPLC/ESI/MS system consisted of a Hewlett-Packard 1090 liquid chromatograph connected to a Hewlett-Packard 5989A quadrupole mass spectrometer equipped with a nebulizer-assisted electrospray interface. Samples were introduced into the HPLC system by autoinjector and components were separated on a silica column (Supelcosil LC-Si, 5 µm, 250 mm × 4.6 mm i.d.; Supelco Inc., Bellefonte, PA). The solvent system consisted of solvent mixtures A (chloroform/methanol/30% ammonium hydroxide, 80:19.5:0.5, by vol) and B (chloroform/methanol/water/30% ammonium hydroxide, 60:34:5.5:0.5, by vol) (18). The column was eluted at 1 mL/min with a linear gradient starting with 100% solvent A and changing to 100% solvent B in 14 min after holding the starting composition for 3 min. The final composition was held for 10 min. HPLC effluent was split 1:50 using a commercial splitter (LC Packings) to deliver suitable flow to the electrospray interface. Full scan mass

spectra ranging from *m/z* 400–1300 were collected in negative and positive ionization mode.

Analysis of phospholipid molecular species. Molecular species of diradyl glycerophosphoethanolamine (GroPEtn), glycerophosphocholine (GroPCho), glycerophosphoserine (GroPSer), and glycerophosphoinositol (GroPIns) were analyzed by injecting approximately 8–10 μg of brain total lipid extract directly into the HPLC/ESI/MS system. GroPCho species were analyzed in positive ionization mode while other species were analyzed in negative ion mode. Phosphatidylcholine (PtdCho), phosphatidylserine (PtdSer), and phosphatidylinositol (PtdIns) were distinguished directly by HPLC/ESI/MS according to chromatographic retention times of phospholipid classes and molecular weights of individual molecular species. Alkenylacyl, diacyl, and alkylacyl subclasses of GroPEtn were determined by analyzing samples before and after mild acid treatment performed to hydrolyze the vinyl ether bond of alkenylacyl species. Alkenylacyl species could then be calculated by subtracting spectra derived from the samples after acid treatment from spectra obtained before acid treatment. Diacyl and alkylacyl species of GroPEtn were distinguished using spectra derived from the acid treated sample. To hydrolyze alkenylacyl GroPEtn species, an aliquot of total lipid extract was dried down and treated with 200 μL of 2 M methanolic HCl for 30 min at room temperature (19,20). After the acid treatment, the sample was dried down and reconstituted in HPLC solvent A for analysis. 1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine (25 μg/mL) and 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (25 μg/mL), which were not present in brain lipid extracts, were added to samples as internal standards prior to analysis. An average of three analyses of each sample was used to calculate the results. The relative responses for analyzed phospholipid classes in negative ionization mode were determined by co-injecting known concentrations of phospholipid standards into HPLC/ESI/MS system, and response factors were calculated relative to GroPEtn.

Statistical analyses. Significant differences in fatty acid composition and phospholipid molecular species composition between dietary groups were tested using a one-way analysis of variance with a significance level of 0.05 (*P*-values).

RESULTS

Fatty acid composition. The PUFA composition of different phospholipid classes of guinea pig brain (cerebrum) is presented in Table 2. The proportion of PUFA varied from 7.8 to 39.3% as a percentage of total fatty acids in phospholipids depending on phospholipid class, with the most polyunsaturated classes being diradyl GroPEtn and PtdIns. The proportion remained constant regardless of diet in all brain phospholipid classes ($P > 0.05$). There were clearly significant differences between diet groups in proportions of DHA and DPA in all phospholipid classes. The minor differences in some other PUFA also existed with significance level of 0.05 as indicated in Table 2. In all cases, the percentage of DPA in the n-3 fatty acid deficient group equaled approximately the corresponding percentage of DHA in the n-3 fatty acid sufficient group, indicating a nearly quantitative replacement of DHA by DPA. Conversely, the proportion of DHA in the n-3 fatty acid deficient group was lower than that of DPA in the n-3 sufficient group. In phosphatidylethanolamine (PtdEtn), PtdCho, PtdSer, and PtdIns the combined values of percentages of DHA and DPA in the n-3 fatty acid sufficient group were 13.8, 1.9, 14.2, and 1.6% (percentage of total fatty acids), respectively. The corresponding values in the n-3 fatty acid deficient group were 11.0, 1.5, 12.0, and 1.1%, respectively, indicating that the combined value of these fatty acids remained nearly constant regardless of the n-3 fatty acid deficiency.

Analysis of phospholipid molecular species. Phospholipid classes were clearly resolved by the HPLC system used. Neutral lipids eluted at the beginning of the run and gave a very weak response in negative ionization mode. In the negative ion mode, glycolipids followed by cardiolipin, were seen to elute between 5 and 10 min, after which the acidic phospholipids were eluted in the order of PtdEtn, PtdIns, and PtdSer (Fig. 1A). In the positive ionization mode, PtdCho was seen to elute in 15–17 min, clearly resolved from sphingomyelin eluting in 18.5–19.5 min and lysoPtdCho in 23–25 min. PtdEtn gave a weak response in positive ionization mode, but was well separated from PtdCho in retention time. PtdCho and sphingomyelin were not detected in negative ionization mode even as the chloride adducts $[M + 35]^-$. In negative ionization mode, the response factors for PtdSer and PtdIns relative to PtdEtn were determined by co-injecting known concentrations of each phospholipid class standard compounds. PtdSer and PtdIns were detected with higher sensitivity than PtdEtn and the correction factors were 0.35 and 0.42 relative to PtdEtn, respectively. By using internal standards in positive and negative ionization mode and correction factors in negative ionization mode, the relative proportions of phospholipid classes in brain lipid extracts were calculated. The distribution of phospholipids between different phospholipid classes was not affected by diet changes as indicated in Table 3. The relative proportions of diradyl GroPEtn subclasses were also unaffected by diet changes (Table 3). An example of mass spectra averaged over diradyl GroPEtn peak in total lipid extract and in acid hydrolyzed total lipid extract is given in Figure 2. These spectra demonstrate the hydrolysis of the vinyl ether bond of alkenylacyl GroPEtn in acid treatment. The peak at *m/z* 774 in Figure 2A represents alkenylacyl GroPEtn 40:6p [acyl carbon number (ACN):double bond (DB)]. In spectrum derived from the acid treated sample (Fig. 2B), there is no peak at a corresponding *m/z* value indicating the total hydrolysis of the vinyl ether bond. The highest intensity peak at *m/z* 750 in Figure 2A represents 38:4 alkenylacyl GroPEtn (38:4p) and 38:5 alkylacyl GroPEtn (38:5a) in total lipid extract. After acid hydrolysis, the low intensity peak at *m/z* 750 represents alkylacyl GroPEtn (38:5a), which remains intact during acid treatment. The main diacyl GroPEtn species 40:6, 38:4, 40:5, and 40:4 at *m/z* values 790, 766, 792, and 794, respectively, are also

unaffected by acid hydrolysis as shown in Figure 2. In total lipid extract, alkylacyl and alkenylacyl species of GroPEtn with different degrees of unsaturation exist at the same *m/z* value. The alkylacyl and diacyl GroPEtn remaining after acid hydrolysis can be distinguished by differences in the *m/z* values. The acid hydrolysis together with use of internal standard, thus, enables the complete separation of diradyl GroPEtn species with minimal sample preparation. 1-lyso-*sn*-GroPEtn species formed during acid hydrolysis partly coeluted with PtdSer (Fig. 1B), but were easily distinguished according to molecular weight. Figure 1C shows the spectrum averaged over the lysoGroPEtn peak in Figure 1B, showing the lysoGroPEtn species containing PUFA in the *sn*-2 position. In the spectrum, ARA is the most abundant PUFA in the *sn*-2 position of alkenylacyl GroPEtn molecular species, which is in accordance with ARA being the most abundant PUFA in the diradyl GroPEtn molecular species (Table 2).

Phospholipid molecular species in brain. A low ALA diet affected mainly the polyunsaturated GroPEtn and GroPSer molecular species. Although GroPCho was an abundant phospholipid class (Table 3), it was not affected as strongly as GroPEtn and GroPSer since it had a smaller proportion of polyunsaturated molecular species (Tables 4 and 5). GroPIns molecular species were not affected by n-3 fatty acid deficiency (Table 5).

Table 4 lists the polyunsaturated molecular species of diradyl GroPEtn containing at least four DB in the n-3 fatty acid

sufficient and n-3 deficient diet groups. The fatty acid combinations for each ACN:DB class are listed in the decreasing order of probability on the basis of fatty acid composition of phospholipid classes (Table 2). The total proportion of these polyunsaturated molecular species varied from 67.3 to 84.8% (mol% of total molecular species) in diradyl GroPEtn species and remained constant regardless of diet differences. Table 5 shows the corresponding species of diacyl GroPCho, GroPSer, and GroPIns. The combined proportion of polyunsaturated species was also unaffected by diet treatment in these phospholipid classes. The PtdCho contained less polyunsaturated molecular species than other phospholipid classes, while PtdIns consisted almost entirely of molecular species with four or more DB in esterified fatty acid chains (Table 5). The effect of n-3 fatty acid deficiency on molecular species of GroPIns was not detected, although a significant difference in proportions of DHA and DPA fatty acids between diet groups was observed (Table 2). In the alkylacyl GroPEtn subclass, the only significant differences observed were the decreases in 38:6 and 40:6 (ACN:DB) and increases in 40:4 species by n-3 fatty acid deficiency (Table 4). Despite relatively high deviation, it may be concluded that, unlike in other diradyl GroPEtn subclasses, DHA containing species are mainly replaced by 22:4n-6 containing species in alkylacyl-GroPEtn. In all other phospholipid classes, the proportion of DHA containing species was always decreased on the n-3 fatty acid deficient diet, while the proportion of DPA containing species was increased (Tables 4 and 5). A significant proportion of DPA containing molecular species was also present in brains of n-3 sufficient diet group animals, but the

level was further increased by a factor of approximately two in n-3 deficiency (Tables 4 and 5). In addition to alkylacyl GroPEtn, an increase in 18:0/22:4n-6 species was also observed in alkenylacyl GroPEtn and in PtdCho and PtdSer. In all cases there were more DPA containing species in the n-3 fatty acid deficient diet group than corresponding DHA containing species in the n-3 sufficient group. Conversely, the proportion of DPA containing molecular species in the n-3 sufficient group always exceeded the corresponding proportion of DHA containing species in the n-3 fatty acid deficient diet group. The combined proportion of molecular species containing DHA or DPA, calculated separately for 38 and 40 acyl carbons, containing species in the n-3 fatty acid sufficient group ranged from 91 to 111% when compared with the corresponding value in the n-3 deficient group (Tables 4 and 5). The result indicates a nearly quantitative replacement of DHA containing species by DPA species. There were no significant differences in proportions of main ARA containing species between diet groups in any phospholipid classes. These data suggest the main consequence of n-3 fatty acid deficiency to be the replacement of DHA fatty acid containing phospholipid molecular species by DPA containing species in guinea pig cerebrum.

DISCUSSION

Deficiency of n-3 fatty acids in infant nutrition has been shown to affect neurobehavioral development and visual acuity (2–4). However, studying the changes of lipid composition in the human nervous system is restricted to post mortem studies (6–8). Therefore, studying these changes is most easily conducted using animal models. Rhesus monkeys, deprived of 18:3n-3 during development, have lower than normal neural accumulation of DHA (21,22). If fed 18:2n-6,

neural DHA is replaced by DPA (21,22). The n-3 deficient animals are physically healthy and grow normally in contrast to n-6 deficient animals, but they have lower visual development, higher reactivity, and longer look duration compared with monkeys fed n-3 fatty acids (21,22). Attempts to deplete mammals, such as rats and monkeys, of retinal n-3 fatty acids by dietary manipulation (chow-feeding), however, have led to limited success (23,24). Since the guinea pig is the only mammal studied that can be almost completely depleted of retinal DHA by dietary manipulation, it has been suggested (16) that it metabolizes n-3 fatty acids differently from rats and monkeys. Thus, optimal retinal function was achieved in the guinea pig where the retinal DHA level was even lower than that of rats and monkeys raised on n-3 deficient diets. In the present study, therefore, we analyzed molecular species of the glycerophospholipids of brains (cerebrum) of guinea pigs maintained either on an n-3 fatty acid sufficient or an n-3 deficient diet. The complete analysis of molecular species of all glycerophospholipid classes and diradyl GroPEtn subclasses and to fatty acid analyses were performed to monitor the changes in proportions of phospholipid classes and molecular species.

The molecular species composition of the phospholipids of a developing guinea pig brain has been reported by Burdge and Postle (25). Only the choline and ethanolamine glycerophospholipids were examined. The results obtained in the later gestational stages (40 and 68 d) for the molecular species of these phospholipids were not unlike those just described for the mature guinea pig brain on the n-3 sufficient diet. The present study confirms our previous finding (26,27) that in n-3 deficiency, 22:6n-3 is primarily replaced by 22:5n-6. The replacement of DHA containing phospholipid molecular species took place similarly in the diradyl GroPEtn and in PtdCho and PtdSer. In contrast, the ARA rich PtdIns and ARA containing molecular species of other glycerophospholipids were not affected. The present data obtained for the

phospholipid molecular species of whole brain (cerebellum) of guinea pig differ from the data obtained for rat brain microsomes (11). This does not necessarily imply that rat brain responds to n-3 fatty acid deficiency differently than guinea pig brain, as it is well established that fatty acid composition of various subcellular lipid fractions within the same species may differ. Garcia *et al*. (11) studied rat brain microsomes, where the major arachidonoyl species (18:0/20:4n-6 GroPSer) decreased while the minor arachidonoyl species (16:0/20:4n-6 GroPSer) remained unaffected. In the diacyl GroPEtn, the major arachidonic acid-containing species (16:0/20:4n-6 and 18:0/20:4n-6) remained unchanged, while the minor species (18:1/20:4n-6 GroPEtn) was increased fourfold. The various diradyl GroPEtn subclassses responded to the n-3 deficiency in a similar manner as also noted by Zhang *et al*. (28), who examined the pineal phospholipids of the rat brain. The ARA-containing PtdCho species remained unaffected by n-3 deficiency in our studies or in the studies reported by Garcia *et al.* (11), who did not examine the molecular species of the PtdIns of rat brain microsomes.

It has been concluded that the distribution of PtdEtn and PtdCho species between the monolayers of single lamellar vesicles is modulated by acyl chain composition as well as packing requirements of polar head groups of mixed phospholipids (29). The cooperativity of the phase transition of GroPCho bilayer decreased as unsaturation increased from 16:0/18:1 to 16:0/20:4 or to 16:0/22:6 GroPCho (30). The effect of acyl chain packing in the PtdCho bilayer on the equilibrium concentration of metarhodopsin II in a reconstituted system consisting of different diacyl GroPCho bilayers has also been studied (31). The results indicated that an increasing degree of unsaturation in the *sn*-2 position of PtdCho leads to a more permissive bilayer with better capability to accommodate expanded protein in the metarhodopsin II state (31). In a similar study, a difference between 16:0/22:6 and 16:0/20:4 GroPCho vesicles was observed in respect of metarhodopsin II formation (32). In the present study, the DHA in the *sn*-2 position of phospholipid molecular species in guinea pig brain was mainly replaced by DPA as an aftermath of the n-3 fatty acid deficient diet. Based on the above discussion, it may be postulated that changes in phospholipid molecular species caused by n-3 fatty acid deficiency may have an effect on those reactions in the brain that are dependent on interaction between cell membrane and integral membrane proteins.

The biosynthesis of PtdSer in mammalian cells takes place primarily through the serine base exchange reaction (33). The serine exchange enzyme catalyzes the calcium-dependent, energy-independent incorporation of L-serine in exchange for a choline or ethanolamine headgroup. The serine base exchange enzyme is located in the endoplasmic reticulum, mainly from where the freshly synthesized PtdSer is transferred to mitochondria where it can be decarboxylated to PtdEtn (34). PtdEtn may be further converted to PtdCho by stepwise methylation (35,36). The serine base exchange enzyme of rat brain has been isolated and characterized (37) and several factors have been reported to regulate the synthesis of PtdSer in brain (38,39). Although we did not specifically investigate the effect of DHA on the synthesis of PtdSer in guinea pig cerebrum, we can nevertheless comment upon the potential conversion of PtdSer into PtdEtn. A comparison of the major molecular species of the PtdCho or PtdEtn with PtdSer would appear to exclude a direct precursor-product relationship, although a limited base exchange cannot be excluded. The high level of the 1-stearoyl-2-docosahexaenoyl (18:0/22:6n-3 GroPSer) molecular species in the brain may reflect preference for serine exchange enzyme for 22:6n-3 containing phospholipids. Any more significant base exchange would have to be accompanied or followed by a remodeling of the molecular species by acyl exchange.

In this study, the effect of a low ALA diet on glycerophospholipid molecular species in guinea pig brain was investigated. In conclusion, the study shows that a low ALA diet led to an extensive replacement of the DHA containing glycerophospholipid species by DPA containing molecular species in the guinea pig brain. Specifically, dietary deficiency of n-3 fatty acids mainly affected the molecular species of alkenylacyl and diacyl GroPEtn and PtdSer, while PtdCho was affected less and PtdIns remained unchanged. The proportions of the phospholipid classes and the subclasses of the ethanolamine containing phospholipids also remained unchanged. The selective replacement of DHA by DPA is unprecedented and requires further study.

ABSTRACT: Docosahexaenoic acid (DHA, 22:6n-3) is an n-3 polyunsaturated fatty acid which attenuates the development of hypertension in spontaneously hypertensive rats (SHR). The effects of DHA on delta-9-desaturase activity in hepatic microsomes and fatty acid composition were examined in young SHR. Two groups of SHR were fed either a DHA-enriched diet or a control diet for 6 wk. Desaturase activity and fatty acid composition were determined in hepatic microsomes following the dietary treatments. Delta-9-desaturase activity was decreased by 53% in DHA-fed SHR and was accompanied by an increase in 16:0 and a reduction in 16:1n-7 content in hepatic microsomes. The DHA diet also increased the levels of eicosapentaenoic acid (20:5n-3) and DHA. The n-6 fatty acid content was also affected in DHA-fed SHR as reflected by a decrease in gamma-linolenic acid (18:3n-6), arachidonic acid (20:4n-6), adrenic acid (22:4n-6), and docosapentaenoic acid (22:5n-6). A higher proportion of dihomo-gamma-linolenic acid (20:3n-6) and a lower proportion of 20:4n-6 is indicative of impaired delta-5-desaturase activity. The alterations in fatty acid composition and metabolism may contribute to the antihypertensive effect of DHA previously reported.

Paper no. L8459 in *Lipids 35,* 1011–1015 (September 2000).

Alterations in fatty acid biosynthesis and metabolism may contribute to the pathogenesis of hypertension (1–4). Fatty acids are incorporated into tissues and organs and influence cell membrane properties important to physiological functions such as blood pressure regulation. Fatty acid composition can affect membrane fluidity, intracellular signaling, and the activity of membrane-bound receptors and enzymes (5–7).

Fatty acid composition is dependent on hepatic metabolism through a sequence of desaturation and elongation steps. One major pathway of tissue fatty acid biosynthesis begins with desaturation of palmitic acid (16:0) and stearic acid (18:0) (8). Delta-9-desaturase is the key enzyme necessary for the conversion of palmitic to palmitoleic acid (16:1n-7) and stearic to oleic acid (18:1n-9). Delta-6 and delta-5 desaturase enzymes are required for the metabolism of essential fatty acids, linoleic (18:2n-6) and alpha-linolenic (18:3n-3), to long-chain polyunsaturated fatty acids. Hormonal and dietary factors can affect the activity of delta-9-, delta-6-, and delta-5-desaturases, which alters monounsaturated and polyunsaturated fatty acid composition (9,10).

Risk factors linked to coronary heart disease including hypertension, diabetes, and aging have also been associated with impaired delta-6 and delta-5 desaturase activities (4,8,11–14). Fish oil rich in long-chain n-3 fatty acids, eicosapentaenoic (EPA, 20:5n-3) and docosahexaenoic (DHA, 22:6n-3) acids, reportedly offers a protective effect against coronary artery disease by lowering blood pressure, modulating inflammatory and thrombotic responses, and reducing plasma lipid levels (15–20). We have recently shown that DHA alone has a blood pressure-lowering effect in spontaneously hypertensive rats (SHR), which is associated with an increase in n-3 fatty acids in plasma, tissues, and organs (21,22). Previous studies have demonstrated a reduction in hepatic delta-6- and delta-5-desaturase activities in SHR (1,2). Moreover, supplementation with EPA and DHA also decreased delta-6- and delta-5-desaturase activities in SHR hepatocytes and affected n-6 polyunsaturated fatty acid composition (23,24). Increased levels of 18:1n-9 in total liver lipids have been evidenced in SHR compared to Wistar Kyoto (WKY) rats (4). It is not known whether dietary DHA influences delta-9-desaturase activity in SHR.

The purpose of this study was to determine the effects of dietary DHA on hepatic microsomal delta-9 desaturation of stearic acid in hypertension. To investigate whether the metabolism of fatty acids is altered by dietary DHA, hepatic microsomal fatty acid composition was also determined in SHR.

MATERIALS AND METHODS

Animals and diets. Male SHR aged 7 wk, obtained from Harlan (Indianapolis, IN) were randomized into two groups and housed in cages at constant temperature (26°C) and lighting (12 h light/12 h dark cycle). Diets and water were provided

ad libitum. The rats were fed one of two diets for 6 wk. The purified fat-free basal mix diets contained a combination of corn and soybean oils (Research Diets Inc., New Brunswick, NJ) as the fat component; however, the experimental diet also consisted of a DHA-enriched oil (DHASCO®; Martek Biosciences Corp., Columbia, MD). The dietary constituents included (g/kg): corn starch, 423; sucrose, 231; casein, 150; cellulose, 50; fat, 50 (control diet, corn oil/soybean oil: 25:25; experimental diet, corn oil/soybean oil/DHASCO: 15:15:20); maltodextrin 10, 40; mineral mix, 23; calcium phosphate, 13; vitamin mix, 10; calcium carbonate, 5.5; and DL-methionine, 2.3. The fatty acid composition of the control and experimental diets is shown in Table 1. The diets were stored at 0°C and provided fresh daily. At the end of the dietary treatments, SHR were anesthetized with halothane (5%) in a mixture of oxygen and nitrous oxide. Liver tissue was excised quickly and rinsed in cold saline. The samples were placed immediately in dry ice and then stored at −70°C until analysis. All experimental procedures were reviewed and conducted according to the guidelines of the Committee on Animal Research at the University of California, San Francisco.

Desaturation assays. Liver tissue (3 g) was washed in ice-cold 0.15 mol/L NaCl, cut into thin slices, homogenized at 4°C in a Potter-Elvejhem homogenizer with 6 vol of 0.05 mol/L phosphate buffer (pH 7.4) and 0.25 mol/L sucrose solution. All subsequent operations were performed at the same temperature. The crude homogenate was centrifuged at 13,000 × *g* for 30 min in a Beckman model J-21B centrifuge, JA 20 rotor (Beckman Instruments, Palo Alto, CA); the pellet was then discarded and the supernatant was centrifuged again at 105,000 × *g* for 60 min in a Beckman model L8-55 ultracentrifuge, Ti 60 rotor, to obtain the microsomal pellet. The microsomal fraction was resuspended in 0.4 mL supernatant and 0.8 mL of 0.05 mol/L phosphate buffer (pH 7.4) and 0.25 mol/L sucrose solution. All subsequent enzymatic assays (delta-9-desaturase activity) and composition analysis used these microsomal membrane fractions. Microsomal protein concentrations were estimated by the method of Layne (25) with fatty acid-free crystalline bovine serum albumin as a standard. The delta-9 desaturation by liver microsomes was measured by estimation of the percentage of conversion of ^{14}C stearic acid to its corresponding product, ^{14}C oleic acid. Before enzyme activity measurement, [1-^{14}C]stearic acid (1-^{14}C 18:0; 50 mCi/mmol, 98% pure; NEN Life Products-France SA, Le Blanc Mesnil, France) was diluted in ethanol (Prolabo, Paris, France) to a specific activity of 5 mCi/mmol with the corresponding unlabeled fatty acid (Sigma Chemical Co, St. Louis, MO). Under such conditions the reaction was linear, proportional to the time of incubation and protein concentration (26). Before the incubation, the microsomes were preincubated at 37°C for 3 min. The incubations were then performed in duplicate (with good reproducibility in terms of results) in open shaking flasks, at 37°C for 15 min, with 5 mg microsomal protein in a total volume of 2.1 mL in each flask containing 150 µmol/L phosphate buffer (pH 7.4), 7.4 µmol ATP (pH 7.4), 1 µmol CoA, 2.5 µmol NADPH, 10 µmol $MgCl_2$, and 0.05 µmol (1-^{14}C 18:0). The coenzymes and other reagents were pure products from Sigma or Merck (Darmstadt, Germany). The desaturation reaction was terminated by addition of 15 mL $CHCl_3$/MeOH (1:1, vol/vol). Then, the incubation mixtures were saponified for 20 min at 80°C. The transesterification was performed by addition of 2 mL 14% boron trifluoride (Sigma Chemical Co.) in methanol and incubated at 80°C for 20 min, according to Slover and Lanza (27). After addition of 2 mL 35% sodium chloride, the fatty acid methyl esters were extracted two times with 1 mL isooctane (Carlo Erba, Milan, Italy). The samples were kept in 2 mL at −20°C under nitrogen. The distribution of radioactivity between substrates and products was determined by the reverse-phase high-performance liquid chromatography technique described by Narce *et al.* (28) using a Waters Set (510 HPLC pump and 410 differential refractometer; Millipore, Molsheim, Germany) equipped with a Merck Lichrocart column (Superspher RP 18, 250 × 4 mm i.d.; Merck). Analyses were carried out isocratically using acetonitrile/water (95:5, vol/vol) as the mobile phase at a flow rate of 1.0 mL/min. The fatty acid methyl ester mixtures were dissolved in pure acetone before injection. To collect the ^{14}C radioactive methyl ester fractions, the solvent obtained from the detector was recovered and the radioactivity was directly measured in the solvent by liquid scintillation counting twice for 5 min (Ultimagold; Packard Instrument, Rungis, France) in 20 mL Zinsser polyethylene vials (Frankfurt, Germany) with a Packard Tri-Carb Model 1900 TR liquid scintillation analyzer. Counting efficiencies were estimated by external standardization. The fatty acid methyl esters were identified according to their retention times by comparison with "cold" reference standards (Nu-Chek-Prep, Elysian, MN). The specific activity, expressed as pmol converted per min per mg microsomal protein, was calculated from the conversion percentage determined from the radioactivity distribution percentage of total fatty acids. A control assay with addition of microsomes, but also 15 mL $CHCl_3$/MeOH (1:1, vol/vol),

[a]Values represent % of total fatty acids. —, fatty acid not detected, 15–18% could not be identified; CO, control diet; DHA, docosahexaenoic acid.

was done at time 0 of the reaction and no desaturation was observed.

Lipid analysis. Fatty acid composition of total liver lipids in microsomes was determined by gas–liquid chromatography of methyl esters. Briefly, total lipids were extracted by the method of Folch *et al*. (29), saponified, and methylated by the method of Slover and Lanza (27) at 80°C for 20 min. Fatty acid methyl esters were then extracted with 2 mL isooctane, separated by gas–liquid chromatography in a Packard, Model 417 gas–liquid chromatograph equipped with a flame-ionization detector and a 30-m capillary glass column coated with Carbowax 20M. Conditions were as follows: oven, 194°C; and injector and ionization detector, 240°C. Helium was used as the carrier gas, with a flow rate of 0.4 mL/min. Quantitative analysis was achieved with reference to the internal standards (Nu-Chek-Prep) by means of a DELSI ENICA 31 (Delsi Nermag Instruments, Rungis, France). The percentage of total fatty acid was given by weight for the fatty acids of main interest.

Statistical analysis. Results are shown as mean ± SEM for control and DHA groups. Statistical significance of differences between means was assessed using the Student's *t*-test. Values were considered significant when P was less than 0.05.

RESULTS

Hepatic desaturase activity. The effect of dietary DHA on delta-9-desaturase activity in hepatic microsomes when stearic acid (18:0) was used as a substrate is shown in Table 2. In SHR fed the DHA diet, the activity of 18:1n-9 delta-9-desaturation was significantly decreased, approximately 53%, compared to activity in control SHR.

Hepatic microsomal fatty acid composition. The fatty acid composition of hepatic microsomal total lipids is presented in Table 3. DHA-fed SHR had a higher percentage of 16:0 compared to control SHR. Interestingly, no significant difference in microsomal 18:0 and 18:1(n-9 + n-7) levels was found between groups. A marked reduction in n-6 fatty acids 18:3n-6, 20:4n-6, 22:4n-6, and 22:5n-6 was observed in hepatic microsomes in DHA-fed SHR. This was accompanied with a significant increase in 20:3n-6, which is consistent with impaired delta-5-desaturase activity. The DHA diet also increased levels of n-3 fatty acids, 20:5n-3 (EPA) and 22:6n-3 (DHA) by 8.5- and 3.3-fold, respectively. A reduction in 18:3n-3 and 22:5n-3 levels was found in DHA-fed SHR compared to control SHR.

DISCUSSION

Several experimental studies have demonstrated that alterations in tissue fatty acid metabolism are associated with hypertension (1–4). Increasing evidence suggests that dietary fish oils, EPA and DHA, have an antihypertensive effect (15–17). Our recent investigation shows that the attenuation of high blood pressure in DHA-fed SHR (13 wk old) is associated with profound changes in the fatty acid composition of the vasculature, liver, and organs involved in blood pressure regulation (22). We observed an increase in hepatic levels of 18:0 and a decrease in 18:1n-9 indicative of inhibition of delta-9-desaturase activity. This result is attributed to dietary DHA since a previous investigation found decreased levels of 18:0 and increased levels of 18:1n-9 in total liver lipids of 13-wk-old SHR compared to WKY rats fed standard chow (4).

In the present study, the direct effects of dietary DHA on delta-9-desaturase activity and fatty acid composition was investigated in hepatic microsomes of SHR. This is the first study known to examine the influence of dietary DHA on delta-9-desaturase in SHR. A recent investigation reported that DHA administered by gastric intubation for 10 d in normotensive rats decreased delta-9-desaturase mRNA by 70% (30). Our results demonstrate that delta-9-desaturase activity is reduced by 53% in microsomes of DHA-fed SHR. This finding is supported by the fatty acid compositional changes of 16:0 and 16:1n-7 in hepatic microsomes of DHA-fed SHR even though 16:1n-7 levels are not statistically significant. There is, however, a 30% reduction in the ratio of 16:1n-7/16:0 in the DHA fed SHR compared to control SHR, which is a better reflection of the depressed delta-9-desaturase activity. The rise in 16:0 is significant, especially since this fatty acid is a major constituent in hepatic microsomes as well as total liver lipids (22). Saturated fatty acids have several functions in cell physiology including production and storage

of energy, lipid transport, synthesis of membrane lipids, and modification of membrane proteins (6). In a previous study, we have shown that total liver lipids were increased in SHR fed a standard diet, with a concomitant increase of 18:1n-9 (4). The decreased delta-9-desaturation, due to dietary DHA evidenced in the present work indicates that, in fact, such a diet tends to modify the altered delta-9-desaturation to the level observed in nonhypertensive rats. Such a result is of interest, related to the hypotensive effect of DHA. However, the limited delta-9-desaturase activity was not consistent with changes in 18:0 and 18:1n-9 in hepatic microsomes in contrast to our previous results in total liver lipids (22). This apparent discrepancy could be related to the compositional difference of microsomes and total lipids. Total liver lipids also contain storage lipids, which may modify their composition in response to dietary changes. Consequently, the more stable membrane structural lipids in microsomes are less affected. Other enzyme systems involved in lipid metabolism such as acyltransferase or fatty acid synthetase may maintain 18:0 and 18:1n-9 levels at the microsomal level, despite impairment of delta-9-desaturase activity. This could also reflect strong membrane stability of saturated and monounsaturated fatty acids.

The supplementation of DHA in the diet increased the proportion of DHA by 3.3-fold in hepatic microsomes. This finding is comparable to our previous results in total liver lipids of SHR fed a DHA-enriched diet (22). In the present study, a marked increase was also observed in the level of EPA in DHA-fed SHR. Since EPA is not preformed or available in the diet, the data suggests that DHA is retroconverted to EPA in hepatic microsomes. This has been demonstrated in a previous study in isolated rat hepatocytes (31). The elevation in EPA content in SHR may be of significance since EPA is a precursor for vasoactive eicosanoids.

Dietary DHA affected the composition of long-chain n-6 polyunsaturated fatty acids 18:3n-6, 20:4n-6, 22:4n-6, and 22:5n-6 in SHR. Other investigators have shown that dietary fish oil rich in both EPA and DHA increases the profile of serum and hepatic microsomal n-3 fatty acids in Sprague-Dawley rats at the expense of n-6 polyunsaturated fatty acids (32). The present study shows that DHA alone has an influence on the fatty acid composition of hepatic microsomes in favor of n-3 fatty acids in SHR. Our findings of increased levels of 20:3n-6 and decreased content of 20:4n-6 are indicative of impaired delta-5-desaturase activity induced by dietary DHA. A previous investigation demonstrated that hepatic delta-5-desaturase activity is depressed in SHR aged 13 wk fed an EPA- and DHA-enriched diet for 9 wk (24). We also reported a concomitant increase in 20:3n-6 and a reduction in 20:4n-6 in hepatocyte total lipids.

Alterations in the fatty acid composition of hepatic microsomes of DHA-fed SHR may influence the supply of long-chain unsaturated fatty acids to other tissues such as the kidney, which is involved in the pathogenesis of hypertension. Numerous epidemiological and experimental studies have suggested that dietary n-3 fatty acids have a beneficial effect on the development of kidney diseases (33,34). By giving a supplement of purified EPA, DHA, or corn oil, we have demonstrated that increasing levels of n-3 fatty acids in membranes affects the uptake and intracellular metabolism of fatty acids as well as membrane fluidity in the kidney (35). We have also shown that dietary DHA increases n-3 fatty acids and reduces the levels of n-6 fatty acids in the vasculature and organs of SHR (22). The resulting physiochemical changes in membrane structure may modify cellular responses important to blood pressure regulation. The n-3 fatty acids reportedly modulate intracellular calcium concentrations in vascular smooth muscle in SHR (36–38). This may explain why DHA elicits a vasorelaxant response in SHR aorta (39). A similar effect in systemic arteries would decrease vascular resistance and lower blood pressure. Another recent study demonstrated that dietary DHA affects the renin-angiotensin-aldosterone system in SHR by reducing adrenal synthesis of aldosterone (21). The results from these studies may be related to the effects of dietary DHA on desaturation and unsaturated fatty acid composition in SHR.

In conclusion, dietary DHA decreases delta-9-desaturase activity in hepatic microsomes in SHR and tends to modify it to the level observed in nonhypertensive rats. The DHA diet also produced increased proportions of n-3 fatty acids in hepatic microsomes at the expense of long-chain n-6 fatty acids in SHR. It is possible that dietary DHA influences cellular membrane properties and function as a result of the fatty acid compositional changes. These effects may be important to blood pressure regulation in SHR.

ACKNOWLEDGMENTS

This work was supported in part by the National Institutes of Health grant #HL 55038. We thank Diane Heininger (San Francisco) for preparation of this manuscript and Joseph Gresti (Dijon) for helpful suggestions in performing chromatography analysis.

Secretion of Hepatic Lipase by Perfused Liver and Isolated Hepatocytes

Xavier Galan, Monique Q. Robert, Miquel Llobera, and Ignasi Ramírez*

Departament de Bioquímica i Biologia Molecular, Facultat de Biologia, Universitat de Barcelona, Barcelona, E-08071 Spain

ABSTRACT: Hepatic lipase is found in liver and in adrenal glands and ovaries. Because in adult rats, neither adrenals nor ovaries synthesize this enzyme, it is assumed that the liver is the origin of their hepatic lipase. Our aim was to study the secretion of hepatic lipase by the liver. We observed that plasma of both fed and fasted rats contained hepatic lipase activity. This activity was significantly correlated with that in the liver. Isolated livers, perfused with heparin-free medium, secreted fully active hepatic lipase to the perfusate. The addition of heparin resulted in a rapid and larger release of hepatic lipase to the perfusate. In isolated hepatocytes, heparin did not affect the secretion of hepatic lipase mass, although it increased the stability of the enzyme activity. To study the degradation of hepatic lipase by hepatocytes, protein synthesis was blocked with cycloheximide, and both secreted and intracellular hepatic lipases were analyzed by Western blotting. We observed that the amount of hepatic lipase secreted equaled the decrease of intracellular mass. The total mass of the enzyme (inside and outside the cells) remained constant, at least for 90 min. In the next experiment, 0.7 nM ^{125}I-hepatic lipase was added to hepatocyte suspensions, and the appearance of trichloracetic acid-soluble products was analyzed. Only 12% of the radioactivity added was associated with the cells after 90 min of incubation, and less than 2% of the hepatic lipase added was degraded. Although the association was decreased in the presence of heparin, the amount of ^{125}I-hepatic lipase degraded was not affected. Taking all these results into account, we propose a model for the continuous secretion of hepatic lipase by the liver.

Paper no. L8382 in *Lipids 35,* 1017–1026 (September 2000).

Rat hepatic lipase is a 476-amino acid glycoprotein with two potential sites for *N*-glycosylation (1). This enzyme belongs to a lipase gene family that includes lipoprotein lipase and pancreatic lipase (1,2). The first studies on the function of hepatic lipase, performed in whole animals treated with specific antibodies, revealed that the enzyme was involved in the metabolism of remnant lipoproteins (3) and of triglyceride-rich high density lipoproteins-2 (HDL_2) (4). As a result of the hydrolysis of both triglycerides and phospholipids, hepatic lipase promotes the uptake of HDL cholesterol by the liver (5) and generates pre-β_1 HDL (6). These particles appear to be the first acceptor of cellular cholesterol (see Ref. 7 for review). The relevance of hepatic lipase in lipoprotein metabolism was emphasized by the observation that total plasma cholesterol level was decreased in transgenic rabbits over-expressing human hepatic lipase compared to nontransgenic littermates (8). However, in mice strains with targeted inactivation of the hepatic lipase gene, only a mild dyslipemia was reported (9). Similarly, only a moderate hyperlipemia appeared in humans with identified hepatic lipase deficiency (10). Recent kinetic studies made in hepatic lipase-deficient mice provide *in vivo* evidence of the significant role of hepatic lipase in the selective delivery of HDL-cholesteryl esters to the liver (11).

By using immunocytochemistry, most hepatic lipase molecules were seen in the Space of Disse of the hepatic sinusoid (12–14). These enzyme molecules are synthesized and secreted by hepatocytes (15). The secretion of hepatic lipase was initially studied in isolated rat liver parenchymal cells (16), and in primary cultures of rat hepatocytes (17). Three conclusions arose from these early studies: (i) continuous secretion required protein synthesis, (ii) heparin induced a two- to fourfold increase in the secretion of hepatic lipase activity, and (iii) secretion required glycosylation. Later studies attempted to characterize the intracellular processing of the enzyme (15,18), the role of heparin (19,20), and the relevance of glycosylation for the activation/secretion process (21,22).

Adrenal glands and ovaries also contain hepatic lipase (23). In the former, it was immunolocalized in capillaries of the zona fasciculata (24), and in the latter it was seen in thin-walled blood vessels of theca interna of the follicles, corpora lutea, and interstitial cells (25). Since neither adrenal glands (26) nor ovaries (27) in the adult rat synthesize hepatic lipase, it is assumed that the enzyme is produced in the liver. Here we report direct evidence of the constitutive secretion of hepatic lipase by the liver.

EXPERIMENTAL PROCEDURES

Experiments in whole animals. Wistar rats were obtained from our own colony. At the age of 60 d, animals (either fed of fasted for 24 h) were killed by decapitation. The blood was

collected in heparinized vials and plasma was obtained by centrifugation (30 min at 10,000 × *g* at 4°C). The liver was immediately frozen in liquid N_2. Liver homogenates were made with 10 mM Hepes pH 7.5 containing 1 mM EDTA and 1 mM dithiothreitol in a Polytron homogenizer (Kinematica GmbH, Luzern, Switzerland). Homogenates were clarified by centrifugation (10 min at 10,000 × *g* at 4°C). Clarified supernatants and blood plasma were kept at –40°C and used to determine hepatic lipase activity.

Experiments in perfused livers. Rats were anesthetized with sodium pentobarbital 60 mg/kg (i.p.). The portal vein was cannulated, and the liver was perfused for 10 min with washing solution [bicarbonate-containing isotonic buffer supplemented with 5.5 mM glucose and 1% albumin (28), maintained at 37°C] at a flow rate of 40 mL/min. During this time, the liver was carefully isolated and placed in a perfusion chamber as described (29). The perfusion was then made to recirculate with 50 mL of fresh buffer with or without heparin (5 units/mL). At selected times, a sample of the perfusate (0.4 mL) was obtained and kept at –40°C and used for further assays. At the end of the perfusion, the liver was homogenized as indicated above. Clear supernatants were kept at –40°C. Lactate dehydrogenase activity was determined as described by Vassault (30).

Hepatocyte isolation and incubation. Hepatocytes were isolated according to the methods of Peinado-Onsurbe *et al.* (28). Before incubation, cells were rinsed twice with an amino acid- and vitamin-containing buffer (buffer D in Ref. 31), and finally suspended at a density of 2.5×10^6 cells/mL in the same buffer supplemented with heparin (5 units/mL) when indicated. After isolation, cells were immediately used for incubations, which were carried out in a rotatory water bath at 37°C under O_2/CO_2 (19:1) atmosphere. At indicated times, a sample was taken and the cells were precipitated by centrifugation at 12,000 × *g* for 10 s. The medium was immediately frozen and stored at –40°C for no more than 1 mon. The cells were disrupted by sonication in lysis buffer (1 mM EDTA, 1 mM dithiothreitol, 10 mM Hepes pH 7.5 containing 10 milliunits/mL aprotinin, 25 mM benzamidine, 1 μM leupeptin, 1 μM pepstatin, 0.2 mM phenylmethyl sulfonyl fluoride, 5 units/mL heparin, and 1.5 % Triton X-100). After centrifugation (10 min, 1,000 × *g* at 4°C), the supernatant was stored at –40°C for further analysis, always for less than 1 mon. The storage conditions affected neither hepatic lipase activity nor the relative amount of hepatic lipase, as determined by Western blot. Viability of the cells was routinely determined by the Trypan blue exclusion test, and sometimes by lactate dehydrogenase release (30). Preparations with initial cell viability lower than 90% were discarded.

Hepatic lipase activity was determined by the method of Ehnholm *et al.* (32) as previously described (29). One unit of enzyme activity was defined as the amount of enzyme that released 1 μmol of oleate per min at 25°C.

Thermal stability of hepatic lipase. To quantify the effect of heparin on the thermal stability of hepatic lipase activity in solution, we first obtained the enzyme from perfused rat livers. Isolated livers were perfused, in recirculation conditions, for 30 min at 37°C with 50 mL of buffer D. Heparin was not included during perfusion to avoid any residual amount of heparin in control conditions. The perfusate containing hepatic lipase activity (5.9 mU/mL) was divided in two halves. One was adjusted to a final heparin concentration of 5 U/mL; the other did not receive heparin. Both were then placed into a water bath at 37°C and at selected times a sample was taken and kept in ice-cold water until the incubation was terminated. Then, the remaining hepatic lipase activity was determined. We had previously observed that hepatic lipase activity was stable at 4°C. In some experiments the perfusate was diluted with conditioned medium (in which hepatocytes had been incubated for 3 h at 37°C) with or without heparin, with similar results. The inactivation constants were estimated by adjusting the decay curves to a negative exponential ($a_t = a_0\, e^{-kt}$), where a_t is the activity remaining at time t, a_0 is the activity at time zero, and k is the inactivation constant. The inactivation constants were used to correct enzyme activity in medium for inactivation as described by Peinado-Onsurbe *et al.* (33).

Hepatic lipase purification and antibodies. Hepatic lipase was purified from heparin perfusates from rat livers by a combination of heparin-Sepharose and diethylaminoethyl-Sepharose chromatography according to Waite *et al.* (34). The hepatic lipase appeared homogeneous in 10%-polyacrylamide gels upon silver staining (not shown). Rabbit anti-rat hepatic lipase antiserum was obtained as previously described (35).

Western blot analysis. Incubation medium (6.25 μL diluted 1:4 in sampling buffer), cell lysates (25 μL diluted 1:2 in sampling buffer), or liver perfusates (4.17 μL diluted 1:4 in sampling buffer) were run in 10%-polyacrylamide gels in denaturing and reducing conditions (36). The separate proteins were then transferred to Immobilon-P membranes (Millipore, Milford, MA) by electroblotting. After transfer, the membranes were soaked in blocking solution [2% bovine serum albumin (BSA) in phosphate-buffered saline (PBS)] for 90 min at 37°C, rinsed [5 × 5 min in 100 mL of rinsing solution: 1% sodium dodecyl sulfate (SDS), 1% Triton X-100, and 0.5% defatted powdered-milk in PBS] and incubated overnight at 4°C with the primary antibody [rabbit anti-rat hepatic lipase serum diluted 1:1000 in buffer A (0.1% SDS, 0.1% Triton X-100, and 0.5% defatted powdered-milk in PBS) supplemented with 5% BSA and 0.5% gelatin]. The membranes were rinsed as indicated above and incubated for 30 min at room temperature with the secondary antibody [biotin-labeled goat anti-rabbit IgG (Vector, Burlingame, CA) diluted 1:5000 in buffer A]. After rinsing as above, the membranes were incubated with the ABC-complex [VECTASTAIN (ABC-kit); Vector] and developed with the ECL-system (Amersham, Arlington Heights, IL). Films were analyzed with Phoretix 1D Gel Analysis software (Newcastle upon Tyne, United Kingdom) after scanning in an Epson GT-8500 (Epson Iberica, Barcelona, Spain). In each gel, a lane was loaded with a constant amount of hepatic lipase to correct for differences in the results. In experiments with isolated cells, the final densitometric quantifications were referred to 10^6 cells to make the results comparable.

Analysis of ^{125}I-hepatic lipase and ^{125} I-lipoprotein lipase degradation. Purified rat hepatic lipase was labeled as described for lipoprotein lipase by Wallinder *et al.* (37); ^{125}I-labeled bovine milk lipoprotein lipase was obtained from Dr. T. Olivecrona (University of Umeå, Sweden). Hepatocytes (2.5×10^6 cells/mL, 2 mL final volume) were incubated in the presence of 70 ng of ^{125}I-labeled hepatic lipase (891 cpm/ng), or 10 ng of ^{125}I-labeled lipoprotein lipase (12,689 cpm/ng), in an incubation medium with or without heparin (5 U/mL). The concentration of labeled hepatic lipase was 0.7 nM and that of labeled lipoprotein lipase was 0.1 nM. At indicated times 0.2-mL samples were taken and the medium was immediately separated from the cells by centrifugation (1 min, 13,000 × *g* at 4°C). The cells were rinsed twice in ice-cold fresh buffer. The amount of 10% trichloracetic acid (TCA)-soluble and 10% TCA-precipitable radioactivity was measured in both medium and cells.

Animal care. All experimental procedures were approved by The Committee on Animal Care of the University of Barcelona.

RESULTS

Several reports indicate that hepatic lipase is present not only in liver, adrenal glands, and ovaries but also in plasma (38). We showed that the activity in plasma is affected by fasting, as is the activity in liver (39). To study the relationship between hepatic lipase activity in liver and plasma we determined these activities in animals either fed or fasted for 24 h. Figure 1 shows the individual values obtained in this study. There was a significant ($P < 0.001$) linear relationship between both parameters. In overnight-fasted humans, significant correlation between pre- and post-heparin (which may reflect liver activity) hepatic lipase activities was also reported (40).

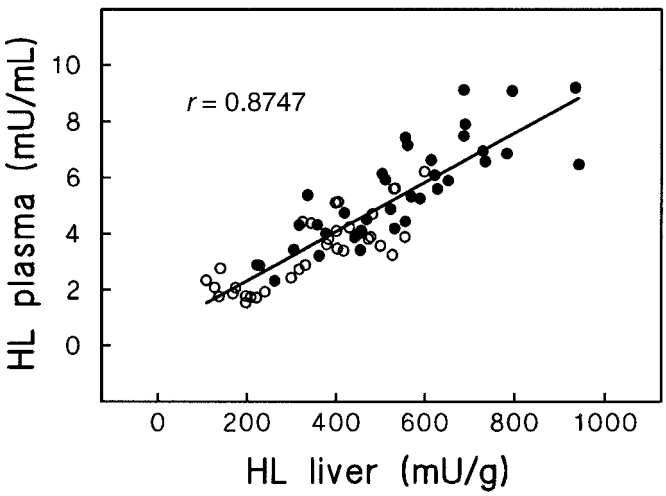

FIG. 1. Relationship between hepatic lipase activity in liver and plasma. Hepatic lipase (HL) activity was measured in the liver and plasma of rats either fed (●) or fasted for 24 h (○) before sacrifice. The mean ± SE for the hepatic lipase in the liver of fed and fasted rats was 548 ± 30 and 346 ± 24 mUnits/g, respectively ($P < 0.001$). In plasma the activity was 5.58 ± 0.30 and 3.40 ± 0.22 mUnits/mL for fed and fasted animals, respectively ($P < 0.001$).

In the next experiment, we analysed the secretion of hepatic lipase by isolated livers perfused with a recirculated medium. Figure 2 shows that the liver continuously released hepatic lipase to the perfusion medium. After 30 min of perfusion, we recovered 295 mUnits of hepatic lipase in the perfusate. This accounted for nearly 10% of the whole system hepatic lipase activity (released + residual). There was also release of lactate dehydrogenase, but the activity recovered in the perfusate at the end of the experiment accounted for only 0.02% of the whole system activity. The addition of heparin resulted in a rapid release of hepatic lipase to the perfusate, which accounted for 70% of the whole system activity after 30 min of perfusion. The release of lactate dehydrogenase was not affected by heparin (the symbols corresponding to these results cannot be observed in the figure because they overlap with those corresponding to nonheparin-perfused liver).

Released hepatic lipase appeared in SDS–polyacrylamide gel electrophoresis (PAGE) gels as a single band with an apparent M_r of 55,000 (Fig. 2). At zero time there was no detectable hepatic lipase in the perfusate, but 5 min afterward a tiny band was observed, the intensity of which increased as the perfusion continued. In the presence of heparin, a large amount of hepatic lipase was observed in the perfusate in the first sample obtained. When the activity (μUnits loaded to the gels) to mass (densitometric arbitrary units) ratio was calculated, we found no differences between heparin-free and heparin-containing perfusates. At 30 min of perfusion this ratio was 0.024 ± 0.002 and 0.022 ± 0.001, respectively. Identical values were obtained at every time studied (data not shown).

Next, we studied the secretion of hepatic lipase by isolated hepatocytes. Secreted hepatic lipase appeared in SDS–PAGE gels as a single band with an apparent M_r of 55,000 (Fig. 3), which is similar to the values reported by others in several cell systems (15,18). We identified two forms of hepatic lipase inside the cells with apparent M_r 52,000 and 55,000 (Fig. 3). By immunoprecipitating ^{35}S-labeled hepatic lipase, Laposata *et al.* (15) and Cisar and Bensadoun (18) also identified two intracellular forms of hepatic lipase, corresponding to the fully and partially glycosylated forms of the enzyme. The bands of higher M_r observed in cell lysates were biotin-containing proteins since these bands were also observed when the membranes were incubated without the specific primary antibody, but with the biotin-detecting ABC-reagent.

Since the early studies of Schoonderwoerd *et al.* (41), it has been known that heparin increases by nearly twofold the amount of hepatic lipase activity secreted from isolated hepatocytes. We found that the amount of hepatic lipase secreted after 3 h of incubation was not affected by heparin (Fig. 3). The scanning of the gels indicated that differences were nonsignificant (67 ± 9 and 72 ± 5 densitometric units in the medium of cells incubated without and with heparin, respectively). Heparin did not affect the amount of either intracellular forms (33 ± 2 and 22 ± 3 densitometric units for the 55,000 and 52,000 forms of hepatic lipase in cells incubated without heparin; 31 ± 1 and 19 ± 1 densitometric units for each form

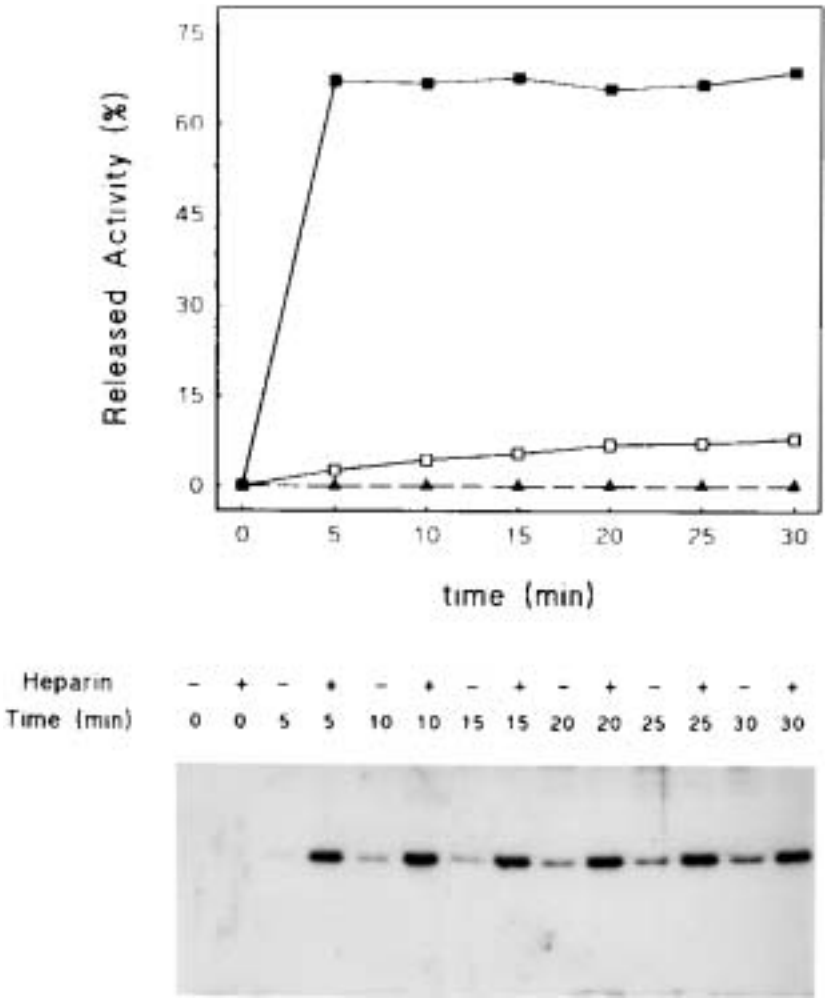

FIG. 2. The secretion of hepatic lipase in perfused livers is increased by heparin. Upper panel: isolated livers were perfused at 37°C with 50 mL of medium containing (■,▲) or not containing (□,△) 5 Units heparin/mL in a recirculatory system. Hepatic lipase (■,□) and lactate dehydrogenase (▲,△) released to the perfusate were determined at the indicated times. (△ cannot be observed because they overlap with ▲.) At the end of the perfusion the liver was homogenized to determine the residual activity. Results are the mean of two livers perfused in each condition and are expressed as percentage of released activity compared to the total (released after 30 min + residual) activity to make the results of hepatic lipase and lactate dehydrogenase comparable. Lower panel: hepatic lipase mass in perfusate obtained at the indicated times from livers perfused with or without heparin was analyzed by Western blot. The result shown corresponds to one of the livers perfused in each condition. The second liver was also analyzed with identical results, but these are not shown in this figure.

of hepatic lipase in cells incubated with heparin). However, when activity was measured, we observed that heparin had increased the hepatic lipase activity secreted to the incubation medium 4.3-fold (Fig. 4A). Since the active conformation of hepatic lipase is rather unstable in solution (32,41), we studied whether thermal inactivation could explain the differences between the mass and the activity detected in the medium. First, we determined the inactivation constants of soluble hepatic lipase (obtained from isolated livers perfused without heparin to avoid any exposure of the enzyme to this molecule) in the presence or the absence of heparin. As shown in Figure 4B, heparin decreased the inactivation rate constant. When these inactivation constants were used to correct the measured activity in medium, no significant differences were found in the corrected activity secreted by cells incubated with or without heparin (Fig. 4C).

The time course of hepatic lipase secretion, when protein synthesis was either allowed or blocked by the addition of 20 μM cycloheximide, is shown in Figure 5. Cycloheximide addition resulted in a progressive decline in the rate of hepatic lipase secretion. This is in accordance with previous results (16; and many others thereafter). The effect became significant after 45 min of incubation. At 90 min, the activity/mass ratio in the medium was 0.024 and 0.025 for control and cy-

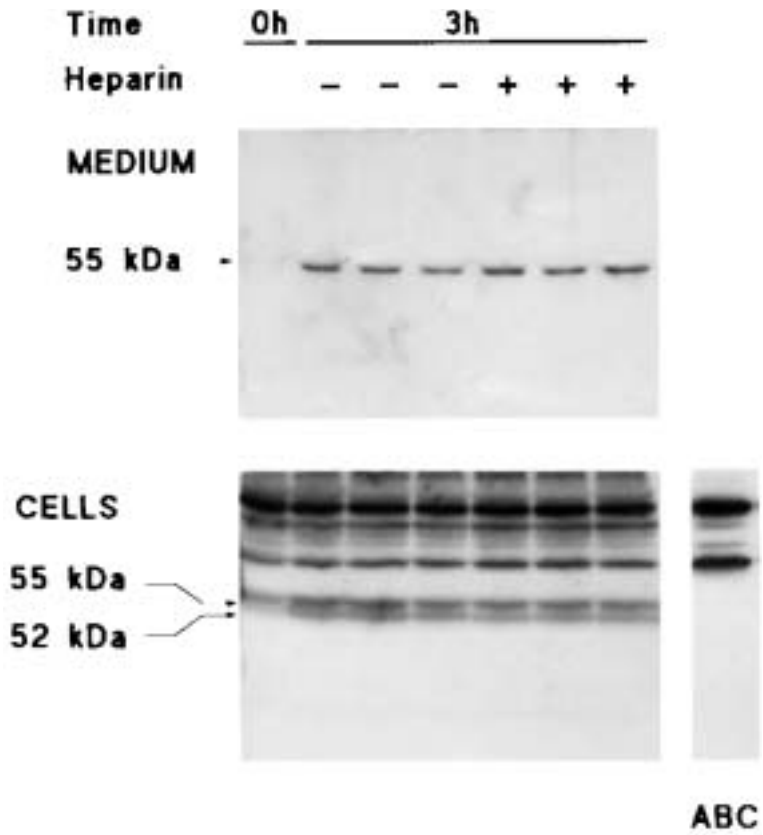

FIG. 3. Heparin does not increase the amount of hepatic lipase secreted by rat hepatocytes. Hepatocytes were incubated in the absence or in the presence of 5 Units heparin/mL. At zero time and after 3 h of incubation, samples were obtained. The cells were separated from the medium by centrifugation, and the amount of hepatic lipase was determined by Western blot analysis. Incubation medium (6.25 µL) or cell lysate (25 µL) was loaded in each lane (upper and lower panels, respectively). ABC lane corresponds to a membrane containing the transferred proteins from zero-time cells, incubated without the primary antibody but with the secondary antibody and the ABC-reagent (Vector, Burlingame, CA).

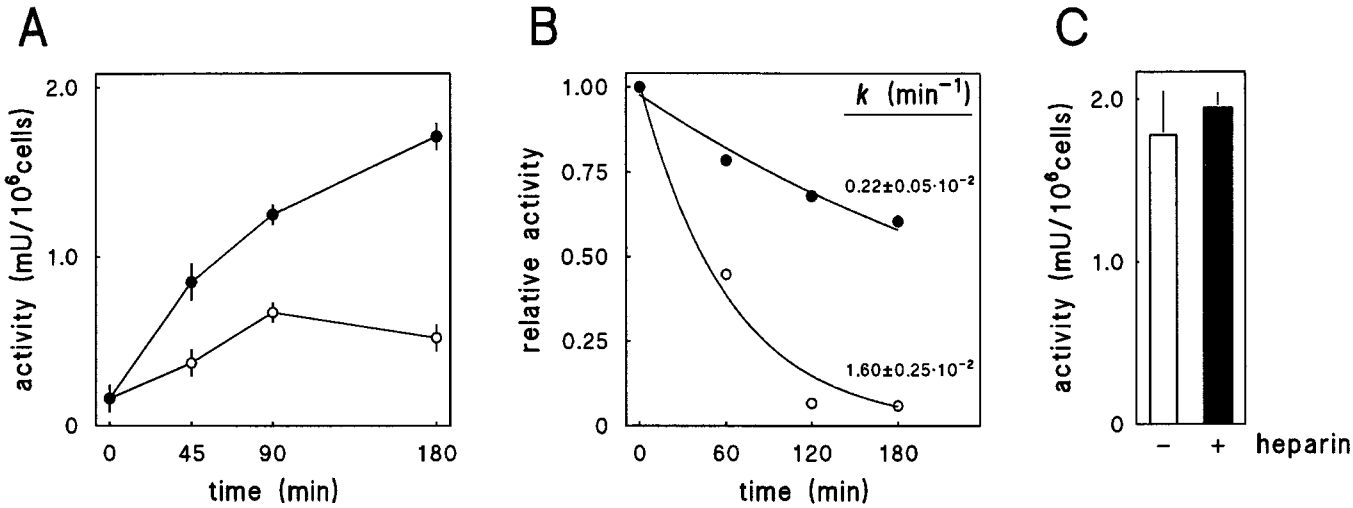

FIG. 4. The apparent effect of heparin on the secretion of hepatic lipase is a consequence of stabilization of enzyme activity. (A) The amount of hepatic lipase activity secreted by hepatocytes incubated at 37°C in the absence (○) or in the presence of 5 Units heparin/mL (●) was determined at the indicated incubation times. The results are the mean ± SE of triplicate values. (B) The thermal stability of the activity of hepatic lipase released from nonheparin-perfused livers was determined at 37°C either in the absence (○) or in the presence (●) of added heparin (5 Units/mL). The inactivation constants (k) were obtained by fitting the decay curves to a negative exponential (rel act = e^{-kt}). (C) The inactivation constant values were used to correct the apparently secreted activity (panel A) by inactivation (see the Experimental Procedures section). This panel shows the corrected activity accumulated in the medium after 3 h of incubation in the absence or in the presence of heparin.

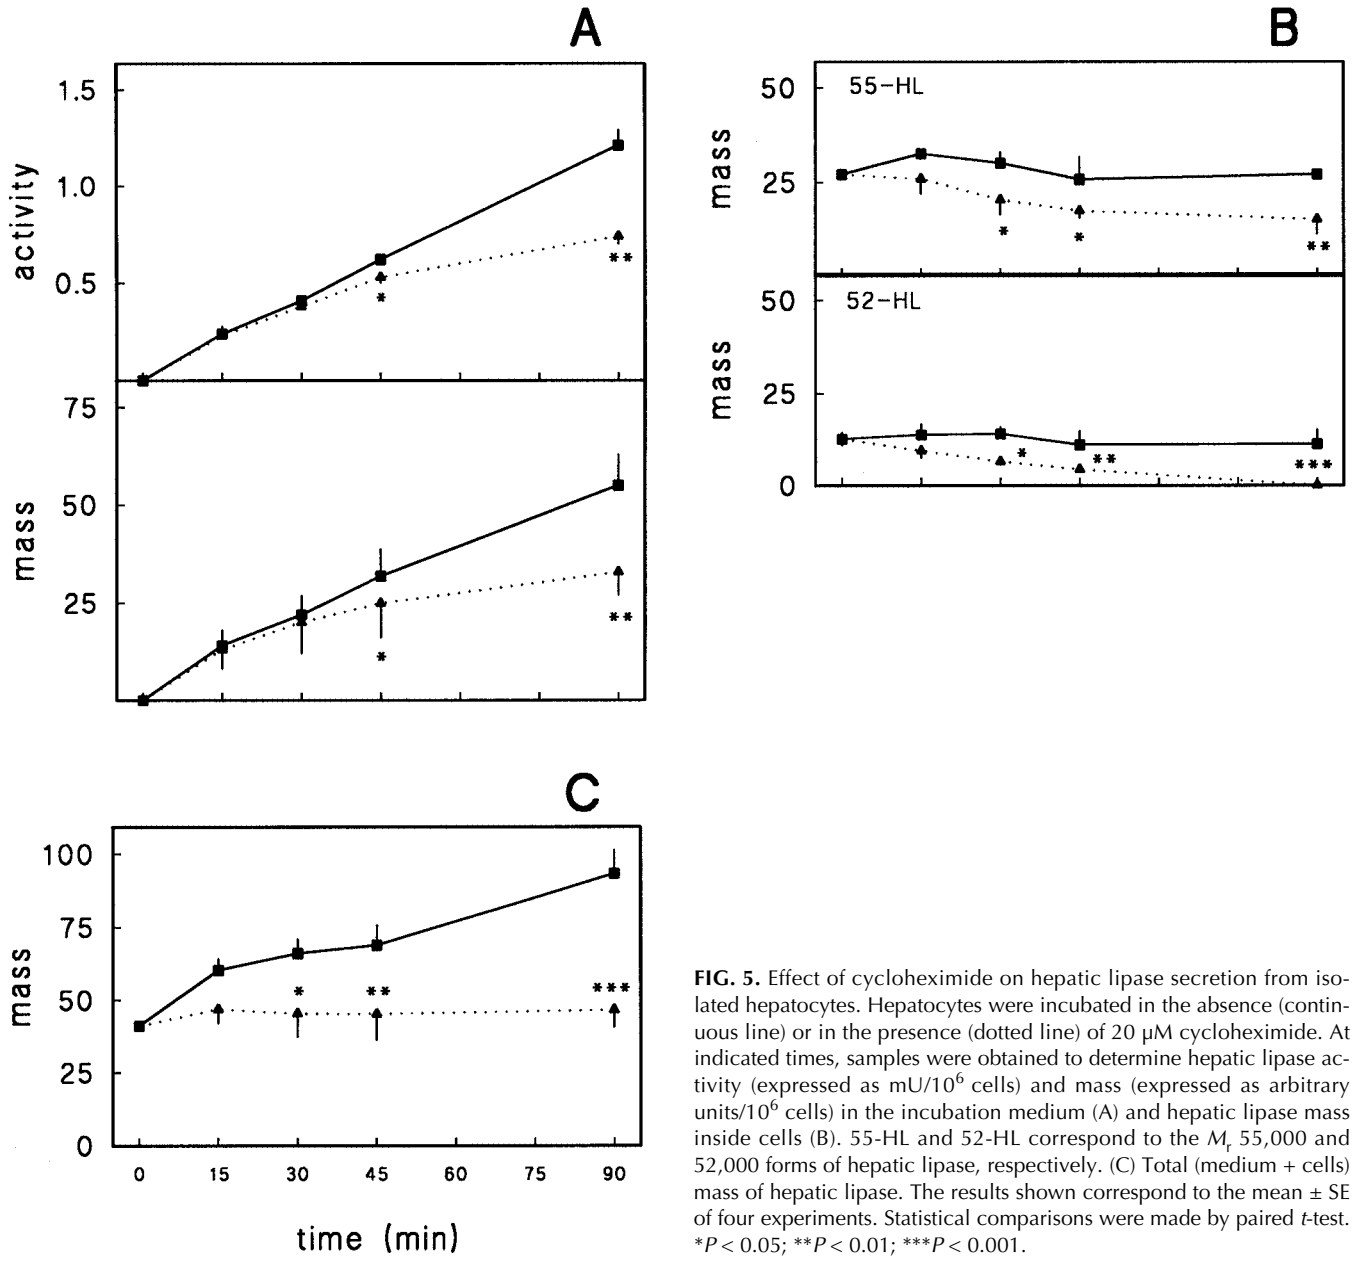

FIG. 5. Effect of cycloheximide on hepatic lipase secretion from isolated hepatocytes. Hepatocytes were incubated in the absence (continuous line) or in the presence (dotted line) of 20 μM cycloheximide. At indicated times, samples were obtained to determine hepatic lipase activity (expressed as mU/10^6 cells) and mass (expressed as arbitrary units/10^6 cells) in the incubation medium (A) and hepatic lipase mass inside cells (B). 55-HL and 52-HL correspond to the M_r 55,000 and 52,000 forms of hepatic lipase, respectively. (C) Total (medium + cells) mass of hepatic lipase. The results shown correspond to the mean ± SE of four experiments. Statistical comparisons were made by paired *t*-test. $^*P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$.

cloheximide-incubated cells, respectively. This indicates that cycloheximide did not affect the catalytic properties of the secreted enzyme molecules. Regarding intracellular hepatic lipase, in cells incubated without cycloheximide, the amount of each of the intracellular forms remained constant throughout the incubation period. However, in cells exposed to cycloheximide, the M_r 52,000 form was almost completely absent at 90 min, whereas the amount of the M_r 55,000 form was 50% decreased. Total hepatic lipase mass (the sum of that in medium and both intracellular forms) increased linearly in control cells throughout the incubation time. Indeed, the total amount of hepatic lipase did not increase in the cells exposed to cycloheximide, but it did not decrease either.

We also studied the effect of heparin on the degradation of ^{125}I-labeled hepatic lipase, exogenously added to isolated hepatocytes. To minimize interferences due to release of endogenous unlabeled hepatic lipase, we estimated first, from results shown in Figures 4 and 5, the amount of enzyme that was spontaneously released to the incubation medium. Jansen and Bensadoun (42) reported a specific activity for the purified enzyme of 45 mmol/h/mg protein. If we assume that this also corresponds to the specific activity of the enzyme released from hepatocytes, we can calculate that after 3 h incubation the amount of hepatic lipase released may reach nearly 0.07 nM [this calculation assumes that the amount of corrected activity secreted after 3 h is 2 mU/10^6 cells, a cell density of 2.5×10^6 cells/mL, and a M_r of the protein moiety of the enzyme of 53,222 (1)]. Therefore, we added 0.7 nM ^{125}I-hepatic lipase in these experiments. For comparison, the degradation of 0.1 nM ^{125}I-labeled lipoprotein lipase was

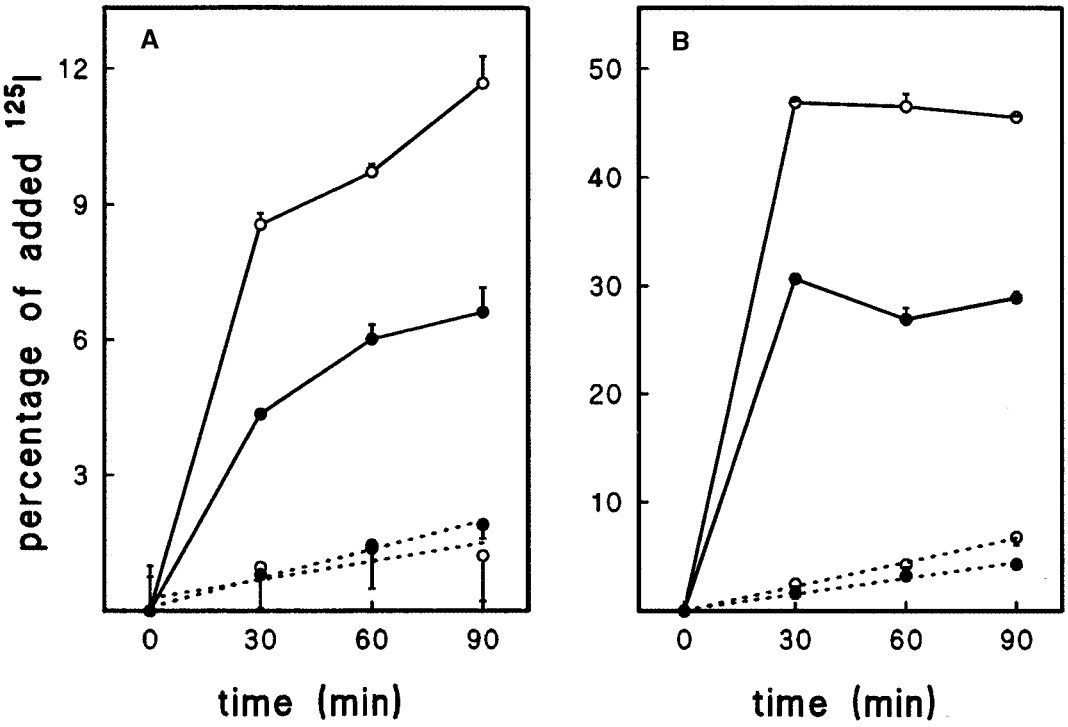

FIG. 6. Heparin does not affect degradation of added ^{125}I-labeled hepatic lipase. (A) Hepatocytes were incubated with 0.7 nM of ^{125}I-labeled hepatic lipase and either in the absence (○) or in the presence of 5 units-heparin/mL (●). At the indicated times, a sample was obtained to determine the amount of cell-associated (continuous lines) and the degraded (dotted lines) ^{125}I- labeled hepatic lipase. The results are the mean SE of triplicate values. (B) For comparison, another set of cells were incubated with 0.1 nM ^{125}I-labeled lipoprotein lipase instead of ^{125}I-labeled hepatic lipase.

studied. The results are shown in Figure 6. After 90 min of incubation, hepatocytes had taken up nearly 12% of the ^{125}I-hepatic lipase. Heparin decreased the uptake to about 6%. Only a very minor proportion of the radioactivity appeared as TCA-soluble (degraded) end products (less than 2%). Heparin did not affect this proportion. The estimated rate constants of ^{125}I-labeled hepatic lipase degradation were 0.014 ± 0.006 and 0.021 ± 0.002%/min in cells incubated in the absence and in the presence of heparin, respectively (nonsignificant differences). Isolated hepatocytes also took up ^{125}I-lipoprotein lipase and heparin decreased this uptake. The estimated rate constant of ^{125}I-labeled lipoprotein lipase degradation was decreased by heparin (0.074 ± 0.004 and 0.048 ± 0.003%/min in cells incubated in the absence and in the presence of heparin, respectively, $P < 0.01$). Heparin-sensitive pathways for uptake and degradation of active lipoprotein lipase in perfused livers have already been described (43).

DISCUSSION

Although hepatic lipase is synthesized in parenchymal liver cells (15,18), most of the enzyme molecules are found in the extracellular space (24). Schoonderwoerd *et al.* (44) found that heparin-sensitive sites accounted for most of the extracellular hepatic lipase binding sites. In agreement with these results, we observed that the perfusion of isolated livers with heparin released about 70% of the whole liver activity. Similar results were previously obtained in several laboratories (28,44).

Two different lines of evidence indicate that the liver continuously releases hepatic lipase to the circulation. The first is indirect: there was a highly significant correlation between hepatic lipase activity in liver and plasma. The second is more direct: isolated livers secreted hepatic lipase to the perfusate when they were perfused in the absence of heparin. This cannot be attributed to leakage of intracellular enzyme due to tissue damage because lactate dehydrogenase release was almost negligible. Furthermore, since the activity to mass ratio was similar in nonheparin and in heparin perfusates, we conclude that the spontaneously secreted enzyme was fully active.

From data in Figure 2 we calculated a secretion rate of 10 mUnits/min/liver. In heparin perfusates we recovered 2,065 mUnits (mean of two experiments). Since it is conceivable that the spontaneously secreted enzyme comes from that bound to some extracellular site [and among these sites, heparin-sensitive ones are the majority (44)], we may calculate a fractional turnover rate of 4.8×10^{-3} min^{-1}. This value predicts a half-residence time of about 150 min for the enzyme in the extracellular space. Cisar and Bensadoun (18) studied the intracellular processing of hepatic lipase in FU5AH rat hepatoma cells. They obtained a half-residence time of hepatic lipase inside the cells of nearly 60 min, which is in keeping with the results reported by Laposata *et al.* (15) concerning the process-

ing of this enzyme in nontransformed rat hepatocytes. The comparison of our predicted half-residence time in the extracellular space with that described for the processing of the enzyme inside hepatocytes explains why most of the enzyme molecules are found in the extracellular space.

In order to maintain a steady-state number of enzyme molecules in the extracellular space, the amount of hepatic lipase released to the perfusate (or to the blood stream in the whole animal) has to be replaced by new enzyme molecules synthesized in hepatocytes. Our results indicate that freshly isolated rat hepatocytes, incubated in amino acid- and vitamin-containing medium, maintain steady-state amounts of hepatic lipase inside the cells for several hours and that these cells continuously, and linearly, secrete active hepatic lipase at a rate of 10–12 μU/min × 10^6 cells (obtained from data in Fig. 4). It is known that adult rat liver contains about 10^9 hepatocytes (45). Thus, we may estimate a secretion rate of 10–12 mU/min × (whole liver), which is similar to the rate of hepatic lipase secretion obtained in perfusion experiments (see above).

Although heparin was reported to increase the amount of hepatic lipase secreted from hepatocytes (17), we observed that the apparent effect on secreted activity was actually the result of stabilization of the active conformation. Neither when the amount of secreted hepatic lipase mass was determined nor when the secreted activity was corrected by inactivation did heparin produce a significant effect.

Cisar *et al.* (20) studied the short-term effect of heparin on hepatic lipase secretion in a hepatoma cell line. They found that heparin increased the secretion of hepatic lipase mass because it decreased the degradation of both newly synthesized hepatic lipase and ^{125}I-labeled hepatic lipase added to the culture medium. They also reported the presence of a class of high-affinity binding sites on the cell surface [dissociation constant (K_D) 10^{-7} M]. A similar dissociation constant for the binding of hepatic lipase to purified low density lipoprotein receptor-related protein (LRP) was described more recently (46). These authors concluded that LRP mediates internalization and degradation of ^{125}I-labeled hepatic lipase by cultured cells, and that surface proteoglycans are also required. In all these cultured cell systems, heparin might prevent degradation by displacing hepatic lipase from its binding sites, which suggests that, as proposed for the lipoprotein lipase processing in avian adipocytes (47), degradation requires the passage of the enzyme by the cell surface.

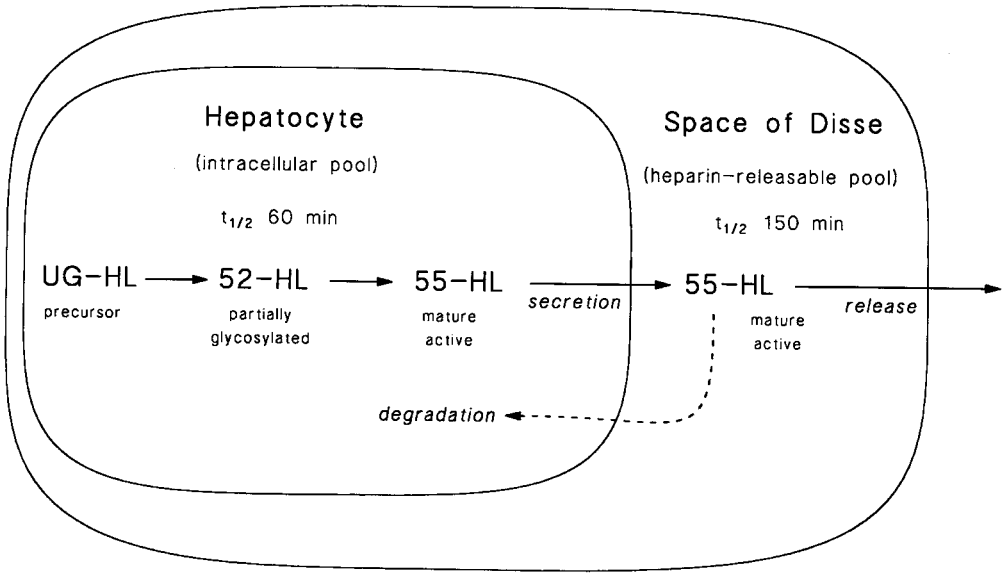
In contrast to these results, we observed that a very minor proportion of added ^{125}I-labeled hepatic lipase was degraded in our cell system. In these experiments we added 0.7 nM ^{125}I-hepatic lipase, a concentration much lower than that used by Cisar *et al.* (20). In these conditions, given the K_D value for the association to LRP, one may expect a low binding of the enzyme to the cells, as we observed. Although heparin displaced some of the cell-associated enzyme, it did not affect the amount of enzyme degraded. We estimated that hepatic lipase produced endogenously reached an even lower concentration in the medium. Therefore, most of the enzyme that reached the cell surface might dissociate from binding sites and remain free in solution. This explains why there was no effect of heparin on the amount of enzyme released to the medium. If retention of hepatic lipase at the cell surface is required for degradation, we would expect to find no degradation of endogenous hepatic lipase in our cell system. In fact, we did not observe any decrease in the total amount of hepatic lipase in cells exposed to cycloheximide (Fig. 5), which indicates that there was no degradation of endogenous hepatic lipase.

It can be argued that, provided we used the cells immediately after isolation, the isolation procedure could have destroyed proteoglycans of the cell surface. However, we observed that these cells bound and degraded ^{125}I-lipoprotein lipase and that heparin decreased both binding and degradation of ^{125}I-lipoprotein lipase. Furthermore, the amount of ^{125}I-lipoprotein lipase bound to the cells that was displaced by heparin corresponded to that predicted by the K_D and association rate constant for the interaction of purified lipoprotein lipase with heparan sulfate (48). In addition, kinetics of binding and degradation of ^{125}I-lipoprotein lipase obtained in our experiments agree with those obtained in perfused livers (43).

Other arguments could explain the discrepancy concerning degradation of endogenous hepatic lipase. One is that the rate of hepatic lipase production may be much higher in hepatoma cells than in hepatocytes. Another is the fact that cultured cells produce a matrix around them, which is missing in freshly isolated cells. Although it was reported (13,49) that, in intact liver, most of extracellular hepatic lipase localizes at the Space of Disse associated apparently to the hepatocyte microvilli, the fixation techniques used in those reports did not allow for a precise identification of the structures at which the immunogold particles are bound, when samples are observed at 15,000× magnification. In fact, Vilaró (50), at a much higher magnification (75,000–127,000×), observed that most of the gold particles are actually associated with collagen-like fibers of the extracellular matrix. Binding of hepatic lipase to secreted fibers may contribute to explain why degradation of hepatic lipase was observed in cell culture (20,46), but not in freshly isolated cell suspensions.

Based on the results presented here, together with those reported in the literature and discussed above, we propose a model for the processing of hepatic lipase in the whole liver. Hepatocytes continuously secrete active hepatic lipase to the Space of Disse, where enzyme molecules are retained by extracellular matrix proteins. Some of the enzyme molecules in this extracellular compartment may eventually bind to LRP and return to hepatocytes, where they can be degraded (Scheme 1, where UG = unglycosylated; HL = hepatic lipase; and 52 and 55 refer, respectively, to molecular sizes of 52,000 and 55,000). Most of the secreted molecules will be released to the blood stream. Released enzyme molecules are then available to adrenal glands and ovaries, where they may contribute to the uptake of HDL-cholesterol.

This model predicts that the size of the extracellular pool of hepatic lipase is controlled primarily by the rate of secretion from hepatocytes. Literature shows some examples of this relationship. Both the amount of heparin-releasable hepatic li-



SCHEME 1

pase (51) and the secretion rate from isolated hepatocytes (52) are lower in corticosteroid-treated than in control rats. Short-term fasting (24 h) reduces both the amount of heparin-releasable activity in perfused livers and the secretion rate from isolated hepatocytes (28). This model does not exclude that other factors also contribute to control the amount of extracellular hepatic lipase, as it was previously proposed (52).

ACKNOWLEDGMENTS

We express our gratitude to Dr. Thomas Olivecrona (University of Umeå, Sweden) for the ^{125}I-labeled lipoprotein lipase and to Robin Rycroft for the editorial help. This work was supported by grants (PB91-0803 and PB92-0548) from D.G.I.C.Y.T. (Ministerio de Educación y Ciencia, Spain).

Study of Individual *trans*- and *cis*-16:1 Isomers in Cow, Goat, and Ewe Cheese Fats by Gas–Liquid Chromatography with Emphasis on the *trans*-Δ3 Isomer

Frédéric Destaillats[a], Robert L. Wolff[a,*], Dietz Precht[b], and Joachim Molkentin[b]

[a]Institut des Sciences et Techniques des Aliments de Bordeaux, Talence, France, and [b]Bundesanstalt für Milchforschung, Kiel, Germany

ABSTRACT: Low-temperature gas–liquid chromatography (GLC) was applied to study the distribution profiles of isomeric *trans*- and *cis*-hexadecenoic acids in ruminant (cow, goat, and ewe) milk fat after their fractionation by argentation thin-layer chromatography (Ag-TLC). The fat was extracted from cheeses (12 samples of each species), the most common foods made with goat and ewe milks. The predominant *trans*-16:1 isomer is palmitelaidic acid (the Δ9 isomer), but it does not exceed one-third of the total group, which itself represents 0.17% (cow), 0.16% (goat), and 0.26% (ewe) of the total fatty acids. The *trans*-Δ3 16:1 isomer, which is reported for the first time in ruminant lipids and which likely comes from the animals' feed, is present at a level of *ca.* 10% of the *trans*-16:1 acid group. Otherwise, all isomers with their ethylenic bond between positions Δ4 and Δ14 are observed in the three species studied, roughly showing the same relative distribution pattern. Quantitatively, the *trans*-16:1 isomers only represent *ca.* 5% of the sum of the *trans*-16:1 plus *trans*-18:1 isomers, and they appear of little importance in comparison. It is inferred from this and recent studies that some previously reported data that were established for consumption assessments dealt in fact mainly with iso-17:0 acid, which was confused with (and added to) *trans*-Δ9 (palmitelaidic) acid; consequently, these results were large overestimates. Regarding the *cis*-16:1 acids, the Δ9 isomer is the prominent constituent as expected, but the second-most important isomer is the Δ13 isomer. It does not appear that *trans*-16:1 isomers are from ruminant milk fats of great nutritional importance as compared with *trans*-18:1 isomeric acids. As for *trans*-18:1 isomers, the combination Ag-TLC/GLC is a necessary procedure to quantitate *trans*-16:1 acids accurately and reliably. Ag-TLC allows removal of interfering branched 17:0 acids and *cis*-16:1 acids, and low-temperature GLC permits an accurate measurement of all individual isomers most of which with baseline resolution.

Paper L8463 in *Lipids 35,* 1027–1032 (September 2000).

In some earlier reports on the possible health effects of *trans* fatty acid consumption, dietary *trans*-16:1 isomers were alleged to be a potential cause in the etiology of ischemic heart diseases (1,2). Such isomers may indeed be present in the human diet; the main sources would be partially hydrogenated fish oils (3) and ruminant fats (4–10), but partially hydrogenated vegetable oils would be negligible (3,10) because native vegetable oils contain only very small amounts of unsaturated C_{16} acids.

However, the overlap of *trans*-16:1 isomers and branched 17:0 acids [mainly iso and anteiso forms, and also other methyl-hexadecanoic acids (3,6–10)] during gas–liquid chromatography (GLC) on highly polar columns (generally used in the study of *trans* fatty acids) is a pitfall that is well known to gas chromatographers (3,6–10) and that precludes any reliable conclusions based on single chromatographic runs of fatty acids containing both *trans*-16:1 isomers and branched 17:0 acids, as well as *cis*-16:1 isomers. Moreover, little is known about the nature (position of the ethylenic bonds) and the distribution of individual *trans*-16:1 isomers in ruminant fats. These fats (particularly cow milk fat) are important dietary sources of *trans* fatty acids in many European countries (9,11,12). The little information that has appeared about isomeric distribution of *trans*-16:1 isomers in bovine milk fats was published 30 yr ago by Hay and Morrison (4), who used a combination of argentation thin-layer chromatography (Ag-TLC), preparative GLC, oxidative cleavage, and further GLC of the resulting fragments, and more recently by Precht and Molkentin (10), who used Ag-TLC and low-temperature GLC on 100-m capillary columns. Other *trans*-16:1 acid profiles have been reported for steer perinephric fat (5), for margarines, cooking fats, and shortenings containing partially hydrogenated fish oil (3), and for human milk (10).

Another common error made by nutritionists is to consider *trans*-16:1 isomers as being limited to a single component, palmitelaidic (*trans*-9 16:1) acid, probably because this is the only *trans*-hexadecenoate isomer commercially available as a standard. On 50-m columns coated with 100% cyanopropylpolysiloxane stationary phases as well as also on 100-m columns not operated under optimized conditions, palmitelaidic acid exactly coincides with the branched iso-17:0 (methyl-15-hexadecanoic) acid (3,9,10). In ruminant fats, in particular, the latter acid accounts for 0.3 to 0.5% of total fatty acids, depending on the cattle feed (13). The confusion between these two acids may explain why high levels of *trans*-

16:1 acids are reported in some nutritional or food survey studies (14). In fact, as already demonstrated 30 yr ago (4), as well as in recent studies (3,10), the *trans*-16:1 acid group encompasses several isomers, the major one being indeed palmitelaidic acid. Further, the other *trans*-16:1 isomers partly overlap with anteiso-17:0 and 17:0 acids, even on a 100-m column operated at low oven temperatures of 120 to 125°C (3,10).

The purpose of the present study was to quantitate each individual *trans*-16:1 isomer in ruminant milk fats. We chose cheeses as starting material, with the assumption that their fatty acid compositions are representative of the corresponding milks, i.e., from cow, goat, and ewe. The cheeses, which were purchased in May–June, are supposed to be representative mostly of spring milks in the case of cow milk. Data for *trans*-16:1 isomers were already partially available for cow milk fat [$n = 27$ (3) and $n = 3$ (10)]. In particular, the whole group of *trans*-16:1 isomers represents between 0.05 and 0.25% of the total fatty acids, averaging *ca*. 0.13% (3). We report here on the detailed *trans*- as well as *cis*-16:1 isomeric acid profiles of fat from French cheeses manufactured with cow, goat, and ewe milk. The analytical method used for this purpose involves a combination of Ag-TLC and GLC on 100% cyanopropyl-polysiloxane-coated 100-m capillary columns operated under optimal temperature and carrier gas pressure. Also evidence is given for the first time on *trans*-Δ3 16:1 acid occurring in ruminant milk fats, likely originating from the animals' feed (green parts of plants). It is common knowledge that the *trans*-Δ3 16:1 acid is a major constituent of chloroplast diacylglycerylphosphorylglycerol (15).

EXPERIMENTAL PROCEDURES

Samples. Three lots each of 12 different cheeses made with cow, goat, and ewe milks (produced in France) were purchased locally in supermarkets near Bordeaux (France) in May–June 1999. Frozen spinach leaves were bought in a supermarket in Kiel (Germany). Genuineness of the cheese samples was ascertained by establishing the 12:0/10:0 acid ratios (11).

Fat extraction. Cheese fat was extracted according to Wolff *et al*. (16) using isopropanol and hexane. Representative portions of the cheeses (*ca*. 40 g) were homogenized in a mortar with a pestle, and 5 g of the homogenate was dispersed in 10 mL of isopropanol in a Teflon-coated beaker with an Ultraturrax T25 (Janke & Kunkel GmbH & Co. KG, Staufen, Germany). A sufficient amount of anhydrous Na_2SO_4 and 15 mL of hexane were then added, and a second dispersion was carried out with the Ultraturrax. The suspension was then filtered on a glass column containing a lower layer of anhydrous Na_2SO_4 and an upper layer of Celite 545 (*ca*. 2 cm height each). The lipid solution was eluted three times successively with 25-mL portions of hexane/isopropanol (3:2, vol/vol) and collected in a 250-mL flask. After the solvents were removed in a rotary evaporator at 45°C, the fat was weighed and then transferred into 5-mL vials and stored at 4°C until use.

Fatty acid methyl ester (FAME) preparation. As cheese fats may contain a higher amount of free fatty acids (FFA), the fat acidity of all 36 samples was determined according to International Dairy Federation standard 6B (17). In contrast to methylation with trimethyl sulfonium hydroxide (TMSH), sodium methoxide does not transform FFA into FAME. To choose a suitable transesterification method, we prepared FAME from cheese fat samples having a particularly high FFA content by using both methods. However, the results showed that the fatty acid composition was not significantly influenced by FFA contents. Compared to the TMSH method, the sodium methoxide procedure as used with our samples was more precise. The following procedure was thus chosen. FAME were prepared by vigorously shaking for 3 min a mixture of 1.2 mL *n*-heptane, 0.3 mL of a 10% fat solution in *n*-heptane, and 30 µL of a 2 N sodium methoxide solution in methanol. After centrifugation, the supernatant was directly used for GLC analysis. For Ag-TLC, a 20% fat solution was used. The fat solutions used for FAME preparation were obtained by blending equal amounts of fats from each of the 12 cheeses from a given species. Data reported here are thus for composite samples.

Fractionation of FAME by Ag-TLC. FAME were fractionated according to the number and geometry of double bonds by TLC on silica-gel plates prepared by immersion in a 20% aqueous solution of $AgNO_3$ as described by Precht and Molkentin (18). The developing solvent was the mixture *n*-heptane/diethyl ether (90:10, vol/vol). At the end of the chromatographic runs, the plates were briefly air-dried, lightly sprayed with a solution of 2′,7′-dichlorofluorescein, and viewed under ultraviolet light (234 nm). The *trans*- and *cis*-monoenoic acid bands were scraped off separately and eluted several times with diethyl ether. Complete evaporation of the combined eluates of each fraction was achieved with a light stream of N_2. The residues were dissolved in an appropriate volume of *n*-heptane for further GLC analysis.

Analysis of FAME by GLC. The total fatty acid composition covering *ca*. 70 fatty acids in the carbon chain length range of 4:0 to 24:0 was determined by GLC analysis of the methyl esters on a CP 9001 chromatograph (Chrompack, Middelburg, The Netherlands) equipped with a split injector (split ratio, 1:50) and a flame-ionization detector, using a 25-m capillary CP-Wax 58 CB column (0.25 mm i.d., 0.20 µm film depth; Chrompack). The operating conditions were: H_2 as the carrier gas at an inlet pressure of 40 kPa; injector and detector temperature, 265°C; oven program: 50°C, 1 min, then 5°C/min to 225°C, 15 min isothermal, and finally 5°C/min to 260°C. Calibration of the individual fatty acids was achieved using the reference material CRM 164 obtained from the Community Bureau of Relevence, Commission of the European Communities (Brussels, Belgium).

Analyses of the *cis* and *trans* isomers in total FAME as well as of individual *cis*- and *trans*-16:1 isomer fractions isolated by Ag-TLC were performed using a gas chromatograph CP 9000 (Chrompack) with a split injector, a flame-ionization detector, and a fused-silica capillary column (100 m × 0.25 mm i.d.) coated with 0.20 µm CP-Sil 88 (Chrompack)

under the following conditions: H_2 as the carrier gas; injector temperature 255°C; detector temperature 280°C. The unfractionated FAME were analyzed isothermally at 172°C with a column head pressure of 160 kPa (split ratio, 1:50). Monoenoic TLC fractions were analyzed isothermally at a lower temperature, 120°C, with a column head pressure of 220 kPa (split ratio, 1:25), as described earlier (3,10). Under these conditions, elution of *cis*- as well as *trans*-16:1 isomers took approximately 100 min.

The calibration of positional isomers of the *trans*-16:1 and *trans*-18:1 acids present in the *trans*-monoenoate fraction was achieved with the isomer *trans*-Δ11 18:1, which had been quantitated by stearic acid in the isothermal chromatography of the unfractionated FAME on the CP-Sil 88 column. Stearic acid was determined beforehand by total FAME analysis on the CP-Wax 58 CB column. Further, the *cis*-16:1 and -17:1 isomers found in the *cis*-monoenoate fraction were calibrated by *cis* 9-17:1 acid, which could be determined in the isothermal chromatogram of unfractionated FAME (10). Calibration of GLC data included the conversion from methyl esters to FFA. Thus, results expressing absolute concentrations are given as g/100 g or mg/100 g of total fatty acids.

Identification of individual isomeric *trans*- and *cis*-hexadecenoic acids was achieved according to Precht and Molkentin (3,9,10), except for the *trans*-Δ3 16:1 acid (see below). Integration and quantitation were accomplished with a HP 3365 II ChemStation system (Hewlett-Packard, Palo Alto, CA).

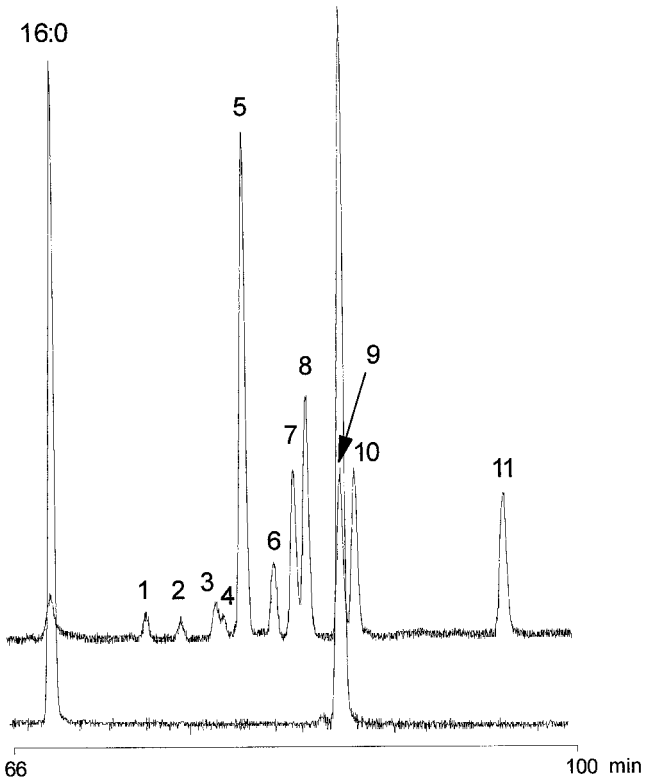

FIG. 1. Representative chromatogram of *trans*-isomeric hexadecenoic acid methyl esters prepared from ewe cheese fat (upper chromatogram) and spinach leaf lipid extract (lower chromatogram, spiked with methyl palmitate for time calibration) and fractionated by argentation thin-layer chromatography prior to analysis by low-temperature gas–liquid chromatography on a 100-m CP-Sil 88 capillary column (Chrompack, Middelburg, The Netherlands) operated 120°C, with H_2 as the carrier gas at an inlet pressure of 220 kPa. Peak numbering as in Table 1.

RESULTS AND DISCUSSION

Figure 1 shows a typical gas chromatogram of *trans*-16:1 isomers prepared from ewe milk fat after Ag-TLC fractionation followed by low-temperature GLC. Baseline resolution of most peaks could only be achieved by reducing the temperature to 120°C, resulting in 100-min analysis times. *Trans*-16:1 fractions from the three species studied here were qualitatively similar. Identifications were made according to Precht and Molkentin (3,10), using in particular a corresponding fraction isolated from hydrogenated fish oil as a secondary standard. In addition to peaks identified in this way (Δ4 to Δ14), a supplementary peak was observed that preceded the Δ13 isomer (arrow in Fig. 1). A possibility for the structure of this peak was *trans*-Δ3 16:1, as we knew that a *trans*-Δ3 18:1 standard elutes just before the Δ15 18:1 *trans* isomer (10,19; Wolff, R.L., and Destaillats, F., unpublished data). This also seemed logical, as the *trans*-3 16:1 isomer is a normal constituent of plant lipids, being more specifically esterified to the *sn*-2 position of diacylglycerophosphorylglycerol in chloroplasts (13), and hence present in the cattle feed. Also, Ackman and Macpherson (6) suspected its presence in butterfat.

To test this hypothesis, we isolated *trans*-Δ3 16:1 acid from lipids extracted by the method of Folch *et al.* (20) from frozen spinach leaves by Ag-TLC of the FAME. Although we saw no band between the saturated and *cis*-monoenoic acid fractions, where *trans*-3 16:1 acid was expected to migrate (21), we scraped off the gel between these two fractions and eluted its content. This intermediate fraction contained a single peak, *trans*-Δ3 16:1 acid, which coeluted with the unknown component in the *trans*-monoenoic acid fraction isolated from ruminant milk fat (Fig. 1). The experiment was repeated with *trans*-Δ3 16:1 acid isolated from fresh leaves of *Araucaria araucana* (monkey puzzle tree), *Pinus pinaster* (maritime pine), and *Aster tongolensis*, the latter plant being known for its particularly high level of *trans*-Δ3 16:1 acid. The unknown peak is thus the *trans*-Δ3 16:1 isomer. This peculiar isomer does not seem to have been reported previously in ruminant fats, or more generally, in herbivore fats, although the hypothesis of its presence in the latter source was put forth as early as 1964 (22). Because *A. tongolensis* also contains a *trans*-Δ3 18:1 acid (Aitzetmüller, K., personal communication), we looked for its presence among ruminant *trans*-18:1 isomers, but we could not detect it. A dietary origin of *trans*-Δ3 16:1 acid, rather than a β-oxidation of the Δ5 *trans*-18:1 acid (a very minor isomer in milk fats), is the most probable explanation for the presence of that isomer. Interestingly, human milk lipids are devoid of the *trans*-Δ3 isomer, although all other *trans*-16:1 isomers are present in that source (10).

Table 1 displays the relative proportions of individual

trans-16:1 isomers established in cow, goat, and ewe milk fats. The first remark concerns the level of palmitelaidic acid, which represents only one-fourth to one-third of total *trans*-16:1 isomers. This observation supports older estimates established by oxidative cleavage of monoenoic fatty acids, which indicate similar or slightly higher values, 33 and 46% for two samples of cow milk fat (4). This observation also agrees with recent results for German bovine milk fat (10). In taking into account the range indicated above, this acid represents on average 0.04% of total fatty acids. A second point is that the content of the Δ3 isomer is not negligible, as it is ranked second to fourth, depending on the species, with values in the range 8.6–14.7% of the *trans*-16:1 fraction. Other isomers with contents in the same approximate range are the Δ12, Δ13, and Δ14 isomers. Isomers with their ethylenic bond between the carboxylic group and the Δ9-position (Δ4 to Δ8) are practically all less than 5%, with the Δ10 isomer showing a somewhat intermediate range (*ca.* 5–7%).

The *cis*-16:1 isomer group is much simpler than the corresponding *trans* fraction with only six visible peaks instead of 11 (Fig. 2). As expected, palmitoleic (*cis*-9 16:1) acid is by far the major isomer (two-thirds and more) (Table 2). However, in contrast to what occurs in most plants and animals, as well as in human milk fat (10), the second major isomer is not the Δ7 isomer, but the Δ13 isomer. As regards the *cis*-18:1 isomers, it is known that the Δ15 isomer is derived from α-linolenic (9,12,15-18:3) acid by biohydrogenation (23). However, in ruminant milk fats, this isomer is present at levels not exceeding 1% of total *cis*-18:1 acids (Precht, D., Molkentin, J., Destaillats, F., and Wolff, R.L., unpublished data). A possibility is that the *cis*-Δ13 16:1 isomer derives from the *cis*-Δ15 18:1 isomer by β-oxidation, but another possibility would be the biohydrogenation of 16:3n-3 (7,10,13-16:3) acid, also a common constituent of plant lipids. This possibility could also hold for the *trans*-16:1 isomers. It should be noted that the *cis*-Δ7, -Δ9, and -Δ13 16:1 isomers give three peaks that are quite well separated on 50-m CP-Sil 88 columns after Ag-TLC fractionation (see, e.g., Ref. 11, where the Δ13 isomer was tentatively and erroneously assigned the structure Δ11).

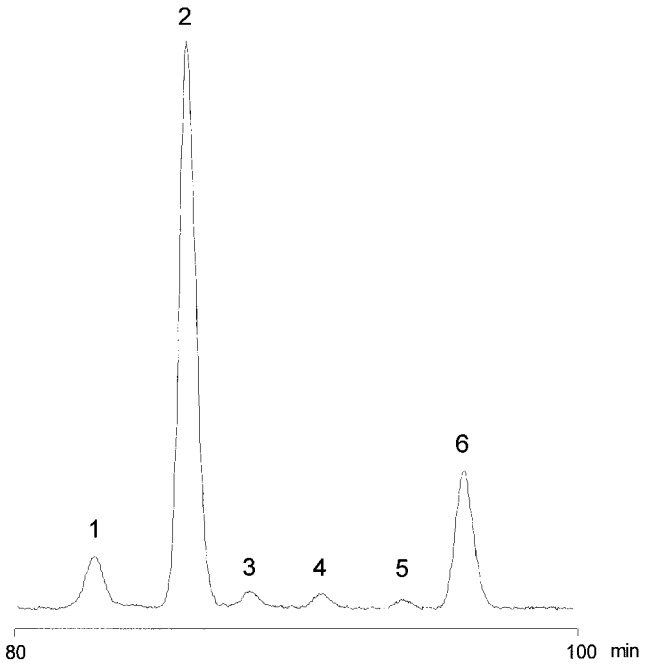

FIG. 2. Representative chromatogram of *cis*-isomeric hexadecenoic acid methyl esters prepared from ewe cheese fat and fractionated by argentation thin-layer chromatography prior to analysis by low-temperature gas–liquid chromatography on a 100-m CP-Sil 88 capillary column (commercial source and operating conditions as in Fig. 1). Peak numbering as in Table 2.

A comparison of the different *trans*- and *cis*-16:1 acid relative distributions immediately shows a profound similarity between the three species analyzed here (Tables 1 and 2). As expected, with the exception of the exogenous *trans*-Δ3 isomer, the bulk of *trans*-16:1 isomeric acids has its double bonds between positions Δ9 and Δ14, in the same way that *trans*-18:1 acids have their ethylenic bonds mostly between positions Δ11 and Δ16. The similarity between the three profiles (Table 1) suggests that the same biosynthetic pathways operate in the formation of the *trans*-16:1 acids, although it is

not possible to decide whether they originate from *trans*-18:1 isomers by β-oxidation, or by biohydrogenation of 16:3n-3 acid from the feed. Both mechanisms might operate as well.

Regarding the absolute concentrations of *trans*-16:1 acids in French cheese fat samples, the following amounts could be established: cow, 0.17; goat, 0.16; and ewe, 0.26 g/100 g (results not shown). These values are in the range determined by Precht and Molkentin (3) for German cow milk fat under various feeding conditions. For the major isomer, palmitelaidic acid, we found 54, 41, and 80 mg/100 g of total fatty acids for cow, goat, and ewe, respectively. However, it should be stressed that *trans*-16:1 isomers only represent from 4.2 (cow milk) to 5.6% (goat milk) of the sum *trans*-16:1 plus *trans*-18:1 acids (practically all *trans*-monoenoic acids; results not shown). Thus they are very minor isomers in ruminant milk fats. As for the *trans*- and *cis*-18:1 isomers, accurate and reliable determinations of *trans*- and *cis*-16:1 isomers can only be obtained by using the Ag-TLC/GLC combination. Direct GLC cannot distinguish between all components, as many peak overlaps between the *cis*- and *trans*-16:1 acids occur, in addition to those with branched-17:0 acids. Clearly, data obtained by direct GLC are inaccurate and unreliable, owing in particular to a confusion between *trans*-Δ9 16:1 and iso-17:0 acids. Determination of the *trans*-16:1 as well as the *trans*-18:1 isomers by single GLC runs without Ag-TLC prefractionation is thus a faulty procedure (24). However, in the former case, large overestimates are obtained, whereas in the latter case, underestimates of variable amplitude are made (25). This can be examplified by data reported in the industry-sponsored TRANSFAIR study (14). In that study, the so-called *trans*-Δ9 16:1 acid reached almost 0.8% of total fatty acids in some instances. In comparison with our data, this represents overestimates by as much as 2,000%. This undoubtedly is due to the fact that iso-17:0 acid (major) and *trans*-Δ9 16:1 acid (minor) were both reported as *trans*-16:1 isomers. Regarding the *trans*-18:1 isomers, we reported elsewhere (25) that data from the same study were underestimates by *ca.* 35%. In both cases, assessments resemble more haphazard assessments than accurate measurements. The same would hold for data relating to beef fat (14,26).

Regarding the consumption of *trans*-16:1 acids by the French population, for whom an intake of 1.5 g/p/d of *trans*-18:1 acids from ruminant fats is admitted (7,11), our results would imply that the consumption of total *trans*-16:1 isomers (5% of total *trans*-monoenoic acids) would not exceed 0.08 g/p/d. Of these, at most *ca*. 0.03 g/p/d (one-third) should correspond to the sole *trans*-9 16:1 isomer. In the TRANSFAIR study (27), the estimate for this isomer was 0.36 g/p/d, that is, 12 times more than our own determination based on the Ag-TLC/GLC procedure. Interestingly, our consumption estimate is supported by studies from Combe *et al*. (28,29) who employed the Ag-TLC/GLC procedure and found 0.08% of total *trans*-16:1 acids in the milk of lactating French women, and 0.06% in the adipose tissue of nonparturient women (0.10% in parturient women and in men).

Finally, it should be emphasized that the use of low-temperature conditions in operating the 100-m column (i.e., 120°C), which are not commonly employed, is a simple alternative to the formerly used oxidative cleavage of 16:1 isomers isolated by Ag-TLC and preparative GLC, and further analysis of the resulting fragments by GLC (4,5). The 18:1 isomeric acids isolated along with the 16:1 acids can be analyzed during the same GLC run but with long retention times of *ca*. 3.5 h (Precht, D., Molkentin, J., Destaillats, F., and Wolff, R.L., unpublished data).

ACKNOWLEDGMENTS

The authors thank Birte Fischer and Bärbel Krumbeck for their contribution to the analytical work. Elodie Pasquier contributed to the preparation of the *trans*-3 16:1 acid fraction from *Araucaria araucana* and *Pinus pinaster* leaves. Professor Kurt Aitzetmüller kindly donated a sample of plant oil from *Aster tongolensis*. F. Determination of the Phospholipid/Lipophilic Compounds Ratio in Liposomes by Thin-Layer Chromatography Scanning Densitometry

S. Rodríguez, M.V. Cesio, H. Heinzen*, and P. Moyna

Cátedra de Farmacognosia y Productos Naturales, Facultad de Química, Universidad de la República, Montevideo, Uruguay

ABSTRACT: The determination of the ratio of phospholipid/lipophilic compounds in liposomes was achieved after thin-layer chromatography (TLC) by measuring the spot intensities of dipalmitoyl phosphatidylcholine and the lipophilic compound. The liposome components under study were separated on one TLC plate, developed in two steps, and detected after charring the plate with specific visualization reagents. The method shows good reproducibility and provides a simple way to quantify the level of lipophilic compound incorporated in the liposome bilayer.

Paper no. L8324 in *Lipids 35*, 1033–1036 (September 2000)

Liposomes have been used as model systems for studying the interaction of the phospholipid-bilayer with individual components of the cell membrane such as proteins or other lipids. The simplicity of the system provides a suitable model for the study of such interactions within the cellular membrane framework, since the effects due to other membrane components are avoided (1). They have also been used to study the interaction of lipids exogenous to the cell membrane with the bilayer, for example, the potential biological activity of compounds such as triterpenes (2,3). The inclusion of sterols and other lipophilic molecules in the bilayers introduces concentration-dependent changes in properties such as phase transition, permeability, and fluidity, which could relate to their biological activity (1–7).

During our study on the influence of wax triterpenes on the phase transition of dipalmitoyl phosphatidylcholine (DPPC) liposomes (2), we faced the problem of quantifying the amount of compound included in the liposome bilayer. The point, which has received only scant attention (8), is not trivial. Erroneous evaluation of this parameter could lead to misinterpretation of the observed effects. In spite of this, the great majority of scientific communications assume that the lipophilic compound under study is completely included in the bilayer (3,4,9,10). The results obtained during our studies indicate that this is not always the case (2).

To address this issue, we developed a thin-layer chromatography (TLC)-scanning based method. TLC-scanning is particularly suitable for the quantification of lipophilic substances such as triterpenoids, sterols, and lecithins within mixtures. Such a method only requires a TLC separation of the components, avoiding most of the possible interferences while having very high sensitivity. We have previously applied direct TLC-densitometric quantification to a number of natural products, e.g., cuticular waxes (11), carbohydrates (12), steroidal alkaloids (13), and terpenes in essential oils (14). The measured refraction values are linearly dependant on the applied concentration, and the unknown concentration can be calculated from the standard curves. In all the cases, the results presented high accuracy and reproducibility.

MATERIALS AND METHODS

Materials and apparatus. Aluminum or plastic-supported silica gel G TLC plates were obtained from Macherey Nagel (Düren, Germany) or Merck (Darmstadt, Germany). Solvents were all analytical grade and redistilled in glass prior to use. DPPC was purchased from Aldrich Chemical Co. (Milwaukee, WI). Cholesterol was obtained by recrystallization from ethanol of a commercial sample. Lupeol and taraxerol were isolated from the cuticular wax of *Colletia paradoxa* Spr. (15,16), ursolic acid was isolated from apple (*Malus domestica* fruit) cuticular wax (17), and uvaol was obtained by reduction of ursolic acid (15). Betulin was purchased from Sigma Chemical Co. (St. Louis, MO). The densitometer was a Flying Spot Shimadzu TLC Scanner 9000 (Kyoto, Japan) operating in the visible range ($\lambda = 560$ nm), in the zig-zag and refraction mode. The gas chromatograph was a Shimadzu GC-6AM, using a SE-52 fused-silica column (0.25 mm thickness, 25 m) with N_2 as the carrier gas. The temperature program was 120°C for 4 min; 10°C/min to 280°C; 50 min at 280°C.

Treatment of liposomes. Liposomes were prepared according to Bangham (18). Fifteen micromoles of DPPC, along with the desired amount of the compound under study, were dissolved in 10 mL of chloroform and rotary-evaporated to

obtain a thin film on the bottom of a 25-mL round-bottomed flask. After breaking vacuum under nitrogen, 1.00 mL of water at 50°C and a 2-mm round glass bead were added. The suspension was vortexed for 1 min and sonicated for 5 min. The sample was checked with an optical microscope for the presence of nonincorporated crystals. The suspension of liposomes was first filtered through cotton to remove crystals and nonliposomal particles. The filter was then washed with distilled water (3 × 5 mL), and the combined washes were pooled together with the filtrate. Finally, the sample was freeze-dried, and the residue was dissolved in 1 mL of dichloromethane.

Quantification. In a typical experiment, 1, 2, 4, 6, and 8 μL of a DPPC solution (1 mg/mL) were spotted with a micropipette on a 20 × 20 cm TLC plate, together with 1, 2, 4, 6, and 8 μL of a solution containing 1 mg/mL of the triterpene or steroid under study. Triplicates of 2 μL of the liposome problem solution were spotted in between both calibration curves. The plate was then developed twice, first using $CHCl_3/CH_3OH/NH_4OH$ 2% (70:30:5) for an 8-cm run followed by $CHCl_3$ (for cholesterol and monotriterpenols) or $CHCl_3/(CH_3)_2CO$ (95:5) (for triterpene diols and acids) in the same direction for the full plate (18 cm).

The plate was cut at the first solvent front. The lower 10 cm was sprayed with ammonium molybdate/perchloric acid reagent (19) and heated for 10 min at 110°C to detect and quantify the phospholipids with the densitometer at λ = 560 nm. The area values were recorded. The top part of the plate was sprayed with $CuSO_4/H_3PO_4$ reagent and heated for 5 min at 110°C for cholesterol and taraxerol, 6 min at 110°C for ursolic acid, and 10 min at 110°C for uvaol. The spot intensities were measured and recorded as reported (11,12,14).

Gas chromatography (GC) analysis. Five milligrams of the liposome problem solution was heated for 5 min at 60°C with 1 mL of methanol/BF_3 reagent (Aldrich). The solvent was evaporated and the residue trimethylsilylated using 0.5 mL of trimethylsilyl (TMSi) imidazole/pyridine (1:2) at 60°C for 1 h. The resulting solution was injected into the gas chromatograph operating under the described conditions.

Data treatment. The values for each class of compound were graphed by means of a linear correlation (11–14). The concentrations in the problems were calculated, averaged, and expressed as the molar ratio of (lipophilic compound)/(DPPC + lipophilic compound).

RESULTS

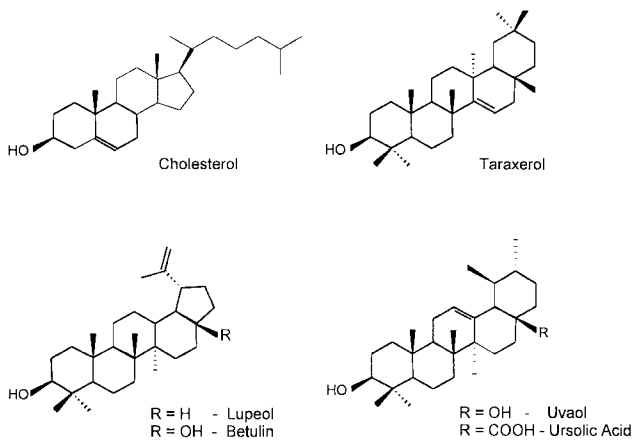
The different polarities of phospholipids and sterol-like molecules established the need for a two-solvent system. With this procedure, lecithins were easily separated from nonpolar lipids by TLC with very good resolution ($R_{f\text{ of DPPC}} = 0.25$; $R_{f\text{ of cholesterol}} = 0.75$; $R_{f\text{ of ursolic acid}} = 0.60$).

The ammonium molybdate/perchloric acid reagent provided the best results for the visualization of phospholipids. Draggendorf reagent was also assessed for the quantification of these compounds, but it was half as sensitive. Care must be taken when using the ammonium molybdate/perchloric acid reagent since it decomposes very easily. It must be prepared 24 h prior to use, and it is usable for 3 wk when kept in the refrigerator, under nitrogen, and in dark bottles. For the quantification of steroids and triterpenoids, the detection agent of choice was $CuSO_4/H_3PO_4$, as previously reported (12).

Exact amounts of the tested compounds were spotted on a TLC plate along with three samples of the liposome solution. Both groups of components were measured with the TLC scanner. The plates were read transversely so all the spots were read at the same time ± 2 min, avoiding differential charring of the compounds. The observed areas and the concentration of compounds spotted were graphed by means of linear correlation.

The coefficients of variation were calculated employing only curves with $r > 0.992$ for the DPPC and $r > 0.999$ for the triterpenoid (or steroid). The data obtained for each of the values were averaged. The values corresponded to a coefficient of variation ≤3% for the phospholipid, and ≤1% for the triterpenoid (or sterols). The reproducibility of the measurements on the same DPPC spot was assayed by measuring the same spot 30 times. The values were then averaged and the coefficient of variation was <3%. The reproducibility of the measured data was assessed by performing the analysis of DPPC/cholesterol, 12% liposomes in three different plates. The resulting values showed a coefficient of variation of 4%. The incorporation levels in DPPC liposomes of the different tested compounds (Scheme 1) are summarized in Table 1.

GC provides an alternative to the present methodology; however, direct determination of the compounds is not possible and derivatization is necessary. Phospholipids were quantitatively converted to the corresponding fatty acid methyl esters (FAME) by BF_3-catalyzed methanolysis of the mixture. Cholesterol can be determined without derivatization or as TMSi derivative. Triterpenols were also analyzed as TMSi derivatives. In the case of polyfunctional triterpenes, it is advisable to prepare their TMSi derivatives overnight, since



SCHEME 1

[b]Expected amount of triterpene (or sterol) included in the liposomes.
[c]TLC measured ratio of compounds included in liposomes.

some compounds (betulin) can decompose when heated in the normal derivatization protocol (15). For hydroxyacids, the procedure was similar. The acid function was methylated during the transesterification step, and the TMSi derivative was prepared in a second reaction.

In a single GC run, the phospholipid fatty acids (as FAME) were separated from sterol and triterpene TMSi derivatives. The different retention times of the compounds under study were as follows: (i) myristic acid, 15 min; palmitic acid, 17 min; linoleic acid, 18 min; oleic acid, 18.5 min; stearic acid, 19 min; (ii) cholesterol, 35 min; taraxerol, 38 min; uvaol, 52 min; betulin, 54 min; and ursolic acid compounds listed under (i) were analyzed as the methyl ester derivatives, (ii) as TMSi derivatives, and (iii) as TMSi methyl ester derivatives. Tetracosane was employed as an internal standard, and a correction factor was applied due to the differential responses of the flame-ionization detector (FID) to each lipophilic compound depending on their oxidation degree and structure (20). A GC run was completed in 70 min, and calculations were simple since the phospholipid, DPPC, had only one fatty acid component. If more complex lipids are used, calculations must be adjusted.

DISCUSSION

The accurate measurement of the precise amounts of lipophilic compound incorporated into membranes is crucial for the rigorous understanding of the resulting changes in the physicochemical properties of liposomes. It has been assumed that the total amount of a compound blended with the phospholipid is completely included within the bilayer, but this is not always the case. Although cholesterol achieves complete incorporation in the bilayer (Table 1, entry 1) (2), triterpenes such as ursolic acid or uvaol only attain low incorporation levels (Table 1, entries 4 and 5). Recent studies on the dynamic properties of DPPC and ursolic acid 1:0.3 liposomes have been reported (3); however, our results show that the highest attained incorporation of ursolic acid in the liposome bilayer (Table 1, entry 4) was close to 5% molar ratio.

The TLC method achieves an accurate determination of the concentration of sterols and steroid-like molecules within phospholipid bilayers in a single analysis, without prior derivatization. The method can be applied to liposomes formed by complex phospholipids or containing more than one lipophilic compound. The study of the changes of DPPC-cholesterol liposomes that include another lipophilic compound can provide interesting information, and might be nearer the biological membrane model. Table 1, entry 7 shows the case of a simultaneous triple determination. In addition, the method is not limited to steroid-like molecules and can be applied to any lipophilic compound as long as its concentration can be determined by TLC. As an example, the incorporation levels of β-diketones and resorcinols in liposomes was also determined in our laboratory (21).

GC provides an alternative method for the simultaneous quantification of lipophilic compounds and phospholipids present in bilayers; however, it presents some major drawbacks. Analysis of each sample requires two derivatization steps that make the process more tedious and time consuming. In addition, it requires the use of correction factors for the FID response, which have to be experimentally established. A major advantage of TLC scanning is that the compound under study is the one used as the internal standard, a situation that is not possible with GC. Furthermore, while the determination of a complex phospholipid by TLC implies determining only one compound, with the GC methodology, the concentration of all fatty acid components should be established.

In summary, the TLC-scanning method reported herein provides a fast, convenient, and accurate way of determining the incorporation of lipophilic compounds in the bilayer. Furthermore, the method is not limited to the case of DPPC-triterpene liposomes, and more complex systems can be analyzed. This technique allows determining the actual incorporation level of a lipophilic compound in the bilayer, and consequently it permits a more rigorous understanding of the observed associated effects.

Deuterium Uptake and Plasma Cholesterol Precursor Levels Correspond as Methods for Measurement of Endogenous Cholesterol Synthesis in Hypercholesterolemic Women

Nirupa R. Matthan[a], Mahmoud Raeini-Sarjaz[a], Alice H. Lichtenstein[b], Lynne M. Ausman[b], and Peter J.H. Jones[a,*]

[a]School of Dietetics and Human Nutrition, McGill University, Macdonald Campus, Ste-Anne-de-Bellevue, Québec, Canada H9X 3V9, and [b]Jean Mayer USDA Human Nutrition Center on Aging at Tufts University, Boston, Massachusetts 02111

ABSTRACT: To assess the validity of two techniques used to measure human cholesterol synthesis, the rate of uptake of deuterium (D) into plasma free cholesterol (FC), and plasma cholesterol precursor (squalene, lanosterol, desmosterol and lathosterol) levels were compared in 14 women [65–71 yr with low density lipoprotein-cholesterol (LDL-C) ≥ 3.36 mmol·L^{-1}]. Subjects consumed each of six diets for 5-wk periods according to a randomized crossover design. The experimental diets included a baseline diet (39% energy as fat, 164 mg chol·4.2 MJ^{-1}) and five reduced-fat diets (30% of energy as fat), where two-thirds of the fat was either soybean oil; squeeze, tub or stick margarines; or butter. Fractional and absolute synthesis rates (FSR and ASR) of FC were determined using the deuterium incorporation (DI) method, while cholesterol precursor levels were measured using gas–liquid chromatography. Data were pooled across diets for each variable and correlation coefficients were calculated to determine if associations were present. There was good agreement among levels of the various cholesterol precursors. In addition, FSR in pools/d (p·d^{-1}) and ASR in grams/d (g·d^{-1}) were strongly associated with lathosterol (r = 0.72 and 0.71, P = 0.0001), desmosterol (r = 0.75 and 0.75, P = 0.0001), lanosterol (r = 0.67 and 0.67), and squalene (r = 0.69 and 0.68) when levels of the precursors were expressed as μmol·$mmol^{-1}$ C. Significant but lower correlations were observed between the D uptake and plasma cholesterol precursor levels when the latter were expressed in absolute amounts (μmol·L^{-1}). The wide range of fatty acid profiles of the experimental diets did not influence the degree of association between methods. In conclusion, the DI method and levels of some cholesterol precursors correspond as methods for short-term measurement of cholesterol synthesis.

Paper no. L8503 in *Lipids 35,* 1037–1044 (September 2000).

Cholesterol homeostasis is maintained by regulatory mechanisms that balance input and output so as to prevent net accumulation of cholesterol (1). Alterations in homeostasis, resulting in elevated circulating cholesterol concentrations, are associated with undesirable plasma lipid responses that increase the risk of developing cardiovascular disease (CVD) (2,3). A factor known to influence *de novo* cholesterogenesis is dietary fat modification (4–6). Several techniques have been used to measure cholesterol synthesis in humans, including sterol balance (7–11), kinetic approaches (12,13), activity of the enzyme 3-hydroxyl-3-methylglutaryl coenzyme A (HMG-CoA) reductase (14,15), and cholesterol precursor levels (14,16–22). More recent approaches include the mass isotopomer distribution analysis (MIDA) (23–25) and deuterium incorporation (DI) methodology (26–31).

The sterol balance method provides an accurate value for biosynthesis once internal sterol pools have equilibrated, but has the disadvantage of being laborious, requiring complete stool collections and accuracy in recording food intake (32). Kinetic studies with [^{13}C]cholesterol provide detailed information about pool sizes, distribution, and formation rates of cholesterol, but require prolonged measurement intervals consistent with metabolic steady state (6). Determination of the activity of HMG-CoA reductase, the rate-limiting enzyme in the synthetic pathway of cholesterol, provides an index of cholesterol synthesis over the short term, but is restricted by the need for a liver biopsy (15). Sterol precursor levels in plasma, including mevalonic acid (16,17), squalene (14,18), lanosterol (14,19), desmosterol (14,20) and lathosterol (14,21,22), are alternate indicators of synthesis; however, the sensitivity of these techniques is still under investigation. The MIDA technique, despite its advantages, is invasive, requiring indwelling catheters for delivery of isotope label, serial blood sampling, and lengthy data analysis with elaborate mathematical processing (6).

Alternatively, the deuterium (D) uptake method, capable of directly measuring the rate of incorporation of D from body water into newly formed cholesterol (26–31), offers a safe, noninvasive alternative for detecting changes in cholesterol synthesis rates over short periods of time. This method

Abbreviations: ASR, absolute synthesis rate; C, cholesterol; CVD, cardiovascular disease; D, deuterium; DI, deuterium incorporation; D_{max}, maximum number of deuterium molecules; FC, free cholesterol; FSR, fractional synthesis rate; HMG-CoA, 3-hydroxyl-3-methylglutaryl coenzyme A; MIDA, mass isotopomer distribution analyses; TC, total cholesterol.

has been validated against levels of plasma mevalonic acid (33), sterol balance (32), and MIDA (34) techniques; however, a direct comparison between DI and the commonly used cholesterol precursor level assessment method has not been performed. Thus, the objective of the present investigation was to determine whether levels of some cholesterol precursors (squalene, lanosterol, desmosterol, and lathosterol) correlate with the D uptake method for measurement of endogenous cholesterogenesis. The study was originally designed to assess the effect of different *trans* and fatty acid profiles on cholesterol synthesis. The specific effects induced by the diet change are reported elsewhere. Here, the focus of attention will be to determine whether an association exists between the two methods.

MATERIALS AND METHODS

Subjects. Fourteen postmenopausal, middle-aged to elderly, moderately hypercholesterolemic (low density lipoprotein-cholesterol ≥ 3.36 mmol·L^{-1}) women (65–71 yr) were recruited as previously described (35). Subjects had no family history of premature CVD, nor showed any signs of hepatic, renal, thyroid, or intestinal disease. None of the subjects was taking any medication known to alter lipid metabolism such as lipid-lowering drugs, β-blockers, diuretics, or hormones. The protocol was reviewed and approved by the Human-Investigation Review Committee of New England Medical Center and Tufts University. All potential subjects were given a verbal and written description of the study prior to obtaining written consent.

Study design and diets. Subjects were given, in a double-blind fashion, each of six diets for 5-wk periods, separated by washout periods ranging from 2 to 4 wk. The experimental diets included a baseline diet designed to approximate that currently consumed in the United States (39% energy as fat, 164 mg cholesterol·4.2 MJ^{-1}), and five reduced fat diets (30% of energy) where two-thirds of the total fat was provided by either soybean oil or soybean oil-based margarines in the squeeze, tub, or stick forms, as well as butter. All food and drink were provided by the Metabolic Research Unit of the Jean Mayer U.S. Department of Agriculture Human Nutrition Research Center on Aging at Tufts University (Boston, MA) to be consumed on-site or packaged for take-out. Energy intakes of the subjects were tailored to individual requirements, as verified by the ability to maintain stable body weight. Analysis of the macronutrient, fatty acid, and cholesterol content of the diets was carried out by Covance Laboratories (Madison, WI) and Best Foods Research and Engineering Center (Union, NJ). These compositions are given in Table 1. Levels of the cholesterol precursors proposed to be measured in plasma were not detected in the different diets.

Protocol and analyses. During the final week of each dietary phase, fasting blood samples were collected in tubes containing EDTA (0.15%). This was immediately followed by administration of an oral dose of D_2O (1.2 g per kg total body water). Twenty-four hours postdose, another fasting blood sample was collected. Plasma was separated, aliquoted, and frozen at −80°C until further analysis.

Cholesterol precursor analyses. Plasma total cholesterol (TC) concentrations were analyzed using enzymatic procedures (36,37). The precursor sterols were quantified using gas–liquid chromatography (GLC). An internal standard containing 150 μL of 5α-cholestane was added to 1 mL of plasma. The sample, in duplicate, was then saponified for 1 h at 100°C, with 0.5 M methanolic potassium hydroxide in 15-mL Teflon-capped glass tubes. After saponification, samples were allowed to cool to room temperature, followed by the addition of 2.5 mL of distilled water and 3 mL petroleum ether to each tube. The tubes were vortexed, centrifuged at 1500 × *g* for 15 min, and the upper layers containing the non-saponifiable materials were transferred into clean glass tubes. The extraction procedure was repeated twice. Combined extracts were then dried down under nitrogen and resuspended in 1 mL of chloroform. A sample volume of 2 μL was injected into a gas–liquid chromatograph equipped with a flame-ionization detector (HP 5890, Series II; Hewlett Packard, Palo Alto, CA) using a 30-m capillary column (SAC-5; Supelco, Bellefonte, PA). Injector and detector temperatures were 300 and 310°C, respectively. A multiramp oven temperature program was used. The initial temperature, 80°C, was held for 1 min and then increased to 120°C at a rate of 20°/min. After

15 min, the temperature was further increased to 269°C at a rate of 20°/min and held for 25 min. The final temperature of 320°C was reached using a rate of 20°/min and held for 5 min. Peaks of interest were identified by comparison with authentic standards (Supelco).

Deuterium uptake analyses. Additional plasma aliquots were used to determine D enrichment in body water and free cholesterol (FC) as previously described (26–31). Briefly, lipids were extracted (38) and FC was separated by thin-layer chromatography using petroleum ether/ethyl ether/acetic acid (135:15:1.5, by vol). FC was eluted with hexane/chloroform/ethyl ether (5:2:1, by vol) and dried under a stream of nitrogen. The purified cholesterol was converted into water and carbon dioxide by combustion over cupric oxide and silver wire at 520°C for 2 h. In addition, pre- and post-D_2O samples diluted twofold and tenfold, respectively, to produce D enrichments within detectable ranges on the mass spectrometer, were distilled into zinc-containing tubes. This enabled measurement of D enrichment of plasma water. The combustion water from FC and plasma was then vacuum-distilled into Pyrex™ tubes containing zinc reagent and reduced to hydrogen D gas by heating at 520°C for 30 min. D enrichment of the gas was analyzed by isotope ratio mass spectrometry (VG isomass 903 D; Cheshire, England). The instrument was calibrated daily using water standards of known isotopic composition. Values were expressed relative to the enrichment of standard mean ocean water in parts per mil (‰). The per mil designation was used because of the relatively small enrichments encountered. Duplicate samples for each subject were analyzed concurrently against a single set of standards. Maximum acceptable precision for D was 5‰ at enrichments over 500‰, and 2‰ at enrichments below 200‰.

Fractional synthesis rate (FSR) of FC, defined as the proportion of the central or M_1 pool replaced daily by newly synthesized cholesterol, was calculated as the change in product enrichment over time divided by the maximum possible enrichment, based on a linear rate of uptake of label into cholesterol over time (27,29). The equation used was:

$$\text{FSR–FC } \left(\text{p}\cdot\text{d}^{-1}\right) = \frac{\delta \text{ cholesterol (\%)}}{\delta \text{ plasma water (\%)} \times 0.478} \qquad [1]$$

where δ is the difference in D enrichment over 24 h. Model parameters and assumptions underlying the use of D_2O as a tracer for FSR measurements have been described previously (27,29). Absolute synthesis rate (ASR) of FC, which is an approximation of the daily production of newly synthesized cholesterol expressed in grams/day ($g\cdot d^{-1}$), was derived by multiplying the FSR–FC by M_1 pool size and a factor of 0.33. The M_1 pool size was calculated using Goodman's equation (39), which takes into account subjects' body weights, plasma TC and triglyceride concentrations. The factor of 0.33 was included to account for the proportion of FC in the overall plasma TC pool.

Statistical analysis. Prior to analyses, the distribution of each outcome variable was checked for normality (Proc Univariate, SAS version 6.12; SAS Institute Inc., Cary, NC) and, if necessary, the appropriate transformations were performed. Data were pooled across diets for each variable and Pearson's correlation coefficients were determined to test for associations between variables, with significance set at $P < 0.05$ (Proc Corr, SAS version 6.12; SAS Institute Inc.). Untransformed data are presented in text and tables as means ± SD.

RESULTS

This study was originally designed to determine the effect of changes in dietary fatty acid composition on endogenous cholesterol synthesis. However, it is the purpose of the present study to focus on the association between plasma levels of cholesterol precursors and D uptake as indicators of cholesterol synthesis. The results of the diet-induced changes in cholesterol synthesis have been reported elsewhere (40). Nevertheless, it was deemed appropriate to provide these values in summary form to be read only as background information. Table 2 lists the pooled mean (±SD) plasma concentrations of total cholesterol, its precursors, as well as FSR and ASR of free cholesterol. The range of values for each variable is in good agreement with those previously reported for humans (14,20,22,41,42).

Table 3 summarizes the correlations between the various cholesterol precursors when expressed as $\mu mol\cdot L^{-1}$ or $\mu mol\cdot mmol^{-1}$ of cholesterol (C). In general, good agreement was observed between concentrations of all four precursors (range from $r = 0.88$ to 0.95). Figure 1 depicts the relation between FSR ($p\cdot d^{-1}$) obtained using the DI method and plasma concentrations of squalene, lanosterol, desmosterol, and lathosterol (expressed as either $\mu mol\cdot L^{-1}$ or $\mu mol.mmol^{-1}$ C). Higher correlations ($P = 0.0001$) were obtained between FSR

TABLE 2
Pooled Mean Values for Total Cholesterol, Its Precursors, FSR, and ASR[a]

Variable	Concentration range	Mean ± SD
Total cholesterol		
$mmol\cdot L^{-1}$	4.32–8.25	6.28 ± 0.84
Squalene		
$mmol\cdot L^{-1}$	0.01–2.77	0.74 ± 0.58
$\mu mol\cdot mmol^{-1}$ [b]	0.13–45.37	12.11 ± 10.05
Lanosterol		
$\mu mol\cdot L^{-1}$	0.39–5.36	1.78 ± 1.08
$\mu mol\cdot mmol^{-1}$ [b]	5.98 –103.13	28.78 ± 19.36
Desmosterol		
$\mu\mu mol\cdot L^{-1}$	0.41–6.09	2.47 ± 1.45
$\mu mol\cdot mmol^{-1}$ [b]	7.18–110.74	40.08 ± 24.62
Lathosterol		
$\mu mol\cdot L^{-1}$	6.12–32.53	13.63 ± 4.47
$\mu mol\cdot mmol^{-1}$ [b]	81.52–625.93	220.82 ± 84.37
FSR		
$p\cdot d^{-1}$	0.01–0.22	0.07 ± 0.03
ASR		
$g\cdot d^{-1}$	0.06–1.71	0.61 ± 0.28

[c]Relative to concentration of total cholesterol. C, cholesterol.

and plasma concentrations of desmosterol (r = 0.71 and 0.75) and lathosterol (r = 0.68 and 0.72). Significant (P = 0.0001), but lower associations were observed between FSR and squalene (r = 0.67 and 0.69), and FSR and lanosterol (r = 0.65 and 0.67). The total amount of cholesterol synthesized per day (ASR) was also computed and correlated with absolute (μmol·L^{-1}) or relative (mol·mmol^{-1} C) concentrations of the cholesterol precursors (Fig. 2). Similar to the FSR data, we found that desmosterol (r = 0.75 and 0.75) and lathosterol (r = 0.71 and 0.76) were better correlated with ASR than were squalene (r = 0.68 and r = 0.69) and lanosterol (r = 0.67 and 0.69). Overall, concentrations of the precursors were found to correlate better with FSR and ASR, when expressed relative to cholesterol (μmol·mmol^{-1} C) than when expressed in absolute amounts (μmol·L^{-1} of plasma).

DISCUSSION

A variety of methods exists for measuring human cholesterol biosynthesis. These methods vary in the duration needed to attain equilibrium, and thus represent either a short-term or longer-term picture into *de novo* cholesterogenesis (6). Among the short-term approaches, both the D uptake and cholesterol precursor assessment methods offer potential advantages over other indices of cholesterol formation rates. However, a direct cross-comparison of these techniques has not been carried out. We present new evidence that the D uptake method corresponds well with levels of the cholesterol precursors—lathosterol, desmosterol, lanosterol, and squalene. In addition, the degree of association was not influenced by the differing fatty acid composition of the experimental diets.

The rationale for using plasma levels of cholesterol precursors as indicators of cholesterol synthesis stems from the assumption that these compounds leak into plasma lipoproteins at rates proportional to their formation in the cholesterol synthetic pathway (14). On the other hand, the DI method is based on the incorporation of deuterated water tracer into *de novo* cholesterol from a precursor pool of body water, which is in equilibrium with NADPH (27). Labeled water equilibrates quickly between the intracellular site of cholesterogenesis and extracellular body fluid. Thus, newly synthesized cholesterol is derived from a pool of known enrichment that can be determined by measuring either urine, saliva or plasma. Despite the different assumptions of each method, both are considered valid tools to assess changes in endogenous cholesterogenesis under various physiological and pathological conditions (20,22,29,30,41).

Comparatively, plasma cholesterol precursor concentrations and the D uptake method each offer advantages and disadvantages. The former method is rapid and easy, but values obtained are relative indicators of synthetic rates. In contrast, results obtained by the D uptake method yield a direct measure of net synthesis. However, this method has its drawbacks, both procedural and theoretical. Technically, the DI method is labor intensive, requiring lengthy multistage sample preparation. Theoretically, the major concern is establishing the maximum number of D molecules (D_{max}) incorporated per molecule of newly synthesized cholesterol. Over the long term, D_{max} has been shown to increase, as the acetyl-CoA pool begins to incorporate D. However, over the short term it has been established that D_{max} fluctuates between the narrow range of 20 and 22 (n = 7 hydrogen from water and 14 from NADPH). Thus, the D uptake method is considered a valid and reliable indicator of endogenous cholesterol synthesis when measurements are made around 24 h.

Similarly, the cholesterol precursor assessment method has been criticized because differences in plasma levels of the precursors could be a mere consequence of varying number of lipoprotein acceptor particles in the plasma compartment (18). It has been suggested that expressing plasma levels of precursors relative to the levels of free or total cholesterol would be a more valid index of cholesterol synthesis, as it would account for these differences in number of lipoprotein acceptor particles (18). Indeed, we found stronger correlations between levels of cholesterol precursors and the D uptake method when precursor levels were calculated relative to plasma cholesterol concentrations. In addition, our results indicate that desmosterol and lathosterol were more closely associated with FSR and ASR, while squalene and lanosterol showed significant but smaller associations. Since a certain degree of accumulation of precursors must occur inside the cells before there is a significant leakage into circulation, and given that there is a high capacity to convert squalene and lanosterol into other cholesterol intermediates, it seems reasonable that these early intermediates in the cholesterol synthetic pathway would be associated to a lesser degree than intermediates formed at later stages of the pathway.

Our results demonstrate that the D uptake method correlates well with some plasma cholesterol precursor levels. While this association demonstrates the strength of the relation between the two methods, it does not indicate the agreement between them. The Bland and Altman (43) technique is considered an accurate statistical method for assessing agreement between two methods as it plots the difference among the methods against their mean. Unfortunately, this type of analysis could not be performed in the present study given the

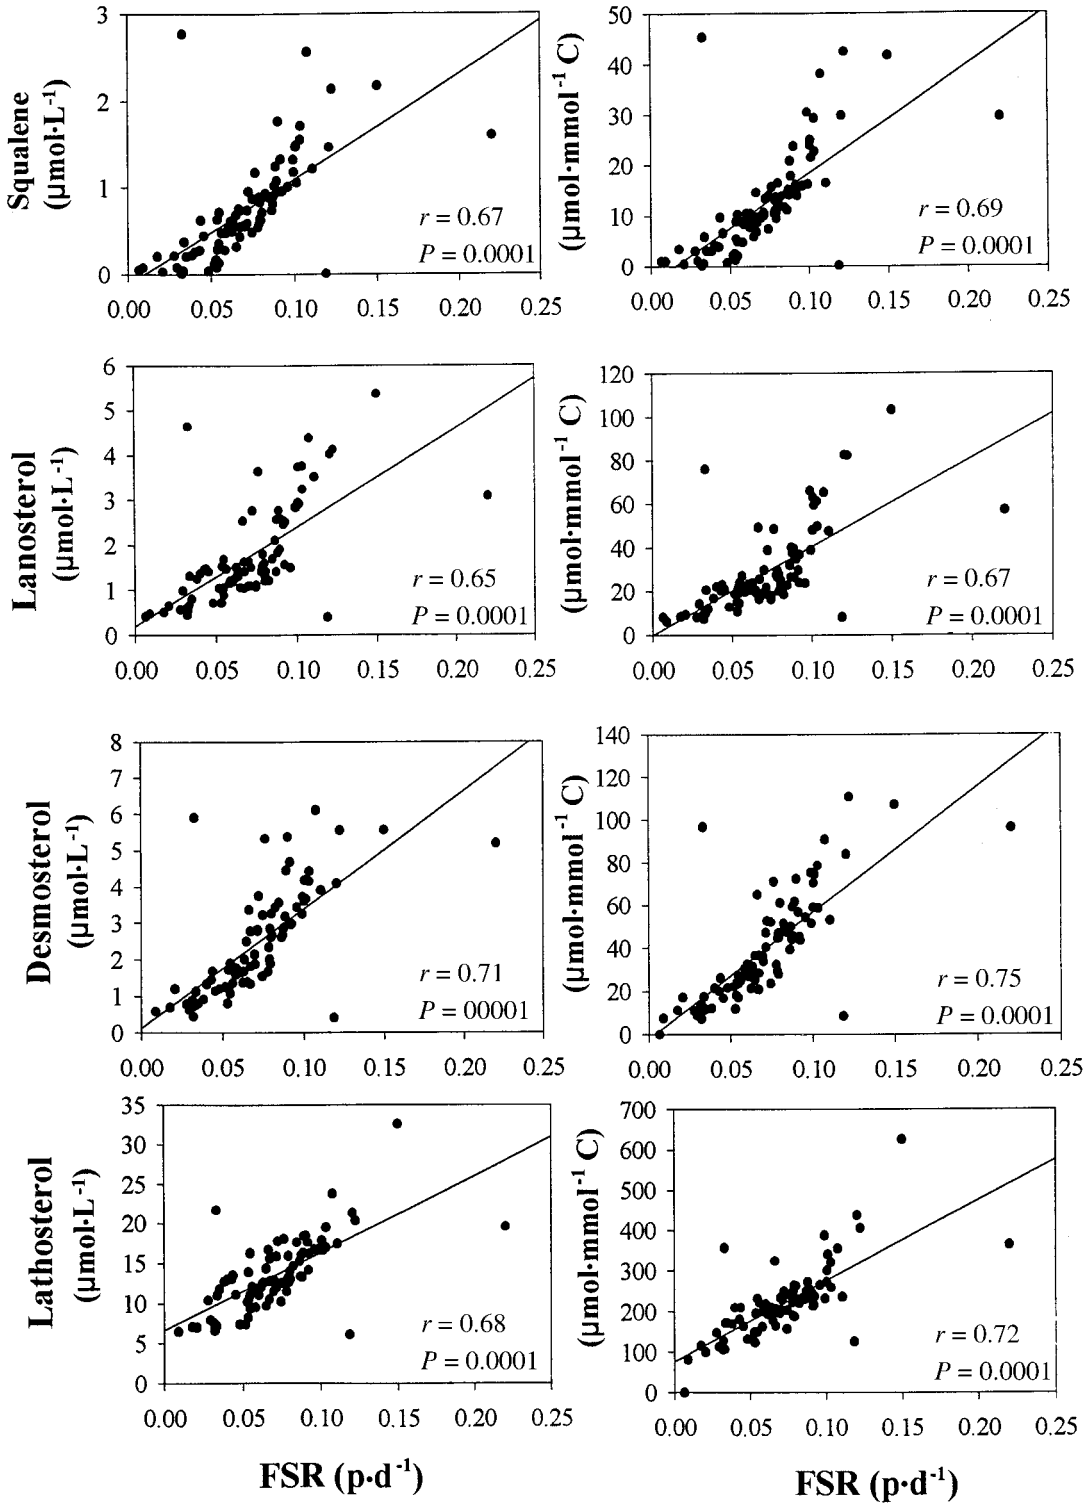

FIG. 1. Correlation between fractional synthesis rate (FSR) ($p \cdot d^{-1}$) and concentrations of different precursors to cholesterol expressed as $\mu mol \cdot L^{-1}$ and $\mu mol \cdot mmol^{-1}$ of cholesterol (C). Data were obtained from 14 subjects and pooled across the six diets for each variable.

different units of measurements for each method. However, using the above technique, good agreement has been demonstrated between the DI method and sterol balance (33) and MIDA (34) techniques. In addition, plasma levels of some of the precursors have also been validated against HMG-CoA reductase (14) and sterol balance (21). Thus in their own right, the accuracy of the D uptake and plasma cholesterol precursor levels has been established. Consequently, it is felt

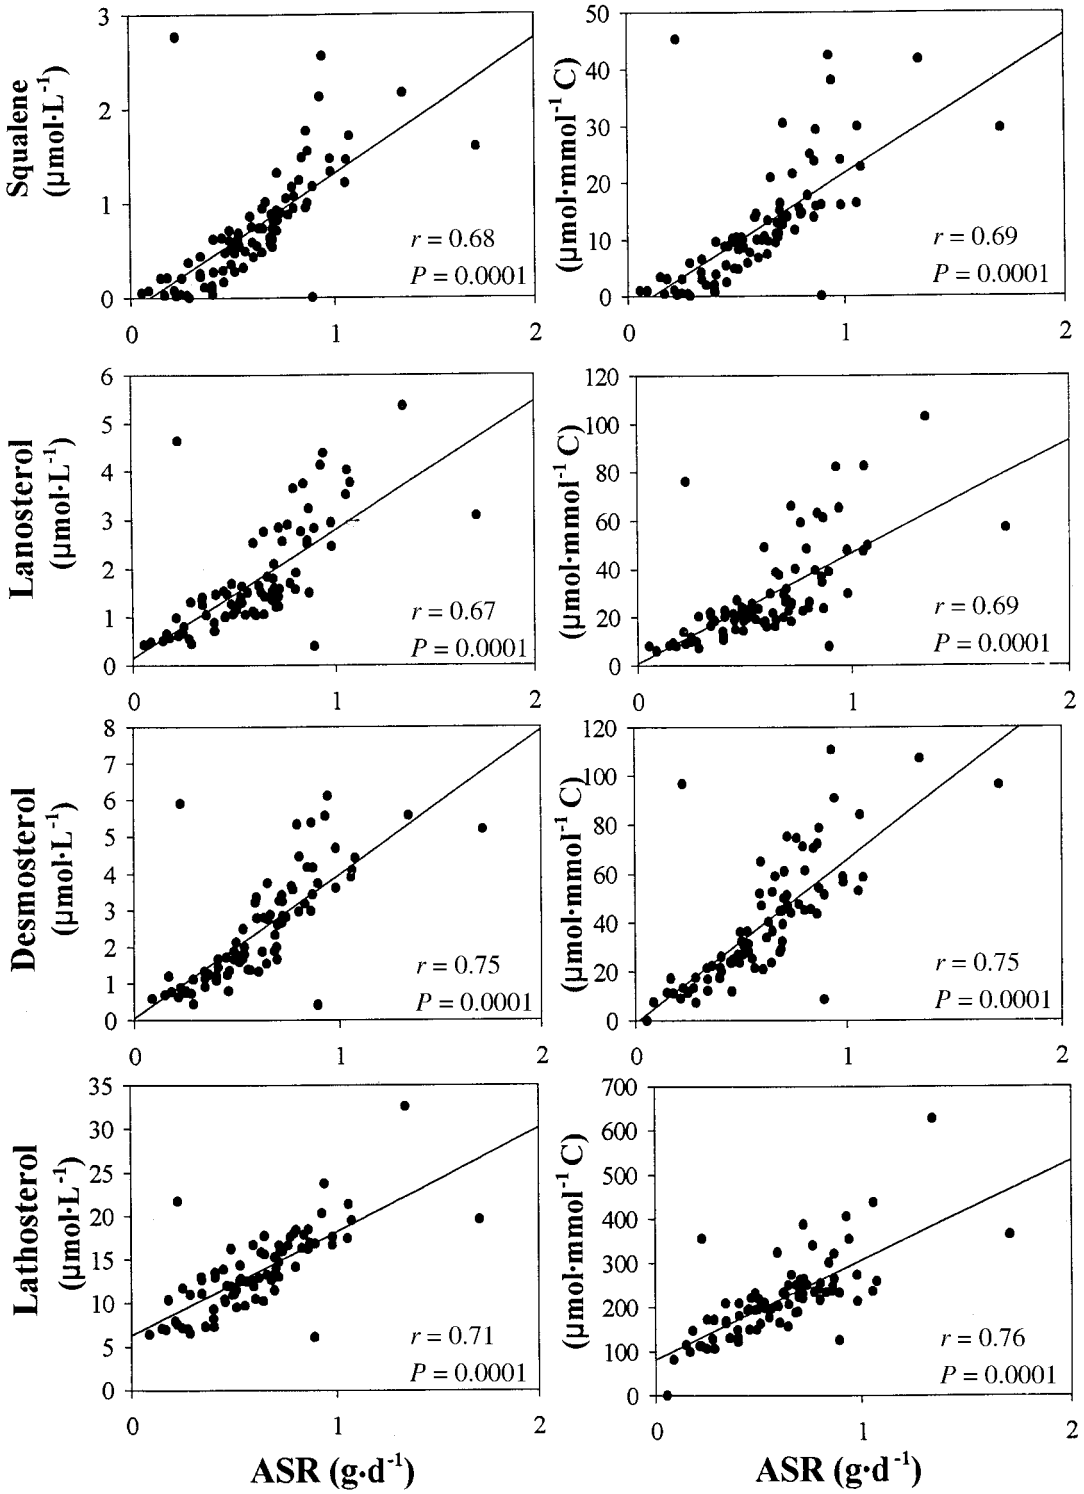

FIG. 2. Correlation between absolute synthesis rate (ASR) ($g \cdot d^{-1}$) and concentrations of different precursors to cholesterol expressed as $\mu mol \cdot L^{-1}$ and $\mu mol \cdot mmol^{-1}$ of C. Data was obtained from 14 subjects and pooled across the six diets for each variable. See Figure 1 for other abbreviation.

that the association observed in this study provides evidence that both methods are reliable and suitable for relatively uninvasive, short-term detection of cholesterol synthesis. Furthermore, these methodologies can be used to study factors known to influence human cholesterol metabolism and consequently the risk of developing CVD.

Antioxidant Reactions of α-Tocopherolhydroquinone

Daniel C. Liebler* and Jeanne A. Burr

Department of Pharmacology and Toxicology and Southwest Environmental Health Sciences Center, College of Pharmacy, The University of Arizona, Tucson, Arizona 85721-0207

ABSTRACT: α-Tocopherolhydroquinone (TQH_2) is a product of α-tocopherol oxidation/reduction that exerts antioxidant effects in biological systems. TQH_2 inhibited autoxidation of methyl linoleate initiated by peroxyl radicals derived from thermolysis of 2,2′-azobis(2,4-dimethylvaleronitrile) in acetonitrile. TQH_2 oxidation yielded α-tocopherolquinone (TQ) as a major product and 2,3-epoxy-α-tocopherolquinone and 5,6-epoxy-α-tocopherolquinone as minor products. Each TQH_2 consumed approximately two peroxyl radicals in the course of the oxidation. The data suggest that TQH_2 scavenges peroxyl radicals primarily by electron transfer to form TQ and secondarily by addition-elimination to form the epoxyquinones.

Paper no. L8493 in *Lipids 35*, 1045–1047 (September 2000).

Antioxidant reactions of α-tocopherol (vitamin E: TH) with peroxyl radicals generate 8a-substituted tocopherones and epoxytocopherones as initial products. The former hydrolyze to α-tocopherolquinone (TQ), which also is a product of TH oxidation by several other types of oxidants. Several reports indicate that TQ is present in tissues, although the reported levels vary (1–9). Previous work in our laboratory suggested that much of the TQ formed in tissues is present as the two-electron reduction product α-tocopherolhydroquinone (TQH_2) (10). Although TQH_2 is at the same oxidation state as TH, it is a hydroquinone rather than a chroman-6-ol. Nevertheless, TQH_2 would be expected to display antioxidant properties similar to TH and structurally analogous ubiquinols.

An interesting recent finding is that TQ undergoes reduction by NAD(P)H:quinone oxidoreductase (DT-diaphorase) to yield TQH_2 (11). Cells expressing the enzyme and supplemented with TQ displayed increased resistance to oxidant challenges, and this protection paralleled the reduction of TQ to TQH_2. Thus, TQH_2 may contribute to biological antioxidant protection by exerting direct antioxidant effects in cells. To further explore the potential role of TQH_2 as a cellular antioxidant, we have studied the antioxidant reactions of TQH_2 in chemically defined solution systems. Here we report that TQH_2 reacts with peroxyl radicals to generate TQ as the principal reaction product. Identification of epoxyquinone reaction products indicates that competing reactions also occur.

EXPERIMENTAL PROCEDURES

Reagents. TQH_2 was synthesized by $NaBH_4$ reduction of TQ as described previously (12). TQH_2 was prepared fresh immediately prior to each experiment. Preparation of TQ, 5,6-epoxy-α-tocopherolquinone (TQE_1), and 2,3-epoxy-α-tocopherolquinone (TQE_2) was done as described previously (10). The compound 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN) was obtained from Polysciences, Inc. (Warrington, PA). Methyl linoleate was from Nu-Chek-Prep, Inc. (Elysian, MN).

Kinetics of TQH_2 and methyl linoleate oxidation. Reactions contained 200 μmol methyl linoleate, 0.4 μmol TQH_2, and 20 μmol AMVN in 3 mL acetonitrile at 50°C. Aliquots (10 μL) were taken at 2-min intervals, diluted with 1 mL acetonitrile, and analyzed by ultraviolet (UV)-visible spectroscopy. Methyl linoleate oxidation was monitored by the appearance of conjugated dienes at 235 nm. TQH_2 and TQ were monitored by absorbances at 292 and 268 nm, respectively. The stoichiometry of AMVN-initiated TQH_2 oxidation by peroxyl radicals in acetonitrile was measured by the inhibited autoxidation method of Boozer *et al.* (13), as modified in our laboratory (14). Butylated hydroxytoluene (4-methyl-2,6-di-*tert*-butylphenol) was used as an antioxidant standard with an assigned stoichiometry value *n* of 2.0.

Analysis of TQH_2 oxidation products. Products of TQH_2 oxidation were analyzed by gas chromatography–mass spectrometry (GC–MS) as trimethylsilyl ethers following extraction and derivatization as previously described (10).

RESULTS AND DISCUSSION

Peroxyl radical-dependent oxidation of TQH_2 in homogeneous acetonitrile solution at 50°C was initiated with the azo initiator AMVN, which produces peroxyl radicals by thermolysis and oxygen addition . Oxidation of TQH_2 by AMVN-derived peroxyl radicals resulted in near-quantitative conversion of TQH_2 to TQ, as assessed by UV spectroscopic analysis of the reaction mixtures. TQ displays distinctive doublet absorbance maxima at 262 and 268 nm, whereas TQH_2 dis-

Abbreviations: AMVN, 2,2′-azobis(2,4-dimethyvaleronitrile); GC–MS, gas chromatography–mass spectrometry; TH, α-tocopherol; TQ, α-tocopherolquinone; TQE_1, 5,6-epoxy-α-tocopherol-quinone; TQE_2, 2,3-epoxy-α-tocopherolquinone; TQH_2, α-tocopherolhydroquinone; UV, ultraviolet.

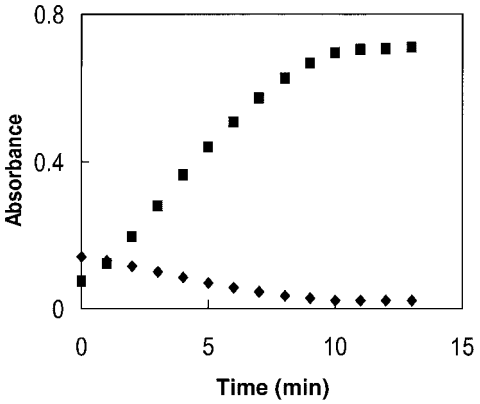

FIG. 1. Time course of 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN)-initiated α-tocopherolhydroquinone (TQH_2) disappearance (292 nm, ◆) and α-tocopherolquinone (TQ) appearance (268 nm, ■) in acetonitrile at 50°C.

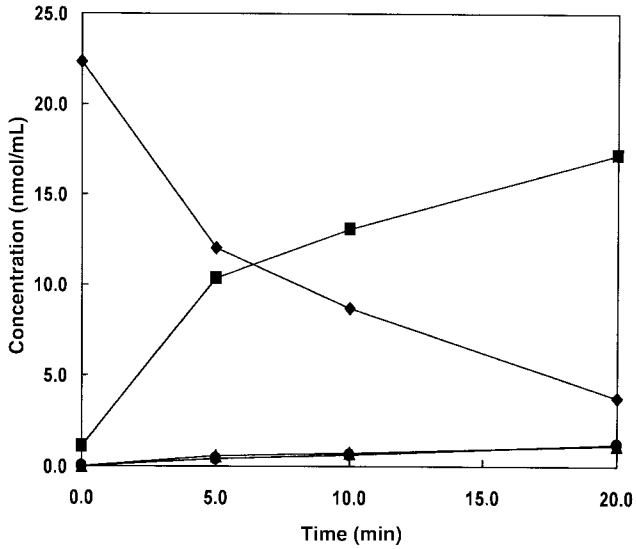

FIG. 2. Time course of TQH_2 (◆), TQ (■), 5,6-epoxy-α-tocopherolquinone (●), and 2,3-epoxy-α-tocopherolquinone (▲) in AMVN-initiated oxidation containing methyl linoleate (67 mM) and TQH_2 (0.13 mM). Products were analyzed by gas chromatography–mass spectrometry with selected ion monitoring. See Figure 1 for abbreviation.

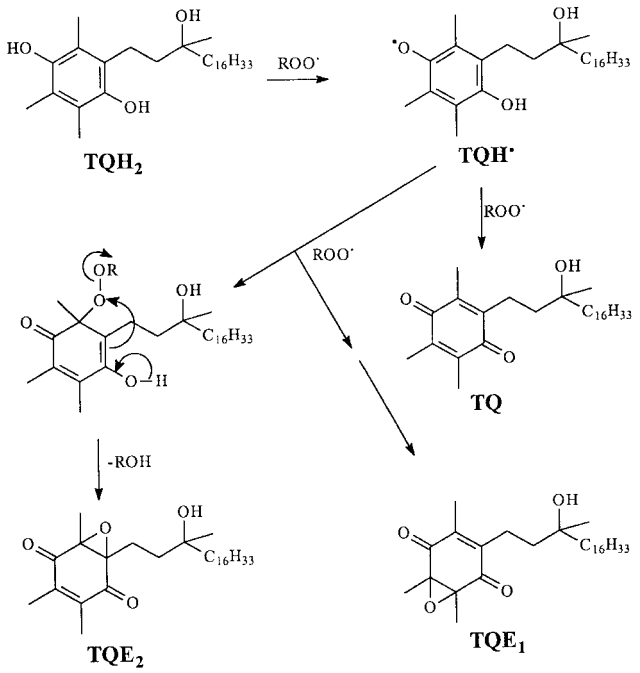
plays a less intense absorbance maximum at 292 nm. Upon AMVN-initiated oxidation, absorbance for TQH_2 at 292 nm rapidly declined and absorbance of TQ at 268 nm concomitantly increased (Fig. 1).

TQH_2 inhibited AMVN-initiated methyl linoleate oxidation in acetonitrile at 50°C. By using the inhibited autoxidation method, a rate of chain initiation R_i of 0.0082 ± 0.0001 mM min^{-1} was measured and a stoichiometric factor n of 1.933 ± 0.223 ($n = 4$) was calculated for TQH_2, indicating that two peroxyl radicals are scavenged for each molecule of TQH_2 oxidized. GC–MS analysis of the reaction mixture indicated that TQ and TQH_2 were the principal species present throughout the reaction and that TQ was converted almost entirely to TQH_2 (Fig. 2). In GC–MS analyses, formation of small amounts of the epoxyquinones TQE_1 and TQE_2 were detected (Fig. 2). Quantitation of $TQE_{1/2}$ formation based on selected ion monitoring with stable isotope-labeled internal standards indicated that at 20 min of oxidation, TQ, TQE_1, and TQE_2 accounted for 87, 6, and 6%, respectively, of the TQH_2 oxidized.

Our data indicate that TQH_2 acts as a chain-breaking antioxidant with efficiency similar to that of TH, when measured by antioxidant stoichiometry. This result is consistent with previous reports that TQH_2 acts as an antioxidant in liposomes and submitochondrial particles (12), in low density lipoprotein (16), and in intact cells (11). The antioxidant stoichiometry for radical scavenging measured in our studies is approximately 10-fold above that measured by Shi *et al.* (17). The difference in the measured values evidently was attributable to the different conditions under which the measurements were made. Shi *et al.* employed a lower concentration of the AMVN initiator and conducted the reaction at a lower temperature. Both differences are expected to reduce the rate of generation of peroxyl radicals from AMVN and to reduce the efficiency of the reaction of the semiquinone intermediate $TQH^{\cdot}$ with peroxyl radicals. As demonstrated previously (16,17), oxidation of this semiquinone by oxygen to produce TQ and superoxide appears to be a facile reaction. Another possible reaction in this system is the dismutation of two $TQH^{\cdot}$ semiquinone radicals to TQ and TQH_2. This would appear not to be a significant reaction in our experiments, as it would have reduced the measured antioxidant stoichiometry to values below two. However, as with redox cycling of the semiquinone, dismutation would be disfavored under conditions where rapid generation of AMVN-derived peroxyl radicals efficiently trapped the semiquinone. These considerations underscore the importance of competing autoxidation and radical-trapping reactions to the antioxidant action of TQH_2.

Our data indicate that the principal reaction of TQH_2 with peroxyl radicals probably proceeds either by electron transfer/deprotonation or by hydrogen abstraction to form TQ (Scheme 1). (For clarity, only the mechanism of formation TQE_2 is depicted in detail. The formation of TQE_1 would proceed by an analogous mechanism.) However, the formation of $TQE_{1/2}$ suggests that a radical addition/elimination reaction also occurs. In this mechanism, a peroxyl radical adds to the hydroquinone and the unstable peroxide adduct rearranges to the epoxyquinone with concomitant elimination of an alcohol (Scheme 1). This addition/elimination mechanism also has been invoked to explain the formation of β-carotene epoxides in peroxyl radical oxidations (18). The addition/elimination mechanism results in the same net consumption of radicals as the TQ-forming pathway (i.e., two peroxyl radicals trapped for each epoxyquinone formed from TQH_2) and thus is also consistent with the measured antioxidant stoichiometry of TQH_2. One interesting aspect of epoxyquinone formation is that TQE_1 and TQE_2 are formed in equal amounts by TQH_2 oxidation, in contrast to the yields of these epoxides in TH oxidations, where TQE_2 usually is formed in a twofold excess over TQE_1 (14,19–21). This probably reflects the relative ease of attack of peroxyl radicals at either C-2 or C-6 of the TQH_2 ring, in contrast to the apparent preference for attack at C-5 over C-7 in



SCHEME 1

TH (C-5 and C-7 in TH are equivalent to C-2 and C-6, respectively, in TQH_2) (22).

In summary, our data indicate that TQH_2 scavenges peroxyl radicals primarily by an electron transfer mechanism that yields TQ as the major product. TQH_2 thus could contribute to antioxidant protection in biological membranes and lipoproteins. Interestingly, Neuzil *et al.* (16) demonstrated that TQH_2 contributed to antioxidant protection of low density lipoprotein by reducing tocopheroxyl radicals formed by oxidation of TH. This suggests that TQH_2 may contribute to antioxidant protection both by directly scavenging peroxyl radicals and by driving redox cycles of TH. Further work to explore these relationships is ongoing in our laboratory.

Biotransformation of Linoleic Acid by *Clavibacter* sp. ALA2: Heterocyclic and Heterobicyclic Fatty Acids

Harold W. Gardner[a], Ching T. Hou[b,*], David Weisleder[c], and Wanda Brown[b]

[a]Bioactive Agents Research, [b]Oil Chemical Research, and [c]Analytical Chemical Services, National Center for Agricultural Utilization Research, ARS, USDA, Peoria, Illinois 61604

ABSTRACT: *Clavibacter* sp. ALA2 transformed linoleic acid into a variety of oxylipins. In previous work, three novel fatty acids were identified, (9*Z*)-12,13,17-trihydroxy-9-octadecenoic acid and two tetrahydrofuran-(di)hydroxy fatty acids. In this report, we confirm the structures of the tetrahydrofuran-(di)hydroxy fatty acids by nuclear magnetic resonance as (9*Z*)-12-hydroxy-13,16-epoxy-9-octadecenoic acid and (9*Z*)-7,12-dihydroxy-13,16-epoxy-9-octadecenoic acid. Three other products of the biotransformation were identified as novel heterobicyclic fatty acids, (9*Z*)-12,17;13,17-diepoxy-9-octadecenoic acid, (9*Z*)-7-hydroxy-12,17;13,17-diepoxy-9-octadecenoic acid, and (9*Z*)-12,17;13,17-diepoxy-16-hydroxy-9-octadecenoic acid. Thus, *Clavibacter* ALA2 effectively oxidized linoleic acid at C-7, -12, -13, -16, and/or -17.

Paper no. L8514 in *Lipids 35*, 1055–1060 (October 2000).

In previous work (1) biotransformation of linoleic acid by *Clavibacter* sp. ALA2 produced a number of products, among which (9*Z*)-12,13,17-trihydroxy-9-octadecenoic acid (**7**) was the predominant metabolite. Among the other metabolites, two tetrahydrofuran fatty acids were identified by gas chromatography–mass spectrometry (GC–MS), microchemical techniques, and preliminary nuclear magnetic resonance (NMR) data (2). In this report, these latter tetrahydrofuran fatty acids are fully confirmed by complete ^{1}H NMR and ^{13}C NMR analyses. In addition, two other unknowns, "unknown 3" and "unknown 5" (2), were isolated and identified as heterobicyclic fatty acids, (9*Z*)-12,17;13,17-diepoxy-9-octadecenoic acid (**1**) and (9*Z*)-12,17;13,17-diepoxy-7-hydroxy-9-octadecenoic acid (**4**), respectively. In addition, a positional isomer of **4** was identified, (9*Z*)-12,17;13,17-diepoxy-16-hydroxy-9-octadecenoic acid (**6**).

Abbreviations: ANS, Na 8-anilino-1-napthalenesulfonate; CS, chemical shift; EI–MS, electron impact–mass spectrum; GC, gas chromatography; GC–MS, gas chromatography–mass spectrometry; HPLC, high-performance liquid chromatography; NMR, nuclear magnetic resonance; OTMSi, trimethylsilyloxy ether; RT, retention time; TLC, thin-layer chromatography; UV, ultraviolet.

MATERIALS AND METHODS

Production and purification of products. The bioconversion of linoleic acid by *Clavibacter* sp. ALA2, separation of the products fatty acids into fractions by high-performance liquid chromatography (HPLC), and preparation of chemical derivatives were described previously (2). Incubation of 0.22 g linoleic acid/50 mL for 4–5 d afforded about a 60% yield of products. Thin-layer chromatography (TLC) of HPLC-fractionated products as their methyl ester derivatives was completed with Silica Gel 60 F_{254} plates (20 × 20 × 250 μm, Merck, Darmstadt, Germany), and detection of compounds was done with a nondestructive spray reagent, 0.1% aqueous 8-anilino-1-naphthalenesulfonic acid (ANS) (Eastman Kodak, Rochester, NY) as sodium salt, followed by viewing under long-wave ultraviolet (UV). TLC developing solvents were: solvent A, hexane/diethyl ether (1:1, vol/vol); solvent B, hexane/ethyl acetate (6:4, vol/vol); solvent C, hexane/diethyl ether (9:1, vol/vol); and solvent D, ethyl acetate/hexane (6:4, vol/vol). TLC bands were scraped with a razor blade and recovered by ethyl acetate elution.

Spectral and microchemical methods. GC–MS of methyl esters or methyl esters/trimethylsilyloxy ethers (OTMSi) was completed as described previously (3). Fatty esters oxidatively cleaved by $KMnO_4$/acetic acid were separated by the same GC–MS system described (3), except the temperature programming was modified to 65°C to 260°C at 10°C/min in order to accommodate the short-chain esters . Less than obvious mass spectral fragment ions were analyzed by Xcalibur HighChem Mass Frontier Software from Finnigan Corporation (San Jose, CA). NMR spectra were obtained with a Bruker model ARX-400 spectrometer (Billerica, MA) equipped with a 5 mm $^{13}C/^{1}H$ dual probe (^{1}H NMR, 400 MHz; ^{13}C NMR, 100 MHz). NMR spectra were recorded with $CDCl_3$ as internal standard and solvent. Chemical shifts of the carbons were determined by heteronuclear multiple quantum correlation spectroscopy.

Fatty acids were methyl esterified for 30 s with diazomethane in diethyl ether/methanol (9:1, vol/vol). Hydroxyls were converted into OTMSi derivatives for 30 min with trimethylchlorosilane (Applied Sciences, State College, PA)/hexamethyldisilazane (Sigma, St Louis, MO)/anhydrous pyridine (3:2:2, vol/vol/vol), followed by evaporation of the

reagent with a stream of nitrogen and solvation in hexane. Methyl esterified samples were hydrogenated by stirring in 2 mL methanol under a hydrogen atmosphere with 20 mg 5% palladium on calcium carbonate catalyst (Aldrich, Milwaukee, WI). Double bonds were oxidatively cleaved with 12 mg $KMnO_4$ in 0.3 mL acetic acid at 37°C for 1 h (4).

RESULTS AND DISCUSSION

Biotransformation products of linoleic acid. Fatty acid products were separated by HPLC as described previously (2). The HPLC fractions were methyl esterified with diazomethane, and the unknown fractions previously separated by HPLC (2) were further purified and identified in this communication. A representative total product mixture analyzed by GC–MS is shown in Figure 1. Relative amounts of products varied somewhat depending on culture conditions. For structures of *Clavibacter* sp. ALA2 oxylipins derived from linoleic acid see Scheme 1.

*(9Z)-12,17;13,17-Diepoxy-9-octadecenoic acid (**1**).* The fatty acid methyl ester previously referred to as "unknown 3" [see Fig. 1 in Hou *et al.* (2)] was analyzed by GC–MS showing that it was largely one component, but included four minor impurities ranging in amounts of 1–4%, compared to the main component. Methyl esterified HPLC fraction isolated as described previously (2) containing **1** (16 mg) was purified by TLC developing with solvent A. From the main band, detected by ANS spray (R_f = 0.72), 5.4 mg was recovered. GC–MS showed that this component was one peak [15.1 min retention time (RT)] (**1**, methyl ester). This methyl ester afforded the following electron impact-mass spectrum (EI-MS) *m/z* (relative intensity): 324 $[M]^+$ (0.1), 293 $[M - CH_3O]^+$ (0.8), 282 $[M - CH_2CO]^+$ (1), 165 (0.8), 150 (1), 127 [ether bicyclic ring, $M - CH_2CH{=}CH(CH_2)_7COOCH_3]^+$ (100), 99 (8), 85 (6), 81 (13), 67 (9), 55 (10). Treatment of **1** (methyl ester) with either 15 mg of $NaBH_4$/0.5 mL methanol or OTMSi reagent resulted in no change in the GC–MS profile; therefore, this fatty acid possessed neither aldehyde, ketone, nor hydroxyl moiety.

Fatty acid (methyl ester) **1** was hydrogenated, and this product had a slightly longer retention time by gas chromatography (GC) and a mass spectrum with more intense fragment ions, also showing a gain in the molecular ion of two hydrogens (EI–MS) *m/z* (relative intensity): 326 $[M]^+$ (0.3), 308 $[M - H_2O]^+$ (0.7), 295 $[M - CH_3O]^+$ (9), 284 $[M - CH_2CO]^+$ (34), 283 $[M - CH_3CO]^+$ (21), 277 $[M - CH_3O - H_2O]^+$ (5), 266 (4), 255 (16), 242 (34), 227 (13), 223 (20), 195 (18), 185 (11), 184 (12), 152 (26), 127 [ether bicyclic ring, $M - CH_2CH{=}CH(CH_2)_7COOCH_3]^+$ (20), 112 (32), 98 (93), 81 (56), 74 (31), 69 (42), 67 (50), 55 (100). This confirmed the presence of one double bond.

A portion of **1** (methyl ester, 0.1 mg) was oxidatively

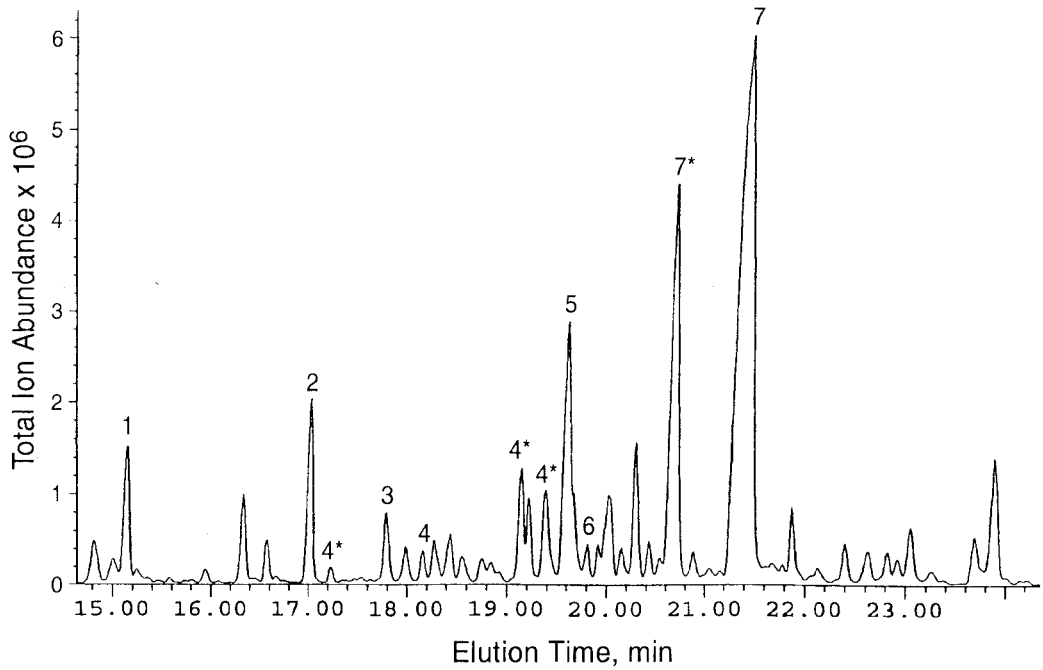

FIG. 1. GC–MS of a total mixture of products [as methyl esters/trimethylsilyloxy (OTMSi) ethers] from bioconversion of linoleic acid by *Clavibacter* ALA2. Peak numbering corresponds to the numbered identity of the isolated fatty acids (see Scheme 1). Numbers with asterisks identify possible isomers that possessed mass spectra very similar to the isomer identified in this study (plain number). Not shown is unconverted linoleic acid (methyl ester) eluting at a retention time of 12.3 min amounting to 26% (total ionization) of all peaks analyzed. Culture conditions were as described previously (2), except for some modifications to the culture medium. Culture medium (per L): dextrose, 5 g; K_2HPO_4, 5 g; yeast extract, 5 g; soybean flour, 5 g; $MgSO_4{\cdot}7H_2O$, 0.5 g; $FeSO_4{\cdot}7H_2O$, 0.5 g; $ZnSO_4$, 0.014 g; $MnSO_4{\cdot}H_2O$, 0.008 g; and nicotinic acid, 0.01 g. The medium was adjusted to pH 6.8 with dilute phosphoric acid. Linoleic acid (0.22 g) was incubated with 50 mL culture medium.

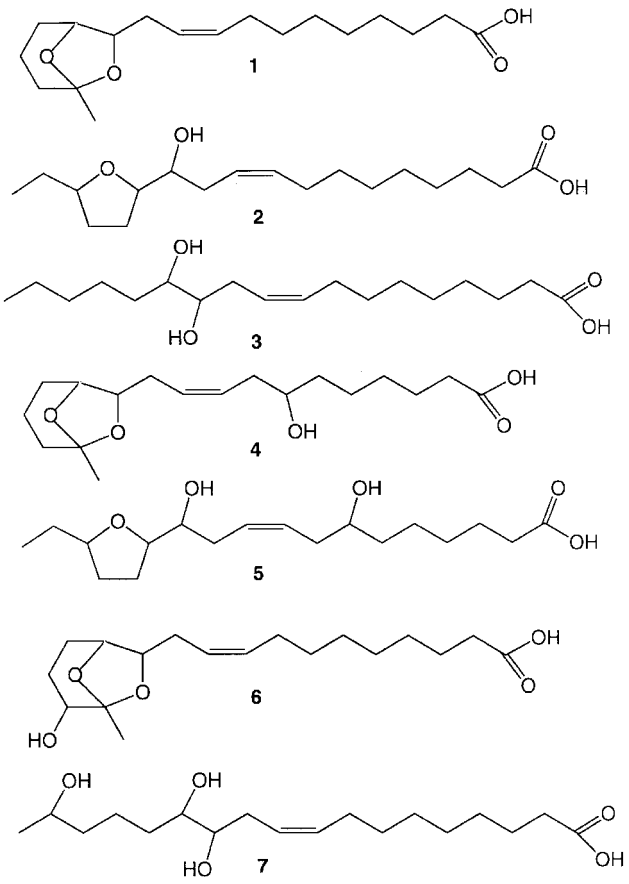

SCHEME 1

cleaved with $KMnO_4$/acetic acid, and reesterified with diazomethane. GC–MS of the oxidation mixture afforded two major peaks. The first at 9.2 min RT gave a mass spectrum that was consistent with methyl 3,8;4,8-diepoxy-nonanoate (EI–MS) *m/z* (relative intensity): 200 $[M]^+$ (0.7), 169 $[M - OCH_3]^+$ (11), 158 $[M - CH_2CO]^+$ (65), 157 $[M - CH_3CO]^+$ (27), 141 $[M - COOCH_3]^+$ (15), 130 (20), 129 (100), 127 [ether bicylic ring, $M - CH_2COOCH_3]^+$ (11), 116 (13), 98 (56), 81 (14), 74 (8), 71 (10), 70 (11), 59 (11), 55 (18), 43 $[CH_3CO]^+$ (93). The second GC peak at 11.9 min was identical to standard dimethyl nonanedioate. Therefore, a double bond is located at C-9,10.

^1H and ^{13}C NMR of **1** suggested that the compound was a heterobicyclic fatty acid (Tables 1 and 2). The singlet multiplicity of the terminal methyl showed that there was no coupling with C-17, and the chemical shift of C-17 by ^{13}C NMR was consistent with its diether functionality. The ^{13}C resonance assignment for the C-15 methylene of **1** at the unusual chemical shift of δ17.1 is consistent with a heterobicyclic structure based on the predicted chemical shift of δ16.0 assigned to C-15 in the ^{13}C NMR shift prediction module of ChemIntosh (Bio-Rad, Richmond, CA). The introduction of a hydroxyl group at C-16 in (9*Z*)-12,17;13,17-diepoxy-16-hydroxy-9-octadecenoic acid (see below) causes a downfield shift of the C-15 methylene to δ25.5, verifying the initial assignment. The H-12 resonance is a triplet because of coupling to the freely rotating H-11 protons. Coupling between H-12 and H-13 is not observed, indicating that the configuration of the ethers between C-12 and -13 was *threo*. The *threo* configuration causes the dihedral angle of the protons to be 90 degrees with the preferred chair-form of the six-membered ring giving the lack of coupling. The *threo* configuration was consistent with that found for the dihydroxyls at C-12 and -13 for a product discussed later, 12,13-dihydroxy-9-octadecenoic acid. The H-13 resonance appears as a broad singlet. The dihedral angle for H-13 and either of the H-14 protons is about 60 degrees, resulting in small unresolved splittings of the H-13 signal. The coupling constant for C-9,10 of 10.9 Hz was consistent with (*Z*)-double bond geometry.

*(9Z)-13,16-Epoxy-12-hydroxy-9-octadecenoic acid (**2**).* Fatty acid **2**, previously identified as "unknown 4" [see Fig. 1 in Hou *et al.* (2)], was structurally characterized by GC–MS and microchemical methods, including preliminary ^1H NMR data indicating a terminal ethyl group (2).

Further work with this fraction by GC–MS of its OTMSi derivative showed that it was a mixture containing about 50% of the compound previously identified as "unknown 4." This fraction (as methyl ester) was further purified by TLC using development by solvent A, affording 5.0 mg of **2** (R_f = 0.50). GC–MS indicated that the recovered material was a single component [see Hou *et al.* (2) for additional structural proof of **2**, including mass spectral data of **2** and its derivatives]. Isolate **2** was analyzed by NMR. The structure of **2** (methyl ester) was confirmed by complete ^1H and ^{13}C NMR data (Tables 1 and 2). The double bond at C-9 was determined to be (9*Z*) because of the ^{13}C NMR chemical shift at C-8 of 27.3 δ (5).

*12,13-Dihydroxy-9-octadecenoic acid (**3**).* The methyl ester OTMSi derivative of **3** was tentatively identified by an excellent comparison of its mass spectrum and GC RT (17.82 min) with the identical compound obtained by soybean epoxide hydrolase action on vernolic acid [(12*S*,13*R*,9*Z*)-12,13-epoxy-9-octadecenoic acid from Sigma, St Louis, MO]. It is known that *cis*-epoxides are hydrolyzed by epoxide hydrolase into *threo*-dihydroxyls (6). On the other hand, $NaBH_4$ reduction of the α-ketol obtained from allene oxide synthase action on the 13-hydroperoxide of linoleic acid gave two separable isomers of (9*Z*)-12,13-dihydroxy-9-octadecenoic acid (as methyl ester/OTMSi derivative) composed of *erythro* and *threo* diols at retention times of 17.82 and 18.05 min (7). Therefore, the isomer detected in the *Clavibacter* product was the *threo*-12,13-dihydroxy; that is, either (12*R*,13*R*) or (12*S*,13*S*).

*(9Z)-12,17;13,17-Diepoxy-7-hydroxy-9-octadecenoic acid (**4**), and (9Z)-12,17;13,17-diepoxy-16-hydroxy-9-octadecenoic acid (**6**).* The fatty acid methyl ester referred to as "unknown 5" [see Fig. 1 in Hou *et al.* (2)] was analyzed by GC–MS as its methyl ester or methyl ester/OTMSi ether showing that it was a mixture. Analysis of the mass spectra indicated that most of the GC peaks were isomers of two principal compounds; a number of other minor compounds were found with unrelated mass spectra. A portion of this HPLC

[b]Fatty esters 4 and 6 were analyzed as their trimethylsilyloxyethers (OTMSi). NMR, nuclear magnetic resonance.

fraction, as methyl esters, was purified by TLC using solvent B. The main band at $R_f = 0.37$ (15 mg) was found by GC–MS to be a mixture of two different fatty acids, which subsequently were identified as **4** (methyl ester) and the other as the methyl ester of **6**. A second band at $R_f = 0.47$ (7.5 mg) was shown by GC–MS to be one major and three minor peaks having mass spectra consistent with **4** (methyl ester/OTMSi ether). As shown in Figure 1, there are a number of peaks identified as **4*** that gave mass spectra similar to **4** (methyl ester/OTMSi ether). The third band at $R_f = 0.53$ (1.7 mg) was unrelated material that comprised two main peaks and a few minor ones as assessed by GC–MS.

The main TLC band described above ($R_f = 0.37$), comprising two main components, was selected for further separation, but it was determined that the two could not be separated by conventional TLC. However, it was found that the two compounds could be readily separated by "chemical chromatography" (3). A portion of this TLC fraction (4.5 mg) was silylated and the OTMSi derivative was separated by TLC using three-fold development with solvent C. Two main bands at $R_f = 0.20$ and 0.26 were isolated. As assessed by GC–MS, the band at $R_f = 0.20$ (1.7 mg) was the OTMSi ether/methyl ester of **4** with a very minor satellite peak indicative of conversion of a OTMSi group into hydroxyl. The ^{1}H NMR data are listed in Table 1; interpretation of the data for H-12, H-13 is the same as described for fatty ester **1**; that is, a *threo* configuration of the ethers at C-12 and -13. The mass spectrum of **4** (methyl ester/OTMSi ether) was indicative of its structure (EI–MS) *m/z* (relative intensity): 397 [M – CH_3]$^+$ (0.1), 381 [M – CH_3O]$^+$ (0.9), 283 [M – $(CH_2)_5COOCH_3$]$^+$ (1), 231 [CHOTMSi$(CH_2)_5COOCH_3$]$^+$

[a]Chemical shifts marked by *, **, *** or **** are interchangeable.
[b]Fatty esters **4** and **6** were analyzed as their OTMSi ethers.
[c]Hydrogenated sample. See Table 1 for abbreviations.

(100), 199 (11), 171 (11), 155 (6), 133 (8), 127 [ether bicyclic ring, M – $CH_2CH{=}CHCH_2CHOTMSi(CH_2)_5COOCH_3]^+$ (89), 113 (11), 99 (11), 81 (57), 73 $[TMSi]^+$ (81), 55 (16).

As described above, the band obtained by "chemical chromatography" at R_f = 0.26 (0.5 mg) was found by GC–MS to be one component identified as **6** (methyl ester/OTMSi ether, see NMR data, Tables 1 and 2). Interpretation of the H-12 and H-13 resonance indicates a *threo* configuration as described for **1** and **4** (methyl ester). The mass spectrum of **6** (methyl ester/OTMSi ether) gave useful marker ions for determining molecular weight, but many of the fragment ions were difficult to interpret. Thus, Xcalibur software from Finnigan was used to interpret some of the ions affording diagnostic fragments, some of which located the hydroxyl at C-16. The data is given as follows (EI–MS) *m/z* (relative intensity): 412 $[M]^+$ (0.1), 381 $[M - CH_3O]^+$ (0.3), 379 $[M - H_2O - CH_3]^+$ (0.4), 352 $[TMSiOCH{\cdot}(CH_2)_2CH^+CH{=}CHCH{=}CH(CH_2)_7\text{-}COOCH_3]$ (8), 309 (2), 291 (2), 262 (4), 236 $[{\cdot}CH_2CH^+CH{=}CHCH{=}CH(CH_2)_7COOCH_3]$ (41), 215 [ether bicyclic ring containing one OTMSi group, M – $CH_2CH{=}CH(CH_2)_7\text{-}COOCH_3]^+$ (14), 195 (8), 181 (16), 168 (11), 155 (44), 143 (33), 116 $[{\cdot}CH_2CH{=}O^+TMSi]$ (100), 101 $[CH_2{=}CHO^+{=}Si(CH_3)_2]$ (76), 73 $[TMSi]^+$ (86), 55 (26). A mass spectrum of **6** (methyl ester) afforded some diagnostic ions as follows (numerous ions of lower *m/z* are not listed) (EI-MS) *m/z* (relative intensity): 309 $[M - CH_3O]^+$ (3), 291 $[M - CH_3O - H_2O]^+$ (3), 280 $[O{=}CH(CH_2)_2CH{\cdot}CH^+CH_2CH{=}\ CH(CH_2)_7\text{-}COOCH_3]$ (3), 262 (12), 248 (14), 236 $[{\cdot}CH_2\text{-}CH^+CH{=}\ CHCH{=}CH(CH_2)_7\ COOCH_3]$ (43), 143 [hydroxylated ether bicyclic ring, M – $CH_2CH{=}CH(CH_2)_7COOCH_3]^+$ (62). A third minor TLC band at R_f = 0.32 (0.2 mg) was isomeric **6** (methyl ester/OTMSi ether) with a slightly smaller retention time compared to the former; this fraction was not characterized further.

Another portion (9.2 mg) of the main band (R_f = 0.37 containing mixed methyl esters of **4** and **6**) was hydrogenated, and the same "chemical chromatography" procedure described in the preceding paragraphs was completed. TLC of the methyl ester/OTMSi ether using twofold development with solvent C afforded 5.6 mg hydrogenated **4** (methyl ester/OTMSi ether; R_f = 0.22), 1.8 mg hydrogenated **6** (methyl ester/OTMSi ether; R_f = 0.30), and 0.5 mg of another isomer of hydrogenated **6** (methyl ester/OTMSi ether; R_f = 0.35) with a slightly smaller GC RT. The mass spectrum of hydrogenated **4** (methyl ester/OTMSi ether) showed there was a gain of two hydrogens (i.e., one double bond) as follows (EI–MS) *m/z* (relative intensity): 399 $[M - CH_3]^+$ (0.1), 383 $[M - CH_3O]^+$ (1), 324 $[M - TMSiOH]^+$ (0.6), 285 $[M - (CH_2)_5COOCH_3]^+$ (3), 282 (11), 264 (7), 253 (4), 231 $[CHOTMSi(CH_2)_5COOCH_3]^+$ (67), 195 $[285 - TMSiOH]^+$ (45), 171 (9), 159 (12), 149 (34), 127 (25), 98 (32), 81 (54), 73 $[TMSi]^+$ (100), 67 (25), 55 (33). The ^{13}C NMR data for hydrogenated **4** (methyl ester) is shown in Table 2. As described for **1**, the chemical shift of C-17 at δ107.7 in **4** was indicative of diether carbon. The unusual methylene chemical shift of C-15 at δ17.1 is consistent with the heterobicyclic structure as explained previously for **1**.

The mass spectrum of the principal isomer of hydrogenated **6** (methyl ester/OTMSi ether) gave useful ions suggesting its molecular weight (an increase of two indicating one double bond) and the position of the 16-hydroxyl as follows (EI-MS) *m/z* (relative intensity): 414 $[M]^+$ (0.3), 381 $[M - CH_3 - H_2O]^+$ (0.4), 354 $[TMSiOCH{\cdot}(CH_2)_2CH^+CH{=}CH(CH_2)_9COOCH_3]$ (11), 311 (5), 293 (3), 264 (3), 250 (2), 207 (2), 169 (6), 155 (33), 143 (29), 133 (28), 116 $[{\cdot}CH_2CH{=}O^+TMSi]$ (100), 101 $[CH_2{=}CHO^+{=}Si(CH_3)_2]$ (70), 73 $[TMSi]^+$ (59), 55 (23). Both ^1H NMR and ^{13}C NMR of hydrogenated **4** and **6** (methyl ester/OTMSi ether) decisively showed that one double bond in each compound was saturated.

In the data given above it can be seen that **4** and **6** both have at least one hydroxyl group from the observation that both compounds were derivatized as OTMSi ethers. The unsilylated compounds both had an apparent molecular weight of 340 from observation of *m/z* 309 $[M - CH_3O]^+$, which is the theoretical *m/z* 72 less than that of corresponding ions of the mono-silylated derivatives. A coupling constant of 10.9 Hz (Table 1) showed that the double bond was (*Z*) for both **4** and **6**.

To demonstrate the position of the double bond, the methyl ester/OTMSi of **4** was oxidatively cleaved with $KMnO_4$ and then derivatized with diazomethane and silylating reagent. Five cleavage products were found for **4**. The earliest eluting peak was identical to the $KMnO_4$ oxidation fragment obtained from **1**; that is, a spectrum suggesting methyl 3,8;4,8-diepoxy-nonanoate. The second and third peaks were relatively small; the former gave a mass spectrum consistent with dimethyl heptanedioate and the third was unknown. The mass spectrum of the fourth peak was consistent with dimethyl nonenedioate, possibly from hydroxyl elimination, and the fifth peak was very indicative of dimethyl 3-OTMSi-nonanedioate as follows (EI–MS) *m/z* (relative intensity): 289 $[M - CH_3]^+$ (22), 273 $[M - CH_3O]^+$ (1), 257 $[M - CH_3O - CH_3]^+$ (12), 231 $[M - CH_2COOCH_3]^+$ (12), 225 (10), 215 (16), 202 (9), 183 (45), 175 $[CHOTMSiCH_2COOCH_3]^+$ (62), 159 (38), 155 (34), 151 (49), 133 (46), 123 (19), 105 (17), 89 (84), 73 (100), 59 (32), 55 (23). Together these data were very suggestive of a 9,10-double bond.

$KMnO_4$ oxidation of **6** (methyl ester/OTMSi ether) afforded two main cleavage products after treating with diazomethane and silylating reagent. The first GC–MS peak was identical to standard dimethyl nonanedioate and the second peak was consistent with methyl 3,8;4,8-diepoxy-nonanoate additionally possessing one OTMSi group as follows (EI–MS) *m/z* (relative intensity): 273 $[M - CH_3]^+$ (12), 257 $[M - CH_3O]^+$ (2), 245 (4), 228 (14), 185 (10), 169 (8), 155 (34), 143 (32), 116 (82), 101 (100), 87 (10), 74 (18), 73 $[TMSi]^+$ (56), 59 (17), 55 (13). Therefore, these data indicate a 9,10-double bond.

*(9Z)-13,16-Epoxy-7,12-dihydroxy-9-octadecenoic acid (**5**).* Fatty acid **5** was previously identified as "unknown 6" [see Fig. 1 in Hou *et al.* (2)]. In the previous work, the structure was determined by GC–MS and microchemical methods. The terminal ethyl group was indicated by preliminary ^1H

NMR data; that is, triplet multiplicity of the C-18 methyl group (2).

From the HPLC fraction (2) **5** was isolated by TLC developing with solvent D (R_f = 0.32). GC–MS of its OTMSi derivative indicated that the recovered methyl ester (14 mg) was one component [see Hou *et al.* (2) for additional structural proof of **5**, including mass spectral data of **5** and its derivatives]. The structure of **5** (methyl ester) was confirmed by complete ^{1}H and ^{13}C NMR data (Tables 1 and 2). The ^{1}H NMR resonance pattern for the C-9 and -10 protons was very similar to that of **2**, so it was surmised that this olefin was also (9*Z*).

The fatty acids identified in this study and previous work (1,2) showed that *Clavibacter* ALA2 is especially efficient at oxidizing C-12, -13 and -17 with hydroxyl groups. To a lesser extent hydroxyls also occurred at C-7 and -16. It seems probable that these oxidations are catalyzed by cytochromes P450. Since fatty acid **3** was exclusively the *threo* isomer some stereospecificity of the oxidations at C-12 and -13 was indicated; however, we did not complete studies on absolute stereoconfiguration. Since all the fatty acids reported in this study have either an ether or hydroxyl functionality at C-12 and -13, it is a reasonable assumption that these products may also possess the *threo* configuration at these carbons. Although not proved, it would appear that conversion into heterocyclic and heterobicyclic fatty acids occurs as a subsequent step from precursor hydroxyl fatty acids, such as **7**. In regard to the heterobicyclic fatty acids, it would appear that oxidation of the 17-hydroxyl to a 17-ketone may precede cyclization. Incubation of **7** with *Clavibacter* ALA2 should resolve this question.

ABSTRACT: The eicosapentaenoic acid (EPA) synthesis gene cluster from an EPA-producing bacterium, *Shewanella* sp. SCRC-2738, was cloned into a broad-host range vector, pJRD215, and then introduced into a marine cyanobacterium, *Synechococcus* sp. NKBG15041c, by conjugation. The transconjugant cyanobacteria produced 3.7 ± 0.2% (2.24 ± 0.13 mg/L) EPA (n-3) and 2.5 ± 0.2% (1.49 ± 0.06 mg/L) eicosatetraenoic acid (n-3) of the total fatty acids when the cells were cultured at 23°C at a light intensity of 1,000–1,500 Lux. The EPA and eico-satetraenoic acid contents of the cells were increased to 4.6 ± 0.6% (3.86 ± 1.11 mg/L) and 4.7 ± 0.3% (3.86 ± 0.82 mg/L), and 7.5 ± 0.3% (1.76 ± 0.10 mg/L) and 5.1 ± 0.2% (1.19 ± 0.06 mg/L) when they were cultured at low temperature (18°C) and at lower light intensity (40 Lux), respectively.

Paper no. L8450 in *Lipids 35*, 1061–1064 (October 2000).

The n-3 group of polyunsaturated fatty acids (PUFA), in particular eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3) have received much attention for their importance in keeping the human circulation and nervous systems in a healthy condition (1,2). Moreover, these compounds are also essential nutrients to larval marine fish (3). At present, the main sources of dietary EPA are marine fish and algae such as *Porphyridium* and *Nannochloropsis* (4,5). Marine cyanobacteria like *Synechococcus* are widely distributed in the sea and have important roles as primary producers in the marine food chain. Utilization of these cyanobacteria for purposes of fish culture is convenient, because they are bioavailable as whole cells without any extraction. However, marine cyanobacteria do not produce EPA. Therefore, by introducing an EPA synthesis gene cluster to marine cyanobacteria, it is expected that they might be a valuable source of n-3 fatty acids for fish culture.

The EPA synthesis gene cluster [approximately 38 kb, composed of nine open reading frames (ORF) (Yamada, A., Yu, R., Watanabe, K., Yazawa, K., and Konda, K., unpublished data)] was isolated from a marine bacterium, *Shewanella* sp. SCRC-2738 (6,7). In previous work, we confirmed that a marine cyanobacterium, *Synechococcus* sp. NKBG042902, produced EPA after the introduction of an EPA synthesis gene cluster (8). However, plasmid pJRDEPA, including all nine ORF of this gene cluster, was unstable in the cells, and the total amount of EPA produced was low. In this paper, we demonstrate EPA production by a transgenic marine cyanobacterium, *Synechococcus* sp. NKBG15041c (9), carrying a plasmid containing the essential ORF for EPA synthesis and its enhancement under different growth conditions.

EXPERIMENTAL PROCEDURES

Strains and plasmids. A marine cyanobacterium, *Synechococcus* sp. NKBG15041c, isolated from a Japanese coastal area, was used as a host strain. It was cultured in BG11 medium (American Type Culture Collection catalog, medium no. 617) supplemented with 3% (wt/vol) NaCl (BG11-M) under aerobic conditions with continuous light at 23°C unless otherwise stated. *Escherichia coli* JM109 and S17-1 (10) were cultured under aerobic conditions in LB medium [10 g/L Bacto-tryptone 5 g/L Bacto-yeast extract, both from Difco (Detroit, MI) and 10 g/L NaCl] at 37 or 25°C. Cloning vector pBSIIKS(+) (Stratagene, La Jolla, CA) and broad-host range vector pJRD215 (10.2 kb, containing Km^r and Sm^r genes; 11) were used in this work. As the source of the EPA synthesis gene cluster, pEPA (46.6 kb; 7,8) was used. pEPA is a plasmid that is carrying an EPA synthesis gene cluster (GenBank accession number, U73935) isolated from *Shewanella* sp. SCRC-2738.

Construction of pJRDEPA-S. DNA constructs were produced using standard methods. Restriction enzymes were purchased from New England Biolabs (Beverly, MA) and Takara Shuzo (Kyoto, Japan). At first, the subcloning of essential ORF (2,5,6,7, and 8) for EPA production from pEPA was carried out. A 8,398 bp *Xba*I-*Spe*I fragment (23,045–31,443 bp, containing the 3′ end of ORF6, ORF7, and the 5′ end of ORF8), a 10,731 bp *Xba*I-*Xba*I fragment (12,314–23,045 bp, containing the 3′ end of ORF3, ORF4, 5 and the 5′ of ORF6), and a 1,071 bp *Spe*I-*Nhe*I fragment (31,443– 32,514 bp, containing the 3′ end

Abbreviations: EPA, eicosapentaenoic acid; GLC, gas–liquid chromatography; GC–MS, gas chromatography–mass spectrometry; ORF, open reading frame; PUFA, polyunsaturated fatty acid; TLC, thin-layer chromatography.

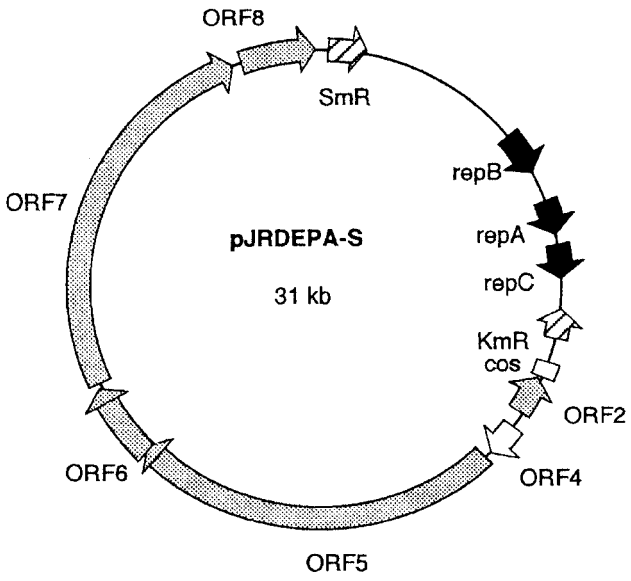
of ORF8) of the EPA synthesis gene cluster were cloned in order into the *Xba*I-*Spe*I, *Xba*I site, and *Spe*I sites of pBSIIKS(+), respectively. The resultant plasmid was named ΔX4XbNh/pBS. After digestion with *Not*I, ΔX4XbNh/pBS was treated with T4 DNA polymerase (Takara Shuzo) to make blunt ends, and then cut with *Xho*I to obtain fragment A. For ORF2, a fragment cut out from R/pSTV28 [a plasmid containing ORF2, 7,951–9,129 bp, in pSTV28 (Takara Shuzo, Kyoto, Japan)] with *Eco*RI and *Pst*I, was cloned into the *Eco*RI-*Pst*I site of pBSIIKS(+) to obtain R/pBS. After treatment with *Pst*I and T4 DNA polymerase, a *Xho*I linker was inserted into R/pBS. Then, fragment B was obtained from R/pBS by XhoI digestion. Fragments A and B were cloned into the *Xho*I-*Stu*I and *Xho*I sites of pJRD215 by *in vitro* packaging (PackageneR Lambda DNA Packaging System; Promega, Madison, WI) and by using a DNA ligation kit (Takara Shuzo), respectively. The final plasmid constructed was designated as pJRDEPA-S (Scheme 1).

Conjugal gene transfer to the cyanobacterium. Conjugal gene transfer to the cyanobacterium was carried out as previously reported (8) with some modifications. Cyanobacterial cells at the mid-growth phase were centrifuged, washed with BG11-M medium, and then resuspended in fresh medium. Freshly transformed *E. coli* S17-1 cells harboring pJRDEPA-S were collected from Luria broth plates containing 50 μg kanamycin/mL and 50 μg streptomycin/mL, and then suspended in BG11-M medium. Suspensions of cyanobacterial cells and *E. coli* cells were mixed in the cell number ratio of 1:10 (cyanobacterium/*E. coli*) and then spotted onto dried BG11 plates supplemented with 15 mM NaCl. After 48 h of incubation under light, the cells were collected from the plates with BG11-M medium, and then streaked on BG11-M plates containing 75 μg kanamycin/ mL to select cyanobacterial transconjugants.

Gas–liquid chromatography (GLC). Fatty acid methyl esters were prepared from the lyophilized cyanobacterial cells or *E. coli* cells by treatment with 5% methanolic hydrochloric acid (12). The fatty acid methyl esters, which were purified by using thin-layer chromatography (TLC), were analyzed by GLC. The analytical conditions were as previously reported (8), with minor modifications.

Fatty acid methyl esters prepared from *Shewanella* sp. SCRC-2738 that had been confirmed to contain EPA and 20:4n-3 (12) and EPA methyl ester (Sigma Chemical Co., St.Louis, MO) were used as standard samples. Heneicosanoic acid (21:0) was also used as an internal standard.

GC–mass spectrometry (GC–MS). PUFA methyl ester fractions were prepared from the fatty acid methyl esters by $AgNO_3$-TLC (12), and then subjected to GC–MS. The analytical conditions were previously reported (8) with minor modifications.



SCHEME 1

RESULTS AND DISCUSSION

Construction of a plasmid containing an EPA synthesis gene cluster and EPA production in E. coli. Functional analysis of each ORF in the EPA synthesis gene cluster isolated from SCRC-2738 indicated that five (ORF2, 5, 6, 7, and 8) of the nine ORF were required for EPA synthesis in *E. coli* (Yamada, A., Yu, R., Watanabe, K., Yazawa, K., and Kondo, K., unpublished data). In this experiment, after excluding noncoding regions present both upstream and downstream of the ORF, five essential ORF and one nonessential ORF (ORF4) for EPA synthesis were ligated into pJRD215. With this procedure, plasmid pJRDEPA-S (Scheme 1) is approximately 17 kb shorter than pJRDEPA. To determine the EPA productivity of pJRDEPA-S, it was transferred into *E. coli* JM109. The fatty acid methyl esters of the JM109 were analyzed with GLC and GC–MS. The EPA content in the total fatty acids reached 5.7%, i.e., more than that of pEPA (less than 4.5%; 7), although the copy number was lower in *E. coli* cells (data not shown). This suggested reduction in the size of the EPA synthesis gene cluster enhanced the EPA productivity.

EPA production by cyanobacterial cells. Fatty acid methyl esters prepared from the total wild type cyanobacterial cells and transconjugant cells harboring pJRDEPA-S were analyzed by GLC (Table 1). For the transconjugant, there were two novel peaks that were never detected in wild-type, corresponding to authentic 20:4n-3 and EPA (20:5n-3), respectively. The methyl esters of total fatty acids and PUFA were analyzed by GC–MS (Table 1). For the two GLC peaks mentioned above, ion peaks were detected at *m/z* 318 and 316, consistent with the molecular weights of 20:4 and 20:5, respectively, and an ion peak at *m/z* 79, typical of polyunsaturated fatty acids was also seen (data not shown). Therefore, it was confirmed that the transgenic cyanobacterium was able to produce EPA and 20:4n-3 on the introduction of pJRDEPA-S.

In comparing with the wild-type cyanobacteria, percentages of 18:1n-9 and 18:2n-6 to total fatty acids were lower in the transconjugant (Table 1). The decrease might be correlated to production of EPA and 20:4n-3.

EPA production in cyanobacterial cells under different culture conditions. The cyanobacterial transconjugant harboring

Others	8.6 ± 0.9	15.0 ± 1.4	9.3 ± 2.4	3.1 ± 0.6

[a]Condition A: 23°C, 1,000–1,500 Lux, 14 d; Condition B: 23°C, *ca.* 40 Lux, 48 d; Condition C: 18°C, 800–1,000 Lux, 22 d (with shaking at 100 rpm). For conditions A–C $n = 3$. Abbreviation, ND, not detected.

pJRDEPA-S was cultured at different growth temperatures and light intensities. Table 1 shows the major fatty acid compositions of the transconjugant and wild type grown at 18 and 23°C, and at high and low light intensities. In the case of culture at 18°C, flasks were shaken at 100 rpm to compensate for biased illumination. The transconjugant grown at 18°C exhibited higher EPA content and higher absolute yield (4.6 ± 0.6%; 3.86 ± 1.11 mg/L) than when grown at 23°C (3.7 ± 0.2%; 2.24 ± 0.13 mg/L). The increase of EPA content associated with a decrease of culture temperature was also observed in the experiments using *E. coli* JM109 carrying pEPA at 20 and 25°C (7). It seems that these tendencies might be related to chilling tolerance by accumulation of PUFA into cell membranes (13,14). For the transconjugant grown at 18°C, the increase of EPA productivity might also be affected by aeration. In a marine cyanobacterium, *Synechococcus* sp. NKBG042902, harboring pJRDEPA, the EPA content in the total fatty acids was 0.7 ± 0.2% at 17°C (8). With a different cyanobacterial host and a shortened plasmid, the EPA content increased to eightfold more than in the previous work.

When the light intensity was lowered to 40 Lux, the transconjugant exhibited the highest content of EPA (7.5 ± 0.3%). Its absolute yield, however, was lower than that of the transconjugant cultured at 23°C (1.76 ± 0.10 mg/L), even though given a longer culture period (Table 1). The cause of this phenomenon is not clear. The cells might find a more suitable condition to synthesize EPA under weak light intensity because the light-induction of photosynthetic systems does not fully function (15,16).

In SCRC-2738 or *E. coli* with the EPA synthesis gene cluster introduced, as high content of 20:4n-3 as that of the cells in this study was not observed (12; Yamada, A., Yu, R., Watanabe, K., Yazawa, K., and Kondo, K., unpublished data). This tendency may depend on the fatty acid composition intrinsic to the particular organisms. According to the hypothetical pathway for the EPA synthesis in SCRC-2738 (17), 18:3n-3, which is present in considerable amounts in cyanobacteria (Table 1; 18), is a likely precursor of 20:4n-3 or EPA.

In the previous work, pJRDEPA was shown to be unstable in *Synechococcus* sp. NKBG042902 (8). In contrast, pJRDEPA-S was maintained well in NKBG15041c. This stability may be attributed to the size of plasmid and host characteristics of NKBG15041c, carrying no native plasmids to compete against introduced plasmids (19).

In this paper, we demonstrated that a transgenic marine cyanobacteria produced EPA and 20:4n-3, and the productivity was changed related to culture conditions. We need more precise optimization of culture condition to make them useful on a large scale. These transgenic cyanobacteria may also be useful in elucidating the synthetic pathway of EPA in bacteria, because they make precursors to EPA such as 20:4n-3 (17), and undergo regulation by factors such as temperature, osmotic pressure and light intensity (13,14,16).

Dietary Conjugated Linoleic Acid Did Not Alter Immune Status in Young Healthy Women[1]

D.S. Kelley[a,*], P.C. Taylor[a], I.L. Rudolph[a], P. Benito[a], G.J. Nelson[a], B.E. Mackey[b], and K.L. Erickson[c]

[a]U.S. Department of Agriculture, Agricultural Research Service, Western Human Nutrition Research Center, University of California, Department of Nutrition, Davis, California, [b]Western Regional Research Center, Albany, California, and [c]University of California, Department of Cell Biology and Human Anatomy, School of Medicine, Davis, California

ABSTRACT: The purpose of this study was to examine whether conjugated linoleic acid (CLA) supplementation in human diets would enhance indices of immune status as reported by others for animal models. Seventeen women, 20–41 yr, participated in a 93-d study conducted in two cohorts of 9 and 8 women at the Metabolic Research Unit of Western Human Nutrition Research Center. Seven subjects were fed the basal diet (19, 30, and 51% energy from protein, fat, and carbohydrate, respectively) throughout the study. The remaining 10 subjects were fed the basal diet for the first 30 d, followed by 3.9 g CLA (Tonalin)/d for the next 63 d. CLA made up 65% of the fatty acids in the Tonalin capsules, with the following isomeric composition: *t*10,*c*12, 22.6%; *c*11,*t*13, 23.6%; *c*9,*t*11, 17.6%; *t*8,*c*10, 16.6%; and other isomers 19.6%. Most indices of immune response were tested at weekly intervals, three times at the end of each period (stabilization/intervention); delayed-type hypersensitivity (DTH) to a panel of six recall antigens was tested on study day 30 and 90; all subjects were immunized on study day 65 with an influenza vaccine, and antibody titers were examined in the sera collected on day 65 and 92. None of the indices of immune status tested (number of circulating white blood cells, granulocytes, monocytes, lymphocytes, and their subsets, lymphocytes proliferation in response to phytohemagglutinin, and influenza vaccine, serum influenza antibody titers, and DTH response) were altered during the study in either dietary group. Thus, in contrast to the reports with animal models, CLA feeding to young healthy women did not alter any of the indices of immune status tested. These data suggest that short-term CLA supplementation in healthy volunteers is safe, but it does not have any added benefit to their immune status.

Paper no. L8543 in *Lipids 35*, 1065–1071 (October 2000).

Conjugated linoleic acid (CLA) is a mixture of the isomers of the 18:2 fatty acids that have conjugated double bonds. One of the prominent isoforms of CLA is the 9-*cis* and 11-*trans* (9*c*,11*t*-18:2) isomer. This isomer, rumenic acid, is found naturally in beef and dairy products. Several other isomers of CLA are produced industrially during the processing of vegetable oils. The most abundant among these isomers include the 8*t*,10*c*-18:2, 10*t*,12*c*-18:2, and11*c*,13*t*-18:2. In addition, there are several other minor isomers.

Feeding a mixture of the CLA isomers was found to provide several health benefits in animal models, including anticancer (1–8), antiatherogenic (9,10), and antidiabetogenic actions (11). It has also been reported to decrease body fat while increasing muscle (12,13) and bone mass (14). Additionally, it has been reported to block the endotoxin-induced suppression of growth (15,16) and to alter several indices of immune status (17–19). For example, feeding diets containing CLA to experimental animals enhanced *ex vivo* splenocyte proliferation, IL-2 production, delayed-type hypersensitivity (DTH) response, and macrophage phagocytosis (16–18). In contrast, other investigators found no effect of CLA feeding on lymphocyte proliferation (17), DTH (18), and tumor necrosis factor α (TNF α) production (19). Others report a decrease in the production of IL-2, IL-6, and TNF α, and the macrophage phagocytic activity by the feeding of diets containing CLA (7,19). Overall, the observed effects of dietary CLA on immune functions in animal models have been variable.

Despite the variability in data from animals and the lack of data from humans, there are healthy people who are eager to supplement their diets with CLA. We do not know if supplementation of human diets with CLA has any beneficial health effects, or even if it is safe. Therefore, the purpose of this study was to determine whether it is safe to supplement human diets with CLA, and if it will enhance human immune status. We conducted this study with healthy adults rather than with a group having compromised immune status, because we wanted to know if there are any added benefits from CLA supplementation. We examined the effect of feeding a mixture of CLA isomers on a number of indices of immune status, such as lymphocyte subsets and proliferation, DTH, and influenza antibody titers in young healthy women.

[1]Parts of data included here were published as an abstract for the Experimental Biology 2000, meeting.

Abbreviations: BMI, body mass index; CD, cluster differentiation; CLA, conjugated linoleic acid; CI, 95% confidence intervals; CT, cytotoxic T lymphocytes; DTH, delayed-type hypersensitivity; GM, geometric mean; IL, interleukin; LPS, lipopolysaccharide; MRU, metabolic research unit; NK, natural killer; PBMNC, peripheral blood mononuclear cells; PHA, phytohemagglutinin; PPAR, peroxisomal proliferation activation receptor; RDA, recommended dietary allowance; TNF α, tumor necrosis factor α; USDA, U.S. Department of Agriculture; WBC, white blood cells.

MATERIALS AND METHODS

Subjects and study design. Seventeen healthy women were selected to participate in two cohorts of a 93-d metabolic research unit study after a physical and clinical evaluation by a physician. Nine women (5 CLA group and 4 control group) participated in the first cohort (January 25 to April 28, 1998), and eight women (5 CLA group and 3 control group) participated in the second cohort (September 8 to December 10, 1998). Subjects were randomly assigned to the two groups, but to increase the power in the CLA group, we purposely assigned more subjects to the CLA group. They were all nonsmokers and non–drug-users and had body weights within 110–120% of ideal body weight (1983 Metropolitan Life Insurance Co.). Mean body weights, age, and body mass index for the study subjects are given in Table 1.

The study protocol was approved by the human use committees of the University of California, Davis, and the U.S. Department of Agriculture (USDA), Houston, TX. The study lasted for 93 d, although because of other scheduled procedures, no immunological tests were conducted after study day 92. All subjects were immunized on day 65 with a trivalent 1997–1998 influenza vaccine (Connaught Laboratories Inc., Swiftwater, PA). All subjects remained on the premises of the metabolic suite of the Western Human Nutrition Research Center for the duration of the study, except when going for daily walks (2 mi, twice daily) or other scheduled outings. Subjects were under supervision when going out of the metabolic unit. They consumed only those foods prepared by the staff of the unit. As shown in Figure 1, all study participants were fed a basal diet supplemented with a placebo (sunflower oil 3.9 g/d) for the first 30 d, after which they were divided into two groups; 7 subjects consumed the basal diet for the entire period of the study (control group), while for the remaining 10 subjects, a mixture of CLA isomers (3.9 g/d) replaced the placebo supplement from study days 31 to 93 (CLA group). We used a mixture of CLA isomers because that is what has been used in animal studies, and because purified isomers of CLA for human feeding trials were not available at the time the study was conducted. The body weights of the subjects were maintained within 2% of their initial body weights throughout the study by adjusting their caloric intake if necessary.

The nutrient content of the diets was calculated using USDA Handbook 8 (20); all known nutrients were at or above the recommended dietary allowance (RDA) level, and were not different between the two diets. Diets contained 1 × RDA of vitamin E from natural foods. An additional 100-mg capsule of α-tocopherol (Bronson Pharmaceutical, St. Louis, MO) was supplemented every 5 d to reduce the increased oxidative stress from CLA supplementation. The proportion of energy from protein, fat, and carbohydrate in both diets was 19, 30, and 51%, respectively. Diets were organized according to a 5-d rotating menu, comprised of 3 meals and a postdinner snack. Specific menus were designed so that the fat would consist of saturated, monounsaturated, and polyunsaturated types providing 10% energy for both the control and intervention groups. Tonalin (gift from Pharmanutrient, Inc., Lake Bluff, IL) was the source of CLA. It was served as capsules by replacing an equivalent amount of the placebo oil. Both Tonalin and placebo oil capsules were administered to the subjects before each meal (breakfast, lunch, and dinner) under the supervision of the kitchen staff. As shown in Table 2, CLA isomers made up 65 wt% of the total fatty acids present in Tonalin, while other fatty acids made up the remaining 35%. The fatty acid composition of Tonalin and the placebo oil (sunflower) is given in Table 2. The major isomers of CLA present in Tonalin, expressed as a percentage of total CLA were: *t*10,*c*12, 22.6%; *c*11,*t*13, 23.6%; *c*9,*t*11, 17.6%; *t*8,*c*10, 16.6%; and other isomers 19.6%. Placebo capsules were made from sunflower oil containing 72.6% linoleic acid and no detectable CLA.

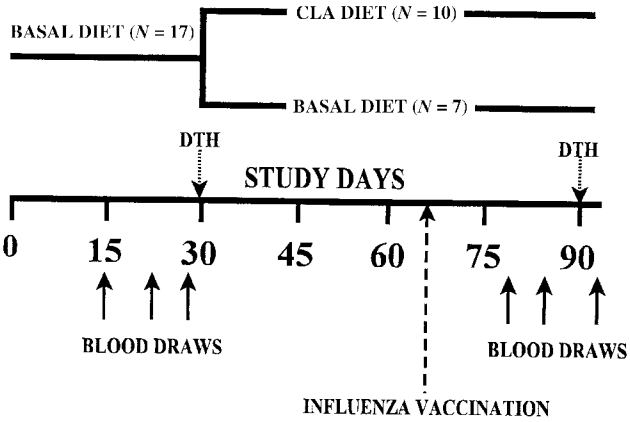

FIG. 1. Study design. Blood samples drawn on study day 15, 22, 29 (stablization period), and 78, 85, 92 (intervention period) were used to determine immune cell numbers and functions. DTH, delayed-type hypersensitivity response; CLA, conjugated linoleic acid.

Laboratory procedures. Blood samples were collected between 0700 and 0800 after an overnight fast on study days 15, 22, 29, 78, 85, and 92 by antecubital venipuncture into evacuated tubes containing heparin for cell culture experiments, EDTA for blood cell count and phenotypic analysis, and no anticoagulant for preparation of sera.

Blood cell count and lymphocyte phenotypic analysis. For each blood draw, a complete and differential cell count was performed using a Serono Baker Automated System (Model 9000 diff; Allentown, PA). Phenotypic analysis for B [cluster differentiation (CD) 19+ or CD19+], T (CD3+), helper (CD3+, CD4+), suppressor (CD3+,CD8+), natural killer (NK) (CD3–, CD16+,56+), and cytotoxic T (CT)(CD3+,CD16+, 56+) lym-

[a]Values given as means ± SD (n = 5). See Table 1 for abbreviation. Tonalin was a gift from Pharmanutrient, Inc. (Lake Bluff, IL).

phocytes was done with a Becton-Dickinson FACStar flow cytometer (San Jose, CA) as previously reported (21). Briefly, whole blood collected in EDTA-containing vacutainer tubes was transferred into tubes containing fluorochrome-labeled monoclonal antibodies against specific CD antigens. After incubation for 30 min, the red cells were lysed with formaldehyde and removed by washing the leukocytes twice with Dulbecco's phosphate-buffered saline (PBS) without calcium and magnesium. The stained cells were fixed in 1% paraformaldehyde prior to analysis with the flow cytometer. A total of 10,000 lymphocytes were counted to determine their percentage distribution as lymphocyte subsets.

Isolation and culture of peripheral blood mononuclear cells (PBMNC). The PBMNC were isolated using Histopaque-1077 as previously reported (22). The culture medium used was RPMI-1640 (Gibco, Grand Island, NY) containing 10% autologous serum and L-glutamine (2 mmol/L), penicillin (100 KU/L), streptomycin (100 mg/L), and gentamicin (20 mg/L). One hundred microliters of the culture medium containing 1×10^5 PBMNC was added to each well of a 96-well flat-bottom culture plate, followed by an additional 100 μL of the culture medium with or without phytohemagglutinin (PHA; Sigma Chemical Co., St. Louis, MO), or influenza vaccine (Connaught Laboratories Inc.). Cells treated with PHA (0, 1.25, 2.5, 5.0, 10.0, and 20.0 mg/L) were cultured for 72 h, and those treated with influenza vaccine (0, 1/250, 1/500, 1/1000, 1/2000, and 1/4000) were cultured for 120 h. [^{3}H]Thymidine, 37 K Bq, in 50 μL, was added to each well during the last 24 h of cell culture. Cells were collected on filter strips, and the radioactivity was determined using a Packard β-gas counter (Hewlett-Packard Co., Palo Alto, CA). [^{3}H]thymidine incorporation into cellular DNA (Bq/1000 cell) was used as the index of PBMNC proliferation.

DTH skin testing. DTH was tested by intradermally injecting a battery of six recall antigens (tuberculin, mumps, tetanus, candida, streptokinase, and trichophyton) as previously described (22), and the induration diameters in mm were determined 48 h after the application of the antigens. An induration of 4 mm or more was considered positive. The total induration was determined by adding all the positive responses. The antigen score indicates the number of positive responses to the test antigens.

Serum antibody titers. The antibody titers were determined by using the hemagglutination inhibition assay (23) and the viral strains AH1N1, AH3N2, and B/Habrin (strains included in the vaccine). Results for antibody titers are expressed as the geometric mean of the antibody titers, with 95% confidence intervals.

Data analysis. The data from the two cohorts were combined for a repeated measures ANOVA using the SAS PROC MIXED procedure (24). Day, diet, and the interaction between them were considered the fixed effects, while cohort, diet × cohort, subjects within diet × cohort, and diet × cohort × day were the random effects. The period 1 (stabilization) vs. period 2 (intervention) × diet contrast was partitioned out of the day × diet effect. Pooled means ± SEM for the three measurements made at the ends of stabilization (day 15, 22, and 29) and intervention (day 78, 85, and 92) periods are shown in the Results section. Changes in the parameters examined are considered significant for $P < 0.05$ unless stated otherwise.

RESULTS

Both diets provided 19, 30, and 51% energy from protein, fat, and carbohydrates, respectively. The average daily caloric intake was approximately 2100 Kcal (2117 ± 191, mean ± SD) and was not significantly different between the two groups. Fatty acid composition of the diets is shown in Table 3. Fatty acids other than CLA and linoleic acid were not significantly different between the two diets. The control diet contained a nondetectable amount of CLA, while in the CLA diet, CLA isomers were 5.28% of the total fatty acids. The linoleic acid content of the control diet was about 5% higher than that in the CLA diet. This was because the placebo supplement contained sunflower oil, which contained 73 wt% linoleic acid.

Effect of CLA on circulating white blood cells (WBC). The number of total circulating WBC and their specific subgroups, at the ends of periods 1 (stabilization) and 2 (intervention), are shown in Table 4. This table shows that the number of total WBC, granulocytes, monocytes, and lymphocytes in both groups remained unchanged throughout the study. Also unchanged were the numbers of circulating B, NK, total T, helper, suppressor, and CT lymphocytes in both groups.

Effect of CLA on PBMNC proliferation. The influence of dietary CLA on the proliferation of lymphocytes cultured

with different concentrations of a T cell mitogen, PHA, and a B cell antigen, influenza vaccine are shown in Tables 5 and 6, respectively. Increasing the concentration of PHA increased lymphocyte proliferation, with the maximum attained at a PHA concentration of 10 mg/L. At all PHA concentrations, the proliferation of lymphocytes was not different between periods one and two in both dietary groups. B lymphocyte proliferation in response to the influenza vaccine increased with the increasing concentration of the vaccine, the maximum being attained at a dilution of 1/1000 in both groups (Table 6). B cell proliferation in response to influenza vaccine in period two was significantly higher ($P < 0.05$) than that in period one in both groups. This increase in proliferation was caused by the immunization with the same vaccine on day 65. Thus, CLA feeding did not alter proliferation of either T or B lymphocytes.

Effect of CLA on DTH skin response. The induration responses were examined 48 h after the intradermal injection of six recall antigens on study days 28 and 90. All 17 subjects responded to mumps, tetanus, and candida antigens. The data from the other three antigens (trichophyton, streptokinase, and tuberculin purified derivative) were pooled, because fewer than 25% of the subjects responded to each of these antigens (data not shown). The induration score (sum of induration) and the antigen score (number of antigens testing positive) did not differ from study days 30 to 92 in either group (Table 7). The induration in response to individual antigens also did not change during the course of the study.

CLA feeding and serum influenza antibody titers. The pre- (day 65) and postimmunization (day 92) serum antibody titers against the three strains (AH1N1, AH3N2, B/Habrin) of influenza virus for both groups of subjects are shown in Table 8. For all three viral strains, the pre-immunization antibody titers were not different between the two groups. Immunization caused approximately 2-, 4-, and 10-fold increases in the concentration of circulating antibodies against AH3N2, B/Habrin, and AH1N1, respectively, in both groups. The increases in the antibody titers between the CLA and control group also were not different. The results shown regarding antibody titers in Table 8 were obtained with the hemagglutination inhibition assay; however, the results from enzyme-linked immunosorbent assay also lead to the same conclusion (data not shown).

DISCUSSION

The purpose of this study was to examine whether CLA supplementation of human diets would stimulate indices of human immunity as previously reported for animals (16–19).

TABLE 4
Effects of CLA Feeding on Circulating WBC[a]

10.00	24.31 ± 2.57	27.07 ± 2.67	21.49 ± 1.93	23.03 ± 2.62
20.00	24.06 ± 2.41	26.21 ± 2.48	21.51 ± 1.41	21.86 ± 1.81

[a]Abbreviations: PBMNC, peripheral blood mononuclear cells; Bq, Becquerel; PHA, phytohemagglutinin. See Table 1 for other abbrevation. Data for periods one and two represent the same study days as in Table 4. At all PHA concentrations, PBMNC proliferation in both groups did not change during the study.

The concentration of CLA in the basal diet used in our study was nondetectable, while in the CLA-supplemented diet, it was 5.3 wt% of the total fatty acids (providing approximately 1.5% of daily energy intake). Thus, the CLA concentration used in our study was comparable to that used in many of the animal studies. However, the isomeric composition of the CLA used in our study was different from that reported for the animal studies. Most of the animal studies report that *c*9,*t*11-18:2, and *t*10,*c*12-18:2 made up about 80% of all the CLA isomers (3,8). In our study, these two isomers were only about 40% of all isomers. The CLA used in our study was prepared by refluxing a natural oil (safflower oil), while a mixture of the synthetic isomers of CLA was used in many of the animal studies. At the time we conducted this study, synthetic isomers of CLA for human consumption were not available. The difference in isomeric composition may also be due to inaccurate identification of CLA isomers in some of the other studies. The acid-catalyzed methylation causes isomerization of CLA isomers (25,26). In our study, we used sodium-methoxide for fatty acid methylation, thus avoiding this problem (25,26).

None of the indices of immunity tested (number of circulating

TABLE 6
CLA Feeding Does Not Alter the Proliferation (Bq/10^6 cells) of PBMNC Cultured with Influenza Vaccine[a]

	CLA group (n = 10)		Control group (n = 7)	
Vaccine concentration	Period 1	Period 2	Period 1	Period 2
0.00	54 ± 15	52 ± 15	62 ± 16	53 ± 10
1/250	563 ± 163	1183 ± 225	527 ± 252	1110 ± 324
1/500	1226 ± 290	2297 ± 439	1439 ± 408	2499 ± 615
1/1000	1519 ± 345	2255 ± 477	1897 ± 502	2544 ± 554
1/2000	1307 ± 314	1866 ± 432	1610 ± 488	2070 ± 507
1/4000	812 ± 230	1382 ± 345	1134 ± 390	1584 ± 522

[a]See Tables 1 and 5 for abbreviations and data presentations. *In vivo* immunization with the vaccine on day 65 caused a significant ($P < 0.05$) increase in the proliferation of PBMNC cultured with all concentrations of the same vaccine *in vitro* during period two; however, there was no effect of CLA on this response.

TABLE 7
Effect of CLA Feeding on Delayed-Type Hypersensitivity Response (DTH)[a]

	CLA group (n = 10)		Control group (n = 7)	
	Study day 30	Study day 90	Study day 30	Study day 90
Mumps (mm)	16.8 ± 3.4	22.3 ± 3.1	17.1 ± 2.5	15.6 ± 2.5

[a]GM, geometric mean; CI, 95% confidence intervals. See Table 1 for other abbreviation. All subjects were immunized with influenza vaccine on day 65. Immunization significantly ($P < 0.05$) increased the antibody titers for all three viral strains in both groups. However, the increase in antibody titers was not significantly different between the two groups.

WBC, lymphocytes within different subsets, T and B lymphocyte proliferation, DTH, and serum antibody titers) were stimulated by CLA supplementation of the diets. Our results, showing no change in human lymphocyte proliferation with CLA supplementation are at variance with those of others who found increases in this response in mice, rats, and chickens (7,16,18). However, our results are in agreement with those of other investigators (17) who failed to detect an increase in splenocyte proliferation in mice fed CLA-containing diets for 6 wk. Similarly, our results regarding antibody production, DTH, and lymphocyte phenotypic analysis are consistent with the results from animal studies (16,18,27). While CLA supplementation did not improve any of the indices of immune status tested, it did not have any adverse effects either.

The discrepancy between our results and those obtained from animal models may simply be due to species' differences. Perhaps humans do not respond to CLA the same way rats, mice, and chickens do. One of the perceived mechanisms by which CLA exerts its health effects in animal models is through the induction of peroxisomal proliferation activation receptor (PPAR)-responsive genes in the liver (28). Humans appear to be resistant to peroxisome proliferation, and the promotor region of the human acetyl-CoA oxidase is resistant to transcriptional regulation by PPAR (29). Thus, inadequacy of the PPAR and their response elements may be why CLA failed to stimulate immune response in our human study. Even in the animal models, the effects of CLA on immune response have been only modest and have ranged from inhibition to stimulation. Based on these results, CLA does not seem to be a strong modulator of the immune response. Most of the animal experiments with CLA have involved growing animals, and in one study, the effects of CLA were less pronounced in the older mice than in the younger mice (18). It is possible that CLA did not stimulate indices of immune status in our study subjects because they were healthy adults, but it may stimulate them in growing human subjects, or in those with a compromised immune status. Another explanation may be that different isomers of CLA have opposing effects, and they may neutralize the effects of each other. Studies with purified isomers of CLA are needed to address this issue.

Other results from this study demonstrated that CLA supplementation did not affect body weight, fat-free mass, fat mass, percent body fat, or energy expenditure (30). Nor did it alter appetite, or the serum concentrations of insulin, glucose and lactic acid (31). There was a transient decrease in the concentration of serum leptin; however, it was not maintained until the end of the study (31). Taken together, the results from our study suggest that short-term supplementation of the diets of healthy adult humans with a mixture of CLA isomers is safe; however, there is no added benefit to the immune status and body composition. It is possible that CLA isomers have some health benefits to humans with a compromised immune status, or that one or more of the purified isomers may be beneficial to healthy adults. Until such information is obtained, CLA supplementation to improve human immune status or body composition should not be recommended.

ACKNOWLEDGMENTS

The authors are appreciative of the support provided by the dietary and nursing staff of the MRU in conducting this study. We thank the volunteers who participated in the study, the Bioanalytical Laboratory for sample processing, Health Services Department of California in Berkeley for determining influenza antibody titers, and Pharmanutrient, Inc. for donating the Tonalin oil.

Absorption by Rats of Tocopherols Present in Edible Vegetable Oils

Trine Porsgaard* and Carl-Erik Høy

Department of Biochemistry and Nutrition and Center for Food Research, Technical University of Denmark, 2800 Lyngby, Denmark

ABSTRACT: The absorption of tocopherols (α, γ, and δ) and fatty acids from rapeseed (RO), soybean (SOO), and sunflower (SUO) oil, both from the natural oils and from the oils following moderate heating (180°C for 15 min), was measured in lymph-cannulated rats. Oils were administered as emulsions through a gastrostomy tube, and lymph samples were collected for 24 h. The composition of tocopherols in oils and lymph fractions was measured by high-performance liquid chromatography, and fatty acids were measured by gas–liquid chromatography. The highest accumulated transport of α-tocopherol was observed after SUO administration, the lowest after SOO, with RO in between, corresponding to their relative contents (41.6 ± 8.8, 32.7 ± 5.0, and 24.9 ± 4.3 μg at 24 h after administration of SUO, RO, and SOO, respectively). The calculated recoveries (in %) 24 h after oil administration were 21.4 ± 4.5, 45.7 ± 7.0, and 78.8 ± 13.5 for SUO, RO, and SOO, respectively, suggesting that the absorption efficiency decreased when the α-tocopherol concentration increased. The recovery of α-tocopherol was higher than the recoveries of γ- and δ-tocopherol, indicating that the different tocopherols were not absorbed to the same extent or with similar rates. No differences between unheated and heated oils were observed in the absorption of tocopherols, whereas heating led to lower absorption of fatty acids, thus showing no direct association between absorption of tocopherols and fatty acids.

Paper no. L8425 in *Lipids 35,* 1073–1078 (October 2000).

Vitamin E is the major lipid-soluble antioxidant present in membranes and is important for the protection of polyunsaturated fatty acids against peroxidative damage, and thereby also for the normal function of membranes (1–3). Vitamin E is the term used for eight naturally occurring molecules, four tocopherols and four tocotrienols (named α, β, γ, and δ), all exhibiting vitamin E activity. The biological activities of the tocopherols differ, with α-tocopherol being the most active (4,5).

Tocopherols are absorbed together with other lipid-soluble components in the intestine. The presence of bile salts for micelle formation is important for the absorption (6,7). Disease states with impaired bile salt and pancreatic enzyme secretion lead to malabsorption of dietary fat and also of the lipid-soluble vitamins (8,9). Data based on mechanistic studies with everted intestinal sacs indicate that absorption into the enterocytes takes place by a passive diffusion process at the highest rate in the medial portion of the small intestine (10). On the other hand, studies by Kelleher *et al*. (11) and Brink *et al.* (12) using fecal excretion as a measure of unabsorbed tocopherol amounts showed decreased absorption at high dose levels compared to lower dose levels. The absorbed tocopherols are secreted into the lymphatics associated with chylomicrons (13,14), although small amounts can be transported from the intestine *via* the portal vein, but this is only a minor pathway under normal circumstances (15). From the lymphatics chylomicrons enter the circulation where they are catabolized. Lipoprotein lipase in the endothelial lining transfers fatty acids from chylomicrons to the tissues along with a minor part of the tocopherols (16), while the major part is absorbed together with chylomicron remnants into the liver and secreted in very low density lipoprotein (17,18).

Generally, tocopherol absorption is measured in two ways, either by measuring the unabsorbed part remaining in the intestine and feces or by estimating the level of absorbed tocopherol in the body. Infusion of radiolabeled tocopherols or large amounts of unlabeled standards followed by estimation of the amount transported in lymph is widely used to measure absorbed amounts (13,15,19,20). Vegetable oils are among the richest sources of vitamin E in the diet (21,22). In the present study, we investigated the absorption measured as lymphatic transport in rats of tocopherols as well as of fatty acids from three vegetable oils: rapeseed (RO), soybean (SOO), and sunflower (SUO). This study focuses on the absorption efficiencies of tocopherols in naturally occurring concentrations in edible oils. Furthermore, the effect of moderate heating, simulating household heating with fresh oils, on tocopherol absorption was examined since heating is known to reduce the tocopherol content (23). To our knowledge no groups have compared the absorption of tocopherols present in natural amounts in vegetable oils and related the effects of heating to absorption.

EXPERIMENTAL PROCEDURES

Animals. The following experiment was approved by the Danish Committee for Animal Experiment. Male Wistar rats

*To whom correspondence should be addressed at Department of Biochemistry and Nutrition, The Technical University of Denmark, Building 224, DK-2800 Lyngby, Denmark. E-mail: trine@mimer.be.dtu.dk

Abbreviations: HPLC, high-performance liquid chromatography; RO, rapeseed oil; SOO, soybean oil; SUO, sunflower oil.

were fed a standard nonpurified diet (Altromin No. 1324, Chr. Petersen A/S, Ringsted, Denmark) containing 4% fat and 75 mcg Vitamin E per g diet before the experiment. They were subjected to surgery as described previously (24) and fasted until the following day. Five (SOO, SUO, heated RO, and heated SOO) or six (RO, heated SUO) rats were used in each group.

Administration of oil and collection of lymph. On the postoperative day, the experiment was started by collection of a baseline fraction of lymph from –1 to 0 h. At time zero, a sonicated emulsion of 0.3 mL (corresponding to 270 mg) oil and 0.3 mL of a solution containing 20 mM taurocholate (Sigma Chemical Company, St. Louis, MO) and 10 mg/mL choline (Sigma Chemical Company) in distilled water was injected through the feeding tube followed by 0.6 mL saline, and the infusion of saline was continued at 2 mL/h. Lymph was collected in tubes in 1-h fractions for the following 8 h and a combined fraction was obtained from 8 to 23 h followed by a 1-h fraction from 23 to 24 h after administration of fat. The tubes contained 100 μL of a 10% (wt/vol) Na_2-EDTA-solution (E. Merck, Darmstadt, Germany) and they were frozen immediately after collection and kept at –20°C until analysis.

Analysis of tocopherol contents in oil and lymph. The following oils were used for the experiment: a low α-linolenic rapeseed oil (seed selected by DLF-Trifolium, St. Heddinge, Denmark; oil refined at the Department of Biotechnology, DTU, Lyngby), and a soybean and a sunflower oil (Aarhus Olie A/S, Aarhus, Denmark). The oils were heated in a stainless steel pan at 180°C in a 5-mm layer for 15 min. The unheated oils and corresponding heated oils were administered to rats as described above. Tocopherols (α, γ, and δ) in oils were determined by high-performance liquid chromatography (HPLC) as described in Porsgaard *et al.* (24).

Tocopherols (α, γ, and δ) in lymph samples were determined by the method of Kaplan *et al.* (25) after the following sample preparation performed in the dark. The values were not corrected for the baseline lymph tocopherol values. All solvents used were of HPLC-grade. Lymph (200 μL) together with 200 μL α-tocopherol acetate (133.7 μg/mL ethanol) as internal standard was extracted twice with 3 mL hexane alternating with centrifugation (5 min, 4000 rpm, room temperature, Heraeus Megafuge 1.0). The supernatants were combined and evaporated under vacuum for 40 min at 25°C in a Christ Alpha RVC vacuum-centrifuge. The residue was reconstituted in 150 μL acetonitrile/chloroform (80:40, vol/vol), filtered, and transferred to colored vials before injection of 80 μL into the HPLC. The HPLC system consisted of the following equipment purchased from Waters Corporation (Milford, MA): a programmable 490 ultraviolet detector measuring at 292 nm, an automated 717 sample injector, and a model 510 pump with a Supelcosil LC-18 column (25 cm × 4.6 mm, 5 μm, Supelco, Bellefonte, PA). The mobile phase consisted of acetonitrile/chloroform/2-propanol/water (78:16:3.5:2.5, by vol) at a flow rate of 2 mL/min. The concentrations of individual tocopherols were determined from standard curves using the internal standard.

Fatty acids in oils and lymph. The fatty acid composition of triacylglycerols in oils and lymph was determined as described in Porsgaard *et al.* (24). The fatty acid composition of the oils before as well as following heating is presented in Table 1.

Statistics. The results were presented as means ± SEM. Absorbed amounts of tocopherols in lymph after administration of different oils as well as the fractional absorption of different tocopherols were compared with one-way analysis of variance using the Jandel SigmaStat statistical package (Jan-

del Corporation, Erkrath, Germany). The correlation between tocopherol concentrations in oils and absorbed amounts was tested by Pearson correlation analysis. Differences were considered significant if the P value was <0.05.

RESULTS

Tocopherol content of oils. The content of total and individual tocopherols varied between RO, SOO, and SUO (Table 2). SUO contained the highest amount of α-tocopherol followed by RO and SOO. SOO had the highest content of γ- and δ-tocopherol. Heating of oils had only a minor effect on the tocopherol content.

Lymphatic transport of tocopherols. A significant positive correlation between the amounts of α-tocopherol transported in lymph and the content in the oils was observed ($P = 0.003$, $r = 0.95$) with the highest transport observed after SUO, the lowest after SOO, and with RO in between (Fig. 1). The accumulated amounts of individual tocopherols transported at 8 and 24 h after oil administration are shown in Table 3. The amount of α-tocopherol transported 8 h after administration of SUO was higher than the amount transported after SOO, heated SOO, and heated RO. In contrast to the differences observed at 8 h, the values for accumulated transport of α-tocopherol at 24 h did not show any significant differences, suggesting that differences in the content between the oils were counterbalanced by differences in absorbed amounts. This was further elucidated in the calculated recoveries of administered tocopherols at 8 and 24 h (Table 4). Eight hours after administration of SUO and heated SUO, the α-tocopherol recovery was significantly lower compared to the recovery after administration of the other four oils. Furthermore, the recovery of α-tocopherol after SOO was higher than the recovery after RO and heated RO. These differences were also observed 24 h after administration.

No differences were observed in the absorption of γ-tocopherol between RO and SOO when calculated in actual amounts (Table 3), even though the amount in SOO was almost twice as high as in RO.

When the absorption of individual tocopherols was compared, differences were observed suggesting that α-, γ-, and δ-tocopherol were not absorbed to the same extent or with similar rates. Eight hours after administration, a significantly higher recovery of administered amounts was observed for α-tocopherol compared to γ- and δ-tocopherol after SOO administration. This was also seen at 24 h together with similar differences after heated SOO administration. Differences in the absorption of α- and γ-tocopherol were observed 24 h after administration of RO and heated RO.

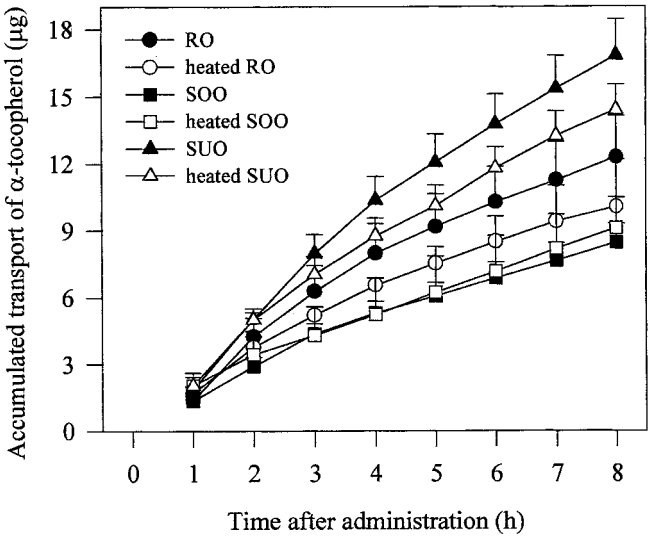

FIG. 1. Accumulated lymphatic transport (μg) of α-tocopherol in rats after administration of oils that had or had not been heated. Values represent means ± SEM (n = 5 or 6). RO, rapeseed oil; SOO, soybean oil; SUO, sunflower oil.

The absorption of tocopherols from heated and unheated oils showed no differences for any of the oils, suggesting that heating did not affect the absorption of tocopherols.

Absorption of fatty acids. The dominant fatty acid in SUO and SOO was linoleic acid, representing 61 and 51% of total fatty acids, respectively, while lower in RO (23%). On the other hand, RO contained 58% oleic acid (Table 1). The absorption of total fatty acids at 24 h after administration of unheated oils amounted to more than 100% (Table 4), indicating that the rats were able to digest and absorb these oils and thereby also were assumed to be able to absorb tocopherols. The absorption of total fatty acids from heated oils was lower than from unheated oils, but this did apparently not affect the absorption of tocopherols as no differences were observed between unheated and heated oils. The observed differences in absorption of fatty acids from unheated and heated oils were commented upon in Porsgaard *et al.* (24).

DISCUSSION

Absorption of vitamin E has received great attention because of the essentiality of this vitamin in the protection of polyunsaturated fatty acids against peroxidation. In this study we investigated the absorption in rats of individual tocopherols (α, γ, and δ) occurring at their natural levels in three different vegetable oils by following the lymphatic transport for 24 h after oil administration. The highest accumulated amount of α-tocopherol transported in lymph at 8 and 24 h was observed after administration of SUO and the lowest after SOO, corre-

sponding to the relative amounts in the oils. On the other hand, when recoveries of administered amounts of α-tocopherol were compared, SUO showed the lowest recovery indicating that the absorption efficiency decreased with high contents of tocopherol in the oil. This resulted in recoveries of administered α-tocopherol amounts of 21.4 ± 4.5, 45.7 ± 7.0, and 78.8 ± 13.5% at 24 h after SUO, RO, and SOO administration, respectively. The content of γ-tocopherol in SOO was nearly twice the amount in RO, but no statistically significant differences in recoveries were observed (9.7 ± 1.7% at 24 h after SOO administration compared to 17.1 ± 4.4% after RO).

Gallo-Torres *et al.* (26) proposed that the nature of the accompanying fat might influence the lymphatic absorption of tocopherols. Increased levels of linoleic acid depressed the lymphatic absorption in rats of vitamin E, suggesting that polyunsaturated fatty acids have a negative influence on the absorption of vitamin E. In our study, we compared the absorption of three oils normally applied in household frying, and all three oils were rich in unsaturated fatty acids. The highest content of linoleic acid was in SUO, but it cannot alone account for the observed differences in recoveries between oils because SOO also contained high amounts of this fatty acid.

Tocopherol absorption has been examined in many studies. It was suggested that tocopherols were absorbed into the enterocytes through a passive diffusion process (10). Kelleher *et al.* (11) showed that the absorption of radioactive α-tocopherol in rats was decreased when the dose was increased and suggested that some kind of saturable process existed limiting the absorption at high dose levels. This was also observed by Brink *et al.* (12), who compared the absorption measured from fecal excretion of tocopheryl acetate added in three different concentrations. Bjørneboe *et al.* (13) measured a lymphatic recovery of 15 ± 9% after intraduodenal feeding

of 10 mg α-tocopherol in soybean oil to rats compared with a recovery of 22 ± 8% after 1 mg α-tocopherol showing slightly higher recovery after the low dose, but the difference was not statistically significant. Traber *et al.* (14) found that the efficiency of α-tocopherol absorption was decreased when the amount given to rats was increased. The results from these studies and those obtained in the present study suggest that the absorption efficiency decreases when the tocopherol concentration increases, but further studies are needed to clarify the underlying mechanisms.

The observed tocopherol recoveries in rats vary widely between different studies. When administered as ^{3}H-α-tocopherol in micellar solution a mesenteric lymphatic recovery of 42% was observed after 24 h (15), while Traber *et al.* (14) found 65% of the administered α-tocopherol in thoracic duct lymph. The 24-h thoracic duct lymph recovery of α-tocopherol measured by Ikeda *et al.* (20) was 25%. In intestinal loops an α-tocopherol absorption of 32% over 6 h was measured (27). Brink *et al.* (12) measured absorption efficiencies between 73 and 90% by feces collection. These large differences in recoveries may be the result of different ways of administering the tocopherols as well as different ways of measuring the absorption. Often, very high doses of vitamin E are administered and, as discussed above, this could affect the relative absorption.

Interest has concentrated on α-tocopherol because of its high biological activity, but γ-tocopherol is also important because it constitutes a considerable amount of the daily intake. When present in different amounts during infusion, almost similar lymphatic recoveries were found in rats for α- and γ-tocopherol, indicating that the absorption of these two tocopherols was independent of each other (14). In another study, Traber *et al.* (28) found that in humans α- and γ-tocopherol were absorbed and secreted in chylomicrons with equal efficiencies. Pearson and Barnes (27) observed similar absorption of α- and γ-tocopherol from intestinal loops in rats, while the absorption of δ-tocopherol was more than 15 times lower. In mesenteric lymph γ-tocopherol was found to be absorbed to an extent 15% lower than that of α-tocopherol (19). We found a significantly lower absorption of γ-tocopherol compared to α-tocopherol after RO administration and lower absorption of γ- and δ-tocopherol after SOO administration, suggesting that in our model there was discrimination between different tocopherols during the absorption.

The moderate heating procedure applied in our experiment had limited effect on tocopherol contents in the oils (Table 2). Previously, it was shown that heating decreased the tocopherol content in rapeseed oil (23), but this oil was exposed to a more severe heating procedure, including stirring and heating for 4 h. The absorption of fatty acids from unheated oils was higher than 100% (Table 4), indicating lymphatic transport of endogenous fatty acids in addition to the exogenous administered fatty acids (29). Heating of oils decreased the absorption of total fatty acids (the decrease was significant after administration of RO and SOO, $P < 0.01$), caused among other things by the formation of polymers during heating. In contrast to this, the absorption of tocopherols was unaffected by heating, indicating that there was no direct association between the absorption of fatty acids and tocopherols.

This study has shown that within the range of concentrations in vegetable oils, there is an increase in efficiency of tocopherol absorption at low dietary levels, although there is still a positive correlation between the amounts of tocopherols absorbed in lymph and the concentrations in the oils. The results emphasize the importance of investigating the absorption of tocopherols from natural sources. Moderate heating of RO, SOO, and SUO has no effect on tocopherol absorption, while fatty acid absorption is reduced following heating of SUO and RO.

ACKNOWLEDGMENTS

The authors wish to thank Kirsten Nielsen and Bente Pedersen for technical assistance, Steen Balchen, Department of Biotechnology, DTU, for refining the low α-linolenic rapeseed oil, and Robert G. Nielsen, Biotechnological Institute, Kolding, for heating oils. Financial support was given from the Danish Programme for Advanced Food Technology (FØTEK 2) and from The Danish Research Councils.

ABSTRACT: Sepsis leads to hypertriglyceridemia in both humans and animals. Previously, we reported that plasma very low density lipoprotein apolipoprotein (apo) B and hepatic production of apoB increased during *Escherichia coli* sepsis. The present experiments were undertaken to determine whether the altered hepatic secretion of apoB was associated with an increase in synthesis or a decrease in degradation rate. Sepsis was induced in male, Lewis rats (225–275 g) by intravenous injection of 3.8×10^8 live *E. coli* colonies/100 g body. Twenty-four hours later rats were sacrificed, and primary hepatocytes were prepared and incubated overnight with ^{35}S-methionine. Hepatocytes from *E. coli*-treated rats secreted twice as much apoB-48 and total apoB than the hepatocytes from control rats. *Escherichia coli* sepsis increased cellular triglyceride mass by 86%, which was due to a stimulation in triglyceride synthesis from newly synthesized fatty acids, measured by ^3H_2O incorporation into triglycerides. The apoB synthesis rate, apoB mRNA levels, and apoB mRNA editing were not altered during *E. coli* sepsis. The pulse-chase experiments showed that the rate of apoB degradation decreased in *E. coli*-treated rats. These findings demonstrate that the secretion of apoB is regulated posttranslationally during *E. coli* sepsis by decreasing the degradation of newly synthesized apoB, which contributes to the development of hypertriglyceridemia.

Paper no. L8372 in *Lipids 35*, 1079–1085 (October 2000).

Gram-negative sepsis continues to be a serious complication in hospitalized patients with major trauma injuries or surgery (1,2). Normal metabolic processes, including lipid and lipoprotein metabolism, are altered (3,4). A prominent feature of the disordered lipid metabolism is an early rise in plasma triglycerides (TG) accompanied by an increase in hepatic production of lipids (5,6).

Hypertriglyceridemia may result from (i) decreased clearance of TG lipoproteins, (ii) increased synthesis of hepatic TG, (iii) increased synthesis and secretion of apolipoprotein (apoB)-containing lipoprotein particles, (iv) decreased hepatic uptake of lipoprotein remnant particles, and/or (v) decreased activities of low density lipoprotein (LDL) receptor. Previously we showed that increased production of very low density lipoprotein (VLDL)-TG and reduced clearance contributed to the development of hypertriglyceridemia of gram-negative sepsis (5–7). The defect in TG clearance during *E. coli* sepsis is attributable in part to reduced activities of lipoprotein lipase (LPL) in skeletal muscles, heart, and adipose tissues (5). The hypertriglyceridemia is characterized by an increased number of VLDL particles (8) with a normal composition of TG. The higher concentration of circulating VLDL in the *E. coli*-treated rats was associated with increased hepatic production of total apoB relative to the control rats (9).

The purpose of this study was to investigate the regulatory mechanisms by which *E. coli* sepsis increased hepatic production of apoB. In rats the liver is capable of synthesizing both forms of apoB; apoB-48 is formed by RNA editing of apoB-100 RNA. We used freshly isolated hepatocytes in suspension or in primary culture from *E. coli*-treated rats to measure the rate of secretion and synthesis of apoB-48 and apoB-100 and the synthesis of TG and total cholesterol. The molecular regulation of apoB was evaluated by measuring mRNA levels and RNA editing. Because degradation can also modify secretion of apo, we measured the recovery of newly synthesized apoB using pulse-chase studies.

MATERIALS AND METHODS

Male, Lewis inbred rats (225–275 g) were used in all experiments. They were maintained in the animal facility under standard conditions (12 h light/12 h dark cycle) and allowed free access to a standard rat chow (Purina 5001, Ralston-Purina, St. Louis, MO) for at least 1 wk prior to the beginning of each study. All experiments were performed in accordance with the guidelines of the National Institute of Health and with a proto-

col approved by the Thomas Jefferson University Animal Care and Use Committee.

Escherichia coli Type 25922 (American Type Tissue Culture Collection, Rockville, MD) was used to induce sepsis. Rats in the *E. coli*-treated group received intravenously (i.v.) 3.8×10^8 colonies/100 g body weight. Control rats received i.v. sterile 0.9% NaCl. Food was removed from both groups after inducing sepsis, and hepatocytes were isolated 24 h later.

The hepatocytes were isolated following the procedure of Seglen (10) and were suspended in Waymouth's medium containing 0.2% bovine serum albumin (BSA) and 0.1 nM insulin, pH 7.4, gentamycin and streptomycin/penicillin (basal medium). Hepatocyte yield was approximately 1.5 to 2.0×10^8 cells/liver. Damaged cells were removed by centrifugation through Percoll and then washed twice with basal medium (11). More than 85% of the cells isolated excluded trypan blue. The hepatocytes were then counted and incubated in 125-mL polypropylene Erlenmeyer flasks at approximately 3×10^6 cells/mL.

Measurement of secreted apoB. Primary hepatocyte cultures were prepared for secretion studies. Approximately 1.75 to 2×10^6 cells were plated on 60 × 15 mm culture dishes and allowed to adhere for 2–4 h. Adherent cells were washed with basal medium and reincubated with the RPMI-1640 medium containing 0.38 mM leucine, 1.3 mM lysine, 2.4 mM glutamine, 1.8 mM choline chloride, 50 μM methionine; 28 mM glucose, 0.2% BSA, 0.1 nM insulin, 50 μg/mL gentamicin, and 100 μg/mL streptomycin plus 40 μCi of ^{35}S-methionine for 14 h at 37°C in 95% O_2/5% CO_2. After incubation, medium was collected for measurement of apoB secretion. Cells were washed twice with phosphate-buffered saline (PBS), then 0.3 mL of solubilization buffer [0.01 M sodium phosphate buffer (pH 7.4), 0.125 M sodium chloride, 0.5% Triton X-100, 0.5% sodium deoxycholate, 0.5% lithium dodecyl sulfate, 0.5% BSA (fatty acid-free) plus protease inhibitors (1 mM phenyl methyl sulfonyl fluoride, 1 mM EDTA, 1 mM benzamidine, 10 μg/mL leupeptin, 1 μM Aprotinin)] was added to the cells and they were transferred to a microcentrifuge tube.

The solubilized cells were sonicated and apoB was immunoprecipitated and separated by gel electrophoresis as described by Tripp *et al.* (9).

Measurement of mRNA and mRNA editing. Total RNA from hepatocytes was extracted using the method of Chomczynski and Sacchi (12). RNA was separated by 1% agarose-formaldehyde gel, stained with ethidium bromide to verify equal loading of RNA, and transferred to nylon membranes for Northern analysis.

ApoB cDNA was isolated, purified, and radiolabeled with ^{32}P-dCTP using a random priming kit (RPN1601Z, Amersham; Arlington Heights, IL). The blot was hybridized with the radiolabeled cDNA overnight at 42°C. After hybridization the membrane was washed several times with SSC (0.15 M NaCl/0.15 M Na citrate, pH 7.4)/SDS solutions at 55°C and the membranes were exposed to XAR-5 film at –70°C. After exposing the film, the membrane was stripped and re-hybridized with S-14 as a control probe. The intensity of the bands on the film for apoB and S-14 was quantified by scanning densitometry.

The editing of apoB was determined as previously described (13). Briefly, 2 to 10 μg of total RNA was treated with DNase as described by Giannoni *et al.* (14), and approximately 100 ng was used for reverse transcription-polymerase chain reaction (RT-PCR). Each sample was checked for DNA contamination by running a negative control with rTth. To exclude PCR product contamination, each reaction had an additional tube with all of the above buffers and enzymes, but without RNA. An aliquot of the PCR products was analyzed on a 2% agarose gel to confirm the expected 275 base pair apoB amplification product. RT-PCR products were purified by spin kit columns (Quigen, Studio City, CA), and apoB editing was assayed by primer extension. The extension products were resolved on an 8% denaturing polyacrylamide gel, dried, and exposed at –80°C with enhancing screens. The autoradiographs were scanned by laser densitometry.

ApoB synthesis and degradation. Freshly isolated hepatocytes were used in these studies to determine differences in basal apoB synthesis between *E. coli*-treated and control rats. To measure the synthesis of apoB, the freshly isolated hepatocytes were preincubated in RPMI-1640 medium without methionine and then pulsed with 50 μCi/mL ^{35}S-methionine for 15 min. Aliquots (1 mL) of the cells plus medium were taken for immunoprecipitation, and 750 μL of solubilization buffer was added. The immunoprecipitation procedure was the same as listed for the secretion experiments, except that 600–800 μL of the sonicated homogenate were analyzed.

Degradation of apoB was measured by pulsing freshly isolated hepatocytes as described above. Then the cells were washed three times with RPMI-1640 and incubated in RPMI-1640 plus 10 mM L-methionine for the times indicated in Table 1. ApoB from cells plus medium were identified by immunoprecipitation as described previously (9).

De novo *triglyceride and total cholesterol synthesis.* Freshly isolated hepatocytes (2.5×10^6 cells/mL) were incubated with ^3H_2O (0.5 mCi/mL) for 60 min at 37°C in 95% O_2/5% CO_2. Incorporation of ^3H_2O into TG and total cholesterol was measured

TABLE 1
Effect of *Escherichia coli* Bacteremia on the Recovery[a] of Labeled Total apoB from Cell and Medium After 45- to 180-min Chase Periods[b]

	Chase times (min)		
Group	45	90	180
Control	89 ± 5	70 ± 4	39 ± 3
E. coli-treated	96 ± 6	89 ± 5*	75 ± 4*

[a]Freshly isolated hepatocytes were pulsed with ^{35}S-methionine (50 μCi/mL) for 15 min. After pulse the cells were washed with fresh medium and chased with unlabeled methionine for selected time periods. Labeled apolipoprotein (apo) B was determined in cells plus medium by immunoprecipation and sodium dodecyl sulfate polyacrylamide gel electrophoresis. Bands from gels corresponding to apoB were quantitated by scintillation counting.

[b]The data presented are expressed as a mean percentage ± SEM of the ^{35}S-methionine incorporated into cellular total apoB at the end of the 15-min pulse for three independent experiments performed in triplicate. Asterisk (*): differs significantly ($P \leq 0.05$) from control.

in the cells plus medium by extracting total lipids and separating the lipid classes by thin-layer chromatography as described previously (5). After the 60-min incubation, lipids were extracted from the cell pellet and were used for mass determination of TG and total cholesterol (5).

Enzyme-linked immunosorbent assay (ELISA) and protein determination. A competitive ELISA using a goat anti-rat apoB antibody was performed according to the procedure developed by Wong and Pino (15,16).

Total protein of the radiolabeled cellular homogenates from secretion and synthesis experiments was determined using the method of Lowry *et al.* (17).

Statistics. Each sample was analyzed in triplicate. Results are expressed as average of averages ± standard error of the mean (SEM). All data were statistically analyzed by unpaired *t*-test.

RESULTS

ApoB secretion. Steady-state secretion of apoB from primary hepatocyte from control and *E. coli*-treated rats was determined by incubation overnight in RPMI-1640 plus ^{35}S-methionine. Cellular protein was not significantly different due to sepsis (control = 2.26 ± 0.34 and *E. coli*-treated = 2.03 ± 0.37 mg/mL). The secretion of apoB, as measured by immunoprecipitation and separation by gel electrophoresis, indicated that the *E. coli*-treated rats secreted more than twice as much apoB-48 ($P < 0.05$) as the hepatocytes from the control rats, which led to a twofold increase in total apoB secreted into the medium (Fig. 1A). There were no significant differences in cellular ^{35}S-labeled apoB (Fig. 1B).

ApoB synthesis, apoB mRNA, apoB editing. To determine whether the increased secretion of apoB was related to increased synthesis, freshly isolated hepatocytes were pulsed for 15 min with ^{35}S-methionine, and the incorporation of radiolabel into cells plus medium was measured by immunoprecipitation and gel electrophoresis. In our previous studies with *E. coli* bacteremia we found that freshly isolated hepatocytes in suspension cultures maintained the disturbances in lipid metabolism that were observed *in vivo* (5,6,18). Moreover, our findings demonstrated that the *E. coli*-induced increase in apoB secretion observed in perfused livers was also present when primary hepatocytes were cultured overnight (9). Approximately 40 min is required for newly synthesized apoB to be secreted in measurable amounts in the medium (19). Thus, the amount of ^{35}S-labeled apoB represents initial cellular synthesis. As shown in Figure 2, there were no significant differences in the incorporation of ^{35}S-methionine into apoB-48 or apoB-100 in hepatocytes from control and *E. coli*-treated rats. Total apoB concentrations, as measured by ELISA in cells plus medium (control = 1.40 ± 0.6 μg/mL; *E. coli*-treated = 1.25 ± 0.5 μg/mL), were similar, indicating that the pool size of these apo was not altered during sepsis.

We next evaluated apoB mRNA and apoB editing since the increase in apoB secretion may be due to changes in mRNA levels or the proportion of apoB mRNA that encoded for apoB-48 and apoB-100. As indicated in Figure 3, *E. coli* bacteremia did not alter apoB mRNA levels, as measured by Northern analyses on hepatocyte total RNA. ApoB editing, as expressed as % TAA, did not differ between the two groups (control = 50 ± 1, *E. coli*-treated = 52 ± 1) (Fig. 4).

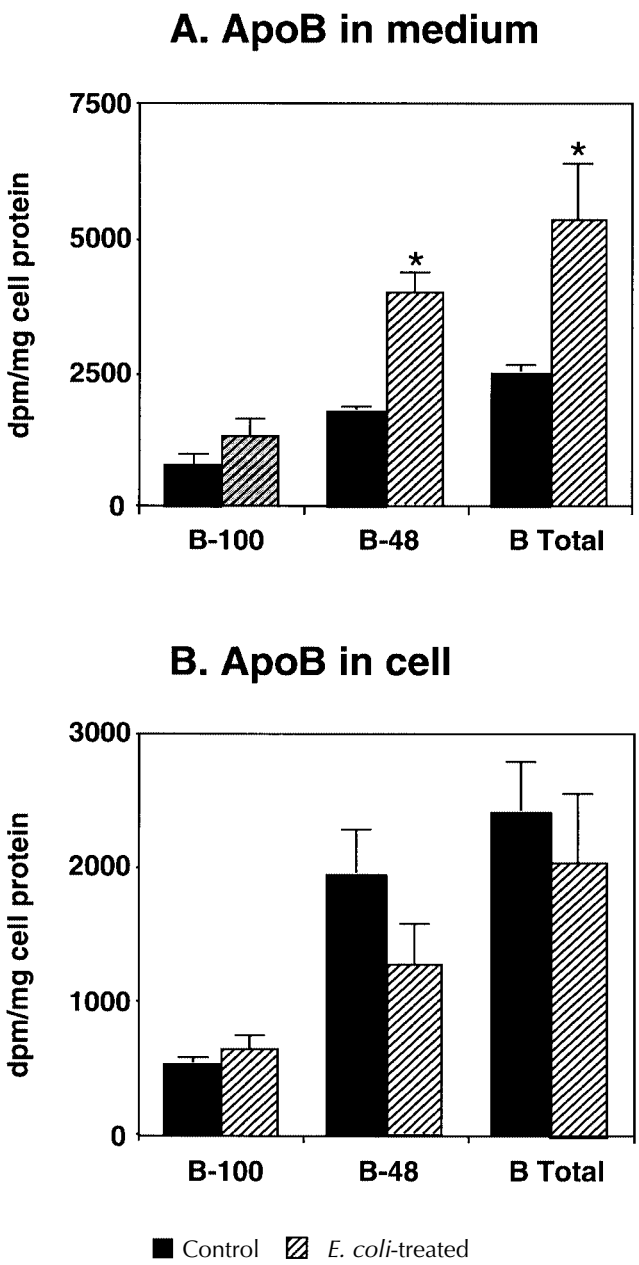

FIG. 1. Secretion of apolipoprotein (apo) B-48, apoB-100, and total apoB from primary hepatocytes from control and *Escherichia coli*-bacteremic rats. Primary cultured hepatocytes from control and *E. coli*-treated rats were prepared as described in the Materials and Methods section and cultured with RPMI medium containing 0.2% bovine serum albumin plus 40 μCi of ^{35}S-methionine for 14 h. After incubation, media and cells were prepared for immunoprecipitation and labeled apoB-48 and apoB-100 were separated by sodium dodecyl sulfate/polyacrylamide gel electrophoresis. Data were calculated as the average radioactivity of six experiments in which apoB was assayed in triplicate; bars represent the average of averages ± SEM. Asterisk (*) differs significantly ($P \leq 0.05$) from control.

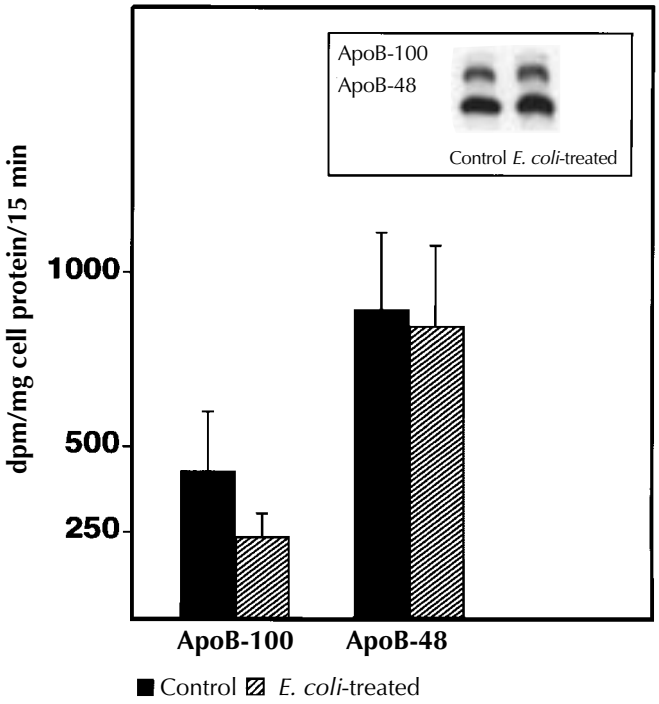

FIG. 2. Initial synthesis of apoB-48 and apoB-100 in freshly isolated hepatocytes from control and *E. coli*-bacteremic rats. Freshly isolated hepatocytes were pulse-labeled for 15 min by adding 50 μCi/mL of ^{35}S-methionine. The insert shows a representative autoradiograph of apoB-100 and apoB-48. Data were calculated as the average radioactivity of 6 experiments in which apoB was assayed in triplicate; bars represent the average of averages ± SEM. Asterisk (*) differs significantly ($P \leq 0.05$) from control. For abbreviations see Figure 1.

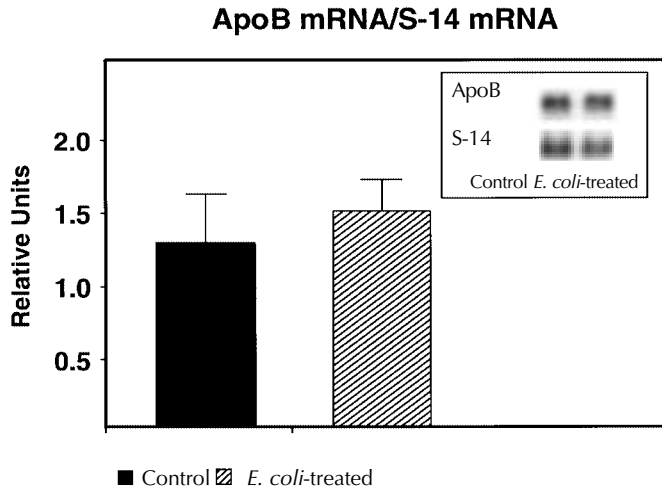

FIG. 3. Northern analysis of apoB mRNA and S-14 nRNA from freshly isolated hepatocytes from control and *E. coli*-bacteremic rats. RNA was separated on 1% agarose-formaldehyde gel, transferred to nylon membranes, hybridized to ^{32}P-labeled cDNA, and exposed to film. ApoB mRNA signal was quantified by densitometric analysis and normalized to S-14 signal. The insert shows a representive autoradiograph of apoB mRNA. Data were calculated as the average radioactivity of six experiments in which apoB was assayed in triplicate; bars represent the average of averages ± SEM. For abbreviations see Figure 1.

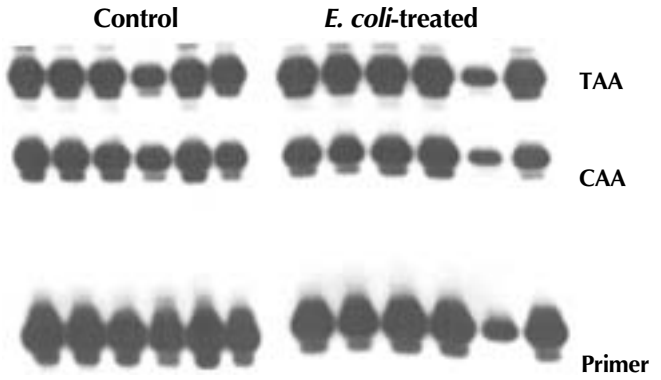

FIG. 4. ApoB mRNA editing in freshly isolated hepatocytes from control and *E. coli*-bacteremic rats. RNA was treated with DNase and used for reverse transcription-polymerase chain reaction (PCR). Purified PCR products were subject to primer extension analysis to demonstrate the proportion of edited (TAA) vs. unedited (CAA) apoB cDNA. For abbreviations see Figure 1.

Since apoB synthesis or changes in apoB mRNA were not altered in freshly isolated hepatocytes, we investigated whether a decrease in the rate of degradation could account for the increase in secretion rate. Pulse-chase studies were conducted to measure the degradation of the newly synthesized apoB. The recovery of labeled apoB in hepatocytes plus media was measured over time. After 180 min more labeled apoB remained in the hepatocytes plus their media from the *E. coli*-treated rats than the hepatocytes from the control rats (Table 1).

De novo *synthesis of TG and total cholesterol.* The availability of lipids is thought to have a role in regulating apoB degradation and secretion. We determined TG and total cholesterol synthesis from newly synthesized fatty acids and the content of TG and total cholesterol in hepatocytes. Syntheses of TG and total cholesterol were three- and sixfold higher, respectively, in hepatocytes from *E. coli*-treated rats than control rats (Fig. 5). These increases in synthesis were accompanied by similar increases in the content of hepatocyte TG and total cholesterol (Fig. 6).

DISCUSSION

One of the first metabolic responses to sepsis is the elevation in plasma TG. Plasma TG and apoB levels are elevated over twofold (5,8). The initial rise in TG results from an increase in hepatic production of VLDL-TG. The increase in the number of VLDL particles in the plasma is due to an increase in hepatic production of apoB and a decrease in the clearance of VLDL remnants (6–9). The present experiment explores the mechanisms for the altered apoB production during *E. coli* sepsis using an isolated hepatocyte system.

We have found that primary cultured hepatocytes from *E. coli*-treated rats secreted over twofold more apoB, which is consistent with previous findings in our laboratory using i*n vivo* and *in situ* liver perfusion systems (9). Cytokines such as tumor necrosis factor α(TNF-α) may mediate the hyper-

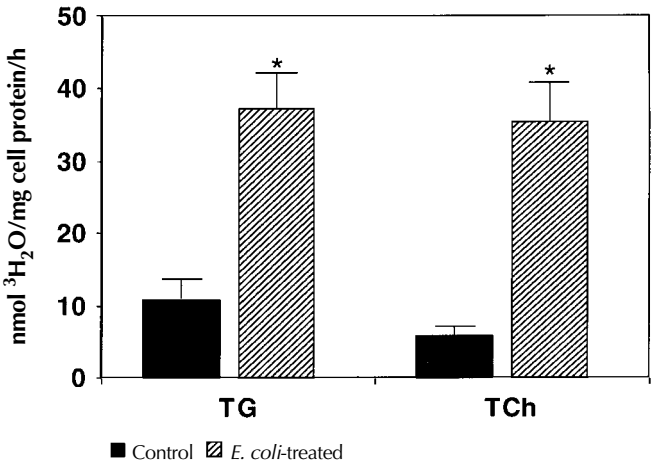

FIG. 5. *De novo* triglyceride (TG) and total cholesterol (TCh) synthesis in freshly isolated hepatocytes from control and *E. coli*-bacteremic rats. Hepatocytes were incubated with ^3H_2O (0.5 mCi/mL) for 60 min at 37°C in 95% O_2/5% CO_2. Total lipids were extracted in cell plus medium. Incorporated of ^3H_2O into TG and TCh was measured after separation by thin-layer chromatography as described in the Materials and Methods section. Bars are means ± SEM from four separate experiments which were conducted in triplicate. Asterisk (*) differs significantly ($P \leq 0.05$) from control. For abbreviations see Figure 1.

lipidemia of infection and sepsis (20). *Escherichia coli* bacteremia (6) and endotoxemia (18) produced an elevation in serum TNF-α within 60 to 90 min after administration. TNF also led to a rapid rise in serum VLDL within 45–90 min that was due to an initial increase in hepatic secretion of VLDL (20). Yet, treatment of *E. coli*-bacteremic rats with anti-TNF antibody did not prevent the rise in VLDL-TG (6).

The altered secretion of apoB in primary hepatocytes from *E. coli*-treated rats was not associated with changes in the synthesis rate or mRNA levels in the freshly isolated cells.

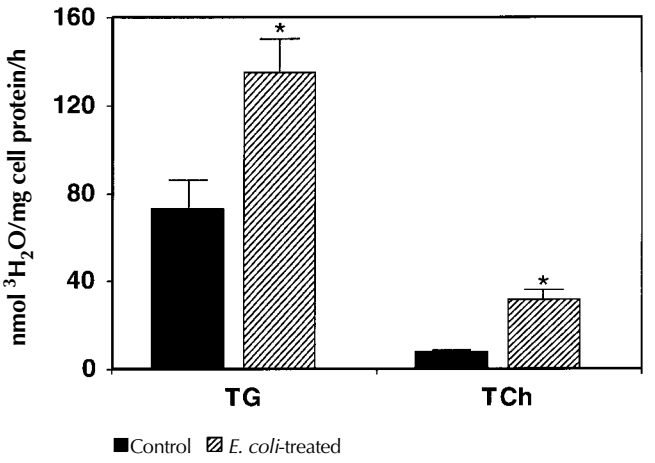

FIG. 6. TG and TCh mass in freshly isolated hepatocytes from control and *E. coli*-bacteremic rats. Hepatocytes were incubated for 60 min at 37°C in 95% O_2/5% CO_2; total lipids were extracted in cell plus medium for mass determination of TG and TCh. Bars are means ± SEM from four separate experiments which were conducted in triplicate. Asterisk (*) differs significantly ($P \leq 0.05$) from control. For abbreviations see Figures 1 and 5.

These findings agree with those of Delers *et al.* (21) who found that rats injected with mouse recombinant TNF had no change in the levels of apoB mRNA in the liver. Other investigators have shown in rat primary cultured hepatocytes and Hep G2 cells that the apoB message is relatively stable during changing metabolic situations in which apoB secretion is altered (22,23).

Posttranscriptional editing of apoB-100 mRNA in the livers of rodents produces apoB-48, so that both B-100 and B-48 are secreted (24–26). The increased secretion of apoB-48 from the primary cultured hepatocytes from the *E. coli*-treated rats could not be attributed to changes in apoB editing. Fasting has been shown to affect apoB editing (27). In this study we observed that fasting reduced apoB mRNA editing in both control and *E. coli*-treated rats compared with fed rats even though the total amount of apoB mRNA did not change (Lanza-Jacoby, S., unpublished observation). Hepatocytes used in the present study were from fasted rats and were considered to remain in a fasted state relative to mRNA concentration and apoB synthesis. Davis *et al.* (28) found that synthesis in cultured hepatocytes obtained from rats fasted for 3 d was not changed by addition of glucose to the medium.

Since apoB mRNA, synthesis, and editing did not account for the increased secretion of apoB, we investigated whether posttranslational mechanisms were involved. Studies from rat hepatocytes and HepG2 cells have indicated that intracellular degradation regulates the secretion of apoB (28,29). Degradation was evaluated in freshly isolated hepatocytes, which may lead to higher degradation rates than primary hepatocytes. However, the relative differences in degradation rates between control and *E. coli*-treated rats are evident in the freshly isolated hepatocytes. Our results indicate that degradation of apoB in the hepatocyte from the *E. coli*-treated rats was less than half the value of control rats, which would account for the increased secretion of apoB. Hormones such as insulin and glucocorticoids alter apoB secretion in primary cultured hepatocytes by regulating apoB degradation (23,29). Plasma concentration of insulin, glucagon, and glucocorticoids are elevated in this *E. coli* septic model (5,6), which may account, in part, for the increased secretion of apoB. Insulin decreased apoB secretion in cultured rat hepatocytes by reducing synthesis and degradation (19). In contrast, dexamethasone increased apoB secretion in rat cultured hepatocytes by increasing synthesis of apoB-48 and apoB-100 and decreasing intracellular degradation of newly synthesized apoB (22).

Degradation of apoB may be modified by altering TG synthesis and availability (30,31). Several studies in rabbit hepatocytes and HepG2 cells have demonstrated that the availability of TG protected apoB from degradation and thus increased apoB secretion (32–34). During sepsis the amount of *de novo* synthesized fatty acids incorporated into TG and total cholesterol is increased leading to an accumulation of these lipids in cells, which could facilitate lipoprotein assembly and secretion. Previously we also demonstrated that the activities of glycerol-3-phosphate acyltransferase and phosphatidate phos-

phohydrolase, key rate-limiting enzymes in TG synthesis, are elevated in hepatocytes from *E. coli*-treated rats (18).

Recently, the LDL receptor was shown to have a role in posttranslational regulation of apoB (35). ApoB secretion was increased in primary hepatocytes in the absence of the LDL receptor because degradation of apoB-100 and apoB-48 were reduced (35). We observed that the LDL receptor protein is downregulated in hepatocytes from *E. coli*-treated rats (Lanza-Jacoby, S., Phetteplace, H., and Sedkova, A., unpublished observations), which may also account for the decrease in apoB degradation.

Posttranslational changes in apoB metabolism increased secretion and contributed to the hypertriglyceridemia of sepsis. The twofold increase in apoB secretion correlated with a twofold rise in plasma apoB concentration. The physiological function of the hyperlipoproteinemia is not well understood. Recent reports have suggested that the rise in plasma lipoproteins may have a protective role by modifying the bioavailability and clearance of bacteria (36). Several mechanisms are involved in maintaining the elevation in plasma lipoproteins during sepsis (5–9). The onset of bacteremia leads to increased production of VLDL-TG arising from increased synthesis of lipids (5,6,8). During the course of the septic episode the clearance of TG decreases due to altered transcriptional regulation of LPL (5,37). The present studies explain how *E. coli* sepsis increases the plasma concentration of VLDL particles by decreasing the degradation of apoB, thus stimulating hepatic production of apoB-containing lipoproteins.

ACKNOWLEDGMENTS

The authors wish to thank Dr. Edward A. Fisher of Mount Sinai School of Medicine, New York, NY, for the gift of the apoB cDNA and Dr. Laurence Wong, Louisiana State University Medical Center for the goat anti-rat apoB antibody. We also thank Dr. Wong for his advice concerning the apoB ELISA. This study was supported by Grant No. GM31828 to S.L.J. from the National Institutes of General Medical Sciences and grants DK 56260 and HL 38180 to N.O.D.

Cu^{2+}-Induced Low Density Lipoprotein Peroxidation Is Dependent on the Initial O_2 Concentration: An O_2 Consumption Study

John K. Lodge[a,*], Maret G. Traber[b], and Peter J. Sadler[a,1]

ABSTRACT: Atherosclerotic plaques form in the arterial intima, where low density lipoprotein (LDL) is thought to be oxidatively modified at sites which may contain catalytic amounts of copper in the presence of low O_2 tension. We have investigated O_2 consumption during LDL peroxidation induced by Cu^{2+} ions *in vitro* and found two phases: a lag phase followed by a phase of rapid O_2 consumption. The length of the lag phase was dependent on Cu^{2+} and on initial O_2 concentrations; increasing either decreased the lag time; however, LDL concentration had no effect. LDL-induced Cu^{2+} reduction, however, was not affected by low initial O_2 concentrations, suggesting that O_2 is not required for LDL-mediated reduction of Cu^{2+}. Following the lag phase, O_2 consumption was dependent upon LDL or initial O_2 concentrations; Cu^{2+} concentrations had little effect, suggesting that the propagation phase is more dependent on the presence of LDL lipids and O_2 as substrates for the reaction. In summary, LDL peroxidation takes place in the presence of Cu^{2+} at low O_2 tension; however, the reaction is dependent upon initial O_2 concentrations; increases shorten the lag phase and accelerate O_2 consumption.

Paper no. L8251 in *Lipids 35*, 1087–1092 (October 2000).

Oxidation of polyunsaturated fatty acids (peroxidation) is a complex chain reaction, and can be initiated by either free radicals or lipoxygenase enzymes (1). Peroxidation involves a rearrangement of double bonds forming conjugated diene systems and the uptake of O_2, leading to the production of various isomeric hydroperoxides. The reaction is sustained, in the presence of O_2, by the abstraction of hydrogens from nearby lipids. Consequently, a single initiating event can lead to the formation of many hydroperoxide molecules. A commonly cited hypothesis for the pathogenesis of atherosclerosis involves formation of oxidatively modified low density lipoproteins (LDL) in the artery wall as a result of lipid peroxidation (2,3).

The precise initiating event in LDL peroxidation *in vivo* remains unclear; however, the addition of Cu^{2+} ions is a commonly used technique to induce these reactions *in vitro*. Indeed, Cu^{2+}-modified LDL shares properties with LDL oxidized by cells, a process that is also believed to involve transition metal ions (4,5). Significant amounts of copper have been detected in atherosclerotic plaques (6–8), and catalytic amounts of copper and iron are released from the intima after mechanical disruption (9), highlighting a possible role for transition metal-induced lipid peroxidation in the pathogenesis of atherosclerosis. However, markers of copper-induced LDL oxidation in atherosclerotic plaques have suggested that copper has a role only at an advanced stage (10).

In vivo LDL is thought to be peroxidized only when trapped within the arterial wall (2). The microenvironment of the arterial intima is such that O_2 saturation (11) and pH are low. Oxygen saturation may be lower here than surrounding tissues as a result of increased O_2 consumption by the growing atheroma (2,11), or by the altered permeability of the artery wall, caused by endothelial damage.

Although O_2 is fundamental to lipid peroxidation, few studies investigating O_2 uptake during LDL oxidation *in vitro* have been carried out. Oxygen consumption during LDL peroxidation has been measured (12–14); however, variations in response to O_2 saturation were not evaluated. In this study we have investigated the role of O_2 in Cu^{2+}-induced LDL peroxidation, and in particular, the role of the initial O_2 concentration in determining lag time and propagation rates.

MATERIALS AND METHODS

LDL isolation. LDL was isolated from heparinized blood of nonfasted, healthy, normolipidemic volunteers by fast protein liquid chromatography (FPLC) as described previously (15), using a modification of published methods (16,17). Occasionally, LDL was concentrated from plasma by precipitation with phosphotungstate and magnesium, as previously described (15,18), then purified by FPLC. The protein content of the pooled LDL fractions was determined by a variation of the Lowry method (Total protein–micro, Sigma diagnostics). The LDL solution was converted to molarity using an apoprotein

Abbreviations: apoB, apoprotein B; FPLC, fast protein liquid chromatography; LDL, low density lipoprotein; PBS, phosphate-buffered saline; UV, ultraviolet.

B (apoB) molecular size of 500,000. LDL was stored in sealed vials at 4°C and used within 2 d of isolation.

O_2 uptake. Oxygen uptake was followed using a Clarke-type O_2 electrode (Rank Brothers, Cambridge, England). The platinum electrode was polished, and the semipermeable membrane changed every other day prior to use. The electrode was calibrated to a chart-recorder using air-saturated phosphate-buffered saline (PBS) pH 7.4 as the 100% O_2 mark; the 0% O_2 mark was achieved by addition of sodium dithionate crystals to the PBS. The final volume of the reaction cell was 3600 μL. The percentage O_2 was converted to molarity, taking air-saturated buffer to contain 240 μM O_2 according to published approximate values (19,20).

LDL peroxidation. At the start of the experiment, after setup of the electrode, PBS (0.1 M phosphate, 0.15 M NaCl, pH 7.4) was added to the chamber and allowed to air-equilibrate for 10 min. LDL, at the requisite concentration, was then added, and the top placed on the chamber. The recorder was set at the 100% O_2 mark. After a baseline was recorded, Cu^{2+} was added *via* injection through the plug, and the O_2 consumption was followed. For various experiments, either the LDL concentration was varied (0.01–0.106 μM) keeping the Cu^{2+} concentration constant (2.77 μM), or the Cu^{2+} concentration was varied (0.27–5.53 μM), while the LDL concentration was kept constant (0.052 μM). In other experiments the initial O_2 concentration was varied (480-43 μM) *via* degassing with helium or bubbling with pure O_2, while the LDL and Cu^{2+} concentrations were kept constant (0.054 and 2 μM, respectively), and the temperature sustained at 24°C.

Cu^+ formation. LDL-mediated Cu^{2+} reduction was measured photometrically using the specific Cu^+ probe bathocuprione. The bathocuprione:Cu^+ complex exhibits a maximum at 480 nm (ε = 9047 M^{-1} cm^{-1}) (21). Bathocuprione (300 μM) was incubated with LDL (100 μg/mL ~0.2 μM) in PBS at pH 7.4. The reaction was followed after addition of Cu^{2+} (15 μM). Experiments were performed with air-saturated PBS, or that which was degassed with helium to ~20% of the original O_2 concentration as measured with the O_2 electrode. The ultraviolet (UV) cuvette was sealed and the cap coated with petroleum jelly (Vaseline) to prevent O_2 exchange.

UV spectroscopy. Electronic absorption spectroscopy was carried out on a PerkinElmer Lambda 16 spectrometer using 0.5 mL of solution in 1-cm pathlength cells. Parallel conjugated diene assays were undertaken *via* measurement of absorbance at 234 nm. Similar concentrations of LDL and Cu^{2+} were used as described in the above sections.

Kinetics. Kinetic analyses of O_2 consumption data were carried out during the propagation phase. Rates were determined from the gradient of the line from $\ln(a - x)$ vs. t, where $(a - x)$ is the O_2 concentration at time t, minus the initial O_2 concentration.

RESULTS

Oxygen uptake during Cu^{2+}-induced LDL peroxidation typically shows a lag phase of slow consumption followed by an increased O_2 consumption phase, then a second phase of slow consumption. These phases are comparable to the characterized lag, propagation, and termination phases identified with a conjugated diene assay (22) under similar conditions used in this study.

Varying LDL concentration. To estimate the effect of LDL concentration on O_2 uptake, the final LDL concentration in the reaction chamber was varied from 0.01 to 0.106 μM, while the Cu^{2+} concentration was kept constant at 2.77 μM (Fig. 1). Lag times were unaffected by LDL concentrations and were all approximately 50 min. However, each curve plateaued at a different point, dependent upon the initial LDL concentration such that the final O_2 concentration decreased with increasing LDL concentration. A conjugated diene assay from similar experiments (data not shown) also revealed that lag time was unchanged, but that the maximal absorbance at 234 nm increased with increasing LDL concentrations.

Varying Cu^{2+} concentration. To evaluate the effect of copper on O_2 consumption, the LDL concentration was kept constant (0.053 μM), and the Cu^{2+} concentration was varied from 0.27 to 5.53 μM (Fig. 2). Oxygen consumption curves were parallel for each Cu^{2+} concentration, and after 250 min all curves were at a similar level.

Varying the initial O_2 concentration. To evaluate the rates of O_2 consumption when O_2 is limiting or in excess, the LDL and Cu^{2+} concentrations were kept constant (0.053 and 2.77 μM, respectively), and the initial O_2 concentration was varied from 43 to 480 μM (18–200% of control) (Fig. 3). When the initial O_2 concentration was 240 μM (100%, air-saturated solution) or higher, O_2 consumption plateaued at 100 min,

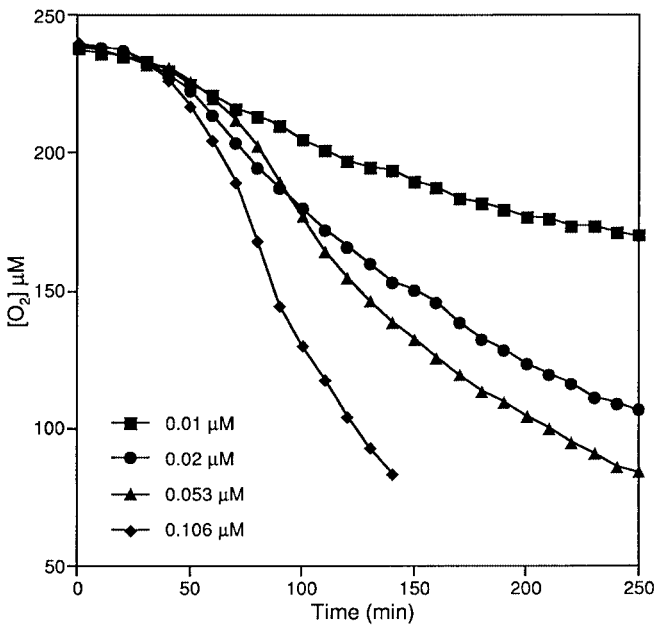

FIG. 1. Varying the low density lipoprotein (LDL) concentration affects O_2 consumption during Cu^{2+}-catalyzed peroxidation of LDL. The LDL concentration was varied as shown with a fixed Cu^{2+} concentration of 2.77 μM and an initial O_2 concentration of 240 μM at 24°C. Shown are representative traces of at least duplicate independent experiments.

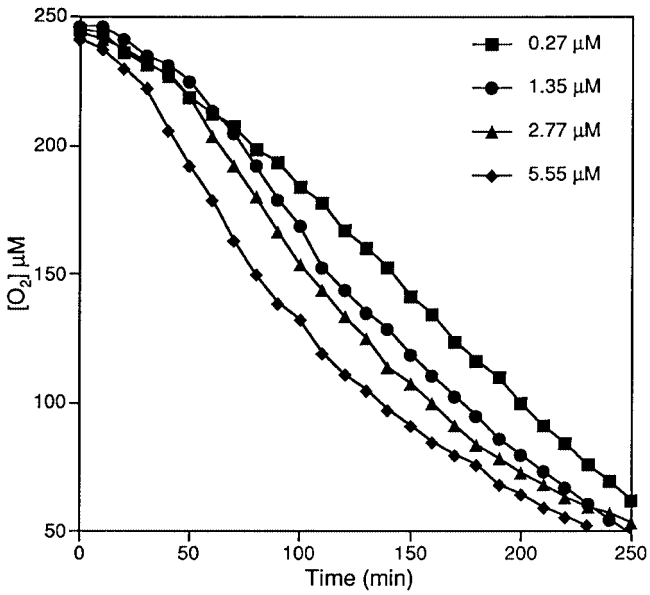

FIG. 2. Varying the Cu^{2+} concentration affects O_2 consumption during Cu^{2+}-catalyzed peroxidation of LDL. The Cu^{2+} concentration is varied as shown with a fixed LDL concentration of 0.053 μM and an initial O_2 concentration of 240 μM at 24°C. Shown are representative traces of at least duplicate independent experiments. See Figure 1 for abbreviation.

and the reaction did not result in complete O_2 depletion. This was not the case when the initial O_2 concentration was lower. Here the O_2 consumption following the lag phase was slow and came to an abrupt halt because the O_2 had been depleted

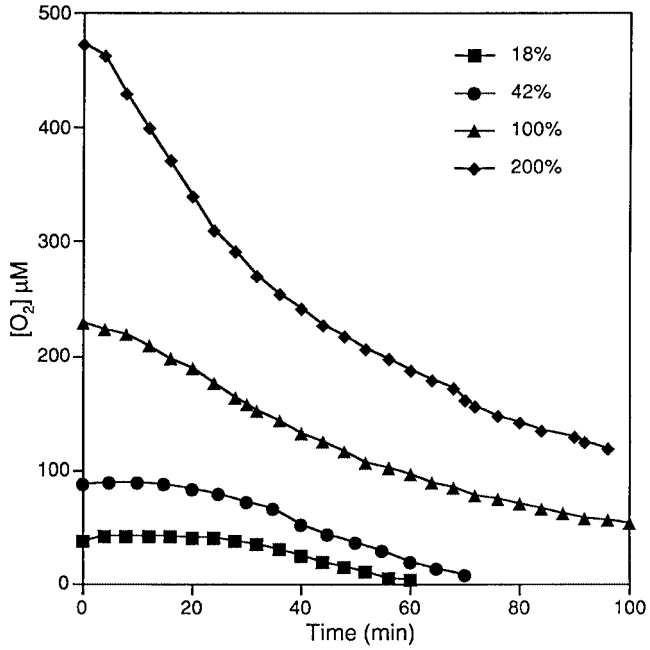

FIG. 3. Varying the initial O_2 concentration affects O_2 consumption during Cu^{2+}-catalyzed peroxidation of LDL. The initial O_2 concentration was varied as shown. Cu^{2+} and LDL concentrations are 2.77 and 0.053 μM, respectively, at 24°C. Representative traces of at least duplicate independent experiments are shown. See Figure 1 for abbreviation.

in the chamber. Addition of O_2 at this stage resulted in immediate O_2 uptake, at a similar rate to that observed prior to O_2 depletion (data not shown).

O_2 consumption lag times. Figure 4 shows graphically the effect of the above variables on the lag time of Cu^{2+}-mediated LDL peroxidation measured by O_2 consumption. While increasing the LDL concentration (Fig. 4A) had no effect on lag time, increasing Cu^{2+} concentration (Fig. 4B), or initial O_2 concentration (Fig. 4C) decreased the lag time. Indeed, there was a linear correlation between lag-time and Cu^{2+} concentration over the range studied ($r^2 = 0.973$), while increasing the initial O_2 concentration caused an exponential decrease in the lag time ($r^2 = 0.95$).

O_2 consumption rates. In order to obtain O_2 consumption rates, the O_2 uptake over a given period during the propagation phase was calculated as $d[O_2]/dt$. Oxygen uptake increased linearly with increasing LDL ($r^2 = 0.968$) (Fig. 5A) or exponentially with increasing initial O_2 concentration ($r^2 = 0.98$) (Fig. 5C). Increasing the Cu^{2+} concentration also linearly increased oxygen uptake ($r^2 = 0.982$) but not markedly (Fig. 5B); a fivefold increase in Cu^{2+} concentration did not even double the rate of O_2 consumption. Also the intercept of this graph (Fig. 5B) did not go through zero indicating that in the absence of Cu^{2+}, O_2 is consumed. In a control experiment with no added Cu^{2+}, O_2 was consumed at a steady rate, but only after a long lag time. The rate of this consumption is shown on the graph as the zero Cu^{2+} point.

Cu^+ formation. Since LDL is known to reduce Cu^{2+} and this may be an important step in the initiation process, LDL-mediated Cu^{2+} reduction was investigated at low initial concentrations of O_2. Figure 6 shows a typical experiment, comparing Cu^+ formation in control (air-saturated) and at low initial O_2 concentrations. No differences between the two treatments are seen, suggesting that LDL reduces Cu^{2+} equally well at normal and low O_2 concentrations. These data indicate that O_2 is not required for LDL-mediated reduction of Cu^{2+} to Cu^+.

DISCUSSION

In this study we investigated various parameters which could modulate the time course of Cu^{2+}-mediated LDL peroxidation by monitoring O_2 consumption. We demonstrate here that varying the Cu^{2+} concentration and the initial O_2 concentration, but not the LDL concentration, will affect peroxidation lag times. During the propagation phase, O_2 consumption rates are dependent upon LDL concentration and initial O_2 concentration, but do not vary much with Cu^{2+} concentration.

Although the importance of O_2 concentrations in peroxidation reactions is unquestionable, there have been very few reports in which the uptake of O_2 during LDL peroxidation was measured, and even fewer which have studied this reaction under various levels of O_2 saturation. This is surprising, given that the arterial intima, the probable site of LDL oxidative modification, is a site of low O_2 saturation (11,23). Since it is likely that LDL *in vivo* is peroxidized under conditions of low O_2 saturation, it is important to investigate how the initial O_2 concentration modulates LDL peroxidation.

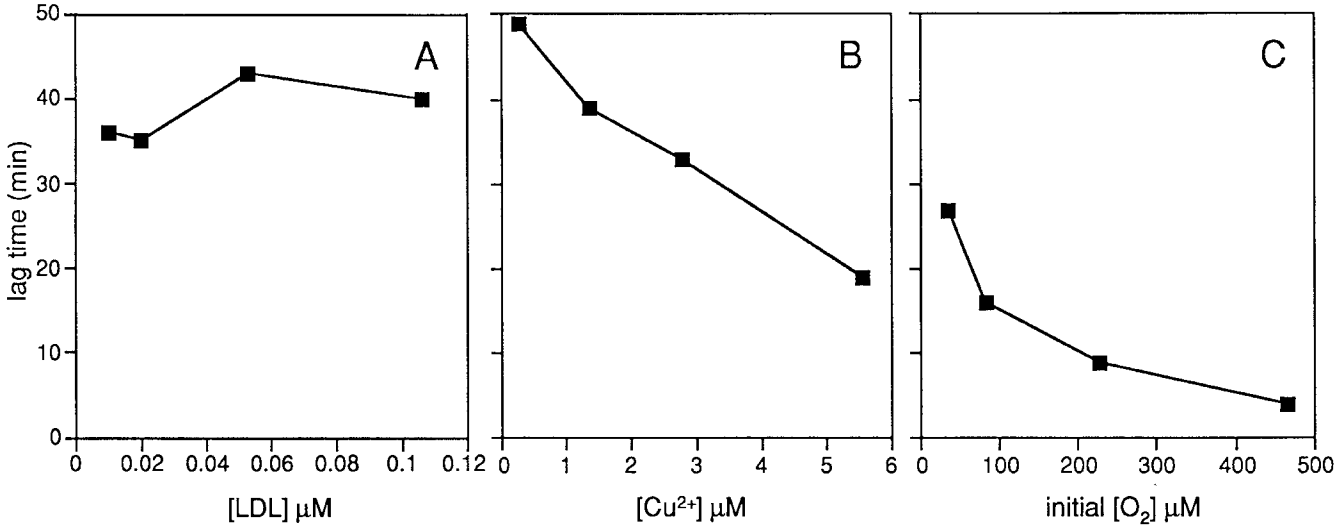

FIG. 4. Graphs showing the relationship between the reaction parameters and the lag-times of O_2 consumption during Cu^{2+}-catalyzed LDL peroxidation. Conditions are for Figures 1–3. Average values are shown from at least duplicate measurements. (A) Varying LDL concentration; (B) varying Cu^{2+} concentration; (C) varying initial O_2 concentration. Significance values for linear or exponential fits are given in the text. See Figure 1 for abbreviation.

A major observation in this study is that the lag times and O_2 consumption rates were both dependent upon the initial O_2 concentrations. At low initial O_2 concentrations the lag-phases were extended and the subsequent peroxidation rates were low (Figs. 3 and 4C). As initial O_2 concentrations increased, lag times shortened and peroxidation rates increased. Since Cu^{2+} and LDL concentrations also affected these variables, certain assumptions can be drawn regarding each phase in LDL peroxidation and are discussed in the following sections.

The lag phase. The lag times were dependent upon both initial O_2 concentrations and copper concentrations; low concentrations of either prolonged the lag times. Interestingly, lag times were not dependent upon LDL concentrations over the ranges studied (Figs. 1 and 4A); LDL concentrations were varied over 10-fold while the lag times remained relatively constant between 35 and 40 min. Since the initiation event in Cu^{2+}-induced LDL oxidation is thought to involve Cu^{2+} reduction, it is likely then that the lowest LDL concentration used was sufficient to reduce all the Cu^{2+} to Cu^{+}. Lynch and Frei (21) showed that at a constant Cu^{2+} concentration, increasing the LDL concentration beyond a certain limit resulted in no further Cu^{2+} reduction; 0.025 μM LDL (~10 μg/mL) was sufficient to reduce 10 μM Cu^{2+}. Thus, in their experiments a 400-fold excess of Cu^{2+} was reduced by

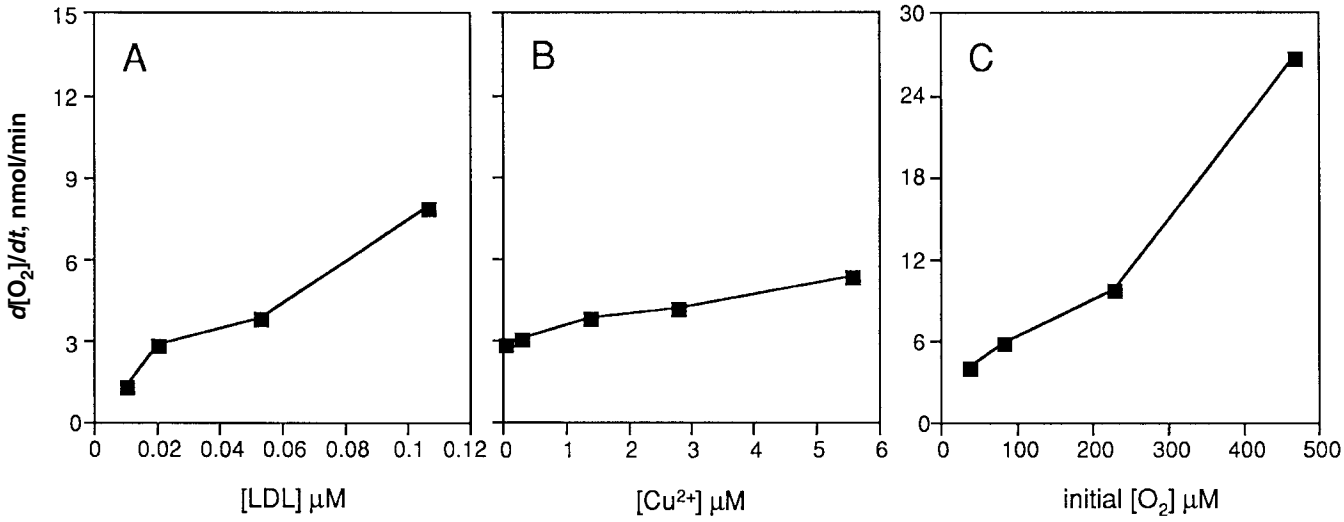

FIG. 5. Graphs showing the relationship between the reaction parameters and the rates of O_2 consumption during Cu^{2+}-catalyzed LDL peroxidation. Conditions are for Figures 1–3. Rates are taken as $d[O_2]/dt$ (nmol O_2 consumed/min) for a given period during the propagation phase. Average values are shown from at least duplicate measurements. (A) Varying LDL concentration; (B) varying Cu^{2+} concentration; (C) varying initial O_2 concentration. Significance values for linear or exponential fits are given in the text. See Figure 1 for abbreviation.

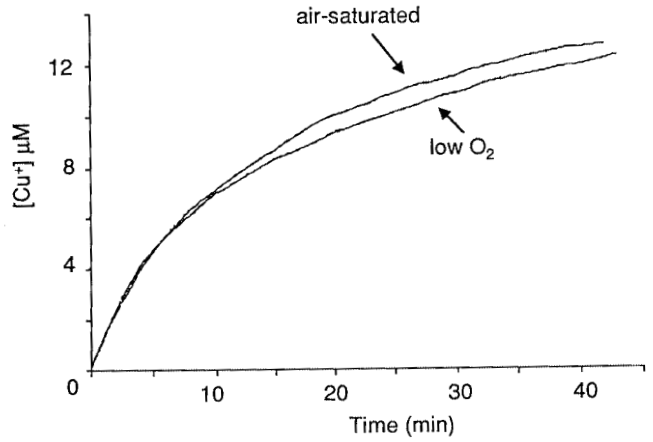

FIG. 6. Low initial O_2 concentration does not affect LDL-mediated Cu^{2+} reduction. Cu^+ formation was measured using the specific probe bathocuprione (300 μM) with LDL (100 μg/mL) and Cu^{2+} (15 μM) in either air-saturated (100% or 240 μM) or O_2 depleted (18% or 43 μM) buffer. See Figure 1 for abbreviation.

LDL, in our experiments the maximal excess of Cu^{2+} was only 280-fold.

The mechanism for Cu^{2+}-induced LDL oxidation is unknown. Reduction of Cu^{2+} may be important, and the reductant for Cu^{2+} in LDL has been proposed to be α-tocopherol (24,25), although lipid hydroperoxides may play a role (27,28). LDL also binds copper , and a number of these binding sites are believed to be reactive (29). It has been shown that peroxidation of LDL lipids only proceeds with normal kinetics when Cu^{2+} binds preferentially to sites on apoB that contain histidine residues, and that these sites are not involved in Cu^{2+} reduction (29). LDL-mediated Cu^{2+} reduction was unaffected by a low initial O_2 concentration (Fig. 6); however, the lag times were dependent on initial O_2 concentrations (Figs. 3, 4C). Thus, O_2 must be involved in the initiating event, but not with Cu^{2+} reduction. One potential explanation is the formation of a reactive intermediate species between copper and O_2; however, no direct evidence is presented here. One would expect that if the initiating species were derived from a reaction between Cu^+ and O_2, then adding Cu^+ directly would be highly prooxidant. Studies have shown this not to be the case. Cu^+ does not oxidize LDL efficiently, and antagonizes α-tocopherol depletion and lipid peroxidation under certain conditions (30).

Therefore, it is likely that a radical chain event involving O_2 occurs upon Cu^{2+} reduction, the number of reactive species formed being proportional to the O_2 and Cu^{2+} concentrations, hence a requirement for LDL-induced Cu^{2+} reduction.

The propagation phase. The propagation phase immediately follows the lag phase, and it is characterized by a rapid increase in hydroperoxide formation and, as shown in these experiments, O_2 consumption. All variables tested appeared to affect the rate of O_2 uptake during this phase; however, varying Cu^{2+} concentration had the smallest effect (Fig. 2). Increasing the copper concentration has been shown previously to increase the rate of peroxidation (28), however, in those systems O_2 was not limiting. Presumably, because Cu^{2+} was in excess over the LDL concentration, further increases in Cu^{2+} had little effect as excess radicals had been generated. Indeed the rate of hydroperoxide formation has been shown to depend on the ratio of bound Cu^{2+} to LDL (31).

It is interesting that increasing the LDL concentration increased the rate of peroxidation (Figs. 1, 5A). In this respect LDL is behaving as a prooxidant species, although it has been shown that LDL particles do not rapidly exchange radicals (32). It appears that LDL concentrations (or to be more specific, LDL polyunsaturated fatty acids) are rate-limiting for peroxidation. This is not surprising since LDL is the substrate. Indeed, total O_2 consumption was proportional to the LDL concentration (Fig. 1). Interestingly though, Noguchi *et al.* (14) proposed from their studies that a proportion of oxygen uptake by oxidizing LDL could not be accounted for by conjugated diene or total peroxides. Similarly, O_2 concentration is a dependent factor and is also a substrate. Oxygen is required both for the initial reactive species and for the formation of hydroperoxides.

Similar findings were reported by Hatta and Frei (33) and Reaven *et al.* (34) who both found decreased rates of LDL oxidation at lower O_2 concentrations, indicating that O_2 concentration is a rate-limiting factor for LDL peroxidation.

The termination phase. The rate of O_2 consumption only slows during the termination phase, suggesting that hydroperoxide formation is still occurring, but the extent of hydroperoxide breakdown must exceed formation. This termination phase is dependent upon the LDL concentration. This is not surprising since LDL is the substrate for the reaction, hence when the substrate reaches low concentrations then the rate of reaction must slow. In following this rationale it would be expected that as the O_2 concentration falls (as it is being consumed in the reaction vessel) the rate of O_2 uptake and hence peroxidation would also fall. This was clearly not the case (Fig. 3). When the initial O_2 concentration was low, O_2 uptake came to an abrupt stop when the O_2 concentration in the reaction vessel fell below a critical level (1.5%). The rate of O_2 consumption only decreases when the LDL polyunsaturated fatty acid concentration is low, that is, when the termination phase begins.

These findings possibly have *in vivo* implications since atherosclerotic lesions are known to be ischemic, engorged with LDL lipids, and contain redox active transition metals. In such circumstances peroxidation could readily occur, and will not be limited by low O_2 concentrations.

Adaptation of Composition and Biophysical Properties of Phospholipids to Temperature by the Crustacean, *Gammarus* spp.

Eila Lahdes[a], Gabor Balogh[b], Elfrieda Fodor[b], and Tibor Farkas[b,*]

[a]Finnish Institute of Marine Research, FIN-00930 Helsinki, Finland, and [b]Institute of Biochemistry, Biological Research Center, Hungarian Academy of Sciences, H-6701 Szeged, Hungary

ABSTRACT: The compositions of lipid classes as well as the molecular species composition of subclasses (diacyl, alkylacyl, and alkenylacyl forms) of choline and ethanolamine phosphoglycerides in marine amphipod crustaceans, *Gammarus* spp., collected in the Baltic Sea at 8 and 15°C, were studied in relation to environmental temperature. The structural order of phospholipid multibilayers was also determined. Environmental temperature had little effect on fatty acid composition. The level of some polyunsaturated fatty acids, such as 20:4, even increased in choline and ethanolamine phosphoglycerides at 15°C. Ethanolamine phosphoglycerides were rich in alkenylacyl forms, especially in crustaceans collected at 15°C. The accumulation of *sn*-1 monoenic, *sn*-2 polyenic diacyl, alkyl, and alkenylacyl phosphatidylethanolamines and diacyl phosphatidylcholines was observed at 8°C. The phospholipid vesicles of crustaceans collected at 8°C were more disordered than expected compared to those obtained from animals collected at 15°C. It was concluded that, in addition to variations in the levels of *sn*-1 monoenic and *sn*-2 polyenic phospholipid molecular species with temperature, ethanolamine plasmalogens may play a role in controlling membrane biophysical properties in marine amphipod crustaceans.

Paper no. L8470 in *Lipids 35*, 1093–1098 (October 2000).

An inherent property of cells in poikilothermic animals is their capacity to adjust the physicochemical characteristics of their membranes to prevailing temperatures. The so-called homeoviscous adaptation of membrane fluidity was first described by Sinensky in *Escherichia coli* (1), and this observation was extended to numerous invertebrate (2–4) and poikilothermic vertebrate species, from fish to birds (5,6). In fish, during adaptation to reduced temperatures, unsaturation of the constituent fatty acids increases (7–9), with the polar head group as well as the molecular species composition of membrane phospholipids being reorganized. Hazel *et al.* (10) demonstrated that exposure to cold results in an increase of a wedge-shaped phospholipid, phosphatidylethanolamine (PE), in the membranes of the gills of rainbow trout. This response was shown to occur with freshwater planktonic crustaceans (11), but not with marine calanoid copepods collected around Norway and India (2). One of the most spectacular changes taking place with phosphatidylcholines (PC) and PE during the adaptation of fish to reduced temperature is the accumulation of monoenoic fatty acid in the *sn*-1 position of the molecule combined with a polyunsaturated fatty acid in position *sn*-2 (6,12). A monounsaturated fatty acid in position *sn*-1 increases the surface area which the molecule occupies in a monolayer by about 25–30% relative to its saturated homolog (13), which renders these structures ideal for controlling membrane order during thermal adaptation. Indeed, model experiments have proved that this type of phospholipids increases membrane fluidity at reduced temperatures in fish phospholipids and membranes (6).

Whereas all of these data were obtained for fish, little information is available to show whether the same response to temperature occurs in invertebrates. The nematode *Caenorhabditis elegans* also accumulates monoenoic fatty acid in position *sn*-1 of its phospholipids when grown at reduced temperatures (14). We showed earlier that the PE of the cold-adapted marine shrimps from Norway were richer in 18:1/22:6 than those collected in the southern Mediterranean Sea (15). In the present paper, the fatty acid composition of phospholipids, the molecular species composition of the two major phospholipids, PC and PE, as well as the fluidity of phospholipid vesicles obtained from a Baltic Sea amphipod crustacean, *Gammarus* spp. collected from different thermal environments, are compared. It is hoped that studying the molecular composition of membrane phospholipids in invertebrates that are evolutionally or seasonally adapted to extreme temperatures will shed some light on the strategies followed by the vertebrates and invertebrates in order to preserve the structural and functional integrity of their membranes under various thermal conditions.

MATERIAL AND METHODS

Animals. *Gammarus* spp. were collected near the Archipelago Research Institute in the Archipelago Sea (the Baltic Sea) (60°15.25′ N, 21°57.30′ E) in spring (May) and summer

(August) at temperatures of 8 and 15°C, respectively. The salinity remained at the constant level of 6 ppt except in early spring after the melting of the ice, when it was *ca.* 0.5 ppt lower. Animals were sampled from a belt of *Fucus vesiculosus,* which grew freely on the sandy bottom. The depth to the bottom was 1.5–2 m. The animals were kept in aerated, filtered (using Whatman GF/C glass fiber filter) sea water at the *in situ* temperature for 24 h in order to empty their guts before quick-freezing in liquid nitrogen in a small volume of filtered sea water. Sea water was used after the observation that samples were better preserved in liquid. The storage temperature of the samples was –80°C. The populations consisted of *G. oceanicus*, *G. locusta*, and *G. zaddachi*. Because we wanted to see the variation in membrane characteristics in an existing *Gammarus* community between seasons rather than between individuals, species and sexes were not separated. *Gammarus* spp. have a wide geographical distribution in the littoral zones from the Arctic region in the north to the east coast of North America in the west. In general, they tolerate well the changes in salinity and temperature, as one would expect considering their wide geographical distribution (16).

Analytical techniques. Lipids were extracted using chloroform/methanol (2:1, vol/vol) according to Folch *et al.* (17). Silicic acid column chromatography was used to separate neutral and polar lipids. Chloroform eluted the neutral and methanol the polar lipids. The lipids were stored in benzene containing 0.01% butylated hydroxytoluene at –70°C until processing. Fatty acid methyl esters were separated on a FFAP column (0.25 mm i.d. capillary column of 30 m length from Supelco, Bellefonte, PA) in a Hewlett-Packard Model 6890 gas chromatograph, after transesterification in absolute methanol containing 5% HCl at 80°C. Peaks were identified with the aid of authentic standards such as those marketed by Sigma (St. Louis, MO).

Phospholipids were segregated according to polar head groups by thin-layer chromatography (TLC) following the method of Fine and Sprecher (18). PC and PE, after visualization with 5-amino 8-naphthalene sulfonic acid in methanol under ultraviolet light, were eluted with chloroform/methanol/H_2O (50:50:1, by vol). The purified phospholipids were then digested with phospholipase C (Sigma) and the obtained diradylglycerols were converted to fluorescent anthroyl derivatives as described by Takamura and Kito (19). Diacyl, alkylacyl, and alkenylacyl subclasses were separated on TLC and further segregated into molecular species on a Supelcosil LC-18 column (1 mm i.d. and 30 cm in length, Supelco) as well as on a C-8 column (1 mm i.d., 30 cm in length, Supelco) using a Hitachi Merck high-performance liquid chromatograph (HPLC) equipped with a fluorescent detector and acetonitrile/isopropanol (80:20, vol/vol) and methanol/water/acetonitrile (93:5:2, by vol) as solvent. Peaks were identified using authentic standards and also on an HPLC–mass spectrometer (Shimadzu SCL-10Avp connected to a Shimadzu LCMS-QP8000 mass spectrometer) using the same columns and solvents. A known amount of derivatized 12:0/12:0 was added to the spots on the TLC plate to quantify the phospholipid subclasses. The 12:0/12:0 was selected as internal standard because it did not overlap with any molecular species in the sample.

The fluidity of phospholipid vesicles was determined using 1,6-diphenyl 1,3,5-hexatriene (DPH) (Molecular Probes, Eugene, OR) in tetrahydrofuran in a molecular ratio of 1:1000 (lipid/fluorescent probe). Approximately 250 mg of phospholipids was evaporated under high vacuum onto the wall of a test tube, and the film was rehydrated in 3 mL of 20 mM Tris-HCl (pH 7.4) buffer under vigorous vortexing. The steady-state fluorescence anisotropy parameter was measured on a T-format fluorescence spectrometer (Quanta Master QM-1; Photon Technology International, Princeton, NJ) as $R_{ss} = [(R_V/R_H) - 1]/[(R_V/R_H) + 2]$, where R_V and R_H are the ratios of the intensities detected in the two emission channels with the excitation polarizer in the vertical and horizontal position, respectively. The excitation and emission wavelengths were 360 and 430 nm. The temperature of the sample was controlled by a circulating water bath and measured directly in the cuvettes with a platinum electrode. Measurements were made between 5 and 40°C using a heating rate of 0.4°C/min.

RESULTS

Table 1 shows the fatty acid composition of the neutral and polar lipids (phospholipids) of *Gammarus* spp. acclimatized to two extreme temperatures, 8 and 15°C, respectively. In general, the distribution of the fatty acids in lipids is similar to that found within gammarides such as *G. duebeni* (20,21), i.e., the level of 22:6 is lower than that of 20:5. Except for palmitoleic acid, the environmental temperature had little effect on the fatty acid composition of the separated lipid classes. Palmitoleic acid was more abundant in the triglycerides of crustaceans collected at 8°C than in those collected at 15°C. Since the fatty acid composition of the food triglycerides represents more or less the fatty acid composition of neutral lipids, it is possible that the animals at 8°C consumed food more rich in this acid. It is interesting, however, that it did not accumulate in polar lipids. Higher levels of 20:5 and 22:6 in neutral lipids at 8°C might also indicate increased uptake of these fatty acids. The linoleic (18:2), arachidonic (20:4), and eicosapentaenoic acids (20:5) in polar lipids responded to environmental temperature in the opposite sense than expected: their level was higher at 15°C than at 8°C. In contrast, the level of docosahexaenoic acid (22:6) remained unchanged. Owing to this and to the high content of 18:0 in cold-acclimatized animals (13.7 vs. 4.3%), the ratio of saturated to unsaturated fatty acids was considerably higher in phospholipids at 8°C. Both PC and PE showed little response to temperature, except 16:0 in PC at 15°C (25 vs. 20%). The presence of dimethylacetals in PE indicates the presence of ether lipids (Table 1).

Table 2 shows the subgroup composition of the major phospholipids, PC and PE. The PC fraction consisted of only diacyl forms, but in the PE fraction the ether lipids dominated. The level of ethanolamine plasmalogens was higher in animals collected from warmer environments (52.2 vs.

68.2%). Chapelle and Benson (22) also reported high levels of ethanolamine plasmalogens in the gills of some marine decapods.

Eighteen to 20 different molecular species were separated from both phospholipids, but only the most characteristic ones are listed in Table 3. In diacyl PC the fraction 16:0/18:1 was the major component followed by 16:0/16:0. There was a seasonal variation in the levels of these species: at 8°C the levels of 16:0/18:1 and 16:0/16:0 were roughly half of those found at 15°C. The sum of the disaturated species (16:0/16:0 + 18:0/18:0) was 21 vs. 13.9% in the warm- and cold-adapted states, respectively. In diacyl PE the fraction 16:0/18:1 was also the dominant species, and its level also varied slightly with the environmental temperature: it rose from 17.7% in cold-adapted specimens to 22.1% in warm-adapted ones. In contrast to diacyl PC, 16:0/16:0 did not vary with temperature in diacyl PE. The ratios 18:1/20:5, 18:1/22:6, and 18:1/20:4 also varied with temperature in such a way that they were represented by higher values at the lower environmental temperature. It is important to note that the sum of *sn*-1 monoenic, *sn*-2 polyenic species in both PC and PE was roughly three to four times higher in the cold-adapted state than the warm-adapted state.

Twenty to 25 different molecular species were also detected in the alkylacyl and alkenylacyl forms of PE, some of them in amounts less than 0.1%; they are therefore not listed in Table 4. In the alkenylacyl form almost all the molecular

[b]ΣMONO/POLY represents the sum of the molecular species containing monounsaturated fatty alcohol in the *sn*-1 position and polyunsaturated fatty acid in the *sn*-2 position.

species and their sum (36.6%) containing monoenic fatty alcohol in position *sn*-1 and polyenic fatty acid in position *sn*-2 were more abundant in cold-adapted animals (except 18:1a/20:4, where "a" represents alcohol) than in warm-adapted ones, and their sum was even higher than in the diacyl forms (36.6 vs. 29.4%). Alkylacyl PE from animals collected at 8°C were also rich in these species. Molecular species containing a saturated fatty alcohol in position *sn*-1 and a polyenic fatty acid in position *sn*-2 varied inconsistently with temperature, levels of some of them being higher, i.e., 16:0a/22:6 in alkylacyl PE (0.0 vs. 28.5%), or 16:0a/20:5 in alkenylacyl PE (5.1 vs. 10.0%), whereas the levels of alkylacyl 16:0a/20:5 and 16:0a/20:4 PE were lower at 8°C. Neither alkylacyl nor alkenylacyl 18:0a/20:4 showed any response to environmental temperature.

Measurement of the structural order of phospholipid vesicles revealed less ordered, more fluid structures in the case of the cold-adapted specimens (Fig. 1), indicating that *Gammarus* is capable of regulating membrane fluidity according to the environmental temperature. In fact there is an "overfluidization" of phospholipid structures in the cold: equal R_{SS} values were measured at 20°C in cold-adapted specimens instead of 15°C.

DISCUSSION

The experimental animals were collected directly from natural surroundings. Accordingly, in evaluating the results, the temperature history of the animals should be considered. In spring the water temperature increased over a short period from a value of almost zero to the temperature existing at the sampling time. It is possible that the spring animals were still adapted to a somewhat lower temperature than that of the sampling temperature. In summer a more stable temperature had prevailed for a longer period.

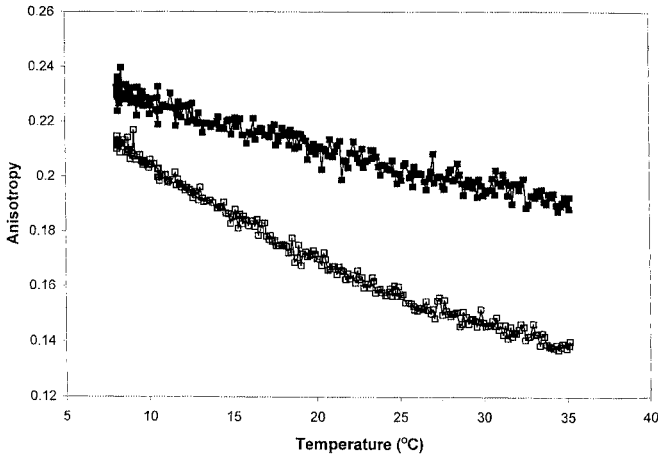

FIG. 1. Temperature dependency of the fluorescence anisotropy, R_{SS}, of 1,6-diphenyl 1,3,5-hexatriene embedded in phospholipid vesicles obtained from *Gammarus* spp. acclimatized to spring (8°C) and summer (15°C) temperatures. Filled squares: phospholipids from 15°C; open squares: phospholipids from 8°C.

Despite only a small variation in the fatty acid composition of phospholipids, the present result shows a drastic difference in the fluidity of phospholipid vesicles obtained from spring and summer *Gammarus*. In earlier studies it was proven that differences in dietary lipids have only a minor effect on the fluidity of fish membranes (15,23). On the basis of these observations we conclude that temperature has a major impact on the physicochemical characteristics of *Gammarus* spp. also. Lipids taken up with food might have been similar in both 8- and 15°C-adapted specimens as judged from similarities in the fatty acid composition of neutral lipids (Table 1). It is interesting that palmitoleic acid, abundant in triglycerides, did not appear in polar lipids. The presence of palmitoleic and eicosapentaenoic acids might indicate the presence of diatoms in the diets of these crustaceans.

Based on observations made of the membranes of vertebrates having different body temperatures (5) it was expected that the R_{SS} values of phospholipid vesicles would also be similar at the respective body temperatures in *Gammarus* spp. Figure 1 shows, however, that an overfluidization takes place at the level of isolated phospholipids. Similar overfluidization was observed in the branchial microsomal membranes, but not in the neural membranes, of the antarctic amphipod *Orchomene plebs* adapted to –1.2°C and Baltic Sea isopod, *Saduria entomon*, adapted to +4°C (3). On the other hand, only a partial compensation was observed in the plasma membranes of leg muscles from a cold stenothermic crustacean, *Cancer pagurus*, and with the same membranes of a less cold stenothermic crustacean, *Carcinus maenas* (4). A possible explanation for the observation presented in Figure 1 is that we used total phospholipids, a mixture of phospholipids from different membranes, devoid of other membrane components such as proteins and sterols which might have rendered these structures more rigid. A study in progress shows that the cholesterol content of the mitochondrial membranes of the winter-active *Gammarus* spp. was 5.2 and 6.2% of the total lipids

in spring and summer animals, respectively. In general, cholesterol has a stabilizing effect on the membranes, but its role in membrane fluidity is a matter of controversy (24).

The increased fluidity of *Gammarus* at 8°C cannot be explained on the basis of the fatty acid composition of total phospholipids. The level of polyunsaturated fatty acids was almost identical at both temperatures. The ratio of saturated/unsaturated fatty acid, which is often regarded as an index of membrane fluidity, was higher in cold due to the high level of 18:0 (0.54 vs. 0.36). The striking difference between the molecular species compositions is that levels of 16:0/16:0 PC as well as of 1-monoenic, 2-polyenic species of PC and PE (Tables 3 and 4), first of all 18:1/20:5, are higher in specimens collected at 8°C (Table 3). The kink at the ninth carbon atom of 18:1 combined with the extended configuration of 22:5 and 22:6 (25) in PE with a reduced level of 16:0/16:0 in PC in cold-adapted ones might be at least partly sufficient to increase membrane disorder and to compensate for the effect of reduced temperature on chain ordering. It thus appears that *Gammarus* follows the same strategy to control membrane fluidity in the cold as do the fish species investigated so far (6,12), namely *Gammarus* also accumulates *sn*-1 monoenic and *sn*-2-polyenic phospholipid molecular species at reduced temperatures. The accumulation of these species cannot be traced back to differences in food ingested at the two temperatures because the fatty acid composition of triglycerides, which is supposed to represent the fatty acid composition of food, is also similar, except for the higher level of palmitoleic acid in the cold (Table 1). It must be mentioned that these crustaceans are active also at 8°C. It has been shown earlier that winter-active crustacean species have a better ability to adjust their membrane composition to prevailing conditions (11,26).

We believe that the increase in the levels of 1-monoenic, 2-polyenic molecular species cannot fully explain the differences in the fluidities of *Gammarus* living at 8 and 15°C. Model experiments using a mixture of synthetic 16:0/22:6 PC and synthetic 18:1/22:6 PE, and using 2-, 12-anthroyloxy stearic acid, and 16-anthroyloxy palmitic acid showed that 18:1/22:6 PE exerted the greatest disordering effect at the level above the twelfth carbon atom in the bilayer and almost no effect was seen in the hydrophobic core with 16-anthroyloxy palmitic acid (6). Considering that DPH distributes evenly in the bilayer and that the difference in the levels of total 1-monoenic, 2-polyenic molecular species is only 14%, the involvement of some other membrane component must be considered.

A determination of subclass composition of PE showed a 20% decrease in the level of alkenylacyl species at 8°C (Table 2). Ethanolamine plasmalogens have been shown to reduce the ordering of bilayers in other systems (27). From these observations the conclusion may be tentatively drawn that, besides the above-mentioned phospholipid molecular species, *Gammarus* utilizes ethanolamine plasmalogens, for this purpose so far undescribed elements, to adjust membrane fluidity to the prevailing temperature.

However, the question arises as to how these crustaceans maintain the bilayer structure of their membranes with such high contents of ether lipids. These lipids are prone to form so-called non-bilayer structures. The highest level of ethanolamine plasmalogens was demonstrated from the brain, where they amount to 40–60% of the ethanolamine phosphoglycerides (28) in contrast to 68% in the ethanolamine phosphoglycerides of *Gammarus* spp. (Table 2). A possible explanation could be that these crustaceans utilize some proteins capable of arranging phospholipids, otherwise only forming non-bilayer phases, into a bilayer phase arrangement. The existence of such proteins has already been described in other systems (29–31).

ACKNOWLEDGMENTS

The authors wish to thank Carita Sunell for her field work, and Erika Zukic, Judith Baunoch, and Tuovi Vartio for their excellent work in the laboratory. This research was funded by the Finnish Academy of Sciences and the Hungarian Academy of Sciences as a bilateral exchange grant to Eila Lahdes.

ABSTRACT: The phospholipid fatty acid (FA) composition and functional properties of skeletal muscle and liver mitochondria were examined in cold-acclimated (CA, 4°C) ducklings. Phospholipid FA of isolated muscle mitochondria from CA birds were longer and more unsaturated than those from thermoneutral (TN, 25°C) reared ducklings. The rise in long-chain and polyunsaturated FA (PUFA, mainly 20:4n-6) was associated with a higher State 4 respiration rate and a lower respiratory control ratio (RCR). Hepatic mitochondria, by contrast, were much less affected by cold acclimation. The cold-induced changes in phospholipid FA profile and functional properties of muscle mitochondria were reproduced by giving TN ducklings a diet enriched in grapeseed oil (GO, rich in n-6 FA), suggesting a causal relationship between the membrane structure and mitochondrial functional parameters. However, hepatic mitochondria from ducklings fed the GO diet also showed an enrichment in long-chain PUFA but opposite changes in their biochemical characteristics (lower State 4, higher RCR). It is suggested that the differential modulation of mitochondrial functional properties by membrane lipid composition between skeletal muscle and liver may depend on muscle-specific factors possibly interacting with long-chain PUFA and affecting the proton leakiness of mitochondrial membranes.

Paper no. L8546 in *Lipids 35,* 1099–1106 (October 2000).

When chronically exposed to cold, most endotherms are able to enhance their metabolic capacity to generate heat to compensate for the rise in heat loss and maintain homeothermy. Small rodents are thus well known to develop nonshivering thermogenic (NST) capacity in the cold (1). Some species of birds, including chickens, ducks, and penguins, can also develop NST in response to cold acclimation or acclimatization (2–5). This remarkable adaptation to cold exposure differs from the situation in mammals, as birds lack the specialized thermogenic brown adipose tissue (BAT) of newborn mammals, hibernators, and small rodents (6–8). In the absence of BAT, skeletal muscle appears as the main site of cold-induced NST (9).

Muscle NST may be based on a loose-coupling of mitochondrial oxidative phosphorylation controlled by fatty acids (FA) on the basis of results obtained with isolated mitochondria in cold-acclimated (CA) ducklings (3,10,11). These studies have contributed to clarify the earlier observation of loose-coupled mitochondria and possible involvement of FA in CA birds (12,13). The molecular mechanisms of such loose-coupling are still unclear, but involve an increase (+40%) in the mitochondrial membrane conductance to protons in CA ducklings (11). No uncoupling protein with protonophoric properties similar to those expressed in mammalian tissues has yet been described in CA birds (7,8). Nevertheless, because phospholipid membranes are inherently leaky to protons (14,15) and the degree of proton leak correlates with the composition in unsaturated FA (16,17), a change in the phospholipid composition of mitochondrial membrane may contribute to the increased leakiness of mitochondrial membranes in CA ducklings. Differences in nonphosphorylating respiratory rates of isolated mitochondria from various species have already been related to mitochondrial phospholipid composition (18). Consistent with this idea is the observation that in CA rats, the membranes of BAT mitochondria contain more polyunsaturated FA (PUFA), possibly contributing to the thermogenic activation of BAT mitochondria (19). Furthermore, an enrichment of membranes with PUFA obtained through changes in the lipid composition of the diet was associated with an increased skeletal muscle oxygen consumption (20).

The aim of this study was therefore to assess whether the development of skeletal muscle NST in CA ducklings was accompanied by changes in the FA composition of tissue membranes. In a first experiment with whole tissues, we found that there was an enrichment in PUFA in skeletal muscle phospholipids of CA ducklings. In a second experiment, we examined whether the cold-induced changes in phospholipid composi-

tion were causally related to the functional characteristics of isolated mitochondria. To this purpose, mitochondrial membrane FA composition was altered at thermoneutrality by changing the lipid composition of the diet (21). The consequences of a diet supplemented with grapeseed oil rich in n-6 FA on the phospholipid composition and functional properties of hepatic and muscle mitochondria were thus examined in ducklings kept at thermoneutrality and compared to those observed after cold acclimation.

MATERIALS AND METHODS

Animals. Animals were cared for under the French Code of Practice for the Care and Use of Animals for Scientific Purposes, and the experimental protocols were approved by the French Ministry of Agriculture Ethics Committee (section animals). Male Muscovy ducklings (*Cairina moschata* L., pedigree R51, Institut National de la Recherche Agronomique, France) were obtained from a commercial stockbreeder (Ets Grimaud, France). They were fed *ad libitum* with a commercial mash (Genthon 5A; Genthon, Cheyssieu, France, see Table 1) and had free access to water. From 1 wk of age, ducklings were assigned to experimental groups.

A first batch of ducklings was divided into two groups; one was kept at 25°C and constituted the thermoneutral (TN) control group, while the other one was reared in the cold (4°C) and constituted the CA group. These birds were kept on the Genthon 5A commercial mash. This cold-acclimation schedule was shown to stimulate the development of skeletal muscle NST by 5 wk of age (6,9). Ducklings were killed by decapitation and tissues (gastrocnemius muscle and liver) were sampled and frozen in liquid nitrogen and kept at −70°C until FA analysis of total tissue phospholipids.

Following the results of the first experiment, a second batch of ducklings was divided into three experimental groups. Two groups of TN or CA ducklings were fed *ad libitum* with a commercial mash [UAR 115; Usine d'Alimentation Rationnelle (U.A.R.), Villemoisson, France]. A third group of ducklings kept at thermoneutrality was fed with the UAR 115 mash supplemented with 6.5% (w/w) grapeseed oil (GO; U.A.R.). Composition and energy content of diets are presented in Table 1. By 5 wk of age, ducklings were killed by decapitation. As the CA group grew a little bit more slowly (Fig. 1), they were killed a few days later at the same body weight as the TN and GO groups. Red internal gastrocnemius, rich in slow-oxidative and fast-oxidative glycolytic (FOG) fibers, white external gastrocnemius, rich in fast glycolytic and FOG fibers (22), and liver samples were taken and used for the analysis of mitochondrial function and FA composition of mitochondrial phospholipids. Photoperiod was 8 h/16 h (light/dark). Food consumption and body weight of ducklings were measured daily.

Isolation of skeletal muscle mitochondria. Internal and external gastrocnemius muscle and liver samples were rapidly taken out, freed of fat and connective tissues, and mixed in a cold isolation medium with a Teflon glass homogenizer. Mus-

[a]Unsaturation index = $(\sum m_i \cdot n_i)/100$, where m_i is the mole percentage and n_i is the number of C–C double bonds of the fatty acid *i*.
[b]Mean chain length index = $(\sum m_i \cdot n_i)/100$, where m_i is the mole percentage and n_i is the number of C of the fatty acid *i*.
[c]Energetic value has been calculated according to 4 kcal/g for digestible proteins and carbohydrates and 9 kcal/g for digestible lipids. GO, grapeseed oil; SFA, saturated fatty acid; MUFA, monounsaturated fatty acid; PUFA, polyunsaturated fatty acid.

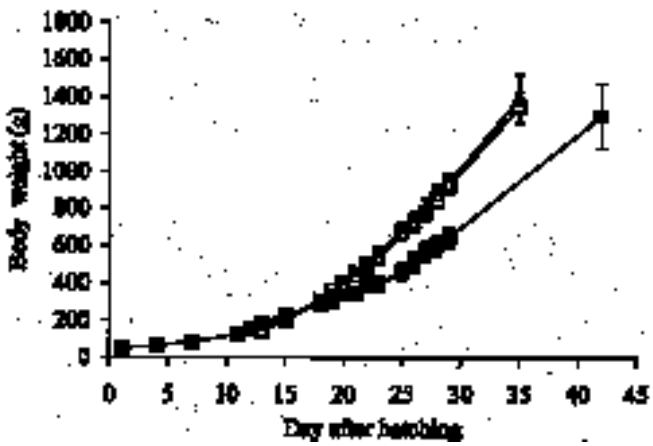

FIG. 1. Effects of grapeseed oil (GO) feeding or cold acclimation on growth rate. GO ducklings reared at thermoneutrality (△) and CA ducklings (■) are compared with thermoneutral controls (□). Values are means ± SE (n = 7).

cle intermyofibrillar mitochondria and liver mitochondria were isolated as described previously (10,11).

Lipid analysis. Tissue and mitochondrial total lipids were extracted according to Folch *et al*. (23). Residual water of the extracts was removed by oil-vacuum. The lipid extracts were weighed, diluted in chloroform, and stored at –20°C until use.

Phospholipids and triglycerides from tissue extracts were separated by thin-layer chromatography on silica gel (G60 plates) using diisopropyl ether as migration solvent. Phospholipids were recovered by scratching the gel and then methylating according to Slover and Lanza (24) before FA analysis.

The FA analysis of phospholipids from mitochondrial extracts was performed with total lipids because the presence of tri- and diglycerides was found negligible, and only traces of cholesterol were detected. The FA of total lipids were therefore assumed to be those of phospholipids. Methylation was performed according to Lepage and Roy (25) using acetylchloride.

FA methyl esters were stored in hexane (high-performance liquid chromatography grade). Gas–liquid chromatography of FA methyl esters was performed using a Chrompack CP9001 chromatograph (Chrompack, Middelburg, The Netherlands) equipped with a 50-m capillary column (CP-Sil 88, 0.25 mm internal diameter) and Chrompack Maestro2 integrator software. The split injector was at 270°C and the flame-ionization detector at 260°C. Temperature program was 150°C for 8 min, rising to 185°C by 10°C/min, 185°C for 10 min, rising to 200°C by 10°C/min, and then 200°C for 20 min. Nitrogen was used as carrier gas (100 kPa). FA were identified by comparison with commercially available standards (Supelco, Bellefonte, PA).

Mitochondrial respiration and enzymatic activities. The respiration of isolated mitochondria (0.5 mg mitochondrial protein/mL) was determined polarographically with a Clark oxygen electrode (oxygraph Gilson 5/6 H), in a glass cell of 1.5 mL volume, thermostated at 25°C as described previously (10,11). The ATP synthesis of mitochondria was determined by the bioluminescence procedure of Wibom *et al*. (26) at 25°C with some modifications as described previously (11). The cytochrome oxidase activity of isolated mitochondria was determined polarographically as described elsewhere (10). As the protein/lipid ratio remained unchanged in all the experiments (data not shown), the specific activity of the enzymes was expressed per mg of protein.

Statistics and chemicals. Data are presented as means ± SE. One-way or two-way analysis of variance (ANOVA) and post-ANOVA Fisher PLSD tests and Student's *t* tests were used to determine significant differences between groups. Statistical difference was accepted at $P < 0.05$.

Solvent of analytical grade for lipids extraction and analysis was from SDS (Peypin, France); the other chemicals were purchased from Sigma.

RESULTS

Experiment 1: Effect of cold acclimation on the FA composition of tissue phospholipids. At the time of killing, TN ducklings were slightly heavier than CA birds (1.43 ± 0.03 vs. 1.20

[a]Values are mean ± SE from six (gastrocnemius) or five (liver) animals kept on the Genthon 5A diet. *$P < 0.05$ vs. TN. Fatty acids representing a small proportion of the total are not shown but values are included when possible in the totals presented. See Table 1 for abbreviations.

± 0.03 kg, $P < 0.05$) despite a lower food intake by 5 wk of age (106 ± 3 vs. 139 ± 4 kcal·kg$^{-0.75}$·d^{-1}). The FA profile of tissue phospholipids (Table 2) differed between the two tissues, the gastrocnemius muscle being poorer in saturated fatty acids (SFA) but richer in monounsaturated fatty acids (MUFA) than the liver. In the gastrocnemius muscle, cold acclimation led to a marked increase in the proportion of total PUFA and to a lesser extent of SFA at the expense of total MUFA. The cold-induced rise in total PUFA was mainly accounted for by 20:4n-6, and to a lesser extent by 22:4n-6 and 22:6n-3. The unsaturation index of total phospholipids was thus higher in skeletal muscle from CA than from TN ducklings. In liver, by contrast, the cold-induced rise in long-chain PUFA was not observed, and there was only a slight increase in the proportion of total MUFA mainly accounted for by 18:1n-9 FA in CA ducklings. The unsaturation index of liver phospholipids was similar between TN and CA ducklings.

Experiment 2: Effect of GO diet or cold on food intake and growth rate. Despite differences in the energy content of the diet, TN and GO ducklings had a similar energy intake by 5 wk of age (441 ± 3 and 439 ± 12 kcal·kg$^{-0.75}$·d^{-1}, respectively) and grew at similar rates (Fig. 1). Again, the energy intake of CA ducklings was higher (496 ± 5 kcal·kg$^{-0.75}$·d^{-1}) and their growth rate lower than those of the ducklings kept at thermoneutrality.

Experiment 2: Effect of GO diet or cold on the FA profile of mitochondrial phospholipids. Whatever the diet or cold-acclimation status, the FA composition of mitochondrial phospholipids differed between tissues (Table 3). As seen in the composition of tissue phospholipids, there were more SFA and less PUFA in the phospholipids of mitochondria isolated from liver than from gastrocnemius muscles. Mitochondrial phospholipids from the red internal part of the gastrocnemius muscle were richer in PUFA than those from the white part. Despite these differences, the unsaturation indexes were similar in the three tissues studied, mainly because of the differences in the pattern of n-6 FA. The content in 20:4n-6 was higher in hepatic than in muscle mitochondria, while the 18:2n-6 was the most abundant FA in muscle mitochondria. The n-3/n-6 ratio was similar in the three tissues.

The mitochondrial FA profile was differentially affected by cold acclimation in liver and skeletal muscles. In both parts of the gastrocnemius muscle, a higher unsaturation index and a longer mean chain length were observed in CA ducklings. These parameters reflected the increased proportion of PUFA (especially 20:4n-6, and to a lesser extent

[a]Values are means ± SE ($n = 7$). FA representing less than 0.4% are not shown, but are taken into account for the calculation of the totals. Each tissue value with a different roman superscript is significantly different ($P < 0.05$), two-way analysis of variance (ANOVA) and Fisher post-ANOVA test. See Tables 1 and 2 for abbreviations.

22:4n-6). The proportion of 22:6n-3 was not significantly increased in mitochondrial phospholipids. The rise in long-chain PUFA was somehow compensated for by a decrease in the proportion of MUFA (especially 18:1n-9) and an increase in the mean chain length of SFA (rise in 18:0 and drop in 16:0). In liver, by contrast, the rise in long-chain PUFA was not observed, and cold acclimation induced only minor changes in mitochondrial FA profile, i.e., a slight increase in 18:1, compensated for by a decrease in 18:2n-6. The n-3/n-6 ratio was not affected by cold acclimation in the three tissues.

Contrary to cold acclimation, the GO diet at thermoneutrality affected the three tissues studied similarly and induced a nonspecific increase in the proportion of all n-6 phospholipid FA. In muscle mitochondria, these increases were at least up to the levels observed in CA ducklings. Consequently, in muscle mitochondria of GO ducklings, the mean chain length and the unsaturation index reached the values observed in CA ducklings, while in hepatic mitochondria, these parameters were higher than in both TN and CA ducklings. In the three tissues of GO ducklings, the increased proportion of n-6 FA was compensated for by a decreased proportion of MUFA and the n-3/n-6 ratio was markedly decreased.

Experiment 2: Effect of cold acclimation or GO diet on the biochemical characteristics of isolated mitochondria. Cold acclimation affected the functional characteristics of skeletal muscle mitochondria (Table 4), especially in the red part of gastrocnemius, but not those of liver mitochondria (Table 5). In both parts of the gastrocnemius muscle, there was a higher State 4 respiratory rate, and consequently a lower respiratory control ratio (RCR) in CA than in TN ducklings. The ADP/O ratio was, however, not affected by cold acclimation. The specific (per mg mitochondrial protein) ATP synthesis was higher in muscle mitochondria from CA ducklings, but the specific cytochrome oxidase activity was unaffected. Because of a higher amount of mitochondrial proteins in skeletal muscles of CA ducklings, the total oxidative capacity and ATP production capacity per organ were increased by cold acclimation in both skeletal muscles.

The GO diet affected the functional characteristics of hepatic and skeletal muscle mitochondria differently. In liver, the GO diet led to a higher ADP/O ratio and a higher RCR due to a lower respiratory State 4 as compared with ducklings fed the standard diet. The other parameters remained unchanged. In both parts of the gastrocnemius muscle, the GO diet induced a lower RCR due to a higher respiratory State 4 than in control TN ducklings. The specific ATP synthesis activity was intermediate between that of TN and CA ducklings, but because of the increased mitochondrial amount, the total ATP production per gram of muscle reached the level observed after cold acclimation. Taken together, present results

[a]The respiratory reaction medium contained 200 mM sucrose, 5 mM KH_2PO_4, and 20 mM Tris-HCl, pH 7.4 with a final fatty-acid-free bovine serum albumin concentration of 2 mg/mL (0.2% wt/vol). The controlled state of respiration (State 4) was initiated by the addition of 5 mM succinate (sodium salt) in the presence of rotenone (5 μM) and the active state of respiration (state 3) was initiated by the addition of 100 μM ADP. The method of Estabrook (44) was used for the calculation of State 4 and state 3 respiration and the respiratory control ratio (RCR). The latter respiratory parameter is a measure of the degree of control imposed on oxidation by phosphorylation. ADP/O ratio was calculated by using the total oxygen consumed during phosphorylation of a pulse of ADP added to initiate state 3 respiration.

showed that in skeletal muscles, but not in liver, the GO diet at thermoneutrality globally mimicked the changes in the mitochondrial lipid composition and biochemical parameters induced by cold acclimation.

DISCUSSION

Two main results emerged from the present study. First, CA ducklings showed alterations in the lipid composition of skeletal muscle membranes leading to an increased proportion of long-chain PUFA. Second, the enrichment of mitochondrial phospholipids with n-6 PUFA, created by giving ducklings kept at thermoneutrality a diet rich in GO, partly reproduced the alterations in the functional properties of skeletal muscle mitochondria observed in CA ducklings.

Present results clearly show that cold acclimation altered the FA composition of tissue and mitochondrial phospholipids in the gastrocnemius muscle. Indeed, there was a higher proportion of the longer and more unsaturated FA (mainly 20:4n-6) in tissue and mitochondrial phospholipids from gastrocnemius muscle of CA than in those of TN ducklings resulting in increased (+10%) unsaturation index and mean chain length of membrane FA. By contrast, these changes in FA profile were not observed in liver mitochondria. We do not favor the possibility that the difference between liver and skeletal muscle is related to the fact that these tissues experience different temperatures during cold acclimation. Although living at low temperature indeed results in increased unsaturation in ectotherms (see Ref. 27 for a recent review), the difference between liver and skeletal muscle temperature is likely to be small in endothermic ducklings and would not exceed a few degrees. This is far less than the thermal challenge used to induce phospholipid changes in ectotherms. A similar enrichment in PUFA resulting in an increase in the total FA unsaturation index of mitochondrial phospholipids has been described in the thermogenic BAT of rodents (19). By contrast, there was a decrease in the proportion of total unsaturated FA in heart mitochondria from CA rats (28), mainly resulting from a rise in the proportion of 18:0 and a decrease in that of 18:1. No marked changes in the unsaturation index of phospholipid FA have been reported in hepatic mitochondria of CA rodents (29). These results therefore indicate a tissue-specific modulation of the FA composition of membrane phospholipids toward an enrichment in long-chain PUFA in the thermogenic organs (BAT or skeletal muscles) of endotherms. Such enrichment in long-chain PUFA in mitochondrial membranes of CA ducklings suggests specific roles of these FA in the biophysical properties of these membranes. It is indeed generally accepted that changes in FA profile of biological membranes alter the fluidity, leakiness to protons, and may contribute to the modulation of the activity of membrane-bound enzymes (30–33).

The FA composition of mitochondrial phospholipids could be altered by giving ducklings kept at thermoneutrality a diet rich in GO, providing more n-6 PUFA. This diet composition, rich in 18:2n-6, was chosen in order to provide ducklings with the FA that were the most affected by cold acclimation as shown in the first experiment with total tissue phospholipids (Table 2). Results of experiment 2 indicate that in birds, as in mammals (21), the mitochondrial membrane FA composition can be manipulated by the FA composition of the diet. However, the enrichment in membrane PUFA is lower than what could be expected from the diet composition, indicating some homeostatic control of the membrane lipid composition already noted by others (34). Because the diet similarly affected the FA profile of mitochondrial phospholipids of the three tissues investigated, it follows that the tissue-specific changes observed after cold acclimation are precisely regulated and, for instance, are not dependent on the higher food intake or alterations in the supply of blood lipids (35). These changes may therefore reflect active processes controlling the incorporation of specific long-chain highly unsaturated FA into

membranes for particular metabolic and thermogenic purposes. Thyroid hormones are good candidates for the modulation of phospholipid composition in CA ducklings. Indeed, they are known to increase 20:4n-6 and decrease 18:2n-6 (36,37) and concomitantly increase the unsaturation index (38). Furthermore, they are suspected to play a role in the development of NST in birds (4,5).

Cold acclimation as well as GO feeding, both leading to an enrichment of mitochondrial phospholipids in n-6 FA, similarly altered the functional properties of isolated skeletal muscle mitochondria. In both cases, there was an increase in State 4 respiration rates and a decrease in respiratory control, indicating a lower degree of control imposed on oxidation by the phosphorylation. Similar loose-coupling of muscle mitochondria in CA ducklings has already been reported (11,22) and has been related to an increase in mitochondrial membrane conductance to protons (11). The present results support the hypothesis that the FA composition of ducklings' mitochondrial membranes may contribute, at least in part, to an increased proton leak across mitochondrial inner membrane. In mammals as well, the degree of proton leak is correlated with the composition in unsaturated FA (16,17) and differences in nonphosphorylating respiratory rates of isolated mitochondria from various species are related to mitochondrial phospholipid composition (18). However, the PUFA composition of mitochondrial membranes may not be the only factor responsible for the altered coupling of muscle mitochondria as similar changes in FA composition induced by the GO diet were observed in liver mitochondria, while there were opposite changes in mitochondrial characteristics (decreased State 4, increased RCR). This difference is difficult to interpret, but may possibly be related to the muscle-specific expression of mitochondrial membrane proteins interacting with membrane phospholipids and modulating membrane proton leakiness. This hypothesis is based on the recent description of an uncoupling protein 3 expressed at high levels in mammalian skeletal muscles and BAT, but not in hepatocytes (39,40) although the presence of a similar protein in duckling muscle is still not demonstrated. It is also based on the observation that reconstituted liposomes of differing fatty acid composition do not exhibit differences in proton leak (41), while in intact mitochondria, differences in FA composition affect membrane proton leakiness (17). It is therefore tentatively postulated that a muscle-specific avian uncoupling protein, the protonophoric activity of which may be potentiated by the FA composition of the mitochondrial membrane, contributes to the functional properties of muscle mitochondria induced by either cold acclimation or the GO diet. More studies are required to confirm the existence and clarify the regulatory activity of such protein.

On an other hand, the lipid composition of mitochondrial membranes may be important in modulating the activity of membrane-bound enzymes, and the enrichment in PUFA induced by cold acclimation was indeed related to an increase of the ATP synthesis in skeletal muscles. The ATPase complex activity was already shown to be regulated by the chain length and the degree of unsaturation of membrane FA (42). The GO diet had less clear-cut effects on the ATP synthesis, despite marked changes in membrane PUFA, possibly because the proportion of the 18:2n-6 was also markedly increased. In rats, the ATP-synthase activity was indeed shown to be inversely related to the content in 18:2n-6 (43). A specific role of the 20:4n-6 or longer n-6 FA in modulating these activities remains to be clarified.

In conclusion, this study showed that in CA young birds, there is a muscle-specific enrichment of mitochondrial phospholipids in long and unsaturated FA. Similar changes do not occur in liver mitochondria. Feeding a GO diet rich in n-6 PUFA induced similar changes in lipid composition and mitochondrial functional activity in skeletal muscles as did cold acclimation. It is suggested that the FA composition of mitochondrial membranes may contribute to the increased proton leakiness of muscle mitochondria observed in CA ducklings, but that muscle-specific factors control this effect.

ABSTRACT: Docosahexaenoic acid (DHA, 22:6n-3) is one of the major polyunsaturated fatty acids esterified predominantly in aminophospholipids such as ethanolamine glycerophospholipid (EtnGpl) and serine glycerophospholipid (SerGpl) in the brain. Synaptosomes prepared from rats fed an n-3 fatty acid-deficient safflower oil (Saf) diet had significantly decreased 22:6n-3 content with a compensatory increased 22:5n-6 content when compared with rats fed an n-3 fatty acid-sufficient perilla oil (Per) diet. When the Saf group was shifted to a diet supplemented with safflower oil plus 22:6n-3 (Saf + DHA) after weaning, 22:6n-3 content was found to be restored to the level of the Per group. The uptake of [^{3}H]ethanolamine and its conversion to [^{3}H]EtnGpl did not differ significantly among the three dietary groups, whereas the formation of [^{3}H]lysoEtnGpl from [^{3}H]ethanolamine was significantly lower in the Saf group than in the other groups. The uptake of [^{3}H]serine, its incorporation into [^{3}H]SerGpl, and the conversion into [^{3}H]EtnGpl by decarboxylation of [^{3}H]SerGpl did not differ among the three dietary groups. The observed decrease in lysoEtnGpl formation associated with a reduction of 22:6n-3 content in rat brain synaptosomes by n-3 fatty acid deprivation may provide a clue to reveal biochemical bases for the dietary fatty acids–behavior link.

Paper no. L8384 in *Lipids 35*, 1107–1115 (October 2000).

Polyunsaturated fatty acids (PUFA) derived from n-6 or n-3 fatty acids are fundamental components of structural membrane lipids in the central nervous system. These PUFA, mainly arachidonic acid (20:4n-6) and docosahexaenoic acid (DHA, 22:6n-3), can be derived from essential fatty acid precursors, linoleic (18:2n-6) and α-linolenic acids (18:3n-3), which must be supplied from dietary sources in mammals (1–3). A reduction in 22:6n-3 content and a small but significant increase in 20:4n-6 content caused by dietary deprivation of n-3 fatty acids for long periods (e.g., through two generations) were shown to cause impaired retinal function and learning ability as well as altered behavior and drug sensitivity in rodents (4–9). These results suggest that 22:6n-3 plays an important role in the maintenance of normal neural functions, for which n-6 PUFA cannot compensate. However, the extent of dietary modification of fatty acid composition and its effect on phospholipid metabolism have not been well defined.

In the brain, 22:6n-3 is particularly enriched in aminophospholipids such as ethanolamine glycerophospholipid (EtnGpl) and serine glycerophospholipid (SerGpl). Recently, it was suggested that bioactive metabolites of 22:6n-3 are not responsible for its functions in the brain but that 22:6n-3-containing aminophospholipids are critical for optimal neural function and structure (10). We have reported that dietary n-3 fatty acid deficiency and a learning task synergistically induce ultrastructural changes in synapse in the hippocampus (11) and some functional changes in the brain microsomal membrane surfaces (12). EtnGpl has been described to be associated with a specific protein in phospholipid bilayer. For example, EtnGpl is preferentially located in the extracellular leaflet in acetylcholine receptor-rich membranes (13). SerGpl in membranes is known to be an essential cofactor for the activation of protein kinase C (14). Several lines of evidence have shown that SerGpl regulates the activity of various enzymes such as diacylglycerol kinase (15), Na^+, K^+-ATPase (16), and nitric oxide synthase (17), and acts as a ligand in recognition of apoptotic cells (18).

In previous studies we demonstrated that in rat pheochromocytoma PC12 cells, nerve growth factor (NGF)-induced neurite outgrowth was enhanced by 22:6n-3 but suppressed by 20:4n-6 (19). The 20:4n-6 also reduced incorporation of [^{3}H]ethanolamine into EtnGpl *via* suppression of [^{3}H]ethanolamine uptake into the cells whereas 22:6n-3 had no effect (19,20). On the other hand, 22:6n-3, but not 20:4n-6, increased SerGpl and EtnGpl synthesis from [^{3}H]serine in PC12 cells irrespective of NGF-induced differentiation (20). En-

Abbreviations: ANOVA, analysis of variance; BSS, balanced salt solution; ChoGpl, choline glycerophospholipid; DHA, docosahexaenoic acid (22:6n-3); EtnGpl, ethanolamine glycerophospholipid; NGF, nerve growth factor; PBS, phosphate-buffered saline; Per, perilla oil; PLA, phospholipase A; PtdIns, phosphatidylinositol; PUFA, polyunsaturated fatty acid; Saf, safflower oil; SerGpl, serine glycerophospholipid; TLC, thin-layer chromatography.

hancement by 22:6n-3 of SerGpl synthesis from [^{3}H]serine has been observed in C6 glioma cells (21). These results from *in vitro* cultured cells suggest that 22:6n-3 enhances but 20:4n-6 suppresses both aminophospholipid synthesis and neurite elongation.

In vivo studies using autoradiographic methods led to apparently inconsistent conclusions; brain phospholipid synthesis was lowered, but protein synthesis was enhanced by n-3 fatty acid deficiency (22,23). However, a methodological problem was pointed out about specific radioactivity of the direct precursor pool of phospholipid synthesis (24), and we observed no significant changes in protein synthesis in the rat brain under n-3 fatty acid deficiency (25).

In this study we investigated the effect of reduction of 22:6n-3 content on aminophospholipid metabolism using synaptosomes prepared from rats under n-3 fatty acid deficiency. The data presented here demonstrate that, unlike in cultured cells and *in vivo* autoradiographic results, dietary n-3 fatty acid deficiency does not affect aminophospholipid synthesis evaluated using [^{3}H]ethanolamine and [^{3}H]serine as precursors, but suggest that turnover of EtnGpl to lysoEtnGpl is lowered.

EXPERIMENTAL PROCEDURES

Materials. The ethyl ester of 22:6n-3 (>95% pure) was produced by Harima Chemicals, Inc. (Tsukuba, Japan). Percoll was purchased from Pharmacia Biotech (Uppsala, Sweden). [1-^{3}H]Ethanolamine hydrochloride (28 Ci/mmol) and [^{3}H(G)] L-serine (27.5 Ci/mmol) were purchased from Amersham (Buckingham, United Kingdom) and Moravek Biochemicals Inc. (Brea, CA), respectively. Silica Gel 60G thin-layer chromatography (TLC) plates were purchased from Merck (Darmstadt, Germany).

Animals and diets. All procedures for animal use were approved by the Center for Laboratory Animals, Faculty of Pharmaceutical Sciences, Nagoya City University. The semipurified diet (Clea Japan Inc., Tokyo, Japan) contained, by weight, 47% corn starch, 24.6% milk casein, 2% α-starch, 8% cellulose powder, 5% sucrose, 2% vitamin mixture, 6% mineral mixture, 0.4% DL-methionine, 0.6% choline chloride, and 5% of the indicated oil. The fatty acid compositions of diets supplemented with the oils are shown in Table 1. Female Wistar rats (F_0) (SLC Co., Shizuoka, Japan) at 4 wk of age were fed a safflower oil (Saf) or perilla oil (Per) diet for 2 mon. The rats (F_0) were mated at 11 wk of age and the litters (F_1) were weaned at 3 wk. The male pups (F_1) fed the Saf diet were divided randomly into two groups. One group was fed the same Saf diet and the other group was fed a diet supplemented with 4.5% Saf plus 0.5% 22:6n-3 (Saf + DHA). The male pups (F_1) from the Per diet group were fed the same Per diet. The male rats (F_1) at 19 wk of age were used for the experiments.

Preparation of rat brain synaptosomes. The 19-wk-old rats (F_1) were decapitated, and the brains were isolated rapidly. The synaptosomes were prepared by a Percoll gradient procedure (26) as follows. The brains were homogenized in 10 vol of buffer composed of 0.32 M sucrose, 5 mM Hepes pH 7.4, and 0.1 mM EGTA. The homogenate was centrifuged at 1,100 × *g* for 5 min, and the supernatant was layered on a discontinuous two-step Percoll density gradient composed of equal volumes of 10 and 23% (w/w) Percoll. The density gradient separations were performed by centrifugation at 15,000 × *g* for 30 min. The synaptosomes were banded at the interfacial fractions found between 10 and 23% Percoll. The synaptosomal fractions were isolated and centrifuged at 15,000 × *g* for 10 min. The pellets obtained were suspended in balanced salt solution (BSS; 128 mM NaCl, 2.4 mM KCl, 1.2 mM $MgSO_4$, 1.2 mM KH_2PO_4, 10 mM Hepes pH 7.4, 10 mM D-glucose) and centrifuged at 15,000 × *g* for 10 min to remove the remaining Percoll. The pellets obtained were suspended in BSS and used immediately for the experiments. The purity of synaptosomes was checked by marker enzymes as described previously (27). Protein concentration was determined using a bicinchoninic acid reagent (28).

TABLE 1
Fatty Acid Composition of Diets[a]

Fatty acid	Safflower oil diet	Safflower oil + DHA diet	Perilla oil diet
16:0	6.6	5.9	6.8
18:0	2.4	2.2	2.3
18:1	13.5	12.1	21.9
18:2n-6[b]	76.8	69.1	13.2
18:3n-3	0.2	0.2	54.7
20:5n-3	ND	0.5	ND
22:6n-3	ND	9.5	ND
n-6/n-3[c]	>300	6.79	0.24

[a]The fatty acid composition of the diets (% of total fatty acids, w/w) was analyzed by gas–liquid chromatography. ND, not detected (below 0.05% of the total); DHA, docosahexaenoic acid.
[b]The position of the double bond numbered from the methyl terminus is designated as n-6 or n-3.
[c]n-6/n-3 indicates the ratio of the total n-6 fatty acids/total n-3 fatty acids.

Analysis of fatty acid composition. Synaptosomal lipids were extracted three times with chloroform/methanol according to the method of Bligh and Dyer (29). The lipid classes were separated by silica gel TLC with chloroform/methanol/acetic acid/formic acid/water (70:30:12:4:2, by vol) as the developing solvent. The regions corresponding to individual phospholipids were scraped off, and phospholipids were extracted from the silica gel twice with chloroform/methanol/3% NH_4OH (6:5:1, by vol) and then once with chloroform/methanol (2:1, by vol). Fatty acids were converted to their methyl esters by treatment with 5% HCl in methanol and were quantified by capillary column gas–liquid chromatography using heptadecanoic acid as an internal standard as described previously (4).

Ethanolamine and serine uptake by synaptosomes. Synaptosomes containing 200 μg of protein were preincubated at 37°C for 5 min in BSS. The uptake assay was started by adding 0.25–1.0 μM [^{3}H]ethanolamine (2 Ci/nmol) or [^{3}H]serine (2 Ci/nmol) at a final volume of 0.5 mL. After incubation at 37°C for 5 min, the suspension was centrifuged at 15,000 × *g* at 2°C for 10 min. The pellet was washed three times with ice-cold BSS and the synaptosome-associated radioactivity was measured.

Incorporation of [^{3}H]ethanolamine and [^{3}H]serine into aminophospholipids. Synaptosomes containing 200 μg of protein were preincubated at 37°C for 5 min in BSS. After the addition of 2 μCi/mL [^{3}H]ethanolamine or 3 μCi/mL [^{3}H]serine in a final volume of 0.5 mL, the mixture was incubated at 37°C for 0.5 to 4.0 h. The reactions were stopped by addition of 2 vol of methanol, and the synaptosomal lipids were extracted three times with chloroform/methanol according to the method of Bligh and Dyer (29). The lipids were separated by TLC with chloroform/methanol/acetic acid/water (25:15:4:2, by vol) as the developing solvent. The regions corresponding to individual phospholipids were scraped into scintillation vials, the contents of silica gel were adjusted to the same amounts, and the radioactivities were measured using a liquid-scintillation counter (LSC-5100; Aloka, Tokyo, Japan) by using the optimized scintillation cocktail (30). For the pulse-chase experiments, synaptosomes were incubated for 1 h with 2 μCi/mL [^{3}H]ethanolamine. After the pulse-labeling, the BSS was removed and the synaptosomes were washed three times. Then the buffer was replaced with BSS containing 1 mM unlabeled ethanolamine, and the synaptosomes were incubated for 0.5 to 4.0 h.

Statistics. Results were compared by one-way analysis of variance followed by a Bonferroni multiple comparison test. A difference was considered significant at $P < 0.05$.

RESULTS

Fatty acid composition of synaptosomal phospholipids. Among the three dietary groups, weight gain, litter size, brain weight, and synaptosomal protein were not significantly different (data not shown). Table 2 shows the fatty acid composition of choline glycerophospholipid (ChoGpl) in rat brain synaptosomes. Total fatty acid contents of ChoGpl (μg/mg protein) were not significantly different among the three groups. The major fatty acids in ChoGpl were saturated and monounsaturated fatty acids (>85%), which did not differ among the three groups. The contents of PUFA in ChoGpl were relatively small, but in the Saf group, 22:6n-3 was lower and 20:4n-6, 22:4n-6, and 22:5n-6 were significantly higher compared with the Per and the Saf + DHA groups.

Fatty acid compositions of EtnGpl and SerGpl are presented in Tables 3 and 4, respectively. Total fatty acid contents per protein in EtnGpl and SerGpl were not significantly different among the three dietary groups. The aminophospholipids contained relatively higher amounts of PUFA. In the Saf group, n-3 fatty acid deficiency led to marked decreases of 22:6n-3 in both EtnGpl and SerGpl as compared with the Per and the Saf + DHA groups. The total PUFA contents were similar; in the Saf group the marked decrease in 22:6n-3 was compensated for by increases in 22:4n-6 and 22:5n-6 in both aminophospholipids. In the Saf + DHA group, the level of 22:5n-6 was similar to that in the Per group in both EtnGpl and SerGpl, while the level of 22:4n-6 was intermediate between those of the Saf and the Per groups. EtnGpl contained relatively higher amounts of 20:4n-6 than SerGpl. In both

aminophospholipids, the 20:4n-6 level in the Saf group was 1.5-fold higher than the Per group, whereas its level in the Saf + DHA group was intermediate between the Saf and the Per groups.

Phosphatidylinositol (PtdIns) had the highest content of 20:4n-6 among the major phospholipid classes (Table 5); the 20:4n-6 content in the Saf group was 13% higher than in the Per group. However, C_{22} PUFA content was relatively low and was affected relatively little by the dietary n-3 fatty acid deficiency, although a significantly lower 22:6n-3 content and concomitantly higher 22:4n-6 and 22:5n-6 contents were observed in the Saf group as compared with the other phospholipids.

[a]Synaptosomes were prepared from rats fed semipurified diets supplemented with Saf, Saf + DHA, or Per. Values represent means ± SD for four rats. Values of the same fatty acid with different superscripts are significantly different ($P < 0.05$) in one-way ANOVA using Bonferroni's test. For abbreviations see Tables 1 and 2.

Ethanolamine and serine uptake by synaptosomes. The uptake of ethanolamine and serine by synaptosomes increased linearly for up to 10 min at concentrations of 0.25 to 1.0 μM (data not shown). Therefore, we compared the uptake of ethanolamine and serine among the three dietary groups after 5 min of incubation (Fig. 1). The uptake of ethanolamine at 0.25 to 1.0 μM did not differ among the three dietary groups (Fig. 1A). Similarly, serine uptake was not different among the three

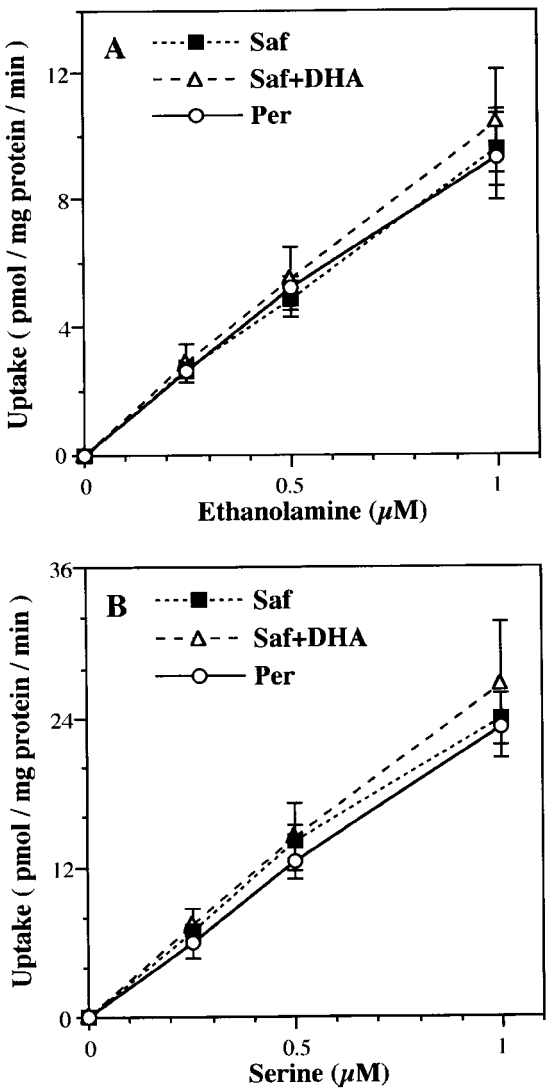

FIG. 1. Ethanolamine and serine uptake by brain synaptosomes. Synaptosomes prepared from rats fed semipurified diets supplemented with safflower oil (Saf), safflower oil plus DHA (Saf + DHA) or perilla oil (Per) were incubated with [^{3}H]ethanolamine (A) or [^{3}H]serine (B) at the indicated concentration for 5 min. The radioactivities associated with the synaptosomes were measured as described in the text. Values represent means ± SD for six rats.

dietary groups (Fig. 1B). Thus, n-3 fatty acid deficiency did not affect ethanolamine and serine uptake by synaptosomes.

Incorporation of [^{3}H]ethanolamine into aminophospholipids. The incorporation of [^{3}H]ethanolamine into [^{3}H]EtnGpl and its conversion to [^{3}H]lysoEtnGpl increased linearly for up to 2 and 4 h, respectively (Fig. 2). Incorporation of [^{3}H]ethanolamine into [^{3}H]EtnGpl after 1 h incubation was not significantly different among the three dietary groups (Fig. 3A). However, the formation of [^{3}H]lysoEtnGpl was significantly lower by about 20% in the Saf group than in the Per and Saf + DHA groups (Fig. 3B). Synaptosomes were first pulse-labeled for 1 h with [^{3}H]ethanolamine, then incubated for an additional 4 h in the presence of 1 mM unlabeled ethanolamine (Fig. 4). The lysoEtnGpl/EtnGpl ratio decreased with time, which is a type of label kinetics indicating an EtnGpl–lysoEtnGpl precursor–product relationship, i.e., a simultaneous decline of [^{3}H]EtnGpl and an increase of [^{3}H]lysoEtnGpl.

Incorporation of [^{3}H]serine into aminophospholipids. The incorporation of [^{3}H]serine into [^{3}H]SerGpl and its conversion to [^{3}H]EtnGpl by decarboxylation increased linearly for up to 2 and 4 h, respectively (Fig. 5). The formation of [^{3}H]lysoEtnGpl from [^{3}H]serine-derived [^{3}H]EtnGpl was essentially negligible (lower than 100 dpm per 200 μg of protein) during 4 h incubation (data not shown). The incorporation of [^{3}H]serine into [^{3}H]SerGpl for 1 h incubation did not differ among the three dietary groups (Fig. 6A). Similarly, the conversion of [^{3}H]SerGpl to [^{3}H]EtnGpl by decarboxylation was not significantly different among the three dietary groups (Fig. 6B). Thus, n-3 fatty acid deficiency did not affect [^{3}H]SerGpl synthesis from [^{3}H]serine and its conversion to [^{3}H]EtnGpl in synaptosomes.

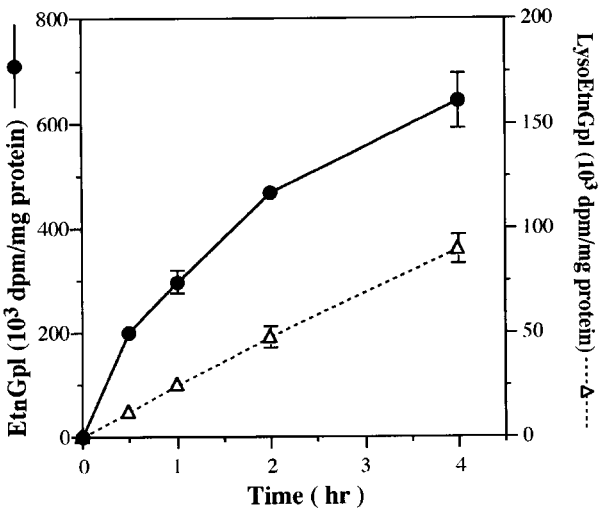

FIG. 2. Time course of incorporation of [^{3}H]ethanolamine into aminophospholipids in brain synaptosomes. Synaptosomes prepared from rats fed a conventional chow were incubated with 2 μCi/mL [^{3}H]ethanolamine for 0.5 to 4.0 h. The radioactivities incorporated into ethanolamine glycerophospholipid (EtnGpl) and lysoEtnGpl were measured as described in the text. Values represent means ± SD for four rats. In some cases error bars are included within the symbols.

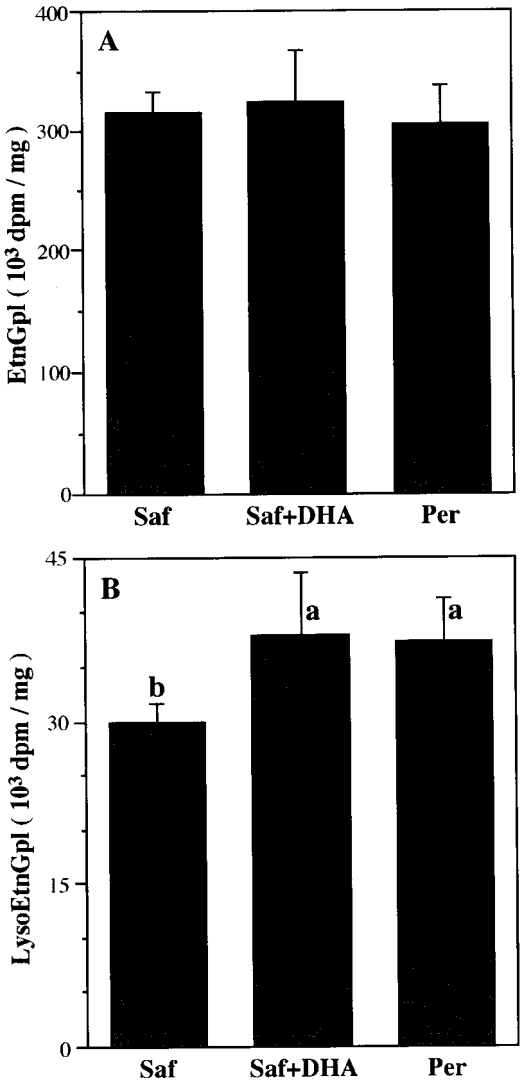

FIG. 3. Effect of dietary fatty acid status on incorporation of [^{3}H]-ethanolamine into aminophospholipids in brain synaptosomes. Synaptosomes prepared from rats fed semipurified diets supplemented with Saf, Saf + DHA, or Per were incubated with 2 μCi/mL [^{3}H]ethanolamine for 1 h. The radioactivities incorporated into EtnGpl (A) and lysoEtnGpl (B) were measured as described in the text. Values represent means ± SD for six rats. Values with different superscripts are significantly different ($P < 0.05$) in one-way analysis of variance using Bonferroni's test. For abbreviations see Figures 1 and 2.

DISCUSSION

In the previous study using cultured PC12 cells, 20:4n-6 added to the medium decreased ethanolamine uptake in a dose-dependent manner (20). The 20:4n-6 treatment resulted in a three- to fivefold increase in 20:4n-6 content (17–20% of total fatty acids vs. 5.8–6.6% in the control) with a concomitant decrease in 18:1 content (about 60% decrease compared with the control) in membrane phospholipids (19). In brain synaptosomes prepared from rats fed one of the three diets, the n-3 fatty acid-deficient (Saf), n-3 fatty acid-replenished (Saf + DHA), or n-3 fatty acid-sufficient (Per) diet, the up-

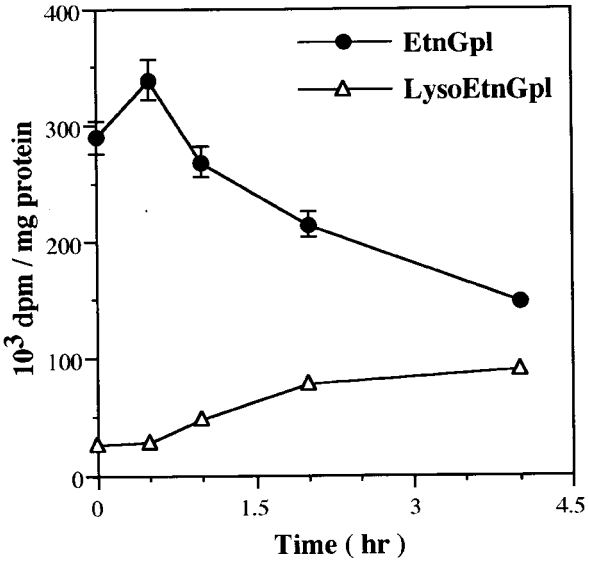

FIG. 4. Effect of exogenous unlabeled ethanolamine on [^{3}H]EtnGpl and [^{3}H]lysoEtnGpl in synaptosomes prelabeled with [^{3}H]ethanolamine. Synaptosomes prepared from rats fed a conventional chow were incubated with 2 μCi/mL [^{3}H]ethanolamine for 1 h. The pulse medium was removed and the synaptosomes were incubated in chase medium with 1 mM unlabeled ethanolamine, for 0.5–4.0 h. At the time intervals indicated, lipids were extracted and the level of [^{3}H]EtnGpl and [^{3}H]lysoEtnGpl were determined as described in the text. Each point represents the mean ± SD of four rats. In some cases error bars are included within the symbols.

take of aminophospholipid precursors such as ethanolamine and serine was not affected by altered n-6 and n-3 PUFA profiles in membrane phospholipids. The 20:4n-6 contents in the Saf group were 1.62-, 1.49-, and 1.51-fold greater in ChoGpl,

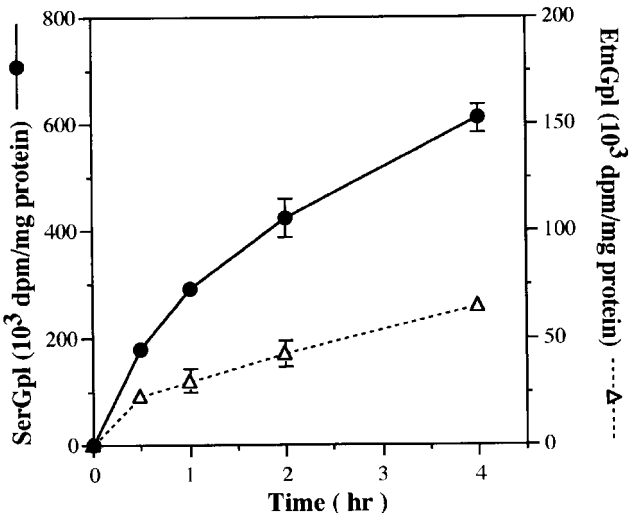

FIG. 5. Time course of incorporation of [^{3}H]serine into aminophospholipids in brain synaptosomes. Synaptosomes prepared from rats fed a conventional chow were incubated with 2 μCi/mL [^{3}H]serine for 0.5 to 4.0 h. The radioactivities incorporated into serine glycerophospolipid (SerGpl) and EtnGpl were measured as described in the text. Values represent means ± SD for four rats. In some cases error bars are included within the symbols. For other abbreviations see Figures 1 and 2.

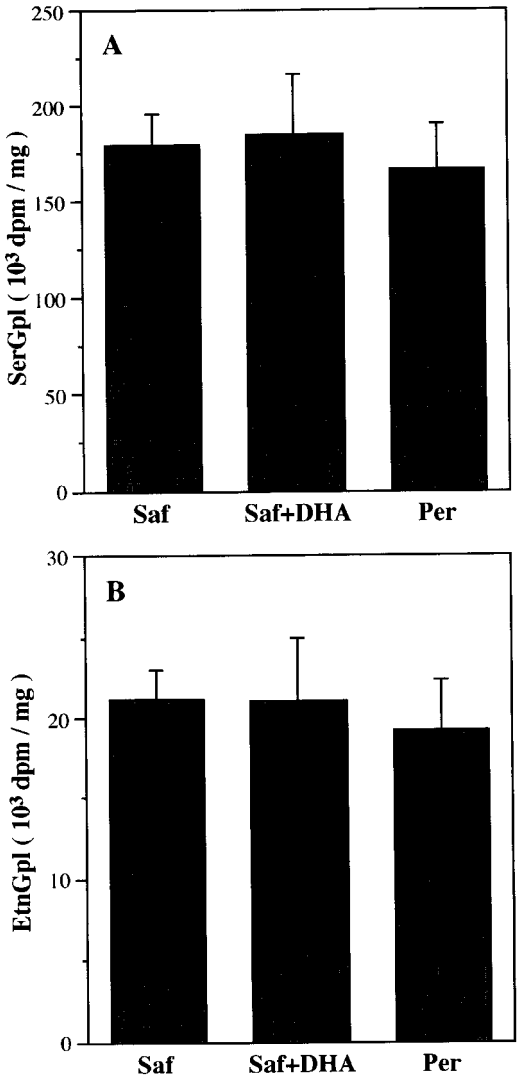

FIG. 6. Effect of dietary fatty acid status on incorporation of [^{3}H]serine into aminophospholipids in brain synaptosomes. Synaptosomes prepared from rats fed semipurified diets supplemented with Saf, Saf + DHA, or Per were incubated with 2 μCi/mL [^{3}H]serine for 1 h. The radioactivities incorporated into SerGpl (A) and EtnGpl (B) were measured as described in the text. Radioactivity in lysoEtnGpl was negligible (< 100 dpm/200 μg protein). Values represent means ± SD for six rats. For abbreviations see Figures 1, 2, and 5.

EtnGpl, and SerGpl, respectively, compared with the Per group. These changes were relatively smaller than those with PC12 cells cultured in the presence of 20:4n-6. The total PUFA contents in synaptosomes did not differ among the three dietary groups, whereas significant increases in PUFA contents and concomitant decreases in 18:1 contents were detected in PC12 cells treated with 20:4n-6 (about 60% low compared with the control). Differential extents of fatty acid modification and difference in cell types may account for the observed difference in aminophospholipid metabolism between PC12 cells and synaptosomes. Moreover, the differential effects may arise from the different method of fatty

acid modification between the *in vivo* and the *in vitro* experiments.

Although the [^{3}H]ethanolamine uptake and incorporation into EtnGpl in synaptosomes were not affected by n-3 fatty acid deficiency, the formation of [^{3}H]lysoEtnGpl, a probable deacylation product of [^{3}H]EtnGpl, was 20% less in the Saf group compared with the Per group. Moreover, the lower [^{3}H]lysoEtnGpl formation was restored by supplementing the Saf group with 22:6n-3 after weaning. This is the first demonstration of altered phospholipid metabolism observed in synaptosomes from rats nutritionally manipulated with respect to n-6 and n-3 fatty acid status.

At least four enzymatic pathways could be involved in the altered [^{3}H]lysoEtnGpl contents: (i) degradation by phospholipase A_1 (PLA_1), (ii) degradation by phospholipase A_2 (PLA_2), (iii) transfer of the acyl-moiety of EtnGpl to other phospholipids by transacylase, and (iv) lysophospholipase. PLA_1 preferentially hydrolyzing EtnGpl in the presence of Mg^{2+} has been observed in the soluble fraction of bovine brain (31), but this enzyme preferentially hydrolyzes phosphatidic acid in the absence of Mg^{2+} (32).

Several different PLA_2 enzymes exist in the mammalian brain (33,34). They are classified into two subtypes, Ca^{2+}-dependent and Ca^{2+}-independent, based on their catalytic dependence on Ca^{2+}. In Ca^{2+}-dependent subtypes, cytosolic PLA_2 preferentially hydrolyzes arachidonate-containing molecular species (34). Type II secretory PLA_2, another Ca^{2+}-dependent subtype found in rat brain, has no specificity for the acyl-chain of phospholipids *in vitro* but can hydrolyze arachidonate from membrane phospholipids by physiological stimuli in intact cells (35). Group IV Ca^{2+}-independent PLA_2 is considered to function in membrane phospholipid remodeling such as 20:4n-6 incorporation and redistribution (36). Plasmalogen-selective and Ca^{2+}-independent PLA_2 has been observed in bovine brain cytosol (37), but its specificity for acyl chains remains to be clarified. In this study, [^{3}H]lysoEtnGpl formation was correlated with 22:6n-3 levels but not 20:4n-6 levels in aminophospholipids of the three dietary groups (Table 3 and Fig. 3B). Therefore, the substrate specificity of PLA reported previously could not account for the difference in [^{3}H]lysoEtnGpl formation. Moreover, n-3 deficiency does not affect brain contents and composition of phospholipid or plasmalogen content (4,8), therefore phospholipid and plasmalogen content could not account for our results.

Transacylase activity using diacylphospholipids as acyl donors for the transacylation of lysophospholipids has been observed in human brain homogenate (38). This enzyme transfers radiolabeled acyl chains from the *sn*-2 position of EtnGpl to lysoChoGpl. Lysophospholipase (38) may also affect lysoEtnGpl formation in brain synaptosomes. In the hamster heart, newly imported ethanolamine is preferentially utilized for EtnGpl biosynthesis (39) and newly synthesized EtnGpl may be remodeled by deacylation–reacylation. Although SerGpl-derived EtnGpl is preferentially deacylated and reacylated in cultured rat hepatocytes (40), the formation of EtnGpl by SerGpl decarboxylation in rat brain synaptosomes is relatively low compared with that in hepatocytes (40) and PC12 cells (20). It is suggested that CDP-ethanolamine:diacylglycerol ethanolaminephosphotransferase shows selectivity for 22:6n-3-containing species (41), and that 22:6n-3-containing EtnGpl is mainly synthesized *de novo* (41), whereas 20:4n-6 is introduced into phospholipids mainly through the remodeling pathway (42). The physiological roles of deacylation of newly synthesized EtnGpl in fatty acid remodeling are not yet clear.

Treatment of PC12 cells with 60 μM 22:6n-3 led to a fivefold increase in 22:6n-3 levels and a concomitant decrease in 18:1 (about 60% decrease compared with control) in membrane phospholipids (19). As a result, 22:6n-3 treatment increased C_{22} PUFA content (fivefold) and incorporation of [^{3}H]serine into SerGpl in PC12 cells (20). Phospholipids containing C_{22} PUFA are selectively used for the synthesis of SerGpl by a base exchange reaction (43,44). This step may contribute to the 22:6n-3 level which was significantly higher in the Saf + DHA group relative to the Per group in SerGpl but not EtnGpl. Garcia *et al.* reported that n-3 fatty acid deficiency led to a decrease in both C_{22} PUFA-containing SerGpl and a decrease in incorporation of [^{3}H]serine into SerGpl in rat brain microsomes (21). However, the incorporation of [^{3}H]serine into SerGpl in synaptosomes was not affected by n-3 fatty acid deficiency in this study (Fig. 6). In the Saf group, the markedly lower 22:6n-3 content was compensated for by higher n-6 C_{22} PUFA contents in phospholipids. As a result, total PUFA contents in individual phospholipids in synaptosomes were not different among the three dietary groups. The observed differences may be attributable to the differences between types of fractions, synaptosomes vs. microsomes.

In summary, n-3 fatty acid deficiency in synaptosomes induced by a Saf diet does not affect the uptake of aminophospholipid precursors such as ethanolamine and serine by synaptosomes and their incorporation into aminophospholipids such as EtnGpl and SerGpl. However, n-3 fatty acid deficiency leads to significantly lower formation of [^{3}H]lysoEtnGpl through [^{3}H]EtnGpl newly synthesized from [^{3}H]ethanolamine in synaptosomes. Detailed analysis of molecular species of [^{3}H]lysoEtnGpl and determination of these enzymes are necessary to correlate the observed changes in lysoEtnGpl formation with many types of enzymes involved in EtnGpl metabolism.

ABSTRACT: The introduction of the double bond in the sphingoid backbone of sphingolipids occurs at the level of dihydroceramide *via* an NADPH-dependent desaturase, as discovered in permeabilized rat hepatocytes. In the rat, the enzyme activity, which has now been further characterized, appeared to be mostly enriched in liver and Harderian gland. By means of subcellular fractionation of rat liver homogenates and density gradient separation of microsomal fractions, the desaturase was localized to the endoplasmic reticulum. Various detergents were inhibitory to the enzyme, and maximal activities were obtained in the presence of NADPH and when the substrate was complexed to albumin. In the presence of albumin, the chain length of the fatty acid of the truncated dihydroceramides hardly affected the activity. Finally, in view of a likely evolutionary relationship between desaturases and hydroxylases, the formation of hydroxylated intermediates was analyzed. No evidence for their presence was found under our assay conditions.

Paper no. L8364 in *Lipids 35*, 1117–1125 (October 2000).

Although the major portion of sphingoid bases found in sphingolipids contains a 4-*trans* double bond in mammals, for some time it was neither clear whether this double bond is added at the level of sphinganine (D-*erythro*-2-amino-1,3-octadecanediol) or of dihydroceramide (*N*-acyl-sphinganine), nor known where in the cell and by which mechanism this reaction takes place. Based on incorporation studies with labeled sphinganine, dihydroceramide, or serine (1–3) and on the cellular effects of fumonisin B1 (4,5), a toxin produced by *Fusarium moniliforme* that blocks the acylation of sphingoid bases (4,6), it was established that dihydroceramide is an intermediate in the *de novo* synthesis of sphingolipids. Dihydroceramide, generated by acylation of sphinganine, is subsequently converted into ceramide. Until recently, the nature of the enzyme responsible for the introduction of the double bond was obscure.

By comparing the release of labeled water from the truncated dihydroceramide analog, *N*-hexanoyl-[4,5-^{3}H]sphinganine, in intact and permeabilized rat hepatocytes, we could evaluate the importance of NADPH in the formation of ceramide, a cofactor pointing to a role for a desaturase (7,8). This idea was further sustained by the effect of specific inhibitors and electron-donors/acceptors (8), indicating that the dihydroceramide desaturase (DHCD) complex consists of a flavin-containing cytochrome (cyt) b_5 reductase, a heme-containing cyt b_5, and a nonheme-containing desaturase (see Fig. 1 for an overview of the biosynthesis of ceramide). Independently, Michel *et al*. (9), who investigated the influence of NADH on the metabolism of *N*-[1-^{14}C]octanoyl-sphinganine in rat liver microsomes, reached similar conclusions. In their hands, however, NADH and NADPH worked equally well (9), whereas in permeabilized rat hepatocytes, NADH was effective only in the presence of ATP (8).

Upon liver fractionation, the desaturase activity was recovered mainly in the microsomal fraction (8). This would be consistent with an association with endoplasmic reticulum (ER) vesicles, also the subcellular site of sphinganine-*N*-acyltransferase (10,11), the enzyme generating the substrate for the desaturase reaction. Desaturation rates of *N*-C_6-[4,5-^{3}H]sphinganine (where C_6 = hexanoyl) in rat liver homogenates under optimized conditions reached only 30% of those observed in intact hepatocytes (8). Contributing factors were postulated to be an exchange reaction that occurs in intact cells (8,12), whereby the short chain of the truncated substrate is replaced by a more physiological long-chain fatty acid, and nonoptimal delivery of the substrate, complexed to albumin, to the enzyme in broken systems. In the present report, the tissue distribution of DHCD in the rat and the subcellular localization of the activity in rat liver were investigated. To further optimize the assay, the use of substrate/de-

Abbreviations: BSA, bovine serum albumin; C_6, hexanoyl; C_x, acyl chain containing *x* carbon atoms; CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate; CMC, critical micellar concentration; Cyt, cytochrome; DHCD, dihydroceramide desaturase; ER, endoplasmic reticulum; Mops, morpholino propane sulfonic acid; sphinganine, D-*erythro*-2-amino-1,3-octadecanediol; sphingenine: D-*erythro*-2-amino-1,3-4*E*-octadecenediol; TLC, thin-layer chromatography.

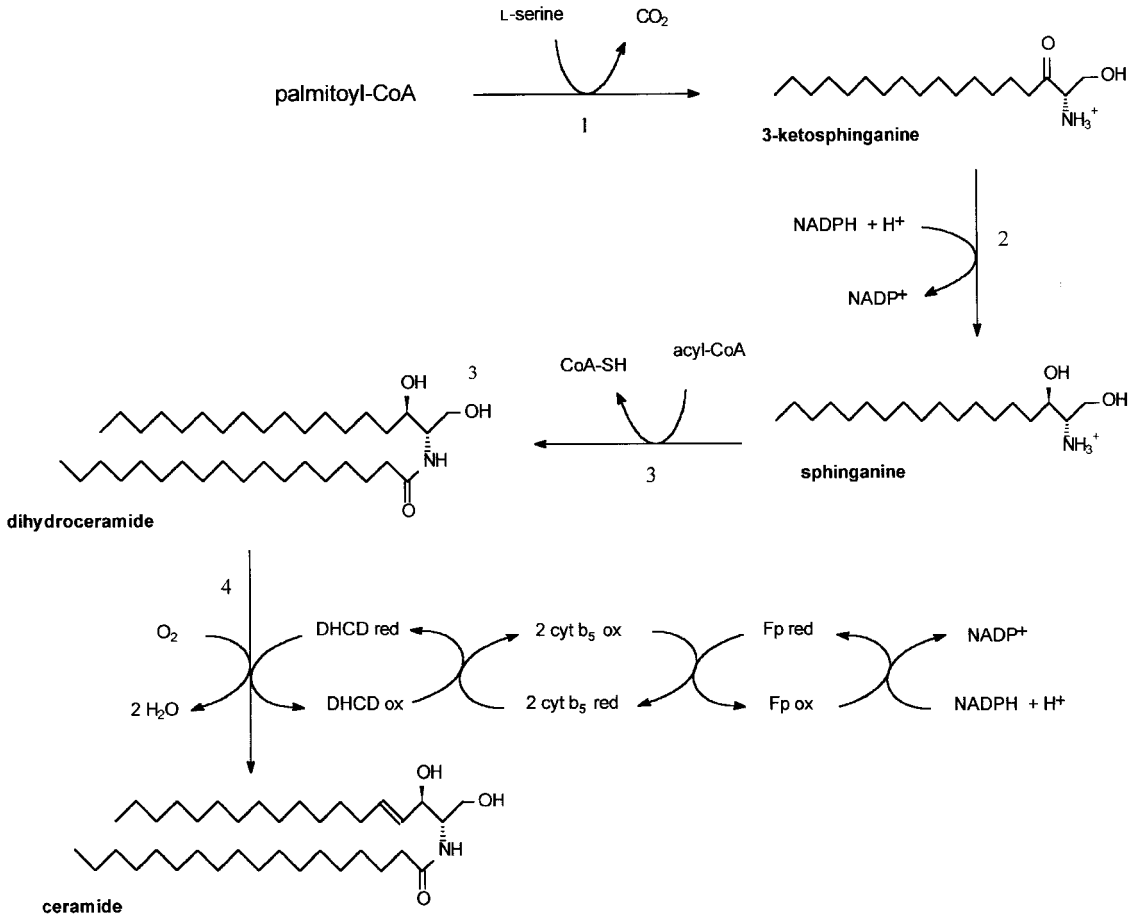

FIG. 1. Biosynthesis of ceramide. The pathway depicted shows the current view of ceramide biosynthesis whereby the following enzymes are involved: (1) serine palmitoyl-CoA transferase; (2) 3-ketosphinganine reductase; (3) sphinganine-*N*-acyltransferase; (4) dihydroceramide desaturase (DHCD). The desaturation of dihydroceramide is catalyzed by an enzyme complex consisting of a flavoprotein (Fp), a cytochrome (cyt) b_5, and a desaturase, and is driven by NADPH.

tergent micelles and the specifity toward the *N*-acyl chain length of the dihydroceramide substrate were evaluated. Finally, the role of NADPH vs. NADH as cofactor was studied whereby the formation of possibly hydroxylated intermediates was analyzed.

MATERIALS AND METHODS

Materials. Analytical-grade solvents and biochemicals were purchased from commercial suppliers. Anhydrous solvents were obtained from Fluka (Buchs, Switzerland). Sphingolipids, *N*-dodecyl sarcosine (Sarkosyl), *N*-dodecyl- and *N*-tetradecyl-*N*,*N*-dimethyl-3-ammonio-1-propane sulfonate were from Sigma; 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS), cyclodextrins, dodecylmaltoside, octanoyl-*N*-methylglucamide (MEGA-8), octylglucoside, sucrose monolaurate, Thesit [dodecylpoly(ethyleneglycolether)$_n$; where $n \approx 9$], Triton X-100, and protease inhibitors were from Boehringer (Mannheim, Germany); lauryl-*N*,*N*-dimethylamine *N*-oxide (*N*,*N*-dimethyl-*N*-dodecylamine oxide) was from Serva (Heidelberg, Germany); and *N*-octanoyl-β-D-glucosamine, *N*-octyl *N*,*N*-dimethyl-3-ammonio-1-propane sulfonate, and decylmaltoside were from Calbiochem (LaJolla, CA).

Preparation of substrates. [4,5-^{3}H]Sphinganine, obtained as a side product of the acidic hydrolysis of tritiated dihydrosphingomyelin (13), was purified by silica gel chromatography and mixed with unlabeled sphinganine, prepared by hydrogenation of sphingenine (D-erythro-2-amino-1,3-4*E*-octadecenediol; Ref. 14), and purified in the same way as the labeled compound, to obtain a specific activity of 86.7 μCi/μmol. Radiochemical purity was more than 95% as determined by thin-layer chromatography (TLC: silica G60 Alugram plates; Machery-Nagel, Düren, Germany) using chloroform/methanol/2 M NH_4OH (60:30:5, by vol; solvent A) and chloroform/methanol/water (60:35:8, by vol; solvent B). Concentrations of sphinganine solutions were determined by means of derivatization with trinitrobenzenesulfonic acid (15). *N*-[1-^{14}C]C_6-sphinganine, *N*-C_6-sphinganine, *N*-C_6-sphingenine, and *N*-C_6-4*D*-hydroxysphinganine were synthesized as described before (8). Truncated tritiated dihydroceramides were obtained by acylation of [4,5-^{3}H]sphinganine using either the appropriate anhydrides (for *N*-

C_2- and *N*-C_6-sphinganine) as described (8,15,16) or acyl chlorides (for *N*-C_4 and *N*-C_8-sphinganine) as adapted from Reference 17. The other dihydroceramide analogs (*N*-C_{10}-, *N*-C_{12}-, *N*-C_{14}-, and *N*-C_{16}-sphinganine) were generated by means of diethyl phosphorocyanidate (18) as condensing reagents. Briefly, fatty acids were dissolved in anhydrous dimethylformamide/dichloromethane (2:1, vol/ vol), to 20 mM, followed by addition of a fivefold molar excess (over fatty acids) of triethylamine and of an equimolar amount of diethyl phosphorocyanidate. After incubation for 5 min, an aliquot of this mixture was mixed with 1 vol of 10 mM [4,5-^{3}H]sphinganine [in dimethylformamide/dichloromethane (2:1, vol/vol)], and allowed to react for 2 h at room temperature. Acylation of sphinganine appeared to be almost complete as revealed by TLC analysis [solvent C: chloroform/methanol/acetic acid (90:10:1, by vol)]. All acylated products were subjected to an alkaline hydrolysis (15) to remove any formed *O*-acylester, extracted into chloroform and, if necessary, purified by preparative TLC in solvent C. Yields ranged between 90 and 95% when using diethyl phosphorocyanidate. The radiochemical purity of the different dihydroceramides was more than 97% as determined by TLC (solvents C and A). Lipids were transiently visualized by iodine vapor followed by specific spraying (ninhydrin-cupric nitrate, molybdenum blue reagent) and/or charring (19). Labeled lipids were scraped into 0.5 mL of 1% (wt/vol) sodium dodecyl sulfate, and radioactivity was measured in a liquid scintillation counter after adding 4 mL of Optifluor and corrected for background radioactivity.

Subcellular fractionation and marker enzyme analysis. Maintenance and treatment of male Wistar rats were approved by the local Institutional Ethics Committee. Animals (body weight approximately 200 g) were fasted overnight and killed by decapitation. The tissues were removed and homogenized in 0.25 M sucrose/5 mM morpholino propane sulfonic acid (Mops) pH 7.2/0.1% (vol/vol) ethanol. Liver homogenates were fractionated as described before (13). The microsomal fraction was further separated by means of sucrose density gradient centrifugation. Optimal resolution was obtained by layering an aliquot (2.5 mL) of a microsomal fraction derived from 2.5 g of rat liver on top of a 25–75% (wt/vol) linear sucrose gradient (18 mL), containing 5 mM Mops pH 7.2/0.1% (vol/vol) ethanol, and supported by a cushion of 75% (wt/vol) sucrose (2.5 mL). The gradient was spun at 4°C in a Beckman 55.2 Ti fixed-angle rotor for 2 h at 100,000 × *g* (slow acceleration mode). After centrifugation, gradient fractions were collected starting from the bottom by means of a needle connected to a peristaltic pump. Measurements of protein and most marker enzymes were done according to the modifications described previously: protein (20), glutamate dehydrogenase (20), acid phosphatase (20), glucose-6-phosphatase (20), 5′-nucleotidase (21), galactosyltransferase (13), and urate oxidase (22). Catalase was assayed as in Reference 23, but the final assay volume was reduced to 2.6 mL. Alkaline phosphatase activities were followed kinetically at 400 nm (ε = 18,300 $cm^{-1} \cdot M^{-1}$) after a 5-min preincubation of the samples at pH 10.5 with Mg and Zn ions. Final assay concentrations were 50 mM glycine-NaOH pH 10.5/2 mM $MgCl_2$/20 μM Zn acetate/0.1% (wt/vol) Triton X-100/2 mM *p*-nitrophenyl-phosphate (final volume of 0.5 mL). For a comprehensive review on tissue fractionation and the use of marker enzymes, see Reference 24.

DHCD. Desaturase activity measurements were based on the formation of tritiated water using *N*-C_6-[4,5-^{3}H]sphinganine as substrate. Assays on tissue homogenates and subcellular fractions were done exactly as described before (8). Briefly, 200 μL of sample, appropriately diluted in homogenization medium, was mixed with 800 μL of reaction mixture (final concentrations: 40 μM *N*-C_6-[4,5-^{3}H]-sphinganine [1:1 molar complex with bovine serum albumin (BSA)], 20 mM Bicine pH 8.5, 50 mM NaCl, 2 mM NADPH), and the mixture was incubated for 20 minutes at 37°C. After adding 100 μL of 8% (wt/vol) BSA, the mixture was acidified with 100 μL of 72% (wt/vol) trichloroacetic acid. Denatured proteins were removed by centrifugation; and a 0.8-mL aliquot of the supernatant, adjusted to pH 5.5 with 1 M Na_2HPO_4, was applied to a C_{18} solid-phase extraction column (500 mg Bond Elut; Varian). The amount of label not retained, corrected for the presence of non-volatile tritium (8), was taken as a measure for the desaturation reaction. For the analysis of N-acyl chain length specificity and the influence of detergents in microsomal fractions, volumes of the assay and stop solutions were reduced twofold.

In some experiments, the C_{18}-Bond Elut columns were further washed with methanol to elute bound lipids. The methanol fractions were dried and separated on silica G60 glass plates (solvent A). The following R_f values were found: *N*-C_6-sphinganine 0.90; *N*-C_6-sphingenine 0.86; *N*-C_6-4*D*-hydroxysphinganine 0.81; sphinganine 0.46; sphingenine 0.54; 4*D*-hydroxysphinganine 0.30–0.34.

In some experiments, *N*-[1-^{14}C]C_6-sphinganine alone or mixed with *N*-C_6-[4,5-^{3}H]sphinganine was used as substrate. In addition to the above described analysis, the protein/lipid precipitate after acidification was subjected to chloroform/methanol extraction, followed by phase separation. The organic phase was analyzed by TLC using borate-impregnated silica G60 Alugram plates (8) which were developed twice (solvent D; chloroform/methanol 9:1, vol/vol) in order to separate *N*-C_6-sphinganine (R_f 0.62) from *N*-C_6-sphingenine (R_f 0.44) and *N*-C_6-4*D*-hydroxysphinganine (R_f 0.04).

RESULTS AND DISCUSSION

To find a suitable tissue to study the subcellular localization of the desaturase and to use as starting material for the isolation of the desaturase complex, the tissue distribution of DHCD was analyzed in the rat. As shown in Table 1, a rather unusual picture emerged: liver and Harderian gland contained the highest activities. The role of the desaturase in the eye gland is not clear. This sebaceous gland is known to be very lipid-rich and particularly active in ether lipid synthesis (25). Since the formation of vinylether lipids is also dependent on the action of a desaturase complex, called Δ1-alkyl desaturase (26), one could argue that this desaturase contributes to the

TABLE 1
Tissue Distribution of Dihydroceramide Desaturase (DHCD) in Rat[a]

Tissue	Activity	
	pmol/min·g	pmol/min·mg protein
Liver	548	2.30

Heart	6	0.03
Thymus	6	0.05

[a]Rat tissues were homogenized in 0.25 M sucrose/5 mM morpholino propane sulfonic acid pH 7.2/0.1 % (vol/vol) ethanol in the presence of a cocktail of protease inhibitors from Boehringer (Mannheim, Germany) (0.2 mM EDTA, 0.1 mM Pefabloc, 4 μM bestatin, 2 μM E-64, 1 μM pepstatin A, and 1 mM benzamidine) and assayed for desaturase activity by using *N*-hexanoyl-[4,5-^{3}H]sphinganine as substrate as described in the Materials and Methods section. Results are averages of values obtained in two separate experiments. Control experiments in which the protease inhibitors were not or were separately added to the medium to prepare the homogenates did not reveal significant differences in rat liver (data not shown).

dihydroceramide desaturation. However, both complexes differ with regard to stereochemistry and cofactor requirement, Δ1-alkyl desaturase introducing *cis*-bonds and being NADH dependent (see also Ref. 8).

Based on the tissue distribution data, liver was chosen to study the subcellular site of dihydroceramide desaturation. Upon cell fractionation by differential centrifugation, the majority of the activity was recovered in the microsomal fraction, and the distribution profile resembled that of the ER-markers, glucose-6-phosphatase and esterase (Fig. 2). Further separation of the vesicles present in the microsomal fraction by means of sucrose density gradient centrifugation followed by DHCD and marker enzyme measurements revealed that the desaturase is associated with ER-vesicles enriched in glucose-6-phosphatase activity (designated as class c vesicles) (27) (Fig. 3). Vesicles derived from the plasma membrane or the Golgi apparatus appeared to contain (virtually) no desaturase activity. These data are in agreement with the findings of Michel and van Echten-Deckert (28) who reported an enrichment of the (NADH-dependent) DHCD in purified ER-vesicles, but not in purified Golgi fractions of rat liver. Proteolysis experiments have indicated that the catalytic site(s) of the complex face the cytosol (28).

Hence, the enzymes catalyzing the first four steps in the synthesis of ceramide—serine-palmitoyl-CoA transferase (11), 3-ketosphinganine reductase (11), sphinganine *N*-acyltransferase (11,29), and DHCD–all co-localize to the ER and their active sites face the cytosol (11,28,29). How the substrate is presented to the desaturase remains unknown, however. One might envision that dihydroceramide, formed by the N-acyltransferase, becomes inserted in the outer leaflet of the lipid bilayer and reaches the desaturase by lateral diffusion. As a consequence, the use of a substrate, complexed to albumin, may not be physiologically meaningful. This argument was also used to explain the lower desaturation rates in broken systems (8). Therefore, in an attempt to further optimize the assay, various detergents were screened for their ability to support the desaturation reaction in rat liver microsomal fractions. Most detergents, tested in the assay at a concentration equaling their critical micellar concentration (CMC), resulted in very poor activities, except for some nonionic compounds such as octylglucoside, decyl- or dodecylmaltoside, and sucrose monolaurate (Table 2; Fig. 4). However, rates obtained in the presence of these detergents were still substantially lower than those obtained with the albumin-complexed substrate. The zwitterionic detergent CHAPS, employed by Michel *et al.* (9), displayed a sharp optimum well below its CMC value. When present at concentrations above their CMC value, nonionic detergents were even more inhibitory (Fig. 4). When added to assay mixtures containing albumin-bound substrate, all detergents tested also lowered the activity, even at concentrations equaling their CMC values (data not shown).

Despite this thorough screening of detergents, none resulted in higher activities than those measured in the presence of albumin. Also the use of dihydroceramide/cyclodextrin complexes was not succesful (Table 2). Therefore, the influence of the N-acyl chain length was analyzed in the hope to find a better substrate. As shown in Figure 5, the activities obtained with the different truncated dihydroceramides did not dramatically differ, but tended to decrease with longer chain lengths. The N-butyryl derivative was the best substrate. A much more drastic influence of the N-acyl chain length was reported by Michel *et al.* (9), who showed that the (NADH-dependent) activity with *N*-C_8-sphinganine is approximately 10-fold higher than that with *N*-C_{12}- or *N*-C_{16}-sphinganine. This difference might be related to the way these substrates were delivered: ethanol/dodecane solubilization followed by dilution in aqueous medium and sonication (9) vs. albumin in our experiments. Presumably the length of the N-acyl chain will not markedly modulate the binding of truncated dihydroceramides to albumin. Although addition of [4,5-^{3}H]sphinganine to rat hepatocytes resulted in the production of labeled water (8), sphinganine was not desaturated by rat liver microsomal fractions under our assay condition (data not shown). This finding is in agreement with earlier data (5) and shows that the desaturase recognizes the presence of the amide bond. At the primary hydroxyl group of the substrate, some substitutions are allowed since truncated dihydrosphingomyelin can be desaturated (9); truncated dihydroceramide-1-phosphate, however, did not appear to be a substrate (data not shown).

Because Michel *et al.* (9) reported that NADH and NADPH could support the desaturation of dihydroceramide equally well, the requirement for NADPH vs. NADH was reinvestigated in the presence of albumin and some detergents. NADH was effective, but in all conditions tested, NADPH resulted in higher activities (Table 2), confirming our initial observations (8). Furthermore, the NADPH-dependent

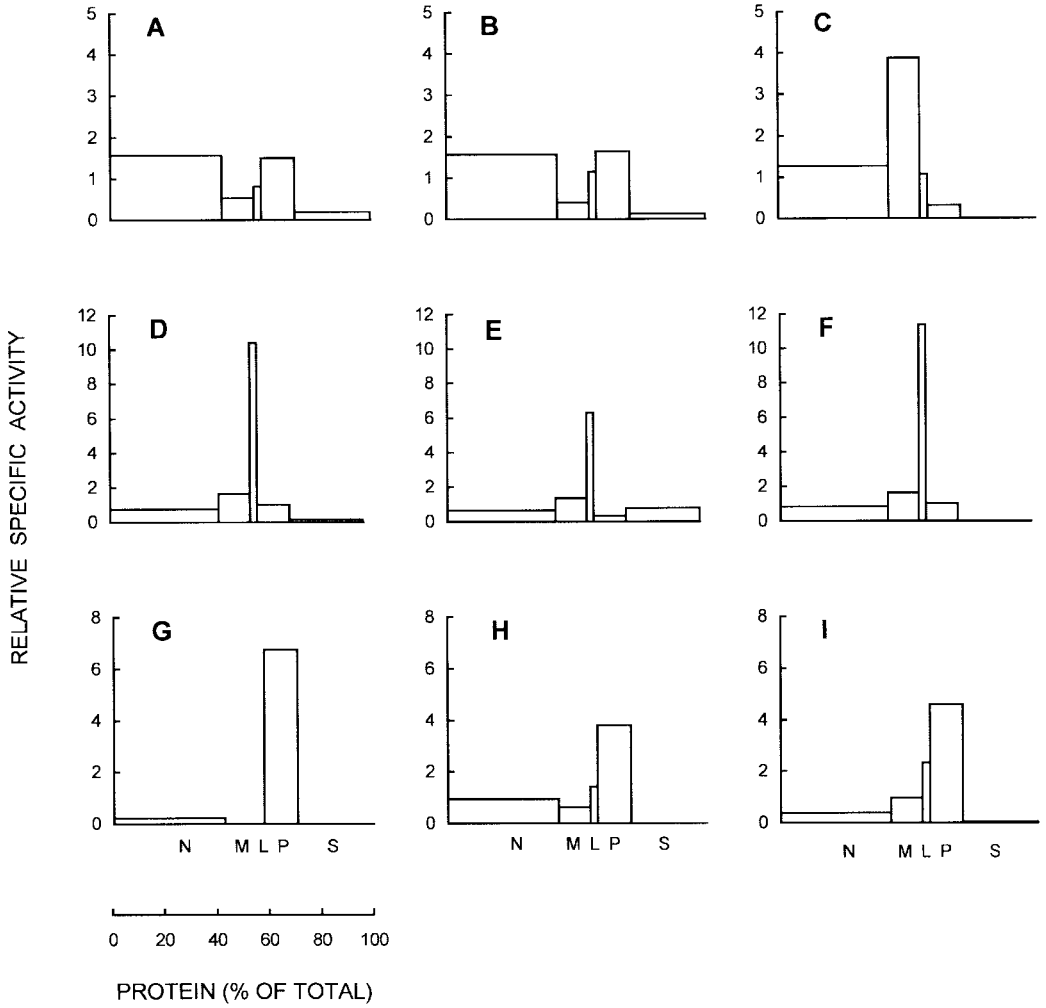

FIG. 2. Subcellular distribution of DHCD in rat liver. A rat liver homogenate was fractionated into a nuclear (N), a heavy mitochondrial (M), a light mitochondrial (L), a microsomal (P), and a cytosolic (S) fraction. In each fraction marker enzymes, DHCD, and protein were measured. Results are expressed as relative specific activities (RSA) vs. the cumulative percentage of protein. To calculate the percent activity of a marker in a particular fraction compared to the total homogenate, one has to multiply the RSA value with the percent protein present in that fraction (for N, M, L, P, and S, the percent proteins were 42.8, 12.3, 2.7, 12.9, and 29.3). The following markers were measured (in parentheses are indicated: recovery; activity, expressed in U per g of liver whereby a unit is defined as μmol substrate used per min; subcellular site): (A) 5′-nucleotidase (100%; 13.1 U/g; plasma membrane); (B) alkaline phosphatase (99.7%; 614 mU/g; plasma membrane); (C) glutamate dehydrogenase (109%; 327 U/g; mitochondria); (D) acid phosphatase (97.8%; 10.7 U/g; lysosomes); (E) catalase (89.9%; 79.0 U/g; peroxisomal matrix); (F) urate oxidase (98.9%; 3.17 U/g; peroxisomal core); (G) galactosyl transferase (96.9%; 3.41 mU/g; *trans*-Golgi apparatus); (H) glucose-6-phosphatase (101%; 28.4 U/g; endoplasmic reticulum); (I) DHCD (94.9%; 0.58 mU/g); not shown, lactate dehydrogenase (100%; 307 U/g; cytosol); and protein (95.1%; 235 mg/g). A similar histogram for DHCD was obtained in another fractionation experiment in which fewer marker enzymes were analyzed. For abbreviation see Figure 1.

activity was not further increased by addition of NADH (data not shown). Also when *N*-[1-^{14}C]C_6-sphinganine was used as substrate, followed by separation of substrate and the produced *N*-[1-^{14}C]C_6-sphingenine on borate-impregnated plates, as done by Michel *et al.* (9), NADPH appeared to be a better cofactor (data not shown).

Most likely, the NADPH-dependent desaturase, as reported in this paper and before (8), and the NADH-dependent desaturase described by others (9,28), reflect the activity of the same complex. Nevertheless, some discrepancies exist that are not readily explainable. In addition to the above-mentioned difference with respect to NADPH and NADH, reported K_m values differ substantially, being 6.1 μM for *N*-C_6-sphinganine (8) vs. 340 μM for *N*-C_8-sphinganine (9). It is unlikely that this difference is due only to the slight difference in N-acyl chain length. On the other hand, it cannot be excluded that substrate delivery is a critical factor as already mentioned above. Also the NADH-dependent reaction rates,

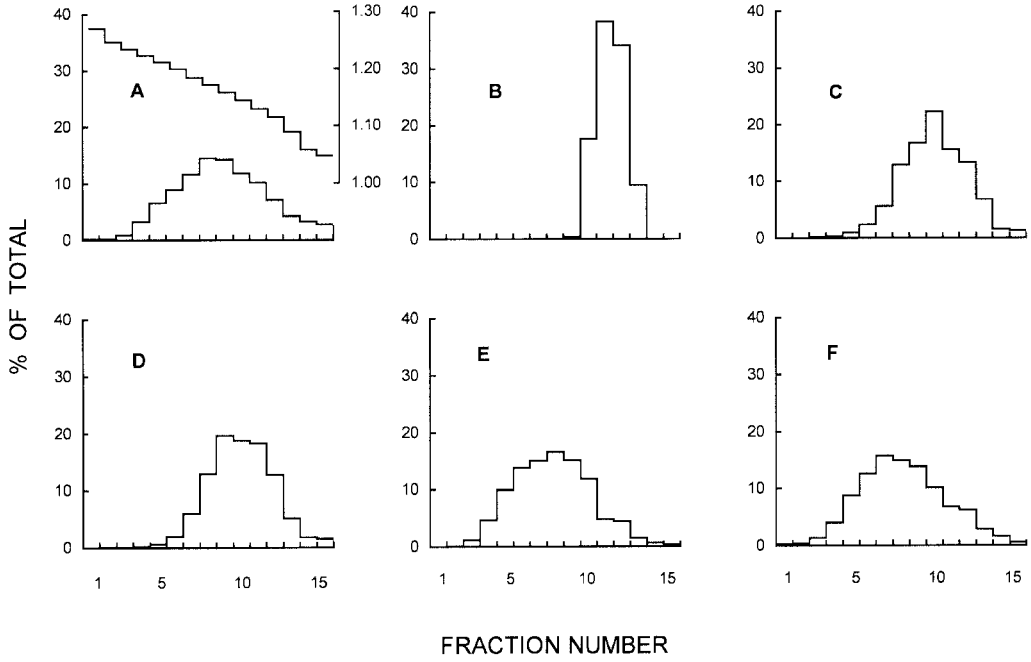

FIG. 3. Subfractionation of a microsomal fraction by sucrose density gradient centrifugation. A microsomal fraction, prepared from rat liver by differential centrifugation, was subfractionated on a sucrose density gradient as described in the Materials and Methods section. The gradient fractions were analyzed for refraction, marker enzymes, DHCD, and protein. Results of a representative experiment are shown and expressed as percentages of total recovered gradient activity or content present in each fraction. Panels represent the following marker (recoveries indicated in parentheses): (A) protein (95.5%); (B) galactosyl transferase (71.0%); (C) alkaline phosphatase (91.8%); (D) 5′-nucleotidase (110%); (E) glucose-6-phosphatase (98.0%); (F) DHCD (102%). Density of the fractions is shown in the insert of panel A. For abbreviation see Figure 1.

as calculated from the data reported by Michel *et al*. (9), appear to be approximately 30-fold higher than the NADPH-dependent rates obtained under our conditions, raising some concern about the validity of the different assays. In our assay the release of water from carbons 4 and 5 from the sphinganine backbone is followed. The other assay relies on a difference in the mobility of truncated ^{14}C-labeled ceramide and dihydroceramide upon chromatography on borate-impregnated plates. However, metabolic alterations other than 4,5-desaturation of dihydroceramide, such as a 8,9-desaturation that was recently discovered in plants (30), will result in similar mobility changes. In mammals, only a small portion of the sphingolipids contains a 4D-hydroxysphinganine backbone, but the introduction of this 4-hydroxy group, if occurring at the level of dihydroceramide and if happening in mammals, will alter the mobility of and can also cause the release of tritium from *N*-C_6-[4,5-^{3}H]sphinganine. Likewise, hydroxylation of (dihydro)ceramide in the fatty acid moiety cannot be excluded, the more since lauramide diethanolamine (*N*-dodecanoyl-diethanolamine), a compound used in cosmetics and showing some resemblance to ceramide, is hydroxylated at position 11 or 12 of the fatty acid by rat liver microsomes (31). Other (theoretical) metabolic conversions of the truncated dihydroceramide, like desaturation of the fatty acid chain, a hydroxylation at the ω-end of the sphinganine moiety or at the α-carbon of the fatty acid, would also result in mobility changes. To reveal whether dihydroceramide can undergo such conversions, microsomal fractions were incubated with *N*-C_6-[4,5-^{3}H]sphinganine and/or *N*-[1-^{14}C]C_6-sphinganine in the presence of NADH or NADPH, followed by analysis of the water-soluble and water-insoluble reaction products. In our hands, due to tailing of the (labeled) substrate during separations on borate-impregnated plates, it was difficult to obtain accurate values for the desaturation product which migrates somewhat slower than the substrate. Despite this problem, the reaction rates based on the release of tritiated water or the formation of ^{14}C-labeled *N*-C_6-sphingenine did not differ by more than 40% (data not shown). The different TLC analyses performed showed some hydrolysis of the substrate and product to sphinganine and sphingenine, respectively, but did not reveal the occurrence of hydroxylated intermediates, either at the sphinganine or (dihydro)ceramide level. These findings by no means exclude hydroxylation of sphingolipids in mammalian systems since these reactions might be dependent on other assay conditions, substrates, or enzyme sources. In yeast, the enzyme responsible for the 4-hydroxylation of sphingolipids has recently been characterized (Sur2p), but it is not clear yet at which level, sphinganine or dihydroceramide, the 4-hydroxy group is introduced (32). Since Sur2p appears to be a member of the hydroxy-

[a]Microsomal fractions were prepared from rat liver homogenates and assayed for DHCD using *N*-hexanoyl-[4,5-^{3}H]sphinganine as substrate (0.5 mL final assay volume). The substrate (20 nmol), dissolved in 2.5 μL of ethanol, was added either to an albumin solution (final concentration 40 μM) or to a detergent solution (final concentrations equaling one or five times the reported critical micelle concentration (CMC) of the detergents (34), unless otherwise indicated). After adjusting the volumes, the reaction mixture containing NADPH or NADH was added and reactions were started by adding the microsomal fraction. Activities are expressed as percentage of the control activity determined in the presence of NADPH and substrate bound to an equimolar concentration of albumin. Most values are averages of two determinations, done with different batches of microsomal fractions. The control activity was 282 ± 16 pmol/min·microsomal fraction derived from 1 g of liver [mean ± SEM (n = 6)]. With NADH, activities were on the average 1.7-fold lower in albumin-containing reaction mixtures [161 ± 30; mean ± SEM (n = 3)]. In the presence of detergents, NADH resulted likewise in lower activities (data not shown). Appropriate controls indicated that the lower activities in the presence of detergents or cyclodextrins were not due to inadequate substrate solubilization. For other abbreviation see Table 1.
[b]DMAPS, *N*,*N*-dimethyl-3-ammonio-1-propane sulfonate; ND, not determined; LDAO, lauryl-*N*,*N*-dimethylamine *N*-oxide; CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate.
[c]When measured at *N*-dodecyl sarcosine/substrate molar ratios varying between 1 and 6, activities reached 55% of the control value.
[d]Activities obtained at a substrate/cyclodextrin molar ratio of 0.5.

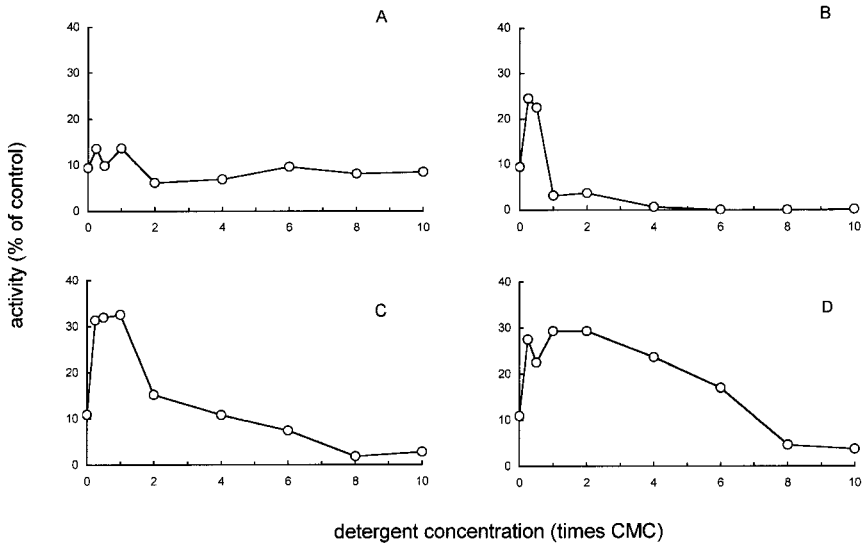

FIG. 4. Influence of detergents on DHCD activity. DHCD activities were measured in microsomal fractions using *N*-hexanoyl-[4,5-^{3}H]sphinganine as substrate and NADPH as cofactor in a final volume of 0.5 mL in the presence of different detergents, Triton X-100 (A), 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (B), decylmaltoside (C), sucrose monolaurate (D), and dodecylmaltoside (not shown; similar curve as in C). Concentrations of the detergents are expressed as times their reported critical micelle concentration (CMC) values (see Table 2). Data are expressed as percentage of the activities obtained with substrate in the presence of an equimolar concentration of albumin (288 ± 47 pmol/min·microsomal fraction derived from 1 g of liver; mean ± SEM; n = 3). Dissolution of the substrates was checked by removing and counting a 5-μL aliquot of the reaction mixtures just before adding the microsomal fraction. For the detergents shown, substrate solubilization became complete between 0.5 and 1 times the CMC values. For abbreviation, see Figure 1.

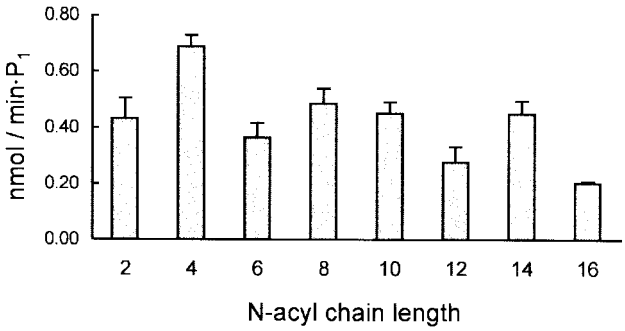

FIG. 5. Influence of *N*-acyl chain length of dihydroceramide analogs on DHCD activity. DHCD activities were measured in microsomal fractions using 40 μM of truncated dihydroceramides differing in their N-acyl chain length (number of carbon atoms indicated in the abscissa), bound to an equimolar concentration of albumin. NADPH was used as cofactor and final assay volumes were 0.5 mL. Data are means ± SEM of values obtained with three different microsomal fractions. P_1: microsomal fraction derived from 1 g of liver. For abbreviation see Figure 1.

lase/desaturase family (33), this raises the interesting possibility that the introductions of the 4-*trans* double bond (major pathway in mammals) and of the 4-hydroxy group (major pathway in yeast) in sphingoid bases are evolution-related processes.

Identification of the Pathway of α-Oxidation of Cerebronic Acid in Peroxisomes

Rajat Sandhir, Mushfiquddin Khan, and Inderjit Singh*

Department of Pediatrics, Medical University of South Carolina, Charleston , South Carolina 29425

ABSTRACT: Cerebronic acid (2-hydroxytetracosanoic acid), an α-hydroxy very long-chain fatty acid (VLCFA) and a component of cerebrosides and sulfatides, is unique to nervous tissues. Studies were carried out to identify the pathway and the subcellular site involved in the oxidation of cerebronic acid. The results from these studies revealed that cerebronic acid was catabolized by α-oxidation to CO_2 and tricosanoic acid (23:0). Studies with subcellular fractions indicated that cerebronic acid was α-oxidized in fractions having particulate bound catalase and enzyme systems for the β-oxidation of VLCFA (e.g., lignoceric acid), suggesting peroxisomes as the subcellular organelle responsible for α-oxidation of cerebronic acid. Etomoxir, an inhibitor of mitochondrial fatty acid oxidation, had no effect on cerebronic acid α-oxidation. Further, cerebronic acid oxidation was found to be dependent on the presence of NAD^+ but not FAD, NADPH, ATP, Mg^{2+}, or CoASH. Intraorganellar localization studies indicated that the enzyme system for the α-oxidation of cerebronic acid was associated with the peroxisomal limiting membranes. Studies on cultured fibroblasts from normal subjects and patients with peroxisomal disorders indicated an impairment of α-oxidation of cerebronic acid in cell lines that lack peroxisomes [e.g., Zellweger syndrome (ZS)]. On the other hand, α-oxidation of cerebronic acid was found to be normal in cell lines from X-linked adrenoleukodystrophy, adult Refsum disease, and rhizomelic chondrodysplasia punctata. Our results clearly demonstrate that α-oxidation of α-hydroxy VLCFA (cerebronic acid) is a peroxisomal function and that this oxidation is impaired in ZS. Furthermore, this α-oxidation enzyme system is distinct from the one for the α-oxidation of β-carbon branched-chain fatty acids (e.g., phytanic acid).

Paper no. L8363 in *Lipids 35,* 1127–1133 (October 2000).

α-Hydroxy long-chain and α-hydroxy very long-chain fatty acids (VLCFA) are characteristically abundant in brain and other nervous tissue as components of cerebrosides and sulfatides, most of which are found in myelin (1). These constitute α-hydroxy derivatives of C_{18} to C_{26} straight carbon-chain saturated and/or monounsaturated fatty acids (2). The α-hydroxy fatty acids are derived from corresponding nonhydroxy fatty acids by an enzyme system (fatty acid α-hydroxylase) present in brain microsomes. However, Kishimoto *et al.* (2) were not able to detect free cerebronic acid or cerebronoyl-CoA, an intermediate in the synthesis of α-hydroxy fatty acid containing ceramides and cerebrosides. This indicates that cerebronic acid, synthesized by fatty acid α-hydroxylase from lignoceric acid, is directly transferred to sphingosine for the synthesis of ceramide. This in turn is converted to cerebrosides and sulfatides by enzymes present in the endoplasmic reticulum-Golgi (3). Cerebronic acid is released from cerebronic acid-containing lipids by enzymes present in lysosomes. Sulfatides are degraded to cerebrosides by sulfatidase, followed by the conversion of cerebrosides to ceramides by cerebrosidase. Ceramides, in turn, are degraded to sphingosine and fatty acids by ceramidase. Although the detailed steps in the degradation of straight-chain and branched-chain fatty acids have been elucidated (4–6), the mechanism and subcellular site of oxidation of 2-hydroxy fatty acids remains uncertain. α-Hydroxy fatty acids probably cannot undergo β-oxidation because of the presence of a hydroxyl group at their α-carbon. The degradation of α-hydroxy fatty acids, derived from corresponding nonhydroxy fatty acids, to odd-numbered fatty acids with one less carbon atom was previously shown in a series of *in vivo* experiments (7,8). Using rat brain preparations, Levis and Mead (9) subsequently showed *in vitro* conversion of α-hydroxy fatty acids to fatty acids one carbon shorter, by rat brain microsomal preparations *via* oxidative decarboxylation. Interestingly, they also observed that the liver microsomes were not active toward α-oxidation of α-hydroxy fatty acids**.** Understanding the pathway and subcellular site for oxidation of cerebronic acid, 2-hydroxy VLCFA, is important as they are the major components of myelin lipids. Furthermore, VLCFA and branched-chain fatty acids are known to accumulate in excessive amounts in peroxisomal disorders in various tissues because of a deficiency in their catabolic activities in peroxisomes (5,6,10–12).

Therefore, the purpose of the present studies was to elucidate the pathway and subcellular organelle responsible for the oxidation of cerebronic acid and its metabolism in peroxisomal disorders. These studies report that cerebronic acid was

Abbreviations: DMEM, Dulbecco's modified Eagle's minimum essential medium; BCS, bovine calf serum; MOPS, 3-(*N*-morpholino)propanesulfonic acid; PBr_3, phosphorus tribromide;PMSF, phenylmethylsulfonyl fluoride; RCDP, rhizomelic chondrodysplasia punctata; RD, Refsum disease; VLCFA, very long-chain fatty acid; X-ALD, X-linked adrenoleukodystrophy; ZS, Zellweger syndrome.

α-oxidized to CO_2 and a fatty acid with one carbon atom short in peroxisomes. This activity is present in the limiting membrane of peroxisomes and was deficient in cells from Zellweger syndrome (ZS) and peroxisome-deficient cells, but not in cells from patients with other peroxisomal disorders, e.g., X-linked adrenoleukodystrophy (X-ALD), Refsum disease (RD), and rhizomelic chondrodysplasia punctata (RCDP). The normal activity of cerebronic acid α-oxidation in cell lines from RD patients, having a defect in phytanic acid oxidation, a requirement of NAD^+ only as compared to other cofactor requirements for phytanic acid oxidation, and a localization of oxidation activity in the peroxisomal-limiting membranes as compared to the matrix localization of phytananoyl-CoA hydroxylase (12), clearly indicates that the enzyme system for α-oxidation of cerebronic acid is different from the one responsible for the α-oxidation of phytanic acid to pristanic acid.

MATERIALS AND METHODS

Cell lines. ZS (GM 00228), X-ALD (04934), RD (03896), and RCDP (11347) skin fibroblast cell lines were obtained from the NIGMS Human Genetic Mutant Cell Repository (Camden, NJ). Other cell lines from patients with peroxisomal disorders (ZS, X-ALD, and RCDP) and from control healthy subjects were established in this laboratory.

Materials. Nycodenz was obtained from Accurate Chemical and Scientific Corp. (Westbury, NY). Cytochrome c, α-cyclodextrin, FAD, NAD, desulfo-CoA, ATP, L-carnitine, L-malate, imidazole, sucrose, antipain, leupeptin, pepstatin, phenylmethylsulfonyl fluoride (PMSF), dithiothreitol, and coenzyme A were purchased from Sigma Chemical Co. (St. Louis, MO). Bromine and phosphorus tribromide (PBr_3) were obtained from Aldrich Chemical Co. (Milwaukee, WI). Etomoxir was obtained from Research Biochemicals, Inc. (Natick, MA). [1-^{14}C]Palmitic acid (50 mCi/mmol) and K^{14}CN (55 mCi/mmol) were purchased from American Radiolabeled Chemicals, Inc. (St. Louis, MO). 2-Hydroxytetracosanoic (cerebronic) acid and tetracosanoic (lignoceric) acid were obtained from Matreya Inc. (Pleasant Gap, PA). Dulbecco's modified Eagle's minimum essential medium (DMEM), trypsin-EDTA, and Hank's balanced salt solution were obtained from GIBCO BRL (Grand Island, NY). Bovine calf serum (BCS) was from Hyclone (Logan, UT).

Methods. (i) Synthesis of [1-^{14}C]cerebronic acid from [1-^{14}C]lignoceric acid. [1-^{14}C]Lignoceric acid with a specific activity of 54.5 mCi/mmol was synthesized and characterized as described in our earlier publication (13). [1-^{14}C]Lignoceric acid (1 mCi) was allowed to melt in a screw-capped (16 × 100 mm) glass tube equipped with a stirring bar at 80°C. PBr_3 (5 μL) was slowly added, in the bottom of this tube. Bromine (8 μL) was added dropwise in the bottom of the tube with stirring, and the tube was closed immediately after addition of the final drop of bromine. The tube was then left at room temperature for 20 h, after which water (1 mL) was added to the reaction mixture and tube was left open in a well-ventilated fume hood at room temperature overnight. The product was extracted three times with 3-mL portions of ether. The combined ether extracts were washed with water and then evaporated to dryness. The radioactive product, α-bromolignoceric acid, was obtained in quantitative yield as examined by thin-layer chromatography (TLC)-radioscanning. α-Bromolignoceric acid was converted to the corresponding α-hydroxy acid as described earlier (14) with some modifications on a micro scale. The crude product was treated with 1.2 mL 95% ethanol, having 2 mg KOH/mL, and refluxed for 24 h. Alcohol was removed under nitrogen, 2 mL water was added, and the content was acidified with 2 N HCl. The product was extracted five times with 5-mL portions of ethers. The combined pool of ether was washed once with water, and solvent was removed. The labeled compounds were identified by TLC and co-TLC [K6 silica gel 60 plates; solvent system, hexane/ether/acetic acid 50:50:1 (by vol)] with nonradioactive standards (obtained either commercially or prepared in our laboratory). The desired compound, 2-hydroxylignoceric acid, was purified by TLC as described above and the yield was 20%. A fraction of the radiolabeled product was converted to the methyl ester by treatment with 1.5% (vol/vol) H_2SO_4 in anhydrous methanol at 80°C for 2 h. The product was compared by TLC and was found to be identical to the corresponding authentic nonradioactive methyl cerebronate.

(ii) Fibroblast cell culture. Cell lines were grown in DMEM supplemented with 15% BCS in a 5% CO_2 air atmosphere at 37°C (15). Cells were harvested by trypsinization 3–4 d after they reached confluence and were washed with Hank's balanced salt solution. The cells were then suspended in DMEM supplemented with 15% BCS and incubated for 1 h at 37°C, following which they were centrifuged, washed, and suspended in Hank's balanced salt solution prior to use.

(iii) Glial cell culture. Mixed glial cell cultures were established from 1- to 2-d-old rat pups as previously described (16). Cells were maintained in DMEM containing 5% glucose, 10% BCS, and antibiotic/antimycotic mixture. After 10 d of culture, microglia were removed by shaking for 2 h in an orbital shaker at 200 rpm. The medium was changed and the flask was again shaken for 24 h at 240 rpm. The detached cells, predominantly oligodendrocytes, were further purified from microglia by seeding on petri dishes for 30–60 min. The nonattached cells (oligodendrocytes) were further cultured on poly-L-lysine-coated plates. The flasks containing the remaining cells, astrocytes, were trypsinized (0.1% trypsin in 10 mM Tris-EDTA saline, pH 7.4) and seeded for studies.

(iv) Isolation of peroxisomes from rat liver. Liver peroxisomes were prepared from Sprague-Dawley rats (200–250 g) by the procedure described previously (17). Briefly, livers were homomogenized in a buffer (0.25 M sucrose, 1 mM EDTA, 0.5 μg leupeptin, 0.5 μg antipain, 0.7 μg pepstatin/mL, 0.2 mM PMSF, and 0.1% ethanol in 3 mM imidazole, pH 7.4) and fractionated by differential centrifugation to prepare the light mitochondrial fraction (the "lambda" fraction). Peroxisomes from the lambda fraction were prepared by isopycnic equilibrium centrifugation on a continuous gradient of

0–50% (wt/vol) Nycodenz with 55% Nycodenz as cushion. The gradient fractions were collected from the bottom of the tubes, and subcellular fractions were analyzed by their respective marker enzymes: catalase for peroxisomes (18), cytochrome c oxidase for mitochondria (19), and NADPH cytochrome c reductase for microsomes (20).

(v) Preparation of peroxisomal matrix and membranes. Isolated peroxisomes were sedimented by centrifugation to remove Nycodenz, and the peroxisomal pellet was washed with a homogenization buffer. Peroxisomes were lysed by incubating with digitonin (0.2 mg/mL) for 1 h at 4°C and then centrifuged at 50,000 rpm for 1 h in a Beckman 70 Ti rotor. Separation of membrane and matrix was confirmed by measuring catalase activity. Catalase activity was mainly present in the peroxisomal matrix fraction.

(vi) Assay for activation and oxidation of [1-^{14}C] fatty acids. Activation of fatty acids by ligase to fatty acyl CoA was measured as described previously (21). The reaction mixture (0.25 mL) contained 4.96 μM [1-^{14}C] fatty acid (150,000 dpm), 10 mM ATP, 80 μM CoASH, 30 mM KCl, 5 mM $MgCl_2$, and 0.05 mM dithiothreitol in 30 mM 3-(*N*-morpholino)propanesulfonic acid (MOPS)-HCl, pH 7.8. The reaction was terminated by addition of Dole's reagent (isopropyl alcohol/heptane/1 N H_2SO_4, 40:10:1 by vol). Denatured protein was removed by centrifugation, followed by addition of 0.45 mL water and 0.8 mL heptane. The aqueous layer was washed three times with heptane and radioactivity in the aqueous layer was counted.

α-Oxidation of cerebronic acid to $C_{23:0}$ fatty acid was measured as $^{14}CO_2$, released from [1-^{14}C]cerebronic acid according to methods described previously for α-oxidation of phytanic acid (22). Briefly, 0.25 mL of the reaction mixture contained 4.96 μM [1-^{14}C] fatty acid (150,000 dpm), 30 mM KCl, 5 mM $MgCl_2$, 8.5 mM ATP, 0.25 mM NAD^+, 0.08 mM CoASH, and 1 mg of α-cyclodextrin in 20 mM MOPS-HCl buffer, pH 7.8. The reaction was started by addition of the peroxisomal fraction and was incubated at 37°C and stopped with 50 μL of 5 N H_2SO_4 after 1 h. $^{14}CO_2$ was collected in KOH-wetted cotton by shaking overnight, and radioactivity was measured. β-Oxidation of [1-^{14}C] labeled fatty acids to acetate was measured as previously described (10). The reaction mixture contained 4.96 μM [1-^{14}C] fatty acid (150,000 dpm), 30 mM KCl, 5 mM $MgCl_2$, 8.5 mM ATP, 0.25 mM NAD^+, 0.17 mM FAD, 2.5 mM L-carnitine, 0.08 mM CoASH, and 1 mg of α-cyclodextrin in 20 mM MOPS-HCl buffer, pH 7.8. The oxidation was stopped by addition of 0.625 mL 1 M KOH in methanol, and the denatured protein was removed by centrifugation. The supernatant was incubated at 60°C for 1 h, neutralized with 0.125 mL of 6 N HCl, and partitioned with chloroform and methanol. The amount of radioactivity in the aqueous phase was taken as an index of [1-^{14}C] fatty acid oxidized to acetate. Fatty acid substrates used for activation and oxidation were solubilized with α-cyclodextrin (23). Fatty acids were first dried under nitrogen and then suspended in homogenization buffer containing α-cyclodextrin (20 mg/mL) and sonicated for 30 min.

RESULTS AND DISCUSSION

The oxidation of cerebronic acid was studied in subcellular organelles purified by differential and isopycnic gradient techniques (17) from rat liver. Figure 1 shows that peroxisomes, mitochondria, and microsomes were resolved from each other in the Nycodenz gradient as judged by the distribution of the marker enzymes: catalase for peroxisomes, cytochrome c oxidase for mitochondria, and NADPH cytochrome c reductase for microsomes. Cerebronic acid α-oxidation activity was essentially observed to be localized in fractions that paralleled the distribution of catalase, a well-established peroxisomal marker**.** The peroxisomes prepared by the method described here were approximately 97% pure with minor contamination of mitochondria (0.5%) and microsomes (2.83%) as described by Fujiki *et al.* (24). The specific activities for oxidation of cerebronic acid and other fatty acids are presented in Table 1. Specific activities for α-oxidation of cerebronic acid were 16 and 17 times higher in the peroxisomal fraction compared to the mitochondrial and microsomal fractions, respectively. Lignoceric acid β-oxidation, a peroxisomal function (5), was observed to be localized mainly in peroxisomes. Consistent with previous reports, palmitic acid was oxidized both in peroxisomes and mitochondria (10,15). These results indicated that the site for α-oxidation of cerebronic acid was peroxisomes.

To further establish the subcellular site for α-oxidation of cerebronic acid, we examined the effect of Etomoxir, an inhibitor of mitochondrial fatty acid oxidation, on the oxidation of cerebronic, lignoceric, and palmitic acids in human cultured skin fibroblasts (Table 2). As expected, the β-oxidation of palmitic acid was inhibited by Etomoxir in fibroblasts. On the other hand, Etomoxir had no effect on the oxidation of cerebronic and lignoceric acids, further confirming the observation that cerebronic acid is α-oxidized in an organelle other than mitochondria. The observed higher specific activity of α-oxidation of cerebronic acid in purified peroxisomes and the lack of effect of Etomoxir on the oxidation of cerebronic acid suggest that the catabolism of cerebronic acid is a peroxisomal function.

Activation of fatty acid to its CoA-ester is an obligatory step for oxidation. However, we failed to detect any acyl-CoA synthetase activity for cerebronic acid in subcellular fractions

TABLE 1
α- and β-Oxidation of Fatty Acids in Subcellular Fractions from Rat Liver[a]

	Cerebronic acid	Lignoceric acid	Palmitic acid
	(nmol/h/mg protein)

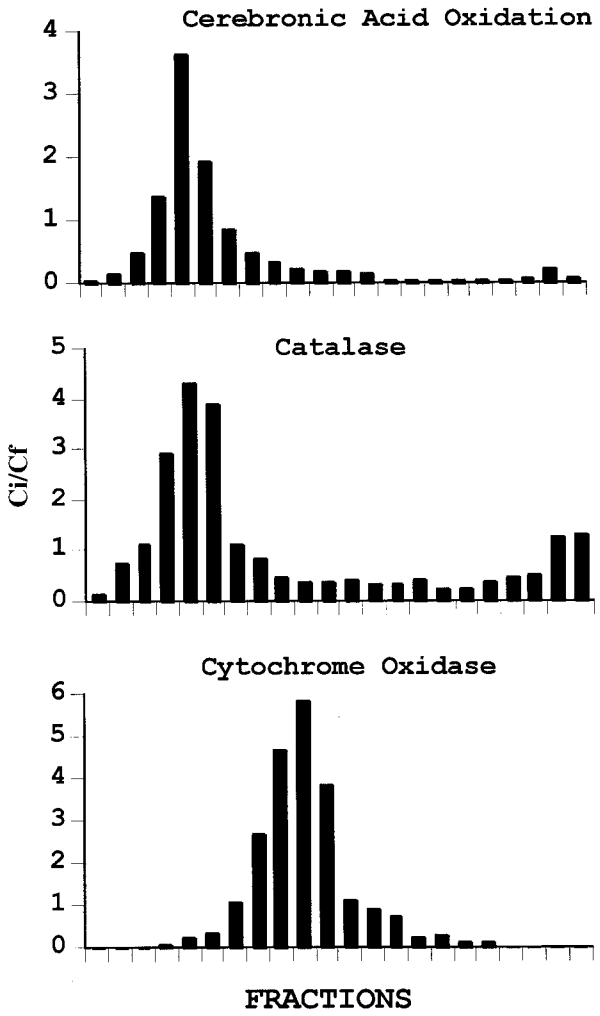
[a]Subcellular fractions were prepared from rat liver, and the α- and β-oxidation of fatty acids was measured as described in the Materials and Methods section. Values are mean ± SD for four separate experiments. Protocol for studies with animals were approved by the Institutional Review Board and conform to accepted standards.



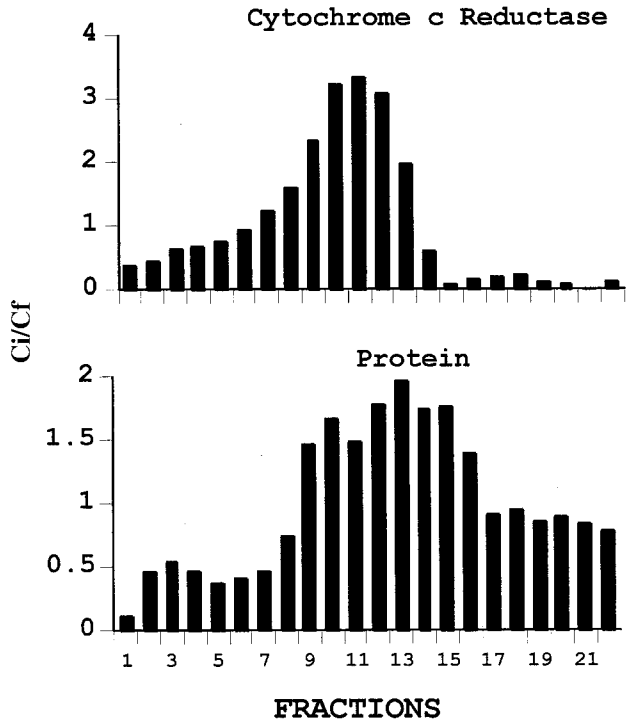


FIG. 1. Subcellular localization of cerebronic acid oxidation in rat liver. Rat liver was fractionated by differential and density gradient centrifugation as described in the Materials and Methods section. The distribution of subcellular organelles in the gradient was analyzed by their marker enzymes, catalase for peroxisomes, cytochrome c oxidase for mitochondria, and NADPH cytochrome c reductase for microsomes. The relative concentration is derived by dividing the actual concentration of the enzyme in a particular fraction by the concentration of the enzyme that would be observed if the enzyme were homogeneously distributed throughout the gradient. These results are averages of three gradients. Cerebronic acid oxidation was carried out as described in the Materials and Methods section.

from rat liver (data not shown). In order to confirm the observation that conversion of cerebronic acid to its CoA derivative was not prerequisite for its α-oxidation, we studied the effect of desulfo-CoA (a nonfunctional CoA analog that cannot form a thioester bond with fatty acid) on cerebronic acid oxidation. Consistent with the requirement for activation to acyl-CoA derivative for β-oxidation, the desulfo-CoA inhibited the oxidation of lignoceric and palmitic acids (Fig. 2),

TABLE 2
Effect of Etomoxir on the Oxidation of Fatty Acids in Human Skin Fibroblasts[a]

	Fatty acid oxidation (pmol/h/mg protein)	
	Etomoxir (–)	Etomoxir (+)
Cerebronic acid	333.35 ± 37.21	313.46 ± 46.45
Lignoceric acid	353.26 ± 29.43	309.57 ± 38.04
Phytanic acid	118.96 ± 23.27	120.21 ± 20.39
Palmitic acid	1142.94 ± 55.26	80.28 ± 19.20

[a]Fatty acid oxidation was studied in human cultured skin fibroblasts. The cells suspended in Hank's balanced salt solution were incubated in the presence of 10 μM Etomoxir for 30 min and the oxidation of labeled fatty acids was measured as described in the Materials and Methods section. Values are mean ± SD for three separate experiments.

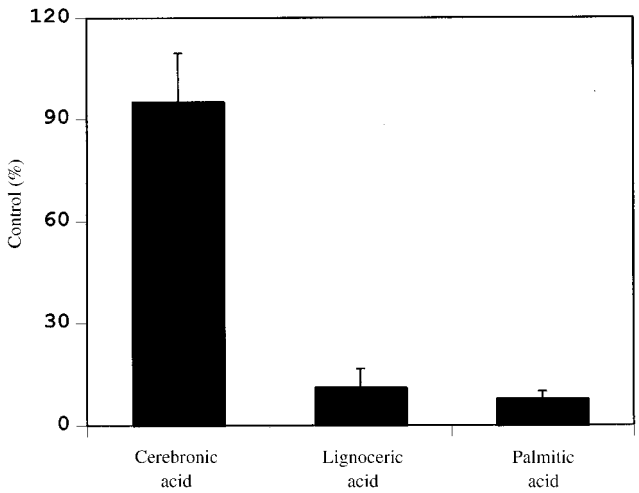

FIG. 2. Effect of desulfo-CoA on the oxidation of fatty acids in purified peroxisomes. Rat liver peroxisomes were prepared, and the rate of oxidation of fatty acids was studied in the presence of 50 μM desulfo-CoA as described in the Materials and Methods section. Data are presented as mean ± SD for three separate experiments.

whereas, it had no effect on the α-oxidation of cerebronic acid (Fig. 2). Furthermore, we investigated the cofactor requirements for the enzyme system for α-oxidation of cerebronic acid (Fig. 3). The α-oxidation of cerebronic acid was observed to be dependent on the presence of NAD whereas ATP, Mg^{2+}, CoASH, FAD, and NADPH did not support the α-oxidation of cerebronic acid. Based on these results, it appears that cerebronic acid oxidation is NAD-dependent for its oxidative decarboxylation to CO_2 and C_{n-1} fatty acid and that cerebronic acid did not need to be activated to its CoA-ester. An earlier study by Akanuma and Kishimoto (25) was also unable to detect cerebronyl-CoA while studying the mechanism of hydroxylation of VLCFA. These observations indicate that α-oxidation of cerebronic acid does not require its activation to CoA derivative. It may be possible that for decarboxylation, free cerebronic acid rather than its CoA derivative is the substrate. Formation of the odd carbon-chain fatty acid as an intermediate in degradation of 2-hydroxy fatty acids has already been established (26,27). Moreover, it is well documented that peroxisomes have a distinct matrix and limiting membrane (5). Enzyme systems for activation of straight-chain fatty acids (e.g., palmitic acid and lignoceric acid) and branched-chain fatty acids (e.g., phytanic acid and pristanic acid) are localized in the peroxisomal-limiting membrane, and enzyme systems for β-oxidation of straight-chain fatty acids and α-oxidation of branched-chain fatty acids are localized in the peroxisomal matrix (5). It was found that the enzyme systems involved in the oxidation of cerebronic acid were associated with the peroxisomal-limiting membrane and not with the matrix (Fig. 4). This supports the observation that the enzymes involved in the α-oxidation of cerebronic acid are different from those of phytanic acid (12). The α-oxidation of phytanic acid involves at least two steps: α-hydroxylation and α-decarboxylation. Furthermore, contrary to cerebronic acid oxidation, which required NAD, the oxidation of phytanic acid and 2-hydroxyphytanic acid does not need NAD. Phytanic acid (3,7,11,15-tetramethylhexadecanoic acid) is a branched-chain fatty acid that undergoes α-oxidation yielding pristanic acid (2,6,10,14-tetramethylpentadecanoic acid) with 2-hydroxyphytanoyl-CoA as an intermediate (12,28,29). We have previously demonstrated that the subcellular localization of phytanic acid α-oxidation systems is in the peroxisomes (30). We and others have also reported that phytanic acid oxidation activity is deficient in cells from patients with RD, due to mutation in phytanoyl-CoA α-hydroxylase gene (31–33); RCDP, due to abnormality in the PEX 7 gene product, a protein required for targeting phytanic acid oxidase to peroxisomes (34); and in ZS cells due to lack of peroxisomes (5). Moreover, the activity of 2-hydroxyphytanic acid oxidation was also deficient in cells from ZS patients and the levels of 2-hydroxyphytanic acid were higher in plasma of these patients (35). The different substrate specificity (free fatty acid vs. acyl-CoA), cofactor requirement (NAD vs. 2-ketoglutarate-dependent dioxygenase cofactors), intraperoxisomal localization (membrane vs. matrix), and observed differential α-oxidation (normal vs. deficient in RD and RCDP human skin fibroblasts cell lines) indicate that the enzymes responsible for α-oxidation of phytanic acid and cerebronic acid have different properties. Furthermore, the oxidation of 2-hydroxyphytanic acid involves an oxidase that requires oxygen and produces H_2O_2 (36). In the present study, we failed to detect any H_2O_2 production during cerebronic acid α-oxidation (data not shown).

In order to understand the metabolism of 2-hydroxy VLCFA in peroxisomal disorders, oxidation of cerebronic acid along with lignoceric acid and phytanic acid was studied in human cultured skin fibroblasts from patients with peroxisomal disorders. Consistent with previous observations, the α-oxidation of phytanic acid was deficient in cell lines from ZS, RD, and RCDP patients. Cerebronic acid oxidation in X-ALD, RD, and RCDP was normal (Table 3). However, ZS

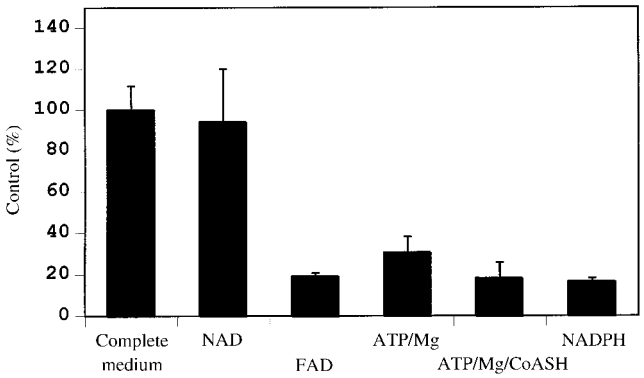

FIG. 3. Cofactor requirements for cerebronic acid oxidation by rat peroxisomes. Oxidation of cerebronic acid was studied in the presence of complete medium containing ATP, CoASH, $MgCl_2$, NAD, FAD, and L-carnitine and then in the presence of individual cofactors as shown on the X-axis and described in the Materials and Methods section. Values are mean ± SD for three separate experiments.

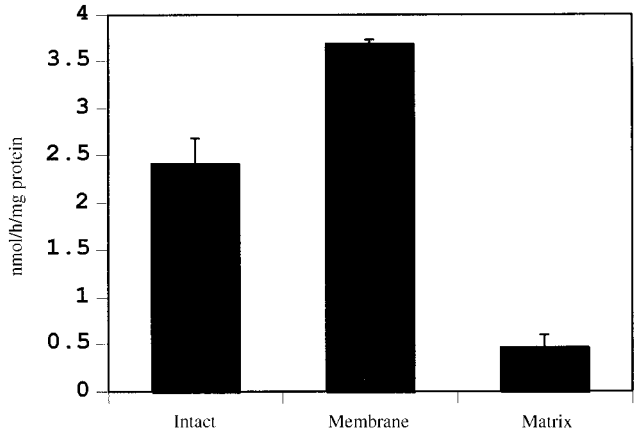

FIG. 4. Intraorganellar localization of cerebronic acid oxidation. Peroxisomal membrane and matrix fractions were prepared from rat liver peroxisomes, and cerebronic acid oxidation activity was studied as described in the Materials and Methods section. Catalase activity was assayed in membrane and matrix to monitor the percent lysis. Catalase activity was found mainly in the matrix. Values are mean ± SD for three separate experiments.

TABLE 3
Fatty Acid Oxidation Ratios in Fibroblasts from Control Subjects and Patients with Peroxisomal Disorders[a]

	Fatty acid oxidation		
	Cerebronic/palmitic	Lignoceric/palmitic	Phytanic/palmitic
Control	0.363 ± 0.050	0.36 ± 0.05	0.036 ± 0.005
ZS	0.184 ± 0.021	0.03 ± 0.02	0.002 ± 0.002
X-ALD	0.321 ± 0.035	0.09 ± 0.03	0.036 ± 0.006
RD	0.296 ± 0.030	0.30 ± 0.04	0.007 ± 0.003
RCDP	0.334 ± 0.017	0.30 ± 0.01	0.008 ± 0.002

[a]Fatty acid oxidation was studied in cultured human skin fibroblasts suspended in Hank's balanced salt solution as described in the Materials and Methods section. Values are mean ± SD for four separate experiments and are expressed as ratio of cerebronic acid or lignoceric acid or phytanic acid to palmitic acid oxidation. ZS, Zellweger syndrome; X-ALD, X-linked adrenoleukodystrophy; RD, Refsum disease; RCDP, rhizomelic chondrodysplasia punctata.

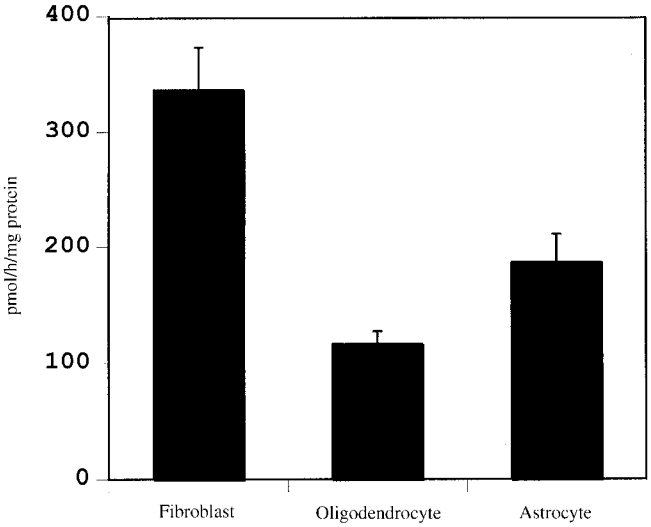

FIG. 5. Oxidation of cerebronic acid in glial cells. Oligodendrocytes and astrocytes were isolated from rat brain and cerebronic acid oxidation was studied as described in the Materials and Methods section. Values are mean ± SD for three separate experiments.

cells from human skin fibroblasts had a significant level of cerebronic acid α-oxidation activity (approximately 50% of the normal control). As expected, lignoceric acid oxidation activity was normal in RD and RCDP, but deficient in ZS by approximately 92%. At present, we do not fully understand the basis of such a high residual activity of cerebronic acid oxidation in cell lines that lack peroxisomes. It may be possible that cerebronic acid decarboxylase is relatively stable as compared to other peroxisomal proteins in cell lines that lack peroxisomes. The partial loss of activity for α-oxidation of cerebronic acid in ZS indicates that some level of cerebronic acid may accumulate in ZS tissue/patients; however, no report is yet available on the accumulation of 2-hydroxy VLCFA in peroxisomal disorders. It may be of interest to monitor levels of 2-hydroxy VLCFA in the brain of ZS patients. The pathological significance of impaired oxidation of cerebronic acid is not clear, as no report is available regarding the toxic effects of α-hydroxy fatty acids. Recently, 2-hydroxy long-chain fatty acids have been demonstrated to have antiviral activity (37). Cerebronic acid oxidation was also studied in the primary glial cells (oligodendrocytes and astrocytes) since cerebronic acid is a major fatty acid of cerebroside and sulfatide in the nervous system (Fig. 5). It was observed that both oligodendrocytes and astrocytes oxidize cerebronic acid and that the specific activity was higher in astrocytes as compared to oligodendrocytes. Consistent with our previous observations for β-oxidation of nervonic acid (13), the cerebronic acid α-oxidation activity in human skin fibroblasts was also higher than in oligodendrocytes and astrocytes (Fig. 5).

In summary, the studies reported here clearly demonstrate that 2-hydroxy VLCFA (cerebronic acid) are catabolized by α-oxidation in peroxisomes and that this enzyme system seems to be different from that which α-oxidizes phytanic acid.

ACKNOWLEDGMENTS

We would like to thank Dr. Avtar Kaur Singh for reviewing the manuscript and Lucinda Burridge for typing the manuscript. The study is supported by grants from the National Institutes of Health (NS-22576, NS-34741 and NS-37766).

Novel Lipidic Enaminones from a C_{18} Keto-allenic Ester

Marcel S.F. Lie Ken Jie* and Maureen M.L. Lau

Department of Chemistry, The University of Hong Kong, Hong Kong, China

ABSTRACT: Primary amines (ammonia, methyl, propyl, octyl, octadecyl, phenyl, benzyl, phenethyl) including methyl esters of amino acids (glycine, DL-alanine, L-valine, L-leucine, L-tyrosine, and L-methionine), and secondary amines (dimethyl, diethyl, dipropyl, diisopropyl, dioctyl, and diphenyl) attack regiospecifically the central carbon atom of the allene system of methyl 12-keto-9,10-octadecadienoate (**1**) to give the corresponding lipidic enaminone derivatives (**2–21**) with an average yield of 77%. The E- and Z-configuration of the enaminone system of these novel lipid derivatives was confirmed by infrared and nuclear magnetic resonance spectroscopic techniques. Primary amines furnished Z-enaminones, while secondary amines gave E-enaminones.

Paper no. L8498 in *Lipids 35*, 1135–1145 (October 2000)

We have recently reported the synthesis of pyrazole fatty esters from a C_{18} keto-allenic ester, methyl 12-oxo-9,10-octadecadienoate (Scheme 1). The latter compound was obtained by the isomerization of methyl 12-oxo-9-octadecynoate (1). The allenic

$$CH_3(CH_2)_5\text{-}CO\text{-}CH{=}C{=}CH\text{-}(CH_2)_7COOCH_3$$

SCHEME 1

system adjacent to the keto function in this compound makes this substrate a very reactive functional group for nucleophilic addition reactions. During such nucleophilic addition reactions, the attack is specific at the central carbon atom of the allene system (i.e., the C-10 of the alkyl chain of the fatty ester). Regiospecific addition products can therefore be obtained. When the nucleophile is an (alkyl or aryl) amine, the resulting product is an enaminone.

Enaminones are important synthetic intermediates and are particularly useful in heterocyclic chemistry (2). The addition reactions of cyclic enaminones with Grignard reagents have been recently reported (3). Many organic compounds containing the enaminone system have been shown to possess potent biological activities. For example, methyl 4-[(*p*-chlorophenyl) amino]-6-methyl-2-oxo-3-cyclohexen-1-oate exhibits anticonvulsant activities with a remarkable lack of neurotoxicity (4). Pyrrolidino-, isoquinolino-, and indolo-enaminones have been shown to inhibit cyclooxygenase and 5-lipoxygenase as determined in bovine thrombocytes and polymorphonuclear leukocytes, respectively (5).

Of interest is the reduction of an enaminone to give a diamino alcohol, which is a key intermediate in the large-scale synthesis of Ritonavir (a human immunodeficiency virus protease inhibitor) (6).

The chemistry of enaminones has been extensively described (7,8). Despite the importance of this organic functional group, no lipid molecule containing an enaminone system has been reported in the chemical literature. This paper presents the first synthesis of a number of C_{18} enaminone fatty ester derivatives. To reflect the high reactivity of the α-keto-allene system toward amines, reactions with amino acids are also included in this study. The configuration of the double bond of the enaminone system is determined by a combination of spectroscopic techniques.

MATERIALS AND METHODS

Column chromatographic separation was performed on neutral aluminum oxide (Merck, Art. 1077, 70–230 mesh ASTM) as the adsorbent using gradient elution with mixtures of *n*-hexane/diethyl ether in various proportions as the mobile phase. The column run was monitored by thin-layer chromatography (TLC) analysis of the eluent. Infrared (IR) spectra were recorded on a Bio-Rad FTS-165 Fourier-transform IR spectrometer. Samples were run as neat films on NaCl plates. Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Avance DPX_{300} (300 MHz) or Avance DRX (500 MHz) Fourier-transform NMR spectrometer (Bruker, Fallanden, Switzerland) from solutions in deuteriochloroform ($CDC1_3$) (0.2–0.3 mM) with tetramethylsilane (TMS) as the internal reference standard. Chemical shifts are given in δ-values in ppm downfield from TMS ($\delta_{TMS} = 0$ ppm). Mass spectral analyses were carried out on a Finnigan MAT-95 (Finnigan Corp., San Jose, CA). Methyl 12-oxo-9,10-octadecadienoate (**1**) was obtained by $NaHCO_3$ isomerization of methyl 12-hydroxy-9-octadecynoate. The latter compound was pre-

pared by bromination/dehydrobromination of ricinoleic acid, which was obtained from castor oil. The procedures for the synthesis of compound **1** are described elsewhere (1).

General procedure for the synthesis of C_{18} enaminone derivatives as exemplified by the reaction of methyl 12-oxo-9,10-octadecadienoate with ammonia. A mixture of methyl 12-oxo-9,10-octadecadienoate (**1**, 0.5 g, 1.6 mmol), ethanol (95%, 30 mL), and ammonium hydroxide (35% w/w of ammonia in water, 0.3 mL, 19.5 mmol) was stirred at room temperature for 3 h. Water (30 mL) was added, and the reaction mixture was extracted with diethyl ether (3 × 30 mL). The ethereal extract was washed with brine (20 mL) and dried over anhydrous Na_2SO_4. The filtrate was evaporated to give pure methyl 10-amino-12-oxo-10*Z*-octadecenoate (**2**, 0.43 g, 86%) as a viscous liquid. TLC on silica: R_f = 0.4 (*n*-hexane/diethyl ether, 1:1 vol/vol, as developer); IR (NaCl, neat): 3413 (*m*, N-H), 3184 (*m*, N-H), 2930, 2857, 1741, 1615, 1529, 1462, 1436, 1361, 1245, 1198, 1172, 1100, 1025, 882, and 725 cm^{-1}; ^1H NMR ($CDCl_3$, δ_H) 0.88 (*t*, *J* = 6.7 Hz, 3H, C*H*$_3$), 1.2–1.7 (*m*, 20H, C*H*$_2$), 2.11 (*t*, *J* = 7.7 Hz, 2H, 9-*H*), 2.26 (*t*, *J* = 7.7 Hz, 2H, 13-*H*), 2.30 (*t*, *J* = 7.5 Hz, 2H, 2-*H*), 3.67 (*s*, 3H, COOC*H*$_3$), 5.03 (*s*, 1H, 11-*H*), and 9.79 (*br. s*, 2H, N-*H*); ^{13}C NMR ($CDCl_3$, δ_C) 14.10 (C-18), 22.58 (C-17), 24.88 (C-3), 25.96 (C-14), 27.94 (C-8), 29.04, 29.11, 29.26 (C-15), 31.77 (C-16), 34.05 (C-2), 36.44 (C-9), 42.57 (C-13), 51.47 (COO*C*H$_3$), 94.57 (C-11), 165.00 (C-10), 174.28 (*C*OOCH$_3$), and 200.15 (C-12); high-resolution mass spectral analysis (HRMS), found: M^+, 325.2620, $C_{19}H_{35}NO_3$ requires 325.2617.

This reaction procedure (performed in ethanol at room temperature) was suitable for the following nucleophiles: methylamine, propylamine, dimethylamine, diethylamine, dipropylamine, diisopropylamine, phenylamine, benzylamine, and phenethylamine. In the case where the nucleophile was either octylamine, octadecylamine, dioctylamine, or diphenylamine, the reaction was performed in chloroform instead of ethanol under reflux. And for the reactions involving the HCl salts of the methyl esters of amino acids (glycine, DL-alanine, L-valine, L-leucine, L-tyrosine, and L-methionine), the reactions were performed in methanol under reflux in the presence of triethylamine. An excess amount of amine (about fivefold molar equivalent) to compound **1** was used in each case. After isolation of the reaction products, the unreacted amine was removed either by reduced pressure distillation or by washing the isolated product mixtures with dilute HCl. The final purification of the enaminone derivatives was carried out by alumina column chromatography (gradient elution using a mixture of *n*-hexane and diethyl ether). The results of the spectroscopic and spectrometric analyses of the various derivatives (**3–21**) are listed below.

Methyl 10-methylamino-12-oxo-10Z-octadecenoate (**3**, 84% yield). TLC on silica: R_f = 0.4 (*n*-hexane/diethyl ether, 1:1 vol/vol, as developer); IR (NaCl, neat): 3455 (*w*, N-H), 2929, 2856, 1739, 1610, 1580, 1520, 1436, 1358, 1249, 1171, 727 cm^{-1}; ^1H NMR ($CDCl_3$, δ_H) 0.87 (*t*, *J* = 6.7 Hz, 3H, C*H*$_3$), 1.2–1.7 (*m*, 20H, CH$_2$), 2.15–2.25 (*m*, 4H, 9-*H* and 13-*H*), 2.31 (*t*, *J* = 7.5 Hz, 2H, 2-*H*), 2.93 (*d*, *J* = 5.3 Hz, 3H, N-C*H*$_3$), 3.67 (*s*, 3H, COOC*H*$_3$), 4.96 (*s*, 1H, 11-*H*), 10.86 (*br. s*, 1H, N-*H*); ^{13}C NMR ($CDCl_3$, δ_C) 14.19 (C-18), 22.67 (C-17), 24.97 (C-3), 26.51 (C-14), 27.69 (C-8), 29.14, 29.19, 29.21 (N-*C*H$_3$), 29.37, 29.46, 31.81 (C-16), 31.87 (C-9), 34.12 (C-2), 42.23 (C-13), 51.53 (COO*C*H$_3$), 93.76 (C-11), 168.05 (C-10), 174.32 (*C*OOCH$_3$), and 198.26 (C-12); HRMS, found: M^+, 339.2774, $C_{20}H_{37}NO_3$ requires 339.2773.

Methyl 12-oxo-10-propylamino-10Z-octadecenoate (**4**, 80% yield). RESULTS AND DISCUSSION

The nucleophiles used in the reactions with the keto-allene ester, methyl 12-oxo-9,10-octadecadienoate (**1**), were either primary alkyl and aryl amines including methyl esters of amino acids or secondary alkyl and aryl amines (Scheme 2). The reactions of compound **1** with the short-chain primary alkylamines (ammonia, methylamine, and propylamine) and aryl amines (phenylamine, benzylamine, and phenethylamine) were achieved at room temperature in ethanol in high yield. However, owing to the poor solubility of octylamine and octadecylamine in ethanol, the reactions involving these reactants were conducted in chloroform under reflux with the keto-allene substrate (**1**) to give the corresponding enaminones **5** and **6** in 35 and 20% yield, respectively. The reactions with HCl salts of the methyl esters of amino acids (glycine, DL-alanine, L-valine, L-leucine, L-tyrosine, L-methionine) were performed in methanol (reflux for 3 h) with an average yield of 87%.

The reactions of most of the secondary alkyl (dimethyl, diethyl, dipropyl, and diisopropyl) amines with compound **1** were also readily achieved in ethanol at room temperature (average 83%), except those involving dioctyl and diphenyl amine. Again owing to the poor solubility of the last two reactants, these reactions were carried out in chloroform (under reflux for 3 h) where dioctylamine gave a 95% and diphenylamine furnished a 40% yield of the corresponding enaminones. The overall average yield of the enaminone derivatives (**2–21**) obtained from these reactions was 82%.

A weak N-H stretching vibration of enaminones derived from primary amines (compounds **2–15**) appeared at about 3460 cm^{-1} in the IR spectra. The stretching vibration of the keto carbonyl group in the enaminone derivatives containing an N-H bond (**2–15**) was found to be 20–30 cm^{-1} lower in wavenumbers than enaminones (**16–21**) derived from secondary amines. This observation indicates that enaminone derivatives (**2–15**) formed from primary amines with the C_{18} keto allene have the N-H group hydrogen-bonded to the oxygen atom of the keto group at C-12 to give a Z-configuration to the double bond (9). Enaminones derived (**16–21**) from secondary amines have the E-configuration with the nitrogen and its attached groups placed in a less sterically hindered position of the molecule. The general structures of these E- and Z-derivatives are shown in Scheme 2.

The enaminone system was confirmed by proton and carbon NMR spectroscopic analyses. In the ^1H NMR spectral analysis the proton at the C-11 olefinic carbon atom appeared as a singlet at about δ_H 5.0, whereas the protons of the methylene group adjacent to the keto function (13-*H*) gave a characteristic triplet at δ_H 2.1–2.2, which merged with the signal of the 2-*H* protons. The carbon NMR spectral analysis showed the effect of the nitrogen atom on the shifts of the olefinic carbon (C-10), which appeared much more downfield (δ_C 164–168) than the other olefinic carbon atom (C-11, at δ_C 93–95) adjacent to the keto group. The carbon shift of the keto carbonyl appeared at about δ_C 197–200. All these shifts were in close agreement with data reported in the literature for various enaminones (10–15). The *N*-alkyl, *N*-aryl groups and the various amino acid residues incorporated in the enaminone system of compounds **2–21** were readily identified by proton and carbon NMR spectral analyses. The ^{13}C-^1H homonuclear correlation spectroscopy and heteronuclear multiple bond correlation spectroscopy spectra of compound **2** are shown in Figures 1 and 2, respectively.

Of significance was the carbon shift of C-9, i.e., the methylene group attached to the double bond of the enaminone system, of compounds **2–15**. The carbon shift of this methylene group appeared at about δ_C 32. Such downfield shift position for a methylene group adjacent to a double bond is normally observed for olefins with a *trans* double bond. The result therefore showed that the C-9 methylene group was in the *anti* position relative to the keto function of the enaminone. As a result, this would signify a Z-configuration for the double bond of the enaminone system, and thus support the proposal that the incoming nucleophile occupied the same side as that of the keto group. This arrangement would therefore allow the hydrogen of the N-H to be hydrogen-bonded to the keto group. In the ^{13}C NMR spectra of compounds **16–21**, no additional signal was found in the region of δ_C 32, except those for C-2 (δ_C 34) and C-16 (δ_C 31.8). The shift of the C-9 carbon atom of compounds **16–21** appeared to fall within the "methylene envelope" region of δ_C 27–30. From this differ-

SCHEME 2

ence in spectral detail, it could be implied that the alkanoate chain was attached to the double bond of the enaminone system in a *cis* manner. This would therefore place the alkanoate chain on the same side of the keto group. The nitrogen and its attached groups would therefore be found *anti* to the keto group. A number of reports have studied the various tautomeric forms of enaminones (2,11,14), but no relevant information from such studies could be extracted to assist in the confirmation of the enaminones (**2–21**) under study. It was therefore decided to conduct further NMR experiments on these derivatives.

To confirm the stereochemistry of the E- and Z-enaminone system, two-dimensional nuclear Overhauser enhancement spectroscopy (2D-NOESY) experiments were conducted on these derivatives. Compounds **16–21** showed a distinct interaction between the 11-*H* and the protons of the groups attached to the nitrogen atom. This result confirmed that the nitrogen and its attached groups were on the same side as that

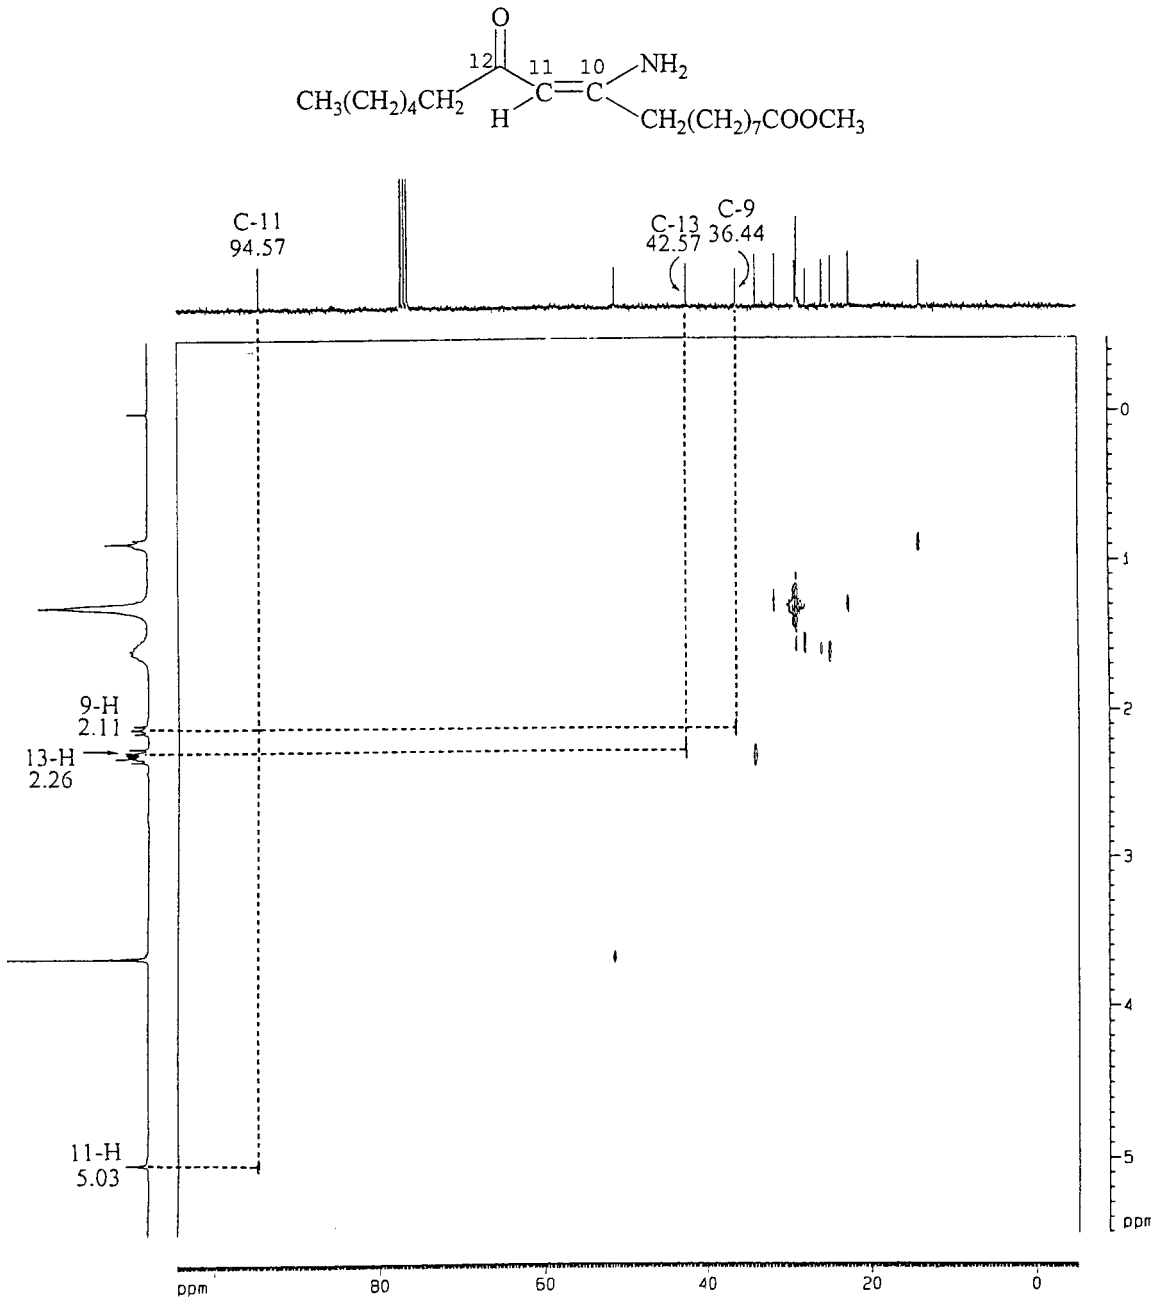

FIG. 1. ^{13}C-^{1}H homonuclear correlation spectroscopy spectrum of methyl 10-amino-12-oxo-10*Z*-octadecenoate (**2**).

of the 11-*H* of the double bond, thus placing the nitrogen atom on the *anti* position relative to the keto group (hence, an E-configuration). When the 2D-NOESY experiments were carried out on compounds **2–15**, no such interactions between the 11-*H* proton were found with protons from groups attached to the nitrogen. This observation showed that the nitrogen and its attached group were too far apart from the 11-*H* to interact. The situation would be so when the nitrogen atom was placed *anti* to the 11-*H* proton and on the same side as the keto group. From these NOESY experiments, it can therefore be concluded that the enaminones derived from primary amines (compounds **2–15**) have a Z-configuration, and enaminones derived from secondary amines (compounds **16–21**) have an E-configuration at the double bond.

The results of the high resolution mass spectral analyses of compounds **2–21** confirmed the molecular weight (formula) of each derivative. The results of the electron impact (EI) mass spectral analyses of compounds **2–21** are presented in Table 1. One significant peak (M – 85), resulting from the cleavage of the C-12/C-13 (adjacent to the keto group), was characteristic in almost every spectrum (ion fragment *a*). This result indicated the position of the keto group at the C-12 position. This fact was further confirmed

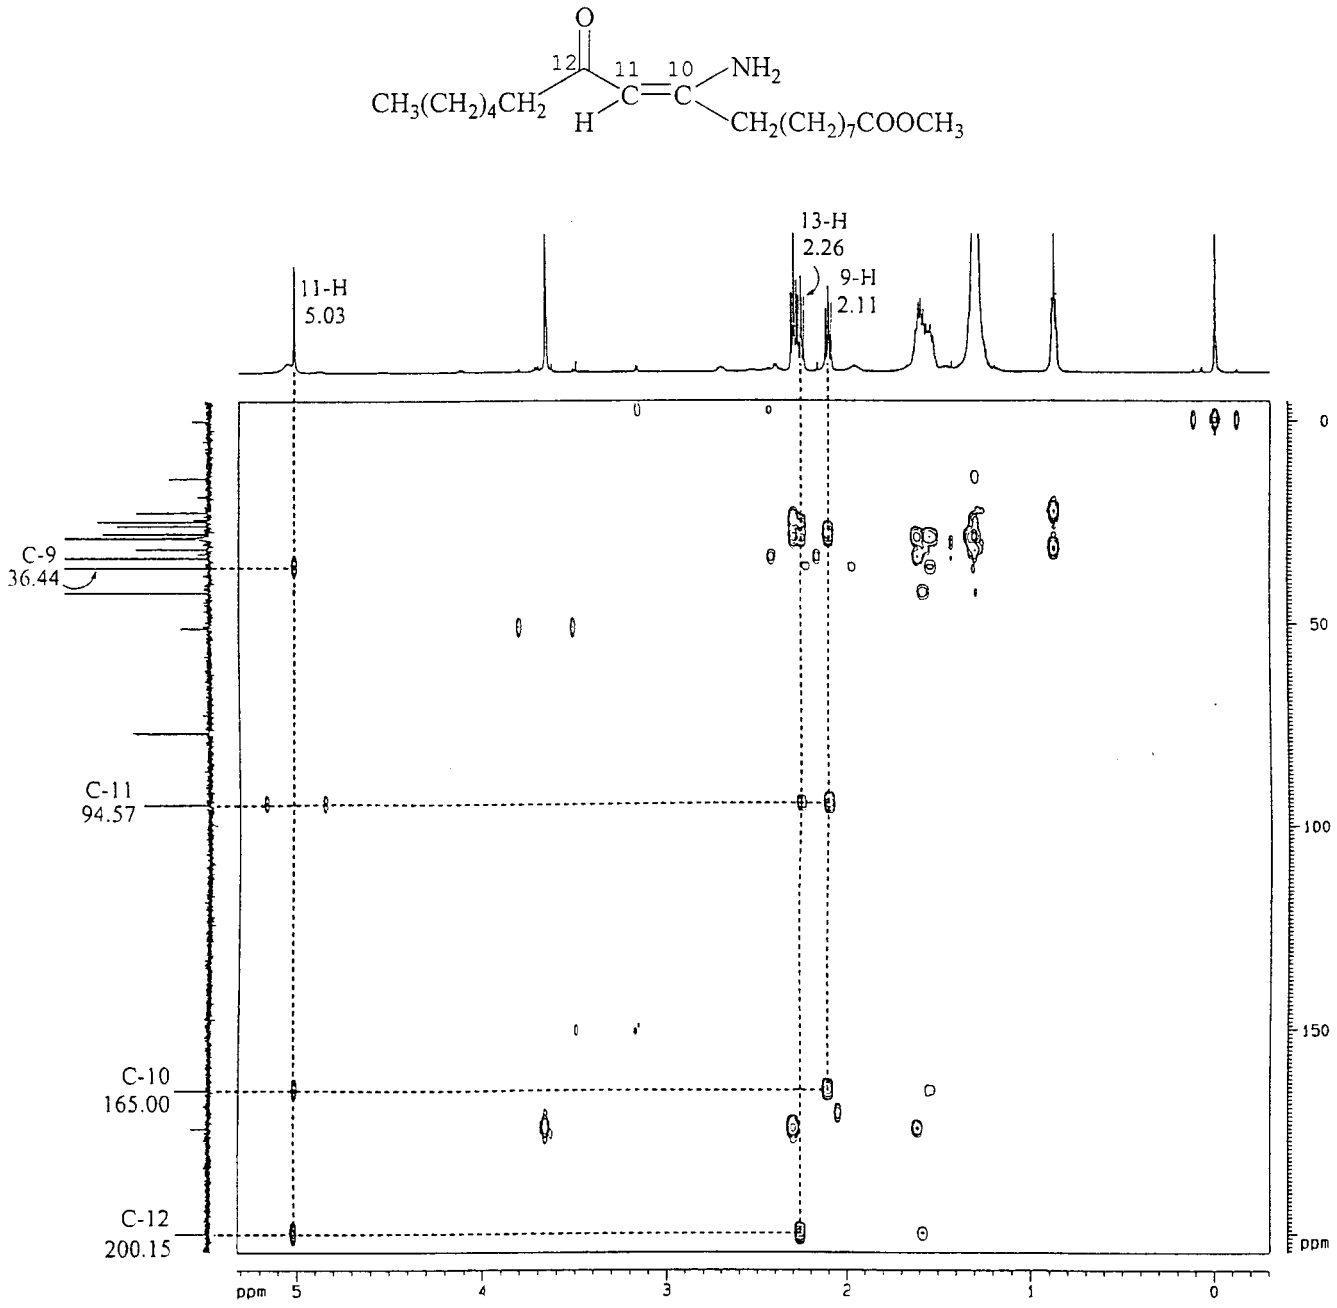

FIG. 2. Heteronuclear multiple bond correlation spectroscopy spectrum of methyl 10-amino-12-oxo-10*Z*-octadecenoate (**2**).

by the peak at $m/z = 113$ (ion fragment *c*) and from ion fragment *b* in most cases. Ion fragment *d*, which resulted from the cleavage of the allylic C-C bond (C-9/C-10), was also a significant peak in most spectra. However, in the case of compounds **12–21** (which contain either a phenyl or an amino ester group near the enaminone system), the mass spectra of these derivatives gave some very intense peaks due to the loss of the phenyl group or part of the ester group. No definite cleavage pattern could be recognized, which would allow the structure of these molecules to be further confirmed.

This work shows that the central atom of a conjugated keto-allene system in compound **1** was very reactive to nucleophilic attack by primary and secondary alkyl and aryl amines (including amino acid esters) to give the corresponding lipidic enaminones.

Comparison of Silver-Ion High-Performance Liquid Chromatographic Quantification of Free and Methylated Conjugated Linoleic Acids

Ewa Ostrowska[a,b], Frank R. Dunshea[b], Morley Muralitharan[c], and Reginald F. Cross[a,*]

[a]School of Engineering and Science, Swinburne University of Technology, Hawthorn, Victoria 3122, Australia, [b]Agriculture Victoria, Victorian Institute of Animal Science, Werribee, Victoria 3030, Australia, and [c]Charles Sturt University, Wagga Wagga, NSW 2650, Australia

ABSTRACT: Silver-ion high-performance liquid chromatography was used to fractionate a mixture of conjugated linoleic acid (CLA) isomers (as the free fatty acids, CLAFFA) in commercial CLA mixtures and biological samples. Due to the unchanged retention mechanism, it was assumed that the elution order of the isomers remained the same as that of methyl esters separated on the same column. The most abundant isomers, *cis/trans* 10,12-18:2 and *cis/trans* 9,11-18:2, were separated better as free acids on a single column than in the methyl ester form. Quantification of the CLA standard was used as the reference profile to evaluate different methylation methods commonly used to prepare CLA methyl esters for quantitation. Acid- and base-catalyzed derivatization methods resulted in CLA intraisomerization and losses in total conjugated dienes content. Acid (HCl and BF_3) methylations significantly elevated the level of *trans,trans* isomers and significantly reduced the *cis/trans* isomers. Base methylation, tetramethylguanidine/methanol, resulted in loss of *trans,trans* isomers, and a substantial loss of total underivatized conjugated dienes. Other catalysts such as the trimethylsilyldiazomethane produced additional peaks of unidentified artifacts. The analysis of CLAFFA appears to provide more accurate quantification of CLA isomers in commercial and biological samples.

Paper no. L8452 in *Lipids 35,* 1147–1153 (October 2000).

Conjugated linoleic acid (CLA) comprises a mixture of positional and geometric isomers of linoleic acid (*cis,cis*-9,12-octadecadienoic acid) with conjugated double bonds (1). These conjugated dienes were found to be responsible for many biological properties that relate to health. One of the most important is the anticarcinogenic activity in both the *in vivo* and *in vitro* models that is often attributed to the *cis,trans* 9,11 isomer of CLA, abundant in products of ruminant origin (2–5). CLA was demonstrated to possess antiatherogenic properties in hamsters (6) and antidiabetic properties in the Zucker diabetic fatty acid *fa/fa* rats (7). It was also found to reduce the catabolic effects of immune stimulation in mice, rats, and chickens (8,9). Another biological effect of CLA relates to fat accreation and nutrient partitioning. CLA significantly reduces body fat and increases lean body mass in rats and mice (10–12) and in farm animals such as pigs (13). The fat metabolism and body composition are thought to be influenced by the *trans,cis* 10,12 isomer (2,14,15).

Although the effects of CLA have been investigated for a number of years, its mechanism of action is poorly understood. This can be largely attributed to the methods used in the past to analyze these acids. The most common means of analysis, gas chromatography (GC), produced overlapping peaks of major isomers of CLA, the *cis/trans*-9,11 and *cis/trans*-8,10 and their geometric isomers (*cis,cis* and *trans,trans*). For optimal quantification, long columns are required and these are associated with prolonged retention times. Furthermore, GC separation requires fatty acids to be in a methyl ester form, which is less polar and more volatile in comparison to the parent form. Some derivatization methods can be time consuming and can also result in small losses of unconverted acids (16). Derivatization of acids in biological samples raises the possibility of interisomerization (conversion between unconjugated linoleic acid and CLA due to shifts in double bonds), resulting in inaccurate CLA isomer data (17). Additionally, biological samples may contain allylic hydroxy oleate (AHO), which is a secondary oxidation product of oleic acid. AHO undergoes reactions during exposure to strong acids such as HCl and BF_3 resulting in artifacts and increased levels of CLA (18). Recently, it was reported that 20:2 conjugated fatty acid isomers synthesized by alkali isomerization eluted in the region of the silver-ion high-performance liquid chromatography (Ag^+-HPLC) chromatogram close to the geometric CLA isomers (19). Therefore, the selection of methylation method is crucial to successfully quantifing acids such as CLA.

In recent years, a method has been developed which involves the use of Ag^+-HPLC (19–21). In commercial mix-

Abbreviations: ACN, acetonitrile; Ag^+-HPLC, silver-ion high-performance liquid chromatography; AHO, allylic hydroxy oleate; CLA, conjugated linoleic acid; *cis/trans*, all the CLA isomers having a *cis,trans* or *trans,cis* configuration; CLAFFA, conjugated linoleic acid as the free fatty acids; FAME, fatty acid methyl esters; FFA, free fatty acid; GC, gas chromatography; TAG, triacylglycerol; TMG, tetramethylguanidine; TMS, trimethylsilyldiazomethane.

tures, it allows for well-resolved separation of three groups of geometric isomers of CLA (*trans,trans*, *cis/trans,* and *cis,cis*) under isocratic conditions. Within each group, there is further separation into positional isomers 13,15-18:2; 12,14-18:2; 11,13-18:2; 10,12-18:2; 9,11-18:2; 8,10-18:2; and 7,9-18:2. The separation of the positional isomers improves by connecting silver columns in series (19,22).

Most recently, we have demonstrated that the same Ag^+-HPLC may be adapted to analyze CLA as the free fatty acids (CLAFFA), thus eliminating the need to methylate prior to assay (23). In addition to the potential waste of time and resources in the event of a separate methylation process, there are also questions about loss and modification of the isomer distribution that occur during methylation that have been frequently discussed in the literature. Thus, in this present study, single-column Ag^+-HPLC was used to evaluate the effect of derivatization methods on CLA distribution and the extent of intraisomerization (conversion of one isomer of CLA to another). The results have been compared to the distribution of CLA in the standard mixture that was separated using the same column, but different mobile phase compositions. The effect of different methylation procedures on interisomerization of CLA and other fatty acids present in biological samples was not investigated in the current study. The identity of isomers found in biological samples was also not investigated.

MATERIALS AND METHODS

Materials and reagents. A mixture of CLA isomers in free acid form and CLA methyl esters (FAME) were obtained from Sigma (St. Louis, MO). The commercial mixture of CLA (55%) and a mixture of *trans,cis* 10,12 (45%) and *cis,trans* 9,11 (43%) isomers were obtained from Natural Lipids Ltd. (Hovdebygda, Norway). All solvents and chemicals were reagent grade.

Animals and diets. Ethics approval for this investigation was given by the Animal Experimentation Ethics Committee of the Victorian Institute of Animal Science in July 1997, permit number 1755. Samples of adipose tissue and longissimus muscle were obtained from pigs (Large White gilts × Landrace) fed *ad libitum* for 8 wk with diets containing 5.5 g of CLA per kg diet (13).

Lipid extraction, saponification, and preparation of fatty acid esters. Total lipids were extracted with chloroform/methanol (2:1, vol/vol) as described previously by Folch *et al.* (24). A mild saponification method was employed for fats extracted from adipose and muscle tissues of pigs (25). In that paper it was demonstrated that the use of strong acids and bases and elevated temperatures can lead to altered isomer distributions. However, mild conditions of saponification (low temperatures and minimal base concentrations) are possibly the least likely to alter the CLA distribution.

FAME were prepared by methylating in 15-mL tubes with Teflon-lined screw caps under N_2. HCl/methanol (26) was heated for 1 h at 80°C or at room temperature for 30 min. Tetramethylguanidine (TMG)/methanol (27) and BF_3 (28) were heated for 2 min at 100°C. Trimethylsilyldiazomethane (TMS) catalyzed transesterification (29) was carried out at room temperature for 30 min. Solvents were removed by stream of nitrogen and the acids were dissolved in 1 mL of hexane.

Ag^+-HPLC conditions. A ChromSpher 5 Lipids analytical silver-impregnated column (4.6 × 250 mm i.d. stainless steel; 5 µm particle size; Chrompack, Bridgewater, NJ) was used. The column was protected by a 3.0 × 10 mm i.d. guard column containing the same stationary phase. HPLC analyses were performed with a Varian (Walnut Creek, CA) isocratic solvent delivery system equipped with a 9012 pump, a Polychrom 9065 diode array detector (recently replaced by a Prostar 330 photodiode array detector), and a Star Workstation (recently upgraded to version 5.3 Star software). All measurements were taken at 234 nm. Samples were introduced *via* a Rheodyne (Cotati, CA) 8125 injector fitted with a 5-µL injection loop. A Timberline column heater maintained the temperature at 30°C for all runs. Minimum tubing diameters and distances were used between the injector and detector.

Integration and quantitation. Self-consistent integration procedures were adopted for all quantitation. Hence, notwithstanding a far smaller degree of resolution than is always desirable for quantitation, the integration procedures utilized and thus the results of this study are highly relevant to all who use Ag^+-HPLC for CLA quantitation, whether as CLAFFA or CLA FAME. It is indeed particularly useful for the quantitation to have been done under the same conditions of resolution as used by others.

Fractionation of CLA FAME by Ag^+-HPLC. Separation of total CLA methyl esters was performed according to Sehat *et al.* (21) protocol. Mobile phase consisted of 0.1% vol/vol acetonitrile (ACN) in hexane and the solvent flow was set to 1.0 mL/min. CLA content in the sample size ranged from 5 to 10 µg. Four analyses from one of the methylation methods and two analyses of underivatized CLA were performed on each day. The experiment was carried out over 6 d, 1 d for each of six methylation methods.

Fractionation of CLAFFA by Ag^+-HPLC. The standard CLA mixture of FFA was separated using a mobile phase consisting of hexane, ACN, and glacial acetic acid. The investigated concentrations of those cosolvents varied from 0–5% vol/vol for ACN and 0–5% vol/vol for acetic acid. The reproducibility of the separation was very sensitive to small changes in concentration of acetic acid and more so to the concentration of ACN, possibly due to its low solubility in hexane. Therefore, the ACN/acetic acid/hexane mix was stirred thoroughly before use. The column was equilibrated with the new solvent mix for at least 30 min before sample injection, and every run was repeated four times or until reproducible retention times were obtained.

Statistical analyses. Different methylation methods were compared by an analysis of variance using Genstat (30) adjusted for the blocking factor of the day of assay. Thus, error variation was commonly estimated using between-assay variability from every day. One assay method (CLA methyl esters purchased from Sigma) was unreported, but was included

in the analysis to increase the residue degrees of freedom from 20 to 24. The isomers' distribution in the CLA mixture was treated as the control and compared to the treatment mean of CLA distribution resulting from each methylation method. For this type of analyses, the many-one *t* statistics technique was appropriate (31), as it takes into account that five methods are being compared to the control. The ratios of the positional groups presented in Table 1 were analyzed as log values for more heterogeneous distribution of residuals and presented in the form of geometric means.

RESULTS AND DISCUSSION

Fractionation of CLAFFA. Recently, we reported successful separation of the FFA on a commercially available silver-impregnated column (23). In that study, we attempted first to separate the FFA using the method of Sehat *et al.* (21). However, the CLA isomers were not eluted in 2 h. High concentrations of the strong solvent (ACN) removed the CLA from the stationary phase, but even moderate ACN concentrations destroyed the separation. On the other hand, the addition of a competing acid (acetic acid) reduced the run times as desired, but did not interfere with the separation. Hence, it was clear that the acetic acid was an excellent mobile phase additive for the removal of the carboxylic acid end of the CLA from the abundant surface silanols on the stationary phase, but a very poor strong solvent for the removal of the CLA double bonds from the Ag^+ ions in the stationary phase. ACN was the opposite of this. Thus, it is clear that the retention mechanism in the separation of FFA and separation of methyl esters of CLA was in both cases due to interactions of double bonds with Ag^+ ions. The additional interactions of the free acid group with the excess silanols on the stationary phase of the column were canceled out with the addition of the competing acid (glacial acetic acid) (23). Furthermore, from Figures 1A and 1B, notwithstanding the statistically significant differences between them, the gross distribution of species in the two chromatograms can be seen to be qualitatively indistinguishable. Without the detailed analysis to follow, it would not be possible to differentiate between the distributions. The amounts of the major isomers are so different from each other that any change in order of elution is improbable in the extreme. These chromatograms (Figs. 1A and 1B) were run on the Sigma standard mix of FFA and our esters (methylated by the BF_3 method). Chromatograms on the Sigma standard mixes of FFA and methyl esters were related in exactly the same way. Hence, the order of elution of the isomers of CLA must be assumed to be the same for the CLA and the methyl esters. Mobile phase conditions chosen in this study consisted of 2.5% vol/vol acetic acid and 0.025% vol/vol ACN, although the conditions may need to be optimized for individual columns since there appears to be batch-to-batch variations in the stationary phases supplied. Under the chosen conditions, the separation was equivalent to the separation of CLA methyl esters described by Sehat *et al.* (21), but the most abundant and the isomers thought to be biologically active, *cis/trans* 10,12 and *cis/trans* 9,11, were almost baseline-resolved (see Fig. 1A vs. 1B).

Intraisomerization of CLA due to methylation procedures. To study the extent of CLA intraisomerization, an assumption was made that the free acids analyzed using Ag^+-HPLC represented a true distribution of CLA content and resulted in 100% recovery of conjugated dienes. The results presented in Table 2 show the difference in the composition of all the positional and geometric isomers of CLA present in the commercial mixture resulting from commonly used methylation methods. Statistical analysis showed that there was a highly significant difference among all methylation methods tested ($P < 0.001$). All catalysts contributed to changes to the isomer distribution and the overall loss of total CLA. In terms of the recovery of total CLA, the boron trifluoride method was the most suitable method with 1.6% ($P < 0.10$) loss of conjugated dienes. TMS- and HCl-catalyzed reactions (reaction carried out at ambient temperature) produced the second-smallest losses of total CLA with 8% ($P < 0.05$) and 8.9% ($P < 0.05$), respectively. The remaining HCl (at 80°C) and TMG resulted in a highly significant loss of total CLA (20 and 29%, respectively).

All acid catalysts were associated with significantly increased levels of *trans,trans* isomers of CLA and significantly lower levels of *cis/trans* isomers (Table 2). For example, HCl methylation at 80°C resulted in approximately 70% ($P < 0.01$) recovery of both the *cis/trans* 8,10-18:2 and 9,11-18:2 isomers (Table 1). Three- and fivefold increases in *trans,trans* 8,10-18:2 and 9,11-18:2 were obtained, respectively. The method was also associated with the formation of artifacts (Fig. 1C). Sehat *et al.* (21) identified the additional peaks formed during HCl methylation as positional allylic methoxy derivatives formed due to acid and heat treatment.

Several investigators detected changes in the CLA isomer distribution pattern due to the combination of acid and heat, but limited data were presented to confirm the extent of intraisomerization of CLA due to lack of chromatographic resolution (18). It was claimed that the isomerization of the conju-

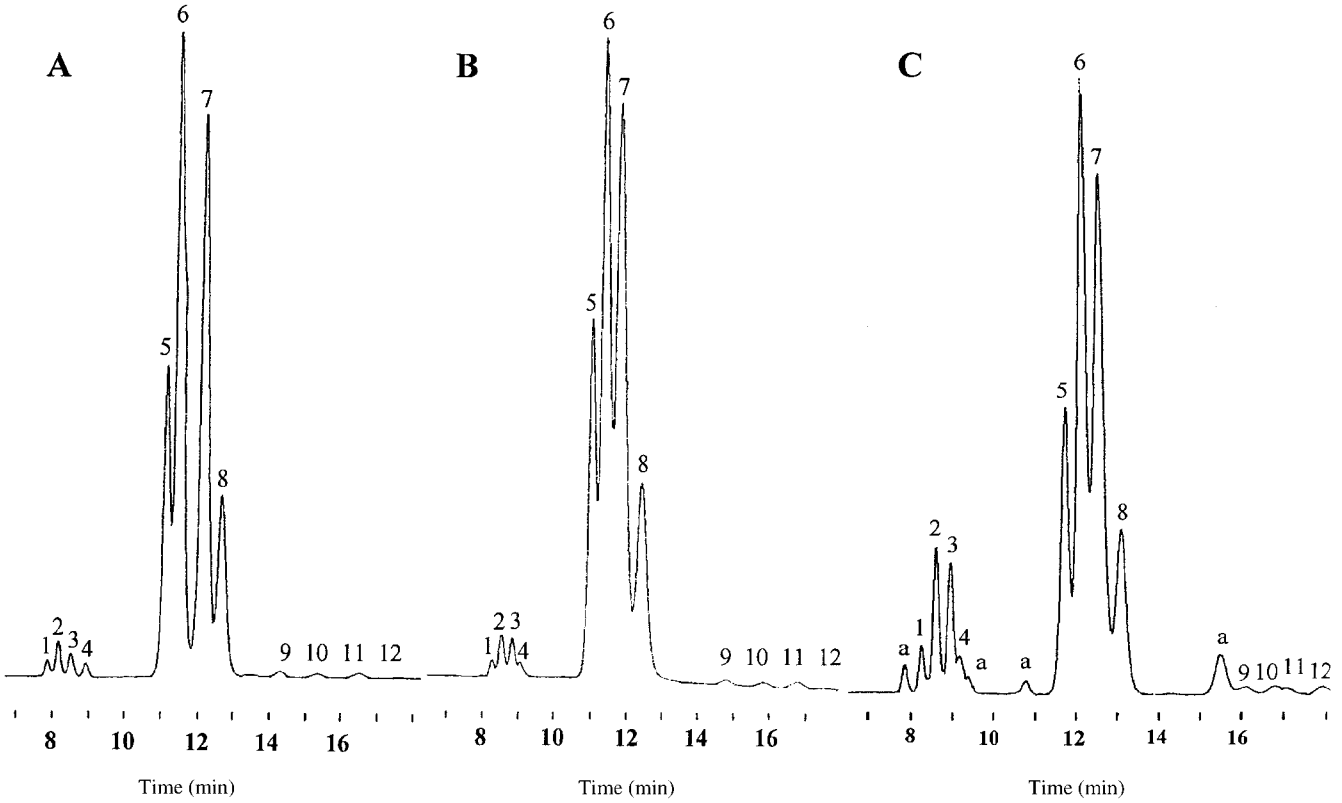

FIG. 1. (A) Ag^+ ion chromatogram of the Sigma standard conjugated linoleic acid (CLA) mixture using 2.5% vol/vol acetic acid and 0.025% vol/vol acetonitrile at 1mL/min flow. gated dienes during acid-catalyzed methanolysis can be minimized by carrying out reactions at room temperature (17,32, 33). HCl in methanol at room temperature yielded a significantly higher level of total *trans,trans* fatty acids (+73%, $P < 0.01$) than in any other method and the control, but was reduced approximately twofold compared to the same reaction carried out at a higher temperature (Table 2). Consequently, the level of *cis/trans* isomers was higher than in the high-temperature HCl methylating procedure, although still significantly reduced when compared to the true distribution (−4%, $P < 0.01$).

Werner *et al.* (17) investigated the effect of temperature on CLA isomer composition in the methanolic boron trifluoride methylating procedure. The effects on both the intraisomerization of CLA and interisomerization of linoleic acid and CLA were negligible. In the present study, a significant increase in the average content of *trans,trans* isomers (+22%, $P < 0.01$) was observed at a short incubation time of 2 min at a high temperature (100°C) and the *cis/trans* was significantly reduced by 1% ($P < 0.01$) whereas *cis,cis* isomers were not affected. The ratio of the *cis/trans* 9,11 and *cis/trans* 10,12 (Table 1) was significantly different from the controls (0.94 vs. 1.03, respectively), but this could be attributed to poorly resolved peaks compared with the baseline-resolved underivatized sample.

Base catalysis by TMG results did not yield artifacts, but significant changes in CLA composition were recorded. The levels of *trans,trans* and *cis/trans* isomers were significantly reduced (−35%, $P < 0.01$ and −1%, $P < 0.01$, respectively), whereas the levels of *cis,cis* isomers were increased fourfold ($P < 0.01$). Consequently, the ratios of *trans,trans* and *cis/trans* to the *cis,cis* groups were much lower (Table 2). Therefore, this method is unsuitable for the analysis of CLA.

The extent of intraisomerization was minimized with TMS methanolysis, although the level of all *trans,trans* isomers was significantly higher (+20%, $P < 0.01$) than the levels recorded for the underivatized reference mixture of CLA. The changes in the *cis/trans* and *cis,cis* isomer composition were minimal, but not significantly different from the underivatized sample. However, the method produced several additional peaks. The identity and the origin of these artifacts were not investigated.

Eulitz and co-workers (34) reported intraisomerization of CLA methyl esters as a result of reaction with *p*-toluenesulfinic acid and I_2. The reaction resulted in migration of the double bonds and formation of eight geometric isomers of the 11,13-, 10,12-, 9,11-, and 8,10-octadecadienoic acid methyl esters, which were partially separated using three columns connected in series. The geometric isomers of the 10,12-isomer were not resolved and the *trans,cis* 9,11 coeluted with the *cis,trans* 8,10 isomer. The coelution of the *cis,trans* 8,10 methyl ester with the *trans,cis* 9,11 methyl ester has not been reported previously, possibly due to the absence of the *trans,cis* 9,11 isomer in commercial mixtures of CLA.

Separation of CLA from biological samples in the FFA form. Commercial sources of CLA occur in a FFA form. The biologically occuring CLA are, however, present in triacylglycerols (TAG) (35). The fatty acids present as TAG need to be freed from the molecules of glycerol by the process of saponification prior to methylation and analysis. The process of saponification may also involve the use of heat in the presence of strong bases and strong acids and may contribute to the isomerization of CLA. The effect can be minimized by adopting milder conditions (25) but, as it was shown in this study, even the reactions carried out at room temperature and using weaker acid can result in modification of the isomer distribution. However, eliminating the methylation (if it were to be carried out as a second, separate reaction from the saponification), would certainly enable us to establish a less erroneous distribution of CLA in biological samples. Where saponification and methylation are achieved in one step (16), it is possible that errors are incurred similar to those in the separate methylation under comparable conditions. However, this needs to be determined experimentally.

Figure 2 shows an example of a single column Ag^+-HPLC separation of CLA derived from pig tissue and in the free acid form. The identities of the labeled CLA isomers in Figures 2A and 2B were assigned on the basis of coincidence of retention with the known isomers in the standard Sigma mix. It should be noted that retention times and resolution of the CLA mixtures were found to be subject to sample size, as has been reported in other studies. Furthermore, loss of retention over time as the columns aged necessitated frequent checking of the standards. The identities of the *cis/trans* 10,12 and *cis/trans* 9,11 major isomers were confirmed by spiking the sample with the reference mixture of those two isomers (Fig. 2C). The identities of the remaining isomers were based on the relative elution order. The CLA isomer distribution of the commercial sample shown in Figure 2A (CLA 55% wt/vol; Natural Lipid Ltd.) was as follows: 0.17% *trans,trans*-12,14; 0.42% *trans,trans*-11,13; 1.96% *trans,trans*-10,12; 2.07% *trans,trans*-9,11; 0.43% *trans,trans*-8,10; 0.30% *trans,trans*-7,9; 0.37% *cis/trans*-12,14; 17.94% *cis/trans*-11,13; 30.49% *cis/trans*-10,12; 24.65% *cis/trans*-9,11; 14.52% *cis/trans*-8,10; 0.88% *cis,cis*-11,13; 2.71% *cis,cis*-10,12; 2.21% *cis,cis*-9,11; and 0.74% *cis,cis*-8,10. The commercial mixture of CLA was supplemented in pigs' diets at concentrations of 0–5.5 mg/kg of diet. The effect of CLA supplementation on CLA isomer distribution in pig tissue will be discussed elsewhere. Peaks 8, 9, 10, and 11 in Figure 2B corresponded to the isomers found in the standards (Fig. 2C); however, the presence of additional peaks could suggest the separation of the *trans,cis* and *cis,trans* isomers. Therefore, the conjugated double-bond geometry and position as well as the purity of these isomers in biological samples need to be confirmed by GC-direct deposition-Fourier transform infrared and GC-electron impact–mass spectrometry.

The resolution of the peaks, especially of the most abundant isomers in the *cis/trans* group, appears to be dependent on its concentration in the sample (22). With lower levels of *trans,cis*-10,12 compared to the *cis,trans*-9,11 found in intramuscular fat of pigs (Fig. 2B), the separation is more difficult due to the great differences in the relative amounts. We found that the resolution between the overlapping peaks can be fur-

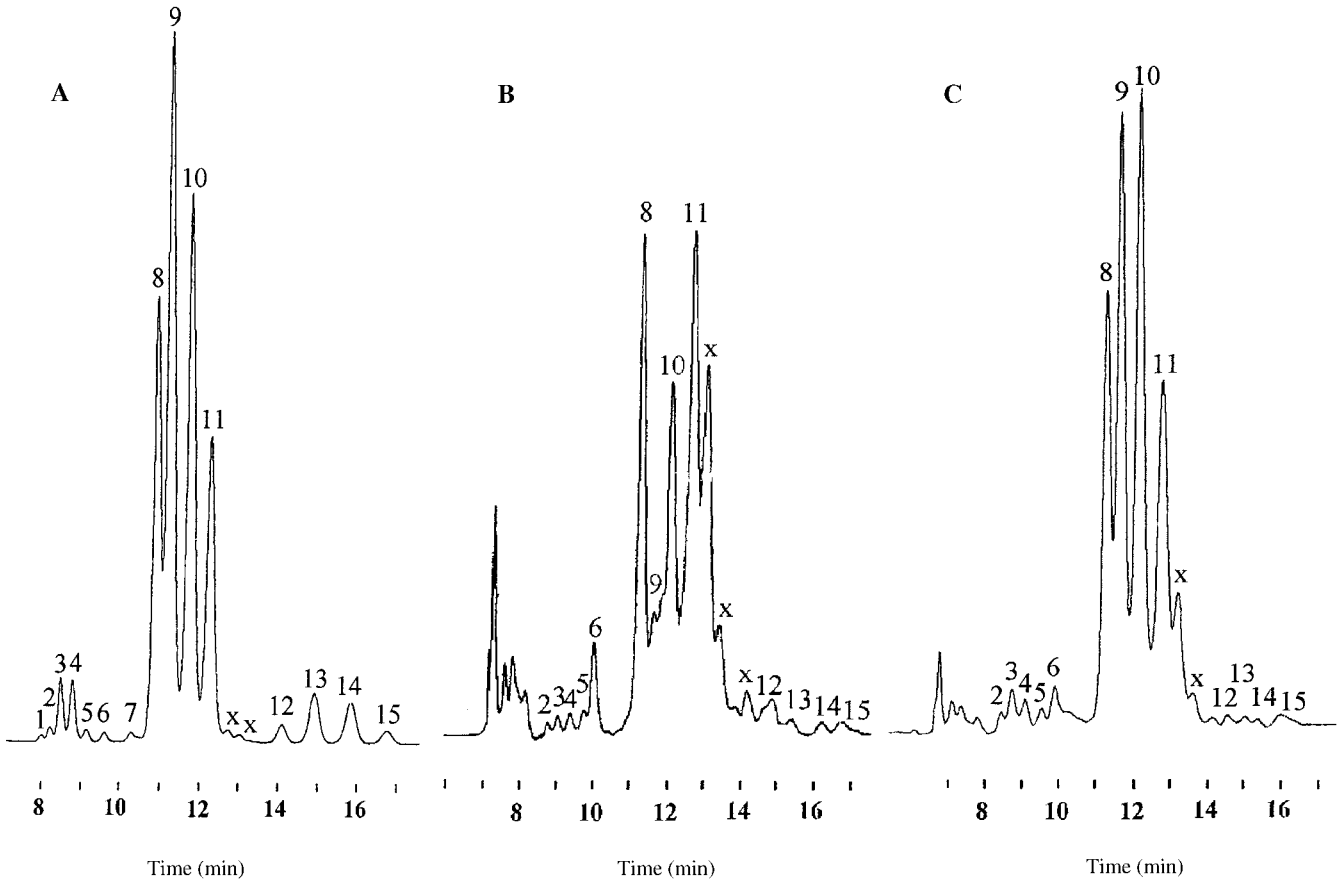

FIG. 2. (A) Ag^+ ion chromatogram of a commercial CLA solution that was added to pigs' diets (55% wt/vol; National Lipid Ltd., Hovdebygda, Norway). (B) A typical chromatogram of the pig muscle sample. (C) Muscle sample spiked with CLA isomer reference. Samples were separated using 2.5% vol/vol acetic acid and 0.025% vol/vol acetonitrile at 1 mL/min flow. The individual isomers are thought to be: 1, *t,t*-12,14; 2, *t,t*-11,13; 3, *t,t*-10,12; 4, *t,t*-9,11; 5, *t,t*-8,10; 6, *t,t*-7,9; 7, *c/t*-12,14; 8, *c/t*-11,13; 9, *c/t*-10,12; 10, *c/t*-9,11; 11, *c/t*-8,10; and possibly *t,c*-9,11; 12, *c,c*-11,13; 13, *c,c*-10,12; 14, *c,c*-9,11; and 15, *c,c*-8,10. Peaks labeled "x" correspond to isomers not present in the standards. See Figure 1 for abbreviation.

ther improved by adjusting the mobile phase conditions, e.g., removing the ACN from the mobile phase and lowering the concentration of acetic acid to 1.5% vol/vol (data not shown). Another way is to increase the number of columns used. Recently, Sehat *et al*. (19) reported the use of up to six columns connected in series in order to improve separation of CLA isomers present in beef tissue. Since addition of competing acid to the mobile phase improves the separation of CLA in the free acid form, similar separation resulting from tandem-column chromatography could be achieved with a smaller number of columns.

CONCLUSION

The present study shows that the composition of CLA was significantly affected by the catalyst used in the methylation procedure. Furthermore, CLA methylation appears to be sensitive to temperature changes that can result in the formation of artifacts. Boron trifluoride and TMS were the most appropriate methylation procedures, boron trifluoride achieving the best recovery and TMS the most accurate distribution. However, both methods were associated with significantly increased levels of *trans,trans* isomers and in the case of TMS, formation of unidentified artifacts. Therefore, direct injection of the mildly saponified lipids to the FFA is likely to be the most accurate method of quantifying CLA isomers. This should, in turn, aid in understanding the mechanisms responsible for the diverse biological functions reported for CLA, due to more confident measurements of CLA isomer distributions.

ABSTRACT: The structures of three kinds of phospholipids (PL-X, PL-Y, and PL-T) isolated from *Thermoplasma acidophilum* have been characterized. The core lipid of PL-Y was caldarchaeol, and that of PL-X was archaeol. The composition of the hydrocarbon chains of the PL-T core lipid was C_{20} phytane and C_{40} isoprenoid in a molar ratio of 2 to 1. The major molecular species of the C_{40} isoprenoid was acyclic without the cyclopentane ring. These three kinds of intact phospholipids commonly had glycerophosphate residues as polar head groups. The structure of PL-T was characterized as trialkyl-type caldarchaetidylglycerol, PL-Y as caldarchaetidylglycerol, and PL-X as archaetidylglycerol.

Paper no. L8569 in *Lipids 35*, 1155–1157 (October 2000).

The membrane lipid structures of Archaea are basically ether-type, such as derivatives of archaeol, 2,3-di-*O*-phytanyl-*sn*-glycerol, and caldarchaeol, tetra-*O*-di(biphytanyl)diglycerol (1–3). The core lipids of thermoacidophilic Archaea, such as *Sulfolobus* or *Thermoplasma*, are mainly caldarchaeol and their derivatives, and about 10% archaeol (4). As the minor isoprenoid ether core lipid, 3-*O*-phytanyl-*sn*-glycerol and glycerol-trialkyl-glycerol tetraether are also detected in *S. solfataricus* (5). The constituents of the C_{40}-hydrocarbon chains in these caldarchaeols have a wide range of variety, which depends on the number of cyclopentane rings. These hydrocarbon chains contain from a minimum of zero to a maximum of four cyclopentane rings (6,7).

Recently, we have reported the structures of neutral glycolipids of *T. acidophilum*, and all of their core lipids were caldarchaeol (8). The existence of diether-type polar lipids and also the phosphatidyl diether lipid was suggested by two groups (9, 10).

In this paper, we clarified the structures of three intact lipids having glycerophosphate groups attached to caldarchaeol, archaeol, or glycerol-trialkyl-glycerol tetraether (trialkyl-type-caldarchaeol) as core lipids. The last one is a novel phospholipid from *T. acidophilum*.

EXPERIMENTAL PROCEDURES

Organisms and preparation of lipids. Thermoplasma acidophilum (ATCC 27658) was grown aerobically at 59°C in a medium containing inorganic salts, 0.1% yeast extract, and 1% glucose described previously (8,11). The preparation and separation procedures of neutral and acidic lipids were described previously by Uda *et al.* (8). The acidic lipids [1 g in 1.5 mL chloroform/methanol (9:1, vol/vol)] were further fractionated by silicic acid column (36 × 1 cm) chromatography, eluted with a linear gradient of chloroform/methanol from 9:1 (vol/vol) to 1:4 (vol/vol) in a total vol of 600 mL. Five-milliliter fractions were collected. Further purification of acidic lipids [pooled fractions 27–37 in chloroform/methanol/water (1:6:1, by vol)] was performed using reversed-phase column (5 × 1 cm) chromatography eluted with solvent mixture of chloroform/methanol/water. After PL-X was eluted with the solvent of 2:6:1 (by vol), PL-T and PL-Y were eluted together with 3:6:1 (by vol).

Analytical procedures. Analytical procedure of core lipids and hydrocarbon chains were described previously (12,13).

Thin-layer chromatography (TLC) of acidic lipids was performed using boric acid-impregnated high-performance TLC (HPTLC) plates of silica gel (8). Four kinds of solvent systems were used for this study, A: chloroform/methanol/0.2% $CaCl_2$ (55:45:7, by vol), B: chloroform/methanol/1 M NH_4OH (65:35:5, by vol), C: chloroform/methanol (4:1, vol/vol), and D: hexane/diethyl ether/acetic acid (60:40:2, by vol). The TLC of core lipids was performed using an HPTLC plate of silica gel and a double development system, with the first development one-third high with solvent C, and the second development up to the top of the plate with solvent D. Caldarchaeol and archaeol, prepared from *S. solfataricus,* were used as standard substances (14). Lipids were detected by spraying with 18 M H_2SO_4 followed by heating at 150°C. The contents of each lipid in the total cellular lipids were estimated using a Dual-Wavelength Chromato Scanner (CS-930; Shimadzu, Kyoto, Japan).

Fast atom bombardment-mass spectrometry (FAB-MS) was carried out in a positive or negative mode with a matrix

[*m*-nitrobenzylalcohol and diethanolamine (DEA)] using a mass spectrometer (model JMS-AX505H; JEOL, Tokyo, Japan).

Preparation and analytical procedures of glycerophosphate were described previously (15).

Periodate oxidation of lipids was performed using sodium periodate. The resulting products were reduced with sodium borohydride. The resulting periodate oxidation products of acidic lipids were analyzed by FAB-MS.

RESULTS AND DISCUSSION

The acidic lipids were gradually eluted in due order from nonpolar lipids to polar lipids by silicic acid column chromatography. The main phosphoglycolipid, gulosyl-caldarchaetidylglycerol (GPL-A) (10), which occupies 46% of the total lipids, eluted around fraction 40, and its R_f value using solvent A was 0.73. PL-X (R_f = 0.81) and PL-Y (R_f = 0.84) were eluted before GPL-A. Purified PL-X was obtained by reversed-phase column chromatography, and a PL-T and PL-Y mixture was separated further with preparative TLC developed with solvent system B. The R_f values of the lipids by solvent B were as follows: PL-T, 0.56; PL-Y, 0.50; and PL-X, 0.46. The PL-X content in the total cellular lipids, based on the calculation of TLC scanning, was about 5%, and PL-Y was less than 1%. Further, the PL-T content was less than one-tenth of the PL-Y content.

Core lipids obtained from PL-X and PL-Y co-chromatographed on the TLC with archaeol (R_f = 0.80) and caldarchaeol (R_f = 0.55), respectively. An unknown core lipid (R_f = 0.73) was detected in PL-T. The gas chromatogram of the hydrocarbon chain from PL-X showed only one peak. Its gas chromatography–mass spectrometry (GC–MS) (electron ionization, EI) spectrum showed a peak for $[M]^+$ at *m/z* 282, which was identified as $C_{20}H_{42}$ phytane. The hydrocarbon chain from PL-Y showed four peaks in the gas chromatogram corresponding to the same C_{40} hydrocarbon chains detected in *S. solfataricus* (7). The peaks for $[M]^+$, obtained from the GC–MS (EI) spectra, at *m/z* 562, 560, 558, and 556 were identified as $C_{40}H_{82}$ (acyclic), $C_{40}H_{80}$ (monocyclic), $C_{40}H_{78}$ (bicyclic), and $C_{40}H_{76}$ (tricyclic), respectively. The average cyclization percentages of each hydrocarbon chain in caldarchaeol, calculated from the peak area of the gas chromatograms, are shown in Table 1. The gas chromatogram, of the hydrocarbon chain from PL-T showed the peaks of both C_{20} and C_{40} hydrocarbons, and their molar ratio was 2 to 1. Distribution of the cyclopentane rings in the PL-T core lipid is shown in Table 1. The main molecular species of the C_{40} hydrocarbon chain of the PL-T core lipid did not contain a cyclopentane ring (C_{40} acyclic). One mole of the core lipid of PL-T was constructed with two moles of glycerol, two moles of C_{20} phytane, and one mole of C_{40} hydrocarbon. These results were according to the data for glycerol-trialkyl-glycerol tetraether (trialkyl-type caldarchaeol) from *S. solfataricus* (5).

PL-X, PL-Y, and PL-T were positive for Dittmer reagent. The molar ratios of phosphorus content vs. the core lipid for each lipid were all 1:1 by phosphorus measurement assay (16). The polar head groups of PL-X, PL-Y, and PL-T were identified as glycerol-3-phosphate by comparison with the result of GPL-A, according to TLC, gas–liquid chromatography (GLC) analysis, and enzymatic assay.

The negative FAB-MS spectrum of PL-X showed a molecular ion peak at 805.6 as *m/z* $[M - H]^-$ corresponding to the structure of archaetidylglycerol. The proposed structure of PL-X was consistent with the phosphoryl-diether lipid structure previously suggested (10). The positive FAB-MS spectrum of PL-Y showed molecular ion peaks at *m/z* 1456, 1478, and 1561, corresponding to $[M + H]^+$, $[M + Na]^+$, and $[M + DEA + H]^+$, respectively. In the case of using DEA as a matrix, a characteristic ion peak *m/z* $[M + DEA + H]^+$ (M + 106) was observed, and the molecular weight [M] of PL-Y was estimated to be 1455. A negative FAB-MS spectrum of PL-Y showed a molecular ion peak at 1454 as *m/z* $[M - H]^-$, corresponding to the structure of caldarchaetidylglycerol with a core lipid composed of C_{40} acyclic, as the major molecular species. The molecular ion $[M - H]^-$ at *m/z* 1454 was according to the values calculated from the proposed structure of PL-Y. The negative FAB-MS spectrum of PL-T always showed a molecular ion at 1456, which was two mass units larger than that of PL-Y at any experimental conditions. These results strongly supported the proposed structure of PL-T, which was caldarchaetidylglycerol (trialkyl-type) composed of one mole of a C_{40} acyclic-hydrocarbon chain and two moles of C_{20} phytane.

The FAB-MS of periodate oxidation products of these phospholipids showed that the molecular ion of the degradation products was 30 ($-CH_2O$) mass units less than that of intact PL-X, PL-Y, and PL-T. These values completely overlapped the theoretically calculated values.

The core lipids of PL-X and PL-Y were identified as archaeol and caldarchaeol, respectively, and that of PL-T was trialkyl-type caldarchaeol, by comparison of the R_f values on TLC, the GLC patterns, and the GC-MS spectra with the stan-

TABLE 1
Distribution of Cyclopentane Rings in Core Lipids from *Thermoplasma acidophilum*

	C_{40} (%)					Average cyclization[a]
	Acyclic	Monocyclic	Bicyclic	Tricyclic	Tetracyclic	
PL-Y	70.8	13.3	13.2	2.6	ND[b]	0.48
PL-T	70.0	16.5	13.5	<0.1	ND	0.44

[a]Average cyclization: (% monocyclic + 2 × % bicyclic + 3 × % tricyclic + 4 × % tetracyclic) × 10^{-2}.
[b]ND: not detected.

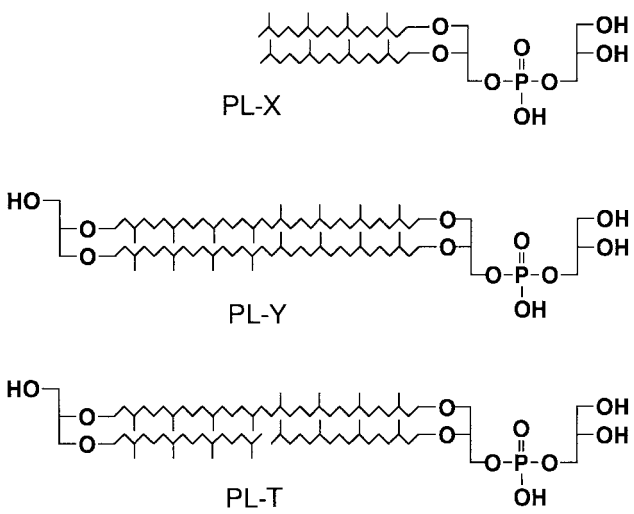

FIG. 1. Proposed structures of PL-X, PL-Y, and PL-T. The core lipid of PL-T is composed of two moles of C_{20} phytane and one mole of acyclic C_{40} hydrocarbon chains. Which hydrocarbon chain binds with the *sn*-2 or *sn*-3 hydroxy group of glycerol is not clear.

dard substances. The phosphate-base constituting these lipids was *sn*-glycerol-3-phosphate in each case. Consequently, it became clear that the PL-X of the *T. acidophilum* is archaetidylglycerol, PL-Y is caldarchaetidylglycerol, and PL-T is caldarchaetidylglycerol (trialkyl-type). The proposed structures of PL-X, PL-Y, and PL-T are shown in Figure 1.

Two types of intact lipid constituents of trialkyl-type caldarchaeol core lipid were also reported in *S. acidocaldarius*, which have inositolphosphates as their polar head groups, bonded to one or both sides of the core lipid (17). In *T. acidophilum*, the trialkyl-type caldarchaeol core lipid was detected not only in PL-T but also in fraction 60, obtained by silicic acid column chromatography. It is assumed to be a lipid having glycerophosphates bonded to both sides of the core lipid. Those lipids might exist in membrane lipids of *T. acidophilum*, which is important to consider concerning their metabolism, and PL-T might be an intermediate in the biosynthesis process from PL-X to PL-Y.

ACKNOWLEDGMENT

The authors greatly appreciate Naoya Tsutsumi for his technical assistance.

The Effect of Maternal Diets on the Mean Melting Points of Human Milk Fatty Acids

Sir:

Triacylglycerols (TAG) are synthesized in the rough endoplasmic reticulum of the secreting cells of the mammary gland. The TAG must be liquid at body temperature for formation of microdroplets in the cell, for fusion of these into droplets, and for secretion of the droplets as globules (1). The core of the globule is TAG, and most of these must be liquid. The liquidity of TAG is related to their structure and to the melting points (MP) of the fatty acids (FA). For example: the MP of 16:0 is 63°C; 18:1*t*, 44°C; and 18:1*c*, 16°C. The MP of 16:0–16:0–16:0 is 66°C, 16:0–16:0–18:1, 37°C, and 16:0–18:1–18:1, 24°C (2).

The diets of lactating women contain wide-ranging amounts of the major FA: 10:0, 12:0, 14:0, 16:0, 18:0, 18:1*t*, 18:1*c*, 18:2, and 18:3. Changes in diets alter the kinds and amounts of the FA, and as a result, the TAG in milk (3). It would appear that ingestion of large quantities of FA with MP above 38°C, which includes all of those listed above except 10:0, 18:1*c*, 18:2, and 18:3, would raise the MP of milk TAG. In addition, the production of 10:0–14:0, which are synthesized in the mammary gland, is stimulated by maternal diets high in carbohydrate, and this should increase the MP of milk TAG. However, the influence of changes in the maternal diet on the liquidity or MP of milk fat has not been reported. In this paper we provide the mean melting points (MMP) of the FA in milks from women who consumed a variety of diets.

Holman *et al.* (4) developed a measure of liquidity or fluidity of membranes. They calculated the MMP of FA in plasma phospholipids. They found, for example, that the MMP was 14.8°C for normal American omnivores and 21.3°C for patients with multiple sclerosis. The authors briefly described their method for calculating MMP. The contribution of the molar fraction of the MP of each FA was determined. All increments were summed and the MMP calculated. One of us (RGJ) was told (Holman, R.T., personal communication) to add 100 to each FA-MP so as to avoid negative numbers. Dr. Frank D. Gunstone (personal communication) evaluated our method for calculating MMP and simplified the procedure. A description of the procedure follows: (i) Determine the mol% of each FA. We used only the major milk FA listed above. Inclusion of all FA had little effect. (ii) Multiply each mol% by the (MP + 100) of each FA to obtain MP fractions. See Reference 2 for MP. (iii) Sum the MP fractions and subtract 100 to obtain the MMP of the FA mixture.

The contents of the major FA in milks from women on different diets and the MMP of their FA are shown in Table 1. The diets in the paper by Insull *et al.* (5) were given sequentially to a patient, and their effects on the FA profiles of her milk samples determined. The ingestion of 228 g of corn oil/d increased the 18:2 + 18:3 of her milk from 9.0 to 42.0%, while the MMP dropped markedly. Milks from the Nigerian (6,7), Tanganyikan (8), and Bedouin women (8) contained FA with MMP close to body temperature. Lauric (12:0) and 14:0 contents were high in these milks because their synthesis in the mammary gland is increased by the consumption of large quantities of dietary carbohydrates. The fat contents and volumes of milk were not reported so we do not know if those high MMP affected the secretion of milk fat. The MMP of the milks from mothers who ate diets high in 18:1*t* (9) were lower than those who did not. This may be caused by their lower contents of 14:0. The fat contents of the milks were; high, 18:1*t*, 4.51; and low, 4.14%. The low MMP in milks from the mothers on vegetarian diets (10) were caused by the relatively large amount of 18:2, 28.8%, therein. The milk fat contents were; vegetarian, 3.1 and omnivorian, 4.2%. These were not significantly different when tested by the Wilcoxon rank sum method. However, this large difference may be biologically important. These results illustrate the value of determining and reporting the fat contents of the milks when FA are analyzed. The milks from all mothers, including those on unusual diets, had MMP at or below body temperature, thus all the milk fats should be liquid.

The maintenance of milk TAG liquidity regardless of the ingestion of large quantities of FA with high MP indicates the ability of the mammary gland to synthesize TAG with the required MP and to incorporate them into milk fat globules. Human milk TAG are unique in that about 70% of the 16:0 are esterified to the *sn*-2 position (3,11–13). Based on their study, Winter *et al.* (11) stated that the amounts of 16:0 and 18:0 in TAG of human milk fat appear to be modulated by nonrandom distributions of 18:1*c* and 18:2 or 8:0–12:0, so that the fat is liquid at body temperatures. The small quantities of trisaturated TAG in human milk (11) will be dissolved in the liquid TAG. The acyltransferase systems in the gland are able to combine the FA into TAG that will be liquid at

body temperature. This occurs even though changes in the maternal diet alter the amounts of FA in the TAG (3). Preferential retention of polyunsaturated FA was observed in the milk lipids containing higher levels of 10.0–14:0 [Refs. 7 and 8 in Table 1 (14)]. A reasonable explanation is that these are needed to maintain fat liquidity.

A desaturase that converts 18:0 to 18:1 has been found in the mammary gland of dairy cattle (1) but not in the human gland. We made a thorough search and found no evidence that the desaturase exists in the gland. In humans, most of the desaturation occurs in the liver (15). The conjugated linoleic acid 9*c*,11*t*-18:2 was found in human serum when vaccenic (11*t*-18:1) acid was fed (16). However, this desaturation probably occurred in the liver. The conversion of 11*t*-18:1 to 9*c*,11*t*-18:2 in humans was recently confirmed using deuterated FA (17). This desaturation appears to be a major pathway, but it is not available in the human mammary gland.

Thus, it is evident the secreting cell tends to incorporate patterns of FA into TAG that will produce lipid droplets, and ultimately fat globules, that are liquid at body temperature. How might this selection mechanism work? A clue may be provided by bovine milk fat, which contains about 5% of a high-melting (55°C) TAG fraction containing about 75% 16:0 and 18:0 (18). These data make it quite unlikely that the discrimination depends on the melting property of each TAG molecule, but more plausibly on the capacity of an accumulating liquid TAG droplet to dissolve newly synthesized molecules of TAG. In this manner, a certain small proportion of high-melting molecules would be expected to dissolve in the growing liquid droplet. Beyond that amount, additional high-melting molecules apparently are rejected and may undergo FA exchange to make them extractable or acceptable as to the melting point. We conceive of the rough endoplasmic reticulum membrane system as the most likely site for this MP discrimination process (19). It is well established that the endoplasmic reticulum is the site of TAG synthesis in the lactating cell (1,20), and a mechanism for accumulation of TAG within the bilayer of the endoplasmic reticulum membrane has been postulated (see Fig. 4 in Ref. 21). Maintaining liquidity in the hydrophobic region of this membrane appears essential to gathering of TAG into droplets. These considerations lead to the prediction that the yield of milk fat is dependent on melting properties of the FA available for TAG synthesis. We did not have information about the fat contents of most of the milks in Table 1.

To summarize, the MMP of milk FA from women who consumed a variety of test and indigenous diets were lower than or near body temperature. The MMP of milk FA from women who consumed high-carbohydrate diets were near 37.5°C. Liquidity of the FA was maintained. The results indicate the ability of the mammary gland to synthesize TAG that will be liquid at body temperature. Our results are probably applicable to other particles that transport TAG, such as chylomicrons.

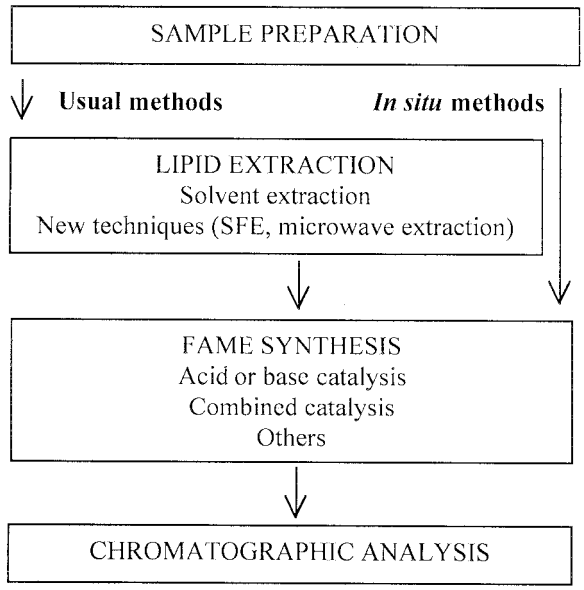
Development in Lipid Analysis: Some New Extraction Techniques and *in situ* Transesterification

Ana I. Carrapiso* and Carmen García

Laboratory of Food Technology, Extremadura University, 10071 Cáceres, Spain

ABSTRACT: The development of methods for analyzing fatty acids that provide rapid and reliable results is currently in great demand. Recently, different lipid extraction procedures such as microwave or supercritical fluid extraction have been researched. Both procedures avoid the use of large volumes of solvents and provide rapid lipid isolations. Only a few papers have reported work on microwave extraction, but many studies about supercritical fluid extraction have been carried out and have been gaining acceptance within the scientific community. Avoiding the lipid isolation step, by synthesizing fatty acid esters by simultaneous lipid extraction and derivatization through *in situ* reactions, has also been proposed. The saving of time and reagents is significant. Owing to the differences among the procedures, some knowledge of their characteristics is essential in order to improve methods and achieve reliable and accurate results. Clearly, results depend on factors such as the type of catalysis selected, the use of nonpolar solvents, heating applied during the synthesis, and the degree of suitability of the procedure chosen for the particular features of each sample.

Paper no. L8465 in *Lipids 35,* 1167–1177 (November 2000).



SCHEME 1

In recent years, the analysis of fatty acids has gained in importance because of their nutritional and health implications. The beneficial relation between n-3 fatty acids and chronic diseases such as atherosclerosis (1) or rheumatoid arthritis (2) has been known for a number of years. In addition, the accuracy and the usefulness of fatty acid analysis to determine fat content have been the focus of recent works (3,4) and have brought about the new fat definition of the Nutrition and Labeling Education Act (NLEA) (5).

Fatty acids are determined mainly by gas–liquid chromatography and flame-ionization detectors (FID). In accordance with fatty acid characteristics, chromatographic analysis is applied to fatty acid esters such as methyl (6,7), isopropyl (8) or butyl esters (9) instead of fatty acids since the analysis is more accurate and selective. Fatty acid methyl esters (FAME) are prepared more often than others in biological tissues and foods because of the lower temperatures required to change their volatility, thus improving peak shape and resolution for the more common fatty acids (14:0–22:0). To avoid interference in the FAME synthesis, lipids are usually extracted from samples with organic solvents. The whole procedure is time-consuming and expensive, and therefore several options have been attempted to make it easier. Some knowledge of these methods and their performance in lipid extraction and FAME synthesis is required before one can decide which method to use.

In line with these facts, the present work reviews (i) advances in isolating lipids (focusing on microwave and supercritical fluid extractions) and in synthesizing FAME (focused on *in situ* synthesis) (Scheme 1) with respect to their feasibility to obtain accurate and reliable results and (ii) critical conditions and limitations of their application. Since most attention is paid to *in situ* transesterification methods, this review will be restricted to research related to total fatty acid composition. The reader will need to consult alternative procedures if separation and characterization of individual lipid classes is desired.

EXTRACTION METHODS: NEW TECHNIQUES

Currently, a large number of methods are available for extracting lipids from biological materials. Most of them use or-

ganic solvents, usually in mixtures such as chloroform and methanol, as in the Bligh and Dyer (10) and Folch *et al.* (11) procedures. These methods often produce large amounts of hazardous solvent wastes and are generally cumbersome. Automated extraction equipment such as the Soxhlet or Goldfisch apparatus has been successfully described (12,13), but they require long extraction times. The interest in lipid extraction and the lack of efficiency found in some cases have led to continual research on this topic (13,14). Furthermore, the need for easier and quicker analyses has prompted the development of new techniques. Among them, the more outstanding have been in the use of microwaves and supercritical fluids as well as fatty acid extraction combined with ester synthesis in a single step.

The use of microwaves. The use of microwaves for isolating lipids has recently been reported. To date, their application has been limited and focused only on the digestion of samples for measuring trace metals (15–17), and on the extraction of organic contaminants (18–22). However, microwave technology has allowed the development of rapid, safe, and cheap methods for extracting lipids and does not require samples devoid of water (23).

The feasibility of microwave irradiation for extracting lipid was first reported in the mid-1980s. Ganzler *et al.* (24) developed a microwave extraction method that proved to be more effective than the conventional procedure in isolating lipids and pesticides from seeds, foods, feeds, and soil. This improvement was obtained by irradiating the mixture of a sample and an appropriate solvent several times for 30 s each. Recently, extraction equipment that combines microwave energy with small volumes of solvents has appeared, resulting in the procedure known as microwave-assisted extraction. Results from various types of biological samples obtained by this method were qualitatively and quantitatively compared to the Folch *et al.* method (11) in feeds and powdered rat for all classes of lipids (25), and these were also similar to a solvent extraction method with a previous hydrolysis in milk and egg powders and meat samples (23). Partial extraction without solvents has also been useful in studying qualitatively fatty acids from adipose tissue (26), although this method has a limited application: it is appropriate only for samples with a high lipid content, and a validation must be performed because fatty acid profiles can vary according to the extraction method and its efficiency (27).

Although treatments with microwave energy can result in lipid oxidations and in quantitative modifications in the fatty acid composition (28), these changes seem to be imperceptible in the usual conditions (26,29,30). In fact, the irradiation provides selective heating of the sample–solvent mixture, and hence lipids may undergo conditions even less adverse than in some solvent extraction procedures which include heating.

Furthermore, microwave technology can be used for performing chemical reactions, such as hydrolysis (31,32), FAME synthesis (33) and *in situ* derivatizations (extraction and simultaneous reaction) such as ethylations (34).

Up to now, only a few studies about microwave lipid extraction have been reported. However, in view of its growing use for isolating organic compounds and its significant advantages, the future introduction and dissemination of microwave equipment seem to be assured for lipid extraction.

The use of supercritical fluids. Supercritical fluid extraction (SFE) has received increasing attention as an alternative to conventional extraction methods (35). Not only is there a significant reduction in the use of organic solvents but concern about waste is also avoided. Although the time reduction is not so great as in some microwave procedures, SFE has gained much more widespread acceptance. It potentially causes fewer adverse conditions to the fatty acids owing to the low temperature of the extractant fluid, usually supercritical carbon dioxide (S-CO_2).

Several conditions must be improved to achieve suitable and reliable results (36). Optimal temperature and pressure are critical because they affect the extraction yield (37–39) and the extract composition (39,40). Extractions that use only S-CO_2 usually yield good recoveries of nonpolar lipids (41). However, polar lipids may remain unextracted because of their lower solubility in S-CO_2, and therefore samples containing a certain quantity of these types of lipids (e.g., milk) may present extraction difficulties. To improve the extraction of nonpolar lipids, the polarity of S-CO_2 can be varied by using solvents such as methanol, ethanol, or even water. Several researchers have reported that lipid solubility in S-CO_2 is greatly increased by adding ethanol, and some phospholipids are extracted at levels directly proportional to the added ethanol (42,43). The presence of water dissolved in the supercritical fluid also increases the solubility of polar compounds, and it has been used successfully to analyze several dairy products (44). Sample preparation must be considered as well. Particle size affects lipid recovery since it influences the surface area of sample exposed to S-CO_2 (36). The moisture content of samples also affects the extraction efficiency by conditioning their surface structure (45). High moisture content reduces S-CO_2-sample contact owing to the pasty consistency of samples, and moisture acts as a barrier to the diffusion of S-CO_2 in the sample as well as the diffusion of lipids outside the sample (46). In this way, an increase in lipid recovery with decreased moisture content has been demonstrated in wet samples such as meat (47) and fish (48), although moisture does not affect extractability at a low content (48–51). Therefore, samples with high moisture content are usually freeze-dried before the S-CO_2 extraction to improve efficiency (38,47,48,51,52).

Several researchers have compared SFE with conventional extraction methods. Ikushima *et al*. (51) reported yields similar to those from a hot hexane extraction. An S-CO_2 method obtained recoveries of 97–100% when compared to a Soxhlet extraction in potato chips and puff-dried products (53), seeds and seed meals (54), and several other food products (55). King *et al*. (56) concluded that there were no significant differences between fatty acids extracted with an SFE method and with the solvent extraction step of the NLEA procedure in beef samples. Berg *et al*. (57) showed that results for total fat

and several lipid classes in meat coincided with those from the Bligh and Dyer procedure (10), and yields reported by Maness *et al*. (58) and Melinz *et al*. (59) seem to be similar to those obtained with conventional methods. Likewise, fatty acid contents determined by an SFE method and by an acid hydrolysis solvent extraction procedure were comparable in beef and bakery samples (60). Cheung *et al*. (39) showed significantly higher recoveries of lipid and fatty acid contents with SFE than with a chloroform and methanol Soxhlet extraction in seaweeds. Dionisi *et al*. (44) reported satisfactory results for fat content and fatty acid profiles in several dairy products, although for other samples the recovery was only between 83.1 and 96.4%. Similarly, Zou *et al*. (61) showed that SFE and conventional extraction (acid hydrolysis and diethyl ether extraction) were statistically equivalent for some bakery products, whereas for others (cereal matrices subjected to baking or toasting) the treatment by acid hydrolysis released some bound fat not otherwise available for extraction.

Results mentioned above show that SFE could replace solvent extraction methods in a large variety of samples. In fact, SFE has recently been included in the recommended methods from the Association of Official Analytical Chemists (AOAC) to extract fat from oilseed (62). However, for materials with strong interactions between lipids and matrix, methods involving alkaline or acid pretreatment could be required. Furthermore, the simultaneous extraction and FAME synthesis have been reported (63–65), and the feasibility of combining lipases with S-CO_2 to synthesize esters *in situ* has been demonstrated (66,67). At the moment the main shortcomings are the cost of supercritical extraction equipment, the extraction of nonfat material such as water (46,49,68,69), and incomplete lipid extractions under some conditions. Consequently, further development is needed since each biological system is unique. Conditions must be investigated and improved in order to optimize yields for each sample type.

The in situ *synthesis of FAME. In situ* ester synthesis has also been a focus of attention. Although it was proposed as early as 1963 (70), most procedures have been performed for only a few years. The separate lipid extraction step is avoided, and fatty acids are simultaneously extracted and transesterified, allowing for a significant reduction in the length of the total procedure, for a saving of time and work, and for the use of minimal sample amounts. The use of reagents and solvents is reduced, the analysis is less expensive and easier, and the concern about waste disposal is avoided. Moreover, the temperature and reaction time required for the synthesis do not seem to be increased after elimination of the separate lipid extraction step. Therefore, lipids experience fewer adverse conditions than in conventional procedures that include the lipid extraction step and subsequent derivatization. Many studies demonstrate that *in situ* procedures often bear comparison with conventional methods, and fat can be estimated using an internal standard. In spite of important limitations such as the restriction to analyzing only total fatty acids from samples, these procedures offer the chance to derivatize fatty acids from the separate lipid classes scraped from thin-layer chromatography (TLC) plates.

FAME SYNTHESIS AND *IN SITU* PROCEDURES

General considerations. Before performing the FAME synthesis, a certain knowledge about reaction principles is required so that accurate and reliable results will be obtained by using brief procedures for each sample type. Derivative reactions are usually catalyzed by acidic or basic media (Table 1), but they can also occur in the presence of diazomethane or other catalysts. The reactions usually occur with the following: (i) free fatty acids in media with acid pH (Eq. 1) or with diazomethane (Eq. 2). The reaction is called esterification or methylation.

$$R'-CO-CH + CH_3-OH \overset{H^+}{\rightleftharpoons} R'-CO-OCH_3 + HOH \quad [1]$$

$$R'-CO-OH + CH_2N_2 \longrightarrow R'-CO-OCH_3 + N_2 \quad [2]$$

(ii) fatty acids included in complex lipids by *O*-acyl bonds (ester) (e.g., triacylglycerols, phospholipids) in acid or basic media. The reaction is called transesterification or transmethylation (also known as alcoholysis or methanolysis) (Eq. 3).

$$R'-CO-OR'' + CH_3-OH \overset{H^+ \text{ or } OCH_3^-}{\rightleftharpoons} R'-CO-OCH_3 + R''-OH \quad [3]$$

(iii) fatty acids from N-acyl complex lipids (amine) in acid medium (Eq. 4), although special considerations have to be taken into account.

$$R'-CO-NHR'' + CH_3-OH \overset{H^+}{\rightleftharpoons} R'-CO-OCH_3 + R''-NH_2 \quad [4]$$

Given that most fatty acids in biological samples are included in triacylglycerols and phospholipids, the derivatization of fatty acids from samples is mainly a transesterification. Hence transesterification often refers to FAME synthesis from fatty acid mixtures. The term *in situ* is used when the derivatization occurs without a previous extraction step to isolate lipids, not only from tissue matrixes, but also from other matrixes such as adsorbents from TLC.

The two main concerns in performing *in situ* reactions are lipid solubilization (advisable to achieve fast and complete reactions) and prevention of the interference of water or other

TABLE 1
Characteristic of Catalytic Medium in Esterification/Transesterification Reactions

	Acidic	Basic
Temperature	High	Ambient
Time	Minutes–hours	Seconds–minutes
Esterifying power	Medium–high	No
Transesterifying power	Low	High
Risk of saponification	Low	High
Water interference	Low	High

compounds. Therefore, sample features must be considered to decide which is the best solvent, whether a previous step is required to achieve samples devoid of water, and what type of catalyst can be applied.

The effectiveness of the solvent depends on its ability to solubilize lipids (and specifically nonpolar lipids due to their limited solubility in the methanolic medium used for the synthesis) and to create a one-phase system with lipids, methanol, and other reagents. If water is present, it must also be integrated into the system. When a derivatization method is performed with isolated lipids, problems usually do not appear because water is absent, but in using *in situ* procedures water is not always excluded. Above specific water levels, triacylglycerols, particularly those with long-chain saturated fatty acids, tend to precipitate and react much more slowly (71) in media that include most frequently used solvents, although this drawback has not been reported with dioxane (71, 72). In this way, 10% water in an alkaline methanolic medium with hexane is enough to interfere noticeably with the reaction (73). In acidic methanolic media with toluene, FAME recovery remains unaffected in the presence of 5 (74) or 20% water (75), although 40 μL (larger than the sample weight) (76) and 100 mg (about 20–100% of the sample weight) (77) cause a drastic interference.

The concern for water content depends not only on the catalyst and the moisture content of the sample but also on its lipid content, which determines the sample amount required and thus the amount of water introduced. Moreover, water may interfere with the reactions since it is a stronger electron donor than methanol. Hence *in situ* synthesis must be carried out in samples with low moisture contents, or after removing water to below critical limits. This pretreatment adds the advantage of facilitating the penetration of solvents and is often used prior to the lipid extraction (7), although in some samples the extraction yield may be reduced as a consequence of the alteration of the physical structure of the matrix (78). In performing *in situ* FAME synthesis, different procedures have been used to remove water. 2,2′-Dimethoxypropane, a reagent which has been used as methylating reagent (79), was successfully utilized as a water scavenger, but spurious peaks on the chromatograms were ascribed to the unreacted reagent (76,80). These peaks can be avoided by removing both the acetone produced in the reaction and the unreacted 2,2′-dimethoxypropane before adding the catalyst, so that the mixture with the catalyst is prevented and the artifacts are absent (81,82). Oven-drying procedures can bring about alterations in unsaturated fatty acids (75,78), so when pretreatment is necessary, freezing-drying the samples is mainly chosen for removing water.

In choosing the catalytic reagent, some sample characteristics must be considered, such as the occurrence of free fatty acids and the type of bond of the fatty acids linked, the feasibility of using strong heating conditions, and the accuracy required. Most *in situ* derivatization procedures are similar to those applied to lipid extracts (Table 2).

Catalysis with diazomethane. This reagent provides fast esterifying reactions, but it shows no ability to catalyze transesterifying reactions in the usual conditions. Its use has been limited owing to its short shelf life and the great care required in handling it. Its feasibility through *in situ* methods for quantifying plasma free fatty acids more quickly (about 15 min) than conventional methods (extraction, fractionation, and esterification steps) has been reported (83), although the bibliographic values shown as comparison were larger than those obtained by using this procedure.

Basic catalysis. Derivatizations performed in the presence of basic catalysts have advantages such as their speed (84–86) and the mild heating conditions needed, which can be as low as room temperature (71,72,87). For these reasons, this type of catalysis is recommended in samples with short-chain fatty acids, such as milk fats or coconut oil, given that these fatty acids are highly volatile and conventional methods fail in quantifying them (88). It is also a useful alternative to acid-catalyzed reactions when samples contain acid-labile fatty acids, e.g., those with cyclopropene rings, epoxyl groups, or some conjugated unsaturations, present in some vegetable tissues (6).

However, alkali-based transesterification has two main shortcomings. First, free fatty acids (71,89,90) and sphingolipids (91) remain unreacted. Second, esters undergo saponification reactions. In the presence of methoxide, water yields free hydroxide ions (Eq. 5).

$$CH_3O^- + H_2O \rightleftharpoons CH_3OH + OH^- \quad [5]$$

In the presence of these ions, the hydrolysis of sample esters

TABLE 2
Characteristics of the Main Catalysts Used in *in situ* Esterification/Transesterification

	Acid in methanol			Alkali in methanol	
Reagents	HCl	H_2SO_4	BF_3	$NaOCH_3$	TMG
Concentration	5%	1–2%	6–14%	0′2–2 N	1:4 (vol/vol)
Temperature	60°C–refluxing			Ambient–refluxing	
Time of reaction	30 min–2 h		2–60 min	s–1 h	s–5 min
Form of starting material	Gas/liquid	Liquid	Gas	Metal	Liquid
Ease of preparation	No	Yes	No	No	Yes
Introduction of water	No	Yes	No	No	Yes
Danger of preparation	Yes	No	Yes	Yes	No

and the newly generated FAME occurs (Eq. 6). It is irreversible because the carboxylate ion is not subjected to nucleophilic attack by the alcohol as a consequence of its negative charge (6). Furthermore, Na^+ or K^+ ions join with it to form soap, which can promote emulsifications and delays in the FAME extraction (92).

$$R'-CO-OR'' + OH^- \longrightarrow R'-CO-O^- + H-OR'' \quad [6]$$

According to Suter *et al*. (71), 6% water in samples is stoichiometrically enough to cause a complete saponification, and so these methods are usually influenced by the belief that the complete absence of water is a prerequisite. However, more than 80 yr ago Reid, Anderson, and Pardee proved that base-catalyzed transesterification is about 1,500 times faster than saponification (71). This fact was later confirmed by Glass (89), and this enables suitable FAME recoveries even in the presence of water, provided that the reaction has been stopped before significant saponification has taken place (71,92), usually by adding HCl to neutralize the pH of the medium.

Nonpolar solvents used in *in situ* alkali-based transesterification have been hexane (73), petroleum benzine (87), and dioxane (71,72), although others can be applied. Despite the fact that dioxane integrates water better in the reaction medium, it has a flaw: in using polar columns, it can be confused or overlapped with methyl butyrate (71). Chloroform should be excluded because in the presence of methoxide it presumably produces dichlorocarbene, which can react with the double bonds of unsaturated fatty acids (6).

Solubilization and the subsequent reaction of lipids are usually performed without problems. However, when fatty acids remain partially unsolubilized and unreacted, an increase in the temperature or in the time of reaction is not advised owing to the occurrence of saponification and degradation in unsaturated fatty acids. As a feasible option in samples with enclosed lipids, such as meat and dry meat, solubilization can be achieved by first refluxing samples in dimethylformamide (71,72).

Among the reagents used for *in situ* base-catalyzed reactions, sodium methoxide has been the most widely used. It is prepared by adding sodium metal in dry methanol (Eq. 7), and it can be stored for some months.

$$2CH_3OH + 2Na \longrightarrow 2Na^+OCH_3^- + H_2 \quad [7]$$

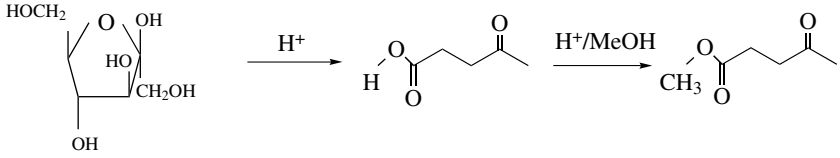
Initially, sodium methoxide was applied *in situ* to rapeseeds with satisfactory results (93). Long *et al*. (73) used sodium methoxide and hexane in dry grain and dairy products at 80°C for 10 min, and found that the results were reproducible and quantitatively comparable to those from the AOAC method (ether extraction before FAME synthesis with KOH and methanolic BF_3) (94) for all the determinations, both as individual and as total FAME. Later, Cantellops *et al*. (95) performed a similar method in infant formula powder, with results comparable to those from the AOAC method (96) (also ether extraction, KOH, and methanolic BF_3), although some differences in the contents of some groups of fatty acids were reported. Suter *et al*. (71,72) applied sodium methoxide to a wide variety of foods at room temperature for 60–90 s with dioxane as the nonpolar solvent; the work focused on the fat content determination (by conversion of FAME content to triacylglycerols), and *in situ* values were almost comparable to those from official methods.

A special type of alkaline catalyst is the organic base reagent. Not only are these reagents strong bases used as catalysts for transesterification reactions, but they also react with free fatty acids, being easily pyrolyzed in the injection port of the gas chromatograph to yield methyl esters (6,97). In this way, tetramethylguanidine (TMG) seems to be suitable for performing *in situ* derivatizations. Schuchardt and Lopes (85) used it in refined and in degummed fats and oils. Heating for 2 min at 100°C was enough to obtain more than 99% FAME yield (determined by ^1H nuclear magnetic resonance spectroscopy) even in the presence of 6.7% free fatty acids, and therefore the authors suggest that guanidinium carboxylate (formed by the joining of free fatty acids and the guanidinium ion) can be attacked by methanol before the injection. The procedure did not induce *trans*-isomerization in unsaturated fatty acids, according to the infrared spectra, and fatty acid profiles were comparable to those obtained using methanolic BF_3. Marx and Stender (87) also applied *in situ* TMG and petroleum benzine (nonpolar solvent) to oilseeds, and in most cases results for the fatty acid contents were similar to those obtained using a conventional method.

Acid catalysis. The ability to catalyze derivatization from all the fatty acids (free or linked) has led to a widespread use of acid catalysis. However, heating is required and the reaction time needed is longer than in basic catalysis. In samples containing sugar, a chromatographic peak eluted just after lauric (12:0) acid methyl ester. This peak corresponds with methyl levulinate, which appears when this type of sample is subjected to heating in an acid medium and later esterified (Eq. 8) (98). In any case, these reactions involve mainly a gravimetric hazard in lipid extraction procedures with previous acid hydrolysis (99), given that in chromatographic analysis the methyl levulinate peak can be identified.

Different solvents have been used in performing *in situ* acid-based methods: hexane (100–102), tetrahydrofuran (79), benzene (74,75,79,103,104), toluene (75,77,79,105), and chloroform (75). Pentane, hexane, or isooctane were not beneficial when used to replace benzene (74), and benzene and toluene extracted FAME better than chloroform (75). Owing to the toxicity of benzene, several researchers have preferred toluene. Although the peak for toluene can overlap the peaks for short-chain FAME, no problems were reported in analyzing milk fat (75), although quantitative results were not suitable.

In samples with enclosed lipids and therefore slow FAME synthesis, the reaction time may be increased because no saponification appears. Harsh conditions (high temperatures, heating for long time) can cause degradation in fatty acids,



Fructose (levulose) Levulinic acid Methyl levulinate [8]

but mild conditions yield low FAME recoveries. Hence, heating must be tailored to the minimal requirement, which varies as a result of the procedure applied (e.g., catalyst, nonpolar solvent, reagent ratio) and is also a consequence of the type of samples (106). The main concern is water interference, as mentioned above, although the derivatization is affected to a lesser extent than in basic catalysis. Hydrogen chloride, sulfuric acid, and boron trifluoride in methanol are the reagents used most frequently for *in situ* reactions.

Methanolic hydrogen chloride (HCl) is, according to some authors, the best general purpose esterifying agent. It is the most widely mentioned one being used in *in situ* procedures, probably because it is affected less by small amounts of water. With regard to its drawbacks, its unstability in storage, its inconvenient preparation, and the production of artifacts under certain conditions (101,107) must be mentioned. Methanolic HCl is usually prepared by bubbling dry gaseous hydrogen chloride into methanol, but adding acetyl chloride to anhydrous methanol has been preferred for performing *in situ* procedures. The methyl acetate which is generated does not interfere with FAME synthesis at this concentration, but the reagent is useful only for a week (6).

The *in situ* acid-based procedures are quite varied, both in the heating and in the use of nonpolar solvents, and therefore the accuracy of the results has been different. After heating with benzene for 2 h at 70°C, Outen *et al*. (103) quantified fatty acids with an accuracy similar to that of a conventional method (hexane extraction after basic hydrolysis and reaction with methanolic HCl) in feeds, digesta, and feces from sheep. Suitable results in mammalian tissues were also obtained by Shimasaki *et al*. (82) using a similar method. Lepage and Roy (104) successfully applied methanolic HCl and benzene at 100°C for 60 min to fatty acid standards and triacylglycerols in mammalian tissues. The same procedure was later used in all classes of lipids, obtaining FAME yields higher than in the transesterification of lipid extracts (74), and in plasma fatty acids (108). After heating at 80°C for an hour, Browse *et al*. (76) reported low recoveries (15–20% lower than the conventional method) in fresh leaf tissues, probably owing to the absence of a nonpolar solvent during the reaction and the incomplete FAME extraction before adding the internal standard. Sukhija and Palmquist (75) improved the method of Outen *et al*. (103) and achieved results which were quantitatively comparable to those of the conventional method in feedstuffs and feces, although only the fatty acid profile was similar in milk fat. Ulberth and Henninger (77) replaced benzene with toluene in analyzing in fats, oils, and processed foods, obtaining fatty acid contents higher than these in the conventional method with acid hydrolysis and ether extraction but lower than others with chloroform and methanol extraction. Comparable results were obtained with the same procedure in fish oil capsules and fish fillets (105). Bohnert *et al*. (102) applied methanolic HCl and hexane at 100°C for an hour to infant formulae, producing results statistically comparable to those obtained by chloroform and methanol extraction and methanolic HCl catalysis. Sönnichsen and Müller (109) reported a low recovery (70–83%) by using two internal standards in fungal mycelia after heating at 100°C for an hour with hexane, although no comparison to an established method was included. In any case, these authors propose a correction factor to quantify the total fatty acid content.

Methanolic HCl has also been used *in situ* in methods employing milder heating conditions to selectively methylate plasma free fatty acids, this adaptation was made because they are esterified much faster than other lipids being transesterified. After heating at 25°C for 45 min, Lepage and Roy (110) reported results similar to those obtained with the conventional method, and no significant hydrolysis of standards of triacylgylcerols, cholesterol esters, and phospholipids was found. Welz *et al*. (101) (who also heated samples at 25°C for 45 min) confirmed the feasibility of a similar method in human plasma, rat liver microsomes, and encapsulated fish oil; and they found that trioleate, cholesterol esters, and lecithin were converted into FAME to a neglectible extent (less than 3%). In any case, the low margin of error allowed in these methods is an important shortcoming.

Catalysis with methanolic sulfuric acid is similar to that one previously described. This reagent has been widely used because of its long shelf life and easy and safe preparation, and some researchers consider it to be the most useful. Decomposition of polyunsaturated fatty acids may occur if the reagent is used carelessly or under certain conditions (6), as with acidic reagents (111).

Methanolic sulfuric acid was applied *in situ* by Dugan *et al*. (112) in biological materials with diethyl ether at a low temperature. The method was also successfully used in seed crops and flour (113), and 98% recovery was obtained in tripalmitin after heating for a rather long time (3 h at 95°C) (114). Harrington and D'Arcy-Evans (115) performed an *in situ* method to synthetize large amounts of FAME from sunflower seeds, resulting in a yield larger than that from a conventional method (hexane extraction). However, the length of time for both procedures was long (above 4 h at 100°C for the catalysis). Dahmer *et al.* (100) used a short reaction time (20 min at 90°C) and hexane as the nonpolar solvent, and obtained only 70% recovery from soybean seeds, probably owing to insufficient heating. Garcés and Mancha (80) also carried out a method with methanolic sulfuric acid

and several solvents in fresh plant tissues with different water and lipid contents, reporting results comparable to those obtained by using the Hara and Radin procedure (116).

Methanolic boron trifluoride (BF_3) is one of the most commonly used catalysts for FAME preparation because of its high esterifying power, although this does not necessarily mean that this reagent is the best (7). In fact, methanolic BF_3 is toxic, expensive, and relatively unstable in storage. It is prone to the formation of artifacts (117), and the use of old or too highly concentrated solutions may result in the loss of large amounts of polyunsaturated fatty acids (6). Furthermore, this reagent is quickly destroyed in the presence of water, and therefore must be applied to water-free samples (118). In fact, most *in situ* procedures involving BF_3 have been performed in samples devoid of large amounts of water, such as lipids from TLC plates or freeze-dried samples.

Initially, *in situ* derivatization by using methanolic BF_3 was reported successfully on microorganisms (70). Later, Ohta *et al*. (119) treated plasma lipids contained in silica gel scraped from TLC plates at 100°C for 30 min, reporting results that were quantitatively similar to those from a conventional method. Sattler *et al*. (118) demonstrated that their method (110°C for 90 min) provided recoveries higher than the conventional procedure [lipid extraction with Folch *et al.* (11) method and also methanolic BF_3] in the main lipoprotein classes. Later, Sattler *et al*. (120) successfully applied the method to lipoprotein and macrophage lipid subclasses scraped from TLC plates. House *et al*. (121) reported a high FAME yield in soy oil after heating it with benzene at 100°C for 45 min, but recoveries in foodstuffs were unsatisfactory owing to inconsistent results and distorted fatty acid profiles, probably due to the presence of water in the samples. Rule (106) showed, by heating at 80°C for 2 h without a nonpolar solvent, a similar effectiveness to that of a conventional method [extraction by Bligh and Dyer method (10) and FAME synthesis with BF_3] in adipose tissue and muscle, and a higher recovery in liver from lambs.

Methanolic aluminum chloride can be considered as an atypical acid catalyst: it provides pH values below 1, but shows no ability to derivatizate free fatty acids. Segura (122) investigated its *in situ* application (at 100°C for 60 min) in milk, several vegetable oils, and in the presence of silica gel. Although fatty acid values seem to be suitable, aluminum chloride has no advantage over the much faster basic catalysts.

Acid catalysis after alkali-catalyzed reaction. As was mentioned above, acid catalysis has significant advantages over basic catalysis. To overcome the large reaction time needed, the consecutive use of basic and acid reagents was proposed. Fatty acids from triacylglycerols are saponified or transesterified by fast reactions in basic media, and free fatty acids are later esterified in an acid medium, making use of its esterifying power, which is higher than transesterifying. The first process may consist of a hydrolysis (e.g., KOH in ethanol), but more often it is a transesterification (e.g., methanolic KOH, NaOH, or sodium methoxide). In the subsequent acid catalysis, sulfuric acid may be used, but BF_3 is usually preferred because of its higher esterifying power. The reduction of time in the combined procedure quickly gave these methods popularity. Moreover, they are especially useful for analyzing *N*-acyl lipids. Basic catalysis is unsuitable for it, and the rigorous conditions required for the FAME synthesis in acid medium led to the formation of artifacts from the long-chain bases. Therefore, when both the fatty acid and base components have to be analyzed, an aqueous alkaline hydrolysis before acid catalysis is preferred (6).

In situ procedures with methanolic BF_3 after an alkali-based catalysis have been reported by several researchers. Lambert and Moss (123) found that fatty acid from bacterial suspensions could be determinated by *in situ* derivatization. Divakaran and Ostrowski (124) applied methanolic sodium hydroxide to fish eggs for 10 min of refluxing prior to the methanolic BF_3 catalysis for 2–3 min, and no significant differences were reported for most individual fatty acid contents with respect to a conventional method [solvent extraction method (94) and the same catalysis]. Guillou *et al*. (125) applied the same method to brook charr tissues. Results in liver and skin were similar to those obtained with the AOAC (126) method, and in flesh samples the *in situ* procedure showed significantly higher fatty acid contents. Park and Goins (90) used a similar method (heating for 10 min at 90°C during the two steps) in several foodstuffs and obtained fatty acid profiles similar to those obtained by using a conventional procedure (no quantification was included).

Final considerations. In spite of the general assumption that lipid extraction is required to obtain usable results, numerous studies about *in situ* FAME preparation seem to contradict this. Owing to the great advantages of saving the extraction step prior to the FAME synthesis, *in situ* procedures mean a significant advance to the widespread application of fatty acid analysis. However, some considerations must be taken into account.

When the type of catalysis chosen is appropriate and conditions are favorable (water content suitable; the heating and the amount of sample and reagents adapted; the use of nonpolar solvents), no obstacle appears in theory to obtaining results which are qualitatively and quantitatively comparable to those from conventional methods. In fact, lipids do not undergo any further adverse conditions, and the lipid extraction can be even more exhaustive since samples are subjected to acid or basic treatments and extraction with mixtures of polar (methanol) and nonpolar solvents while heating is applied. Therefore, digestion, extraction, and derivatization are all included in one step; thus, the experimental error is potentially less. Nevertheless, in real conditions samples often include some amount of water or lipids that remain unreacted (e.g., owing to strong bonds with the matrix), and in some cases the pretreatment required to obtain reliable and accurate values can lead to awkward procedures. In any case, *in situ* methods seem to be a feasible and useful option in most samples, and advantages are especially significant for samples that are prone to forming emulsions during lipid extraction (the saving of time is significant) or for analyzing fatty acids when

only small sample sizes are available (e.g., lipids from plasma or from TLC). However, prior to their application, some knowledge of their shortcomings and how to avoid them is advisable. Research about the selected method and each type of sample may be conducted for the kind of reaction to be adapted. In addition, although *in situ* synthesis is usually carried out in the presence of an acidic reagent, the use of basic catalysis, which provides much faster reactions, should be attempted. Hence a good knowledge about sample characteristics and the shortcomings of each type of catalysis seems to be essential in order to achieve accurate and reliable results using brief analytical procedures.

Polyunsaturated Fatty Acids in Plasma Lipids of Obese Children With and Without Metabolic Cardiovascular Syndrome

Tamás Decsi*, Györgyi Csábi, Katalin Török, Éva Erhardt, Hajnalka Minda, István Burus, Szilárd Molnár, and Dénes Molnár

Department of Paediatrics, University of Pécs, Pécs, H-7623 Hungary

ABSTRACT: Previously we reported significantly higher values of γ-linolenic acid (GLA, 18:3n-6), dihomo-γ-linolenic acid (DHGLA, 20:3n-6), and arachidonic acid (20:4n-6) in plasma lipid classes in obese children than in nonobese controls. In the present study, fatty acid composition of plasma phospholipids (PL) and sterol esters (STE) was determined by high-resolution capillary gas–liquid chromatography in obese children with and without metabolic cardiovascular syndrome [MCS: defined as simultaneous presence of (i) dyslipidemia, (ii) hyperinsulinemia, (iii) hypertension, and (iv) impaired glucose tolerance] and in nonobese controls. Fatty acid composition of PL and STE lipids did not differ between obese children without MCS and controls. Obese children with MCS exhibited significantly lower linoleic acid (LA, 18:2n-6) values in PL (17.43 [2.36], % wt/wt, median [range from the first to the third quartile]) than obese children without MCS (19.14 [3.49]) and controls (20.28 [3.80]). In contrast, PL GLA values were significantly higher in obese children with (0.13 [0.08]) than in those without MCS (0.08 [0.04]), whereas STE GLA values were higher in obese children with MCS (1.04 [0.72]) than in controls (0.62 [0.48]). DHGLA values in PL were significantly higher in obese children with MCS (4.06 [0.74]) than in controls (2.69 [1.60]). The GLA/LA ratio was significantly higher, whereas the AA/DHGLA ratio was significantly lower in obese children with MCS than in obese children without MCS and in controls. In this study, LA metabolism was affected only in obese children with but not in those without MCS. In obese children with MCS, Δ6-desaturase activity appeared to be stimulated, whereas Δ5-desaturase activity appeared to be inhibited. Disturbances in LA metabolism may represent an additional health hazard within the multifaceted clinical picture of MCS.

Paper no. L8486 in *Lipids 35,* 1179–1184 (November 2000).

Prevalence of childhood obesity is high and still increasing in many affluent countries. In children and adolescents investigated from 1988 to 1991 in the United States, the prevalence of overweight based on body mass index was 11% according to the 95th and 22% according to the 85th percentile cutoff points (1). In Hungary, the prevalence of childhood obesity defined as body mass index exceeding the 90th percentile is around 13% (2). The long-term morbidity and mortality associated with childhood obesity are closely connected to the cardiovascular and metabolic status detectable in the pediatric age group (3). Therefore, identification of cardiovascular risk factors in obese children is of practical importance.

Previously we found significantly higher percentage contributions of the n-6 long-chain polyunsaturated fatty acids (LCPUFA), γ-linolenic acid (GLA, 18:3n-6), dihomo-γ-linolenic acid (DHGLA, 20:3n-6), and arachidonic acid (AA, 20:4n-6) to the fatty acid composition of plasma lipid classes in obese children than in nonobese controls (4). Since LCPUFA are prone to lipid peroxidation, their enhanced availability in circulating lipids may represent a further risk factor of atherogenesis in obese children. Moreover, nonphysiological LCPUFA content of membrane lipids may also influence receptor functions and signal transduction.

However, data on LCPUFA status in obese subjects are controversial. A significantly lower percentage contribution of AA to plasma phospholipids (PL) was reported in obese than in nonobese adults in one study (5), whereas in another study significantly higher AA values in plasma sterol esters (STE) were found in obese adults than in controls (6). The clear controversy between data obtained in apparently similar studies comparing fatty acids in obese vs. nonobese subjects might be explained by interindividual differences in LCPUFA status in obesity.

Accumulating evidence suggests that a clustering of risk factors such as abdominal adiposity, hyperinsulinemia, impaired glucose tolerance, dyslipidemia and high blood pressure is characteristic of a group of obese individuals who have an especially high risk for cardiovascular morbidity (for recent reviews see Refs. 7,8). The clustering of risk factors is already detectable in the pediatric age group (9,10). In a recent epidemiological survey, we found 9% prevalence of the metabolic cardiovascular syndrome (MCS)—defined as simultaneous presence of (i) dyslipidemia, (ii) hyperinsulinemia, (iii) hypertension, and (iv) impaired glucose tolerance—in obese children referred to medical attention (11). Here we report fatty acid composition of plasma PL and STE lipids in obese children with and without MCS and in nonobese controls.

Abbreviations: AA, arachidonic acid; DHGLA, dihomo-γ-linolenic acid; EFA, essential fatty acid; GLA, γ-linolenic acid; LA, linoleic acid; LCPUFA, long-chain polyunsaturated fatty acid; MCS, metabolic cardiovascular syndrome; PL, phospholipid; PUFA, polyunsaturated fatty acid; STE, sterol ester.

SUBJECTS AND METHODS

The investigations were carried out with obese children referred to the Outpatient Clinic for Obesity of the Department of Paediatrics, University of Pécs (Pécs, Hungary), because of their overweight. The children were free of other known illnesses, were not dieting, and were not participating in physical training programs. The cohort of control children was recruited from children referred to the general outpatient clinic of our department for routine investigations. The study was carried out in accordance with the Declaration of Helsinki II and with approval of the ethics committee of the University of Pécs. Informed parental consent was obtained for each child before enrollment in the study.

Anthropometric measurements were carried out by the same investigator. Body weight was determined to the nearest 0.5 kg with the child dressed only in underwear and wearing no shoes. Height was measured to the nearest 0.1 cm by a Holtain stadiometer (Holtain Limited, Crymich, Dyfed, Britain). The waist and hip circumferences were measured with the subject in the supine position. Body fat was estimated according to Parizková and Roth (12) from five skinfold thicknesses measured on the left side of the body three consecutive times with the help of a Holtain caliper. Lean body mass was calculated by subtracting body fat from actual body weight. Relative body weight was calculated as the ratio between actual body weight and the ideal body weight for age, gender, and height (13). The pubertal stage of the children was determined according to Tanner (14).

Blood pressure was measured according to published recommendations (15) at least five times in each subject on five separate days by the same observer, using a mercury-gravity manometer with proper cuff size in standard conditions. If the average of the five blood pressure values was above the 95th percentile for age and sex, 24-h ambulatory blood pressure monitoring was carried out. Those children whose mean arterial blood pressure values exceeded the 95th percentile value for height and sex (16) were considered to be hypertensive.

Blood samples were taken from the antecubital vein in the fasting state early in the morning. Blood was collected into tubes containing 2 mg/mL EDTA for triglyceride, cholesterol, high-density lipoprotein cholesterol, plasma glucose, and insulin determinations, and into another tube for fatty acid analysis. The samples were centrifuged immediately at 4°C and plasma was stored at –20°C until analysis. Plasma samples were thawed only once.

Plasma glucose concentrations were determined by the glucose oxidase method (17). Plasma insulin concentrations were measured with commercially available radioimmunoassay kits (Isotope Institute of the Hungarian Academy of Sciences, Budapest, Hungary). With this method, the cutoff value for insulin was 18.7 μU/mL (95th percentile value of 100 healthy children). The oral glucose tolerance test consisted of oral administration of glucose (1.75 g/kg body weight, maximum 75 g) followed by plasma glucose and insulin determinations at 30, 60, 90, 120, and 180 min. The test results were evaluated according to published criteria (18,19). Ethical considerations did not allow us to carry out oral glucose tolerance tests in the control subjects.

Triglyceride and cholesterol were determined with an enzymatic kit (Boehringer Mannheim, Mannheim, Germany). High-density lipoprotein cholesterol was measured by the precipitation method of Steele *et al.* (20). Plasma cholesterol, high-density lipoprotein cholesterol, and triglyceride were considered high or low when they fell above or below the recommended value of the Hungarian Lipid Consensus Conference (21): cholesterol 5.2 mmol/L, high-density lipoprotein cholesterol 0.9 mmol/L, and triglyceride 1.5 mmol/L.

Altogether, 180 obese and 239 nonobese children participated in the epidemiological survey investigating the prevalence of MCS (11). We considered children as obese if their body weights exceeded the normal weight for height by more than 20%, and if body fat content was higher than 25% in males and 30% in females. Finally, MCS was diagnosed in 16 of the obese and none of the nonobese children. To the 16 obese children with MCS, 16 obese children who fulfilled none or only one of the four aforementioned criteria of MCS and 16 nonobese control children were assigned by computer-generated simple randomization. This sample size allowed the detection of differences of one standard deviation with an 80% chance at a 5% significance level. Owing to technical reasons, a plasma sample for fatty acid analysis was not available for one obese child with MCS; therefore, one further obese child without MCS was entered into the study.

For fatty acid analysis, plasma lipids were extracted from 0.25 mL plasma with chloroform/methanol (22) after addition of internal standards (phosphatidyl- and cholesteryl pentadecanoic acid, 15:0). Lipid classes were separated on silica gel plates (Nr. 5721; E. Merck, Darmstadt, Germany) with one 18-cm run of hexane/diethlyether/chloroform/acetic acid (105:30:15:15, by vol). Fatty acids in plasma PL and STE were transesterified with methanol and hydrochloric acid (23). Fatty acid methyl esters were determined by high-resolution capillary gas–liquid chromatography using a Finnigan 9001 chromatograph (Finnigan/Tremetrics Inc., Austin, TX) with split injection (ratio: 1 to 15) and a flame-ionization detector. A cyanopropyl column of 40 m length (DB-23, J&W Scientific, Folsom, CA) was used. The temperature program was the following: initial temperature 100°C for 0.1 min, temperature increase by 40°C min^{-1} up to 180°C, 1-min isotherm period, temperature increase by 2°C min^{-1} up to 200°C, 1-min isotherm period, temperature increase by 10°C min^{-1} up to 240°C, 9.9-min isotherm period. The constant linear velocity was 0.3 m s^{-1} (referred to 100°C). Identification of fatty acids was secured by comparison with authentic standards (Nu-Chek-Prep, Elysian, MN).

Results were evaluated with SPSS for Windows, Release 7.5 (SPSS Inc., Chicago, IL). All data except fatty acids have been presented as mean ± SD and were evaluated by analysis of variance followed by the least significant difference comparison test to compare mean values of subgroups. The fatty acid data are presented as median and range from the first to

the third quartile values, because skewed distributions were found especially in fatty acids present at lower concentrations. Fatty acids were analyzed by the Kruskal-Wallis nonparametric analysis of variance followed by Mann-Whitney's two-sided rank test to compare median values of subgroups. Differences were regarded as statistically significant at $P < 0.05$.

RESULTS

Neither obese children without MCS nor controls were absolutely free from cardiovascular risk factors: dyslipidemia, hyperinsulinemia, and impaired glucose tolerance were seen in one, one, and two obese children without MCS, respectively, whereas one control child exhibited dyslipidemia. The subjects' characteristics are shown in Table 1. Sex did not differ among the three groups. The children investigated were in puberty, median Tanner stages for pubic hair/genitalia development were between 3 and 5 in the six subgroups formed on the basis of gender and study stratification. Age did not differ between obese children with and without MCS, whereas control subjects were significantly older than obese children. Body weight, body mass index, and waist/hip ratio were significantly higher in both groups of obese children than in controls, and they were significantly higher in obese children with than in those without MCS. Relative body weight and body fat were significantly higher in both groups of obese children than in controls. Lean body mass was significantly higher in obese children with MCS than in obese children without MCS and in controls. Height was significantly lower in obese children without MCS than in controls. Both systolic and diastolic blood pressures were significantly higher in obese children with MCS than in obese children without MCS and in controls. Plasma triglyceride, cholesterol, and insulin concentrations were significantly higher in obese children with MCS than in obese children without MCS and in controls. Plasma high-density lipoprotein cholesterol and glucose concentrations did not differ among the three groups.

TABLE 1
Characteristics of the Subjects[a]

	Obese, MCS (n = 15)	Obese, no MCS (n = 17)	Control (n = 16)
Sex (male:female)	11:4	11:6	10:6
Age (yr)	13.4 ± 2.1[f]	14.4 ± 2.4[b]	16.2 ± 1.0[b,f]
Weight (kg)	95.5 ± 15.2[d,f]	78.3 ± 17.4[d,e]	60.6 ± 9.2[e,f]
RBW (%)	177 ± 23[f]	163 ± 42[g]	103 ± 10[f,g]
BMI (kg/m^2)	34.2 ± 3.1[b,f]	30.4 ± 6.2[b,g]	20.7 ± 1.9[f,g]
BF (%)	37.8 ± 2.2[f]	36.3 ± 5.9[g]	25.6 ± 5.7[f,g]
LBM (kg)	58.9 ±11.0[b,d]	49.5 ± 9.9[b]	45.8 ± 8.4[d]
Waist/hip ratio	0.88 ± 0.07[b,f]	0.84 ± 0.05[b,d]	0.77 ± 0.06[d,f]
Height (cm)	167 ± 12	161 ± 12[b]	171 ± 9[b]
Systolic BP (mm Hg)	135 ± 6[f,g]	116 ± 9[f]	115 ± 7[g]
Diastolic BP (mm Hg)	83 ± 5[f,g]	69 ± 8[f]	69 ± 8[g]
Triglyceride[b] (mmol/L)	1.67 ± 0.54[d,f]	1.03 ± 0.29[f]	1.06 ± 0.40[d]
Cholesterol[b] (mmol/L)	4.71 ± 0.97[b,c]	4.09 ± 0.65[b]	3.77 ± 0.94[c]
HDL-cholesterol[b] (mmol/L)	1.39 ± 0.19	1.32 ± 0.24	1.33 ± 0.26
Glucose (mmol/L)	4.81 ± 0.64	4.51 ± 0.87	4.49 ± 0.75
IRI (μU/mL)	30.5 ± 14.4[f,g]	10.6 ± 4.3[f]	8.9 ± 4.5[g]

[a]Values are mean ± SD. Means in a row sharing a common roman superscript (b–g) are significantly different ([b,c]$P < 0.05$, [d,e]$P < 0.01$, [f,g]$P < 0.001$) using analysis of variance followed by Student's unpaired t test; MCS, metabolic cardiovascular syndrome; RBW, relative body weight; BMI, body mass index; BF, body fat content; LBM, lean body mass; BP, blood pressure; HDL-cholesterol, high-density lipoprotein cholesterol; IRI, fasting immunoreactive insulin.
[b]Cutoff points of cholesterol, HDL-cholesterol, and triglyceride in children were set by the Hungarian Lipid Consensus Conference (21) as 5.2, 0.9, and 1.5 mmol/L, respectively.

The fatty acid composition of plasma PL and STE lipids is shown in Table 2. Values of total saturated fatty acids in PL were significantly higher in obese children with MCS than in obese children without MCS and in controls. Percentage contributions of palmitoleic acid (16:1n-7) to both PL and STE lipids were significantly higher in obese children with MCS than in obese children without MCS and in controls. In contrast, values of vaccenic acid (18:1n-7) in the PL fraction were significantly lower in obese children with MCS than in obese children without MCS and in controls. Total monounsaturated fatty acid values did not differ among the three groups.

Percentage contribution of linoleic acid (LA, 18:2n-6) to PL was significantly lower in obese children with MCS than in obese children without MCS and in controls. In contrast, PL GLA values were significantly higher in obese children with than in those without MCS, and STE GLA values were significantly higher in obese children with MCS than in controls. Contribution of DHGLA to PL was significantly higher in obese children with MCS than in controls. Neither AA nor α-linolenic acid (18:3n-3) and docosahexaenoic acid (22:6n-3) values differed among the three groups. There were no differences in the values of the intermediary metabolites [eicosatrienoic acid (20:3n-3), eicosapentaenoic acid (20:5n-3), docosapentaenoic acid (22:5n-3)] of docosahexaenoic acid synthesis (data not shown).

Product/substrate ratios for n-6 LCPUFA biosynthesis are compared among the three groups in Table 3. The ratios of GLA to LA as well as the ratio of GLA plus DHGLA to LA were higher in PL in obese children with than in those without MCS, and were higher in STE in obese children with MCS than in obese children without MCS and in controls. In contrast, the ratio of AA to DHGLA was significantly lower in both PL and STE in obese children with MCS than in obese children without MCS and in controls. The ratio of AA to LA, i.e., the ratio reflecting the activity of the whole pathway of AA synthesis, did not differ among the three groups.

DISCUSSION

In the present study, fatty acid composition of plasma PL and STE lipids was investigated in obese children with and without MCS and in nonobese controls. We defined MCS as simultaneous presence of four well-established cardiovascular risk factors (dyslipidemia, hyperinsulinemia, impaired glucose tolerance, and hypertension). The clustering of these risk factors is strongly related to morbidity and mortality (7,8), and obese children with MCS represent about 1% of the

TABLE 2
Major Fatty Acids of Plasma Phospholipids and Sterol Esters in Obese Children With and Without MCS and in Controls[a]

	Phospholipids			Sterol esters

[a] Values are % wt/wt [median (range from the first to the third quartile)]. Obese, MCS: $n = 15$, obese, no MCS: $n = 17$, control: $n = 16$, MCS denotes metabolic cardiovascular syndrome. Medians in a row sharing a common roman superscript (b,c,d,e,f) are significantly different ([b,c]$P < 0.05$, [d,e]$P < 0.01$, [f]$P < 0.001$) using the Kruskal-Wallis analysis of variance followed by Mann-Whitney's two-sided rank test.
[b]Total n-6 long-chain polyunsaturated fatty acids (LCPUFA) denotes (20:2n-6 + 20:3n-6 + 20:4n-6 + 22:4n-6 + 22:5n-6).
[c]Total n-3 LCPUFA denotes (20:5n-3 + 22:5n-3 + 22:6n-3). For abbreviations see Table 1.

teenager population, at least in our country (2,11). Therefore, further delineation of the metabolic status of obese children with MCS is of practical importance.

The major finding of the present study is the significant difference observed in n-6 polyunsaturated fatty acid (PUFA) values between obese children with MCS, on the one hand, and obese children without MCS and controls, on the other hand. In spite of significantly lower values of the precursor fatty acid, LA, values of GLA and DHGLA were significantly higher in obese children with MCS than in obese children without MCS or in controls. This fatty acid pattern is consistent with—but does not prove—an enhanced conversion of LA to its longer-chain metabolites in obese children with MCS. However, values of the principal n-6 LCPUFA, AA, did not differ among the three groups.

The interpretation of the data obtained in this study is complicated by the fact that the control subjects proved to be significantly older than the obese children investigated. For three major reasons, however, we do not think that this unintentional selection bias could have influenced the results obtained to any significant extent. First, pubertal status did not differ among the groups, and it is puberty which might be linked to most of the age-related issues in teenagers. Second, we did not find any significant difference in the fatty acid composition of plasma PL and STE lipids between children aged 10 to <15 yr and >15 yr in a previous study carried out in a sizable cohort of healthy children (24). Third, age did not differ between obese children with and without MCS, and it is difficult to assume such age-related influences that would, in parallel, (i) mask differences between obese children with-

TABLE 3
Product/Substrate Ratios of n-6 LCPUFA Biosynthesis in Plasma Phospholipids and Sterol Esters of Obese Children With and Without MCS and in Controls[a]

	Phospholipids			Sterol esters

20:4n-6/20:3n-6	2.79 (0.86)[d,e]	3.73 (1.58)[d]	4.32 (1.65)[e]	6.49 (2.91)[d,e]	9.73 (4.24)[d]	11.21 (3.30)[e]
20:4n-6/18:2n-6	0.62 (0.45)	0.66 (0.34)	0.58 (0.22)	0.14 (0.08)	0.16 (0.08)	0.16 (0.06)

[a]Values are % wt/wt [median (range from the first to the third quartile)]. Obese, MCS: $n = 15$; obese, no MCS: $n = 17$; control: $n = 16$. Medians in a row sharing a common superscript (b,c,d,e) are significantly different ([b,c]$P < 0.05$, [d]$P < 0.01$, [e]$P < 0.001$) using the Kruskal-Wallis analysis of variance followed by Mann-Whitney's two-sided rank test. For abbreviations see Tables 1 and 2.

out MCS and controls, and (ii) cause differences between obese children with MCS and controls. It is also to be noted that not only body fat contents but also lean body masses were significantly higher in obese children than in the controls in the present study. Higher accumulation rate of lean tissues usually accompanies enhanced deposition of fat in obese children, and it remains to be clarified whether expansion of lean tissues contributes, in part, to the metabolic complications of obesity.

Metabolism of n-6 PUFA has been investigated in various experimental models of obesity (25–29). In the Zucker rat model of monogenic obesity, significantly reduced LA, significantly enhanced DHGLA, and significantly reduced AA values were found in total liver lipids, liver PL, and total microsomal liver lipids in the genetically obese (fa/fa) as compared to the genetically lean (Fa/–) animals investigated at the ages of 6, 9, and 12 wk (26). The AA/DHGLA ratios were consistently lower in the obese than in the lean animals, whereas the AA/LA ratios showed inconsistent results depending on the lipid class and age investigated. Another extensive study comparing phospholipid fatty acid composition of nine different tissues demonstrated higher DHGLA/LA and lower AA/DHGLA ratios in genetically obese as compared to lean Zucker rats (27). In a mouse model of multigenic obesity, reduced LA, enhanced DHGLA but similar AA values were found in the obese as compared to the lean animals (28).

In the ob/ob mouse model of obesity, significantly reduced LA but significantly enhanced DHGLA and AA values were reported (25). In another study in ob/ob mice, significant enhancement of the Δ6-desaturase index (DHGLA/LA) and significant reduction of the Δ5-desaturase index (AA/DHGLA) were reported (29). These latter findings are in close agreement with the product/substrate ratios found in obese children with MCS in the present study. The multifaceted results seen in animal experiments as well as in human studies *(vide infra)* inspired the concept of AA maldistribution, i.e., a shift of AA from PL to STE lipids in obesity (30). In the present study, however, AA values showed similar patterns among the three groups both in PL and STE lipids.

Several nutritional and hormonal factors play a role in the regulation of EFA desaturation (31,32). On the one hand, insulin has been reported to be a potent activator of the Δ6-desaturase enzyme (33–36), and the obese children with MCS in this study were, by definition, hyperinsulinemic. On the other hand, hypertriglyceridemia was associated with diminished AA values in various animal tissues investigated (37), and many obese children with MCS in this study had elevated plasma triglyceride values.

It is tempting to speculate that the net effect of various hormonal and metabolic factors influencing Δ6- and Δ5-desaturase enzyme activities may differ among obese individuals with different degrees of the metabolic complications accompanying obesity. The data obtained in the present study indicate that the presence or absence of hyperinsulinemia and dyslipidemia (among other possible factors) in a group of obese subjects is associated with significant differences in plasma essential fatty acids (EFA) and PUFA values. When we recently reviewed human data on the effect of overnutrition on EFA metabolism (38), we found striking controversies between apparently similar studies. For instance, significantly lower AA values in plasma PL were found in obese than in nonobese adults in one study (5), whereas significantly higher AA values in plasma STE were reported for obese than for nonobese adults in another study (6). Moreover, significantly lower erythrocyte membrane phosphatidylethanolamine AA values were found in obese French children than in nonobese controls (39), whereas previously we reported significantly higher plasma PL and STE AA values in obese Hungarian children than in nonobese controls (4). These apparently contradictory results may well be explained by differences in the metabolic status of the obese subjects studied.

The data obtained in the present study allow two practical conclusions to be drawn. First, the significantly higher contribution of saturated fatty acids to plasma PL in obese children with MCS than in obese children without MCS and in controls provides further link between high saturated fatty acid intake and cardiovascular morbidity in obesity. Second, alterations of PUFA metabolism appear to be characteristic of certain subsets of the obese population but not necessarily to obesity itself. The pathophysiological consequences of the alterations observed in n-6 PUFA metabolism in obese children with MCS are unclear; however, nonphysiological availability of n-6 LCPUFA (e.g., that of DHGLA for eicosanoid synthesis) may represent an additional health hazard within the multifaceted clinical picture of MCS.

Children with MCS represent a well-defined and relatively sizable cohort of the obese population. Further investigations on fatty acid status in this subgroup of obese individuals may yield valuable data for better understanding of the alterations of fatty acid metabolism in obesity. It is to be emphasized, however, that fatty acid composition of plasma lipid classes as well as product/substrate ratios calculated on this basis represent only an indirect indicator of EFA metabolism. Today both sophisticated stable isotope techniques (40) and cloning of the Δ6-desaturase enzyme (41) provide novel research tools for further studies on EFA and PUFA metabolism in obesity.

ABSTRACT: Little is known about the association between dietary fatty acids and serum triglyceride concentrations. Plasma fatty acids may reflect dietary intake and can be used to study the relationship between concentrations of individual fatty acids and serum lipids. We examined the cross-sectional relationship of plasma fatty acids with serum nonfasting triglyceride and total cholesterol concentrations. Relative concentrations of individual plasma phospholipid fatty acids were determined by gas–liquid chromatography among 4,158 men aged 40–42 yr, who participated in a population study. The pattern of associations between individual fatty acids and cholesterol was different from that between individual fatty acids and triglyceride concentrations. All fatty acids displayed positive associations with total cholesterol concentration except linoleic acid, which was inversely related to cholesterol. In contrast, associations between individual fatty acids and triglyceride concentrations differed in strength and direction depending on both carbon chain length and the degree of unsaturation. Concentrations of very long chain (20 carbon atoms or more) saturated, monounsaturated, and n-3 polyunsaturated fatty acids showed significant inverse associations with triglycerides, whereas shorter fatty acids within these classes were positively associated with triglyceride concentrations. The present data suggest that the associations between concentrations of serum triglycerides and plasma phospholipid fatty acids depend on both fatty acid chain length and the degree of unsaturation.

Paper no. L8466 in *Lipids 35,* 1185–1193 (November 2000).

Serum triglyceride concentration is probably an independent risk factor for coronary heart disease (1), and the increased risk seems to start at relatively low concentrations of triglycerides (2). Dietary supplementation with n-3 polyunsaturated fatty acids decreases serum triglyceride concentrations (3). Little is known about the effects of other dietary fats (4), although a meta-analysis indicated that dietary polyunsaturated fat lowered triglycerides compared with monounsaturated fat (5).

There is an increasing awareness that individual fatty acids within the saturated, monounsaturated, and n-6 and n-3 polyunsaturated fatty acid classes may have different effects on serum lipid and lipoprotein concentrations (6). Dietary fat intake is difficult to measure, and blood concentrations of fatty acids may be used to examine the relationship between individual fatty acids and serum lipids. Plasma concentrations of essential n-6 and n-3 polyunsaturated fatty acids are highly correlated with dietary intake (7–9). Concentrations of nonessential fatty acids are less reliable indicators of diet because they reflect dietary consumption as well as fatty acid synthesis and metabolism. Nevertheless, plasma concentrations of palmitic, stearic, and monounsaturated fatty acids correlated with intake of saturated fat in individuals consuming a Western diet (7,8), probably because of their common sources in milk products and animal fat (10). In addition, high concentrations of eicosatrienoic (20:3n-9) and dihomo-γ-linolenic (20:3n-6) acids may reflect a diet relatively rich in saturated fatty acids (11,12).

Studies examining the relationship of blood concentrations of individual fatty acids with serum triglycerides and total cholesterol are not consistent (13–18). Most studies included few subjects (13–15), or measured a limited number of fatty acids (13,15,17,18).

We analyzed the association of individual plasma phospholipid fatty acids with serum concentrations of total cholesterol and triglycerides among 4,158 men aged 40–42 yr. This large data set allowed a detailed investigation of the relationship between plasma fatty acids and serum triglycerides and total cholesterol in a population consuming a Western diet.

METHODS

Subjects. In 1988–1989, all men and women aged 40–42 yr living in Nordland county, Norway, were invited to a health screening organized by the National Health Screening Service, the University of Tromsø, and the local health authorities (19). Plasma phospholipid fatty acids were quantitated in men, of whom 5,492 were invited and 4,302 participated (78%). Measurements of plasma phospholipid fatty acids were missing in 144 men, leaving 4,158 for the analysis. A second questionnaire was completed by 3,590 men; thus the analysis on certain variables is restricted. The Norwegian Data Inspectorate considered legal and ethical issues and approved the study. The subjects gave informed consent.

Abbreviations: BMI, body mass index; LDL, low density lipoprotein; VLDL, very low density lipoprotein.

Questionnaires. The letter of invitation gave information about the survey and included a questionnaire about previous cardiovascular disease and smoking habits (yes/no). Leisure time physical activity was graded from I to IV according to which of the following categories would best describe the participant's usual level of physical activity. I: reading or watching television or other sedentary activity; II: walking, cycling or other forms of exercise at least 4 h/wk; III: participation in recreational sports, heavy gardening etc. for at least 4 h/wk; IV: participation in hard training or sports competitions regularly several times a week. Categories III and IV were merged in our analysis. A nurse checked the questionnaire for logical inconsistencies and incomplete items at the examination and obtained information about time since last meal. A second questionnaire, covering alcohol consumption and dietary habits, was handed out at the screening site and returned by mail. Alcohol consumption was categorized from I to VI. I: teetotaler; consumption of alcohol equivalent to 5 units of alcohol (1 unit equals 9 g of alcohol) II: no times last year; III: a few times last year; IV: 1 or 2 times per month; V: 1 or 2 times per week; and VI: 3 times per week or more. We merged categories V and VI in the analysis. Two questions about habitual consumption of lean and fat fish for dinner meals were categorized from I to V. I: less than once weekly; II: once weekly; III: twice weekly; IV: three times weekly; V: four times weekly or more. We merged the two questions into four categories covering total weekly consumption of lean and fat fish for dinner. The questionnaire also assessed present use of fish oil supplements (yes/no).

Measurements. Body weight was measured on an electronic scale with subjects wearing light inner clothing and no shoes, and height was measured to the nearest centimeter. Body mass index (BMI) was calculated as the body weight in kilograms divided by the square of the height in meters (kg/m^2). Systolic and diastolic blood pressure were measured by an automatic device (Dinamap, Critikon, Tampa) (19). A nonfasting blood sample was collected and analyzed in fresh serum for total cholesterol and triglycerides at the Central Laboratory, Ullevål Hospital, Oslo. The analyses were performed by an enzymatic colorimetric method (20,21), on a Hitachi 737 Automatic Analyzer (Boehringer Mannheim, Mannheim, Germany) with reagents from the manufacturer. Measurement precision, expressed as the coefficient of variation, was 3% for both serum total cholesterol and triglycerides.

EDTA plasma was stored at –80°C for a maximum of 2 yr before phospholipid fatty acids (14:0, 16:0, 18:0, 20:0, 22:0, 24:0, 16:1, 18:1, 20:1, 22:1, 24:1, 20:3n-9, 18:2n-6, 20:2n-6, 20:3n-6, 20:4n-6, 22:4n-6, 22:5n-6, 18:3n-3, 20:5n-3, 22:5n-3 and 22:6n-3) were quantitated by gas–liquid chromatography as described previously (22). The coefficients of variation for individual fatty acids estimated from replicate analyses (n = 55) of a serum sample ranged from 3.3 to 6.6%. Fatty acids were measured as relative concentrations (mol%). *Trans*-fatty acids were not measured.

Statistical analysis. All variables were normally distributed except serum triglycerides and plasma 20:5n-3, which were right-skewed. Log transformation had minor impact on the results, and we therefore used untransformed data in the analysis. Pearson correlation coefficients were computed to evaluate the relationships between concentrations of individual plasma phospholipid fatty acids. We used simple linear regression analysis to predict change and 95% confidence interval in serum triglyceride and total cholesterol concentrations by 1 standard deviation increase in fatty acid concentration. Next, we developed multiple linear regression models to examine independent associations between individual fatty acids and serum lipids. Fatty acids significantly associated with serum triglycerides and total cholesterol in univariate analysis were considered for inclusion in the regression models. We included up to two fatty acids from each fatty acid class. Within each fatty acid class we chose the fatty acid which had the strongest positive and inverse relationship with triglycerides (18:0, 22:0, 16:1, 24:1, 20:3n-6, 22:6n-3) and total cholesterol (22:0, 22:1, 20:3n-9, 18:2n-6, 22:4n-6), and where intercorrelations between fatty acids were less than r = 0.60. Fatty acids significantly associated with triglycerides and total cholesterol, respectively, were retained in the models. Finally, we adjusted for BMI and evaluated the effects of potential confounding variables, such as physical activity, alcohol consumption, daily smoking, and time since last meal. Residual analyses confirmed the model assumptions (23). Differences between means were tested by two sample t-tests. Two-sided P-values < 0.05 were considered statistically significant. The SAS software package was used (24).

RESULTS

Characteristics of study participants are shown in Table 1. Among the 4,158 men, 34% had serum total cholesterol concentrations ≥6.50 mmol/L, and 24% had nonfasting triglycerides >2.50 mmol/L. A history of myocardial infarction, angina pectoris, stroke, diabetes mellitus, or use of antihypertensive drugs was reported by 176 men. Fish consumption was relatively high, and 26% were present users of fish oil supplements. Nonfasting serum triglyceride level decreased with time since last meal (Table 2). Plasma phospholipid palmitic (16:0), palmitoleic (16:1), 20:3n-9, 20:3n-6, eicosapentaenoic (20:5n-3), and docosahexaenoic (22:6n-3) acids increased, whereas linoleic (18:2n-6) acid concentrations decreased slightly when time since last meal increased (data not shown).

Interrelationships between concentrations of plasma phospholipid fatty acids. Concentrations of very long chain (20–24 carbon atoms) fatty acids within the saturated and n-3 polyunsaturated fatty acid classes were highly intercorrelated (Table 3). Very long chain polyunsaturated fatty acids of the n-3 class were positively correlated with very long chain monounsaturated fatty acids and inversely correlated with fatty acids of the n-6 class.

Univariate relationship of plasma phospholipid fatty acids with serum nonfasting triglycerides and total cholesterol. Concentrations of stearic (18:0) acid, 16:1, and 20:3n-6

TABLE 1
Characteristics of Study Participants: 4,158 Men 40–42 yr Old

Characteristic	Mean ± SD or %
Serum total cholesterol (mmol/L)	6.12 ± 1.16
Serum nonfasting triglycerides (mmol/L)	1.98 ± 1.22
Systolic blood pressure (mm Hg)	133 ± 14
Diastolic blood pressure (mm Hg)	81 ± 10

showed strong positive associations with triglyceride concentrations (Table 4 and Figs. 1,2). Very long chain saturated, monounsaturated, and n-3 polyunsaturated fatty acids, particularly lignoceric (24:0) acid, nervonic (24:1) acid, and 22:6n-3, were inversely associated with triglycerides. Both fatty acid chain length and the degree of unsaturation were related to triglyceride concentrations (Table 5). The association between triglycerides and chain length appeared to be stronger than the association between triglycerides and degree of unsaturation. Very long chain saturated and monounsaturated fatty acids were positively associated with total cholesterol and inversely associated with triglyceride concentrations (Table 4 and Fig. 1). The associations of saturated and monounsaturated fatty acids with triglycerides differed depending on carbon chain length, whereas all saturated and monounsaturated fatty acids were positively associated with total cholesterol. The associations of fatty acids with triglyceride concentrations were generally stronger than the associations with total cholesterol. The compound 18:2n-6 was the only fatty acid showing a significant inverse association with cholesterol concentrations.

TABLE 2
Nonfasting Serum Triglycerides According to Time Since Last Meal in 4,158 Men

Time since last meal (h)	n	Serum triglycerides (mmol/L), mean ± SD

Multivariate relationship of plasma phospholipid fatty acids with serum nonfasting triglycerides and total cholesterol. Fatty acids explained 19% of the variance in triglyceride concentration (Table 6, model I). Concentrations of 18:0, 16:1, 24:1, and 20:3n-6 were independently associated with triglycerides. The associations remained significant when controlling for BMI, physical activity, and alcohol consumption (Table 6, model II). The n-3 fatty acids were not significantly associated with triglycerides when 24:1 was included in the multiple regression model. There was interaction between alcohol consumption and 16:1 in prediction of triglycerides. Concentrations of 16:1 increased significantly when alcohol consumption increased (P = 0.0001, data not shown). The association between 16:1 and triglyceride concentrations weakened with increasing alcohol consumption, and 16:1 was not significantly associated with triglycerides among men in the highest category of alcohol consumption. The strongest association between concentrations of 16:1 and triglycerides was observed among nondrinkers (data not shown).

Fatty acids explained 7% of the variance in total cholesterol concentration (Table 6, model I). Concentration of 18:2n-6 was not significantly associated with cholesterol after adjustment for BMI (Table 6, model II). Adjustment for daily smoking did not affect the results of the multiple regression analyses. Both stratified and adjusted analyses showed that time since last meal did not influence the relationship of plasma phospholipid fatty acids with serum triglycerides and total cholesterol.

Consumption of fish products, plasma phospholipid fatty acids, and serum triglycerides. Use of fish oil supplements and the level of habitual fish consumption were positively associated with concentrations of gondoic (20:1) acid, erucic (22:1) acid, 24:1, and n-3 fatty acids (all $P < 0.001$) (data not shown). Present users of fish oil had 10% lower mean triglyceride concentration compared with nonusers (P = 0.0001). In multiple regression analysis, fish consumption was inversely associated with serum triglyceride concentrations after adjustment for BMI (P = 0.047). Fish consumption was not significantly associated with serum triglyceride concentrations when 24:1 or 22:6n-3 was added to the regression model.

DISCUSSION

This study shows that fatty acid chain length, as well as the degree of unsaturation, is associated with serum nonfasting triglyceride concentrations. Very long chain fatty acids of the saturated, monounsaturated, and n-3 classes were inversely associated with triglycerides, and the associations increased

[a]Pearson correlation coefficients between relative concentrations (mol%) of fatty acids. Values > |0.03|, |0.04| and |0.05| are significant at $P < 0.05$, $P < 0.01$, and $P < 0.001$, respectively.

in magnitude with increasing fatty acid chain length. Interestingly, individual very long chain saturated and monounsaturated fatty acids were positively associated with total cholesterol and inversely associated with triglyceride concentrations. This observation has to our knowledge not been reported previously.

Associations of fatty acids with nonfasting triglycerides were not influenced by time since last meal. The analysis can reflect that plasma phospholipid fatty acids explain a component of the interindividual variability in serum triglyceride levels, which is not determined by time since last meal.

Dietary supplementation with very long chain n-3 fatty acids decreases liver very low density lipoprotein (VLDL) synthesis (25) and serum triglyceride concentrations (3). Studies in rats showed that 20:5n-3 increased mitochondrial β-oxidation and reduced fatty acid substrate for VLDL synthesis (26). Mitochondria, the major sites for fatty acid oxidation, are poor oxidizers of very long chain fatty acids (27), but proliferated during dietary supplementation with very long chain n-3 fatty acids (28). Based on these observations we speculate that very long chain saturated and monounsaturated fatty acids stimulate mitochondrial proliferation, whereby fatty acid oxidation increases and VLDL triglycerides decrease. Contrasting fatty acids of the saturated, monounsaturated and n-3 classes, n-6 fatty acids displayed no distinct pattern of association with triglycerides.

We found that concentrations of very long chain monounsaturated and n-3 fatty acids were positively associated with habitual fish consumption and inversely associated with serum triglycerides. Others have reported that the level of fish consumption and triglyceride concentrations were inversely related (14,29). In previous cross-sectional studies however, concentrations of 20:5n-3 were both positively (13), and inversely (14) associated with serum triglycerides.

Cross-sectional studies indicate that plasma phospholipid levels of essential polyunsaturated fatty acids reflect dietary intake (7–9). Dietary supplementation studies confirm that plasma phospholipid concentrations of 18:2n-6, 18:1, 20:5n-3, and 22:6n-3 are sensitive to changes in dietary intake of these fatty acids (30,31). The origins of very long chain saturated and monounsaturated fatty acids are less clear. They may be metabolic products of shorter fatty acids. Fish and fish oils contain 20:1 and 22:1 as well as n-3 fatty acids (10), and one cross-sectional study showed that plasma phospholipid concentrations of 24:1, 20:5n-3, and 22:6n-3 were positively associated with fish consumption (14). It is possible that concentrations of very long chain monounsaturated fatty acids reflect dietary fish and fish oil intake.

In the present study, the inverse associations of 22:1 and 24:1 with triglycerides were stronger than the association of 22:6n-3 with triglyceride concentrations. When 22:1 or 24:1 was added to a regression model including only 22:6n-3, the explained variability in triglycerides increased significantly. This indicates that very long chain monounsaturated fatty acids are independently associated with triglyceride concentrations and are not merely indicators of dietary n-3 fatty acids.

TABLE 4
Concentrations of Plasma Phospholipid Fatty Acids, and Change in Serum Nonfasting Triglycerides and Total Cholesterol by One Standard Deviation (SD) Increase in Fatty Acid Concentration in 4,158 Men

Fatty acid	Mean ± SD (mol%)	Predicted mean change (95% CI) Triglycerides (mmol/L)	Total cholesterol (mmol/L)
Saturated fatty acids[a]	44.10 ± 1.34	0.02 (–0.02, 0.06)	0.16 (0.13, 0.19)

[a]Saturated fatty acids include 14:0, 16:0, 18:0, 20:0, 22:0, 24:0.
[b]Monounsaturated fatty acids include 16:1, 18:1, 20:1, 22:1, 24:1.
[c]n-6 fatty acids include 18:2n-6, 20:2n-6, 20:3n-6, 20:4n-6, 22:4n-6, 22:5n-6.
[d]n-3 fatty acids include 18:3n-3, 20:5n-3, 22:5n-3, 22:6n-3. Abbreviation: CI, confidence interval.

Plasma phospholipid concentrations of 18:0, 16:1, and 20:3n-6 displayed independent positive associations with triglyceride concentrations. The observation finds support in the Paris Prospective Study, where plasma concentrations of 16:1 and 20:3n-6 were positively associated with triglycerides (16). A dietary intervention trial showed that serum triglyceride concentration increased significantly on an 18:0-enriched diet, compared with a diet rich in 18:2n-6 (32). Plasma concentrations of 18:0 and 16:1 were positively associated with dietary saturated fat in cross-sectional studies (7,8), and 20:3n-6 increased on a saturated fat diet (11). Thus, plasma concentrations of 18:0, 16:1, and 20:3n-6 appear to reflect dietary saturated fat to some extent.

Alcohol consumption may be a potential confounder in the relationship between 16:1 and triglycerides, since alcohol intake is associated with high levels of 16:1 (16,33,34) and serum triglycerides (35). In the present study the association between 16:1 and triglycerides remained significant when controlling for alcohol intake, but residual confounding may remain since we used a rather crude estimate of alcohol intake. However, stratified analyses showed that the association between 16:1 and triglycerides was particularly strong among teetotalers and those who consumed alcohol less than yearly or a few times yearly. It appears that the association between 16:1 and triglycerides does not depend on alcohol intake.

Serum nonfasting triglycerides are subject to larger intraindividual variation than are total cholesterol concentrations (36), and this will tend to dilute any association between triglycerides and concentrations of fatty acids. We found that fatty acids explained 19% of the variability in triglyceride, and 7% of the variability in total cholesterol concentrations. Therefore, the biological association of plasma phospholipid fatty acids with serum triglycerides appears to be stronger than the association with total cholesterol.

In the present study, plasma phospholipid concentrations of 22:0, 22:1, and 20:3n-9 were independently and positively associated with serum total cholesterol concentrations. It is not clear which factors determine plasma concentrations of 22:0, 22:1, and 20:3n-9. They may be metabolic products of shorter saturated fatty acids. Fish products can be a source of 22:1, as noted above. When dietary intake of polyunsaturated fat is low, the metabolic conversion of 18:1 to 20:3n-9 increases (12). High levels of plasma 20:3n-9 may thus reflect a diet relatively rich in saturated fat.

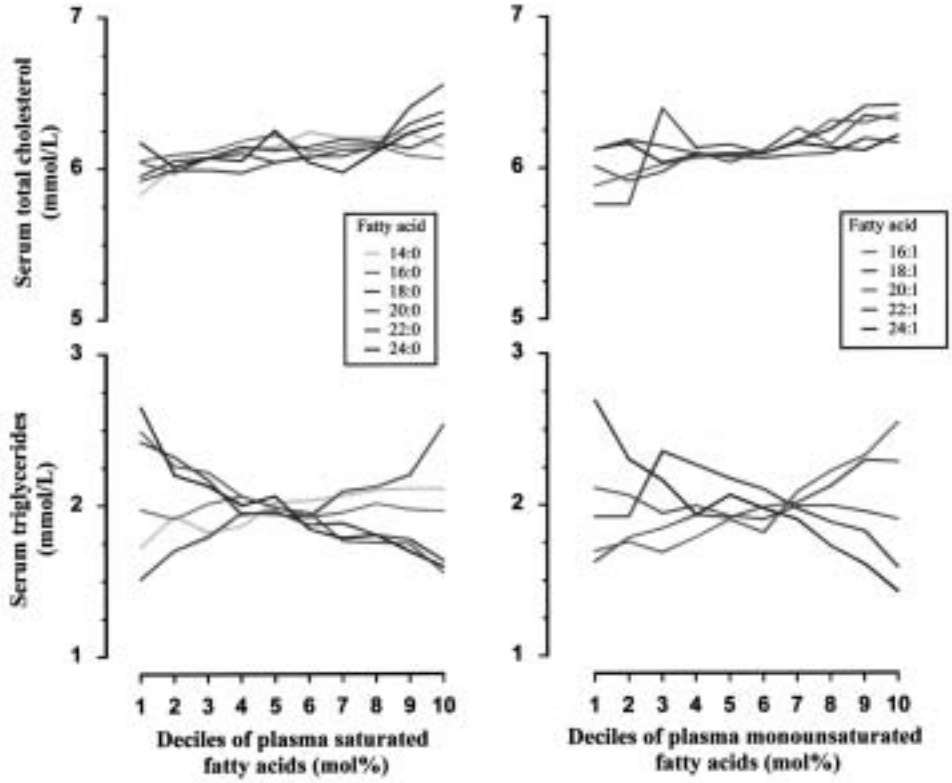

FIG. 1. Mean serum total cholesterol (upper panels) and triglyceride (lower panels) concentrations by deciles of plasma phospholipid saturated (left panels) and monounsaturated (right panels) fatty acids.

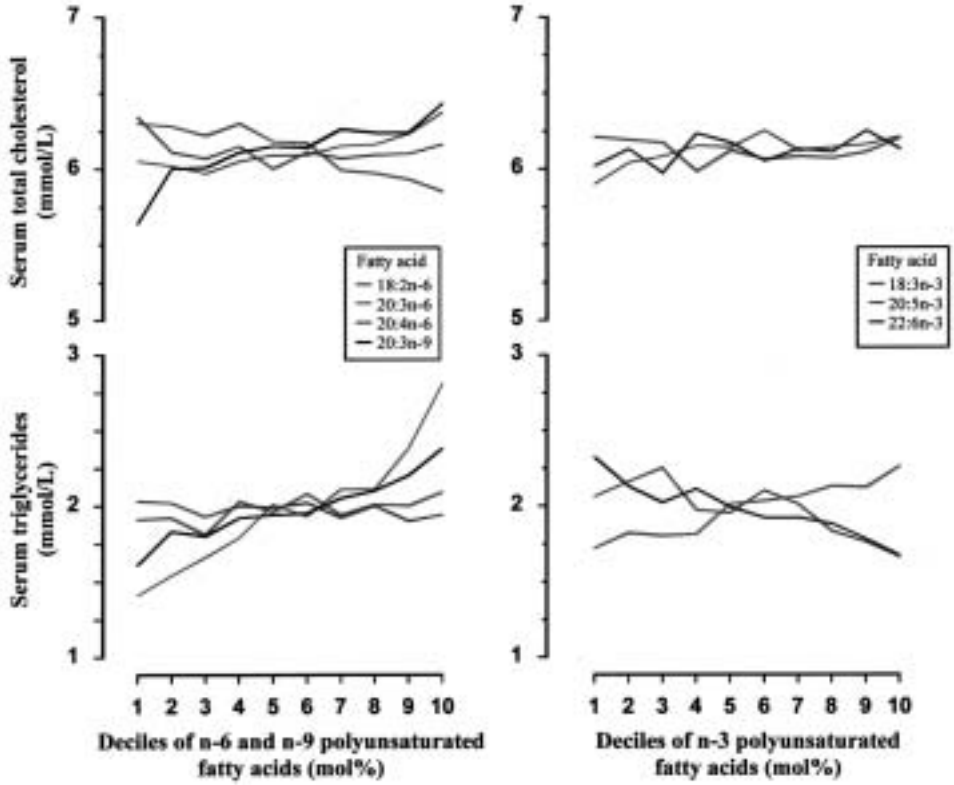

FIG. 2. Mean serum total cholesterol (upper panels) and triglyceride (lower panels) concentrations by deciles of plasma phospholipid n-6 and n-9 polyunsaturated (left panels) and n-3 polyunsaturated (right panels) fatty acids.

TABLE 5
Concentrations of Plasma Phospholipid Fatty Acids and Change in Serum Nonfasting Triglyceride Concentrations According to Fatty Acid Chain Length and Number of Double Bonds in 4,158 Men

Fatty acid group	Mean ± SD (mol%)	Change in triglycerides[a] (mmol/L)
Carbon chain length[b]		
C_{20}	13.99 ± 2.11	–0.02 (–0.06, 0.02)
C_{22}	10.37 ± 1.93	–0.24 (–0.28, –0.20)
C_{24}	2.24 ± 0.76	–0.33 (–0.37, –0.30)
Number of double bonds[c]		
4	8.37 ± 1.46	–0.03 (–0.07, 0.01)
5	3.70 ± 1.87	–0.15 (–0.18, –0.11)
6	6.54 ± 1.67	–0.17 (–0.20, –0.13)

[a]Values are predicted mean change (95% CI) by one SD increase in fatty acid concentration.
[b]C_{20} = 20:0 + 20:1 + 20:3n-9 + 20:2n-6 + 20:3n-6 + 20:4n-6 + 20:5n-3. C_{22} = 22:0 + 22:1 + 22:4n-6 + 22:5n-6 + 22:5n-3 + 22:6n-3. C_{24} = 24:0 + 24:1.
[c]4 = 20:4n-6 + 22:4n-6. 5 = 22:5n-6 + 20:5n-3 + 22:5n-3. 6 = 22:6n-3. For abbreviations see Table 4.

Plasma concentrations of 18:2n-6 are correlated with dietary intake (7,8). We found that 18:2n-6 concentrations were inversely associated with total cholesterol. Small observational studies failed to detect any association between 18:2n-6 and total cholesterol (13,15). Larger studies however, found that plasma (16,18) and adipose tissue (37,38) concentrations of 18:2n-6 were inversely associated with total cholesterol. These data are supported by feeding experiments showing that dietary 18:2n-6 decrease total and low density lipoprotein (LDL) cholesterol concentrations (6), supposedly by increasing liver LDL receptor activity (39).

Our findings are strengthened by the population-based study design, the relatively high participation rate, and large sample size. The study was conducted among men in a narrow age range consuming a Western diet, and the results need confirmation among women and other age groups. We did not measure *trans*-fatty acids, and it is not known how they may influence the results. Relative concentrations (proportions) of fatty acids were used in the analysis. The use of proportions is problematic since an increase in one proportion is associated with a decrease in some other proportion(s). However, as seen in Table 2, most correlations between fatty acids in-

TABLE 6
Multiple Linear Regression Analysis of Serum Nonfasting Triglycerides and Total Cholesterol in 4,158 Men[a]

Predictor variable	Model I	Model II

Body mass index (kg/m^2)		0.20 (0.17, 0.23)
Physical activity (1–3)[b]		–0.10 (–0.14, –0.05)
Adjusted R^2 (%)	7	11[d]

[a]Values are predicted mean change (95% CI) by one SD increase in predictor variable and by one category increase in physical activity and alcohol consumption. See Table 4 for abbreviations.
[b]See Table 1 for categories of physical activity and alcohol consumption.
[c]n = 3499.
[d]n = 4,155.

cluded in the present analyses were not particularly strong. We therefore believe the findings reflect biologic differences between individual fatty acids and not simply the interrelationship between proportions of fatty acids. Many associations of individual fatty acids with serum triglyceride and total cholesterol concentrations weakened after adjustment for BMI. It is, however, questionable whether adjustment for BMI is appropriate, since plasma phospholipid fatty acids and BMI may be intermediate variables in the relationship of dietary fat with serum cholesterol and triglycerides.

In summary, the present data show that there are major differences with regard to both the strength and the direction of the association between serum triglyceride concentrations and individual fatty acids within the same fatty acid class. These results suggest that the association between triglycerides and fatty acid depends on both fatty acid chain length and degree of unsaturation.

Discovery of an 11(*R*)- and 12(*S*)-Lipoxygenase Activity in Ovaries of the Mussel *Mytilus edulis*

Gianguido Coffa and Elizabeth M. Hill*

School of Chemistry, Physics and Environmental Science, University of Sussex Falmer, Brighton BN1 9QJ, United Kingdom

ABSTRACT: Eicosanoid biosynthesis was investigated in mussel gonads by incubation of tissue homogenates with radiolabeled arachidonic acid and analysis of the products by radio-high-performance liquid chromatography. No radiolabeled metabolites were formed in homogenates of testes, but two major metabolites were synthesized by ovarian preparations. The radiolabeled metabolites were analyzed by mass spectrometry and chiral chromatography and identified as 11(*R*)-hydroxy-5,8,12,14-eicosatetraenoic acid and 12(*S*)-hydroxy-5,8,10,14-eicosatetraenoic acid. In addition, four other nonlabeled metabolites, formed from endogenous substrates, were detected in ovarian extracts. Their structures, determined by mass spectrometric analysis, were the corresponding 11- and 12-hydroxy analogs formed from eicosapentaenoic acid (11-HEPE and 12-HEPE) and 9-hydroxy-6,10,12,15-octadecatetraenoic acid (9-HOTE) and 13-hydroxy-6,9,11,15-octadecatetraenoic acid formed from stearidonic acid. The biosynthesis of the 11- and 12-hydroxy products was calcium dependent, localized to the 100,000 × *g* supernatant cell fraction, and was inhibited by nordihydroguaiaretic acid, but not inhibited by the prostaglandin synthase inhibitors aspirin and indomethacin, or the monoxygenase inhibitor proadifen. Together these data suggested that both the 11(*R*)- and 12(*S*)-hydroxy products were formed from lipoxygenase-type enzymes. Incubation of homogenates of immature ovaries with eicosapentaenoic acid revealed the major product to be 12-HEPE, whereas in mature ovaries mainly 11-HEPE was formed. Extraction of spawned eggs with methanol revealed that predominantly 11-HEPE and 9-HOTE were formed from endogenous substrates. This study shows that female gonads of the mussel express an 11(*R*)- and 12(*S*)-lipoxygenase activity whose expression is dependent on differentiation of the ovary.

Paper no. L8597 in *Lipids 35,* 1195–1204 (November 2000).

Eicosanoids are biologically active lipid metabolites that are formed from the action of either lipoxygenase, prostaglandin synthase, or cytochrome P450 enzymes on polyunsaturated fatty acids (PUFA) such as arachidonic acid (AA). The biosynthesis and physiological role of eicosanoids have been widely studied in mammals whereas there is less information on the identity and activity of these lipid mediators in lower organisms. A number of studies have reported the biosynthesis and/or activity of eicosanoids in a variety of reproductive processes in aquatic invertebrates (1). Many of these compounds have been identified as hydroperoxyeicosatetraenoic acids (HPETE), or their reduction products hydroxyeicosatetraenoic acids (HETE), which are thought to be stereospecific products of lipoxygenase (LO)-mediated metabolism. Unlike mammalian LO, which tend to form products with the *S* stereochemistry, many invertebrate LO biosynthesize eicosanoids with the *R* configuration. For instance, starfish oocytes have been reported to synthesize 8(*R*)-HETE, which triggers oocyte maturation (meiosis reinitiation) prior to spawning (2). Eggs of the surf clam (*Spisula solidissima*) biosynthesized high levels of 5(*R*)-HETE and 8(*R*)-HETE, although these metabolites did not stimulate oocyte maturation in this species and their physiological role in the surf clam is currently unknown (3). However 5-HETE (chirality not given) was reported to stimulate oocyte maturation in the clam *S. sachalinensis* (4). The LO products 11(*R*)- and 12(*R*)-HETE have been identified in eggs of the sea urchin *Strongylocentrotus purpuratus* although their biological activity was not determined (5). It has been reported that *Hydra magnipapillata* synthesized 11(*R*)-HETE, which inhibited head formation, and 12(*S*)-HETE, which enhanced bud formation in this species (6). 11(*R*)-HETE was also formed in *H. vulgaris* and was shown to promote tentacle regeneration in this hydroid (7). During metamorphosis, larvae of the marine hydroid, *Hydractinia echinata,* synthesize 8(*R*)-HETE, however the biological role of this metabolite has yet to be defined (8). A number of 8-hydroxylated eicosanoid metabolites, including 8(*R*)-HEPE, have been reported to stimulate hatching of barnacle (*Semibalanus balanoides*) embryos (9,10). LO products have been implicated in sperm activation of the polychaete *Arenicola marina* (11). Together, these studies suggest that LO metabolites may play an important role in the reproductive physiology of a number of aquatic invertebrates.

In our laboratory, initial investigations of eicosanoid biosynthesis in different tissues of the mussel, *Mytilus edulis,* identified the gonads as a potent source of hydroxy fatty

Abbreviations: AA, arachidonic acid; BSTFA, bis(trimethylsilyl)trifluoroacetamide; EPA, eicosapentaenoic acid; GS–MS, gas chromatography–mass spectrometry; 11-HEPE, 11-hydroxy-5,8,12,14,17-EPA; 12-HEPE, 12-hydroxy-5,8,10,14,17-EPA; HETE, hydroxyeicosatetraenoic acid; 9-HOTE, 9-hydroxy-6,10,12,15-octadecatetraenoic acid; 13-HOTE, 13-hydroxy-6,9,11,15-octadecatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid; HPLC, high-performance liquid chromatography; IMC, indomethacin; LO, lipoxygenase; NDGA, nordihydroguaiaretic acid; PGB_2, prostaglandin B_2; PUFA, polyunsaturated fatty acid; RP-HPLC, reversed-phase HPLC; SA, stearidonic acid; SP-HPLC, straight-phase HPLC; UV, ultraviolet.

acids. In this study we report on the identity and properties of LO enzymes in the ovaries of *M. edulis.*

MATERIALS AND METHODS

Materials. 5,8,11,14-Eicosatetraenoic acid (AA), 5,11,14,17-eicosapentaenoic acid (EPA), 6,9,12,15-octadecatetraenoic acid (stearidonic acid, SA), indomethacin (IMC), nordihydroguaiaretic acid (NDGA), aspirin, proadifen, baicalein, bis(trimethylsilyl)trifluoroacetamide (BSTFA), 1-methyl-3-nitro-1-nitrosoguanidine, and (–)-menthyl chloroformate were purchased from Sigma Chemical Company (Poole, Dorset, United Kingdom). 1-[^{14}C]-AA (specific activity 2220 Mbq/mmol, radioactive purity >90%) was obtained from Amersham Life Science (Little Chalfont, Buckinghamshire, United Kingdom). (±)11-HETE, (±)12-HETE, and 11(*R*)-HETE were purchased from Cayman Chemical Co. (Ann Arbor, MI), and 12(*S*)-HETE was purchased from Biomol (Plymouth Meeting, PA). Rhodium (5% on alumina) was obtained from Lancaster Synthesis Ltd. (Morecombe, Lancashire, United Kingdom). All solvents used were of high-performance liquid chromatography (HPLC) grade, purchased from Rathburn Chemicals, Ltd. (Walkerburn, United Kingdom).

Animals and preparation of gonads. Mussels (*M. edulis),* length 5–8 cm, were collected between January 1998 and April 1999 from Brighton, East Sussex, United Kingdom, and transported to the laboratory where the gonads were immediately removed and placed on ice. Sex was determined by microscopic examination and gonads were classified as either immature (no gametes visible), partly mature (gonad contains developing gametes), or mature (gonad distended with ripe gametes). For each experiment, gonads were used at identical reproductive stages.

Preparation of gonad homogenates. Gonads (typically 1 gonad/2 mL) were homogenized (30 s, 6000 rpm, Potter-Elvehjem homogenizer; Wheaton Science Products, Millville, NJ) in an ice-cold solution of Tris buffer (50 mM), containing EDTA (5 mM), pepstatin A (0.6 μg/mL), aprotinin (3 μg/mL), and leupeptin (0.6 μg/mL). The tissue preparations were centrifuged at 3,000 × *g* for 5 min, and the supernatants were removed for studies on eicosanoid biosynthesis in crude homogenates.

In some experiments microsomal and cytosolic fractions were prepared as follows. The tissue homogenate was centrifuged at 10,000 × *g* (5°C) for 15 min and the resulting supernatant centrifuged at 100,000 × *g* (5°C) for 1 h. The supernatant (cytosolic extract) was removed and the microsomal pellet washed with Tris buffer (2 × 0.5 mL) and resuspended in Tris buffer at 100 μL/gonad.

Incubation with substrate. Gonad homogenates (1 mL) were incubated with 20 μM (1 μL of 20 mM ethanolic stock) of either AA or EPA followed by 10 mM calcium chloride (10 μL of 1 M aqueous stock). The samples were incubated in a water bath for 30 min at 18–19°C. The reaction was stopped by adding ice-cold methanol (0.3 mL) and the solutions stored at –20°C before eicosanoid extraction. Incubations with boiled homogenates (100°C, 5 min) were used to monitor for nonenzymatic oxidation of substrate. In some experiments radiolabeled [1-^{14}C]AA was used as substrate at a final concentration of 20 μM and 3.7 kBq/mL. In other experiments, homogenates were pre-incubated at 16°C for 15 min with several inhibitors prior to the addition of substrate and calcium. The inhibitors, baicalein (5–30 μM final concentration), NDGA (10–30 μM final concentration), proadifen (30 μM final concentration), aspirin (30 μM final concentration), and IMC (10–25 μM), were added in 1 μL/mL of ethanol carrier.

Collection of eggs. To investigate eicosanoid synthesis in released eggs, mussels were kept in small aquaria with fresh seawater and the spawning was induced by injection of 2.5 mL of KCl (0.5 M) into the mantle cavity. The released eggs of each mussel were then washed and suspended in fresh seawater (2 mL) and divided in two portions, one of which was incubated for 30 min with 20 μM EPA (2 μL of 10 mM ethanolic stock) prior to the addition of methanol (0.3 mL) and the other was incubated with vehicle (2 μL ethanol) prior to the addition of methanol (0.3 mL). The samples where then quickly frozen at –20°C before extraction.

Solid phase extraction of eicosanoids. Prior to extraction, prostaglandin B_2 (PGB_2, 0.4 μg in 40 μL ethanol) was added to each sample as an internal standard. The methanolic samples were centrifuged (3,000 × *g*, 5 min), the supernatants decanted, and the pellets extracted with 0.5 mL methanol. The supernatants were combined and diluted with 16 mL of 17.5 mM ammonium acetate buffer (pH 4). One hundred milligram C_{18} solid phase extraction columns (Waters Corp., Milford, MA) were conditioned with 10 mL of methanol, followed by 10 mL of ammonium acetate buffer. After loading of the sample, the columns were washed with 5 mL of buffer (pH 4) and eicosanoids eluted with 4 mL of methanol. The solvent was removed under vacuum and the residue redissolved in 300 μL of methanol and 300 μL of water pH 5.7 (0.1% acetic acid, pH adjusted with ammonium hydroxide, NH_4OH) for reversed-phase (RP)-HPLC analysis.

RP-HPLC analysis. Samples were analyzed by RP-HPLC using a C_{18} column (5 μM, 4.6 × 150 mm, Nova-Pak; Waters Corp.). Metabolites were detected using a photodiode array detector (996; Waters) followed in series by an on-line radioactivity monitor model (LB 506 C-1; Berthold, Wildbad, Germany). RP-HPLC mobile phase was a mixture of 20% methanol (solvent B) and 80% buffer (0.1% glacial acetic acid buffered to pH 5.7 with NH_4OH) (solvent A) changing to 70% solvent B in 20 min, and increasing to 100% B from 40 to 50 min. Recoveries were monitored by measurement of PGB_2 peak height at 280 nm.

In order to collect samples for further analyses, some incubations were combined prior to HPLC analysis. Where it was necessary to separate and collect closely eluting compounds, the following modified program was used: 40% methanol, 10% acetonitrile, for 20 min, increasing as a step to 50% methanol at 30 min and to 60% at 58 min, with a gradient to 100% from 60 to 70 min. Metabolites were collected from the ultraviolet (UV) detector, the HPLC eluent removed under

vacuum, and the sample redissolved in methanol and stored under oxygen-free nitrogen at –20°C for further analysis.

Gas chromatography–mass spectrometry (GC–MS). Samples, in 10 µL of methanol, were methylated by reaction with an excess of ethereal diazomethane at room temperature for 15 min. The solvent was evaporated and the residues were derivatized to their silyl ethers by addition of 20 µL of BSTFA and 20 µL of pyridine for 15 min at 60°C. The BSTFA was removed under nitrogen and the derivatives redissolved in hexane prior to injection in GC–MS. In addition, an aliquot of some samples was hydrogenated as follows: samples were dissolved in 0.5 mL methanol with 2–5 mg of rhodium (5% on alumina) catalyst. Hydrogen was bubbled through the solution for 15 min (room temperature). Rhodium was removed by centrifugation, the methanol removed under vacuum, and the samples silylated as described above prior to analysis by GC–MS.

Electron ionization mass spectrometry was performed on a Kratos MS890 instrument (Ramsey, NJ) coupled to a Carlo Erba MFC 500 gas chromatograph (Milano, Italy). Samples were injected in splitless mode onto a capillary column (10 m BPX5; SGE Ltd., Milton Keynes, United Kingdom). The injector and source temperatures were 280°C, and the column temperature was increased from 100 to 280°C at a rate of 10°C/min. The accelerating potential was 4 kV, electron energy 70 eV, and the magnetic sector cycled from 600 to 50 amu during 0.8 s.

Steric analysis of 11- and 12-HETE by HPLC. 11- and 12-HETE, obtained from mussel extracts, were purified by RP-HPLC, and methylated as described above. To determine the chiralty of 11-HETE, the methyl ester was converted to the (–)-menthoxycarbonyl derivative by addition of 100 µL of dry toluene, 10 µL of dry pyridine and 5 µL of menthylchloroformate. After 30 min of reaction at room temperature, the solvents were evaporated to dryness under nitrogen and the menthoxycarbonyl derivatives extracted from the solid residue with hexane. The hexane was removed, the sample redissolved in methanol and purified by RP-HPLC (5 µm, 4.6 × 150 mm Waters Nova-Pak C_{18}; solvent methanol/water, 97:3, flow 1 mL/min). The menthoxycarbonyl derivative eluted after ≅8 min. The diastereoisomer was resolved by straight-phase (SP)-HPLC using an Alltech 5-µm silica column (4.6 × 250 mm) and eluting with a mixture *n*-hexane/isopropanol 100:0.1 vol/vol at 1 mL/min. The retention time of 11-HETE from mussel was compared with a racemic mixture of 11-HETE and with 11(*R*)-HETE.

For the chiral analysis of 12-HETE, the methyl ester was resolved by chiral HPLC using a Diacel Chiralcel OD (4.6 × 250 mm) chiral column eluting with a mixture *n*-hexane/isopropanol 99:1 at 1 mL/min. The retention time of 12-HETE from mussel was compared with the racemic mixture and with 12(*S*)-HETE.

RESULTS

Eicosanoid production in male and female gonads. Incubation of [^{14}C]-AA with crude homogenates of partly mature male gonads did not result in the production of any metabolites (Figs. 1A and B). In addition, no radiolabeled or UV-absorbing metabolites were detected when homogenates of either immature or mature male gonads were incubated with radiolabeled substrate (data not shown). However, incubation of crude homogenates of partly mature female gonads of *M. edulis* with [^{14}C]AA resulted in the complete incorporation of radioactive substrate into two major metabolites, designated **I** and **II** (Figs. 1C and 1D). These metabolites were also detected by UV absorption and photodiode array analysis showed that they both contained a chromophore typical of a conjugated diene structure, with a λ_{max} of 235 nm for both metabolites (data not shown). In addition, UV detection showed the presence of three other metabolites that were not radiolabeled (metabolites **III, IV,** and **V**), suggesting they were formed from endogenous substrate. Photodiode array analysis of these metabolites revealed a similar UV spectrum to that of metabolites **I** and **II**. No peaks were formed after incubation of substrate with boiled homogenates suggesting that these five metabolites were not formed from nonenzymatic oxidation (data not shown).

GC–MS analysis of metabolites. The five metabolites produced by homogenates of female gonads were purified by RP-HPLC and analyzed by GC–MS after derivatization to the methyl esters and silyl ethers.

*Metabolite **I**.* GC–MS analysis of **I** [GC retention time (rt) 18.2 min] gave major ions at *m/z* 406 (M^+), *m/z* 391 (M – CH_3), *m/z* 375 (M – OCH_3), and *m/z* 295 (base ion, cleavage between C-12 and C-13) (data not shown). Analysis of the hydrogenated sample (GC rt, 18.6 min) revealed ions at: *m/z* 399 (M – CH_3), *m/z* 383 (M – OCH_3), *m/z* 215 base ion, cleavage at C-12 and loss of $(CH_2)_{10}COOCH_3$, *m/z* 301 cleavage between C-12 and C-13 and loss of $(CH_2)_7CH_3$, and *m/z* 272 cleavage at C-12 and rearrangement of $Si(CH_3)_3$ to the carboxyl group (data not shown). These results are consistent with the structure of 12-hydroxy-5,8,10,14-eicosatetraenoic acid (12-HETE).

*Metabolite **II**.* The mass spectrum of **II** (GC rt, 18.2 min) revealed ions at *m/z* 406 (M^+), *m/z* 391 (M – CH_3), *m/z* 375 (M – OCH_3), and *m/z* 225 (base ion, cleavage between C-10 and C-11). GC–MS analysis of the reduced compound (GC rt, 18.5 min) gave ions at *m/z* 399 (M – CH_3), *m/z* 383 (M – OCH_3), *m/z* 287, cleavage at C-11 and loss of $CH_3(CH_2)_8$, *m/z* 229 base ion, cleavage at C-11 and loss of $(CH_2)_9COOCH_3$, and *m/z* 258 cleavage at C-11 and rearrangement of $Si(CH_3)_3$ to the carboxyl group (data not shown). These results are consistent with the structure of 11-hydroxy-5,8,12,14-eicosatetraenoic acid (11-HETE).

*Metabolite **III**.* GC–MS analysis of metabolite **III** (GC rt, 18.4 min) revealed ions at *m/z* 404 (M^+), *m/z* 389 (M – CH_3), *m/z* 373 (M – OCH_3), and *m/z* 295 (base ion, cleavage between C-12 and C-13). The following ions were observed when the reduced sample was analyzed (GC rt, 18.6 min): *m/z* 399 (M – CH_3), *m/z* 383 (M – OCH_3), *m/z* 215 base ion, cleavage at C-12 and loss of $(CH_2)_{10}COOCH_3$, *m/z* 301 cleavage at C-12 and loss of $(CH_2)_7CH_3$, and *m/z* 272 cleavage at

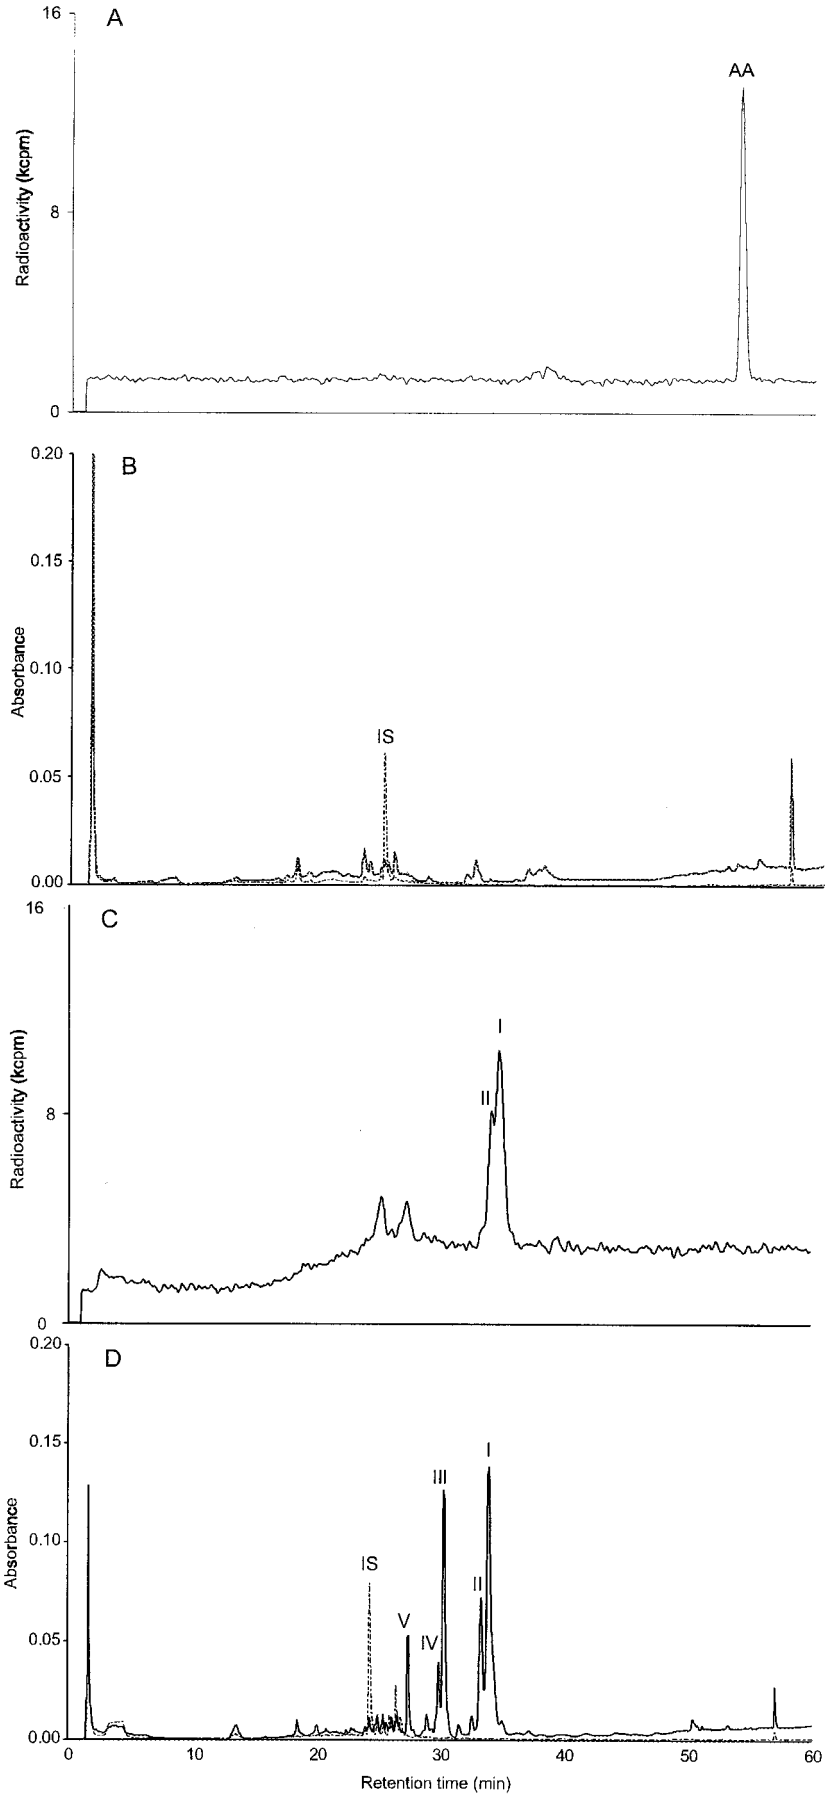

FIG. 1. Reversed-phase high-performance liquid chromatography (RP-HPLC) chromatogram obtained after incubation of mussel gonad tissue preparations with [^{14}C]arachidonic acid. (A) [^{14}C] Radiochromatogram of testis extract; (B) ultraviolet (UV) chromatogram of testis extract (— 235 nm, --- 280 nm); (C) [^{14}C] radiochromatogram of ovary extract; (D) UV chromatogram of ovary extract (— 235 nm, ---280 nm). IS = prostaglandin B_2 (PGB_2) internal standard. Retention time of 11-HETE standard 32.7 min, 12-HETE standard 33.5 min. HETE, hydroxyeicosatetraenoic acid.

C-12 and rearrangement of $Si(CH_3)_3$ to the carboxyl group (data not shown). These results are consistent with the structure of 12-hydroxy-5,8,10,14,17-EPA (12-HEPE).

*Metabolite **IV***. Metabolite **IV** (GC rt, 18.3 min) revealed ions at *m/z* 404 (M^+), *m/z* 389 (M – CH_3), *m/z* 373 (M – OCH_3), and *m/z* 223 (base ion, cleavage between C-10 and C-11). The reduced compound (GC rt, 18.5 min) revealed ions at *m/z* 399 (M – CH_3), *m/z* 383 (M – OCH_3), *m/z* 287 cleavage at C-11 and loss of $CH_3(CH_2)_8$, *m/z* 229 base ion, cleavage at C-11 and loss of $(CH_2)_9COOCH_3$, and *m/z* 258 cleavage at C-11 and rearrangement of $Si(CH_3)_3$ to the carboxyl group (data not shown). These results are consistent with the structure of 11-hydroxy-5,8,12,14,17-EPA (11-HEPE).

*Metabolite **V***. Analysis of this fraction revealed two peaks on GC–MS. Analysis of the major compound (GC rt, 16.6 min) revealed ions at *m/z* 378 (M^+), *m/z* 363 (M – CH_3), *m/z* 347 (M – OCH_3) and *m/z* 223 base ion, cleavage between C-8 and C-9 and loss of $CH_2(CH)_2(CH_2)_4COOCH_3$ (Fig. 2A). The reduced compound (GC rt, 17.1 min) revealed ions at *m/z* 371 (M – CH_3), *m/z* 355 (M – OCH_3), *m/z* 259 base ion, cleavage at C-9 and loss of $CH_3(CH_2)_8$, and *m/z* 229 cleavage at C-9 and loss of $(CH_2)_7COOCH_3$ (Fig. 2B). Assuming the formation of this product from endogenous SA, these results are consistent with the structure of this metabolite as 9-hydroxy-6,10,12,15-octadecatetraenoic acid (9-HOTE).

Analysis of the minor compound (GC rt, 16.6 min) revealed ions at *m/z* 378 (M^+), *m/z* 363 (M – CH_3), *m/z* 347 (M – OCH_3), *m/z* 309 cleavage at C-13 and loss of $CH_3CH_2(CH)_2CH_2$, and *m/z* 223 cleavage at C-8 and loss of $CH_2(CH)_2(CH_2)_4COOCH_3$ (Fig. 3A). After reduction, GC–MS analysis (rt 17.2, min) revealed ions at *m/z* 371 (M – CH_3), *m/z* 355 (M – OCH_3), *m/z* 315 cleavage at C-13 and loss of $CH_3(CH_2)_4$, and *m/z* 173 cleavage at C-13 and loss of $(CH_2)_{11}COOCH_3$ (Fig. 3B). If the precursor substrate was SA, these results are consistent with the structure of this metabolite as 13-hydroxy-6,9,11,15-octadecatetraenoic acid, 13-HOTE.

Steric analyses of 11- and 12-HETE. The chirality of 11-HETE was determined by SP-HPLC analysis of the methyl ester (–)-menthoxycarbonyl derivatives. The racemic standard eluted as two peaks at 11.5 and 12.1 min with the *R* form eluting before the *S* enantiomer (Fig. 4A) similar to a previous report (5). Co-injection of the natural mussel product with the racemic standard resulted in an increase of the *R* enantiomer (Fig. 4B). Analysis of the natural product alone revealed that it predominantly consisted of the *R* enantiomer with less than 1% m/m of the *S* form (Fig. 4C).

The chirality of the 12-HETE metabolite was determined by separation of the methyl ester derivatives on a Chiracel OD column. The racemic mixture of 12-HETE eluted as two peaks at 13.0 and 16.0 min with the *R* enantiomer eluting before the *S* form (Fig. 5A). Co-injection of the mussel natural product resulted in an increase of the *S* form (Fig. 5B). Analysis of the natural product alone revealed that 12-HETE consisted solely of the *S* enantiomer (Fig. 5C).

Eicosanoid production during ovarian development. Initial results with incubation of crude homogenates of ripe ovaries with different PUFA substrates showed that HETE metabolites were only formed from the addition of exogenous substrate (AA) whereas HEPE metabolites were formed even without addition of substrate as well as from addition of exogenous EPA. This suggested the possibility that EPA may be the natural endogenous substrate for biosynthesis of these monohydroxy fatty acids. To investigate changes in the profile of the 11- and 12-hydroxy fatty acids produced during ovarian development, crude homogenates of immature or ripe gonads were incubated with EPA and the resulting eicosanoid profiles analyzed by RP-HPLC. In order to confirm the structures of closely eluting metabolites, RP-HPLC peaks were collected and structures confirmed after GC–MS analysis of the silylated derivatives. In immature female gonads, the major metabolite was 12-HEPE with lesser amounts of 11-HEPE (Fig. 6A). In mature ovaries, the major metabolite produced was 11-HEPE with only low amounts of 12-HEPE present (Fig. 6B).

In order to determine whether these eicosanoids were produced in spawned eggs, mussels were induced to spawn by injection with KCl and spawned eggs were collected, immediately extracted with methanol, and subjected to RP-HPLC analysis. The eicosanoid profile showed high levels of 11-HEPE and HOTE (predominantly the 9-isomer), but low levels of 12-HEPE or HETE (Fig. 6C). There was no increase in the biosynthesis of 11-HEPE when eggs were preincubated with substrate (20 μM EPA, 30 min) prior to extraction (data not shown).

Calcium dependence of the reaction. To determine whether the enzymes involved in the biosynthesis of 11- and 12-HEPE were calcium dependent, crude homogenates of partly mature ovaries (in Tris buffer containing 5 mM EDTA) were incubated with EPA in the presence of different concentrations of calcium. When no calcium was added, only trace amounts of 11- or 12-HEPE were formed. Addition of 10 mM Ca^{2+} or more (final concentration) resulted in maximal response of both enzyme activities (Table 1). These results suggest that the formation of both 11- and 12-HEPE is calcium dependent.

Effects of inhibitors on eicosanoid biosynthesis. The effects of NDGA, baicalein, proadifen, aspirin, and IMC on biosynthesis of 11- and 12-HEPE were investigated. Crude homogenates of partially mature ovaries were preincubated with inhibitors prior to addition of EPA (20 μM) and calcium. Neither aspirin (at 30 μM, an inhibitor of the prostaglandin synthase I isoform) nor IMC (30 μM, a nonselective inhibitor of the prostaglandin synthase pathway) reduced biosynthesis of either eicosanoid. An inhibitor of the cytochrome P450 pathway, proadifen (30 μM), did not inhibit the biosynthesis of either 11- or 12-HEPE. Baicalein is a selective inhibitor of mammalian (platelet) 12(*S*)-LO with an ID_{50} of 0.12 μM (12). In our study, preincubation with 5 μM baicalein did not reduce eicosanoid synthesis but at 20 μM, baicalein inhibited the biosynthesis of 11-HEPE by 54% and only inhibited 12-HEPE biosynthesis by 11% (data not shown). NDGA (10 μM) was the most effective inhibitor and inhibited the biosynthesis of 11-HEPE by 91% and 12-HEPE by 86%.

Cellular localization of the lipoxygenase activity. In order to determine the localization of enzyme activity, 100,000 × *g*

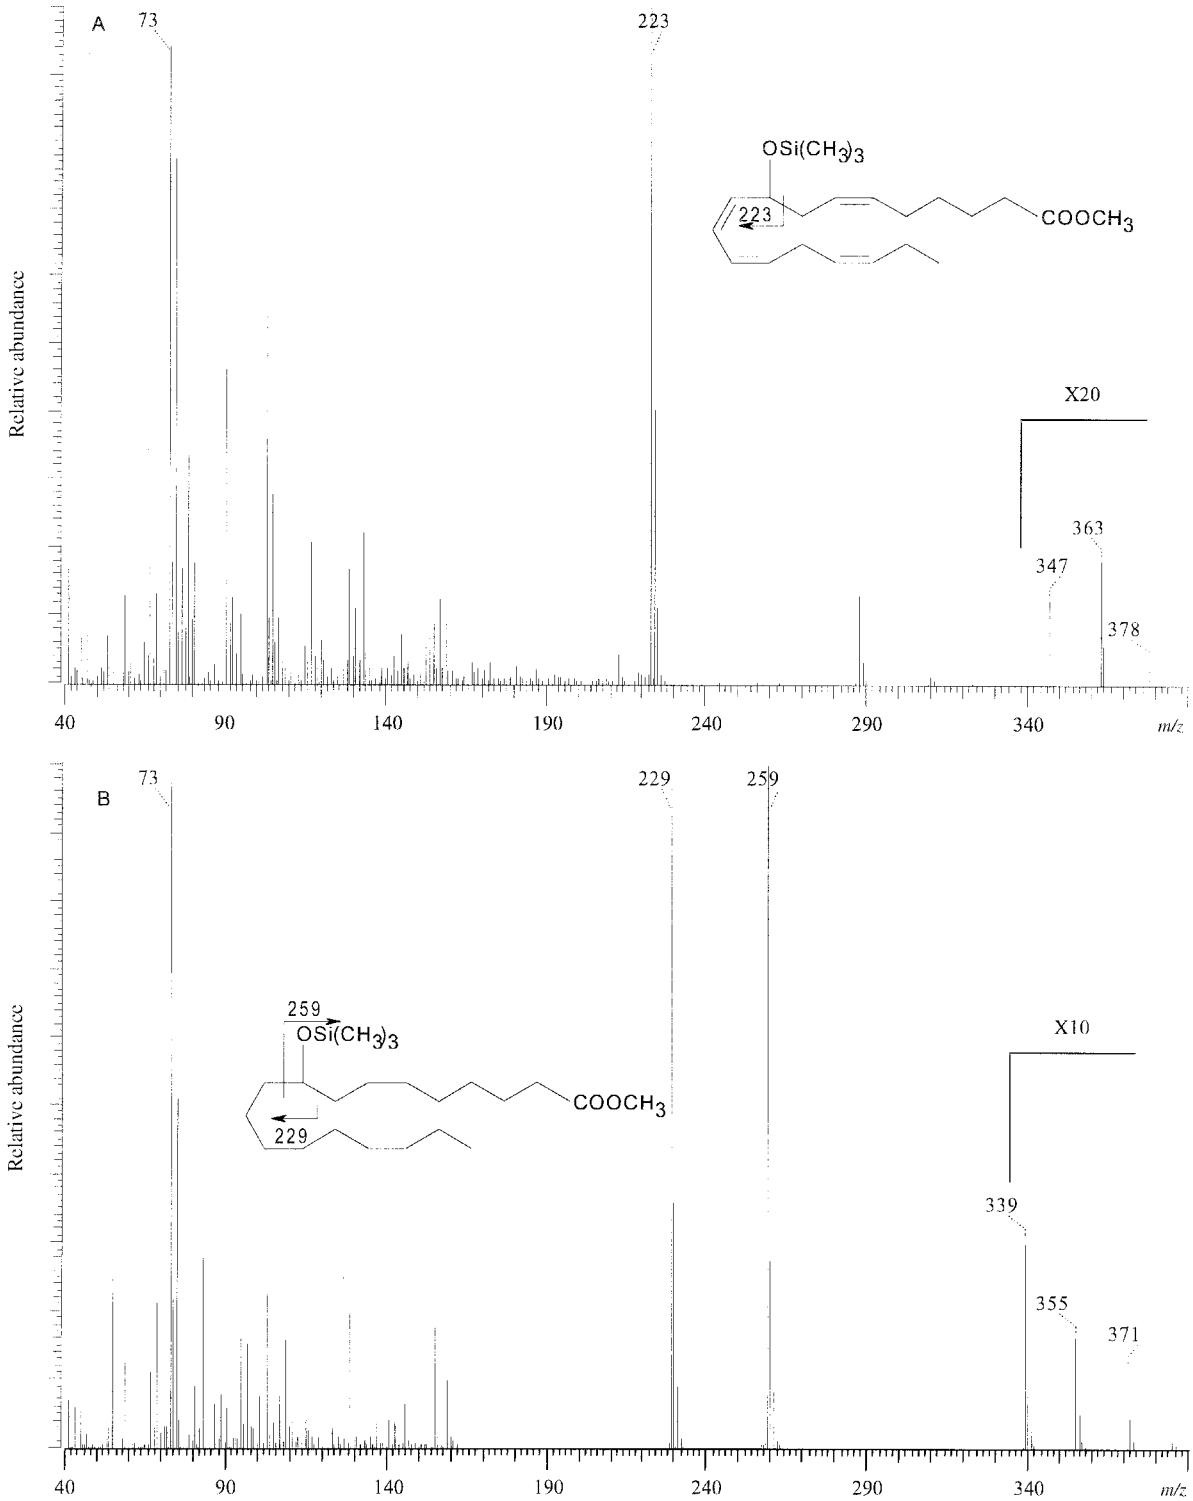

FIG. 2. Gas chromatography–mass spectrometry (GC–MS) analysis of the methyl ester, trimethylsilyl ether of the major compound in the RP-HPLC fraction of metabolite **V**. (A) Native structure; (B) after hydrogenation. See Figure 1 for other abbreviation.

supernatant and pellet preparations were made with partially ripe ovarian tissue. The preparations were incubated with EPA and calcium and the products analyzed by RP-HPLC. Over 96% of both the 11- and 12-LO activity was associated with the 100,000 × *g* supernatant suggesting that both these enzymes were localized in the cell cytosol.

DISCUSSION

This study shows that the synthesis of eicosanoids in the mussel gonad is sex dependent. No eicosanoids were detected in immature or ripe testes, but a number of hydroxy fatty acids were synthesized in mussel ovaries from both endogenously

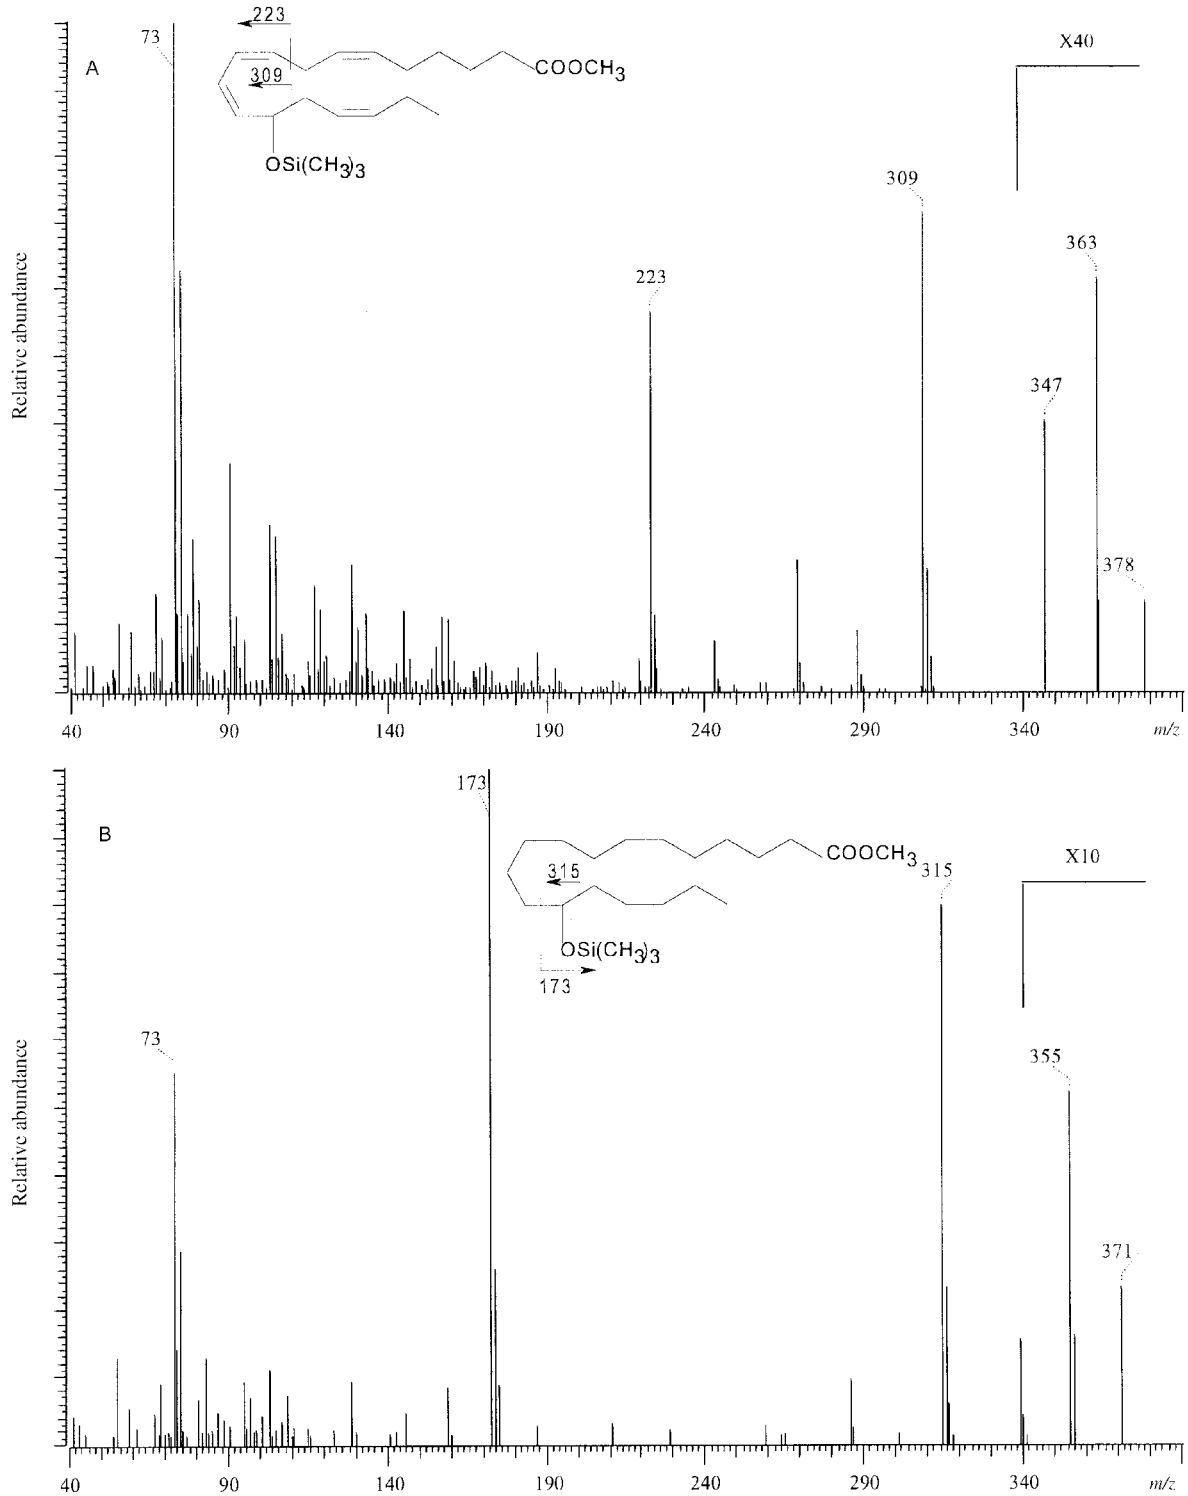

FIG. 3. GC–MS analysis of the methyl ester, trimethylsilyl ether of the minor compound in the RP-HPLC fraction of metabolite **V**. (A) Native structure; (B) after hydrogenation. See Figures 1 and 2 for abbreviations.

and exogenously added substrates. The major metabolites formed from the addition of AA were identified by GC–MS and chiral analyses as 11(*R*)-HETE and 12(*S*)-HETE. The biosynthesis of these metabolites was not inhibited by the prostaglandin synthase inhibitors aspirin and IMC, nor by proadifen, an inhibitor of the cytochrome P450 pathway. Their formation was inhibited by NDGA (10 μM) at a concentration which inhibits mammalian LO enzymes. In addition, unlike the cytochrome P450 and prostaglandin synthase enzymes, the enzymes involved in the biosynthesis of these HETE were localized in the cytosol and not the microsomal fraction, and product formation was calcium dependent. Fur-

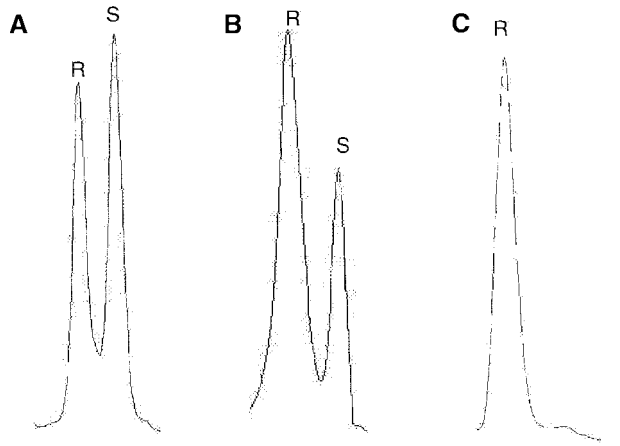

FIG. 4. Chiral analysis of mussel-derived 11-HETE. The methyl ester (–)-menthoxycarbonyl derivatives of standards and samples were analyzed by straight-phase HPLC. thermore, in contrast to many cytochrome P450 metabolites (13), the HETE formed in this study were highly enantiospecific being either all *R* (11-HETE) or all *S* (12-HETE). Together these data suggest that these metabolites are formed from the action of LO enzymes.

The HETE products of LO action in many aquatic invertebrates tend to be of the *R* enantiomer in contrast to most of the HETE products formed by many mammalian tissues. Therefore, the presence of a 12(*S*)-LO is unusual in aquatic invertebrates although a 12(*S*)-LO activity has been reported in *H. magnipapillata* and *Aplysia californica* (6,14). Mammalian platelet 12(*S*)-LO is inhibited by submicromolar concentrations of baicalein (12) but in our study 200-fold higher concentrations of baicalein only resulted in a slight reduction in 12(*S*)-LO activity. Furthermore, the activity of mussel-derived 12(*S*)-LO was calcium dependent unlike that of platelet

TABLE 1
The Effect of Calcium Concentration on Lipoxygenase Product Formation[a]

Calcium concentration (mM)	11-HEPE (nmol/30 min)	12-HEPE (nmol/30 min)
0	0.1	0.1
10	2.2	2.2
13	2.1	2.1
15	2.1	2.1

[a]10,000 × *g* homogenates of mussel ovaries (in Tris buffer containing 5 mM EDTA) were incubated with eicosapentaenoic acid (EPA) in the presence of different concentrations of calcium chloride. HEPE products were extracted and quantified by reversed-phase high-performance liquid chromatography. Data are means of two replicate assays. 11-HEPE, 11-hydroxy-5,8,12,14,17-EPA; 12-HEPE, 12-hydroxy-5,8,10,14,17-EPA.

or porcine leukocyte 12(*S*)-LO, which suggested that the mussel enzyme was not the same form as the mammalian 12(*S*)-LO enzymes (15,16). 11(*R*)-LO activity has been reported in two species of *Hydra*, however, unlike mussel 11(*R*)-LO, this activity in *Hydra* was not inhibited by NDGA, which suggests that there are different forms of 11(*R*)-LO enzymes in these two invertebrates (6,7).

There is the possibility that 11(*R*)-HETE and 12(*S*)-HETE could be formed from the same enzyme by abstraction of a co-planar pro-*S* hydrogen atom at either the C-13 or C-10 positions of AA, respectively. However, in our study high concentrations of baicalein inhibited the synthesis of 11(*R*)-HETE much more than 12(*S*)-HETE and, in addition, 12-LO activity predominated in immature ovaries whereas 11-LO was the major activity in ripe ovaries. Together these data suggested that two independent LO enzymes are present in mussel ovaries and that their relative activity is dependent on gonad differentiation.

During incubation of ovary tissue preparations with either exogenous AA or EPA, HOTE metabolites were detected, which could have been formed from endogenous SA. GC–MS analysis of these metabolites showed that they were a mixture of 9- and 13-HOTE. These could be products of an 11-LO activity or, alternatively, 13-HOTE could also be formed by a 12-LO, analogous to the activity of porcine 12(*S*)-LO, which forms alcohols at both the n-9 and n-6 positions of AA and linoleic acid (17).

When spawned eggs were extracted with methanol, both 11-HEPE and HOTE (predominantly 9-HOTE) were formed from endogenous substrate. Incubation of eggs with EPA substrate prior to eicosanoid extraction did not increase biosynthesis of 11-HEPE, which suggested that either the oocyte 11-LO is product-inactivated similar to many other lipoxygenases (18) or that 11-HEPE was formed in surrounding ovarian tissue and diffused into the oocytes prior to spawning. The biosynthesis of eicosanoids from endogenous SA has not been reported before in animal tissues although 13-HOTE has been detected in female gametophytes of the marine alga *Laminaria saccharina* (19). Marine organisms contain high levels of n-3 PUFA and EPA, and to a lesser extent SA, linolenic acid (18:3n-3) as well as AA, are predominant

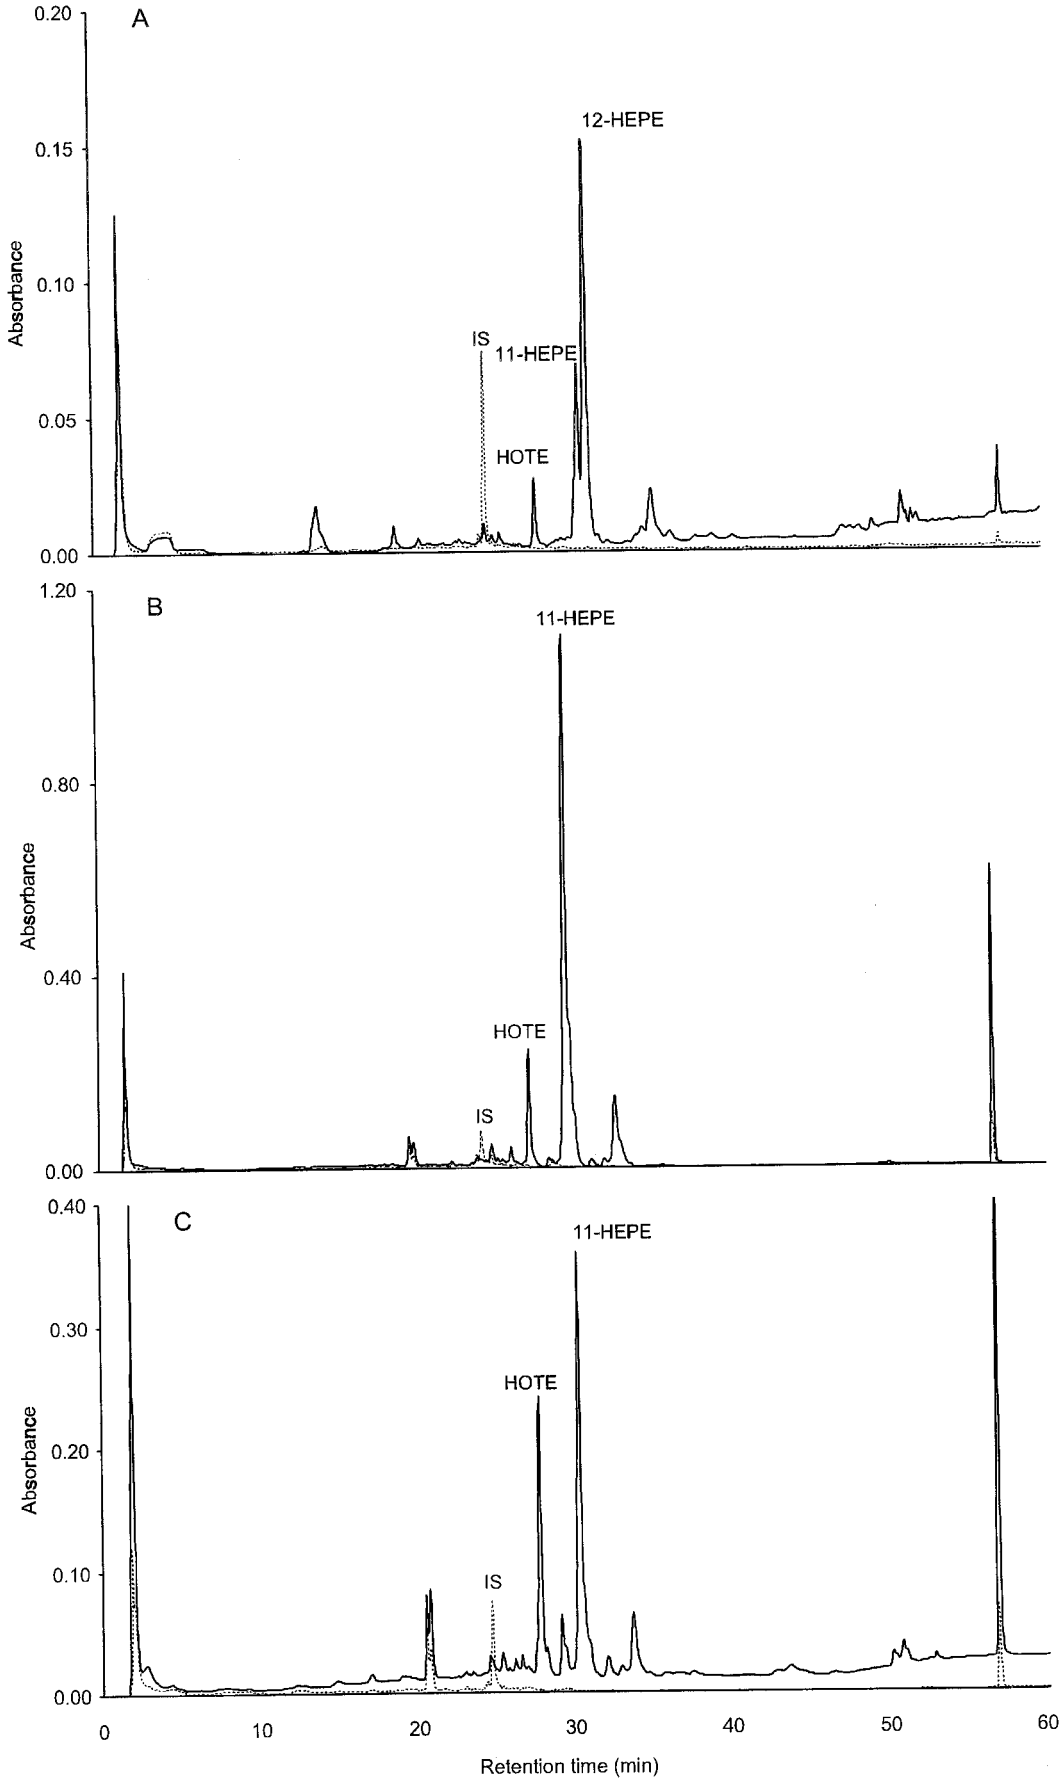

FIG. 6. Eicosanoid biosynthesis during ovarian development. Crude homogenates (10,000 × *g* supernatant) of (A) immature and (B) ripe ovaries were incubated with eicosapentaenoic acid (EPA) (20 μM) and the resulting eicosanoid profile was analyzed by RP-HPLC UV detection. (C) Spawned eggs from one mussel were extracted with methanol and the eicosanoids analyzed by RP-HPLC UV. (— 235 nm, --- 280 nm). IS = PGB_2 internal standard. HOTE, 9- and 13-hydroxyoctadecatetraenoic acids; 11-HEPE, 11-hydoxy-5,8,12,14,17-EPA; 12-HEPE, 12-hydroxy-5,8,1,14,17-EPA. See Figure 1 for other abbreviations.

PUFA in *M. edulis* (20). The detection of only EPA- and SA-, but not AA-derived metabolites suggests either that high levels of EPA and SA substrates are released from oocyte membranes during cell activation and/or that EPA and SA are preferred substrates for mussel LO. The major LO products generated by ionophore activation of sea squirt (*Ciona intestinalis*) tissues were metabolites of EPA rather than AA, suggesting that EPA could be the endogenous substrate for eicosanoid synthesis in some marine organisms (21).

The physiological role of these 11(*R*)-LO and 12(*S*)-LO enzymes in *Mytilus* is unknown at present; however, the isolation of these metabolites in the ovaries and not in the testes suggests a connection with the female reproductive cycle. These results are in contrast to that reported for some other marine invertebrates where LO activity in the testes of the surf clam and the starfish is similar to the activity in the ovaries (3). Our studies, conducted in different periods of the year, have shown that the production of eicosanoids is seasonal; in particular, metabolites of 12(*S*)-LO are the major products in spent and immature ovaries whereas 11(*R*)-LO activity appears to predominate in mature ovaries. 12(*S*)-HETE has been shown to be an important second messenger in a variety of vertebrate and invertebrate cells (6,22,23) and it is possible that metabolites of 12(*S*)-LO may act as second messengers in mussel cells and regulate cell differentiation and gametogenesis in the female gonad. The role of the 11(*R*)-HEPE and/or the HOTE metabolites detected in spawned *Mytilus* oocytes is unclear but the detection of 11(*R*)-LO activity in spawned eggs of the sea urchin suggests this enzyme may also be involved in oocyte function in other species (5).

ABSTRACT: The biosynthesis of 3*R*-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid (3*R*-HETE) from arachidonic acid (20:4n-6) by the hyphal-forming yeast, *Dipodascopsis uninucleata,* in cell-free enzyme extracts required CoASH, ATP, NAD^+ and Mg^{2+}; 3*R*-HETE was present as the CoA derivative in enzyme extracts and its biosynthesis was associated with mitochondria. Its synthesis was high from arachidonoyl-CoA (15% conversion of the substrate; 22 nmol mg protein^{-1}·h), but significantly higher from *trans*-2-arachidonoyl-CoA (53 nmol mg protein^{-1}·min). Aspirin, an inhibitor of prostaglandin endoperoxide synthase synthase (cyclooxygenase), did not significantly inhibit 3*R*-HETE biosynthesis in enzyme extracts, as opposed to antimycin A (46% inhibition). The chirality of 3-HETE was 95% *R* and 5% *S*. 3*R*-HETE has the same chirality as the products of peroxisomal enoyl-CoA hydratases of *Neurospora crassa* and *Saccharomyces cerevisiae*; the difference appears to be that in *D. uninucleata* the *R*-enantiomers are synthesized in mitochondria. Exogenously supplied eicosapentaenoic acid was converted to 3-hydroxy 5*Z*,11*Z*,14*Z*,17*Z*-eicosapentaenoic acid by cell-free enzyme extracts though there was no requirement for a 5*Z*,8*Z*-diene structure for the biosynthesis of 3-hydroxylated fatty acids as 3-hydroxy-8*Z*,11*Z*,14*Z,* and 3-hydroxy-11*Z*,14*Z*,17*Z*-eicosatrienoic acids were synthesized from the corresponding fatty acids. We found no evidence for the synthesis of the prostaglandins $F_{2\alpha}$ and E_2.

Paper no. L8523 in *Lipids 35,* 1205–1214 (November 2000).

Currently there is considerable interest in harvesting microorganisms to synthesize valuable secondary products, which may find potential in the pharmaceutical industries. For example, the hyphal-forming yeast *Dipodascopsis uninucleata* was discovered to synthesize the novel fatty acid derivative 3-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid (3-HETE) when incubated with exogenously supplied arachidonic acid (1). Because the synthesis of 3-HETE was inhibited by the inclusion of 1 mM aspirin (*O*-acetylsalicylic acid) in the incubation medium, it seemed possible that one of the enzymes involved in the synthesis of 3-HETE was prostaglandin endoperoxide synthase (PGH synthase), an enzyme well known to be inhibited by such concentrations of aspirin (1). The involvement of PGH synthase or a similar type of enzyme was further supported by the identification of two isomers of the prostaglandin metabolite α-pentanor $PGF_{2\alpha}$-γ-lactone, a breakdown product of prostacyclin (2,3). Evidence was presented suggesting the existence of two further prostaglandins, $PGF_{2\alpha}$ and PGE_2, in the closely related yeast *Dipodascopsis töthii* (4).

Both Kock *et al*. (5,6) and we (7–9) have proposed that the conversion of 20:4n-6 to 3-HETE by *D. uninucleata* involves a modification of the fatty acid β-oxidation cycle. In addition, both we (7,8) and Venter *et al*. (10) have found that the major product (approximately 95%) is the *R*-enantiomer of 3-HETE (7–10). Consequently, a separate hydroxylase for the direct formation of 3*R*-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid (3*R*-HETE) was postulated (10). Interestingly the β-oxidation pathway in fungi is not analogous to that found in mammals and plants. Indeed Kunau *et al*. (11), in a review of β-oxidation, including their own research on this topic, have reported that the 3-hydroxyacyl-CoA intermediates in the fungal β-oxidation pathway have the D-configuration (corresponding to *R*-enantiomers) unlike the mammalian and plant pathways where the intermediates are in the L-configuration (*S*-enantiomers). This then re-opens the possibility that 3*R*-HETE is being formed by β-oxidation in this yeast.

Here we present results from experiments with cell-free enzyme extracts and isolated organelles that indicate that 3*R*-HETE biosynthesis in *D. uninucleata* involves an incomplete β-oxidation process with the intermediates having the same chirality as are found in other fungi. Moreover, this β-oxidation activity in *D. uninucleata* is constitutive and appears to be located in mitochondria, unlike the inducible β-

oxidation system, which is located in peroxisomes and specialized microbodies (11). The term "peroxisomes" is used here to refer to organelles containing acyl-CoA oxidase (11).

We reported earlier (7,8) that whole cells of *D. uninucleata* converted both 8*Z*,11*Z*,14*Z*- and 11*Z*,14*Z*,17*Z*-eicosatrienoic acids to their corresponding 3-hydroxy derivatives. We now show that similar reactions are catalyzed by cell-free enzyme extracts. Finally, because of the findings of earlier work with this yeast (1–4), we tried to address the question of whether *D. uninucleata* can be used to synthesize prostaglandins from 20:4n-6.

MATERIALS AND METHODS

Yeast growth. Conical flasks (1 L) containing 400 mL yeast nitrogen base (YNB) medium (7 g YNB, 10 g glucose, and 5 g peptone/L) were inoculated with *Dipodascopsis uninucleata* (UOFS Y128) previously grown on YNB agar plates. After growing at 30°C for 4 d and shaking at 140 rev/min, cultures were filtered through glass wool and the filtrates centrifuged at 10,000 × *g* for 10 min to pellet ascospores. The ascospores were inoculated to give a final concentration of 1.5×10^5 per mL (12) in 400 mL of medium comprising (g/L) glucose, 40 (referred to as 4% glucose medium); YNB (without amino acids), 6.7; peptone, 5; malt extract, 2.4; pH 6. The cultures were maintained at 25°C and 140 rev/min for 48 h. In other experiments, the ascospores were inoculated to the same concentration into an identical medium (400 mL), but one which contained 1% glucose, with YNB (6.7 g/L) without peptone or malt extract (referred to as 1% glucose medium). Likewise, ascospores were also inoculated into a medium (400 mL) containing 1% ethanol as the sole carbon source with YNB (6.7 g/L), but without peptone and malt extract.

Chiral analysis. 3-HETE was isolated from 48-h grown cultures of *D. uninucleata* grown as previously detailed (13). 3-HETE was methylated with diazomethane and catalytically hydrogenated to produce methyl 3-hydroxyeicosanoic acid. This compound was treated with *S*-phenylpropionyl chloride to form the *S*-phenylpropionate ester. The final analysis was carried out by gas chromatography–mass spectrometry (GC–MS) using the *S*-phenylpropionate ester of 3-(*R*,*S*)-hydroxyeicosanoic acid as the reference compound. The reference compound was prepared by anodic coupling of methyl 3(*R,S*)-acetoxy-4-carboxybutanoate (5 mmol; 14) and heptadecanoic acid (15 mmol) in methanol (20 mL) containing sodium methoxide (0.5 mmol). Purification of the saponified and methyl-esterified product by open column silicic acid chromatography afforded methyl 3(*R,S*)-hydroxyeicosanoate as a white solid (0.4 g; 23% yield). The mass spectrum of the Me_3Si derivative showed prominent ions at *m/z* 399 (100%; $M^+ - 15$; loss of $\cdot CH_3$), 341 (6; $M^+ - 73$; loss of $\cdot CH_2–COOCH_3$), 175 (25; $Me_3SiO^+=CH–CH_2–COOCH_3$), 159 (7; $Me_2Si=O^+–CH=CH–COOCH_3$), 89 (14; Me_3SiO^+), and 73 (14; Me_3Si^+). The two enantiomers of methyl 3-acetoxy-4-carboxybutanoate can be easily obtained by resolution of the racemic half ester (14), thus permitting synthesis of the optically active forms of 3-hydroxyeicosanoate.

Preparation of cell-free enzyme extracts. Cells, 5 g wet wt, were harvested by filtration after 24 or 48 h growth. They were washed thoroughly with distilled water before being resuspended in 25 mL 1 mM mercaptoethanol, 5 mM EGTA, 5% (vol/vol) glycerol, and 500 mM Tris (hydroxymethyl) methylamine hydrochloride (Tris/HCl), pH 7.6. The mixture was passed twice through a hydraulic press (Bundenberg, Manchester, United Kingdom) at a pressure of 5.1×10^3 kPa. The homogenate was clarified by centrifugation at 30,000 × *g* for 15 min and the supernatant used as the cell-free enzyme extract (referred to as enzyme extracts; note, these extracts did not contain intact mitochondria). Subsequent incubations were of 1 mL and were maintained at 25°C for 30 min. For experiments with fatty acids the final concentrations were 20:4n-6 (sodium salt), 0.5 mM; 20:4n-6-CoA (Sigma Chemical Co., Poole, United Kingdom), 0.1 mM; CoASH, 0.5 mM; ATP, 5 mM; NAD^+, 0.2 mM; and Mg^{2+}, 1 mM. For analysis of the [^{14}C]acyl-CoA fraction, 18.5 kBq [1-^{14}C]20:4n-6 was included (sp. act. 2,035 MBq/mmol) in an otherwise identical incubation medium (1 mL). For experiments with potential inhibitors of 3-HETE biosynthesis, the final concentration was 1 mM, unless otherwise stated.

Isolation of mitochondria. Cells (10–20 g wet wt) grown on the 4% glucose medium were harvested after 48 h and transferred to extraction buffer (5 mL buffer/1 g wet wt) comprising 0.6 M sucrose, 1 mM EGTA, 0.4% (wt/vol) bovine serum albumin (BSA) (fraction V, essentially fatty acid free; Sigma), 300 mM Tris/HCl, pH 7.4. The mixture was stored on ice for 30 min. Cells were disrupted with a Bead Beater (bead mesh <106 µm; Biospec Products, Bartlesville, OK) during which the apparatus was chilled with dry ice. The homogenate was passed through one layer of muslin, removing most of the beads. Decanting the solution into centrifuge tubes (50 mL) removed the remaining beads. The homogenate was centrifuged at 1,085 × *g* and the supernatant collected and centrifuged at 27,000 × *g* for 10 min. The pellet was resuspended in resuspension medium (50 mL) comprising 0.4 M sucrose, 1 mM EGTA, 0.1% (wt/vol) BSA, 50 mM Tris/HCl, pH 7.4 and centrifuged at 1,085 × *g* for 5 min. The supernatant was recentrifuged at 27,000 × *g* and the pellet resuspended in resuspension medium (1 mL). This was layered onto a discontinuous sucrose gradient comprising 60% (3 mL), 52% (4 mL), 45% (4.5 mL), 41% (4.5 mL), and 30% (3 mL) (vol/vol) sucrose in 10 mM *N*-[2-hydroxyethyl]piperazine-*N*′-[2-ethanesulfonic acid] buffer, pH 7.4. The gradients were centrifuged at 42,000 × *g* for 80 min in a swing-out rotor (3 × 25 mL) at 2°C. Fractions (1 mL) were collected from the bottom of the gradients and used for enzyme assays. In a separate series of experiments, to measure 3-HETE biosynthesis, the organelle bands were removed with a Pasteur pipette from the interfaces between the different sucrose concentrations (*ca*. 2 mL fractions) and diluted to 20–30 mL with resuspension medium. They were pelleted at 27,000 × *g* for 10 min at 2°C. The pellets were resuspended in 4–5 mL

resuspension medium (i.e., containing sucrose as osmoticum). For incubations with fatty acids and cofactors, to measure 3-HETE synthesis, concentrations were as listed for those with enzyme extracts (i.e., incubations of 1 mL). In order to burst mitochondria, they were incubated in resuspension medium but without the sucrose. The respiratory control ratio (RCR) was measured as detailed by Rickwood *et al*. (15) and protein determined using a protein assay kit (Sigma).

Preparation of enoyl-CoA thioesters. *Trans*-2-enoyl derivatives of acyl-CoA thioesters were prepared by incubation of 1.125 U acyl-CoA oxidase (Boehringer Mannheim Ltd., Lewes, United Kingdom) per micromole acyl-CoA in 25 mM potassium phosphate, pH 7.5 at 25°C (Dr. S. Eaton, Institute of Child Health, London, United Kingdom, personal communication). The enoyl-CoA derivatives of acyl-CoA elute immediately before their straight-chain derivatives (16). The reaction, which went to completion after 30 min, was quenched with 100 µL formic acid. The *trans*-2-enoyl-CoA thioesters were purified by high-pressure liquid chromatography (HPLC) on a Lichrosorb 7 RP18 10 × 0.3 cm column (Chrompack International, Middelburg, The Netherlands). HPLC conditions comprised an isocratic gradient of 50 mM KH_2PO_4 (pH 5.6)/acetonitrile (1:1, vol/vol) with a flow rate of 0.5 mL min^{-1} and ultraviolet detection at 260 nm. The fraction containing enoyl-CoA thioesters was stored at –80°C.

Enzyme assays. Spectrophotometric assays were performed at 25°C on a double-beam spectrophotometer. Activities of long-chain acyl-CoA dehydrogenase (17; assayed using arachidonoyl-CoA), acyl-CoA oxidase (18; assayed using arachidonoyl-CoA), long-chain enoyl-CoA hydratase (19; assayed with synthesized *trans*-2-enoyl-CoA thioesters of different chain length and saturation), D-3-hydroxyacyl-CoA dehydrogenase (20; assayed with 3*R*-HETE), 3-ketoacyl-CoA thiolase (21; assayed with a racemic mixture of acetoacetyl-CoA in the reverse direction), fumarase (22), catalase (23), isocitrate lyase (24), malate synthase (25), and $NADP^+$-dependent cytochrome *c* oxidoreductase (26) were determined by established procedures though some of the substrates were altered (as listed).

PGH synthase was assayed in enzyme extracts and microsomal pellets. Microsomes were sedimented at 100,000 × *g* for 90 min from the enzyme extract, giving a brown translucent pellet, and resuspended in resuspension medium. The enzyme PGH synthase was assayed from enzyme extracts as this is the first enzyme in the synthesis of prostaglandins from 20:4n-6 [*viz.* breadown products of prostaglandins had previously been detected in this yeast (3,4)]. The procedure used a polarographic O_2 electrode to measure the decrease in O_2 concentrations upon addition of 20:4n-6 (27). PGH synthase was also assayed by analysis of the products of 20:4n-6 metabolism as detailed by Yamamoto (28) (0.1 mg 20:4n-6, containing 18.5 kBq [1-^{14}C]20:4n-6, sp. act. 2,035 MBq/mmol per mL enzyme extract or microsome preparation). After incubation of extracts (final vol 2 mL) at 25°C for 30 min, the products of [1-^{14}C]20:4n-6 metabolism were extracted (×3) with an equal volume of chloroform and acidified with 50 µL glacial acetic acid. Samples were concentrated to a small volume under N_2 gas prior to separation of polar fatty acids by thin-layer chromatography (TLC) using silica gel G plates (Kieselgel, Anachem, United Kingdom). After application of the samples, the plates were developed at 4°C with the organic phase of the following solvents: ethyl acetate/2,2,4-trimethylpentane/acetic acid/water (110:50:20:100, by vol). ^{14}C was detected by scintillation counting (Bioscan Autochanger 4000, Bioscan Inc., Washington, DC).

Acyl-CoA analysis. The following method is based on that of Watmough *et al*. (16). Enzyme extracts, after incubation with 20:4n-6 and cofactors (final vol 1 mL), were acidified with glacial acetic acid (50 µL) and extracted (×3) with an equal volume of diethyl ether. The organic phases were discarded. Chloroform/methanol (1:2, vol/vol, 9 mL) was added to the aqueous phase and after 40 min protein was precipitated at 40,000 × *g*. The pellet was re-extracted with 1 mL chloroform/methanol. The combined organic phases were concentrated to a small volume and taken up in 1 mL KH_2PO_4 (50 mM, pH 5.6). The sample was injected (200 µL) onto a Lichrosorb 7 RP18 10 × 0.3 cm column. A gradient was run comprising initially 95% KH_2PO_4 (50 mM, pH 5.6), 5% acetonitrile, and a flow rate of 0.5 mL min^{-1}. This was altered to 40% KH_2PO_4 (50 mM, pH 5.6) after 30 min and 60% acetonitrile and maintained for another 20 min. Absorbance of acyl-CoA thioesters was measured at 260 nm.

Fatty acid analysis. For GC with flame-ionization detection, or for GC–MS, samples were subjected to alkaline hydrolysis and extracted (29) before being derivatized by methylation and silylation (30). GC analysis was carried out using a 30 m HP-1 capillary column (Hewlett-Packard, Palo Alto, CA; cross-linked methyl siloxane), internal diameter (int. diam.) 0.25 mm. GC parameters comprised an initial temperature of 200°C with a ramp rate of 2°C min^{-1} to 270°C and with a helium flow rate of 18.7 kPa. 3-HETE was prepared from whole cells of *D. uninucleata* (13) for use as a standard. 3-HETE was identified by the retention time of the compound, 15.00–15.05 min, by GC as described. This method was subsequently used to quantify the compound from incubations with enzyme extracts.

GC–MS was carried out using a Finnigan series 1020 automated GC–mass spectrometer operating in the electron impact mode. GC parameters were: BP-5 25 m fused-silica capillary column (SGE Ltd., Milton Keynes, United Kingdom); helium carrier gas at 13.8 kPa head pressure; 10:1 split; injector temperature, 220°C; initial temperature, 200°C; ramp rate, 2°C min^{-1}; final temperature, 280°C; final time, 10 min; injection volume, 1 µL. MS parameters were: source temperature, 240°C; manifold temperature, 100°C; ionization current, 0.30 A; scan range, 70 amu (arbitary mass units) to 600 amu in 1 s.

RESULTS

Chirality of 3-HETE. 3-HETE was found to be 95% *R* and 5% *S* (Fig. 1). This was in agreement with Venter *et al*. (10) and showed that, as in *Neurospora crassa* and *Saccharomyces cere-*

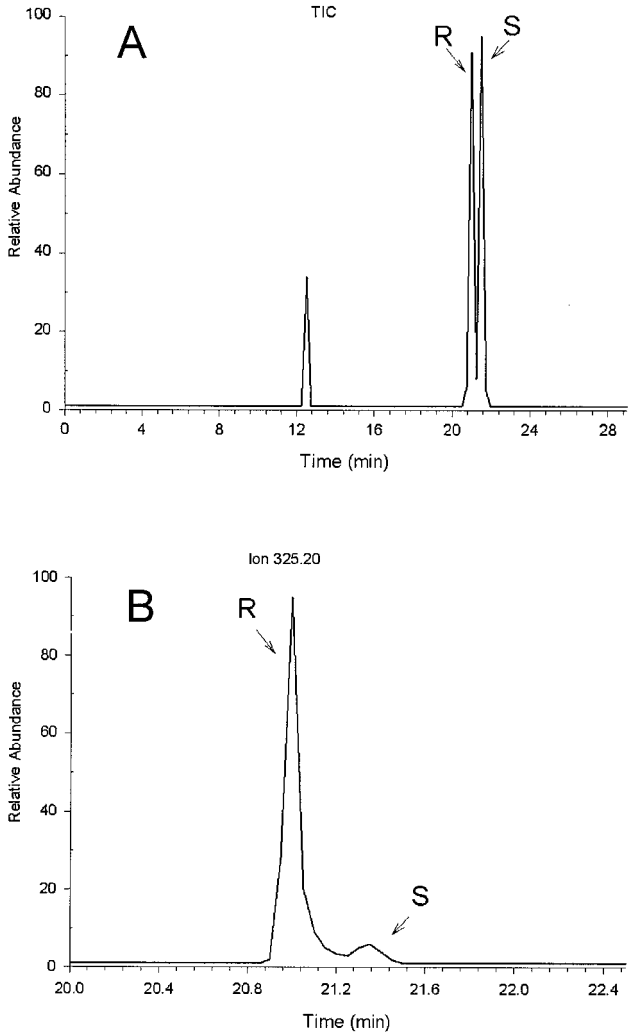

FIG. 1. (A) Total ion chromatogram (TIC) of the separation of the phenylpropionate ester of 3(*R,S*)-hydroxyeicosanoic acid standard by gas chromatography–mass spectrometry (GC–MS). (B) Partial selective ion chromatogram (M^+ = 325) of the GC–MS separation of 3(*R*)-hydroxyeicosanoic acid derived from 3-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid and isolated from the yeast *Dipodascopsis uninucleata* supplied exogenous 20:4n-6 (see Ref. 13). The compound co-chromatographed with the 3(*R*)-hydroxyeicosanoic acid standard. Integration of the peaks from several runs gave an enantiomeric composition of 95% *R* and 5% *S*.

TABLE 1
The Effect of Cofactors of the β-Oxidation System on the Biosynthesis of 3*R*-HETE by Enzyme Extracts of *Dipodascopsis uninucleata* Grown on 4% (wt/vol) Glucose Medium

20:4n-6 added	3*R*-HETE biosynthesis (nmol mg protein^{-1}·h)	Conversion of 20:4n-6 to 3*R*-HETE (%)
None	ND[a]	0
CoASH	0.5[b]	0.1

20:4n-6-CoA added	**3*R*-HETE biosynthesis (nmol mg protein^{-1}·h)**	**Conversion of 20:4n-6-CoA to 3*R*-HETE (%)**
None	22.0	15.0
CoASH, ATP, NAD^+, Mg^{2+}	24.5	19.1

[a]ND, not detected; 3*R*-HETE, 3*R*-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid.
[b]Standard deviations over three experiments were 10–15% of the mean.

visiae, long-chain enoyl-CoA hydratase from *D. uninucleata* generated *R*-3-hydroxy-acyl-CoA thioesters (11). This is unlike the equivalent enzymes of mammalian origin and may explain the potent pharmacological activity of 3*R*-HETE derived from *D. uninucleata* against human neutrophils (31). This is because the *R* chirality of certain monohydroxylated eicosanoids in mammalian cells, e.g., 12*R*-HETE, has been reported to enhance the chemotactic and chemokinetic properties of such molecules (32).

*Biosynthesis of 3*R*-HETE*. Enzyme extracts from cells cultivated on 4% glucose for 48 h did not convert 20:4n-6 to *3R*-HETE unless CoASH was added (Table 1). The subsequent addition of the known cofactors of mitochondrial β-oxidation, namely, ATP, NAD^+, and Mg^{2+}, each led to an increase in the percentage conversion of 20:4n-6 to *3R*-HETE. The increases in *3R*-HETE synthesis after the addition of these cofactors, were statistically significant to $P = 0.02$ (Student's *t*-test). The maximal percentage conversion of 20:4n-6 to *3R*-HETE was 2.6%.

When 20:4n-6-CoA, rather than the free acid, was added to the enzyme extracts there was a statistically significant increase in the rate of conversion to *3R*-HETE ($P = 0.02$, Table 1) compared to 20:4n-6 with CoASH, ATP, NAD^+, and Mg^{2+}. Without additional cofactors, the percentage conversion of 20:4n-6-CoA was 15% (corresponding to a rate of 22 nmol mg protein^{-1}·h) as opposed to 2.6% for 20:4n-6 and all cofactors. Addition of ATP, NAD^+, and Mg^{2+} did not result in a statistically significant increase in the percentage conversion of the substrate 20:4n-6-CoA (19%, $P = 0.1$). Thus it seemed that 20:4n-6 was being activated to its CoA thioester by long-chain acyl-CoA synthetase, an enzyme requiring ATP and Mg^{2+} as cofactors. The increase in *3R*-HETE biosynthesis with NAD^+ suggested that long-chain acyl-CoA dehydrogenase and not acyl-CoA oxidase (no NAD^+ requirement, it uses FAD^+) was responsible for the biosynthesis of the *trans*-2-enoyl-CoA thioester of 20:4n-6-CoA.

Further evidence for the biosynthesis of *3R*-HETE-CoA was obtained by analysis of the acyl-CoA fraction by HPLC (Fig. 2). These fractions, from incubations of enzyme extracts with 20:4n-6 and CoASH, ATP, NAD^+, and Mg^+, yielded a number of peaks. Peak 2 was collected, subjected to alkaline hydrolysis and converted to its methyl silyl derivative. It produced a peak by GC–MS that possessed a mass spectrum identical to that described by Van Dyk *et al.* for *3R*-HETE (1). Therefore, peak 2, which was not observed in the absence of CoASH, was assigned as *3R*-HETE-CoA. Peak 3 was identified as arachidonoyl-CoA by co-elution with the authentic

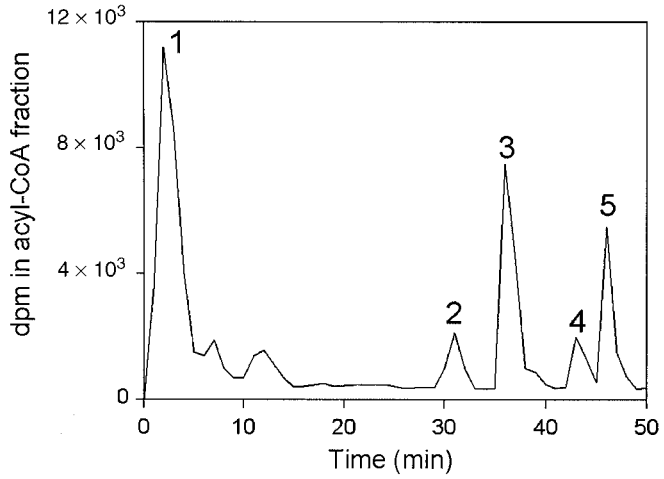

FIG. 2. Radio high-pressure liquid chromatogram of the separation of the [^{14}C] acyl-CoA fraction from enzyme extracts of *D. uninucleata* grown on 4% glucose medium and incubated with [1-^{14}C]20:4n-6, CoASH, ATP, NAD^+, and Mg^{2+}. The identity of the numbered peaks was investigated by GC–MS. For abbreviation see Figure 1.

standard. We were unable to identify the other peaks: we suspect that they included the 3-keto derivative of 20:4n-6-CoA, which would arise from 3*R*-HETE by action of the 3-hydroxyacyl-CoA dehydrogenase as the next enzyme of the β-oxidation cycle.

*Inhibition of 3*R*-HETE biosynthesis.* The conversion of both 20:4n-6 and 20:4n-6-CoA in enzyme extracts to 3*R*-HETE in comparison to controls, where no inhibitors were added, and with all cofactors listed in Table 1 was not significantly inhibited by a range of concentrations of aspirin from 0.1–1 mM (5 and 6%, respectively; experimental error ±10%; fresh solutions of the drug were used due to the instability of aspirin in water) or by 1 mM *N*-(2-cyclohexyloxy-4-nitrophenyl)-methane sulfonamide (NS-398; 4 and 3%, respectively). Both of these compounds are known inhibitors of PGH synthase; evidently, as Van Dyk *et al*. first discovered, aspirin only has inhibitory effects on 3*R*-HETE biosynthesis from added 20:4n-6 in whole cells of *D. uninucleata* (e.g., Ref. 1) rather than enzyme extracts, as in the current work.

The inhibition of 3*R*-HETE biosynthesis from 20:4n-6 and from 20:4n-6-CoA was not significant with aesculetin (1 mM; 11 and 6%, respectively), but was with nordihydroguaiaretic acid (NDGA) (1 mM; 60 and 90%, respectively); both are well-known as lipoxygenase inhibitors. However, we believe that the inhibition recorded with NDGA probably reflected its antioxidative properties, which the compound is known to possess (33).

The inhibition of 3*R*-HETE biosynthesis from 20:4n-6 and 20:4n-6-CoA by antimycin A (0.1 mM) was the second-highest recorded (46 and 64%, respectively). This inhibition suggests some coupled enzyme reactions associated with β-oxidation were still occurring in the cell-free extracts even though such extracts would not contain intact mitochondria. Antimycin A was presumably inhibiting the re-oxidation of NADH by long-chain acyl-CoA dehydrogenase.

Enzyme activities in cells grown in different media. Long-chain acyl-CoA dehydrogenase activity, assayed using arachidonoyl-CoA, was the lowest of the β-oxidation enzymes and was lowest in ethanol-grown cells (Table 2). This may explain the significantly lower rate of synthesis of 3*R*-HETE from 20:4n-6-CoA (22 nmol mg protein^{-1}·h) as opposed to the *trans*-2 derivative of 20:4n-6-CoA. Long-chain enoyl-CoA hydratase, assayed using *trans*-2-arachidonoyl-CoA (*trans*-2-5*Z*,8*Z*,11*Z*,14*Z*-eicosapentaenoyl-CoA), was the most active of these enzymes; the highest rate we recorded was from cells grown on 4% glucose medium of 53 nmol mg protein^{-1}·min. The enzyme was also assayed with other long-chain *trans*-2-acyl-CoA derivatives but there was no significant variation in activity, except with *trans*-2-lignoceroyl-CoA ($C_{24:0}$), 11 nmol mg protein^{-1}.min. Acyl-CoA oxidase activity was absent in extracts from all media. There was no increase in 3*R*-HETE synthesis with enzyme extracts from ethanol-grown cells; this suggested that 3*R*-HETE was not synthesized in

TABLE 2
Enzyme Activity in Cell-Free Enzyme Extracts of *D. uninucleata* After Growth on Different Media[a]

		Growth medium and enzyme activity (nmol·min mg protein^{-1})		
Enzyme*	Time of culture (h)	1% Glucose	4% Glucose	Ethanol
Long-chain acyl-CoA dehydrogenase[b]	24	3	2	<1

[a]Figures represent the average of three experiments. *Also assayed fatty acyl-CoA oxidase but no activity found in any cell-free extract. Standard deviations were ±10–15% of the mean.
[b]Assayed with arachidonoyl-CoA.
[c]Assayed with *trans*-2-arachidonoyl-CoA.
[d]Assayed with 3*R*-HETE.
[e]Assayed with acetoacetyl-CoA. For abbreviation see Table 1.

glyoxysomes or peroxisomes as such growth conditions lead to induction of peroxisome formation.

The activity of D-3-hydroxyacyl-CoA dehydrogenase, assayed using 3*R*-HETE, was the second-lowest of the β-oxidation enzymes, and this activity decreased significantly from 24 to 48 h in cells grown on 4% glucose medium. This may be the factor that leads to accumulation of *3R*-HETE as the rate of formation of 3*R*-HETE has to exceed the rate of its oxidation in order for it to accumulate. 3-Ketoacyl-CoA thiolase activity was likewise low. Ideally this enzyme should have been measured using the 3-keto derivative of arachidonoyl-CoA. The results overall show that glucose did not completely repress β-oxidation activity in *D. uninucleata*, when fatty acid synthesis was occurring; other evidence from electron microscopy (results not shown) revealed an abundance of oil bodies, as well as mitochondria in the 48-h grown cells.

Catalase activity from enzyme extracts of *D. uninucleata* cells grown on either 4% or 1% glucose medium was barely detectable, <1 nmol mg protein^{-1}·min, suggesting peroxisomes had not developed. Malate synthase and isocitrate lyase, glyoxysomal marker enzymes, were present at low activity in glucose-grown cells, but their activity was induced by growth on ethanol, *ca.* 7 and 40–50-fold increased activity, respectively; again there was no inducement of catalase. The glyoxysomal pathway is essential for the synthesis of sugars from C_2 carbon skeletons and glyoxysomes were observed under electron microscopy (EM) (results not shown) from cells grown on ethanol, but not in cells grown on either 4% or 1% glucose medium. We were unable to grow *D. uninucleata* on oils, fatty acids, or methyl esters of fatty acids.

*Location of 3*R*-HETE biosynthesis*. Organelle bands (all from cells grown on 4% glucose medium) occurred at the interfaces between the different sucrose concentrations, as reported in reference 15. These organelle bands are referred to here as bands 1–4, i.e., band 1, 30–41% sucrose interface; band 2, 41–45% interface; band 3, 45–52% interface, and band 4, 52–60% interface. The sucrose gradients appeared to contain two mitochondrial bands (bands 2 and 3). Both were reddish-brown in appearance, presumably due to cytochrome content and identifiable from the peaks of activity for fumarase and NADP$^+$-dependent cytochrome *c* oxidoreductase (Fig. 3). Band 2 had an RCR (the state III to state IV rates of oxygen consumption, a common criterion used to judge the quality of a mitochondrial preparation) of 2.5–3.1, slightly lower than like-extracted mitochondria from *S. cerevisiae* whose mitochondria have an RCR value of *ca.* 4.5 (15). The RCR of band 3 was 1.5–2.5; bands 1 and 4 did not exhibit a positive RCR. Bands 2 and 3 did not contain measurable activities for isocitrate lyase. Bands 2 and 3, viewed under EM by negative-staining (results not shown), contained spherical bodies similar in appearance to the mitochondria described by Mergner *et al.* (34). Low activities of β-oxidation enzymes, apart from long-chain enoyl-CoA hydratase, were associated with bands 2 and 3. Acyl-CoA oxidase activity was absent from the gradients.

As glucose-grown cells do not contain peroxisomes (or glyoxysomes), whose presence in yeasts is induced by growing cells on ethanol, acetate, and fatty acids, we conclude that the mitochondria of these cells were located primarily in bands 2 and 3 after separation by sucrose density gradient centrifugation. No other organelles or subcellular components could be detected in these bands by EM. Thus, the presence of large portions of the endoplasmic reticulum (microsomal fraction) and/or Golgi apparatus in these bands could be ruled out and, from their respiration control ratios, we concluded that the mitochondria in bands 2 and 3 were reasonably pure and free of major amounts of other cellular material.

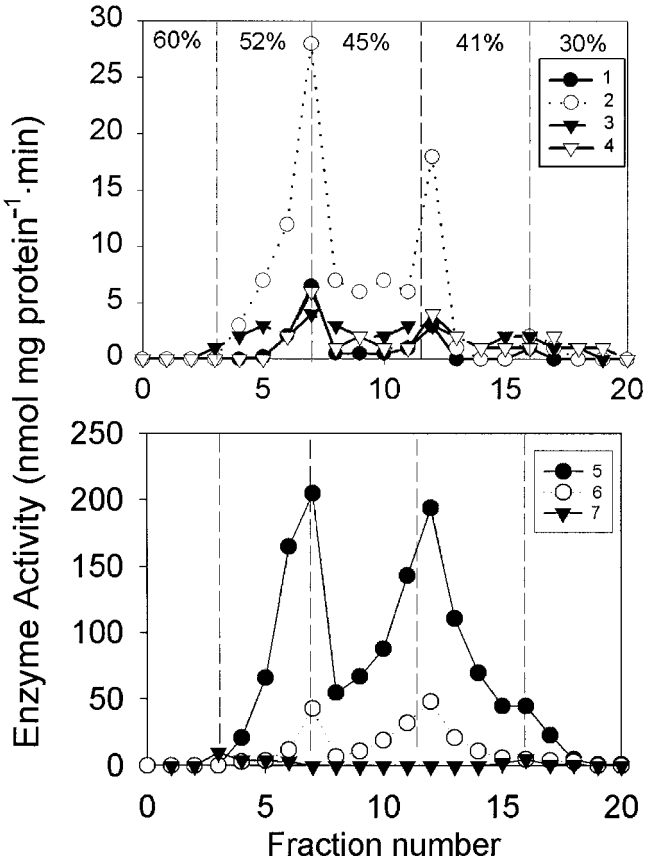

FIG. 3. Distribution of enzymes from *D. uninucleata* cells grown on 4% glucose and fractionated on sucrose gradients to separate cellular organelles. Key: 1, long-chain acyl-CoA dehydrogenase; 2, long-chain enoyl-CoA hydratase; 3, *D*-3-hydroxyacyl-CoA dehydrogenase; 4, ketoacyl-thiolase; 5, fumarase; 6, NADP$^+$-dependent cytochrome *c* oxidoreductase; 7, isocitrate lyase.

When bands 1–4 were each incubated with 20:4n-6, as detailed in the Materials and Methods section, and with addition of all the cofactors listed in Table 1, 3*R*-HETE synthesis was 0.9, 5.2, 7.9, and 0.6 nmol mg protein^{-1}·h in bands 1–4, respectively. The 10-fold higher rate of 3*R*-HETE synthesis in bands 2 and 3 again suggested that it occurred in the mitochondrial reaction. Its biosynthesis was slightly higher when mitochondria were subsequently burst in hypotonic medium (6.2 and 9.5 nmol mg protein^{-1}·h in bands 2 and 3, respectively), which could reflect the impermeability of 20:4n-6-CoA to the membrane and that the acylcarnitine is synthe-

sized *in vivo*. In yeast and animals, carnitine acyltransferases are important regulatory proteins responsible for transporting acyl groups across membranes. The greater increase in 3*R*-HETE biosynthesis in band 3 upon incubation in hypotonic medium may indicate that the latter contained more intact mitochondria than band 2 (it is common to witness both intact and broken organelles in separations of this kind).

Biosynthesis of 3-hydroxyeicosenoic acids by enzyme extracts. The products of 20:3n-6, 20:3n-3, and 20:5n-3 metabolism from enzyme extracts (not containing intact mitochondria) were analyzed as methyl ester silyl ethers by GC and compared with that for the metabolism of 20:4n-6. In each case, upon inclusion of all cofactors listed in Table 1, a peak was detected with a similar retention time to 3*R*-HETE (Fig. 4). These extracts, then analyzed by GC–MS, gave the following mass spectrum results; major ions are reported with our interpretation of structures. In all cases the base ion was *m/z* 73 (silyl group).

(*i*) *20:3n-6. 3-hydroxy-8Z,11Z,14Z-eicosatrienoic acid, (Fig. 5). m/z* 408 [M^+], 393 [$M^+ - 15$], 318 [$M^+ - 90$] and 175 [$(CH_3)_3SiO^+$=CH–CH_2–COO–CH_3]. *m/z* 207, 159 and 105 were not identified.

(*ii*) *20:3n-3. 3-hydroxy-11Z,14Z,17Z-eicosatrienoic acid. m/z* 408 [M^+], 393 [$M^+ - 15$], 318 [$M^+ - 90$] and 175 [$(CH_3)_3SiO^+$=CH–CH_2–COO–CH_3]. Unknown ions included *m/z* 207 and 159.

(*iii*) *20:5n-3. 3-hydroxy-5Z,8Z,11Z,14Z,17Z-eicosapentaenoic acid. m/z* 404 [M^+], 389 [$M^+ - 15$], 314 [$M^+ - 90$] and 175 [$(CH_3)_3SiO^+$=CH–CH_2–COO–CH_3].

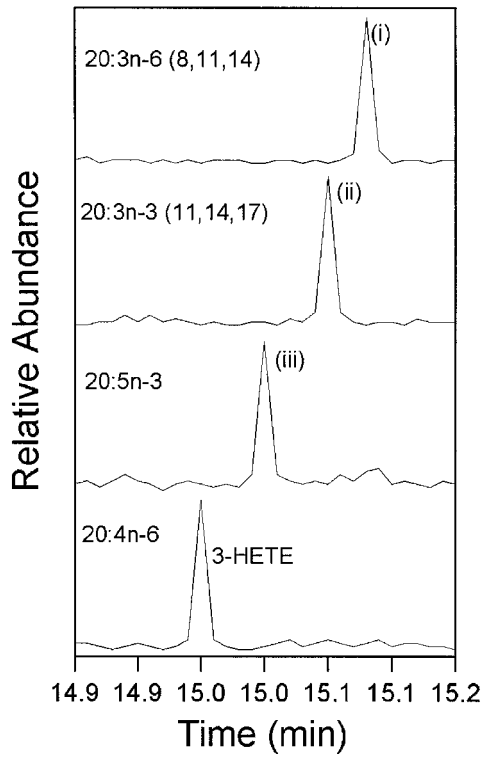

FIG. 4. Comparison of four partial GC chromatograms illustrating the separation of the oxygenated products of four different eicosanoids (as listed) by enzyme extracts of *D. uninucleata* grown on 4% glucose medium. The retention times of the three unknown peaks (i–iii) are shown in relation to one of the products of 20:4n-6 metabolism, 3*R*-hydroxy-5*Z*, 8*Z*,11*Z*,14*Z*-eicosatetraenoic acid. The identities of peaks (i–iii) were analyzed by GC–MS. 3-HETE, 3-hydroxyeicosatetraenoic acid. See Figure 1 for abbreviations.

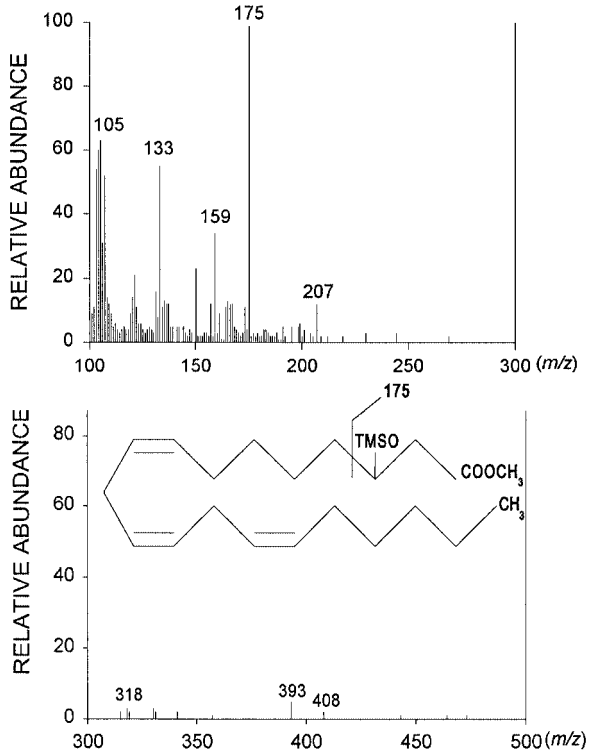

FIG. 5. Electron impact (EI) mass spectrum of the methyl ester silyl ether of 3-hydroxy-8*Z*,11*Z*,14*Z*-eicosatrienoic acid. The compound was isolated from enzyme extracts of *D. uninucleata* incubated with 20:3n-6 and all cofactors listed in Table 1. TMSO, trimethyl silyl ether; for other abbreviation see Figure 1.

In mammalian cells, the degradation of fatty acids with double bonds extending from odd-numbered carbons, such as 20:4n-6, requires additional reactions which result in the saturation of the *cis*-5 double bond and the synthesis of *trans*-2-*cis*-8*Z*,11*Z*,14*Z*-eicosatetraenoic acid (29). However, it now appears that the presence of a 5*Z*,8*Z* diene structure is not required for the synthesis of 3-hydroxyl derivatives of eicosanoids by enzyme extracts of *D. uninucleata*.

Assay of PGH synthase. As previous suggestions (1–4) had been made that the yeast under current study was able to synthesize prostaglandins and that 3*R*-HETE could be an intermediate in this process (1,2), we examined this possibility hoping to corroborate these claims. Prostaglandins are valuable products and their synthesis in microorganisms could be of interest to the pharmaceutical industry. If prostaglandin biosynthesis could be confirmed, then, by extension of the above studies we should be able to elucidate the pathway in greater detail. The first enzyme of prostaglandin biosynthesis is PGH synthase, which introduces dioxygen (O_2) into 20:4n-6 to produce a hydroperoxide at C_{11}. Hence, PGH synthase is often measured using a polarographic O_2 electrode

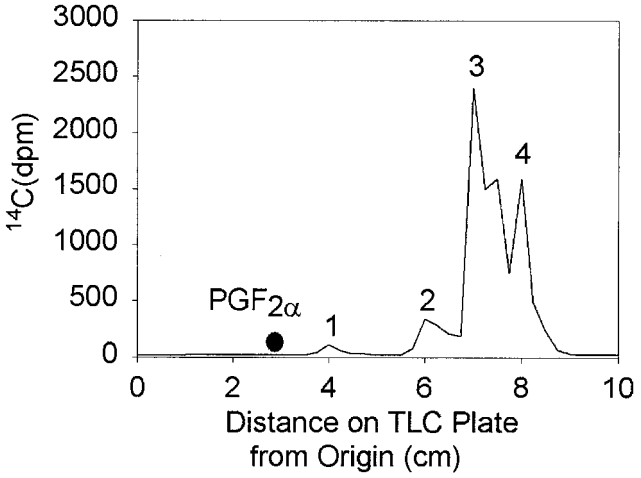

FIG. 6. Separation by thin-layer chromatography (TLC) of the radiochemical products of [1-^{14}C]20:4n-6 metabolism produced by enzyme extracts of *D. uninucleata*. A comparison (●) is given with the R_f of the prostaglandin $PGF_{2\alpha}$. The identities of peaks 1, 2, 3, and 4 were further analyzed by GC–MS. See Figure 1 for other abbreviation.

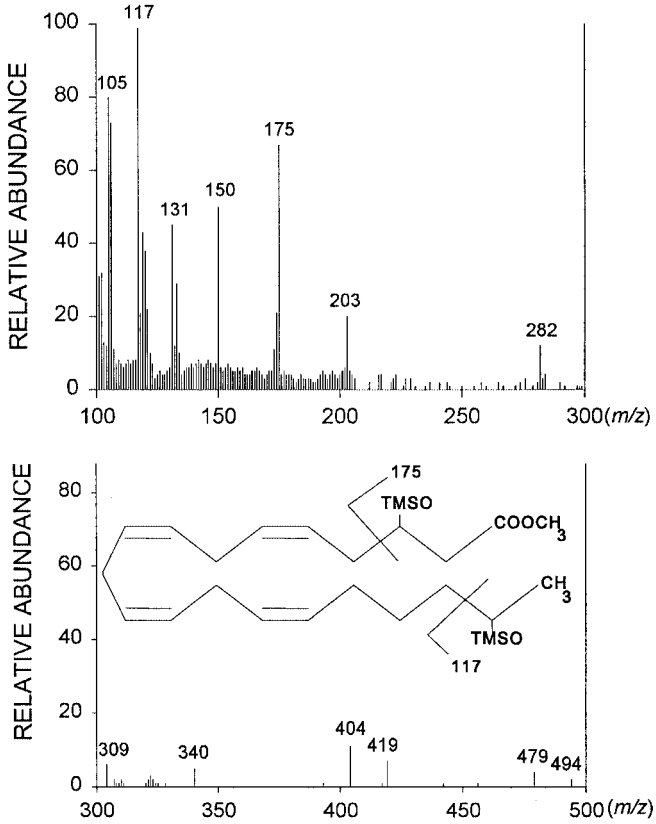

FIG. 7. EI mass spectrum of peak 2 (see Fig. 6) from the TLC separation of the products of [1-^{14}C]20:4n-6 metabolism from enzyme extracts of *D. uninucleata* grown for 48 h on the 4% glucose medium. The compound was assigned as 3,19-di-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid. See Figures 5 and 6 for abbreviations.

(27). We used this method but, upon addition of 20:4n-6 there was no decrease in O_2 concentration in comparison to the control experiment in which no fatty acid was added. This applied to enzyme extracts and microsomal fractions.

A second method to assay PGH synthase, which follows the metabolism of [1-^{14}C]20:4n-6 (Fig. 6), revealed that with enzyme extracts a small peak of radioactivity occurred (peak 1) in a region close to the R_f of the prostaglandin $PGF_{2\alpha}$. Microsomal extracts, the usual location of the enzyme (27,28), did not metabolize 20:4n-6. The [^{14}C]compound(s) of peak 1 were analyzed as methyl silyl derivatives by GC–MS. A peak was detected (Fig. 7) which produced ions at *m/z* 494 [M^+], 479 [$M^+ - 15$], 404 [$M^+ - 90$], 175 [$(CH_3)_3SiO^+$=CH–CH_2–COO–CH_3], 150 [possibly 175 – 15], 117 [$(CH_3)_3SiO^+$=CH–CH_3], and a base ion of 73 [silyl group]. Prominent ions were also detected at *m/z* 340, 282, 203, and 105. The compound was assigned as 3,19-di-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid.

Selective ion searches were made from GC–MS data of methylated and silylated samples from enzyme extracts and microsomal preparations incubated with 20:4n-6, as described in the Materials and Methods section. We also frequently carried out experiments in which 20:4n-6 was added to whole cells of *D. uninucleata*, as described in reference 1, from which we analyzed the oxylipins (results not shown). We were unable to identify the breakdown products of prostacyclin (3), isomers of α-pentanor $PGF_{2\alpha}$-γ-lactone, or any other prostaglandin from any of these samples.

DISCUSSION

Dipodascopsis uninucleata accumulates 3*R*-HETE and other 3-hydroxy fatty acids from exogenously supplied 20:4n-6 and other polyunsaturated fatty acids. These hydroxy-lipins are then considered to play key roles in the growth cycle of the yeast (35,36) and may even involve their conversion to prostaglandins (1–6), which would function as physiologically important molecules as they do in higher animals. The mechanism of 3*R*-HETE formation has remained unclear; the principal routes could be *via* a specific hydroxylase system, perhaps being cytochrome *P*450-dependent, or *via* the β-oxidation cycle which is responsible for fatty acid oxidation in all cell systems. The research group of Kock *et al*. have favored the former explanation (6,10), principally because the chirality of 3-HETE was the *R*-isomer, which was thought to be the opposite of the *S*-isomer that is produced by β-oxidation. However the *S*-enantiomer is only so produced by the fatty acid β-oxidation cycle of plants and animals; in fungi, which include yeasts, it is the *R*-isomer that is found (11). Thus this favors the second option, formation by a β-oxidation system. The results presented here would strongly support this mechanism.

Normally, β-oxidation of fatty acids is considered to occur in specific organelles, i.e., peroxisomes, sometimes known as glyoxysomes. However, such organelles are inducible entities requiring cells to be grown on ethanol, acetic acid, or fatty acids (37). In the absence of peroxisomes, as in cells grown on glucose, cells must carry out vestigial β-oxidation in the mitochondrion as has been shown by Dommes *et al*. (37) for *Candida tropicalis*. Without such a system, cells could not

use exogenous fatty acids, and would not be able to make the transition from growth on glucose to growth on fatty acids. A mitochondrial β-oxidation system is therefore essential and moreover has to be a constituitive cellular activity if cells must oxidize fatty acids *ab initio* prior to, or without, the induction of peroxisome formation.

Such a mitochondrial β-oxidation system has been shown here to occur in *D. uninucleata* and is able to account for the oxidation of a wide range of fatty acids. However, in this particular yeast, the enzymes of the β-oxidation cycle appear not to be closely integrated in their activity and, indeed, in mitochondria in general all such enzymes appear to be separable monofunctional proteins (11,38). It is therefore this imbalance in activities (Table 2) that leads to a faster rate of formation of 3*R*-HETE than its oxidation. Hence 3*R*-HETE accumulates in the mitochondrion. Presumably it must then be translocated from this organelle, probably *via* a carnitine acyltransferase system (38), so that it can exert a physiological role within the cell to control some key aspects of development.

This imbalance in enzyme activities in the β-oxidation cycle of the mitochondrion appears to be greater in older (48 h) cells where our results, with the inhibition of β-oxidation by antimycin A, indicate a possible limitation in the supply of NAD^+ thereby affecting the activity of the long-chain acyl-CoA dehydrogenase. This is the initial enzyme activity of the β-oxidation cycle following activation of 20:4n-6 to its CoA ester by long-chain acyl-CoA synthetase. A similar situation had been observed with mitochondrial extracts from pea cotyledons (Fox, S.R., unpublished work): peas do not synthesize 20:4n-6 or other fatty acids with a Δ^5 *cis* double bond and yet are able to form 3*R*-HETE from 20:4n-6. Thus the partial oxidation of polyunsaturated fatty acids including both representatives of the n-6 and n-3 series may occur in a number of mitochondrial systems all having an imbalance in the sequence of β-oxidation cycle enzymes.

Suggestions that 3*R*-HETE may be a precursor of prostaglandins in this yeast (1,3,4), however, could not be substantiated by this work, although we were able to detect synthesis of 3,19-dihydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid in cell-free extracts of this yeast incubated with 20:4n-6. This, we presume, will have arisen from 3*R*-HETE as an intermediate possibly *via* an n-1 terminal oxidase system, but this remains speculative. Chromatographically, this metabolite behaved very much like prostaglandin $PGF_{2\alpha}$, which might then account for the earlier suggestions of prostaglandin formation in this yeast (1–6). However, no prostaglandins have been detected in our detailed examination of this yeast, but it is not impossible that some related compounds such as α-pentanor $PGF_{2\alpha}$-γ-lactone may have arisen as minor artifacts (e.g., Ref. 39) from some of the unstable hydroxylipins that this yeast undoubtably can synthesize. Although absence of prostaglandins does not mean they are not occasionally synthesized, the absences of key enzyme activities associated with prostaglandin formation, such as PGH synthase, even after detailed examination suggest that these materials are not produced in this yeast. We therefore conclude, somewhat reluctantly because of the clear interest that would arise from substantiation of the prior claims for the occurrence of prostaglandins in yeasts, that it is unlikely that such entities are being synthesized. Undoubtably though hydroxyeicosanoids are produced and these compounds will almost certainly exert profound effects on yeast cell physiology.

Effects of α-Tocopherol and Ascorbyl Palmitate on the Isomerization and Decomposition of Methyl Linoleate Hydroperoxides

E. Marjukka Mäkinen* and Anu I. Hopia

Department of Applied Chemistry and Microbiology, Food Chemistry Division, 00014 University of Helsinki, Finland

ABSTRACT: In order to study antioxidant action on lipid hydroperoxide decomposition, the effects of α-tocopherol (TOH) and ascorbyl palmitate on the decomposition rate and reaction sequences of 9- and 13-*cis,trans* methyl linoleate hydroperoxide (*cis,trans* ML-OOH) decomposition in hexadecane were studied at 40°C. Decomposition of *cis,trans* ML-OOH as well as the formation and isomeric configuration of methyl linoleate hydroxy and ketodiene compounds were followed by high-performance liquid chromatographic analysis. TOH effectively inhibited the decomposition of ML-OOH. The decomposition rate was two times slower at 0.2 mM and more than 10 times slower at 2 and 20 mM of TOH. Ascorbyl palmitate (0.2, 2, and 20 mM) slightly accelerated the decomposition of ML-OOH. Both compounds had an effect on the reaction sequences of ML-OOH decomposition. At high levels TOH inhibited the isomerization of *cis,trans* ML-OOH to *trans,trans* ML-OOH through peroxyl radicals and increased the formation of hydroxy compounds. Further, the majority of the hydroxy and ketodiene compounds formed had a *cis,trans* configuration, indicating that *cis,trans* ML-OOH decomposed through alkoxyl radicals without isomerization. These results suggest that when inhibiting the decomposition of hydroperoxides, TOH can act as a hydrogen atom donor to both peroxyl and alkoxyl radicals. In the presence of ascorbyl palmitate, *cis,trans* ML-OOH decomposed rapidly but without isomerization. In contrast to TOH, the majority of hydroxy compounds were *cis,trans,* but the ketodiene compounds were *trans,trans* isomers. This indicates that ascorbyl palmitate reduced *cis,trans* ML-OOH to the corresponding hydroxy compounds. However, the simultaneous formation of *trans,trans* ketodiene compounds suggests that ML-OOH decomposition, similar to the control sample, also occurred in these samples. Thus, under these experimental conditions, the reduction of ML-OOH to more stable hydroxy compounds did not occur to an extent significant enough to inhibit the radical chain reactions of ML-OOH decomposition.

Paper no. L8515 in *Lipids 35*, 1215–1223 (November 2000).

Lipid hydroperoxides are the primary products of lipid oxidation. They decompose further to a complex mixture of decomposition products (1,2). The damaging effect of lipid oxidation on biological materials as well as the flavor deterioration of foods is, to a significant extent, caused by these decomposition products (3,4). Thus, when studying the effects of lipid oxidation on biological systems, not only the formation of lipid hydroperoxides but also their decomposition rate and reactions need to be clarified. Moreover, in antioxidant research it is important to distinguish between their effects on the formation and decomposition of lipid hydroperoxides. The effect of antioxidants on the stability and decomposition reactions of lipid hydroperoxides in foods, membranes, and other biological systems is still largely unknown.

Previous results of the effects of the α-tocopherol (TOH) and ascorbyl palmitate on the stability of lipid hydroperoxides are controversial. Further, their mechanism of action during hydroperoxide decomposition is not fully understood. Hopia *et al.* (5) showed that TOH inhibits the decomposition of methyl linoleate hydroperoxides (ML-OOH) and suggested that the mechanism may involve the conversion of ML-OOH into more stable hydroxy compounds. Huang *et al.* (6) used hexanal as an indicator of hydroperoxide decomposition in bulk corn oil stripped of natural tocopherols and showed that TOH has a stabilizing effect on lipid hydroperoxides during thermal decomposition at 60°C. Also, Lampi *et al.* (7) showed that TOH reduces the amount of volatile decomposition products of hydroperoxides during the autoxidation of rapeseed oil triacylglycerols. However, this stabilizing effect is highly system dependent as TOH accelerates the decomposition of 13-ML-OOH at 100°C (8).

The reported effects of ascorbyl palmitate on the stability of lipid hydroperoxides are also controversial and depend strongly on the experimental conditions. Schieberle and Grosch (9) showed that ascorbyl palmitate inhibits the breakdown of 13-*cis,trans* ML-OOH in the presence of copper(II) ions by reducing hydroperoxides into their corresponding hydroxy compounds. A stabilizing effect was also found by Von Uhl and Eichner (10) who suggested that ascorbyl palmitate reduces hydroperoxides into more stable hydroxy compounds, which do not continue the radical-intermediated decomposition reactions. On the other hand, O'Brien (11) showed that the decomposition of linoleic acid hydroperoxides in the presence of metal ions is catalyzed by ascorbates.

Abbreviations: HPLC, high-performance liquid chromatography; ML-OOH, methyl linoleate hydroperoxides, TOH, α-tocopherol.

The homolytic decomposition of lipid hydroperoxides proceed either through peroxyl or alkoxyl radicals. Due to the high bond dissociation energy of the ROO-H and RO-OH bonds, they are relatively difficult to generate from the preformed hydroperoxides. However, the presence of catalytic quantities of transition metal ions (Eqs. 1 and 2) or other catalyst enhances the formation of these radicals (1).

$$ROOH + M^{n+1} \rightarrow ROO^{\bullet} + H^{+} + M^{n} \quad [1]$$

$$ROOH + M^{n} \rightarrow RO^{\bullet} + OH^{-} + M^{n+1} \quad [2]$$

Antioxidants can retard the radical-mediated decomposition of hydroperoxides by scavenging intermediate radicals, by chelating metal ions, or by reducing hydroperoxides to more stable hydroxy compounds (12). Analysis of selected decomposition products provides specific information about the mechanism of antioxidant action in various sequences of lipid hydroperoxide decomposition.

In this study we compared the effects of two lipid-soluble antioxidants, TOH and ascorbyl palmitate, on the decomposition rate of of 9- and 13-*cis,trans* ML-OOH. To get further information about the effects of these antioxidants on the intermediate radicals and the reaction sequences of ML-OOH decomposition, the isomeric configuration of ML-OOH and the formation and isomeric configuration of selected decomposition products were followed. The effects of antioxidants were studied in purified 9- and 13-*cis,trans* ML-OOH to avoid the consumption of antioxidants in the reactions involving unoxidized material.

MATERIALS AND METHODS

Materials. Methyl linoleate was purchased from Nu-Chek Prep Inc. (Elysian, MN) and TOH from Merck (Darmstadt, Germany). Ascorbyl palmitate and hexadecane were purchased from Sigma Chemicals Co. (St. Louis, MO). Heptane and diethyl ether were from Rathburn (Walkerburn, Scotland) and sodium borohydride from BDH (Poole, United Kingdom).

Preparation of cis,trans *ML-OOH*. Methyl linoleate was oxidized at 40°C in the dark until the oxidation level reached 10–15%. The oxidation was done with 5% TOH to produce only *cis,trans* ML-OOH (13). *Cis,trans* ML-OOH were separated from nonoxidized methyl linoleate and TOH by solid-phase extraction (5). The nonpolar methyl linoleate was first eluted with heptane/diethyl ether (95:5, vol/vol) and then the *cis,trans* ML-OOH fraction was collected with heptane/diethyl ether (85:15, vol/vol). The purity of the *cis,trans* ML-OOH fraction was checked by thin-layer chromatography, and the concentration of *cis,trans* ML-OOH was measured spectrophotometrically at 234 nm (5). As measured by high-performance liquid chromatography (HPLC), a small amount of *cis,trans* hydroxy compounds (0.4–2.5% of total ML-OOH) and *cis,trans* ketodienes (0.8–2.1% of total ML-OOH) was present after solid-phase extraction. The TOH content was less than 0.01 mM as measured by HPLC.

HPLC analysis. Four isomers of ML-OOH, hydroxy, and ketodiene compounds were separated by HPLC. The instrumentation included a model 501 pump equipped with a model 700 autosampler (Waters, Milford, MA). The column was a silica column (25 cm × 2.1 mm, 5 μm; Supelco, Bellefonte, PA) and the elution solvent heptane/diethyl ether (82:18, vol/vol) with a flow rate of 0.4 mL/min. ML-OOH and hydroxy compounds were monitored at 234 nm and ketodienes at 268 nm using a diode array detector (model 996; Waters). The relative standard deviation of six injections was 0.6%.

Identification of the ML-OOH isomers was based on their ultraviolet spectra (14). The retention times of the hydroxy compounds were confirmed by reducing the ML-OOH isomers to their corresponding hydroxy isomers with sodium borohydride (15). Tentative identification of ketodiene geometrical isomers was based on the transition of their maxima in the ultraviolet spectra (14) and on the elution order previously reported by Schieberle *et al.* (16). In the chromatogram (Fig. 1), peaks 1–4 were identified as 13-*cis,trans* ML-OOH, 13-*trans,trans* ML-OOH, 9-*cis,trans* ML-OOH, 9-*trans,trans* ML-OOH and peaks 5–8 as 13-*cis,trans* hydroxy compound, 13-*trans,trans* hydroxy compound, 9-*cis,trans* hydroxy compound and 9-*trans,trans* hydroxy compound. Peaks 9 and 10 were *cis,trans* ketodienes and peaks 11 and 12 were *trans,trans* ketodienes. The amounts of ML-OOH, hydroxy, and ketodiene

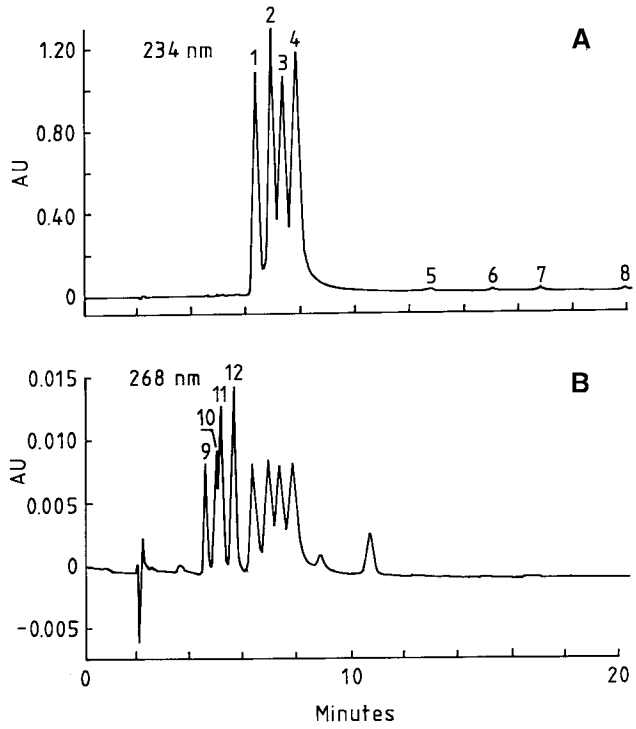

FIG. 1. High-performance liquid chromatograms of methyl linoleate hydroperoxides (ML-OOH) and its decomposition products monitored at 234 nm (A), and 268 nm (B). Peaks 1–4: 13-*cis,trans* ML-OOH, 13-*trans,trans* ML-OOH, 9-*cis,trans* ML-OOH, and 9-*trans,trans* ML-OOH; peaks 5–8: 13-*cis,trans* hydroxy, 13-*trans,trans* hydroxy, 9-*cis,trans* hydroxy, and 9-*trans,trans* hydroxy compounds; peaks 9 and 10: *cis,trans* ketodiene compounds; and peaks 11 and 12: *trans,trans* ketodiene compounds.

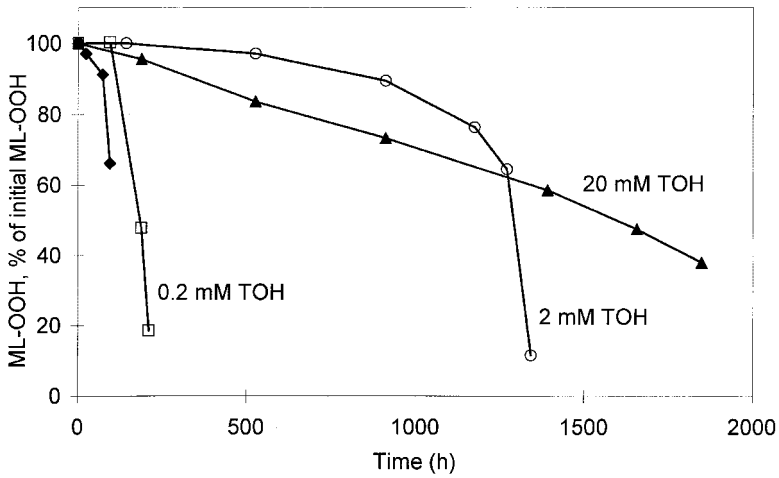

FIG. 2. Effect of α-tocopherol (TOH) on the decomposition of ML-OOH at 40°C. Control (-◆), 0.2 mM TOH (-□-), 2 mM TOH (-○-), and 20 mM TOH (-▲-). For other abbreviation see Figure 1.

compounds were monitored as total areas of four isomer peaks in the chromatograms and then converted to a percentage of the initial content of ML-OOH by using the molar extinction coefficients of 28,600 for ML-OOH (14), 27,200 for hydroxy compounds (14), and 28,000 for ketodienes (17).

Decomposition of cis,trans *ML-OOH.* A solution of *cis,trans* ML-OOH (40 mM) in hexadecane was incubated at 40°C in the dark in screw-capped glass vials (12 mL) with magnetic stirring with or without added antioxidants. The concentrations of TOH and ascorbyl palmitate were 0.2, 2, and 20 mM. Duplicate sample aliquots were taken periodically for HPLC analysis, and each experiment was done in duplicate.

RESULTS

TOH efficiently inhibited the decomposition of ML-OOH (Fig. 2). The inhibition was strongest at 2 mM of TOH. At the higher level of TOH (20 mM), the initial decomposition rate of ML-OOH was higher when compared to 2 mM TOH. In contrast to TOH, ascorbyl palmitate at 2 and 20 mM slightly accelerated the decomposition of ML-OOH (Fig. 3).

Without antioxidants the majority of *cis,trans* ML-OOH isomerized to *trans,trans* ML-OOH prior to decomposition (Fig. 4A). The amount of total ML-OOH started to decrease after a 67-h incubation when only 27% of the total ML-OOH still had the *cis,trans* configuration. Also the majority of hydroxy and ketodiene compounds formed had the *trans,trans* configuration (Figs. 4B and 4C). The level of decomposition products having the *cis,trans* configuration remained at their initial level whereas the level of *trans,trans* decomposition products increased during the decomposition. No differences were seen in the proportions of 9- and 13-isomers of ML-OOH during the decomposition.

At a 2-mM level TOH partly inhibited the isomerization of *cis,trans* ML-OOH to *trans,trans* ML-OOH (Fig. 5A). The

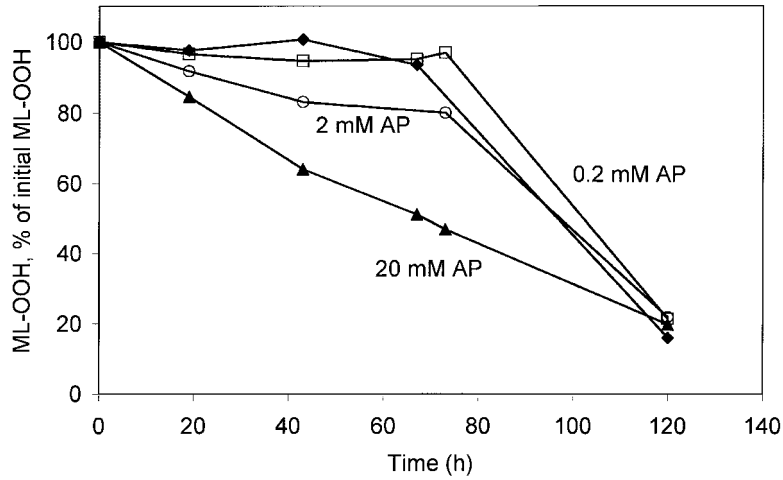

FIG. 3. Effect of ascorbyl palmitate (AP) on the decomposition of ML-OOH at 40°C. Control (-◆-), 0.2 mM AP (-□-), 2 mM AP (-O-), and 20 mM AP (-▲-). For other abbreviation see Table 1.

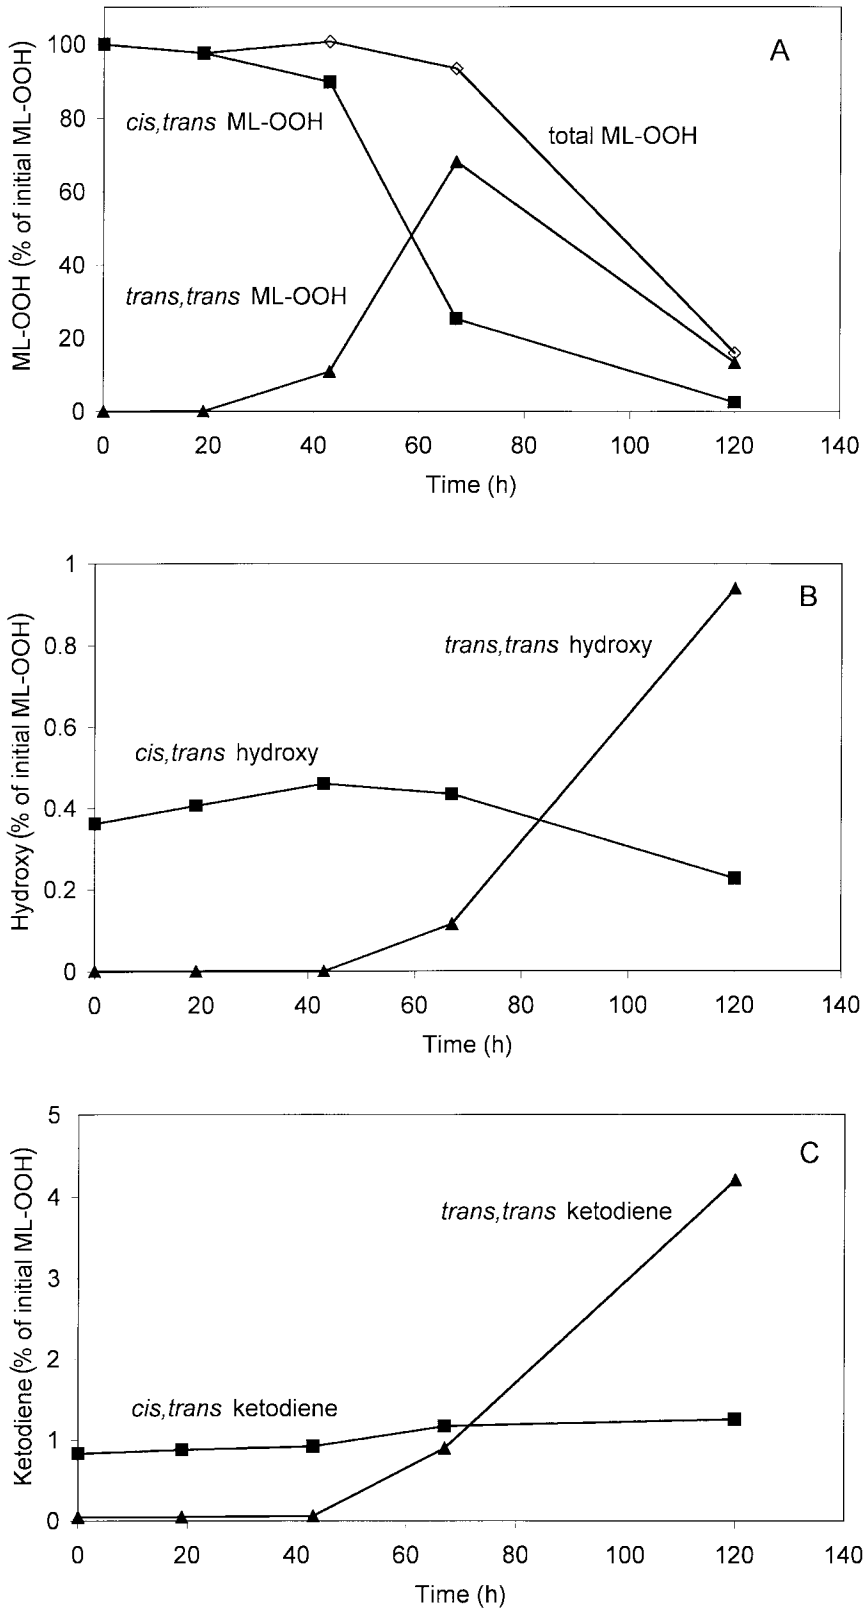

FIG. 4. Decomposition of ML-OOH at 40°C without added antioxidants. (A) ML-OOH, (B) hydroxy compounds, and (C) ketodiene compounds. Total ML-OOH (-◇-), *cis,trans* isomers (-■-), and *trans,trans* isomers (-▲-). For abbreviation see Figure 1.

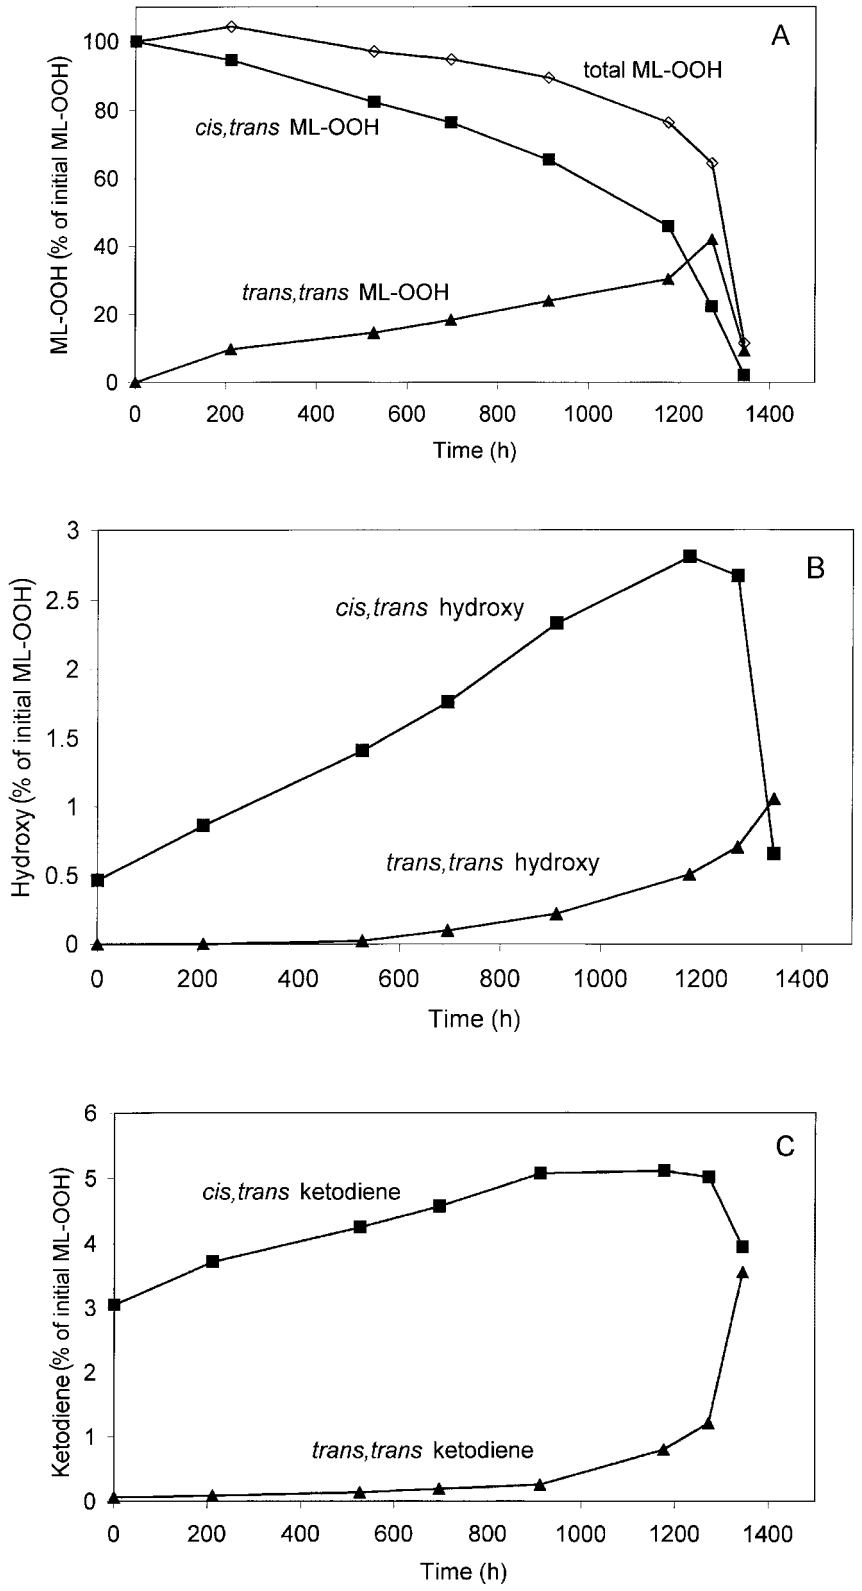

FIG. 5. Decomposition of ML-OOH at 40°C in the presence of 2 mM of α-tocopherol. (A) ML-OOH, (B) hydroxy compounds and (C) ketodiene compounds. Total ML-OOH (-◇-), *cis,trans* isomers (-■-), and *trans,trans* isomers (-▲-). For abbreviation see Figure 1.

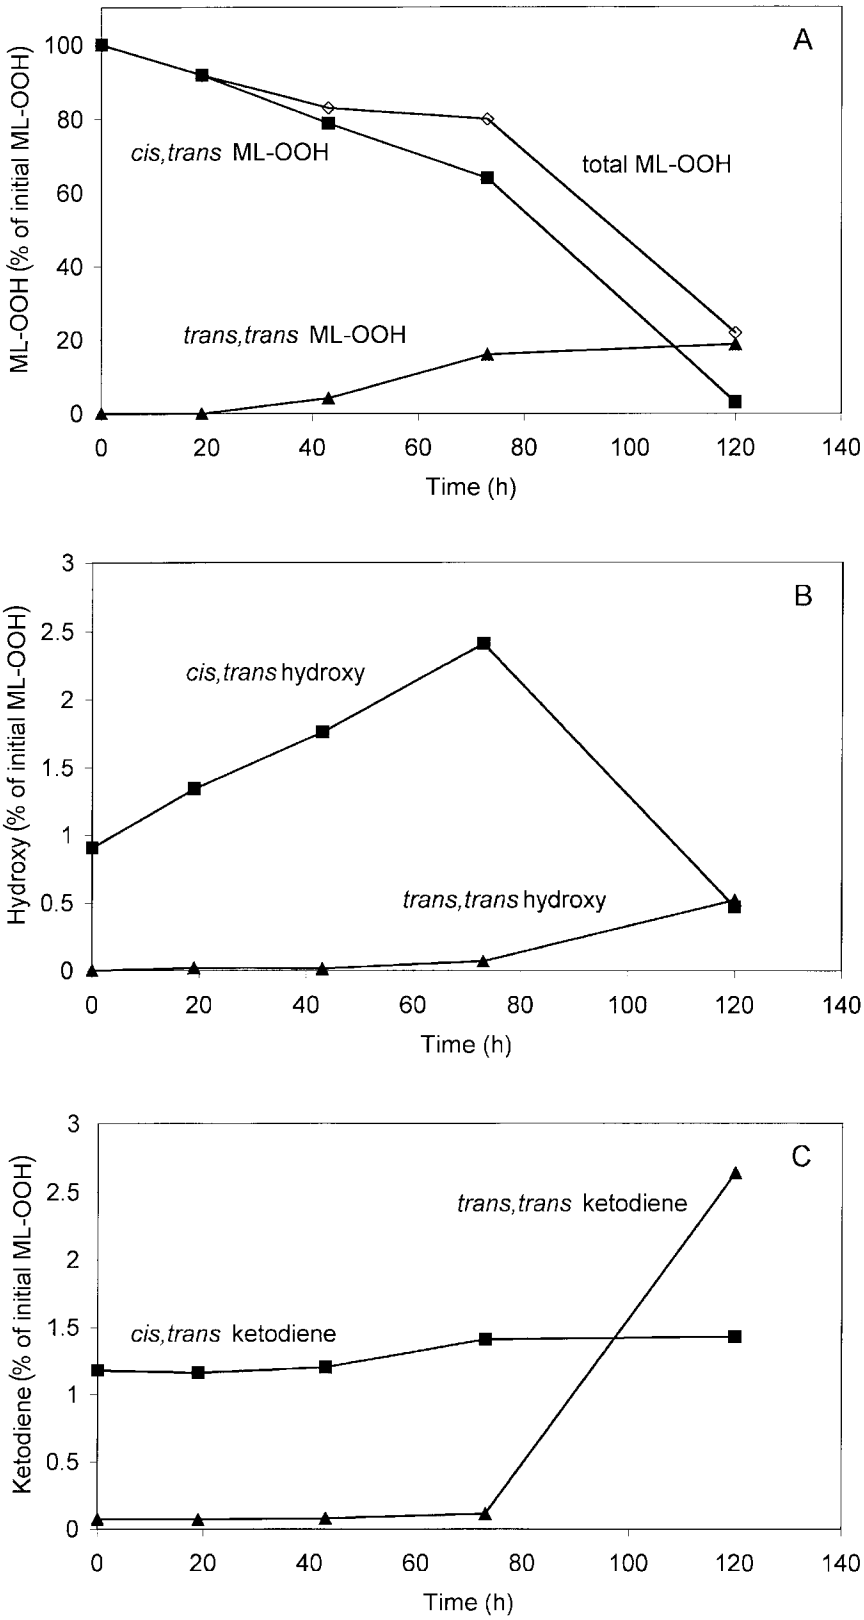

FIG. 6. Decomposition of ML-OOH at 40°C in the presence of 2 mM of ascorbyl palmitate. (A) ML-OOH, (B) hydroxy compounds, and (C) ketodiene compounds. Total ML-OOH (-◇-), *cis,trans* isomers (-■-), and *trans,trans* isomers (-▲-). For abbreviation see Figure 1.

fast decomposition of ML-OOH started after a 1176-h incubation when 61% of the total ML-OOH still had the *cis,trans* configuration. A tenfold increase in TOH (20 mM) completely inhibited the isomerization, and ML-OOH decomposed as *cis,trans* isomers without prior isomerization to *trans,trans* isomers (data not shown). TOH also had a marked effect on the isomeric configuration of decomposition products as the majority of hydroxy and ketodiene compounds had c*is,trans* configuration. Figures 5B and 5C show the isomeric distribution of hydroxy and ketodiene compounds formed in the presence of 2 mM TOH. With 20 mM TOH, more than 90% of the total hydroxy and ketodiene compounds were *cis,trans* isomers during the decomposition of ML-OOH.

In a 2-mM concentration of ascorbyl palmitate *cis,trans* ML-OOH decomposed mainly as *cis,trans* isomers without any change in isomeric configuration (Fig. 6A). Also, most of the hydroxy compounds were *cis,trans* isomers (Fig. 6B). However, the majority of ketodiene compounds were *trans,trans* isomers (Fig. 6C). A tenfold increase in ascorbyl palmitate (20 mM) had similar effects on the isomeric distribution of ML-OOH and its decomposition products (data not shown).

The amount of hydroxy compounds formed during the decomposition of ML-OOH is shown in Table 1 after a fixed time of incubation (67 h) and at a certain level of ML-OOH decomposition (30%). Both TOH and ascorbyl palmitate increased the formation of hydroxy compounds during incubation in a concentration-dependent way. In the presence of ascorbyl palmitate, the amount of hydroxy compounds was already increased at the beginning of the incubation.

DISCUSSION

The effect of antioxidants and pro-oxidants on hydroperoxide decomposition is of great importance in biological systems. This study shows that different antioxidants each have a characteristic effect on further radical chain reactions of hydroperoxides and on the formation of secondary oxidation products.

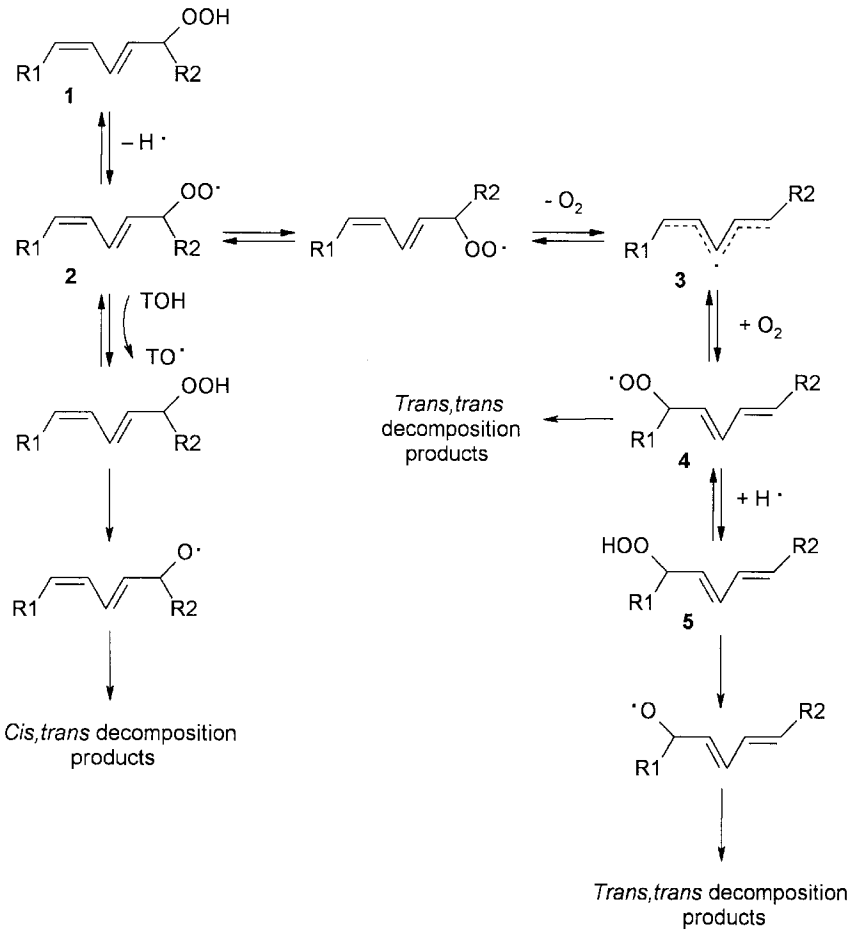
Both TOH and ascorbyl palmitate had an effect on the decomposition rate of ML-OOH. Under these experimental conditions TOH efficiently inhibited and ascorbyl palmitate slightly accelerated the decomposition of hydroperoxides. The result of TOH is in agreement with the previous result of Hopia *et al.* (5) showing that TOH inhibits the decomposition of a mixture of four ML-OOH isomers at 60°C. However, contradictory results for ascorbyl palmitate's ability to inhibit the decomposition of hydroperoxides have been reported (9,10,18). Clearly the experimental conditions used have a more profound effect on its activity.

TABLE 1
Effects of α-Tocopherol and Ascorbyl Palmitate on the Formation of Hydroxy Compounds During the Decomposition of ML-OOH

Antioxidant concentration	Hydroxy compounds (% of initial ML-OOH)	
	After 67-h incubation	At 30% decomposition level of ML-OOH
α-Tocopherol		
Control	0.4	0.5
0.2 mM	0.6	0.9
2 mM	0.6	3.3
20 mM	0.7	3.5
Ascorbyl palmitate		
Control	0.5	0.7
0.2 mM	0.8	0.8
2 mM	2.2	2.1
20 mM	4.5	3.9

The decomposition of hydroperoxides can proceed either through peroxyl or alkoxyl radicals. If the intermediate radicals are *cis,trans* peroxyl radicals, they have time to rearrange into the thermodynamically more favorable *trans,trans* configurations (19,20,21). As described in Scheme 1, *cis,trans* peroxyl radicals (**2**) are formed from *cis,trans* ML-OOH (**1**). Peroxyl radicals isomerize to *trans,trans* configuration (**4**) through pentadienyl radicals (**3**) and then abstract hydrogen atoms to form *trans,trans* ML-OOH (**5**). *Trans,trans* ML-OOH decompose further into a variety of *trans,trans* decomposition products, such as hydroxy and ketodiene compounds, either through peroxyl or alkoxyl radicals. Thus, if peroxyl radicals are intermediates in the decomposition of *cis,trans* hydroperoxides, the majority of decomposition products have a *trans,trans* configuration in their conjugated diene structure. This was previously shown by Schieberle and Grosch (9) who reported that during the decomposition of 13-*cis,trans* ML-OOH through peroxyl radicals in the presence of copper(II) ions, the majority of ketodiene compounds and some of the hydroxy compounds were *trans,trans* isomers. However, if the decomposition products are formed through more reactive alkoxyl radicals, the original *cis,trans* configuration of hydroperoxide remains in the decomposition product. This was demonstrated earlier by Gardner and Kleiman (22) who showed that the *cis,trans* configuration retained in the decomposition products in cysteine-$FeCl_3$ catalyzed decomposition of *cis,trans* hydroperoxides of linoleic acid. Thus, if the decomposition products of *cis,trans* hydroperoxides still have the *cis,trans* configuration, it indicates that the intermediate radicals of decomposition are alkoxyl radicals.

In this study, the isomerization of *cis,trans* ML-OOH to *trans,trans* ML-OOH was clearly seen in the control sample since the amount of *trans,trans* ML-OOH increased during the incubation. As described above, this isomerization was due to the formation and isomerization of peroxyl radicals. Thus, the importance of peroxyl radicals as intermediates during the decomposition of ML-OOH was demonstrated. TOH at higher levels inhibited this isomerization as no increase in the amount of *trans,trans* ML-OOH was seen. This result indicates that TOH acted as a hydrogen atom donor to *cis,trans* peroxyl radicals before they isomerized to *trans,trans* peroxyl radicals (Scheme 1). Previously Peers *et al.* (13) and Porter (20) showed that TOH acted as a hydrogen atom donor during the autoxidation of methyl linoleate since it increased the *cis,trans* to *trans,trans* ratio of hydroperoxides. TOH may also scavenge other radicals capable of initiating the isomerization and decomposition reac-



SCHEME 1

tions. However, the scavenging of peroxyl radicals is considered to be the main reaction.

In addition to the isomeric distribution of ML-OOH, TOH had an effect on the isomeric configuration of decomposition products. The majority of hydroxy and ketodiene compounds formed with high levels of TOH had a *cis,trans* configuration, whereas in the control sample most of decomposition products had a *trans,trans* configuration. The high levels of *cis,trans* decomposition products in the presence of TOH indicate that they were formed from *cis,trans* ML-OOH through alkoxyl radicals (Scheme 1), as no isomerization which would occur through peroxyl radicals was seen. Thus, alkoxyl radicals are intermediates during ML-OOH decomposition in the presence of hydrogen donating antioxidants, which can scavenge the peroxyl radicals formed during the decomposition. TOH increased the formation of hydroxy compounds in a concentration dependent way. The mechanism suggested for hydroxy compound formation involves the abstraction of hydrogen atoms by alkoxyl radicals. This reaction pathway may be favored in the presence of strong hydrogen donors such as TOH (Eq. 3) (5):

$$RO^{\bullet} + TOH \rightarrow ROH + TO^{\bullet} \quad [3]$$

Thus the increase in hydroxy formation gives further evidence of the presence of alkoxyl radicals during the decomposition of ML-OOH and of the ability of TOH to donate hydrogen atoms also to these radicals.

The effect of ascorbyl palmitate on ML-OOH decomposition differed markedly from TOH. Ascorbyl palmitate was not capable of inhibiting the decomposition of ML-OOH and at higher levels it even acted as a hydroperoxide decomposer. The analysis of ML-OOH and its decomposition products indicates that the mechanism of action of ascorbyl palmitate is more complex when compared to TOH. As with TOH, most of the of *cis,trans* ML-OOH decomposed without isomerization, but the isomeric configuration of decomposition products was characteristic for ascorbyl palmitate. The majority of hydroxy compounds in the presence of ascorbyl palmitate had a *cis,trans* configuration whereas ketodiene compounds had a *trans,trans* configuration. The increase in the formation of *cis,trans* hydroxy compounds with higher levels of ascorbyl palmitate is obviously due to the direct reduction of *cis,trans* ML-OOH to *cis,trans* hydroxy compounds without radical-intermediated isomerization. The amount of hydroxy compounds was already higher at the early stage of decomposition, which supports this hypothesis. It is interesting to

notice that in contrast to some previous studies (9,10), the reduction of ML-OOH to hydroxy compounds did not have a stabilizing effect on ML-OOH. Thus, under these experimental conditions, the reduction of hydroperoxides to more stable hydroxy compounds did not occur to an extent significant enough to inhibit the radical chain reactions of ML-OOH decomposition. The simultaneous formation of *trans,trans* ketodiene compounds indicates that ML-OOH decomposition similar to control sample occurred in these samples. However, the exact mechanism for ketodiene compound formation is not known at present time. In the literature, both mechanisms through peroxyl and alkoxyl radicals have been suggested (1).

The results of this study show that the stabilizing effect of TOH is partly due to its ability to act as a hydrogen atom donor to both peroxyl and alkoxyl radicals that are formed during the decomposition of hydroperoxides. Under these experimental conditions, ascorbyl palmitate has no stabilizing effect on ML-OOH since the reduction of hydroperoxide to a more stable hydroxy compound does not occur to an extent which inhibits the radical chain reactions of ML-OOH decomposition.

Vitamin E and Probucol Reduce Urinary Lipophilic Aldehydes and Renal Enlargement in Streptozotocin-Induced Diabetic Rats

Song-Suk Kim, D.D. Gallaher, and A. Saari Csallany*

Department of Food Science and Nutrition, University of Minnesota, St. Paul, Minnesota 55108

ABSTRACT: Diabetes mellitus is characterized by complications affecting several organs, including the kidney. Lipid peroxidation increases in diabetes and has been implicated in the pathogenesis of diabetic complications. In this study, we examined the ability of two antioxidants, vitamin E and probucol, to reduce lipid peroxidation *in vivo* and renal hypertrophy, an early stage of diabetic nephropathy, in rats. Animals were divided into four groups: non-diabetic, diabetic, diabetic treated with vitamin E, and diabetic treated with probucol. Animals were given antioxidants by intraperitoneal injection after induction of diabetes by streptozotocin injection. After 7 wk, lipid peroxidation *in vivo* was measured by analyzing urinary excretion of lipophilic aldehydes and related carbonyl compounds (LACC) as 2,4-dinitrophenylhydrazones by high-performance liquid chromatography. A number of urinary lipophilic nonpolar and polar aldehydes and related carbonyl compounds were identified, almost all of which increased in diabetes. Antioxidant treatment resulted in significantly decreased excretion of urinary LACC excretion. Antioxidant treatment of diabetic rats reduced renal hypertrophy. There was a high correlation between kidney weight and urinary LACC. Since LACC are accepted markers of lipid peroxidation, these results indicate that antioxidants can reduce the elevated lipid peroxidation of diabetes and may slow the onset of diabetic nephropathy.

Paper no. L7851 in *Lipids 35*, 1225–1237 (November 2000).

Lipid peroxidation has been implicated in a number of pathological conditions that are related to cellular damage induced by the oxidative alteration of polyunsaturated fatty acids (PUFA) (1). Diabetes is one such condition. Elevated lipid peroxidation *in vivo,* as measured by increased malondialdehyde and lipid hydroperoxides, has been observed in plasma (2–4), erythrocytes (5), and retina (6) of diabetic human subjects and rats. Diabetics, over time, often develop complications such as nephropathy, retinopathy, neurological problems, and atherosclerosis. Development of these complications has been proposed to be related to increased reactive oxygen species and to enhanced lipid peroxidation in cellular membranes (7,8). Free radicals, such as superoxide and hydroxyl radicals, may play important roles in the oxidative modification of lipid molecules during diabetes (9,10). Mechanisms that contribute to the peroxidative damage to membrane lipids in diabetes may include not only increased reactive oxygen species but also decreased efficiency of antioxidant defense systems. Diminished serum and erythrocyte antioxidant status has been detected in diabetic rats and human subjects (11–13).

Recently in this laboratory, significant increases of thiobarbituric acid-reactive substances were found in the urine of streptozotocin (STZ)-induced diabetic rats (14). This indicates enhanced lipid peroxidation *in vivo* and the oxidative modification of cellular lipid molecules. Based on this finding, it was speculated that certain secondary lipid peroxidation products, such as lipophilic aldehydes and related carbonyl compounds (LACC), might be excreted in the urine of STZ-induced diabetic rats. The first objective of the present experiment was to examine this hypothesis. The second objective was to evaluate the protective effects after the onset of diabetes of two antioxidants, vitamin E (*RRR*-α-tocopherol) and probucol, on renal hypertrophy, an early stage of diabetic nephropathy.

MATERIALS AND METHODS

Chemicals. 2,4-Dinitrophenylhydrazine (DNPH) and hexanal were obtained from Sigma Chemical Company (St. Louis, MO), pentan-2-one, hept-2-enal, hepta-2,4-dienal, decanal, and deca-2,4-dienal from Aldrich Chemical Co. (Milwaukee, WI), hydrochloric acid and high-performance liquid chromatography (HPLC)-grade acetone, methanol, dichloromethane, hexane, and water from EM Science (Gibbstown, NJ). DNPH derivatives of butanal, butanone, hexanal, octanal, non-2-enal, 4-hydroxyhex-2-enal (HHE), and 4-hydroxynon-2-enal (HNE) were a gift from Dr. Esterbauer, University of Graz

Abbreviations: D, STZ-induced diabetic; DNPH, 2,4-dinitrophenylhydrazine; DNP-hydrazone, 2,4-dinitrophenylhydrazone; HHE, 4-hydroxyhex-2-enal; HNE, 4-hydroxynon-2-enal; HPLC, high-performance liquid chromatography; LACC, lipophilic aldehydes and carbonyl compounds; N, nondiabetic control; NONPOL, nonpolar carbonyl compounds; PKC, protein kinase C; POL, polar carbonyl compounds; PUFA, polyunsaturated fatty acids; STZ, streptozotocin; D+E, vitamin E-treated diabetic; D+P, probucol-treated diabetic; TGF-β, transforming growth factor-β; TLC, thin-layer chromatography.

(Graz, Austria). Pentan-2-one, hept-2-enal, hepta-2,4-dienal, and deca-2,4-dienal DNPH derivatives were synthesized from pure standards and purified by repeated recrystallization from methanol. Silica gel thin-layer chromatographic (TLC) plates (Silica Gel 60, aluminum-backed 20 × 20 cm, 0.2 mm thickness) were purchased from Alltech Associates, Inc. (Deerfield, IL).

Instrumentation. The HPLC system consisted of an Altex Model 110A solvent metering pump, an Altex Model 110A sample injector (Beckman Instruments, Berkeley, CA), a Spectra-Physics Model SP8400 uv/vis detector and a Spectra-Physics Model SP4100 computing integrator (Spectra-Physics, Arlington, IL). The HPLC separations were performed on an Ultrasphere ODS C_{18} reverse phased-column (25 cm × 4.6 mm i.d., 5 μm particle size; Altex, Berkeley, CA) with a 2 cm × 2 mm i.d. guard column (Chrom Tech, Apple Valley, MN). Samples were filtered through 0.2 μm polyvinylidene difluoride membranes (Chrom Tech).

Animal treatment and urine collection. All experimental procedures were conducted in compliance with the University of Minnesota's policy on animal care and use. Four groups of male Wistar rats (Harlan, Indianapolis, IN) weighing 165–190 g (seven animals/group) were used: nondiabetic control (N), STZ-induced diabetic (D), and vitamin E-treated (D+E), or probucol-treated (D+P) diabetic animals. The diet for the N, D, D+E, and D+P groups was the standard AIN-76 diet (15), which provides 50 IU/kg vitamin E as DL-α-tocopheryl acetate. After adaptation to the diet for 4 d, animals in the D, D+E, and D+P groups were injected intraperitoneally with STZ (40 mg/kg body weight in 0.1 M citrate buffer, pH 5.5) (Sigma Chemical Co.). The animals in the N group were given sham injections of citrate buffer only. After confirmation of diabetes by testing for glucose in the urine using glucose oxidase-impregnated strips (Diastix; Miles Inc., Elkhart, IN), the D+E and D+P groups were injected with *RRR*-α-tocopherol (Sigma Chemical Co.) or probucol (Sigma Chemical Co.) intraperitoneally for three consecutive days, respectively. A fourth injection was given 2 wk later. Each injection of α-tocopherol provided approximately 70 times the daily intake. High levels of antioxidants were injected to quickly achieve saturation of blood and tissues with the antioxidant. Animals in the D+E and D+P groups received 79 mg (89 IU) *RRR*-α-tocopherol and 91 mg probucol, respectively, dissolved in 0.5 mL of vacuum-distilled corn oil (Eastman Kodak Co., Rochester, NY). Body weights were determined at the beginning of the experiment, at wk 2, and weekly thereafter. Twenty-four hour food intake was determined once a week at wk 2 and weekly thereafter. At the end of the 7-wk experimental period, urine was collected for 24 h from each animal and stored at −70°C until analysis. Animals were fasted overnight, then anesthetized and blood collected by cardiac puncture. An aliquot of whole blood was taken for determination of glycated hemoglobin and the remainder was centrifuged and the collected plasma was used for glucose and ascorbate analyses. The liver and both kidneys were removed and weighed. Glycated hemoglobin was determined in whole blood by affinity chromatography using a commercial kit (GlycAffin; Isolabs, Akron, OH). Plasma glucose concentration was measured by the hexokinase method (kit #115-A; Sigma Chemical Co.). An aliquot of plasma was diluted 1:4 with 5% meta-phosphoric acid immediately after collection for preservation of ascorbic acid content. Total ascorbate (ascorbate + dehydroascorbate) was subsequently analyzed fluorometrically by the method of Omaye *et al.* (16).

Measurement of urinary LACC. Urine analysis for LACC was carried out by the method of Kim, Gallaher, and Csallany (17,18). Briefly, urine was ultrafiltered to remove compounds with molecular masses larger than 500 daltons using Amicon cells, followed by synthesis of 2,4-dinitrophenylhydrazone (DNP-hydrazone) derivatives of urinary aldehydes and carbonyl compounds, extraction of the DNPH-hydrazones with dichloromethane (CH_2Cl_2) and preliminary separation of nonpolar compounds (NONPOL) and polar carbonyl compounds (POL) by TLC on silica gel plates developed with CH_2Cl_2. Separation and quantitation of the hydrazones was achieved by HPLC on a reversed-phase C_{18} column in two different solvent systems. NONPOL were eluted using methanol/water (75:25, vol/vol) and POL using methanol/water (50:50, vol/vol). Identification of DNP-hydrazones was accomplished by cochromatography with pure standards in three different solvent systems. Urinary excretion of the individual DNPH derivatives of lipophilic nonpolar and polar aldehydes and carbonyl compounds is expressed as the area detected by HPLC per day per 100 g body weight.

Statistical analysis. As the variances among groups were unequal, comparison of the N, D, D+E, and D+P groups was performed by a Kruskal-Wallis analysis of variance on ranks (SigmaStat 1.0; Jandel Scientific, San Rafael, CA). Specific group differences were determined by Student-Newman-Keuls' method or Dunn's method. Pearson correlation coefficients were calculated using group means, although we recognize that this is a nonideal means of correlating log-normalized and nonnormally distributed data. A P-value < 0.05 was considered significant for all analyses.

RESULTS AND DISCUSSION

Growth, food intake, glucose control, ascorbate levels, and organ weights. Diabetic animals had a greater food intake, but lower final body weight than normal animals (Table 1); differences were unaffected by antioxidant treatment. Fasting plasma glucose concentration was greatly elevated in diabetes, confirming the diabetic state. Both antioxidants produced slight but statistically significant reductions in plasma glucose. A reduction in fasting plasma glucose concentration has been found in humans consuming high doses of vitamin E for 3 mon (19), but not in rats fed high doses of either vitamin E or probucol for 6 wk (20). Glycated hemoglobin, an indicator of long-term blood glucose control (21), was elevated to approximately the same degree in all diabetic animals. Ceriello *et al.* (22) reported that vitamin E reduced stable HbA_1 (the major fraction of glycated hemoglobin) after 2

TABLE 1
Changes in Body Weight, Food Intake, Plasma Glucose and Ascorbate, Glycated Hemoglobin, and Organ Weights in Diabetic Rats Treated with Antioxidants for 7 wk[a]

	Normal	Diabetic	Diabetic + vitamin E	Diabetic + probucol
Final body wt (g)	381 ± 23[a]	215 ± 9[b]	229 ± 13[b]	252 ± 20[b]
Food intake (g/d)	24.1 ± 1.0[a]	34.7 ± 1.2[b]	35.8 ± 0.8[b]	34.3 ± 1.5[b]
Plasma glucose (mmol/L)	2.10 ± 0.43[c]	7.64 ± 0.50[a]	5.57 ± 0.67[b]	4.55 ± 0.93[b]
Glycated hemoglobin (%)	6.3 ± 1.0[b]	16.0 ± 0.4[a]	17.4 ± 0.7[a]	16.8 ± 0.4[a]
Plasma ascorbate (mmol/L)	6.39 ± 0.42[a]	1.99 ± 0.36[c]	2.25 ± 0.40[bc]	3.57 ± 0.73[b]
Kidney wt (g/100 g b.w.)	0.75 ± 0.07[c]	1.43 ± 0.02[a]	1.33 ± 0.04[ab]	1.22 ± 0.04[b]
Liver wt (g/100 g b.w.)	3.16 ± 0.20[b]	4.38 ± 0.13[a]	4.31 ± 0.08[a]	4.31 ± 0.15[a]

mon in diabetic subjects, but not after 1 mon; however, they found no effect of vitamin E on fasting plasma glucose concentrations. Paolisso *et al.* (19) found that vitamin E supplementation of type II diabetics for 3 mon reduced both fasting blood glucose concentrations and HbA_1 levels. In our study, a reduction in glycated hemoglobin might have been found with a longer trial period. However, it is possible that antioxidants may reduce fasting glucose levels, but that overall blood glucose control remains unchanged. Thus, the effect of antioxidant treatment during diabetes on glucose control remains uncertain.

Diabetic rats had greatly reduced concentrations of plasma ascorbate compared to normal animals, in agreement with the results of others (24). Treatment of diabetic rats with probucol and, to a lesser extent, vitamin E increased plasma ascorbate, suggesting that treatment of diabetic rats with antioxidants spares ascorbate.

Diabetic rats had heavier kidneys and livers, when expressed per 100 g body weight, than normal animals. In diabetic rats treated with probucol, however, kidneys showed less enlargement than in untreated diabetic rats, and there was a trend toward less renal enlargement in vitamin E-treated diabetic rats. The effect of antioxidants on organ weight was specific to the kidney, as there was no liver weight reduction due to antioxidants. Renal enlargement is one of the first consequences of diabetes and is the earliest event in the development of diabetic nephropathy (24). This growth is characterized in both humans (25) and rats with STZ-induced diabetes (26) by glomerular hypertrophy and basement membrane thickening. The pathological changes of diabetic renal disease are always preceded by this hypertrophy (27). The degree of enlargement strongly correlates with fasting plasma glucose concentrations (28) and with glycated hemoglobin levels (29). In diabetic dogs, improved glycemic control has prevented or regressed renal enlargement. These animals also showed an improved renal morphology compared to animals maintained on poor glycemic control (30). The reduction in renal enlargement by antioxidant treatment in the present study strongly suggests that antioxidants may slow the development of diabetic kidney disease.

Excretion of urinary LACC in diabetes. Typical HPLC separations of 2,4-DNPH derivatives of urinary lipophilic NONPOL and POL aldehydes and carbonyl compounds from STZ-induced diabetic rats are presented in Figures 1 and 2, respectively. Similar HPLC separations were also achieved in the urine of the normal, D+E, and D+P groups. Ten out of 13 NONPOL were identified by using cochromatography in three different solvent systems. These were butanal, butan-2-one, pentan-2-one, hex-2-enal, hexanal, hepta-2,4-dienal, hept-2-enal, octanal, non-2-enal, and deca-2,4-dienal. Two lipophilic polar aldehydes out of eight POL were also identified. These were HHE and HNE.

Comparison of the urinary excretion of lipophilic NONPOL and POL from normal and diabetic rats is presented in Figures 3–10. The results in the figures are presented as box plots because the data were not normally distributed. Eleven compounds, butanal, butan-2-one, pentan-2-one, hexanal, hept-2-enal, octanal, non-2-enal, deca-2,4-dienal, and unidentified compounds C, E, and J, out of 13 total NONPOL detected, were significantly increased in the diabetic group not given antioxidants, compared to excretion of these compounds in the N group (Figs. 3–6). Hex-2-enal (Fig. 5) and hept-2,4-dienal (Fig. 3) tended to be greater in the diabetic group compared to the N group, although these differences did not achieve statistical significance. Elevated levels of urinary lipophilic POL were also observed in the diabetic group compared to the N group, as shown in Figures 7 and 8. Seven of eight lipophilic POL, including the cytotoxic HHE and HNE, were significantly increased in the diabetic group compared to the N group. Unidentified compound G (Fig. 7) showed a trend toward an increase in the diabetic group compared to the N group. The sum of individual NONPOL and POL was significantly increased in the diabetic group compared to the N group, as indicated in Figure 10.

The significant increases in a number of lipophilic NONPOL and POL aldehydes and related carbonyl compounds in the urine of STZ-induced diabetic rats confirm lipid peroxidation *in vivo* and the consequent generation of certain secondary peroxidation products in the diabetic state. Mukherjee *et al.* (31) recently documented elevated lipid peroxidation not only in the pancreas but also in the liver, kidney, and brain tissues of STZ-induced diabetic rats, as measured by increases in thiobarbituric acid-reactive substances. Moreover, significant elevations of saturated aldehydes (hexanal, heptanal, octanal, and decanal) and unsaturated aldehydes (2-butenal, 2,4-pentadienal, 2-octenal, and 2-nonenal) have been

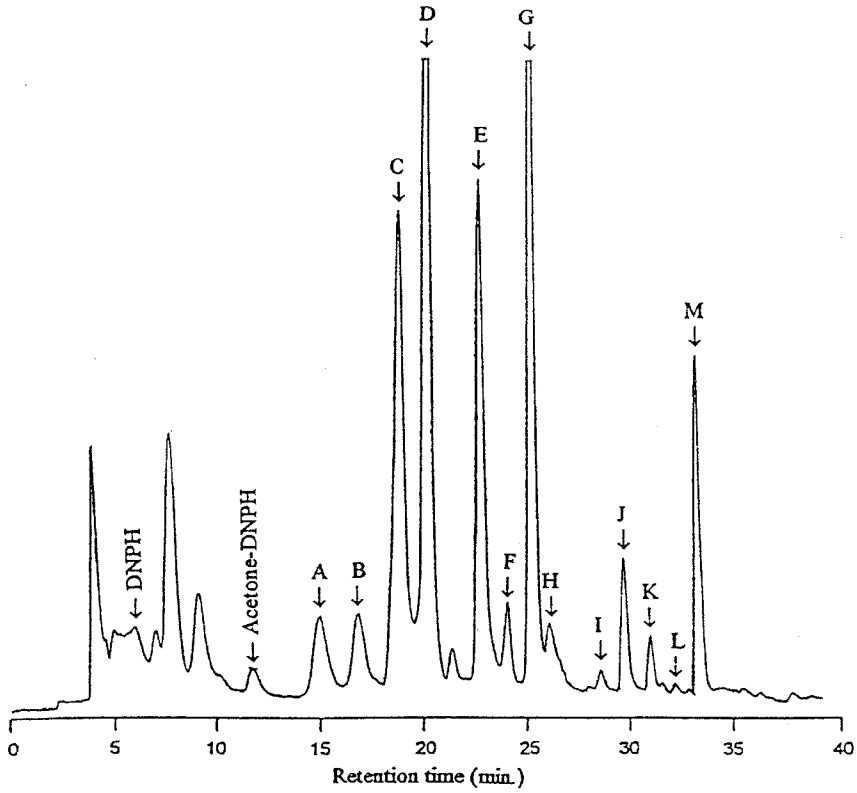

FIG. 1. High-performance liquid chromatography (HPLC) separation of 2,4-dinitrophenyl hydrazine (DNPH) derivatives of urinary nonpolar lipophilic aldehydes and related carbonyl compounds from streptozotocin (STZ)-treated diabetic rats. A, butanal; B, butan-2-one; D, pentan-2-one; F, hex-2-enal; G, hexanal; H, hepta-2,4-dienal; I, hept-2-enal; K, octanal; L, non-2-enal; M, deca-2,4-dienal; C, E, and J, unidentified. Separation conditions: Ultrasphere ODS column (4.6 mm × 25 cm, 5 μm), isocratic elution with 75% methanol in water for 10 min, followed by a linear gradient from 75% methanol in water to 100% methanol for 30 min; flow rate, 0.8 mL/min; detector wavelength, 378 nm; injected volume, 100 μL.

detected in the serum of diabetic human subjects and rats (32). It is established that these lipophilic aldehydes and related secondary peroxidation products can accumulate in cellular membranes and may interact with important biomolecules (33). In particular, HNE is capable of damaging functional proteins, inhibiting enzyme activities, and causing cell lysis in various tissues, at sites beyond where it is produced (34,35). This raises the possibility that the characteristic damage to eyes, kidneys, and arteries seen in diabetes (36,37) may be related to secondary lipid peroxidation products such as lipophilic aldehydes (20).

Effect of antioxidants on urinary excretion of LACC. Treatment of diabetic rats with vitamin E (D+E group) or probucol (D+P group) after the onset of diabetes decreased the urinary excretion of lipophilic NONPOL and POL to varying degrees, as shown in Figures 3 through 9. The unidentified compound E (Fig. 5) and hexanal (Fig. 6) were significantly decreased in the D+E group relative to those in the D group. Excretion of all NONPOL, except butanal, decreased in the D+E group compared to the D group. Six of eight POL exhibited moderate decreases in the D+E group (Figs. 7 and 9). Of particular interest is the significant decrease in HNE excretion observed in the D+E group compared to the D group (Fig. 7).

Excretion of butanal (Fig. 3), pentan-2-one (Fig. 6), hex-2-enal and unidentified compound E (Fig. 5) were significantly decreased in the D+P group compared to those in the D group, and all other lipophilic NONPOL aldehydes and carbonyl compounds tended to decrease. Similar decreases in urinary lipophilic POL were also detected in the D+P group. However, in contrast to vitamin E treatment, probucol treatment had no effect on the excretion of HNE (Fig. 7). Neither antioxidant had an effect on compounds G and F. These results are summarized in Tables 2 and 3.

Both vitamin E and probucol treatment of diabetic rats greatly reduced excretion of the sum of individual NONPOL, as indicated in Figure 10. The D+P group excreted lesser amounts of total NONPOL compared to the D+E group. Probucol treatment also reduced excretion of total POL and there was a tendency toward a reduced excretion with vitamin E treatment. Thus, overall, both antioxidants appeared to

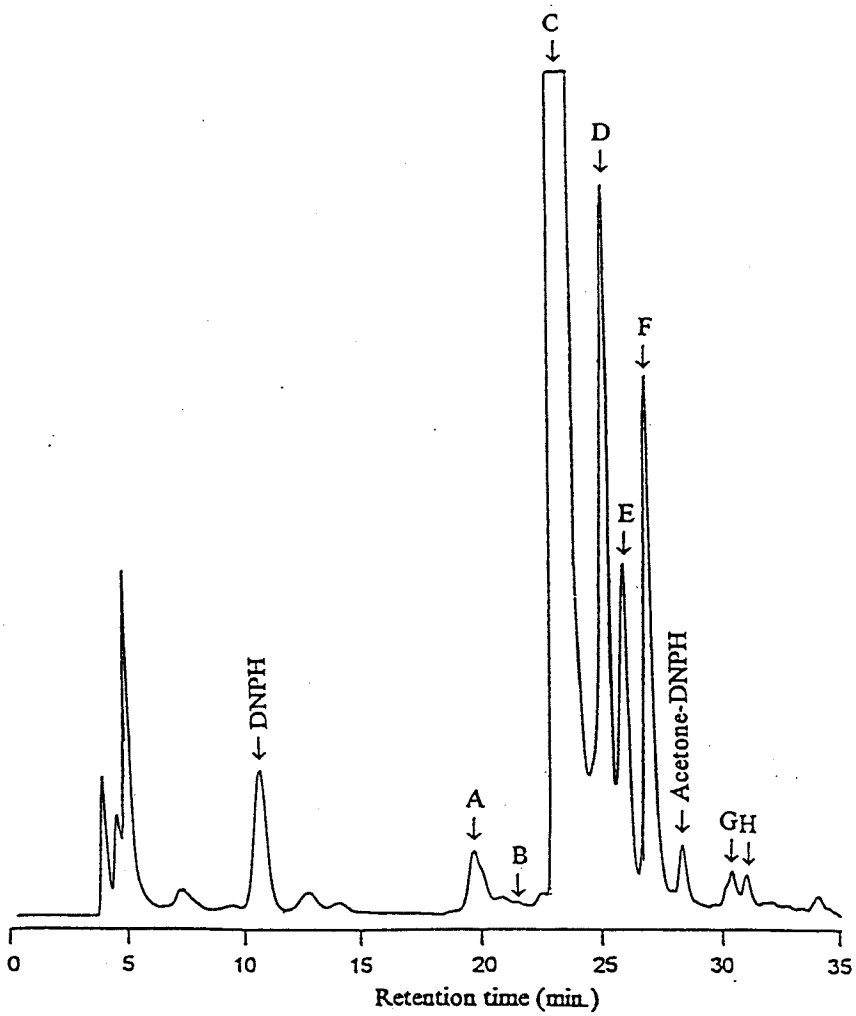

FIG. 2. HPLC separation of DNPH derivatives of urinary lipophilic polar aldehydes and related carbonyl compounds from STZ-treated diabetic rats. E, 4-hydroxyhex-2-enal; H, 4-hydroxynon-2-enal; and A, B, C, D, F, and G, unidentified. Separation conditions: Ultrasphere ODS column (4.6 mm × 25 cm, 5 μm), isocratic elution with 50% methanol in water for 10 min, followed by a linear gradient from 50% methanol in water to 100% methanol for 30 min; flow rate, 1.0 mL/min; detector wavelength, 378 nm; injected volume, 100 μL. See Figure 1 for abbreviations.

be effective at reducing urinary excretion of LACC. However, at the doses used, probucol appeared to be somewhat more effective.

Relationship between urinary LACC and renal enlargement. The relationship between urinary excretion of NONPOL and POL and renal enlargement is shown in Figure 11. There were high correlations between the group means for NONPOL excretion and kidney weight ($r^2 = 0.996$) and POL excretion and kidney weight ($r^2 = 0.990$) when plotted as an exponential curve. Similarly, the correlation, as an exponential curve, between the means of fasting plasma glucose and kidney weight ($r^2 = 0.995$, $P = 0.15$) was high. The correlation between glycated hemoglobin and kidney weight as an exponential was somewhat lower and not statistically significant ($r^2 = 0.88$, $P > 0.05$). The high correlations between the NONPOL and POL and kidney weight would suggest a causal relationship between the level of secondary lipid peroxidation products and renal enlargement.

Kidney failure in diabetes is ultimately caused by glomerulosclerosis as a result of chronic overproduction of mesangial matrix components by glomerular mesangial cells (38). It is now established that increased mesangial expression of the cytokine transforming growth factor-β (TGF-β) is intimately involved in the process of renal hypertrophy and accumulation of mesangial matrix components in diabetes (39). Bioactivation of TGF-β is caused, in part, by activation of protein kinase C (PKC), due to increased synthesis of the PKC activator diacylglycerol (40). An increase in the NADH/NAD^+ ratio appears to be responsible for the increase in diacylglycerol. Potentially, the increase in diacylglycerol

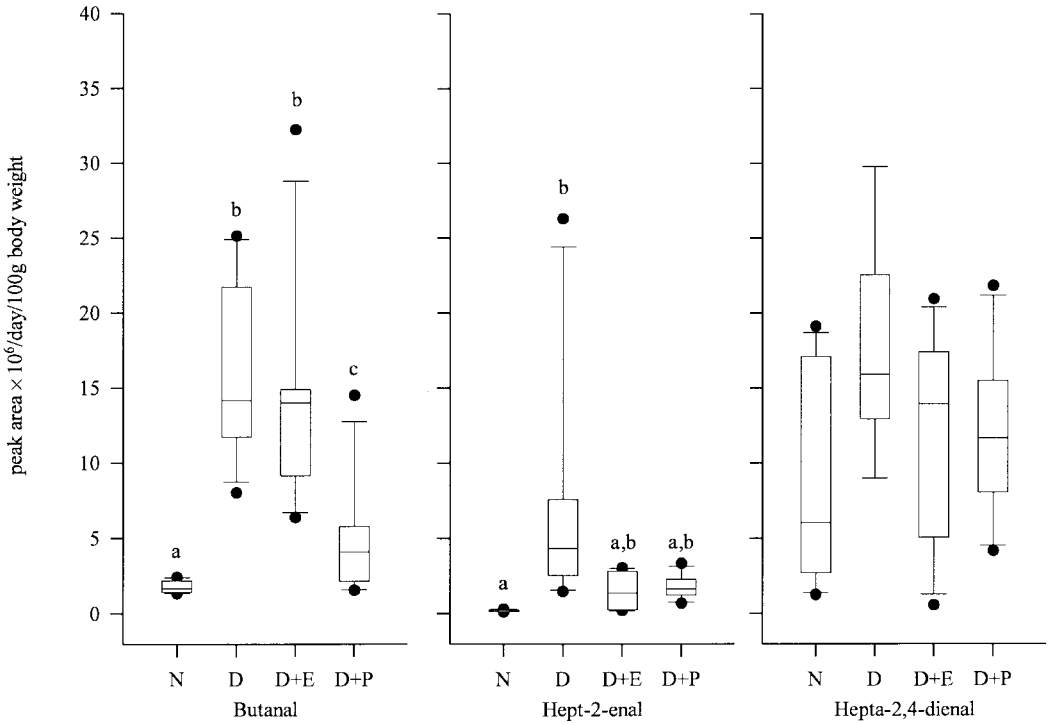

FIG. 3. Comparison of the urinary excretion of butanal, hept-2-enal, and hepta-2,4-dienal DNPH derivatives measured by HPLC from rats in nondiabetic control (N), STZ-treated diabetic (D), vitamin E-treated (D+E), and probucol-treated (D+P) diabetic animals. Values represent seven animals per group. The solid line within each boxplot represents the median. The top and bottom of the box are the 25 and 75% intervals of the data, the top and bottom of the error bars indicates the 5 and 95% interval of the data. Circles above or below the error bars represent data points that exceed the 5 and 95% interval of the data. Different letters denote significant differences ($P < 0.05$) among group medians by the Student-Newman-Keuls' test. See Figure 1 for other abbreviations.

could be due to increased flux through the polyol pathway, which converts glucose into fructose by way of the intermediate sorbitol *via* an NAD^+-dependent reaction. Under normoglycemic conditions, little glucose is metabolized *via* this pathway. However, during the hyperglycemia that characterizes poorly controlled diabetes, glucose flux through the

See Figures 1 and 3 for abbreviations.

polyol pathway may account for as much as one-third of total glucose turnover (41). This can increase the NADH/NAD^+ ratio in tissues that undergo insulin-independent uptake of glucose, such as the kidney. It has recently been demonstrated that numerous other aldehydes, in particular HNE, are excellent substrates for aldose reductase, the first and rate-limiting enzyme in the polyol pathway (42). Indeed, HNE has a K_m for aldose reductase over 1,000-fold lower than that of glucose (43). Thus, in diabetic rats, the increase in HNE, and perhaps of other aldehydic compounds, would contribute to the flux through the polyol pathway. Whether the reduction in these aldehydes by antioxidant treatment is responsible for the at-

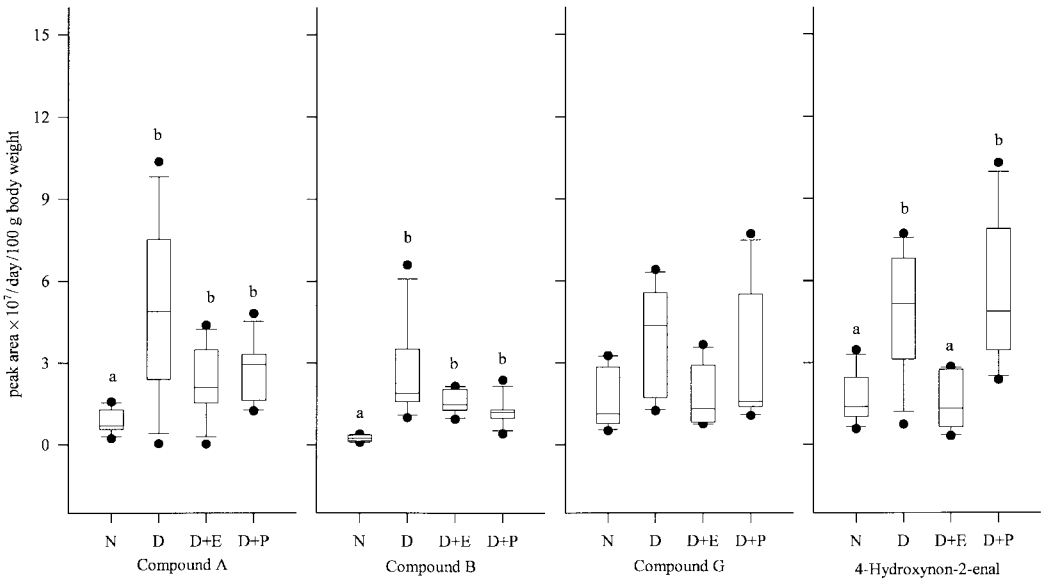

FIG. 7. Comparison of the urinary excretion of 4-hydroxynon-2-enal and the unidentified polar carbonyl compounds A, B, and G DNPH derivatives measured by HPLC from rats in N, D, D+E, and D+P. Values represent seven animals per group. See Figure 3 for description of boxplot symbols. Different letters denote significant differences ($P < 0.05$) among group medians by the Student-Newman-Keuls' test. See Figures 1 and 3 for abbreviations.

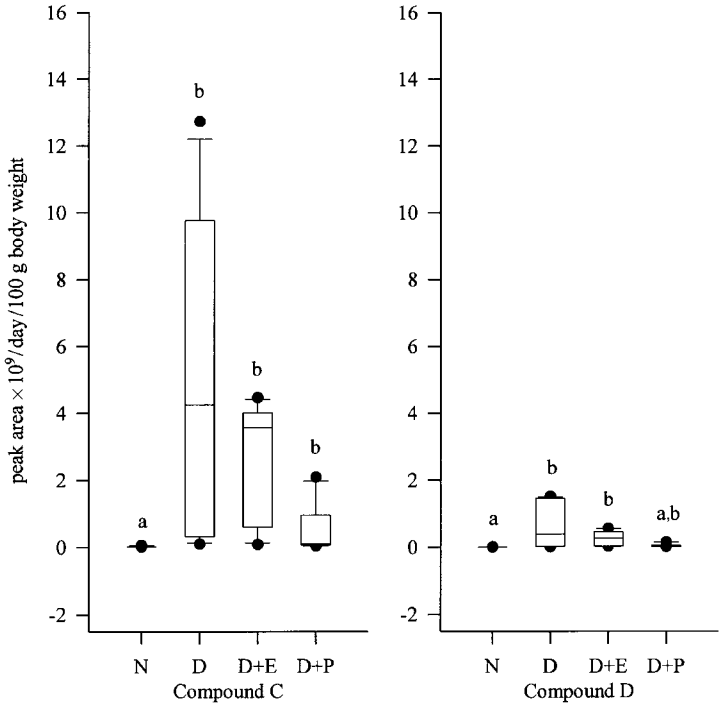

FIG. 8. Comparison of the urinary excretion of the unidentified polar carbonyl compounds C and D DNPH derivatives measured by HPLC from rats in N, D, D+E, and D+P. Values represent 6–7 animals per group. See Figure 4 for description of boxplot symbols. Different letters denote significant differences ($P < 0.05$) among group medians by Dunn's method. See Figures 1 and 4 for abbreviations.

tenuation of renal enlargement by reducing the flux through this pathway is uncertain because of contradictory reports regarding the role of the polyol pathway in renal enlargement. Osterby and Gunderson (44) found that STZ diabetic rats treated with an aldose reductase inhibitor for 6 mon showed less renal enlargement than untreated diabetic rats, whereas Korner *et al.* (45) reported that aldose reductase inhibitor treatment of STZ diabetic rats had no effect on renal enlargement.

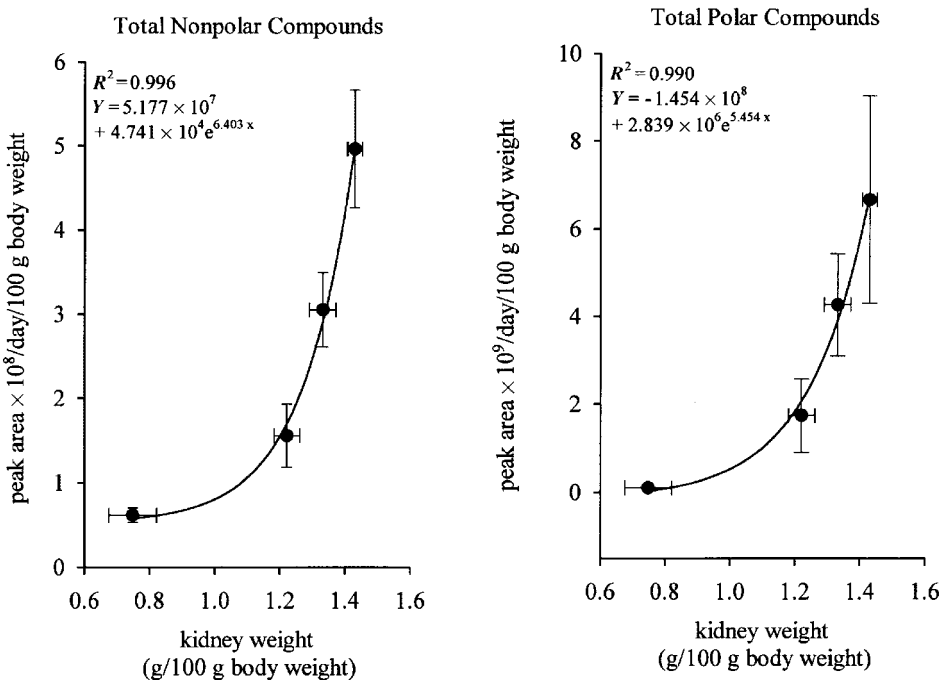

FIG. 11. Correlation between group means of urinary excretion of total nonpolar and total polar carbonyl compounds-DNPH derivatives and kidney weight. Values represent seven animals per group. See Figure 1 for abbreviation.

Recent studies suggest an alternative mechanism by which lipid-soluble antioxidants may inhibit renal enlargement. Kunisaki *et al.* (46) reported that intraperitoneal injections of vitamin E to STZ-induced diabetic rats decreased the membranous (i.e., active form) PKC specific activity and diacylglycerol content in aorta compared to untreated animals. Tran *et al.* (47) found that in cultured endothelial cells vitamin E increased the activity of diacylglycerol kinase, thus increasing conversion of diacylglycerol to phosphatidic acid. These studies raise the possibility that vitamin E, and possibly other lipophilic antioxidants, will lessen renal enlargement by direct activation of diacylglycerol kinase in mesangial cells, which would subsequently reduce diacylglycerol concentrations, leading to a decrease in PKC activity and TGF-β bioactivity. Thus, the mechanism by which antioxidant treatment of diabetic rats lessens renal enlargement is uncertain. Regardless of the mechanism, the results of the present study strongly suggest that antioxidants may be a useful adjunctive therapy for prevention of diabetic renal complications.

Our study confirms that diabetes increases LACC production (the secondary products of peroxidation), and therefore lipid peroxidation *in vivo*. Treatment with antioxidants such as *RRR*-α-tocopherol or probucol provides some protection against this peroxidation, as shown by the reduced urinary excretion of lipophilic aldehydes and related carbonyl compounds. Why diabetes increases lipid peroxidation is, however, uncertain. Based on *in vitro* studies, Wolff *et al.* (48) originally proposed that transition-metal-catalyzed oxidation of glucose was an important source of the oxidative stress of diabetes. More recently, Hunt *et al.* (49) indicated that the oxidation of glucose-protein adducts is the more likely source of oxidants. This is consistent with the results of Al-Abed *et al.* (50), who found that, *in vitro*, formation of advanced glycosylation end products in low density lipoproteins generates 4-hydroxynonenal and 4-hydroxyhexenal, indicating that the "late" products (carbonyl compounds) of the Maillard reaction result in lipid oxidation. These studies implicate high concentrations of glucose in the production of lipid peroxidation products. However, high glucose concentrations may also impair the antioxidant defense system. An *in vitro* study by Kunisaki *et al.* (51) demonstrated that high glucose concentrations reduced the specific binding affinity of *RRR*-α-tocopherol to aortic endothelial cells, potentially resulting in an intracellular vitamin E deficiency and increased levels of hydroperoxides. Further, Jain and Levine (52) reported increased levels of *RRR*-α-tocopheryl quinone, the primary oxidation product of *RRR*-α-tocopherol, in heart ventricles of diabetic rats, indicating an accelerated loss of *RRR*-α-tocopherol for scavenging oxygen radicals. Interestingly, increased vitamin E levels were reported in the liver of STZ-induced diabetic rats (53). This is likely due to the mobilization of *RRR*-α-tocopherol from the adipose tissue to the liver as a result of the high rate of lipolysis associated with the diabetic state (54).

The cholesterol-lowering drug probucol has been suggested to have antioxidant activity based on its chemical structure, in which two butylated hydroxytoluene moieties possess hydrophobic antioxidant activities (55). Fukuda *et al.* (56) suggested that the protective effect of probucol in diabetes may be mediated by its inhibition of oxygen radical generation and therefore reducing lipid peroxidation. It is likely that pre- or posttreatment with probucol could partially inhibit the lipid peroxidation process by its antioxidant action in diabetic conditions.

In the present experiment it was found that after the onset of diabetes, the ability of vitamin E and probucol to prevent formation and urinary excretion of LACC varied. In the urine of rats of the D+E group, significant decreases of hexanal and HNE, the decomposition products of n-6 PUFA, were found. This result may indicate that after the onset of diabetes the antioxidant effect of vitamin E is more effective in reducing the levels of lipid hydroperoxides and peroxy radicals produced from n-6 PUFA in comparison to probucol. Hydroxyaldehydes such as HNE and HHE are believed to cause extensive tissue injury due to their high reactivity with biomolecules (30,57). The action of vitamin E in lowering HNE in diabetic conditions could play an important role in reducing tissue damage related to diabetic complications. Overall, however, vitamin E and probucol were similarly effective in reducing the elevation in urinary excretion of secondary lipophilic products of lipid peroxidation due to diabetes.

The Effect of γ-Interferon to Inhibit Macrophage-High Density Lipoprotein Interactions Is Reversed by 15-Deoxy-$\Delta^{12,14}$-prostaglandin J_2

Steven H. Zuckerman*, Constantinos Panousis, Jacques Mizrahi, and Glenn Evans

ABSTRACT: Macrophage activation has been recognized as playing a central role in chronic inflammatory diseases in general and, more specifically, in the vascular wall during the progression of atherosclerotic lesions. Macrophage-activating factors present within the atherosclerotic lesion include the colony-stimulating factors and gamma interferon (IFNγ). In the present study, the effects of IFNγ on macrophage binding and uptake of fluorochrome-labeled high density lipoprotein (HDL) were investigated by flow cytometry and by measuring the amount of the type B scavenger receptors CD36 and scavenger receptor type B (SR-BI) by Northern blot analysis. IFNγ-, but not granulocyte macrophage colony-stimulating factor (GM-CSF)-treated murine peritoneal macrophages displayed a two- to threefold decrease in DiI-labeled HDL uptake. This effect was observed in the absence of a comparable decrease in SR-BI message and protein or CD36 message. This decrease in both HDL binding and uptake was reversed by the peroxisome proliferator-activated receptor gamma (PPARγ) agonist, 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2 (15d-PGJ_2), which also inhibited the IFNγ induction of the β2 integrin CD11a. Furthermore, 15d-PGJ_2 increased the expression of SR-BI and CD36 message and SR-BI protein which was reflected in an increase in HDL binding and uptake. These results suggest a role for PPARγ agonists in modulating the IFNγ-mediated macrophage effector functions relevant to atherosclerotic disease progression.

Paper no. L8497 in *Lipids 35,* 1239–1247 (November 2000).

The macrophage plays a central role in the pathology associated with atherosclerotic lesion development and progression (1–5). The biologic responses mediated by the macrophage are influenced by cytokines, resulting in both autocrine and paracrine regulatory circuits. Gamma interferon (IFNγ) represents one such macrophage-activating factor elaborated by activated Th1-type T cells within the atheroma that could modulate lesion progression (6–8). To this extent, the well-documented effects of IFNγ on macrophage effector functions including induction of inducible nitric oxide synthetase (iNOS), cytokine and protease secretion, increases in class I and II antigen expression, as well as other membrane markers represent effector functions that could impact on lesion development (9,10). More specifically, IFNγ has been demonstrated to downregulate macrophage apolipoprotein (apo) E secretion and lipoprotein receptors, including type I scavenger receptor SR-A, CD36, low density lipoprotein (LDL) receptor-related protein, as well as lipoprotein lipase secretion and cholesterol efflux (11–17). These effects would suggest a contributory role for IFNγ in the progression of atherosclerotic plaque. Consistent with these observations is the report that apo E knockout (KO) mice crossed with IFNγ receptor KO mice resulted in the double homozygote KO having *ca.* 60% reduction in lesion size, lipid accumulation, and cellularity (16). Similar results were observed with CSF-1-deficient mice (18).

One such mechanism for inhibiting IFNγ-mediated macrophage activation involves peroxisome proliferator-activating receptor gamma (PPARγ)/retinoid X receptor, heterodimer nuclear receptors. PPARγ agonists were reported to inhibit IFNγ-iNOS activity, gelatinase, and scavenger receptor A promoter activity by mouse peritoneal macrophages and macrophage cell lines (19,20), as well as phorbol myristate acetate induction of tumor necrosis factor secretion (21), and matrix metalloprotease-9 activity (22) in monocyte-derived macrophages. The demonstration that oxidized LDL upregulate PPARγ expression and that increased PPARγ is observed within atherosclerotic lesions (22–25) clearly suggests the potential for a negative feedback loop for modulating IFNγ-driven processes within the atherosclerotic lesion.

To this extent, the current studies focused on the impact of the PPARγ agonist, 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2 (15d-PGJ_2) (26,27) on IFNγ-regulated processes which could play a role in modulating atherosclerotic lesion progression. As high density lipoprotein (HDL)-cellular interactions can promote cholesterol efflux, the present study was designed to evaluate the effect of IFNγ and PPARγ agonists on this specific interaction. These studies demonstrate that IFNγ decreased both the binding and uptake of fluorochrome-labeled HDL by mouse peritoneal macrophages and that PPARγ agonists blocked these inhibitory effects as well as the IFNγ induction of the β2 integrin CD11a.

Abbreviations: apo, apolipoprotein; GM-CSF, granulocyte macrophage colony-stimulating factor; HDL, high density lipoprotein; IFNγ, gamma interferon; iNOS, inducible nitric oxide synthetase; KO, knockout; LDL, low density lipoprotein; 15d-PGJ_2, 15-deoxy-^{12,14}-prostaglandin J_2; PPARγ, peroxisome proliferator-activated receptor gamma; RXR, a member of the retinoid nuclear receptor family; SR-BI, scavenger receptor type B.

MATERIALS AND METHODS

Macrophage cultures and flow cytometry assays. Elicited macrophages were obtained 3–4 d following thioglycolate priming of Balb/C mice and were maintained in culture in RPMI 1640 medium supplemented with 2% fetal calf sera (HyClone Laboratories, Logan, UT). Macrophages were stimulated with varying concentrations of recombinant murine IFNγ (BioSource Intl., Camarillo, CA) or recombinant murine granulocyte macrophage colony-stimulating factor (GM-CSF; R&D Systems, Minneapolis, MN) in the presence or absence of 15-d-PGJ_2 (Biomol, Plymouth Meeting, PA). In additional experiments, the effects of other PPARγ agonists on HDL binding including ciglitazone and 12d-PGJ_2 (Biomol) (26,27) were also evaluated. After 48 h culture with the indicated treatments, macrophages were evaluated for changes in DiI (1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate), DiI-labeled HDL uptake, Alexa 488-labeled HDL binding, CD11a expression, and phagocytosis. CD11a expression was measured using phycoerythrin-labeled monoclonal antibody (Pharmingen, San Diego, CA). Cells were first washed three times in flow buffer and then were incubated in the same buffer with the antibody at 4 μg/mL on ice for 1 h. Following staining and subsequent washes, cells were detached by a rubber policeman and evaluated by flow cytometry. Parallel cultures were incubated with 50 μg/mL of commercially available human DiI-labeled HDL (for 2–4 h in the existing media) (Intracel Corp., Rockville, MD) or opsonized tetramethylrhodamine-conjugated *Escherichia coli* (Molecular Probes, Eugene, OR). Incubations were performed at 37°C for the indicated period as previously described (28). Human HDL binding to macrophage monolayers was performed at 4°C, using 20–25 μg/mL Alexa 488-labeled HDL prepared following the supplier's recommended protocol (Molecular Probes Alexa 488 protein labeling kit). This binding of Alexa-labeled HDL to macrophages was competed with a 50:1 excess of unlabeled HDL (Intracel Corp.), LDL, acetylated LDL, and fucoidan (data not shown). Following all fluorometric procedures, cells were washed, detached, and evaluated by flow cytometry. All flow cytometry experiments were evaluated on 10,000 individual cells gated for macrophages, based on their forward and side light-scatter profiles. The mean fluorescence intensity was measured using a Becton Dickinson FacSort with Cellquest software (Becton Dickinson, San Jose, CA).

Northern and Western blot analysis. Macrophage cultures with the indicated treatments were lysed at 48 h and processed for RNA and membrane protein. Total RNA and subsequently poly A^+ RNA were isolated using RNA isolation kits (Qiagen, Santa Clarita, CA). Poly A-enriched RNA, 0.5 μg per lane, was separated by 0.7% formaldehyde agarose gels and transferred to Nytran nylon membrane overnight using the turboblotter system (Schliecher and Schuell Inc., Keene, NH). Membranes were prehybridized in hybridization buffer and hybridized with [α-^{32}P]dCTP DNA probes labeled by random primers (Gibco, Grand Island, NY) in fresh hybridization buffer. Scavenger receptor type B (SR-BI), CD36, and CaB45 probes were polymerase chain reaction-amplified using 5′TCCTGAGCCCCGAGAGCCCCTTCCGC, 3′CTGGCTGCGCAGTTGGCAGATGATGGC; 5′CAGCCCAATGGAGCCATC, 3′CAGCGTAGATAGACCTGC; and 5′ AGCTGCTCATGGCCTCTGGTTCTT, 3′ GGTCTCTGAGGTTCCCAAGGACTT primer sets, respectively. Membranes were washed in 2× SSC (saline-sodium citrate buffer) 1% sodium dodecyl sulfate and exposed either to Kodak Biomax-MS film or to phosphoscreen. Quantitation was performed using a phosphoimager (Molecular Dynamics).

Macrophage membrane preparations were obtained following resuspension of detached cells in hypotonic lysis buffer (10 mM Tris pH 7.4, 1 mM EDTA, 5% protease inhibitor cocktail; Sigma Chemical Co., St. Louis, MO) and incubation on ice for 15–30 min. The suspension was then homogenized with a Virtis homogenizer, and the nuclei were removed by centrifugation at 800 × *g* for 10 min. Membranes were then pelleted from the supernatant by ultracentrifugation at 100,000 × *g* for 1 h and resuspended in 40 mM octyl glucoside by stirring on ice for 2–3 h. Solubilized proteins were separated on 8% polyacrylamide Tris-glycine gels (Novex, San Diego, CA), with comparable amounts of protein loaded and were transferred onto nitrocellulose using a semi-dry blotting system. Primary, affinity-purified rabbit anti-human SR-BI antibody (provided by Dr. Sue Acton, Millennium Pharmaceuticals Inc., Cambridge, MA) was incubated at 4°C overnight, and antibody detection was by peroxidase conjugated anti-rabbit IgG followed by enhanced chemiluminescence using Pierce Supersignal Ultra as substrate (Pierce Chemical, Rockford, IL). Preliminary experiments with this antibody demonstrated its cross-reactivity with murine SR-BI.

Nitric oxide measurements. Supernatants from macrophage cultures after 48 h co-culture with IFNγ and varying concentrations of 15d-PGJ_2 were measured for NO levels using the Griess reaction as previously described (29). Briefly, 100-μL aliquots of supernatants were mixed with 100 μL of Griess reagent containing 1% sulfanilamide, 0.1% naphthylethylene diamine dihydrochloride, and 2% phosphoric acid. The optic density change at 10 min was measured at 550 nm and converted to μM concentrations of nitrite based on a sodium nitrite standard curve.

Statistics. Statistical analysis was performed by unpaired (two-tail) *t*-test. Values are reported as means ± SD. The 95% confidence limit was taken as significant ($P < 0.05$).

RESULTS

Elicited murine peritoneal macrophages that had been activated with 1,000 units/mL of IFNγ demonstrated a significant reduction in the uptake of DiI-labeled HDL as evaluated by flow cytometry (Fig. 1A). Whereas untreated control macrophages had a mean fluorescence intensity of 285 fluorescence units, IFNγ resulted in a two- to fourfold decrease in DiI-

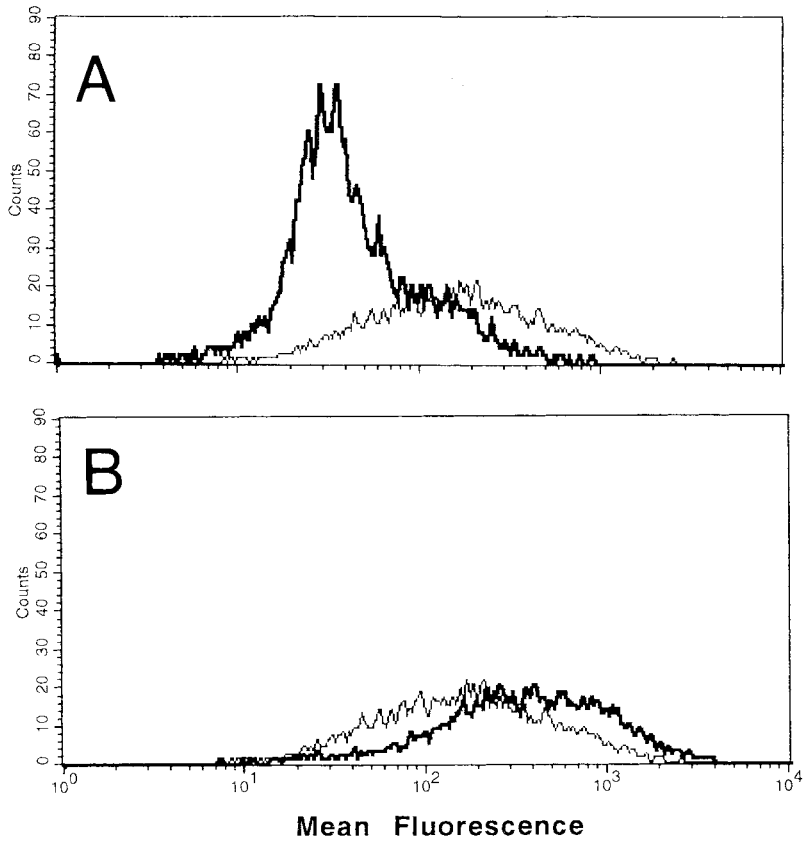

FIG. 1. Effect of macrophage activation on uptake of DiI-labeled high density lipoprotein (HDL). Macrophages were incubated with 1,000 units/mL of gamma interferon (IFNγ) (A) or 10 ng/mL of granulocyte macrophage colony-stimulating factor (GM-CSF) (B) for 48 h prior to challenge with 30 μg/mL of DiI-labeled HDL for 3 h at 37°C. Representative histograms, the mean fluorescence intensity in the control untreated macrophages (thin line) was 283 while IFNγ reduced the mean fluorescence to 72 and GM-CSF (bold lines) increased it to 505.

labeled HDL uptake. This decrease in the uptake of the DiI-labeled HDL was not a general property of activated macrophages as parallel GM-CSF-treated macrophages exhibited an increase in mean fluorescence intensity (Fig. 1B). Therefore, downregulation of DiI-labeled HDL uptake mediated by IFNγ was not a general event associated with macrophage activation.

The signaling pathway and the involvement of PPARγ heterodimer nuclear receptors in the regulation of specific macrophage effector functions modulated by IFNγ such as iNOS induction (19,20) raised the possibility that the IFNγ-mediated effects on HDL interactions could also be modulated through the PPAR pathway. Accordingly, the ability to reverse the IFNγ-mediated decrease in DiI-labeled HDL uptake was investigated using 15d-PGJ_2, a PPARγ agonist. A relevant concentration of 15d-PGJ_2 for the HDL studies was based on the dose response for this compound to inhibit NO accumulation in IFNγ-stimulated macrophage culture supernatants. As evident (Fig. 2) and consistent with previous reports (19,20), 15d-PGJ_2 inhibited in a dose-dependent manner the increase in nitrite detected in culture supernatants by the Griess reagent. Accordingly, a 15d-PGJ_2 concentration of 1.5 μM was chosen for all subsequent experiments. At this concentration, there was no apparent effect of the prostaglandin analog on cellular morphology or viability (data not shown).

The effect of the PPARγ agonist 15d-PGJ_2 on reversing the inhibition of DiI-labeled HDL uptake by IFNγ-activated macrophages was then evaluated at varying concentrations of IFNγ (Fig. 3A). As evident, IFNγ reduced in a dose-dependent manner the uptake of DiI-labeled HDL, and this effect was effectively reversed at all IFNγ concentrations by 15d-PGJ_2. Furthermore, 15d-PGJ_2 by itself resulted in an increase in DiI-labeled HDL uptake. The reduction in DiI-labeled HDL uptake by IFNγ did not reflect a nonspecific effect on all macrophage endocytic or phagocytic processes as uptake of opsonized *E. coli* was not reduced in parallel cultures of activated macrophages, nor was there any apparent nonspecific increase in phagocytosis mediated by 15d-PGJ_2 (Fig. 3B). These results would thus suggest that IFNγ was able to reduce HDL uptake in a dose-dependent manner and that this effect was inhibited by co-culture with the PPARγ agonist 15d-PGJ_2.

In an attempt to directly correlate the changes in DiI-la-

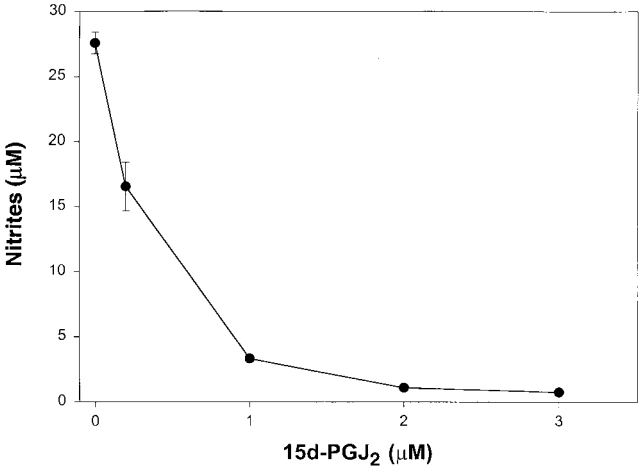

FIG. 2. Effect of the peroxisome proliferator-activated receptor gamma (PPARγ) agonist 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2 (15d-PGJ_2) on inducible nitric oxide synthase (iNOS) activity. Macrophages were incubated with 1,000 units/mL of IFNγ for 48 h in the presence or absence of the indicated concentrations of 15d-PGJ_2. Supernatants were assayed for iNOS activity by measuring nitrite accumulation through the Griess reaction. In the absence of IFNγ, 15d-PGJ_2 treatment did not result in any increase in the basal levels of nitrites detected, which were already below detectable levels. Representative experiment of 3. Brackets indicate standard deviation of the mean based on triplicate cultures. See Figure 1 for other abbreviations.

beled HDL uptake with the expression of HDL receptors, macrophage lysates were evaluated for both CD36 and SR-BI mRNA levels by Northern blot analysis. Macrophage cultures incubated with IFNγ did exhibit a reduction in mRNA levels for both CD36 (Figs. 4A and 4C) and SR-BI (Figs. 5A and 5B). In contrast, parallel cultures incubated with 15d-PGJ_2 alone resulted in an increase in SR-BI and a more significant increase in CD36 message while the combination of IFNγ and 15d-PGJ_2 resulted in type B scavenger receptor message levels similar to the control values. The increases observed in SR-BI and CD36 messages were not related to poly A-enriched RNA loading as there were no differences observed in quantitation of an irrelevant message coding for the Golgi-associated soluble calcium-binding protein, CaB45 (30) (Figs. 4B and 4D). The modest increase observed in the IFNγ-treated cells was also observed with other housekeeping genes including G3PDH (data not shown). Quantitation of the Northern blots by phosphoimager suggested that there was *ca.* tenfold more message for CD36 (Fig. 4C) than SR-BI (Fig. 5B). This quantitative difference between the two type B scavenger receptors was apparent using PCR probes labeled to a comparable specific activity and adding an equal amount of labeled probe into the two hybridizations, suggesting that CD36 is the more abundantly expressed type B scavenger receptor in murine peritoneal macrophages.

Macrophages stimulated with 15d-PGJ_2 also demonstrated changes in SR-BI protein content as evaluated by Western blot analysis (Fig. 5C). While there was no effect observed on SR-BI by IFNγ, 15d-PGJ_2 did result in a twofold increase in SR-BI, and this was also apparent in macrophages cocultured with IFNγ + 15d-PGJ_2. Accordingly, the effects of 15d-PGJ_2 on SR-BI were more apparent at the protein rather than the message levels. While it was not possible to evaluate changes in CD36 protein, due to the absence of an available antibody against murine CD36, HDL binding was evaluated at 4°C using Alexa 488-labeled HDL to distinguish between binding and uptake. Consistent with the increases in SR-BI and CD36 message, 15d-PGJ_2 increased the amount of HDL bound to the macrophage cultures with an apparent threefold increase in the mean fluorescence intensity (Fig. 4E), a magnitude similar to that observed for the increase in CD36 message (Fig. 4C). IFNγ-treated cells did demonstrate a reduction in HDL binding, and this effect was reversed in the presence of 15d-PGJ_2. Therefore, the reductions in SR-BI and CD36 message were consistent with the decrease in Alexa HDL binding while the increases in CD36 and SR-BI message and SR-BI protein by 15d-PGJ_2 were also reflected in an increase in the binding of Alexa-labeled HDL. Furthermore, the effects of 15d-PGJ_2 on increasing HDL binding were also apparent although more modest with two additional PPARγ agonists (Table 1), suggesting that the effects of PPARγ agonists on increasing macrophage binding of HDL are likely to reflect a pharmacologic class effect rather than being unique to a specific agonist structure.

In addition to the IFNγ effects on HDL-macrophage interactions and iNOS induction, other macrophage effector functions relevant to atherosclerotic lesion progression include increases in β2 integrin surface antigen expression. Therefore, the effects of the PPARγ heterodimer pathway on the β2 integrin CD11a were evaluated by flow cytometry. IFNγ, as expected, increased CD11a surface expression in a dose-dependent manner and, as with HDL uptake, these effects were inhibited by 15d-PGJ_2 (Fig. 6). These results clearly demonstrate that PPARγ agonists are capable of modulating both IFNγ-stimulating (CD11a and iNOS activity) and IFNγ-inhibiting (HDL binding and uptake) processes, occurring at

TABLE 1
Effect of PPARγ Agonists on HDL Binding by Murine Peritoneal Macrophages[a]

Treatment	– IFNγ	+ IFNγ
Control	214 (3)	146 (2)
Ciglitazone	288 (7.5)[b]	184 (7.4)[b]
12d-PGJ_2	266 (28)[c]	219 (2)[b]

[a]Ciglitazone and 12 deoxy-$\Delta^{12,14}$-prostaglandin J_2 (12d-PGJ_2) were evaluated at their optimal doses of 3 and 1 μM, respectively. Macrophages were cultured in the presence or absence of 300 units/mL of gamma interferon (IFNγ) with the indicated concentrations of peroxisome proliferator-activated receptor gamma (PPARγ) agonists. Following 48-h incubation, monolayers were washed and incubated for 3 h at 4°C with 25 μg/mL Alexa-labeled high density lipoprotein (HDL). Monolayers were again washed after the binding period, detached, and mean fluorescence intensities (MFI) in triplicate cultures were determined by flow cytometry. In a parallel study, 15d-PGJ_2 increased HDL binding from a control of 204 MFI to 371, and in IFNγ-treated cells from 136 to 289. Parentheses represent the standard deviation of the mean from triplicate cultures.
[b]Differences between the experimental group, and the relative control was significant by a Student's unpaired two-tailed *t*-test ($P < 0.01$).
[c]Or ($P < 0.1$).

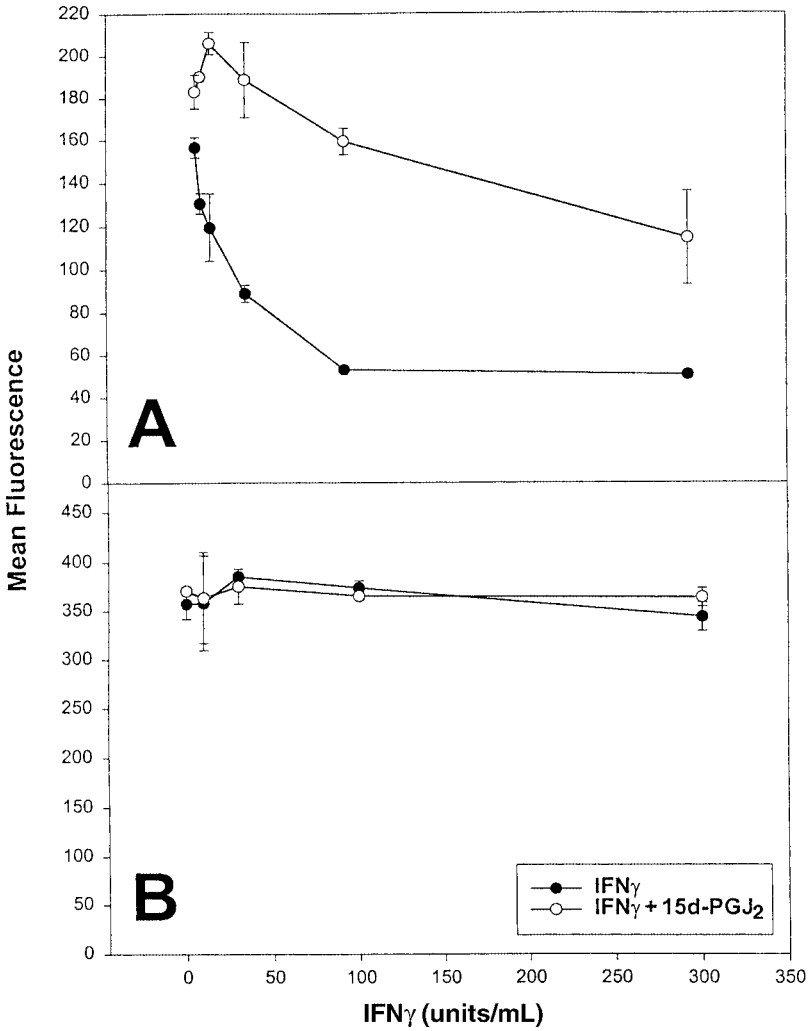

FIG. 3. Reversal of IFNγ-mediated downregulation of DiI-labeled HDL uptake by 15d-PGJ_2. Macrophages in triplicate cultures were incubated with the designated concentrations of IFNγ for 48 h in the presence (○) or absence (●) of 1.5 μM 15d-PGJ_2. Following incubation, macrophage cultures were challenged with DiI-labeled HDL (A) or fluorochrome-labeled opsonized *Escherichia coli* (B) for 3 h or 30 min, respectively, at 37°C. Monolayers were then washed, detached, and evaluated by flow cytometry. Brackets indicate standard deviation of the mean. See Figures 1 and 2 for abbreviations.

the plasma membrane level. In additional experiments, it was apparent that these IFNγ-mediated changes occurred with similar kinetics (Fig. 7). The IFNγ effects on CD11a expression and HDL uptake were apparent by 15 h with further increases (CD11a) or decreases (DiI-HDL) observed at 24 h. Maximal effects for both the reduction in HDL uptake and the increase in CD11a expression were observed by 48 h. With further IFNγ incubation for 72 h, CD11a expression appears to be reduced relative to the 48-h time point while HDL uptake remains inhibited to a comparable degree. These results could suggest that IFNγ within the micro-environment of an atherosclerotic lesion would contribute to plaque progression by increasing β_2 integrin expression and reducing macrophage–HDL interaction, a process likely to be important in reverse cholesterol transport.

DISCUSSION

The demonstration of Th1-type T cells within atherosclerotic lesions suggests a mechanism for the *in situ* activation of both macrophages and macrophage-derived foam cells by exposure to macrophage-activating factors within the microenvironment of the developing atheroma (6–8). In the present study, IFNγ-stimulated murine peritoneal macrophages displayed a reduced uptake of DiI-labeled HDL particles which is maximal by 48 h. This observation is consistent with a previous study, in which IFNγ resulted in a reduction in cholesterol efflux (17). These changes in lipid binding, which are functions attributed to SR-BI (31–33), occurred with only modest changes in SR-BI mRNA and no change in membrane protein. In the previous study from this laboratory, IFNγ had no effect on

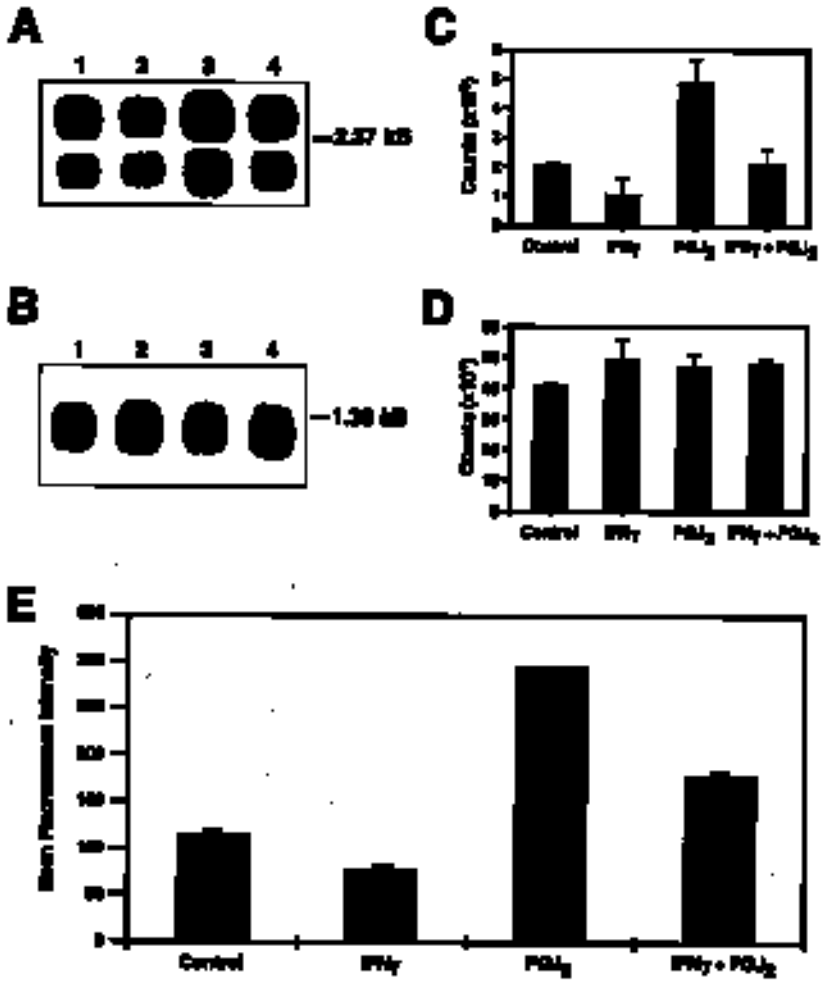

FIG. 4. Effect of IFNγ and 15d-PGJ_2 on CD36 mRNA levels and HDL binding. Macrophage cultures were untreated (lane 1) or incubated for 48 h in the presence of 300 units/mL of IFNγ (lane 2), 1.5 μM 15d-PGJ_2 (lane 3), or 15d-PGJ_2 + IFNγ (lane 4) and lysed for Northern blot analysis based on poly A-enriched mRNA. Nitrocellulose filters were probed with polymerase chain reaction (PCR)-labeled probes specific for CD36 (A), and the Golgi-associated calcium-binding protein Cab45 (B). Quantitation of the hybridized signals for each blot was by phosphoimager analysis (C,D). Band intensities for CD36 were normalized to the band intensity of Cab45 to control for any differences in poly A-enriched mRNA loading. Brackets represent the standard deviation of the mean (n = 3). Parallel cultures were incubated at 4°C with 25 μg/mL Alexa-labeled HDL for 3 h, washed, detached, and evaluated by flow cytometry (E). Brackets indicate the standard deviation of the mean fluorescence intensity in replica cultures. See Figures 1 and 2 for other abbreviations.

SR-BI message levels in macrophage-derived foam cells, whereas in the present study on macrophages that were not lipid-loaded, a modest reduction was observed. Therefore, whether the changes in HDL interactions which occur with IFNγ-activated macrophages reflect changes in functional SR-BI or CD36 which are not apparent when evaluating total protein or message remains to be determined. The more significant effects on DiI-labeled HDL uptake relative to the binding of Alexa labeled HDL would suggest additional effects of IFNγ beyond modulation of type B scavenger receptor levels.

The results of this study demonstrate that the pathway by which IFNγ downregulates HDL uptake is modulated by the PPARγ agonist 15d-PGJ_2, suggesting a role for PPARγ heterodimer nuclear receptors. Involvement of this pathway was supported by the observation that coincubation of macrophages with 1.5 μM 15d-PGJ_2, 12d-PGJ_2, or the unrelated PPARγ agonist ciglitazone resulted in an inhibition of the IFNγ effects on HDL binding. In addition, the present study has also demonstrated that the PPARγ agonist 15d-PGJ_2 was also able to reduce the IFNγ-mediated increases in CD11a expression and iNOS activity. The effect of 15d-PGJ_2 on inhibiting IFNγ-induced CD11a suggests additional IFNγ-regulated pathways modulated through PPARγ agonists. As these activities including iNOS induction are associated with macrophage activation, the ability to specifically inhibit these processes with PPARγ agonists offers therapeutic possibili-

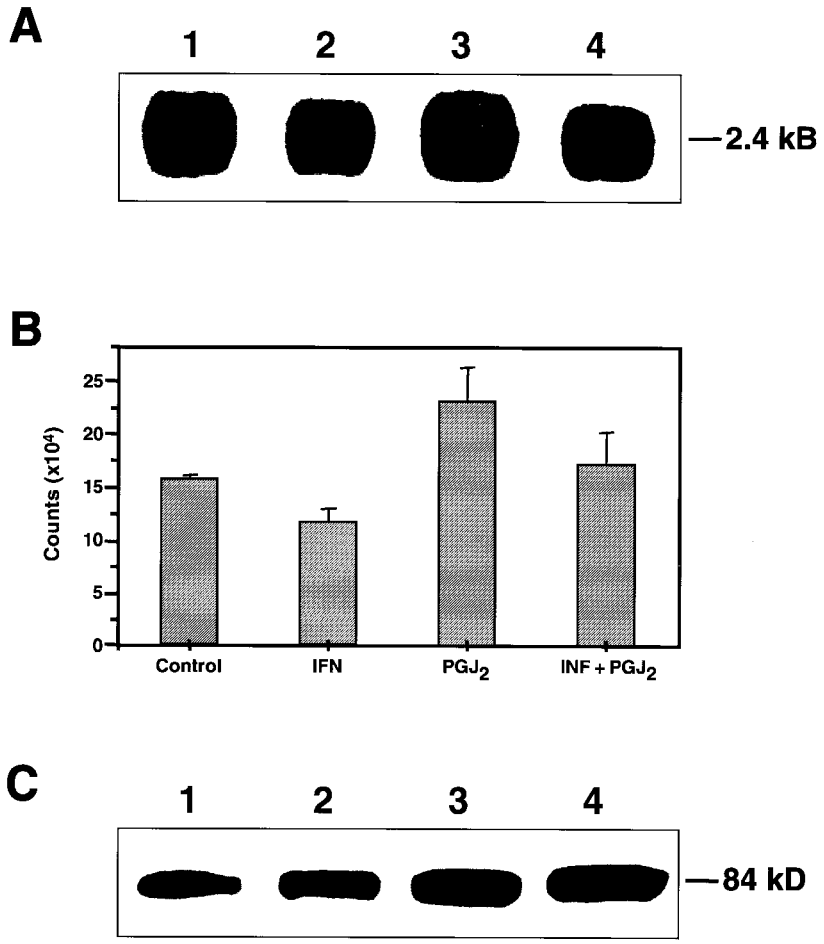

FIG. 5. Effects of IFNγ and 15d-PGJ_2 on SR-BI message and protein. Macrophages were incubated for 48 h in the absence (lane 1) or presence of 300 units/mL of IFNγ (lane 2), 1.5 μM 15d-PGJ_2 (lane 3), or 15d-PGJ_2 + IFNγ (lane 4) and lysed for Northern blot analysis. Poly A-enriched mRNA filters were hybridized with PCR-labeled probes specific for SR-BI (A). Quantitation of the radiolabeled bands was by phosphoimager (B). Band intensities for SR-BI were normalized to the band intensity of Cab45 to control for any differences in poly A-enriched mRNA loading. Brackets indicate standard deviations of the mean, $n = 3$. Parallel cultures were evaluated for SR-BI membrane protein in a membrane fraction following hypotonic lysis. SR-BI was detected by antibody staining using enhanced chemiluminescence (C). For abbreviations see Figures 1, 2, and 4.

ties for impacting the inflammatory aspects of activated macrophage effector functions without compromising functions such as phagocytosis of opsonized microorganisms.

These studies support a role for PPARγ/RXR heterodimers (where RXR is a member of the retinoid nuclear receptor family) in the modulation of macrophage effector functions within the atherosclerotic lesion. Furthermore, the demonstration that PPARγ transcription is increased by oxidized LDL or lipid components (23–25) and also by cytokines including macrophage CSF and GM-CSF (23) suggests an autocrine loop which would ensure maximal expression of PPARγ within an atherosclerotic lesion. Whether the observed increase in DiI-labeled HDL uptake in GM-CSF-treated macrophages in the present study is due to an increase in PPARγ expression remains to be determined.

The additional observations that agonists for this heteronuclear receptor pathway can promote macrophage differentiation as evidenced by increased expression of CD14, CDllb, and CD18 in HL60 cells and CD14 in human monocytes (25) suggest that their role in modulating macrophage effector functions is complex and likely to be dependent upon the state of macrophage activation and differentiation as well as on the relative amounts of other stimuli present within the microenvironment. For example, PPARγ agonists have been reported to decrease SR-A promoter activity in U937 transfectants (19) and the presence of oxidized LDL plus the RXR ligand LG268 increased SR-A message in THP-1 cells (24). These studies as well as the present observations that 15d-PGJ_2 inhibits the IFNγ-mediated decreases in macrophage-HDL interaction and also the induction of CD11a suggest that PPARγ agonists may have a profound effect on the expression of macrophage surface antigens and receptors relevant to the atherosclerotic process.

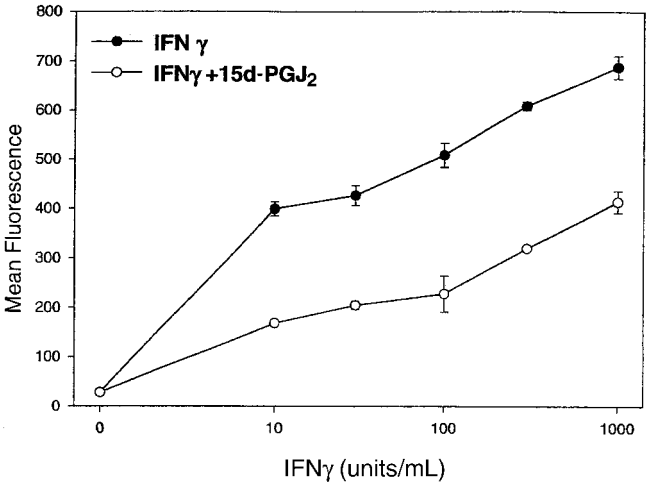

FIG. 6. Inhibition of IFNγ induction of CD11a expression by 15d-PGJ_2. Macrophages were cultured in the absence (●) or presence of 1.5 μM 15d-PGJ_2 (○) at the indicated concentrations of IFNγ. Following 48 h incubation, cultures were stained for CD11a surface expression, and the mean fluoresence intensity was quantitated by flow cytometry. Note inhibition of CD11a expression at all concentrations of IFNγ by the PPARγ agonist. Brackets indicate standard deviation of the mean from triplicate cultures. Representative experiment of 3. See Figures 1 and 2 for abbreviations.

IFNγ by inhibiting apo E secretion (11–13), reducing scavenger receptor activity and cholesterol efflux (14,15,17), promoting macrophage activation (9,10), and as demonstrated in the present study inhibiting macrophage HDL binding would suggest a negative role for this cytokine on the process of reverse cholesterol transport (34–37). Clearly, the reduction in atherosclerotic lesions in the apo E KO mouse when crossed with the IFNγ receptor KO (16) is consistent with its negative role in reverse cholesterol transport. Macrophage-HDL interactions are likely to involve both SR-BI and CD36 (38,39). That IFNγ reduced HDL uptake with only a modest change in SR-BI message and no effect on protein would suggest either an impact on membrane trafficking or function of this receptor through a post-translational modification or, alternatively, downregulation of an HDL receptor distinct from SR-BI. While CD36 would represent a logical candidate, here too, there was only a modest effect on message levels. In distinction, the increase in both the binding of Alexa-labeled HDL and the uptake of DiI-labeled HDL by 15d-PGJ_2 as well as the associated increase in SR-BI protein would suggest that this PPARγ agonist can enhance reverse cholesterol transport by increasing SR-BI and CD36 expression and antagonizing other inflammatory aspects of IFNγ-mediated macrophage activation. The recent demonstration (40) that a CD36 KO mouse had an increase in serum cholesterol primarily within the HDL fraction provides further evidence for the role of this receptor in HDL clearance. Whether PPARγ agonists will modulate HDL binding by macrophages in mice expressing this null mutation remains to be determined. Finally, the global anti-inflammatory effects of PPARγ agonists on macrophages raise the question as to whether more potent agonists of this pathway will promote lesion regression without a negative impact on macrophage effector functions associated with host defense.

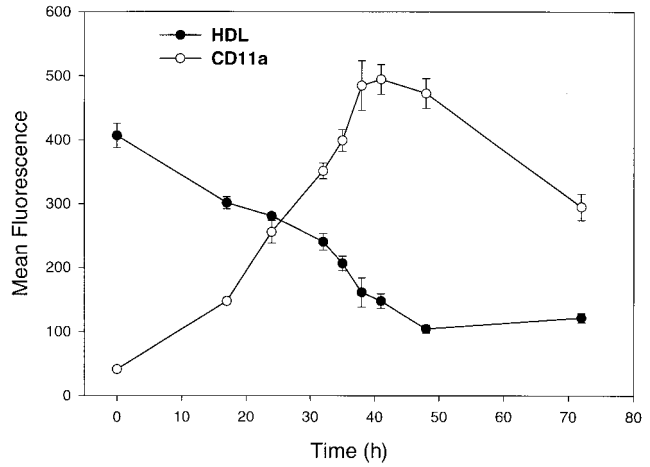

FIG. 7. Kinetics of IFNγ-mediated changes in HDL uptake and CD11a expression. Macrophage cultures in triplicate were incubated with 300 units/mL of IFNγ and at designated intervals were stained for CD11a expression (○) at 4°C or in parallel wells evaluated for the uptake of DiI-labeled HDL at 37°C (●). Parentheses indicate the standard deviation of the mean. See Figure 1 for abbreviations.

ACKNOWLEDGMENTS

The authors wish to thank Dr. Ray Kauffman for his review of our manuscript and Dr. Sue Acton (Millennium Pharmaceuticals Inc.) for providing the antibody against SR-BI.

Human, but Not Bovine, Oxidized Cerebral Spinal Fluid Lipoproteins Disrupt Neuronal Microtubules

M.D. Neely*, L.L. Swift, and T.J. Montine

Department of Pathology, Vanderbilt University, Nashville, Tennessee 37232

ABSTRACT: Cerebral spinal fluid (CSF) lipoproteins have become a focus of research since the observation that inheritance of particular alleles of the apolipoprotein E gene affects the risk of Alzheimer's disease (AD). There is evidence of increased lipid peroxidation in CSF lipoproteins from patients with AD, but the biological significance of this observation is not known. A characteristic of the AD brain is a disturbance of the neuronal microtubule organization. We have shown previously that 4-hydroxy-2(*E*)-nonenal, a major product of lipid peroxidation, causes disruption of neuronal microtubules and therefore tested whether oxidized CSF lipoproteins had the same effect. We exposed Neuro 2A cells to human CSF lipoproteins and analyzed the microtubule organization by immunofluorescence. *In vitro* oxidized human CSF lipoproteins caused disruption of the microtubule network, while their native (nonoxidized) counterparts did not. Microtubule disruption was observed after short exposures (1 h) and lipoprotein concentrations were present in CSF (20 μg/mL), conditions that did not result in loss of cell viability. Importantly, adult bovine CSF lipoproteins, oxidized under identical conditions, had no effect on the microtubule organization of Neuro 2A cells. Comparison of human and bovine CSF lipoproteins revealed similar oxidation-induced modifications of apolipoproteins E and A-I as analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis and Western blotting. Fatty acid analysis revealed substantially lower amounts of unsaturated fatty acids in bovine CSF lipoproteins, when compared to their human counterparts. Our data therefore indicate that oxidized human CSF lipoproteins are detrimental to neuronal microtubules. This effect is species-specific, since equally oxidized bovine CSF lipoproteins left the neuronal microtubule organization unchanged.

Paper no. L8492 in *Lipids 35,* 1249–1257 (November 2000).

Cerebral spinal fluid (CSF) lipoproteins have received increased attention since the discovery that the inheritance of the ε4 allele of the apolipoprotein E (apoE) gene increases the risk of late-onset familial and sporadic Alzheimer's disease (AD) (1). Human CSF lipoproteins consist of a subpopulation of particles, which differ in their physical characteristics as well as protein and lipid composition (2–8). Two types of high density lipoprotein (HDL)-like spherical particles, one enriched in one of the major CSF apolipoproteins, apoE, the other enriched in the second major CSF apolipoprotein, apoA-I, constitute the majority of the CSF lipoproteins (2,3). In addition, other less abundant classes of larger lipoprotein particles have been identified (3–6). Although no genotype-specific differences in the overall protein and lipid composition of CSF lipoproteins ($d < 1.21$ g/mL) were observed (7), the apoE genotype does seem to affect the distribution profile of apoE-containing lipoproteins (5).

There is increasing evidence that oxidative stress and lipid peroxidation in particular play important roles in the pathogenesis of AD (9–19). Lipid peroxidation also has been implicated in another age-related disease, atherosclerosis, where oxidized plasma lipoproteins are thought to contribute to disease progression (for review see Ref. 20). We have observed evidence of increased lipid peroxidation in CSF lipoproteins from AD patients when compared to CSF lipoproteins from non-demented individuals (21). In addition, others have demonstrated increased concentration of the lipid peroxidation product 4-hydroxy-2(*E*)-nonenal (HNE) in CSF of AD patients compared to controls (22). These findings are consistent with the hypothesis that CSF lipoproteins in AD patients are present in an environment favorable for lipid peroxidation or are derived from tissue experiencing lipid peroxidation. In either case, oxidized CSF lipoproteins may act as vehicles to deliver lipid peroxidation products to neurons. Oxidized plasma lipoproteins have been shown to be toxic to a variety of cultured cells, including neurons (23–27). To our knowledge, only one study has examined the potential neurotoxicity of oxidized human CSF lipoproteins (28). The authors observed significant loss of cell viability after 24 h exposures of Neuro 2A cells to *in vitro* oxidized human CSF lipoproteins; however, the mechanism(s) by which the oxidized CSF lipoproteins cause cell death is not known (28).

A hallmark of the AD brain is the change in biochemical and structural features of neuronal microtubules. Abnormal organization and general deficiency of microtubules have been observed in dendrites of neurons in the frontal cortex of AD patients (29–32). Furthermore, in the AD brain, tau, a mi-

Abbreviations: AAPH, 2,2′-azo-bis-(2-aminopropane) hydrochloride; AD, Alzheimer's disease; apo, apolipoprotein; blotto, 4% dry milk in Tris-buffered saline with 0.05% Tween 20; CNS, central nervous system; CSF, cerebral spinal fluid; DMEM/F12, Dulbecco's Modified Eagle Medium/Nutrient Mixture F-12; HDL, high density lipoproteins; HNE, 4-hydroxy-2(*E*)-nonenal; LDL, low density lipoproteins; PBS, phosphate-buffered saline; PUFA, polyunsaturated fatty acid; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis.

crotubule-associated protein, is localized to neuronal somatodendritic region, whereas in the normal brain it is found exclusively in axons (33). Abnormally phosphorylated tau is the major protein component of neurofibrillary tangles (34,35). We have shown previously that some HNE-protein adducts co-localize with neurofibrillary tangles in the AD brain (11,12) and that the lipid peroxidation product HNE causes disruption of the neuronal microtubule network (36). Here, we show that *in vitro* oxidized human CSF lipoproteins cause rapid (within 1 h) disruption of the microtubule organization in Neuro 2A cells. Strikingly, lipoproteins isolated from bovine CSF and oxidized in the same manner did not affect neuronal microtubules.

MATERIAL AND METHODS

Materials. Materials used for cell culture were from Life Technologies (Grand Island, NY). Reagents for sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and Western blotting were obtained from Bio-Rad (Hercules, CA). All other chemicals were from Sigma (St. Louis, MO) unless otherwise indicated.

Case selection and preparation of CSF lipoproteins. Following informed consent, CSF was removed, post mortem, from the lateral ventricles. All autopsies were performed at Vanderbilt University Medical Center within 5 h of death. All individuals had histopathologically confirmed AD (3 patients) or, in controls, age-related changes only (3 subjects). Ventricular fluid (≥8.5 mL), visually free of contamination by blood, was collected. In our extensive experience with human CSF, we have never detected apoB in CSF that was visually free of blood (21,37). After collection, the CSF was immediately sedimented at 1,000 × *g* for 10 min and frozen at −80°C. Ventricular fluid density was raised to $d = 1.210$ g/mL by addition of KBr before centrifugation at 4°C in a Beckman (Fullerton, CA) L8-55 ultracentrifuge using either a 40 rotor at 95,581 × *g* (38,000 rpm) for 42 h or a 50.3 Ti rotor at 165,667 × *g* (48,000 rpm) for 24 h. Floating lipoproteins were recovered by tube slicing and washed once under identical conditions used for initial isolation. The lipoproteins were then dialyzed into phosphate-buffered saline (PBS) and the protein concentration determined by the bicinchoninic acid assay according to the manufacturer's protocol (Pierce, Rockford, IL) except that 0.1% SDS was included in each sample. Frozen adult bovine CSF (guaranteed blood free) was purchased from Pel-Freez (Rogers, AR) and stored at −80°C until use. Isolation and oxidation of bovine CSF lipoproteins were performed exactly as for the human lipoproteins.

Oxidation and analysis of CSF lipoproteins. Lipoproteins were isolated from human and adult bovine CSF, and samples were adjusted to a protein concentration of 40 μg/mL and oxidized with increasing concentrations of 2,2′-azo-bis-(2-aminopropane) hydrochloride (AAPH) (Wako Chemicals, Richmond, VA). AAPH, a water-soluble azo compound that thermally decomposes to produce a constant radical flux, has been used extensively in studies of plasma lipoproteins (38). In order not to lose any metabolites resulting from oxidation, the lipoproteins were not dialyzed after their incubation with AAPH. This was possible because a control solution of 10 mM AAPH (the highest concentration used in our experiments) that had been incubated under identical conditions had no effect on the microtubule organization of Neuro 2A cells. After oxidation, the lipoprotein samples were stored in working aliquots of 50–100 μL at −80°C until use. The effect of lipoprotein oxidation on apoE and apoA-I was analyzed by SDS-PAGE and Western blot analysis. The proteins were separated by electrophoresis in a 12% polyacrylamide gel (39) and stained using the silver nitrate method or transferred to a membrane (#162-0170; Bio-Rad) for Western blot analysis. Nonspecific binding sites on the membrane were blocked with "blotto" (4% dry milk in Tris-buffered saline with 0.05% Tween 20) for at least 3 h at room temperature. The proteins were immunoreacted, first with either a polyclonal anti-human apoE antibody (#A0077; DAKO, Carpinteria, CA) or a polyclonal anti-human apoA-I antibody (#178422; Calbiochem, San Diego, CA), each diluted 500-fold into blotto, and then with an horseradish peroxidase-conjugated anti-rabbit IgG (#A0545; Sigma, St. Louis, MO) diluted 1:4000 into blotto. The signal was visualized with chemiluminescence reagent (#NEL100; New England Nuclear, Boston, MA).

For fatty acid analysis, bovine CSF lipoproteins were isolated from two different 50-mL bovine CSF samples on two different occasions as described above. In one of our analyses, the lipoprotein fraction was divided into two equal samples for analysis, and in the second analysis, the lipoprotein fraction in its totality was lyophilized and delipidated using ethanol/ether. Phospholipids, triglycerides, and cholesteryl esters of the whole samples were separated by thin-layer chromatography (40) and quantified by gas chromatography after fatty acid transmethylation with BF_3/methanol (21,41). Fatty acids were identified by comparison of their retention times with those of known standards, and the lipid mass was determined by comparison with an internal standard (dipentadecanoylphosphatidylcholine, trieicosenoin, or cholesteryl eicosenoate) that was added at the time of delipidation. Approximately 10% of the total isolated lipid fractions was used for each gas chromatographic analysis. In every analysis, the total mass of fatty acid esters exceeded 5 μg, which is the minimum mass we routinely require to ensure accuracy of the analysis (21). Levels of unesterified cholesterol were below detection using a colorimetric method following elution from silica gel (42).

Cell culture and immunocytochemistry. Neuro 2A neuroblastoma cells were purchased from American Type Culture Collection (Rockville, MD). Neuro 2A cells are particularly well suited for cytoskeletal analysis because of their spread morphology and high content of microtubules (36,43). Cells were grown in growth medium [Dulbecco's Modified Eagle Medium/Nutrient Mixture F-12 (DMEM/F12) (1:1) with 10% fetal bovine serum and penicillin-streptomycin at 100 units/mL and 100 μg/mL, respectively]. The day before the experiment, the cells were subcultured and 150 μL of a cell

suspension containing 5×10^4 cells/mL were placed into the wells of 35-mm glass bottom micro well dishes (MatTek Corp., Ashland, MA) and left to adhere for 24 h. The growth medium was then removed and the cells incubated in N2-medium (DMEM/F12 medium containing penicillin-streptomycin and N-2 supplement) overnight, before a 60 min exposure to native (nonoxidized) or oxidized CSF lipoproteins (fraction $d < 1.210$ g/mL) diluted with Earle's balanced salt solution to a final concentration of 20 μg/mL. CSF lipoproteins were used within 4 wk after their isolation and oxidation. Only samples that had never been thawed after the oxidation were used for these experiments. After treatment, the cells were washed and immediately fixed in 4% paraformaldehyde in PBS for 30 min at room temperature. To visualize the microtubules, the cells were permeabilized with 1% Triton X-100 in PBS containing 2% fetal bovine serum for 20 min at room temperature, then incubated with anti-β-tubulin at 0.25 μg/mL (#1111876; Boehringer Mannheim, Indianapolis, IN) in PBS containing 2% fetal bovine serum overnight at 4°C. The secondary antibody (a fluorescein isothiocyanatel-coupled anti-mouse IgG; #55514; Cappel, Durham, NC) was applied at 3 μg/mL in PBS with 2% fetal bovine serum for 2 h at room temperature. The glass slides with the cells were carefully removed from the 35-mm dishes with a razor blade and mounted in ProLong mounting medium (#P-7481; Molecular Probes, Eugene, OR). The microtubules were visualized with a Zeiss Axiovert 135 microscope (Carl Zeiss, Inc., Thornwood, NY) using Plan-Apochromat 63×/1.4 or 100×/1.4 objectives. For semi-quantitative analysis of the microtubule organization, microscope slides were scanned along a fixed y-coordinate using an electronically controlled microscope stage, and the microtubule organization in at least 200 cells per slide was categorized as either normal, mildly disrupted, or severely disrupted. The analysis was done blinded to exposure conditions. Analysis of variance, followed by repeated *t*-tests with Bonferroni correction for multiple comparisons, was used to compare the effects of the different lipoprotein samples.

Cytotoxicity. Cell viability was assessed using a Live/Dead kit containing two different dyes (Molecular Probes) following the manufacturer's protocol. One of these dyes, the cell permeant calcein AM, is cleaved in live cells by intracellular esterases to the fluorescent calcein, thus labeling live cells green. The other dye, ethidium homodimer, enters cells with damaged plasma membranes where it undergoes a 40-fold enhancement of fluorescence upon binding to nucleic acids labeling dead cells red. Neuro 2A cells were incubated with native CSF lipoproteins or lipoproteins that had been oxidized with 0.5, 1, 5, or 10 mM AAPH for 18 h at 37°C. After 40 min, the dyes were added and the cells were incubated for another 20 min, resulting in a total exposure to lipoproteins of 60 min. The cultures were then observed by phase microscopy to find areas of appropriate cell densities. Six such areas per dish were imaged using both fluorescein isothiocyanate and tetramethylrhodamine-5(and-6-) isothiocyanate fluorescence microscopy, and green and red cells were counted manually on the recorded images. Between 1,000 and 2,500 cells were counted per dish. Four experiments with human CSF lipoproteins isolated from two individuals and three experiments with lipoproteins isolated from two different bovine CSF were performed. Viability ≥94% was observed in all cultures analyzed.

RESULTS

Human oxidized CSF lipoproteins disrupt the neuronal microtubule network. Neuro 2A cells were incubated with native (nonoxidized) and *in vitro* oxidized human CSF lipoproteins for 1 h, and their microtubule organization was analyzed by immunocytochemistry. For semiquantitative analysis, the microtubule organization in at least 200 cells per slide was categorized as either normal (Fig. 1A), mildly disrupted (Fig. 1C), or severely disrupted (Fig. 1D). We analyzed the effects of CSF lipoproteins from six different subjects. In all six cases, incubation with native CSF lipoprotein samples left the microtubule organization of Neuro 2A cells unchanged (Fig. 1A; Fig. 2A). In four cases (three control and one AD, all patients had apo E3/E3 genotype) microtubules were only disrupted by the most heavily oxidized lipoproteins (10 mM AAPH). In one case (AD, apo E3/E4 genotype), none of the lipoprotein samples caused significant disruption of the microtubules. In another case (AD, apo E3/E4 genotype) all the oxidized samples, including a lipoprotein sample incubated with 0.1 mM AAPH, but not the native lipoproteins, caused loss of the microtubules.

There was no statistically significant difference in the degree of microtubule disruption caused by oxidized CSF lipoproteins from control and AD patients. Only the most heavily oxidized lipoproteins caused a significant change in the microtubule organization, increasing the number of cells with severely disrupted microtubules from ≤1% in Neuro 2A cultures incubated with native lipoproteins to 39 ± 9.4% ($P < 0.001$) (Fig. 2A). Although our observations suggest a larger variability of the effect on the microtubules by oxidized lipoproteins from patients with AD than from control individuals, the relatively small number of lipoprotein preparations limits our conclusions.

Phase contrast microscopy revealed minor morphological changes in occasional Neuro 2A cells only in cultures exposed to the most heavily oxidized CSF lipoproteins. They manifested themselves as beading, loss of neurites, and rounding of cell bodies. Neuro 2A cell viability was assayed after a 1-h exposure to CSF lipoproteins. We performed seven separate experiments (four with human CSF lipoproteins isolated from two different patients and three with bovine CSF lipoproteins isolated from two different bovine CSF). In all experiments and under all conditions, including native or oxidized lipoproteins, cell viability was ≥94% (data not shown). Therefore, the disruption of the microtubule network by oxidized human CSF lipoproteins was not a consequence of cell death.

Bovine oxidized CSF lipoproteins do not disrupt the neuronal microtubule network. Next, we isolated and oxidized bovine CSF lipoproteins under exactly the same conditions

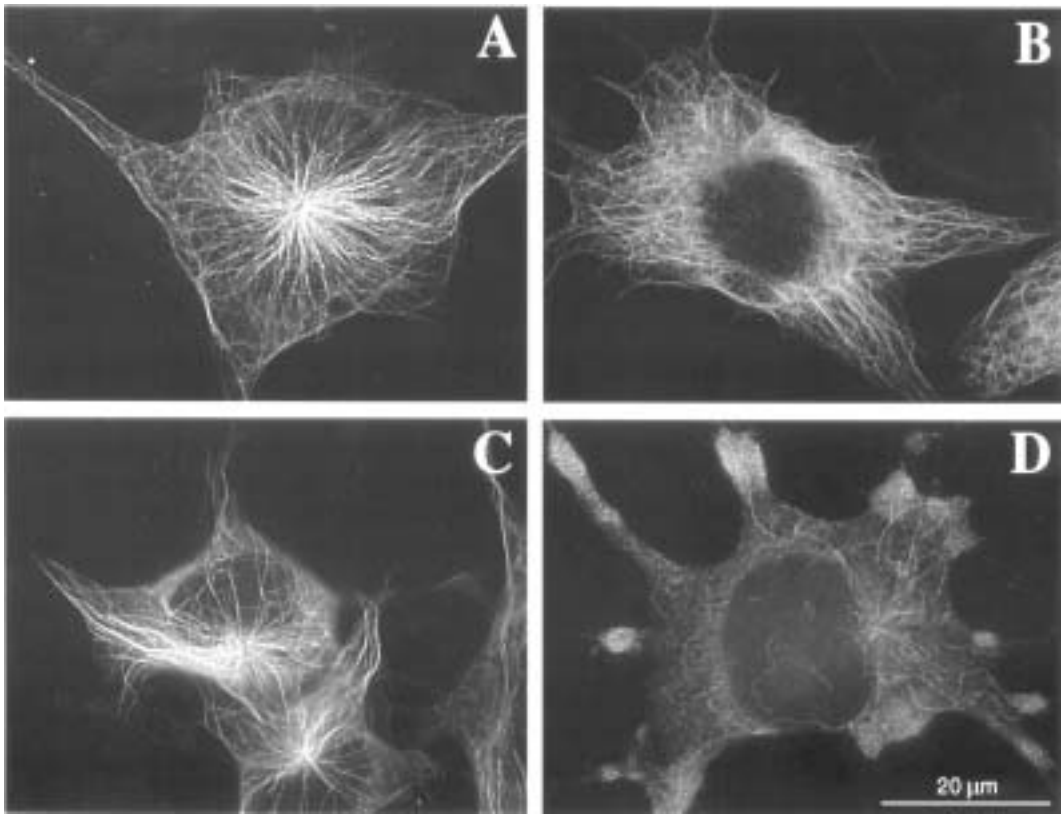

FIG. 1. Oxidized human cerebral spinal fluid (CSF) lipoproteins disrupt neuronal microtubules. Neuro 2A cells were exposed to native and oxidized CSF lipoproteins ($d < 1.21$ g/mL) for 1 h and microtubule organization was analyzed by immunofluorescence using an antibody against β-tubulin. In cells exposed to native human CSF lipoproteins a dense microtubule network radiating from the center to the periphery of the cells can be seen (A). Human CSF lipoproteins that had been oxidized with 10 mM 2,2′-azo-bis-(2-aminopropane) hydrochloride (AAPH) caused microtubule disruption to a varying degree. Neuro 2A cells with mild and severe disruption of the microtubule network are shown in C and D, respectively. Bovine CSF lipoproteins oxidized with 10 mM AAPH had no effect on the microtubule organization in Neuro 2A cells (B). Scale bar = 20 μm.

used for human CSF lipoproteins and analyzed their effect on the microtubules in Neuro 2A cells. In all cases neither native nor any of the oxidized bovine CSF lipoproteins showed a significant effect on the microtubule distribution in Neuro 2A cells (Figs. 1B and 2B). This stands in sharp contrast to the effect of human CSF lipoproteins which, when oxidized with 10 mM AAPH, cause a significant reduction in cells with normal microtubule organization and a significant increase in the number of cells with severely disrupted microtubules (Fig. 2A). This striking difference in the microtubule-disrupting effect of human and bovine oxidized CSF lipoproteins led us to examine the protein and lipid composition of bovine CSF lipoproteins.

Analysis of bovine CSF lipoproteins. Bovine CSF lipoproteins ($d < 1.210$ g/mL) were isolated and analyzed as previously described for human CSF lipoproteins (21). Both total protein and lipid concentrations were lower in bovine than human CSF lipoproteins ($d < 1.210$ g/mL) (protein and lipid concentrations were 21.2 ± 3.3 and 9.4 ± 2.3 for human and 9.1 ± 0.9 and 2.4 ± 0.4 μg/mL for bovine CSF lipoproteins, respectively) (Table 1) (21). The protein to lipid ratio was 3.8 in bovine and 2.3 in human CSF lipoproteins (Table 1) (21). The lipids of the bovine CSF lipoproteins were fractionated by thin-layer chromatography. Similar to human CSF lipoproteins (21), phospholipids constituted the main lipid component (66%) in bovine CSF lipoprotein (Table 1). Phospholipid and cholesteryl ester concentrations were lower in the bovine samples compared to human CSF lipoproteins; triglyceride levels were comparable in the CSF lipoproteins from the two species (Table 1) (21). Unesterified cholesterol levels were below detection in bovine CSF lipoproteins.

The main fatty acids in the phospholipids of bovine CSF lipoproteins were 16:0 (66.5%) and 18:0 (20.8%). The low amount of 18:1 in bovine CSF lipoproteins (0.1%) stands in sharp contrast to its levels (20.9%) in human CSF lipoproteins (21). Linoleate (18:2) is barely detectable (0.1%) and 22:6 is undetectable in the phospholipid fraction of bovine CSF lipoproteins, whereas these two polyunsaturated fatty acids (PUFA) are present in human CSF lipoprotein phospholipid (0.7 and 5.5%, respectively). Arachidonate (20:4) is also present at lower levels in bovine (4.3%) than in human CSF lipoproteins (13.3%), while 18:3 were more prevalent in

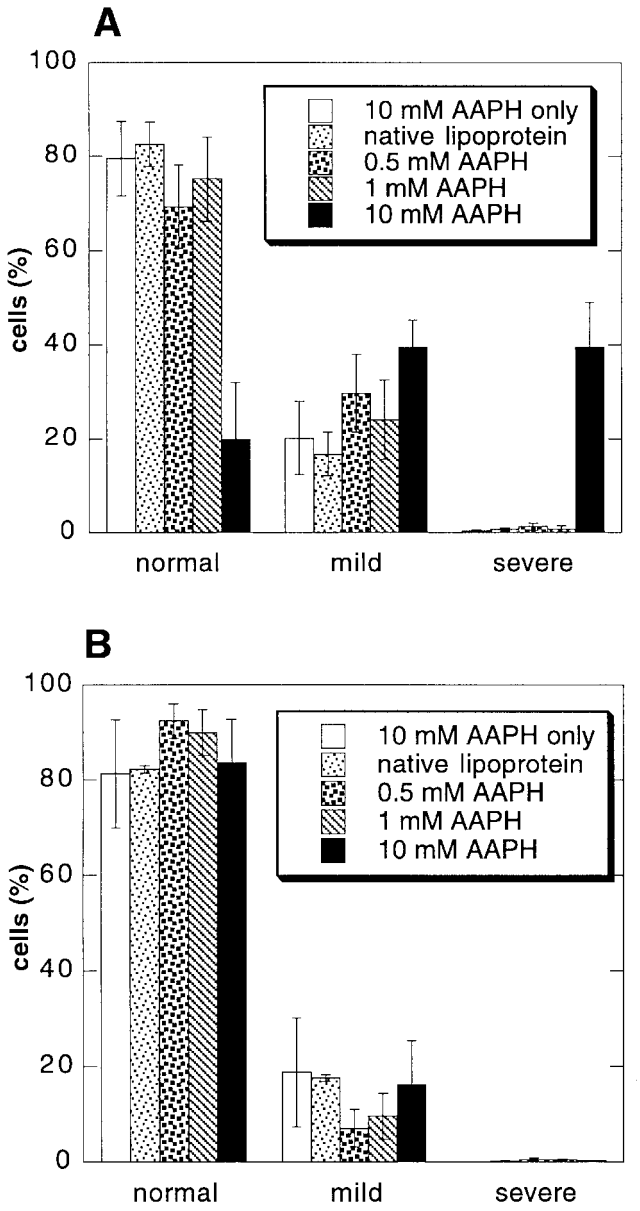

FIG. 2. Comparison of microtubule disruption caused by oxidized human and bovine CSF lipoproteins. The effect of human (A) and bovine (B) CSF lipoproteins ($d < 1.21$ g/mL) on microtubules was compared. In order not to lose any metabolites resulting from oxidation, the lipoproteins were not dialyzed after their incubation with AAPH. This was possible, because a control solution of 10 mM AAPH (without lipoproteins) that had been incubated under identical conditions had no effect on the microtubule organization of Neuro 2A cells (10 mM AAPH only). Neuro 2A cells were incubated with native or oxidized (0.5, 1, and 10 mM AAPH) CSF lipoproteins and microtubule organization was assessed as described in the Materials and Methods section. The majority of the cells incubated with native human or bovine CSF lipoproteins displayed normal microtubule organization characterized by a dense network of microtubules extending to the cell periphery (82.6 ± 4.7% and 85.1 ± 2.9% for human and bovine, respectively). Exposure to the most extensively oxidized human CSF lipoproteins significantly increased the percentage of cells with severely disrupted microtubule networks from ≤1% in cells exposed to native lipoproteins to 39.6 ± 9.4% ($P < 0.001$) (A). Bovine CSF lipoproteins oxidized with 10 mM AAPH, however, did not cause severe microtubule disruption (B). Values are the mean and SEM ($n_{human} = 6$; $n_{bovine} = 3$). See Figure 1 for abbreviations.

bovine (2.2%), than in human (0.2%) CSF lipoprotein phospholipids (21). Overall, the relative levels of monounsaturated fatty acids (0.1%) and PUFA (7.4%) in the phospholipids of bovine CSF lipoproteins were substantially lower than in the human lipoproteins, where the monounsaturated fatty acids and PUFA constitute 20.9 and 19.9%, respectively (Table 1) (21). The relative abundance of the major fatty acids in bovine CSF lipoprotein cholesteryl esters was 16:0 > 14:0 > 18:0. The relative amounts of monounsaturated fatty acids and PUFA again were much smaller (0.1 and 3.5%, respectively) than in the human counterparts, where they make up 34.9 and 29.0% of the total fatty acids, respectively (Table 1) (21). In bovine CSF lipoprotein triglycerides the prevalence of the major fatty acids was 16:0 > 18:0 > 14:0. As in the other two lipid fractions, the unsaturated fatty acids made up a small fraction (3.2%) of the total fatty acids (Table 1). Bovine CSF lipoproteins therefore contain substantially less unsaturated fatty acids than their human counterparts.

Effect of CSF lipoprotein oxidation on apoA-I and apoE. As previously observed, the two main proteins in human and bovine native CSF lipoproteins are apoA-I and apoE (2,44,45) (Fig. 3). The effect of oxidation on human and bovine CSF apolipoproteins was analyzed by SDS-PAGE followed by silver staining (Fig. 3A) and Western blotting (Figs. 3B and C). Oxidation with AAPH concentrations of ≤0.5 mM caused a slight reduction in the electrophoretic mobility of both apoE and apoA-I and the appearance of higher molecular weight protein species (Figs. 3A, B, and C). Oxidation with AAPH concentrations ≥5 mM led to a complete loss of apoE and apoA-I monomer and the appearance of abnormal higher molecular weight protein species that were immunoreactive with antibodies against apoE and apoA-I (Figs. 3A, B, and C). This analysis shows that AAPH induced protein changes were comparable for human and bovine CSF apolipoproteins.

DISCUSSION

To our knowledge, this is the first study to investigate the possible mechanism by which oxidized human CSF lipoproteins cause neurotoxicity. Since one of the pathological hallmarks in AD is a change in neuronal microtubules (29–35) and since we have shown previously that HNE, a major product of lipid peroxidation, causes microtubule disruption, we tested the hypothesis that oxidized CNS lipoproteins disrupt neuronal microtubules. We found that the most heavily oxidized human CSF lipoproteins cause significant disruption of the microtubule network, whereas native and less extensively oxidized lipoproteins had no effect. Microtubule disruption was observed after short exposures (1 h) and at lipoprotein concentrations present in CSF (20 μg/mL) (21). *In vitro* oxidized human CSF lipoproteins have been shown to be toxic to Neuro 2A cells after 24 h exposures (28), but the loss of microtubule organization described here was observed in the absence of cytotoxicity. Therefore, CSF lipoprotein-induced microtubule disruption precedes cell death, but may play a

TABLE 1
Composition of Bovine Cerebral Spinal Fluid (CSF) Lipoproteins[a]

Bovine CSF (d < 1.210 g/mL)	Concentration (μg/mL CSF)	Saturated FA (%)	Monounsaturated FA (%)	Polyunsaturated FA (%)
Protein	9.1 ± 0.9	—	—	—
Phospholipid	1.6 ± 0.3	92.1 ± 0.9	0.1 ± 0.1	7.4 ± 1.5
Triglyceride	0.30 ± 0.06	95.9 ± 4.1	3.2 ± 1.5	0.0
Cholesteryl esters	0.25 ± 0.03	97.0 ± 3.0	0.1 ± 0.1	3.5 ± 2.7
Unesterified Cholesterol	Not detectable	—	—	—
Free fatty acids	0.26 ± 0.02	100 ± 0.0	0.0 ± 0.0	0.0 ± 0.0

[a]Protein and lipids were quantified from three bovine CSF lipoproteins samples (d < 1.210 g/mL). Values are means ± SEM. FA, fatty acid.

mechanistic role in the eventual loss of cell viability. Importantly, while the effect of oxidized human CSF lipoproteins on the neuronal microtubules was dramatic, bovine CSF lipoproteins oxidized under identical conditions left the microtubule organization unchanged.

CSF lipoproteins isolated from AD patients show signs of increased lipid peroxidation when compared with controls (21). However, we did not see microtubule disruption after exposure of Neuro 2A cells to native CSF lipoproteins isolated from AD patients. In addition, the degree of lipoprotein oxidation, as estimated by apolipoprotein modification (this study) or the extent of PUFA consumption (28) necessary to induce disruption of the microtubules, exceeds that observed in CSF lipoproteins isolated from AD patients (21). A similar discrepancy is observed in atherosclerosis. Although many experiments involving *in vitro* oxidized low density lipoprotein (LDL) suggest that oxidation of these lipoproteins plays a role in atherogenesis, the presence of similarly modified LDL has been difficult to demonstrate in plasma (38). The oxidation of LDL is believed to occur locally in the arterial wall; therefore, the oxidized LDL particles may not reach concentrations in the general circulation necessary for detection (20,46). A similar situation may exist in the central nervous system (CNS), where locally induced oxidative changes in CNS lipoproteins do not manifest themselves in CSF.

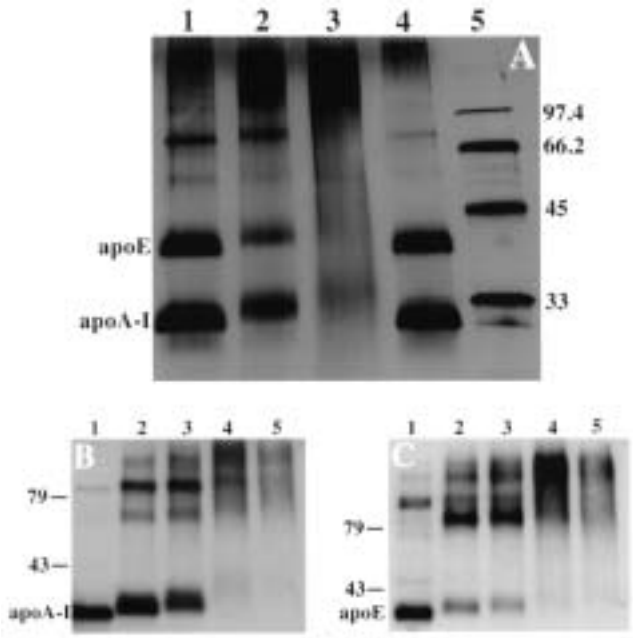

FIG. 3. Analysis of apolipoproteins (apo) in native and oxidized CSF lipoproteins. (A) Bovine CSF lipoproteins (d < 1.21 g/mL) were oxidized with 0.1 (lane 1), 1 (lane 2), and 10 mM AAPH (lane 3) or incubated without AAPH (lane 4) for 18 h at 37°C and the proteins separated by electrophoresis on a 12% sodium dodecyl sulfate-polyacrylamide gel and stained using the silver nitrate method. The protein bands corresponding to native apoE and apoA-I are marked and the molecular weight markers are shown in lane 5. Comparable protein patterns were observed for human CSF lipoproteins (not shown). (B,C) Native (lane 1) or oxidized human CSF lipoproteins (d < 1.21 g/mL) (lanes 2, 3, 4, 5 correspond to 0.5, 1, 5, and 10 mM AAPH, respectively) were separated by electrophoresis on a 12% sodium dodecyl sulfate-polyacrylamide gel and immunoblotted with anti-human apoA-I (B) and anti-human apoE (C) antibodies. The protein bands corresponding to native apoA-I and apoE are indicated and molecular weight markers are shown on the left. Comparable immunoreactivities were observed for bovine CSF lipoproteins (not shown). See Figure 1 for other abbreviations.

CSF lipoproteins have been described as "HDL-like" (2–4). However, differences between plasma HDL particles and CSF lipoproteins exist. The two major apolipoproteins in HDL are apoA-I and apoA-II (47), while in human and bovine CSF lipoproteins (d < 1.21 g/mL) the two main apolipoproteins are apoA-I and apoE (2,44,45). While apoA-I is synthesized in the periphery and presumably transported into the CNS (48), CNS apoE is made and secreted by astrocytes (49). The major fraction of CNS apoE is di-, tri-, or higher sialylated, a posttranslational modification not present in the major portion of human plasma apoE (2,5,7,49,50). In addition to these differences in apolipoproteins, the lipid composition of human CSF lipoproteins shows a greater similarity with brain lipids than with plasma lipoproteins (2,51). These observations underline the importance of the source (CSF vs. plasma) of the lipoproteins when examining their effects on neurons.

Effects of oxidized plasma lipoproteins on neurons have generally been observed after exposures lasting several hours to several days. Necrosis and apoptosis was observed in primary neurons and neuroblastoma cells after 24-h exposures to oxidized LDL at 10 to 100 μg/mL. Neurotoxicity could be inhibited by antioxidants in some cases suggesting that cell damage was mediated through oxidative stress initiated by

oxidized LDL (23–26). These findings demonstrate that *in vitro* neurons can be sensitive to oxidized plasma lipoproteins; however, *in vivo* neurons are unlikely to be exposed to oxidized LDL in the absence of severe disruption of the blood brain barrier (2,3,21,44). Oxidized plasma HDL particles from chicken have been shown to cause neuronal degeneration, disruption of microtubules and hyperphosphorylation of tau (27). These effects were dependent on the aggregation of HDL particles as a result of oxidation (27). We have never observed such aggregates in any of our native or oxidized CSF lipoprotein samples inspected by electron microscopy (not shown). In addition, as discussed above, CSF lipoproteins differ in their protein and lipid composition from plasma HDL. Also, in birds there is no evidence of apoE synthesis (52,53), the apolipoprotein central to the connection between CSF lipoproteins and AD (48,54).

The importance of species differences with respect to the effect of lipoproteins on cellular targets is demonstrated by our observation that human, but not bovine, oxidized CSF lipoproteins caused the disruption of neuronal microtubules. At this point, the reason(s) for the different effect of human and bovine oxidized CSF lipoproteins on microtubules is not clear. It is possible that species differences in apolipoproteins underlie different efficiencies in endocytosis of CSF lipoproteins. Oxidation of human and bovine CSF lipoproteins with AAPH resulted in covalent modifications of apoE and apoA-I and the appearance of higher molecular weight protein species. There was no obvious difference in the degree of these oxidation-induced protein modifications between human and bovine apolipoproteins, suggesting that the human and bovine apolipoproteins are equally susceptible to oxidation. Disruption of microtubules was observed only after incubation with the most heavily oxidized human CSF lipoproteins, which contained little if any native monomeric apolipoproteins. This raises the possibility that oxidized CSF lipoproteins are internalized into neurons by a different mechanism from native CSF lipoproteins. Studies analyzing plasma LDL suggest that oxidized lipoproteins are internalized by endocytotic pathways different from their native counterparts (55). However, the damaging effects of oxidized LDL observed in endothelial cells and erythrocytes are independent of receptor binding and endocytotic uptake of the oxidized LDL (56). In addition, the toxic effects of oxidized LDL on fibroblasts have been observed to lie within the lipid-extractable fraction, again suggesting that receptor-mediated endocytosis may not be required for the cytotoxicity induced by oxidized LDL (57). Similar experiments will have to be performed with the oxidized CSF lipoproteins to analyze the mechanism by which oxidized CSF lipoproteins exert their deleterious effects on neuronal microtubules.

Analysis of bovine CSF lipoproteins revealed substantial differences when compared to their human counterparts. The amount of protein in bovine CSF lipoprotein (9.1 μg/mL CSF) was approximately 50% of that measured in human CSF lipoproteins (21.2 μg/mL CSF; Ref. 21). The mass of lipids associated with CSF lipoproteins was also substantially less in bovine (2.4 μg/mL CSF) than that measured in human CSF (9.4 μg/mL CSF) using exactly the same method (21). To our knowledge this is the first detailed analysis of isolated bovine CSF lipoproteins. One other study quantified some of the lipid components in bovine CSF and reported undetectable triacylglycerol levels and higher cholesterol levels (45). Although the reasons for these differences are not clear, they at least partially might result from differences in biological material used and methods applied. These authors analyzed lipids in whole bovine CSF, while we determined lipid composition of isolated CSF lipoproteins. We used gas chromatography to quantify lipids, while Puppione *et al.* (45) analyzed the lipids using the less sensitive enzymatic kits. This might explain why they were unable to detect triglycerides, while we were able to detect low amounts of these lipids by gas chromatography. We assayed cholesterol levels with two different methods and were unable to detect cholesterol using an enzymatic kit and detected only low levels of cholesterol esters by gas chromatography. The cholesteryl ester levels we measured in bovine CSF lipoproteins (0.25 μg/mL CSF) are comparable to the ones we measured for human CSF lipoproteins (1.2 mg/mL CSF) using the same method when we take into consideration that the total lipid mass is fourfold lower in bovine than in human CSF (21). The higher cholesterol levels reported by Puppione *et al.* (45) might be due to the fact that they used bovine CSF from cows at parturition and postpartum, physiological conditions that the authors show have substantial effects on CSF cholesterol levels.

Another striking difference between human and bovine CSF lipoproteins was the difference in the amount of unsaturated fatty acids. Phospholipids are the main lipid component in human (69%) and bovine (67%) CSF lipoproteins. However, the levels of monounsaturated fatty acids (0.1%) as well as PUFA (7.4%) were much lower in bovine CSF lipoprotein phospholipids than in their human counterparts (20.9% monounsaturated and 19.9% polyunsaturated) (21). The same trend was observed for the triglycerides and cholesteryl esters. The reason for these low levels of unsaturated fatty acids in bovine CSF is difficult to explain given the present lack of knowledge of CSF lipoprotein metabolism. Bovines are ruminants, and PUFA undergo extensive biohydrogenation in the rumen (58); however, in humans the lipid composition of CSF lipoproteins has been shown to be different from plasma lipoproteins (2,51). An explanation for this observation likely has to await further progress in our understanding of brain lipid physiology.

It has been suggested that HNE is one of the molecules responsible for the toxic effects of oxidized LDL, since HNE-modified LDL or HNE by itself could mimic the effects of oxidized LDL (59,60). We have previously shown that HNE causes disruption of neuronal microtubules with a time course and pattern comparable to what we observed after incubation with oxidized human CSF lipoproteins (36). HNE is a product of the peroxidation of the n-6 PUFA 18:2 and 20:4 (61). It is therefore interesting that bovine CSF lipoproteins, which did not disrupt microtubules when oxidized, contained barely de-

tectable levels of 18:2 and very low levels of 20:4, whereas human CSF lipoproteins contain substantial amounts of these two PUFA (21). However, HNE is only one of many products formed during lipoprotein oxidation, and other products of lipoprotein oxidation may mediate the microtubule disruption caused by oxidized human CSF lipoproteins. We did not dialyze the CSF lipoproteins after oxidation in order to retain all oxidation products in our samples. To identify the molecules responsible for certain biological effects caused by oxidized lipoproteins and to analyze their mechanism of action remain a challenge for research in the fields of atherosclerosis and AD.

ABSTRACT: Neutral sphingomyelinase (Smase) is a cell membrane-associated phospholipase that hydrolyzes sphingomyelin to phosphocholine and ceramide, a lipid second messenger involved in cell differentiation and/or apoptosis. We first evidenced that porcine cultured thyroid cells could express neutral Smase activity even if thyrotropin (TSH), an essential hormone in thyroid cell differentiation, was found to induce a 1.7-fold decrease in Smase activity. Triggering the ceramide pathway by exogenous addition of neutral bacterial Smase (0.1 U/mL for 48 h), which transiently increased ceramide level by fourfold, drastically modified thyroid cell morphology. The follicle-like structures generated by TSH were disrupted, and the Smase-induced cell spreading was accompanied by a parallel loss of cell ability to iodinate proteins as well as a decrease of the adenylate cyclase system response. These inhibitory effects have been reproduced using short-chain exogenous ceramide analogs (C_2-ceramides). Overall these data showed that ceramides emerged as potential mediators of dedifferentiation in thyroid cells.

Paper no. L8446 in *Lipids 35,* 1259–1268 (November 2000).

In the presence of thyrotropin (TSH), porcine thyroid cells reconstituted follicle-like structures similar to those found *in vivo*. This polarized cell organization is closely related to the expression of thyroid cell function (1). TSH exerts its effects on cell behavior mainly *via* the cAMP cascade, since forskolin (F), a classical adenylate cyclase activator, mimicks TSH effects on cell morphology and differentiated status.

Otherwise, the absence of hormone or a long-term treatment with phorbol myristate acetate (PMA) promotes the destabilization of the follicular structures, which form a monolayer. The initial steps of signal transduction involved in the control of differentiated porcine thyroid cells cultures are the subject of the present report.

During the last decade, neutral sphingomyelinase (Smase), a cell membrane-associated phospholipase that hydrolyzes sphingomyelin (SM) to phosphocholine and ceramide, has been described in many tissues (2) including FRTL-5 cells (3); however, its presence in normal thyroid cells had never been demonstrated. It has been shown that ceramides activate different signaling pathways involved in apoptosis as well as differentiation (4,5). Ceramides appear to induce typical morphological changes in many types of cells (6–8). SM hydrolysis is induced by cytokines such as tumor necrosis factor α (TNF α), interleukin-1β (IL1β), nerve growth factor (NGF), and interferon γ (IFN γ), and by cross-linking of Fas, and also by physical stresses such as heat shock, radiation, and chemotherapeutic drugs (9).

The exact role of ceramides remains to be elucidated, but it can be suggested that ceramides act as an important regulator of antiproliferative and apoptotic pathways and as an inhibitor of protein trafficking and secretion.

In this paper we demonstrated that porcine thyroid cells in culture display Smase activity. SM hydrolysis is down regulated by TSH, which physiologically controls cell differentiation. Increasing the cellular content of ceramide, in TSH-treated cells, with exogenous Smase led to dedifferentiation of thyroid cells with a progressive loss of functional activity.

EXPERIMENTAL PROCEDURES

Primary cultures of porcine thyroid cells. The preparation of thyroid cells has been described in detail elsewhere (10). Briefly, thyroid epithelial cells were isolated from adult porcine glands by a discontinuous trypsin-EGTA treatment. Freshly isolated cells suspended at a concentration of 10^6 cells/mL in Eagle's minimum essential medium (pH 7.4), containing 10% (vol/vol) fetal calf serum, penicillin (200 U/mL), streptomycin sulfate (0.05 mg/mL), and TSH (1 mU/mL) were plated directly onto 24-well poly (L-lysine)-treated culture dishes at the density of 10^6 cells per well, and incubated at 37°C in a 95% air/5% CO_2 atmosphere. Two days after the onset of cultures, the medium was withdrawn and replaced for metabolic experiments with fresh "serum-free" medium containing either Smase, truncated ceramide (C_2-Cer 1-20 μM), or other agonists for 2 d in the presence of TSH 1 mU/mL. The morphology of cells was examined using phase contrast micrography (Olympus IMT 2, magnification × 37.5).

Abbreviations: DAG, diacylglycerol; ECM, extracellular matrix; EGF, epidermal growth factor; F, forskolin; FITC, fluorescein isothiocyanate; ILIβ, interleukin-1β; IMBX, isomethylbutyl xanthine; IFN γ, interferon gamma; PBI, protein bound iodine; PBS, phosphate-buffered saline; PI, phosphatidylinositol; PMA, phorbol myristate acetate; PS, phosphatidylserine; SM, sphingomyelin; Smase, sphingomyelinase; TSH, thyrotropin; TNF α, tumor necrosis factor α.

Thyroid protein iodination. Cells seeded in plastic dishes were cultured as indicated above. At day 4, they were rinsed with 20 mM Earle's Hepes buffer (pH 7.2) and incubated for 45 min at 37°C in the same buffer containing 1 μCi Na [^{125}I]. Factors were added to the medium at concentrations indicated in the legends of figures. At the end of the incubation period, the cells were rinsed with Earle's Hepes buffer containing 0.1 mM KI and 5 mg/mL bovine serum albumin. Proteins were precipitated with ice-cold trichloroacetic acid [10% final (wt/vol)]. After centrifugation (5,000 × *g* for 5 min), the pellets were resuspended and washed twice with cold 10% (wt/vol) trichloroacetic acid and counted as protein-bound iodine (PB^{125}I).

cAMP assay. Cells seeded in plastic dishes were cultured as indicated above. At day 4, they were rinsed with 20 mM Earle's Hepes buffer (pH 7.2) and incubated for 5 min at 37°C in the same buffer containing 1 mM isomethylbutyl xanthine (IBMX) and TSH (10 mU/mL). Reactions were stopped by the addition of 1 M final concentration of $HClO_4$ followed by immersion into an ice bath. The cells were homogenized and their cAMP contents quantified by a radioimmunological method as described by Cailla *et al*. (11), except that bound and free ligand were separated by precipitation of bound ligand with a mixture of γ-globulin (2.5 mg/mL) in citrate buffer (pH 6.2) and polyethyleneglycol 6000 (20 g in 100 mL water).

SM quantification. For SM quantification, $8{\cdot}10^6$ thyroid cells were cultured for 48 h with TSH (1 mU/mL) and then incubated for a period of 48 h in a total volume of 4 mL of complete medium containing 0.4 μCi/mL of [methyl-^{3}H]choline (sp. act. 81.0 Ci/mmol, Dupont de Nemours NEN, Les Ulis, France). Cells were then washed and resuspended in serum-free medium with or without bacterial Smase (sp. act. 180 U/mg; BioMol®, Philadelphia, PA) for acute treatments. Cell supernatants were then withdrawn and cells were collected, resuspended in PBS (phosphate-buffered saline), and frozen. For extraction and separation of labeled SM, frozen cells were thawed and sonicated for 3 × 15 s. An aliquot was taken for protein determination (12), and the remainder was extracted with 2.5 mL of chloroform/methanol, (2:1, by vol), vortex-mixed, and centrifuged at 1,000 × *g* for 15 min. Labeled SM was isolated according to Jaffrezou *et al*. (13).

Ceramide quantification. Ceramide levels were quantified by the diacylglycerol (DAG) kinase assay (14). Briefly, monolayers of thyroid cells cultured as described above were stimulated with Smase for various periods. The medium was removed, and cells were collected in PBS by scraping and centrifugation. Total cellular lipids were then extracted using the method of Bligh and Dyer (15), and the organic phase was dried under a nitrogen stream. The resulting lipids were resuspended in 20 μL solubilization buffer (cardiolipin 5 mM, diethylenetriaminepentaacetic acid 1 mM, octylglucopyranoside 7.5% wt/vol). To the solubilized lipids, 80 μL of imidazole buffer (50 mM, pH 6.5) containing NaCl (50 mM), EGTA (1 mM), $MgCl_2$ (12.5 mM), 50 μCi [^{32}P-γ]ATP (sp. act. 3000 Ci/mmol, Dupont de Nemours NEN) and DAG kinase (10 μL/63 mU) was added. After incubation for 30 min at 25°C, the reaction was stopped by extraction with 3 mL of methanol/chloroform (2:1, vol/vol), 1.7 mL of 1% (wt/vol) $HClO_4$, and 1 mL of chloroform. The organic phase was washed twice with 2 mL of 1% (wt/vol) $HClO_4$, and an aliquot (0.5 mL) was dried under a nitrogen stream. The lipids were then resuspended in 100 μL of chloroform/methanol (100:5, vol/vol). An aliquot (20 μL) of the lipid solution was then applied to a thin-layer chromatographic plate (silica gel 60; Merck, Darmstadt, Germany) and developed in chloroform/methanol/acetic acid (65:15:5, by vol). The dried plate was autoradiographed and ceramide-1-phosphate (R_f = 0.14) spots were scraped off and counted. For ceramide levels, quantification of known amounts of commercial ceramides (0–80 pmol) was performed to generate a standard curve.

Neutral Smase assay. Membranes were prepared from thyroid cells as follows. Cells were washed with PBS and homogenized in lysis buffer (20 mM Tris-HCl pH 7.5, 2 mM EDTA, 5 mM EGTA, 1 mM phenylmethylsulfonyl fluoride, 10 μg/mL leupeptin, 10 μg/mL aprotinin, and 1 mM sodium orthovanadate) with 10 strokes in a Dounce homogenizer and centrifuged at 30,000 × *g* for 20 min. The resulting pellet was suspended in reaction buffer (150 mM NaCl, 25 mM Hepes pH 7.5, 5 mM EGTA, 1 mM EDTA, 3 mM $MgCl_2$, 40 mM β-glycerophosphate, 200 μM octylglucoside). Smase activity was quantified using 4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*S*-indacene-3-propionyl-sphingomyelin (D-3522; Molecular Probes, Eugene, OR) fluorescent substrate, essentially as described by Ella *et al*. (16).

Apoptosis assay. A fluorescein isothiocyanate (FITC) conjugate of the phosphatidylserine (PS)-binding protein, annexin V, has been used previously to detect PS externalization in apoptotic cells (17–19). The cells were washed with 0.5 mL of PBS and resuspended in 200 μL of binding buffer containing Hepes 10 mM (pH 7.4), NaCl 140 mM, $CaCl_2$ 5 mM, and propidium iodine 50 μg/mL. FITC-annexin V solution (5 μL) and phosphatidylinositol (PI) solution (5 μL at a final concentration of 0.5 μg/mL) were added. After gentle mixing, the cell suspension was stored in the dark at room temperature for 10 min and then analyzed using microscopy fluorescence (510 nm emission filter) to visualize the green FITC fluorescence and 580 nm filter to detect the red PI staining.

Statistical analysis. Statistical analysis of data was performed using Student's *t*-test. Differences were considered as statistically significant for *P* values lower than 0.05.

RESULTS

The presence of TSH in the culture medium is essential for a correct expression of thyroid function, which is related to the reorganization of isolated cells into polarized multicellular structures (Fig. 1A). A similar morphological situation is observed when thyroid cells are cultured in the presence of F (Fig. 1B) suggesting a cAMP-dependent mechanism. In contrast, the follicular structures are destabilized under stimulation by phorbol ester or in absence of TSH (Figs. 1C and 1D).

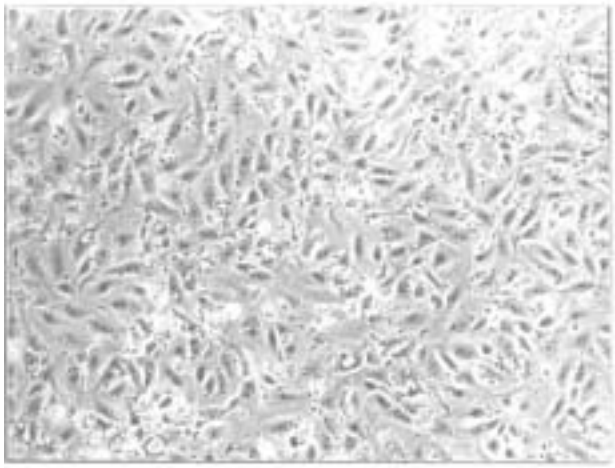
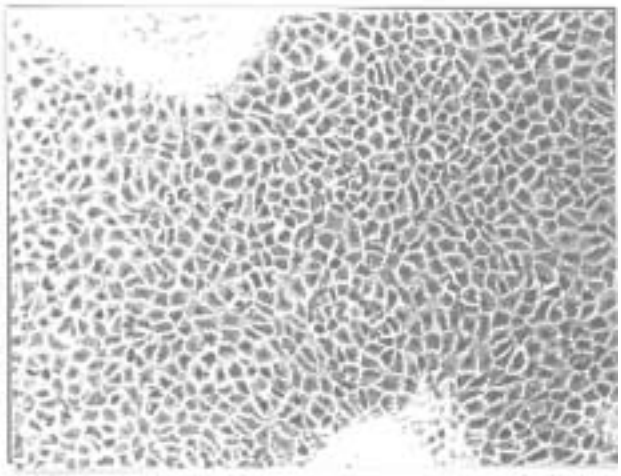
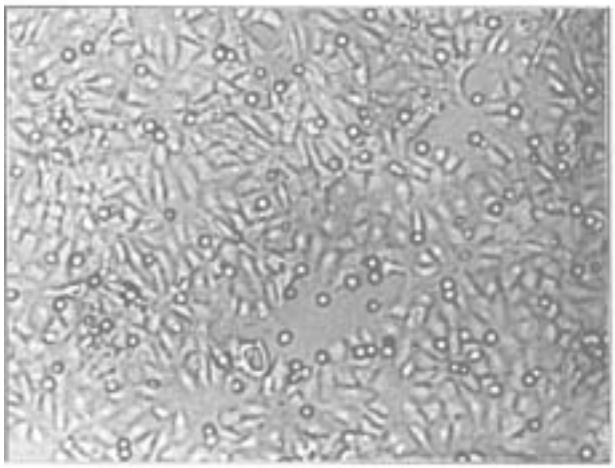
B. Forskolin-cells



C. PMA-cells



D. Control-cells



E. TSH-cells 48 hours after sphingomyelinase treatment

FIG. 1. Influence of different culture treatments on the morphology of porcine thyroid cells. Phase-contrast microscopy of living cells in presence of various agonists. (A) Cells treated with thyrotropin (TSH) (1 mU/mL). (B) Cells treated with Forskolin (F) (10^{-5} M). (C) Cells treated with phorbol myristate acetate (PMA) (10^{-7} M). (D) Cells cultured without agonist. (E) Cells treated with sphingomyelinase (Smase) 0.1 U/mL.

Follicle disruption rapidly leads to the constitution of a monolayer displaying a fibroblastic phenotype.

Increasing the intracellular levels of ceramides by addition of exogenous bacterial Smase induces conspicuous morphological changes. Treatment of thyroid cells for 48 h promotes a progressive spreading of the cells as shown on Figure 1E. This phenomenon could be attributed to a modification in extracellular matrix (ECM) remodeling, since during that time no cell proliferation was observed.

The Smase activity measured under different culture conditions allowed us to suggest a strong relationship between ceramide level and the maintenance of differentiated phenotype and thyroid function.

Therefore, neutral Smase activity of thyroid cells was found to be negatively regulated by TSH as shown in Figure 2A. Control cells and PMA-treated cells exhibited a 1.7-fold higher neutral Smase activity as compared to TSH cells or F-treated cells.

Moreover, basal ceramide levels were measured under the same culture conditions (Fig. 2B) and exhibited a pattern in

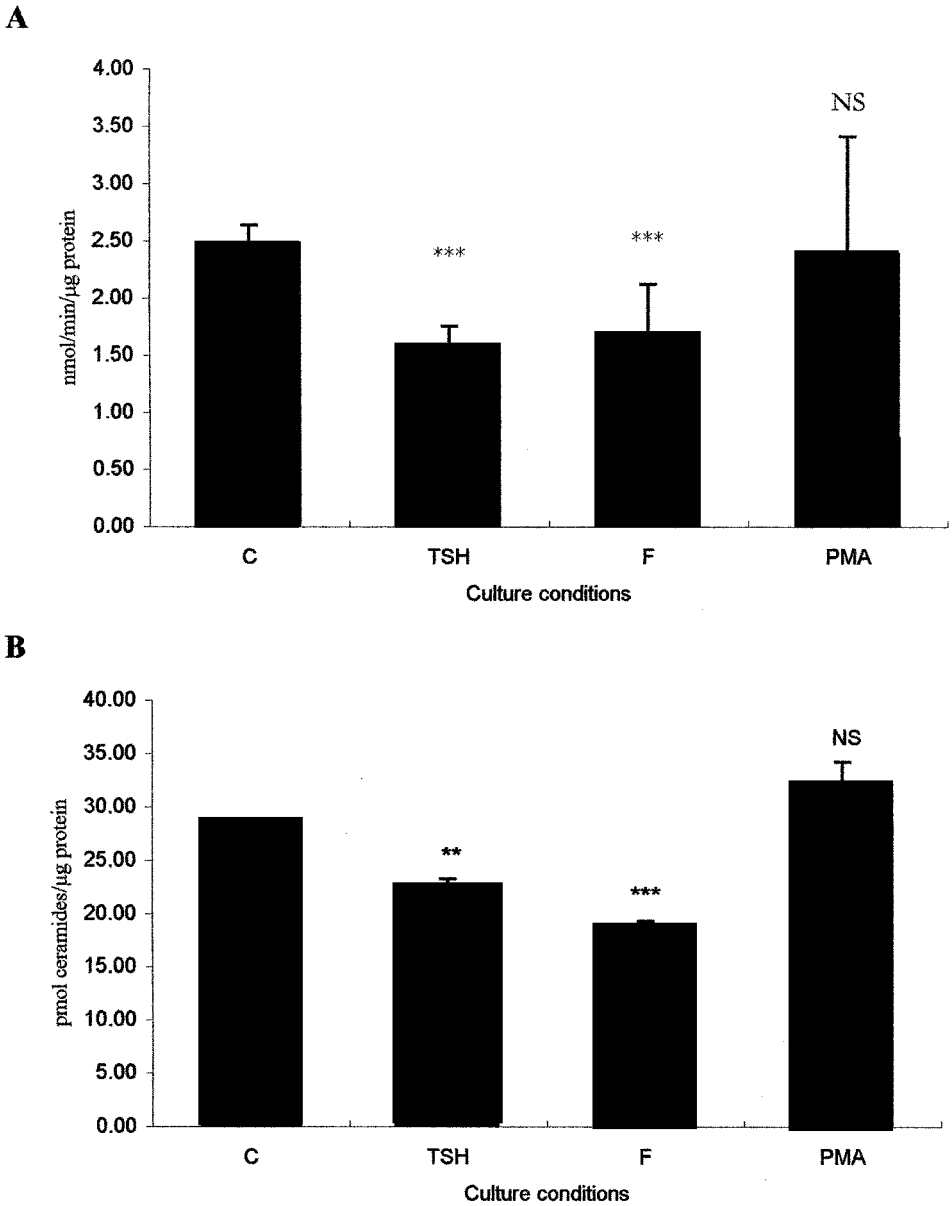


FIG. 2. Effects of culture conditions on (A) neutral Smase activity and (B) ceramides basal levels in porcine thyroid cells. Cells were treated for 96 h with TSH (1 mU/mL), F (10^{-5} M), PMA (10^{-7} M), or (C) without any agonist. (A) Membranes were prepared and Smase activity was quantified using 4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*S*-indacene-3-propionyl-sphingomyelin (SM) as substrate (as described in the Experimental Procedures section). (B) After total lipid extraction, amount of ceramide was quantified using diacylglycerol kinase method. Each data point represents the average ± SEM of triplicate. NS, nonsignificant, $^{**}P < 0.001$, $^{***}P < 0.0001$. See Figure 1 for abbreviations.

agreement with the neutral Smase activity: higher levels in control and in PMA cells compared to F and TSH cells (30 pmol vs. 20 pmol).

To analyze the existence of a ceramide signaling pathway in porcine thyroid cells, we evaluated the effect of exogenous bacterial Smase on ceramide and SM production. Figure 3 demonstrates that exogenous Smase induced a rapid increase of intracellular ceramides (3.5-fold) after 5 min of treatment, with a parallel decrease of SM (50%) level at the same time. Then, amounts of ceramides and SM progressively reached a plateau after 45 min of treatment with exogenous Smase. These results are in agreement with the existence of the SM/ceramide cycle in porcine thyroid cells since we observed a rapid and transient increase in ceramide levels coupled to the disappearance of its precursor. This increase supported the hypothesis of a putative role of second messenger for ceramides issued from SM hydrolysis.

Since DAG kinase tests are controversial (20), we have confirmed our results by metabolic labeling with [9,10-^{3}H]-palmitic acid both on ceramide production and SM degradation (data not shown).

The capacity to organify iodine reflects thyroid cells' biological activity. Figure 4 shows the dose-dependent effect of exogenous Smase on the ability of porcine thyroid cells cultured for 4 d with TSH (0.1 U/mL) to iodinate proteins; PBI was significantly inhibited by Smase with a 50% inhibition at 0.1 U/mL. To demonstrate that the effect of Smase was not simply due to any disturbing effect on membrane structure, a ceramidase inhibitor (which provokes an accumulation of intracellular ceramides by blocking their metabolism to sphingosine) was added together with Smase to cell culture medium. Under such experimental conditions, the ceramidase inhibitor also potentiated the Smase effect even though the lack of specificity of *N*-oleyl ethanolamine must be taken into consideration.

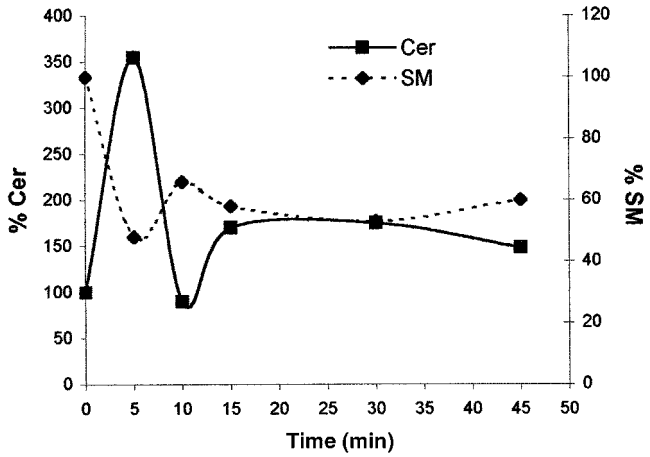

FIG. 3. Effect of exogenous bacterial Smase on ceramide (cer) and sphingomyelin (SM) levels in TSH-treated thyroid cells. Cells were treated for the indicated times with 0.1 U/mL Smase, lipids were extracted, and cer and Smase were then quantified as described in the Experimental Procedures section. One hundred percent is defined as the basal level. This experiment was repeated three or more times with identical results. See Figure 1 for other abbreviations.

An effect on adenylate cyclase activity was also evidenced (Fig. 5). Following 4 d of culture with TSH (0.1 mU/mL),

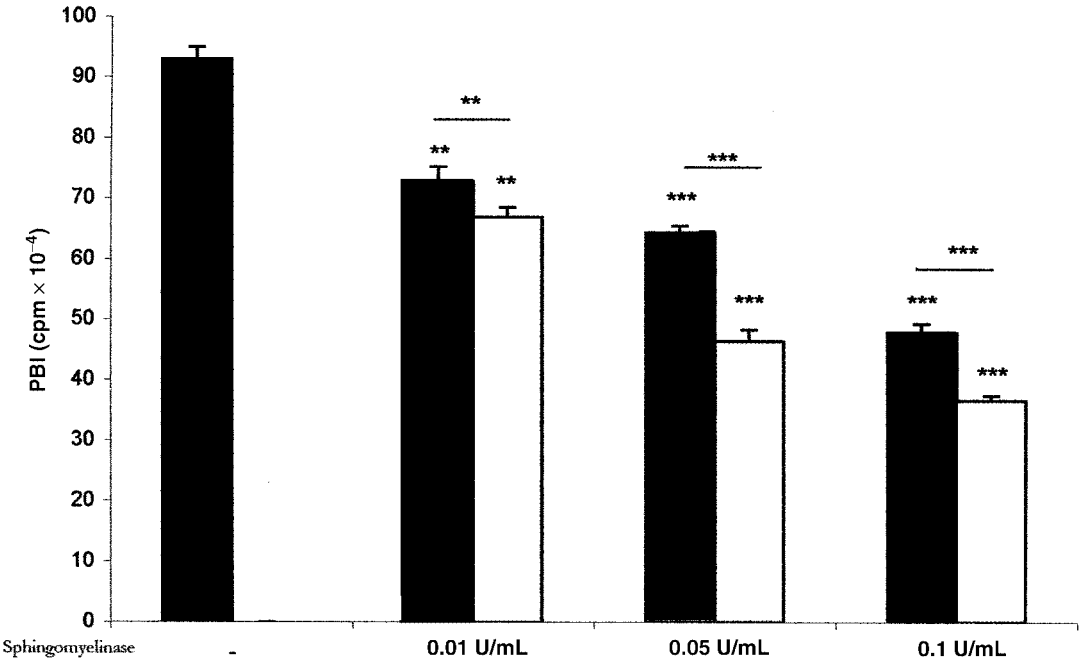

FIG. 4. Effect of exogenous Smase on protein iodination. Thyroid cells were cultured 4 d in the presence of TSH (0.1 mU/mL). After washing, aliquots of thyroid cell suspension were treated for 45 min with Smase (solid column) or Smase and ceramidase inhibitor *N*-oleoylethanolamine (1 μM: open column) at the concentration indicated. Protein-bound iodine (PBI) was measured as described in the Experimental Procedures section. Each data point represents the average ± SEM of triplicate. NS, nonsignificant, $^*P < 0.05$, $^{**}P < 0.001$, $^{***}P < 0.0001$. See Figure 1 for other abbreviations.

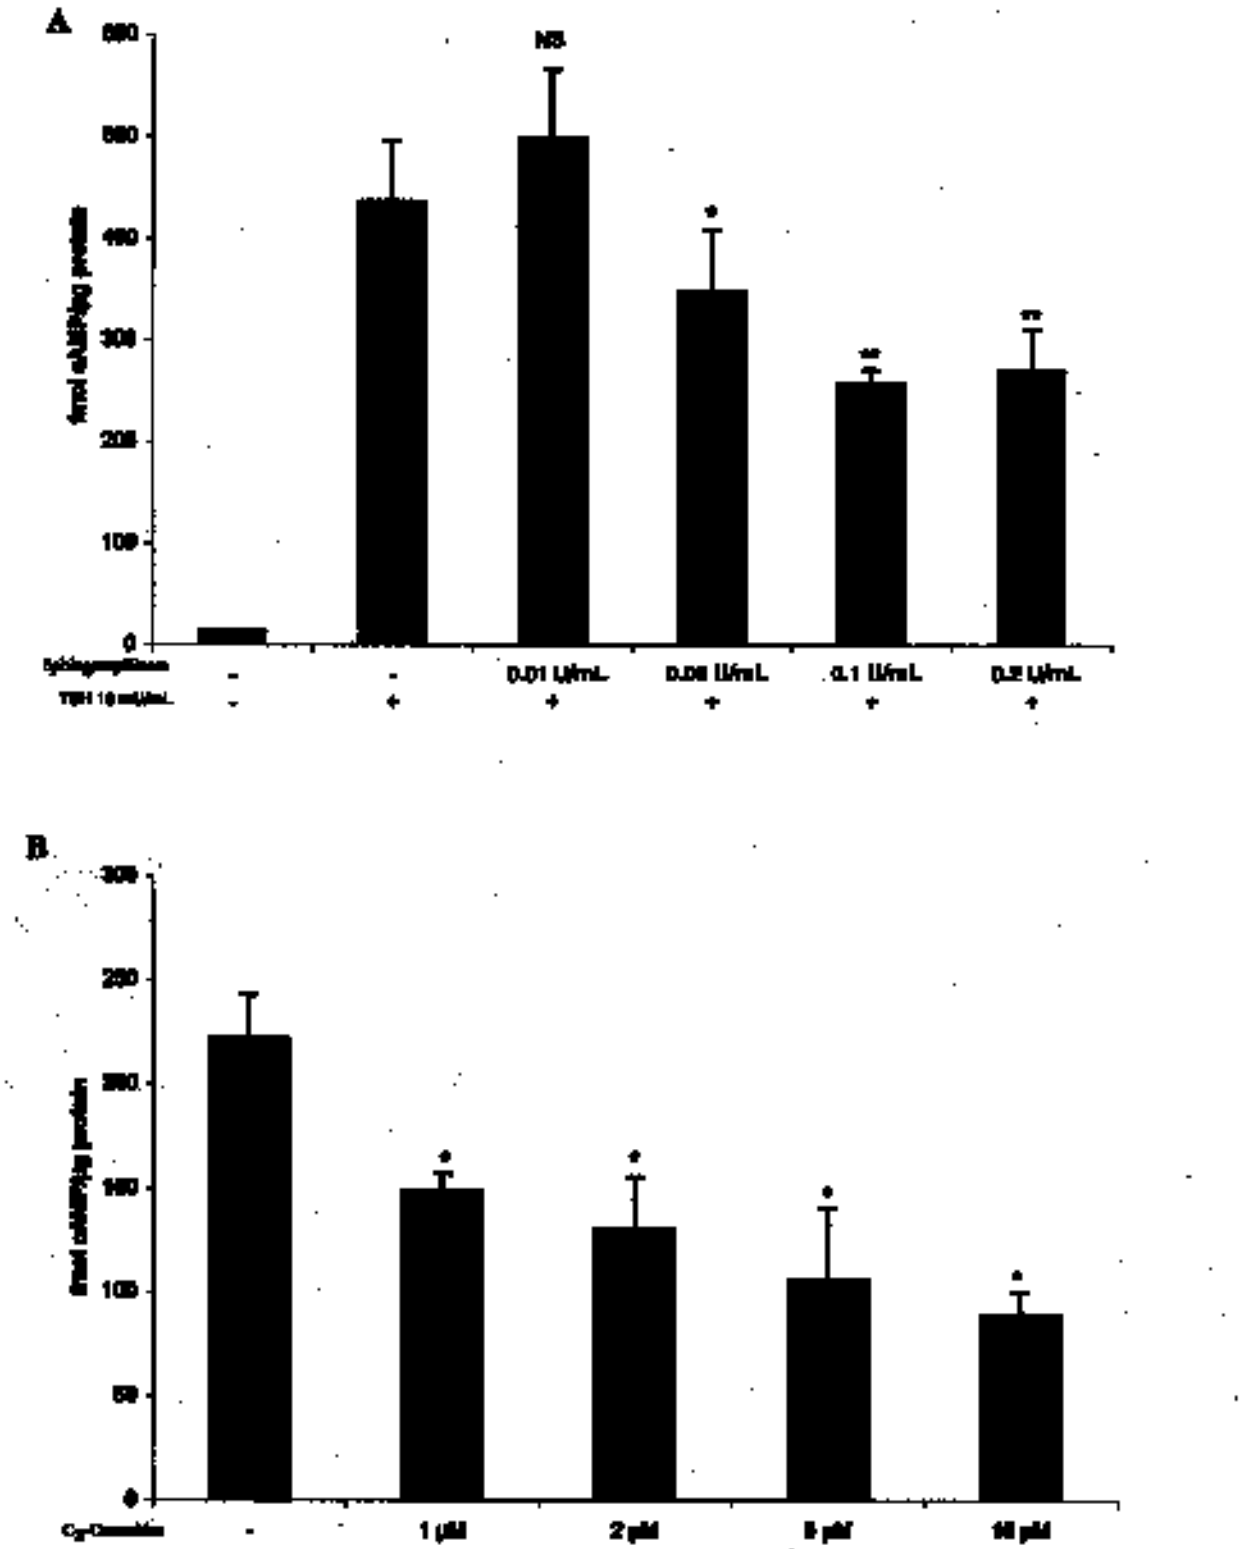

FIG. 5. Effect of exogenous Smase on cAMP accumulation. Reconstituted thyroid follicles were cultured for 4 d with TSH (0.1 mU/mL). (A) Aliquots of washed thyroid cell suspension were incubated for 5 min with TSH (10 mU/mL), IMBX (10^{-3} M), and with Smase at the concentration indicated. (B) Aliquots of washed thyroid cell suspension were incubated for 5 min with TSH (10 mU/mL), IMBX (10^{-3} M), and with C_2-ceramides in a range of 1 to 10 μM. cAMP was measured as described in the Experimental Procedures section. Each data point represents the average ± SEM of triplicate determinations. NS, nonsignificant, $*P < 0.05$, $**P < 0.001$, $***P < 0.0001$. IMBX, isomethylbutyl xanthine; for other abbreviations see Figure 1.

washed thyroid cells were incubated 5 min in the presence of TSH (10 mU/mL) and IBMX (10^{-3} M), an inhibitor of phosphodiesterases. Under these conditions, a dose-dependent inhibition of TSH-stimulated cAMP production by Smase was obtained (Fig. 5A). A 55% maximal extent of inhibition was reached using 0.1 U/mL Smase (598 fmol/μg protein vs. 270 fmol/μg protein). In parallel, we reproduced these observations using C_2-ceramides, which inhibited cAMP production in a dose-dependent manner (Fig. 5B).

The physiological relevance of the ceramide signaling pathway has been considered by studying the apoptotic process under different conditions. We measured apoptosis after a 24-h treatment period in the presence of 20 μM C_2-ceramides or in the presence of 0.5 U/mL Smase using two distinct methods. We measured either the fluorescence linked to the intercalation of bis-benzamidine intercalation in DNA in order to analyze chromatin condensation or annexin V-FITC to visualize PS flip-flop.

Figure 6 showed that addition of Smase (0.5 U/mL) for 24 h in the culture medium had no effect on these two parameters (Figs. 6A and 6C) in spite of important morphological changes as shown in Figure 1D. In contrast, permeant C_2-ceramides (20 μM) used under a similar experimental procedure induced chromatin condensation as underlined with arrows in Figure

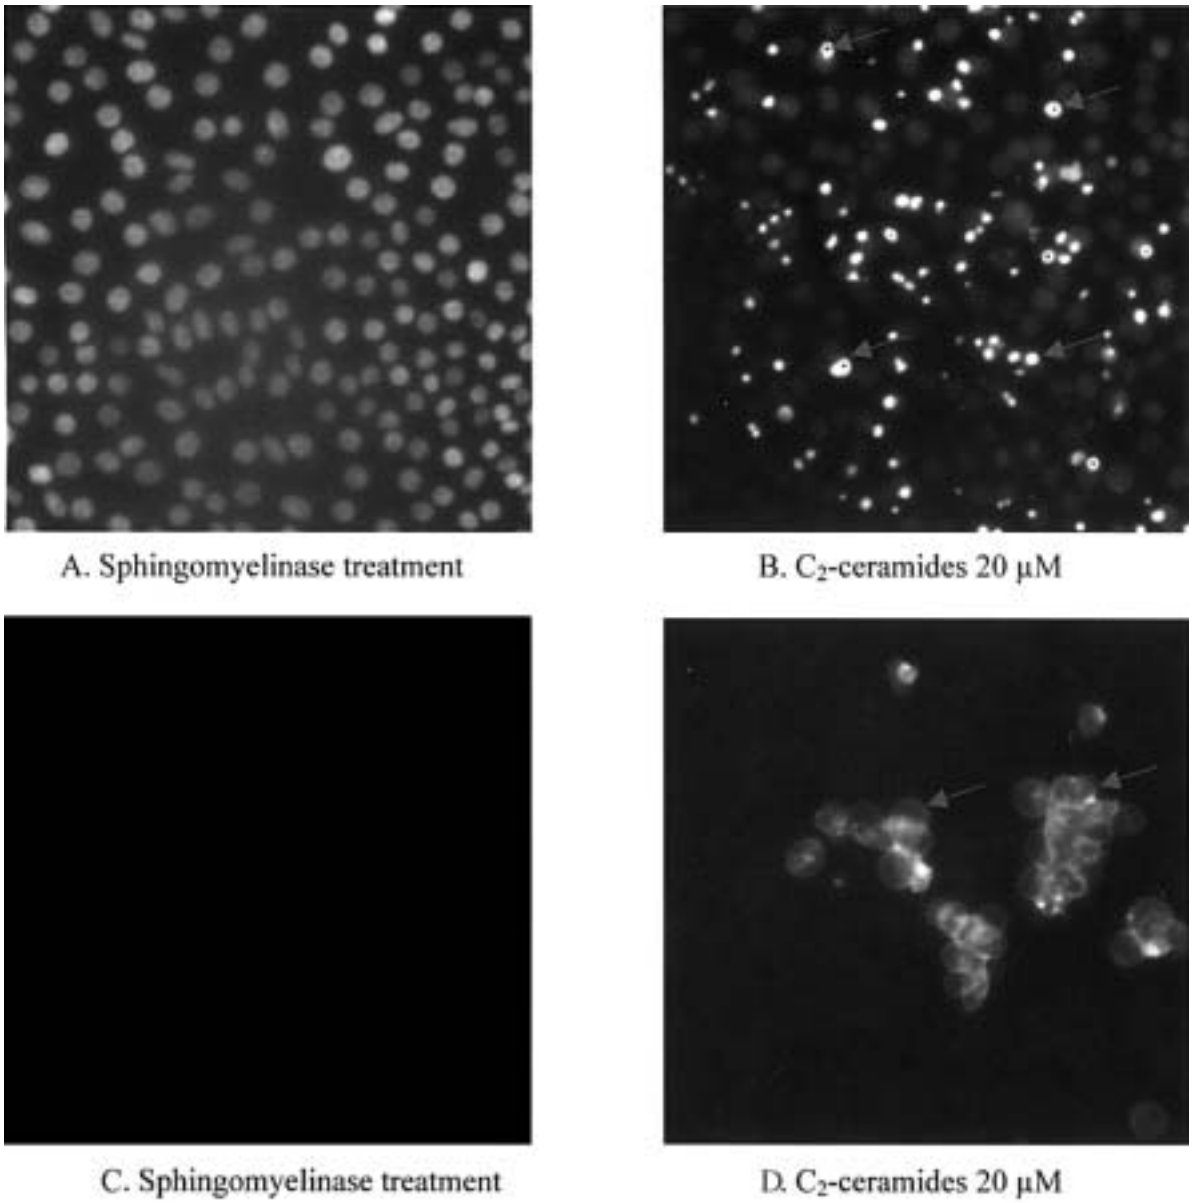

FIG. 6. Influence of exogenous Smase and C_2-ceramides on apoptosis. Porcine thyroid cells were cultured 48 h with TSH (1 mU/mL) as described in the Experimental Procedures section. After the culture period, the medium was withdrawn and replaced with medium containing Smase (0.5 U/mL) or truncated ceramides (C_2-ceramides). (A,B) Bis-benzamidine fluorescence corresponding to chromatin condensation was evaluated after 24 h of treatment. (C,D) Annexin V-fluorescein isothiocyanate (FITC) evidenced the phospholipidic flip-flop in the same conditions. See Figure 1 for other abbreviations.

6B). This effect was confirmed with annexin-FITC (Fig. 6D) insofar as annexin V tightly bound PS when this phospholipid was located at the outer leaflet of the cell membrane.

DISCUSSION

TSH can be considered as the main physiological regulator of the thyroid gland. *In vitro,* TSH induced porcine thyroid cultured cells to reconstitute follicle-like structures, which allow cells to incorporate iodine into thyroglobulin and to display adenylate cyclase responsiveness. These two parameters generally reflected a differentiated state of thyroid cells. TSH exerts its effects during the culture period, mainly *via* the cAMP cascade. However, this situation cannot be considered as exclusive, and part of the TSH effects occurred *via* cAMP-independent mechanisms. As in our previous studies, these results have demonstrated the involvement of glycosyl phosphoinositide-derived metabolites in the control of organification, iodide transport, and cAMP accumulation (21). Moreover, other factors like epidermal growth factor (EGF) (22) and transforming growth factor β (23) also contribute, through signaling pathways that involved protein phosphorylation on tyrosine or serine/threonine residues, to maintain a fine balance between proliferation and differentiation mechanisms.

During the last decade, another class of membrane lipids, the sphingolipids and their metabolites, have been shown to play an active role in complex signaling pathways including cell growth, differentiation (24), or programmed cell death (25). Several cytokines, such as TNF α, ILIβ, or IFN γ can trigger ceramide pathway, following Smase activation in different biological models (9).

In this report, we demonstrated the existence of a neutral Smase in porcine thyroid cells. This is a cell-surface associated enzyme that hydrolyzes SM to ceramide, and we clearly evidenced such a precursor-product relationship in our system. Since levels of endogenous neutral Smase activity were lower in 4 d in TSH-treated follicles as compared to control cells, it suggested that this hormone exerted a long-term negative control on intracellular ceramide amounts. TSH chronic treatment of porcine thyroid cells is essential to restore follicular morphology and thyroid functions. This control occurs through a cAMP-dependent mechanism as it was mimicked by F. In the absence of TSH in culture medium, thyroid cells progressively lose their functional characteristics and form a monolayer. The physiological relevance of this breakdown could correspond to a precise equilibrium between signaling pathways leading either to cell survival or to apoptosis. Long-term TSH treatment, *via* a cAMP mediation, triggers the positive signals for function and differentiation in porcine thyroid cells and in parallel represses Smase activity and ceramide production. On the other hand, the lack of TSH-altered cell program allowed cells to exhibit higher Smase activity and ceramide levels. In opposition, Pekary and Hershman (3) reported in FRTL-5 cells that TNF α markedly increased ceramide levels and Smase activity, but that TSH had no significant effect on ceramide release. In the same way, the Smase signaling pathway has been related to TNF α action in thyroid disorder (26).

For our part, we are unable to evidence in porcine thyroid cultured cells any effect of TNF α on Smase activity. Moreover, TNF α production in the culture medium cannot be detected. Nevertheless, it must be indicated that the FRTL-5 cell line differs from normal thyroid cells, particularly in the ability of iodide binding to proteins or in the lack of growth control by EGF (27). Alternatively, ceramide content of thyroid cells could directly modulate their differentiated state. To verify such a hypothesis, cells were treated with exogenous bacterial Smase or short-chain permeant ceramides. Such treatment altered follicular structures and, in parallel, induced loss of the functional activity of thyroid cells. Iodine organification and production of cAMP were markedly inhibited.

In contrast, other investigations using different cell types demonstrated that ceramides can positively regulate adenylate cyclase activity. Pyne *et al*. (28) showed that short-chain cells permeant ceramides (C_2 and C_6) increased the intracellular level of cAMP. Similar results were obtained by Bösel and Pfeuffer (29) using long-chain ceramides (C_{16} and $C_{18/24}$). However, it remains difficult to precisely evaluate the exact penetration and efficiency of ceramides inside the cells, and long-chain ceramides could affect the structural organization of membrane bilayers. In our study, however, C_2-ceramides were able, in a dose-dependent manner, to reproduce the effects of Smase on cAMP levels in thyroid cells.

The TSH-controlled ability to express differentiated thyroid functions is linked to the spatial reorganization of cells into follicular structures. Thyroid cells cultured in the absence of TSH form monolayers, where cells progressively lose their functional activity and exhibit a Smase activity higher than in TSH-treated cells. Otherwise, it has been reported that Smase could cause morphological changes (30) and that TNF α was able to induce the expression of cell adhesion molecules in keratinocytes and microvascular endothelial cells through a ceramide-dependent mechanism. Modification of thyroid cell morphology has been reported to be associated with not only the redistribution of the cytoskeleton network (31) and changes in the expression of junctional proteins such as E-cadherin (32) but also with modifications of extracellular matrix composition (33).

Our results suggested a crosstalk between two signaling pathways leading to distinct morphologic behaviors and functions. Elevation of cyclic adenosine monophosphate levels induced the expression of thyroid specialized genes and directed the differentiation process. In contrast, the increase in cellular ceramide content can be related to dedifferentiation according to the cell monolayer constitution and to PBI inhibition. The reciprocal control of these second messenger levels could influence downstream the balance between protein kinase A and protein kinase C activities. The determination of intracellular targets of ceramide action will provide us interesting information about the cascade of events governing cell programming. In this field of investigations, the mitogen-activated protein kinases cascade, the ceramide-activated pro-

tein phosphatase, and atypical protein kinase C zeta (9) appear to be the best candidates for mediating ceramide effects. In this field, apoptosis seems to be largely associated with ceramide generation (9). More recently, Wang *et al.* (34) postulated the existence of a balance between cell survival and programmed cell death as a function of ceramide concentration.

The spectacular morphological changes observed during long-term treatment of thyroid cells prompted us to investigate whether Smase and ceramides could induce apoptosis in these culture conditions. The analysis of chromatin condensation using bis-benzamidine and the annexin V-FITC technique for study of the PS flip-flop showed that ceramides were able to induce an apoptotic effect as early as 24 h of treatment (Fig. 1). However, the absence of programmed cell death induction under Smase treatment is questionable. Different explanations can be proposed to illuminate this point. First, the amount of intracellular ceramide released after Smase addition is not sufficient to induce apoptosis compared to the concentration of exogenous ceramides used in this set of experiments. The second point is related to the localization of the signaling pool of ceramides as described in leukemic cells (35) where exogenous Smase caused elevation of the ceramide levels without alterations of the cell viability. Further investigations are in progress to detail the mechanisms of ceramide action in governing cell death.

In conclusion, our reported data strongly supported an essential role of the ceramide signaling pathway in the control of programs that lead to the progressive conversion of functionally normal thyroid cells to a dedifferentiated phenotype.

ACKNOWLEDGMENTS

We thank Odette Legué for her excellent technical assistance. We are grateful to the Sobevir (Rethel, France) for the supply of thyroid glands. This work was supported by the Ministere Education Nationale Recherche et Technologie (MENRT), the Centre National de la Recherche Scientifique (CNRS), and by grants from Europol'agro, the region Champagne Ardenne and the Ligue contre le Cancer de l'Aube.

Modulation of Arachidonate and Docosahexaenoate in *Morone chrysops* Larval Tissues and the Effect on Growth and Survival

Moti Harel*, Eric Lund, Sonja Gavasso, Ryan Herbert, and Allen R. Place

Center of Marine Biotechnology, University of Maryland, Baltimore, Maryland 21202

ABSTRACT: The extent to which extreme dietary levels of arachidonate (AA) and/or docosahexaenoate (DHA) modulate lipid composition in the body tissues and consequently affect growth and survival in freshwater *Morone* larvae species was examined. White bass, *M. chrysops,* larvae (day 24–46) were fed *Artemia* nauplii enriched with algal oils containing varying proportions of AA and DHA (from 0 to over 20% the total fatty acids). Growth was significantly reduced ($P < 0.05$) in larvae fed a DHA-deficient *Artemia* diet. Increases in dietary levels of AA also were associated with a significant growth reduction. However, the inhibitory effect of AA on larvae growth could be suppressed by the dietary addition of DHA (at a level of 21.6% of the total fatty acids in enrichment lipids). Larval brain + eyes tissue accumulated over 10 times more DHA than AA in its structural lipids (phosphatidylcholine, phosphatidylethanolamine) at any dietary ratio. In contrast, DHA accumulation, as compared to AA, in gill lipids declined considerably at higher than 10:1 DHA/AA tissue ratios. DHA and eicosapentaenoic acid (EPA) contents in brain + eyes tissue were most sensitive to competition from dietary AA, being displaced from the tissue at rates of 0.36 ± 0.07 mg DHA and 0.46 ± 0.11 mg EPA per mg increase in tissue AA, and 0.55 ± 0.14 mg AA per mg increase in tissue DHA. On the other hand, AA and EPA levels in gill tissue were most sensitive to dietary changes in DHA levels; AA was displaced at rates of 0.37 ± 0.11 mg, whereas EPA increased at rates of 0.68 ± 0.28 mg per mg increase in tissue DHA. Results suggest that balanced dietary DHA/AA ratios (that allow DHA/AA ratios of 2.5:1 in brain + eyes tissue) promote a high larval growth rate, which also correlates with maximal regulatory response in tissue essential fatty acids.

Paper no. L8399 in *Lipids 35,* 1269–1280 (November 2000).

The white bass, *Morone chrysops,* is a freshwater fish species, closely related to the striped bass, *M. saxatilis*. Adult white bass are piscivorus, occupy freshwater habitats, and as such may retain and preferentially conserve their limited dietary n-3 polyunsaturated fatty acid (PUFA) sources (1,2). *Morone* larvae, in common with many other commercially important marine larval species, are not able to elongate and desaturate n-3 and n-6 precursors into their PUFA metabolites. In fact, of the four marine teleosts including ayu, *Plecoglossus altivelis,* red sea bream, *Pagrus major,* and puffer fish, *Fugu rubripes,* members of the genus *Morone* demonstrated the lowest conversion rate of 18:n-3 precursor to its C_{20} and C_{22} fatty acid metabolites (3). Thus, larvae must be provided with or be able to preserve sufficient levels of PUFA in order to meet the nutritional requirements for optimal growth.

Because the n-6 and n-3 fatty acids share a common biosynthetic pathway, the relationship between dietary n-6 and n-3 fatty acids and their distribution in larval body tissue is of interest. In brain tissue and eye retinal tissue of mammals, docosahexaenoic acid (DHA, 22:6n-3) is the most prominent fatty acid (4–7). Rapid DHA accumulation also coincides with neuronal differentiation and development of structural phospholipids of the central nervous system (5,6,8). In addition to DHA, arachidonic acid (AA, 20:4n-6) is a critical component of membrane lipids and specifically accumulates in brain phospholipids during early development (9,10). AA plays an active role in signal transduction both through the production of eicosanoids in whole body tissues and as a second messenger in neural tissue (11–14). Recent studies have shown that dietary supplementation of AA together with DHA inhibited DHA accretion in the phospholipid fraction of tissue lipids (10). This antagonistic relationship might be detrimental to the proper function of brain and neural tissues, where DHA is believed to serve a vital function.

Conversely, the developing brain, because of its high affinity for PUFA, may be very susceptible to an excess of PUFA in the diet. The adverse effects on larval growth and survival caused by excessive essential fatty acids (EFA) in the diet have been previously reported (15–17). Furthermore, it can be deduced from (i) the established involvement of DHA and eicosapentaenoic acid (EPA, 20:5n-3) in modulating production of AA-derived eicosanoids and (ii) the low Δ-5 and Δ-6 fatty acid desaturase activities in some vertebrates that marine fish might require AA in their diet not only preformed but also in balanced ratio with other EFA. Such an absolute re-

Abbreviations: AA, arachidonic acid; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid (22:5n-3); EFA, essential fatty acids; EPA, eicosapentaenoic acid; HUFA, highly unsaturated fatty acids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; psu, practical salinity units; PUFA, polyunsaturated fatty acids; TAG, triacylglycerols; UV, ultraviolet.

quirement for AA has been recently established for juvenile turbot, *Scophthalmus maximus* (18), and Japanese flounder, *Paralichthys olivaceus* (19); however, the combined requirement for these two EFA in both absolute and relative amounts is not known for any species.

The objectives of this study were to examine the extent to which extreme nutritional levels of DHA, AA, or a combination of the two would modulate lipid composition in larval tissues, and to establish the combined nutritional requirements for both DHA and AA. Animals used in this study were metamorphosed white bass larvae (day 24–46), which were at a sensitive developmental stage when high mortality generally occurs.

MATERIALS AND METHODS

Formulation of enrichment emulsions. A 3 × 3 factorial design (two factors, DHA and AA, at nine different combinations in duplicate blocks) was used to simultaneously study the effect of increasing dietary levels of DHA and AA on larval performances. Nine different emulsions having varying proportions of DHA-rich triacylglycerols (TAG) from heterotrophically grown algae, *Crypthecodinium* spp., and AA-rich TAG from fungi, *Mortierella* spp. (DHASCO and ARASCO, respectively, Martek Biosciences Corp., Columbia, MD) were formulated (Table 1). TAG of the algae *Crypthecodinium* spp. and the fungi *Mortierella* spp. contain 49% DHA and 54% AA of the total fatty acids, respectively, and less than 0.5% EPA. A mixture of 2% alginic acid, 2% polyoxyethylene sorbitan mono-oleate (Tween-80), 1% ascorbic acid, 1% vitamin E, 1% silicon-based anti-foaming agent (all made by Sigma Chemical Co., St. Louis, MO) and 5% soy lecithin [80% phosphatidylcholine (PC); Archer Daniels Midland Co., Decatur, IL] were added to the oils (all additions made by weight). Oil mixtures were emulsified with an equal amount of distilled water by first homogenizing at low speed (Ultra-Turrax T8; IKA Labortechnik, Staufen, Germany) for 15 s and then sonicating for an additional 15 s at one-third of the maximal sonication energy level (Sonifier 450; Branson Sonic Power Company, Danbury, CT). Fresh emulsions were prepared on a weekly base and stored at 4°C for daily use.

Enrichment of Artemia *nauplii. Artemia* cysts (premium grade; Sanders Brine Shrimp Co., Ogden, UT) were dehydrated in fresh water for 1 h and decapsulated in a 0.1 M NaOH solution containing 3% active chlorine. Hatching was carried out in 20 psu (practical salinity units) artificial seawater at 28°C with vigorous aeration. The nauplii were harvested after 16 h, separated from unhatched cysts and hatching debris, thoroughly rinsed, and kept at room temperature for an additional 6–8 h until they reached Instar-II stage (complete development of digestive system) before being transferred to the enrichment medium. Then 0.4 g/L of each enrichment emulsion (doses were based on the oil quantity in the emulsion) was fed to Instar II-stage *Artemia* nauplii (200,000 nauplii per liter) at time 0 (1700). At 0900 the following day (after 16 h), half of the nauplii were removed and fed to larvae. An additional 0.2 g/L of enrichment emulsion

[a]Total sat, percentage of saturated fatty acids in the diet; Total mono, percentage of fatty acids containing one double bond; Total diene, percentage of fatty acids containing two double bonds; Total poly, percentage of fatty acids containing three or more double bonds; ND, not detectable; FAME, fatty acid methyl ester. Docosahexaenoic acid triacylglycerols (DHA-TAG) and arachidonic acid triacylglycerols (AA-TAG) are DHA- and AA-rich TAG (49% DHA and 54% AA, respectively, obtained from Martek Biosciences, Columbia, MD); olive oil was obtained from a local market.

was added, and the remaining nauplii were fed to the larvae at 1600. A random set of samples of 16-h enriched *Artemia* nauplii were analyzed for lipid and fatty acid composition (Table 2).

Larvae rearing. Newly hatched white bass *M. chrysops* larvae were obtained from Aquafuture Inc. (Turners Falls, MA). Larvae were grown for 17 d on DHA- and AA-deficient rotifers, *Brachionus plicatilis* (2–5 rotifers/mL), which had been cultured on freshwater *Chlorella* paste (Martek Biosciences) at 0.5 g/10^6 rotifers/d. Larvae were randomly distributed in eighteen 60-L larval rearing tanks at an initial density of 160 larvae per tank. The tanks were gently aerated and the water volume was exchanged 1–2 times per day with biofiltered, ultraviolet (UV) light-treated recirculating water. A 14:10 h light/dark photoperiod was maintained using fluorescent light tubes (Daylight; 40 watts; 800–1200 lux at the water surface). Temperature was maintained at 24 ± 2°C and salinity at 2–6 psu. Water quality was monitored daily, and levels of total NH_3, un-ionized NH_3, NO_2, and pH were maintained below 0.2 ppm, 0.001 ppm, 0.3 ppm, and at 8.02, respectively, by partial replacement with fresh water. Pooled samples of forty 17-d-old larvae were taken for initial dry weight determinations (lyophilized to constant weight; balance: Mettler UMT2, Toledo, Switzerland, sensitivity = ±0.1 mg; lyophilizer: Labconco, Kansas City, MO) and fatty acid analysis.

Newly hatched *Artemia* nauplii were introduced to the larvae from day 17 until day 24 (once a day at 20–40 nauplii/L), while rotifer concentrations were gradually reduced to complete removal by day 24. Larvae were then fed twice daily with previously enriched *Artemia* nauplii, as described above, at concentrations of 50–100 nauplii/L for the next 22 d. Feeding experiments were terminated on day 46, at which time 40 larvae were sampled from each rearing tank. Samples were washed with distilled water, dried on paper towels, placed into test tubes, and lyophilized to constant weight. Muscle tissue, gill tissue, and eyes, including contiguous brain tissue, were dissected from each freeze-dried larva. The dry weight of a whole larva and the weight of a pooled sample containing 10 separated tissues were recorded to the nearest 0.1 mg (Mettler UMT2; Toledo, Switzerland). Survivorship was determined based on the initial and final counts of larvae in each rearing tank.

Lipid and fatty acid analysis. Total lipids were extracted from enriched *Artemia* nauplii, larvae muscle, gills, and brain + eye tissues according to the method of Folch *et al.* (20). Lipid weight was determined gravimetrically and expressed as a percent dry weight. The fatty acid compositions of total lipids from *Artemia* nauplii and larvae muscle, gills, and brain + eye tissues were determined following the method of Morisson and Smith (21). The lipid extracts, including internal standards (25 µg of each 19:0 and 21:0 fatty acids, Nu-Chek-Prep, Inc., Elysian, MN) were saponified with saturated KOH in methanol and transmethylated with 10% boron trifluoride in methanol (Supelco Inc., Bellefonte, PA).

Tissue lipid classes were separated on silica gel-G thin-layer chromatography taper plates (20 × 20 cm, uniplate; Analtech, Newark, DE) using a double-solvent development system (22). The plates were first developed to half-length in chloroform/methyl acetate/isopropanol/methanol/0.25% aqueous potassium chloride (25:25:25:10:9, by vol) to separate the individual polar lipid classes. Full-length development in hexane/diethyl ether/glacial acetic acid (80:20:2, by vol) was used to separate the neutral lipid classes. Spots for polar and neutral lipid classes were identified by comparison with authentic standards after visualization with 0.025% (wt/vol) 2′,7′-dichlorofluorescein in ethanol under UV light.

[a]See Table 1 for abbreviations.

PC, phosphatidylethanolamine (PE), phosphatidylinositol + phosphatidylserine (PI + PS), and TAG spots were scraped into tubes for transmethylation of the fatty acid components, as described above. The fatty acid methyl esters were analyzed by using a Hewlett-Packard 5890A gas chromatograph equipped with a flame-ionization detector and a 30 m × 0.25 mm i.d. capillary column with 0.25 µm film thickness (DB Wax, J&W Scientific, Folsom, CA). The carrier gas was helium at 1 mL/min flow rate. Injector and detector temperatures were 300°C, and the oven temperature was programmed from an initial temperature of 50°C, held for 2 min, to 200°C in 16 min, from 200 to 210°C in 11 min, and from 210 to 220°C in 18 min. The integrated peak areas of the fatty acid methyl esters were identified by comparison with known standards and quantified through the use of known amounts of internal standards. Fatty acid compositions of whole tissue lipids and lipid classes were expressed in mg fatty acid/g dry weight tissue.

Statistical analysis. Both *Artemia* nauplii enrichment and larvae feeding experiments were arranged in a complete block design (two blocks), including DHA and AA as treatment factors. All data are reported as means ± SEM. Analysis of variance was used (23) to determine differences between and within treatment means of survival, weight, whole tissue lipid and lipid classes content, and fatty acid composition. Percentage data were normalized by arcsine transformation prior to analysis. When significant differences between the means were detected, a Bonferroni multiple comparison test was applied. A significance level of 95% ($P < 0.05$) was used throughout.

RESULTS

Retention of lipid and fatty acids in Artemia *nauplii.* Table 2 presents the lipid and fatty acid composition in *Artemia* nauplii after enrichment for 16 h with various DHA/AA ratios. Overall, *Artemia* retained equal amounts of dietary lipids ($P > 0.05$) regardless of enrichment treatments, whereas the EFA composition reflected that of the dietary composition. AA retention by *Artemia* was almost four times higher than that of DHA retention (25.3 mg AA/g dry weight vs. 7.4 mg DHA/g dry weight). Retention efficiency of dietary AA and DHA (relative to maximum retention obtained at a minimum level of competing fatty acid) by the *Artemia* as a function of increased competition between the two fatty acids is shown in Figure 1. A reduction of over 55% of maximal DHA retention was observed in the presence of increasing levels of dietary AA, whereas reduction in AA retention as a result of increasing competition by dietary DHA was only 25% of its maximal levels. Moreover, the proportion of AA in *Artemia* lipids was generally equal to its dietary proportion, whereas the DHA proportion was almost 25% lower than its dietary proportion. As a result of retroconversion activities of the absorbed DHA, the relative proportion of the EPA metabolite in *Artemia* lipids was also increased from its basal levels of 2.1–2.9 mg/g dry weight. The net increase in *Artemia* EPA was estimated as approximately 20% of that of the corresponding DHA increase, based on the mg/g dry weight values [net percentage increase in EPA/(net increase in EPA + DHA)] as derived from the data presented in Table 2. Levels of linoleic and linolenic fatty acids (18:2n-6) in the enriched *Artemia* were nearly constant and mostly reflected their endogenous resources.

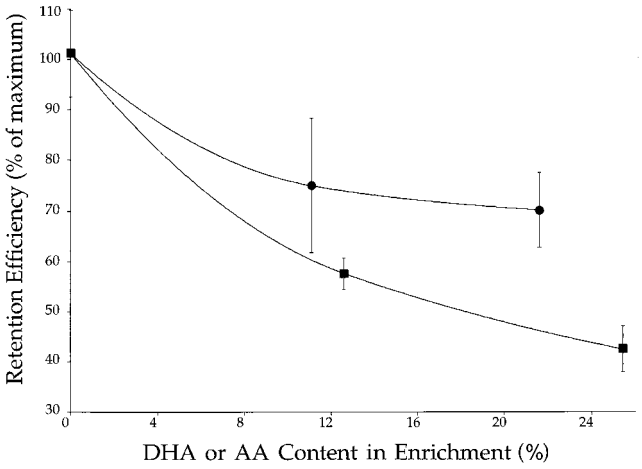

FIG. 1. Retention efficiency in *Artemia* nauplii (relative to maximum retention at zero competition) of dietary docosahexaenoic acid (DHA) (■) and arachidonic acid (AA) (●) as a function of the competition level between the two fatty acids. *Artemia* were enriched for 16 h with diets containing equal amount of DHA (21.6% of total fatty acids) but increasing levels of AA (0–26.9% of total fatty acids), or with diets containing equal amounts of AA (25.4% of total fatty acids) but increasing levels of DHA (2.6–23.3% of total fatty acids). Data are mean ± SEM values, $n = 3$.

Dietary effects on larval growth and survival. Larval growth was significantly affected after 22 d of dietary treat-

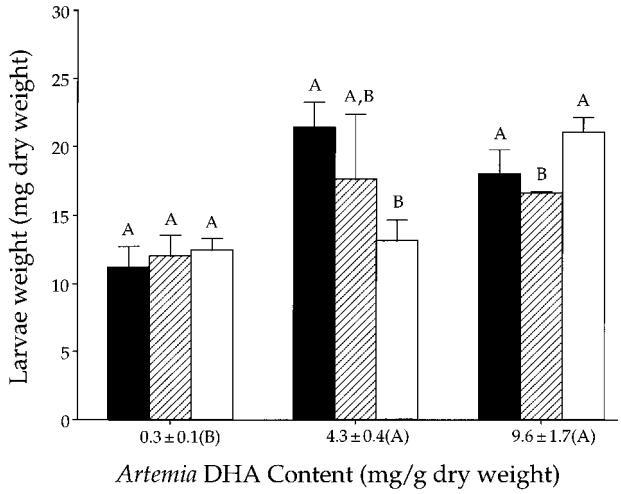

FIG. 2. Weight of white bass larvae after 22 d of feeding on enriched *Artemia* with varying DHA/AA dietary contents. AA content in enriched *Artemia* are: 3.1 ± 1.0 (solid bar), 14.5 ± 1.8 (diagonally lined bar), and 24.7 ± 0.4 mg/g dry weight (open bar). Data are means ± SEM values, $n = 3$. Bars with different letters indicate significant weight differences within dietary treatments ($P < 0.05$). *Artemia* DHA levels with different letters in parentheses indicate significant weight difference between dietary treatments ($P < 0.05$). For abbreviations see Figure 1.

[a]See Table 1 for abbreviations.

ments (Fig. 2, $P < 0.05$), but larval survival was not significantly different (64.9 ± 1.7%, $P > 0.05$). Larvae grew significantly slower ($P < 0.05$) when fed a DHA-deficient *Artemia* diet regardless of AA levels. Increasing contents of dietary AA at a moderate DHA level (4.3 ± 0.4 mg DHA/g dry weight) resulted in a significant growth inhibition, as larval growth was reduced from 21.3 ± 1.8 mg dry weight at no dietary AA to 13.1 ± 1.5 mg dry weight at 24.7 mg AA/g dry weight ($P < 0.05$). The inhibitory effect of high dietary AA on larval growth was nearly eliminated by the inclusion of high levels of DHA in the *Artemia* diet (9.6 ± 1.7 mg DHA/g dry weight). Nevertheless, increasing *Artemia* DHA levels above 4.3 mg DHA/g dry weight regardless of AA levels did not result in further improvement in larval growth.

Dietary effects on lipids and fatty acid composition of larval body tissues. Larval total lipid content was not affected by dietary treatments (17.1 ± 0.5% dry weight in all dietary groups, $n = 18$, $P > 0.05$). At the beginning of the experiment (on day 24), the lipid composition of larval tissues mainly reflected their *Chlorella*-enriched rotifer diet. Muscle and gill lipids were mostly composed of monounsaturated fatty acids (49.2 and 47.7% of all fatty acids, respectively, Table 3), while the largest proportion of PUFA was found in brain + eye tissue lipids (44.6% of all fatty acids). After 22 d of feeding, the lipid composition of all larval tissues responded to dietary changes. Most changes occurred in the proportion of monounsaturated and polyunsaturated fatty acid classes. The proportion of PUFA in brain + eye tissue lipids increased from 31.0 ± 1.1% to a maximum of 54.1 ± 0.8%. This dramatic increase in the proportion of PUFA in brain + eye lipid was at the expense of a corresponding decrease in the proportion of monounsaturated fatty acids (Table 4). The same pattern of response to dietary changes was observed in larval muscle and gill tissues, although the adjustment was not as pronounced (Tables 5 and 6). The gill tissue lipids were the most effective in increasing the proportion of PUFA over the course of the experiment (over 60% increase, Tables 3 and 6.), whereas brain + eye tissue lipids from larvae fed deficient diets lost 50% of their original proportions (Tables 3 and 4).

All three larval tissues responded to AA dietary shortage by exhibiting a selective accumulation of AA at low dietary content (Fig. 3B). Higher selectivity, especially in gill tissue,

[a]See Tables 1and 4 for abbreviations and experimental design.

was apparent at dietary contents lower than 2.8 mg AA/g dry weight. Tissue selectivity was largely unchanged at dietary contents higher than 4.9 mg AA/g dry weight. Conversely, DHA accumulation was almost five times higher in brain + eye tissue than in gill and muscle tissue (Fig. 3A). In addition, the selective accumulation of DHA in larvae brain + eyes in response to dietary increase was twofold higher than the selective accumulation of AA. The specific accumulation of DHA in larval brain + eye lipids reached its maximal selectivity at a dietary content of about 5 mg/g dry weight, with only moderate reduction at higher dietary levels. Gill and muscle tissues exhibited only minor selectivity to DHA, mostly at lower than 5 mg/g dry weight as compared to 3–5 times higher selectivity for AA at lower dietary AA levels.

The overall preference of each individual lipid class in larval tissue for both DHA and AA over a wide range of dietary ratios is presented in Figure 4. It is apparent that the PE fraction retained the highest proportion of DHA over AA in each larval tissue at all dietary ratios, whereas PI + PS fraction retained the lowest proportion. High proportions of DHA were also retained in brain + eye tissue PC, especially at high dietary DHA/AA ratios (>1). In addition, changes in DHA/AA

[a]See Tables 1 and 4 for abbreviations and experimental design.

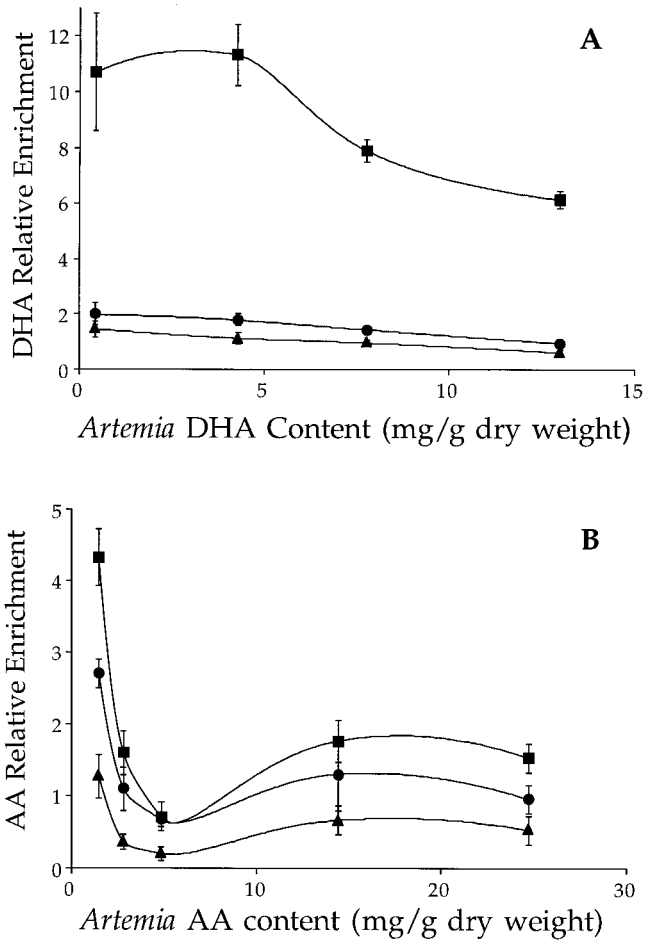

FIG. 3. Selective incorporation of DHA (A) and AA (B) in white bass larval brain + eyes (■), gills (●), and muscle (▲) tissues as a function of increasing dietary content. Larvae were fed for 22 d on *Artemia* enriched with increasing levels of DHA and AA. Values are calculated from data presented in Tables 4, 5, and 6. Data are pooled mean ± SEM values for two blocks. For abbreviations see Figure 1.

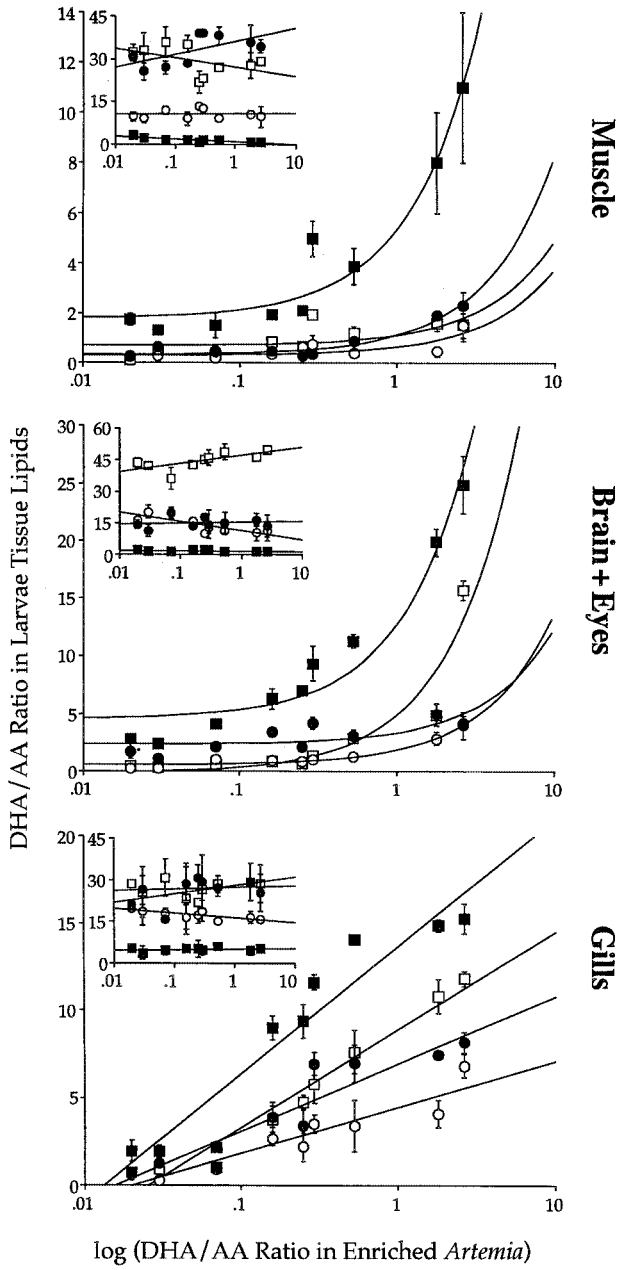

FIG. 4. Effects of enriched *Artemia* dietary DHA/AA ratio on the DHA/AA ratio of white bass larvae muscle, brain + eyes and gill phosphatidylcholine (□), phosphatidylethanolamine (■), phosphatidylinositol + phosphatidylserine (○), and triacylglycerols (●). Insets show the effect of dietary treatment DHA/AA ratio on the percentage of total fatty acids in each lipid class relative to total tissue fatty acids. White bass larvae were fed *Artemia* diets enriched with increasing DHA/AA ratio from day 24 to day 46. The best fit curvilinear lines show a linear relationship of the dietary treatments with gill lipid classes, whereas in muscle and brain + eye tissues the relationship includes a quadratic component. Data are pooled mean ± SEM values for two blocks. For abbreviations see Figure 1.

ratios in larval muscle and brain + eye tissues corresponded linearly with dietary changes, but the magnitude of the change in gill tissue was considerably smaller at higher dietary ratios. The neutral lipids in muscle and brain + eyes exhibited little change in the DHA/AA ratios with dietary changes, although the brain + eye neutral lipids DHA/AA ratio was nearly threefold higher. The gill neutral lipid stores generally reflected the saturable DHA/AA ratio of the polar classes.

Specific accumulation of linolenic acid, EPA, and docosapentaenoic acid (DPA, 22:5n-3) in brain + eye tissue of larvae fed on a diet deficient in both DHA and AA was also noticed (Table 4). Although both linolenic acid and EPA were present in the enriched *Artemia* diets, the proportion of brain + eyes and gill linolenic acid and EPA was nearly twofold higher in larvae fed a DHA- or AA-deficient diet. On the other hand, 22:5n-3 was completely absent in muscle and gill tissue lipids, whereas EPA was not as responsive to DHA or AA dietary changes. Similarly, high levels of 22:5n-6, which is the elongated/desaturated metabolite of AA also accumulated in larval tissues, particularly in brain + eye tissue of larvae fed high levels of AA. However, accumulation of this fatty acid metabolite in larval tissues could be eliminated by dietary inclusion of DHA. Figure 5 illustrates the ratios of

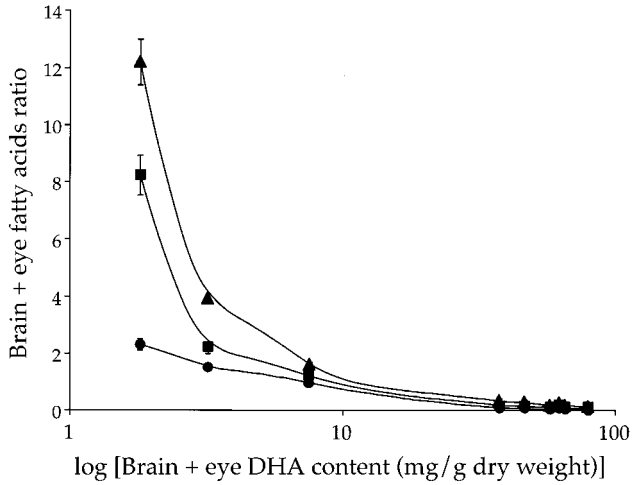

FIG. 5. Relationship between linolenic acid/DHA (▲), EPA/DHA (■), and docosapentaenoic acid (22:5n-3)/DHA (●) and DHA contents in larval white bass brain + eye tissue. Values are calculated from data presented in Table 4. Data are mean ± SEM values for two blocks. For abbreviations see Figure 1.

linolenic acid/DHA, EPA/DHA, and 22:5n-3/DHA in brain + eye tissue lipids relative to its DHA content. It clearly shows that larval brain + eye tissue compensates for its DHA shortage by dramatically increasing the proportion of both EPA and 22:5n-3 as well as linolenic acid. Compensation occurred mainly at levels lower than 10 mg DHA/g dry weight tissue, while at higher tissue DHA contents these fatty acids tended to level off.

Displacement or accumulation rates for each of the essential fatty acids, DHA, AA, EPA, linolenic acid, linoleic acid as well as oleic acid (18:1n-9), in relation with increasing uptake of DHA or AA in larval tissues are summarized in Table 7. In muscle and gill tissues, increased uptake of DHA significantly increased tissue EPA (0.53–0.68 mg increase in EPA per mg increase in tissue DHA). Brain + eye EPA content was not changed by increased uptake of DHA, but was reduced significantly with the increasing uptake of AA (at a rate of 0.46 ± 0.11 mg EPA per mg AA). Dramatic displacement rates were also found for DHA and AA. Brain + eye DHA content was the most sensitive to competition from AA, being displaced at a rate of 0.36 ± 0.07 mg DHA/mg increase in tissue AA, while muscle and gill tissue DHA was not sensitive to increasing levels of AA. On the other hand, AA content in all larval tissues was sensitive to changes in DHA levels, being displaced from brain + eyes at the highest rate of 0.55 ± 0.14 mg AA/mg DHA followed by gills (0.37 ± 0.11 mg AA/mg increase in tissue DHA) and muscle tissue (0.25 ± 0.06 mg AA/mg increase in tissue DHA). Both linolenic and linoleic acids were significantly accumulated in muscle tissue with the increasing uptake of AA (0.16 ± 0.03 and 0.29 ± 0.04 mg/mg AA, respectively), whereas oleic acid was significantly displaced (0.13 ± 0.02 mg/mg AA). Oleic acid was also rapidly displaced from brain + eye tissue with the increasing uptake of AA (0.36 ± 0.11 mg/mg AA) and from gill

TABLE 7

[a]First-order linear regressions between each pair of fatty acids were obtained by plotting the amount of each essential fatty acid that accumulated in the tissue (in mg/g dry weight) at equal dietary levels (excluding deficient treatments) vs. increasing tissue levels of DHA or AA. A plus or minus sign represents accumulation or displacement, respectively. Rates are mean ± SE value of the slope for two blocks. Regression coefficient (R^2) and P-values indicate the significance level of interaction. *Significant degree of interaction at $P < 0.05$, **low degree of interaction ($P < 0.1$), ***no interaction between the fatty acids ($P > 0.1$). Each regression plot was based on six data point. Displacement rates were calculated based on data presented in Tables 4–6.

tissue with the increasing uptake of DHA (0.28 ± 0.1 mg/mg DHA).

DISCUSSION

Varying dietary DHA and AA ratios affect growth and tissue fatty acid composition during larval development and metamorphosis of white bass, *M. chrysops.* In addition, we observed a marked competition between EFA with both DHA and AA levels fluctuating greatly with the dietary challenges, suggesting that white bass larvae are unable to regulate their EFA composition in the face of dietary changes. These results with *M. chrysops* larvae support previous works that showed *Morone* species, including striped bass and hybrid striped bass (24,25), had PUFA requirements similar to marine fish. Unlike mammals, which can further elongate and desaturate dietary fatty acid precursors to maintain phospholipid composition (26,27), marine fish larvae require a continuous dietary supplementation in an appropriate balance of both AA and DHA. Our results demonstrate the dose-response nature of DHA and AA and their interaction in specific body tissues and lipid classes. Moreover, results specifically suggest that gill tissue AA may decrease sharply at dietary DHA/AA ratios higher than 10.

The ability to convert linolenic acid and EPA to DHA has been generally attributed to freshwater fish species (28); therefore, it was interesting to see whether white bass larvae retained such elongation/desaturation capabilities when raised under almost freshwater conditions (2–6 psu). In fact, larval brain + eye tissue retained only small amounts of DHA (as low as 1.8 ± 0.2 mg/g dry weight) when fed on both linolenic acid and EPA-rich but DHA-deficient *Artemia* diets, suggesting a very low capacity to further elongate and desaturate existing levels of EPA. High accumulation of these fatty acids in brain + eye tissue generally occurred at low DHA levels (<5 mg DHA/g dry weight, Fig. 5), with a significant reduction at increasing DHA levels. Recent studies in mammals have found only trace amounts of EPA in the brain (7), while 22:5n-3 is a product of Δ-6 desaturase systems and generally exhibits a considerable enrichment only in brain + eye tissue, and probably has a low rate of further desaturation to DHA.

The low level of desaturation observed may also be a reflection of dietary input. Tissue lipids of larvae fed DHA- and AA-deficient diets contained high levels of oleic acid, which originated from its elevated levels in the diets. This was particularly noticeable in brain + eye tissues, which doubled in their monounsaturated fatty acid levels in the case of dietary DHA and AA deficiency. Studies in mammals have shown that high dietary intake of oleic acid (18:1n-9) can be associated with a reduced Δ-6 desaturation activity, thereby further limiting the tissue capacity to produce long-chain highly unsaturated fatty acid (HUFA) metabolites from their precursors (29,30), although we are unaware of similar findings in fish larvae. Based on our results, we estimate that in order to avoid compensation by less functional fatty acids, such as oleic acid, EPA, and 22:5n-3, white bass larvae brain + eye tissue must retain a minimum of 5 mg DHA/g dry weight. Our results demonstrate that DHA is specifically incorporated into the structural lipids (mainly PC and PE) of brain + eye tissue, and also that PC containing DHA was the major component in this tissue. This observation is consistent with other works in showing that DHA-rich phospholipids, mainly PC and PE, are the largest constituents of DHA-rich lipid classes in tissues such as neural, retinal, and testicular tissues of many teleost fish (31–34).

Dietary supplementation of AA enhanced DHA accretion in larval brain + eye tissue, as well as 22:5n-6, but only when fed as part of DHA-deficient diets (an elevation from 1.8 ± 0.2 mg DHA/g dry weight at no dietary AA up to 7.5 ± 1.2 mg DHA/g dry weight at the highest content of dietary AA). By contrast, increasing levels of brain + eye DHA were associated with lower accumulation of AA (a reduction from 6.5 ± 0.2 mg AA/g dry weight at no dietary DHA to 3.5 ± 0.3 mg AA/g dry weight at the highest content of dietary DHA). This implies that uptake of AA into brain + eye tissue lipids could preserve more DHA in case of its deficiency, thereby reducing tissue requirement for dietary DHA. Studies have suggested that in a state of deficiency the metabolic conversion of 18:3n-3 and 18:2n-6 to long-chain metabolites is much more efficient than under normal conditions (35,36). Given that both n-3 and n-6 families share the same metabolic pathways of degradation and desaturation and chain elongation, and that the conversion efficiency of long-chain HUFA precursors increases in a state of dietary deficiency, it is not surprising that more DHA was accumulated at higher dietary AA. Therefore, by supplementing with n-6 long-chain metabolites (such as AA), more limiting resources of desaturation and chain elongation will be freed for the production and preservation of tissue DHA.

The question therefore has been raised whether diets rich in n-6 long-chain metabolites could offset the need for n-3 long-chain metabolites. Results show that brain + eye tissue of larvae fed a DHA-deficient but AA-rich diet accumulated, besides a significant amount of 22:5n-6, a maximum of 7.5 ± 1.2 mg DHA/g dry weight, which is slightly above the suggested minimal requirement of 5 mg/g dry weight (Fig. 3). Nonetheless, growth of these larvae was retarded almost by half relative to that of DHA-fed larvae. It is therefore more likely that the observed growth impediment in larvae fed AA-rich but DHA-deficient diets was a result of other functional disorders associated with DHA deficiency. For example, Bell *et al*. (33) found dietary PUFA-deficiency effects on visual performance and predation activity, especially at low light intensities. Other studies have found that eicosanoid production in juvenile turbot, *Scophthalmus maximus,* is dependent on dietary PUFA (37). Consequently, we have concluded that DHA could not be replaced in larvae white bass diets either by its dietary precursors or by n-6 metabolites (including EPA, AA, and 22:5n-6).

Our results clearly showed that when both DHA and AA were supplemented in the diet, DHA was more efficient in displacing AA from larvae gill tissue than AA was in displac-

ing DHA (0.37 ± 0.11 mg decrease in AA per mg increase in DHA vs. no displacement of DHA with increasing tissue AA, $P = 0.23$). On the other hand, DHA increase was associated with a significant accumulation in gill EPA. Such a dramatic reduction in AA or elevation in EPA would have a marked influence on the ability of the larval gill to osmoregulate effectively, since AA-derived prostanoids are essential for regulating fluid and electrolyte balance in fish gill and kidney (38). In fact, we obtained evidence in striped bass, a related species to white bass, that larvae fed DHA-rich diets with no addition of AA survived poorly when challenged by hypersaline water (39).

We also observed higher accumulations of AA relative to DHA in the enriched *Artemia* (Fig. 1). *Artemia* nauplii have been found to metabolize dietary lipids actively and to store them mainly as TAG (40). This would suggest that fatty acid β-oxidation in *Artemia* is more similar to animal models in which n-3 long-chain PUFA were chain-shortened more rapidly than n-6 fatty acids (41–43). This contrasts with mammals, which actively oxidize PUFA by the peroxisomal β-oxidation system. Fish oxidized PUFA mainly by the mitochondrial β-oxidation system, hence enabling them to conserve more n-3 PUFA in their tissues (44).

In contrast with the general tendency of DHA to level off in the lipids of gill tissue, that of the muscle and brain + eye lipids showed a strong linear increase with increasing dietary levels. Furthermore, there were major differences between brain + eyes, muscle, and gills tissues in response to dietary DHA/AA changes. Brain + eyes preferentially accumulating DHA over AA especially into structural lipids (PC, PE), while muscle was equally responsive to both fatty acids. Gills tissue progressively accumulated larger amounts of AA, mainly into the PI fraction, which is a likely source of eicosanoid production in fish (see recent review, Ref. 45). Gills were also the most responsive tissue to a low dietary DHA/AA ratio, but with a limited extent of increase in DHA absorption at high DHA/AA ratios. This result suggests a specific tissue response that regulates either retention or incorporation of EFA into its lipids. Such a specific regulatory response reflects distinct and separate roles that each fatty acid may play in a particular tissue. DHA accumulates particularly in brain synaptic membranes (5,6,10,46), and in the photoreceptor rod outer segments (47). In addition to DHA, AA also accumulates in brain phospholipids (10,14,48), where it actively participates in signal transduction and second messenger functions in neural cells (11,12,49). Furthermore, AA is important as a precursor of eicosanoid production throughout the body (37,50). In the gills and kidney, eicosanoids are involved in the stimulation of ionic transport that regulates the osmotic pressure in the larvae during environmental change (18). Given the antagonistic effect of DHA on AA, and the competition between both, which presumably outweighs the preferential effect in different tissues, an appropriate dietary balance between the two seems essential for the proper functioning of these sensitive tissues.

Finally, our results indicate that the maximal regulatory effect of DHA in brain + eyes was obtained at about 5 mg/g tissue content, whereas maximal regulatory effect of AA was obtained at about 2 mg/g. These estimated values suggest an optimal DHA/AA ratio of *ca*. 2:1 in *Artemia* enrichment diet for larval white bass. Similar ratios were also reported for sea bass larvae (45), of which an optimal dietary ratio of DHA/EPA of *ca.* 2:1 and EPA/AA at *ca*. 1:1 has been suggested.

These findings may be of relevance to questions concerning both the deprivation and excessive loading of long-chain EFA in larval diets. Results suggest that provision of linolenic acid, EPA, and 22:5n-3 may help to offset the decrease in DHA observed in brain + eye tissue, although at the expense of optimal growth. They also clearly support a trend toward regulatory limits on the incorporation of DHA into larval tissues, showing a maximum tissue response at DHA/AA ratio of approximately 2.5:1. At higher than 10:1 ratios, the EFA imbalance in tissue lipids could increase exponentially in favor of DHA.

Effects of Fructose and Troglitazone on Phospholipid Fatty Acid Composition in Rat Skeletal Muscle

John N. Clore*, Jing Li, and William B. Rizzo

Departments of Medicine and Pediatrics, Virginia Commonwealth University, Richmond, Virginia

ABSTRACT: Skeletal muscle phospholipid fatty acid (PLFA) composition is associated with insulin sensitivity in animal models and in man. However, it is not clear whether changes in insulin sensitivity cause a change in PLFA composition or vice versa. The present studies have examined the effects of agents known to increase or decrease insulin sensitivity on PLFA composition of the major phospholipids, phosphatidylcholine (PC) and phosphatidylethanolamine (PE), in soleus and extensor digitorum longus muscle. Four groups of Sprague-Dawley rats—control, 0.2% troglitazone (Tgz), 60% fructose fed, and fructose + Tgz—were treated for 3 wk. Fructose feeding was associated with a decrease in muscle membrane polyunsaturated fatty acids (PUFA) and n-3 fatty acids in both PC and PE. Administration of Tgz alone resulted in an increase in liver (3.75 ± 0.93 to 6.93 ± 1.00 μmol/min/mg tissue, $P < 0.05$) and soleus muscle (0.34 ± 0.03 to 0.67 ± 0.09 μmol/min/mg, $P < 0.01$) elongase activity, which would be expected to increase membrane PUFA. However, Tgz decreased PLFA associated with greater insulin sensitivity (e.g., PUFA and n-3 fatty acids) and increased PLFA associated with decreased insulin sensitivity (16:0 and n-6 fatty acids) in both PC and PE. Co-administration of fructose and Tgz did not reverse the decrease in PUFA observed with fructose alone. We conclude that the improvement in insulin sensitivity reported with Tgz is associated with an apparently paradoxical effect to decrease PUFA and n-3 PLFA composition in rat skeletal muscle. These studies suggest that Tgz-mediated increases in insulin sensitivity do not result in improved PLFA composition.

Paper no. L8537 in *Lipids 35*, 1281–1287 (November 2000).

Insulin sensitivity is related in part to the composition of skeletal muscle membranes. We (1) and others (2–4) have shown an inverse relationship between insulin resistance and the percentage of long-chain polyunsaturated fatty acids (PUFA) in human muscle membrane phospholipids (PL). Moreover, increased PUFA are found in membrane PL of more insulin sensitive muscle (Type I) compared to Type II fibers (2,5), suggesting that membrane PL fatty acid composition may play a significant role in the relative insulin responsiveness of muscle fiber types. Of particular interest are the PL phosphatidylcholine (PC) and phosphatidylethanolamine (PE), which together account for more than 75% of the total plasma membrane PL. It is known that the outer and inner layers of the plasma membrane bilayers contain greater proportions of PC and PE, respectively. Thus, differences in the fatty acid composition of these two PL species could have independent effects on insulin responsiveness. In support of this hypothesis, we recently demonstrated that the fatty acid composition of PC (but not PE) in Type II rat muscle was characterized by an enrichment of palmitic acid (16:0) relative to stearic acid (18:0), which suggested a defect in fatty acid elongation in the insulin-resistant muscle. In addition, studies performed in our laboratory in normal human volunteers demonstrated for the first time that the fatty acid composition of PC, but not PE, was related to insulin sensitivity.

Although considerable evidence exists for an association between PL fatty acid (PLFA) composition and insulin sensitivity, recent studies suggest that changes in insulin sensitivity are also associated with changes in fatty acid composition. In studies performed in rats, Storlein *et al.* (8) showed that diets high in fat are associated with increased insulin resistance and that alterations in the fatty acid composition of the diet could ameliorate that effect. Marked changes in skeletal muscle PLFA induced by diets low in PUFA have also been shown to reduce insulin binding and, presumably, insulin action in rats (9,10). In man, Anndersson *et al.* (11) have demonstrated that increasing exercise, which is well known to increase insulin sensitivity, is associated with a decrease in skeletal muscle membrane saturation and total n-6 fatty acids. Finally, we have recently reported that nicotinic acid, an agent known to reduce insulin sensitivity, decreases skeletal muscle membrane PUFA composition of PC but not PE (12). Despite these and other data demonstrating a relationship between changes in insulin sensitivity and PLFA composition, it is by no means clear whether changes in insulin sensitivity mediate the changes in PLFA composition or vice versa. To address this issue, we have examined the effects of (i) high fructose feeding, which is known to increase insulin resistance (13), and (ii) troglitazone, an agent known to improve insulin sensitivity (14) and to reverse the effects of fructose in animal models (15) on skeletal muscle membrane PLFA. Our studies have demonstrated adverse effects of both trogli-

tazone and high fructose diet on fatty acid composition. These studies suggest that the improvement in insulin sensitivity known to occur with troglitazone administration is not mediated by induction of a more favorable skeletal muscle membrane fatty acid profile.

MATERIALS AND METHODS

Study design. Male Sprague Dawley rats (~120 gm) were used in all of the described studies. Animals were housed individually and had free access to food and water. After adaptation to a powdered standard chow, the animals were divided into four groups and fed *ad libitum* with the following diets for 3 wk: standard powdered chow; powdered chow supplemented with troglitazone (0.2%) as previously described (Tgz); 60% fructose (F) diet (Harlan Teklad, Madison, WI); and 60% fructose supplemented with 0.2% troglitazone (F + Tgz). Analysis of the fatty acid composition of the regular chow diet and the high fructose diet is shown in Table 1. Mean body weights of animals (170.8 ± 2.9 g, $n = 52$) were not different at sacrifice in any of the treatment groups (data not shown). Overnight-fasted male Sprague-Dawley rats were killed by cervical dislocation after undergoing ether anesthesia. Blood samples were obtained by cardiac puncture, and soleus and extensor digitorum longus (EDL) muscles were removed immediately for assessment of insulin sensitivity and/or PL analyses. All studies were approved by the Institutional Animal Care Utilization Committee of Virginia Commonwealth University.

PLFA composition. PLFA were analyzed according to Borkman *et al.* (16) with minor modifications. Hemi-muscles (50–60 mg) were homogenized and total lipids were extracted by the method of Folch *et al.* (17). The lipid extracts were dried under nitrogen, dissolved in 10 mL of hexane, and applied to 3 mL silica gel columns (J.T. Baker, Inc., Phillipsburg, NJ). After elution of less polar lipids with 20 mL hexane followed by 10 mL dichlormethane, PL were eluted with 10 mL methanol. The methanol eluates were dried under nitrogen and transmethylated with 1.5 mL 1 N methanolic HCL at 80°C overnight. Fatty acid methyl esters were extracted with 6 mL hexane and dried under nitrogen.

To determine the fatty acid composition of individual PL species, PC, PE, sphingomyelin (SM), phosphatidylinositol (PI), cardiolipin (CL), and phosphatidylserine (PS) were first separated by thin-layer chromatography (TLC) on silica gel G plates (LK6D; Whatman, Maidstone, England) using a solvent system consisting of chloroform/ethanol/triethylamine/water (30:34:30:8, by vol) for the first development and hexane/dimethyl ether (50:50, vol/vol) for the second development. PL were visualized under ultraviolet light after spraying the plate with rhodamine G. The separated PL spots were scraped and placed into glass tubes. Fatty acid methyl esters were prepared as described above by treatment with methanolic acid.

Fatty acid methyl esters from both the total PL fractions and the individual PL species were redissolved in 20 μL hexane, separated, and quantitated on a Hewlett-Packard 5890 gas chromatograph equipped with a 30 × 0.2 mm fused-silica capillary column (Omega Wax 320; Supelco, Inc., Bellefonte, PA,) and flame-ionization detector. The injection temperature was 250°C and the detector temperature was 300°C. The initial oven temperature was 140°C. After 5 min the oven temperature was increased from 140 to 200°C at a rate of 20°C/min, then to 280°C at 5°C/min. Fatty acids were identified by comparing their retention times with those of authentic standards.

Most of the gas chromatograph peaks were identified as specific fatty acid methyl esters. In the total PL and PC preparations, these fatty acid methyl esters accounted for 87 and 93% of the total integrated area, respectively, whereas they comprised only 79% of the integrated area in the PE fraction. In all samples, however, there were peaks immediately preceding 16:0 and 18:0 that were suspected to be dimethyl acetal derivatives of fatty aldehydes released from ether PL (plasmalogens). To confirm this identification, PE from bovine brain containing 60% plasmalogens (Sigma, St. Louis, MO) was chromatographed before and after mild acid fume hydrolysis (18). After mild acid fume hydrolysis and separation on TLC plates, the peaks before 16:0 and 18:0 suspected of being derived from plasmalogens completely disappeared, essentially confirming their identity.

Plasma insulin concentrations were determined by radioimmunoassay (19). In some experiments, microsomal elongase activity was determined in liver and skeletal muscle samples using 2-^{14}C-malonyl CoA as previously described (18). Concentrations of malonyl CoA were determined by the incorporation of ^{3}H-acetyl CoA into palmitic acid (20) following the addition of fatty acid synthetase isolated from rat liver (21). PL, triglyceride, cholesterol, and fatty acid standards were obtained from Sigma. High-performance precoated silica gel Hp-K plates (10 × 10 cm) were purchased from Whatman (Clifton, NJ). All other reagents and solvents were of analytical or high-performance liquid chromatography-grade from Sigma or Fisher (Pittsburgh, PA).

Statistical analysis. All analyses were performed using SPSS v10.0.5 (SPSS, Inc., Chicago, IL). Comparison of groups was performed using one-way analysis of variance and Tukey's HSD *post hoc* test. Comparison of groups to

control was performed by one-way analysis of variance and Dunnett's *post hoc* test. Statistical significance was assumed at the 5% level.

RESULTS

No differences in fasting plasma glucose (94.3 ± 5.4, 96.1 ± 2.9, 101.1 ± 4.2 mg/dL, ns) or insulin (0.22 ± 0.03, 0.21 ± 0.02, 0.20 ± 0.03 ng/mL, ns) concentrations were seen in animals fed F, Tgz, or control diet, respectively. However, significant effects of Tgz and a high F diet on soleus and EDL muscle PC fatty acids were observed. As shown in Table 2, treatment with Tgz increased the content of oleic (18:1) and linoleic (18:2) acids and decreased stearic (18:0), eicosapentanoic (22:5n-3), and decosahexanoic (22:6) acid as well as the total PUFA content of soleus muscle. Following 3 wk of a high F diet, the content of oleic acid in PC fatty acids obtained from soleus muscle increased from 8.1 ± 0.1 to 16.3 ± 0.9% ($P < 0.001$) whereas a broad-based reduction in the content of long-chain PUFA was observed ($P < 0.001$) compared to regular chow-fed animals. These changes likely reflect the lower content of long-chain PUFA in the F diet (Table 1) (22). Contrary to our hypothesis, supplementation with Tgz again decreased PC content of 18:0 despite greater dietary content, and total PUFA decreased further compared to F alone. Comparison of the PC fatty acid composition of the insulin sensitive soleus (Table 2) and insulin-resistant EDL (Table 3) muscle demonstrates the known striking differences in the two muscle types (7) with a greater ratio of 16:0 to 18:0 (4.0 ± 0.2 vs 1.1 ± 0.1, $P < 0.01$) and decreased PUFA (24.2 ± 0.9 vs. 30.4 ± 0.4, $P < 0.01$) in EDL compared to soleus muscle, respectively. However, nearly identical directional changes were observed in the fatty acid content of EDL muscle following Tgz administration without or with high F feeding

[a]Results shown are mean percentage ± SEM; $n = 6$ animals in each group. *$P < 0.05$, **$P < 0.01$ compared to control. $^{\dagger}P < 0.05$, $^{\ddagger}P < 0.01$ compared to fructose alone. See Table 2 for abbreviations.

(Table 3) when compared to those in soleus muscle (Table 2).

Analysis of the fatty acid composition of PE from soleus and EDL muscles was also performed (Tables 4 and 5). Expected differences in the fatty acid composition of soleus and EDL muscle between PC and PE were observed, with greater content of saturated fatty acids in PC and greater PUFA in PE (7). Despite these differences in fatty acid composition, administration of Tgz resulted in similar changes in the proportion of fatty acids in PE to those observed in PC. As shown in Figure 1A (soleus muscle), the content of total n-6 fatty acids in PC was significantly greater than that of PE ($P < 0.001$). Alternatively, the content of n-3 fatty acids was greater in PE compared to PC ($P < 0.001$). However, the content of total n-6 fatty acids increased ($P < 0.01$) and n-3 decreased ($P < 0.01$) following Tgz administration in both PL. Similar directional changes of n-6 and n-3 fatty acids were observed in the more insulin-resistant EDL muscle following Tgz administration (data not shown). The effect of F administration on n-6 and n-3 fatty acids was also examined (Fig. 1B). Striking reductions in n-3 fatty acids were observed in PC ($P < 0.01$) and PE ($P < 0.01$) in soleus muscle. Similar reductions in n-3 fatty acids were observed in EDL muscle in PC (4.89 ± 0.0.26 to 1.67 ± 0.10%, $P < 0.01$) and PE (21.2 ± 0.3 to 13.9 ± 1.3%, $P < 0.01$). Significant increases in PE n-6 fatty acids were observed in soleus (Fig. 1B) and EDL muscle (data not shown) after F feeding compared to control animals. In contrast, no significant changes in PC n-6 fatty acids were observed with F feeding.

We did not expect that an insulin sensitizer would decrease fatty acid elongation. However, the increase in the ratio of 16:0 to 18:0 (inversely correlated with elongase activity) observed in these studies following Tgz administration suggests that elongase activity was decreased. Since increases in this marker have generally been associated with decreased insulin

[a]Results shown are mean percentage ± SEM; $n = 6$ animals in each group. *$P < 0.05$, **$P < 0.01$ compared to control. $^{\dagger}P < 0.05$, $^{\ddagger}P < 0.01$ compared to fructose alone. See Table 2 for abbreviations.

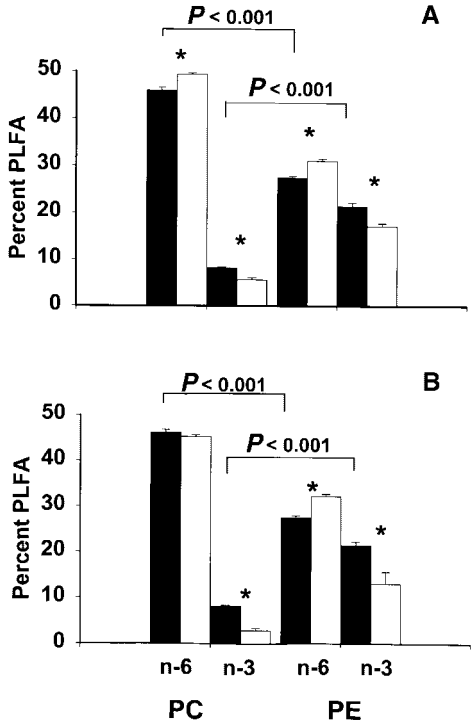

FIG. 1. Percent fatty acid composition of total n-6 and n-3 fatty acids in phosphatidylcholine (PC) and phosphatidylethanolamine (PE) from rat soleus muscle. (A) Results in the absence (■) or presence (□) of 0.2% troglitazone for 3 wk. (B) Results in animals fed standard chow (■) or 60% fructose chow (□) for 3 wk. Results shown are mean percentage ± SEM; $n = 6$ animals in each group. *$P < 0.01$.

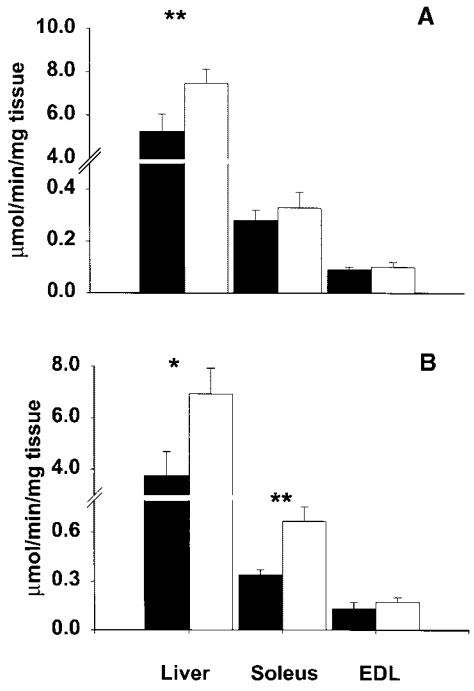

FIG. 2. Microsomal elongase activity (expressed as μmol/min/mg tissue) in liver, soleus, and extensor digitorum longus (EDL) muscle. (A) Results in animals fasted overnight (■) and in fed animals (□) ($n = 6$ in each group). (B) Results in fasted animals fed standard chow (■) or chow supplemented with 0.2% troglitazone for 3 wk (□) ($n = 4$ animals in each group). Results shown are mean ± SEM; *$P < 0.05$, **$P < 0.01$.

sensitivity, additional experiments were performed to determine the effect of Tgz on elongase activity measured directly in liver and muscle. In preliminary experiments, elongase activity was determined in liver, soleus, and EDL muscles from fed and fasted rats. As shown in Figure 2A, liver elongase activity increased in fed animals compared to fasted animals ($P < 0.01$). Skeletal muscle enzyme activity was less than 5% of that in liver, with the activity in soleus muscle threefold higher than that in EDL (0.28 ± 0.04 vs. 0.09 ± 0.01 μmol/min/mg tissue). In contrast to results obtained with liver, enzyme activity did not change with feeding in either soleus or EDL. To confirm a physiologic effect of feeding in skeletal muscle in our studies, malonyl CoA concentrations were also determined. As expected, tissue malonyl CoA levels increased in both soleus (2.2 ± 0.6 to 2.9 ± 0.6 nmol/g, $P < 0.01$) and EDL (0.6 ± 0.2 to 1.4 ± 0.4 nmol/g, $P < 0.01$) with feeding. The effects of Tgz on elongase activity were then examined. As shown in Figure 2B, liver enzyme activity increased in liver and soleus muscle following Tgz administration. No change in elongase activity was observed in EDL following Tgz administration. Thus, a decrease in elongase activity, which might explain the observed increase in the ratio of 16:0 to 18:0 and the decrease in PUFA following Tgz administration, was not found.

DISCUSSION

The present studies were designed to determine the effect of F (an agent known to induce insulin resistance) and Tgz (an agent known to improve insulin resistance) on PL fatty acids in insulin-sensitive and insulin-resistant skeletal muscle. Numerous studies have demonstrated an association between PL fatty acid content and insulin sensitivity. Increased 16:0 (7) and decreased long-chain PUFA have been described in association with reduced insulin sensitivity. In addition, strategies to increase or decrease insulin sensitivity have been shown to alter PL fatty acid composition in animals and man (4,5,23,24). Based on these data, we hypothesized that Tgz administration would be associated with improvements in PLFA composition of rat skeletal muscle (EDL in particular) and that this effect would be greater in the insulin-resistant model of F feeding. Indeed, F feeding was associated with changes in the fatty acid composition of rat skeletal muscle, which have been associated with insulin resistance. However, the expected improvement in PLFA composition following Tgz administration was not observed.

High F diets are well known to induce insulin resistance in animals. Both peripheral and hepatic insulin resistance have been shown in F-fed animals using the euglycemic

clamp technique (15,25). Two mechanisms have been proposed for the increase in insulin resistance. F feeding is known to increase plasma and tissue triglycerides in association with a reduction in insulin sensitivity (15,25,26). Particular attention has been given to the potential role for tissue triglycerides in this model of insulin resistance, with the effect attributed to the fat composition of high F diets (26). An effect of Tgz to reduce skeletal muscle tissue triglycerides in association with an increase in insulin-stimulated glucose disposal has been demonstrated (27,28). Total tissue triglycerides were not determined in the present studies.

Changes in PLFA composition of skeletal muscle membrane may also contribute to the improvement in insulin sensitivity. The higher saturated fatty acid content of the commercial high F diet used in the present studies (Table 1) and in most reported studies would be expected to alter membrane composition and skeletal muscle insulin sensitivity. Storlein *et al.* (8) have shown a 50% reduction in total body glucose disposal and an 80% reduction in skeletal muscle glucose disposal in rats fed a high saturated fat diet in association with changes in skeletal muscle PL fatty acid composition. Striking reductions in total PL long-chain n-3 fatty acids were observed in these studies. Similar reductions in long-chain n-3 fatty acids in both PC and PE were observed in animals fed the high F diet in the present studies. Administration of any of several thiazolidinediones has been shown to ameliorate the induction of insulin resistance induced by diets high in F (15) or fat (29,30). Thus, our model should have permitted us to observe an improvement in PLFA composition with Tgz administration if such a mechanism was involved in improvement of insulin sensitivity. However, an improvement in PLFA composition in the F-fed animals was not observed after Tgz administration. Rather, long-chain n-3 fatty acids (22:5n-3, 22:6n-3) as well as total PUFA fell after Tgz treatment in both muscle types. These results were virtually identical to those observed following Tgz administration in animals fed a standard chow diet, suggesting an independent effect of Tgz. The Tgz-induced changes in PL fatty acid composition observed in the present studies appear to contradict previous studies using BRL 49653, another thiazolidinedione (29). In the latter studies, BRL 49653 was shown to increase insulin sensitivity (measured using the clamp technique) in fat-fed animals without a change in PL fatty acid composition. However, these investigators examined total PL fatty acids whereas we have examined two individual PL species, namely, PC and PE, which together account for more than 75% of total PL (7). It is certainly possible that opposing changes in the fatty acid composition of PI, SM, CL, and PS to those of PC and PE might account for this discrepancy. Nevertheless, both the present studies and those of Oakes *et al.* (29) support the contention that the improvement in insulin sensitivity induced by thiazolidinediones is not mediated by changes in PL fatty acid composition.

Potential mechanisms for the changes in composition of PL fatty acids observed in the present studies following Tgz treatment are a reduction in fatty acid elongation and/or desaturation. Elongase is a ubiquitous enzyme complex, which is responsible for the addition of two-carbons from malonyl CoA to both saturated and unsaturated fatty acids in liver and muscle. The consistent increase in ratio of 16:0 to 18:0 in both PC and PE as well as the marked reduction in n-3 long-chain fatty acids in both soleus and EDL muscle after Tgz treatment is consistent with this hypothesis. However, an insulin sensitizer would be expected to increase, not decrease, elongation. To examine this possibility further, we have measured microsomal elongase activity directly in liver and muscle using palmitoyl CoA as substrate. Liver activity increased significantly following refeeding and Tgz treatment, consistent with an insulin-mediated effect. In keeping with the greater insulin sensitivity of oxidative muscle, malonyl CoA concentrations and enzyme activity were greater in soleus compared to EDL muscle. Moreover, elongase activity increased in soleus but not EDL muscle after treatment with Tgz. Moreover, elongase activity is inhibited by certain fatty acids (31), and a decrease in free fatty acid availability by Tgz (27) would also be expected to increase elongase activity. Thus, a Tgz-induced reduction in elongase activity, either *in vivo* or *in vitro,* seems unlikely. With regard to the possibility that Tgz may have decreased desaturase activity, consistent changes in Δ^5 desaturase (20:4/20:3 ratio) or Δ^6 desaturase (20:3/18:2 ratio) activity were not observed in our studies (Tables 3–6).

In conclusion, our data have shown that Tgz administration is associated with changes in PLFA composition, which have been previously linked to insulin resistance. These studies suggest that the improvement in insulin sensitivity mediated by TGZ is not the result of changes in PLFA composition.

[a]Department of Biology, Amherst College, Amherst, Massachusetts 01002, and [b]Conte National Center for Polymer Research, Department of Polymer Science and Engineering, University of Massachusetts at Amherst, Amherst, Massachusetts 01003

ABSTRACT: An approach to the direct quantification of phospholipids from two-dimensional ^{31}P-^{1}H nuclear magnetic resonance (NMR) spectroscopy with isotropic proton mixing has been developed as a general method for phospholipid analysis of minor membrane vesicle subfractions. Membrane vesicles were subfractionated by sedimentation to density equilibrium in a sucrose gradient, and a modified Folch method was employed to extract their phospholipids. The coefficient for the NMR detection efficiency of each phospholipid and the relative mole percentage of the phospholipids present in the membrane vesicles were calculated. We demonstrate low detection limits such that relative concentrations of phospholipids in membrane subfractions may be determined even in the submicromolar range.

Paper no. L8443 in *Lipids 35,* 1289–1297 (November 2000).

Various types of high-resolution nuclear magnetic resonance (NMR) spectroscopy have been used to analyze lipids present in biological samples (1–8). NMR spectroscopy as a tool for analysis of lipids and phospholipids has advantages over chromatographic techniques because prior separation and derivitization of components are not required (2,7). Proton and phosphorus NMR can determine exact structures of phospholipids and have been employed for the quantification of different head groups and fatty acid chains (1–3,7).

Although conventional one-dimensional (1D) proton NMR has been used to determine lipid profiles for different types of tissues (1), overlapping chemical shifts often limit precise peak assignments. One-dimensional ^{31}P NMR spectroscopy is restricted by the small chemical shift range (i.e., 1.5 ppm) and the different short relaxation times for each phospholipid (6,7). Furthermore, the phospholipid chemical shifts and line widths are significantly dependent on the lipid composition, solvent composition, pH, counterions, and water content (6,7). The chemical shift of a phosphate group is also sensitive to very slight changes in conformation, and to fatty acid chain composition and length (4,8). For example, introduction of unsaturated groups on either side of the phosphatidylcholine acyl chains causes an upfield shift, and an increase in the length of disaturated acyl chains results in the phosphorus chemical shift shifting closer to the absolute value of –0.500 ppm (8).

To acquire unambiguous peak assignments, two-dimensional (2D) heteronuclear (^{31}P-^{1}H) multiple quantum coherence NMR spectroscopy (HMQC) with isotropic proton mixing has been used as an analytical method. Previously, 1D and 2D NMR were used for the analysis of plasma membranes of whole cells, tumor cells, and tissue extracts (1,4–6). Here we extend the HMQC method to identify and directly quantify submicromolar levels of phospholipids present in individual membrane subfractions separated by buoyant density.

HMQC, an inverse correlation technique (where the protons of the lipid head group and lipid backbone are observed as edited by the phosphorus resonance to which they are coupled) is effective at lower detection limits than the usual low millimolar (mM) range. As previously shown by Edzes *et al.* (4), the incorporation of isotropic proton mixing in a 2D heteronuclear correlated NMR spectroscopy method greatly increases the clarity of assignment of head group and lipid backbone protons. Each phospholipid can be characterized by its specific "fingerprint" proton pattern. However, isotropic proton mixing causes a complication in the direct quantification of the specific phospholipids by HMQC. Unlike the case for 1D NMR, peak integrals at the same concentration of sev-

eral phospholipids will vary according to different efficiencies of the spin mixing that are dependent on $J_{H\text{-}H}$ coupling constants as well as mobility. Therefore, the 2D peaks in different phospholipids are not detected at the same efficiency. To resolve this problem in a simple and practical way, coefficients of efficiency of NMR detection (K) of each relevant phospholipid were calculated. By determining the K values for each, the relative mole percentage of the phospholipids present in the membrane vesicles could be directly calculated from the 2D HMQC spectra.

The biological properties and functions of sea urchin egg cytoplasmic membrane vesicles (MV) have been studied, although until now there has not been a measure of their phospholipid composition. The importance of determining the phospholipid composition of these distinct MV subfractions lies in the fact that such MV populations cooperate in forming the nuclear envelope *in vitro* (9). MV are from egg cytoplasmic origin and can be resolved into four different subsets: MV1, MV2, MV3, and MV4, differing in buoyant density. MV1 and MV2 are involved directly in nuclear envelope formation, and MV1 contains vesicles crucial for the fusion of MV2 subfractions (9). Owing to the particular roles of the MV in the formation of the nuclear envelope and the unique properties of MV1 (9), we investigated the phospholipid compositions of MV1, MV2, and MV3.

This paper demonstrates that with minimal sample handling the lipid/phospholipid profile of minor membrane subfractions can be easily determined and shows how the individual phospholipids present can be directly quantified from the HMQC spectra with isotropic proton mixing.

MATERIAL AND METHODS

Materials. Lytechinus pictus (sea urchins) were obtained from Marinus, Inc. (Long Beach, CA). All phospholipid standards, [DL-α-phosphatidyl-L-serine, dipalmitoyl (DPPS), L-α-phosphatidylcholine, dipalmitoyl (DPPC), DL-α-phosphatidylethanolamine, dipalmitoyl (DPPE), L-α-phosphatidylinositol sodium salt (PI), dipalmitoyl sphingomyelin (DPSM), β-acetyl-γ-*O*-alkyl-L-α-phosphatidylcholine (AAPC)], deuterated solvents (deuterium oxide, chloroform, methanol), EDTA, and potassium hydroxide were purchased from Sigma Chemical Co. (St. Louis, MO). Porcine blood was acquired from Cleveland Scientific (Cleveland, OH). Solvents used for lipid extraction, chloroform, and methanol were high-performance liquid chromatography (HPLC) grade and purchased from Fisher Scientific (Fair Lawn, NJ). Buffers were egg lysis buffer [LB; 10 mM Hepes, 250 mM NaCl, 5 mM $MgCl_2$, 110 mM glycine, 250 mM glycerol, 1 mM phenylmethylsulfonylfluoride (PMSF), 1 mM dithiothreitol, pH 8.0], Tris-NaCl (TN; 10 mM Tris-HCl, 0.15 M NaCl at pH 7.2), and membrane wash buffer (MWB; 250 mM sucrose, 50 mM KCl, 2.5 mM $MgCl_2$, 50 mM Hepes, 1 mM dithiothreitol, 1 mM ATP, 1 mM PMSF, pH 7.5).

Methods. (i) Egg extracts: The gametes of the *L. pictus* were collected and fertilized, and sea urchin egg extracts were prepared according to Collas and Poccia (10). Briefly, fertilized eggs were washed in Millipore-filtered seawater and egg LB, resuspended in an equal volume of LB, and homogenized on ice, using a 22-gauge needle and syringe. The lysate was centrifuged at 10,000 × *g* for 10 min at 4°C in a microcentrifuge. The clear cytoplasm (S_{10}) was withdrawn and further centrifuged for 2 h at 100,000 × *g* at 4°C in a Ti50 rotor (Beckman Instruments, Carlsbad, CA). The clear cytosolic fraction (S_{100}) was recentrifuged for 1 h at 100,000 × *g* to collect the remaining pelleted membrane fractions. S_{100} was frozen in liquid nitrogen and stored at –80°C.

(ii) Membrane vesicle isolation and subfractionation. All solutions contained fresh 1m M protease inhibitor PMSF. The MV pelleted at 100,000 × *g* were washed twice by resuspension in MWB and centrifuged at 40,000 × *g* for 10 min. These membrane vesicles are referred to as (MV0). The quantity of MV0 was maintained constant in all experiments. The MV were routinely obtained from 2.5 mL of S_{10} extracts and resuspended in 200 μL of MWB. The MV0 was subfractionated by sedimentation to density equilibrium in a sucrose gradient. The 200 μL of MV0 in MWB was suspended in 0.5–1 mL of ice-cold TN buffer containing 1 mM PMSF. By using a gradient maker (Biorad, Richmond, CA), 15 mL of a 0.2–2.0 M linear sucrose gradient in TN buffer was made and slowly deposited into a 16 mL SW28 ultracentrifuge tube held on ice. The MV0 suspension was applied to the gradient and fractionated by sedimentation to density equilibrium at 150,000 × *g* for 20 h at 4°C in a SW28 rotor (Beckman, Fullerton, CA). Vesicles were fractionated into four fractions, MV1, MV2, MV3 and MV4, with respective median densities of 1.02, 1.04–1.08, 1.13, and 1.18. The fractions were collected as described by Collas and Poccia (9). Each fraction was washed with 4 vol of MWB and recentrifuged at 150,000 × *g* for 30 min. The fractions were resuspended in a minimal volume of MWB and stored at –80°C.

(iii) Lipid extraction of membrane subfractions. A modified Folch procedure, adapted by Glonek *et al.* (11), was used for the extraction of MV subfractions. Each subfraction was resuspended in 200 μL of MWB and added to 4 mL of ice-cold chloroform/methanol (2:1, vol/vol). The solvent-to-sample ratio was 20:1 (mL solvent/g sample). The homogenate was sonicated for 2 min and was allowed to settle for 1 h at room temperature. It was then filtered, and K_4-EDTA (0.2 M, pH 6.0, at 0.2 mL per mL of chloroform/methanol) was added. The mixture was agitated vigorously and allowed to separate overnight at room temperature. The lower chloroform phase was collected and evaporated under a stream of argon. The dried lipid samples either were used immediately or were stored at –80°C.

(iv) Preparation of porcine red blood cell ghosts. Erythrocyte ghosts were utilized to verify the accuracy of the quantification method. Ghost erythrocytes were prepared using the procedures in the *Current Protocols in Immunology* (12). The lipids of 1×10^{10} ghost were extracted and stored at –80°C.

(v) NMR spectroscopy. All spectra were obtained on a Bruker AMX-2 500MHz NMR spectrometer with a Bruker 5-mm broadband indirect probe tuned to 202 MHz and

500.13 MHz. The probe temperature was stabilized at 298 K, and samples were left to stabilize for 20 min at this temperature before data acquisition. The parameters for the HMQC-total correlation spectroscopy (TOCSY) 2D spectra shown in this work are as follows: ^{1}H and ^{31}P 90 degree pulses, respectively 8.0 and 9.5 μs, recycle delay 2 s, acquisition time 0.68 s, sweep width F_2 2008 Hz in 2750 real points, sweep width F_1 607Hz in 64 slices, MLEV17 mixing at 7.1 kHz power for 101 ms (45 cycles), globally optimized alternating phase rectangular pulse (GARP) ^{31}P decoupling during acquisition at 2.4 kHz power, refocus delay 0.071 s ($J_{P\text{-}H}$ = 7 Hz). Data sets were processed with zero-shifted sine-bell window functions in both directions and displayed in magnitude mode for 2D integration. The number of scans was varied to give sufficient signal. Two-hour runs with 48 scans were performed for concentrated extracts, and 20-h runs with 480 scans for submicromolar lipid extracts. Furthermore, owing to the presence of three deuterated solvents, for reproducibility the field was adjusted by systematically locking on the $CDCl_3$ signal. To confirm that the field was locked on the $CDCl_3$ signal, the proton chemical shifts were verified prior to running the HMQC.

Extracted lipids were dissolved in a ternary solvent system consisting of a mixture of $CDCl_3$/CD_3OD/K_4EDTA in D_2O (100:40:20 by vol). The K_4EDTA was at the same concentration in D_2O as explained above. The solvent system was optimized because the chemical shift and the linewidths of the phospholipid peaks (in ^{31}P NMR) vary depending on the solvent composition (6,7). The lipid sample and the solvent system were mixed in a glass vial and allowed to equilibrate for an hour prior to transfer to a 5-mm NMR tube. A small aqueous phase was formed at the top after 1 min. This layer above the sample allowed a proper equilibrium to be maintained and prevented significant organic solvent evaporation during NMR analysis. Care was taken to have a clean separation between the organic and aqueous phase. Any emulsion of water in the organic layer degraded the homogeneity of the magnetic field.

HMQC choice and parameters. To maximize sensitivity and resolution we chose from the currently available array of NMR pulse sequences an indirectly detected 2D method with its potential $(\gamma_H/\gamma_P)^{2.5}$ = 9.5-fold increase in signal over direct ^{31}P observation. (γ_H/γ_P is the gyromagnetic ratio of protons/phosphorus.) The ^{31}P-^{1}H connectivity can be established *via* either heteronuclear single quantum coherence (HSQC) (13,14) or multiple quantum coherence HMQC, which give proton resonances along the F_2 axis and a single phosphorus resonance for each phospholipid in the projection along the F_1 axis. Although the former method has been generally used for its often simpler line shape, we chose to look at both methods and, as seen below, found the HMQC slightly better for our purposes. The intensity of each correlation depends on the specific ^{31}P to ^{1}H coherence transfer, which is different for different protons in various phospholipids. To spread out the proton dimension to all protons coupled to a phosphorus spin with their range of coupling constants, the magnetism at the end of the sequence was mixed throughout the spin system with a Malcolm Levitt decoupling scheme (MLEV)17 total spin correlation sequence (TOCSY) (15). Since a large number of scans would be required for our low concentrations and our laboratory did not have a gradient probe capable of observing ^{31}P through the ^{1}H spins, we chose to use pulse programs without gradient selection. The required phase cycle of eight has the advantage of giving a square root of two benefit to signal-to-noise ratio over the same number of scans with gradient selection. The pulse programs were taken from a modern NMR handbook (16). The final HSQC-TOCSY and HMQC-TOCSY 2D sequences were made simply by splicing the TOCSY program onto the original HMQC or HSQC. Pulse sequence parameter optimization was carried out on a 4 μM DPPC sample in the standard ternary solvent system described above. The delay for coherence transfer, $1/2*J_{P\text{-}H}$ for HMQC and $1/4*J_{P\text{-}H}$ for HSQC, was varied with $J_{P\text{-}H}$ from 1 to 9 Hz and found to maximize the signal at the expected 7 Hz. The TOCSY spin lock interval was varied from 34 to 135 ms and, although some signals were still increasing and some decreasing, the compromise value was set to 101 ms.

Previous work employing 2D-NMR techniques to fingerprint phospholipids differed somewhat from our technique of choice and did not choose for optimal signal-to-noise. Edzes *et al.* (4) used an INEPT-TOCSY with WALTZ mixing thus detecting ^{31}P signals directly. Although gaining fourfold in sensitivity over simple ^{31}P detection, this technique loses the very significant additional 2.5-fold sensitivity increase accruing from indirect detection *via* the protons. Henke *et al.* (6) used gradient-enhanced HSQC-TOCSY with MLEV proton mixing. While this technique takes advantage of the full enhancement available in the indirect detection, normal gradient selection results in 41% loss in sensitivity for a comparable number of scans compared to phase cycling selection.

Phospholipid quantification. To determine the detection limit for our protocol, several different concentrations of phospholipid standards were analyzed from 4 to 0.04 μM. The 2D integration mode in XWIN-NMR (Bruker, Billerica, MA) software was used to integrate each peak. To determine the integration values of different concentrations of phospholipids, various dilutions were prepared. The first set consisted of 3.9 μM DPPC, 3.9 μM PI, 3.9 μM DPPS, and 3.9 μM DPPE, the second set 0.4 μM DPPC, 0.39 μM PI, and 0.40 μM DPPE, and the third set 0.04 μM DPPC, 0.039 μM PI, and 0.04 μM DPPE. To achieve reproducibility and optimize our system, saturated acyl chain standards were used since their chemical shifts are most stable and these standards were used previously (8). Phospholipid standards were dissolved in 700 μL of 100:40:20 (by vol) deuterated chloroform, methanol, and K_4EDTA in D_2O. The efficiency coefficients (K) of each phospholipid relative to DPPC in the standard mix were calculated so that the relative mole percentage of phospholipids in the samples could be determined. K was calculated using Equation 1:

$$K_{2/1} = \frac{[PL_1] \times A_2}{[PL_2] \times A_1} \quad [1]$$

where A_1 and A_2 are the integration values of the most intense peak per phospholipid. [PL_1] and [PL_2] are molar concentrations of the phospholipids.

K values were determined from the three sets, and the standard deviations were evaluated. The relative molarity of each particular phospholipid in the different membrane subfractions was obtained by multiplying the ratio of A_1/A_2 by its corresponding *K* value. For example the relative molarity of DPPE to DPPC was calculated as follows:

$$\left[\frac{\text{DPPE}}{\text{DPPC}}\right] = K_{\text{PC/PE}} \frac{A_{\text{PC}}}{A_{\text{PC}}} \quad [2]$$

The mole percentage of phospholipid was determined relative to the most prominent phospholipid in the 2D spectrum, where the value of the most prominent phospholipid was considered to be 1.

To verify the accuracy of this quantification method with a complex biological system, phospholipids of porcine erythrocyte ghosts were quantified and results compared to literature values. Data obtained for the composition of the MV were compared to endoplasmic reticulum and Golgi membranes.

RESULTS AND DISCUSSION

Both HMQC-TOCSY and HSQC-TOCSY 2D spectra were run on a mixture of four standard phospholipids [DPPC, L-α-phosphatidylinositol, dipalmitoyl (DPPI), DPPS, and DPPE] in order to determine the optimal method. Signal-to-noise levels were comparable, but HMQC-TOCSY spectra consistently gave approximately 20% better signal-to-noise for most peaks. To the F_1 resolution level which the experiments were run, any residual proton splitting of the HMQC peaks was not problematic, although the line shapes were not elegant. HSQC gave some clean simple peaks and some split peaks, the latter apparently due to the problematic case of $J_{\text{H-H}}$–$J_{\text{P-H}}$. In any case the resulting peaks were reproducibly integrable.

Chemical shifts and the detection limit. The 2D chemical shifts of the phospholipid standard HMQC spectra were determined from their corresponding 1D spectra. Edzes *et al.* (7) and Pearce and Komoroski (8) have demonstrated that the ^{31}P chemical shifts of various phospholipids are not comparable in different samples. Nonetheless, the order of appearance relative to a reference standard of choice remains constant. The irreproducibility of the exact resonance positions is due to the sensitivity of the chemical shift of a phosphate group to very slight changes in its conformation, environment, or the acyl chain composition (4,8). In this study DPPC, with a chemical shift of –0.510 ppm (8), was defined as a reference standard owing to its stability in all solvent systems and environments such as variations in pH (3). The 1D ^{31}P NMR spectra were calibrated by analyzing 4 μM DPPC standard under the same conditions as the sample analyses. The dipalmitoyl (16:0) saturated chain of PC has the closest value to –0.510 ppm (8). To avoid variations in 2D chemical shifts caused by chain length and saturation, the dipalmitoyl derivatives of phosphatidylserine, phosphatidylethanolamine, and sphingomyelin were utilized for optimization of the method. The 1D phosphorus chemical shifts were verified by spiking samples with DPPC, AAPC, PI, DPPS, DPSM, and DPPE.

Figures 1A and 1B show the variation in chemical shifts with different ternary solvent compositions. Comparing the high quality of resolution in Figure 1A to the lower resolution in Figure 1B, we see that an increase in the methanol/K_4EDTA portion of the ternary solvent results in narrowing the line widths of the phospholipid peaks. The 100:40:20 (by vol) solvent system chosen for our experiments promoted resolution of PE from cardiolipin and PI from lysophosphatidylcholine (LPC) and so

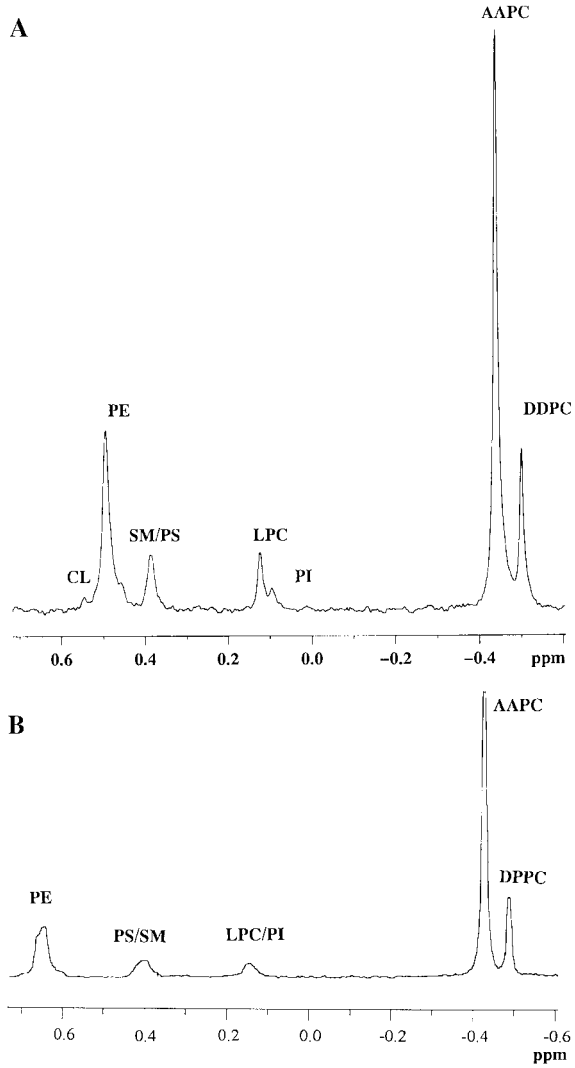

FIG. 1. Phosphorus spectrum of MV0 in a ternary solvent of chloroform/methanol/0.2 M K_4-EDTA at 298.1K. (A) Solvent ratio 100:40:20 by vol; with this methanol and K_4-EDTA ratio the phospholipid peak widths become narrower and better resolution is achieved. This solvent was chosen for all NMR spectra in this work. (B) Solvent ratio 100:16:4 by vol; in this spectrum phospholipid peaks are not so well resolved as in Figure 1A. CL, cardiolipin; PE, phosphatidylethanolamine; SM/PS, sphingomyelin/phosphatidylserine; LPC, lysophosphatidylcholine; PI, phosphatidylinositol; AAPC, β-acetyl-γ-*O*-alkyl-L-α-phosphatidylcholine; DDPC, L-α-phosphatidylcholine, dipalmitoyl; NMR, nuclear magnetic resonance.

TABLE 1
Phosphorus Chemical Shifts of Phospholipids from Literature and MV0[a] Extracts in $CDCl_3/CH_3OH/K_4EDTA$ (100:40:20, by vol)

Phospholipids	Literature[b] (ppm)	MV0 extracts (ppm)
DPPC	–0.51	–0.50
AAPC	–0.45	–0.47
PI	–0.2, 0.00	–0.1, 0.098
LPC	0.10	0.12
PS	0.25	0.40
SM	0.30	0.40
PE	0.43	0.44
PE plasmalogen	0.44	0.48
CL	0.51	0.53

[a]DDPC, L-α-phosphatidylcholine, dipalmitoyl; AAPC, β-acetyl-γ-*O*-alkyl-L-α-phosphatidylcholine; Pl, L-α-phosphatidylinositol sodium salt; LPC, lysophosphatidylcholine; PS, phosphatidylserine; SM, sphingomyelin; PE, phosphatidylethanoloamine; CL, cardiolipin; MV0, membrane vesicles treated with protease inhibitor, centrifuged, washed with membrane wash buffer, and centrifuged.

this solvent was used as the optimal solvent system. Table 1 gives the 1D ^{31}P NMR chemical shifts of a variety of phospholipids from the literature (3) and of peaks observed in lipid extracts of MV0. Special note should be taken of the variations in literature and experimental values of PI chemical shifts.

Since HMQC was used to determine the fingerprint profile of each distinct membrane vesicle subfraction, the proton chemical shift region of interest was 3.0 to 5.8 ppm identity peaks, where each phospholipid head group and the glycerol backbone proton is observed. Table 2 shows the specific values of the proton identity peaks for each phospholipid.

Other chemical shifts in this region correspond mostly to protons on the glycerol backbone or to head groups that overlap one another. The common proton on the backbone of all glycerophospholipids is at 5.2 to 5.4 ppm (C**H**OCOR) (4). These identity peaks and their correlation with phosphorus in the HMQC spectra define the fingerprint profile.

Figures 2A and 2B demonstrates the fingerprint profiles of a mixture of (A) phospholipid standards at 4 μM DPPC, 3.9 μM PI, 3.9 μM DPPS, and 3.9 μM DPPE and (B) a mixture of phospholipid standards at 0.4 μM DPPC, 0.30 μM PI, and 0.4 μM DPPE. The F_1 and F_2 coordinates for DPPC, PI, DPPE, and DDPS are –0.5, 3.50 ppm; –0.17, 3.83 ppm; 0.20, 3.9 ppm; and 0.44, 3.1 ppm, respectively. Figure 2C shows that a concentration of 0.04 μM per phospholipid is the detection limit for a 20-h HMQC run with the specific parameters indicated in the previous section. In an attempt to shorten recycle time we tried a 10 mM final concentration of chromium (III) acetylacetonate [$Cr(acac)_3$] (17) in the 4 μM mixture of standards. However, this addition resulted in the disappearance of the phospholipid peaks from the 2D spectra.

For the 0.04 μM HMQC (Fig. 2C) , a 1D horizontal slice through the DPPC spectrum gives a signal-to-noise ratio of 3:1 for the DPPC identity peak. This indicates that we are near the limit for sufficient signal to characterize.

Figure 2D is the fingerprint profile of 3.9 μM PI. Unlike other phospholipids, there is a difference in the F_1 coordinate of PI alone and in a mixture of standards. This variation in the phosphorus chemical shift, due to the effect of different fatty acid chains, has also been pointed out in previous studies (7,11). Furthermore, the charged PI is highly sensitive to slight changes of pH, and thus its chemical shift varies to a greater extent than zwitterionic phospholipids such as DPPC. In a mixture of standards, F_1 and F_2 are –0.17, 3.83 ppm, respectively. The F_1 and F_2 values when PI is not in the mixture are –0.24, 3.80 ppm, respectively. It can also be seen that, unlike the phosphorus chemical shift, the proton chemical shift varies only slightly (0.03 ppm). Thus, for identifying the phospholipids in different MV, both coordinates have to be taken into consideration and specific attention has to be paid to the proton identity peak with its correlated phosphorus peak when assigning the phospholipid peaks.

Quantification of standards and determination of their efficiency coefficients K. The most intense peaks in the 2D spectra for each phospholipid, at three concentrations i.e., 4, 0.4, and 0.04 μM, were integrated. For 4 μM DPPC, PI, and DPPE these respective ^{31}P, ^{1}H peaks were –0.5, 3.5 ppm, –0.17, 5.2 ppm, and 0.44, 3.9 ppm. Even at 0.04 μM the most prominent peaks of DPPC, PI, and DPPE were still integrable and the signal-to-noise was greater than 3, as mentioned previously. The linearity of the 2D integrations with respect to the three sets of lipid concentrations is shown in Figure 3.

Since in biological membranes PC is generally more prominent than phospholipids with other head groups, it is taken to be the reference phospholipid. The *K* values of PI with respect to different concentrations of DPPC were calculated as follows:

$$K_{PI/PC} = (4.0\ \mu M/3.9\ \mu M) \times (1357_{PI}/2600_{PC}) \quad [3]$$

$$K_{PI/PC} = 0.53 \quad [4]$$

$$K_{PI/PC} = (0.04\ \mu M/0.039\ \mu M) \times (16_{PI}/25_{PC}) \quad [5]$$

$$K_{PI/PC} = 0.66 \quad [6]$$

The *K* values for PI/DPPC, DPPS/DPPC, and DPPE/DPPC are 0.71 ± 017; 0.88 ± 0.13; and 0.95 ± 0.14, respectively.

TABLE 2
Proton Chemical Shifts of the Phospholipid Head Groups: The Identity Peaks

Identity peaks	Chemical shift (ppm)	Peak profile
PC-N^+-($C\mathbf{H}_3$)$_3$	3.20[a], 3.18[b]	Singlet
PS-C**H**(OCO^-)NH_3^+	4.00[a], 3.93[b]	Multiplet
PI-**H**^{6} of inositol (IUPAC) nomenclature	3.75[a], 3.87[b]	Triple peak (not 1:2:1)
PE-C**H**^{2}N	3.16[a], 3.11[b]	Triplet

[a]From Reference 1.
[b]From Reference 4. PC, phosphatidylcholine; for other abbreviations see Table 1.

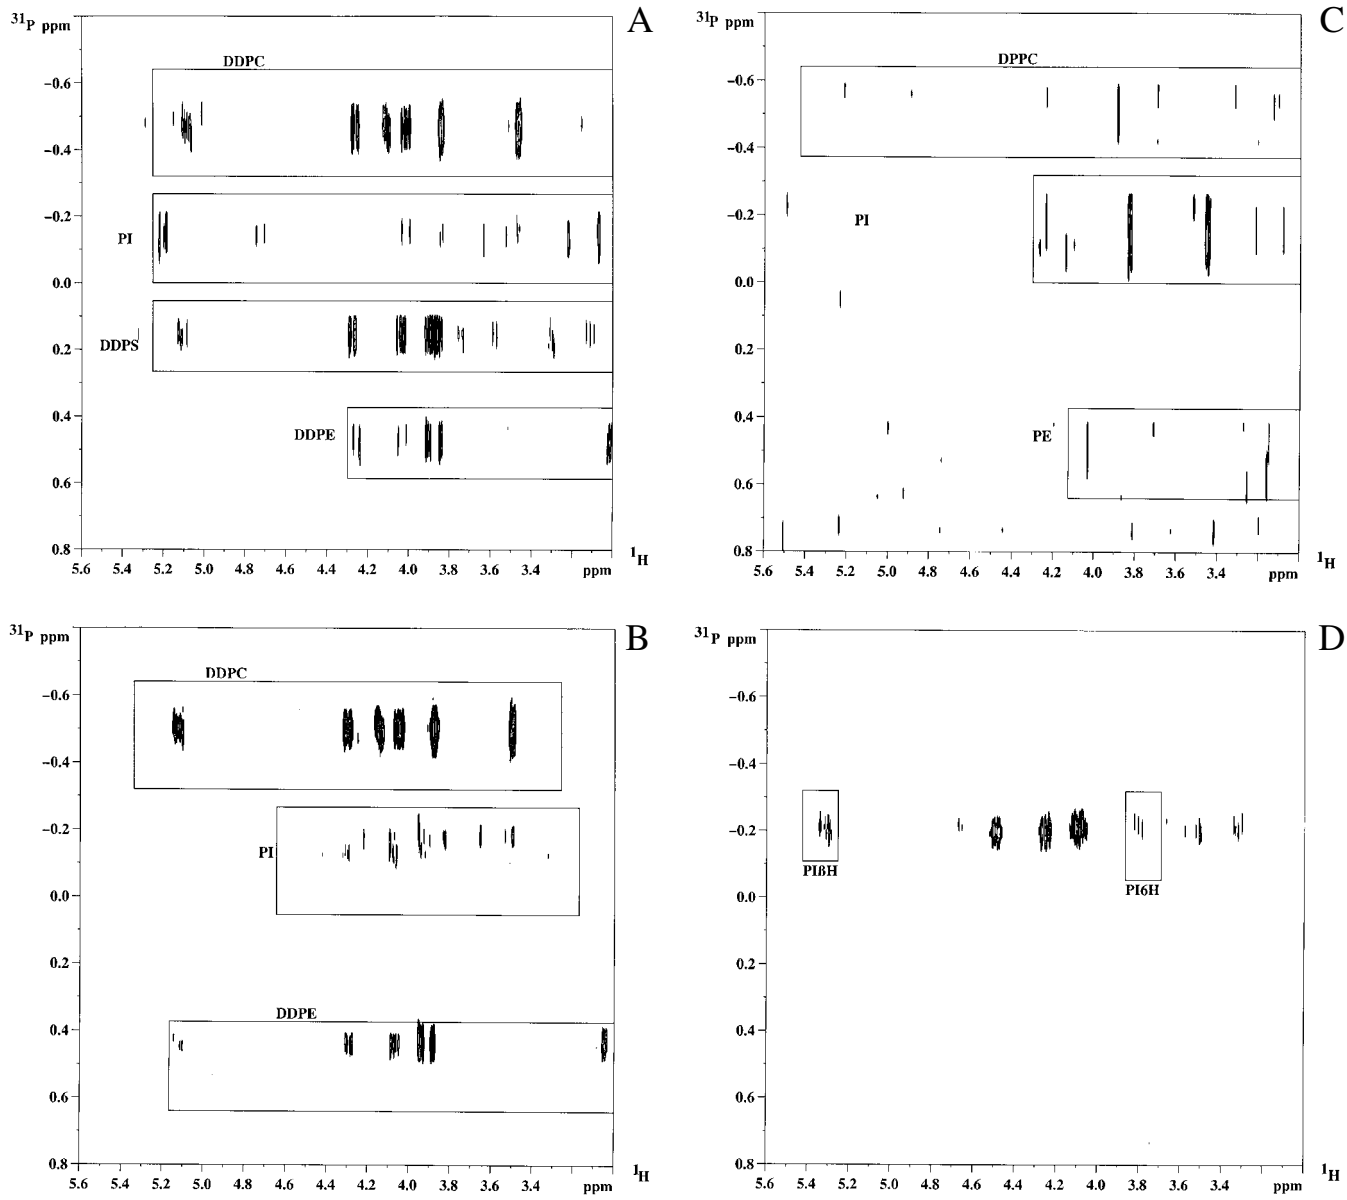

FIG. 2. Heteronuclear multiple quantum coherence (HMQC) fingerprint profiles (A, B, C), all taken at 298.1 K in 100:40:20 (by vol) chloroform/methanol/0.2 M K_4EDTA. (A) 4 μM DPPC, 3.9 μM DPPS, and 3.9 μM DPPE; (B) 0.4 μM DPPC, 0.39 μM Pl, and 0.4 μM DPPE; (C) 0.04 μM DPPC, 0.039 μM Pl, and 0.04 μM DPPE. A one-dimensional horizontal slice through the DPPC peaks gives a signal-to-noise ratio of 3:1, indicating an approach to the limits for reliable integration. (D) HMQC of 3 μM pure Pl standard in 100:40:20 (by vol) chloroform/methanol/0.2 M K_4EDTA at 298.1 K. The labeled regions indicate the identity peak of Pl (–0.2, 3.75 ppm) and the proton on the β carbon of the glycerol backbone (–0.2, 5.2 ppm) (C**H**OCOR), respectively. DPPS, DL-α-phosphatidyl-L-serine, dipalmitoyl; DPPE, DL-α-phosphatidylethanolamine, dipalmitoyl; for other abbreviations see Figure 1.

Standard deviations were calculated from integral values of the three sets of dilutions. To verify the accuracy of the *K* values, they were used to calculate the relative phospholipid molarity in porcine erythrocyte ghosts. Figure 4 shows the HMQC spectrum of the porcine erythrocyte ghosts. The relative phospholipid molarity calculated from the most intense peaks is shown in Table 3. The similarity of the experimental values to those already in the literature (19,20) illustrates that this method of quantification of HMQC spectra is reliable and accurate.

Phospholipid profile and quantification of distinct membrane vesicle subfractions. Figure 5 illustrates the 2D phospholipid profile of the MV1 fraction. MV1 fractions were obtained from three separate preparations of MV0 and analyzed to show the reproducibility of the MV1 phospholipid profile. The fingerprint profile of MV1 demonstrates a peak at –0.2, 3.77 ppm and at –0.2, 5.3 ppm. The triple peak at 3.77 ppm represents the identity peak of PI-$\mathbf{H}^6$ (IUPAC nomenclature) from the inositol head group. The –0.2 ppm chemical shift

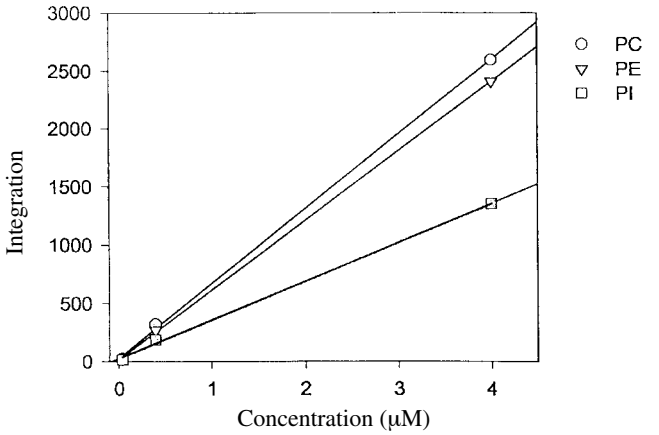

FIG. 3. Integral values from two-dimensional (2D) spectra vs. concentration for phospholipids demonstrating linearity of 2D integrations with phospholipid concentration.

TABLE 3
Phospolipid Composition of Erythrocyte Ghosts

Phospholipids (PL)	Ghost human RBC[a] PL (mol%)	Ghost porcine RBC[b] PL (mol%)	Ghost porcine RBC[c] PL (mol%)
Phosphatidylcholine	30	40	34

corresponds to the PI phosphorus chemical shift when PI is in a pure form and not mixed with other phospholipids. From the unique coherence of the proton triple peak at 3.77 ppm with the phosphorus peak at –0.2 ppm it can be concluded that MV1 is mainly composed of PI.

This result can be directly compared to the pure PI standard (Fig. 2D) and furthermore to the 1D F_2 slice through the characteristic PI triplet structure as shown by Casu *et al.* (1) and Henke *et al.* (6). The absence of the other peaks (–0.2, 4.01 ppm; –0.2, 4.2 ppm; and –0.2, 4.4 ppm) in the MV1 HMQC spectrum, with respect to the PI standard, may be due to the variability in the coherence transfer in a biological environment relative to the pure environment of the standard. This means that a given initial coherence follows a certain pathway in a pure sample through single and multiple quantum levels before it is transferred to a single quantum coherence that can be detected by the NMR spectrometer. Mobility is a crucial factor in coherence transfer; lower mobility may be eliminating the unobserved crosspeaks. Whatever the mechanism, because of the presence of other types of molecules in the MV1 extracts, the coherence transfer pathway and its time of evolution to be transferred to a single quantum coherence may be different from that of the pure standard. However, the –0.2, 3.77 ppm (identity peak) is consistently detected as is the –0.2, 5.3 ppm peak. The 5.3 ppm chemical

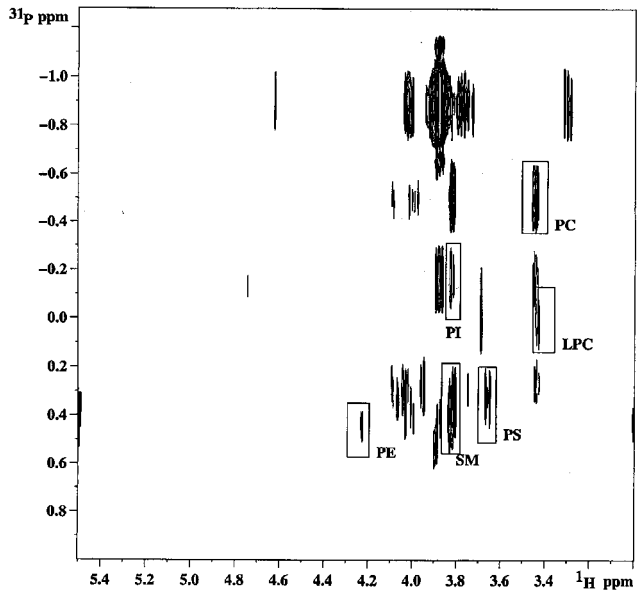

FIG. 4. HMQC of porcine erythrocyte ghosts. The most intense phospholipid peaks were used for calculating relative mol% of phosopholipids and are outlined with a square. The sample also contained tributylphosphate as a standard not used for this analysis. PC, phosphatidylcholine; for other abbreviations see Figures 1 and 2.

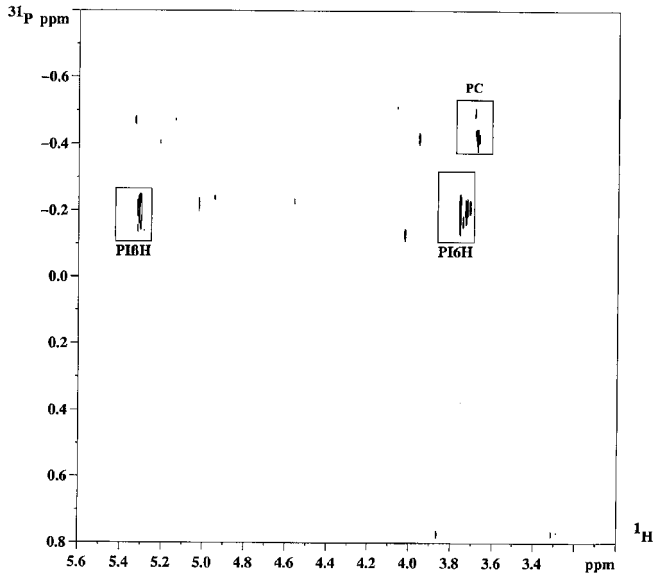

FIG. 5. HMQC fingerprint profile of MVI phospholipids showing PI is the main component. The identity peak at –0.22, 3.75 ppm illustrates the characteristic proton triplet of PI-**H**^{6} of the inositol head group and the proton on the β carbon of the glycerol backbone. The profile of this identity peak is analogous to that shown in Henke *et al.* (6) and to the PI standard in Figure 2D. PC is present as a minor fraction. For abbreviations see Figures 1 and 2.

TABLE 4
Phospholipid Composition of Egg Cytoplasmic Membrane Vesicles and Related Membranes

Phospholipids (PL)	ER rat liver[a] PL (mol%)	Golgi, rat liver[a] PL (mol%)	MV0 PL (% total)	MV1 PL (mol%)	MV2 PL (mol%)	MV3 PL (mol%)
Phosphatidylcholine	58	50	63	11 ± 5[b]	62	73
Phosphatidylethanolamine	22	20	21	—	28	13
Phosphatidylserine	3	6	7.5	—	5	4
Phosphatidylinositol	10	12	3.1	89 ± 5[b]	6	10

Lysophosphatidylglycerides	No accurate data	No accurate data	5.2	—	—	—

[a]From Reference 18.
[b]Standard deviation from three separate MV1 extractions.

shift corresponds to the proton of the β carbon on the glycerol backbone (C**H**OCOR).

The mole percentage of PC relative to PI was determined in the following way:

$$\frac{[PC]}{[PI]} = K_{PI/PC}\frac{(A_{PC})}{(A_{PI})} \quad [7]$$

$$\frac{[PC]}{[PI]} = 0.7\frac{(76)}{(563)} = 0.094 \quad [8]$$

Values from these replicates were normalized and the mole percentage for the MV1 fraction were calculated to be 89 ± 5 and 11 ± 5% for PI and PC, respectively.

Figure 6 represents the phospholipid profile of MV2. Similar spectra (not shown) are found for MV3. MV2 is composed of DPPC, PI, DPPS, and DPPE with the following identity peaks: PC (–0.56, 3.5 ppm), PI (–0.25, 3.36 ppm), PS (0.29, 4.1 ppm), and PE (0.4, 3.05 ppm). MV3 also is composed of the above phospholipids with PC at –0.53, 3.5 ppm; PI at –0.22, 3.9 ppm; PS at 0.2, 3.7–3.8 ppm, and PE at 0.44, 3.04 ppm. The order of appearance of each phospholipid relative to the reference standard, DPPC, remains constant in both MV2 and MV3. All peaks were consistently twofold greater than the noise level. The lowest integration value of the phospholipid peaks was 89 and the signal-to-noise ratio of a slice was 3:1.

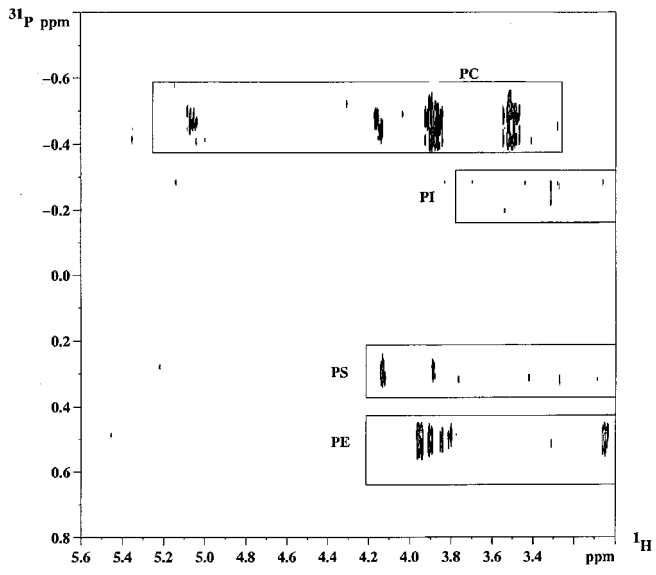

FIG. 6. Phospholipid profile of MV2 membrane vesicles, showing a completely different profile from MV1. MV2 is composed of PC, PI, PS, and PE. MV2 was extracted from the same sucrose gradient as MV1. For abbreviations see Figure1.

The *K* values were used to calculate the mole percentage phospholipid per membrane subfraction. MV2 contains enzymatic markers of the Golgi and ER (9) so results were compared to ER and Golgi from rat liver (18) (Table 4). It can be concluded that MV0, MV2, and MV3 have similar compositions typical of the ER or Golgi membranes. However, MV1 exhibits a striking difference. This membrane subfraction is mainly composed of phosphatidylinositol with PC being the minor phospholipid.

This new method of analysis may be used as a general protocol for the simultaneous identification and quantification of phospholipids in cellular membrane subfractions at a detection limit of 0.04 μM per phospholipid, with minimum sample handling.

ACKNOWLEDGMENTS

The authors are grateful to Drs. John M. Pearce and Thomas Glonek for sharing sample preparation protocols and reviewing the initial phosphorus NMR spectra. This work was supported by U.S. National Institute of Health Award GM55970 and an Amherst College Faculty Research Award to D.L.P.

ABSTRACT: Fatty acid differences, including docosahexaenoic acid (DHA; 22:6n-3) have been shown in the brains of Alzheimer's patients (AD) as compared with normal age-matched individuals. Furthermore, low serum DHA is a significant risk factor for the development of AD. The relative concentration of DHA and other fatty acids, however, in the plasma of AD patients compared with patients with other kinds of dementias (other dementias; OD), patients who are cognitively impaired but nondemented (CIND), or normal patients is not known. In this study we analyzed the total phospholipid, phosphatidylcholine (PC), phosphatidylethanolamine (PE), and lysophosphatidylcholine (lysoPC) fractions of plasma from patients diagnosed with AD, OD, or CIND and compared them with a group of elderly control subjects with normal cognitive functioning. Plasma phospholipid and PC levels of 20:5n-3, DHA, total n-3 fatty acids, and the n-3/n-6 ratio were lower in the AD, OD, and CIND groups. Plasma phospholipid 24:0 was lower in the AD, OD, and CIND groups as compared with the group of control patients, and total n-6 fatty acid levels were higher in the AD and CIND groups only. In the plasma PE fraction, levels of 20:5n-3, DHA, and the total n-3 fatty acid levels were significantly lower in the AD, OD, and CIND groups. DHA levels were lower in the lysoPC fraction of CIND individuals only. There were no other differences in the fatty acid compositions of the different phospholipid fractions. Therefore, in AD, OD, and CIND individuals, low levels of n-3 fatty acids in the plasma may be a risk factor for cognitive impairment and/or dementia. Interestingly, a decreased level of plasma DHA was not limited to the AD patients but appears to be common in cognitive impairment with aging.

Abbreviations: AA, arachidonic acid; AD, Alzheimer's Disease; ANCOVA, analysis of covariance; ANOVA, analysis of variance; CIND, cognitively impaired nondemented; CNS, central nervous system; CT, computer tomography; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; lyso PC, lysophosphatidylcholine; MUFA, monounsaturated fatty acid; N, normal; OD, other dementias; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PL, phospholipid; PUFA, polyunsaturated fatty acid; SAT, saturated fatty acid; TLC, thin-layer chromatography.

Alzheimer's disease (AD) is a neurodegenerative disorder that is characterized by progressive memory loss, intellectual decline, and eventually global cognitive impairment. Major symptoms include short- and long-term memory loss, impairments of language and speech, decline of abstract reasoning, and visual-spatial perceptual changes. The incidence of dementia in Western countries, of which AD is the leading cause, is estimated to be approximately 10% of the population over the age of 65 y and 47% of the population over 80 y of age (1). Although much research has been conducted in the area of prevention and treatment of AD, the cause of AD is as yet unknown. It is most likely that a combination of factors contributes to the etiology of AD.

The diversity in the fatty acid composition of brain phospholipids (PL) may influence the biophysical properties of membrane lipids including, for example, fluidity properties and charge (2). Optimal functioning of membrane proteins of the neuron depends on membrane potential, receptor occupancy, phosphorylation-dependent intermolecular associations, and protein and lipid composition (2). In neurons, synaptosomes have the highest concentration of long-chain polyunsaturated fatty acids (PUFA), including docosahexaenoic acid (DHA) and arachidonic acid (AA) (3). The exact function of these PUFA is not clear although AA is the main substrate for synthesis of various eicosanoid mediators (4) and DHA appears to exert a role in membrane fluidity and long-term potentiation, a process that is necessary for memory function (5).

Expanding knowledge in the area of lipid biochemistry suggests that AD is associated with brain lipid defects (6–9). Decreased levels of AA and DHA have been shown in phosphatidylcholine (PC) and phosphatidylethanolamine (PE) fractions from various regions of the AD brain (frontal grey, frontal white, hippocampus, pons) by some (6,10) but not all investigators (11). Aging itself has no influence on the fatty acid composition of PC and/or PE in these fractions of the brain (6). Membrane destabilization, due to a loss of potentially important unsaturated fatty acids, may contribute to AD pathogenesis or it may facilitate the deposition of the neuro-

toxic amyloid β-protein. Other lipid defects that have been associated with the AD brain include a deficiency in the PL ethanolamine plasmalogen (12) and PE (13), and increases in phosphatidylinositol and PC (7) in various brain regions.

As yet, it is not clear whether the plasma fatty acid composition of AD patients differs from other aging patients. It is also not known whether there are plasma fatty acid differences of individuals with other types of dementia or cognitive impairment as compared with elderly controls. It is known, however, that a decreased level of at least one fatty acid in plasma, DHA, is a risk factor for the development of AD (14). Several neurological disorders, which present with altered neuronal fatty acid composition, are also associated with changes in plasma fatty acid composition, such as schizophrenia, depression, attention deficit hyperactivity disorder, and retinitis pigmentosa (15–18). Although AD is not similar to the above-mentioned neuronal disorders, it is possible that the plasma fatty acid composition of AD patients is altered relative to control subjects as well as subjects with other kinds of cognitive impairment.

In this study we examined whether the plasma fatty acid composition of various PL fractions [total PL, PC, PE, lysophosphatidylcholine (lysoPC)] of AD patients differed from those of normal elderly control subjects as well as patients with other kinds of dementias and cognitive impairments. These PL fractions were chosen as they constitute the major repository for fatty acids and are structurally important. The cognitively impaired nondemented (CIND) group was included in order to examine the cross-sectional continuum of cognitive changes in people who were aging normally to those who showed cognitive impairment with no dementia to those with dementia in order to shed light on potential developmental changes in the individual.

MATERIALS AND METHODS:

Subjects. Participants in this study included 84 people who were recruited from a large urban center, and who were screened for one of two ongoing longitudinal studies. Participants in our normal (N) control group are part of a study investigating predictors for the development of AD (19). The other study involves the identification of cognitive and other factors associated with increased risk of harm among seniors living alone in the community (20). Of 96 subjects who were eligible to participate in this study, 84 agreed to donate their blood for this investigation. Informed consent was obtained from all subjects or their legal guardians. Each individual in the study received a thorough physical examination, a computer tomography (CT) scan, and hematology, renal, liver, and metabolic function tests, as well as a detailed neuropsychological assessment by a geriatrician. For the purposes of this investigation, participants were classified as being members of one of the following four groups.

(i) Normal control group. Nineteen people were individually screened by a study physician to ensure there was no history or evidence of brain damage, psychiatric illness, chronic drug or alcohol abuse, or any medical illness likely to affect the brain. All individuals meeting medical criteria for the study were screened with a battery of neuropsychological tests to ensure normal cognitive functioning.

(ii) AD group. Nineteen individuals were diagnosed as having AD based on the consensual decisions of a board-certified geriatrician and a board-certified neuropsychologist that the person met the National Institute of Neurological and Communication Disorders-Alzheimer's Disease and Related Disorders Association criteria for probable AD (21). All individuals were medically screened to ensure that they did not have alternative causes for their cognitive impairment, including chronic alcohol or drug abuse, chronic infections, stroke, hypoxia, metabolic disorders, nutritional disorders, intracranial mass lesions, psychoses, brain trauma, or other neurological diseases. If evidence for these other causes of cognitive impairment was noted they were excluded from the AD group.

(iii) Other dementia (OD) group. Ten individuals met diagnostic criteria for dementia (DSM-IV; Ref. 22) with an etiology other than AD. Eight participants in this group were diagnosed with vascular dementia based on DSM-IV criteria and CT scan evidence of a vascular lesion, one had alcohol-induced persisting dementia, and one had dementia due to head trauma.

(iv) CIND group. Thirty-six were categorized as CIND if they did not meet the DSM-IV criteria for dementia but were found on the neuropsychological examination to score at least one standard deviation below the norm for their age group on tests of verbal and visual memory, language, apraxia, or other areas of cognitive functioning.

Measures. The following tests were used for the neuropsychological diagnostic assessment of the subjects. The Weschler Adult Intelligence Scale-Revised (WAIS-R) (23), Digit symbol, California Verbal Learning Test (24), Rey Osterrieth copy and short delay (25), the Benton Visual Naming Test (26), and the Boston Naming Test (27).

Blood collection. For each participant 10–15 mL of blood was collected by antecubital venipuncture into tubes containing the anticoagulant sodium citrate. Centrifugation (15 min, 3,000 rpm) was carried out on the samples, and 1.5 mL of plasma was removed and placed into Eppendorf tubes for storage at –70°C until analysis. Samples were analyzed for saturated fatty acid (SAT), PUFA and monounsaturated fatty acid (MUFA) composition of total PL, PC, PE, and lysoPC fractions.

Fatty acid analysis of PL, PC, PE and lysoPC. Total PL, PC, PE, and lysoPC were isolated from plasma following lipid extraction as described by Folch (28). The fatty acid analysis of the total PL, PC, PE, and lysoPC was accomplished following thin-layer chromatography (TLC), transmethylation, and gas–liquid chromatography. The individual phospholipids (PC, PE, and lysoPC) were separated by two-dimensional TLC using pre-coated Silica Gel 60 plates (20 × 20 cm, 250 μm; EM Separations Technology, Merck, Gibbstown, NY) and developed in a solution of chloroform/methanol/acetic acid/water in a ratio of 50:37.5:3.5:2. Silica bands containing these PL bands were scraped off, and 5.0 μL of 17:0 standard

was added as an internal standard. Transmethylation was as previously described (29). Gas–liquid chromatography of the fatty acid methyl esters from the total PL, PC, and PE fractions, was performed using a Varian 3800 gas chromatograph (Palo Alto, CA) equipped with a 30 m DB-23 capillary column (0.32 mm internal diameter, 0.1 μm film thickness) using hydrogen as the carrier gas (60 cm/s) with flow rates for air hydrogen, and nitrogen of 320, 35, and 25 mL/min, respectively. The initial column temperature (60°C) was held for 0.8 min and increased to 170°C at 20°C/min. Next, the column temperature was increased to 193°C at a rate of 1.5°C/min and then to 250°C at a rate of 40°C/min. The initial temperature of the injector (60°C) was held for 0.3 min and then increased to 250°C at 175°C/min and held for 25 min.

Statistical analysis. All data are reported as mean (standard error; SEM). Comparisons of demographic characteristics among groups were analyzed by analysis of variance (ANOVA), followed by least squared means only if $P < 0.05$. Significance is reported if $P < 0.05$. Fatty acid composition multifactorial data were analyzed by ANOVA (SAS 6.0, SAS Institute, Cary, NC). If $P < 0.05$, this was followed by analysis of covariance (ANCOVA) with age and education as the covariates. Least squared means analysis was performed only if $P < 0.05$ for the ANCOVA. Significance is reported if $P \leq 0.05$.

RESULTS

Table 1 shows the subject characteristics for all groups. There were more females than males in every group (AD, CIND, and N) other than the OD group, which had equal numbers of each sex. Patients with AD and CIND were significantly older than controls, but the average age of patients with OD was not significantly different from controls ($P > 0.05$). There was also a significant difference in the number of years of education (a gross indicator of socioeconomic levels) among the four groups: patients with AD, OD, and CIND had less education than controls. In order to correct for this, in statistical comparisons between the four groups, an ANCOVA, with age and education as the covariates, was done to account for possible effects of these parameters .

Multifactorial ANOVA results were $P < 0.05$ for total PL, PC, PE, and lysoPC. The fatty acid composition of the plasma total PL of individuals who were designated AD, OD, CIND, or N are given in Table 2 [mean (SEM), wt%]. The levels of most fatty acids from plasma PL were similar among the four groups. However, the amounts of 20:5n-3, 22:6n-3, 24:0, total n-3 fatty acids, and the n-3/n-6 ratio were lower in the AD, OD, and

Total MUFA	17.0	(0.5)	17.6	(0.6)	16.9	(0.3)	16.1	(0.4)
Total PUFA	39.3	(0.4)	38.1	(0.8)	39.4	(0.2)	39.2	(0.5)
Total n-3	5.6	(0.2)[a]	6.0	(0.3)[a]	6.0	(0.3)[a]	7.8	(0.5)[b]
Total n-6	33.7	(0.5)[a]	32.1	(0.7)[a,b]	33.4	(0.3)[a]	31.4	(0.6)[b]
n-3/n-6	0.17	(0.01)[a]	0.19	(0.01)[a]	0.18	(0.01)[a]	0.25	(0.02)[b]
Total PL (mg/dl)	209.0	(8.4)	202.5	(7.1)	224.2	(6.4)	211.4	(6.9)

[a]Values are reported as means (SEM) for $n = 19$ (AD), 10 (OD), 36 (CIND), and 19 (N) individuals. [a,b]Significantly different as measured by ANCOVA ($P < 0.05$) followed by least squared means. Fatty acids found at less than 0.5% were not included in the table. Abbreviations: SAT, saturated fatty acid; MUFA, monounsaturated fatty acid; PUFA, polyunsaturated fatty acid; PL, phospholipid; DHA, docosahexaenoic acid; PL, phospholipid; for other abbreviations see Table 1.

CIND groups as compared with controls (N). Total n-6 fatty acids were significantly higher in the AD and CIND groups only. The levels of total SAT, MUFA, and PUFA as well as total PL (mg/dL) were similar among the four groups ($P > 0.05$).

Table 3 shows the levels of fatty acids in the plasma PC fraction of individuals designated as AD, OD, CIND, or N. The plasma PC fatty acid composition differed among the four groups. The levels of 20:5n-3, 22:6n-3, total omega-3 fatty acids, and the n-3/n-6 ratio were lower in the AD-, OD-, and CIND-designated individuals than in the controls (N). Total SAT, PUFA, and MUFA as well as total n-6 fatty acids and total PC (mg/dL) did not differ among the four groups ($P > 0.05$).

The fatty acid composition of the plasma PE fraction (AD, OD, CIND, and N) is given in Table 4. Levels of 20:5n-3 and 22:6n-3 were significantly lower in the AD, OD, and CIND groups as compared with control (N). Total n-3 fatty acids were also significantly lower in the AD, OD, and CIND groups. As in the PC fraction there were no significant differences in total SAT, MUFA, n-6 fatty acids, and total PE (mg/dL) ($P > 0.05$). There was also no difference in the n-3/n-6 fatty acid ratio among the groups ($P > 0.05$).

Table 5 shows the fatty acid composition of plasma lysoPC in individuals designated as AD, OD, CIND, and N. There were no significant differences in the fatty acid composition of lysoPC as shown ($P > 0.05$). However, DHA levels were significantly lower in individuals with CIND (0.10 %) vs. AD (0.49 %), OD (0.40 %), and N (0.48%) (data not shown).

DISCUSSION

This is the first study to compare the compositions of plasma total PL, plasma PC, plasma PE, and plasma lysoPC fractions from patients with AD, OD, and CIND with a group of normal elderly controls. Recent studies suggest that dietary intake of fish, the most important source of long-chain n-3 fatty acids such as 20:5n-3 (eicosapentaenoic acid; EPA) and DHA, is inversely correlated with the development of dementia, and in particular Alzheimer's disease, in Western countries (30–32). Furthermore, Kyle *et al.* (14) suggest that decreased DHA levels in the plasma PC of elderly individuals is predictive of the development of AD after 10 y. These results, coupled with the results of earlier studies (6,10) showing decreased levels of DHA in the brain of individuals with AD, as well as papers suggesting a link between decreased levels of DHA in serum and various neurologic pathologies (15–18), suggest that plasma levels of DHA, and possibly other n-3 fatty acids, may be lower in the plasma of AD patients as well as patients with other dementias.

Dietary n-3 fatty acids consist mainly of α-linolenic acid (18:3n-3), EPA (20:5n-3), and DHA (22:6n-3). In young, healthy individuals, it is generally accepted that total plasma PL n-3 fatty acid status (including DHA status) represents n-3 fatty acid intake (33–35). Although metabolism of α-linolenic acid to EPA and DHA occurs in humans, it is limited to approximately 5% (36). Comparison of fatty acid levels between individuals with AD, OD, and CIND and normal elderly individuals clearly suggests differences in the fatty acid composition of total PL. The decreased levels of EPA (by approximately 42%), DHA (by 17–33%) and total n-3 levels (by 23–28%) in the plasma PL of patients with AD, OD, and CIND suggest that the dietary intake of the n-3 fatty acids is lower than that of normal subjects. The possibility of increased breakdown, either before or after disease onset, cannot be ruled out. The increased levels of F_4-isoprostanes ob-

[a]Values are reported as means (SEM) for $n = 19$ (AD), 10 (OD), 36 (CIND), and 19 (N) individuals. [a,b]Significantly different as measured by ANCOVA ($P < 0.05$) followed by least squared means. Fatty acids found at less than 0.5% were not included in this table. PE, phosphatidylethanolamine; for other abbreviations see Tables 1 and 2.

served in both the brain and cerebrospinal fluid of AD patients (37,38) suggest that DHA breakdown and other oxidative damage are occurring in AD. Furthermore, results indicate that it possibly occurs early in the course of AD. Although the reason for decreased levels of n-3 fatty acids in plasma PL of AD, OD, and CIND patients is not clear, our data are in agreement with those of Kyle *et al.* (14), who suggested that decreased DHA levels were found to be a risk indicator for the development of AD, and with recent publications inversely linking fish intake to development of dementia (30–32). There is very little information on fatty acid status and actual cognitive functioning in adults. It is not clear whether DHA levels in various parts of the brain play a role in cognitive functioning of human adults, including the elderly.

Decreased levels of EPA (by 41%) and DHA (by 22–35%) were also observed in the PC fraction of individuals with AD, OD, and CIND vs. normal individuals. This resulted in decreased levels of total n-3 fatty acids (25–32%) and a decreased ratio of n-3/n-6 fatty acids (28–36%) in these groups. Since PC makes up most of the total PL in plasma (approximately 75%), these results were expected. The decreased levels of DHA in plasma PC support the results of Kyle *et al.* (14). Interestingly, although EPA (54–57%), DHA (26–44%), and total n-3 fatty acid (25–40%) levels were also decreased in the plasma PE of

[a]Values are reported as means (SEM) for $n = 8$ (AD), 5 (OD), 10 (CIND), and 10 (N) individuals. Fatty acids found at less than 0.5% are not included in this table. For abbreviations see Tables 1 and 2.

AD, OD, and CIND patients, as compared with normal individuals, there were no significant differences in the ratio of n-3/n-6 fatty acids within this faction. The decreased levels of DHA, EPA, and total n-3 fatty acids in the PE fraction of AD, OD, and CIND individuals, are consistent with the decreased levels of these fatty acids as observed in PC and total PL.

This study is the first to examine differences in the fatty acid composition of the PE and lysoPC fractions in AD, OD, and CIND individuals as compared with elderly controls. In contrast with the differences in n-3 fatty acid levels of the PL, PC, and PE fractions, there were no measurable differences in the fatty acid composition of lysoPC in AD, OD, or CIND patients as compared with the normal group.

It has been suggested that the PC pool is used as a pathway for the supply of various PUFA, including DHA, to the brain (38). Thus, decreased levels of DHA in total PL, PC, and PE in the plasma of AD patients may also be partially responsible for decreased levels of this fatty acid in the brain. It is not clear whether individuals with CIND and OD also have decreased brain levels of DHA. Although decreased brain levels of DHA could be due to a combination of decreased plasma DHA levels and increased DHA breakdown in the brain itself, there is as yet no clear indication as to whether the decreased DHA levels in plasma occur prior to or post-disease onset. The results of Kyle *et al.* (14) and others (30–32) suggest however, that plasma fatty acid compositional changes may occur prior to disease onset.

The decreased levels of EPA in the plasma of the AD, OD, and CIND patients as observed in this study can be explained by decreased consumption of EPA-containing foods, such as fish or fish oils. There are no other studies with which to compare these results, as levels of EPA have not been previously compared in plasma of AD, OD, and CIND individuals. Thus, one can hypothesize that decreased fish consumption prior to disease onset, as suggested by Kalmijn *et al.* (30,31) and Grant (32), may be at least partially responsible for both the lower levels of EPA and DHA and the initiation or potentiation of cognitive decline. One limitation of this study is that no dietary intakes or histories were done on the patients. Thus, it is not clear whether the patients presently consume, or consumed in the past, diets that were lower in n-3 fatty acids. Furthermore, socioeconomic background may have played a role in dietary choices since the patient groups were less educated than the control group, and education is a gross indicator of socioeconomic level. However, our statistical analysis indicated that differences among the groups in levels of EPA and DHA remained when education was used as a covariate in these analyses. It remains to be tested whether decreased levels of n-3 fatty acids in the plasma and/or brain of patients with AD, as well as OD and CIND, contribute to disease symptoms, or whether they were only a biochemical change that occurs alongside those other changes responsible for disease symptoms. However, data in humans suggest that neural membranes are characterized by high concentrations of DHA (approximately 31% in adult human cerebral cortex PE) (40), which suggests an important role in central nervous system (CNS) functioning. Furthermore, dietary DHA levels in infants correlate with brain levels of DHA as well as cognitive functioning (41,42). The actual role of DHA in CNS functioning is not clear, although it is likely that more than one process is involved (40).

Very few studies have investigated whether DHA, or n-3 fatty acid, supplementation reduces the occurrence and/or the symptoms of AD and the other dementias. As mentioned earlier, Kalmijn *et al.* (30,31) and Grant (32) have suggested that decreased fish consumption is correlated with cognitive impairment. Another study involving the supplementation of AD patients with SR-3 (n-3/n-6, 1:4) in a double-blind manner showed improvements in mood, cooperation, appetite, sleep, and short-term memory (43). A more recent study, by Terano *et al.* (44), suggests that supplementation of elderly people with mild to moderate dementia (of thrombotic cerebrovascular disorders) with 0.72 g DHA per day for one year resulted in improvements in both the serum fatty acid content and scores on the Mini-Mental State examination and the Hasegawa's Dementia rating scale. A study in adult rats suggests that chronic administration of DHA results in a significant improvement in the spatial learning deficit following occlusion (45). Although data on the effects of n-3 fatty acid supplementation on symptoms of dementia and cognitive decline are limited, the effort to increase fish, fish products, or other sources of omega-3 fatty acids in the diets of both the population at large and the elderly seems prudent. This may be difficult to do in groups of noninstitutionalized elderly, such as the subjects in our study, but would be feasible for the elderly in nursing homes, retirement homes, and hospitals.

In conclusion, this study suggests that the fatty acid composition of plasma total PL, as well as PC and PE, differs between individuals with AD, OD, and CIND as compared with healthy elderly men and women. In general, decreased levels of EPA, DHA, total n-3 fatty acids, and the ratio of n-3/n-6 fatty acids, were noted. It is not clear whether the decreased levels of these fatty acids are due to dietary differences between the groups, or whether the levels of these fatty acids decreased prior to or after disease onset. Furthermore, it is not clear why decreased levels of EPA, DHA, and total n-3 fatty acids were observed in the OD and CIND groups, in addition to the AD group. It is likely that some of the CIND patients had incipient AD and were showing early signs of the disease. Of the patients in the OD group, 80% had vascular dementia, and although there is no evidence to suggest that plasma DHA levels are inversely correlated with stroke, there is indirect evidence to suggest that DHA supplementation improves cognition in patients with dementia due to stroke (43). It would be interesting to answer these questions as well as to determine the effect of supplementation with DHA, or total n-3 fatty acids, in future studies. Differences in levels of various n-3 fatty acids in the plasma of AD, OD, and CIND individuals may add further information to our expanding knowledge of biochemical abnormalities that occur outside of the brain in AD and other dementias.

ACKNOWLEDGMENTS

We would like to thank the Scottish Rite Charitable Foundation for funding this investigation. In addition, special thanks go to Dr. Diana Philbrick for her input in the development of the manuscript.

ABSTRACT: Magnetic resonance spectroscopy (^{1}H MRS) and imaging (MRI) were used to investigate the effects of a bout of moderate prolonged exercise on intra (IMCL)- and extramyocellular lipid (EMCL) utilization in the soleus, tibialis anterior, and gastrocnemius muscles of five trained human subjects. MRI and ^{1}H MRS measurements were obtained before and after a 90 min run on a calibrated treadmill at a velocity corresponding to 64 ± 1.5% of each subjects' maximal rate of oxygen consumption. There were significant decreases in IMCL following exercise in the tibialis (pre: 22.37 ± 4.33 vs. post: 15.16 ± 3.25 mmol/kg dry wt; $P < 0.01$) and soleus (pre: 36.93 ± 1.45 vs. post: 29.85 ± 2.44 mmol/kg dry wt; $P < 0.01$) muscles. There was also a decrease in the gastrocnemius muscle, although this did not reach the level of significance (pre: 33.78 ± 5.35 vs. post: 28.48 ± 5.44 mmol/kg dry weight; $P < 0.10$). No significant changes were observed in EMCL or subcutaneous fat. In conclusion, this study showed that IMCL were significantly utilized in the tibialis and soleus muscles of aerobically endurance-trained humans. The absence of significant utilization of IMCL in the gastrocnemius may reflect differences in fiber type and/or intensity of contraction for each muscle group.

Paper no. L8579 in *Lipids 35*, 1313–1318 (December 2000).

There is increasing interest in the study of intramyocellular lipid (IMCL), both because of its potential role as an energy depot and because of its possible contribution to the pathogenesis of certain diseases (1–3). IMCL accounts for approximately 2,000–3,000 kcal of stored energy, making it a greater source of potential energy than muscle glycogen, which in an average person can contribute 1,000–2,000 kcal (1).

Compared to glycogen utilization by muscle, relatively little is known about net IMCL oxidation during exercise. It has been suggested that during moderate-intensity exercise, total fat oxidation is far in excess of the rate of plasma free fatty acids and triglyceride (TG) uptake, requiring additional net fat oxidation from a pool of IMCL (4). However, several groups have investigated IMCL levels following exercise with variable results. While some groups have reported significant reductions in IMCL following exercise (1–3,5–7), other groups have reported no changes in IMCL (8–10). The reason for the discrepancy is unclear, but differences in subject population, type, intensity and duration of exercise, and variations in methodology may be important contributory factors.

A number of studies have shown that *in vivo* magnetic resonance spectroscopy (MRS) can be utilized to study muscle TG in human subjects (11–16). The advantages of this technique over muscle biopsy include its noninvasive nature and its significantly higher reproducibility of measurements (11,13). This has opened up the opportunity to assess changes in IMCL metabolism in human subjects in different regions within a muscle and in different muscle groups. In a recent study of a single subject, Boesch *et al.* (11) showed a net decrease in IMCL levels in the tibialis muscle following 3 h of cycling (11), while Krssak *et al.* (16) reported a significant decrease in IMCL in the soleus muscle following a 2–3 h treadmill run to exhaustion at 65–70% maximal rate of oxygen consumption (VO_2max). Rico-Sanz *et al.* (13) reported no net utilization of IMCL following a protocol of alternating velocity. These results, as with needle biopsy studies, suggest that IMCL utilization may be conditional to factors such as type, intensity, and duration of exercise.

In this study we have used *in vivo* ^{1}H MRS and MR imaging (MRI) to determine the extent to which IMCL and extramyocellular lipids (EMCL) are utilized during exercise, in endurance-trained athletes, during a 90-min run at 64 ± 1.5% VO_2max. The results showed that levels of IMCL were significantly reduced in the tibialis and soleus muscles after the exercise program.

METHODS

Six healthy, non-smoking Caucasian male subjects (age 35.0 ± 1.5 yr) were studied. The subjects, all distance runners, with recent half-marathon times of less than 1 h 40 min, were recruited from running clubs in London. Written informed consent was obtained from all volunteers. The research was approved by the Ethics Committee of the Royal Postgraduate

Medical School, Hammersmith Hospital, London (REC. 96/5030). Exclusion criteria included claustrophobia, metal implants, medication, or sports supplements. One subject was not included in the final data analysis, as he struggled to complete the exercise protocol and his VO_2max during the run was considerably higher than the 64% VO_2max required in the protocol (he was running at close to 85% VO_2max). Furthermore, it was subsequently ascertained that this subject had completed a full marathon the previous day, thus invalidating his inclusion in the study.

Exercise testing. All participants were assessed for their physical fitness at the National Sports Medicine Institute of the UK (Sports and Exercise Performance Unit) prior to inclusion in the study. All tests were performed on fully rested subjects, i.e., no training in the 48 h preceding the test, and all subjects were asked to maintain their standard pre-test dietary and physical preparation. This was done to avoid potential confounding factors such as changes in dietary and physical activity influencing muscle TG content (17).

VO_2max. VO_2max measurements were made for each subject 2–7 days prior to the exercise test. The British Association of Sport and Exercise Sciences (BASES) physiological testing guidelines (1997) and protocol for middle- and long-distance runners were used to assess VO_2max (18). In brief, each subject performed an incremental velocity treadmill running test with a 1% elevation. Treadmill velocity was then incremented 1 km/h every 2 min until the runner reached a respiratory quotient of approximately 1. Following this, the treadmill elevation was increased by 1% per minute, while maintaining the same constant velocity achieved in the last 2-min stage. All subjects were encouraged to continue the test to volitional exhaustion. Oxygen consumption was measured by continuously analyzing expired air for percentage of oxygen and carbon dioxide using an on-line, breath-by-breath metabolic cart (Medgraphics CPX/D system; Medical Graphics Corporation, Minneapolis, MN). Subjects rated their perceived exertion in the last 30 s of each treadmill stage using an unmodified Borg scale (19). Subjects' heart rates were monitored continuously throughout the test (using a Hewlett- Packard 43120A combined 3-lead electrocardiogram monitor/defibrillator). Resting (seated) heart rate (HR) before the test, and recovery HR (3 min immediately posttest) were also recorded. All measurements were carried out by the same accredited (BASES) exercise physiologist (JM). The HR corresponding to VO_2max was taken as maximum HR.

MRS and MRI. Imaging and spectroscopy data were acquired with a 1.5T Picker Eclipse multinuclear system using a quadrature bird-cage coil 30 cm in diameter. In each examination, subjects lay in a supine position with the left calf placed along the axis of the coil and immobilized with firm padding. Transverse T_1-weighted MR images [repetition (TR), 600 ms; echo time (TE), 16 ms] were acquired to determine the placement of the ^{1}H MRS voxels, with a slice thickness of 5 mm, a 20-cm field of view and 192 × 256 data matrix. Spectra were obtained from the soleus, tibialis, and gastrocnemius muscles of the left leg, using a PRESS sequence, from a 2 × 2 × 2 cm^3 voxel with TE/TR = 135/1500 ms and 256 averages. The spectra were acquired without water suppression. Following the exercise bout, subjects were carefully repositioned in the magnet, ensuring correct muscle level and fiber orientation, and the above MR protocol was repeated.

MR data analysis. Spectra were analyzed as previously described (13). Briefly, the muscle spectra were analyzed by VARPRO, an iterative non-linear least square fitting method operating in the time domain. The water peak was quantified by using one exponentially decaying sinusoid (corresponding to one Lorentzian line in the frequency domain), while total creatine (Cr_{tot} = phosphocreatine + free Cr) and choline (Cho) resonances were modeled as two single Gaussian decaying sinusoids with equal damping factors. The $(–CH_2–)_n$ and $–CH_3$ resonances from IMCL and EMCL were deconvoluted and modeled as one Gaussian decaying sinusoid each. Peak areas for each signal were obtained and lipid resonances were quantified with reference to Cr_{tot} after correcting for T_1 and T_2 as previously described (13).

MR images were analyzed as previously described (20), using an image segmentation software program that employs a threshold range and a contour-following algorithm with an interactive image editing facility. The volumes (cm^3) of each compartment (subcutaneous and extramyocellular adipose tissue, bone marrow, and bone) were calculated by summing the relevant pixel counts and multiplying by the pixel volume in cm^3.

Exercise protocol. Following the first MR scan, the subjects (having restrained from exercising for 48 h prior to the examination) were given a 5-min warm-up period and permitted to stretch adequately before the test commenced. This was followed by a run at a pace corresponding to 64 ± 1.5% of each subjects VO_2max for 90 min, on a calibrated [using standardized American College of Sport Medicine guidelines (21)] Pulse treadmill, in an air-conditioned environment (17°C). Subjects were given free access to plain water during the run and levels were recorded for each subject. HR was monitored and recorded every 5 s using a Polar Accurex Plus heart rate monitor. Subjects were instructed to give an overall rating of perceived exertion using the Borg scale (19) during the last 30 s of each 5-min interval throughout the continuous 90-min run. All subjects were returned to the MR scanner within 10 min for their postexercise examination.

Statistical analysis. All data are presented as mean ± SEM (except where individual values are quoted). Possible differences before and after exercise were tested for by using the Student's paired *t*-test. Significance was taken as $P < 0.05$. Pearson product movement correlation coefficients (r) were used to assess the relationship between variables.

RESULTS

Subject characteristics. Individual VO_2max and body mass index (BMI) for each volunteer are shown in Table 1. The mean VO_2max for the volunteers was 61.2 ± 3.4 mL/kg/min (range: 54.0 to 74.3 mL/kg/min). The average BMI was 22.5 ± 1.0 kg/m^2 (range: 20.2 to 25.7 kg/m^2).

TABLE 1
Subjects' Characteristics[a]

Subject	Age (yr)	BMI (kg/m^2)	VO_2max (mL/kg/min)	HR_{max} (beats/min)
1	38	25.7	59.9	180
2	35	21.8	64.4	188
3	38	23.5	60.0	182
4	34	20.2	74.3	174
5	30	21.1	54.0	164

In vivo ^1H MRS. Typical *in vivo* ^{1}H MR spectra from the tibialis muscle before and after exercise are shown in Figure 1. Changes in IMCL were measured in the soleus, tibialis, and gastrocnemius. Comparing the group as a whole, the tibialis muscle (pre: 22.37 ± 4.33 vs. post: 15.16 ± 3.25 mmol/kg dry weight; $P < 0.01$) and the soleus (pre: 36.93 ± 1.45 vs. post: 29.85 ± 2.44 mmol/kg dry weight; $P < 0.01$) but not the gastrocnemius (pre: 33.78 ± 5.35 vs. post: 28.48 ± 5.44 mmol/kg dry weight; $P = 0.10$) showed a significant decrease in IMCL following exercise. However, considering each runner individually (Fig. 2A–C), decreases in IMCL were observed in four of five subjects in the gastrocnemius muscle.

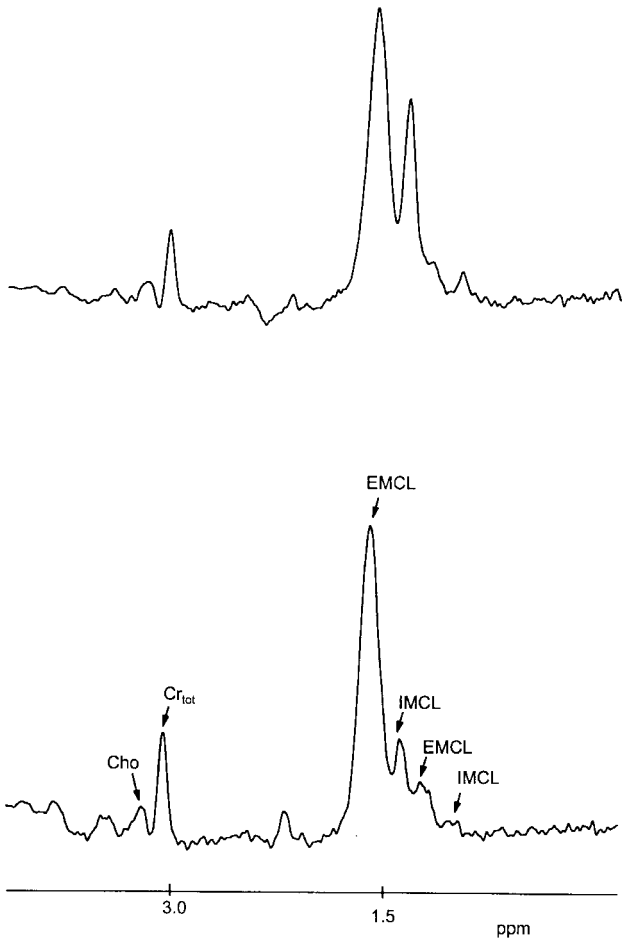

FIG. 1. Typical *in vivo* ^{1}H magnetic resonance spectra from tibialis muscle before (top) and after (bottom) exercise. Cho, choline-containing compounds (carnitine + glycerophosphocholine); Cr_{tot}, creatine + phosphocreatine; IMCL, intramyocellular lipid; EMCL, extramyocellular lipid.

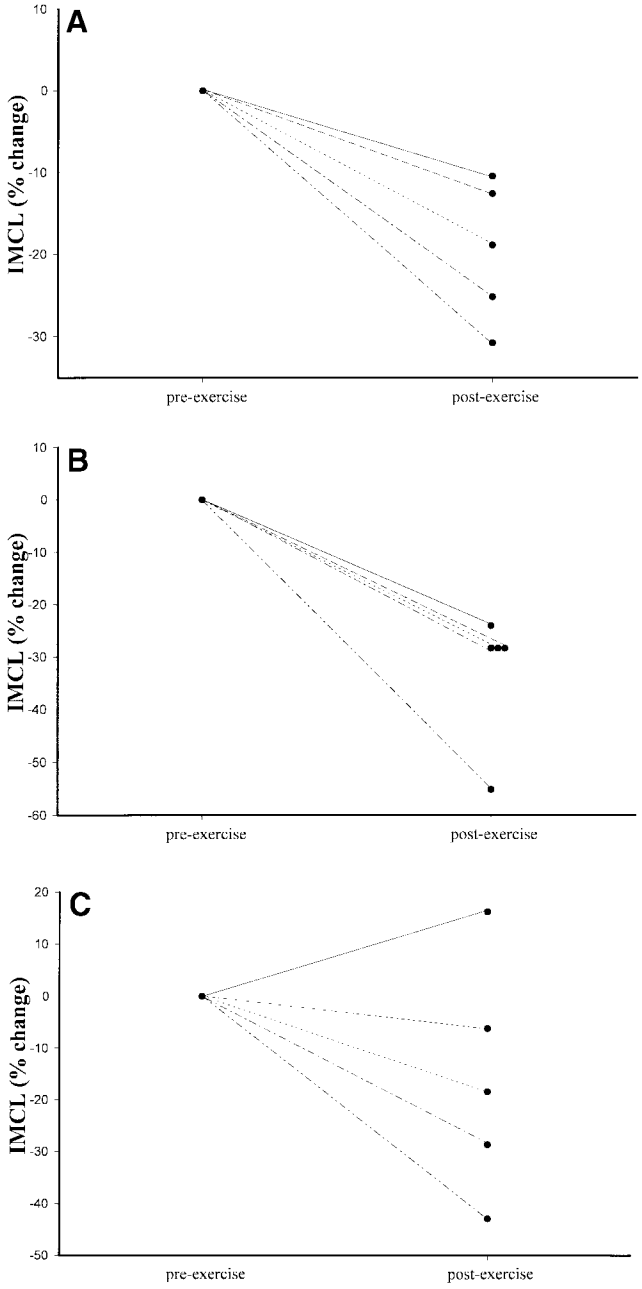

FIG. 2. Individual changes in IMCL in the (A) soleus, (B) tibialis, and (C) gastrocnemius muscles following exercise. See Figure 1 for abbreviation.

A significant decrease in Cho/Cr levels (pre: 0.67 ± 0.09; post: 0.55 ± 0.08, $P < 0.01$) was observed in the gastrocnemius after exercise. No such changes were observed in other muscle groups.

MRI. There were no significant changes in the levels of EMCL (37.08 ± 5.68 vs. 34.87 ± 5.90 cm^3, $P = 0.22$), subcutaneous fat (360.85 ± 87.59 vs. 349.15 ± 82.95 cm^3, $P = 0.47$),

bone marrow (108.22 ± 9.44 vs. 108.94 ± 9.08 cm^3, $P = 0.73$) or bone (190.00 ± 9.55 vs. 186.97 ± 8.68 cm^3, $P = 0.24$) measured by MRI following the exercise intervention.

DISCUSSION

In this study we have shown that IMCL levels are significantly decreased in the tibialis and soleus muscles following a 90-min bout of exercise at 64 ± 1.5% VO_2max. A decrease in IMCL was also observed in the gastrocnemius muscle of some subjects, but it did not reach significance for the subject population as a whole. No changes were observed in levels of EMCL in any of the muscle groups.

Assessment of IMCL content in human skeletal muscle has, to date, been carried out principally by the use of needle biopsy. However, this technique has the drawback of, besides being invasive, showing relatively poor reproducibility due to contamination from associated adipose tissue. Indeed, Wendling *et al.* (10) reported that changes in IMCL levels above 24% could be considered meaningful by this technique (10). Using needle biopsies, several groups have reported changes in IMCL between 20 and 50% following exercise (1–3,5–7), while others have reported no changes (8–10). In part, these contradictory results may arise from the high coefficient of variation associated with needle biopsies. In the present study we have partly overcome this problem by the use of *in vivo* ^{1}H MRS to evaluate muscle IMCL noninvasively. It has been previously demonstrated that ^{1}H MRS estimation of IMCL in healthy volunteers shows good agreement with published literature values (13), with good intra-examination (2%) and interexamination (*ca.*13%) coefficients of variation (13). Moreover, Boesch *et al.* (11) have reported that, using this technique, they have detected a significant decrease in IMCL in one subject after 3 h of mountain cycling, suggesting that prolonged continuous exercise may lead to a net decrease in IMCL. This is clearly confirmed by the present study. Moreover, during the preparation of this manuscript, Krssak *et al.* (16) have reported a significant decrease in IMCL in the soleus muscle following a 2–3 h treadmill run to exhaustion at 65–70% VO_2max.

The degree of IMCL utilization observed in our study varied significantly between muscle groups for any given subject. In most subjects, IMCL utilization was observed in all muscle groups, though the extent of these changes varied between muscles, with the largest changes associated with the tibialis muscle (−24 to −55%). The general trend appeared to be tibialis > gastrocnemius > soleus. The possible reasons for this variation are unclear, but may reflect differences in oxidative capacity of the muscle groups (22–24). According to the histochemical literature, the gastrocnemius and tibialis muscles are composed of relatively higher percentages of fast twitch fibers compared to the soleus (22–24). Furthermore, the metabolic and oxidative potential of these muscle groups is relatively different as a direct consequence of their muscle fiber composition and adaptation (24). We have recently shown differences in the level of IMCL in different muscle types at rest, which appear to be partly associated with the oxidative capacity of those muscles (12). Studies in animals have shown that IMCL provides a significant amount of energy for contraction in fast twitch red muscle fibers, but not in other fiber types (25). In addition, IMCL levels are affected by the ability of different muscle types to take up circulating TG. Studies with labeled chylomicron have shown that exogenous TG contributes to the turnover of IMCL in slow twitch fiber (26). Therefore, the relative levels of IMCL in a given muscle fiber will reflect the opposing effects of oxidation and TG uptake (27,28).

These results suggest that the tibialis muscles of the subjects in the present study were probably composed of more fast twitch oxidative glycolytic fibers (FTa) than the soleus and gastrocnemius, and that the metabolic capacity of IMCL resynthesis of slow twitch fibers in our subjects might be relatively high. In those subjects where IMCL degradation was also observed in the soleus and gastrocnemius muscle, it is probable that these muscle groups contained a significant proportion of the FTa fibers. Coupled with these differences in muscle fiber composition, it is also possible that the individual muscles groups may be working at different intensities. The whole body may experience an overall intensity of 64 ± 1.5%, but each muscle group might experience an intensity of 40, 70, or 90% or any other value depending on the oxidative capacity of that particular muscle. This could clearly affect the levels of IMCL utilization during the exercise in different muscle groups. Further work is therefore required to determine the relative contribution of Type I and Type II fibers to IMCL muscle content and metabolism.

The reason for the differences in IMCL utilization between subjects for a given muscle group may be due to a combination of factors including level of training and fiber type adaptation. Since exercise intensity is a major factor in determining the nature of the fuel oxidized during exercise, this may partly explain why some subjects utilized IMCL to a greater or lesser extent following exercise. As exercise intensity increases, there is an increase in carbohydrate utilization and decrease in circulating lipids (29). Indeed, it has been reported that circulating fatty acids are used as an energy substrate for exercise at intensities below 80–90% VO_2max; above this intensity, carbohydrates are the predominant substrate (30). Thus, it is possible that for each subject the combination of the overall and local (for each muscle) exercise intensity played a significant role in the recruitment of fibers, leading to significant individual differences in levels of IMCL utilization. Work is presently underway in an effort to try to unravel the possible mechanism by which different factors, including fiber type composition, levels of training, exercise intensity, genetics and diet, influence the relative rate of IMCL utilization and resynthesis during exercise.

The role of IMCL as an energy source during exercise appears to be highly dependent on the duration, type and intensity of the exercise protocol. In the present study we have shown a significant decrease in IMCL following continuous exercise at 60–70% VO_2max. However, previous studies, including our own, have shown no change in IMCL following intermittent or high-intensity exercise (8–10,13). We observed no change in IMCL following an exercise protocol of alternat-

ing intensity to fatigue, including walking, jogging, running and sprinting (13). Similar lack of effects was recently reported by Brechtel *et al.* (31) using a protocol of continuous exercise at an intensity >80% VO_2max (31). Thus, to maximize IMCL utilization during exercise, continuous exercise at an intensity of 60–70% VO_2max is necessary. Further work is, however, required to ascertain the time course of IMCL utilization during prolonged exercise.

The metabolic role of EMCL, if any, in muscle is not fully understood. This study has shown that, following 90 min of exercise, there was no significant utilization of EMCL. This finding is in agreement with previous research, which has suggested that EMCL is relatively metabolically inert and does not contribute to fat oxidation during exercise at intensities greater than 25% VO_2max (4,14). Interestingly, recent work by Goodpaster *et al.* (32) suggects that EMCL levels are altered following significant weight loss. The general level of EMCL in this study appeared to reflect each subjects overall body fat content (results not shown).

An unexpected finding in this study was the significant decrease in Cho/Cr ratio in the gastrocnemius muscle. The Cho peak (3.20 ppm) in the *in vivo* ^{1}H MR spectrum is composed primarily of carnitine and glycerophosphocholine (33). Previous studies have reported a decrease in muscle carnitine following prolonged exercise, accompanied by a corresponding increase in acetylcarnitine (34). This, however, cannot explain the results observed in the present study since signals from carnitine and acylcarnitine co-resonate (*ca.* 3.20 ppm). Therefore, the overall intensity of the Cho peak would remain unchanged. It is, however, possible that during intense lipid utilization some of these metabolites may become bound to other metabolites, leading to T_2 shortening and an apparent decrease in signal intensity. In the case of the tibialis muscle, the net levels of Cho/Cr are relatively low, so potential decreases in this ratio may be below the detection level of the technique. Further work is therefore required to elucidate the exact metabolic mechanism by which exercise may affect the intensity of the Cho-containing resonance and its physiological significance.

In summary, the results of the present study show that IMCL is significantly utilized by the tibialis and soleus muscles during prolonged continuous exercise. The lack of group significance for the gastrocnemius muscle might reflect muscle group differences in fiber type composition and capacity to oxidize and resynthesize IMCL. Finally, this study shows that *in vivo* MRS is a useful tool for noninvasively studying substrate utilization during exercise. This may in future allow us to investigate the influence of factors such as training status and exercise intensity, as well as diet and genotype, on energy substrate utilization.

Linoleic Acid Metabolism in the Spontaneously Diabetic Rat: Δ6-Desaturase Activity vs. Product/Precursor Ratios

J.E. Brown[a,1], R.M. Lindsay[b,2], and R.A. Riemersma[a,c]*

[a]Cardiovascular Research Unit, Departments of Cardiology and Medicine, University of Edinburgh, Edinburgh EH8 9XF, Scotland, [b]Metabolic Unit, Western General Hospital, Edinburgh EH4 2XU, Scotland, and [c]Department of Medical Physiology, University of Tromsø, Tromsø, Norway

ABSTRACT: The activity of Δ6-desaturase of linoleic acid, a rate-limiting step in the formation of arachidonic acid, is decreased in animal models of severe, uncontrolled diabetes. The aim of the study was to measure the activity of liver microsomal Δ6-desaturase of spontaneously diabetic BioBreeding/Edinburgh rats receiving subcutaneous insulin daily and of genetically related nondiabetic animals. The activity of Δ6-desaturase was then compared with indices of activity (plasma lipid fatty acid product/precursor ratios) frequently used in human studies. Diabetic rats treated with insulin had 75 ± 8% of the activity of microsomal Δ6-desaturase of nondiabetic controls ($P < 0.05$). Insulin withdrawal tended to reduce the activity further (61% of control), although the activity did not differ from insulin-treated diabetic rats. The ratio of plasma phospholipid or cholesteryl ester γ-linolenic over linoleic acid was not decreased in insulin-treated diabetic rats. By contrast, the ratio of γ-linolenic over linoleic acid of microsomes was almost threefold higher in insulin-treated diabetic rats ($P < 0.05$). The γ-linolenic over linoleic acid ratio as an index of activity gave inconsistent results in insulin-deprived rats. The ratio of γ-linolenic over linoleic acid of cholesteryl esters did not differ between control and diabetic rats, nor did it correlate with microsomal Δ6-desaturase activity. Furthermore, the index of Δ6-desaturase activity, derived from the fatty acid composition of microsomal phospholipids, did not correlate with microsomal Δ6-desaturase activity. Diabetes, even when controlled by regular insulin injections, reduces the metabolism of linoleic acid, but the effect is less than previously published. The fatty acid compositions of plasma and liver microsomal lipids are not reliable indices of Δ6-desaturase activity in diabetes.

Paper no. L8455 in *Lipids 35,* 1319–1323 (December 2000).

The ability to provide sufficient amounts of long-chain polyunsaturated fatty acids such as arachidonic acid (20:4n-6) depends greatly on the conversion of linoleic acid (18:2n-6) to γ-linolenic acid (18:3n-6) *via* the rate-limiting enzyme Δ6-desaturase. Impaired 18:2n-6 metabolism is associated with diabetic neuropathy and altered prostanoid synthesis (1–3) and has been implicated in the microvascular complications of diabetes (4). Plasma fatty acid compositions are by and large used in human studies as an index of the activity of Δ6-desaturase, since for obvious reasons enzyme activity cannot be measured in liver biopsies. Increased levels of 18:2n-6 with decreased levels of 20:4n-6 in plasma, platelet and red blood cell lipids from subjects with insulin-dependent diabetes mellitus may indicate an impairment in 18:2n-6 metabolism (5,6). However, not all studies on diabetes have revealed such fatty acid patterns (7–9). Tissue fatty acid composition can also be affected by diet. Diabetic patients consume 40% more 18:2n-6 than nondiabetic subjects (8), in accordance with World Health Organization recommendations (10). Therefore, an important question remains whether the higher tissue levels of 18:2n-6 in diabetic patients are indeed due to an impaired conversion of 18:2n-6 to other longer-chain n-6 fatty acids.

The spontaneously diabetic, insulin-dependent BioBreeding Wistar rat from Edinburgh (BB/E) is an animal model with a pathology of destructive insulitis comparable with human diabetic subjects (11,12). The aim of this study was to examine the effect of diabetes on the Δ6-desaturation of 18:2n-6 in BB/E rats stabilized with regular insulin treatment. We compared our results with an index of Δ6-desaturase activity based on fatty acid compositional analyses of plasma phospholipids (PL) and cholesterol esters (CE) under controlled dietary conditions.

MATERIALS AND METHODS

Male insulin-dependent diabetic Wistar BB/E rats ($n = 12$, 151 ± 15 d old, duration of diabetes 61 ± 7 d) and male nondiabetic rats from a related strain ($n = 6$, 152 ± 5 d old) were used (11). Diabetic rats required a daily subcutaneous insulin injection (2.9 ± 0.3 IU/d, Bovine Ultratard U40; Novo Nordisk, Bagsvaerd, Denmark). Animals had free access to water and a chow (Rat & Mouse No. 1 diet; S.D.S., Witham, United Kingdom) that contained 2.5% (w/w) fat. The fatty acid composition was: 19.1% saturates, 16.5% monounsaturates, 57.4% 18:2n-6, and 6.5% α-linolenic acid. Experiments were carried out under the Animal (Scientific Procedures) Act 1986.

Oxidative desaturation of [1-^{14}C]18:2n-6 by liver microsomes (500 μg) was estimated by measuring the formation of radioactive 18:3n-6, dihomo-γ-linolenic acid (20:3n-6), and 20:4n-6 (13). The incubation mixture (1.2 mL) contained (in μmol): ATP, 4.0; Coenzyme A, 0.25; NADH, 1.25; $MgCl_2$, 0.5; bovine serum albumin (essentially fatty acid free), 0.01; glutathione, 1.5; potassium phosphate, 45.0 (pH 7.2), and [1-^{14}C]18:2n-6, 0.2 (~140,000 dpm; Amersham International, Amersham, United Kingdom) and were carried out in room air at 37°C. Incubations were terminated after 20 min by addition of 10% (wt/vol) potassium hydroxide in aqueous methanol containing 0.005% (wt/vol) butylated hydroxytoluene. After saponification, methyl esters formed using BF_3-methanol reagent were separated into dienes and trienes plus tetraenes by argentation thin-layer chromatography using $CHCl_3$/CH_3OH/acetic acid/H_2O (90:7.5:7.5:0.8, by vol) as the solvent mixture (14). The two fractions were scraped directly into scintillation vials and counted (1217 Rackbeta counter; Wallac Oy, Turku, Finland). The activity of Δ6-desaturase is related to the amount of microsomal protein (250–750 μg) and substrate (40–200 nmol) (15). Routinely, 500 μg protein and 200 nmol substrate were used, and under these conditions the dilution of [1-^{14}C]18:2n-6 by endogenous substrate is negligible and the protein binding of the substrate is controlled (15). Enzyme activity was expressed as pmol of products formed by 1 mg of microsomal protein per minute with a correction of the specific activity due to the presence of free 18:2n-6 in microsomes. [This is particularly important when a large amount of microsomal protein, i.e., 5 mg, is used (15).]

Plasma phospholipid fatty composition was determined by gas chromatography (16). Microsomal nonesterified linoleic acid content was determined as follows. Lipids from microsomes (10 mg in 1 mL) and heptadecanoic acid (internal standard) were extracted using Folch's mixture and separated by thin-layer chromatography using hexane/diethylether/formic acid (80:20:2, by vol) as the solvent mixture. The nonesterified fatty acid band was scraped off and methylated using diazomethane. The methyl esters were concentrated and redissolved in a small amount of $CHCl_3$ (5–10 μL) and analyzed by gas chromatography (16).

The ratio of 18:3n-6 over 18:2n-6 was used as an index of Δ6-desaturase. An overall index of 18:2n-6 desaturation was also used. This was calculated as follows:

$$(18:3n\text{-}6 + 20:3n\text{-}6 + 20:4n\text{-}6 + 20:5n\text{-}6 + 22:5n\text{-}6)/18:2n\text{-}6 \quad [1]$$

Plasma insulin was assayed by radioimmunoassay using rat insulin standards (17) (Novo Research Institute, Bagsvaerd, Denmark) and plasma glucose using the glucose oxidase method (18). Red blood cell glycosylated hemoglobin was determined by boronic acid affinity chromatography [Pierce & Warriner (UK) Ltd., Chester, United Kingdom].

Diabetic rats were divided into two groups (n = 6) and matched for age, duration of diabetes, and daily insulin dose. One group continued to receive insulin injections and was sacrificed 6 h after their last insulin dose (insulin treated). Insulin treatment of the other group was discontinued for 54 h, after which time the rats were sacrificed (insulin deprived). The dose of insulin did not differ between the two groups (3.0 ± 0.3 and 2.7 ± 0.1 IU/d). Nondiabetic rats were studied at the same time. Rats were sacrificed under anesthesia (Sagatal®; Rhône Mérieux, Dublin, Eire) between 1545 and 1615 h in view of the circadian rhythm of Δ6-desaturase, and livers were removed for microsome preparation (19).

Statistical analysis. Results are shown as mean ± SD. Statistical analyses were conducted using Minitab (CLE.COM Ltd., Birmingham, United Kingdom). The data were analyzed by one-way analysis of variance, followed by unpaired Student's *t*-test.

RESULTS

Plasma glucose levels in insulin-treated diabetic rats were reduced by more than 60 % ($P < 0.05$) compared to controls despite similar plasma insulin levels (Table 1). Insulin withdrawal for 54 h caused significant weight loss, hyperglycemia, and undetectable insulin levels in 3 of 5 rats (Table 1).

Δ6-Desaturase activity in insulin-treated diabetic rats was decreased to 75 ± 8% of control values ($P = 0.013$; Table 1). Insulin withdrawal tended to reduce the activity further (61% of control), although this does not differ from insulin-treated diabetic rats. Liver microsomal nonesterified 18:2n-6 levels were significantly raised ($P < 0.05$) in insulin-deprived diabetic rats (Table 1; the detailed fatty acid composition of plasma and microsomal lipids can be obtained from the authors), demonstrating the need to correct the specific activity of radioactive linoleic acid for this. Insulin-treated diabetic rats had significantly higher plasma PL levels, and the total

amount of n-6 fatty acids increased proportionally (Table 2). The ratio of 18:3n-6/18:2n-6, which arguably reflects the activity of Δ6-desaturation, was, however, normal. Plasma PL levels increased further after insulin deprivation, and the Δ6-desaturation index was significantly reduced ($P < 0.05$; Table 2). This plasma PL index of Δ6-desaturation was related to the activity of liver microsomal Δ6-desaturase determined *in vitro* ($r = 0.54$, $P < 0.05$; Fig. 1). The overall index of 18:2n-6 desaturation derived from plasma PL fatty acid composition was also correlated to microsomal Δ6-desaturase activity ($r = 0.55$; $P < 0.05$; Table 2).

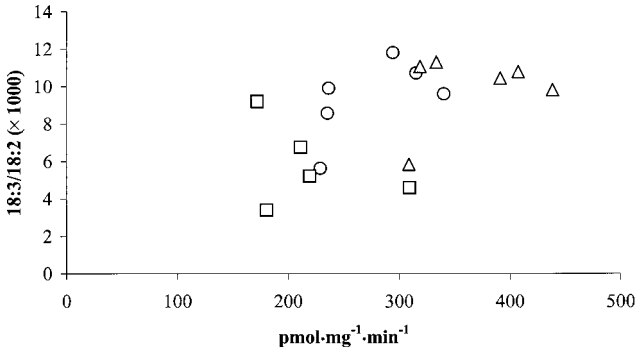

FIG. 1. The relation between microsomal Δ6-desaturation of 18:2n-6 and the index of Δ6-desaturation derived from plasma phospholipid fatty acid composition in normal and diabetic rats. The correlation coefficient is 0.54, $P < 0.05$. Control (n = 6), △; diabetic-insulin treated (n = 6), ○; diabetic-insulin withdrawn (n = 5), □.

By contrast, the 18:3n-6/18:2n-6 ratio derived from plasma CE did not differ significantly between control and diabetic rats. However, the overall index of 18:2n-6 desaturation calculated from the plasma CE composition was reduced in both groups of diabetic rats and correlated well with liver Δ6-desaturase activity ($r = 0.53$, $P < 0.05$).

The ratio of microsomal PL 18:3n-6/18:2n-6 was not related to the measured activity ($r = -0.2$, not significant), but despite this, the overall index of 18:2n-6 desaturation derived from this fatty acid pool was related to the activity of Δ6-desaturase estimated *in vitro* ($r = 0.73$, $P < 0.001$).

DISCUSSION

Δ6-Desaturase in liver microsomes of diabetic rats maintained on regular insulin injections is reduced by some 25%. Insulin withdrawal tended to cause a further small, though nonsignificant, reduction in Δ6-desaturase activity. Nevertheless, the reduction in Δ6-desaturase activity is not as large as previously observed in untreated streptozotocin-induced diabetic rats (20) or diabetic rats that did not receive insulin for 48 h (21). The reason for this apparent discrepancy is largely methodological (see below).

The activity of Δ6-desaturase in our study is much higher (200–400 vs. 40–80 pmol·min^{-1}·mg protein^{-1}) than in previous reports (21–23). These differences apply to both nondiabetic and diabetic animals and are therefore not due to different strains, severity of diabetes, etc. They are more likely explained by important methodological aspects. Microsomes from nondiabetic rats, isolated and washed at low ionic strength, lose a lipoprotein-like fraction, and associated with this is a reduction in Δ6-desaturase activity from 284 ± 9 to 72 ± 3 pmol·min^{-1}·mg protein^{-1} (24). Thus, our activity of Δ6-desaturase in nondiabetic rats is in good agreement with that of Brenner's group (19,24). It is important to note that some of the low activities were observed in the presence of cytoplasmic protein, since the microsomes were suspended in the supernatant (23). This is important, as the cytosolic protein fraction activates Δ6-desaturase of washed microsomes (24).

An additional factor must contribute to the low activity of Δ6-desaturase in microsomes from diabetic animals previously published. Plasma and microsomal nonesterified 18:2n-6 (see Table 1) increase to high levels in uncontrolled diabetes. This can lead to a significant dilution of the [1-^{14}C]-18:2n-6 in the assay, particularly when a large amount (5 mg) of microsomal protein is used. Using our data in Table 2 we calculated that the microsomal nonesterified 18:2n-6 of ~8 nmol/mg protein would reduce Δ6-desaturase activity by 30%. This problem of course is more severe if smaller amounts of substrate (40 nmol) are used (21,23). In our method a smaller amount of microsomal protein (0.5 mg) is used, containing <4 nmol free 18:2n-6 (0.5 mg × 7.7 nmol/mg protein). Thus, the dilution of the radioactive substrate (200 nmol) is less than 2%. Hence any correction has a negligible effect. Only a systematic study of Δ6-desaturase activity and of inhibitory and activating factors can resolve this method-

ological question fully. Nevertheless, our results strengthen previous suggestions that diabetes, whether controlled with daily insulin injections or not, causes a significant reduction in Δ6-desaturase activity in the BB diabetic rat model, though it is probably less than previously thought (21,23).

Plasma lipid n-6 fatty acid ratios are frequently used in human studies as an index of Δ6-desaturase activity (8,9). There was a good relationship between liver microsomal Δ6-desaturase activity determined *in vitro* and some of the indices of Δ6-desaturase based on the n-6 fatty acid composition of plasma PL. This was not the case for the 18:3n-6/18:2n-6 ratio derived from either plasma CE or liver microsomal PL, although, in each case, the overall index of 18:2n-6 desaturation did correlate with the activity of Δ6-desaturase. Clearly the type of lipid analyzed for fatty acid composition and the specific ratio used is of critical importance.

The lipid composition of plasma depends on the nutritional and hormonal state, and this is particularly relevant in diabetes, when in uncontrolled diabetes, plasma lipids (particularly triacylglycerol) increase (25,26). As the fatty acid compositions of these lipid classes are quite different, the changing lipid composition, after the induction of diabetes, would alter the Δ6-desaturase indices *per se*. The use of a defined lipid pool, such as low density lipoprotein phosphatidylcholine, may therefore be superior to monitor Δ6-desaturase activity.

Another concern about the use of n-6 fatty acid ratios as an index of Δ6-desaturase activity stems from the relatively large measurement error of the minor n-6 fatty acids that determine these ratios. Even when injecting large amounts of methyl esters during gas chromatography, the coefficient of variation for minor peaks (<1% of total fatty acids) was about 17.5% while it was less that 5% for 18:2n-6 (16). Clearly, whatever n-6 fatty acid ratio is used as an index of Δ6-desaturase, many factors will determine the precise value. Concerns about the use of fatty acid ratios as an index of Δ6-desaturase activity have been expressed previously (27).

Recent advances in the use of uniformly ^{13}C-labeled 18:2n-6 combined with high-precision combustion gas–liquid chromatography–isotope ratio mass spectrometry (28) has made it possible to demonstrate, but not to quantify, the conversion of 18:2n-6 to 20:4n-6 in man (29). An early study concentrating on Δ5-desaturation of ^{2}H-labeled dihomo-γ-linolenic acid suggested that the activity of this enzyme was impaired in newly diagnosed diabetics (30). However, even today, precise quantification of the activities of these enzymes using stable isotopes is not easy. This is because of the difficulty the differential incorporation of fatty acids into plasma lipid fractions poses. The assessment of relative activities (i.e., before and after treatment within an individual) is simpler, provided the fatty acid composition of the plasma lipid fractions does not change during the experiment. Methods to quantify the Δ6-desaturation of linoleic acid and to monitor the biological requirements for its long-chain polyunsaturated fatty acids in man need to be developed.

In summary, the activity of Δ6-desaturase is depressed in the insulin-treated BB diabetic rat, but to a smaller degree than shown previously. The apparent discrepancy is largely explained by methodological factors that led to an overestimation of the inhibition of Δ6-desaturase in earlier studies. The activity is perhaps reduced fractionally further by insulin withdrawal. The ratio of 18:3n-6 over 18:2n-6 derived from plasma lipids (CE, PL) as a marker of Δ6-desaturase yields inconsistent results, although PL 18:3n-6 over 18:2n-6 is related to the actual microsomal activity. Many factors will affect the fatty acid composition of plasma lipids, making these ratios unreliable markers to monitor the activity of 18:2n-6 conversion in humans.

ABSTRACT: The roles of peroxisomes and microsomes on the biosynthetic pathway for docosahexaenoic acid (DHA) from α-linolenic acid (ALA) were investigated. Microsomes and peroxisomes were prepared from livers of fetal and neonatal piglets by a combination of differential and gradient layer centrifugation. Microsomes, peroxisomes, and combined cell fractions were incubated with [^{13}C-U]18:3n-3. The [M] and [M + 18] isotopomers of the fatty acids in the long-chain polyunsaturated fatty acid (LCPUFA) n-3 pathway were detected by gas chromatography–mass spectrometry. The quantity of each fatty acid was determined by gas chromatography, and synthesis of each fatty acid was calculated for a 30-min period. Synthesis of DHA was not detected in combined fetal liver fractions. The data suggest that DHA in the fetus is probably supplied from maternal sources through the placenta. In either singly incubated microsomal or peroxisomal preparations from neonatal livers, no DHA synthesis was detected. After combination of the microsomal and peroxisomal fractions, DHA synthesis was evident and increased rapidly between birth and 2 wk of age. This is the first demonstration of the entire biosynthetic LCPUFA n-3 pathway in subcellular organelles starting from isotopically labeled ALA to the final product, DHA, with all the intermediates present and isotopically labeled. The primary importance of the data is that it unequivocally demonstrates that peroxisomes are required for biosynthesis of DHA from ALA.

Paper no. L8580 in *Lipids 35*, 1325–1333 (December 2000).

Interest in long-chain polyunsaturated fatty acids (LCPUFA) biosynthesis has recently been renewed because impaired biosynthesis of the LCPUFA, docosahexaenoic acid (DHA), is now known to be associated with peroxisomal disorders (1–4). LCPUFA are present in all animal cell membranes and are important components of lipids unique to brain and other neural tissues. In peroxisomal disorders, LCPUFA are either absent or are present in low amounts in cells. The classic idea for the biosynthesis of LCPUFA is that it is a microsomal process (5). The classically accepted pathway for the biosynthesis of n-6 LCPUFA series is that it proceeds from linoleic acid by a microsomal system of sequential desaturation followed by elongation: 18:2n-6 → 18:3n-6 → 20:3n-6 → 20:4n-6 → 22:4n-6 → 22:5n-6. For the n-3 LCPUFA series, the classic pathway proceeds from α-linolenic acid (ALA): 18:3n-3 → 18:4n-3 → 20:4n-3 → 20:5n-3 → 22:5n-3 → 22:6n-3.

Singh *et al.* (6) reported that children with adrenoleukodystrophy accumulated long-chain saturated fatty acids due to impaired oxidation of long-chain fatty acids such as 24:0 and 26:0. Martinez (1) observed that infants with Zellweger's syndrome, total absence of peroxisomes, were unable to synthesize docosapentaenoic acid (22:5n-6) and DHA. These reports clearly indicated that peroxisomes are involved in LCPUFA biosynthesis. Sprecher and his colleagues have published several papers on the possible intracellular pathway and putative sites of synthesis of intermediates in LCPUFA biosynthesis (7–9). In isolated microsomes and peroxisomes, they studied one step at a time in the pathway and suggested that elongation of 22:4n-6 to 24:4n-6 and desaturation to 24:5n-6 occur in the microsomes followed by peroxisomal β-oxidation to 22:5n-6. In the n-3 series of LCPUFA, a similar pathway is suggested for biosynthesis of 22:6n-3. If the Sprecher hypothesis is correct, biosynthesis of 22:5n-3, but not 22:6n-3 from 18:3n-3, should be detected in microsomes. If peroxisomes are then added to the microsomal preparation, biosynthesis from 18:3n-3 to 22:6n-3 should be demonstrable. To our knowledge, no one has demonstrated the entire biosynthetic LCPUFA n-3 series in subcellular organelles from isotopically labeled ALA to the final product, DHA, with all the intermediates present and isotopically labeled.

The data reported here are the first to demonstrate in mixed microsomal and peroxisomal fractions isotopic enrichment and biosynthesis of all the intermediates in the conversion of ALA to DHA. Furthermore, the data unequivocally demonstrate that peroxisomes are required for biosynthesis of DHA from ALA.

EXPERIMENTAL PROCEDURES

Animals. The project was approved by Iowa State University (ISU) Committee on Animal Care. Four 70–72-d-old and five 110–112-d-old gestation Yorkshire fetal male piglets were ob-

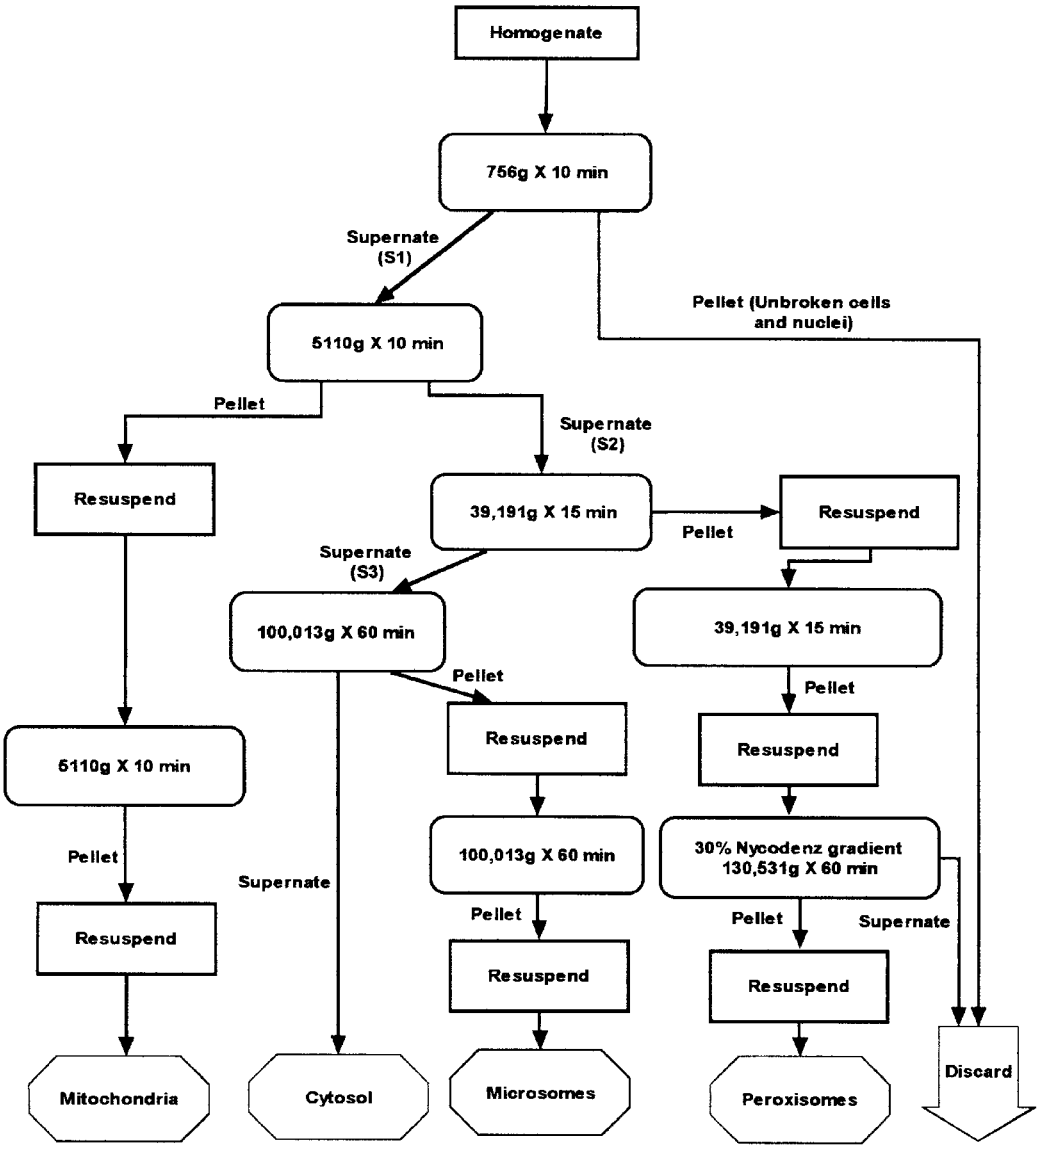
Abbreviations: ALA, α-linolenic acid; ANOVA, analysis of variance; BSA, bovine serum albumin; DHA, docosahexaenoic acid; GC–FID; gas chromatography–flame-ionization detector; GC–MS, gas chromatography–mass spectrometry; ISU, Iowa State University; LCPUFA, long-chain polyunsaturated fatty acids; PFB, pentafluorobenzyl.

tained from the ISU Meat Laboratory. Animals were obtained only two at a time. The sows were stunned by electrocution, hung on a hoist, and killed by exsanguination by standard procedures used for U.S. Department of Agriculture-inspected slaughter houses. The uteri were dissected, weighed, and placed on ice at the slaughter facility and immediately transferred to an adjoining laboratory. After approximately 5 min, the livers of the fetuses were dissected, weighed, and placed into iced 0.9% NaCl and transferred to our laboratory within 5 min. Fifteen Yorkshire neonatal piglets were obtained from the Swine Breeding Farm, ISU. The piglets were divided into three groups: 2–3-d-old, 1-wk-old, and 2-wk-old. Each group contained five animals. Only two female piglets were in the 2–3-d-old group. The other 13 animals were males. The neonatal piglets were removed from the sows and immediately killed by a rapid blow to the head; the livers were dissected, weighed, and placed into iced 0.9% NaCl immediately at the Swine Breeding Farm. The livers were transferred to our laboratory within 15 min.

Organelle isolation. Livers were homogenized with one part liver to four parts media that contained 250 mM sucrose, 1 mM EDTA, 20 mM Tris-HCl, pH 7.4 at 4°C. Mitochondria, peroxisomes, microsomes, and cytosol were isolated by a combination of differential and gradient layer centrifugation as outlined in Scheme 1. The method was essentially a modification of the methods outlined by Ghosh and Hajra (10) and Das *et al.* (11) to increase the yield and purity of the peroxisomes and the purity of microsomes. The purity of the cell fractions was verified by assays of enzymatic markers. Succinate dehydrogenase (EC 1.3.99.1) was used as the mitochondrial membrane marker, and was assayed by the method of Singer and Kearney (12) with phenazine methosulfate and 2,6-dichloroindophenol as the artificial electron acceptors. Glutamate dehydrogenase (EC 1.4.1.2) was used as mito-



SCHEME 1

chondrial matrix marker and was assayed by the method of Fisher (13). Catalase (EC 1.11.1.6) was used as the peroxisomal marker and was assayed by the method outlined by Aebi (14), which followed the absorbance of H_2O_2 at 240 nm. Glucose-6-phosphatase (EC 3.1.3.9) was used as the microsomal marker and was assayed by the method of Nordlie and Arion (15) with determination of the inorganic phosphate released. Lactate dehydrogenase (EC 1.1.1.27) was used as the cytosolic marker and was assayed by the method of Kaplan and Fried (16).

Cell fractions were used immediately for LCPUFA synthesis as outlined below. The remainder of each of the cell fractions was rapidly frozen by immersion of the tubes into liquid nitrogen and stored at −80°C for enzyme assays and protein determination at a later time. The protein was assayed by the method of Lowry *et al.* (17).

LCPUFA biosynthesis. The procedure of LCPUFA biosynthesis was a modification of the method outlined by Voss *et al.* (9). The incubation media was made fresh on the day of use. Ten milliliters of reaction buffer that contained 150 mM KH_2PO_4, 10 mM $MgCl_2$, and 1.5 mM dithioerythritol, pH 7.4, was added to 32 mg β-NADH, 36 mg β-NADPH, 110 mg ATP, 8 mg CoASH, 7.4 mg malonyl-CoA, and 40 mg bovine serum albumin (BSA) to obtain Part 1 of the incubation media. Hexane was used to dilute [^{13}C-U]18:3n-3 (Martek, Columbia, MD) to 2 mg per mL stock solution of labeled substrate. Then 4.4 mL of the stock substrate solution was dried under N_2 and dissolved in 10 mL reaction buffer that contained 150 mM KH_2PO_4, 10 mM $MgCl_2$, and 1.5 mM dithioerythritol, pH 7.4. This was heated and shaken in a water bath at 55°C until well dissolved to obtain Part 2 of the incubation media. Incubation media Part 1 was held at 37°C, and then slowly added to incubation media Part 2 to obtain the final incubation media that was held at 37°C until promptly used. The reaction mixture consisted of 0.3 mL of a specific cell fraction to which was added 0.6 mL of the final incubation media that contained 150 mM KH_2PO_4, 10 mM $MgCl_2$, 1.5 mM dithioerythritol, 2 mg BSA/mL, 1.5 mM [^{13}C-U]18:3n-3, 2 mM β-NADH, 2 mM β-NADPH, 10 mM ATP, 0.46 mM CoASH, 0.4 mM malonyl-CoA, pH 7.4. For the combined microsomal and peroxisomal incubation, 0.15 mL of each fraction was used. The mixtures were incubated at 37°C with shaking in 16 × 100 mm tubes for 30, 60, and 120 min, and the reactions were stopped by addition of 0.1 mL 3 N HCl. The tubes were capped, frozen at −20°C, and saved for later analysis.

Analytical procedures. The lipids were extracted by the method of Radin (18) with minor modifications. Optima grade solvents (Fisher Scientific, Chicago, IL) were used. Internal standards that contained 185 nmol of heptadecanoic acid (17:0) and 0.104 nmol of pentacosanoic acid (25:0) were added to each sample. The lipids were extracted with 2 mL hexane/isoproponal (4:1, vol/vol), followed by the addition of 1.0 mL saturated NaCl solution. After shaking, the samples were centrifuged at 1000 × *g* for 10 min. The supernatant was pipetted into a clean 16 × 100 mm tube, the bottom layer was extracted three more times with 2.0 mL hexane and all the supernate fractions from the same sample were combined.

The extracted lipids were evaporated to dryness at 37°C under N_2 and then were saponified by addition of 1 mL 15% KOH in methanol, layered with N_2, sealed tightly, and heated at 80°C for 1 h. After the tubes cooled, 2 mL of H_2O was added. Nonsaponifiable lipids were extracted three times with 2 mL hexane and discarded. Small pieces of Congo red pH papers were added to the remaining lower aqueous layers followed by addition of 1 mL 12 N HCl. The samples were extracted three times with 2 mL hexane; the supernates were collected and dried under N_2.

Pentafluorobenzyl (PFB) esters were prepared as described by Hachey *et al.* (19). To each sample was added 1.0 mL 0.1 M tetrabutyl ammonium hydrogen sulfate in 0.1 M phosphate buffer, pH 9.0 followed by sonication for 5 min. Then, 500 μL of 0.13 M α-bromo-2,3,4,5,6-pentafluorotoluene (Aldrich Chemical Co., Milwaukee, WI) solution was added, and the samples were sonicated for 30 min. The PFB esters were extracted into autosampler vials twice with 1 mL hexane and evaporated to dryness under N_2, and the PFB-fatty acids were re-dissolved in 0.5 mL hexane.

The PFB esters were injected into a Fisons Trio 1000 gas chromatograph–mass spectrometer (GC–MS) (Thermoquest, San Jose, CA) tuned for negative chemical ionization with methane as the reagent gas. The GC column was a medium polar, Omegawax-320 capillary column (Supelco, Bellefonte, PA) that was 30.0 m × 320 μm × 0.25 μm film. The injector and detector temperatures were 250°C. The initial oven temperature was 150°C and increased at a rate of 5°C/min to 280°C, then held at 280°C for 9 min. Helium velocity was 10 mL/min and the split ratio was 1:25. A second splitless injection of each sample was made to detect the very low concentration of 20-, 22-, and 24-carbon fatty acids in the n-3 series. The tracer/tracee ratios were calculated from the areas of the [M] and [M + 18] isotopomers for each fatty acid. The total amount of each fatty acid was determined on a Hewlett-Packard 6890 GC equipped with a flame-ionization detector (FID). The same column, temperature program, and flow rate were used as for the GC–MS. Both 1:25 split and splitless injections were also made in the GC. The amount of enriched fatty acid was calculated by multiplying the tracer/tracee ratio by the total amount of each fatty acid determined by GC–FID.

Statistical analysis. Data were analyzed by analysis of variance (ANOVA) using the Generalized Linear Models procedure from the Statistical Analysis System (SAS, Version 6.12 SAS Institute Inc., Cary, NC). Pair-wise comparisons were made by the protected *t*-test, which uses the mean square error term from the ANOVA. Data were considered statistically significant at $P < 0.05$.

RESULTS

Body weight, liver weight, and litter size of fetal and neonatal piglets in this study are presented in Table 1. Fetal growth was very rapid between 70 and 110 d of gestation with nearly a sixfold gain in body weight and liver weight. Postnatal growth between birth and 1 wk of age was also very rapid.

TABLE 1
Body Weight, Liver Weight, and Litter Size of Fetal and Neonatal Piglets

	Fetal group 1	Fetal group 2	Pig group 1	Pig group 2	Pig group 3
Number of animals	4	5	5	5	5
Age[a] (d)	70–72	110–112	2–3	6–8	13–14
Weight[b] (g)	253.5 ± 6.9[a]	1476.2 ± 132.6[b]	1139.2 ± 187.3[a]	2526.0 ± 324.1[b]	3586.6 ± 332.1[c]
Liver weight[b] (g)	9.00 ± 0.11[a]	50.33 ± 6.96[b]	34.42 ± 5.32[a]	82.59 ± 8.98[b]	103.93 ± 15.08[c]
Litter size	12–13	8–15	10–15	8–13	10–12

[a]Age of fetuses are the days of gestation. All animals are males except two females in pig group 1.
[b]Weight and liver weight values are means ± SEM. Values in the same row for fetal groups and pig groups with different roman superscripts were significantly different at least at the $P < 0.05$ level.

Body weight and liver weight doubled during this first postnatal week. Between birth and 2 wk of age, the accretion of body weight and liver weight was a threefold increment.

Enzyme activities were assayed within 1 wk after isolation of the hepatic organelles. Five neonatal piglets and five fetal pigs were randomly selected to measure recovery of organelles by assay of enzymatic markers. Comparisons were made to activities in the 756 × *g* supernate fraction. For fetal pigs, only animals from Fetal group 2 (110–112 d gestation) were used for enzymatic assays because the amounts of each cell fraction isolated from animals in Fetal group 1 (70–72 d gestation) were very limited. The percentage recovery and specific activity of each enzymatic marker in the cell fractions of neonatal piglets are shown in Table 2. The microsomes had a low contamination by peroxisomes (1.42% catalase recovery). The peroxisomes also had a low contamination by microsomes (5.30% glucose-6-phosphatase recovery). Both fractions had a very high percentage recovery, 41.20 and 17.49%, respectively, for the microsomes and peroxisomes. Both microsomes and peroxisomes had very low contamination by mitochondria. The purities of the cytosol and mitochondria were relatively low because both fractions had high peroxisomal contamination, 22.70 and 31.58% catalase recovery, respectively. The goal of the procedure for isolation of the organelles was to obtain microsomes and peroxisomes without significant presence of mitochondria. In Table 3, the percentage recovery and specific activity of the enzymatic markers in fetal pigs are shown. The results are similar to the results from the neonatal piglets, except that the microsomes had a relatively low percentage recovery (25.54%) and relatively high contamination with mitochondria (9.58% succinate dehydrogenase recovery, 14.11% glutamate dehydrogenase recovery).

All detectable enrichments of the [M + 18] isotopomers of each fatty acid were integrated, including the precursor fatty acid, 18:3n-3. In Figure 1, typical peaks from GC–MS chromatograms of enriched key fatty acids, 20:5n-3, 22:6n-3, 24:5n-3, and 24:6n-3 are shown. Isotopic enrichment of all the fatty acids of n-3 series from 18:3n-3 to 24:6n-3 was detected.

Incubations of the cell fractions were carried out for 30, 60, and 120 min. Isotopic ratios and the amounts synthesized from [^{13}C-U]18:3n-3 were not different between these time periods. Therefore, only the data for the 30-min incubation period are reported. In Table 4, the amounts of fatty acids synthesized in the 756 × *g* supernate fractions of each group are shown. In the three neonatal piglet groups, syntheses of all the fatty acids from 18:4n-3 to 24:6n-3 were detected. In Fetal group 1, only syntheses of 18:4n-3, 20:3n-3, 20:4n-3, and 20:5n-3 were detected. In Fetal group 2, besides the 18-carbon and 20-carbon fatty acids, 22:4n-3 and 24:5n-3 syntheses were also detected. Among the five groups, Fetal group 1 had the lowest syntheses of 18:4n-3, 20:3n-3, and 20:5n-3 ($P < 0.05$). Within the three neonatal pig groups, there were no differences in syntheses of

18:4n-3 and 20:5n-3. Pig group 2 had the highest synthesis of 20:3n-3, and Pig group 1 had the highest synthesis of 20:4n-3 ($P < 0.05$). There were no differences in synthesis of 22:4n-3 among the four groups that had detectable synthesis of 22:4n-3. For 22:5n-3 and 22:6n-3, the amount of syntheses increased with an increase in age. Pig group 3 had highest synthesis of 22:5n-3 compared with Pig groups 1 and 2 ($P < 0.05$). Pig groups 2 and 3 had higher synthesis of 22:6n-3 than Pig group 1 ($P < 0.05$). For 24:6n-3, no differences in synthesis were detected, although Pig groups 1 and 3 had the higher synthesis of 24:5n-3 than Fetal group 2 and Pig group 2 ($P < 0.01$). The data show that, in the 756 × *g* supernate, synthesis of 22:6n-3 was detected in the neonatal pigs and rapidly increased by the first week of postnatal life. Furthermore, synthesis of 22:6n-3 was undetected in the two fetal groups.

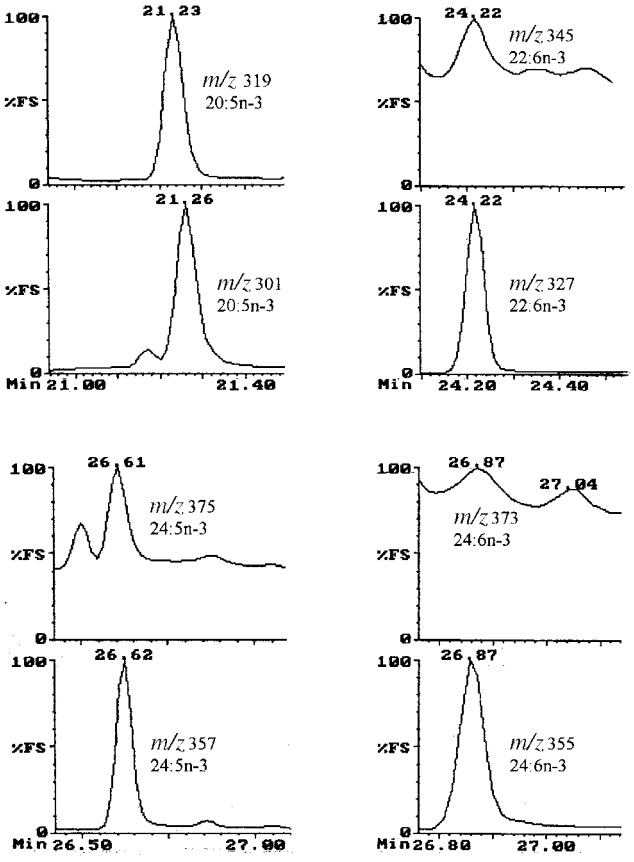

FIG. 1. Typical peaks from gas chromatography–mass spectrometry chromatograms of nonenriched [M] and enriched [M + 18] isotopomers of key fatty acids, 20:5n-3, 22:6n-3, 24:5n-3, and 24:6n-3.

Microsomal synthesis of LCPUFA in the n-3 series is presented in Table 5. The most important difference from Table 4 is that only two animals in pig group 1 had detectable 22:6n-3 enrichment (not significantly different from 0). Only syntheses of fatty acids 18:4n-3, 20:3n-3, 20:4n-3, and 20:5n-3 could be detected in Fetal group 1. In Fetal group 2, 24:5n-3 and 24:6n-3 enrichments were also detected. There were no differences among the five groups in synthesis of 18:4n-3. Synthesis of 20:3n-3 in pig groups 2 and 3 was higher than in Fetal group 1 and Pig group 1 ($P < 0.05$). Pig group 3 had the highest synthesis of 20:4n-3 ($P < 0.05$). For 20:5n-3, Fetal group 2 had the highest synthesis. For the 24-carbon fatty acids, there were no differences among the four groups that had detectable enrichments. The early Fetal group 1 had no detectable enrichment of 24-carbon fatty acids. Within the three neonatal piglet groups, there were no differences in the 22-carbon fatty acids except that Pig group 3 had the most 22:4n-3 synthesized ($P < 0.01$).

In Table 6, isotopic incorporation into peroxisomal LCPUFA is presented. For Fetal group 1, no isotopic label was detected in any n-3 LCPUFA. For Fetal group 2 and Pig group 2, only the fatty acids 18:4n-3, 20:3n-3, 20:4n-3 and 20:5n-3 had detectable ^{13}C enrichments. For Pig groups 1 and 3, although there were detectable 22-carbon LCPUFA enrichments, none of them was significantly different from 0 ($P < 0.05$).

The amounts of newly synthesized LCPUFA in mixtures of microsomes and peroxisomes are presented in Table 7. The re-

[a]The cell fractions were incubated in media that contained [^{13}C-U]18:3n-3 as described in the Experimental Procedures section. Values are the means in nmol fatty acids synthesized in 30 min per mg protein. Across a row the means with different roman superscripts were significantly different at least at the $P < 0.05$ level.
[b]Age of fetuses are in days of gestation. LCPUFA, long-chain polyunsaturated fatty acids; MSE; mean square of the error (general linear model-analysis of variance).

sults were very similar to the results from the complete system in the 756 × *g* supernate in Table 4. For the two fetal groups, Fetal group 1 had ^{13}C enrichments only in 18:4n-3, 20:3n-3, 20:4n-3, and 20:5n-3. In Fetal group 2, also detected were low syntheses of 24:5n-3 and 24:6n-3. In the three neonatal piglet groups, syntheses of all the fatty acids from 18:4n-3 to 24:6n-3 were detected except 24:4n-3. Within the five groups, Fetal group 2 and Pig group 1 had higher synthesis of 18:4n-3 than Fetal group 1 and Pig group 2 ($P < 0.05$). Pig group 3 had the highest syntheses of 20:3n-3 and 20:4n-3, and Fetal group 2 had the highest synthesis of 20:5n-3. For 22:4n-3 synthesis, there were no differences among the three neonatal piglet groups. For 22:5n-3 and 22:6n-3, syntheses in the postnatal piglets increased with increased age. Pig groups 2 and 3 had higher synthesis of 22:5n-3 than Pig group 1 ($P < 0.05$). Pig group 3 had the highest, and Pig group 1 had the lowest synthesis of 22:6n-3 ($P < 0.05$). For the 24-carbon fatty acids, synthesis also increased with increased age. For 24:5n-3, Pig groups 2 and 3 had higher syntheses than did Fetal group 2 and Pig group 1 ($P < 0.05$). For 24:6n-3, Pig group 3 had higher synthesis than did Fetal group 2 ($P < 0.01$). The most striking result from the data above is that after addition of microsomes and peroxisomes together in the system, 22:6n-3 was synthesized, but synthesis was not detected in the separate microsomal and peroxisomal incubations.

The comparisons of key products in the LCPUFA biosynthetic pathway between incubations of microsomal fractions and mixtures of microsomes and peroxisomes within the three neonatal pig groups are summarized in Figure 2. All the groups had significant differences in 22:6n-3 synthesis ($P < 0.01$) when peroxisomes were added to microsomal preparations. Pig groups 1 and 2 also had significant differences in 24:5n-3 synthesis. But in Pig group 1, microsomes alone had higher synthesis of 24:5n-3 than the mixture ($P < 0.05$) whereas in Pig group 2, the mixture had higher synthesis than microsomes alone ($P < 0.01$).

DISCUSSION

The data reported above showed that fetal growth between 70 and 110 d of gestation was very rapid. Postnatal growth between birth and 1 wk of age was also very rapid. Synthesis in late fetal life is high for fatty acids at the beginning of the LCPUFA n-3 pathway with some detection of isotopic label in 24:5n-3. In late fetal life, the synthetic system may be ready to develop because EPA accumulates and there is some label in the 24-carbon fatty acids. Synthesis of EPA in Fetal group 2 was sixfold higher than in the three neonatal pig groups (Table 4). Synthesis of DHA was not detected in the combined fetal liver fractions. This probably is the only reported examination of hepatic LCPUFA synthesis in midgestational and late-gestational fetal tissue. Our data support the hypothesis that DHA in the fetus is probably supplied from maternal sources through the placenta (20). In humans, fetal DHA accumulation occurs primarily during the last intrauterine trimester (21). In human studies, a positive relationship exists between maternal ingestion of DHA during pregnancy and concentrations of DHA in infant tissues. Low concentrations of DHA in plasma phospholipids of umbilical cord arteries were detected in infants of vegetarian mothers (22). Maternal diets high in fish oils during pregnancy increased DHA concentration in newborns (23).

Our data also indicate that synthesis of DHA in the 756 × *g* supernate increased rapidly in neonatal piglets as age increased, corresponding to the rapid neonatal rate of growth. Synthesis increased 20-fold from 2–3 d of age to 1 wk of age and increased 27-fold between 2–3 d of age and 2 wk of age (Table 4). This result is consistent with the recent reports that human infants can synthesize DHA from ALA (24,25).

DHA, until recently, was thought to be synthesized directly from 22:5n-3 by the action of a microsomal acyl-CoA-

dependent Δ4-desaturase (5,26). However, one recent study suggested that microsomes do not have an acyl-CoA-dependent Δ4-desaturase (9). DHA synthesis is reported to occur by β-oxidation of 24-carbon fatty acids in peroxisomes (9,27,28). Our study demonstrates that the entire biosynthetic LCPUFA n-3 pathway from ALA to DHA is evident only when microsomes and peroxisomes are mixed. The data also indicate that microsomes alone are not able to synthesize 22:6n-3 (Table 5), which is consistent with studies that show elongation from 22:5n-3 to 24:5n-3 followed by desaturation to 24:6n-3 in microsomes followed by β-oxidation in peroxisomes to 22:6n-3 (9,27,28). In peroxisomal fractions, only 18- and 20-carbon fatty acids could be synthesized (Table 6). This might be due to the 5% contamination with microsomes, which are very active (Tables 2 and 3).

Our data, to our knowledge, are the first demonstration of the entire biosynthetic LCPUFA n-3 pathway in sucellular organelles. The primary importance of the data is that it supports the Sprecher hypothesis (9) and unequivocally demonstrates that both microsomes and peroxisomes are required for biosynthesis of DHA from ALA. Furthermore, this report demonstrated that DHA synthesis in combined fetal liver fractions was not demonstrable *in vitro*.

ACKNOWLEDGMENTS

This work is Journal Paper No. J-18952 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa, Project No. 3542, and supported in part by Hatch Act, State of Iowa Funding, Special Research Initiation Grant from Iowa State University, and USDA contract 94-3415-0269.

The authors thank Dr. Stephen Ford for provision of fetal and neonatal piglets and Matthew Wilson for his help in euthanizing the piglets.

Dietary Cholesterol Induces Changes in Molecular Species of Hepatic Microsomal Phosphatidylcholine

Ana M. Bernasconi, Horacio A. Garda, and Rodolfo R. Brenner*

Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), CONICET-UNLP, Facultad de Ciencias Médicas, 1900-La Plata, Argentina

ABSTRACT: After 21 days on a diet containing 1 g% cholesterol and 0.5 g% cholic acid, rats had an increased content of cholesterol in liver microsomal lipids. In liver, both cholesterol content and Δ9 desaturase activity increased, whereas Δ6 and Δ5 desaturase activities decreased. These changes correlated with increases in oleic, palmitoleic, and linoleic acids and decreases in arachidonic and docosahexenoic acids in total microsomal lipids. Similar fatty acid changes were found in phosphatidylcholine (PC), the principal lipid of the microsomal membrane. In PC the predominant molecular fatty acid species (67% of the total) in the control rats were 18:0/20:4, 16:0/20:4, and 16:0/18:2; and they mainly determined the contribution of PC to the biophysical and biochemical properties of the phospholipid bilayer. The cholesterol diet decreased specifically the 18:0/20:4 species, and to a lesser extent, 16:0/20:4 and 18:0/22:6. The 18:1-containing species, especially 18:1/18:2 and less so 16:0/18:1 and 18:1/20:4, were increased. A new 18:1/18:1 species appeared. The independent effects of the presence of cholesterol and change of the fatty acid composition of the phospholipid bilayer of liver microsomes on the packing were studied by fluorescence methods using 6-lauroyl-2,4-dimethylaminonaphthalene, 1,6-diphenyl-1,3,5-hexatriene and 1-(4-trimethylammonium phenyl)-6-phenyl-1,3,5-hexatriene, which test different parameters and depths of the bilayer. Data showed that the increase of cholesterol in the membrane, and not the change of the fatty acid composition of phospholipids, was the main determinant of the increased bulk packing of the bilayer. The increase of fluid oleic- and linoleic-containing species almost compensated for the drop in 20:4- and 22:6-containing molecules. But the most important effect was that the general drop in essential n-6 and n-3 polyunsaturated fatty acids meant that this endogenous source for the needs of the animal decreased.

Cholesterol and phospholipids are obligatory and simultaneous components of many eukaryotic membranes. The cholesterol content of membranes is modified by the amount of cholesterol ingested. We (1,2) and other authors (3) have shown that the ingestion of cholesterol not only increases the cholesterol content of rat liver microsomes but also increases the Δ9 fatty acid desaturase activity that converts stearic to oleic acid and decreases the Δ6 and Δ5 desaturases that convert linoleic and α-linolenic acids to higher polyunsaturated fatty acids. These changes in desaturase activities are correlated with modifications in the percentage of fatty acid in the phospholipids of liver membrane. An increase of oleic acid and a decrease in arachidonic and docosahexaenoic acids were shown. A rise in cholesterol in the microsomes increased the overall rigidity of the microsomal membrane as measured by fluorometric methods (1).

Considering that changes in membrane fluidity produced by different factors can alter the activity or kinetics of intrinsic enzymes and lipid protein interactions (4), as shown for the UDP-glucuronyl transferase (5,6), glucose-6-phosphatase (7,8), fatty acid desaturases (7,8) and NADH-cytochrome-C-reductase (7,8), Leikin and Brenner (1,2) suggested that dietary cholesterol induced rigidity of microsomes could be a factor for the fatty acid Δ9 desaturation increase. In addition to this suggestion, which was verified in experiments in which cholesterol was incorporated *in vitro* in the microsomes (7), it was pointed out that some of this activation effect could be due to a change in desaturase synthesis (1).

This last suggestion was confirmed by Landau *et al.* (9) who showed that cholesterol feeding induced an increase of stearoyl-CoA desaturase RNA in rat liver, but no information was given on the Δ6 and Δ5 desaturase problem and on the mechanism of the changes evoked by cholesterol in microsome fluidity.

We know from preceding publications (1) that the cholesterol diet increases the proportion of oleic acid and decreases the proportions of arachidonic and docosahexaenoic acid in microsomal phospholipids, but we do not know which specific molecules are modified.

In the present work, we addressed this question and also which molecular species of microsomal phosphatidylcholine (PC), the principal phospholipid component of the membrane,

are specifically modified by the change in Δ9, Δ6, and Δ5 desaturase activity as evoked by the high-cholesterol diet.

Moreover, the preceeding publication (1) showed, as expected, that the cholesterol incorporation in the liver microsomal membrane increased the microsomal membrane overall packing. However, at that time, the extent to which the change of fatty acid composition of the bilayer phospholipids, as evoked by the modification of the Δ9, Δ6, and Δ5 desaturation activity, contributed to this effect was not investigated; nor was the cholesterol-specific effect investigated. For these reasons, the biophysical properties of a bilayer prepared only with liver microsomal membrane phospholipids were compared to one prepared with whole lipids. Special probes that tested the properties at different depths of the bilayer were used.

EXPERIMENTAL PROCEDURES

Animals and diets. International regulations for animal care were observed throughout these experiments. Male Wistar rats were separated after weaning into two groups of eight animals each. The control group was fed, as in the experiment of Leikin and Brenner (1), a diet composed of 64 g% starch, 23 g% delipidated casein, and 13 g% corn oil plus 2% vitamins and 4% minerals, as described by Rogers and Harper (10). The test group was fed the same diet as the control, with the addition of 1 g% cholesterol and 0.5 g% cholic acid. The reason for the cholic acid addition to the food was to increase cholesterol absorption in the intestine. Ingestion of a small amount of cholic acid did not alter the microsomal membrane composition (Brenner, R.R., unpublished). The animals were pair-fed, and both groups gained the same amount of weight. After an experimental period of 21 d, the animals were killed by decapitation without anesthesia and exanginated. The liver from each animal was rapidly excised and placed in an ice-cold homogenizing solution (1:3 wt/vol) composed of 0.25 M sucrose, 1 mM EDTA, and 10 mM phosphate buffer (pH 7.2). Microsomes were obtained by differential ultracentrifugation at 100,000 × *g* (Beckman Ultracentrifuge) as described elsewhere (11). They were kept stored at –80°C.

Protein concentration was measured according to the procedure of Lowry *et al.* (12).

Lipid analysis. Lipids were extracted from microsomes according to the procedure of Folch *et al.* (13). Total lipid content was measured by aliquot evaporation to constant weight. Cholesterol content was determined by the procedure of Huang *et al.* (14), and total phosphorus by the method of Chen *et al.* (15).

Total phospholipids were separated from nonpolar lipids by absorption on activated silicic acid. Between 8 and 10 mg of total lipids, dissolved in 3 mL of chloroform, was mixed with 25 times their weight of silicic acid. Nonpolar lipids were washed out twice with chloroform.

PC and other phospholipid classes were separated from total lipids by high-performance liquid chromatography (HPLC) using an evaporative light-scattering detector (ELSD) (16). An Econosil silica column of 10 μm and 250 × 4.6 mm from All-tech Associates (Deerfield, IL), was used. Elution was performed at a flow rate of 1 mL/min by a gradient of hexane/isopropanol/dichloromethane (40:48:12, by vol) to hexane/isopropanol/dichloromethane/water (40:42:8:8, by vol) for 15 min followed by additional elution with the latter solvent for 30 min. Solvents were previously sonicated to eliminate air. Lipids (300 μg) dissolved in 50 μL of mobile phase were injected.

Nebulization in the ELSD was set at 90°C drift tube temperature and 2.20 L/min of nitrogen gas flow to the nebulizer the PC peak was collected manually from the column effluent using a flow splitter. The solvent was evaporated under N_2 and redissolved in methanol/triethylamine (2:1).

PC molecular species separation. The separation of the molecular species was done by using the method of Brouwers *et al.* (17). In this case, triethylamine proved to be very efficient for the removal of specific interactions between the phospholipid headgroup and HPLC column material. Resolution of molecular species was performed on two 5 μm endcapped Lichrosphere 100-RP18 columns in series obtained from Merck (Darmstadt, Germany). Isocratic elution was applied with a solvent composed of methanol/acetonitrile-triethylamine (58:40:2, by vol) at a flux of 1 mL/min. The detection and quantification were done in an ELSD using N_2 as nebulizer gas at a flux of 1.8 L/min and a temperature of 100°C (17).

A sample of 1 mg of PC was injected; 5 parts out of 100 went to the detector, and the remaining materials of the peaks were collected and identified by gas–liquid chromatography (GLC) analysis.

Fatty acid compositions of both PC and molecular species were analyzed by GLC in a Hewlett-Packard 5840 apparatus after esterification with methanol. A 10% SP2330 column (Supelco Inc., Bellefonte, PA) packed on Chromosorb WAW was used. The temperature was programmed to obtain a linear increase of 3°C/min from 140 to 220°C. The chromatographic peaks were identified by comparison of the retention times with those of standards.

Fluorescence measurements. (i) Fluorescent probes. 1,6-Diphenyl-1,3,5-hexatriene (DPH) was purchased from Sigma Chemical Co. (St. Louis, MO). 6-Lauroyl-2,4-dimethylaminonaphthalene (Laurdan) and 1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene (TMA-DPH) were purchased from Molecular Probes (Eugene, OR).

(ii) Liposome preparation. Two types of liposomes were prepared, one with the total microsomal lipids and the other with the phospholipids. Lipids (0.8 mg) in $CHCl_3$ were added to a rounded-bottom glass tube. $CHCl_3$ was evaporated under a N_2 stream, and 1 mL of buffer A (Tris-HCl 0.1 M, NaCl 0.15 M, pH 8.0) was added. After 15 min at room temperature to allow hydration, samples were vigorously vortexed for 2 min. Then the lipid suspensions were extruded 11 times through a 100-nm-pore filter using a LiposoFast extruder (Avestin, Inc., Ottawa, Ontario, Canada).

(iii) Liposome labeling. Extruded liposomes (0.25 mL) were mixed with 0.25 mL of a $4 \cdot 10^{-6}$ M suspension of the fluorescent probe (DPH, TMA-DPH, or Laurdan) in buffer A and vigorously vortexed. Samples were kept at room temper-

ature for at least 30 min, and then diluted 5 times with buffer A before the fluorescent measurements were made. The final concentration of the samples was 80 μg/mL of lipids and $4 \cdot 10^{-7}$ M of the fluorescent probe.

(iv) Fluorescence measurements. All measurements were made in an SLM 4800 spectrofluorometer in 1 × 1 cm cuvettes.

DPH and TMA-DPH fluorescence. DPH or TMA-DPH steady-state fluorescence anisotropy (r_S), lifetime (τ) and differential polarized phase lifetime (Δτ) were measured using an excitation wavelength of 361 nm and observing the total emission at wavelengths >389 nm through a sharp cut-off filter (KV389) according to Lakowicz *et al.* (18,19) with some modification (20–22). For the τ and Δτ measurements, the exciting light was modulated sinusoidally in amplitude at 18 or 30 MHz with a Debye-Sears modulator and vertically polarized with a Glan-Thompson polarizer. For τ, the emission was observed through a Glan-Thompson polarizer oriented 55° to the vertical to eliminate the effect of Brownian rotation (23). The phase shift and demodulation of the emitted light were measured relative to the reference standard 1,4-bis(5-phenyloxazol-2-yl)benzene in ethanol (τ = 1.35 ns) (24) and used to compute the phase (τ_P) and modulation (τ_M) lifetimes of the samples (25). Δτ was obtained from the phase shift between the parallel and perpendicular components of the emission observed with the emission polarizer vertically or horizontally oriented, respectively. Data were interpreted according with the model of hindered wobbling rotation (26). The values obtained for r_S, τ, and Δτ were used to compute: (i) the rotational correlation time (τ_R), which is inversely related to the rotational rate and reflects the local viscous resistance to the probe rotation; and (ii) the limiting anisotropy (r_∞), which is related to the order parameter S ($S2 = r_\infty/r_o$) and reflects the limitation imposed by the local environment to the extent or range of the probe wobbling. τ_R was obtained from the positive solution of Equation 1:

$$0 = A\,\tau_R^2 + B\,\tau_R + C \qquad [1]$$

where,

$$A = \Delta\tau\,[\,\omega^2\,\tau^2\,(1 + 2\,r_o)\,(1 - r_o) + (1 + 2\,r_S)\,(1 - r_S)\,] - 3\tau\,(r_o - r_S) \qquad [2]$$

$$B = \tau\,[\,2\,\Delta\tau\,(1 + 2\,r_S)\,(1 - r_S) - 3\tau\,(r_o - r_S)\,] \qquad [3]$$

$$C = \tau^2\,\Delta\tau\,(1 + 2\,r_S)\,(1 - r_S) \qquad [4]$$

where r_o is the fundamental anisotropy (0.39 for DPH and TMA-DPH) (27) and $\omega = 2\,\pi \times F$, F being the modulation frequency in hertz. r_∞ was calculated from

$$r_\infty = r_S - (r_o - r_S)\,\tau_R/\tau \qquad [5]$$

Laurdan fluorescence. Intensity and generalized polarization spectra were taken essentially with monochromator bandpasses of 8 nm in excitation and emission as previously described (28). All spectra were corrected for background contribution by subtracting the signal of unlabeled samples. An excitation wavelength of 360 nm was used for emission intensity spectra and an emission wavelength of 430 nm was used for excitation intensity spectra. Generalized polarization (GP) spectra were obtained by measuring the excitation intensity spectra using 440 nm (I_{440}) and 490 nm (I_{490}) for the emission, and the emission intensity spectra at 340 nm (I_{340}) and 410 nm (I_{410}) excitation wavelength. GP in the excitation (exGP) and emission (emGP) bands were obtained from $exGP = (I_{440} - I_{490})/(I_{440} + I_{490})$ and $emGP = (I_{410} - I_{340})/(I_{410} + I_{340})$, respectively.

RESULTS

Effect of cholesterol on microsomal lipid composition of liver. Increased ingestion of cholesterol for 21 d produced an increased content of cholesterol in the liver microsomal lipids (Table 1), as shown by Leikin and Brenner (1). However, it did not decrease either the total phospholipid percentage (Table 1) or the relative proportion of different phospholipid classes (data not shown). The ratio of microsomal lipid to protein was not significantly different (0.56 ± 0.08 for the control animal vs. 0.58 ± 0.10 for the cholesterol-treated rats).

The relative fatty acid composition by weight of total lipids in liver microsomes from cholesterol-fed rats was very different from control animals (Table 2); these results were similar to those of Leikin and Brenner (1). A decrease in palmitic and stearic acids was shown, together with a sharp

[a]Only principal fatty acids were considered. Data are the mean of eight animals ± SD of the mean.

increase in oleic acid that correlates with the enhancement of the Δ9 desaturase activity already shown in other works (1,9). An increase in linoleic acid and a decrease in arachidonic acid, essential n-6 fatty acids, and a decrase in docosahexaenoic acid of n-3 family would be in accordance with the experimentally determined decrease of Δ6 and Δ5 desaturase activities, which diminish their biosynthesis, as shown by Leikin and Brenner (1,2).

The effect of cholesterol diet on fatty acid composition of microsomal PC (Fig. 1) follows a similar pattern to total lipid fatty acids (Table 2). A decrease in palmitic and stearic acids, which are substrates of the Δ9 desaturase, and an increase in palmitoleic and oleic acids, their enzymatic products, were shown. Similarly to Table 2, an increase in linoleic acid and a decrease in arachidonic acid (which is the product of Δ6 and Δ5 desaturation of linoleic acid) were found along with a decrease of docosahexaenoic n-3 acid.

Effect of cholesterol on microsomal PC molecular species. The application of the method of Brouwers *et al.* (17) to separate molecular species of microsomal PC gave a very good resolution and quantification for them. Eleven major peaks were separated and identified for the control animals and 12 for the cholesterol-fed rats (Fig. 2). The distribution by weight percentage of the molecular species of PC is given in Table 3. As expected, no fully saturated species were detected. The majority of the species were constituted by saturated and unsaturated acids and even some of them by two unsaturated acids. The major species found were 18:0/20:4, 16:0/20:4, and 16:0/18:2, which are in accordance with the fatty acid composition of PC (Fig. 1). The same predominance was found in the PC of other liver and kidney organelles such as the nucleus (Ves Losada, A., Maté, S.M., and Brenner, R.R., unpublished data). Therefore, we must admit that these three molecular species, and mainly 18:0/20:4, are the ones that particularly determine the contribution of PC molecules to the biophysical properties and structure of the phospholipid bilayer in liver microsomes of animals fed a corn-oil diet. Undoubtedly, they also determine possibly important membrane points susceptible to oxidation.

The effect of cholesterol feeding, as expected produced on the PC composition (Fig. 1), an important change not only in the proportion of the different molecular species but also an indication of an interchange of the components.

The decrease of arachidonic acid biosynthesis from linoleic acid (1,2) evoked by cholesterol feeding would apparently explain the notable decrease of the 18:0/20:4 molecular species and the lesser decrease in 16:0/20:4, also favored by the decrease of 16:0 and 18:0, substrates of the increased Δ9 desaturase.

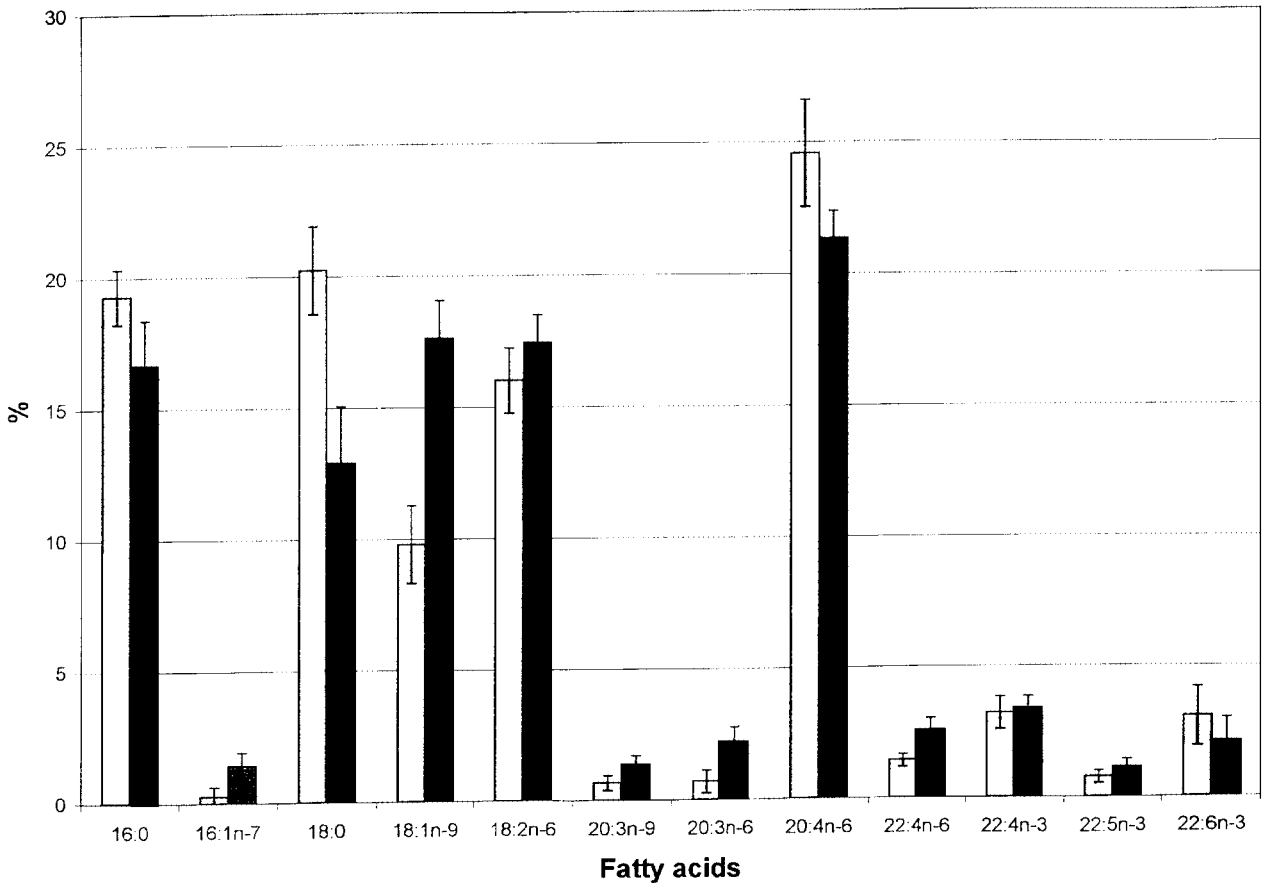

FIG. 1. Fatty acid composition (wt%) of rat liver microsomal phosphatidylcholine (PC). Results are the average of six animals analyzed individually ± SD. Open bars correspond to control animals; black bars, to cholesterol-fed rats.

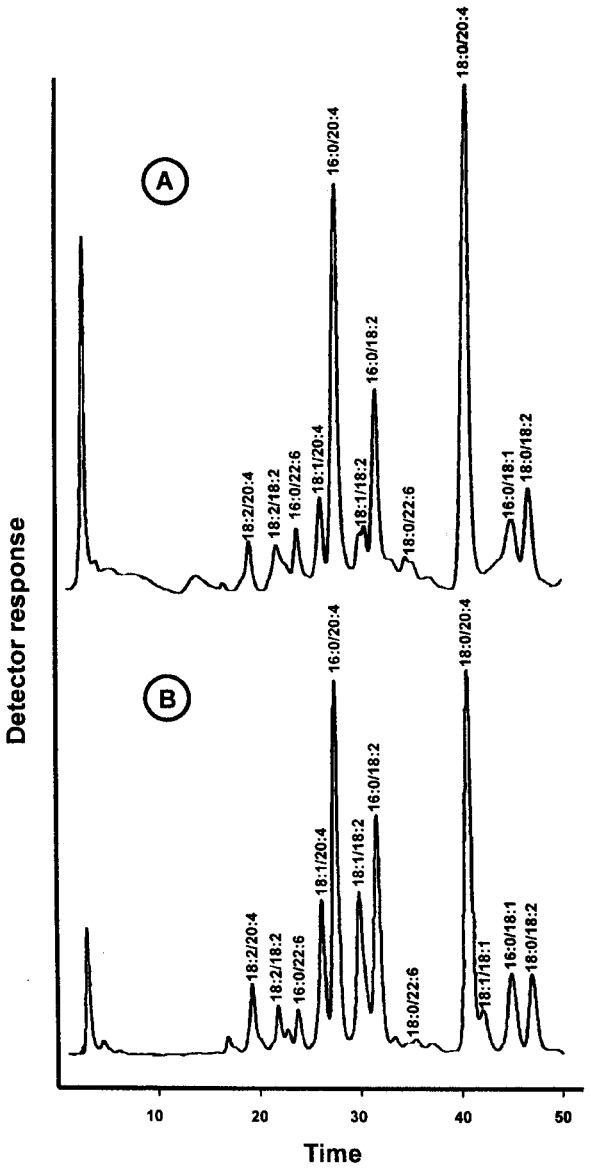

FIG. 2. High performance liquid chromatogram of PC molecular species carried out as explained in the Experimental Procedures section in two Lichrosphere 100-RP 18 columns. Peaks separated and identified by gas–liquid chromatography. (A) Control; (B) cholesterol-treated. For abbreviation see Figure 1.

However, the small increase in the minor species 18:2/20:4 and 18:1/20:4 could be due to the enhancement of 18:2 and 18:1 components as a consequence of the decrease of Δ6- and increase of Δ9-desaturase activities (1,2). It is also notable that 16:0/18:2 species did not change, probably owing to the compensatory effects of the 16:0 decrease and 18:2 increase in cholesterol-treated rats. The decrease in docosahexaenoic n-3 acid biosynthesis could be the cause of a major decrease in the 18:0/22:6 molecular species and the smaller one in 16:0/22:6.

The increase in Δ9 desaturase (1,9) evoked by the cholesterol administration enhanced not only the18:1-containing species 18:1/20:4, 18:1/18:2, and 16:0/18:1 but also the appearance of a new 18:1/18:1 molecular species. These changes produced compensation and stability of phospholipid liposome fluidity, matter that will be discussed later.

[a]Molecular species were separated and quantified by high-performance liquid chormatography as described in the Experimental Procedures section. Results represent the average of seven animals ± SD of the mean.

Although 18:0/20:4, 16:0/20:4, and 16:0/18:2 are still the predominant PC molecules in cholesterol-treated rats, 18:1/18:2 and to a lesser extent 18:1/20:4 and 16:0/18:1 species also play an important role in the contribution of PC to the properties and structure of the lipid bilayer.

Packing changes produced by diet in the cholesterol-containing and pure phospholipid liposomes of microsomal membranes studied by fluorometric methods. The influence of dietary cholesterol on the lipid bilayer dynamical properties was studied by measuring the dipolar relaxation of Laurdan and the rotational diffusion of DPH and TMA-DPH, which test different zones of the bilayer. With the aim of distinguishing between the specific effect of cholesterol content and that of the change in the phospholipid acyl chain composition, these measurements were made in large unilamellar vesicles composed of total microsomal lipids and in those composed of only microsomal phospholipids.

The effects of Laurdan on the fluorescence excitation and emission spectra of both types of vesicles are shown in Figure 3. No large differences were found in the excitation spectra. In contrast, the emission spectrum, which is very sensitive to the acyl chain packing, is significantly changed by the treatment in total microsomal vesicles. In these vesicles, dietary cholesterol evoked an increase in the blue-shifted unrelaxed emission at 440 nm. The blue-shifted emission, however, disappears almost completely in the vesicles made with only microsomal phospholipids, and no large effect is observed after the treatment. These Laurdan spectral changes can be quantified by the GP parameter calculated as explained in the Experimental Procedures section. GP spectra are shown in Figure 4. On the excitation band, the GP calculated between emission wavelengths of 440 and 490 nm is increased by the dietary cholesterol in the total lipid vesicles. In the cholesterol-free phospholipid vesicles, the GP values are much

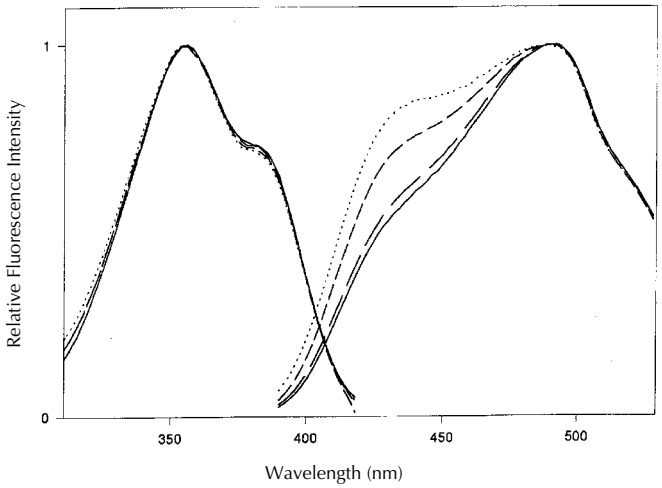

FIG. 3. Normalized excitation and emission fluorescence spectra of 6-lauroyl-2,4-dimethylaminonaphthalene (Laurdan) in unilamellar vesicles of microsomal phospholipids of control (——) and treated (— —) rats, and unilamellar vesicles of total microsomal lipids of control (– – –) and treated (·····) rats.

lower, and only a small increase in GP is observed for the phospholipid vesicles of treated microsomes with respect to the controls.

Thus, the effect of dietary cholesterol on lipid packing is mainly due to changes in the cholesterol content, and only a small effect is due to the change produced in the fatty acid composition.

Additional information on the lipid bilayer dynamical properties was obtained by studying the rotational diffusion of the neutral probe DPH, which locates deep in the bilayer, as well as of the charged TMA-DPH, which is anchored to the polar interface. These results are shown in Table 4. The steady-state anisotropy (r_s) of DPH is increased in the vesicles of total microsomal lipids of rats fed the cholesterol-rich diet. This is in accordance with previous results of Leikin and Brenner (1). Complete information on the probe rotational behavior cannot be obtained from the r_s parameter alone, since it depends on the fluorescence lifetime and is affected by both the rate and extension of the rotation. Additional lifetime and differential polarized phase measurements allow to one calculate the correlation time (τ_r), which is inversely related to the rotational rate, and the limiting anisotropy (r_∞), which is related to the wobbling extension and therefore to the membrane order. The influence of dietary cholesterol on the behavior of DPH in total lipid vesicles is mainly due to a change in the wobbling extension as indicated by marked changes in the r_∞ parameter. The rate of DPH rotation is also slowed by dietary cholesterol as shown by the change of the correlation time. DPH r_s is lower in the cholesterol-free phospholipid vesicles and in this case, on the contrary, no effect of diet is observed. The r_∞ and τ_r were also maintained in the phospholipid liposomes in spite of the change of diet.

Contrary to DPH, the r_s of the TMA-DPH probe is not changed by dietary cholesterol in other total lipid liposomes on phospholipid liposomes. The differential polarized phase measurements, however, indicated that a significant increase in TMA-DPH r_∞ is produced by the cholesterol diet only in total lipids.

Not only fluorescence lifetime is necessary to allow the calculation of the rotational parameters, but also it can inform on the probe environment polarity and water penetration into the

lipid bilayer. DPH lifetime is only slightly decreased by dietary cholesterol. However, after cholesterol elimination, DPH lifetime is notoriously shorter in the microsomal phospholipid vesicles of animals treated with the cholesterol-rich diet. This indicates that changes in fatty acid composition produced by treatment resulted in a more polar environment for DPH in the phospholipid vesicles. This fact may be a consequence of packing defects that allow an increased water penetration in the bilayer interior. However, when cholesterol is present, it would eliminate them by decreasing water penetration. In the case of the externally located TMA-DPH probe, the fluorescence lifetime is significantly shorter in the phospholipid vesicles than in the total lipid ones, showing the sealing effect of cholesterol against water penetration. However, in contrast to DPH, no dietary effect and therefore no molecular species change were observed on the TMA-DPH lifetime.

DISCUSSION

The ingestion by the rate of 1% dietary cholesterol evokes in the rat its incorporation into the animal's tissue including liver microsomes (Table 1), a well-documented increase in microsomal Δ9 desaturation of fatty acids, and a decrease of Δ6- and Δ5-desaturase activity (1–3,9). Whereas Leikin and Brenner (1,2) suggested the increase of Δ9 desaturation of fatty acids was the consequence of the increased packing produced by the cholesterol incorporation to the membrane, Landau *et al.* (9) presented data showing that the stearoyl-CoA desaturase RNA increases, to some extent, before the microsomal cholesterol incorporation into microsomes. This effect was investigated during short periods of time (up to 7 d), and results indicated that the enzyme synthesis was modified at the beginning of the event, in part as a result of an increase of the transcription rate as discussed by the authors (9). This result did not discard the possibility that a later viscotropic regulation of desaturase activity might be exerted by the incorporation of cholesterol to the microsomal membrane. Moreover, this fact has been shown to be produced on the Δ9 desaturase by *in vitro* incorporation of cholesterol into microsomes (7) and into other microsomal enzymes (5–8). Besides, the effect of a downward shift of temperature on membrane fluidity may be the triggering cause for the activity change in desaturase genes (29).

Ntambi (30) recently indicated that the transcriptional activation of genes containing sterol-responsive element (SRE) is under the regulation of sterols through modulation of the proteolytic maturation of the SRE-binding proteins (SREBP-1 and SREBP-2). In sterol-rich cells, proteolytic cleavage of SREBP inserted in the endoplasmic reticulum to the N-terminal mature polypeptide form does not take place. Therefore, its entrance to the nucleus, its binding to the SRE, and the activation of the Δ9 desaturase are avoided. This conclusion is deduced from cell studies (31). These interesting and important *in vitro* results do not agree with the *in vivo* results already cited (1–3,9) showing that dietary cholesterol activates the Δ9 desaturation. Therefore, more investigation on this subject is necessary to elucidate the cause for this apparent discrepancy and the possible direct or indirect effect of microsomal cholesterol on the membrane-bound Δ9 desaturase.

In fact, whichever mechanism is evoked upon Δ9-, Δ6-, and Δ5-desaturase activities by cholesterol ingestion, the fatty acid composition of the total lipids of liver microsomes is changed (Table 2) in such a way that it correlates with an increase of Δ9-desaturase activity and with a decrease in Δ6- and Δ5-desaturase activities, as shown experimentally (1–3,9). The amount of Δ9-desaturase substrates, 16:0 and 18:0, is decreased, whereas the amount of products, 18:1 and 16:1, is increased. Correspondingly, the amount of Δ6 desaturase substrate, linoleic acid, is increased whereas the amount of products of Δ6 and Δ5 desaturases, arachidonic and docosahexaenoic acids, is decreased. As expected, similar results are shown in the fatty acid composition of the microsomal PC (Fig. 1).

These effects on fatty acid composition, produced by a cholesterol-rich diet, of liver total microsomal lipids and PC

are apparently general since they have already been found by Veno and Okuyama in total liver and plasma (32). It is difficult to suppose that these changes might be due to the movement of lipids between organelles. Moreover, since the fatty acid composition of control and cholesterol-fed rats is the same from our point of view, the more plausible cause for the fatty acid changes is the modification of the desaturase activity already demonstrated (1–3,9). Of course, not all lipid classes and not all organs will show identical change. The possible effect of fatty acid capture by esterification to cholesterol as well as of specificity of enzymes involved in different phospholipid synthesis and retailoring and even fatty acid oxidation may also alter the final composition of the phospholipid species and PC molecular species.

PC is the principal phospholipid of liver endoplasmic reticulum. PC coerces other lipids into a bilayer structure and is a major determinant of the biophysical properties of phospholipid bilayers. Moreover, since the proportion of phospholipid classes was not changed in the present experiment due to the cholesterol diet, we may admit that the changes of PC composition would reflect, in some way, the biophysical changes of the phospholipidic part of the microsomal membrane.

After 21 d of the cholesterol diet, the composition of the molecular species of liver microsomal PC had reached an equilibrium, and the liver microsomal membrane had been adapted to the new situation. The following phenomena were produced in the membrane: (i) the incorporation of cholesterol increased the packing of the microsomal membrane, shown by an increase in the GP of Laurdan-labeled microsomal lipids (Fig. 4) and in the fluorescence r_∞ of DPH and TMA-DPH labeled ones (Table 4); (ii) there was a decrease in the Δ6 and Δ5 fatty acid desaturation and an increase of Δ9 desaturation, which is already well-documented (1–3,9); and (iii) there was a change of the relative ratios of palmitic, stearic, oleic, linoleic, arachidonic, and docosahexaenoic acids in phospholipid molecules like PC. These changes modified the proportion of PC molecular species. However, these changes were produced in such a way that the fluidity of the phospholipidic part of the membrane was roughly maintained, as shown by the fluorescence properties of Laurdan (Figs. 3 and 4), DPH, and TMA-DPH (Table 4).

The decrease in arachidonic acid (Fig. 1) led to a decrease mainly in the 18:0/20:4 PC molecular species, but also to a lesser extent in 16:0/20:4 that is more fluid. The 16:0/20:4 species is more fluid since it shows less rotational correlation and fluorescence anisotropy of DPH-labeled species as shown by Tricerri *et al.* (20) and Garda *et al.* (33). It also correlates with a decrease in saturated fatty acids, especially stearic acid. However, the even more fluid 18:2/20:4 species increased, along with the 18:2/18:2 species, which corresponds to an enhancement of 18:2n-6 acid (Fig. 1). Linoleic acid was fully provided by the diet, and the cholesterol diet decreased its conversion to arachidonic acid.

In this way, the effect of the decrease of highly polyunsaturated fatty acid-containing species on phospholipid membrane rigidity has been reduced to a minimum. It is even better compensated by the increase of oleic acid-containing species 18:1/20:4, 18:1/18:2, 16:0/18:1, and the appearance of a new species of 18:1/18:1 (Table 3).

As it is known, whereas saturated acids produce less fluid phospholipids with increasing chain length (20,33), polyunsaturated acids evoke only slightly more fluid liposomes than monounsaturated ones (34). Therefore, the substitution of 20:4-containing species by 18:1-containing species nearly compensates for the fluidizing effect. These results are similar to ones found in the molecular species of all phosphoglycerides of hepatic microsomal lipids of rats fed on a fat-free diet (33). Although the effect in this case was due not to cholesterol but to a dietary deficiency of fats that evoked an essential fatty acid-deficient status, the change in the availability of fatty acids to build up the membrane phospholipids was rather similar. There was an increase of oleic acid and palmitic acid and a decrease of arachidonic, stearic and obviously and differentially, linoleic acid. The eicosatrienoic n-9 acid was also enhanced by an increased biosynthesis. The distribution of the resulting molecular species was similar to the cholesterol effect, and it showed an important decrease of the 18:0/20:4n-6 species and a lesser one for 16:0/20:4n-6. Both were the major molecular species found in PC. In compensation, 16:0/18:1, 16:0/20:3n-9, and 18:0/20:3n-9 species were increased. The final result was that this molecular compensation in the phosphoglycerides in fact avoided a change in the packing of the microsomal phospholipid bilayer measured by fluorescent methods and it was similar to our actual case.

The change in the fatty acid composition found in the PC molecular species (Table 3) indicates that the type and proportion of the fatty acids at both the *sn*-1 and *sn*-2 positions had been altered. This is a consequence not only of the availability of different fatty acids but also of the changes in the specific activity of enzymes involved in PC biosynthesis. A re-tailoring process was produced; and a deacylation-reacylation at carbon *sn*-2 through a phospholipase A_2 and an acyltransferase known as Lands pathway (35) is apparent. Remodeling of PC molecular species at the *sn*-1 position of glycerol (36) also takes place. Moreover, the contribution of a *de novo* synthesis of phospholipids is also important considering especially the change in the proportion and type of fatty acids at the *sn*-1 position. The profile of PC species might also be influenced by different types of pathways of synthesis such as the phosphatidylethanolamine methylation.

In conclusion, we suggest that the re-tailoring of PC, as well as other phosphoglyceride molecular species, evoked by a high-cholesterol diet was able to nearly maintain the liquid-crystalline structure and bulk fluidity of the phospholipidic part of the microsomal membrane. However, it was unable to compensate for the striking packing effect produced by the incorporation of cholesterol molecules in the membrane.

Although the bulk average biophysical properties of the phospholipidic part of the microsomal membrane did not change, we found different molecular phospholipidic composition that un-

doubtedly alters other microscopic properties of the membrane, e.g., its chemical reactivity and possibly the interaction with proteins. The substitution, in part, of arachidonic and docosahexaenoic acid PC-containing species for oleic and linoleic-containing species evoked by cholesterol diet decreases the density of double bonds in the proximity of the membrane border, modifies the position and number of the clouds of polarizable π electrons surrounding the double bonds, and alters possible effects on membrane bound proteins. However, the most important effect produced by the fall in the amount of molecular species containing arachidonic and docosahexaenoic acids is the decrease of the endogenous source of these acids for their specific functions in brain and retina, as well as the activation of nuclear receptors, synthesis of eicosanoid, hepoxiline and lipoxine, etc.

ABSTRACT: The present study was carried out to examine if the positional distribution of medium-chain fatty acid (MCF) in dietary synthetic fat influences lymphatic transport of dietary fat and the chemical composition of chylomicrons in rats with permanent cannulation of thoracic duct. Four types of synthetic triacylglycerol were prepared: (i) *sn*-1(3) MCF-*sn* 2 linoleic acid, (ii) interesterified *sn*-1(3) MCF-*sn* 2 linoleic acid, (iii) *sn*-2 MCF-*sn*-1(3) linoleic acid, and (iv) interesterified *sn*-2 MCF-*sn*-1(3) linoleic acid. A purified diet composed of equal amounts of the synthetic fat and cocoa butter was given to rats with permanent lymph duct cannulation. The positional distribution of MCF in the dietary fat had no significant effect on the lymph flow, triacylglycerol output, phospholipid output, lipid composition of chylomicrons, or the particle size. The positional distribution of MCF in the synthetic triacylglycerol was maintained in the chylomicron triacylglycerol. These results showed that MCF in the dietary triacylglycerol is transported into lymphatics and the positional distribution is well preserved in chylomicron triacylglycerol.

Paper no. L8397 in *Lipids 35,* 1345–1351 (December 2000).

Octanoic and decanoic acids are representative medium-chain fatty acids (MCF) that meet a prompt demand for energy under conditions where surgical operations are carried out and pancreatic insufficiency occurs (1,2). MCF, compared with longer-chain fatty acids, are readily absorbed through the stomach as well as intestine *via* the portal route, as they have a relatively high polarity and susceptibility to β-oxidation (1,2). MCF are included to a relatively greater extent in mammalian milk and coconut oils as a form of triacylglycerol. Synthetic fats containing MCF are now used in various fields to improve the physiological properties of MCF (3–11). Absorption of MCF seems to be better than longer-chain fatty acids, but little attention has been directed to the interactive effects of MCF on longer-chain fatty acids with regard to absorption of synthetic fats and dietary fats (6,7,12). The position of longer-chain saturated fatty acids in a triacylglycerol molecule greatly influences related intestinal absorption and consequently modifies absorption rates of other longer-chain fatty acids (13–19). The importance of the position of MCF in a triacylglycerol molecule has also been advocated by us (5) and others (6,7,9–12,20,21).

Occasionally, lymphatic transport of dietary fats in rats has been measured by infusing fat-emulsion into the stomach or duodenum (22). This method has an advantage of making the interpretation of data easy since it does not need to take the interaction of lipid emulsion with other dietary components into account. Conversely, this is a drawback of this method, since the interaction of dietary components, particularly proteins, carbohydrates, and phospholipids, which influence emulsification of dietary fats from the mouth to intestine, are not taken into consideration (23). In addition, rats used for this purpose do not always recover from surgery-related stress (24). To address these problems, permanent cannulation of the thoracic duct has been done in rats (24,25), but application of this method, to characterize the lymphatic transport of dietary lipids during active dietary fat absorption, is not widespread.

In the present studies, rats were kept on diets supplemented with structure-specific fats containing MCF either in *sn*-2 or *sn*-1(3) and their interesterified fats. The lymphatic transport of dietary fats or chemical composition of lymph chylomicrons during active absorption of these dietary fats was determined in rats with a permanent lymph duct cannulation.

MATERIALS AND METHODS

Diets. All diets were prepared, based on the AIN-93G formulation (26), as described by Ni *et al.* (27). Soybean oil (7 g/100 g diet) was used for a basal diet. Cocoa butter (10.25 g/100 g diet) plus synthetic fats (10.25 g/100 g diet) was used for an experimental diet, in order to simulate a Western diet, which provides approximately 40% energy through dietary fat. Diets were prepared once a week and stored in a pow-

dered form at 4°C until feeding.

Unilever (Vlaardingen, The Netherlands) provided four types of synthetic fats. According to the manufacturer, two types of structure-specific fats, one predominantly composed of MCF in *sn*-1(3) and linoleic acid in *sn*-2 [*sn*-1(3)MCF-structured] or MCF in *sn*-2 and linoleic acid in *sn*-1(3) [*sn*-2MCF-structured] were initially prepared and each structure-specific fat was interesterified and designated as *sn*-1(3)MCF-interesterified or *sn*-2MCF-interesterified. *sn*-1(3)MCF type fats, compared with *sn*-2MCF type fats, contained less MCF (octanoic and decanoic acid) and more linoleic and oleic acid (Table 1). *sn*-1(3)MCF-structured fats included triacylglycerols with the following total number of carbon (C): in g/100 g, 0.9 C24–C30, 10.0 C34, 13.4 C36, 5.3 C38, 24.1 C44, 15.1 C46, and 12.5 C54. Similarly, *sn*-1(3)MCF-interesterified fats included the following triacylglycerols: 3.0 C24–C30, 8.7 C34, 9.9 C36, 3.2 C38, 25.4 C44, 13.3 C46, and 18.7 C54. Accordingly, *sn*-1(3)MCF-structured fats contained molecular species with three MCF (0.9 g/100 g), two MCF and one C18 fatty acid (28.7 g/100 g), one MCF and two C18 fatty acid (39.2 g/100 g), and three C18 fatty acid (12.5 g/100 g): molecular species corresponding to *sn*-1(3)MCF-interesterified fats were three MCF (3.0 g/100 g), two MCF and one C18 fatty acid (38.7 g/100 g), and three C18 fatty acid (18.7 g/100 g). Table 2 summarizes the fatty acid composition of the experimental diet.

Animals and permanent lymph duct cannulation. Male Sprague-Dawley rats, 8 wk old, obtained from Seiwa Experimental Animals (Fukuoka, Japan) were maintained in a temperature-controlled room. Rats were trained to consume the basal diet for 1 wk and then the experimental diet for 3 wk twice a day during 1000–1100 and 1700–1800, respectively. Deionized water was freely available throughout the feeding periods. Body weight and food intake were measured daily, and feces were collected for the last 5 d and freeze-dried.

All the rats were anesthetized with Nembutal anesthesia prior to the permanent cannulation of the thoracic duct lymph, as described (25). Briefly, a cannula (Silicon tube SH, i.d. 0.5 mm and o.d. 1.0 mm; Kaneka Medics, Osaka, Japan) filled with a heparinized saline was inserted into the thoracic duct and secured within the abdominal cavity. Following closure of the abdominal wall and tunneling of the cannula to the crown of the head of the rat, an adapter made from a 1-mL plastic syringe and placed on the cannula was filled with a polyvinyl pyrrolidone solution; a flame was then used to seal the tip of the tube. The rats were returned to their cages and

[a]Values are means of duplicate analyses. See Table 1 for abbreviation.

provided the experimental diet twice a day, as described above. On the third day, the rats were attached to a long PE-cannula (i.d. 0.58 and o.d. 0.97 mm; Becton Dickinson and Company, Baltimore, MD) to collect lymph. The end of the cannula was between 5–10 cm below the bottom of the cage in order to provide sufficient underpressure to allow lymph into the cannula. The lymph was collected for 15 min and the rats were then freely given access to the experimental diet for 20 min and the lymph collection was continued for another 9 h. The rats freely consumed the deionized water during the collection of lymph. After removing fibrin, ethylenediaminetetraacetic acid at a final concentration of 0.01% was added to the lymph solutions. The portion of lymph collected between 2.33 and 6.33 h was subjected to ultracentrifugation to isolate chylomicrons at $3 \times 10^6 \times g$-av. min at 10°C, using a Beckman L5-50 ultracentrifuge (Palo Alto, CA) (28).

These experiments were carried out under the guidelines for Animal Experiment in Faculty of Agriculture and the Graduate Course, Kyushu University, Fukuoka, Japan and the Law (No. 105) and Notification (No. 6) of the Government of Japan.

Determination of chylomicron particle size. Samples of lymph chylomicrons were fixed in 20 g/L osmium tetroxide (Nisshin EM, Tokyo, Japan) and examined using a JEOL JEM-2000FXII transmission electron microscope (JEOL, Tokyo, Japan) by shadow-casting with carbon-platinum pellets as described (13). Particle diameters seen on the photographic negatives (×10,000) were measured, making use of NIH Image Software (version 1.56; National Institute of Health, Bethesda, MD). The mean diameter of the chylomicrons was estimated regarding approximately 600 particles.

Biochemical analyses. The triacylglycerol structure of dietary fats and chylomicrons was analyzed by the Grignard degradation method, as described by Ikeda *et al.* (29). Dietary fats, triacylglycerols, and 2-monoacylglycerols were transmethylated with a sulfuric acid/methanol mixture (1:115, vol/vol). To prevent losses of the highly volatile methylesters of the MCF, fatty acid methyl esters were not concentrated after the hexane extraction and before injection into the gas–liquid chromatograph. Fatty acid methyl esters were analyzed by gas–liquid chromatography, as described previously (29). Analyses were performed under the following conditions: temperature program starting at 100°C followed by 5°C/min increments until the final temperature reached 220°C; detector temperature 250°C; injector temperature 250°C; flow rate of nitrogen carrier gas 15 mL/min, with a column of 10% Silar10C, Chromosorb W (AW-DMCS) 80–100 mesh (Japan Kuromato Kogyo, Tokyo, Japan). Lipids were extracted from whole lymph and chylomicrons by the method of Folch *et al*. (30). The triacylglycerols, phospholipids, and cholesterol were measured chemically (15). Lymph cholesterol was derivatized to the trimethylsilyl ether and then quantified by gas–liquid chromatography (Shimadzu, Kyoto, Japan) with an OV-17 (GL Science, Tokyo, Japan) column (29). 5-α-Cholestane (Nacalai Tesque, Kyoto, Japan) was used as an internal standard. Chylomicron-triacylglycerols were separated by thin-layer chromatography on a precoated silica gel G plate with a developing solvent (petroleum ether/diethylether/acetic acid, 82:18:1, by vol) containing *t*-butylhydroquinone as an antioxidant (29). Fecal fats were extracted according to the method of Jeejeebhoy *et al*. (31). Briefly, 1 g of freeze-dried feces was acidified with two drops of concentrated HCl to release the free fatty acids, and extracted sequentially with solvent No. 1 and solvent No. 2. The lipid extracts were dried in a vacuum desiccator and weighed, and the apparent absorption rate (%) of dietary fat was calculated as follows: 100 × [amount of daily fatty acid intake − amount of fecal fatty acids excreted]/[amount of daily fatty acid intake].

Statistics. Data were expressed as means ± SEM and analyzed by Duncans' New Multiple range test, as described previously (27).

RESULTS

Initial body weights were 305 ± 6, 304 ± 3, 308 ± 6, and 307 ± 4 g for *sn*-1(3)MCF-structured, *sn*-1(3)MCF-interesterified, *sn*-2MCF-structured, and *sn*-2MCF-interesterified group, respectively. There were no significant differences in the body weight just prior to lymph duct cannulation among the groups: 380 ± 9, 381 ± 8, 396 ± 8, and 381 ± 11 g for *sn*-1(3)MCF-structured, *sn*-1(3)MCF-interesterified, *sn*-2MCF-structured, and *sn*-2MCF-interesterifed group, respectively. Also, there were no significant differences in the food intake among the groups: 20.3 ± 1.0, 19.2 ± 0.7, 22.0 ± 0.9, and 19.8 ± 0.8 g/d for *sn*-1(3)MCF-structured, *sn*-1(3)MCF-interesterified, *sn*-2MCF-structured, and *sn*-2MCF-interesterifed group, respectively. Fecal weight was greater for rats fed the diet containing *sn*-2 MCF-structured fat than for those fed other synthetic fats: 2.09 ± 0.14^a, 2.06 ± 0.13^a, 2.70 ± 0.11^b, and 2.02 ± 0.14^a g/d for *sn*-1(3) MCF-structured group, *sn*-1(3) MCF-interesterified group, *sn*-2 MCF-structured group, and *sn*-2 MCF-interesterified group, respectively (different superscript roman letters shows significant difference at $P < 0.05$). Apparent fat absorption rate, however, was not significantly different among the groups (91.3 ± 0.9, 91.7 ± 0.8, 89.4 ± 1.6, and 92.2 ± 1.3% for *sn*-1(3) MCF-structured group, *sn*-1(3) MCF-interesterified group, *sn*-2 MCF-structured group, and *sn*-2 MCF-interesterified group, respectively).

Differences in food intake for 20 min on the day of lymph collection were not statistically significant among the groups: 4.7 ± 0.6, 4.5 ± 0.9, 4.4 ± 0.8, and 4.9 ± 0.7 g/20 min for *sn*-1(3)MCF-structured, *sn*-1(3)MCF-interesterified, *sn*-2MCF-structured, and *sn*-2MCF-interesterified, respectively. Lymph flow rates prior to, during, and after consumption of food were similar among the groups (Fig. 1). All the rats evidently increased lymph flow at 20 min and reached a maximal level 1 h after feeding and then declined to basal levels. Consumption of different synthetic fats led to no significant effect on the flow rate, at any time point.

Lymphatic lipid (triacylglycerol, phospholipid, and cholesterol) output rate prior to food consumption was similar among the groups (Fig. 2). Triacylglycerol output rate

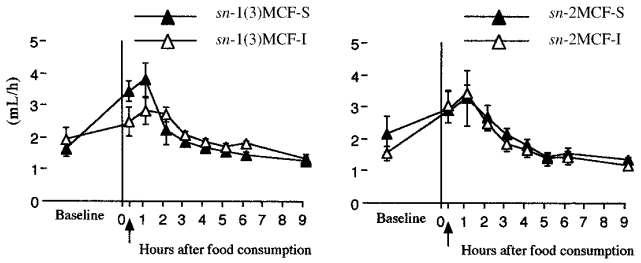

FIG. 1. Lymph flow rates in rats fed diet containing *sn*-1(3)medium-chain fatty acid (MCF)-structured plus cocoa butter [*sn*-1(3)MCF-S], *sn*-1(3)MCF-interesterified plus cocoa butter [*sn*-1(3)MCF-I], *sn*-2MCF-structured plus cocoa butter [*sn*-2MCF-S], or *sn*-2MCF-interesterified plus cocoa butter [*sn*-2MCF-I]. Arrow indicates termination of food consumption. Values are means ± SEM, $n = 6$.

reached the maximum between 2 and 4 h after food consumption, was maintained by the sixth hour, and gradually declined thereafter. There were no significant differences in triacylglycerol output rates among the four groups. Triacylglycerol mass in the lymph collected for 9.33 h after the start of food consumption did not differ significantly among the groups: 608 ± 81, 559 ± 102, 528 ± 100, and 608 ± 68 μmol/9.33 h for *sn*-1(3)MCF-structured, *sn*-1(3)MCF-interesterified, *sn*-2MCF-structured, and *sn*-2MCF-interesterified group, respectively. The pattern of phospholipid output rate was similar to that for triacylglycerol and the rate was similar among the groups. Phospholipid mass in the lymph collected for 9.33 h was also similar among the groups: 68.7 ± 4.5, 71.6 ± 7.5, 73.7 ± 8.3, and 72.7 ± 8.1 μmol/9.33 h for *sn*-1(3)MCF-structured, *sn*-1(3)MCF-interesterified, *sn*-2MCF-structured, and *sn*-2MCF-interesterified group, respectively. In contrast to these lipids, the pattern of cholesterol output rate was similar to the lymph flow. The *sn*-1(3)MCF-interesterified group maintained a higher cholesterol output rate between 2 and 6 h after food consumption than did the other groups ($P < 0.05$), hence the lymphatic cholesterol mass was greater in *sn*-1(3)MCF-interesterified group (22.5 ± 1.6 μmol/9.33 h) than in *sn*-1(3)MCF-structured group (17.4 ± 0.9 μmol/9.33 h), *sn*-2MCF-structured group (19.5 ± 0.6 μmol/9.33 h), and *sn*-2MCF-interesterified group (18.3 ± 1.6 μmol/9.33 h), which did not differ.

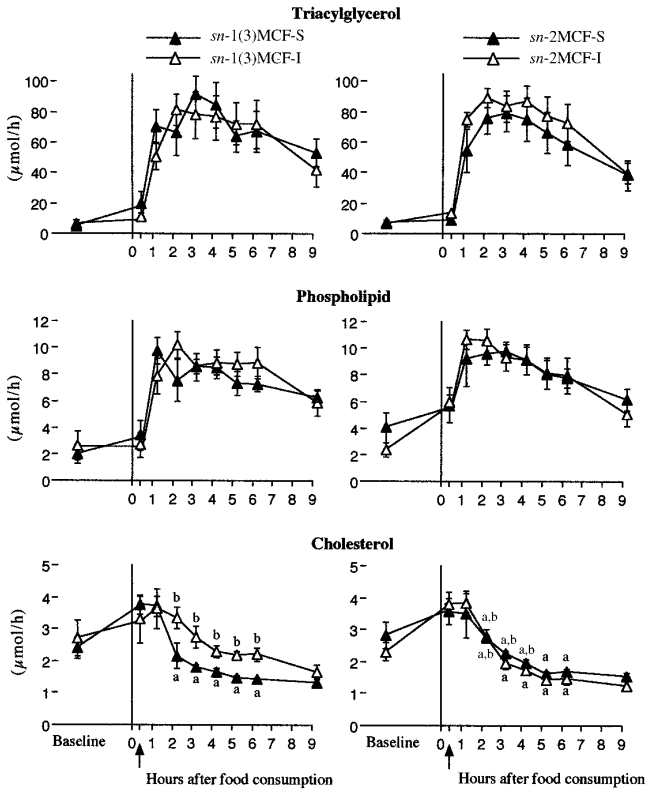

FIG. 2. Lymphatic output rates of triacylglycerol, cholesterol, and phospholipid in rats fed diets containing *sn*-1(3)MCF-structured plus cocoa butter [*sn*-1(3)MCF-S], *sn*-1(3)MCF-interesterified plus cocoa butter [*sn*-1(3)MCF-I], *sn*-2MCF-structured plus cocoa butter [*sn*-2MCF-S], or *sn*-2MCF-interesterified plus cocoa butter [*sn*-2MCF-I]. Arrow indicates termination of food consumption. Values are means ± SEM, $n = 6$. Values at each time in both panels assigned different letters are significantly different at $P < 0.05$. See Figure 1 for abbreviation.

Lymph chylomicrons were isolated from the lymph collected during 2–6 h after the food consumption and used for determinations of the chemical composition and particle size. Different structure of dietary fats did not influence the chemical composition and the particle size (Table 3). The dietary fats reflected total as well as *sn*-2 fatty acid compositions of the chylomicron triacylglycerol (Table 4). Chylomicron-triacylglycerol contained more decanoic acid than octanoic acid. Reflecting the proportion of MCF and linoleic acid in the diet, chylomicrons prepared from rats fed *sn*-2MCF type synthetic fats included more MCF than did those from the *sn*-1(3)MCF type synthetic fat-fed group and vice versa for linoleic acid. The proportion of MCF and linoleic acid in *sn*-2 position also reflected the positional specificity of these fatty acids in the diet. In contrast, the proportion of MCF in total fatty acid was not influenced by the positional distribution of MCF in the synthetic fats; there were no marked differences in the MCF proportion within *sn*-1(3)MCF type fat group and *sn*-2MCF type fat group, respectively. There were also no marked differences in the cocoa butter-derived fatty acids (palmitic, stearic, and oleic acid) in total or *sn*-2 fatty acid composition among the groups.

DISCUSSION

Evidence suggests that emulsification of dietary fat with dietary components (phospholipids, hydrophobic proteins, and carbohydrates) in the stomach and upper intestine, gastric lipolysis, stimulation of gastric hormone secretion, and fine emulsification by the lipolytic products (fatty acids and diacylglycerols) impact absorption and digestion of dietary fats (23). However, stomach or duodenum infusion of lipid emulsion was usually done to assess the transport of the emulsified lipid and composition of lymph chylomicrons (22). In this respect, our approach is particularly relevant to evaluate lymphatic transport of dietary fats in normally fed rats.

The present study showed that the positional distribution

TABLE 3
Chemical Composition and Particle Size of Lymph Chylomicrons in Rats Fed *sn*-1(3)MCF or *sn*-2MCF Type Synthetic Fats-Containing Diet[a]

	sn-1(3)MCF + cocoa butter		*sn*-2MCF + cocoa butter	
	Structured	Interesterified	Structured	Interesterified
Triacylglycerols (mol/100 mol)	85.9 ± 1.2	85.1 ± 1.4	85.0 ± 1.0	86.9 ± 0.4
Phospholipids (mol/100 mol)	11.7 ± 0.8	11.9 ± 0.9	12.4 ± 0.7	11.1 ± 0.4
Free cholesterol (mol/100 mol)	1.5 ± 0.2	2.0 ± 0.4	1.7 ± 0.1	1.3 ± 0.1
Esterified cholesterol (mol/100 mol)	0.9 ± 0.2	1.1 ± 0.3	1.0 ± 0.2	0.6 ± 0.1
Particle size (nm)	140 ± 16	121 ± 10	120 ± 7	137 ± 10

[a]Values are means ± SEM, $n = 6$. See Table 1 for abbreviation.

of MCF or the amount of MCF in the synthetic triacylglycerols exerted no significant effect on the lymphatic output rate of triacylglycerol or phospholipid, suggesting less effect of the MCF position on dietary fat absorption. These results are in agreement with apparent fat absorption in rats prior to lymph duct cannulation. However, the present results are in contrast to our previous observations (32); we found that MCF positioned in *sn*-1(3), rather than in *sn*-2, resulted in a significant increase in the absorption of dietary fats, particularly long-chain saturated fatty acids, as reflected in a lowered fecal excretion of palmitic and stearic acid, when rats were freely fed on the diets containing the synthetic fats. Although the reason for this discrepancy is not clear, it may be due to the way of feeding; in the present study, rats were restrictedly fed the diet, in contrast to the previous study in which they were fed freely. Alternatively, it may be that we failed to observe any differences between rats fed the different types of synthetic triacylglycerols due to the presence of protein or carbohydrate in the diet.

In contrast to the transport of triacylglycerol and phospholipid, the type of synthetic fats affected the pattern of cholesterol output. The *sn*-1(3) MCF-interesterified group maintained a higher cholesterol output rate than did the other groups. The reason for this remains to be determined.

Chemical compositions and particle sizes of chylomicron found in the present study were similar to those for rats to which artificial fat-emulsions were administered into the duodenum as described previously (28,33), indicating that dietary fats are transported as large chylomicrons during active fat absorption. The positions of MCF in the synthetic fats had no significant effect on the chemical composition and the sizes of chylomicrons. Despite these similarities, the type of dietary fats altered fatty acid compositions of the chylomicron-triacylglycerols. As expected, *sn*-2 positioned linoleic acid in the synthetic fats was maintained to the *sn*-2 position of the lymph chylomicron triacylglycerol because reacylation of 2-monoacylglycerol is the predominant pathway during active absorption of dietary fat (19). Interestingly, MCF was well preserved in both the *sn*-2 and *sn*-1(3) positions in the chylomicron-triacylglycerol depending on their position in the synthetic fats ingested, indicating that the MCF released from the *sn*-1(3) position of synthetic fats was also utilized in the intestine for reesterification of 2-monoacylglycerols. Therefore, these findings differ from data in previous reports that preduodenal lipases preferentially hydrolyze MCF derived from medium-chain triacylglycerols and that the resulting MCF can be absorbed predominantly through the stomach (34). It appears that MCF in 2-monoacylglycerols isomerize more rapid than do long-chain length fatty acids, thereby facilitating rapid and complete hydrolysis (35).

Positional distribution of MCF in lymph chylomicron triacylglycerol can be relevant to the catabolism of chylomicrons

in blood plasma, because chylomicrons derived from the *sn*-2MCF-structured group had a longer half life in the circulation than those from the corresponding interesterified group, when they were intravenously infused into recipient rats (Carvajal, O., Kishi, T., Tomoyori, H., Sato, M., Ikeda, I., Sugano, M., and Imaizumi, K, unpublished observations).

Comparison of the proportion of octanoic and decanoic acid in the dietary fats with their proportion of the lymph chylomicron triacylglycerol allows for estimation of the transport route of these MCF into the lymphatic or portal vein circulation. More than 60% of decanoic acid in the diet seemed to be transported into the lymphatics, whereas it was less than 30% for octanoic acid. These findings are in agreement with other results that canine lymph contained more decanoic acid than octanoic acid despite a higher ratio of octanoic acid to decanoic acid in the diet (7).

In summary, our studies confirmed that MCF in the dietary triacylglycerols are transported into lymphatics and the positional distribution is well preserved in chylomicron triacylglycerol.

Kinetics of 2-Monoacylglycerol Acyl Migration in Model Chylomicra

Galina Lyubachevskaya and Elizabeth Boyle-Roden*

Department of Nutrition and Food Science, University of Maryland, College Park, Maryland 20742

ABSTRACT: In the metabolism of triacylglycerol (TG)-rich lipoproteins, 2-monoacylglycerols (2-MG) are produced by lipoprotein lipase (LPL) hydrolysis of TG. The metabolic fate of 2-MG is not known with certainty. 2-MG that accumulate on the chylomicra surface have been proposed to isomerize spontaneously to 1(3)-MG, which are then hydrolyzed by LPL to free fatty acids and glycerol. In this study the rate and the effect of acyl chain saturation on the spontaneous acyl migration of 2-MG in *in vitro* model chylomicra emulsions were determined. After 1 h of incubation at 37°C, less than 20% of 2-monoolein (2-MO) or 2-monopalmitin (2-MP) spontaneously isomerized to 1(3)-MO or 1(3)-MP, respectively. Accordingly, it was concluded that spontaneous isomerization of 2-MG is not the major mechanism for 2-MG metabolism post-TG hydrolysis in chylomicra. Isomerization rates, expressed as decrease in percentage of 2-MG remaining per hour, were –5.12 and –5.86 in water, and –0.43 and –0.41 in hexane for 2-MO and 2-MP, respectively. There was no significant difference between the isomerization rates of 2-MO and 2-MP. Thus, in the present study, saturation of the MG acyl chain did not influence spontaneous acyl migration in either water or hexane, but isomerization of 2-MG was faster in water than in hexane.

Paper no. L8577 in *Lipids 35*, 1353–1358 (December 2000).

Historically, the acyl migration of 2-monoacylglycerols (2-MG) has been problematic in the characterization, isolation, and synthesis of acylglycerols, thus hindering progress in lipid metabolism research. 2-MG isomerizaton significantly interfered with the interpretation of data regarding the specificity of lipoprotein lipase (LPL) (1–3). Currently, 2-MG isomerization has proven to be a serious obstacle in the synthesis of structured lipids (4–8). However, few data on the kinetics of 2-MG acyl migration are available.

Triacylglycerol (TG) in chylomicra is hydrolyzed by LPL, which cleaves the ester bonds at the 1- and 3-TG positions, producing free fatty acids (FFA) and 2-MG. Several theories are currently proposed for the metabolic fate of 2-MG post-TG hydrolysis, including the following: 2-MG diffuse away from the site of lipolysis and fuse with cell membranes (9,10), 2-MG are bound and transported by serum albumin (11,12), 2-MG remain in chylomicra remnants or transfer to low density lipoprotein and high density lipoprotein, which are then taken up by the liver (13,14), and 2-MG spontaneously isomerize to 1(3)-MG, which are then hydrolyzed by LPL to glycerol and FFA (1–3,15). None of these theories, however, is supported by a consensus of scientific evidence.

Many investigators agree that on the surface of chylomicra, 2-MG may quickly isomerize to 1(3)-MG, which is in turn hydrolyzed by LPL. However, there are few published data that directly support this hypothesis. Nilsson-Ehle *et al.* (1–3) directly measured the degree of 2-MG isomerization that occurs during LPL hydrolysis of chylomicra-like TG emulsions; however, their data were inconsistent. Conclusions about isomerization of 2-MG in chylomicra from other studies are for the most part based on indirect methods (13, 14,16,17). Furthermore, the *in vitro* models used to investigate chylomicra lipolysis and potential 2-MG isomerization always included LPL and usually albumin, making direct interpretation of their results in regard to spontaneous 2-MG isomerization difficult. Thus, the primary goal of the present study was to determine the kinetics of spontaneous 2-MG acyl migration in chylomicra.

The degree of saturation of fatty acid acyl chains of MG may influence chylomicra lipolysis by LPL and subsequent remnant clearance by the liver (18). It has been reported that unsaturated 2-MG isomerize faster than saturated 2-MG, which suggests that differential isomerization rates of 2-MG may affect chylomicra metabolism (15). Therefore, a secondary goal of the present study was to determine the possible influence of saturation on the rate of 2-MG isomerization in model chylomicra emulsions.

An *in vitro* chylomicra emulsion model, free of other potentially complicating components such as enzymes or albumin that might induce or even catalyze 2-MG isomerization, was used. Both the 2- and 1(3)-isomers of monoolein (MO) and monopalmitin (MP) were quantified directly. Isomerization rates in water and hexane were compared to assess the effects of aqueous and organic media on the rate of acyl migration.

Abbreviations: ANOVA, analysis of variance; CE, cholesteryl ester; FFA, free fatty acids; GC, gas chromatography; LPL, lipoprotein lipase; MG, monoglycerine; MO, monoolein; MP, monopalmitin; PC, phosphatidylcholine; TG, triacylglycerol; TLC, thin-layer chromatography; TO, triolein.

EXPERIMENTAL PROCEDURES

Preparation of model chylomicra emulsions. 2-MO and 2-MP were purchased from Doosan Serdary Research Laboratories (Englewood Cliffs, NJ), stored at –20°C and analyzed for purity prior to use as described below. 2-MO contained 89.9% of 2-MO and 10.1% of 1(3)-MO, and 2-MP contained 90.9% of 2-MP and 9.1% of 1(3)-MP. Model chylomicra emulsion particles were prepared by a method similar to that reported by Derkson *et al.* (19). Lipids (Table 1) were combined in organic solvent in a 4-mL vial and mixed with a vortex mixer. The solvent was evaporated under nitrogen and 1 mL of aqueous Tris buffer, pH 7.4, containing 0.15 M sodium chloride and 0.008 M sodium azide, which was used as an antimicrobial agent, was added to the lipids. The mixture was sonicated for 30 min in continuous mode at power level 2 using a Heat Systems Sonicator (Plainview, NY). During sonication, samples were held in an ice-water bath to prevent heating, which can induce isomerization. Sample temperature during sonication did not exceed 15°C.

Incubations and sample analysis. Synthesized model chylomicra emulsions were held in a shaker-water bath at 37°C for 50 h. Aliquots of 25 μL were taken for thin-layer chromatography (TLC) and gas chromatography (GC) analysis at various times. There were three replicate experiments; in each, both 2-MO and 2-MP were measured in duplicate.

Particle sizing. Particles were sized using dynamic laser-light scattering to determine mean particle diameter on a number weight basis with a Nicomp Model 370 laser particle sizer (Particle Sizing Systems, Santa Barbara, CA). The size distribution of model chylomicra emulsion particles was determined to ensure that *in vitro* particles were within the biologically relevant range. Samples for particle sizing were taken at 10 min and at 24 h after preparation.

Microbial plate count. Analysis of microbial growth in the samples was necessary to ensure that isomerization of 2-MG to 1(3)-MG was not a result of microorganism metabolism. Samples for microbial plate counts were taken in duplicate after 5 and 24 h. Samples (20 μL) were plated onto nondifferentiating LB media (Lennox Broth; Sigma, St. Louis, MO) and incubated at 36°C for 24 h.

Temperature controls. The influence of temperature on the rate of 2-MG isomerization was monitored by measuring the degree of isomerization of three 10-μL aliquots of sample taken at 10 min, which were then held at –10, 10, or 25°C for 30 h.

TABLE 1
Composition of Model Chylomicra Emulsions

Lipid	Concentration (mg/mL)	Molar ratio (%)	Weight ratio (%)
Triolein	79	68.8	77.8
L-α-Phosphatidylcholine	16	16.1	15.7
Cholesterol	1	1.9	0.98
Cholesteryl laurate	0.5	0.6	0.5
2-Monoolein	3	6.4	2.9
2-Monopalmitin	3	6.4	2.9

Sonication controls. To confirm that sonication did not influence isomerization, controls were prepared as follows: the same amount and proportions of total lipid used to prepare emulsions (Table 1) were dispersed in hexane at the same time that aqueous buffer was added to emulsion samples. While samples were sonicated, the controls were kept in an ice-water bath. The 2-MG content of both sonicated and unsonicated control lipid mixtures was analyzed immediately following sonication.

Solvent controls. Solvent controls were used to determine the effect of solvent on the rate of acyl migration of 2-MG. Aqueous and hexane solvents were compared. For this purpose, the sonication controls were kept in the shaker-water bath at 37°C with the samples and were analyzed after 0, 2, 5, 9, 24, 30, and 50 h of incubation. The effect of total lipid content of model chylomicra emulsions on 2-MG isomerization was examined by comparing the percentage of 2-MG in mixtures containing 2-MG, triolein (TO), phosphatidyl choline (PC), cholesterol, and cholesteryl ester (CE) in hexane and samples containing only 2-MG and PC in hexane.

Boric acid TLC. TLC plates impregnated with 1.2% boric acid were used to separate 2-MG and 1(3)-MG (20). Samples (10 μL) containing 30 μg each of MO and MP were applied to TLC plates (silica gel 60, 250-μm layer thickness, 10 × 5 cm; Whatman, Clifton, NJ) in duplicate. The developing solvent was chloroform/methanol (98:2, vol/vol). The separated lipid bands were visualized by iodine vapors and extracted from the silica with 1 mL of benzene.

GC. MG isomers were transmethylated by addition of acetyl chloride/methanol (1:15, vol/vol). Linoleic acid (Sigma) and methyl laurate (Nu-Chek-Prep, Elysian, MN) were used as internal standards. A Hewlett-Packard 5890 series gas chromatograph equipped with a DB-23, 30-m capillary column (J&W Scientific, Folsom, CA), automatic controller, autosampler, and HP 3396A integrator was used to quantify MG isomers. For each aliquot and time point, the percentage of 2-MG remaining in the samples was calculated as 2-MG/[2-MG + 1(3)-MG] × 100.

Statistical analysis. Two statistical models, analysis of variance (ANOVA) and analysis of covariance, were used to compare rates of 2-MP and 2-MO isomerization, using the SAS software package (SAS Institute Inc., version 6.12, Cary, NC). 2-MG, time, and 2-MG vs. time were the sources of variation in the ANOVA model. Goodness of fit statistics provided in the mixed model were used to select a model that accounted for any heterogeneity associated with either time or 2-MG. The best-fitting model indicated that variances were different over time, but were homogeneous for 2-MG. Therefore, 2-MG variances were pooled to provide a more precise estimate of the random variance. In the analysis of covariance, 2-MG was a class variable, whereas time was a continuous regression variable. All nonsignificant sources of variation, except for the linear sources of variation, were removed. Linear regression effects over time were presented if all higher-order terms were not significant. Differences were considered significant at $P < 0.05$.

RESULTS AND DISCUSSION

Particle size. The particle size distribution of model chylomicra emulsions was stable over time and consistent for all experiments. The mean particle diameter on a number–weight basis ranged between 155–194 nm with a standard deviation (SD) of 34 nm and thus resembled the physiological distribution of chylomicra (19).

Microbial growth. Results of the microbial plate count indicated that all samples were free from microbial growth throughout the time course of the experiments.

Effect of temperature. The effect of temperature on the isomerization rate of 2-MG in model chylomicra emulsions is given in Table 2. In agreement with the literature, temperature was directly related to isomerization rate of 2-MG, with the rate of 2-MG migration increasing with an increase in incubation temperature. At –10°C there was no acyl migration detected at 30 h incubation in aqueous medium for either 2-MP or 2-MO.

Effect of sonication. There was no significant difference in the percentage of 2-MG remaining in the sonicated and unsonicated samples. The average percentages of 2-MP and 2-MO, with standard errors of the means, in sonicated emulsions were 91.42 ± 1.66 and 90.85 ± 1.66, respectively, and in sonication controls were 90.87 ± 1.89 and 89.90 ± 1.89, respectively. Thus, the thermal and mechanical energy resulting from sonication did not induce additional isomerization in either 2-MO or 2-MP. The initial presence of 1(3)-MG in samples is the result of acyl migration during long-term storage of 2-MG at –20°C.

Acyl migration. The acyl migration of 2-MO and 2-MP occurred slowly in model chylomicra reaching the equilibrium ratio of approximately 12:88 [2-MG/1(3)-MG] by 30 h (4,5, 15). The acyl migration of 2-MO and 2-MP, reported as means of all duplicates and experiments in model chylomicra emulsions from 0 to 5 h at 37°C and pH 7.4, is shown in Figure 1. The degree of acyl migration is presented as the percentage of 2-MG remaining at each time point based on the total amount of 2- and 1(3)-isomers in each aliquot. The results are presented as the linear regression lines because both ANOVA and analysis of covariance indicated that the best fit for the data was linear. Statistical analysis confirmed no significant difference in the variability of data among three experiments. The regression lines of 2-MO and 2-MP shown in Figure 1 overlap, showing that there was no difference between the isomerization rates of 2-MO and 2-MP as confirmed by ANOVA and analysis of covariance. There also was no effect of acyl chain saturation on isomerization rate between 2-MP and 2-MO. The only significant effect was that of time. Because 2-MG over time was not significant, change over time was not different for 2-MO or 2-MP. This suggests that saturation of acyl chain may not influence spontaneous acyl migration of 2-MG.

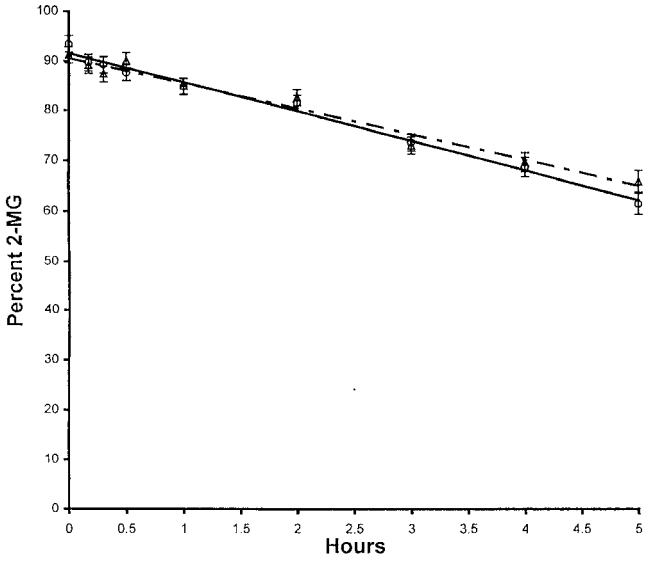

FIG. 1. Kinetics of 2-monoolein (2-MO) and 2-monopalmitin (2-MP) isomerization in model chylomicra emulsions. Values are the means ± SEM (n = 6) of the percentage of 2-MO (Δ, broken line) and 2-MP (○, solid line) remaining at different incubation times. Equations of linear regression: 2-MO, $y = -5.12x + 90.68$; and 2-MP, $y = -5.86x + 91.59$. Abbreviation: 2-MG, 2-monoacylglycerol.

The finding that saturation did not affect the 2-MG spontaneous isomerization is very important because this topic has been a subject of scientific controversy. Since the report of Mattson and Volpenhein in 1962 (15), it has been assumed that 2-MG with unsaturated acyl chains isomerize faster than 2-MG with saturated acyl chains. However, the authors admitted that their results could be erroneous due to the limited dispersability of saturated 2-MG in water. In the present study, both saturated and unsaturated 2-MG were equally dispersed in the model chylomicra emulsions.

After 1 h of incubation, less than 20% of 2-MG was isomerized to 1(3)-MG, and after 5 h, less than 40% of 2-MG was isomerized to 1(3)-MG. The rates of 2-MO and 2-MP isomerization were –5.12 and –5.86% of 2-MG/h, respectively. Thus, the rate of spontaneous isomerization of 2-MG in the model chylomicra emulsions tested in the present study was considerably less than the rate of chylomicra clearance *in vivo*. Indeed, for humans, the normal residence time of chylomicra in the circulation is less than 1 h (21). Therefore, although spontaneous isomerization of 2-MG produced from LPL hydrolysis of TG does occur, it does not appear to be the major mechanism of 2-MG metabolism in chylomicra.

TABLE 2
Temperature Controls[a]

Temperature controls (°C)	2-MO (%)	2-MP (%)
37	12.34 ± 1.90	17.07 ± 1.90
25	35.72 ± 1.66	34.24 ± 1.66
10	71.12 ± 2.34	71.69 ± 2.34
–10	89.55 ± 0.47	91.03 ± 2.47

[a]Values are the mean ± SEM (n = 6) of the percentage of 2-MG remaining at 30 h. Abbreviations: 2-MO, 2-monoolein; 2-MP, 2-monopalmitin; MG, monoacylglycerol.

A number of researchers investigating chylomicra lipolysis have commented on the potential significance of spontaneous acyl migration in lipid metabolism (1–3,10,13–17). However, their conclusions about 2-MG acyl migration were based mainly on indirect measurements of 2-MG with variable statistical significance. Most studies did not relate the rate of chylomicra clearance to the rate of 2-MG isomerization. Only Nilsson-Ehle *et al.* (1–3) directly measured the degree of 2-MG isomerization during LPL hydrolysis. However, the extent of 2-MG isomerization varied considerably for different experiments. After 20-min/incubation the amount of 2-MO recovered ranged from 95 to 36%. These variable results could be due to the fact that the objective of their studies was to investigate the specificity of LPL, not necessarily 2-MG isomerization. As a result, experimental conditions such as incubation temperature, concentrations and source of LPL, and presence or absence of albumin varied considerably. Another reason could be the difficulty in quantifying the 1(3)-isomer because of its susceptibility to further LPL hydrolysis.

The present study was designed to mimic physiological chylomicra with respect to lipid content, aqueous environment, sodium chloride concentration, particle size, pH, and temperature. Factors that might contribute to 2-MG migration, such as sonication and microbiological growth, were also controlled. Albumin and LPL were excluded so that only spontaneous chemical isomerization of 2-MG would be measured. Both 2- and 1(3)-MG isomers were quantified directly and separately. Results were reproducible, having only minimal variability among experiments as well as between duplicates. Therefore, taking into consideration the experimental design of the present study, it is likely that the spontaneous isomerization of 2-MG and their subsequent hydrolysis by LPL is not the major mechanism of 2-MG metabolism post-TG hydrolysis in chylomicra. However, direct application of these *in vitro* results to *in vivo* processes is limited because other factors may affect isomerization. Components, such as LPL or albumin, that were deliberately omitted from the model may in fact catalyze 2-MG isomerization. Scow and Olivecrona (16) reported that bovine LPL hydrolyzed chylomicra TG to mostly fatty acids and glycerol when incubations contained sufficient albumin to bind all fatty acids formed. The transient accumulation of MG under these conditions suggested that 2-MG may first isomerize to 1(3)-MG and then be hydrolyzed to fatty acid and glycerol (16). However, when albumin was either limited or added in excess, MG accumulated in the reaction mixture (16). Thus, in the presence of sufficient albumin LPL may either catalyze the isomerization of 2-MG or directly hydrolyze 2-MG.

Effect of solvent. The degree of isomerization in hexane compared to model chylomicra emulsions is shown in Figure 2. The hexane solutions of 2-MG contained the same amounts and proportions of total lipid as the emulsions (Table 1), and both were mixed and held at the same temperature for the same time. Also, the effect of total lipid content on 2-MG isom-erization was examined by comparing the rates of isomerization of 2-MG in two mixtures: 2-MG, TO, PC, cholesterol and CE, and 2-MG and PC in hexane (results not shown).

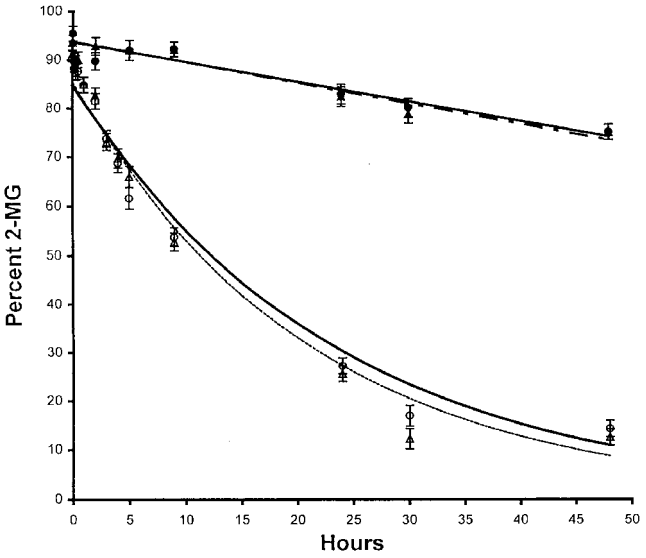

FIG. 2. Isomerization kinetics of 2-MO and 2-MP in water and hexane. Values are the means ± SEM (n = 6) of the percentage of 2-MO in water (Δ) or hexane (▲), and 2-MP in water (○) or hexane (●) remaining at different incubation times. Equations of linear regression for MG in hexane are: 2-MP, $y = -0.41x + 93.71$; and 2-MO, $y = -0.43x + 93.89$; and exponential curve fits for MG in water are: 2-MP, $y = 84.77\ e^{-0.043x}$, and 2-MO, $y = 85.61\ e^{-0.047x}$.

Both 2-MO and 2-MP isomerized more slowly in hexane than in aqueous buffer, regardless of lipid content. At 50 h of incubation, less than 30% of the 2-MG isomerized in hexane, whereas the ratio of 2-MG/1(3)-MG reached equilibrium at 30 h in water. Results presented in Figure 2 confirm that there was no difference in degree or extent of acyl migration for 2-MO and 2-MP in either water or hexane.

The literature is contradictory regarding the effects of water on 2-MG isomerization. Whereas some investigators reported that water in an organic solvent-free system is not involved in spontaneous isomerization of 2-MG (6–8,22), others suggest that water is a critical factor in promoting acyl migration (4,23–25). In the present study, isomerization of 2-MG in an aqueous environment was significantly faster than in hexane (see Fig. 2).

The presence of lipids other than MG in the emulsions did not affect the rates of 2-MG isomerization. Two different solvent controls were used. One contained 2-MG and PC in hexane and the other contained 2-MG and all other emulsion lipid components in hexane. There was no difference in isomerization rate between samples of 2-MG and PC and samples of 2-MG and all emulsion component lipids (data not shown). Thus, it can be inferred that addition of other lipid classes in proportions found in native chylomicra did not influence the rate of spontaneous acyl migration in hexane. Therefore, water is a contributing factor of 2-MG isomerization.

Several mechanisms have been proposed to explain the role of water in 2-MG acyl migration. Kodali *et al.* (25) sug-

gested that the catalytic effect of water is due to its ability to lower activation energy of formation of the 1,2-orthoester acylglycerol intermediate in isomerization of 2-MG to 1(3)-MG. Based on results of the present study, the differences between rates of isomerization in water and hexane are also proposed to be related to the physical state of 2-MG in each solvent. Currently, there is no information in the literature on the possible correlation between the physical aggregation state or mesophase of 2-MG and the rate of acyl migration. In pure organic solvent, 2-MG would be present as scattered monomers with complete freedom of rotational and translational movement in three dimensions. In organic solvent with small amounts of water, 2-MG would probably form reverse micelles with hydrophobic tails dispersed in the surrounding organic solvent, with the hydrophilic heads grouped together and with water sequestered in the center. In aqueous solvent, either lamellae or micelles would be formed, depending on the concentration of 2-MG. Molecules in lamellae are arranged in layers packed head-to-head and tail-to-tail, whereas in micelles, the tails aggregate together as the polar heads disperse in the surrounding water to form a small sphere. 2-MG in both lamellae and micelles have less freedom of movement compared to 2-MG in monomers or reverse micelles in organic solvent. Therefore, it is possible that these particular alignments are more favorable for formation of the orthoester intermediate, which would consequently increase the rate of acyl migration.

This study showed that in model chylomicra 2-MO and 2-MP spontaneously isomerized significantly more slowly than expected and that there was no difference in the rates of isomerization between the saturated and unsaturated 2-MG. In taking into account the normal plasma residence time of chylomicra *in vivo*, it can be concluded that although the spontaneous isomerization of 2-MG to 1(3)-MG may occur, it is not likely the major mechanism of 2-MG metabolism post-TG hydrolysis. Additionally, the rate of spontaneous 2-MG isomerization is significantly faster in water than in hexane. In conclusion, the differences in reported rates of 2-MG isomerization may be due to differences in the physical aggregation state of MG in the various systems studied.

Purification, Characterization, and Molecular Cloning of Group I Phospholipases A_2 from the Gills of the Red Sea Bream, *Pagrus major*

Noriaki Iijima*, Satoshi Uchiyama, Yukichi Fujikawa, and Muneharu Esaka

Faculty of Applied Biological Science, Hiroshima University, Higashihiroshima 739-8528, Japan

ABSTRACT: Phospholipase A_2 (PLA_2) activity was investigated in various tissues of male and female red sea bream. In both male and female fishes, the specific activity of PLA_2 in the gills was 70 times higher than that in other tissues, such as the adipose tissue, intestine, and hepatopancreas. Therefore, we tried to purify PLA_2 from the gill filaments of red sea bream to near homogeneity by sequential chromatography on Q-Sepharose Fast Flow, Butyl-Cellulofine, and DEAE-Sepharose Fast Flow columns, and by reversed-phase high-performance liquid chromatography. Two minor and one major PLA_2, tentatively named G-1, G-2 and G-3 PLA_2, were purified, and all showed a single band with an apparent molecular mass of approximately 15 kDa by sodium dodecylsulfate-polyacrylamide gel electrophoresis. The exact molecular mass values of G-1, G-2, and G-3 PLA_2 were 14,040, 14,040 and 14,005 Da, respectively. G-1, G-2, and G-3 PLA_2 had a Cys 11 and were all identical in N-terminal amino acid sequences from Ala-1 to Glu-56. A full-length cDNA encoding G-3 PLA_2 was cloned by reverse transcriptase-polymerase chain reaction and rapid amplification of cDNA ends methods, and G-3 PLA_2 was found to be classified to group IB PLA_2 from the deduced amino acid sequence. G-1, G-2, and G-3 PLA_2 had a pH optimum in an alkaline region at around pH 9–10 and required Ca^{2+} essentially for enzyme activity, using a mixed-micellar phosphatidylcholine substrate with sodium cholate. These results demonstrate that three group I PLA_2, G-1, G-2, and G-3 PLA_2, are expressed in the gill filaments of red sea bream.

Paper no. L8433 in *Lipids 35,* 1359–1370 (December 2000).

Phospholipase A_2 (phosphatide 2-acyl hydrolase, EC 3.1.1.4) (PLA_2) hydrolyzes the fatty-acyl ester bond at the *sn*-2 position of glycerophospholipids. PLA_2 has now become recognized as being a large superfamily of distinct enzymes that play a central role in diverse cellular processes including phospholipid digestion and metabolism, host defense, and signal transduction (1). New groups of Ca^{2+}-dependent low molecular mass enzymes, so-called secretory PLA_2, have recently been purified and are now classified into six groups, group I, II, III, V, IX, and X, based on their primary structures (1–3). Mammalian pancreatic type PLA_2, group IB PLA_2, was originally found in large amounts in the pancreas and was considered to function in the digestion of dietary phospholipids. However, this enzyme was later found to express in nonpancreatic tissues including the spleen, lung, kidney, and ovary (4–12). It has now been proposed to function as a kind of cytokine/growth factor in several cell lines by interacting with specific binding sites on the cell surface (13,14). Two major types of receptors, N-type and M-type receptors, have been recently identified for secretory PLA_2, including snake venom group IA PLA_2 and mammalian group IB PLA_2, and the involvement of mammalian group IB PLA_2 *via* M-type receptor in various physiological and pathophysiological responses such as cell proliferation, cell contraction, lipid mediator release, acute lung injury, and endotoxic shock has been proposed (13,15,16). These aspects indicate that the physiological importance of group I PLA_2 in the nondigestive tissues and cells is higher than considered previously.

On the other hand, there is little information about the enzymology of fish PLA_2. Attempts have been made to purify PLA_2 from liver, hepatopancreas, and muscles of fish such as rainbow trout *(Salmo gairdneri)* (17,18) and cod *(Gadus morhua)* (19,20). However, only one PLA_2 has been purified from cod muscle (19). Zambonino Infante and Cahu (21) recently analyzed the mRNA level of PLA_2 in *Dicentrarchus labrax* larvae cultured with diets containing different lipid levels but did not obtain the purified enzyme. To understand the enzymology of digestive lipolysis in fish, we purified three secretory PLA_2 from the digestive organs including the pyloric ceca and hepatopancreas of red sea bream, and two PLA_2, DE-1 and DE-2 PLA_2, purified from the hepatopancreas were found to be classified as group I PLA_2 based on

Abbreviations: *p*-APMSF, *p*-amidinophenylmethylsulfonyl fluoride; *p*-BPB, *p*-bromophenacyl bromide; CHAPS, 3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate; CTAB, cetyl trimethylammonium bromide; HPLC, high-performance liquid chromatography; MALDI-TOF, matrix-assisted laser desorption ionization-time of flight; PAGE, polyacrylamide gel electrophoresis; PCR, polymerase chain reaction; PLA_2, phospholipase(s) A_2; POPC, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine; POPE, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine; POPG, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoglycerol; POPS, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoserine; RACE, rapid amplification of cDNA ends; RP–HPLC, reversed-phase–HPLC; RT, reverse transcriptase; SDS, sodium lauryl sulfate; TFA, trifluoroacetic acid.

the amino acid sequence (22–24). We also found that an antiserum against *Naja naja* venom PLA_2 reacted weakly with the partially purified PLA_2 from the hepatopancreas of red sea bream and that it labeled zymogen granules of the pancreatic acinar cells and secretory materials of certain epithelial cells of epithelial crypts in the pyloric ceca of red sea bream (25). In the present report, we investigated the distribution of PLA_2 activity in the various tissues of red sea beam and found extremely high PLA_2 activity in the nondigestive tissue, gills. We further purified two minor and one major PLA_2, tentatively named G-1, G-2, and G-3 PLA_2 from the gill filaments of red sea bream. The N-terminal amino acid sequences of G-1, G-2, and G-3 PLA_2 show that they belong to group I PLA_2. Furthermore, we isolated a full-length cDNA clone of G-3 PLA_2 by polymerase chain reaction (PCR) methods and showed that G-3 PLA_2 is classified to group IB PLA_2 from the deduced amino acid sequence.

MATERIALS AND METHODS

Materials. 1-Palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine (POPE), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoserine (POPS), and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoglycerol (POPG) were purchased from Avanti Polar Lipids, Inc. (Birmingham, AL). Sodium cholate was purchased from Nacalai Tesque (Kyoto, Japan). 9-Anthryldiazomethane was purchased from Funakoshi Co., Ltd. (Tokyo, Japan) and *n*-heptadecanoic acid from Tokyo Kasei Organic Chemicals (Tokyo, Japan). 3-[(3-Cholamidopropyl) dimethylammonio]-1-propanesulfonate (CHAPS) and *p*-bromophenacyl bromide (*p*-BPB) were obtained from Dojindo Laboratories (Kumamoto, Japan). DEAE-Sepharose Fast Flow and Q-Sepharose Fast Flow were purchased from Pharmacia (Uppsala, Sweden). Butyl-Cellulofine was purchased from Seikagaku Kogyo (Tokyo, Japan), Asahipak ODP-50 was obtained from Showa Denko (Tokyo, Japan), YMC-Pack Protein-RP from YMC Co., Ltd. (Tokyo, Japan), and TSKgel Octadecyl-NPR from Tosoh (Tokyo, Japan). High-performance liquid chromatography (HPLC) grade CH_3CN was purchased from Nacalai Tesque, and 2-mercaptoethanol, 4-vinylpyridine, cetyl trimethylammonium bromide (CTAB), *p*-amidinophenylmethylsulfonyl fluoride (*p*-APMSF), and a silver staining kit were from Wako Pure Chemicals (Osaka, Japan). The DC Protein Assay Kit was obtained from Bio-Rad Laboratories (Richmond, CA).

Standard assay for PLA_2. PLA_2 activity was determined as described previously (23). The standard incubation systems (100 μL) for the assay of PLA_2 contained 2 mM POPC, 6 mM sodium cholate, 100 mM NaCl, 50 mM glycine-NaOH (pH 9.5), and 5 mM $CaCl_2$. One unit (U) was defined as the liberation of 1 μmol of free fatty acid/min as measured by reversed-phase (RP)–HPLC. In assays without detergent, the substrate was sonicated for 2 min in a water bath sonicator (Transsonic T460; Elma GmbH & Co. KG, Singen, Germany).

Preparation of dialyzate. Gill filaments, heart, spleen, adipose tissue, testis or ovary, hepatopancreas, stomach, pyloric ceca, and intestine were collected from five freshly killed farm-raised male and female red sea bream, *Pagrus (Chrysophrys) major* (0.8–1.0 kg), and were immediately frozen using dry ice. Frozen tissues were lyophilized, and the delipidated powder was prepared as described previously (23). Each 0.5 g of the resulting delipidated powder was solubilized in 5 mL of 5 mM Tris-HCl buffer (pH 7.4) for 1 h to yield a crude extract. The pH of the crude extract was adjusted to 4 by adding 6 N HCl, and the acidified extract was then heated at 80°C for 3 min. The cooled extract was centrifuged at 10,000 × *g* for 15 min at 4°C. The supernatant was dialyzed overnight against 5 mM Tris-HCl buffer (pH 7.4) and centrifuged at 10,000 × *g* for 15 min at 4°C. The resulting dialyzate was used for the determination of PLA_2 activity in the various red sea bream tissues.

For the purification of PLA_2, gill filaments were collected from 58 freshly killed farm-raised red sea bream (0.8–1.0 kg) and were immediately frozen using dry ice. The delipidated powder (125.5 g) of the gill filaments was solubilized in 10 vol of 5 mM Tris-HCl buffer (pH 7.4) containing 0.5 mM *p*-APMSF and a dialyzate was prepared as described above.

Purification of gill PLA_2. All steps were carried out at 4°C except for the HPLC runs, which were performed at room temperature. The dialyzate was loaded onto a Q-Sepharose Fast Flow column (5 × 5.5 cm) which was equilibrated with 5 mM Tris-HCl buffer (pH 7.4). The column was washed extensively with the same buffer, and PLA_2 activity was eluted with 5 mM Tris-HCl buffer (pH 7.4) containing 2 M NaCl at a flow rate of 5 mL/min. The active fractions were directly applied to a Butyl-Cellulofine column (2.6 × 19 cm) which was equilibrated with 5 mM Tris-HCl buffer (pH 7.4) containing 2 M NaCl. The column was washed extensively with the same buffer, followed by elution with 5 mM Tris-HCl buffer (pH 7.4) containing 0.5 M NaCl and with 5 mM Tris-HCl buffer (pH 7.4), respectively, at a flow rate of 0.6 mL/min. PLA_2 activity was eluted with 5 mM Tris-HCl buffer (pH 7.4). The active fractions were pooled, lyophilized, and dissolved in 20 mM Tris-HCl buffer (pH 8.0) containing 0.5% CHAPS. This solution was applied to a DEAE-Sepharose Fast Flow column (1.6 × 15 cm) which had been equilibrated with 20 mM Tris-HCl buffer (pH 8.0) containing 0.5% CHAPS. The PLA_2 activity was bound to the column and was eluted with a linear gradient of NaCl. The active fractions were pooled. Trifluoroacetic acid (TFA) was added to the active fractions at a final concentration of 0.1%, and the resulting solution was applied to a YMC-Pack Protein RP column (4.6 × 150 mm) which was equilibrated with 0.1% TFA/10% CH_3CN. The PLA_2 activity was bound to the HPLC column, and the column was eluted with a CH_3CN linear gradient. The active fractions were pooled. Disodium hydrogenphosphate was added to the active fractions to a final concentration of 10 mM. The resulting solution was applied to an Asahipak ODP-50 column (6 × 250 mm) that was pre-equilibrated with 10 mM Na_2HPO_4. PLA_2 activity was bound to the HPLC column. The column was then washed with 10 mM Na_2HPO_4

and eluted with a linear gradient from 10 mM Na_2HPO_4 to 0.5 mM Na_2HPO_4/60% CH_3CN. Peaks 1, 2, and 3 showing PLA_2 acivity were pooled and stored as final enzyme preparations, tentatively named G-1, G-2 and G-3 PLA_2, respectively. During the purification step, the protein concentration was measured with a DC Protein Assay Kit with bovine serum albumin as a standard. The protein concentration of G-3 PLA_2 was measured as described above. For G-1 and G-2 PLA_2, an HPLC protein determination method was devised. G-1 and G-2 PLA_2 were injected on a TSK gel Octadecyl-NPR (4.6 × 35 mm) column that had been equilibrated with 10 mM Na_2HPO_4. The column was eluted with a linear gradient from 10 mM Na_2HPO_4 to 0.5 mM Na_2HPO_4/60% CH_3CN, and the eluate was analyzed at 220 nm. G-3 PLA_2 was used for HPLC analysis as a protein standard.

Molecular weight determination of the purified enzymes. The molecular weights of purified enzymes were determined by sodium lauryl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and a matrix-assisted laser desorption ionization time of flight (MALDI-TOF) mass spectrometer (Dynamo, Finnigan-MAT, San Jose, CA). SDS-PAGE was carried out as described by Laemmli (26) using a 16% polyacrylamide gel in the presence of 2-mercaptoethanol, and the protein bands were stained with Coomasie Brilliant Blue-R250.

For MALDI-TOF mass spectrometry, the purified enzymes were desalted by RP–HPLC with a TSKgel Octadecyl-NPR column having a linear gradient of CH_3CN from 10% CH_3CN/0.1% TFA to 70% CH_3CN/0.1% TFA, at a flow rate of 0.8 mL/min. One microliter (approximately 0.3 pmol) of the desalted enzyme solution was mixed with an equal volume of matrix solution [10 mg/mL 2,5-dihydroxybenzoic acid/10 mg/mL 5-methoxysalicylic acid (9:1, vol/vol)] on a target disk and allowed to dry. Subsequently, spectra were obtained using a MALDI-TOF mass spectrometer, with horse apomyoglobin (16,951 Da) as a calibration standard.

N-terminal amino acid sequence determination. The purified PLA_2 were reduced with 2-mercaptoethanol and were S-pyridylethylated with 4-vinylpyridine as described previously (24). The amino acid sequence of the S-pyridylethylated PLA_2 was analyzed with a Hewlett-Packard G1005A protein sequencing system (Palo Alto, CA).

Extraction of mRNA. Gill filaments were removed immediately from freshly killed red sea bream (approximately 200 g) and were stored in liquid nitrogen. Total RNA was extracted from the gill filaments using Isogen (Nippon Gene, Tokyo, Japan), and mRNA was isolated using Oligotex-dT30 <Super> (Roche Diagnostics K.K., Tokyo, Japan), according to the manufacturer's protocol.

cDNA amplification of gill G-3 PLA_2 by PCR. Primers P20 and P2a are 5′-ATCTGGCAGTTCGGCGACATGATCGAG-3′ and 5′-GC(A/G)GCCTT(C/T)CTGTCGCACTC(A/G)CA-3′, that were derived from possible cDNA sequences corresponding to parts of amino acid sequence of red sea bream gill G-3 PLA_2, IWQFGDMIE (Residues 2–10, Fig. 5), and that of conserved amino acid sequence of mammalian pancreatic PLA_2 (27) and red sea bream hepatopancreas DE-2 PLA_2 (DDBJ/EMBL, Accession No. AB009286), CECDRKAA (Residues 96–103), respectively. One microgram of red sea bream gill mRNA was used to prepare first-stranded cDNA with a RNA PCR kit (Takara, Tokyo, Japan), employing molony murine leukemia virus reverse transcriptase. An internal cDNA fragment encoding PLA_2 was generated by PCR from first-stranded cDNA of red sea bream gill using degenerated primers P20 and P2a and *Pyrococcus kodakaraensis* KOD1 (KOD dash) DNA polymerase (Toyobo, Tokyo, Japan). After an initial denaturation for 160 s at 94°C, 30 cycles of amplification were carried out, with 30 s at 94°C, 10 s at 58°C, 30 s at 74°C, followed by incubation at 74°C for 10 min. Then the PCR product was isolated from an agarose gel using Ultrafree R-MC centrifugal filter unit (0.45 μm) (Millipore, Bedford, MA) and was sequenced. From the determined nucleotide sequence of the internal cDNA, new oligomers, primers P26 (5′-CATGACGACTGCTATGGA-GCACA-3′, identical to nt 211–233) and AP22 (5′-GGTC-GCTGAGCAGGTCACCTTGCG-3′, complementary to nt 307–330) were designed for 3′- and 5′-end amplifications, respectively. A first- and second-stranded cDNA were synthesized using red sea bream gill mRNA and Marathon cDNA Amplification kit (Clontech, Palo Alto, CA) according to the manufacturer's protocol. Briefly, 1 μg of red sea bream gill mRNA was reverse-transcribed using 10 μM of cDNA synthesis primer and 20 units of avian myeloblastosis virus reverse transcriptase at 42°C for 1 h. Second-stranded cDNA synthesis was carried out using *Escherichia coli* DNA polymerase I (24 units), DNA ligase (4.8 units), and RNase H (1 unit) at 16°C for 1.5 h, followed by T4 DNA polymerase (10 units) at 16°C for 45 min. The resulting second-stranded cDNA was precipitated and ligated to Marathon cDNA Adaptor (2 μM) using 1 unit of T4 DNA ligase for 40 min at room temperature. The 5′-end amplification of PLA_2 cDNA was carried by reverse transcriptase-polymerase chain reaction (RT-PCR) with adaptor-ligated double-stranded cDNA, Adaptor primer 1 (5′-CCATCCTAATACGACTCACTATAGGGC-3′), AP22 antisense primer and KOD Dash, and 3′-end amplification of PLA_2 cDNA was with adaptor-ligated double stranded cDNA, Adaptor primer, P26 sense primer, and KOD Dash. PCR conditions of 5′- and 3′-end amplification were as follows. After an initial denaturation for 160 s at 94°C, 30 cycles of amplification were carried out, with 30 s at 94°C, 10 s at 66°C, 30 s at 74°C, followed by incubating at 74°C for 10 min. The resulting PCR products were subcloned into pGEM-T vector (Promega, Madison, WI) and were transformed into JM109 cells, and positive clones were selected on LB/ampicillin/IPTG/X-Gal plates according to the manufacturer's protocol. Plasmid DNA was purified from positive clones with QIAprep Spin Miniprep Kit (Qiagen, Tokyo, Japan) and was sequenced.

Sequencing of PCR products. Cycle sequencing reaction of PCR products was performed using Dye terminator cycle sequencing kit (PerkinElmer, Norwalk, CT), according to the manufacturer's protocol, and the sequences of PCR products

TABLE 1
Distribution of Phospholipase A_2 (PLA_2) Activity in the Various Tissues of Red Sea Bream[a]

Tissues	Specific activity (mU/mg protein)		Specific activity (mU/g tissue)	
	Male	Female	Male	Female
Gills	1000	1040	14,659	13,769
Heart	1	7	6.7	49.3
Spleen	0.4	0.4	4.3	7.1
Muscle	0.1	0.8	1.5	3.1
Adipose tissue	14.5	10	19.1	8.1
Testis	1.5	—	13.4	—
Ovary	—	0.4	—	3.9
Hepatopancreas	3	1.5	15.2	16
Stomach	0.4	0.6	2.3	11.2
Pyloric ceca	0.7	0.5	13.7	12.9
Intestine	4.2	3	69.3	34.3

[a]The reaction mixture consisted of 50 mM glycine-NaOH (pH 9.5), 2 mM 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), 6 mM sodium cholate, 5 mM $CaCl_2$, and 0.1 M NaCl in a final volume of 0.1 mL. Data were obtained in duplicate.

were determined with an Applied Biosystems 373A DNA sequencer (Foster, CA).

RESULTS

Distribution of PLA_2 activity in the various tissues of red sea bream. The dialyzate was prepared from the various tissues of red sea bream, and PLA_2 activity in the dialyzate was measured using the mixed-micellar POPC substrate with sodium cholate. As shown in Table 1, the specific activity (mU/mg protein) of PLA_2 in the gills was extremely high, followed by adipose tissue, intestine, and hepatopancreas of male fish; PLA_2 activity of gills was over 70 times higher than that of adipose tissue and 200 times higher than that of other tissues, such as intestine, hepatopancreas and so on. Also in female fish, PLA_2 activity in the gills was exceedingly high, followed in order by adipose tissue, heart, and intestine. In comparison with PLA_2 activity per gram of tissue, specific activity of PLA_2 in the gills was 200 times higher than that in other tissues of male and female fishes.

Purification of PLA_2 from the gills of red sea bream. The purification procedure is summarized in Table 2. In starting from the crude extract, G-1, G-2, and G-3 PLA_2 were purified more than 10,000-fold, and the yields of G-1, G-2, and G-3 PLA_2 were 0.4, 0.3, and 5.5%, using mixed-micellar POPC substrate, respectively. Figure 1 documents the results obtained from a first RP–HPLC. The active fractions (fraction No. 62–70) were pooled and applied to a second RP–HPLC (Fig. 2). Three peaks of PLA_2 activity appeared in fraction No. 126–129, 133–136, and 141–148, respectively. Peaks 1, 2, and 3 (shown by the bars in Fig. 2) were pooled and were further applied to a TSKgel Octadecyl-NPR column. Peaks 1, 2, and 3 were eluted separately, and PLA_2 activity was also found in these peaks (data not shown). When peaks 1, 2, and 3 were mixed and applied to the same column, each peak eluted separately (Fig. 3). Therefore peaks 1, 2, and 3 were pooled as G-1, G-2, and G-3 PLA_2 to yield final enzyme preparations. G-1, G-2, and G-3 PLA_2 yielded a single protein band by SDS-PAGE under reducing conditions with an estimated molecular mass of approximately 15 kDa, identical to that of porcine pancreatic PLA_2 (Fig. 4). From the analysis of MALDI-TOF mass spectrometry, the exact molecular mass values of G-1, G-2, and G-3 PLA_2 were calculated to be 14,040, 14,040, and 14,005 Da, respectively. The specific activities of G-1, G-2, and G-3 PLA_2 amounted to 1294, 1143, and 1293 μmol/min/mg protein, respectively (Table 2).

N-terminal amino acid sequence of G-1, G-2, and G-3 PLA_2. The purified PLA_2 were reduced, S-pyridylethylated, and subjected to automated Edman analysis. Then, the N-terminal amino acid sequences of S-pyridylethylated G-1, G-2, and G-3 PLA_2 were determined as in the following: AIWQFGDMIECVQPGVDPINYNNYGCYCGLGGKGTPVDDLDRCCKVHDDCYGAQME.

G-1, G-2, and G-3 PLA_2 contained Cys 11 and were all identical in amino acid sequences from Ala1 to Glu56.

TABLE 2
Purification of G-1, G-2, and G-3 PLA_2 from the Gills of Red Sea Bream[a]

Purification step	Total protein (mg)	Total activity (U)	Specific activity (U/mg)	Purification (-fold)	Yield (%)

[a]The reaction mixture consisted of 50 mM glycine-NaOH (pH 9.5), 2 mM POPC, 6 mM sodium cholate, 5 mM $CaCl_2$, and 0.1 M NaCl, in a final volume of 0.1 mL. Data were obtained in duplicate. Protein concentration was determined with a DC Protein assay kit. For further information on purification see the Materials and Methods section. See Table 1 for abbreviations.

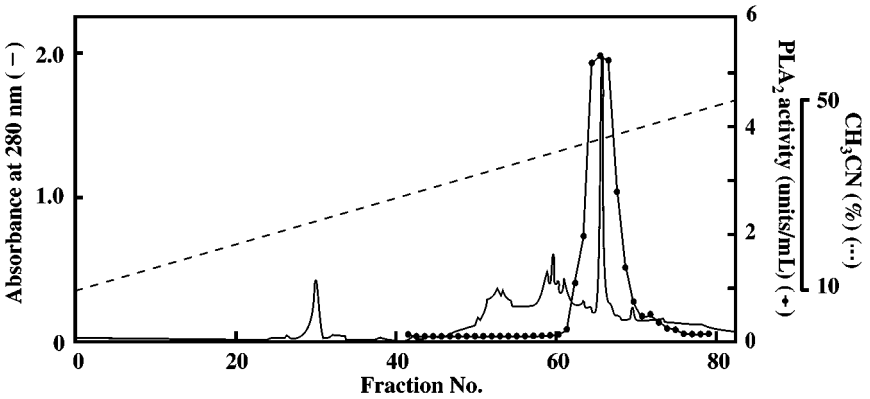

FIG. 1. Elution profile of phospholipase A_2 (PLA_2) on first reversed-phase–high-performance liquid chromatography (RP–HPLC). The pooled active fraction from the DEAE-Sepharose Fast Flow (Pharmacia, Uppsala, Sweden) column was applied to a YMC-Pack Protein RP (YMC Co. Ltd., Tokyo, Japan) column (4.6 × 250 mm) pre-equilibrated with 10% CH_3CN/0.1% trifluoroacetic acid (TFA). The elution of protein was followed by monitoring the absorbance at 280 nm (–). The dashed line indicates the linear gradient of CH_3CN. The flow rate was 1.0 mL/min. The fraction volume was 0.5 mL. The PLA_2 activity (●) of a 2 μL aliquot of each fraction was measured as described in the Materials and Methods section.

cDNA cloning of gill G-3 PLA_2. A full-length cDNA clone of gill G-3 PLA_2 was isolated by RT-PCR and rapid amplification of cDNA ends (RACE) methods. The nucleotide sequence of gill G-3 PLA_2 cDNA (1084 bp) included a 444 bp open reading frame that encoded for a signal peptide of 24 amino acids, followed by a mature protein of 124 amino acids, as shown in Figure 5. The calculated molecular mass and isoelectric point of the mature protein were 14,007 Da and 5.17, respectively. The 3′-noncoding region contained two putative polyadenylation signals located upstream of the poly A tail. An alignment of the mature amino acid sequences of bovine pancreatic PLA_2 (28), porcine pancreatic PLA_2 (29), and *N. naja kaouthia* venom PLA_2 (30) with the sequence of gill G-3 PLA_2 is presented in Figure 6. The sequence of gill G-3 PLA_2 has common characteristics with mammalian pancreatic type, group IB PLA_2, including the presence of Cys11 and the alignment of other Cys residues; residues of N-terminal helix Gln4, Phe5, and Ile9, and the presence of the absolutely conserved active-site His48, Tyr52, Tyr73 and Asp99; a "pancreatic loop" of residues 63–67 that are conserved in group IB PLA_2; the conserved sequence of the calcium-binding segment Tyr25-Gly33.

Properties of G-1, G-2, and G-3 PLA_2. Effects of pH and concentrations of Ca^{2+} and sodium cholate on the purified

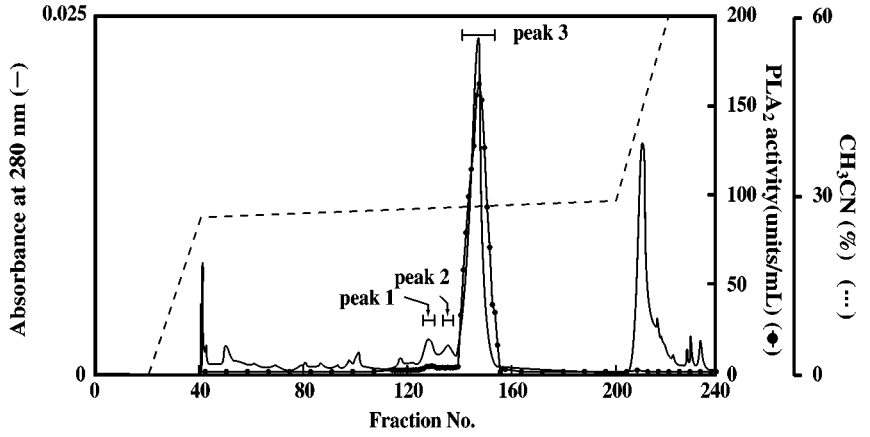

FIG. 2. Elution profile of PLA_2 on second RP–HPLC. The pooled fraction from the YMC-Pack Protein RP column was applied to an Asahipak ODP-50 (Showa Denko, Tokyo, Japan) column (6.0 × 250 mm) pre-equilibrated with 10 mM Na_2HPO_4. The elution of protein was followed by monitoring the absorbance at 280 nm (–). The dashed line indicates the linear gradient of CH_3CN. The flow rate was 1.0 mL/min. The fraction volume was 0.25 mL. Each fraction was diluted 50 times with 30% CH_3CN/0.1% TFA, and the PLA_2 activity (●) of a 2 μL aliquot of each diluent was measured as described in the Materials and Methods section. For abbreviations and other manufacturer see Figure 1.

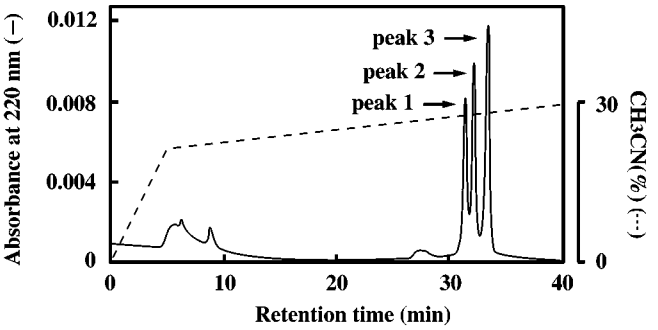

FIG. 3. Elution profile of G-1, G-2, and G-3 PLA_2 on RP–HPLC. The pooled fractions of peak 1, peak 2, and peak 3 eluted from the Asahipak ODP-50 column were mixed and were applied to a TSKgel Octadecyl-NPR (Tosoh, Tokyo, Japan) column (4.6 × 35 mm) pre-equilibrated with 10 mM Na_2HPO_4. The elution of protein was followed by monitoring the absorbance at 220 nm (–). The dashed line indicates the linear gradient of CH_3CN. The flow rate was 0.8 mL/min. For other abbreviations and manufacturer see Figures 1 and 2.

PLA_2 activity are shown in Figure 7. G-1, G-2, and G-3 PLA_2 hydrolyzed POPC efficiently in an alkaline pH region, and optimal activities for all PLA_2 were found to be at around pH 9–10 (Fig. 7A). The activities of G-1, G-2, and G-3 PLA_2 were barely detected in the presence of 1 mM EGTA (Fig. 7B). The maximal activities were observed in the presence of 2–40 mM Ca^{2+}. Activities of G-1, G-2, and G-3 PLA_2 toward POPC were not detectable in the absence of bile salts. However, they were stimulated dramatically by the addition of sodium cholate, and their optimal activities were found at cholate concentrations of about 6–8 mM (cholate/POPC molar ratio of 3–4) (Fig. 7C). The effects of various agents on the activity of purified PLA_2 were investigated using a mixed-micellar POPC substrate (Table 3). The activities of G-1, G-2, and G-3 PLA_2 toward the POPC substrate were almost completely inhibited by the addition of 1 mM EGTA or EDTA, and Mg^{2+}, Zn^{2+}, Fe^{3+}, and Cu^{2+} could not replace Ca^{2+}. CTAB and SDS greatly inhibited the activities of G-1, G-2, and G-3 PLA_2. *p*-APMSF, a serine protease inhibitor, did not inhibit the activities of G-1, G-2, or G-3 PLA_2 (data not shown). *p*-BPB, an alkylating reagent of His, inhibited all three enzymes but was less sensitive than porcine pancreatic and *N. naja kaouthia* venom PLA_2. Mixed micelles of sodium cholate and phospholipids containing various head groups (POPC, POPE and POPG) or aqueous phospholipid dispersions (without sodium cholate) were prepared and were used as substrates for examining the substrate specificity of the purified enzymes (Table 4). Porcine pancreatic PLA_2 was the most active for the micellar POPG substrate, and *N. naja kaouthia* venom PLA_2 was for micellar POPC. On the other hand, red sea bream gill G-1, G-2, and G-3 PLA_2 hydrolyzed efficiently both POPC and POPG micelles at similar rates. G-1, G-2, and G-3 PLA_2 were active for POPE and POPG liposomes, but not for POPC liposome. All PLA_2 tested were inactive for both micellar and dispersed POPS (data not shown).

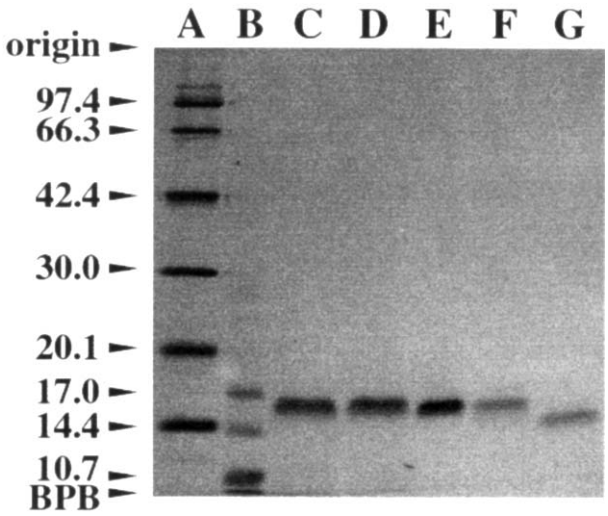

FIG. 4. Sodium lauryl sulfate-polyacrylamide gel electrophoresis of red sea bream gill G-1 (lane C), G-2 (lane D), and G-3 (lane E) PLA_2, porcine pancreatic PLA_2 (lane F), and *Naja naja kaouthia* venom PLA_2 (lane G). Molecular masses of marker proteins (lane A) from top to bottom: 97.4, 66.3, 42.4, 30.0, 20.1, and 14.4 kDa, and those of marker peptides (lane B) from top to bottom: 17.0, 14.4, and 10.7 kDa. BPB, bromophenacyl bromide; for other abbreviation see Figure 1.

DISCUSSION

We investigated the distribution of PLA_2 activity in the various tissues of red sea bream and found extremely high activity in the gills (Table 1). We had found previously that PLA_2 activity in the crude enzyme extract of pyloric ceca and hepatopancreas of red sea bream increased significantly due to dialysis (23,24). This suggests the presence of PLA_2 inhibitory materials in the crude enzyme extract. Therefore, we used a dialyzate as a sample for measuring PLA_2 activity in the present experiment. In mammals, pancreatic PLA_2 are stored as a form of proenzyme, which are converted into the active form by limited tryptic proteolysis in the intestinal lumen (31,32). Also, in red sea bream, PLA_2 activity in the hepatopancreas increased dramatically during autolysis (22). Therefore, it exists as a proenzyme in the hepatopancreas of red sea bream, similarly to porcine pancreatic PLA_2 (33). As the crude enzyme extract of hepatopancreas was not autolyzed in the present experiment, it is inappropriate to compare the PLA_2 activities of the hepatopancreas and gills. However, the specific activity of PLA_2 in a gill dialyzate (Table 1) was over 150-fold higher than that of the hepatopancreas (7 mU/mg protein) after autolysis (24). As we could not find any PLA_2 activity in the plasma of red sea bream, PLA_2 activity in the gills originated from the gills. It remains unclear whether PLA_2 exists as a proenzyme or active enzyme in other tissues in addition to hepatopancreas. However, it is thought that somewhat higher PLA_2 activity expresses in the gills of red sea bream. Therefore, we tried to purify PLA_2 from red sea bream gill filaments.

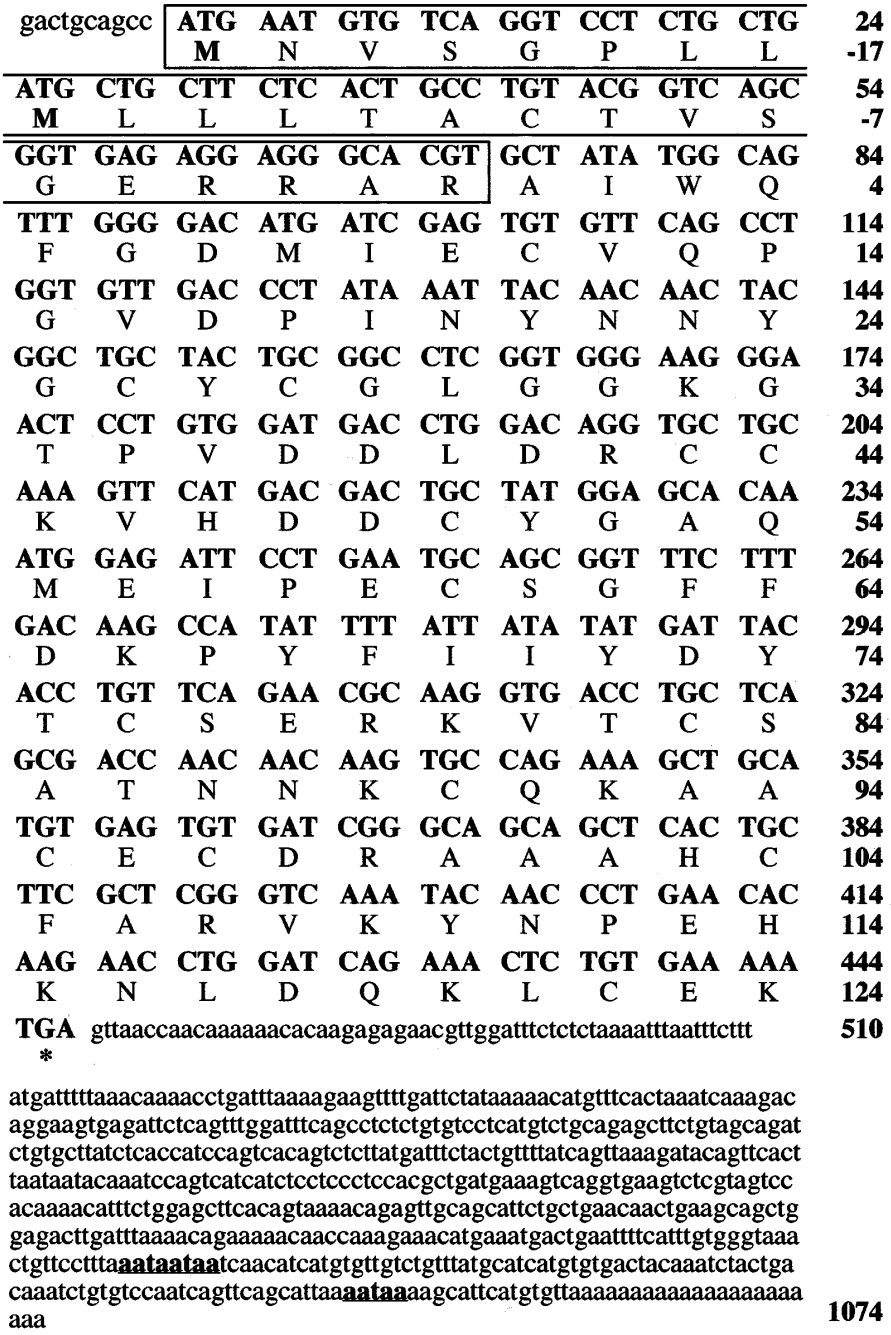

FIG. 5. Nucleotide and deduced amino acid sequences of red sea beam gill G-3 PLA_2. The predicted preprosegment is boxed and possible initiator methionines are shown in **bold**. The putative polyadenylation signal is underlined and in **bold**. Asterisk shows termination codon. For abbreviation see Figure 1.

Two minor and one major PLA_2, tentatively named G-1, G-2, and G-3 PLA_2, were finally purified with second RP–HPLC (Figs. 2 and 3) and were all identical in their N-terminal amino acid sequences from Ala1 to Glu56. A full-length cDNA clone for G-3 PLA_2 was isolated by RT-PCR and RACE methods (Fig. 5), and the molecular mass (14,005 Da) of G-3 PLA_2 obtained by time of flight mass spectrometric analysis almost coincided with that by predicted amino acid sequence of mature enzyme (14,007 Da, Fig. 6). G-3 PLA_2 contains 14 cysteines including Cys11 and Cys77 and a pancreatic loop of residues 63–67, which are commonly conserved in group IB PLA_2. In addition, G-3 PLA_2 had a pH optimum in an alkaline region at around pH 9–10 and required the presence of millimolar concentrations of Ca^{2+} for enzyme activity, using a mixed-micellar POPC substrate with sodium cholate. These results indicate that red sea bream gill G-3

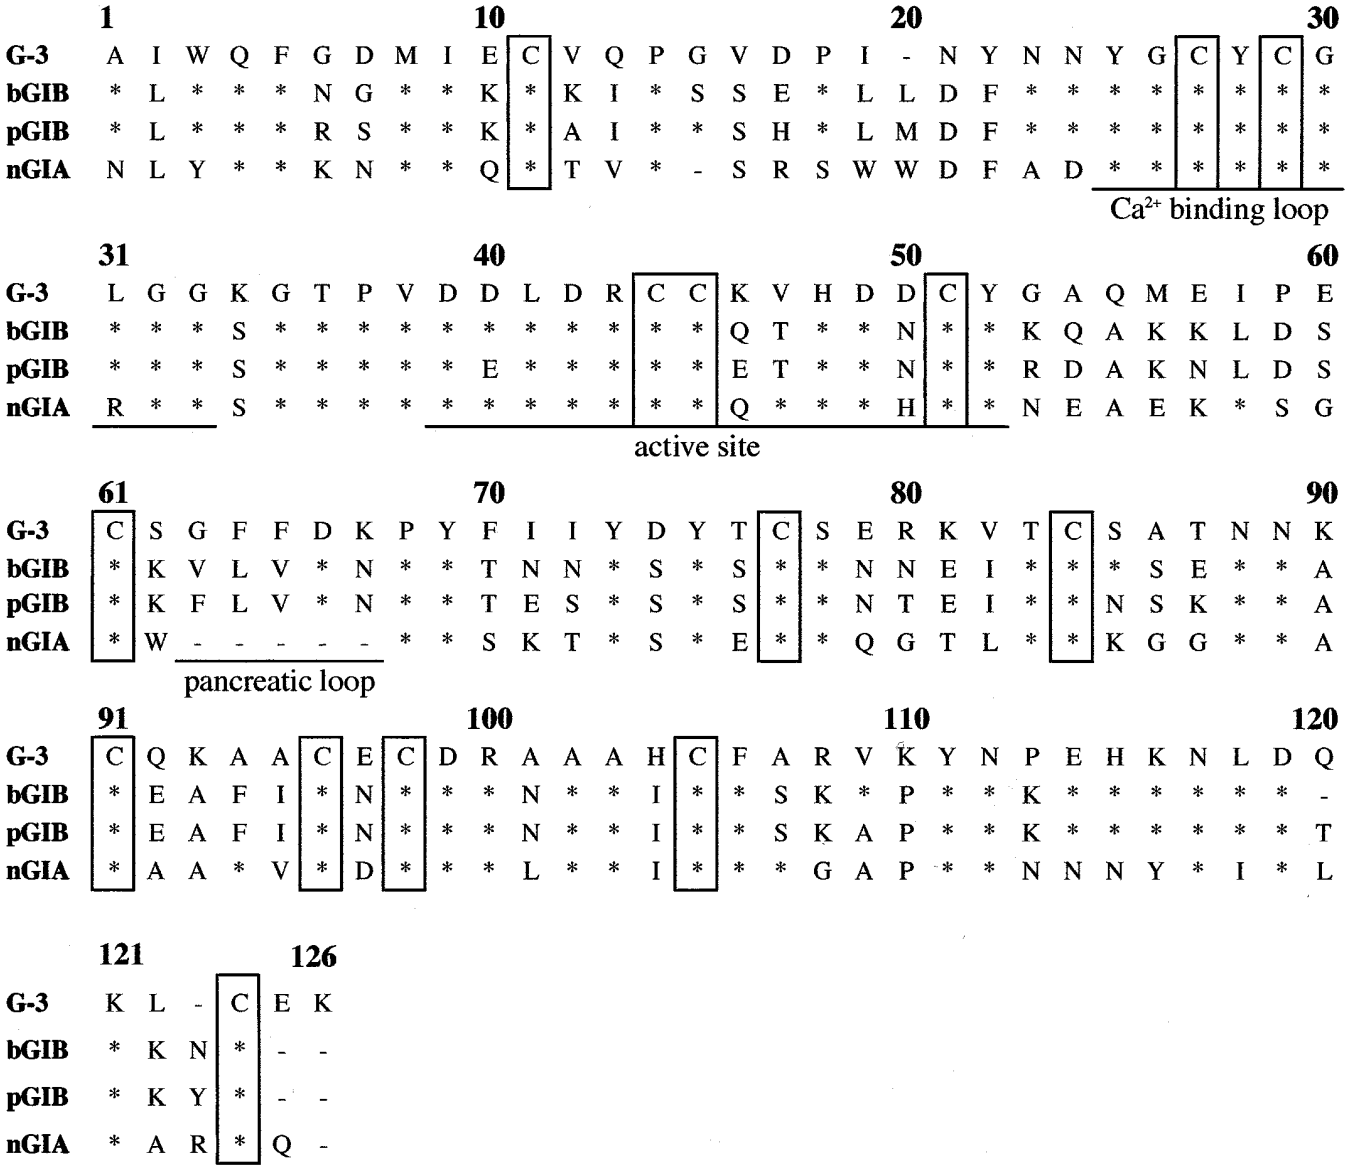

FIG. 6. Alignment of the amino acid sequences of red sea bream gill G-3 PLA_2 with other group I PLA_2. Only mature protein sequences of PLA_2 are shown. G-3, red sea bream gill G-3 PLA_2; bGIB, bovine pancreatic group IB PLA_2 (19); pGIB, porcine pancreatic group IB PLA_2 (29); nGIA, *N. naja kaouthia* venom group IA PLA_2 (30). Asterisks indicate the amino acid residues identical to those of red sea bream gill G-3 PLA_2. Cysteines that are conserved in all PLA_2 are boxed.

PLA_2 belongs to group IB PLA_2. The sequence similarity and hydropathy profiles suggest that the N-terminal 24 residues are prepropeptide sequence (Fig. 5). SignalP computer analysis (34) for the potential cleavage positions in its signal sequence suggests that the signal peptide cleavage site is present between position Gly-6 and Glu-5 preceding the mature protein. Furthermore, arginine doublet, which is the cleavage site of subtilisin-like convertase in the Golgi apparatus (35), is also included at positions –3 and –4 preceding the mature protein. Further studies are needed to understand the maturation process of gill G-3 PLA_2.

Red sea bream gill G-3 PLA_2 hydrolyzed efficiently both mixed-micellar POPG and POPC at similar rates (Table 4). It is well known that snake venom and porcine pancreatic PLA_2 show high affinity toward zwitterionic substrate POPC and negatively charged substrate POPG, respectively (31). A similar result was obtained for *N. naja kaouthia* venom and porcine pancreatic PLA_2 in the present experiment (Table 4). It has been shown that ionic residues 53 through 58 (Fig. 6) located at the end of a long α-helix loop of group IA, IB, IIA, and V PLA_2 are involved in binding to the head group of the phospholipid substrate (36–41). The cationic and anionic charges of residues 53 and 56 in mammalian pancreatic and *N. naja kaouthia* venom PLA_2 (Fig. 6) appear to be responsible for the anionic and zwitterionic phospholipid preference of these enzymes, but substitution of cationic residues 53

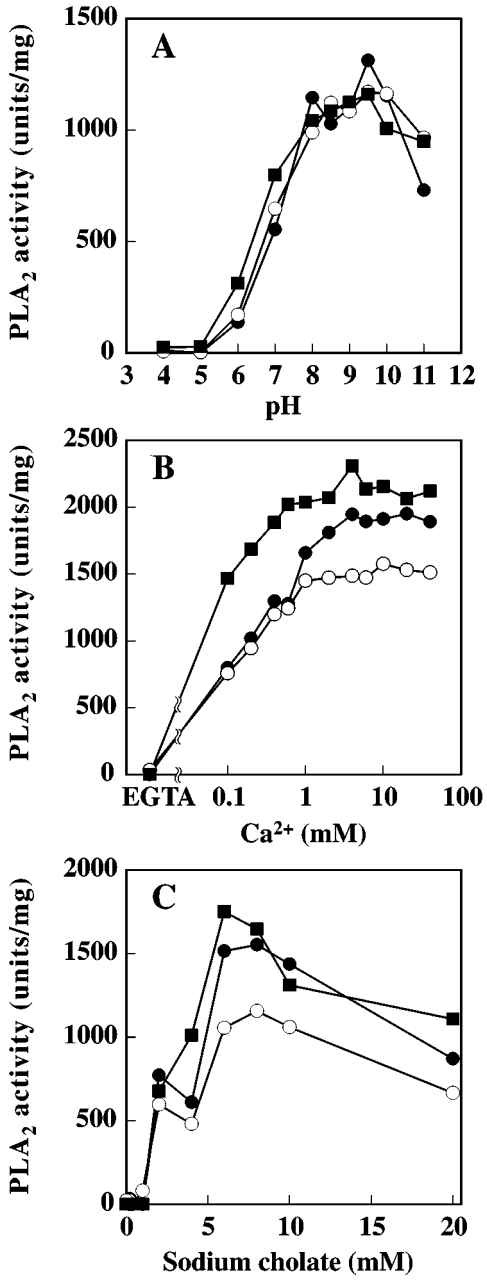

FIG. 7. Effect of pH (A), concentrations of Ca^{2+} (B) and sodium cholate (C) on the activities of red sea bream gill G-1 (●), G-2 (○), and G-3 (■) PLA_2. (A) Reaction mixtures containing purified G-1, G-2, or G-3 PLA_2, 2 mM 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), 6 mM sodium cholate, 100 mM NaCl, and 5 mM $CaCl_2$ were incubated for 15 min at 37°C in a total volume of 100 µL. The buffers used were 50 mM acetate buffer from pH 4.0 to 5.0, 50 mM Tris-maleate buffer from pH 5.0 to 8.0, 50 mM Tris-HCl from pH 8.0 to 9.0, and 50 mM glycine-NaOH from pH 9.0 to 11.0. (B) Reaction mixtures containing purified G-1, G-2, or G-3 PLA_2, 2 mM POPC, 6 mM sodium cholate, 100 mM NaCl, 50 mM glycine-NaOH (pH 9.5), and 1 mM EGTA or 0–40 mM $CaCl_2$ were incubated, and PLA_2 activity was measured as described in the Materials and Methods section. (C) In the presence of various concentrations of sodium cholate, the activity of purified G-1, G-2, or G-3 PLA_2 was examined in a reaction mixture containing 2 mM POPC, 100 mM NaCl, 50 mM Tris-HCl (pH 8.5), and 10 mM $CaCl_2$, as described in the Materials and Methods section. Results are shown as means of two separate experiments. For abbreviation see Figure 1.

and/or 56 to nonionic residues of mammalian pancreatic PLA_2 improves higher preference for zwitterionic substrate but keeps the higher activity toward anionic substrate. In bovine and porcine pancreatic PLA_2, the methionine mutant (53M or 56M) shows a large increase in activity toward zwitterionic substrate and a slight decrease toward anionic substrate (36,39,42). Interestingly, red sea bream gill G-3 PLA_2 contains nonionic residues at residues Gly53 and Met56. As N-terminal helix Gln4, Phe5 and Ile9, Ca^{2+}-binding loop (Y25-G33) and active-site His48, Tyr52, Tyr73, and Asp99 are all conserved in red sea bream gill G-3 PLA_2 (Fig. 7), residues Gly53 and Met56 of gill G-3 PLA_2 may be interacted with choline moiety of POPC, in addition to keep the higher affinity toward POPG micelles. However, it cannot be denied that other residues of gill G-3 PLA_2 are involved in the preference for both POPC and POPG micelles, in addition to Gly53 and Met56. It is necessary to define the substrate specificity of gill G-3 PLA_2 for POPC and POPG micelles, using gill G-3 PLA_2 mutants such as G53R, M56K and G53RM56K.

In the absence of bile salts, aqueous dispersions of POPG and POPE (liposome) were appreciably hydrolyzed, whereas those of POPC were hardly hydrolyzed at all by G-3 PLA_2, similar to porcine pancreatic PLA_2 (Table 4) and rat splenic group I PLA_2 (5). The low affinity of gill PLA_2 toward POPC liposomes remains to be established.

Multiple group I PLA_2 enzymes are found in snake venom and also in the mammalian pancreas. Of 14 group I PLA_2 in the venom of the Australian king brown snake, *Pseudechis australis,* six group I PLA_2, PG-1Ga and -1Gb, Pa-3a and -3B, and Pa-15a and -15b showed microheterogeneity at the 103rd position with Thr/Ala, Thr/Pro, and Ala/Pro, respectively (43). Two group I PLA_2 isoforms exist in the porcine pancreas (44). In addition, commercially available porcine pancreatic PLA_2 consists of at least four enzymes within a range of 13,036 to 14,001 Da, and they are assumed to be genetic variants of PLA_2 (45). The N-terminal amino acid sequences of two minor PLA_2, G-1 and G-2 PLA_2, were all identical to that of G-3 PLA_2 from Ala1 to Glu56, but molecular masses of G-1 and G-2 PLA_2 (14,040 Da) were slightly higher than that of G-3 PLA_2 (14,005 Da). In addition, the enzyme properties of G-1 and G-2 PLA_2 were almost similar to that of G-3 PLA_2 (Fig. 7, Tables 3,4). Concerning the above aspects, G-1 and G-2 PLA_2 may be genetic variants of G-3 PLA_2 in which replacement or modification of amino acids occurred in the amino acid sequences from the 57th position to the carboxyl-terminus.

We recently purified two group I PLA_2 isoforms, DE-1 and DE-2 PLA_2, from the hepatopancreas of red sea bream (24). In the present report, we found one major and two minor group I PLA_2 variants in the gills of red sea bream. As we could not find a large difference in the molecular masses and amino acid sequences among three group I PLA_2 in the gills, we conclude that one group I PLA_2 isoform exists in the gills. These aspects indicate the existence of at least three structurally distinct group I PLA_2 isoforms in the hepatopancreas (DE-1 and DE-2

TABLE 3
Effect of Various Compounds on the Activities of Red Sea Bream Gill G-1, G-2, and G-3 PLA_2, Pig Pancreas PLA_2, and *Naja naja kaouthia* Venom PLA_2[a]

Compounds	Final concentration	Red sea bream gill G-1	Red sea bream gill G-2	Red sea bream gill G-3	Porcine pancreas	*N. naja kaouthia* venom
		Remaining activity (%)

p-BPB	1.0 mM	63.0	74.8	76.1	24.1	15.0

[a]The activity of PLA_2 was measured in reaction mixtures containing 50 mM glycine-NaOH (pH 9.5), 2 mM POPC, 5 mM $CaCl_2$, 0.1 M NaCl, and 6 mM sodium cholate. To determine the effect of ions, $CaCl_2$ was depleted or replaced by EGTA, EDTA, $MgCl_2$, $ZnCl_2$, $FeCl_3$, $CuCl_2$, or $CuSO_4$, and the effect of detergents, sodium cholate was replaced by cetyl trimethylammonium bromide (CTAB), sodium lauryl sulfate (SDS) or Triton X-100. To determine the effect of *p*-bromophenacyl bromide (*p*-BPB), it was added to PLA_2 and incubated for 10 min at 37°C before starting the reaction. ND, not detectable; for other abbreviations see Table 1.

PLA_2) and gills (G-3 PLA_2) of red sea bream. In addition, Ca^{2+}-dependent low molecular mass PLA_2 was also found in the pyloric ceca of red sea bream (23). It is well known that multiple group I PLA_2 variants locate in the same tissue or organ such as porcine pancreas and snake venom. However, it remains unclear whether group I PLA_2 isoforms distribute in different tissues and cells of mammals and snakes. This may be the first report indicating that structurally different group I PLA_2 isoforms distribute in different tissues such as the hepatopancreas and gills of red sea bream.

TABLE 4
Comparison of Substrate Specificities of Red Sea Bream Gill G-1, G-2, and G-3 PLA_2, Porcine Pancreatic PLA_2, and *Naja naja kaouthia* Venom PLA_2 for Various Phospholipid Head Groups[a]

Origin	POPC Micelle	POPC No bile salts	POPE Micelle	POPE No bile salts	POPG Micelle	POPG No bile salts
	(units/mg protein)					
Red sea bream gill						
G-1 PLA_2	1,369	ND	170	137	1,155	128
G-2 PLA_2	1,166	ND	153	142	872	118
G-3 PLA_2	1,592	ND	357	161	1,211	119
Pig pancreas PLA_2	101	ND	278	243	1,861	250
N. naja kaouthia venom PLA_2	563	66	212	93	135	100

[a]The reaction mixture consisted of 50 mM glycine-NaOH (pH 9.5), 2 mM phospholipid, 5 mM $CaCl_2$, and 0.1 M NaCl with or without 6 mM sodium cholate in a final volume of 0.1 mL. Data were obtained in duplicate. POPE, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine; POPG, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-[phospho-*rac*-(1-glycerol)]; for other abbreviations see Tables 1 and 3.

Finally, this study demonstrates that three group I PLA_2 variants exist in the gills, an organ not part of the digestive system like the hepatopancreas and pyloric ceca. Fish gills constitute a multifunctional and complex organ. The branchial epithelium consists of various cell types such as pavement cells, mucous cells, neuroepithelial cells, and ionocytes that are involved in respiratory, osmoregulatory, and excretory functions (46). We obtained monoclonal antibodies raised against purified gill PLA_2. We are now investigating the localization of PLA_2 proteins and expression of PLA_2 mRNA in the gills and other tissues of red sea bream using immunohistochemical staining and *in situ* hybridization.

ACKNOWLEDGMENTS

We would like to sincerely thank Hidetoshi Ikezawa, Application Chemist of ThermoQuest K.K. (Tokyo, Japan) for the determination of the molecular mass of PLA_2 by MALDI-TOF mass spectrometer. This work was supported in part by Grants in Aid for Scientific Research from the Ministry of Education, Science, Sports, and Culture of Japan.

ABSTRACT: The lipid composition of a *Bacillus* sp., isolated from Lake Pomorie in Bulgaria, was unusual and consisted of 26 different fatty acids between C_{12} and C_{26}, with anteiso C_{15}–C_{17} saturated fatty acids predominating. The furan fatty acid, 10,13-epoxy-11-methyloctadeca-10,12-dienoic acid, was also identified, a new finding for this genus. The hydrocarbons consisted of 30 different monounsaturated hydrocarbons, between C_{25} and C_{30}, with the iso-iso, iso-anteiso, anteiso-anteiso, iso-normal, and anteiso-normal methyl branching for odd-numbered chains, and the iso-iso, iso-anteiso, iso-normal, and anteiso-normal methyl branching for even-numbered chains. The double bond positions in these hydrocarbons were determined by dimethyl disulfide derivatization followed by GC–MS, and the double-bond *cis* configuration was confirmed by infrared spectroscopy. Some previously unknown hydrocarbons in bacteria, such as (*Z*)-3,21-dimethyl-9-tricosene, (*Z*)-3,21-dimethyl-10-tricosene, (*Z*)-2,24-dimethyl-11-pentacosene, and (*Z*)-2,25-dimethyl-13-hexacosene were identified. Sterols were detected and were based on the sitosterol nucleus.

Paper no. L8285 in *Lipids 35,* 1371–1375 (December 2000).

Some microorganisms are particularly interesting for their ability either to generate or to use hydrocarbons in their metabolism (1–3). Earlier examples included bacteria capable of synthesizing monounsaturated hydrocarbons with terminal *iso-anteiso* branching distributed in either a symmetrical or unsymmetrical fashion along the terminus of the chains (4). In the case of *Sarcina lutea* ATCC 533 (*Micrococcus luteus*), a monounsaturated hydrocarbon composition of iso-anteiso C_{23}–C_{27} hydrocarbons was characterized, while *Sarcina lutea* FD 533 contained iso-anteiso C_{25}–C_{30} monounsaturated hydrocarbons (4). Further work revealed that the monounsaturation in these hydrocarbons was in or near the center of the chain, as determined by mass spectrometry (MS) on the corresponding trimethylsilyl ether derivatives (5). However, at that time no attempts were made to elucidate the double bond positions in those hydrocarbons identified in small amounts, such as the iso-anteiso 25:1 series. The accepted biosynthetic pathway to these monounsaturated hydrocarbons is that they arise from the head-to-head condensation of the appropriate combination of iso/anteiso fatty acids, with one of the fatty acids undergoing decarboxylation (5). This is consistent with the observation that only branched anteiso-anteiso hydrocarbons occur in the odd-numbered series (4).

Monounsaturated iso/anteiso hydrocarbons are not exclusive metabolites of the Micrococcaceae since they have also been reported in pseudomonads (6). For example, *Stenotrophomonas maltophilia* (previously *Pseudomonas maltophilia* and *Xanthomonas maltophilia*) biosynthesizes not only C_{27}–C_{32} monounsaturated hydrocarbons but also di- and triunsaturated hydrocarbons such as branched 30:2 (Δ9,16) and branched 30:3 (Δ8,14,21). In this particular pseudomonad, the double bond in the iso-iso and anteiso-anteiso C_{29} monounsaturated hydrocarbons occurred at C-14, but other double bond positions, for the smaller chain analogs, were not determined (6).

The fatty acid composition of this type of hydrocarbon-producing bacteria is relatively simple, inasmuch as it mainly consists of saturated C_{14}–C_{19} fatty acids with iso-anteiso methyl branching, but in all reported cases the branched even-carbon fatty acids only had the iso ramification (4,5). In most strains an 18:1 fatty acid was identified, but no double bond position was specified (5).

In this paper we report the unusual lipid composition of a *Bacillus* sp. isolated from Lake Pomorie in Bulgaria. To the best of our knowledge this is the first report of this type of iso-anteiso monounsaturated hydrocarbons for the genus *Bacillus*. The furan fatty acid 10,13-epoxy-11-methyloctadeca-10,12-dienoic acid is also reported for the first time in a *Bacillus* sp., as well as other longer-chain fatty acids.

MATERIALS AND METHODS

Instrumentation. Gas chromatography (GC)–MS data were collected at 70 eV in a Hewlett-Packard 5972A MS ChemStation (Palo Alto, CA) equipped with a 30 m × 0.25 mm special performance capillary column (HP-5MS) cross-linked

with 5% phenyl methylpolysiloxane. The temperature program for the analyses was as follows: 130°C for 2 min, then increased at 3°C/min to 270°C and maintained for 40 min. Infrared spectra were run in a Magna-IR 750 Nicolet (Madison, WI) spectrometer.

Bacterial isolation. Microorganisms were collected from the water of Lake Pomorie, partially connected to the Black Sea, during 1998. Samples were inoculated on 5 mL liquid YPD medium (1% wt/vol yeast extract, 2% wt/vol bactopeptone, 2% wt/vol glucose) and cultivated overnight in test tubes at 37°C. Different dilutions from each test tube were plated onto petri dishes with solid YPD medium (containing 2% wt/vol agar) and further cultivated for single colonies. Colonies with characteristic morphologies were isolated and studied. A *Bacillus* sp. was grown on liquid YPD medium supplemented with marine water in order to obtain 4% wt/vol NaCl concentration in the stationary growth phase. Cells were harvested by centrifugation and washed two times. Characterization was done by routine biochemical and antibiotic tests modified for marine bacteria. The microorganism in question was identified using the API 20E system (Analytab Products, Plainview, NY) as a *Bacillus* sp., close but not identical to *B. subtilis*.

Lipid isolation and characterization. The lipids were extracted from the bacterium (8–10 g) with chloroform/methanol (2:1, vol/vol) affording 40–45 mg of total lipids following the procedure of Bligh and Dyer (7). Hydrocarbons were isolated from the lipids by dilution in hexane followed by silica gel column chromatography utilizing only hexane as eluent. Fatty acids were identified as methyl esters, which were prepared by direct methylation of the lipid extract with 1.5 M HCl/methanol, as previously described (8).

Derivatives. The hydrocarbons and methyl esters were hydrogenated in 10 mL of absolute methanol and catalytic amounts of PtO_2. The double-bond positions in these compounds were determined by dimethyl disulfide (DMDS) derivatization following a procedure that was previously described (9). Double-bond positions and methyl branching were further confirmed by $NaIO_4/KMnO_4$ oxidation followed by acidic methanolysis. Some representative mass spectral data for the novel hydrocarbons, and their derivatives, are presented below.

RESULTS

After the isolation and characterization procedure described above, at least 30 monounsaturated hydrocarbons were identified in this *Bacillus* sp. ranging in length between C_{25} and C_{30} (Table 1). All hydrocarbons displayed a similar mass spectrum, but they occurred as clusters with different molecular weights. Almost complete characterization was accomplished by further derivatization of the whole hydrocarbon mixture. Catalytic hydrogenation was used to locate methyl branching, inasmuch as the unsaturated and saturated hydrocarbon gas chromatographic profiles were practically the same, and methyl branching was easily distinguished in the saturated hydrocarbons by mass spectrometry (5). In particular, iso-iso and iso-normal saturated hydrocarbons display a significant $M^+ - 43$ peak, while anteiso-anteiso, iso-anteiso, and anteiso-normal hydrocarbons display a prominent $M^+ - 29$ peak (5). For example, 2,24-dimethylpentacosane (iso-iso) displays a strong $M^+ - 43$ fragmentation at *m/z* 337 (6%), but either 2,23-dimethylpentacosane (iso-anteiso) or 3,23-dimethylpentacosane (anteiso-anteiso) displays a strong $M^+ - 29$ fragmentation at *m/z* 351 (9–11%) upon electron impact. Plots of GC retention times vs. iso/anteiso ramifications were used to distinguish between the different branching possibilities in the hydrogenated samples, and this was extrapolated to the monounsaturated analogs. For example, it was observed that the order of elution in the C_{27} series was iso-iso, iso-anteiso, anteiso-anteiso, and iso-normal, while the elution order in the C_{28} series was iso-iso, iso-anteiso, iso-normal, and anteiso-normal (5). Further confirmation of the branch-

[a]The values are the percentages based on the total peak area of the hydrocarbons. Traces (0.01–0.05%) of two different kinds of C_{30} hydrocarbons were also detected. The values are the average of at least three different samples with an average error of ±0.1%.
[b]It was not possible to distinguish between these two isomers.
[c]Not identified before in bacteria.

ing was obtained *via* sodium periodate/potassium permanganate oxidation followed by acid-catalyzed methylation, which afforded the corresponding iso-anteiso and normal C_{10}–C_{15} fatty acid methyl esters. The principal cleavage product was the anteiso-15:0 acid, which mainly arose from 3,25-dimethyl-14-heptacosene.

DMDS derivatization followed by MS was used to locate the double-bond positions in the hydrocarbons. Since only monounsaturated hydrocarbons were present, the DMDS derivatives displayed a similar GC profile as the original monounsaturated hydrocarbons. Methyl branching was the key feature for the GC separation, but different double bond isomers, with the same branching, co-eluted in the same peak due to a lack of difference in polarity between the two ends of the chain. While inconvenient, this also helped in the assignment of corresponding peaks between the original hydrocarbons, the hydrogenated mixture, and the DMDS derivatives. As an example, in a single GC peak we were able to identify three isomers for the anteiso-anteiso 25:1 series, namely, the hydrocarbons 3,21-dimethyl-9-tricosene, 3,21-dimethyl-10-tricosene, and 3,21-dimethyl-11-tricosene, of which only the Δ11 isomer was previously reported in bacteria (5). The DMDS derivatives of these hydrocarbons co-eluted in a single peak. However, they were distinguishable by MS since their mass spectra displayed a M^+ at *m/z* 444 and key fragmentations at *m/z* 187 and 257 for the Δ9 isomer, at *m/z* 201 and 243 for the Δ10 isomer, and at *m/z* 215 and 229 for the Δ11 isomer. Likewise, in the iso-iso 28:1 series both 2,25-dimethyl-12-hexacosene and 2,25-dimethyl-13-hexacosene were identified in a single C_{28} iso-iso peak *via* GC–MS of their corresponding DMDS derivatives, but only the former was previously reported (5). These DMDS derivatives presented a mass spectrum with a M^+ at *m/z* 486 and key fragmentations at *m/z* 229 and 257 for the Δ12 isomer, and a single fragment at *m/z* 243 for the Δ13 isomer due to symmetry.

In the unsymmetrical hydrocarbons it was possible to narrow the possibilities to only two double-bond isomers using DMDS derivatization. However, even after $NaIO_4$/$KMnO_4$ oxidation of the whole mixture, the assignment remained ambiguous owing to the complexity of the mixture, i.e., the same fragments can arise from different hydrocarbons. For example, 2,21-dimethyl-10,11-bis(methylthio)tricosane or 2,21-dimethyl-13,14-bis(methylthio)tricosane has a M^+ at *m/z* 444 and the same fragmentations at *m/z* 201 and 243 upon electron impact (Table 1). The infrared spectrum of the monounsaturated mixture displayed no significant absorption in the 960–980 cm^{-1} region, but rather an absorption in the 760–780 cm^{-1} region, bespeaking *cis* double bonds in all of the studied monounsaturated hydrocarbons (10).

The fatty acid composition of this *Bacillus* sp. consisted of 26 different fatty acids between C_{12} and C_{26}, but the anteiso C_{15} and C_{17} saturated fatty acids were the predominant branched fatty acids in the mixture (Table 2). Saturated fatty acids accounted for 83% of the total composition. These acids were characterized by GC–MS as fatty acid methyl esters and by comparison of reference equivalent chain-length values (ECL). Noteworthy was the identification of the very long chain fatty acids tetracosanoic acid (24:0) and hexacosanoic acid (26:0). In addition, traces of 2-hydroxytetracosanoic acid (24:0) were also identified in the mixture by GC–MS. Of particular interest was the identification of 10,13-epoxy-11-methyloctadeca-10,12-dienoic acid, which was identified for the first time in a *Bacillus* sp. This acid was identified as the methyl ester by comparison of its mass spectrum with the one already reported in the literature from bacteria such as *Shewanella* or *Pseudomonas* (11,12). The mass spectrum of the methyl ester displayed a molecular ion peak (M^+) at *m/z* 322, a $M^+ - 15$ peak at *m/z* 307, a $M^+ - 31$ peak at *m/z* 291, a $M^+ - 57$ peak at *m/z* 265, a McLafferty rearrangement peak at *m/z* 74, and the most characteristic base peak at *m/z* 165 (11,12).

The sterol composition of this strain was also characterized by GC–MS, and it mainly consisted of sitosterol (79%), stigmasterol (14%), and fucosterol (7%), as judged by com-

TABLE 2
Identified Fatty Acids in the *Bacillus* sp. from Lake Pomorie

Fatty acids	Relative abundance[a] (%)
Dodecanoic (12:0)	0.9

[a]The values are the percentages based on the total peak area of the fatty acid methyl esters, and the average of at least three different samples with an average error of ±0.1%. Traces (0.01–0.05%) of 2-OH-24:0 were also identified.

paring their mass spectra with known standards (13). Therefore, the sterols were based on the sitosterol nucleus.

DISCUSSION

The *Bacillus* sp. identified in this work has a hydrocarbon branching profile similar to that of either *S. lutea* FD 533 (*M. luteus*) or *M. lysodeikticus*, but a more complex double bond isomeric composition than either *S. lutea* ATCC 533 or *S. flava* ATCC 540 (4,5). Differences and similarities were observed for each chain length between C_{25} and C_{29}. In the 25:1 series previous findings reported the (*Z*)-3,21-dimethyl-11-tricosene as the only 25:1 anteiso-anteiso isomer, but in our *Bacillus* two additional anteiso-anteiso isomers were identified, namely, the previously unreported (*Z*)-3,21-dimethyl-9-tricosene and (*Z*)-3,21-dimethyl-10-tricosene (Table 1). The same complexity of unsaturations was also observed in the iso-anteiso 25:1 series where the three compounds (*Z*)-2,21-dimethyl-(9 or 14)-tricosene, (*Z*)-2,21-dimethyl-(10 or 13)-tricosene, and (*Z*)-2,21-dimethyl-(11 or 12)-tricosene were identified (Table 1). However, in this iso-anteiso 25:1 series it was not possible to distinguish, using DMDS derivatization, between two possible unsaturated isomers for each of the three observed combinations because of their lack of symmetry. In the 26:1 series the (*Z*)-2,22-dimethyl-(10 or 14)-tetracosene is also novel, as it has not been reported before from other bacteria (5). However, a similarity in the hydrocarbon composition of our *Bacillus* to other hydrocarbon-producing bacteria was observed inasmuch as we also identified the (*Z*)-2,22-dimethyl-(11 or 13)-tetracosene and the (*Z*)-2,22-dimethyl-12-tetracosene, both of which were reported from *S. lutea* ATCC 533 and *S. flava* ATCC 540 (5). In the 27:1 series the (*Z*)-2,24-dimethyl-11-pentacosene is unprecedented since the (*Z*)-2,24-dimethyl-12-pentacosene was the only hydrocarbon identified before in bacteria (5). Another interesting difference between the hydrocarbons of this *Bacillus* and other hydrocarbon-producing bacteria was noted with the other 27:1 isomers. For example, while *S. lutea* ATCC 533 contained only (*Z*)-3,23-dimethyl-12-pentacosene, and *S. flava* ATCC 540 only had (*Z*)-3,23-dimethyl-11-pentacosene, our *Bacillus* contained both isomers (5). This same finding, i.e., the presence of both double-bond isomers, was observed for the 27:1 iso-anteiso and 27:1 iso-normal isomers. In the 28:1 series the (*Z*)-2,25-dimethyl-13-hexacosene was not recognized in any bacteria before, inasmuch as the (*Z*)-2,25-dimethyl-12-hexacosene was the only iso-iso isomer reported in *S. flava* ATCC 540 (5). Likewise, while the (*Z*)-2,24-dimethyl-13-hexacosene was the only *iso-anteiso* isomer identified in the latter strain, the (*Z*)-2,24-dimethyl-(12 or 14)-hexacosene was not reported. However, either the 28:1 iso-iso or the 28:1 iso-anteiso series had both double-bond isomers. The remaining 28:1 iso-normal and 28:1 anteiso-normal hydrocarbons in our *Bacillus* corresponded to those previously reported in other bacteria such as the *Micrococcus* (5). The 29:1 isomers identified here also corresponded to those previously characterized in other strains (6). We also detected, in trace amounts, two C_{30} monounsaturated hydrocarbons, but the amount of material precluded any further characterization. Much of the structural data presented here also supports a biogenesis of hydrocarbons from the head-to-head condensation of two fatty acids with the concomitant decarboxylation of one of the two acids (6).

The higher abundance of anteiso fatty acids over their iso counterparts, in particular that of ai-15:0 (16%), was noteworthy in this *Bacillus*. Branched-chain fatty acids are characteristic of the genus *Bacillus*, and it has been reported that the genus can be divided into two main groups based on the ai-15:0/i-15:0 ratio (14,15). In addition, the identification of 10,13-epoxy-11-methyloctadeca-10,12-dienoic acid, although a minor component, is interesting since it was identified for the first time in a *Bacillus* sp. Much discussion has arisen as to the origin of furan fatty acids in fish, since they cannot biosynthesize these acids *de novo,* and recent findings indicate that they arise from intestinal bacteria such as *Shewanella putrefaciens* or *P. fluorescens* (12). Our findings expand the origin of these furan fatty acids to *Bacillus.* Work is in progress in our laboratories elucidating the lipid composition of unusual marine bacteria.

ABSTRACT: *Schizochytrium* sp. is an algae-like microorganism utilized for commercial production of docosahexaenoic acid (DHA)-rich oil and dried microalgae for use as a source of DHA in foods, feeds, and nutritional supplements. Electron microscopic analysis of whole cells of *Schizochytrium* sp. employing sample preparation by high-pressure freeze substitution suggests the presence of secondary and tertiary semicrystalline structures of triacylglycerols within the oil bodies in *Schizochytrium* sp. A fine secondary structure consisting of alternating light- and dark-staining bands was observed inside the oil bodies. Dark bands were 29 ± 1 Å in width, and light bands were 22 ± 1 Å in width. The tertiary (three-dimensional) structure may be a multilayered ribbon-like structure which appears coiled and interlaced within the oil body. In freeze-fracture photomicrographs, *Schizochytrium* oil bodies exhibited fracture planes with terraces averaging 52 ± 7 Å in height which could correspond to the combined width of two halves of two light bands and one dark band observed in the high-pressure freeze substitution photomicrographs. The results suggest that triacylglycerols within *Schizochytrium* sp. oil bodies may be organized in a triple chain-length structure. High-pressure freeze substitution electron micrographs of two other highly unsaturated oil-producing species of microalgae, *Thraustochytrium* sp. and *Isochrysis galbana,* also revealed this fine structure, whereas microalgae containing a higher proportion of saturated oil did not. The results suggest that the staining pattern is not an artifact of preparation and that the triple chain-length conformation of triacylglycerols in *Schizochytrium* sp. oil bodies may be caused by the unique fatty acid composition of the triacylglycerols.

Paper no. L8589 in *Lipids 35,* 1377–1386 (December 2000).

Schizochytrium sp., a thraustochytrid in the kingdom Stramenopila, is an algae-like microorganism that is commercially utilized to produce docosahexaenoic acid (DHA) by fermentation (1). The triacylglycerols can constitute over 70% of the weight of *Schizochytrium* sp. Additionally, *ca.* 25–45% of the fatty acids in the triacylglycerols are DHA (2), depending on culture conditions (3). Very little is known about oil-body formation in this microorganism as thraustochytrids historically are not recognized as significant oil-producing microorganisms (4).

We recently utilized electron microscopy in an attempt to identify the location of oil production in *Schizochytrium* sp. Analysis of microbial oil bodies has historically been conducted by glutaraldehyde fixation with osmium tetroxide staining wherein DHA-containing oil bodies appear as homogeneous dark-staining inclusions (5). Following normal precedent, we analyzed *Schizochytrium* sp. cells using this technique and found that the oil bodies were homogeneous and dark. In addition to this method, we utilized high-pressure freeze substitution, a relatively new type of cell preparation that is theoretically capable of preserving very fine structures within cells. Fine structures are preserved because high pressure prevents the formation of damaging ice crystals in the cells during freezing. The cells are treated with an acetone-osmium tetroxide (OsO_4) solution which removes intracellular water by successive dehydration and stains any double bonds present in organelles within the cells (6).

When electron micrographs produced using the high-pressure freeze substitution technique were observed, a fine structure was revealed within the DHA-rich oil bodies of *Schizochytrium* sp. that was organized and nonrandom. Triacylglycerols in some types of biological systems, for example milk, have been proposed to occur in semicrystalline states (7). Confirmation of these semicrystalline triacylglycerol structures has only been observed indirectly by use of freeze-fracture electron microscopy (7). In this analysis, triacylglycerol structure was also observed as a terrace-like structure in the freeze-fracture planes.

This paper describes the structures we observed within the oil bodies of *Schizochytrium* sp. using both high-pressure freeze substitution and freeze-fracture electron microscopy preparation techniques. Other types of oil-producing microalgae were also examined using high-pressure freeze substitution electron microscopy in an effort to determine whether this fine structure was an artifact of the method of preparation. A model is proposed which may describe the triacylglycerol structure of the unique DHA-rich oil in *Schizochytrium* sp.

MATERIALS AND METHODS

Cell culture. Schizochytrium sp. (ATCC 20888, Rockville, MD) was grown in 250-mL shake flasks in 50 mL of a 50% artificial seawater medium containing a low carbon-to-nitrogen ratio of *ca.* 10:1 (molar concentrations) to produce low oil-content cells. This medium consisted of (on a per liter basis): NaCl, 12.5 g; $MgSO_4 \cdot 7H_2O$, 2.5 g; KCl, 0.5 g; $CaCl_2$, 100 mg; glucose, 2.5 g; monosodium glutamate, 2.5 g; KH_2PO_4, 0.5 g; metals, 5 mL; and vitamin mix, 1 mL. The pH of the solution was adjusted to 7.0, and the solution was filter-sterilized. The trace metal solution contained per liter: Na_2EDTA, 6.0 g; $FeCl_3 \cdot 6H_2O$, 0.29 g; H_3BO_3, 6.84 g; $MnCl_2 \cdot 4H_2O$, 0.86; $ZnCl_2$, 0.06 g; $CoCl_2 \cdot 6H_2O$, 0.026 g; $NiSO_4 \cdot 6H_2O$, 0.052 g; $CuSO_4 \cdot 5H_2O$, 0.002 g; and $NaMoO_4 \cdot 2H_2O$, 0.005 g. The pH of the trace metals solution was adjusted to 8.0. The vitamin mix contained per liter: thiamin, 100 mg; biotin, 0.5 mg; and cyanocobalamin, 0.5 mg. The flasks were shaken at 220 rpm, maintained at 29°C, and exposed to light at an intensity of *ca.* 100 $\mu E/m^2 \cdot s$. After 24 h, a small volume from this flask was used to inoculate a separate flask containing growth medium with a high carbon-to-nitrogen ratio of *ca.* 30:1 to stimulate oil production. As described by Barclay (8), the components of this medium (per liter) were as follows: Na_2SO_4, 5 g; $MgSO_4 \cdot 7H_2O$, 1.2 g; $CaCO_3$, 0.067 g; glucose, 10.0 g; monosodium glutamate, 1.0 g; KH_2PO_4, 0.2 g; Difco yeast extract, 0.4 g; trace metals solution, 5 mL; vitamin mix, 1 mL. The culture medium was adjusted to pH 7.0, and the medium was filter-sterilized. This culture was grown for 48 h. The culture was sampled (at 0, 24, 48, and 72 h) after the inoculum of the high oil production flask for electron microscopy preparation.

Nannochloropsis occulata (UTEX LB 2164) and *Neochloris oleoabundans* (UTEX 1185) strains were obtained from the Culture Collection of Algae at the University of Texas at Austin (UTEX) and grown at 25°C with light (*ca.* 100 $\mu E/m^2 \cdot s$). *Nannochloropsis occulata* cultures were grown in f/2 medium (9) containing 60% strength sterilized seawater as well as the following additions on a per liter basis: $NaNO_2$, 0.15 g; KH_2PO_4, 0.01 g; $NaHCO_3$, 0.2 g; vitamin mix, 1 mL; soil extract, 5 mL; and f/2 trace metals mix, 5 mL. The f/2 trace metal solution contained the following per liter: Na_2EDTA, 4.36 g; $FeCl_3 \cdot 6H_2O$, 3.15 g; $MnCl_2 \cdot 4H_2O$, 180 mg; $CuSO_4 \cdot 5H_2O$, 10 mg; $ZnSO_4 \cdot 7H_2O$, 22 mg; $CoCl_2 \cdot 6H_2O$, 10 mg; $NaMoO_4 \cdot 2H_2O$, 6 mg. The medium was adjusted to pH 8.0, and the medium was autoclaved. Cultures were grown under light (*ca.* 100 $\mu E/m^2 \cdot s$) for *ca.* 4 wk.

Neochloris oleoabundans was grown in Bolds basal medium (10) containing on a per liter basis: $NaNO_3$, 250 mg; $CuCl \cdot 2H_2O$, 25 mg; $MgSO_4 \cdot 7H_2O$, 75 mg; KH_2PO_4, 250 mg; H_3BO_3, 11 mg; Bolds Basal EDTA mix, 1 mL; Bolds basal trace metals, 1 mL; and soil extract, 5 mL. Bolds Basal EDTA mix contained the following per liter: EDTA, 50 g; KOH, 31 g. Bolds Basal trace metals solution contained the following per liter: $ZnSO_4 \cdot 7H_2O$, 8.82 g; $MnCl_2 \cdot 4H_2O$, 1.44 g; MoO_3, 0.71 g; $CuSO_4 \cdot 5H_2O$, 1.57 g; $Co(NO_3)_2 \cdot 6H_2O$, 0.49 g. The medium was adjusted to pH 7.0 and autoclaved. Cultures were grown under light (*ca.* 100 $\mu E/m^2 \cdot s$) for 3–4 wk. Cells were harvested for sample preparation by gentle vacuum filtration.

Thraustochytrium sp. (ATCC 20890) was grown in 250-mL shake flasks on a rotary shaker at 220 rpm and maintained at 29°C. It was grown in a full-strength seawater culture medium with a high carbon-to-nitrogen ratio. This medium contained the following per liter: Reef Crystals™ Synthetic Sea Salts Enriched Blend made by Aquarium Systems (Mentor, OH), 40 g; glucose, 20 g; monosodium glutamate, 4 g; Difco (Detroit, MI) yeast extract, 1 g; trace metal solution, 5 mL; and vitamin mix, 1 mL. The medium was adjusted to pH 7.0 and autoclaved. Cultures were sampled at 48 h.

Crypthecodenium cohnii (ATCC 30334 sibling species G) was grown in 250-mL flasks containing 50 mL of culture medium. Cultures were grown in *Porphyridium* medium (11). This medium consisted of 50% strength seawater, 10% soil extract, and the following nutrients on a per liter basis: Difco yeast extract, 1.0 g; tryptone, 0.1 g; glucose, 3 g; biotin 0.001 mg; and thiamin 0.1 mg. The culture medium was autoclaved. Cultures were grown in the dark at room temperature. After 7 d, 100 mL of fresh *Porphyridium* medium containing one-tenth of the original concentration of yeast extract and tryptone was added to the 50 mL of culture to nitrogen-stress the culture for oil production. The *C. cohnii* culture was grown in this manner for 6 d and was then sampled for electron microscopy preparation.

Isochrysis galbana (UTEX LB 987) cultures were grown in 250-mL flasks containing 50 mL of f/2 culture medium (previously described) (10). After growing for 22 d at room temperature with light exposure, 100 mL of fresh f/2 medium lacking $NaNO_3$ was added to the 50 mL of culture to nitrogen-stress the culture and to enhance oil production. The cells were allowed to grow for six more days and were subsequently sampled for electron microscopy preparation.

Lipid analysis. Fatty acids in whole-cell *Schizochytrium* sp. and *Thraustochytrium* sp. were transesterified using 4% wt/vol sulfuric acid in methanol (100°C for 1 h). The fatty acid methyl esters (FAME) were separated and quantified on a Varian 3500 gas–liquid chromatograph (Palo Alto, CA) equipped with a flame-ionization detector and a 30 m × 0.25 mm (i.d.) Rtx 2330 fused-silica capillary column (Restek, Bellefonte, PA). Nu-Chek-Prep (Elysian, MN) fatty acid standards were employed in the analysis. Fatty acid standards were reported as percentage of total FAME.

Separation of lipid classes. Lipids were extracted from lyophilized *Schizochytrium* sp. by using the method of Bligh and Dyer (12) assisted by sonication of the cells. The total lipid extract was fractionated into the major lipid classes (phospholipid, triacylglycerols, free fatty acids, and sterols) by thin-layer chromatography (TLC) using the method outlined in St. John and Bell (13). The fractions were scraped from the TLC plates, transesterified, and analyzed by gas chromatography using the method described above.

^{13}C nuclear magnetic resonance (NMR) spectroscopy.

Quantitative ^{13}C spectra were obtained on the purified triacylglycerol fraction from *Schizochytrium* sp. microalgae (*ca.* 50–100 mg dissolved in 0.6 mL $CDCl_3$ in 5-mm tubes) at a frequency of 75 MHz with the NOE (nuclear Overhauser effect)-suppressed, inverse-gated, proton-decoupled technique. The free induction decay was acquired with a pulse delay of 40 s as described by Aursand *et al.* (14). The chemical shifts were referenced indirectly to tetramethylsilane by using the central peak of $CDCl_3$ (δ = 77.08 ppm). In this analysis, assignments of the downfield resonance at 173.2, 172.8 ppm, based on literature precedent (14), were attributed to carboxyl carbons of all fatty acids except DHA/docosapentaenoic acid (DPAn-6) (fatty acids that contain a Δ-4 unsaturation) located at positions *sn*-1,3 (α-position) and *sn*-2 (β-position) on the glycerol backbone, respectively. Assignments of the downfield resonance at 172.5 and 172.1 ppm were attributed to carboxyl carbons of DHA/DPAn-6 (fatty acids that contain a Δ-4 unsaturation) located at positions *sn*-1,3 (α) and *sn*-2 (β) on the glycerol backbone, respectively. Integration of carboxyl groups was used to estimate the amount of DPAn-6 and DHA esterified to the *sn*-2 and *sn*-1,3 positions.

High-pressure freeze substitution. Cell samples were collected and washed briefly in 15% wt/vol dextran (avg. MW 39 kD), a nonpermeating cryoprotectant, in growth medium or 5 g/L Na_2SO_4. The samples were then frozen in a BAL-TEC HPM-010 high-pressure freezer (Technotrade International, Manchester, NH) and stored under liquid nitrogen. The samples were freeze-substituted in 2% OsO_4 in acetone at −80°C following the procedures outlined by Staehelin *et al.* (15).

Freeze-fracture. Samples were collected at 48 h, and glutaraldehyde was added to the sample over 15 min to a final concentration of 1%. The cells were then washed and resuspended in a solution of 5 g Na_2SO_4/L. Glycerol, which was used as a cryoprotectant, was added over a period of 20 min to a final concentration of 30%. Samples were frozen in propane near its melting point and freeze-fractured at −113°C in a BAL-TEC BAF-060 freeze-etch system (Technotrade International). Replicas were cleaned on bleach followed by a 7.8% wt/vol potassium dichromate, 33% vol/vol sulfuric acid solution, then picked up on specimen grids for viewing by transmission electron microscopy.

Lipid-layer measurement. Crude lipid-layer widths and terrace heights were measured on resulting contact print photomicrographs using a Bausch & Lomb Stereozoom 7 (Rochester, NY) dissecting microscope with a calibrated eyepiece. Measurements were averaged and standard deviations calculated.

RESULTS AND DISCUSSION

The fatty-acid profile of *Schizochytrium* sp. is variable, depending on culture conditions which ultimately influence the ratio of triacylglycerols to phospholipids in the lipid fraction. Differences in the fatty acid composition of the triacylglycerols and phospholipids from *Schizochytrium* sp. are illustrated in Table 1. The overall fatty-acid profile of *Schizochytrium* sp. is relatively simple, consisting of five major fatty acids: DHA (22:6n-3) and DPAn-6 are the primary polyunsaturated fatty acids, and myristic (14:0), palmitic (16:0), and palmitoleic (16:1) acids are the major saturated and monounsaturated fatty acids. Together, these five fatty acids constitute over 90% of the total fatty acids in the triacylglycerols of *Schizochytrium* sp. The ratio of DHA to DPAn-6 in the triacylglycerols is *ca.* 3:1. The phospholipids are highly enriched in DHA, DPAn-6, and palmitic acid.

The results of ^{13}C NMR analysis indicated that DHA and DPAn-6 are preferentially (71–75%) esterified in the *sn*-2 position of the glycerol with the remainder (25–29%) linked in the *sn*-1,3 position (Fig. 1). Given this and the total fatty acid composition of the oil, most of the *sn*-2 positions were found to be occupied by DHA or DPAn-6. This stereospecific distribution of DHA and DPAn-6 fatty acids is similar to that reported for other highly unsaturated fatty acid-rich oils of marine, algal, and microbial origin (16). By subtraction, most of the remaining *sn*-1,3 positions would be occupied by either 14:0, 16:0, or 16:1 acids.

When the *Schizochytrium* sp. cells were prepared by high-pressure freeze substitution, patterns within the oil bodies were suggestive of both secondary and tertiary (three-dimensional) structures (Figs. 2 and 3). The fine pattern of alternating light- and dark-staining bands may be indicative of a secondary structure in the triacylglycerols. The light bands measured 22 ± 1 Å (n = 10). Larsson (7) provides a diagram drawn to scale of trilaurin as viewed along the shortest axis of the triacylglycerol unit. The length from the alpha-carbon to the end of the 12-carbon fatty acid chain is depicted as 11.7 Å. Correspondingly, Holte *et al*. (17) report that the length of palmitate should fall within the range of 13–15 Å. The width of the light bands measured approximately twice the length of crystalline myristate (14:0) and/or palmitate (16:0) as can be calculated at 11.38–12 Å and 13 Å, respectively, from the data of Larsson *et al.* (7) and Holte *et al.* (17).

OsO_4 reacted with the double bonds of unsaturated fatty acids which made them appear dark in the electron micrographs. Dark-staining bands measured 29 ± 1 Å (n = 10) in

TABLE 1
Fatty Acid Composition of Oil Extracted from *Schizochytrium* sp.

Fatty acid	Phospholipids	Triacylglycerols	Total fatty acids (%)
14:0	1.2	17.5	14.3
14:1	—	0.7	0.6
16:0	19.3	26.4	25.1
16:1	1.4	13.9	11.4
18:0	—	0.6	0.5
18:1	2.6	3.6	3.4
20:4n-6	—	0.1	0.1
20:5n-3	—	0.4	0.3
24:1	—	0.2	0.2
22:5n-6	21.3	8.8	11.0
22:5n-3	—	0.2	0.2
22:6n-3	54.2	27.6	32.9

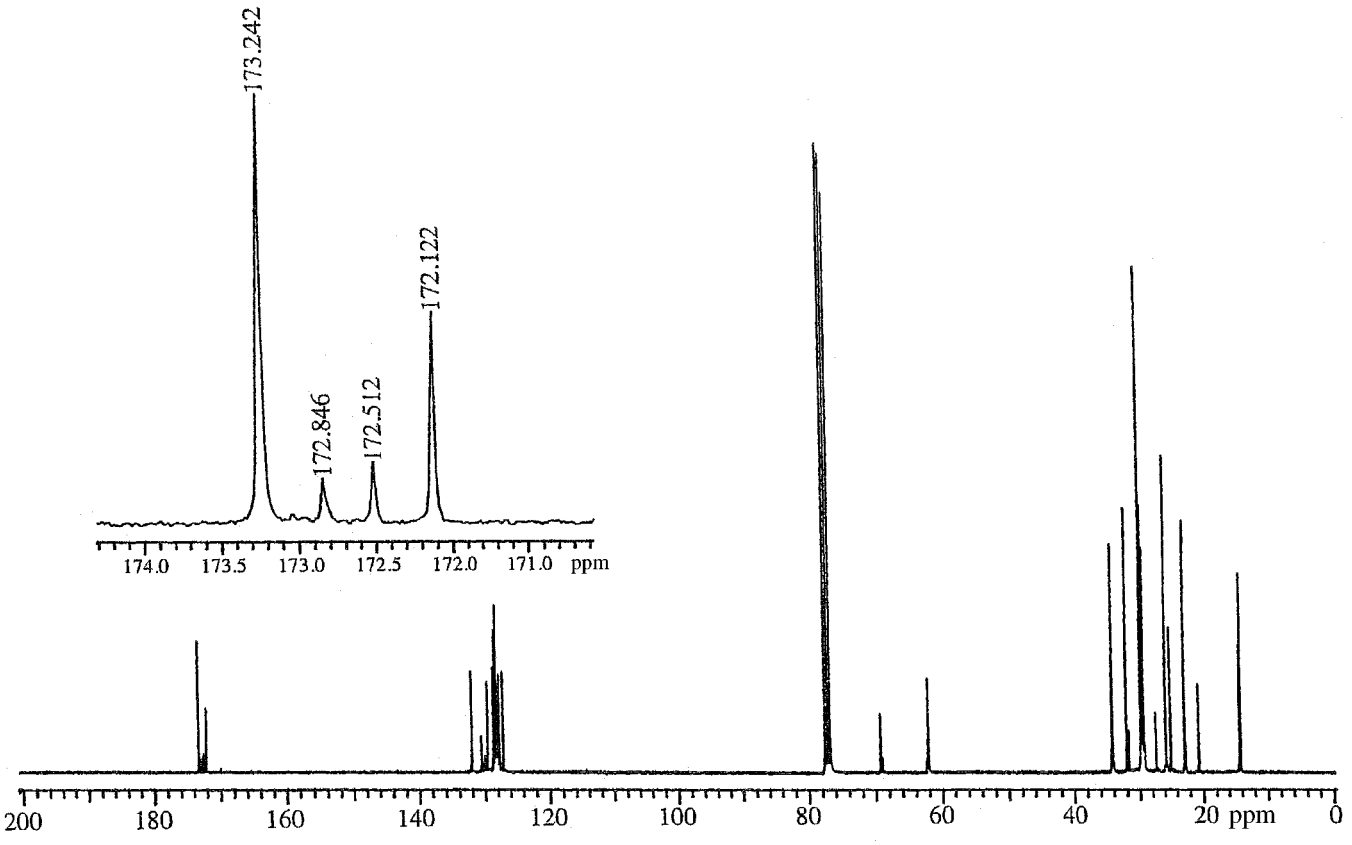

FIG. 1. ^{13}C nuclear magnetic resonance spectrum of the triacylglycerols of *Schizochytrium* sp. The data illustrate the relative amounts of docosahexaenoic acid and docosapentaenoic acid esterified to the *sn*-2 and *sn*-1,3 positions (see text for explanation).

width. The width of dark bands correspond relatively closely to the reported length of DHA in the crystalline state, 29.03 and 24.85 Å in the *sn*-1 and *sn*-2 positions of a phospholipid molecule, respectively (18). Applegate and Glomset (18), using a molecular modeling computer program (PROPHET II, BBN Systems and Technology, Cambridge, MA), have suggested that the conformational shape of the DHA molecule is a straight helical structure. In contrast, Crawford *et al.* (19), using a molecular orbital package computer program (MOPAC, Alchemy 2000 v. 20; Tripos Inc., St. Louis, MO), calculated the energy-minimized configurations of DHA and DPAn-6 and report that the molecules as being folded approximately in half. If the dark bands observed in electron photomicrographs do correspond to stained DHA and DPAn-6 molecules, a measurement of 29 ± 1 Å may provide more support for a straight helical structure of the molecules.

The fine structures within the oil bodies cannot be thylakoid membranes (which are typically associated with plastid-like organelles) because: (i) the bilayer thickness of known thylakoid membranes is thicker (*ca.* 80 Å) (20) than the thickness of the terrace heights (51 ± 7 Å) observed in freeze-fracture micrographs of *Schizochytrium*, (ii) the phospholipid content of oil in *Schizochytrium* sp. cells is less than 5% of the total lipids (Zeller, S., unpublished data), and (iii) the freeze-fracture technique revealed that there are no proteins present on the surface fracture planes of these laminar structures inside *Schizochytrium* sp. oil bodies as would normally be found on thylakoid membranes (21) (Fig. 4).

Larsson (7) previously proposed that crystalline triacylglycerol structures can occur in one of two alternative chain-layer configurations based on segregation of similar fatty acid tails. The banding pattern observed in *Schizochytrium* sp. oil bodies may best be described using Larsson's triple chain-length model, suggesting that the triacylglycerols in the oil bodies are organized in a semicrystalline state by segregation of the different fatty-acid types into separate layers. We propose that the highly unsaturated fatty-acid chains containing DHA and possibly DPAn-6 may be segregated into one interlocking dark-staining layer and the saturated and monounsaturated fatty acid chains may be segregated end-to-end to form light-staining layers. This type of arrangement may have been facilitated by the predominance of the long-chain, highly unsaturated fatty acids DHA and DPAn-6 in the *sn*-2 position of the triacylglycerol. Thus, following Larsson's triple chain-length model for mixed triacylglycerols (7), the suggested secondary structure of the triacylglycerols in *Schizochytrium* sp. may be illustrated by the model presented in Figure 5. Analysis of the freeze-fracture photomicrographs appears to confirm this layered structure in oil bodies as evidenced by terraced fracture planes (Fig. 4). Terrace heights averaged 51

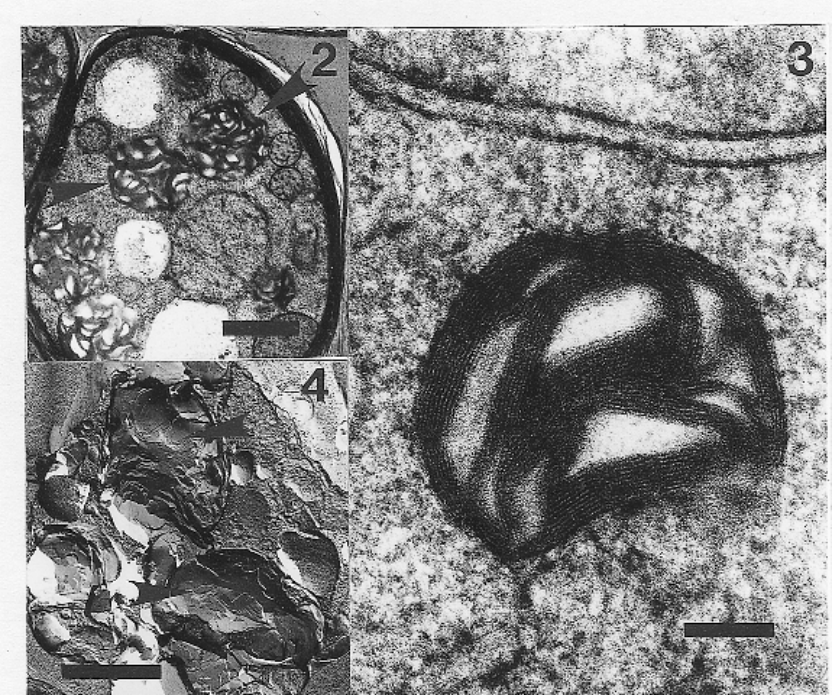

FIG. 2. Electron micrograph of a cell from an exponential culture of *Schizochytrium* sp. as preserved by high-pressure freezing and freeze-substitution. Early developing oil bodies are indicated by arrows. Bar = 1 μm.

FIG. 3. Example of the layered, fingerprint-like pattern observed inside a *Schizochytrium* sp. oil body as preserved by the high-pressure freeze substitution method. The alternating light and dark bands in the fingerprint-like structure measure 21.56 ± 1.35 Å and 28.78 ± 1.35 Å, respectively. Bar = 0.1 μm.

FIG. 4. Whole-cell *Schizochytrium* sp. as preserved by freeze fracture showing fracture planes through oil bodies. The triacylglycerol triple-layer freeze-fracture terrace shadow height averages 52.18 ± 6.8 Å. Fractured terraces inside oil bodies are indicated by arrows. Bar = 1 μm.

± 7 Å (n = 10) which, in the proposed model, may correspond to the distance from one fracture plane between two saturated lipid layers, including one interlocked dark-staining layer, to the next fracture plane between the next two end-to-end saturated lipid layers (Fig. 5).

Larsson's model (7) has been previously confirmed indirectly by freeze-fracture techniques on oil droplets in milk. This is the first time an ordered pattern has been visually observed in oil bodies of an oil-accumulating microorganism. Cell sample preparation procedures could possibly affect the conformation of the triacylglycerols within the oil bodies. However, the high-pressure freeze substitution technique rapidly freezes the cells within *ca.* 10 ms by exposure to liquid nitrogen under pressure (6). The high-pressure flash freeze should instantaneously arrest molecular movement, and subsequent segregation of the fatty-acid chains would most likely not occur (22). Thus, the triple-layer structure may be the native conformation of the triacylglycerols in the cells prior to freezing. Possibly, this secondary light- and dark-staining pattern is due to the unique fatty-acid profile of the oil produced by *Schizochytrium* sp. The composition of the oil can be generalized as containing a 2:1 ratio of saturated and monounsaturated fatty acids to highly unsaturated fatty acids.

A possible tertiary (three-dimensional) structure of the lipids in the oil bodies was revealed in the high-pressure freeze substitution photomicrographs as a ribbon-like multilayer structure of triacylglycerols coiled within the oil body (Fig. 3). These ribbon-like bands of triacylglycerols average *ca.* 500 Å in width in *Schizochytrium* sp. Their relatively constant width is surprising, and we have not yet developed a model to explain this structure.

The question has been raised of whether the light- and dark-staining pattern could merely be an artifact of electron microscopy preparation. In order to address this question, we analyzed oil-body structure in other algal and algae-like microorganisms with a variety of fatty-acid profiles. The high-pressure freeze substitution technique was used to prepare cell samples of *N. oleoabundans, N. occulata, I. galbana, C. cohnii, Thraustochytrium* sp. (ATCC 20890), and a repeat of *Schizochytrium* sp. (ATCC 20888). Electron micrographs from this experiment were compared with earlier micrographs of *Schizochytrium* sp. These specific microorganisms were selected based on prior knowledge (in the literature and from FAME analysis) of their fatty acid profiles (4,23–26). All of these algae or algae-like species of microorganisms are known

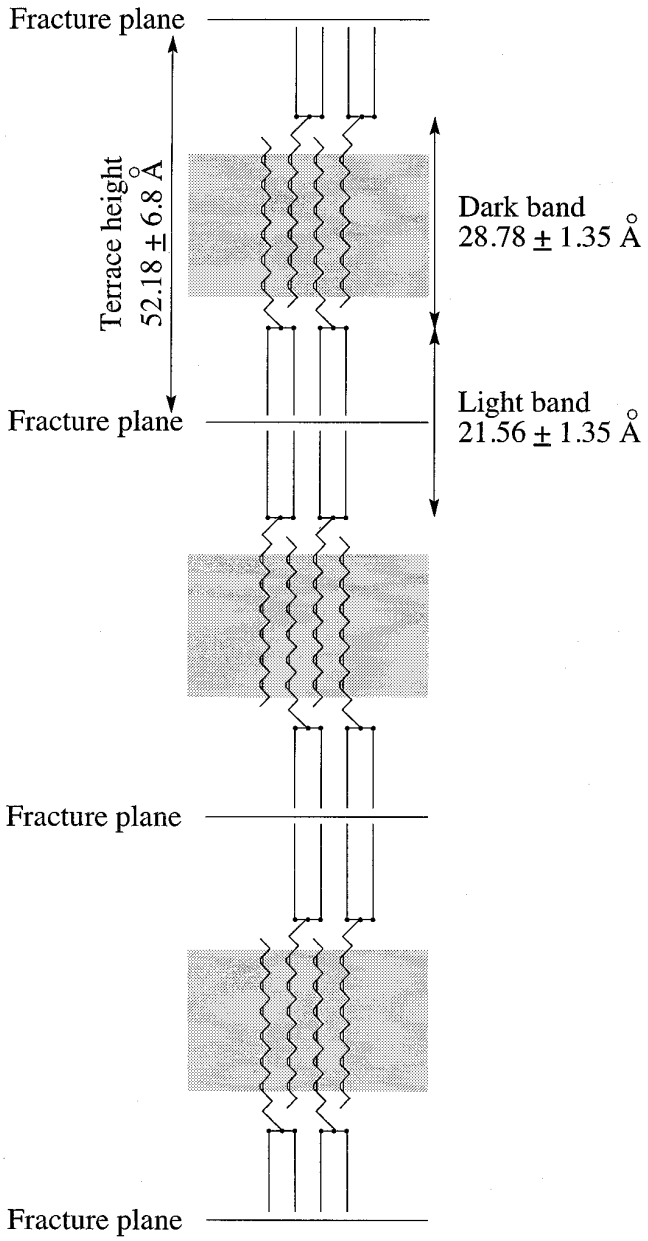

FIG. 5. Proposed model (triple-layer structure) of triacylglycerols in *Schizochytrium* sp. oil bodies which is consistent with the light- and dark-band staining pattern observed in freeze-substitution electron micrographs.

to contain significant amounts of either of the long-chain n-3 fatty acids eicosapentaenoic acid (20:5n-3) or DHA (4,24–26) except *N. oleoabundans,* which contains *ca.* 81% saturated fatty acids (23).

Electron photomicrographs did not reveal the secondary structure which has a fingerprint-like pattern in *N. oleoabundans, N. occulata*, or *C. cohnii*. Oil bodies from *N. oleoabundans* were homogeneous and did not stain (Fig. 6). This was expected because the fatty-acid profile of *N. oleoabundans* contains mostly saturated fatty acids (23) (Table 2). Oil bodies from *N. occulata* (Fig. 7) and *C. cohnii* (Figs. 8–10) were homogeneous, staining gray. The ratio of saturated and monounsaturated to highly unsaturated fatty acids in *C. cohnii* and *N. occulata* were *ca.* 6:1 and 1:1, respectively. This may not be close enough to the 2:1 ratio of saturated and monounsaturated to polyunsaturated fatty acids found in *Schizochytrium* sp. triacylglycerols, a ratio which may favor a triple chain-length formation of fatty acid tail segregation.

Electron photomicrographs of *I. galbana* exhibited oil bodies that contained the tertiary, three-dimensional interlaced pattern, but the secondary fingerprint pattern was not visible (Figs. 11–13). The tertiary ribbon-like bands measured an average of 405 ± 50 Å (n = 25). It can be confirmed that the structure inside the oil bodies differs significantly from that of the structure of thylakoid membranes seen inside chloroplasts. Figure 12 clearly shows an *I. galbana* cell containing an oil body displaying the tertiary pattern adjacent to a chloroplast containing mature thylakoid membranes. The two types of lipid structures are different with respect to shape and size. The bilayer thickness of thylakoid membranes in this organism's chloroplasts is an average of 56 ± 15 Å (n = 10), and the lumen of the granal stacks (white areas) measured 102 ± 9 Å in width. The secondary light- and dark-staining pattern was not visible within the ribbon-like bands inside oil bodies of *I. galbana*. However, the fatty-acid profile ratio of saturated and monounsaturated fatty acids to highly unsaturated fatty acids of *I. galbana* may have favored the formation of a triple-layer structure within the triacylglycerols (Fig. 13). The major saturated fatty acids 14:0 and 16:0 in addition to the major monounsaturated fatty acids (and including linoleic acid 18:2 which would most likely stain fairly lightly) add up to *ca.* 56% of the total fatty acids (24). The highly unsaturated fatty acids containing four or more double bonds add up to *ca.* 38% of total fatty acids (Table 2). These roughly correspond to the 2:1 saturated and monounsaturated to highly unsaturated fatty-acid ratio observed in *Schizochytrium* sp. The tertiary ribbon-like bands measure an average of 405 ± 50 Å (n = 25). This width is slightly different from the width of tertiary bands previously observed in *Schizochytrium* sp.

Thraustochytrium sp. electron photomicrographs exhibit both a secondary and tertiary pattern (Figs. 14,15). Tertiary ribbon-like bands measure 286 ± 74 Å. The dark bands measure 29 ± 3 Å (n = 25) in width, and the light bands measure 22 ± 3 Å (n = 25) in width. This is very similar to the measurements of the secondary dark and light bands observed within oil bodies of *Schizochytrium* sp. The fatty-acid profile of *Thraustochytrium* sp. was reported to be *ca.* 31% saturated and 68% highly unsaturated (Table 2) (4). The fatty-acid profile of *Thraustochytrium* sp. does not contain a significant amount of monounsaturated fatty acids. This fatty-acid profile produces a ratio of 1:2 saturated to highly unsaturated fatty acids. This is opposite of the fatty-acid ratios observed for *Schizochytrium* sp. Correspondingly, oil bodies of *Thraustochytrium* sp. seem to have a high percentage of dark-staining bands compared to *Schizochytrium* sp. (Fig. 16). Perhaps a different triple chain-length conformation could be hypothesized to exist in *Thraustochytrium* sp., wherein two highly

unsaturated fatty-acid chains of the triacylglycerol segregate into the same layer while only one saturated fatty acid from each triacylglycerol segregates into a separate layer.

Repetition of the high-pressure freeze substitution technique with *Schizochytrium* sp. gave results essentially identical to those described above (Figs. 16,17). Ribbon-like bands measured an average of 267 ± 49 Å. These results differ from previous measurements of *ca.* 500 Å, but as can be seen by the large standard deviation of the measurements, the width of the tertiary ribbon-like bands was highly variable in pictures from the repeat experiment. Dark bands inside oil bodies measured 29 ± 2 Å, and light bands measured 22 ± 3 Å. These results are very similar to earlier measurements of dark and light bands in *Schizochytrium* sp. photomicrographs. The results of the study of other algal and algae-like microorganisms add support to the hypothesis that the staining patterns in the oil bodies of *Schizochytrium* sp. were not artifacts of the high-pressure freeze substitution preparation for electron microscopy. It also provides more evidence that the secondary light- and dark-staining pattern may be representative of the structure of triacylglycerols in their native conformation prior to freezing. The secondary staining pattern was observed in both *Schizochytrium* sp. and *Thraustochytrium* sp. It is interesting that these results were seen in two very closely related species of algae-like microorganisms (27) with fatty-acid profiles that are either 2:1 or 1:2 saturated plus monounsaturated fatty acids to highly unsaturated fatty acids. The results of this experiment suggest that the formation of a semicrystalline structure, such as the triple chain-length structure, in the microbial oil bodies may depend on the ratio of saturated and monounsaturated plus highly unsaturated fatty acids in the oil.

The tertiary ribbon-like banding pattern could be observed in two closely related species, *Schizochytrium* and *Thraustochytrium*, and in the unrelated species *I. galbana. Isochrysis galbana* is a member of the eustigmatophytes, a separate group of the heterokont algae within the stramenopiles (24,28). Although the secondary light- and dark-staining pattern could not be seen inside the tertiary, three-dimensional bands of *I. galbana*, it is encouraging that the tertiary pattern was present and that this organism had a similar fatty-acid profile of 2:1 saturated plus monounsaturated to highly unsaturated fatty acids.

In conclusion, the light- and dark-staining pattern observed in *Schizochytrium* sp. and *Thraustochytrium* sp. oil bodies may be representative of the formation of a semicrystalline structure in the triacylglycerols in the oil bodies. This interpretation is supported by: (i) the thickness of the light- and dark-staining bands corresponds to known lengths of fatty acids, (ii) freeze-fracture terrace heights in the oil bodies correspond very closely to the observed staining pattern exhibited in freeze substitution-treated oil bodies, and (iii) this pattern appears to occur in oil bodies containing triacylglycerols with a 2:1 or 1:2 ratio of saturated and monounsaturated to highly unsaturated fatty acids, a ratio which may favor the triple chain-length conformation. Further studies investigating electron micrographs of oil-producing species of microorganisms with either a 2:1 or 1:2 saturated and monounsaturated to highly unsaturated fatty acid ratio or studies of *Schizochytrium* sp. or *Thraustochytrium* sp. mutants with altered fatty-acid ratios may aid in the elucidation of factors that facilitate the unique organization of the triacylglycerols observed in *Thraustochytrium* sp. and *Schizochytrium* sp. Additionally, X-ray diffraction experiments of extracted oil samples may provide additional evidence for a triple chain-length structure in these microbial oils.

ABSTRACT: *Perkinsus marinus* is one of two important protozoan parasites of the eastern oyster, *Crassostrea virginica*. The other is *Haplosporidium nelsoni*. Lipids extracted from 7-d-old *in vitro* cultured *P. marinus* meronts, incubated with fluorescent-labeled phosphatidylcholine (FL PC) and nonincubated *P. marinus* meronts, were analyzed by a high-performance liquid chromatography (HPLC) system equipped with a diol phase column, in combination with thin-layer chromatography coupled with a flame-ionization detector (TLC/FID), and high-performance thin-layer chromatography (HPTLC). Various polar and neutral lipid classes were separated by HPLC using a two-gradient solvent system. Five polar lipid classes—phosphatidylcholine (PC), phosphatidylethanolamine (PE), cardiolipin (CL), sphingomyelin (SM), and phosphatidylserine (PS)—were identified from *P. marinus* extracts. Four neutral lipid classes—triacylglycerol (TAG), steryl ester (SE), cholesterol (CHO), and fatty alcohol—were distinguished. TLC/FID analysis of meront lipids showed that the weight percentages of PC, PE, CL, SM, PS/PI, TAG, SE, and CHO were 21, 10.7, 4, 2.3, 4.3, 48.7, 7.8, and 1.2%, respectively. HPLC and HPTLC analyses revealed the presence of two SM and PS isomers in *P. marinus* extracts. *Perkinsus marinus* effectively incorporated FL PC acquired from the medium and metabolized it to various components (i.e., free fatty acid, monoacylglycerol, diacylglycerol, TAG, PE, and CL). Uptake and interconversion of FL PC in *P. marinus* meronts increased with time. After 48 h the total uptake of fluorescence (FL) was 28.9% of the FL PC added to the medium, and 43% of the incorporated FL resided in TAG.

Paper no. L8391 in *Lipids 35*, 1387–1395 (December 2000).

The protistan, *Perkinsus marinus* (Dermo), which parasitizes American (eastern) oysters (*Crassostrea virginica*) is an apicomplexan in the class Perkinsasida (1). It was originally described by Mackin *et al.* (2) as *Dermocystidium marinum*. This parasite infects eastern oyster populations along the East and Gulf Coasts of the United States and has caused severe oyster mortality from the mid-Atlantic to the Gulf since the 1950s. Presently, *P. marinus* is the most prevalent parasite of the eastern oyster in mid-Atlantic waters. The disease caused by *P. marinus* is infectious (see Ref. 3). Four life stages, meront (trophozoite), prezoosporangium, zoosporangium and biflagellate zoospore, have been identified and described (4,5). Immature meronts (merozoites), usually found in the phagosomes of hemocytes and tissues of infected oysters, are 2–4 μm and coccoid. Meronts (10–20 μm) are mature merozoites with an eccentric vacuole which often contains a refringent vacuoplast. The mature meront (schizont, 20 to 40 μm) contains 8 to 32 cells. Prezoosporangia, developed from meronts, are sometimes observed in moribund and dead oyster tissues and can enlarge to 150 μm. When tissue-associated merozoites/meronts are placed in fluid thioglycollate medium (FTM) for 4 to 5 d, they also develop into prezoosporangia (hypnospores). Prezoosporangia are characterized by having a large vacuole and an eccentric nucleus adjacent to the cell wall. Zoosporulation (production of biflagellate zoospores) usually occurs after incubating FTM-cultured prezoosporangia in estuarine or seawater (20–22 ppt) for 4–5 d. The three life stages—meront, prezoosporangia, and biflagellate zoospore—are infective (3). The merozoite/meront stage is the primary agent for disease transmission (3,5). The recent advancement in culture of meront stage of this parasite in defined media (6–8) provides the opportunity to study the biochemistry and physiology of meronts.

Host lipids play a critical role for long-term survival and life cycle completion of endogenous parasites. Investigation of host lipid utilization in parasites is thus important in understanding the disease processes and the interaction between the host and parasite. Numerous studies have been conducted and advancements have been made in understanding the processes of lipid uptake and metabolism in several mammalian parasites (e.g., *Plasmodium* sp., *Schistosoma mansoni*, *Trypanosoma brucei, Giardia lamblia*) (9–19).

Abbreviations: Bodipy, 4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene; CER, ceramide; CHE, cholesteryl ester; CHO, cholesterol; CL, cardiolipin; DAG, diacylglycerol; FA, fatty acid; FAME, fatty acid methyl ester; FFA, free fatty acids; FH, fatty alcohol; FL, fluorescent-labeled; FTM, fluid thioglycollate medium; HPLC, high-performance liquid chromatography; HPTLC, high-performance thin-layer chromatography; LPC, lysophosphatidylcholine; MAG, monoacylglycerol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; SE, steryl ester; SM, sphingomyelin; TAG, triacylglycerol; TLC-FID, thin-layer chromatography coupled with a flame-ionization detector; UV, ultraviolet; YRW, York river water.

In most of the lipid metabolism studies in parasites, thin-layer chromatography (TLC) has been utilized to analyze the uptake and interconversion of fluorescent lipid analogs and/or radiolabeled lipids by parasites. Only one recent study (13) employed a high-performance liquid chromatography (HPLC) equipped with a fluorescent detector and a silica gel column to investigate the uptake and metabolism of fluorescent lipid analogs by *S. mansoni*. Polar lipid classes were separated using one solvent system (acetonitrile, methanol, phosphoric acid) in the study by Furlong *et al.* (13) and no analysis was conducted on neutral lipid components.

Several methods have been described for lipid class separation (20). Polar lipid classes are typically resolved by HPLC using columns with silica gel phases (20). Detection has normally been with either ultraviolet (UV) (200–210 nm) or light-scattering detectors (21–26). Only limited work has been done on neutral lipid class separation using the above systems (27–31).

The "diol" (1,2-dihydroxypropyl covalently bonded to silica gel) phase has not been used as extensively as silica gel alone for lipid class separation. The "diol" phase is slightly less polar than silica gel, but provides a similar resolution for polar (32–37) and neutral lipid class separation (37). The "diol" phase does have an advantage in that it is more resistant to water deactivation than silica gel phase.

Solvents such as hexane, isopropanol, methanol, acetonitrile, and water have been employed as eluents in these methods (20). By using either Silica Gel or "diol" phases, gradient elution with a mixture of hexane/isopropanol/water appeared to be the most widely used and showed satisfactory results for neutral and/or polar lipid class separation (20,25,32,37–42).

To better understand lipid metabolism in the meront stage of this parasite, we have analyzed the neutral and polar lipid class composition of meronts and of metabolites derived from the metabolism of the fluorescent lipid analog, [2-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-dodecanoyl)-1-hexadecanoyl-*sn*-glycero-3-phosphocholine]. Phosphatidylcholine (PC) is the most abundant polar lipid class in both meront and prezoosporangia stages (49.8 and 75.7%, respectively) (43) and in oyster tissues (34%) (Chu, F.-L.E., and Soudant, P., unpublished data). An HPLC, equipped with photodiode array and fluorescent detectors, and a "diol" phase column, was used for lipid class analysis, in combination with TLC coupled with a flame-ionization detector (TLC/FID) and high-performance TLC (HPTLC).

EXPERIMENTAL PROCEDURES

Chemicals. (i) Lipid standards. Both fluorescent and nonlabeled lipid standards were used for identification of lipid classes. Fluorescent lipid analogs were obtained from Molecular Probe (Eugene, OR). They include: *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-pentanoyl) sphingosyl phosphocholine (Bodipy® FL C_5-sphingomyelin, FL SM), 2-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-dodecanoyl)-1-hexadecanoyl-*sn*-glycero-3-phosphocholine (Bodipy® FL C_{12}-HPC, FL PC), 2-(4,4-difluoro-5,7-diphenyl-4-bora-3a,4a-diaza-*s*-indacene-3-dodecanoyl)-1-hexadecanoyl-*sn*-glycero-3-phosphoethanolamine (β-Bodipy® FL 530/550 C_{12}-HPE, FL PE), 4,4-difluoro-5,7-diphenyl-4-bora-3a,4a-diaza-*s*-indacene-3-hexadecanoic acid (Bodipy® FL C_{16}, FL C16), cholesteryl 4,4-difluoro-5,7-diphenyl-4-bora-3a,4a-diaza-*s*-indacene-3-dodecanoate (cholesteryl Bodipy® FL C_{12}, FL CHE).

Nonlabeled lipid standards, cholesteryl ester (CHE), free fatty acids (FFA), triacylglycerol (TAG), fatty alcohol (FH), diacylglycerol (DAG), monoacylglycerol (MAG), cholesterol (CHO), ceramide (CER), cardiolipin (CL), phosphatidylglycerol (PG), phosphatidylinositol (PI), phosphatidylserine (PS), phosphatidylethanolamine (PE), phosphatidylcholine (PC), lysophosphatidylcholine (LPC), and sphingomyelin (SM) were obtained from Sigma (St. Louis, MO). Ninhydrin was obtained from ICN Pharmaceutical (Cleveland, OH).

(ii) Solvents. Hexane, isopropanol, water, methyl acetate, chloroform, methanol, and diethyl ether were HPLC grade (Burdick and Jackson, Muskegon, MI). Carbon disulfide was ultra resi-analyzed quality (J.T. Baker, Phillipsburg, NJ). The 10% (w/w) boron trifluoride in methanol (BF_3) was obtained from Supelco (Bellefonte, PA).

Incubation with fluorescent lipid analogs and lipid extraction. Perkinsus marinus meronts were cultured in a modified Dulbecco's modified Eagle medium/Ham's F-12 medium according to Gauthier and Vasta (7) for 7 d. The lipids in the medium were derived from the 5% (vol/vol) bovine fetal serum added to the medium. Lipid analysis conducted on this medium revealed a concentration of 58.9 ± 6.0 μg lipid/mL of medium, containing 46.2 μg steryl esters (SE) and 13.9 μg phospholipids. Meront cells were harvested at 7 d postinoculation, washed, and resuspended in 0.2 μm-filtered York River Water (YRW) at a concentration of 20×10^6 cells mL^{-1}. Ten microliters of fluorescent-labeled (FL) PC dissolved in dimethylsulfoxylate at 200 μM were added to 10 mL of meront suspension and incubated at 28°C for 48 h. The optimal concentration in the medium was determined empirically. Meronts were sampled, washed three times with YRW to removed free (nonincorporated) lipid analogs, freeze-dried, and stored at –20°C for later lipid analysis after incubation with FL PC for 3, 6, 12, 24, and 48 h.

Total lipid extraction. Total lipids were extracted from FL PC-incubated and nonincubated 1-wk-old meront cells with chloroform/methanol/water mixture according to the procedure described by Bligh and Dyer (44). To prevent fading of fluorescence, all extraction steps for FL PC-incubated meronts were performed protected from light.

Fatty acid analysis. Analysis of fatty acid methyl esters (FAME) was conducted on all lipid samples to assess the biomass of meront cell used for FL PC incubation. Briefly, FL and nonlabeled lipids were transesterified with 10% (w/w) BF_3 in methanol for 10 min at 100°C (45). After cooling, the FAME were extracted with carbon disulfide (46). The organic phase was evaporated, and redissolved in hexane. Separation of FAME was carried out on a gas–liquid chromatograph

(Varian 3300) equipped with a flame-ionization detector, using a DB Wax capillary column (25 m × 0.32 mm i.d.; 0.2 μm film thickness). The column was temperature programmed from 60 to 150°C at 30°C min $^{-1}$ and 150 to 220°C at 2°C min^{-1}, injector and detector temperatures were 230 and 250°C, respectively; the flow rates of compressed air and hydrogen were 300 and 30 mL min^{-1}, respectively. Helium was used as the carrier gas (1.5 mL min^{-1}). Identification of FAME was based on the comparison of retention times with those of authentic standards.

Analysis of FL and nonlabeled lipids. (i) Analysis of lipid classes by HPLC and TLC/FID. Separation of lipid standard mixtures (FL and nonlabeled) and lipids extracted from FL PC-incubated and nonincubated *P. marinus* was carried out using a Waters HPLC system (equipped with a 717 plus autosampler, 600E multisolvent delivery system, 996 photodiode array detector, and 474 scanning fluorescence detector; Milford, MA), a Lichrosorb diol column (5 μm; 250 × 4.6 mm i.d.) (Phenomenex, Torrance, CA) and two successive solvent gradient systems. Polar lipids and FFA were separated at 30°C with a ternary gradient system: 4 min of solvent A (hexane/isopropanol, 90:10, vol/vol), 6 min of a linear gradient from solvent A to solvent B (hexane/isopropanol/water, 46:52:2, by vol), 5 min of solvent B, 15 min of a linear gradient from solvent B to solvent C (hexane/isopropanol/water, 42:52:8, by vol), and 20 min of solvent C. The column was then reactivated with solvent A for 25 min. When analysis was conducted on *P. marinus* lipid extracts, the solvent front containing all neutral lipids except FFA was collected for later separation prior to reaching the detectors, using a Rheodyne® valve (Rohmert Park, CA).

Neutral lipids were separated at 30°C with a binary gradient system: 20 min of solvent A (hexane/isopropanol, 99.7:0.3, vol/vol), 10 min of a linear gradient from solvent A to solvent B (hexane/isopropanol, 90:10, vol/vol), 30 min of solvent B. The column was reactivated with 100% hexane for 25 min.

Because of the unavailability of a light-scattering detector for lipid class quantification, nonfluorescent lipids were analyzed with HPLC using the photodiode array detector at 203 nm, in combination with TLC/FID. At a wavelength of 203 nm the absorption of fatty acids with double bonds present in lipids was maximal (20). However, the use of a UV detector has disadvantages: (i) the baseline varies with eluting solvent mixtures, and (ii) it is ineffective to quantify the lipid classes. Lipid class contents of non-FL PC-incubated *P. marinus* were thus further analyzed and quantified with TLC/FID using an Iatroscan TH-10, MK-III analyzer (Iatron Laboratories, Tokyo, Japan) (47). Briefly, after activation for 30 min at 110°C, silica gel rods were spotted, using a Hamilton syringe, with lipid samples (1–10 μL/sample). Silica gel rods were then developed using a solvent mixture containing hexane/diethyl ether/formic acid (85:15:0.04, by vol). Following development, silica gel rods were analyzed in an Iatroscan analyzer. Operating conditions were 2000 mL min^{-1} air flow, 0.73 kg cm^{-3} hydrogen pressure, and a scan speed of 3.1 mm/s. Lipid classes were identified by comparison with the co-chromatographed lipid standards. Lipid standards, CHE, FFA, TAG, DAG, MAG, CHO, FH, and PC were obtained from Sigma (St. Louis, MO). Peak area integrations were performed by computer analysis (T DataScan; RSS Inc., Bemis, TN). Standard curves were constructed for each lipid class standard (1, 2, 3, 5, and 10 μg) to determine response factors of the detector. The quantity of lipid classes was determined by comparison with an internal standard. Results are expressed as percentage of total lipids.

Fluorescent lipids were detected and quantified with the fluorescence detector (excitation, 350 nm; emission, 510 nm). The responses of the fluorescence detector to various fluorescent lipid analogs were tested. The excitation at 350 nm was used since this wavelength gave the best linear response in amounts from 0.5 pmol to 0.5 nmol for all the tested components in our study. A "Microgravimetric" correlation between μmol of fluorescent lipid analogs and fluorescent peak areas was determined, based on information provided by the supplier. Peak identification was accomplished by the comparison of retention times with FL and nonlabeled lipid standards. Incorporated FL PC and its metabolite were expressed as nmol of fluorescent lipid mg^{-1} of meront fatty acids and as a percentage of the total fluorescent lipids. The nmol of fluorescent lipid mg^{-1} of meront fatty acids were calculated by first converting the quantity of the detected fluorescent lipid to nmol using calibration curves (area vs. mass) and then dividing by the amount of total lipid (mg) present in the lipid samples.

(ii) Analysis of lipid classes by HPTLC. To further confirm the identification, components eluted from the HPLC were collected and reanalyzed by HPTLC according to Olsen and Henderson (48). Briefly, after activation for 30 min at 110°C, the plates (HPK silica gel 60, 10 × 10 cm, Whatman Laboratory Division, Clinfton, NJ) were spotted, using a Hamilton syringe, with lipid class samples collected from HPLC and analyzed in parallel with mixed lipid standards containing various lipid classes employing two solvent mixtures (polar and neutral). The polar solvent mixture consisted of methyl acetate/isopropanol/chloroform/methanol/KCl 0.25% (25:25:25:10:9, by vol) and separated the polar lipids into PI/PS, PE, PC, and SM. The neutral solvent mixture contained hexane/diethyl ether/formic acid (85:15:0.05, by vol), which separated neutral lipids into different classes (i.e., CHE/SE, MAG, TAG, and FFA). Following development, lipid classes were charred by heating the plate at 160°C for 6 min after dipping it in a cupric sulfate (3%, w/w) phosphoric acid (8%, vol/vol) solution. Free amino groups in phospholipids (e.g., PE and PS) were visualized by spraying with a solution containing 0.2% ninhydrin in butanol and incubated at 100°C for 2–3 min. Lipid classes were identified by comparison with co-chromatographed standards.

Additionally, each polar lipid component from HPLC was subjected to a mild alkaline transesterification as described by Christie (49) to test for the presence of sphingolipids which are unaffected by the procedure. The by-products were extracted with chloroform and reanalyzed in parallel with the initial polar lipid components by HPTLC using the polar sol-

vent mixture described above.

To resolve PI from PS, polar lipids were redeveloped using a solvent mixture of chloroform/methanol/acid acetic/water (25:15:4:2, by vol; 38). In order to verify the identification, two-dimensional development was also utilized for polar lipid separation using a chloroform/methanol/14 N ammonium hydroxide/water (65:30:2:2, by vol) mixture and then a mixture of chloroform/methanol/water (50:20:2, by vol).

RESULTS AND DISCUSSION

Total fatty acid contents and meront cell number. Total fatty acid contents in meront cells and cell number did not appear to change during the 48 h FL PC incubation period. These observations were expected since the FL PC incubation was conducted in nutrient-limited water (YRW). Also the fluorescent lipid analog did not appear to cause death of meronts within 48 h.

Analysis of P. marinus *lipid classes by HPLC.* The HPLC system employed in the present study separated various polar and neutral lipid standards. The elution order of polar lipid and FFA standards was: FFA, CER (peak is not shown), PE, CL, PC, SM, PI/PS, and LPC (Fig. 1A). All of these lipids eluted within 40 min. PS and PI coeluted. Inclusion of acetic acid in the mobile phase was reported to enhance separation of these two components (37). To avoid the potential degradation of Bodipy fluorescent structure by acid, acetic acid was excluded from the solvent mixture in our study. Additionally, based on the HPTLC analysis of *P. marinus* lipid classes, PI was barely detectable. The elution of neutral lipid standards was completed in 45 min and in the order of CHE, TAG, FH, DAG, CHO, MAG, and FFA (Fig. 1B).

Five polar lipids were isolated from *P. marinus* total lipid extracts, i.e. PC, PE, CL, SM, and PS (Fig. 2A). As in most parasitic protozoans, PC and PE are the two major lipid classes (9,50–52). Quantitative analysis using TLC-FID revealed that PC, PE, CL, PS/PI, and SM accounted for, respectively, 21.0,

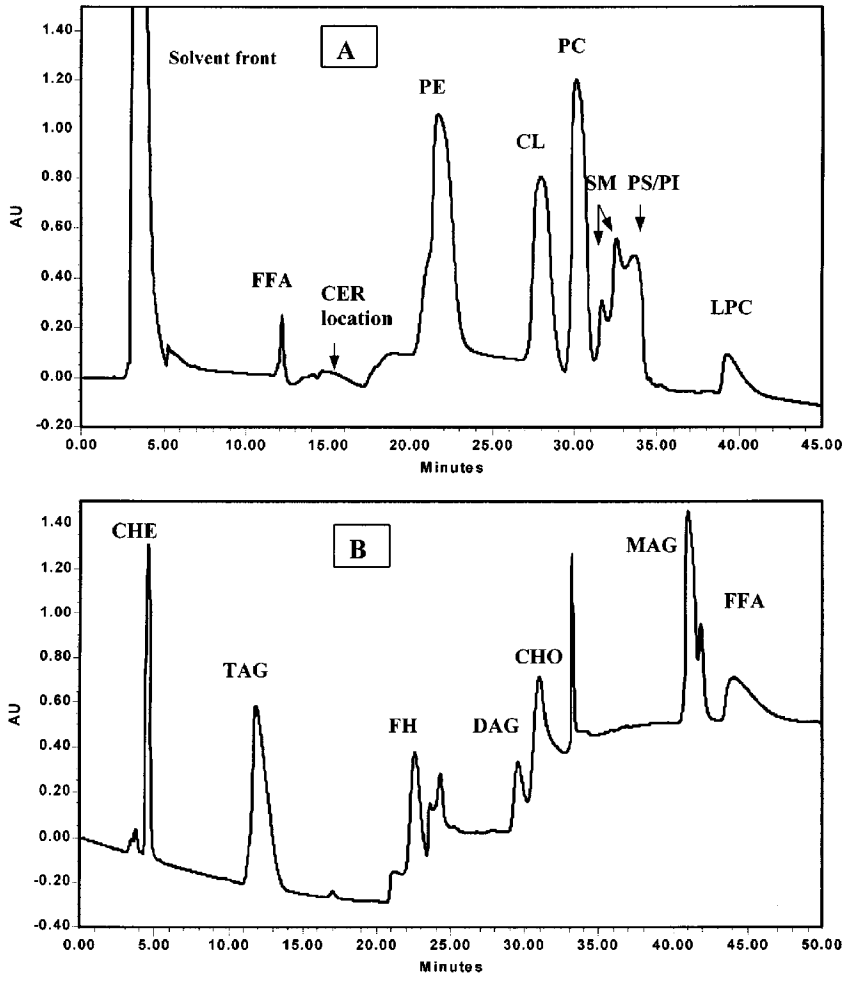

FIG. 1. High-performance liquid chromatography (HPLC) of standard lipid classes detected by ultraviolet (UV) spectrophotometry. (A) Polar lipids; (B) neutral lipids. Abbreviations: CER, ceramide; PE, phosphatidylethanolamine; CL, cardiolipin; PC, phosphatidylcholine; SM, sphingomyelin; Pl, phosphatidylinositol; PS, phosphatidylserine; LPC, lysophosphatidylcholine; CHE, cholesteryl ester; TAG, triacylglycerol; FH, fatty alcohol; DAG, diacylglycerol; CHO, cholesterol; MAG, monoacylglycerol; FFA, free fatty acid.

10.7, 4.0, 4.3, and 2.3% of the total lipids in 7-d-old meronts/merozoites (Table 1). Unlike most of the other apicomplexan species, *P. marinus* contains significant concentration of CL. CL usually locates in mitochondria, the site where it is synthesized (20,53). Numerous cytoplasmic mitochondria were noted in *P. marinus* meronts/merozoites (4,5). CL was not detected in lipids of free-living protozoans such as *Paramecium* sp., *Tetrahymena* sp., and *Entodinium* sp., and parasitic protozoans such as *Plasmodium* sp., *Toxoplasma* sp., *Giardia* sp., and *Trypanosoma* sp. (52). However, a small amount of CL (0.9% of the total complex lipids) was detected in cells of an apicomplexan species, *Crytosporidium parvum* (54). About 4% CL was also found in the polar lipids of *Leshmania tarentolae* (51). Its biosynthetic precursor, PG, in the CDP-DAG pathway (10), was also found at levels up to 10.4% in the polar lipids of trophozoites of a primitive protozoan, *G. lamblia* (55).

PS and SM coeluted into two peaks. Subsequent HPTLC analysis of these two peaks confirmed the presence of two PS and two SM isomers. The existence of these isomers in *P. marinus* was also confirmed using two-dimensional TLC. The two PS isomers were ninhyndrin positive, and the two SM isomers were unaffected by mild alkaline transesterification. Detection of two SM isomers has been reported previously (20,24–26,37). SM was reported in the protozoan parasites, *Plasmodium* sp. (9,10) and *C. parvum* (54). PS has been detected in most of the investigated protozoan species (52,56). When the two unknown components (UK1 and UK2) eluting from the HPLC column were analyzed with HPTLC, no color was developed, after dipping the plate in the cupric sulfate/phosphoric acid solution and charring at 160°C for 6 min. A group of peaks appeared near the elution time of FFA. However, when they were collected and analyzed with HPTLC, no FFA were detected. Also, no FFA was found when *P. marinus* lipid classes were analyzed by TLC-FID (Table 1).

Four neutral lipids, TAG, SE, CHO and FH, were identified in *P. marinus* lipids. (Fig. 2B). TAG was the dominant neutral lipid. This is in agreement with the results of lipid class analysis using a TLC-FID analyzer (Table 1). TAG, SE, and cholesterol (CHO) accounted for 48.7, 7.8 and 1.2% of the total lipids, respectively, in 7-d-old meront/merozoites. CHO did not appear to be an important membrane constituent of *P. marinus*, since only about 1% of CHO was detected in

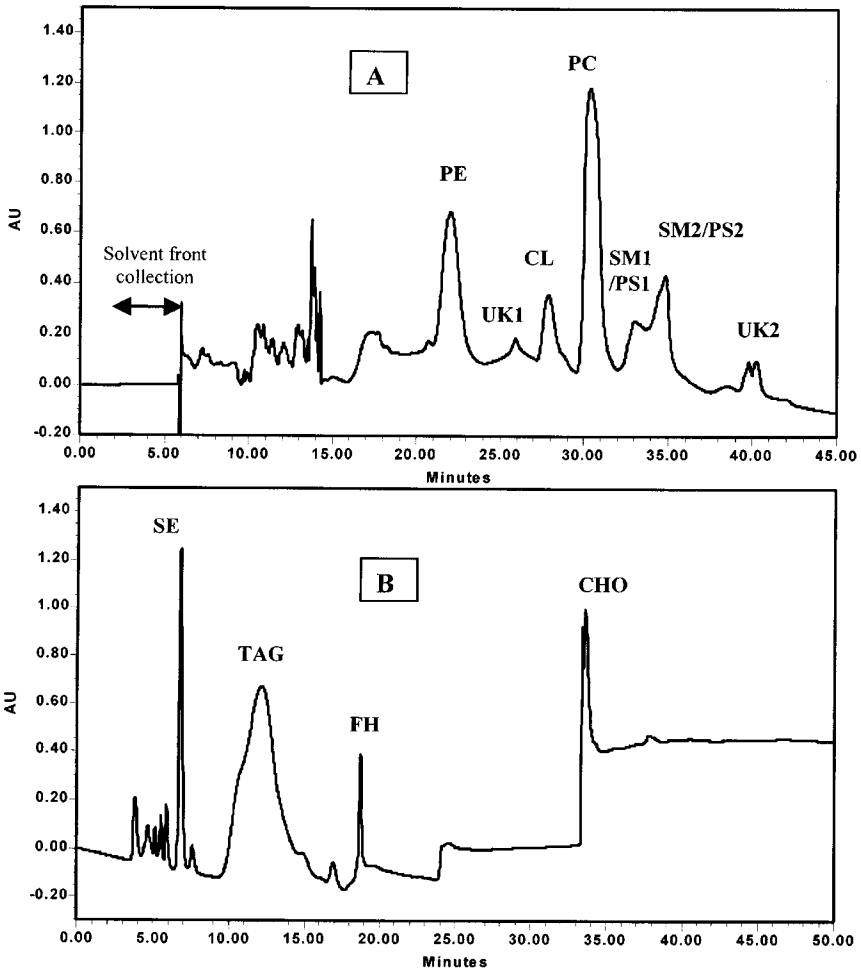

FIG. 2. HPLC chromatogram of nonfluorescent lipids from *in vitro* culture *P. marinus* cells (meronts/merozoites) detected by UV spectrophotometry. (A) Polar lipids (UK1 = unknown 1; UK2 = unknown 2); (B) neutral lipids. SE, steryl esters; for other abbreviations see Figure 1.

TABLE 1
Lipid Class Composition of 7-d-old Pellets of *in vitro Perkinsus marinus* (meronts/merozoites) Cultures[a]

Percentage of total lipids	Mean	SD
SE	7.8	0.5
TAG	48.7	1.9
FFA	ND	ND
CHO	1.2	0.1
CL	4.0	0.4
PE	10.7	0.9
PS and PI	4.3	0.5
PC	21.0	0.9
SM	2.3	1.2
µg Total lipids/10^6 cells	2.9	0.2

[a]Compositions determined by thin-layer chromatography coupled with flame-ionization detection. Results are expressed as percentage of the total lipids ($n = 3$ for mean and SD).
Abbreviations: SE, steryl ester; TAG, triacylglycerol, FFA, free fatty acids; CHO, cholesterol; PE, phosphatidylethanolamine; CL, cardiolipin; PC, phosphatidylcholine; PI, phosphatidylinositol; PS, phosphatidylserine; SM, sphingomyelin; ND, not detected.

P. marinus by TLC-FID analysis. The membrane of *Plasmodium* spp. is also deficient in CHO (9,10). Therefore, in common with most eukaryotes, TAG is the major storage lipid in *P. marinus*. Parasitic protozoans store lipids either as TAG (e.g., *Plasmodium* spp.) (57,58), as SE (e.g., *G. lamblia*) (19), or as TAG and SE (Trypanosomatidae) (51,56). In the host oyster tissues, TAG (51–67% of the total neutral lipids) is the dominant lipid class and polar (structural) lipids are predominated by PC (34%) and PE (25%) (Chu, F.-L.E., and Soudant, P., unpublished data). Sterols account for only 12% of the total neutral lipids.

Incorporation and metabolism of FL PC by P. marinus *meronts.* The UV (photodiode array) detector was ineffective to detect FL PC and its metabolites. A higher retention time was noted in fluorescent lipids compared to their nonlabeled counterparts. The increased molecular weights and polarity due to the presence of fluorescent radical in the labeled lipid may be the causes of increased retention time.

Results of HPLC analysis of FL lipids extracted from meronts/merozoites (Figs. 3A, 3B) demonstrated that *P. marinus* incorporated and modified FL PC. The detected FL PE, FL TAG, FL CL, FL MAG, FL FFA, and FL DAG are believed to be the products of FL PC metabolism and/or results of reacylation of the fluorescent acyl chain hydrolyzed off FL PC. No fluorescence was incorporated in SE. This is similar to the results obtained by Kasurinen (59) studying Bodipy 12 fatty acid incorporation by BHK (baby hamster kidney) cells.

The presence of FL DAG suggests the existence of the glycerol phosphate pathway, a common pathway for *de novo* phospholipid and TAG synthesis (53), in *P. marinus* meronts. PC and PE are synthesized *via* cytidine diphospho (CDP)-base pathway using a common precursor DAG and their respective CDP-bases. The CDP-base pathway is considered to be the most active one in synthesis of phospholipids in eukaryotes under normal conditions. The FL PE detected in meronts previously incubated with FL PC is likely synthesized *via* this pathway, using FL DAG originated from FL PC. Conversion of PC to PE has also been reported in *Plasmodium* spp. (10). However, transfer of the fluorescent acyl chain from FL PC to non-FL PE may have also taken place *via* deacylation–reacylation reactions or *de novo* synthesis of phosphatidic acid. This pathway involves the cleavage of the acyl chain by phospholipases. Our preliminary study has shown the presence of phospholipase A_2 in *P. marinus* meront. The parasite contained higher levels of this enzyme than its host hemocytes and plasma. Similarly, FL TAG was probably produced by using either FL DAG released from FL PC through the glycerol phosphate pathway, *via* reacylation of the fluorescent acyl chain, or both.

The finding of CL as one of the metabolic byproducts of FL PC implies the presence of the polyglycerophospholipid pathway in *P. marinus* mitochondria (53). The removal of the FL acyl chain from FL PC and recycling of the acyl radical for CDP-DAG synthesis is a prerequisite for this pathway. As mentioned earlier, cleavage of acyl radicals by phospholipase A_2 present in the parasite probably occurred. The intestinal protozoan parasite, *G. lamblia*, was reported to be capable of incorporating exogenous fatty acids into PG, probably *via* the CDP-DAG pathway (55). Unlike *P. marinus*, the polyglycerophospholipid pathway in *G. lamblia* appeared to end after PG synthesis.

The incorporation and interconversion of FL PC in *P. marinus* increased with time and, up to 8.5 nmol mg^{-1} FA at 48 h (Table 2). The highest uptake of FL PC from the medium was 28.9% at 48 h of postincubation. Initially (3–6 h), most of the incorporated FL PC remained as FL PC. Significant amounts of FL PE (12%), FL CL (8%), and FL TAG (18.4%) appeared after 12 h. After 48 h of incubation, a high proportion (43%) of the incorporated FL PC resided in FL TAG. These results suggest that *P. marinus* actively acquires FL PC from the nutrient-limited incubation medium (YRW) not only for membrane synthesis but also for energy reserve. Similarly, in a separate study we found that, in incubating meronts with FL palmitic acid (16:0), most of the incorporated FL 16:0 (86.9%) deposited in TAG (43).

In summary, the HPLC system employed in the present study adequately separated most polar and neutral lipid classes. An exception was that PS coeluted with PI (Fig. 1A) or SM (Fig. 2A). The oyster protozoan parasite, *P. marinus*, contains five polar lipids (PC, PE, CL, SM, and PS), with PC and PE as the two dominant lipid classes. SM and PS were characterized by the presence of two isomers. Four neutral lipids (TAG, SE, CHO, and FH) were found, with TAG as the predominant neutral lipid class. *Perkinsus marinus* metabolized FL PC to six components (i.e., FFA, MAG, DAG, PE, TAG, and CL). Incorporation and interconversion of FL PC increased with time. After 48 h of incubation, almost half

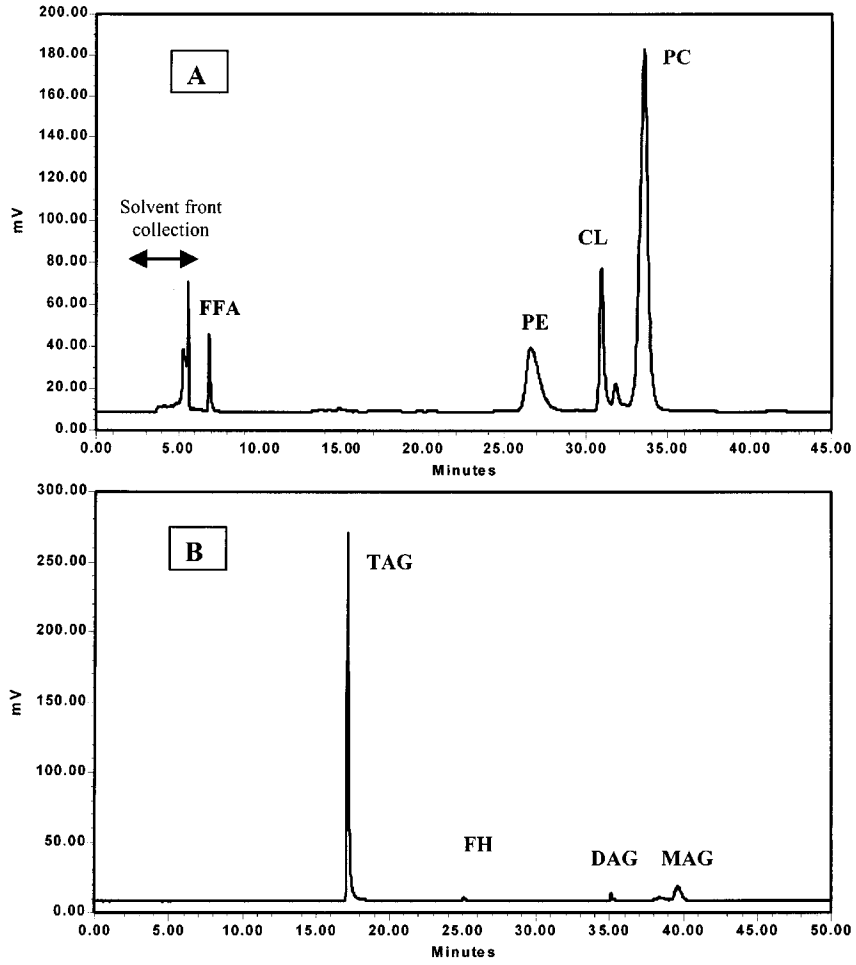

FIG. 3. HPLC separation of polar lipids + FFA and (B) neutral lipids, from *in vitro* cultures of *P. marinus* cells (meronts/merozoites) incubated 48 h with fluorescent-labeled PC and detected by a fluorescence detector. For abbreviations see Figure 1.

Properties of a Fluorescent Bezafibrate Derivative (DNS-X). A New Tool to Study Peroxisome Proliferation and Fatty Acid β-Oxidation

Jean-Pierre Berlot, Thomas Lutz, Mustapha Cherkaoui Malki, Val rie Nicolas-Frances, Brigitte Jannin, and Norbert Latruffe*

Université de Bourgogne, Laboratorie de Biologie Moléculaire et Cellulaire, Faculté des Sciences Gabriel, 21000 Dijon, France

ABSTRACT: The first peroxisome proliferator-activated receptor (PPAR) was cloned in 1990 by Issemann and Green. Many studies have reported the importance of this receptor in the control of gene expression of enzymes involved in lipid metabolic pathways including mitochondrial and peroxisomal fatty acid β-oxidation, lipoprotein structure [apolipoprotein (apo) A2, apo CIII], and fatty acid synthase. By using radiolabeled molecules, it was shown that peroxisome proliferators bind and activate PPAR. As an alternative method, we developed a fluorescent dansyl (1-dimethylaminonaphthalene-5-sulfonyl) derivative peroxisome proliferator from bezafibrate (DNS-X), a hypolipidemic agent that exhibits an *in vitro* peroxisome proliferative activity on rat Fao-hepatic derived cultured cells. However, until now, the effect of this new compound on the liver of animals and subcellular localization was unknown. In addition to *in vivo* rat studies, we present a more efficient large-scale technique of DNS-X purification. Treating rats (DNS-X in the diet at 0.3% w/w) for 6 d leads to a hepatomegaly and a marked increase in liver peroxisomal palmitoyl-CoA oxidase activity. We also developed a method to localize and quantify DNS-X in tissues or cell compartment organelles. The primarily cytosolic distribution of DNS-X was confirmed by direct visualization using fluorescence microscopy of cultured Fao cells. Finally, transfection assay demonstrated that DNS-X enhanced the PPARα activity as well as other peroxisome proliferators do.

Paper no. L8377 in *Lipids 35*, 1397–1404 (December 2000).

Despite numerous works on the process of peroxisome proliferation as triggered by hypolipidemic agents of the fibrate family, the mechanism is not fully understood. It is now considered that induction of peroxisomal fatty acid β-oxidation enzymes by these agents involves the peroxisome proliferator-activated receptor alpha (PPARα), a member of the nuclear hormone receptor superfamily (1). Recently, the evidence of the direct binding of peroxisome proliferators (PP) to PPARα was demonstrated (2). Another possibility of the gene transcription mechanism should be the signal transduction pathway as suggested by overphosphorylation of several cellular proteins in the presence of PP (3,4). The identification of molecular complexes with an affinity for PP and of their subcellular localization will help to clarify the peroxisome proliferative process.

To elucidate these questions, we synthesized a dansylated fibrate (DNS-X: 2-[4-(*N*-dansyl-2-aminoethyl) phenoxy]-2-methylpropanoic acid) derived from bezafibrate (2-{4-[2-(4-chlorobenzamido)ethyl]phenoxy}-2-methylpropanoic acid), a hypolipidemic agent. Such fluorescent probes offer a sensitivity threshold as good as radioactively labeled compounds (5). Moreover, DNS-X was shown to be an *in vitro* PP in rat hepatic-derived Fao cells (5). This fluorescent fibrate has properties similar to those of other fibrates and is able to induce palmitoyl-CoA oxidase activity, a peroxisome proliferation marker (6). However, the effect of *in vivo* treatment of animals and the subcellular localization of this compound needs to be established.

To obtain a more efficient procedure and a better-characterized final product, in the present work we improved the DNS-X synthesis method. We also developed a high-performance liquid chromatography (HPLC) method to estimate the DNS-X purity that could be used for analytical studies as well.

To study the ability of DNS-X to be an *in vivo* PP, we treated rats with different amounts of dietary DNS-X (see the Material and Methods section). After the treatment, the peroxisomal fractions of the rat livers were isolated, the palmitoyl-CoA oxidase activity was determined in these fractions, and the *in vivo* peroxisome proliferative effect of DNS-X was observed.

Our goal was to identify the subcellular distribution of DNS-X and its concentration in blood serum and coagulate. To this end, we developed a quick and simple method to estimate the DNS-X content in biological samples. This method takes advantage of the strong fluorescence of this compound. Moreover, direct visualization of the DNS-X subcellular distribution was accomplished using fluorescence microscopy of cultured Fao cells.

Finally we tested the properties of DNS-X as a PPAR-activating molecule in transfection assays using a peroxisome pro-

liferator response element (PPRE)-driven luciferase reporter gene and a plasmid coding for PPARα.

MATERIALS AND METHODS

Chemicals. Bezafibrate was obtained from Boehringer (Ingelheim, Germany). Dansyl chloride and Nycodenz are products of Sigma (St. Louis, MO).

DNS-X chemical synthesis; new purification step. The DNS-X synthesis was carried out according to the method previously reported (5). That is, the amide group of bezafibrate was hydrolyzed in a mixture of ethanolic/aqueous 10 M KOH solution (70:30) for 5 h at 100°C. The mixture was then neutralized with 12.5 M HCl and precipitates were separated by filtration. To obtain the resulting amine in a high purity, cation exchange chromatography of the filtrate on Dowex 50 W-XS (Sigma) was used to separate it from other residues.

Then, the amine was conjugated with 5-(dimethylamino)-naphthalene-1-sulfonyl chloride (dansyl chloride, or DNS-Cl), in a solution of water/acetone (1:1) (7). In contrast to the published method (5) (in which the instructions were to dry this solution completely after the reaction), only acetone was evaporated. DNS-X was extracted three times from the remaining aqueous phase (adjusted to pH 4) with chloroform; the combined organic phases were dried over Na_2SO_4 and evaporated. The resulting product was stored at −20°C.

The amine was obtained after cationic exchange chromatography with a yield of about 40%. DNS-X was recovered after chloroform extraction with a yield of about 70%. In its high-purity form it has a translucent luminous appearance and a yellow-greenish color.

Purity analysis of the final product. The amine, DNS-X, and the residues were analyzed by thin-layer chromatography (TLC) as previously described (1) using Merck 60F-254 (20 × 20 cm; Darmstadt, Germany) plates. The developing solvents used were butanol/acetic acid/water (80:20:20), to separate compounds after cation exchange chromatography, and chloroform/ethanol/acetic acid (84:9:7), to analyze the final product.

To estimate the DNS-X purity by reversed-phase (RP)-HPLC we used the following materials and conditions: IsoChrom LC pump, Spectra-Physics (St. Albans, United Kingdom); Spectra 100 detector, Spectra-Physics; Shimadzu C-R5A Chromatopac integrator (Kyoto, Japan); Waters μBondapak C_{18} 125 Å 10 μm Guard-Pak Insert (Milford, MA); Waters μBondapak C_{18} 125 Å 10 mm, 3.9 × 300 mm column; acetonitrile/0.01 M acetate buffer, pH 4 (60:40) as mobile phase, flow rate of 1.2 mL/min. Detection was monitored at a 219 nm wavelength. Chromatography was carried out at room temperature.

Extraction of DNS-X with chloroform from the synthesis medium led to a pure final product as shown by TLC and HPLC analysis (Figs. 1 and 2). The spots of 5-(dimethylamino)naphthalene-1-sulfonic acid (DNS-OH) appeared on the TLC plate at the lowest R_f (about 0.09) with a blue fluorescence. This compound is formed by DNS-X hydrolysis and is also seen as an impurity in the DNS-Cl standard.

DNS-Cl appeared at highest R_f (about 0.97) with a yellow fluorescence, whereas DNS-X appeared at about 0.86. DNS-X showed the strongest fluorescence and was also yellow. TLC showed that the newly introduced purification step separated DNS-OH as well as DNS-Cl residues from DNS-X, since their corresponding spots on TLC disappeared after this procedure. Therefore, DNS-Cl and DNS-OH remain in the polar aqueous phase during the purification whereas DNS-X is found in the organic fraction (chloroform).

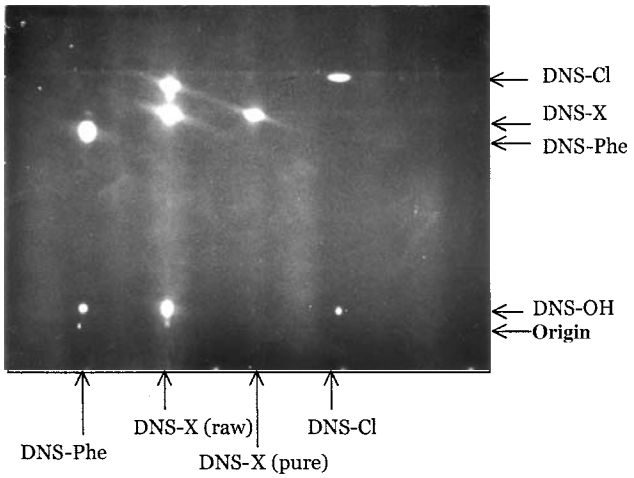

FIG. 1. Thin-layer chromatography of purifed (pure) and nonpurified (raw) DNS-X. The spots were detected under ultraviolet light at 365 nm. About 30 μg DNS-X was applied; Phe-DNS (dansyl phenylalanine) and DNS-Cl (dansyl chloride) were used as references. For further experimental conditions, see the Materials and Methods section. One can see that, after the purification, the spots of DNS-OH (dansyl hydroxyl) and DNS-Cl residues disappeared. DNS-Cl, 5-(dimethylamino)naphthalene-1-sulfonyl chloride [= dansyl chloride]; DNS-X, 2-[4-(*N*-dansyl-2-aminoethyl)phenoxy]-2-methylpropanoic acid.

The longer retention time of the ethyl ester DNS-X derivative during RP-HPLC analysis is in agreement with its higher lipophilic properties as compared to the DNS-X. The ethyl ester DNS-X derivative was probably formed during the neutralization of the ethanolic solution following hydrolysis of bezafibrate by using concentrated HCl. Indeed, this was the only step during synthesis in which ethanol was used.

The chromatogram also shows a small DNS-OH peak at 9.67 min, but it does not show either amine (no retention time) or DNS-Cl residues (generally at about 13 min). DNS-X was obtained with a purity greater than 95%. Of that 95%, 15% was present as DNS-X ethyl ester; that is, DNS-X was actually present in two forms, unesterified and esterified. This latter compound cannot be considered as contaminant since cellular esterases are known to convert the ester form into the acid form, as happens with clofibrate and fenofibrate, which are commercially available only in their ethylester forms (8).

Identification of the compounds. To assign HPLC signals to the corresponding compounds, preparative RP-HPLC and ^1H nuclear magnetic resonance (NMR) spectroscopy were used. The preparative RP-HPLC was carried out with a Waters μBondapak C_{18} 125 Å 10 μm, on a 7.8 × 300 mm column, by using acetonitrile/0.01 M acetate buffer at pH 4 (60:40) as the

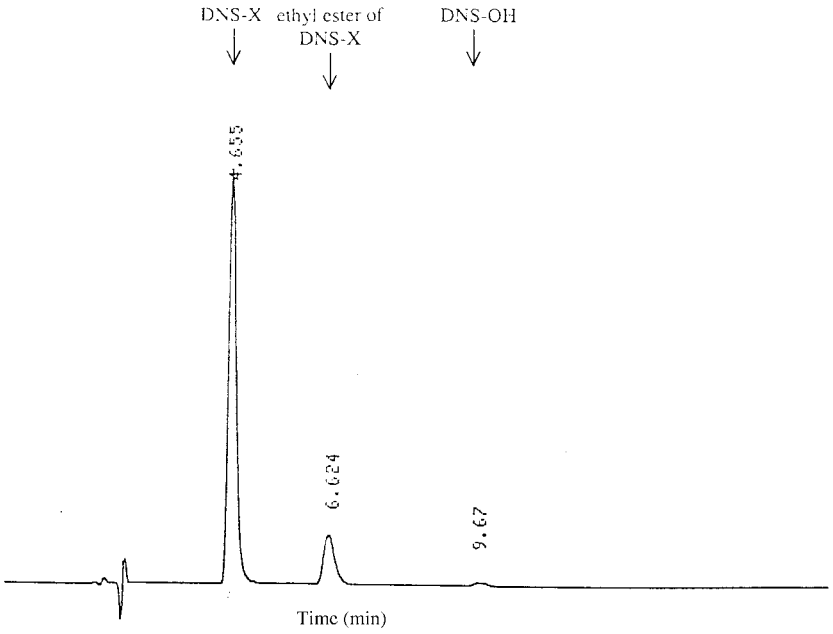

FIG. 2. Reversed-phase high-performance liquid chromatography (HPLC) of purified DNS-X. The injected quantity was about 10 nmol DNS-X per run; the compounds were detected at an absorbance wavelength of 219 nm. The main peak at 4.66 min corresponds to DNS-X, whereas the peak at 6.62 min represents the ethyl ester of DNS-X (see text and Scheme 1). The ethyl ester form of DNS-X is obtained as a by-product during synthesis. The chromatogram also shows a small peak of DNS-OH (dansyl hydroxyl) at 9.67 min, but none for either amine (which generally would elute, without retention, at about 2.5 min) or DNS-Cl residues (generally would elute at about 13 min). Thus, DNS-X was obtained with a purity of >95%; of that 95%, 15% was present as DNS-X ethyl ester. For further experimental conditions, see the Materials and Methods section. For abbreviations see Figure 1.

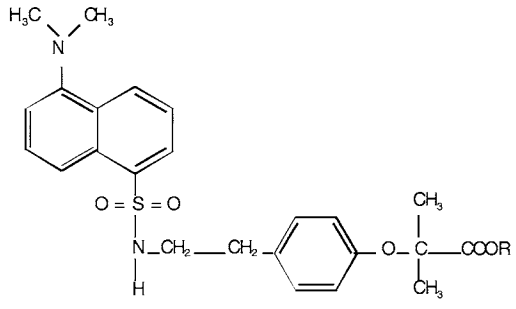
mobile phase at a flow rate of 3.8 mL/min. The other materials and conditions were similar to the previous analytical method (5). The RP-HPLC fractions were collected and evaporated. RP-HPLC runs were repeated in the same way to obtain at least 3 mg of each compound. ^{1}H NMR spectroscopy of the compounds was performed in $CDCl_3$ using a Bruker AC 200 machine (Karlsruhe, Germany).

Analysis of the final product by RP-HPLC (using a 3.9 × 300 mm column and a flow rate of 1.2 mL/min) showed that it yielded a main peak at 4.66 min and a small one at 6.62 min (Fig. 2). Such a resolution was not obtained by TLC analysis. By using preparative HPLC, followed by 200 MHz ^{1}H NMR analysis, the two compounds belonging to the corresponding HPLC fractions were identified, respectively, as DNS-X and its ethyl ester form (Scheme 1). In the ethyl ester fraction a triplet at $\delta = 1.19$ (t, $^3J_{HH} = 6.9$ Hz, 3 H, -CH_3) and a quadruplet at $\delta = 3.47$ (q, $^3J_{HH} = 6.9$ Hz, 2 H, -CH_2-) were seen during NMR analysis. These signals correspond to the ethyl group of the ester, and they were not present in the fraction of DNS-X. Other signals were similar to those reported before (5).

Treatment of rats. Experiments carried out with animals were in conformity with French bioethics law; our animal care facilities are approved by the Veterinary Service. Two experiments were carried out with rats (5 wk old, male Wistar rats, 120–160 g from IFFA Credo, L'Arbresle, France) having different DNS-X amounts in their diet. They were housed, three or four per cage, under conditions of controlled temperature (20 ± 2°C), humidity (30–40%), and 12 h light/12 h dark cycle. The diet was prepared by soaking the chow (standard laboratory rodent chow; UAR, Villemoisson/Orge, France) in an acetone solution of the relevant compounds (DNS-X or bezafibrate). The chow was dried at room temperature. During the treatment rats were fed exclusively with the prepared diet; drinking water was provided *ad libitum*.

In the first assay (assay 1) four rats were treated with 0.04% DNS-X (w/w) and three rats with 0.04% bezafibrate (w/w) over a 10-d period. Three nontreated rats served as controls. In the second experiment (assay 2) three rats were treated with 0.1



R = -H DNS-X
R = -CH_2CH_3 ethyl ester of DNS-X

SCHEME 1

and 0.3% DNS-X (w/w) for 6 d. As previously, three control rats were used. Before being sacrificed, the rats were starved overnight.

Subcellular fractionation. Rats were decapitated under ether anesthesia, and blood was collected and stored at +4°C. Then the livers were taken out, sliced, and cleaned in ice-cold isolation buffer [250 mM sucrose, 5 mM 3-(*N*-morpholino) propane sulfonic acid, 1 mM EDTA, 0.1% ethanol]. The livers were homogenized once in isolation buffer using a Potter-Elvejhem at 1,500 rpm. The homogenate was filtered through four layers of cheesecloth.

Fractionation of the liver tissue by differential centrifugation in isolation buffer was performed as described by de Duve *et al.* (9). Five fractions were isolated: nuclear fraction (N), mitochondrial fraction (M), light mitochondrial fraction (L), microsomal fraction (P), and soluble cytosolic fraction (S). Peroxisome fraction was isolated from the L fraction using 30% Nycodenz step gradient centrifugation as described by Ghosh and Hajra (10). The purity of each subcellular organelle fraction was checked as previously reported (11,12) using the following marker enzymes: cytochrome c oxidase, succinate dehydrogenase for mitochondria, catalase, α-hydroxy acid oxidase and D-amino acid oxidase for peroxisomes, lactate dehydrogenase for cytosol, cathepsin C and acid phosphatase for lysosomes, and NADPH-cytochrome c reductase for endoplasmic reticulum.

As far as possible all procedures were carried out on ice. Centrifugations were performed at 4°C. All subcellular fractions were frozen in liquid nitrogen and stored at −20°C.

Blood was separated into serum and coagulate. The coagulate was homogenized in a solution of 250 mM sucrose using an Ultra Turrax (Janke & Kunkel, Staufen, Germany) at 24,000 rpm. Both fractions were frozen and stored at −20°C.

Protein content and palmitoyl-CoA oxidase activity. Protein contents of the subcellular fractions, the serum, and the blood coagulate homogenates were determined using the method of Bradford (13).

The activities of the peroxisomal palmitoyl-CoA oxidase in the different subcellular fractions were measured by a fluorometric assay. This assay depends on H_2O_2 produced by the peroxisomal acyl-CoA oxidase, leading to a fluorescent dimer of homovanillic acid in the presence of peroxidase (6,14).

DNS-X analysis in biological samples. To show the DNS-X stability, TLC as well as spectrofluorometric assays was performed on extracts of cell liver homogenates. To estimate the DNS-X concentration in the samples the following procedure was applied for subcellular fractions, serum, or blood coagulate homogenate. To 100 µL of each sample, 900 µL acetone was added. This solution was shaken for about 5 s with a vortex and then centrifuged for 5 min at 13,000 × *g* to separate the denaturated proteins. Then the relative fluorescence of the clear supernatant was measured at 25°C using a spectrofluorimeter (Type SFM 25; Kontron Instruments, Hemile, Switzerland) and 500 µL cuvettes. The measurements were carried out at an excitation wavelength of 350 nm and an emission wavelength of 498 nm.

A calibration curve was obtained by applying the same procedure to corresponding samples from control rats. For instance, when mitochondrial fractions of treated rats were analyzed, an equal amount of mitochondrial fractions of control rats was used to obtain the calibration curve. To get the most accurate control values, mixtures of corresponding samples belonging to the three control rats were used in the ratio of 1:1:1. Thus, different volumes of DNS-X standard solutions (1,000, 500, or 100 µM DNS-X in ethanol) were added to each 100 µL of control sample.

Fluorescence microscopy. Fao cells (a rat hepatoma-derived cell line, given by Jean Dechartrette, INSERM, Hôpital Kremlin-Bicetre, Paris, France) cultured overnight (5) were washed three times with phosphate-buffered saline (PBS), then incubated for 15 min in a 0.025% DNS-X solution in PBS containing 1% vol/vol dimethylsulfoxide. Next, the cells were washed three times with PBS and fixed for 30 min with a 4% solution of paraformaldehyde in PBS. The cells were studied under a phase contrast using a Leica LB fluorescence microscope. A DAPI filter (λ excitation 340–380 nm) was used. The observed fluorescence was based on the DNS-X emission wavelength of 498 nm.

Statistics. All samples from the treated rats as well as control and calibration samples were analyzed at least three times. The mean values were taken for further calculations using Student's *t*-test.

Plasmids and transfection assays. pG.Luc BFE (-2952/2918) contains an oligonucleotide corresponding to the PPRE sequence of the bifunctional enzyme gene (8) upstream from the β-globin promoter of the luciferase expression vector pGluc. The pSG5m PPARα plasmid, a gift from Dr. S. Green (Zeneca, Macclesfield, United Kingdom), contains the mouse PPARα cDNA downstream from the SV40 promoter of pSG5.

HepG2 cells (a human hepatoblastoma cell line) were seeded in 24-well dishes at 2×10^5 cells/well in Dulbecco's modified Eagle's medium supplemented with 2 mM glutamine, 20 mM Hepes, 10% fetal calf serum, 125 µg/mL streptomycin, and 125 U/mL penicillin. After being cultured overnight, the cells were washed in serum-free medium (optiMEM; Life Technologies, Gibco BRL, Grand Island, NY) and transfected by mixing 400 ng of plasmid DNA purified on Qiagen (Studio City, CA) column [200 ng of pG.luc (-2952/-2918) containing the PPRE with or without 200 ng of pSG5m PPARα] with 2 µg of lipofectin (Gibco) in 300 µL of optiMEM which was applied to the cells. After 5 h, the transfection media were replaced by 1 mL of complete media containing, or not, Wy 14,643 (50 µM), DNS-X (50 µM), or bezafibrate (100 µM), where Wy 14,643 is 4-chloro-6-(2,3-xylidino)-2-pyrimidinylthio)acetic acid (Wyeth Laboratories, Philadelphia, PA). The media were changed after 24 h. After 48 h, the cells were washed twice with PBS and harvested in 100 µL of Reporter Lysis Buffer (Promega, Madison, WI), then centrifuged after three freeze-thaw cycles. The cleared cytosol extract (10 µL) was added to 100 µL of luciferase assay reagent (Promega) and the light emission measured for 10 s in a TLX1 luminometer (Dynatech Laboratories, McLean, VA). The luciferase values were normalized using the protein concentration values determined by Bradford (13).

RESULTS

Rat treatment. (i) Hepatosomatic index. The hepatosomatic indexes obtained after different treatments of rats show that there is only a weak increase in liver mass in rats treated with 0.04 or 0.1% DNS-X in their diet (Table I). The hepatosomatic index increased by factors of about 1.2 and 1.3, respectively, compared to the control. In contrast to this assay, rats treated either with 0.04% bezafibrate or 0.3% DNS-X showed a higher and comparable liver mass increase. The hepatosomatic indexes increased by factors of about 1.5 and 1.7, respectively. Thus, DNS-X shows a dose-dependent effect on rat liver, leading to a liver mass increase that is more marked the higher the given dose is.

Since fibrates are known to lead to both hyperplasia and hypertrophy, these data indicate that DNS-X properties are the same as those of other fibrates, although this effect is weaker than the bezafibrate effect.

(ii) Palmitoyl-CoA oxidase activity, a peroxisome marker. A strong increase in the palmitoyl-CoA oxidase activity was observed by treatment with 0.04% bezafibrate, whereas no increase was found in peroxisomes of rats treated with the same dose of DNS-X (Fig. 3A). The same results were obtained using homogenates (data not shown). The potency of DNS-X to induce palmitoyl-CoA oxidase appears weaker than that of bezafibrate. This tendency can be correlated with the small increase in hepatosomatic of rats after the treatment with DNS-X at 0.04%, compared to the one observed after bezafibrate treatment given at the same dosage.

In contrast to the assays with 0.04% DNS-X, the treatments with 0.1 and 0.3% DNS-X reveal a dose-dependent stimulation of the palmitoyl-CoA oxidase activity in the peroxisomal fraction (Fig. 3B). One can see a slight but significant increase in enzyme activity after treatment with 0.1% DNS-X in the diet. A significant increase in oxidase activity was also found in the homogenate (data not shown). Contrary to this weak effect, en zyme activity is strongly activated in peroxisomes (Fig. 3B) as well as in homogenate (data not shown) after the treatment with 0.3% DNS-X. Indeed, enzyme activity in peroxisomes increases by about 10- and in the homogenate by 12-fold (data not shown).

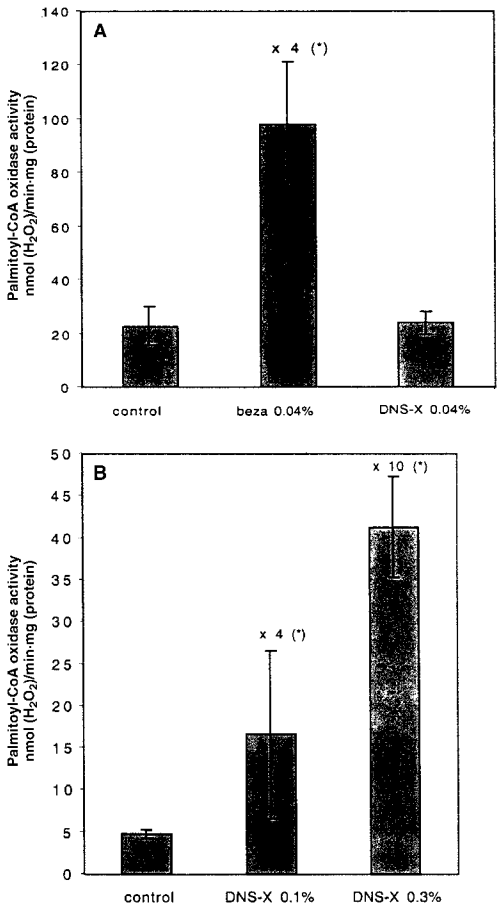


FIG. 3. Palmitoyl-CoA oxidase activity in peroxisomal fraction of rat liver. The histogram shows mean values from three or four independent treatments and error bars corresponding to the standard deviation. The factors (x ...) show an increase in enzyme activity compared to the control. (A) Over a 10-d period four rats were treated with 0.04% DNS-X (w/w) and three rats with 0.04% bezafibrate (w/w). (B) For the 6-d period there were two groups of three rats each treated with 0.1 and 0.3% DNS-X (w/w), respectively. Three nontreated control rats were used. The enzyme activity was measured by a fluorometric assay depending on oxidase-produced H_2O_2. Strong induction was obtained by bezafibrate treatment, whereas no induction was seen with DNS-X. For further experimental conditions, see the Materials and Methods section. (*) Statistically significant, $P < 0.01$. Beza, bezafibrate; for other abbreviations see Figure 1.

TABLE I
Hepatosomatic Index Obtained After Treatment of Rats with the Given Concentrations and Compounds[a]

	Hepatosomatic index (g of liver/100 g of body weight)	Factor compared to control
Control[b]	3.2 ± 0.1	—
Bezafibrate[b] 0.04%	5.0 ± 0.2 (*)	×1.5
DNS-X[b], 0.04%	3.9 ± 0.2 (*)	×1.2
DNS-X[c], 0.1%	4.4 ± 0.3 (*)	×1.3
DNS-X[a], 0.3%	5.4 ± 0.5 (*)	×1.7

[a]*Note*: Each mean value with corresponding standard deviation (±) was obtained from at least three independent assays. For further experimental conditions, see the Materials and Methods section.
[b]Indicates 10 d of treatment.
[c]Indicates 6 d of treatment. The data show only a weak liver hyperplasia in rats treated with 0.04% DNS X (40 mg of compound per 100 g of diet) and a strong and comparable liver hyperplasia in rats treated with 0.3 % DNS-X or 0.04% bezafibrate. Abbreviations: (*) Statistically significant $P < 0.01$; bezafibrate, 2-{4-[2-(chlorobenzamido)ethyl]phenoxy}-2-methylpropanoic acid; DNS-X, 2-[4-*N*-dansyl-2-aminoethyl)phenoxy]-2-methylpropanoic

Therefore, since palmitoyl-CoA oxidase activity is a marker of peroxisome proliferation (4), DNS-X can be considered as a new *in vivo* PP in rats, showing properties similar to other members of the fibrate family.

DNS-X subcellular distribution. TLC analysis of cell liver homogenate shows only one spot (not shown here) with the same R_f value as DNS-X (0.84). No trace of DNS-OH was found. This result is confirmed by spectrofluorimetric assays (Fig. 4A). Thus, DNS-X is not hydrolyzed, and the measured fluorescence is not due to scission products carrying the dansyl portion of the molecule.

Extracts of subcellular control samples followed by fluo-

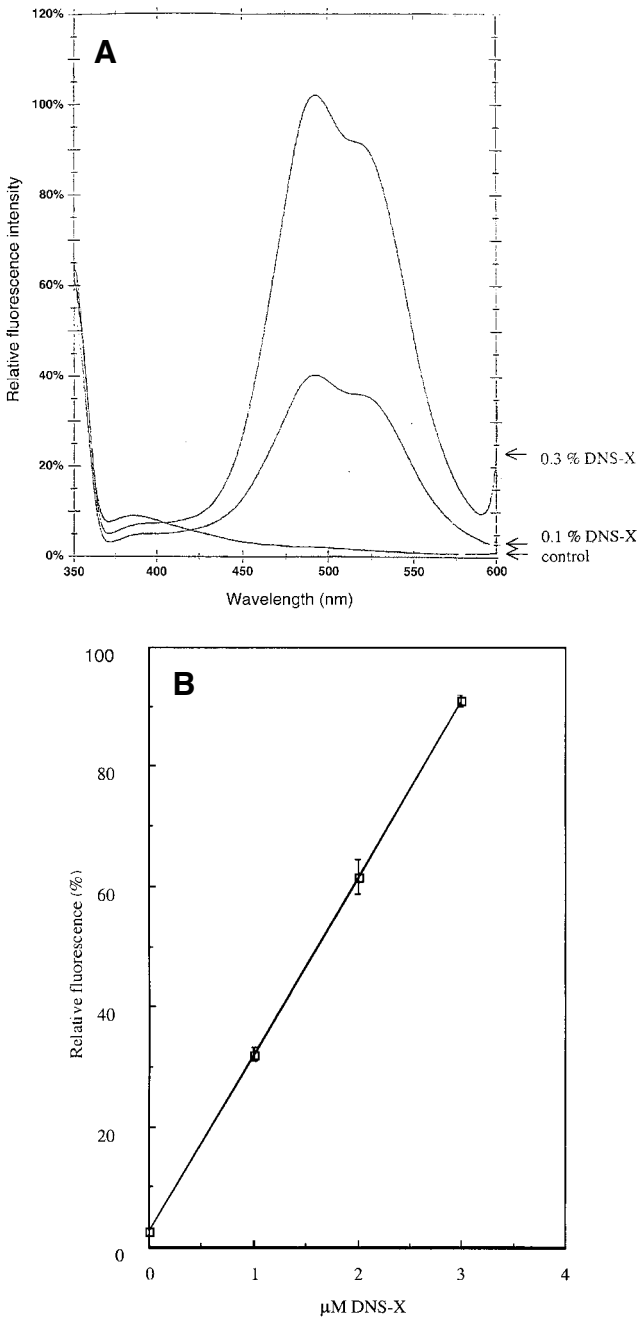

FIG. 4. Titration of DNS-X fluorescence. (A) Emission spectra of cytosolic extracts at an excitation wavelength of 350 nm are shown. The x-axis gives the emission wavelength, and the y-axis shows the relative fluorescence intensity. The extracts were obtained by taking 100 µL of a sample (in this case cytosolic fraction) and diluting to a volume of 1000 µL with acetone. After centrifugation, the spectra were measured. One can see that the fluorescence of the control is very weak. Consequently, the strong fluorescence of the other samples was dependent on the DNS-X content. Therefore, it was possible to quantify DNS-X by fluorescence measurement. (B) Calibration curve. The error bars correspond to the standard deviation of three or four independent measurements. The values were obtained by taking 100 µL of control sample (in this case cytosolic fraction), adding an appropriate volume of DNS-X standard solution, and diluting to a volume of 1000 µL with acetone. After centrifugation the relative fluorescence was measured. For experimental conditions, see the Materials and Methods section. For abbreviation see Figure 1.

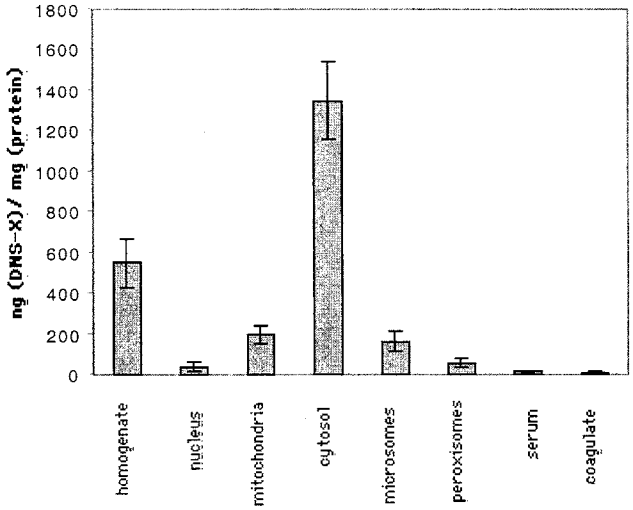

FIG. 5. Subcellular distribution of DNS-X as well as concentration in blood serum and coagulate. The histogram shows mean values from three or four independent treatments at 0.3% DNS-X. The error bars correspond to the standard deviation. The analyses were carried out as described in the text (see also Fig. 4). The results reveal a great affinity of DNS-X for cytosolic components. For further experimental conditions, see the Materials and Methods section. For abbreviation see Figure 1.

rescence measurement generally showed a weak fluorescence, compared to samples resulting from rats treated with DNS-X (Fig. 4A). Consequently, the strong fluorescence of these samples depended on the DNS-X content and therefore it was possible to develop a calibration curve by adding appropriate volumes of DNS-X standard solutions to control samples (Fig. 4B). DNS-X could be quantified for all samples obtained from 0.3%-treated rats (Fig. 5). In these samples, fluorescence was never less than the control. However, in samples obtained from rats treated with 0.1% DNS-X the fluorescence difference between sample and control was often too small to determine the DNS-X content accurately. Consequently, in these samples, DNS-X was quantified only in liver homogenate and cytosol.

For the homogenate, a content of about 210 ng of DNS-X/mg of protein was found in the samples obtained from rats treated with 0.1% DNS-X, whereas about 550 ng of DNS-X/mg of protein was found in samples from the 0.3% DNS-X assays. This represents a 2.6-fold increase in DNS-X concentration in liver homogenate for the 0.3% DNS-X assays, which is in agreement with the threefold higher concentration of this compound in the diet during treatment. The results obtained with the cytosol samples showed the same tendencies.

The DNS-X distribution in other samples obtained by the 0.3% assays showed that DNS-X was accumulated mostly in the cytosolic fraction (Fig. 5) at a concentration of about 1350 ng of DNS-X/mg of protein, much higher than in mitochondrial and microsomal fractions (~180 ng of DNS-X/mg of protein) as well as in nucleic and peroxisomal fractions (48 ng of DNS-X/mg of protein).

In serum and coagulate the concentration of DNS-X found was small (15 and 10 ng of DNS-X/mg of protein, respectively).

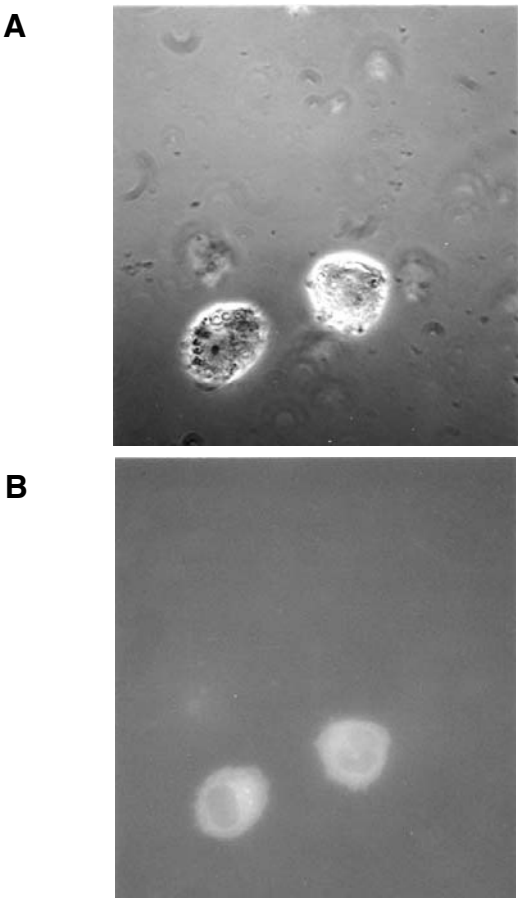

FIG. 6. Phase contrast micrograph (A) and corresponding fluorescence micrograph (B) of cultured hepatic-derived Fao cells in the presence of DNS-X (magnification × 630). Note: Although we used a 15 min incubation of DNS-X with the cells in this experiment, we also observed a rapid appearance of fluorescence for shorter time (3–5 min).

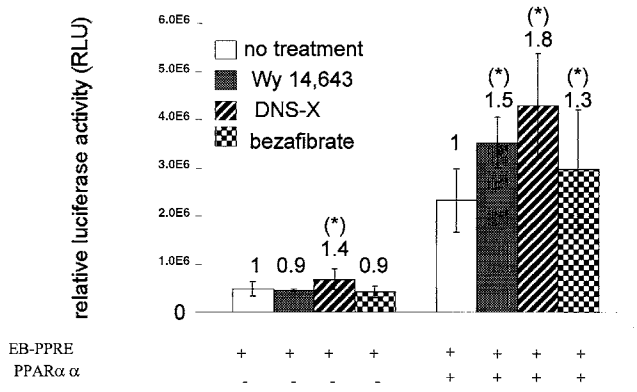

FIG. 7. Peroxisome proliferator-activated receptor α (PPARα)-activated reporter gene in transfected HepG2 cells treated with DNS-X, Wy 14,643, or bezafibrate. The histogram shows mean value of three independent transfections for each condition. The error bars correspond to the standard deviation. (*) Statistically significant, $P < 0.05$. EB:pG.luc BFE (–2952/-2918) plasmid; PPARα:pSG5m PPARα plasmid. For other abbreviations see Figure 1. The + and – signs indicate presence or absence of plasmid coding for the mouse PPARα.

This indicates a rapid plasma disappearance of DNS-X in rats, explaining the threshold concentration necessary to lead to peroxisome proliferation (see Fig. 3). Moreover, it shows that the DNS-X found in subcellular samples really belongs to intracellular components.

The estimation (data not shown) of protein content (in percentage) of each subcellular fraction compared to the total protein content (homogenate) made possible the comparison of DNS-X values obtained for the homogenate with the sum of the single values of the different subcellular fractions. For instance, if the DNS-X value per milligram of protein in homogenate is 100%, the fluorescence that is present is essentially in three subcellular compartments: 90% in the cytosol, 5% in mitochondria, 3% in endoplasmic reticulum, and only minor amounts in nuclei and peroxisomes (data not shown). Thus, the described method of analysis allows the estimation of DNS-X in biological samples.

Fluorescence microscopy. Direct observation of the subcellular distribution of DNS-X in hepatic-derived Fao cells confirms this probe accumulates mostly in the cytosolic fraction, whereas only a little penetrates the nucleus (Fig. 6A,B).

Transfection assays. It is now established that PP activate the expression of target genes having a PPRE *via* an interaction with PPAR. To evaluate if DNS-X could induce a reporter gene under control of PPARα, we transfected HepG2 cells with a luciferase gene under control of the bifunctional enzyme PPRE with or without a plasmid coding for the mouse PPARα. After transfection, cells were treated with different PP: Wy 14,643, bezafibrate (the precursor of DNS-X), or DNS-X. The results show an increase in luciferase activity in the presence of each of the three PP (Fig. 7). This increase in the presence of DNS-X is observed even in the absence of transfected PPARα plasmid suggesting that HepG2, a human hepatic-derived cell line, contains endogenous PPARα as human hepatocytes (15). Nevertheless, after transfection of the plasmid coding for PPARα, DNS-X shows a 1.8-fold increase compared to the control. These results confirm DNS-X as a PP molecule able to modulate the gene expression of enzymes involved in lipid metabolism.

DISCUSSION

With the new purification step introduced during the DNS-X synthesis, a final product with a high purity is obtained in gram quantities that is stable for months when stored under dry conditions at –20°C in the dark. Moreover, by carrying out the synthesis under the conditions described here, less time is required than for the previous method (5), e.g., from 1 or 2 d vs. a few hours. The identified ethyl ester form of DNS-X, which represents about 15%, does not interfere in assays using the final product, since fibrates are used in free or esterified form equally. Nevertheless, the formation of the ethyl ester can be avoided by performing the neutralization after the hydrolysis of bezafibrate under milder conditions.

We show here that DNS-X is a new *in vivo* PP in rats. Moreover, this PP activity is dose dependent. The property of DNS-X as an *in vivo* PP confirms and expands the results of the prelim-

inary publication (5) where DNS-X is shown as a PP only in rat cultured Fao hepatic-derived cells. To obtain comparable data on the *in vivo* effect of bezafibrate, a dose of DNS-X that was unusually high had to be given. Related to this, a possible fast pharmacokinetics of DNS-X can explain the absence of fluorescence in serum of treated rats (see Fig. 5), although DNS-X is not hydrolyzed in the liver cells of rats.

Transfection assays confirm that DNS-X can be considered as a PPARα activator since PPARα activity on PPRE-driven gene is enhanced by DNS-X as well as by other PP.

From this study we propose a fluorescent tool that exhibits PP activity *in vitro* as well as *in vivo*. In addition, this compound is not hydrolyzed in the rat liver cells, and the cell homogenates are not contamined by the external medium. This tool is useful to find out subcellular distribution of fibrates, since its fluorescence allows a low level of detection. Our findings concerning the distribution of fibrates will help elucidate the peroxisome proliferation process as triggered by hypolipidemic agents of the fibrate family (16).

The assays on DNS-X subcellular distribution obtained by quantitative analysis and by fluorescence microscopy revealed a high affinity of the molecule for cytosolic components, whereas the presence of DNS-X in other subcellular fractions was relatively weak. The fact that a high level of DNS-X was found in the cytosol is in agreement with several works where cytosolic proteins with high affinity toward fibrates were found (17–21). On the other hand, these results are in contrast with previous studies suggesting an accumulation of radioactive bezafibrate over the endoplasma reticulum (22). The weak accumulation of DNS-X in the nuclei fraction does not rule out that this compound does not bind PPARα since this nuclear receptor can be activated in the cytosol (its biosynthesis compartment) before being translocated in small amount into the nucleus.

ABSTRACT: A chemiluminescence-based high-performance liquid chromatographic method was developed for the analysis of the addition products of α-tocopherol with phosphatidylcholine-peroxyl radicals (TOO-PC). The TOO-PC eluted from a reversed-phase column was reacted with a chemiluminescent reagent consisting of a *Cypridina* luciferin analog and a lipid-soluble iron chelate in acidic methanol at 50°C, and the generated chemiluminescence was monitored. The detection limit for TOO-PC by this method was about 1 pmol. This method was applied to the detection of TOO-PC in the peroxidized membranes prepared from rabbit erythrocyte ghosts. When the erythrocyte ghosts were peroxidized by the addition of a water-soluble free radical initiator, a peak corresponding to TOO-PC was detected on the chromatogram with chemiluminescent detection. The amount of TOO-PC in the erythrocyte membranes increased with the depletion of endogenous α-tocopherol. The results indicate that this method proved useful for the detection of the TOO-PC formed by the peroxyl-radical scavenging reactions of α-tocopherol in biological systems.

Paper no. L8511 in *Lipids 35*, 1405–1410 (December 2000).

Peroxidation of lipid membranes is implicated in a variety of damaging pathological events (1–3). α-Tocopherol (vitamin E), an important natural antioxidant in both foods and biological systems, inhibits peroxidation of membrane phospholipids by trapping peroxyl radicals (4). α-Tocopherol efficiently transfers a hydrogen atom to a peroxyl radical, giving a hydroperoxide and an α-tocopheroxyl radical. The α-tocopheroxyl radical, once formed, reacts with a second peroxyl radical to form a nonradical product (4–7). The peroxyl radical-trapping reaction of α-tocopherol yields 8a-substituted tocopherones and isomeric epoxytocopherones as the primary oxidation products (8–18). The formation of these products therefore is consistent with the behavior of α-tocopherol as a chain-breaking antioxidant in biological systems. We have previously reported the isolation and characterization of 8a-(phosphatidylcholine-dioxy)-α-tocopherones (TOO-PC) as the products of the α-tocopheroxyl radical with phospholipid-peroxyl radicals during the peroxidation of 1,2-diacyl-3-*sn*-phosphatidylcholine (PC) liposomes (16–18) (Fig. 1). However, no evidence has been published on the occurrence of such TOO-PC in biological systems. In most biological membranes, the ratio of α-tocopherol to polyunsaturated fatty acids is on the order of 1:1,000 (19,20). Therefore, the research requires a highly sensitive and specific methodology to quantify the oxidation products of α-tocopherol in biological samples.

A weak chemiluminescence has been observed when lipid hydroperoxide is decomposed, and chemiluminescent probes

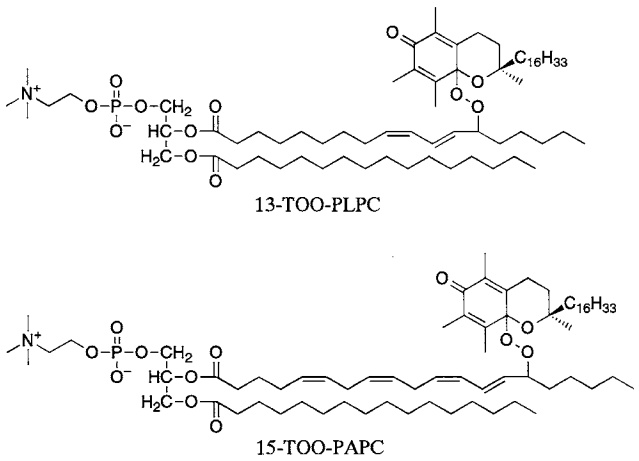

FIG. 1. Typical structures of 8a-(phosphatidylcholine-dioxy)-α-tocopherones, 1-palmitoyl-2-[(9*Z*,11*E*)-13-(8a-dioxy-α-tocopherone)-9,11-octadecadienoyl]-3-*sn*-phosphatidylcholine (13-TOO-PLPC) and 1-palmitoyl-2-[(5*Z*,8*Z*,11*Z*,13*E*)-15-(8a-dioxy-α-tocopherone)-5,8,11,13-

Abbreviations: AAPH, 2,2′-azobis(2-amidinopropane)dihydrochloride; Ch18:2-OOH, cholesteryl linoleate hydroperoxides; CLA, a *Cypridina* luciferin analog, 2-methyl-6-phenyl-3,7-dihydroimidazo[1,2-a]pyrazin-3-one; Fe(III)AA, iron(III) acetylacetonate; HPLC, high-performance liquid chromatography; PAPC, 1-palmitoyl-2-arachidonoyl-3-*sn*-phosphatidylcholine; PC, 1,2-diacyl-3-*sn*-phosphatidylcholine; PC-OOH, phosphatidylcholine hydroperoxides; PLPC, 1-palmitoyl-2-linoleoyl-3-*sn*-phosphatidylcholine; PLPC-OOH, 1-palmitoyl-2-linoleoyl-3-*sn*-phosphatidylcholine hydroperoxides; TOO-PC, 8a-(phosphatidylcholine-dioxy)-α-tocopherones; TOO-PAPC, 1-palmitoyl-2-[(8a-dioxy-α-tocopherone)-eicosatetraenoyl]-3-*sn*-phosphatidylcholines; TOO-PLPC, 1-palmitoyl-2-[(8a-dioxy-α-tocopherone)-octadecadienoyl]-3-*sn*-phosphatidylcholines.

are often used to amplify emission of luminescence (21). Luminol or isoluminol has usually been used as the chemiluminescent probe to detect lipid hydroperoxides (21–25). Miyazawa *et al*. (22,23) and Yamamoto *et al*. (24,25) have adapted the chemiluminescent assay of lipid hydroperoxides using high-performance liquid chromatography (HPLC) with postcolumn detection. Miyazawa *et al*. (26) have also described the hydroperoxide-specific detection of 8a-hydroperoxy-α-tocopherone, which was formed during the reaction of α-tocopherol with photochemically generated singlet oxygen, with this HPLC system. In the present study, we applied the chemiluminescence-based HPLC method for the assay of TOO-PC. We used 2-methyl-6-phenyl-3,7-dihydroimidazo[1,2-*a*]pyrazin-3-one, a *Cypridina* luciferin analog (CLA), which has been reported to be effective in amplifying the emission by superoxide anion and lipid free radicals (27,28), as a sensitive amplifier of the chemiluminescence produced by iron-induced decomposition of TOO-PC under acidic conditions.

MATERIALS AND METHODS

Chemicals. *RRR*-α-Tocopherol was purchased from Sigma Chemical Co. (St. Louis, MO) and purified by reversed-phase HPLC (16). *RRR*-γ-Tocopherol was prepared from mixed isomers of tocopherol (Hohnen Oil Co., Tokyo, Japan). α-Tocopherylquinone was prepared by the oxidation of α-tocopherol with $FeCl_3$ (17). Authentic 1-palmitoyl-2-[(8a-dioxy-α-tocopherone)-octadecadienoyl]-3-*sn*-phosphatidylcholines (TOO-PLPC) and 1-palmitoyl-2-[(8a-dioxy-α-tocopherone)-eicosatetraenoyl]-3-*sn*-phosphatidylcholines (TOO-PAPC) were prepared by reacting α-tocopherol with 1-palmitoyl-2-linoleoyl-3-*sn*-PC (PLPC) and 1-palmitoyl-2-arachidonoyl-3-*sn*-PC (PAPC), respectively (18). Authentic PLPC hydroperoxides (PLPC-OOH) were prepared by the oxidation of PLPC (18). Cholesteryl linoleate hydroperoxides (Ch18:2-OOH) were prepared by the autoxidation of cholesteryl linoleate in the presence of α-tocopherol (24). A free-radical initiator 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH) was obtained from Wako Pure Chemical Co. (Osaka, Japan). CLA was purchased from Tokyo Chemical Industry (Tokyo, Japan), and iron(III) acetylacetonate [Fe(III)AA] was from Dojindo Laboratories (Kumamoto, Japan).

Chemiluminescence-based HPLC system. The HPLC system used in the present study was essentially the same as that reported by Miyazawa *et al*. (23) and Yamamoto (25). HPLC was carried out with a Waters model 600E system (Waters, Milford, MA) connected to a Waters model 486 ultraviolet detector and a Jasco CL-925 chemiluminescence detector (Japan Spectroscopic Co., Tokyo, Japan). The mobile phase of 99% methanol containing 1 mM choline chloride was passed through an Inertsil C8 column (4.6 × 150 mm; GL Sciences Co., Tokyo, Japan) at a flow rate of 1.0 mL/min. The column eluate was monitored by an absorbance at 240 nm and subsequently passed to a reaction coil (0.76 mm × 300 cm, an inner coil volume of 1.4 mL), which was maintained at 50°C.

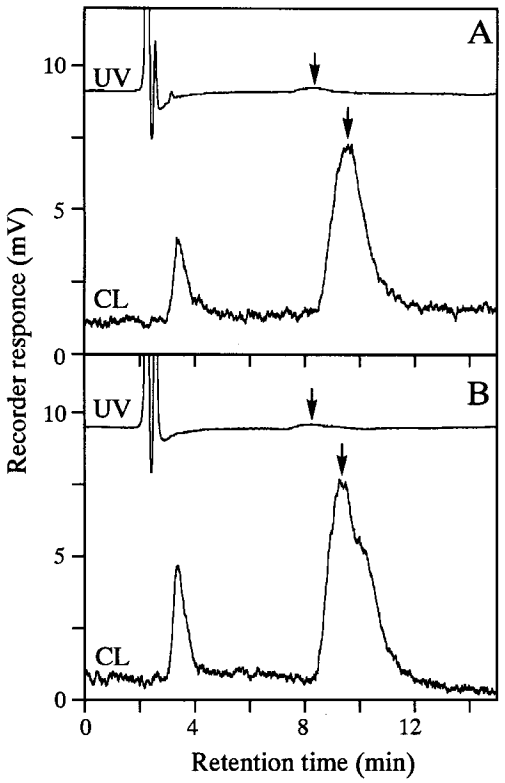

FIG. 2. High-performance liquid chromatograms (HPLC) of the standard 1-palmitoyl-2-[(8a-dioxy-α-tocopherone)-octadecadienoyl]-3-*sn*-phosphatidylcholines (TOO-PLPC) and 1-palmitoyl-2-[(8a-dioxy-α-tocopherone)-eicosatetraenoyl]-3-*sn*-phosphatidylcholines (TOO-PAPC). A solution of TOO-PLPC (13 pmol, A) or TOO-PAPC (17 pmol, B) was injected into the HPLC column. HPLC was done with an Inertsil C8 column (4.6 × 150 mm), which was developed with 1 mM choline chloride in methanol at 1.0 mL/min. After the eluate was monitored at 240 nm (UV), the chemiluminescent reagent was mixed at a flow rate of 1.0 mL/min and the resulting chemiluminescence (CL) was monitored. The arrow indicates the elution position of each 8α-(phosphatidylcholine-dioxy)-α-tocopherone (TOO-PC).

At the inlet of the reaction coil, a chemiluminescent reagent was pumped using an HPLC pump (Waters model 510) at a flow rate of 1.0 mL/min and mixed with the eluate in a T-connector. The chemiluminescent solution consisted of CLA (2 mg/L), Fe(III)AA (5 mg/L), and trifluoroacetic acid (5 mM) in methanol and was maintained at 4°C on an ice bath before mixing. The mobile phase and chemiluminescent solution were continuously sparged with helium gas. The chemiluminescence, generated by the reaction of TOO-PC with the luminescent reagent, was measured with a chemiluminescent detector. Chromatographic data were recorded by a MacLab data acquisition system with a Peaks application program (AD Instruments Pty. Ltd., Castle Hill, Australia).

Erythrocyte ghost preparation. The fresh, heparinized blood from male rabbits (JBC Inc., Gifu, Japan) was centrifuged at 1000 × *g* for 10 min to separate erythrocytes from plasma and buffy coat, and washed three times with a physiological saline. The erythrocytes were hemolyzed in 40 vol of hypotonic buffer (10 mM sodium phosphate, pH 7.4) and centrifuged at 20,000

× *g* for 40 min at 4°C. This procedure was repeated and obtained erythrocyte ghost membranes.

Peroxidation of erythrocyte ghosts. The erythrocyte ghost membranes were suspended in a 10-mM sodium phosphate buffer at pH 7.4 to give a final protein concentration of 1.0 mg/mL. After preincubating for 5 min at 37°C in a shaking water bath, AAPH (a final concentration of 0.5 mM) was added to the membrane suspensions to start lipid peroxidation (29).

Quantification. At specific intervals, a 1.0-mL aliquot of the reaction mixture was taken for lipid extraction. Total lipids were extracted by the method of Bligh and Dyer (30). The extraction solvents (methanol and chloroform) contained 0.03% butylated hydroxytoluene. The extracted lipids were evaporated to dryness under a stream of nitrogen gas, dissolved in 100 μL of ethanol, and analyzed by HPLC; α- and γ-tocopherols were quantified by reversed-phase HPLC with fluorescence detection (16). TOO-PC was quantified by the established chemiluminescence-based HPLC method described in the present study. To determine the percentage recovery of TOO-PC, authentic TOO-PLPC (130 pmol in 100 μL of ethanol) was spiked into the erythrocyte ghost sample (1.0 mL) and then extracted with chloroform/methanol as described above. PC hydroperoxides (PC-OOH) were quantified by the same conditions as the analysis of TOO-PC except for the use of an Inertsil ODS-3 column (4.6 × 150 mm; GL Sciences). A peak corresponding to PC-OOH was eluted in about 5 min under this condition. PLPC-OOH was used as the standard. α-Tocopherylquinone was analyzed by reversed-phase HPLC after the solid-phase extraction of the lipid extracts (17). In another experiment, a mixture of 3-h reaction was treated with 1 M HCl (0.1 mL) prior to extraction and the hydrolysis products were then analyzed to detect oxidized α-tocopherol present as tocopherone compounds (31).

RESULTS AND DISCUSSION

It is possible to detect TOO-PC using the method of chemiluminescence-based HPLC. Figure 2 shows typical chromatograms of authentic TOO-PLPC and TOO-PAPC monitored by an absorbance at 240 nm and the chemiluminescent detector. A very intense peak corresponding to TOO-PLPC or TOO-PAPC was observed on the chromatogram by the chemiluminescent detection, while a peak of only weak intensity was detected by ultraviolet. A mixture of CLA, Fe(III)AA, and trifluoroacetic acid in methanol as the postcolumn reagent was most suitable for this assay. Luminol has already been used in chemiluminescence-based HPLC assay for 8a-hydroperoxy-α-tocopherone under alkaline conditions (26). However, chemiluminescence was not observed when luminol was used instead for the assay of TOO-PC under acidic and alkaline conditions (data not shown). Yamamoto *et al*. (24) reported that the isoluminol assay gave a positive for all of the hydroperoxides, but not for the endoperoxide prostaglandin H_2. These results indicate that the luminol or isoluminol reagent might be unreactive with endoperoxides. On the contrary, the present assay using CLA gave positive responses for TOO-PC. Therefore, our method described here might be useful for quantification of endo-type peroxides such as TOO-PC. In addition, our chemiluminescent reagent also gave a positive response for PC-OOH and cholesteryl ester hydroperoxides. These hydroperoxides, however, did not interfere with the detection of TOO-PC under the present HPLC conditions; PLPC-OOH was eluted from the C8 column at 3.1 min of retention time and Ch18:2-OOH at 6.6 min, respectively.

We have varied the concentrations of CLA, Fe(III)AA, and trifluoroacetic acid and the length and temperature of the reaction coil in order to improve the sensitivity of chemiluminescence and to lower the detection limit of TOO-PC. CLA in solution has been reported to be relatively unstable and autoxidizable under light or in the presence of iron ions, and a chelating agent has been known to form stable complexes with these ions and inhibit the oxidation of CLA (32). Therefore, we added Fe(III)AA as a chelating agent into the chemiluminescent reagent. To decrease the chemiluminescent intensity due to autoxidation, the reagent was continuously sparged with helium gas and maintained at 4°C before mixing with the column eluate. Furthermore, the optimum generation of chemiluminescence needed 1.4 mL of the mixing coil volume and a high temperature at 50°C. The most suitable conditions were determined to be as described in the Materials and Methods section.

Standard curves for the determination of TOO-PC by this method were developed using TOO-PLPC and TOO-PAPC (Fig. 3). Each standard curve showed a good correlation between the peak area measured by chemiluminescent detection and the amount of TOO-PC ($r > 0.999$), and the two TOO-PC gave similar regression lines (TOO-PLPC, $y = 22.6x - 22.4$; TOO-PAPC, $y = 22.8x - 19.1$). The lowest detectable level of each TOO-PC as a signal-to-noise ratio of 3 was estimated to be about 1 pmol, respectively.

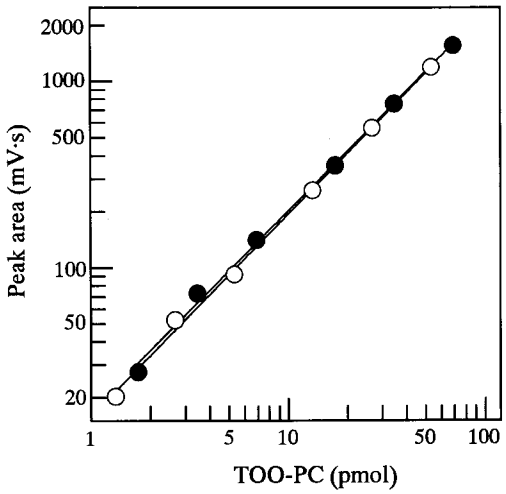

FIG. 3. Standard curve for the analysis of TOO-PLPC (○) or TOO-PAPC (●) by chemiluminescent detection. Each point represents the average value from triplicate determinations. See Figure 2 for abbreviations.

Scheme 1 shows a possible mechanism of iron-catalyzed chemiluminescent reaction of CLA with TOO-PC. Completion of the iron-catalyzed reaction of CLA with TOO-PC requires acid catalysis. The reactions might involve the hydrolysis of TOO-PC to α-tocopherone cation (T^+) and PC-OOH; that is, the 8a-(PC-dioxy) moiety is probable lost following protonation to generate PC-OOH (Eqs. 1 and 2) (12). The next reaction would be an iron-dependent free radical formation by either oxidizing PC-OOH to a peroxyl radical (PC-OO•) or reducing it to an alkoxyl radical (PC-O•) (Eqs. 3 and 4) (33). Since the acid hydrolysis preferentially occurs before the iron-dependent redox reaction, the possibility that iron ions directly catalyze hemolysis of TOO-PC is removed.

$$\text{TOO-PC} + H^+ \rightarrow \text{T}(H^+)\text{OO-PC} \quad [1]$$

$$\text{T}(H^+)\text{OO-PC} \rightarrow T^+ + \text{PC-OOH} \quad [2]$$

$$\text{PC-OOH} + Fe^{3+} \rightarrow \text{PC-OO}^{\bullet} + Fe^{2+} + H^+ \quad [3]$$

$$\text{PC-OOH} + Fe^{2+} \rightarrow \text{PC-O}^{\bullet} + Fe^{3+} + OH^- \quad [4]$$

CLA has been reported to be an effective amplifier of the chemiluminescence produced by iron-induced decomposition of lipid hydroperoxides (28). Thus, the produced free radicals (PC-OO• and PC-O•) can react with CLA, and the resulting oxidized CLA in the excited state (CLA^*_{ox}) emits chemiluminescence at 380 nm to return to its ground state (CLA_{ox}) (26,27).

We applied the chemiluminescence-based HPLC method to the detection of TOO-PC in the membranes prepared from rabbit erythrocyte ghosts. Before the detection of TOO-PC, the percentage recovery of TOO-PC in the erythrocyte ghosts was determined. In using the present method, the recovery of added TOO-PLPC was 71.4 ± 2.6% (n = 4). Liebler *et al.* (14,15) have reported that 8a-(alkyldioxy)-α-tocopherones are relatively resistant to hydrolysis in liposomal systems. Thus, TOO-PC in the erythrocyte ghosts would be relatively stable during the analytical process.

The erythrocyte ghosts suspensions were reacted with peroxyl radicals that had been generated in the aqueous phase by the thermal decomposition of AAPH. The starting reaction mixtures contained endogenous α-tocopherol (0.562 ± 0.064 μM) and γ-tocopherol (0.023 ± 0.018 μM) in the membranes (protein concentration of 1.0 mg/mL). Figure 4 shows the HPLC trace of the lipid extract from the 3-h reaction mixture. A peak corresponding to TOO-PC appeared around 9.4 min of retention time by the chemiluminescent detection, while there was no detectable peak corresponding to TOO-PC by ultraviolet detection. The identity of this peak was confirmed

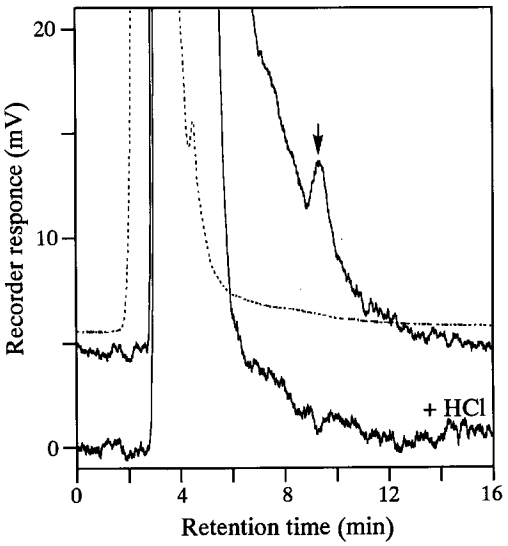

FIG. 4. HPLC of the addition products of α-tocopherol with phosphatidylcholine-peroxyl radicals from the peroxidized erythrocyte ghosts. The erythrocyte ghosts of male rabbits were suspended in 10 mM sodium phosphate buffer at pH 7.4 (a final concentration of 1.0 mg protein/mL) and incubated at 37°C for 3 h in the presence of 0.5 mM 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH). The reaction mixture was extracted with chloroform/methanol, and the total lipid fraction was injected into the HPLC. The eluate was monitored by an absorbance at 240 nm (dotted line) and by a chemiluminescence (solid line). The reaction mixture was treated with 1 M HCl prior to extraction and analyzed by HPLC with chemiluminescent detection (+ HCl). The arrow indicates the elution position of authentic TOO-PLPC. See Figure 2 for other abbreviations.

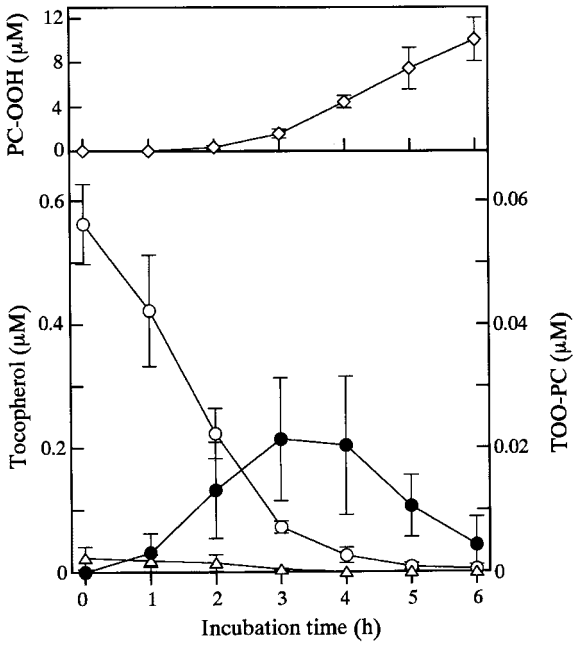

FIG. 5. Changes of endogenous tocopherols, TOO-PC, and phosphatidylcholine hydroperoxides (PC-OOH) during the AAPH-initiated peroxidation in erythrocyte ghosts. The erythrocyte ghosts of male rabbits were suspended in 10 mM sodium phosphate buffer at pH 7.4 (a final concentration of 1.0 mg protein/mL) and incubated at 37°C in air. Peroxidation was initiated by the addition of AAPH (a final concentration of 0.5 mM). The formation of PC-OOH (◇), the consumption of α- (○) and γ-tocopherols (△), and the formation of TOO-PC (●) are shown. Each value is expressed as mean ± standard deviation of four different experiments. See Figures 2 and 4 for other abbreviations.

by co-elution against the authentic standards. The peak completely disappeared when the sample extract was treated with 1 M HCl prior to analysis. This HCl treatment released additional α-tocopherylquinone (Table 1), presumably from 8a-substituted α-tocopherone precursors (31). From these results, this peak was identified to be TOO-PC although the isomeric molecular species were unknown.

The oxidation of erythrocytes and their ghost membranes serves as a model for the oxidative change of biomembranes (34). It has been found that free radicals generated in the aqueous phase attack the membrane to induce the chain oxidation of lipids and proteins and eventually cause hemolysis (29,35). Vatassery (36) reported that α-tocopherylquinone is one of the products of α-tocopherol during the peroxidation of red cell membranes. In the present study, the endogenous α-tocopherol in erythrocyte ghosts could scavenge PC-peroxyl radicals to suppress the formation of PC-OOH when the peroxidation was initiated by AAPH (Fig. 5). TOO-PC, the products of α-tocopherol with PC-peroxyl radicals, appeared with the depletion of α-tocopherol. These results indicate that the endogenous α-tocopherol in the membranes could scavenge PC-peroxyl radicals to suppress PC-OOH formations and produce TOO-PC. However, the formation of TOO-PC in the 3-h sample only accounted for 4% of the consumed α-tocopherol.

There are two pathways to scavenge peroxyl radicals by α-tocopherol (6). The first forms 8a-substituted α-tocopherones and their hydrolysis product α-tocopherylquinone, and the second involves the formation of hydroperoxyepoxy-α-tocopherones and their hydrolysis products epoxy-α-tocopherylquinones. These two pathways depend on characteristics of the experimental systems. In a polar medium or a liposomal system, both 8a-substituted tocopherones and epoxytocopherones are the major products (13–15,17,18), whereas 8a-substituted tocopherones predominate in a nonpolar medium (10,11). In the erythrocyte ghosts, only a small percentage of the total depleted α-tocopherol could be accounted for as TOO-PC (Fig. 5). This indicates that the α-tocopherol may react primarily with AAPH-derived peroxyl radicals, rather than with PC-peroxyl radicals, and form AAPH-derived tocopherones or epoxytocopherones as the major products. However, we could not detect such compounds under the present HPLC conditions.

Liebler *et al.* (37) have developed a new methodology of a stable isotope dilution capillary gas chromatography–mass spectrometry for analyzing α-tocopherol and its oxidation products. This methodology has been applied to the antioxidative reaction of α-tocopherol in a perfused rat liver model (31). The principal oxidation products of α-tocopherol in such an intact organ system were assumed to be 8a-substituted α-tocopherones rather than their hydrolyzed products. This was assumed only from the evidence that the additional release of α-tocopherylquinone was observed in the HCl-treated sample. Further studies on the identification of 8a-substituted α-tocopherones are needed to elucidate the antioxidative action of α-tocopherol *in vivo* systems.

In conclusion, the HPLC technique presented here is found advantageous for the sensitive and specific determination of TOO-PC in biological samples. We believe that such definite quantification of TOO-PC provides us with much information on the antioxidant function of α-tocopherol in biological systems. Further application of this methodology to biological materials is under study.

ABSTRACT: Beneficial effects of dietary phytic acid (*myo*-inositol hexaphosphate; IP_6) have often been explained by its strong iron ion-chelating ability, which possibly suppresses iron ion-induced oxidative damage in the gastrointestinal tract. Because phytic acid is hydrolyzed during digestion, this work aimed to know whether its hydrolysis products (IP_2, IP_3, IP_4, and IP_5) could still prevent iron ion-induced lipid peroxidation. Studies using liposomal membranes demonstrated that hydrolysis products containing three or more phosphate groups are able to inhibit iron ion-induced lipid peroxidation although their effectiveness decreased with dephosphorylation. Similarly, they also prevented iron ion-induced decomposition of phosphatidylcholine hydroperoxide. These results demonstrate that intermediate products of phytic acid hydrolysis still possess iron ion-chelating ability, and thus they can probably prevent iron ion-induced lipid peroxidation in biological systems.

Paper no. L8625 in *Lipids 35,* 1411–1413 (December 2000).

Phytic acid (*myo*-inositol hexaphosphate; IP_6) is a highly phosphorylated molecule present in cereal grains and seeds that functions as an excellent chelator of metal ions (1–3). A number of studies suggest the involvement of free iron ions in the development of gastrointestinal diseases, such as colon cancer (4–8). Dietary iron remains largely unabsorbed in the intestine, and it is hypothesized to participate in the generation of hydroxyl radical by a Fenton-type reaction in conjunction with colonic microflora (5). Therefore, inhibition of iron ion-mediated lipid peroxidation is suggested to be important for the prevention of gastrointestinal diseases. Although phytic acid has a strong inhibitory effect on iron-induced oxidative reactions, dietary phytic acid is inevitably hydrolyzed during digestion by phytase of either dietary or intestinal origin (9,10). This enzyme sequentially cleaves phosphate groups from the inositol ring, and less phosphorylated forms (IP_5, IP_4, IP_3, IP_2, and IP_1) of phytic acid are apparently present as intermediate products in the digestive tract.

The aim of this study was to clarify whether phytic hydrolysis products still have the ability to prevent iron ion-induced lipid peroxidation. For this purpose we used lower phosphorylated forms of inositol phosphate (IP_2–IP_5) derived from phytic acid hydrolysis and evaluated their protective effect against iron ion-induced lipid peroxidation in liposomal membrane.

EXPERIMENTAL PROCEDURES

Myo-inositol bis-, tris-, tetrakis- and pentakisphosphate (IP_2, IP_3, IP_4, IP_5) were prepared by the method described previously (11). Briefly, phytic acid solution (50% wt/vol, Daiichi Pharmaceutical Co., Tokyo, Japan) was adjusted to pH 6.0 with 5 N NaOH and diluted to 10%. Hydrolysis was carried out by the addition of microbial phytase (Amano Pharmaceutical Co., Nagoya, Japan), and incubated at 40°C for 24 h. Separation of phytic acid hydrolysis products was performed by anion exchange column chromatography (Dowex 1-X2, 200–400 mesh, chloride form) by stepwise gradient elution with hydrochloric acid (0.05–1.0 N). The purity of eluted fractions containing IP_2, IP_3, IP_4, and IP_5 was checked by HPLC (12).

Phytic acid and egg yolk phosphatidylcholine (EYPC; type III-E), were purchased from Sigma Chemical Co. (St. Louis, MO). EYPC was purified to remove contaminant peroxides by reversed-phase column chromatography (13). The phosphatidylcholine hydroperoxides (PC-OOH) content in the purified EYPC was lower than 0.008%. Iron(III) nitrate nonahydrate [$Fe(NO_3)_3 \cdot 9H_2O$], 3,5-di-*tert*-butyl-4-hydroxytoluene and 2-thiobarbituric acid were purchased from Nacalai Tesque Inc. (Kyoto, Japan). Ascorbic acid was from Daiichi. Desferrioxamine B methanesulfonate (Desferal) was obtained from CIBA-Geigy Japan (Tokyo, Japan). All other chemicals and solvents were of analytical grade. PC-OOH was prepared from EYPC using soybean lipoxygenase and purified by reversed-phase column chromatography by the method described previously (14).

Liposomal suspension (6.25 mM EYPC) was prepared in 10 mM Tris-HCl buffer (pH 7.4) without the addition of diethylenetriaminepentaacetic acid as previously described (15).

Abbreviations: Desferal, Desferrioxamine B methanesulfonate; EYPC, egg yolk phosphatidylcholine; HPLC, high-performance liquid chromatography; IP_6, *myo*-inositol hexakisphosphate; IP_5, *myo*-inositol pentakisphosphate; IP_4, *myo*-inositol tetrakisphosphate; IP_3, *myo*-inositol trisphosphate; IP_2, *myo*-inositol bisphosphate; PC-OOH, phosphatidylcholine hydroperoxides; TBARS, thiobarbituric acid-reactive substances.

Aliquots of the liposomal suspension were mixed with 100 μM (final concentration) of phytic acid hydrolysis products. Lipid peroxidation was induced by the addition of $Fe(NO_3)_3$ and ascorbate (final concentrations 10 and 100 μM, respectively). Incubation was carried out at 37°C with continuous shaking, and at specific time intervals aliquots were withdrawn for the analysis of PC-OOH by high-performance liquid chromatography (HPLC) (14). At the end of incubation the amount of thiobarbituric acid-reactive substances (TBARS) was quantified by the method of Uchiyama and Mihara (16).

The ability of phytic acid hydrolysis products to chelate iron ion was estimated by measuring their inhibitory effect on iron ion-induced PC-OOH decomposition. PC-OOH solution in chloroform (0.1 μmol) was put into a test tube and the solvent completely evaporated by nitrogen stream. The residue was dispersed in 0.8 mL of Tris-HCl buffer (10 mM, pH 7.4) by vigorous mixing on a vortex mixer for 1 min and by ultrasonic irradiation for 30 s in an Astrason Ultrasonic Processor (Misonix Inc., New York). PC-OOH suspension was then mixed with phytic acid hydrolysis products or Desferal (final concentration 100 μM) and the reaction was started by the addition of $Fe(NO_3)_3$ and ascorbate solution (final concentrations 10 and 100 μM, respectively). After 10 min incubation at 37°C the residual amount of PC-OOH was quantified by HPLC as previously described (14).

Data were analyzed by one-way analysis of variance followed by the Bonferroni/Dunn *post hoc* multiple comparison test to determine statistical differences between means. A value of $P < 0.05$ was judged as statistically significant.

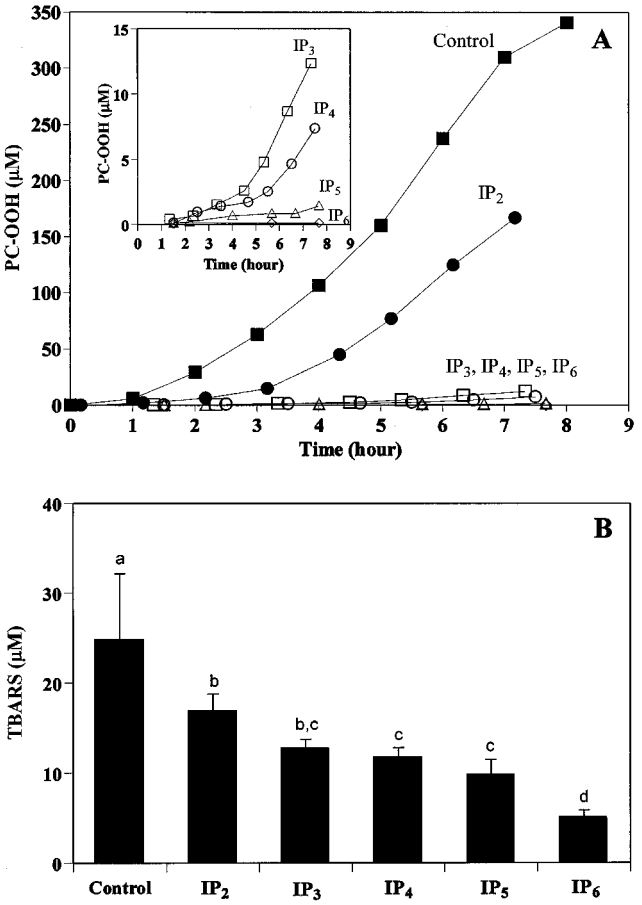

FIG. 1. Effect of phytic acid hydrolysis products on iron ion-induced lipid peroxidation of large unilamellar vesicle liposomal suspension. Liposomal suspension, consisting of 5 mM egg yolk phosphatidylcholine in Tris-HCl buffer (pH 7.4; 10 mM), was incubated with each phytic hydrolysis product (100 μM), and the oxidation was initiated by the addition of $Fe(NO_3)_3$ and ascorbic acid (10 and 100 μM, respectively). Oxidation level was determined by the measurement of phosphatidylcholine hydroperoxides (PC-OOH) and thiobarbituric acid-reactive substances (TBARS). (A) Accumulation of PC-OOH in control (■), *myo*-inositol bisphosphate (IP_2) (●), *myo*-inositol trisphosphate (IP_3) (□), *myo*-inositol tetrakisphosphate (IP_4) (○), *myo*-inositol pentakisphosphate (IP_5) (△), and *myo*-inositol hexakisphosphate (IP_6) (◇). The values shown represent the typical results of at least three experiments. (B) TBARS level after 8 h of incubation. Each value is the mean ± SD of at least four experiments. Means not sharing a common letter are significantly different ($P < 0.05$), as determined by Bonferroni/Dunn's multiple comparison test.

RESULTS AND DISCUSSION

The antioxidant effect of phytic acid hydrolysis products was evaluated in iron ion-induced large unilamellar vesicle (LUV) liposomal lipid peroxidation. Figure 1 shows the effect of phytic acid hydrolysis products on the accumulation of PC-OOH and TBARS in liposomal suspension. The accumulation of PC-OOH was slightly retarded by IP_2, whereas IP_3, IP_4, IP_5, and IP_6 suppressed PC-OOH formation (Fig. 1A); the order of suppression was $IP_3 < IP_4 < IP_5 \leq IP_6$. The amount of TBARS formed after 8 h of incubation was also significantly decreased by the addition of IP_2, IP_3, IP_4, IP_5, and IP_6 (Fig. 1B). A slight but gradual decrease in TBARS formation from IP_2–IP_6 was observed. IP_2, IP_3, IP_4, IP_5, or IP_6 by themselves had no effect on TBARS determination. Thus it is suggested that phytic acid hydrolysis products are still able to protect biological membranes against iron ion-induced lipid peroxidation.

The ability of phytic acid hydrolysis products to block iron ion-induced PC-OOH decomposition is shown in Figure 2. The strong iron chelator Desferal was used in the assay as a positive control; it inhibited the decomposition of PC-OOH almost completely. IP_2 was unable to prevent PC-OOH decomposition, whereas hydrolysis products with three or more phosphate groups significantly prevented PC-OOH decomposition ($IP_6 > IP_5 > IP_4 > IP_3$).

Antioxidant properties of phytic acid are ascribed to its strong metal ion-chelating ability (1). In this study we evaluated the antioxidant and/or chelating ability of less phosphorylated forms of inositol phosphate derived from phytic acid hydrolysis. The study using liposomal suspension as a model for biological membranes clearly demonstrated that dephosphorylation decreases the antioxidant effectiveness of IP_6 against iron ion-induced lipid peroxidation (Fig. 1). However, phytic acid hydrolysis products significantly protected liposomal membrane lipid peroxidation. It has been recognized that iron ion catalyzes the decomposition of lipid hydroperoxide with consequent generation of reactive peroxyl and/or

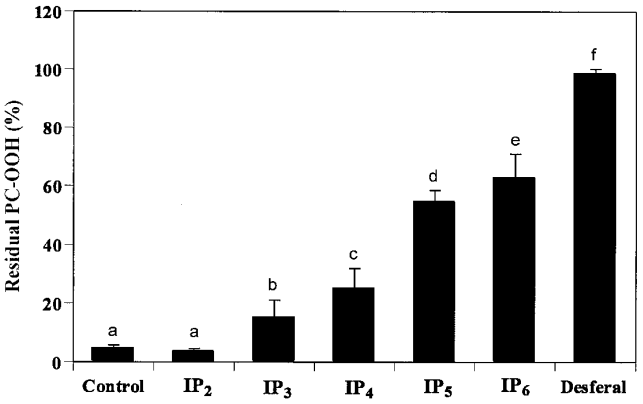

FIG. 2. Effect of phytic acid hydrolysis products on iron ion-induced decomposition of PC-OOH. Phytic acid hydrolysis product (100 μM) was added to PC-OOH suspension (100 μM) in Tris-HCl buffer (pH 7.4; 10 mM) and incubated with $Fe(NO_3)_3$ and ascorbic acid (10 and 100 μM, respectively) at 37°C for 10 min. The amount of residual PC-OOH was measured by high-performance liquid chromatography. Each value is the mean ± SD of at least four experiments. Means not sharing a common letter are significantly different ($P < 0.05$), as determined by Bonferroni/Dunn's multiple comparison test. Desferal, desferrioxamine B methanesulfonate; for other abbreviations see Figure 1.

alkoxyl radicals (4). Our results suggest that partially hydrolyzed products of phytic acid are still able to bind iron ion in a way that prevents or lowers its catalytic activity toward lipid hydroperoxides. To confirm this hypothesis, we measured their ability to prevent iron ion-induced PC-OOH decomposition (Fig. 2). In our model system IP_3, IP_4, and IP_5 significantly suppressed hydroperoxide decomposition, whereas IP_2 was unable to prevent decomposition. Graf *et al.* (2) postulated that, to have catalytic activity, iron ion requires at least one coordination site be open or occupied by a readily dissociable ligand. They have shown that phytic acid inhibits iron-mediated generation of hydroxyl radical by occupying all six iron coordination sites (2). Later studies conducted by Hawkins *et al.* (17) and Phylippy and Graf (18) demonstrated that all six phosphate groups on *myo*-inositol structure are not necessary for the inhibition of hydroxyl radical generation. Phylippy and Graf (18) proposed that 1,2,3-phosphate grouping on phytic acid structure is responsible for the inhibition of iron ion reactivity. Although we did not determine the isomers of inositol phosphate present in each product of phytic acid hydrolysis, our results demonstrate that hydrolysis of phytic acid generates compounds that are still able to prevent iron ion-induced lipid peroxidation. From the above evidences, it is probable that the hydrolysis of phytic acid in this study generated isomers containing the 1,2,3-phosphate grouping on the inositol structure.

In conclusion, hydrolysis of phytic acid generates several compounds that are still effective against iron ion-induced lipid peroxidation. It is likely that their effectiveness is modulated by the degree of hydrolysis and by the type of isomers of partially hydrolyzed inositol phosphate formed. Nevertheless, it can be expected that phytic acid hydrolysis products prevent iron ion-induced lipid peroxidation in biological system.
